Although **1** reacts with neutral ligands with phosphine substitution, sometimes followed by dihydrogen elimination, reacting **1** with anionic ligands normally results in the substitution of the methanol ligand. Thus, **1** reacts with a methanol solution of X^- to give the derivatives $ReHX(NO)(PPh_3)_3$ (**4–9**). These complexes are all air-sensitive in the solid state and decompose readily in solution. Attempts to recrystallize **4** and **6–8** from dichloromethane–methanol in air produced materials apparently containing hydroperoxy ligands, which are the subject of further research. Because of their solution sensitivity, the characterization of **4–9** in solution was restricted to the more stable chloride, bromide, and azide derivatives only. The ^1H nmr spectra of all three compounds exhibit a doublet of triplets for the hydride proton with $^2J_{HP}$ (*cis*) in the range of 26–28 Hz and $^2J_{HP}$ (*trans*) around 67–72 Hz, in keeping with a *mer*-arrangement of phosphine ligands with the hydride *trans* to the unique phosphorus atom. The ^{31}P nmr spectra are consistent with this stereochemistry, consisting of a doublet and triplet in a 2:1 ratio, with $^2J_{PP}$ around 8 Hz. Not surprisingly, this coupling was most clearly resolved at low temperatures, implying the existence of

[a] CD_2Cl_2 as solvent, all calibrated with reference to the $CHDCl_2$ triplet at 5.32 ppm or H_3PO_4 at 0.00 ppm. All signals give satisfactory integrals.

[b] Coupling constants in Hz.

an exchange process between the phosphine *trans* to the hydride and adventitious triphenylphosphine, present either as a trace impurity or resulting from minor decomposition in the sample.

Infrared spectra of **4–9** are also in keeping with a *trans* arrangement of the X and nitrosyl ligands. The observed range for νNO is 1634 to 1665 cm^{-1} comparable to the νCO range of 1893 to 1927 cm^{-1} seen in the isoelectronic series $OsHX(CO)(PPh_3)_3$ of similar geometry (4). Furthermore, the trend seen in νNO as X varies is analogous to that seen in the osmium series, especially so with the lower extreme of the two series. In both cases, OR (R = H for the osmium case) and F ligands generate the lowest νNO and νCO values, further illustrating their strong π-donor characteristics (5). Infrared spectra also establish that for $ReH(NCO)(NO)(PPh_3)_3$ (**9**) the cyanate ligand is N-bonded (ν(NC) = 2237 cm^{-1}) (6).

Attempts to synthesize members of this series with X = I and

SCN met with mixed success. Following the usual procedure yielded yellow solids exhibiting clean ir spectra virtually identical to those observed for the other members, except for bands attributable to methanol. Both ^1H and ^{31}P nmr spectra, on the other hand, indicated the presence of complex mixtures in solution. Despite being mixtures, however, both products formed single derivatives when reacted with CO and *p*-tolylisocyanide (*vide infra*).

The *trans* hydride ligand in $ReHX(NO)(PPh_3)_3$ contributes to the lability of the unique phosphine making substitution with small neutral ligands very facile. Thus reacting complexes **4–9** with ligands L gives rise to the hydride series $ReHX(L)(NO)(PPh_3)_2$ (**10–15**, L = CO; **18–23**, L = RNC).[3] Reacting the yellow materials described above, obtained from the reaction of **1** with I^- or SCN^- yielded further members of the series, **16**, **17**, **24**, and **25**. There can be little question that the complexes **10–25** share the same stereochemistry, viz *trans* PPh_3 ligands and X *trans* to NO, which further supports the geometry assigned for $ReHX(NO)(PPh_3)_3$. The presence of *trans* PPh_3 groups in **10–25** is confirmed by the hydride signal in the ^1H nmr existing as a triplet in all cases, with fairly typical $^2J(HP)$ coupling constants of *ca.* 20–24 Hz. As we have observed with most other rhenium hydrido nitrosyls, chemical shifts for the hydride ligand are low by comparison to analogous complexes from groups 8–10 (1, 3).

That the X group is *trans* to NO is shown most clearly in $ReH(OCH_3)(CO)(NO)(PPh_3)_2$ (**10**) prepared in this way and $ReHF(CO)(NO)(PPh_3)_2$ (**11**). Complex **10** has identical spectroscopic parameters with samples isolated by different means and shown by deuteration studies to have the OCH_3 ligand *trans* to NO (1). We have also shown previously that reacting the cation $[ReF(CO)(NO)(PPh_3)_3]^+$ with BH_4^- gives $ReHF(CO)(NO)(PPh_3)_2$ (**11***a*), for which deuteration established that the fluoro ligand was *trans* to CO (3). We postulated at the time that this was probably a kinetic isomer, even though attempts to isomerize this isomer to the thermodynamically stable form with F *trans* to NO failed. Not surprisingly, therefore, complex **11** has quite different spectroscopic properties from its previously isolated isomer **11***a*. The data for both isomers are presented in the tables for ease of comparison.

Changing from H *trans* to NO in **11***a* to H *trans* to CO in **11** has some predictable consequences in the infrared spectra. Because νReH in both complexes **11** and **11***a* is intermediate in value between νCO and νNO, the presence of a Fermi resonance interaction will raise the former and decrease the latter. Thus, on going from **11***a* to **11**, νCO increases because a resonance interaction is introduced and νNO is likewise increased because a similar interaction is removed. The effect of the resonance interactions is overlaid with the electronic effects inherent in changing the ligand *trans* to CO and NO. The fluoro ligand is known for its excellent π-donor characteristics and hence its ability to lower νCO and νNO when *trans* to those ligands (5, *vide supra*). In the case of **11** and **11***a*, these two effects work in the same direction for νCO but oppose each other in determining the value of νNO. Since νNO shifts to a lower values in **11***a*, it would appear that the resonance interaction is the more important. Unfortunately, and for reasons which are not clear, νReH in the series **10–17** could not be observed, even though it is seen at 1870 cm^{-1} in $ReH(OCH_3)(CO)(NO)(PPh_3)_2$, at 1835 cm^{-1} in **11***a* and in the entire series **18–25**. The spectroscopic differences between **11** and its isomer **11***a* in the ^1H nmr are less pronounced, except for $^2J(HF)$ which for **11** is over twice that of **11***a*. The significance of this difference is not apparent since such coupling constants are sufficiently rare for it to be impossible to establish what represents a normal value.

It is interesting to note that the thiocyanate ligand in both **17** and **25** appears to be S-bound. The νNC values for these complexes of around 2125 cm^{-1} fall well within the S-bound range and there is no evidence of νCS in the 800–850 cm^{-1} region (6, 8). This situation is to be contrasted with that found for the complexes $ReX(NCS)(CO)(NO)(PPh_3)_2$ (X = OR, Cl)[4] in which νNC occurs around 2080 cm^{-1} and is accompanied by a sharp νCS absorption in the vicinity of 845 cm^{-1}. The observation of S-bound thiocyanate groups comes as a surprise since, in our experience, the site *trans* to NO in Re(I) nitrosyls seems to favor coordination by hard ligands (1, 3). It would appear therefore that **17** and **25** are kinetic isomers derived from a precursor in which the thiocyanate ligand is also S-bound. There is in fact some evidence to support this conjecture. Infrared spectra of the precursor show νNC absorptions at 2105 cm^{-1}, borderline between the ranges normally accepted for the two coordination modes, and no evidence of a νCS band. Without knowing the exact nature of the component(s) in the precursor that give rise to **17** and **25**, it is impossible to determine what factors might be responsible for determining the mode of thiocyanate coordination. There is, however, a growing body of evidence suggesting that steric pressures play a significant role (ref. 6, pp. 338–354, 382–385; ref. 9). So, for example, arguments based on steric grounds have been used to help explain the mode of thiocyanate bonding in *mer*-$Mn(NCS)(CO)_3L_2$ versus *fac*-$Mn(SCN)(CO)_3L_2$ (L = $AsPh_3$, $SbPh_3$) (10). This could be taken to indicate that the principal component of the mixture responsible for the generation of **17** and **25** is simply $ReH(SCN)(NO)(PPh_3)_3$.

[3]Complex **11**, $ReHCl(CO)(NO)(PPh_3)_2$, has been alluded to in a recent publication (7).

Drop calorimetry of the compounds $NbCl_5$, $TaCl_5$, $RbNbCl_6$, $CsNbCl_6$, $RbTaCl_6$, and $CsTaCl_6$

E. E. SHAWKI,[1] S. N. FLENGAS, AND D. R. SADOWAY[2]

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received February 9, 1988[3]

E. E. SHAWKI, S. N. FLENGAS, and D. R. SADOWAY. Can. J. Chem. **67**, 1193 (1989).

Enthalpy contents for $NbCl_5$, $TaCl_5$, $RbNbCl_6$, $CsNbCl_6$, $RbTaCl_6$, and $CsTaCl_6$ were measured as functions of temperature using a high temperature aluminum block drop calorimeter. It was found that the solid compounds $RbNbCl_6$, $CsNbCl_6$, $RbTaCl_6$, and $CsTaCl_6$ undergo allotropic solid–solid transformations and the enthalpies and entropies associated with these phase changes, as well as from fusion, have been evaluated.

Molar heat capacities for the systems investigated are reported as linear functions of temperature.

The molar heat capacities for solid and molten $NbCl_5$ or $TaCl_5$ were used together with available vapour pressure data to express enthalpies and free energies of vaporization for these compounds as functions of temperature through the third law calculation method.

Key words: calorimetry, heat capacities, transition enthalpies, niobium compounds, tantalum compounds.

E. E. SHAWKI, S. N. FLENGAS et D. R. SADOWAY. Can. J. Chem. **67**, 1193 (1989).

Utilisant un calorimètre adiabatique en aluminium opérant à haute température, on a mesuré les enthalpies du $NbCl_5$, du $TaCl_5$, du $RbNbCl_6$, du $CsNbCl_6$, du $RbTaCl_6$ et du $CsTaCl_6$ en fonction de la température. On a trouvé que les composés solides $RbNbCl_6$, $CsNbCl_6$, $RbTaCl_6$ et $CsTaCl_6$ subissent des transformations allotropiques solide–solide et on a évalué les enthalpies et les entropies associées avec ces changements de phase ainsi qu'avec la fusion.

On rapporte les capacités calorifiques molaires des systèmes étudiés sous la forme de fonctions linéaires de la température.

Faisant appel à la méthode de calcul de la troisième loi de la thermodynamique et utilisant les capacités calorifiques molaires des $NbCl_5$ et $TaCl_5$ solides et fondus de concert avec les données disponibles relatives aux pressions de vapeur, on a pu obtenir une expression permettant de relier les enthalpies et les énergies libres de vaporisation de ces composés en fonction de la température.

Mots clés: calorimétrée, capacités calorifiques, enthalpies de transition, composés de niobium, composés de tantalum.

Introduction

The complex compounds $NaNbCl_6$, $NaTaCl_6$, $KNbCl_6$, $KTaCl_6$, $RbNbCl_6$, $RbTaCl_6$, $CsNbCl_6$, and $CsTaCl_6$ have been synthesized in this laboratory by the reaction of $NbCl_5$ or $TaCl_5$ vapours with the respective alkali metal chlorides, in closed reactors, under specific temperature and vapour pressure conditions. The preparation method has been given elsewhere (1). X-ray diffraction patterns were also determined and temperatures for phase transformations were measured by the cooling curve technique.

These compounds represent thermodynamically stable forms of the volatile covalently bonded pentachlorides of Nb and Ta (2, 3) and, as such, they are of interest for the separation of Nb from Ta (4), and as potential electrolytes for the recovery of these metals by used salt electrolysis.

Crystal structures of the $AMCl_6$ type compounds, where A is an alkali metal like Na, K, Rb, and Cs, and M is either Nb or Ta, and parts of the phase diagrams of the ACl–MCl_5 type binary systems have also been reported by several investigators (1, 5–9).

In the present investigation the thermal properties of the compounds $NbCl_5$, $TaCl_5$, $RbNbCl_6$, $CsNbCl_6$, $RbTaCl_6$, and $CsTaCl_6$ were measured by drop calorimetry from various high temperatures. From these measurements molar heat capacities have been calculated as functions of temperature, and enthalpy changes representing solid–solid allotropic transformations and melting have been obtained.

Thermal data for these compounds, with the exception of $NbCl_5$ and $TaCl_5$, are not available in the literature.

Experimental

The preparation of anhydrous $NbCl_5$ and $TaCl_5$ having a purity better than 99.99% by weight and the synthesis of the stoichiometric $AMCl_6$-type compounds having a purity better than 99.8% by weight, have been described elsewhere (1, 2). The stoichiometry of each complex compound was determined from the weight gain of the alkali chloride when it is reacted with either $NbCl_5$ or $TaCl_5$ vapours. In all cases the mole ratio MCl_5/ACl was better than 0.995.

The twin Al-block drop calorimeter used for these measurements was the same instrument previously designed and built in this laboratory (10, 11).

The calorimeter proper was calibrated with synthetic sapphire certified by the U.S. Bureau of Standards. Its enthalpy content is known to be the following function of temperature (12),

$$[1] \quad H_T - H_0 = 82.1461 + 1.7106 \times 10^{-6} T^2 - 46.9949 \times \log_{10} T + 0.1485704\, T \ (\text{in kJ mol}^{-1})$$

where T is in Kelvin.

A typical calorimetric trace is given in Fig. 1.

The measured thermopile signals were all referred to a common reference temperature of 298 K, using the linear correction method of Goodkin *et al.* (13).

Since evacuated silica glass capsules lined with Pt-foil 0.5 mm thick were used as containers for the sapphire and for the salt samples, experiments were performed to determine the thermopile output per gram of silica and per gram of Pt, for temperatures up to 650°C. The least squares fit to 27 experimental points for SiO_2 corresponds to the linear equation,

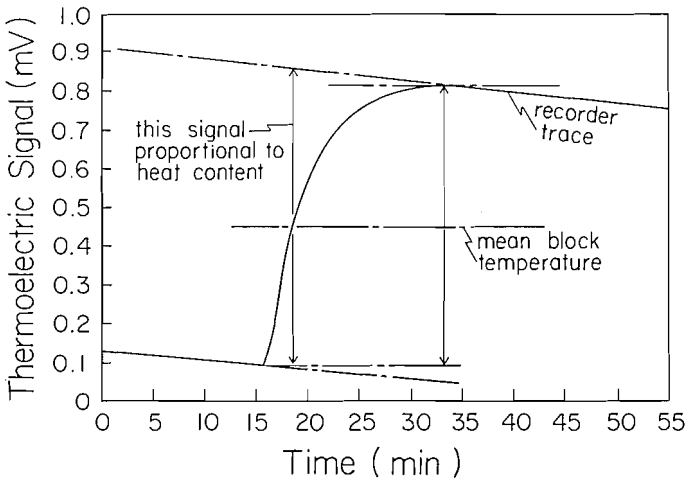

FIG. 1. Typical calorimetric trace of the thermopile signal.

[2] $V_{SiO_2} = -2.3943 \times 10^{-2} + 6.4691 \times 10^{-5} T + 1.83271 \times 10^{-8} T^2 + 849.5 \times 10^{-3} T^{-1}$ (in mV/g SiO_2)

where T is given in Kelvin. The correlation coefficient is 0.9997 and the standard error of estimate is 3.129×10^{-3} mV/g SiO_2.

The latter is a measure of the scatter about the linear regression curve and is calculated from the well known expression

$$S_{y,x} = \sqrt{\frac{\Sigma d^2}{n}}$$

where d's are the differences between the experimental and the estimated values of a dependent variable y, where $y = f(x)$.

The corresponding thermoelectric signal for platinum, based on eleven determinations, was

[3] $V_{Pt} = 4.692 \times 10^{-3} + 4.498 \times 10^{-6} T + 3.205 \times 10^{-9} T^2 + 177.194 \times 10^{-6} T^{1/2}$ (in mV/g Pt)

The correlation coefficient is 0.9996 and the standard error is 6.5×10^{-6} mV/g Pt, for temperatures up to 650°C.

Eleven drops were made with capsules containing the NBS sapphire to cover the temperature range from 150 to 650°C.

In a typical calibration experiment, the weight of the silica capsule was 7.0 g, the weight of Pt liner was 1.0 g, and that of the synthetic sapphire was 7 g.

The calorimetric constant of the instrument, or the number of joules corresponding to one millivolt of thermopile emf, was calculated from eqs. [1], [2], and [3]. The mean of eleven determinations, from 160 to 663°C, gave a value of 11 853 ± 259 J per mV.

There was no detectable temperature dependence.

With this value, and eqs. [1] and [2], the enthalpy contents of silica and platinum, at 600°C, were calculated and compared well with literature values (14). Thus, $H_{600} - H_{298}$ for platinum, which is given as 8 066 J mol^{-1}, compares well with the present value of 8 100 J mol^{-1} calculated from the present results. Similarly, for silica, the literature value of 16 556 J mol^{-1} compares well with the present 16 300 J mol^{-1}.

From such comparisons and from calculations of the standard errors, it is estimated that the calorimeter used for the present measurements was capable of measuring enthalpy contents with confidence to better than 2%.

Enthalpy contents for the various compounds were measured on at least two samples for each compound. Sample weights were between 10 and 15 g. The vapour space in the capsules was small enough that vaporization had a negligible effect on enthalpies.

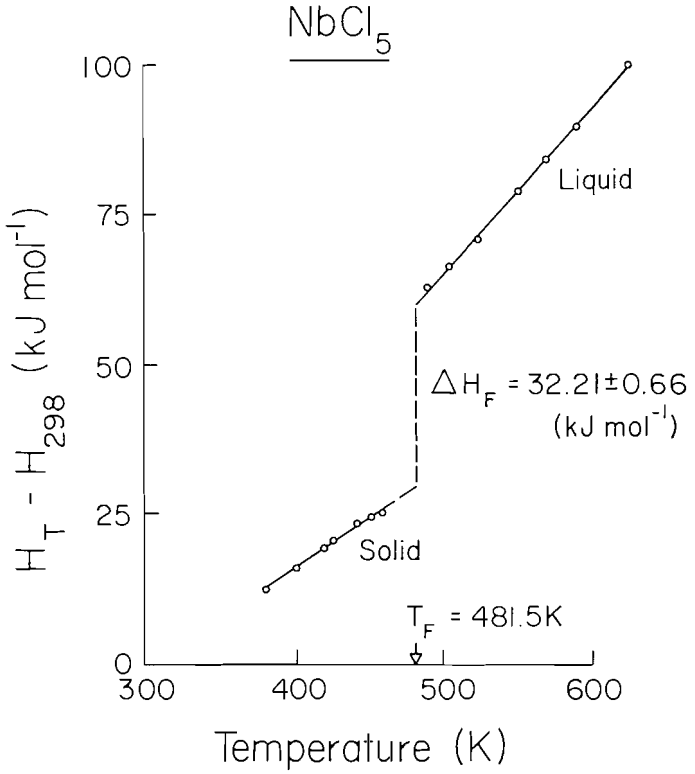

FIG. 2. Enthalpy content of $NbCl_5$ as a function of temperature. Points are experimental. Curves drawn through points represent the least squares fit from Table 1.

Results

Plots of $H_T - H_{298}$ for the various compounds investigated are presented in Figs. 2 to 7. The data have been fitted by least squares to second order polynomials of the form,

[4] $H_T - H_{298} = a + bT + cT^2$ (kJ mol^{-1})

Values of the coefficients a, b, and c are given in Table 1 together with the corresponding standard errors and the temperature ranges of measurements.

Molar heat capacities are readily calculated from eq. [4] from the expression $(\partial H/\partial T)_p = C_p$, as

[5] $C_p = A + BT$ (J K^{-1} mol^{-1})

The coefficients A and B for the molar heat capacities, transition enthalpies, and transition temperatures, are given in Table 2.

Enthalpy changes corresponding to solid–solid transformations, or to melting, have been obtained by extrapolating the enthalpy contents for any two different phases to the corresponding transition temperatures.

Prior to a drop, solid samples of a compound in either the α or the β configuration were kept at the desired constant high temperature for time periods differing by over 6 h with no detectable effect on their enthalpy contents. It appears, therefore, that complete conversion to the higher temperature configuration was achieved in all cases.

Discussion

A survey of the literature shows only one other calorimetric study of the enthalpy content of $NbCl_5$. Keneshea *et al.* (15) measured the enthalpy increments above 298 K for solid and

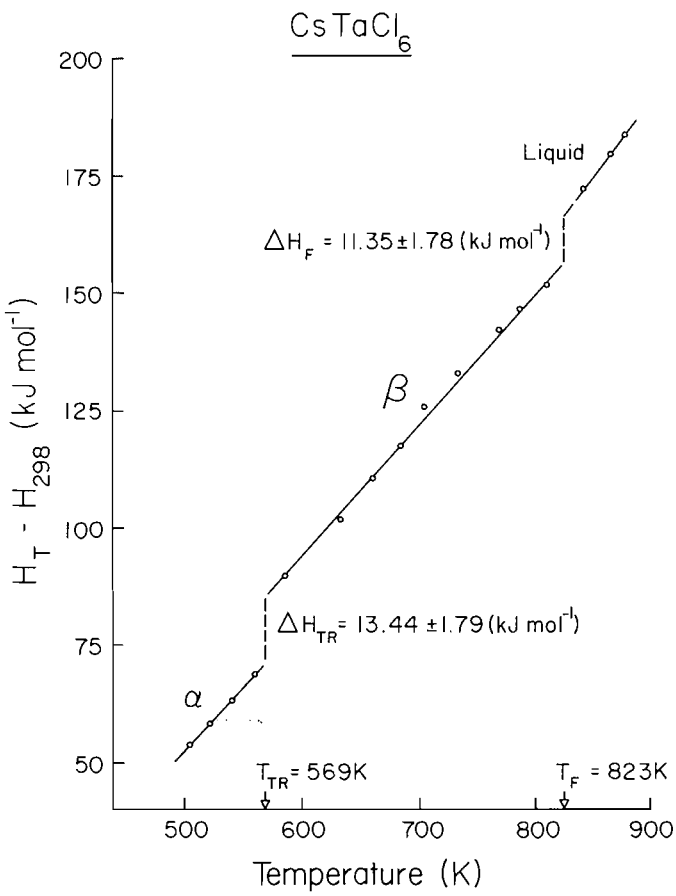

FIG. 7. Enthalpy contents of $CsTaCl_6$ as a function of temperature. Curves drawn through the experimental points represent the least squares fit from Table 1.

Experimental measurements of the heat capacities of solid and liquid $TaCl_5$ could not be found in the literature. However, Schaefer and Kahlenberg (16) estimated the heat capacity of $TaCl_5$ by comparison with the heat capacities of $ZrCl_4$ and $HfCl_4$. According to their estimates

[8] $C_{p(s)TaCl_5} = 159.0 - 12.55 \times 10^5 T^{-2}$ (J K^{-1} mol^{-1})

Heat capacities for solid $TaCl_5$ calculated from eq. [8] are about 8% lower than the present results.

A comparison between enthalpies of fusion for $NbCl_5$, reported by several investigators, is given in Table 3.

The standard enthalpy and entropy increments for $TaCl_5$ up to 550 K calculated from the present results are tabulated in Table 1.

Interpolation of the solid and liquid enthalpy lines to the melting points at 497 K gives the heat of fusion of $TaCl_5$ as

$$\Delta H_{f(TaCl_5)} = 32.56 \pm 0.66 \text{ (kJ mol}^{-1}\text{)}$$

This value is compared with the literature values in Table 3. It appears from the above comparison that the measured enthalpy of fusion is in excellent agreement with values by Shchukarev *et al.* (19) and by Saeki *et al.* (20) calculated from vapour pressure measurements. The present value is about 10% lower than that obtained by Dobrotin *et al.* (17) from calorimetric measurements for which no error limits were given.

Uncertainties in transition enthalpies are obtained by taking the square root of the sum of the squares of the standard errors of estimates for each of the enthalpy curves before and after a transition temperature, respectively.

As the equilibrium vapour pressures for the pure solid and pure liquid $NbCl_5$ (1, 21–26) and $TaCl_5$ (27), respectively, are available, the temperature dependence of the thermodynamic functions for each system may be calculated using the well known Σ-function method (28).

Molar heat capacities for gaseous $NbCl_5$ and $TaCl_5$ are also known and have been included in Table 2. If the heat capacities of either the gaseous or condensed state materials are represented by eq. [5]. The Σ-function for either the vaporization or sublimation reactions of $NbCl_5$ and $NbCl_5$ is given as

[9] $$\Sigma = \frac{\Delta H_0}{T} + \mathrm{I} = -R \ln P + \Delta A \ln T + \frac{\Delta B}{2} T$$

where ΔA and ΔB are the differences between the heat capacity constants of the gaseous and the corresponding condensed phases.

The enthalpy of vaporization, ΔH_v, or sublimation, ΔH_s, can then be expressed in the form

$TaCl_5$	33.05	Vapour pressure	20
$TaCl_5$	25.52	Vapour pressure	21

*The melting points are those reported in the respective investigations.

$$[10] \quad \Delta H_{v \text{ or } s} = \Delta H_0 + \Delta AT + \frac{\Delta B}{2} T^2$$

and similarly, the free energies of vapourization or sublimation are given as

$$[11] \quad \Delta G_{v \text{ or } s} = IT + \Delta H_0 - \Delta AT \ln T - \frac{\Delta B}{2} T^2$$

the unknowns in the above equations, i.e., ΔH_0 and I, are integration constants that can be determined from a plot of Σ versus $1/T$, as the slope and the intercept, respectively.

For the vaporization reaction,

$$[12] \quad NbCl_{5(liquid)} \rightarrow NbCl_{5(vapour)}$$

for temperatures up to 600 K, the corresponding Σ-plot was linear and least squares regression analysis yielded the enthalpy and free energy functions as

$$[13] \quad \Delta H_v = 126.54 - 0.1354\,T + 11.20 \times 10^5\,T^{-1} \quad (\pm 0.79 \text{ kJ mol}^{-1})$$

and as

$$[14] \quad \Delta G_v = 126.53 + 1.0924\,T + 0.1354\,T \ln T + 5.6 \times 10^{-3}\,T^{-1} \quad (\pm 0.79 \text{ kJ mol}^{-1})$$

The enthalpy of vaporization calculated from eq. [13] at the boiling temperature of 502.3 K is 60.67 ± 0.79 kJ mol^{-1}. Literature values vary from 46.86 to 62.76 ± 6.3 kJ mol^{-1}, while the vapour pressures calculated from the free energy function in eq. [14] compare very well with the vapour pressures measured in our laboratory (2).

For the sublimation reaction,

$$[15] \quad NbCl_{5(s)} \rightarrow NbCl_{5(vap)}$$

$$[16] \quad \Delta H_s = 95.621 + 1.548 \times 10^3\,T^{-2} \quad (\pm 3.0 \text{ kJ mol}^{-1})$$

For $TaCl_5$, the upper temperature limit for vapourization was 511 K, where the vapour pressure of $TaCl_5$ reaches 1 atm pressure. Σ-function plots for vapourization were linear, and the enthalpy and free energy functions by the least squares method are given, respectively, as:

$$[17] \quad \Delta H_{v(TaCl_5)} = 141.038 - 0.1747\,T + 1.548 \times 10^3\,T^{-1} \quad (\pm 0.21 \text{ kJ mol}^{-1})$$

and as

$$[18] \quad \Delta H_{v(TaCl_5)} = 141.038 - 1.3694\,T + 0.1747\,T \ln T + 7.74 \times 10^2\,T^{-1} \quad (\pm 0.21 \text{ kJ mol}^{-1})$$

ΔH_v at the boiling temperature of 502.7 K, is 56.27 ± 0.21 kJ mol^{-1}. Literature values vary between 62.34 and 48.95 (±4 kJ mol^{-1}).

Again, vapour pressures for $TaCl_5$ calculated from eq. [18] compare well with experimental measures (2).

For the sublimation reaction

$$[19] \quad TaCl_{5(s)} \rightarrow TaCl_{5(vap)}$$

the Σ-function method yielded the equation,

$$[20] \quad \Delta H_s = 93.960 + 1.548 \times 10^3\,T^{-2} \quad (\pm 3.94 \text{ kJ mol}^{-1})$$

The larger errors shown in eqs. [16] and [20] reflect differences between the available experimental vapour pressure data and possible uncertainty in the molar heat capacity data from which the Σ-function values were evaluated.

The linearity of the Σ-plots is usually taken as an indication of the accuracy and of compatibility between the calorimetric molar heat capacities and the corresponding vapour pressure data representing the equilibria between the condensed and the vapour phases. Thus, the Σ-function method is also a test of the accuracy of the experimental data used for the calculations, because, if either the calorimetric or the vapour pressure measurements are in error then the Σ versus $1/T$ plots cannot be linear (28).

Regarding the four complex compounds, $CsNbCl_6$, $RbNbCl_6$, $CsTaCl_6$, and $RbTaCl_6$, the large enthalpy and entropy effects associated with their allotropic changes suggest that their solid structures undergo dramatic changes before melting. Such large enthalpy and entropy effects may indicate fast-ion conduction in the high-temperature phases and to the possible use of these compounds in solid state chemical sensors (30).

Electronic spectrum of bibenzimidazole homologue: effects of solvents and acid concentration

AWADESH KUMAR, HEMANT K. SINHA, AND SNEH K. DOGRA[1]
Department of Chemistry, Indian Institute of Technology, Kanpur – 208 016, India

Received June 14, 1988[2]

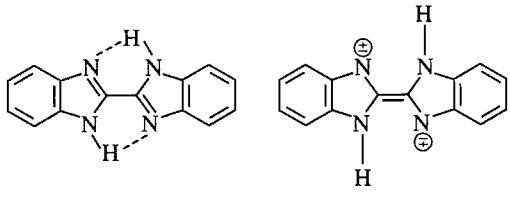
AWADESH KUMAR, HEMANT K. SINHA, and SNEH K. DOGRA. Can. J. Chem. **67**, 1200 (1989).

The absorption and fluorescence spectra of bibenzimidazole (BBI), *N,N'*-dimethylbibenzimidazole (MBBI), and methylene, 2,2'-bibenzimidazole (MtBBI) have been recorded in six solvents of different characteristics and at various acid concentrations. This study indicates the presence of intramolecular hydrogen bonding in BBI in both S_0 and S_1 states, leading to large conjugation of two benzimidazole (BI) rings. The geometry of BBI is the same in the S_0 and S_1 states. The spectral characteristics of BBI are insensitive to the solvents. The interaction of solvent molecule attached to the nitrogen lone pair and methyl group rotates the benzimidazolyl ring in MBBI around the single bond. This leads to a blue shift in the long wavelength absorption band maximum and a decrease in the intensity of this band. The two MBI rings are coplanar in the S_1 state. Presence of methylene group inhibits the direct interaction between the BI groups and these rings behave almost independently, i.e., the spectral characteristics of this molecule nearly resemble those of benzimidazole.

Key words: absorption spectrum, fluorescence spectrum, pK_a, bibenzimidazoles, excited state pK_a.

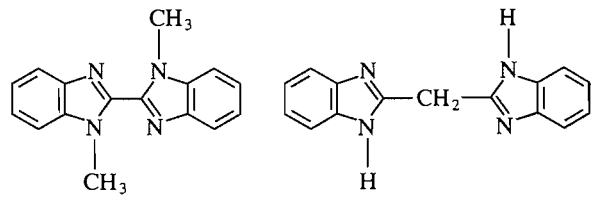
AWADESH KUMAR, HEMANT K. SINHA et SNEH K. DOGRA. Can. J. Chem. **67**, 1200 (1989).

Opérant à diverses concentrations d'acides et dans six solvants de caractéristiques diverses, on a déterminé les spectres d'absorption et de fluorescence du bibenzimidazole (BBI), du *N,N'*-diméthylbibenzimidazole (MBBI) et du méthylène-bibenzimidazole-2,2' (MtBBI). Cette étude indique qu'il existe des liaisons hydrogènes dans les états S_0 et S_1 du BBI. Les caractéristiques des spectres du BBI ne sont toutefois pas sensibles aux solvants. Dans le MBBI, l'interaction entre le groupement méthyle et la molécule de solvant attachée à la paire d'électrons libres de l'azote provoque une rotation du cycle benzimidazolyle autour de la simple liaison. Ceci provoque un déplacement vers le bleu du maximum de la bande d'absorption présente aux grandes longueurs d'onde ainsi qu'une diminution de l'intensité de cette bande. Dans l'état S_1, les deux cycles MBI sont coplanaires. La présence d'un groupement méthylène inhibe l'interaction directe des groupements BI et ces cycles se comportent comme s'ils étaient pratiquement indépendants, c'est-à-dire que les caractéristiques spectrales de cette molécule ressemblent beaucoup à celles du benzimidazole.



Mots clés : spectre d'absorption, spectre de fluorescence, pK_a, bibenzimidazoles, pK_a de l'état excité.

[Traduit par la revue]



Introduction

Benzimidazole and its derivatives have been used extensively in medicine and industry (1–3). The chemistry of bibenzimidazoles has received attention recently because of its potential to act as a potent inhibitor of rhinoviruses (4) and as an effective chelating agent for metal ions (5, 6). However, until recently, there have been no reports in the literature on the photophysics and the photochemistry of these molecules.

In the present study we have selected 2,2'-bibenzimidazole (BBI), *N,N'*-dimethyl-2,2'-bibenzimidazole (MtBBI), and methylenebibenzimidazole (MBBI). Looking at the structure of BBI, one would expect the presence of intramolecular hydrogen bonding, resulting in a planar conformation (**I**) both in S_0 and S_1 states even though the imino N—H bond will be distorted and will lead to non-linear N—H—N bond. This interaction may bring about conjugation in the two rings. Apart from intramolecular hydrogen bonding, BBI may also possess a resonance dipolar structure (**II**) similar to quinoxaline (7–9). This will increase the bond order to the link that joins the two benzimidazole moieties. This interaction may bring about drastic changes in the spectral characteristics and dissociation constants of the various prototropic reactions, which this molecule may undergo, as compared to those of benzimidazole (BI) (10, 11). In MBBI (**III**), though the intramolecular hydrogen bonding will be absent, the molecule may possess a resonance dipolar structure. On the other hand, in MtBBI (**IV**)

I **II**

III **IV**

both intramolecular hydrogen bonding and dipolar resonance structure will be absent. Thus the spectral characteristics of MBBI and MtBBI and their prototropic species will be different from those of BBI and its prototropic species. To prove these points and to see the differences in the spectral characteristics of three molecules and their prototropic species, the absorption and fluorescence spectra have been recorded in six solvents of different polarities and hydrogen bond forming tendencies, as well as at various acid concentrations. The pK_a values for the different prototropic reactions have been determined in the S_0 and S_1 states and are discussed.

Materials and method

BBI was prepared by reacting *o*-phenylenediamine monohydrochloride with methyltrichloroacetimidate with acetic acid

as a solvent (12). MBBI was synthesized (13) by condensing *N*-methylbenzimidazole using powdered sodium, whereas the *N*-methylbenzimidazole required for this purpose was prepared by methylating (14) BI with methyliodide in alkaline medium. MtBBI (15) was prepared by condensing *o*-phenylenediamine with malonic acid in 2:1 molar ratio using polyphosphoric acid. These compounds were recrystallized from alcohol and their purity was checked by noting the melting point, thin layer chromatography, absorption spectra, and similar fluorescence spectra obtained when excited at different wavelengths. Analytical grade sulphuric acid, sodium hydroxide, *o*-phosphoric acid (all BDH), trifluoroacetic acid (TFA, Fluka), and spectroscopic grade methanol (BDH) were used as such. Cyclohexane, ether, dioxane, and acetonitrile (all AR) were further purified for spectral purposes as reported in literature (16). Triply distilled water was used for making aqueous solutions. The pH of the solutions in the range of 3 to 11 were adjusted by adding appropriate amounts of *o*-phosphoric acid and sodium hydroxide. The phosphate buffers in these concentrations do not quench the fluorescence of the desired compound and do not affect the prototropic equilibrium (17). Solutions below pH 1 were prepared by following Jorgenson and Hartter's H_0 scale (18) for H_2SO_4–H_2O mixtures and above pH 13 by Yagil's H_- scale (19) for NaOH–H_2O mixtures. The pH of the solutions between 1–13 were measured on a Toshniwal pH meter model CL44A. Absorption measurements were made on Shimadzu UV-190 spectrophotometer, equipped with a U-135 chart recorder. The fluorescence spectra were recorded on a laboratory-made scanning spectrofluorimeter, the details are available elsewhere (20). The fluorescence spectra were corrected according to the procedure suggested by Parker (21) and the fluorescence quantum yields were determined with the solutions of absorbances less than 0.1, using quinine sulphate in 0.1 *N* H_2SO_4 as a standard (22). For calculating the equilibrium constants for the various prototropic reactions, solutions were prepared just before making measurements. For fluorimetric titrations, the isosbestic wavelengths were used for the measurements of the relative fluorescence intensities at the analytical wavelengths as a function of H_0/pH/H_-.

Results and discussion

Effect of solvents

The absorption and fluorescence spectra of BBI, MBBI, and MtBBI were recorded in solvents of different polarity and hydrogen bond forming capacity. The relevant data are compiled in Tables 1 and 2, respectively. Due to the poor solubility of these compounds in all solvents except methanol, the molecular extinction coefficients are reported for methanol only. The long wavelength absorption band maxima of BBI are very large red shifted with respect to that of benzimidazole (BI) (23) and the absorption spectrum can be divided into four band systems, whereas there are only three band systems for BI. The band above 300 nm is highly structured with the vibrational frequency 1400 ± 50 cm^{-1}. The other three band systems are similar to that of BI, but slightly red shifted (i.e. at 280 nm, 250 nm, 210 nm). Similar to the absorption spectrum, the fluorescence spectrum of BBI is also red shifted as compared to BI (11) and is highly structured, with vibrational frequency of ~1420 ± 50 cm^{-1}. The short wavelength band at 339 nm can be assigned to the zero–zero transition. Both the absorption (long wavelength band) and fluorescence spectra are nearly insensitive to the polarity and hydrogen bond forming capacity of the solvents.

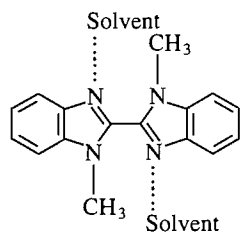
The absorption spectrum of MBBI resembles that of BBI in cyclohexane, but the band system above 300 nm, unlike BBI, is very sensitive to the solvent polarity and hydrogen bonding nature. For example, the vibrational structure of this band (above 300 nm) is completely lost and a large blue shift is observed in this band maximum. The intensity of this band also decreases and in water this band system is a weak shoulder. On the other hand, the fluorescence spectrum of MBBI exactly resembles that of BBI in all the solvents (zero–zero transition can be assigned to 344 nm band and ν_{vib} = 1440 ± 50 cm^{-1}). The fluorescence quantum yield of MBBI is less than that of BI (24). Lastly, the absorption and fluorescence spectra of MtBBI resembles that of BI (11, 24) in all respects. The zero–zero transition in fluorescence spectrum can be assigned to 288 nm and ν_{vib} = 1200 ± 50 cm^{-1}.

In biphenyl, the long wavelength absorption band is broad (~247 nm) and it has been shown to be a mixture of two or three transitions (25–27). Furthermore, it has also been proved that the two phenyl rings are not coplanar in the ground state whereas the distortion angle changes in the excited singlet and BP (28) is more planar (not completely) in S_1 than in S_0. However, from the data of Tables 1 and 2, it is possible to say that the fluorescence band of BBI is not separated much from and makes a mirror image with its long wavelength absorption band, indicating that the molecular conformation in the first excited singlet state differs little from that in the ground state. The fluorescence spectrum was found to be independent of the excitation wavelengths and of concentration. It is thus suggested that the two benzimidazolyl rings are coplanar in S_0 and S_1 states and the suggested conformation of BBI is structure **I**, i.e., a symmetrical structure. The following points can be made in its favour.

(*i*) The long wavelength absorption band and the fluorescence spectrum are highly structured and substantially red shifted as compared to BI, indicating extensive conjugation between the two rings.

(*ii*) A similar vibrational frequency (~1400 cm^{-1}) is also observed in the compounds, where the conjugated substituent is present at the position 2 of BI, thereby forming a three- or four-membered ring system, e.g., 2-phenylbenzimidazole (29), 2-(2′-aminophenyl) (30), 2-(2′-hydroxyphenyl) (31), 2-(3′-hydroxyphenyl) (32), 2-(3′-aminophenyl) (33), 2-(4′-aminophenyl) (34), and 2-(4′-hydroxyphenyl)benzimidazoles (32). This vibrational frequency is very different from that noticed in BI and MtBBI. The direct conjugation of two benzimidazolyl rings is absent in the latter molecule.

(*iii*) The presence of intramolecular hydrogen bonding in BBI, leading to the presence of rigidity in the BBI structure, is further reflected in the insensitivities of the absorption and fluorescence spectra in the presence of the different solvents. The structure **I** of BBI is totally symmetric and both the lone pairs on the tertiary nitrogen atoms are blocked by the intramolecular hydrogen bonding. Thus, no change in absorption and fluorescence spectral characteristics are observed in the above environments. It is further manifested in the fluorescence quantum yields, which nearly remain constant in different solvents. The high value of fluorescence quantum yield also reflects that the molecule is rigid.



(*iv*) Near rigidity in BBI can also be achieved if we assume the resonance structure **II**. Similar resonance structure can also be achieved in MBBI. However, the effect of solvents on the absorption spectra of BBI and MBBI excludes a major contribution of structure **II** to the main structures of BBI and MBBI.

The absorption spectrum of MBBI in cyclohexane indicates that conjugation is possible in MBBI without involving intramolecular hydrogen bonding (which is not possible). In other solvents, it can be explained by a possible direct interaction between the lone pairs of MBBI and the solvents. This leads to steric interactions between the methyl groups and the solvent molecule as shown below and thus, rotation around the single bond takes place. A large blue shift in the absorption spectrum and a decrease in the absorbance in water and methanol substantiate their interactions. A weak shoulder at 294 nm in the protonic solvents indicates that a complete noncoplanarity is not achieved. On the other hand, the data in Table 2 show that the two rings of MBBI are coplanar and conjugation is achieved in the excited state in all solvents. The driving force behind this seems to be the transition moment vector which is long axis polarised, increasing the bond order of the single bond joining

the two rings. The small red shift observed in the fluorescence spectra of MBBI in water and methanol is due to the hydrogen bonding interaction with the lone pair of the tertiary nitrogen atoms. The decrease in the fluorescence quantum yield in any given solvent, as compared to BBI, may be due to the presence of methyl groups, which can increase the rates of radiationless processes. This is due to an increase in the number of vibrational

modes. The value of the fluorescence quantum yield of MBBI resembles that of 2-methylbenzimidazole (35).

The absorption and fluorescence characteristics of MtBBI are exactly the same as those of 2-methylbenzimidazole (35) in all solvents, indicating that the presence of a methylene group in between the two benzimidazolyl rings has drastically reduced their interaction. Similar behaviour has been observed in many cases where the presence of a methylene group inhibits the interaction of the two functional groups (36–38).

Effect of acid concentration

The absorption and fluorescence spectra of BBI, MBBI, and MtBBI have been studied in the H_0/pH/H_- range of −10 to 16. The relevant data have been compiled in Tables 1 and 2, respectively. The spectral changes observed in the absorption and fluorescence spectra, due to the formation of various prototropic species of the neutral molecules, are consistent with earlier studies on these chromophores (36–38), i.e. the red shift is observed in the absorption and fluorescence spectra when the protonation occurs at the tertiary nitrogen atom and deprotonation takes place at the imino group if $\pi \rightarrow \pi^*$ is the lowest energy transition. Thus the monocation at pH 1 and the dication at H_0 −6 are formed by protonating one and both the tertiary nitrogen atoms, respectively, in all cases. The monoanion at pH 12 and dianion of BBI at H_- 15 are formed by the deprotonation of one and both the imino groups, respectively. The monoanion and dianion of MBBI cannot be obtained as there are no dissociable imino protons whereas only the monoanion is formed in the case of MtBBI at H_- 15 and no dianion is formed even in the highly basic solutions used in our experiments. The spectral shifts occurring in this compound are similar to those noticed in case of BI (23) and an explanation similar to that given earlier can be offered.

The monocation of MBBI and dications of MBBI and MtBBI showed broad red shifted fluorescence bands. The nonfluorescent nature of monocation of MtBBI can be explained as follows. As said earlier, the spectral characteristics of MtBBI are similar to those of BI. The fluorescence quantum yield of neutral BI (0.7) is nearly ten times more than that of its monocation (0.07) (24). It is possible that the fluorescence quantum yield of the monocation of MtBBI is too low to be detected by our instrument. This indicates that the interaction of water with the monocation of MtBBI increases the rates of radiationless processes. This has been manifested in the fluorescence spectrum (368 nm) of MtBBI in cyclohexane + 1% (v/v) TFA. The absorption and fluorescence spectra in the latter solvent resemble that of monocation of BI, indicating that the rates of radiationless processes in the monocation of MtBBI are quite large in polar solvents. Furthermore, it is clear that the monoanion of MtBBI gives rise to the fluorescence band maximum (i.e. 306 nm), similar to that of BI. From our data, it is very difficult to pinpoint why the monocation and monoanion are nonplanar (or having a broad fluorescence band) and the dication and dianion of BBI are coplanar (or have structured fluorescence bands with similar vibrational frequencies as noticed for neutral BBI). The fluorescence spectra of the monocation and monoanion of BBI are broad band with band maxima at 390 and 396 nm, respectively, whereas those of dication and dianion are structured with ν_{vib} equal to 1400 ± 50 cm^{-1} and 1410 ± 50 cm^{-1}, respectively. This indicates that both the dication and dianion could be planar. No dianion of the latter molecule similar in ground state behaviour has been observed in the excited singlet state. This is because of the formation of strong intramolecular hydrogen bonding between $>N^-$ and >NH, as shown below.

Dissociation constants

The dissociation constants (pK_a) for the various prototropic reactions of all three molecules in their ground state have been determined spectrophotometrically. The relevant data have been compiled in Table 3. The pK_a (2) values (monocation–neutral equilibrium) of all three compounds are much less than that of similar reaction of BI (i.e. 5.48) (39). Similar results have also been observed in case of prototropic reactions of pyrazine (pK_a = −0.6) (8) and quinoxaline (pK_a = 0.7) (9). These values are low when compared with the similar proto-

[a](a),(b): by Forster cycle method, using absorption and fluorescence data; (c) by fluorimetric titration.

tropic reaction of pyridine (pK_a = 5.4) or quinoline (pK_a = 4.90) (40). In these cases it is due to the presence of a second nitrogen atom at the *para* position with respect to the first one, which will lead to the formation of an exactly equivalent dipolar structure in the non-ionised molecule and these may strengthen the resonance of these species at the expense of the ion. These molecules (quinoxaline, phenanzine, and pyrazine) are analogues of azabenzenes (41), which are very weak base for similar reason. The same argument can be given in case of BBI and MBBI. Even though the two tertiary nitrogen atoms are not on the same ring, the charge transfer can lead to an exactly similar dipolar structure **II**. This may be one reason that pK_a(2) for BBI and MBBI does not decrease as much in pyrazine as in pyridine and not as much in quinaoxaline as in quinoline. The pK_a (3) for BBI (11.0) is lower than that for BI (13.25) (38). This seems to be consistent with structure **I** as the imino proton will be partially polarized by intramolecular hydrogen bonding. pK_a(3) for MtBBI (13.0) agrees with the deprotonation reaction of BI (13.25), but pK_a (2) is quite low in comparison to BI. This indicates that one methylene group can inhibit a direct interaction of two BI rings but cannot stop the charge migration completely.

The excited state pK_a values for the three molecules have been calculated fluorimetrically as well as with the help of the Forster cycle method (42) (wherever applicable) using absorption and fluorescence data. Similar to the earlier studies, the fluorimetric titrations gave the ground state pK_a values for the first protonation (pK_a(2)) and first deprotonation reaction (pK_a(3)) (9). This indicates that the prototropic equilibria 2 and 3 in the S_1 state are not established during the lifetimes of these molecules, i.e., the rate of protonation or deprotonation are much slower than the rate of radiative deactivation of these species. Data in Table 3 indicate that pK_a*(1) is greater than pK_a(1), clearly showing that the tertiary nitrogen atom becomes more basic on excitation. Similarly the value of pK_a*(4) shows that the imino group becomes a stronger acid in the excited singlet state. The pK_a* calculated for the various prototropic reactions with the help of Forster cycle method also follows a similar trend that the tertiary nitrogen atom becomes more basic and the imino group becomes more acidic on excitation. The discrepancies observed between the pK_a* values calculated using absorption and fluorescence data are due to the fact that: (*i*) fluorescence spectra of the conjugate acid–base species involved are either structured or broad, thus difficult to locate 0–0 transitions or band maxima; (*ii*) solvent relaxation for the conjugate acid–base species may be different in the ground and excited singlet states.

Conclusions

The effect of solvents on the absorption and fluorescence spectra have clearly indicated that (*i*) intramolecular hydrogen bonding is present in BBI, both in S_0 and S_1 states and thus the geometry of BBI in both the states are same; (*ii*) extended conjugation is present in MBBI in cyclohexane but steric hindrance in the solvated molecule by the methyl groups removes this conjugation and the long wavelength absorption band is blue shifted. Conjugation between the two rings in the S_1 state in all solvents is stronger, and thus MBBI is more planar in S_1 state; (*iii*) the presence of methylene group inhibits direct interaction between BI groups, thus making these rings behave almost independently; (*iv*) the small pK_a values for protonation and deprotonation reactions of BBI, MBBI as compared to BI are due to the presence of the dipolar structure **II** stabilized by resonance; (*v*) the prototropic equilibria between the monocation–neutral and neutral–monoanion are not established in the S_1 state during the lifetimes of the conjugate acid–base pair.

Chemoselective reductions with sodium borohydride

DALE E. WARD[1] AND CHUNG K. RHEE
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received January 5, 1989

DALE E. WARD and CHUNG K. RHEE. Can. J. Chem. **67**, 1206 (1989).

Under the appropriate reaction conditions, sodium borohydride is a highly chemoselective reducing agent. The order of reactivity among carbonyl groups is conjugated enones < ketones < conjugated aldehydes < aldehydes. In general, a carbonyl group of one type can be selectively reduced in the presence of a carbonyl group of a less reactive type. Reactions are conducted with excess sodium borohydride at −78°C in solvent mixtures of methanol or ethanol in dichloromethane.

Key words: sodium borohydride, chemoselective reductions.

DALE E. WARD et CHUNG K. RHEE. Can. J. Chem. **67**, 1206 (1989).

Utilisé dans des conditions réactionnelles appropriées, le borohydrure de sodium est un agent de réduction très chémosélectif. Pour les groupements carbonyles, l'ordre de réactivité est le suivant : énones conjuguées < cétones < aldéhydes conjugués < aldéhydes. En général, un certain type de groupement carbonyle peut être réduit sélectivement lorsqu'il est en présence d'un autre groupement carbonyle d'un type moins réactif. On réalise ces réactions en opérant en présence d'un excès de borohydrure de sodium, à −78°C, dans des mélanges de solvants formés de méthanol ou d'éthanol avec du dichlorométhane.

Mots clés : borohydrure de sodium, réductions chémosélectives.

[Traduit par la revue]

Introduction

The use of sodium borohydride as a reducing agent in organic chemistry has been known for over 40 years (1). Its mild reducing properties allow for considerable selectivity in the reduction of organic compounds. Aldehydes and ketones are, in general, readily converted into their corresponding alcohols in the presence of a variety of functional groups including nitro, carboxylic acid, ester, amide, carbonate, carbamate, lactone, epoxide, nitrile, halide, alkene, and alkyne. The ready availability, high stability, mild reaction conditions, ease of "work-up", and high yields contribute to the widespread use of sodium borohydride for the reduction of aldehydes and ketones (1).

The development of methods for the chemoselective reduction of the carbonyl group (e.g., aldehydes vs. ketones) continues to be of interest in organic chemistry (2–7). In this paper we report the full results[2] of our studies on the chemoselective reduction of various types of aldehydes and ketones with sodium borohydride. The order of reactivity among carbonyl groups is conjugated enones < ketones < conjugated enals < aldehydes. In general, a carbonyl group of one type can be selectively reduced in the presence of a carbonyl group of a less reactive type.

Sodium borohydride (as well as other complex metal hydrides) is a "nucleophilic" reagent in that the rate of reduction is related to the electrophilicity of the carbonyl group (1). The difference in reactivity between aldehydes and ketones towards sodium borohydride can vary by more than three orders of magnitude (8). This suggests the possibility of selective reduction.

In recent years, a large number of reagents that can selectively reduce aldehydes in the presence of ketones have been reported (2). Generally, aldehydes are more susceptible to reduction than ketones, for both electronic and steric reasons. The reagents "normally" employed for carbonyl group reduction, such as sodium borohydride, lithium aluminum hydride, and diborane, are too reactive under the usual conditions to usefully take advantage of the inherent difference in reactivity between aldehydes and ketones. The majority of the reported methods achieve chemoselectivity through the modification of the ligands on the hydride donor in order to attenuate reactivity. This approach has resulted in the development of a large number of new reagents for reduction. A conceptually different strategy would involve the modification of the reaction conditions to attenuate reactivity. Using this strategy, we have found (2*ae*) that sodium borohydride alone[3] provides chemoselectivity comparable to the best of the reported methods.

The detailed mechanism of sodium borohydride reduction of ketones remains unknown (9). A hydroxylic solvent (or additive) is required for reduction. The rate of reduction is solvent dependent with the order of reactivity among alcohols being MeOH > EtOH > *i*-PrOH > *t*-BuOH. When reactions are performed in an aprotic solvent with 2-propanol added as a reagent, the kinetic order with respect to 2-propanol is 1.5 (10). Thus sodium borohydride reactivity may be attenuated by the nature of the hydroxylic solvent and its concentration, as well as by temperature. We have examined the effect of these parameters on the selectivity observed in competitive reductions of selected aldehydes and ketones.

Results and discussion

The reactivity of carbonyl groups of a particular type can vary over a wide range. The ranges of reactivity for different types of carbonyl groups are not distinct and some overlap occurs. To define reaction conditions to maximize selectivity, compounds of similar reactivity were chosen for study. Since a high degree of selectivity will be most difficult to achieve when reactivity is similar, the examples used should represent the lower limit of selectivity. Reactions were performed with equimolar amounts of each substrate. By limiting the amount of sodium borohydride and (or) the reaction time, the total amount of reduction was less than 35%. Thus, the ratio of the alcohol products obtained is a reasonable approximation of the relative reactivity of the substrates under the conditions employed. The results are summarized in Tables 1 and 2.

[1]Author to whom correspondence may be addressed.

[2]Preliminary results have been reported (2*ae*, 5*a*).

[3]The use of $NaBH_4$ for selective reduction of aldehydes in the presence of ketones has been reported (2*c*) for two examples. The method uses 1 equiv. of hydride in ethanol at room temperature. This method gives poor selectivity (40%) with 4-methylcyclohexanone vs. hexanal.

As expected, the rate of reduction is strongly dependent on the reaction conditions. This is illustrated for the reduction of benzaldehyde (**2***a*). The approximate reaction time required for 50% reduction of **2***a* under various conditions is given in Table 3. In each case, **2***a* (0.2 mmol) was added to $NaBH_4$ (0.2 mmol) in the appropriate solvent mixture (2 mL). The solubility of $NaBH_4$ varies with solvent and temperature; in many cases a suspension is formed. The reaction rate was found to be dependent on the mixing time before the addition of

substrate. For example, if **2***a* was added immediately to $NaBH_4$ in 10% EtOH, 21 min were required for 50% reduction. Alternatively, if the $NaBH_4$ suspension was stirred for 10 min prior to the addition of **2***a*, reduction was essentially complete within 30 s. Similar results were observed in *i*-PrOH and *t*-BuOH. A possible explanation is that in the absence of dissolved $NaBH_4$ (or a derived species) a much slower heterogeneous reduction occurs in such a way as to inhibit the dissolution of $NaBH_4$ (or a derived species). To insure presaturation, mixing times of up to 30 min were employed.

While the reaction rate is attenuated with reduced concentration of alcohol, the relative reactivity remains fairly constant (typically with 25%, Table 1). Only in the case of **1***d*/**2***a* (in MeOH and EtOH) does the relative reactivity change more than a factor of 2. Similarly, at a fixed concentration (v/v), changing the nature of the alcohol has little effect on relative reactivity. Again the effect is largest with **1***d*/**2***a* (in 100% and 50% alcohol).

Interestingly, **1***d* is more reactive than **1***a* despite the apparent difference in steric hindrance. The additional α-C,C bond in **1***d* may be activating in a Felkin–Ahn sense. The difference in reactivity is related to the steric bulk of the alcohol used; however, the effect is small. The nature of the alcohol also has little effect on the relative reactivity of **3***a*/**3***c*. This is consistent with Wigfield's proposal of a "late" transition state in sodium borohydride reductions (*9a*).

Table 2 presents the effect of temperature on relative reactivity. Here a clear trend emerges. In all cases, maximum differentiation occurs at low temperature. The magnitude of the alcohol effect varies from case to case. With the exception of **1***d*/**1***a*, relative reactivity follows the order MeOH < EtOH < *i*-PrOH < *t*-BuOH. At −78°C, 50% *t*-BuOH (solid) cannot be used, while in 50% *i*-PrOH the rate of reduction of ketones and enones is very slow. In summary, the nature of the alcohol and its concentration, as well as temperature, have a significant effect on the reaction rate. The relative reactivity is influenced most strongly by temperature, to a lesser extent by the nature of the alcohol, and little by the alcohol concentration.

In developing reaction conditions for the chemoselective reduction of different types of carbonyl groups, we wished to employ sodium borohydride in excess. This would not only ensure a high degree of conversion but also provide for experimental simplicity. Similarly, we sought to control the rate of reaction such that the more reactive carbonyl group would require a few hours for complete reduction. Since maximum selectivity was observed at low temperature, we employed solvent mixtures in which the more reactive carbonyl group was completely reduced within a few hours in the presence of excess sodium borohydride at −78°C.

Selective reduction of aldehydes

Typical aldehydes are completely reduced in 1 h at −78°C with excess sodium borohydride in 30% EtOH in CH_2Cl_2 (*2ae*). Under these conditions, various aldehydes were reduced in the presence of enals, ketones, and enones. Reactions were quenched by the addition of acetaldehyde (*2ae*) and analyzed by gc and (or), after work-up, by ^1H nmr (300 MHz). The results of these competitive reductions are summarized in Table 4. Selectivity ([% reduction of aldehyde − % reduction other] ÷ [% reduction aldehyde + % reduction other])[4] is generally greater than 90%. While the conversion is typically high, some aldehydes are not reduced to completion even with prolonged reaction time (3 h), presumably due to hemiacetal formation. A typical ketoaldehyde (**1***e*)[5] is reduced with excellent selectivity. The observed selectivity compares favorably with the best of the previously reported methods (2).

The high selectivity with **3***b* is noteworthy. Relatively few of the reported methods (2) can selectively (>80%) reduce aldehydes in the presence of cyclohexanone (*2i,k,s,z,ab*). To the best of our knowledge, no methods for the selective reduction of aldehydes in the presence of conjugated aldehydes have been reported. Only in competition with benzaldehyde is the selectivity as low as 40%. The selectivity is high with other enals tested. Few methods report on the reduction of aldehydes in the presence of conjugated ketones (other than aceto-

[4]This is analogous to ee or de and thus is an indication of the potential yield obtainable in an intramolecular case. A different method of calculating selectivity was used in our previous work (*2ae*).

[5]Prepared from α-pinene (*i*. O_3, 10% MeOH in CH_2Cl_2, −78°C; *ii*. Me_2S); cf. ref. 12.

phenone). Excellent discrimination is observed with all enones tested.

Selective reduction of enals

Conjugated aldehydes are intermediate in reactivity between aldehydes and ketones. Benzaldehyde (**2***a*) is about five times more reactive than cyclohexanone (**3***a*) and about one-fifth as reactive as cyclohexane carboxaldehyde (**1***d*). Citral (**2***d*)[6] is only about one-fifth as reactive as cyclohexanone but more reactive than cyclopentanone (**3***e*). The enals studied were reduced in 1–3 h in 30% MeOH in CH_2Cl_2 at −78°C. Interestingly, we did not observe reduction, or addition of alkoxide, in a 1,4 sense under these conditions (11). Table 5 gives the results of the reduction of conjugated aldehydes in the presence of ketones and enones. While the selectivity is poor vs. cyclohexanone (**3***a*),[7] good selectivity is observed with other ketones. The selectivity is excellent with enones. With the exception of benzaldehydes (2), methods for the selective reduction of conjugated aldehydes have not been reported.[8]

Selective reduction of ketones

The reactivity of ketones varies over a wide range. In 50% MeOH in CH_2Cl_2, cyclohexanone (**3***a*) is reduced within 1 h whereas cycloheptanone (**3***e*) requires 14 h for complete reduction. Table 6 gives the results of the reduction of ketones in the presence of enones under these conditions. Despite the wide range in reaction time, selectivity remains high.

There are few reports on the selective reduction of ketones in

[6]Citral was a 65:35 mixture of geranial and neral. Geranial is more reactive than neral.

[7]Excellent selectivity has been achieved with benzaldehyde vs. cyclohexanone using highly hindered reagents (2*i*,*k*,*s*).

[8]For a micromethod for discriminating between conjugated aldehydes and conjugated ketones involving selective reduction see ref. 13.

the presence of enones (5).[9] We have expanded on our previous study (5*a*) in order to define the limitations of the method. While the less reactive ketones (**3***d–f*) show only modest selectivity against cyclohexenone (**4***a*), good selectivity is observed against α and β substituted cyclohexenones (**4***b,c*). Excellent discrimination was observed in all other cases studied. Two intramolecular examples (**4***h,i*)[10] were reduced with excellent selectivity.

The high reactivity of cyclohexanone compared to other ketones suggests the possibility of selective reduction. Under our conditions, modest to good selectivity is observed in the reduction of unhindered cyclohexanones (**3***a,c*) in the presence of other unhindered ketones (**3***d–f*) (Table 6). The reactivity of ketones towards sodium borohydride will be attenuated by steric factors. To predict selectivity in competitive reductions on the basis of steric effects is not straightforward (8*c*). The magnitude of steric effects in sodium borohydride reductions can be very different from those with other reagents (6–8).

Conclusion

Under the appropriate reaction conditions, sodium borohydride provides excellent chemoselectivity in the reduction of various types of carbonyl groups. The selectivity observed is comparable to the best of the previously reported methods. The ready availability and experimental simplicity associated with the use of sodium borohydride is noteworthy. Interestingly, reduction under Luche's conditions ($NaBH_4/CeCl_3$) often reverses the order of selectivity (3, 4).

Experimental

All solvents were distilled prior to use. Acetaldehyde, benzaldehyde (**2***a*), and cinnamaldehyde (**2***b*) were freshly distilled. Acetone was reagent grade. Ketoaldehyde **1***e* was prepared from α-pinene.[5] All other carbonyl compounds are commercially available and were used as received. The ^1H nmr spectra were obtained in $CDCl_3$ solution on a Bruker AM-300 instrument. A Hewlett–Packard 5890A gas chromatograph equipped with a FID detector, an HP-3393A integrator, and an HP-20M (Carbowax) column was used for gas chromatography. Helium was used as the carrier gas. In most cases, baseline separation of the components of interest could be achieved through temperature programming. The % selectivity is calculated as the ([% reduction of the group of interest − % reduction of the other group] ÷ [% reduction of the group of interest + % reduction of the other group]) × 100.[4]

Measurement of relative reactivities

Each carbonyl compound (0.2 mmol) and mesitylene (0.2 mmol, internal standard) were added to the appropriate solvent mixture (2 mL) and the resulting solution was analyzed by gc. The solution was cooled to the desired temperature and $NaBH_4$ (1–10 mg)[11] was added. Reactions at 22°C or 0°C were monitored directly by gc. For reactions at −78°C, small aliquots were quenched by addition to an acetaldehyde solution (CH_2Cl_2) prior to gc analysis. When analysis showed that the most reactive carbonyl compound was 30–40% reduced, the reaction was quenched by addition of acetaldehyde (0.2 mL)[12] and analyzed by gc. The amount of reduction was measured in two ways. The percentage loss of starting material was measured by comparison with the internal standard and the percentage of alcohol product formed was measured by comparison with the remaining starting material. These two measures of the amount of reduction were generally within 10%. The relative reactivity was calculated as the ratio of the percentage reduction of each component. The values in Tables 1 and 2 represent the average of at least two experiments.

*Reduction of benzaldehyde (***2***a)*

The appropriate solvent mixture (2 mL) was added to $NaBH_4$ (ca. 7 mg) and the resulting suspension (solution) was stirred for 3 min (50% MeOH), 20 min (50% EtOH), or 30 min (50% *i*-PrOH, 50% *t*-BuOH). The resulting mixtures were cooled to the appropriate temperature and benzaldehyde (**2***a*, 1 molar equivalent) was added. The reactions were monitored as above by gc. In cases where the reduction was greater than 90% complete within 30 s we estimate the time required for 50% reduction to be less than 0.1 min. In all other cases, reaction times for 45–55% reduction were obtained. Values are reported in Table 3.

Selective reduction of aldehydes

Most reactions (**1** vs. **3**, **1** vs. **4**, and **1***e*) were analyzed by ^1H nmr. $NaBH_4$ (20 mg) was dissolved in EtOH (1.5 mL) and CH_2Cl_2 (3.5 mL) was added. The resulting suspension was cooled to −78°C (Dry Ice – acetone) and each carbonyl compound (20 μL) was added. After stirring for 1 h, acetaldehyde (0.5 mL) was added and the mixture was allowed to warm to room temperature. The solution was diluted with CH_2Cl_2, washed with saturated $NaHCO_3$, dried with Na_2SO_4, and concentrated. The percentage reduction of each component was calculated by integration of appropriate signals in the ^1H nmr spectrum.

In the reaction of **1***e* (20 mg), work-up gave the corresponding hydroxyketone (21 mg, quantitative yield), which was essentially homogeneous by tlc and by ^1H nmr.

Reactions **1** vs. **2** were analyzed by gc. Reactions were carried out as above except that CH_2Cl_2 (3 mL) was added. After cooling to −78°C, a solution of each carbonyl compound and mesitylene (20 μL each) in CH_2Cl_2 (0.5 mL) was added. After stirring for 1 h, the reactions were quenched (acetaldehyde, 0.5 mL) and analyzed by gc as described above for the determination of relative reactivities.

Selective reduction of conjugated aldehydes

Reactions were conducted in 30% MeOH in CH_2Cl_2 at −78°C. To $NaBH_4$ (20 mg) was added a solution of MeOH (1.5 mL) in CH_2Cl_2 (3.0 mL). After stirring for 3 min, the mixture was cooled to −78°C (Dry Ice – acetone) and a solution of each carbonyl compound and mesitylene (20 μL each) in CH_2Cl_2 (0.5 mL) was added. After stirring for 1–3 h (reactions with **2***a*, 1 h; with **2***b,c*, 2 h; with **2***d*, 3 h), the reactions were quenched (acetaldehyde, 0.5 mL) and analyzed by gc as described above for the determination of relative reactivities.

The enals **2***b–d* were reduced individually as above. Products resulting from reduction or addition in a 1,4 sense were not detected by gc or, after work-up as above, by ^1H nmr.

Selective reduction of ketones

Reactions with **3***b* were conducted (5*a*) by adding $NaBH_4$ (20 mg) to a solution of carbonyl compounds (20 μL each) in 50% MeOH in CH_2Cl_2 (5 mL) at −78°C. After stirring for 1 h, the reactions were quenched (acetone, 0.5 mL) and allowed to warm to room temperature. The reaction mixture was diluted with CH_2Cl_2, washed with 1 M NaOH, dried with Na_2SO_4, concentrated, and analyzed by ^1H nmr.

Reaction of **4***h* (21 mg) as above gave, after work-up, the 1-β alcohol (21 mg), which was contaminated by less than 3% of the corresponding diol. Similar reduction of **4***i* (20 mg) for 6 h gave a 93:7 mixture (21 mg) of the 17-β alcohol and the 3β,17β diol. Recrystallization (acetone/hexane) gave the 17β alcohol (14 mg), mp 152–154°C (lit. (6*a*) mp 154–155°C).

When using the above method, we periodically encountered incomplete reduction (selectivity remains high) of the less reactive ketones (**3***d–f*) after 14 h. Thus the following conditions were employed. To $NaBH_4$ (20 mg) was added a solution of MeOH (2.5 mL) in CH_2Cl_2

[9]The reverse selectivity has been reported using $NaBH_4$ (3) or boranes (1*a,b*).

[10]Selective reductions of **4***h* (5*b*) and **4***i* (6*a,b,e,f*) have been reported.

[11]The amount of $NaBH_4$ added was a function of the reaction rate. For very fast reactions (MeOH or EtOH at 0°C or 22°C), 1–2 mg was added. For slower reactions, up to 10 mg was added.

[12]In a control experiment, **1***a* (0.2 mmol) and acetaldehyde (0.2 mL) in 50% MeOH in CH_2Cl_2 (2 mL) were reduced with $NaBH_4$ (0.1 mmol) at −78°C. After warming to room temperature, gc analysis indicated <5% reduction of **1***a*.

(2.0 mL). After stirring for 3 min, the mixture was cooled to −78°C (Dry Ice – acetone) and a solution of each carbonyl compound and mesitylene (20 μL each) in CH_2Cl_2 (0.5 mL) was added. After stirring for 1–14 h (reactions with **3***a*, 1 h; with **3***c*, 3 h; with **3***d–f*, 14 h), the reactions were quenched (acetone, 0.5 mL) and were analyzed by gc (as described above for the determination of relative reactivities) or, after work-up as above, by ^{1}H nmr.

Ketone **3***b* was reduced to an 85:15 mixture of *trans*:*cis* isomers; **3***c* to a 2:1 mixture of *trans*:*cis* isomers; **4***h* and **4***i* gave only the β alcohol. The ratio of 1,2:1,4 products from reduction of enones **4***b*,*e*,*f*,*g*,*h*,*i* was >10:1; for **4***a* and **4***c*, 3:1; for **4***d*, 0.5:1.

A 1:1 complex of 18-crown-6 ether and benzenesulfonamide has been prepared, whose melting point is within 4° of the previously reported 1:2 complex. The X-ray crystallographic structure shows pseudo D_{3d} symmetry in the crown ether portion of this complex, in contrast to the 1:2 complex, which exhibits C_i symmetry in the macrocycle. The temperature dependent ^{13}C CPMAS NMR spectra of these complexes have two regions of broadening for the crown ether carbons. At higher temperatures, a dipolar "washout" mechanism is operative, leading to broadening when molecular motion has a correlation time approximately equal to the inverse of the decoupling field. At lower temperatures broadening occurs when the motional correlation time is equal to the inverse of the chemical shift difference. From application of the Arrhenius equation, the activation energy for the molecular motion in solid 18-crown-6 is found to be approximately 10 kcal/mol. Evidence for independent anisotropic motion in the benzenesulfonamide moiety of the 1:1 complex is also presented.

Key words: crown ether, molecular motion, solid phase NMR.

G. W. BUCHANAN, C. MORAT, J. P. CHARLAND, C. I. RATCLIFFE et J. A. RIPMEESTER. Can. J. Chem. **67**, 1212 (1989).

On a préparé un complexe 1 : 1 de l'éther 18-couronne-6 et du benzènesulfonamide; son point de fusion ne diffère de celui rapporté antérieurement pour le complexe 1 : 2 que par 4°. Une étude de la structure par diffraction des rayons-X indique que la portion éther couronne possède une symétrie D_{3d}; par opposition, la portion macrocyclique du complexe 1 : 2 présentait une symétrie C_i. On a déterminé les spectres RMN CPMAS du ^{13}C en fonction de la température; ils présentent deux régions dans lesquelles les raies des carbones de l'éther couronne sont élargies. Aux températures élevées, un mécanisme dipolaire intervient pour provoquer un élargissement lorsque le temps de corrélation du mouvement moléculaire est approximativement égal à l'inverse du champ des découplage. Aux températures plus basses, l'élargissement se produit lorsque le temps de corrélation du mouvement est égal à l'inverse de la différence des déplacements chimiques. En appliquant l'équation d'Arrhénius, on a trouvé que l'énergie d'activation du mouvement moléculaire dans la 18-couronne-6 est approximativement 10 kcal/mol. On présente aussi des données suggérant l'existence d'un mouvement anisotrope indépendant dans la portion benzènesulfonamide du complexe 1 : 1.

Mots clés : éther couronne, mouvement moléculaire, RMN des phases solides.

Introduction

Recent publications from these laboratories (1, 2) have dealt with the observation of dynamic ^{13}C NMR phenomena in crystalline 18-crown-6 ether (1), its KNCS complex (1), and its $NaNCS \cdot H_2O$ complex (2). In each case, the low temperature ^{13}C chemical shift differences could be interpreted in terms of torsional angle effects, with the geometrical data being available from X-ray crystallographic results.

In an effort to extend these studies to *molecular* inclusion complexes of 18-crown-6, we have prepared a number of complexes with neutral guest molecules, one such case being benzenesulfonamide.

Results and discussion

The literature (3) describes the X-ray crystallographic structure of a 1:2 18-crown-6:benzenesulfonamide complex (melting point 92°C) in which the macrocyclic ring adopts a centrosymmetric conformation that is nearly identical to that for 18-crown-6 itself (4, 5). Accordingly, based on our recent results (1, 2), we anticipated that the ^{13}C CPMAS spectra in the crown ether region of these two systems would be quite similar. To our surprise, the complex that we initially prepared (mp 88–89°C) possesses solid phase ^{13}C spectra for the crown ether region as a function of temperature (Fig. 1) that much more closely resemble those of the KNCS:18-crown-6 complex having approximate D_{3d} symmetry (1, 6).

In view of this apparent dichotomy of results, we proceeded to examine the structure of our 88–89°C complex via X-ray crystallography. The ORTEP diagram of the structure obtained is presented in Fig. 2 and clearly represents that of a *1:1* benzenesulfonamide:18-crown-6 complex. For this complex the refined coordinates of the non-H-atoms are listed in Table 1, while Table 2 gives the geometrical data (bond lengths, bond angles, and torsional angles).

In this 1:1 complex, the "guest" benzenesulfonamide molecule is hydrogen bonded to the "host" crown ether. The two N---O distances (Table 2) are identical within standard deviations and are similar to those observed in the 2:1 guest:host complex (3). Figure 2 shows that the crown ether in the 1:1 complex has a nearly circular conformation, similar to that found in the 1:1 complex with KSCN (6). By contrast, in the 2:1 complex with benzenesulfonamide (3) the crown ether adopts an elliptical shape. Hence one sees here cases of stoichiometrically induced conformation changes in the 18-crown-6 structure, with simultaneous optimization of hydrogen bonding and van der Waals or stacking interactions.

Detailed examination of the torsional angle data indicates that

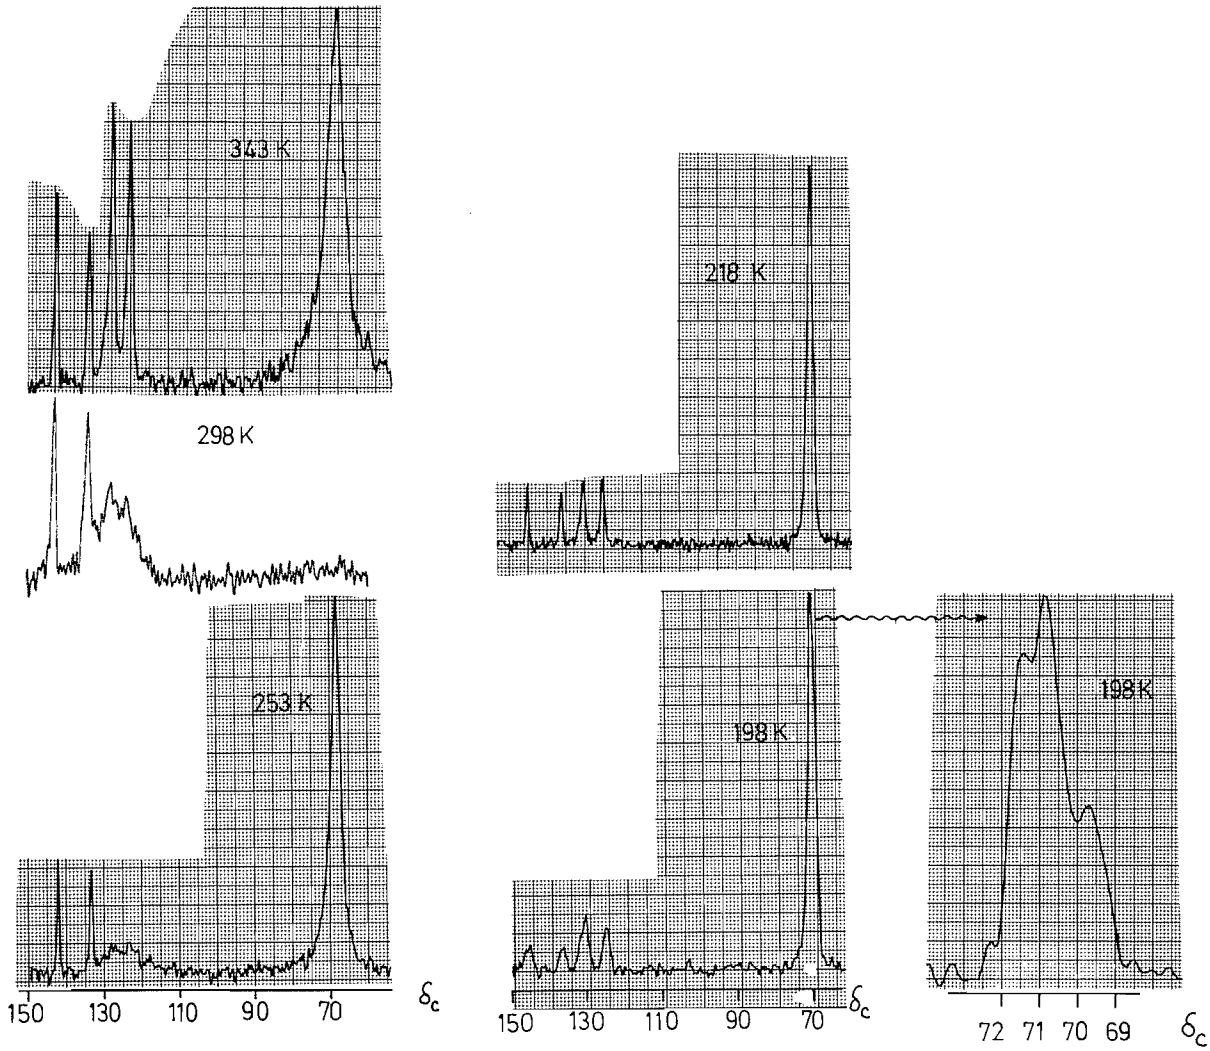

FIG. 1. The 45.3-MHz ^{13}C CPMAS spectrum of the 1:1 18-crown-6:benzenesulfonamide complex as a function of temperature.

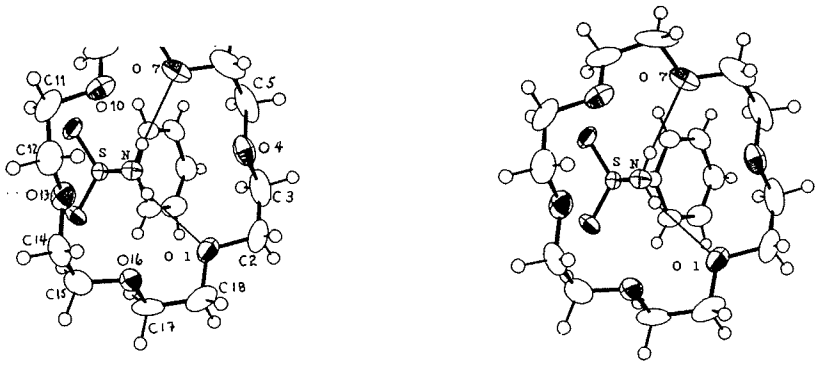

FIG. 2. Stereodiagram of the 1:1 complex.

the 18-membered ring in the 1:1 complex possesses pseudo D_{3d} symmetry. Each carbon has a skew *gauche* geometry for the O—C*—C—O network and pseudo *trans* geometries for the other torsional networks (Table 3).

The ^{13}C CPMAS spectra of the 1:1 complex as a function of temperature are presented in Fig. 1. Clearly, there are marked temperature dependencies in both the guest and host ^{13}C resonances. At the high temperature limit of 343 K, a relatively broad (linewidth ca. 230 Hz) crown ether resonance is observed with a chemical shift near 70 ppm. In the aromatic region there are four sharp lines at $\delta_C = 144.7$, 135.9, 129.7, and 125.2. From solution work (7), C-19 (below) will be the most deshielded position, followed by C-22 and then the C-21,23 pair. The *ortho* sites, C-20,24, will be the most shielded, appearing at 125.2 ppm.

At 298 K, there is severe broadening of the crown ether

*B_{iso} is the mean of the principal axes of the thermal ellipsoid; esd's refer to the last digit printed.

resonance, followed by a resharpening to a minimum linewidth at 218 K. Subsequently, there is a more subtle broadening of the crown ether resonance until the low temperature limit is reached at 198 K. At this point there are three resolvable resonances for the crown ether carbons.

The higher temperature broadening can be described as "dipolar washout" (8) and will occur when the molecular motions have rates such that the correlation time for the C—H vector, τ_c, is the inverse of the decoupling field amplitude of 60 kHz; i.e., $\tau_c = 1/2\pi\gamma H_1 = 1/2\pi \times 60\,\text{kHz} = 2.7 \times 10^{-6}$ s.

An estimate of the barrier for this process can be obtained by application of the Waugh–Fedin Approximation (9). Employing a temperature of 298 K, the value obtained is ca. 11 kcal/mol.

The low temperature broadening will occur when motions have correlation times of the same order as the chemical shift differences. Since the chemical shift differences between conformationally different carbons are found to be ca. 2 ppm in this complex, these correlation times at a ^{13}C resonance frequency of 45.3 MHz will be ca. $1/(45.3 \times 2) = 10^{-2}$ s.

Converting these correlation times to rates and using the temperatures of 298 K and 198 K for the fast and slow broadening mechanisms, respectively, yields, by application of the Arrhenius equation, a value for the activation energy of ca. 10 kcal/mol. The reasonable agreement between this value and that obtained from the Waugh–Fedin Approximation lends support to the hypothesis that only one process is being detected here with two time scales being accessible via the variable temperature ^{13}C CPMAS experiment.

For the benzenesulfonamide resonances, a similar dipolar washout occurs, but only for the C20,24 and C21,23 pairs, and is apparent in the spectrum at 253 K. The fact that only these resonances experience this phenomenon indicates that the preferred direction of motion in the benzenesulfonamide moiety is about the C19—C22 axis. Similar behaviour was noted previously (10) in the solid state ^{13}C spectrum of benzaldehyde encapsulated in cyclodextrin.

From a conformational viewpoint, the chemical shift differences in the 18-crown-6 at 198 K are of interest. In light of the X-ray results and assuming a dominance of torsional angle effects on the ^{13}C chemical shifts (11), one would thus anticipate only minor chemical shift differences between the carbons of the macrocycle. Indeed this is observed, since at 198 K three lines of relative intensity ca. 4:5:3 are found at δ_C = 71.4, 70,9, and 69.7 ppm, respectively. At higher temperatures, the fact that only one crown ether resonance is resolved indicates that torsional angle averaging is occurring in the solid on the NMR time scale.

It is of interest to attempt to assign the three resolved resonances in the solid phase spectrum to particular groups of carbons in the X-ray structure. The basic tenets for analysis here are that any expansion of the O—C—C—O angle above 60° will induce deshielding while any contraction of the C—O—C—C angle below 180° will induce shielding at all carbon sites. Such tenets are in accord with experimental data (11).

Thus if one assumes an approximately equal angular dependence of the chemical shift for each type of torsional network, a relative order of shielding can be established. Such a procedure involves calculating Σ (contractions from 180°) and then subtracting the expansion above 60°. The carbon possessing the highest resulting value is predicted to be the most shielded. On this rather crude basis, we suggest that carbons 9, 11, and 12 constitute the most shielded intensity 3 resonance at 69.7 ppm. Similarly, C 2, C 6, C 8, C 17, and C 18 may give rise to the intensity 5 line at 70.9 ppm and the remaining four carbons appear at 71.4 ppm.

Of course one cannot rule out other contributions to the ^{13}C shifts of the macrocycle, such as steric and anisotropic effects arising from the guest, since the overall chemical shift difference is only 1.7 ppm.

For the 1:2 18-crown-6:benzenesulfonamide complex, the ^{13}C CPMAS spectra as a function of temperature are presented in Fig. 3. The dipolar washout of the crown ether resonance is again clear from the spectrum at 298 K, with the conformational broadening becoming apparent in the 220 K spectrum.

In the X-ray structure of the 1:2 complex (3), the two benzenesulfonamide moieties are equivalent due to the presence of the centre of symmetry. At 340 K in the ^{13}C CPMAS spectrum, there are only three aromatic carbon resonances observed, at 129.3, 132.5, and 148.1 ppm respectively. In this case it appears that C20, C21, C23, and C24 are accidently chemical shift degenerate. There are appreciable temperature dependent chemical shifts for the benzenesulfonamide carbons since at 298 K their chemical shifts, 126.3, 129.9, 133.8, and 144.4 ppm, are substantially different from those at 340 K. The fact that only four aromatic resonances appear indicates two possible situations: (*i*) rapid twofold flips of the aromatic ring about the C19–C22 axis, or (*ii*) accidental coincidence of the C20,24 and C21,23 pairs of resonances.

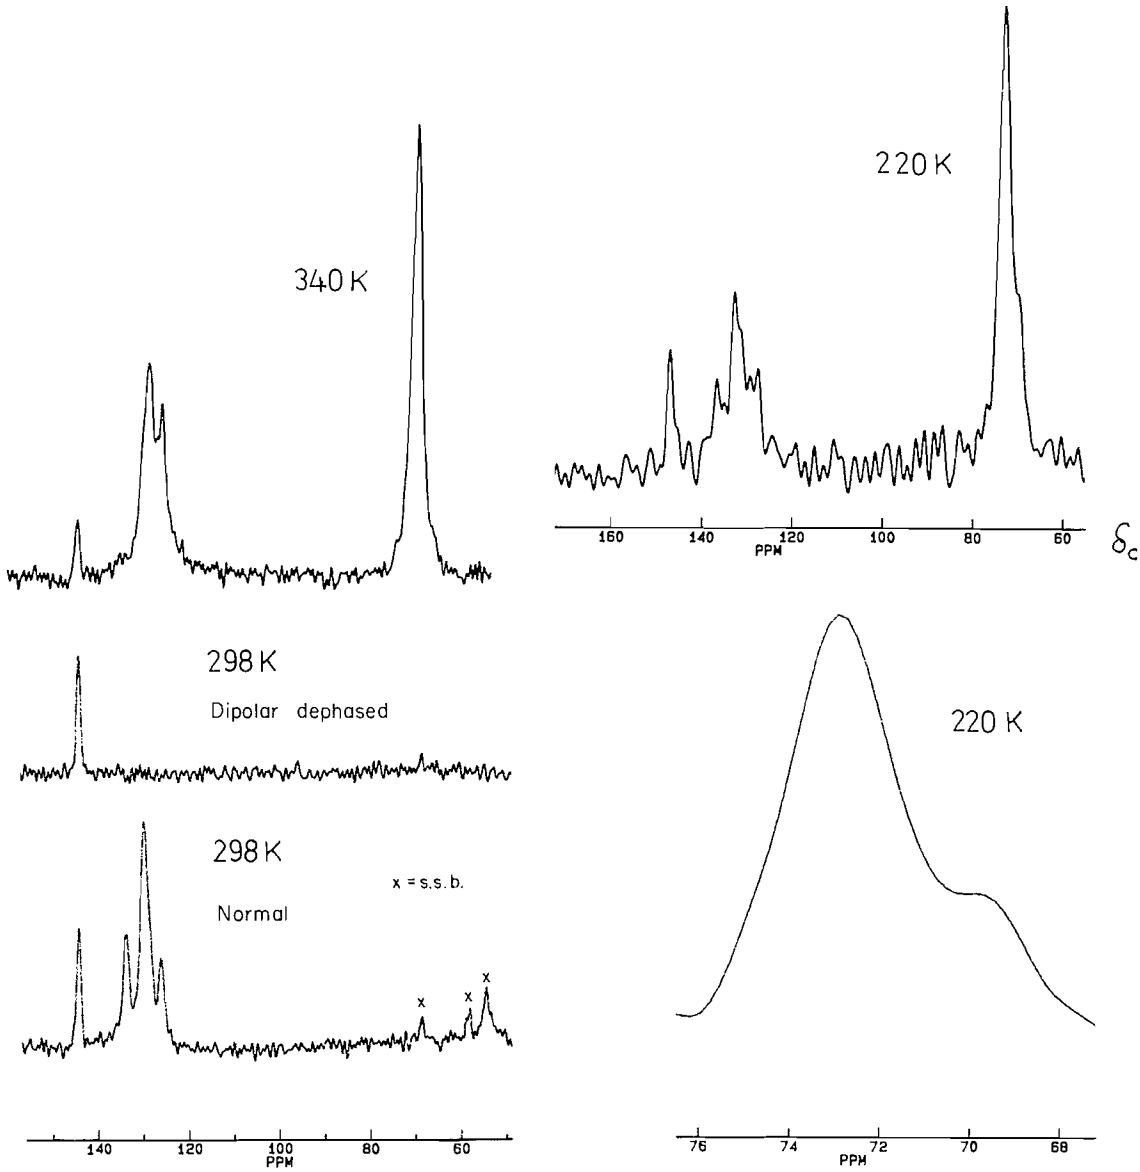

FIG. 3. The 45.3-MHz ^{13}C CPMAS spectrum of the 1:2 18-crown-6:benzenesulfonamide complex as a function of temperature.

To distinguish between these two possibilities, the spectrum was recorded under conditions of dipolar dephasing (12), with a delay time of 40 μs in the interrupted decoupling sequence. The resulting spectrum (Fig. 3) shows that the protonated carbon resonances have completely disappeared, indicating (13) that there must be relatively rigid benzenesulfonamide units in this complex. Had there been rapid molecular motion about the C19—C22 axis, the dipolar couplings would be averaged to near zero with the exception of C22. The C22–H dipolar interaction would not be averaged by flipping about such a twofold axis and would thus have had approximately the same intensity as the nonprotonated carbon in the dipolar dephased spectrum. Hence the resonance overlap observed in the normal ^{13}C CPMAS spectrum can be attributed to accidental chemical shift equivalence.

In the low temperature limit of 220 K, little change is evident in the aromatic carbon region of the spectrum. The crown ether resonance, however, has reappeared as a doublet with components having an intensity ratio of ca 1:3 with chemical shifts of 69.6 and 72.9 ppm, respectively.

It is of interest to attempt to analyze the crown ether spectral appearance in terms of the torsional angle and steric chemical shift tenets employed for the 1:1 complex (*vide supra*). The previously determined (3) torsional angles for the 18-crown-6 portion of the 1:2 complex are presented in Table 4. Consideration of the torsional angle contractions below 180° and the expansions above 60°, as was done in the 1:1 case, leads one to expect that C-2 will be the most shielded carbon followed by C-3, C-5, C-9, C-8, and, finally, the most deshielded position C-6. It appears that only the C-2 resonance is resolvable at 220 K.

The low temperature chemical shift difference of 3.3 ppm in the crown ether carbons of the 1:2 complex reflects the more diverse torsional environments present in the centrosymmetric crystal structure than was the case for the pseudosymmetric D_{3d} 1:1 complex where the limiting chemical shift difference was only 1.7 ppm.

To conclude, a limitation exists in the analysis as presented, since the torsion angles from the X-ray data were measured at ca. 300 K, and these data are employed in an attempt to interpret

^{13}C CPMAS spectra at temperatures that are nearly 100 K lower. Ideally, only X-ray data obtained at comparable temperatures should be utilized; however, the logistics of obtaining such data are often difficult.

These results present the first cases where overall motion of the crown ether host molecule that is independent of the motion of the molecular guest species has been detected. In an attempt to determine the detailed nature of the motions in the 18-crown-6 moieties, further studies of these phenomena in the solid state, utilizing deuterated crown ether complexes, are in progress.

followed. This report, however, does not specify the solvent employed for recrystallization. In our hands, even when the stoichiometry of reagents is 1:2 (3), recrystallization from THF gives initially a white solid, mp 88–89°C, in 34% yield, which turns out to be the 1:1 complex. The 1:2 complex, mp 92–93°C, can be subsequently isolated from the mother liquors. If the reagent stoichiometry is 1:1 then the 1:1 complex is obtained exclusively.

Spectra

The 45.3-MHz ^{13}C CPMAS spectra were obtained via techniques described previously (1, 2).

Crystallographic measurements and structure solution (1:1 complex)

$C_{18}H_{31}NO_8S$ fw = 420.44

Monoclinic, $P2_1/n$, $a = 8.401(2)$ Å, $b = 16.936(2)$ Å, $c = 15.6170(2)$ Å, $\beta = 94.70(1)°$, $V = 2214.77$ Å^3, $Z = 4$, $D_c = 1.264$ Mg·m^{-3}. A single crystal of the title compound, dimensions 0.25 × 0.30 × 0.35 mm, was mounted on a glass fiber and transferred on a Nonius CAD4 diffractometer driven by the NRCCAD control program (14). Cell parameters and intensity data were obtained at room temperature using graphite-monochromatized Mo Kα radiation. The accurate cell parameters were obtained from 30 well-centered reflections with 2θ in the range 30–35°. Intensity data were measured up to 45°, 2θ. A total of 4368 ± *hkl* and *hkl* reflections were measured. After averaging the symmetry-related reflections and correcting them for the Lorentz and polarization ratio effects, the data set consisted of 2871 unique reflections, of which 1760 were considered observed ($I_{net} \geq 2.5\,\sigma(I_{net})$).

The space group $P2_1/n$ was unambiguously defined from the systematic absences noted in the data set. The structure was solved by direct methods using MULTAN (15). The hydrogen atoms were located on the next D-map after preliminary full-matrix least-squares refinement. They were included and refined isotropically while non-H atoms were refined anisotropically by full-matrix least squares, using the following weighting scheme: $1/[\sigma(F_o)^2 + 0.0003(F_o^2)]$. Final residuals are $R_f = 0.051$ and $R_w = 0.052$, with a goodness-of-fit ratio of 1.4 and $(\Delta/\sigma)_{max}$ of 0.2 in the last refinement cycle. The final D-map was featureless with a background noise ≤0.18 e$^-$/Å^3. Scattering

Nitrogen-15 shielding in *trans*-azobenzene

RODERICK E. WASYLISHEN,[1] WILLIAM P. POWER, GLENN H. PENNER, AND RONALD D. CURTIS
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

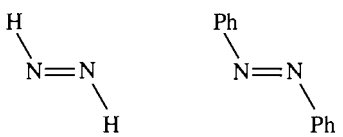
Received September 23, 1988

RODERICK E. WASYLISHEN, WILLIAM P. POWER, GLENN H. PENNER, and RONALD D. CURTIS. Can. J. Chem. **67**, 1219 (1989).

The principal values of the nitrogen nuclear magnetic resonance shielding tensor for *trans*-azobenzene have been measured and compared with theoretical values recently reported for *trans*-diazene. The shielding anisotropy for the two crystallographically nonequivalent molecules in *trans*-azobenzene is 925 and 880 ppm respectively, about 40% smaller than the value calculated for *trans*-diazene. Interestingly, the isotropic shielding constants for the two nonequivalent molecules are the same within experimental error. The most shielded component of the ^{15}N shielding tensor, σ_{33}, is approximately perpendicular to the molecular plane, as it is in other planar π-systems; σ_{11}, the least shielded component, is directed in the same general direction as the N—C_{ipso} bond. The theoretical calculations overestimate the paramagnetic contribution to σ_{11}. The magnitude and relative orientation of the nitrogen shielding tensor in *trans*-azobenzene are also compared with the corresponding phosphorus values in a diphosphene.

Key words: ^{15}N chemical shielding anisotropy, solid state NMR, *trans*-azobenzene.

RODERICK E. WASYLISHEN, WILLIAM P. POWER, GLENN H. PENNER et RONALD D. CURTIS. Can. J. Chem. **67**, 1219 (1989).



On a mesuré les principales valeurs du tenseur de blindage en résonance magnétique nucléaire de l'azote du *trans*-azobenzène et on les a comparées avec les valeurs théoriques rapportées récemment pour le *trans*-diazène. L'anisotropie de blindage est respectivement de 925 et 880 ppm pour les deux molécules de *trans*-azobenzène qui ne sont cristallographiquement pas équivalentes; ces valeurs sont environ 40% plus faibles que les valeurs calculées pour le *trans*-diazène. Il est intéressant de noter que les constantes de couplage isotrope des deux molécules qui ne sont pas équivalentes sont les mêmes, aux erreurs expérimentales près. La composante la plus blindée du tenseur de blindage du ^{15}N, σ_{33}, est approximativement perpendiculaire au plan de la molécule, comme c'est le cas dans d'autres systèmes π plans; la composante la moins blindée, σ_{11}, est orientée dans le même direction générale que la liaison N—C_{ipso}. Les calculs théoriques surévaluent la contribution magnétique à la composante σ_{11}. On a aussi comparé l'amplitude et l'orientation relative du tenseur de blindage de l'azote dans le *trans*-azobenzène avec les valeurs correspondantes du diphosphène.

Mots clés : anisotropie de blindage, RMN de l'état solide, *trans*-azobenzène.

[Traduit par la revue]

Introduction

Recently Schindler (1) used an individual gauge for localized molecular orbital method (IGLO) to calculate nitrogen nmr shielding tensors for various classes of nitrogen-containing molecules. The *ab initio* method has been very successful in calculating reliable carbon shielding tensors in a variety of molecules (2). Unfortunately, few experimental ^{15}N shielding tensors are available for direct comparison with the theoretical calculations (3–8). Of the molecules considered in ref. 1, *trans*-diazene (**I**) was predicted to have the largest ^{15}N shielding anisotropy, approximately 1500 ppm. This is more than twice the value observed in dinitrogen (9); hence, we felt that it would be of interest to measure the value in a related stable compound. By obtaining a ^{15}N homonuclear dipolar spectrum of a static powder sample of *trans*-azobenzene-$^{15}N_2$ (**II**) we are able to

I **II**

determine the principal components of the ^{15}N shielding tensor and obtain valuable information regarding its orientation. Although the phenyl rings of *trans*-azobenzene will perturb the diazene system and complicate a direct comparison between experiment and theory, our results are the first measurement of the principal components of the nitrogen shielding tensor in a diazene. Our results will be compared with the ^{31}P shielding tensor recently reported for the P=P double bond in an aryl-substituted diphosphene (10).

Theory

For a pair of like spins, A_2, such as the directly bonded ^{15}N spins of *trans*-azobenzene-$^{15}N_2$ the chemical shielding (CS) and direct dipolar interactions are orientation dependent (11–13). That is, for any given crystallite the nmr resonance frequency will depend on the orientation of the principal components of the CS tensor in the applied magnetic field, B_0, and the orientation of the dipolar vector in the principal axis system (PAS) of the CS tensor (see eq. [1], below). The orientation of the CS tensor in B_0 is defined by the angles θ and ϕ, and the orientation of the dipolar vector, r_{NN}, in the PAS of the CS tensor is defined by the angles α and β (see Fig. 1).

$$[1] \quad \nu_m(\theta,\phi) = \nu_L - \nu_{CS} - \tfrac{3}{2}\nu_D m$$

where

$$\nu_L = \gamma_N B_0/2\pi$$

$$\nu_{CS} = (\gamma_N B_0/2\pi)[\sigma_{11}\sin^2\theta\cos^2\phi + \sigma_{22}\sin^2\theta\sin^2\phi + \sigma_{33}\cos^2\theta]$$

$$\nu_D = R[1 - 3(\sin\beta\sin\theta\cos(\phi-\alpha) + \cos\beta\cos\theta)^2]$$

and

$$R = \frac{\gamma_N^2\hbar}{2\pi}\left(\frac{\mu_0}{4\pi}\right)\langle r_{NN}^{-3}\rangle$$

The nmr spectrum of a powder sample is simulated by adding the two subspectra $\nu_{\pm 1/2}(\theta,\phi)$, and integrating over all angles θ and ϕ. We have used the standard convention $\sigma_{33} > \sigma_{22} > \sigma_{11}$

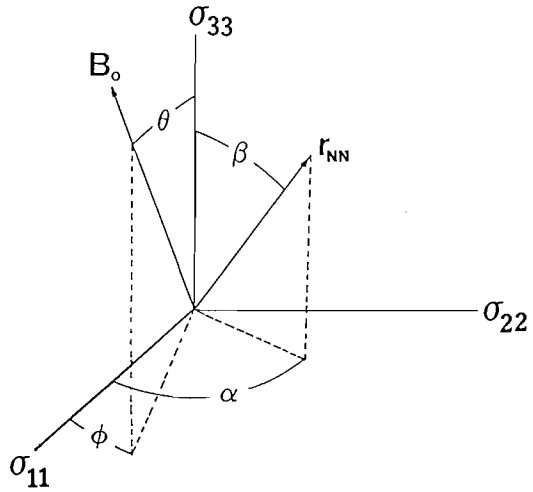

FIG. 1. Definition of the angles α, β, θ, and φ. α and β define the orientation of $r_{N,N}$ in the principal axis system of the CS tensor. θ and φ define the orientation of the molecule in the magnetic field, B_0.

(3, 4, 14). β is an angle between r_{NN} and the most shielded component of the CS tensor, σ_{33}, and α is the angle between the projection of r_{NN} onto the σ_{11}–σ_{22} plane and the least shielded component of the CS tensor σ_{11}. Note that the experimentalist has no control over the angles α and β; they will depend upon the particular molecule and spin-pair under consideration.

The principal components of the chemical shielding tensors are often expressed as chemical shifts, δ_{ii}, with respect to some reference (14). Since chemical shifts to high frequency of the reference are by convention positive, $\delta_{11} > \delta_{22} > \delta_{33}$. (Note that δ_{33} still corresponds to the most shielded component of the chemical shift tensor.)

Experimental

trans-Azobenzene-$^{15}N_2$ was obtained from MSD isotopes, Montreal.

The sample was ground to a fine powder and packed into an aluminum oxide rotor (7 mm o.d.). Nitrogen-15 nmr spectra were obtained at 21 ± 2°C on a Bruker MSL-200 spectrometer operating at 20.29 MHz. Spectra were acquired under the conditions of the Hartmann–Hahn match (3) using the FLIPBACK pulse sequence (15) and high power ^1H decoupling at 200.106 MHz. The $\pi/2$ pulse width was 5.5 μs and the recycle time was 120 s. The contact time was optimized and found to be 12 ms. The static spectrum (2750 transients) was acquired using an acquisition time of 106.5 ms; the corresponding time for the MAS spectrum (100 transients) was 426 ms. A sensitivity enhancement corresponding to 100 Hz and 10 Hz of line broadening respectively was applied to the static and MAS spectra prior to Fourier transformation. A polynomial baseline correction was used to compensate for baseline roll in the experimental static spectrum.

Nitrogen-15 chemical shifts were referenced with respect to the ammonium ^{15}N signal of external ammonium nitrate, which has a shift of 23.8 ppm with respect to liquid ammonia at 20°C.

Simulations were performed using the POWDER simulation routine (16) on a VAX 8800 computer.

Results and discussion

Before discussing the static ^{15}N nmr powder spectrum of *trans*-azobenzene-$^{15}N_2$ we will briefly discuss the structure of *trans*-azobenzene and the ^{15}N nmr spectrum obtained with magic angle spinning (MAS).

Crystal structure and MAS spectrum

X-ray diffraction experiments indicate that *trans*-azobenzene crystals are monoclinic, $P2_1/c$, with two crystallographically independent molecules (17, 18). The molecule at one of the two sites has much larger thermal parameters than that at the other, and N,N bond lengths of 1.172 Å and 1.243 Å were reported in an early refinement of the crystal structure (17). The shorter bond length was obtained for the molecule at the disordered site. A more recent reinvestigation of the disorder has led to the conclusion that the N,N bond lengths are essentially equal at the two sites, 1.247 Å at the ordered site and 1.240 Å and 1.249 Å for two possible orientations of the molecule at the disordered site (18). The occupancy ratio for the two disordered molecules was found to be 0.83:0.17, thus one of the two possible orientations at the disordered site is more favored than the other. The centrosymmetric molecules at each of the two crystallographic sites are essentially planar, with the torsional angles NNCC being approximately 17° at the ordered site and less than 10° at the disordered site. Nitrogen-15 spectra obtained with magic angle spinning appear to support the conclusion that the structures of the two crystallographically independent molecules are very similar. Only a single isotropic peak of linewidth $\nu_{1/2} \leq 20$ Hz is observed in the MAS spectrum (Fig. 2). Although no splitting due to crystallographic nonequivalence has been reported in previous CP/MAS ^{13}C nmr studies of *trans*-azobenzene (19, 20), we do observe a splitting of approximately 0.8 and 0.7 ppm respectively for C_{ipso} and C6; the other carbon resonances (C2, C3, C4, and C5) overlap extensively.

The slow spinning ^{15}N nmr spectrum in Fig. 2 has rotational sidebands that are modulated by both the ^{15}N chemical shielding and ^{15}N,^{15}N dipolar interaction (21). Since rotational sidebands of significant intensity are observed over a frequency range in excess of 18 kHz it is clear that the shielding anisotropy is much greater than the direct dipolar coupling constant, $R = 636.6$ Hz. Ignoring the dipolar interaction and applying the Herzfeld–Berger (21) analysis at rotor speeds of 1500 and 2000 Hz we obtain $\delta_{11} = 991$ ppm, $\delta_{22} = 487$ ppm, and $\delta_{33} = 55$ ppm. Thus the chemical shielding anisotropy, $\Delta\sigma = \delta_{11} - \delta_{33}$, is approximately 936 ppm. As indicated below, the error in the components of the CS tensor is substantial (±100 ppm) if one carries out the Herzfeld–Berger analysis ignoring the ^{15}N,^{15}N dipolar coupling.

The isotropic ^{15}N chemical shift of solid *trans*-azobenzene with respect to external liquid ammonia is 511.5 ppm. In chloroform solution the ^{15}N chemical shift of *trans*-azobenzene with respect to nitromethane is 129.0 ppm (22). Taking the chemical shift of nitromethane with respect to NH_3 (*l*, 20°) as 380.4 ppm (5) leads to a solution shift of 509.4 ppm, in excellent agreement with the value measured in the solid state.

Analysis of the static powder pattern

The static ^{15}N nmr powder spectrum of *trans*-azobenzene-$^{15}N_2$ obtained after approximately 4 days of signal averaging is shown in Fig. 3. Expansions of the high and low frequency shoulders are shown in Figs. 4a and 4b respectively. From the appearance of the low frequency shoulders (δ_{33} region) it is apparent that the principal components of the ^{15}N shielding tensor for the two nonequivalent molecules are different even though the average values (trace) of the two tensors are the same within ±0.5 ppm. Only two shoulders as opposed to four would be observed in the low frequency region if the spectrum could be interpreted in terms of a single dipolar split site (see Figs. 5 and 6 and the discussion to follow).

X-ray diffraction results indicate that molecules at the disordered site of *trans*-azobenzene exhibit much larger thermal

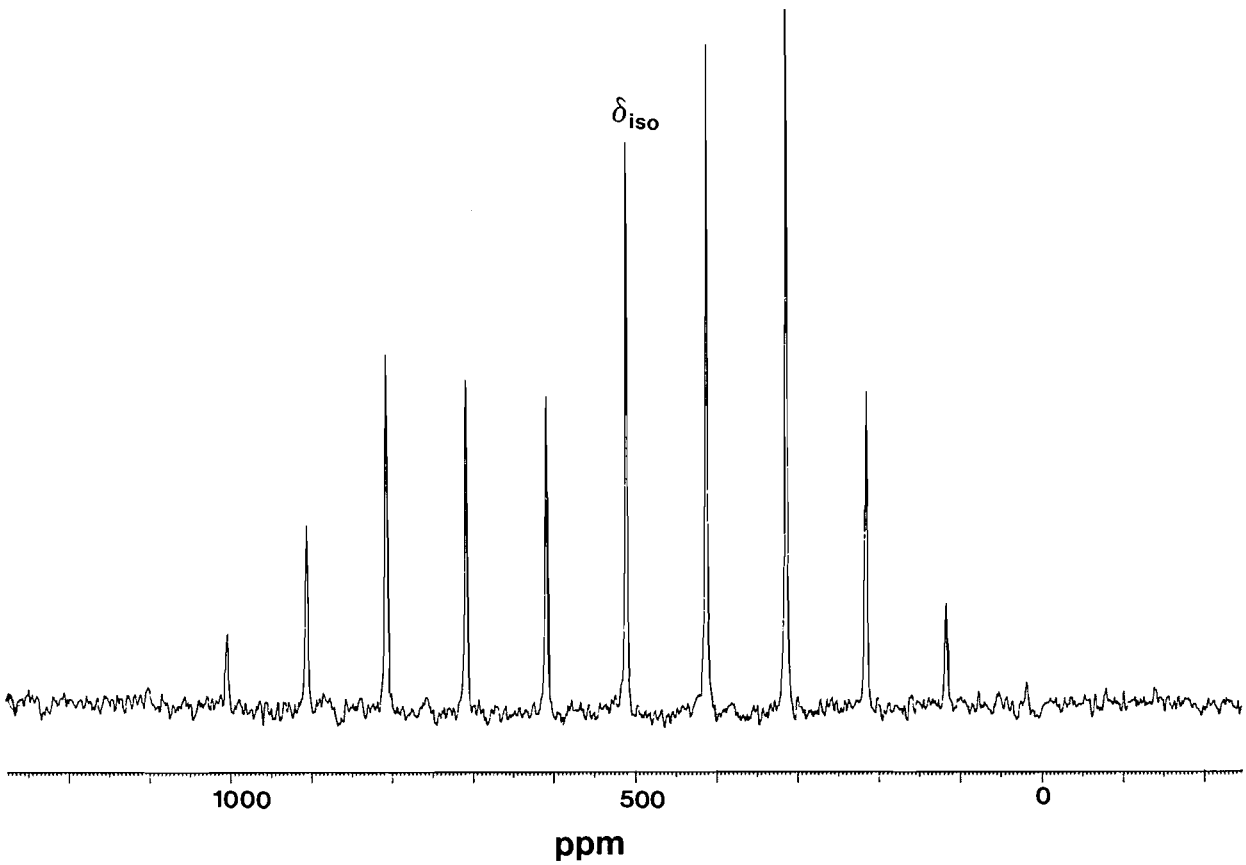

FIG. 2. Nitrogen-15 nmr spectrum of a powder sample of *trans*-azobenzene-$^{15}N_2$ obtained with high power ^1H decoupling, cross-polarization, and magic angle spinning (2 kHz).

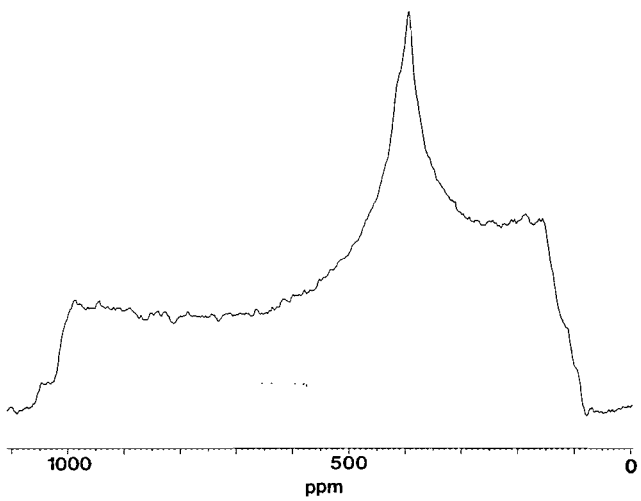

FIG. 3. Dipolar ^{15}N nmr spectrum of a static powder sample of *trans*-azobenzene-$^{15}N_2$ obtained with high power ^1H decoupling and cross-polarization.

ellipsoids than those at the ordered site; therefore it is reasonable to assume that the thermal motion at the disordered site will result in partial averaging of the chemical shielding tensor. On this basis we have assigned the outer features of the δ_{33} and δ_{11} shoulders (see Fig. 4) to molecules at the ordered site, site 1. The inner features of these regions are associated with the disordered site of *trans*-azobenzene, site 2.

To describe how the spectrum in Fig. 3 was analyzed it is useful to consider how a theoretical dipole-coupled CS powder spectrum depends on the angles α and β when $|\nu_{11} - \nu_{iso}|$ and $|\nu_{33} - \nu_{iso}|$ are much greater than R. Using eq. [1], it is easy to derive the following relationships for dipolar splitting at δ_{11}, δ_{22}, and δ_{33}:

$$[2] \quad \Delta\nu_{11} = \pm(3/2)R[1 - 3(\sin\beta\cos\alpha)^2]$$

$$[3] \quad \Delta\nu_{22} = \pm(3/2)R[1 - 3(\sin\beta\sin\alpha)^2]$$

$$[4] \quad \Delta\nu_{33} = \pm(3/2)R[1 - 3\cos^2\beta]$$

We have found these expressions extremely useful in obtaining initial estimates for the angles α and β in simulating dipolar coupled spectra. The value of R in eqs. [2]–[4] was fixed at 636.6 Hz; this value was calculated from the N,N bond length obtained from X-ray diffraction experiments, $r_{NN} = 1.247$ Å.

For *trans*-azobenzene-$^{15}N_2$ one expects $\beta = 90°$ (1, 6, 23, 25–28; see also footnotes 2 and 3); that is, the most shielded component of the ^{15}N shielding tensor should be approximately perpendicular to the molecular plane. This appears to be a general observation for systems where nitrogen is a part of a planar π-system (6, 25–28, footnote 3) and is supported by molecular orbital calculations (1, 23, footnote 2). One can obtain β at each of the two sites of *trans*-azobenzene from the splittings at the δ_{33} region, $\Delta\nu_{33}(1) = 910 \pm 30$ Hz and $\Delta\nu_{33}(2) = 825 \pm 30$ Hz using eq. [4]. Using these splittings

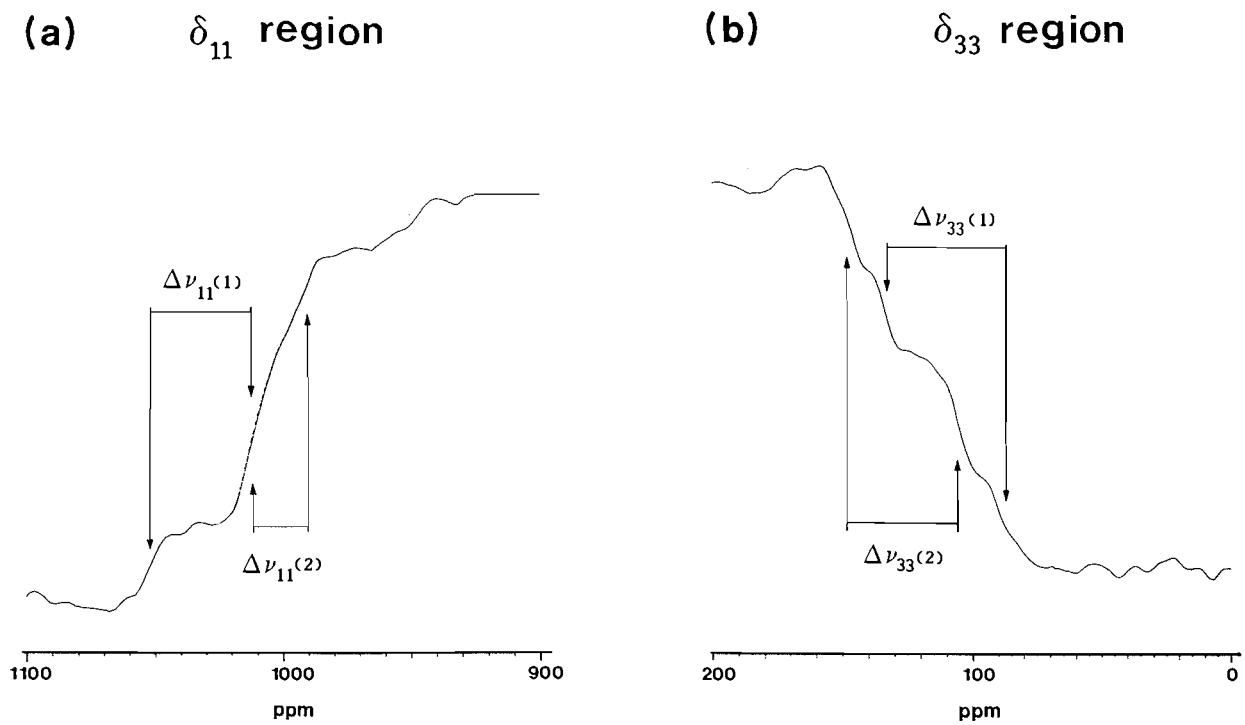

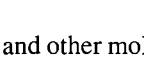

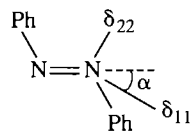

FIG. 4. (*a*) Expansion of the high frequency end (δ_{11} region) of the ^{15}N nmr spectrum of *trans*-azobenzene-$^{15}N_2$. (*b*) Expansion of the low frequency end (δ_{33} region) of the same spectrum.

one obtains $\beta = 83°$ and 78° repectively. As expected, the values of β at site 1 and site 2 are close to 90°. The values calculated here must be considered as lower limits since any molecular motion would reduce R and lead to values of β that are too small. The values of δ_{33} at sites 1 and 2 are 109.4 ± 1.5 and 125.4 ± 1.5 ppm respectively.

To demonstrate the sensitivity of the ^{15}N spectrum to the angle α we have generated a number of theoretical homonuclear dipolar coupled powder spectra varying α in steps of 15° (Fig. 5). Note that the splitting of the central feature, δ_{22}, is very sensitive to the value of α. Our experimental spectrum (Fig. 3) indicates that the splitting of this feature is definitely less than 600 Hz at both sites, implying that α must lie between 21° and 48°.

More accurate estimates of α can be obtained from the δ_{11} region of the spectrum. From the splittings, $\Delta\nu_{11} = 830 \pm 80$ Hz centered at $\delta_{11}(1) = 1034 \pm 4$ ppm and $\Delta\nu_{11} = 380 \pm 80$ Hz centered at $\delta_{11}(2) = 1005 \pm 4$ ppm, α values of 37° and 46° are obtained for sites 1 and 2, respectively. (Note that the errors in the $\Delta\nu_{11}$ and δ_{11} values are larger than the corresponding values at the low frequency end of the spectrum where the splittings are well defined.) These values for the angle α lead to splittings in the δ_{22} region of approximately 80 and 450 Hz. Final values for this angle were obtained by visually fitting the experimental and calculated spectra.

The results of our analysis for the angle α imply that the axis of the least shielded principal component (δ_{11}) of the nitrogen shielding tensor is directed in the same general direction as the N—C_{ipso} bond, and the axis of the intermediate component (δ_{22}) bisects the NNC angle (i.e., lies along the direction of the nitrogen lone pair). For site 1, $\alpha = 37°$, and the approximate orientation of δ_{11} and δ_{22} is illustrated in **III**. A value of $\alpha = 37°$ would also be compatible with δ_{11} being approximately perpendicular to the N—C_{ipso} bond axis; however, this is extremely unlikely on the basis of molecular orbital calculations on diazene (1) and other molecules containing the  fragment (ref. 23 and footnote 2). A value for α of 42° has been found for ^{15}N in a similar molecule, benzylideneaniline.[3] The different values of the angle α derived for sites 1 and 2 (37° and 46°) could result from the slightly different structure of the molecules at these two sites and subtle differences in their intermolecular interactions; there is more available space at the disordered site (18).

III

We have ignored the indirect spin–spin coupling interaction in our analysis of the ^{15}N dipolar spectrum. This is expected to be an excellent assumption since $J(^{15}N,^{15}N)_{iso}$ is only 15.5 Hz in a related *trans*-azobenzene where one of the benzene rings has a *para* substituent (30).

Comparison with theory and related molecules

The principal components of the ^{15}N chemical shift tensor may be converted to absolute shielding components since the absolute ^{15}N chemical shielding constant of liquid ammonia is known to be approximately 244.6 ppm at 20°C (31). The absolute ^{15}N shielding components are given in Table 2 together with those calculated for *trans*-diazene (1). The calculated least shielded component, σ_{11}, is obviously too paramagnetic. It is apparent that Schindler is correct in concluding that it will be necessary to include electron correlation and to use large basis sets to obtain an adequate description of nitrogen shielding in systems with NN multiple bonds. The large negative contribution to σ_{11} arises mainly from the molecular orbital

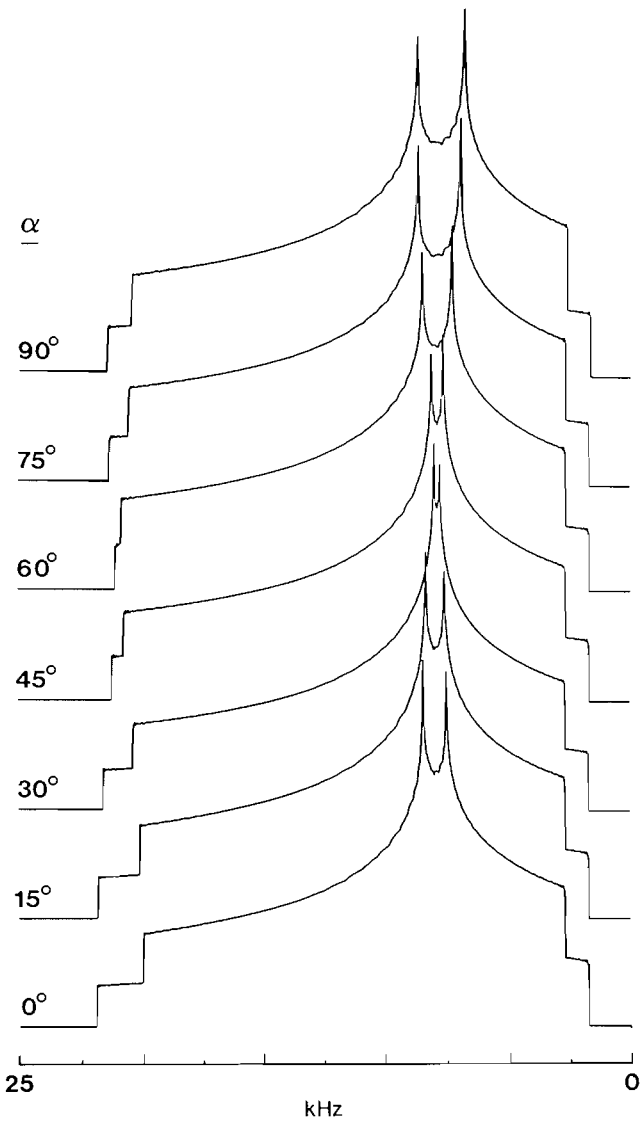

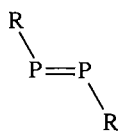

FIG. 5. Calculated homonuclear dipolar ^{15}N nmr spectra as a function of the angle α. β = 90° and r_{NN} = 1.247 Å; values of ν_{11}, ν_{22}, and ν_{33} are comparable to those given for azobenzene in Table 1 (B_0 = 4.70 T).

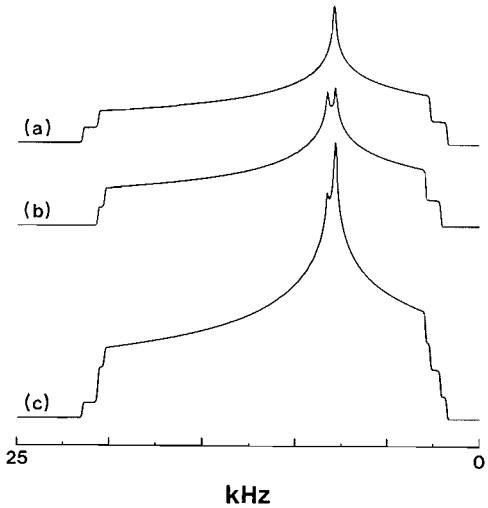
associated with the nitrogen lone pair that is involved in low-lying singlet $n \rightarrow \pi^*$ transitions (1, 32, 33).

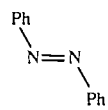
It is of interest to compare the principal components of the nitrogen shielding tensor of *trans*-azobenzene with the corresponding ^{31}P components recently reported in the diphosphene (**IV**) (10). The principal components of the ^{31}P shielding tensor

R = 2,4,6-tri-*tert*-butylphenyl

IV

are σ_{11} = −880 ppm, σ_{22} = 107 ppm, and σ_{33} = 359 ppm; σ_{iso} = −138 ppm; the shielding anisotropy is 1239 ppm and the asymmetry parameter is 0.34. We have converted the components of the shift tensor given in ref. 10 to those of a shielding tensor, taking the absolute phosphorus shielding constant of H_3PO_4, 85%, as 356 ppm (14, 34). The most shielded component, σ_{33}, is perpendicular to the plane containing the CP=PC fragment; σ_{11} is directed at approximately 60° from the P=P bond vector towards the substituted phenyl ring, while the intermediate component, σ_{22}, is oriented in the same general direction as the phosphorus lone pair. As one would intuitively expect, the relative orientation of the principal components of the nitrogen and phosphorus shielding tensors is similar in the diazene (**II**) and the diphosphene (**IV**). Qualitatively, the larger shielding anisotropy observed for the diphosphene (**IV**) is probably related to the larger value of $\langle a_0^3/r^3 \rangle$ for phosphorus as compared to nitrogen (14, 29) and





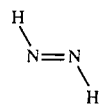


FIG. 6. Simulation of the dipolar coupled ^{15}N spectrum (powder) of *trans*-azobenzene-$^{15}N_2$. The spectrum of molecules in site 1 and site 2 is shown in (a) and (b) respectively; the spectrum obtained by summation of (a) and (b) is given in (c). Line broadening corresponding to 100 Hz was used to generate (a), (b), and (c), with all other parameters as given in Table 1 and the text.

TABLE 1. Principal components and orientation of the nitrogen-15 chemical shift tensor in *trans*-azobenzene[a]

	δ_{11}	δ_{22}	δ_{33}	δ_{iso}[b]	$\Delta\sigma$[c]	η[d]	α	β
Site 1	1034	391	109	511	925	0.54	37°	83°
Site 2	1005	400	125	510	880	0.56	46°	78°

[a]The δ_{ii}, δ_{iso}, and $\Delta\sigma$ values are in ppm; errors are estimated to be less than ±4 ppm. The errors in the angles α and β are estimated to be less than ±5°. As indicated in the text, the values reported for β are lower limits.
[b]$\delta_{iso} = \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33})$.
[c]$\Delta\sigma = \sigma_{33} - \sigma_{11}$.
[d]$\eta = (\sigma_{22} - \sigma_{33})/(\sigma_{11} - \sigma_{iso})$.

TABLE 2. Principal values of the nitrogen shielding tensor measured for *trans*-azobenzene (site 1) and calculated for *trans*-diazene (1)

Molecule	σ_{11} (ppm)	σ_{22} (ppm)	σ_{33} (ppm)	σ_{iso} (ppm)	$\Delta\sigma$ (ppm)	η
	−789	−146	136	−267	925	0.54
	−1370	−362	186	−515	1556	0.64

the lower energy of the $n \rightarrow \pi^*$ transition in the diphosphene (32).

Although a direct comparison between the observed ^{31}P shielding in **IV** and that calculated for the parent compound is difficult because of unknown substituent effects, it appears that *ab initio* molecular orbital calculations of $\sigma_{iso}(^{31}P)$ are too paramagnetic (24, 32). For *trans*-diphosphene the SOS CI (32) and IGLO (24) calculations predict $\sigma_{iso} = -359$ and -396 ppm respectively. These values are approximately 221 and 258 ppm respectively more negative than the isotropic value observed for **IV**; however, the bulky tri-*tert*-butylphenyl substituents could exert a substantial substituent effect. The same theoretical SOS CI calculations of Galasso (32) yield $\sigma_{iso} = -416$ ppm for the *trans*-diazene, approximately 149 ppm more negative than the value observed for **II**.

We have made new measurements of excess heat capacities and excess volumes of mixtures of chloroform and dioxane. In combination with published vapor pressures and excess enthalpies the results have been analyzed using the ideal associated solution model to yield K, ΔH^θ, ΔC_p^θ, and ΔV^θ for the formation of AB and A_2B complexes. It is demonstrated that the ideal associated solution model is consistent with all of the available thermodynamic data for this system, indicating that chemical interactions of the two components can account for nearly all of the deviations from ideal solution behavior. The results of our thermodynamic analysis are discussed in relation to the results of similar analyses of other systems in which there are strong chemical interactions of chloroform with electron-donor molecules.

Key words: complex formation, hydrogen bonding, ideal associated solution model, chloroform, 1,4-dioxane.

L. BARTA, Z. S. KOONER, L. G. HEPLER, G. ROUX-DESGRANGES et J.-P. E. GROLIER. Can. J. Chem. **67**, 1225 (1989).

On a effectué de nouvelles mesures des capacités calorifiques en excès et des volumes en excès de mélanges du chloroforme et du dioxane. Afin de déterminer les valeurs de K, de ΔH^θ, de ΔC_p^θ et ΔV^θ pour la formation des complexes AB et A_2B, on a analysé les résultats à l'aide du modèle de la solution associée idéale et en combinaison avec des pressions de vapeur et des enthalpies en excès déjà publiées. Il a été démontré que le modèle de la solution associée idéale est en accord avec toutes les données thermodynamiques disponibles pour ce système; ceci indique que les interactions chimiques entre les deux composants peuvent expliquer pratiquement toutes les déviations par rapport au comportement d'une solution idéale. On discute des résultats de notre analyse thermodynamique en fonction d'analyses semblables effectuées sur d'autres systèmes dans lesquels il existe de fortes interactions chimiques entre le chloroforme et des molécules qui donnent des électrons.

Mots clés : formation de complexes, liaisons hydrogènes, modèle de la solution associée idéale, chloroforme, 1,4-dioxane.

[Traduit par la revue]

Introduction

Many studies (1–13) have shown that thermodynamic data for binary mixtures of chloroform with Lewis bases can be interpreted in terms of the formation of either 1:1 or both 1:1 and 2:1 complexes. That such an interpretation is physically realistic has in some cases been substantiated by other types of investigation, including measurements of NMR relaxation rates (14, 15), measurements of dielectric properties (16), and determination of stable phases in the solid state (17, 18). The simplest and most convenient thermodynamic model that has been applied for this purpose assumes that the species present at equilibrium mix ideally. In effect, all of the deviations of the mixture from ideal solution behavior are treated in terms of chemical equilibria, with neglect of activity coefficients (activity coefficients equal to unity at all compositions, temperatures, and pressures). Accordingly there has been considerable interest in investigating the accuracy with which this simple "ideal associated solution" model describes the equilibrium properties of associated solutions.

The ideal associated solution model has recently been extended and applied with encouraging results to the analysis of thermodynamic properties of binary mixtures in which 1:1 complexes are formed (1–4). For both practical and theoretical reasons we have had an interest in extending this model to systems in which 2:1 as well as 1:1 complexes are expected to form, as represented by the coupled chemical equilibria,

[1] $A + B = AB$

[2] $AB + A = A_2B$

Previous investigations have shown that the ideal associated solution model gives a consistent account of vapor pressures and excess enthalpies of binary solutions of chloroform with dioxane (13), acetone (11, 12), dimethylsulfoxide (8–10), and selected ketones and esters (5). We have recently shown that the model also is reasonably consistent with partial molar enthalpies of solution, excess heat capacities, and excess volumes of chloroform + dimethylsulfoxide (7).

In the present work we have made new measurements of thermal and volumetric properties of chloroform + dioxane mixtures at 25°C. Vapor pressures and excess enthalpies at 50°C have been available for some time (13). We have combined these data with our heat capacity data to obtain, by way of the ideal associated solution model, values of the equilibrium constants and enthalpies and heat capacities of reactions [1] and [2] at 25°C. The resulting values have been used to calculate excess enthalpies at 35°C which have then been compared with experimental values reported by others (6, 19). Using the ideal associated solution model the volume changes of reactions [1] and [2] have also been evaluated.

The values of the thermodynamic properties of reactions [1] and [2] for chloroform + 1,4-dioxane are compared with those for chloroform + dimethylsulfoxide (7). The thermodynamic properties of formation of the 1:1 complexes of chloroform with 1,4-dioxane and with dimethylsulfoxide are compared with those that have been reported for the formation of 1:1 complexes of chloroform with triethylamine (1, 4) and with benzene (3).

Experimental

Heat capacities and densities at 298.15 ± 0.05 K were measured with a Picker flow calorimeter (20) and vibrating tube densimeter (21).

Chloroform (Fluka, IR 0.5% ethanol) and dioxane (Fluka, puriss.,

>99.5 mol%) were purified and handled as described previously (3, 22).

Results of calorimetric and volumetric measurements

Table 1 lists the results of our measurements of heat capacities and densities. For convenience we have also expressed these results as molar excess properties, defined by the general relationship

$$Y^E = Y - x_A Y_A^0 - x_B Y_B^0$$

where Y represents the property of a mixture containing exactly one mole of stoichiometric A + B, x_A and x_B are stoichiometric mole fractions of A and B, and Y_A^0 and Y_B^0 are the molar properties of the pure liquids. Our heat capacity and density of pure chloroform are $C_{pA}^0 = 114.32$ J K^{-1} mol^{-1} and $\rho_A^0 = 1.47890$ g cm^{-3}, in excellent agreement with values that recently have been reported elsewhere (3, 7). Our heat capacity and density of pure dioxane are $C_{pB}^0 = 149.489$ J K^{-1} mol^{-1} and $\rho_B^0 = 1.027737$ g cm^{-3}.

Thermodynamic analysis

In applying the ideal associated solution model it is assumed that all deviations of the properties of the solution from ideality are due to complex formation, with all activity coefficients equal to unity at all temperatures, pressures, and compositions. For mixtures of chloroform (A) and dioxane (B) we consider the coupled chemical equilibria represented by reactions [1] and [2] and then take these mixtures to be ideal solutions of the four distinct chemical species A, B, AB, and A_2B. Since physical interactions are neglected and activity coefficients are set equal to unity, the equilibrium activity of species i is equal to the equilibrium mole fraction (z_i), and the equilibrium constants for reactions [1] and [2] may be written

$$[3] \quad K_1 = z_{AB}/(z_A z_B)$$

$$[4] \quad K_2 = z_{A_2B}/(z_{AB} z_A)$$

Combination of eqs. [3] and [4] with the mass balance constraint

$$[5] \quad 1 = z_A + z_B + z_{AB} + z_{A_2B}$$

leads to

$$[6] \quad (1 - z_A - z_B)/(z_A z_B) = K_1 + K_1 K_2 z_A$$

Since the solution is considered as an ideal mixture, the partial pressure of each of the four components is given by Raoult's law, $p_i = z_i p_i^0$. If the condensed phase is ideal, then it is reasonable that the vapor phase is also an ideal mixture and that the partial pressure of species i may be calculated as the product of the total vapor pressure and the equilibrium mole fraction of species i in the vapor phase, $p_i = y_i P$. At the low pressures of the vapor pressure measurements for this system (13) there will be little or no association in the vapor phase, and the equilibrium mole fraction of species A in solution can be calculated from the equilibrium mole fraction of A in the vapor phase (y_A), the total vapor pressure (P), and the vapor pressure of pure A (p_A^0): $z_A = y_A P/p_A^0$. Similarly, $z_B = (P - z_A p_A^0)/p_B^0$.

The molar excess enthalpy (enthalpy of mixing) and excess volume are given by equations of the form

$$[7] \quad Y^E = r\Delta Y_1^\theta + s\Delta Y_2^\theta$$

where r and s are the extents of reactions [1] and [2], respectively. The relationships between r, s, the stoichiometric mole fractions (x_A and x_B) of the two components, and the equilibrium mole fractions (z_i) are summarized in Table 2. The temperature derivative of eq. [7] and with Y = H, gives the excess heat capacity:

$$[8] \quad C_p^E = r\Delta C_{p1}^\theta + s\Delta C_{p2}^\theta + (\partial r/\partial T)_p \Delta H_1^\theta + (\partial s/\partial T)_p \Delta H_2^\theta$$

Once the values of the equilibrium constants are known, the quantities r and s in eq. [7] and [8] may be obtained by iterative solution of the simultaneous equations

$$[9] \quad K_1 = [(r - s)(1 - r - s)]/[(x_A - r - s)(x_B - r)]$$

$$[10] \quad K_2 = [s(1 - r - s)]/[(x_A - r - s)(r - s)]$$

that result from substituting for the z_i in eqs. [3] and [4] using the expressions listed in Table 2. If the enthalpies of reaction are known, then the temperature derivatives of r and s may be evaluated by solving the simultaneous equations

$$[11] \quad (\partial \ln K_1/\partial T)_p = (\partial r/\partial T)_p[1/(r - s) - 1/(1 - r - s) + 1/(x_A - r - s) + 1/(x_B - r)] + (\partial s/\partial T)_p[1/(x_A - r - s) - 1/(r - s) - 1/(1 - r - s)] = \Delta H_1^\theta/RT^2$$

$$[12] \quad (\partial \ln K_2/\partial T)_p = (\partial r/\partial T)_p[1/(x_A - r - s) - 1/(r - s) - 1/(1 - r - s)] + (\partial s/\partial T)_p[1/s - 1/(1 - r - s) + 1/(r - s) + 1/(x_A - r - s)] = \Delta H_2^\theta/RT^2$$

To use eqs. [3] – [12] to evaluate the desired properties of complex formation at 25°C, we begin with evaluation of the equilibrium constants at 50°C, the temperature of the available vapor pressure data (13). Fitting of eq. [6] to these data leads to $K_{1,323} = 1.10$ and $K_{2,323} = 0.83$. Iterative solution of eqs. [9] and [10] then yields r_{323} and s_{323} for any stoichiometric mixture. Using eq. [7] and excess enthalpy data at 50°C (also from ref.

TABLE 2. Reaction table for formation of AB and A_2B complexes in the system A + B

Species	Initial amount	Initial mole fraction	Amount at equilibrium	Equilibrium mole fraction[a]
A	N_A	x_A	$N_A - n - m$	$z_A = (x_A - r - s)/(1 - r - s)$
B	N_B	x_B	$N_B - n$	$z_B = (x_B - r)/(1 - r - s)$
AB	0	0	$n - m$	$z_{AB} = (r - s)/(1 - r - s)$
A_2B	0	0	m	$z_{A_2B} = s/(1 - r - s)$

[a] $r = n/(N_A + N_B)$; $s = m/(N_A + N_B)$; equilibrium mole fraction of species $i = z_i$.

TABLE 3. Thermodynamic properties for formation of AB and A_2B complexes in mixtures of chloroform + dioxane based on the ideal associated solution model

Property[a]	A + B = AB[b]	A + AB = A_2B[b]
K_{323}	1.10 (1.11)	0.83 (1.12)
ΔH^θ_{323}	−8.6 (−8.4)	−9.2 (−6.7)
K_{298}	1.41	1.09
ΔH^θ_{298}	−7.9	−8.3
ΔC_p^θ	−29±3	−37±10
ΔV^θ_{298}	0.07±0.05	−4.23±0.16

[a] Equilibrium constants have been expressed in terms of mole fractions; units are kJ mol^{-1} (enthalpies), J K^{-1} mol^{-1} (heat capacities), and cm^3 mol^{-1} (volumes).
[b] Values in parentheses are from ref. 13.

13) we have obtained $\Delta H_1{}^\theta_{323} = -8.6$ kJ mol^{-1} and $\Delta H_2{}^\theta_{323} = -9.2$ kJ mol^{-1}.

We now introduce the thermodynamic relationship

[13] $(\partial \Delta H^\theta/\partial T)_p = \Delta C_p{}^\theta$

and assume that the $\Delta C_p{}^\theta$ values are independent of temperature over the range 298 K to 323 K. The values of $\Delta C_p{}^\theta$ have been obtained by an iterative method, choosing initial values of $\Delta C_p{}^\theta = 0$. Integration of the van't Hoff relationship

[14] $(\partial \ln K/\partial T)_p = \Delta H^\theta/RT^2$

using eq. [13] yields estimates of the values of ΔH^θ_{298} and K_{298}. Substitution of these values of K into eqs. [9] and [10] then yields estimates of r_{298} and s_{298}, and these in combination with the ΔH^θ_{298} values and eqs. [11] and [12] lead to estimates of $(\partial r/\partial T)_p$ and $(\partial s/\partial T)_p$ at 298 K. New estimates of the values of $\Delta C_p{}^\theta$ may then obtained by fitting eq. [8] to our excess heat capacities. The iteration was terminated when the values of both of the $\Delta C_p{}^\theta$ from successive iterations differed by less than 1%.

Using the final values of r_{298} and s_{298}, $\Delta V_1{}^\theta_{298}$ and $\Delta V_2{}^\theta_{298}$ were evaluated by fitting eq. [7] to our excess volumes.

Discussion

The results of our analysis are summarized in Table 3, where the values of K_{323} and ΔH^θ_{323} reported by McGlashan and Rastogi (13) are included for comparison. The relative errors (based on eleven measurements) in our values of $K_{1,323}$ and $K_{2,323}$ are of the order of 5% and 10%, respectively. The relative errors (based on five measurements) in our values of $\Delta H_1{}^\theta_{323}$ and $\Delta H_2{}^\theta_{323}$ are both of the order of 10%; thus our enthalpies of stepwise formation of AB and A_2B complexes are the same within the uncertainties of the analysis. This result may be contrasted with that of McGlashan and Rastogi, who found that the formation of A_2B from AB and A was slightly less exothermic than the formation of AB from A and B. In view of the uncertainties in their calculations, the result of McGlashan and Rastogi may be fortuitous although physically reasonable, as these authors have discussed. Use of the values of K and ΔH^θ as reported by McGlashan and Rastogi leads to a fit to our heat capacity and volumetric data that is slightly worse than that obtained using our values of these quantities.

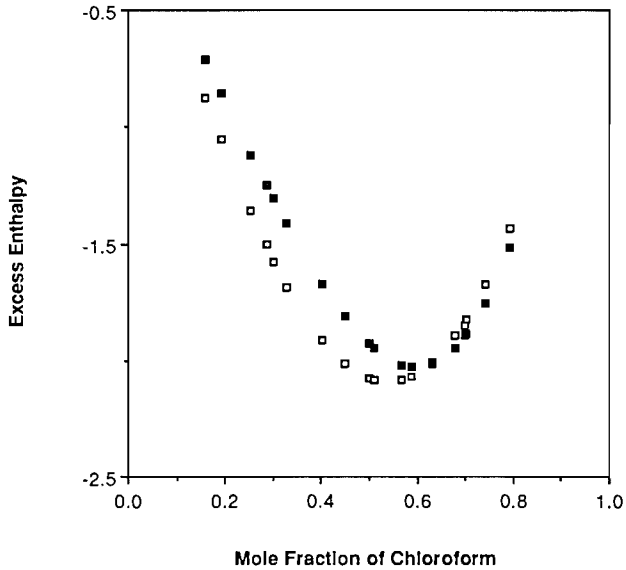

FIG. 1. Excess enthalpy (kJ mol^{-1}) of chloroform + 1,4-dioxane at 308.15 K versus stoichiometric mole fraction of chloroform. Open squares represent the data of ref. 6; solid squares represent the corresponding values predicted by the ideal associated solution model. Interpolated values based on the data of Van Ness and Abbott at 303.15 K and 318.15 K lie on the curve defined by the solid squares.

We have calculated excess enthalpies at 308.15 K using eq. [7]. Values of ΔH^θ_{308} were calculated using eq. [13] and values of ΔH^θ_{298} and $\Delta C_p{}^\theta_{298}$ from Table 3. Values of r and s at 308 K were calculated from eqs. [9] and [10] using values of K obtained from eqs. [11] and [12] and the information in Table 3. The results are displayed in Fig. 1 and are compared there with the experimental results of Singh (6). This author has reported a maximum value of $H^E_{max,308} = -2.10$ kJ mol^{-1} at a mole fraction of chloroform of 0.55 and has compared these values with $H^E_{max,308} = -2.08$ kJ mol^{-1} at $x_A = 0.6$ obtained by interpolation of the data of Van Ness and Abbott (19) at 303 K and 318 K. Singh has also noted that his excess enthalpies in comparison to those of Van Ness and Abbott are slightly more exothermic (by about 0.2 kJ mol^{-1}) at $x_A < 0.45$ and slightly less exothermic (by about 0.1 kJ mol^{-1}) at $x_A > 0.6$. On this basis our calculated values are in excellent agreement with the data of Van Ness and Abbott.

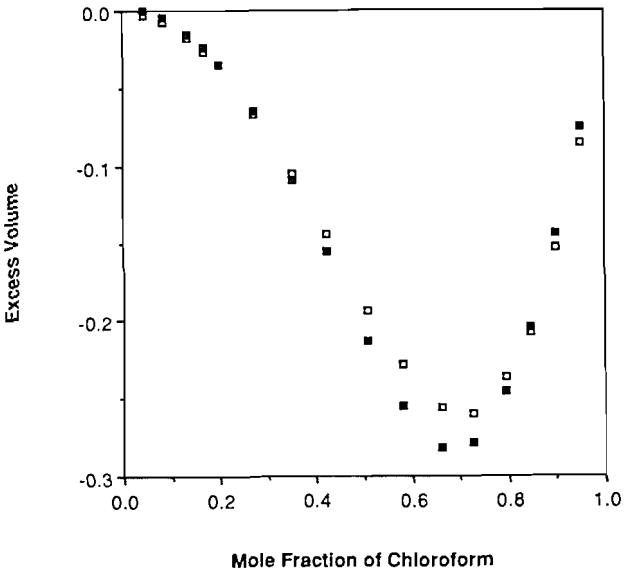

FIG. 2. Excess volumes ($cm^3\ mol^{-1}$) of chloroform + 1,4-dioxane at 298.15 K versus stoichiometric mole fraction of chloroform. Open squares represent our experimental data (Table 1); solid squares represent the corresponding values predicted by the ideal associated solution model (eq. [7]).

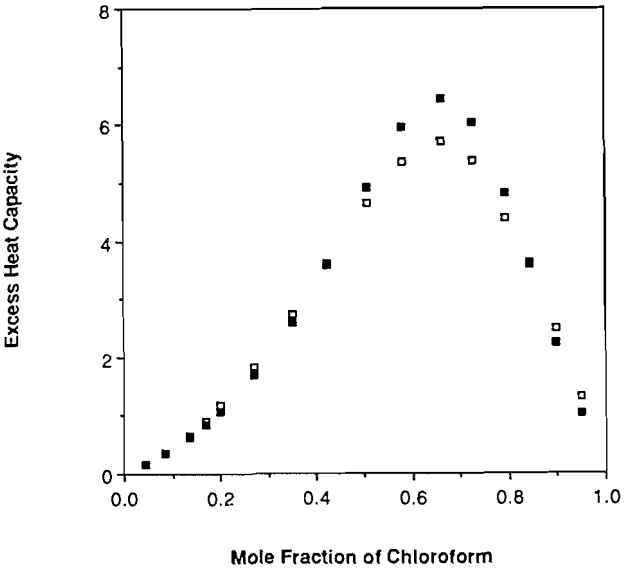

FIG. 3. Excess heat capacities ($J\ K^{-1}\ mol^{-1}$) of chloroform + 1,4-dioxane at 298.15 K versus stoichiometric mole fraction of chloroform. Open squares represent the data reported here (Table 1); solid squares represent the corresponding values predicted by the ideal associated solution model (eq. [8]).

We may also compare calculated values of excess enthalpies at 298.15 K with experimental values reported by Searles and Tamres (23). These authors obtained $H^E_{298} = -2.02 \pm 0.06$ kJ mol^{-1} at $x_A = 0.598$; our calculated value of -2.08 ± 0.06 kJ mol^{-1} is in excellent agreement. At $x_A = 0.400$ the experimental and calculated values are -1.90 kJ mol^{-1} and -1.70 kJ mol^{-1}, respectively.

The accuracy of the ideal associated solution model in representing our molar excess volumes and heat capacities is displayed in Figs. 2 and 3, respectively. We note that the overall representation of thermodynamic properties by the ideal associated solution model is more accurate for chloroform + 1,4-dioxane than for chloroform + dimethylsulfoxide (7).

TABLE 4. Thermodynamics of 1:1 complex formation of chloroform with electron donors at 25°C; units are J mol^{-1} (ΔG^θ), kJ mol^{-1} (ΔH^θ), J K^{-1} mol^{-1} (ΔS^θ, $\Delta C_p{}^\theta$), and cm^3 mol^{-1} (ΔV^θ)

Electron donor	ΔG^θ	ΔH^θ	ΔS^θ	$\Delta C_p{}^\theta$	ΔV^θ
Triethylamine	−2350	−17.0	−49.1	−42	−8.3
Benzene	1979	−4.9	−23.1	−17	2.1
DMSO[a]	−361	−10.5	−33.9	−89	1.8
	(−3267)	(−6.2)	(−9.8)	(56)	(−4.8)
1,4-Dioxane[a]	−860	−7.9	−23.6	−29	0.07
	(−220)	(−8.3)	(−27.1)	(−37)	(−4.2)

[a]Values in parentheses refer to the reaction A + AB = A_2B

In Table 4 the thermodynamic properties for complex formation in chloroform + 1,4-dioxane are compared with those for complex formation in chloroform + other electron donors. Certain features are common to the formation of the AB complex in each of the four systems listed. The reactions are exothermic and hence all of the AB complexes become less stable with increasing temperature. Formation of AB becomes more exothermic with increasing basicity of the electron donor molecule. The change in entropy is unfavorable to complex formation ($\Delta S^\theta < 0$) and, like ΔH^θ, becomes less negative with increasing temperature ($\Delta C_p{}^\theta < 0$). $\Delta C_p{}^\theta < 0$ also indicates that the reactions become more exothermic with increasing temperature.

For the system chloroform + 1,4-dioxane formation of the first bond and formation of the second bond of chloroform with the base are approximately equivalent in terms of standard enthalpy, entropy, and heat capacity changes. This result may be contrasted with that for chloroform + dimethylsulfoxide, where formation of the first bond is considerably more exothermic than that of the second, ΔS^θ is considerably more negative, and $\Delta C_p{}^\theta$ is of opposite sign. Thus formation of the second bond in the chloroform + dioxane system follows the general pattern observed for formation of AB complexes as discussed above. Formation of the second bond in the chloroform + dimethylsulfoxide system departs from this general pattern in that the reaction becomes *less* exothermic with increasing temperature.

While formation of a complex results in a reduction in intermolecular distance, the geometry of the complex relative to that of A and B molecules may lead to a net increase in void space due to reduction in packing efficiency of molecules in the solution. It therefore seems reasonable that values of ΔV^θ may range from negative (efficient packing) to positive (inefficient packing). It is noteworthy that in those cases where ΔV^θ is positive, the values are small.

Synthesis and reaction chemistry of the heterobimetallic FeIr complexes $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$ and $(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-}COD)$

HILARY A. JENKINS AND STEPHEN J. LOEB[1]

HILARY A. JENKINS and STEPHEN J. LOEB. Can. J. Chem. **67**, 1230 (1989).

Reactions of $Li[Fe(CO)_4(PCy_2)]$ with *trans*-$IrCl(CO)(PPh_3)_2$ and $[IrCl(1,5\text{-}COD)]_2$ (COD = cyclooctadiene) results in the formation of the μ-PCy_2 bridged complexes $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1**, and $(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-}COD)$, **2**, respectively. **1** is coordinatively saturated with an FeIr dative bond and does not form an adduct with CO or undergo oxidative addition with H_2, HCl, or CH_3I. The protonation of **1** with HBF_4 gives the Ir hydride compound $[(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(H)(PPh_3)(CO)][BF_4]$. **1** undergoes phosphine substitution reactions in which PPh_3 is replaced by PR_3. Substitution is at Ir for PEt_3, $PnBu_3$, $PiPr_3$, PBz_3, and PCy_3, at Fe for PMe_2Ph, and at both metal centers for PPh_2Me. The substitution pattern is selective and appears to be sterically controlled. There is also evidence for cooperativity between metal centers in the formation of the PPh_2Me adduct since only the disubstituted product can be detected. Coordinative unsaturation was generated at the Ir centre by thermally induced CO loss from $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)_2$ to give $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)$. The reaction of **2** with excess CO(g) resulted in the formation of the carbonyl species $(CO)_4Fe(\mu\text{-}PCy_2)Ir(CO)_3$. **2** also reacts with 2 PEt_3 or DPPE (DPPE = 1,2-bis(diphenylphosphino)ethane) under CO(g) to give the disubstituted products $(CO)_3(PEt_3)Fe(\mu\text{-}PCy_2)Ir(PEt_3)(CO)_2$ and $(CO)_3Fe(\mu\text{-}PCy_2)(\mu\text{-DPPE})Ir(CO)_2$ with loss of 1,5-COD.

Key words: heterobimetallic FeIr complexes, cooperativity, phosphido-bridge.

HILARY A. JENKINS et STEPHEN J. LOEB. Can. J. Chem. **67**, 1230 (1989).

La réaction du $Li[Fe(CO)_4(PCy_2)]$ avec le *trans*-$IrCl(CO)(PPh_3)_2$ et le $[IrCl(1,5\text{-}COD)]_2$ (COD = cyclooctadiène) conduit à la formation des complexes pontés par un μ-PCy_2, respectivement le $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1**, et $(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-COD})$, **2**. Le composé **1** est saturé par une coordination avec une liaison dative FeIr; il ne forme pas d'adduit avec le CO et il ne subit pas d'additions oxydantes avec le H_2, le HCl ou le CH_3I. La protonation du composé **1** avec du HBF, conduit à un hydrure de Ir, le composé $[(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(H)(PPh_3)(CO)_2][BF_4]$. Le composé **1** subit des réactions de substitution des phosphines au cours desquelles le PPh_3 est remplacé par des PR_3. Les substitutions se produisent au niveau du Ir avec PEt_3, $PnBu_3$, $PiPr_3$, PBz_3 et PCy_3 et au niveau du Fe avec le PMe_2Ph et aux deux centres métalliques avec le PPh_2Me. Le patron des substitutions est sélectif et il semble contrôlé par des facteurs stériques. Puisqu'on ne peut détecter que le produit disubstitué, il semble aussi y avoir de la coopération entre les centres métalliques dans la formation de l'adduit PPh_2Me. On a généré une insaturation de coordination au niveau du Ir par une perte de CO induite d'une façon thermique à partir du $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)_2$ et conduisant à la formation de $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)$. La réaction du composé **2** avec un excès de CO(g) conduit à la formation d'espèces carbonylées $(CO)_4Fe(\mu\text{-}PCy_2)Ir(CO)_3$. Sous une atmosphère de CO(g), le composé **2** réagit aussi avec 2 PEt_3 ou DPPE (DPPE = 1,2-bis(diphénylphosphino)éthane) pour donner les produits disubstitués, $(CO)_3(PEt_3)Fe(\mu\text{-}PCy_2)Ir(PEt_3)(CO)_2$ et $(CO)_3Fe(\mu\text{-}PCy_2)(\mu\text{-DPPE})Ir(CO)_2$, avec perte de 1,5-COD.

Mots clés : complexes hétéro-bimétalliques de FeIr, coopérativité, pont phosphido.

[Traduit par la revue]

Introduction

It is well known that sterically demanding trialkyl and triarylphosphine ligands can be used to induce coordinative unsaturation at a metal centre (1, 2). This is usually the result of creating a crowded environment at the metal which precludes coordination of the full compliment of ligands necessary for coordinative saturation. This technique has been used very successfully in the design of reactive metal systems such as the 16-electron complexes *trans*-$M(PR_3)_2(CO)_4$ (M = Mo, W: R = Cy, *i*Pr,) (3) and the 14-electron species $M(PR_3)_2$ (M = Pd, Pt; R = *i*Pr, Cy, *t*Bu) (4–6) and $RhH(PR_3)_2$ (R = *i*Pr, *t*Bu, Cy) (7). These coordinatively unsaturated complexes are known to react specifically with small molecules (3–7) such as N_2, H_2, C_2H_4, SO_2, and CO.

We are currently interested in extending this concept to multi-centred complexes. Our approach has been to use the bulky dicyclohexylphosphido group in combination with various large ancillary ligands, such as PR_3, in attempts to produce coordinatively unsaturated heterobimetallic complexes. Initially, we studied complexes containing two μ-PCy_2 ligands linking Mo or W to Ni, Pd, and Pt (8). However, these sterically crowded molecules exhibited little chemical reactivity. Recently, we employed a *single* μ-PCy_2 unit with the assumption that this would lessen the overall steric shielding and produce a more exposed metal–metal bond resulting in an increase in reactivity. In a preliminary study, we prepared some coordinatively unsaturated heterobimetallic complexes of FeRh containing a single μ-PCy_2 bridge (9). These complexes were observed to undergo adduct formation with small molecules and also showed substitution for a donor–acceptor metal–metal bond. In general, the reactivity patterns were not those observed for similar μ-PPh_2 bridged complexes. In this paper, we describe the preparation and reactivity of some analogous FeIr complexes.

Experimental section

General

trans-$IrCl(CO)(PPh_3)_2$, $[IrCl(1,5\text{-}COD)]_2$ (COD = cyclooctadiene), $Fe(CO)_4(PCy_2H)$, and DMA·HCl (DMA = dimethylacetamide) were prepared by the literature methods (9–12). $Fe_2(CO)_9$, $IrCl_3 \cdot xH_2O$, PCy_2H, PBz_3 (Bz = benzyl), $PiPr_3$, PCy_3 (Strem), PPh_3, DPPE (1,2-bis(diphenylphosphino)ethane), PEt_3, $PnBu_3$, PPh_2Me, PMe_2Ph, and *n*-BuLi (Aldrich) were purchased and used as received. THF (tetrahydrofuran), toluene, and *n*-hexane were dried by distillation from Na-benzophenone ketyl under N_2. All reactions were conducted under an atmosphere of dry N_2 using standard Schlenk techniques.

$^{31}P\{^1H\}$, $^{13}C\{^1H\}$, and ^1H NMR spectra were obtained at 121.5, 75.5, and 300.1 MHz, respectively, on a Bruker AM300 spectrometer

using deuterated solvents as lock. Phosphorus chemical shifts were measured relative to external 85% H_3PO_4 with positive shifts downfield. Infrared spectra were recorded on a Perkin-Elmer 781 grating spectrometer.

*Preparation of $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1***

Method A

n-Butyllithium (1.65 mL, 2.56 mmol of 1.55 *M* solution in hexanes) was added via syringe to a brown solution of $Fe(CO)_4(PCy_2H)$ (0.938 g, 2.56 mmol) in THF (15 mL). This solution was stirred for 10 min and then added dropwise to a yellow slurry of *trans*-$IrCl(CO)(PPh_3)_2$ (2.00 g, 2.56 mmol) in THF (30 mL) at 23°C. The resulting orange-brown solution was stirred for 24 h at room temperature and the solvent removed *in vacuo*. The remaining brown semi-solid was washed with *n*-hexane (3 × 10 mL), and extracted with CH_2Cl_2 (5 × 10 mL). The volume was reduced to 10 mL and the solution cooled to −20°C for 18 h. This yielded yellow-orange microcrystals of **1**. (2.21 g, 1.98 mmol, 75%).

Method B

$(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-COD})$ **2**, (0.265 g, 0.398 mmol) was dissolved in toluene (5 mL) and PPh_3 (0.209 g, 0.796 mmol) added. The resulting orange–brown solution was then placed under an atmosphere of CO(g) and stirred for 18 h. The orange solution was then taken to dryness *in vacuo* and the solid residue washed with diethyl ether (2 × 10 mL). The residue was recrystallized from CH_2Cl_2 to give yellow–orange microcrystals of **1**, 0.362 g (82%). *Anal.* calcd. for $C_{53}H_{52}FeIrO_5P_3$: C 57.31, H 4.73; found: C 57.24, H 4.63.

*Preparation of $(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-COD})$, **2***

n-Butyllithium (0.511 mL, 0.819 mmol of 1.6 *M* solution in hexanes) was added via syringe to a brown solution of $Fe(CO)_4(PCy_2H)$ (0.300 g, 0.819 mmol) in THF (10 mL). The resulting dark brown solution was stirred at room temperature for 10 min and then cooled to 0°C. This cooled solution was then added dropwise to an orange solution of $[IrCl(1,5\text{-COD})]_2$ (0.275 g, 0.409 mmol) in THF (10 mL). An immediate colour change was observed from orange to an intense dark red–brown. Stirring was continued for 4 h at 0°C, the solution taken to dryness *in vacuo* and the resulting reddish-brown oil extracted with toluene (3 × 5 mL). The solution was filtered and the volume reduced to 5 mL. After the solution was cooled at −20°C for 48 h, red microcrystalline material was isolated (0.365 g, 67%). $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ 214.5 (br, CO), δ 77.2, 76.8 (CH, COD), δ 26.8 (CH_2, COD); ^1H NMR (toluene-d_8) δ 4.70, 4.36 (br s, 4H, COD), δ 2.21 (br s, 8H, COD), δ 0.95–1.80 (br m, 22H, Cy). *Anal.* calcd. for $C_{24}H_{34}FeIrO_4P$: C, 43.31, H 5.16; found: C 43.01, H 5.04.

*Reactions of $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1**, with CO or H_2*

$(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1** (0.100 g, 0.090 mmol), was partially dissolved in toluene-d_8 (5 mL). The reagent gas was introduced as the atmosphere in place of N_2(g) and this mixture stirred for 4 h at 23°C with no visible change. A 3 mL sample of the solution was then removed, filtered and the $^{31}P\{^1H\}$ NMR recorded under an atmosphere (1 atm) of the reagent gas. $^{31}P\{^1H\}$ NMR showed only resonances due to **1**.

*Reactions of $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1** with CH_3I or DMA·HCl*

$(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1**, (0.100 g, 0.090 mmol), was partially dissolved in toluene-d_8 (5 mL). Equimolar amounts of either CH_3I or DMA·HCl were then added and the resulting solution stirred for 18 h. A 3 mL sample of the solution was removed, filtered, and the $^{31}P\{^1H\}$ NMR recorded. $^{31}P\{^1H\}$ NMR showed only resonances due to **1**.

*Preparation of $[(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(H)(PPh_3)(CO)][BF_4]$, **3***

$(CO)_3(PPh_3)Fe(PCy_2)Ir(PPh_3)(CO)_2$ **1** (0.120 g, 0.108 mmol), was partially dissolved in THF (5 mL) and HBF_4–etherate (0.025 mL, 0.108 mmol) added. A clear pale yellow solution resulted immediately. The mixture was stirred for a further 18 h at 23°C. The volume was reduced to 3 mL and the solution cooled to −20°C for 48 h to yield pale yellow microcrystals of **3**, 0.044 g (35%). Although this compound appeared to be pure from all spectroscopic evidence, a satisfactory elemental analysis could not be obtained.

*Preparation of $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PR_3)(CO)_2$, (R = Et, **4**; n-Bu, **5**; i-Pr, **6**; Bz, **7**; and $(CO)_3(PPh_2Me)Fe(\mu\text{-}PCy_2)Ir(PPh_2Me)(CO)_2$, **8***

$(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1** (0.150 g, 0.135 mmol), was partially dissolved in toluene (10 mL) and two molar equivalents of the appropriate phosphine added via microsyringe. The solution was stirred for 15 min during which time **1** completely dissolved resulting in an orange solution. This solution was then stirred for a further 12 h at 23°C. The toluene was removed *in vacuo* and the resulting oily solid washed with diethyl ether (2 × 3 mL) to leave the product as a yellow or orange–yellow solid, **4**, 0.143 g (57%). *Anal.* calcd. for $C_{41}H_{52}FeIrO_5P_3$: C 50.96, H 5.43; found: C 51.27, H 5.53; **5** 0.150 g (63%). *Anal.* calcd. for $C_{47}H_{64}FeIrO_5P_3$: C 53.74, H 6.15; found: C 53.27, H 5.89; **6**, 0.081 g (61%). *Anal.* calcd. for $C_{44}H_{58}FeIrO_5P_3$: C 52.41, H 5.81; found: C 52.43, H 5.63; **7**, 0.132 g (58%). *Anal.* calcd. for $C_{56}H_{61}FeIrO_5P_3$: C 58.19, H 5.08; found: C 57.39, H 4.92; **8**, 0.116 g (63%). *Anal.* calcd. for $C_{43}H_{48}FeIrO_5P_3$: C 52.35, H 4.91; found: C 52.11, H 4.75.

*Preparation of $(CO)_3(PMe_2Ph)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **9**, and $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)_2$, **10***

$(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1** (0.150 g, 0.135 mmol), was partially dissolved in toluene (10 mL) and two molar equivalents of the appropriate phosphine added. The mixture was stirred for 30 min during which time the remaining **1** completely dissolved. The reaction solution was stirred for a further 12 h at 23°C. The toluene was removed *in vacuo* and the resulting orange–red oil dissolved in the minimum amount of diethyl ether. This solution was then cooled to −20°C for 24 h producing orange microcrystals of the product. **9**, 0.072 g (55%). *Anal.* calcd. for $C_{43}H_{48}FeIrO_5P_3$: C 52.36, H 4.92; found: C 52.99 H 4.86; **10**, 0.079 (68%). *Anal.* calcd. for $C_{53}H_{70}FeIrO_5P_3$: C 56.40, H 6.26; found: C 55.43, H 6.52.

*Preparation of $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)$, **12***

$(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)_2$, **10** (0.150 g, 0.133 mmol), was dissolved in toluene (10 mL) and this solution refluxed for 12 h. The solution gradually darkened in colour from orange to orange–red over this time. The resulting solution was cooled, filtered, and the volume reduced to 3 mL. After cooling at −20°C for 18 h a small amount of orange–red solid (0.065 g, 44%) was isolated. Although this material can be identified spectroscopically as **12** and could seemingly be recrystallized from toluene, the final product was persistently contaminated with **10**. As a result no satisfactory elemental analysis could be obtained.

*Preparation of $(CO)_4Fe(\mu\text{-}PCy_2)Ir(CO)_3$, **13***

$(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-COD})$, **2** (0.200 g, 0.298 mmol), was dissolved in toluene (10 mL) and the N_2(g) atmosphere replaced by CO(g). The solution was stirred for 90 min and then taken to dryness and the residue dried *in vacuo* for 4 h to remove 1,5-COD. *n*-Hexane (2 mL) was added to dissolve the residue and after cooling at −20°C for 48 h red microcrystals of **13** were collected, 0.136 g (71%). $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ 210.5 (br, Fe—CO), 179.6 (br, Ir—CO). Free 1,5-COD was detected in the original reaction mixture with no evidence for unreacted **2**. *Anal.* calcd. for $C_{19}H_{22}FeIrO_7$: C 35.58, H 3.46; found: C 34.89, H 3.37.

*Preparation of $(CO)_3(PEt_3)Fe(\mu\text{-}PCy_2)Ir(PEt_3)(CO)_2$, **14***

$(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-COD})$, **2**, (0.340 g, 0.511 mmol) was dissolved in toluene (5 mL) and PEt_3 (0.121 g, 1.02 mmol) added. The resulting orange–brown solution was then placed under an atmosphere of CO(g) and stirred for 18 h. The orange solution was then taken to dryness *in vacuo* and the semi-solid residue washed with *n*-hexane. The residue was recrystallized from toluene/*n*-hexane to give yellow–orange microcrystals of **14**, 0.344 g (82%). *Anal.* calcd. for $C_{29}H_{52}FeIrO_5P_3$: C 42.38, H 6.39; found: C 41.88, H 6.19.

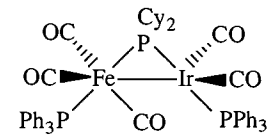
[c]$^3J_{PP}$ = 9.6 Hz.

Preparation of $(CO)_3Fe(\mu\text{-}PCy_2)(\mu\text{-DPPE})Ir(CO)_2$, 15

$(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-COD})$, **2** (0.285 g, 0.428 mmol), was dissolved in toluene (10 mL) and DPPE (0.341 g, 0.856 mmol) added with stirring. The orange solution was then placed under an atmosphere of CO(g). The resulting yellow–orange solution was stirred for 24 h and the solvent removed *in vacuo*. The residue was washed with diethyl ether (3 × 10 mL) and then recrystallized from toluene at −20°C to give yellow microcrystals of **15**, 0.185 g (44%). *Anal.* calcd. for $C_{43}H_{46}FeIrO_5P_3$: C 52.49, H 4.72; found: C 51.88, H 4.49.

Results

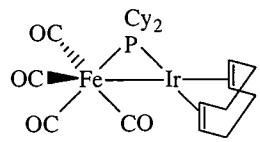


Synthesis and characterization of 1 and 2

The heterobimetallic FeIr complexes $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2$, **1**, and $(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-COD})$, **2**, were prepared by the bridge-assisted synthetic method (13) according to eqs. [1] and [2].

[1] *trans*-$IrCl(CO)(PPh_3)_2 + Li[Fe(CO)_4(PCy_2)] \rightarrow (CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)_2 + LiCl$

[2] $[IrCl(1,5\text{-COD})]_2 + 2Li[Fe(CO)_4(PCy_2)] \rightarrow 2(CO)_4Fe(\mu\text{-}PCy_2)Ir(1,5\text{-COD}) + 2LiCl$



The $^{31}P\{^1H\}$ NMR spectral data for **1** and **2** are summarized in Table 1. Complex **1** shows a downfield resonance (δ 148.9 (dd)) due to the bridging PCy_2 ligand coupled to two different PPh_3 groups ($^2J_{pp}$(Fe) = 20.6 Hz and $^2J_{pp}$(Ir) = 178.2 Hz). The two different PPh_3 groups (δ(Fe) 74.3 (d), δ(Ir) 10.7 (d)) can be distinguished by comparison with the analogous FeRh complex (9) which showed PPh_3 bound to Fe at 77.4 ppm and PPh_3 bonded to Rh at 36.0 ppm with unambiguous characterization aided by the presence of $^1J_{PRh}$. The downfield chemical shift for the μ-PCy_2 ligand is indicative of a phosphido group bridging a metal–metal bond (14). This correlation has been observed for μ-PPh_2 (15) ligands and also for bulky groups such as μ-$PtBu_2$ (16–18) and μ-PCy_2 (8, 9, 19), and is well supported by X-ray studies. The $^2J_{PP}$ couplings between the bridging group and the terminal PPh_3 ligands supports a structure in which both the PPh_3 groups are *trans* to the μ-PCy_2 bridge (20). The infrared spectrum of **2** in CH_2Cl_2 solution (ν(CO); 1987 m, 1951 s, 1926 s, br, 1887 w, 1878 w, cm^{-1}) showed five bands assignable to five CO groups. We therefore formulate the structure of **1** as shown.

1

This is the same structural arrangement determined spectroscopically and verified crystallographically for the μ-PPh_2 bridged species (21) $(CO)_3(PPh_3)Fe(\mu\text{-}PPh_2)Ir(PPh_3)(CO)_2$.

The $^{31}P\{^1H\}$ NMR of **2** shows only a single downfield singlet due to the μ-PCy_2 ligand (δ 201.4 (s)) and this chemical shift is also attributed to the phosphido ligand bridging a metal–metal bond. The infrared spectrum (CH_2Cl_2 solution) shows four bands (ν(CO); 2034 m, sh, 2010 s, 1999 s, 1978 s, br cm^{-1}) due to the four CO groups which are bonded to Fe and both $^{13}C\{^1H\}$ and ^1H NMR show resonances due to coordinated 1,5-COD ($^{13}C\{^1H\}$; δ 77.2, 76.8 CH, δ 26.1 CH_2, ^1H; δ 4.70, 4.36 CH, 2.21 CH_2). Thus, the most probable structure for **2** is that of an $Fe(CO)_4$ fragment and an Ir(1,5-COD) fragment bridged by the μ-PCy_2 ligand with an Fe to Ir dative bond and a coordinatively unsaturated Ir center.

2

Reaction chemistry of 1

We find that no adduct formation occurs when **1** is reacted with CO and no oxidative addition reactions occur with H_2, HCl, or CH_3I. However, the reaction of **1** with one equivalent of HBF_4–etherate resulted in the protonation of **1** to give a single product **3**, as evidenced by $^{31}P\{^1H\}$ NMR. Complex **3** showed a single downfield resonance (δ 165.6 (dd)) due to the μ-PCy_2 ligand bridging the FeIr bond and two upfield resonances due to PPh_3 on Fe (δ 51.5(dd)) and PPh_3 on Ir (δ 5.7(dd)). The $^2J_{PP}$ couplings indicated a *trans* disposition for the PCy_2 and PPh_3(Fe) groups and a *cis* arrangement of the

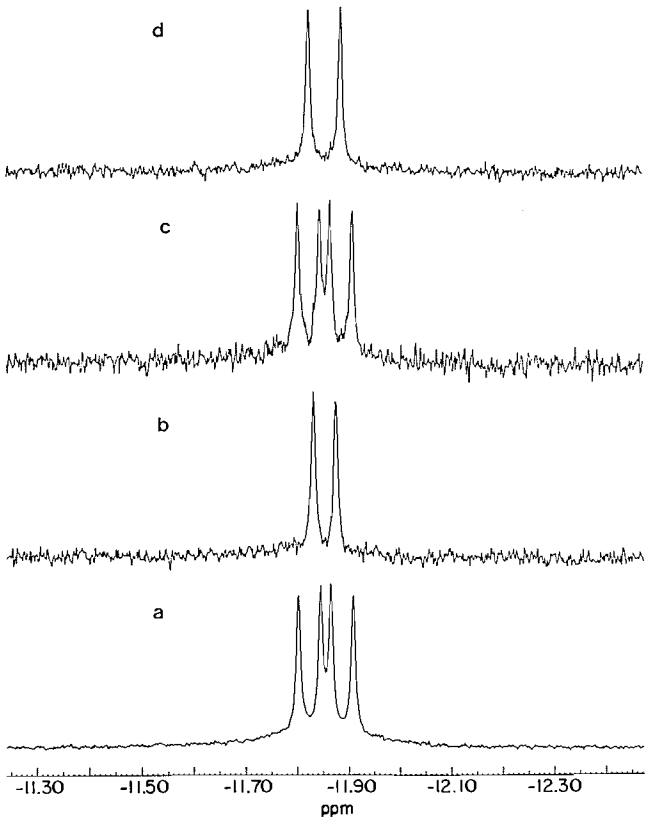

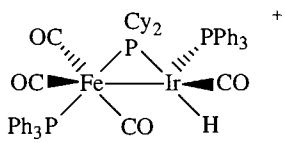

FIG. 1. $^1H\{^{31}P\}$ NMR decoupling experiment to identify the position of the hydride ligand for $[(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(H)(PPh_3)(CO)]^+$, **3**. (*a*) The fully coupled spectrum. (*b*) The ^{31}P resonance at δ 165.6 due to the μ-PCy_2 ligand is decoupled. (*c*) The ^{31}P resonance at δ 51.5 due to PPh_3(Fe) is decoupled. (*d*) The ^{31}P resonance at δ 5.7 due to PPh_3(Ir) is decoupled.

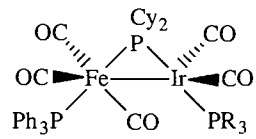
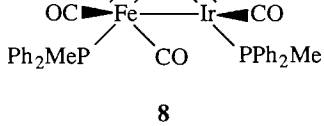
PCy_2 and PPh_3(Ir) ligands. Interestingly, there was also a small $^3J_{PP}$ coupling of 9.6 Hz between the Ph_3P(Fe) and PPh_3(Ir) ligands which appears to be unique in PR_2 bridged complexes. A ^1H NMR spectrum of the hydride region of **3** showed a single resonance (δ −11.2 (dd)) due to the hydride ligand coupled to two of the phosphorus ligands. A selective $^1H\{^{31}P\}$ decoupling experiment (Fig. 1) unambiguously showed that the hydride is coupled to the PCy_2 group (^2J = 19.0) and the PPh_3(Ir) ligand (^2J = 12.7). This infers that the H ligand is bound to Ir and not Fe, although the change in chemical shift of these resonances upon protonation might lead to the conclusion that the site of protonation was the Fe centre. The reason for a large shift in the PPh_3(Fe) resonance (δ 74.3 to 51.5) and very little change for PPh_3(Ir) (δ 10.7 to 5.7) is unclear. We formulate the structure of **3** as $(CO)_3(PPh_3)Fe(\mu\text{-}PCy_2)Ir(H)(PPh_3)(CO)$ based on these



3

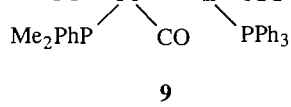
NMR results which show the site of protonation to be the Ir metal as shown below. A reasonable comparison can be made with the complex $(CO)(PPh_3)Fe(\mu\text{-}PPh_2)IrCl(H)(PPh_3)(CO)$ which is the result of HCl addition to the complex $(CO)(PPh_3)Fe(\mu\text{-}PPh_2)Ir(PPh_3)(CO)$ (21). The $^2J_{HP}$ and relative chemical shift changes upon protonation are similar to those observed for the conversion of **1** to **3**.

Phosphine substitution reactions of 1



One of the objectives of this study was to use ancillary PR_3 ligands to create steric congestion at the metal sites and consequently produce coordinatively unsaturated complexes capable of small molecule activation. To this end, we studied the phosphine substitution patterns of **1** with PR_3 ligands (PEt_3, $PnBu_3$, $PiPr_3$, PBz_3, PPh_2Me, PMe_2Ph, PCy_3) of varying cone angle. In a typical experiment, two equivalents of the phosphine were added to a solution of **1**. Two equivalents were used since it was found that only one equivalent generally produced a mixture of **1** and product. The reactions were monitored by $^{31}P\{^1H\}$ NMR to determine the types and numbers of products formed. In each case only one major product was detected and eventually isolated.

The products formed depended on the nature of the PR_3 ligand but in all cases the result was simple PR_3 substitution for PPh_3. For PR_3 = PEt_3, $PnBu_3$, PBz_3, $PiPr_3$, and PCy_3 the compound formed was the result of PR_3 substitution for PPh_3 at Ir.



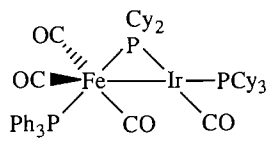
4 (R = Et), **5** (R = *n*Bu), **6** (R = *i*Pr), **7** (R = Bz), **10** (R = Cy)

For PR_3 = PMe_2Ph, substitution was for the PPh_3 group on Fe and when either one or two equivalents of PPh_2Me were used the only product detected was the result of PR_3 substitution for both PPh_3 ligands on Fe and Ir. $^{31}P\{^1H\}$ NMR spectral data for **4**–**8** are found in Table 1 and infrared data in Table 2.

8

9

Generation of coordinatively unsaturated complexes



Geoffroy has shown that the μ-PPh_2 complex $(CO)_3(PPh_3)Fe(\mu\text{-}PPh_2)Ir(PPh_3)(CO)_2$ can be converted to the coordinatively unsaturated species $(CO)_3(PPh_3)Fe(\mu\text{-}PPh_2)Ir(PPh_3)(CO)$ by removing CO thermally or photochemically (21). However, **1** does not easily lose CO under these conditions. Only after prolonged reflux in toluene, was there $^{31}P\{^1H\}$ NMR spectral evidence for reaction, but full conversion to $(CO)(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PPh_3)(CO)$, **11** did not occur before decomposition of the product. By introducing bulky ancillary ligands in place of PPh_3, it was anticipated that loss of a ligand such as CO may occur due to increased steric demands. However, even when PCy_3 was used in place of PPh_3, only the coordinatively saturated species $(CO)(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)_2$, **10** was formed. Complex **10** does display an increase tendency for loss of CO and this was achieved thermally by refluxing a toluene solution for 12 h, to give $(CO)(PPh_3)Fe(\mu\text{-}PCy_2)Ir(PCy_3)(CO)$, **12**. The $^{31}P\{^1H\}$ NMR of **12** shows the three resonances expected but the $^2J_{PP}$ coupling between μ-PCy_2 and PCy_3 indicates a *cis* orientation for these ligands. This is consistent with the loss of CO from Ir to give the coordinatively unsaturated species **12**. The change in geometry

12

Reaction chemistry of 2

The problems associated with producing coordinative unsaturation via phosphine substitution on complex **1** prompted us to study **2** as an alternative to **1**. This complex has a number of advantages over **1**. It is not only coordinatively unsaturated but also contains the potentially labile 1,5-COD ligand and has no ancillary PR_3 ligands. The initial experiment performed was the reaction of **2** with CO to determine if the 1,5-COD ligand could be easily removed. The result of this reaction was the complete conversion of **2** to $(CO)_4Fe(\mu\text{-}PCy_2)Ir(CO)_3$, **13**. This formulation is based on the infrared and $^{31}P\{^1H\}$, $^{13}C\{^1H\}$, and ^1H NMR data. These spectra show that the 1,5-COD ligand has been displaced and are consistent with the idea that the complex is coordinatively saturated and still contains the FeIr bond. There is no evidence for substitution of the metal–metal interaction even under an atmosphere (1 atm) of CO. This is in contrast to the analogous FeRh complex $(CO)_4Fe(\mu\text{-}PCy_2)Rh(1,5\text{-COD})$ for which solution studies showed a mixture of complexes, $(CO)_4Fe(\mu\text{-}PCy_2)Rh(CO)_x$, $x = 1$–3, and thus evidence for both a coordinatively unsaturated species and substitution of the FeRh bond by CO (9).

Phosphine substitution reactions of **2** were not as straightforward. The simple addition of *one* equivalent of PEt_3 produced a mixture of compounds as observed by $^{31}P\{^1H\}$ NMR. The only discernable product was the coordinatively saturated species $(CO_3)(PEt_3)Fe(\mu\text{-}PCy_2)Ir(PEt_3)(CO)_2$, **14**. This was formulated as such due to the $^2J_{PP}$ coupling between the μ-PCy_2 and PEt_3(Ir) groups (162.8 Hz) which indicated a *trans* geometry for these ligands similar to **1**. The formation of this complex requires two equivalents of PEt_3 and the abstraction of CO from some source. In order to avoid the mixture of products and to optimize the formation of **14**, the reaction was carried out with two equivalents of PEt_3 under an atmosphere of CO(g). This produced almost quantitative conversion of **2** to **14** as shown by $^{31}P\{^1H\}$ NMR and an eventual isolated yield of 82%. The same reaction was repeated using PPh_3 and this gave **1** in good yield as well. Since the coordination of two PR_3 ligands seemed to be favored in these substitutions we also investigated the reaction of the bidentate phosphine ligand DPPE under these same conditions. The resulting complex, **15**, was formulated as resulting from coordination of the DPPE to both the Fe and Ir centers. The bridging mode for this ligand appears to allow for a geometry similar to that observed for all of the FeIr complexes with the PPh_2 groups of DPPE bound *trans* to the μ-PCy_2 ligand. In fact, the $^{31}P\{^1H\}$ NMR spectral data for **15** (δ(μ) 145.3 (dd), δ(Fe) 66.7 (dd), δ(Ir) −2.3 (dd); $^2J_{PP}$(μ-Fe) = 23.4 Hz, $^2J_{PP}$(μ-Ir) = 172.8 Hz) are similar to that for **8** (δ(μ) 148.9 (dd), δ(Fe) 58.0 (dd), δ(Ir) −13.6 (dd); $^2J_{PP}$(μ-Fe) = 18.6 Hz, $^2J_{PP}$(μ-Ir) = 173.4 Hz) which contains PPh_2Me coordinated to both Fe and Ir in the proposed geometry.

14

Discussion

Complex **1** is coordinatively saturated if the dative Fe to Ir interaction is assumed to be a formal, two electron donation. For this complex to undergo oxidative addition or adduct formation a reaction must occur to either remove an ancillary ligand or substitute for the FeIr dative bond. This latter type of reaction has been observed for a number of heterobimetallic phosphido-bridged complexes, most notably $(CO)_3(PPh_3)Fe(\mu\text{-}PPh_2)Ir(PPh_3)(CO)_2$ in which the FeIr bond is replaced upon adduct

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

formation with CO or oxidative addition of H_2 (21). The fact that **1** does not react in this manner can be rationalized as being the result of a stronger donor–acceptor interaction for the μ-PCy_2 species. The ready protonation of **1** is also evidence for the robustness of this μ-PCy_2 bridge and could be due to the increased basicity of the complex with the dialkyl-phosphido group PCy_2 versus the diaryl-phosphido group PPh_2.

An interesting problem in the study of heterobimetallic complexes is the question of whether both metal sites actively participate in the observed chemistry. One might expect to see evidence for site preference under different substitution conditions or perhaps cooperativity between the metals which effects the substitution pattern. Since there is a possible site of substitution on each metal in **1**, we can use these simple experiments as a probe for metal site preferences and cooperativity effects by observing product distribution. Since all the phosphines except PMe_2Ph, which has the smallest cone angle, substitute preferentially at Ir, and there is little difference in the basicities of the PR_3 ligands, it is likely that steric considerations are predominate in site selection. It could be rationalized that the preferred site of substitution is at the Fe atom when steric considerations are relatively unimportant, such as for PMe_2Ph, but that the less crowded Ir centre becomes the site of preference when steric demands are important as occurs for ligands such as PCy_3. The substitution at Fe occurs only when the PR_3 molecule is small enough to minimize steric demands at this site.

In the case of PPh_2Me, for which substitution occurs at both metals, we can assume that the first substitution significantly enhances substitution at the second metal, since no monosubstituted product is observed. Although there is no evidence to show at which site the first substitution occurs, it could be that the initial substitution at Fe effects the Ir site electronically via the FeIr dative interaction. Overall, we see that there is a definite pattern for substitution likely based on steric demands and a cooperative effect between the adjacent metals is evident from the disubstitution pattern observed for $(CO)(PPh_2Me)Fe(\mu\text{-}PCy_2)Ir(PPh_2Me)(CO)_2$.

Attempts to create coordinative unsaturation by simply substituting bulky ancillary phosphines for PPh_3 on **1** were not successful. Although complex **10** did lose CO upon heating to generate the coordinatively unsaturated species **12**, this type of transformation has already been readily achieved for the μ-PPh_2 complex (21) analogous to **1** and can not be considered unique to these μ-PCy_2 bridged compounds.

The reaction chemistry of **2** is dominated by the facile loss of the 1,5-COD ligand. This should allow for the introduction of a wide range of ancillary ligands however, we have only investigated the simple reactions with CO and a few phosphines to date. The trend appears to be the formation of coordinatively saturated species with a relatively unreactive FeIr bond. This is evidenced by the lack of substitution for the metal–metal bond under a CO atmosphere and the clean reactions to form compounds **1**, **13**, **14**, and **15** from **2**.

Reassignment of the structure of $M_3(CO)_{12}(Cl)(SnCl_3)$ (M = Ru, Os)

ANNA BECALSKA AND ROLAND K. POMEROY[1]
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

AND

WILLIAM A. G. GRAHAM
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 30, 1989

ANNA BECALSKA, ROLAND K. POMEROY, and WILLIAM A. G. GRAHAM. Can. J. Chem. **67**, 1236 (1989).

Reaction of $M_3(CO)_{12}$ (M = Ru, Os) with $SnCl_4$ in benzene at room temperature affords $M_3(CO)_{12}(Cl)(SnCl_3)$ in essentially quantitative yield. The ^{13}C nmr spectra of these complexes indicate they have a $ClM_3(SnCl_3)$ arrangement of atoms with the Cl ligand *cis* and the $SnCl_3$ group *trans* to a linear Os_3 chain. This is contrary to previously proposed structures for these compounds. The ^{13}C nmr spectrum of $Os_3(CO)_{12}(I)_2$ which has the iodo ligands *cis* to the Os_3 chain is also reported for comparison.

Key words: ruthenium–tin, osmium–tin, osmium–iodine, ^{13}C nmr spectroscopy.

ANNA BECALSKA, ROLAND K. POMEROY et WILLIAM A. G. GRAHAM. Can. J. Chem. **67**, 1236 (1989).

La réaction des composés $M_3(CO)_{12}$ (M = Ru, Os) avec le $SnCl_4$, dans le benzène, à la température ambiante, conduit aux produits $M_3(CO)_{12}(Cl)(SnCl_3)$ avec un rendement qui est essentiellement quantitatif. Les spectres rmn du ^{13}C de ces complexes indiquent que l'arrangement des atomes dans la portion $ClM_3(SnCl_3)$ comporte un ligand Cl *cis* et un groupement $SnCl_3$ *trans* par rapport à une chaîne Os_3 linéaire. Ce résultat est contraire aux structures proposées antérieurement pour ces composés. Pour fins de comparaison, on rapporte aussi les spectres rmn du ^{13}C du composé $Os_3(CO)_{12}(I)_2$ dans lequel les ligands iodo sont *cis* par rapport à la chaîne OsO_3.

Mots clés : ruthénium–étain, osmium–étain, osmium–iode, spectroscopie en rmn du ^{13}C.

Introduction

The syntheses of $M_3(CO)_{12}(Cl)(SnCl_3)$ (M = Ru, Os) from $M_3(CO)_{12}$ and $SnCl_4$ were originally communicated in 1969 (1, 2). At that time the compounds were formulated with a linear $(Cl)M(CO)_4M(CO)_4M(CO)_4(SnCl_3)$ arrangement of non-carbonyl atoms. This arrangement was apparently assumed in an investigation of some aspects of the chemistry of $Os_3(CO)_{12}(Cl)(SnCl_3)$ (3). It has, however, been suggested (4, 5) that these complexes may be Lewis acid – Lewis base adducts especially as they are formed under mild conditions and $Fe_3(CO)_{12}$ does not react with $SnCl_4$ under the same conditions. Another possibility that has been put forward (6) has both the Cl and $SnCl_3$ ligands *cis* to the linear Os_3 chain, analogous to the structure found for $Os_3(CO)_{12}(I)_2$ (7). Unfortunately, crystals of $M_3(CO)_{12}SnCl_4$ suitable for X-ray crystallographic study could not be obtained so as to distinguish these possibilities.

Here we report the ^{13}C nmr spectra of these complexes which are not consistent with any of the previously proposed structures but rather one with a linear Os_3 chain with the Cl ligand *cis* and the $SnCl_3$ group *trans* to this chain. (The ^{13}C nmr spectrum of $Os_3(CO)_{12}(I)_2$ is reported for comparison.) The preparation of $Ru_3(CO)_{12}(Cl)(SnCl_3)$ is also described in detail for the first time.

Experimental

The reaction and isolation of products were carried out under a nitrogen atmosphere with the use of Schlenk techniques; solvents were scrupulously dried before use. The starting materials $M_3(CO)_{12}$ (M = Ru, Os) were prepared by literature methods (8). The ^{13}CO-enriched compounds were obtained from ^{13}CO-enriched $M_3(CO)_{12}$ that were in turn prepared by heating $M_3(CO)_{12}$ in toluene under ~1.5 atm of ^{13}CO (99% ^{13}C) for 3 days; reaction temperatures were 100°C for M = Ru and 125°C for M = Os. It was estimated that this procedure produce a level of enrichment of 10–15% for $Ru_3(CO)_{12}$ and ~35% for $Os_3(CO)_{12}$. The iodo derivative, $Os_3(CO)_{12}(I)_2$, was prepared by a literature method (7) and recrystallized from CH_2Cl_2–hexane.

Infrared spectra were recorded on a Perkin-Elmer 983 spectrometer; the internal calibration of the instrument was periodically checked against the known absorptions frequencies of gaseous CO. Electron impact mass spectra were obtained on an Associated Electrical Industries MS-12 instrument. Nuclear magnetic resonance spectra were recorded at room temperature on a Bruker WM400 spectrometer; the solvent was CH_2Cl_2/CD_2Cl_2 (4/1). The microanalysis was performed by Pascher Mickroanalytisches Laboratorium, Bonn.

Preparation of $Ru_3(CO)_{12}(Cl)(SnCl_3)$

A suspension of $Ru_3(CO)_{12}$ (0.64 g, 1.0 mmol) in benzene (25 mL) was stirred with $SnCl_4$ (1 mL, 8.6 mmol) at room temperature. After 40 min (there was no appreciable evolution of gas during this time), a fine yellow solid had formed. The benzene was removed and the product washed twice with *n*-hexane (2 × 25 mL) and dried under vacuum. The yield was essentially quantitative. The analytical sample of $Ru_3(CO)_{12}(Cl)(SnCl_3)$ was obtained in the form of yellow platelets by recrystallization from CH_2Cl_2–hexane at −78°C: mp dec. > 80°C. *Anal.* calcd. for $C_{12}Cl_4O_{12}Ru_3Sn$: C 16.0, H 0.0, Cl 15.8, O 21.3, Ru 13.2; found: C 15.9, H 0.1, Cl 15.4, O 20.9, Ru 12.7. Infrared (CH_2Cl_2): ν_{CO} 2148 (m), 2119.5 (m), 2089 (sh), 2073.5 (s), 2057 (vs), 2039.5 (w), 2019 (m) cm^{-1}; ^{13}C nmr δ 201.4 (4C), 196.2 (4C), 195.0 (2C), 191.1 (1C), 178.0 (1C) ppm. The compound was insufficiently volatile below its decomposition temperature for an EI mass spectrum. The compound could be handled in air for short periods without apparent decomposition but decomposed on prolonged exposure. Solutions of $Ru_3(CO)_{12}(Cl)(SnCl_3)$ in CH_2Cl_2 were initially green but rapidly turned yellow on exposure to light. The green color was partially restored by storage in the dark.

The osmium analogue, $Os_3(CO)_{12}(Cl)(SnCl_3)$, was prepared in a similar manner: infrared (CH_2Cl_2): ν_{CO} 2152 (w), 2124.5 (m), 2087 (sh), 2069 (s), 2049.5 (vs), 2031.5 (m), 2005.5 (m) cm^{-1}; ^{13}C nmr δ 183.4 (4C) 176.9 (4C, J_{Sn-C} = 62.7 Hz), 176.6 (2C), 168.3 (1C), 160.8 (1C) ppm (see Fig. 1). MS (EI) m/z 1166 (M^+). A satisfactory elemental analysis was obtained in the original preparation (6). The compound was a white, air-stable solid.

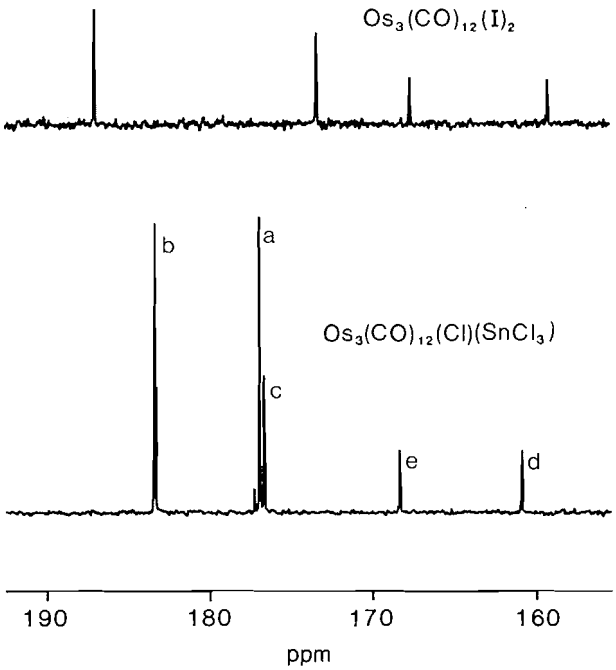

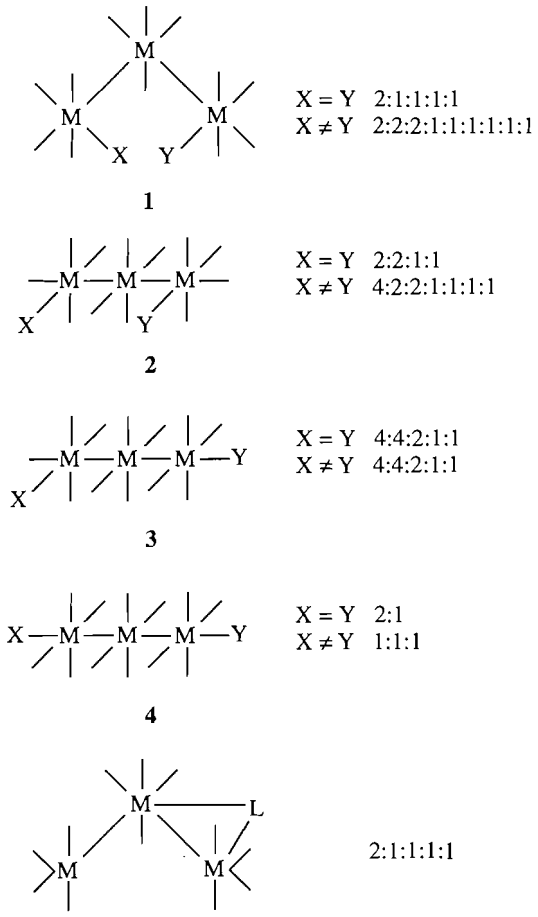

FIG. 1. ^{13}C nmr spectra of $Os_3(CO)_{12}(I)_2$ and $Os_3(CO)_{12}(Cl)(SnCl_3)$ (^{13}CO-enriched samples; CH_2Cl_2/CD_2Cl_2 solution).

Spectroscopic data for $Os_3(CO)_{12}(I)_2$: infrared (CH_2Cl_2): ν_{CO} 2144 (w), 2114 (s), 2085 (vw), 2058 (vs, br), 2029.5 (s), 2000 (w) cm^{-1}; ^{13}C nmr δ 186.9, 173.2, 167.4, 159.1 ppm (in an approximate ratio of 2:2:1:1; see Fig. 1).

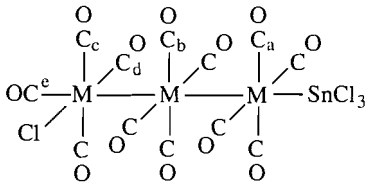
Results and discussion

Addition of $SnCl_4$ to a suspension of $M_3(CO)_{12}$ (M = Ru, Os) in benzene at room temperature results in essentially quantitative formation of $M_3(CO)_{12}SnCl_4$ over 40 min. The ruthenium compound is a yellow solid that can be handled for short periods in air but prolonged exposure causes decomposition. The osmium analogue (which is white) is much more robust in air. Both complexes are insoluble in hexane but soluble in CH_2Cl_2. The infrared spectrum of each in CH_2Cl_2 shows seven terminal CO stretches. Evidence is presented below that these compounds should be formulated as (OC)—M(CO)$_3$(Cl)—M(CO)$_4$—M(CO)$_4$—($SnCl_3$) with C_s symmetry. Such an asymmetric structure should have 12 infrared-active CO stretches so that some of the modes must either be accidentally degenerate in CH_2Cl_2 solution or of zero intensity.

Several possible structures for a compound having the formula $M_3(CO)_{12}(X)(Y)$ are shown in Scheme 1 (eclipsed configurations are drawn for convenience). There are other isomers of this formulation but those shown in the scheme are thought to be the most reasonable from a survey of $M_3(CO)_{12}$ derivatives reported in the literature (5, 9). As can be seen from the scheme, the various structures can, for the most part, be distinguished by ^{13}C nmr spectroscopy provided the structures are rigid on the nmr time scale with the exception that there is free rotation about the M—M and M—Sn bonds. The intensities of ^{13}C nmr signals of metal carbonyl derivatives such as these are usually found to be proportional to the number of carbons of a particular type within the molecule. This is presumably due to the carbonyl carbons having similar T_1 values and there is, of course, no Overhauser effect on the signals.

SCHEME 1. Expected ^{13}C nmr spectra.

Structure **1** is found when X and Y are linked as for example in $Os_3(CO)_{12}$[MeOC(O)NNC(O)OMe] (10). This structure is thought unlikely for $M_3(CO)_{12}(Cl)(SnCl_3)$.



Structure **2** has been found by X-ray crystallography for $Os_3(CO)_{12}(I)_2$ (7). The previously unreported ^{13}C nmr spectrum of this compound is shown in Fig. 1; it shows the expected 2:2:1:1 pattern for structure **2** with X = Y = I. A similar spectrum has been found for $Os_3(CO)_{12}(H)_2$ (11). The dimethyl analogue of these complexes, $Os_3(CO)_{12}(Me)_2$, also has the same structure (12).

Compounds with structure **3** have not been previously observed but evidence is presented below that the $M_3(CO)_{12}$-(Cl)($SnCl_3$) derivatives have this structure. Structure **4**, although rare, has been shown by X-ray crystallography to be adopted by $Os_3(CO)_{12}(SiCl_3)_2$ (13). The ^{13}C nmr spectrum of this compound shows the expected two resonances in the ratio of 1:2 at δ 186.8 and 177.9 ppm (13). Note that the ^{13}C resonances of the Os(CO)$_4$($SiCl_3$) units can be assigned unambiguously and appear to higher field of those of the central Os(CO)$_4$ unit. The $^{13}C\{^1H\}$ nmr spectrum of $[Os_3(CO)_{12}(H)]^+$ shows five resonances of relative intensity 1:2:1:1:1 as expected for structure **5** (L = H) (14).

The room temperature ^{13}C nmr spectrum of $Os_3(CO)_{12}(Cl)$-($SnCl_3$) (^{13}CO-enriched sample, CH_2Cl_2/CD_2Cl_2 solution) is shown in Fig. 1. The spectrum of the ruthenium analogue was similar although the signal to noise ratio was not as good and the tin coupling was not observed. As can be seen, the spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

consists of five resonances in a 4:4:2:1:1 pattern (peak positions are δ 183.4, 176.9, 176.6, 168.3, and 160.8 ppm). Furthermore, the resonance of intensity 4 at δ 176.9 ppm exhibits coupling to $^{117,119}Sn$ of 62.7 Hz which indicates $Os_3(CO)_{12}(Cl)(SnCl_3)$ contains a *trans*-Os—$Os(CO)_4(SnCl_3)$ unit. The position of this resonance is also in the region found for the peak due to carbonyls of the analogous units of $Os_3(CO)_{12}(SiCl_3)_2$ (see above). The ^{13}C nmr data are therefore consistent with structure **3**, with X = Cl and Y = $SnCl_3$, for the $M_3(CO)_{12}(Cl)(SnCl_3)$ complexes, as shown. The assignment (as shown) of the signals in the ^{13}C nmr spectrum of $Os_3(CO)_{12}(Cl)(SnCl_3)$ is straightforward if it is assumed that the resonance furthest upfield is due to the carbonyl *trans* to the chlorine ligand. The positions of the resonances of the $Os_3(CO)_{12}(X)(Y)$ derivatives may be compared with those of the parent carbonyl $Os_3(CO)_{12}$ at 170.4 (equatorial carbonyls) and 182.3 ppm (axial carbonyls) (15).

M = Ru, Os

3

Of the five isomers shown in the scheme, structure **3** would appear to be the least likely to be formed from the reaction under mild conditions of a triangular $M_3(CO)_{12}$ cluster with an X—Y reagent. However, there always appears to be rapid isomerization about the central osmium atom in the formation of $Os_3(CO)_{12}(X)(Y)$ derivatives when the X and Y groups are not connected. This presumably relieves the steric interactions between the substituents on the terminal osmium atoms in the product. Furthermore, derivatives of the type $M(CO)_4(X)_2$ (M = Fe, Ru, Os) tend to be stable as the *cis* isomer for X = H, Cl, Br, I (9, 16) but when X = ER_3 (E = Si, Ge, Sn; R = Cl or organic group) the *trans* isomer can be the most stable (1, 4, 17).[2] This is especially the case for M = Ru, Os with ECl_3 ligands. We have rationalized this observation in terms of the steric and electronic properties of the ECl_3 ligands: the ECl_3 ligands have π-acceptor properties comparable to CO so that neither the *cis* nor the *trans* site is preferred on electronic grounds and hence the ECl_3 ligands adopt *trans* positions so as to minimize steric interactions (4, 13). (For the poor π-acceptor ligands, hydride or halogen, the *cis* site is electronically preferred since it avoids, as far as possible, carbonyl ligands competing for the same electron density on the metal atom.) It is, therefore, not unexpected that the $M_3(CO)_{12}(Cl)(SnCl_3)$ complexes are stable with the Cl *cis* but with $SnCl_3$ ligand *trans* to the Os_3 chain.

A further question arises as to whether the $M_3(CO)_{12}(Cl)(SnCl_3)$ complexes initially form as isomer **2** followed by rapid isomerization to give the observed isomer **3**. Although this might have been expected, evidence will be presented in a subsequent paper that the reaction, in CH_2Cl_2, of $Os_3(CO)_{12}$ and Cl_2, surprisingly, gives $Os_3(CO)_{12}(Cl)_2$ mainly as isomer **3** as the initial product and that this isomer subsequently rearranges to isomer **2**. This suggests the formation of $M_3(CO)_{12}(Cl)(SnCl_3)$ does not proceed via isomer **2**. We have no evidence for or against the initial formation of adduct **5** (L = $SnCl_4$) in the synthesis of the $M_3(CO)_{12}(Cl)(SnCl_3)$ compounds.

[2]The structure of $[Ru(CO)_4(SnMe_3)]_2$ also shows an all *trans* arrangement of metal atoms (18).

Antiferromagnetic exchange in manganese(II) monophenylphosphinate and the effects of cadmium doping

JING-LONG DU AND ROBERT C. THOMPSON

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received December 2, 1988

JING-LONG DU and ROBERT C. THOMPSON. Can. J. Chem. **67**, 1239 (1989).

$Mn[H(C_6H_5)PO_2]_2$, its cadmium analogue, and mixed metal materials of composition $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$ (x = 0.005, 0.01, 0.09, 0.27, and 0.47) have been synthesized and characterized by X-ray powder diffraction, infrared spectroscopy, differential scanning calorimetry and low-temperature (4.2 to 80 K) magnetic susceptibility studies. The materials are shown to be isomorphous and are considered to have polymeric structures in which chains of metal atoms are linked by bridging phosphinate groups. The pure manganese compound is antiferromagnetic (maximum in χ_M at ~35 K) and the magnetic data for the compound have been analyzed according to two theoretical models for linear chains of antiferromagnetically coupled manganese(II) (d^5, spin-free) ions. The Wagner and Friedberg model gives $J = -3.00\ cm^{-1}$ and the Weng model gives $J = -2.78\ cm^{-1}$. The effects of replacing Mn^{2+} by Cd^{2+} ions in the polymer is to increase the magnetic susceptibility (per mol of Mn) at all temperatures. Analysis of the data as a function of Cd doping indicates the incorporation of a paramagnetic component to the susceptibility which increases with increasing Cd content. In addition, the absolute value of the exchange coupling constant appears to decrease as the Cd content increases. These effects are considered in terms of a random defect model in which the replacement of Mn ions in the polymer by Cd ions results in the formation of Cd ion separated finite magnetic chain fragments.

Key words: manganese(II) monophenylphosphinate, magnetic properties, coordination polymer, cadmium doped antiferromagnet.

JING-LONG DU et ROBERT C. THOMPSON. Can. J. Chem. **67**, 1239 (1989).

On a synthétisé le $Mn[H(C_6H_5)PO_2]_2$, son analogue du cadmium, ainsi que des matériaux métalliques mixtes de composition $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$ (x = 0,005, 0,01, 0,09, 0,27 et 0,47) et on les a caractérisés par diffraction des rayons-X sur des poudres, par spectroscopie infrarouge, par calorimétrie à balayage différentiel et par des études de susceptibilités magnétiques à basses températures (4,2 à 80 K). On a démontré que les matériaux sont isomorphes et on considère qu'ils possèdent des structures polymériques dans lesquelles des chaînes d'atomes métalliques sont reliées par des groupements phosphinates agissant comme ponts. Le composé ne contenant que du manganèse est antiferromagnétique (la valeur maximale de χ_M apparaît à ~35 K) et on a analysé les données magnétiques suivant deux modèles théoriques pour des chaînes linéaires d'ions de manganèse(II) couplés d'une façon antiferromagnétique (d^5, sans spin). Le modèle de Wagner et Friedberg donne une valeur de $J = -3{,}00\ cm^{-1}$ alors que le modèle de Weng donne une valeur de $J = -2{,}78\ cm^{-1}$. A toutes les températures, le remplacement dans le polymère d'ions Mn^{2+} par des ions Cd^{2+} provoque une augmentation de la susceptibilité magnétique (par mole de Mn). L'analyse des données en fonction d'un dopage par le Cd indique que la susceptibilité est modifiée par l'incorporation d'une composante paramagnétique et qu'elle augmente avec une augmentation de la concentration du Cd. De plus, la valeur absolue de la constante de couplage de l'échange semble diminuer avec une augmentation de la concentration du Cd. On considère ces effets en fonction d'un modèle de défaut au hasard dans lequel le remplacement dans le polymère d'ions Mn par des ions Cd conduit à la formation de fragments de chaînes magnétiques définies séparées par des ions Cd.

[Traduit par la revue]

Introduction

The tendency of phosphinate anions, $R_2PO_2^-$, to coordinate to metal ions in a bridging rather than chelating mode is now well established by a number of X-ray crystallographic studies which have shown metal phosphinate compounds to be polymeric with infinite chains of metal ions linked by phosphinate bridges (1). In addition, it has been shown in several instances that bridging phosphinates are capable of transmitting magnetic exchange effects between paramagnetic centres via a super-exchange mechanism; examples of both ferromagnetic and antiferromagnetic coupling have been observed (2). It has been pointed out that in the formation of extended polymers of this type the incorporation of random defects in the polymer would effectively break it into finite segments and this may have a significant effect on the magnetic properties (3). To investigate this factor as it applies to poly-metalphosphinates we have examined the magnetic properties of manganese(II) monophenylphosphinate and samples of the compound doped with varying amounts of cadmium. The partial replacement of manganese by diamagnetic cadmium ions in the polymer would have the effect of chemically fragmenting the magnetic chain and should permit a quantitative examination of the effect of chain fragmentation on magnetic properties.

We chose to examine a manganese(II) system because the $^6A_1$ ground state renders the measurement and interpretation of the magnetic properties relatively straightforward. An examination of the magnetic properties of a number of different manganese(II) phosphinates revealed that the monophenylphosphinate derivative is appropriate for such studies for two reasons: (*i*) the pure compound is relatively strongly antiferromagnetic, exhibiting a broad maximum in χ_M at ~35 K and (*ii*) the cadmium(II) analogue is isomorphous; hence it is possible to readily prepare materials of composition $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$, where x varies from 0 to 1, for study.

Experimental

Synthesis: manganese(II) monophenylphosphinate, $Mn[H(C_6H_5)PO_2]_2$

Monophenylphosphinic acid (1.99 g, 14.0 mmol) was dissolved in 200 mL ethanol. A manganese(II) acetate tetrahydrate solution was prepared by dissolving 1.47 g (6.01 mmol) of salt in 150 mL ethanol. The salt solution was added dropwise to the stirring acid solution. The reaction mixture became cloudy after about one sixth of the salt solution had been added. The reaction mixture was totally opaque and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

pink in color once the addition was completed. The solution was left stirring for a further 24 h, then allowed to stand for another 5 days. The precipitate was collected on a sintered glass filter, washed with ethanol, and set aside to air-dry between pieces of filter paper. The dry product is a pink, fine-grained powder. *Anal.* calcd. for $MnC_{12}H_{12}P_2O_4$: C 42.76, H 3.59; found: C 42.90, H 3.70.

Cadmium(II) monophenylphosphinate, $Cd[H(C_6H_5)PO_2]_2$

Monophenylphosphinic acid (1.42 g, 10.0 mmol) was dissolved in 55 mL ethanol. Cadmium(II) acetate dihydrate (1.33 g, 5.00 mmol) was dissolved in 150 mL ethanol, then added dropwise to the acid solution. A white product began to precipitate after about 10 mL of cadmium acetate solution had been added. The precipitate was collected, left to air-dry overnight, then dried in vacuum at 85°C for 12 h. *Anal.* calcd. for $CdC_{12}H_{12}P_2O_4$: C 36.53, H 3.07; found: C 36.64, H 3.10.

Manganese(II) (cadmium(II)) monophenylphosphinate, $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$

The mixed metal materials were made by adding separately, and simultaneously, solutions of the metal acetates in appropriate relative proportions to a stirring solution of monophenylphosphinic acid. The conditions of precipitation were kept as near as possible to those used for the preparation of the pure manganese compound.

Consider the preparation of $Mn_{0.53}Cd_{0.47}[H(C_6H_5)PO_2]_2$: monophenylphosphinic acid 1.99 g (14.0 mmol) was dissolved in 200 mL ethanol. A manganese(II) acetate tetrahydrate solution was prepared by dissolving 0.734 g (3.00 mmol) of the salt in 75 mL ethanol. Similarly, a cadmium(II) acetate dihydrate solution was prepared by dissolving 0.800 g (3.00 mmol) of the salt in 75 mL ethanol. The two salts were added to the stirring acid solution from separate funnels. The rest of the procedures for this and other mixed metal systems of the type $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$, where $x = 0.27, 0.09, 0.01, 0.005$, were identical to those used for the preparation of $Mn[H(C_6H_5)PO_2]_2$. *Anal.* calcd. for $Mn_{0.995}Cd_{0.005}C_{12}H_{12}P_2O_4$: C 42.72, H 3.58; found: C 42.62, H 3.71. *Anal.* calcd. for $Mn_{0.99}Cd_{0.01}C_{12}H_{12}P_2O_4$: C 42.68, H 3.58; found: C 42.78, H 3.77. *Anal.* calcd. for $Mn_{0.91}Cd_{0.09}C_{12}H_{12}P_2O_4$: Mn 14.6, Cd 2.96, C 42.11, H 3.53; found: Mn 13.7, Cd 2.89, C 41.96, H 3.55. *Anal.* calcd. for $Mn_{0.73}Cd_{0.27}C_{12}H_{12}P_2O_4$: Mn 11.4, Cd 8.61, C 40.87, H 3.43; found: Mn 10.9, Cd 8.62, C 40.96, H 3.53. *Anal.* calcd. for $Mn_{0.53}Cd_{0.47}C_{12}H_{12}P_2O_4$: Mn 8.00, Cd 14.5, C 39.58, H 3.32; found: Mn 7.57, Cd 14.1, C 39.63, H 3.36.

Elemental analyses

Manganese and cadmium were determined using, respectively, Varian AA5 and Perkin Elmer 305 Atomic Absorption Spectrophotometers. The sample solution was prepared by dissolving a known amount (20 to 70 mg) of the metal phosphinate in 15 mL of 37% HCl. This solution was then heated gently until all the solids were dissolved, and was diluted with distilled water to about 3 ppm in concentration. Mn and Cd standard solution (1–5 ppm) were made using spectrum grade manganese or cadmium nitrates. C and H microanalyses were performed by P. Borda of this Department.

The measured Mn to Cd ratio as determined by atomic absorption spectroscopy was used to determine x in the $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$ materials where $x = 0.47$, 0.27, and 0.09. From the relative proportions of Mn and Cd in the solutions from which the polymers were precipitated values of 0.50, 0.25, and 0.09 would have been predicted. For the samples of lower x where the Cd proportion was too low for meaningful determination by AA spectroscopy we used the value predicted from the relative proportions of the metal ions in solution.

Infrared spectroscopy

Infrared spectra were recorded on a Perkin Elmer 598 spectrophotometer. Samples were mulled in Nujol and pressed between KRS-5 plates (Harshaw Chemical Co.). Calibration was achieved using polystyrene and frequencies are reproducible to $\pm 3\ cm^{-1}$. Bands observed in the range 2500 to 250 cm^{-1} are given. $Mn[H(C_6H_5)PO_2]_2$: 2346 sh, 2336 m, 1598 w, 1442 m, 1147 s, 1127 sh, 1121 s, 1076 w, 1034 s, 1018 s, 995 s, 933 w, 923 w, 763 m, 758 w, 751 m, 710 m, 694 m, 668 w, 560 s, 504 wsh, 490 m, 421 w, 366 w. $Cd[H(C_6H_5)PO_2]_2$: 2342 sh, 2331 m, 1593 w, 1438 m, 1147 s, 1129 s, 1120 s, 1072 w, 1033 s, 1015 s, 990 s, 931 w, 921 w, 757 m, 751 m, 709 m, 692 m, 670 w, 556 s, 503 wsh, 486 m, 416 w, 360 w. $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$: as above for $Mn[H(C_6H_5)PO_2]_2$ to within $\pm 3\ cm^{-1}$ (w = weak, m = medium, s = strong, sh = shoulder).

Differential scanning calorimetry (DSC)

DSC studies were made using a Mettler DSC 20 cell interfaced with a Mettler TC 10 TA processor. In a typical experiment, a finely powdered sample of approximately 3 to 12 mg was accurately weighed into an aluminium crucible (with a small pinhole on the lid allowing atmospheric access) and the sample was heated from ca. 35 to 350°C at a rate of 4 degrees per minute. The temperature calibration of the platinum sensor was achieved using the known fusion temperature of indium. The heat flow was calibrated using an exactly known quantity of indium. The peak temperature and enthalpy of a particular thermal event were obtained respectively from the maximum in the DSC curve and the integrated area beneath the curve.

$Mn[H(C_6H_5)PO_2]_2$ is stable up to about 200°C at which temperature exothermic decomposition begins (peak temperature = 220°C, $\Delta H = 160\ kJ\ mol^{-1}$). $Cd[H(C_6H_5)PO_2]_2$ shows onset of exothermic decomposition at about 270°C (peak temperature = 290°C, $\Delta H = 240\ kJ\ mol^{-1}$).

$Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$ materials, all except one, showed a single exothermic decomposition peak at 220 ± 4°C. The peak was shifted to ~237°C in the compound with $x = 0.47$.

X-ray powder diffractometry

Powder diffraction patterns were obtained on a Philips X-Ray Diffraction (XRD) unit using Cu Kα as the radiation source. The measurements were done with a diffractometer 2θ setting of 2° per minute and chart speed of 2 centimeters per minute. Samples were prepared by dispersing the specimen by grinding under alcohol in an agate mortar. The sample slurry was mounted on a glass side and allowed to dry. The diffraction patterns were calibrated by using Si as an internal standard. $Mn[H(C_6H_5)PO_2]_2$ d(Å) with relative intensities in parentheses: 10.63 (100), 7.97 (3), 6.24 (6), 6.05 (7), 5.34 (6), 5.18 (6), 4.62 (25), 4.46 (2), 3.98 (20), 3.45 (2), 3.27 (5). $Cd[H(C_6H_5)PO_2]_2$: 15.56 (7), 10.78 (100), 7.81 (2), 6.29 (10), 6.12 (8), 5.39 (10), 5.25 (6), 4.67 (15), 4.59 (4), 4.01 (5), 3.48 (4), 3.33 (6). $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$: patterns as for the pure manganese compound except additional weak peaks are observed at 14.73 (7) and 15.28 (2) for $x = 0.99$ and 0.91, respectively, the weak 7.97 peak is not observed for $x = 0.53$ and the weak 4.46 peak is not observed for $x = 0.995$, 0.99, 0.91.

Solubilities

Qualitative solubility tests show $Mn[H(C_6H_5)PO_2]_2$ to be soluble in water (>0.1 g in 100 mL) but only slightly soluble to insoluble in methanol, ethanol, acetone, benzene, petroleum ether, carbontetrachloride, dichloromethane, and chloroform. $Cd[H(C_6H_5)PO_2]_2$ is soluble in water and methanol but only slightly soluble to insoluble in the other solvents tested.

Magnetic susceptibility measurements

Magnetic susceptibilities over the range 4.2 to 82 K were made using a Princeton Applied Research Model 155 Vibrating Sample Magnetometer with an applied field of 7501 G. The equipment and calibration procedures were described previously (4). Molar magnetic susceptibilities were corrected for diamagnetism of the metal ions and ligands; the corrections were (in $10^{-6}\ cm^3\ mol^{-1}$): manganese, −14; cadmium, −22; $H(C_6H_5)PO_2^-$, −78. Magnetic susceptibility data from 4.2 to 82 K are given in Table 1.[1]

Results and discussion

$Mn[H(C_6H_5)PO_2]_2$ was prepared by the dropwise addition of a dilute ethanol solution of manganese(II) acetate tetrahydrate to a dilute ethanol solution of monophenylphosphinic acid. This material is antiferromagnetic, exhibiting a broad maximum in magnetic susceptibility at ~35 K. We have found that it is important to control the conditions under which the precipitation occurs. Using solutions approximately twice as concentrated as those described in the Experimental section resulted in more rapid precipitation and the isolation of products containing a significant amount of paramagnetic, structural, impurity. We will return to this point later.

Since crystals of $Mn[H(C_6H_5)PO_2]_2$ suitable for single crystal X-ray diffraction studies could not be obtained, we have had to rely on other studies for structural information. Evidence that the compound is polymeric comes from its lack of significant solubility in a range of solvents, the observation that it decomposes without melting and the fact that it is magnetically concentrated (discussed later). Information on the nature of phosphinate coordination may be obtained from infrared studies particularly in the PO_2 stretching region (5). For this purpose we compared the spectrum of $Mn[H(C_6H_5)PO_2]_2$ with that of $Mn(HCONH_2)_2[H(C_6H_5)PO_2]_2$, a compound shown by single crystal X-ray diffraction studies (6) to have the double phosphinate-bridged chain structure with terminal *trans*-bound formamide ligands completing a distorted octahedral coordination about manganese. In the latter compound a strong broad band at 1133 cm^{-1} and a medium intensity band at 1050 cm^{-1} may be assigned to the PO_2 antisymmetric and symmetric stretching vibrations, respectively. In comparison, $Mn[H(C_6H_5)PO_2]_2$ shows a broad split, band centered around 1130 cm^{-1} and a band at 1018 cm^{-1} assigned to these vibrations.

The absence of the terminal ligands in $Mn[H(C_6H_5)PO_2]_2$ would be expected to have some effect on the phosphinate frequencies but the rather large shift to lower frequencies in the symmetric mode and the splitting of the antisymmetric mode suggests that the phosphinate bridging is more unsymmetrical in this compound than it is in the bis(formamide) derivative. It seems likely that the double phosphinate bridged structure is maintained in $Mn[H(C_6H_5)PO_2]_2$ but that interchain interactions involving coordination of oxygens in one phosphinate chain to manganese atoms in another occur, thus completing a distorted octahedral environment around manganese. Such a structure was proposed earlier for $Mn[(CH_3)_2PO_2]_2$ (7). Further evidence in support of a chain structure comes from the analysis of the magnetic data to be discussed below.

$Cd[H(C_6H_5)PO_2]_2$ was prepared by a procedure analogous to that used to obtain the manganese compound. The X-ray powder diffraction patterns indicate that the manganese and cadmium compounds are isomorphous, a conclusion supported by the infrared spectra which are virtually identical. As would be expected, the materials also have similar thermal and solubility properties. The X-ray powder diffraction patterns and infrared spectra of all of the mixed metal samples were examined and found to be virtually indistinguishable from those of the pure manganese compound. No evidence for acetate, water, or other impurities were found. Proof that these are single phase materials and not physical mixtures of the manganese and cadmium compounds comes from magnetic susceptibility studies.

Plots of magnetic susceptibility (per mol of Mn) and the effective magnetic moment of manganese versus temperature

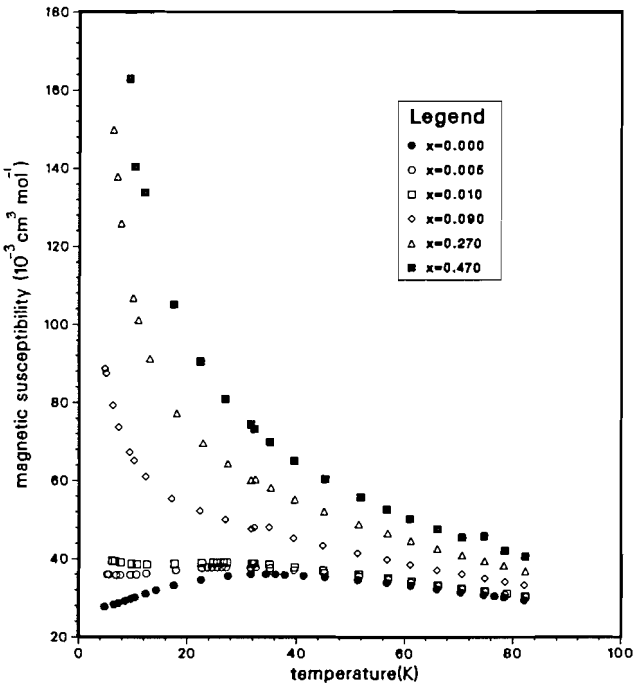

FIG. 1. Magnetic susceptibility versus temperature data for $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$.

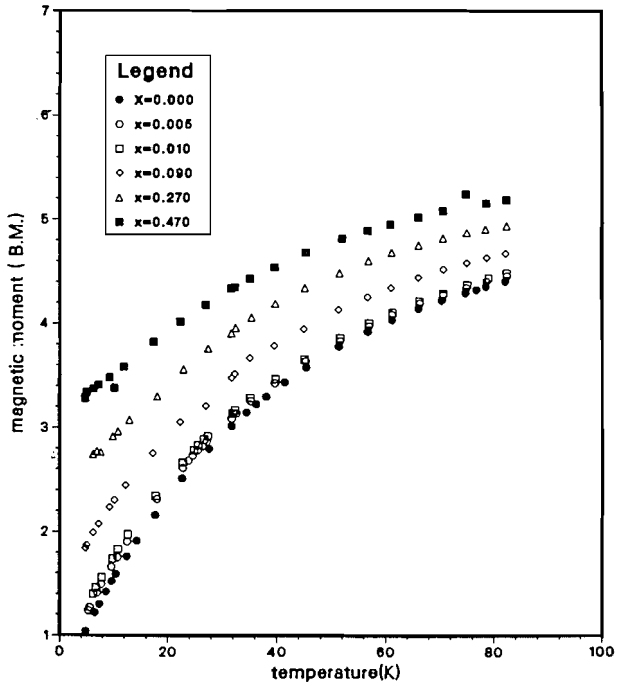

FIG. 2. Magnetic moment versus temperature data for $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$.

(4.2 to 82 K) are given in Figs. 1 and 2. At all temperatures both the susceptibility and the moment increase as the fraction of manganese decreases in the sample. In a physical mixture, of course, neither would be expected to change. As the proportion of manganese decreases the maximum in susceptibility appears to shift to lower temperatures and the susceptibility increase is greatest at the lowest temperatures.

The magnetic susceptibilities of pure $Mn[H(C_6H_5)PO_2]_2$

[b]$100p$ = % paramagnetic component.
[c]F = function minimized in obtaining the best fit; ref. 7.
[d]$100p$ set at zero. The measured susceptibilities at the lowest temperatures are lower than predicted by the model and including p as a variable parameter here generates an unrealistic negative value.

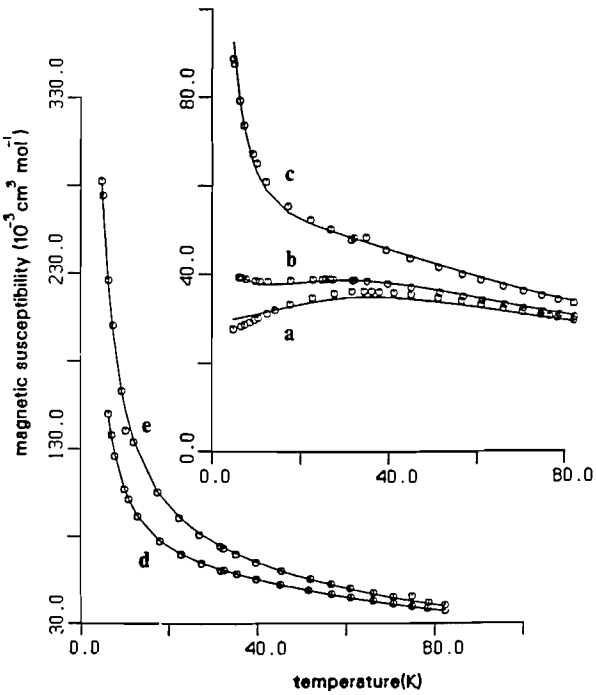

FIG. 3. Magnetic susceptibility versus temperature plots for $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$ (x = 0.00, 0.01, 0.09, 0.27, and 0.47 for a, b, c, d, e, and f, respectively). Solid lines are the best fit to the Wagner–Friedberg model.

were analyzed according to three models, all of which use the isotropic Heisenberg Hamiltonian. It was not possible to obtain a reasonable fit of the data to the Lines two-dimensional model (8); whereas satisfactory fits were possible employing either of the one-dimensional models tested. These were the scaling model of Wagner and Friedberg (9) and the interpolation scheme developed by Weng (10, 11). The fits using these two models were very similar (Table 2) although the Weng model does not reproduce the temperature of the susceptibility maximum as well as was found previously for $Mn[(CH_3)_2PO_2]_2$, a compound which exhibits very similar magnetic properties to the monophenylphosphinate (7). The magnetic analysis, then, is consistent with linear chains of antiferromagnetically coupled manganese ions.

Initial trials indicated the susceptibilities of the mixed metal systems could be fitted to the linear chain models provided allowance was made for a paramagnetic component p. Hence calculated susceptibilities were obtained from

$$\chi_{calc} = (1 - p)\chi_{chain} + p\chi_{para}$$

where χ_{chain} is the susceptibility calculated according to either chain model, χ_{para} is the susceptibility for magnetically dilute manganese(II) and p is the fraction of manganese making up the paramagnetic component. Fits were made to the susceptibility data with g fixed at 2.00 and J, the exchange coupling constant and p as fitting parameters. Best fit values of J and p are given in Table 2. The observed susceptibilities are compared with calculated for the Wagner–Friedberg model for some of the materials in Fig. 3.

It is clear from the data analysis that the change in magnetic properties with Cd doping is accounted for primarily by the incorporation of a paramagnetic component which increases with increasing Cd content. Such an effect can be rationalized if we consider the "random defect" model of de Jongh (3). According to this model any chain system will suffer from a certain concentration of defects which, in turn, will break the magnetic chain into finite segments. Half of these finite segments will contain an odd number of magnetic atoms and, coupled antiferromagnetically, these odd numbered segments will have a net spin at low temperatures. This net spin will be very weakly coupled along the chain, since the effective magnetic interaction will have to traverse the defects, and will therefore be much smaller than the nearest neighbour intrachain interaction. In our case, Cd plays the role of a defect, breaking up the long chains of contiguous Mn atoms into smaller isolated fragments. For example, consider the case where $x = 0.09$. For a random distribution of Cd atoms we would expect the average chain of contiguous Mn atoms to be about 9 atoms long but that there would be a distribution of chain lengths about this average. Half of the chains will be odd numbered producing a net spin at low temperatures as described by the random defect model. The magnetic analysis indicates that this leads to 6 to 7% paramagnetic component in this particular sample. According to this model, as the cadmium doping increases the average chain length would decrease and therefore the paramagnetic component should increase as is in fact, observed (Table 2).

The magnetic analysis also shows a decrease in the absolute value of the exchange coupling constant as doping is increased (Table 2). That this variation is, in fact, significant was verified by a careful examination of the sensitivity of the fits to changes in the parameter J. For example, employing the Wagner–

For personal use only.

Friedberg model, setting $|J|$ at 5% above or below its best fit value and allowing p to vary produced significantly poorer fits both visually and in terms of the fitting function F (function minimized in obtaining the best fit; ref. 7). This function is increased to a valve in the range 1.5 to 3 times the best fit value for all samples except that with $x = 0.47$. In this case the large paramagnetic component renders the fit less sensitive to variations in J although even here F is increased by 10% of its best fit value. The changes in the best fit values of J from sample to sample as x increases are of the order of 6 to 11% (except for the small change going from $x = 0.005$ to 0.01) and the overall change from $x = 0$ to 0.47 is about 30% (Table 2). Even assuming an uncertainty of ±5% in J, the variation must be considered significant. The fact that $|J|$ decreases with increasing Cd doping and hence, presumably with decreasing average chain length suggests that the exchange is not limited to nearest neighbour interactions in the chain but that longer range intrachain as well as interchain effects may be important. Alternatively, the effect may result from weaker coupling between manganese neighbours when one of the metals is adjacent to a cadmium ion or may simply reflect the limitations of an analysis which involves fitting a system of random-length chains to infinite-chain models.

Samples of $Mn[H(C_6H_5)PO_2]_2$ and Cd-doped materials prepared under conditions of rapid precipitation (solution concentrations about twice as large as those described in the experimental section) invariably gave higher susceptibilities (per mole Mn) than those reported here. Analyses of the data showed higher values for p and lower values for $|J|$ than corresponding samples prepared under conditions of slow crystallization. It appears that rapid precipitation results in the incorporation of natural structural defects which have the same effect on the magnetic properties as does the incorporation of diamagnetic Cd atoms into the polymer. Mixed metal materials prepared from concentrated solutions then have both natural and chemical (Cd atom) structural defects contributing to the fragmentation of the magnetic chain.

Conclusions

$Mn[H(C_6H_5)PO_2]_2$ is antiferromagnetic and the susceptibility versus temperature behaviour may be reasonably modeled according to an infinite chain of coupled manganese ions. Incorporation of diamagnetic Cd ions into the polymer fragments the magnetic chains resulting in the formation of a significant paramagnetic component arising from the net spins associated with odd numbered fragments. Natural defects can also fragment the chains and lead to a paramagnetic component. Since no paramagnetic component is detected for samples of the pure manganese compound (prepared from dilute solutions) one can conclude that chain fragmentation in this sample is minimal and that one is dealing here with magnetic chains which on average contain 100 or more contiguous manganese ions. This estimate is based on the observation that we were able to detect levels of paramagnetic component as low as about 0.5% in the mixed metal systems and average chain lengths of less than 100 in the pure manganese compound should generate paramagnetic component levels greater than this.

As x varies from 0 to 0.47 in the $Mn_{1-x}Cd_x[H(C_6H_5)PO_2]_2$ samples the average number of contiguous Mn atoms is considered to go from greater than 100 to presumably two or three atoms at most in a chain. This is accompanied by an apparent decrease of about 30% in the absolute value of the exchange coupling constant J. This result suggests that factors other than nearest neighbour intrachain interactions such as longer range intrachain exchange and interchain exchange may also be affecting the magnetic properties of these materials.

Preparation of and addition of carbanions to 6-methyl-6-nitrocyclohexa-2,4-dienones[1]

ALFRED FISCHER,[2] GEORGE N. HENDERSON, AND S. SANKARARAMAN
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received January 9, 1989

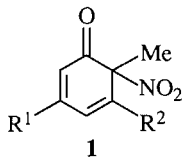
ALFRED FISCHER, GEORGE N. HENDERSON, and S. SANKARARAMAN. Can. J. Chem. **67**, 1244 (1989).

Nitration of 2-methylphenols with nitric acid and trifluoroacetic anhydride in ether at −78°C gives 6-methyl-6-nitrocyclohexa-2,4-dienones that can be isolated. Carbanions add to 5,6-dimethyl-6-nitrocyclohexa-2,4-dienone to give the 5-substituted 2,3-dimethyl-2-nitrocyclohex-3-enone anion, which, with additional carbanion, gives the 5-substituted 2,3-dimethylphenoxide anion by elimination of nitrous acid.

Key words: nitration, dienone, addition, carbanion, nucleophilic.

ALFRED FISCHER, GEORGE N. HENDERSON et S. SANKARARAMAN. Can. J. Chem. **67**, 1244 (1989).

La nitration des méthyl-2 phénols par l'acide nitrique et l'anhydride trifluoroacétique, dans l'éther à −78°C, conduit à la formation de méthyl-6 nitro-6 cyclohexadiène-2,4 ones que l'on peut isoler. Les carbanions s'additionnent sur la diméthyl-5,6 nitro-6 cyclohexadiène-2,4 one pour conduire à l'anion diméthyl-2,3 nitro-2 cyclohexène-3 one substituée en position 5 qui, sous l'action d'un autre carbanion et par élimination d'acide nitreux, conduit à la formation de l'anion diméthyl-2,3 phénolate substitué en position 5.



Mots clés : nitration, diénone, addition, carbanion, nucléophile.

Introduction

Formation of 6-methyl-6-nitrocyclohexa-2,4-dienones in the low temperature nitration of 2-methylphenols in acetic anhydride has been reported (1, 2). However, these dienones were not isolated as they are thermally very labile. 6-Methyl-6-nitrocyclohexa-2,4-dienone (**1***a*) isomerizes above −40°C to 6-nitro-*o*-cresol, and in the nitration mixture at −20°C the dienone has a half-life of approximately 8 min. The normal procedure for work-up of nitration reactions carried out in acetic anhydride usually involves treatment with liquid ammonia or concentrated ammonium hydroxide. In this process the temperature of the reaction mixture rises to at least −10°C and 6-methyl-6-nitrocyclohexa-2,4-dienones do not survive. Nitrodienone **1***a* was formed in the nitration of *o*-cresol in dichloromethane, but again isomerized during work-up with liquid ammonia, nominally at −78°C. During a search for a convenient procedure to isolate the thermally unstable 4-halo-4-nitrocyclohexa-2,5-dienones, Clewley developed a nitration procedure for the nitration of 4-halophenols in ether using trifluoroacetyl nitrate (3, 4). Several unstable nitrodienones have been isolated for the first time using this procedure. This appears to be a general method for the low temperature nitration of phenols and we now report the isolation of 6-methyl- (**1***a*), 5,6-dimethyl- (**1***b*), and 3,6-dimethyl-6-nitrocyclohexa-2,4-dienone (**1***c*) in yields of 30–50%.

Results and discussion

Nitration of 2-methylphenols

Nitration was carried out at −78°C and the reaction mixture was worked up by the addition of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) at −78°C. The trifluoroacetate salt of TMEDA precipitated, and the ethereal solution containing the nitrodienone and the nitrophenols was filtered through a column of basic alumina at −78°C. Only the nitrodienone was eluted and the more acidic nitrophenols remained at the top of the column. Pure nitrodienone was obtained after removal of the solvent at −60°C in a vacuum rotary evaporator. The method has several advantages over the nitration in acetic anhydride. Nitration of 2-methylphenols occurs rapidly at −78°C and the reaction is complete within minutes using one equivalent of the nitrating agent; nitration is carried out in anhydrous conditions and thus the dienones are isolated pure and dry; the reaction mixture can be diluted with additional ether at −78°C and there is no large excess of acid or anhydride, thus the heat of neutralization during work-up and its effect in raising the temperature are minimized, allowing the isolation of thermally labile dienones. Since ether is a basic solvent it is necessary to use the powerful nitrating agent trifluoroacetyl nitrate. When acetyl nitrate was used reaction did not occur, even at 0°C. The basic alumina must be freshly activated. Deactivation of alumina due to prolonged storage usually led to the elution of nitrophenols along with the nitrodienone. The nmr spectral data of the isolated dienones are given in Tables 1 and 2.

The nitrodienones isomerized by specific 1,3 rearrangement of the nitro group, yielding the corresponding 6-nitro-*o*-cresols. No 4-nitro-*o*-cresols were obtained.

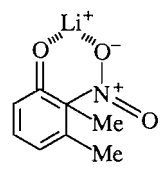

SCHEME 1

Addition of carbanions to 6-methyl-6-nitrocyclohexa-2,4-dienones

Organolithium reagents (RLi) add in a 1,2 fashion to the carbonyl group of 4-alkyl-4-nitrocyclohexa-2,5-dienones to form 1-*R*-4-alkyl-4-nitrocyclohexa-2,5-dienols (5, 6). We hoped that the 6-methyl-6-nitrocyclohexa-2,4-dienones would undergo the same reaction to form 1-*R*-6-methyl-6-nitrocyclohexa-2,4-dienols. The 1,2-addition of carbanions to 6,6-dialkylcyclohexa-2,4-dienones has been reported (7), although the resulting dienols are unstable and readily undergo allylic rearrangement (8) or dehydration (9) to form more stable products. The high reactivity of the conjugated cyclohexadienols is attributed to the steric repulsion of the substituents on the adjacent tetrahedral ring carbons, which is relieved during the further reactions of the dienols.

Dienone **1***b* was chosen as the substrate for study of the addition reactions because it was the most thermally stable. Addition of methyllithium and lithium dimethylcuprate yielded, in each case, 2,3-dimethylphenol as the only product. It is likely that the anionic species abstracts the nitro group to leave the phenoxide anion, which is protonated to the phenol on work-up. An alternative pathway is electron transfer from carbanion to dienone followed by cleavage of nitrogen dioxide (6). Addition of methylmagnesium bromide, methyl lithioacetate, *N*,*N*-dimethyllithioacetamide, and potassium cyanide/18-crown-6 yielded the corresponding *meta*-substituted phenol (**2**). Two mole proportions of the reagent were required for the completion of the reaction. When only one mole of the reagent was used, a mixture of 1,4-addition product (**3**), *meta*-substituted phenol, and 2,3-dimethyl-6-nitrophenol was obtained, the latter product arising from the isomerization of the unreacted nitrodienone. The 1,4-addition product resulting from the addition of methyl lithioacetate, 5-carbomethoxymethyl-2,3-dimethyl-2-nitrocyclohex-3-enone (**3***n*), was isolated as a mixture of two diastereomers. These results suggest that the *meta*-substituted phenol is formed by a stepwise process via an initial 1,4-addition of the reagent to the nitrodienone followed by the 1,4-elimination of nitrous acid in the presence of excess reagent (Scheme 1).

Two factors may be responsible for the different reactivity of the 6-methyl-6-nitrocyclohexa-2,4-dienones as compared with that of the 2,5-dienones. Steric hindrance at the carbonyl group due to the presence of the two bulky α substituents would prevent the carbanion from approaching the carbonyl carbon. Furthermore, the lithium ion is probably strongly chelated by the carbonyl oxygen and the oxygen of the nitro group as shown in **4**. This would add to the hindrance for 1,2-addition, yet

4

increase the reactivity of the carbanion towards 1,4-addition. Carbanions are known to add in 1,4 fashion to enones in cation complexing solvents such as hexamethylphosphoramide (10). The acetoxy analogue of **1** and other *o*-quinol acetates add Grignard reagents and alkyllithium reagents in a 1,4 fashion,

then eliminate acetic acid to give *meta*-substituted phenols in a mechanism analogous to that of Scheme 1 (7, 11).

Reaction of 3,6-dimethyl-6-nitrocyclohexa-2,4-dienone (**1***c*) with methyl lithioacetate yielded an unidentifiable insoluble polymer. Its analog, 3,6-dimethyl-*o*-quinol acetate, reacts with carbanions to yield 3-(substituted-methyl)phenols, presumably via a methylenecyclohexadiene intermediate. An analogous intermediate may be involved in the polymerization.

Experimental

Instrument and general experimental methods have been described previously (6, 12). *o*-Cresol, 2,3-, and 2,5-dimethylphenol were Aldrich reagent grade. *N,N,N′,N′*-Tetramethylethylenediamine (Aldrich) was purified by distillation from lithium aluminium hydride under argon.

Nitration of 2-methylphenols

Trifluoroacetic anhydride (7.8 cm^3, 55 mmol) was carefully added, with stirring, to fuming nitric acid (3.4 g, 55 mmol) at −40°C. A solution of the nitrating mixture in ether (10 cm^3) at −78°C was added dropwise with stirring to a solution of 2-methylphenol (50 mmol) in ether (50 cm^3) at −78°C. Stirring was continued for 30 min at −60°C and the mixture was cooled to −78°C. The ^1H nmr of the reaction mixture showed that **1***a* and 4-nitro- and 6-nitro-2-methylphenol had been formed, and that no unreacted 2-methylphenol remained. *N,N,N′,N′*-Tetramethylethylenediamine (57.5 mmol) in ether (10 cm^3) at −78°C was added dropwise, with stirring. The resulting slurry was filtered through a jacketed filter funnel that had been precooled to −78°C, and the solid residue was washed with ether (2 × 20 cm^3) at −60°C. The filtrate, collected at −78°C, was then filtered through a column of basic alumina (50 g, packed with ether) at −78°C, in a jacketed glass column. The column was further eluted with ether (250 cm^3) at −60°C. Upon evaporation of ether from the eluate at −40°C, **1***a* was obtained as a white crystalline solid in 30% yield. The dienone was dried at −40°C and 2 Pa for 10 h. Dienones **1***b* and **1***c* were prepared similarly.

*Addition of carbon nucleophiles to 5,6-dimethyl-6-nitrocyclohexa-2,4-dienone (**1**b)*

Methyllithium (10 mmol) in ether (27 cm^3) at −78°C was added dropwise to a stirred solution of **1***b* (5 mmol, 0.83 g) in tetrahydrofuran (THF) (70 cm^3) under an argon atmosphere. The reaction mixture was stirred at −78°C for 20 min. Aqueous ammonium chloride (10 cm^3, 30 mmol) was added and the mixture was warmed to 0°C and extracted with ice-cold ether. The organic layer was dried ($MgSO_4$) at −20°C and the solvent was removed at −30°C under reduced pressure to give a viscous oil shown to be 2,3-dimethylphenol by ^1H nmr, and confirmed by glc.

Cuprous iodide (5 mmol, 0.95 g) was added to a stirred solution of methyllithium (10 mmol) in ether (7 cm^3) and THF (75 cm^3) at 0°C and under an argon atmosphere. The mixture was stirred for 15 min and then added, as described for methyllithium, to the **1***b* (5 mmol, 0.83 g) in THF and stirred for 1.5 h. The product (0.53 g) was 2,3-dimethylphenol with a small amount of 2,3-dimethyl-6-nitrophenol.

Methylmagnesium bromide (11 mmol) in ether (24 cm^3) was added to the **1***b* (10 mmol, 1.67 g) in THF (50 cm^3) as described above and stirred for 1 h. The product oil was a mixture of 2,3-dimethyl-6-nitrophenol (50%) and 2,3,5-trimethylphenol (**2***m*) (50%).

Methyl lithioacetate (6) (10 mmol) in THF (50 cm^3), was added to the **1***b* (5 mmol, 0.83 g) in THF (70 cm^3) and stirred for 1.5 h. The crude product, a colorless viscous oil (0.30 g, 30%), on crystallization from ether – petroleum ether at −20°C gave colorless crystals of methyl (4,5-dimethyl-3-hydroxyphenyl)acetate (**2***n*): mp 89–90°C; ir (KBr): 3360 (br, OH), 2950, 1705 (C=O), 1590, 1450, 1320, 1265, 1140, 1085, 870, and 800 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.62 (s, 1, 6-H), 6.57 (s, 1, 2-H), 5.50 (s, 1, OH), 3.64 (s, 3, $COOCH_3$), 3.46 (s, 2, CH_2COO), 2.20 (s, 3, 5-CH_3), 2.08 (s, 3, 4-CH_3); ^{13}C nmr ($CDCl_3$) δ_C: 172.4 (C=O), 153.7 (C-3), 138.4 (C-5), 131.6 (C-4), 123.1 (C-6), 121.5 (C-1), 113.4 (C-2), 52.0 ($COOCH_3$), 40.7 (CH_2), 19.9 (5-CH_3), 11.2 (4-CH_3); ms, *m/z* (relative intensity): 194.096 (25, M_r $C_{11}H_{14}O_3$: 194.094), 136 (11), 135 (100), 91 (17), 77 (7), 65 (4).

When the reaction was repeated by adding methyl lithioacetate (11 mmol) to the dienone (10 mmol) the crude product, an oil (1.3 g), was a mixture of 2,3-dimethyl-6-nitrophenol (35%) and 5-carbomethoxymethyl-2,3-dimethyl-2-nitrocyclohex-3-enone (65%). An ethereal solution of this product was washed with ice-cold 2% aqueous sodium hydroxide, followed by ice-cold water, and this afforded 5-carbomethoxymethyl-2,3-dimethyl-2-nitrocyclohexa-3-enone (**3***n*) (0.05 g) as a colorless oil: ir (film): 2950, 1735 (C=O), 1550 and 1375 (NO_2), 1440, 1260, 910, and 730 cm^{-1}; ^1H nmr ($CDCl_3$, 250 MHz) δ: 5.84 (m, 1, 4-H), 3.63 (s, 3, $COOCH_3$), 3.12 (m, 1, 5-H), 2.83 (dd, J = 14.4 Hz, 5.8 Hz, 1, 6-H), 2.44 (dd, J = 14.4 Hz, 8.2 Hz, 1, 6-H), 2.38 and 2.35 (d, J = 1.8 Hz, 2.3 Hz, 2, CH_2COO), 1.74 (s, 3, 2-CH_3), 1.70 and 1.69 (d, J = 1.4 Hz, 3, 3-CH_3); ^{13}C nmr ($CDCl_3$) δ_C: 199.0 (C-1), 170.2 (*C*OOMe), 132.0 (C-3), 131.6 (C-4), 92.9 (C-2), 50.8 ($COOCH_3$), 40.2 and 38.3 (C-6 and CH_2COO), 31.8 (C-5), 19.6 and 16.8 (2-CH_3 and 3-CH_3).

N,N-Dimethyllithioacetamide (12 mmol) in THF (50 cm^3) was added to the dienone (5 mmol) in THF (45 cm^3) and stirred for 1.5 h. The product, *N,N*-dimethyl(4,5-dimethyl-3-hydroxyphenyl)acetamide (**2***o*) (0.47 g, 45%), was obtained as colorless crystals on recrystallization from dichloromethane–hexane at −20°C: mp 138–140°C; ir (KBr): 3290 (br, OH), 2920, 1625 (C=O), 1585, 1510, 1450, 1400, 1285, 1135, 1090, 860, and 790 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.45 (br, OH), 6.79 (s, 1, 6-H), 6.48 (s, 1, 2-H), 3.55 (s, 2, CH_2COO), 2.92 (s, 6, $N(CH_3)_2$), 2.18 (s, 3, 5-CH_3), 2.08 (s, 3, 4-CH_3); ^{13}C nmr ($CDCl_3$) δ_C: 172.2 (C=O), 155.3 (C-3), 137.9 (C-5), 131.8 (C-4), 121.8 (C-6), 121.6 (C-1), 112.3 (C-2), 40.8 (CH_2), 37.9 and 35.9 ($N(CH_3)_2$), 19.9 (5-CH_3), 11.2 (4-CH_3); ms, *m/z* (relative intensity): 208 (2), 207.129 (10, M_r $C_{12}H_{17}NO_2$: 207.125), 135 (34), 91 (14), 85 (30), 77 (9), 72 (100).

A mixture of potassium cyanide (20 mmol, 1.30 g), 18-crown-6 (2 mmol, 0.53 g), and the dienone (2 mmol, 0.34 g) in acetonitrile (10 cm^3) was stirred at −40°C for 3 h. The product, 5-cyano-2,3-dimethylphenol (**2***p*), was recrystallized from a mixture of ether and hexane at −20°C: mp 122°C (lit. (13) mp 122.5–123°C); ir (KBr): 3250 (br, OH), 2230 (CN) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.03 (s, 1, 4-H), 6.96 (s, 1, 6-H), 5.92 (br s, 1, OH), 2.26 (s, 3, 3-CH_3), 2.19 (s, 3, 2-CH_3); ^{13}C nmr ($CDCl_3$) δ_C: 154.0 (C-1), 139.0 (C-3), 129.5 (C-2), 125.0 (C-4), 119.0 (CN), 115.7 (C-6), 108.9 (C-5), 19.8 (3-CH_3), 11.9 (2-CH_3); ms, *m/z* (relative intensity): 147.068 (92, M_r C_9H_9NO: 147.068), 146 (34), 132 (100), 77 (21).

Kinetic study of the oxidation mechanism of glutathione by hydrogen peroxide in neutral aqueous medium

Z. ABEDINZADEH, M. GARDES-ALBERT, AND C. FERRADINI

Laboratoire de chimie-physique, 45, rue des Saints-Pères, F-75270, Paris CEDEX 06, France

Received July 21, 1988[1]

Z. ABEDINZADEH, M. GARDES-ALBERT, and C. FERRADINI. Can. J. Chem. **67**, 1247 (1989).

The oxidation kinetics of glutathione (GSH) by hydrogen peroxide has been studied at neutral pH for different concentration ratios $[GSH]_0/[H_2O_2]_0$ between 0.2 and 2 ($5 \times 10^{-4}\ M \leq [H_2O_2]_0 \leq 2.5 \times 10^{-3}\ M$; $4 \times 10^{-4}\ M \leq [GSH]_0 \leq 2.5 \times 10^{-3}\ M$). In all cases studied, glutathione disulfide GSSG is the main product formed via two different oxidation ways, each of them contributing respectively to 80–85% and 10–15%.

Our kinetic data indicate that an important fraction of hydrogen peroxide disappears without oxidizing the thiol function. This can be attributed to a combination between GSH and H_2O_2 protecting the sulfide group. Chemical evidences of the existence of a peroxide bond with GSSG are described. In our experimental conditions, the overall oxidation equation is 2 mol GSH reacting with 2 mol H_2O_2 giving 1 mol GSSG. It is very different from the usually accepted stoichiometric reaction:

$$H_2O_2 + 2GSH \rightarrow GSSG + 2H_2O$$

A kinetic scheme is proposed and the corresponding rate constants are determined.

Key words: glutathione, hydrogen peroxide, kinetic mechanism, glutathione disulfide.

Z. ABEDINZADEH, M. GARDES-ALBERT et C. FERRADINI. Can. J. Chem. **67**, 1247 (1989).

Opérant à un pH neutre et à des rapports de concentration de $[GSH]_0/[H_2O_2]_0$ allant de 0,2 à 2 ($5 \times 10^{-4}\ M \leq [H_2O_2]_0 \leq 2{,}5 \times 10^{-3}\ M$; $4 \times 10^{-4}\ M \leq [GSH]_0 \leq 2{,}5 \times 10^{-3}\ M$), on a étudié la cinétique de l'oxydation du glutathion (GSH) par le peroxyde d'hydrogène. Dans tous les cas étudiés, le disulfure de glutathion, GSSG, est le produit principal qui est formé par deux voies d'oxydation principales qui apportent des contributions respectives de 80 à 85% et 10 à 15%.

Nos données cinétiques indiquent qu'une fraction importante du peroxyde d'hydrogène disparaît sans oxyder la fonction thiol. On peut attribuer ce fait à une combinaison du GSH et du H_2O_2 qui protégerait le groupement sulfure. On décrit des données chimiques qui suggèrent l'existence d'une liaison du peroxyde avec le GSSG. Dans nos conditions expérimentales, l'équation globale d'oxydation implique donc deux moles de GSH qui réagissent avec deux moles de H_2O_2 pour donner une mole de GSSG. Cette équation diffère beaucoup de la réaction stoechimétrique généralement admise:

$$H_2O_2 + 2GSH \rightarrow GSSG + 2H_2O$$

On propose une schéma cinétique et on a déterminé les constantes de vitesse correspondantes.

Mots clés : glutathion, peroxyde d'hydrogène, mécanisme cinétique, disulfure de glutathion.

[Traduit par la revue]

Introduction

Glutathione (GSH) is present in almost all cells in rather high concentration. The conversion of glutathione (GSH) to glutathione disulfide GSSG, *in vivo*, is catalyzed by glutathione peroxidase, which acts on hydrogen peroxide and other peroxides. The overall oxidation reaction of GSH by H_2O_2 in presence of peroxidase is

$$[1]\quad 2GSH + H_2O_2 \xrightarrow{GPX} GSSG + 2H_2O$$

It is generally agreed that in the absence of the enzyme the overall oxidation process is not different from this reaction (1). But the real mechanism of oxidation of GSH by H_2O_2 is unknown.

However, the oxidation kinetics of a variety of sulfur compounds such as hydrogen sulfide (2), sulfur dioxide (3), thioureas (4), thioxane (5), thiocyanate (6, 7) and 2 mercaptoethanol (8) by hydrogen peroxide in aqueous solution have been studied. A common mechanism for the acid-catalyzed nucleophilic attack consists of a heterolytic cleavage of oxygen–oxygen bond of hydrogen peroxide with the release of either hydroxide ion or water as leaving group according to

$$RSH + H_2O_2 \rightarrow RSOH + H_2O$$

The hydroxy intermediate (RSOH) subsequently reacts with either a second molecule of reductant to form a dimer as a final product or with an additional molecule of H_2O_2 (2).

Concerning the reaction of H_2O_2 with GSH, McCormic *et al.* (9) have shown that a UV chromophore having a maximal absorption at 305 nm appears during the reaction. But the kinetics of the reaction were not studied. The same observation was obtained when aerated aqueous solutions of GSH were irradiated with a 254 nm radiation (9). From several comparative studies with other thiols in the same conditions, they attributed the absorbance at 305 nm to a product which is formed on the *N*-acetylcysteinamide (—CONH—CH(—CH_2—SH)—$CONH_2$) part of GSH.

In order to carefully investigate the mechanism of oxidation of GSH by H_2O_2, the kinetics of this reaction have been studied in neutral aerated aqueous medium, in absence of peroxidase for different concentrations: $4 \times 10^{-4}\ M \leq [GSH]_0 \leq 2.5 \times 10^{-3}\ M$, $5 \times 10^{-4}\ M \leq [H_2O_2]_0 \leq 2.5 \times 10^{-3}\ M$, and different ratios $[GSH]_0/[H_2O_2]_0$ (0.2 to 2).

Materials and methods

Chemicals were of the purest grade available and were used without further purification. The only exception was glutathione sulfonic acid which was used as a standard for HPLC and spectral analysis. It was prepared according to Calam and Waley (10). GSH and GSSG were obtained from FLUKA; 5,5′-dithiobis(2-nitrobenzoic acid), NADPH, glutathione reductase were supplied by Sigma Chemical Co.; hydrogen

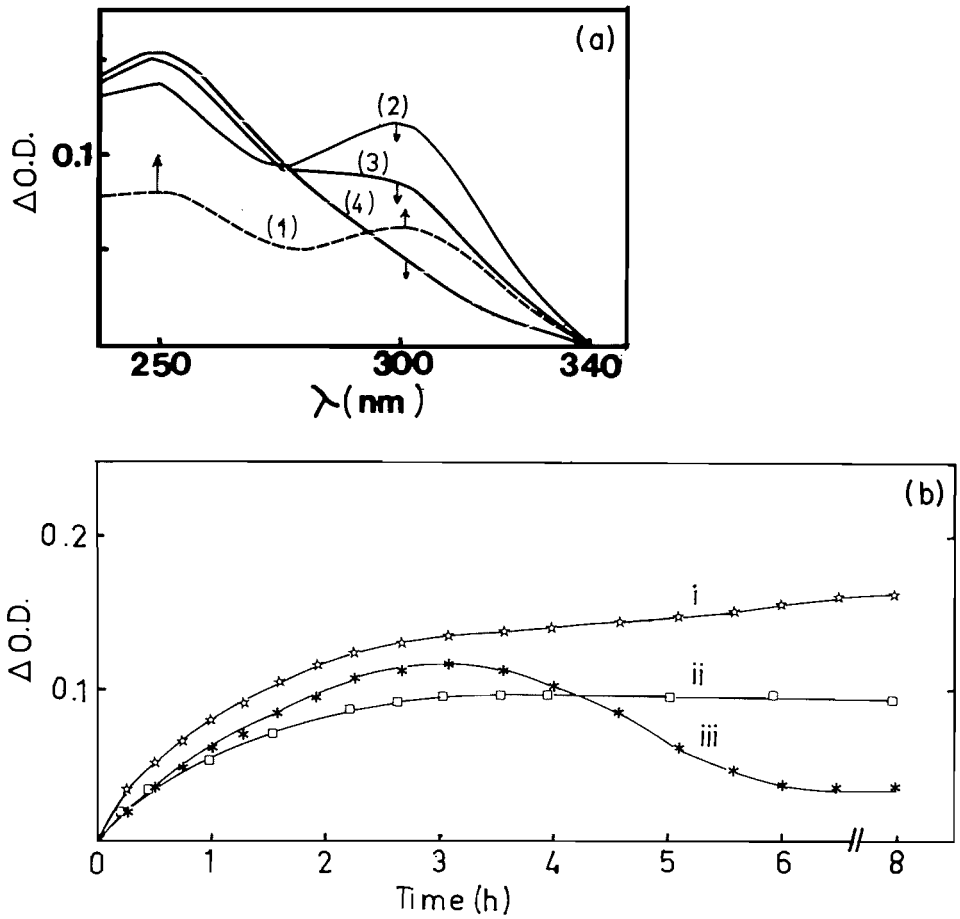

FIG. 1. (*a*) Differential absorption spectra at various times after mixing. $[GSH]_0 = [H_2O_2]_0 = 10^{-3}$ *M*, phosphate buffer 0.1 *M*, 22°C, pH 7, *l* = 0.875 cm. Reference: $[GSG]_0 = 2 \times 10^{-3}$ *M* (*l* = 0.4375 cm) (two chambers cell, see Experimental section). (*1*) 1 h, (*2*) 3 h 5 min, (*3*) 4 h 35 min, (*4*) 5 h 35 min after mixing of the reactants. (*b*) Evolutions of the differential absorption densities as a function of time at three different wavelengths: (☆) λ 250 nm, (□) λ 268 nm, (★) λ 305 nm.

peroxide, sodium acid phosphate were from Merck. All solutions were prepared with triply distilled water, the purity of which was controlled by conductivity measurements (10^{-6} Ω cm^{-1}).

Thiol concentration was determined with Ellman's reagent, 5,5'-dithiobis(2-nitrobenzoïc acid) which undergoes a thiolate disulphide exchange reaction to yield 2-nitromercaptobenzoïc acid (11). This product was measured spectrophotometrically (λ_{max} = 412 nm, ϵ = 13600 ± 600 M^{-1} cm^{-1}) against an appropriate blank. The oxidized form GSSG was titrated by its reduction by NADPH in the presence of glutathione reductase, the NADPH in excess being measured spectrophotometrically (λ_{max} = 340 nm, ϵ = 5400 ± 250 M^{-1} cm^{-1}). This titration was carried out with solutions containing an excess of GSSG to avoid any parasitical oxidation of NADPH due to an oxidase activity of glutathione reductase (12).

Hydrogen peroxide concentrations were measured spectrophotometrically by the titanium sulfate method (13, 14) using ϵ_{410} = 700 M^{-1} cm^{-1}.

For the differential spectrophotometric measurements of reaction mixtures, we used two chamber cells, each having an optical path of 0.4375 cm. The reference cell in one chamber contained H_2O_2, (with $[H_2O_2]_0$ = 2 $[H_2O_2]_0$ reaction mixture) and in the other GSH (with $[GSH]_0$ = 2 $[GSH]_0$ reaction mixture). The measure cell in each chamber contained the same reaction mixture.

Another method for determining GSSG was deduced from the differential optical densities at 250 nm. At this wavelength the extinction coefficient for GSH is equal to zero and for H_2O_2 ϵ_{250} = 25 M^{-1} cm^{-1} (15). According to Beer's law, the differential extinction coefficient of GSSG 330 ± 4 M^{-1} cm^{-1} has been determined.

Oxygen concentration was determined by Gilson oxygraph model IC TS-KI. All solutions were prepared just prior to use and buffered at pH 7 in a 10^{-1} *M* phosphate medium. Temperature was maintained constant at 22°C with a BIOBLOCK Polystat circulating water bath.

HPLC analysis has been done according to Reed (16) on a ZORBAX-NH_2 (25 cm × 4.6 mm) column.

Results

1. Differential absorption spectra of the reaction mixture in function of time

For various times after the mixing the differential absorption spectra of a solution containing initially H_2O_2 10^{-3} *M* and GSH 10^{-3} *M* (phosphate buffer 0.1 *M*, pH 7) can be seen in Fig. 1*a* (between 240 and 340 nm). The differential absorption spectrum (*1*) recorded 1 h after the mixing presents two maxima at 250 nm and 305 nm. The absorption band at 250 nm increases (spectra (*2*) and (*3*)), until the end of the reaction (spectrum (4), ΔOD^{250} (5 h 35 min) = 0.16). Simultaneously the absorption band at 305 nm increases and reaches a maximum value at 3 h 20 min (spectrum (*2*), ΔOD^{305} (3 h 20 min) = 0.12) and decays. We note the presence of an isobestic point at 268 ± 8 nm.

The kinetics at 250, 268, and 305 nm are reported on the Fig. 1*b*. The curve (*i*) at 250 nm appears to be composed of a fast increase until ≃ 3 h, followed by a much slower growth until the end of the reaction. This absorption band at 250 nm has been attributed to GSSG ($\Delta\epsilon^{250}$ = 330 M^{-1} cm^{-1}, see Experimental section). At the end of the reaction, the disulfide concentration is equal to 4.85 × 10^{-4} *M* which corresponds to the transfor-

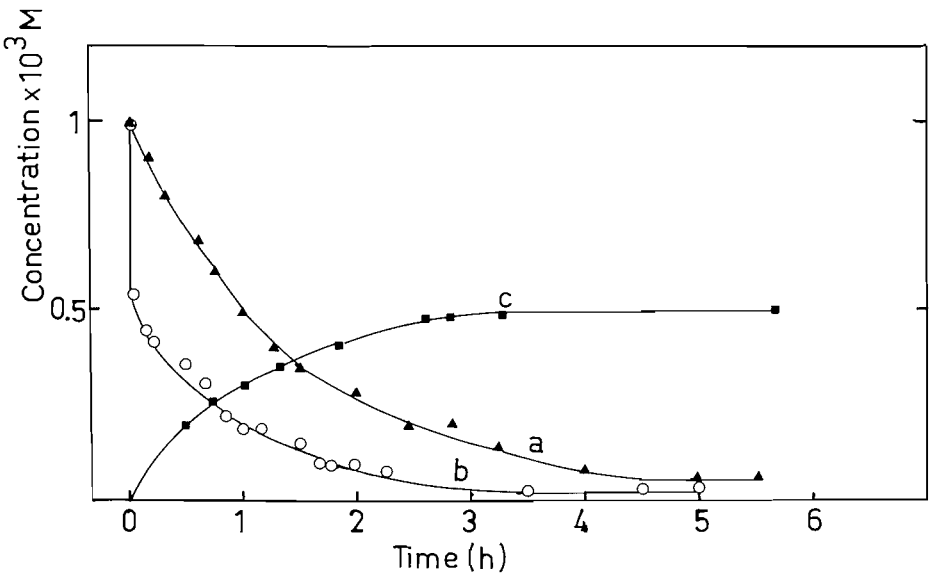

FIG. 2. Evolution of the concentration of GSH (▲), H_2O_2 (○), and GSSG (■). $[GSH]_0 = [H_2O_2]_0 = 10^{-3}$ M, phosphate buffer 0.1 M, pH 7, 22°C.

mation of 97% of GSH initially present in the solution. Consequently, we can consider that the thiol GSH is stoichiometrically oxidized to GSSG within experimental errors. Curve (*iii*) characterizes a transient which exhibits an absorption maximum (at 3 h 20 min), then decays until 7 h, and reaches a final value of ΔOD^{305} (7 h) = 0.035. We will call this intermediate X^{305}. Curve (*ii*) gives the ΔOD^{268} evolution at the isobestic point and it can be observed that a plateau value of $\Delta OD^{268} = 0.095$ is reached and is maintained constant between 3 h 20 min and the end of the reaction. This isobestic point shows that the decay of the intermediate X^{305} gives rise only to GSSG. It can be noticed that ϵ_{305} GSSG = 0 so the absorption at 305 nm is only due to X^{305}. The variations of GSSG concentration during the decay of X^{305} can be measured: it is equal to 6.5×10^{-5} M which represents 13% of the total amount of GSSG appeared. Hence the thiol oxidation via intermediate X^{305} is a minor oxidation phenomenon.

2. Evolution of GSH, H_2O_2, and GSSG

Figure 2 shows the kinetic changes in the concentration of GSH, H_2O_2, and GSSG (curves *a*, *b*, and *c*), when the solutions contain initially the same concentrations of GSH and H_2O_2, 10^{-3} M (phosphate buffer 10^{-1} M, pH 7). We remark that the decay of H_2O_2 measured by the titanium composed of two distinct phenomena: the first, a very fast decrease which ends in 2 min and corresponds to the disappearance of 50% of the H_2O_2 initial concentration. The second phenomenon lasts about 6 h, and corresponds to the disappearance of the last 50% of H_2O_2. Identical processes have been observed for numerous experiments; the corresponding initial concentrations are reported in Table 1 (see the three first columns).

The decay of GSH (Fig. 2*a*) and the formation of GSSG (Fig. 2*c*) are contemporary with the slow decrease of H_2O_2 (Fig. 2*b*). We note that, at the end of the reaction, the thiol GSH is quantitatively oxidized to GSSG. This fact confirms the previously stoichiometric oxidation demonstrated according to the results of Fig. 1*b*.

Furthermore, at the end of the reaction the whole H_2O_2 has disappeared (detection by the titanium method), leading us to conclude that 2 mol of H_2O_2 react with 2 mol of GSH to give 1 mol of GSSG. This overall reaction is very different from the usually accepted stoichiometry [1].

[1] $2GSH + H_2O_2 \rightarrow GSSG + 2H_2O$

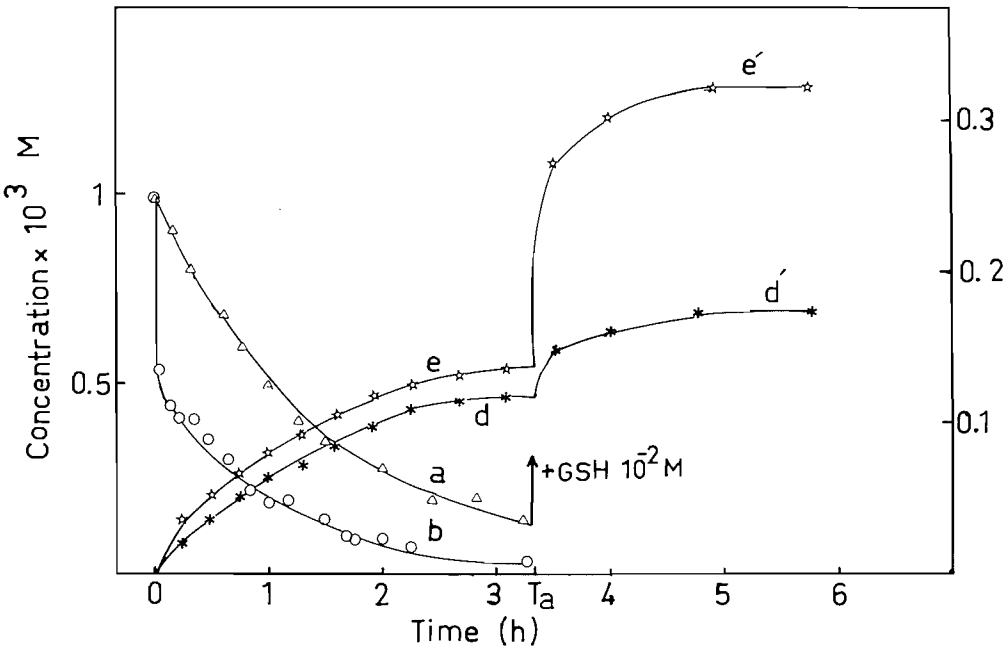

FIG. 3. Addition of GSH at the end of the reaction. Initial reaction: $[GSH]_0 = [H_2O_2]_0 = 10^{-3}$ *M*, phosphate buffer 0.1 *M*, pH 7, 22°C. $[GSH]_t$ (*a*), $[H_2O_2]_t$ (*b*), ΔOD^{250} (*e*), ΔOD^{305} (*d*). T_a = 3 h 20 min, addition of GSH 10^{-2} *M*, ΔOD^{250} (*e'*), ΔOD^{305} (*d'*).

It seems that 1 mol of H_2O_2 disappears without oxidizing the thiol function. To find out what has become with H_2O_2, three experiments have been done.

(a) Oxygen measurements

We have tested the possibility of formation of oxygen by Gilson Oxygraph (see Experimental section) in a solution initially containing GSH and H_2O_2 at the same concentration 10^{-3} *M* (phosphate buffer, pH 7). However, neither at the beginning nor during the reaction was any formation of oxygen observed. Hence H_2O_2 is not oxidized nor does it disproportionate.

(b) Addition of an excess of GSH

An excess of GSH was added (see Fig. 3, time T_a) ($[GSH] \simeq 10^{-2}$ *M*) when H_2O_2 had totally disappeared, i.e. 3 h 20 min after the beginning of the reaction ($[H_2O_2]_0 = [GSH]_0 = 10^{-3}$ *M*, phosphate buffer 10^{-1} *M*, pH 7). We observed a new formation of GSSG (curve *e'*) whose final concentration was equal to 9.85×10^{-4} *M*. Hence this total concentration of GSSG is about the initial H_2O_2 amount (85%), leading us to conclude that an excess of GSH is necessary to reduce quantitatively the whole amount of hydrogen peroxide.

(c) Addition of catalase

To determine the nature of the oxidant property in the final solution, we added catalase 10^{-7} *M*, six hours after mixing the reactants GSH and H_2O_2 ($[GSH]_0 = [H_2O_2]_0 = 10^{-3}$ *M*, phosphate buffer 10^{-1} *M*, pH 7). We observed the formation of oxygen in concentration 5×10^{-4} *M* corresponding to the bound H_2O_2 whereas there was no free H_2O_2 (measured by the titanium method) in the reaction medium.

3. Studies of the X^{305} intermediate

We have shown that the decrease of X^{305} intermediate gives rise to 15% of the total GSSG formed (see Fig. 1*b*). Thus the oxidation process occurring via X^{305} was a minor one. Hence X^{305} cannot be responsible of the oxidant property of the final solution. Nevertheless, to determine the nature of X^{305}, we attempted HPLC analysis of the reaction medium to detect a possible sulfonate product, GSO_3H. We found no GSO_3H because either it was not present or its concentration was too small to be detected by our experimental conditions ($<10^{-5}$ *M*). To determine the chemical behavior of X^{305} we checked the effect of GSH or H_2O_2 on the reaction. An excess of GSH ($\simeq 10^{-2}$ *M*) was added when the differential optical density at 305 nm was maximum (T_a), ($[H_2O_2]_0 = [GSH]_0 = 10^{-3}$ *M*, phosphate buffer 10^{-1} *M*, pH 7). As it can be seen in Fig. 3, we observed that ΔOD^{305} (curve *d'*) increases and remains constant until the end of the reaction. Consequently an excess of GSH protects the X^{305} intermediate and it seems that there is an equilibrium between GSH and X^{305}.

A similar phenomenon has been observed (Fig. 4) when the GSH initial concentration is greater than those of H_2O_2 ($[GSH]_0 = 10^{-3}$ *M*, $[H_2O_2]_0 = 5 \times 10^{-4}$ *M* phosphate buffer 10^{-1} *M*, pH 7). Thus at the end of this reaction ($\simeq$4 h 30 min), free H_2O_2 has totally disappeared (curve *b*), GSSG 5×10^{-4} *M* is formed (curve *e*, ΔOD^{250}), half of GSH is still present (curve *a*) and the X^{305} intermediate reached a plateau value ΔOD^{305} = 0.075 (curve *d*) and does not decrease. In inset of Fig. 4, the differential absorption spectra recorded for different times after mixing are reported. There is no isobestic point because the X^{305} intermediate does not disappear. Therefore we confirm that an initial excess of GSH protects the X^{305} intermediate.

Hydrogen peroxide 2×10^{-3} *M* was added when ΔOD^{305} was maximum (T_b), ($[GSH]_0 = [H_2O_2]_0 = 10^{-3}$ *M*, phosphate buffer 10^{-1} *M*, pH 7). As it can be seen in Fig. 5, the added H_2O_2 accelerates the decrease of X^{305} (curve *d*) giving GSSG (curve *e*). Figure 5 inset shows the differential absorption spectra recorded after the addition of H_2O_2 present an isobestic point at 268 nm, showing that the X^{305} intermediate is transformed into GSSG. We can therefore conclude that H_2O_2 reacts with the X^{305} intermediate to give GSSG.

A similar phenomenon occurs when the initial concentration of H_2O_2 is greater than those of GSH as it can be seen in Fig. 6 ($[GSH])_0 = 10^{-3}$ *M*, $[H_2O_2]_0 = 2.5 \times 10^{-3}$ *M*, phosphate buffer 10^{-1} *M*, pH 7). When ΔOD^{305} is maximum (curve *d*, $t \simeq$

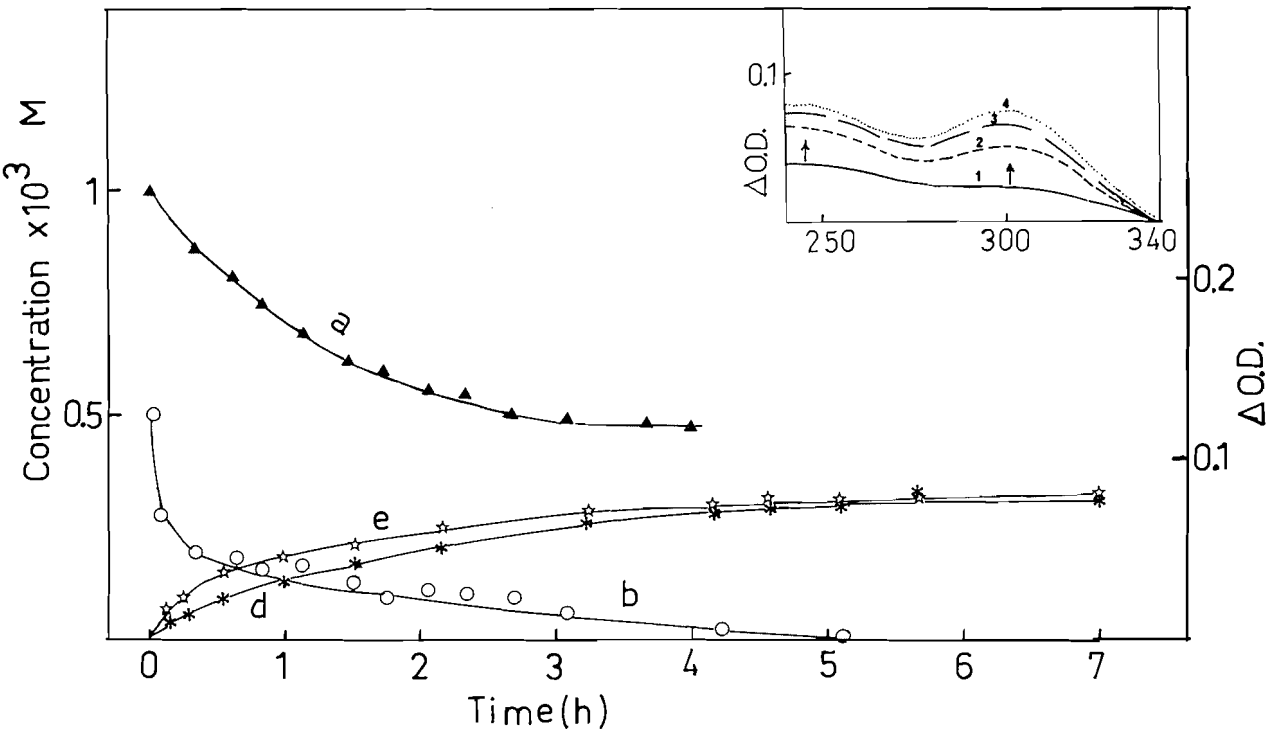

FIG. 4. Kinetic curves of [GSH] (*a*), $[H_2O_2]_0$ (*b*), ΔOD^{250} (*e*), and ΔOD^{305} (*d*). $[GSH]_0 = 10^{-3}$ *M*, $[H_2O_2]_0 = 5 \times 10^{-4}$ *M*, phosphate buffer 0.1 *M*, pH 7, 22°C. Inset: differential absorption spectra of the reaction mixture: (*1*) 32 min, (*2*) 2 h 10 min, (*3*) 3 h 15 min, (*4*) 5 h 7 min after the start of the reaction.

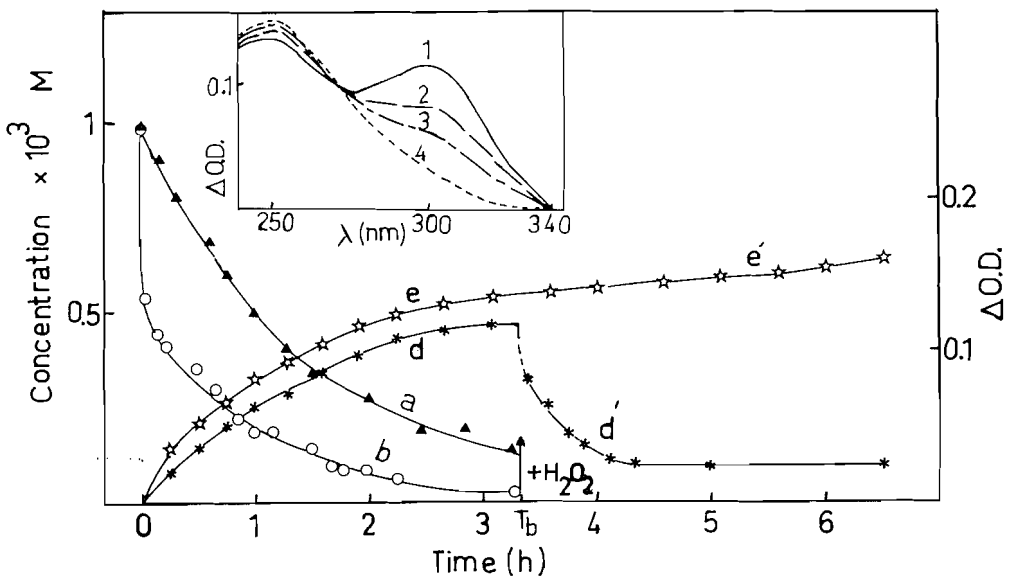

FIG. 5. Addition of $[H_2O_2]$ at the end of a reaction. Initial reaction: $[GSH]_0 = [H_2O_2]_0 = 10^{-3}$ *M*, phosphate buffer 0.1 *M*, pH 7, 22°C. $[GSH]_t$ (*a*), $[H_2O_2]_t$ (*b*), ΔOD^{250} (*e*), ΔOD^{305} (*d*). T_b = 3 h 20 min, addition of H_2O_2 2×10^{-3} *M*, ΔOD^{250} (*e'*), ΔOD^{305} (*d'*). Inset: the differential absorption spectra after the addition of H_2O_2 2×10^{-3} *M*: (*1*) 3 h 20 min (time 0 for the addition of H_2O_2), (*2*) 3 h 25 min, (*3*) 3 h 45 min, (*4*) 4 h after the beginning of the reaction.

50 mn), free H_2O_2 has a high concentration (1.5×10^{-3} *M*, curve *b*) resulting in the X^{305} intermediate decreasing faster than when there is no free H_2O_2 in the medium (Fig. 1*b*, curve *4*). During the decrease of X^{305}, however, hydrogen peroxide remains constant. The decay of X^{305} is thus catalyzed by H_2O_2. Figure 6 inset shows the differential absorption spectra, recorded at different times after the mixing, present an isobestic point at 268 nm when ΔOD^{305} decreases showing the transformation of X^{305} into GSSG.

Discussion

Fast initial decay of H_2O_2

The fast decay of H_2O_2 can be explained by the formation of a compound between GSH and H_2O_2 which could be, for

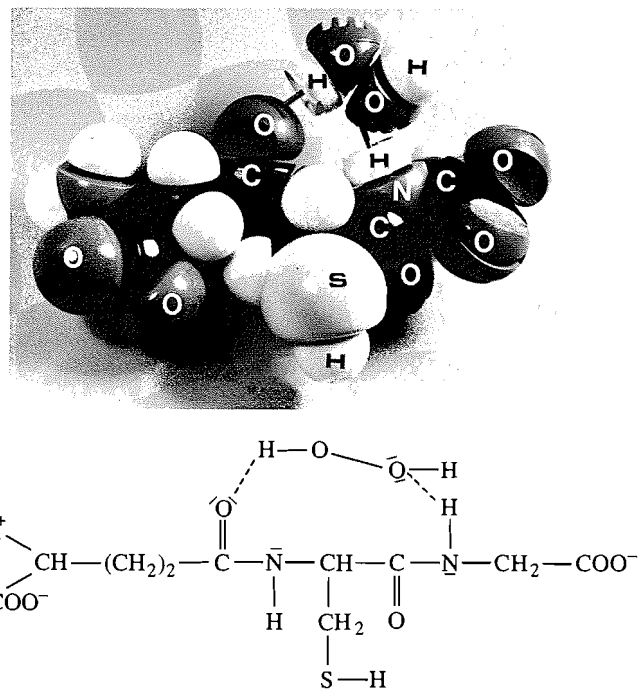

FIG. 8. A chelate model between GSH and H_2O_2.

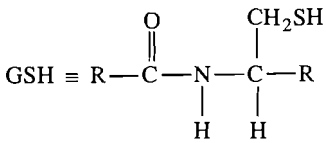
example, either a peroxide (covalently bond) or a chelate (hydrogen bonds). If we suppose that this product is formed with 1 mol of GSH and 1 mol of H_2O_2, we will use the symbole [GSH—H_2O_2], according to the equilibrium [2]

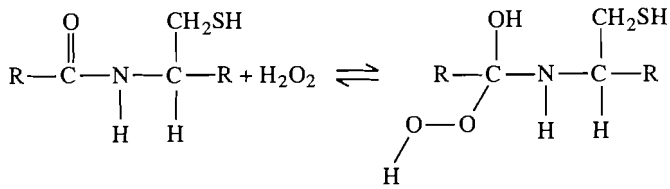
[2] $GSH + H_2O_2 \rightleftharpoons [GSH—H_2O_2]$ K_2

Since the thiol function of this complex [GSH—H_2O_2] is measured by the Ellman's method (see Experimental section) the curves showing [GSH] versus time would represent the sum [GSH] + [GSH—H_2O_2] versus time. We have to notice that the peroxide or the chelate ([GSH—H_2O_2]) cannot be determined

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.



by the titanium method. Let us suppose the concentration of the complex is equal to the concentration of initial disappearance of free H_2O_2. The equilibrium constant is given by



$$K_2 = \frac{[GSH—H_2O_2]_{eq}}{[GSH]_{eq}[H_2O_2]_{eq}}$$

$$= \frac{[H_2O_2]_0 - [H_2O_2]_{eq}}{([GSH]_0 - [H_2O_2]_0 + [H_2O_2]_{eq})[H_2O_2]_{eq}}$$

These values are reported in Table 1. A plot of $[GSH—H_2O_2]_{eq}$ against $[H_2O_2]_{eq} \times [GSH]_{eq}$ is given in Fig. 7, the straight line being consistent with the above mentioned hypothesis. The slope of this line gives $K_2 = 1950 \pm 50$.

Several hypotheses can be considered on the nature of the complex symbolized by $[GSH—H_2O_2]$. It would be a chelate formed from two hydrogen bonds between H_2O_2 and the peptide parts of the glutathione molecule (see Fig. 8 as a model). Another possibility could be a peroxide formed by the nucleophilic addition of H_2O_2 on one of the carbonyl groups of GSH according to

Such an organic peroxide could account for the residual oxidizing power noted experimentally. This type of addition is well known for aldehydes and ketones and, for example, the equilibrium constant between HCHO and H_2O_2 has been determined to be 7000 M^{-1} (17). Thus our value for $K_2 = 1950 \pm 50$ is consistent with this type of addition or adduct formation.

Kinetic scheme

Our experimental results can be explained by two separate kinetic pathways. Pathway I involves reaction [2] and [3]; and pathway II is composed of reactions [4] to [7]

Pathway I
[2] $GSH + H_2O_2 \rightleftharpoons [GSH—H_2O_2]$
[3] $2[GSH—H_2O_2] \rightarrow [GSSG—H_2O_2] + H_2O$

Pathway II
[4] $[GSH—H_2O_2] \rightarrow GSOH + H_2O$
[5] $2GSOH \rightleftharpoons GSH + GSO_2H$
[6] $GSO_2H + [GSH—H_2O_2] \rightarrow [GSSG—H_2O_2] + H_2O_2$
[7] $GSOH + H_2O_2 \rightarrow GSO_2H + H_2O$

In pathway I, equilibrium [2] indicates the disappearance of H_2O_2 without oxidizing the thiol, giving the complex $[GSH—H_2O_2]$ which cannot be distinguished from GSH by the Ellman's method. $[GSH—H_2O_2]$ could disproportionate according to reaction [3], giving the final product $[GSSG—H_2O_2]$ which accumulates. The formation of this peroxide or chelate between GSSG and H_2O_2 is consistent with the following experimental results: at the end of a reaction, when there is no free H_2O_2 (*i*) the addition of catalase stimulates the formation of oxygen (see Fig. 2, curve *c*) and (*ii*) the presence of an excess of GSH gives an amount of GSSG equal to those of the hound peroxide (see Fig. 3, curve *e'*).

In pathway II, reaction [4] occurs in competition with reaction [3] and could explain the formation of another oxidized from of GSH like, for example, GSOH, which is named X^{305} in the text. This reaction which can be described as a nucleophilic attack on H_2O_2 initiates the minor oxidation mechanism. It is consistent with previous works where H_2O_2 acts with thiocyanate (6), 2-mercaptoethanol (8), hydrogen sulfide (2), thiourea or *N,N'*-dialkylthioureas (4) giving an intermediate type of RSOH.

We have admitted that GSOH diproportionates according to reaction [5] giving GSH and GSO_2H, this reaction being similar to those of CySOH (18) and HSOH (2). The backward reaction [−5] could explain the stabilization of the intermediate GSOH when an excess of GSH is present at the end of a reaction (see Fig. 3). GSO_2H would react with $[GSH—H_2O_2]$ giving $[GSSG—H_2O_2]$ according to reaction [6]. Both reactions [5] plus [6] explain the transformation of GSOH (= X^{305}) into $(GSSG—H_2O_2]$ (λ_{max} = 250 nm) that is consistent with the presence of an isobestic point (268 nm) when the intermediate X^{305} decays (see Figs. 1, 5, and 6, curves *iii*, *d'*, *d*); reaction [7] takes place only when there is an excess of free H_2O_2 in the medium and could explain the fast decrease of X^{305} (see Figs. 5 and 6). The sum of the reactions [7] plus [6] involves the non-decomposition of H_2O_2 as it has been experimentally verified (see Fig. 6, curve *d*), the decay of X^{305} being catalyzed by H_2O_2.

Simulation of the kinetic curves have been done by four successive steps; one step for pathway I and three other steps for pathway II.

(i) Pathway I: We have calculated only with pathway I (reactions [2], [−2], and [3]), the three rate constants k_2, k_{-2}, and k_3 (knowing the experimental constant $K_2 = 1950 \pm 50$) with the following values:

$$k_2 \geq 15\ M^{-1}\ s^{-1}$$
$$k_{-2} \geq 7.5 \times 10^{-3}\ s^{-1}$$
$$K_2 = 2000 \pm 700$$
$$k_3 = 0.9 \pm 0.1\ M^{-1}\ s^{-1}$$

The kinetic scheme [2], [−2], and [3] is consistent with 85% of the overall oxidation of GSH and the calculated curves agree with experimental ones during 1.5 to 2 half times (calculated curves not shown).

Several comments can be made. The quantitative treatment of the kinetic scheme shows that reaction [3] is the rate-limiting step for GSH oxidation. Indeed rate constant k_3 (0.9 $M^{-1}\ s^{-1}$) is smaller than the rate constant of the initiation reaction k_2 (≥ 15 $M^{-1}\ s^{-1}$). We gave the lower limit values of the rate constants k_2 and k_{-2} which are consistent with the k_3 limiting step value (the ratio k_2/k_{-2} being constant). The slow decay of free H_2O_2 can be explained by the displacement of equilibrium [2] to the right by reaction [3]. Two reactions [2] and [3] correspond to the overall reaction:

[8] $2GSH + 2H_2O_2 \rightarrow [GSSH—H_2O_2] + 2H_2O$

We have calculated that 80–85% of the total of $[GSSG—H_2O_2]$ is formed according to both reactions [2] and [3] ($k_2 \geq 15$ $M^{-1}\ s^{-1}$, $k_{-2} \geq 7.5 \times 10^{-3}\ s^{-1}$, $K_2 = 2000 \pm 700$, $k_3 = 0.9 \pm 0.1\ M^{-1}\ s^{-1}$).

(ii) Pathway II: This pathway involves three other steps. We have determined the rate constant k_4 of reaction [4] which initiates the minor oxidation process by studying the kinetic formation of X^{305}. We have made the following hypothesis: since the disappearance of X^{305} gives the formation of GSSG,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

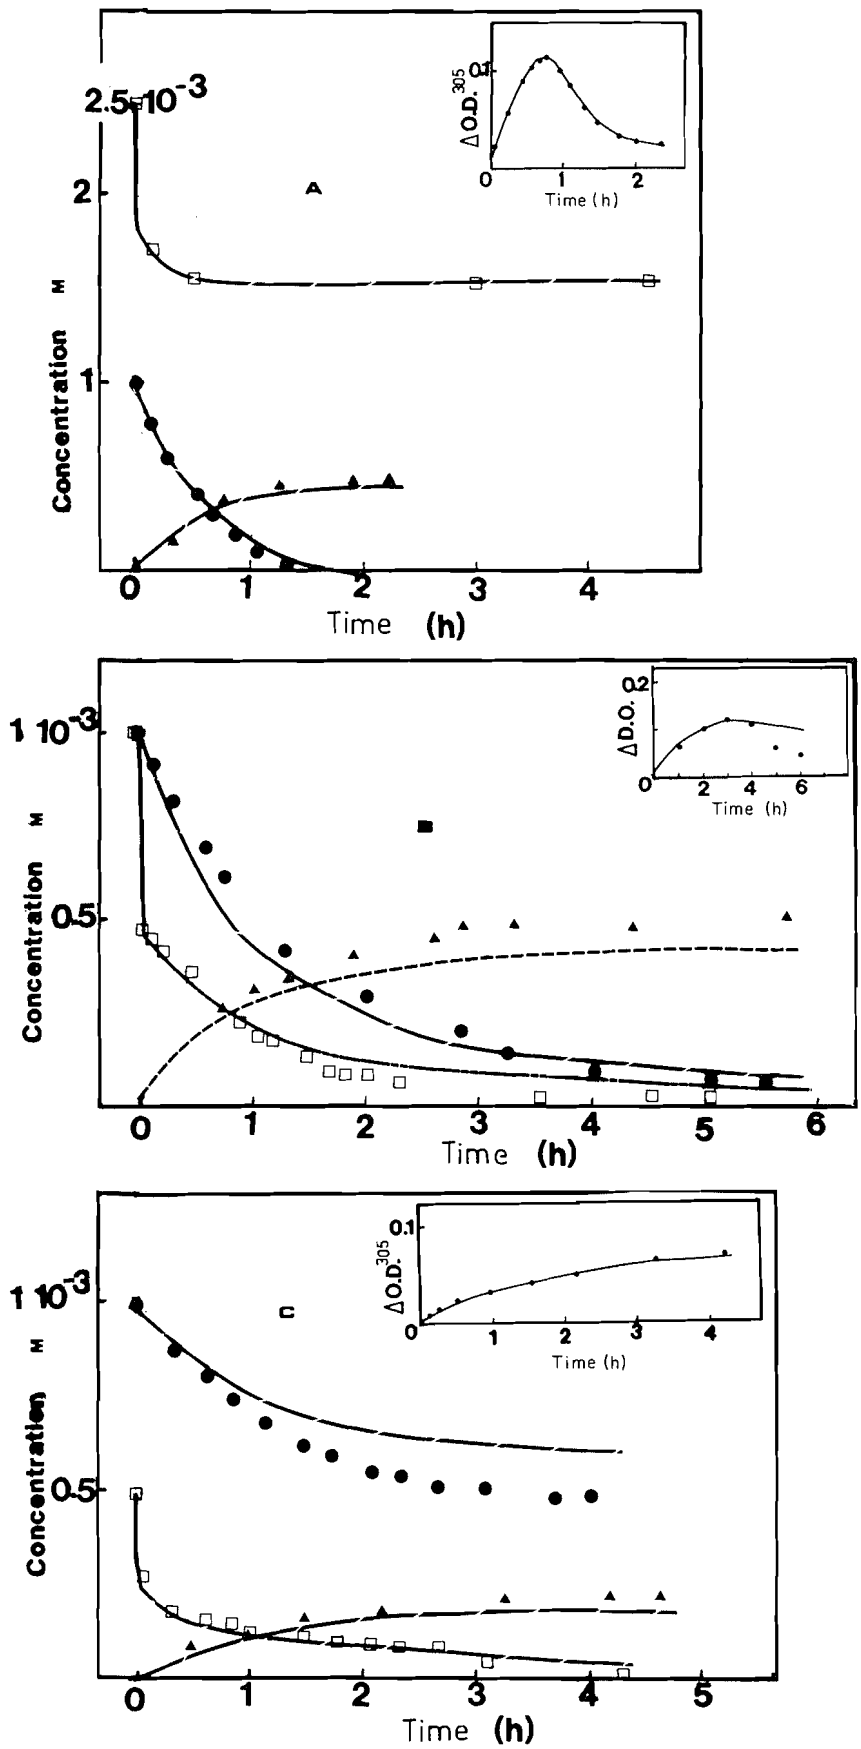


FIG. 9. Comparison between the computed kinetic curves and the experimental points [GSH] + [GSH − H_2O_2] (●), [H_2O_2] (□), [GSSG—H_2O_2] (▲) for three different experiments: (*A*) $[GSH]_0 = 10^{-3}$ *M*, $[H_2O_2]_0 = 2.5 \times 10^{-3}$ *M*; (*B*) $[GSH]_0 = [H_2O_2]_0 = 10^{-3}$ *M*; (*C*) $[GSH]_0 = 10^{-3}$ *M*, $[H_2O_2]_0 = 5 \times 10^{-4}$ *M*, phosphate buffer 0.1 *M*, pH 7, 22°C. Inset: computed curves of ΔOD^{305} (taking $\Delta\epsilon^{305} = 750 \pm 50$ M^{-1} cm^{-1}, see text) for three experiments (points are experimental).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

we supposed that the variation $\Delta[X^{305}]$ was equal to [GSSG]/2. Therefore

$$\Delta\epsilon X^{305} = \frac{\Delta OD^{305}}{\Delta[GSSG]/2} = 750 \pm 50\ M^{-1}\,cm^{-1}$$

Using this method we could obtain the evolution of X^{305} concentration and consequently the initial rate of formation of X^{305}. Thus from different experimentations we have obtained the mean value of k_4 which is equal to $(1.5 \pm 0.5) \times 10^{-4}\ s^{-1}$.

The second step was the determination of k_7 and k_6. As we have seen before in the experimental results (paragraph 3), the decay of X^{305} is accelerated by added H_2O_2 (Fig. 5). This phenomenon has also been seen when $[H_2O_2]_0 > [GSH]_0$ (Fig. 6). Hence we have supposed that reactions [7] and [6] were predominant under these conditions and that reactions [5] and [−5] can be ignored.

k values of reactions [7] and [6] have been calculated using the kinetic scheme composed of reactions [2], [−2], [3], [4], [7], and [6]. The following k values gave the best agreement with the experimental curves in Fig. 6:

$$k_7 = 0.25 \pm 0.05\ M^{-1}\,s^{-1}$$

$$k_6 = 30 \pm 5\ M^{-1}\,s^{-1}$$

The third step consists of the calculation of the rate constants k_5 and k_{-5} in the case where $[GSH]_0 \geq [H_2O_2]_0$ (Fig. 9*C*). We then used the total kinetic scheme comprising reactions [2], [−2], [3], [4], [5], [−5], [6], and [7] to obtain

$$k_5 = 0.05 \pm 0.02\ M^{-1}\,s^{-1}$$

$$k_{-5} = 0.06 \pm 0.01\ M^{-1}\,s^{-1}$$

From these we obtain

$$K_5 = 0.83 \pm 0.17$$

Thus this reaction mechanism (reactions [2] to [7]) has been shown to adequately describe all kinetic results (Fig. 9 *A*, *B* and *C*).

Figure 9 *A*, *B*, and *C* insets show the calculated curves of ΔOD^{305}, points are experimental. We can see a good agreement with the experimental values.

When there is initially an excess of GSH it can be supposed that another reaction takes place, for example,

[9] $[GSSG—H_2O_2] + 2GSH \rightarrow 2GSSG + 2H_2O$

This reaction explains the results reported before showing that an excess of GSH gives an amount of GSSG equal to those of the peroxide $[GSSG—H_2O_2]$.

Reactions [8] and [9] add together to give reaction [1], in good agreement with the usually accepted overall reaction:

[1] $2GSH + H_2O_2 \rightarrow GSSG + 2H_2O$

Hence when there is a sufficient excess of GSH, the overall stoichiometry of the reaction could be accurately expressed by reaction [1].

Conclusion

The analytical methods used in this work allowed us to measure (*i*) free H_2O_2 and not other peroxide with the titanium method, (*ii*) the SH group with Ellman's method, (*iii*) the disulfide S—S with the enzymatic NADPH reduction or with the differential absorption at 250 nm, (*iv*) the intermediate X^{305} (which could be GSOH) with the differential absorption at 305 nm.

Our kinetic data indicate that in our experimental conditions $(0.2 \leq [GSH]_0/[H_2O_2]_0 \leq 2)$ the overall oxidation equation has been established to be 2 mol GSH with 2 mol of H_2O_2 giving 1 mol GSSG:

[8] $2GSH + 2H_2O_2 \rightarrow [GSSG—H_2O_2] + 2H_2O$

This implicates that an important part of H_2O_2 disappears without oxidizing the thiol function. We attributed this result to the formation of a peroxide or a chelate between GSH and H_2O_2, in which bound H_2O_2 cannot be measured by our titanium sulphate method.

Since GSH can rapidly scavenge H_2O_2 before reducing it, GSH appears as a carrier of H_2O_2 and therefore as a protector against the toxicity of H_2O_2.

Moreover, it has been shown that the oxidation of GSH by H_2O_2 has also a minor oxidation process (15% of the total GSSG formation). This phenomenon is mediated by an intermediate compound absorbing at 305 nm, which has been seen by McCormick *et al.* (9) in the same conditions.

Reçu le 6 juin 1988[2]

BRIGITTE CHARLES, HELENE GUINAUDEAU, JEAN BRUNETON et PIERRE CABALION. Can. J. Chem. **67**, 1257 (1989).

À côté de huit aporphinoïdes, six alcaloïdes possédant une structure de morphinane ont été isolés des parties aériennes de *Stephania zippeliana* Miq. (Ménispermacées) : quatre d'entre eux sont nouveaux : la (+)-erromangine **2**, la (+)-tannagine **3**, la (+)-zippeline **5** et la (+)-zippelianine **6**. La (+)-stephodeline **1**, la (+)-isostephodeline **4** et les composés **2** et **3** sont isomères. La structure de la (+)-isostephodeline **4** a été corrigée.

Mots clés : *Stephania zippeliana*, morphinanes, alcaloïdes.

BRIGITTE CHARLES, HELENE GUINAUDEAU, JEAN BRUNETON, and PIERRE CABALION. Can. J. Chem. **67**, 1257 (1989).

Eight aporphinoids and six morphinans have been isolated from aerial parts of *Stephania zippeliana* Miq. (Menispermaceae): four of them are new: (+)-erromangine **2**, (+)-tannagine **3**, (+)-zippeline **5**, and (+)-zippelianine **6**. The previously isolated alkaloids (+)-stephodeline **1**, (+)-isostephodeline **4**, and compounds **2** and **3** are isomeric. The structure of (+)-isostephodeline **4** has been revised.

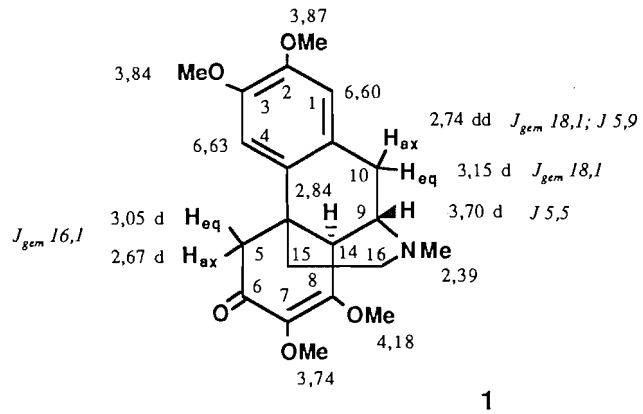
Key words: *Stephania zippeliana*, morphinans, alkaloids.

L'analyse de l'extrait alcaloïdique total obtenu à partir de 3 kg des parties aériennes sèches de *Stephania zippeliana* a fourni 14 alcaloïdes dont huit aporphinoïdes; ces derniers sont quatre aporphines, la (+)-corydine, la (+)-dicentrine, la (+)-crebanine et la (+)-stesakine, deux oxoaporphines, la dicentrinone et l'oxocrebanine et deux hydroxy-4 aporphines, la (+)-épiglaufidine et la (+)-hydroxy-4 dicentrine (1). Les six autres alcaloïdes sont des morphinanes, la (+)-stephodeline **1**, la (+)-erromangine **2**, la (+)-tannagine **3**, la (+)-isostephodeline **4**, la (+)-zippeline **5** et la (+)-zippelianine **6**. Les alcaloïdes **1** et **4** ont été isolés précédemment à partir de *Stephania delavayi*; les autres sont nouveaux.

Les alcaloïdes **1**, **2**, **3**, **4** sont isomères. Leurs spectres de masse (impact électronique) sont qualitativement semblables mais diffèrent par l'abondance des ions. Le pic moléculaire à m/z 373 correspond à la formule brute $C_{21}H_{27}O_5N$. Le spectre infrarouge de ces quatre composés présente deux bandes d'absorption vers 1615 et 1665 cm^{-1} mettant en évidence une fonction carbonyle conjuguée.

Le premier morphinane nouveau isolé est la (+)-erromangine **2**. Le spectre de rmn du proton (reporté autour de la formule **2**) présente quatre singulets de trois protons chacun dus à quatre méthoxyles (δ 3,78, 3,83, 3,84 et 4,08 ppm). Un système de quatre signaux conjugués est présent dans la région des protons aliphatiques; ce système est dû à un groupement méthylène (doublet de doublet à δ 2,68 ppm, et doublet à δ 3,18 ppm, J_{gem} = 17,7 Hz) conjugué à un groupement CH (doublet à δ 3,83 ppm, J_{ax} = 5,5 Hz), lui-même couplé à un second groupe CH (singulet élargi à δ 2,42 ppm). La présence de cet enchaînement -CH_2—CH—CH- est en faveur d'un squelette morphinane et exclut une structure hasubanane qui est caractérisée par la présence d'un système -CH_2—CH_2-. Les constantes de couplages des signaux de la séquence CH_2—CH—CH sont du même ordre que celles observées pour la stephodeline **1** (reportées autour de la formule **1**), et indiquent un enchaînement *trans* des cycles B et C de la (+)-erromangine comme pour la (+)-stephodeline (2). Dans la région des protons aromatiques, la présence de deux singulets de un proton à 6,59 et 6,60 ppm indique que le cycle A est substitué en 2,3. Deux doublets de un proton chacun à δ 2,83 et 2,88 ppm, présentant une constante de couplage de 16 Hz, sont dus à un groupement méthylène isolé. L'existence simultanée de la fonction carbonyle conjuguée et d'un groupement méthylène isolé dans la molécule impose que le groupement carbonyle soit en 6 ou 8. La différence des déplacements chimiques des protons en 14 et en 5, ainsi que celle d'un des méthoxyles du cycle C, indique une substitution différente de ce cycle C entre la stephodeline **1** et l'alcaloïde **2**. Dans le cas de la stephodeline, l'étude des effets Overhauser indique que le groupement carbonyle est en 6; en effet, l'irradiation du proton en 14 provoque l'augmentation du signal dû au méthoxyle à 4,18 ppm et inversement. Par suite, pour la (+)-erromangine **2**, la fonction carbonyle ne peut être qu'en 8.

L'étude du spectre de rmn du ^{13}C confirme cette attribution. Le déplacement chimique du carbone 5 est de 48,2 ppm dans le spectre de **1** et 39,1 ppm dans celui de **2**. La valeur observée dans le spectre de **2** est à rapprocher de celle présentée par la (+)-tridictyophylline (δ 34,6 ppm) (3) ou de celle observée dans le cas de la (+)-stephaphylline (δ 37,2 ppm) (4).



Le deuxième alcaloïde isolé, la (+)-tannagine **3**, présente, sur son spectre de masse, des fragmentations différentes de celles observées sur le spectre de masse de **1** et de **2**. En particulier, le fragment à m/z 59 a une abondance de 15% alors qu'il est pratiquement inexistant sur le spectre des alcaloïdes précédents; l'abondance de ce fragment est considérée comme indicative d'un enchaînement *cis* (5, 6).

Le spectre de rmn ^1H de **3** diffère de celui de l'alcaloïde précédent par la présence du signal dû au méthoxyle en 7 dans les champs plus élevés (δ 3,32 ppm), par le déplacement vers les champs plus faibles du multiplet dû à un des protons en C-15 (δ 1,47 ppm) ainsi que par la modification des constantes de couplage des protons en C-9 et C-14. Le découplage sélectif

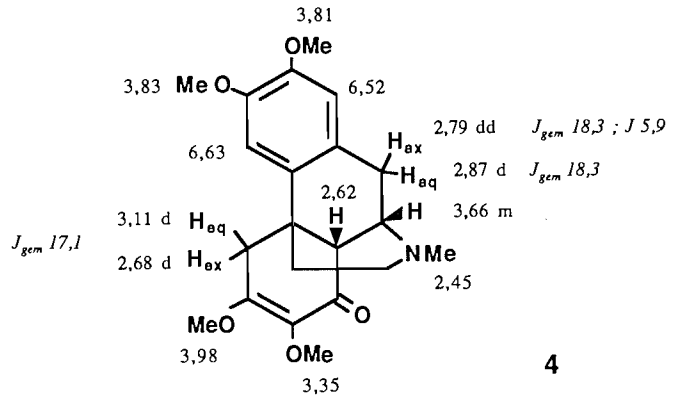
du spectre de rmn du proton ainsi qu'une étude des effets Overhauser confirment l'enchaînement *cis* des cycles B et C. En particulier, l'irradiation du doublet du proton en 14 (δ 3,09 ppm) entraîne une augmentation de l'intensité du multiplet à δ 1,92 ppm dû à H-15_{ax}, l'effet inverse étant également observé. L'analyse du spectre de ^{13}C permet de placer la fonction carbonyle en 6 étant donné le déplacement chimique du carbone 5 à 48,9 ppm; en effet, cette valeur est voisine de celle observée sur le spectre de la (+)-stephodeline **1**. La (+)-tannagine est donc un céto-6 morphinane tétraméthoxylé en 2, 3, 7 et 8 avec une jonction *cis* des cycles B et C. Cette structure est celle qui a été attribuée à la (+)-isostephodeline (7). Cependant, les données spectrales de la (+)-tannagine **3** sont différentes de celles décrites pour la (+)-isostephodeline.

Le morphinane **4**, isolé au cours de notre travail, présente en revanche des données spectrales identiques à celles indiquées pour la (+)-isostephodeline (7).

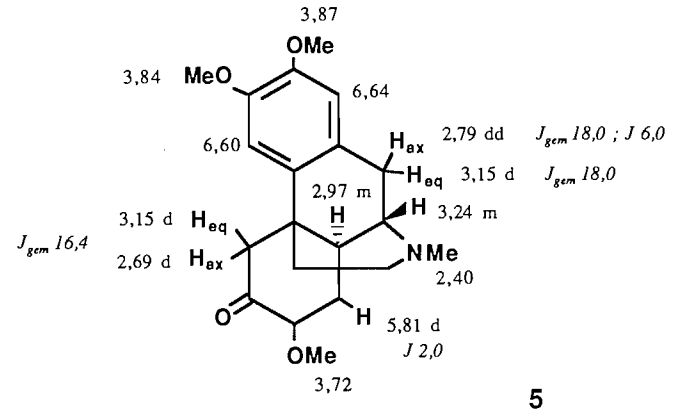
Le déplacement chimique à δ 39,2 ppm du carbone 5 sur le spectre de ^{13}C de l'alcaloïde **4** permet de placer la fonction carbonyle en 8 et non en 6 comme indiqué antérieurement pour l'isostephodeline. D'une part, les valeurs des constantes de couplage des signaux dus aux protons en 9 et 14 sont proches de celles observées dans le spectre de la (+)-tannagine; d'autre part, l'étude des effets Overhauser montre un effet réciproque entre les protons en 14 (δ 2,62 ppm) et celui en 15_{ax} (δ 1,92 ppm). De plus, le fragment à m/z 59 a une abondance de 12%. Ces données permettent de déterminer la stéréochimie *cis* de la jonction des cycles B et C. De même que pour les deux alcaloïdes précédents, le déplacement chimique du carbone 5 dans le spectre de ^{13}C est indicatif de la position du carbonyle; ce carbone résonnant à δ 39,2 ppm, la cétone doit être en 8.

La (+)-isotephodeline **4** est donc un céto-8 morphinane d'enchaînement B/C *cis* et la (+)-stephaphylline de *Stephania suberosa* lui est identique (4).



Les deux autres morphinanes isolés appartiennent au même type structural. La (+)-zippeline **5** a pour formule brute $C_{20}H_{25}O_4N$ et son spectre de masse présente un pic moléculaire décalé de 30 uma par rapport à celui de la (+)-stephodeline. Le spectre de rmn du proton de **5** est proche de celui de la (+)-stephodeline; cependant, il ne présente que trois singulets attribuables à des méthoxyles (δ 3,72, 3,84, 3,87 ppm) et comporte un doublet supplémentaire (δ 5,81 ppm, J = 2 Hz) dû à un proton qui couple avec celui en 14 (δ 2,97 ppm) comme l'a indiqué le découplage systématique. Une étude partielle des effets Overhauser montre une augmentation réciproque des intensités des signaux entre les protons en 8 et 14. Le méthoxyle porté par le carbone 8 dans la (+)-stephodeline est remplacé dans la (+)-zippeline **5** par un hydrogène.

Le dernier alcaloïde isolé, la (+)-zippelianine **6**, présente des données spectrales également proches de celles de la (+)-stephodeline **1**. Le spectre de masse de **6** présente un pic moléculaire à $M^{+\bullet}$ 359, c'est à dire inférieur de 14 uma à celui de la (+)-stephodeline; il correspond à la formule brute $C_{20}H_{25}O_5N$. Le spectre uv présente un effet bathochrome en milieu alcalin, ce qui indique la présence d'une fonction phénolique. Le spectre de rmn du proton montre l'absence du singulet dû au méthoxyle en 2 qui résonne sur le spectre de la (+)-stephodeline à δ 3,87 ppm. Une étude partielle des effets Overhauser montre la proximité du méthoxyle qui résonne à 3,85 ppm et du proton en 4 (δ 6,59 ppm). La (+)-zippelianine **6** est donc une (+)-déméthyl-2 stephodeline. La méthylation de l'alcaloïde **6** par le diazométhane conduit à la (+)-stephodeline **1**.



Jusqu'alors, l'étude approfondie des spectres de rmn du proton des céto-6 ou céto-8 morphinanes (enregistrement des spectres à hauts champs, découplage, étude des effets Overhauser) ne permettait pas de déterminer avec certitude la stéréochimie de la jonction des cycles B et C. Seul le déplacement chimique du carbone 5 sur le spectre de ^{13}C est indicatif de la position du carbonyle en position 6 ou 8. L'examen du spectre de masse en impact électronique n'est pas non plus concluant. En effet, l'abondance de l'ion fragment à m/z 59 ne semble pas être un élément de diagnostic très sûr en ce qui concerne l'enchaînement des cycles B et C; cette abondance n'est en effet pas reproductible d'un spectre à l'autre, les conditions dans lesquelles sont enregistrées les spectres semblant intervenir de façon non négligeable.

Par contre, l'étude des spectres en ms/ms en ionisation chimique positive nous a donné des résultats dépourvus d'ambiguïté (8); dans le cas d'un céto-6 morphinane, l'ion fragment correspondant aux carbones 7 et 8 éliminé aux cours des fragmentations (m/z 87 dans le cas d'une substitution diméthoxy-

4

5

6

7,8) est abondant. Dans le cas d'un céto-8 morphinane, c'est le fragment correspondant à l'élimination des carbones 6 et 7 qui est important (*m/z* 101 dans le cas d'une substitution diméthoxy-7,8); ces résultats sont très reproductibles (8).

Dans la mesure où il nous a été possible d'analyser les données spectrales d'au moins un alcaloïde correspondant à chaque type d'enchaînement des cycles B et C ainsi que des deux positions du groupement carbonyle, des règles de détermination de structure par analyse des déplacements chimiques des spectres de rmn du proton sont proposées.

Le déplacement chimique du singulet dû au méthoxyle en 7 permet de différencier un enchaînement B/C *cis* ($\delta \approx 3{,}35$ ppm) d'un enchaînement *trans* ($\delta \approx 3{,}75$ ppm); de même le proton équatorial en 15 résonne à des champs plus élevés dans le cas d'un enchaînement *trans* ($\delta \approx 1{,}15$ ppm) que dans le cas d'un enchaînement *cis* ($\delta \approx 1{,}50$ ppm). Enfin, la valeur de la constante de couplage entre les protons en 9 et 14 est différente dans les deux types d'enchaînement, ce qui entraîne un aspect différent des signaux concernés (l'aspect attendu de doublet pour H-14 et de doublet dédoublé pour H-9 étant plus net dans le cas de l'enchaînement *cis* que dans celui d'un enchaînement *trans*). La position du groupement carbonyle en 6 ou 8 ne peut être déterminée que par l'examen du spectre de rmn du ^{13}C; le déplacement chimique du signal dû au carbone 5 permet de différencier les deux types de composés; ce déplacement est de l'ordre de 39 ppm dans le cas d'un céto-8 morphinane, alors qu'il est d'environ 49 ppm lorsque la fonction cétone est en 6; le déplacement vers les champs faibles est, dans ce dernier cas, dû à la proximité de la cétone.

Partie expérimentale

Appareillage

Les pouvoirs rotatoires sont mesurés à température ambiante dans le chloroforme à l'aide d'un polarimètre Schmidt et Haensch, les spectres uv enregistrés sur un appareil Beckman 530 et les spectres ir sur un spectromètre Perkin Elmer 580. Les spectres de rmn du proton ont été réalisés sur des solutions dans le $CDCl_3$ à l'aide des appareils Varian EM 360 (60 MHz) et Bruker WB 360 (360 MHz) et WM 500 (500 MHz). Les spectres de carbone 13 ont été enregistrés également sur des solutions dans le $CDCl_3$ à l'aide d'un appareil Bruker WM 500.

Matérial végétal

L'échantillon (3 kg de parties aériennes ligneuses) a été récolté en juillet 1984 à Erromango (Vanuatu) sur la pente nord de la péninsule du Rantop et est référencé sous le n° 187.

Extraction des alcaloïdes et purification

Après traitement de la poudre par l'hexane, l'extraction des alcaloïdes conduite suivant le processus classique (alcalinisation du marc suivi d'une extraction par le chlorure de méthylène et d'une purification par passage à l'état de sels) fournit 42 g d'alcaloïdes totaux (rendement 1,4%). Les alcaloïdes sont isolés et purifiés par chromatographie sur colonne de silice (silice pour ccm) puis par chromatographie préparative sur couche mince.

Description des produits isolés

(+)-Stephodeline **1** (rendement 4,5%) : $[\alpha]_D$ +20° ($CHCl_3$, *c* 0,60); ir (KBr) : 1665, 1615 cm^{-1}; uv (EtOH) : 273, 224, 212 nm; rmn ^1H : 2,30 (m, H-15_{ax}), 1,15 (m, H-15_{eq}), 2,09 (m, H-16_{ax}), 2,37 (m, H-16_{eq}); rmn ^{13}C : 110,3 (C-1), 147,5 (C-2), 147,5 (C-3), 106,5 (C-4), 48,2 (C-5), 193,9 (C-6), 137,1 (C-7), 162,9 (C-8), 52,2 (C-9), 26,8 (C-10), 133,4 (C-11), 133,4 (C-12), 34,6 (C-13), 48,2 (C-14), 32,7 (C-15), 45,9 (C-16); sm (IE) *m/z* : 373 (80) $M^{+\bullet}$, 358 (60), 342 (100), 330 (40), 222 (11), 192 (1,7), 59 (1,8). *Masse Exacte* calc. pour $C_{21}H_{27}O_5N$: 373,1894; trouvé (sm) : 373,1889.

Received January 5, 1989

KIMIHIKO HIRAO and PAUL KEBARLE. Can. J. Chem. **67**, 1261 (1989).

The geometries and the energies of the reactants, transition state, and products for the gas phase reaction: $Cl^- + CH_3Br = ClCH_3 + Br^-$, were obtained from *ab initio* calculations using a closed shell SCF method with a MINI basis set developed by Huzinaga *et al.* The energy changes predicted by the calculations are found in good agreement with the experimental data. The energies and geometries of the reactants and the transition state for the gas phase reactions: $Cl^- + RBr = ClR + Br^-$, where $R = C_2H_5$ and iso-C_3H_7, were also obtained. The resulting activation energies follow the same trend as the experimental data: Me < Et < iso-Pr; however, the predicted increase of activation energy is considerably larger. The energies and geometries for the reactants, transition state, and products of the gas phase ion-dihydrate reaction: $Cl^-(H_2O)_2 + CH_3Br \rightarrow H_2O(ClCH_3Br)^-H_2O \rightarrow Br^-(H_2O)_2 + CH_3Cl$ were obtained as well. These data provide an interesting comparison with experimental results in aqueous solution. The reaction coordinate of the ion-dihydrate reaction is very much closer to that for aqueous solution than to that for the gas phase.

Key words: nucleophilic substitution reactions, ion–molecule reactions, activation energy.

KIMIHIKO HIRAO et PAUL KEBARLE. Can. J. Chem. **67**, 1261 (1989).

Faisant appel à des calculs *ab initio* et utilisant la méthode en champ auto-cohérent, en couches fermées et basée sur un ensemble MINI, qui a été développée par Huzinaga et ses collaborateurs, on a déterminé les géométries ainsi que les énergies des réactifs, des états de transition et des produits de la réaction en phase gazeuse : $Cl^- + CH_3Br = ClCH_3 + Br^-$. On a trouvé que les changements d'énergie prédits par les calculs sont en bon accord avec les données expérimentales. On a aussi déterminé les énergies et les géométries des réactifs et des états de transition pour les réactions en phase gazeuse : $Cl^- + RBr = ClR + Br^-$ dans lesquelles $R = C_2H_5$ et iso-C_3H_7. Les énergies d'activation qui en résultent sont dans le même ordre que les données expérimentales : Me < Et < iso-Pr; toutefois, l'augmentation prédite pour l'activation d'énergie est beaucoup plus grande. On a aussi déterminé les énergies et les géométries des réactifs, des états de transitions ainsi que des produits de la réaction en phase gazeuse du dihydrate ionique : $Cl^-(H_2O)_2 + CH_3Br \rightarrow H_2O(ClCH_3Br)^-H_2O \rightarrow Br^-(H_2O)_2 + CH_3Cl$. Ces données fournissent une base intéressante de comparaison avec les résultats expérimentaux déterminés en solution aqueuse. Les coordonnées de la réaction du dihydrate ionique sont beaucoup plus proches de celles de la réaction en solution aqueuse que de celles de la réaction en phase gazeuse.

Mots clés : réactions de substitution nucléophile, réactions ion–molécule, énergie d'activation.

[Traduit par la revue]

Introduction

Studies of the kinetics and mechanism of bimolecular nucleophilic S_N2 reactions in solution have played a fundamental role in the development of physical organic chemistry (1). More recently a number of kinetic studies of S_N2 reactions in the gas phase were also reported and these have been recently reviewed (2*a*). The gas phase kinetic studies also include hydrated ionic reactants (2*b*). A number of quantum mechanical calculations relating to the structures and energies of reactants and transition states are also available (3, 4).

Reaction [1] is probably the most extensively studied S_N2 process in solution and has also received much attention in gas phase work. Experimental measurements of the rates of [1] in

[1] $Cl^- + RBr = ClR + Br^-$

R = Me, Et, *n*-Pr, iso-Pr, *n*-Bu, iso-Bu

the gas phase provide information on key points of the reaction coordinate, i.e., potential energy profile of the reaction. Initial work by Brauman and co-workers (5) based on ICR measurements at a single temperature led to a framework for the interpretation of the low pressure data, leading to predictions for the height of the energy barrier associated with the transition state. This was followed by work from this laboratory (6–8) at higher pressures and at variable temperature, which extended the results and interpretation.

The present work presents results from *ab initio* calculations for R = Me, Et, and iso-Pr. These data allow a comparison to be made between the experimental and theoretical data. Since the motivation for much of the above work was to seek comparison with the analogous reactions in solution (7, 8), the present calculations also include results that illustrate the effect of the presence of solvent molecules (H_2O) on the reaction coordinate for the reaction involving MeBr.

Results and discussion

a. Method of calculation, general

The energy profiles of reaction [1] (R = Me, Et, iso-Pr) were constructed on the basis of closed shell SCF calculations with a MINI basis set developed by Huzinaga *et al.* (9). A variety of basis sets was tested to determine the theoretical level appropriate for the present problems, particularly for the relative energies involved. The larger basis sets lead to improved

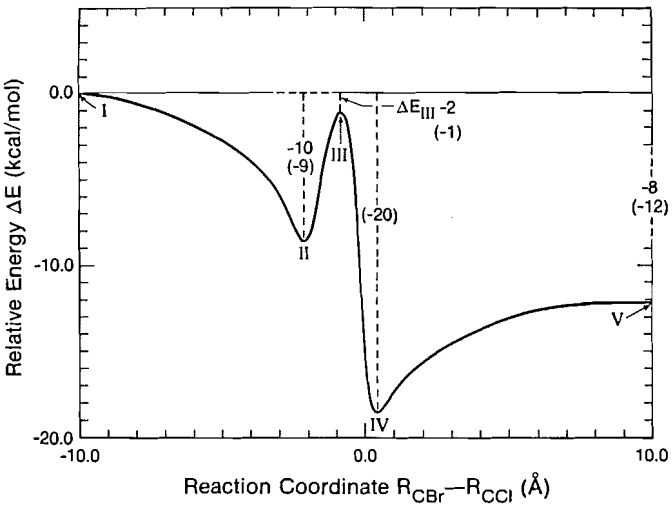

FIG. 1. Reaction coordinate for: $Cl^- + CH_3Br = ClCH_3 + Br^-$ in the gas phase. Energy changes in kcal/mol, without parentheses experimental results, with parentheses present calculations. For geometries of I–V see Fig. 2 and Table 1.

prediction for the energy of the individual molecules such as CH_3Cl and CH_3Br, but the agreement with experiment was not as good for the relative energies that are involved in Fig. 1. The SCF with MINI basis set provides a uniformly good description for the four key points on the reaction surface, viz., the separated reactants, the ion–dipole complex, the transition state, and the products. The good performance of this theoretical level may be due to fortuitous cancellation of errors arising from the incomplete basis set and neglect of electron correlation.

The energy profiles were obtained by using given fixed R_{CCl} values and optimizing the remaining geometry parameters with the energy gradient method.

b. Reaction coordinate of $Cl^- + CH_3Br \rightarrow ClCH_3 + Br^-$

The resulting energy profile is given in Fig. 1. It includes the energies of the reactants I, the precursor ion–dipole complex II, the transition state III, the post reaction ion–dipole complex IV, and the products V. The optimized geometries of I–V are given in Fig. 2.

The full reaction profile was constructed by calculating the energies at 17 points between reactants and products. For each fixed value of R_{ClC}, the remaining geometry parameters were optimized in C_{3v} symmetry. The calculated geometries and energies as well as the net atomic charges derived from a Mulliken population analysis are given in Table 1. The reaction coordinate, R_C is defined as

$$R_C = R_{CBr} - R_{ClC}$$

The R_C reflects the symmetry of the reaction. In the present calculations R_C takes on values of $-\infty$, -1.005 Å, -0.008 Å, 1.443 Å, and ∞ for the reactants, the ion–dipole complex, the transition states, the post reaction ion–dipole complex, and the products.

The increase of the H—C—Br angle (111.30°) in the dipole complex II relative to the angle in undisturbed CH_3Br (109.6°) must be due to the attractive interaction of the partially positive hydrogens of the CH_3 group with the negative Cl^-. The increase of the C—Br bond (2.073 Å) in II relative to that in undisturbed CH_3Br (2.026 Å) is quite small, see Fig. 2.

The transition state III has a geometry that is somewhat closer

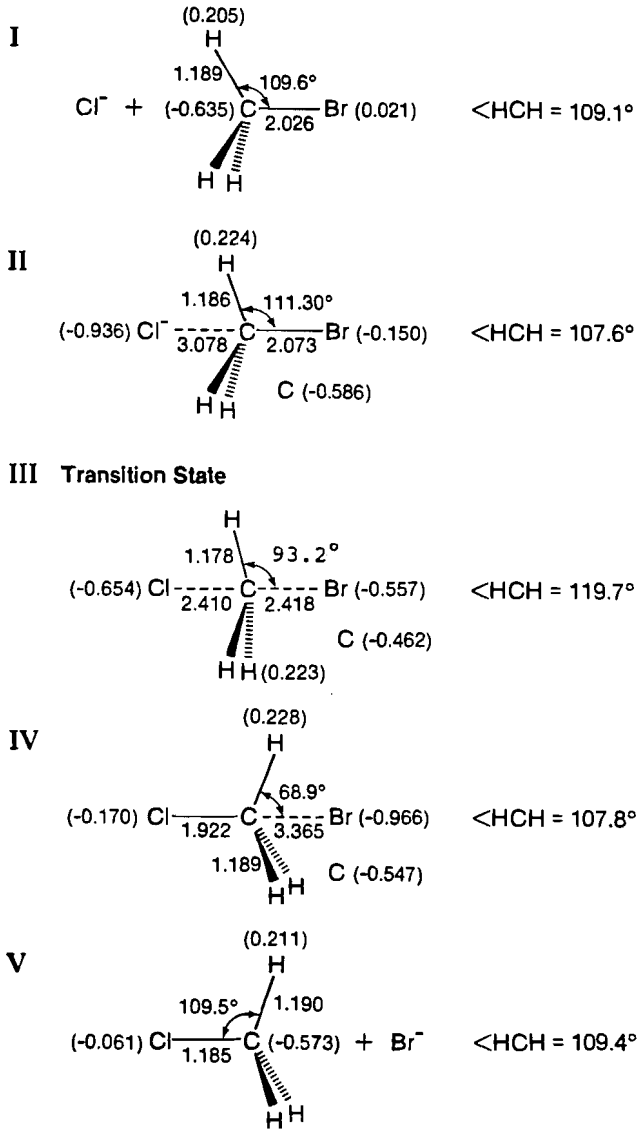

FIG. 2. Optimized geometries of reactants and transition state for gas phase reaction: $Cl^- + CH_3Br = ClCH_3 + Br^-$. Values in parentheses are net atomic charges. Distance is in angström, energies in atomic units.

to the reactants than the products. Thus the H—C—Br angle, although decreased relative to that in II and in CH_3Br, is still not 90° but 93.24°, see Fig. 2. Also, more of the negative charges appears on the Cl (−0.66) when compared to that on Br (−0.55).

In the dipole complex IV, $Br^-...CH_3Cl$, the H—C—Cl angle (111.1°) is similar to the analogous H—C—Br angle (111.3°) in the dipole complex II, i.e., now the attraction between the partially positive H atom and the Br^- pulls the CH_3 umbrella in, towards the negative Br^-.

Examining the data in Table 1 one finds that the distances R_{CCl} and R_{CBr} change smoothly as the system moves from the reactants to the products. The change in R_{CH} is also smooth but small. The change in the net atomic charges on Cl and Br is given in Fig. 3. The charge migration from Cl^- to Br also occurs smoothly and changes rapidly in the region of the transition state. The charge delocalization effect is maximum at the

[a]Distances in angstroms, angles in degrees, and relative energies in kcal/mol. Cl^-: −457.302114, Br^-: −2562.219615, CH_3Br: −2601.449297, CH_3Cl: −496.551118 (au).

transition state and this stabilizes the complex at the point where the chemical bond weakening is at its maximum.

The opening and shutting of the CH_3 umbrella as a function of the reaction coordinate is also shown in Fig. 3. In the initial stage of the reaction, the CH_3 umbrella shuts a little to help the approach of the Cl^-, which accelerates the reaction. This implies that the electrostatic attraction between the somewhat positive H atoms on the CH_3 group and the negative Cl^- plays a dominant role in the long-range interaction. Beyond this point, the umbrella begins to open and approaches a planar CH_3 at the transition state region. After the transition state, the umbrella begins to shut again in the opposite direction and overextends somewhat on formation of the dipole complex IV.

The theoretically predicted energy changes are very close to those determined experimentally and are also given in Fig. 1. Thus, the binding energy in the ion–dipole complex II is calculated as 9 kcal/mol while the experimental result is ~10 ± 1 kcal/mol, Larson and McMahon (10). The ΔE_{III}, i.e., the difference in energy between the transition state and the reactants, is −0.8 kcal/mol calculated, while the experimental results (5, 7) give −2 kcal/mol. Experimental data for the dipole complex IV, $Br^-...CH_3Cl$, are not available; however, the exothermicity of the reaction, ΔE_V, can be obtained from thermochemical data (7), so that the comparison of −12 kcal/mol, theoretical, versus −8 kcal/mol, experimental, can be made.

c. The $Cl^- + C_2H_5Br = C_2H_5Cl + Br^-$ and $Cl^- + iso\text{-}C_3H_7Br = iso\text{-}C_3H_7Cl + Br^-$ reactions

The energies of the reactants and the transition state were calculated. The transition state energies relative to the reactants and the geometries are given in Table 2 and in Figs. 4 and 5.

Methyl substitution increases the energy of the central barrier in Fig. 1 and increases ΔE_{III} from −0.9 for CH_3 to +5.3 for C_2H_5 and +15.7 kcal/mol for iso-C_3H_7. The changes are in the same direction as those observed by experiment (7); however, the calculation predicts progressively higher energies, see Table 3.

The increase of the energy barrier with methyl substitution is generally attributed to a steric effect. The net atomic charges of the reactant alkyl bromides, see Figs. 3, 4, and 5, provide an elaboration of this effect. As the negative Cl^- approaches the CH_3 group it experiences an attractive interaction with the three positive hydrogens, see preceding section. When one of the hydrogens is replaced by methyl, as in ethyl bromide, the carbon of the new methyl group has a negative charge (−0.54), see Figs. 4, 5, and the exchange repulsion with the negative Cl^- leads to an increase of energy. The effect repeats itself with the next new methyl for hydrogen replacement, i.e., isopropyl-bromide, see Fig. 5. The increasing repulsion with methyl substitution leads also to a very noticeable deviation from linearity in the $Cl^{-\delta}$—C—$Br^{-\delta}$ axis of the transition state, which is R = Me, 0.0°; R = Et, 13.2°; R = iso-Pr, 17.5°, see Figs. 4 and 5.

Concerning the discrepancy with the experimental ΔE_{III}, see Table 3, we give precedence of the experimental results over the calculated ones, particularly since the present calculations do not include diffuse augmentary basis functions. However, it should be mentioned that the interpretation of the experimental results (7) was not fully satisfactory. It was pointed out (7) that the preexponential factors of the rate constants k_1 increased by two orders of magnitude from MeBr to iso-PrBr. This is an unexpected result that could indicate a change of mechanism. One possibility is the occurrence of elimination, E2, rather than substitution for the larger alkyl groups. This alternative was considered, see discussion on p. 965 of ref. 7, and rejected

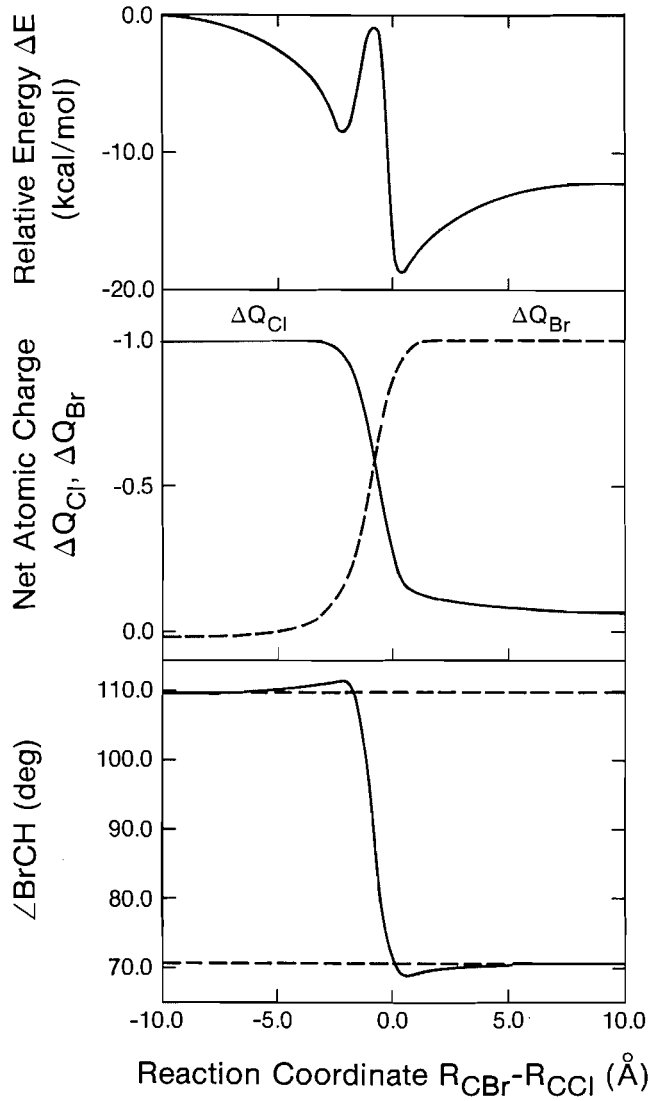

FIG. 3. Changes of relative energy ΔE (kcal/mol), net atomic charge on Cl resp. Br, Q_{Cl} resp. Q_{Br}, in atomic units, and angle BrCH for dilute gas phase reaction: $Cl^- + CH_3Br \rightarrow ClCH_3 + Br^-$ predicted by calculation.

on the basis of the known endothermicity of the reactions. However, the endothermicity is removed if the elimination proceeds initially not to HCl + Br^- but to $BrHCl^-$, which later dissociates (7). While the intermediate $BrHCl^-$ was not observed (7), this does not constitute a proof that it was not formed. Another alternative is a change of the transition state of the S_N2 reaction for the higher alkyl bromides. For example, one could speculate that in these reactions the Cl^- comes in on the same side as the Br atom and displaces it without Walden inversion. When the present calculations were made, such "extreme" transition state geometries were not considered.

d. Effect of dihydration on the reaction: $Cl^- + CH_3Br = ClCH_3 + Br^-$

Ab initio SCF calculations were performed also for the gas phase reaction:

$$Cl^-(H_2O)_2 + CH_3Br \rightarrow HOHCl\cdots C(H)(H)\cdots Br^-HOH \rightarrow ClCH_3 + Br^-(H_2O)_2$$

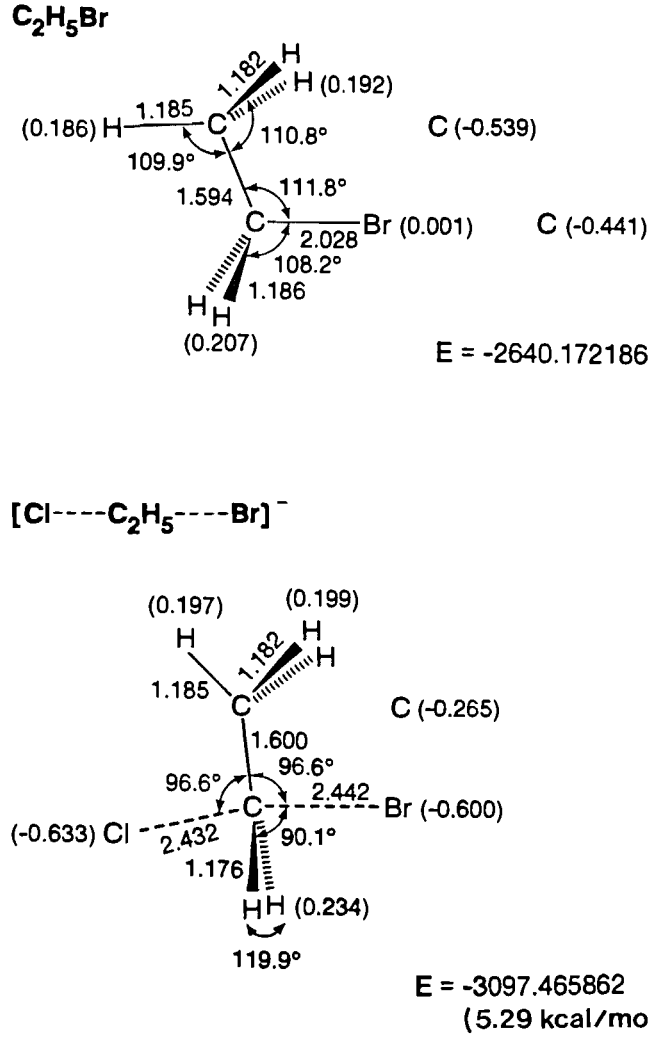

FIG. 4. Optimized geometries of ethyl bromide and transition state for gas phase reaction: $Cl^- + C_2H_5Br = ClC_2H_5 + Br^-$. Values in parentheses are net atomic charges. Distance is in angström, energies in atomic units.

Only partial geometry optimizations were performed for the dihydrate reaction. The geometries of the ion–dipole complex I, the transition state III, and the ion–dipole complex IV were taken as in the water-free reaction, see Fig. 2. However, the positions of the two water molecules were optimized in each case. The standard experimental geometries were used throughout for the H_2O molecules, i.e., O—H = 0.96 Å and HOH = 104.5°.

The optimized geometries of $Cl^-(H_2O)_2$, the dihydrate of the transition structure, and $Br^-(H_2O)_2$ are given in Fig. 6. It should be noted that the dihydrate of the transition structure $(ClCH_3Br)^-$ given in Fig. 6 should not be considered as the transition state of the gas phase reaction. As has been pointed out by Henchman and co-workers (11), states of higher energy occur as one of the two solvent molecules is transferred from the Cl side to the Br side of the transition structure ($ClCH_3Br$). Results from *ab initio* calculations, due to Morokuma (3*k*), giving points on the reaction coordinate of the symmetric Cl^- substitution reaction [2], *vide infra*, illustrate the energy increases associated with the transfer of a water molecule for the dihydrate reaction. The symmetrically hydrated transition structure in Fig. 6 represents, rather, one of the intermediate states of the reaction, and this state is of special interest from

shown for four important positions in the reaction coordinate. The origins of the experimental data are given in the Appendix. The three cases A, B, C provide an interesting comparison. Although the ion dihydrate curve B is only ~27 kcal/mol below the gas phase, i.e., ΔE_I (B) = −27, while ΔE_I (C) = −86 kcal/mol, it is much closer in its general shape to the solution curve (C) than to the gas phase (A). Thus, the activation energies ΔE_{III} are (A) −2, (B) 18, (C) 26 kcal/mol. The depths of the well for the precursor complex are (A) −22, (B) −4, (C) 0, and the energy changes for the reaction ΔE_V are: (A) −8, (B) −5, (C) −4.6. Thus the presence of only two water molecules attached to the ion in the reactants, transition state, and products provides a good qualitative model for the major energy changes occurring in solution.

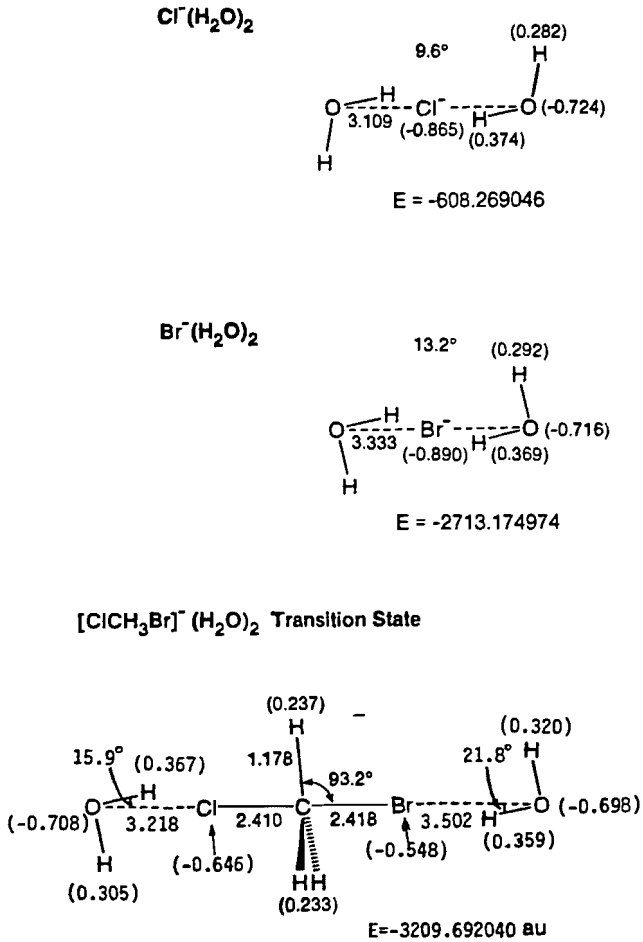

FIG. 6. Optimized geometries for ion dihydrate reaction: $Cl^-(H_2O)_2 + CH_3Br = CH_3Cl + Br^-(H_2O)_2$ giving geometries of hydrated ions, including the dihydrated transition state. Distances are in angströms, energies in atomic units. Values in parentheses are net atomic charges.

calculations was obtained by Jorgensen and co-workers (4) and was then used for Monte Carlo simulation of the effect of the liquid solvents. Jorgensen's work, which involves much more extensive calculations, provides very valuable insights on the solvation effects and the specific action of protic (H_2O) and dipolar aprotic solvents (DMF). It is interesting to note that reliable experimental rate constants for reaction [2] in the gas phase were published only very recently (12). Apparently, these results confirm Jorgensen's activation energy; however, details on how the rate data were used to obtain the activation energy were not given (12).

The present results, which deal with the computationally more difficult bromine-atom-containing reaction [1] and the effect of the alkyl groups, are expected to be less accurate. Also, the present results deal with hydration by only two molecules. Nevertheless they should be useful. Reaction [1] has been the subject of numerous experimental studies and can be considered as the historic prototype of aliphatic S_N2 processes. The very limited dihydration results, see Fig. 7, while not a quantitative model for aqueous solution, have didactic value since they illustrate, on the basis of only two solvent molecules, the major energy changes occurring with solvation, i.e., the large decrease of solvation of the charge dispersed ionic transition state II relative to the solvation of the ionic reactant Cl^-.

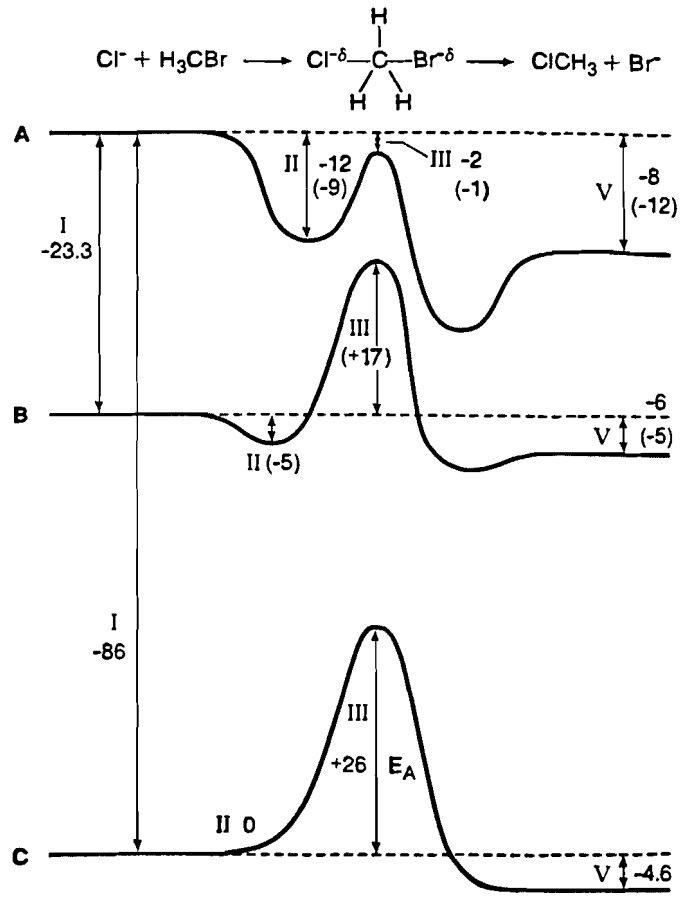

FIG. 7. Schematic reaction coordinates for reaction $Cl^- + CH_3Br = ClCH_3 + Br^-$; (A) in the gas phase, (B) ions including ionic transition state are dihydrated, see Fig. 6 (C) in aqueous solution. Energy changes in kcal/mol, values without parentheses from experiment, values in parentheses from present calculations. For origin of experimental values see Appendix. ΔE_I are energies of reactants B and C relative to gas phase reactants. Other energies are relative to reactants in the given phase. Energy changes drawn approximately to scale.

Appendix: Energy changes based on experimental measurements

The experimental energy changes for the gas phase coordinate (A) in Fig. 7 were discussed in Sect. (b), see Fig. 1.

The experimental energy change ΔE_I for B in Fig. 7 corresponds to $\Delta H^0_{0,2}$, i.e., the enthalpy change for the gas phase reaction: $Cl^- + 2H_2O = Cl^-(H_2O)_2$. This is obtained from $\Delta H^0_{0,1} + \Delta H^0_{1,2}$ for Cl^-. Experimental results by Arshadi *et al.* (13*a*) and Keese and Castleman (13*b*) provide $\Delta H^0_{0,2} = -27 \pm 3$ kcal/mol. Setting the zero energy level for the reaction at $Cl^- + CH_3Br + (H_2O)_2$ and using the dimerization energy of H_2O, $\Delta H = -3.7$ kcal/mol (14), one obtains $\Delta H_I \approx \Delta E_I = -23.3 \pm 3$ kcal/mol.

The ΔE_V for curve B in Fig. 7 corresponds to $\Delta E_V = \Delta H^0_{0,2}(Br^-) - \Delta H^0_{0,2}(Cl^-) + \Delta H^0_V(A) = -25 + 27 - 8 = -6 \pm 3$ kcal/mol, where $\Delta H^0_{0,2}(Br^-) = -27 \pm 3$ kcal/mol is from Arshadi *et al.* (13*a*).

The $\Delta E_{II} = -4$ kcal/mol for curve B in Fig. 7 is a rough estimate. $\Delta H^0_{2,3}(Cl^-) = 10.5$ kcal/mol (13*a*) for H_2O. The required value is not for H_2O but for CH_3Cl addition to $Cl^-(H_2O)_2$. We have taken 0.3 of $\Delta H^0_{2,3}$, i.e., $\Delta E_{II} = -0.3 \times 10.5 = -4$ kcal/mol. The factor 0.3 is justified by the larger effective distance expected between Cl^- and the locus of the dipole and the polarizability of CH_3Cl relative to that of H_2O.

The $\Delta E_I = -86$ kcal/mol for curve C, aqueous solution, was obtained from the hydration energies of Cl^-, $\Delta H_h = -81.3$ kcal/mol, Desnoyers and Jolicoeur (15), and the hydration energy of CH_3Br, $\Delta H_h(CH_3Cl) \approx -5$ kcal/mol (16), and $\Delta E_I = \Delta H_h(Cl^-) + \Delta H_h(CH_3Br) = -86.3$ kcal/mol.

The $\Delta E_{III} = +26$ kcal/mol is the activation energy in aqueous solution, Bathgate and Moelwyn-Hughes (17).

The ΔE_V is based on the hydration energies $\Delta H_h(Cl^-) = -81.3$ kcal/mol (15), $\Delta H_h(Br^-) = -77.9$ kcal/mol (15), $\Delta H_h(CH_3Cl) \approx \Delta H_h(CH_3Br)$, and $\Delta H_1 = -8$ kcal/mol in the gas phase (7). $\Delta E_{III} = \Delta H^0_1 + \Delta H_h(Br^-) - \Delta H_h(Cl^-) = -4.6$ kcal/mol.

Gibbs energies of transfer of individual ions from water to acetone + water solvents

MAHMOUD MOHAMAD ELSEMONGY[1] AND AHMED AHMED ABDEL-KHALEK[2]

Chemistry Department, Faculty of Education, Umm Al-Qura University, Al-Taif City, Shihar, Saudi Arabia

Received November 10, 1988

MAHMOUD MOHAMAD ELSEMONGY and AHMED AHMED ABDEL-KHALEK. Can. J. Chem. **67**, 1268 (1989).

The standard absolute potentials of hydrogen, Ag–AgX (X = Cl, Br, and I) and M/M^+ (M = Li, Na, K, Rb, and Cs) electrodes in nine different acetone + water solvents containing up to 80 wt.% acetone were determined from the emf data at 25°C of the cells: glass electrode/HCl (*m*), solvent/AgCl–Ag and glass electrode (M)/MX (*m*), solvent/AgX–Ag. The standard Gibbs free energies of a transfer of halogen acids and alkali metal halides as well as their constituent individual ions from water to the respective solvents were computed. The observed increases in ΔG_t^0 values of all ions with increasing acetone content of the solvent and their relative order in each solvent were interpreted and discussed. A comparison of the present results with those obtained earlier in the dimethyl sulphoxide (DMSO) + water solvents shows the different nature of the two dipolar aprotic solvents, acetone and DMSO, in their aqueous mixtures.

Key words: acetone + water solvents, electrode potentials, emf measurements, individual ions, transfer free energies.

MAHMOUD MOHAMAD ELSEMONGY et AHMED AHMED ABDEL-KHALEK. Can. J. Chem. **67**, 1268 (1989).

En se basant sur des données de fem, mesurées à 25°C, pour les cellules: électrode de verre/HCl (*m*), solvant/AgCl–Ag et électrode de verre (M)/MX (*m*), solvant/AgX–Ag, on a déterminé les potentiels absolus standard des électrodes hydrogène, Ag–AgX (X = Cl, Br et I) et M/M^+ (M = Li, Na, K, Rb et Cs) dans neuf solvants différents formés d'acétone + eau et contenant jusqu'à 80% en poids d'acétone. On a calculé les énergies libres standard de Gibbs pour le transfert des acides halogénés, des halogénures des métaux alcalins ainsi que de leurs ions constituants individuels de l'eau aux divers solvants. On interprète et on discute de l'augmentation qui est observée pour les valeurs des ΔG_t^0 de tous les ions avec une augmentation de la concentration d'acétone dans le solvant ainsi que de leur ordre relatif dans chacun des solvants. Une comparaison de résultats obtenus au cours de cette étude avec ceux obtenus antérieurement dans des solvants formés de diméthylsulfoxyde (DMSO) + eau met en évidence la nature différente des deux solvants dipolaires aprotriques, acétone et DMSO, dans leurs mélanges aqueux.

Mots clés : solvants acétone + eau, potentiels d'électrode, mesures de fem; ions individuels, énergies libres de transfert.

[Traduit par la revue]

Introduction

A new procedure for the determination of standard absolute electrode potentials in aqueous and non-aqueous, protic and aprotic solvents, as well as the thermodynamics of individual ions in these media, was described recently (1). The procedure was applied successfully to the emf data of cells connecting silver, silver halide electrodes with hydrogen or alkali metal amalgam electrodes (1–3). The interest, validity, and general applicability of the procedure in various solvent systems have been demonstrated (1–3).

As far as electrochemical methods are concerned, amalgam electrodes have been considered for a long time as the most reliable means for the determination of alkali metal ion activity in solution (4–7). However, the failure of alkali metal amalgam electrodes to function satisfactorily in acetone + water solvent mixtures has dictated the use of cation-sensitive glass electrodes to determine free energies of transfer for the alkali metal halides from water to these solvent mixtures (4). Therefore, instead of amalgam electrodes, we used glass electrodes reversible to the alkali metal ions in the cells:

[I] Glass electrode (M)/MX (*m*), solvent/AgX–Ag

(where M = Li, Na, K, Rb, and Cs for X = Cl and M = Na for X = Br and I) and also glass electrodes reversible to the H^+ ions in the cells:

[II] Glass electrode/HCl (*m*), solvent/AgCl–Ag

in order to perform emf measurements at 25°C in nine different acetone + water solvents, containing up to 80 wt.% acetone. Thus, in the present paper, the new procedure (1) is further applied to the emf data of cells [I] and [II] in the aqueous mixtures of acetone, on the one hand for verification of the used procedure for cells with glass electrodes, on the other to obtain standard absolute electrode potentials in such aqueous dipolar aprotic media as well as Gibbs free energies of transfer for individual ions from water to each solvent.

Glass electrodes were used for the determination of Gibbs free energy of transfer (ΔG_t^0) for the alkali metal chlorides from water to aqueous solvents containing *t*-butanol up to 40 wt.% (5, 6), dioxane (D) up to 40 wt.% (5), or dimethyl sulphoxide (DMSO) up to 85 wt.% (7*a*), and for HCl (7*b*) and RbCl (7*c*) to a large number of aqueous organic solvents containing up to 85 wt.% of organic solvent. Comparisons show that agreement between the two types of electrode, amalgam and glass, is generally good up to ca. 40 wt.% of organic solvent (5, 7*a*). The differences tend to increase with increasing concentration of the organic solvent, but this leaves the percentage error of the ΔG_t^0 values (4) approximately the same (ca. 2%). Therefore, Smits *et al.* (7*a*) believe that cationic glass electrode measurements not only represent a fast and easy method for determining Gibbs free energies of transfer of the alkali metal halides, but also quite an accurate one. Thus, cationic glass electrodes were used recently (4) to determine free energies of transfer of alkali metal halides from water to aqueous mixtures containing up to 60 wt.% acetone. The values of ΔE_m^0 obtained by Feakins *et al.* (4) for RbCl are uniformly higher than those obtained by Smits *et al.* (7*c*), who also used glass electrodes, by ca. 1 mV at the lowest and 2 mV at the highest acetone concentration (4). On the other hand, Bax *et al.* (8, 9), who used amalgam electrodes for KCl at 20, 40, 60, and 80 wt.% acetone, gave ΔE_m^0 values which are 4–5 mV higher than those of Feakins *et al.* (4) at the two lower concentrations. The present investigation was undertaken not

only to check the previous data but also to extend the work to other solvent compositions. This enables us to study solvent influence on standard absolute electrode potentials and related transfer free energies.

Experimental

Acetone (BDH, AnalaR) was further purified as before (10). It was stored over anhydrous $CaSO_4$ in an atmosphere of nitrogen, redistilled freshly, and used within a few hours. AnalaR and Merck quality alkali metal salts were further purified (2, 3), dried at 120°C, and kept in a desiccator over P_2O_5 (7). Redistilled deionized water (2, 3, 10) was generally used in the preparation of the solutions. All solutions were freshly prepared before taking measurements. The compositions of the solvents were accurate to ±0.01 wt.%. The solutions were all stored in dark bottles under a nitrogen atmosphere.

Emf measurements on cells [I] and [II] were carried out using Corning glass electrodes. Electrodes no. 476022 were used for H^+ ion determinations, sodium-sensitive electrodes no. 476210 for all Na^+ ion determinations, and monovalent cation selective electrodes no. 476220 for all the remaining cations. Silver, silver halide electrodes were as before (2–4, 10). The cell design, general experimental procedure, and mathematical treatment of the results were described earlier (4, 7*b*, 11). The molality of cell solutions was in the range 0.002–0.10 mol kg^{-1}. The values of m are accurate to ca. 0.01%. As reported by Feakins *et al.* (4), a possible source of error in their work is that Ag^+ ion from the halide electrodes could interfere with glass electrodes, since both were in the same cell compartment. Therefore, in our study, the two electrodes were put in different compartments, as done later by Feakins *et al.* (11), and their simpler method of compensating for drift and asymmetry potentials (11) was used. The cell measurements were made in triplicate, and the mean values of these observations recorded. The triplicates generally agreed within ±0.1 mV. The temperature of the measuring cells was carefully maintained at 25 ± 0.01°C.

Succinate buffered solutions were used with Ag–AgBr and Ag–AgI electrodes in all acetone + water solvents, as in previous investigations (12–14). In this way, it is possible to obtain steady potentials for these electrodes in solvents containing up to 80 wt.% acetone. Attempts to perform measurements with cell [I] for X = I in 90 wt.% acetone were unsuccessful as we failed to obtain steady potentials. This could have been due to dissolution of silver iodide (4).

Results

For cells [I] or [II] in water (w) and in acetone + water solvent (s), if the same glass electrode is used in each and the emf values are corrected for drift (4, 11), we can define

[1] $\Delta E = {}^{w}E - {}^{s}E$

and

[2] $\Delta G_t = F\Delta E$

where ΔG_t is the free energy of transfer of 1 mole of electrolyte from water to the mixed solvent at the stated molalities (4). The

values of ΔE were analysed in the way previously described for amalgam cells (4, 11) to give ΔE_m^0 values in the different acetone + water solvents. These are listed in Table 1. Note that the behaviour of the electrodes was so satisfactory when used as described (4, 11) that extrapolation of the individual ^wE or ^sE values obtained over a few weeks to give the individual E_m^0 values was possible; ΔE_m^0 values obtained as the difference of these data agreed well with those obtained by extrapolation of ΔE. Generally, the values of ΔE_m^0 are precise to better than ±0.1 and ±0.2 mV for solvents containing up to 50 and 80 wt.% acetone, respectively. The values of ΔG_t^0 on the molal scale calculated from ΔE_m^0 values are recorded in Table 2.

TABLE 4. The least-squares results of applying eq. [3] to the emf data of cells [I] and [II] in acetone + water solvents at 25°C, ΔG_t^0 values on the molal scale

These are therefore precise to ±10 and ±20 J mol^{-1} for solvents containing up to 50 and 80 wt.% acetone, respectively, based on the precision of the ΔE^0_m values.

Further, all the values of ${}^{w}E^0_m$ of cell [I] or [II], obtained using glass electrodes in the present investigation, agree very well with those reported recently (1, 2) for cells containing HCl or MX electrolytes with different electrodes. The values of ${}^{s}E^0_m$ of the cells, containing HCl, LiCl, NaCl, NaBr, NaI, KCl, RbCl, and CsCl in various acetone + water solvents, are given in Table 3.

Standard absolute electrode potential

The new procedure, developed recently (1, 2) for determination of absolute electrode potentials and the thermodynamics of individual ions in solution, has been applied to the emf data of cell [I] in acetone + water solvents. According to this procedure, the oxidation potential of any electrode varies directly with the radius (r) of the solvated ion on the activity of which the potential depends. Therefore, the cell emf is linearly related to the radius of the solvated ion which is being varied in a series of electrolytes having a common ion (1). Thus, in any solvent, the plot of the standard emf (E^0_m) values of cell [I], containing NaCl, NaBr, and NaI, against the radius of the solvated anion r_- should yield a straight line according to eq. [3], at any temperature (1).

$$[3] \quad E^0_m = a^0_1 r_+ - a^0_1 r_-$$

This holds in various acetone + water solvents, and the least-squares results at 25°C are collected in Table 4. In all solvents, perfect straight lines were obtained, and the extent of correlation is indicated by the correlation coefficients (corr) and the differences, Δ(mV), between the E^0_m values obtained experimentally and those calculated by eq. [4],

$$[4] \quad E^0_m = {}^{ox}_{L}E^0_m - {}^{ox}_{R}E^0_m$$

where ${}^{ox}_{L}E^0_m$ and ${}^{ox}_{R}E^0_m$ are the oxidation potentials of the left and right electrodes, respectively (1, 2). Thus, the standard absolute potential of the Na/Na^+ and Ag–AgX (X = Cl, Br, and I) electrodes, the radius (r_+) of the solvated Na^+ ion and thus its solvation extent (S_e), in the standard state, have been computed as before (1, 2).

From the computed values of the standard absolute potential of the Ag–AgCl electrode in each solvent (Table 4), those of H_2/H^+, Li/Li^+, K/K^+, Rb/Rb^+, and Cs/Cs^+ electrodes could

CsI	220	455	941	1590	2370	3372	4817	6881	9108

be obtained (by eq. [4]) from the E^{0}_{m} values of cells [II] and [I] containing HCl and LiCl, KCl, RbCl, and CsCl, respectively, Table 3. The radii of the solvated cations and their solvation extent as well as the individual ionic contributions to ΔG^{0}_{t} values of electrolytes, in each solvent, were calculated as before (1–3). All these results are also included in Table 4.

Furthermore, by coupling the standard absolute potentials ($^{ox}_{L}E^{0}_{m}$) of hydrogen or M/M^{+} (M = Li, K, Rb, or Cs) electrodes with those ($^{ox}_{R}E^{0}_{m}$) of Ag–AgX (X = Br or I) electrodes, using eq. [4], the values of E^{0}_{m} for cell [III] or [I], containing HBr, HI, LiBr, LiI, KBr, KI, RbBr, RbI, CsBr, or CsI, could be computed. Thus, all the values of E^{0}_{m} of these cells in various acetone + water solvents so computed at 25°C are listed in Table 3.

Standard Gibbs free energies

The standard free energy changes (ΔG^{0}_{E}) involved in the half-cell reactions are related to the standard absolute electrode potentials ($^{ox}_{E}E^{0}_{m}$) by the relation (1, 2):

[5] $\Delta G^{0}_{E} = -F\,^{ox}_{E}E^{0}_{m}$

Thus, the values of ΔG^{0}_{E} can be computed on the molal scale using the $^{ox}_{E}E^{0}_{m}$ values given in Table 4.

The values for the standard Gibbs free energy ΔG^{0}_{t} for the transfer of an individual ion from water to various acetone + water solvents were calculated (1–3) on the molal scale from the standard absolute electrode potentials in water ($^{w}_{E}E^{0}_{m}$) and in the respective mixed solvents ($^{s}_{E}E^{0}_{m}$), Table 4, using eq. [6].

[6] $\Delta G^{0}_{t} = F(^{w}_{E}E^{0}_{m} - {}^{s}_{E}E^{0}_{m})$

The values of ΔG^{0}_{t} calculated at 25°C on the basis of the oxidation potential scale (1–3) are also included in Table 4. These are accurate to better than 20 and 40 J mol^{-1} for solvents containing up to 50 and 80 wt.% acetone, respectively.

The values of ΔG^{0}_{t} for halogen acids as well as alkali metal halides can be obtained by coupling the transfer free energies of cations with those of anions, i.e., from the differences between those for the ion constituents, both based on the same oxidation potential scale (1–3), in any solvent.

[7] $\Delta G^{0}_{t}(HX \text{ or } MX) = \Delta G^{0}_{t}(H^{+} \text{ or } M^{+}) - \Delta G^{0}_{t}(X^{-})$

The values of ΔG^{0}_{t} so calculated at 25°C, by eq. [7], in various acetone + water solvents are listed in Table 5. To check the reliability of the calculations, the values of ΔG^{0}_{t} (Table 5) for HCl, LiCl, NaCl, NaBr, NaI, KCl, RbCl, or CsCl can be compared with those based on ΔE^{0}_{m} values and given in Table 2. Full agreement between the values is always seen.

Discussion

Now, the values of ΔE^{0}_{m} and ΔG^{0}_{t}, obtained in the present work (Tables 1 and 2), can be compared with other results. These were taken from the literature with all significant digits as they were originally given (on the molal scale) and are also included in Tables 1 and 2. For the alkali metal halides, the new values are in good agreement with most values obtained by Feakins *et al.* (4) and Smits *et al.* (7*c*), who also used glass electrodes; the differences are roughly within the combined error of the two determinations. Bax *et al.* (8) used amalgam electrodes for KCl at 20, 40, 60, and 80 wt.% acetone. Their results give ΔE^{0}_{m} values which are 4.7–5.5 mV higher than ours at the two lower concentrations. On the other hand, the agreement is good at 60 and 80 wt.% acetone. As noted before (4), the observed differences between the amalgam and glass electrodes in other systems point to an accuracy of ΔE^{0}_{m} and ΔG^{0}_{t} of 2%. This is important in comparing the present results with others.

Bax *et al.* (9) also determined differences in ΔG^{0}_{t} between the H^{+} ion and the K^{+}, Rb^{+}, and Cs^{+} ions at these solvent compositions from a combination of data obtained by emf and solubility methods. A combination of these values with those given for the sum of ΔG^{0}_{t} for the H^{+} and Cl^{-} ions leads to sets for KCl, RbCl, and CsCl which show good agreement with the new values for KCl at 60 and 80 wt.% acetone and CsCl at 40 wt.% acetone, and fair agreement for CsCl at 80 wt.% acetone.

For HCl, the new values are in good agreement (taking into account the combined precision limits of the measurements) with those of Smits *et al.* (7) at 5–60 wt.% acetone and Morel (15) at 20, 70, and 80 wt.% acetone, both obtained by glass electrode measurements, and Feakins and French (16) at 5 and 10 wt.% acetone, using hdyrogen electrodes. However, Feakins *et al.* (4) reported that hydrogen electrodes misbehave in acetone + water solvents, and therefore, the new values of ΔE^0_m in these solvents, obtained by glass electrodes should be preferred.

It is evident from Table 4 that the value of a^0_I decreases with increasing acetone content of the solvent system. As reported earlier (1, 2), the values of a^0_I appear to be universal constants for all electrodes, and dependent only on the medium, at any temperature. However, as the acetone content of the solvent increases, the radius (r_+) of the solvated H^+ ion decreases, i.e., the solvation extent of the protons decreases, and the oxidation potentials of both left and right electrodes decrease. These features have been noticed recently (1–3) in the D–, methanol (MeOH)–, ethylene glycol (EG) – , and propylene glycol (PG) – water solvent systems.

The protons, therefore, are less solvated in the mixed solvent than in water, Table 4. The solvation of protons in aqueous acetone solvents can be compared with that in aqueous DMSO solvents, where the protons become gradually more solvated (r_+ values increase) on the successive addition of DMSO to the aqueous medium (2). This reflects the different nature of the two dipolar aprotic solvents, acetone and DMSO, in their aqueous mixtures.

On the other hand, the radii of the solvated cations and thus their solvation extent increase with increasing acetone content in the solvent. This can be explained by successive substitution of water molecules by the larger sized acetone dipoles in the solvation sheath, on gradual addition of acetone to the solvent. This explanation is supported by the very interesting feature that, in any solvent, the extent of solvation increases in the expected well-known order: $Cs^+ < Rb^+ < K^+ < Na^+ < Li^+$, and the Li^+ ion is always highly solvated. Similar results were also obtained for the alkali metal ions in D–, MeOH–, EG–, PG–, and DMSO–water solvent systems (1–3). Thus, the values of r_+ indicate that, so far as any M^+ ion is concerned, any mixed solvent is a stronger solvating agent than water. This is probably due to the charge density distribution in the acetone molecule, combined with its spatial structure, which strongly favours solvation of positive M^+ ions. A relatively large negative charge is localised on the oxygen atom, while the positive charge is delocalised over the propyl group (9).

As the acetone content of the solvent increases, the oxidation potentials of H_2/H^+, M/M^+, and Ag–AgX electrodes decrease. In any solvent, the standard absolute potentials of Ag–AgX electrodes decrease in the regular expected (1–3) order: ${}^{ox}E^0_m(AG–AgI) > {}^{ox}E^0_m(Ag–AgBr) > {}^{ox}E^0_m(Ag–AgCl)$. On the other hand, the irregular order of variation of the standard absolute potentials of the alkali metal electrodes, from Li/Li^+ to Cs/Cs^+ in any solvent, is dictated by the extent of solvation of the alkali metal ions, and thus by the radii of solvated cations. These trends of variation of electrode potentials with solvent composition were observed in all the solvent systems studied recently (1–3).

It is noticed from Table 4 that the values of ΔG^0_t for all ions are positive and increase with increasing acetone concentration. The increasingly positive values of ΔG^0_t of individual ions signify that the transfer of the ions from water to acetone + water solvents is increasingly unfavourable. Thus, the values of ΔG^0_t show a qualitative resemblance to other solvent systems (1–3).

It is generally thought that changes of Gibbs free energies for the transfer from one medium to another are closely related to changes in ion solvation. Since the transfer process is not spontaneous, the ions are more strongly stabilised by solvation in water than in any aqueous acetone solvent. However, this is not reflected by the values of r_+, Table 4. Increased desolvation of the proton (r_+ values decrease), and on the other hand, increased solvation of the M^+ ions (r_+ values increase), with increasing amounts of acetone in the solvent, are observed. This is also noticed in D–, MeOH–, EG–, and PG–water solvent systems (1–3). This, and the increasingly positive values of ΔG^0_t for all (H^+ and M^+) ions indicate that there is no relationship between ΔG^0_t values and solvation of ions (2).

In any solvent, the relative order of non-spontaneity for the anions is $\Delta G^0_t(Cl^-) < \Delta G^0_t(Br^-) < \Delta G^0_t(I^-)$, while that for the cations is $\Delta G^0_t(H^+) < \Delta G^0_t(Li^+) < \Delta G^0_t(Na^+) > \Delta G^0_t(K^+) > \Delta G^0_t(Rb^+) > \Delta G^0_t(Cs^+)$. Similar behaviour has been observed in the DMSO–water solvent system (2), and the similarity in the profiles of ΔG^0_t points to a common cause for the behaviour of these simple ions in the two solvent systems.

Finally, the whole of the obtained results, in acetone + water solvents, lend another proof and extra confidence to the general applicability of the new procedure (1) applied to the emf data of cells with the glass electrodes, and hence, more reliability in the evaluated data.

General acid catalysis in the enolization of acetone

KEVIN P. SHELLY, S. VENIMADHAVAN, K. NAGARAJAN, AND ROSS STEWART[1]
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received January 27, 1989

KEVIN P. SHELLY, S. VENIMADHAVAN, K. NAGARAJAN, and ROSS STEWART. Can. J. Chem. **67**, 1274 (1989).

We have used iodometry to study the enolization of acetone in water catalyzed by a series of general acids, comprised of hydrochloric acid, methanesulfonic acid, 24 aliphatic monocarboxylic acids, nine aromatic monocarboxylic acids, eight aliphatic dicarboxylic acids, and 20 monoanions of dicarboxylic acids. The log $k-pK$ profile for unbuffered solutions of strong and moderately strong acids shows a maximum near $pK \approx 0$. The Brønsted α value for a set of eight aliphatic monocarboxylic acids in which effects of bulk, charge, and polarizability are at a minimum is 0.56. Steric effects, probably augmented by polarizability effects in some cases, cause positive deviations from the Brønsted line drawn with respect to these standard acids. Anionic carboxylic acids are also more reactive than would be predicted from their equilibrium acid strengths, whereas cationic acids tend to be less reactive. Using D_2O as solvent has only a small effect on the rate of carboxylic acid catalysis. Using acetone-d_6 gives values of k_H/k_D in the range of 7.0–8.0 at 25°C, values consistent with proton or deuteron being transferred between two bases of comparable strength, the carboxylate anion and the enol form of acetone.

Key words: general acid catalysis, enolization, Brønsted relation, steric effects, deuterium isotope effects.

KEVIN P. SHELLY, S. VENIMADHAVAN, K. NAGARAJAN et ROSS STEWART. Can. J. Chem. **67**, 1274 (1989).

On a utilisé l'iodométrie pour étudier l'énolisation de l'acétone, en milieux aqueux et sous l'influence d'une série d'acides généraux comme l'acide chlorhydrique, l'acide méthanesulfonique, 24 acides aliphatiques monocarboxyliques, neuf acides aromatiques monocarboxyliques, huit acides aliphatiques dicarboxyliques et 20 monoanions d'acides dicarboxyliques. La courbe log $k-pK$, pour des solutions non-tamponnées d'acides forts et modérément forts, présente un maximum près d'un pK de 0. La valeur α de Brønsted est de 0,56 pour un ensemble de huit acides monocarboxyliques pour lesquels les valeurs des effets d'encombrement, de charge et de polarisabilité sont minimales. Les effets stériques, probablement amplifiés dans certains cas par des effets de polarisabilité, provoquent des déviations positives par rapport à la ligne de Brønsted tracée en utilisant ces acides de référence. Les anions des acides dicarboxyliques sont aussi plus réactifs que prévu sur la base de la force de leurs acides; toutefois, les acides cationiques tendent à être moins réactifs. L'utilisation de D_2O comme solvant ne provoque qu'un léger effet sur la constante de la catalyse des acides carboxyliques. À 25°C, l'utilisation d'acétone-d_6 conduit à une valeur de k_H/k_D de l'ordre de 7,0–8,0; cette valeur est en accord avec un mécanisme dans lequel un proton ou un deutéron est transféré entre deux bases de force comparable, l'anion carboxylate et la forme énolique de l'acétone.

Mots clés : catalyse acide générale, énolisation, relation de Brønsted, effets stériques, effets isotopiques du deutérium.

[Traduit par la revue]

Introduction

The acid-catalyzed enolization of acetone occupies an important place in the evolution of our understanding of the phenomenon of general acid catalysis. In 1913, Dawson and Powis examined the effect of weak acids on this reaction and recognized that their catalytic effect was due both to the hydrogen ions that they produce and to the undissociated acid molecules themselves (1). A decade later Brønsted and Pedersen (2) showed that catalysis by the latter could be quantified, and we now refer to the governing relationship as the Brønsted equation, which appears in eq. [1] with the appropriate statistical corrections. The latter attempt to account for variations in the number of protonic sites (p) in the acid catalysts that are used and in the number of basic sites (q) in their corresponding conjugate bases (3–5).

$$[1] \quad \log (k_{HA}/p) = \alpha \log (K_{HA} q/p)$$

The mechanism of the general acid-catalyzed enolization process is generally agreed to be that shown in eq. [2] (ref. 5, p. 259, and ref. 6).

$$[2a] \quad CH_3-\overset{\overset{O}{\|}}{C}-CH_3 + H^+ \leftrightharpoons CH_3-\overset{\overset{+OH}{\|}}{C}-CH_3$$

$$[2b] \quad CH_3-\overset{\overset{+OH}{\|}}{C}-CH_3 + A^- \longrightarrow CH_3-\overset{\overset{OH}{|}}{C}=CH_2 + HA$$

[1]Author to whom correspondence may be addressed.

The present paper concerns itself with five aspects of the reaction: (a) catalysis in unbuffered systems, (b) steric and polarizability effects in HA, (c) the behaviour of cationic and anionic acids, (d) the catalytic role of monoanions of dicarboxylic acids, and (e) deuterium isotope effects.

Results and discussion

Catalysis in unbuffered systems

It has long been recognized that H^+ is generally a less effective catalyst in general acid-catalyzed proceses than would be expected from its formal pK (−1.74) (ref. 4, p. 200, and ref. 5, p. 278). The catalytic constant, k_{H^+}, for the enolization of acetone has been determined many times over the years; Hine *et al.* averaged 18 such reports in the literature and obtained a value of 2.84×10^{-5} M^{-1} s^{-1} at 25°C (9). We have made 24 measurements of this quantity using various concentrations of hydrochloric acid. The results are shown in Fig. 1. A number of additional measurements were made on solutions to which 1/3 to 4/5 equivalent of sodium hydroxide had been added. These points fall very close to the line in Fig. 1, indicating that salt effects on the reaction are negligible, at least in the more dilute solutions. The slope of the line in Fig. 1 gives a value of 2.56×10^{-5} M^{-1} s^{-1} (25°C) for k_{H^+}, slightly lower than the average value from the literature.

We find a small but consistent difference between the stoichiometric concentration of H^+ and the concentration determined directly from our glass electrode measurements. The latter, which is strictly speaking an activity, is always found to be slightly lower than the former, which has been determined

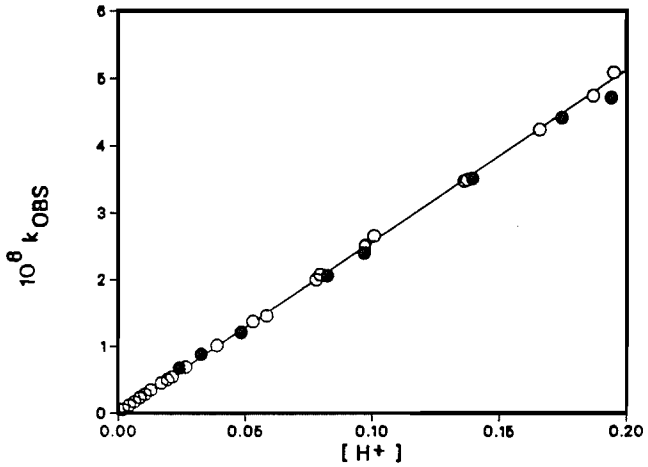

FIG. 1. Plot of observed rate of enolization of acetone against the stoichiometric concentration of hydrochloric acid; open circles, slope = $(2.56 \pm 0.01) \times 10^{-5}\,M^{-1}\,s^{-1}$, corr. coeff. = 0.9998; closed circles represent solutions containing sodium chloride as a result of adding sodium hydroxide.

by titration with standardized sodium hydroxide. Thus, k_{H^+} based directly on glass electrode measurements without any activity/concentration corrections would be slightly higher ($2.95 \times 10^{-5}\,M^{-1}\,s^{-1}$, based on all 32 points in Fig. 1).

We have measured the rate of enolization of acetone in 0.1 M unbuffered solutions of a number of strong and moderately strong acids. In these cases the hydrogen ion concentration is high enough to be unaffected by the iodometric process that is used to follow the reaction and which generates acid on a small scale. The results are shown in Fig. 2, with the dotted lines being those based on the H^+ and HA contributions, which have been calculated from the known dissociation constants of the acids themselves. The value of $2.56 \times 10^{-5}\,M^{-1}\,s^{-1}$ was used for the H^+ curve, and the Brønsted value of 0.56 for carboxylic acids (*vide infra*) was used for the HA curve. The solid line represents the expected sum of the H^+ and HA contributions in unbuffered solutions of acid concentration 0.1 M. As can be seen there is a maximum in the curve at a pK_{HA} of about −0.2. The eight acids for which experimental points are given range from chloroacetic acid, pK_{HA} 2.86, to methanesulfonic acid, pK_{HA} −1.92 (ref. 5, p. 12, and ref. 10). The latter, which falls precisely on the theoretical line, is the only acid that is not a carboxylic acid and it could be argued that there is no reason to assume that its catalytic ability will be governed by the Brønsted curve for carboxylic acids. However, the undissociated form of this particular acid will make only small contributions to the overall rate and so any deviations on this score will be minor.

The three trihaloacetic acids are more interesting since their acid strengths are such that their undissociated forms make significant contributions to the overall rate. There is a decrease in catalytic effectiveness going from tribromoacetic to trifluoroacetic acid, that is, as acid strength increases, and if the theoretical curve were displaced some 1.6 units to the right these acids would fall directly on the line. A much more reasonable explanation for this effect, however, is the following. Phenylphosphonic acids, containing an iodine or bromine atom at the *ortho* position, exhibit enhanced catalytic activity in acetone enolization and this effect has been tentatively attributed to the polarizability of these atoms (12). A similar effect may be at work here with the proton-transfer step shown in eq. [2*b*] being facilitated by polarization of the nearby halogen atoms.

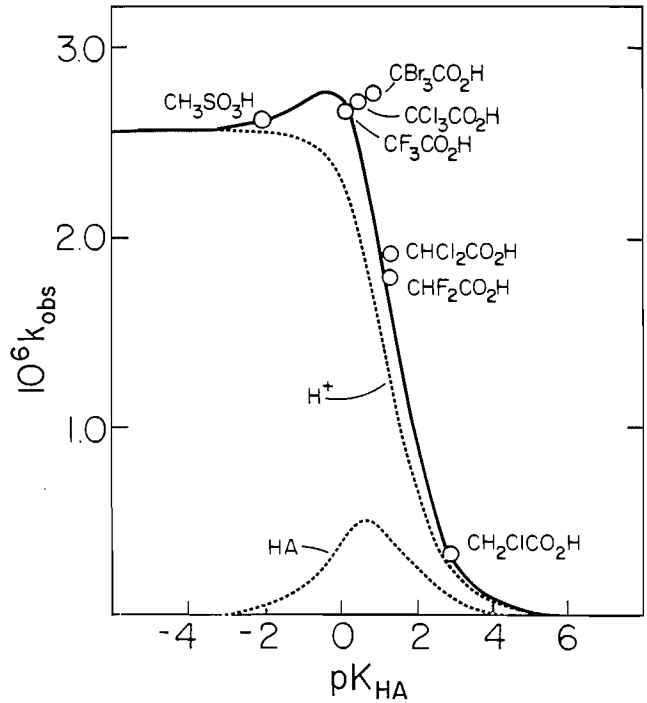

FIG. 2. Plot of observed rate for catalysis by 0.1 molar acid solutions as a function of the p*K* of the catalyzing acid. Dotted lines are calculated curves for the proton and undissociated acid; the solid line represents the sum of the values that produce the dotted lines. The curve for HA was calculated using the equation for the solid line in Fig. 4.

(Unfortunately, triiodo- and diiodoacetic acids cannot be used since they give curved rate plots, presumably because they undergo partial solvolysis in the reaction mixture.) Whatever the cause of the reactivity order here, there is no doubt that the three trihaloacetic acids, particularly the tribromo compound, are more effective catalysts in aqueous solution than are hydrochloric acid and other strong acids, whose catalytic power depends only on the hydrogen ion that they generate.

Buffer catalysis

Two methods have been used to measure k_{HA}, which is the catalytic constant of the undissociated acids used as catalysts. The first, the buffer-ratio method of Bell and Lidwell (13), has been used for the weaker acids, where contributions from the buffer anion A^- are significant. This method requires a large number of rate measurements to be made using several buffer ratios. At a constant buffer ratio (n) the observed rate constant (k_{obs}) is plotted against [HA] and the slope (s) measured. This procedure is repeated for several other buffer ratios and the slopes then plotted against $1/n$, according to eq. [3], to give both catalytic constants, k_{HA} as the intercept and k_{A^-} as the slope.

$$[3] \quad s = k_{HA} + (1/n)k_{A^-}$$

When $k_{HA} < k_{A^-}$, as it is for acetic acid and weaker acids, then it is often convenient to plot k_{obs} against $[A^-]$; the corresponding plot of s against $1/n$ is governed by eq. [4] in these cases,

$$[4] \quad s = k_{A^-} + nk_{HA}$$

For stronger acids, those whose pK_{HA} values are lower than, say, 3.2, the contribution of A^- to the rate becomes so small

that it becomes possible to simply plot k_{obs} against [HA] and determine k_{HA} from the slope of the plot, that is, from eq. [5], where k_{sum} represents the contributions of H^+, H_2O, and A^-.

$$[5] \quad \log k_{obs} = k_{sum} + k_{HA}[HA]$$

In the case of stronger acids k_{sum} can be shown to be simply the contributions from $k_{H^+}[H^+]$. Figure 3 shows the effect of plotting $k_{obs} - k_{H^+}[H^+]$ against [HA], the calculated concentration of the acid component of a series of difluoroacetic and dichloroacetic acid buffer solutions. The intercepts are essentially at the origin, showing that contributions from water and buffer anion are negligible. Since we have used values of $[H^+]$ obtained directly from glass electrode measurements, we have used here the value of $2.95 \times 10^{-5} M^{-1} s^{-1}$ for k_{H^+}.

Table 1 lists the catalytic constants for a total of 41 neutral or cationic carboxylic acids of various types and 19 anions of dicarboxylic acids; the latter species are amphoteric but, as we shall see later, they function as acid, not base, catalysts in the enolization process.[2] The low solubility of the aromatic acids made determinations of their catalytic constants somewhat difficult and resulted in higher error limits than in the case of aliphatic acids. In the case of the phthalic and isophthalic acids and some of the aliphatic dicarboxylic acids it was not found possible to determine the catalytic constants of the undissociated acids at all, although catalysis by the monoanions could be measured. Many of these acids have a further problem; their first and second dissociation constants are sufficiently close that pains had to be taken to determine the concentration of the various catalytic species present (14–16).

Figure 4 is the Brønsted plot for acetone enolization using all the carboxylic acid catalysts for which we have been able to measure rate constants. Even though all the catalysts are

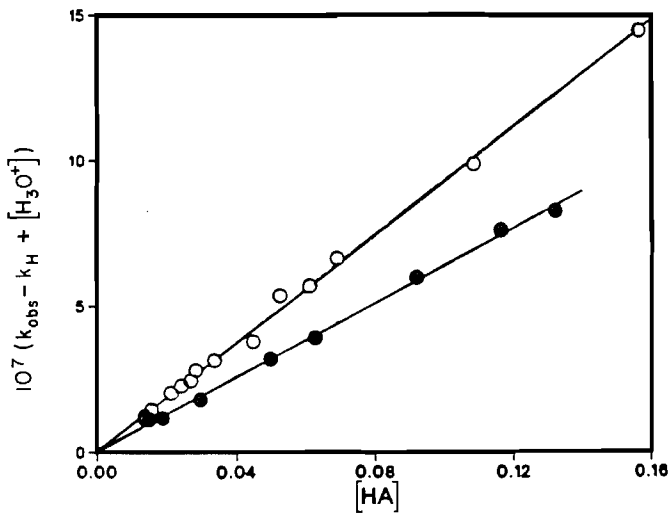

FIG. 3. Plot of $k_{obs} - k_{H^+}[H^+]$ against the concentration of undissociated buffer acid; open circles, dichloroacetic acid, corr. coeff. = 0.9985; closed circles, difluoroacetic acid, corr. coeff. = 0.9990.

carboxylic acids there is considerable diversity in structural and charge type and it is perhaps not surprising that the plot shows significant scatter. The least-squares line for all the points is shown as a dotted line in Fig. 4; its slope α is 0.482 ± 0.024 with a correlation coefficient of 0.9374. We prefer to attach more significance to the unbroken line, which refers to a subset of acids in which ancillary effects are at a minimum.

Of the 60 acids listed in Table 1 that are displayed in Fig. 4 there is a group of eight, identified by an asterisk in Table 1 and by solid symbols in Fig. 4, that possess no charge and in which steric and polarizability effects are small. The α value of 0.56 (0.560 ± 0.12, corr. coeff. 0.9986) is close to the value of 0.57 determined by Bell and Lidwell for a group of four aliphatic carboxylic acids, three of which are members of our standard

group and one of which, pivalic acid, possesses steric bulk. (The rate constants for the acids that are common to both sets are in reasonable agreement.)

As is usual for Brønsted plots the lines drawn in Fig. 4 are straight. The question of curvature in Brønsted plots is a question of current interest (17, 18) and examination of the solid points and unbroken line in Fig. 4 raises the question as to whether a quadratic, rather than a linear, relationship better represents the variation in catalyst strength with acid strength for the eight standard acids. Moreover, if a slight degree of curvature is present, it is in the expected direction; that is, the stronger acids are marginally less effective catalysts than would be predicted from a straight line based on the weaker acids. Too much should not be made of this point, however, since, if glycollic acid had not been included in the study, the question of curvature might not have arisen. Regardless of whether the Brønsted line is straight or slightly curved, our analysis of the causes of deviation of the remaining points will be essentially unaffected. This having been said, we will use the linear Brønsted relationship for the eight standard acids as the basis for subsequent discussion.

Steric and polarizability effects

In Fig. 5 the line for the eight standard acids is displayed, together with the points for the remaining neutral monocarboxylic acids, all of which possess steric bulk. It can be seen that virtually all such acids are *more* effective catalysts than would be suggested by a consideration of their equilibrium acid strengths. The effects are not large but they are consistently in this direction. Steric acceleration of proton transfer reactions has been observed in a number of other instances, both when the steric bulk is in the substrate (19) and in the catalyst. In particular, the base-catalyzed deprotonation of the 6-methyl group in the pyrazinium ion **I** and the methylene group of **II** (marked by asterisks), by a series of aliphatic and aromatic carboxylate bases showed the effects of marked steric activation (20, 21). However, previous studies of acetone enolization by arylphosphonate anions (base catalysis) and by arylphosphonic acids (acid catalysis) showed such effects to be absent in the former and small in the latter (12). It could well be that acetone, being a small molecule, does not exhibit as much sensitivity to steric bulk as does **I** or **II**.

It is significant that in virtually all cases in which steric activation in the catalyst has been observed the proton is being abstracted from a cation. In the cases of **I** and **II** the substrate is cationic; in the present case, and in the case of arylphosphonic acid catalysis, the rate-controlling step involves a cationic intermediate (see eq. [2*b*]).

I **II**

The effect of a group's polarizability is not always easy to separate from that of its size. Several of the deviating points in Fig. 5 represent acids that contain chlorine, bromine, or iodine atoms near the carboxyl group. All such catalysts exhibit exalted effects, except chloroacetic acid, which would be expected to be the one with the smallest polarizability/steric effect and is included as one of our standard catalysts. Is there any evidence in these results for the notion that polarizable groups in the catalyst stabilize the transition state of prototropic reactions (ref. 12; see also ref. 22)? Or are steric effects alone sufficient to explain the deviation of acids containing the large halogen units? If one examines the steric parameter E_s (23) of all the groups in Fig. 5 for which this quantity is available, one finds that the positive deviations from the Brønsted line are roughly in accordance with the magnitude of E_s; the major exception is the CH_2I group, **13**, which has a large deviation despite having a modest value of E_s. The high polarizability of iodine could explain this group's exalted catalytic effect. Unfortunately, the groups that would have further tested the polarizability hypothesis (the bromo- and iodoacetic acids

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12

that are missing from Table 1, and various sulfur-containing carboxylic acids) were all found to react under the reaction conditions employed. One can conclude that steric activation occurs in the general acid catalysis of acetone enolization, probably augmented by polarizability effects in some cases. As to the cause of the steric activation, we simply draw attention to the following points: (1) The effect seems to be most clearly evident when cationic substrates and anionic bases are involved in the rate-controlling step. (2) As has been previously noted (21), it is unwise to try to explain deviations from Brønsted lines on the basis of exalted or depressed rate constants alone; the equilibrium acid or base strengths of the catalysts are of equal importance in determining a point on a Brønsted plot, and a substituent's effect on these parameters should receive an equal degree of scrutiny.

Charged catalysts

In Fig. 6 the effect of positive or negative charge in the acid catalyst is displayed; again the Brønsted line for our eight standard acids is shown for comparison. It can be seen that all anionic acid catalysts show exalted effects and most cationic acids show depressed effects, results similar to those reported by Kresge and Chiang for vinyl ether hydrolysis (24). (The anionic catalysts, which are amphoteric, are assumed to be acting as general acids, not as general bases or as bifunctional catalysts; see later.) It is clear that proximity of the positive charge to the catalytic site is important since the largest negative deviations occur for the three ammonioacetic acids, whereas an ammonio group at the 4- or 6-position produces virtually no effect. It should be noted that the depressed catalytic constant for the hydrated proton, which has often been remarked upon (8), fits well into this general picture (24).

The deviations of the anionic acid catalysts from the Brønsted line are generally greater than those of their cationic counterparts, as was also the case for vinyl ether hydrolysis (24, 25). (The opposite effect has been observed in a base-catalyzed reaction (26).) Many of the anionic catalysts are sterically hindered, e.g., the 2-substituted isophthalic acid anions, and some of the rate exaltation may be due to this factor. However, it should be noted that the catalyst that deviates most from the Brønsted line is the anion of succinic acid **46**, which does not have a large degree of encumbrance.

The present results, when taken in conjunction with previous work that showed that dianionic bases (eq. [5]) are less effective than monoanionic bases in removing protons from neutral acetone (27), confront us with a paradox. The rate-controlling step of the reaction of the monoanionic catalysts examined herein is, presumably, the reaction of protonated acetone with these very dianionic bases (eq. [6*b*]), and yet here these catalysts exhibit exalted, not depressed, effects.

[5] $Z + A^{2-} \rightarrow$ products

[6*a*] $Z + HA^{-} \leftrightarrows ZH^{+} + A^{2+}$

[6*b*] $ZH^{+} + A^{2-} \rightarrow$ products

Put another way, the proton activating factor, paf (28), appears to be markedly greater for dianionic bases than for monoanionic bases. Perhaps the presence of a positive charge in the substrate and a double negative charge in the base provides a special interaction in the transition state of eq. [6*b*] that is not taken into account when only protolytic equilibria, which are the basis of the Brønsted relation, are considered. (Such an interaction in the transition state has been invoked previously by

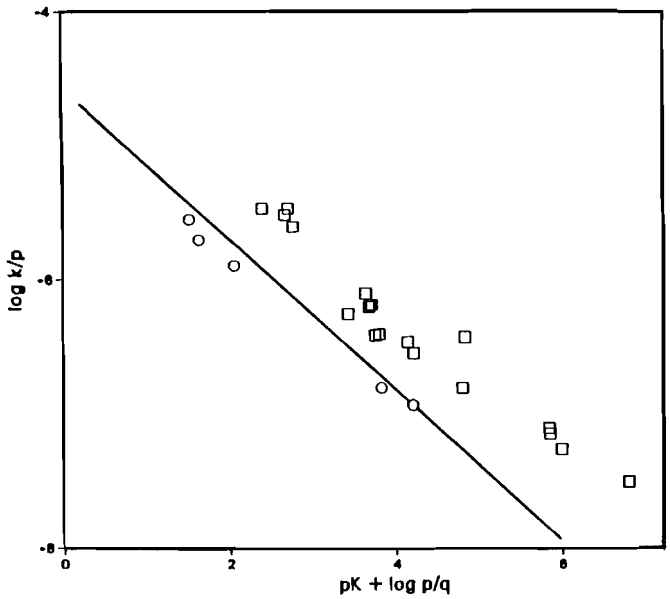

FIG. 6. Brønsted plot for charged acid catalysts; circles represent cationic acids, and squares, anionic acids; line drawn as in Fig. 5.

Kresge and co-workers to explain the greater catalytic effect of phosphonate monoanionic acids than carboxylic acids of the same acid strength in the hydrolysis of vinyl ethers (25).) One would have expected, then, that proton abstraction from the cation **II**, a reaction that is analogous to [6*b*], would be faster for dianionic carboxylate bases than for monocarboxylate bases of the same strength. The reverse, in fact, is found (20). It may be that the mesoionic character of the species formed from **II** makes it a less than satisfactory model for the enol formed in the present case. Unfortunately, the carboxylate bases used to construct the Brønsted line for the cation **I** (which would give a neutral intermediate analogous to an enol) did not include any dicarboxylate ions (21) and so we regard as still unsettled the question of the effect of charge in the catalyst on the enolization process.

Dicarboxylic acids

We have shown previously that dianions of dicarboxylic acids have, as a group, lower catalytic constants for acetone enolization than those of monoanions of comparable base strength (27). Moreover, among these dianions is a group whose catalytic effects are even further depressed and whose behaviour was traced to the ability of the corresponding monoanions to form internal hydrogen bonds. That is, the kinetic base strength of their dianions is lower than expected because the product stabilization caused by hydrogen bonding is absent in the transition state. Since the monoanion acts as the basic component in dicarboxylic acid catalysis (eq. [6*b*]), we have scrutinized the results for dicarboxylic acid catalysis to see if the same anomalies are present. In Fig. 7 it can be seen that the dicarboxylic acids, **34**–**41**, conform fairly well to the Brønsted line for the standard acids, although **35**, **37**, **39**, and **41** show small but probably significant negative deviations. These four acids (plus **40**) are the ones for which a high degree of internal hydrogen bonding is present in the monoanion and whose dianions exhibit large anomalies in the general base-catalyzed process. It appears as if internally hydrogen-bonded anions tend to be slightly less effective bases in reaction [6*b*] than their nonbonded counterparts. Unlike the case of base catalysis by

dianions, where the anomalies are large and readily explainable, no obvious cause of the small deviations shown in Fig. 7 springs to mind.

Catalytic role of dicarboxylic acid monoanions

It can be seen in Fig. 6 that the behaviour of dicarboxylic monoanions is consistent with their acting as general acids; that is, the greater the acid strength (pK_2) the greater the catalytic effect. They do, of course, fall above the Brønsted line for simple acids and there is considerable scatter, presumably caused in part by steric effects in the catalyst. To be satisfied that the monoanions are acting as general acids, not general bases, we have compared their catalytic effects with those for simple general bases. Figure 8 shows the Brønsted line for the anions of the standard acids used herein, making use of data from refs. 12 and 16. It can be seen that the dicarboxylic acid monoanions lie very poorly on the plot and, indeed, the stronger the base the poorer the catalyst tends to be. Moreover, most of the points fall well above the Brønsted line for simple bases. Considering that (a) steric effects in the general base catalysis are small (27) and (b) an uncharged carboxyl group elsewhere in the molecule does not seem to have a large effect on catalytic activity (previous section), we can conclude that the monoanions are not acting as general bases. This conclusion is in line with that reached earlier

with respect to the monoanions of arylphosphonic acids, which are also amphoteric (12).

There remains the possibility that the dicarboxylate monoanions are acting as bifunctional catalysts, transferring and receiving a proton in one operation, which would be in line with their being more effective catalysts than simple acids and bases of the same strength. (This is not so with arylphosphonate monoanions (12).) A concerted reaction would be expected to have a flattish Brønsted plot (see ref. 29, where bifunctional

catalysis, albeit of a different type, is described). Since catalytic activity is very roughly a function of acid strength for these species, we conclude that the group as a whole is acting as general acids, although it is possible that some of the rather large positive deviations in Fig. 6 are due in part to bifunctional catalysis.

Isotope effects

The effect of deuterium substitution in both substrate and solvent is shown in Tables 2 and 3. The results in D_2O (Table 2) are more extensive than those Reitz and Kopp reported in the early days of isotope study, but generally confirm their work (30). (See refs. 31 and 32 for a discussion of the factors responsible for deuterium solvent isotope effects.)

Reitz and Kopp also examined the general acid-catalyzed enolization of acetone-d_6, using acetone containing 92 at.% deuterium. Our kinetic isotope effects, listed in Table 3, have been obtained using 99.9% isotopically pure substrate and are markedly higher than theirs. It is clear that the primary kinetic isotope effects are substantial in all cases and that the magnitude of the effect is not significantly dependent on the catalytic power of the acid catalyst. There are grounds for believing that primary isotope effects should be at a maximum in proton transfer processes when the two bases sharing the proton in the transition state are of comparable strength (33, 34, and ref. 5, p. 169), and this may be the case here. The strength of protonated acetone as a carbon acid can be estimated from its strength as an oxygen acid and from the keto–enol equilibrium constant for acetone, since it can be readily shown (ref. 5, p. 181ff) that $K^c = K^0 K_E$, where K^c and K^0 are the carbon and oxygen acid dissociation constants of protonated acetone and K_E is the keto–enol equilibrium constant.

Values of -3 for pK^0 (ref. 5, p. 121) and -8 for $\log K_E$ (36, 37) give a pK of about 5 for the carbon acidity of the conjugate acid of acetone. If acetone is less basic than this, that is, if the pK of the protonated form is more negative than -3, as some believe (ref. 5, p. 121), its pK as a carbon acid will be lower than 5, possibly in the range of 2–3. Since the pK values of the buffer acids fall near these values, it is perhaps not surprising to find kinetic isotope effects that are large and that are generally insensitive to changes in catalyst pK.

Experimental

The enolization reaction was followed iodometrically and the results analyzed essentially by the methods previously described (12).

Many of the buffer acids are commercially available. The preparation of others, notably the dicarboxylic acids, is described elsewhere (27, 38), except for a number of 2-substituted isophthalic acids whose preparation and characterization are described below and in Table 4.

The 2-methoxy, 2-chloro, 2-bromo, and 2-nitro derivatives of isophthalic acid were prepared by the aqueous permanganate oxidation of the corresponding *meta*-xylenes. The 2-chloro- and 2-bromo-*meta*-xylenes were prepared by the diazotization of the corresponding amino compounds.

2-Aminoisophthalic acid was prepared by the aqueous permanganate oxidation of 2-acetamido-*meta*-xylene followed by acid hydrolysis of 2-acetamidoisophthalic acid. 2-Acetamido-*meta*-xylene was prepared by acetylation of 2-amino-*meta*-xylene using a mixture of acetic anhydride and acetic acid.

2-Iodoisophthalic acid was prepared from 2-aminoisophthalic acid by treating it with sodium nitrate/sulfuric acid and potassium iodide at 0–5°C.

2-Methylisophthalic acid was synthesized from 2,6-dichlorotoluene by refluxing it with cuprous cyanide in the presence of *N*-methylpyrrolidine for 2 days, followed by its hydrolysis by 20% ethanolic potassium hydroxide.

Received February 14, 1989

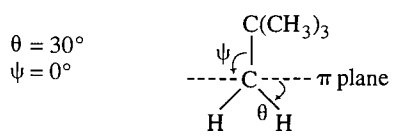
TED SCHAEFER, GLENN H. PENNER, CRAIG S. TAKEUCHI, and CHRISTIAN BEAULIEU. Can. J. Chem. **67**, 1283 (1989).

The ^1H nuclear magnetic resonance spectra and their analyses are reported for benzyltrimethyl X (X = C, Si, Ge, Sn, Pb) and for the 2,6-dichloro derivatives where X = Si, Ge, Sn, Pb. The steric barrier to rotation about the C_{sp^2}—C_{sp^3} bond for X = C, based on the long-range proton–proton coupling constant over six bonds, $^6J(H,CH_2)$, must be greater than 20 kJ/mol. Unexpectedly, $^6J(H,CH_2)$ implies that the barriers for X = Si, Ge, Sn, Pb have relatively minor steric components. If these barriers are dominated by hyperconjugative interactions of the C—X bond with the aromatic π system, then they are probably mainly twofold in nature. Furthermore, their magnitude is likely to be near 9.5 kJ/mol for X = Si, Ge, Sn and may be as high as 12 kJ/mol for X = Pb.

Key words: NMR, benzyl $X(CH_3)_3$, X = C, Si, Ge, Sn, Pb; NMR, conformations; NMR, hyperconjugation.

TED SCHAEFER, GLENN H. PENNER, CRAIG S. TAKEUCHI et CHRISTIAN BEAULIEU. Can. J. Chem. **67**, 1283 (1989).

On a déterminé et analyse les spectres de résonance magnétique nucléaire du ^1H des benzyl-X-triméthyl (X = C, Si, Ge, Sn ou Pb) et de leurs dérivés dichloro-2,6. Lorsque X = C, la barrière stérique à la rotation autour de la liaison C_{sp^2}—C_{sp^3}, telle qu'évaluée en se basant sur la constante de couplage proton–proton à longue distance à travers six liaisons, $^6J(H,CH_2)$, doit être plus grande que 20 kJ/mol. Lorsque X = Si, Ge, Sn ou Pb, il est toutefois surprenant que les valeurs de $^6J(H,CH_2)$ suggèrent que ces barrières ne comportent que des composantes stériques relativement mineures. Si ces barrières sont dominées par des interactions d'hyperconjugaison de la liaison C—X avec le système π aromatique, il est probable que leur nature est principalement binaire. De plus, il est probable que leur amplitude est de l'ordre de 9,5 kJ/mol pour X = Si, Ge et Sn et qu'elle aille jusqu'à 12 kJ/mol pour X = Pb.



Mots clés : RMN, benzyl $X(CH_3)_3$, X = C, Si, Ge, Sn, Pb; RMN, conformations; RMN, hyperconjugaison.
[Traduit par la revue]

Introduction

The present nmr measurements are meant to probe further the idea (1–3) that hyperconjugation of the carbon–metal bond with the aromatic π electron system determines the conformational preference about the C_{sp^2}—C_{sp^3} bond in benzyltrimethyl X (X = Si, Ge, Sn, Pb). Such an origin for its conformational behaviour was not suggested for benzyltrimethylmethane (neopentylbenzene), where steric interactions presumably are dominant (4–7).

A variety of neopentylbenzene derivatives have been investigated by dynamic nmr methods with a view to establishing the free energies of activation, $\Delta G^{\ddagger}$, for rotation about the C_{sp^2}—C_{sp^3} bonds (4–7). For the parent compound the reorientation rate is too fast to measure by such methods. ^{13}C and ^2H relaxation times suggest a $\Delta G^{\ddagger}$ of 18–23 kJ/mol (5). For 2-bromo-3,5-di-*tert*-butylneopentylbenzene (7) only a line-broadening is observed in the ^1H nmr spectrum, attributed to a rate process characterized by an upper limit to $\Delta G^{\ddagger}$ of 23 kJ/mol for rotation past the *ortho* C—H bond.

Molecular mechanics calculations on neopentylbenzene itself yield 26.7 kJ/mol for the maximum in the rotational potential for the C_{sp^2}—C_{sp^3} bond (4); the most stable conformer corresponds to **1**. Because of the experimental data given above, it is stated (4) that the barrier is probably less than 23 kJ/mol.

1

If the barrier to internal rotation in neopentylbenzene is too small to measure by lineshape methods, then it is possible that the *J* method is applicable (8). In this method, the long-range proton–proton coupling constant, ^6J, between the methylene and *para* ring protons is related to the internal barrier via the expectation value of $\sin^2\theta$. The angle θ is defined in **1** and is 90° when the α C—H bond lies in a plane perpendicular to that of the benzene framework. ^6J is given by $^6J_{90}\langle\sin^2\theta\rangle$. We report here the analysis of the ^1H nmr spectrum of neopentylbenzene and discuss the spectral parameters in terms of the internal rotational potential.

The ^1H nmr spectral parameters are also obtained for the other title compounds and imply rather lower internal rotational potentials. In an attempt to discriminate between steric and hyperconjugative origins of the barrier, the spectral parameters are measured for the 2,6-dichloro derivatives of the metal compounds because a steric component for rotation of the side chain past the benzene plane should be enhanced by the chlorine substituents.

The ^{13}C nmr spectra for the tin compounds are presented in a number of solvents, to assess environmental influences on the conformational behaviour.

Experimental

Neopentylbenzene (Frinton) and benzyltrimethylsilane (Fluka) were purchased. The other compounds were prepared by standard procedures (1, 9). A typical procedure for the preparation of an nmr sample went as follows. A 5.0 mol% solution of neopentylbenzene (Frinton) in CCl_4, containing also 10 mol% of cyclohexane-d_{12} and ca. 0.5 mol% tetramethylsilane (TMS), was transferred to a 5 mm o.d. nmr tube. This solution was degassed by several cycles of the freeze–pump–thaw technique and the nmr tube was then flame-sealed.

The ^1H nmr spectra were accumulated on an AM300 FT spectrometer in exactly the way recently described in detail for toluene (10). The protons in the three equivalent methyl groups were spin coupled

to the methylene and, by a small amount, also to the ring protons. Decoupling procedures reduced the peak widths of the ring protons to ca. 0.10 Hz.

The ^{13}C nmr spectra of the stannane in three solvents and of its 2,6-dichloro derivative in acetone-d_6 were collected as previously described (11), and at 300 K and 75.469 MHz on the AM300 instrument.

Results and discussion

Spectral analysis

The ^{1}H nmr spectra of the ring protons were analyzed with the computer program NUMARIT (12), as extensively modified by R. Sebastian in this laboratory. The spectral parameters appear in Tables 1 and 3. There were no substantial correlations involving the crucial parameter, $^6J(H,CH_2)$.

The internal barriers about the C_{sp^2}—C_{sp^3} bonds

$^6J(H,CH_2)$ is known to obey eq. [1]

$$[1] \quad {}^6J = {}^6J_{90}\langle\sin^2\theta\rangle$$

in a substantial number of benzyl derivatives (8, 11, 13–16). The expectation value of $\sin^2\theta$ can be calculated classically, or quantum mechanically using a hindered rotor model. The value of $^6J_{90}$ depends on the electronegativity of the group attached to the methylene carbon atom (1, 16). For a methyl substituent, i.e., for ethylbenzene, $^6J_{90}$ has been taken as −1.16 Hz (14), as compared to the −1.20 Hz established for toluene (10). The electronegativities of the $C(CH_3)_3$ and $Si(CH_3)_3$ groups have been given as equal to that of the methyl group (17).

In neopentylbenzene, $^6J(H,CH_2)$ is −0.300(3) Hz, corresponding to a $\langle\sin^2\theta\rangle$ of −0.300/−1.16 or 0.259(5); the indicated error allows for an actual error of 0.006 Hz in ^6J. For a rigid conformation, **1**, $\langle\sin^2\theta\rangle$ is 0.25, corresponding to a ^6J of −0.29 Hz. Clearly, the barrier about the C_{sp^2}—C_{sp^3} bond is large. The *J* method is insensitive for a barrier as large as 20 kJ/mol or more. However, the given MMP1 potential (4) can be closely reproduced by $V(\psi)/\text{kJ mol}^{-1} = 27.7\sin^2\psi + 7.4\sin^2 2\psi$, where ψ is the angle by which the *tert*-butyl group twists out of conformation **1**. At 300 K this potential implies $\langle\sin^2\theta\rangle$ as 0.262 (classical average). In other words, the potential agrees with the observed ^6J in neopentylbenzene. The fourfold term (in $\sin^2 2\psi$) serves to decrease $\langle\sin^2\theta\rangle$ from the value expected in its absence in the above equation, producing a rapid rise in strain energy as the angle ψ increases from 15° to 60°.

While the theoretical fourfold term is not large enough to contribute to the height of the barrier, the suggested barrier in neopentylbenzene itself, although not measured, is 23 kJ/mol (4). It should be remembered that, for such a high barrier, the α C—H bonds sample only a small region of the internal potential at ambient temperatures. Consequently, it is best to conclude that the observed ^6J is compatible with a two-component barrier whose magnitude is rather larger than 20 kJ/mol. Of course, DNMR measurements are inapplicable to neopentylbenzene itself because of the symmetry of the conformation, **1**, of lowest energy.

Turning to the benzyltrimethylsilane, ^6J is −0.418(3) Hz, implying a $\langle\sin^2\theta\rangle$ of 0.360(6) if $^6J_{90}$ is again −1.16 Hz. *If* the barrier about the C_{sp^2}—C_{sp^3} bond is purely twofold, then its magnitude is 6.9(4) kJ/mol (hindered rotor model). However, if a substantial fourfold component exists as well, then various combinations of the two components yield a $\langle\sin^2\theta\rangle$ of 0.36, for example, V_2/V_4 values of 12.2/5.0, 10.0/3.2, 9.0/2.3, 8.0/1.5, 6.9/0.0 (in units of kJ/mol). For the MMP1 potential of neopentylbenzene, $V_2/V_4 \sim 3.7$. A similar ratio for the

For personal use only.

silane derivative would have V_2 and V_4 as 9.0 and 2.3 kJ/mol, respectively. From the discussion in ref. 4 it may be inferred that the fourfold component has much to do with the close approach of two methyl groups to the phenyl moiety in neopentylbenzene. Because such an approach will be less marked in the silane (Si—C bonds are ca. 0.4 Å longer than C—C bonds), the V_2/V_4 ratio is likely to be larger in this compound. Hence it is perhaps more likely that the following V_2/V_4 values in kJ/mol apply to benzyltrimethylsilane: 9.0/2.3, 8.0/1.5, 7.5/0.9, 6.9/0.0. The ^6J value is compatible with all these combinations, of course.

It should be noted, however, that, if the barrier arises from $\sigma-\pi$ hyperconjugation of the C—Si bond with the aromatic π electrons and having a maximum value at $\psi = 0°$ (see **1**), then a twofold character is expected for the barrier, the hyperconjugation varying as $\cos^2\psi$.

The drastic reduction in internal barrier about the C_{sp^2}—C_{sp^3} relative to neopentylbenzene, caused by replacement of the quaternary carbon atom by silicon, is not entirely without precedent. Thus, in hexakis(dimethylsilyl) benzene an empirical force field yields 65.7 kJ/mol for the barrier to rotation about the C_{sp^2}—Si bond (18), compared to an approximate experimental value 60.0 kJ/mol. In the carbon analog, hexaisopropylbenzene, the computed internal barrier is 146.4 kJ/mol. These, presumably steric, barriers again illustrate the large changes caused by substitution of C—Si for C—C bonds. Similar phenomena have been observed for phenyldimethylsilane (19) as compared to isopropyl benzene.

The apparent twofold barriers in benzyltrimethylgermane and its tin and lead analogues are effectively the same as in the silane derivative, judging by the values of ^6J in Table 1. However, as can be seen from the discussion of the silane compound, combinations of V_2 and V_4 other than that appropriate to the latter are also compatible with the same ^6J for all three compounds. The group electronegativities of trimethyl X (X = C, Si, Ge, Sn, Pb) are here assumed equal.

An alternative assumption

The naive expectation, that the apparent V_2 will decrease monotonically from C to Pb, is not fulfilled. This order would be compatible with the measured ^6J only if $^6J_{90}$ were to *decrease* in magnitude in a monotonic way in going from carbon to lead; that could occur only if the electronegativity were increasing in that order. An alternative assumption uses the iota (inductive) substituent parameters, applicable to ^{13}C nmr chemical shifts (20). These parameters are 2.12, 1.72, 1.80, 1.66, and 1.50 for $C(CH_3)_3$, $Si(CH_3)_3$, $Ge(CH_3)_3$, $Sn(CH_3)_3$, and $Pb(CH_3)_3$, respectively. For hydrogen and the methoxy substituents, iota is 2.00 and 2.83, whereas $^6J_{90}$ is −1.20 and −1.02 Hz, respectively (10, 16). $^6J_{90}$ is then −1.17, −1.26, −1.24, −1.27, and −1.31 Hz, respectively, for X = C, Si, Ge, Sn, Pb in $X(CH_3)_3$. The $\langle\sin^2\theta\rangle$ becomes 0.256, 0.331, 0.328, 0.331, and 0.303, in that order. While these numbers imply somewhat higher apparent twofold barriers, near 9.5 kJ/mol for X = Si, Ge, Sn, than do the $\langle\sin^2\theta\rangle$ values when assuming equal electronegativities of the $X(CH_3)_3$ groups for all X, they *also* imply equal barrier *heights* for X = Si, Ge, Sn and a somewhat larger apparent V_2 of 14 kJ/mol for X = Pb.

Finally, the most recent determination of the relative electronegativities of CH_3 and $X(CH_3)_3$, when attached to CH_2, has the order C > H > Ge > Si > Pb > Sn (3). This order agrees with the iota scale above, *except* for $Pb(CH_3)_3$. The iota values for $Si(CH_3)_3$ and $Sn(CH_3)_3$ are 1.72 and 1.66, respectively. If the iota value for $Pb(CH_3)_3$ is taken as 1.69, then $\langle\sin^2\theta\rangle$ for this substituent becomes 0.313, corresponding to an apparent V_2 of 12 kJ/mol.

Given that the steric forces favor **1** ($\psi = 0°$, $\theta = 30°$) in all these compounds, ^6J showing that **1** is indeed of lowest energy (were the stable conformer described by $\psi = 30°$, for example, then a *rigid* form of this conformer would correspond to a $\langle\sin^2\theta\rangle$ of 0.375 and any motion would tend to increase $\langle\sin^2\theta\rangle$ towards a limiting value of 0.5 for free rotation), the barrier relationships for X = Si, Ge, Sn, Pb strongly imply an additional source of the stabilization of **1**. This second source may be the hyperconjugative interaction of the C—X bond with the π electron system of the benzene ring (1–3). A measure of such interactions is the σ_R^0 scale (3), giving the order of hyperconjugative electron release of CH_2XR_3 groups. At least one set of such substituent constants has Si < Ge < Sn < Pb,[3] an order consistent with the present results for the apparent barrier heights if the stabilization of **1** by increasing hyperconjugative interactions, going down the group, is compensating the decreasing steric forces. Alternatively, on the assumption that no steric barrier exists for X = Pb, for example, an upper limit to the hyperconjugative stabilization of **1** for this compound is near 12 kJ/mol. These matters are discussed further below, following a discussion of $^5J(^{13}C,^{117,119}Sn)$.

Comparison with $^5J(^{13}C,^{117,119}Sn)$

Kitching *et al.* (27) deduce an approximate value of 30° for ψ in benzyltrimethyl stannane, based (1) on a $\sigma-\pi$ mechanism for $^5J(^{13}C,^{117,119}Sn)$, and of 28° for its 4-fluoro derivative. The $\langle\sin^2\theta\rangle$ of 0.331 quoted above corresponds to an arc sin $\langle\sin^2\psi\rangle^{1/2}$ of 24°, while the assumption that $^6J_{90}$ is −1.16 Hz, as in the earlier discussion, implies 29°. ^6J is for a dilute solution in acetone-d_6 at 300 K, whereas $^5J(^{13}C,^{117,119}Sn)$ is for a solution in $CDCl_3$ (1). The absence of substantial differential solvent effects on the conformational stability of benzyltrimethylstannane is affirmed by the ^{13}C nmr data for three solvents in Table 2. $^5J(^{13}C,^{117,119}Sn)$ is independent of solvent to within experimental error.

For 4-methylbenzyltrimethylstannane, $^7J(^1H,^{117,119}Sn)$ is quoted as 9 Hz (28). A $\sigma-\pi$ coupling mechanism implies its proportionality to $\langle\sin^2\psi\rangle$. Furthermore, because the hyperfine interaction parameters, Q_{CH}^H and Q_{CCH}^H, are almost equal in magnitude, $^6J(^1H,^{117,119}Sn)$ should also be near 9 Hz in magnitude, although of opposite sign. From Table 2 it follows that $^5J(^{13}C,^{117,119}Sn)/^6J(^1H,^{117,119}Sn)$ has a magnitude of 1.75 ± 0.25. To within experimental error, this ratio is the same as $^5J(^{13}C,^{13}C)/^6J(^1H,^{13}C)$, precisely −1.50, found for eight anisole, thioanisole, and benzyl cyanide derivatives (29). The negative sign is expected on the basis of a positive Q_{CH}^C and a negative Q_{CH}^H (21); these quantities represent transmission of unpaired spin density from the aromatic π orbitals to the sites of *para* ^{13}C or ^1H nuclei. $^6J(^1H,^{117,119}Sn)$ is rather difficult to measure in the parent compound because of the complexity of the ^1H nmr spectrum of aromatic protons; we have not attempted to do so. Similar remarks would apply to $^6J(^1H,^{207}Pb)$ in the plumbanes, although from $^5J(^{13}C,^{207}Pb)$ in the parent compound (1) an estimate of near 20 Hz is obtained from a factor of 1.5.

2,6-Dichlorobenzyltrimethyl X (X = Si, Ge, Sn, Pb)

The striking result is that ^6J has not altered significantly

(Table 3) on introduction of chlorine substituents at the *ortho* positions. This is also true for $^5J(^{13}C,^{117,119}Sn)$ in Table 2. This extraordinary result may be contrasted, for example, with ethylbenzene (14) and 2,6-dichloroethylbenzene (22). In the former, ^6J is −0.455(1) Hz in CS_2 solution, corresponding to a (probable) steric barrier of about 5.4 kJ/mol, the stable conformer being that analogous to **1**. In the 2,6-dichloro derivative, ^6J drops to 0.3 Hz in magnitude and indicates an internal barrier larger than 20 kJ/mol.

More precisely, the *ortho* chlorine substituents alter $^6J_{90}$ somewhat, $^6J(H,CH_3)$ being −0.641(1) Hz for 2,6-dichlorotoluene in acetone-d_6 solution. Hence $^6J_{90}$ is −1.28 Hz. Then the approach described above, and taking iota for $Pb(CH_3)_3$ as 1.69, leads to apparent V_2 values of 12.5 kJ/mol for X = Si, Ge, Sn and to 15.1 kJ/mol for X = Pb. Accordingly, the steric contribution to the barrier in the compounds of Table 3 is perhaps as large as 3 kJ/mol; that is, considering the relative steric effects of C—H and C—Cl bonds (4, 7, 23, 24), the present data imply that hyperconjugative interactions are mainly responsible for the conformational preferences about the C_{sp^2}—C_{sp^3} bonds in benzyltrimethyl X (X = Si, Ge, Sn, Pb).

Other spectral parameters

With due regard for solvent effects on chemical shifts, the shifts of H-4 in Table 3 are consistent with the conclusions from detailed studies of the chemical shifts of C-4 and of ^{19}F in the 4-fluoro derivatives (2), namely, that hyperconjugative electron release by $CH_2X(CH_3)_3$ follows the order Pb ~ Sn > Ge ~ Si. Actually, the shifts of H-3 can also be grouped in this fashion for the 2,6-dichloro compounds.

Comparisons for the parent compounds are more ambiguous because of the solvents involved. In a further comparison, it may be noted that the chemical shift of H-4 in ethylbenzene

in CCl_4 solution (14) is 0.033 ppm smaller than that in neopentylbenzene in the same solvent, implying that the CH_2CCH_3 releases electrons hyperconjugatively less readily than the CH_2CH_3 group, whereas the $CH_2Si(CH_3)_3$ group does so more readily (Table 1).

The chemical shifts of C-4 for the stannane and its 2,6-dichloro derivative in Table 2 are consistent with the indications from $^6J(H,CH_2)$ and $^5J(^{13}C,^{117,119}Sn)$ that the two chlorine substituents do not markedly alter the conformational behaviour of the $CH_2Sn(CH_3)_3$ moiety. This consistency follows from the fact that C-5 in 1,3-dichlorobenzene is deshielded by just over 2 ppm relative to benzene (25).

The values of $^5J(H,CH_2)$ in Tables 1 and 3 can also be rationalized. Thus, for toluene, $^5J(H,CH_3)$ is written in Hz as $0.336\langle\sin^2\theta\rangle + 0.322\langle\sin^2(\theta/2)\rangle$, the second term representing the σ electron contribution to ^5J (10). A $\langle\sin^2\theta\rangle$ of 0.33, and the fact that $\langle\sin^2\theta\rangle$ is 0.5 for any evenfold barriers, yields 0.27 Hz for ^5J. A $\langle\sin^2\theta\rangle$ of 0.26 entails a ^5J of 0.25 Hz, applicable to neopentylbenzene in Table 1. The measured value is 0.24 Hz and the other model value above is considered sufficiently close to measured values for the metalloid compounds.

In 2,6-dichlorotoluene, $^5J(H,CH_3)$ is 0.441(2) Hz. In terms of previous detailed discussions (10, 26) one may write $^5J/\text{Hz} = 0.359\langle\sin^2\theta\rangle + 0.583\langle\sin^2(\theta/2)\rangle$. Hence ^5J for the compounds in Table 3, where $\langle\sin^2\theta\rangle$ is near 0.31, should be close to 0.40 Hz. The measured values are somewhat higher, by as much as 0.06 Hz for Pb, but only 0.02 Hz for Si.

Conclusions

While the barrier to internal rotation about the C_{sp^2}—C_{sp^3} bond in neopentylbenzene is no doubt steric and greater than 20 kJ/mol in magnitude, the corresponding barriers in benzyltrimethyl X (X = Si, Ge, Sn, Pb) are very much smaller and, it appears, dominated by hyperconjugation between the C—X bond and the aromatic π electron system. If these barriers are purely twofold, then they may be as low as 7 kJ/mol, but more likely near 9.5 kJ/mol, for X = Si, Ge, Sn, and as high as 12 kJ/mol for X = Pb.

New aromadendranic sesquiterpenes from *Sideritis varoi* ssp. *cuatrecasasii*

ANDRÉS GARCÍA-GRANADOS[1] AND ANTONIO MOLINA

Departamento de Química Orgánica, Facultad de Ciencias, Universidad de Granada, 18071 Granada, Spain

Received August 5, 1988[2]

ANDRÉS GARCÍA-GRANADOS and ANTONIO MOLINA. Can. J. Chem. **67**, 1288 (1989).

Two new aromadendrane sesquiterpenes 4β,9β-dihydroxyaromadendrene and 4β-hydroxy-9β-acetoxyaromadendrene have been isolated from *Sideritis varoi* ssp. *cuatrecasasii*, and their stereochemistry has been established by a series of 2D nuclear magnetic resonance experiments.

Key words: *Sideritis*, *Labiatae*, new aromadendrenes, sesquiterpenes, 2D NMR.

ANDRÉS GARCÍA-GRANADOS et ANTONIO MOLINA. Can. J. Chem. **67**, 1288 (1989).

On a isolé deux nouveaux sesquiterpènes de l'aromadendrane, les dihydroxy-4β,9β et hydroxy-4β acétoxy-9β aromadendrène, à partir du *Sideritis varoi* ssp. *cuatrecasasii* et on a déterminé leur stéréochimie en se basant sur une série d'expériences de résonance magnétique nucléaire en 2D.

Mots clés : *Sideritis*, *Labiatae*, aromadendrènes nouveaux, sesquiterpènes, RMN 2D.

Introduction

Many diterpenic compounds with *ent*-kaurenic (1, 2), *ent*-beyerenic (3), *ent*-atis-13-enic (4), and *ent*-labdanic (5) skeletons have been isolated from the genus *Sideritis*. The number of sesquiterpenes found in this genus, however, are scarce, with only some eudesmanes (6, 7), germacranes (8), and guaianes (8) having been isolated from two subspecies of *S. varoi*. We report here on a study of the structure of two new natural products that have the uncommon aromadendrane skeleton. This is the first time that this class of compound has been isolated from *Labiatae* in Spain, and from the genus *Sideritis* anywhere. Their structures have been determined by a combination of chemical and spectroscopic techniques. 2D-NMR experiments have rarely been applied to this type of skeleton (9) as the considerable mobility within its cycloheptane moiety makes the stereochemical analysis of these molecules somewhat difficult.

Results and discussion

The first compound isolated (**1**) had a molecular weight of 236 and an elemental analysis compatible with the molecular formula $C_{15}H_{24}O_2$. Its ir spectrum showed bands at 3345 (OH), 1630 (C=C), and 895 (C=CH_2) cm^{-1}. These functions were confirmed by high resolution ^1H nmr experiments (300 MHz), which showed signals of exocyclic methylene at δ 5.10 and 4.85 (1H each, dd) and a signal of one proton geminal to a hydroxyl group (δ 4.05, J_1 = 10.9, J_2 = 1.8, J_3 = 1.4, J_4 = 1.1 Hz), as well as three methyl singlet signals at δ 1.27, 1.02, and 1.01 (3H each), the first of them possibly geminal to a hydroxyl group and hence relatively deshielded. There were also two complex signals of a cyclopropane ring (δ 0.76, 1H, ddd, J_1 = 11.25, J_2 = 9.38, and J_3 = 6.56 Hz; δ 0.48, 1H, dd, J_1 = 11.33, J_2 = 9.38 Hz) in this spectrum (see Table 1). Taking everything into account, product **1** should be a tricyclic sesquiterpene with one cyclopropane ring, a secondary hydroxyl group, and some other tertiary group. The ^{13}C nmr spectra of **1** revealed the presence of three methyl, four methylene (one of these unsaturated exomethylene), and five methine groups (one of these binding with a hydroxyl group), as well as three quaternary carbons (one oxygenated and another sp^2 one), all of which confirms the type of skeleton proposed.

SCHEME 1

The oxidation of **1** with pyridinium dichromate (10) under very mild conditions gave an unstable product that could not be isolated. A series of experiments were carried out to find out the position on the skeleton of the oxidable hydroxyl group (see Scheme 1). The epoxidation of **1** with metachloroperbenzoic acid (MCPBA) yielded as the major product (51%) the epoxy

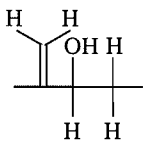
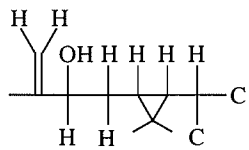
J(Hz): 5,6 = 11.33; 6,7 = 9.38; 7,8β = 11.30; 7,8α = 6.56; 8β,8α = 13.74; 9,8β = 10.9; 9,8α = 1.8; 14-H1, 14-H2 = 2.7; 14-H1, 9 = 1.4; 14-H2, 9 = 1.1.



compound **2**, which, when treated with $LiAlH_4$, gave **3**. The oxidation of **3** with $NaIO_4$ resulted in the ketoaldehyde **4**, which proved that the secondary hydroxyl group in **1** is allylic.

To determine the size of the ring on which the secondary hydroxyl group is situated, compound **1** was hydrogenated to give a main product (**5**), which was then oxidized to a stable ketone (**6**). The ir spectrum of **6** showed a ketonic band at 1690 cm^{-1}, which eliminated the possibility of a cyclopentanone. The ^{1}H nmr spectrum of **6** (80 MHz) showed signals at δ 2.77 (1H, m, $W_{1/2}$ = 20 Hz) and 2.33 (2H, complex broad signal). After treating **6** with D_2O/DO^- the last signal was greatly simplified. The cyclopropane signal at δ 0.76 also showed significant variations. The ^{13}C nmr spectra of **6** and its deuterated derivative were significant: experiment DEPT (135°C) showed a positive triplet signal at δ 35.89, which can be attributed to a -CHD- group, very close to another, slightly deshielded, negative signal of a methylene group. The introduction of deuterium is greater on the methylene side than on the methine side.

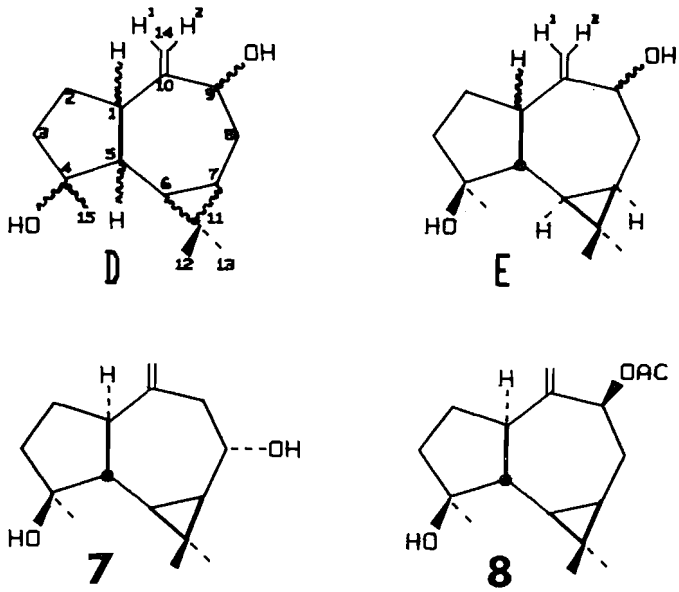
From these experiments a partial structure (A) could be deduced for **6** and hence a partial structure (B) for **1**.



A

B

As mentioned above, the deuteration at the methylene group contiguous to the keto group modified the multiplicity of one of the protons (δ 0.76) of the cyclopropane ring. Several double-resonance experiments carried out with **6** showed that the methylene group that was deuterated in the previous experiment was also contiguous to this cyclopropane proton. Thus, the irradiation at δ 2.33 transformed the signal at δ 0.76 into a doublet signal (J = 9 Hz), which allowed us to extend the partial structure to C, bearing in mind the multiplicity of the signal of the other cyclopropane proton (δ 0.5, dd, $J_1 = J_2$ = 9.5 Hz).



A reconsideration of the ^{13}C nmr spectrum of **1** leads to the conclusion that its structure might be D. This structure has six asymmetric centers and its relative stereochemistry was established by high resolution 1D and 2D-NMR procedures.

C

The ^{1}H nmr assignments for all the protons of **1** were achieved by combining the proton homonuclear correlation (COSY 90) results and those of the C/H heteronuclear correlation. Thus, the C/H correlation allowed us to assign the ^{13}C and ^{1}H chemical shifts of positions 4, 6, 7, 9, 10, 11, 12/13, 14, and 15, and the COSY experiments allowed us to assign the protons at C-8 (by correlation with H-9 and confirmed by correlation 2H-8/H-7) and also confirmed the assignments carried out by the C/H correlation. The correlation H-6/H-5 allowed us to assign the last one. Nevertheless, the fact that the signals of H-8α and H-8β overlapped with the signals of H-5/H-1 made this important correlation difficult. After these assignments only the C-1 methine and the C-2 and C-3 methylene groups remained to be assigned. On reconsidering, at this point, the C/H correlation for product **1** we assigned the signal at δ 50.30 to C-1 and δ 2.15 to H-1. A new analysis of the COSY experiment now allowed us to assign the protons at C-2 (δ 2.01 and 1.63). We then assigned the signal at δ 26.34 to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

C-2 and finally the signal at δ 41.89 to C-3 with its proton signal at δ 1.80 and 1.60 by C/H correlation.

The homonuclear *J*-resolved experiment allowed us to confirm the chemical shifts for the protons of **1** by considering the F2 projection, which provided a "full decoupled proton spectrum". By plotting the columns of this experiment, clear figures of many proton signals could be obtained. A complete analysis of the *J* values was fairly difficult because of considerable overlapping of the protons (H-1/H-8 and H-5/H-8/3H-15) and a considerable coincidence between one of the protons at C-2 and another at C-3 even in the *J*-resolved experiment (only apparent *J* values, read directly on the spectral chart, could be used because the signals were so close that there were few first-order systems). All the assignments are shown in Table 1. Some coupling constants were useful in the determination of certain points of the relative stereochemistry. The value of the coupling constants between H-5/H-6 and H-6/H-7 (11.33 and 9.38 Hz respectively) are very similar to those indicated for the *cis*-cyclopropane **7** (11). Next, it is necessary to establish the relative configurations of C-1, C-4, and C-9, as well as the absolute configuration of the molecule.

The 2D nOe-correlated experiments for product **1** were of help in the determination of its stereochemistry. Dipolar couplings between H-6/3H-15, H-6/3H-13, and H-6/H-7, the latter very small in value, were found. This 2D-NMR experiment also confirmed the chemical shifts of the pairs of geminal protons at C-2, C-3, C-8, and C-14. The stereochemistry of **1** can now be proposed as indicated in structure E, although with the doubt remaining whether the cross signal in the NOESY experiment between H-6/3H-15 was due to its dipolar interaction or due to the dipolar coupling between H-6 and some of the signals (H-5 or H-8) beneath the intense signal of 3H-15. The possibility of dipolar coupling between H-6 and H-8 was eliminated after considering the scalar coupling constant of this proton at C-8 (J_1 = 13.74, J_2 = 11.3, J_3 = 10.97 Hz), which indicated that this had an 8β disposition. In addition, the clear signal of H-6 indicated a *trans* disposition with regard to H-5 ($J_{5,6}$ = 11.33 Hz). The 8β-H proton showed cross signals with 14-H2, the 14-H1 with one of the H-2 (δ 2.01) protons, and, although not so clearly, between H-5 and 14-H1. In this experiment H-9 (geminal to the hydroxyl group) did not show any cross signals and hence the relative configurations of C-1, C-9 remain undetermined.

The limitations shown by the NOESY experiments for the small molecules are known because in this type of experiment the zero-quantum (W_0) and not the double-quantum transitions are measured (12). Therefore careful monodimensional nOe difference experiments (12) were performed for **1**, as described in the Experimental, and the results appear in Table 1. These experiments confirm the dipolar coupling shown by the NOESY experiment but also reveal clear signals of nOe difference between H-6 and H-1 (or H-8α) and between H-9 with H-1 (or H-8α) and H-7. It can be deduced from the H-9 coupling constants (J_1 = 10.9, J_2 = 1.8, J_3 = 1.4, J_4 = 1.1 Hz) that there is a *trans* disposition between H-9 and H-8β and a dihedral angle of nearly 90° between H-9 and H-8α. Thus H-8α was not near H-6 (Dreiding stereomodels), and the nOe effect between H-6 and H-1 is clear. This conformation for C-8 is also confirmed by the nOe effect between H-9 and H-7. This proved that H-1, H-6, H-7, and H-9 were all within the cycloheptane ring, and the study of the relative stereochemistry of product **1** was thus complete.

The *S* configuration at C-9 was established by Horeau's procedure (13). Product **1** is 4β,9β-dihydroxyaromadendrene, a new natural product for which we propose the name *sesquivarodiol*.

Another new natural product was **8**, with a molecular weight of 278 and ir bands of hydroxyl (3454), exocyclic double bond (3102, 1639, and 900), and acetoxy group (1735 and 1244 cm^{-1}). The ^1H nmr spectrum (300 MHz) of product **8** was very similar to that of product **1**, with the exception of the acetate group at δ 2.09 (3H, s) and the presence of a proton at δ 5.08 (1H, dd, J_1 = 11.22, J_2 = 1.5 Hz). Saponification of product **8** led to product **1**. Hence **8** is a natural acetate at C-9 of product **1**.

Experimental

Melting points (Kofler apparatus) are uncorrected. The nmr spectra (80-MHz ^1H and 20.13-MHz ^{13}C) were obtained with a Bruker WP80SY spectrometer or at 7 tesla (300-MHz ^1H) and 300 K with a Bruker AM-300 equipped with process controller and "array processor". A 60-mg sample of product **1** was used for the 2D experiments. A 30-mg sample of product **1** was used for nOe difference spectroscopy. The programs from Bruker's library were utilized for COSY (45°) (14), NOESY (15), C/H correlation (16), homonuclear *J*-resolved (17), and CONOESY (90°) (18). The carrier frequency was centered in all cases at the centre of frequencies in both axes, with a precise number of scans in all cases to provide complete phase cycles. For the COSY, 128 experiments of 64 scans, relaxation delay of 1 s, spectral widths of 1420.45 Hz in *f*2 and 710.23 in *f*1 (2K and 1K data points respectively), and digital resolution of 1.387 Hz/point were used. The resulting matrix was symmetrized. The same conditions were utilized for NOESY experiments, with a mixing time of 0.7 s. For the ^1H–^{13}C measurement, shift correlated 2D-NMR, 128 experiments of 16 scans, a relaxation delay of 2 s, and spectral widths of 7462.687 and 764.994 Hz were used in the *f*1 and *f*2 dimensions (digital resolution of 3.64 and 0.74 Hz/point respectively). For the 2D *J*-resolved experiments, 64 experiments of 32 scans, a relaxation delay of 2.8 s, spectral widths of 500 and 31.25 Hz (digital resolution of 0.488 and 0.122 Hz/point) in the *f*1 and *f*2 dimensions, and TILT and *J*-symmetrized matrix were used. Monodimensional nOe difference experiments were achieved by irradiation for 4 s in series of 8 scans, on-resonance and off-resonance alternately. The ir spectra were recorded on a Perkin–Elmer 983G spectrometer. The rotatory powers were measured on a Perkin–Elmer 240 polarimeter. Mass spectra were

recorded on a Hewlett Packard 5988A instrument. Silica gel, Merck 7729 (less than 0.08 mm), was used for column chromatography. Voucher specimens have been deposited at the Herbarium of the Faculty of Pharmacy (University of Granada).

Isolation of sesquiterpenes

Dried plants (2.8 kg), collected from around Carboneras (Almería) in April, were processed to give 84 g of the terpenic fraction; 60 g of this fraction was processed as indicated in ref. 5, yielding, apart from the sesquiterpenes previously described (6, 8), the following products in order of elution: 4β-hydroxy-9β-acetoxyaromadendrene (**8**) (20 mg) and 4β,9β-dihydroxyaromadendrene (**1**) (1.05 g).

4β,9β-Dihydroxyaromadendrene (1): mp 129–131°C; $[\alpha]_D$ −5° ($CHCl_3$, *c* 1); ir ν_{max} (KBr): 3345, 3040, 1630, and 895 cm^{-1}; ^1H nmr (300 MHz) and ^{13}C nmr (75 MHz): see Table 1; ms *m/z* (rel. int.): 236 $[M]^+$ (12), 221 (31), 218 (17), 203 (26), 200 (12), 189 (40), 185 (23), 175 (51), 160 (73), and 145 (100). *Anal.* calcd. for $C_{15}H_{24}O_2$: C 76.23, H 10.23; found: C 76.25, H 10.21%.

Determination of absolute configuration at C-9 of **1**: 25 mg **1** and 100 mg (±)-α-phenylbutyric anhydride (13); $[\alpha]_D$ −6.4° (C_6H_6, *c* 6.6).

Epoxidation of 1: 60 mg **1** was dissolved in $CHCl_3$ (10 mL) and epoxidized with MCPBA (48 mg), KF (8 mg), and NaF (17.5 mg) for 75 min. The usual processing followed by column chromatography gave product **2** (32 mg); mp 126–128°C; $[\alpha]_D$ −9.3° ($CHCl_3$, *c* 1); ^1H nmr (80 MHz) δ: 3.76 (1H, dd, J_1 = 10.5, J_2 = 1.5 Hz, H-9), 2.93 and 2.68 (2H, ABq, J = 4 Hz, 2H-14), 1.28 (3H, s, 3H-15), 1.08 (6H, s, 3H-12 and 3H-13), 0.76 (1H, m, H-7), 0.47 (1H, dd, J_1 = 11, J_2 = 9 Hz, H-6).

$LiAlH_4$ reduction of epoxide 2: 20 mg **2** was reduced with $LiAlH_4$ (7 mg). Usual work-up followed by column chromatography gave 12 mg **3**. Colourless gum; ir ν_{max} (neat): 3450 cm^{-1}; ^1H nmr (80 MHz) δ: 3.43 (1H, dd, J_1 = 11, J_2 = 2 Hz, H-9), 1.25 (3H, s, 3H-15), 1.13 (3H, s, 3H-14), 1.05 (6H, s, 3H-12 and 3H-13), 0.75 (1H, m, H-7), and 0.38 (1H, dd, J_1 = 11, J_2 = 9 Hz, H-6).

Oxidation of 3: 11 mg **3** was treated with $NaIO_4$ (20 mg), affording, after chromatography, 8 mg of product **4**. Colourless gum; $[\alpha]_D$ +16.7° ($CHCl_3$, *c* 1); ir ν_{max} (neat): 3426 and 1708 cm^{-1}; ^1H nmr (80 MHz) δ: 9.7 (1H, s, H-9), 2.88 (1H, m, $W_{1/2}$ = 16 Hz, H-1), 2.12 (3H, s, 3H-14), 1.26 (3H, s, 3H-15), 1.06 and 1.02 (3H each, s, 3H-12 and 3H-13), 0.76 (1H, m, $W_{1/2}$ = 16 Hz, H-7), and 0.4 (1H, dd, J_1 = 11, J_2 = 9 Hz, H-6).

Hydrogenation of 1: 20 mg **1** was hydrogenated for 2.5 h with H_2 (5 atm; 1 atm = 101.3 kPa). After chromatography **5** (13 mg) was isolated; mp 111–113°C; $[\alpha]_D$ −14° ($CHCl_3$, *c* 1); ir ν_{max} (KBr): 3350 cm^{-1}; ^1H nmr (80 MHz) δ: 3.83 (1H, dt, J_d = 10, J_t = 4 Hz, H-9), 1.25 (3H, s, 3H-15), 1.08 and 1.03 (3H each, s, 3H-12 and 3H-13), 0.9 (3H, d, J = 6.5 Hz, 3H-14), 0.63 (1H, m, H-7), and 0.38 (1H, t, J = 10 Hz, H-6).

Oxidation of 5: 12 mg **5** was oxidized with 30 mg pyridinium dichromate (10) and, after chromatography, gave ketone **6** (10 mg); mp 85–87°C; ir ν_{max} ($CHCl_3$, *c* 3.5): 3450 and 1690 cm^{-1}; ^1H nmr (80 MHz) δ: 2.77 (1H, m, $W_{1/2}$ = 20 Hz, H-10), 2.33 (2H, complex wide signal, 2H-8), 1.3 (3H, s, 3H-15), 1.13 and 1.08 (3H each, s, 3H-12 and 3H-13), 1.07 (3H, d, J = 6.5 Hz, 3H-14), 0.82 (1H, m, $W_{1/2}$ = 18 Hz, H-7), and 0.5 (1H, t, J = 9.5 Hz, H-6); ^{13}C nmr: see Table 2.

$$[\alpha]_D = \frac{\begin{matrix}589 & 578 & 546 & 436\end{matrix}}{\begin{matrix}-176.1 & -186 & -219.3 & -463.5\end{matrix}} (CHCl_3, c\ 1)$$

4β-Hydroxy-9β-acetoxyaromadendrene (8): mp 76–78°C; $[\alpha]_D$ +3.2° ($CHCl_3$, *c* 1); ir ν_{max} (KBr): 3454, 3102, 1735, 1639, 1244, and 900 cm^{-1}; ^1H nmr (300 MHz) δ: 5.09 (1H, dd, J_1 = 11.24, J_2 = 0.5 Hz, H-9), 4.88 and 4.81 (1H each, s, H1-14 and H2-14), 2.19 (1H, m, $W_{1/2}$ = 19.8 Hz, H-1), 2.09 (3H, s, AcO group), 2.06 (1H, ddd, J_1 = 13.74, J_2 = 6.33, J_3 = 1.85 Hz, H-8α), 1.97 (1H, m, $W_{1/2}$ = 22 Hz, H-2β), 1.78 (1H, m, $W_{1/2}$ = 16.37 Hz, H-3β), 1.26 (3H, s, 3H-15), 1.05 (3H, s, 3H-13), 1.01 (3H, s, 3H-12), 0.81 (1H, ddd, J_1 = 11.37, J_2 = 9.4, J_3 = 6.39 Hz, H-7), and 0.49 (1H, dd, J_1 = 11.33, J_2 = 9.41 Hz, H-6); ^{13}C nmr (75 MHz): see Table 2; ms *m/z* (rel. int.): 278 $[M]^+$ (4), 236 (7), 221 (13), 218 (40), 203 (34), 201 (10), 200 (38), 185 (46), 175 (47), 160 (100), 157 (40), 149 (30), 145 (84).

Received December 20, 1988

LUCIE PARENTEAU and FRANÇOIS BRISSE. Can. J. Chem. **67**, 1293 (1989).

Attempts to prepare stoichiometric complexes of the type dicarboxylic acid·18C6·H_2O succeeded only with oxalic, succinic, and glutaric acids. The crystal structure of the succinic acid complex was established by X-ray diffraction at 173 K, and was refined to R_w = 0.038 for 3204 observed reflections. The stoichiometry of the complex is 1:1:1 (succinic acid·H_2O·18C6). In the solid state there is a dimeric H-bonded association, through a center of symmetry, of two succinic acid molecules. Each diacid is also hydrogen bonded to a water molecule. The water molecules, in turn, form two hydrogen bonds each with the crown ether. The diacid–diacid, diacid–water, and the two water–18C6 hydrogen bonds are 2.657(2), 2.636(2), 2.819(2), and 2.910(2) Å long respectively. They are all nearly linear. The structural units are associated and form the centrosymmetric dimer (18C6–H_2O – succinic acid)$_2$. The conformation of the macrocyclic polyether differs significantly from that normally found. Instead of the usual $(ttg)_6$ conformation, that adopted in this complex is $(ttgttgstg)_2$. The two s torsion angles have values of 90.1(3) and 86.9(3)°. In this complex the succinic acid itself is in the *gauche* conformation.

Key words: macrocycle – succinic acid complex.

LUCIE PARENTEAU et FRANÇOIS BRISSE. Can. J. Chem. **67**, 1293 (1989).

On n'a réussi à préparer des complexes du type acide carboxylique·18C6·H_2O qu'avec les acides oxalique, succinique et glutarique. Faisant appel à la diffraction des rayons-X, à 173 K, on a déterminé la structure cristalline du complexe avec l'acide succinique et on l'a affinée jusqu'à une valeur de R_w de 0,038 pour 3204 réflexions observées. La stoechiométrie du complexe est 1:1:1 (acide succinique·H_2O·18C6). À l'état solide, on observe l'existence d'un dimère centrosymétrique formé par ponts-hydrogène entre deux molécules d'acide succinique. Chaque diacide est aussi relié par un pont hydrogène avec une molécule d'eau. Par ailleurs, les molécules d'eau forment chacune deux liaisons hydrogènes avec l'éther couronne. Les longueurs des liaisons hydrogènes diacide–diacide, diacide–eau et des deux molécules d'eau–18C6 sont respectivement de 2,657(2), 2,636(2), 2,819(2) et 2,910(2) Å. Elles sont pratiquement toutes linéaires. Les unités structurales ainsi liées forment un dimère centrosymétrique (18C6–H_2O – acide succinique)$_2$. La conformation du polyéther macrocyclique diffère beaucoup de celle normalement trouvée. Plutôt que le conformation $(ttg)_6$ habituelle, celle qui est adoptée dans ce complexe est $(ttgttgstg)_2$. Les valeurs des deux angles de torsion, s, sont de 90,1(3) et 86,9(3)°. Dans ce complexe, l'acide succinique adopte une conformation *gauche*.

Mots clés : complexe macrocycle – acide succinique.

[Traduit par la revue]

Introduction

In a previous investigation (1) we reported on the crystal and molecular structure of a complex formed between a dicarboxylic acid, oxalic acid, and the macrocyclic polyether, 18-crown-6 (abbreviated 18C6). The oxalic acid complex formed by incorporating H_2O has the stoichiometry $(COOH)_2 \cdot 2H_2O \cdot 18C6$, i.e., 1:2:1 (acid/water/18C6). Such complexes have also been observed with monocarboxylic acids. These included one or two water molecules with such resulting stoichiometries as 2:2:1 and 1:1:1 (2). Most unsubstituted 18C6 crown ethers adopt the highly symmetrical $(ttg)_6$ conformation (1, 9, 15, 18). However, other conformations such as $(tgttttg^-g^+t)_2$ for the uncomplexed macrocycle (16) or (ttg ttg$^-$ttg stgttt sg$^-$g$^-$) in complexes of 18C6 and small cations (17) have also been reported. We decided to study complexes incorporating other dicarboxylic acids such as HOOC—$(CH_2)_n$—COOH to establish if a trend in the stoichiometry and the packing mode could be detected as the number of methylenic groups increased. The points of interest are therefore to find: (a) the stoichiometry of the complex and, in particular, whether the water molecules are always required and in the same proportion; (b) whether the conformation of the diacid is the same as in the uncomplexed state, i.e., in the fully extended conformation; (c) whether the diacid molecule is disordered, as was reported in the case of the oxalic acid complex; (d) whether the conformation of the macrocyclic polyether is always the same.

Experimental

The complexes were prepared by addition of the acid (2.69 mmol), in the solid state, to a solution of 18C6 crown ether (3.78 mmol) in tetrahydrofuran (10 mL) with a small amount of water (0.3 mL). In these preparations, the following diacids were used: succinic, glutaric, adipic, suberic, malonique, decanedioic, and dodecanedioic.

For the X-ray study of the succinic acid complex, a well-formed single crystal was mounted on a Nonius-CAD4 diffractometer. The unit-cell dimensions (see Table 1) and the orientation matrix were computed by a least-squares refinement of the angular settings of 25 well-centered reflections in the range $40 \leq 2\theta \leq 50°$. The integrated intensities of 4011 reflections were measured within the sphere of reflection limited by $2\theta \leq 140°$ and $0 \leq h \leq 13$, $0 \leq k \leq 18$, $-18 \leq l \leq 14$ using graphite monochromatized copper radiation. The $\omega/2\theta$ scan mode was used with a scan range defined by $\Delta\omega = (1.00 + 0.14 \tan\theta)°$. The orientation of the crystal and the intensities of seven reference reflections were monitored every 100 measurements and every hour respectively. The intensity fluctuations were no higher than 1.9% over the duration of the measurements. The 3204 reflections satisfying the criterion $I/\sigma(I) \geq 2.50$ were considered observed and retained for the structure determination and refinement; $\sigma(I)$ was derived from the counting statistics. The diffracted intensities were corrected[1] for Lorentz and polarization effects but not for absorption since the absorption coefficient for the Cu radiation was small.

[1]The programs used are NRC-2, data reduction; NRC-10, bond distances and angles; FORDAP Fourier and Patterson syntheses (A. Zalkin); MULTAN80, multisolution program; NUCLS, least-squares refinement; ORTEP, stereodrawings (refs. 3–6).

TABLE 1. Crystal data

$C_{12}H_{24}O_6 \cdot H_2O \cdot C_4H_6O_4$ ($C_{16}H_{32}O_{11}$)		FW = 400.423	MP = 393 K
Monoclinic	Space group $P2_1/c$	$F(000)$ = 864 e	λ = 1.54178 Å
a = 11.347(3)	b = 15.278(4)	c = 15.023(4) Å	β = 128.78(2)°
V = 2030.26 Å^3	d_0 = 1.29	d_c = 1.310 g cm^{-3}	Z = 4
Crystal size	0.21 × 0.34 × 0.50 mm	μ(CuKα) = 9.04 cm^{-1}	T = 173 K

The structure was solved by direct methods using the MULTAN80 program. All the atoms were located from the E-map computed with the set of phases having the highest combined figures of merit. Once the block-diagonal least-squares refinement of the non-hydrogen atoms, with isotropic then anisotropic temperature factors, had converged, a difference Fourier synthesis revealed all the H-atoms of the 18C6 molecule. These were included in all subsequent cycles of refinement with isotropic thermal parameters. The H-atoms of the water molecule and those of the succinic acid were located in another difference Fourier synthesis. These were also included in the refinement. It was then discovered that one of the acid hydrogens occupied two distinct positions in a 60/40 proportion. Convergence was reached at R = 0.044 and R_w = 0.038 for 3204 reflections.[2] On the final refinement cycle the average parameter shift was 0.03σ (maximum 0.46σ); the mean error of an observation of unit weight S was 2.67. The extreme fluctuations of the residual electron density as shown on the final difference Fourier synthesis were −0.23 and 0.36 e Å^{-3}. The quantity minimized was $\Sigma w\Delta F^2$. The scattering factors used were taken from ref. 7 for non-hydrogen atoms and from ref. 8 for H-atoms.

Results and discussion

Of all attempts undertaken at obtaining complexes with diacids, only those with the oxalic, succinic, and glutaric acids were successful. In all other cases only the starting compounds were recovered. Usually it was the 18C6 molecules that crystallized out first. A complex of 1:1:1 stoichiometry, succinic acid·H_2O·18C6, was obtained after a slow evaporation of the solvent. The crystal structure of the succinic acid complex is discussed below and compared to that of its oxalic acid analog. The final atomic coordinates and the equivalent U values of the anisotropic temperature factors are given in Table 2.[3] A stereoview showing the molecular conformation and the atomic numbering is shown in Fig. 1.

Conformation of the 18C6 crown ether

The bond distances, bond angles, and torsion angles and their esd's are presented in Table 3. The C—C bond distances vary little (range 1.490(3)–1.502(3) Å) and average 1.495 Å. The C—O bond distances also remain in a narrow interval (1.415(3)–1.429(3) Å) and average 1.422 Å. The average of the C—O—C bond angles, 112.7°, is slightly higher than that of the C—C—O bond angles, 109.7°. These features, and in particular the relatively short C—C bond distances, are consistent with the corresponding quantities found in structures containing the 18C6 molecule (9, 11–18).

The salient feature of the 18C6 molecule in this complex is its conformation, which can be described by the (ttgttgstg)$_2$ sequence of torsion angles (t = trans ≃ 180°, g = gauche ≃ 60°, s = skew ≃ 90°). The average value of the torsion angle around the C—C bond is 71.7° and the spread is only ±5°. The conformation about these bonds is *gauche*. On the other hand, 10 out of the 12 torsion angles around the C—O bonds have values within ±3° of their average of 177.2°. These are in the *trans* conformation. The other two torsion angles, C(6)—C(7)—O(8)—C(9) and C(15)—C(16)—O(17)—C(18) have values of 90.1(3) and 86.9(3)° rather than the 180° value usually observed for this crown ether in the D_{3d} symmetry. In a search of the Cambridge Data File[4] for crystal structures containing the 18C6 macrocycle it was found that only one out of 57 reported structures came close to our situation. This conformation was observed by Weber and Sheldrick (9) in a 2:1 complex of 2,4-dinitroaniline and 18-crown-6. However, it should be pointed out that in this centrosymmetric complex, besides the two skew torsion angles, there are also two other torsion angles, which depart quite significantly from a *trans* value that the authors consider to be strongly distorted *trans*. Histograms representing the distribution of the C—C—O—C and O—C—C—O torsion angles, based on the crystal struc-

tures listed in the Cambridge Data File, are shown in Fig. 2. It is clear that in most structures containing the 18C6 crown ether, the macrocycle adopts the $(ttg)_6$ conformation. There are very few examples where the torsion angles deviate significantly from ±60° or 180°. Perrin, Décoret, Bertholon, and Lamartine (10) have proposed six energetically acceptable conformations for the 18C6 macrocycle. These are based on theoretical calculations and dipolar moment measurements. Although

[a]The occupancy factor of H(O23) is 0.60 and that of H(O24) is 0.40.

there are actual examples for only three of the six proposed conformations, our case cannot be associated with any of the six situations examined by Décoret and co-workers (10).

The succinic acid

The bond distances, bond angles, and torsion angles for the succinic part of the complex are given in Table 4. In the succinic acid·H_2O·18C6 complex, the succinic group of atoms is not planar since the main torsion angle, C(20)—C(21)—C(22)—C(23) = 65.5(2)°, is *gauche*. This is unusual since in most compounds containing the succinic group, including the β-form of succinic acid, the conformation around the central bond is *trans* (19). In monomethyl succinate, however, the succinic group is also in the *gauche* conformation (14). Also deviating from planarity are the two carboxylic groups, which are tilted by about 15° as indicated by the torsion angles O(20)—C(20)—C(21)—C(22) and C(21)—C(22)—C(23)—C(24) in Table 4. Another interesting result, caused by the formation of a dimer through O(23)···O(24*) and O(24)···O(23*), is that the two "ends" of the acid molecule are chemically distinct. There is a "carboxylic end" at C(20) since the two C—O bonds are clearly unequal: C(20)—O(19) = 1.207(2) Å and C(20)—O(20) = 1.329(2) Å, while at C(23), the "carboxylate end", the corresponding distances are nearly equal: C(23)—O(23) = 1.283(3) and C(23)—O(24) = 1.252(3) Å. This difference is also reflected in the values taken by the following bond angles: C(21)—C(20)—O(19) = 123.6(1)° and C(21)—C(20)—O(20) = 113.4(1)° at the carboxylic end compared to C(22)—C(23)—O(23) = 116.5(1) and C(22)—C(23)—O(24) = 120.9(2)° at the carboxylate end. A situation in all respects comparable to ours was observed by Kanters *et al.* (14) in monomethyl succinate. There, the two C—O bonds and C—C—O bond angles at the ester end were clearly very different from one another. At the other end of the molecule these quantities, although significantly different, tended to be more equal.

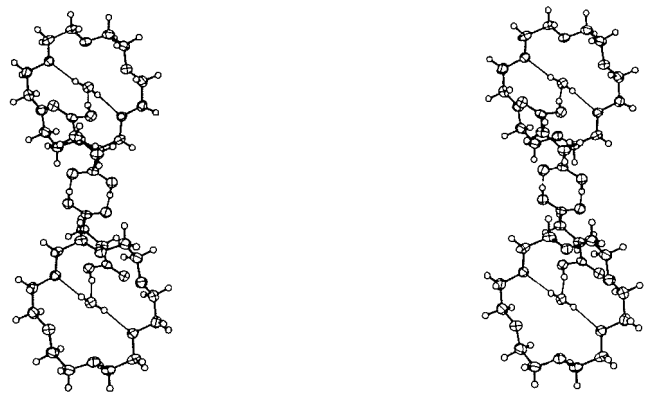

FIG. 3. Stereopair showing the "dimeric" unit formed of (18C6–H_2O – succinic acid)$_2$.

Association of the structural units

The crown ether, the water, and the succinic acid molecules form the crystalline complex through a number of hydrogen bonds. A stereoview of the association of the structural units is shown in Fig. 3. Two centrosymmetrically related acid molecules form strong hydrogen bonds where both O···O distances are 2.657(2) Å. In this dimer, it is found that the H-atoms are delocalized over two sites with respective occupancy factors of 0.60 and 0.40. The H-bonds are nearly linear since the two angles O(23)—H(O23)···O(24*) and O(24)—H(O24)···O(23*) have values of 178(3) and 163(3)° respectively. Except for the disorder of the H-atoms, the H-bonding scheme described here matches that reported for monomethyl succinate (14). There, the O—H···O angle is 172.5° while the O···O distance is 2.66 Å.

The "acid end" of the molecule forms another strong, almost linear, H-bond with the water molecule, d(O···O) = 2.636(2) Å.

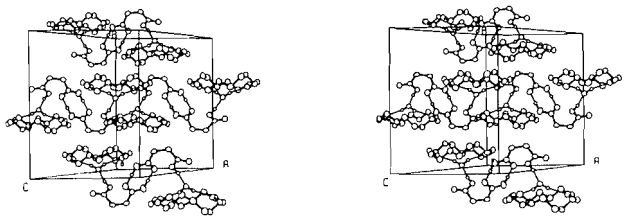

FIG. 4. Stereopair showing the molecular packing.

It is this water molecule which links, through two other hydrogen bonds, the succinic acid and the crown ether. These two H-bonds are relatively long; the O(W)···O(2) and O(W)···O(11) distances are 2.910(2) and 2.819(2) Å respectively. The other geometrical parameters characterizing these hydrogen bonds are given in Table 5. It is to be noted that this mode of association of the structural units bears no relation to that found in the parent oxalic acid complex. In the latter case, the units form a pseudo-polymer through a series of H-bonds that could be described as $(18C6\cdots H_2O\cdots HOOCCOOH\cdots H_2O)_n$. The relative disposition of the dimeric units of the succinic complex in the unit cell is shown in Fig. 4.

It could be that the large size difference between the structural units (diacid vs. 18C6) or the fact that there is a *gauche* torsion angle around the central CH_2—CH_2 bond of succinic acid is responsible for the disorder of the oxalic acid molecule (1). We are still attempting to synthesize higher members in the series to verify this point.

Conclusions

A complex of 1:1:1 stoichiometry is formed between succinic acid, H_2O, and the 18C6 macrocycle. The water molecule that forms two H-bonds with the 18C6 crown ether is also H-bonded to a succinic acid molecule. It, in turn, is centrosymmetrically H-bonded to another succinic acid, thus forming the dimer $(18C6{-}H_2O$ – succinic acid$)_2$. The diacid is not in a fully extended conformation but has a torsion angle of 65° around the central CH_2—CH_2 bond. The crown ether adopts the unusual $(ttgttgstg)_2$ conformation.

Received September 26, 1988[2]

SUPOT V. HANNONGBUA, SIRIRAT U. KOKPOL, and JUMRAS P. LIMTRAKUL. Can. J. Chem. **67**, 1298 (1989).

An *ab initio* MO-SCF calculations have been performed with a minimal Gaussian lobe basis set for numerous Mg(II) 1,4,7,10-tetraazacyclododecane (cyclen) configurations. Mg(II) shows a strong interaction with all functional groups of cyclen. The strongest interaction occurs when magnesium points to the cavity and perpendicular to the ligand plane. However, in the complex formation processes, the ion does not prefer to move along this direction because of the repulsive interaction with the NH functional groups. The favourable path for entering the cavity of the ligand encloses an angle of 30° with the *z* axis and lies in the plane between the opposite NH groups.

Key words: cyclen, macrocyclic effect, complex formation, favourable path, *ab initio* calculations.

SUPOT V. HANNONGBUA, SIRIRAT U. KOKPOL et JUMRAS P. LIMTRAKUL. Can. J. Chem. **67**, 1298 (1989).

Utilisant un ensemble de base gaussien minimal de Lobe, on a réalisé des calculs *ab initio* d'orbitales moléculaires en champ auto-cohérent pour diverses configurations du Mg(II) tétraaza-1,4,7,10 cyclododécane (cyclen). Le Mg(II) interagit fortement avec tous les groupements fonctionnels du cyclen. On observe l'interaction la plus importante lorsque le magnésium est orienté vers la cavité et qu'il est perpendiculaire au plan du ligand. Toutefois, dans le processus de formation du complexe, les interactions répulsives générées par les groupements fonctionnels NH font que l'ion ne se déplace préférentiellement pas le long de cette direction. La voie d'accès la plus favorable pour l'entrée du ligand dans la cavité implique un angle de 30° par rapport à l'axe des *z* et elle se trouve dans le plan qui se trouve entre les groupements NH opposés.

Mots clés : cyclen, effet macrocyclique, formation du complexe, voie d'accès favorable, calculs *ab initio*.

[Traduit par la revue]

Introduction

The term "macrocyclic effect" was introduced by Margerum and co-worker (1) in 1969 to indicate the unusually high stability constants of metal complexes with cyclic ligands compared to equivalent open chain compounds. Several suggestions were made to explain details of this effect. The most frequent suggestions postulate that this effect arises from (*i*) the lower degree of solvation of cyclic ligands due to the steric hindrance of the ring, hence termed "solvation effect" (2, 3), (*ii*) the "prestrained" conformation of the cyclic ligands which is already the conformation suitable for complexation (4, 5), (*iii*) the presence of more secondary donor atoms, resulting in a higher "ligand field strength" of cyclic ligands (6), and (*iv*) the easier dissociation process due to less fixed atoms in the open chain ligand, leading to the term "multiple juxtapositional fixeness" of cyclic ligands (7).

In our previous works (8, 9, 10*a*), the factors contributing to the macrocyclic effect were investigated by means of quantum chemical calculations, neglecting solvation effects and selecting cyclic and open chain ligands with the same number of donor atoms. The results showed that open chain ligands spend considerable energy adapting their structure for optimal ion binding, a conclusion that agrees with the suggested advantages of the "prestrained" cyclic ligands. However, it was also found that electronic effects arising from charge density rearrangements, in their contribution to the stability, are similar in both cases (10*a*).

Solvent effects have been considered by Monte Carlo simulations for 1,4,7,10-tetraazacyclododecane (10*b*–*d*) and its magnesium complex (11, 12) in water. Those investigations have shown that both ligand and complex form discrete solvated structure containing 12 and 18 water molecules, respectively, among which one is located directly above and one below the center of the macrocyclic cavity. According to these results, it has to be expected that enthalpic rather than entropic effects of hydration will influence the stability of macrocyclic complexes, and that substitutions at the macrocycle's nitrogen atoms should

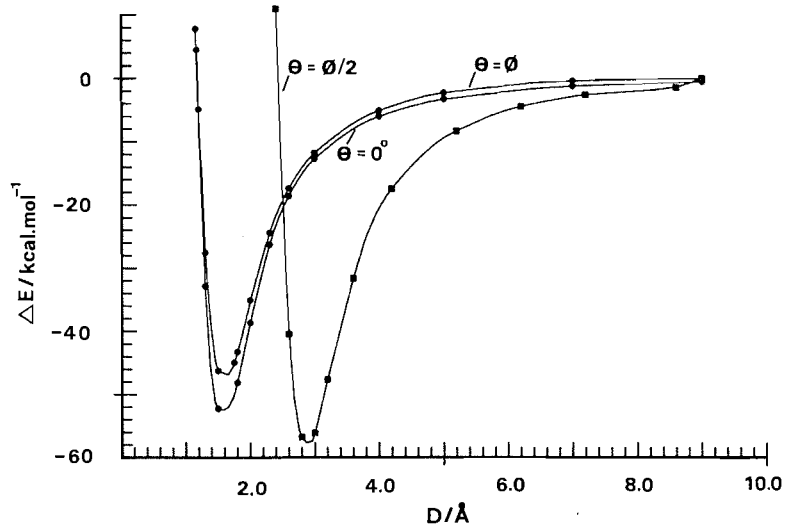

FIG. 2. Mg(II)–cyclen interaction potentials near the hydrophobic CH_2 functional groups in H—C—H plane. θ is the angle between C—H bonds and a vector ***r*** pointing to the C atoms. $\phi = \angle HCH$.

have a considerable influence on such solvation contributions (12).

In the present study, the interaction potential between Mg(II) and cyclen is analyzed in detail. The optimal path of Mg(II) approach through the potential field of cyclen to its cavity is evaluated and discussed.

Methods of calculation

Considering the solvation structure around cyclen from our Monte Carlo results (10*c*, *d*) the ligand field can be divided into three different regions, the strongest hydrophilic funnel-shaped regions above and below the molecular plane around the molecular center (see Fig. 1), the hydrophilic regions around the NH functional groups and the hydrophobic regions near the CH_2 groups. Interaction energies between Mg(II) and 1,4,7,10-tetraazacyclododecane for numerous configurations in these three regions have been evaluated by *ab initio* LCAO-MO-SCF calculations with a minimal Gaussian lobe basis set (13) successfully used in previous investigations (8–11). The optimized geometry of cyclen was taken from our previous work (9) (Fig. 1) and kept constant throughout the calculations, since optimization of the Mg(II)/cyclen complex has led to only minor changes of conformation (10*a*, 14). An estimation of the basis set superposition error (15) was performed for the configuration where Mg(II) is located in the center of the cavity.

All calculations were performed on the IBM-3031 computer of Chulalongkorn University, using an adapted version of the MO-SCF program given in ref. 16.

Results and discussion

The Mg(II)–cyclen interaction potentials for the three important regions around CH_2 and NH functional groups and near the molecular center are shown in Figs. 2, 3, and 4, respectively.

(i) Mg(II)–cyclen interactions near the hydrophobic CH_2 functional groups

In Fig. 2, curves are characterized by the angles θ and φ, where θ being the angle between C—H bonds and a vector ***r*** pointing to the C atoms, and φ being the H—C—H angle. The interactions between Mg(II) and cyclen in the H—C—H plane are plotted for three different orientations, i.e. along the two different types of C—H bonds, where $\theta = 0°$ and $\theta = \phi$ (cf. ref. 10*b*), and bisecting the H—C—H angle, where $\theta = \phi/2$. The results show that Mg(II) interacts strongly with cyclen even when approaching this hydrophobic area. The energy minimum differ by about 6 kcal, as the axial H atom ($\theta = 0°$) has a smaller partial charge, +0.14 atomic charge units according to Mulliken population analysis (17) compared to +0.02 of the equatorial one ($\theta = \phi$). Besides this lower repulsion, the approach near the axial hydrogen brings the metal ion into a position very close to the hydrophilic region and hence favours this pathway.

(ii) Mg(II)–cyclen interactions near the hydrophilic NH functional groups

The interaction of Mg(II) with NH functional groups of cyclen are shown in Fig. 3. The angle between the *z* axis and a vector ***r*** pointing to N atoms is denoted by θ and φ; where θ is the angle between the *z* axis and the N—H bonds. Angles $\theta = 0°$, 90° and φ represent interactions parallel and perpendicular to *z* axis and along the N—H bond, respectively. The depth of the minima is directly proportional to the angle between that path and the N—H bond. This relation can be described by the repulsive interaction between Mg(II) ion and the partial positive charge of hydrogen atoms (of the NH functional groups) of cyclen.

(iii) Mg(II)–cyclen interactions in the hydrophilic funnel regions above and below the molecular plane

In Fig. 4, where θ is the angle formed by the *z* axis and a vector ***r*** in the *xz* plane (Fig. 1), interactions of Mg(II) with the molecular center of cyclen in five different orientations are given. In all cases, Mg(II) ion is attracted into the molecular center of the ligand except for $\theta = 90°$ because of the hindrance by the dimethylene bridges. In cases where $\theta = 45°$ and 60°, Mg(II) shows a very strong repulsion with the molecular backbone of cyclen within a distance of 1.2–3.4 Å. At shorter distances, the curves are lowering steadily until Mg(II) ion reaches the cavity. When $\theta = 0°$, repulsion with the NH functional groups can also be recognized from a fluctuation of the curve between 2.2–2.4 Å.

The trajectory where $\theta = 30°$ is the only one displaying no shoulder and leads to optimal stabilization (about 50 kcal lower than for $\theta = 0°$ at 2.3 Å). Therefore, it will be the most

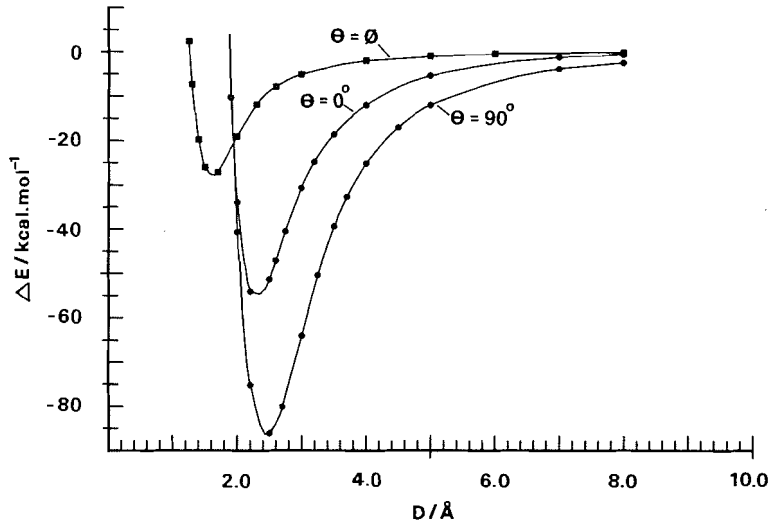

FIG. 3. Mg(II)–cyclen interaction potentials near the hydrophilic NH functional groups in the plane passing through the N—H bond and the z axis. θ is the angle between z axis and a vector $\boldsymbol{r}$ pointing to N atoms. ϕ is the angle between z axis and N—H bond.

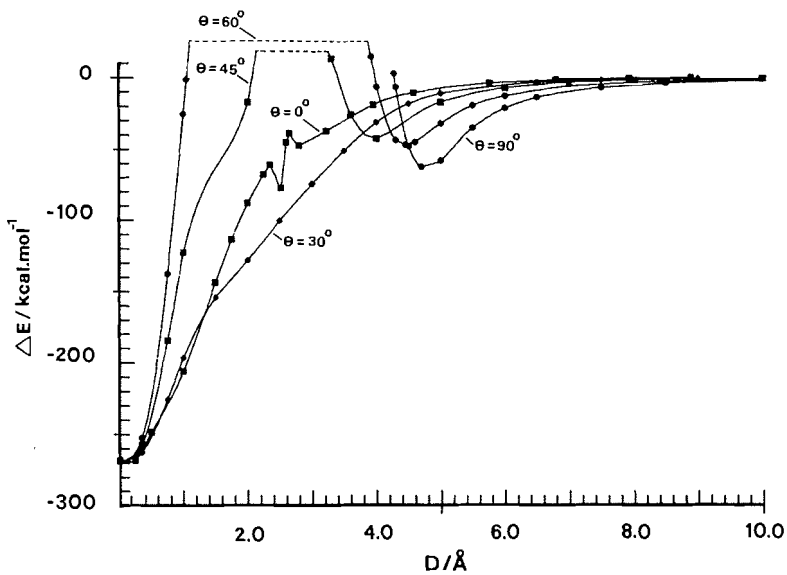

FIG. 4. Mg(II)–cyclen interaction potentials near the hydrophilic "funnel regions" above and below the molecular center in "xz" plane. θ is the angle between the z axis and a vector $\boldsymbol{r}$ pointing to the molecular center.

favourable path for moving the ion into the cavity of the ligand in the complexation process, avoiding repulsion with NH functional groups and dimethylene bridges of the molecular backbone of the ligand.

Further, such an approach will strongly facilitate the elimination of the one central water molecule located above the cavity according to the Monte Carlo results (10*d*), expelling it simultaneously as the ion moves in. The binding energy of the water molecule is only 12 kcal mol^{-1} (10*b*) compared to 270 kcal mol^{-1} for Mg(II) ion (Fig. 4). The water molecule on the other side of the plane needs not to be moved, and can immediately become a part of the complex's solvation shell. The other solvation water molecules located farther in the shape of a funnel (10*d*) can cooperate in the displacement of the metal ion's hydration water by offering alternative coordination site.

The above conclusion also confirms the kinetic inertness of macrocyclic complexes (18) in exchanging the metal ion. Any collision between macrocyclic ligand and ion will result in exchange only if this specific trajectory is followed. Thus, the reaction will be able to occur only within a reaction area which is less than 20% of the whole space around the macrocyclic ligand.

The results reported here provide some first information for the complexation process. Although stabilization energies computed with the small basis set are usually overemphasized due to basis set superposition error (13.5 kcal mol^{-1} or 5% at the lowest-energy configuration), relative stabilities are satisfactorily reproduced in almost every case (8–10, 19). On the other hand, the size of the system under consideration did not allow the use of extended basis sets because of the enormous computation time that would have been required.

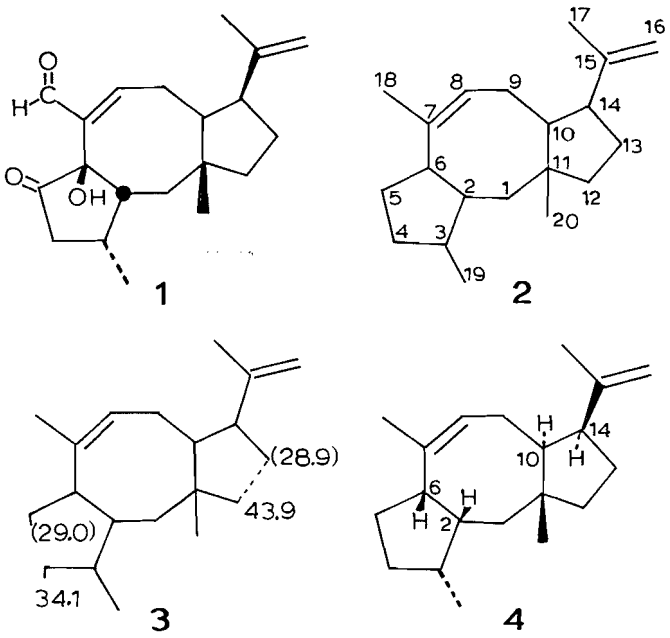
Received February 27, 1989

ALBERT STOESSL, G. L. ROCK, and J. B. STOTHERS. Can. J. Chem. **67**, 1302 (1989).

A tricyclic diene, traversiadiene, isolated from cultures of *Cercospora traversiana* has been shown to have the structure and stereochemistry of the previously postulated hydrocarbon intermediate on the biosynthetic pathway to traversianal (**1**). Detailed ^1H and ^{13}C magnetic resonance studies, including homo- and heteronuclear correlation spectra, led to the gross structure, and the stereochemistry was established through a series of nuclear Overhauser effect difference spectra.

Key words: diterpene, traversiadiene, ^1H and ^{13}C magnetic resonance spectra.



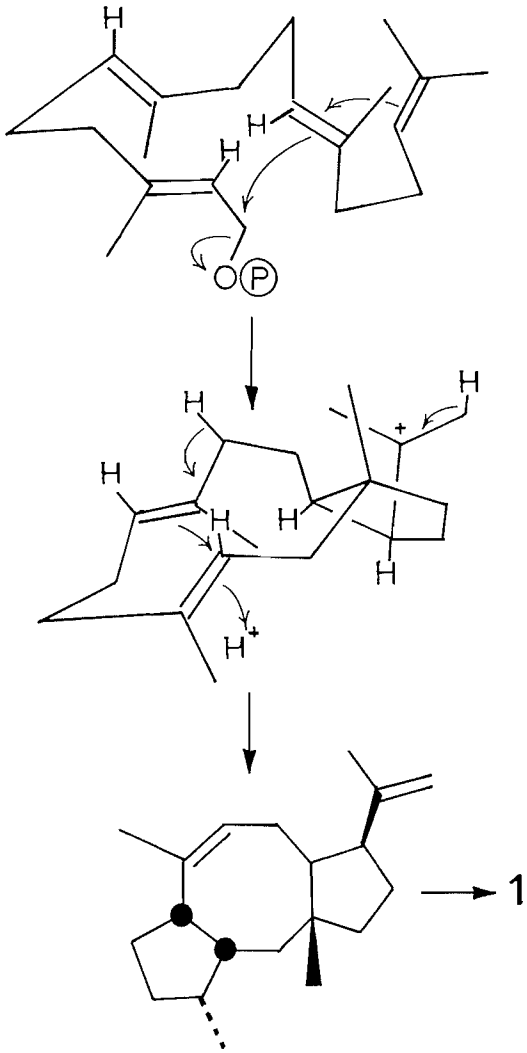
ALBERT STOESSL, G. L. ROCK et J. B. STOTHERS. Can. J. Chem. **67**, 1302 (1989).

On a démontré qu'un diène tricyclique, le traversiadiène, isolé de cultures de *Cercospora traversiana* possède la structure et la stéréochimie de l'hydrocarbure intermédiaire dont la présence sur le chemin biogénétique allant au traversianal (**1**) avait été postulée antérieurement. Des études détaillées de résonance magnétique nucléaire du ^1H et du ^{13}C, comportant des spectres de corrélation homonucléaire et hétéronucléaire, ont été utilisées pour déterminer la structure; pour établir la stéréochimie, on a fait appel à une série de spectres permettant d'évaluer la différence d'effet Overhauser nucléaire.

Mots clés : diterpène, traversiadiène, spectres de résonance magnétique du ^1H et du ^{13}C.

[Traduit par la revue]

Traversianal (**1**), a novel tricyclic diterpenoid aldehyde, recently isolated as a fungal metabolite of *Cercospora traversiana*, has been fully characterized (1). In the course of the study, the probable biosynthetic origin of the aldehyde was found to be similar to that demonstrated by other workers for several ophiobolins but, nevertheless, to differ therefrom in an important stereochemical feature and its consequences. A tricyclic diene was proposed as the likely hydrocarbon precursor of **1** (Scheme 1). A careful chromatographic search of the extracts of the fungal cultures for related metabolites has now led to the isolation of a diene, which in fact has the proposed structure **2** and has been named traversiadiene. Its structure and stereochemistry have been established through a series of nmr experiments which we wish to report in this paper.



Mother liquors from which traversianal had separated were carefully chromatographed over silica to yield **2**, which was readily purified by recrystallization. The compound showed end absorption in the uv spectrum, and the ^1Hmr spectrum indicated the presence of one trisubstituted double bond (δ 5.51, 1H) and a terminal olefinic methylene group (δ 4.65, 4.73). Its constitution as a diterpenoid tricyclic diene was confirmed from a precise mass measurement giving its molecular formula as $C_{20}H_{32}$. Other readily discernible features in the proton spectrum included signals for four methyl groups: a doublet, δ 0.80 (J = 7.1 Hz), a broadened singlet, δ 0.97, and two olefinic methyls, δ 1.67 (dd, J = 0.7 and 1.4 Hz) and δ 1.71 (bd, $J \sim 1.4$ Hz), and five separately resolved one-proton multiplets, three having identical patterns to three multiplets in the ^1H spectrum of **1**. The ^{13}Cmr spectrum contained 20 signals including those for four methyl, six methylene, five methine, and a quaternary carbon in addition to those for a terminal and a trisubstituted double bond. All of these data are quite compatible with structure **2** for this diene and confirmation was sought through a series of correlation experiments.

Initially, the individual ^{13}C signals were correlated with specific ^1H patterns through a heteronuclear ^{13}C–^1H COSY experiment which (a) readily matched the methyl signals, (b) revealed that three of the five resolved multiplets noted above arise from methine protons while the other two arise from an individual methylene group, and (c) gave the approximate positions of the remaining methylene and methine patterns. The spectrum obtained from a homonuclear ^1H COSY experiment showed that the terminal olefinic protons, H-16, δ 4.65 and 4.73, are coupled to the olefinic 15-methyl protons, δ 1.67 (δ_C 23.0), and that at δ 4.65 is also coupled to the 14-methine

SCHEME 1

proton at δ 2.92 (δ_C 51.0). The latter is coupled to a pair of methylene protons, H-13, near 1.65 and 1.80 ($\delta_C \sim 29$) and to a methine proton, H-10, near 1.60 ppm (δ_C 56.2). Thus, the diene contains an isopropenyl group bonded to a methine centre, which in turn is bonded to another methine and a methylene group. The individual shieldings of these nine protons and six carbons are very similar to the data previously determined for this fragment in **1**. The lone olefinic proton, H-8, at δ 5.51 was clearly coupled to the 18-methyl group at δ 1.71 (δ_C 22.0), the 9-methylene protons at δ 1.8, 2.1 (δ_C 24.3), and the 6-methine proton at δ 3.02 (δ_C 42.4). The lower field methylene proton (2.1) appeared to be coupled to the 10-methine proton at δ 1.6. The H-6, δ 3.02, multiplet, a broadened "triplet", was found to be also coupled with the 2-methine absorption at δ 2.26 (δ_C 46.5) and the 5-methylene group near 1.65 and 1.85 ppm ($\delta_C \sim 29$). The δ 2.26 methine proton, H-2, is coupled to the remaining 3-methine pattern near δ 2.15 and the only clearly resolved methylene proton multiplets in the spectrum, δ 1.17 and 1.49, H-1, appearing as the AB part of an ABX pattern, $J_{AB} = 13.6$, $J_{AX} = 12.8$, $J_{BX} = 3.6$ Hz. The lack of additional resolvable coupling indicates that this methylene group is bonded to the quaternary centre, δ_C 44.3. The fifth methine proton, δ_C 2.15, H-3, is that coupled to the 19-methyl group at 0.80 (δ_C 18.7). These methyl protons were shown to be vicinally coupled to the 2-methine carbon at δ_C 46.5 (δ_H 2.26)

[a]Shieldings in ppm from internal TMS in CD_2Cl_2 solution; ^{1}H–^{1}H couplings in Hz listed in parentheses. The corresponding shielding data for several positions in **1** are included, in square brackets, for comparative purposes.

[b]These two values may be interchanged.

and the 4-methylene carbon at δ_C 34.1 through a long range heteronuclear ^{13}C–^{1}H correlation experiment utilizing the XCORFE sequence (2). This spectrum also revealed vicinal coupling of the angular methyl protons, H-20, at δ 0.97 (δ_C 19.1) with the 10-methine carbon at δ_C 56.2 and the methylene carbons at δ_C 39.9 and 43.9 (C-1 and -12), as well as geminal coupling with the quaternary carbon, δ_C 44.3. A complete tabulation of the ^{1}H and ^{13}C results is given in Table 1, in which are included some of the shielding data for **1**, for comparison. The results for **2** lead directly to fragment **3**, for which the ^{13}C shieldings for the "end" groups are indicated. While the completion of the structure requires two linkages between these four "end" groups, only structure **2** could arise from geranylgeranyl pyrophosphate with no carbon–carbon rearrangement during the biosynthesis, as has been established for **1** (1). The dashed linkage in **3** follows from comparison of the shieldings for C-9 through C-17 in the two compounds (see Table 1), providing support for the proposed structure **2** for the diene.

To obtain further evidence bearing on the relative disposition of some of the nuclei in the diene a series of nuclear Overhauser effect (nOe) experiments was carried out. Saturation of the angular methyl protons at δ 0.97 enhanced the methine absorptions at δ 2.26 and 3.02 (H-2 and -6, respectively) as well as the methylene pattern at δ 2.13 (H-9). Irradiation of the olefinic proton, δ 5.51, enhanced the second 9-methylene proton at δ 1.83. Enhancement of the δ 2.13 proton was also observed upon saturation of H-6 (δ 3.02), which also increased the intensity of H-2 absorption (δ 2.26). Saturation of the latter pattern enhanced the absorptions for H-6, the angular methyl, the 9-proton at δ 2.13, and H-1 at δ 1.49. Consequently, we could conclude that these nuclei are on the same side of the molecule. Irradiation of the other 1-methylene proton (δ 1.17) enhanced the pattern for its partner, δ 1.49, and the methine absorption, a broadened triplet, δ 1.60, due to H-10. This

pattern was also enhanced by irradiation of the methine proton at δ 2.92, H-14, which, in addition, increased the intensity of the olefinic methylene proton at δ 4.65. The latter observation indicates this to be the proton *trans* with respect to the olefinic methyl group, δ 1.67, δ_C 23.0. Saturation of the methyl doublet, δ 0.80, led to enhancement of the patterns for H-3, δ 2.15, and those for the 1-methylene protons, H-1. These results are exactly analogous to our findings for **1** with the added feature of the stereochemistry at C-5 (see **4**). Since **1** bears a hydroxyl group at this position, its orientation was not established, but models indicated that a *cis* junction of the cyclopentanoid ring at C-2 and -6 is the more favorable. For diene **2**, the nOe results clearly show that H-2 and -6 are *cis* with respect to each other *and* the angular methyl group, while the secondary methyl group, H-10 and -14, is on the opposite side of the molecule as depicted in **4**.

Another compound obtained from one of the chromatographic fractions was identified as brassicasterol by direct comparison with specimens, both from *C. arachidicola* (3) and *Taphrina deformans* (4). We have also isolated the same sterol from *C. kikuchii*. The isolation from three *Cercospora* spp. suggests that it may be a frequent metabolite of this genus. The common occurrence of the compound in several families of the *Ascomycotina* has been discussed by Weete *et al.* (5).

Experimental

General procedures and routine instrumentation were employed as previously described (1). Cultures of *Cercospora traversiana* were grown on potato-dextrose agar in 92 Petri dishes and extracted as before after 16 days' growth. The mother liquors from which crude traversianal (**1**, 43 mg) had separated were chromatographed over SiO_2 (Camag DFO, 100 g), impregnated by slurrying with tartaric acid (7.5% in MeOH), filtering, and drying, first at room temperature, finally at 110°C for 1.5 h) with $EtOAc/C_6H_5Me$ (5:95 v/v; 10-mL fractions). Pure traversiadiene (18 mg) was obtained from fractions 13–15 by evaporation, trituration with MeOH, and two recrystallizations from $MeOH/CH_2Cl_2/$, mp 70–72°C; $[\alpha]_D^{24}$ +6° (*c* 1.0, CCl_4); ir (CCl_4): 3107 (w), 3069, 2948, 2874, 1635 (m), 1453, 1380, 892; ^1H and ^{13}Cmr: see Table 1; ms *m/e*: 272 (M^+), 257, 229, 215, 189, 175, 161, 149, 148, 147, 135, 121, 109, 107 (100). *Exact Mass* calcd. for $C_{20}H_{32}$: 272.2504; found: 272.2501.

Another 10 mg of good quality traversiadiene was obtained by sublimation (35°C, ca. 0.7 Torr (1 Torr = 133.3 Pa)) of the trituration and recrystallization mother liquors.

The nmr spectra were recorded with a Varian XL-300 system using a 9-mg sample of **2** in CD_2Cl_2 solution. The $^1H-^1H$ coupling interactions were identified by a homonuclear correlation (COSY) spectrum using the HOMCOR pulse sequence of the XL software. The spectrum was obtained with a 1024 × 512 data point matrix transforming 1024 points in both F_1 and F_2 with pseudo echo processing and a 1650-Hz spectral width in both domains. A series of nOe difference spectra were recorded with a spectral width of 1650 Hz, 90° pulses, a 2-s acquisition time, and a 17% duty cycle. A total of seven 16-transient blocks, each with 8 steady-state pulse cycles, was collected at 10 frequencies, one of which was 5000 Hz off-resonance. Subtraction of the latter free-induction decay (fid) from each of the nine fids containing a saturated absorption before 32 K transformation gave the required difference spectra. The ^{13}Cmr spectra were obtained at 75.4 MHz and the protonation level for each carbon signal was determined by recording the APT spectrum. Specific assignments of the protonated carbon signals were obtained by heteronuclear correlation with the proton spectrum using the HETCOR sequence of the XL software. The $^{13}C-^1H$ correlation spectrum utilized a 2048 × 128 data matrix with a 10-kHz spectral width for ^{13}C and a 1.6-kHz width for ^1H, transforming 2048 and 512 points, respectively, with modest (1 Hz) line broadening. Two- and three-bond carbon–hydrogen correlations for the methyl protons were revealed through an experiment utilizing the XCORFE sequence (2). This spectrum was obtained with a 1024 × 220 data matrix, 3000-Hz spectral width for ^{13}C, 1000 Hz for ^1H, and transforming 2048 and 512 points, respectively, after pseudo-echo processing.

The kinetics and mechanism of the reaction between Cr(III) and 2,4-hexanedione in aqueous solution have been studied. Complexation occurs by coordination of both oxygen atoms of the ligand to the chromium(III) center, with concomitant loss of a proton yielding 1:1 complex of the type $[Cr(CH_3COCHCOC_2H_5)(H_2O)_4]^{2+}$. When the metal ion is in pseudo first-order excess the concentration dependence of the observed rate constants agrees with a mechanism involving reversible reaction between the enol tautomer of 2,4-hexanedione and the metallic species $Cr(H_2O)_6^{3+}$ and $Cr(H_2O)_5OH^{2+}$, with rate constants of 8.0×10^{-4} and 3.5×10^{-2} dm^3 mol^{-1} s^{-1}, respectively.

Key words: chromium(III), β-diketones, β-diketonates, kinetics, complexation.

CARLOS BLANCO, JOSÉ M. HERNANDO et MANUEL MATEO. Can. J. Chem. **67**, 1305 (1989).

La cinétique et le mécanisme de la réaction de la 2,4-hexanedione avec le Cr(III) en solution aqueuse ont été étudiés. La complexation se produit par la coordination de tous deux atomes d'oxygène du ligand avec le chrome(III), avec une perte simultanée d'un proton pour produire le complexe 1:1 du type $[Cr(CH_3COCHCOC_2H_5)(H_2O)_4]^{2+}$. Quand l'ion métallique se trouve en pseudo premier-ordre excès, l'influence de la concentration sur la constante de vitesse observée s'accorde avec une mécanisme réversible selon lequel le tautomére énol réactionne avec les espèces $Cr(H_2O)_6^{3+}$ and $Cr(H_2O)_5OH^{2+}$. Les constantes de vitesse qui correspondent à ces réactions ont pour valeur $8{,}0 \times 10^{-4}$ et $3{,}5 \times 10^{-2}$ dm^3 mol^{-1} s^{-1}, respectivement.

Mots clés : chromo(III), β-dicétones, β-dicétonates, cinétique, complexation.

Introduction

In recent years a number of papers dealing with the kinetics and mechanisms of the reactions of metal and oxometal ions with β-diketones have appeared in the literature (1–6).

Chromium(III) complexes have been less well studied than the Cu(II), Co(II), Ni(II), or Fe(III) systems which are classified as "labile" metal ions. The particularly interesting feature of chromium(III) chemistry is that the complex-formation reactions from hexaaquachromium(III) or its monohydroxy species are very slow. Substitution at chromium(III) centres has received attention (7) because of the possibility of A (or I_a) (8) associative mechanisms for the d^3 electronic configuration.

We have studied the reaction of chromium(III) with 2,4-hexanedione in the pH region 2.0–3.0 at temperatures typically used for chromium kinetics work (50°C) and ionic strength I = 0.5 mol dm^{-3}.

The aim of the present work is the elucidation of the mechanism and the rate of 1:1 complex formation in aqueous solution by measuring the chemical reaction rate using a spectrophotometric method.

Experimental

The solutions of Cr(III) were prepared from Aldrich reagent grade $Cr(NO_3)_3.9H_2O$, and they were standardized by oxidizing the chromium(III) to chromium(VI). 2,4-Hexanedione (propionylacetone, PAH) obtained as Kodak reagent grade, was freshly distilled prior to use. Unless otherwise indicated, all materials were of reagent grade (Merck) and were used without further purification. The ionic strength of all solutions was adjusted to 0.5 mol dm^{-3} using $HClO_4$–$NaClO_4$ solutions. Spectra were recorded on a Spectronic 1201 UV-visible spectrophotometer and the kinetic data were obtained by following the absorbance increase in the vicinity of 327 nm using a kinetic programme. pH measurements were made with a Crison 501 pH-meter equipped with an Ingold combined glass-and-reference electrode.

[1]Revision received April 3, 1989.

Results

Tautomerization equilibrium

The keto–enol tautomerization equilibrium of 2,4-hexanedione may be represented by reaction [1] where PAH_k and PAH_e represent the keto and enol tautomers, respectively.

$$[1] \quad PAH_k \underset{k_f}{\overset{k_e}{\rightleftharpoons}} PAH_e$$

The enolization rates of β-diketones (k_e) are measured by a bromination procedure (2). Usually, the enol tautomer and any enolate ion present react rapidly with bromine added. To maintain equilibrium some of the keto tautomer converts to the enol tautomer which then reacts with bromine; hence the rate of enolization parallels the rate of bromination. Therefore

$$[2] \quad -d[Br_2]/dt = -d[PAH_k]/dt = k_e[PAH_k]$$

$$[3] \quad [Br_2] = A/\epsilon \quad \text{and} \quad [PAH_k] = (A/\epsilon + a - b)$$

where A is the optical density at time t due to the absorbance of bromine, ϵ is the molar absorptivity of bromine in a cell of 1 cm path length, a is the total concentration of β-diketone, and b is the total concentration of bromine. Making the appropriate substitution in eqs. [2] and [3], we obtain [4]

$$[4] \quad -\ln (A/\epsilon + a - b) = k_e t + C$$

where C is a constant.

A plot of the left-hand side of eq. [4] against time gives a straight line of slope k_e, the rate of enolization of the β-diketone.

Since $[PAH] = [PAH_k] + [PAH_e]$, from intercepts obtained in eq. [4] the 2,4-hexanedione enol fraction $y = [PAH_e]/[PAH]$ has been determined equal to 0.16 at 20°C. This result is in agreement with literature values (9, 10).

Stability constant of complex

The composition of the complex that chromium(III) forms

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12

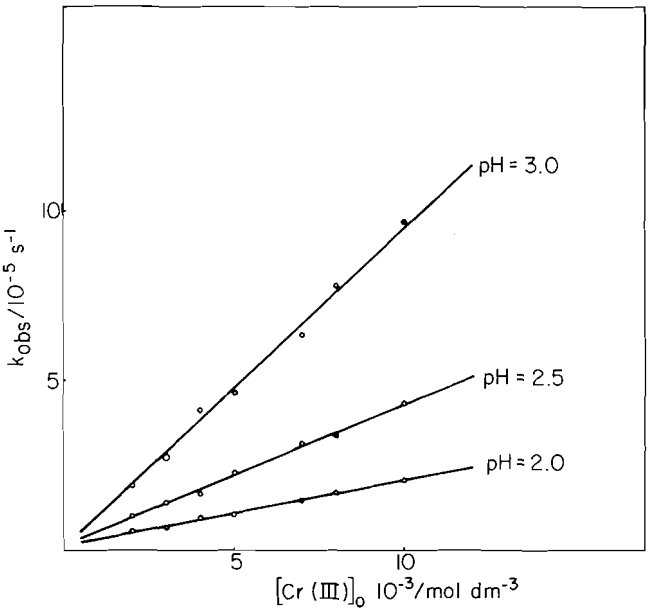

FIG. 1. k_{obs} as a function of the total concentration of chromium(III) at 50°C and ionic strength 0.5 M ($NaClO_4$). [PAH] = 1.0×10^{-4} M.

with 2,4-hexanedione in aqueous solution has been investigated spectrophotometrically using the Job (11) and Yoe–Jones (12) methods. The pH range was low enough to prevent hydrolysis products other than $Cr(H_2O)_5OH^{2+}$ and the ionic strength was kept at a constant value with $HClO_4/NaClO_4$ buffer solutions. The results from both methods agree on a 1:1 stoichiometry (13).

Although the complex ion which will be studied in this work is $Cr(H_2O)_4PA^{2+}$, for the sake of simplicity, the solvent molecules will not be written, so the stability constant of $CrPA^{2+}$ complex can be written as,

$$K = \frac{[CrPA^{2+}]}{[Cr(III)][PA^-]}$$

The direct determination of this equilibrium constant is rather complicated because several competing reactions can take place which can affect the extent the complex formation. This is quantitatively expressed by the conditional constants:

$$[5] \quad K' = \frac{[CrPA^{2+}]}{[Cr'][PA^{-\prime}]}$$

where [Cr'] and [$PA^{-\prime}$] are the total concentration of chromium and the total concentration of ligand that does not form the complex, respectively (14). The stability constant can be connected with the conditional constant by

$$[6] \quad K = K'\left\{1 + \frac{K_1}{[H^+]} + \frac{K_2}{[H^+]^2} + 2\frac{K_3[Cr^{3+}]}{[H^+]^2}\right\}\left\{1 + \frac{[H^+]}{K_I}\right\}$$

where K_1, K_2, and K_3 are the hydrolysis constants of Cr^{3+} to form $Cr(OH)^{2+}$, $Cr(OH)_2^+$, and $Cr_2(OH)_2^{4+}$, which are known from the literature (14, 15) amount to $10^{-4.0}$, $10^{-9.7}$, and $10^{-2.4}$, respectively, at 20°C.

The ionization constant of the ligand, $K_I = 10^{-9.40}$ has been determined in our previous paper (16).

K' can be determined from absorption values at the stoichiometric point according to Job's method in the same way as in a previous paper (17). When data range from 1.00×10^{-1} to 1.00×10^{-3} M acid, $K = 9.6\ (\pm 0.8) \times 10^{10}$ mol^{-1} dm^3.

Kinetic measurements

The reaction of Cr(III) with PAH was carried out with the metal ion concentration in excess over the ligand, at the hydrogen ion concentration 0.01–0.001 M. If the complex stability constant value is taken into account, only the propionylacetonatechromium(III) ($CrPA^{2+}$) ion is formed quantitatively under our experimental conditions. The pseudo first-order rate constants were obtained from plots of ln ($A_\infty - A$) against time, where A_∞ is the complex absorption when the reaction is over.

To study the influence of the Cr(III) concentration on k_{obs}, several series of experiments with constant [PAH], pH, ionic strength, and temperature were performed. It was evaluated by plotting k_{obs} against [Cr(III)], yielding a linear correlation (Fig. 1).

Discussion

Taking into consideration the 2,4-hexanedione tautomeric equilibrium, the mechanism that we have considered is presented in Scheme 1 (coordinated H_2O is omitted for clarity), it is consistent with the assumption that the formation of $CrPA^{2+}$ proceeds via two paths, one involving the reaction of Cr^{3+} with the enol tautomer of PAH, (PAH_e), and the other involving the reaction of $CrOH^{2+}$ with (PAH_e).

[I] $Cr^{3+} \overset{K_h}{\rightleftharpoons} CrOH^{2+} + H^+$

[II] $Cr^{3+} + PAH_e \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CrPA^{2+} + H^+$

[III] $CrOH^{2+} + PAH_e \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} CrPA^{2+}$

[IV] $PAH_k \underset{k_f}{\overset{k_e}{\rightleftharpoons}} PAH_e$

SCHEME 1

The rate of formation of $CrPA^{2+}$ is then given by

$$\frac{d[CrPA^{2+}]}{dt} = k_1[Cr^{3+}][PAH_e] - k_{-1}[CrPA^{2+}][H^+] + k_2[CrOH^{2+}][PAH_e] - k_{-2}[CrPA^{2+}]$$

Substituting the enol fraction $y = [PAH_e]/[PAH]$, then

$$[8] \quad \frac{d[CrPA^{2+}]}{dt} = -(k_{-1}[H^+] + k_{-2})[CrPA^{2+}] + \left(k_1 y + \frac{k_2 K_h y}{[H^+]}\right)[Cr^{3+}][PAH]$$

Moreover

$$[CrPA^{2+}] = [PAH]_0 - [PAH]$$

and

$$\frac{d[CrPA^{2+}]}{dt} = -\frac{d[PAH]}{dt}$$

Therefore

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

$$[9] \quad -\frac{d[PAH]}{dt} = -(k_{-1}[H^+] + k_{-2})[PAH]_0 + (k_{-1}[H^+] + k_{-2})[PAH] + \left(k_1 y + \frac{k_2 K_h y}{[H^+]}\right)[Cr^{3+}][PAH]$$

Integrating this equation and considering the conditions used in this investigation, we get

$$[10] \quad \ln \frac{[PAH]_0 - [CrPA^{2+}]}{[PAH]_0} = -\left\{(k_{-1}[H^+] + k_{-2}) + \left(k_1 y + \frac{k_2 K_h y}{[H^+]}\right)[Cr^{3+}]\right\} t$$

if we consider $[PAH]_0 = [CrPA^{2+}]_\infty$

$$[11] \quad \ln (A_\infty - A) = \ln A_\infty - \left\{(k_{-1}[H^+] + k_{-2}) + \left(k_1 y + \frac{k_2 K_h y}{[H^+]}\right)[Cr^{3+}]\right\} t$$

where A and A_∞ are the absorbances of the reaction system at t seconds after the start of the reaction and at equilibrium, respectively. Thus the conditional first-order rate constant obtained by experiment is

$$[12] \quad k_{obs} = (k_{-1}[H^+] + k_{-2}) + \left(k_1 y + \frac{k_2 K_h y}{[H^+]}\right)[Cr^{3+}]$$

Since $[Cr(III)]_0 \gg [PAH]$, it follows that

$$[13] \quad [Cr^{3+}] = \frac{[Cr(III)]_0[H^+]}{[H^+] + K_h}$$

where $[Cr(III)]_0$ is the total concentration of chromium(III), thus

$$[14] \quad k_{obs} = \frac{k_1[H^+]}{K_E} + \frac{k_2 K_h}{K_E} + \left(\frac{k_1[H^+]y + k_2 K_h y}{[H^+] + K_h}\right)[Cr(III)]_0$$

where $K_E = k_1/k_{-1}$.

The value of K_h at 50°C was found to be 3.98×10^{-4} (18) while the value of y was found by extrapolation of the data at 50°C, taking into account ref. 10, to be 0.10.

Equation [14] suggests that a plot of k_{obs} against $[Cr(III)]_0$ at a constant acid concentration should be linear.

Consequently, the values of rate constants k_1 and k_2 were determined from the slopes of Fig. 1 plots by the method of least squares: $k_1 = 8.0(\pm 0.1) \times 10^{-4}$ and $k_2 = 3.5(\pm 0.1) \times 10^{-2}$ dm^3 mol^{-1} s^{-1}, respectively. Due to the relatively small value of the intercept and the resulting uncertainty, the kinetic data can not be reliably used to obtain a value of K_E.

The mechanisms of the complex formation reactions of β-diketones have been widely investigated [1]–[6] and the reactivity toward metal ions has been found to be enolate ion > enol tautomer > keto tautomer. In the present investigation the results show that the reaction of PAH with Cr(III) occurs by a mechanism in which the metal ions $[Cr(H_2O)_6]^{3+}$ and $[Cr(H_2O)_5OH]^{2+}$ react with the enol form of the β-diketone.

Although the reactions of chromium(III) with 2,4-pentanedione have been thoroughly studied (19–21), and the rate constants can be predicted on the basis of the Eigen–Wilkins mechanism (22, 23), it is not easy to get clear predictions on Cr(III)–2,4-hexanedione complexation.

The relative inertness of chromium(III) with similar ligands (20, 24), may be the reason for the retarded rates of complex formation, when compared with other β-diketonate systems (1–6). For solvent exchange on chromium(III) in aqueous solution $\Delta H^{\neq} = 109.7$ kJ mol^{-1} while $\Delta S^{\neq} = 1.2$ J K^{-1} mol^{-1} (25). Thus the solvent exchange rate in water is 1.4×10^{-5} s^{-1} at 50°C. It is clear that the rate of formation of the $CrPA^{2+}$ complex is considerably larger than the rate of solvent exchange on the metal ion. It follows that the mechanism must be interchange associative (I_a) which involves association of the enol tautomer with the hexacoordinated chromium(III) in a rate-determining step to give an intermediate of increased coordination number. High pressure solvent exchange studies in Cr(III) and other non-labile metal ions Co(III), Rh(III), and Ir(III) (26–28) are in accord with an associative interchange for Cr(III), Rh(III), and Ir(III), while a dissociative interchange is indicated for Co(III). It has been suggested that I_a mechanisms are the rule for the 3+ ions, Co(III) being the exception due to its small size.

[Traduit par la revue]

Introduction

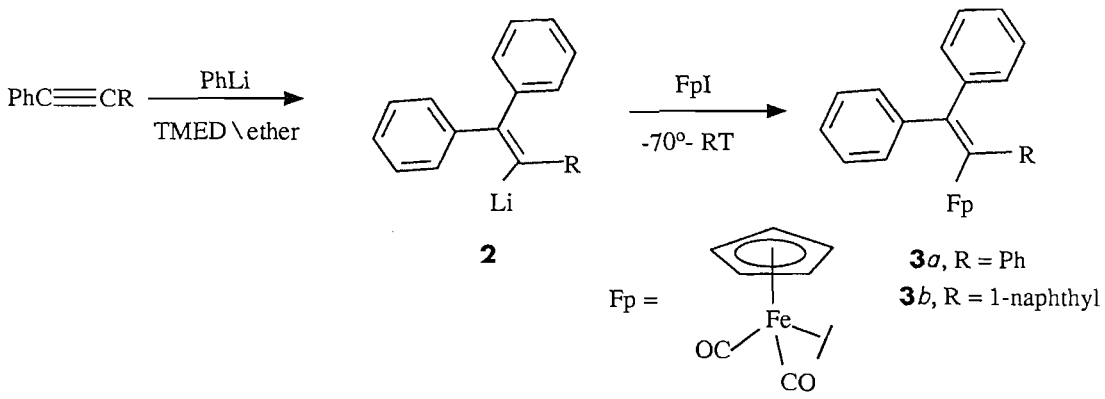
A recent communication described the thermal reactions of Fp—Ar (Fp = dicarbonyl-(η^5-cyclopentadienyl)iron), Ar = Aryl or Aroyl with diarylacetylenes to give 2,3-disubstituted indenones (1). However, the indenone yields are fairly low, typically 10–40%, since a number of byproducts such as aryl and 1,1′-diarylferrocenes, Fp_2, and hexa-arylbenzenes (from acetylene trimerization) are also obtained.[2] A tentative mechanism for indenone formation was proposed which included alkenyliron derivatives, **1**, as possible key intermediates in the

1 L = acetylene or CO, R = 4-methyl, 2-fluoro, 2-chloro, 3-fluoro

synthesis. This intermediate is the product of diarylacetylene insertion into the metal–aryl bond. In an effort to improve the efficiency of the indenone synthesis it was decided to prepare some related alkenyliron complexes independently to use as alternate synthons to the iron–aryl precursors.

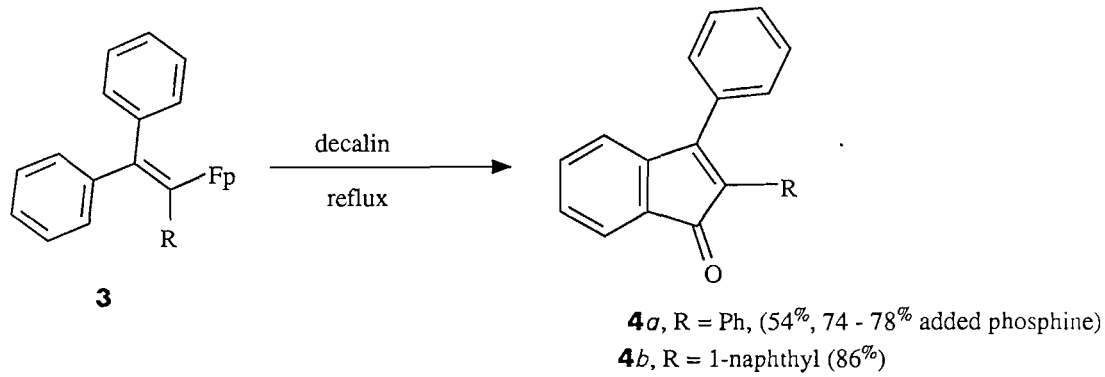
The reaction of 2 molar equivalents of aryllithium with diphenylacetylene (2) in the presence of tetramethylethylenediamine (TMED), followed by metathesis with organometallic titanium halides has been used by Rausch and co-workers (3) to prepare a series of metallocycles. We decided to approach the synthesis of iron–alkenyl compounds using a similar method, since the starting reagents are all commercially available or relatively easy to synthesize. We were, however, interested in the utilization of monolithioalkene derivatives instead of the 1,4-dilithioarylalkenes which had previously been used.

[1]Author to whom correspondence should be addressed.



[2]We have carried out a detailed investigation into the reaction mechanism using deuterium labelling studies, and have examined the reactions of acetylenes with a variety of substrates such as Fp—2-thienyl, Fp—naphthyls, and Fp—*p*-tolyl.

Results and discussion



The ambient temperature reaction of phenyllithium with either diphenylacetylene or 1-naphthyl(phenyl)acetylene in the presence of TMED (24 h) in diethyl ether followed by metathesis with FpI at low temperature gave the alkenyliron compounds **3** (Scheme 1), isolated under an inert atmosphere following column chromatography on neutral alumina. In the case of **3*b*** where there are two possible isomers, preliminary tlc and mass spectroscopic studies of the reaction mixture indicated that both were present. However only one was obtained on crystallization of the mixed product solution following chromatography. Compound **3*b***, thus obtained, is the product from lithiation of 1-naphthyl(phenyl)acetylene to give the least sterically hindered alkenyllithium intermediate. The ^{1}H nmr spectra of **3*a*** and **3*b*** exhibit cyclopentadienyl resonances at 4.53 δ and 4.48 δ, respectively. The ^{13}C nmr spectra ($CDCl_3$) are as anticipated with the cyclopentadienyl ring carbon chemical shifts at 84.2 and 85.9 ppm, respectively. Interestingly **3*b*** exhibits two closely situated (215.1 and 214.8 ppm) resonances for the terminal carbonyl groups. There is no evidence for doubling of any of the other resonances. This is presumably due to restricted rotation, due to the presence of the bulky 1-naphthyl group on the α-carbon of the coordinated alkene. In the electron impact mass spectra these compounds either do not show parent ions or exhibit only weak parent ions: as expected intense peaks are observed corresponding to the loss of two carbonyl groups in each case. In the case of **3*b*** the most intense peak is observed at *m/e* 306 corresponding to the 1,1-diphenyl-2-(1′-naphthyl)ethylene fragment formed by cleavage of the organo-iron fragment and its replacement by a proton.

Heating **3** in decalin at reflux for 10 min under N_2 gave the desired indenones, **4**, in clean, relatively high yielding reactions (Scheme 2). The separation and isolation of the coloured indenones is readily achieved by column chromatography on a short alumina column. Indenone **4*a*** was identified by spectral comparison with an authentic sample and **4*b*** was characterized by a melting point comparison using the literature data, mass spectroscopy, and 2D-^{1}H nmr spectroscopy. A similar reaction of **3*a*** in refluxing xylenes (3 h) or refluxing toluene (5 h) in the presence of a molar equivalent of triphenylphosphine also gave **4*a*** in 74% and 78% yields, respectively.

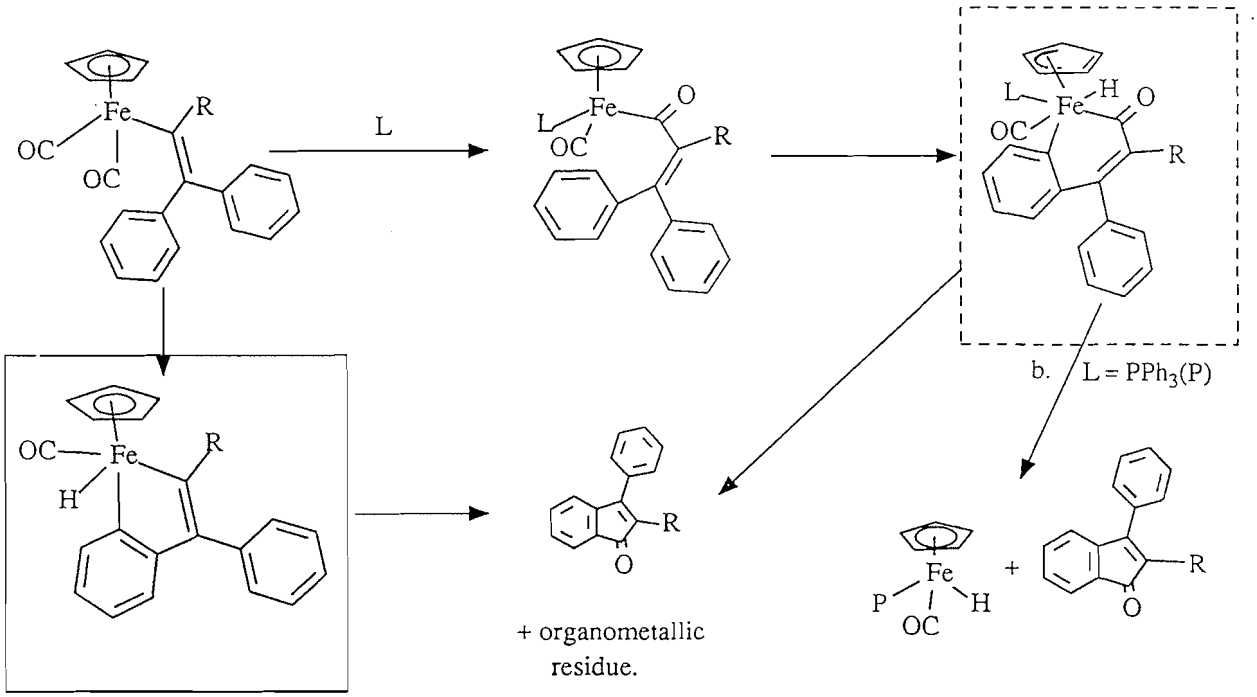
SCHEME 1

SCHEME 2

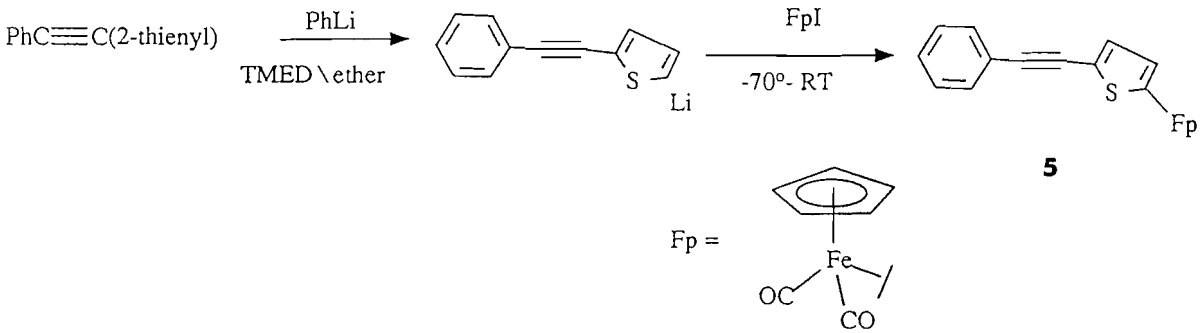
It should be noted that related σ-alkenyl derivatives can be prepared from the reaction of nucleophiles with cationic iron acetylene complexes and thus offer an alternate synthesis of the required precursors **3** (4–6). In addition the desired alkenyllithium reagents can be made perhaps more conveniently by metathesis of the appropriate haloalkenyl compound (7), again allowing an alternate route to the required synthons. Such an approach has been successfully used by Cardin and co-workers in the synthesis of alkenyltitanium, chromium, palladium, platinum, and tin derivatives (8, 9).



The reaction mechanism for the conversion of **3** to **4** requires the insertion of carbon monoxide into the metal–alkenyl bond. Reger *et al.* (10) have shown that related insertion (alkenyl migration) reactions proceed catalytically in the presence of trace oxidants such as ferricinium or Ce(IV) salts. In the present case trace decomposition may be responsible for the generation of an active catalyst. The reaction mechanism is not clear, however: the intermediate may be a five- or six-membered metallocycle depending on whether or not the carbonyl insertion precedes the aryl metallation. Slippage of the η^5-cyclopentadienyl ring to an η^3- or an η^1-coordination mode in the intermediate may occur to maintain a stable electron configuration around iron. In the presence of triphenylphosphine it might be expected that the monocarbonyl(η^5-cyclopentadienyl)triphenylphosphine(hydrido)iron (11–13) is generated but under the experimental conditions used here the hydride would be unstable and decompose to give a mixture of by-products (Scheme 3*b*). In addition to the indenone small quantities of an unidentified deep green complex containing terminal carbonyl, η^5-cyclopentadienyl, and triphenylphosphine in the ratio 1:1:1 are obtained.

An attempted reaction of phenyllithium with 2-thienylphenylacetylene followed by metathesis with FpI gave **5** as a consequence of preferential lithiation of the thienyl ring (Scheme 4). **5** was obtained following column chromatography (in the dark). It is light-sensitive in solution. Compound **5**, unlike the alkenyliron derivatives, exhibits a clear parent ion in its thermal ionization mass spectrum. The ^{1}H nmr spectrum clearly indicates that only two thienyl proton resonances, J_{H-H} = 2.5 Hz, are present. Heating **5** in refluxing decalin results in the formation of a dark polymeric material, presumably the result of intermolecular reaction of the iron centre with the acetylene.

Experimental section



All reactions were performed using conventional Schlenk glassware under an inert atmosphere. Solvents were dried according to standard methods and were distilled prior to use. 1-Naphthyl(phenyl)acetylene was prepared in 96% yield by the palladium catalyzed coupling of phenylacetylene and 1-iodonaphthalene by the adaption of the general procedures of Cassar (14) and Ames and co-workers (15). Nuclear magnetic resonance spectra were recorded using a Varian XL-300 instrument using $CDCl_3$ as sample solvent. Mass spectra were obtained by the electron impact (70 MeV) method on a VG. Analytical 7070E instrument at the University of Ottawa Mass Spectroscopy Centre. Column chromatography was carried out on an activated neutral alumina support starting initially with hexanes as the eluent then using progressively more polar mixtures of hexanes, diethyl ether, and dichloromethane throughout the separations.

(L = CO or triphenylphosphine)

SCHEME 3

SCHEME 4

Preparation of **3**a

A solution of phenyllithium (10 mL of a 2.5 *M* solution), diphenylacetylene (3.00 g, 16.8 mmol), and TMED (1.95 g, 16.8 mmol) was stirred for 24 h in diethylether (100 mL). The reaction mixture was cooled to ca. −70°C and dicarbonyl(η^5-cyclopentadienyl)iodoiron (7.6 g, 25 mmol) was added. After stirring for 1 h at this temperature the mixture was warmed slowly to room temperature. The volume was reduced under vacuum to a few mL and the resulting oil was chromatographed on a neutral alumina support. The deep yellow product band was collected under nitrogen and was crystallized from a 50/50 mixture of hexane/diethyl ether at −20°C to give **3***a* as yellow–orange nodules (47%).

3*a*: ir (hexane) ν_{CO} = 2023, 1968 cm^{-1}. ^{1}H nmr data ($CDCl_3$), δ, 4.53 (s, 5), 6.77–6.91 (m's, 7), 6.92–7.03 (broad t, 1), 7.18–7.24 (m, 1), 7.29–7.40 (m's, 5). ^{13}C, δ (relative intensity): 84.24 (251); 122.99 (61); 124.36 (51); 125.61 (57); 126.88 (125); 126.93 (151); 127.24 (110); 127.87 (139); 130.36 (137); 131.45 (80); 145.58 (29); 148.73 (25); 151.52 (30); 157.84 (32); 214.66 (60).

Preparation of **3**b

The synthesis of **3***b* is identical to that of the above except that diphenylacetylene is replaced by 1-naphthyl(phenyl)acetylene (14). Examination of the reaction mixture by tlc indicated the presence of three yellow bands preceding Fp_2. The first of these was identified as dicarbonyl(η^5-cyclopentadienyl)phenyliron by spectral comparison with an authentic sample. Collection of the latter two bands (mixed isomers 53%, identified individually as such by mass spectroscopy following preparative plate chromatographic separation) followed by crystallization as described above gave **3***b* as yellow/orange needles in 35–40% yield.

3*b*: ir (hexane) ν_{CO} = 2022, 1968 cm^{-1}. ^{1}H nmr data ($CDCl_3$) δ, 4.48 (s, 5); 6.69 (m, 1); 6.74 (t + m, 2); 6.89–6.96 (2m, 3); 7.20 (t, 1); 7.26 (m, 1); 7.31–7.46 (m's, 5); 7.57 (d, 2); 7.65 (d, 1); 8.10 (d, 1). ^{13}C, δ (relative intensity, $CDCl_3$) 85.89 (202); 123.05 (46); 124.84 (57); 124.63 (98); 125.21 (56); 125.27 (20); 126.52 (58); 126.82 (102); 128.14 (123); 128.51 (106); 129.87 (35); 133.57 (37); 142.44 (29); 145.32 (33); 148.58 (31); 152.03 (28); 155.66 (34); 214.76 (24); 215.06 (28).

289 (13.2); 229 (33.1); 228 (52.4); 226 (14.3). *Anal.* calcd. for $C_{31}H_{22}FeO_2$: C 77.19, H 4.60; found: C 76.95, H 4.56.

Preparation of indenones

3*a* or **3***b* in decalin were heated to reflux for 10 min. The cooled mixture was chromatographed on a neutral alumina support (length 15 cm, diameter 6 cm). Initial elution with hexanes developed the decalin. Addition of diethyl ether to the eluent results in the collection of the orange indenone band, which is pure as shown by nmr after solvent removal under vacuum. The indenone may be crystallized at −20°C from a mixture of the eluting solvents. **3***a* was characterized by spectral comparison with an authentic sample and **3***b* was characterized as follows: melting point 159°C, lit., 156°C (16) (lit. mp for the other isomer, 2-phenyl-3-(1′-naphthyl)inden-1-one = 180°C). Ultraviolet: λ_{max}(visible) = 428 nm, lit. = 432 nm. The nmr spectrum was identical to that of a product obtained from the reaction of Fp—benzoyl with 1-naphthyl(phenyl)acetylene.[2]

Preparation of **5**

A mixture of 2-thienyl(phenyl)acetylene (1.84 g, 10 mmol), phenyllithium (10 mL of a 2 *M* solution), and TMED (1.16 g, 10 mmol) in diethylether was stirred for 2 days. FpI (6.08 g, 20 mmol) was added to the chilled (−70°C) solution. After warming to room temperature and stirring at this temperature for 2 h the solvent volume was reduced under vacuum to a few mL and the mixture was chromatographed (the column should be wrapped with aluminum foil to exclude light). Collection of the second yellow band (eluting just prior to Fp_2) and solvent removal gave 2.5 g (69%) of **5** initially as a yellow oil, which was then crystallized from a hexanes/diethyl ether mixture to give yellow/brown needles.

5: ir (hexane) ν_{CO} = 2037, 1987 cm^{-1}. ^1H nmr, δ, 4.98 (s, 5) Cp; 6.72 (d, 1); 7.21 (d, 1), thienyls; 7.43–7.46 (2d's, 2), 7.26–7.30 (m's, 3) phenyls. ^{13}C, δ (relative intensity, $CDCl_3$) 83.67 (9); 85.76 (97); 93.69 (7); 123.84 (11); 127.51 (23); 128.11 (46); 128.20 (15); 131.00 (47); 133.58 (21); 138.44 (21); 142.16 (9); 123.72 (17).

Mass spectrum: 361 (5.6); 360 (26.8) $M^{+\cdot}$; 332 (19.1) $M^{+\cdot} - CO$; 305 (18.0); 304 (85.2); 302 (10.7); 249 (21.8); 248 (100.0); 247 (35.5); 246 (13.5); 216 (18.4); 215 (55.3); 202 (11.5); 186 (48.5); 185 (11.3); 184 (72.9). *Anal.* calcd. for $C_{19}H_{12}FeO_2S$: C 63.00, H 3.33; found: C 62.96, H 3.32.

Reaction of **3**a *in the presence of triphenylphosphine*

The reactions were carried out on a 10 mmol scale as described above using toluene (5 h) or xylenes (3 h) replacing decalin and in the presence of a two-fold molar excess of triphenylphosphine. The product indenone was collected by column chromatography as described above (yields 74% and 78%, respectively). The excess triphenylphosphine is eluted with hexanes/diethyl ether prior to product elution. In addition to the product indenone a green band following Fp_2 (trace, faint red/brown band) was eluted with diethyl ether. On solvent removal this product was crystallized from diethyl ether to give green nodules which gave the following spectroscopic data. Mass spectrum: electron impact, *m/e* (relative intensity) 665 (0.8); 345 (0.8); 284 (5.0); 283 (2.1); 263 (20.6); 262 (100.0); chemical ionization: 335 (5.8); 321 (15.3); 285 (14.5); 263 (100.0). mp 180–181°C. ^1H nmr 4.46 (s, 5); 7.36–7.59 (m, 9).

Reçu le 15 juin 1988[2]

ANDRE G. MICHEL, CHAKIB AMEZIANE-HASSANI, GASTON BOULAY et GILLES LAJOIE. Can. J. Chem. **67**, 1312 (1989).

Cette étude rapporte la synthèse, la détermination de structures cristallines et l'analyse conformationnelle par calculs empiriques de la *N*-tertiobutyloxycarbonyl *N'*-méthylthioalanine (Boc-AlaS-NHCH$_3$, $C_9H_{18}N_2O_2S$) et de la *N*-tertiobutyloxycarbonyl *N'*-méthylthioglycine (Boc-GlyS-NHCH$_3$, $C_8H_{16}N_2O_2S$), composés à l'intérieur desquels la liaison amide conventionnelle a été remplacée par un lien thioamide. Boc-AlaS-NHCH$_3$ cristallise dans le système quadratique, le groupe d'espace étant $P4_32_12$. Boc-GlyS-NHCH$_3$ a cristallisé dans le système monoclinique, correspondant au groupe d'espace $P2_1/c$. Les deux structures ont été résolues par méthodes directes et affinées par la méthode des moindres carrés (matrices entières), jusqu'à des valeurs de *Rw* de 0,045 et 0,035 pour 827 et 1335 réflexions respectivement pour lesquelles l'intensité *I* était supérieure à $2{,}5\sigma(I)$. Les conformations observées pour Boc-AlaS-NHCH$_3$ et Boc-GlyS-NHCH$_3$ correspondent toutes à des minima d'énergie conformationnelle calculés pour les résidus classiques. La longueur du lien C=S de 1,665(9) Å et de 1,650(3) Å constitue la modification majeure en comparaison avec les molécules oxygénées; la présence de l'atome de soufre ne semble pas modifier les propriétés du lien peptidique. À partir des structures cristallines ainsi déterminées, les cartes d'énergie conformationnelle pour des dérivés de la dithioalanine et la dithioglycine ont été calculées par une méthode classique dans le cadre de l'étude structurale des peptides (ECEPP/2) et comparées à celles que l'on obtient pour les résidus classiques. On peut conclure que la synthèse d'une part et l'analyse conformationnelle d'autre part permettent d'inclure le lien thiopeptidique dans des structures plus complexes et d'en prévoir les conformères préférentiels.

Mots clés : conformation moléculaire, structures peptidiques, cristallographie.

ANDRE G. MICHEL, CHAKIB AMEZIANE-HASSANI, GASTON BOULAY, and GILLES LAJOIE. Can. J. Chem. **67**, 1312 (1989).

The present study reports the synthesis, crystal structure determinations, and the conformational analysis of *N*-tertiobutyloxycarbonyl *N'*-methylthioalanine (Boc-AlaS-NHCH$_3$, $C_9H_{18}N_2O_2S$) and of *N*-tertiobutyloxycarbonyl *N'*-methylthioglycine (Boc-GlyS-NHCH$_3$, $C_8H_{16}N_2O_2S$). The particular feature of these compounds is the replacement of the classical oxopeptide linkage by a thioamide bond. Crystals of Boc-AlaS-NHCH$_3$ are tetragonal, space group $P4_32_12$. Those of Boc-GlyS-NHCH$_3$ are monoclinic, space group $P2_1/c$. Both structures were solved by direct methods and refined by full-matrix least-squares methods to *Rw* = 0.045 and 0.035 for 827 and 1335 reflections respectively, with intensities greater than $2.5\sigma(I)$. The conformations of both compounds correspond to conformational energy minima, calculated for classical amino acids. The C=S bond lengths of 1.665(9) and 1.650(3) Å constitute the major difference compared to oxopeptides; the crystal structures reveal that the presence of the sulfur atom does not change the electronic properties of the peptide bond. Using a classical method for the study of peptides (ECEPP/2), conformational energy maps were computed for derivatives of dithioalanine and dithioglycine and are compared to the oxo residues. We conclude that the synthesis and conformational analysis of thionated amino acids allow us to introduce the thioamide linkage into more complex peptide structures and to predict the conformational behaviour.

Key words: molecular conformations, peptidic structure, crystallography.

Introduction

Les processus physiologiques à l'intérieur desquels les peptides sont impliqués, sont très nombreux. La compréhension des mécanismes d'action est d'autant plus grande que chacun de ces processus constitue un endroit propice en vue d'une intervention pharmacologique. Les difficultés sont cependant nombreuses, tenant compte de la courte durée de vie des peptides endogènes et de la diversité de leurs modes d'action. Au cours des dernières années, diverses méthodes ont été développées en vue de synthétiser des molécules de nature peptidique, dont la conformation était contrainte, par l'introduction de groupements spécifiques. De telles recherches visent à conférer aux dérivés peptidiques une conformation telle que la reconnaissance par un récepteur biologique donné soit accrue (1). De plus il s'agit d'augmenter la durée d'action de ces molécules, en les protégeant des agents hydrolytiques. Diverses approches sont apparues en vue de conférer une plus grande intégrité conformationnelle aux molécules. Certains chercheurs ont préconisé d'introduire un caractère plus rigide en intervenant au niveau des chaînes latérales (2). D'autres ont préféré effectuer des modifications sur la chaîne principale des peptides. Parmi ces méthodes, il fut considéré de remplacer un ou plusieurs liens peptidiques par des analogues thiocarbonylés. Il a été démontré que l'introduction de tels résidus dans la séquence de peptides possédant une activité chimiotactique faisait disparaître l'activité comme la libération de lysosymes (3, 4). D'autre part, il était de première importance d'examiner de quelle manière de telles modifications pourraient influencer la susceptibilité des substrats, vis à vis de l'hydrolyse enzymatique (5).

Par ailleurs, les dérivés thiocarbonylés d'acides aminés représentent un intérêt particulier car ils ont été montrés complètement résistants à l'hydrolyse enzymatique par l'α-chymotrypsine (3) et la leucine aminopeptidase ainsi que plus stables que leurs homologues oxygénés à l'hydrolyse par la

carboxypeptidase (6*a*,*b*). D'autre part, il a été récemment observé que la résistance enzymatique des thiopeptides était dépendante de la nature du résidu dans le cas de l'enzyme de conversion de l'angiotensine (7). D'autres composés thiocarbonylés dérivés de la glycine et de l'alanine ont par ailleurs servi dans des études de mécanismes avec la papaïne par spectroscopie Raman (8). En vue de poursuivre de telles études, il a été envisagé de synthétiser des analogues thiocarbonylés de substrats de l'α-chymotrypsine et de vérifier si le mécanisme d'action proposé pour l'hydrolyse des substrats habituels, serait également effectif pour des analogues thiocarbonylés. Dans le but de comprendre les propriétés conformationnelles caractéristiques de molécules peptidiques, nous avons entrepris la détermination de structures cristallines de deux composés : *N*-tertiobutyloxycarbonyl *N'*-méthylthioalanine Boc-AlaS-$NHCH_3$ et *N*-tertiobutyloxycarbonyl *N'*-méthylthioglycine Boc-GlyS-$NHCH_3$. Les structures moléculaires résultantes ont alors été utilisées en vue de paramétriser les calculs d'énergies conformationnelles dans le cadre de l'application des méthodes empiriques. Disposant ainsi des fonctions énergétiques adéquates, nous espérons qu'il sera possible de prédire les conformations des composés à l'intérieur desquels de telles unités thiopeptidique seraient ultérieurement introduites.

Partie expérimentale

Synthèse

Synthèse des amides des N-*tertiobutyloxycarbonyl* N'-*méthylamino-acides*

L'acide *N*-tertiobutyloxycarbonyl-amino et l'hydroxybenzotriazole (1,1 équiv.) ont été dissouts dans CH_2Cl_2, la température de la solution étant maintenue à 0°C. La *N*,*N'*-dicyclohexylcarbodiimide (1,05 équiv.) a été ajoutée et la solution agitée à 0°C pendant 30 min. Une solution à 1% dans le tétrahydrofurane de méthyl amine (1,1 équiv.) fut ensuite ajoutée sous agitation à 0°C. L'agitation fut maintenue pendant 1 h à cette température et ensuite 20–24 h à la température normale. La dicyclohexylurée fut alors éliminée par filtration, et la solution diluée avec CH_2Cl_2 et lavée à l'acide citrique (5%), $NaHCO_3$ (5%), séchée ($MgSO_4$) et évaporée sous vide. Les rendements et les propriétés physico-chimiques sont données au tableau 1.

Thionation des amides des N-*tertiobutyloxycarbonyl* N'-*méthyl-amino-acides*

Le réactif de thionation **1** (0,6 équiv.) (9) a été ajouté en une seule fois à la solution de l'amide appropriée (1–10 mmol) dans le tétrahydrofurane sec (10% en solution). Le mélange fut ensuite agité à 23 ± 2°C sous atmosphère d'azote. L'avancement de la réaction fut alors contrôlé par chromatographie en couche mince et la durée de réaction déterminée par la disparition de l'amide de départ (ninhydrine). Les composés furent alors purifiés par chromatographie sur gel de silice. Les propriétés physico-chimiques, les temps de réactions et les rendements sont donnés au tableau 1.

Détermination des structures cristallines

Des cristaux de Boc-AlaS-$NHCH_3$ et de Boc-GlyS-$NHCH_3$ ont été obtenus par évaporation lente d'une solution d'acétate d'éthyl/hexane. Les données ont été mesurées à l'aide d'un diffractomètre Nonius CAD4 en utilisant le rayonnement Kα du cuivre, rendu monochromatique grâce à un monochromateur au graphite. Les dimensions de la maille ont été obtenues par une technique de moindres-carrés à partir de 18 réflexions dans un domaine de $15° \leq \theta \leq 23°$. Deux réflexions de contrôle d'intensité ont été mesurées chaque 50 réflexions. Aucun changement significatif n'a été observé quant à l'intensité de ces deux réflexions. Le système de programmes cristallographiques NRCVAX (10) a été employé pour tous les calculs. Le groupe spatial $P4_32_12$ dans le cas de Boc-AlaS-$NHCH_3$ a été fixé de telle sorte que l'isomère L du résidu Ala utilisé pour la synthèse du composé soit respectée. Cependant, afin de juger de l'applicabilité de la diffusion anomale de l'atome de soufre, nous avons confirmé cette polarité en calculant les valeurs des résidus globaux obtenus pour chacun des isomères, soient 0,067 pour le groupe $P4_12_12$ et 0,064 pour le groupe $P4_32_12$. La liste des réflexions calculées et les plus affectées par le changement d'isomère fait partie du matériel supplémentaire.[3] Les structures ont été résolues par application des méthodes directes et affinées par la technique des moindres-carrés en matrice entière, basés sur les valeurs de *F*. Des facteurs thermiques anisotropes ont été affinés pour tous les atomes autres que l'hydrogène. Les atomes d'hydrogène ont été localisés par différence de Fourier, mais leurs positions n'ont pas été affinées. Un schéma de pondération basé sur les comptages statistiques a été appliqué. Les courbes de diffusion utilisées ont été celles que fournit le système NRCVAX (10). Les données cristallographiques relatives aux déterminations de structures sont données au tableau 2.

Calculs d'énergie conformationnelle

Les conventions standard (IUPAC) quant aux définitions des angles dièdres ω, ϕ, φ dans les peptides ont été observées tout au long de ce travail (19).

Les propriétés conformationnelles du résidu alanine ont été étudiées antérieurement par méthodes classiques (11) et quantiques (12). Se référant au calcul quantique *ab initio* (12), il s'est avéré que des calculs d'énergie conformationnelle effectués à l'aide du programme

[a]Température 293 K, diffractomètre Enraf–Nonius CAD4, radiation CuKα (λKα = 1,54178 Å) monochromateur au graphite, angle de départ 3°, ouverture de la fente du détecteur 4,0 × 4,0 mm à une distance de 173 mm du cristal; largeur de balayage étendue de 25% de chaque côté de la réflexion pour tenir compte du bruit de fond $\sigma^2(I) = C + 2B$ (C = nombre de coups; B = nombre de coups normalisé du bruit de fond).

Fonction minimisée : $\Sigma w(|F_o| - |F_c|)^2$ où $w = 1/\sigma^2(F)$; $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$; $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$.
Les valeurs données pour R, R_w et S sont basées sur les réflexions avec $I \geq 2{,}5\sigma(I)$.

ECEPP/2 (11) (13*a*, *b*, *c*) donnaient des résultats tout à fait comparables. Ce programme a donc été utilisé pour évaluer l'énergie de conformation des molécules peptidiques dans le cadre de la mécanique moléculaire. L'énergie est calculée comme la somme de quatre contributions : celle des interactions électrostatiques, les liaisons hydrogènes, les énergies de torsion et enfin des interactions entre atomes non liés. Ce champ de force a été présenté en détail par F. A. Momany *et al.* (13*c*). Nous développons ici la composante que nous avons modifiée, celle des interactions entre atomes non liés. Cette composante est donnée par la relation suivante :

$$E_{NB} = \Sigma_i\Sigma_j FA^{kl}/R_{ij}^{12} - C^{kl}/R_{ij}^{6}$$

où R_{ij} est la distance entre atomes i et j.
Coéfficient du terme attractif,

$$C^{kl} = 3/2[eh/2\pi m_e^{1/2}]\alpha_k\alpha_l/[(\alpha_k/N_k)^{1/2} + (\alpha_l/N_l)^{1/2}]$$

e : charge de l'électron; α_k : polarisabilité de l'atome de type k; h : constante de Planck; N_k : nombre effectif des électrons de l'atome de type k; m_e : masse de l'électron.
Coéfficient du terme répulsif déduit à partir de C^{kl},

$$A^{kl} = (1/2)C^{kl}(r_g^{kl})^6$$

r_g^{kl} : rayon correspondant à l'énergie minimale entre des atomes de type k et l. $F = 0{,}5$ pour les interactions de type 1–4 et $F = 1{,}0$ pour les autres types d'interactions.

L'utilisation du programme ECEPP/2 pour des molécules thiopeptidiques demandait cependant que des paramètres adéquats soient introduits dans le champ de force utilisé. Les paramètres que nous avons utilisés sont donnés dans le tableau 3. La longueur de liaison C—S a été déterminée par cristallographie. Les charges atomiques partielles ont été calculées par la méthode CNDO/2 en utilisant le programme PCILO3 (14). Les valeurs du rayon de van der Waals pour l'atome de soufre ainsi que la polarisabilité pour cet atome ont été choisies telles que proposé antérieurement (11). Ce dernier paramètre permet de calculer les coefficients du terme attractif intervenant dans la contribution des interactions entre atomes non liés dans l'énergie conformationnelle totale en utilisant les relations précédemment mentionnées.

Résultats et discussion

Structures moléculaires et cristallines

Les paramètres atomiques obtenus par diffraction de rayons-X pour les atomes autres que les hydrogènes sont donnés au tableau 4. La figure 1 présente les structures moléculaires obtenues pour Boc-AlaS-$NHCH_3$ (fig. 1a) et Boc-GlyS-$NHCH_3$ (fig. 1b).

Les longueurs de liaisons ainsi que les angles de valence sont donnés au tableau 5. La géométrie du lien peptidique déterminée pour les deux composés correspond aux valeurs moyennes obtenues après une recherche dans la base de données «Cambridge Crystal Structure Data Base» et ulté-

rieurement optimisée par calculs quantiques (Gaussian 80/82) (15). L'allongement de la liaison thiocarbonyle (1,66 Å) est la différence essentielle entre la liaison thiopeptidique et le lien classique (16). Une valeur particulièrement courte (1,64 Å) avait été précédemment proposée (17) à partir de résultats cristallographiques préliminaires. Cependant, on a pu montrer que la valeur de cette longueur de liaison constitue un paramètre important dans les calculs des propriétés électroniques. Aucune modification notoire n'a été observée quant à la longueur du lien C—N, laissant croire que peu de changements sont apportés aux propriétés électroniques du lien peptidique par l'introduction de l'atome de soufre. Cette proposition est appuyée par les valeurs des angles ω proches de 180° (tableau 5).

Les deux structures cristallines déterminées correspondent à des conformères proches de minimas énergétiques calculés pour les oxopeptides correspondants. Pour Boc-AlaS-$NHCH_3$, les valeurs des angles $\phi = -85,7(8)$ et $\psi = 130,8(8)$ correspondent à une conformation située à la limite des zones C et F (18), comme on peut le voir à la figure 3c. Il s'agit d'un conformère propice à la formation d'axes d'ordre 3 et 4 dans une chaîne polypeptidique. Grâce à cette conformation, la molécule peut former dans le cristal des chaînes en hélices 4_3, comme le montre la figure 2a. Une liaison hydrogène N2—H---O1 (tableau 6) assure la cohésion le long de cette hélice.

En ce qui concerne le composé Boc-GlyS-$NHCH_3$, les angles ϕ, ψ de la chaîne principale ont des valeurs proches de 180°. Ceci correspond à une structure très planaire pour l'unité peptidique. Cette conformation appartient à la zone E dans la classification de Scheraga (fig. 3c). La préférence pour cette conformation est aussi favorisée par le fait que les molécules peuvent s'associer en dimères par liaisons hydrogène (tableau 6), formant dans le cristal des associations et un empilement montré à la figure 2b.

Analyse conformationnelle

La figure 3 montre les cartes d'isoénergie [ϕ, ψ] calculées pour les composés **7** (fig. 3a) et **11** (fig. 3b) à l'aide du

programme ECEPP/2, paramétrisé pour les résidus AlaS et GlyS. Des rotations de −180° à 180° par pas de 15° ont été effectuées autour des angles ϕ et ψ indiqués sur le schéma moléculaire. Les conventions classiques (19) ont été utilisées dans la définition et la rotation des angles dièdres. Les courbes d'isoénergie ont été tracées par interpolations quadratiques par niveaux équidistants de 2 kcal/mol.[4] Pour chacune des cartes, le minimum global a été considéré comme zéro. Comparant l'allure générale des cartes obtenues à celles des dérivés oxopeptidiques (12, 20), on constate qu'il y a peu de modifications dans le cas de Ala et Gly. Les modifications les plus importantes apparaissent dans la zone C [$\phi = -75°$, $\psi = 75°$]. On sait d'autre part que cette zone comporte également les conformères correspondant au minimum global pour les oxopeptides (12, 15, 20). Ces conformères forment un cycle à sept membres incluant une liaison hydrogène intramoléculaire, la chaîne latérale étant

4. 1 kcal/mol = 4,18 kJ/mol.

4	$R^1 = CH_3$	X = O	$R^2 = CH_3$	Y = O	Ac-Ala-$NHCH_3$
5	$R^1 = CH_3$	X = S	$R^2 = CH_3$	Y = O	AcS-Ala-$NHCH_3$
6	$R^1 = CH_3$	X = O	$R^2 = CH_3$	Y = S	Ac-AlaS-$NHCH_3$
7	$R^1 = CH_3$	X = S	$R^2 = CH_3$	Y = S	AcS-AlaS-$NHCH_3$
8	$R^1 = CH_3$	X = O	R^2 = H	Y = O	Ac-Gly-$NHCH_3$
9	$R^1 = CH_3$	X = S	R^2 = H	Y = O	AcS-Gly-$NHCH_3$
10	$R^1 = CH_3$	X = O	R^2 = H	Y = O	Ac-GlyS-$NHCH_3$
11	$R^1 = CH_3$	X = S	R^2 = H	Y = O	AcS-GlyS-$NHCH_3$

placée en position équatoriale (C_7^{equ}). Cependant l'allongement de la liaison C=S et les orientations moins propices à une interaction stabilisante ont pour effet de déplacer légèrement ce minimum, tout en conservant une conformation C_7^{equ}.

Il ressort que les minima d'énergie, tout en étant situés pratiquement aux mêmes endroits de la carte, ont des valeurs relatives différentes de celles qui ont été observées pour les composés oxopeptidiques. Afin de mettre en évidence les effets de thio-substitution spécifiquement en X et Y, nous avons calculé à l'aide du programme ECEPP/2, les énergies conformationnelles des conformères correspondant aux divers minima globaux pour les différentes combinaisons : X = O, Y = O; X = S, Y = O; X = O, Y = S et X = S, Y = S, respectivement pour les résidus Ala (**4**–**7**) et Gly (**8**–**11**). Les résultats sont présentés au tableau 7.

Dans le cas des dérivés mono-substitués X = S on trouve que la conformation la plus stable est située dans la zone E [$\phi = -150°$, $\psi = 150°$] dans le cas du composé **5** et [$\phi = -180°$, $\psi = 180°$] pour le composé **9**.

On remarque également que la mono-substitution Y = S dans les composés **6** et **10** n'affecte pas la position du minimum global situé dans la zone C [$\phi = -75°$, $\psi = 75°$] tel qu'on le retrouve dans les oxopeptides.

Finalement, la disubstitution X = S, Y = S dans les composés **7** et **11** affecte légèrement la position du minimum global en le déplaçant de [$\phi = -75°$, $\psi = 75°$] à [$\phi = -90°$, $\psi = 90°$] tout en le conservant dans la même zone.

Revenant à l'examen des cartes conformationnelles, il ressort que si les conformations préférentielles sont modifiées lors de la substitution d'un atome d'oxygène par un atome de soufre, on ne constate cependant pas de restriction majeure apportée à l'espace conformationnel. Cependant on devrait s'attendre à ce que des changements plus accentués soient observés dans les cas où le lien thioamide est introduit dans un résidu pour lequel la chaîne latérale serait plus encombrée.

Conclusion

Nous avons montré que l'insertion du lien thioamide dans la chaîne peptidique peut tout d'abord se réaliser par synthèse

classique et ensuite être étudiée d'un point de vue conformationnel. De ce point de vue, en poursuivant une approche combinant la diffraction des rayons-X des mono-cristaux et l'étude conformationnelle par méthodes classiques, il est possible de mettre en évidence les propriétés conformationnelles caractéristiques que le lien thioamide induit. Cette méthode doit permettre d'envisager l'étude de composés de plus grandes complexités et ainsi considérer les polypeptides à l'intérieur desquels le lien thioamide serait spécifiquement introduit en vue de générer des propriétés conformationnelles caractéristiques.

Remerciements

A.M. et G.L. remercient le Conseil de la recherche en sciences naturelles et en génie du Canada pour le support financier qui leur a été octroyé. Nous remercions particulièrement M. Y. Le Page (N.R.C. Chemistry Division, Ottawa) pour son aide dans l'analyse cristallographique. Nous remercions également M. D. P. Vercauteren (Chimie-physique, F.U.N.D.P., Namur, Belgique) pour son assistance dans la préparations des diagrammes d'isoénergie.

Insoluble mercury(II) complexes of a water-soluble phosphine, 1,3,5-triaza-7-phosphaadamantane (PTA), have been studied by solid state ^{31}P CP-MAS NMR, infrared and Raman spectroscopies. Complexes of the type $(PTA)HgX_2$ show larger coordination chemical shifts but similar $J(^{31}P—^{199}Hg)$ coupling constants to those previously observed for similar trialkylphosphine complexes. These complexes all appear to be dimeric or polymeric. The nitrate complex of the form $(PTA)_2Hg(NO_3)_2$ has also been isolated and complexes of the type $(PTA)_4Hg^{2+}$ are shown to exist.

Key words: mercury(II) phosphine complexes, solid state ^{31}P NMR studies.

ELMER C. ALYEA, KEITH J. FISHER et STEVE JOHNSON. Can. J. Chem. **67**, 1319 (1989).

Faisant appel aux méthodes spectroscopiques Raman, infrarouge et RMN CP-MAS du ^{31}P, on a étudié les complexes insolubles du mercure(II) obtenus à partir d'une phosphine soluble dans l'eau, le triaza-1,3,5 phospha-7 adamantane (PTA). Les complexes du type $(PTA)HgX_2$ présentent des déplacements chimiques de coordination qui sont plus grands que ceux observés antérieurement avec des complexes semblables de trialkylphosphines; toutefois, les constantes de couplage $J(^{31}P—^{199}Hg)$ sont semblables. Il semble que tous ces complexes sont des dimères ou des trimères. On a aussi isolé le complexe contenant un nitrate, $(PTA)_2Hg(NO_3)_2$ et on a démontré que les complexes du type $(PTA)_4Hg^{2+}$ existent.

Mots clés : complexes de mercure(II) phosphine, études en RMN du ^{31}P de l'état solide.

[Traduit par la revue]

Introduction

1,3,5-Triaza-7-phosphaadamantane (PTA), first reported in 1974 (1), is potentially a very important ligand. The solubility of this compound in water and the difficulty of oxidation make this an unusual aliphatic phosphine. The small cone angle of 102° (2) suggests that this phosphine should be a good substitute for trimethylphosphine. Darensbourg and Daigle (3) were able to prepare the complexes $PTAM(CO)_5$ where M = Cr, Mo, W, and $PTAFe(CO)_4$. The ^{31}P NMR spectra indicated that these complexes were P-bound to the metal. The ability of this phosphine to form stable organic derivatives (4), which leave the donor ability of the phosphorus intact, suggests that a fine tuning of useful properties of metal complexes may be possible.

We have undertaken an investigation of the synthesis of metal complexes of PTA and our initial results indicated that many metals form complexes (20); those with mercury(II) salts are reported here. The insolubility of the mercury(II) PTA complexes in water and non-aqueous solvents required us to study the properties of the complexes prepared by cross polarization magic angle spinning ^{31}P NMR spectroscopy (5). The importance of observing phosphorus–mercury coupling also required us to use a side band suppression technique (6).

Monodentate phosphine complexes of mercury(II) are generally of the form L_xHgX_2 (x = 1, 2, 3, or 4) (7) but complexes having the unusual formula $L_3(HgX_2)_2$ have also been observed (8). Small phosphines can form complexes where x = 1, 1.5, 2, 3, or 4 whereas bulky phosphines generally tend to form complexes where x = 1 or 2 only. Most of the $LHgX_2$ complexes have mercury(II) in a tetrahedral or distorted tetrahedral environment leading to a dimeric (centrosymmetric) or polymeric structure. There are exceptions such as the non-centrosymmetric structure observed for α-Pr_3PHgI_2 (9) and the five coordinate structures observed for Me_3PHgCl_2 and Et_3PHgCl_2 (10). L_2HgX_2 complexes have tetrahedral or distorted tetrahedral coordination about mercury(II). L_3HgX_2 and L_4HgX_2 complexes are generally tetrahedral ionic species (7).

^{31}P and ^{199}Hg NMR have proved useful tools in the investigation of mercury phosphine complexes. The correlation of chemical shifts (^{31}P and ^{199}Hg) and $J(^{31}P—^{199}Hg)$ are not always in agreement but in general there is a decrease in $J(^{31}P—^{199}Hg)$ with increasing value of x in the complexes L_xHgX_2. The coordination chemical shift of the ^{31}P resonance also tends to indicate the σ donor property of the phosphine (7, 11).

Our study of some new insoluble PTA–mercury complexes highlights the utility of solid state ^{31}P CP-MAS NMR spectroscopy in their characterization.

Experimental

Preparation of the complexes

$HgCl_2$, $HgBr_2$, HgI_2, $Hg(NO_3)_2$, and $Hg(SCN)_2$ were reagent grade and used as received. PTA was prepared (1), recrystallized from aqueous methanol, and its purity confirmed by its ^{31}P [^1H] NMR spectrum (singlet at −97.4 in methanol).

The complexes were prepared by adding hot methanolic solutions of mercury salt to hot methanolic solutions of PTA. Molar ratios of Hg:PTA of 1:2 and 1:1 were used. The mercury complexes precipitated almost immediately and the filtered precipitates were washed with hot methanol. The complexes were insoluble in water and organic solvents.

In all cases except the nitrate the order of addition of mercury salt solution to PTA solution or vice versa resulted in the major product $PTAHgX_2$. The attempted preparations of $PTAHg(NO_3)_2$ resulted in the isolation of $(PTA)_2Hg(NO_3)_2$ and when mercuric nitrate solution was added to a large excess of PTA in methanol solution, analytical results indicated that species approximating $(PTA)_4Hg(NO_3)_2$ were obtained.

The attempted preparations of the acetate and perchlorate complexes

†Δ is the complex coordination chemical shift = $(\delta_{complex} - \delta_{(free\ ligand)})$.

resulted in the precipitation of metallic mercury. This reduction to metallic mercury may be evidence for the strong basicity of PTA which we have observed in our study of molybdenum carbonyl complexes of PTA (20).

Elemental analyses were performed by M-H-W Laboratories, Phoenix, Arizona.

^{31}P-CP MAS NMR measurements

The mercury complexes were packed in Delrin spinners along with a small amount of KBr. The ^{79}Br resonance was used to set the spinning angle for each sample and side bands used to determine the spinning rate. Spinning rates of approximately 3.7 kHz were used.

The spectra were acquired at 81 MHz on a Bruker CXP-200 NMR spectrometer using a standard CP-MAS probe. 85% H_3PO_4 was used as an external reference. The spectra were obtained with proton decoupling and the spectrometer in a Fourier transform mode using 4K memory blocks. A total suppression of sidebands (TOSS) sequence was used as outlined by Dixon (6). Line broadenings of 0 or 20 Hz were found to give good spectra. Normally the number of scans needed to give good spectra were less than 1000 but up to 5000 scans were used in some cases to resolve the ^{199}Hg satellites.

Infrared and Raman spectra

Infrared spectra were recorded as Nujol mulls on a Nicolet 20 DXS FT-IR spectrometer.

Raman spectra were recorded on a Dilor, Omars 99 Multichannel Spectrometer using the multichannel mode and excitation line of 514.53 nm and laser power from 10 to 30 mW.

Results

The analytical results and melting points of the mercury compounds are given in Table 1. Some samples of the chloride, bromide, and nitrate were shown to be impure and these impurities were indicated in the ^{31}P NMR spectra. Samples of the cyanide gave low carbon analyses and appeared to be unstable to light.

The ^{31}P NMR results are shown in Table 2. Data for the major compounds are shown in the top part of the table and those for the $(PTA)_4HgX_2$ impurities observed in some samples are shown lower in the Table.

The infrared and Raman absorptions are shown in Table 3, together with possible assignments.

Discussion

The major mercury–PTA species produced seem to be largely independent of the mode of addition of the reagents or the ratio of reactants. The major species were $(PTA)_2Hg(NO_3)_2$ and $PTAHgX_2$ where X = Cl^-, Br^-, I^-, CN^-, and SCN^-. Minor impurities were observed in some spectra of the chloride, bromide, and nitrate. Analytical results of several samples of the chloride indicated the presence of species containing more than one PTA per mercury. Attempts to prepare the nitrate complex $PTAHg(NO_3)_2$ were unsuccessful and reactions involving aqueous solutions resulted in the precipitation of metallic mercury. The 1:2 nitrate complex in contrast with all the other complexes was slightly soluble in water but the solution darkened rapidly at room temperature and gave a broad resonance having no ^{199}Hg satellites in the ^{31}P NMR spectrum at −63 ppm. It is probable that $(PTA)_4Hg(NO_3)_2$ is being formed by decomposition in water, with the signal being

*These compounds decomposed during the observation of Raman spectra.

broadened by exchange with free PTA, since a resonance at −58 ppm is observed for this species in the solid state (see below). The reduction to metallic mercury in the attempted preparation of the acetate and perchlorate may be evidence of the high basicity of PTA as the deposition of metallic mercury from mercuric solutions is common with reducing ligands such as phosphines (7).

^{31}P CP-MAS NMR spectra

The spectrum of the nitrate indicated a major species and a minor impurity. The mercury satellites were well resolved using the total suppression of side band technique. The resonance at −29.9 ppm with $J(^{31}P—^{199}Hg)$ = 5111 Hz is attributed to the species $(PTA)_2Hg(NO_3)_2$. The coordination chemical shift is much larger than observed for the similar tricyclohexylphosphine (11*a*) or the tri-*n*-butylphosphine (11*b*) complex. The coupling constants of 4805 Hz for $(Cy_3P)_2Hg(NO_3)_2$ and 5200 Hz for $(Bu_3P)_2Hg(NO_3)_2$ are of similar magnitude and much smaller than for the monophosphine complexes, $Cy_3PHg(NO_3)_2$ (8540 Hz) and $Bu_3PHg(NO_3)_2$ (9230 Hz). The large coordination chemical shift for the PTA complex suggests a strong σ interaction, if we can assume that the C—P—C angles of this "tied back" phosphine cannot change appreciably. The only other comparable nitrate complex studied in the solid state was the triphenylphosphine complex $(Ph_3P)_2Hg(NO_3)_2$ studied by Allman and Lenkinski (5). This complex gave a lower coordination chemical shift (~46 ppm) and a higher coupling constant, 5560 Hz. The nitrate gave the highest coordination chemical shift and coupling constant of all the $(Ph_3P)_2HgX_2$ complexes studied and it is therefore tempting to suggest that the PTA and Ph_3P complexes are two coordinate ionic species $L_2Hg^{2+}2NO_3^-$.

The other PTA species observed at δ −58.0 ppm has a much smaller coordination chemical shift (46.4 ppm) and a much smaller coupling constant (1876 Hz). This coupling constant may be compared with the value for $(Me_3P)_4Hg(NO_3)_2$ (2255 Hz) observed by Schmidbaur and Räthlein (12) and the values for some chelate phosphine complexes observed by Dean

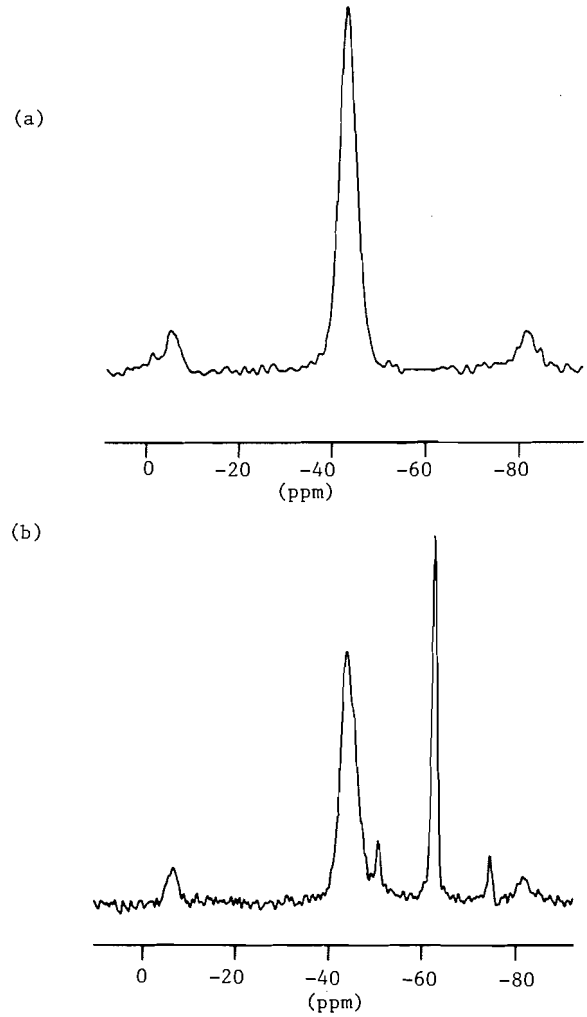

FIG. 1. The ^{31}P CP-MAS spectrum of $PTAHgBr_2$, (*a*) a pure sample; (*b*) an impure sample, showing the presence of $(PTA)_4Hg^{2+}$ (−62.8 ppm) in addition to $PTAHgBr_2$ (−44.1 ppm).

and Srivastava (13), e.g. $[Hg(dppp)_2]^{2+}$ (1979 Hz); dppp is bis(diphenylphosphino)propane. We therefore assign this species as $(PTA)_4Hg^{2+}2NO_3^-$.

Minor impurities were also observed by the appearance of peaks in some spectra of the chloride and bromide; spectra for the bromide are shown in Fig. 1. These resonances with coordination chemical shifts of 41.0 ppm (chloride) and 41.6 ppm (bromide) and $J(^{31}P—^{199}Hg)$ of 1937 and 1953 Hz, respectively, we also tentatively assign to the presence of the $(PTA)_4Hg^{2+}$ cation.

The remaining complexes of the form $PTAHgX_2$ show the previously observed correlation of increasing magnitude of the $J(^{31}P—Hg)$ with increasing electronegativity of the X ligand and the coordination chemical shift for the complex (11*a*, 14). This relationship is shown in Fig. 2; note that there are two points for both the cyanide and thiocyanate but that the line has been drawn using only one data point for these compounds (see later). The coordination chemical shifts are again larger than those observed in solution for other similar trialkyl–phosphine complexes (11) but the coupling constants are of a similar magnitude. Solid state spectra, with no potentially important solvent interactions, may differ from solution spectra but it has been shown that the chemical shift changes are small and coupling constant changes of a few hundred Hertz may be observed (5).

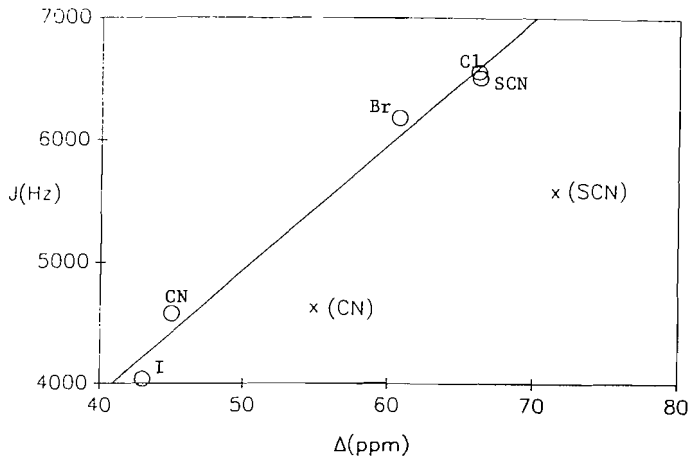

FIG. 2. The correlation of the coordination chemical shift Δ with $J(^{31}P—^{199}Hg)$ for the compounds $PTAHgX_2$.

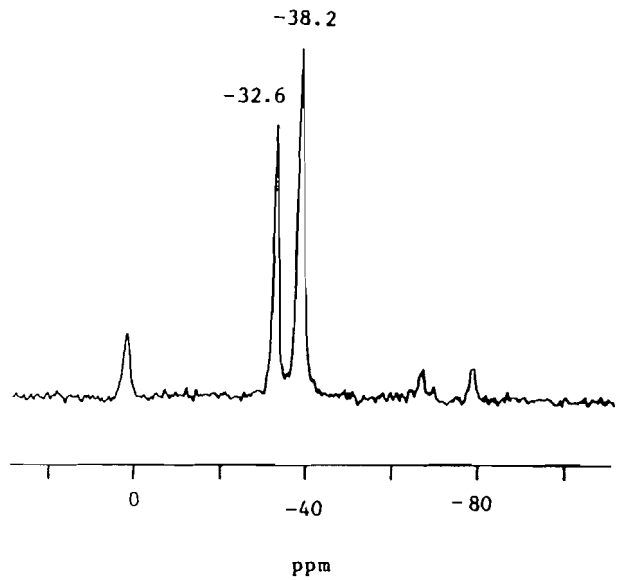

FIG. 3. The ^{31}P CP-MAS spectrum of $PTAHg(SCN)_2$.

The cyanide and thiocyanate deserve more discussion. Both complexes gave two ^{31}P resonances. The major peak for the cyanide at δ −50.4 ppm does not correlate with those for the other complexes but the minor resonance at δ −59.4 ppm correlates well with the peaks observed for the other 1:1 complexes. There may be two different infinite chains in this complex (5) but, in any case, the similar coupling constants observed for each species suggests a similar coordination environment for the mercury.

The thiocyanate also gave two well separated resonances, as illustrated in Fig. 3. The more intense resonance at δ −38.2 ppm with $\nu_{1/2}$ = 130 Hz was slightly broader than the resonance at δ −32.6 ppm and had a larger coupling constant (Table 2). $(Ph_3P)Hg(SCN)_2$ was observed to occur in two crystalline forms (15). Two species in solution (having similar chemical shifts but widely differing coupling constants) have also been observed for $(Bu_3P)Hg(SCN)_2$ (11*b*). Allman and Lenkinski (5) observed three species in the solid state spectrum of $(Ph_3P)_2Hg(SCN)_2$ although only one species was observed in solution. It appears that $(PTA)Hg(SCN)_2$ may exist in two crystalline forms consisting of two types of infinite chain.

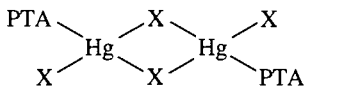

TABLE 4. Symmetric Hg—X (terminal) and Hg—P stretching frequencies for $(R_3P)HgX_2$ complexes

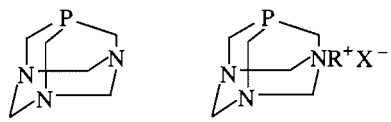

Complex	ν(Hg—X)	ν(Hg—P)	Reference

*Only one band observed in this region.

Infrared and Raman spectra

The assignments in Table 3 are tentative but if correct indicate some interesting trends. For the chloride, bromide, and iodide we have tried to assign the mercury–halogen and mercury–phosphine stretching frequencies assuming the centrosymmetric structure found in the complex Ph_3PHgCl_2 (16)

PTA $PTAR^+X^-$

PTA has infrared absorptions at 452 and 405 cm^{-1} which are shifted on coordination to 448 and 388 cm^{-1}, respectively. The weak Raman absorption at 256 cm^{-1} was not observed in the complexes and so we have assigned all absorptions below 350 cm^{-1} to metal–halogen or metal–phosphorus vibrations.

The chloride should give rise to only one IR- and one Raman-active frequency, assuming C_{2h} skeletal symmetry. The IR spectrum gave an absorption at 319 cm^{-1} which we assign to the antisymmetric stretching frequency. The Raman spectrum gave a major band at 307 cm^{-1} with a shoulder at 300 cm^{-1}. Assigning these bands to the symmetric Hg—Cl vibrations also suggests a distortion from ideal C_{2h} symmetry. This is not surprising as PTA having a small cone angle may form polymeric structures observed for $HgCl_2(PMe_3)$ or $HgCl_2(PEt_3)$ (10). Bell *et al.* (17) have pointed out that small structural changes can have a marked influence on the IR spectral pattern but sometimes major structural variations can have very little influence on the spectrum. The observed frequencies are similar to other phosphine – mercury halide complexes (17, 18) as shown in Table 4, and so we feel confident that our assignments are correct. The changes observed for $\nu_s(HgX)$ for Cl, Br, and I are similar to the other complexes and show the same general trends. The ν(HgP) values are also similar. Thus it appears that the PTA complexes have a centrosymmetric structure or a chain polymer structure that approximates the centrosymmetric structure.

The thiocyanate gave more than two IR bands near 2100 cm^{-1} in accordance with the ^{31}P data indicating more than one environment for the SCN group. The absorptions are compatible with the expected Hg—S bonding and bridging of the SCN groups (18).

The IR absorptions of $PTAHg(CN)_2$ in the CN region were very weak and the observed Raman absorptions are comparable with the spectrum observed for $Cy_3PHg(CN)_2$ (19). This again suggests two types of CN groups and with the insight imparted by the ^{31}P NMR data is in agreement with a crystalline form containing two different polymeric structures.

The IR spectrum of the nitrate indicated the presence of ionic nitrate due to the broad absorptions at 1358 and 1345 cm^{-1}. Unfortunately this compound decomposed while the Raman spectrum was being observed and thus the presence of the two coordinate cation $(PTA)_2Hg^{2+}$ as indicated by the ^{31}P data was only partially confirmed by the vibrational spectral data.

On the partitioning of the viscosity *B* coefficient and the correlation of ionic *B* coefficients with partial molar volumes of ions for aqueous and non-aqueous solutions

MONI MOHAN BHATTACHARYYA

Physical Chemistry Section, Department of Pure Chemistry, University College of Science, Calcutta-700009, India

Received September 26, 1988[1]

MONI MOHAN BHATTACHARYYA. Can. J. Chem. **67**, 1324 (1989).

A new method of partitioning the viscosity *B* coefficients has been proposed on the basis of the assumption that ionic *B* values should be a monotonic function of crystal radii cubed, independent of the sign of the charge, for aqueous and various non-aqueous systems. Ionic *B* values thus obtained in different solvents by a single method of division provide a basis for uniform comparison among themselves as well as with the existing values. The usual assumption of equal contributions of K^+ and Cl^- ions has been discarded. The internal consistency of the derived set of B_i values is demonstrated by correlation with the ionic radii, hydrated ionic radii, partial molal volumes, temperature coefficient of equivalent conductance, and partial molal ionic entropy. The salient feature of the set of B_i values is noted by its linear relationship not only with the partial molal volumes but the same is also observed with the ionic radii of ions of different valence and charge types. Eyring's equation for viscosity using Frank–Wen's model of ion–solvent interaction has been utilised for the calculation of void viscosity and electrostriction viscosity. The latter is compared with the corresponding component of partial molal volumes using the Drude–Nernst equation based on the continuum model for solvent.

Key words: ion–solvent model, ionic *B* values, *B* coefficients, division of *B* coefficient, void viscosity, micro viscosity.

MONI MOHAN BHATTACHARYYA. Can. J. Chem. **67**, 1324 (1989).

En faisant l'hypothèse que, pour des systèmes aqueux ainsi que divers systèmes non-aqueux, les valeurs ioniques B devraient être une fonction monotone du cube du rayon cristallin qui serait indépendante du signe de la charge, on propose une nouvelle méthode pour séparer les coefficients de viscosité *B*. Les valeurs ioniques *B* que l'on obtient ainsi, dans divers solvants et utilisant une seule méthode de division, peuvent servir de base pour faire une comparaison uniforme entre elles ainsi qu'avec des valeurs existantes. On n'a pas retenu l'hypothèse habituelle selon laquelle les contributions des ions K^+ et Cl^- sont égales. Pour démontrer la cohérence interne de l'ensemble des valeurs B_i qui en dérivent, on a utilisé une corrélation avec les rayons ioniques, les rayons ioniques d'hydratation, les volumes molals partiels, le coefficient de température de la conductivité équivalente et l'entropie ionique molale partielle. La caractéristique principale de l'ensemble des valeurs B_i est mise en évidence par leur relation linéaire non seulement avec les volumes molals partiels mais aussi avec les rayons ioniques des ions de valence et de types de charges différents. Pour le calcul des viscosités libre et d'électrostriction, on a utilisé l'équation de Eyring pour la viscosité et le modèle de Frank–Wen pour l'interaction ion–solvant. Faisant appel à l'équation de Drude–Nernst, basée sur le modèle continue pour le solvant, on a comparé la viscosité d'électrostriction avec la composante correspondante des volumes molals partiels.

Mots clés : modèle ion–solvant, valeurs ioniques *B*, coefficients *B*, division du coefficient *B*, viscosité libre, microviscosité.

[Traduit par la revue]

Introduction

The viscosities of aqueous and non-aqueous electrolyte solutions can be well represented by the following semi-empirical equation, introduced by Jones and Dole (1)

$$[1] \quad \eta/\eta_0 = 1 + A\sqrt{c} + Bc$$

where the first term, $A\sqrt{c}$, represents the contribution from the long range ionic interaction, theoretically calculated by Falkenhagen and Dole (2). The second term, known as the viscosity *B* coefficient, has been established as being additive (3–6) in the contributions from the cationic and anionic interactions with the solvent molecules. However, unlike some other similar additive properties, e.g., mobilities, diffusivities, for which sound experimental methods exist for the determination of the extremely important and revealing ionic values, there is as yet no definitive assignment (6–8) for the single ion *B* values.

A survey of the literature shows that the methods so far adopted to divide the *B* coefficient in different solvent systems are mostly based upon the viscosity–mobility relationship. Cox and Wolfenden (9) first carried out the partitioning of the *B* values in aqueous solutions by assuming that ionic components B_{Li^+} and $B_{IO_3^-}$ are proportional to the volumes of the solvated ions and hence inversely to the cubes of the ionic mobilities. Gurney (3) and later Kaminsky (10), partitioned the *B* coefficient by assuming the ionic *B* coefficient of K^+ ion is equal to that of Cl^- ion, based upon the equality of conductance values for the ions over a wide range of temperature. However, the division of *B* coefficient on the basis of KCl has been criticised by later workers (11–14) and as such, a number of alternatives to KCl has been suggested for the purpose.

In the case of non-aqueous systems, Tuan and Fuoss (15) utilised $B_{Bu_4N^+} = B_{Ph_4B^-}$ in acetonitrile solutions, Gopal and Rastogi (16) assumed $B_{Et_4N^+} = B_{I^-}$ at all temperatures in *N*-methyl propionamide solutions (NMP), Criss and Mastroianni (17) adopted the equality of B_{K^+} and B_{Cl^-} in methanol, and in dimethyl sulfoxide (DMSO), Yao and Bennion (18) assumed $B_{i\text{-}Am_3BuN^+} = B_{Ph_4B^-}$ to resolve the respective *B* values.

Martinus and Vincent (19) partitioned the *B* coefficient in formamide solution by constructing a correspondence plot of partial molar entropy and the ionic *B* coefficient, following the manner of Gurney (3). Besides, other methods similar to the extrapolation method (20) or Millero's tetraphenyl arsonium tetraphenyl boron method (21) as used for the separation of partial molal volumes have also been extended in a slightly modified form to the case of partitioning the *B* coefficients by Krumgalz (8) and Gill *et al.* (22), respectively. However, the results obtained by these methods (8, 22) are in poor agreement with each other for the same ions in the same solvent. It is also to be noted that the methods described are mostly specific for

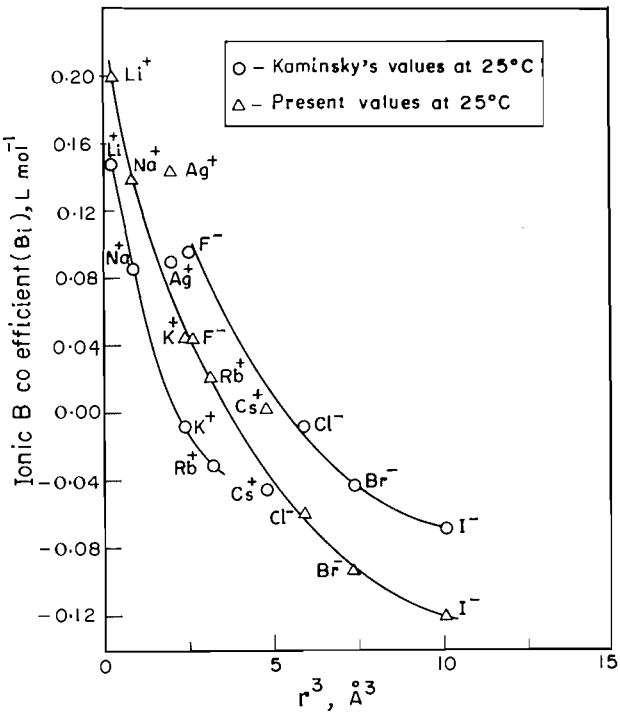

FIG. 1. The viscosity B coefficient of alkali metal ions and halide ions plotted against r_i^3 for two different values of B_i based on (*i*) $B_{K^+} = B_{Cl^-}$ scale and (*ii*) the proposed scale for aqueous system.

solvent, indicating the complexity of behavior of electrolyte solutions.

The purpose of the present article is therefore to propose a more general method for obtaining individual ionic values of B coefficient valid for both aqueous and non-aqueous systems from an entirely different approach.

Derivation of the model

It has been shown by various workers (4, 12, 23, 24) that there exist some correlations between the viscosity B coefficient and the partial molal volume (V) of a salt in solution, and these can be summarised either by the equation $B = 2.5\bar{V}$ or by the equation $B = a\bar{V}^0 - b$. Apart from these, the similarity of the two parameters with respect to additivity and measure of ion–solvent interaction has been well established. Moreover, since well known methods of separation of partial molal volumes are also applicable to B coefficient, it is assumed that the ionic B values should be monotonic functions of crystal radii cubed, independent of the sign of the charge. This follows from the treatment of Couture and Laidler (25) that for large monoatomic monovalent ions, B_i, like $\bar{V}_i^0$, does not depend on the sign of the charge (26).

The B values for alkali metal halides in aqueous system at 25°C are first of all partitioned on the basis of $B_{K^+} = B_{Cl^-}$ and then plotted against crystal radii cubed as shown in Fig. 1. As regards the choice of crystal ionic radii which are very critical for the present purpose, both the Pauling radii (27) and those of Gourary and Adrian (28) have been tried. However, the former is preferred since the derived set of B_i values are reasonable, give better fits with the radii, and show superior internal consistency with various other parameters as discussed in a later section. Figure 1 shows two smooth curves, one for the alkali metal ions, and the other for the halide ions. According to our assumption, since the B_i values for both monovalent cations and anions should be a smooth function of crystal radii cubed, irrespective of the charge of the ions, the curves for these two types of ions should merge on a single curve. It is interesting to note that if an estimated value of 0.052 is added to the B_i values of cations, and the same also is subtracted from those of the anions, the two curves smoothly fuse together into a single one, thus adding support to our assumption. The only alkali metal ion found to be off the line is Cs^+.

The method of partitioning the B values for aqueous system has been extended to other tempratures also, viz. 15°C, 35°C, and it has been found that the same estimated value (i.e., 0.052) is obtained in each of these cases. Thus, in order to get B_i values of any ion at any temperature, one requires to add 0.052(Z) to the cationic B values (10), and subtract the same from the anionic B values, as obtained on the assumption that $B_{K^+} = B_{Cl^-}$, where Z is the charge on the ion.

To test the applicability of the present method of division to other more complex monoatomic monovalent ions than the ions considered, the silver ion in aqueous solution has been chosen for this purpose and is shown in Fig. 1. The position of the ion is seen markedly off from the smooth curve given by the alkali metal and halide ions, and thus largely disagrees with the basic premise of the proposed model. Moreover, in such non-aqueous solvents as *N*-methyl formamide (NMF) (29, 30) and *N*-methyl propionamide (NMP) (16), the present method seems inapplicable.

However, the present method has been successfully applied to the partitioning of B coefficients for alkali metal halides in methanol (31, 32), formamide (19), dimethyl sulphoxide (33), ethylene carbonate (34), hexamethyl phosphotriamide (35), and sulfolane (36) solvents at 25°C. The initial B_i values required for B_i vs. r^3 plots were obtained on the basis of $B_{K^+} = B_{Cl^-}$ for methanol and formamide, whereas for the rest of the solvents $B_{Cs^+} = B_{I^-}$ was followed for the same purpose. The new set of B_i values thus obtained for monovalent ions together with the existing values for different systems are shown in Table 1. Also included in Table 1 are the different estimated values for addition or subtraction to the existing B_i values for all the solvents.

Results and discussion

The significance of the proposed model is best illustrated by the fact that the set of B_i values obtained in various solvents for different class of ions lead to internally consistent correlations with the ionic partial molal volumes, ionic radii, temperature coefficient of equivalent conductance and ionic partial molal entropy respectively.

Partial molal volume of ions

In Fig. 2, plots of B_i vs. $\bar{V}_i^0$ are shown for alkali metal and halide ions, using ionic B values of the new scale (Table 1, column 2) along with those of the existing ones. The $\bar{V}_i^0$ values were taken from the experimental values using ultrasonic vibration potential method (37). The figure illustrates that, while the nature of the B_i–$\bar{V}_i^0$ curve is U-shaped for the existing B_i values (10, 14), the new set of B_i values, excepting Li^+ ion, gives almost a linear plot with $\bar{V}_i^0$. Exactly similar plots are also obtained for the same ions in methanol and formamide systems using $\bar{V}_i^0$ values from the UVP method (37) and Mukerjee's method (38), respectively.

The B_i vs. $\bar{V}_i^0$ plots have also been extended to di- and trivalent cations and polyatomic anions in aqueous system. The $\bar{V}_i^0$ values ($H^+ = -4.5$ mL scale) for polyatomic anions,

bivalent and trivalent cations taken from the compilations of Mukerjee (26), Millero (39), and Spedding's reported values (40), respectively, and the corresponding B_i values are all included in Table 2.

It is interesting to note that the B_i vs. $\bar{V}_i^0$ plots for various ions as mentioned, follow linear relationships in anticipation with the earlier assertions, and are summarised in the form of the following equation [2]

$$[2] \quad B_i = \pm a\bar{V}_i^0 \pm b$$

where a and b are adjustable parameters and the values, calculated by computerised least square technique, are shown in Table 3. The values of a in Table 3 indicate that contrary to what is stated in the Einstein relation (4), the B_i values of different class of ions do not increase monotonically with r_i either in aqueous or non-aqueous systems.

Crystal ionic radii and effective hydrated radii

The new set of B_i values for a number of uni-, di-, and trivalent cations and anions are plotted as a function of crystal ionic radius in Fig. 3. The most striking feature of the plot in the case of univalent ions for aqueous system is that a distinct minimum is obtained at the crystal radius 2.4 Å. The minimum demonstrates that the ion–dipole interaction persists up to this size and beyond this, formal ion–solvent interaction ceases to function, rendering the larger ions (polyatomic cations and anions) unhydrated. Nightingale (11) also observed a similar minimum at 2.3 Å in the plot of hydrated crystal radius versus crystal ionic radius for a number of uni-, di-, and trivalent ions, thus strengthening the above view point. The minimum is shifted considerably towards right (3.4 Å) for MeOH, formamide, and DMSO, indicating more ions within this size are also solvated in these solvents compared to water.

The B_i–r_i plots also show that not only the monovalent cations and anions fall on a single straight line but also the divalent ions and the trivalent ions follow similar paths, thereby supporting the very basis of the present model. The behavior of transition metal ions, e.g., the silver ion in aqueous solution as mentioned is quite anomalous, and has been explained in terms of an effective charge higher than the formal charge and due to the presence of the exposed d-electrons (41).

Temperature coefficient of limiting equivalent conductance

The ratio of the Walden product, $(\lambda^0\eta^0)^{25°C}/(\lambda^0\eta^0)^{0°C}$ at the two temperatures decreases with increasing ion size because of gradual decrease in peripheral charge; this function also seems to be related to the ionic B coefficient (4). The temperature coefficient of mobility for aqueous system has been calculated for temperatures 0 and 25°C, procuring data from the compilation of Robinson and Stokes (42), and are shown plotted versus ionic B coefficient in Fig. 4. Two different linear plots are obtained, one for alkali metal ions, and the other for anions. It also points out that the temperature coefficient values for K^+ and Cl^- ions are not the same, contrary to what was observed by Gurney from a similar plot, considering 0 and 18°C as the two intervening temperatures.

Partial molal entropy of ion

Gurney demonstrated a linear relation between the viscosity B coefficient and the partial molal entropy for monoatomic ions, based on the value −5.5 eu, as the absolute partial molal entropy of hydrogen ion at 25°C. However, the literature now abounds with compilations of such data by various workers (43), but due to variations in the values of partial molal entropies of ions, the recommended CODATA values (43) for monoatomic ions have been used for the present purpose. The scale is, however, based on $\bar{S}_{H^+} = 0.0$. Linear relations between ionic B coefficient and entropy for both the monoatomic cations and anions for aqueous system represented by two different lines are obtained (slopes and intercepts for cations, −0.007 and 0.225; anions, −0.006 and 0.025). Since the B coefficient is also a measure of order or disorder introduced by the ions in a solvent, the trend of the curves is in line with the concept of entropy.

Comparison of B_i *values from other workers*

Based on the transition state theory, Feakins *et al.* (44) deduced the following equation [3] for viscosity B coefficient

$$[3] \quad B = \frac{\bar{V}_1^0 - \bar{V}_2^0}{1000} + \frac{\bar{V}_1^0}{1000}\left(\frac{\Delta\mu_2^{0\neq} - \Delta\mu_1^{0\neq}}{RT}\right)$$

where $\bar{V}_1^0$, $\bar{V}_2^0$ are partial molal volume of pure solvent and solute at infinite dilution. According to this equation, the viscosity B coefficient is a function of molar volume of solvent and therefore the order of increasing B_i values is

$$B_{water} < B_{Formamide} < B_{MeOH} < B_{EC} < B_{DMSO} < B_{TMS} < B_{HMPT}$$

The ionic values obtained here strictly follow this order, thereby justifying the present method (Table 1). However, the B_i values obtained by Sacco *et al.* (35) in EC and those by Bicknell *et al.* (33) in DMSO following identical method do not follow this order. Krumgalz's values (8) in methanol also deviate considerably from this trend.

The agreement between the different ionic values in form-

‡Formamide.

amide obtained by the present method with those of Krumgalz (8) and Vincent *et al.* (19) from entirely different assumptions is striking (Table 1). Very recently, Lawrence *et al.* (45) have obtained B_i value for bromide ion in HMPT (= 0.732) by using the extrapolation method, almost identical to our value of 0.73. However, very low anionic values in EC and especially negative value for chloride ion in sulfolane obtained by Sacco *et al.* (36) are not justified in these non-associated solvents. If steric hindrance is regarded as the origin for such low values, then one would also expect similar results in HMPT and DMSO.

Splitting of B_i *values*

Based on Frank and Wen's model (46) of ion–solvent interaction, Mandal *et al.* (47) has split the ionic viscosity B coefficient by the following relation [4] using Eyring's equation of viscosity proposed for non-associated liquids

$$[4] \quad B_i = A_1 r^3 - A_2 r^2 + A_3 \frac{Z^2}{r}$$

where the first, second, and the third term represent the intrinsic, void, and electrostriction viscosities of ions, respectively. If the intrinsic viscosity and void space viscosity are combined, the following relation [5] analogous to Hepler's semi-empirical relation (48) for ionic partial molal volume is obtained.

$$[5] \quad B_i = A_\eta r^3 + B_\eta \frac{Z^2}{r}$$

The first term originates from the geometry of the solvated ion and the second term from electrostriction.

Equation [5] has been tested graphically using the various B_i values of inorganic ions at 25°C in water, methanol, formamide, DMSO, EC, sulfolane, and HMPT (Fig. 5). Single straight line plots of $B_i r$ versus r^4 are obtained for cations and anions in most of the solvents, indicating the validity of eq. [5] as well as the similarity of cation–solvent and anion–solvent interactions in those solvents. Moreover, the inapplicability of the present method to the *N*-substituted amide solvents supports the earlier experimental observation by Kawaizumi and Zana (49) that the anionic solvation in these solvents is sterically hindered. The slopes (A_η) and intercepts (B_η) of eq. [5] obtained for different solvents are shown in Table 4.

Significance of A_η *values*

The A_η values shown in Table 4 are a reflection of void volumes of solvated ions transformed into the corresponding contribution to viscosity. Now since these two quantities are inversely related (47), one can expect the lowest value in water and steadily increasing values in the other solvents with increasing molar volumes (Table 4, column 2). Experimental

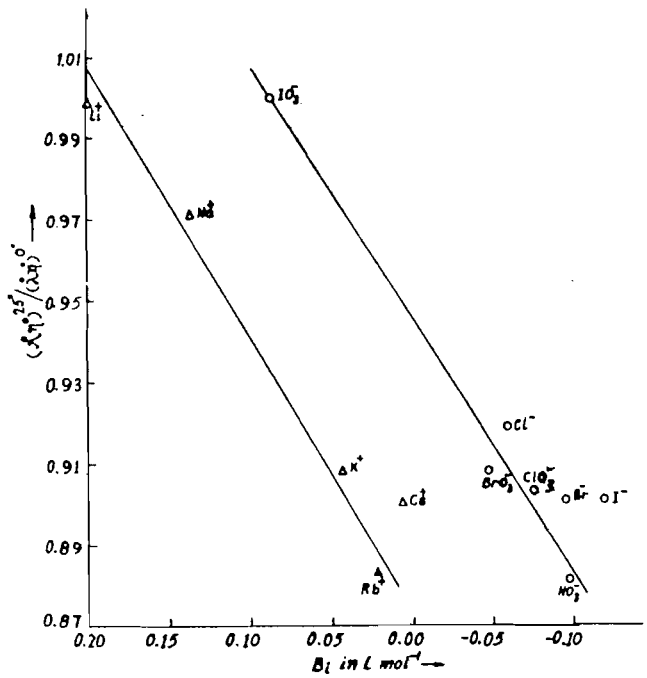

FIG. 4. Variation of $(\lambda^0\eta^0)^{25°C}/(\lambda^0\eta^0)^{0°C}$ with ionic B coefficient at 25°C for aqueous system.

values for the partial molal volumes (49, 50) show that the void volumes around ions are significantly smaller in methanol and propylene carbonate compared to that in water. The negative values obtained for the hydrogen bonded solvents are unwarranted by eq. [5]. However, if one recalls that the above equation was deduced for non-associated solvents, the negative values may be accounted for from the effect of destructuring of the hydrogen bonded solvents by these ions.

Electrostriction viscosity (B_η)

Electrostriction causes a decrement in volume but an increment in viscosity. The magnitudes of B_η shown in Table 4 indicate that electrostriction is lowest in water, moderate in formamide, EC, DMSO, and highest in methanol and HMPT. Zana *et al.* (49, 50) observed from experimental values of $\bar{V}_i^0$ a moderate electrostriction for water, ethanol, DMSO, and PC but higher for methanol and DMF.

The Drude–Nernst equation (51), which is based on a continuum model for a solvent, leads for monovalent ions to the equation

$$[6] \quad V_e = -\frac{Ne^2}{2Dr_i}\left(\frac{\partial \ln D}{\partial P}\right)_T = -\frac{\beta e^2}{2Dr_i}\left(\frac{\partial \ln D}{\partial \ln \rho}\right)_T$$

where $\beta = (\partial \ln \rho/\partial P)_T$ is isothermal compressibility, D the dielectric constant, ρ, the density of the solvent. The equation predicts a direct proportionality between electrostriction volume (V_e) and compressibility but inverse with the dielectric constant of the medium. This is reasonably followed in the present case, as seen from Table 4. Since the electrostriction volume and electrostriction viscosity are proportional (47), one is tempted to convert the various calculated values of V_e using eq. [6] into the corresponding contribution of viscosity through eq. [2].

To calculate V_e values in various solvents, the $(\partial \ln D/\partial P)_T$ values required for the purpose are not available for most of the solvents. We have used instead the isothermal compressibilities

from the compilation of Dack *et al.* (52) following the suggestion of Kawaizumi and Zana (49). The dielectric constants (42, 53), compressibilities, and calculated values of V_e are all included in Table 4. The agreement between the B_η values and the converted V_e values in the three protic solvents is satisfactory, considering the approximate nature of D–N equations as well as other approximations. The results also point out that the continuum model works better in the case of viscosity than in partial molal volume (54) (Table 4).

Carbanions phosphonate préparés par voie électrochimique : formation et réactivité vis-à-vis d'un aldéhyde

JEAN-CHRISTOPHE LE MENN, JEAN SARRAZIN[1] ET ANDRÉ TALLEC

Laboratoire d'électrochimie, Unité associée au Centre national de la recherche scientifique, n° 439, Université de Rennes, Campus Beaulieu, 35042 Rennes, France

Reçu le 14 décembre 1988

JEAN-CHRISTOPHE LE MENN, JEAN SARRAZIN et ANDRÉ TALLEC. Can. J. Chem. **67**, 1332 (1989).

On a étudié la réactivité, vis-à-vis du *p*-méthoxybenzaldéhyde (noté ArCHO), de carbanions phosphonate formés par voie électrochimique. Les électrolyses sont effectuées sur cathode de mercure, en milieu DMF, et deux voies d'accès aux carbanions ont été comparées : (*i*) Déprotonation de phosphonates de formule générale $(EtO)_2P(O)CHYW$ (Y = W = Cl; Y = H, W = Cl; Y = Cl, W = CO_2Et; Y = H, W = CO_2Et; Y = CH_3, W = CO_2Et; Y = Cl, W = CH_3) par les bases résultant de l'électroréduction de l'azobenzène; dans tous les cas, le carbanion formé s'additionne au carbonyle pour conduire à l'adduit $(EtO)_2P(O)CYW(Ar)O^-$. (*ii*) La réduction biélectronique de phosphonates halogénés $(EtO)_2P(O)CXYW$ (X = Cl, Y et W comme ci-dessus; X = Br, W = CO_2Et, Y = Cl, Br, ou CH_3); si le carbone auquel est lié le groupement phosphonate ne porte aucun atome d'hydrogène (Y et W ≠ H) la même évolution conduisant à l'adduit ci-dessus est observée; par contre, si Y = H, le carbanion électrogénéré déprotone le substrat et c'est le carbanion résultant $(EtO)_2P(O)\bar{C}XW$ qui réagit avec l'aldéhyde pour conduire à $(EtO)_2P(O)CXW(Ar)O^-$.

L'évolution de l'intermédiaire anionique dépend de la nature des substituants W et Y (ou X) mais pas du mode de génération du carbanion : pour W = CO_2Et, quelle que soit la nature de Y, une élimination de phosphate de diéthyle avec formation d'un éthylénique est observée (réaction de Wittig–Horner); la même évolution se produit pour Y = W = Cl. Lorsque W = Cl et Y = H ou CH_3, le produit final est un époxyde phosphonate provenant d'une élimination d'ion chlorure (réaction de Darzens).

La stéréochimie des produits ne dépend que de Y et W; elle est indépendante du mode de formation du carbanion. Les rendements ne sont limités que par l'intervention de protonations parasites, liées à la basicité des carbanions phosphonate. L'analyse de l'ensemble des résultats permet de définir les conditions optimales d'électrolyse, utilisée comme technique de synthèse.

Mots clés : électrosynthèse, bases électrogénérées, phosphonates, Wittig–Horner.

JEAN-CHRISTOPHE LE MENN, JEAN SARRAZIN, and ANDRÉ TALLEC. Can. J. Chem. **67**, 1332 (1989).

Reactivity towards *p*-methoxybenzaldehyde (ArCHO) of electrochemically generated phosphonate carbanions has been investigated. Electrolyses were carried out at a mercury cathode in DMF and two routes to the desired carbanion have been compared: (*i*) Deprotonation of phosphonates of general formula $(EtO)_2P(O)CHYW$ (Y = W = Cl; Y = H, W = Cl; Y = Cl, W = CO_2Et; Y = H, W = CO_2Et; Y = CH_3, W = CO_2Et; Y = Cl, W = CH_3), by the bases resulting from the electroreduction of azobenzene; addition of the carbanion formed onto the carbonyl group takes place and leads to the adduct $(EtO)_2P(O)CYW(Ar)O^-$. (*ii*) Two-electron reduction of halophosphonates $(EtO)_2P(O)CXYW$ (X = Cl, Y and W as above; X = Br, W = CO_2Et, Y = Cl, Br, or CH_3); when no H atom is present on the carbon bearing the phosphonate group (Y and W ≠ H), the same evolution leading to the above adduct is observed; on the contrary, when Y = H, the electrogenerated carbanion deprotonates the substrate and the resulting carbanion $(EtO)_2P(O)\bar{C}XW$ reacts with the aldehyde, giving the adduct $(EtO)_2P(O)CXW(Ar)O^-$.

Evolution of the intermediate adduct depends on the substituants Y (or X) and W: when W = CO_2Et, whatever the nature of Y (or X), diethyl phosphate is eliminated with formation of the ethylenic ArCH=CWY (or X) (Wittig–Horner reaction); the same evolution is observed when Y = W = Cl. When W = Cl and Y = H or CH_3, the final product is the phosphonate epoxyde resulting from chloride elimination (Darzens reaction).

Chemo- and stereoselectivity depend only on the nature of Y and W but are independent of the mode of generation of the carbanion. Yields are limited by side-protonation reactions, which are related to the basicity of the phosphonate carbanions. Analysis of the results permits selection of the optimal electrolysis conditions for purposes of synthesis.

Key words: electrosynthesis, electrogenerated bases, phosphonates, Wittig–Horner.

Introduction

L'utilisation de carbanions phosphonate, comme intermédiaires de synthèse en chimie organique, a fait l'objet de nombreuses études (1, 2). La réaction de ces carbanions avec des composés carbonylés, qui a été réalisée pour la première fois par Horner *et al.* (3), est généralement considérée comme une modification de la réaction de Wittig et elle est dénommée réaction de Wittig–Horner ou réaction de Horner–Emmons.

$$RR'CO + (EtO)_2P(O)\bar{C}YW \rightarrow RR'C{=}CYW + (EtO)_2PO_2^-$$

Les carbanions phosphonate $(EtO)_2P(O)CYW^-$ peuvent résulter du traitement basique des phosphonates porteurs d'un atome d'hydrogène sur le carbone en α $(EtO)_2P(O)CHYW$. Différentes techniques ont ainsi été mises en oeuvre pour la conduite de réactions de Wittig–Horner. L'utilisation, en milieu homogène, dans de nombreux solvants, de bases telles que des alcoolates, des amidures ou des hydrures, correspond simplement à de légères modifications des conditions employées initialement par Horner *et al.* (3) ou par Wadsworth et Emmons (4). La catalyse par transfert de phase liquide–liquide a également retenu l'attention : elle implique un système biphasique constitué de soude aqueuse et d'un solvant organique, en présence de cations ammonium ou d'éthers-couronne ou même en l'absence de catalyseur (5). Enfin, plus récemment, l'utilisation d'une base minérale solide en suspension dans un solvant tel que le tétrahydrofuranne s'est avérée une technique de synthèse particulièrement efficace (6).

D'autre part, il a été montré que des bases électrogénérées,

résultant de la réduction cathodique de probases telles que l'azobenzène, sont capables de déprotoner des phosphonates que la présence de substituants attracteurs rend suffisamment acides; des réactions de Wittig–Horner peuvent ainsi être initiées par voie électrochimique (7, 8).

Par ailleurs, les phosphonates halogénés constituent une autre source de carbanions phosphonate. En effet, la réduction chimique, par le butyl lithium, à basse température, du trichlorométhylphosphonate de diéthyle **1** $(EtO)_2P(O)CCl_3$ a été étudiée par Seyferth et Marmor (9) puis par Normant et ses collaborateurs (10) : le dichloro carbanion lithié ainsi obtenu $(EtO)_2P(O)CCl_2Li$ peut être alkylé au moyen d'iodures ou de bromures d'alkyle; par réaction avec des aldéhydes ou des cétones, il conduit aux dichloro-1,1 alcènes correspondants.

La réduction électrochimique des phosphonates halogénés n'a donné lieu qu'à peu d'études; elles concernent presque exclusivement le trichlorométhylphosphonate **1**. En solution hydroalcoolique acide (11), l'électroréduction de celui-ci conduit, par coupures successives de liaisons carbone–chlore, aux dichlorométhylphosphonate **2** $(EtO)_2P(O)CCl_2H$ et chlorométhylphosphonate de diéthyle **3** $(EtO)_2P(O)CClH_2$. L'électroréduction de **1** a également été réalisée en milieu aprotique en présence d'électrophiles; nous avons ainsi montré qu'en présence d'halogénures d'alkyle RX, des dichloro-1,1 alkylphosphonates de diéthyle $(EtO)_2P(O)CCl_2R$ peuvent être synthétisés électrochimiquement (12). De même, une étude de l'électroréduction du phosphonate **1** en présence de composés carbonylés a été menée (13, 14); enfin, l'examen du comportement du phosphonodichloroacétate de triéthyle **4** $(EtO)_2P(O)CCl_2CO_2Et$ a fait l'objet d'une note préliminaire (14) : les alcènes chlorés attendus sont effectivement obtenus, mais les rendements ne dépassent pas 50–55%.

Le présent article est consacré à la génération par voie électrochimique de carbanions phosphonate et à l'étude de leur réactivité vis-à-vis d'aldéhydes.

Les phosphonates ont été choisis de telle sorte que soient disponibles à la fois le substrat hydrogéné $(EtO)_2P(O)CHYW$ et l'homologue halogéné $(EtO)_2P(O)CXYW$, afin qu'une comparaison puisse être établie entre les deux voies d'accès à un même carbanion (schéma 1) : déprotonation (voie A) ou réduction (voie B). Leurs formules sont regroupées dans le tableau 1. Compte-tenu de leur comportement, les substrats étudiés peuvent être classés en deux groupes selon qu'ils portent ou non un substituant carboxylate.

L'aldéhyde choisi est le paraméthoxybenzaldéhyde, noté ArCHO. Un tel composé présente en effet l'avantage de ne pas porter d'atome d'hydrogène sur l'atome de carbone en α du carbonyle; par ailleurs, la présence sur le noyau aromatique d'un substituant donnant un signal RMN est particulièrement intéressante pour l'analyse des produits de réaction.

Enfin, pour qu'une comparaison puisse être établie entre les comportements des différents phosphonates étudiés, les conditions de réaction ont été préalablement définies et un mode opératoire standard a été adopté.

Résultats et discussion

1. Détermination des conditions expérimentales

Le choix des conditions expérimentales résulte de l'étude de l'influence de deux paramètres (nature de l'électrolyte-support et concentration des réactifs) sur le rendement de la réaction de

SCHÉMA 2

Wittig–Horner dans le cas de l'électroréduction du dichlorophosphonoacétate de triéthyle **4** et du trichlorométhylphosphonate de diéthyle **1** antérieurement examinée par d'autres auteurs.

L'électroréduction de **4**, à potentiel contrôlé en solution dans le DMF et en présence d'une quantité stoechiométrique de *p*-méthoxybenzaldéhyde, nécessite 2 faradays par mole. Elle conduit à un mélange de l'éthylénique attendu **16**, d'aldéhyde n'ayant pas réagi et de phosphonate réduit **5** qui résulte de la protonation du carbanion électrogénéré **4***A* (schéma 2). Les proportions dépendent de la concentration initiale des réactifs et de la nature du cation de l'électrolyte-support, comme on peut le constater à la lecture du tableau 2. Ce tableau montre que le carbanion intermédiaire **4***A* est plus facilement protoné par le cation tétrabutylammonium que par le cation tétraméthylammonium. D'autre part, on constate qu'une augmentation de la concentration des réactifs phosphonate et aldéhyde favorise l'attaque nucléophile du carbanion sur le carbonyle au détriment de sa protonation; le rendement en produit de Wittig–Horner est plus élevé.

Ces conclusions, relatives à l'intérêt de l'emploi du cation tétraméthylammonium et d'une concentration en réactifs élevée, sont confirmées par l'étude du comportement du phosphonate **1** : le tableau 3 montre en effet que les quantités de phosphonate réduit **2** et d'aldéhyde n'ayant pas réagi sont moins importantes lorsque ces conditions sont réunies. Le rendement de la réaction de Wittig–Horner est alors augmenté. Mais il semble surtout que ces conditions soient favorables à la formation du phosphate **21**, espèce qui résulte d'une évolution, sans élimination d'anion diéthylphosphate, de l'adduit formé entre le carbanion et l'aldéhyde (schéma 2). La présence de ce phosphate parmi les produits de réaction ne présente pas d'inconvénient majeur pour notre étude; en effet, sa formation n'a été observée qu'à partir du carbanion phosphonate dichloré **1***A*. De plus, ce phosphate peut être converti en éthylénique **18** par un traitement basique;

TABLEAU 2. Influence de la concentration des réactifs et de la nature du cation de l'électrolyte-support. Electroréduction du dichlorophosphonoacétate de triéthyle **4** dans le DMF (E_T = −0,7 V vs. AgI/Ag) en présence d'une quantité stoechiométrique de *p*-méthoxybenzaldéhyde ArCHO. Les rendements indiqués sont les rapports des quantités de matière obtenues après extraction à la quantité de phosphonate introduite dans la cellule d'électrolyse

C (mol L^{-1})	4×10^{-2}		10^{-1}	
Cation	Bu_4N^+	Me_4N^+	Bu_4N^+	Me_4N^+
ArCHO (%)	45	20	15	10
Phosphonate réduit **5** (%)	20	10	15	7
ArCH=CClCO$_2$Et **16** (%)	45	60	65	75

TABLEAU 3. Influence de la concentration des réactifs et de la nature du cation de l'électrolyte-support. Electroréduction du trichlorométhylphosphonate **1** dans le DMF (E_T = −1 V) en présence d'une quantité stoechiométrique de *p*-méthoxybenzaldéhyde ArCHO. Rendements calculés comme dans le tableau 2

C (mol L^{-1})	4×10^{-2}	10^{-1}	
Cation	Bu_4N^+	Bu_4N^+	Me_4N^+
ArCHO (%)	33	5	5
Phosphonate réduit **2** (%)	30	10	0
(EtO)$_2$P(O)—O—CHArCCl$_2$H **21** (%)	0	10	18
ArCH=CCl$_2$ **18** (%)	53	57	62

en particulier, on n'obtient pas **21** lorsque l'électrolyse est réalisée avec un léger excès de phosphonate **1** comparativement à l'aldéhyde : le milieu est alors rendu suffisamment basique par l'excès de carbanion **1***A* électrogénéré.

*Cathode de cuivre.

Aussi, pour conduire l'étude comparative des différents phosphonates, une concentration de 0,1 mol L^{-1} a été adoptée pour le phosphonate et l'aldéhyde, et le tétrafluoroborate de tétraméthylammonium a été choisi comme électrolyte-support. Les rendements observés dans ces conditions sont nettement supérieurs à ceux de la littérature (13, 14).

Notons de plus que la réduction électrochimique s'avère une méthode de synthèse intéressante : la conversion de l'aldéhyde en éthylénique chloré est en effet réalisée quantitativement si l'on met en oeuvre un excès de l'ordre de 10–20% du phosphonate initial. On forme alors du phosphonate réduit en quantité correspondante à cet excès; son élimination est très aisée puisqu'il est retenu sur la colonne par simple filtration sur silice (voir partie expérimentale).

II. Carbanions phosphonate substitués par un groupement carboxylate

Les résultats des électrolyses préparatives (repérées E1–E9) impliquant la formation intermédiaire de tels carbanions sont regroupés dans le tableau 4. Les expériences ont été conduites dans les conditions standard choisies comme cela a été indiqué précédemment.

1. Déprotonation (voie A) par les bases issues de l'électroréduction de l'azobenzène

On électrolyse, à un potentiel tel que seul l'azobenzène soit réduit, une solution contenant un mélange, dans les proportions molaires 0,5 : 1 : 1, d'azobenzène, d'aldéhyde et de phosphonate porteur d'un atome d'hydrogène. Parmi les phosphonates étudiés, seuls les composés **6** (Y = H) et **9** (Y = CH_3) peuvent se prêter à ce type d'étude; le dérivé **5** (Y = Cl) doit être exclu car il est aussi facilement réductible que l'azobenzène.

La réaction consomme environ 2 faradays par mole d'azobenzène, et l'on extrait un mélange d'hydrazobenzène et d'éthylénique. Ainsi, **6** et **9** (électrolyses E4 et E1) conduisent à une consommation complète de l'aldéhyde : la réaction de Wittig–Horner se produit quantitativement et les pertes que l'on remarque, si l'on effectue les bilans de matière dans le tableau 4, sont dues à l'extraction.

Le groupement carboxylate rend le phosphonate suffisamment acide pour qu'il n'intervienne pas de protonation parasite des bases électrogénérées par un autre donneur de proton; dans le même ordre d'idée, aucune protonation du carbanion intermédiaire n'est observée. Le mécanisme de la déprotonation du phosphonate a déjà été discuté (7) et est résumé sur le schéma 3.

Cette réaction est suivie d'une attaque nucléophile rapide du carbanion sur le carbonyle, puis de l'élimination de phosphate de diéthyle :

$$(EtO)_2P(O)\bar{C}YCO_2Et + ArCHO \rightarrow ArCH{=}CYCO_2Et + (EtO)_2PO_2^-$$

5*a* Y = H — **15**(*E*) Y = H

7*a* Y = CH_3 — **14**(*E*) Y = CH_3

On remarquera la stéréospécificité de la réaction qui conduit exclusivement à l'éthylénique de configuration *E*.

*2. Réduction (voie B) des phosphonates halogénés **4**, **5**, **7**, **8**, **10**, **11***

On électrolyse, au potentiel de réduction du phosphonate, une solution équimolaire de phosphonate $(EtO)_2P(O)CXYCO_2Et$ (X = Cl ou Br) et d'aldéhyde. Les produits extraits en fin d'électrolyse contiennent toujours une certaine quantité d'aldéhyde n'ayant pas réagi, du phosphonate réduit $(EtO)_2P(O)CHYCO_2Et$ (remplacement de l'halogène du substrat initial par un atome d'hydrogène) et un éthylénique (tableau 4). Aucun autre produit n'est mis en évidence.

2.1. Réduction avec élimination de l'ion chlorure (composés **4**, **5** et **7**). (*a*) Les réductions des phosphonates chloré **7** (X = Cl, Y = CH_3) et dichloré **4** (X = Y = Cl) conduisent avec des rendements satisfaisants aux éthyléniques attendus (électrolyses E2 et E7). L'étape électrochimique conduit au carbanion (**7***A* ou **4***A*) qui réagit principalement avec l'aldéhyde (schéma 4); une protonation parasite peu importante, par action de l'eau résiduelle ou du cation de l'électrolyte-support, entraîne la formation de phosphonate réduit (**9** ou **5**); la quantité d'aldéhyde recouvré reflète également l'importance de cette protonation.

Au plan stéréochimique, la réaction de Wittig–Horner est encore spécifique dans le cas du dérivé monochloré (formation exclusive de l'isomère *E*) alors que le phosphonate dichloré conduit à un mélange des deux isomères *E* et *Z* (proportion *E*/*Z* = 30 : 70).

On notera aussi dans ce dernier cas que le rendement en éthylénique est nettement supérieur à celui obtenu au terme d'électrolyses comparables, réalisées avec $LiClO_4$ comme électrolyte-support (14). Comme nous l'avons déjà montré

SCHÉMA 4

(12), la présence d'ions Li^+ dans le milieu inhibe partiellement la nucléophilie des carbanions électrogénérés.

(*b*) Le phosphonate chloré **5** (X = Cl, Y = H) présente un comportement particulier.

La réduction à −0,9 V (électrolyse E6) ne consomme qu'un électron par molécule de substrat; elle ne conduit pas au composé attendu **15** mais à l'éthylénique chloré **16**. Ce résultat s'explique par une protonation du carbanion électrogénéré **5***A* par le phosphonate initial (schéma 5). L'équilibre acido-basique (réaction [2]) est très déplacé vers la droite, conformément à l'effet attendu du substituant chloro (**5** est plus acide que **6**). De plus, le transfert de proton étant plus rapide que l'attaque d'un carbanion sur l'aldéhyde, seul le carbanion chloré **4***A* réagit pour conduire au produit **16** de la réaction Wittig–Horner (réaction [3] du schéma 5); à l'appui de cette interprétation, notons que la proportion des isomères **16**(*E*) et **16**(*Z*) est la même que celle obtenue lors de la réduction du phosphonate dichloré **4**.

Dans ces conditions, le rendement en **16** ne saurait excéder 50% puisque la moitié du phosphonate initial est consommé comme probase. Les pourcentages indiqués dans le tableau 4, si l'on tient compte des difficultés d'extraction des phosphonates, sont en parfait accord avec cette interprétation, et le bilan de la réduction de **5** à −0,9 V peut s'écrire :

$$\underset{\mathbf{5}\,(100\%)}{2(EtO)_2P(O)CHClCO_2Et} + 2e^- + \underset{(50\%)}{ArCHO} \rightarrow$$

$$\underset{\mathbf{6}\,(50\%)}{(EtO)_2P(O)CH_2CO_2Et} + \underset{\mathbf{16}\,(50\%)}{ArCH{=}CClCO_2Et} + Cl^- + (EtO)_2PO_2^-$$

Des résultats très différents sont obtenus lors de la réduction du même substrat (X = Cl, Y = H) au potentiel −1,3 V (électrolyse E5). Le résultat coulométrique est proche de 2 F/mol, et l'éthylénique extrait est le produit non chloré **15**. En outre, les deux isomères **15**(*E*) et **15**(*Z*) sont présents, contrairement à ce qui a été observé par déprotonation de l'homologue hydrogéné **6** au cours de l'électrolyse E4. Pour rendre compte de la présence de **15**(*Z*), il est donc nécessaire de proposer une voie d'accès à **15** autre que la réaction du carbanion **5***A* avec l'aldéhyde.

Nous avons vérifié que le chlorocinnamate d'éthyle **16**, non électroactif à −0,9 V, est réduit lentement à −1,3 V. Cependant, cette réaction électrochimique (étape [4] du schéma 5) ne peut à elle seule expliquer les résultats obtenus : d'une part, comme pour l'électrolyse E6, le rendement en éthylénique **15** ne devrait pas excéder 50%; d'autre part, le pourcentage en isomère **15**(*E*) est supérieur à celui attendu par électroréduction de **16**.[2]

L'ensemble des réactions qui permettent de rendre compte de l'électrolyse de **5** à −1,3 V (E5) est regroupé sur le schéma 5. L'obtention d'un rendement en **15** supérieur à 50% est attribuable au rôle de probase joué par **16**. En effet, le carbanion vinylique issu de **16** est suffisamment basique pour déprotoner les phosphonates **5** et **6** (réactions [5] et [6]). La déprotonation de **5**, qui est le plus acide, doit conduire, par l'intermédiaire de

2. Nous avons vérifié qu'en présence d'un donneur de protons la réduction électrochimique de **16** s'effectue avec rétention de configuration; ainsi un mélange des deux isomères **16**(*E* et *Z*), en proportion 30 : 70 conduit à un mélange des deux isomères **15**(*E* et *Z*), en proportion 70 : 30.

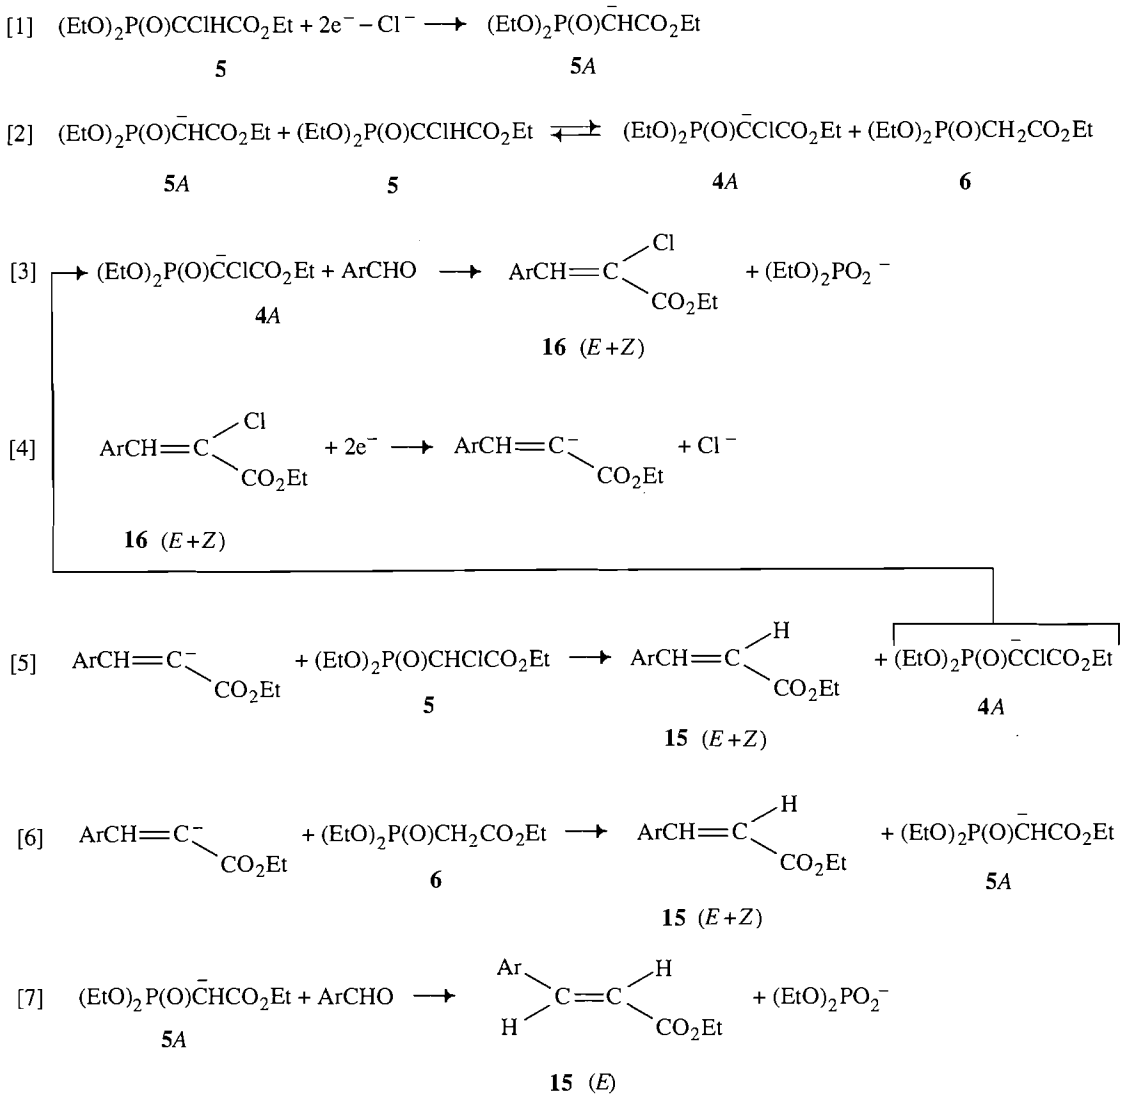

SCHÉMA 5

4A, au mélange d'isomères *Z* et *E*. Celle de **6**, qui interviendra surtout vers la fin de l'électrolyse, lorsque **5** aura été consommé, conduit, par l'intermédiaire de **5A**, au seul isomère *E* (réaction [7]). L'écart entre le résultat stéréochimique des électrolyses E6–E8 et celui de l'électrolyse E5 est attribuable à l'intervention de cette dernière réaction. Enfin, la quantité d'aldéhyde n'ayant pas réagi est liée à l'importance des protonations parasites de tous ces carbanions.

2.2. Réduction avec élimination de l'ion bromure (composés **8**, **10** et **11**). (*a*) Elle est observée dans le cas du dérivé monobromé **8**, du dérivé dibromé **10** et du dérivé chlorobromé **11**; comme attendu, dans ce dernier cas, il y a coupure sélective de la liaison C—Br.

Les électrolyses correspondantes s'accompagnent d'un déficit coulométrique marqué par rapport aux 2 faradays par mole attendus; de plus, le rendement en produit de Wittig–Horner est plus faible. Les réactions du schéma 4 (X = Br) n'interviennent donc que pour une part. A priori, deux types de comportement supplémentaires peuvent expliquer la différence observée entre substrats bromés et analogues chlorés : (*i*) L'existence d'une réaction de substitution nucléophile entre le carbanion électrogénéré et le composé bromé initial justifierait le déficit coulométrique; cette hypothèse ne nous paraît pas devoir être retenue car nous n'avons jamais pu mettre en évidence la formation du diphosphonate auquel conduirait cette réaction. (*ii*) Il est plus vraisemblable que l'étape électrochimique corresponde, en partie, à un transfert monoélectronique avec élimination d'ion bromure et formation d'un radical; le même phénomène a déjà été observé lors de la réduction de bromures d'alkyle sur cathode de mercure (15). Dans cette hypothèse, le phosphonate réduit, présent en quantité notable, se formerait également par transfert d'atome d'hydrogène du solvant sur le radical intermédiaire.

(*b*) À l'appui de l'interprétation précédente, il convient d'indiquer les difficultés particulières rencontrées lors de l'électrosynthèse du bromocinnamate **17** à partir du phosphonate dibromé **10**. Dans les conditions standard (cathode de mercure, sel de tétraméthylammonium), le rendement en éthylénique **17** est inférieur à 5%, l'aldéhyde est presque entièrement récupéré en fin d'expérience. En cours d'électrolyse, la précipitation du bromure de tétraméthylammonium (qui indique la formation d'ions bromure en solution) ne se produit que tardivement; de plus, le mercure a tendance à se rassembler en petites billes ternes comme celà se produit lors de formation d'espèces radicalaires ou de composés organomercuriques (16).

Ces inconvénients peuvent être évités soit en utilisant un sel de tétrabutylammonium si la cathode est en mercure, soit

en conservant le cation tétraméthylammonium mais en utilisant une cathode de cuivre. Les rendements obtenus dans ces dernières conditions sont indiqués dans le tableau 4 (électrolyse E9).

3. Conclusion

On retiendra de cette étude que les quatre carbanions phosphonate, porteurs d'un groupement carboxylate, mis en jeu dans les électrolyses E1–E9 donnent une réaction d'addition sur le *p*-méthoxybenzaldéhyde, même si le carbanion est par ailleurs substitué par un atome de chlore ou un atome de brome. L'adduit ainsi formé se décompose avec élimination de phosphate de diéthyle pour conduire à un dérivé éthylénique.

L'ensemble des résultats est résumé sur le schéma 6.

La stéréosélectivité de la réaction est imposée par les étapes chimiques. Elle apparaît indépendante du mode de formation du carbanion mais varie selon la nature du substituant Y. Si celui-ci est un atome d'hydrogène ou un groupement méthyle, la réaction conduit exclusivement à l'éthylénique de configuration *E*. Par contre, si celui-ci est un atome d'halogène, on obtient un mélange où prédomine l'isomère *Z*, la stéréosélectivité étant légèrement supérieure pour Y = Cl.

On se rappelera enfin que du fait de la présence d'un atome d'hydrogène sur le phosphonate **5**, le carbanion qui réagit sur l'aldéhyde n'est pas le carbanion formé par réduction, mais celui-ci issu de la déprotonation du substrat.

III. Carbanions phosphonate halogénés sans substituant carboxylate

1. Déprotonation par les bases issues de l'électroréduction de l'azobenzène (voie A)

On électrolyse, à un potentiel tel que seul l'azobenzène soit réduit, une solution contenant un mélange d'azobenzène (1,5 mmol), de *p*-méthoxybenzaldéhyde ArCHO (3 mmol) et de phosphonate (3 mmol). Les phosphonates concernés $(EtO)_2P(O)CHYW$ sont **2** (Y = W = Cl), **3** (Y = H, W = Cl) et **13** (Y = CH_3, W = Cl) (tableau 5).

(a) L'étape de déprotonation. La réduction de l'azobenzène dans ces conditions consomme 2 faradays par mole et conduit à l'hydrazobenzène que l'on extrait parmi les produits d'électrolyse. On constate que le cours de la réaction dépend du phosphonate étudié. En effet, lorsque l'électrolyse est réalisée en présence de **2** (électrolyse E10), la solution reste incolore, alors que en présence de **13** ou de **3** (respectivement E11 et E12), une coloration noire apparaît intermédiairement; celle-ci est due à une accumulation en solution du radical-anion de l'azobenzène qui ne s'avère donc pas assez basique pour déprotoner les phosphonates **3** ou **13**. Ainsi, le mécanisme proposé précédemment (schéma 3) pour la déprotonation des phosphonocarboxylates **6** et **9** est également valable pour celle de **2**. En revanche, les déprotonations de **3** et de **13** ne peuvent être assurées que par les espèces plus basiques, le monoanion

SCHÉMA 7. Evolutions de l'adduit aldéhyde-carbanion phosphonate chloré.

$(C_6H_5NHNC_6H_5)^-$ ou le dianion $(C_6H_5NNC_6H_5)^{2-}$, qui résultent de la dismutation du radical-anion formé à l'électrode; un tel comportement a déjà été observé lors de l'étude du benzylphosphonate de diéthyle (7).

En outre, on peut s'attendre à ce que les protonations parasites des bases électrogénérées prennent d'autant plus d'importance que le phosphonate présent est moins acide. De fait, comme on peut le constater à la lecture du tableau 5, les quantités d'aldéhyde et de phosphonate qui n'ont pas réagi augmentent lorsque l'on remplace le substituant Y = Cl de **2** par un atome d'hydrogène, dans **3**, et plus encore par un groupe Y = CH_3, dans **13**. Ces résultats sont en accord avec la variation d'acidité des substrats attendue d'après les effets inducteurs des substituants Y (17).

(b) Les produits de réaction. Il apparait, à la lecture du tableau 5, que la nature des produits de la réaction du carbanion phosphonate et de l'aldéhyde dépend de la nature du phosphonate. Alors que la réaction de Wittig–Horner est observée dans le cas du carbanion dichloré issu de la déprotonation de **2**, les phosphonates **3** et **13** fournissent des époxydes selon la réaction de Darzens. Cette sélectivité est identique à celle qui est observée lorsque les déprotonations sont conduites dans l'hexane à basse température au moyen de la base butyllithium (18, 19).

Ainsi trois évolutions sont possibles pour l'anion résultant de l'addition du carbanion phosphonate sur l'aldéhyde (schéma 7). (*i*) L'élimination de phosphate de diéthyle (schéma 7a) se produit lorsque W est suffisamment attracteur, comme nous l'avons déjà observé dans la première partie (W = Cl) et dans la deuxième partie (W = CO_2Et) de ce mémoire. (*ii*) La formation du phosphate **21** est en compétition avec l'évolution précédente lorsque W = Cl (schéma 7b); le mécanisme bimoléculaire proposé, également envisagé par d'autres auteurs (20), rend compte de l'influence de la concentration du substrat rapportée dans la première partie. (*iii*) Une substitution nucléophile interne se produit (schéma 7c) lorsque W n'est pas attracteur (W = H ou CH_3). L'élimination d'un ion chlorure entraîne alors la formation d'un époxyde.

(c) Application synthétique. Étant donné la sélectivité des réactions mises en jeu, l'électrolyse peut être utilisée comme technique de synthèse. En effet, l'utilisation d'un excès convenable de probase azobenzène doit permettre une conversion quantitative de l'aldéhyde et du phosphonate. Nous avons effectivement vérifié que l'électrolyse conduite en présence de **2** avec un excès d'azobenzène et arrêtée au moment où la couleur de la solution commence à foncer parce que le radical anion formé à la cathode ne trouve plus de donneur de proton disponible, fournit quantitativement l'éthylénique **18**. De même, l'emploi d'un excès d'azobenzène (0,75 mole consommée par mole de phosphonate) permet d'augmenter le taux de conversion du réactif **13** en époxyde **19** de 34% à 65%.

2. Réduction des phosphonates polyhalogénés (voie B)

On électrolyse, au potentiel de réduction du phosphonate, une solution équimolaire de phosphonate $(EtO)_2P(O)CClYW$ et d'aldéhyde. Les phosphonates étudiés sont **1** (Y = W = Cl), **2** (Y = H, W = Cl) et **12** (Y = CH_3, W = Cl). En fin d'électrolyse, après consommation de 2 F/mol, on récupère un peu d'aldéhyde qui n'a pas réagi, du phosphonate réduit $(EtO)_2P(O)CHYW$, ainsi que des produits de condensation issus du phosphonate et de l'aldéhyde. Les résultats, qui sont regroupés dans le tableau 6, permettent d'établir une comparaison avec ceux obtenus à partir des phosphonates homologues par la voie A.

2.1. Comparaison des deux voies d'accès aux carbanions phosphonate. (a) Electroréduction de 1 et de 12. Il n'apparaît pas de différence fondamentale entre les deux premières colonnes des tableaux 5 et 6: l'électroréduction de **1** (E13) fournit l'éthylénique dichloré **18** et le phosphate **21** avec des rendements semblables à ceux de l'électrolyse E10; celle de **12** (E14) conduit à l'époxyde **19** avec un rendement légèrement supérieur à celui de l'électrolyse E11, et la stéréochimie est la même.

Remarque : la présence de l'éthylénique **18** (ArCH = CCl_2) et l'absence de l'acétylénique chloré **27** (ArC≡CCl) parmi les produits des électrolyses E10 et E13 indiquent que **18** n'est pas déshydrohalogéné par les bases électrogénérées issues de l'azobenzène ni par le dichlorocarbanion **1***A*, du moins tant que de l'aldéhyde est présent; l'anion **1***A* subit une attaque électrophile par l'aldéhyde plus rapide que sa protonation par **18**. Cependant, si on réalise une électrolyse sur 3 mmol de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

TABLEAU 6. Electroréduction des phosphonates **1**, **2** et **12**, dans le DMF 0,1 mol L^{-1} en Me_4NBF_4, en présence de *p*-méthoxybenzaldéhyde ArCHO; phosphonate 3 mmol, ArCHO 3 mmol. Le rendement est calculé comme dans le tableau 2

Electrolyse	E13	E14	E15
Phosphonate	**1**	**12**	**2**
$(EtO)_2P(O)CClYW$			
Y	Cl	CH_3	H
W	Cl	Cl	Cl
E_T (V)	−1,0	−1,3	−1,35
Q (F/mol)	1,9	2,0	1,9
Aldéhyde recouvré (%)	5	15	23
Phosphonate réduit (%)	**2** 0	**13** 6	**3** 24
Produits (%)	$ArCH{=}CCl_2$ (**18**) (62) $(EtO)_2P(O){-}O{-}CH(Ar)CCl_2H$ (**21**) (18)	$(EtO)_2P(O){-}C(H_3C)(O){-}CHAr$ (**19**) (*E*/*Z* 60 : 40) (41)	$ArCH{=}CHCl$ (**22**) (*E*/*Z* 70 : 30) (30) $ArC{\equiv}CH$ (**23**) (13) $(EtO)_2P(O)CH{-}CHAr$ (**20**) O (3)

phosphonate **1** et seulement 1,5 mmol d'aldéhyde, on obtient 20% d'oléfine **18** et 20% d'acétylénique **27**. Cette remarque sera utile à la discussion du paragraphe 2.2.

(b) Electroréduction de 2. Au contraire, par comparaison à l'électrolyse E12 du tableau 5, l'examen des résultats de E15 (tableau 6) fait apparaitre des différences notables : Le produit majoritaire est l'éthylénique **22** attendu d'après la réaction de Wittig–Horner, alors que l'époxyde provenant de la réaction de Darzens est maintenant nettement minoritaire. Des quantités relativement grandes d'aldéhyde n'ayant pas réagi et de phosphonate réduit **3** sont obtenues. Parmi les produits de E15, il apparait l'acétylénique **23** (ArC≡CH); signalons en outre que les rapports entre les pourcentages de **22** et **23** d'une part, et entre les pourcentages des isomères *E* et *Z* de **22** d'autre part, ne sont pas reproductibles.

Il est donc peu probable que l'éthylénique **22** et l'époxyde **20** puissent provenir de deux évolutions concurrentes d'un même adduit comme cela peut être suggéré par le schéma 7.

Afin d'élucider la nature des réactions intervenant dans E15, nous avons été conduits à examiner plus en détail le comportement du phosphonate dichloré **2**.

2.2. Réduction du dichlorométhylphosphonate 2 dans des conditions expérimentales variées. Le tableau 7 regroupe les résultats des électrolyses relatives à l'électroréduction du phosphonate **2** dans des conditions différentes des conditions standard déterminées dans la première partie.

Nous avons envisagé la réduction indirecte de **2** par catalyse rédox (21). Le couple formé par la benzophénone et son radical-anion permet une telle réduction (électrolyse E16) et l'on obtient alors, outre **22** et **23**, une quantité plus importante de l'époxyde **20**; il apparait donc que la formation de **22** et celle de **20** sont compétitives.

Si l'on remplace le cation tétraalkylammonium de l'électrolyte-support par un cation alcalin (électrolyses E17), tous les autres paramètres expérimentaux étant identiques à ceux de E15, le bilan coulométrique de l'électrolyse n'est que de 1 F/mol; on obtient essentiellement l'éthylénique dichloré **18** à côté d'une faible quantité de phosphate **21**.

L'ensemble des réactions rassemblées sur le schéma 8 permet de rendre compte des résultats des électrolyses E16 et E17 : Le carbanion **2***A* formé à la cathode par transfert de deux électrons et élimination d'un chlorure peut subir une réaction nucléophile et une protonation concurrentes. L'attaque nucléophile de l'aldéhyde conduit à un alcoolate intermédiaire dont nous avons vu qu'il évoluait vers la formation d'époxyde avec élimination de chlorure. La réaction acido-basique est un échange de proton entre le carbanion **2***A* électrogénéré et le phosphonate **2** pour former le carbanion dichloré **1***A* qui réagit avec l'aldéhyde. Nous avons vu que cette dernière réaction conduit à l'éthylénique **18** et au phosphate **21**. Lorsque le cation de l'électrolyte-support est un alcalin, la nucléophilie des carbanions est diminuée, et **2***A* subit exclusivement la protonation. Le second chemin réactionnel, semblable à celui décrit précédemment pour la réduction du phosphonocarboxylate **5**, est le seul observé; le rendement maximum en produits **18** et **21** est alors 50% puisque la moitié du phosphonate initial joue le rôle de probase.

Une autre façon de privilégier la protonation de **2***A* au détriment de sa réaction nucléophile consiste à lui opposer un aldéhyde peu électrophile. Nous avons ainsi pu vérifier lorsque l'électrolyse est conduite en présence de triméthoxy-2,4,6 benzaldéhyde (E18), de *p*-diméthylaminobenzaldéhyde (E19) ou d'heptanal (E20), le bilan coulométrique est de 1 F/mol et seul l'éthylénique dichloré est obtenu (tableau 7) avec un rendement qui n'est pas très inférieur à la valeur maximum théorique 50%.

Enfin, la présence de l'éthylénique monochloré **22** et de l'acétylénique **23** parmi les produits de l'électrolyse E16 est imputable à la réduction de l'éthylénique dichloré **18**. Une telle réduction ne se produit pas dans le cas de E17 (*vide infra*).

De même, lorsque l'aldéhyde est plus désactivé que le *p*-méthoxybenzaldéhyde (E18–E20), le potentiel de réduction de l'éthylénique dichloré correspondant est suffisamment cathodique pour que sa réduction ne soit pas observée au potentiel de travail choisi.

2.3. Retour sur l'électrolyse du dichlorométhylphosphonate 2 dans les conditions standard. Il est maintenant possible de rendre compte des résultats de l'électrolyse E15 (tableau 6), pour laquelle on peut grossièrement distinguer deux périodes successives.

Dans un premier temps, il se produit surtout l'électroréduction de **2** en **2***A*; ce dernier déprotone rapidement **2** en **1***A*. L'arrêt de l'électrolyse lorsque le résultat coulométrique atteint environ 1 F/mol montre alors la présence de l'éthylénique dichloré **18**, de l'aldéhyde et du phosphonate réduit **3**, en quantités peu différentes de celles de E17.

Mais la réaction ne s'arrête pas là, et dans un second temps, l'électroréduction de **18** se produit. Nous avons vérifié que **18**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

est électroactif à −1,3 V lorsque le cation de l'électrolyte-support est le cation tétraméthylammonium, mais qu'il n'est pas réduit à ce potentiel si l'on utilise un cation alcalin comme dans E17; il est en effet bien connu que le potentiel de réduction de certains substrats dépend de la nature de l'électrolyte-support (22, 23). La réduction biélectronique de **18** conduit à un carbanion vinylique dont la protonation donne le produit **22** (schéma 9).

Il est probable que l'espèce qui protone le carbanion vinylique est essentiellement l'éthylénique dichloré **18**; pour ce dernier, le bilan est une déshydrohalogénation qui fournit l'acétylénique chloré Ar—C≡C—Cl. L'acétylénique chloré est réductible à deux électrons au potentiel de l'électrolyse; la protonation du carbanion résultant par l'éthylénique monochloré **22** conduit exclusivement à l'acétylénique vrai **23**. Comme le montre la dernière équation du schéma 9, le bilan de la réduction de **18** seul, en l'absence de donneur de proton, devrait être la formation quantitative de **23**; nous avons effectivement pu vérifier que l'électroréduction de **18** seul, à −1,5 V, conduit bien à **23** (rendement après extraction 75%). De plus, si d'autres donneurs de protons sont présents, les produits devraient contenir **22**; c'est bien le cas puisque l'électroréduction de **18** en présence de deux équivalents d'acide acétique fournit un mélange de **22** et **23** (rendements après extraction respectivement 71% et 13%). Ainsi, la présence de **22** dans les produits de E15 (et également de E16) est attribuable à l'intervention de protonations parasites pendant la lente réduction de **18** qui suit celle de **2**.

3. Conclusion

Les trois carbanions phosphonate mis en jeu dans les réactions étudiées donnent une réaction d'addition sur le paraméthoxybenzaldéhyde.

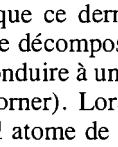
La décomposition de l'adduit est fonction des substituants portés par le carbanion phosphonate. Lorsque ce dernier est porteur de deux atomes de chlore, l'adduit se décompose avec élimination de phosphate de diéthyle pour conduire à un dérivé éthylénique dichloré (réaction de Wittig–Horner). Lorsque le carbanion phosphonate est porteur d'un seul atome de chlore, que le second substituant soit un atome d'hydrogène ou un groupement méthyle, il y a élimination d'un ion chlorure et formation de l'époxyde correspondant (réaction de Darzens).

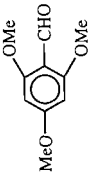
La stéréosélectivité de la formation des époxydes semble indépendante du mode de formation du carbanion; elle varie avec la nature du substituant Y = H ou CH_3.

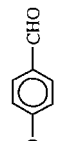
Enfin, dans le cas du phosphonate **2**, porteur d'un atome d'hydrogène, le carbanion qui réagit sur l'aldéhyde n'est pas le carbanion électrogénéré par réduction de **2**, mais celui qui résulte de la déprotonation du substrat.

Partie expérimentale

Réactifs







Les aldéhydes sont des échantillons commerciaux utilisés sans autre purification.

Le chlorométhylphosphonate de diéthyle **3**, le phosphono-acétate de triéthyle **6** et le phosphono-2 propionate de triéthyle **9** sont des échantillons commerciaux utilisés sans autre purification.

Le trichlorométhylphosphonate de diéthyle **1** est synthétisé par réaction de la triéthylphosphite et du tétrachlorométhane selon la réaction d'Arbusov (24).

Le dichlorométhylphosphonate de diéthyle **2** et le chloro-1 éthylphosphonate de diéthyle **13** sont préparés par réduction électrochimique, respectivement de **1** et de **12**, sur cathode de mercure, en milieu hydro-alcoolique, selon une méthode semblable à celle décrite récemment pour la synthèse de **2** (11).

TABLEAU 7. Réduction du dichlorométhylphosphonate de diéthyle **2** dans le DMF 0,1 mol L^{-1} en électrolyte-support (tétrafluoroborate), en présence d'un équivalent d'aldéhyde. Les rendements sont calculés comme dans le tableau 2

Electrolyse	E16*	E17	E18	E19	E20
Aldéhyde					$nC_6H_{13}CHO$
Cation de l'électrolyte-support	Bu_4N^+	Li^+, Na^+ ou K^+	Me_4N^+	Me_4N^+	Me_4N^+

*En présence de benzophénone (0,6 mmol) comme catalyseur rédox.

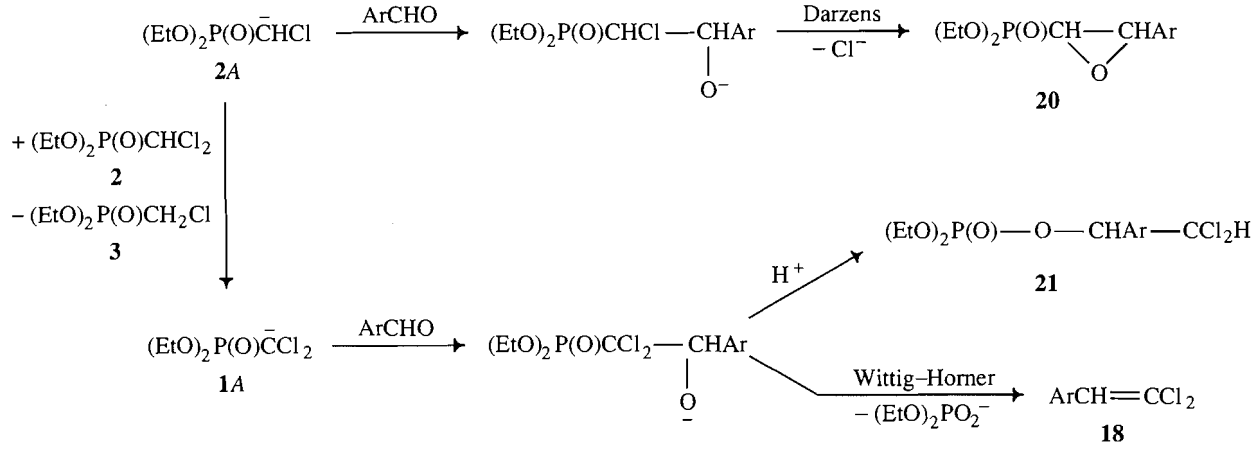

SCHÉMA 8

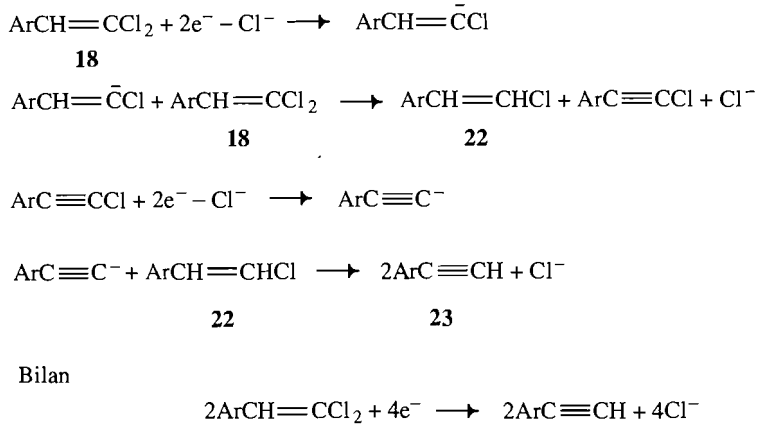

SCHÉMA 9

Le dichloro-1,1 éthylphosphonate de diéthyle **12** est un échantillon qui nous a gracieusement été fourni par Pr. Villieras de l'Université de Nantes; il peut également être obtenu par méthylation lors de l'électroréduction de **1** en présence d'iodure de méthyle (12).

Les phosphonates halogénés **4**, **5** et **10** sont synthétisés selon la méthode décrite dans la littérature (25).

Le bromo-2 phosphono-2 propionate de triéthyle **8** et le bromo chloro phosphonoacétate de diéthyle **11** sont obtenus par bromation, respectivement de **9** et de **5**, selon la technique décrite dans la référence 25.

Le chloro-2, phosphono-2 propionate de triéthyle **7** est synthétisé par méthylation de **5** par l'iodure de méthyle dans le THF en présence de carbonate de potassium.

Techniques électrochimiques

Les électrolyses préparatives sont réalisées à potentiel contrôlé (E_T), sous argon, à température ambiante, sur cathode de mercure, dans une cellule à compartiments séparés. Le volume de la solution de travail est 30 mL. Le générateur est un potentiostat Tacussel PRT 20-2X et un intégrateur Tacussel IG5-LN permet les mesures coulométriques. L'électrode de référence est un fil d'argent plongé dans une solution 0,1 mol L^{-1} d'iodure de tétrabutylammonium dans le DMF. Les électrolytes-supports sont employés à la concentration 0,1 mol L^{-1}.

Le tétrafluoroborate de tétrabutylammonium est recristallisé deux fois dans un mélange eau–méthanol (50 : 50) puis séché sous vide à 100°C. Le tétrafluoroborate de tétraméthylammonium est un produit commercial et il est utilisé sans autre purification. Le solvant DMF, de qualité Puran (diméthylamine < 50 ppm), est utilisé sans distillation. Il est séché sur tamis moléculaire 4Å et la teneur en eau résiduelle, déterminée par la méthode de Karl–Fischer juste avant emploi, peut être estimée à 60–100 ppm.

Le compartiment anodique, séparé du compartiment cathodique par un verre fritté, contient 20 mL d'une solution de chlorure de tétraalkylammonium. Le chlorure a été préféré au tétrafluoroborate à cause de la réaction anodique : avec NR_4BF_4, il se forme à l'anode des espèces acides susceptibles de migrer vers le compartiment cathodique. Avec NR_4Cl, le contenu du compartiment anodique doit néanmoins être changé une fois en cours d'électrolyse pour éviter la diffusion vers le compartiment cathodique du chlore formé à l'anode.

Lors de l'électroréduction des phosphonates halogénés en présence de tétrafluoroborate de tétraméthylammonium comme électrolyte-support, on observe, quelques minutes après le début de l'électrolyse, la précipitation de l'halogénure de tétraméthylammonium.

Produits

En fin d'électrolyse, le contenu du compartiment cathodique est versé dans 120 mL d'eau saturée en chlorure de sodium. La solution résultante est extraite à l'éther, la phase éthérée est ensuite lavée à l'eau puis séchée sur sulfate de magnésium, et l'éther est évaporé sous vide. Le résidu ainsi obtenu est pesé.

Un tel mode opératoire permet l'extraction de l'essentiel (supérieur à 80%) des produits non phosphorés; les phosphonates ne sont que partiellement extraits. Cependant, l'application systématique de ce mode opératoire permet d'effectuer des comparaisons entre les résultats des différentes expériences.

Les spectres de RMN du proton sont enregistrés à 60 MHz sur une solution, dans $CDCl_3$, du résidu obtenu après évaporation comme décrit précédemment. La quantité de chaque produit dans ce résidu est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

déterminée d'après la masse du résidu et l'intégration des signaux RMN après identification de tous les signaux du spectre.

Pour effectuer cette identification, la préparation d'échantillons purs a été nécessaire. La séparation entre composés phosphorés et composés non phosphorés s'effectue très facilement par filtration du mélange à travers une colonne de silice avec un mélange d'hexane et d'acétate d'éthyle (90 : 10) comme éluant : les phosphonates sont retenus sur la colonne, et ils peuvent être récupérés par lavage à l'acétate d'éthyle pur. La séparation des phosphonates contenus dans les mélanges ainsi recueillis peut être effectuée, pour des raisons d'analyse, par distillation sous pression réduite dans un four à boules rotatives. L'élution de la colonne à l'aide du mélange hexane/acétate d'éthyle permet d'isoler les aldéhydes et les éthyléniques isomères. En cas de nécessité pour une identification certaine, il a été fait appel à d'autres études spectroscopiques : RMN ^{13}C, RMN ^{31}P, RMN ^{1}H 80 MHz ou spectroscopie de masse. Les données sont rassemblées ci-dessous :

Chloro-2 phosphono-2 propionate de triéthyle (**7**) $(EtO)_2P(O)CCl(CH_3)CO_2C_2H_5$; RMN ^1H : 1,2–1,5 (m, 9); 1,95 (d, 3, J_{PH} = 14 Hz); 4–4,5 (m, 6).

Bromo-2 phosphono-2 propionate de triéthyle (**8**) $(EtO)_2P(O)CBr(CH_3)CO_2C_2H_5$; RMN ^1H : 1,2–1,5 (m, 9); 2,06 (d, 3, J_{PH} = 14 Hz); 4–4,5 (m, 6).

p-Méthoxyphényl-3 méthyl-2 propénoate d'éthyle (**14**) *p*-$CH_3O—C_6H_4—CH=C(CH_3)CO_2C_2H_5$. **14**(*E*) : RMN ^1H : 1,33 (t, 3, J = 7 Hz); 2,13 (d, 3, J = 2 Hz); 3,80 (s, 3); 4,20 (q, 2, J = 7 Hz); 6,87–7,33 (AB, 4, J = 9 Hz); 7,60 (m, 1).

p-Méthoxyphényl-3 propénoate d'éthyle (**15**) *p*-$CH_3O—C_6H_4—CH=CHCO_2C_2H_5$. **15**(*Z*) : RMN ^1H : 1,26 (t, 3, J = 7 Hz); 3,78 (s, 3); 4,17 (q, 2, J = 7 Hz); 5,78 (d, 1, J = 13 Hz); 6,82 (d, 1, J = 13 Hz); 6,87–7,68 (AB, 4, J = 9 Hz). **15**(*E*) : RMN ^1H : 1,33 (t, 3, J = 7 Hz); 3,80 (s, 3); 4,23 (q, 2, J = 7 Hz); 6,27 (d, 1, J = 16 Hz); 6,85–7,43 (AB, 4, J = 9 Hz); 7,60 (d, 1, J = 16 Hz).

p-Méthoxyphényl-3 chloro-2 propénoate d'éthyle (**16**) *p*-$CH_3—C_6H_4—CH=CClCO_2C_2H_5$. **16**(*Z*) : RMN ^1H : 1,35 (t, 3, J = 7 Hz); 3,80 (s, 3); 4,30 (q, 2, J = 7 Hz); 6,90–7,80 (AB, 4, J = 9 Hz); 7,80 (s, 1). RMN ^{13}C : 14,22; 55,30; 62,34; 114,14; 119,77; 125,74; 132,78; 136,57; 161,33; 163,71. **16**(*E*) : RMN ^1H : 1,23 (t, 3, J = 7 Hz); 3,77 (s, 3); 4,18 (q, 2, J = 7 Hz); 6,80–7,27 (AB, 4, J = 9 Hz); 7,07 (s, 1). RMN ^{13}C : 13,84; 55,30; 62,05; 113,80; 120,94; 126,32; 130,65; 137,15; 160,41; 163,85.

p-Méthoxyphényl-3 bromo-2 propénoate d'éthyle (**17**) *p*-$CH_3O—C_6H_4—CH=CBrCO_2C_2H_5$. **17**(*Z*) : RMN ^1H : 1,37 (t, 3, J = 7 Hz); 3,82 (s, 3); 4,32 (q, 2, J = 7 Hz); 6,90–7,85 (AB, 4, J = 9 Hz); 8,13 (s, 1). **17**(*E*) : RMN ^1H : 1,23 (t, 3, J = 7 Hz); 3,79 (s, 3); 4,22 (q, 2, J = 7 Hz); 6,80–7,25 (AB, 4, J = 9 Hz); 7,25 (s, 1).

p-Méthoxyphényl-2 dichloro-1,1 éthylène (**18**) *p*-$CH_3O—C_6H_4—CH=CCl_2$; RMN ^1H : 3,77 (s, 3); 6,80 (s, 1); 6,88–7,50 (AB, 4, J = 8 Hz). Masse exacte, calculée : 201,9952; trouvée : 201,9939.

p-Méthoxyphényl-2 méthyl-1 époxy-1,2 éthanephosphonate (**19**) $(EtO)_2P(O)—C(CH_3)—CH(O)—C_6H_4$-*p*-$OCH_3$. Masse exacte calculée : 300,1127; trouvée : 300,1116. **19**(*Z*) : RMN ^1H 80 MHz : 1,13 (t, 3, J = 6,0 Hz); 1,19 (t, 3, J = 6,8 Hz); 1,64 (d, 3, J_{PH} = 10,3 Hz); 3,80 (s, 3); 3,9–4,4 (m, 5); 6,87–7,36 (AB, 4, J = 8,5 Hz). **19**(*E*) : RMN ^1H : 1,24 (d, 3, J_{PH} = 11,7 Hz); 1,37 (t, 3, J = 7,2 Hz); 1,38 (t, 3, J = 7 Hz); 3,81 (s, 3); 3,9–4,4 (m, 5); 6,9–7,23 (AB, 4, J = 8,9 Hz).

p-Méthoxyphényl-2 époxy-1,2 éthanephosphonate (**20**) $(EtO)_2P(O)CH—CH(O)—C_6H_4$-*p*-$OCH_3$. Masse exacte, calculée : 286,0970; trouvée : 286,0963. **20**(*Z*) : RMN ^1H : 1,34 (t, 3, J = 7 Hz); 1,37 (t, 3, J = 7 Hz); 3,05 (dd, 1, J_{HH} = 2,5 Hz; J_{PH} = 31 Hz); 3,75 (s, 3); 3,7–4,4 (m, 5); 6,83–7,18 (AB, 4, J = 8 Hz). **20**(*E*) : RMN ^1H : 1,13 (t, 3, J = 7 Hz); 1,18 (t, 3, J = 7 Hz); 3,17 (dd, 1, J_{HH} = 4,5 Hz; J_{PH} = 28 Hz); 3,75 (s, 3); 3,7–4,4 (m, 5); 6,83–7,33 (AB, 4, J = 8 Hz).

Phosphate de diéthyle et de paraméthoxyphényl-1 dichloro-2,2 éthyle (**21**) $(EtO)_2P(O)—O—CH(p\text{-}CH_3O—C_6H_4)—CCl_2H$. RMN ^1H : avec structure fine 1,13 (t, 3, J = 8 Hz); 1,30 (t, 3, J = 8 Hz); 3,80 (s, 3); 4,03 (dq, 4, J_{HH} = 8 Hz, J_{PH} = 8 Hz); 5,50 (dd, 1, J_{HH} = 4 Hz, J_{PH} = 9 Hz); 5,92 (d, 1, J = 4 Hz); 6,90–7,37 (AB, 4, J = 9 Hz).

p-Méthoxyphényl-2 chloro-1 éthylène (**22**) *p*-$CH_3O—C_6H_4—CH=CHCl$. Masse exacte, calculée : 168,0342; trouvée : 168,0350. **22**(*E*) : RMN ^1H : 3,77 (s, 3); 6,40 (d, 1, J = 14 Hz); 6,7–8 (m, 5). **22**(*Z*) : RMN ^1H : 3,77 (s, 3); 6,00 (d, 1, J = 8 Hz); 6,7–8 (m, 5).

p-Méthoxyphényl acétylène (**23**) *p*-$CH_3O—C_6H_4—C\equiv CH$. RMN ^1H : 2,95 (s, 1); 3,77 (s, 3); 6,82–7,38 (AB, 4, J = 9 Hz).

(Triméthoxy-2,4,6 phényl)-2 dichloro-1,1 éthylène (**24**) $(CH_3O)_3C_6H_2—CH=CCl_2$. RMN ^1H : 3,80 (s, 9); 6,10 (s, 2); 6,60 (s, 1).

p-Diméthylamino phényl-2 dichloro-1,1 éthylène (**25**) *p*-$(CH_3)_2N—C_6H_4—CH=CCl_2$. RMN ^1H : 3,03 (s, 6); 6,83 (s, 1); 6,77–7,60 (AB, 4, J = 9 Hz). Masse exacte, calculée : 215,0269; trouvée : 215,0270.

Dichloro-1,1 octène-1 (**26**) *n*-$C_6H_{13}—CH=CCl_2$. RMN ^1H : 0,9 (t, 3, J = 5 Hz); 1,2–2,5 (m, 10); 5,80 (t, 1, J = 7 Hz).

p-Méthoxyphényl-2 chloro-1 acétylène (**27**) *p*-$CH_3O—C_6H_4—C\equiv CCl$. RMN ^1H : 3,77 (s, 3); 6,82–7,40 (AB, 4, J = 9 Hz). Masse exacte, calculée : 166,0185; trouvée : 166,0187.

Received January 6, 1989

GARRY W. BUCHKO, FRANK E. HRUSKA, and KRISHAN L. SADANA. Can. J. Chem. **67**, 1344 (1989).

Syntheses are described for d(i^{4}TpT) (**1**), d(Tpi^{4}T) (**2**), and d(Tpi^{4}TpT) (**3**), the O4-isopropylated analogues of d(TpT) (**4**) and d(TpTpT) (**5**). The detection of the molecular $[M - H]^-$ ions and some $[2M - H]^-$ aggregates shows that Fast Atom Bombardment mass spectrometry operating in the negative ion mode is useful for structural analysis of these DNA oligomers. In contrast with the monomer, i^{4}dT, the two O4-isopropyl methyl groups of **1** and **2** are magnetically nonequivalent and give rise to separate ^{1}H and ^{13}C NMR signals. Their chemical shift difference (Δ) decreases gradually with increasing temperature, and can be interpreted as reflecting intramolecular base stacking, in line with circular dichroic data. This chemical shift difference is not seen in the ^{1}H NMR spectra of **3**, and is attenuated in the ^{13}C spectra of this trimer. Coupling constant data indicate a shift towards the 3′-*endo* conformation of the sugar of the i^{4}Tp moiety of **1**, a trend observed for the corresponding O4-ethylated moiety of d(e^{4}TpT). ^{13}C–^{31}P and ^{1}H–^{31}P coupling constants indicate that the structural features monitored by these couplings are not significantly altered by O4-isopropylation of the thymine base.

Key words: oligonucleotides, O-alkylation, stereochemistry, NMR, mass spectrometry.

GARRY W. BUCHKO, FRANK E. HRUSKA et KRISHAN L. SADANA. Can. J. Chem. **67**, 1344 (1989).

On décrit la synthèse des d(i^{4}TpT) (**1**), d(Tpi^{4}T) (**2**) et d(Tpi^{4}TpT) (**3**), les analogues O4-isopropylés des d(TpT) (**4**) et d(TpTpT) (**5**). La détection des ions moléculaires $[M - H]^-$ et de quelques agrégats $[2M - H]^-$ démontre que la spectrométrie de masse, par bombardement avec des atomes rapides (FAB) et opérée en mode d'ions négatifs, est utile pour l'analyse des structures de ces oligomères de l'ADN. Par opposition avec le monomère, i^{4}dT, les deux groupements méthyles de l'isopropyle en O-4 ne sont pas équivalents d'un point de vue magnétique et ils donnent lieu à des signaux séparés en RMN tant du ^{1}H que du ^{13}C. La différence (Δ) dans leurs déplacements chimiques diminue avec une augmentation de la température; en conformité avec ce qui a pu être déduit sur la base de données de dichroïsme circulaire, on peut interpréter ce résultat en fonction d'un empilement moléculaire des bases. On n'observe pas cette différence dans les déplacements chimiques des spectres RMN du ^{1}H du composé **3** et elle est atténuée dans le spectre du ^{13}C de ce trimère. Les données relatives aux constantes de couplage indiquent qu'il se produit un déplacement vers la conformation 3′-*endo* du sucre de la portion i^{4}Tp du composé **1**; cette tendance a été observée pour la portion O4-éthylée correspondante du d(e^{4}TpT). Les constantes de couplage ^{13}C–^{31}P et ^{1}H–^{31}P indiquent que les caractéristiques structurales déterminées par ces couplages ne sont pas altérées d'une façon significative par une O4-isopropylation de la base thymine.

Mots clés : oligonucléotides, O-alkylation, stéréochimie, RMN, spectrométrie de masse.

[Traduit par la revue]

Introduction

There is considerable interest in the biological effects of O-alkylation of thymine (1, 2). Information about the electronic and geometric changes effected by this modification is being provided by X-ray crystallographic and spectroscopic studies of nucleosides and nucleotides (3–7) and, more recently, oligonucleotides with an O4-methylated thymine (m^{4}T) have been examined by NMR (8, 9). We have initiated a program for the synthesis of oligomers containing an O4-alkylated thymine (r^{4}T) for study by physical methods. These syntheses require considerable care since the r^{4}T base is labile in acid and basic solution (1, 6). Thus, our initial focus has been on oligonucleotides containing only r^{4}T and T bases; such molecules were deemed to be the most easily prepared because protection of the T base is generally not required. In our previous work (10), we described the synthesis of d(e^{4}TpT) and d(Tpe^{4}T), the O4-ethylated analogues of d(TpT), and their characterization by ^{1}H NMR, Fast Atom Bombardment (FAB) mass spectrometry, and circular dichroism (CD). Singer *et al.* (11) have shown that O4-isopropyl, as well as methyl and ethyl, substituents on thymidine lead to transitions during replication. For the present work, we extended our synthesis to the isopropylated dimers, d(i^{4}TpT) (**1**) and d(Tpi^{4}T) (**2**), and the trimer d(Tpi^{4}TpT) (**3**) (Fig. 1). ^{1}H and ^{13}C NMR data as well as FAB and CD data are compared with those of d(TpT) (**4**) and d(TpTpT) (**5**) (provided here and in the literature (12–15)), and with those of d(e^{4}TpT) (**6**) and d(Tpe^{4}T) (**7**). In an earlier study (5) we reported NMR data for the mononucleoside i^{4}dT and some analogs, and discussed the effects of O-alkylation at the monomer level.

Experimental

Materials and methods

Materials

Thymidine and the reagents used for protection, coupling, and deblocking were purchased (Aldrich or Sigma Chemical Co.), or synthesized as described by Buchko *et al.* (10). Chromatographic solvents were purchased from Fisher Scientific. Kieselgel 60 (Merck) was used for dry-column flash chromatography (DCFC). Thin-layer chromatography (TLC) was carried out on Kieselgel 60 F_{254} plates from Merck. For paper chromatography, Whatman paper (No. 3001 917) was used.

Synthetic methods

The O4-isopropylated derivative **1** was prepared according to the procedure (10) for the corresponding O4-ethylated dimer (**6**), except that sodium isopropoxide replaced sodium ethoxide to introduce the O4-isopropyl group and to remove the 3′-terminal acetyl group in the final deprotection step. Isomer **2** with the O4-isopropyl group on the 5′-linked nucleotidyl unit was conveniently obtained by treating 133 A_{260} units of the trimer d(Tpi^{4}TpT) (**3**; see below) with 249 units of snake venom phosphodiesterase (Russell's viper; Calbiochem) at 32°C for 24 h in a 0.1 M Tris buffer (pH 8.0). This exonuclease

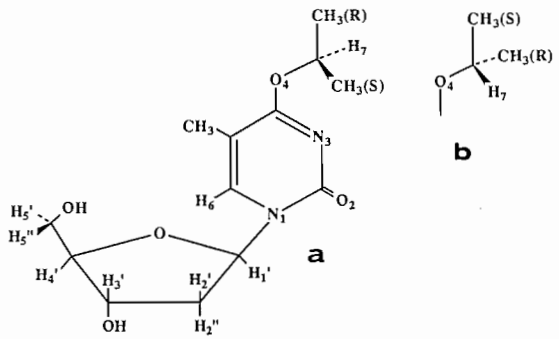

FIG. 1. (a) Structure and numbering scheme of i^{4}dT (O4-isopropylthymidine), the modified component of d(i^{4}TpT) (**1**), d(Tpi^{4}T) (**2**), and d(Tpi^{4}TpT) (**3**). C7 and C8 refer respectively to the tertiary and the methyl carbons of the isopropyl group. *R* and *S* give the *pro-R* and *pro-S* assignments of the diastereotopic 8-methyl groups. C7 is *syn-periplanar* to N3, the *pro-S* methyl flanks the base on its 3′ face, and the *pro-R* group is directed away from the ring. (b) An alternate conformation of the isopropyl group, obtained by rotation about the C7—O4 bond, in which the *pro-R* methyl flanks the base on its 5′ face and the *pro-S* methyl is directed away from the ring.

degrades single strands with a free 3′-hydroxyl group, but the presence of the O4-isopropyl lesion apparently retards the enzyme's progress, and **2** is obtained as the only product following the cleavage of the pT fragment from the 3′ end of the trimer. (Our recent experiments on the methylated and ethylated analogs of **3** show that an O4-ethyl also retards this phosphodiesterase, whereas an O4-methyl does not.[3])

Compound **3** was synthesized starting with fully-blocked **1** (3′ end: acetyl; 5′ end; 4,4′-dimethoxytrityl (DMT); phosphate: *para*-chlorophenyl), which was prepared following Buchko *et al.* (10), except that the DMT replaced the *tert*-butyldimethylsilyl group at the 5′ end. This blocked dimer was extended in the 5′ direction, after removal of the DMT group with $ZnBr_2$ (16), by coupling with 5′-DMT thymidine; the coupling was carried out as described (10) for the synthesis of **7**. Compound **3** was obtained from this blocked trimer by sequential treatment with (*i*) $ZnBr_2$, (*ii*) oximate reagent for phosphate deprotection, and (*iii*) sodium isopropoxide. The unmodified trimer **5** was obtained from the blocked trimer by treatment with sodium hydroxide rather than sodium isopropoxide. All of the molecules were purified initially by descending paper chromatography followed by HPLC (Perkin Elmer Series 4 liquid chromatograph) using a semipreparative ODS-Hypersil column and a gradient of methanol and 0.1 M aqueous ammonium acetate (pH 6.0).

The following UV absorption data for H_2O solutions were obtained on a Cary 219 spectrophotometer: **1**: λ_{max} = 272 nm, λ_{min} = 239 nm; **2**: λ_{max} = 270 nm, λ_{min} = 238 nm; **3**: λ_{max} = 269 nm, λ_{min} = 237 nm; **4**: λ_{max} = 267 nm, λ_{min} = 235 nm; **5**: λ_{max} = 266 nm, λ_{min} = 234 nm. The data for **1** and **2** are in good agreement with those reported for the corresponding O4-ethylated dimers (10).

Mass spectrometric experiments

Positive- and negative-ion FAB mass spectra (glycerol matrix, 8-keV xenon atoms) were obtained on a VG 7070E-HF spectrometer. As was the case for **6** and **7** (10), the negative-ion spectra proved to be more diagnostic; some of the more prominent negative-ion peaks are reported here as follows: *m/z* (relative intensity, [ionic species]), with the relative intensity normalized to the molecular ion $[M - H]^-$. *d(i^{4}TpT)*: 587 (100, $[M - H]^-$); 1175 (1.6, $[2M - H]^-$); 125 (65, [thymine $- H]^-$); 167 (41, [O4-isopropylthymine $- H]^-$); 321 (23, [5′-dTMP $- H]^-$); 363 (23, [3′-i^{4}dTMP $- H]^-$); 545 (6, $[M - CH(CH_3)_2]^-$). *d(Tpi^{4}T)*: 587 (100, $[M - H]^-$); 1175 (4, $[2M - H]^-$); 125 (62, [thymine $- H]^-$); 167 (7, [O4-isopropylthymine $- H]^-$); 321 (19, [3′-dTMP $- H]^-$); 363 (21, [5′-i^{4}dTMP $- H]^-$); 545 (18, $[M - CH(CH_3)_2]^-$). *d(Tpi^{4}TpT)*: 891 (100, $[M - H]^-$); 125 (93, [thymine $- H]^-$); 167 (14, [O4-isopropylthymine $- H]^-$); 321 (58, [3′-dTMP $- H]^-$ + [5′-dTMP $- H]^-$); 587 (5, [d(i^{4}TpT) $- H]^-$ + [d(Tpi^{4}T) $- H]^-$); 667 (36, [d(pi^{4}TpT) $- H]^-$ + [d(Tpi^{4}Tp) $- H]^-$); 849 (11, $[M - CH(CH_3)_2]^-$). *d(TpTpT)*: 850 (100, $[M - H]^-$); 872 (54, $[M + Na - H]^-$); 125 (187, [thymine $- H]^-$); 321 (106, [3′-dTMP $- H]^-$ + [5′-dTMP $- H]^-$); 625 (42, [d(pTpT) $- H]^-$ + [d(TpTp) $- H]^-$).

^{1}H NMR experiments

Most of the ^{1}H NMR spectra were obtained at 300.134 MHz (Bruker AM300). The samples were contained in 5 mm (o.d.) tubes at concentrations in D_2O that preclude significant intermolecular interaction: **1**, 0.0048 M; **2**, 0.0083 M; **3**, 0.0025 M; **5**, 0.0030 M. The concentrations were calculated from UV absorbance measurements, assuming additivity of the molar extinction coefficients (ε_{max}) of the component nucleosides; literature values for ε_{max} of a thymidine (dT) unit (9600) and an O4-alkylated thymidine (6700) were used (17, 18). The solutions contained 0.01 M sodium phosphate buffer (pH = 6.9), EDTA (0.001 M) to chelate paramagnetic ions, 0.1 M NaCl to maintain a constant ionic strength, and, for an NMR reference, a trace of *tert*-butanol (assigned a chemical shift of 1.231 ppm on the DSS scale). The samples were lyophilized twice from 99.8% D_2O and taken up in 99.9% D_2O. One-dimensional (1D) FIDs were obtained at 10° intervals from 10 to 70°C in 16K of computer memory and processed with a Lorentz-to-Gaussian lineshape transform (GB = 0.2, LB = −2.0) prior to zero-filling (to 32K). The HDO resonance was suppressed by presaturation (Bruker PRESAT. AU microprogram). Conventional homonuclear decoupling, nOe, and two-dimensional (COSY-45°) (19) experiments were carried out for spectral assignments. Spectra for the trimers at 10 and 70°C were also obtained at 500.137 MHz (Bruker AM500; McMaster University). Spectra were analyzed (NUMARIT) (20) at two temperatures (10 or 20°C, and 70°C), and computer-generated spectra confirmed the data.

Proton-decoupled ^{13}C data were obtained (27 and 70°C) at 75.5 MHz (Bruker AM300) for molecules **1–5** in the buffer solution used for the ^{1}H NMR experiments; a trace of dioxane was used as the internal reference. The concentrations were the same as for the ^{1}H NMR studies except for **3** (0.05 M).

Circular dichroism experiments

CD spectra were obtained on a Jasco J-500A spectropolarimeter in cells equipped for temperature control by a water bath. Each molecule was studied at (8.3–9.5) × 10^{-5} M (calculated from UV absorbance measurements (10)) in the phosphate buffer solution used for the NMR experiments.

Results and discussion

NMR spectra, data, and assignments

Tables 1–5 provide ^{1}H and ^{13}C chemical shift (δ) and coupling constant (J) data. Complete ^{1}H NMR spectra for **1** and **2** are not given since they are similar (except for the bands of the O4-alkyl groups) to those of **6** and **7** (10). As discussed further in the next section, the isopropyl methyl groups of **1** and **2** are diastereotopic (5) (see Fig. 1 for the *pro-R* and *pro-S* designations), and give rise to separate doublets (inset of Fig. 2) with $J(78)$ = 6.2 Hz. On the other hand, the methylene protons of the O4-ethyl groups of **6** and **7** are diastereotopic, giving rise to ABX_3 patterns for these groups (10).

A partial one-dimensional ^{1}H NMR spectrum of the trimer **3** is given in Fig. 2. Note that, in contrast with the dimers, the prochiral H8 protons of the trimer (δ = 1.33 ppm) are isochronous and a single doublet ($J(78)$ = 6.2 Hz; Table 3) is observed. The isochronicity of these protons is retained over the 10–70°C range.

Figure 3 shows a ^{13}C (^{1}H-decoupled) spectrum of **3** at 27°C. Expanded spectra reveal that the peak (22.2 ppm) assigned to

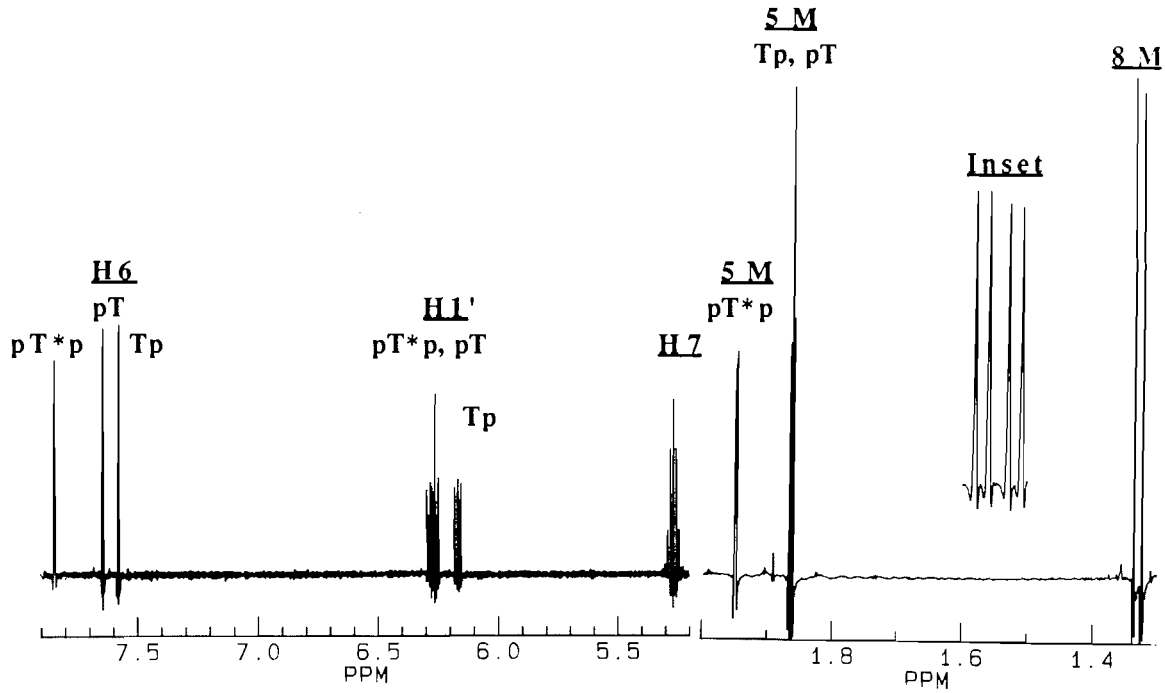

FIG. 2. Partial 500-MHz ^{1}H NMR spectrum (70°C) of d(Tpi^{4}TpT) (**3**) showing the peaks for the H6, 5M (5-methyl), H1′, H7, and 8M (8-methyl) protons. The chemical shifts were measured relative to internal *tert*-butanol and converted to a DSS scale by addition of 1.231 ppm. For the two diastereotopic 8-methyl groups, only a single doublet (1.33 ppm, $J(78) = 6.2$ Hz) is observed. Inset: The two doublets observed (300 MHz, 12°C) for the 8M protons of d(i^{4}TpT) (**1**) at 1.37 ppm and 1.32 ppm ($J(78) = 6.2$ Hz). A pair of doublets ($J(78) = 6.2$ Hz) is also seen for the 8M protons of d(Tpi^{4}T) (**2**) in the 12–70°C range (Tables 1, 2).

[c]Δ: chemical shift in Hz at 300.134 MHz between the 8R and 8S protons.

the isopropyl methyl carbons (C8) is a doublet with a 1.9-Hz splitting, reflecting the slight differential shielding of the *pro-R* and *pro-S* groups. The doublet shown in the inset reveals a much larger differential shielding (8.1 Hz) of the prochiral carbons in **1**. A doublet is also observed for the C8 carbons of **2** (6.9 Hz separation at 27°C; Table 4).

The ^{1}H NMR spectra were assigned following the study of **6** and **7** (10), and the extensive literature data for thymine oligonucleotides (12–15). Particularly useful are the characteristic effects of O4-alkylation on the base proton shifts, and the observation that ^4J splitting in the H6 and 5-CH_3 bands is consistently smaller by 0.1–0.2 Hz in an O4-alkylated base relative to the parent base (10). ^{1}H-Decoupling and COSY (45°C) spectra were used to connect the sugar protons, and nOe

[a]Data at 500.137 MHz. Proton labelling (Fig. 1): 5M: 5-methyl; H7 and H8: tertiary and methyl hydrogens of the O4-isopropyl group, respectively. In contrast with the dimers **1** and **2** (Table 1), no difference can be detected in the shielding of the protons of the two 8-methyl groups.
[b]When δ2′ ~ δ2″, only the sum of connected couplings (]) is significant, and J(2′2″) is arbitrary.
[c]H7 is identically coupled to the protons on the two isopropyl methyl carbon atoms.

experiments were used to connect the H6 and H1′ protons. The ^{13}C spectra were assigned using as guides (a) the extensive chemical shift data for O4-alkylated and unmodified monomers (6, 7) and for thymine oligonucleotides (14, 15), and (b) the trends in ^{13}C–^{31}P coupling constants for nucleotides and DNA oligonucleotides (14, 15, 21, 22). Selective ^{1}H-decoupling experiments were useful for assigning the 5-methyl, C1′, and C3′ resonances of the **3**. Unfortunately, we are not able to provide an unambiguous assignment of the *pro-R* and *pro-S* groups in either the ^{1}H or ^{13}C spectra; the *R*, *S* labelling in the tables is arbitrary.

The O4-isopropyl group

Two important points about this group must be made. First, due to the presence of chiral centers in the sugar, the C8 methyl groups are diastereotopic. In general, such prochiral groups give rise to separate NMR signals (23, 24). However, at the *monomer* level (i^{4}dT), separate peaks are not observed in either

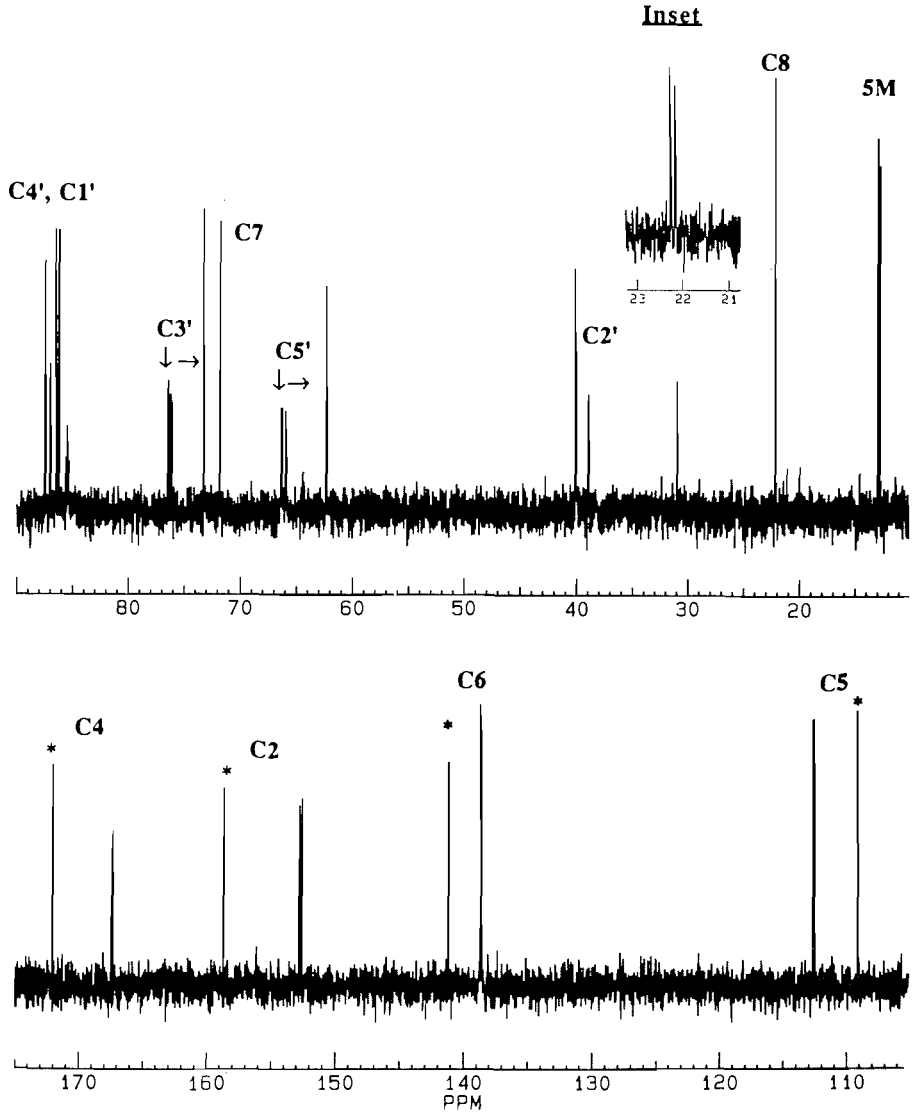

FIG. 3. The 75.5-MHz ^{13}C NMR spectra of d(Tpi^{4}TpT) (**3**) at 27°C in the range 10–90 ppm (top panel) and 105–175 ppm (bottom panel). The chemical shifts were measured relative to internal dioxane and converted to a TMS scale by addition of 67.86 ppm. The "starred" peaks in the bottom panel refer to carbons of the pi^{4}Tp unit. The peak at 22.2 ppm is a doublet (1.9 Hz separation) assigned to the two diastereotopic C8 atoms of the O4-isopropyl group. *tert*-Butanol peak at 31 ppm. Inset: An expanded view of the distinct resonances (8.1 Hz separation) observed for the two C8 atoms of d(i^{4}TpT) (**1**) at 27°C; distinct resonances are also observed for these carbons in d(Tpi^{4}T) (**2**) (Table 4).

the ^1H or the ^{13}C spectra (5), and thus we can conclude that the sugar is too distant from the O4-isopropyl group to cause differential shielding, in line with the observations (23) that such shielding falls off rapidly with the distance between the chiral and prochiral centers.

The second point concerns the conformation of the isopropyl group relative to the base ring. Figure 1 shows the two conformers expected to occur in solution, on the basis of the crystallographic structure of O2-isopropylthymidine (5). In both, C8 is *syn-periplanar* to N3, with the *pro-S* methyl flanking the base on its "3′ face" in one conformer (Fig. 1a) and the *pro-R* methyl flanking the base on its "5′ face" in the other (Fig. 1b). A third conformer in which both methyls flank the base is unlikely for steric reasons (5). (We define as 3′ or 5′ the face that would point to the 3′ or 5′ end of a strand of a normal B-DNA.) There is no apparent reason for a bias, at the *mononucleoside* level, for one or other of the two *syn-periplanar* (*sp*) conformations, and thus equal proportions of the two forms (and rapid interconversion between them) should obtain in solution. In line with this expectation is the isochronicity of prochiral groups of i^{4}dT, in both the ^1H and the ^{13}C NMR spectra (ref. 5 and Table 4).

In contrast with the monomer, the C8 methyl groups of the dimers **1** and **2** give rise to separate NMR signals in the proton spectra (doublets; $J(78) = 6.2$ Hz; Table 2) and in the carbon spectra. These bands for **1** are given in the insets of Figs. 2 and 3; similar patterns are observed in the spectra of **2**, but the chemical shifts are somewhat less than those seen for **1** (Tables 1, 4). As noted above, we cannot provide an absolute assignment of the *R* and *S* resonances of the dimers in either their ^1H and ^{13}C NMR spectra. Figure 4 provides a temperature profile for the H8 proton shifts, and shows that Δ, the separation between the two doublets, decreases monotonically with increasing temperature. The decrease is more pronounced for **1**, but in both dimers some separation remains even at 70°C. Furthermore, in the case of **1**, the two peaks approach the H8

[a]δ in ppm were measured relative to internal dioxane and converted to a TMS scale by δ(TMS) = δ(dioxane) + 67.86 ppm. δC2 through δC5′ for d(i^{4}TpT) (**1**) and d(Tpi^{4}T) (**2**) are given relative to the corresponding δ in d(TpT), with positive numbers indicating a deshielding relative to this reference. The δ for the O4-isopropyl groups are relative to TMS. The data for i^{4}dT are from ref. 5 (δC2 through δC5′ are relative to dT; δC7 and δC8 are relative to TMS). See Fig. 1 for atom labelling.

[b]The base carbon assignments for Tp and pT may be interchanged.

[c]The *R* and *S* assignment is arbitrary. The first entry is for 27°C, and the second for 70°C.

chemical shift of i^{4}dT. The ^{13}C NMR data were collected at only two temperatures (27 and 70°C). However, the trends here are in line with the proton data in that the separation of the resonances decreases at the higher temperature, with the larger change occurring for dimer **1** (Table 4).

Since no differential shielding of the prochiral methyl groups is observed in the monomer i^{4}dT (5), the temperature dependence of Δ at the dimer level can be accounted for by intramolecular base stacking, the rationale presented for the chemical shifts of the prochiral methylene protons of **6** and **7** (10). Space-filling molecular models of the dimers in a right-handed base-stacked conformation (with both bases oriented *anti* about the N-glycosyl bond and with the O4-isopropyl group oriented as in Fig. 1a) suggest that the ^1H and ^{13}C shielding of the *pro-S* methyl of **1** would be more influenced by the second base, whereas the *pro-R* group would be more affected in **2**. However, models also suggest that we cannot, for the time being, discount contributions from base stacks involving the alternate *sp* conformation of the isopropyl group (Fig. 1b). Because of our uncertainty as to the favored orientation of the isopropyl group, we do not feel confident to use the shift trends in Fig. 4 as a basis for assigning the *pro-R* and *pro-S* resonances, or to derive more precise details of the base stacks. Nevertheless, because the 8-methyl peaks are intense and occur in isolated regions of the ^1H and the ^{13}C spectra, it would seem that their chemical shifts might provide a convenient means to monitor, in longer oligonucleotides, helix–coil transitions in the vicinity of the modified base.

In striking contrast with the dimers, only a single doublet is observed in the ^1H NMR spectrum of the trimer **3** over the 10–70°C range (Fig. 4, Table 3), and the ^{13}C spectra reveal only a small differential shielding (Fig. 3, Table 5). Furthermore, the ^1H chemical shift of the 8M protons shows no dependence on temperature in the 10–70°C range (Fig. 4). This is unexpected in view of the behaviour of the prochiral groups of **1** and **2**, and because the CD spectra of **3** show changes that suggest some degree of base stacking at low temperature (see below). Perhaps there is a cancellation of the shielding effects of the Tp and pT bases; magnetic shielding of the O4-alkyl and CD changes have different origins, and therefore must report different features of the same ordered structure. Interestingly, we have recently noted that, for the ethyl analogue of **3**, d(Tpe^{4}TpT), *both* the CD and the Δ for the diastereotopic methylene protons of the O4-ethyl group are temperature dependent.[4]

Sugar pucker

This feature of a 2′-deoxyribose ring can be evaluated from the vicinal proton coupling constants $J(1'2')$ through $J(3'4')$ (Tables 2 and 3), or from certain sums of these couplings such as $\Sigma 1' = J(1'2') + J(1'2'')$ (25). Comparing the 20°C data for the dimers (Table 2), one sees that O4-isopropylation of the Tp unit of **4** leads to an increase of 1.1 Hz in $J(3'4')$ and 1.5 Hz in $J(2''3')$, and a decrease of 1.2 Hz in $J(1'2')$, consistent with a destabilization of the *S* (2′-*endo*) pucker (26). The same trend

[4]Communicated at the 13th International Conference on Magnetic Resonance in Biological Systems, Madison, WI, August 14–19, 1988.

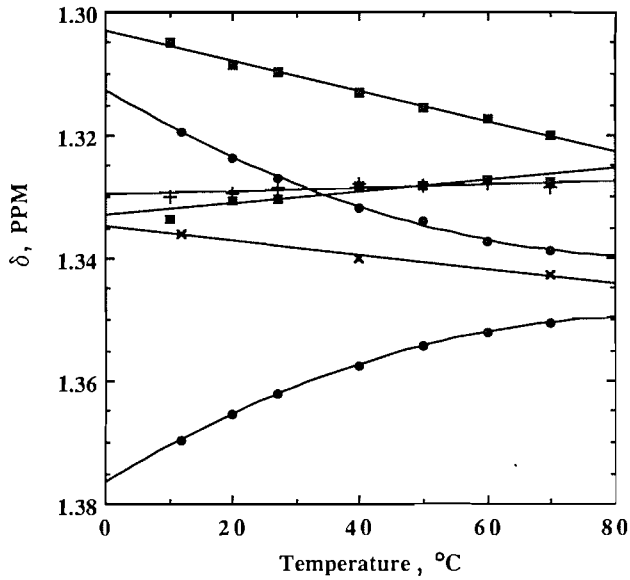

FIG. 4. Temperature (°C) profile of the chemical shifts (δ, ppm from DSS) of the diastereotopic methyl (8M) protons of the O4-isopropyl groups of d(i^{4}TpT) (**1**) (solid circle), d(Tpi^{4}T) (**2**) (solid square), d(Tpi^{4}TpT) (**3**) (+), and i^{4}dT (×). Distinct doublets (J(78) = 6.2 Hz) are observed for the *pro-R* and *pro-S* groups in the spectra of **1** and **2**, but the protons on the two groups are isochronous in **3** and i^{4}dT so that only a single doublet (J(78) = 6.2 Hz) is observed.

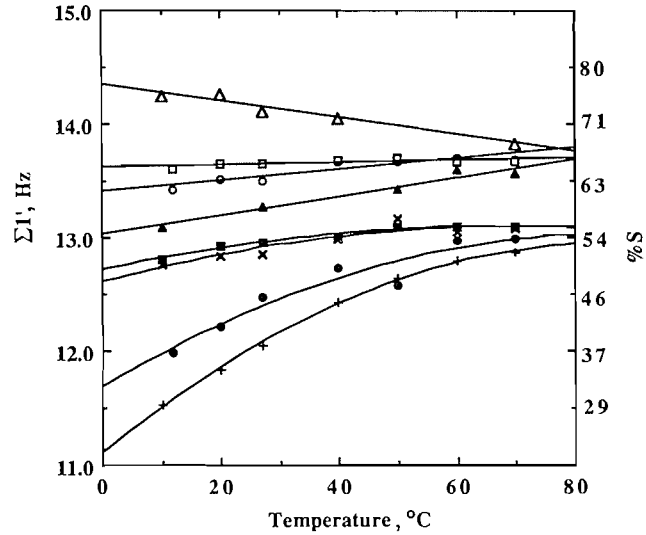

FIG. 5. Temperature profiles of $\Sigma 1' = J(1'2') + J(1'2'')$ in Hz for the modified units i^{4}Tp (**1**) (solid circle), e^{4}Tp (**6**) (+), pi^{4}T (**2**) (solid square), pe^{4}T (**7**) (×), and pi^{4}Tp (**3**) (solid triangle), and the corresponding unmodified units Tp (**4**) (open circle), pT (**4**) (open square), and pTp (**5**) (open triangle). The data are taken from Tables 2 and 3, ref. 10, or from the width of the H1′ band. The vertical axis at the right provides the *%S* (2′-*endo*) conformation of the sugar ring calculated according to ref. 25. For comparison, Σ1′ is 13.1 Hz (55% *S*) for i^{4}dT and 13.6 Hz (65% *S*) for dT in the 10–70°C range.

was noted for O4-ethylation (10), but the changes were larger. However, the effect of O4-isopropylation on the pT unit is small. For the modified segment of **1**, increasing the temperature to 70°C leads to decreases in $J(2''3')$ and $J(3'4')$, and to an increase in $J(1'2')$, reflecting a shift back to the *S* pucker at high temperature. These general trends are evident in the temperature profiles of Σ1′ in Fig. 5, which show the shift towards the *N* type pucker for the i^{4}Tp unit of **1**. In the figure, Σ1′ data are also provided for e^{4}Tp of **6** (10), and reveal a slightly larger shift towards *N* for this unit. On the other hand, Σ1′ for the modified (pi^{4}T, pe^{4}T) and unmodified (pT) 5′-nucleotidyl units show relatively little variation with temperature.

Data (500 MHz) are provided for the trimer **3** at 10 and 70°C (Table 3) for comparison with the 30°C data (500 MHz) on the unmodified trimer **5** published by Rycyna *et al.* (14). The coupling constants of the unmodified Tp and pT ends of **3** show little variation from 10 to 70°C (≅0.2 Hz), and are identical to within 0.2 Hz to the corresponding couplings of **5**. Comparing the low temperature data for the pNp units of the trimers, we note that O4-alkylation causes a decrease in $J(1'2')$ from 8.1 to 6.6 Hz with a concomitant increase in $J(2''3')$ from 3.1 Hz to 3.7 Hz, in line with a destabilization of the *S* pucker. Unfortunately, at 10°C the HDO resonance is uncomfortably close to the H3′ (pi^{4}Tp) band, and so we are less confident about the magnitude of $J(3'4')$ of this unit, though a small increase of 0.4 Hz relative to the pTp unit is indicated. Figure 5 shows that at 10°C Σ1′(pNp) is smaller by 1.2 Hz in **3**, indicating a reduction of about 20% in the *S* pucker relative to **5**. At 70°C, their Σ1′ are identical to within experimental error.

We have also measured the Σ1′ for a series of monomeric r^{4}dT (r = methyl, ethyl, isopropyl, *n*-propyl) and for the 3′-nucleotide (3′-e^{4}dTMP), and found that they are independent of temperature in the 10–70°C range (13.1 Hz; 55% *S*). Since no temperature dependence is seen for the monomers, the effect of temperature on the pucker of certain modified units of the oligomers, as discussed above, would seem to be related to intramolecular base stacking. As noted in a previous section and in our study of the O4-ethylated dimers (10), the variation of Δ points to some base association at low temperature. Since stacked, single-stranded 2′-deoxyoligonucleotides containing the major bases favor the *S* pucker (25), our results reveal that certain nucleotidyl units containing the O4-alkylthymine must adjust their conformation to be accommodated in the ordered structure.[5]

The C4′—C5′ (γ) bond

Table 6 gives the populations for the *gauche*$^+$ (g$^+$), *trans* (t), and *gauche*$^-$ (g$^-$) conformers about the γ bond of **1**–**5**, calculated from the $J(4'5')$ and $J(4'5'')$ data according to Haasnoot *et al.* (27). At the low temperature, the Np fragments of the dimers and the trimers show preferences for g$^+$ in the narrow ranges 59 ± 3% whereas the pN and pNp units lie in the range 77 ± 4%, with the two units of **1** lying at the high ends of their respective ranges. Elevating the temperature to 70°C reduces g$^+$ to 54 ± 2% (Np) and 65 ± 3% (pN, pNp). The g$^-$ conformer is always the least populated, particularly for the pN and pNp units. Similar results were observed for the O4-ethylated molecules (10), and so it seems that O4-alkylation does not have much effect on the γ bonds at the dimer and trimer level.

[5]A referee has stated that our calculations based on Σ1′ data lead to *%S*, which can be quite different from those obtained by the more complete calculation using the PSEUROT program (25). For example, at 20°C the calculated *S* populations differ by 13% for the i^{4}Tp (**1**): 41% via Σ1′ (Fig. 5) and 54% via PSEUROT (calculated by the referee). There are uncertainties in all of these methods but they reveal the same trends. Our tabled data are available for the PSEUROT calculations.

[a]The chemical shift data are measured at 75.5 MHz relative to internal dioxane and converted to a TMS scale by addition of 67.86 ppm. δC2 through δC5′ for **3** are relative to the carbon shift of the corresponding fragment of **5**; a negative sign indicates a resonance at high field of the reference. The δC7 and δC8 are relative to TMS. The assignments of the base carbons of Tp and pT may be interchanged. See Fig. 1 for atom labelling. The J data for **5** at 30°C are from ref. 15.

[b]Δ is the chemical shift in Hz at 75.5 MHz between the two diastereotopic isopropyl methyl carbons at 27°C; at 70°C, distinct resonances for these carbons are not detected, and thus Δ must be less than about 1 Hz.

The C5′—O5′ (β) bond

The population of the favored *trans* (t) conformation of the β bond of the pN and pNp fragments can be estimated from $\Sigma' = J(5'P) + J(5''P)$ (28). This sum falls into the narrow range from 7.9 to 9.1 Hz for these fragments of **1** and **2** (20°C, Table 2), **3** (10°C, Table 3), **4** (20°C) (10), **5** (30°C) (15), and **6** and **7** (20°C) (10). With the parameterization of Cheng *et al.* (13), these data yield %t populations in the range 76–84%. The unmodified pT units of **1** and **6** are found at the high end of the range (82–84%) but, overall, the data do not reveal any large effect of alkylation for the molecules studied. Increasing the temperature to 70°C invariably leads to an increase in Σ' (range 9.3–10.1 Hz), corresponding to a decrease in %t (72–76% range). Similar trends are generally observed for dimers and trimers containing only the normal bases.

The preference for the t(β) conformer for the 5′-nucleotidyl fragments is confirmed by the ^3J(C4′P5′) data (27°C) for **1**–**5**, which fall into the narrow range 9.0 ± 0.3 Hz, except for the pTp unit of **5** (8.2 Hz) (Tables 4, 5), and correspond to 80 ± 3% for the t(β) conformer (calculated according to Lankhorst *et al.* (29)). The value for pTp (**5**), 8.2 Hz, taken from Rycyna *et al.* (15), corresponds to 73% t(β).

The C3′—O3′ (ε) bond

The behaviour of this bond of a 3′-nucleotidyl fragment can be followed with the ^3J(H3′P3′), ^3J(C4′P3′), and ^3J(C2′P3′) coupling constants (15, 21, 29–31). The ^3J(H3′P3′) data, collected over the 20–70°C range for the 3′-nucleotidyl fragments of **1**, **2**, and **4** (Table 2), **3** (Table 3), **5** (15), **6** and **7** (10), lie in the narrow range 6.3–6.8 Hz. A thorough evaluation of the orientation of the ε bond would require ^3J(C4′P3′) and ^3J(C2′P3′) data over a range of temperature (29), but we are limited so far to data near ambient temperature. However,

TABLE 6. Calculated % population[a] of the *gauche*$^+$ (g$^+$), *trans* (t), and *gauche*$^-$ (g$^-$) rotamers about the C4′—C5′ bond for d(i^{4}TpT) (**1**), d(Tpi^{4}T) (**2**), d(TpT) (**4**), d(Tpi^{4}TpT) (**3**), and d(TpTpT) (**5**)

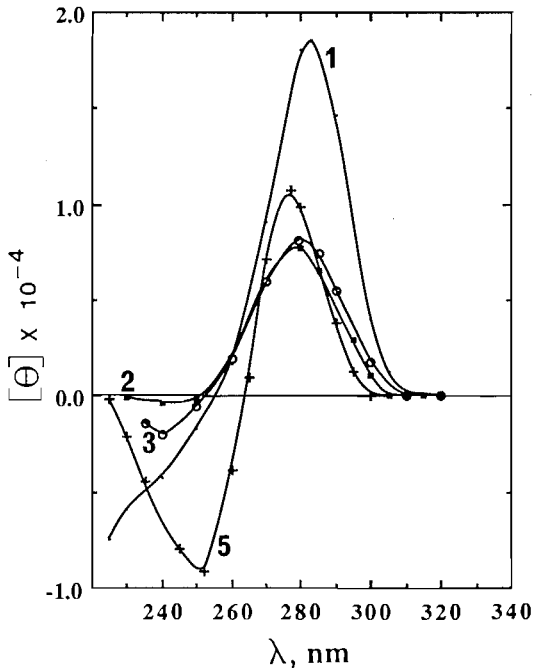

FIG. 6. Circular dichroism (CD) spectra at 9–12°C for d(i^{4}TpT) (**1**) (●), d(Tpi^{4}T) (**2**) (■), d(Tpi^{4}TpT) (**3**) (○), and d(TpTpT) (**5**) (+) at (8.3–9.5) × 10^{-5} M in phosphate buffer (pH = 6.9). The vertical axis gives [θ] in deg M^{-1} cm^{-1}, the molar ellipticity per residue calculated following Cantor and Schimmel (32). For comparison, spectra for d(e^{4}TpT) (**6**), d(Tpe^{4}T) (**7**), and d(TpT) (**4**) are found in ref. 10.

one clear feature in the available data is that ^3J(C4′P3′) is invariably larger than ^3J(C2′P3′) (typically about 7 and 3 Hz, respectively). This collection of data points to a preference for the *trans* conformer of the C4′—C3′—O3′—P3′ fragment over the *gauche*$^-$.

^{1}H and ^{13}C chemical shifts

^{1}H NMR spectra were obtained for our O4-isopropylated molecules (and their unmodified parents) at 10° intervals in the 10–70°C range, and computer-analyzed at two temperatures (Tables 1–3); estimates of the shifts at other temperatures can be easily obtained with the information provided by the computer-derived data. Temperature profiles for the O4-isopropylated dimers (other than those in Fig. 4) are not given here since they closely resemble the profiles of their O4-ethylated counterparts provided by Buchko *et al.* (10). The most noteworthy effect of O4-alkylation, observed at the dimer and trimer levels, is the deshielding of H6 (0.22–0.29 ppm) and the 5-CH_3 protons (0.06–0.08 ppm) of the modified base (Fig. 2).

To facilitate comparison of the effects of O4-alkylation on the carbon shifts, the δ(^{13}C) values for the dimers **1** and **2** are given (Table 4) relative to the corresponding value in the parent dimer **4** (except for the O4-isopropyl carbons, which are relative to TMS), whereas data for **4** are given relative to TMS. Also provided are the published (5) δ values of the monomer i^{4}dT relative to dT. In Table 5 are found the data for the unmodified trimer **5** relative to TMS and the data for the modified trimer **3** relative to **5**. Clearly, the major effects of O4-alkylation are restricted to the base of the altered nucleoside unit, with close agreement at monomer, dimer, and trimer levels: deshielding of C2, C4, and C6 (2.5–6.2 ppm) and shielding of C5 (−3.5 to −3.8 ppm). Only a small deshielding is found at the 5-methyl carbon (5M (< −0.2 ppm). It is interesting to note that in all instances the effect at the C2 carbonyl carbon is about 30% larger than at the directly affected C4 position; this points to an extensive polarization of the entire O4—C4—N3—C2—O2 fragment. The effect of O4-alkylation on the carbons of the unmodified segments of the oligomers is in all cases less than 0.3 ppm. These trends, as well as those of ^{1}H NMR data, would facilitate the assignment of pyrimidine bases in the spectra of longer oligonucleotides.

Circular dichroism

Figure 6 provides [θ], the molar ellipticity per residue, for **1**, **2**, **3**, and **5** at 9–11°C; the spectrum for **4** (in ref. 10) is not provided here since it is identical to that of **5**. Our CD spectrum of **5** (λ_{max}: 277 nm, $[\theta]_{max}$ = 10 700; λ_{min}: 252 nm, $[\theta]_{min}$ = −9100) is in good agreement with that of d(pTpTpT) (33). O4-Isopropylation causes a dramatic reduction in the negative CD peak at 252 nm and a shift of λ_{max} of the positive peak to longer wavelengths (284 nm (**1**), 280 nm (**2**), 279 nm (**3**)). In addition, the magnitude of the positive peak is considerably enhanced in **1** ($[\theta]_{max}$: 18 600), but decreased slightly in **2** and **3**. These trends are identical to those noted for the corresponding ethylated derivatives **6** and **7** (10). It is interesting to note that the CD spectra of **1** and **2** are qualitatively similar to those of d(CpT) and d(TpC) (33). This correspondence was noted earlier for **6** and **7** and suggests that in some respects an O4-alkylated base is "cytosine-like," in line with crystallographic data (3, 4).

CD spectra were obtained at 15–20°C intervals up to about 65°C, and invariably show a gradual diminution of the extrema with increasing temperature. For the prominent positive peak, the decrease in $[\theta]_{max}$ is larger (40–44%) for the Np-modified dimers (**1**, **6**) and the unmodified molecules (**4**, **5**), and less for the pN-modified dimers (**2**, **7**) (10–15%) and the modified trimer (**3**) (24%). This temperature dependence points to the formation of some base stacking at low temperature. At the dimer level, the trends are in qualitative agreement with the effects of temperature on Δ (Fig. 4), which were interpreted in terms of base stacking. On the other hand, no differential shielding of the diastereotopic 8-methyl groups of **3** was observed (see above), an inconsistency that we cannot now explain.

Mass spectrometric experiments

Our FAB-MS data for the O4-isopropylated molecules, as well as those for their O4-ethylated analogs in Buchko *et al.* (10), demonstrate the utility of this technique for the characterization of DNA oligomers containing the r^{4}T base. Particularly useful is the presence of an intense $[M - H]^-$ molecular ion of **1**, **2** and **3**, and of the fragment [O4-alkylthymine − H]$^-$, which results from the scission of the N-glycosyl bond of the modified unit. The spectra of **1** and **2** show peaks at *m/z* 363, which correspond to the nucleotidyl fragments [3′-i^{4}dTMP − H]$^-$) and [5′-i^{4}dTMP − H]$^-$), respectively. Also of diagnostic value is the presence of peaks at *m/z* 1175 in the spectra of **1** and **2** (2–4% of the $[M - H]^-$ ion) that can be assigned to the molecular aggregates $[2M - H]^-$. An aggregate of *three* molecules was also apparent (at very low intensity) in the negative ion FAB spectra of **6** (10), but no such aggregate was seen here. No aggregates were apparent in the spectrum of either **3** or **5**. In a subsequent report, discussion of molecular scissions and rearrangements of our modified oligomers will be provided, as has been done for the parent nucleosides (34). Our studies could be useful for determining the site of modification of longer DNA fragments.

Reactions of polar dienes with *o*-quinones

JACQUES PAQUET AND PAUL BRASSARD[1]
Département de chimie, Université Laval, Québec (Québec), Canada G1K 7P4

Received November 22, 1988

JACQUES PAQUET and PAUL BRASSARD. Can. J. Chem. **67**, 1354 (1989).

The behaviour of various types of polar dienes towards halogenated *ortho* quinones has been investigated in a number of representative cases. As compared to the commonly used *para* analogues, *o*-quinones provide a wide range of products that indicate a keener response to the nature, number, and position of substituents on both reactants. 3-Halogenated-*o*-naphthoquinones **1** and **2** react smoothly with a representative vinologous ketene acetal **3**, vinylketene acetals **4** and **5**, and a monooxygenated diene **6** to provide variously substituted phenanthrenequinones **7–11**. Only monooxygenated dienes on the other hand add to *o*-benzoquinones **14–16** and give convenient syntheses of the corresponding *o*-naphthoquinones **18–20**.

Key words: cycloaddition, *o*-naphthoquinones, phenanthrenequinones, regiospecificity.

JACQUES PAQUET et PAUL BRASSARD. Can. J. Chem. **67**, 1354 (1989).

Le comportement de divers types de dienes polaires vis-à-vis les *o*-quinones halogénées a été étudié dans un certain nombre de cas significatifs. Par comparaison avec les isomères-1,4 d'usage plus répandu, les *o*-quinones fournissent une gamme plus étendue de produits qui traduisent une sensibilité accrue à la nature, au nombre et à la position des substituants dans les deux réactants. Les *o*-naphtoquinones halogénées **1**, **2**, par réaction avec le vinylogue d'acétal de cétène **3**, des acétals de vinylcétènes **4**, **5** et un diène monoxygéné **6**, fournissent les phénanthrènequinones **7–11** attendues. Seuls les diènes monoxygénés, par contre, réagissent bien avec les benzoquinones **14–16** et conduisent aux *o*-naphtoquinones correspondantes **18–20**.

Mots clés : cycloaddition, *o*-naphtoquinones, phénanthrènequinones, régiospécificité.

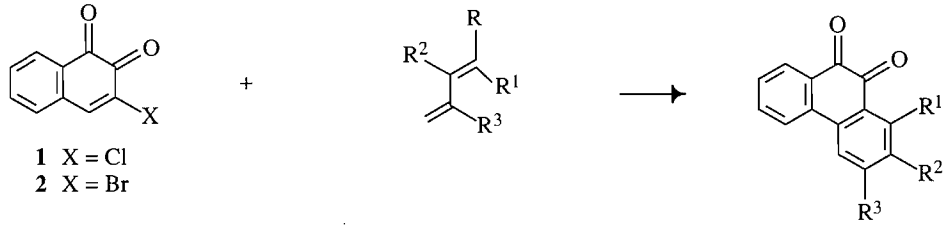
The Diels–Alder reaction of simple dienes with *o*-quinones has been intensively examined by a number of investigators over the years (1). Various regiochemical problems such as the involvement of 3,4 or 5,6 double bonds in the case of substituted *o*-benzoquinones (2–5), the ease of addition to carbonyl groups (6), the formation of dioxanes (6*b*, 7), and the dienic character of *o*-quinones (8) have all received considerable attention. The orientation of weakly polar dienes in the process has not been addressed systematically although regioselective behaviour has been established in a few instances (3–5, 9). Enhanced reactivity in the case of halogenated quinones has been repeatedly pointed out (2, 9) and this type of substituent has been used to direct addition from the 3,4 to the 5,6 double bond (4) but does not seem to have been otherwise used to assist in the orientation of the diene.

The concomitant application of electron-rich dienes and halogenated *p*-benzo- and *p*-naphthoquinones to effect regiospecific annulations (10) was extended to *ortho* isomers in the expectation that naturally occurring *o*-naphthoquinones, phenanthrenequinones, and eventually phenanthrenoid phytoalexins could be synthesized expeditiously by this simple approach. It has previously been shown that cycloadditions with *o*-benzoquinones generally affect the carbon–carbon double bond of lowest electron density (2). However, *o*-naphthoquinones substituted in the 4-position with electron-attracting groups give mainly adducts involving the 2-carbonyl function (6*a*). Nevertheless, with sufficiently electrophilic *o*-quinones, 1,6 rather than 1,4 additions of nucleophiles are known to occur (11), and it was hoped that polar dienes like vinylogous ketene acetals and vinylketene acetals should not only produce the expected products with 3-halogenated substrates but might also considerably facilitate the inverse addition with the 4-substituted isomers.



Both 3- and 4-halogenated *o*-naphthoquinones are more readily available and better able to demonstrate the usefulness of the method than the variously substituted monocyclic analogues. Initial tests involving the electron-rich 2-methyl-1,3-bistrimethylsiloxy-1,3-butadiene (**3**) and quinone **2** easily gave an adduct, which was aromatized with HCl at room temperature and provided a 74% yield of the expected phenanthrenequinone **7**. A similar reaction with chloroquinone **1** proved more difficult to complete and yielded the same product in 40% yield only upon refluxing the intermediate in toluene for 18 h.

Subsequent experiments with a vinylketene acetal, 1,3-dimethoxy-1-trimethylsiloxy-1,3-butadiene (**4**) proceeded as smoothly as before but produced somewhat startling results. A reaction between this diene and quinone **2**, when conducted in THF at 0°C, gave only 1-hydroxy-3-methyl phenanthrenequinone (**8**) in 70% yield after the reaction was allowed to come to room temperature. On the other hand, when the cycloaddition was carried out in benzene at 6°C, only the 1,3-dimethoxy derivative **9** was obtained. Although reactions with dienic mixed acetals that do not involve hydrolysis of the intermediate adduct generally afford mixtures of such products as the foregoing, this is the only case, to our knowledge, of such a selective outcome (12).

The eventual application of this approach to the synthesis of natural products requires the use of such compounds as 1-methoxy-3-methyl-1-trimethylsiloxy-1,3-butadiene (**5***a*). This reactant is often less satisfactory than the preceding one, giving on occasion small amounts of an open-chain by-product (10*b*). An initial experiment with 3-chloro-*o*-naphthoquinone (**1**) gave only 40% of the desired phenanthrenequinone **10** along with 10% of the open-chain compound **12**. Frequently, in this area, improvement of a yield can be obtained by decreasing the rate either by lowering the temperature of the reaction or by using a more hindered diene. A second reaction with such a reactant **5***b* and naphthoquinone **2** provided a similar overall yield but to the advantage of the open-chain by-product **13**. This behaviour remains obscure but could reflect the diminished polarity of these dienes, with aromatization of adducts (facilitated by a bromine substituent) being rapid with respect to the formation of a dipolar intermediate.

A recently developed approach to the annulation of quinones involves a cycloaddition of monooxygenated dienes followed by oxidation of the resultant adduct (13). This type of reactant

had been found to be particularly useful since it combined readily with all sorts of quinonoid dienophiles. In this case the adduct obtained from *o*-naphthoquinone **1** and 1-trimethylsiloxy-1,3-butadiene (**6**) was oxidized with CrO_3 and provided an easy access to 1-hydroxyphenanthrenequinone (**11**) (Scheme 1).

At this point attention was turned to the potentially even more useful 3,5- and 3,6-dihalogenated-*o*-benzoquinones (**14**–**16**). The 3,5-disubstituted catechols are easily prepared by Dakin oxidation of the corresponding salicylaldehydes (14) while the 3,6 isomers are conveniently available by halogenation of cyclohexanones using copper(II) halides, followed by aromatization of the intermediates (15). Reactions of the quinones, prepared *in situ*, with the usual electron-rich dienes, however, produced only unstable colourless compounds, which probably resulted from addition to a carbonyl group.

The cycloaddition–oxidation sequence with monooxygenated dienes fortunately gave more promising results. When adducts formed from diene **6** and quinones **14**–**16** were oxidized with MnO_2, the corresponding novel *o*-naphthoquinones **17**–**19** were obtained, albeit only in fair yield. Although the chloro derivatives **17** and **19** are quite stable, the bromo compound **18** decomposed completely within a few days. Analogous results were also available with the use of 3-trimethylsiloxy-1,3-pentadiene, and the structure of the resulting *o*-naphthoquinone **20** is inferred from results obtained with *p*-quinones (13) and is consistent with the nmr data (a relatively shielded H-5) (Scheme 2).

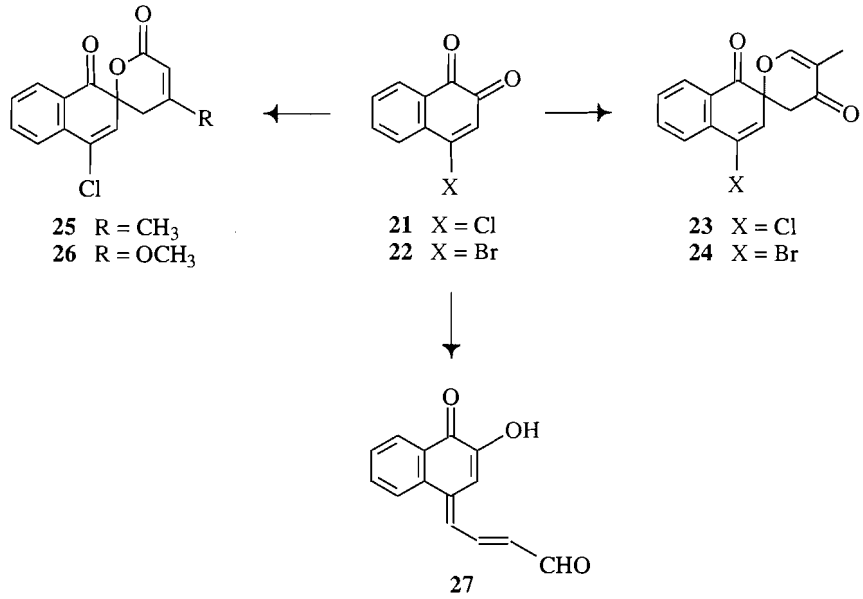
SCHEME 2

In the case of 3-halogenated *o*-quinones, the electronic effects of this substituent and the 2-oxo group are complementary and produce a rather electrophilic 4-position. In the 4-substituted isomers **21** and **22**, on the other hand, the opposition of the foregoing effects results in the enhanced reactivity of the 2-carbonyl group. Expectations of inducing the nucleophilic end of electron-rich dienes to attack the 4-substituted substrates in the 3-position, however, proved illusory. Vinylogous ketene acetals (e.g., **3**) and vinylketene acetals such as **4** and **5***a* give only spiro-γ- (**23** and **24**) and -α-pyrones (**25** and **26**) respectively. (Attempts to modify this result with the use of mild Lewis acids, i.e., boron trifluoride etherate and "boron acetate", were unsuccessful.) A significantly different result was obtained with the use of 1-trimethylsiloxy-1,3-butadiene (**6**), when substitution in the 4-position was observed to result in the unusual open-chain quinonemethide **27** (Scheme 3).

Although annulations of *o*-quinones with electron-rich dienes have been found to be somewhat restricted with respect to those of the *para* analogues, nevertheless the method does provide greatly improved syntheses of a variety of phenanhrenequinones as well as entry to some heretofore unavailable *o*-naphthoquinones. This approach therefore allows easy access in principle to numerous naturally occurring phenanthrene derivatives.



Experimental

All mp's were taken for samples in capillary tubes with a Thomas–Hoover apparatus and are not corrected. The uv spectra were determined on a Hewlett–Packard 8450A spectrophotometer, the ir spectra on a Beckman model IR-4250 instrument, and were calibrated with a film of polystyrene. The nmr spectra were recorded with Varian XL-200 and Bruker HX-90 spectrometers using tetramethylsilane as internal standard. Mass spectra were obtained with a Hewlett–Packard 5995A spectrometer. Merck silica gel $60F_{254}$, for dry column chromatography, was used throughout in a product-to-adsorbent ratio of 1:50–100. Elemental analyses were carried out by Galbraith Laboratories, Inc., Knoxville, Tenn. Ether refers to diethyl ether.

A. Preparation of halogenated o*-quinones*

o-Naphthoquinone was halogenated as proposed for juglone methyl ether (16). Chlorination gave 3-chloro-*o*-naphthoquinone (**1**) (40%),

SCHEME 3

mp 170–172°C ($CHCl_3$–CCl_4) (lit. (17) mp 172°C) while treatment with bromine provided 3-bromo-*o*-naphthoquinone (**2**) (43%), mp 175–176°C ($CHCl_3$–CCl_4) (lit. (17) mp 177–178°C).

2,4-Dichloro- and 2,4-dibromo-1-naphthol, obtained essentially according to de la Mare and Suzuki (18), were oxidized with $Pb(OAc)_4$ as recommended by Perumal and Bhatt (19) to give 4-chloro- (**21**) and 4-bromo-*o*-naphthoquinone (**22**) respectively.

3,5-Dichloro- (**16**), 3,6-dichloro- (**14**), and 3,6-dibromo-*o*-benzoquinones (**15**) were obtained by oxidation of the corresponding catechols with Ag_2O in THF and used immediately without isolation. 3,5-Dihalogenated catechols are available from the suitable salicylaldehyde as described by Dakin (14). The 3,6 isomers can readily be obtained from cyclohexanone and copper(II) halides by aromatizing the intermediates with $LiCO_3$ in DMF (15).

3,6-Dibromocatechol, mp 83–84°C (pet. ether, bp 60–80°C); ir ν_{max}(KBr): 3400, 1450, 1230, 1120 cm^{-1}; ^1H nmr δ ($CDCl_3$; 60 MHz): 5.7 (2H, s, OH-1,2), 7.1 (2H, s, H-4,5); ms, *m/z*: 270/268/266 $(M)^+$. *Anal.* calcd. for $H_6H_4Br_2O_2$: C 26.90, H 1.51, Br 59.65; found: C 26.96, H 1.53, Br 59.43%.

B. General methods

(*a*) *Cycloaddition*

Method A: The diene (2.50 mmol) dissolved in benzene (5 mL) was added slowly (15–30 min) to a solution of the quinone (2.00 mmol) in the same solvent (5 mL) at 6°C. Stirring was continued at room temperature until disappearance of the substrate was revealed by tlc.

Method B: The reaction was carried out as in A but replacing the solvent by THF and initiating the process at 0°C.

(*b*) *Aromatization*

Method C: The adduct was adsorbed on a column of silica gel. Elution was started with benzene and the polarity of the solvent was gradually increased by addition of ethyl acetate.

Method D: Upon evaporation of the solvent, a mixture of concentrated HCl (4 mL) and THF (10 mL) was added at 0°C to the residue dissolved in the same solvent (10 mL), and stirring was continued at room temperature for 1 h. The crude product was then extracted with CH_2Cl_2 and purified by chromatography.

Method E: The adduct was pyrolyzed in refluxing toluene for 18 h.

C. Reactions with 3-halo-o-naphthoquinones

3-Hydroxy-2-methylphenanthrenequinone (7)

(*a*) 2-Methyl-1,3-bistrimethylsiloxy-1,3-butadiene (**3**) and 3-chloro-*o*-naphthoquinone (**1**) were brought together according to method A (1 h). Aromatization of the adduct as per method E gave phenanthrenequinone **7** (192 mg; 40%), mp 298–300°C (methanol); ir ν_{max}(KBr): 3310, 1685, 1650, 1580, 1560 cm^{-1}; uv λ_{max} (MeOH) (log ε): 239(4.06), 264(4.19), 322(3.54), 378(3.57) nm; ^1H nmr δ (200 MHz; DMSO-d_6): 2.20 (3H, s, CH_3-2), 7.50 (1H, s, H-4), 7.52 (1H, qd, *J* = 7.6, 7.5, 0.7 Hz, H-7), 7.80 (1H, td, *J* = 7.6, 1.5 Hz, H-6), 7.82 (1H, s, H-1), 7.94 (1H, dd, *J* = 7.6, 0.7 Hz, H-5), 7.99 (1H, dd, *J* = 7.5, 1.5 Hz, H-8); ms, *m/z*: 238$(M)^+$. *Anal.* calcd. for $C_{15}H_{10}O_3$: C 75.62, H 4.23; found: C 75.48, H 4.16%.

(*b*) In a similar reaction with 3-bromo-*o*-naphthoquinone (**2**) (method A; 3 h), the adduct was aromatized according to method D and provided the same quinone (**7**) (350 mg; 74%).

1-Hydroxy-3-methoxyphenanthrenequinone (8) and 1,3-dimethoxyphenanthrenequinone (9)

(*a*) Method B applied to 1,3-dimethoxy-1-trimethylsiloxy-1,3-butadiene (10*b*) (**4**) and quinone **2** resulted in spontaneous aromatization at room temperature and afforded upon filtration only phenanthrenequinone **8** (352 mg; 70%), mp 304–306°C (methanol); ir ν_{max}(KBr): 3210, 1685, 1642, 1590, 1580 cm^{-1}; uv λ_{max} (MeOH) (log ε): 256(4.36), 400(3.86) nm; ^1H nmr δ (200 MHz; DMSO-d_6): 3.83 (3H, s, OCH_3-3), 6.53 (1H, br s, H-2), 7.20 (1H, br s, H-4), 7.52 (1H, t, *J* = 7.6 Hz, H-6), 7.76 (1H, td, *J* = 7.6, 1.5 Hz, H-7), 7.94 (1H, dd, *J* = 7.6, 1.5 Hz, H-5), 8.10 (1H, d, *J* = 7.6 Hz, H-8); ms *m/z*: 254$(M)^+$. *Anal.* calcd. for $C_{15}H_{10}O_4$: C 70.86, H 3.97; found; C 70.84, H 3.92%.

(*b*) The same reaction conducted as in method A (20 min), at room temperature, yielded by filtration only the dimethyl ether **9** (153 mg; 57%), mp 209–210°C (methanol) (lit. (20) mp 215–216°C); ir ν_{max}(KBr): 1680, 1655, 1595, 1570 cm^{-1}; uv λ_{max} (MeOH) (log ε): 258(4.76), 400(4.24) nm; ^1H nmr δ (200 MHz; DMSO-d_6): 3.90 and 3.98 (2 × 3H, 2s, OCH_3-1,3), 6.69 (1H, br s, H-2), 7.35 (1H, br s, H-4), 7.53 (1H, t, *J* = 7.6 Hz, H-6), 7.76 (1H, td, *J* = 7.6, 1.0 Hz, H-7), 7.94 (1H, dd, *J* = 7.6, 1.0 Hz, H-5), 8.30 (1H, d, *J* = 7.6 Hz, H-8); ms *m/z*: 268$(M)^+$. *Anal.* calcd. for $C_{16}H_{12}O_4$: C 71.64, H 4.51; found: C 71.33, H 4.57%.

1-Hydroxy-3-methylphenanthrenequinone (10)

(*a*) Addition of 1-methoxy-3-methyl-1-trimethylsiloxy-1,3-butadiene (10*b*) (**5***a*) to quinone **1** following method A (1 h) gave a mixture, which was treated according to method C. Separation by chromatography (benzene – ethyl acetate 10:1) provided phenanthrenequinone **10** (192 mg; 40%), which decomposes at 240–245°C (acetone – pet. ether, bp 60–80°C); ir ν_{max}(KBr): 1680, 1635, 1590 cm^{-1}; uv λ_{max} (MeOH) (log ε): 214(4.60), 260(4.52), 280sh(4.74), 335(3.54), 442(3.69) nm; ^1H nmr δ (200 MHz; $CDCl_3$): 2.44 (3H, br s, CH_3-3), 7.28 (1H, br s,

H-2), 7.34 (1H, brs, H-4), 7.47 (1H, td, J = 7.6, 0.8 Hz, H-7), 7.70 (1H, ddd, J = 8.1, 7.6, 0.8 Hz, H-6), 7.99 (1H, dd, J = 8.1, 0.8 Hz, H-5), 8.17 (1H, dd, J = 7.6, 0.8 Hz, H-8); ms m/z: 238$(M)^+$. *Anal.* calcd. for $C_{15}H_{10}O_3$: C 75.62, H 4.23; found: C 75.57, H 4.28%.

A second band consisted of methyl 4-(3-chloro-*o*-naphthoquinonyl-4)-3-methyl-2-butenoate (**12**) (61 mg; 10%), mp 153–155°C (acetone–pet. ether, bp 60–80°C); ir ν_{max}(KBr): 1730, 1705, 1695, 1675 cm^{-1}; ^1H nmr δ (200 MHz; $CDCl_3$): 2.39 (3H, d, J = 1.1 Hz, CH_3-3), 3.66 (3H, s, OCH_3-1), 3.84 (2H, br s, H-4), 5.59 (1H, q, J = 1.1 Hz, H-2), 7.40 (1H, dd, J = 7.7, 1.5 Hz, H-5), 7.54 and 7.68 (2H, 2td, J = 7.7, 1.5 Hz, H-6,7), 8.17 (1H, dd, J = 7.7, 1.5 Hz, H-8); ms m/z: 306/304 $(H)^+$.

(*b*) When a reaction was carried out with 3-methyl-1,1-bistrimethylsiloxy-1,3-butadiene (**5***b*) prepared from 3-methylcrotonic acid essentially as in ref. 10*b* (bp 74–78°C/5 Torr (1 Torr = 133.3 Pa) (94%); ir ν_{max} (film): 2960, 1650, 1255, 1200, 1060, 840 cm^{-1}; ^1H nmr δ (200 MHz; $CDCl_3$): 0.16 and 0.20 (18 H, 2s, OTMS-1,1), 1.84 (3H, s, CH_3-3), 4.20 (1H, s, H-2), 4.44 and 4.66 (2H, 2d, J = 2.8 Hz, H-4). *Anal.* calcd. for $C_{11}H_{24}O_2Si_2$: C 54.04, H 9.89%; found: C 53.79, H 10.07%) and 3-bromo-*o*-naphthoquinone (**2**) according to methods A (1 h) and D, a similar mixture of products was obtained. Separation by chromatography (dichloromethane) gave phenanthrenequinone (**10**) (143 mg; 30%) and, eluting with ethyl acetate, 4-(3-bromo-*o*-naphthoquinonyl-4)-3-methyl-2-butenoic acid (**13**) (128 mg; 19%), mp 210–211°C (dec.) (ethanol); ir ν_{max}(KBr): 3080, 2580, 1680, 1665, 1635, 1585, 1550 cm^{-1}; uv λ_{max} (MeOH) (log ε): 214(4.57), 260(4.50), 333(3.58), 442(3.63) nm; ^1H nmr δ (200 MHz; DMSO-d_6): 2.26 (3H, s, CH_3-3), 3.84 (2H, br s, H-4), 5.60 (1H, br s, H-2), 7.52–7.74 (3H, m, H-5′,6′,7′), 7.98 (1H, dd, J = 7.7, 1.5 Hz, H-8′), 12.04 (1H, s, OH-1); ms m/z: 336/334 $(M)^+$. *Anal.* calcd. for $C_{15}H_{11}BrO_4$: C 53.75, H 3.31, Br 23.84; found: C 53.73, H 3.42, Br 23.73%.

*1-Hydroxyphenanthrenequinone (**11**)*

1-Trimethylsiloxy-1,3-butadiene (13) (**6**) (315 mg; 2.22 mmol) in CH_2Cl_2 (5 mL) was added at 0°C to 3-chloro-*o*-naphthoquinone (**1**) (387 mg; 2.01 mmol) in the same solvent (5 mL). The mixture was stirred for 16 h at room temperature and evaporated. The residue was oxidized with CrO_3 (330 mg; 3.30 mmol) in acetic acid (10 mL) at reflux temperature (1.5 h) and the crude product, taken up in ether and washed with water, was purified by chromatography (benzene – ethyl acetate (9:1), giving phenanthrenequinone **11** (224 mg; 50%), mp 221–222°C (acetone – pet. ether, bp 60–80°C) (lit. (21) mp 220°C); ir ν_{max}(KBr): 1680, 1630, 1595 cm^{-1}; uv λ_{max} (MeOH) (log ε): 256(4.40), 279sh(4.06), 336(3.47), 448(3.61) nm; ^1H nmr δ (200 MHz; $CDCl_3$): 7.03 (1H, br d, J = 8.2 Hz, H-2), 7.45–7.64 (3H, m, H-3,4,7), 7.72 (1H, td, J = 7.9, 1.6 Hz, H-6), 8.01 (1H, br d, J = 7.9 Hz, H-5), 8.20 (1H, dd, J = 7.9, 1.6 Hz, H-8), 12.50 (1H, s, OH-1); ms m/z: 224$(M)^+$. *Anal.* calcd. for $C_{14}H_8O_3$: C 75.10, H 3.60; found: C 75.00, H 3.60%.

D. Reactions with dihalo-o-benzoquinones

*3-Chloro-8-hydroxy-o-naphthoquinone (**17**)*

A mixture of 3,6-dichlorocatechol (15) (360 mg; 2.01 mmol) and silver(I) oxide (1.2 g; 5.2 mmol) in THF (10 mL) was stirred at room temperature for 2 h, then cooled to 0°C. To this suspension was then added dropwise, over 30 min, a solution of 1-trimethylsiloxy-1,3-butadiene (**6**) (351 mg; 2.51 mmol) in the same solvent (5 mL) and stirring was continued at room temperature for 5 h. The adduct was then hydrolyzed by addition of 5% aqueous HCl (30 mL) over 30 min to the reaction mixture at 0°C, and stirring was again continued for 1 h. The solid was next filtered off and washed well with ether (3 × 30 mL). Evaporation of the solvent gave a residue, which was dissolved in THF (20 mL) containing MnO_2 (361 mg; 4.15 mmol). This mixture was stirred for 16 h, filtered, and evaporated. Purification of the crude product by chromatography (CH_2Cl_2) gave naphthoquinone **24** (145 mg; 35%), mp 119–122°C (dec.) (dichloromethane – pet. ether, bp 60–80°C); ir ν_{max}(KBr): 1685, 1630, 1585, 1560 cm^{-1}; uv λ_{max} (MeOH) (log ε): 256(4.05), 366(3.62), 371(3.62) nm; ^1H nmr δ (200 MHz; $CDCl_3$): 6.89 (1H, dd, J = 7.7, 1.0 Hz, H-7), 7.08 (1H, dd, J = 9.0, 1.0 Hz, H-5), 7.55 (1H, s, H-4), 7.57 (1H, dd, J = 7.7, 9.0 Hz, H-6), 11.88 (1H, s, OH-8). *Anal.* calcd. for $C_{10}H_5ClO_3$: C 57.58, H 2.42, Cl, 17.00; found: C 57.38, H 2.39, Cl 17.22%.

*3-Bromo-8-hydroxy-o-naphthoquinone (**18**)*

Under conditions similar to the foregoing, 3,6-dibromocatechol (270 mg; 1.02 mmol) was converted to quinone **15** and the latter combined with diene **6** (117 mg; 1.25 mmol). Oxidation of the hydrolyzed adduct with MnO_2 (180 mg; 2.00 mmol) gave quinone **18** (96 mg; 38%), which decomposed completely within a few days; ^1H nmr δ (90 MHz; $CDCl_3$): 6.9 (1H, br d, J = 7.5 Hz, H-7), 7.1 (1H, br d, J = 9.0 Hz, H-5), 7.6 (1H, dd, J = 7.5, 9.0 Hz, H-6), 7.8 (1H, s, H-4), 12.9 (1H, s, OH-8); ms m/z: 252/254$(M)^+$.

*4-Chloro-8-hydroxy-o-naphthoquinone (**19**)*

In a reaction similar to the preceding ones, diene **6** (156 mg; 1.10 mmol) and quinone **16** obtained from 3,5-dichlorocatechol (179 mg; 1.00 mmol) gave an adduct that was converted by MnO_2 (860 mg; 10.0 mmol) to the corresponding quinone **19** (66 mg; 32%), which decomposes at 135–140°C; ir ν_{max}(KBr): 1670, 1640, 1580, 1555 cm^{-1}; ^1H nmr δ (200 MHz; $CDCl_3$): 6.75 (1H, s, H-3), 7.20 (1H, dd, J = 8.7, 1.3 Hz, H-5), 7.47 (1H, dd, J = 7.4, 1.3 Hz, H-7), 7.67 (1H, dd, J = 8.7, 7.4 Hz, H-6), 12.29 (1H, s, OH-8). *Anal.* calcd. for $C_{10}H_5ClO_3$: C 57.58, H 2.42, Cl 17.00; found: C 57.26, H 2.51, Cl 16.60%.

*3-Chloro-7-hydroxy-8-methyl-o-naphthoquinone (**20**)*

3-Trimethylsiloxy-1,3-pentadiene (13) (630 mg; 4.04 mmol) in THF (1 mL) was added to the residue obtained from the oxidation of 3,6-dichlorocatechol (361 mg; 2.02 mmol), and evaporation of the solvent. The mixture was stirred at room temperature for 24 h, MnO_2 (170 mg; 1.95 mmol) was added to the adduct, and stirring again continued for 16 h. Upon purification of the crude product by chromatography (CH_2Cl_2), a first zone (106 mg) consisted of what seemed to be an unidentified dimer of the quinone.

A second band provided the desired quinone **20** (74 mg; 17%), mp 243–244°C (dec.) (dichloromethane – pet. ether, bp 60–80°C); ir ν_{max}(KBr): 3280, 1680, 1650, 1560 cm^{-1}; uv λ_{max} (MeOH) (log ε): 276(3.62), 406(3.08) nm; ^1H nmr δ (200 MHz; $(CD_3)_2CO$): 2.39 (3H, s, CH_3-8), 7.00 (1H, d, J = 8.3 Hz, H-5), 7.80 (1H, d, J = 8.3 Hz, H-6), 8.11 (1H, s, H-4); ms m/z: 222/224$(M)^-$. *Anal.* calcd. for $C_{11}H_7ClO_3$: C 59.34, H 3.17, Cl 15.93; found: C 59.05, H 3.22, Cl 15.46%.

E. Reactions with 4-halo-o-naphthoquinones

*4-Chloro-3′,4′-dihydro-5′-methylspiro[naphthalene-2(1H),2′-(2H)pyran]-1,4′-dione (**23**)*

Diene **3**, when added to 4-chloro-*o*-naphthoquinone **21** following method A (1.5 h), gave spirodione **23** (480 mg; 88%), mp 114–116°C (benzene – pet. ether, bp 60–80°C); ir ν_{max}(KBr): 1690, 1665, 1615, 1595, 1585, 1550 cm^{-1}; uv λ_{max} (MeOH) (log ε): 232(4.80), 294(4.44); ^1H nmr δ (200 MHz; $CDCl_3$): 1.72 (3H, s, CH_3-5′), 2.92 and 3.04 (2H, 2d, J = 17.1 Hz, H-3′), 6.37 (1H, s, H-3), 7.44–7.60 (2H, m, H-6,7), 7.48 (1H, br s, H-6′), 7.67–7.72 (1H, m, H-5), 7.87–7.92 (1H, m, H-8); ms m/z: 274/276$(M)^+$. *Anal.* calcd. for $C_{15}H_{11}ClO_3$: C 65.59, H 4.04, Cl 12.91; found: C 65.64, H 4.18, Cl 12.61%.

*4-Bromo-3′,4′-dihydro-5′-methylspiro[naphthalene-2(1H),2′-(2H)pyran]-1,4′-dione (**24**)*

In a reaction similar to the preceding one, diene **3** and bromo-*o*-naphthoquinone **22**, after 2 h, gave spirodione **24**, (473 mg; 74%), mp 124–126°C (benzene – pet. ether, bp 60–80°C); ir ν_{max}(KBr): 1695, 1675, 1625, 1600, 1590, 1560 cm^{-1}; ^1H nmr δ (200 MHz; $CDCl_3$): 1.72 (3H, d, J = 1.3 Hz, CH_3-5′), 2.93 and 3.06 (2H, 2d, J = 17.1 Hz, H-3′), 6.64 (1H, s, H-3), 7.44–7.57 (2H, m, H-6,7), 7.48 (1H, m, H-6′), 7.65–7.72 (1H, m, H-5), 7.85–7.90 (1H, m, H-8).

*4-Chloro-3′,6′-dihydro-4′-methylspiro[naphthalene-2(1H),2′-(2H)pyran]-1,6′-dione (**25**)*

(*a*) Application of method A to diene **5***a* and quinone **21**, after 1 h, afforded spirodione **25** (470 mg; 86%), mp 148.5–150.0°C (benzene – pet. ether, bp 60–80°C); ir ν_{max}(KBr): 1725, 1695, 1655 cm^{-1}; uv

λ_{max} (MeOH) (log ϵ): 231(4.17), 237(4.17), 310(3.84) nm; ^{1}H nmr δ (200 MHz; $CDCl_3$): 1.85 (3H, br s, CH_3-4′), 2.77 (2H, s, H-3′), 5.97 (1H, br s, H-5′), 6.38 (1H, s, H-3), 7.45–7.62 (2H, m, H-6,7), 7.72–7.80 (1H, m, H-5), 7.87–8.01 (1H, m, H-8); ms *m/z*: 274/276(M)$^+$. *Anal.* calcd. for $C_{15}H_{11}ClO_3$: C 65.60, H 4.00, Cl 12.90; found: C 65.72, H 4.15, Cl 12.81%.

(*b*) A reaction analogous to the foregoing one, in which diene **5***a* was replaced by diene **5***b*, gave the same spirodione **25** (484 mg; 88%).

*4-Chloro-3′,6′-dihydro-4′-methoxyspiro[naphthalene-2(1*H*),2′-(2*H*)pyran]-1,6′-dione (**26**)*

Cycloaddition of diene **4** to chloronaphthoquinone **21** according to method A (1 h) gave the corresponding spirodione **26** (369 mg; 63%), mp 169–171°C (benzene – pet. ether, bp, 60–80°C); ir ν_{max}(KBr): 1730, 1695, 1630, 1600, 1555 cm^{-1}; uv λ_{max} (MeOH) (log ϵ): 232(4.42), 237(4.44), 311(3.99) nm; ^{1}H nmr δ (200 MHz; $CDCl_3$): 2.91 (2H, s, H-3′), 3.71 (3H, s, OCH_3-4′), 5.32 (1H, s, H-5′), 6.39 (1H, s, H-3), 7.45–7.62 (2H, m, H-6,7), 7.76–7.81 (1H, m, H-5), 7.87–7.91 (1H, m, H-8); ms *m/z*: 290/292(M)$^+$. *Anal.* calcd. for $C_{15}H_{11}ClO_4$: C 61.98, H 3.81, Cl 12.20; found: C 62.34, H 3.92, Cl 11.82%.

*4-(4-Oxo-2-buten-1-ylidene)-2-hydroxynaphthalen-1(4*H*)-one (**27**)*

A mixture of 1-trimethylsiloxy-1,3-butadiene (**6**) (568 mg; 4.00 mmol) and 4-chloro-*o*-naphthoquinone (**21**) (387 mg; 2.01 mmol) in benzene (10 mL) was heated at reflux for 2 h. Purification of the crude product by chromatography (benzene) gave naphthalenone **27** (144 mg; 32%), mp 204–206°C (benzene); ir ν_{max}(KBr): 3020, 2840, 1660, 1640, 1595, 1580 cm^{-1}; uv λ_{max} (MeOH) (log ϵ): 237(3.50), 336(3.23), 404(3.51) nm; ^{1}H nmr δ (200 MHz; $CDCl_3$): 6.54 (1H, ddd, J = 14.8, 7.8, 1.2 Hz, H-3′), 7.08 (1H, s, OH-2), 7.34 (1H, d, J = 1.0 Hz, H-3), 7.54 (1H, br d, J = 12.9 Hz, H-1′), 7.57–7.76 (2H, ~ 2dt, H-6,7), 7.85 (1H, dd, J = 12.9, 14.8 Hz, H-2′), 8.11 (1H, ~dd, H-5), 8.31 (1H, ~dd, H-8), 9.81 (1H, d, J = 7.8 Hz, H-4′); ms *m/z*: 226(H)$^+$. *Anal.* calcd. for $C_{14}H_{10}O_3$: C 74.33, H 4.46; found: C 74.19, H 4.52%.

Xestolide and secoxestenone, degraded triterpenoids from the sponge *Xestospongia vanilla*

PETER T. NORTHCOTE AND RAYMOND J. ANDERSEN[1]

Departments of Chemistry and Oceanography, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

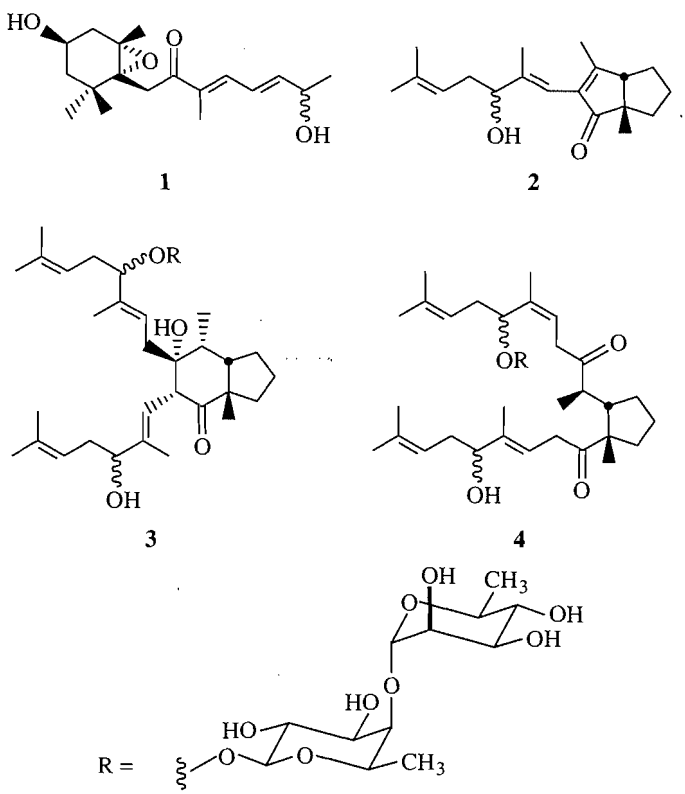
Received March 22, 1989

PETER T. NORTHCOTE and RAYMOND J. ANDERSEN. Can. J. Chem. **67**, 1359 (1989).

Xestolide (**5**) and secoxestenone (**6**), two metabolites with new terpenoid carbon skeletons, have been isolated from the northeastern Pacific sponge *Xestospongia vanilla*. Proposed structures for **5** and **6** are based on spectroscopic analysis and chemical interconversions. The similarity in structure between xestolide (**5**), secoxestenone (**6**), xestenone (**2**), and the aglycone of secoxestovanin A (**4**) has prompted the biogenetic proposal that metabolites **2**, **5**, and **6** are degraded triterpenoids.

Key words: sponge, terpenoids, *Xestospongia*.

PETER T. NORTHCOTE et RAYMOND J. ANDERSEN. Can. J. Chem. **67**, 1359 (1989).



On a isolé la xestolide (**5**) et la sécoxesténone (**6**), deux métabolites possédant un nouveau squelette carbonné terpénique, à partir de l'éponge *Xestospongia vanilla* du Pacifique Nord-est. Les structures proposées pour ces deux composés s'appuient sur l'analyse spectroscopique et sur des transformations chimiques. La similarité de structure entre la xestolide (**5**), la sécoxesténone (**6**), la xesténone (**2**) et l'aglycone de la sécoxestovanine A (**4**) suggère une dégradation biogénétique des métabolites **2**, **5** et **6** en triterpènes.

Mots clés : éponge, terpènoïdes, *Xestospongia*.

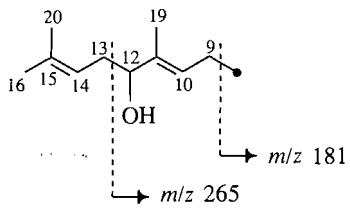
The northeastern Pacific sponge *Xestospongia vanilla* is a rich source of normal carbon number and degraded terpenoids having new carbon skeletons. We previously reported the isolation of xestodiol (**1**) (1), xestenone (**2**) (2), xestovanin A (**3**) (3), and secoxestovanin A (**4**) (3) from extracts of *X. vanilla*. This varied group of metabolites includes a C_{18} apocarotenoid, a C_{19} degraded terpenoid, and two triterpenoid glycosides. We now wish to report the structures of two new *X. vanilla* metabolites, xestolide (**5**) and secoxestenone (**6**). The discovery of xestolide and secoxestenone provides further support for the hypothesis that compounds **2**, **5**, and **6** are degraded triterpenoids (3).

[1]Author to whom correspondence may be addressed.

Xestospongia vanilla was collected along the shoreline of the Deer Group of islands in Barkley Sound, British Columbia. The sponge was extracted and the metabolites purified as previously described (2, 3).

Xestolide (**5**) was isolated as a colorless oil that gave a parent ion in the electron impact high resolution mass spectrum (EIHRMS) at 334.2158 daltons, corresponding to a molecular formula of $C_{20}H_{30}O_4$ (ΔM +1.4 mmu). The infrared (IR) spectrum of xestolide showed bands at 3360 and 1688 cm^{-1} that could be assigned to hydroxyl and conjugated carbonyl stretching vibrations, respectively. All 20 carbons were observed in the ^{13}C nmr spectrum of **5** and an APT experiment revealed 28 protons attached to carbon atoms (Table 1). The two remaining protons had to be attached to the oxygen atoms of hydroxyl functionalities. Seven deshielded carbon resonances (δ 165.5, 164.7, 144.1, 135.3, 119.6, 117.2, and 117.0) were assigned to one ester carbonyl and six olefinic carbons. The two additional sites of unsaturation not accounted for by the ester and olefinic functionalities but required by the molecular formula had to be rings.

A ten-carbon acyclic portion (Fragment A) of xestolide (**5**) was routinely identified from information obtained in a series of ^1H nmr experiments. The nature of the two independent scalar-coupled spin systems in Fragment A was established by analysis of COSY and double resonance data (Table 1). The indicated connectivity between the scalar-coupled spin systems (i.e., C11 → C12) was required by the observation of a nOe in H12 (δ 4.12) upon irradiation of H10 (δ 5.68). This nOe result also established the *E* configuration for the C10–C11 olefin. Intense peaks at *m/z* 265.1431 ($C_{15}H_{21}O_4$, ΔM +0.1 mmu: $M^+ - C_5H_9$) and 181.0871 daltons ($C_{10}H_{13}O_3$, ΔM +0.6 mmu: M^+ − Fragment A) in the EIHRMS of **5** were consistent with the presence of Fragment A in xestolide. Fragment A is also a substructure of the co-occurring metabolite secoxestovanin A (**4**) (3).



The remaining bicyclic portion of xestolide (**5**) had to have an elemental composition of $C_{10}H_{13}O_3$. In addition, it had to contain a trisubstituted α,β-unsaturated ester (IR: 1688 cm^{-1}; ^{13}C nmr δ: 165.5(C), 117.2(C), 164.7(C)), an olefinic methyl (^1H nmr δ: 1.80, s), an aliphatic methyl attached to a quaternary carbon (^1H nmr δ: 1.14, s), a ketal (^{13}C nmr δ: 105.3(C)), a

hydroxyl, and three aliphatic methylenes (^{13}C nmr δ: 29.3, 22.5, 34.0). Correlations in the ^1H COSY spectrum of xestolide (**5**) revealed that the three methylene carbons were contiguous (Table 1) and the oxygen count required that the hydroxyl and ester groups be attached to the ketal carbon. The apparent biogenetic similarity between xestolide and secoxestovanin A (**4**) guided the assembly of the identified components into the proposed structure shown in **5**.

Fragment A

A pair of SINEPT experiments (4), optimized for polarization transfer through C/H scalar couplings of 7 Hz, provided support for the proposed structure. Irradiation of the aliphatic methyl singlet protons at δ 1.14 (Me18) gave polarization transfer through three-bond couplings to the ketal (δ 105.3: C8) and β olefinic carbons (δ 164.7: C3), and through two-bond coupling to the quaternary carbon (δ 49.5: C7). Irradiation of the olefinic methyl protons at δ 1.80 (Me17) gave polarization transfer through three-bond coupling to the ester carbonyl carbon (δ 165.5: C1). These results are only compatible with the constitution shown in **5**. Further support for the proposed structure came from the EIHRMS. A prominent ion at *m/z*

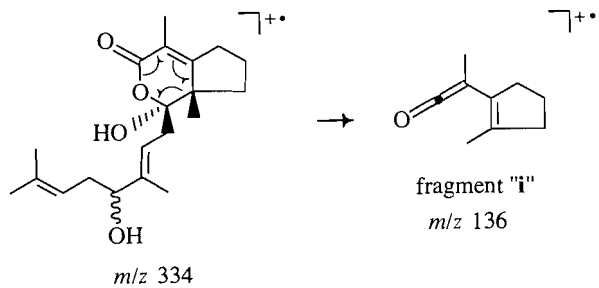

FIGURE 1

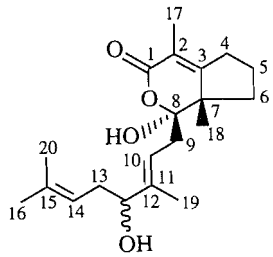
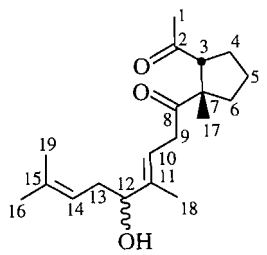


136.0885 daltons ($C_9H_{12}O$, ΔM −0.3 mmu) could be attributed to fragment **i** formed via a retro-Diels–Alder reaction as shown in Fig. 1.

A difference nOe experiment was used to establish the relative stereochemistry at carbons 7 and 8. Irradiation of the Me18 protons at δ 1.14 induced nOe's in both of the C9 methylene protons at δ 2.51 and 2.66, demonstrating that the acyclic side chain and the quaternary methyl group were *cis* as shown. Rather surprisingly, we were not able to detect any of the corresponding *trans* isomer that should be in equilibrium with the *cis* isomer through the open-chain form of the C8 hemiketal. Chemical proof that the lactone–hemiketal/carboxylic acid – keto equilibration does exist came from the treatment of xestolide (**5**) with diazomethane, resulting in a quantitative conversion to the ketoester **7**. Clearly the *cis* isomer is significantly more stable than the *trans* isomer.



Secoxestenone (**6**) was isolated in very low yield as a colorless oil. The highest mass ion in the EIHRMS of **6**

SCHEME 1

appeared at m/z 288.2081 daltons ($C_{19}H_{28}O_2$, ΔM −0.8 mmu) and the ^{13}C nmr spectrum of **6** showed 19 resonances, in agreement with the elemental composition of the ion. However, additional information in the ^{13}C nmr spectrum demonstrated that the mass spectral peak at m/z 288 daltons was not a molecular ion. Two ^{13}C nmr resonances at δ 212.6 and 210.6 could be assigned to ketone carbonyl carbons and a resonance at δ 77.2 could be assigned to a carbinol methine carbon, indicating that the molecule actually contained a total of three oxygen atoms. Therefore, we assumed that secoxestenone was readily losing water in the mass spectrometer and that the true molecular formula was $C_{19}H_{30}O_3$.

The ^1H nmr spectrum of secoxestenone (**6**) showed a strong resemblance to that of xestolide (**5**) and a series of double resonance and difference nOe experiments conducted on **6** demonstrated that it contained a ten-carbon acyclic residue identical to fragment A previously identified in **5** (C9 → C16: Table 1). The downfield shift of the C9 methylene protons in secoxestenone (**6**) (δ 3.26 and 3.34), relative to their position in xestolide (**5**) (δ 2.51 and 2.66), was attributed to the replacement of the C8 hemiketal functionality in **5** with a C8 ketone functionality in **6**. A methyl singlet at δ 2.16 in the ^1H nmr spectrum and one of the ketone carbonyl resonances in the ^{13}C nmr spectrum of **6** were assigned to an acetyl appendage. The absence of ^{13}C nmr evidence for additional unsaturated functionality demanded that the remainder of secoxestenone (C_6H_{10}) be monocyclic, to satisfy the unsaturation number required by the molecular formula. An aliphatic methyl singlet at δ 1.29 in the ^1H nmr spectrum of **6** had a nearly identical chemical shift to the protons on the ring junction methyl in secoxestovanin A (**4**) (DMSO-d_6 δ 1.33). This observation implied that both molecules contained similarly substituted cyclopentane rings and, along with the assumption of a common biogenetic origin for both of these *X. vanilla* metabolites, it led to the proposed structure **6** for secoxestenone. A strong nOe between the methyl protons at δ 1.29 (Me17) and the methine proton at δ 2.86 (H3) defined the relative stereochemistry around the cyclopentane ring as shown. Treatment of secoxestenone (**6**) with hot aqueous sodium hydroxide converted it cleanly into xestenone (**2**), providing chemical verification of the proposed structure.

Xestolide (**5**), secoxestenone (**6**), and xestenone (**2**) all have new terpenoid carbon skeletons. We previously suggested that xestenone (**2**) was a norditerpenoid (2). Implicit in our proposal was the assumption that the xestenone carbon skeleton had been formed from geranylgeranylpyrophosphate and that one methyl carbon had been lost at a late stage in the biogenesis. The subsequent discovery of xestovanin A (**3**), secoxestovanin A (**4**), xestolide (**5**), and secoxestenone (**6**) has made our original suggestion untenable. The similarity in structure between the aglycone of secoxestovanin A (**4**) and compounds **2**, **5**, and **6** suggests that the latter metabolites are degraded triterpenoids. Cleavage of the secoxestovanane skeleton at points "a" and "b" as shown in Scheme 1 would give the carbon skeletons of xestolide (**5**) and secoxestenone (**6**) directly. A biological aldol condensation on secoxestenone (**6**) followed by dehydration would give xestenone (**2**).

Experimental

Isolation of xestolide (5) and secoxestenone (6)

Xestospongia vanilla was collected in Barkley Sound, British Columbia, in January 1988. Fresh sponge material was homogenized with methanol in a Waring blender (2 kg dry weight). Concentration of the methanol extract *in vacuo* gave an aqueous suspension that was diluted with water (1 L) and extracted with dichloromethane (3 × 600 mL). The dried (Na_2SO_4) dichloromethane extract was concentrated *in vacuo* and fractionated via gel filtration chromatography on Sephadex LH20 (9:1 MeOH/CH_2Cl_2). Late eluting fractions were combined and further fractionated by gradient silica gel flash (CH_2Cl_2 to MeOH/EtOAc 1:4), silica gel preparative thin-layer (EtOAc), and reversed phase preparative thin-layer (MeOH/H_2O 8:2) chromatographies to give pure samples of xestolide (**5**) (7 mg, 3.5×10^{-4}%) and secoxestenone (**6**) (1.6 mg, 8×10^{-5}%).

Xestolide (5): colorless oil; FTIR (film): 3360, 1688 cm^{-1}; UV (MeOH): 233 nm (ε 7260); ^1H and ^{13}C nmr, see Table 1; EIHRMS, M^+: 334.2158 ($C_{20}H_{30}O_4$ ΔM 1.4 mmu); EILRMS: 334, 316, 265, 247, 181, 165, 153, 136.

Methylation of xestolide: A solution of xestolide (**5**) (3 mg) in diethyl ether (1 mL) was treated with excess diazomethane in ether at room temperature for 15 min. Removal of the ether and excess diazomethane *in vacuo* gave a quantitative yield of the keto methyl ester **7** as a colorless oil; ^1H nmr (300 MHz, $CDCl_3$) δ: 5.61 (t, 6.9, H10), 5.09 (t, 6.6, H14), 4.03 (t, 6.7, H12), 3.62 (s, OMe), 3.20 (dd, 16.6, 7.0, H9), 3.12 (dd, 16.6, 6.2, H9′), 2.72 (dd, 16.8, 7.5, H13), 2.55 (dd, 16.8, 8.8, H13′), 1.92 (s), 1.71 (s), 1.63 (s), 1.58 (s), 1.32 (s).

Secoxestenone (6): colorless oil; FTIR (film): 3444, 1705 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr (75 MHz, $CDCl_3$) δ: 212.6, 210.6, 139.9, 134.7, 119.9, 118.2, 77.2, 61.3, 59.5, 37.9, 35.5, 34.1, 29.9, 27.8, 26.0, 25.4, 22.5, 18.1, 12.2; EIHRMS, M − H_2O: 288.2081 ($C_{19}H_{28}O_2$, ΔM −0.8 mmu); EILRMS: 288, 270, 255, 219, 153, 125.

Conversion of secoxestenone (6) to xestenone (2)

Secoxestenone (**6**) (1 mg) was dissolved in a mixture of methanol (0.25 mL) and 0.1 N aqueous NaOH (0.75 mL) and the reaction mixture was stirred at room temperature for 7 days. The reaction mixture was diluted to 3 mL with water, neutralized with 0.1 N HCl, and extracted with dichloromethane (3 × 10 mL). Removal of the dichloromethane *in vacuo* gave a residue that was purified by thin-layer chromatography to give pure xestenone (**2**), identical to the authentic material by tlc and ^1H nmr comparison.

Tris-imidazole tripodands: synthesis and complexation

PIERRE G. POTVIN,[1] ROBERTO GAU, CATHLEEN M. UNRAU, AND NIKOLAUS K. GEHL
Department of Chemistry, York University, 4700 Keele Street, North York, Ont., Canada M3J 1P3

Received November 1, 1988[2]

PIERRE G. POTVIN, ROBERTO GAU, CATHLEEN M. UNRAU, and NIKOLAUS K. GEHL. Can. J. Chem. **67**, 1363 (1989).

Simple syntheses of seven imidazole-terminated tripodands are described. Some are *N*-methylated and water-soluble and others are *N*-benzylated and only lipo-soluble. Pronounced and unusual selectivity for hydrazinium ion was found in complexation experiments using Cram's extraction methods.

Key words: imidazole, tripodands, extraction, selectivity, hydrazinium.

PIERRE G. POTVIN, ROBERTO GAU, CATHLEEN M. UNRAU et NIKOLAUS K. GEHL. Can. J. Chem. **67**, 1363 (1989).

On décrit la synthèse simple de sept tripodands portant chacun trois groupements imidazoles. Certains sont *N*-méthylés et solubles dans l'eau et d'autres sont *N*-benzylés, seulement solubles en phases organiques. On rapporte des expériences suivant les méthodes d'extraction de Cram qui ont démontré une sélectivité inhabituelle et prononcée pour l'ion hydrazinium par ceux-ci.

Mots clés : imidazole, tripodands, extraction, sélectivité, hydrazinium.

In complexation chemistry, podands (1), multi-"armed" acyclic ligands, can offer many of the benefits of cryptands without much of the associated synthetic cost. The "lariat ethers" and BIBLEs are good examples of podando-coronands isomorphic with [2]- and [3]-cryptands that display cryptand-like binding (2). In related work (3), we prepared a large tripodand bearing six imidazole imino N^{π} (N-3) binding sites. In the molecule's binding conformation(s), these are arranged in two loci that are contained within the concave portion. Thus, the acyclic ligand becomes cryptating or encapsulating as it binds, and isomorphic with [2]-cryptands. Herein we describe the one-step preparation, using the same chemistry, of both lipophilic and hydrophilic varieties of simpler tripodands bearing imidazole binding groups at the arms' termini. The flexible tripod of N-3 donor atoms can define a tetrahedral or octahedral binding locus most suitable for hydrogen bond donors and transition metal ions. We also report preliminary results of complexation studies with these substrates.

5-Oxo-5,6,7,8-tetrahydro-imidazo[1,5-*c*]pyrimidine (3, 4), **1**, can be specifically alkylated at N-3 with CH_3I (3, 5) or $PhCH_2Br$ (6) to produce salts **2***a* or **2***b*, respectively, as latent N^{τ} (N-1)-alkylated histamine units. These salts (and **1**) can be ring-opened by a variety of primary and secondary amines. In dry DMF at 80–90°C, salt **2***a* reacted with triamines **3**, **4**, and **5** to produce the N—CH_3 podands **6***a*,[3] **7***a*,[4] and **8***a*,[5] in 82%, 80%, and 70% unoptimized yields, respectively.[6,7] These podands are readily soluble in both organic solvents and H_2O. Salt **2***b* similarly furnished the N—CH_2Ph podands **6***b*,[8] **7***b*,[9] and **8***b*[10] from the same triamines in 37%, 27%, and 44%

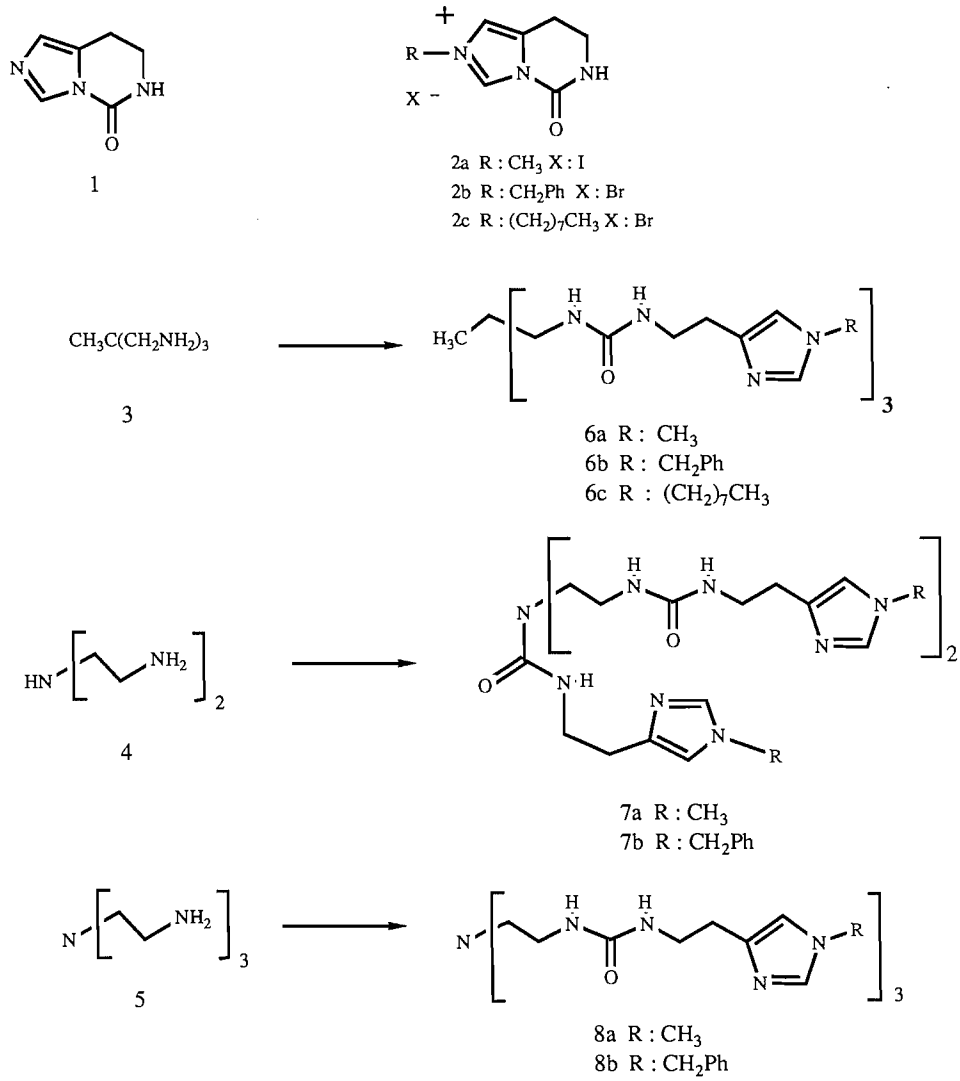
[3]Results for **6***a* ^{1}H-nmr ($CDCl_3$): δ 7.28 (s, 3H, H-2′), 6.65 (s, 3H, H-5′), 6.19, 5.38 (2bt, 3H + 3H, NH), 3.58 (s, 9H, NCH_3), 3.39 (dt, 6H, J = 5.9, 6.3 Hz, CH_2NH), 2.83 (d, 6H, J = 6.2 Hz, CH_3CCH_2), 2.67 (t, 6H, J = 6.4 Hz, CH_2CH_2NH), 0.72 (s, 3H, CCH_3) ppm. ^{13}C-nmr ($CDCl_3$): δ 159.1 (CO), 140.1 (C-4′), 137.1 (C-2′), 117.1 (C-5′), 43.2 (CH_2CH_2NH), 41.0 (CCH_3), 40.1 (CH_3CCH_2), 33.1 (NCH_3), 28.6 (CH_2CH_2NH), 18.9 (CCH_3) ppm.

[4]Results for **7***a*: ^{1}H-nmr (CD_3OD): δ 7.49 (s, 3H, H-2′), 6.86, 6.83 (2s, 3H, H-5′), 3.65 (s, 9H, NCH_3), 3.35, 3.31 (2t, 12H), 3.18 (t, 2H, CCH_2CH_2NH), 2.72, 2.66 (2t, 6H, CCH_2CH_2NH) ppm. ^{13}C-nmr ($CDCl_3$): δ 159.1, 158.6 (CO), 139.5, 139.2 (C-4′), 136.6 (C-2′), 117.0 (C-5′), 47.4 (NCH_2CH_2NH), 40.5, 39.6, 38.7 (NCH_2CH_2NH, CCH_2CH_2NH), 32.8 (NCH_3), 28.2, 28.0 (CCH_2CH_2NH) ppm.

[5]Results for **8***a*: ^{1}H-nmr ($CDCl_3$): δ 7.32 (s, 3H, H-2′), 6.68 (s, 3H, H-5′), 6.05, 5.85 (2bt, 3H + 3H, NH), 3.61 (s, 9H, NCH_3), 3.37 (bdt, 6H, NCH_2CH_2NH), 3.15 (bdt, 6H, CCH_2CH_2NH), 2.67 (bt, 6H, NCH_2CH_2NH), 2.46 (bt, 6H, CCH_2CH_2NH) ppm. ^{13}C-nmr ($CDCl_3$): δ 159.2 (CO), 140.3 (C-4′), 136.8 (C-2′), 117.2 (C-5′), 54.6 (NCH_2CH_2NH), 40.1 (CCH_2CH_2NH), 38.1 (NCH_2CH_2NH), 33.3 (NCH_3), 28.7 (CCH_2CH_2NH) ppm.



[6]General synthetic procedure for **6**, **7**, **8**: A mixture of 1 mmol of salt **2***a*, **2***b*, or **2***c* and 0.33 mmol of triamine **3**, **4**, or **5** in 1–5 mL dry DMF was heated in a capped, Ar-flushed flask at 80–90°C overnight. The cooled mixture was diluted with H_2O and neutralized by Dowex IRA-400 resin (OH^- form). After evaporation to dryness, the crude products were purified by centrifugal chromatography on a Harrison Research Model 7924T Chromatotron, using rotors coated with 4 mm Merck GF_{254} Al_2O_3 containing 10 wt.% $CaSO_4$, and eluting with 5–20 vol.% MeOH in CH_2Cl_2.

[7]All of the podands described were thick, hygroscopic oils that were chromatographically homogeneous on tlc plates and were characterized by ^{1}H-nmr, ^{13}C-nmr, ir and mass spectroscopy. Attempts at preparing crystalline hydrochloride or picrate salts failed and resulted in darkened material. As well, $CHCl_3$ solutions of these ligands became discoloured over a period of a few days, probably owing to reactions with the photo- or base-induced decomposition products of the solvent.

[8]Results for **6***b*: ^{1}H-nmr ($CDCl_3$): δ 7.42 (s, 3H, H-2′), 7.33 (m, 9H, Ph), 7.14 (m, 6H, Ph), 6.68 (s, 3H, H-5′), 5.91, 5.12 (2bt, 3H + 3H, NH), 5.03 (s, 6H, CH_2Ph), 3.43 (dt, 6H, J = 5.8, ≅6 Hz, CH_2CH_2NH), 2.87 (d, 6H, J = 6.4 Hz, CH_3CCH_2NH), 2.71 (t, 6H, J = 6.4 Hz, CH_2CH_2NH), 0.72 (s, 3H, CH_3) ppm. ^{13}C-nmr ($CDCl_3$): δ 159.0 (CO), 140.3 (C-4′), 136.6 (C-2′), 136.0, 128.9, 128.1, 127.3 (Ph), 50.7 (CH_2Ph), 43.4 (CH_2CH_2NH), 41.0 (CH_3C), 40.2 (CH_3CCH_2NH), 28.6 (CH_2CH_2NH), 19.1 (CH_3) ppm.

[9]Results for **7***b*: ^{1}H-nmr ($CDCl_3$): δ 7.39, 7.35 (2s, 1H + 2H, H-2′), 7.28 (m, 9H, Ph), 7.10 (m, 6H, Ph), 6.69, 6.65 (s, 1H + 2H, H-5′), 6.56, 6.29, 6.04 (3bt, 1H + 2H + 2H, NH), 4.95, 4.93 (2s, 6H, CH_2Ph), 3.37 (bm, 8H, NCH_2CH_2NH), 3.20 (bm, 6H, CCH_2CH_2NH), 2.67, 2.65 (2t, 6H, CCH_2CH_2NH) ppm. ^{13}C-nmr ($CDCl_3$): δ 159.2, 158.7 (CO), 140.3, 140.1 (C-4′), 136.6 (C-2′), 136.0, 128.6, 127.9, 127.1 (Ph), 50.4 (CH_2Ph), 47.8 (NCH_2CH_2NH), 40.7, 39.8, 39.0 (CH_2NH), 28.7, 28.3 (CCH_2CH_2NH) ppm.

[10]Results for **8***b*: ^{1}H-nmr ($CDCl_3$): δ 7.57 (s, 3H, H-2′), 7.30 (m, 9H, Ph), 7.16 (m, 6H, Ph), 6.75 (s, 3H, H-5′), 6.37, 6.28 (2bt,

unoptimized yields, respectively.[6,7] Although the reactions had proceeded to completion, contamination by impurities with very similar chromatographic mobilities was responsible for the lower isolated yields. When $CDCl_3$ solutions of the N—CH_2Ph ligands were shaken with D_2O, no ligand could be detected in the D_2O layer. *N*-octyl podand **6***c* was similarly prepared, albeit in only poor yield, from salt **2***c*, itself obtained by heating **1** and 1-bromooctane at 80–90°C overnight in dry DMF, followed by trituration with ether.

$CHCl_3$ or $CDCl_3$ solutions of the N—CH_2Ph podands **6***b* and **7***b* were able to extract picrate (Pic^-) salts of Na^+, K^+, and NH_4^+, and $H_2NNH_3^+$ (7) from aqueous solutions. With the latter substrate, the yellow colour of Pic^- was very strong in the organic phase. The extractions could be monitored by ^{1}H-nmr spectroscopy. The ratio R^{nmr}, reported in Table 1, of complexed substrate to total ligand (8) was calculated, assuming 1:1 stoichiometry, as three times the ratio of the integration of the Pic^- signal (near 9 ppm) divided by that of the ligand CH_2Ph signals (near 5 ppm). By this method, it was also found that Na^+ tosylate, Na^+ salicylate, and K^+ hydrogen phthallate were not measurably extracted. Unfortunately, extractions of Zn^{2+} or Co^{2+} (as the nitrates) in the presence of NaPic resulted in the deposition of thick oils. This also occurred with the more lipophilic *N*-octyl analogue **6***c*.

Integration of the Pic^- peak is subject to much error, especially with very poor or very good substrates. The more accurate uv method of Cram *et al.* (9) was therefore also used: aliquots of both the aqueous and organic phases were diluted in CH_3CN and the absorbances at 380 nm of each were measured against appropriate blanks. Table 1 summarizes the results obtained with **6***b*. Ligand **7***b* behaved very similarly. The quantities R^{uv}, representing the ratios of substrate to total ligand, calculated (9) from the absorbances of the diluted aliquots from the organic layers, were closer to those calculated from nmr integration ratios. The aliquots from the aqueous phases furnished ratios that deviated significantly from these values. We have traced this to a significant drop in the extinction coefficients with increasing concentration of both H_2O and Pic^-, depending on the cation. Accordingly, extraction constants and association constants were calculated using the *R* values from the organic phases. The errors in Table 1 were calculated according to the analysis of ref. 9*c*. Using pessimistic error estimates in weights and volumes, errors of 1.1% and 0.7%

3H + 3H, NH), 5.01 (s, 6H, CH_2Ph), 3.36 (bt, 6H, NCH_2CH_2NH), 3.11 (bt, 6H, CCH_2CH_2NH), 2.68 (bt, 6H, NCH_2CH_2NH), 2.40 (bt, 6H, CCH_2CH_2NH) ppm. ^{13}C-nmr ($CDCl_3$): δ 159.1 (CO), 139.2 (C-4′), 136.0 (C-2′), 135.7, 128.7, 128.0, 127.3 (Ph), 54.3 (NCH_2CH_2NH), 50.7 (CH_2Ph), 39.7 (CCH_2CH_2NH), 37.5 (NCH_2CH_2NH), 28.6 (CCH_2CH_2NH) ppm.

[b] Calculated using a ± 4.2% error (9*c*) in the $CHCl_3$–H_2O distribution constants taken from ref. 9*b*.
[c] A value for the distribution constant of NH_2NH_3Pic is lacking.

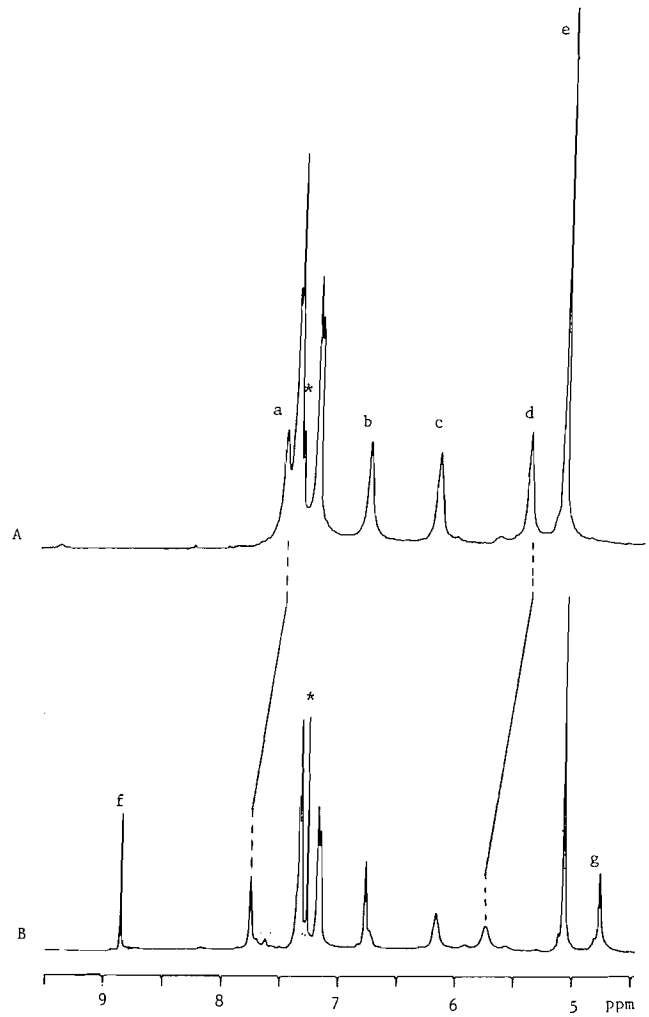

FIG. 1. Downfield regions of ^1H-nmr spectra of free **6***b* (trace A) and the complex of **6***b* with NH_2NH_3Pic (trace B) showing downfield displacements of ligand signals (see text). Assignments are (*a*) imidazole H-2, (*b*) imidazole H-5, (*c*) and (*d*) NH, (*e*) CH_2Ph, (*f*) Pic^-, (*g*) entrained H_2O, and (*) $CHCl_3$.

were calculated for ligand and metal concentrations, respectively. This led to an error estimate of 5.6% in R^{uv} (*cf.* 4.9% in ref. 9*c*). The corresponding uncertainties in K_e, which depend on the value of R^{uv}, are large but lead to much smaller uncertainties in log K_e and log K_a.

1:1 Complex stoichiometries were assumed, but were difficult to prove. Job plots of the chemical shifts of ligand signals during titration of a $CDCl_3$ solution of **6***b* with concentrated DMSO-d_6 solutions of $NaClO_4$ and $Zn(ClO_4)_2$ showed no asymptotic behaviour. We found that DMSO-d_6 alone induced strong upfield shifts (*cf.* ref. 8), but subtraction of these effects also failed to yield asymptotic behaviour. Evidence for binding at the N^π sites was provided by the sizeable shifts for the imidazole H-2 and H-4 signals from their positions in the free ligands. For instance, shaking equal volumes of 1.000×10^{-2} *M* NH_2NH_3Pic in D_2O and 4.355×10^{-3} *M* **6***b* in $CDCl_3$ resulted in downfield shifts of 0.33 ppm and 0.08 ppm for the imidazole H-2 and H-5 signals, respectively, and 0.50 ppm for one NH signal, while all other signals were shifted less than 0.05 ppm (Fig. 1). The order of extraction selectivity and the NH shift, virtually absent with Na^+ or K^+, suggested that the urea groups may be involved in secondary binding of the ammonium ions. Indeed, when a 3.964×10^{-3} *M* $CDCl_3$ solution of **7***b* was mixed with an equal volume of a 1.000×10^{-2} *M* aqueous solution of H_2NNH_3Pic, the two *C*=O resonances were shifted downfield by an average 0.42 ppm, compared to a 0.91 ppm upfield shift for the imidazole C-2 signal. All of the complexes were in rapid exchange with free ligand, on the nmr time scale.

Ligand **6***b* is less selective overall than macrocyclic carriers, but clearly preferring $NH_2NH_3^+$. To our knowledge, this is the first instance of such preference. Although NH_4^+ is extracted to a greater extent than Na^+, it is also more soluble in $CDCl_3$, and their association constants are about the same and comparable to those of K^+-selective 2,3-naphtho-18-crown-6 (with log K_a values of 5.93 for Na^+ and 6.88 for NH_4^+; see ref. 9*c*). The extraction constants calculated for NH_4Pic and NH_2NH_3Pic suggest that the N—CH_2Ph podands may be good passive ion carriers for ammonium ions (10). Further studies with alkylammonium ion substrates are underway. The insolubility of the transition metal complexes somewhat restricts the usefulness of these ligands as carriers. Complexation studies in H_2O with the N—CH_3 ligands and transition metal ions will be reported elsewhere.

Absolute rate constants for lipid peroxidation and inhibition in model biomembranes

LAWRENCE ROSS COATES BARCLAY,[1] KIMBERLY ANN BASKIN, STEVEN JEFFREY LOCKE, AND MELINDA RUTH VINQVIST
Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received October 7, 1988

LAWRENCE ROSS COATES BARCLAY, KIMBERLY ANN BASKIN, STEVEN JEFFREY LOCKE, and MELINDA RUTH VINQVIST. Can. J. Chem. **67**, 1366 (1989).

The benzophenone-photosensitized free radical autoxidation of linoleic acid in 0.50 M SDS and of dilinoleoylphosphatidylcholine (DLPC) bilayers follows the classical equation, $-d[O_2]/dt = k_p/2k_t^{1/2} \times [RH]R_i^{1/2}$. Rate constants for chain propagation, k_p, and termination, $2k_t$, at 37°C in 0.50 M SDS ($k_p = 39.1\ M^{-1}\ s^{-1}$, $2k_t = 4.17 \times 10^5\ M^{-1}\ s^{-1}$), and in DLPC bilayers ($k_p = 36.1\ M^{-1}\ s^{-1}$, $2k_t = 1.32 \times 10^5\ M^{-1}\ s^{-1}$) are reduced markedly compared to those in homogeneous solution. Results are interpreted in terms of hydrogen bonding of polar peroxyl radicals that diffuse towards the aqueous phase. The activities, measured by the inhibited autoxidation method, of typical phenolic antioxidants 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMHC), α-tocopherol (α-T), 2,5,7,8-tetramethyl-6-hydroxychroman-2-carboxylate (Trolox), and butylated hydroxytoluene (BHT) range from 4.3×10^3 to $1.9 \times 10^3\ M^{-1}\ s^{-1}$ for photoinitiated runs and from 8.9×10^3 to $2.7 \times 10^3\ M^{-1}\ s^{-1}$ for runs thermally initiated with azobis-2,4-dimethylvaleronitrile (DMVN). The large reductions in k_{inh} for α-T, PMHC, and Trolox in DLPC bilayers compared to known values in chlorobenzene are explained in terms of hydrogen bonding of the *para* ether oxygen and phenolic hydroxyl group.

Key words: autoxidation, membranes, antioxidants, rate constants.

LAWRENCE ROSS COATES BARCLAY, KIMBERLY ANN BASKIN, STEVEN JEFFREY LOCKE et MELINDA RUTH VINQVIST. Can. J. Chem. **67**, 1366 (1989).

L'auto-oxydation radicalaire de l'acide linoléique, photosensibilisée par la benzophénone et effectuée dans du SDS à 0,50 M ou dans des bicouches de dilinoléoylphosphatidylcholine (DLPC), suit l'équation classique : $-d[O_2]/dt = k_p/2k_t^{1/2} \times [RH]R_i^{1/2}$. Les constantes de vitesse pour la propagation de la chaîne, k_p, et pour la terminaison, $2k_t$, mesurées à 37°C, sont : $k_p = 39{,}1\ M^{-1}\ s^{-1}$, $2k_t = 4{,}17 \times 10^5\ M^{-1}\ s^{-1}$ dans du SDS à 0,50 M et $k_p = 36{,}1\ M^{-1}\ s^{-1}$, $2k_t = 1{,}32 \times 10^5\ M^{-1}\ s^{-1}$ dans des bicouches de DLPC. On interprèts les résultats en fonction de liaisons hydrogènes des radicaux peroxyles polaires qui diffusent vers la phase aqueuse. Les activités des anti-oxydants phénoliques typiques, pentaméthyl-2,2,5,7,8 hydroxy-6 chromane (PMHC), α-tocophérol (α-T), tétraméthyl-2,5,7,8 hydroxy-6 chromanecarboxylate-2 (Trolox) et hydroxytoluène butylé (BHT), telles que mesurées par la méthode de l'inhibition de l'auto-oxydation, varient de $4{,}3 \times 10^3$ à $1{,}9 \times 10^3\ M^{-1}\ s^{-1}$ pour les essais photosensibilisés et de $8{,}9 \times 10^3$ à $2{,}7 \times 10^3\ M^{-1}\ s^{-1}$ pour des essais initiés d'une façon thermique à l'aide d'azobis-2,4-diméthylvaléronitrile (DMVN). On explique les réductions importantes qui sont observées pour les valeurs de k_{inh} du α-T, du PMHC et du Trolox dans des bicouches de DLPC, comparées aux valeurs connues dans le chlorobenzène, en faisant appel à une liaison hydrogène du groupement hydroxyle phénolique avec l'oxygène de l'éther en position *para*.

Mots clés : auto-oxydation, membranes, anti-oxydants, constantes de vitesse.

[Traduit par la revue]

Peroxidation of polyunsaturated fatty acid (PUFA) chains in phospholipid membranes is related to important pathological events (1–5). We now report some recent results on the quantitative kinetic behavior of peroxyl radicals photochemically or thermally generated in phosphatidylcholine (PPC) membranes by measurements of (*i*) the absolute rate constants of peroxyl radical propagation and termination steps in autoxidation, and (*ii*) the activity of phenolic antioxidants as inhibitors of free radical peroxidation.

[1]Author to whom correspondence may be addressed.

Autoxidation of PUFA chains in PPC membranes (6–10) and micelles (11–13) follows the classical rate law [1]:

$$[1] \quad -d[O_2]/dt = k_p/(2k_t)^{1/2} \times [RH]R_i^{1/2}$$

where RH is the substrate, R_i the rate of free radical chain initiation, k_p the propagation rate constant, and $2k_t$ the chain termination rate constant. The kinetic studies to date give useful information on the *oxidizability* of PUFA in aggregates in terms of the rate ratios, $k_p/(2k_t)^{1/2}$. The separate absolute rate constants provide much more significant information on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

dynamics of peroxyls in membranes and we now report values of k_p and $2k_t$ for bilayers. The activities of peroxyl radical trapping phenolic antioxidants are also of continuing interest (14–22) and we report herein for the first time on the absolute reactivity of several phenolic antioxidants in PPC membranes by determinations of the rate constants for eq. [2].

$$[2] \quad ROO^{\bullet} + ArOH \xrightarrow{k_{inh}} ROOH + ArO^{\bullet}$$

Dilinoleoylphosphatidylcholine (DLPC), purified and in multilamellar vesicles (MLV) in phosphate buffer (pH 7.0) containing benzophenone (BP) or the water-soluble derivative 4-sulphomethylbenzophenone (BP^-) as photoinitiators, was used as oxidizable substrate. 2,5-Dimethylazobisvaleronitrile (DMVN) was used as a lipid-soluble thermal initiator. The antioxidants used were α-tocopherol (α-T), 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMHC), 2,5,7,8-tetramethyl-6-hydroxychroman-2-carboxylate (Trolox), and 2,6-di-*tert*-butyl-4-methylphenol (BHT). The procedures for preparing the MLV bilayers and the rotating sector method for measuring absolute rate constants have been described in detail (13). The inhibition rate constants (k_{inh}) were determined from oxygen uptake during antioxidant inhibition periods by using the integrated expression for the kinetics during inhibition (14, 16), eq. [3],

$$[3] \quad \Delta[O_2]_t = -k_p/k_{inh} \times [RH] \ln (1 - t/T)$$

where k_p is the propagation rate constant determined separately for the same system. Plots of $\Delta[O_2]$ versus $-\ln (1 - t/T)$, where T is the induction period and t the time during the inhibition period after injection of the antioxidant, were used to calculate k_{inh}, and the values were comparable to those calculated from the oxygen consumed at points during the induction period. The kinetic order in R_i for photoinitiated runs was determined by varying the light intensity with six neutral density filters.

Absolute rate constants determined for linoleate in bilayers and 0.50 M SDS at 37°C for comparison purposes are given in Table 1. The kinetic order in light intensity, 0.532, for these MLV liposomes indicates half-order dependence on the R_i, which is required for the classical rate law in eq. [1] to be obeyed. Absolute rate constants for linoleate (Table 1) are depressed significantly in membranes, $k_p = 36.1 \pm 1.2$ and $2k_t = (1.32 \pm 0.16) \times 10^5$ (Runs 2(a)–(c)), and micelles, $k_p = 39.1 \pm 1.1$ and $2k_t = (4.17 \pm 0.17) \times 10^5$ (Runs 1(a)–(c)), compared with those in solution (units of $M^{-1}\ s^{-1}$). For example, the k_p for DLPC bilayers is reduced by 1/4 and the $2k_t$ reduced by 1/50 of those values reported for DLPC in *tert*-butyl alcohol (8), and the $2k_t$ for the linoleate chain in bilayers is more than two orders of magnitude less than for linoleic acid in this solvent (13). The marked reduction in the $2k_t$ term observed in SDS micelles (13) and in bilayers is attributed to the intrinsic polarity of peroxyl radicals (23). Such polar species would diffuse rapidly from the hydrophobic region of micelles or bilayers, where they initially form, towards the polar aqueous region, where strong hydrogen bonding interactions would lower the $2k_t$ substantially.

The k_{inh} values, determined by photoinitiation, are summarized in Table 2. The k_{inh} values of the three lipid-soluble antioxidants α-T, PMHC, and BHT show remarkable differences from those found in homogenous solution (14), in two respects: (*i*) in bilayers the values are all similar, within experimental error, whereas in chlorobenzene BHT is much less active, and (*ii*) the activities of α-T and PMHC in bilayers *are reduced by at least three orders of magnitude compared to*

TABLE 1. Absolute rate constants for autoxidation of linoleate in SDS micelles and DLPC bilayers photoinitiated with benzophenone at 37°C

Run no.[a]	Substrate[b]	Medium	R_i[c] ($M\ s^{-1} \times 10^7$)	Oxidizability ($M^{-1/2} s^{-1/2} \times 10^2$)	ν[d]	γ	m	k_x (s^{-1})	$2k_t$[e] ($M^{-1} s^{-1} \times 10^{-5}$)	k_p[e] ($M^{-1} s^{-1}$)

[a]BP amounts used: 1(a), (b), 2.22×10^{-5} mol; 1(c), 4.44×10^{-7} mol; 2(a)–(c) 8.23×10^{-7} mol. Run 2(d) used BP^- (see text) 1.00×10^{-6} mol.
[b]L.A., linoleic acid, 4.76×10^{-4} mol; DLPC, dilinoleoylphosphatidylcholine, 4.48×10^{-5} mol.
[c]R_i, rate of chain initiation measured by the induction period method (13) with Trolox.
[d]The kinetic chain length; $\nu = (-d[O_2]/dt)/R_i$.
[e]Methods of calculation and the parameters γ, m, k_x are given in ref. 13. The errors in $2k_t$ and k_p in each run were determined by three measurements.

TABLE 2. Inhibition rate constants for phenolic antioxidants during photoinitiated peroxidation of DLPC bilayers at 37°C

No.[a]	Antioxidant (mol × 10^7)	R_i[b] ($M\ s^{-1} \times 10^6$)	k_{inh}[c] ($M^{-1}\ s^{-1} \times 10^{-3}$)	ν range[d]
1	α-T (1.87)	0.561–2.15	2.9 ± 0.3	2.9–6.3
2	PMHC (1.88)	2.32 –3.14	4.3 ± 1.1	2.5–5.8
3	BHT (1.89)	2.24 –2.46	1.9 ± 0.1	2.7–8.4
4	Trolox (1.78–1.88)	1.90 –2.78	2.5 ± 0.3	2.6–8.4

[a]Each run was repeated at least three times, using 8.17×10^{-7} mol benzophenone and DLPC $(4.58–4.76) \times 10^{-5}$ mol, giving calculated reaction volumes of $(4.48–4.70) \times 10^{-5}$ L.

[b]The R_i was varied by using different light intensities.

[c]k_{inh} values calculated from plots of $\Delta[O_2]$ versus $-\ln(1 - t/T)$, and using an averaged $k_p = 36.1\ M^{-1}\ s^{-1}$.

[d]The chain length calculated at points along the induction period from the equation (ref. 14, using $n = 2$) $\nu_t = ([O_2]_t - [O_2]_{t=0})/n[AH]_0(1 - t/T) \ln(1 - t/T)$.

TABLE 3. Antioxidant activities of phenolic antioxidants during thermally initiated peroxidation of DLPC bilayers by DMVN[a] at 37°C

No.[b]	Antioxidant (mol × 10^8)	R_i ($M\ s^{-1} \times 10^8$)	k_{inh}[c] ($M^{-1}\ s^{-1} \times 10^{-3}$)	ν range[d]
1	α-T (0.630)	1.65	3.9 ± 0.1	47–116
2	PMHC (1.50)	5.10–5.28	8.9 ± 0.7	7–31
3	BHT (1.51)	5.19–5.37	2.7	26–86
4[e]	Trolox (0.211–0.633)	1.46–4.80	6.5 ± 0.7	29–317

[a]Amounts of DMVN used; Run No. 1, 9.6×10^{-7} mol; Nos. 2 and 3, 32×10^{-7} mol; No. 4, $(9.6–32) \times 10^{-7}$ mol.

[b]Each run was repeated at least twice. The amount of DLPC used was $(5.74–5.93) \times 10^{-5}$ mol, giving calculated reaction volumes of $(5.61–5.80) \times 10^{-5}$ L.

[c,d]See footnotes *c* and *d*, Table 2.

[e]Results averaged from 13 separate runs.

those in chlorobenzene. The superior antioxidant activity of α-T and PMHC in solution was attributed to stereoelectronic effects, involving overlap of electron lone pairs on the *para* ether oxygen with the aromatic π system (14). In bilayers, the chroman ring of α-T (and presumably PMHC) is now known to be situated near the aqueous surface (24). We suggest that, in this aqueous bilayer, the stereoelectronic effect is inhibited by hydrogen bonding interactions of the ether oxygen lone pair with water. The antioxidant activity of BHT, which has no ether oxygen, is not so dramatically affected by the bilayer system. Such aqueous solvation effects are also used to explain the depressed antioxidant activities in micelles (13, 16).

k_{inh} values can vary somewhat with the initiation method (16, 21). To further illustrate this point, we report some recent results for k_{inh} determined in DLPC bilayers where peroxidation was thermally initiated with DMVN, when the sample sizes and rates of chain initiation (R_i) were selected to give chain lengths ranging approximately an order of magnitude higher (see Table 3) than in the photoinitiated runs. The k_{inh} values for lipid-soluble inhibitors α-T, BHT, and PMHC are 1.3 to 2 times those measured by photoinitiation.[2] These results do not alter our main conclusion, namely, that these phenolic antioxidant activities are dramatically lowered, by as much as 2 to 3 orders of magnitude, in phospholipid membranes compared to those in homogeneous solution. The antioxidant activities in SDS micelles (13, 16, 21) are intermediate between those in solution and the present values in membranes, while the order of activity of the lipid-soluble ones appears to be PMHC > α-T > BHT in the three systems. We postulate that the more dramatic reduction in model membranes is due to a combination of solvation forces and differential diffusion dynamics of bilayer-bound lipid peroxyl radicals and inhibitors in membranes compared to either homogeneous solution or micelles.

[2]Our k_{inh} values in Table 2 are *not* corrected for oxygen uptake during inhibition periods, it being assumed that the ketyl radicals do *not* compete significantly for O_2, $(C_6H_5)_2$—$\dot{C}OH + O_2 \rightarrow (C_6H_5)_2$—$C(OH)O\dot{O}$, with substrate radicals. As a referee points out, this could lead to "incorrect values" at short chain lengths. Oxygen absorbed by initiating radicals would tend to reduce measured k_{inh} values.

Metabolites of the fairy ring fungus, *Marasmius oreades*. Part 2. Norsesquiterpenes, further sesquiterpenes, and agrocybin

WILLIAM A. AYER AND PETER A. CRAW
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 10, 1989

WILLIAM A. AYER and PETER A. CRAW. Can. J. Chem. **67**, 1371 (1989).

The fungus *Marasmius oreades* has previously been reported to produce the sesquiterpenes marasmone (**1**), anhydromarasmone (**2**), isomarasmone (**3**), and dihydromarasmone (**4**) when grown in liquid culture. We report herein several other sesquiterpene metabolites of the same skeleton but with differing oxidation patterns. The norsesquiterpenes *O*-formyloreadone (**15***a*), 3α-hydroxyoreadone (**15***c*), and dehydrooreadone (**17***b*) are also reported. It is suggested that the formyl group in **15***a* is derived biogenetically from C-15 of a precursor sesquiterpene. Oxidation of 1α,15-dihydroxymarasmene (**13***a*), one of the new sesquiterpenes reported, with one equivalent of pyridinium dichromate gives *O*-formyloreadone (**15***a*) as one of the products. Agrocybin (**5**), a polyacetylene amide previously isolated from the fungus *Agrocybe dura*, has also been isolated from the cultures of *M. oreades*. It is suggested that agrocybin (**5**) is the phytotoxic compound responsible for the killing of grass caused by the fairy ring mushroom fungus.

Key words: sesquiterpenes, fungal metabolites, drimanes, fairy ring mushroom, agrocybin.

WILLIAM A. AYER et PETER A. CRAW. Can. J. Chem. **67**, 1371 (1989).

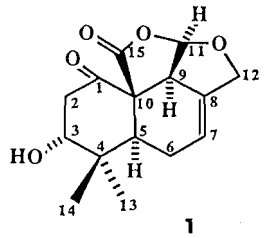
On a déjà rapporté que le champignon *Marasmius oreades*, en croissance dans une culture liquide, produit les sesquiterpènes marasmone (**1**), l'anhydromarasmone (**2**), l'isomarasmone (**3**) et la dihydromarasmone (**4**). On rapporte dans cet article plusieurs autres métabolites sesquiterpéniques ayant le même squelette mais avec des modèles d'oxydation différents. Nous décrivons également les norsesquiterpènes : la *O*-formyloréadone (**15***a*), l'hydroxy-3α-oréadone (**15***c*) et la déhydrooréadone (**17***b*). On suggère que le groupe formyle du terpène (**15***a*) dérive biogénétiquement du carbone C15 d'un sesquiterpène précurseur. L'oxydation du dihydro-1α,15-marasmène (**13***a*), un des nouveaux sesquiterpènes rapportés, avec un équivalent de dichromate de pyridinium donne entre produits la *O*-formyloréadone (**15***a*). On a également isolé l'agocybine (**5**), un amide polyacétylénique isolé antérieurement du champignon *Agrocybe dura* à partir des cultures de *M. oreades*. On suggère que l'agrocybine (**5**) est le composé phytotoxique responsable de la destruction du gazon provoquée par le mousseron du champignon.

Mots clés : sesquiterpènes, métabolites du champignon, drimanes, mousseron, agrocybine.

[Traduit par la revue]

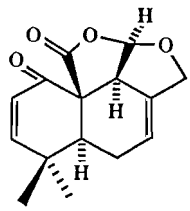
Introduction

The mycelium of many mushrooms has a tendency to grow in all directions from a control point in the ground, forming a large circular colony. When the time for sporulation arrives, the fruiting bodies are produced at the periphery of the colony and thus produce a ring. This ring is called a fairy ring because of an old superstition that mushrooms growing in a circle represent the path of dancing fairies (1). *Marasmius oreades* (Bolt.: Fr) Fr., known as the fairy ring mushroom, is the best known of a number of mushrooms that form rings. In the case of *M. oreades*, these rings have an inner and outer zone of stimulated grass growth and a zone of dead grass in the middle (2). The perennial mycelium is known to live for as many as 400 years, forming rings on the prairies over a kilometer in diameter and producing a crop of edible mushrooms each year (1, 2). In the previous paper on the metabolites of *M. oreades* we reported the structures of four related drimane-type sesquiterpenes, marasmone (**1**), anhydromarasmone (**2**), isomarasmone (**3**), and dihydromarasmone (**4**), produced when the fungus is grown in liquid culture on a potato dextrose – yeast (PDY) medium (3). In this article we describe several more metabolites produced by liquid cultures of *M. oreades*, including some biogenetically interesting norsesquiterpenes. We also describe the isolation of agrocybin (**5**), which we believe may be the compound responsible for the phytotoxicity of culture filtrates of *M. oreades* (4) and for the dead zone in the middle of the band of the fairy ring.



Results and discussion

In the previous paper (3) we reported the structures of four new sesquiterpene metabolites (**1–4**) produced when *M. oreades* is grown in liquid culture on a PDY medium. We find that these compounds are not produced in isolable amounts when the fungus is grown on a malt extract – glucose (MEG) medium, but that several related metabolites, some of which are also produced on the PDY medium, are obtained.[1] One of the major metabolites produced on the MEG medium is the hemiacetal **6***a*, 3α,15-dihydroxymarasmene,[2] obtained as an inseparable mixture of the C-15 epimeric hemiacetals. 3α,15-Dihydroxymarasmene (**6***a*), mp 146–147°C, $C_{15}H_{22}O_4$ (determined by high resolution electron impact mass spectrometry (hreims)), shows complex ^{1}H nmr and ^{13}C nmr spectra (see Experimental) reflecting the presence of the two epimeric hemiacetals and a trace of the aldehyde. Oxidation of **6***a* with an excess of pyridinium dichromate gave the ketolactone **8**, which shows carbonyl absorption at 1761 (γ-lactone) and 1707 (cyclohexanone) cm^{-1} in its infrared (ir) spectrum. Acetylation of **6***a* gave a separable mixture of the diacetate **6***b* (only one epimer at C-15 (^{1}H nmr: δ 6.08 (s, H-15), δ 5.74 (d, *J* 4 Hz, H-11)) and the diacetoxyaldehyde **9** (^{1}H nmr: δ 9.80 (d, *J* 2 Hz, H-15), δ 5.91 (d, *J* 4 Hz, H-11)). The signal for H-3 in both **6***a* and **9** shows two small couplings (<3 Hz) indicating the equatorial nature of H-3. Reduction of ketone **8** with sodium borohydride gave the 3β alcohol **10***a* in which the C-3 hydrogen is axial (*J*'s 11.5, 4 Hz). The strong nuclear Overhauser effect (nOe) enhancement



[1]Since the PDY and MEG cultures were grown at different times, and since the inoculum was not necessarily identical, it is unclear as to whether the difference in metabolite spectrum is due entirely to the difference in media (5).

[2]We suggest the trivial name marasmene for the acetal **7**, and have named several of the metabolites as derivatives of **7**. Marasmene (**7**) itself is a metabolite of *M. oreades* (*vide infra*).

of the C-3 hydrogen observed when *either* of the C-4 methyl groups of **9** is irradiated confirms the location of the secondary alcoholic hydroxyl group in 3α,15-dihydroxymarasmene (**6***a*). Oxidation of **6***a* with one equivalent of pyridinium dichromate in dichloromethane gave a mixture of the ketolactone **8**, starting material, the hydroxy lactone **10***b*, and the ketolactol **11***a*. The latter two were separated in the form of their acetyl derivatives **10***c* (ir 1774, 1717 cm^{-1}) and **11***b* (ir 1752, 1706 cm^{-1}). The C-3 hydrogen in **10***c* appears as a double doublet at δ 4.83 (*J* 4 and 2 Hz) and H-15 in **11***b* appears as a singlet at δ 6.25. The ketolactol **11***a* (15-hydroxymarasmen-3-one) has been isolated as the equilibrium mixture (**11***a* ⇄ **12***a*), as one of the metabolites of *M. oreades* grown on PDB. Acetylation of the natural product **11***a* afforded the acetate **11***b* and a lesser amount of the aldehyde form, **12***b* (^{1}H nmr: δ 9.93 (d, *J* 2 Hz, H-15), δ 5.97 (d, *J* 4 Hz, H-11)).

A hydroxylactol, mp 152–155°C, isomeric with **6***a* has been isolated from both the MEG and the PDB media and has been shown to be 1α,15-dihydroxymarasmene (**13***a*). The molecular formula was established by hreims. The nmr spectra are again complicated by the presence of an equilibrium mixture of the two epimeric hemiacetals (in this case no aldehyde signal was detected in the ^{1}H nmr spectrum). Oxidation of **13***a* with an excess of pyridinium dichromate gave the ketolactone **14** (marasmene-1,15-dione) showing carbonyl absorption at 1767 (γ-lactone) and 1713 (cyclohexanone) cm^{-1} in the ir. The carbonyl signals in the ^{13}C nmr spectrum of **14** (δ 169.3 (lactone) and 205.5 (ketone)) are considerably upfield from those in **8** (δ 174.3 and 213.6), indicative of a 1,3 dipole–dipole interaction between the two carbonyls in **14**, similar to that observed in marasmone (**1**) (3). Reduction of anhydromarasmone (**2**) with triethylsilane – trifluoroacetic acid (6) gave ketolactone **14**. Since the structure and stereochemistry of anhydromarasmone (**2**) is well established (3), the correlation serves to confirm the structure, except for the stereochemistry, at C-1, of 1α,15-hydroxymarasmene (**13***a*). Oxidation of **13***a* with one equivalent of pyridinium dichromate gave, in addition to some of the diketone **14** and starting material, the hydroxy-

20

lactone **13***b*, as well as another product discussed below. The hydroxylactone **13***b* shows lactone carbonyl absorption at 1769 cm^{-1} in the ir. In the ^1H nmr spectrum of **13***b*, the signal for H-1 appears as a broad singlet, indicating that the hydrogen is equatorial and thus that the hydroxyl is α-axial.

Another of the minor metabolites isolated from the PDY culture proves to be the interesting *O*-formyl compound **15***a* (we suggest the name oreadone for the corresponding hemiacetal **15***b*). *O*-Formyloreadone (**15***a*) does not show a molecular ion in the hreims, the highest mass peak (and base peak) at *m/z* 218 ($C_{14}H_{18}O_2$) corresponding to the loss of formic acid from the molecular ion. The ^{13}C nmr spectrum shows the presence of 15 carbons, and the chemical ionization mass spectrum (cims) indicates a molecular weight of 264 ($C_{15}H_{20}O_4$). The *O*-formyl group is apparent from the ^{13}C (160.8, d) and ^1H (8.10, s) nmr spectra. The ir spectrum shows formate (1732 cm^{-1}) and saturated ketone (1702 cm^{-1}) absorption. With the exception of the formyl signal and the signal for the hydrogen at C-10, the ^1H nmr spectrum of **15***a* is very similar to that of ketone **14**. The C-11 hydrogen appears downfield (δ 6.62) to that in **14** (δ 6.12) but has a similar coupling to H-9 (4.8 Hz vs. 4.5 Hz). *O*-Formyloreadone (**15***a*) *is identical with* the minor oxidation product obtained (see above) when 1α,15-dihydroxymarasmene (**13***a*) is oxidized with one equivalent of pyridinium dichromate. Oxidative cleavage of the C-10 to C-15 bond may occur as illustrated in **16**, or **15***a* may arise by a retroaldol cleavage of a first formed C-1 ketone. The *trans* AB stereochemistry in **15***a* is assigned on the basis of the fact that the C-10 hydrogen (δ 2.35) shows diaxial couplings (13 Hz and 10 Hz) with both H-5 and H-9.

The related norsesquiterpene 3α-hydroxyoreadone (**15***c*) has been isolated from both PDY and MEG cultures of *M. oreades*. The compound shows a molecular ion ($C_{14}H_{20}O_4$) in the hreims as confirmed by cims, 14 signals in the ^{13}C nmr, and hydroxyl and carbonyl (1710 cm^{-1}) absorption in the ir. The ^{13}C and ^1H nmr spectra indicate that only one form of the C-11 hemiacetal is present in solution and this is tentatively assigned the β configuration on the basis of the coupling constant (5 Hz) observed between H-11 and H-9. The coupling is similar to that observed in **1**–**4** and other compounds of similar stereochemistry discussed herein (*J*'s 4–5 Hz). Irradiation of H-11 brings about significant (10%) nOe enhancement of the signal for H-9, and vice versa. The signal for H-3 (δ 3.91) appears as an apparent triplet (*J*'s 3 Hz) and is coupled to signals at δ 2.47 and δ 2.89 (H-2's), which show no further coupling other than to each other (J_{gem} = 15 Hz). The signal for H-3 shows significant nOe enhancement when either of the C-4 methyls is irradiated, confirming both the position and the orientation of the hydroxyl function. The signal for H-10 (δ 2.45) shows two large couplings (each 10 Hz), in agreement with the *trans* AB stereochemistry. The remainder of the ^1H nmr spectrum is consistent with structure **15***c*. Treatment of 3α-hydroxyoreadone (**15***c*) with acetic anhydride – pyridine gave a mixture of the diacetyl derivative **15***d*, the monoacetyl derivative **15***e*,

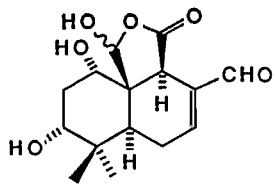
and the dehydration product **17***a*. The ^{1}H nmr spectrum of the dehydration product **17***a* was consistent with this compound being the acetate of dehydrooreadone (**17***b*), a metabolite isolated from the PDY culture. The ^{1}H nmr spectrum of dehydrooreadone (**17***b*) shows the vinyl signals of an α,β-unsaturated ketone at δ 5.89 (d, *J* 10 Hz) and 6.74 (d, *J* 10 Hz) for the hydrogens at H-2 and H-3, respectively.

The isolation of the norsesquiterpenes **15***c* and **17***b* is biogenetically interesting, especially in view of the co-occurrence of the formyl compound **15***a*. It appears that the course of biological demethylation may involve oxidation at C-15 to the aldehyde stage, hemiacetal formation (as seen in **13***a*), and then oxidative cleavage of the C-10, C-15 bond to give the *O*-formyl compound. Subsequent hydrolysis then furnishes the norsesquiterpene (**15***c*, **17***b*) at the C-1 ketone oxidation level.

A series of compounds in which C-15 is oxidized to the alcohol level has also been isolated. Marasmene (**7**) was obtained from the MEG culture. It is a crystalline solid, mp 70–74°C, which elutes early on flash chromatography of the crude metabolites. The hreims shows the molecular ion ($C_{15}H_{22}O_2$, *m/z* 234) and also shows a pronounced peak at $M^+ - 30$, corresponding to the loss of formaldehyde (C-15 plus attached hydrogens and oxygen) from the molecular ion, which is characteristic of the compounds at this oxidation level (compounds with a carbonyl at C-15, e.g., **1–4**, **8**, **10**, **14**, lose this carbon as CO_2). The C-15 hydrogens appear at δ 3.68 and 3.73. Besides the *geminal* coupling (8 Hz), the signal at δ 3.73 shows additional long-range W-plan coupling (2.1 Hz), believed to be with H-1α. Both 3β-hydroxymarasmene (**18***a*) and the corresponding ketone, marasmen-3-one (**18***b*) were also present as metabolites of *M. oreades*. The C-3 hydroxyl group was assigned the β (equatorial) configuration since H-3 showed both axial–axial (11.5 Hz) and axial–equatorial (4 Hz) couplings. Irradiation of the methyl signal at δ 1.04 caused significant (10.6%) enhancement of the H-3 signal, whereas irradiation of the methyl signal at δ 0.74 did not. Irradiation of the δ 0.74 methyl did, however, bring about enhancement of the signals for the hydrogens on C-15. Oxidation of **18***a* with pyridinium dichromate gave marasmen-3-one (**18***b*), identical with the natural material (ν_{max} 1708 cm^{-1}).

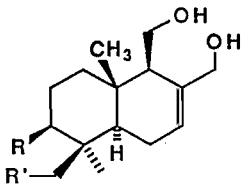
Two other marasmene derivatives, 13-hydroxymarasmene (**19***a*), and 14-hydroxymarasmene (**19***b*) have also been isolated. These showed nmr spectra very similar to those of marasmene except each shows only one methyl singlet (δ 0.60 in **19***a*, δ 1.03 in **19***b*) and an AB quartet for a primary alcohol (δ 3.14, 3.37 (*J* 11 Hz) in **19***a*, δ 3.37, 3.48 (*J* 11 Hz) in **19***b*). The stereochemical assignments at C-4 were made on the basis of nOe experiments that demonstrated the proximity of the C-4 methyl group to the C-15 hydrogens in **19***a*, and the proximity of the C-4 methyl in **19***b* to H-5 and one of the H-6's.

A metabolite in which C-12 is oxidized to the aldehyde level was isolated from PDY culture. This compound, for which we suggest the name marasmal, has the molecular formula $C_{15}H_{20}O_6$ and appears to possess structure **20**. The presence of the α,β-unsaturated aldehyde was indicated by strong conjugated aldehyde absorption at 1687 cm^{-1} in the ir spectrum, signals at δ 9.36 (s, CHO) and δ 7.15 (br d, H-7) in the ^{1}H nmr spectrum, and signals at δ 195.2 (d, C-12), 156.2 (d, C-7), and 140.4 (s, C-8) in the ^{13}C nmr spectrum. Lactone and lactol groups are indicated by signals at δ 178.9 (s, C-15) and δ 101.5 (d, C-11) in the ^{13}C nmr spectrum and absorptions at 1754 and 3465 cm^{-1} in the ir spectrum. The presence of the axial hydroxyl groups at C-1 and C-3 is indicated by the doublets of doublets at δ 3.51 (*J*'s 3 Hz) and δ 4.34 (*J*'s 3 Hz), which are each coupled to *geminally* coupled (J_{gem} 15 Hz) signals at δ 1.95 and 2.18. Similar small *vicinal* coupling constants for the signals of H-1 and H-3 are observed in the spectrum of dihydromarasmone (**4**) (3). The signal for H-11 appears as a broad singlet, not as a doublet, *J* 4–5 Hz, as oberved in the previously described compounds in which H-11 has an α orientation. The alternative lactol structure **21** for marasmal may be ruled out on the basis of nOe experiments that demonstrate the proximity of H-11 to H-9 and H-12.



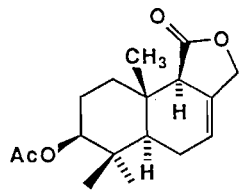
A series of compounds in which C-15 is not oxygenated was also isolated from the PDB and MEG cultures. Two of these compounds are the isomeric triols 3,11,12-trihydroxydrimene (**22**) and 11,12,14-trihydroxydrimene (**23**), which both give molecular ions at *m/z* 254 in the hreims corresponding to a molecular formula of $C_{15}H_{26}O_3$. The triol **22**, like all of the other sesquiterpenes from *M. oreades*, has not been previously isolated from natural sources. However, **22** was prepared by reduction of the naturally occurring sesquiterpene 3β-acetoxydrimenin (**24**) (7), as well as by total synthesis (8), and by microbiological hydroxylation of the (±) drimenediol (**25**) (9). The mp and optical rotation of the naturally occurring material from *M. oreades* agree with those reported for the reduction product of 3β-acetoxydrimenin (**24**) (7).

The drimenetriol **23** isolated from *M. oreades* possesses ^{1}H and ^{13}C nmr spectra similar to those of **22** except that the ^{1}H spectrum of **23** displays only two methyl singlets (δ 0.76, 0.99) and an additional AB quartet (δ 3.49, 3.83, *J* 10.5 Hz), which has replaced the signal due to H-3 (δ 3.26) in the ^{1}H nmr spectrum of **22**. Furthermore, the ^{13}C nmr spectrum of **23** shows signals for three hydroxymethyl carbons (δ 61.4, 64.7, 66.9) whereas the spectrum of **22** shows signals for two primary alcohol carbons (δ 61.2, 66.8) and a secondary alcohol carbon (δ 79.6). Thus either C-13, C-14, or C-15 must be a primary alcohol group in **23**. The location of the additional primary hydroxyl group in **23** was established by nOe eperiments that demonstrate the proximity of the C-15 hydrogens to the primary hydroxyl groups at C-11 and C-14, and the proximity of the C-13 methyl group to the C-14 hydroxymethyl group.



Another compound lacking a C-8—C-12, C-15 dioxabicyclooctane moiety is the lactol **26**, which has a molecular formula of $C_{15}H_{24}O_3$ as determined by hreims. The related C-14 deoxy compound, isodrimeninol (**27**), is a natural product (10), and (±)-**27** along with 3β-hydroxyisodrimeninol (**28**) have been prepared by synthesis (9). The ^{1}H nmr spectrum of **26** and those reported (9) for **27** and **28** are very similar, except that in the spectrum of **26** an AB quartet (δ 3.56, 3.85, *J* 10.7 Hz) indicates that either C-13, C-14, or C-15 is a primary hydroxyl group in this compound. The position of the primary hydroxyl group in **26** was established by nOe experiments that demonstrate the proximity of H-15 to both the lactol hydrogen (thereby confirming the assigned stereochemistry at C-11) and to one of the H-14 signals of the AB quartet. The hydrogens of the second methyl group (C-13) show significant nOe's to the other H-14 signal as well as to H-5 and both H-6's.

Small amounts of a uv-active sesquiterpene, 3β-hydroxycinnamolide (**29**), were isolated from the PDB culture. An abundant ion at *m/z* 232 in the low resolution mass spectrum (lrms) is consistent with loss of H_2O from the molecular ion. The ^{1}H nmr spectrum of **29** is very similar to that reported (9) for (±)-3β-hydroxycinnamolide obtained by microbiological hydroxylation of cinnamolide (**30**).



Very small amounts of a drimenediol to which we have

20 R = H

31*a* R = H
31*b* R = Ac

tentatively assigned the structure **31***a* were isolated from the MEG culture. The ^{1}H nmr spectrum of this compound shows three saturated methyl singlets (δ 0.86, 0.87, 0.98), alkenic hydrogen (δ 5.54) and alkenic methyl (δ 1.78) signals, and signals due to primary (δ 3.75, dd, *J* 11.5, 5.0 Hz, and δ 3.86, dd, *J* 11.1, 3.4 Hz) as well as secondary (δ 3.26, dd, *J* 10.5, 5.4 Hz) hydroxyl groups, which are all consistent with the assigned structure. For the corresponding diacetate (**31***b*), nOe experiments demonstrated the proximity of one of the methyl groups (δ 0.86, H-13) to the secondary carbinyl hydrogen (δ 4.51, dd, *J* 11.5, 4.8 Hz, H-3), and of another methyl group (δ 0.84, H-15) to the primary carbinyl hydrogens (δ 4.11, 4.21, H-11).

During the preliminary separation of the crude metabolites from the MEG culture, which involved flash chromatography over silica gel, some of the intermediate fractions eluted with ethyl acetate – Skellysolve B (1:1 and 2:1) deposited relatively large amounts of a heat- and light-sensitive crystalline compound. This compound shows only one signal (δ 4.26, s) in its ^{1}H nmr spectrum (in methanol-d_4). The ^{13}C nmr spectrum shows eight signals and the hreims suggested the molecular formula $C_8H_5NO_2$. The mp and spectral properties led to the identification of this compound as agrocybin (**5**), previously obtained as a metabolite of *Agrocybe dura* (11).[3] This compound has been shown to possess antibiotic activity (12). Preliminary tests in our laboratories have shown that agrocybin (**5**), but none of the sesquiterpenes isolated and tested, causes browning and death of grass (creeping red fescu) seedlings. It has also been shown that agrocybin (12.5 ppm) inhibits the growth of *Lemna minor* (duckweed) and that it displays phytotoxic activity when sprayed on whole plants (soybean, wheat) at 1.75 kg/ha.[4] We feel that agrocybin may be responsible, at least in part, for the destruction of grass caused by the fairy ring fungus *M. oreades* (2, 4).

Experimental

For general experimental details see the first paper in this series (3).

Growth of Marasmius oreades *on potato dextrose yeast broth and isolation of metabolites*

The details of the growth of the fungus on PDY broth, and column chromatography of the ethyl acetate extract of the broth, are described in the previous paper (3). The metabolites of fractions 33–45 (compound **2**), and fractions 46–49 (compounds **1**, **2**, **3**, and **4**) were discussed in the previous report.

Fractions 50–59 (0.42 g) were combined and, after extensive chromatography on several columns of silica gel, eluting with mixtures of ethyl acetate – Skellysolve B, the following compounds were obtained (in order of decreasing R_f value): **2** (3.4 mg), **18***b* (3.0 mg), **15***a* (1.4 mg), **1** (20.1 mg), **3** (3.5 mg), **4** (16.4 mg), **19***a* (3.8 mg), **29** (0.6 mg), **11***a* (6.7 mg), **18***a* (125.7 mg), and **19***b* (17.0 mg).

Fractions 60–67 (0.39 g) were combined and chromatographed on a column of silica gel (ethyl acetate – Skellysolve B, 2:1) to give **13***a* (30.6 mg) and **6***a* (159.0 mg).

Fractions 68–77 (0.55 g) were combined and chromatographed on a column of silica gel (ethyl acetate – Skellysolve B, 3:1) to give **17***b* (2.6 mg), **20** (3.8 mg), **6***a* (28.5 mg), and **15***c* (172 mg).

Fractions 78–84 (0.51 g) were combined and chromatographed on a column of silica gel (ethyl acetate – Skellysolve B, 2:1) to give several fractions enriched in **22** and **23**. Further chromatography (ethyl acetate – Skellysolve B, 3:1) of these fractions successively gave **23**, which crystallized from dichloromethane – Skellysolve B as needles (17.3 mg), and a mixture (ca. 1:1 by ^{1}H nmr) of **22** and an unidentified compound (28 mg).

3α,15-Dihydroxymarasmene (**6***a*) crystallized from ethyl acetate – Skellysolve B as prisms, mp 146–147°C; Ftir (KBr disc): 3529

[3]This compound was not isolated from the PDY culture reported previously (3). We attribute this to the fact that the metabolites were isolated by continuous extraction with ethyl acetate, and agrocybin is thermally unstable. It has been isolated from later PDY cultures that were extracted with ethyl acetate at room temperature.

(br, OH), 1705 (w), 1385, 1370 (m, *gem* dimethyl), 1125, 1003 (C—O) cm^{-1}; Ftir ($CHCl_3$ cast): 3374 (br, OH), 1725 (w), 1705 (w), 1380, 1360 (m, *gem* dimethyl) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.99 (3H, s, CH_3), 1.02 (3H, s, CH_3), 1.03 (6H, s, $2CH_3$), 1.48–2.48 (ca. 14H, m), 2.68 (2H, br s), 2.87 (1H, br s, H-9), 3.54–3.57 (1H, br s, H-3), 3.57–3.60 (1H, br s, H-3), 4.37 (2H, br s, H-12), 4.47 (br d, *J* 11.1 Hz, H-12), 4.55 (ddd, *J* 11.0, 1.2, 1.2 Hz, H-12), 5.22 (1H, d, *J* 10.2 Hz, H-15), 5.40 (1H, d, *J* 5.7 Hz, H-15), 5.71 (1H, d, *J* 4.7 Hz, H-11), 5.73 (1H, d, *J* 5.1 Hz, H-11), 5.79 (1H, br s, H-7), 5.91 (1H, br s, H-7), 9.79 (≪1H, CHO), 9.90 (≪1H, CHO); ^{13}C nmr ($CDCl_3$) δ: 19.9, 22.2, 26.3, 27.2, 38.0, 38.1, 54.7, 57.8, 76.0, 76.4, 99.1, 103.1, 104.3, 106.6, 116.4 (weak), 117.4 (weak), 122.2, 122.9, 206.4 (weak), 206.7 (weak) (CH, CH_3); 22.8, 24.9, 25.8, 26.1, 26.7, 30.3, 36.9, 37.7, 44.6, 46.0, 71.6, 72.6, 134.0, 136.9 (C, CH_2); hreims (probe 160°C), *m/z* calcd. for $C_{15}H_{22}O_4$ (M^+): 266.1518; found: 266.1514 (6), 248 ($M^+ - H_2O$, 36), 220 (57), 202 (29), 201 (25), 174 (20), 173 (100), 172 (63), 159 (35), 132 (26), 131 (43), 124 (27), 119 (44), 117 (27), 107 (28), 105 (80), 104 (28), 93 (28), 91 (71), 81 (24), 79 (46), 69 (58), 67 (29), 57 (30), 55 (49), 53 (27).

15-Hydroxymarasmen-3-one (**11***a*) was obtained as a clear oil; Ftir ($CHCl_3$ cast): 3410 (br, OH), 1705 (s, C=O) cm^{-1}; (major epimer) ^1H nmr ($CDCl_3$) δ: 1.12 (3H, s, H-14), 1.23 (3H, s, H-13), 1.50–1.66 (1H, m, H-1), 2.15 (1H, dd, *J* 10.0, 7.5 Hz, H-5), 2.27 (1H, ddd, *J* 14.7, 5.2, 2.6 Hz, H-6), 2.30–2.38 (1H, m, H-6), 2.54 (1H, ddd, *J* 13.5, 6.2, 2.2 Hz, H-2α), 2.68 (1H, m, H-9), 2.89 (1H, d, *J* 4.2 Hz, OH), 3.29 (1H, ddd, *J* 14.2, 14.0, 6.5 Hz, H-2β), 4.42 (2H, br s, H-12), 5.60 (1H, d, *J* 4.4 Hz, H-15), 5.80 (1H, d, *J* 4.0 Hz, H-11), 5.83 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 19.4, 23.3, 23.4, 32.9, 36.1, 45.7, 47.5, 57.4, 71.5, 98.6, 103.3, 121.3, 133.8, 215.5, one signal obscured; (minor epimer) ^1H nmr ($CDCl_3$) δ: 1.13 (3H, s, H-14), 1.20 (3H, s, H-13), 1.50–1.66 (1H, m, H-1), 2.11 (1H, ddd, *J* 14.0, 6.2, 2.6 Hz, H-2α), 2.20 (1H, dd, *J* 10.5, 3.6 Hz, H-5), 2.30–2.38 (1H, m, H-6), 2.68 (1H, m, H-9), 2.82 (1H, ddd, *J* 15.0, 15.0, 6.2 Hz, H-2β), 2.86 (1H, d, *J* 9.3 Hz, OH), 4.49 (1H, br d, *J* 11.0 Hz, H-12), 4.60 (1H, dddd, *J* 11.0, 1.4, 1.4, 1.4 Hz, H-12), 5.48 (1H, d, *J* 9.3 Hz, H-11), 5.79 (1H, d, *J* 4.9 Hz, H-11), 5.83 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 21.6, 22.8, 25.3, 34.6, 36.5, 44.3, 45.8, 48.5, 54.5, 106.5, 122.5, 135.8, 213.9, two signals obscured; hreims (probe 190°C), *m/z* calcd. for $C_{15}H_{20}O_4$ (M^+): 264.1362; found: 264.1359 (5), 246 ($M^+ - H_2O$, 25), 218 (19), 132 (100), 119 (27), 105 (41), 91 (40), 77 (20).

1α,15-Dihydroxymarasmene (**13***a*) crystallized from ethyl acetate – Skellysolve B as prisms, mp 152–155°C; Ftir (KBr disc): 3419 (br, OH), 1730 (w), 1710 (w), 1625 (m) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.965 (s, CH_3), 0.96 (s, CH_3), 0.975 (s, CH_3), 0.995 (s, CH_3), 2.27 (d, *J* 8.5 Hz), 2.31–2.37 (m), 2.60 (dd, *J* 4.5, 1.5 Hz), 2.93 (d, *J* 10.8 Hz), 3.36–3.41 (m), 3.60–3.64 (m), 4.36–4.43 (m), 4.49 (br d, *J* 11.0 Hz), 4.56 (ddd, *J* 11.0, 1.3, 1.3 Hz), 5.05 (d, *J* 10.9 Hz), 5.73 (d, *J* 5.5 Hz), 5.73 (m), 5.75 (d, *J* 4.5 Hz), 5.86 (m); hreims (probe 180°C), *m/z* calcd. for $C_{15}H_{22}O_4$ (M^+): 266.1518; found: 266.1516 (3), 248 ($M^+ - H_2O$, 57), 220 (29), 219 (31), 202 (21), 201 (33), 191 (22), 190 (20), 174 (38), 173 (100), 164 (20), 159 (32), 146 (26), 145 (21), 133 (21), 131 (48), 129 (20), 121 (33), 119 (45), 118 (71), 117 (47), 107 (27), 96 (20), 95 (23), 93 (47), 92 (25), 91 (99), 83 (21), 81 (65), 78 (49), 77 (54), 71 (33), 70 (28), 69 (64), 67 (35), 65 (28), 57 (57), 56 (25), 55 (81), 53 (35).

O-*Formyloreadone* (**15***a*) was obtained as a glass; $[\alpha]_D^{24}$ +278° (*c* 0.07, CH_3OH); Ftir ($CHCl_3$ cast): 1732 (s, formate C=O), 1702 (s, ketone C=O), 1387, 1364 (m, *gem* dimethyl), 1157, 1052 (s, C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.03 (3H, s, H-14), 1.13 (3H, s, H-13), 1.66 (1H, ddd, *J* 13.5, 13.0, 4.3 Hz, H-3α), 1.72 (1H, ddd, *J* 12.5, 6.0, 2.0 Hz, H-5), 1.78 (1H, ddd, *J* 13.5, 6.0, 2.5 Hz, H-3β), 2.08–2.34 (2H, m, H-6), 2.35 (1H, dd, *J* 12.8, 9.8 Hz, H-10), 2.53 (1H, dddd, *J* 15.0, 15.0, 6.0, 0.8 Hz, H-2β), 2.92 (1H, m, H-9), 4.41 (1H, ddd, *J* 12.5, 2.2, 2.2 Hz, H-12), 4.49 (1H, ddd, *J* 12.5, 2.2, 2.2 Hz, H-12), 5.63 (1H, m, H-7), 6.62 (1H, d, *J* 4.8 Hz, H-11), 8.10 (1H, s, H-15); ^{13}C nmr ($CDCl_3$) δ: 19.3 (C-14), 27.1 (C-6), 29.1 (C-13), 32.8 (C-4), 38.0 (C-2), 41.4 (C-3), 44.4 (C-5), 46.2 (C-9), 47.0 (C-10), 69.6 (C-12), 99.4 (C-11), 117.6 (C-7), 134.3 (C-8), 160.8 (C-15), 210.9 (C-1); hreims (probe 100°C), *m/z* calcd. for $C_{14}H_{18}O_2$ ($M^+ - HCO_2H$): 218.1307; found: 218.1301 (100); cims, *m/z*: 282 ($M^+ + 18$, 11).

3α-Hydroxyoreadone (**15***c*) crystallized from dichloromethane – Skellysolve B as prisms, mp 103–108°C; $[\alpha]_D^{24}$ +130.2° (*c* 1.00, CH_3OH); Ftir (KBr disc): 3465 (br, OH), 1710 (s, C=O), 1226 (s, C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.13 (3H, s, CH_3), 1.14 (3H, s, CH_3), 2.14–2.35 (3H, m, H-5, H-6), 2.45 (1H, dd, *J* 10.0, 10.0 Hz, H-10), 2.47 (1H, dd, *J* 14.9, 3.4 Hz, H-2α), 2.81 (1H, m, H-9), 2.89 (1H, ddd, *J* 15.0, 3.2, 0.8 Hz, H-2β), 3.91 (1H, dd, *J* 3.0, 3.0 Hz, H-3), 4.36–4.37 (2H, m, H-12), 5.66 (1H, m, H-7), 5.85 (1H, d, *J* 5.0 Hz, H-11); ^1H nmr (C_6D_6) δ: 0.57 (3H, s, H-14), 0.76 (3H, s, H-13), 1.00 (1H, br s, OH), 1.68–1.88 (2H, m, H-6), 2.02 (1H, br d, *J* 2.8 Hz, OH), 2.10 (1H, ddd, *J* 12.2, 10.5, 6.5 Hz, H-5), 2.11 (1H, dd, *J* 14.5, 3.2 Hz, H-2α), 2.25 (1H, ddd, *J* 14.5, 3.2, 0.8 Hz, H-2β), 2.43 (1H, dd, *J* 12.0, 9.8 Hz, H-10), 2.85 (1H, m, H-9), 3.11 (1H, br s, H-3), 4.31 (1H, dddd, *J* 10.5, 3.0, 2.0, 2.0 Hz, H-12), 4.36 (1H, dddd, *J* 10.6, 3.0, 2.2, 2.2 Hz, H-12), 5.25 (1H, m, H-7), 6.04 (1H, dd, *J* 4.8, 2.6 Hz, H-11); ^{13}C nmr ($CDCl_3$) δ: 20.3 (C-14), 24.9 (C-13), 26.5 (C-6), 37.4 (C-4), 40.4 (C-5), 44.8 (C-9), 45.7 (C-2), 46.5 (C-10), 68.3 (C-12), 79.5 (C-3), 98.1 (C-11), 117.3 (C-7), 136.1 (C-8), 210.2 (C-1); hreims (probe 150°C), *m/z* calcd. for $C_{14}H_{20}O_4$ (M^+): 252.1362; found: 252.1364 (2); calcd. for $C_{14}H_{18}O_3$ ($M^+ - H_2O$): 234.1225; found: 234.1257 (100), 206 (35), 188 (20), 173 (21), 120 (47), 119 (22), 93 (35), 92 (59), 91 (64), 79 (21), 71 (34); cims, *m/z*: 270 ($M^+ + 18$, 18).

Dehydrooreadone (**17***b*) was obtained as a solid; ^1H nmr ($CDCl_3$) δ: 1.09 (3H, s, H-14), 1.18 (3H, s, H-13), 2.09 (1H, ddd, *J* 12.5, 9.5, 7.0 Hz, H-5), 2.21–2.29 (2H, m, H-6), 2.51 (1H, d, *J* 3.6 Hz, OH), 2.56 (1H, dd, *J* 12.8, 10.0 Hz, H-10), 2.64 (1H, m, H-9), 4.42–4.46 (2H, m, H-12), 5.70 (1H, m, H-7), 5.89 (1H, d, *J* 10.1 Hz, H-2), 5.99 (1H, br dd, *J* 4.0, 4.0 Hz, H-11), 6.74 (1H, d, *J* 10.1 Hz, H-3).

3β-Hydroxymarasmene (**18***a*) crystallized, on standing, as a microcrystalline solid, mp 129–133°C; $[\alpha]_D^{24}$ +34.0° (*c* 1.05, CH_3OH); Ftir ($CHCl_3$ cast): 3450 (br, OH), 1370, 1360 (m, *gem* dimethyl), 1016 (s, C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.67 (3H, s, H-14), 1.01 (3H, s, H-13), 1.29 (1H, dddd, *J* 14.0, 14.0, 4.5, 2.0 Hz, H-1α), 1.45 (1H, d, *J* 5.0 Hz, OH), 1.58 (1H, dddd, *J* 13.5, 13.5, 13.5, 4.0 Hz, H-2β), 1.73 (1H, dd, *J* 10.8, 6.9 Hz, H-5), 1.75–1.80 (1H, m), 1.94 (1H, ddd, *J* 13.5, 3.5, 3.5 Hz, H-1β), 2.02–2.18 (1H, m), 2.23–2.38 (1H, br d, *J* 18 Hz, H-6), 2.58 (1H, m, H-9), 3.35 (1H, ddd, *J* 11.5, 4.2, 4.2 Hz, H-3), 3.64 (1H, d, *J* 8.2 Hz, H-15α), 3.73 (1H, dd, *J* 8.2, 2.0 Hz, H-15β), 4.30–4.41 (2H, m, H-12), 5.65 (1H, d, *J* 4.8 Hz, H-11), 5.79 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 14.0 (C-14), 23.4 (C-6), 25.8 (C-13), 27.7 (C-2), 34.2 (C-1), 39.1 (C-4), 43.6 (C-10), 44.0 (C-5), 55.7 (C-9), 69.3 (C-15), 72.2 (C-12), 78.3 (C-3), 105.6 (C-11), 121.1 (C-7), 133.3 (C-8); hreims (probe 120°C), *m/z* calcd. for $C_{15}H_{22}O_3$ (M^+): 250.1569; found: 250.1572 (42), 232 ($M^+ - H_2O$, 12), 220 (29), 204 (72), 186 (36), 175 (24), 173 (73), 172 (22), 171 (35), 161 (24), 145 (34), 143 (30), 133 (24), 132 (88), 131 (39), 119 (78), 118 (46), 117 (43), 107 (34), 106 (22), 105 (92), 104 (54), 96 (100), 95 (77), 93 (28), 91 (88), 82 (30), 81 (25), 79 (43), 77 (41), 69 (57), 67 (42), 65 (23), 57 (20), 55 (46), 53 (31).

Marasmen-3-one (**18***b*) was obtained as a clear oil, which crystallized from dichloromethane – Skellysolve B as microcrystals, mp 135–138°C; $[\alpha]_D^{24}$ −1.6° (*c* 1.00, CH_3OH); cd (*c* 3.63 mM, CH_3OH), 24°C: $[\theta]_{293}$ −3000; Ftir ($CHCl_3$ cast): 1708 (s, C=O), 1388, 1369 (m, *gem* dimethyl), 1006 (s, C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.95 (3H, s, H-14), 1.09 (3H, s, H-13), 1.60 (1H, ddd, *J* 14.5, 4.5, 1.2 Hz, H-1β), 2.14 (1H, dd, *J* 10.2, 6.5 Hz, H-5), 2.15–2.30 (2H, m, H-6), 2.25 (1H, ddd, *J* 13.5, 6.0, 2.5 Hz, H-1α), 2.33 (1H, ddd, *J* 14.5, 4.2, 2.5 Hz, H-2α), 2.67 (1H, m, H-9), 2.75 (1H, ddd, *J* 14.7, 14.7, 6.0 Hz, H-2β), 3.93 (1H, d, *J* 1.7 Hz, H-15β), 3.94 (1H, br s, H-15α), 4.37 (1H, br d, *J* 10.5 Hz, H-12), 4.43 (1H, ddd, *J* 10.6, 1.2, 1.2 Hz, H-12), 5.71 (1H, d, *J* 4.9 Hz, H-11), 5.83 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 20.7 (C-14), 22.6 (C-13), 23.6 (C-6), 34.8, 35.6 (C-1, C-2), 43.6 (C-10), 45.6 (C-5), 48.1 (C-4), 55.4 (C-9), 68.5 (C-15), 72.2 (C-12), 105.6 (C-11), 120.7 (C-7), 133.4 (C-8), 214.1 (C-3); hreims (probe 100°C), *m/z* calcd. for $C_{15}H_{20}O_3$ (M^+): 248.1412;

found: 248.1418 (41), 205 (27), 133 (22), 132 (100), 123 (23), 119 (36), 118 (46), 117 (20), 107 (68), 105 (45), 96 (23), 95 (33), 91 (47), 79 (23), 77 (31), 69 (20), 55 (25), 53 (20).

13-Hydroxymarasmene (**19***a*) crystallized, on standing, as microcrystals, mp 147–150°C; $[\alpha]_D^{24}$ +37° (*c* 0.20, CH_3OH); Ftir ($CHCl_3$ cast): 3350 (br, OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.60 (3H, s, H-14), 1.15–1.65 (4H, m), 1.83 (1H, br d, *J* 13.5 Hz), 1.87–1.98 (1H, m), 2.03–2.11 (2H, m), 2.16 (1H, br d, *J* 18 Hz, H-6), 2.55 (1H, m, H-9), 3.14 (1H, br d, *J* 11.0 Hz, H-13), 3.37 (1H, br d, *J* 11.0 Hz, H-13), 3.63 (1H, d, *J* 8.0 Hz, H-15α), 3.68 (1H, dd, *J* 8.0, 2.0 Hz, H-15β), 4.25–4.33 (2H, m, H-12), 5.60 (1H, d, *J* 4.5 Hz, H-11), 5.70 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 16.6 (C-14), 18.4 (C-2), 23.2 (C-6), 29.7 (C-3), 35.8 (C-1), 37.8 (C-4), 38.6 (C-5), 43.5 (C-10), 55.2 (C-9), 69.5 (C-15), 70.8 (C-13), 72.4 (C-12), 105.8 (C-11), 121.0 (C-7), 133.5 (C-8); hreims (probe 150°C), *m/z* calcd. for $C_{15}H_{22}O_3$ (M^+): 250.1569; found: 250.1572 (15), 232 ($M^+ - H_2O$, 7), 220 (42), 191 (21), 189 (25), 174 (36), 173 (91), 159 (72), 145 (34), 143 (21), 132 (27), 131 (51), 129 (24), 119 (37), 118 (39), 117 (42), 107 (24), 106 (23), 105 (100), 104 (43), 96 (33), 95 (34), 93 (34), 91 (90), 82 (29), 81 (40), 79 (48), 77 (46), 69 (35), 67 (41), 65 (24), 57 (24), 55 (59), 53 (34).

14-Hydroxymarasmene (**19***b*) crystallized on standing. Recrystallization from dichloromethane – Skellysolve B gave prisms, mp 162.5–163°C; $[\alpha]_D^{24}$ +23.8° (*c* 0.32, CH_3OH); Ftir ($CHCl_3$ cast): 3351 (br, OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.03 (3H, s, H-13), 1.00–1.15 (1H, m), 1.18–1.32 (2H, m), 1.57–1.62 (2H, m), 1.97 (1H, dd, *J* 11.8, 6.5 Hz, H-5), 1.90–2.03 (2H, m), 2.07–2.20 (1H, m), 2.37 (1H, br d, *J* 18.5 Hz, H-6), 2.63 (1H, m, H-9), 3.37 (1H, br d, *J* 11.0 Hz, H-14), 3.48 (1H, br d, *J* 11.0 Hz, H-14), 3.67 (1H, d, *J* 8.5 Hz, H-15α), 3.72 (1H, dd, *J* 7.5, 2.0 Hz, H-15β), 4.33–4.42 (2H, m, H-12), 5.68 (1H, d, *J* 4.5 Hz, H-11), 5.78 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 18.7 (C-2), 23.0 (C-6), 25.2 (C-13), 35.8, 36.2 (C-1, C-3), 37.7 (C-4), 43.8 (C-10), 44.7 (C-5), 55.9 (C-9), 64.5 (C-14), 72.3 (C-12), 105.9 (C-11), 121.3 (C-7), 133.5 (C-8); hreims (probe 140°C), *m/z* calcd. for $C_{15}H_{22}O_3$ (M^+): 250.1569; found: 250.1570 (9), 232 ($M^+ - H_2O$, 7), 220 (42), 204 (74), 174 (38), 173 (72), 161 (39), 159 (52), 145 (34), 133 (20), 132 (30), 131 (48), 129 (20), 119 (47), 118 (43), 117 (40), 109 (24), 107 (32), 106 (28), 105 (100), 104 (51), 96 (39), 95 (37), 93 (41), 92 (21), 91 (97), 83 (25), 82 (33), 81 (46), 79 (66), 77 (58), 71 (36), 70 (29), 69 (65), 67 (54), 65 (29), 59 (66), 57 (73), 55 (98), 53 (42).

Marasmal (**20**) crystallized from chloroform as prisms, mp 195–200°C; $[\alpha]_D^{24}$ −73.1° (*c* 0.32, CH_3OH); Ftir (KBr disc): 3465 (s, OH), 3264 (s, OH), 1754 (s, lactone C=O), 1687 (s, conj. aldehyde C=O), 1655, 1632 (m, C=C), 1370, 1365 (m, *gem* dimethyl) cm^{-1}; ^1H nmr (CD_3OD) δ: 0.99 (3H, s, H-14), 1.13 (3H, s, H-13), 1.87 (1H, dd, *J* 12.8, 3.5 Hz, H-5), 1.95 (1H, ddd, *J* 14.8, 2.8, 2.8 Hz, H-2α), 2.12 (1H, br ddd, *J* 12.8, 3.0, 2.0 Hz, H-6β), 2.18 (1H, ddd, *J* 14.8, 2.8, 2.8 Hz, H-2β), 2.43 (1H, br dddd, *J* 19.4, 7.0, 3.5, 1.5 Hz, H-6α), 3.51 (1H, br dd, *J* 2.8, 2.8 Hz, H-3), 3.69 (1H, m, H-9), 4.34 (1H, br dd, *J* 2.8, 2.8 Hz, H-1), 5.31 (1H, br s, H-11), 7.15 (1H, br d, *J* 6.5 Hz, H-7), 9.36 (1H, s, H-12); ^{13}C nmr (CD_3OD) δ: 23.0 (C-6), 25.8 (C-14), 28.9 (C-2), 30.4 (C-13), 37.3 (C-5), 38.2 (C-4), 47.7 (C-9), 54.6 (C-10), 70.8 (C-1), 77.9 (C-3), 101.5 (C-11), 140.4 (C-8), 156.2 (C-7), 178.9 (C-15), 195.2 (C-12); hreims (probe 180°C), *m/z* calcd. for $C_{15}H_{18}O_5$ ($M^+ - H_2O$): 278.1154; found: 278.1152 (100), 260 ($M^+ - 2H_2O$, 15), 250 (20), 249 ($M^+ - CHO$, 18), 234 ($M^+ - H_2O - CO_2$, 9), 232 ($M^+ - 2H_2O - CO$, 35), 206 (23), 188 (25), 187 (33), 186 (50), 181 (50), 171 (26), 164 (20), 162 (41), 159 (22), 157 (38), 151 (25), 143 (36), 135 (46), 133 (37), 119 (27), 117 (33), 107 (27), 105 (49), 98 (100), 91 (78), 79 (64), 77 (57), 72 (65), 71 (27), 69 (44), 67 (20), 65 (22), 55 (29), 53 (27); cims, *m/z*: 314 ($M^+ + 28$, 26).

11,12,14-Trihydroxydrimene (**23**) crystallized from ethyl acetate as needles, mp 178–180°C; $[\alpha]_D^{24}$ −10.7° (*c* 0.15, CH_3OH); Ftir (KBr disc): 3306 (br, OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.76 (3H, s, H-15), 0.99 (3H, s, H-13), 1.12–1.28 (2H, m), 1.44 (1H, dd, *J* 12.8, 4.5 Hz, H-5), 1.47–1.56 (2H, m), 1.65 (1H, ddd, *J* 13.5, 4.9, 3.2 Hz), 1.95 (1H, ddd, *J* 12.8, 4.1, 2.1 Hz), 2.05 (1H, ddd, *J* 11.0, 4.9, 3.2 Hz), 2.12–2.21 (2H, m), 2.80 (2H, br s, OH), 3.49 (1H, br d, *J* 10.5 Hz, H-14), 3.68 (1H, dd, *J* 10.5, 8.0 Hz, H-11), 3.83 (1H, br d, *J* 10.5 Hz, H-14), 3.92 (1H, dd, *J* 10.5, 2.0 Hz, H-11), 4.00 (1H, d, *J* 12.0 Hz, H-12), 4.34 (1H, br d, *J* 12.0 Hz, H-12), 5.79 (1H, m, H-7); ^1H nmr (CD_3OD) δ: 0.79 (3H, s, H-15), 0.93 (1H, ddd, *J* 13.5, 13.5, 3.5 Hz), 0.95 (3H, s, H-13), 1.18 (1H, ddd, *J* 13.2, 13.2, 4.0 Hz), 1.37 (1H, dd, *J* 12.6, 4.5 Hz, H-5), 1.46 (1H, ddd, *J* 14.0, 4.5, 4.5 Hz), 1.56 (1H, ddddd, *J* 13.5, 13.5, 13.5, 3.0, 3.0 Hz, H-2β), 1.90 (1H, br d, *J* 14.0 Hz), 1.95–2.09 (3H, m), 2.14 (1H, br ddd, *J* 17, 4.5, 4.5 Hz, H-6), 3.38 (1H, d, *J* 11.0 Hz, H-14), 3.60 (1H, dd, *J* 11.0, 7.5 Hz, H-11), 3.78 (1H, d, *J* 11.0 Hz, H-14), 3.83 (1H, dd, *J* 11.1, 2.7 Hz, H-11), 3.95 (1H, d, *J* 12.6 Hz, H-12), 4.24 (1H, d, *J* 12.6 Hz, H-12), 5.76 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 16.0 (C-15), 19.5 (C-2), 24.0 (C-6), 27.5 (C-13), 36.4 (C-1), 36.8 (C-3), 39.1 (C-10), 40.6 (C-4), 52.1 (C-5), 56.0 (C-9), 61.4 (C-11), 64.7 (C-14), 66.9 (C-12), 126.4 (C-7), 138.6 (C-8); hreims (probe 150°C), *m/z* calcd. for $C_{15}H_{26}O_3$ (M^+): 254.1883; found: 254.1884 (1), 236 ($M^+ - H_2O$, 5), 218 ($M^+ - 2H_2O$, 2), 188 (21), 173 (24), 163 (21), 119 (22), 109 (100), 93 (21), 91 (20), 81 (23), 55 (26); cims, *m/z*: 272 ($M^+ + 18$, 8).

3β-Hydroxycinnamolide (**29**) was obtained as an oil; ^1H nmr ($CDCl_3$) δ: 0.81 (3H, s), 0.92 (3H, s), 1.05 (3H, s), 3.32 (1H, dd, *J* 10.5, 5.5 Hz, H-3), 4.05 (1H, dd, *J* 9.0, 9.0 Hz, H-11), 4.39 (1H, dd, *J* 9.0, 9.0 Hz, H-11), 6.91 (1H, ddd, *J* 3.8, 3.8, 3.8 Hz, H-7); lrms (probe 170°C), 232 ($M^+ - H_2O$, 20), 217 (17), 172 (30), 125 (20), 122 (100), 96 (84).

Growth of Marasmius oreades *on malt extract broth and isolation of metabolites*

Twenty 2.8-L Fernbach flasks each containing 1 L of malt extract liquid medium (20 g glucose, 20 g malt extract broth (Difco Laboratories, Detroit, Michigan, USA), 1 g peptone, 1 L water) were inoculated with ca. 10 mL of a mycelial suspension of *Marasmius oreades* (UAMH 5750) (3) and the still cultures were kept at room temperature (20–25°C) for 7 weeks.

The mycelium was separated by filtration through cheesecloth and air-dried for 72 h before being ground to a coarse powder (39.8 g). The filtered broth was concentrated to 1.8 L at reduced pressure (waterbath 40–45°C) and the concentrate was stirred for 12-h periods with three successive 1.5-L volumes of ethyl acetate. The combined ethyl acetate extracts were dried with magnesium sulfate and then evaporated at reduced pressure to give a brown foam (1.495 g). The foam was adsorbed onto silica gel (10 g) and then loaded onto a column of silica gel (150 g) that had been packed with ethyl acetate – Skellysolve B (1:2). Fractions of 25 mL were collected, eluting successively with 1:2 (fractions 1–24), 1:1 (fractions 25–53), 2:1 (fractions 54–81) ethyl acetate – Skellysolve B, and ethyl acetate (fractions 82–100). Each fraction was examined by tlc (ethyl acetate – Skellysolve B, 2:1) and those fractions with similar components were combined.

Fractions 8–10 (6.0 mg) were combined and chromatographed on a column of silica gel (ethyl acetate – Skellysolve B, 1:10) to give *marasmene* (**7**).

Fractions 36–43 (26.4 mg) were combined and chromatographed on a column of silica gel (ethyl acetate – dichloromethane, 1:2) and then the fractions rich in **19***a* were combined and subjected to preparative tlc (methanol–dichloromethane, 1:40, several developments) to give *13-hydroxymarasmene* (**19***a*, 3.1 mg). Fractions enriched in lactol **26** were combined and chromatographed over silica gel (methanol–dichloromethane, 1:20) to give pure lactol **26** (1.2 mg). Fractions enriched in diol **31***a* were combined and chromatographed on silica gel (methanol–dichloromethane, 1:20) to give diol **31***a* (1.5 mg).

The ethyl acetate soluble material from fractions 44–63 (0.15 g) was chromatographed on a column of silica gel (methanol–dichloromethane 1:20) to give successively **18***a* (6.0 mg), **19***b* (5.4 mg), and an oil, which was separated by chromatography on a column of silica gel (ethyl acetate – Skellysolve B, 1:1) into *1α,15-dihydroxymarasmene* (**13***a*, 7 mg) and *3α,15-dihydroxymarasmene* (**6***a*, 15 mg).

The ethyl acetate soluble material from fractions 64–75 (0.06 g) was chromatographed on a column of silica gel (methanol–dichloromethane, 1:20) to give successively **6***a* (7 mg) and fractions containing

3α-hydroxyoreadone (**15***c*) and *11,12,14-trihydroxydrimene* (**23**), which were combined and crystallized from dichloromethane to give pure **23** (4 mg). The mother liquors were chromatographed on silica gel to give pure **15***c* (4.3 mg).

The material that deposited from ethyl acetate solutions of fractions 44–63 and 64–75 was recrystallized from ethyl acetate to give *agrocybin* (**5**) as a heat- and light-sensitive off-white solid (0.294 g), mp 133–140°C (dec.) (lit. (11) mp 133°C (dec.)); Ftir (KBr disc): 3275 (br), 3105 (br), 2206 (s, C≡C), 1679 (s, C=O), 1625 (s, NH bend) cm^{-1}; ^1H nmr (CD_3OD) δ: 4.26 (s, CH_2OH); ^{13}C nmr (CD_3OD) δ: 51.0 (t, CH_2OH), 61.2 (s), 67.6 (s), 68.9 (s), 69.9 (s), 70.5 (s), 81.9 (s), 155.3 (s, C=O); hreims (probe 150°C), *m/z* calcd. for $C_8H_5NO_2$ (M^+): 147.0319; found: 147.0319 (100), 131 ($M^+ - NH_2$, 11), 118 (93), 91 (36), 86 (21), 85 (20), 75 (44), 74 (43), 73 (22), 65 (47).

Fractions 76–91 (84 mg) were combined and chromatographed on a column of silica gel (ethyl acetate – Skellysolve B, 2:1) to give several fractions rich in *3,11,12-trihydroxydrimene* (**22**), which were combined and further chromatographed (5% methanol–dichloromethane) to give pure **22** (14.5 mg).

Marasmene (**7**) crystallized, on standing, as needles, mp 70–74°C; $[\alpha]_D^{24}$ +57° (*c* 0.07, CH_3OH); Ftir ($CHCl_3$ cast): 1380, 1360 (m, *gem* dimethyl), 1280, 1225 (s, C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.71 (3H, s, H-14), 0.91 (3H, s, H-13), 1.16 (1H, dddd, *J* 13.0, 13.0, 4.8, 2.0 Hz, H-1α), 1.29 (1H, br, ddd, *J* 13.5, 13.5, 5.2 Hz), 1.43–1.62 (1H, m), 1.77 (1H, dd, *J* 11.4, 6.8 Hz, H-5), 1.89 (1H, br d, *J* 13.5 Hz), 1.94–2.07 (1H, m, H-6), 2.29 (1H, br d, *J* 19 Hz, H-6), 2.58 (1H, m, H-9), 3.68 (1H, d, *J* 8.0 Hz, H-15α), 3.73 (1H, dd, *J* 8.0, 2.1 Hz, H-15β), 4.30–4.40 (2H, m, H-12), 5.65 (1H, d, *J* 4.5 Hz, H-11), 5.78 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 19.1 (C-2), 20.7 (C-14), 23.6 (C-6), 31.1 (C-13), 33.2 (C-4), 36.2 (C-1), 42.3 (C-3), 43.7 (C-10), 45.0 (C-5), 55.7 (C-9), 69.4 (C-15), 72.3 (C-12), 105.8 (C-11), 121.4 (C-7), 133.4 (C-8); hreims (probe 100°C), *m/z* calcd. for $C_{15}H_{22}O_2$ (M^+): 234.1620; found: 234.1624 (34), 204 (41), 188 (22), 177 (25), 175 (27), 173 (23), 151 (21), 145 (42), 133 (24), 132 (38), 131 (24), 119 (69), 118 (32), 117 (29), 109 (66), 107 (30), 106 (28), 105 (100), 104 (43), 96 (51), 95 (41), 93 (30), 92 (25), 91 (73), 82 (32), 81 (25), 79 (37), 77 (36), 69 (48), 67 (41), 65 (23), 55 (44), 53 (26); cims, *m/z*: 252 (M^+ + 18, 26).

Lactol **26** was obtained as a clear oil; Ftir ($CHCl_3$ cast): 3395 (br, OH), 1717 (w), 1385, 1366 (m, *gem* dimethyl) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.80 (3H, m, H-13), 0.99 (3H, s, H-15), 1.18 (1H, br s, OH), 1.30 (1H, ddd, *J* 13.0, 13.0, 4.4 Hz), 1.45–1.54 (2H, m), 1.50 (1H, dd, *J* 11.5, 5.1 Hz, H-5), 1.83 (1H, ddd, *J* 13.0, 5.2, 2.0 Hz), 1.91 (1H, ddd, *J* 13.7, 5.2, 2.0 Hz), 1.98 (1H, br d, *J* 13.5 Hz), 2.17–2.25 (2H, m, H-6, H-9), 2.60–2.90 (1H, br m, OH), 3.56 (1H, d, *J* 10.7 Hz, H-14), 3.85 (1H, d, *J* 10.8 Hz, H-14), 4.17 (1H, ddd, *J* 11.4, 1.4, 1.4 Hz, H-12), 4.47 (1H, br d, *J* 11.4 Hz, H-12), 5.26 (1H, d, *J* 4.3 Hz, H-11), 5.49 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 15.0 (C-15), 18.1 (C-2), 23.2 (C-6), 26.6 (C-13), 33.4, 35.8 (C-1, C-3), 38.0, 39.0 (C-4, C-10), 50.8 (C-5), 61.8 (C-9), 64.8 (C-14), 69.0 (C-12), 99.4 (C-11), 117.0 (C-7), 136.6 (C-8); hreims (probe 150°C), *m/z* calcd. for $C_{15}H_{24}O_3$ (M^+): 252.1726; found: 252.1729 (9), 234 ($M^+ - H_2O$, 4), 188 (54), 175 (100), 173 (33), 163 (76), 159 (61), 145 (28), 133 (29), 132 (37), 123 (25), 122 (21), 120 (23), 119 (73), 118 (49), 117 (22), 109 (76), 107 (58), 106 (27), 105 (76), 95 (34), 93 (54), 91 (65), 81 (56), 79 (44), 77 (33), 69 (35), 67 (42), 57 (22), 55 (68), 53 (25).

3β,11-Dihydroxydrimene (**31***a*) was obtained as an oil containing small amounts of inseparable impurities; ^1H nmr ($CDCl_3$) δ: 0.86 (3H, s), 0.87 (3H, s), 0.98 (3H, s), 1.1–1.4 (m), 1.6–1.7 (m), 1.78 (3H, br s, H-12), 1.90–2.08 (4H, m), 3.26 (1H, dd, *J* 10.5, 5.4 Hz, H-3), 3.75 (1H, dd, *J* 11.5, 5.0 Hz, H-11), 3.86 (1H, dd, *J* 11.1, 3.4 Hz, H-11), 5.54 (1H, m, H-7); hreims (probe 150°C), *m/z* calcd. for $C_{15}H_{26}O_2$ (M^+): 238.1932; found: 238.1934 (22), 220 ($M^+ - H_2O$, 14), 189 (21), 139 (21), 123 (29), 122 (58), 121 (25), 119 (51), 107 (36), 105 (21), 98 (33), 96 (100), 93 (21), 91 (22), 81 (27), 69 (34), 55 (32). Acetylation of the impure **31***a* with acetic anhydride in pyridine and column chromatography (9% ethyl acetate – Skellysolve B) of the product gave the diacetate **31***b* (0.8 mg) as a clear oil; ^1H nmr ($CDCl_3$) δ: 0.84 (3H, s, H-15), 0.86 (3H, s, H-13), 0.98 (3H, s, H-14), 1.30 (1H, dd, *J* 10.5, 6.2 Hz, H-5), 1.34 (1H, br ddd, *J* 13.2, 13.2, 4.8 Hz, H-1α), 1.60–1.72 (2H, m), 1.67 (3H, br s, H-12), 1.95–2.09 (4H, m), 2.04 (3H, s, OAc), 2.05 (3H, s, OAc), 4.11 (1H, dd, *J* 11.7, 6.5 Hz, H-11), 4.21 (1H, dd, *J* 11.5, 3.8 Hz, H-11), 4.51 (1H, dd, *J* 11.5, 4.8 Hz, H-3), 5.50 (1H, m, H-7); hreims (probe 150°C), *m/z* calcd. for $C_{17}H_{26}O_2$ (M^+ − HOAc): 262.1933; found: 262.1931 (70), 202 (82), 187 (100), 160 (22), 159 (63), 146 (20), 135 (24), 133 (42), 131 (20), 119 (41), 108 (28), 107 (38), 105 (25), 91 (23), 55 (20).

3,11,12-Trihydroxydrimene (**22**) crystallized from ethyl acetate – Skellysolve B as prisms, mp 164–165°C; $[\alpha]_D^{24}$ −10.7° (*c* 0.15, CH_3OH) (lit. (7) mp 165–166°C; $[\alpha]_D^{20}$ −10.9°); Ftir (KBr disc): 3327 (br, OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.78 (3H, s, H-14), 0.87 (3H, s, H-15), 1.00 (3H, s, H-13), 1.29 (1H, dd, *J* 12.0, 4.5 Hz, H-5), 1.32–1.42 (2H, m), 1.65 (1H, ddd, *J* 13.0, 3.6, 1.8 Hz), 1.70 (1H, ddd, *J* 12.8, 4.5, 4.5 Hz), 2.04 (1H, ddd, *J* 13.5, 3.5, 3.5 Hz), 1.94–2.05 (1H, m), 2.08 (1H, ddd, *J* 5.3, 5.3, 2.0 Hz), 2.13–2.18 (1H, m), 2.80 (2H, br s, OH), 3.26 (1H, br dd, *J* 11.0, 3.5 Hz, H-3), 3.69 (1H, dd, *J* 10.6, 8.2 Hz, H-11), 3.91 (1H, dd, *J* 10.7, 2.0 Hz, H-11), 4.01 (1H, br d, *J* 12.0 Hz, H-12), 4.35 (1H, br d, *J* 12.0 Hz, H-12), 5.82 (1H, m, H-7); ^1H nmr (CD_3OD) δ: 0.81 (3H, s, H-14), 0.86 (3H, s, H-15), 0.98 (3H, s, H-13), 1.20–1.40 (2H, m), 1.60–1.75 (2H, m), 2.00–2.20 (4H, m), 3.20 (1H, dd, *J* 10.5, 5.5 Hz, H-3), 3.63 (1H, dd, *J* 11.0, 7.4 Hz, H-11), 3.84 (1H, dd, *J* 11.0, 2.5 Hz, H-11), 3.96 (1H, d, *J* 12.4 Hz, H-12), 4.25 (1H, dd, *J* 12.4 Hz, H-12), 5.80 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 15.0 (C-14), 15.9 (C-15), 24.3 (C-6), 28.1 (C-2), 28.6 (C-13), 36.6 (C-1), 38.9 (C-10), 39.8 (C-4), 50.7 (C-5), 55.8 (C-9), 61.2 (C-11), 66.8 (C-12), 79.6 (C-3), 126.4 (C-7), 138.5 (C-8); hreims (probe 150°C), *m/z* calcd. for $C_{15}H_{26}O_3$ (M^+): 254.1883; found: 254.1883 (10), 236 ($M^+ - H_2O$, 4), 218 ($M^+ - 2H_2O$, 4), 188 (100), 173 (48), 122 (24), 119 (25), 107 (25), 105 (28), 96 (63), 55 (24); cims, *m/z*: 272 (M^+ + 18, 100).

Acetylation of 3α,15-dihydroxymarasmene (**6**a)

Treatment of 3α,15-dihydroxymarasmene (**6***a*, 20 mg) with acetic anhydride (0.10 mL) in pyridine (0.10 mL) for 10 h, followed by addition of benzene (4 mL) and removal of the solvents, gave an oil, which was chromatographed on a column of silica gel. Elution with ethyl acetate – Skellysolve B (1:4) gave first aldehyde **9** (6.7 mg), then **6***b* (7 mg). Aldehyde **9** crystallized from Skellysolve B as prisms, mp 136–137°C; $[\alpha]_D^{24}$ −41.5° (*c* 0.33, CH_3OH); Ftir ($CHCl_3$ cast): 1742 (OAc), 1731 (OAc), 1714 (CHO) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.85 (3H, s, H-14), 0.94 (3H, s, H-13), 1.27 (1H, dddd, *J* 14.5, 14.0, 4.1, 1.6 Hz, H-1α), 1.65 (1H, ddd, *J* 15.5, 4.5, 3.0 Hz, H-1β), 1.82 (1H, dddd, *J* 15.5, 14.3, 4.1, 2.5 Hz, H-2β), 2.07 (3H, s, OAc), 2.08 (3H, s, OAc), 2.17 (1H, ddd, *J* 13.5, 4.1, 3.0 Hz, H-2α), 2.30 (1H, dd, *J* 9.0, 9.0 Hz, H-5), 2.41–2.48 (2H, m, H-6), 2.83 (1H, m, H-9), 4.31 (1H, ddd, *J* 11.3, 1.4, 1.4 Hz, H-12), 4.46 (1H, dddd, *J* 11.2, 2.0, 2.0, 2.0 Hz, H-12), 4.73 (1H, dd, *J* 2.8, 2.8 Hz, H-3), 5.78 (1H, m, H-7), 5.91 (1H, d, *J* 4.2 Hz, H-11), 9.80 (1H, d, *J* 1.8 Hz, H-15); ^{13}C nmr ($CDCl_3$) δ: 20.4 (C-14), 21.18 (OAc), 21.24 (OAc), 22.8 (C-6), 22.9 (C-13), 25.7 (C-2), 26.1 (C-1), 36.8 (C-4), 43.4 (C-5), 47.0 (C-10), 55.6 (C-9), 70.0 (C-12), 77.6 (C-3), 97.7 (C-11), 118.2 (C-7), 134.5 (C-8), 169.8 (OAc), 170.3 (OAc), 205.2 (C-15); hreims (probe 130°C), M^+ not detected, *m/z* calcd. for $C_{17}H_{22}O_4$ (M^+ − HOAc): 290.1518; found: 290.1516 (26), 261 (M^+ − HOAc − CHO, 8), 202 (23), 201 (100), 173 (20); cims, *m/z*: 368 (M^+ + 18, 2). *3α,15-Diacetoxymarasmene* (**6***b*) was obtained as an oil; Ftir ($CHCl_3$ cast): 1734 (OAc) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.81 (3H, s, H-14), 0.93 (3H, s, H-13), 1.16–1.22 (1H, m), 1.70 (1H, ddd, *J* 14.0, 7.0, 2.5 Hz), 2.03–2.12 (2H, m), 2.09 (6H, s, OAc), 2.16 (1H, ddd, *J* 14.0, 4.5, 2.5 Hz), 2.20–2.28 (1H, m), 2.30 (1H, dd, *J* 13.1, 5.5 Hz, H-5), 2.71 (1H, m, H-9), 4.36–4.43 (2H, m, H-12), 4.75 (1H, dd, *J* 2.5, 2.5 Hz, H-3), 5.75 (1H, d, *J* 4.0 Hz, H-11), 5.94 (1H, m, H-7), 6.08 (1H, s, H-15); ^{13}C nmr ($CDCl_3$) δ: 14.2 (C-14), 19.3 (OAc), 21.3 (OAc), 22.6 (C-2), 24.2 (C-6), 26.6 (C-13), 27.8 (C-1), 36.0 (C-4), 39.2 (C-5), 44.0 (C-10), 57.4 (C-9), 71.6 (C-12), 77.6 (C-3), 96.7 (C-15), 104.0 (C-11), 122.6 (C-7), 133.6 (C-8),

169.6 (OAc), 170.5 (OAc); hreims (probe 130°C), M^+ not detected, m/z calcd. for $C_{17}H_{23}O_5$ ($M^+ - CH_3CO$): 307.1545; found: 307.1548 (11), 290 (M^+ − HOAc, 4), 262 (16), 201 (41), 173 (23), 172 (31), 105 (21), 91 (26), 71 (100); cims, m/z: 368 ($M^+ + 18$, 12).

*Acetylation of 15-hydroxymarasmen-3-one (**11**a)*

Compound **11***a* (6.0 mg) was treated with acetic anhydride (0.05 mL) in pyridine (0.02 mL) at room temperature for 1 h and then benzene (4 mL) was added and the mixture was evaporated to dryness. Column chromatography, eluting with ethyl acetate – Skellysolve B (1:2), gave successively aldehyde **12***b* (0.6 mg) and acetate **11***b* (2.8 mg). Aldehyde **12***b* was obtained as an oil; Ftir ($CHCl_3$ cast): 1745 (sh, acetate C=O), 1708 (s, aldehyde C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.01 (3H, s, H-14), 1.13 (3H, s, H-13), 1.36 (1H, dddd, *J* 13.8, 13.8, 4.6, 1.9 Hz, H-1α), 2.07 (3H, s, OAc), 2.16 (1H, dd, *J* 11.5, 6.6 Hz, H-5), 2.28 (1H, ddd, *J* 14.2, 4.7, 2.8 Hz, H-2α), 2.44–2.61 (2H, m, H-6), 2.66 (1H, ddd, *J* 13.8, 5.9, 2.9 Hz, H-1β), 2.77 (1H, ddd, *J* 14.2, 14.2, 5.9 Hz, H-2β), 2.78 (1H, m, H-9), 4.36 (1H, dddd, *J* 11.6, 1.5, 1.5, 1.5 Hz, H-12), 4.48 (1H, dddd, *J* 11.6, 1.9, 1.9, 1.9 Hz, H-12), 5.84 (1H, m, H-7), 5.97 (1H, d, *J* 4.0 Hz, H-11), 9.93 (1H, d, *J* 2.0 Hz, H-15); hreims (probe 120°C), m/z calcd. for $C_{15}H_{18}O_3$ (M^+ − HOAc): 246.1257; found: 246.1257 (43), 218 (28), 217 (M^+ − HOAc − CHO, 100), 175 (28), 132 (65), 119 (24), 117 (20), 105 (36), 91 (45), 77 (23), 55 (24). *15-Acetoxymarasmen-3-one* (**11***b*) crystallized from dichloromethane – ethyl acetate – Skellysolve B as long thin flakes, mp 168–171°C; $[\alpha]_D^{24}$ +15.1° (*c* 0.35, CH_3OH); Ftir ($CHCl_3$ cast): 1752 (s, acetate C=O), 1706 (s, ketone C=O), 1384, 1370 (m, *gem* dimethyl) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.98 (3H, s, H-14), 1.13 (3H, s, H-13), 1.72 (1H, ddd, *J* 14.0, 14.0, 5.5 Hz, H-1α), 2.13 (3H, s, OAc), 2.19 (1H, dd, *J* 9.9, 7.5 Hz, H-5), 2.32–2.41 (3H, m, H-1β, H-6), 2.60 (1H, ddd, *J* 13.9, 6.6, 2.5 Hz, H-2α), 2.72 (1H, m, H-9), 3.06 (1H, ddd, *J* 14.8, 14.0, 6.6 Hz, H-2β), 4.43 (1H, dddd, *J* 11.0, 1.4, 1.4, 1.4 Hz, H-12), 4.49 (1H, dddd, *J* 11.0, 1.4, 1.4, 1.4 Hz, H-12), 5.82 (1H, d, *J* 4.0 Hz, H-11), 5.88 (1H, m, H-7), 6.25 (1H, s, H-15); ^{13}C nmr ($CDCl_3$) δ: 19.3 (C-14), 21.2 (OAc), 23.3 (C-6), 23.4 (C-13), 33.5 (C-2), 35.7 (C-1), 43.8 (C-10), 45.6 (C-5), 47.3 (C-4), 57.1 (C-9), 71.5 (C-12), 96.4 (C-15), 104.1 (C-11), 121.9 (C-7), 133.3 (C-8), 169.4 (OAc), 214.3 (C-3); hreims (probe 200°C), m/z calcd. for $C_{15}H_{18}O_3$ (M^+ − HOAc): 246.1256; found: 246.1261 (14), 218 (M^+ − HOAc − CO, 16), 132 (100), 119 (23); cims, m/z: 324 ($M^+ + 18$, 14).

*Oxidation of 3α,15-dihydroxymarasmene (**6**a)*

(i) With excess pyridinium dichromate. A suspension of 3α,15-dihydroxymarasmene (**6***a*, 7.4 mg) and pyridinium dichromate (50 mg) in dichloromethane (2 mL) was stirred at room temperature for 12 h and then diluted with ether and filtered to remove precipitated chromium complexes. The filtrate was evaporated to give an oil, which was chromatographed on a column of silica gel, eluting with ethyl acetate – Skellysolve B (1:2), to give marasmene-3,15-dione (**8**, 2.5 mg), which crystallized from ethyl acetate – Skellysolve B as prisms, mp 166–167°C; $[\alpha]_D^{24}$ −18.9° (*c* 0.18, CH_3OH); cd (*c* 6.68 mM, CH_3OH), 24°C: $[\theta]_{294}$ −1800, $[\theta]_{226}$ −800; Ftir ($CHCl_3$ cast): 1761 (s, lactone C=O), 1707 (s, ketone C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.20 (3H, s, H-13), 1.46 (3H, s, H-14), 2.01 (1H, ddd, *J* 13.5, 13.5, 4.2 Hz, H-1α), 2.14 (1H, dd, *J* 11.8, 5.8 Hz, H-5), 2.30–2.56 (4H, m, H-1β, H-2α, H-6), 2.98 (1H, m, H-9), 3.04 (1H, ddd, *J* 14.5, 14.5, 5.0 Hz, H-2β), 4.52–4.62 (2H, m, H-12), 6.02 (1H, d, *J* 4.5 Hz, H-11), 6.05 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 21.9, 24.7 (C-13, C-14), 24.4 (C-6), 33.5, 34.4 (C-1, C-2), 45.8 (C-5), 47.5, 48.8 (C-4, C-10), 53.3 (C-9), 72.7 (C-12), 103.9 (C-11), 126.2 (C-7), 131.4 (C-8), 174.3 (C-15), 213.6 (C-3); hreims (probe 140°C), m/z calcd. for $C_{15}H_{18}O_4$ (M^+): 262.1205; found: 262.1208 (44), 262 (67), 234 (M^+ − CO, 13), 132 (100), 120 (21), 119 (34), 105 (22), 91 (31), 77 (20), 67 (21).

(ii) With 1 equivalent of pyridinium dichromate. A suspension of **6***a* (20 mg, 0.075 mmol) and pyridinium dichromate (30 mg, 0.08 mmol) in dichloromethane (5 mL) was stirred at room temperature for 18 h and then diluted with ether and filtered through a short column of silica gel to remove precipitated chromium complexes. The column was washed with ether and the combined filtrates were evaporated to give an oil, which was chromatographed over silica gel. Elution with ethyl acetate – Skellysolve B (1:2) gave successively marasmene-3,15-dione (**8**, 2.7 mg), an oil (7.8 mg) that was a mixture of **10***b* and **11***a*, and unreacted **6***a* (4.0 mg).

The mixture of **10***b* and **11***a* was acetylated with acetic anhydride (0.10 mL) and pyridine (0.10 mL) at room temperature for 2 h, and the resulting oil was chromatographed on silica gel, eluting with ethyl acetate – Skellysolve B (1:3), to give first **10***c* (3.1 mg), then **11***b* (3.8 mg). Compound **10***c* crystallized from dichloromethane – ethyl acetate – Skellysolve B as blades, sublimes from 167–205°C to give prisms, mp 220.5–221°C; Ftir ($CHCl_3$ cast): 1774 (s, lactone C=O), 1717 (s, acetate C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.97 (3H, s, H-13), 1.31 (3H, s, H-14), 1.75 (1H, ddd, *J* 13.8, 3.5, 2.9 Hz, H-2α), 1.85 (1H, br ddd, *J* 13.7, 3.8, 3.8 Hz, H-1β), 1.94 (1H, ddd, *J* 13.5, 13.5, 2.8 Hz, H-1α), 2.04 (1H, dddd, *J* 13.6, 13.6, 3.9, 1.8 Hz, H-2β), 2.09 (3H, s, OAc), 2.14 (1H, dd, *J* 9.8, 8.5 Hz, H-5), 2.23–2.30 (2H, m, H-6), 2.90 (1H, m, H-9), 4.48 (1H, dddd, *J* 10.4, 1.4, 1.4, 1.4 Hz, H-12), 4.53 (1H, dddd, *J* 10.5, 1.4, 1.4, 1.4 Hz, H-12), 4.83 (1H, dd, *J* 3.9, 1.8 Hz, H-3), 5.94 (1H, d, *J* 4.5 Hz, H-11), 5.98 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 21.2 (C-14), 21.9 (OAc), 22.5 (C-2), 23.7 (C-6), 27.2 (C-13), 28.1 (C-1), 36.0 (C-4), 39.6 (C-5), 48.6 (C-10), 53.9 (C-9), 72.6 (C-12), 77.6 (C-3), 103.5 (C-11), 126.3 (C-7), 131.6 (C-8), 170.3 (OAc), 171.4 (C-15); hreims (probe 100°C), m/z calcd. for $C_{17}H_{22}O_5$ (M^+): 306.1467; found: 306.1439 (0.3); m/z calcd. for $C_{16}H_{22}O_3$ ($M^+ - CO_2$): 262.1569; found: 262.1571 (76), 202 (41), 173 (35), 172 (100), 157 (36), 145 (26), 143 (23), 132 (48), 131 (23), 129 (25), 119 (39), 105 (39), 104 (22), 91 (28), 69 (24); cims, m/z: 324 ($M^+ + 18$, 100).

*Oxidation of 1α,15-dihydroxymarasmene (**13**a)*

(i) With excess pyridinium dichromate. A suspension of **13***a* (5.6 mg) and pyridinium dichromate (50 mg) in dichloromethane (2 mL) was stirred at room temperature for 18 h and then diluted with ether and filtered. The filtrate was evaporated to give an oil, which was chromatographed on silica gel, eluting with ethyl acetate – Skellysolve B (1:4), to give marasmene-1,15-dione (**14**, 2.7 mg), which crystallized from dichloromethane – Skellysolve B as prisms, mp 110.5–111.5°C; $[\alpha]_D^{24}$ +70.8° (*c* 0.26, CH_3OH); cd (*c* 9.92 mM, CH_3OH), 24°C: $[\theta]_{308}$ +7300, $[\theta]_{299}$ −7800, $[\theta]_{219}$ −2800; Ftir ($CHCl_3$ cast): 1767 (s, lactone C=O), 1713 (s, ketone C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.04 (3H, s, H-13), 1.43 (3H, s, H-14), 1.71 (1H, ddd, *J* 14.2, 14.2, 3.5 Hz, H-3α), 1.92 (1H, ddd, *J* 14.0, 5.1, 3.8 Hz, H-3β), 2.02 (1H, dd, *J* 11.3, 6.0 Hz, H-5), 2.28–2.48 (2H, m, H-6), 2.36 (1H, ddd, *J* 14.0, 3.8, 3.8 Hz, H-2α), 2.89 (1H, ddd, *J* 14.5, 14.5, 5.1 Hz, H-2β), 3.35 (1H, m, H-9), 4.43 (1H, ddd, *J* 10.5, 1.2, 1.2 Hz, H-12), 4.52 (1H, br d, *J* 10.5 Hz, H-12), 5.93 (1H, m, H-7), 6.12 (1H, d, *J* 4.5 Hz, H-11); ^{13}C nmr ($CDCl_3$) δ: 21.5, 31.4 (C-13, C-14), 25.4 (C-6), 32.7, 36.5 (C-2, C-3), 41.4 (C-4), 47.9 (C-5), 48.8 (C-9), 64.7 (C-10), 72.3 (C-12), 105.4 (C-11), 126.0 (C-7), 131.3 (C-8), 169.3 (C-15), 205.5 (C-1); hreims (probe 150°C), m/z calcd. for $C_{15}H_{18}O_4$ (M^+): 262.1205; found: 262.1211 (44), 234 (M^+ − CO, 4), 218 ($M^+ - CO_2$, 100), 176 (55), 161 (29), 134 (26), 120 (39), 119 (27), 91 (39), 77 (21).

(ii) With 1 equivalent of pyridinium dichromate. A suspension of **13***a* (20 mg, 0.075 mmol) and pyridinium dichromate (30 mg, 0.08 mmol) in dichloromethane (5 mL) was stirred at room temperature for 18 h and then diluted with ether and filtered through a short column of silica gel to remove precipitated chromium complexes. The column was washed with ether and the combined filtrates were evaporated to give an oil, which was chromatographed on a column of silica gel. Elution with ethyl acetate – Skellysolve B (1:2) gave successively a mixture of **14** and **15***a* (4.4 mg, approx. 6:4 by ^1H nmr spectrum), **13***b* (1.7 mg), impure 15-hydroxymarasmen-1-one (1.6 mg), and unreacted **13***a* (2.1 mg). The mixture of **14** and **15***a* was separated by column chromatography, eluting with ethyl acetate – Skellysolve B (1:10), to give marasmene-1,15-dione (**14**) (2.6 mg) and *O*-formyloreadone (**15***a*) (0.8 mg). Compound **13***b* was obtained as an oil; Ftir ($CHCl_3$ cast): 3430 (br, OH), 1769 (s, lactone C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.01 (3H, s, H-13), 1.25 (3H, s, H-14), 1.35 (1H, ddd, *J* 13.9, 3.6,

3.6 Hz, H-3β), 1.63–1.70 (1H, m), 1.75 (1H, ddd, *J* 13.9, 13.9, 3.5 Hz, H-3α), 2.02 (1H, dd, *J* 11.4, 6.3 Hz, H-5), 2.07 (1H, dddd, *J* 13.9, 13.9, 3.6, 2.2 Hz, H-2β), 2.16–2.40 (2H, m, H-6), 3.54 (1H, m, H-9), 3.96 (1H, br s, H-1), 4.47 (1H, ddd, *J* 10.6, 1.4, 1.4 Hz, H-12), 4.55 (1H, br d, *J* 10.6 Hz, H-12), 5.91 (1H, m, H-7), 5.96 (1H, d, *J* 4.5 Hz, H-11); ^{13}C nmr ($CDCl_3$) δ: 21.9, 24.3, 26.3, 32.4, 32.7, 33.7, 38.9, 48.2, 67.3 (C-1), 72.7 (C-12), 103.7 (C-11), 125.6 (C-7), 131.7 (C-8), 173.9 (C-15) (one signal obscured); hreims (probe 150°C), *m/z* calcd. for $C_{15}H_{20}O_4$ (M^+): 264.1362; found: 264.1363 (72), 220 (100), 202 (23), 201 (22), 190 (91), 187 (20), 174 (51), 173 (31), 164 (75), 159 (34), 157 (34), 151 (28), 149 (29), 146 (45), 145 (36), 133 (24), 132 (27), 131 (37), 129 (33), 121 (41), 120 (32), 119 (74), 118 (74), 117 (60), 115 (24), 105 (63), 104 (23), 95 (21), 93 (53), 92 (29), 91 (99), 81 (46), 79 (39), 77 (52).

Reduction of anhydromarasmone (2)

Triethylsilane (10 μL of a 0.6 mol L^{-1} solution in carbon tetrachloride) was added to a stirred solution of anhydromarasmone (**2**, 1.1 mg) in trifluoroacetic acid (0.2 mL). The yellow solution was stirred at room temperature for 5 h, then a further 10 μL of the triethylsilane solution was added and stirring continued for a further 12 h. The mixture was diluted with dichloromethane (1 mL), and saturated aqueous sodium hydrogen carbonate (0.5 mL) was added. The dichloromethane layer was separated, dried with magnesium sulfate, and evaporated to give an oil, which was chromatographed on silica gel. Elution with ethyl acetate – Skellysolve B (1:10) gave marasmene-1,15-dione (**14**) as an oil, identical (^{1}H nmr, tlc) with that prepared by oxidation of **13***a*.

Reduction of marasmene-3,15-dione (8)

Sodium borohydride (1.0 mg) was added to a solution of **8** (4.5 mg) in methanol (0.5 mL) and the mixture was stirred at room temperature for 15 min, then 1 M hydrochloric acid (0.1 mL) was added. The solution was diluted with ethyl acetate, dried with magnesium sulfate, and evaporated to give an oil, which was chromatographed on silica gel. Elution with ethyl acetate – Skellysolve B (1:1) gave **10***a* (3.8 mg), which crystallized from dichloromethane – ethyl acetate – Skellysolve B as prisms, mp 202.5–203.5°C; Ftir ($CHCl_3$ cast): 3483 (br, OH), 1753 (s, lactone C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.10 (3H, s, H-13), 1.18 (3H, s, H-14), 1.48 (1H, br d, *J* 5.4 Hz, OH, D_2O exchangeable), 1.64 (1H, dd, *J* 13.5, 3.5 Hz, H-5), 1.68–1.76 (2H, m), 1.79 (1H, dddd, *J* 13.4, 13.4, 2.5, 2.5 Hz, H-2β), 2.13 (1H, ddd, *J* 13.6, 3.2, 3.2 Hz, H-1β), 2.30–2.36 (2H, m, H-6), 2.80 (1H, m, H-9), 3.35 (1H, br d, *J* 10.5 Hz, H-3, collapsed to a dd, *J* 11.4, 3.9 Hz upon addition of D_2O), 4.47 (1H, ddd, *J* 10.6, 1.2, 1.2 Hz, H-12), 4.52 (1H, br d, *J* 10.7 Hz, H-12), 5.93 (1H, d, *J* 4.3 Hz, H-11), 5.97 (1H, m, H-7); ^{13}C nmr ($CDCl_3$) δ: 14.5 (C-14), 24.0 (C-6), 27.0 (C-2), 27.7 (C-13), 33.4 (C-1), 38.8 (C-4), 44.6 (C-5), 48.8 (C-10), 54.2 (C-9), 72.6 (C-12), 78.6 (C-3), 103.4 (C-11), 126.3 (C-7), 131.3 (C-8), 174.4 (C-15); hreims (probe 100°C), *m/z* calcd. for $C_{15}H_{20}O_4$ (M^+): 264.1362; found: 264.1357 (40), 220 (21), 208 (100), 173 (22), 172 (28), 145 (24), 132 (61), 119 (57), 118 (21), 117 (21), 105 (59), 104 (43), 91 (53), 79 (23), 77 (25), 69 (44), 55 (24).

Oxidation of 3β-hydroxymarasmene (18a)

Pyridinium dichromate (75 mg) was added to a solution of **18***a* (50 mg) in dichloromethane (10 mL) and the mixture was stirred at room temperature for 24 h. The mixture was diluted with ether and washed successively with 1 M hydrochloric acid, water, saturated aqueous sodium hydrogen carbonate, and brine. Evaporation of the dried solution gave a pale yellow oil, which was chromatographed on silica gel, eluting with ethyl acetate – Skellysolve B (1:2) to give marasmen-3-one (**18***b*, 25 mg), which crystallized from dichloromethane – Skellysolve B as microcrystals, mp 135–138°C.

Acetylation of 3α-hydroxyoreadone 15c)

3α-Hydroxyoreadone (**15***c*) (5.0 mg) was acetylated with acetic anhydride (0.02 mL) and pyridine (0.05 mL) at room temperature for 3 h, then benzene (2 mL) was added and the mixture was evaporated to give a pale yellow oil (6.1 mg). Column chromatography, eluting with ethyl acetate – Skellysolve B (1:2), gave successively impure dehydrooreadone acetate (**17***a*) (0.3 mg), diacetate **15***d* (4 mg), and monoacetate **15***e* (0.7 mg). Diacetate **15***d* was obtained as an oil; ^{1}H nmr ($CDCl_3$) δ: 1.04 (3H, s), 1.21 (3H, s), 1.99 (3H, s, OAc), 2.04 (3H, s, OAc), 2.18–2.27 (3H, m), 2.36 (1H, dd, *J* 12.0, 9.5 Hz, H-10), 2.52 (1H, dd, *J* 15.5, 3.0 Hz, H-2α), 2.79 (1H, ddd, *J* 15.5, 3.4, 0.8 Hz, H-2β), 2.95 (1H, m, H-9), 4.39 (1H, dddd, *J* 12.3, 2.0, 2.0, 2.0 Hz, H-12), 4.47 (1H, dddd, *J* 12.5, 2.0, 2.0, 2.0 Hz, H-12), 5.06 (1H, dd, *J* 3.2, 3.2 Hz, H-3), 5.65 (1H, m, H-7), 6.63 (1H, d, *J* 5.0 Hz, H-11); ^{13}C nmr ($CDCl_3$) δ: 19.9, 21.0, 21.3, 24.6, 26.4, 36.5, 41.3, 42.5, 43.8, 46.2, 69.2, 80.1, 97.8, 117.0, 135.3, 170.0, 170.1, 207.6. Monoacetate **15***e* was obtained as an oil; ^{1}H nmr ($CDCl_3$) δ: 1.13 (3H, s), 1.14 (3H, s), 1.98 (3H, s, OAc), 2.16–2.35 (4H, m), 2.45 (1H, dd, *J* 14.8, 3.5 Hz), 2.84 (1H, dd, *J* 14.8, 3.0 Hz), 2.95 (1H, m), 3.90 (1H, ddd, *J* 3.2, 3.2, 3.2 Hz), 4.37 (1H, dddd, *J* 12.2, 2.0, 2.0, 2.0 Hz), 4.46 (1H, dddd, *J* 12.5, 2.0, 2.0, 2.0 Hz), 5.64 (1H, m), 6.63 (1H, s).

Surfactant assisted permanganate oxidation of aromatic compounds

BRANKO JURŠIĆ
Laboratory of Organic Chemistry, Faculty of Science, University of Zagreb, Strossmayerov trg 14, 41000 Zagreb, Yugoslavia

Received April 12, 1988[1]

BRANKO JURŠIĆ. Can. J. Chem. **67**, 1381 (1989).

Potassium permanganate in aqueous solutions of surfactant can be used to oxidize aromatic compounds to the corresponding acids. It has been found that oxidation of aromatic alcohols and aldehydes proceeds under mild reaction conditions, while the oxidation of alkylbenzenes requires higher temperatures. The yields are very high and the work-up is simple, which makes oxidation with potassium permanganate a convenient synthetic method.

Key words: surfactant, oxidation, aromatic compounds, catalysis.

BRANKO JURŠIĆ. Can. J. Chem. **67**, 1381 (1989).

On peut utiliser le permanganate de potassium, dans des solutions aqueuses d'agent de surface, pour oxyder les composés aromatiques en acides correspondants. On a trouvé que l'oxydation des alcools et des aldéhydes aromatiques s'effectue dans des conditions douces, tandis que celle des alkylbenzènes requiert des températures plus élevées. Les rendements très élevés et la simplicité des manipulations rendent cette oxydation par le permanganate attrayante du point de vue synthétique.

Mots clés : agent de surface, oxydation, composés aromatiques, catalyse.

[Traduit par la revue]

Introduction

The oxidation of alcohols by permanganate ion has been the subject of extensive study (1–4). It is generally accepted that in acidic or basic media the permanganate ion oxidizes primary alcohols to acids; alcohols are relatively inert to neutral permanganate solutions. However, as reported by Lee (4*a*, citing Fatiati (4*b*)), potassium permanganate may be used in acidic, neutral, and basic aqueous solutions, but not in completely nonaqueous solvents. This is particularly useful for the oxidation of such hydroxy compounds as lactic and mandelic acids, which are completely soluble in aqueous base. Aqueous acetic acid or aqueous acetone has been used as the solvent; the use of two-phase systems, such as ether/water, dichloromethane/water, or petroleum ether/water has been described for permanganate oxidation of hydroxy compounds such as ethyl lactate or ethyl pyruvate. In a series of new methods, the effective use of phase-transfer catalysis with permanganate ion for the oxidation of hydroxy compounds has been demonstrated (5, 6).

The permanganate ion oxidizes the side chain of aromatic compounds; the products obtained are usually the corresponding acids (7). A series of alkyl-aromatic compounds has recently been oxidized by potassium permanganate in the presence of a phase-transfer catalyst (8–12). In this way toluene, stilbene, *p*-xylene, mesitylene, and durene were oxidized with potassium permanganate in a two-phase system (hydrocarbon/water) containing cetyltrimethylammonium bromide (CTAB) in 1:1:3.3 × 10^{-3}:138 molar ratio (ArH:$KMnO_4$:CTAB:H_2O) at 70–80°C, yielding the corresponding benzenecarboxylic acids, i.e., benzoic (93%), terephthalic (95%), trimesic (90%), pyromellitic (80%), and benzoic (84%) acids, respectively (8).

The conditions under which surfactant can be used in preparative organic chemistry are quite varied. Although the mechanism for many surfactant assisted reactions is well understood, there are still limitations to the application of micelles in preparative chemistry. The advantage of large rate enhancement is offset by the limited amount of substrate solubilization, the restricted temperature range, and the difficulty of separating the products from the surfactants (13). In spite of these limitations, Menger *et al.* succeeded in increasing the yield of $KMnO_4$ mediated oxidation of piperonal to piperonylic acid from 37 to 65% by the addition of catalytic amounts of cationic CTAB (14).

In this paper I would like to demonstrate the beneficial use of surfactants in several oxidation reactions. In water solution, surfactant probably forms some kind of aggregate, for instance micelles, and disperses organic compounds in water, which could conceivably result in higher yields and shorter reaction times. Surfactant also is capable of catalyzing many organic reactions (13), yet neither "emulsion catalysis" nor the micellar catalysis by surfactants have been exploited to any degree in synthetic organic chemistry.

TABLE 1. Percent yields of benzoic acid produced from the oxidation of benzyl alcohol (0.01 mol) by $KMnO_4$ (0.01 mol/0.5 L water)

Concentration of surfactant	Molar ratio surfactant/benzyl alcohol	Yield (%)
0	—	32
0.0001 M CTAB[a]	0.01	38
0.001 M CTAB	0.1	47
0.01 M CTAB	1	87
0.1 M CTAB	10	81
0.5 M CTAB	50	80
0.0001 M SS[b]	0.01	45
0.001 M SS	0.1	87
0.01 M SS	1	92
0.1 M SS	10	92

[a]CTAB = cetyltrimethylammonium bromide.
[b]SS = sodium stearate.

Results and discussion

I first investigated the heterogeneous oxidation of benzyl alcohol to benzoic acid. The reaction was carried out by stirring benzyl alcohol (1.0 g; 0.01 mol) with 500 mL of aqueous $KMnO_4$ (1.06 g; 0.01 mol) at room temperature in the presence or absence of surfactant (Table 1). After 8 h the reaction mixture was worked up. The yields of benzoic acid are listed in Table 1. As can be seen from the table, under the conditions employed

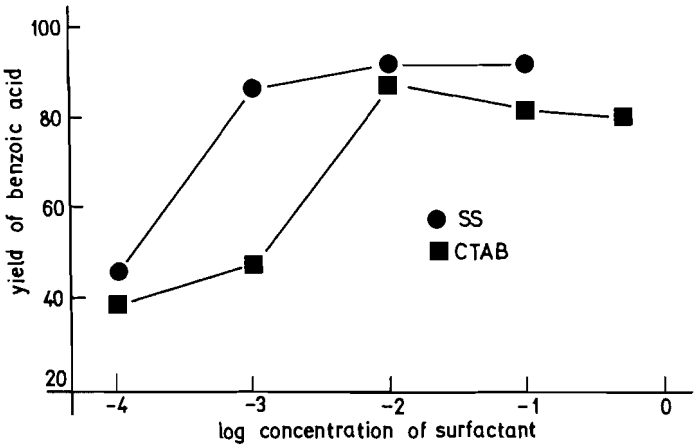

FIG. 1. Yield of benzoic acid from benzyl alcohol by $KMnO_4$ oxidation as a function of surfactant concentration.

the presence of surfactant, cetyltrimethylammonium bromide (CTAB) or sodium stearate (SS), plays an important role in accelerating the reaction, and an overall 40–60% increase in yield of benzoic acid was observed (Fig. 1). The same results were obtained when benzaldehyde and toluene were oxidized in the presence of surfactant. On the basis of these results the most suitable concentration of surfactant (0.01 mol surfactant/0.5 L water) was determined. The yields obtained for oxidation of a number of aromatic substrates by potassium permanganate in CTAB or SS are given in Table 2. The permanganate ion, as evidenced by vis spectroscopy, resides in the aqueous medium and the oxidation can proceed at the surface of the aggregates

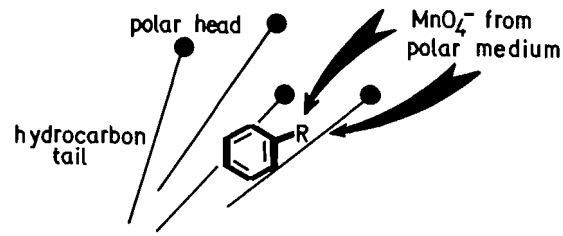

FIG. 2. Schematic representation of $KMnO_4$ oxidation at surface of the surfactant aggregate.

(Fig. 2) giving rise to the formation of benzoic salt, which, being soluble in water, resides in the bulk water. The work-up was simple and involved saturation of the reaction mixture with NaCl, filtration, acidification of the water layer, separation of precipitate, and purification by recrystallization.

It can be concluded that in some cases cationic and anionic surfactants can increase the yield and shorten the reaction time. Surfactant catalysis might be advantageous in large-scale reactions and in reactions of sensitive water-soluble liquids that require minimum exposure to aqueous solution. Therefore oxidation with potassium permanganate in the presence of surfactant is a valuable addition to the methods already available to synthetic organic chemists.

Experimental

Melting points are uncorrected. The starting alcohols, aldehydes, and alkylbenzenes are commercially available. Cetyltrimethylammonium bromide (CTAB) was commercial quality (Fluka) and used without further purification. Sodium stearate (SS) was prepared immediately before use from stearic acid and sodium hydroxide. The

^{1}H nmr spectra were recorded on a JEOL FX-90Q spectrometer. Infrared spectra of samples in KBr were recorded on a Perkin–Elmer 257 spectrometer. All acids isolated gave ir and ^{1}H nmr spectra identical with those of authentic specimens.

Oxidation of benzaldehyde by $KMnO_4$ in the presence of SS

To water (100 mL) were added stearic acid (0.56 g; 0.002 mol) and sodium hydroxide (0.08 g; 0.002 mol). After heating to 80°C and vigorously stirring for 1 h, the reaction suspension was cooled down and benzaldehyde (5.3 g; 0.05 mol) and potassium permanganate (5.9 g; 0.0375 mol) were added; the reaction suspension was then heated and stirred vigorously at 50°C. After 6 h the suspension was cooled down and the aqueous layer separated by filtration through a short column of sodium chloride. The water layer was acidified to pH 3 by the addition of hydrochloric acid. The precipitate of benzoic acid was separated by filtration and washed with cold water (3 × 10 mL). Recrystallization from water yielded pur benzoic acid (4.6 g; 75%), mp 120–122°C.

Oxidation of benzaldehyde by $KMnO_4$ in the presence of CTAB

To an aqueous solution (100 mL) of cetyltrimethylammonium bromide (0.728 g; 0.002 mol), benzaldehyde (5.3 g; 0.05 mol) was added with stirring at 40°C. After 6 h the reaction suspension was cooled down and the aqueous layer separated by filtration through a short column of sodium chloride. The water layer was extracted with ether (2 × 20 mL) and acidified to pH 3 by addition of hydrochloric acid. The precipitate of benzoic acid was separated by filtration and washed three times with 10-mL portions of cold water. Recrystallization from water yielded pure benzoic acid (5.1 g; 82%), mp 121–122°C.

The oxidation of other aromatic compounds with $KMnO_4$ in the presence of SS or CTAB was achieved in the same manner and under same conditions as presented in Table 2.

Received January 12, 1989

CHEUK K. LAU, HAYDN W. R. WILLIAMS, SYLVIE TARDIFF, CLAUDE DUFRESNE, JOHN SCHEIGETZ, and PATRICE C. BÉLANGER. Can. J. Chem. **67**, 1384 (1989).

Reaction of a phenol with an aldehyde in the presence of phenylboronic acid gives a 1,3,2-benzodioxaborin. The latter could be reduced to the corresponding *ortho*-alkylphenol with *tert*-butylamine borane in the presence of aluminum chloride. Alternatively, the dioxaborin, when reacted with an alkylthiol or an alcohol in the presence of an acid, gave the corresponding *ortho*-alkylthiomethyl- or *ortho*-alkoxymethylphenol.

Key words: phenol, alkylation, *ortho*-specific, 1,3,2-benzodioxaborin.

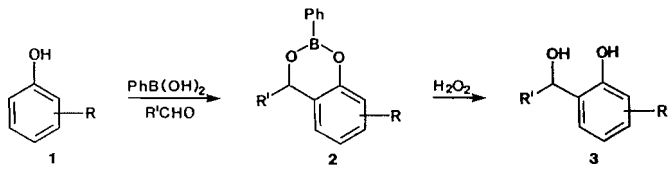
CHEUK K. LAU, HAYDN W. R. WILLIAMS, SYLVIE TARDIFF, CLAUDE DUFRESNE, JOHN SCHEIGETZ et PATRICE C. BÉLANGER. Can. J. Chem. **67**, 1384 (1989).

La réaction d'un phénol avec un aldéhyde, en présence d'acide phénylboronique, conduit à une 1,3,2-benzodioxaborine qui, sous l'influence d'une *tert*-butylamine borane en présence de chlorure d'aluminium, peut être réduite en *ortho*-alkylphénol correspondant. Par ailleurs, lorsqu'on fait réagir la dioxaborine avec un alkylthiol ou un alcool en présence d'un acide, on obtient les dérivés *ortho*-alkylthiométhyl- ou *ortho*-alkoxyméthyl-phénols correspondants.

Mots clés : phénol, alkylation, *ortho*-spécifique, 1,3,2-benzodioxaborine.

[Traduit par la revue]

Introduction



ortho-Alkyl- and *ortho*-thioalkylphenols are useful intermediates in organic synthesis. However, most direct alkylations of phenols are not selective, usually resulting in a mixture of *ortho*-, *para*-, and poly-substitution (for a recent review on *ortho*-thioalkylation, see ref. 1). *ortho*-Thioalkylation of phenols based on the [2,3]-sigmatropic rearrangement of the ylide formed from the corresponding oxasulfonium salt of the phenol is *ortho*-specific (2). The method generally gives good yield of the corresponding alkylthiomethylphenol, which could be elaborated further to other products. Recently, an improved procedure based on the same principle was reported (2*c*). *o*-Metallation of protected phenol derivatives followed by trapping with electrophiles provides a useful alternative for substrates that are stable to the metallation condition (3). Metal coordinated *o*-alkylation of phenol, though not as well studied, could also be quite useful (4). In a similar approach, Peer (5) and Nagata *et al.* (6) demonstrated the utility of phenylboronic acid in the condensation of an aldehyde with a phenol to give a 1,3,2-benzodioxaborin **2**, which, after oxidative work-up, gave the corresponding α-hydroxyalkyl derivative **3** (Scheme 1).

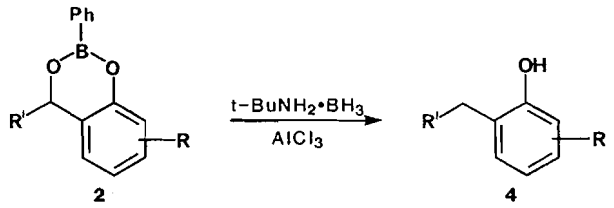
Herein we would like to report the further elaboration of such dioxaborins to give the corresponding *o*-alkyl phenol directly, as well as various *o*-thioalkylphenols and *o*-alkoxymethylphenols.

Results and discussion

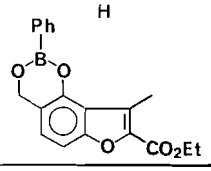
ortho-*Alkylation of phenols*

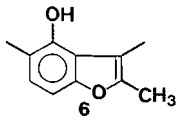
Using the procedure of Nagata *et al.* (6), phenols were allowed to react with phenylboronic acid and an aldehyde in refluxing toluene in the presence of propanoic acid or trichloroacetic acid to give the corresponding 2-phenyl-4-alkyl-1,3,2-benzodioxaborins **2**. The latter were reduced with *tert*-butylamine borane in the presence of aluminum chloride in dichloromethane to give the corresponding *o*-alkylphenols **4**. The reagent was originally developed for the reductive deoxygenation of aryl ketones and aldehydes (7). The results are summarized in Table 1. Various aldehydes, including paraformaldehyde, benzaldehyde, and aliphatic aldehydes, were used. If desired, the intermediate dioxaborin can be isolated and characterized. In the preparation of **2***b*, we were able to obtain a higher yield (71%) than reported (49%) by using excess benzaldehyde. The conditions for the reduction of **2** to the corresponding *o*-alkylphenol depend on the reactivity of the substrate. The double benzylic benzaldehyde derivative **2***b* was reduced to 2-benzylphenol in 45 min at 0°C. Most substrates require reaction at room temperature overnight for completion. Reduction of the 5-methyl derivative **2***a* at room temperature overnight gave only 50% of the desired 2,5-dimethyl phenol with 25% starting material recovered. Interestingly, the dioxaborin derivative obtained from ethyl 4-hydroxybenzofuran-2-carboxylate **5** was reduced to 4-hydroxy-2,3,5-trimethylbenzofuran **6** after 3 days at room temperature, the ester being completely reduced to a methyl group. If the reaction was interrupted after 1 day, a mixture of intermediate alcohols at positions 2 and 5 resulted. Other reducing agents, such as triethylsilane in the presence of boron trifluoride, may also be used in the reduction of the dioxaborin in most cases. An exception is the 4-hydroxybenzofuran derivative **5**, in which case a complex mixture resulted.

SCHEME 1



ortho-*Thioalkylation and* ortho-*alkoxymethylation*





Reaction of a 2-phenyl-4-alkyl-1,3,2-benzodioxaborin **2** with various thiols in the presence of aluminum chloride in dichloromethane at 0°C gave the corresponding *o*-alkylthiomethylphenol **7**. Reaction of **2** in refluxing alcohol with a catalytic amount of concentrated sulphuric acid gave the

SCHEME 2

corresponding *o*-alkoxymethylphenol derivative **8**. The results are summarized in Table 2. In general, the overall yield of the *o*-alkylthiomethylphenol obtained in this reaction is higher than in the sulfonium ylide rearrangement method (2), especially in the case of the 4-hydroxybenzofuran derivative **5**. Furthermore, various *o*-alkylthiomethyl and *o*-alkyloxymethyl derivatives can be prepared from the same intermediate, making this a very versatile approach in preparing analogs.

The 2-phenyl-4-alkyl-1,3,2-benzodioxaborin **2** has been shown to be a very useful and versatile synthetic intermediate, since its formation is *ortho*-specific and regioselective. It can be readily oxidized to the corresponding α-hydroxyalkylphenol (5, 6), reduced to *o*-alkylphenol, or transformed to alkylthiomethylphenol or alkoxymethylphenol derivatives, and thus provides an efficient route to any of these classes of compounds (Scheme 2).

Experimental

General information

Proton nuclear magnetic resonance spectra were obtained on a Bruker AM250 spectrometer. Reported boiling points are those observed during distillation with a Kugelrohr apparatus and are uncorrected. Melting points were measured on a Buchi 510 melting point apparatus and are uncorrected. Low-resolution mass spectral analyses were performed by the Morgan–Schaffer Corporation, Montreal. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario. All reactions, as well as column chromatography, were monitored routinely with the aid of thin-layer chromatography using precoated silica gel GF plates (Analtech).

tert-Butylamine borane was purchased from Callery Chemical Co. Ltd. and was used without purification. Dichloromethane and aluminum chloride were used without purification. Most of the compounds used in this study were commercial products, others were prepared using known procedures. The products obtained were readily available materials in most cases. If not, identification was based on ^{1}H nmr, ir, mass spectra, and elemental analyses.

Since all the reactions performed are similar in many aspects, a typical reaction is described as a specific example. In general, most reactions were performed with 10 mmol of starting material for ease of handling and isolation of products.

General procedure A

*Preparation of 2-phenyl-4-(4-phenylbutyl)-1,3,2-benzodioxaborin (**2**d)*

A mixture of phenol (0.941 g, 10 mmol), phenylboronic acid (1.46 g, 12 mmol), 4-phenylbutyraldehyde (2.22 g, 15 mmol), and trichloroacetic acid (0.5 g) in toluene was heated under reflux for 20 h, with azeotropic removal of water using a Dean–Stark trap. The reaction mixture was concentrated and the resulting oil was chromatographed (eluting with 5% ethyl acetate in hexane) to give 1.6 g (50%) of the title compound; mp 78–79°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 8.0 (d, 2H), 7.4 (m, 3H), 7.0–7.3 (m, 9H), 5.3 (m, 1H, C*H*O), 2.7 (m, 2H), 1.95 (m, 4H).

*2,4-Diphenyl-1,3,2-benzodioxaborin (**2**b)*

According to the general procedure, using excess benzaldehyde, the title compound was obtained from **5***d* in 71% yield; ^{1}H nmr (250 MHz, $CDCl_3$) was identical to that reported (6).

*Preparation of 2-phenyl-4-phenylmethyl-1,3,2-benzodioxaborin (**2**c)*

According to general procedure, from **5***d*, 33% yield; mp 55–57°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 7.8–7.98 (d, 2H, J = 6 Hz), 6.9–7.6 (m, 12H), 5.47 (t, 1H, J = 3.7 Hz, C*H*O), 3.06–3.3 (m, 2H). *Anal.* calcd. for $C_{20}H_{17}BO_2$: C 80.03, H 5.70; found: C 79.90, H 5.54.

*Preparation of ethyl 9-methyl-2-phenyl-4*H*-1,3,2-dioxaborin [6,5-e]-benzofuran-8-carboxylate (**5**)*

According to the general procedure, from **2***d*, 77% yield after recrystallization from acetonitrile; mp 171–172°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 7.97 (d, 2H, J = 7.9 Hz), 7.50 (m, 3H), 7.22 (d, 1H, J = 7.5 Hz), 7.00 (d, 1H, J = 7.5 Hz), 5.31 (s, 2H, CH_2O), 4.46 (q, 2H, J = 7.5 Hz), 2.95 (s, 3H), 1.46 (t, 3H). *Anal.* calcd. for $C_{19}H_{17}BO_5$: C 67.89, H 5.10, B 3.22; found: C 67.24, H 5.09, B 3.11.

General procedure B

*Preparation of 2-(4-phenylbutyl)phenyl (**4**d)*

To a suspension of anhydrous aluminum chloride (0.4 g, 3 mmol) in dichloromethane (15 mL) at 0°C was added *tert*-butylamine borane (0.52 g, 6 mmol). The resulting mixture was allowed to react at 0°C for 20 min. A colorless solution resulted. A solution of 2-phenyl-4-(4-phenylbutyl)-1,3,2-benzodioxaborin (**5***d*) (0.328 g, 1 mmol) in 2 mL of dichloromethane was added. The mixture was warmed to room temperature and allowed to react for 20 h. Cold dilute (1 N) HCl was added. The product was extracted with dichloromethane. The organic extracts were dried over anhydrous magnesium sulfate, and concentrated to an oil. Chromatography of the latter on silica gel (eluted with 10% ethyl acetate in hexane) gave 0.214 g (95% yield) of the title compound; mp 78–79°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 7.0–7.3 (m, 7H), 6.85 (t, 1H, J = 11.4 Hz), 6.72 (d, 1H, J = 7.6 Hz), 4.78 (s, 1H, O*H*), 2.7 (m, 4H), 2.65 (m, 4H). *Anal.* calcd. for $C_{16}H_{18}O$: C 84.95, H 7.96; found: C 84.62, H 7.92.

*2,5-Dimethylphenol (**4**a)*

According to the general procedure, from **4***d*, 50% yield after chromatography; mp 68–69°C; spectral data identical to commercial material. Another 25% of starting material (**5***a*) was recovered.

For personal use only.

*2-Phenylmethylphenol (**4**b)*

According to the general procedure, from **4***d*, 97% yield after only 45 min at 0°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 7.09–7.35 (m, 7H), 6.75–6.95 (s, 2H), 4.68 (s, 1H, O*H*), 4.00 (s, 2H, CH_2Ph). *Anal.* calcd. for $C_{13}H_{12}O$: C 84.80, H 6.50; found: C 84.49, H 6.86.

*2-Phenylethylphenol (**4**c)*

According to the general procedure, from **4***d*, 71% yield; mp 80–81°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 7.03–7.30 (m, 8H), 6.83–6.93 (m, 1H), 6.75 (d, 1H), 4.57 (s, 1H, O*H*), 2.93 (s, 4H). *Anal.* calcd. for $C_{14}H_{14}O$: C 84.81, H 7.11; found: C 84.32, H 7.27.

*4-Hydroxy-2,3,5-trimethylbenzofuran (**6**)*

According to the general procedure, from **4***d*, 40% yield after 3 days at 20°C; mp 122–123°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 6.90 (ABq, 2H, J = 3 Hz), 4.78 (s, 1H, O*H*), 2.35 (s, 6H), 2.30 (s, 3H). *Anal.* calcd. for $C_{11}H_{12}O_2$: C 75.00, H 6.81; found: C 75.12, H 7.06.

General procedure C

*Preparation of ethyl 4-hydroxyl-3-methyl-5-methylthiomethylbenzofuran-2-carboxylate (7*c)*

A mixture of **5** (5.04 g, 15 mmol), methanethiol (3.85 g, 89.5 mmol), and dichloromethane (100 mL) was cooled in an ice-bath, and anhydrous aluminum chloride (7.98 g, 60 mmol) was added in portions with stirring. The reaction mixture was stirred in the ice-bath for 0.5 h and then at room temperature for 0.5 h, after which it was quenched with ice and 6 N hydrochloric acid. The crude product isolated from the organic phase was purified by column chromatography (eluted with 1:4 ethyl acetate/hexane) to afford **7***c*, 2.37 g (56%); ^{1}H nmr (90 MHz, $CDCl_3$), δ: 7.49 (s, 1H, OH), 7.13 (d, 1H), 7.12 (d, 1H), 4.52 (q, 2H, J = 7 Hz), 3.92 (s, 2H, SCH_2), 2.86 (s, 3H), 2.07 (s, 3H), 1.51 (t, 3H, J = 7 Hz). *Anal.* calcd. for $C_{14}H_{16}O_4S$: C 60.00, H 5.75, S 11.40; found: C 60.08, H 5.70, S 11.31.

*2-Ethylthiomethylphenol (7*a)*

The title compound was prepared by the general procedure C, yield 83%; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 7.1–7.3 (m, 1H), 7.09 (d, 1H, J = 6.3 Hz), 6.82–6.95 (m, 2H), 6.75 (s, 1H, O*H*), 3.84 (s, 2H, SCH_2Ph), 2.43 (q, 3H, J = 5.6 Hz), 1.22 (t, 3H, J = 5.6 Hz). *Anal.* calcd. for $C_9H_{12}OS$: C 64.24, H 7.18, S 19.05; found: C 64.00, H 7.16, S 18.96.

*2-Ethylthiomethyl-5-methylphenol (7*b)*

According to the general procedure C, yield 94%; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 6.95 (d, 1H, J = 7.5 Hz), 6.63–6.78 (m, 3H), 3.80 (s, 2H, SCH_2Ph), 2.42 (q, 2H, J = 5.6 Hz), 2.31 (s, 3H), 1.23 (t, 3H, J = 5.6 Hz). *Anal.* calcd. for $C_{10}H_{14}OS$: C 65.89, H 7.74, S 17.58; found: C 65.76, H 7.34, S 17.30.

*Ethyl 5-butylthiomethyl-4-hydroxy-3-methyl-benzofuran-2-carboxylate (7*d)*

Using butanethiol in the above procedure C, the title compound was obtained in 49% yield; mp 59–60°C; ^{1}H nmr (90 MHz, $CDCl_3$), δ: 7.55 (s, 1H, O*H*), 7.1 (d, 1H), 7.0 (d, 1H), 4.45 (q, 2H, J = 7 Hz), 3.88 (s, 2H, SCH_2Ph), 2.79 (s, 3H), 2.42 (m, 2H), 1.4 (m, 7H), 0.89 (t, 3H, J = 7 Hz). *Anal.* calcd. for $C_{17}H_{22}O_4S$: C 63.33, H 6.88, S 9.94; found: C 63.40, H 6.97, S 9.93.

*Ethyl 5-benzylthiomethyl-4-hydroxy-3-methyl-benzofuran-2-carboxylate (7*e)*

The use of toluenethiol in the general procedure C provided **7***e* in 75% yield; mp 103–104°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 7.23 (m, 5H), 6.95 (s, 2H), 4.40 (q, 2H, J = 7 Hz), 3.64 (s, 2H, SCH_2), 3.50 (s, 2H, SCH_2), 2.80 (s, 3H), 1.45 (t, 3H, J = 7 Hz). *Anal.* calcd. for $C_{20}H_{20}O_4S$: C 67.39, H 5.60, S 9.00; found: C 67.42, H 5.82, S 9.21.

*Ethyl 5-carboxymethylthiomethyl-4-hydroxy-3-methyl-benzofuran-2-carboxylate (7*f)*

In this case, a slightly increased proportion of aluminum chloride was used. Using 13 mmol of aluminum chloride, 2.5 mmol of **5**, and 10 mmol of mercaptoacetic acid, the title compound was obtained in 28% yield; mp 165–166°C; ^{1}H nmr (90 MHz, $CDCl_3$), δ: 7.32 (d, 1H, J = 8 Hz), 7.06 (d, 1H, J = 8 Hz), 4.42 (q, 2H, J = 7 Hz), 3.99 (s, 2H, SCH_2), 3.34 (s, 2H, SCH_2), 2.80 (s, 3H), 1.43 (t, 3H, J = 7 Hz). *Anal.* calcd. for $C_{15}H_{16}O_6S$: C 55.55, H 4.97, S 9.89; found: C 55.76, H 5.09, S 10.15.

General procedure D

*Preparation of ethyl 5-ethoxymethyl-4-hydroxy-3-methyl-benzofuran-2-carboxylate (8*b)*

A mixture of **5** (840 mg, 2.5 mmol), ethanol (17 mL), and concentrated sulphuric acid (0.1 mL) was heated under reflux for 1 h, and then evaporated to ca. 5 mL before the addition of ether and water. The crude product from the ether extract was purified by column chromatography to give 331 mg (48%) of **8***b*; mp 97–98°C, ir (KBr) ν: 1729, 3310 cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 8.40 (s, 1H, OH), 6.99 (s, 2H), 4.81 (s, 2H, OCH_2), 4.45 (q, 2H), 3.68 (q, 2H), 2.78 (s, 3H), 1.45 and 1.32 (2t, 6H). *Anal.* calcd. for $C_{15}H_{18}O_5$: C 64.74, H 6.52; found: C 64.74, H 6.39.

*2-Ethoxymethylphenol (8*a)*

Following the general procedure D, yield 48%; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 7.74 (s, 1H, O*H*), 7.14–7.27 (m, 1H), 7.0 (d, 1H, J = 6.5 Hz), 6.78–6.93 (m, 2H), 4.71 (s, 2H, OCH_2), 3.62 (q, 2H, J = 6.5 Hz), 1.27 (t, 3H, J = 6.5 Hz); ms (70 eV) (m/e): 152 (M^+).

R. SZWEDA, U. SPOHR, R. U. LEMIEUX, D. SCHINDLER, D. F. BISHOP, and R. J. DESNICK. Can. J. Chem. **67**, 1388 (1989).

Reaction at room temperature of either 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α- or -β-D-galactopyranosyl chloride with a twofold excess of 4-methylumbelliferone and silver trifluoromethanesulfonate in dichloromethane containing an equimolar amount of *sym*-collidine yielded 4-methylumbelliferyl tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranoside in 33% yield. The β anomer was formed in 20 and 10% yields, respectively. Reduction of the azido group, acetylation followed by de-*O*-acetylation, provided the desired 4-methylumbelliferyl 2-acetamido-2-deoxy-α- and -β-D-galactopyranosides (*N*-acetyl-α- and -β-D-galactopyranosaminides). The α-glycoside proved to be an effective substrate for the highly sensitive fluorimetric detection of *N*-acetyl-α-D-galactopyranosaminidase activity in human tissues and was used to examine the deficiency of this activity, which is the enzymatic defect in Schindler disease.

Key words: synthesis of 4-methylumbelliferyl *N*-acetyl-α- and -β-D-galactopyranosaminides, *N*-acetyl-α-D-galactosaminidase deficiency (Schindler disease).

R. SZWEDA, U. SPOHR, R. U. LEMIEUX, D. SCHINDLER, D. F. BISHOP et R. J. DESNICK. Can. J. Chem. **67**, 1388 (1989).

La réaction, à la température ambiante, des chlorures des 3,4,6-tri-*O*-acétyl-2-azido-2-déoxy-α- ou -β-D-galactopyranosyles avec deux moles de 4-méthylumbelliférone et de trifluorométhanesulfonate d'argent, dans du dichlorométhane contenant une quantité équimolaire de *sym*-collidine, conduit au tri-*O*-acétyl-2-azido-2-déoxy-α-D-galactopyranoside de 4-méthylumbelliféryle, avec un rendement de 33%. L'anomère β se forme avec des rendements respectifs de 10 et 20%. La réduction du groupement azido, suivie d'une acétylation et d'une de-*O*-acétylation, conduit aux 2-acétamido-2-déoxy-α- et -β-D-galactopyranosides de 4-méthylumbelliféryles désirés (*N*-acétyl-α- et -β-D-galactopyranosaminides). L'α-glycoside s'avère être un substrat efficace pour la détection fluorimétrique hautement sensible de l'activité de la *N*-acétyl-α-D-galactopyranosaminidase dans les tissus humains et on l'a utilisé pour examiner le manque de cette activité qui est le défaut enzymatique de la maladie de Schindler.

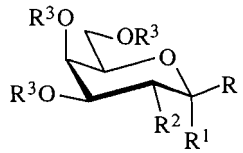
Mots clés : synthèse de 4-méthylumbelliféryle *N*-acétyl-α- et -β-D-galactopyranosaminides, manque de la *N*-acétyl-α-D-galactopyranosaminidase (maladie de Schindler).

[Traduit par la revue]

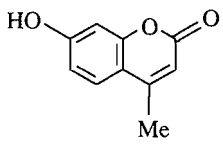
Introduction

In 1955, Mead, Smith, and Williams (1) observed that although umbelliferone fluoresced strongly in ultraviolet light at pH 9–10, its glucuronide was practically nonfluorescent. The possibility therefore existed that glucuronide could be used for the determination of enzymes in very small amounts of material. Indeed, 4-methylumbelliferyl β-D-glucuronide proved to be an excellent substrate for a fluorimetric assay for β-D-glucuronidase. In the following year, Robinson (2) synthesized 4-methylumbelliferyl β-D-glucopyranoside and used it to study β-D-glucopyranosidases from a variety of sources. In 1961, Leaback and Walker (3) published the use of 4-methylumbelliferyl *N*-acetyl-β-D-glucosaminide as a substrate and Winchester (4) then demonstrated the use of the corresponding *N*-acetyl-β-D-galactopyranosaminide to detect *N*-acetyl-β-D-galactosaminidase activity in tissues. Since these early studies, 4-methylumbelliferyl glycosides have found widespread applications for the detection and assay of a number of glycosidases (5, 6) and their use was extended to fluorimetric studies of their binding by lectins (7, 8).

Although 4-methylumbelliferyl *N*-acetyl-β-D-galactopyranosaminide (**9**) has long been commercially available, its preparation does not appear to have been published. *p*-Nitrophenyl *N*-acetyl-α-D-galactopyranosaminide has been used for the characterization of human *N*-acetyl-α-D-galactosaminidase. Use of the corresponding 4-methylumbelliferyl glycoside (**7**) could be expected to provide a much higher sensitivity, and its availability became a high priority with the discovery that Schindler disease is a neurodegenerative disorder that results from a deficiency of a lysosomal *N*-acetyl-α-D-galactopyranosaminidase (9, 10). The purpose of this communication is to report both the preparation of **7** and its β anomer (**9**) and to demonstrate the utility of **7** for the detection of hydrolases specific for terminal *N*-acetyl-α-D-galactopyranosaminidyl units as occur in human blood group A active glycolipids and O-linked glycoproteins.



Results and discussion



Possibly, 4-methylumbelliferyl *N*-acetyl-α-D-galactopyrano-

saminide (**7**) would be obtained by way of a Koenigs–Knorr type reaction of 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranosyl chloride (**11**) with 4-methylumbelliferone. Indeed, Lemieux and Ratcliffe (12) prepared the A-blood group related blocked trisaccharide, 8-methoxycarbonyloctyl 3-*O*-(3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl)-2-*O*-(2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl)-4,6-*O*-benzylidene-β-D-galactopyranoside in 74% yield using silver carbonate/silver trifluoromethanesulfonate (silver triflate) (45:1) as promoter for the reaction of **1**. Thus, reaction with simple inversion of the anomeric center was obtained and the formation of an intermediate glycosyl triflate did not occur. In contrast, Lemieux, Takeda, and Chung (13) introduced the use of a mixture of silver triflate (AgOTf) and *sym*-collidine to promote the reaction of 2-deoxy-2-phthalimido-glycosyl halides with alcohols to form β-glycosides, and demonstrated that glycosyl triflate was formed in the first stage of the reaction sequence. It was considered, therefore, of interest to examine the reaction of 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl chloride (**2**) with 4-methylumbelliferone (**3**) in the presence of the silver triflate – *sym*-collidine complex since the β-triflate (**12**) could be the first product of the overall reaction. Furthermore, the α-chloride (**2**) is much more readily available than is the β anomer (**1**) (11). In this regard, it is important to note that the use of the Vilsmeier reagent, as recommended by Sabesan and Lemieux (14), to convert the by-product *N*-(3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl) acetamide to **2** has now provided a one-stage process from the crude product of azidonitration of D-galactal triacetate (11). Chromatographically pure **2** was obtained in 75% yield.

As mentioned above, it seemed likely that reaction of **2** with silver triflate would proceed with inversion to provide the β-glycosyl triflate (**12**). Reaction of **12** with umbelliferone would then provide the desired α-glycoside (**4**). In fact, **4** was the main product (33% yield) but the β anomer (**5**) was also formed (10% yield). The two products were readily isolated in a high state of purity by column chromatography on silica gel. Thus, although the yields are low, the procedure provides both the α- and β-glycosides. When the β-chloride (**1**) was starting material, much the same result was obtained (33% yield of **4** and 20% yield of **5**). These results suggest that the reactions proceeded by way of a common intermediate and could be

TABLE 1. *N*-Acetyl-α-D-galactosaminidase and *N*-acetyl-β-D-galactosaminidase activities in cultured fibroblasts from affected homozygotes with Schindler disease

Source	Activity (nmol·h^{-1}·(mg protein)$^{-1}$)	
	α-NAcGalase	β-NAcGalase
Affected homozygote 1	3.2	1500
Affected homozygote 2	1.8	1830
Normal male	146.0	1340

rationalized on the basis of the formation of a free oxocarbonium ion. On the other hand, a rapid interconversion of the initially formed glycosyl triflates (**10** and **12**) by way of the ion triplet (**11**), as was found for the anomerization of glycosyl halides in the presence of halide ion (15), is considered the more plausible route.

The conversions of the acetylated azido compounds (**4** and **5**) to the desired glycosides (**7** and **9**) involved standard transformations that proceeded in high yields. The main difficulty encountered was with the high insolubility of α-glycoside (**7**), which resisted crystallization. Crystals of the β-glycoside (**9**) were obtained without difficulty.

To establish the utility of **7** for the detection of enzymes specific for a terminal αDGalNAc residue, the deficient activity of *N*-acetyl-α-D-galactosaminidase was demonstrated in cultured fibroblasts from sibs affected with Schindler disease. Residual activities of 1–2% were observed in the affected sibs as compared to the high activity in a normal male control (Table 1). Mixing experiments with fibroblast extracts from an affected sib (1.4 nmol·h^{-1}·mg^{-1}) and an unrelated normal control (181 nmol·h^{-1}·mg^{-1}) revealed the expected intermediate activity (95.1 nmol·h^{-1}·mg^{-1}), thereby excluding the presence of an inhibitor or the absence of an activator as the cause of the enzymatic defect. In contrast, the *N*-acetyl-β-D-galactosaminidase activities were normal in cultured fibroblasts from the affected sibs and the normal male control (Table 1).

Experimental

General methods

All solvents and reagents were purified according to standard procedures (16).

Thin-layer chromatograms (tlc) were performed on precoated silica gel 60 F_{254} plates (E. Merck, Darmstadt) and visualized by charring after spraying with 5% sulphuric acid in ethanol. For column chromatography, silica gel G (type 60) (E. Merck, Darmstadt) and distilled solvents were used.

The ^{1}H nmr spectra were recorded at 300 MHz and 296 K. In $CDCl_3$ the ^{1}H chemical shifts (δ, in ppm) are relative to internal tetramethylsilane (δ = 0). When DMSO-d_6 was the solvent, the reference was the $(CH_3)_2SO$ signal set at 2.49 ppm.

The melting points are uncorrected.

*4-Methylumbelliferyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α- (**4**) and -β-D-galactopyranoside (**5**)*

*(a) From 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranosyl chloride (**1**)*

4-Methylumbelliferone (**3**) (0.895 g, 5.09 mmol), dry silver trifluoromethanesulfonate (1.308 g, 5.09 mmol), *sym*-collidine (0.34 g, 2.55 mmol), and 4 Å molecular sieves (4 g, powdered) in dichloromethane (10 mL) were stirred for 1 h under dry nitrogen in the dark. A solution of 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranosyl chloride (11) (**1**) (0.89 g, 2.55 mmol) in dichloromethane (9 mL) was then added to the stirred mixture at room temperature. The disappearance of the chloride (**1**) was monitored by tlc using chloroform – ethyl acetate, 4:1 (v/v). After 6 h the mixture was filtered. The filtrate was evaporated to give a red syrup (~2.4 g), which was chromatographed on a silica gel column (250 g, solvent chloroform – ethyl acetate, 8:1 (v/v)) to give 4-methylumbelliferyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranoside (**4**) (0.41 g, 33%) as a white foam. The analytical sample was recrystallized from ethanol, mp 131–132°C; $[\alpha]_D^{20}$ +195° (*c* 0.5, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 7.56 (d, 1H, H-5, $J_{5,6}$ = 8.75 Hz), 7.13 (d, 1H, H-8, $J_{6,8}$ = 2.5 Hz), 7.04 (dd, 1H, H-6), 6.21 (d, 1H, H-3, J_{3,CH_3} = 1.4 Hz), 5.70 (d, 1H, H-1′, $J_{1',2'}$ = 4 Hz), 5.58 (dd, 1H, H-3′, $J_{2',3'}$ = 11 Hz, $J_{3',4'}$ = 3 Hz), 5.53 (dd, 1H, H-4′, $J_{4',5'}$ = 1 Hz), 4.30 (m, 1H, H-5′), 4.10 (m, 2H, H-6′a and H-6′b), 3.90 (dd, 1H, H-2′), 2.43 (d, 3H, CH_3 (MeUmb)), 2.19, 2.11, 1.97 (3s, each 3H, $3CH_3CO$). Continued elution of the column provided 4-methylumbelliferyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranoside (**5**) (0.25 g, 20%) as a yellowish foam; $[\alpha]_D^{20}$ +2° (*c* 0.5, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 7.56 (dd, 1H, H-5, $J_{5,6}$ = 9 Hz, $J_{5,8}$ = 1 Hz), 7.03 (d, 1H, H-8), 7.02 (dd, 1H, H-6, $J_{6,8}$ = 2 Hz), 6.22 (d, 1H, H-3, J_{3,CH_3} = 1.4 Hz), 5.43 (dd, 1H, H-4′, $J_{3',4'}$ = 3.5 Hz, $J_{4',5'}$ = 1 Hz), 5.00 (d, 1H, H-1′, $J_{1',2'}$ = 8 Hz), 4.92 (dd, 1H, H-3′, $J_{2',3'}$ = 11 Hz), 4.19 (m, 2H, H-6′a, H-6′b), 4.07 (m, 1H, H-5′), 4.03 (dd, 1H, H-2′), 2.43 (d, 3H, CH_3 (MeUmb)), 2.19, 2.12, 2.09 (3s, 9H, $3CH_3CO$). *Anal.* calcd. for $C_{22}H_{23}N_3O_{10}$: C 53.99, H 4.74, N 8.58; found for **4**: C 53.64, H 4.76, N 8.70; for **5**: C 53.25, H 4.90, N 8.82.

*(b) From 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl chloride (**2**)*

The crude product of azidonitration of 3,4,6-tri-*O*-acetyl-D-galactal (11) (0.31 g) was dissolved in dichloromethane (2 mL) and DMF (0.2 mL) and a solution of oxalyl chloride (140 μL, 1.61 mmol) in dichloromethane (0.5 mL) was added at 0°C with stirring. After 1 h, a solution of anhydrous tetraethylammonium chloride (0.64 g, 3.86 mmol) in dry acetonitrile (2 mL) was added and the stirring was continued for 6 h. The solution was then diluted with dichloromethane (100 mL) before washing with water (2 × 20 mL). Solvent removal left a syrup (0.287 g). Chromatography on a silica gel column (50 g, solvent *n*-hexane – ethyl acetate (3:1)) gave 0.215 g (75%) of very pure (^{1}H nmr) syrupy α-chloride (**2**) (11); $[\alpha]_D^{20}$ +146° (*c* 0.67, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 6.18 (d, 1H, H-1, $J_{1,2}$ = 4 Hz), 5.51 (dd, 1H, H-4, $J_{3,4}$ = 3 Hz, $J_{4,5}$ = 1.5 Hz), 5.38 (dd, 1H, H-3, $J_{2,3}$ = 11 Hz), 4.52 (m, 1H, H-5), 4.15 (m, 2H, H-6a, H-6b), 4.11 (dd, 1H, H-2), 2.17, 2.08, 2.06 (3s, each 3H, $3CH_3CO$).

4-Methylumbelliferone (**3**) (3.35 g, 19 mmol), silver trifluoromethanesulfonate (8.81 g, 34.2 mmol), *sym*-collidine (2.3 g, 17.17 mmol), and 4 Å molecular sieves (10 g, powdered) in dichloromethane (30 mL) were stirred for 1 h under nitrogen in the dark. A solution of the above α-chloride (**2**) (6 g, 17.17 mmol) in dichloromethane (20 mL) was then added dropwise over a period of 0.5 h to the stirred mixture at room temperature. The disappearance of the chloride was monitored by tlc using chloroform – ethyl acetate 4:1 (v/v). After 16 h the mixture was filtered. Evaporation of the dichloromethane left a red syrup (~10 g), which was chromatographed on a column of silica gel (500 g, solvent chloroform – ethyl acetate 8:1 (v/v)) to give 4-methylumbelliferyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranoside (**4**) (2.79 g, 33%) and its β-anomer (**5**) (0.84 g, 10%).

*4-Methylumbelliferyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactopyranoside (**6**)*

4-Methylumbelliferyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranoside (**4**) (2.75 g, 5.62 mmol) was dissolved in 95% ethanol (150 mL) and hydrogenated at room temperature in the presence of 5% palladium-on-charcoal (2.75 g). After 2 h the catalyst was removed. Evaporation of the ethanol left a white foam (~2.25 g), which was acetylated in pyridine (5 mL) and acetic anhydride (5 mL). The mixture was kept 1 h at room temperature. Evaporation provided a white foam (~2.4 g). Chromatography on a column of silica gel (200 g, solvent chloroform – ethyl acetate 1:1 (v/v)) gave the title compound (**6**) (2.02 g, 71%) as a white foam; $[\alpha]_D^{20}$ +202° (*c* 0.5, chloroform);

^{1}H nmr ($CDCl_3$) δ: 7.57 (d, 1H, H-5, $J_{5,6}$ = 8.75 Hz), 7.09 (d, 1H, H-8, $J_{6,8}$ = 2.5 Hz), 7.02 (dd, 1H, H-6), 6.20 (d, 1H, H-3, J_{3,CH_3} = 1.4 Hz), 5.78 (d, 1H, NH, $J_{NH,2'}$ = 9 Hz), 5.69 (d, 1H, H-1′, $J_{1',2'}$ = 3.5 Hz), 5.46 (dd, 1H, H-4′, $J_{3',4'}$ = 3 Hz, $J_{4',5'}$ = 1 Hz), 5.40 (dd, 1H, H-3′, $J_{2',3'}$ = 11.5 Hz), 4.79 (ddd, 1H, H-2′), 4.24 (dt, 1H, H-5′), 4.09 (m, 2H, H-6′a, H-6′b), 2.42 (d, 3H, CH_3 (MeUmb)), 2.20, 2.06, 2.00, 1.95 (4s, each 3H, $4CH_3CO$).

4-Methylumbelliferyl 2-acetamido-2-deoxy-α-D-galactopyranoside (7)

A solution of 4-methylumbelliferyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactopyranoside (**6**) (1.96 g, 3.88 mmol) in dry methanol (100 mL) containing 0.5 N methanolic sodium methoxide (6 mL) was stirred at room temperature. After 15 min a precipitate appeared. The tlc analysis (chloroform–methanol, 9:1) of the liquid phase showed the reaction to be complete. The precipitate was filtered and washed 3 times with cold methanol to provide the title compound in 90% yield (1.32 g) as a white solid, mp 264–265°C (dec.), $[\alpha]_D^{20}$ +251° (*c* 0.4, DMSO); uv (H_2O) λ_{max} (log ε): 318 nm (4.01); ^{1}H nmr (DMSO-d_6) δ: 7.91 (d, 1H, NH, $J_{NH,2'}$ = 9 Hz), 7.70 (d, 1H, H-5, $J_{5,6}$ = 8.5 Hz), 7.07 (dd, 1H, H-6, $J_{6,8}$ = 2 Hz), 7.05 (br s, 1H, H-8), 6.24 (d, 1H, H-3, J_{3,CH_3} = 1 Hz), 5.53 (d, 1H, H-1′, $J_{1',2'}$ = 3 Hz), 4.78 (d, 1H, OH-4′, $J_{4',OH}$ = 4 Hz), 4.69 (d, 1H, OH-3′, $J_{3',OH}$ = 6 Hz), 4.58 (t, 1H, OH-6′, $J_{OH,6'a}$ = $J_{OH,6'b}$ = 5.5 Hz), 4.24 (m, 1H, H-2′), 3.87–3.77 (m, 2H, H-3′, H-4′), 3.67 (m, 1H, H-5′), 3.52 (m, 1H, H-6′a), 3.41 (m, 1H, H-6′b), 2.39 (d, 3H, CH_3 (MeUmb)), 1.83 (s, 3H, CH_3CONH). *Anal.* calcd. for $C_{18}H_{21}NO_8$: C 56.99, H 5.58, N 3.69; found: C 56.45, H 5.70, N 3.62.

*4-Methylumbelliferyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-galactopyranoside (8)*

4-Methylumbelliferyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranoside (**5**) (0.235 g, 0.48 mmol) was dissolved in 95% ethanol (10 mL) and hydrogenated at room temperature for 3 h in the presence of 5% palladium-on-charcoal (0.24 g). Catalyst removal and evaporation provided a white foam (0.205 g). It was dissolved in methanol (5 mL) and acetic anhydride (1.5 mL) was added. After 6 h the solvent was evaporated to give a white foam (0.21 g). Chromatography on a column of silica gel (25 g, chloroform – ethyl acetate 1:1 (v/v)) gave the title compound (**8**) (0.17 g, 70%) as a white foam; $[\alpha]_D^{20}$ −3° (*c* 0.4, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 7.50 (dd, 1H, H-5, $J_{5,6}$ = 8 Hz, $J_{5,8}$ = 1.5 Hz), 6.97 (br s, 1H, H-8), 6.95 (dd, 1H, H-6, $J_{6,8}$ = 2.5 Hz), 6.17 (d, 1H, H-3, J_{3,CH_3} = 1.4 Hz), 5.79 (d, 1H, NH, $J_{NH,2'}$ = 9 Hz), 5.46 (d, 1H, H-4′, $J_{3',4'}$ = 3.5 Hz), 5.44 (d, 1H, H-1′, $J_{1',2'}$ = 8 Hz), 5.43 (dd, 1H, H-3′, $J_{2',3'}$ = 11 Hz), 4.31 (m, 1H, H-2′), 4.21–4.09 (m, 3H, H-5′, H-6′a, H-6′b), 2.40 (d, 3H, CH_3 (MeUmb)), 2.18, 2.11, 2.05, 1.98 (4s, each 3H, $4CH_3CO$).

4-Methylumbelliferyl 2-acetamido-2-deoxy-β-D-galactopyranoside (9)

A solution of 4-methylumbelliferyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-galactopyranoside (**8**) (0.145 g, 0.29 mmol) in dry methanol (20 mL) containing 0.5 N methanolic sodium methoxide (2.5 mL) was stirred at room temperature. After 20 min precipitate appeared. The tlc analysis (chloroform–methanol, 9:1) of the liquid phase indicated that the reaction was finished. The mixture was neutralized with Amberlite IRC-50 (H^+) resin. The solvent was isolated by decantation and the resin was washed several times with methanol. The combined methanolic solution was evaporated to give a white solid (0.106 g, 97%). It was crystallized from 50% ethanol (0.07 g, 64%); mp 226–226.5°C (dec.), $[\alpha]_D^{20}$ +20° (*c* 0.4, DMSO); uv (H_2O) λ_{max} (log ε): 317 nm (4.156); ^{1}H nmr (DMSO-d_6) δ: 7.77 (d, 1H, NH, $J_{NH,2'}$ = 9 Hz), 7.68 (d, 1H, H-5, $J_{5,6}$ = 8.5 Hz), 6.99 (d, 1H, H-8, $J_{6,8}$ = 2 Hz), 6.94 (dd, 1H, H-6), 6.24 (d, 1H, H-3, J_{3,CH_3} = 1 Hz), 5.08 (d, 1H, H-1′, $J_{1',2'}$ = 8.5 Hz), 4.80 (d, OH-3′, $J_{3',OH}$ = 6 Hz), 4.71 (t, 1H, OH-6′, $J_{6'a,OH}$ = $J_{6'b,OH}$ = 4 Hz), 4.69 (d, 1H, OH-4′, $J_{4',OH}$ = 4 Hz), 4.01 (ddd, 1H, H-2′, $J_{2',3'}$ = 10 Hz), 3.73 (m, 1H, H-4′), 3.66–3.46 (m, 4H, H-3′, H-5′, H-6′a, H-6′b), 2.39 (d, 3H, CH_3 (MeUmb)), 1.79 (s, 3H, CH_3CONH).

Enzyme assays

N-acetyl-α-D-galactosaminidase and *N*-acetyl-β-D-galactosaminidase activities were determined in cultured skin fibroblasts from two sibs with Schindler disease (*N*-acetyl-α-D-galactosaminidase deficiency) and an unrelated normal individual. Cultured fibroblasts were established, grown, and harvested by standard techniques. The cell pellets were frozen at −70°C until use. Fibroblasts were sonicated (70 W; five 20-s bursts) in the presence of 0.1 M citrate/0.1 M sodium phosphate buffer, pH 4.5, in a cup-horn sonicator. The sonicates were centrifuged (10,000 × *g*; 10 min) and the supernatants were assayed immediately. The standard reaction mixture, containing 90 μL of 1.10 mM of either 4-methylumbelliferyl 2-acetamido-2-deoxy-α- (or β) D-galactopyranoside, and 10 μL of fibroblast supernatant was incubated at 37°C for 30 min. The reactions were terminated by addition of 1.16 mL of 0.1 M ethylenediamine, pH 11.4. Fluorescence was measured in a Turner model 111 fluorometer equipped with a Corning 7.60 excitation filter (365 nm), Wratten 48 and 2A emission filters (450 nm), and a 1% Wratten neutral density filter. Protein concentrations were determined by the fluorescamine procedure (17).

2-Flurophenyl- and 2,5-bis(fluorophenyl)pyrrolidin-1-oxyls (**2** and **6**) were synthesized from the corresponding nitrones **1**, **4**, and **5** with the Grignard reagent prepared from 1-bromo-4-fluorobenzene. The reaction of 2,2,5,5-tetramethyl-3-formyl-3-pyrrolin-1-oxyl (**8**) with $(4\text{-}FC_6H_4)_2Cd$ gave 2,2,5,5-tetramethyl-3-(α-hydroxy-4-fluorobenzyl)-3-pyrrolin-1-oxyl (**9**), which was oxidized with MnO_2 to 2,2,5,5-tetramethyl-3-(4-fluorobenzoyl)-3-pyrrolin-1-oxyl (**10**). The aryl nitroxides **2**, **6**, and **10** were nitrated with concentrated H_2SO_4/HNO_3 to *ortho*-fluoronitrophenyl compounds **3**, **7**, and **11**. The fluoro nitro derivatives served as versatile synthons in the nucleophilic replacement of fluorine with OH, NH_2, α-amino acid ester, or thiol. The hydroxy nitroaryl compounds **16**, **26**, and **30** were nitrated further to give dinitrophenol derivatives **17**, **27**, and **31**.

Key words: fluorophenyl nitroxides, nitroaryl nitroxides, NMR spectra of nitroxides.

H. OLGA HANKOVSZKY, KÁLMÁN HIDEG, M. JUDIT LOVAS, GYULA JERKOVICH, ANTAL ROCKENBAUER, MIKLÓS GYÖR et PÁL SOHÁR. Can. J. Chem. **67**, 1392 (1989).

On a préparé des fluoro-2-phényl- et des bis(fluoro-2,5-phényl)-pyrrolidinoxyles-1 (**2** et **6**) à partir des nitrones correspondants **1**, **4** et **5** en utilisant des réactifs de Grignard préparés à partir du bromo-1-fluoro-4-benzène. Le composé téetraméthyl-2,2,5,5-formyl-3-pyrrolin-3-oxyle-1 (**8**) réagit avec le $(F\text{-}4\text{-}C_6H_4)_2Cd$ pour donner le tétraméthyl-2,2,5,5-(α-hydroxyfluoro-4-benzyle)-3-pyrrolin-3-oxyle-1 (**9**) qui par oxydation avec le MnO_2 donne le tétraméthyl-2,2,5,5-(fluoro-4-benzoyle)-3-pyrrolin-3-oxyle-1 (**10**). Une nitration des nitroxydes aryliques **2**, **6** et **10** par le mélange H_2SO_4/MNO_3 conduit aux composés *ortho*-fluoronitrophényles **3**, **7** et **11**. Les dérivés fluoronitrés peuvent servir d'intermédiaires de synthèses dans le remplacement nucléophile du fluor par du OH, du NH_2, un ester d'acide α-aminé ou par un thiol. Une nitration plus poussée des composés nitroaryles hydroxylés **16**, **26** et **30** conduit aux dérivés du dinitrophénol **17**, **27** et **31**.

Mots clés : oxydes d'azote fluorophényles, oxydes d'azote nitroaryles, spectres en RMN des oxydes d'azote.

[Traduit par la revue]

Introduction

Various chemically reactive functional groups can be incorporated into appropriate paramagnetic molecules, whereby they can be attached to biomolecules (proteins, drugs, etc.) under mild reaction conditions without the involvement of the *N*-oxyl paramagnetic centre (1, 2). The analysis of spin-labelled compounds by esr spectroscopy is an important method in the study of biomolecules (3, 4). It has been found that such nitroxides are resistant against all but a minor group of reagents. The well-known reasons for the stability of these *N*-oxyl paramagnetic centres are the three π-electrons delocalized over two atoms (5) and the lack of *H* substituents on the carbons in the α position to the nitrogen, which prevents any disproportionation to the nitrone and the hydroxylamine.

Such reactions can therefore be utilized when the paramagnetic *N*-oxyl centre is reduced to the labile *N*-hydroxy group, because this function is oxidized back to the *N*-oxyl almost spontaneously by air.

We previously described various syntheses of nitroxides with organometallic reagents (6–8) and the nitration of phenyl-substituted nitroxides (8). In the present work, we described the synthesis of various fluorophenyl pyrrolidine and pyrroline nitroxides as starting compounds in nitration reactions. In fluoronitrophenol-substituted nitroxides, the fluorine has enhanced reactivity toward nucleophiles, similar to known reagents such as fluoro-2,4-dinitrobenzene (Sanger reagent) (9, 10) or spin-labelled fluorodinitrobenzene derivatives (11, 12). This may lead not only to new spin-label reagents, but also to compounds useful for the preparation of polysubstituted aryl nitroxides.

We earlier prepared cationic nitroxide probes such as the triaryl (1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl) phosphonium salt (13) for the investigation of reduction and stability in mitochondria. Several 1-oxyl-2,2,6,6-tetramethylpiperidinyl-amino nitrophenols with low pK_a have been prepared and utilized as anionic probes (30).[2] It has been confirmed by a number of research groups that both pyrrolidine and pyrroline nitroxides exhibit a higher resistance towards reduction than that of piperidines and oxazolines (14–16). This prompted us to prepare a new series of pyrrolidinyl polynitrophenol derivatives.

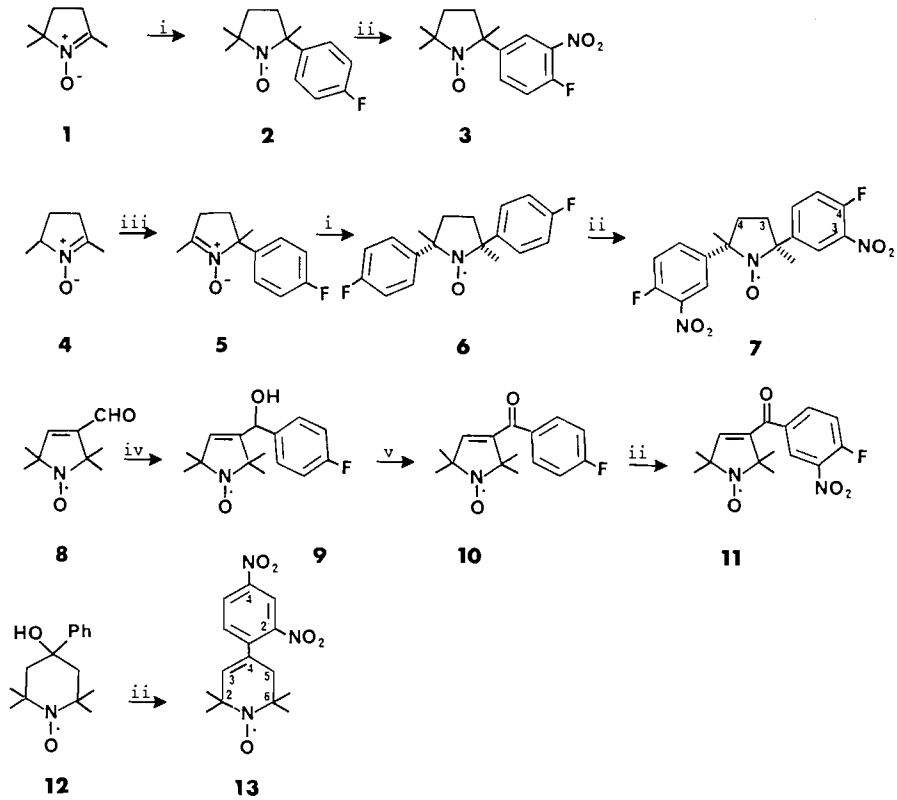
Results and discussion

2,5,5-Trimethyl-1-pyrroline-1-oxide (**1**) (17) was reacted with the Grignard reagent made from 1-bromo-4-fluorobenzene to give 2-(4-fluorophenyl)pyrrolidin-1-oxyl (**2**), which was then nitrated with H_2SO_4/HNO_3 to 2-(3-nitro-4-fluorophenyl)pyrrolidin-1-oxyl (**3**). 2,5-Dimethyl-1-pyrroline-1-oxide (**4**) was functionalized to **6** with the above Grignard reagent in two steps, *via* nitrone **5**. In the reaction of **5** to **6**, the formation of both *cis* and *trans* isomers appeared possible, but only one isomer could be detected and isolated by chromatography. The nitration of **6** led to the formation of single dinitro compound **7**, in accordance with the expected orientation of the substituents of **6** (the protonated nitroxide directs into the *meta* position and the fluorine into the *ortho* position). We could not detect the formation of *m,m'*-dinitrofluorophenyl derivatives. This is evidenced for compound **7** by the three aromatic proton signals (at 7.25, 7.78, and 8.24 ppm) in the ^1H nmr spectrum, and by the three protonated and three quaternary carbon lines in the ^{13}C nmr spectrum. The ^1H nmr chemical shifts are more consistent with the 3-position of the nitro group: for the 2-nitro analogue, the expected shifts (18) are 7.27, 7.37, and 7.82 ppm, while for 3-nitro substitution they are 7.12, 7.52, and 8.07 ppm, in better accordance with the measured data. Analogous observations were found to hold for all examples investigated in this work. The ^1H and ^{13}C nmr spectra of compound **7** clearly showed the existence of a single product, but the symmetry of the molecule did not allow a direct determination by nmr of the *cis* or *trans* orientation of the substituents in positions 2 and 5. The investigation would be of value if the **6** or **7** could be converted into an asymmetric compound, e.g., by acylation of the reduced nitroxide (N÷O → N—OH) with a chiral acyl chloride, such as the Mosher reagent (19), utilized to determine the configuration of nitroxide fatty acids (20). For the symmetrical diaryl-substituted nitroxides **6**, **7**, and **26**, the most salient feature of the esr spectra is the large ^{13}C hyperfine splitting of 1.12 mT caused by two magnetically equivalent ^{13}C nuclei. According to esr studies on open chain nitroxide radicals (21), the large carbon couplings are evidence that the aryl groups are positioned parallel to the lobe of the unpaired electron orbital (Fig. 1.) This in turn presumes *trans* isomers for **6**, **7**, and **26**, since the *cis* isomers would require an energetically less favoured envelope conformation with a large puckering angle and consequently a large C(C)NO pyramidal distortion (22), in clear contradiction to the observed small nitrogen hyperfine couplings (1.33–1.34 mT). On the basis of the above observations we believe the only stereoisomers of **6** and its derivatives have *trans* geometry. The fluorophenyl unsaturated ketone **10** was obtained *via* an allylic alcohol **9** from the reaction of unsaturated aldehyde **8** (23) with di(fluorophenyl) Cd formed *in situ*. Being both a benzylic and an allylic alcohol, **9** is partially oxidized to **10** during the isolation of the reaction product, and therefore completion of the oxidation could easily be achieved with MnO_2. The nitration of **10** in a clear reaction again led to the formation of the single product **11**, due to the fluoro and carbonyl substituents in **10**. 1-Oxyl-2,2,6,6-tetramethyl-4-hydroxy-4-phenylpiperidine (**12**) (24) can be obtained in moderate yield from phenylmagnesium bromide and 1-oxyl-2,2,6,6-tetra-methylpiperidin-4-one. The nitration of **12** gave a dehydrated dinitro derivative **13** (Scheme 1).

1,2,4-Trisubstitution is confirmed by the AMX spin system (two doublets and a double doublet) in the ^1H nmr spectrum, and by the six aromatic carbon lines in the ^{13}C nmr corresponding to an asymmetric substitution of the benzene ring. The 2,5- and the 3,4-dinitro isomers can be ruled out on the basis of the proton chemical shifts. For these compounds, the double doublet of the AMX spin system would be the upfield signal, as shown in Table 1.



The enhanced reactivity of *ortho*-nitrofluorobenzene derivatives **3**, **7**, and **11** toward nucleophiles allows their utilization for the preparation of several useful synthons of spin-labelled analogues of heterocycles, or for use directly as spin-label reagents for the labelling of nucleophilic groups (e.g., in proteins SH, NH_2, and imidazole-NH).

The reaction of **3** with sodium hydroxide in aqueous ethanol led to the formation of an ether **14**, which could be nitrated to a dinitro ether **15**. When the reaction was carried out in aqueous sodium hydroxide, the phenol **16** was formed. The nitration of **16** led to the dinitrophenol **17**, while the reduction of **16** in a transfer hydrogenation (Pd/C, ammonium formate) (8, 25–27) gave the *ortho*-aminophenol derivative **18**. Analogously, reduction of the nitroaniline **19**, formed from **3** with aqueous ammonia in dioxane, allowed the preparation of an *ortho*-phenylenediamine derivative **20**. The conversion of **20** to the benzimidazolethione **21** was achieved with thiocarbonyldiimidazole. The replacement of fluorine by cyanide allowed the preparation of **22**, and reaction with imidazole gave a nitroimidazole **23**. This compound, analogous to reactive nucleophilic dinitrophenylimidazoles (28), is a potentially useful reagent for biomolecules. The reaction of a free thiol nitroxide (2,2,5,5-tetramethyl-3-thiolmethyl-3-pyrrolin-1-oxyl) (29) led to the formation of a biradical **24** in a clean reaction (Scheme 2). Therefore, **3** may serve as a reagent for the spin labelling of a thiol group. This confirms earlier observations that the reaction of a reactive group of a nitroxide reagent does not only permit the labelling of the thiol groups of protein; a highly reactive thiol group in a nitroxide molecule also allows interactions with another nitroxide molecule without any detectable loss of *N*-oxyl radical.

The reaction of **7** with alkali in aqueous ethanol led to the formation of the ethyl ether **25**. In aqueous dioxane the reaction led to **26**, which was nitrated to *trans*-2,5-di(4-hydroxy-3,5-dinitro)phenyl nitroxide **27**. The reaction of **7** with aqueous ammonia in dioxane led to the bis(nitroaniline) nitroxide **28**, and with imidazole to the bisimidazole **29** (Scheme 3).

A similar reaction to the above with alkali converted **11** to **30**, and further nitration of **30** resulted in the formation of a water-soluble unsaturated ketone nitroxide **31**. Besides its expected, more highly acidic phenolic hydroxy group (similar to **17** and **27**), the β-electrophilic centre of the unsaturated ketone

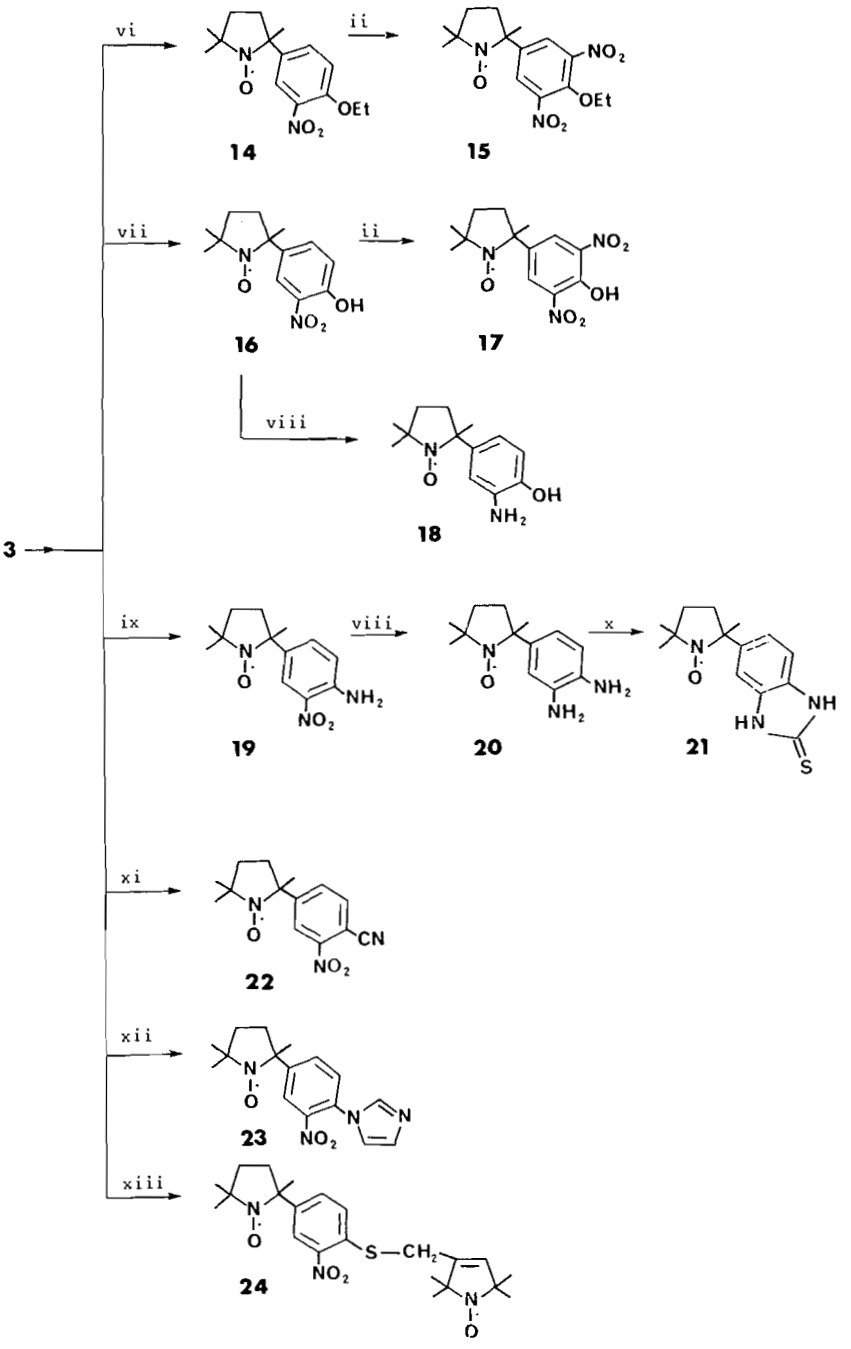
SCHEME 1. *Reagents:* i, Mg, 4-F—C_6H_4—Br, Et_2O; 0°C, NH_4Cl; $CHCl_3$, PbO_2; ii, H_2SO_4, HNO_3, 0°C; iii, Mg, 4-F—C_6H_4—Br, Et_2O; 0°C, NH_4Cl; MeOH, 25% NH_4OH, $Cu(Ac)_2$, O_2; iv, Mg, 4-F—C_6H_4—Br, EtO_2; −10°C, $CdCl_2$; 0°C, NH_4Cl; v, CCl_4, MnO_2, reflux.

TABLE 1. Comparative data concerning chemical shifts of dinitro compounds

	^{1}H nmr chemical shifts			
	Expected (18)		Observed	
Substitution	2,4-di-NO_2	3,4-di-NO_2	2,5-di-NO_2	(split by Hz)
Double doublet	8.62	8.07	8.37	8.29 (8.4, 2.3)
Doublet split by *ca.* 8 Hz	7.92	8.47	8.47	7.43 (8.04)
Doublet split by *ca.* 2Hz	9.17	8.62	8.62	8.59 (2.3)



may offer potential applications for utilization as a synthon or for the covalent labelling of biomolecules. The reaction of **11** with aqueous ammonia led to a ketone-functionalized nitroaniline **32**, that with an amino acid ester (methyl glycianate) to a labelled amino acid **33**, and that with imidazole to a labelled imidazole **34**, which, as a salt (tosylate), may serve as a reactive synthon for further reactions. Compound **34** is a promising model compound for labelling of the imidazole-NH of a histidine in a protein chain (Scheme 4).

In conclusion, we hope that the above experiments offer not only new reactions and potentially useful spin-label reagents, but also several starting synthons for the preparation of nitroxide heterocycles in reactions analogous to those used earlier for the preparation of heterocycles from nitrophenols and nitroanilines.

Experimental

Melting points were determined with a Buchi micro melting point apparatus and are uncorrected. The ir spectra of radicals were measured with a Zeiss Specord 75 spectrometer, in neat oil or in Nujol suspension. The nmr spectra were recorded in 5- or 10-mm tubes at room temperature on a Bruker WM-250 instrument (^{1}H) at 250 MHz, or on a WP-80SY FT-spectrometer controlled by an Aspect 2000 computer at 20.14 MHz (^{13}C), in $CDCl_3$ solution, using the deuterium signal of the solvent as the lock and TMS as internal reference. To get high resolution spectra of radicals the samples were reduced with cosolved PhNHNHPh additive in the nmr tube as described (8). Mass spectra were taken on a Finnigan MAT 8430 mass spectrometer *via* the direct insertion probe. Operation conditions: R = 1250, $T_{\text{ion source}}$ = 250°C, U_{acc} = 3 kV, F_{el} = 70 eV, I_{el} = 500 μA. The evaporation temperatures of the samples varied between 150 and 350°C, and were controlled in each case within ±1°C accuracy. Spectral data were acquired and processed with a Finnigan MAT SS300 data system. The esr spectra were recorded with a JEOL JES-ME spectrometer working in the X band with 100-kHz field modulation. Oxygen-free benzene solutions of concentration 10^{-4} M were studied for radicals **6**, **7**, and **26**. The spectra were identical within experimental error, with the following parameters: g = 2.0058, nitrogen splitting 1.33–1.34 mT, ^{13}C splittings 1.12 and 1.52 mT. The intensity of ^{13}C satellites reveals

SCHEME 2. *Reagents:* ii, H_2SO_4, HNO_3, 0°C; vi, EtOH, 50% NaOH, reflux; 0°C, H^+; vii, dioxane, 50% NaOH, reflux; 0°C, H^+; viii, MeOH, Pd–C, NH_4CO_2H, 40°C; $CHCl_3$, PbO_2, O_2; ix, dioxane, 25% NH_4OH, reflux; x, THF, 1,1′-thiocarbonyldiimidazole, reflux; xi, DMSO, KCN, 50°C; xii, dioxane, imidazole, K_2CO_3, Aliquat 336; xiii, 2,2,5,5-tetramethyl-3-thiomethyl-3-pyrrolin-1-oxyl, EtOH, NaOH, 25°C.

the coupling of two magnetically equivalent nuclei. Flash column chromatography was performed with Silica Gel 60 (0.040–0.063 mm). Qualitative tlc was carried out on commercially prepared plates coated with Merck Kieselgel 60 F_{254}. Preparative layer chromatography was performed on plates (20 × 20 × 0.2 cm) coated with the same material.

2-(4-Fluorophenyl)-2,5,5-trimethylpyrrolidin-1-oxyl (2)

4-Fluorophenylmagnesium bromide, freshly prepared from 1-bromo-4-fluorobenzene (12.25 g, 70 mmol) and magnesium (1.70 g, 70 mmol) in dry ether (100 mL) was reacted under an argon atmosphere with 2,5,5-trimethyl-1-pyrroline-1-oxide (**1**) (7.57 g, 60 mmol). The mixture was stirred at room temperature for 6 h, and the reaction was then quenched by the addition of saturated aqueous ammonium chloride (50 mL) to the stirred, cooled reaction mixture. The ether phase was separated, washed with aqueous sodium chloride solution, and evaporated to dryness. The residue was taken up in chloroform (50 mL) and the well-stirred solution was treated with drying agent ($MgSO_4$) and aerated in the presence of PbO_2 catalyst (ca. 1 g) for 1 h, when all the *N*-hydroxy compound was oxidized to the *N*-oxyl radical. The filtrate was evaporated to dryness and the residue was chromatographed (silica gel, hexane – ethyl acetate, 9:1) to give pure **2** (10.64 g, 80%) as a deep orange-yellow oil.

2-(3-Nitro-4-fluorophenyl)-2,5,5-trimethylpyrrolidin)-1-oxyl (3)

To a stirred, ice-cooled solution of **2** (6.67 g, 30 mmol) in concentrated H_2SO_4 (20 mL) a mixture of 67% HNO_3 and concentrated H_2SO_4 (12 mL, 1:2, v/v) was added dropwise. When the addition was complete (ca. 30 min), the mixture was stirred for a further 30 min. It

34	$C_{18}H_{19}N_4O_4$	60.84 (60.92	5.39 5.18	15.77 15.67)	1655, 1610 (C=C—C=O), 1530, 1370 (NO_2)	355 (M^+, 73.3%), 325 ($M^+ - \dot{N}O$, 53), 310 ($M^+ - \dot{N}O - \dot{C}H_3$, 42), 216 ($ArCO^+$, 100), 109 ($C_{18}H_{13}^+$, 65.5), 67 ($C_3H_3N_2^+$, 77.7)
34	Tosylate $C_{25}H_{27}N_4O_7S$	56.92 (57.03	5.16 5.24	10.62 10.58)	1660, 1610 (C=C—C=O), 1540, 1375 (NO_2), 1240, 1020 (SO_2)	

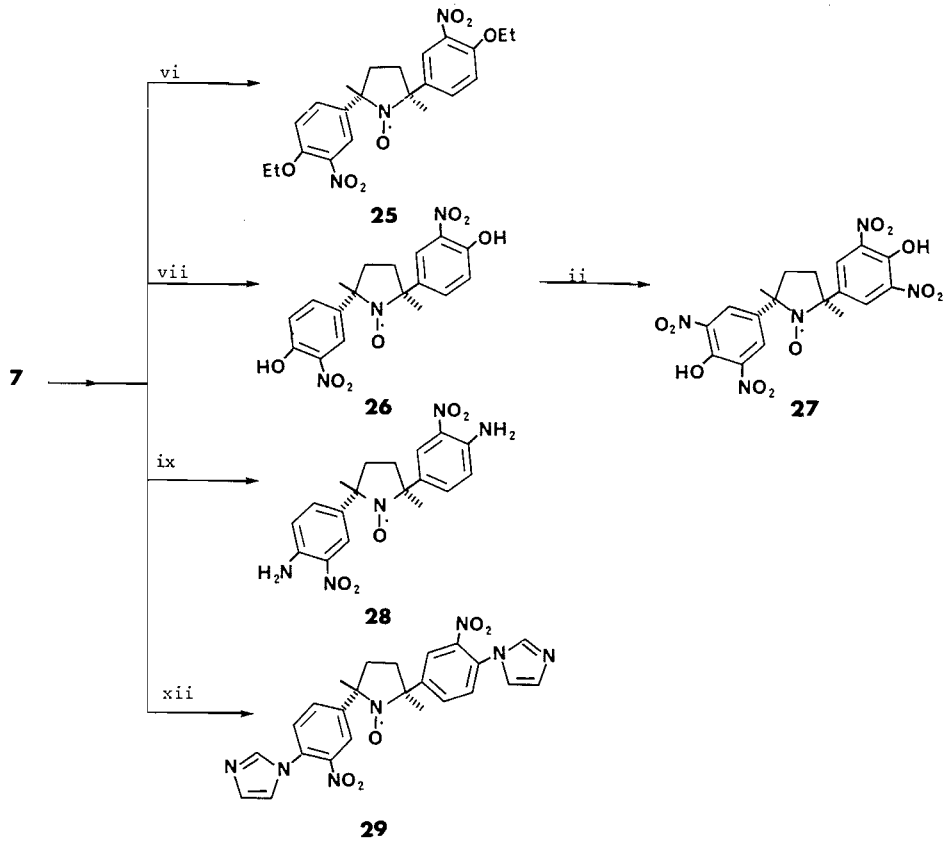
was then poured into ice-water (ca. 300 g), extracted with ether (3 × 30 mL), dried ($MgSO_4$), and evaporated to dryness. The deep-orange solid residue was purified by column chromatography (silica gel, hexane – ethyl acetate, 9:1) to give orange, crystalline **3** (5.90 g, 72%); mp 64–65°C (from chloroform–hexane).

trans-*2,5-Di(4-fluorophenyl)-2,5-dimethylpyrrolidin-1-oxyl (6)*

4-Fluorophenylmagnesium bromide was freshly prepared from 1-bromo-4-fluorobenzene (19.25 g, 0.11 mol) and magnesium (2.67 g, 0.11 mol) in dry ether (200 mL) and was reacted with 2,5-dimethyl-1-pyrroline-1-oxide (**4**) (11.32 g, 0.1 mol). The reaction mixture was worked up as described for compound **2**, but the oxidation was carried out in 25% aqueous ammonia (20 mL) and MeOH (100 mL) containing copper(II) acetate (ca. 0.5 g), by aeration of the stirred solution when the solution turned deep-blue; the aeration was continued for a further 30 min, after which the MeOH was evaporated *in vacuo*. The oily residue was taken up in ether, washed with saturated NaCl, dried ($MgSO_4$), and evaporated to dryness. The residue was bulb-to-bulb distilled at 120°C (bath temp.) at 0.1 Torr (1 Torr = 133.3 Pa), to give the viscous oily nitrone **5** (17.60 g, 85%).

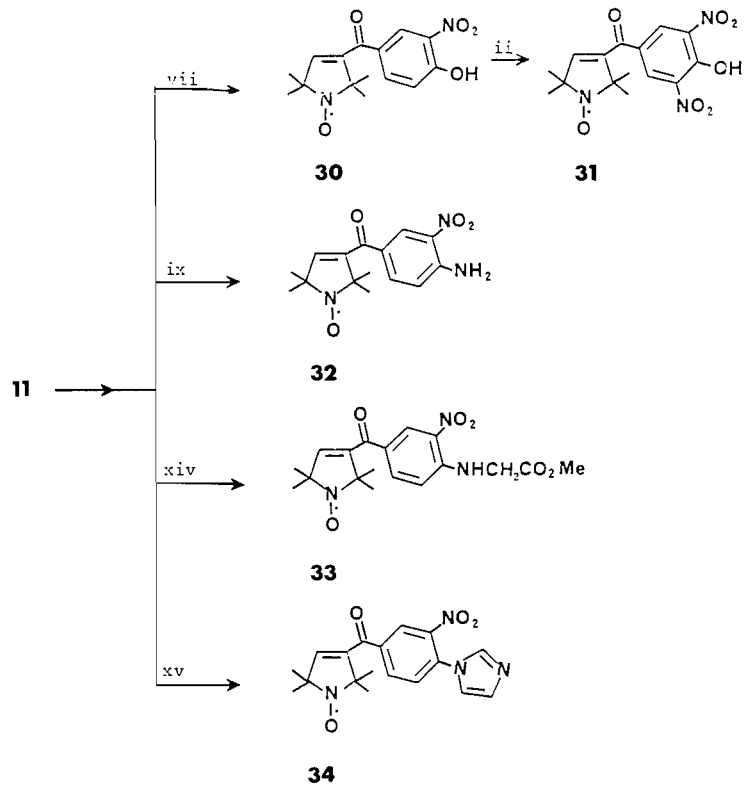
A solution of the nitrone **5** (14.51 g, 70 mmol) in dry ether (50 mL) was added to a well-stirred ethereal solution (100 mL) of freshly prepared 4-fluorophenylmagnesium bromide (80 mmol) at room temperature, and after 6 h the reaction mixture was quenched and worked up as for **2** to give pure *trans* isomer **6** as pale yellow crystals (13.15 g, 62%); mp 105–106°C (from ether–hexane).

trans-*2,5-Di(3-nitro-4-fluorophenyl)-2,5-dimethylpyrrolidin-1-oxyl (7)*



Compound **6** (20 mmol) was nitrated and isolated as described in the preparation of **3**, to give the orange-yellow, crystalline dinitro compound **7** (6.15 g, 63%); mp 176–177°C (from chloroform–hexane); ^1H nmr (δ, $CDCl_3$, 250 MHz): 1.31 (s, 6H, $2CH_3$), 2.08 and 2.32 (2m, 2 × 2H, CH_2CH_2), 7.25 (1H, ArH-5 overlapped by a multiplet of the $(PhNH)_2$ additive), 7.78 (ddd, 1H, ArH-6), 8.24 (dd, 1H, ArH-2, J = 7.2 and 2.4 Hz); ^{13}C nmr (δ, $CDCl_3$): 27.1 (CH_3), 35.3 (CH_2-3,4), 68.1 (C-2,5 Cq sp^3), 117.8 (20.5 Hz, ArC-5), 124.1 (2.4 Hz, ArC-2), 134.8 (8.2 Hz, ArC-6), 136.8 (7.0 Hz, ArC-3), 144.3 (4.3 Hz, ArC-1), 154.2 (264.1 Hz, ArC-4).

2,2,5,5-Tetramethyl-3-(α-hydroxy-4-fluorobenzyl)-3-pyrrolin-1-oxyl (9) and 2,2,5,5-tetramethyl-3-(4-fluorobenzoyl)-3-pyrrolin-1-oxyl (10)



Dry $CdCl_2$ (4.58 g, 25 mmol) was added rapidly to a well-stirred and cooled (−10°C) solution of freshly prepared 4-fluorophenylmagnesium bromide (50 mmol) (as described above for compound **2**). To the stirred suspension of the di(4-fluorophenyl) cadmium (25 mmol) formed in dry ether (100 mL), a solution of 2,2,5,5-tetramethyl-3-formyl-3-pyrrolin-1-oxyl (**8**) (23) (4.21 g, 25 mmol) in dry ether (100 mL) was added slowly under argon at room temperature, and the reaction mixture was stirred for a further 6 h, then cooled with an ice-water bath, and decomposed with saturated aqueous NH_4Cl (50 mL). The organic phase was separated, dried ($MgSO_4$), and evaporated to dryness. The solid yellow residue was a mixture of the allylic alcohol **9** and ketone **10**, formed because the alcohol **9** was partially oxidized during the work-up. Therefore, only an analytical sample of **9** was isolated, by flash chromatography (silica gel, hexane – ethyl acetate, 9:1); mp 106–107°C (from ether–hexane).

The stirred mixture of **9** and **10** was dissolved in CCl_4 (100 mL), refluxed with active MnO_2 (Merck, 30 g) for 6 h, and then filtered. The filtrate was evaporated and chromatographed (silica gel, hexane – ethyl acetate, 9:1) to give pure, yellow crystalline ketone **10** (5.20 g, 79%); mp 123–124°C (from chloroform–hexane).

2,2,5,5-Tetramethyl-3-(3-nitro-4-fluorobenzoyl)-3-pyrrolin-1-oxyl (11)

Compound **10** (2.62 g, 10 mmol) was nitrated and isolated as in the preparation of **3**, and gave the yellow, crystalline nitro ketone **11** (2.60 g, 84%); mp 146–147°C (from chloroform–hexane).

2,2,6,6-Tetramethyl-1,2,5,6-tetrahydro-4-(2,4-dinitrophenyl)pyridin-1-oxyl (13)

A solution of 2,2,6,6-tetramethyl-4-hydroxy-4-phenylpiperidin-1-oxyl (**12**) (24) (0.248 g, 1 mmol) was nitrated to give **13** (0.240 g, 75%); mp 156–157°C (from chloroform–hexane); ^{1}H nmr (δ, $CDCl_3$, 250 MHz): 1.27 and 1.29 (2s, 2 × 6H, $4CH_3$), 2.33 (s, 2H, CH_2), 5.50 (s, 1H, CH), 7.43 (d, 1H, ArH-6, J = 8.4 Hz), 8.29 (dd, 1H, Arh-5, J = 8.4 and 2.3 Hz), 8.59 (d, 1H, Arh-3, J = 2.3 Hz); ^{13}C nmr (δ, $CDCl_3$): 24.8, 25.8 (CH_3), 43.2 (CH_2-5), 57.6, 59.8 (C-2,6 Cq sp^3), 119.4 (ArC-3), 126.3 (ArC-6), 127.9 (ArC-5), 129.3 (C-4, hidden by a line of the $(PhNH)_2$ additive), 131.8 (C-3), 136.4 (ArC-1), 143.1 (ArC-4), 146.0 (ArC-2).

2,5,5-Trimethyl-2-(3-nitro-4-ethoxyphenyl)pyrrolidin-1-oxyl (14)

A solution of **3** (0.802 g, 3 mmol) in EtOH (10 mL) and 50% aqueous NaOH (3 mL) was refluxed for 3 h, then cooled and acidified with 5% H_2SO_4. The reaction mixture was extracted with ether (3 × 10 mL), dried ($MgSO_4$), and evaporated to dryness. The yellow solid residue was recrystallized from ether–hexane to give pure **14** (0.610 g, 69%); mp 90–91°C.

2,5,5-Trimethyl-2-(3,5-dinitro-4-ethoxyphenyl)pyrrolidin-1-oxyl (15)

The nitration of **14** (0.293 g, 1 mmol) gave the dinitro compound **15** (0.169 g, 50%); mp 76–77°C (from ether–hexane).

2,5,5-Trimethyl-2-(3-nitro-4-hydroxyphenyl)pyrrolidin-1-oxyl (16)

The above reaction of **3** (0.802 g, 3 mmol) was carried out in dioxane (10 mL) instead of EtOH, to give **16** (0.655 g, 82%); mp 76–78°C (from chloroform–hexane).

2,5,5-Trimethyl-2-(3,5-dinitro-4-hydroxyphenyl)pyrrolidin-1-oxyl (17)

The nitration of **16** (0.265 g, 1 mmol) gave the dinitrophenol **17** (0.242 g, 78%); mp > 260°C (from chloroform–hexane).

2,5,5-Trimethyl-2-(3-amino-4-hydroxyphenyl)pyrrolidin-1-oxyl (18)

To a stirred solution of nitrophenol **16** (2.65 g, 10 mmol) and 10% Pd/carbon (200 mg) in dry MeOH (20 mL) under argon, ammonium formate (3.78 g, 60 mmol) was added rapidly. The reaction mixture was stirred at 40°C for 3 h, then diluted with water and filtered from the catalyst. The filtrate was extracted with $CHCl_3$ (3 × 30 mL), and the organic phase was washed with saturated NaCl, dried ($MgSO_4$), and aerated in the presence of PbO_2 catalyst to oxidize the hydroxylamine to nitroxide. Finally, the filtrate was evaporated to dryness to give the aminophenol **18** (1.41 g, 60%); mp 148–149°C (from ether–hexane).

2,5,5-Trimethyl-2-(3-nitro-4-aminophenyl)pyrrolidin-1-oxyl (19)

A solution of fluoronitrophenol derivative **3** (2.67 g, 10 mmol) in dioxane (20 mL) was refluxed and stirred with 25% aqueous ammonia (10 mL) for 16 h. The reaction mixture was then extracted with ether (50 mL) and washed with saturated NaCl (2 × 10 mL). The ether phase was dried ($MgSO_4$) and evaporated to dryness. The residue was chromatographed (silica gel, hexane – ethyl acetate, 9:1) to give nonreacted **3** (0.670 g, 25%) and the nitroaniline **19** (1.35 g, 51%); mp 130–131°C (from ether–hexane).

2,5,5-Trimethyl-2-(3,4-diaminophenyl)pyrrolidin-1-oxyl (20)

The nitroaniline **19** (0.529 g, 2 mmol) was transfer-hydrogenated as described in the preparation of aminophenyl **18**, to give the pale-yellow diaminophenyl derivative **20** (0.250 g, 53%); mp 126–127°C (from ether–hexane).

5(6)-(2,5,5-Trimethylpyrrolidin-2-yl)benzimidazole-2-thione (21)

To a solution of diamine **20** (0.234 g, 1 mmol) in dry tetrahydrofuran (5 mL), 1,1′-thiocarbonyldiimidazole (0.214 g, 1.2 mmol) was added. The mixture was heated for 30 min, then diluted with water (10 mL) and extracted with ether (3 × 20 mL). The ether phase was dried ($MgSO_4$) and evaporated to dryness. The residue was purified with chloroform–methanol (8:1) on a preparative silica gel plate, to give **21** (0.125 g, 45%); mp 173–175°C (from chloroform–hexane).

2,5,5-Trimethyl-2-(3-nitro-4-cyanophenyl)pyrrolidin-1-oxyl (22)

A stirred solution of **3** (0.267 g, 1 mmol) and NaCN (0.072 g, 1.1 mmol) in dry dimethyl sulphoxide (5 mL) was heated at 50°C for 1 h, then diluted with water (50 mL) and extracted with ether (3 × 20 mL). The ether phase was dried ($MgSO_4$) and evaporated to dryness. The yellow solid was purified with hexane – ethyl acetate (2:1) on a preparative silica gel plate, to give **22** (0.132 g, 48%); mp 94–95°C (from ether–hexane).

2,5,5-Trimethyl-2-[3-nitro-4-(imidazol-1-yl)phenyl]pyrrolidin-1-oxyl 23

A stirred solution of **3** (0.535 g, 2 mmol) and imidazole (0.204 g, 3 mmol) in dioxane (10 mL) was heated and stirred with K_2CO_3 (400 mg) in the presence of Aliquat 336 (Fluka, 30 mg) for 6 h, then diluted with water (30 mL) and extracted with ether (3 × 10 mL). The dried ($MgSO_4$) ethereal phase was evaporated, and the residual solid was purified on a short silica gel column with chloroform–methanol (30:1) to give the yellow, crystalline, pure imidazole **23** (0.530 g, 84%); mp 107–108°C (from chloroform–hexane).

2,5,5-Trimethyl-2-[3-nitro-4-(1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-methyl)thiophenyl]pyrrolidin-1-oxyl (24)

To a freshly prepared solution of 2,2,5,5-tetramethyl-3-thiolmethyl-3-pyrrolin-1-oxyl (29) (0.186 g, 1 mmol) and **3** (0.267 g, 1 mmol) in ethanol (10 mL), 2% aqueous NaOH (2 mL) was added. The reaction mixture was stirred at room temperature for 3 h, then diluted with water (40 mL) and extracted with ethyl acetate (3 × 10 mL). The organic phase was dried ($MgSO_4$) and evaporated to dryness, and the residue was chromatographed on a silica gel plate (hexane – ethyl acetate, 2:1), to give the biradical **24** (0.204 g, 47%); mp 110–111°C (from chloroform–hexane).

*2,5-Dimethyl-*trans*-2,5-di(3-nitro-4-ethoxyphenyl)pyrrolidin-1-oxyl (25)*

To a solution of difluorodinitro derivative **7** (0.785 g, 2 mmol) in ethanol (20 mL), 50% aqueous NaOH (5 mL) was added and the reaction mixture was heated for 3 h. The bulk of the ethanol was then evaporated, and the residue was acidified with 5% H_2SO_4 and extracted with chloroform (3 × 10 mL). The organic phase was dried ($MgSO_4$) and evaporated to dryness. The solid residue was purified on a short silica gel column (hexane–chloroform, 4:1), to give the yellow crystalline **25** (0.563 g, 63%); mp 156–157°C (from chloroform–hexane).

*2,5-Dimethyl-*trans*-2,5-di(3-nitro-4-hydroxyphenyl)pyrrolidin-1-oxyl (26)*

The difluorodinitro derivative **7** (0.785 mg, 2 mmol) was reacted as in the preparation of **25**, but dioxane (20 mL) was used instead of ethanol, to give **26** (0.560 g, 72%); mp 190–191°C (from ether–hexane).

*2,5-Dimethyl-*trans*-2,5-di(3,5-dinitro-4-hydroxyphenyl)pyrrolidin-1-oxyl (27)*

The dihydroxy derivative **26** (0.388 g, 1 mmol) was nitrated as described in the preparation of **3**. Preparative layer chromatography (chloroform–ethanol, 6:1) gave the red-yellow, crystalline tetranitro derivative **27** (0.384 g, 80%); mp 160–161°C (from chloroform–hexane).

*2,5-Dimethyl-*trans*-2,5-di(3-nitro-4-aminophenyl)pyrrolidin-1-oxyl (28)*

A stirred solution of **7** (0.785 g, 2 mmol) in dioxane (20 mL) and 25% aqueous ammonia (5 mL) was heated for 6 h, then extracted with ethyl acetate (3 × 10 mL). The organic phase was dried ($MgSO_4$) and evaporated to dryness. The yellow residual solid was purified by column chromatography (silica gel, chloroform–ether, 10:1), to give the bis(nitroaniline) **28** (0.572 g, 74%); mp 84–85°C (from chloroform–hexane).

2,5-Dimethyl-trans-*2,5-di[3-nitro-4-(imidazol-1-yl)phenyl]pyrrolidin-1-oxyl (29)*

The diimidazole compound **29** was prepared in good yield from **7** (0.392 g, 1 mmol) with imidazole (0.150 g, 2.2 mmol) as described in the preparation of **23**. Yield: 0.332 g, (68%); mp 193–194°C (from chloroform–hexane).

2,2,5,5-Tetramethyl-3-(3-nitro-4-hydroxybenzoyl)-3-pyrrolin-1-oxyl (30)

To a stirred solution of the fluoronitroketone **11** (3.07 g, 10 mmol) in dioxane (20 mL), 50% aqueous NaOH (5 mL) was added. The reaction mixture was refluxed for 6 h, cooled, acidified with 5% H_2SO_4, and extracted with ether (3 × 20 mL). The organic phase was washed with saturated NaCl, dried ($MgSO_4$), and evaporated. The crude product was purified by column chromatography (silica gel, hexane – ethyl acetate, 10:1), to give the orange, crystalline hydroxy derivative **30** (2.35 g, 77%); mp 130–131°C (from chloroform–hexane).

2,2,5,5-Tetramethyl-3-(3,5-dinitro-4-hydroxybenzoyl)-3-pyrrolin-1-oxyl (31)

The nitrophenol **30** (1.53 g, 5 mmol) was nitrated as described in the preparation of **3**, to give the dinitrophenol derivative **31** (1.40 g, 80%); mp 59–61°C (from chloroform–hexane).

2,2,5,5-Tetramethyl-3-(3-nitro-4-aminobenzoyl)-3-pyrrolin-1-oxyl (32)

A solution of **11** (0.307 g, 1 mmol) in dioxane (10 mL) and 25% aqueous ammonia (5 mL) was refluxed for 3 h, then worked up as described in the preparation of **19** to give **32** (0.278 g, 90%); mp 175–176°C (from ether–hexane).

2,2,5,5-Tetramethyl-3-{3-nitro-4-[N-(methoxy-carbonylmethyl)]aminobenzoyl}-3-pyrrolin-1-oxyl (33)

A solution of **11** (0.307 g, 1 mmol), glycine methyl ester hydrochloride (0.138 g, 1.1 mmol), and K_2CO_3 (140 mg) in 80% aqueous EtOH (10 mL) was refluxed for 3 h, then evaporated to dryness. The residue was taken up in chloroform (20 mL), washed with water, dried ($MgSO_4$), and evaporated to dryness. The solid residue was recrystallized from ether–hexane, to give **33** (0.272 g, 72%); mp 157–158°C.

2,2,5,5-Tetramethyl-3-[3-nitro-4-(imidazol-1-yl)benzoyl]-3-pyrrolin-1-oxyl (34)

A stirred solution of **11** (0.625 g, 2 mmol), imidazole (0.150 g, 2.2 mmol), and K_2CO_3 (300 mg) in water (5 mL) was refluxed for 3 h, then worked up as in the preparation of **23**, to give **34** (0.612 g, 86%); mp 41–42°C (from chloroform–hexane).

The tosylate of **34** was precipitated from a solution of the base in dry acetone, treated with an equivalent amount of toluenesulphonic acid, and then diluted with ether, mp 173–174°C.

On the regioselectivity of Wittig reactions with unsymmetrically substituted succinic anhydrides

MARGARET M. KAYSER[1] AND LIVAIN BREAU

Department of Chemistry, University of New Brunswick, P.O. Box 5050, Saint John, N.B., Canada E2L 4L5

Received December 20, 1988

MARGARET M. KAYSER and LIVAIN BREAU. Can. J. Chem. **67**, 1401 (1989).

Phosphorane ylids react readily with succinic anhydrides to give enol-lactones. With highly substituted succinic anhydrides, condensations occur at the less substituted carbonyl group, suggesting that the reaction is sterically controlled. This, however, is not the case in monosubstituted anhydrides where effects other than steric become dominant. Condensation of phosphorane **1***a* with methoxysuccinic anhydride occurs selectively at the carbonyl group adjacent to the substituent. Stabilization of the transition state through complexation between the oxygen atom of the substituent and an electron-deficient phosphorus of the ylid is proposed.

Key words: cyclic anhydrides, Wittig reaction, regioselectivity, stabilized ylid.

MARGARET M. KAYSER et LIVAIN BREAU. Can. J. Chem. **67**, 1401 (1989).

Les ylides de phosphoranes réagissent facilement avec des anhydrides succiniques pour donner des énol-lactones. Dans le cas des anhydrides succiniques fortement substitués, la condensation se produit au niveau du carbonyle le moins substitué, suggérant ainsi un contrôle stérique de la réaction. La situation est cependant différente dans le cas des anhydrides monosubstitués où des effets autre que stériques deviennent prédominants. La condensation du phosphorane **1***a* sur l'anhydride méthoxysuccinique se fait de façon sélective au niveau du groupe carbonyle adjacent au substituant. On suggère une stabilisation de l'état de transition via une complexation entre l'atome d'oxygène du substituant et un atome de phosphore pauvre en électrons de l'ylide.

Mots clés : anhydrides cycliques, réaction de Wittig, régioséléctivité, ylide stabilisé.

Introduction

Five-member enol-lactones, which occur widely in nature, frequently display an unusual range of biological activities (1). Since many of these compounds hold promise as insecticides, antiviral and antibacterial agents, and as synthetic intermediates for the construction of more complex molecules, a number of methods have been developed for their preparation (2). The condensation of stabilized phosphoranes, such as **1**, with five-member cyclic anhydrides was found to often be a procedure of choice for the synthesis of various enol-lactones (3–5).

In previous publications we outlined the problems of regioselectivity control in the reactions of unsymmetrically substituted maleic (6) and phthalic (7) anhydrides with stabilized phosphorane **1***a*.

$$Ph_3P{=}CHCOOR$$
1

1*a* R = CH_3, **1***b* R = CH_3CH_2

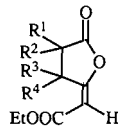
In this paper we describe the results of a complementary study of the condensations of **1***a* with a number of unsymmetrically substituted succinic anhydrides.

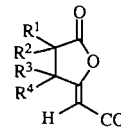
The first reaction between a saturated cyclic anhydride (glutaric anhydride) and ethoxycarbonylmethylenetriphenylphosphorane **1***b* was described in 1965 (8). The yield of the product, an enol-lactone, was low, even after prolonged reflux in dimethoxyethane. In a more recent study, Massy-Westropp and co-workers (9) investigated condensations of phosphoranes with various methyl-substituted glutaric and succinic anhydrides. The reactions of methyl-substituted succinic anhydrides with **1***b* were found to occur exclusively at the sterically more accessible carbonyl function and to give predominantly the (*E*)-enol-lactones (Table 1).

The reported regioselectivities of ylid additions to methylsuccinic and 2,2-dimethylsuccinic anhydrides stood in contrast to the theoretically predicted (10) and experimentally confirmed (11) regioselectivities for metal hydride reductions, which occur preferentially at the "more hindered" carbonyl group.

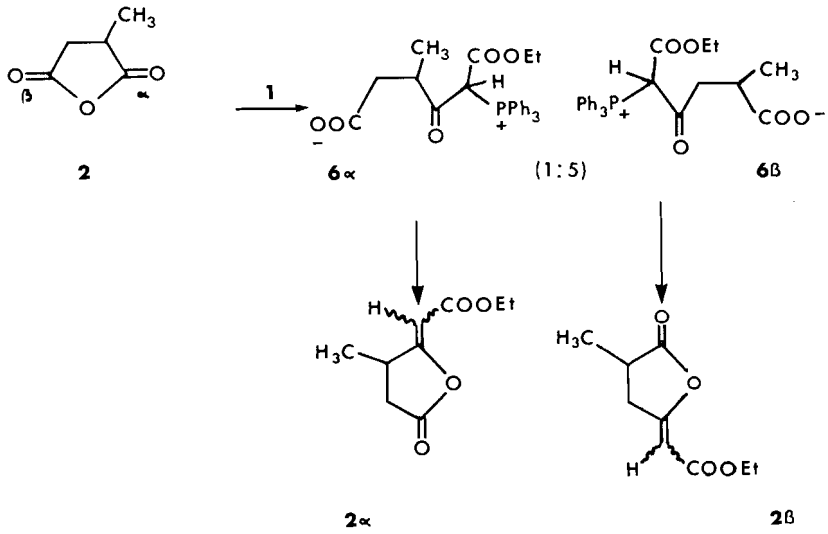
In addition, Massy-Westropp and co-workers reported that the phosphorane **1***b* reacted with methylsuccinic anhydride to give a mixture of *two* intermediate acyclic phosphonium salts **6**α and **6**β, formed by the addition of the ylid to the α- and β-carbonyl groups in the ratio 1:5 respectively, Scheme 1 (9). Since the reaction was postulated to be irreversible, the α addition should have led to the formation of the α-enol-lactone upon reflux.

The above inconsistency and the apparent lack of agreement with theoretical calculations prompted us to reinvestigate these reactions in the course of our studies on the regioselectivity of ylid condensations with cyclic anhydrides.





Results



The reactions of stabilized phosphorane **1** with methylsuccinic anhydride **2**, 2,2-dimethylsuccinic anhydride **3**, and several other substituted anhydrides were carried out; the product ratios were analyzed by ^{1}H nmr and gas chromatography. The enol-lactones were subsequently isolated and, in cases of ambiguity, their structures were confirmed experimentally. The results are listed in Table 2.

The 2,2-dimethylsuccinic anhydride **3** reacted smoothly with phosphorane **1***a* to give an almost quantitative yield of the 3β*E* isomer after 35 h at room temperature, in agreement with the previous findings (9). On the other hand, the condensation of methylsuccinic anhydride **2** with **1***a* gave results significantly different from those reported earlier (compare Tables 1 and 2). Gas chromatographic analysis of the reaction product showed the presence of three enol-lactones in ratio 43:14:43. The minor component, later identified as 2α*Z*, was removed by chromatography; even after repeated attempts the 2α*E* and 2β*Z* could not be separated. Eventually the two geometrical isomers were separated and their structures confirmed by the series of experiments outlined in Scheme 2.

TABLE 1. Condensations between methyl substituted succinic anhydrides and phosphorane **1***b* (ref. 9)

Anhydride					Products		
							
R^1	R^2	R^3	R^4		βE	βZ	Isolated enol-lactone (% yield)
CH_3	H	H	H	**2**	94	6	60
CH_3	CH_3	H	H	**3**	98	2	66
CH_3	CH_3	CH_3	H	**4**	70	30	99
CH_3	CH_3	CH_3	CH_3	**5**	85	15	56

SCHEME 1

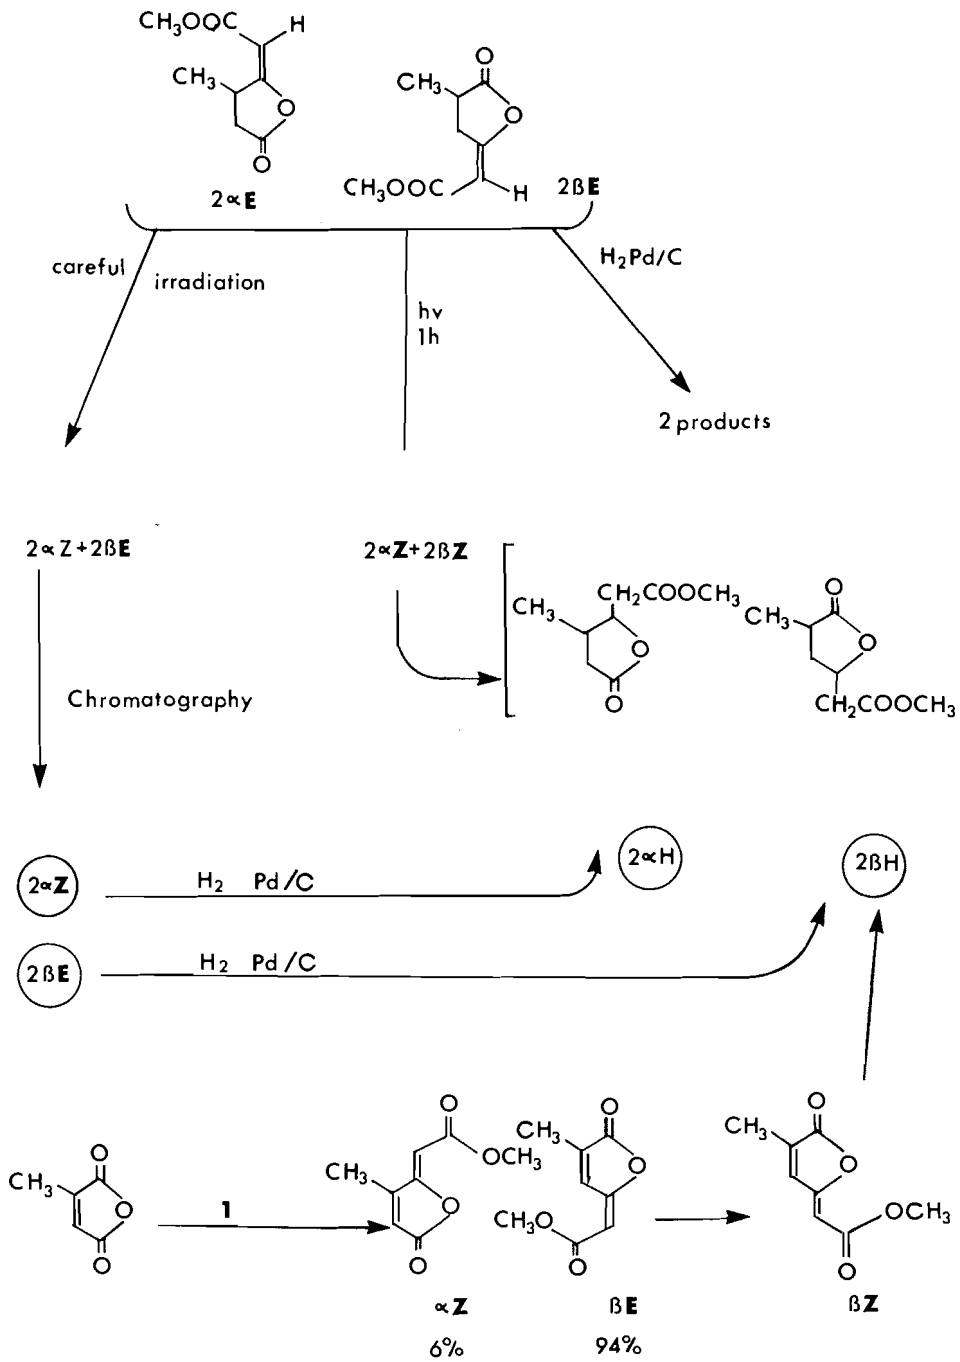
The reaction of *p*-methoxyphenylsuccinic anhydride **7** with phosphorane **1***a* gave a 50:50 mixture **7**α and **7**β. The products were separated by chromatography; their structures were established by ^{1}H nmr and confirmed by hydrogenation experiments, as shown in Scheme 3.

The condensation of phenylsuccinic anhydride **8** with **1***a* gave a 68:32 mixture of the two isomers **8**α and **8**β. The product ratio was established by gas chromatography and by comparison of the ^{1}H nmr spectra of the crude reaction mixtures from the condensations of **1***a* with phenylsuccinic and **1***a* with *p*-methoxyphenylsuccinic anhydrides. We were unable to separate **8**α and **8**β by chromatography.

The hydrogenation of the mixture of **7**α and **7**β produced two new products **7**α*H* and **7**β*H*, of which one was identified by comparison with an authentic sample, as shown in Scheme 3.

The reaction of methoxysuccinic anhydride **11** with phosphorane **1** gave a single product, **11**α*E*, identified on the basis of its high resolution proton nmr spectrum. Its structure was confirmed by isomerization and hydrogenation experiments, as shown in Scheme 4.

The last compound studied in the succinic anhydride series was **12**, prepared by a Diels–Alder addition of furan to bromomaleic anhydride. The condensation of the adduct **12** with **1***a* gave two products, **12**β*E* and **13**, the latter resulting from a facile retro Diels–Alder decomposition of **12**β*E* (Scheme 5). Upon gentle heating the remaining **12**β*E* could be converted to **13**. In fact, the above reaction is the best route to the bromomaleic enol-lactone **13**, since the direct condensation between bromomaleic anhydride and phosphorane **1***a* yields predominantly a polymeric material.



Discussion

The experimental results indicate that, depending on the nature of the substituents and the substitution patterns, we may distinguish two principal types of behaviour in the condensation of succinic anhydrides with stabilized phosphoranes.

Firstly, the 2,2-disubstituted (**3**, **10**) or 2,2,3-trisubstituted anhydrides (**4**, **12**) give enol-lactones resulting from condensation at *the less sterically hindered* carbonyl function. These reactions, completed within a few hours at room temperature, give preferentially the *E* isomers.

The simplest interpretation would suggest that the Wittig condensations with highly substituted succinic anhydrides are sterically controlled. An additional experiment, involving reaction of phosphorane **1***a* with 2,2-dimethyl-3,3-diphenylsuccinic anhydride **14** (12), which gives only one product, **14**β*Z*, supports this view. This reaction has not been included in Table 2, since the yield of the enol-lactone **14**β*Z* is very low (5–8%), and the product identification is based solely on its proton nmr spectrum.

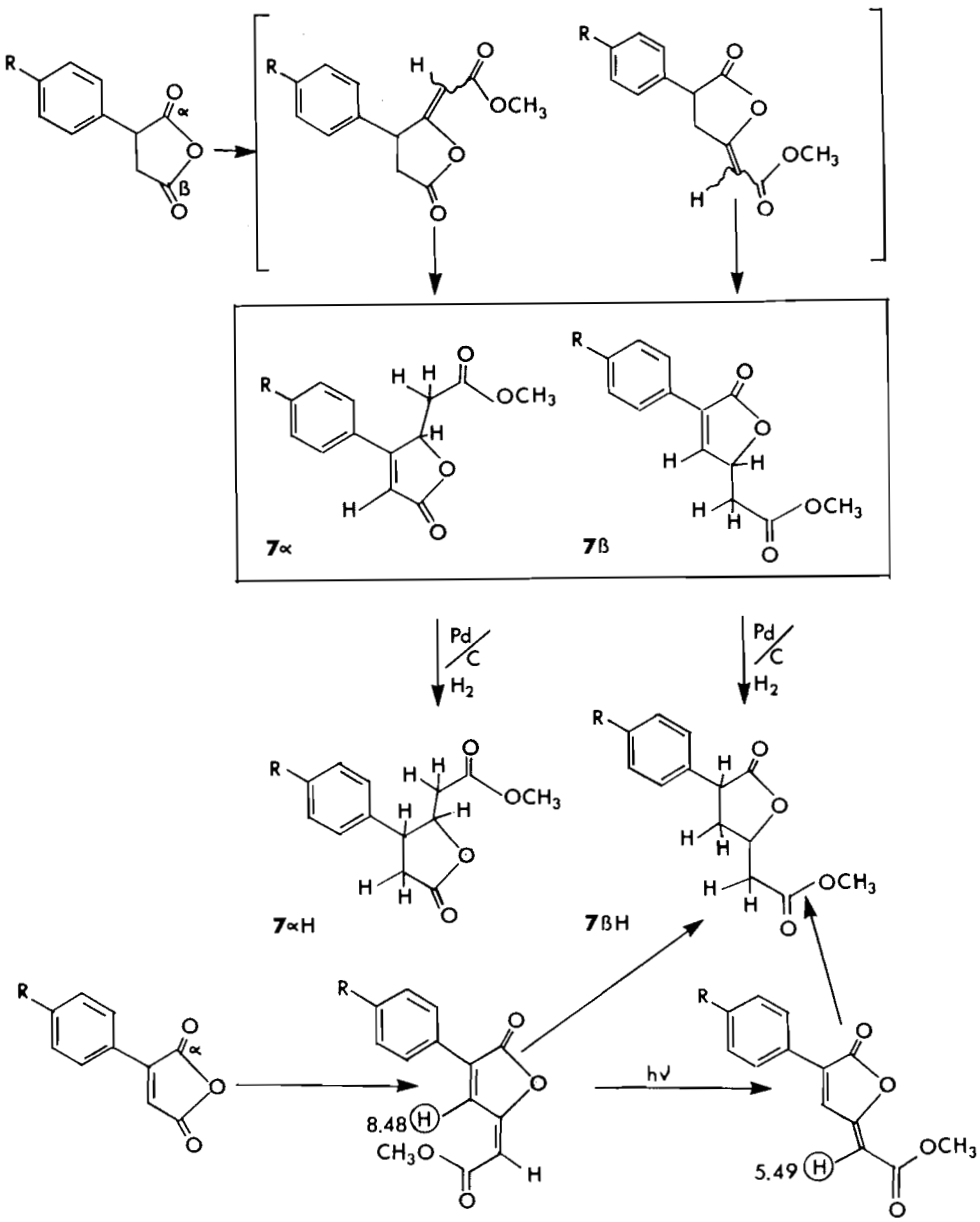
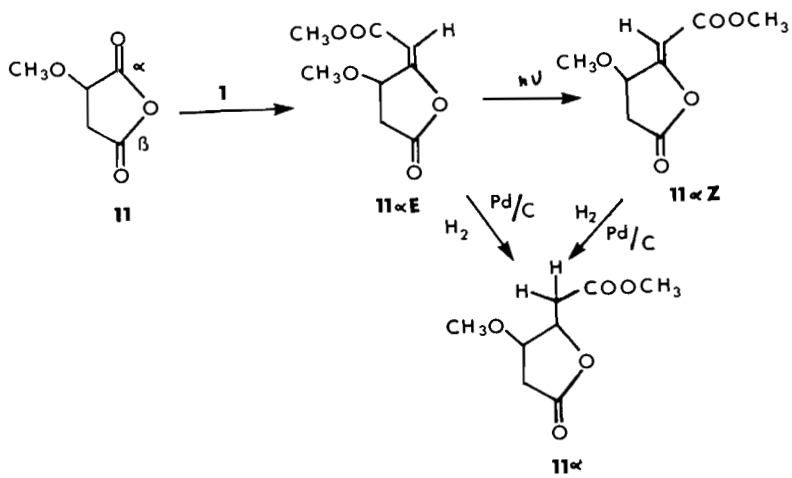
SCHEME 2

The second type of behaviour is exhibited by monosubstituted succinic anhydrides **2**, **7**, **8**, and **11**. These compounds give condensation products ranging from a nonselective 50:50 mixture of regioisomers **7**, to 100:0 selectivity in favour of the carbonyl group adjacent to the substituent in methoxysuccinic anhydride **11**.



To assess the importance of the various effects that influence the regioselectivity of these reactions, the three cases are examined in detail.

Methylsuccinic anhydride



Experimental evidence (13) and various calculations (10, 14) indicate that the succinic anhydride ring is slightly twisted; even an unsubstituted ring exhibits a small deviation from planarity observable by electron diffraction in the gas phase (13). The distortion, resulting most probably from the large out-of-plane vibrations, demonstrates the flexibility of the ring, which can assume a skewed conformation to minimize strain in the transition state, or in the ground state when substituted with large groups. The *ab initio* calculations (10), carried out on methylsuccinic and 2,2-dimethylsuccinic anhydrides, have shown that a distortion from planarity is energetically favourable and that the methyl substituent prefers to assume a quasi-equatorial position (10). More recent MM2 calculations confirm both results, namely that the substitution causes a significant distortion of the anhydride ring and that the conformation having a 2-substituent in the quasi-equatorial position is preferred for phenyl as well as for all alkyl groups studied (14).

14 **14ßZ**

Examination of a model of a twisted methylsuccinic anhydride shows that the quasi-equatorial methyl group is almost eclipsed with the neighbouring carbonyl function.[2]

Ab initio calculations (10) for the hydride addition to methylsuccinic anhydride suggest that the energetically most favourable nucleophilic attack occurs in the antiperiplanar fashion at the α-carbonyl group of the anhydride twisted in a chair-like conformation, with the methyl substituent in a quasi-equatorial position, **16***c*.

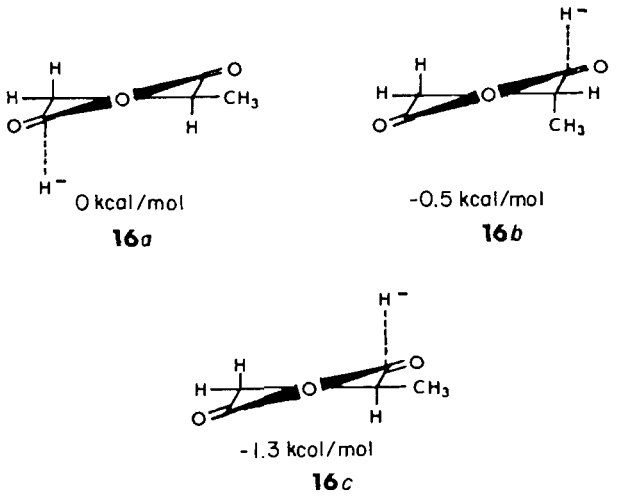
Since the above calculations do not take into account the steric requirements of the large ylid nucleophile, one may assume that the preferred conformation during ylid addition probably most closely resembles the "quasi axial" supermolecule **16***b*. A better HOMO–LUMO overlap (21), and a stabilizing antiperiplanar relationship of the nucleophile to the C—CH_3 bond (22), are likely to be responsible for a weak preference for the α-carbonyl group.

Phenylsuccinic anhydride **8**

In the reaction of phenylsuccinic anhydride with the stabilized phosphorane **1**, the usual condensation products, butanolides, are not observed. Rather, a rapid migration of the *exo* double bond occurs, giving a 68:32 mixture of **8**α and **8**β. Since the rearrangement is irreversible, this ratio represents the distribution of α and β attack at condensation.

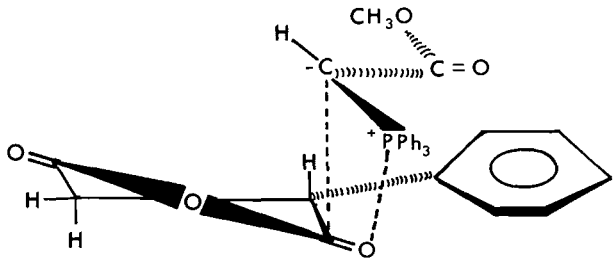
The higher proportion of the α attack may be due to a stabilizing complexation between the electron-rich carbonyl group of the ylid and the electron-poor phenyl ring, as shown in structure **17**. The complexation is facilitated by the flexibility of the succinic anhydride ring and preferred quasi-equatorial conformation of the phenyl substituent (*vide supra*).

The above interpretation is supported by the results obtained in the reaction of *p*-methoxyphenylsuccinic anhydride **7** with the ylid, in which the proportion of the condensation at the α-carbonyl group next to the substituent decreased significantly.



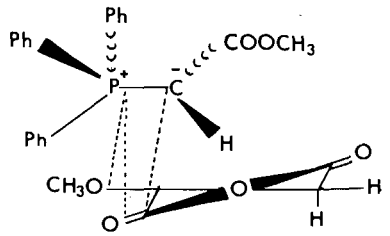
Somewhat related complexing effects were evoked by Chopard *et al.* (4) to explain stereoselectivity patterns observed in the condensation of stabilized phosphoranes with phthalic anhydride (4).

Methoxysuccinic anhydride



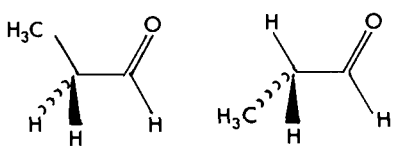
The reaction of methoxysuccinic anhydride **11** with phosphorane **1** is completed within minutes at room temperature to give a single *E* isomer. The reaction can be readily followed by nmr and thereby disappearance of the anhydride and formation of the enol-lactone can be monitored. A similarly regiospecific condensation at the carbonyl group adjacent to the substituent occurs in alkoxy maleic anhydrides (6), while an enhanced selectivity for the 2-carbonyl group has been observed in 3-methoxyphthalic anhydrides (7).

The regioselectivity of these reactions has been interpreted in terms of a particularly effective stabilization of the transition state due to electron donation from the electron-rich oxygen of the alkoxy substituent to the electron-poor phosphorus of the ylid (6, 7).



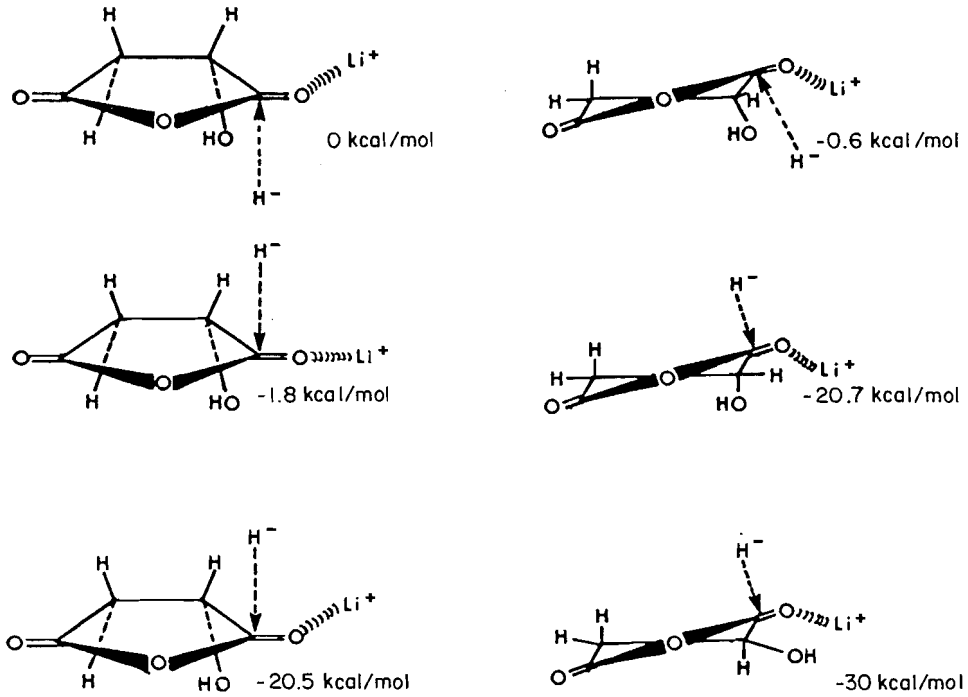
In the reaction between methoxysuccinic anhydride and the ylid the geometry is suitable for an effective O—P overlap (23), providing the anhydride ring is twisted into a chair-like conformation with the methoxy group in the quasi-equatorial position as shown in **18**.

16*a* **16***b* **16***c*



17

18

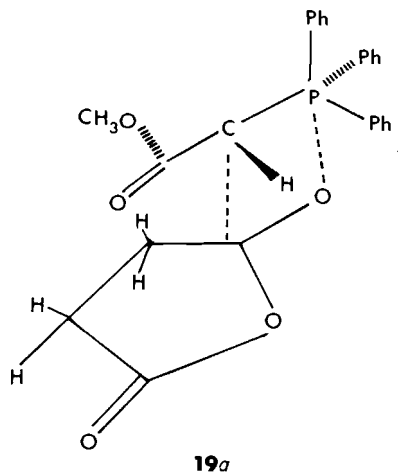


Since it has been demonstrated in the past that the antiperiplanar effect may be particularly important when the substituent α to the carbonyl group is an electronegative atom such as Cl or O (22), we carried out *ab initio* calculations on a simplified model to estimate the relative importance of an antiperiplanar versus a complexation effect for the hydroxysuccinic anhydride supermolecule (24). The results are shown in Table 3. Although

[2]Interestingly, the most stable conformation of propanal is the eclipsed rotamer **15***a*, which is favoured ovr the next low energy conformation **15***b* by approximately 900 cal/mol (15–20).

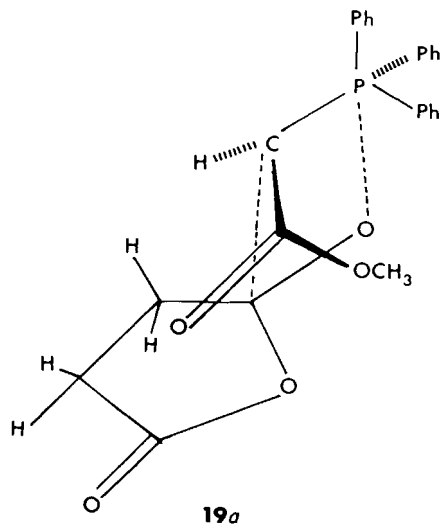
15*a* **15***b*

TABLE 3. Relative energies of planar and twisted supermolecules



the model used (Table 3) clearly does not reflect adequately the geometrical requirements for ylid–anhydride addition, as illustrated in **18**, it does suggest that a twisted conformation, in which the oxygen atom of the substituent can act as a base vis-à-vis a Lewis acid, is particularly favourable. The internal complexation also enhances the positive character of the C atom of the carbonyl group, thereby facilitating nucleophilic attack. Since similar geometry is encountered in the addition of the ylid to the alkoxymaleic anhydrides (6) and the experimental results for these compounds show that the condensations occur entirely at the carbonyl group adjacent to the substituents, the model is probably adequate and complexation in the methoxysuccinic anhydride is the determining factor in regioselectivity control.

The stereochemistry of ylid addition



From the observations recorded in Tables 1 and 2 it is apparent that the additions of stabilized ylids **1***a* and **1***b* to the succinic anhydrides preferentially give the *E* isomers. This stereochemistry may be explained as follows. In the transition state the carboxy group of the ylid assumes preferentially a configuration *trans* to the ring-oxygen atom, **19***a*. Stacking of the carboxy group above the oxygen as shown in **19***b* is clearly unfavourable, probably due to the oxygen – carboxy group repulsion. Even when the substituents on the ring are large and cannot be twisted away from interfering with the nucleophile, the *E* isomer predominates. It is possible that in some cases, when the *Z* isomer was isolated, it had been formed only during the work-up procedures from the sterically more hindered *E* isomer. We have observed such an easy isomerization in a number of reactions, which were followed by proton nmr.

Conclusion

It is quite evident that, although ylid additions to succinic anhydrides are sensitive to steric restrictions and are more likely

to occur at a "less hindered" carbonyl function, various electronic effects cannot be neglected. In particular, complexation between electron-rich substituents and the electron-poor phosphorus of the ylid appears to be important in regioselectivity control. We are presently investigating other substituents as possible electron donors and the geometrical requirements for effective base–phosphorus stabilizing interactions.

Experimental

Melting points were determined on a Fisher Scientific Co. hot-stage melting point apparatus and are uncorrected. Infrared spectra were obtained on a Perkin–Elmer 1420 ratio recording infrared spectrophotometer, neat, or with chloroform as solvent. Ultraviolet spectra were measured in methanol using a Varian Cary 219 spectrophotometer. Proton nmr and ^{13}C nmr spectra were recorded on a Varian EM 300L nmr spectrometer or on a Nicolet 360 spectrometer with $CDCl_3$ as solvent and $(CH_3)_4Si$ as internal standard. Mass spectra were recorded on a VG mass spectrometer with a DANI 7070 gas chromatograph. Gas chromatography analyses were carried out with a Varian 3700 gas chromatograph, using a 50 cm × 1/8 in. 5% OV-101 on Chromosorb G-HP 100/120 mesh column. Chromatographic separations were performed on a preparative, centrifugally accelerated, radial, thin-layer chromatograph (a Chromatotron model 7924T). Tetrahydrofuran (THF) was dried over sodium metal and was distilled under nitrogen.

*General procedure for the reactions of $Ph_3P{=}CHCO_2CH_3$ **1**a with succinic anhydrides*

Molar equivalent amounts of an anhydride (0.01 mol) and methyl)(triphenylphosphoranylidene) acetate **1***a* (0.01 mol) were dissolved in dry THF (100 mL) and the solution was refluxed under N_2 atmosphere. Progress of the reaction was followed by gas chromatography and proton nmr. Crude products were separated on the Chromatotron. The isomeric lactones were identified by proton nmr, hydrogenation, and isomerization experiments.

Photochemical isomerization of enol-lactones

A pure sample of an enol-lactone was dissolved in cyclohexane and placed in a petri dish surrounded by aluminum foil. The solution was irradiated with a uv lamp (UVSL-25 watt) for a period of 15 min – 2 h. After evaporation of the solvent the residue was analyzed by proton nmr and gas chromatography.

Reaction of methylsuccinic anhydride 2

The reaction between methylsuccinic anhydride **2** (1.12 g, 8.77 mmol) and phosphorane **1***a* (2.93 g, 8.77 mmol) in THF was completed in 48 h at 40°C. Proton nmr analysis of the crude reaction mixture showed that the isomers **2**α*E*, **2**α*Z*, and **2**β*E* were present in the ratio 43:14:43. Chromatography with petroleum ether/ether failed to separate the isomeric enol-lactones **2**α*E* and **2**β*E*, but succeeded in removing the triphenylphosphine oxide ($Ph_3P{=}O$) and **2**α*Z* isomer from the mixture. The remaining two enol-lactones were isolated in 67% yield (1.0 g). The assignment of structures was based on the 360-MHz proton nmr spectroscopic data. The following resonances were identified as due to methyl (*E*)-(tetrahydro-3-methyl-5-oxo-2-furanylidene)acetate **2**α*E*: proton nmr ($CDCl_3$) δ: 1.39 (d, J = 7 Hz, 3H, CH_3), 2.26–3.11 (m, 3H, at C-3 and C-4), 3.71 (s, 3H, $COOCH_3$), 5.61 (d, J = 1.3 Hz, 1H, :C*H*COOMe); gc–ms m/z: M^+ 170 (9%), 142 (44%), 139 (23%), 110 (23%), 101 (35%), 69 (100%), and 42 (26%). The methyl (*E*)-tetrahydro-4-methyl-5-oxo-2-furanylidene) acetate **2**β*E* showed characteristic peaks at δ 1.36 (d, J = 7 Hz, 3H, CH_3), 2.26–3.11 (m, 3H, at C-3 and C-4), 3.70 (s, 3H, $COOCH_3$), 5.66 (t, J = 2 Hz, 1H, :C*H*COOMe); gc–ms m/z: M^+ 170 (M^+, 20), 142 (46), 139 (29), 110 (26), 101 (49), 69 (100), and 42 (31).

A solution of **2**α*E* (65%) and **2**β*E* (35%) in cyclohexane was irradiated for 30 min. Proton nmr and glc of the product showed that three enol-lactones were now present: **2**α*E* (24%), **2**α*Z* (41%), and **2**β*E* (35%). The major isomer, methyl (*Z*)-(tetrahydro-3-methyl-5-oxo-2-furanylidene)acetate **2**α*Z*, was characterized by a proton nmr signal at δ 5.13 (d, J = 1 Hz, :C*H*COOMe).

A solution of **2**α*Z* (50 mg) in ethyl acetate (50 mL) was hydrogenated according to the general procedure to give the single product, **2**α*H*, with a characteristic signal in the proton nmr spectrum at δ 4.43 (m, 1H).

Hydrogenation carried out on the mixture of **2**α*Z* and **2**β*Z* (from an exhaustive irradiation of the original mixture of **2**α*E* and **2**β*E*) gave an inseparable mixture of **2**α*H* and **2**β*H*. The proton nmr spectrum of the mixture showed signals at δ 4.43 (m, 1H, C-3) for **2**α*H* and at δ 4.93 (m, 1H, C-4) for **2**β*H*. The identity of **2**β*H* was confirmed by the hydrogenation carried out on the **18**β*E* enol-lactone (6). A solution of pure **18**β*E* (100 mg) in ethyl acetate (100 mL) containing 5% palladium-on-carbon catalyst (25 mg) was shaken under hydrogen at 40 psi (1 psi = 6.9 kPa) overnight. The mixture was filtered and the filtrate evaporated under reduced pressure to give 98 mg (98%) of methyl (tetrahydro-4-methyl-5-oxo-2-furan)acetate, **2**β*H*, as a colourless oil; ir (thin layer) ν_{max}: 2945, 1770, 1740, 1440, 1170, 1030, and 935 cm^{-1}; proton nmr ($CDCl_3$) δ: 1.3 (d, J = 7 Hz, 3H) 1.4–1.95 (m, 1H), 2.25–3.20 (m, 4H), 3.75 (s, 3H, $COOCH_3$), and 4.93 (m, 1H, C-4).

Reaction of 2,2-dimethylsuccinic anhydride 3

2,2-Dimethylsuccinic anhydride **3** (142 mg, 1.0 mmol) and phosphorane **1***a* (334 mg, 1.0 mmol) were dissolved in $CDCl_3$ at room temperature. The reaction was monitored by proton nmr. After 12 h the reaction was essentially completed. The infrared and proton nmr spectra of the product enol-lactone, **3**β*E*, were identical with those described in the literature (9).

Reaction with (p-methoxyphenyl)succinic anhydride 7

Using the general procedure, the reaction between (*p*-methoxyphenyl)succinic anhydride **7** (25) (1.00 g, 4.85 mmol) and phosphorane **1***a* (1.62 g, 4.85 mmol) was completed after 20 h of reflux in THF. Proton nmr analysis of the crude reaction mixture showed that the two isomers **7**α and **7**β were present in the ratio 50:50. Chromatography with petroleum ether/ether gave methyl (3-[2,5-dihydro *p*-methoxyphenyl]-5-oxo-2-furan)acetate **7**α (eluted first), as white flaky leaflets, mp 94–95°C; ir ($CHCl_3$) ν_{max}: 2960, 2930, 2830, 1755, 1740, 1610, 1410, 1260, 1180, 1125, and 840 cm^{-1}; proton nmr ($CDCl_3$) δ: 2.68 (dd, J = 16.4 and 7.2 Hz, 1H), 2.91 (dd, J = 16.4 and 7.0 Hz, 1H), 3.75 (s, 3H, $COOCH_3$), 3.83 (s, 3H, *p*-Ar -OCH_3), 5.39 (td, J = 7.0, 7.2, and 1.6 Hz, 1H, >C*H*—Ph), 6.93 (asym. d, J = 8.8 Hz, 2H, *m*-Ar H), 7.54 (d, J = 1.6 Hz, 1H, :C*H*COOMe), 7.82 (asym. d, J = 8.8 Hz, 2H, *o*-Ar H); ms m/z: 262 (M^+, 38), 202 (100), 189 (19), 161 (45), 133 (88), and 57 (21). *Exact Mass* calcd. for $C_{14}H_{14}O_5$: 262.0841; found: 262.0802. Further elution gave methyl (4-[2,5-dihydro *p*-methoxyphenyl]-5-oxo-2-furan)acetate **7**β as pale yellow cubic crystals, mp 64–66°C; ir ($CHCl_3$) ν_{max}: 3020, 2960, 2940, 2930, 1840, 1605, 1510, 1290, 1260, 1170, 1050, and 830 cm^{-1}; proton nmr ($CDCl_3$) δ: 2.50 (dd, J = 17.5 and 9.4 Hz, 1H), 2.92 (dd, J = 16.5 and 2.6 Hz, 1H), 3.74 (s, 3H, $COOCH_3$), 3.86 (s, 3H, *p*-Ar OCH_3), 5.88 (ddd, J = 9.4, 2.6, and 1.3 Hz, 1H), 6.20 (d, J = 1.3 Hz, 1H, :C*H*COOMe), 6.98 (asym. d, J = 8.8 Hz, 2H, *o*-Ar H), 7.42 (asym. d, J = 8.8 Hz, 2H, *m*-Ar H); ms m/z: 262 (M^+, 63), 171 (32), 202 (19), 189 (23), 161 (48), 133 (100), 131 (52), 71 (19), 57 (36), 43 (20), and 28 (29). *Exact Mass* calcd. for $C_{14}H_{14}O_5$: 262.0841; found: 262.0832. Overall yield of the two isomers was 1.09 g (86%).

A cyclohexane solution of pure **7**α was irradiated. Proton nmr and glc showed on change even after 4 h of irradiation. Some polymeric material was formed upon prolonged irradiation. Identical results were obtained on the irradiation of the **7**β isomer.

A solution of the pure **7**α (100 mg) in ethyl acetate (100 mL) containing 5% palladium-on-carbon catalyst (25 mg) was shaken under hydrogen at 30 psi for 6 h; the mixture was filtered and the filtrate evaporated under reduced pressure to give 105 mg of a pale yellow oil. Chromatography on the Chromatotron with petroleum ether/ether gave the pure methyl (tetrahydro-3-[*p*-methoxyphenyl]-5-oxo-2-furan)acetate, **7**α*H* (90 mg, 89%), as a very pale yellow oil; ir (thin film) ν_{max}: 3005, 2960, 1780, 1735, 1610, 1520, 1255, 1180, 1030, and 835 cm^{-1}; proton nmr ($CDCl_3$) δ: 2.18 (dd, J = 17.0 and 6.5 Hz, 1H), 2.46

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

(dd, J = 17.0 and 7.6 Hz, 1H), 2.74 (dd, J = 17.0 and 4.1 Hz, 1H), 3.02 (dd, J = 17.0 and 8.8 Hz, 1H), 3.61 (s, 3H, $COOCH_3$), 3.80 (s, 3H, *p*-Ar -OCH_3), 3.84 (m, 1H, H-A), 5.16 (m, 1H, H-B), 6.86 (asym. d, J = 8.7 Hz, 2H, *m*-Ar H), and 7.02 (asym. d, J = 8.7 Hz, 2H, *o*-Ar H).

A solution of the mixture of **7**α and **7**β in ethyl acetate (100 mL) containing 5% palladium-on-carbon catalyst (50 mg) was shaken under hydrogen at 30 psi for 6 h; the mixture was filtered and the filtrate evaporated under reduced pressure to give 205 mg of a pale yellow oil. Chromatography on the Chromatotron with petroleum ether/ether gave methyl (tetrahydro-3-[*p*-methoxyphenyl]-5-oxo-2-furan)acetate, **7**α*H* (110 mg), eluted first. The sample had identical spectral properties with the product obtained from the hydrogenation of pure **7**α. Methyl (tetrahydro-4-[*p*-methoxyphenyl-5-oxo-2-furan)acetate **7**β*H* (90 mg), a colourless oil, was eluted second. This fraction corresponded to the hydrogenation product of the pure **7**β: ir (thin film) ν_{max}: 2940, 1770, 1735, 1615, 1515, 1250, 1155, and 1030 cm^{-1}; proton nmr ($CDCl_3$) δ: 2.12 (m, 1H, H-D), 2.71 (dd, J = 16.3 and 6.1 Hz, 1H), 2.86 (m, 1H, H-C), 2.90 (dd, J = 16.3 and 6.7 Hz, 1H), 3.73 (s, 3H $COOCH_3$), 3.79 (s, 3H, *p*-Ar -OCH_3), 3.86 (dd, J = 8.9 and J = 8.6 Hz, 1H, H-A), 4.87 (m, 1H, H-B), 6.89 (asym. d, J = H.7 Hz, 2H, *m*-Ar H), and 7.20 (asym. d, J = 8.6 Hz, 2H, *o*-Ar H).

Synthesis of phenylsuccinic anhydride **8**

A solution of phenylsuccinic acid (23 g, 0.13 mol) in acetic anhydride (25 g, 0.23 mol) was heated under reflux for 2 h. Fractional distillation under reduced pressure yielded phenylsuccinic anhydride **8** (20.6 g, 91%) as a pale yellow oil, bp 153–155°C/0.4 Torr (1 Torr = 133.3 Pa), which crystallized on cooling; mp 53–54°C (lit. (27) mp 54°C); ir ($CHCl_3$) ν_{max}: 3010, 2960, 1865, 1790, 1062, 920, and 908 cm^{-1}; proton nmr ($CDCl_3$) δ: 3.23 (m, 2H, —CH_2), 4.33 (m, 1H, >CH—Ph), 7.33 (m, 5H, Ar H).

Reaction with phenylsuccinic anhydride **8**

Using the general procedure, the reaction between phenylsuccinic anhydride **8** (1.00 g, 5.68 mmol) and phosphorane **1***a* (1.90 g, 5.68 mmol) was completed after 20 h of reflux in THF. Proton nmr analysis of the crude reaction mixture showed that the two isomers **8**α and **8**β were present in the ratio of 68:32. Repeated chromatography failed to separate the isomeric enol-lactones **8**α and **8**β but succeeded in removing triphenylphosphine oxide (Ph_3P=O) from the mixture. The two enol-lactones were isolated in 77% yield (1.01 g). The assignment of the structures was based on the proton nmr spectra by comparison with almost identical chemical shifts observed for a separable mixture of **7**α and **7**β.

Hydrogenation of a mixture of isomers **8**α *and* **8**β

A solution of **8**α and **8**β was hydrogenated, as described previously, to yield an inseparable mixture of methyl (tetrahydro-3-phenyl-5-oxo-2-furan)acetate **8**α*H* and methyl (tetrahydro-4-phenyl-5-oxo-2-furan)acetate **8**β*H* as a colourless oil. The 60-MHz proton nmr ($CDCl_3$) of the reaction mixture showed characteristic peaks at δ 5.10 (m, 1H, H at C-3) for the **8**α*H* isomer and 4.85 (m, 1H, H at C-4) for the **8**β*H* isomer. The **8**β*H* was identical (gc and proton nmr) with a sample of pure methyl (tetrahydro-4-phenyl-5-oxo-2-furan)acetate from the hydrogenation of the enol-lactone obtained by condensation of phenylmaleic anhydride with phosphorane **1***a* (6). *Exact Mass* calculated for $C_{13}H_{14}O_4$: 234.0892; found: 234.0892.

Reaction with p*-nitrophenylsuccinic anhydride* **9**

Upon mixing *p*-nitrophenylsuccinic anhydride **9** (26) (0.35 g, 1.58 mmol) and phosphorane **1***a* (0.53 g, 1.59 mmol) in THF, a deep red colouring developed instantaneously. Neither starting material nor any monomeric enol-lactone could be detected by glc and proton nmr.

Reaction with methoxysuccinic anhydride **11**

The reaction between methoxysuccinic anhydride **11** (27) (0.50 g, 3.84 mmol) and phosphorane **1***a* (1.29 g, 3.84 mmol) was completed in 20 h at 40°C in THF. Proton nmr and glc analyses of the crude reaction mixture showed a single enol-lactone **11**α*E*. Chromatography on the Chromatotron with petroleum ether/ether gave the pure methyl (*E*)-(tetrahydro-3-methoxy-5-oxo-2-furanylidene)acetate **11**α*E* (0.51 g, 71%) as a colourless liquid: ir (thin film) ν_{max}: 3000, 2955, 1830, 1720, 1675, 1270, 1100, and 950 cm^{-1}; 100-MHz proton nmr ($CHCl_3$) δ: 2.66 (dd, J = 18 and 2 Hz, 1H), 2.88 (dd, J = 18 and 5 Hz, 1H), 3.43 (s, 3H, OCH_3), 3.76 (s, 3H, $COOCH_3$), 5.29 (ddd, J = 5, 2, and 0.9 Hz, 1H), and 5.84 (d, J = 0.9 Hz, 1H, :CHCOOMe); ms m/z: 186 (M^+, 5), 171 (1), 156 (34), 123 (49), 101 (24), 85 (26), 84 (22), 69 (92), and 58 (100). *Exact Mass* calculated for $C_8H_{10}O_5$: 186.0528; found: 186.0536.

Isomerization of **11**α*E to* **11**α*Z*

A solution of pure **11**α*E* (100 mg) in cyclohexane was irradiated for 2 h. Proton nmr and glc analyses of the reaction mixture showed that **11**α*E* and **11**α*Z* were in a 50:50 ratio. Upon chromatography with petroleum ether/ether, **11**α*E* (50 mg) was eluted first and the methyl (*Z*)-(tetrahydro-3-methoxy-5-oxo-2-furanylidene)acetate **11**α*Z* (50 mg) eluted second as a colourless oil; ir (thin film) ν_{max}: 3000, 2950, 1830, 1720, 1685, 1235, 1150, 1100, and 960 cm^{-1}; 60-MHz proton nmr ($CDCl_3$) δ: 2.60 (dd, J = 18 and 4 Hz, 1H), 3.02 (dd, J = 18 and 7 Hz, 1H) 3.44 (s, 3H, OCH_3), 3.76 (s, 3H, $COOCH_3$), 4.47 (ddd, J = 7, 4, and 2 Hz, 1H), 5.35 (d, J = 2 Hz, 1H, :CHCOOMe); ms m/z: 171 (M^+ −15 (CH_3, 1), 156 (28), 123 (64), 101 (23), 85 (32), 84 (22), 69 (97), and 58 (100).

Synthesis of exo*-3a-bromo-3a,4,7,7a-tetrahydro epoxyisobenzofuran-1,3-dione* **12**

This anhydride was prepared by a Diels–Alder cycloaddition reaction of bromomaleic anhydride with furan. A mixture of bromomaleic anhydride (3.00 g, 17.0 mmol) and furan (10.0 g, 147 mmol) was stirred, for 24 h at room temperature, in a tightly stoppered flask covered with aluminum foil. The excess furan was evaporated with a gentle stream of dry nitrogen until crystallization had started. The flask was stoppered and cooled for 2 days in a refrigerator. The brown product that precipitated upon cooling was filtered, and washed with ice-cold $CHCl_3/CCl_4$ (50:50) (3 × 10 mL), to yield 3.77 g (91%) of the *exo* adduct: *exo*-3a-bromo-3a,4,7,7a-tetrahydro-4,7 epoxyisobenzofuran-1,3-dione (12). Crystallization from $CHCl_3$/petroleum ether (50:50) gave a sample melting at 95–101°C (dec.) (lit. (28) mp 93–95°C); ir ($CDCl_3$) ν_{max}: 2960, 2878, 1868, 1790, 1248, 1108, 1020, 980, 950, 900, 860, 710, 690, and 650 cm^{-1}; proton nmr ($CDCl_3$) δ: 3.10 (s, 1H, H-7a), 5.43 (d, J = 1 Hz, 1H, H-7), 5.47 (d, J = 1 Hz, 1H, H-4), 6.72 (d, J = 1 Hz, 2H, H-5, 6).

Wittig reaction with exo*-3a-bromo-3a,4,7,7a-tetrahydro-4,7 epoxyisobenzofuran-1,3-dione* **12**

Using the general procedure, the reaction between **12** (1.00 g, 4.08 mmol) and phosphorane **1***a* (1.36 g, 4.07 mmol) was completed after 48 h at room temperature. Proton nmr analysis of the crude mixture revealed that the furan adduct **12**β*E* and the enol-lactone **13** were present in the ratio 45:55. Chromatography with petroleum ether/ether failed to separate the two enol-lactones, but succeeded in removing Ph_3P=O from the mixture. The two enol-lactones: methyl (*E*)-(2,5-dihydro-4-bromo-5-oxo-2-furanylidene)acetate, **13**, and methyl-(*E*)-3a-bromo-3-oxo-1,3,3aα,4α,7α,7aα-hexahydro-4,7 epoxyisobenzofuran-1-ylideneacetate), **12**β*E*, were isolated as white crystals in 96% yield (1.0 g). The **12**β*E* isomer was not purified further; however, 60-MHz proton nmr ($CDCl_3$) showed the following characteristic peaks: δ 3.72 (br s, 1H, H-7a), 3.81 (s, 3H, $COOCH_3$), 5.27 (d, J = 1 Hz, 1H, H-7), 5.32 (d, J = 1 Hz, 1H, H-4).

Received August, 27, 1988[1]

EDWARD DUTKIEWICZ and PIOTR SKOŁUDA. Can. J. Chem. **67**, 1411 (1989).

Studies on the specific adsorption of succinate and maleate anions at polycrystalline gold electrode from solutions at constant cationic strength are reported. The adsorption has been studied by differential capacity – potential measurements. The adsorption can be described by one-constant virial isotherm. The basic parameters of this isotherm are determined. Our experimental results are partly interpreted with the help of the results of the adsorption of dicarboxylic anions on the (210) and (311) faces of gold.

Key words: electrochemistry, adsorption, double layer, gold electrode, dicarboxylic ions.

Opérant à partir de solutions à force cationique constante, on a déterminé l'adsorption spécifique des anions succinate et maléate sur une électrode d'or polycristallin. On a étudié cette adsorption à l'aide de mesures de différentielles de capacité – potentiel. On peut décrire l'adsorption à l'aide d'une isotherme viriale à une constante. On a déterminé les paramètres fondamentaux de cette isotherme. On peut interpréter une partie des résultats à l'aide des résultats obtenus pour l'adsorption des anions dicarboxylates sur les faces (210) et (311) de l'or.

Mots clés : électrochimie, adsorption, couche double, électrode d'or, ions dicarboxylates.

[Traduit par la revue]

Introduction

The adsorption of dicarboxylic anions on single crystals of gold so far has been the object of two quantitative studies (1, 2). In ref. 1 the adsorption of succinate (Su) and maleate (Ma) anions was investigated on a (210) face of gold using the approximate method for determining the charge adsorbed specifically from solutions of mixed electrolytes of different symmetry at constant cationic strength (3). The adsorption was found to increase from Su to Ma anions and was interpreted in terms of the geometric structure and the electric properties of both anions. In ref. 2, thermodynamic analysis of the adsorption of dicarboxylic anions on a (311) face of gold, carried out using the same method of calculation, shows that the Su anions are more strongly adsorbed than Ma anions. These results were interpreted not only in terms of the geometric structure and electric properties of a given ion but also of the arrangement of metal atoms on the electrode surface. In this work, we decided to study the adsorption of succinate and maleate anions on the polycrystalline gold electrode.

Experimental

The solutions were prepared with triple distilled water; analar grade NaF, three times recrystallized and calcined; and organic salts, prepared from the corresponding acid by reacting with sodium carbonate of analar grade.

A classical three-electrode cell was used. The working electrode was a gold sphere made according to the method described by Clavilier and Nguyen Van Huong (4). Before each experiment the electrode was cleaned in deoxygenated supporting electrolyte NaF by a few cycles involving anodic oxidation of the surface and its subsequent reduction. This procedure was performed until the current–potential curves exhibited the known features already reported (5). Next the desired electrolyte was added to the supporting electrolyte solution at potentials corresponding to the so-called double layer region and the capacity–potential measurements were carried out.

The differential capacity – potential dependences $C(E)$ were obtained using the method described in ref. 6 from the alternating current – potential measurements. Measurements were carried out during linear potential sweep at 6 mV s^{-1} with superimposed alternating potential of 6 mV and frequency 24 Hz.

As a very small variation of the differential capacity with the frequency was observed, we assumed that the measured capacities correspond to the equilibrium ones.

All results are reported with respect to the apparent surface area. Measurements were made at 25 ± 2°C.

Results and discussion

The differential capacity of the electrical double layer at polycrystalline gold electrode was measured in mixed [xM Na_2Su + $(0.15 - 2x)M$ NaF] and [xM Na_2Ma + $(0.15 - 2x)M$ NaF] solutions where x denotes the concentration between 0 and 0.014 mol dm^{-3}. The capacity of the double layer is shown as a function of the potential for seven values of x in Figs. 1 and 2.

The form of the capacity curves as a function of potential and disodium succinate or disodium maleate concentration is very similar to that frequently observed in the case of halides adsorbed at the gold electrode/electrolyte solution interface (4, 7). Each curve has two maxima which increase with concentration of both anions. It is worth mentioning that although in the case of halides the peak of $C(E)$ curves in the negative potential range is smaller in comparison with the second peak, in the case of dicarboxylic anion the inverse order is observed. Besides, the values of double layer capacities for Ma anions are lower in comparison with the capacities obtained for Su anions for the same concentration.

On comparing present results with those obtained on single crystals of gold (1, 2), it should be mentioned that the $C(E)$ curves are different. The main difference is the lack of a peak in the positive potential range for single crystals.

It is interesting to note that for the same concentration the potential of capacity peaks for polycrystalline gold and for the (210) face are always less negative for Ma anions than for Su anions, while for the (311) face the inverse order is observed.

In both cases all curves merge together at negative potentials. This allows us to carry out reverse integration and further analysis. For polycrystalline gold electrode the capacity mini-

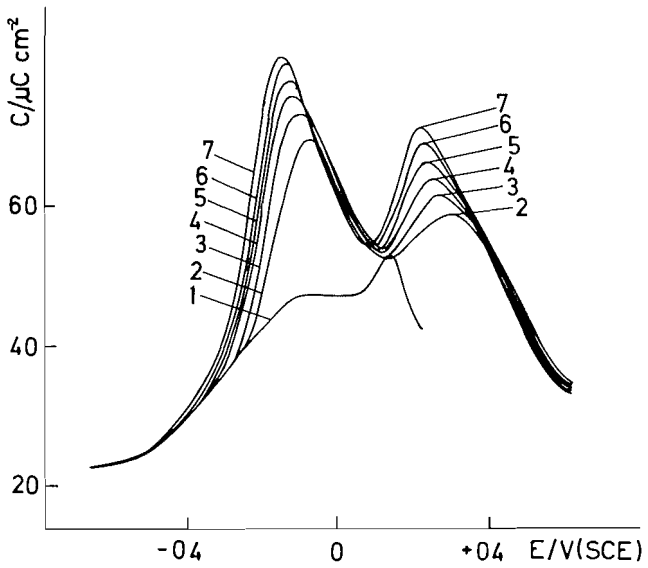

FIG. 1. Differential capacity of the electrical double layer of polycrystalline gold electrode in contact with solutions of xM Na_2Su + $(0.15 - 2x)M$ NaF; x = 0 (*1*); 0.002 (*2*); 0.0035 (*3*); 0.005 (*4*); 0.0075 (*5*); 0.01 (*6*); 0.014 (*7*).

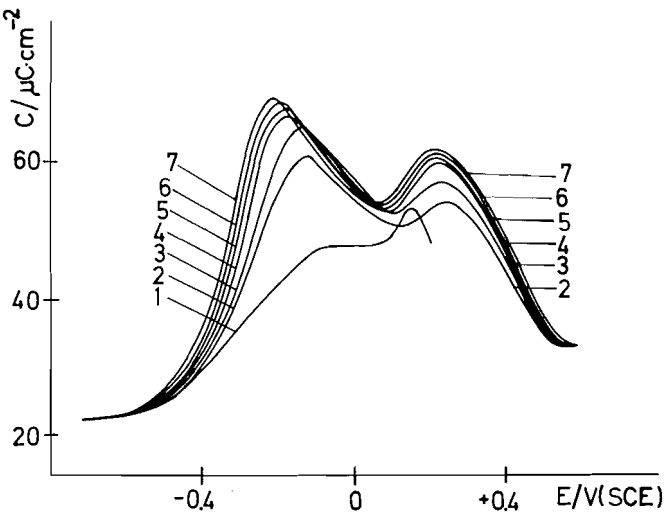

FIG. 2. Same as Fig. 1, but in xM Na_2Ma + $(0.15 - 2x)M$ NaF.

mum is not visible in 0.15 M NaF, the potential of zero charge (pzc) was calculated using the route proposed in ref. 8. For each system the charge–potential curves $\sigma(E)$ were determined by back-integration method from a more negative potentials at which coincidence of all curves take place. At these potentials the electrode charge is identical for all solutions and can be determined by integrating the NaF $C(E)$ curves from pzc. We integrated from charge $\sigma = -21$ μC cm^{-2} which corresponds to −0.689 V vs. SCE for Su anions and from the charge $\sigma = -20$ μC cm^{-2} which corresponds to −0.648 V vs. SCE for Ma anions respectively.

For solids at equilibrium and in reversible conditions, the reversible work required to form unit area of new surface by cleavage γ is equivalent to the surface tension. For our polycrystalline gold electrode relative values of $\Delta\gamma$ versus potential $\Delta\gamma(E)$ curves were obtained by back integration of the

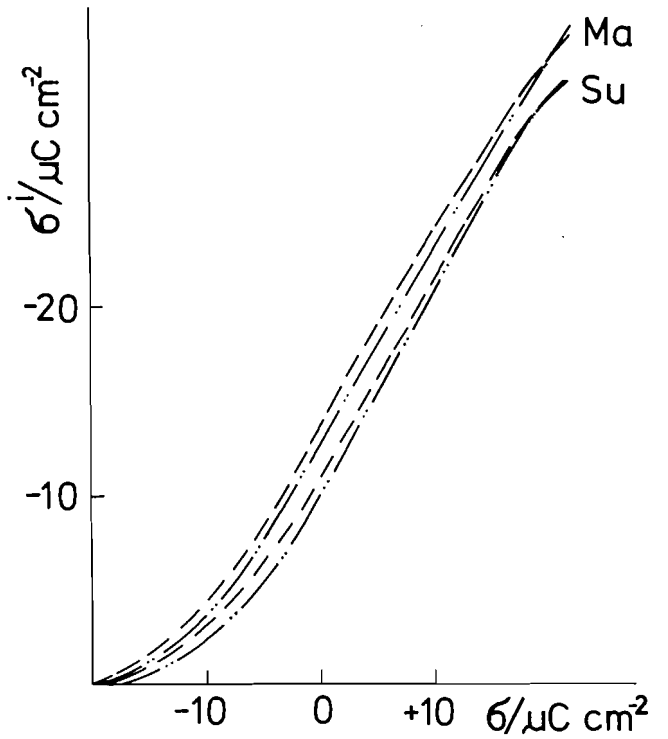

FIG. 3. Comparison of the charge due to specifically adsorbed succinate (Su) and maleate (Ma) anions as a function of electrode charge for x = 0.0075 (—··); 0.01 (---).

$\sigma(E)$ curves, the integration constants were $\gamma = 0$ at $E = -0.690$ V vs. SCE for Su anions and $\gamma = 0$ at $E = -0.648$ V vs. SCE for Ma anions, respectively.

The charge due to specific adsorption of ions (σ^i) has been determined using the method described in detail previously (3). Briefly, it concerns mixed electrolyte solutions of constant cationic strength but with variable concentrations of anions and of a total composition:

$$(m_T - 2m_{K_2B})[KA] + m_{K_2B}[K_2B]$$

where $m_T = m_{KA} + 2m_{K_2B}$ is a constant and represents the total formal molar concentration of salts 1:1 and 1:2, being simultaneously equal to the constant real cationic concentration. In the case of a very low concentration of salt K_2B and an excess of the other one, KA, the Gibbs equation simplifies and takes the approximate form:

$$[1] \quad -\frac{1}{RT}\left(\frac{\partial\gamma}{\partial \ln m_{K_2B}}\right)_{T,p,E^+} = \Gamma_B^i + \Gamma_B^d$$

where Γ_B^i and Γ_B^d are the surface excess of ion B in the inner and diffuse layer and E^+ is the potential of the electrode measured with respect to a reference electrode reversible to the cation in the working solution.

Equation [1] has the form of an equation describing the adsorption of ions from solutions of different ionic strength. Hence, by differentiating γ vs. ln x and using Graham's diffuse-layer theory (9) the surface excess of specifically adsorbed ions from solutions of constant cationic strength can be calculated. This method of calculation of σ^i is the same as that used recently (1, 2). The variation of σ^i as a function of σ for both anions at the two chosen concentration are plotted in Fig. 3.

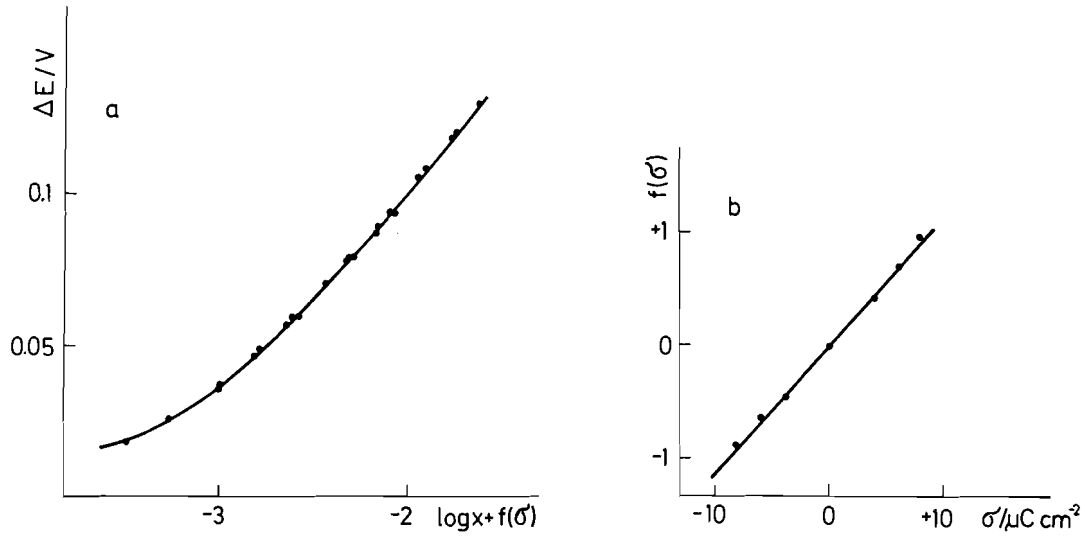

FIG. 4. (*a*) Shift of the electrode potential at constant charge plotted against log concentration of maleate anions. The curves at different values of charge are superimposed by shifting to the log x axis by an amount $f(\sigma)$. (*b*) Plots of $f(\sigma)$ as a function of σ obtained from the results in Fig. 4(*a*).

From Fig. 3 it can be concluded that the Ma anions are more strongly adsorbed when compared to the Su anions. A similar situation was found for the (210) gold electrode but here the difference in σ^i was larger (1). For the (311) gold electrode, however, Su anions are more strongly adsorbed than Ma anions (2).

Moreover, the $\sigma^i(\sigma)$ curves are similar to those observed for various systems of mixed electrolyte solutions, both at constant ionic (10–13) and constant cationic strength (1, 2). In other words, the inversion of variation of σ^i as a function of concentration of anions under investigation is observed and shown in Fig. 3. The appearance of the crossing point on the $\sigma^i(\sigma)$ curves was considered in more general terms in our recent paper (2). Our present results show that the crossing point also occurs for polycrystalline surface. In the studies where NaF was used as a supporting electrolyte, this phenomenon can be attributed to the adsorption of fluoride anions as suggested in refs. 1, 2, 10. The present studies also confirm the fact that the stronger the adsorbability of ions under consideration, the higher the value of charge at which the crossing point occurs (1, 2, 12). Thus for Ma anions which adsorb more strongly in comparison with Su anions, the inversion occurs at a charge (σ = 19 μC cm^{-2}) more positive than for Su anions (σ = 18 μC cm^{-2}).

Because of the anomalous variation of σ^i with ionic concentration, the thermodynamic analysis was only carried out for $\sigma < 10$ μC cm^{-1}, i.e. the electrode charge range concerned the first peak on $C(E)$ curves.

Our next step was to show the congruency in the charge of the adsorption isotherm. To solve this problem we have applied the test based on the relations given in ref. 14. This implies that if the adsorption isotherm is congruent with respect to the charge, then (14) the curves ($E_b - E$) versus logarithm of concentration at constant σ are segments of common adsorption isotherm with the amount adsorbed multiplied by the factor $f(\Delta G^0)$, where E_b and E are potential of the electrode measured in the base electrolyte and in the presence of ions under consideration versus the same reference electrode and ΔG^0 is the standard Gibbs energy of adsorption. For both succinate and maleate

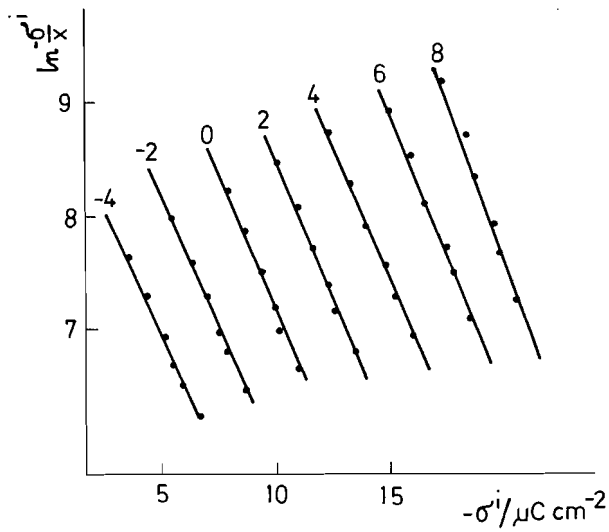

FIG. 5. Virial isotherm plots for succinate anions. The number near each line indicates the charge density of the polycrystalline gold electrode in μC cm^{-2}.

anions all segments fit a common curve. Each segment was superimposed by shifting along the abscissa by the quantity $f(\sigma) = \Delta \ln x = \Delta \ln \beta$, where β is the adsorption equilibrium constant. An example of this displacement of the individual segment parallel to the abscissa is given in Fig. 4(*a*) for Na_2Ma + NaF/gold system.

The linear dependence of $f(\sigma)$ vs. σ was found for both system under investigation. In Fig. 4(*b*) we report the quantity $f(\sigma)$ as a function of charge for the same system.

The linear relation found may confirm the constancy of $(\partial \ln \beta/\partial\sigma)$ within this range for these systems.

The adsorption process of Su and Ma anions agrees with the simple virial isotherm. This isotherm is plotted at constant charge in Figs. 5 and 6 for Su and Ma anions, respectively.

For Ma anions (Fig. 6) satisfactorily straight and parallel lines were obtained for the charge density range examined.

Na_2Ma/Au (210)	102.0	5.4	10
Na_2Su/Au (311)	110.0	7.8	14
Na_2Ma/Au (311)	103.0	5.6	11

[a]The accuracy in the determination of ΔG^0, B, and σ^i is of the order 10%, 10%, and 5%, respectively.

[b]The standard states are 1 mol dm^{-3} in solution and 1 ion cm^{-2} on the surface.

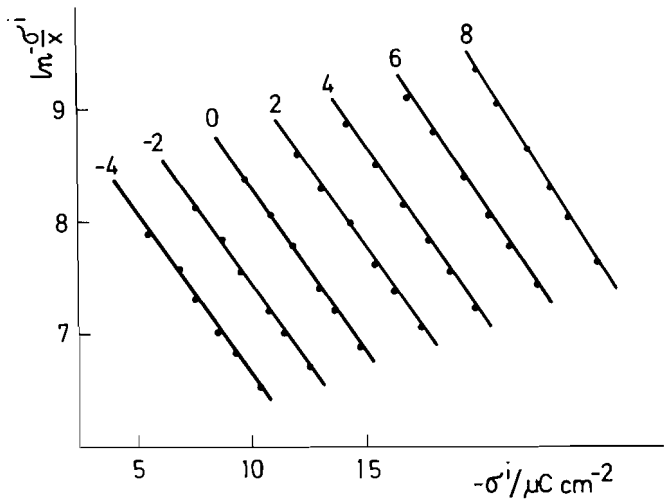

FIG. 6. Same as Fig. 5, but for maleate anions.

From Fig. 5 (Su anions) a linear dependence was also obtained but for the most positive value of $\sigma = 8\ \mu C\ cm^{-2}$ this line was not quite parallel. This line has a little higher slope and consequently higher value of the virial coefficient B at the most positive value of the electrode charge. However, the deviation from linearity is small and within the domain of uncertainty. The ΔG^0 values are found by extrapolating these plots. For uncharged ($\sigma = 0$) polycrystalline gold, the standard free energies of adsorption are reported in Table 1. The slope of these lines allows the B coefficient to be determined (Table 1).

The data on the adsorption of dicarboxylic anions on the polycrystalline gold electrode have been presented. To summarise, it is convenient to compare the adsorption of these anions on the polycrystalline gold with the adsorption on the single crystals of gold (1, 2). All adsorption parameters are tabulated in Table 1.

Generally, the adsorption process is a very complex problem both from the thermodynamic and the molecular point of view. The ionic adsorption from solution on the electrode depends upon the types of ions, the properties of the solvent and the electrode. The properties of the electrode refer both to the type of metal and the crystallographic orientation of its surface. However, only in the case of single crystals is it possible to study the adsorption dependence on the atomic geometry of the metal surface. For polycrystalline electrode, it is well known that some complications are encountered in the quantitative analysis of the $C(E)$ curves, which are connected with the crystallographic inhomogeneity of the surface. In other words, a different proportion of the crystal planes and the number of defects can vary from electrode to electrode, making comparisons between such $C(E)$ curves less rigorous. However, in spite of these difficulties, an attempt was made to describe the $C(E)$ curves of a polycrystalline electrode as an additive sum of the $C(E)$ curves of individual faces of a single crystals of silver in a diluted solution of NaF (15). The calculated curve approximately corresponds to the experimental one. This approach to polycrystalline surface is of course a simplification because the difference in the surface energy of the crystal faces may produce a preferential orientation, which is not accounted for in this model. In addition, the presence of some defects or grains at the surface should also be taken into account. In this paper we interpret the experimental results, to a limited extent, on the basis of our earlier papers concerning the adsorption of dicarboxylic ions on the (210) and (311) faces of gold (1, 2). Analysing the adsorption data of dicarboxylic anions on the single crystals of gold and on the polycrystalline gold, one can note that there is a greater similarity between the polycrystalline gold with the (210) face than with the (311) face. For polycrystalline and gold (210) electrodes σ^i due to specific adsorption of Ma anions is greater than that obtained for Su anions, whereas for the (311) face the reverse was observed. Besides, virial coefficients on polycrystalline and gold (210) electrodes are inversely proportional to σ^i, which was not the case on gold (311) electrode. These observations might lead to a conclusion that the behaviour of dicarboxylic anions on polycrystalline gold electrode is similar to that on gold (210) electrode. Therefore, the different case of adsorption of anions on polycrystalline gold is probably due to their different geometric and electric structure and, as has been suggested in ref. 1, different interaction in the electric field in the double layer. However, the existing differences, i.e. the higher value of σ^i for both anions under investigation in the case of polycrystalline gold in comparison with (210) face of gold, are probably due to the presence on the surface of polycrystalline gold of some faces which have a higher superficial atomic density than the (210) face e.g. (111), (100).

On the other hand, however, increase in strength of specific adsorption is larger for Su anions than for Ma anions. The fact that on the polycrystalline surface there is also a certain number of stepped faces e.g. (311), (211), may provide a partial explanation. According to our suggestion in ref. 2, the adsorption of Su anions can be located on the "step" atoms, which is not the case for Ma anions. Such "step" atoms exist on the stepped faces. This seems to result from a small deviation

For personal use only.

from parallelism of the lines at the most positive value of observed in Fig. 5. However, we cannot exclude the possibility that other adsorption sites may exist on the surface of the polycrystal, e.g. grain boundaries, defects on which Su anions may exclusively adsorbed.

DAVIDE ATZEI, PAOLA DEPLANO, EMANUELE F. TROGU, FRANCESCO BIGOLI, MARIA ANGELA PELLINGHELLI, ANTONIO SABATINI, and ALBERTO VACCA. Can. J. Chem. **67**, 1416 (1989).

Spectrophotometric studies on the reaction between diiodine and the title ligand in ratios ranging from 1:1 to 1:20 in $CHCl_3$ have shown the formation of a 1:1 charge-transfer complex. A general computer program has been used to refine the equilibrium constant and the extinction coefficients simultaneously. In the solid state a 1:2 (donor to acceptor) complex has been isolated and an X-ray structure analysis of the compound indicated that the crystals are monoclinic, space group $C2/c$ with a = 16.317(4), b = 13.912(3), c = 12.879(3) Å, β = 111.24(2)°, Z = 4.

The molecular structure shows that two sulphur-thioamide atoms of the ligand act as donor with respect to two diiodine molecules. The structural data of the organic molecule of the complex and those of the free molecule are very similar.

Key words: diiodine, thioamides, charge-transfer, structure, equilibrium-constants.

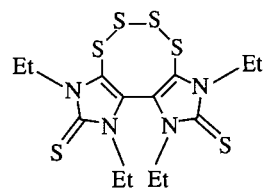
Des études spectrophotométriques sur la réaction entre le diiode et le ligand mentionné dans le titre effectuée dans le $CHCl_3$, à des rapports allant de 1:1 à 1:20, ont permis de démontrer qu'il y a formation d'un complexe de charge 1:1. On a utilisé un programme général d'ordinateur pour déterminer d'une façon simultanée la constante d'équilibre ainsi que les coefficients d'extinction. A l'état solide, on a isolé un complexe 1:2 (donneur à accepteur) et on a réalisé une étude par diffraction des rayons-X qui a permis de préciser que les cristaux du composé sont tricliniques, groupe d'espace $C2/c$ avec a = 16,317(4), b = 13,912(3) et c = 12,879(3) Å, β = 111,24(2)° et Z = 4.

La structure moléculaire démontre que deux atomes de soufre du thioamide du ligand agissent comme donneurs par rapport à deux molécules de diiode. Les données structurales de la molécule organique du complexe et celles de la molécule libre sont très semblables.

Mots clés : diiode, thioamides, transfert de charge, structure, constantes d'équilibre.

[Traduit par la revue]



Introduction

Formation of charge-transfer (c.t.) complexes between I_2 and thiones has long been recognized (1). Moreover, these c.t. complexes may be inert compounds or intermediates in redox reactions. The present studies are therefore of current interest in understanding various types of mechanisms including the reactions of heterocyclic antithyroid drugs with I_2 (2) and the formation of sulphur–iodine complexes showing superconducting ability (3).

We are investigating c.t. complex formations between I_2 and molecules containing thioamide groups, both free (4, 5) and coordinated to transition metals (6–9). In particular, in the case of the following ligands with two N—C=S groups: $R_2NC(S)SSC(S)NR_2$ (**I**) (4), $R_2NC(S)CH_2C(S)NR_2$ (**II**) (10), $R_2NC(S)C(S)NR_2$ (**III**) (5), we have observed different reaction paths depending on the ligand structure. In fact, in **I** and **II** the c.t. adduct formation is the initial step in the oxidation of the ligands to the known trithiolane and dithiolylium (11) cations, while in the dithiooxamide (**III**) case, the 1:1 and 1:2 (donor to acceptor) c.t. complexes are inert.

X-Ray data on a dithiooxamide·$2I_2$ crystal show that the ligand conformation (torsion angle S—C—C—S near 90°) is the most favourable for a minimum hindrance, and that there is no delocalization along the C—C skeleton between the two NC=S moieties.

Et_4todit =

We here report the behaviour of a new ligand: 4,5,6,7-tetrathiocino[1,2-*b*:3,4-*b'*]diimidazolyl-1,3,8,10-tetraethyl-2,9-dithione, recently synthesized by us (12), in which the two donor sites are forced in very distant positions (see below).

Experimental

Materials

The compound Et_4todit was prepared as previously described (12). Twice sublimed diiodine was purchased from Carlo Erba. $CHCl_3$ was Merck Reagent Grade and dried over 4 Å molecular sieves before use. The adduct Et_4todit·$2I_2$ was obtained as brown crystals, suitable for X-ray analysis, by slow concentration of a $CHCl_3$ solution of Et_4todit

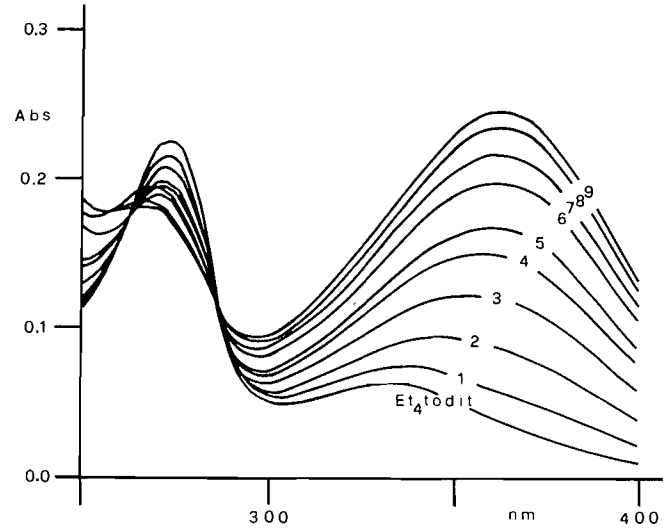

FIG. 2. Ultraviolet spectra at 298 K in 0.1 cm cell of $CHCl_3$ solutions containing constant amounts of Et_4todit (6.3×10^{-5} mol dm^{-3}) and variable diiodine concentrations in the ratios (I_2/Et_4todit): *1* = 2.0; *2* = 5.0; *3* = 10.0; *4* = 15.0; *5* = 19.0; *6* = 29.0; *7* = 38.5; *8* = 48.0; *9* = 58.0.

and I_2 in excess. *Anal.* calcd. for $C_{14}H_{20}N_4S_6I_4$: C 17.81, H 2.13, N 5.93; found: C 17.86, H 2.18, N 5.50.

The elemental analysis was performed by Istituto di Chimica Farmaceutica, Università di Cagliari.

Infrared data (KBr pellets; cm^{-1}) for [Et_4todit]·$2I_2$ are as follows: 2970w, 2922w, 2852w, 1513m, 1438s, 1395vs, 1330m, 1303mw, 1255vs, 1146vs, 1100w, 1080m, 1050w, 980sh, 960m, 797m, 770w, 748vw, 693w, 637vw, 608vw, 534vw, 435sh, 412m, 395sh, 361w.

The infrared spectrum was recorded by using a Perkin Elmer model 983 spectrophotometer.

Spectrophotometric measurements

The electronic spectra were measured at different temperatures in the range 15 to 35°C in $CHCl_3$ solutions with a Varian model Cary 2300 spectrophotometer, equipped with an automatic system of data acquisition.

A set of eight solutions containing a constant diiodine concentration (5×10^{-4} mol dm^{-3}) and variable Et_4todit concentrations (ranging from 1.2×10^{-4} to 3.7×10^{-3}) (see Fig. 1) was prepared and the spectra recorded between 400 and 550 nm using 1 cm silica cells. Two other sets of solutions were prepared with a constant concentration of Et_4todit and variable diiodine concentrations: (*a*) Et_4todit concentration is 6.3×10^{-5} mol dm^{-3} and diiodine in the range 1.3×10^{-4} to 3.6×10^{-3} mol dm^{-3} (nine solutions) and (*b*) Et_4todit is 2.5×10^{-4} and diiodine in the range 5×10^{-4} to 7.5×10^{-3} (seven solutions). Their spectra were measured in the range 240 to 400 nm in 1 mm silica cells. In Fig. 2 the spectra of the (*a*) solutions are reported. Spectrophotometer performance has been tested by measuring absorption spectra of solutions of potassium dichromate according to ref. 13.

Calculations

The experimental points used in the calculations have been taken from the recorded spectra at 10 nm intervals, the total number being always 90 readings for each system at each temperature. A general computer program, derived from "SUPERQUAD" (14), has been used to refine simultaneously equilibrium constants and molar extinction coefficients from the spectrophotometric measurements as described in ref. 5.

X-ray crystallography

Crystal data are as follows:

$C_{14}H_{20}N_4S_6I_4$ MW = 944.316

Monoclinic, space group $C2/c$, a = 16.317(4), b = 13.912(3), c = 12.879(3) Å, β = 111.24(2)° (by least-squares refinement from the θ values, in the range 10–16°, of 30 reflections accurately measured), U = 2725.0(1.2) Å^3, D_c = 2.302 Mg/m^{-3}, Z = 4, F(000) = 1760, Mo-Kα radiation (λ = 0.71073 Å), μ = 49.80 cm^{-1}. Crystal dimensions: 0.08 × 0.16 × 0.29 mm^3.

Data collection and processing

Data collection was made on an SIEMENS AED diffractometer with Nb-filtered Mo-Kα radiation using the θ–2θ scan mode. Of a total of 3097 measured reflections ($\pm h$, $+k$, $+l$), 1090 having $I \geq 3\sigma(I)$ were considered observed and employed in the analysis. The recorded intensities were corrected for Lorentz polarization factor, for absorption (maximum and minimum values 1.05590, 0.91928) and extinction (maximum and minimum values 1.07473, 0.91775) following Walker and Stuart (15).

Structure analysis and refinement

The solution of the structure was achieved by the heavy-atom method through Patterson and Fourier maps. The refinements were carried out by full-matrix least-squares cycles using initially isotropic and then anisotropic thermal parameters for all non-hydrogen atoms. The co-ordinates of the hydrogen atoms, except H(8) and H(10) of the C(7) methyl carbon, were clearly located from a ΔF map; at this stage a full-matrix least-squares cycle was computed including all the hydrogen atoms with individual isotropic thermal parameters and with H(8) and H(10) riding on their bonded carbon atom. In the final blocked full-matrix least squares only the non-hydrogen atoms were refined. The weighting scheme used in the final cycles was: $w = 0.6164[\sigma^2(F_o) + 0.001066F_o^2]^{-1}$. Final convergence was reached at an R value of 0.0371 (R' = 0.0425). The final electron density difference synthesis showed no peaks >0.89 and <−0.66 e Å^{-3}. Scattering factors and corrections for anomalous dispersion effects were those from ref. 16. Calculations were carried out on the CRAY X-MP/48 computer of Consorzio Interuniversitario Nord Est Calcolo Automatico (Casalecchio, Bologna) with financial support from the University of Parma, and on the GOULD-SEL 32/77 computer of the Centro di Studio per la Strutturistica Diffrattometrica del

Results and discussion

We have investigated the interaction between Et_4todit and I_2 in $CHCl_3$ via conventional ultraviolet–visible spectrophotometric techniques between 250 and 550 nm. The spectra obtained in the visible region for the solutions with the constant diiodine concentration and the variable donor concentration are reported in Fig. 1, where a single isosbestic point between complexed (blue-shifted band) and free I_2 is observed at 505 nm. These spectrophotometric data are interpreted quite satisfactorily by assuming that the 1:1 species is the only adduct formed.

The spectra recorded in the 250–400 nm range on solutions

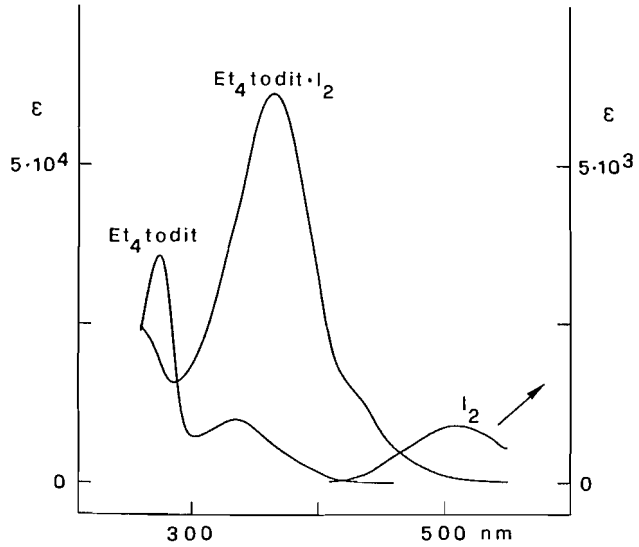

FIG. 3. Calculated uv–vis spectra of the 1:1 adduct between Et_4todit and diiodine at 298 K in $CHCl_3$ solution.

containing constant Et_4todit and variable I_2 concentrations are reported in Fig. 2, where the decrease of the donor band and the increase of the charge-transfer band of the adduct are evident.

By processing the experimental data (spectra *1–5*) up to a ligand to diiodine ratio of 1:20, reliable 1:1 equilibrium constants have been calculated, and the obtained values are reported in Table 3. The refined molar extinction coefficients of the adduct are plotted in Fig. 3 together with those determined for the free reactants. The agreement between calculated and experimental spectra was within the instrumental precision. The thermodynamic functions of the adduct formation ΔH^0 and ΔS^0, have been determined by least-square analysis of the Vant' Hoff plot of log K_1 vs. $1/T$. Such values (Table 3) are comparable with similar thione–diiodine complexes (5).

By processing spectra of solutions having donor to diiodine ratios larger than 1:20, it appears that further equilibria in addition to the 1:1 case occur. However, no satisfactory agreement in the explored wavenumber and temperature range has been obtained for any stoichiometry higher than 1:1. A check of the experimental conditions and instrumental accuracy confirmed the reliability of our data. However, we did not obtain a satisfactory simulation of the experimental spectra, not even by including a 1:2 species with formation constant K_2 differing from K_1 by the statistic factor ($K_2 = K_1/4$ in the case

of two equivalent binding sites and non-cooperativity). This hypothesis seemed to us reliable on the basis of the structural results on the isolated solid Et_4todit·$2I_2$.

These intriguing results may be tentatively explained by assuming that complexes of stoichiometries higher than 1:1 exist in solution at oversaturation or incipient precipitation conditions. Such hypothesis is supported by the fact that, once formed, the Et_4todit·$2I_2$ solid is very sparingly soluble in $CHCl_3$.

Crystal and molecular structure

The molecular structure of this neutral molecular compound belonging, as our previous bis(morpholinothiocarbonyl)—bis-(diiodine) (5), to the series with two S as heteroatoms in the donor and with two diiodine molecules as acceptors, is shown in Fig. 4, together with the atomic numbering scheme. In the molecule the two

moieties are related by a crystallographic two-fold axis. The structural data of the organic molecule in the present adduct and those of the uncomplexed molecule (12) are very similar. In fact, apart from the presence of a crystallographic two-fold axis, it is observed that the imidazoline ring is planar and that the arrangement of the two ethyl substituents lying perpendicular to the ring [C(1)—N(1)—C(4)—C(5) −83°, C(1)—N(2)—C(6)—C(7) 107°] is responsible for the mutual orientation of the two imidazoline rings in the molecule [N(1)—C(3)—C(3′)—N(1′) 76°]. Here a chair-conformation for the eight-membered ring is also observed [S(2)—S(3)—S(3′)—S(2′) −76°, C(2)—C(3)—C(3′)—C(2′) 66°, C(2)—S(2)—S(3)—S(3′) 89°, S(3)—S(2)—C(2)—C(3) −93°] and the value of 1.46(2) Å for C(3)—C(3′) bond distance is consistent with a single bond between two sp^2-hibridized carbon atoms. The S(2)—S(3) bond distance (2.077(5) Å) is related to the value of the S(3)—S(2)—C(2)—C(3) torsion angle (−93°), as observed in uncomplexed disulphides. The only significant differences are obviously the small lengthening of the S(1)—C(1) bond owing to the interaction with the diiodine molecule and the orientation of an ethyl group (C(1)—N(2)—C(6)—C(7) 107° and −87° in the adduct and in the uncomplexed molecule, respectively) due to the interactions involving C(6) and C(7). The C(1)—S(1)—I(1)—I(2) moiety is roughly planar (maximum deviation 0.020(15) Å for C(1) and roughly perpendicular to the imidazoline ring (I(1)—S(1)—C(1)—N(1) 106°, I(1)—S(1)—C(1)—N(2) −76°). In this fragment the values of d(S—I) and d(I—I) are correlated and in good agreement with those reported by Herbstein and Schwotzer in their work on the interactions of thiones with molecular diiodine (ref. 22 and references therein) and with those observed in bis(morpholinothiocarbonyl)—bis(diiodine) (5), while no appreciable variation is observed for d(C—S). The almost linear arrangement for S(1)—I(1)—I(2) (174.8(1)°) and a very small contribution of the sp^3 hybridization for S(1) [C(1)—S(1)—I(1) 95.3(5)°] were also observed in the above cited adducts. The I(2)...I(2) contact of 3.608(2) Å across the symmetry centre (Fig. 5) is important in forming chains running parallel to ***a***. This last value, significantly less than the van der Waals radii sum, is intermediate among those observed in compounds showing the I_2...I_2 arrangement [3.50 Å in crystalline I_2 (23), 3.472 Å in 2(ethylenethiourea)—3(I_2) (22), in the range 3.705(3)–3.931(3) Å in bis(morpholinothiocarbonyl)—bis(diiodine) (5), and 3.720(1) Å in dithia[3.3.1]-propellane·$2I_2$ (24)]. The interaction deviates from linearity more than in the mentioned compounds (I—I...I 148.9(1)°). The packing is determined by

Ultraviolet spectrum of domoic acid[1]

MICHAEL FALK, JOHN A. WALTER, AND PAUL W. WISEMAN

Atlantic Research Laboratory, National Research Council of Canada, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received March 17, 1989

MICHAEL FALK, JOHN A. WALTER, and PAUL W. WISEMAN. Can. J. Chem. **67**, 1421 (1989).

The ultraviolet spectrum of aqueous domoic acid solutions has an intense absorption band, whose λ_{max} shifts from 240.0 ± 0.3 nm at pH 1.3 to 244.7 ± 0.3 nm at pH 12.3. At the same time, its ε_{max} increases from 24 250 to 26 700 L mol^{-1} cm^{-1}. At pH 7 λ_{max} is 242.8 ± 0.3 nm and ε_{max} is 26 035 ± 200 L mol^{-1} cm^{-1}. Analysis of the variation of λ_{max} and ε_{max} with pH allowed us to estimate the values of these quantities for each of the five stages of protonation of domoic acid and to verify the p*K* values reported by Takemoto and Daigo.

Key words: ultraviolet spectrum, p*K* values, protonation, domoic acid.

MICHAEL FALK, JOHN A. WALTER et PAUL W. WISEMAN. Can. J. Chem. **67**, 1421 (1989).

Le spectre ultraviolet de solutions aqueuses d'acide domoïque possède une bande d'absorption intense, dont le λ_{max} se deplace de 240,0 ± 0,3 nm à un pH de 1,3 jusqu'à 244,7 ± 0,3 nm à un pH de 12,3. En même temps, son ε_{max} augmente de 24 250 jusqu'à 26 700 L mol^{-1} cm^{-1}. À un pH de 7, λ_{max} et ε_{max} sont respectivement de 242,8 ± 0,3 nm et 26 035 ± 200 L mol^{-1} cm^{-1}. L'analyse de la variation de λ_{max} et ε_{max} avec le pH nous a permis de les calculer pour les cinq étapes de la protonation de l'acide domoïque et aussi de verifier les valeurs de p*K* rapportées par Takemoto et Daigo.

Mots clés: spectre ultraviolet, valeurs de p*K*, protonation, acide domoïque.

[Traduit par la revue]

Introduction

Domoid acid is an important naturally occurring substance, with insecticidal, neuro-excitatory, and neurotoxic properties (1–4). It was first isolated from the benthic red seaweed *Chondria armata* ("domoi" in Japanese) and was named after it by Takemoto and Daigo (5, 6). Its molecular structure has been determined and confirmed by a total synthesis (7, 8). It is a tribasic imino acid, related structurally to glutamic acid and containing a proline ring; the stereochemistry of the doubly unsaturated side chain is indicated in Fig. 1.

Domoic acid has unexpectedly taken on a much increased importance since it was identified as the cause of a brief but serious outbreak of poisoning in November/December 1987 (9–12). The poisoning resulted from the consumption of cultured blue mussels (*Mytilus edulis*) originating from eastern Prince Edward Island (9–12). This recent event has prompted a renewed interest in the chemistry, biochemistry, and toxicology of domoic acid, with ongoing research in this laboratory and elsewhere (13–17).

Ultraviolet spectroscopy plays a prominent role in further studies of domoic acid, as it affords a fast and practical method of quantitation. By virtue of the occurrence of two conjugated double bonds in its side chain, domoic acid is a strong absorber of ultraviolet light. The maximum absorption has been reported to occur at wavelength λ_{max} = 242 nm with a molar absorptivity ε_{max} = 26 300 L mol^{-1} cm^{-1} or log ε_{max} = 4.42 (5, 6). Unfortunately, the pH value at which the ultraviolet spectra were measured in refs. 5 and 6 was not specified. At least some spectral changes may be expected to occur as a function of pH, as the degree of protonation of domoic acid varies.

In view of the importance of ultraviolet spectra in future analytical procedures involving domoic acid and its analogues, we have initiated the present study (1) to obtain an accurate value of ε_{max} at a known pH that can be recommended for analytical purposes and (2) to measure the dependence of λ_{max} and ε_{max} on pH and interpret any spectral changes in structural terms. In a following study, we intend to use the ultraviolet spectrum to determine the solubility of domoic acid in water and in organic solvents.

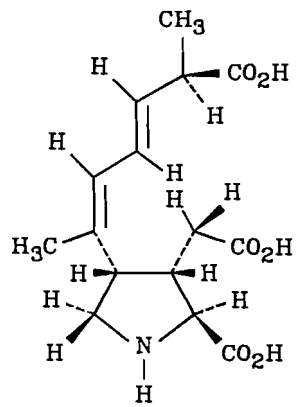

FIG. 1. Molecular structure of domoic acid in its neutral form.

Experimental

Material

High-purity domoic acid was isolated from an aqueous extract of toxic mussels by ion-exchange chromatography (13), followed by crystallization from deionized water as a dihydrate (shiny colorless needles), which dehydrated in vacuum at 50°C within 1 h to anhydrous domoic acid (dull white powder). Upon dehydration, three 10-mg batches of the crystals underwent weight loss of 10.47, 10.01, and 10.54%; calculated for dihydrate: 10.37. Anal. calcd. for $C_{15}H_{21}NO_6$: C 57.87, H 6.80, N 4.50; found: C 57.54, H 6.98, N 4.16%. The material was found to be chromatographically pure (HPLC with UV absorption detection at 200 nm) (13) and its infrared spectrum was identical with that of authentic domoic acid (15). The mass spectrum (14) as well as proton and carbon-13 NMR spectra (13) contained no major signals ascribable to impurities.

Ultraviolet spectroscopy

Spectra in the range of 375–190 nm were recorded on a GCA/-McPherson EU-700 series digital double-beam ratio-recording spectrophotometer. All measurements were made using the transmittance scale, which we found to be more accurate than the absorbance scale. To avoid tracking errors, the wavelength was scanned in small

increments and transmittance values were recorded manually with the wavelength stationary. The photometric accuracy of the spectrometer was checked by means of a set of calibrated rotating sectors, designed by R.N. Jones for the calibration of infrared spectrometers (18, 19), but found by us to be also perfectly suitable in the ultraviolet region. The digital transmittance reading of the spectrometer was found to be accurate within 0.001 in the transmittance range of 0.06–0.84. At transmittance values of about 0.4, typical of those measured in the present work, the relative error in transmittance is therefore 0.001/0.4 = 0.0025. Since transmittance of 0.4 corresponds to absorbance of $-\log(0.4) = 0.4$, relative errors in absorbance and in transmittance are equal, so that the relative error in molar absorptivity, resulting from photometric inaccuracy, is also 0.25%. The wavelength scale was calibrated with holmium oxide glass, using the holmium absorption line at 241.5 nm. The precision of the measurement of the peak wavelength of this line on our instrument was ±0.06 nm, so that our wavelength calibration error in this spectral region is mainly due to the uncertainty of the wavelength standard, ±0.2 nm (20). All the spectra were recorded at 21°C.

Optical path

The optical path of the sample cell (nominal length 1 cm) was measured by means of a travelling microscope and found to be 0.997 ± 0.005 cm. The relative error in molar absorptivity, resulting from the uncertainty of 0.005 cm in the optical path, is 0.5%.

Measurement of pH

The pH measurements were performed with a Fisher Accumet pH Meter model 610A, using Ingold catalogue no. 6030 pH electrodes. The pH scale was calibrated with Anachemia standard buffers. The pH was measured before and after each spectral measurement.

Measurement of ε_{max} (series A)

Two stock solutions of domoic acid in water were independently made up by gravimetry. Each stock solution was diluted to produce eight solutions of accurately known concentration in the vicinity of 1.6×10^{-5} M, which yielded minimum transmittance in the vicinity of 0.37; this value minimizes the relative error of the determination of maximum absorbance (21). The pH of these solutions was found to be 5.5. The wavelength was set at the absorbance maximum. Firstly, transmittance T_1 was measured with the domoic acid solution in the sample cell and pure water in the reference cell. Then transmittance T_2 was measured with both sample and reference cells filled with pure water. The peak absorbance, A, was calculated from $A = -\log(T) = -\log(T_1/T_2)$. The molar absorptivity, ε_{max}, was calculated from the Beer–Lambert law, $\varepsilon_{max} = A/b \cdot c$, where b is the optical path in cm, and c is the concentration of domoic acid in mol L^{-1}.

Variation of ε_{max} with pH (series B)

One stock solution of domoic acid was used; it was diluted 20-fold with water whose pH had been appropriately adjusted with HCl or NaOH. A series of 34 solutions were prepared by this procedure, spanning the pH scale from 1.28 to 12.35 and containing a known concentration of domoic acid near 1.6×10^{-5} M. The reference cell was filled with pure water. Transmittance T_1 was determined at the wavelength of peak maximum as in series A, but T_2 was taken to be the transmittance of the same domoic acid solution, with the same reference solution, at 275 nm, beyond the edge of domoic acid absorption.

Variation of λ_{max} with pH

The wavelength of maximum absorbance, λ_{max}, was determined manually by fitting a third-degree polynomial to 10 pairs of values of wavelength and transmittance spanning the peak. λ_{max} was taken as the wavelength at which the derivative of this polynomial was zero. The measurements were carried out on a series of 49 domoic acid solutions whose pH spanned the range from 1.34 to 12.29.

Results

Qualitative description of the spectrum

Figure 2 shows the ultraviolet absorptivity of domoic acid at pH 7. In the spectral region investigated, 375–190 nm, the absorption consists essentially of a single band, with high-wavelength onset at about 275 nm, maximum at 243 nm, and width at half-height of 33 nm. At low wavelengths, the absorption passes through a minimum at about 200 nm and begins to increase again as we reach the lower wavelength limit, 190 nm.

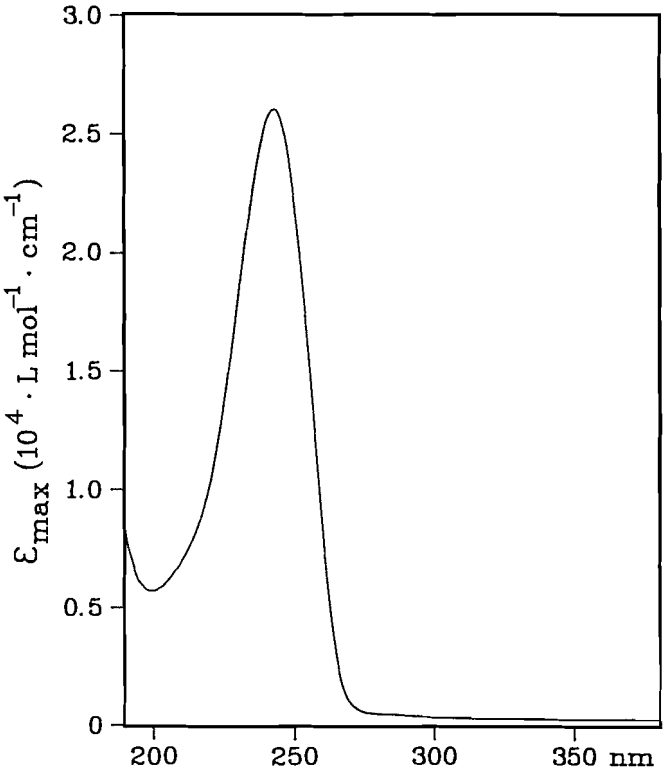

FIG. 2. Ultraviolet spectrum of aqueous domoic acid at pH 7.

ε_{max} at pH 5.5

Averaging the eight measurements on the two independently prepared solutions in series A yielded the values 25 359 and 25 990 L mol^{-1} cm^{-1} for ε_{max} at pH 5.5. Smoothing and interpolation of results from series B yielded the value 26 067 L mol^{-1} cm^{-1} at pH 5.5. Averaging these three values gave 25 805 L mol^{-1} cm^{-1}, which we adopted as the "best" value. This value of ε_{max} agrees with the value of 26 300 L mol^{-1} cm^{-1}, reported by Takemoto and Daigo for an unspecified pH (5, 6). Since the random error of our spectroscopic measurements was well below 1%, our standard deviation of 387 L mol^{-1} cm^{-1}, or 1.5%, probably arises from random errors in the concentration of domoic acid, resulting from errors in the weighings of the rather small (10 mg) domoic acid samples.

Variation of λ_{max} with pH

The λ_{max} results (Table 1,[2] Fig. 3) were obtained in one series of measurements. λ_{max} increases from about 240.0 nm at pH 1.3 to about 244.7 nm at pH 12.3. The λ_{max}/pH plot has a characteristic shape, with three plateau regions (first below pH 2, second between pH 6 and 9, third above pH 11) and relatively steep slope near pH 4 and 10. This behaviour of λ_{max} signifies that the UV absorption is appreciably shifted toward longer

[2]Tables 1, 2, 5, and 6 have been deposited. Copies may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

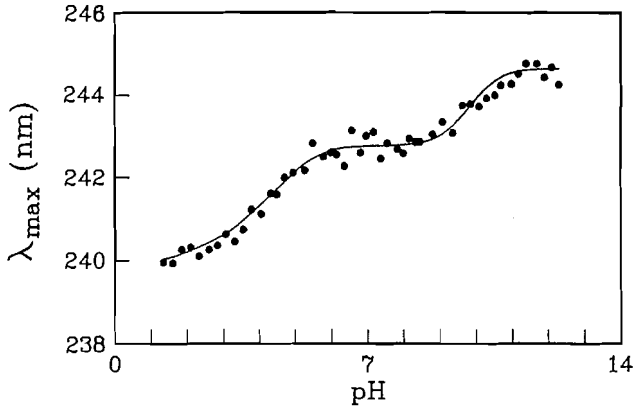

FIG. 3. Variation of λ_{max} with pH. The line was calculated from eqs. [2] and [3] using parameters A'–E' from Table 4 and pK values from ref. 5.

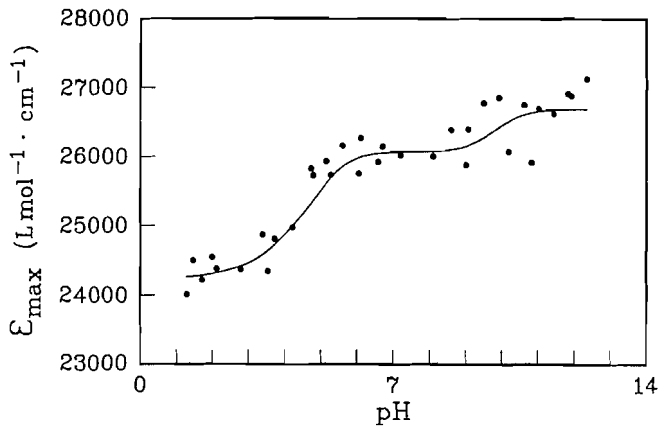

FIG. 4. Variation of ε_{max} with pH. The line as in Fig. 3.

wavelengths at each of the four stages of deprotonation of domoic acid.

A measure of the dispersion of our λ_{max} measurement can be obtained by averaging the 15 values of λ_{max} in the plateau region between pH 5.98 and 8.80. This yields the standard deviation $\sigma = 0.25$ nm. The absolute accuracy of our λ_{max} values ($\pm$ 0.2 nm) does not affect the treatment and discussion of our results. The total shift of λ_{max} with pH is 4.70 nm, which is about 19 times the dispersion of the data. This is good enough to verify the previously reported pK values for domoic acid, as will be done in a following section.

Variation of ε_{max} with pH

The results of series B are recorded in Table 2.[2] Smoothing and interpolation of these data yielded the value of 26 067 L mol^{-1} cm^{-1} for ε_{max} at pH 5.5. Since the best value of this quantity is 25 808 L mol^{-1} cm^{-1}, obtained by averaging the results of series A and B as described above, we have scaled the results from series B by the factor 25 808/26 067 = 0.98995 to obtain the final data recorded in Table 2[2] and plotted in Fig. 4.

ε_{max} varies from 24 250 at pH 1.3 to 26 700 at pH 12.3, for a total shift of 2450 L mol^{-1} cm^{-1}. Allowing for the experimental scatter of about 200 L mol^{-1} cm^{-1}, ε_{max} varies with pH similarly to λ_{max}, continuously increasing and exhibiting three plateau regions. The latter are somewhat less distinct than for λ_{max}, due to the greater experimental scatter. Apparently intensity increase accompanies the blue shift of the absorption band through the four stages of deprotonation. Table 3 lists the

TABLE 3. Values of ε_{max} recommended for analytical purposes

pH	ε_{max} (L mol^{-1} cm^{-1})
2.00	(2.43 ± 0.04) × 10^4
7.00	(2.61 ± 0.04) × 10^4
11.00	(2.70 ± 0.04) × 10^4

smoothed and interpolated values of ε_{max} at pH 2, 7, and 11, recommended for analytical purposes, with estimated standard errors.

Analysis of pH-dependence

Protonation states of domoic acid

Domoic acid contains one imino group, >NH, and three carboxylate groups, —COO$^-$. All of these groups are capable of protonation, so that domoic acid in an aqueous medium must occur as a mixture of five distinct protonation states, A–E, with proportions varying with the pH.

A is the fully protonated cation. It occurs in only one form:

$>NH_2^+$ —COOH —COOH —COOH

B is the neutral molecule. It can undergo site isomerism, alternating between one uncharged form and three zwitterion forms:

$B1$:	>NH	—COOH	—COOH	—COOH
$B2$:	$>NH_2^+$	—COOH	—COOH	—COO$^-$
$B3$:	$>NH_2^+$	—COOH	—COO$^-$	—COOH
$B4$:	$>NH_2^+$	—COO$^-$	—COOH	—COOH

C is the singly charged anion. It can occur in six isomeric forms, corresponding to the six possible locations of the two protons on four distinct sites:

$C1$:	>NH	—COOH	—COOH	—COO$^-$
$C2$:	>NH	—COOH	—COO$^-$	—COOH
$C3$:	>NH	—COO$^-$	—COOH	—COOH
$C4$:	$>NH_2^+$	—COOH	—COO$^-$	—COO$^-$
$C5$:	$>NH_2^+$	—COO$^-$	—COOH	—COO$^-$
$C6$:	$>NH_2^+$	—COO$^-$	—COO$^-$	—COOH

D is the doubly charged anion, occurring in four isomeric forms:

$D1$:	>NH	—COOH	—COO$^-$	—COO$^-$
$D2$:	$>NH_2^+$	—COO$^-$	—COO$^-$	—COOH
$D3$:	$>NH_2^+$	—COO$^-$	—COOH	—COO$^-$
$D4$:	$>NH_2^+$	—COOH	—COO$^-$	—COO$^-$

E is the triply charged anion, occurring in a unique form:

>NH —COO$^-$ —COO$^-$ —COO$^-$

Relation between mole fractions and dissociation constants

We shall, in the following, neglect the complications due to site isomerism and assume that activity coefficients for species A–E are equal. The relative proportions of species A–E are the result of four consecutive equilibria, governed by the four macroscopic dissociation constants, K_1 to K_4:

[1a] $A \rightleftharpoons H^+ + B$ $K_1 = h \cdot b/a$
[1b] $B \rightleftharpoons H^+ + C$ $K_2 = h \cdot c/b$
[1c] $C \rightleftharpoons H^+ + D$ $K_3 = h \cdot d/c$
[1d] $D \rightleftharpoons H^+ + E$ $K_4 = h \cdot e/d$

In the above equations, a, b, c, d, e are the fractions of domoic acid molecules in protonation states A, B, C, D, E, respectively,

For personal use only.

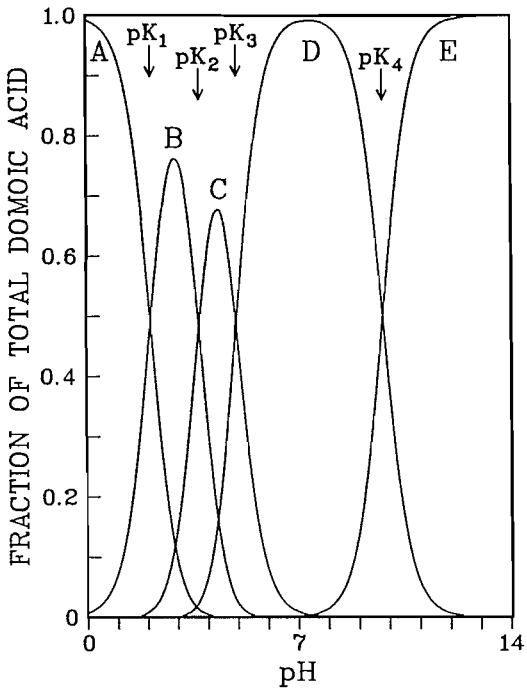

Fig. 5. Protonation stages of domoic acid.

and h stands for the activity of hydrogen ions. The dissociation constants are usually expressed in the logarithmic form, $-\log K_1 = pK_1$, etc.

Equations [1*a*]–[1*d*] can be transformed to yield

$$[2a] \quad a = 1/[F]$$
$$[2b] \quad b = K_1/([F]\cdot h)$$
$$[2c] \quad c = K_1\cdot K_2/([F]\cdot h^2)$$
$$[2d] \quad d = K_1\cdot K_2\cdot K_3/([F]\cdot h^3)$$
$$[2e] \quad e = K_1\cdot K_2\cdot K_3\cdot K_4/([F]\cdot h^4)$$

where $F = 1 + (K_1/h) + (K_1\cdot K_2/h^2) + (K_1\cdot K_2\cdot K_3/h^3) + (K_1\cdot K_2\cdot K_3\cdot K_4/h^4)$.

Equations [2*a*]–[2*e*] relate the fractions a–e of domoic acid molecules in protonation states A–E to the values of dissociation constants K_1–K_4 at any pH. Using the values of the four pK's reported by Takemoto and Daigo (5), $pK_1 = 2.10$, $pK_2 = 3.72$, $pK_3 = 4.97$, $pK_4 = 9.82$, we obtain the fractions a–e shown in Fig. 5.

Model for the variation of spectrum with pH

We will assume that each of the five protonation species has a characteristic value of λ_{max} or ε_{max} (or any other spectral quantity in general), namely A', B', C', D', and E', independent of pH, and that the observed value of that spectral quantity at any pH, S', is the sum of the contributions from the five species:

$$[3] \quad S' = a\cdot A' + b\cdot B' + c\cdot C' + d\cdot D' + e\cdot E'$$

where the five fractions, a–e, can be expressed in terms of the four dissociation constants, K_1–K_4, via eqs. [2*a*]–[2*e*]. Thus, eq. [3] relates the observed λ_{max} or ε_{max} at any pH to the values of nine variable parameters K_1, K_2, K_3, K_4, A', B', C', D', E'.

It is possible to determine the values of these parameters by optimizing the fit of eq. [3] to a set of spectroscopic data as a function of pH. The limit of refinement that can be achieved in the optimization is imposed by the precision of the data.

TABLE 4. Values of initial parameters A'–E' used in the optimization

	A'	B'	C'	D'	E'
λ_{max} data	239.94	240.50	241.60	242.77	244.66
ε_{max} data	24239	24374	24974	26072	26699

Initial values of the variable parameters in the optimization

The initial values of the four pK's were those reported by Takemoto and Daigo (5). The initial values of A'–E' were estimated by assuming that the above pK values are correct, so that the mole fractions of the five protonation species of domoic acid are those plotted in Fig. 5. This plot implies that state A dominates at low pH, state B near pH 2.9, state C near pH 4.4, state D near 7.3, and state E at high pH. The values of constants A'–E' were accordingly estimated from the smoothed values of λ_{max} or ε_{max} at the appropriate pH and are recorded in Table 4.

The optimization procedure

The optimization was carried out on a PC-AT minicomputer using a program for the optimization of up to eight variables adapted from the program described in ref. 22. The program was written in Pascal and uses a modified Simplex method. In each optimization run, some variable parameters were constrained to their initial values and one to eight parameters were optimized. The results of typical optimization runs are shown in Table 5[2] for the λ_{max} data and in Table 6[2] for the ε_{max} data.

Optimization results

The optimization of λ_{max}/pH data leads to sets of values of pK parameters recorded in the different rows of Table 5[2]. It is immediately apparent that the initial values of the nine parameters (first row) are already consistent with the experimental data. The initial value of SSR, the sum of squares of the residuals (i.e., of the differences between λ_{max} observed and λ_{max} calculated from eq. [4]) was 2.119. This corresponds to root-mean-square residual of $(2.119/49)^{1/2} = 0.208$ nm, which is of the order of the experimental scatter of λ_{max} data. Optimization of the values of pK's and of A' through E', carried out in various combinations, produced only a very slight improvement of SSR, from 2.119 to 1.798. The optimization brought about changes in the pK values no greater than 0.32 for K_1, 0.30 for K_2, 0.12 for pK_3, and 0.12 for pK_4. We conclude that the four pK values from ref. 5, $pK_1 = 2.10$, $pK_2 = 3.72$, $pK_3 = 4.97$, and $pK_4 = 9.82$, are roughly correct, the experimental uncertainty being of the order of 0.3. It is not possible to pinpoint the pK values any closer on the basis of the λ_{max}/pH data. Nevertheless, our results do represent an independent rough check of the pK values of Takemoto and Daigo. As a consequence of the pK values from ref. 5 being nearly correct, the plot of Fig. 5 must represent fairly closely the distribution of protonation species of domoic acid in aqueous solution as a function of pH.

Attempts to optimize the pK values on the basis of the ε_{max}/pH data are summarized in Table 6.[2] As before, the initial values of the nine parameters are already consistent with the experimental data. The initial value of SSR is 2.82×10^6, which corresponds to root-mean-square residual of $(2.82 \times 10^6/34)^{1/2} = 288$ L mol^{-1} cm^{-1}, which is of the order of the experimental scatter of the ε_{max} data. Optimization brought about only a minor improvement of SSR, from 2.82×10^6 to 2.28×10^6. The optimization brought about changes in the pK values no greater than 0.35 for pK_1, 0.56 for pK_2, 0.72 for pK_3,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

and 0.57 for pK_4. Therefore, we conclude, as we did from the λ_{max} data, that the pK values from ref. 5 are correct, but because of the greater experimental scatter of the ε_{max} values, the margin of uncertainty is greater.

The initial values of constants $A'-E'$ for λ_{max} and ε_{max} changed only slightly upon optimization. We conclude that the initial values are already close to the true values of these spectral parameters.

Acknowledgements

Metal ion – biomolecule interactions. Part 14.[1] Methylmercury and hydrogen ion catalysis of C(2)-H isotopic exchange in 1-methylhistidine

ERWIN BUNCEL, HELEN A. JOLY, AND DIANE C. YEE
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received December 1, 1988

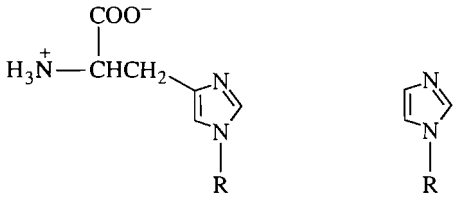
ERWIN BUNCEL, HELEN A. JOLY, and DIANE C. YEE. Can. J. Chem. **67**, 1426 (1989).

The rate constants for detritiation from the C(2) position of 1-methyl[2-^{3}H]histidine have been determined in a series of aqueous buffers at 85°C. The resulting sigmoidal rate–pH profile was indicative of a mechanism involving hydroxide ion attack on the N(3)-protonated (**4**) and the amino-protonated (**5**) forms of 1-methylhistidine, and dissection of the kinetic data allowed the extraction of the second-order rate constants for the two pathways, k and k'. The unusually large value of k' for a species not protonated at N(3) of the imidazole ring suggested the involvement of a kinetically equivalent zwitterionic form of the substrate (**7**). Comparison of the rate constant k with values determined previously for closely related substrates, such as histidine, 1-methylimidazole, and imidazole, led to the use of FMO theory to explain the effect of the various structural changes, e.g., the effect of methylation and a positively charged side chain on k and k'. The addition of $MeHgNO_3$ resulted in a decrease in the pseudo-first-order rate constant for detritiation. The rate retardation was discussed in terms of two mechanisms (Schemes 2 and 3). Analysis of the data in terms of the various metal-ion-coordinated species present under the experimental conditions showed that the reactivity of the protonated substrate greatly exceeds that of the metal-coordinated species. The difference in the catalytic ability of H^+ vs. $MeHg^+$ is discussed in terms of the extent of positive charge developed on the ligating heteroatom in the ylide (carbenoid) reaction intermediate.

Key words: methylmercury, 1-methylhistidine, isotopic exchange, proton transfer, metal ion catalysis.

ERWIN BUNCEL, HELEN A. JOLY et DIANE C. YEE. Can. J. Chem. **67**, 1426 (1989).

On a déterminé les constantes de vitesse de la détritiation à partir de la position C(2) de la méthyl-1[^{3}H-2]-histidine dans une série de solutions tampons à 85°C. Le profil sigmoidal de la courbe de vitesse en fonction du pH obtenue, témoigne l'existence d'un mécanisme faisant intervenir l'attaque de l'ion hydroxyle sur les formes protonées en N(3) (**4**) et amino-protonée (**5**) de la méthyl-1-histidine. Le dépouillement des données cinétiques permet d'extraire les constantes de vitesse d'ordre deux des deux sites d'attaque, k et k'. La grande valeur inhabituelle de k' pour les espèces non protonées au niveau N(3) du cycle imidazole suggèrent l'intervention d'une forme zwitterionique cinétiquement équivalente du substrat (**7**). La comparaison de la constante de vitesse k avec les valeurs déterminées antérieurement pour des substrats très apparentés comme l'histidine, le méthyl-1-imidazole et l'imidazole, conduit à utiliser la théorie des OML pour expliquer l'effet des divers changements structuraux, par exemple, l'effet d'une méthylation et d'une chaîne latérale chargée positivement sur les valeurs de k et de k'. L'addition du $MeHgNO_3$ conduit à une diminution de la constante de vitesse de pseudo ordre un de la détritiation. On discute de la diminution de la vitesse en fonction de deux mécanismes (schémas 2 et 3). L'analyse des données en fonction des diverses espèces ion métallique-coordonné présentes dans les conditions expérimentales décrites, montre que la réactivité du substrat protoné excède de beaucoup celle des espèces métalliques coordonnées. On discute de la différence de pouvoir catalytique de H^+ versus $MeHg^+$ en fonction du taux de charge positive développée au niveau de l'hétéroatome jouant le rôle de ligand dans l'intermédiaire (carbénoide) de réaction de l'ylide.



Mots clés : mercure-méthyle, méthyl-1-histidine, échange isotopique, transfert de proton, catalyse d'ion métallique.

Histidine (**1**) is one of the most important amino acids found in biological systems and is present at the active site of enzyme systems such as ribonuclease and a series of serine proteases including α-chymotrypsin, trypsin, and subtilisin (1). In addition, histidine is an essential constituent of several metalloproteins including haemoglobin, myoglobin, and histidine deaminase, presumably because of the availability of the electron pair on N(3) of the heteroaromatic ring to bind transition-metal cations (2).

In imidazole (**2**), the heteroaromatic component of histidine, the C(2)-H flanked by the two heteroatoms, is relatively labile and upon prolonged heating in D_2O or tritiated water will undergo isotopic exchange (3). This property has proven useful in probing biological systems and was used to identify the metal-coordinated histidine residues of the enzymes β-lactamase II and superoxide dismutase (4, 5).

The optimal use of labelled biochemical reactants for elucidating accurate mechanistic information about an enzymatic process requires that one clearly understands the factors that affect tritium and deuterium loss, such as variation in pH,

1 R = H **2** R = H
1*a* R = Me **2***a* R = Me

temperature, and the presence of various metal ions. In one of the earliest reported studies concerning the effect of metal ions on isotopic hydrogen exchange in heterocyclic compounds, with 1-methyltetrazole as the substrate, Olofson *et al.* (6) found that complexation with the transition metal ions Cu^{2+} and Zn^{2+} enhanced the rate of C(5)-H exchange considerably. Based on a mechanism involving hydroxide ion attack on a 1:1 M^{n+}–1-methyltetrazole complex, it was found that metal complexation was 6 to 403 times less effective for exchange than the path involving the conjugate acid, but 5 to 294 times faster than the path involving the neutral substrate.

Jones and co-workers (7) studied the effect of metal ions on the rate of detritiation of [2-^{3}H]imidazole at 85°C and pH 5.70

[1]Part 13: ref. 26.

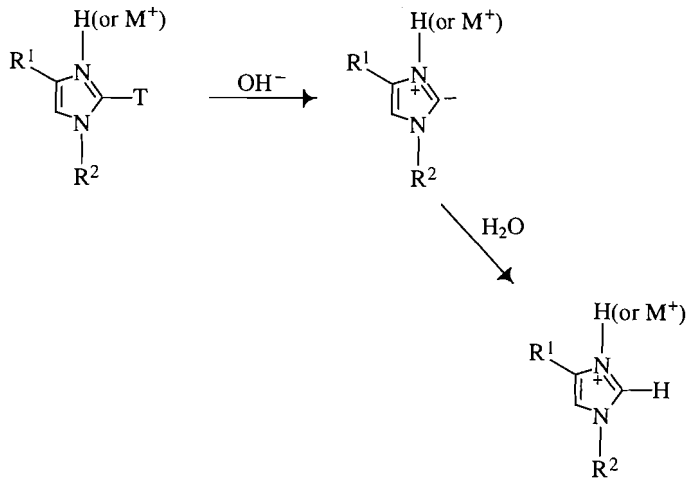
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

and found without exception that addition of metal ions caused rate retardation. The effectiveness of the metal ion increases in the order $Cu^{2+} > Zn^{2+} \approx Ni^{2+} \gg MeHg^{+}$. The results suggested that formation of metal complexes reduced the concentration of the active kinetic species, namely the conjugate acid of imidazole.

Martin and co-workers (8) extended the study of the effect of metal ions on reactivity of the isotopic hydrogen exchange reaction to 1-methylhistidine (**1***a*). The rate constant for deuteration of the 2:1 complex of 1-methylhistidine and Pd^{2+} was measured in D_2O at 61°C at various pH values ranging from 11.3 to 12.0 using NMR spectroscopy. The results showed that hydroxide ion attack occurs $10^{4.8}$ and $10^{5.4}$ times faster for the amino-protonated form (**1***a*) and the 1-methylhistidine species protonated both on N(3) of the imidazole group and the amino group of the side chain, than for the Pd^{2+} complex. Comparison of the rate constants in this fashion gives a quantitative measure of the effect of metal ions on reactivity.

A significant decrease in the detritiation rate constants observed on addition of copper ions to an aqueous solution of 1-methyl[8-^{3}H]guanosine (9) implicates N(7) of 1-methyl-[8-^{3}H]guanosine as the site of metal complex formation, since N(1) and N(9) positions are blocked by a methyl group and a ribose group, respectively. Metal ions added to the reaction mixture compete with H^+ for N(7) of the methylated purine derivatives and, as a result, the rate of isotopic exchange in the presence of metal ion depends upon the rate of hydroxide ion attack on both the protonated substrate (BH^+) and the metal-complexed (BM^{n+}) species. The ratio of the second-order rate constant for hydroxide ion attack for BH^+ to that for BM^{n+}, k and k_{Cu} respectively, was found to be $10^{2.5}$, indicating that Cu^{2+} was not as effective as the proton in accelerating the rate of detritiation. However, a comparison of k_{Cu} to k_n, the second-order rate constant for OH^- attack on neutral 1-methyl[8-^{3}H]guanosine (9), shows that Cu^{2+} coordinated to N(7) does in fact catalyze the reaction ($k_{Cu}/k_n = 10^{6.7}$). The ratio k_m/k_n has been called the metal-activating factor (10).

In a study of the rates of detritiation of 1-methyl[8-^{3}H]inosine in the presence of Cu^{2+}, Zn^{2+}, and Ag^+ ions, the metal ions were found to influence the rate of isotopic exchange in very different ways (10). For example, Zn^{2+} had virtually no effect on the rate of detritiation while Ag^+ was found to suppress the rate of exchange to an even greater degree than Cu^{2+}. This observation is consistent with the ability of the metal ion to coordinate with the N(7) centre. Ag^+, as a soft metal ion, binds more strongly to nitrogen centres than do the two borderline metal ions, Zn^{2+} and Cu^{2+}. Since Ag^+ binds most strongly, the complex will be in higher concentration than the complexes of Zn^{2+} and Cu^{2+}, and thus Ag^+ causes greatest rate retardation.



A similar treatment (9) to that used for 1-methylguanosine results in a metal-activating factor (k_m/k_n) of 10^7 for Cu^{2+} and 10^5 for Ag^+, and a proton activation factor (k/k_m) of 10^3 and $10^{4.7}$ for Cu^{2+} and Ag^+, respectively. From all the metal ion studies carried out so far, it can be concluded that metal ions significantly retard the rate of C(2)-H exchange with respect to the N(3)-protonated species (7, 8). Thus, metal ions are not as effective catalysts as is the proton in promoting C(2)-H exchange.

In the present study, the 1-methylhistidine – methylmercury nitrate system has been chosen on the basis of several considerations. First, methylmercury(II) is known to form relatively strong complexes with N-containing ligands, compared with transition-metal salts of Zn^{2+}, Cu^{2+}, etc. (2, 11). Secondly, the preferred coordination number of $MeHg^+$ is one, unlike transition-metal ions such as Cu^{2+}, which coordinate 1–6 ligands depending upon the experimental conditions. Thirdly, the $MeHg^+$ hydroxides that form are soluble at relatively high pH, allowing rate constants to be measured at higher pH values (11). It is worth noting, however, that hydroxide ion is a very effective competitor for $MeHg^+$ and a delicate balance exists between the pH value that is most appropriate to monitor a change in the magnitude of the rate constant and the pH value that minimizes the competition of hydroxide ion and 1-methylhistidine for $MeHg^+$.

The similarity in structure between 1-methylhistidine (**1***a*) and histidine (**1**) makes it an attractive substrate to study. Blocking N(1) with a methyl group reduces the potential $MeHg^+$ binding sites from 4 to 3, thereby significantly reducing the complexity of the kinetic analysis.

The first section of the paper describes the kinetic analysis of the data collected for 1-methyl[2-^{3}H]histidine (**1***a*) in aqueous buffers at 85°C, so as to obtain a rate–pH profile. With that necessary information, results were obtained for the detritiation of 1-methyl[2-^{3}H]histidine in a series of $MeHgNO_3$ solutions varying in concentration from 0 to 0.007 M.

The observed decrease in pseudo-first-order rate constant with increase in metal-ion concentration can be accounted for by mechanisms involving rate-determining triton abstraction from C(2) of N(3)-protonated or metal-coordinated species to give an ylide (carbenoid) intermediate, which is then rapidly protonated (12). The detailed discussion involves consideration of ionized states in the side chain (R^1) and the relative effectiveness of H^+ vs. M^+ in exchange (see Schemes 2 and 3).

Experimental

Preparation of 1-methyl-L-histidine

1-Methyl-L-histidine dihydrochloride was prepared by the three-step sequence outlined by Noordam *et al.* (13*a*). The ^{1}H NMR spectrum in D_2O compared well to that previously reported (δ ppm: 3.38 (2H, 8-peak multiplet, CH_2), 3.89 (3H, singlet, NMe), 4.24 (1H, triplet, NH_2CH), 7.41 (1H, singlet, CCHN), 8.66 (1H, singlet, NCHN). The IR spectrum showed an absorption at 1709 cm^{-1} characteristic of a carboxylic acid. The presence of the ammonium salt is evidenced by several absorption bands: a medium broad band at 3400 cm^{-1}, a group of strong bands between 1575 cm^{-1} and 1600 cm^{-1}, and one strong absorption found at 1495 cm^{-1}. Finally, ascending paper chromatography was performed on the dihydrochloride product against L-histidine as a standard. The two compounds were spotted (5 μg) on cellulose paper and developed in a chromatography tank saturated with 0.1 M α-picoline for 110 min. The dried paper was sprayed with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

ninhydrin and heated in an oven for 15 min at which time purple spots pertaining to each of the two compounds appeared. The 1-methyl-L-histidine dihydrochloride (R_f = 0.868) was found to migrate further than the L-histidine (R_f = 0.814) consistent with that previously reported (13*b*).

1-Methyl-L-histidine dihydrochloride was desalted using cation exchange chromatography. The 1-methyl-L-histidine dihydrochloride (0.425 g) dissolved in 1.5 mL of 2 N HCl was loaded onto a Dowex 50 × 2–400 (200–400 mesh) column (1 cm diameter × 13 cm high). Deionized distilled water was eluted through the column to remove all chloride ions. This was continued until addition of $AgNO_3$ showed no evidence of AgCl precipitation. To remove the 1-methyl-L-histidine as the free base from the column, 4 N NH_4OH was used as an eluant. Water and ammonia were removed by rotoevaporation. The residue was dried under vacuum overnight (0.208 g, 69.8% yield, mp 239.5–240°C (lit. (12) mp 246–248°C)).

Synthesis of 1-methyl[2-^{3}H]-L-histidine

Tritiated water (30 μL, 150 mCi) was added via a syringe to freshly purified 1-methyl-L-histidine (97.75 mg) in a heavy-walled glass ampoule. The glass ampoule was capped with a rubber septum, its contents frozen in liquid nitrogen, and the ampoule evacuated. After sealing, the ampoule was immersed in an oil bath at 85°C for 17 days, at the end of which period the ampoule was opened, 1 mL of distilled water was added to exchange labile tritium, and the solvent was removed by lyophilization. Addition of 1-mL portions of water was continued until the activity of the lyophilized water was found to be insignificant. The total activity of the substrate was approximately 14 mCi. The material was yellowish brown in colour and tlc analysis indicated two or three other impurities, which were removed as follows.

Using a preparative tlc silica gel plate, approximately 50 mg (7 mCi) of crude material in distilled water was spotted along the baseline of the plate. The plate was developed in a closed tank containing solvent (6:6:4:1 CH_3OH:pyridine:H_2O:glacial acetic acid) and equilibrated overnight at room temperature. Development of the plate required 3 h 35 min.

Under UV light, the band pertaining to the 1-methyl[2-^{3}H]-L-histidine was marked. This band of silica gel was scraped off the plate and placed in a small Erlenmeyer flask. Distilled water (3 × 3 mL) was added to extract the substrate. After filtration, water was removed by lyophilization. The total activity was found to be ≈1.2 mCi.

A kinetic stock solution was prepared by transferring the tritiated material to a test tube containing 1 mL of distilled water. The tube was stoppered, sealed with Parafilm, and stored in the refrigerator until needed.

Preparation of buffer solutions

Potassium hydrogen phthalate and sodium borate buffers were used for kinetic measurements carried out at low and intermediate pH ranges, respectively, while sodium hydroxide solutions were used for measurements at higher pH values.

Preparation of methylmercury nitrate solutions (14)

Methylmercury chloride (3.75 g) was suspended in 25 mL of distilled, deionized water in an Erlenmeyer flask. To this was added a solution containing 2.54 g of $AgNO_3$ in 25 mL of water. The flask was stoppered, covered in aluminum foil, and allowed to stir in the dark for 6 days. At this point the solution was filtered through a sintered glass funnel and the AgCl resulting from the ligand exchange was collected on the filter. To ensure the absence of free Ag^+ ions, 0.4 g of methylmercury chloride was added to the filtrate, which was refiltered after stirring for ca. 2 h. The filtrate was transferred to a beaker and allowed to evaporate in the fume cupboard until a solid residue remained. The residue was recrystallized from hot CCl_4. Upon cooling, white crystals formed and were collected and dried *in vacuo* overnight, yield ca. 2.0 g.

A series of solutions ranging from 0 to 0.007 M were prepared by dissolving the appropriate amount of $MeHgNO_3$ in boiled and cooled, deionized, distilled water in a 100-mL volumetric flask. Potassium nitrate (dried at 100°C) was added to maintain constant ionic strength.

Adjustment of the pH of the metal-ion solutions

The metal-ion solution was placed in a reaction vessel designed to carry out potentiometric titrations, which was fitted with a cover with several openings. A combination pH electrode was inserted into one of the openings while the Teflon tubing attached to a microburette was inserted through a small hole punched through a rubber stopper; all other openings were sealed. A stirring bar was used throughout the pH-adjustment procedure to ensure efficient mixing.

Very small quantities of 5% HNO_3 or 0.01 M NaOH were delivered to the metal salt solution to a desired pH with the aid of the microburette of a Metrohm–Herisau automatic titrator. After addition of the final aliquot of acid or base, the solution was allowed to stir for ca. 3–5 min before the pH reading was recorded.

Kinetic measurements

The rate of detritiation of 1-methyl[2-^{3}H]histidine was measured by monitoring the increase in radioactivity of the reaction mixture with time (t_n). The kinetic stock solution (25 μL) was dispensed by means of an automatic pipette to 20 mL of buffer or metal-ion solution contained in a 50-mL round-bottom flask and equilibrated for no less than 30 min at 85°C. The mixture was shaken for 30–60 s. Aliquots of 1 mL were removed at various times ($t_0 \ldots t_n$) with either a Mohr pipette or an Ependorf automatic pipette and delivered to a 50-mL round-bottom flask containing 0.1 g of sodium chloride. (To prevent sublimation of 1-methylhistidine, the B14 joint of the freeze drying bends was lightly plugged with glass wool.) At this point the time on the stopclock was read and recorded. The round-bottom flask was immediately dipped into a Dewar flask containing liquid nitrogen for quenching the reaction and rotated so as to cause the solution to freeze as a thin film on the inner wall of the flask. Lyophilization of the quenched samples enabled separation of the water from the substrate.

A sample of the water separated from the substrate was withdrawn with a 0.1-mL Mohr pipette and transferred to a 7-mL plastic liquid scintillation vial containing 6 mL of Unisolve E or Beckman HP liquid scintillator. The kinetic sample was assayed for tritium (C_t) on a Beckman LS5801 liquid scintillation counter. Subsequent kinetic samples were treated in the same fashion.

The infinity reading (C_∞), i.e., the radioactivity transferred to the aqueous solution when the exchange reaction had reached completion, was determined by measuring the disintegrations per minute of 0.1 mL of the reaction mixture in 6 mL of Unisolve E or Beckman HP liquid scintillator.

Analysis of kinetic data

First-order kinetics

The first-order rate constants, k_{obs}, for the detritiation of 1-methyl[2-^{3}H]histidine in aqueous buffers and metal-salt solutions were extracted from the slopes ($-2.303\ k_{obs}$) of the plots of log ($C_\infty - C_t$) vs. time.

Initial rates method

For slow reactions, i.e., when $t_{1/2}$ was greater than 6 h, an initial rates method was used to determine the first-order rate constant for the detritiation of 1-methyl[2-^{3}H]histidine. This method required that C_t and the corresponding time be collected for no more than 5% of reaction. A plot of C_t vs. time results in a straight line with a slope equal to k_{obs}/C_∞.

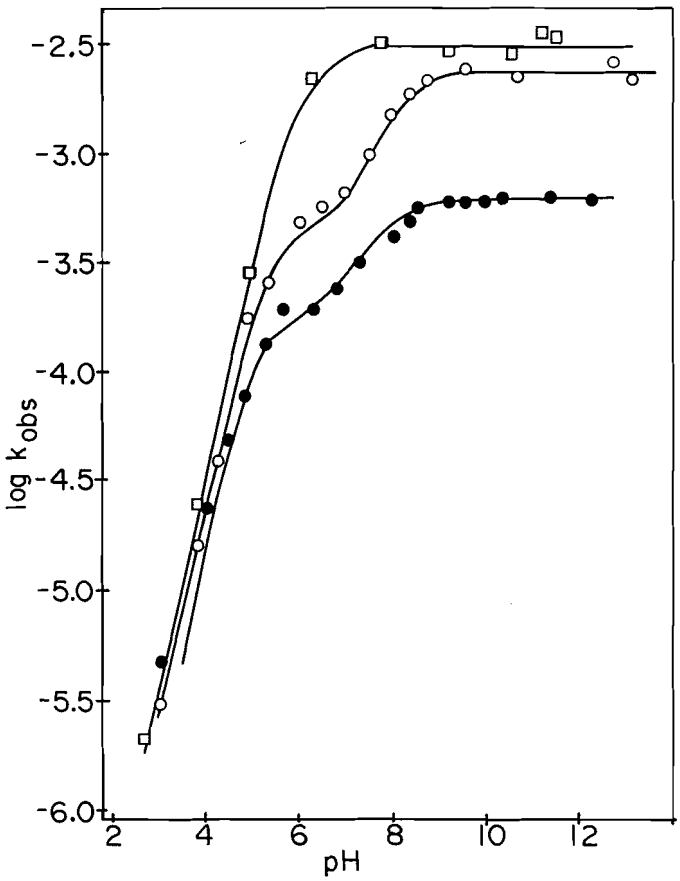
Results and discussion

C(2)-H exchange in the absence of metal ion

The rate constants for the detritiation of 1-methyl[2-^{3}H]-histidine (**1***a*) in aqueous buffer solutions at 85°C are listed in Table 1 and shown graphically in Figure 1 in the form of a rate–pH profile for the pH range 2.9–13.2. Also included for comparison are the rate–pH profiles for 1-methyl[2-^{3}H]-imidazole and [2-^{3}H]histidine.

TABLE 1. Detritiation rate constants (k_{obs}) for 1-methyl[2-^{3}H]histidine (**1***a*) in aqueous buffers at 85°C

pH (at 85°C)	$10^4 k_{obs}$ (s^{-1})	pH (at 85°C)	$10^4 k_{obs}$ (s^{-1})
2.94	0.0307	7.47	10.2
3.69	0.152	7.94	15.1
4.22	0.401	8.27	18.6
4.91	1.78	8.69	22.3
5.36	2.59	9.54	24.5
6.01	4.84	10.63	21.8
6.45	5.49	12.58	25.3
7.00	6.43	13.21	21.4



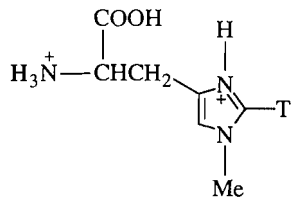


FIG. 1. Rate–pH profiles for the detritiation of 1-methyl[2-^{3}H]-imidazole, (□), [2-^{3}H]-1-methylhistidine (○), and [2-^{3}H]-histidine (●) in aqueous buffers at 85°C. The solid lines represent the theoretical profiles calculated from eq. [7] using the values summarized in Table 2.

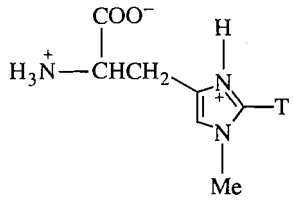
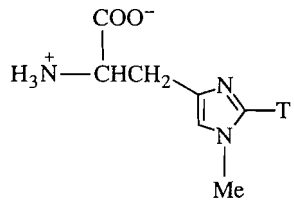
In a previous study (3) involving 1-methyl[2-^{3}H]imidazole (**2***a*) the rate constants were found to increase with increasing pH in the lower pH region, while at intermediate pH (7–10) the rate constants plateaued. If the rate–pH profiles for 1-methyl[2-^{3}H]imidazole (**2***a*) and 1-methyl[2-^{3}H]histidine (**1***a*) are compared, similar behaviour is observed in the lower and upper pH regions. The slight deviation observed in the intermediate pH region for 1-methyl[2-^{3}H]histidine, resulting in sigmoidal behaviour, is thought to arise because of the involvement of one or other of the ionizable groups in the side chain. In fact, the rate–pH profile for 1-methyl[2-^{3}H]histidine resembles that obtained for guanosine (15, 16), inosine (15, 17, 18), 9-methylhypoxanthine (15), and histidine (19), compounds that possess an additional ionizable group on the adjacent pyrimidine ring or side chain.

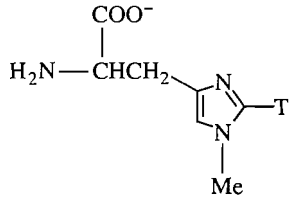


More specifically, the deviation in the intermediate pH region is thought to result from involvement of the amino group in the 1-methylhistidine side chain. Support for this conclusion follows from a comparison of the rate–pH profiles for histidine and histamine (19). The fact that the histamine and histidine profiles are similar suggests that the amino group is responsible for the sigmoidal shape of the curve (19).

1. Kinetic analysis



1-Methyl[2-^{3}H]histidine can exist in various ionic forms (**3–6**) depending upon the solution pH. The pK_a for the ionization of the carboxyl group in 1-methylhistidine has a value of 2.0 at 25°C.[2] Hence, in the pH range under study 1-methylhistidine can exist in 3 forms: the N(3)-protonated form **4** (2-THisH$_2^+$), the amino protonated form **5** (2-THisH), and the anionic form **6** (2-THis$^-$). The rate expression for the



2-THisH$_3^{2+}$ (**3**)

2-THisH$_2^+$ (**4**)

2-THisH (**5**)

2-THis$^-$ (**6**)

isotopic exchange reaction over the entire pH region is given by eq. [1].

$$[1]\quad \text{Rate} = \frac{-\text{d}[\text{2-THis}_t]}{\text{d}t} = k[\text{2-THisH}_2^+][\text{OH}^-] + k'[\text{2-THisH}][\text{OH}^-] + k''[\text{2-THis}^-][\text{OH}^-]$$

[2-THis$_t$] represents the total concentration of 1-methylhistidine-containing species tritiated at C(2), while k, k', and k'' are the rate constants corresponding to 2-THisH$_2^+$, 2-THisH, and 2-THis$^-$ respectively. From past work (10), the second-order rate constant for hydroxide ion attack on a species where N(3) is not protonated, such as 2-THis$^-$, is 10^7 times smaller than that for a species where N(3) of the imidazole ring is protonated. Contribution from the third term in eq. [1] can hence be regarded as insignificant and eq. [1] reduces to

$$[2]\quad \text{Rate} = \frac{-\text{d}[\text{2-THis}_t]}{\text{d}t} = k[\text{2-THisH}_2^+][\text{OH}^-] + k'[\text{2-THisH}][\text{OH}^-]$$

[2]Measured using NMR spectroscopy in our laboratory.

TABLE 2. Comparison of pK_a and rate constants derived from rate–pH profiles for histidine (His), imidazole (Im), benzimidazole (ϕIm), and their 1-methyl derivatives at 85°C

Compound	pK_a	pK'_a	k ($M^{-1}s^{-1}$)	k' ($M^{-1}s^{-1}$)	k_{Me}/k_H	k'_{Me}/k'_H	$k_{A'\text{-}X}/k_{A\text{-}X}$ (A,A′ = His, Im, or ϕIm; X = H or Me)	Ref.
Histidine (**1**)	5.0	7.6	6.1×10^3	49			A′ = ϕIm 10 (A = His; X = H)	8
1-Methylhistidine (**1***a*)	5.2	7.9	1.0×10^4	1.0×10^2	1.6	2.0	A′ = ϕIm 20 (A = His; X = Me)	This work
Imidazole (**2**)	5.9	—	6.0×10^3	—			A′ = ϕIm 10 (A = Im; X = H)	3,13
1-Methylimidazole (**2***a*)	6.0	—	1.0×10^4	—	1.7	—	A′ = ϕIm 20 (A = Im; X = Me)	3
Benzimidazole	4.6	—	6.2×10^4	—			A′ = His 1 (A = Im, X = H)	6,13
1-Methylbenzimidazole	4.6	—	2.0×10^5	—	3.2	—	A′ = His 1 (A = Im; X = Me)	13

The concentrations of 2-THisH$_2^+$, 2-THisH, and 2-THis$^-$ are related by means of the acid dissociation constants K_a and K'_a where K_a = [2-THisH][H$^+$]/[2-THisH$_2^+$] and K'_a = [2-THis$^-$][H$^+$]/[2-THisH], from which eqs. [3]–[5] follow.

$$[3]\quad [\text{2-THis}_t] = [\text{2-THisH}_2^+] + [\text{2-THisH}] + [\text{2-THis}^-]$$

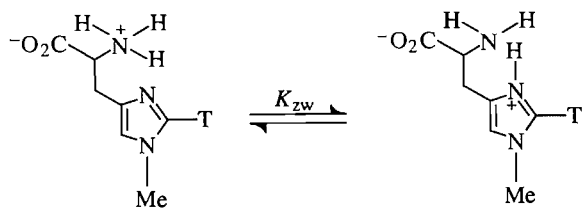
$$[4]\quad [\text{2-THisH}_2^+] = [\text{2-THis}_t] \Big/ \left(1 + \frac{K_a}{[H^+]} + \frac{K'_aK_a}{[H^+]^2}\right)$$

$$[5]\quad [\text{2-THisH}] = [\text{2-THis}_t] \Big/ \left(1 + \frac{[H^+]}{K_a} + \frac{K'_a}{[H^+]}\right)$$

The rate expression for detritiation of 1-methylhistidine becomes

$$[6]\quad \text{Rate} = \frac{-d[\text{2-THis}_t]}{dt} = \frac{kK_w[H^+][\text{2-THis}_t] + k'K_aK_w[\text{2-THis}_t]}{[H^+]^2 + K_a[H^+] + K_aK'_a}$$

upon substitution of eqs. [4] and [5] into [2] and recognizing that [OH$^-$][H$^+$] = K_w, the ionization constant of water. Integration of eq. [6] gives the pseudo-first-order rate constant (k_{obs}) as



$$[7]\quad k_{obs} = \frac{kK_w[H^+] + k'K_wK_a}{[H^+]^2 + K_a[H^+] + K_aK'_a}$$

For the case where $K_a >> [H^+] >> K'_a$ and $k >> k'$, eq. [7] reduces to $k_{obs} = kK_w/K_a$, corresponding to the plateau extending between pH 6 and 7. Similarly, when $K'_a >> [H^+] >> K_a$, eq. [7] reduces to $k_{obs} = k'K_w/K'_a$, corresponding to the second plateau at pH 8.5–13. The solid curve in Fig. 1 represents the best fit of the experimental data to eq. [7] using a nonlinear least-squares program (NOTLIN). The acid dissociation constants that give the best fit are given by pK_a = 5.20 ± 0.05 and pK'_a = 7.86 ± 0.09 respectively. These values are in good agreement with pK_a and pK'_a determined by NMR when corrected to 85°C using the Perrin equation, i.e., 4.99 and 7.78, respectively.[3] The second-order rate constants k and k', corresponding to the best possible fit, were (1.00 ± 0.05) × 10^4 $M^{-1}s^{-1}$ and (1.05 ± 0.20) × 10^2 $M^{-1}s^{-1}$, respectively.

[3]E. Buncel and D. C. Yee. To be published.

2. Reactivity relationships

The second-order rate constants k and k' derived from the kinetic analysis can be compared with the corresponding rate constants previously reported for histidine (19, 20), imidazole (3, 21), and benzimidazole (21) and their 1-methyl derivatives (3, 17), Table 2. There are several interesting points that arise from the data presented in Table 2. As pointed out by Jones and co-workers (19) in a study of the detritiation of histidine, the magnitude of k' for the reaction between hydroxide ion and the amino-protonated histidine species is unusually large compared to similar compounds reacting in the neutral form (k' values normally range between 10^{-1} and 10^{-3} $M^{-1}s^{-1}$ (10)). The 10^3 to 10^5-fold increase in rate constant observed for the amino-protonated form of amino acids, relative to substrates not possessing a protonated side chain, suggests the involvement of a kinetically equivalent species. One such possibility for the 1-methylhistidine case is shown in eq. [8].

[8] 

5 7

The proton can be readily transferred from the ammonium group to N(3) of the imidazole ring, as the side chain can reorient itself to form a six-membered ring as shown above. It has long been known that histidine and its derivatives can chelate metal ions with the nitrogen atoms of the amino and imidazole groups. For instance, the reaction of 2 moles of 1-methylhistidine with 1 mole of K_2PdCl_4 results in a 2:1 complex of 1-methylhistidine:Pd^{2+}, where each ligand chelates via the amino nitrogen and N(3) of imidazole (8).

Hence k' is a composite of two rate constants: k_0, the rate constant for hydroxide ion attack on the amino-protonated species **5**, and k_{zw} the rate constant for attack on the zwitterionic form **7** ($k' = k_0 + k_{zw}K_{zw} = 1.0 \times 10^2\ M^{-1}s^{-1}$). A value for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

the equilibrium constant K_{zw} was obtained by substituting the parameters derived from the above kinetic analysis into the rate expression for the exchange mechanism that includes the zwitterionic form, **7**, of 1-methylhistidine, eq. [9]. More

$$[9] \quad k_{obs} = \frac{kK_w[H^+] + K_aK_w(k_0 + k_{zw}K_{zw})}{[H^+]^2 + K_aK' + K_{zw}K_a[H^+] + K_a[H^+]}$$

specifically, a nonlinear least-squares fit of the experimental rate constants to eq. [9] where $k = 1.0 \times 10^4\ M^{-1}\ s^{-1}$, $K_a = 6.31 \times 10^{-6}$ M, $K'_a = 1.26 \times 10^{-8}$ M, $K_w = 3.16 \times 10^{-13}\ M^2$, and $k_0 + K_{zw}k_{zw} = 1.0 \times 10^2\ M^{-1}\ s^{-1}$, resulted in $K_{zw} = 9.95 \times 10^{-3}$. It is interesting to note that K_{zw} for histidine (8) has been estimated as 2.0×10^{-2} (8, 22).

By assuming a value for k_0 in the range of 10^{-1}–$10^{-3}\ M^{-1}\ s^{-1}$ and a value of 9.95×10^{-3} for K_{zw}, k_{zw} can be estimated from the relationship $k' = k_0 + k_{zw}K_{zw} = 1.0 \times 10^2\ M^{-1}\ s^{-1}$. The resulting second-order rate constant ($k_{zw} = 1 \times 10^4$ to $1 \times 10^5\ M^{-1}\ s^{-1}$) is comparable to those previously obtained for hydroxide ion attack on the conjugate acid of 1-methylimidazole, 1-methylbenzimidazole, etc. (cf. Table 2). Hence, the proton's ability to migrate to N(3) of the imidazole moiety in species **5** results in an ionic form of 1-methylhistidine that is as reactive as **4**. This is consistent with previous studies showing that the reactivity of an N(3)-protonated species is greater than that of the unprotonated species (10).

It should be noted that in attempting to obtain solutions for eq. [9], which involves four unknown parameters, k, k_0, k_{zw}, and K_{zw}, the uncertainty associated with their determination will necessarily be rather high. Nevertheless, the apparent agreement between K_{zw} obtained here and the previously reported value (8, 22), as noted above, gives some confidence in the overall procedure adopted here for the solution of eq. [9]. The overall mechanism that we have proposed is also in agreement with previous studies on related systems (9, 10, 19), i.e., the important reactive species and the corresponding rate constants are the following: **4** (k), **5** (k_0), and **7** (k_{zw}). Species that are found not to be important, or that contribute negligibly, are **3** and **6**.

The effect of N-methylation is demonstrated by a comparison of the second-order rate constants for 1-methylhistidine (**1***a*), 1-methylimidazole (**2***a*), and 1-methylbenzimidazole with those for the corresponding unmethylated parent compounds. Substitution of the hydrogen atom at N(1) of histidine (**1**), imidazole (**2**), and benzimidazole with a methyl group causes the rate constant (k) for proton transfer to increase by factors of 1.6, 1.7, and 3.2 respectively. Similarly, N-methylation results in a 2-fold increase in k' for histidine. It is also interesting to note that this structural change has little effect on the magnitude of the pK_a for N(3)-protonation; a pK_a of 5.1 was found for the pair histidine and 1-methylhistidine, 6.0 for imidazole and 1-methylimidazole, and 4.6 for benzimidazole and 1-methylbenzimidazole.

Finally, a comparison of rate constants (k) for histidine (**1**) and imidazole (**2**), 1-methylhistidine (**1***a*) and 1-methylimidazole (**2***a*), histidine and benzimidazole, and 1-methylhistidine and 1-methylbenzimidazole allows one to assess the effect on k of a charged side chain, relative to benzo annelation of the imidazole nucleus, for instance. This is shown in the eighth column of Table 2. Unlike annelation of a benzo group to the imidazole and 1-methylimidazole nucleus, which results in a 10- or 20-fold increase in k, respectively, substitution of a positively charged side chain has virtually no effect on k relative to the parent compound. Having uncovered the interesting reactivity differences mentioned above, one is left to try to explain their origin.

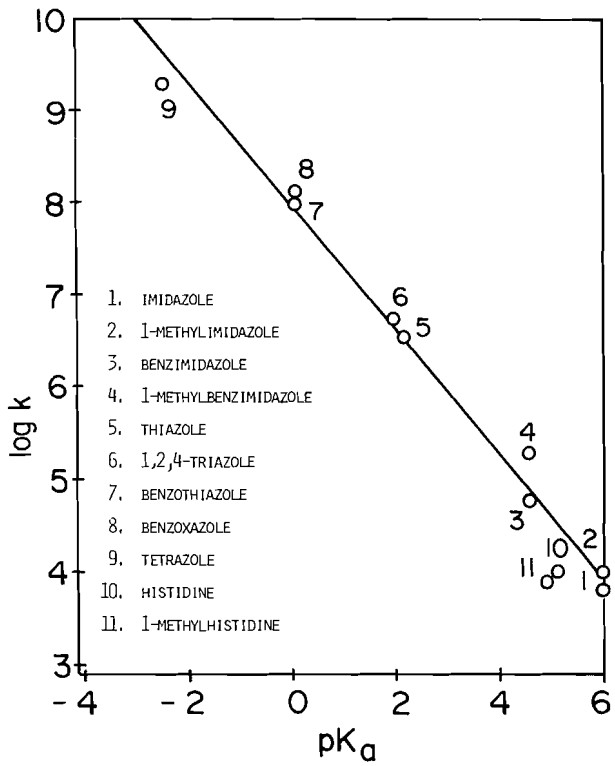


FIG. 2. Plot of log k for detritiation from C(2) of a series of azoles at 85°C versus the pK_a corresponding to N(3) protonation.

Jones and co-workers (10, 21) have shown that there is a linear correlation between log k, the second-order rate constant for C(2)-proton exchange in azoles, and the pK_a for N(3)-protonation; this relationship is followed by histidine (**1**), imidazole (**2**), benzimidazole, and their methyl derivatives. In fact, when the data for 1-methylimidazole and 1-methylbenzimidazole are included with that originally presented (21), the slope and correlation coefficient only vary from −0.72 and 0.993 to −0.66 and 0.995, respectively, Fig. 2. When histidine and 1-methylhistidine are included, the correlation is poorer (correlation coefficient = 0.986) but the slope is similar in magnitude (ca. 0.69). The poorer correlation is not surprising in that Jones and Taylor (10) found that various classes of substrates tended to show separate correlations. More specifically, compounds containing the purine nucleus seemed to show a separate correlation from that of substrates possessing the imidazole nucleus.

The relationship (log k vs. pK_a) is based on the premise that the pK_a is a reflection of the fractional charge at C(2) and hence an indicator of the acidity of C(2)-H. The smaller the negative charge localized at C(2), the more stable is the ylide intermediate, and hence the greater the rate of C(2)-H exchange. The magnitude of the slope of the linear free energy relationship (LFER) is thought to indicate the unequal substituent field effects on the protonation and detritiation process (21).

However, the LFER proposed by Jones cannot provide an explanation for the reactivity difference arising from substrates with identical pK_a values, for example, the reactivity differences observed for histidine and 1-methylhistidine, imidazole

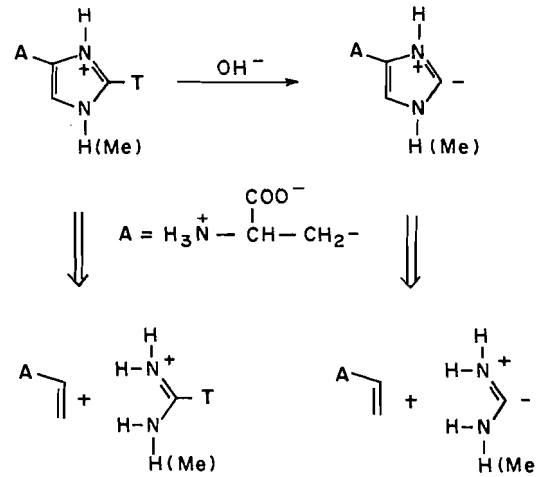
and 1-methylimidazole, and benzimidazole and 1-methylbenzimidazole.

3. FMO–PMO interpretation

In a previous study (3) the increased reactivity observed for the N-methylated and benzo-annelated analogues of imidazole was discussed in terms of frontier and perturbational molecular orbital theory (FMO and PMO theory, respectively). We summarize the salient features of the argument used and then extend it to the present system to account for the reactivity differences observed between 1-methylhistidine and related compounds.

The application of FMO–PMO theory to the components of the rate-determining step for proton transfer from 1-methylimidazole and imidazole (i.e., C(2)-H abstraction from the protonated substrate (R) to form the ylide intermediate (I)), results in the relative energies of the frontier orbitals of the reactants and ylide intermediates and the relative intramolecular stabilization energy effected by structural change. From the ordering of the frontier orbitals, the relative stabilization energy in going from the reactant to the ylide intermediate can be estimated.



R I

The relative energies of the frontier orbitals of the species present in the rate-determining step for proton transfer were determined by dissecting into fragments of known molecular orbitals. The LUMO of one fragment and the HOMO of the remaining fragment are combined arbitrarily, resulting in the frontier orbital for the reacting species. Next, the stabilization energies in the reactant (SE^R) and intermediate (SE^I) states effected by structural change are compared. The closer the energies of the HOMO and LUMO, the better the orbital overlap and hence the greater the stabilization energy. The relative energies of the HOMOs and LUMOs are estimated from ionization potentials (IP) and electron affinities (EA), respectively; $E_{HOMO} = -IP$ and $E_{LUMO} = -EA$ (23). If the difference in the magnitude of the stabilization energy (δSE) effected by structural change is smaller in the reactant state than in the intermediate state ($\delta SE^I > \delta SE^R$), one would expect proton transfer from the substituted substrate to be faster than from the unsubstituted form. Conversely, if δSE is larger in the reactant state than in the intermediate state ($\delta SE^I < \delta SE^R$), then proton transfer from the substituted substrate would be slower than from the unsubstituted substrate.

(i) Effect of methyl substitution

For the case of imidazole and 1-methylimidazole, the difference in the stabilization energies between the N-methylated and unmethylated intermediates, $SE^I_{Me} - SE^I_H$, was found to be greater than that between the reactants $SE^R_{Me} - SE^R_H$ (3). The increased stabilization of the intermediate relative to the reactant effected by substitution of a methyl group at N(1) accounts for the increase in the second-order rate constant, as the transition state should also be stabilized by the structural change.

SCHEME 1

One can account for the reactivity difference observed for C(2)-proton transfer from N(3)-protonated histidine and 1-methylhistidine in a similar fashion. The relative energies of the FMOs of the reactant species and their corresponding intermediate structures, and hence the intramolecular stabilization energy, are estimated from the relative energies of the frontier orbitals of the fragments (Scheme 1). For histidine the fragments are a substituted ethylene and a pseudoallyl fragment, while 1-methylhistidine is fragmented into the same substituted ethylene fragment and a 1-methyl-pseudoallyl fragment. The same procedure is followed for the intermediate structures.

As shown in the previous study (3), methylation is associated with a decrease in ionization potential. This suggests that the HOMO of the 1-methyl-pseudoallyl fragment is higher in energy than that of the unsubstituted pseudo-allyl fragment in both the reactant and the intermediate. Hence in the reactant state the interaction of the LUMO of substituted ethylene and the HOMO of the 1-methyl-pseudoallyl fragment for the methylated substrate is greater, due to the smaller energy gap, than the corresponding orbital interaction for the unsubstituted parent compound. This results in a differential stabilization energy $\delta SE^R = SE^R_{Me} - SE^R_H$, where $SE^R_{Me} > SE^R_H$ (Fig. 3).

In going to the intermediate structures, the HOMO energy of the deprotonated pseudoallyl and 1-methyl-pseudoallyl fragments is expected to increase substantially relative to the corresponding protonated fragments; the energy required to remove an electron from a neutral molecule is greater than from its deprotonated analog. Consequently, the energy gap between the HOMO of the deprotonated pseudoallyl and 1-methyl-pseudoallyl fragment, and the LUMO of the substituted ethylene, is significantly smaller than that in the reactant state (Fig. 3). This results in greater orbital interaction and thus enhanced stabilization in the intermediate structures relative to the reactants. More specifically, $\delta SE^I (= SE^I_{Me} - SE^I_H)$ is greater than $\delta SE^R (= SE^R_{Me} - SE^R_H)$. An intermediate of lower energy results upon N-1 methylation of histidine. Assuming that the energy of the intermediate is in direct correspondence to the transition state energy, it follows that a change in structure from R = H to R = Me leads to stabilization of the transition state for proton transfer, thus accounting for the increase in rate on methyl substitution.

For proton transfer from the amino-protonated species (**5**) where the zwitterionic species **7** has been implicated as the

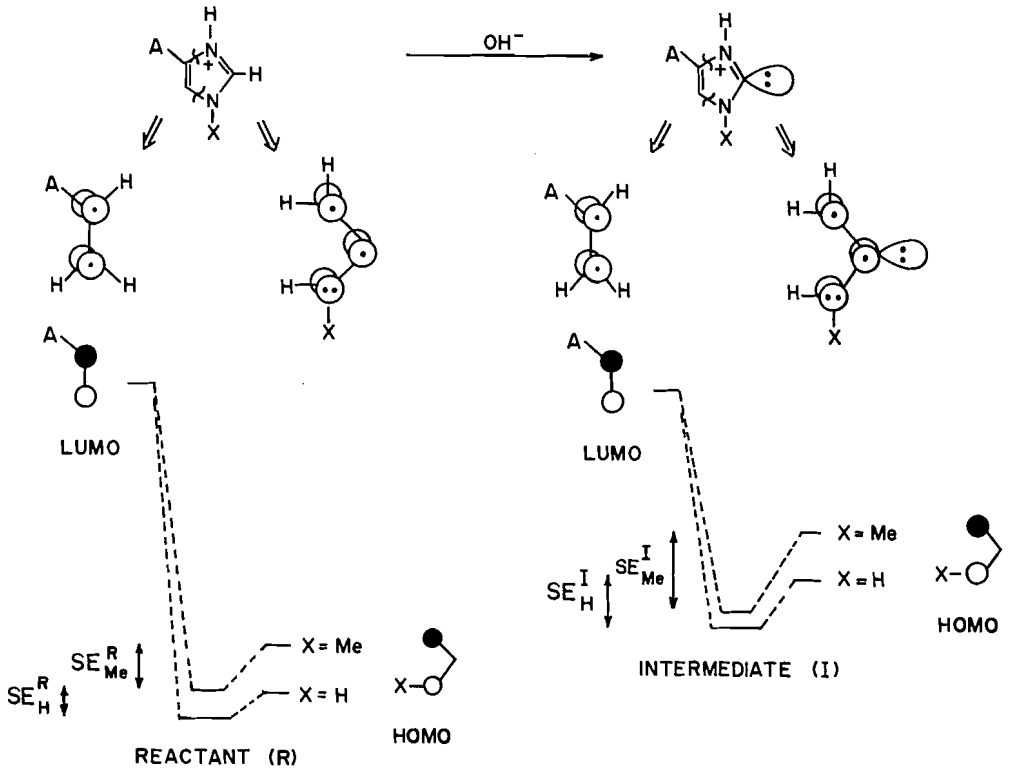

FIG. 3. FMO analysis of the effect of N(1)-methylation on proton transfer from C(2) of histidine (A = $H_3\overset{+}{N}$—CH(COO^-)CH_2-) and imidazole (A = H).

major contributor to k', a similar analysis can be made to explain the rate increase on N-methylation. The reactant substrates and the corresponding ylide intermediates are dissected into a substituted ethylene fragment and a pseudoallyl fragment for the histidine case (A = H_2N—CH(COO^-)—CH_2-, cf. Scheme 1), and a substituted ethylene fragment and a 1-methyl-pseudoallyl fragment for the 1-methylhistidine case (A = H_2N—CH(COO^-)—CH_2-, cf. Scheme 1). The relative ordering of the HOMOs for the pseudoallyl and 1-methyl-pseudoallyl fragments, and the LUMO of the substituted ethylene fragment, both in the reactant and intermediate state, are, however, as described for the diprotonated species (both N(3) and amino group are protonated) of histidine and 1-methylhistidine and hence the same analysis can be used to account for the difference in k' observed for histidine and 1-methylhistidine.

(ii) Effect of structural change on the ethylene moiety

Next one can consider the change of C(2)-H reactivity effected by structural change of the ethylene moiety. It was found previously that annelation of a benzo group to imidazole and 1-methylimidazole results in a 10- or 20-fold increase in k, which could be explained in terms of FMO–PMO theory (3). The present work shows, however, that substitution of the C(4)-H of imidazole and 1-methylimidazole with a charged side chain does not alter k significantly. This observation is interesting in view of the FMO–PMO analysis.

The FMO–PMO treatment of proton transfer from C(2) of imidazole and histidine requires that imidazole be dissected into ethylene and a pseudoallyl fragment ($H_2\overset{+}{N}$=CH—NH_2) while histidine is dissected into a substituted ethylene (CH_2=CHA, where A = ^+H_3N—CH(COO^-)—CH_2-) and a pseudoallyl fragment ($H_2\overset{+}{N}$=CH—NH_2). It is important to note that the pseudoallyl fragments are identical in both cases. Hence the analysis focuses on the change in energy of the LUMO of ethylene effected by substitution of the charged side chain, Fig. 4.

As previously stated, the energy of the LUMO is related to the electron affinity (EA) by the relationship, $E_{LUMO} = -EA$. One would expect that substitution of C(4)-H with a side chain such as ^+H_3N—CH(COO^-)—CH_2-, would result in an increase in the electron affinity, since the positive charge on the ammonio group would aid in binding electrons more tightly than the unsubstituted ethylene system. The negative charge on the carboxylate group, however, will diminish the effect of the positive charge and, while it is difficult to estimate the degree of the reduction in positive charge, one is tempted to argue that the proximity of the charges to the ethylene moiety would play a role. More specifically, as the positive charge is closer to the ethylene moiety it should dominate the overall effect.

As a result of the increase in electron affinity due to the electrostatic effect of the side chain, one would expect the energy of the substituted moiety to be lower. The energy of the HOMO of the pseudoallyl fragment is lower than that of the LUMO of ethylene, as discussed in the previous section. In the intermediate state, the relative energies of the LUMOs of ethylene and substituted ethylene are as stated. For the reactant, however, the HOMO energy for the deprotonated pseudoallyl fragment is significantly larger than that of the parent pseudoallyl fragment, for the same arguments presented in the previous section. Having established the relative energies of the LUMO and HOMO of the respective fragments, one proceeds by assessing the degree of interaction between the LUMOs of ethylene and substituted ethylene with the HOMO of the pseudoallyl fragment in the reactant state, and of the deproto-

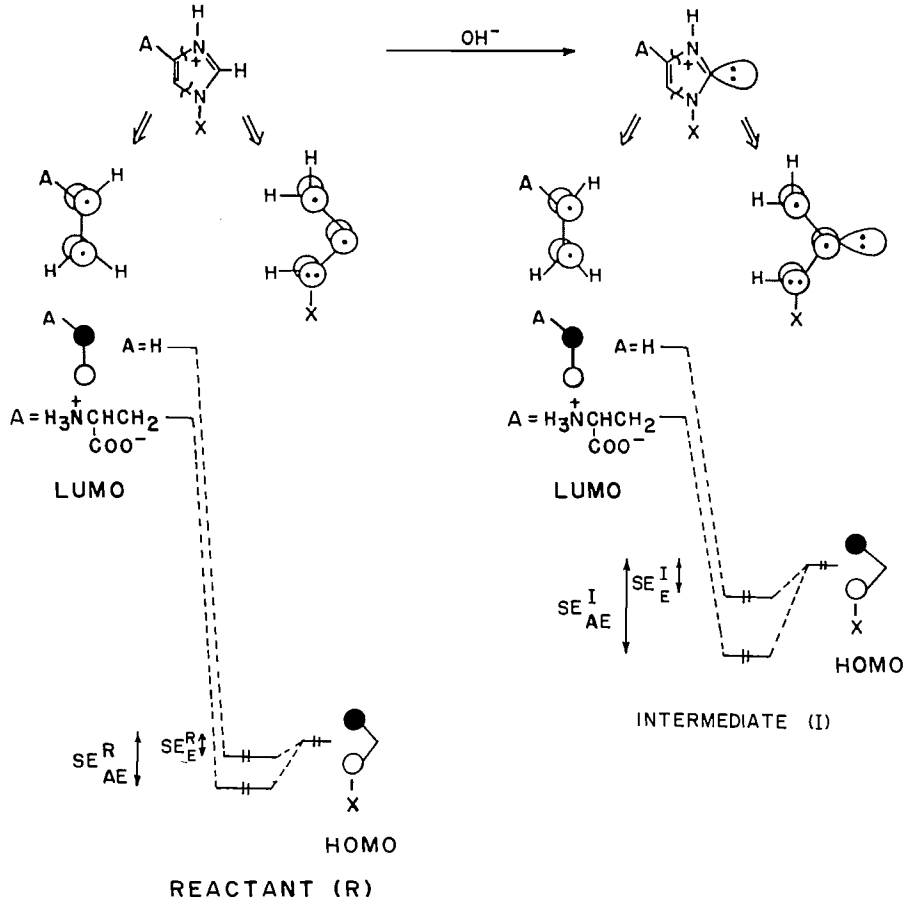

FIG. 4. FMO analysis of the effect of C(4) substitution (A = H vs. A = $H_3\overset{+}{N}$—CH(COO^-)CH_2-) on C(2)-H exchange from imidazole (X = H) and 1-methylimidazole (X = Me).

nated pseudoallyl fragment in the intermediate state. The smaller energy gap between the HOMO of the deprotonated pseudoallyl fragment and the LUMO of ethylene, or the LUMO of substituted ethylene, leads to greater orbital interaction, and thus enhanced stabilization in the intermediate structures relative to the reactants. The difference in the stabilization energies (δSE) of the two intermediate structures, $SE^I_{A\text{-}E} - SE^I_E$ (subscripts A-E and E represent substituted ethylene and ethylene, respectively) is greater than that for the reactants, i.e., $\delta SE^I > \delta SE^R$. The increased stabilization of the intermediate relative to the reactant effected by the side chain at C(4) would predict an increase in k for 1-methylhistidine and histidine relative to 1-methylimidazole and imidazole, respectively. However, as stated before, no significant change in k was observed for 1-methylhistidine and 1-methylimidazole, and for histidine and imidazole.

Jones and co-workers (19) determined k for histamine under the same experimental conditions as for imidazole (21). These workers found that the ratio of the k values for histamine and imidazole was 10/6.0 or 1.6. This result is consistent with the above FMO–PMO analysis. The positive charge of the side chain of histamine, $H_3\overset{+}{N}CH_2CH_2$-, would be expected to increase the electron affinity of ethylene. This would suggest that the effect of the carboxylate group of the histidine side chain has a greater effect in diminishing the positive charge than first anticipated.

Bradbury *et al.* (20) found that the second-order rate constant for C(2)-H deuterium exchange of imidazole acetic acid was 6.4/2.9, i.e., 2.2 times smaller than that for imidazole. The results of the above two studies suggest that the increase in rate due to the ammonium group is equal to the rate-retarding effect of the carboxylate, which is consistent with the k for histidine and imidazole, and for 1-methylhistidine and 1-methylimidazole, to be of the same order of magnitude.

Proton transfer from C(2) of 1-methylhistidine in the presence of $MeHgNO_3$

The pseudo-first-order rate constants for the detritiation of 1-methyl[2-^{3}H]histidine were determined at pH 5.90 and a temperature of 85°C for a series of reaction mixtures varying in $MeHgNO_3$ concentration (0–0.007 M). The results, given in Table 3, show a decrease in the value of the rate constant with increasing metal-ion concentration. The ratio of the pseudo-first-order rate constants at $[M^{n+}] = 0$ and $[M^{n+}] = 0.007$ M is $4.355 \times 10^{-4}/1.695 \times 10^{-5}$, i.e., 26. This decrease is shown graphically in Fig. 5 in the form of a rate constant vs. $[MeHg^+]$ profile.

The observed decrease in rate constant with increasing $MeHg^+$ concentration is not unlike that previously reported for the detritiation of [2-^{3}H]imidazole in the presence of Cu^{2+}, Ni^{2+}, and Zn^{2+} (7). It is interesting to note at this point that there is a discrepancy in the results obtained for [2-^{3}H]imidazole and 1-methyl[2-^{3}H]histidine in the presence of $MeHgNO_3$. Whereas a very small ratio ($k^{M=0}_{obs}/k^{M=0.003}_{obs} = 1.13$, pH =

5.70) was detected for imidazole in the presence of 0.003 M $MeHgNO_3$, a rate ratio of 10 was obtained for 1-methylhistidine under similar experimental conditions.

Two explanations can be put forward to account for the observed decrease in the pseudo-first-order rate constant. These are discussed in terms of two mechanisms, Mechanism I and Mechanism II, and are shown in Schemes 2 and 3 respectively. In the first mechanism, $MeHg^+$ complexes with 1-methyl-[2-^{3}H]histidine at N(3) and the amino nitrogen, respectively. The result is to reduce the concentration of both the amino-protonated (**5**) and the N(3)-protonated form (**4**) of 1-methyl-[2-^{3}H]histidine. Hence the product of the concentration of hydroxide ion and the active species will be smaller, thus accounting for the decrease in observed rate constant.

Support for such a mechanism is afforded by a study of the effect of metal ions on C(2)-H isotopic exchange of imidazole (7). The rate-retarding effect of the metal ions ($Cu^{2+} > Zn^{2+} \sim Ni^{2+} \gg MeHg^+$) was rationalized in terms of complex formation and hence reduction in the concentration of the conjugate acid of imidazole.

The second mechanism also involves complexation of 1-methyl[2-^{3}H]histidine to form an N(3)- and an amino-coordinated complex. The reduction in the magnitude of the pseudo-first-order rate constant in this case results from competition of rate-determining hydroxide ion attack on the metal-coordinated species with the pathways involving hydroxide ion attack on the amino-protonated (**5**) and the N(3)-protonated species (**4**) respectively. The assumption must be made, however, that the magnitude of the second-order rate constants for hydroxide ion attack on the metal-coordinated species is smaller than k and k' determined for the pathways involving the amino-protonated (**5**) and N(3)-protonated species (**4**).

Detritiation of 1-methyl[8-^{3}H]inosine and 1-methyl[8-^{3}H]-guanosine, under conditions where the operative mechanism is reaction between the protonated substrate and hydroxide ion, was retarded by the presence of Ag^+ and Cu^{2+} for 1-methyl[8-^{3}H]inosine and by Cu^{2+} for 1-methyl[8-^{3}H]guanosine (9). This was explained by the formation of a metal-complex species that detritiated at a slower rate than the protonated form of the substrate, but about 10^4 to 10^6 times faster than the neutral form.

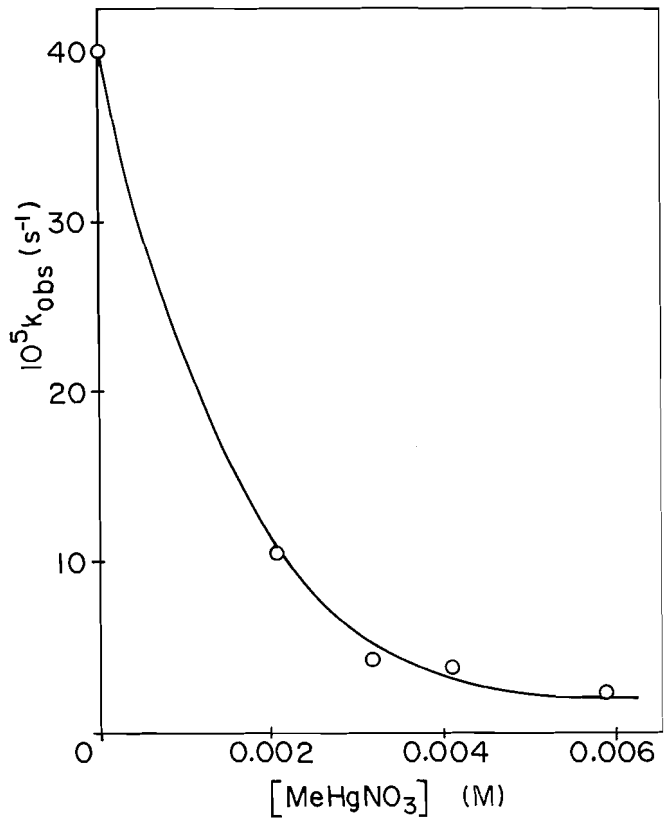

FIG. 5. Effect of metal ions on C(2)-H exchange of 1-methylhistidine. Plot of k_{obs} vs. [$MeHgNO_3$].

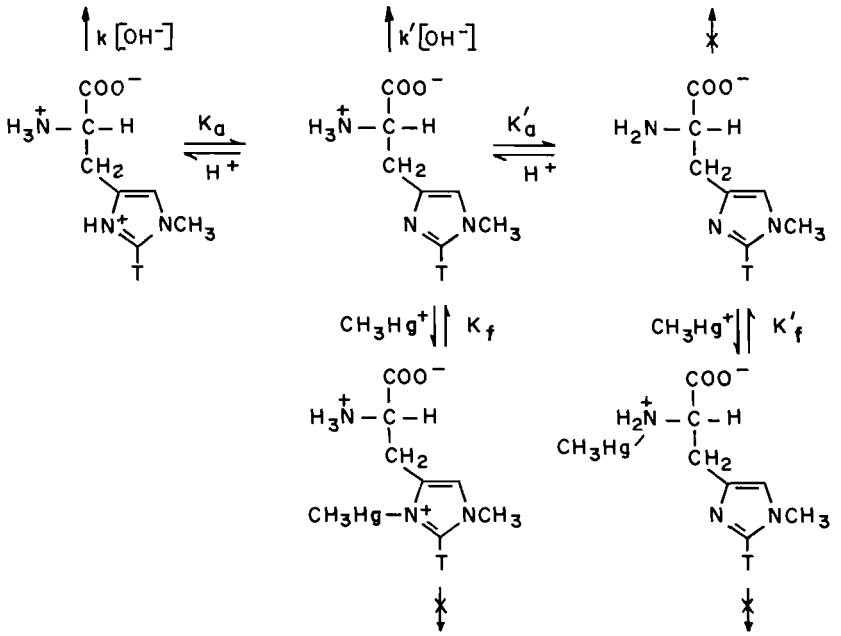
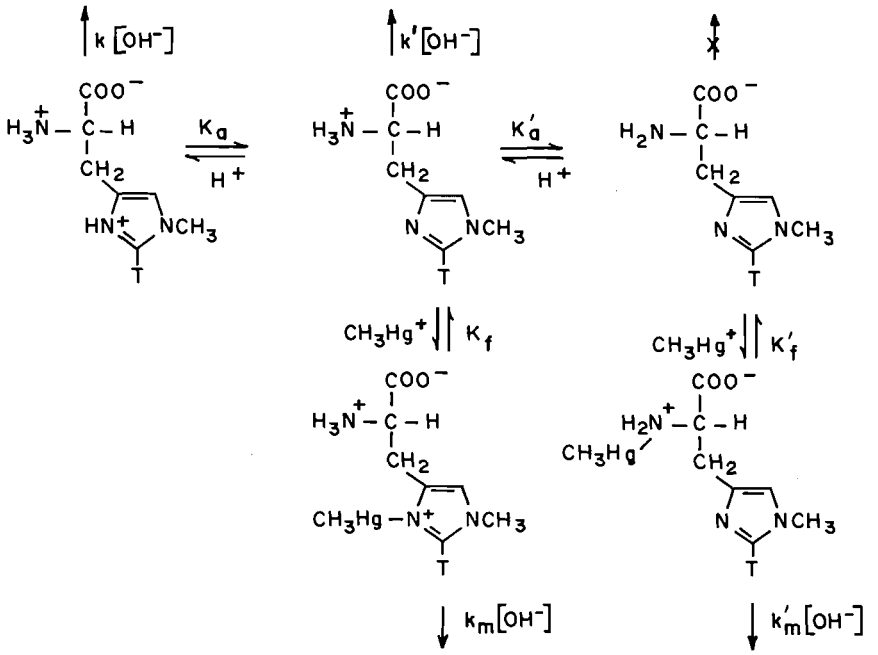


Martin and co-workers (8), on the other hand, investigated deuterium exchange at C(2) and C(8) of the series of Pt^{2+} and Pd^{2+} complexes, namely diethylenetriamineinosineplatinum(II) chloride, ethylenediaminebis(inosine)platinum(II) chloride, diethylenetriamineguanosineplatinum(II) chloride, ethylenediaminebis(guanosine)platinum(II) chloride, and bis(1-methylhistidine)palladium(II) chloride. The proton magnetic resonance method used by these workers to follow the rate of exchange allowed for the direct measurement of the loss of H(2) or H(8) intensity of the complex upon its replacement by deuterium, because the exchange between coordination sites in these compounds is slow on the NMR time scale. Hence specific second-order rate constants could be determined for the individual complexes of histidine and inosine, supporting the existence of a second, less reactive pathway, when metal ions come into play.

Expressions for the pseudo-first-order rate constant (k_{obs}) for Mechanism I and Mechanism II, eqs. [10] and [11] respectively, are derived in a similar fashion to that presented in the first section of the paper. (Detailed derivation of eqs. [10] and [11] is found in Appendices I and II.)



$$[10] \quad k_{obs} = \frac{kK_w[H^+] + K_aK_wk'}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K'_fK'_aK_a[M^{n+}]}$$

$$[11] \quad k_{obs} = \frac{kK_w[H^+] + k'K_aK_w + k_mK_aK_fK_w[M^{n+}] + k'_mK_aK'_aK'_f[M^{n+}][OH^-]}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K'_fK'_aK_a[M^{n+}]}$$

SCHEME 2. Mechanism 1: metal complexes are inactive.

SCHEME 3. Mechanism 2: metal complexes undergo detritiation.

The second-order rate constants for hydroxide ion attack on the N(3)- and amino-$MeHg^+$-coordinated 1-methyl[2-^{3}H]histidine complexes are represented by k_m and k'_m respectively, while K_f and K'_f are the formation constants for the N(3)- and amino-coordinated metal-coordinated 1-methylhistidine complexes. All other symbols are as defined in the first section of the paper.

It is noted that the expression for Mechanism I (eq. [10]) is in fact an extreme case of that for Mechanism II. More specifically, when k_m and k'_m in eq. [11] are zero, the resulting expression is eq. [10].

The experimental data in Table 3 were fitted to the expressions for k_{obs} corresponding to Mechanisms I and II respectively by means of NOTLIN, a nonlinear curvefitting program.

Results of least-squares fitting of rate data to rate expressions for Mechanisms I and II

(*a*) Varying the parameters k_m and k'_m did not give convergence. Allowing k, k', k_m, and k'_m to be zero in different combinations showed that the only important terms are those containing k and k' (i.e., setting k_m and (or) k'_m to zero gave proper convergence as judged by comparing the experimental and theoretical plots.)

(*b*) Cancellation of terms including k and (or) k' showed very poor fit or gave no convergence at all, implying that detritiation of species **4** and **5** is important in the mechanism. The term containing k, the largest second-order rate constant, is the most important. Cancellation of k_m and k'_m did not affect the fit.

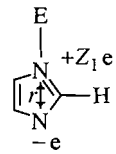
TABLE 4. Comparison of second-order rate constants derived from rate data of several heterocycles

Substrate	Metal ion	k ($M^{-1}s^{-1}$)	k_m ($M^{-1}s^{-1}$)	k/k_m	$-pK_m$
1-Methylguanosine	Cu(II)	5.3×10^6	1.4×10^4	379	1.78
1-Methylinosine	Cu(II)	1.8×10^7	2.1×10^4	818	1.36
	Ag(I)	1.8×10^7	4.0×10^2	4.5×10^4	1.61
	Zn(II)	1.8×10^7	—	—	—
5′-Adenosine monophosphate	Cu(II)	8.6×10^6	8.2×10^3	1.1×10^3	1.58
3′-Adenosine monophosphate	Ag(I)	1.7×10^5	1.3×10^3	1.3×10^2	1.72
1-Methylhistidine	Pd(II)	3.2×10^3	1.3×10^{-2}	2.5×10^5	—
	MeHg(II)	1×10^4	$\leq 1\times10^{-1}$	$\geq 1\times10^3$	4.5

(*c*) Fixing k_m and k'_m to arbitrarily small values such as 10 M^{-1} s^{-1} and 0.0001 M^{-1} s^{-1}, respectively, gave convergence of k and k' to reasonable values. This seems to reemphasize that the variation in k_m and k'_m appears not to affect the observed rate. In other words, the behaviour of the lowering of the observed rate of detritiation in the presence of methylmercury nitrate, evidenced by the exponential decrease of the k_{obs} versus [$MeHg^+$] plot, is not significantly dependent on the terms containing k_m and k'_m.

(*d*) Because K_f and K'_f (determined at 25°C) were not corrected for temperature, these values were adjusted using NOTLIN assuming (*i*) k_m and $k'_m = 0$ and (*ii*) $k_m = 10\,M^{-1}\,s^{-1}$ and $k'_m = 0.0001\,M^{-1}\,s^{-1}$. The resulting values were $-pK_f \approx 4.5$ and $-pK'_f \approx 8.2$. Each value should be lower than the corresponding values at 25°C ($-pK_f = 5.91$ and $-pK'_f = 7.52$). Although the visual fit was satisfactory, the standard deviations pertaining to each value were unusually large.



(*e*) Assuming K_f to be $10^{4.5}$ and K'_f to be $10^{8.2}$, attempts to vary the parameters k_m and k'_m gave negative values or no convergence at all.

One can conclude from the above that although the NOTLIN fitting of the rate data to rate expressions for Mechanisms I and II strongly indicates the operation of Mechanism I, the observation that small values of k_m and k'_m produce convergence with reasonable values for k and k' suggests that Mechanism II cannot be ruled out.

In a study by Martin and co-workers (8) the isotopic exchange of the 2:1 complex of 1-methylhistidine and Pd^{2+} was found to undergo hydroxide ion attack $10^{4.8}$ and $10^{5.4}$ times more slowly than the amino-protonated (**5**) and N(3)-protonated (**4**) species, respectively. In our case, also, there is every indication that C(2)-H exchange of the $MeHg^+$:1-methylhistidine complexes is slower than that of the unmetallated species. These findings are consistent and can be compared with the rate constants for attack on protonated and metal-coordinated species, i.e., k and k_m for a series of systems reported in the literature, Table 4. The relationship $k > k_m$ holds without exception; the ratio of k/k_m varies between 1.3×10^2 and 2.5×10^5.

It is interesting to note that in all cases thus far reported, rate acceleration due to metal coordination has not been observed. On electrostatic considerations one would have expected that the metal ion would mimic the effect of the proton. Both protonation and metal-ion coordination would cause the development of positive charge at the pyridine nitrogen adjacent to the site of hydroxide ion attack. This hypothesis is put in doubt, however, by the observation that addition of metal ion causes a decrease in the pseudo-first-order rate constant.

It is proposed that the disparity in behaviour between the protonated and the metal-coordinated species is a result of the difference in the magnitude of the positive charge on the heteroatom adjacent to the exchange site. Norris, Buncel, and Taylor (24) have treated the model imidazole system **8** in simple

8

electrostatic terms and found that the fractional positive charge residing on N(3) of the imidazole ring could be related to ΔpK_a (difference in pK_a for N(1)-H ionization in the absence of M^{n+} and in the presence of M^{n+}), the effective microscopic permittivity, D_{eff}, and the distance between the charged centres in Å (r^0) in the following way:

$$[12] \quad Z_1 = \frac{\Delta pK_a D_{eff} r^0}{241.7}$$

Using 1-methylimidazolium ion as a standard, and assuming that unit positive charge resides on N(3) of the 1-methylimidazolium ion, eq. [12] reduces to

$$[13] \quad Z_1 = \Delta pK_a/7.1$$

A plot of the C(2) chemical shift as a function of Z_1 for the series where E is Me^+, $Co(NH_3)_5^{3+}$, and no substituent, respectively, shows that the chemical shift at C(2) increases as the charge Z_1 increases, which indicates that the greater the positive charge at N(3), the more labile the C(2) hydrogen. The fractional charge of N(3) in the metal complexes is much lower than with H^+ and Me^+ and hence, according to the above argument, the rate of exchange should also be lower.

Lavallee *et al.* (25) have used ^1H chemical shift differences in heterocycles to indicate the change in charge density effected by metal complexation. These studies showed a decrease in electron density in the complexed heterocycle in the order $H^+ >$ Co(III) > Rh(II). These results are consistent with the model presented above and support our hypothesis of a causal relationship between the magnitude of charge developed on the heteroatom adjacent to the exchange site (C2) by M^{n+} vs. H^+, and the effectiveness of M^{n+} and H^+ in catalysis of proton exchange at C(2).

Conclusions

The plot of k_{obs} vs. pH for the detritiation of 1-methyl[2-^{3}H]-histidine resulted in a sigmoidal profile characteristic of substrates possessing two ionizable functionalities. Kinetic analysis of the data yielded second-order rate constants $k = (1.00 \pm 0.05) \times 10^{-4}$ M^{-1} s^{-1} for hydroxide attack on the N(3)-protonated species **4**, and $k' = (1.05 \pm 0.20) \times 10^2$ M^{-1} s^{-1} as a composite rate constant for attack on the zwitterionic species **5** and **7**. Comparison of k and k' with the corresponding rate constants for histidine, imidazole, and benzimidazole and their 1-methyl derivatives demonstrated some interesting relationships; (1) N(1)-methylation results in a 2- to 3-fold increase in k and a 2-fold increase in k'; (2) benzo annelation results in a 10- or 20-fold increase in k; (3) substitution of a positively charged side chain has virtually no effect on k. The observed reactivity differences could be explained by application of FMO–PMO theory to the proton transfer reaction scheme. Furthermore, it was found that detritiation of 1-methyl[2-^{3}H]histidine is inhibited by the addition of $MeHgNO_3$. The value of the rate constant decreased with increasing metal-ion concentration; the ratio of k_{obs} at $[M^{n+}] = 0$ and $[M^{n+}] = 0.007$ M was 26. A nonlinear least-squares fitting pointed to very small values for k_m and k'_m, consistent with reports on the effects of metal ions in related heterocyclic systems. The large difference in the effectiveness of the proton and the metal ion in promoting C(2)-H exchange has been attributed to the greater ability of the proton to transfer positive charge to the heteroatom adjacent to the exchange site as compared to the metal ion ($MeHg^+$).

Appendix I

Derivation of the rate expression for Mechanism I

The rate expression for the competitive process shown in Scheme 2 is

$$[14] \quad \text{Rate} = \frac{-\mathrm{d}[2\text{-THis}_t]}{\mathrm{d}t} = k[2\text{-THisH}_2^+][OH^-] + k'[2\text{-THisH}][OH^-]$$

where [2-THis$_t$], [2-THisH$_2^+$], and [2-THisH] represent the total concentration of 1-methyl[2-^{3}H]histidine-containing species and the concentration of the N(3)-protonated and the amino-protonated form of the substrate, respectively; k and k' are the second-order rate constants for hydroxide ion attack on 2-THisH$_2^+$ and 2-THisH.

Expressions can be derived for [2-THisH$_2^+$] and [2-THisH] in terms of experimentally measurable quantities by using the mass law equation (eq. [15])

$$[15] \quad [2\text{-THis}_t] = [2\text{-THisH}_2^+] + [2\text{-THisH}] + [2\text{-THis}^-] + [2\text{-THisM}^+] + [2\text{-TMHis}]$$

in conjunction with expressions for the dissociation constants K_a and K'_a and the formation constants K_f and K'_f (eqs. [16]–[19]). 2-THis$^-$, 2-THisM$^+$, and 2-TMHis represent the neutral substrate, the N(3) $MeHg^+$-coordinated, and the amino-$MeHg^+$-coordinated forms of 1-methyl[2-^{3}H]histidine.

$$[16] \quad K_a = \frac{[2\text{-THisH}][H^+]}{[2\text{-THisH}_2^+]}$$

$$[17] \quad K'_a = \frac{[2\text{-THis}^-][H^+]}{[2\text{-THisH}]}$$

$$[18]\quad K_f = \frac{[\text{2-THisM}^+]}{[\text{2-THisH}][M^{n+}]}$$

$$[19]\quad K'_f = \frac{[\text{2-TMHis}]}{[\text{2-THis}^-][M^{n+}]}$$

More specifically, one uses the equations for the acidity constants and the formation constants to obtain expressions for [2-THis$^-$], [2-THisM$^+$], and [2-TMHis], first in terms of [2-THisH$_2^+$] and then in terms of [2-THisH]. Substitution into eq. [15] leads to eqs. [20] and [21] respectively.

$$[20]\quad [\text{2-THisH}_2^+] = \frac{[\text{2-THis}_t][H^+]^2}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K'_fK_aK'_a[M^{n+}]}$$

$$[21]\quad [\text{2-THisH}] = \frac{K_a[\text{2-THis}_t][H^+]}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K'_fK_aK'_a[M^{n+}]}$$

The rate expression for Mechanism I becomes

$$[22]\quad \text{Rate} = \frac{-d[\text{2-THis}_t]}{dt} = \frac{kK_w[H^+][\text{2-THis}_t] + k'K_aK_w[\text{2-THis}_t]}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K'_fK_aK'_a[M^{n+}]}$$

where $K_w = [H^+][OH^-]$. Integration of eq. [22] results in the following expression for the pseudo-first-order rate constant (k_{obs}):

$$[10]\quad k_{obs} = \frac{kK_w[H^+] + K_aK_wk'}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K'_fK_aK'_a[M^{n+}]}$$

Appendix II

Derivation of the rate expression for Mechanism II

In Mechanism II, terms must be included in the rate expression for the pathways involving hydroxide ion attack on the N(3) and amino-MeHg$^+$-coordinated 1-methyl[2-^{3}H]histidine complexes, respectively (2-THisM$^+$ and 2-TMHis). Hence the rate expression for Mechanism II is

$$[23]\quad \text{Rate} = \frac{-d[\text{2-THis}_t]}{dt} = k[\text{2-THisH}_2^+][OH^-] + k'[\text{2-THisH}][OH^-] + k_m[\text{2-THisM}^+][OH^-] + k'_m[\text{2-TMHis}][OH^-]$$

k_m and k'_m are the second-order rate constants for hydroxide ion attack on 2-THisM$^+$ and 2-TMHis respectively.

In a fashion similar to that outlined in Appendix I, expressions can be obtained for [2-THisH$_2^+$], [2-THisH], [2-THisM$^+$], and [2-TMHis] by using the mass law equation and expressions for the dissociation constants K_a and K'_a and the formation constants K_f and K'_f. Hence:

$$[20]\quad [\text{2-THisH}_2^+] = \frac{[\text{2-THis}_t][H^+]^2}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K_aK'_aK'_f[M^{n+}]}$$

$$[21]\quad [\text{2-THisH}] = \frac{K_a[\text{2-THis}_t][H^+]}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K_aK'_aK'_f[M^{n+}]}$$

$$[24]\quad [\text{2-THisM}^+] = \frac{K_aK_f[M^{n+}][H^+][\text{2-THis}_t]}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K_aK'_aK'_f[M^{n+}]}$$

$$[25]\quad [\text{2-TMHis}] = \frac{K_aK'_aK'_f[M^{n+}][\text{2-THis}_t]}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K_aK'_aK'_f[M^{n+}]}$$

Substitution of eqs. [20], [21], [24], and [25] into eq. [23] yields the following rate expression:

$$[26]\quad \text{Rate} = \frac{-d[\text{2-THis}_t]}{dt} = \frac{[\text{2-THis}_t](kK_w[H^+] + k'K_aK_w + k_mK_aK_fK_w[M^{n+}] + k'_mK_aK'_aK'_f[M^{n+}][OH^-])}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K'_fK_aK'_a[M^{n+}]}$$

The expression for the pseudo-first-order rate constant obtained from integration of eq. [26] is

$$[11]\quad k_{obs} = \frac{kK_w[H^+] + k'K_aK_w + k_mK_aK_fK_w[M^{n+}] + k'_mK_aK'_aK'_f[M^{n+}][OH^-]}{[H^+]^2 + K_a[H^+] + K_aK'_a + K_aK_f[M^{n+}][H^+] + K_aK'_aK'_f[M^{n+}]}$$

Metal ion catalysis in nucleophilic displacement reactions at carbon, phosphorus, and sulfur centers.[1] I. Catalysis by metal ions in the reaction of *p*-nitrophenyl diphenylphosphinate with ethoxide

EDWARD J. DUNN AND ERWIN BUNCEL[2]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received December 1, 1988

EDWARD J. DUNN and ERWIN BUNCEL. Can. J. Chem. **67**, 1440 (1989).

The effect of macrocyclic crown ether and cryptand complexing agents on the rate of the nucleophilic displacement reaction of *p*-nitrophenyl diphenylphosphinate by alkali metal ethoxides in ethanol at 25°C has been studied by spectrophotometric techniques. For the reactions of potassium ethoxide, sodium ethoxide, and lithium ethoxide, the observed rate constant increased in the order KOEt < NaOEt < LiOEt. Crown ether and cryptand cation-complexing agents have a retarding effect on the rate. Increasing the ratio of complexing agent to base results in a decrease in k_{obs} to a minimum value corresponding to the rate of reaction of free ethoxide ion. In complementary experiments, alkali metal ions were added to these reaction systems in the form of unreactive salts, causing an increase in reaction rate. The kinetic data were analysed in terms of ion-pairing treatments, which allowed evaluation of rate coefficients due to free ethoxide ions and metal ion – ethoxide ion pairs. Possible roles of the metal cations are discussed in terms of ground state and transition state stabilization. Evaluation of the equilibrium constants for association of the metal ion with ground state (K_a) and the transition state (K'_a) shows that catalysis occurs as a result of enhanced association between the metal ion and the transition state, with K'_a values increasing in the order $K^+ < Na^+ < Li^+$. A model is proposed in which transition state stabilization arises largely from chelation of the solvated metal ion to two charged oxygen centers. This appears to be the first reported instance of catalysis by alkali metal cations in nucleophilic displacement at phosphoryl centers.

Key words: nucleophilic displacement at phosphorus, alkali-metal-ion catalysis.

EDWARD J. DUNN et ERWIN BUNCEL. Can. J. Chem. **67**, 1440 (1989).

Faisant appel à des techniques spectroscopiques, on a étudié l'effet d'un éther couronne macrocyclique et des agents complexants de type cryptand sur la vitesse de la réaction de déplacement nucléophyle du diphénylphosphinate de *p*-nitrophényle par des éthanolates de métal alcalin dans l'éthanol à 25°C. Pour les réactions impliquant les éthanolates de potassium, de sodium et de litium, les constantes de vitesse observées augmentent dans l'ordre suivant : KOEt < NaOEt < LiOEt. L'éther couronne et les agents complexants de type cation cryptand on un effet retardateur sur la vitesse. Une augmentation de l'agent complexant dans la base conduit à une diminution de la valeur de k_{obs} jusqu'à une valeur minimium correspondant à la vitesse de réaction de l'ion éthanolate libre. Dans des expériences complémentaires, on a ajouté des ions de métal alcalin, sous forme de sels non réactifs, au milieu réactionnel provoquant ainsi une augmentation de la vitesse. On a analysé les données cinétiques en fonction du traitement des paires d'ions qui permet d'évaluer les coefficients de vitesse dus aux ions éthanolates libres et aux paires d'ions métal–éthanolate. On discute du rôle possible des cations métalliques en fonction de la stabilisation de l'état fondamental et de l'état de transition de l'ion métallique avec l'état fondamental (K_a) et avec l'état de transition (K'_a) montre qu'il se produit une catalyse en raison d'une association accrue entre l'ion métallique et l'état de transition, avec des valeurs de (K'_a) qui augmentatent dans l'ordre suivant : $K^+ < Na^+ < Li^+$. On propose un modèle dans lequel la stabilisation de l'état de transition provient surtout de la chélation de l'ion métallique solvaté jusqu'à deux centres d'oxygène chargés. Il semble que ce soit la première publication concernant la catalyse par des cations métalliques dans des réactions de déplacement nucléophyle au niveau des centres phosphoryles.

Mots clés : déplacement nucléophyle à phosphore, catalyse des ions de métal alcalin.

[Traduit par la revue]

Introduction

A great deal of research has been conducted into the role that metal ions play in the mechanism of phosphoryl transfer reactions (2), due to their importance in biological processes (3). Most of the attention has been directed towards studying the catalytic effects of divalent metal ions such as Mg^{2+}, Ca^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Cu^{2+}, and Zn^{2+} in the hydrolysis of phosphate esters (4), though phosphonate esters have also received attention (5). However, phosphinate esters have not been examined in this respect.

Despite the ubiquitous presence of alkali metals in biological systems, intensive investigations of catalysis by these monovalent ions have only rarely been undertaken. We have initiated systematic studies of the influence of alkali metal ions in nucleophilic displacement reactions at carbon, phosphorus, and sulfur centres. In the present paper we report our detailed results on the influence of alkali metal ions on nucleophilic displacement in phosphinate esters, which, unexpectedly, have revealed a marked catalytic effect; moreover, catalysis is strongly dependent on the nature of the alkali metal cation (6).

Results

Reactions of LiOEt, NaOEt, and KOEt

The rate of the reaction of *p*-nitrophenyl diphenylphosphinate (**1**) with lithium ethoxide, sodium ethoxide, and potassium ethoxide in ethanol at 25°C was studied spectrophotometrically by following the appearance of the absorption due to *p*-nitrophenoxide ion. Plots of log ($A_\infty - A_t$) vs. t were linear for over 90% reaction.

The dependence of the observed pseudo-first-order rate constants (k_{obs}) on the concentration of alkali metal ethoxide ([MOEt]) (Table 1) indicates that LiOEt is more reactive towards **1** than is NaOEt, over a large range of base concentrations. Similarly, it can be seen from Fig. 1 (Table 1) that NaOEt

[1]This paper is an extension of our series on Bond Scission in Sulfur Compounds. For previous papers in this series see ref. 1.

	1.788	9.80	1.638

is, in turn, more reactive towards **1** than is KOEt. A particularly striking feature of the plots of k_{obs} vs. [MOEt] (Fig. 1) is the upward curvature displayed in the LiOEt, NaOEt, and KOEt systems, indicating a disproportional increase in rate as the concentration of base is increased.

Effect of complexing agents

Reactions of **1** with LiOEt, NaOEt, and KOEt in the presence of excess complexing agent were carried out and the results are given in Table 2 and plotted in Fig. 1 for the lower MOEt concentration range. It can be seen from Fig. 1 that these data fall on the same plot, within experimental error, and that the plot is essentially linear.

Further experiments were performed under varying concentrations of added macrocyclic crown ether and cryptand to base. The effect of adding complexing agent to the reaction of LiOEt and NaOEt with **1** is shown in Fig. 2 (Table 3). Increasing the concentration of complexing agent at a constant base concentration causes a marked decrease in rate until a minimum value is reached, following which addition of more complexing agent no longer has any effect. The minimum value attained is similar for each system and is therefore assumed to correspond to the rate constant for the reaction of free ethoxide ion (k_{EtO^-}), since at the concentrations of crown ethers and cryptands employed the metal ions should be completely complexed. It is apparent from Fig. 2 that the [2.2.2]cryptand is more effective at complexing sodium ion than the macrocyclic ether dicyclohexyl-18-crown-6 (DC18C6), since the minimum rate is reached at a smaller relative concentration of complexing agent.

Effect of metal salts

Since the alkali metal ion apparently plays a significant

For personal use only.

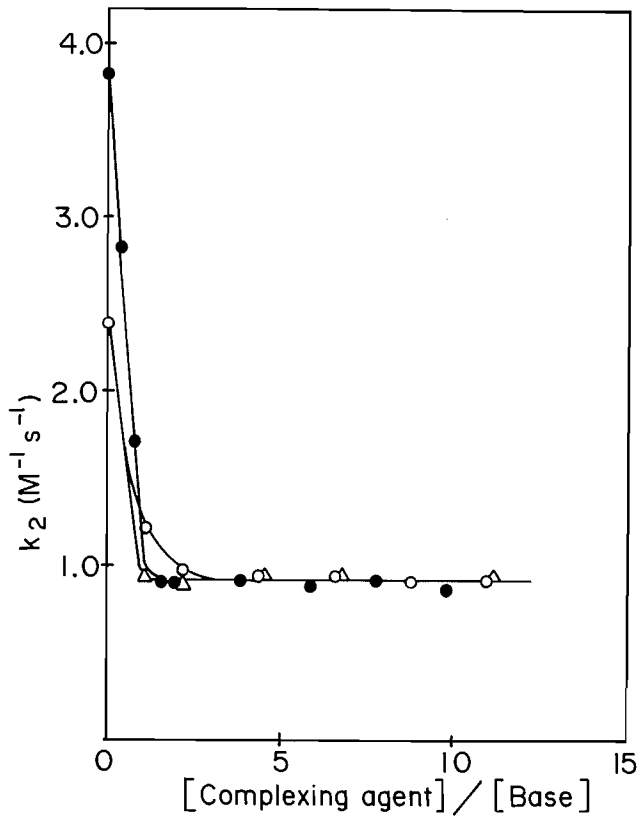

FIG. 2. Effect of added [2.1.1]cryptand on the reaction of **1** with LiOEt (●); effect of added DC18-crown-6 (○) and [2.2.2]cryptand (△) on the reaction of **1** with NaOEt, in EtOH.

catalytic role in this reaction, it was anticipated that addition of metal ion, in the form of an unreactive salt, should produce an increase in reaction rate. Such an increase was in fact observed (Fig. 3) when KSCN and KOAc were added to the KOEt reaction system (Table 4), and when LiSCN, LiOAc, $LiNO_3$, and $LiClO_4$ were added to the LiOEt reaction system (Table 5). As the concentration of metal ion was increased, the rate increased until a plateau was reached; after the initial increase, the rate either leveled off or began to decrease. Since the reactions with added metal ions do not reach a common level, and because of the complexity of possible anionic effects, it is difficult to account quantitatively for these specific salt effects. However, the maximum second-order rate constant attained for the reaction of **1** with LiOEt in the presence of added Li^+ ions was 17.5 M^{-1} s^{-1}. When K^+ ions were added to the reaction with KOEt the maximum rate constant observed was 3.76 M^{-1} s^{-1}. These results clearly demonstrate that the addition of metal ions has a catalytic effect on the reactions.

Discussion

The observed rate behaviour for the reaction of **1** with LiOEt, NaOEt, and KOEt alone (Fig. 1), coupled with the decrease in rate with added complexing agent (Fig. 2), and the increase in rate with added metal ion (Fig. 3), indicate a mechanism in which nucleophilic displacement of **1** by ethoxide is catalysed by the alkali metal cations.

The role that the metal ions play in bringing about the rate enhancement is of interest in this specific system and in general, and the ensuing discussion considers different pathways for metal ion involvement. Association of the metal ion with both ground state and transition state must be considered. As well,

[a]The second-order rate coefficient, $k_2 = k_{obs}/[Base]_0$.

one must consider whether only the free (dissociated) metal and alkoxide ions are involved in the reaction, or whether alkali metal – ethoxide ion pairs are the effective catalytic species, or if an intermediate situation exists.

1. Pathways for metal-ion involvement

First, we define the uncatalysed process, i.e., without the involvement of metal ions; this will occur when excess crown ether or cryptand complexing agent is present to complex the cation. Thus, one can depict the basic reaction of the substrate with ethoxide as proceeding by rate-determining attack of the free nucleophile at the phosphorus centre of **1** to form a pentacoordinate intermediate, **2**, followed by expulsion of the leaving group in a subsequent fast step (eq. [1]):

The rate equation for the reaction can be described by eq. [2], where S denotes the substrate:

[2] Rate = $k_{EtO^-}[EtO^-][S]$

The involvement of metal ions in the reaction can occur in various ways and these have to be examined in order to account for the observed catalysis. We consider below two possibilities: (1) the free (dissociated) M^+ is complexed with the substrate in a rapid preequilibrium, and (2) reaction occurs via the metal–alkoxide ion pairs.

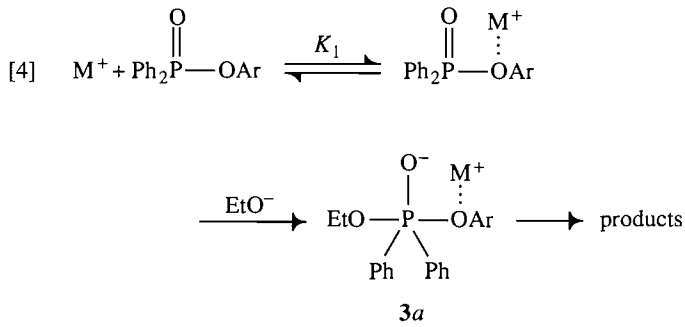
[a]The second-order rate coefficient, $k_2 = k_{obs}/[LiOEt]_0$.

(a) Pre-association of M^+ with substrate

Two possible sites for coordination of the metal cation can be considered:

(*i*) Coordination of the metal ion could occur at the phosphoryl oxygen, i.e.,



3

Coordination of M^+ at P = O will have the effect of increasing the electrophilicity of the phosphorus atom, thereby facilitating attack by the nucleophile at P.

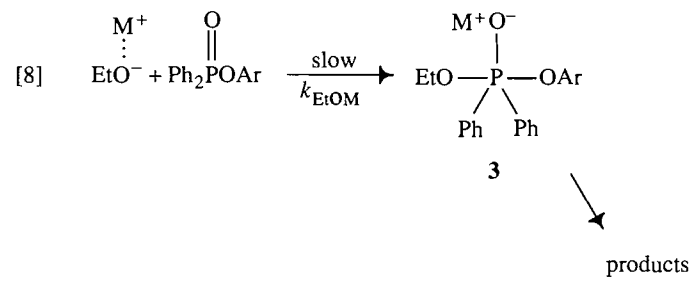
(*ii*) Complexation of the metal ion could also occur with the oxygen of the leaving group, i.e.,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

3*a*

The metal ion would thus act as an electrophilic catalyst in facilitating expulsion of the leaving group. This could be important if cleavage of the P—OAr bond is involved in the rate-determining step.

The rate equation *for both of these cases* will assume the form of [5], and eqs. [6] and [7] then follow:



$$[5] \quad \text{Rate} = k_2[EtO^-][SM^+]$$

$$[6] \quad K_1 = \frac{[SM^+]}{[S][M^+]}$$

$$[7] \quad \text{Rate} = k_2K_1[EtO^-][M^+][S]$$

(b) Reaction via metal–alkoxide ion pairs

In this pathway, attack by the metal–alkoxide ion pair occurs in a concerted fashion to give rise to the pentacoordinate intermediate associated with the metal ion.

3

products

The metal ion would facilitate the reaction by aligning the nucleophile in the best orientation for attack as well as, through coordination at P = O, stabilizing the developing negative charge of the transition state leading to the intermediate.

The rate equation for this mechanism can be described by [9] where k_{EtOM} refers to the second-order rate coefficient of the ethoxide ion pair.

$$[9] \quad \text{Rate} = k_{EtOM}[EtOM][S]$$

The above pathways have been depicted as proceeding through a pentacoordinate intermediate with attack of the nucleophile being rate determining. The formation of a pentacoordinate intermediate in the rate-determining step of the alkaline hydrolysis of aryl diphenylphosphinothioates has been proposed, based on the correlation of rate constants with Hammett σ values rather than σ^- values, and on the magnitude of the Hammett ρ value (7). We have studied the ethanolysis reaction of substituted aryl diphenylphosphinates and, based on Hammett ρ values and correlation of rates with σ^0 constants, similarly propose the formation of an intermediate. The results of these experiments will be presented subsequently in this series.

2. Reactivities of metal–alkoxide ion pairs (k_{EtOM}) and of dissociated anions (k_{EtO^-})

Conventional wisdom would suggest that, in nucleophilic displacement reactions, the free (dissociated) nucleophile should be more reactive than the ion-paired species. However, the plots displayed in Fig. 1 show an *upward curvature* for the rate constants with increasing EtOM concentration, and this contrasts with expected behaviour if free ethoxide were more reactive than the ion-paired species. In fact, a number of S_N2 processes at saturated carbon centres have been found to be characterized by *downward curvature* of the *k* vs. [Nu] plots (8–12), which was interpreted as arising from decreased reactivity of the ion-paired species as compared to the dissociated anions. It was also found that the rate constant varied with the nature of the metal counterion, in parallel with the dissociation constant, i.e., the more tightly associated M^+Nu^- ion pairs were considered to be the least reactive (12).

In the present system, the upward curvature observed in the plot of *k* vs. [EtOM] (Fig. 1), as well as the decrease in rate with added complexing agent (Fig. 2), and the increase in rate with added metal ion (Fig. 3), are indicative of a mechanism in which the ion-paired nucleophile is more reactive than the free ion. Common metal ions should increase the concentration of associated ethoxide relative to free ethoxide by shifting to the left the equilibrium in eq. [10].

$$[10] \quad EtOM \overset{K_d}{\rightleftharpoons} M^+ + EtO^-$$

Considering that in the present system both free and associated ethoxide could be reactive species, the relevant rate equation will be

$$[11] \quad k_{obs} = k_{EtO^-}[EtO^-]_{eq} + k_{EtOM}[EtOM]_{eq}$$

The relative reactivities of the two species can now be derived.

The rate constant for the reaction of **1** with free ethoxide ion (k_{EtO^-}) was determined by linear regression analysis of the kinetic data for the reaction of **1** with LiOEt, NaOEt, and KOEt in the presence of excess complexing agent (Table 3), which yielded $k_{EtO^-} = 0.980\ M^{-1}\ s^{-1}$. To evaluate k_{EtOM} (eq. [11]), it is necessary to calculate the concentrations of the two species, making use of known metal–ethoxide dissociation constants.

K_d values, determined from conductance data, have been reported as follows (13, 14): LiOEt, 0.00472 M; NaOEt, 0.009804 M; KOEt, 0.0111 M. Using these values, the equilibrium concentrations of free ethoxide can be calculated from the initial stoichiometric concentration of ethoxide ($[EtOM]_0 = [EtO^-]_{eq} + [EtOM]_{eq}$) by means of eq. [12], which follows from manipulation of eq. [10] and solution of the resulting quadratic.

$$[12] \quad [EtO^-]_{eq} = 0.5[-K_d + (K_d^2 + 4K_d[EtOM]_0)^{1/2}]$$

The $[EtO^-]_{eq}$ values calculated in this manner are given in Table 6.

Now, eq. [11] can be rewritten as eq. [13], since $[EtOM]_{eq}$ is equal to $[EtO^-]_{eq}^2/K_d$, which predicts a linear plot for $k_{obs}/[EtO^-]_{eq}$ vs. $[EtO^-]_{eq}$, with k_{EtOM}/K_d as slope and k_{EtO^-} as intercept.

$$[13] \quad \frac{k_{obs}}{[EtO^-]_{eq}} = k_{EtO^-} + \frac{k_{EtOM}}{K_d}[EtO^-]_{eq}$$

The resulting plots (Fig. 4) are reasonably linear at the lower base concentrations and the initial slopes yield the ion-paired rate constants: $k_{LiOEt} = 22.8\ M^{-1}\ s^{-1}$, $k_{NaOEt} = 9.30\ M^{-1}\ s^{-1}$, $k_{KOEt} = 4.84\ M^{-1}\ s^{-1}$ (Table 7). The curvature observed in the plots of Fig. 4 in the higher range of ethoxide concentrations suggests the involvement of more than one metal cation,

ethoxide anion, or ion pair. No definite information regarding this aspect is available at this time.

One can also use a nonlinear curve-fitting analysis of the k_{obs} and $[EtOM]_0$ data to derive values of k_{EtOM}, by means of the known K_d and k_{EtO^-} values. This method yielded the following rate constants; $k_{LiOEt} = 24.0\,M^{-1}s^{-1}$, $k_{NaOEt} = 11.6\,M^{-1}s^{-1}$, and $k_{KOEt} = 3.78\,M^{-1}s^{-1}$ (Table 7).

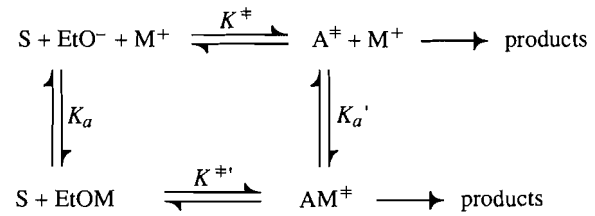
[a]Ion-pairing treatment.
[b]Nonlinear least-squares analysis.

The dissection of k_{obs} into the contributions by free and ion-paired ethoxide by the above treatment yields k_{EtOM} values considerably larger than k_{EtO^-} values, the k_{EtOM}/k_{EtO^-} ratio ranging from ca. 5 for KOEt to ca. 25 for LiOEt. These derived values are concordant with the main experimental observations in the present system. However, on their own, these results do not give insight into the mechanism by which the metal ions catalyse the reaction, and this is considered in the following section.

3. *Catalysis by M^+: ground state versus transition state interactions*



For catalysis to occur in this system, there has to be a decrease in the free energy of activation in the presence of metal ions. This can result from interaction of M^+ with the ground state, transition state, or a combination of the two. In the preceding

section we considered the interaction between M^+ and EtO^-, for which K_a (K_d^{-1}) values are known. Since there is no evidence for an appreciable interaction between M^+ and the substrate, the aforementioned M^+–EtO^- interaction is taken as the main ground state interaction.

Considering now interaction of M^+ with the transition state, Kurz (15) has shown that it is possible to calculate a virtual association constant of a catalyst with the transition state from basic transition theory by means of a thermodynamic cycle as illustrated in Scheme 1.

SCHEME 1

Here, $K^‡$ and $K^{‡\prime}$, are the equilibrium constants for the formation of the uncatalysed and catalysed transition states ($A^‡$ and $AM^‡$), while K_a and K_a' are the equilibrium association constants of M^+ with EtO^- and the transition state, respectively. This scheme requires the assumption that the concentration of transition states is at its equilibrium value with respect to the concentration of reactants. Since EtO^- and EtOM are in equilibrium, then $AM^‡$ will be at its equilibrium concentration with respect to $A^‡$, even though there is no direct dynamic equilibrium between the two transition states. It follows that

$$[14] \quad K_a' = \frac{k_{EtOM}K_a}{k_{EtO^-}} = \frac{k_{EtOM}}{k_{EtO^-}K_d}$$

K_a' values can therefore be determined using the known dissociation constants (K_d) of the metal–ethoxide ion pairs and the rate constants of free ethoxide and the metal–ethoxide ion pair.

For the reaction of **1** with ethoxide ion, the equilibrium constants for the association of the transition state with the cation (K_a') are calculated to be Li^+, 5188 M^{-1}; Na^+, 1207 M^{-1}; K^+, 347 M^{-1}. The association constants (K_a) for the alkali metal ethoxides are LiOEt, 212 M^{-1}; NaOEt, 102 M^{-1}, KOEt, 90 M^{-1} (see Table 8). Comparison of the magnitudes of K_a' and K_a clearly shows that the transition state is more tightly associated with the metal ion than is the ethoxide ion, and hence the transition state is the more stabilized.

The above considerations can nicely be illustrated by means of free energy – reaction coordinate profiles. In Fig. 5A, path *a* describes the uncatalysed reaction of the substrate with EtO^-, while the reaction with EtOM is illustrated in path *b*. Metal ion catalysis of the reaction will be observed when the difference in free energy between $AM^‡$ and $A^‡$ ($\delta G^‡$) is greater than the difference in free energy between EtOM and $M^+ + EtO^-$ ($\delta G°$). That is, when the transition state is stabilized to a greater extent than the ground state of the nucleophile (16, 17). This situation will occur when association of the metal ion with the transition state (K_a') is greater than its association with ethoxide ion (K_a). The present system clearly conforms to this requirement.

It is now necessary to account for catalysis in the reaction of free ethoxide ions as well. In this situation the involvement of both EtO^- and M^+ can be discussed in terms of the preassociation pathway, introduced in the previous section. The free

TABLE 8. Equilibrium constants for the association of alkali metal ion with ethoxide ion (K_a) and transition states (K_a')

Metal ion	K_a (M^{-1})[a]	K_a' (M^{-1})

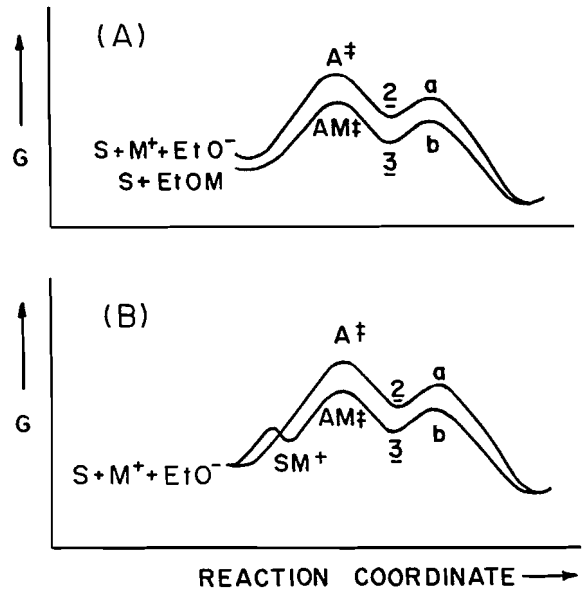

FIG. 5. (A) Path *a* illustrates the uncatalysed reaction of substrate (S) with EtO^-, while path *b* shows the lowering of both ground state and transition state free energies for the reaction of metal-alkoxide ion pairs due to association with M^+. (B) Catalysis by preassociation of M^+ with S is shown in path *b* while path *a* represents again the uncatalysed reaction.

energy – reaction coordinate diagram for this mechanism is shown in Fig. 5B, path *b*, which assumes a small equilibrium constant value ($K_1 \ll 1$), while path *a* depicts again the uncatalysed process. For path *b*, association of the substrate with the metal ion results in formation of a metal ion – substrate complex (SM^+), which can then react with ethoxide ion to give a metal-ion stabilized transition state ($AM^‡$). Lowering of the free energy of activation results from the enhanced electrophilicity of the phosphinyl group following coordination of M^+ with P=O.

In the above analysis we considered catalytic pathways involving (1) preassociation of M^+ with substrate and (2) reaction via metal—alkoxide ion pairs. A combination of these, and still other pathways, may be possible. However, it is difficult to differentiate between (1) and (2) since they are kinetically indistinguishable. Regardless of how S, M^+, and EtO^- come together, the key concern is to find satisfactory explanation for stabilization of the transition state in this system. This is considered in the next section in terms of the ion-pair model. The role of solvent molecules is also discussed.

4. Interaction of M^+ with the transition state: a mechanistic model

In considering transition state interactions involving the

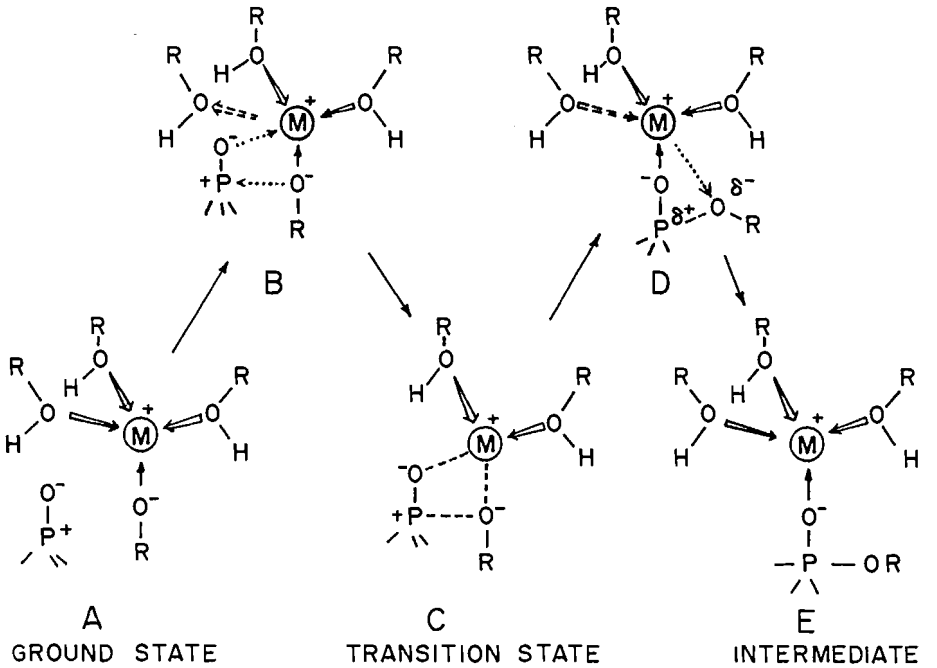

FIG. 6. Proposed model for nucleophilic attack of a metal-ion-paired alkoxide with the phosphinate centre illustrating the role of metal ion and solvent molecules.

metal cation, the size of M^+ and the spatial arrangement of the donor oxygen atoms of the nucleophile, substrate, and solvent in the coordination sphere of M^+ will contribute to the overall effectiveness of complexation. These factors are considered below.

The results in Table 8 clearly show a dependence of the association constant for binding of the metal ion with the transition state and with ethoxide ion (K'_a and K_a), on the size of the metal cation. Ignoring for the moment the role of the solvent, the fact that Li^+ is a better catalyst than Na^+ or K^+ may be a consequence of its smaller size, since the attraction between the metal ion and the intermediate will depend on the distance by which the centres of charge are separated. The crystallographic ionic radii of the metal ions have been given as Li^+, 0.60 Å; Na^+, 0.96 Å; and K^+, 1.33 Å (18). It follows that for the reaction of **1** with EtOM, the smaller the metal ion, the greater its association with the phosphinyl oxygen atom and, consequently, the larger the catalytic effect of the metal ion.

Studies of alkali metal ions in methanol have shown that the inner solvation sphere of Li^+ contains four solvent molecules (19), while Na^+ contains six solvent molecules in its first solvation sphere (20). Assuming for the present purpose that the metal ion has four coordination sites, one can depict the reaction of the ion-paired ethoxide with the phosphinyl group to form a negatively charged pentacoordinate intermediate as in Fig. 6. For simplicity, the solvation of P^+–O^- and RO^- is not shown in this figure.

In this illustration (Fig. 6), bond formation between the alkoxide oxygen and the phosphorus atom of the reactants (A) occurs concomitantly with association of the phosphinyl oxygen with M^+ and displacement of a solvent molecule from the inner coordination sphere of M^+ (Structure B). This leads to a transition state that has the metal ion coordinated to both the phosphinyl and alkoxide oxygen centres as well as to solvent molecules (Structure C). As P—OR bond formation progresses further, the negative charge on the alkoxide moiety decreases, weakening its electrostatic interaction with M^+ while association of M^+ with the phosphinyl oxygen increases (Structure D). It is also shown in Structure D that as the interaction between M^+ and alkoxide weakens, a solvent molecule may then reoccupy a coordination site around the metal ion. This results in the formation of intermediate E, which can be considered as being an essentially contact-ion-paired species.

The overall process A→E is essentially the transfer of M^+ (externally solvated) (21) from one ion-paired species to another, i.e., from the alkoxide oxygen to the phosphinyl oxygen, with bond formation occurring between the alkoxide oxygen and the phosphorus centre. Importantly, one sees that in the transition state C, M^+ is chelated to *two* oxygens, both of which carry substantial negative charge (see below), which leads to increased stabilization relative to alkoxide ion association with M^+.

It has recently been suggested (22, 23), based on MO calculations, that the P = O group (**4**) exists primarily in the dipolar form (**5**), i.e., with a highly developed negative charge on the phosphinyl oxygen atom.

4 **5**

In the transition state for the reaction of EtO^- at the phosphorus center, there would be effectively full negative charge developed on the phosphinyl oxygen, with very little delocalization of negative charge in the transition state of the type usually associated with, for example, addition to carbonyl compounds. This would tend to strengthen the interaction of the metal ion with the phosphinyl group. Therefore, the increase in reactivity due to stabilization of the transition state ($Li^+ > Na^+ > K^+$), as well as the correlation of the rate increase with decreasing crystallographic ionic radius, is consistent with this model of a contact-ion-paired intermediate.

To further investigate the effect of delocalized charge on the association of the metal ion with the transition state in displacement reactions of this type, a number of other substrates in which the charge is expected to be more delocalized (e.g., PhC(O)OAr, $PhS(O)_2OAr$) or less delocalized (e.g., $Me_2P(O)OAr$) have been studied with respect to their reactivities towards ethoxide and other nucleophiles, and the effect of metal ions on these reactions. The results of these investigations will be presented in subsequent papers in this series.

Experimental

Materials

Dry ethanol was obtained by refluxing absolute ethanol with magnesium turnings in the presence of iodine followed by distillation. Solutions of potassium or sodium ethoxide were prepared by dissolving clean potassium or sodium metal (Aldrich) in dry ethanol at 0°C. Lithium ethoxide solutions were prepared in a similar manner by dissolving lithium hydride (Alfa–Ventron) in dry ethanol. The ethoxide solutions were filtered at the end of the reaction in the glove box to remove any insoluble materials. The concentration of base was determined by titration with standard HCl. Solutions were prepared under a stream of nitrogen or in a dry N_2 atmosphere in a glove box.

The inorganic salts KOAc, KSCN (BDH), LiOAc, $LiClO_4$ (Fisher), $LiNO_3$ (Merck), and LiSCN (Alfa), reagent grade, were dried in a desiccator under vacuum (ca. 1 Torr; 1 Torr = 133.3 Pa) over P_2O_5.

The *p*-nitrophenyl diphenylphosphinate (**1**) used in this study was prepared as previously described (24).

Kinetic measuremnts

Kinetic reactions were generally conducted using an alkoxide concentration in the range $(1–5) \times 10^{-3}$ M. Due to the high extinction coefficient of *p*-nitrophenoxide (24 000 M^{-1} cm^{-1}), it was necessary to use a relatively low concentration of substrate (ca. 5×10^{-5} M). This range of concentrations gave pseudo-first-order conditions in which the base was in 20 to 100-fold excess of the substrate.

Kinetic runs that were relatively slow were followed spectrophotometrically using either a Beckman DU-8, Perkin–Elmer Lambda-5, or Perkin–Elmer 552 spectrophotometer. The instruments were equipped with thermostatted cell holders and the temperature inside the 10-mm quartz cuvette was maintained at 25.0°C. For relatively fast kinetic runs the reaction was followed using a Hi-Tech stopped-flow module equipped with a thermostatted water bath coupled to a McPherson monochrometer and Can-Tech transient recorder. The spectral traces were displayed on a Hewlett–Packard oscilloscope and the data were treated directly by a Commodore CBM 8032 computer.

Novel regio- and stereoselective modifications of heparin in alkaline solution. Nuclear magnetic resonance spectroscopic evidence

MAHESH JASEJA, RABINDRA N. REJ,[1] FRANÇOIS SAURIOL, AND ARTHUR S. PERLIN
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received January 3, 1989

MAHESH JASEJA, RABINDRA N. REJ, FRANÇOIS SAURIOL, and ARTHUR S. PERLIN. Can. J. Chem. **67**, 1449 (1989).

Nuclear magnetic resonance spectroscopic evidence is presented in characterizing three new structurally modified forms of heparin. One of these, polymer M-I, represents a conversion of about two-thirds of the α-L-iduronic acid 2-sulfate residues (**1**) into residues of a 2,3-anhydro derivative (**3**), through the action of sodium hydroxide. The formation of **3** is attributed to a base-catalysed displacement of the sulfate group of **1** by an intramolecular attack of O-3 on C-2. In more concentrated sodium hydroxide solution, heparin is transformed almost quantitatively into polymer M-II, which differs from it in having residues of (non-sulfated) α-L-iduronic acid (**4**) in place of **1**. It is likely that **3** is an intermediate, and that a selective nucleophilic attack of hydroxide ion at C-2 accounts for the *ido* configuration in **4**. The third modification, giving polymer M-III, is induced when a neutral or weakly alkaline solution of M-I is heated at 70°C or above, which promotes a different stereochemistry in the hydrolysis of the 2,3-oxirane ring of **3**. Hence, in contrast to residues of **4** in M-II, most of the uronic acid residues of M-III appear to have the alternate, α-L-*galacto*, configuration. As shown by a comparison of beef lung and hog mucosal heparin, the rate at which M-I is converted into M-III is facilitated by the higher level of structural heterogeneity in the mucosal heparin. Whereas the formation of M-I, -II, and -III is accompanied by only moderate depolymerization, these novel polymers retain little of the anti-coagulant and anti-XA activities of the unmodified heparin.

Key words: NMR spectroscopy, heparin, desulfation, anhydroaldoside, base-catalysed displacement.

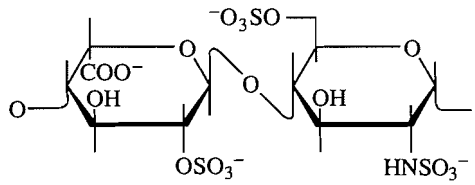
MAHESH JASEJA, RABINDRA N. REJ, FRANÇOIS SAURIOL et ARTHUR S. PERLIN. Can. J. Chem. **67**, 1449 (1989).

On présente les spectres de résonance magnétique nucléaire de trois nouvelles formes d'héparine modifiées structuralement. Dans l'une d'elles, le polymère M-I, environ les deux tiers des résidus sulfates de l'acide α-L-iduronique (**1**) ont été transformés en résidu du dérivé déhydro-2,3 (**3**) sous l'action de l'hydroxyde de sodium. On attribue la formation du dérivé **3** au déplacement, catalysé par une base, du groupe sulfate du composé **1** par suite d'une attaque intramoléculaire de l'oxygène en position 3 (O-3) sur le carbone en position 2 (C-2). Dans une solution plus concentrée d'hydroxyde de sodium, l'héparine se transforme presque quantitativement en polymère M-II qui diffère de l'héparine par la présence de résidus (non sulfatés) de l'acide α-L-iduronique (**4**) au lieu du composé **1**. Il est communément admis que le composé **3** est un intermédiaire, et qu'une attaque nucléophile sélective de l'ion hydroxyde en C-2 est responsable de la configuration *ido* dans le composé **4**. La troisième modification, conduisant au polymère M-III, est obtenue par chauffage à 70°C ou au-dessus d'une solution neutre ou faiblement alcaline du polymère M-I, ce qui favorise une stéréochimie différente dans l'hydrolyse du cycle oxyrane-2,3 du composé **3**. Cependant, contrairement au résidu du composé **4**, dans le polymère M-II, la plupart des résidus de l'acide iduronique du polymère M-III semble avoir possiblement une configuration α-L-*galacto*. La comparaison de l'héparine du poumon de boeuf et de la muqueuse du porc montre que la vitesse avec laquelle le polymère M-I se transforme en polymère M-III est favorisée par un haut degré d'hétérogénéité structurale dans l'héparine de la muqueuse. Cependant, la formation de des polymères M-I, M-II et M-III s'accompagne seulement d'une dépolymérisation modérée. Ces nouveaux polymères retiennent qu'une faible partie des activités anticoagulante et anti-XA de l'héparine non modifiée.

Mots clés : spectroscopie RMN, héparine, désulfation, aldoside déhydro, déplacement catalysé par une base.

[Traduit par la revue]

Introduction



Heparin, the clinically important blood anticoagulant, is an anionic polysaccharide that is generally administered in the form of its sodium salt and, less commonly, as a calcium salt. Barium, benzidene, and quaternary ammonium compounds of heparin find use (1–4) in its purification and fractionation, following its extraction from animal tissue sources.

In carrying out the preparation of the sodium salt of a purified heparin from its barium precursor, we converted the latter into the acid form of heparin with a cation-exchange resin and then, inadvertently, raised the pH of the polymer solution to ~11, rather than to neutrality. The strongly basic preparation of the sodium salt recovered from this solution was found to be characterized by nmr spectra strikingly different from those of neutral sodium salts of heparin. Moreover, during the acquisition of the spectra, which sometimes involved lengthy exposure of solutions of the modified heparin to temperatures of 65–70°C, it became apparent that additional changes in the polymer were induced. Yet another type of alteration was found when the heparin was subjected to more strongly alkaline conditions. To our knowledge, effects of this nature had not been observed previously, and are described here together with proposals as to their origin.

Results and discussion

The kinds of effects observed are illustrated in Fig. 1 with a beef lung heparin. Constituted mainly (5) of α-L-iduronic acid 2-sulfate (**1**) and 2-deoxy-2-sulfamino-α-D-glucose 6-sulfate (**2**), linked (1→4) in disaccharide repeating units (as shown),

1 **2**

this heparin gives (6–8) relatively uncomplicated spectra. Thus, the 300-MHz ^1H nmr spectrum of the *neutral* sodium salt in deuterium oxide (Fig. 1A) clearly reflects the high degree

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

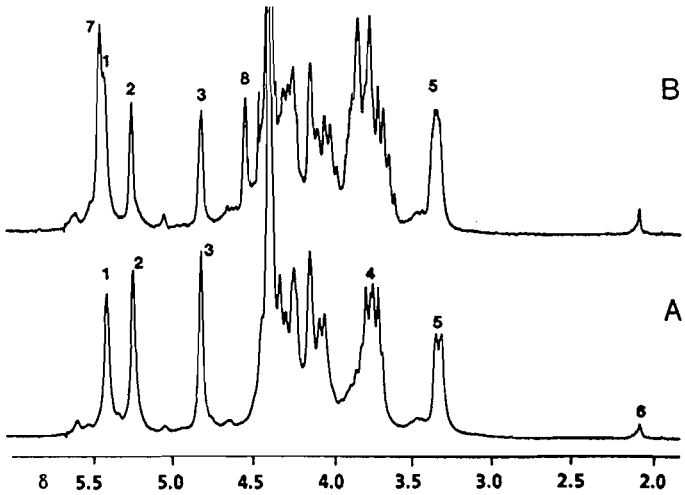

FIG. 1. The ^1H nmr spectra (300 MHz) of (A) beef lung heparin (sodium salt), in D_2O at 65°C; and (B) modified heparin M-I in NaOD (pD ~ 12) at 65°C. Signal designations: 1, A-1; 2, I-1; 3, I-5; 4, A-3, -4; 5, A-2; 6, acetamido CH_3; 7, I′-1; 8, I′-4 (I = **1**, A = **2**, I′ = **3**).

of structural homogeneity in the polymer. When an aqueous solution of the heparin was acidified with Amberlite IR-120 (H^+ form), followed by adjustment to pH 11 with sodium hydroxide, lyophilization, and deuterium exchange of the product, the spectrum shown in Fig. 1B was obtained.

The most striking difference between the spectrum (Fig. 1B) of the modified heparin, which will be referred to as "M-I", and that of the original material (Fig. 1A), is the decrease in the relative intensities of I-1 (δ 5.23) and I-5 (δ 4.80), i.e., the anomeric proton and 5-proton signals (7), respectively, of the iduronic acid 2-sulfate residue (**1**). This change is accompanied by the appearance of new signals such as those at δ 5.48 and 4.53, which, in terms of relative intensities, indicates that the shift displacements involved almost one-half of the uronic acid residues. Signals of the hexosamine residues (**2**) are affected far less: that of proton-2 (A-2), at δ 3.30, is slightly broadened whereas those due (8) to A-3, -4, and -5, in the vicinity of δ 3.6–3.9, are only dispersed somewhat differently. Hence, residues of **1** appeared to be the principal site of the polymer modification.

Formation and identity of polymer M-I

In pursuing these observations, it was found that the formation of M-I is highly sensitive to the experimental conditions used. This aspect of the reaction may be summarized by the following series of comments:

(a) A critical element was the fact that, as a requirement for the deuterium-exchange step with D_2O prior to the nmr examination, the alkaline solution of heparin was evaporated to dryness (either by lyophilization or by vacuum distillation of the solvent). Consequently the initial pH value of ~11 was not definitive, inasmuch as the polymer was subsequently exposed several times to a widely fluctuating concentration of base.

(b) The initial acidification step was only incidental. Providing that a sufficiently high concentration of alkali was used, the formation of M-I was observed. For example, it occurred when a solution of sodium heparin (40 mg) in water (10 mL) was adjusted to pH 11.2–11.5, followed by lyophilization, although not at all when the solution was initially at pH 10.5.

(c) Without the lyophilization step, the transformation of

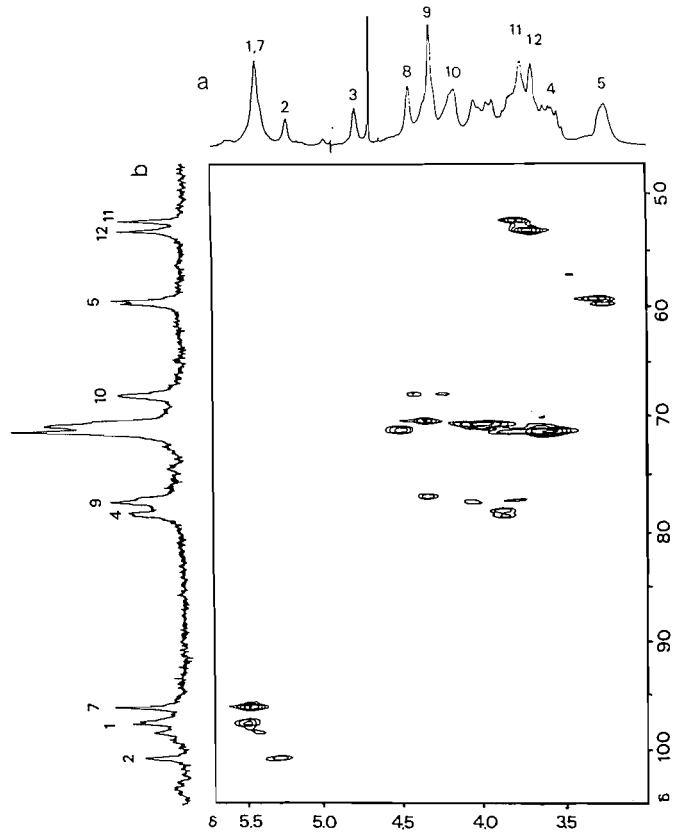

FIG. 2. The ^1H and ^{13}C heterocorrelation spectrum (300/75 MHz) of modified heparin M-I in NaOD (pD ~ 12) at 25°C; (a) ^1H spectrum; (b) ^{13}C spectrum. Signal designations: 1, A-1; 2, I-1; 3, I-5; 4, A-3, -4 (^{13}C-4 is A-4); 5, A-2; 7, I′-1; 8, I′-4; 9, I′-5, A-6; 10, A-6; 11, I′-3; 12, I′-2 (I = **1**, A = **2**, I′ = **3**).

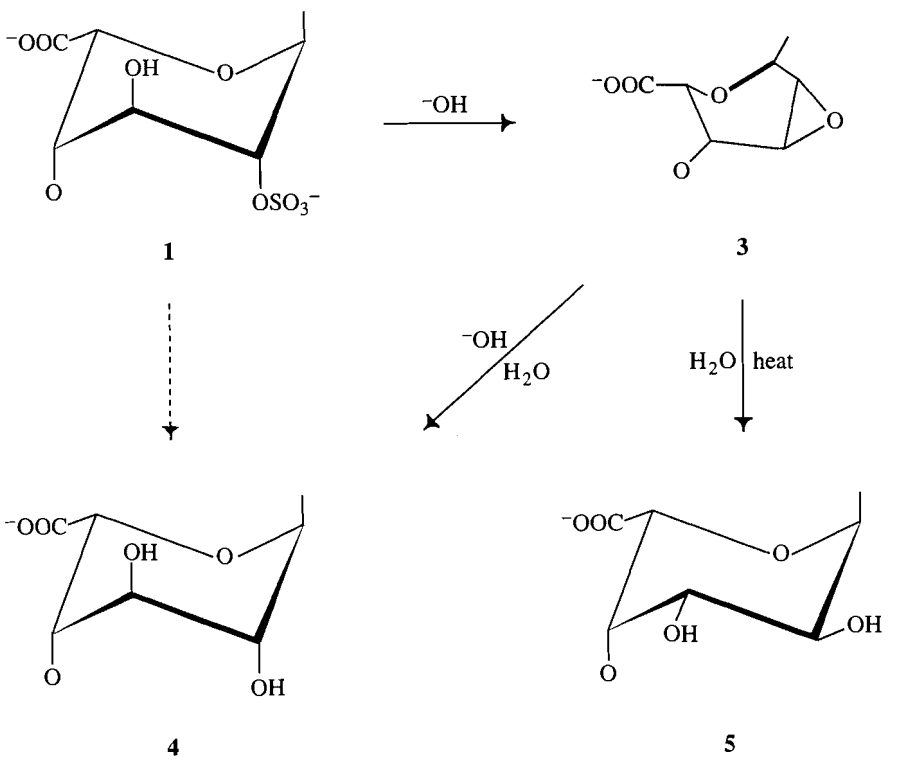
heparin into M-I required a much higher pH, and even then the rate of the reaction was far slower, e.g., a period of 4–5 days for a solution of sodium heparin (30 mg) in D_2O (0.5 mL) at pH ~ 13.5 (as monitored by nmr spectroscopy).

(d) The degree of conversion of heparin into M-I varied substantially among the group of experiments conducted along these lines, undoubtedly in response to differences in the heparin concentration, pH, and rate of lyophilization. Hence, in contrast to its presence at a level of ~40% in the mixed product represented by Fig. 1B, conversion yields of 65–70% were obtained in other instances, as shown in Fig. 2.

The corresponding ^1H–^1H correlation (COSY) spectrum afforded the assignments designated, and the ^1H chemical shifts listed in Table 1. Acquisition of a ^{13}C nmr spectrum and a ^{13}C–^1H heterocorrelation (HETCOR) spectrum (Fig. 2) then provided the ^{13}C chemical shifts given in the table (a DEPT experiment confirmed that only the ^{13}C signal at δ 69 was due to a methylene group, i.e., C-6 of **2**).



These data show that the formation of M-I entailed a number of large displacements of chemical shift of the uronic acid residues relative to those (**1**) of unmodified heparin, whereas those of the amino sugar (**2**) were little affected. Structural changes accompanying these displacements appeared to include such possibilities as (a) a conformational interconversion from the preponderant (7–10) $^1C_4$ (L) chair into the alternate chair, or skew, conformation; (b) the formation of a 2,3-cyclic sulfate, inasmuch as *trans* 2,3-cyclic sulfates are stable entities (11); or (c) the formation of a 2,3-anhydride. However, only the last was

consistent with the striking upfield location of ^{13}C resonances I′-2 and I′-3, at δ 53–54 (Table 1), which is in the range reported (12, 13) for several 2,3-anhydro-aldopyranoside derivatives. (Corresponding ^{13}C values for 2,3-cyclic sulfates are (14) δ ~79–80.) Although less definitive, the ^{1}H values of δ ~3.7 for I′-2 and I′-3 are closer to the range of δ 2.7–3.6 found (13) for the same group of 2,3-anhydrides than that (14) of δ 4–5 for related 2,3-cyclic sulfates.

Consequently, the transformation of heparin into M-I in alkaline solution must involve an intramolecular base-catalysed displacement of the 2-sulfate group of **1** by vicinal O-3 to form a 2,3-oxirane derivative. A facile displacement may readily be envisaged (15) for the $^1C_4$ (L) conformation (see Scheme 1), involving the *antiperiplanar* 2- and 3-substituents, which would give rise to residues of 2,3-anhydro-α-L-gulohexopyranose uronic acid (**3**). According to the relative intensities of the ^{1}H resonances in Fig. 2 (e.g., comparing signal I′-4 with I-5), about two-thirds of the uronic acid residues in polymer M-I are represented by **3**. Consistent with this proposal was the fact that 0.7 moles of sulfate ion (SO_4^{2-} by ion-exchange chromatography) per mole of **1** was liberated during the formation of M-I.

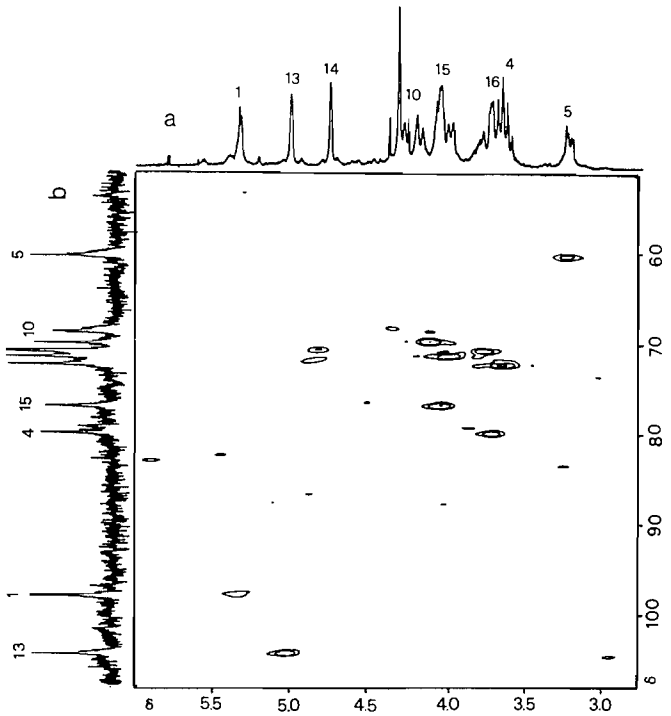

FIG. 3. The ^{1}H and ^{13}C heterocorrelation spectrum (300/75 MHz) of modified heparin M-II in NaOD (pD ~ 13) at 25°C; (a) ^{1}H spectrum (that shown was recorded at 65°C for improved resolution); (b) ^{13}C spectrum. Signal designations: 1, A-1; 4, A-3, -4 (^{13}C-4 is A-4); 5, A-2; 10, A-6; 13, I″-1; 14, I″-5; 15, I″-3, -4; 16, I″-2 (A = **2**, I″ = **4**).

A second, base-catalysed, modification of heparin

As already indicated, the formation of M-I in sodium hydroxide solution occurred only when the heparin was subjected to an appropriate concentration of base. For example, the initial pH of the solution lyophilized was in the region of 11–11.5. However, in analogous experiments with solutions adjusted initially to a range of pH 11.8–12.8, the nmr spectra of the products showed that another product was formed at these more elevated levels. At pH 12.5 and above, this second modification, M-II, was virtually the only species detected, and hence represented an essentially quantitative interconversion from heparin, as is evident from the ^{1}H and ^{13}C nmr spectra in Fig. 3.

The ^{1}H chemical shift data for M-II (Table 1) obtained with the aid of a COSY spectrum, together with the ^{13}C chemical shifts derived from the HETCOR spectrum (Fig. 3), indicate that, as in the formation of M-I, only the L-iduronic acid moiety of the heparin was altered. In this instance, moreover, all such residues were affected and, as shown by the presence of 0.9 moles of SO_4^{2-} per mole of **1** in the reaction medium, the 2-sulfate substituent must have been involved.

That the sulfamino group remained intact is shown by the location of the A-2 signal in all of the ^{1}H spectra (Figs. 1 and 2). Hence, its chemical shift remained essentially constant at δ ~3.3 (as in Fig. 1A for residues of **2**). Had hydrolysis to the amino function occurred, then the proton α to a free amino group would have given rise (6) to a signal at δ ~2.8, at the high pH at which these spectra were recorded. Similarly, hydrolysis of the 6-sulfate group of hexosamine residues (**2**) would have been readily detectable (16) in the ^{13}C spectra as a decrease in the relative intensity of its C-6 signal (δ 69), and the emergence of a corresponding signal at δ 62 for the liberated 6-hydroxymethyl group.

As there is a close similarity between the ^{1}H and ^{13}C chemical shifts for the uronic acid residues of M-II and those of the (non-sulfated) α-L-iduronic acid residue (**4**) in dermatan sulfate (Table 2), it is proposed that M-II is comprised mainly of residues of **4** and hexosamine **2**.

By adjusting the pH of a solution of M-I to 12.5 with sodium hydroxide, then subjecting it to lyophilization and deuterium exchange in the usual manner, it was determined that M-I is almost quantitatively converted into M-II at the concentration of base appropriately higher than that required for the formation of M-I itself. Hence, the ^{1}H nmr spectrum of the product was closely similar to that shown for M-II in Fig. 3. Therefore, the formation of the latter polymer involves M-I as an intermediate, and alkaline hydrolysis of the 2,3-anhydro ring of **3** (in M-I) occurs with high regio- and stereoselectivity, i.e., almost exclusively by nucleophilic attack of OH^- on C-2, to regenerate the α-L-*ido* configuration (**4**) (Scheme 1).

Chemical methods for desulfation of heparin

The removal of the various sulfate groups of heparin has received much attention, in attempts to determine possible functional roles that these substituents may play. Due to its marked acid lability, the sulfamino group undergoes (18) facile selective hydrolysis under conditions that leave other sulfate groups unaffected. However, prolonged treatment of heparin with, e.g., methanol – hydrogen chloride, also leads (19) to

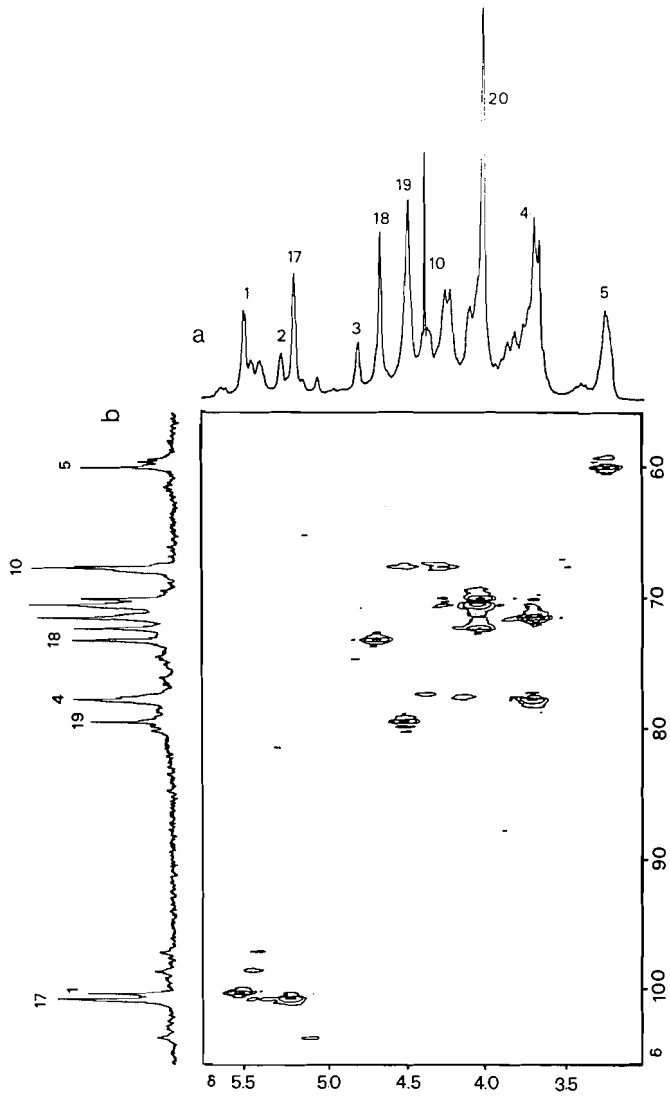

FIG. 4. The ^1H and ^{13}C heterocorrelation spectrum (300/75 MHz) of modified heparin M-III in NaOD (pD ~ 12) at 65°C; (a) ^1H spectrum; (b) ^{13}C spectrum. Signal designations: 1, A-1; 2, I-1; 3, I-5; 4, A-3, -4 (^{13}C-4 is A-4); 5, A-2; 10, A-6; 17, G-1; 18, G-5; 19, G-4; 20, G-2, -3 (I = **1**, A = **2**, G = **5**).

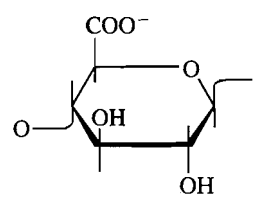
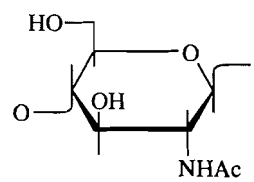
removal of the other sulfate groups. At close to neutrality, the pyridinium salt of heparin is effectively N- and O-desulfated (20) in hot, aqueous, dimethyl sulfoxide, whereby the rates of hydrolysis are (21) sulfamino ≥ ≥ 6-sulfate of **2** ≥ 2-sulfate of **1**. Although desulfation by alkali has long been recognized (22), the products obtained have not been well characterized. Presumably, some of the products would have included M-I and M-II.

A third modification of heparin (M-III)



During the acquisition of 2D spectra of modified heparin M-I, which involved lengthy heating of the solution at ~70°C to minimize line widths, new signals slowly emerged in the spectra. (This also occurred with the neutralized solution, although at a slightly slower rate.) By prolonging the heating period to 72 h, the ^1H spectrum shown in Fig. 4 was obtained. It represents modified polymer M-III. As was seen in the ^1H spectrum of M-I (Fig. 2), minor I-1 and I-5 signals due to intact residues of **1** are also present in Fig. 4, whereas the I′-1 and I′-5 signals of M-I are no longer detected. Rather, they appear to be replaced in this region by two new signals, at δ 5.18 and δ 4.60, designated G-1 and G-5. Other prominent new signals are found at δ 4.45 (no. 19) and δ 4.10 (no. 20), and there now is greater complexity in the signals associated with the anomeric proton (A-1, δ 5.4) and proton-2 (A-2, δ 3.3) of the hexosamine residues, reflecting the structural heterogeneity present.

From the corresponding COSY spectrum of M-III, and the ^{13}C–^1H correlation data illustrated in Fig. 4, the chemical shift parameters in Table 1 were derived. Clearly, during the transformation of M-I into M-III, the hexosamine residues (**2**) remained unaltered, and the 2,3-oxirane ring disappeared, accompanied by the appearance of a uronic acid entity that was distinct from α-L-iduronic acid (**4**). As already noted (Scheme 1), the latter is the product expected by nucleophilic attack of HO^- on C-2 of the oxirane ring of **3**. The alternative diastereomeric uronic acid, resulting from an attack at C-3, would be α-L-galacturonic acid (**5**). In fact, the overall ^1H and ^{13}C parameters for the new uronic acid moiety in M-III are in general agreement with those expected for such a residue as **5** (Table 2), a possibility that has been confirmed by chemical evidence (R. Rej and A. S. Perlin, unpublished data).



It is noteworthy that two different diastereoisomers (**4** and **5**) are produced, each almost exclusively, in the hydrolysis of anhydride **3**, one in concentrated alkali and the other under neutral, or weakly basic, conditions. Based on the known (15, 26) chemistry of ring-opening reactions of 2,3-anhydro-aldopyranosides, this high degree of regio- and stereoselectivity would not have been anticipated, nor are we able to account for it.

Influence of molecular constitution on the transformation of M-I into M-III

Although the preceding observations concern the influence of strong alkali on beef lung heparin, similar experiments were conducted with hog mucosal heparin, and fractions of it obtained by graded sedimentation of the barium salt. The hog mucosal material contains (6, 7) more residues of β-D-glucuronic acid (**6**) and 2-acetamido-2-deoxy-α-D-glucose (**7**)

6

7

than does beef lung heparin and, as its fractionation progresses, the precipitated materials are characterized (27) by an increase in the proportions of **6** and **7** and a decrease in molecular weight. Three of these fractions, nos. 4, 6, and 7 out of a total of seven, were subjected to the treatment with alkali, and heating at 70°C, described for the preparation of M-I and M-III from beef lung heparin. Representative of the ^1H nmr spectra of these fractions is Fig. 5, which shows that of fraction no. 6 (Fig. 5A), and its modified (M-I) product (Fig. 5B).

Whereas in the second stage transformation, to give M-III, the bovine heparin had required a heating period of 48–72 h to reach equilibrium, the hog mucosal fractions were fully modified in 24 h (no. 4), 12 h (no. 6), and 1 h (no. 7), respectively. The ^1H nmr spectra of these final products are shown in Fig. 6. Consequently, there is a direct correspondence

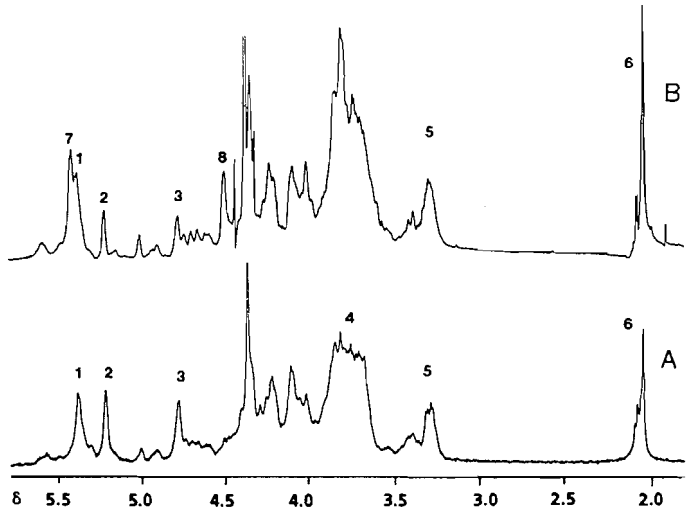

FIG. 5. The ^{1}H nmr spectra (300 MHz) of (A) hog mucosal heparin (fraction no. 6, sodium salt) in D_2O at 65°C; and (B) corresponding to modified heparin M-I in NaOD (pD ~ 12) at 65°C. Signal designations: 1, A-1; 2, I-1; 3, I-5; 4, A-3, -4; 5, A-2, A-2; 6, acetamido CH_3; 7, I′-1; 8, I′-4 (I = **1**, A = **2**, I′ = **3**).

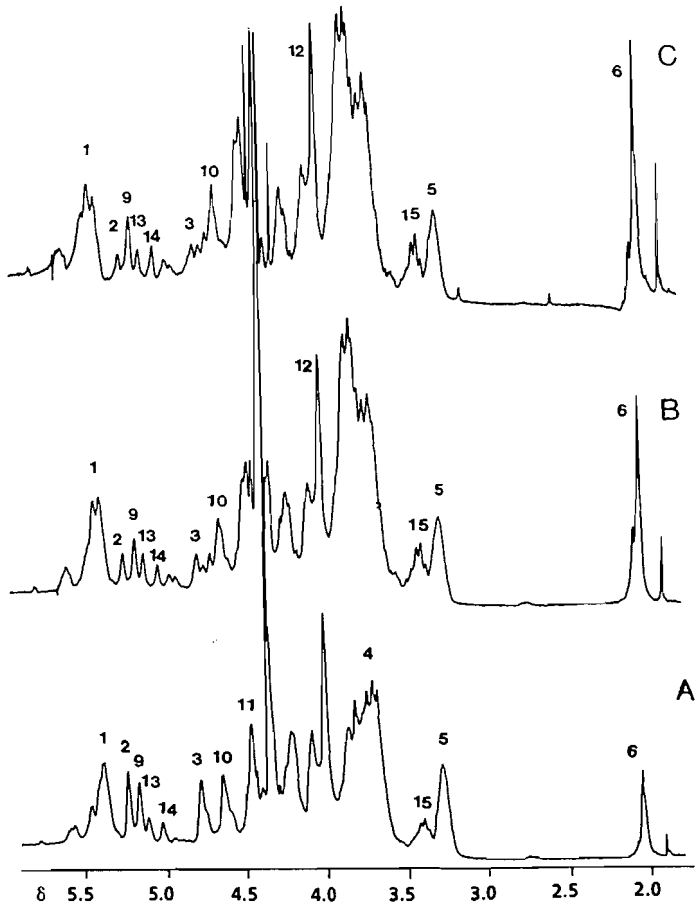

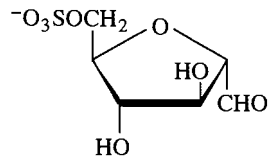

FIG. 6. The ^{1}H nmr spectra (300 MHz) of modified heparin corresponding to M-III, in NaOD (pD ~ 12) at 65°C, prepared from hog mucosal fractions (A) no. 4; (B) no. 6; (C) no. 7. Signal designations: 1, A-1; 2, I-1; 3, I-5; 4, A-3, -4; 5, A-2; 6, acetamido CH_3; 9, G-1; 10, G-5; 11, G-4; 12, G-2, -3; 13, G-1; 14, I′-1; 15, H-2 of D-glucuronic acid (**6**) and 2-acetamido-2-deoxy-D-glucose (**7**) (I = **1**, A = **2**, I′ = **4**, G = **5**).

between the ease with which M-III is produced from M-I and the molecular constitution of the polymers. Although the process is accelerated by both heat and base, it is also enhanced by structural inhomogeneity within the heparin molecule and (or) by a diminution in molecular size. The latter two possibilities are difficult to assess individually, because (27) the increase in heterogeneity is accompanied by a decrease in mass. However, evidence that chemical constitution plays a role has been obtained from the nmr spectra of modified heparin samples that were subjected to selective fragmentation.

Nuclear magnetic resonance spectra of products formed on deaminative degradation

When heparin is treated with nitrous acid, such residues as **2** that contain a 2-sulfamino group are converted by deaminative elimination (28) into *aldehydo*-2,5-anhydro-D-mannose residues (**8**), whereas those containing an N-acetyl group (such as **7**) are unaffected. For example, the depolymerization products of the hog mucosal heparin contain reducing-end residues of **8**

8

together with intact residues of **7**, as shown by the ^{1}H nmr spectrum (Fig. 7A) representing degraded fraction no. 4. Signals attributable to H-1 of **8** and neighboring **1** are observed at δ 5.15 and 5.20. In addition, H-1 peaks due to the unmodified residues of 2-acetamido-2-deoxy-α-D-glucose (**7**) and of residues of the uronic acid appended to it, are found at δ 5.42 and 5.30. The corresponding spectrum (Fig. 7B) for HNO_2-degraded fraction no. 6, a material that is richer in unreactive residues of **4**, clearly reflects the lower level of fragmentation effected.

Also evident from Fig. 7B is the fact that there is only a trace H-1 signal attributable to residues of **1** that are attached to residues of **7**. Consequently, prior to degradation, more of the residues of **1** were linked to **7** than to the 2-sulfamino isomer (**2**). This suggests that the modification of heparin occurs more readily with a disaccharide sequence of **1** and **7** than of **1** and **2**. Consistent with this suggestion, of course, is the greater resistance to change on the part of M-I from beef lung heparin. Perhaps a molecule of this latter type, due to its higher degree of structural homogeneity, is less easily perturbed than is a more heterogeneously constituted molecule derived from the mucosal heparin.

It is worth noting, in retrospect, that the present study originated in the detection, by nmr spectroscopy, of structural changes occurring during preparation of these lower molecular weight mucosal fractions, owing to their extreme sensitivity to alteration. Beef lung heparin was *then* examined as a "model" polymer, because of its greater constitutional homogeneity.

Influence of the chemical modifications of heparin on molecular size and biological activity

Not surprisingly, the structural changes induced in heparin by alkali and (or) heat were accompanied by a decrease in the molecular size of the polymer, as well as a reduction in its anticoagulant activity. Estimates of molecular weight by gel-filtration chromatography (Table 3) show that each modification step caused some depolymerization, which was most pro-

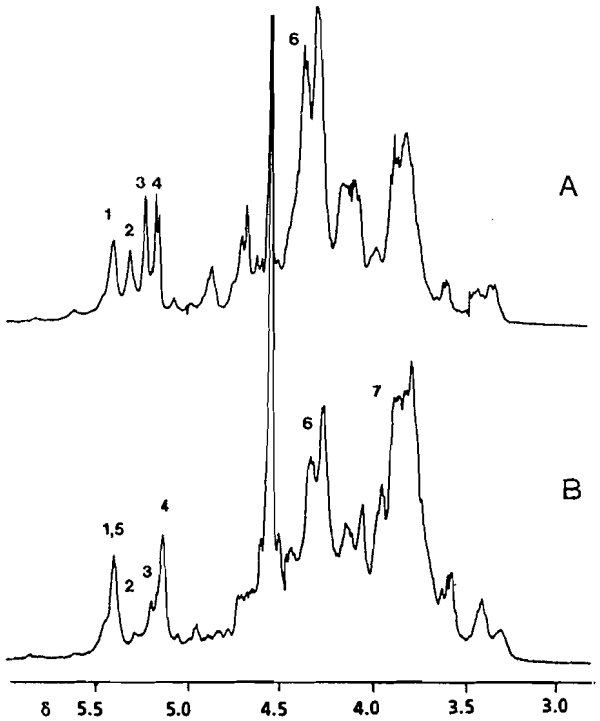

FIG. 7. The ^1H nmr spectra (300 MHz) of the products of deaminative degradation of (A) hog mucosal heparin (fraction no. 4); and (b) modified heparin M-III (from fraction no. 6), in D_2O at 65°C. Signal designations: 1, H-1 of **7**; 2, I-1 of residues appended to **7**; 3, I-1 of residues appended to residues of 2,5-anhydro-D-mannose (**8**); 4, H-1 of **8**; 5, G-1 of residues attached to **7**; 6, G-4; 7, G-2, -3 (I = **1**, G = **5**).

TABLE 3. Molecular weight and anticoagulant potency of modified heparins M-I, -II, and -III

Polymer	Molecular weight[a] (dalton)	USP potency (units/mg)	Anti XA activity (units/mg)
Heparin (beef lung)	9000	126	132
M-I	8000	73	26
M-II	6500	≤5	≤0.5
M-III	7500	70	24

[a]Estimated average value obtained by gel-filtration chromatography.

nounced under the strongly alkaline conditions required for the formation of M-II. As compared with a value averaging about 9000 daltons for the beef lung heparin, the value for M-II averaged about 6500, which also represented a more disperse range than observed with the unmodified polymer. M-I and M-III gave values of intermediate size. Consequently, all three stages of structural modification represent new polymers, of moderately high molecular weight, closely related to the heparin molecule.

Much more striking was the impact on the anticoagulant properties of heparin, as shown by the assays of USP and anti-XA potency (Table 3). Polymer M-II was virtually devoid of activity in both categories. In accord with other observations (9, 29) on modified heparins and synthetic oligosaccharides, this is suggestive (30) of a crucial contribution by the 2-sulfate group of the residues of **1** in heparin toward anticoagulant potency. Although M-I and M-III retain about one-half of the original USP activity, presumably most of this is attributable to the presence of about one-third of the unmodified heparin structure.[2] By contrast, the anti-XA activity was more drastically reduced and, on the basis of composition just discussed, implies a total loss of potency in M-I and M-III, as well as M-II. The two most extensively modified hog mucosal products, represented by Figs. 6B and 6C, gave U.S.P. values of 20 and 10 IU, respectively, as compared with values (27) of 90 and 60 IU for the corresponding, unmodified, heparin fractions. The reduced size of all of these polymers may be an additional factor, in view of the relatively low anticoagulant assays given by enzymatically or chemically produced low-molecular-weight heparins.

On the basis of these findings, it is not unreasonable to suggest that the lack of uniform anticoagulant activity commonly found among heparins (see, e.g., refs. 6, 31, and 32) may be related in certain instances to the observations reported here because, as already noted, some heparins will have been exposed to a wide variety of pH conditions during their isolation and purification.

Experimental

Beef lung heparin was furnished by the Upjohn Co., and hog mucosal heparin by Choay-Chimie. The latter heparin, after conversion into the barium salt, was fractionated from aqueous ethanol mixtures, as described earlier (4, 27).

To induce the formation of modified heparin M-I, a solution of heparin or heparin fraction (40 mg; either the sodium salt, or the acid form obtained from the barium salt by ion exchange) in 10 mL of water was adjusted to pH 11.5 with 0.1 N NaOH, and the solution was lyophilized. In various related experiments, either the initial pH was varied from 10.0 to 11.8, or the solution was concentrated to dryness *in vacuo* at 35°C or, following the formation of M-I, the excess of sodium hydroxide was removed by ion exchange or dialysis. A solution of the product in 99.8% D_2O was then subjected to deuterium exchange by repeated evaporation, or lyophilization, and the deuterated product was examined by nmr spectroscopy at a concentration of 25–30 mg/mL of 99.9% D_2O, with internal sodium 4,4-dimethyl-4-silapentane-1-sulfonate as reference (δ 0.0).

By storage of the nmr specimen of M-I at 65–70°C, or higher, the formation of modified heparin M-III, under basic or neutral conditions, was monitored spectroscopically.

Modified heparin M-II was prepared as described for M-I, except that the initial pH was adjusted to 12.5–12.8, followed by lyophilization, and deuterium exchange. In other experiments, M-II was obtained by lyophilization of a solution of sodium heparin (40 mg) in either 0.05 N, 0.1 N, or 1 N sodium hydroxide (10 mL), followed by the removal of excess base with ion-exchange resin, or by dialysis. The product was pale yellow, suggesting that some elimination had also occurred, a possibility reinforced (33) by the presence of the olefinic doublet at δ 5.8.

The nmr spectra were recorded at 300 MHz with a Varian XL-300 spectrometer. The shift correlation (HETCOR) experiments were acquired at 25 or 65°C, using a spectral width of 4290 Hz with 1 K data points for 64 increments. The data were zero-filled in the evolution domain, providing a matrix of 1 K × 256. A shifted sine-bell function was used prior to the Fourier transformation. The relaxation delay between experiments was 0.4–1.0 s.

For acquisition of the COSY spectra (at either 25 or 65°C), a spectral window of 970 Hz was used, with 512 data points for 128–256 increments. The data were zero-filled and transformed with a sine-bell function, and the relaxation delay was 1 s.

[2]This raises the, as yet unresolved, question as to whether M-I and M-III consist of a mixture of unaltered and altered polymer chains, or mixed structures.

The effect of the nature of the amine leaving group on the nature of the E2 transition state for the reaction of 1-phenylethylammonium ions with sodium ethoxide in ethanol

PETER JAMES SMITH[1] AND MD. AMIN

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received March 28, 1989

PETER JAMES SMITH and MD. AMIN. Can. J. Chem. **67**, 1457 (1989).

To investigate the effect of the leaving group on the elimination reaction of 1-phenylethylammonium ions with sodium ethoxide in ethanol at 60°C, the reaction of seven different quaternary ammonium salts and their β-deuterated analogues with trimethylamine, *N*-methylpiperidine, *N*-methyldiethylamine, triethylamine, *N,N*-dimethylbenzylamine, tripropylamine, and *N,N*-diethylbenzylamine as leaving groups has been studied. In all cases the elimination, which was shown to proceed via the concerted E2 process, was accompanied by competing substitution reactions. Although a significant dependence of the rate of the elimination process on the nature of the leaving group was noted, there was not any linear correlation with the basicity of the amine leaving group. The primary hydrogen–deuterium kinetic isotope effect for the elimination process, $(k^H/k^D)_E$, was found to increase initially with an increase of reaction rate, k_E^H, for substrates containing the leaving groups trimethylamine, *N*-methylpiperidine, *N*-methyldiethylamine, triethylamine, and *N,N*-dimethylbenzylamine; i.e., $(k^H/k^D)_E$ = 5.03, 5.26, 5.40, 5.83, and 5.85, respectively. A further increase in rate, using substrates with tripropylamine and *N,N*-diethylbenzylamine as leaving groups resulted in a decrease of the magnitude of the hydrogen–deuterium isotope effect; i.e., $(k^H/k^D)_E$ = 5.42 and 4.67, respectively. It is concluded that steric effects mainly determine leaving group ability. As well, it is concluded that the leaving group ability of the amine determines the structure of the E2 transition state. For the reaction of the poorer leaving groups, trimethylamine, *N*-methylpiperidine, and *N*-methyldiethylamine, the proton is *more than* one-half transferred at the transition state while for reaction involving the two best leaving groups, tripropylamine and *N,N*-diethylbenzylamine, the C_β—H bond is *less than* one-half broken at the transition state. The conclusions are considered in the light of the More O'Ferrall – Jencks potential energy surface diagram.

Key words: elimination mechanism, transition state, isotope effects, leaving group, quaternary salts.

PETER JAMES SMITH et MD. AMIN. Can. J. Chem. **67**, 1457 (1989).

Dans le but d'étudier l'effet du groupement nucléofuge sur la réaction d'élimination des ions 1-phényléthylammonium sous l'influence de l'éthylate de sodium dans l'éthanol à 60°C, on a étudié la réaction de sept sels d'ammonium quaternaire différents, ainsi que leurs analogues deutérés en position β, portant la triméthylamine, la *N*-méthylpipéridine, la *N*-méthyldiéthylamine, la triéthylamine, la *N,N*-diméthylbenzylamine, la tripropylamine et *N,N*-diéthylbenzylamine comme groupements nucléofuges. Dans tous les cas, l'élimination qui procède par un processus concerte E2 est accompagnée par les réactions de substitution qui sont en compétition. Même si on a noté une corrélation importante entre la vitesse du processus d'élimination et la nature du groupement nucléofuge, il n'existe aucune corrélation linéaire avec la basicité de l'amine qui quitte. On a trouvé que, au début de la réaction, l'effet isotopique cinétique primaire hydrogène–deutérium du processus d'élimination, $(k^H/k^D)_E$, augmente avec une augmentation de la vitesse de la réaction, k_E^H, pour les substrates contenant les groupements nucléofuges triméthylamine, *N*-méthylpipéridine, *N*-méthyldiéthylamine, triéthylamine et *N,N*-diméthylbenzylamine pour lesquels $(K^H/k^D)_E$ = 5,03, 5,26, 5,40, 5,83 et 5,85 respectivement. L'utilisation des groupements nucléofuges tripropylamine et *N,N*-diéthylbenzylamine provoque une autre augmentation de la vitesse de la réaction qui est accompagnée d'une diminution de l'amplitude de l'effet isotopique hydrogène–deutérium alors que $(k^H/k^D)_E$ = 5,42 et 4,67 respectivement. On en conclut que les effets stériques sont prédominants dans la facilité des groupements à agir comme nucléofuges. De plus, on conclut que la facilité d'une amine à partir détermine la structure de l'état de transition E2. Pour les réactions impliquant les groupements les moins aptes à agir comme agents nucléofuges, comme la triméthylamine, la *N*-méthylpipéridine et la *N*-méthyldiéthylamine, le proton est *plus qu'à moitié* transféré au moment de l'état de transition; par ailleurs, dans les réactions impliquant les deux meilleurs groupements nucléofuges, soit la tripropylamine et la *N,N*-diéthylbenzylamine, *moins que la moitié* de la liaison C_β—H est brisée au moment de l'état de transition. On considère les conclusions à la lumière du diagramme d'énergie potentielle de surface de More O'Ferrall – Jencks.

Mots clés : mécanisme d'élimination, état de transition, effets isotopiques, groupement nucléofuge, sels quaternaires.

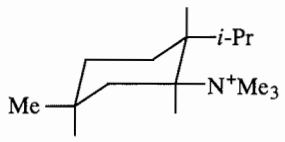
[Traduit par la revue]

Introduction

The effect of the nature of the leaving group on the structure of the E2 transition state has been extensively studied (1–12) for the base-promoted 1,2 elimination reactions of several 2-phenylethyl compounds. However, no systematic investigation on the effect of the nature of the leaving group has been carried out for the elimination reaction of 1-phenylethyl substrates.

The study of the elimination reaction of most 1-phenylethyl compounds is complicated by competing substitution reactions. Hughes *et al.* (13) studied the reaction of 1-phenylethyl bromide with sodium ethoxide in ethanol and interpreted their results in terms of competing E1, E2, S_N1, and S_N2 processes. Subsequently, Sneen and Robbins (14) proposed an "ion-pair" mechanism for this reaction on the basis that the second-order rate constant k_2, calculated from eq. [1], decreased sharply as

$$[1] \quad k_{obs} = k_1 + k_2[OEt^-]$$



the ethoxide concentration increased. However, in an extensive study, McLennan (15) showed that the effect of base concentration on k_2 can be accounted for by a salt effect arising from ion pairing of the base to its counterion and concluded that the competing E1, E2, S_N1, and S_N2 processes satisfactorily account for the experimental results.

Tertiary amines are poor leaving groups and, hence, quaternary ammonium salts generally do not undergo elimination via a carbocation intermediate under solvolytic conditions. However,

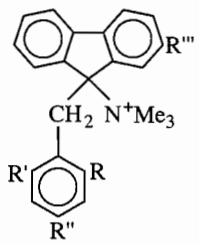
it was reported (16) that the degradation of ax-7-cholestanyltrimethylammonium iodide in boiling ethanol proceeds via the E1 process. Similarly, Hughes and Wilby (17) proposed that menthyltrimethyl- and neomenthyltrimethylammonium hydroxides, **1** and **2**, underwent elimination in water by

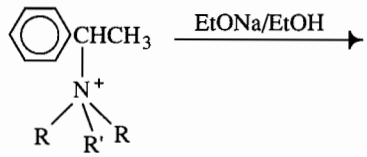


1

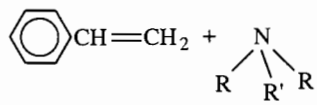
2

the E1 pathway, with the neomenthyl substrate showing a much greater affinity for reaction via the E1 mechanism than the menthyl substrate. The authors proposed that, since in the neomenthyl compound the trimethylammonium group is *cis* to the isopropyl group, the carbocation formation is made favourable due to a relief in steric strain in the molecule.

Recently, Smith and Pradhan (18) reported on the solvolysis of 2-substituted-9-(*ortho*-substituted phenylmethyl)fluoren-9-yltrimethylammonium ions, **3**, in various solvents. It was found



3



that when the phenyl ring contains no substituents in the *ortho* positions (R = R′ = H), the substrates were stable in ethanol. However, when one *ortho* position carried a substituent (R = CH_3, R′ = H), the salts were found to decompose in a first-order process to give both alkene and ether products. The addition of a second *ortho* substituent (R = R′ = CH_3) increased the rate significantly. The authors proposed that the loss of trimethylamine, a poor leaving group, is favoured by a relief of steric interaction between the *ortho* substituents and the onium group.

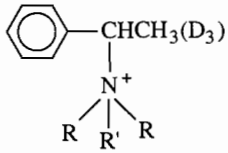
The effect of the nature of the amine leaving groups on the nature of the E2 transition state has been examined (3, 7, and footnote 2) for the reaction of several 2-phenylethylammonium salts. It was found that when the amine leaving group was made less basic the reaction rate increased. In fact, a reasonably good linear correlation was found[2] for a plot of log k_2 and the pK_a of the leaving group that had a slope, $\beta_{\text{leaving group}}$, of −0.25. An approximate linear correlation was found also to exist between the magnitude of the primary hydrogen–deuterium isotope effect observed for the reaction and the basicity of the leaving group. It was concluded[2] that a decrease in the basicity of the leaving group (increase in reaction rate) leads to a transition state with a decreased carbon–hydrogen bond rupture.

A preliminary study of the elimination reaction of 1-phenylethylammonium bromide with ethoxide in ethanol to give styrene has been carried out (20, 21). The observation of a positive Hammett ρ value of +0.98 together with a significant leaving group isotope effect, $[(k^{14}/k^{15})\text{-}1]100 = 1.34$, led the authors to conclude that the reaction proceeds via the concerted E2 mechanism with a transition state where the extent of C_β—H bond rupture is greater than the degree of C_α—N bond weakening (an E1cB-like E2 transition state).

To assess the possible effect of the nature of the leaving group in determining the mechanism of elimination (or changes in E2 transition state structure), it was decided in the present study to investigate the reaction of several 1-phenylethylammonium salts with ethoxide in ethanol at 60°C, eq. [2]. The possibility

[2] 

exists that by improving the leaving ability of the amine leaving group, reaction could proceed by way of the benzylic carbocation (E1 mechanism). Consequently, it might be possible to investigate the borderline between the E2 and E1 mechanisms (or a change from an E1cB-like E2 to an E1-like E2 transition state), by changing the leaving group in terms of both its basicity[2] and the extent of possible steric interactions of the leaving group with other atoms in the molecule (17, 18).



Results and discussion

Determination of the mechanism of the reaction of several 1-phenylethylammonium ions with ethoxide ion in ethanol at 60°C

As indicated in the Introduction, the possibility exists that the elimination reaction of the 1-phenylethylammonium salts with ethoxide in ethanol could proceed by a mechanism other than the usual one-step concerted E2 process.

To test for the possibility of reaction proceeding by rate-determining carbocation formation (E1 mechanism), the stability of all compounds investigated in the present study (**4–10**), as shown in Scheme 1, was determined by heating them in ethanol at 60°C for 2 days. Analysis of all the solutions showed no detectable absorption at 248 nm (λ_{max} for styrene). This observation excludes the possibility of reaction proceeding via the E1 mechanism.

The formation of the benzyl carbocation is not favoured for the reaction of substrates **4–10** in ethanol at 60°C where the amine leaving groups have pK_a values in H_2O ranging from 9 to 11. To further investigate the possible formation of the benzyl

4, R = CH_3; R′ = $C_6H_5CH_2$
5, R = CH_3CH_2; R′ = $C_6H_5CH_2$
6, R = R′ = CH_3
7, NR_2 =  ; R′ = CH_3
8, R = R′ = $CH_3CH_2CH_2$
9, R = CH_3CH_2; R′ = CH_3
10, R = R′ = CH_3CH_2

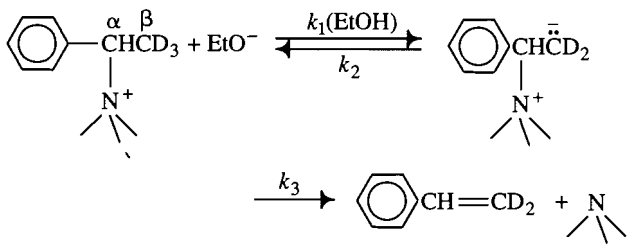
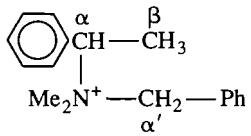
carbocation it was decided to prepare *N,N*-dimethyl-*N*-(1-phenylethyl)anilinium bromide, **11**, since *N,N*-dimethylaniline (pK_a = 5.15 in H_2O) would be expected to be a much better leaving group than those listed above.



Upon heating **11** in ethanol at 60°C it was found that the absorbance measured at 248 nm (λ_{max} for styrene) increased gradually. Gas chromatographic analyses indicated, however, only the presence of ether **12** and *N,N*-dimethylaniline **13** (which has λ_{max} = 251 (22)), eq. [3]. Reaction of the quaternary

[3] 



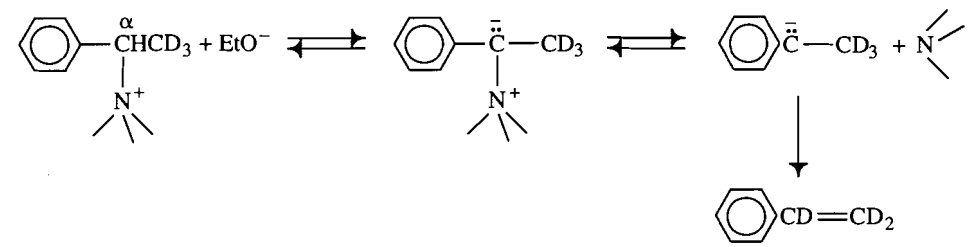
11 **12** **13**

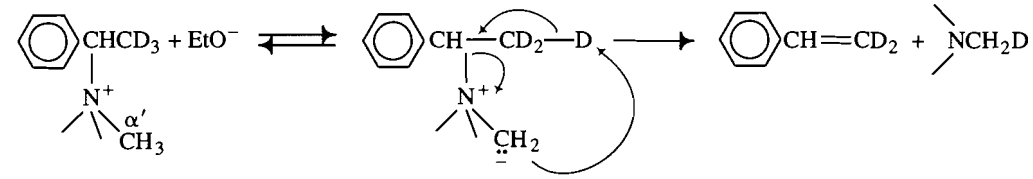
ammonium salt **11** in ethanol, due to the good leaving group **13**, therefore proceeds via carbocation, which preferentially undergoes substitution rather than elimination. Due to the possibility of competition from this first-order process, no studies were carried out on the base-promoted reaction of salt **11**.

Reaction of salts **4–10** with sodium ethoxide in ethanol could proceed by way of the E1cB mechanism, eq. [4]. For reaction via the $(E1cB)_R$ mechanism, $k_2 \gg k_3$, the primary β-hydrogen–deuterium kinetic isotope effect is expected to be small or even inverse. On the other hand, reaction proceeding by way of the $(E1cB)_I$ process, $k_3 \gg k_2$, should exhibit a significant isotope effect (23).

[4] 

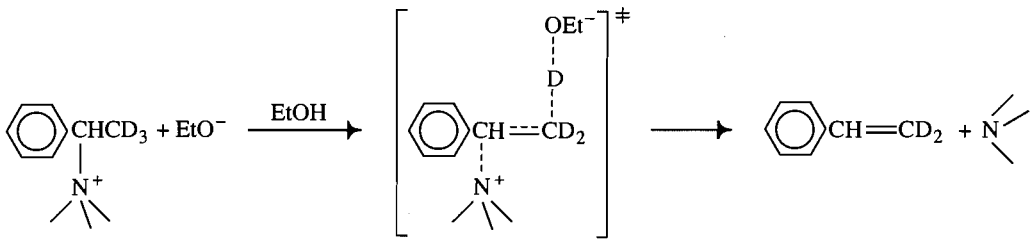
The base-promoted elimination reaction of all the quaternary ammonium salts studied, **4–10**, exhibited large primary hydrogen–deuterium isotope effects, $(k^H/k^D)_E > 4$, Table 1. This indicates that elimination is not proceeeding by way of the $(E1cB)_R$ mechanism. This conclusion receives support from the observation that the styrene isolated from the reaction of the β-trideuterated salts was exclusively β-dideuterated (gc–ms analysis), eq. [4]. Exchange of β-deuteriums with hydrogen from solvent ($k_2 \gg k_3$) would lead to the observation of less than two deuterium atoms at the β-position in styrene.





4

Reaction by way of the $(E1cB)_I$ mechanism is also excluded even though significant primary hydrogen–deuterium isotope effects were observed for the elimination reaction of all of the substrates. The rate of the elimination process should not be significantly affected by a change in the leaving group for the reaction proceeding by this mechanism since the carbon–nitrogen bond will be essentially intact at the transition state of the rate-determining k_1 step. However, in the present study, the rate of elimination has been found to change significantly when the leaving group is varied; i.e., $k_E = 3.60 \times 10^{-5}$ and 90.2×10^{-5} L mol^{-1} s^{-1} for reaction involving the leaving groups trimethylamine and *N,N*-diethylbenzylamine, respectively, Table 1. These results indicate that rupture of the C—N bond is involved in the rate-limiting step, a conclusion that is inconsistent with the $(E1cB)_I$ mechanism.



Two further mechanisms must be considered for the base-promoted elimination reaction of the 1-phenylethylammonium salts, since the acidity of both the α- and α′-hydrogens is expected to be greater than the β-hydrogens, **4**. Consequently, the possibility of reaction proceeding via either the carbene, eq. [5], or ylide, eq. [6], mechanisms was investigated by analyzing the products obtained from reaction involving all β-d_3 substrates. If a reaction involves a carbene intermediate, eq. [5], the resulting styrene will be completely deuterated at both the α and β carbons, while the amine product obtained from the reaction of the same substrate will contain deuterium, eq. [6], if a reaction involves the ylide intermediate. The gc–ms analyses showed that only the β-dideuterated styrenes were formed and the amine products did not contain deuterium. Thus reaction involving either the carbene or ylide intermediates is excluded.

All the experimental information reported herein supports the conclusion that the reaction of all the 1-phenylethylammonium salts with ethoxide ion in ethanol follows the concerted one-step pathway, eq. [7]. The significant primary hydrogen–deuterium isotope effects and leaving group effect indicate appreciable rupture at the transition state **14** of both the carbon (β)–hydrogen and carbon (α)–nitrogen bonds. The observation of the β-dideuterated styrene, when the reactants were trideuterated at C_β, is also consistent with the E2 mechanism.

14

Effect of the nature of the amine leaving group on the nature of the E2 transition state for the reaction of 1-phenylethylammonium ions with ethoxide ion in ethanol at 60°C

Preliminary studies on the reaction of substrates **4–10**, and their β-d_3 analogues, with ethoxide ion in ethanol showed that the elimination process to give styrene was not the sole reaction. Whereas the undeuterated salts gave mainly styrene as product; i.e., % styrene = 97.3, 94.0, 97.3, 99.2, 98.2, 90.0, and 81.4 for reaction of salts **4–10**, respectively, the β-d_3 analogues of **4–10** gave significant amounts of substitution products; i.e., 84.7, 80.1, 87.3, 91.6, 83.1, 65.0, and 75.8% styrene, respectively, Table 1.

Optical density measurements at infinity for the reactions, as well as gas chromatographic – mass spectrometric analyses, indicated that the elimination process was accompanied by two competing substitution reactions. It was shown that nucelophilic attack of ethoxide ion occurs at both the benzylic carbon (C_α) and at $C_{\alpha'}$ of the leaving group, eqs. [8] and [9], respectively.

[8] 

[9] 

The extent of substitution at C_α for the reaction of the β-d_3 analogues of **4–10** was found to be 2.0, 6.0, 2.2, 4.8, 16.9, 2.0, and 3.2%, respectively, while substitution occurred at $C_{\alpha'}$ for the same compounds to the extent of 13.3, 13.9, 10.5, 3.6, 0, 33, and 21%, respectively. In cases where there were two different α′ carbons, substitution occurred exclusively at the benzylic carbon of the leaving group in **4**, only at the methyl group of **7**, and only at the ethyl group of **9**. For reaction of **5** both $C_6H_5CH(NEt_2)CD_3$ (3.5%) and $C_6H_5CH(BzNEt)CD_3$ (10.4%) were produced.

Since in all cases substitution reactions are competing with the elimination process under investigation, the decreased amount of alkene formation observed for the reaction of the β-d_3 compounds as compared with that found for the reaction of the undeuterated **4–10** salts can be readily ascribed to the operation of the primary hydrogen–deuterium isotope effect observed for the concerted E2 process, Table 1. The relative amounts of substitution products, formed from the competing S_N2 processes involving attack at both C_α and $C_{\alpha'}$, can also be qualitatively accounted for by considering both the steric and electronic factors associated with the bimolecular substitution reactions.

As mentioned in the Introduction, an objective of the present study was to investigate the effect of the amine leaving group on the nature of the E2 transition state for the reaction of the 1-phenylethylammonium ions with ethoxide in ethanol at 60°C. Accordingly, the overall rate of the reaction of the salts **4–10**, and their β-d_3 analogues, with ethoxide in ethanol was determined by measuring the formation of the alkene product at 248 nm (where the uv spectra of the substitution products did not show any absorption). The observed overall rate constant k_2, the percent of alkene, the rate constant of the E2 process k_E (calculated from the overall rate constant and the percentage of the elimination reaction), and the primary hydrogen–deuterium isotope effect for the elimination process $(k^H/k^D)_E$, are given in Table 1 along with the pK_a values in water of the various amine leaving groups.

The effect of changes in substrate and base concentrations on the magnitude of the second-order rate constants, k_2 and k_E, was investigated for the reaction of compounds **4**, **5**, and **6**, Table 2. It is seen that when the concentration of both reactants is decreased, a corresponding increase in the magnitude of k_2 and k_E is observed; i.e., $k_2 = 15.0 \times 10^{-5}$ and 25.2×10^{-5} and $k_E = 14.6 \times 10^{-5}$ and 24.5×10^{-5} L mol^{-1} s^{-1} for **4** when the substrate and the ethoxide concentration are changed from 0.1016 and 0.2238 to 0.0511 and 0.1119 M, respectively. Such a dependence of rate constants on substrate and base concentrations can be considered to be due to a salt effect. Such an effect is predicted by the Hughes–Ingold theory of solvent effect (24) and reported (25, 26) for several reactions of onium salts with base. Consequently, in the present study, all rate constant measurements were carried out using the same base and ammonium salt concentrations, ca. 0.150 M and ca. 0.052 M, respectively.

A consideration of the data in Table 1 indicates that the rate constant for elimination k_E changes significantly when the leaving group is varied; i.e., $k_E = 90.2 \times 10^{-5}$ and 3.6×10^{-5} L mol^{-1} s^{-1} for reaction involving the leaving groups *N,N*-diethylbenzylamine and trimethylamine, respectively. However, since the leaving groups are arranged in the table in terms of their pK_a values, it is clear that there is not a linear relationship between the basicity of the amine leaving group and the magnitude of k_E. For example, for reaction of compounds **4**, **5**, and **6**, where the pK_a values of the respective leaving groups are 9.02, 9.48, and 9.81, the rate constant for the elimination k_E varies in the order of 29.0×10^{-5}, 90.2×10^{-5}, and 3.60×10^{-5} L mol^{-1} s^{-1}, respectively.

The relationship between the rate of elimination and the basicity of the amine leaving group can be seen from the Brønsted plot of log k_E^H versus the pK_a of the leaving group, Fig. 1.

[a]k_2 is the overall rate constant.
[b]k_E is the rate constant for elimination.

The obvious absence of a linear correlation, as compared with the reasonably good linear plot found for the reaction of the corresponding 2-phenylethylammonium ions,[2] indicates that in the present system the rate of elimination is not simply related to the basicity of the leaving group. In other words, there must be more than one factor, including the basicity of the leaving group, that determines the reaction rate for the elimination reaction of the 1-phenylethylammonium ions.

Leaving group ability (nucleofugality) has been investigated in detail for several elimination processes (27–35). It has been pointed out (32) that it is difficult to quantitatively evaluate the nucleofugality of a particular leaving group for reaction proceeding by the concerted E2 mechanism where the rupture of both the β-carbon–hydrogen and α-carbon – leaving group bonds occurs at the transition state. However, properties such as inductive effect and polarizability, which allow the leaving group to accept electron density at the transition state (34), as well as steric factors (18), are considered to be important.

To investigate the possible inductive effect of the onium groups of substrates **4–10** on the acidity of both the α and β hydrogens, the chemical shifts of these hydrogens were determined using a 300-MHz nmr spectrometer, Table 3. Although there does not appear to be any relationship between the chemical shift of the α hydrogens and the pK_a value of the amine leaving group, it is noted that for the two best leaving groups, **4** and **5**, the chemical shifts of the β hydrogens of 1.90 and 1.85 ppm, respectively, are significantly greater than the average value of 1.71 ppm found for the other leaving groups. The enhanced reactivity of compounds **4** and **5**, therefore, could be partly due to an increased facility for deprotonation arising from the inductive effect of the positive nitrogens.

Examination of the Brønsted plot, Fig. 1, reveals the absence of a linear correlation between log k_E and pK_a for all of the amine leaving groups studied. However, a reasonably good straight line with a positive slope can be drawn through the points representing the leaving groups trimethylamine, *N*-

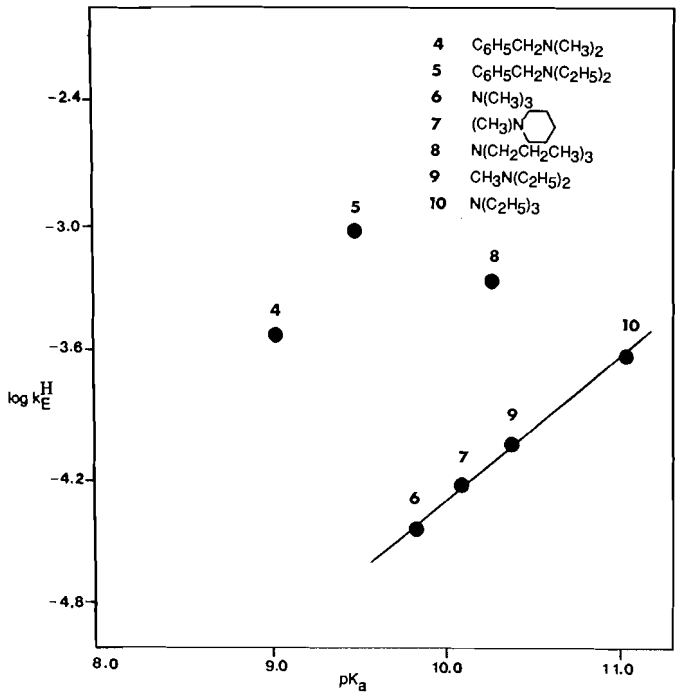

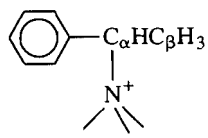

FIG. 1. Plot of log k_E^H versus pK_a of the leaving group for the reaction of 1-phenylethylammonium ions with EtONa / EtOH at 60°C.

TABLE 3. The pK_a values of the amine leaving groups and the proton nmr chemical shifts of the α and β hydrogens of 1-phenylethylammonium salts

Substrate	Leaving groups	pK_a	Chemical shifts, δ (DMSO-d_6), ppm α-H	β-H
4	*N,N*-Dimethylbenzylamine	9.02	5.18	1.90
5	*N,N*-Diethylbenzylamine	9.48	4.91	1.85
6	Trimethylamine	9.81	4.96	1.73
7	*N*-Methylpiperidine	10.08	5.09	1.72
8	Tripropylamine	10.26	4.80	1.71
9	*N*-Methyldiethylamine	10.35	4.82	1.69
10	Triethylamine	11.01	4.85	1.71

methylpiperidine, *N*-methyldiethylamine, and triethylamine, compounds **6**, **7**, **9**, and **10**, respectively. A possible explanation for this correlation is that both pK_a and log k_E increase progressively due to an increase in size of the leaving groups; i.e., from trimethylamine through to triethylamine. In other words, as the ability of the amine to attract a proton decreases, the leaving group ability increases. Consequently, it is suggested that for the reaction of the 1-phenylethylammonium ions with ethoxide in ethanol, the size of the leaving group mainly determines the reaction rate.

Molecular models indicate that there are significant steric interactions between the 1-phenylethyl and onium groups. An increase in the size of the alkyl groups on nitrogen, therefore, will enhance this steric effect and, consequently, reaction will be favoured due to a decrease in these interactions at a transition state that has been shown to have appreciable carbon–nitrogen bond rupture (21).

An alternative explanation of this increased reactivity, when the bulkiness of the leaving group is increased, is a solvation effect. The relative effective sizes of the ammonium groups will determine the relative extents of solvation in the polar ethanol solvent. Since it has been suggested (36) that due to steric factors the positive nitrogen cannot be directly solvated, solvation at the nearby α′ hydrogens must be important. Consequently, the α′ carbons of the larger alkyl groups attached to nitrogen will be solvated to a lesser extent.

Since there is significant carbon – leaving group bond rupture at the activated complex for the reaction of 1-phenylethyltrimethylammonium ion with ethoxide, $[(k^{14}/k^{15})\text{-}1]100 = 1.34$ (18), it is reasonable to conclude that differential solvation between the various ammonium ions might account to some degree for the observed rate differences. The less solvated higher energy substrate molecule will have a greater tendency to proceed to the transition state and, hence, will be more reactive towards ethoxide ion.

The points representing the compounds with the three largest leaving groups, **4**, **5**, and **8**, where it is expected that solvation of the onium group will be less effective, lie significantly above the line through the points **6**, **7**, **9**, and **10** on the log k_E^H versus pK_a plot, Fig. 1. The deviations increases in the order expected for increasing size; i.e., tripropylamine (**8**), *N,N*-dimethylbenzylamine (**4**), and *N,N*-diethylbenzylamine (**5**), respectively. This enhanced reactivity compared with compounds **6**, **7**, **9**, and **10** (where the size of the onium group was systematically increased) can be considered as being due to an appreciable decrease in solvation when, for example, an *N*-methyl group is replaced by a benzyl group. This solvation effect perhaps accounts for the increased chemical shifts of the β-hydrogens of compounds **4**, and **5**, which were noted earlier.

As mentioned in the Introduction, a reasonably good linear correlation between the reaction rate and the magnitude of the primary hydrogen–deuterium isotope effect was found for the E2 reaction of 2-phenylethylammonium ions with ethoxide ion when the amine leaving group was varied.[2] The increase in the magnitude of both the rate constant and the isotope effect was interpreted in terms of an E2 transition state where the extent of carbon–hydrogen bond rupture decreases for reaction involving the better leaving groups. It was considered that in all cases the proton was more than one-half transferred to base at the transition state (2, 23, 37, 38).

To measure the relative extent of C—H bond rupture at the E2 transition state for reaction involving the various 1-phenylethylammonium ions with ethoxide, the primary hydrogen–deuterium kinetic isotope effects for the elimination process, $(k^H/k^D)_E$, were examined, Table 1, A plot of $(k^H/k^D)_E$ against log k_E^H is shown in Fig. 2.

It is seen that $(k^H/k^D)_E$ *increases* approximately in a linear fashion with increasing reactivity of the substrates **6**, **7**, **9**, and **10** with leaving groups trimethylamine, *N*-methylpiperidine, *N*-methyldiethylamine, and triethylamine, respectively; i.e., $(k^H/k^D)_E = 5.03$, 5.26, 5.40, and 5.83 when $k_E^H = 3.60 \times 10^{-5}$, 5.95×10^{-5}, 9.02×10^{-5}, and 24.1×10^{-5} L mol^{-1} s^{-1}, respectively, Table 1 and Fig. 2. This relationship between the magnitude of $(k^H/k^D)_E$ and the reaction rate is in the same direction as that found for the corresponding reaction of the 2-phenylethylammonium ions (23) and suggests that the transition state for the E2 reaction of the 1-phenylethylammonium

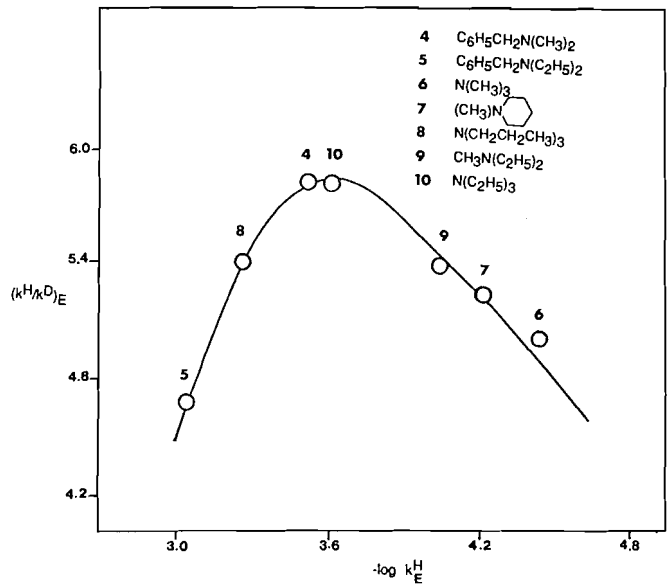

FIG. 2. Plot of $-\log k_E^H$ versus $(k^H/k^D)_E$ for the reaction of 1-phenylethylammonium ions with EtONa / EtOH at 60°C.

ions **6**, **7**, **9**, and **10** has the proton *more than* one-half transferred to base. The increase in the magnitude of $(k^H/k^D)_E$ on going to a better leaving group indicates, therefore, a *decrease* in the extent of carbon–hydrogen bond rupture at the activated complex.

Further increases in reaction rate for the substrates with the three best leaving groups *N,N*-dimethylbenzylamine (**4**), tripropylamine (**8**), and *N,N*-diethylbenzylamine (**5**), however, led to a *decrease* in the magnitude of $(k^H/k^D)_E$; i.e., $(k^H/k^D)_E = 5.85, 5.42, 4.67$ when $k_E^H = 29.0 \times 10^{-5}$, 52.4×10^{-5}, and 90.3×10^{-5} L mol^{-1} s^{-1}, respectively, Table 1 and Fig. 2. Such a decrease in $(k^H/k^D)_E$ with increasing reactivity of the onium salts is consistent with a reactant-like transition state for proton transfer where the hydrogen is *less than* one-half transferred to the base ethoxide. This conclusion is noteworthy since the base-promoted 1,2 elimination reactions of quaternary ammonium salts (involving the poor leaving groups, tertiary amines) have been found to proceed via the concerted E2 pathway with an E1cB-like E2 transition state where the C_β—H bond is more than one-half broken (23, 39, 40).

The plot of $(k^H/k^D)_E$ versus log k_E^H, Fig. 2, resembles a Westheimer (37) – Melander (38) type of curve where the substrates **6**, **7**, and **9**, with the poorest leaving groups trimethylamine, *N*-methylpiperidine, and *N*-methyldiethylamine, respectively, lie on the right hand side, indicating that their respective E2 transition states have the hydrogen more than one-half transferred to the base. The onium salts **8** and **5**, with the best leaving groups tripropylamine and *N,N*-diethylbenzylamine, respectively, lie on the left side of the curve, suggesting a transition state where the hydrogen is closer to the β carbon than the abstracting base. Substrates **10** and **4**, with leaving groups triethylamine and *N,N*-dimethylbenzylamine, respectively, lie at or near the maximum of the curve and, hence, have an E2 transition state where the hydrogen that is being transferred is approximately equidistant between the β carbon and ethoxide ion. To our knowledge this is the second example (41) where a Westheimer–Melander type of curve has been realized for the elimination reaction of a single substrate where the leaving group has been varied.

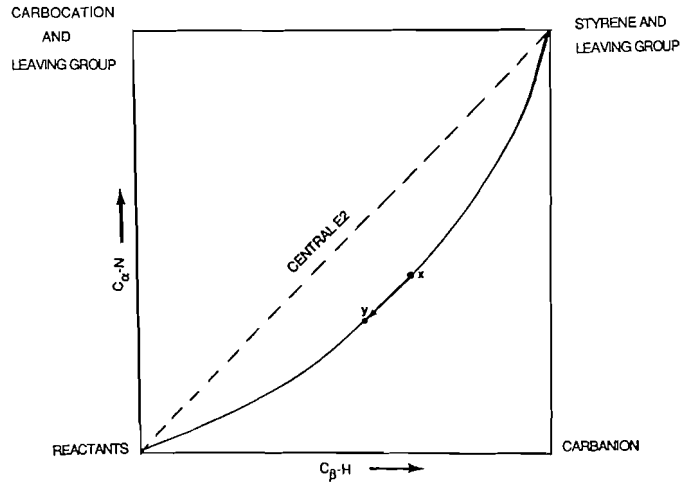

FIG. 3. More O'Ferrall – Jencks diagram showing the effect of changing the leaving group on the transition state structure for the elimination reaction of 1-phenylethylammonium ions with ethoxide ion.

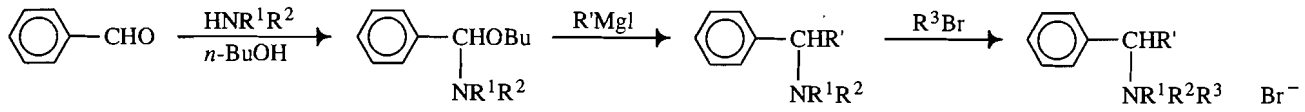
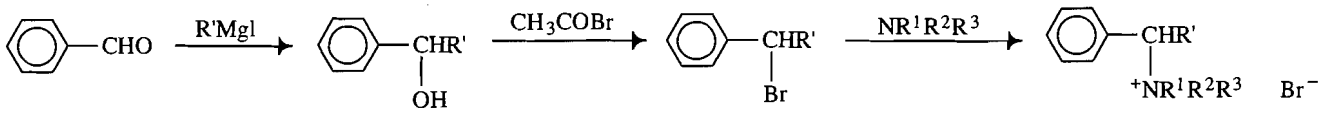
The conclusion reached in the present study that an increase in leaving group ability (increase in k_E^H) leads to a progressive decrease in the extent of β-carbon–hydrogen bond rupture at the transition state can be examined in the light of a More O'Ferrall (42) – Jencks (43) energy surface diagram[3] as represented in Fig. 3. The *x*- and *y*-axes in the plane represent the extent of C_β—H and C_α—N bond rupture, respectively, while the axis perpendicular to the plane represents the potential energy. Reactants are located at the bottom left and the products at the top right corners. The possible carbocation and carbanion intermediates are located at the other two corners.

A consideration of the magnitude of both the primary hydrogen–deuterium and nitrogen isotope effects has been considered (20, 21) to provide strong evidence that the transition state for the E2 reaction of 1-phenylethyltrimethylammonium ion (this substrate has the poorest leaving group in the present study) with ethoxide ion lies to the right of the diagonal in Fig. 3, point x, where C_β—H bond weakening is more advanced than C_α—N bond rupture (an E1cB-like E2 transition state). An increase in the energy of the reactants, raising the bottom left corner, will lead to a shift in transition state structure towards the reactant corner, $x \rightarrow y$, for motion along the reaction coordinate,[4] as represented by the curved solid line in the figure. Consequently, an increase in the reactivity of the reactants (increase in steric interactions within the molecule and (or) decrease in solvation due to the size of the onium group) will result in a decrease in C—H bond rupture at the transition state. This conclusion is in accord with the conclusions reached from a consideration of the primary hydrogen–deuterium isotope results.



Experimental

All melting points and boiling points are uncorrected. Elemental analyses were carried out at the Guelph Chemical Laboratories Ltd, Guelph, Ontario. The nmr spectra were taken using Varian T60 and Bruker AM-300 multinuclear Fourier-transform spectrometers. The



[3]A more recent model, which considers the geometrical nature of transition state variation, has been proposed (44).

[4]The relative difference in stability of various amine leaving groups is considered to be small and, hence, the perpendicular effect, as determined by raising or lowering the top left corner, is neglected.

SCHEME 2

SCHEME 3

ultraviolet absorbances were recorded using a Hewlett Packard 8451A diode array spectrophotometer. Mass spectra were recorded on an AEI MS-12 equipped with a vacuum retrofit. Analytical gas chromatography was carried out using a Hewlett Packard 5890 gas chromatograph equipped with a flame ionization detector. All reagents and solvents were reagent grade and were dried and purified by the usual procedures.

The synthetic procedures for most of the compounds in this study were similar and are outlined in Scheme 2, except for 1-phenylethyltripropylammonium (**8**) and *N,N*-dimethyl-*N*-(1-phenylethyl)anilinium (**11**) ions, which were prepared by the procedure outlined in Scheme 3. The deuterated substrates were better than 99% deuterated since nmr and mass spectrometric analyses indicate complete deuteration.

α-Dialkylaminobenzyl n-butyl ethers

To a 500-mL two-neck round bottom flask fitted with a reflux condenser capped with a calcium chloride drying tube and a magnetic stirrer were added 0.2 mol of aldehyde, 0.22–0.24 mol of amine, 0.2 mol of anhydrous potassium carbonate, and 1.0 mol of butanol-1. With the exception of the dimethylamine and diethylamine experiments, which were done at room temperature, the reactants were stirred for 24 h at an outside temperature of 70–80°C. After cooling to room temperature, excess chloroform was added to facilitate the filtration. The filtrate was evaporated by using a rotary evaporator with bath temperature at about 100°C. The residue, which consisted mainly of the desired amino ether, was purified by distillation under reduced pressure. The amino ethers were characterized by nmr spectroscopy. Most of the amino ethers were found to decompose if they were left for several days and, therefore, were immediately used for the next experiments. The boiling points, yields, and characteristics of the proton nmr spectra of the amino ethers are listed in Table 4.

1-Phenylethanol

In a 500-mL two-neck flask equipped with a magnetic stirrer, an addition funnel, and a double surface condenser with a drying tube at the top, were placed 3.64 g (0.15 mol) of dry magnesium turnings and 50 mL of sodium-dry ether. A stream of dry nitrogen gas was passed through the flask to remove any moisture. Methyl iodide (21.3 g, 0.15 mol) was placed in the addition funnel and a small amount of it was added to initiate the reaction. Ether (150 mL) was then poured through the condenser to slow down the reaction and the rest of the methyl iodide was added at such a rate as to maintain a gentle reflux of the solvent. After the addition was completed, the reactants were stirred for 2 h. Benzaldehyde (0.1 mol) in an equal volume of ether was then added slowly to the Grignard solution over a period of 2 h. The reaction mixture was further stirred overnight. The mixture was poured into 300 g of crushed ice contained in a large beaker and 10% HCl (300 mL) was then added slowly with rapid stirring. The two layers were separated and the aqueous layer was extracted with ether (3 × 100 mL). The ether extracts were combined with the original solution and dried over anhydrous sodium sulfate. Removal of the ether by using a rotary evaporator gave a pale yellow liquid. Distillation under reduced pressure gave a colorless liquid; 86% yield, bp 82–84°C / 0.5 Torr. (lit. (21) bp 79–81°C / 0.4 Torr (1 Torr = 133.3 Pa) lit. (22) bp 100°C / 18 Torr).

1-Phenylethanol-2.2.2.d_3 was prepared from benzaldehyde and methyl-d_3 iodide in the same way; bp 81–83°C / 0.5 Torr.

1-Phenylethyl bromide

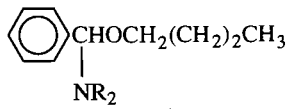
Acetyl bromide (24.4 g, 0.2 mol) was added all at once to the 1-phenylethanol (0.1 mol) in a 100-mL round bottom flask. The reaction was vigorous and the reaction mixture was stirred for a further 5–10 min. Acetic acid and excess reagents were removed by using a rotary evaporator and the resulting pale yellow oil was distilled under reduced pressure to give colorless 1-phenylethyl bromide; 80% yield, bp 38–40°C / 0.05 Torr (lit. (21) bp 45–55°C / 0.1 Torr, lit. (22) bp 85°C / 13 Torr).

1-Phenylethyl-2,2,2-d_3 *bromide* was prepared from 1-phenylethanol-2,2,2-d_3 in the same way; bp 38–40°C / 0.05 Torr.

N,N-*Dialkyl-1-phenylethylamines*

Dry magnesium turnings (2.4 g, 0.1 mol) and 50 mL of sodium-dry ether were placed in a 250-mL two-neck round bottom flask fitted with a double surface condenser capped with a drying tube, an addition funnel, and a magnetic stirrer. The system was flushed with nitrogen to remove moisture. Methyl iodide (14.2 g, 0.1 mol) was placed in the addition funnel and a small amount of it was added to initiate the reaction. Ether (100 mL) was then poured through the condenser to slow down the reaction and the rest of the methyl iodide was added dropwise at such a rate as to maintain a gentle reflux of the solvent. After the addition was complete, the reactants were stirred for an additional 2 h. The corresponding α-dialkylaminobenzyl *n*-butyl ether (0.05 mol) was dissolved in an equal volume of diethyl ether and then added slowly to the Grignard solution over a period of 1 h. The reaction mixture was further stirred overnight. The mixture was then poured into a 1:1 mixture (w / w) of ammonium chloride (0.1 mol) and ice chips. After cooling, 10% sodium hydroxide solution (ca. 100 mL) was added and the mixture was shaken well. The ether layer was decanted and the aqueous layer was shaken for a few times with fresh ether and decanted. The ether extracts were combined and dried over magnesium sulfate. The solvent was evaporated and the residue was distilled under reduced pressure. The synthetic results are listed in Table 5.

N,N-*Dialkyl-1-phenylethylamines-2,2,2-*d_3 were prepared in the same way from the respective α-dialkylaminobenzyl *n*-butyl ether and methyl-d_3 iodide.



Benzyldimethyl-1-phenylethylammonium bromide (4)

Into a 200-mL round bottom flask fitted with a condenser with a magnetic stirrer were placed *N,N*-dimethyl-1-phenylethylamine (0.05 mol), dry ether (75 ml), and the benzyl bromide (17.1 g, 0.1 mol). The reactants were stirred overnight while the salt precipitated. The precipitate was filtered off and washed several times with ether to remove the unreacted benzyl bromide. The crude product was recrystallized at least three times from acetone / ether; 88% yield; mp 154–155°C; ^{1}H nmr δ (DMSO-d_6): 7.46–7.80 (m, 10H, aromatic), 5.18 (q, 1H, CH), 4.65 and 4.53 (AB system, 2H, NCH_2,[5] J = 12.4 Hz), 2.87 (s, 3H,

[5]These benzylic protons are diastereotopic and form an AB system. For the measurement of chemical shifts and coupling constant in an AB system, see ref. 48.

1-Phenylethyltripropylammonium bromide (*8*)

1-Phenylethyl bromide (5.55 g, 0.03 mol) was dissolved in 25 mL of nitromethane and was placed in a 100-mL round bottom flask to which tripropylamine (14.3 g, 0.1 mol) was added. The flask was well stoppered and the reactants were stirred for 48 h. Addition of excess ether gave a solid (6.33 g), which was recrystallized three times from ethanol / ether; mp 161–162°C; 64% yield; ^{1}H nmr δ (DMSO-d_6): 7.42–7.78 (m, 5H, aromatic), 4.80 (q, 1H, CH), 3.10–3.35 (m, 6H, CH_2), 1.71 (d, 3H, CH_3), 0.85 (t, 9H, CH_3). *Anal.* calcd. for $C_{17}H_{30}NBr$: C 62.19, H 9.21, N 4.26; found: C 62.22, H 9.28, N 4.34.

1-Phenylethyltripropylammonium-2,2,2-d_3 *bromide* was prepared in the same way from 1-phenylethyl-2,2,2-d_3 bromide; mp 161–162°C.

Diethylmethyl-1-phenylethylammonium bromide (*9*)

N,N-Diethyl-1-phenylethylamine (5.4 g, 0.03 mol) was treated with bromomethane (11.4 g, 0.12 mol) in the same way as described for the preparation of *N*-methyl-*N*-(1-phenylethyl)piperidinium bromide, **7**, to give a viscous liquid that, on standing overnight, gave 8.2 g of a solid. This was recrystallized three times from acetone:ethanol (5:1) / ether; mp 152–154°C; 98% yield; ^{1}H nmr δ (DMSO-d_6): 7.42–7.75 (m, 5H, aromatic), 4.82 (q, 1H, CH), 2.95–3.55 (m, 4H, NCH_2), 2.82 (s, 3H, NCH_3), 1.69 (d, 3H, $CHCH_3$), 1.28 (t, 3H, NCH_2—CH_3[5]), 1.22 (t, 3H, NCH_2CH_3[6]). *Anal.* calcd. for $C_{13}H_{22}NBr$: C 57.36, H 8.15, N 5.14; found: C 57.42, H 8.20, N 5.11.

Diethylmethyl-1-phenylethylammonium-2,2,2-d_3 *bromide* was prepared in the same way from *N,N*-diethyl-1-phenylethylamine-2,2,2-d_3; mp 152–154°C.

1-Phenylethyltriethylammonium bromide (*10*)

Into a 100-mL round bottom flask fitted with a reflux condenser, capped with a drying tube, were added 5.31 g (0.03 mol) of *N,N*-diethyl-1-phenylethylamine and 25 mL of bromoethane. The mixture was gently refluxed with a constant stirring for 48 h. It was then transferred to a 250-mL round bottom flask and concentrated using a rotary evaporator. Addition of excess ether gave 5.15 g of a solid, which was recrystallized from acetone:ethanol (4:1) / ether; 60% yield; mp 148–150°C; ^{1}H nmr δ (DMSO-d_6): 7.40–7.85 (m, 5H, aromatic), 4.85 (q, 1H, CH), 3.36 (q, 6H, NCH_2), 1.71 (d, 3H, CH_3), 1.17 (t, 9H, CH_3). *Anal.* calcd. for $C_{14}H_{24}NBr$: C 58.74, H 8.45, N 4.90; found: C 58.61, H 8.73, N 4.87.

1-Phenylethyltriethylammonium-2,2,2-d_3 *bromide* was prepared in same way from *N,N*-diethyl-1-phenylethylamine,2,2,2-d_3; mp 148–150°C.

N,N-*Dimethyl*-N-*(1-phenylethyl)anilinium bromide* (*11*)

To a 100-mL round bottom flask fitted with a magnetic stirrer were added 1-phenylethyl bromide (5.55 g, 0.03 mol) and *N,N*-dimethylaniline (12.1 g, 0.1 mol). The flask was well stoppered and the reactants were stirred while a solid started to form. The stirring was continued for 48 h and then excess ether was added. The solid was filtered, washed several times with ether, and recrystallized from cold ethanol / ether; 91.6% yield; mp 126–128°C; ^{1}H nmr δ (DMSO-d_6): 7.40–7.95 (m, 10H, aromatic), 5.38 (q, 1H, CH), 3.53 (s, 3H, NCH_3), 3.45 (s, 3H, NCH_3), 1.55 (d, 3H, CH_3). *Anal.* calcd. for $C_{16}H_{20}NBr$: C 62.75, H 6.58, N 4.57; found: C 62.81, H 6.81, N 4.41.

Absolute ethanol

This solvent was dried by the method of Lund and Bjerrum (19) and stored under anhydrous conditions.

Sodium ethoxide solution

Dry ethanol (300 mL) was placed in the flask and cooled in an ice bath. Nitrogen gas, purified by passing through successive wash bottles containing Fieser's solution, saturated lead acetate solution, and concentrated sulfuric acid to remove oxygen, carbon dioxide, and water, respectively, was bubbled through the ethanol. Sodium metal (~8 g, ~0.3 mol), washed in ether, was cut into small pieces and added to the ethanol through the top of the vessel. After the sodium had been completely dissolved, the flask, containing approximately 1 M sodium ethoxide solution, was stored in the refrigerator.

Product analyses

The solution remaining from the kinetic measurement was placed into a 250-mL separatory funnel. The solution was diluted with 25 mL of water and extracted three times with 50-mL portions of petroleum ether (30–60°C). After the removal of the solvent using a rotary evaporator at room temperature, the residue was diluted with 0.5–1 mL of diethyl ether and passed through a 30-m (J & W Scientific, Inc.) DB-5, 5% phenylmethyl capillary gc column. The products were identified from a comparison with authentic samples as well as from mass spectral data. The mass spectrometer was directly coupled with the gas chromatograph. At least three analyses were carried out on each sample.

Kinetic measurements

The rate of the elimination reaction of the quaternary ammonium salts and their deuterated analogues with sodium ethoxide in ethanol was determined by spectrophotometrically monitoring the increase in the amount of styrene at 248 nm as a function of time. All rate constant measurements were carried out using the same base and ammonium salt concentrations, ca. 0.150 M and ca. 0.052 M, respectively. The quaternary ammonium salts also showed significant absorptions at 248 nm at relatively higher concentrations. During the measurement of absorbance, the reaction solutions were diluted to the extent where the substrate salt did not show any absorption (which was determined independently using the salt). The absorption of other components of the mixture was negligible at 248 nm.

The thermostated oil bath was adjusted to the temperature 60.00 ± 0.02°C. A known weight of the substrate was placed in a 25-mL volumetric flask, containing a side bulb to balance the inside pressure, and dry ethanol (13 mL) was added to dissolve it. Sodium ethoxide solution of approximate six to seven times the substrate concentration was prepared in another flask by the dilution of the previously prepared 1 M base solution. Both flasks were then placed into the bath for about 30–45 min to allow the solutions to reach thermal equilibrium. The base concentration was determined by withdrawing 1 mL of the base, diluting to 50 mL with carbon-dioxide-free distilled water, and titrating with standardized 0.01 N sulfuric acid solution to bromthymol blue end point. A 10-mL aliquot of the base was introduced into the substrate flask and filled up to the mark with thermally equilibrated dry ethanol. The flask was well stoppered using a rubber septum and shaken vigorously to ensure complete mixing. Timing was started approximately halfway through the addition of the base to the substrate solution. At suitable intervals of time, aliquots were withdrawn using a calibrated gastight syringe and diluted to 50 mL in a volumetric flask with 95% ethanol. The absorbance of the solution was then recorded after proper dilution.

Kinetics were studied under second-order reaction conditions and the rate constants were calculated by using the following modified (to account for the competing substitution) form of the integrated second-order rate equation,

$$k_2 = \frac{1}{t(a_0 - b_0)} \ln \left[\frac{b_0}{a_0} \frac{(a_0 - p_1 - p_2)}{(b_0 - p_1 - p_2)} \right]$$

[7]This salt undergoes S_N1 reaction in hot ethanol.

where a_0 and b_0 are initial concentrations of the base and the substrate, respectively, p_1 and p_2 are the concentrations of elimination and substitution products, respectively, at time t, and k_2 is the overall second-order rate constant. The rate constant (k_2) was calculated from the slope of the least-squares plot of $\ln [(a_0 - p_1 - p_2)/(b_0 - p_1 - p_2)]$ vs. t. Excellent second-order plots were obtained in all cases. The rate constant for the elimination reaction (k_E) was then calculated using the following relationship,

$$k_E = k_2 \times \frac{\% \text{ of elimination product}}{100}$$

Test for solvolysis

A known weight of the substrate was placed in a 25-mL volumetric flask and approximately 20 mL of dry ethanol was added to dissolve the salt. The flask was then placed into the thermostated oil bath, which was adjusted to the temperature 60.00 ± 0.02°C. After half an hour, the flask was filled up to the mark with thermally equilibrated dry ethanol. The flask was well stoppered with a rubber septum and shaken vigorously to ensure complete mixing. Aliquots were withdrawn using a calibrated 1.00-mL syringe and diluted to 50 mL in a volumetric flask with 95% ethanol. The absorbance of the solution was recorded at 248 nm (λ_{max} for styrene) after proper dilution. No significant absorbance was observed for compounds **4–10** over a period of 3–4 days. The gc analysis also did not show the presence of any solvolysis product.

However, the absorbance at 248 nm increased progressively for the salt *N,N*-dimethyl-*N*-(1-phenylethyl)anilinium bromide (**11**). The gc–ms analysis indicated the presence of ether substitution product and amine leaving group (which has $\lambda_{max} = 251$ (22)).

Tests for E1cB, carbene, and ylide mechanisms

A known weight of the appropriate deuterated quaternary ammonium salt was dissolved in 25 mL of the base, so that the initial concentrations of the substrate and the base were ca. 0.0525 mol L^{-1} and ca. 0.150 mol L^{-1}, respectively. This solution was allowed to stand at 60°C in a thermostated oil bath for a period of 2–3 days. The products were then isolated and analyzed. In all cases, **4–10**, the resulting styrene was β-dideuterated and the amine product did not contain deuterium.

PATRICK C. DAWSON, E. A. SECCO, and WILLIAM M. OXNER. Can. J. Chem. **67**, 1468 (1989).

The thermodynamic analysis of the condensed phase diagrams of binary system solid solutions of the ascending type, viz. Na_2SO_4–Ag_2SO_4 and of the minimum type, ameltrope, viz. Ag_2SO_4–K_2SO_4, Na_2SO_4–K_2SO_4 is presented. The analysis identifies the basis for ameltrope behavior and provides for the evaluation of α, the fraction of dissociation, and ΔH_{Diss}, the enthalpy of dissociation, of the dissociating component.

Key words: alkali sulfates solid solutions, thermodynamic analysis ameltropes, molten alkali sulfates dissociation, solid–solid phase diagrams, ionic melts.

PATRICK C. DAWSON, E. A. SECCO et WILLIAM M. OXNER. Can. J. Chem. **67**, 1468 (1989).

On présente une analyse thermodynamique des diagrammes de phase condensée de solutions solides de systèmes binaires de type ascendant, comme Na_2SO_4–Ag_2SO_4, ainsi que du type minimal, ameltrope, comme Ag_2SO_4–K_2SO_4, Na_2SO_4–K_2SO_4. L'analyse identifie la base à partir duquel on observe une comportement d'ameltrope et fournit une évaluation de α, la fraction de dissociation, ainsi que du ΔH_{Diss}, l'enthalpie de dissociation, de la composante qui se dissocie.

Mots clés : solutions solides, sulfates alcalins; analyse thermodynamique des ameltropes; dissociation des sulfates alcalins fondus; diagrammes de phase, solide–solide; produits ioniques en fusion.

[Traduit par la revue]

Introduction

Recent advances in materials science and their potential applications in recent years have increased interest in the subject of condensed phase equilibria. The pressure–temperature–composition behavior of multi-component systems has become an active area for experimental and theoretical analysis.

Recently, we reported the isobaric condensed phase diagrams of three binary systems, viz. Na_2SO_4–Ag_2SO_4, Ag_2SO_4–K_2SO_4, Na_2SO_4–K_2SO_4, incorporating both solid–solid and solid–liquid equilibria (1–3). The three sulfate components are orthorhombic solids in the low temperature form: Ag_2SO_4 and Na_2SO_4 are isomorphic, space group *Fddd*, while K_2SO_4 fits the space group *Pnam*. Each component undergoes a solid–solid phase transition to the isomorphic high temperature form space group $P6_3/mmc$ (4–6). The phase diagram of the Na_2SO_4–Ag_2SO_4 system is the simplest with a monotonic ascending solid solution behavior in both the solid–solid and solid–liquid regions. The Ag_2SO_4–K_2SO_4 system diagram shows a eutectoid in the solid–solid region and a constant melting composition[3] of the minimum type in the solid–liquid region paralleling the familiar azeotropic behavior found in boiling of liquid solution. The Na_2SO_4–K_2SO_4 diagram reveals complex solid–solid behavior with an eutectoid, the compound $KNaSO_4$ and another compound $K_3Na(SO_4)_3$ which exhibits eutectoid features along with a minimum constant melting composition in the solid–liquid region. The compounds $KNaSO_4$ and $K_3Na(SO_4)_3$ have been characterized by X-ray structural studies (7) and each undergoes a solid–solid phase transition speculated to be of the order–disorder type $\approx$400°C below their respective melting temperatures.

Solid solutions displaying an ameltrope are rare relative to the liquid solution analog. In this type of solid solution the original components are, as a rule, isostructural and even isomorphic in the solid state; that is, the same solid phase structure coexists with liquid in the solid–liquid region. An intuitive interpretation of a minimum ameltrope suggests a miscibility gap lying submerged beneath the solidus. However, the above described diagrams reveal no such miscibility gap, therefore, our knowledge of the nature and basis for ameltropic behavior is incomplete.

Reisman (8) outlines the overall thermodynamic approach to the analysis of ascending solid solutions including the minimum ameltrope. The latter analysis is based on the dissociation of at least one of the components on melting. The treatment is restricted to the complete dissociation case of the components of which two possibilities are considered: (*i*) a dimer solid dissociates to a monomer liquid and (*ii*) a monomer solid yields twice as many species in the liquid, e.g. ionization. However, a detailed analysis of the minimum ameltropic behavior incorporating various degrees of dissociation of the components is lacking. This paper, therefore, presents an analytical description which correlates the experimental isobaric temperature–composition condensed phase diagrams of three binary systems, viz. Na_2SO_4–Ag_2SO_4, Ag_2SO_4–K_2SO_4, Na_2SO_4–K_2SO_4 with the graphical representations generated by a refinement of the Reisman model.

Results and discussion

A. Na_2SO_4–Ag_2SO_4 — ascending solid solution type

The solid–liquid equilibria are described by

[1] $Na_2SO_{4(s)} \rightleftarrows Na_2SO_{4(l)}$

[2] $Ag_2SO_{4(s)} \rightleftarrows Ag_2SO_{4(l)}$

where the symbols s and l represent the species in the solid solution and liquid solution, respectively. The solid–solid equilibria are given by

[1*a*] $Na_2SO_{4(s)} \rightleftarrows Na_2SO_{4(s')}$

[2*a*] $Ag_2SO_{4(s)} \rightleftarrows Ag_2SO_{4(s')}$

where s and s′ refer to the species in solid solution phase I and solid solution phase II, respectively. Applying the appropriate constraining and conservation conditions with respect to compositions to the equilibria [1] and [2] one obtains for the variation of Na_2SO_4 composition with T in the liquid and solid phases, respectively

$$[3]\quad x^{l}_{Na_2SO_4} = \frac{\exp\left[-\frac{\Delta H^0_{f,Na_2SO_4}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{Na_2SO_4}}\right)\right]\left\{\exp\left[-\frac{\Delta H^0_{f,Ag_2SO_4}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{Ag_2SO_4}}\right)\right]-1\right\}}{\exp\left[-\frac{\Delta H^0_{f,Ag_2SO_4}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{Ag_2SO_4}}\right)\right]-\exp\left[-\frac{\Delta H^0_{f,Na_2SO_4}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{Na_2SO_4}}\right)\right]}$$

$$[4]\quad x^{s}_{Na_2SO_4} = \frac{\exp\left[-\frac{\Delta H^0_{f,Ag_2SO_4}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{Ag_2SO_4}}\right)\right]-1}{\exp\left[-\frac{\Delta H^0_{f,Ag_2SO_4}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{Ag_2SO_4}}\right)\right]-\exp\left[-\frac{\Delta H^0_{f,Na_2SO_4}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{Na_2SO_4}}\right)\right]}$$

Parallel equations in $x^{l}_{Ag_2SO_4}$ and $x^{s}_{Ag_2SO_4}$ are self-evident and unnecessary since the conservation conditions $x^{l}_{Ag_2SO_4} + x^{l}_{Na_2SO_4} = 1$ and $x^{s}_{Ag_2SO_4} + x^{s}_{Na_2SO_4} = 1$ prevail. In these equations x refers to the mole fraction, ΔH^0_f and T^0 refer to the respective enthalpy of fusion and melting temperature of the pure component and R the universal gas constant. Similar equations in $x^{s}_{Na_2SO_4}$ and $x^{s'}_{Na_2SO_4}$ are obtained for the equilibria [1*a*] and [2*a*] for the appropriate solid phases where ΔH^0_t, the respective enthalpy of transition replaces ΔH^0_f and T^0 represents the respective transition temperature instead of the melting temperature of the pure component.

Inserting the ΔH^0_f values of 5830 and 4280 cal/mol with 1155 and 940 K for T^0 of Na_2SO_4 and Ag_2SO_4, respectively (1, 2) in eqs. [3] and [4] we obtain the liquidus and solidus dotted line composition in the upper part of Fig. 1. The open squares represent the experimental melting temperatures in the heat mode of DSC, differential scanning calorimetry. The separate liquidus and solidus temperatures could not be distinguished experimentally because of their proximity. The agreement between the experimental and calculated data is considered to be excellent.

Using the ΔH^0_t values of 1670 and 4060 cal/mol and 530 and 693 K for T^0 of Na_2SO_4 and Ag_2SO_4, respectively, in equations similar to [3] and [4] we obtain the two solidi dotted line compositions in the lower part of Fig. 1. The unfilled circles represent the experimental transition temperatures in the heat mode of DSC. The separate solidi temperatures could not be resolved experimentally because of their proximity. Excellent agreement between the experimental and calculated data is evident above 40 mol% Ag_2SO_4 with deviation increasing towards pure Na_2SO_4. Four solid phases have been confirmed for Na_2SO_4 with the known transitions V ⇄ III ⇄ II ⇄ I occurring. However, short-circuit transitions also occur, viz. III ⇄ I and the metastable III phase can remain untransformed at room temperature, i.e. 250 K below its normal transition temperature, for months. The ΔH^0_t of 1670 cal/mol is for the III → I transition. The temperature 493 K in Fig. 1 obtained in the cool mode is given for comparison only. As noted in an earlier report (2), the behavior of the 10 mol% composition showing two transitions is attributed to existence of two kinds of Na_2SO_4–Ag_2SO_4 solid solutions where Ag_2SO_4 is distributed between two structural forms of Na_2SO_4 — a novel effect where a solute is distributed between two immiscible solid phases of the same compound.

B. Ag_2SO_4–K_2SO_4 and Na_2SO_4–K_2SO_4 — ameltrope solid solution type

This solid solution type involves the dissociation of one of the components on melting. The dissociation type considered here is case (*ii*), that is, the dissociation of the solid into liquid ions as described by Reisman (8). The dissociating solid is taken to be K_2SO_4 on the basis that it is the common component in both systems and by the compositional location of the ameltrope (8). The analytical treatment given here is for case (*ii*) but takes into consideration the fact that K_2SO_4 only partially dissociates into its ion species. We simplify the notation in the treatment by identifying the common component K_2SO_4 as AC and Ag_2SO_4 or Na_2SO_4 as BC, with the same usual symbols s and l for solid and liquid phases.

The heterogeneous equilibria for the case under consideration are described by

[5] $AC_{(s)} \rightleftarrows AC_{(l)} \rightleftarrows A_{(l)} + C_{(l)}$

[6] $BC_{(s)} \rightleftarrows BC_{(l)}$

The temperature dependencies of the equilibrium constants involving dissociation for eq. [5] and eq. [6] are

$$[7]\quad \frac{K_{AC}}{K^0_{AC}} = \exp\left[-\frac{\Delta H^0_{f,AC}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{AC}}\right)\right] = e^{-AC}$$

$$[8]\quad \frac{K_{Diss}}{K^0_{Diss}} = \exp\left[-\frac{\Delta H_{Diss}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{AC}}\right)\right] = e^{-Y}$$

$$[9]\quad \frac{K_{BC}}{K^0_{BC}} = \exp\left[-\frac{\Delta H^0_{f,BC}}{R}\left(\frac{1}{T}-\frac{1}{T^0_{BC}}\right)\right] = e^{-BC}$$

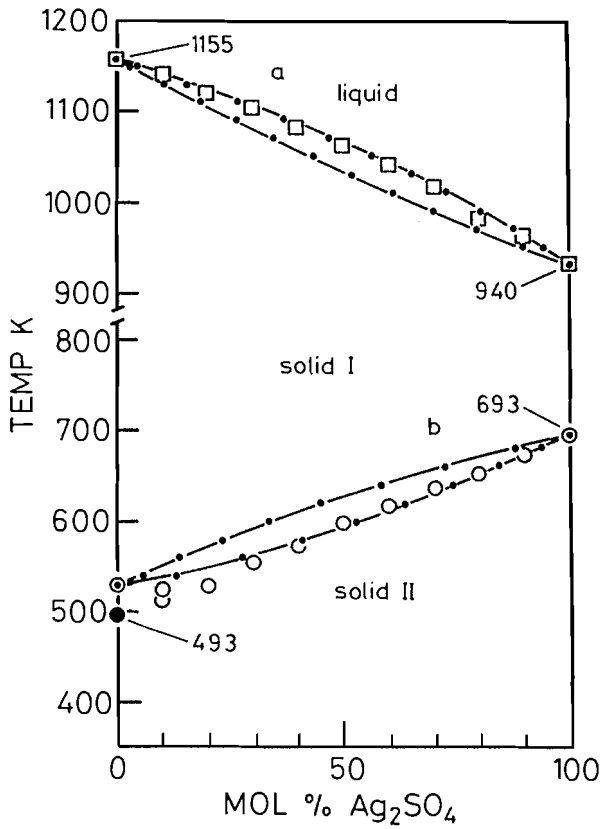

FIG. 1. Isobaric plots of temperature versus composition Ag_2SO_4 for Na_2SO_4–Ag_2SO_4 system: (*a*) solid–liquid equilibrium, ----- calculated and -□-□- experimental from ref. 2; (*b*) solid–solid equilibrium, ----- calculated and -○-○- experimental from ref. 2.

Since AC only partially dissociates we let α represent the fraction of dissociation to obtain the set of concentrations N of the pure dissociating substance:

$$N_{AC}^{0s} = N_{BC}^{0s} = N_{BC}^{0l} = 1.0$$

$$N_{A}^{0l} = N_{C}^{0l} = \alpha/(1 + \alpha)$$

$$N_{AC}^{0l} = (1 - \alpha)/(1 + \alpha)$$

We also have a new set of composition constraints in solution:

$$[10] \quad N_A^l + N_C^l + N_{AC}^l + N_{BC}^l = 1.0$$

$$[11] \quad [(\alpha + 1)/\alpha]N_A^l + N_{BC}^l = 1.0$$

$$[12] \quad N_{AC}^s + N_{BC}^s = 1.0$$

Expanding the form of eqs. [7]–[9] we get

$$[13] \quad N_{AC}^l = \left[\frac{(1 - \alpha)}{(1 + \alpha)} N_{AC}^s\right] e^{-AC}$$

$$[14] \quad (N_A^l)^2 = \left[\frac{\alpha^2}{(1 - \alpha^2)} N_{AC}^l\right] e^{-Y}$$

where

$$e^{-Y} = \frac{(N_A^l)^2/N_{AC}^l}{\alpha^2/(1 - \alpha^2)}$$

$$[15] \quad N_{BC}^l = N_{BC}^s e^{-BC}$$

Substituting N_{AC}^l from eq. [13] into eq. [14] we get

$$[16] \quad (N_A^l)^2 = \left[\left(\frac{\alpha^2}{1 - \alpha^2}\right)\frac{(1 - \alpha)}{(1 + \alpha)} N_{AC}^s e^{-AC}\right] e^{-Y}$$

Replacing N_{AC}^s in [16] and substituting N_{BC}^s from [15] we get

$$[17] \quad (N_A^l)^2 = \left[\frac{\alpha^2}{(1 + \alpha)^2}\frac{(1 - N_{BC}^l)}{e^{-BC}} e^{-AC}\right] e^{-Y}$$

Finally we replace N_{BC}^l in [17] from [11] to obtain

$$[18] \quad (N_A^l)^2 = \frac{\alpha^2}{(1 + \alpha)^2}\left[1 - \frac{[1 - (\alpha + 1)/\alpha]N_A^l}{e^{-BC}}\right] e^{-AC} e^{-Y}$$

which rearranges to the quadratic form in N_A^l

$$[19] \quad (N_A^l)^2 e^{-BC} - \left[\frac{\alpha}{(\alpha + 1)} N_A^l\right] e^{-AC} e^{-Y} - \frac{\alpha^2}{(\alpha + 1)^2}(e^{-BC} - 1) e^{-AC} e^{-Y} = 0$$

whose solution leads to the evaluation of α.

By using the component conservation equations the mole fractions of the components AC and BC in the solid and liquid phases are deduced:

$$[20] \quad x_{AC}^l = (1/\alpha)N_A^l/(\alpha - N_A^l)$$

$$[21] \quad x_{AC}^s = \left(\frac{1 - \alpha}{\alpha}\right) \cdot \frac{N_A^l}{e^{-AC}}$$

$$[22] \quad x_{BC}^s = \left[1 - \left(\frac{\alpha + 1}{\alpha}\right) \cdot N_A^l\right] \Big/ e^{-BC}$$

$$[23] \quad x_{BC}^l = \left[1 - \left(\frac{\alpha + 1}{\alpha}\right) \cdot N_A^l\right] \Big/ (1 - N_A^l)$$

These results allow a graphical description of the solid–liquid T versus x phase diagram as generated by this model of partial dissociation of component AC.

Inserting for the $Ag_2SO_4 - K_2SO_4$ system the values of 4280 and 8100 cal/mol for ΔH_f^0 with 1240 and 940 K for T_f^0 of Ag_2SO_4 and K_2SO_4, respectively, in eqs. [19]–[23] we obtain the T–x plot represented by the solid lines in Fig. 2 for the best fit values of $\alpha = 0.40$ and $\Delta H_{Diss} = 800$ cal/mol. The empty circles and the filled circles are the experimental liquidus and solidus melting temperatures, respectively, reported earlier (3). The half-filled circles in Figs. 2 and 3 indicate the separate liquidus and solidus temperatures to be experimentally indistinguishable in our studies.

Similarly, for the Na_2SO_4–K_2SO_4 system using the values of 5830 and 8100 cal/mol for ΔH_f^0 with 1155 and 1340 K for T_f^0 of Na_2SO_4 and K_2SO_4, respectively, we obtain the T–x plot represented by the solid lines in Fig. 3 for the best fit values of $\alpha = 0.35$ and $\Delta H_{Diss} = 2200$ cal/mol. The empty circles and the filled circles are the experimental liquidus and solidus melting temperatures, respectively, we reported earlier (1). The experimental liquidus and solidus temperature data of Perrier and Bellanca (9) are included in Fig. 3 for comparison purposes. The liquidus temperature data of Bergman and Rubleva (10), not shown in Fig. 3, are in good agreement with the plot. The liquidus and solidus lines of the computer plot cross over near $x_{K_2SO_4} \sim 0.30$ for the best fit and reported α and ΔH_{Diss} values. This cross-over is an artifact which can be eliminated and the two lines merged by adjusting α and ΔH_{Diss}. However, this adjustment of α and ΔH_{Diss} will effect a greater disparity between the theoretical plot and the experimental data for $x_{K_2SO_4} > 0.30$.

Hatem *et al.* (11) reported a thermodynamic analysis of the binary phase diagram K_2SO_4–Na_2SO_4 based on the deduced positive excess entropy of the solid and the enthalpy of mixing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12

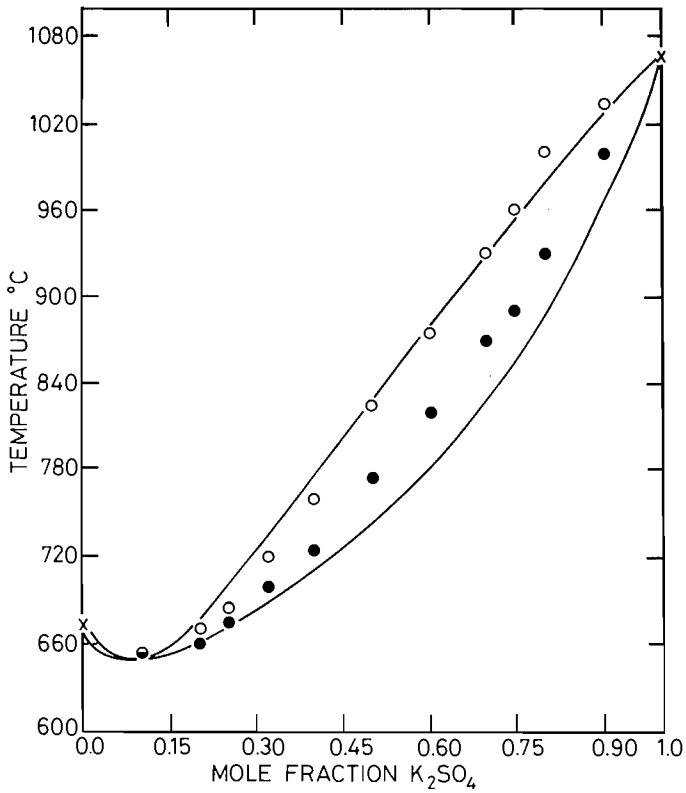

FIG. 2. Isobaric plot of temperature versus composition K_2SO_4 for solid–liquid equilibrium of Ag_2SO_4–K_2SO_4 system, — calculated and ○, ◒, ● experimental from ref. 3.

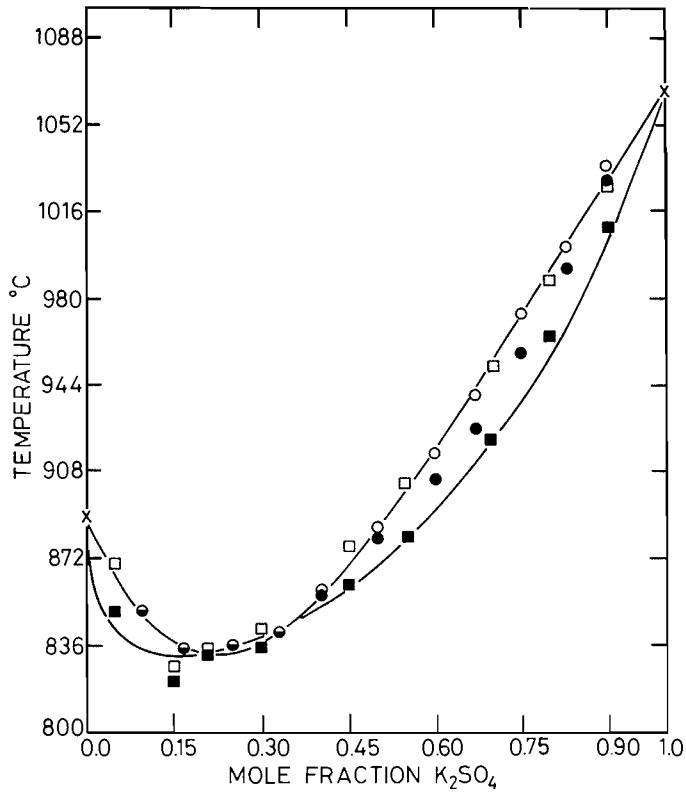

FIG. 3. Isobaric plot of temperature versus composition K_2SO_4 for solid–liquid equilibrium of Na_2SO_4–K_2SO_4 system, — calculated, ○, ◒, ● experimental from ref. 1, □, ■ experimental from ref. 9.

of Na_2SO_4–K_2SO_4 measured by Øsvold and Kleppa (12). The least-squares optimization technique was used with a one-term excess entropy expression and four terms for the enthalpy to obtain the "best" fit to the experimental liquidus and solidus data. Their "best" fit is in good agreement with the plot generated by the model for partially dissociated K_2SO_4 developed here. The more general theoretical analysis presented here incorporates the analytical approach reported by Hatem *et al.* and in addition provides for the evaluation of α, the fraction of dissociation, and the enthalpy of dissociation, ΔH_{Diss}.

It is interesting to note that the fraction of dissociation, α, values, viz. 0.40 and 0.35 obtained for K_2SO_4 in the Ag_2SO_4–K_2SO_4 and Na_2SO_4–K_2SO_4 systems, respectively, are internally consistent as might be expected. However, the spread in the ΔH_{Diss} values of 800 cal/mol for Ag_2SO_4–K_2SO_4 and 2200 cal/mol for Na_2SO_4–K_2SO_4 suggest secondary interactions such as complex association in the liquid phase. Assuming no association occurs in Na_2SO_4–K_2SO_4 then the difference of 1400 cal/mol might be attributed to enthalpy of formation of some complex resembling $K(Ag_2SO_4)^+$. It may be fortuitous that this enthalpy of complex formation is within limits of the difference between $\Delta H^0_{f,Na_2SO_4}$ and $\Delta H^0_{f,Ag_2SO_4}$ or that ΔH_{Diss} of 2200 cal/mol for Na_2SO_4–K_2SO_4 is the difference between $\Delta H^0_{f,Na_2SO_4}$ and $\Delta H^0_{f,K_2SO_4}$.

The concept of dissociation of K_2SO_4 as presented in this analysis may not coincide with that of a formal dissociation process where the usual bond cleavage is involved. In a structural study of molten alkali sulphates including K_2SO_4, Zarzycki (13) considers three principal symmetrical positions of a cation in contact with 3, 2, 1 oxygens of the anion. He focuses on "free volume" as a measure of the degree of packing of the particles in the melt and relates this parameter to free rotation states of SO_4^{2-} whereas Furukawa (14) focuses on restricted orientations of the anion. In the absence of more specific and detailed structural knowledge of molten solid solutions we use dissociation in the broadest sense to include dis-association, detachment, displacement, re-orientation, etc. of ionic groupings.

ipso Nitration in *p*-halophenyl ethers

ROBIN G. CLEWLEY, ALFRED FISCHER, and GEORGE N. HENDERSON
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received March 16, 1989

ROBIN G. CLEWLEY, ALFRED FISCHER, and GEORGE N. HENDERSON. Can. J. Chem. **67**, 1472 (1989).

Addition of nitronium ion *ipso* to halogen occurs on nitration of the *p*-haloanisoles in acetic anhydride at −60°C. In the cases of *p*-fluoro- and *p*-chloro-anisole, addition of the nitronium ion is reversible and only small amounts of *ipso* products are obtained. With *p*-bromoanisole nitrodebromination occurs. When *p*-halophenyl ethers containing a trapping substituent, e.g., 2-(4-chlorophenoxy)-2-methylpropanoic acid, are used as substrates, substantial amounts of the spiro diene with nitro *ipso* to halogen, e.g., 3,3-dimethyl-8-chloro-8-nitro-1,4-dioxaspiro[4.5]deca-6,9-dien-2-one, can be isolated. The results demonstrate that extensive *ipso* attack at the halogen-substituted position is general in the nitration of *p*-halophenyl ethers.

Key words: *ipso* nitration, ether, diene, *p*-haloanisole.

ROBIN G. CLEWLEY, ALFRED FISCHER et GEORGE N. HENDERSON. Can. J. Chem. **67**, 1472 (1989).

Lorsqu'on effectue la nitration des *p*-haloanisoles, dans l'anhydride acétique, à −60°C, l'addition de l'ion nitronium se fait en *ipso* de l'halogène. Dans les cas des *p*-fluoro- et *p*-chloro-anisoles, l'addition de l'ion nitronium est réversible et on n'obtient que des faibles quantités de produits *ipso*. Avec le *p*-bromoanisole, il se produit une nitrodébromation. Lorsqu'on utilise comme substrats des *p*-halophényl éthers portant un substituant pouvant agir comme piège, par exemple l'acide 2-(4-chlorophénoxy)-2-méthylpropanoïque, on isole des quantités importantes du spiro diène portant un groupement nitro en *ipso* de l'halogène, par exemple la 3,3-diméthyl-8-chloro-8-nitro-1,4-dioxaspiro[4.5]déca-6,9-dièn-2-one. Les résultats obtenus démontrent que l'attaque en position *ipso* de l'halogène est généralement importante lors de la nitration des éthers *p*-halophénylés.

Mots clés : *ipso* nitration, éther, diène, *p*-haloanisole.

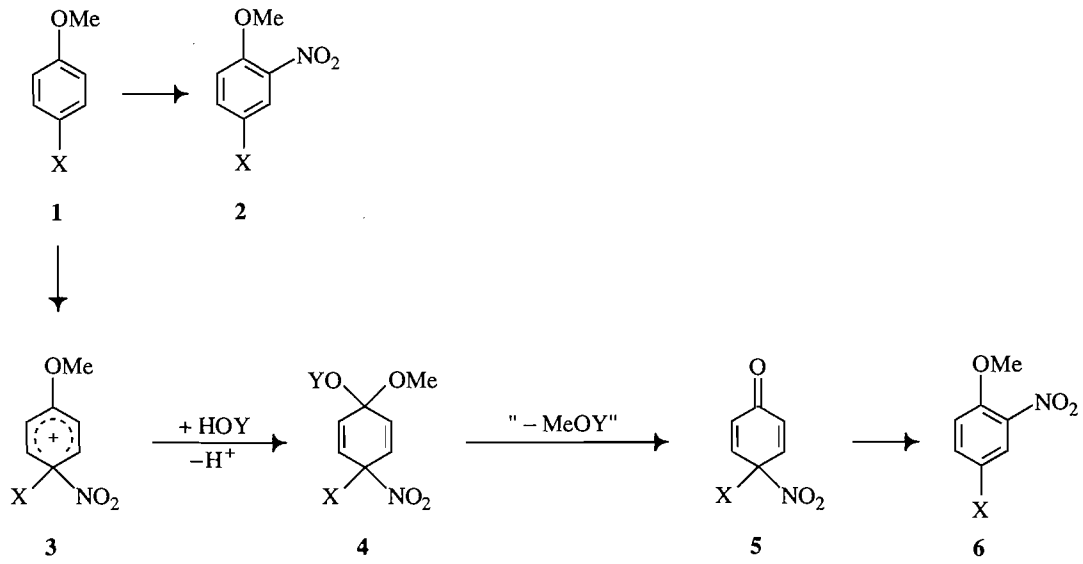
Nitration *ipso* to halogen is well established (1–14). Most examples of the formation of adducts and, from phenols, nitrohalodienones, relate to substrates that are fully substituted at the *ortho* and *para* positions and can therefore only undergo *ipso* attack. However, we have recently shown that it is possible to obtain the *ipso* nitrodienones from the *p*-halophenols although the adducts are labile and rearomatize well below ambient temperature (15). The *p*-haloanisoles provide another simple system from which we anticipated it might be possible to derive *ipso* adducts since it had been established that nitration of *p*-fluoro- and *p*-chloro-anisole in aqueous acetic acid (10) or aqueous sulphuric acid (12) gives the 4-halo-2-nitrophenol, as well as the expected 4-halo-2-nitroanisole, the former being derived via *ipso* attack. Nitration of the *p*-haloanisoles in acetic anhydride at 25°C had been investigated previously (10). It seemed likely to us that the adduct, if formed, might not be stable at this temperature. We hoped that nitration of the 4-haloanisoles in acetic anhydride at low temperatures would give the nitronium acetate adducts.



Results and discussion

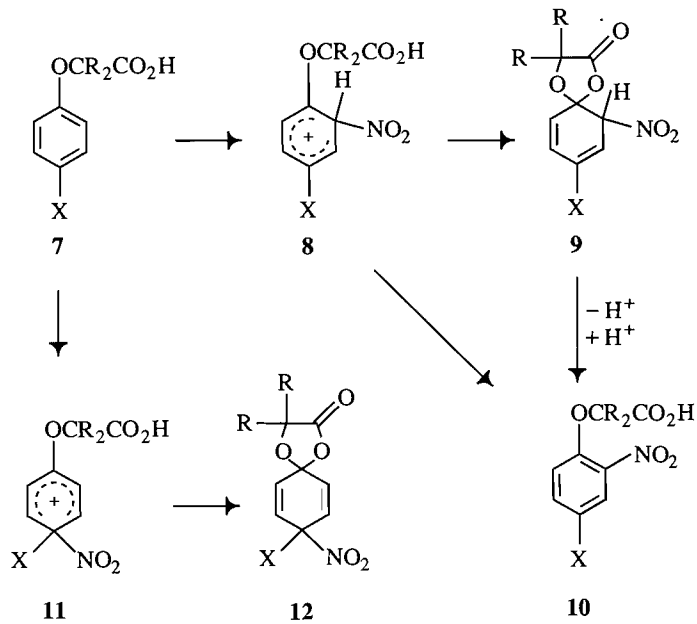
Nitration of p-*fluoro-,* p-*chloro-, and* p-*bromo-anisole*

Nitration of the *p*-haloanisoles was carried out in acetic anhydride at −60°C. *p*-Fluoroanisole (**1***a*) gave a mixture of 4-fluoro-2-nitroanisole (**2***a*) (94%) and 4-fluoro-4-nitrocyclohexa-2,5-dienone (**5***a*) (6%). *p*-Chloroanisole (**1***b*) gave a similar mixture of **2***b* and **5***b* but *p*-bromoanisole (**1***c*) gave only a mixture of aromatic compounds which, after work-up, was shown to consist of **2***c* (68%), *p*-nitro- (15%), 2,4-dibromo- (11%), and 2-bromo-4-nitro-anisole (5%). Formation of **5***a* and **5***b* occurs through addition of the nitronium ion *ipso* to the halogen atom, and capture of the resulting carbocation by acetic acid, followed by loss of the elements of methyl acetate (Scheme 1 (Y = Ac), cf. Scheme 1 ref. 12). Thus, although a small amount of the *ipso* adduct **4** is apparently formed in the nitration of **1***a* and **1***b* in acetic anhydride at −60°C, the adduct is too labile with respect to elimination to the dienone to be detected, even at this temperature.

In the earlier studies the yield of the halonitrophenol **6** increased with the water content of the reaction medium, the maximum yield of **6***b* being 40% in aqueous sulphuric acid (12) and 37% in aqueous acetic acid (10). Similarly, nitration of **1***a* in aqueous sulphuric acid gave **2***a* (77%) and **6***a* (23%), the maximum yield of **6***a* being obtained in 64–74% acid (12). The halonitrophenol **6** is formed by the trapping of the *ipso* Wheland intermediate by water and thus its amount reflects the extent of *ipso* attack under these conditions. Nitration of **1***c* in aqueous acetic acid (10) gave a mixture of **2***c*, 2,4-dibromoanisole, *p*-nitroanisole, *p*-nitrophenol, and 2-bromo-4-nitrophenol; the amount of the products arising via *ipso* nitration (the nitrodebromination products) was 39%. The formation of the nitrodebromination products reflects the fact that Br^+ is a better leaving group than NO_2^+ (9). The fact that phenols are obtained as well as 4-nitroanisole shows that, in aqueous acid, capture of the *ipso* cation by water is competitive with loss of the Br^+.

For **1***a* and **1***b* the apparent extent of *ipso* attack in acetic anhydride, even at −60°C, is substantially lower than that observed in aqueous media. There is no reason to believe that there are gross disparities in the degrees of *ipso* attack in acetic anhydride and aqueous sulphuric acid or aqueous acetic acid. The extent of nucleophilic capture on nitration of 2-methyl- (16, 17), 4-methyl- (17, 18), and 2-chloro-4-methyl-anisole (12, 19) in acetic anhydride is comparable to that observed in nitrations in aqueous sulphuric acid. However, as the stability of the *ipso* nitrocyclohexadienyl cation is reduced, other reactions, such as rearrangement or the loss of nitronium ion, should start to compete with the trapping of the *ipso* cation. It would seem that this is the situation for **3***a* and **3***b* in acetic anhydride. In more nucleophilic solvents (aqueous sulphuric acid, aqueous acetic acid) the trapping reaction competes favourably with the rearrangement or cleavage of nitronium ion. In acetic anhydride **3***a* (**3***b*) rearranges or reverts to **1***a* (**1***b*) and nitronium ion 2–5 times

a X = F; *b* X = Cl; *c* X = Br



SCHEME 1

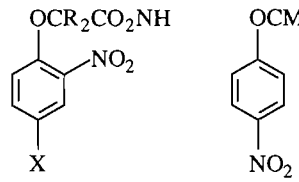
faster than it is trapped by the weaker (than water) nucleophile, acetic acid. The halonitroanisole **2** is the end product whether **3** undergoes rearrangement or cleavage. For **1***c* the amount of products derived from *ipso* attack in acetic anhydride (23%) is more nearly comparable with the amount formed in aqueous acetic acid (39%) (10). Since the ratio of *para:ortho* attack in anisoles increases in aqueous media (10), these percentages may be even more closely comparable. Loss of the bromine from the *ipso* cation, in acetic anhydride, is faster than loss of nitronium ion and also faster than capture by acetic acid.

Nitration of p-*halophenoxy acids in acetic anhydride*

Nitration of 2-(4-fluorophenoxy)-2-methylpropanoic acid (**7***a*) in acetic anhydride at −40°C gave 2-(4-fluoro-2-nitrophenoxy)-2-methylpropanoic acid (**10***a*) (and (or) its anhydride with acetic acid) (72%), 3,3-dimethyl-8-fluoro-8-nitro-1,4-dioxaspiro[4.5]deca-6,9-dien-2-one (**12***a*) (28%), and a trace amount of 3,3-dimethyl-8-fluoro-10-nitro-1,4-dioxaspiro[4.5]deca-6,8-dien-2-one (**9***a*) (Scheme 2). On low temperature work-up with aqueous ammonia, **10***a* (~46%), **12***a* (~19%), and 2-(4-fluoro-2-nitrophenoxy)-2-methylpropanamide (**13***a*) (~26%) were obtained, although the yields varied somewhat from one run to another. Acid **10***a* was separated from the nonaromatic compounds by extraction into base during work-up. The diastereomers of **12***a* (designated as **12***ai* and **12***aj*) and amide **13***a* were separated by low temperature column chromatography.

A mixture of **10***b* (and (or) its anhydride with acetic acid) (53%) and **12***b* (47%) was formed on the nitration of **7***b* in a mixture of acetic anhydride and trifluoroacetic anhydride at −60°C. On work-up, **10***b* (30%), **12***b* (44%), and **13***b* (27%) were obtained and were separated. Nitration of **7***c* at −60°C resulted in the formation of **10***c* (53%) (and (or) its anhydride with acetic acid), **12***c* (36%), and 2-(4-nitrophenoxy)-2-methylpropanoic acid (**14**) (11%). Ammonia work-up gave **10***c* (22%), **12***c* (30%), **13***c* (25%), **14** (18%), and 2-(2-bromo-4-nitrophenoxy)-2-methylpropanoic acid (3%). One diastereomer of **12***c* was obtained by recrystallization and the other diastereomer and amide **13***c* were separated by low temperature

a X = F, R = Me; *b* X = Cl, R = Me; *c* X = Br, R = Me
d X = I, R = Me; *e* X = Cl, R = H



SCHEME 2

chromatography. Acid **7***d* was nitrated in acetic anhydride to give **14** (68%) and **10***d* (32%).

Nitration of 4-chlorophenoxyacetic acid (**7***e*) gave acid **10***e*, acetic 4-chloro-2-nitrophenoxyacetic anhydride, and diene **12***e*. On aqueous ammonia work-up, **10***e* (20%), **12***e* (21%), and amide **13***e* (52%) were obtained. One diastereomer of diene **12***e* was isolated by crystallization.

The structures of the spirodienes were assigned on the basis of spectral information. The ^{1}H nmr (Table 1) showed the *gem* dimethyls (methylene in **12***e*), and four protons in the vinylic region that exhibited an AA′BB′ pattern (AA′BB′X in **12***a*). The ^{13}C nmr (Table 2) showed that there are two pairs of sp^2 carbons bearing hydrogens, and two quaternary sp^3 carbons in

13 14

a X = F, R = Me
b X = Cl, R = Me
c X = Br, R = Me
e X = Cl, R = H

addition to the carbon bearing the *gem* dimethyl groups. The presence of the nitro group was confirmed by the infrared spectra. The spectral data are consistent with the addition of nitronium ion, ring closure with the carboxylic acid, and loss of the acid proton to give a spiro 1,4 adduct. There is insufficient information to allow the assignment of the stereochemistry. The lower-melting isomer, which was eluted first on chromatography, is designated as *i*, and the higher-melting isomer as *j*.

*Nitration of acids 7*a *and 7*b *in chloroform*

Acids **7***a* and **7***b* were also nitrated with trifluoroacetyl nitrate in [^{2}H]chloroform. In each case, in addition to the expected products **10** and **12**, a 3,3-dimethyl-8-halo-10-nitro-1,4-dioxaspiro[4.5]deca-6,8-dien-2-one (**9**) was obtained as a single diastereomer (Table 3). The extent of *ipso* attack in chloroform was similar to that in acetic anhydride. Formation of diene **9** reduced the amount of the nitro substitution product **10**, reflecting the partitioning of the Wheland cation **8** between capture by ring closure to **9** and deprotonation to substitution product **10**. Diene adducts with nitro *ipso* to hydrogen have been obtained by the rearrangement of nitrodiene adducts (16) and by the nitration of substrates subject to internal nucleophilic capture and possessing bulky substituents that hinder the deprotonation step (20). Normally, diene adducts with a secondary nitro group are not obtained from nitrations, as deprotonation of a secondary nitrocyclohexadienyl cation is usually too rapid for nucleophilic capture to compete. The formation of dienes **9***a* and **9***b* can be ascribed to the low nucleophilicity of the medium resulting in slow deprotonation, and to a low degree of solvation of the carboxylic acid side chain allowing ready capture of the carbocation; entropy considerations favour nucleophilic capture. The lower symmetry of the new dienes was apparent in the ^{1}H nmr spectra. Diene **9***b* had four signals in the region 5.5–6.5 ppm. Two of the protons exhibited a 10-Hz coupling and one other showed a 4-Hz coupling (the fourth proton was obscured). The ^{13}C nmr spectrum of the reaction mixture showed a prominent signal at 86.8 ppm; similar values have been observed for carbons with a nitro group *ipso* to a hydrogen in other secondary nitrodienes (16, 20). The spectral data are consistent with structure **9***b*. The nmr spectra of **9***a* were similar and, even more definitive, there was a signal at 87.0 ppm that showed a typical $^3J_{CF}$ coupling (10 Hz). Dienes **9***a* and **9***b* isomerized on work-up to give acids **10***a* and **10***b*.

*Nitration of derivatives of acids 7*b *and 7*c

Nitration of methyl 2-(4-chlorophenoxy)-2-methylpropanoate (**15***m*) in a mixture of acetic anhydride and trifluoroacetic anhydride failed to give nitronium acetate adducts; only methyl 2-(4-chloro-2-nitrophenoxy)-2-methylpropanoate (**16***m*) was obtained. It is likely that the *ipso* Wheland intermediate (**17***m*) cyclizes through addition of the carbonyl oxygen to the cationic centre. However, demethylation of the resulting cation **18***m* is presumably slower than reversion to **17***m*, and to the rearrangement, or further reversion, to **15***m* and nitronium ion and ultimate formation of **16***m* (Scheme 3). A mixture of **12***b* and **16***n* was obtained on nitration of **15***n*, the former through dealkylation of **18***n*, a reflection of the greater electrofugacity of *tert*-butyl compared to methyl. It is clear that the explanation for the failure of dienes to form from the methyl ester can only lie in the ineffective trapping step. The extent of addition of nitronium ion at the *ipso* position must be closely similar for acid **7***b* and esters **15***m* and **15***n*, and these observations also support the earlier conclusion that the failure to obtain adducts from the nitration of **1***a* and **1***b* in acetic anhydride is due to a slow trapping step and is not to be attributed to a lack of *ipso* attack.

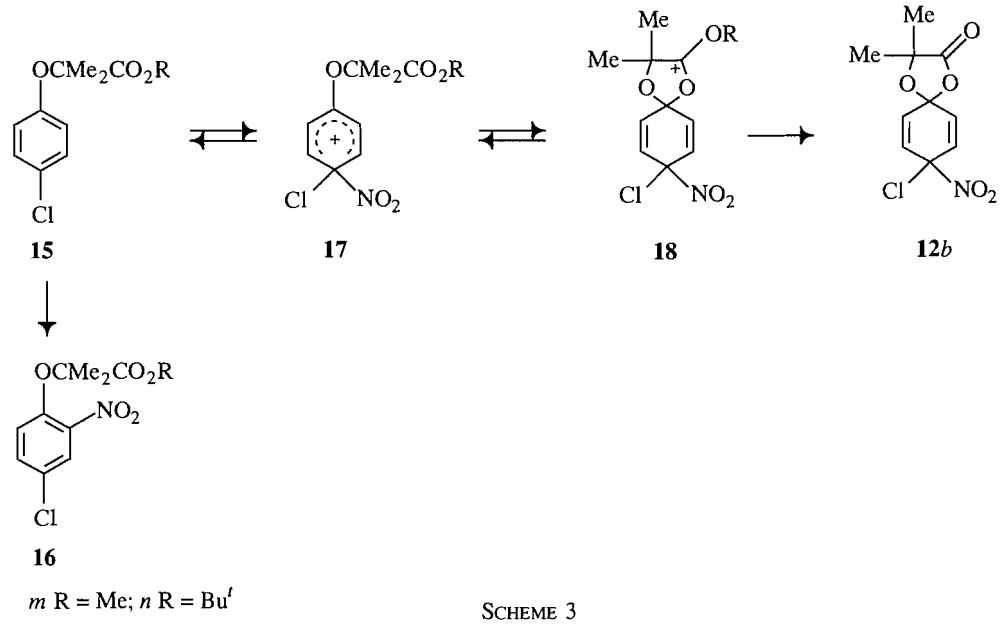
[e]3-H of CH_2.

Nitration of 2-(4-chlorophenoxy)-2-methylpropanamide in acetic anhydride/trifluoroacetic anhydride/[^{2}H]chloroform and in trifluoroacetic anhydride/[^{2}H]chloroform gave 8-chloro-2,2-dimethyl-8-nitro-1-oxa-4-azaspiro[4.5]-deca-6,9-dien-3-one (**21***b*) and **13***b* (Scheme 4). The proportion of **21***b* in the nitration mixture varied between 48 and 60%. Although the amide group was as efficient as the carboxyl group in capturing the *ipso* Wheland intermediate, the resultant diene was not as stable and could not be isolated. On warming to ambient temperature in the presence of acid, **21***b* underwent opening of the lactam ring to give **13***b*. This is a striking contrast to the behaviour of Meisenheimer complexes possessing the same lactam ring, which open to give N-aryl amides (*vide infra* (21)). Under basic conditions 4-chloro-2-nitrophenol was also obtained, presumably via dienone **5***b*. Nitration of **19***c* in acetic anhydride/trifluoroacetic anhydride/[^{2}H]chloroform gave **13***c* (50%), **21***c* (40%), and 2-(4-nitrophenoxy)-2-methylpropanamide (10%). On aqueous ammonia work-up amide **13***c* (67%), 2-(4-nitrophenoxy)-2-methylpropanamide (24%), and 2,6-dibromo-4-nitrophenol (9%) were obtained.



Data for the extent of apparent *ipso* attack in *p*-halophenyl ethers are summarized in Table 4. Whether or not an adduct is formed from the *ipso* cation depends upon the rate of the trapping reaction relative to the rates of other reactions of the cation. We can deduce the following rate relationships in acetic anhydride. For cations **3***a* and **3***b* the trapping reaction (with acetic acid) is 2–5 times slower than the reversion or rearrangement of the cation. For cation **3***c* the cleavage of the carbon–halogen bond is >10 times faster than the trapping reaction (and faster than the rearrangement or reversion) since no diene product was

observed. For cations **11***a*, **11***b*, **11***e*, **17***n*, and **20***b* the trapping reaction (with internal carboxylic acid) is faster (>5 times) than the cleavage or rearrangement of nitronium ion. For cations **11***c* and **20***c* the trapping reaction is 3–4 times faster than the cleavage of Br^+. However, for cation **11***d*, cleavage of I^+ is >10 times faster than the trapping reaction since no trapped product was detected.

Formation and reactions of 4-halo-2-nitrophenoxy amides ***13***

The formation of amides was unexpected, as the only aromatic products resulting from the nitration of 2-methyl-2-(2-methylphenoxy)propanoic acid, 2-methyl-2-(4-methylphenoxy)propanoic acid, and 2-methylphenoxyacetic acid were nitrophenoxy acids (16). The ^1H nmr spectrum obtained when the nitration of *p*-chlorophenoxyacetic acid in acetic anhydride was complete showed, in addition to the signals due to diene **12***e*, two methylene signals, the combined intensity of what was in a 2:3 ratio with the signals in the aromatic region. The intensity of the downfield methylene signal increased with time, consistent with the slow formation of acetic 4-chloro-2-nitrophenoxyacetic anhydride. The formation of a mixed anhydride has also been demonstrated in the nitrations of both 2-methyl-2-(2-methylphenoxy)propanoic acid and 2-methylphenoxyacetic acid in acetic anhydride (16). Nucleophilic attack of ammonia on the mixed anhydride could result in the formation of either acetamide and an aryloxy acid, or acetic acid and an aryloxy amide. How the attack is partitioned will depend on the degree of electron deficiency at the two anhydride carbonyl carbons and the steric requirements at these two sites. With a 2-methyl-4-nitro- or a 4-methyl-2-nitro-aryloxy group, attack is solely at the acetyl carbonyl. However, two electron-withdrawing groups on the aromatic ring suffice to shift nuc-

leophilic attack substantially to the other carbonyl, as was demonstrated by forming acetic 2-(4-chloro-2-nitrophenoxy)-2-methylpropanoic anhydride and subjecting it to the standard work-up conditions whereupon amide **13***b* was formed.

Treatment of amide **13***b* with isoamyl nitrite in dioxane gave acid **7***b* on aqueous work-up, confirming the assigned structure. However, suspension of **13***b* in 20% sodium hydroxide for 1 h at 90°C gave 4-chloro-2-nitroaniline and 2-hydroxy-2-methylpropanoic acid. The Smiles rearrangement of 2-aryloxy-2-methylpropanamides is facile (even 2-(4-methoxyphenoxy)-2-methylpropanamide undergoes rearrangement under sufficiently vigorous conditions) (21). Treatment of **13***b* with sodium hydride in dry dimethylformamide for 10 min gave *N*-(4-chloro-2-nitrophenyl)-2-hydroxy-2-methylpropanamide. Alkaline hydrolysis of this amide gave 4-chloro-2-nitroaniline and 2-hydroxy-2-methylpropanoic acid. Treatment of amide **13***b* with 57% hydriodic acid failed to cleave the ether linkage and gave a product of formula $C_{10}H_{10}ClNO_2$. The ^1H nmr showed the presence of a pair of *gem* dimethyl groups and three aromatic protons. The infrared spectrum contained a lactam band at 1685 cm^{-1}. The spectral information is consistent with the structure 4-aza-6-chloro-2,2-dimethyl-1-oxa-3-oxo-1,2,3,4-tetrahydronaphthalene (**22**). Treatment of acid **10***b* with

22

57% hydriodic acid under the same conditions also gave this lactam. Thus from both **10***b* and **13***b* the lactam must have been formed by reduction of the nitro group followed by closure to form the lactam ring. Reduction of aromatic nitro groups by hydriodic acid was observed previously in 3-(arylmethylene)nitrophthalides (22).

Experimental

Instrumentation and general experimental methods were described previously (15, 18). 4-Fluoro-, 4-chloro-, 4-bromo-, 4-iodo-, and 4-nitro-phenol, 4-chlorophenoxyacetic acid, 4-chloro- and 4-bromoanisole, and 1,1,1-trichloro-2-methyl-2-propanol were Aldrich reagent grade. 4-Fluoroanisole, bp 150°C (lit. (23*a*) bp 157°C) was obtained by alkylation of 4-fluorophenol with dimethyl sulphate. The nmr spectra of substrates and products not given in the text are included in Tables 1,2,5–8.

2-(4-Halophenoxy)-2-methylpropanoic acid (7) and related acids

Pulverized sodium hydroxide (64.0 g, 1.60 mol) was added in five portions, at hourly intervals, to a solution of 4-fluorophenol (22.4 g, 0.20 mol) and 1,1,1-trichloro-2-methyl-2-propanol hydrate (85.2 g) in acetone (400 cm^3). The reaction mixture was cooled to 0°C before each portion of sodium hydroxide was added and the mixture was then allowed to warm to ambient temperature. Additional acetone (400 cm^3) was added after the last portion of sodium hydroxide. The reaction mixture was stirred for 16 h and the solvent was then evaporated under reduced pressure. The residue was taken up in water (500 cm^3) and the aqueous solution was washed with ether (2 × 100 cm^3), acidified with hydrochloric acid, and extracted with ether (3 × 100 cm^3). This ether solution was extracted with saturated sodium bicarbonate (3 × 100 cm^3) and the bicarbonate extract was acidified and extracted with ether

($4 \times 100\ cm^3$). The ether solution was dried ($MgSO_4$) and the ether was evaporated to afford a mixture of **7***a* and methacrylic acid. The latter was removed by heating the oil under reduced pressure and the residue was taken up in ether. On filtration through a thin layer of silica and evaporation of the solvent, **7***a* was obtained (34.7 g, 88%). Recrystallization from ether gave colourless crystals, mp 86–87°C (lit. (24) mp 83°C). The following acids were obtained similarly: **7***b* (90%), mp 123°C (lit. (24) mp 117°C), **7***c* (80%) mp 136°C (lit. (24) mp 135°C), **7***d* (64%), mp 144–145°C (lit. (24) mp 135°C), **14** (53%, after preforming the sodium phenoxide), mp 128°C (lit. (25) mp 123°C), and **10***c* (54%), mp 108°C; ir (KBr): 3000–2500 (OH), 1705 (C=O), 1540 and 1360 (NO_2) cm^{-1}. *Anal.* calcd. for $C_{10}H_{10}BrNO_5$: C 39.50, H 3.31, N 4.61; found: C 39.67, H 3.41, N 4.55.

2-(4-Chlorophenoxy)-2-methylpropanoic acid derivatives

A solution of **7***b* (1.72 g, 8.0 mmol) and pyridine (1.31 cm^3, 16.3 mmol) in ether (25 cm^3) was added dropwise with stirring to a solution of thionyl chloride (0.59 cm^3, 8.2 mmol) in ether (25 cm^3) heated under reflux. After 90 min methanol (0.35 cm^3, 8.6 mmol) was added and after a further 60 min the reaction mixture was washed with aqueous sodium bicarbonate, dried, and the ether was evaporated to afford ester **15***m* (1.70 g, 93%). Ester **15***n* (61%) was prepared by addition of a solution of potassium *tert*-butoxide in tetrahydrofuran to the acid chloride from **7***b* and had mp 38–39°C; ir (KBr): 1725 (C=O), 1235 (C—O) cm^{-1}. *Anal.* calcd. for $C_{14}H_{19}ClO_3$: C 62.11, H 7.07; found: C 61.89, H 6.98. Amide **19***b* was prepared (83%) by adding the acid chloride to a solution of ammonia in ether at −40°C, and had mp 120°C (lit. (24) mp 121°C). Amide **19***c* had mp 127°C (lit (24) mp 128°C).

Nitration of 4-haloanisoles (1)

A solution of **1***a* (0.63 g, 5 mmol) in acetic anhydride (2.55 g, 25 mmol) at −60°C was added with stirring to a solution of nitric acid (0.95 g, 15 mmol) in acetic anhydride (2.55 g, 25 mmol), also at −60°C. Within 45 s a yellow precipitate had formed, which dissolved on the addition of cold [^{2}H]chloroform (5 cm^3). The ^{1}H nmr showed that the reaction had gone to completion and that **2***a* (94%) and **5***a* (6%) (15) had been formed. The reaction mixture was added to ether (250 cm^3) at −60°C and concentrated aqueous ammonia (22 cm^3) was added dropwise. The ethereal fraction was washed with cold brine (2×75 cm^3) and water (75 cm^3). After drying, the ether was evaporated to give **2***a* (0.79 g), mp 61°C (lit. (23*b*) mp 61.5–62°C). The aqueous extracts were combined, acidified, and extracted with ether (3×75 cm^3). Evaporation of the ether afforded an acetic acid solution of **6***a* and a small amount of 2,6-dinitro-4-fluorophenol.

Anisoles **1***b* and **1***c* were nitrated similarly.

Nitration of halophenoxy acids and derivatives

A solution of **7***a* (19.8 g, 0.10 mol) in acetic anhydride (51.1 g, 0.50 mol) was added over 30 min to a solution of nitric acid (18.9 g, 0.30 mol) in acetic anhydride (51.1 g, 0.50 mol) at −60°C. The temperature was raised and held at −40°C for 40 min; ^{1}H nmr showed that **10***a* (71%) and diene (29%) were formed. The solution was added to ether (1.5 dm^3) at −60°C, and concentrated aqueous ammonia (215 cm^3) was added dropwise. The ether phase was separated and washed with brine (2×500 cm^3) and with water (500 cm^3), dried, and the ether evaporated to yield a mixture (9.7 g) of **12***a* (41%) and **13***a* (59%). The aqueous washings were combined, acidified, and extracted with ether (3×500 cm^3). The ether extract was washed with brine (500 cm^3), dried, and evaporated, finally under reduced pressure. The residue was taken up in 1:1 ether–pentane, washed with brine, dried, and the solvent evaporated to afford **10***a* (11.8 g), obtained as colourless crystals on recrystallization from ether, mp 79–81°C; ir (KBr): 3000–2500 (OH), 1715 (C=O), 1540 and 1360 (NO_2), 1205 (C—F) cm^{-1}. *Anal.* calcd. for $C_{10}H_{10}FNO_5$: C 49.39, H 4.14, N 5.76; found: C 49.36, H 3.94, N 5.67. Chromatography of the mixture of **12***a* and **13***a* on silica (800 g) at −40°C and elution with ether–pentane gave **12***a* (4.8 g). The lower melting diastereomer (**12***ai*) separated in the 15% and 20% ether fractions and was obtained as colourless crystals on recrystallization from ether, mp 101–103°C; ir (KBr): 1800 (C=O), 1570 and 1340 (NO_2), 1125 (C—F) cm^{-1}. *Anal.* calcd. for $C_{10}H_{10}FNO_5$: C 49.39, H 4.14, N 5.76; found: C 48.97, H 4.21, N

Recrystalliztion of the residue from the 30% through 100% ether fractions gave the second diastereomer **12***aj*, mp 122–124°C; ir (KBr): 1800, 1570 and 1340, 1125 cm^{-1}. *Anal.* calcd. for $C_{10}H_{10}FNO_5$: C 49.39, H 4.14, N 5.76; found: C 49.09, H 4.28, N 5.66. Elution with dichloromethane followed by methanol gave **13***a* (4.8 g), obtained as yellow crystals on recrystallization from ether, mp 118–119°C; ir (KBr): 3470 (NH_2), 1680 (C=O), 1520 and 1360 (NO_2), 1205 (C—F) cm^{-1}. *Anal.* calcd. for $C_{10}H_{11}FN_2O_4$: C 49.59, H 4.58, N 11.57; found: C 49.50, H 4.53, N 11.47.

A solution of acid **7***a* (198 mg, 1.0 mmol) in [^{2}H]chloroform (2.0 cm^3) was added to a solution of nitric acid (126 mg, 2.0 mmol) and trifluoroacetic anhydride (280 mm^3, 2.0 mmol) in [^{2}H]chloroform (2.0 cm^3) at −50°C. The mixture was warmed to −30°C and after 10 min the ^{1}H nmr spectrum showed that **10***a* (53%), **12***a* (21%), and **9***a* (26%) had been formed. Diene **9***a* had ^{1}H nmr ($CDCl_3$, 250 MHz) δ: 1.59 (s, 6, CH_3), 5.49 (dd, J = 5 and 5 Hz, 1, 10-H), 5.64 (m, 1, 9-H), 5.98 (dd, J = 4 Hz and 10 Hz, 1, 6-H) ppm. The 7-H signal occurred in the range 6.2–6.5 ppm but was obscured. The C-10 signal (87.0 ppm (d, $^3J_{CF}$ = 10 Hz)) was clearly evident in the ^{13}C nmr spectrum of the reaction mixture. The reaction mixture was worked up by adding it to aqueous sodium bicarbonate (20 cm^3) at 0°C, followed by extraction with dichloromethane (3 × 10 cm^3). Diene **12***a* was obtained from the organic phase and acid **10***a* from the aqueous phase. Diene **9***a* had isomerized to **10***a*.

Nitration of other acids and derivatives was carried out by methods similar to those described above. In a number of cases trifluoroacetic anhydride was included in the nitrating solution to boost the reactivity and (or) [^{2}H]chloroform was added to the substrate solution to increase the solubility. The amount of substrate, the ratio of nitric acid:acetic anhydride:trifluoroacetic anhydride:volume of [^{2}H]chloroform per mole of substrate, and the final reaction temperature are shown in parentheses in the following.

Acid **7***b* (0.10 mol; 6:14:3:—; −60°C) gave **10***b* (7.7 g), the diastereoisomers of **12***b* (10.7 g), and **13***b* (5.5 g). Acid **10***b* had mp 96–97°C; ir (KBr): 3000–2500, 1715, 1530 and 1340, 710 (C—Cl) cm^{-1}. *Anal.* calcd. for $C_{10}H_{11}ClNO_5$: C 46.26, H 3.88, N 5.39; found: C 46.21, H 3.67, N 5.33. The first diastereomer **12***bi* had mp 94–96°C (dec.); ir (KBr): 1800, 1560 and 1330, 690 (C—Cl) cm^{-1}. *Anal.* calcd. for $C_{10}H_{10}ClNO_5$: C 46.26, H 3.88, N 5.39; found: C 46.07, H 3.81, N 5.36. The second diastereomer **12***bj* had mp 105–106°C (dec.); ir: 1800, 1560 and 1330, 690 cm^{-1}. *Anal.* calcd. for $C_{10}H_{10}ClNO_5$: C 46.26, H 3.88, N 5.39; found: C 45.92, H 3.79, N 5.30. Amide **13***b* had mp 127°C; ir (KBr): 3470, 1700, 1515 and 1355, 705 (C—Cl) cm^{-1}. *Anal.* calcd. for $C_{10}H_{11}ClN_2O_4$: C 46.44, H 4.29, N 10.83; found: C 46.50, H 4.10, N 10.69. In the absence of acetic anhydride, **7***b* (2 mmol; 2:—:2:4 dm^3; −60°C) gave **10***b* (37%), **12***b* (45%), and **9***b* (17%). Diene **9***b* had ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 1.67 (s, 6, CH_3), 5.55 (d, J = 4 Hz, 1, 10-H), 5.97 (d, J = 10 Hz, 1, 6-H), 6.31 (d, J = 10 Hz, 1, 7-H) ppm. The 9-H signal occurred in the range 6.2–6.3 ppm but was obscured. In the ^{13}C nmr spectrum of the mixture the C-10 signal at 86.8 ppm was unambiguous. On work-up, **10***b* and **12***b* were obtained but **9***b* did not survive. A small amount of 2-(2,6-dinitro-4-chlorophenoxy)-2-methylpropanoic acid was also obtained in the **10***b* fraction. It had ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 1.58 (s, 6, CH_3), 7.97 (s, 2, 3-H and 5-H) ppm; ^{13}C nmr $CDCl_3$, 62.9 MHz) δ_C: 24.5 (CH_3), 87.7 ($C(CH_3)_2$), 128.4 (C-3 and C-5), 130.5 (C-4), 140.6 (C-2 and C-6), 147.4 (C-1), 176.1 (COOH) ppm.

Diastereomer **12***cj* crystallized from the ether solution of the product mixture from nitration of **7***c* (30 mmol; 4:16:3:—; −60°C). It had mp 99°C (dec.); ir (KBr): 1800 (C=O), 1530 and 1340 (NO_2) cm^{-1}. *Anal.* calcd. for $C_{10}H_{10}BrNO_5$: C 39.50, H 3.31, N 4.61; found: C 39.58, H 3.35, N 4.58. The other diastereomer **12***ci* had mp 90–92°C (dec.); ir (KBr): 1800, 1580 and 1340 cm^{-1}. *Anal.* calcd. for $C_{10}H_{10}BrNO_5$: C 39.50, H 3.31, N 4.61; found: C 39.47, H 3.34, N 4.57. amide **13***c* had mp 111°C; ir (KBr): 3470, 1700, 1520 and 1360 cm^{-1}.

Acid **7***d* (0.5 mmol; 3:10:—:—; −60°C) did not give any diene. Acid **7***e* (50 mmol; 6:14:3:—; −30°C) was added as a finely powdered solid to the nitrating mixture, as it was insoluble. On work-up the ether phase afforded **12***e* (2.43 g), obtained as a single diastereomer on recrystallization from ether, mp 98°C (dec.); ir (KBr): 1820, 1580 and 1330 cm^{-1}. *Anal.* calcd. for $C_8H_6ClNO_5$: C 41.49, H 2.61, N 6.05; found: C 41.52, H 2.68, N 6.03. Amide **13***e* (5.98 g) was filtered from the aqueous layer and obtained as colourless crystals on recrystallization from acetone, mp 188–189°C; ir (KBr): 3460 and 3160, 1700, 1520, and 1345 cm^{-1}. *Anal.* calcd. for $C_8H_6ClN_2O_5$: C 41.67, H 3.06, N 12.05; found: C 41.56, H 3.13, N 12.09. Acid **10***e* was obtained from the acidified aqueous layer and had mp 173–174°C (lit. (26) mp 169–170°C).

Ester **15***m* (2.5 mmol; 6:14:3:—; −60°C) did not give diene. The product, **16***m*, had mp 42–45°C; ir (KBr): 1740 (C=O), 1530 and 1355 (NO_2) cm^{-1}; ms m/e (relative intensity): 275 (14), 273.0439 (43, M_r($^{12}C_{11}{}^1H_{12}{}^{35}Cl{}^{14}N{}^{16}O_5$) = 273.0404), 216 (11), 214 (31), 175 (71), 174 (19), 173 (100), 128 (20), 101 (70), 73 (23), 69 (21), 63 (13), 59 (18).

Ester **15***n* (2.5 mmol; 6:14:3:—; −60°C) gave **12***b* and **16***n*. Amide **19***b* (3 mmol; 10:15:5:0.8 dm^3; −40°C; also 1.5 mmol; 10:15:5:1.7

dm^3; −40°C; and 2.5 mmol; 1.5:—:1.5:2.0 dm^3; −50°C) gave **13***b* and diene **21***b*. Work-up using aqueous ammonia, liquid ammonia, and aqueous sodium bicarbonate was variously attempted. In a number of cases a portion of the **21***b* survived through the work-up until the temperature was raised to ambient, whereupon it decomposed to **13***b*. The diene was precipitated from the last reaction mixture, and subsequently filtered off, on the addition of ether and pentane, but even then it decomposed on warming to ambient. One diastereomer of **21***b* had ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 1.55 (s, 6, CH_3), 6.16 (d, J = 10 Hz, 2, 7-H and 9-H), 6.55 (d, J = 10 Hz, 2, 6-H and 10-H) ppm; the other diastereomer had ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 1.57 (s, 6, CH_3), 6.14 (d, J = 10 Hz, 2, 7-H and 9-H), 6.50 (d, J = 10 Hz, 2, 6-H and 10-H) ppm. Diene **21***c*, obtained on the nitration of **19***c* (7.5 mmol; 10:15:5:1.7 dm^3; −40°C) did not survive work-up.

Reactions of 2-(4-chloro-2-nitrophenoxy)-2-methylpropanamide (13b)

A solution of isoamyl nitrite (0.54 cm^3, 4.0 mmol) in dioxane (5 cm^3) was added to a solution of amide **13***b* (519 mg, 2.0 mmol) in dioxane (5 cm^3) over 1 h. After stirring for 2 h at ambient temperature the reaction mixture was heated under reflux for 2.5 h. The solvent was evaporated and the residue taken up in ether (50 cm^3). The ether solution was extracted with aqueous sodium bicarbonate, which was then acidified and extracted with ether. Evaporation of the ether afforded **10***b* (425 mg).

Acid **10***b* (130 mg, 0.5 mmol) was dissolved in acetic anhydride (715 mg, 7.0 mmol) that contained a drop of trifluoroacetic acid and the solution was added to a mixture of nitric acid (347 mg, 5.5 mmol) and trifluoroacetic anhydride (42 cm^3, 3.0 mmol) in acetic anhydride (715 mg, 6.0 mmol) at −60°C. After 15 min the reaction mixture was added to ether (20 cm^3) at −60°C, and aqueous ammonia (3.7 cm^3) was added. The ethereal phase was washed with cold brine, dried, and evaporated to afford **13***b*. When diene **12***b* was subjected to the same treatment it was recovered without loss.

A suspension of **13***b* (200 mg) in 20% sodium hydroxide (3.0 cm^3) at 90°C was stirred for 1 h. The mixture was diluted to 25 cm^3 and extracted with ether (3 × 10 cm^3). The ether solution was dried and the ether was evaporated to afford 4-chloro-2-nitroaniline (123 mg), mp 116°C (lit. (23*c*) mp 116–117°C). The alkaline solution was acidified and extracted with ether (3 × 10 cm^3). Removal of the ether afforded 2-hydroxy-2-methylpropanoic acid (42 mg), mp 78°C (lit. (23*d*) mp 79°C).

A solution of **13***b* (778 mg, 3.0 mmol) in dry dimethylformamide (10 cm^3) was added to 60% sodium hydride dispersion (132 mg, 3.3 mmol) (cf. ref. 21). The solution became dark red immediately. The solvent was removed under reduced pressure and excess aqueous ammonium chloride was added. The mixture was extracted with ether (3 × 30 cm^3), the ethereal solution dried and evaporated to yield *N*-(4-chloro-2-nitrophenyl)-2-hydroxy-2-methylpropanamide (765 mg, 98%). Recrystallization from ether gave yellow crystals, mp 110°C; ir (KBr): 3440 (OH), 3390 and 3290 (NH), 1650 (C=O), 1570 and 1335 (NO_2) cm^{-1}. *Anal.* calcd. for $C_{10}H_{11}ClN_2O_4$: C 46.44, H 4.29, N 10.83; found: C 46.79, H 4.40, N 10.74.

A suspension of **13***b* (200 mg) in 57% hydriodic acid (2.0 cm^3) was heated under reflux for 2.5 h. The reaction mixture was diluted (25 cm^3) and extracted with ether. Evaporation of the ether after drying afforded 4-aza-6-chloro-2,2-dimethyl-1-oxa-3-oxo-1,2,3,4-tetrahydronaphthalene (**22**) (191 mg). Similar treatment of **10***b* gave the same product (156 mg). The heterocycle had mp 165–166°C; ir (KBr): 1685 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 1.50 (s, 6, CH_3), 6.86 (bs, 4, 5-H, 6-H, 7-H, and 8-H) ppm; ^{13}C nmr ($CDCl_3$, 62.9 MHz) δ_C: 23.6 (CH_3), 78.2 (C-2), 115.3 (C-8), 118.4 (C-5), 123.8 (C-7), 127.2 (C-4a or C-6), 127.8 (C-6 or C-4a), 141.2 (C-8a), 170.8 (C-3) ppm. *Anal.* calcd. for $C_{10}H_{10}ClNO_3$: C 56.75, H 4.76, N 6.62; found: C 57.21, H 4.87, N 6.65.

Classical frequency modulation and the Franck–Condon principle

MURRAY N. NEUMAN
Department of Physics, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 29, 1989

MURRAY N. NEUMAN. Can. J. Chem. **67**, 1480 (1989).

A classical frequency-modulation principle is used to calculate the dipole spectrum of a two-freedom oscillator. Its two motions are assumed adiabatically separable; the frequency of motion along the fast coordinate is assumed to have a weak linear dependence on the slow coordinate. At high temperatures, the dipole spectrum of the fast motion, as found by this method, agrees quantitatively with a result based on evaluation of the Franck–Condon factors for the corresponding quantum-mechanical transition. It is suggested that the frequency-modulation approach might be especially useful in studying hydrogen-bond networks whose classical oscillations may be chaotic.

Key words: Franck–Condon factors, frequency modulation, hydrogen bonding.

MURRAY N. NEUMAN. Can. J. Chem. **67**, 1480 (1989).

On utilise un principle classique de modulation de fréquence pour calculer le spectre dipolaire d'un oscillateur à deux degrés de liberté. On fait l'hypothèse que ses deux mouvements peuvent être séparés d'une façon adiabatique; on fait aussi l'hypothèse que la fréquence du mouvement le long de la coordonnée la plus rapide est faiblement lié d'une façon linéaire avec la coordonnée la plus lente. À des températures élevées, tel que trouvé par cette méthode, le specte dipolaire du mouvement rapide est en accord quantitatif avec un résultat basé sur l'évalution des facteurs de Franck–Condon pour la transition de mécanique quantique correspondante. On suggère que l'approche de la modulation de fréquence pourrait s'avérer particulièrement utile pour l'étude de réseaux de liaisons hydrogènes dont les oscillations classiques peuvent être chaotiques.

Mots clés : facteurs de Franck–Condon, modulation de fréquence, liaisons hydrogènes.

[Traduit par la revue]

1. Introduction

The Franck–Condon principle has long been used to interpret the vibrational structure in spectra of electronic transitions. The underlying assumption is that the slow (vibrational) and fast (electronic) coordinates of the active molecule are adiabatically separable. The same principle can be applied to other interacting molecular motions, provided they are sufficiently distinct in time scale. For instance, the Stepanov ladder scheme (1) for interpreting the vibrational spectra of hydrogen-bonded complexes is formally similar to the Franck–Condon principle; it is based on the wide separation between the covalent bond frequencies and the much lower hydrogen bond frequencies responsible for the substructure in the (covalent) vibrational spectra.

The aim of this paper is to show that, at high temperatures, the spectral features derived from the Stepanov scheme can be quantitatively reproduced by a purely classical calculation based on the "frequency-modulation" principle enunciated many years ago by Bateuv (2). In this analysis, one regards the fast coordinate as oscillating at an *instantaneously* well-defined frequency, but attributes to this frequency a secular variation owing to its dependence on the slow coordinate. This adiabatic separation of variables is the classical equivalent of the Born–Oppenheimer approximation, in which one ascribes to the wave function of the fast variable, and hence also to its energy eigenvalue, a parametric dependence on the slow variable. Assuming the existence of a separate eigenvalue for fast motion in the quantum case corresponds to assigning it an instantaneously pure frequency in the classical case.

There is a difficulty with the frequency-modulation concept that ought to be disposed of at the outset. There is a tendency to think that this approach flatly contradicts orthodox quantum mechanics, since, from the latter point of view, a proper account of the coupling between the slow and fast variables, though it will admit *perturbation* of the stationary states, can never cast doubt on their *existence*; and stationary states, of course, have *constant* eigenfrequencies, rather than periodically modulated frequencies as posited by the classical model. Such objections in fact formed the subject of some highly incivil polemics in the early literature (2, 3) on spectroscopic studies of hydrogen bonding, and probably are partially responsible for the eclipse of the classical approach in more recent studies. To deal with this point, we note that, provided the frequency modulation is *periodic* (as it will be if it arises from coupling with a slower normal coordinate), the time dependence of the classical variable may be represented by a *discrete* superposition of pure sinusoidal waves. This merely reflects the fact that the fast variable, which would presumably be a normal coordinate in the absence of coupling with the slow variable, is no longer an exact normal coordinate once the coupling is introduced, but rather contains admixtures of other actual normal coordinates — hence other frequencies. If the classical time dependence were calculated from an application of orthodox correspondence principles, by taking the quantum expectation value as a function of time, the same mixture of frequencies would appear in the result, since the operator corresponding to the classical variable would mix states differing in respect of more than one quantum number.

While this argument may dispel doubts about the correctness of the classical method, one may well wonder why we should ever want to resurrect it. The reasons become apparent when one considers cases in which the slow variable is subject to a stochastic time-dependent perturbation. This could occur because the slow variable is in close energetic contact with a heat bath — the vibrations of a hydrogen bond in a liquid would be an example (4). It could conceivably also occur in certain autonomous systems, such as networks of highly anharmonic hydrogen bonds, the vibrations of which might be chaotic and not resolvable into normal modes. In cases where the classical dynamics are chaotic, quantum-mechanical interpretations are difficult and controversial; classical methods have therefore regained favour with some investigators, at least pending the theoretical clarification of quantum chaos. We therefore feel that there is a useful role for classical approaches to spectros-

copy problems with the features mentioned above, and for the frequency modulation concept in particular.

In this paper we shall analyse the classical vibration of a special two-freedom oscillator — a simple autonomous system *without* external perturbation — and compare the results to those of the analogous quantum analysis using the Franck–Condon principle. In the classical analysis, we shall use the Anderson–Kubo lineshape formalism (5), one that is readily applied to systems *with* random external perturbation. The way to generalize the classical calculations to such cases will thus be clear, whereas the corresponding generalization of the quantum analysis would be relatively difficult. It is hoped that the close correspondence obtained between the results of the two analyses in the unperturbed limit, where both may be readily worked out, will encourage acceptance of the classical results in perturbed or chaotic cases where the quantum analysis is difficult or controversial.

2. Classical analysis

We consider a system having a "fast" coordinate q and a "slow" coordinate Q. The slow motion is regarded as a predescribed harmonic oscillation at frequency Ω. The fast motion is a harmonic oscillation at frequency ω, which, though well defined at any given time, depends on the instantaneous value of Q according to

$$[1] \qquad \omega(Q) = \omega_0 + \beta Q$$

where β is a coupling constant. The linear Q-dependence assumed here is general in the limit of weak coupling. Any back reaction of the fast motion on the slow motion is neglected, or at least is absorbed in the value of Ω; the slow motion responds only to the time-averaged behaviour of q, so no term involving the instantaneous value of q appears in the equation of motion for Q. The frequency Ω might well depend on the *amplitude* of the q-motion, without seriously complicating the analysis. A quantum analogue to this would be the different internuclear potential surfaces governing molecular vibrations in different electronic states.

According to the Anderson–Kubo formalism, the power spectrum of the classical oscillation is

$$[2] \qquad P(\omega) \propto \int_{-\infty}^{\infty} dt\, e^{-i(\omega-\omega_0)t}\phi(t)$$

where the *relaxation function* $\phi(t)$ is defined by

$$[3] \qquad \phi(t) = \left\langle \exp i \int_0^t dt'[\omega(t') - \omega_0] \right\rangle$$

where $\langle\cdot\rangle$ denotes an ensemble average. If the Q-motion is supposed to be harmonic with amplitude Q_0, then eq. [1] becomes

$$[4] \qquad \omega(t') = \omega_0 + \beta Q_0 \cos(\Omega t' + \theta)$$

where θ is the initial phase for a particular oscillator. Using eq. [4] in eq. [3] gives

$$[5] \qquad \phi(t) = \langle \exp i(\beta Q_0/\Omega)[\sin(\Omega t + \theta) - \sin\theta]\rangle$$

Expanding the exponential in a Taylor series and distributing the average over the terms of the resultant series gives

$$[6] \qquad \phi(t) = \sum_{n=0}^{\infty} \frac{1}{n!} (i\beta Q_0/\Omega)^n \langle[\sin(\Omega t + \theta) - \sin\theta]^n\rangle$$

The ensemble average may be interpreted as an average over random phases θ. This vanishes for odd n, and results in

$$[7] \qquad \langle[\sin(\Omega t + \theta) - \sin\theta]^n\rangle = \frac{n!(1 - \cos\Omega t)^{n/2}}{2^{n/2}[(n/2)!]^2}$$

for even n. With eq. [7], and the replacement of running index n by $k = n/2$, eq. [6] becomes

$$[8] \qquad \phi(t) = \sum_{k=0}^{\infty} \frac{(-)^k}{2^k(k!)^2} (\beta Q_0/\Omega)^{2k}(1 - \cos\Omega t)^k$$

The convergence of this series is assured for all t because $|(1 - \cos\Omega t)^k| \leq 2^k$ for all k and t, so that the absolute value of the ratio between successive terms is less than $(\beta Q_0/\Omega k)^2$, which in turn is less than unity for large enough k. The convergence is clearly fastest when $\beta Q_0 \ll \Omega$, that is, in the limit of weak modulation. This limit is assumed in the remaining analysis. We therefore truncate the series in eq. [8] at $k = 1$, leaving

$$[9] \qquad \phi(t) = 1 - \tfrac{1}{4}(\beta Q_0/\Omega)^2(2 - e^{i\Omega t} - e^{-i\Omega t})$$

where $\cos\Omega t$ has been rewritten in exponential form. If eq. [9] is substituted in eq. [2], and the form $\int_{-\infty}^{\infty} e^{i\omega t}\, dt$ is recognised as (2π times) a representation of the delta function $\delta(\omega)$, then

$$[10] \qquad P(\omega) \propto [1 - \tfrac{1}{2}(\beta Q_0/\Omega)^2]\delta(\omega - \omega_0) + \tfrac{1}{4}(\beta Q_0/\Omega)^2[\delta(\omega - \omega_0 + \Omega) + \delta(\omega - \omega_0 - \Omega)]$$

The spectrum thus exhibits side bands at $\omega = \omega_0 \pm \Omega$, each having an intensity approximately $\frac{1}{4}(\beta Q_0/\Omega)^2$ times that of the unmodulated component at $\omega = \omega_0$. the terms discarded by truncating eq. [8] are smaller by at least two orders of $\beta Q_0/\Omega$.

3. Quantum-mechanical analysis

We now reformulate the same problem quantum-mechanically. Following the standard procedure for adiabatic separation of the wave function (6), we write each eigenstate of the coupled oscillator as a product of slow and fast wave functions

$$[11] \qquad \Psi_{sf}(q,Q) = \Phi_s^{(f)}(Q) \cdot \Theta_f(q;Q)$$

where s and f are the quantum numbers associated with the slow and fast variables Q and q respectively. The notation indicates the parametric dependence of the slow function on f, and of the fast function on the instantaneous value of Q.

We shall calculate the intensity of a dipole transition $s,f \rightarrow s',f'$. This depends on the matrix element of the dipole moment operator $\hat{p}$ as follows:

$$[12] \qquad I_{s,f\rightarrow s',f'} \propto |\langle s, f|\hat{p}|s', f'\rangle|^2 = |\int dQ \Phi_s^{(f')*} J_{f\rightarrow f'}(Q)\Phi_s^{(f)}|^2$$

where

$$[13] \qquad J_{f\rightarrow f'}(Q) = \int dq \Theta_{f'}^* \hat{p}(q, Q)\Theta_f$$

If the system consists of oscillating point charges, and if q and Q are obtained by some linear transformation of the Cartesian coordinates of these charges, then $\hat{p}$ is a linear function of q and Q:

$$[14] \qquad \hat{p} = aq + bQ + c$$

where a, b, and c are constants. The terms bQ and c factor out of the integral in eq. [13]; in view of the orthogonality of the Θ_f, these terms contribute nothing to the integral except in the uninteresting case where $f' = f$. Thus $J_{f\rightarrow f'}$ reduces to

$a\int dq\Omega\Theta_{f'}q\Theta_f$. Since the Θ_f are simple harmonic oscillator (SHO) eigenfunctions, this works out at

$$[15] \quad J_{f\to f'} = \begin{cases} a(\hat{f}\hbar/2m\omega)^{1/2}, & |f'-f| = 1 \\ 0, & |f'-f| > 1 \end{cases}$$

where $\hat{f}$ is the larger of f and f', and where m is the reduced mass associated with q-motion. Now $J_{f\to f'}$ takes on a Q-dependence through ω, as is implied by eq. [1]. From eqs. [1] and [15], the fractional change in $J_{f\to f'}(Q)$ over the course of the integral in eq. [12] is roughly $\beta Q_0/\omega_0$, if the classical amplitude Q_0 is construed as the approximate width of the domain over which the $\Phi_f^{(s)}(Q)$ are nonvanishing. For the weak-coupling case assumed in Sect. 2 we had $\beta Q_0/\Omega \ll 1$; since for adiabatic separability we had also supposed $\Omega \ll \omega_0$, it follows that $\beta Q_0/\omega_0 \ll 1$ a fortiori if we make the same assumptions in the quantum as in the classical case. We conclude that $J_{f\to f'}$ is essentially constant over the integration domain in eq. [12] and may be factored out of the integral:

$$[16] \quad I_{s,f\to s',f'} \propto |J_{f\to f'}|^2 |\int dQ \Phi_{s'}^{(f')*}\Phi_s^{(f)}|^2$$

The square of the overlap integral appearing in eq. [16] may be identified as the Franck–Condon factor for the transition (7).

We now focus attention on a particular transition $f\to f'$, and examine the distribution of intensity within its s, s' substructure. For this purpose $J_{f\to f}$ may be regarded as fixed, so that, by eq. [16], the intensities for the various $s \to s'$ components are governed by the overlap between the initial and final slow wave functions. These are *not* necessarily orthogonal when $s' \neq s$, since $\Phi_{s'}^{(f')}$ and $\Phi_s^{(f)}$ are eigenfunctions of different operators when $f' \neq f$.

To evaluate the Franck–Condon factors, we must examine the Q-dependence of the Hamiltonian for the coupled oscillator described in Sect. 2. Following the standard procedure for the solution of adiabatically separable problems, we incorporate the energy eigenvalue of the fast oscillation in the effective Hamiltonian $H^{(f)}$ governing the slow motion. The fast eigenvalue is $(f+\frac{1}{2})\hbar\omega$; if ω is given by eq. [1], then we have

$$[17] \quad H^{(f)} = H_Q + (f+\tfrac{1}{2})\hbar\beta Q + (f+\tfrac{1}{2})\hbar\omega_0$$

where H_Q is the slow-motion SHO Hamiltonian in the absence of coupling. The overlap integral in eq. [16] may be evaluated by expanding $\Phi_s^{(f)}$ and $\Phi_{s'}^{(f')}$ in terms of the eigenfunctions $|j\rangle$ of H_Q. The expansion coefficients may be obtained by treating the second term on the right-hand side of eq. [17] as a small perturbation. (This will be justified presently.) According to first-order perturbation theory,

$$[18] \quad \Phi_s^{(f)} = |s\rangle + \left(f+\frac{1}{2}\right)\hbar\beta \sum_{j\neq s} |j\rangle\langle j|Q|s\rangle/(E_s - E_j)$$

Here the E_j are the energies of the unperturbed SHO states $|j\rangle$:

$$[19] \quad E_j = (j+\tfrac{1}{2})\hbar\Omega$$

Invoking the well-known results for the SHO matrix elements $\langle j|Q|s\rangle$, we obtain from eq. [18]

$$[20] \quad \Phi_s^{(f)} = |s\rangle + (f+\tfrac{1}{2})\epsilon[s^{1/2}|s-1\rangle - (s+1)^{1/2}|s+1\rangle]$$

where

$$[21] \quad \epsilon = (\beta/\Omega)(\hbar/2\Omega M)^{1/2}$$

and M is the reduced mass associated with Q-motion. Now ε is a dimensionless quantity whose value is much less than unity in the weak-coupling limit. This is apparent because the factor $(\hbar/2\Omega M)^{1/2}$ may be recognised as the root mean square value of Q in the ground SHO state $|0\rangle$, and may thus be taken as a lower bound for the classical amplitude Q_0. So ϵ is characteristically less than $\beta Q_0/\Omega$, a quantity that in turn is much less than unity in the weak-coupling limit as defined in Sect. 2. It then follows from eq. [20] that $\Phi_s^{(f)}$ differs little from $|s\rangle$, so that the first-order perturbation treatment is justified a posteriori. Using eq. [20] and the orthonormality of the $|j\rangle$, we calculate the overlaps to lowest order in ϵ:

$$[22] \quad \langle\Phi_{s'}^{(f')}|\Phi_s^{(f)}\rangle \simeq \begin{cases} 1, & s' = s \\ (f-f')s^{1/2}\epsilon, & s' = s-1 \\ (f'-f)(s')^{1/2}\epsilon, & s' = s+1 \end{cases}$$

For $|s'-s| \geq 2$, the inner product is of at least second order in ϵ, and is therefore negligible in the weak-coupling limit.

We have already ascertained (cf. eq. [15]) that the ordinary SHO selection rule applies to the fast coordinate; that is, $f' = f \pm 1$. With this restriction, eqs. [16] and [22] yield

$$[23] \quad I_{s,f\to s',f'} \propto |J_{f\to f'}|^2 |\langle\Phi_{s'}^{(f\pm1)}|\Phi_s^{(f)}\rangle|^2 = |J_{f\to f'}|^2 \times \begin{cases} 1, & s' = s \\ \hat{s}\epsilon^2, & s' = s\pm1 \end{cases}$$

where $\hat{s}$ is the larger of s and s'. Thus, to lowest order in ϵ, the spectrum of the transition $f \to f'$ comprises two side-band components $s' = s \pm 1$, each having a fraction $\hat{s}\epsilon^2$ of the intensity of the main ($s' = s$) component. To demonstrate the equivalence between this and the classical result, it remains to show that the frequency spacing and the relative intensities are the same in both cases.

According to the standard adiabatic treatment, the energy eigenvalue $E_s^{(f)}$ of the coupled-oscillator state Ψ_{sf} is just the expectation value of $H^{(f)}$ in state $\Phi_s^{(f)}$:

$$[24] \quad E_s^{(f)} = \langle\Phi_s^{(f)}|H^{(f)}|\Phi_s^{(f)}\rangle = (f+\tfrac{1}{2})\hbar\omega_0 + \langle\Phi_s^{(f)}|H_Q + (f+\tfrac{1}{2})\hbar\beta Q|\Phi_s^{(f)}\rangle$$

The remaining inner product on the right-hand side is the energy eigenvalue for the slow motion. Since the eigenfunction $\Phi_s^{(f)}$ has evolved from $|s\rangle$ under the action of the perturbation $(f+\frac{1}{2})\hbar\beta Q$, its eigenvalue is

$$[25] \quad \langle\Phi_s^{(f)}|H_Q + (f+\tfrac{1}{2})\hbar\beta Q|\Phi_s^{(f)}\rangle \simeq E_s + (f+\tfrac{1}{2})\hbar\beta\langle s|Q|s\rangle$$

to first order in the perturbation. The matrix element $\langle s|Q|s\rangle$ vanishes for SHO basis functions; so eqs. [24], [25], and [19] give

$$[26] \quad E_s^{(f)} = (f+\tfrac{1}{2})\hbar\omega_0 + (s+\tfrac{1}{2})\hbar\Omega$$

That is, the slow and fast energies are simply additive to first order in the perturbation; no interaction term appears at this level of approximation. From eq. [26], the Bohr transition frequencies composing the transition $f \to f \pm 1$ are ω_0 (for $s' = s$) and $\omega_0 \pm \Omega$ (for $s' = s \pm 1$). These frequencies are the same as those derived classically in Sect. 2.

The results given by eq. [23] have regard to the intrinsic oscillator strengths of the various s, s' subtransitions. The actual spectrum is realised by taking a thermal average, denoted by $\langle\cdot\rangle$, over initial states s. This is easily worked out from eqs. [23] and [26]. To effect a classical correspondence, we take the high-temperature limit ($kT \gg \hbar\Omega$):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

[27a] $$\frac{\langle I_{s\to s-1}\rangle}{\langle I_{s\to s}\rangle} = \epsilon^2 \sum_{s=1}^{\infty} s \exp(-E_s^{(f)}/kT) \Big/ \sum_{s=0}^{\infty} \exp(-E_s^{(f)}/kT) \to \epsilon^2 kT/\hbar\Omega$$

[27b] $$\frac{\langle I_{s\to s+1}\rangle}{\langle I_{s\to s}\rangle} = \epsilon^2 \sum_{s'=1}^{\infty} s' \exp(-E_s^{(f)}{}_{-1}/kT) \Big/ \sum_{s=0}^{\infty} \exp(-E_s^{(f)}/kT) = \exp(\hbar\Omega/kT)\langle I_{s\to s-1}\rangle/\langle I_{s\to s}\rangle \to \epsilon^2 kT/\hbar\Omega$$

To relate the intensities to the amplitude of the Q-oscillation, we note that the thermal root-mean-square displacement from equilibrium in the high-temperature limit is

[28] $$Q_{\text{rms}} \to (kT/M\Omega^2)^{1/2}$$

as is readily found from the matrix elements of Q in the basis set $\{|j\rangle\}$. With eqs. [21] and [28], eq. [27] becomes

[29] $$\frac{\langle I_{s\to s\pm 1}\rangle}{\langle I_{s\to s}\rangle} \to \frac{1}{2}(\beta Q_{\text{rms}}/\Omega)^2$$

We recall that the corresponding classical result for the intensity ratio between each side band and the main component was $\frac{1}{4}(\beta Q_0/\Omega)^2$, where Q_0 was the amplitude of the slow oscillation. For classical SHO motion, $Q_0 = 2^{1/2}Q_{\text{rms}}$. Hence the classical and quantal results for the side-band intensities agree exactly in the high-temperature limit.

At lower temperatures, the classical spectrum, being symmetric, violates detailed balance. This problem is common to all classical lineshape calculations. They are routinely corrected by applying any of several simple desymmetrizing procedures that restore consistency with detailed balance (8, 9). One such formula for approximate recovery of the quantum-mechanical spectrum I_{qm} from the classical spectrum I_{cl} is as follows:

[30] $$I_{\text{qm}}(\omega_0 + \omega) \simeq 2[1 + \exp(-\hbar\omega/kT)]^{-1} I_{\text{cl}}(\omega_0 + \omega)$$

where ω_0 is the frequency of the line centre (as it is in the foregoing discussion). In the present case, it is clear that eq. [30] yields the same intensity ratio between the side bands at $\omega_0 \pm \Omega$ as does the proper quantum-mechanical formula, eq. [27], at any value of T.

4. Summary and conclusions

It has been demonstrated that the frequency-modulation principle, applied to a weakly coupled two-freedom oscillator, predicts essentially the same dipole radiation spectrum as does a correct quantum-mechanical treatment. The classical calculation reproduces the discrete substructure of the spectrum (often thought to be of distinctively quantal nature). At high temperatures, it also yields quantitatively correct values for the intensities of the several subtransitions. Even at lower temperatures, the correct intensities are obtained if one applies a simple desymmetrizing correction to the classical calculation. While, at first blush, this may seem insufficient reason to prefer a classical calculation, it should be pointed out that the classical formalism, eqs. [2]–[3], used here has been well developed and extended to systems in which $\omega(t)$ fluctuates stochastically according to various modulation schemes (e.g., Gaussian, Markovian) (5). The corresponding generalization of orthodox quantum mechanics is difficult and, in some cases, controversial (as in autonomous systems whose classical dynamics are chaotic). Given the recent spate of interest in the classical dynamics of simple coupled-oscillator systems (10) like the one examined here, it seems encouraging that classical calculations produce realistic results in a regime where it is readily possible to test them against quantum mechanics. This suggests the legitimacy of using the classical formalism as a point of departure for the study of coupled oscillators with more formidable dynamics.

The system examined here, with weak linear coupling and adiabatic separability, is an especially apt model for a covalent bond interacting with a hydrogen bond, and has been so applied (11, 12). We envisage the use of the classical lineshape formalism described here in elucidating the infrared and Raman spectroscopy of such systems. Its application would be especially interesting for networks of highly anharmonic hydrogen bonds whose lattice vibrations are conceivably chaotic.

Received March 9, 1989

MANJU TANDON, LEONARD I. WIEBE, and EDWARD E. KNAUS. Can. J. Chem. **67**, 1484 (1989).

The reaction of 3-*N*-3′,5′-di-*O*-tribenzoyl-2′-deoxy-5-vinyluridine (**2**) with dibromocarbene, generated from $PhHgCBr_3$ under thermal neutral conditions, yielded a mixture of the 5-[(1*S*)-2,2-dibromocyclopropyl]- (**3***a*) and 5-[(1*R*)-2,2-dibromocyclopropyl]-3-*N*-3′,5′-di-*O*-tribenzoyl-2′-deoxy-5-vinyluridine (**4***a*) diastereomers, which were separated (1:1 ratio). Treatment of **3***a* and **4***a* with methanolic ammonia afforded the respective 5-[(1*S*)-2,2-dibromocyclopropyl]- (**3***b*) and 5-[(1*R*)-2,2-dibromocyclopropyl]-2′-deoxyuridines (**4***b*). The absolute configuration of **3***b* has been established by X-ray crystal structure determination. Monodebromination of **3***b*, using zinc dust in HOAc at 50°C, gave a mixture of the 5-[(1*S*,2*S*)-2-bromocyclopropyl]- (**5**) and 5-[(1*S*,2*R*)-2-bromocyclopropyl]- (**6**) diastereomers, which were separated and their respective configuration assigned by ^1H nuclear magnetic resonance. A similar monodebromination of **4***b* yielded the 5-[(1*R*,2*R*)-2-bromocyclopropyl]- (**7**) and 5-[(1*R*,2*S*)-2-bromocyclopropyl]-2′-deoxyuridine (**8**) diastereomers. Relationships between physicochemical properties, such as melting point and tlc R_f value, and the configuration of the chiral cyclopropyl carbon(s) were observed. The chemical shifts for the ^{13}C nuclear magnetic resonances are also of diagnostic value for determination of the respective configuration of the cyclopropyl carbons of the 5-(2-bromocyclopropyl) isomers **5–8**.

Key words: bromocyclopropanes, 2′-deoxyuridines, absolute configuration, antiviral activity.

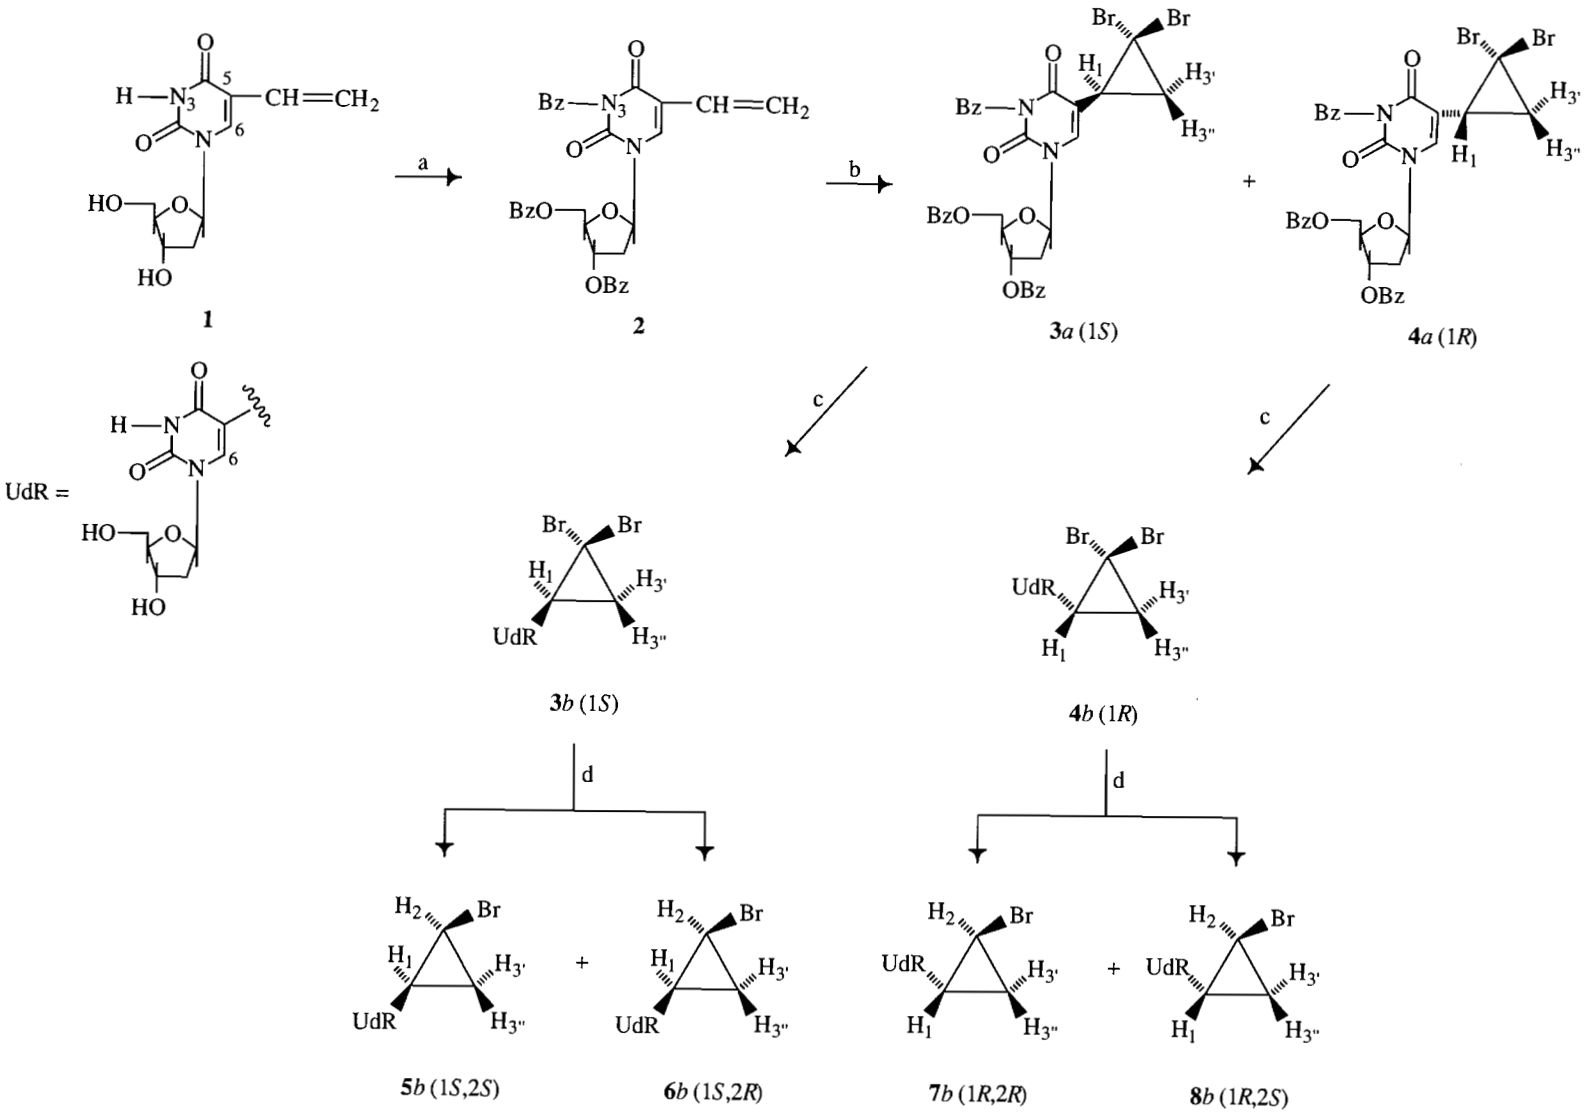
Introduction

(*E*)-5-(2-Bromovinyl)-2′-deoxyuridine (BVDU) is a potent and selective antiviral agent against herpes simplex virus type 1 (HSV-1) and varicella-zoster virus (1). BVDU is selectively phosphorylated by HSV-1 encoded thymidine kinase and metabolically trapped within infected cells, but not in uninfected host cells (2, 3). Structure–activity correlations for olefinic 5-substituted-2′-deoxyuridines indicated optimum inhibition of HSV-1 occurred when the C-5 substituent was unsaturated and conjugated with the pyrimidine ring, was not longer than four carbon atoms in length, had the *E* stereochemistry, and included a hydrophobic electronegative atom (4). It was anticipated that 2′-deoxyuridine possessing a 5-(2,2-dibromocyclopropyl) or 5-(2-bromocyclopropyl) substituent could serve as a biological isostere of the (*E*)-5-(2-bromovinyl) substituent present in BVDU. The hybridization of the cyclopropane bonds is considered to result in a higher electron density for the C—C bonds. Furthermore, the cyclopropyl moiety interacts with neighboring π-electron systems and *p*-electron centers similar to a vinyl group (5, 6).

Acquisition of all dibromocyclopropyl and bromocyclopropyl diastereomers is required to determine the effect of cyclopropyl substituent stereochemistry upon antiviral activity. We now describe the synthesis, separation, and assignment of the absolute configuration for the 5-(2,2-dibromocyclopropyl) **3***b*–**4***b* and 5-(2-bromocyclopropyl) **5–8** derivatives of 2′-deoxyuridine.

Results and discussion



The 5-vinyl substituent of 5-vinyl-2′-deoxyuridine (**1**) is expected to be a poor substrate for dibromocarbene addition since it is conjugated with the 5,6-olefinic bond of the uracil ring. In an earlier study we reported that the reaction of (*E*)-5-(2-ethoxycarbonylvinyl)-3-methyl-2′-deoxyuridine with diazomethane yielded (*E*)-5-(2-ethoxycarbonylvinyl)-3-methyl-2′-deoxyuridine (7). Therefore, **1** was elaborated to 3-*N*-3′,5′-di-*O*-tribenzoyl-2′-deoxy-5-vinyluridine (**2**) as illustrated in Scheme 1 (78% yield). Reaction of **2** with dichlorocarbene, generated from chloroform and sodium hydroxide in the presence of the phase transfer catalyst benzyltriethylammonium bromide, afforded 3-*N*-dichloromethyl-3′,5′-di-*O*-benzoyl-2′-deoxy-5-vinyluridine.[2] The latter result indicates that dibromocarbene must be generated under neutral conditions to preserve the integrity of the 3-*N*-benzoyl substituent. Thus, reaction of

the Seyferth reagent (8) phenyl(tribromomethyl)mercury ($PhHgCBr_3$) with **2** in dry benzene at 80°C yielded a mixture of two diastereomers (**3***a* and **4***a*), which were separated by silica gel column chromatography (1:1 ratio, 63% total isolated yield). Removal of the protective benzoyl substituents from **3***a* and **4***a*, by treatment with methanolic ammonia, yielded 5-[(1*S*)-2,2-dibromocyclopropyl]-2′-deoxyuridine (**3***b*) and 5-[(1*R*)-2,2-dibromocyclopropyl]-2′-deoxyuridine (**4***b*) in 71 and 74% isolated yields, respectively.

The X-ray crystal structure of **3***b* indicated that the absolute configuration of the C-5 substituent was [(1*S*)-2,2-dibromocyclopropyl] (9). The bond lengths and angles for **3***b* are similar to those of 2′-deoxyuridine (10) and the 1,1-dibromocyclopropyl moiety (11, 12) in other compounds. The pyrimidine ring of **3***b* is *anti* with respect to the deoxyribose ring, and the latter ring system is in the 2′-*endo* conformation. Compound **4***b*, which is a diastereomer of **3***b*, must therefore have a 5-[(1*R*)-2,2-dibromocyclopropyl] substituent.

Monodebromination of the 5-[(1*S*)-2,2-dibromocyclopropyl] diastereomer (**3***b*), using zinc dust in glacial acetic acid, yielded a mixture of two diastereomers, which were separated by silica gel column chromatography. In this reaction a new chiral center is introduced at the C-2 position of the 5-(2-bromocyclopropyl) substituent. An ^1H nmr difference nOe spectrum was acquired for the more polar diastereomer (R_f 0.15, solvent system C). Irradiation of the cyclopropyl H-1 proton at δ 1.98 produced a 10.8% enhancement for the cyclopropyl H-2 proton at δ 3.34 and a 7.7% enhancement for the cyclopropyl H-3′ proton at δ 1.42. Therefore, the cyclopropyl H-1 and H-2, as well as H-1 and H-3′ protons, must be *cis* to each other. Since the configuration of this product at the cyclopropyl C-1 position must be *S*, it is therefore the 5-[(1*S*,2*S*)-2-bromocyclopropyl] diastereomer (**5**). A large number of spectra of substituted cyclopropane derivatives have been recorded. The magnitude of the vicinal coupling constant for J_{cis} is always larger than J_{trans} for any given pair of cyclopropyl stereoisomers (13). The vicinal coupling constants for the diastereomer **5** are in agreement with the assigned 1*S*,2*S* configuration where $J_{1,2}$ = 8.5 (*cis*), $J_{1,3''}$ = 6.8 (*trans*), $J_{1,3'}$ = 9.2 (*cis*), $J_{2,3''}$ = 4.4 (*trans*), and $J_{2,3'}$ = 8.5 Hz (*cis*). A long-range allylic coupling $J_{1,6}$ = 1.2 Hz was also observed. The configuration of the other diastereomer **6** (R_f 0.29, solvent system C) obtained in this reaction, which also must have the 1*S* configuration, was assigned on the magnitude of the vicinal coupling constants in the ^1H nmr spectrum that can be correlated with the geometrical arrangement of the cyclopropyl substituents. Diastereomer **6** has a 5-[(1*S*,2*R*)-2-bromocyclopropyl] substituent since it exhibited vicinal coupling constants $J_{1,2}$ = 4.3 (*trans*), $J_{1,3'}$ = 10.1 (*cis*), $J_{1,3''}$ = 6.8 (*trans*), $J_{2,3'}$ = 4.3 (*trans*), and $J_{2,3''}$ = 7.5 Hz (*cis*).

A similar monodebromination of the 5-[(1*R*)-2,2-dibromocyclopropyl] diastereomer **4***b* afforded a mixture of two diastereomers, which were separated by multiple development preparative tlc and then silica gel column chromatography of the enriched tlc fractions. The more polar diastereomer (R_f 0.27, solvent system C) possesses a 5-[(1*R*,2*R*)-2-bromocyclopropyl] substituent (**7**) since the ^1H nmr spectrum exhibited vicinal coupling constants $J_{1,2}$ = 7.1 (*cis*), $J_{1,3'}$ = 7.1 (*trans*), $J_{1,3''}$ = 9.1 (*cis*), $J_{2,3'}$ = 4.3 (*trans*), and $J_{2,3''}$ = 7.1 Hz (*cis*). The less polar diastereomer (R_f 0.32, solvent system C) has a 5-[(1*R*,2*S*)-2-bromocyclopropyl] substituent (**8**) since the ^1H nmr spectrum displayed vicinal coupling constants $J_{1,2}$ = 4.3 (*trans*), $J_{1,3'}$ = 6.8 (*trans*), $J_{1,3''}$ = 9.8 (*cis*), $J_{2,3'}$ = 7.5 (*cis*), and $J_{2,3''}$ = 4.3 (*trans*).

A number of relationships or correlations between physicochemical properties and nmr spectral data for the cyclopropyl hydrogens and carbons were observed, which, in conjunction with the magnitude of the vicinal coupling constants described previously, will be of value in assigning the configuration of the cyclopropyl chiral carbons(s) of **3***b*–**4***b* and **5**–**8** (see Table 1). Compounds having the 1*S* configuration exhibit higher melting points since 1*S* (**3***b*) > 1*R* (**4***b*); 1*S*,2*S* (**5**) > 1*R*,2*R* (**7**); and 1*S*,2*R* (**6**) > 1*R*,2*S* (**8**). Diastereomers having the same configuration at the C-1 and C-2 positions possess higher melting points since 1*S*,2*S* (**5**) > 1*S*,2*R* (**6**) and 1*R*,2*R* (**7**) > 1*R*,2*S* (**8**). Compounds having the 1*S* configuration are more polar as indicated by their relative R_f values since 1*S* (**3***b*) < 1*R* (**4***b*); 1*S*,2*S* (**5**) < 1*R*,2*R* (**7**); and 1*S*, 2*R* (**6**) < 1*R*,2*S* (**8**). Diastereomers having the same configuration at C-1 and C-2 are more polar as the R_f values of 1*S*,2*S* (**5**) < 1*S*,2*R* (**6**) and 1*R*,2*R* (**7**) < 1*R*,2*S* (**8**). Although the rotations are equal, but of opposite sign, **3***b* and **4***b*, **5** and **6**, and **7** and **8**, respectively, are not enantiomers. Since each set of these diastereomers differs in configuration at only one chiral center, each set of diastereomers can also be called epimers. Examination of the ^1H nmr spectral data for the cyclopropyl chemical shifts (Table 1) indicates that the bromine substituent shields the adjacent *cis* H-3 proton relative to the *trans* H-3 proton (**5**–**8**) and the H-2 proton is shielded by a *cis*-2′-deoxyuridine substituent (**6**, **8**) relative to the *trans* H-2 proton (**5**, **7**). These correlations are consistent with the fact that all substituents, including bromine, generally shield *cis* vicinal protons in a cyclopropyl ring system (13). The chemical shifts of the cyclopropyl carbons for the *cis* 1*S*,2*S* (**5**) and 1*R*,2*R* (**7**), as well as these for the *trans* 1*S*,2*R* (**6**) and 1*R*,2*S* (**8**), are very similar. In compounds **5** and **7**, where the 2′-deoxyuridine and bromo substituents are *cis*, C-1 is deshielded δ 3.4–4.3, C-2 is shielded δ 4.4–5.0, and C-3 is shielded δ 3.3–3.6 relative to the corresponding carbon atoms in the *trans* compounds **6** and **8**. These differences in ^{13}C chemical shifts provide a rapid method to distinguish the *cis* (1*S*,2*S*, 1*R*,2*R*) from the *trans* (1*S*,2*R*, 1*R*,2*S*) stereoisomers.

Biological and biochemical studies for **3***b*–**4***b* and **5**–**8** are now in progress and will be reported elsewhere.

Experimental

Melting points were determined on a Büchi capillary apparatus and are uncorrected. The ^1H and ^{13}C nmr spectra were recorded on a Bruker AM-300 spectrometer. Chemical shifts are given in ppm downfield from tetramethylsilane as internal standard. The ^1H nmr assignments were confirmed by double irradiation experiments. The ^{13}C nmr resonances were assigned by use of the *J* modulation technique to determine the number of attached hydrogens. Specific rotations were measured on an Optical Activity Ltd. digital polarimeter. Thin-layer chromatography (tlc) was performed using Whatman MK6F silica gel microslides (250 μm thickness). Preparative tlc was carried out using Whatman PLK5F plates (1 mm thickness). The tlc solvent systems employed were A: toluene:ethyl acetate (4:1 v/v), B: chloroform:methanol (9:1 v/v), C: ethyl acetate:*n*-propanol:water (41:10:20 v/v/v). This last solvent mixture was mixed thoroughly, allowed to separate, and the upper layer was used in all instances where solvent C is indicated. Column chromatography was carried out using Merck 7734 silica gel (100–200 μm particle size). Pyridine and benzene were distilled from CaH_2, and methanol was distilled from Mg/I_2, prior to use. $PhHgCBr_3$ (8) and 5-vinyl-2′-deoxyuridine (14) (Lit. (15) mp 230°C; found mp 228°C) were prepared according to the literature procedures. Abbreviation: cp = cyclopropyl.

3-N-3′,5′-Di-O′-tribenzoyl-2′-deoxy-5-vinyluridine (**2**)

Benzoyl chloride (0.65 g, 4.64 mmol) was added to a solution of **1**

(0.56 g, 2.2 mmol) in dry pyridine (25 mL) at 0–5°C with stirring. The reaction mixture was allowed to warm to 25°C and then maintained at this temperature for 2 h. The reaction mixture was cooled to 0–5°C and then diisopropylethylamine (0.43 g, 3.3 mmol) and benzoyl chloride (0.33 g, 2.32 mmol) were added. The reaction mixture was warmed to 25°C and the mixture was stirred for 12 h. Ice-water (25 mL) was added and the solvent was removed *in vacuo*. Two consecutive extractions of the residue with a chloroform:water mixtue (3:1 v / v, 40 mL), washing the chloroform extract in succession with cold 5% aqueous HCl (10 mL), 5% aqueous $NaHCO_3$ (10 mL), cold water (2 × 15 mL), drying the chloroform extract (Na_2SO_4), filtration, and removal of the solvent *in vacuo* yielded impure **2**. Purification on a silica gel column using toluene:ethyl acetate (19:1 v / v) as eluant gave **2**: 0.973 g, 77.6%; mp 245°C; R_f 0.58 (solvent system A); ^{1}H nmr ($CDCl_3$) δ: 2.44 (ddd, J_{gem} = 13.7, $J_{1',2'}$ = 8.7, $J_{2',3'}$ = 6.6 Hz, 1H, H-2′), 2.88 (ddd, J_{gem} = 13.7, $J_{1',2'}$ = 5.0, $J_{2',3'}$ = 1.5 Hz, 1H, H-2′), 4.68 (m, 1H, H-4′), 4.76–4.98 (m, 2H, H-5′), 5.18 (dd, J = 11.1, 1.7 Hz, 1H, —CH=C*H*H), 5.74 (m, 1H, H-3′), 5.92 (dd, J = 17.2, 1.7 Hz, 1H, —CH=CH*H*), 6.16 (dd, J = 17.2, J = 11.1 Hz, 1H, —*CH*=CHH), 6.54 (dd, $J_{1',2'}$ = 8.7, J = 5.0 Hz, 1H, H-1′), 7.52–8.20 (m, 16H, phenyl hydrogens, H-6).

*5-[(1S)-2,2-Dibromocyclopropyl]-3-*N*-3′,5′-di-*O*-tribenzoyl-2′-deoxyuridine* (**3***a*) *and 5-[(1R)-2,2-dibromocyclopropyl]-3-*N*-3′,5′-di-*O*-tribenzoyl-2′-deoxyuridine* (**4***a*)

Phenyl(tribromomethyl)mercury (1.96 g, 3.7 mmol) was added to a solution of **2** (2.1 g, 3.7 mmol) in dry benzene (50 mL) under a nitrogen atmosphere with stirring and the reaction mixture was heated at reflux for 2 h. Additional aliquots of $PhHgCBr_3$ (1.96 g, 3.7 mmol) were added to the reaction mixture at 2, 4, and 6 h respectively, after initiation of the reaction, which was allowed to proceed for 9 h in total reaction time. The reaction mixture was cooled to 25°C and the PhHgBr, which precipitated during the reaction, was removed by filtration. Removal of the solvent *in vacuo* gave a mixture of **3***a* and **4***a*, which were separated by silica gel column chromatography using a solvent gradient starting with toluene and ending with toluene:ethyl acetate (19:1 v / v). The two diastereomers **3***a* and **4***a* were obtained in a ratio of 1:1 (0.86 g each, 62.8% combined chemical yield) as foams: **3***a*, R_f 0.54 (solvent system A); mp 220°C; ^{1}H nmr ($CDCl_3$) δ: 1.56 (dd, $J_{3',3''}$ = 11.0, $J_{1,3'}$ = 9.1 Hz, 1H, cp H-3′), 1.61 (dd, $J_{3',3''}$ = 11.0, $J_{1,3''}$ = 8.1 Hz, 1H, cp H-3″), 2.28 (ddd, J_{gem} = 13.5, $J_{1',2'}$ = 8.6, $J_{2',3'}$ = 6.6 Hz, 1H, H-2′), 2.44 (ddd, $J_{1,3'}$ = 9.1, $J_{1,3''}$ = 8.1, $J_{1,6}$ = 1.34 Hz, 1H, cp H-1), 2.78 (dd, J_{gem} = 13.5, $J_{1',2'}$ = 5.0 Hz, 1H, H-2′), 4.52 (m, 1H, H-4′), 4.64–4.8 (m, 2H, H-5′), 5.56 (d, $J_{2',3'}$ = 6.6 Hz, 1H, H-3′), 6.34 (dd, $J_{1',2'}$ = 8.6 and 5.0 Hz, 1H, H-1′), 7.32–8.04 (m, 16H, phenyl hydrogens, H-6).

4*a*: R_f 0.63 (solvent system A); mp 228°C; ^{1}H nmr ($CDCl_3$) δ: 1.46 (t, $J_{3',3''}$ = 8.1, $J_{1,3'}$ = 8.1 Hz, 1H, cp H-3′), 1.73 (dd, $J_{1,3''}$ = 10.1, $J_{3',3''}$ = 8.1 Hz, 1H, cp H-3″), 2.22 (ddd, J_{gem} = 13.5, $J_{1',2'}$ = 8.6, $J_{2',3'}$ = 6.6 Hz, 1H, H-2′), 2.52 (dd, $J_{1,3''}$ = 10.1, $J_{1,3'}$ = 8.1 Hz, 1H, cp H-1), 2.74 (dd, J_{gem} = 13.5, $J_{1',2'}$ = 4.8 Hz, 1H, H-2′), 4.48 (m, 1H, H-4′), 4.58–4.78 (m, 2H, H-5′), 5.56 (d, $J_{2',3'}$ = 6.6 Hz, 1H, H-3′), 6.34 (dd, $J_{1',2'}$ = 8.6, $J_{1',2'}$ = 4.8 Hz, 1H, H-1′), 7.3–8.06 (m, 16H, phenyl hydrogens, H-6).

5[(1S)-2,2-Dibromocyclopropyl]-2′-deoxyuridine (**3***b*)

A solution of **3***a* (0.50 g, 0.68 mmol) in a saturated solution of ammonia in methanol (15 mL) was stirred at 25°C for 15 h. Removal of the solvent *in vacuo* yielded a residue, which was purified by silica gel column chromatography using $CHCl_3$:MeOH (19:1 v / v) as eluant to afford **3***b*: 0.205 g, 71%; R_f 0.40 (solvent system B); mp 180–185°C (dec.) after recrystallization from chloroform:methanol; $[\alpha]_D^{23}$ −80.8° (*c* 0.74, MeOH); ^{1}H nmr (CD_3OD) δ: 1.90 (dd, $J_{3',3''}$ = 15.5, $J_{1,3'}$ = 10.0 Hz, 1H, cp H-3′), 1.93 (dd, $J_{3',3''}$ = 15.5, $J_{1,3''}$ = 8.5 Hz, 1H, cp H-3″), 2.18 (m, 2H, H-2′), 2.58 (ddd, $J_{1,3'}$ = 10.0, $J_{1,3''}$ = 8.5, $J_{1,6}$ = 1.33 Hz, 1H, cp H-1), 3.70 (m, 2H, H-5′), 3.86 (m, 1H, H-4′), 4.34 (m, 1H, H-3′), 6.22 (t, $J_{1',2'}$ = 6.1 Hz, 1H, H-1′), 7.96 (d, $J_{1,6}$ = 1.33 Hz, 1H, H-6); ^{13}C nmr (CD_3OD) δ: 26.7 (cp C-3), 29.3 (cp C-2), 29.9 (cp C-1), 41.7 (C-2′), 62.6 (C-5′), 72.2 (C-3′), 86.8 (C-1′), 89.1 (C-4′), 112.9 (C-5), 140.8 (C-6), 152.8 (C-2), 165.5 (C-4). *Anal.* calcd. for $C_{12}H_{14}Br_2N_2O_5$: C 33.82, H 3.31, N 6.57; found: C 33.61, H 3.37, N 6.41.

5-[(1R)-2,2-Dibromocyclopropyl]-2′-deoxyuridine (**4***b*)

Treatment of **3***b* with a saturated solution of ammonia in methanol, as described for **3***a* above, gave **4***b*: 0.215 g, 74.5%; R_f 0.50 (solvent system B); mp 145–150°C (dec.) after recrystallization from chloroform:methanol; $[\alpha]_D^{23}$ +80.8° (*c* 0.74, MeOH); ^{1}H nmr (CD_3OD) δ: 1.98 (dd, $J_{1,3''}$ = 10.5, $J_{3',3''}$ = 10.0 Hz, 1H, cp H-3″), 2.02 (dd, $J_{3',3''}$ = 10.0, $J_{1,3'}$ = 8.6 Hz, 1H, cp H-3′), 2.13 (ddd, J_{gem} = 12.7, $J_{1',2'}$ = 6.35, $J_{2',3'}$ = 5.5 Hz, 1H, H-2′), 2.28 (ddd, J_{gem} = 12.7, $J_{1',2'}$ = 6.35, $J_{2',3'}$ = 3.9 Hz, 1H, H-2′), 2.67 (ddd, $J_{1,3''}$ = 10.5, $J_{1,3'}$ = 8.6, $J_{1,6}$ = 1.34, 1H, cp H-1), 3.75 (dd, J_{gem} = 12.4, $J_{4',5'}$ = 3.3 Hz, 1H, H-5′), 3.84 (dd, J_{gem} = 12.4, $J_{4',5'}$ = 3.3 Hz, 1H, H-5′), 3.93 (m, 1H, H-4′), 4.37 (m, 1H, H-3′), 6.28 (t, $J_{1',2'}$ = 6.35 Hz, 1H, H-1′), 8.05 (d, $J_{1,6}$ = 1.34 Hz, 1H, H-6); ^{13}C nmr (CD_3OD) δ: 26.48 (cp C-3), 29.83 (cp C-1), 29.95 (cp C-2), 42.22 (C-2′), 62.38 (C-5′), 71.73 (C-3′), 86.77 (C-1′), 89.13 (C-4′), 112.82 (C-5), 140.35 (C-6), 151.79 (C-2), 163.20 (C-4). *Anal.* calcd. for $C_{12}H_{14}Br_2N_2O_5$: C 33.82, H 3.31, N 6.57; found: C 34.17, H 3.19, N 6.67.

5-[(1S,2S)-2-Bromocyclopropyl]-2′-deoxyuridine (**5**) *and 5-[(1S,2R)-2-bromocyclopropyl]-2′-deoxyuridine* (**6**)

Zinc dust (0.46 g, 7.0 mmol) was added in aliquots over a 5 h period to a stirred solution of **3***b* (0.2 g, 0.47 mmol) in glacial acetic acid (5 mL) at 50°C. The reaction, which was monitored by tlc, was complete in 5 h. The reaction mixture was cooled to 25°C, filtered, and the filtercake was washed with glacial acetic acid (3 mL). Removal of the solvent from the combined filtrates *in vacuo* gave a residue that was purified on a silica gel column using ethyl acetate:*n*-propanol:water (700:1:2 v / v / v, upper layer) as eluant. This separation provided enriched fractions containing predominantly **5** and **6**, respectively. Each enriched fraction **5** and **6** was individually separated on a silica gel

Apparent and partial molar heat capacities and volumes of aqueous $HClO_4$ and HNO_3 from 10 to 55°C

JAMEY K. HOVEY[1] AND LOREN G. HEPLER
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 16, 1989

JAMEY K. HOVEY and LOREN G. HEPLER. Can. J. Chem. **67**, 1489 (1989).

Apparent molar heat capacities and volumes of aqueous solutions containing $HClO_4$ and HNO_3 have been determined from 10 to 55°C. The temperature dependences of the standard state heat capacities and volumes of ClO_4^- (aq) and NO_3^- (aq) from 10 to 55°C were found to be well represented by the following equations:

$$\tilde{V}^0(HClO_4, aq) = -107.79 + 0.87322T - 0.0012203T^2$$

$$\tilde{C}_p^0(HClO_4, aq) = 1408.2 - \frac{55801}{T - 190} - 3.0767T$$

$$\tilde{V}^0(HNO_3, aq) = 76.67 - \frac{2210.1}{T - 190} - 0.090063T$$

$$\tilde{C}_p^0(HNO_3, aq) = 1154.9 - \frac{49213}{T - 190} - 2.5850T$$

Combination of the experimental results with semiempirical equations for ion–solvent interaction has led to predictions of the standard state volumes and heat capacities for these ionic species at higher temperatures.

Key words: heat capacities, volumes, nitric acid, perchloric acid.

JAMEY K. HOVEY et LOREN G. HEPLER. Can. J. Chem. **67**, 1489 (1989).

Opérant à des températures allant de 10 à 55°C, on a déterminé les capacités calorifiques et les volumes molaires apparents de solutions aqueuses contenant du $HClO_4$ et du HNO_3. On a trouvé que, à des températures allant de 10 à 55°C, les relations qui existent entre la température et les capacités calorifiques et les volumes de l'état standard des ions ClO_4^- (aq) et NO_3^- sont bien représentées par les équations suivantes :

$$\tilde{V}^0(HClO_4, aq) = -107{,}79 + 0{,}87322T - 0{,}0012203T^2$$

$$\tilde{C}_p^0(HClO_4, aq) = 1408{,}2 - \frac{55801}{T - 190} - 3{,}0767T$$

$$\tilde{V}^0(HNO_3, aq) = 76{,}67 - \frac{2210{,}1}{T - 190} - 0{,}090063T$$

$$\tilde{C}_p^0(HNO_3, aq) = 1154{,}9 - \frac{49213}{T - 190} - 2{,}5850T$$

En faisant appel à une combinaison des résultats expérimentaux et d'équations semi-empiriques pour l'interaction ion–solvant, on a pu faire des prédictions concernant les capacités calorifiques et les volumes de l'état standard de ces espèces ioniques à des températures plus élevées.

Mots clés : capacités calorifiques, volumes, acide nitrique, acide perchlorique.

[Traduit par la revue]

Introduction

Heat capacities and volumes of aqueous solutions containing perchloric and nitric acids have been obtained from 10 to 55°C. The derived partial molar volumes and heat capacities of these aqueous species can be used in many calculations through the use of simple thermodynamic relationships. The temperature and pressure dependences of the equilibrium constant (or Gibbs free energy) are related to standard state heat capacities and volumes by the expressions:

$$[1] \quad \left(\frac{\partial \ln K}{\partial T}\right)_p = \frac{\Delta H^0}{RT^2}$$

$$[2] \quad \left(\frac{\partial \Delta H^0}{\partial T}\right)_p = \Delta C_p^0$$

$$[3] \quad \left(\frac{\partial \ln K}{\partial p}\right)_T = \frac{-\Delta V^0}{RT}$$

Knowledge of the standard state volume and heat capacity functions thus permits calculation of the equilibrium constants (or Gibbs free energies) as a function of both temperature and pressure over the experimental temperature range. Combination of these data with semitheoretical models of ionic hydration permits extrapolation of these data to higher temperatures that are more closely associated with many applications.

Experimental

Water used for all experiments was first passed through an activated charcoal filter and then through a Milli-RO4 / Milli-Q reagent grade mixed bed ion exchange and activated carbon system to yield purified water with a resistivity of 18 MΩ cm or greater. Solutions of NaCl (Fisher certified, ACS) were prepared by mass after drying the salt at 110°C until constant weight.

55	0.985695	4.1821	2.4946	42.699

All stock solutions were prepared from concentrated solutions of the acids. Concentrated (60%) perchloric acid and nitric acid were obtained from Fisher (certified, ACS). The molality of each stock solution was determined by titration with THAM (tris(hydroxymethyl)aminomethane). All subsequent solutions were prepared by diluting (by mass) the stock solutions with pure water.

The densities of all solutions were measured relative to water at each of the experimental temperatures ±0.01°C with a Sodev 03D vibrating tube densimeter (1), which was calibrated with pure water and a standard solution of NaCl (densities taken from Millero (2)). Heat capacities were measured at the mean reported temperatures ±0.01°C relative to water with a Sodev CP-C Picker type flow microcalorimeter (3). Temperatures were maintained (constant to ±0.001°C) in both instruments with separate Sodev CT-L circulating baths and monitored with calibrated thermistors. Daily evaluation of the calorimetric heat loss correction factor (4) by way of measurements on standard solutions of NaCl led to $f = 1.006 \pm 0.002$ at 25°C. This correction factor was assumed to be independent of temperature. Densities and heat capacities for pure water were taken from Kell (5, 6) and are listed later.

Results

Apparent molar properties

Table 1 lists the experimentally determined relative densities $(d - d_1^0)$ and heat capacity ratios $[c_p d/(c_{p,1}^0 d_1^0) - 1]$ for all of the aqueous solutions at each temperature. The apparent molar property $^{\Phi}Y$ of a solution is defined generally by

$$[4] \quad {}^{\Phi}Y_2 = \frac{Y_{soln} - 55.509 Y_1^0}{m_2}$$

where Y_{soln} is the extensive property (volume or heat capacity) of a solution that contains 1 kg of solvent (water), Y_1^0 is the molar volume or heat capacity of pure solvent (water), and m_2 is the molality of the solute. Apparent molar volumes and heat capacities were calculated from the results listed in Table 1 using the equations

$$[5] \quad {}^{\Phi}V_2 = \frac{\frac{1 + m_2 M_2}{d} - \frac{1}{d_1^0}}{m_2}$$

and

$$[6] \quad {}^{\Phi}C_{p,2} = \frac{c_p(1 + m_2 M_2) - c_{p,1}^0}{m_2}$$

where M represents the solute molar mass, c_p and d are the specific heat capacity and density of the solution, and $c_{p,1}^0$ and d_1^0 are the specific heat capacity and density of pure water. Table 1 lists values of these apparent molar volumes and heat capacities at the temperatures pertaining to the present measurements.

The functional dependences of the apparent molar volumes and heat capacities of $HClO_4$ and HNO_3 are well represented by extended Debye–Hückel equations of the type (7)

$$[7] \quad {}^{\Phi}Y = \bar{Y}^0 + 1.5 \frac{\omega A_Y}{I}[I - 2I^{1/2} + 2\ln(1 + I^{1/2})] + B_Y I + C_Y I^{3/2}$$

where

$$[8] \quad I = \omega m = \frac{1}{2}\sum m_i z_i^2$$

Values for the Debye–Hückel limiting slopes (A_Y) were taken from Ananthaswamy and Atkinson (8) and are listed in Table 2.

Equation [7] was fitted to the experimental apparent molar properties listed in Table 1 at 10, 40, and 55°C and at 25°C to the data from Hovey *et al.* (9) to generate the values of $\bar{Y}_2^0$, B_Y, and C_Y for nitric and perchloric acid that are listed in Table 3. It was found that the temperature dependence of the B_Y and C_Y parameters for perchloric acid could be represented satisfactorily by equations of the form

$$[9] \quad B_Y(\text{and } C_Y) = p_1 + \frac{p_2}{T} + p_3 T + p_4 T^2$$

using only three of the four parameters without significant loss in the precision of the fits. The p_i parameters are fitting coefficients and T is the temperature in kelvins. We have subsequently refit the data listed in Table 1 using values for the B and C parameters that resulted from the constrained fits.

Application of eq. [9] to the B and C parameters obtained from fits to data for nitric acid was found to increase the overall standard deviation of the fits and thus was not used for refining the limiting standard state values.

Plots of $^{\Phi}Y_2$ minus the Debye–Hückel limiting law (eq. [7]) are shown in Figs. 1 and 2 for perchloric acid and Fig. 3 and 4 for nitric acid. The ability of the above described procedure to represent the high concentration properties and the standard state values (infinite dilution) is illustrated in these plots.

Standard state properties

Direct comparisons

Many of the room temperature standard state partial molar volumes and heat capacities for nitric and perchloric acids were discussed by Hovey *et al.* (9) and the preferred values at 25°C are recommended over the present results. For temperatures above and below 25°C there are results from only a few studies that can be compared with the present work. Millero (10) cites standard state volumes from Zen (11) at 0, 10, and 25°C, of which the 10 and 25°C values are in good agreement with the present results. Smith-Magowan and Goldberg (12) cite several investigations of the heat capacities of aqueous nitric acid solutions. None of the results that were derived from temperature dependent studies are of sufficient precision or to low enough

		HNO_3	
10	−106.4±0.6	41.29±3.4	−11.91±3.0
25	−69.0±0.5	13.57±2.9	2.321±2.6
40	−58.3±0.7	18.18±4.0	−1.27±3.5
55	−48.0±1.3	−4.245±7.9	15.74±6.9

*Expressions at 25°C were derived from fits to data from ref. 9.

†Reported uncertainties are those derived from the fits with unconstrained values of the B_Y and C_Y parameters. For $HClO_4$ calculations from 10 to 55°C use:

$$B_V = -38.635 + 8170.9/T + 0.00012152T^2$$
$$B_C = -3150.1 + 671750/T + 0.010287T^2$$
$$C_C = 1578.4 - 332590/T - 0.0052506T^2$$
$$T/K = t/°C + 273.15$$

ionic strengths for useful comparisons. It is expected that the present results are the most useful over this reported temperature range.

There are more recent data that lead to standard state volumes and heat capacities for perchloric acid. The recent precise volumetric results of Herrington *et al.* (13) from 25 to 75°C are in excellent agreement with the present results. Smith-Magowan and Goldberg (12) have compiled a listing of all heat capacity measurements on perchloric acid prior to 1979, from which it can be seen that no study covers the present temperature range. Very recent direct densimetric and calorimetric investigations of perchloric acid have been reported by Pogue and Atkinson (14) from 15 to 55°C. The volumetric results are in good agreement with the present results, but their standard state heat capacities are more positive than the present results by 3 J K^{-1} mol^{-1} at 25°C and 29 J K^{-1} mol^{-1} at 55°C. This difference is partly due to their apparent neglect of unsymmetrical heat losses in Picker type flow microcalorimeters. The results from Pogue and Atkinson (14) are also just outside of estimated uncertainties

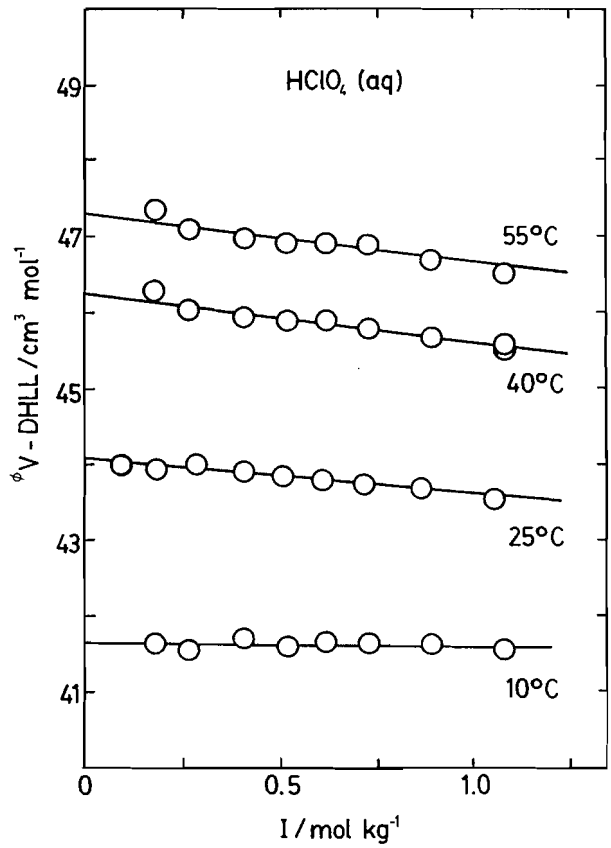

FIG. 1. ${}^{\Phi}V$ minus the extended Debye–Hückel limiting law (DHLL) for aqueous $HClO_4$ from 10 to 55°C versus ionic strength. Lines are least-squares fits of eq. [7].

of other results at room temperature, such as those by Singh *et al.* (15) and Hovey *et al.* (9) and the value based on a critical evaluation of data for perchloric acid and other perchlorate salts (7) that yielded $C_p^0 = 25 \pm 1$ J K^{-1} mol^{-1} for aqueous $HClO_4$. For these reasons, we believe that the present results are most reliable, and that the maximum uncertainty in the results occurs at 55°C and is approximately equal to ±10 J K^{-1} mol^{-1}.

Temperature dependence of standard state properties

It is useful to have analytical representations of the temperature dependence of the standard state partial molar volumes and heat capacities for all of the solutes under present investigation for use in various thermodynamic calculations. One of the most useful representations of the temperature dependence of standard state properties is the equation suggested by Holmes and Mesmer (16):

$$[10] \quad \bar{Y}^0 = a + \frac{b}{T - \theta} + cT + dT^2$$

For ease of calculations involving many species, and from fits of the standard state heat capacities for other electrolytes (17), the temperature represented by θ has been assigned the value 190 K. Most of the fits presented below have been made with data resulting solely from the present work. The fit to standard state volumes of perchloric acid included the accurate results of Wirth and Collier (18), and all of the results from Herrington *et al.* (13) except their 75°C point. Fitting of equations of type [10] (using only 3 of the 4 parameters available) to the selected standard state properties has led to:

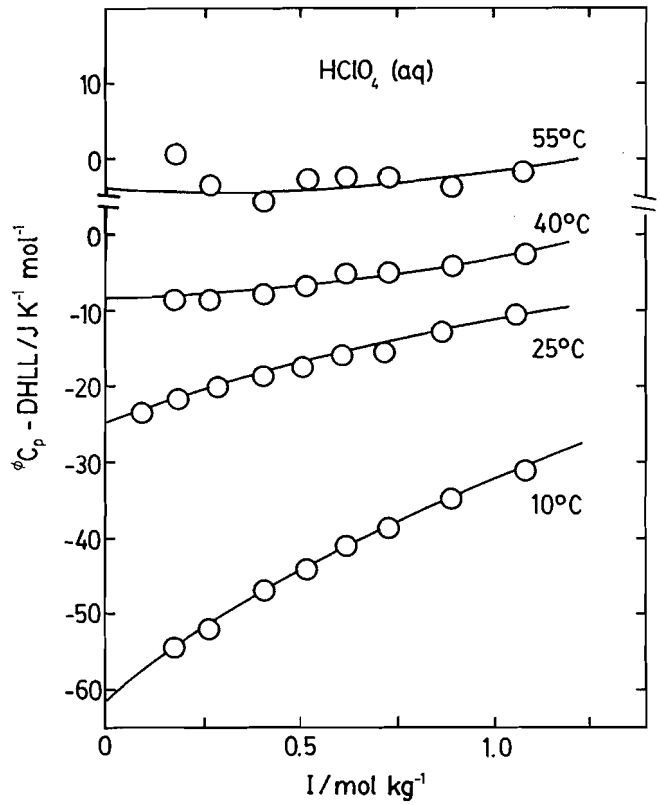

FIG. 2. $^{\Phi}C_p$ minus the extended Debye–Hückel limiting law (DHLL) for aqueous $HClO_4$ from 10 to 55°C versus ionic strength. Lines are least-squares fits of eq. [7].

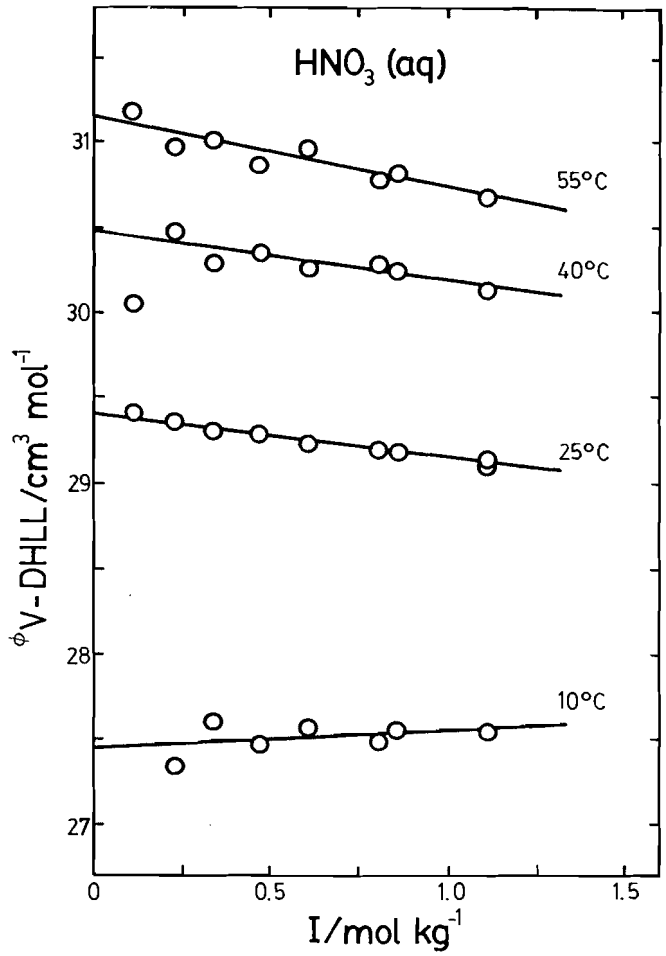

FIG. 3. $^{\Phi}V$ minus the extended Debye–Hückel limiting law (DHLL) for aqueous HNO_3 from 10 to 55°C versus ionic strength. Lines are least-squares fits of eq. [7].

$$[11]\quad \bar{V}^0(HClO_4, aq) = -107.79 + 0.87322T - 0.0012203T^2$$

$$[12]\quad \bar{C}_p^0(HClO_4, aq) = 1408.1 - \frac{55801}{T - 190} - 3.0767T$$

$$[13]\quad \bar{V}^\circ(HNO_3, aq) = 76.67 - \frac{2210.1}{T - 190} - 0.090063T$$

$$[14]\quad \bar{C}_p^0(HNO_3, aq) = 1154.9 - \frac{49213}{T - 190} - 2.5850T$$

All of these equations are accurate over the temperature range from 10 to 55°C, except the expression for $\bar{V}^0(HClO_4, aq)$, which is accurate from 10 to 65°C. Plots of the standard state partial molar volumes and heat capacities are shown in Figs. 5–8. The "goodness of fit" of the above expressions, and the marked temperature dependence of these properties can be seen. These expressions should be used for all calculations requiring the standard state volumes and heat capacities over these specified temperature ranges, rather than the expressions that are derived in the next section for use over wider ranges of temperature.

Conventional ionic volumes and heat capacities of the ions $NO_3^-(aq)$ and $ClO_4^-(aq)$ can be derived from the convention $\bar{Y}^0(H^+, aq) \equiv 0$ at all temperatures. Since all of the solutes that are under present investigation are strong acids, these conventional ionic properties are equal to the standard state properties.

Discussion

Helgeson–Kirkham–Flowers (HKF) model

The change in standard state heat capacity of a chemical reaction is related to the second derivative of the equilibrium constant with respect to temperature. Equilibrium constants or Gibbs free energies can be calculated at elevated temperatures by using heat capacity data, provided that room temperature equilibrium and enthalpy data are available. Because the relationship between equilibrium constants (or Gibbs free energies) and heat capacities is through the second derivative with respect to temperature (see eqs. [1]–[3]), shortcomings in heat capacity functions usually have only a small effect on calculations of Gibbs free energies.

The Helgeson–Kirkham–Flowers equations of state for standard state volumes and heat capacities have the form (at constant pressure) (19)

$$[15]\quad \bar{V}^0 = \sigma + \frac{\xi T}{T - \theta} + \Delta V_{Born}$$

$$[16]\quad \bar{C}_p^0 = c_1 + \frac{c_2 T}{T - \theta} + \Delta C_{p,Born}$$

where σ, ξ, c, and θ are fitting coefficients. The ΔY_{Born} terms come directly from the relationship of the partial molar free energy to partial molar volumes and heat capacities

$$[17]\quad \Delta V_{Born} = \left(\frac{\partial \Delta G_{Born}}{\partial p}\right)_T = -\omega \frac{1}{\epsilon}\left(\frac{\partial \ln \epsilon}{\partial p}\right)_T = -\omega Q$$

$$[18]\quad \Delta C_{p,\mathrm{Born}} = -T\left(\frac{\partial^2 \Delta G_{\mathrm{Born}}}{\partial T^2}\right)_p = \omega T \frac{1}{\epsilon}\left[\left(\frac{\partial^2 \ln \epsilon}{\partial T^2}\right)_p - \left(\frac{\partial \ln \epsilon}{\partial T}\right)_p^2\right] = \omega T X$$

and

$$[19]\quad \omega = 6.94657 \times 10^5 \left(\frac{z^2}{r_{\mathrm{eff}}}\right) \text{ Å J mol}^{-1}$$

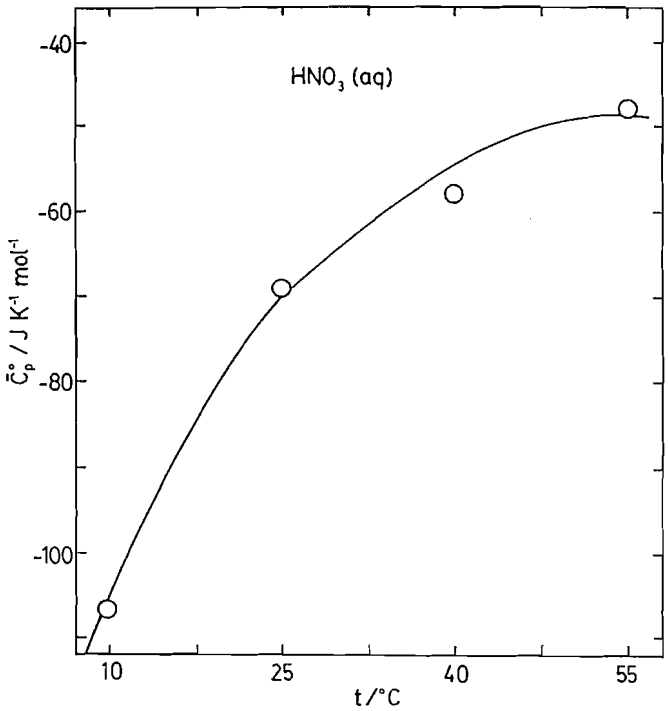

FIG. 8. Standard state heat capacities for HNO_3 from 10 to 55°C.

where Q and X are shorthand notations for the various pressure and temperature dependences of derivatives of the dielectric constant with respect to pressure and temperature, and r_{eff} is the "effective" radius of an ion in water. Numerical values for these terms were taken from Helgeson and Kirkham (20, 21).

The first two terms in eqs. [15] and [16] are purely empirical and are most important at low temperatures where the Born electrostatic model is least satisfactory. The third term in each equation results entirely from the Born equation, which dominates at high temperatures where the model is most satisfactory. Because of the balance of empirical and theoretical components, the HKF treatment is particularly well suited for extrapolation of low temperature data for standard state partial molar properties to higher temperatures.

In all of these equations the effective radii for anionic species are equivalent to crystallographic radii, and for cationic species the effective radii are the crystallographic radii plus 0.94 Å. Effective aqueous radii for all of these solutes were calculated from the crystal "ionic radii" listed by Shannon (22). The results of fitting equations of the type given by eqs. [15] and [16] are listed below

$$(22)\quad \frac{\bar{V}^0(HClO_4, aq)}{cm^3\ mol^{-1}} = 84.508 - \frac{16.465T}{T - 167.4} - 4.75415 \times 10^6 Q$$

$$(23)\quad \frac{\bar{C}_p^0(HClO_4, aq)}{J\ K^{-1}\ mol^{-1}} = 89.43 - \frac{8.6367T}{T - 261.0} - 4.75415 \times 10^5 TX$$

$$(24)\quad \frac{\bar{V}^0(HNO_3, aq)}{cm^3\ mol^{-1}} = 42.830 - \frac{2.5557T}{T - 226.5} - 4.7100 \times 10^6 Q$$

$$(25)\quad \frac{\bar{C}_p^0(HNO_3, aq)}{J\ K^{-1}\ mol^{-1}} = 45.36 - \frac{9.0799T}{T - 259.9} - 4.7100 \times 10^5 TX$$

These latter equations should be employed for calculations involving these solutes at temperatures higher than 55°C until direct results become available.

The magnitude of the standard state volumes and heat capacities for nitric and perchloric acid suggests that ion–solvent interactions in aqueous solutions containing these ions are qualitatively similar. Both the standard state volumes and heat capacities suggest that the total effects due to regions of ordered ion–water dipoles (first hydration sphere) and less ordered, less well-defined, secondary solvation spheres are larger for nitric acid. These observations are expected, due to the possibility of increased molecular motions in perchloric acid and due to the larger size of the anion.

Characterization of metal complexes of 1,10-phenanthroline, 2,2′-bipyridine, and their derivatives by fast atom bombardment mass spectrometry

JACK M. MILLER[1] AND KESAGAPILLAI BALASANMUGAM
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received February 9, 1989

JACK M. MILLER and KESAGAPILLAI BALASANMUGAM. Can. J. Chem. **67**, 1496 (1989).

A series of 1,10-phenanthroline (phen), 5-nitro-1,10-phenanthroline (5-NO_2-phen), 2,9-dimethyl-1,10-phenanthroline (dmp), 2,2′-bipyridine (bpy), and 4,4′-dimethy-2,2′-bipyridine (dmb) metal complexes has been characterized using fast atom bombardment mass spectrometry (FAB MS). Intact cations are observed in the positive ion FAB mass spectra of all tetracoordinated complexes, $[Ag(L)_2]NO_3$, $[Cu(L)_2]_2\ SO_4{\cdot}5H_2O$, $[Cu(L)_2]SO_4$, and $[Tl(L)_2](ClO_4)$, where L = bpy, phen, or dmp. Structurally significant fragment ions (ML_2^+, ML^+, M^+, and $(L + H)^+$, where M^+ = metal ion) are also observed. Species such as $Ag[Ag(L)_2]NO_3^+$, where L = bpy or phen, and $Tl[Tl(phen)_2](ClO_4)^+$ are also seen. The hexacoordinate complexes, $[Co(phen)_3]Cl_2$, $[Ru(bpy)Cl_2]$, $[Fe(phen)_2(CN)_2]$, $[Fe(L)_3](ClO_4)$, where L = 5-NO_2-phen, dmb, or bpy, and $[Fe(L)_3]SO_4$, where L = bpy or phen, show intact cations in the positive ion spectra; $[Ni(bpy)_3]X_2$, where X = Cl^-, Br^-, NO_3^-, ClO_4^-, SCN^-, and tartrate^{2-}, and $[Co(bpy)_3](ClO_4)$ do not. Generally, fragment ions such as ML_3^+, ML_2X^+, ML_2^+, MLX^+, and $(L + H)^+$ are observed, where X = singly charged intact anion or HSO_4^-. Comparison of FAB results with those of laser mass spectrometry (LMS) show that they are comparable, through reduction processes are more important for FAB. LMS always gave the intact cation while FAB was not consistent.

Key words: FAB mass spectrometry, phenanthroline complexes, bipyridine complexes, laser desorption mass spectrometry.

JACK M. MILLER et KESAGAPILLAI BALASANMUGAM. Can. J. Chem. **67**, 1496 (1989).

Faisant appel à la spectrométrie de masse par bombardement avec des atomes rapides (SM FAB), on a caractérisé une série de complexes métalliques de la 1,10-phénanthroline (phen), de la 5-nitro-1,10-phénanthroline (5-NO_2-phen), de la 2,9-diméthyl-1,10-phénanthroline (dmp), de la 2,2′-bipyridine (bpy) et de la 4,4′-diméthyl-2,2′-bipyridine (dmb). On observe des cations intacts dans les spectres de masse FAB de tous les complexes tétracoordonnés, $[Ag(L)_2]NO_3$, $[Cu(L)_2]_2SO_4{\cdot}5H_2O$, $[Cu(L)_2]SO_4$ et $[Tl(L)_2]$ (ClO_4) dans lesquels L = bpy, phen ou dmp. On observe aussi la formation d'ions de fragmentation qui sont significatifs d'un point de vue structural (ML_2^+, ML^+, M^+ et $(L + H)^+$ dans lesquels M^+ = ion métallique). On a aussi observé des espèces comme $Ag[Ag(L)_2]NO_3^+$ dans lesquelles L = bpy ou phen et $Tl[Tl(phen)_2]$ $(ClO4)^+$. Dans les spectres positifs des complexes hexacoordonnés $[Co(phen)_3]Cl_2$, $[Ru(bpy)Cl_2]$, $[Fe(phen)_2(CN)_2]$, $[Fe(L)_3](ClO_4)$, dans lesquels L = 5-NO_2-phen, dmb ou bpy, ainsi que $[Fe(L)_3]SO_4$, dans lesquels L = bpy ou phen, on observe des cations intacts; toutefois, dans les spectres des complexes $[Ni(bpy)_3]X_2$, dans lesquels X = Cl^-, Br^-, NO_3^-, ClO_4^-, SCN^- et tartrate^{2-}, et $[Co(bpy)_3](ClO_4)$, on n'observe pas ces cations. D'une façon générale, on observe les ions de fragmentation ML_3^+, ML_2X^+, ML_2^+, MLX^+ et $(L + H)^+$ dans lesquels X = un anion intact portant une seule charge ou HSO_4^-. Une comparaison des résultats obtenus en FAB avec ceux obtenus en spectrométrie du masse au laser (LMS) démontre qu'ils sont comparables, même si les processus de réduction sont plus importants en FAB. En LMS, on observe toujours un cation intact alors qu'en FAB les résultats ne sont pas consistants.

Most clés : spectroscopie de masse en FAB, complexes de la phénanthroline, complexes de la bipyridine, spectrométrie de masse par désorption au laser.

[Traduit par la revue]

Introduction

Mass spectrometry has been widely applied to the characterization of coordination compounds (1–6). The interest in coordination and related compounds stems from their use in the fields of catalysis (7–9), chemical analysis (7–9), medicine (10), and biological systems (11–14).

Characterization of coordination compounds by conventional mass spectrometry has been limited, (2, 15) because many of them are involatile and thermally labile, although even conventional positive ion electron impact (EI) mass spectrometry has yielded a significant body of useful information (1). However, the newer ionization techniques such as field desorption (FD) (3), fast atom bombardment (FAB) (4, 16, 17), secondary ion mass spectrometry (SIMS) (5, 18), and laser mass spectrometry (LMS) (6, 19), have been used successfully for the characterization of coordination compounds.

In the present work, FAB has been used to investigate a series of 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen), 5-nitro-1,10-phenthroline (5-NO_2-phen), 2,9-dimethyl-1,10-phenanthroline (dmp), and 4,4′-dimethyl-2-2′-bipyridine (dmb) complexes; these complexes are listed in Table 1. Comparison of FAB mass spectral data with those of LMS, which have been previously reported, (6) is also discussed in the appropriate places.

Experimental

The coordination compounds: $[Fe(phen)_3](ClO_4)_2$, $[Fe(bpy)_3]SO_4$, $[Fe(dmb)](ClO_4)_2$, $[Fe(phen)_3]SO_4$, $[Fe(5\text{-}NO_2\text{-}phen)_3]SO_4$, $[Fe(phen)_2(CN)_2]$, $[Co(bpy)_3](ClO_4)_2$, and $[Ru(bpy)_3]Cl_2$ were purchased from G. Frederic Smith Chemical Co., and used without further purification. Other complexes given in Table 1 were synthesized using standard methods (6).

FAB mass spectra were obtained on a Kratos MS 30 mass spectrometer, retrofitted (20) with a Kratos FAB source in beam I and interfaced to a Kratos DS 55 data system. Argon was used as the bombarding gas with atom gun (Ion Tech) energies of 6–8 kV and a gun current of 1 mA. The operating pressure of the ion source was typically $\sim 10^{-5}$ Torr (1 Torr = 133.3 Pa), and the positive secondary ions formed were accelerated to 4 ke V. The source was operated at room temperature (although localized heating on the probe tip and source components in the direct atom beam occurs). The mass analyzer was operated at a nominal resolving power of 1000.

3-Nitrobenzyl alcohol (NBA) was used as the liquid matrix in this study. Samples (2–3 μL) dissolved in NBA (~15 mg / 1 mL) were placed on the stainless steel FAB probe tips for spectral acquisition. The results for each sample are from an average of 6–10 scans, and are reported after matrix background subtraction.

Results and discussion

Tetracoordinate complexes

A positive ion FAB mass spectrum of $[Ag(bpy)_2]NO_3$ is shown in Fig. 1 ($m/z > 100$); the results for this and other tetracoordinate complexes are summarized in Table 1. The formula weight of the intact cation can be deduced from ions corresponding to AgL_2^+ (Fig. 1). Fragment ions such as AgL^+, $(L + H)^+$, and Ag^+, along with the intact cation AgL_2^+, provide structural information, i.e., the number of ligands present and the formula weight of the ligand and of the metal ion. Thus, ions observed for these complexes are characteristic of the composition. The striking feature in the spectrum shown in Fig. 1 is the observation of an ion corresponding to $Ag{\cdot}Comp^+$, where Comp = $[Ag(bpy)_2]NO_3$. This ion was not reported in the studies using SIMS (5) and LMS (6) for the same compound. The above species, $Ag{\cdot}Comp^+$, can be used to infer the molecular weight of the neutral molecule $[Ag(bpy)_2]NO_3$. Thus, a formula including both the anion and the cation can be obtained for $[Ag(bpy)_2]NO_3$ using the positive ion FAB mass spectrum.

The positive ion FAB mass spectra of $[Ag(phen)_2]NO_3$ and $[Tl(phen)_2](ClO_4)$ are very similar to the spectrum of $[Ag(bpy)_2]NO_3$, i.e., ions corresponding to M^+, $(L + H)^+$, ML^+, ML_2^+, and $M{\cdot}Comp^+$ (where M = metal cation, L = phen, and Comp = molecular weight of the complex) are observed (Table 1). In the case of $[Ag(phen)_2]NO_3$ an additional ion corresponding to $Ag(phen)Comp^+$ (m/z = 818) is also observed. The observation of these species suggests that some of the ions may arise as a result of decomposition of cluster ions. The fragmentation observed for $[Cu(L)_2]_2SO_4{\cdot}5H_2O$ (where L = phen or dmp) is the same as reported above, ions corresponding to CuL_2^+, CuL^+, $(L + H)^+$, and Cu^+ being observed in both cases. Thus, the formula weight of the intact cation, CuL_2^+, the ligand, $(L + H)^+$, and the metal ion, Cu^+, can be deduced. Ions of the same kind, as described above, are detected for $[Cu(bpy)_2]SO_4$. In addition, species such as $CuL_n(HSO_4)^+$, where n = 1,2, are also observed. The latter ions are probably produced by proton addition during the FAB ionization processes. These ions along with CuL_2^+ and CuL^+ may be used to infer the anionic species present, i.e., SO_4^{-2}, in the molecule.

Laser mass spectra reported (6) for the same tetracoordinate complexes showed similar fragmentation patterns, i.e., ions corresponding to ML_2^+, ML^+, $(L + H)^+$, and M^+ are observed for all tetracoordinated complexes. In both LMS and FAB, the intensities of ML^+ ions are higher than those of ML_2^+, an observation consistent with the stability constants in solution for tetracoordinate complexes. For example, the stability contant, $\log k_1$, for $Cu(bpy)^{2+}$ formation is higher, 9.3 (20), than $\log k_2$, 6.84, for $Cu(bpy)_2^{2+}$ formation.

There are also some differences observed between the results obtained by LMS and FAB for tetracoordinate complexes. Generally, the extent of dissociation of the complexes seems to be higher in LMS than in FAB. For example, the relative intensities of AgL_2^+ and $(L + H)^+$ in the positive ion mass spectrum of $[Ag(bpy)_2]NO_3$ are 17 and 43% (6) respectively in LMS compared to 33 and 9% respectively in FAB (with respect to the same ion, AgL^+). The higher level of fragmentation in LMS may be attributed to the high laser power (10^8–10^9 W/cm^2) used with the laser beam focused on the sample. Results comparable to those observed in FAB with respect to the level of fragmentation may be obtained in LMS, if the laser beam used is defocused on the sample, as reported recently (22).

The other big difference is the absence of LMS of species such as $M{\cdot}Comp^+$ (where $M = Ag^+, Tl^+$) and other cluster ions

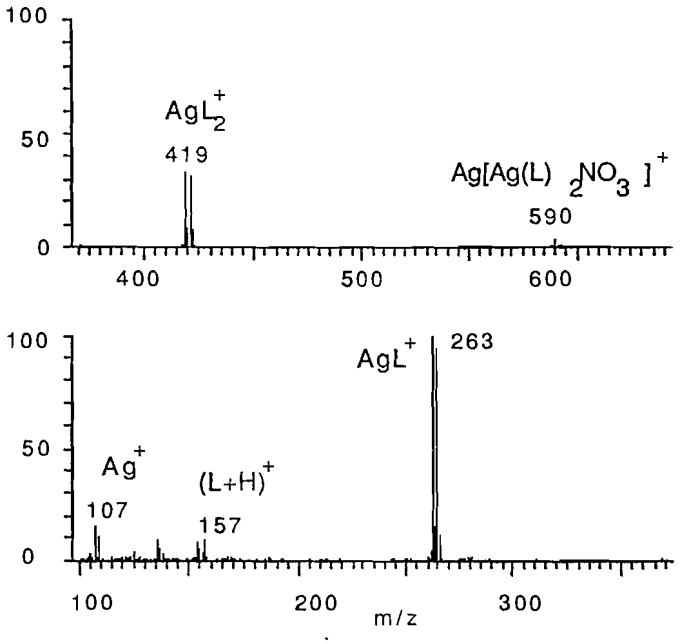

FIG. 1. Positive ion FAB mass spectrum of $[Ag(bpy)_2]NO_3$.

such as $Ag(phen)Comp^+$. Absence of cluster ions in LMS suggests that cluster ion formation may be favoured in a liquid matrix environment, or may occur in the high pressure "selvedge" region above the surface. A comparison study (23) using internal salts showed the same trend, i.e., a higher level of cluster ions in FAB than in LMS for internal salts.

The presence of ions corresponding to $CuL_n(HSO_4)^+$, where n = 1–2 for $[Cu(bpy)_2]SO_4$ only in FAB, not in LMS, may be attributed to the probable presence of protons in the protic liquid matrix, perhaps enhanced by radiation damage to the matrix.

Hexacoordinate complexes

The positive ion FAB mass spectra of $[Co(phen)_3]Cl_2$ and $[Fe(phen)_2(CN)_2]$ are shown in Fig. 2; the results of these two and other hexacoordinate complexes are summarized in Table 1. The highest mass ion detected for $[Co(phen)_3]Cl_2$ corresponds to the intact cation CoL_3^+. Ions corresponding to CoL_2^+, CoL^+, $(L + H)^+$, and Co^+ are also observed; these will provide information such as the number of ligands present and the formula weight of the ligand and the metal ion. Presence of the anion, Cl^-, may be deduced using ions corresponding to CoL_nCl^+, where n = 1–2.

Ions corresponding to $(Comp + H)^+$ and $Comp^{+\bullet}$ are observed in the positive ion FAB mass spectrum of $[Fe(phen)_2(CN)_2]$, where Comp = $[Fe(phen)_2(CN)_2]$. Detection of ions corresponding to FeL_2CN^+ and FeL_2^+ along with $FeL_2CN_2^{+\bullet}$ indicates that there are two cyanide groups present in the molecules, i.e., two successive losses of 26 mass units. The presence of two "phen" ligands can be deduced from the ions corresponding to Fe^+, $FeLCN^+$, and FeL_2CN^+ (Fig. 2a, Table 1). The results indicate that a fair amount of structural information can be obtained for hexacoordinate complexes from the positive ion FAB spectra.

Other hexacoordinate complexes give spectra very similar to those discussed above, and most of them show ions corresponding to ML_n^+, n = 1–3, ML_nX^+, n = 1–2, $(L + H)^+$, and M^+ in the positive ion FAB mass spectra. The absence of ions corresponding to ML_3^+ for nickel complexes and $[Co(bpy)_3](ClO_4)_2$ may be attributed to these complexes being weaker, decompos-

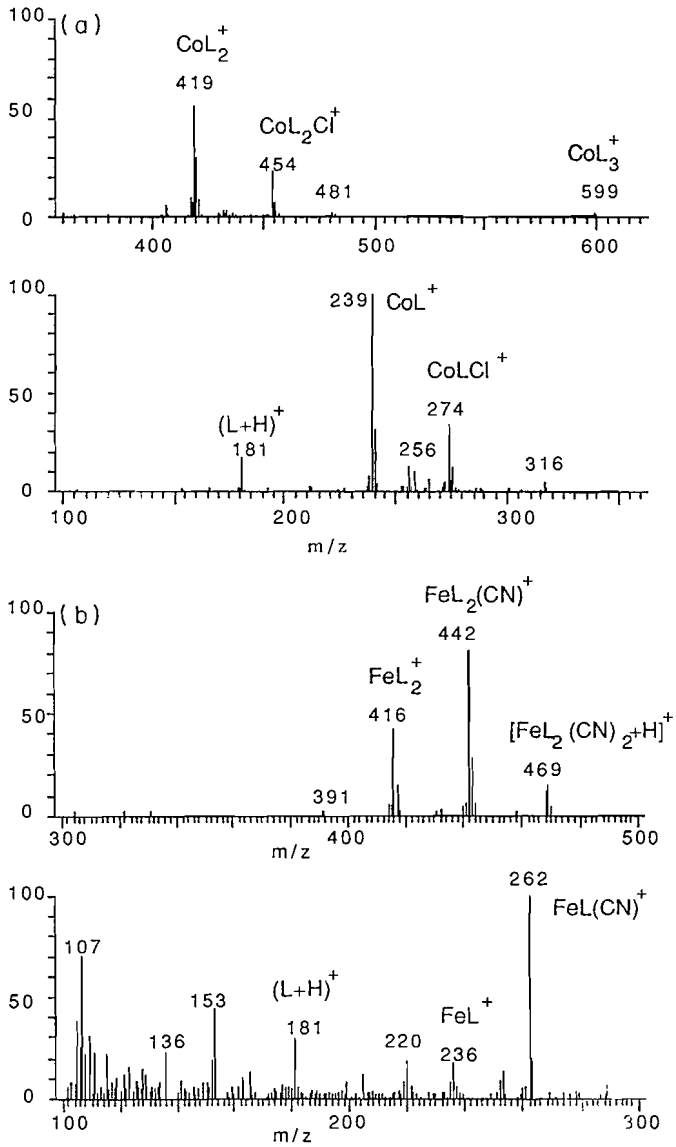

FIG. 2. (a) Positive ion FAB mass spectrum of $[Co(phen)_3]Cl$; (b) Positive ion FAB mass spectrum of $[Fe(phen)_2(CN)_2]$.

ing rapidly in the liquid matrix, NBA, during the ionization processes, leading to fragment ions only. Other liquid matrices such as glycerol, 1,1′-thiodiethanol, thioglycerol, and tetramethylene sulfolane were also tried for these complexes with little success in detecting intact cations.

Other ions of interest

Hydride anion addition leading to $FeL(H)^+$ ions is generally observed for iron complexes (Table 1). In some cases, ions corresponding to $ML(OH)^+$, where M = Fe, Co, are observed. As discussed earlier, radiation damaged liquid matrix may be responsible for production of these of ions.

Ions corresponding to $ML_mO_n^+$, m = 1–2, n = 1–2, are observed for some complexes (Table 1, Compounds **9–14**, **16**, **20**). These ions are very common when the intact anion is an oxidizing agent such as ClO_4^- or NO_3^- (Table 1). These types of ions were not observed for compounds such as $[Fe(phen)_2(CN)_2]$, $[Ru(bpy)_3]Cl_2$, $[Co(phen)_3]Cl_2$, and $[Ni(bpy)_3]X_2$, where X = Cl^-, Br^-, I^-, and SCN^-. These observations indicate that these oxygen-containing species are probably produced either by oxidation of the complexes by the oxidizing anions such as ClO_4^- or NO_3^-, or by internal decomposition of the complexes as suggested in LMS studies of the same complexes (6).

Laser mass spectra reported (6) for the same hexacoordinate complexes showed similar fragmentation patterns, i.e., ions corresponding to ML_3^+, ML_2X^+, ML_2^+, MLX^+, $(L + H)^+$, and M^+ are detected. As observed for tetracoordinate complexes, in both LMS and FAB the intensities of ions corresponding to ML^+, ML_2^+, and ML_3^+ decrease in the following order:

$$ML^+ > ML_2^+ > ML_3^+$$

This again agrees with individual stability constants from solution chemistry where stability constants generally decrease (21) as follows: $k_1 > k_2 > k_3$. For example, the stability constants log k_1, log k_2, and log k_3 for the formation of $Co(phen)^{2+}$, $Co(phen)_2^{2+}$, and $Co(phen)_3^{2+}$ are 7.25, 6.70, and 5.95 respectively (22). In both FAB and LMS, oxidized ionic species are observed for complexes having oxidizing anions such as ClO_4^-. The positive ion laser mass spectrum of $[Ni(bpy)_3](ClO_4)_2$ showed ions corresponding to NiL_3O^+ and $NiL_2O^{+\bullet}$; similar ions are observed for the same compound in FAB (Table 1). Molecular cluster ions were not observed either in LMS or FAB for hexacoordinate complexes.

Some of the differences observed between the results for hexacoordinate complexes using LMS and FAB are the same as discussed for tetracoordinate analogues. No reduced species such as $FeL(H)^+$ were observed in LMS and the degree of dissociation is relatively higher in the latter. This can be seen by the comparison of the intensities of $(L + H)^+$ ions, which vary from 30–90% in LMS and 5–41% in FAB (except for two cases). The other noticeable difference is the observation of NiL_3^+ ions for $[Ni(bpy)_3]X_2$, where X = Cl^-, Br^-, I^-, and SCN^-, only in LMS. The laser seems to heat the sample so fast that the intact ions are probably desorbed from the solid state to the gas phase before decomposition can occur. Interesting ions corresponding to $[ML_2(NBA - H)]^+$, where M = Fe or Ni, indicate the interaction of the liquid matrix with the sample in FAB.

Conclusions

Results discussed indicate that FAB has the potential for the characterization of coordination compounds. Comparison of the results obtained using FAB and LMS shows that the fragmentation patterns observed are similar for the same compounds. However, the reduction processes observed are limited in LMS compared to those in FAB. For this particular system, LMS seems to be slightly better than FAB, since we observed the intact cation for all compounds studied, using this technique. Except for the nickel complexes and $[Co(bpy)_3](ClO_4)_2$, all complexes show intact cations in the positive ion FAB. We observed structurally significant fragment ions for all complexes. Self-cationized species such as $Ag[Ag(bpy)_2]NO_3^+$ are also observed.

^{125}Te and ^{19}F NMR spectroscopic study of the hydrolysis of pentafluorotellurium chloride: evidence for *trans*- and *cis*-$HOTeF_4Cl$ and *cis,mer*-$(HO)_2TeF_3Cl$

LAWRENCE J. LAWLOR, ALBAN MARTIN, MICHAEL P. MURCHIE, JACK PASSMORE,[1] AND JEREMY C. P. SANDERS
Department of Chemistry, University of New Brunswick, Bag Service No. 45222, Fredericton, N.B., Canada E3B 6E2

Received October 5, 1988[2]

LAWRENCE J. LAWLOR, ALBAN MARTIN, MICHAEL P. MURCHIE, JACK PASSMORE, and JEREMY C. P. SANDERS. Can. J. Chem. **67**, 1501 (1989).

The hydrolysis of TeF_5Cl has been followed by ^{125}Te and ^{19}F NMR spectroscopy. The spectra show that the known series $(HO)_nTeF_{6-n}$ (n = 2–6) are present. In addition the spectra are consistent with the presence of the previously unreported series $(HO)_nTeF_{5-n}Cl$ (n = 1–3) as well as unidentified fluorotellurium(IV) species. Evidence is presented for the new species *trans*- and *cis*-$HOTeF_4Cl$ and *cis, mer*-$(HO)_2TeF_3Cl$. The course of the hydrolysis of TeF_5Cl is compared with that of SF_5Cl.

Key words: *trans*-tetrafluorotellurium hydroxychloride, *cis*-tetrafluorotellurium hydroxychloride, *cis,mer*-tetrafluorotellurium dihydroxychloride, pentafluorotellurium chloride, hydrolysis.

LAWRENCE J. LAWLOR, ALBAN MARTIN, MICHAEL P. MURCHIE, JACK PASSMORE et JEREMY C. P. SANDERS. Can. J. Chem. **67**, 1501 (1989).

Faisant appel à la RMN du ^{125}Te et du ^{19}F, on a suivi l'évolution de la réaction d'hydrolyse du TeF_5Cl. Les spectres démontrent que les produits connus de la série $(OH)_nTeF_{6-n}$ (n = 2–6) sont présents. De plus, les spectres sont en accord avec la présence des produits de la série $(OH)_nTeF_{5-n}Cl$ (n = 1–3) qui n'avaient pas été rapportés antérieurement ainsi que d'espèces non-identifiées de fluorotellure(IV). On présente des données relatives aux nouvelles espèces *trans*- et *cis*-$HOTeF_4Cl$ ainsi que *cis,mer*-$(HO)_2TeF_4Cl$. On compare l'hydrolyse du TeF_5Cl avec celle du SF_5Cl.

Mots clés : *trans*- et *cis*-$HOTeF_4Cl$, *cis,mer*-$(HO)_2TeF_4Cl$, TeF_5Cl, hydrolyse.

[Traduit par la revue]

Introduction

It is well established that sulphur hexafluoride is chemically extremely inert (1), especially towards attack by nucleophiles, and that this low reactivity is mainly attributable to kinetic rather than thermodynamic factors. In contrast to this, the related pentafluorosulphur chloride is much more reactive and has an extensive chemistry (1–8). The Group 16 hexafluorides become more reactive as the group is descended and tellurium hexafluoride can form a number of derivatives by direct nucleophilic substitution (9, 10). For example, hydrolysis of TeF_6 yields the hydroxo-substituted series $TeF_n(OH)_{6-n}$, where n = 0–6 (11–14). This reaction has been studied in detail and all the species in the above series characterized by ^{125}Te and ^{19}F NMR spectroscopy (14–19).

The development of a convenient high-yield synthesis of pure pentafluorotellurium chloride in this laboratory has begun to allow an extensive exploration of its chemistry (20). The reactions of TeF_5Cl with a variety of reagents have been reported; the reaction of TeF_5Cl with CH_3OH or $CH_3OSi(CH_3)_3$ yields a mixture of *cis*- and *trans*-$(CH_3O)TeF_4Cl$ in a ratio of 1:6 (21). Thrasher and Seppelt have reported that TeF_5Cl can be added photolytically to nitriles, yielding the first compounds containing the $TeF_5N{=}C\diagdown$ moiety (22). Very recently, Thrasher *et al.* described the reactions of TeF_5Cl with a number of nitrogen nucleophiles; in all the case investigated, reduction to Te(IV) occurred (23). In view of the apparent reactivity of TeF_5Cl it was of interest to study its reaction with water and the results of this study are reported below.

Experimental

TeF_5Cl was prepared by the literature method (20) and its purity checked by infrared and ^{19}F NMR spectroscopy. H_2O was purified by triple distillation prior to use. TeF_5Cl was manipulated in a Monel vacuum line.

NMR samples were made up in either 1/4-in. FEP (polymerized CF_2CF_2 and CF_2CFCF_3, du Pont) tubes fitted with IKS4 Whitey valves or 10 mm o.d. thick-walled glass NMR tubes (Wilmad) containing a concentric 9 mm o.d. FEP insert tube. The 10 mm o.d. glass NMR tube was fitted with a J. Young (o-ringette PTFE stopcock) valve.

NMR spectra were recorded unlocked on a Varian XL-200 pulse FT spectrometer using a 10-mm broadband probe (frequency range 20–125 MHz) for ^{125}Te. The same probe was employed to record the ^{19}F NMR spectra by using the ^{1}H decoupler coils retuned to 188.220 MHz as the observe coils. ^{19}F NMR spectra were obtained at 188.220 MHz and accumulated in 30K of memory over a spectral width of 100 kHz, yielding a data point resolution of 6.7 Hz and an acquisition time of 0.15 s. The number of free induction decays collected varied but was typically 1000–3000 scans using a pulse width of 6 μs. The ^{125}Te spectra were obtained at 63.1940 MHz and accumulated in 32K of memory over spectral widths of 100 and 30 kHz (yielding data point resolutions of 6.3 and 1.9 Hz and acquisition times of 0.16 and 0.53 s, respectively) with a pulse width of 23 μs, in 600–2500 scans.

The respective nuclei were referenced externally to neat samples of $CFCl_3$ (^{19}F) and $(CH_3)_2Te$(^{125}Te) at 23°C. The chemical shift convention used is that a positive sign signifies a chemical shift to high frequency of the reference compound.

Hydrolysis of TeF_5Cl

Samples for direct study by NMR spectroscopy were made up with $TeClF_5$:H_2O ratios varying between 1:1 and 1:15. A known quantity of triply distilled water (0.07–3.45 g, 3.6–192 mmol, depending on the stoichiometry required) was weighed into the NMR tube. The tube was attached to the vacuum line and cooled to −78°C. The tube was then evacuated and the appropriate quantity of TeF_5Cl (0.94–3.48 g, 3.6–13.5 mmol, depending on stoichiometry required) distilled in. The mixture was then allowed to warm to room temperature. Samples contained in 1/4-in. FEP tubes were flame sealed whilst under vacuum with the sample frozen to −196°C. The FEP tube was inserted into a precision 10 mm (o.d.) glass NMR tube to obtain the NMR spectrum of the sample. NMR spectra of the samples were acquired after various time intervals at either 0°C or 25°C.

[a] *t* = *trans*, *c* = *cis*, *m* = meridional, *f* = facial. Where a species formula is preceded by two letters, e.g., *c,m*-$(HO)_2TeF_3Cl$, the first letter refers to the stereochemical arrangement of the OH groups and the second to the stereochemical arrangement of the F ligands.

[b] A = F *trans* F, B = F *trans* Cl, C = F *trans* OH.

[c] $\delta(^{19}F)$ relative to neat $CFCl_3$. Dean and Evans calculated shifts in parentheses. Dean and Evans constants: $C = 48.4$ and $T = 9.4$ for Cl; $C = 5.5$ and $T = 10.9$ for OH.

[d] $\delta(^{125}Te)$ relative to neat $(CH_3)_2Te$.

[e] Species not observed in the ^{125}Te NMR spectrum.

[f] Tentative assignments only. The exact nature of the species giving rise to these resonances could not be ascertained.

Results and discussion

General procedures

The hydrolysis of TeF_5Cl was studied using a number of mixtures of TeF_5Cl and H_2O with different molar ratios, viz., $TeF_5Cl:H_2O$ = 1:1–1:15. Initially each sample comprised two liquid phases, the upper layer being the aqueous phase and the lower one being TeF_5Cl. However, samples with $TeF_5Cl:H_2O$ ratios greater than 1:8 formed a single liquid phase after approximately 12 h at room temperature, whereas samples having $TeF_5Cl:H_2O$ ratios of 1:4 or lower remained as two-phase systems for at least 2 days. Consequently, the NMR spectra of the latter samples were obtained on two-phase systems in the early stages of the hydrolysis reaction. Similar behaviour was observed in the hydrolysis of TeF_6 where a two-phase system was also formed when the TeF_6 and H_2O were first mixed (15). The products of the hydrolysis of TeF_5Cl were monitored and characterized by ^{19}F and ^{125}Te NMR spectroscopy. The NMR data obtained are summarized in Table 1. The data reveal the presence of the series $(HO)_nTeF_{6-n}$, where n = 2–6, and are also consistent with the presence of the series $(HO)_nTeF_{5-n}Cl$, where n = 1–3. In addition, both the ^{19}F and ^{125}Te NMR spectra display a broad singlet characteristic of fluorotellurium(IV) species undergoing exchange. The various species detected in two representative TeF_5Cl/H_2O samples, after various time periods, are presented in Table 2.

Identification of the hydrolysis products of TeF_5Cl by ^{19}F and ^{125}Te NMR spectroscopy: evidence for the previously unknown species trans- *and* cis-*$HOTeF_4Cl$, cis,mer-$(HO)_2TeF_3Cl$, and possibly* mer,cis- *and* fac,cis-*$(HO)_3TeF_2Cl$*

It has been demonstrated for a number of octahedral fluoro-species MX_nF_{6-n} (n = 1–6) that the ^{19}F chemical shifts of such species can be correlated in terms of a linear function. This function is given by eq. [1] where C and T are adjustable parameters

$$[1] \quad \delta(^{19}F) = pC + qT$$

characteristic of the substituent ligand (X), while p and q are the number of substituents (X) in a position *cis* and *trans*, respectively, to the fluorine ligand in question (p = 0–4; q = 0 or 1). This empirical method was first employed by Dean and Evans (24) to assign the ^{19}F NMR spectra of a range of fluorostannate(IV) species $(SnX_nF_{6-n})^{2-}$ where, for example, X = Cl, Br, I, OR, NCO, NCS, and N_3. Since then the same procedure has been successfully applied to a number of analogous systems, e.g., $(PtX_nF_{6-n})^{2-}$ (X = OH or Cl) (25), $(CH_3O)_nWF_{6-n}$ (26), WCl_nF_{6-n} (27), $[SbCl_nF_{6-n}]^-$, and $[AsCl_nF_{6-n}]^-$ (28).

The method may be extended to species having more than one type of substituent ligand (X) according to eq. [2].

$$[2] \quad \delta(^{19}F) = \sum_X p_X C_X + \sum_X q_X t_X$$

In the present work, the assignment of resonances arising from the $(HO)_nTeF_{6-n}$ species was carried out by comparison with the literature ^{19}F and ^{125}Te NMR data (chemical shifts, resonance multiplicities, and coupling constants) obtained for the species formed in the hydrolysis of TeF_6 (14, 15) and the solvolysis of $Te(OH)_6$ in HF (16). Elgad and Selig (14) found that the ^{19}F chemical shifts of the $(HO)_nTeF_{6-n}$ species could be satisfactorily reproduced using eq. [1], and our results (Table 1) are in accord with this finding.

The assignment of the ^{19}F resonances arising from the

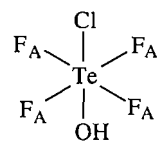
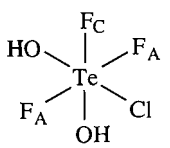
previously unobserved $(HO)_nTeF_{5-n}Cl$ species is based on the observed spin coupling patterns and ^{19}F chemical shift trends. In view of the proven usefulness of the Dean and Evans approach (eq. [2]), it was reasonable to use this method to calculate the expected ^{19}F chemical shifts for the $(HO)_nTeF_{6-n}Cl$ series. The values for the adjustable parameters (*C* and *T*) employed and the calculated $\delta(^{19}F)$ values are given in Table 1. The calculated $\delta(^{19}F)$ values predict that where more than one ^{19}F environment exists in the molecule the following trend will be observed: δ(F *trans* to OH) > δ(F *trans* to F) > δ(F *trans* to Cl). Although only fair agreement was found between the observed and calculated ^{19}F shifts, the predicted trends did hold good and were a useful aid in making assignments.



The ^{19}F NMR spectra provide evidence that the first products of the hydrolysis of TeF_5Cl are the new species *cis*-$HOTeF_4Cl$ **1***a* and *trans*-$HOTeF_4Cl$ **1***b*, as well as fluorotellurium(IV) reduction products. Evidence for the *trans* isomer comes from the observation of a singlet (A_4 spin system) at δ = 3.2 (calcd. value = −0.6). In the same spectrum three resonances with multiplet fine structure were also observed. These are in accord with the expected A_2BC system for *cis*-$HOTeF_4Cl$. The spin system was confirmed by computer simulation using the experimentally measured chemical shifts and coupling constants. In addition, the chemical shifts of the three fluorine environments are in quite good agreement with the trends predicted for *cis*-$HOTeF_4Cl$ by the Dean and Evans method (see Table 1).

Evidence for a new species with the formula $(HO)_2TeF_3Cl$ was provided by the observation of a doublet (δ = 19.2) and a triplet (δ = 1.3) in the ^{19}F NMR spectrum. Both resonances were flanked by ^{125}Te satellites. A corresponding doublet of triplets was observed in the ^{125}Te NMR spectrum. Three isomeric configurations are possible for $(HO)_2TeF_3Cl$: *cis,mer*-$(HO)_2TeF_3Cl$ **2***a*; *trans,mer*-$(HO)_2TeF_3Cl$ **2***b* and *cis,fac*-$(HO)_2TeF_3Cl$ **2***c*. However, only one of these appeared to be present in the samples investigated. All three isomers are expected to give rise to the same splitting patterns in the ^{19}F and ^{125}Te NMR spectra and consequently the splitting pattern does not afford a means of determining which isomer is present. In spite of this, the ^{19}F chemical shifts calculated by the Dean and Evans method provide some aid in this matter. The above method predicts different ^{19}F shifts for the fluorine environments depicted in the three isomeric structures **2***a*, **2***b*, and **2***c*: *cis, mer*- (δ_a = 4.9; δ_c = 10.3); *trans,mer*- (δ_a = 4.9; δ_b = −34.1); and *cis,fac*- (δ_b = −34.1; δ_c = 10.3). From these calculated values it can be seen that the closest agreement with the experimental shifts is for the *cis,mer* isomer. Furthermore, this is the only isomer for which the triplet resonance is predicted to occur to high frequency of the doublet resonance, in accord with the experimentally observed spectrum. In view of this, the isomer is tentatively assigned as *cis,mer*-$(HO)_2TeF_3Cl$.



The ^{19}F NMR spectra of samples with a $TeF_5Cl:H_2O$ ratio of 1:2 reveal two other new resonances not previously reported. The species giving rise to these resonances are of very low concentration and their presence was only detected in the ^{19}F NMR spectrum. In view of the lack of other supportive evidence, only tentative assignments may be ventured for the identity of these species. The doublet at δ = 19 occurs close to the predicted ^{19}F chemical shift value (δ = 15.8) for the C part of the BC spin system belonging to *mer,cis*-$(HO)_3TeF_2Cl$ **3***a*.

The corresponding doublet attributable to the B part of the BC spin system was not observed. The calculated shift for this resonance ($\delta = -28.6$) occurs in a congested region in the ^{19}F NMR spectrum of the TeF_5Cl hydrolysis system so that the resonance could be obscured. Two other isomers are possible for $(HO)_3TeF_2Cl$ (**3***b* and **3***c*); however, both isomers would only give rise to a singlet in the ^{19}F NMR spectrum. The singlet resonance observed at $\delta = 21.5$ could arise from *fac,cis*-$(HO)_3TeF_2Cl$ **3***b* (calcd. $\delta(^{19}F) = 15.8$) or *cis*$(HO)_4TeClF$ **4***a* (calcd. $\delta(^{19}F) = 21.3$). However, without other corroborative evidence, it is impossible to give an unequivocal assignment for this singlet.

The first hydrolysis products of TeF_5Cl: cis- *and* trans-*$HOTeF_4Cl$*

The species observed as the first hydrolysis products are *cis*- and *trans*-$HOTeF_4Cl$ **1***a*, **1***b*. The *cis:trans* ratio was approximately 4:1, which is in agreement with the predicted statistical ratio. In contrast, a very recent publication (29*a*) reports that the related phenyltellurium(VI) pentafluoride $PhTeF_5$ hydrolyses to *cis*- and *trans*-$PhTeF_4OH$, with an isomer ratio of 1:3. None of the spectra in this work revealed any evidence for $HOTeF_5$. Formation of $HOTeF_5$ from TeF_5Cl would involve hydrolysis with loss of HCl rather than HF. However, the formation of HF rather than HCl is thermodynamically favored since the bond energy difference between HF (565 kJ mol^{-1}) (28) and HCl (428 kJ mol^{-1}) (29*b*) can be anticipated to be greater than the bond energy difference between a Te—F bond and a Te—Cl bond in TeF_5Cl. *cis*- and *trans*-$HOTeF_4Cl$ were only observed in samples with TeF_5Cl:H_2O ratios less than 1:3.5 and even at these ratios their concentrations were very low compared with other hydrolysis products, e.g. *cis*- and *trans*-$(HO)_2TeF_4$ and *mer*-$(HO)_3TeF_3$. This indicates that the hydrolysis of *cis*- and *trans*-$HOTeF_4Cl$ **1***a* and **1***b* is rapid in the presence of excess water. In contrast, the related TeF_5OCH_3 hydrolyses exclusively to *cis*-$HOTeF_4OCH_3$ and this, in turn, only hydrolyses further after several hours at 60°C (30).

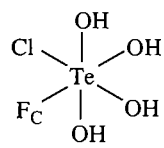
The hydrolysis of cis- *and* trans-*$HOTeF_4Cl$ leading to* cis- *and* trans-*$(HO)_2TeF_4$ and* cis,mer-*$(HO)_2TeF_3Cl$*

The products observed in the second stage of the hydrolysis of TeF_5Cl are *cis*- and *trans*-$(HO)_2TeF_4$ and the previously unknown species *cis,mer*-$(HO)_2TeF_3Cl$ **2***a*. *cis*-$(HO)_2TeF_4$ was observed in all the stoichiometries investigated and showed little change in intensity with time. This is in agreement with Tötsch and Sladky's (15, 18) finding that *cis*-$(HO)_2TeF_4$ hydrolyses very slowly over a period of several days at room temperature. *trans*-$(HO)_2TeF_4$ was observed in the spectra of all samples except those with TeF_5Cl:H_2O ratios greater than 1:10. The concentration of this species rapidly diminished in samples where excess H_2O was present, e.g., TeF_5Cl:$H_2O \geqq$ 1:8.5, in accordance with the rapid hydrolysis behaviour noted for this isomer by Tötsch and Sladky (15, 18). There are three possible isomers for $(HO)_2TeF_3Cl$: *cis,mer*-$(HO)_2TeF_3Cl$ **2***a*; *trans,mer*-$(HO)_2TeF_3Cl$ **2***b*; and *cis,fac*-$(HO)_2TeF_3Cl$ **2***c*. All three isomers can, in theory, arise from the hydrolysis of *cis*-$HOTeF_4Cl$ **1***a*, whereas only *cis,mer*-$(HO)_2TeF_3Cl$ **2***a* can arise from the hydrolysis of *trans*-$HOTeF_4Cl$ **1***b*. In all the samples investigated, evidence was only found for the *cis,mer* isomer. This was observed at all ratios of TeF_5Cl:H_2O except those $\geqq$1:8.5. Interestingly, where it was present, its intensity diminished little with time, indicating that, like the related *cis*-$(HO)_2TeF_4$, hydrolysis of this species is rather slow. Although only the *cis,mer* isomer of $(HO)_2TeF_3Cl$ **2***a* is observed, it is possible that the other two isomers (**2***b* and **2***c*) of this species are also formed, but that they are not observable because their rates of hydrolysis are faster than their rates of formation.

It is interesting that at the second stage of the hydrolysis of TeF_5Cl, products both containing, and not containing, chlorine are produced. The loss of HCl to form the hydroxofluoro species may arise for two reasons: (*i*) the replacement of fluorine ligands by OH ligands may result in an increased weakening of the Te—Cl bond; (*ii*) the Gibbs free energy of hydration is greater for HCl (35.9 kJ mol^{-1}) (31) than for HF (5.6 kJ mol^{-1}) (31). The combination of both factors could favour HCl elimination.

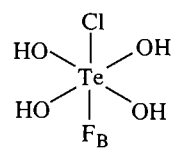
The third stage hydrolysis products of TeF_5Cl: mer-*$(HO)_3TeF_3$,* mer,cis-*$(HO)_3TeF_2Cl$, and* fac,cis-*$(HO)_3TeF_2Cl$*

The third hydrolysis step gives *mer*-$(HO)_3TeF_3$ as the major product. This species was observed in the NMR spectra of all TeF_5Cl:H_2O ratios and its intensity varied little with time. Tötsch and Sladky have shown that *trans*-$(HO)_2TeF_4$ hydrolyses stereospecifically to *mer*-$(HO)_3TeF_3$, whereas *cis*-$(HO)_2TeF_4$ hydrolyses to both *mer*- and *fac*-$(HO)_3TeF_3$ in the ratio 3:1 (18). The *fac*- isomer was not clearly identified in any of the spectra obtained in the present study, although a weak singlet observed at $\delta = -30$ in the ^{19}F NMR spectrum may be attributable to this isomer (lit. (15) δ value = -28).



Two new resonances were observed in the ^{19}F NMR spectra of samples with a TeF_5Cl:H_2O ratio of 1:2. As discussed previously in the identification section, these resonances have been tentatively assigned to *mer,cis*-$(HO)_3TeF_2Cl$ and *fac,cis*-$(HO)_3TeF_2Cl$. Unfortunately, the lack of corroborative data to support these assignments makes further discussion of these species inappropriate.

The fourth, fifth, and sixth hydrolysis products of TeF_5Cl



In samples containing a large stoichiometric excess of water, i.e., TeF_5Cl:$H_2O \geqq$ 1:15, the more highly substituted species *cis*- and *trans*-$(HO)_4TeF_2$ were the dominant products (excluding Te(IV) fluoro species) after 4 days of reaction. The ^{19}F and ^{125}Te NMR data obtained for these species are in good agreement with the literature values (15). The ^{125}Te NMR spectrum showed, in addition to the resonances arising from *cis*- and *trans*-$(Ho)_4TeF_2$, a weak singlet at $\delta = 707.2$, which is attributed to $(HO)_6Te$. $(HO)_5TeF$ was not observed; this is not unexpected since it is reported that this species hydrolyses rapidly and readily dismutates into *cis*-$(HO)_4TeF_2$ and $(HO)_6Te$ (15, 16).

cis- and *trans*-$(HO)_4TeFCl$ **4***a* and **4***b* and $(HO)_5TeCl$ are also possible products. However, none of these species was observed in the NMR spectra obtained for samples with TeF_5Cl:H_2O $\geqq$ 1:15. A very weak singlet was observed at $\delta = 21.5$ in the ^{19}F NMR spectrum of the TeF_5Cl:H_2O = 1:1 sample. As previously indicated in the identification section, this resonance might be attributable to *cis*-$(HO)_4TeFCl$ or *fac,cis*-$(HO)_3TeF_2Cl$. However, the precise nature of the species giving rise to this singlet resonance remains undetermined.

In view of the hydrolytic instability of $(HO)_5TeF$, it seems likely that $(HO)_4TeFCl$ and $(HO)_5TeCl$ would also rapidly hydrolyse. It is also possible that these species are never formed

4*a*

4*b*

and that the hydrolysis pathway only proceeds through *cis*- and *trans*-$(HO)_4TeF_2$.

Formation of fluorotellurium(IV) species

In all the samples investigated, both the ^{19}F and ^{125}Te NMR spectra displayed a broad unresolved resonance that could be attributed to fluorotellurium(IV) species (Table 1). No ^{125}Te-^{19}F spin–spin coupling was resolved, which is indicative of intermolecular fluorine exchange. Such exchange has previously been observed in other fluorotellurium(IV) species, e.g., TeF_4 (32) and TeF_5^- (33). The ratio of Te(IV) to Te(VI) species varied somewhat from reaction to reaction, although the ratio was approximately 1:1 in most cases. The formation of Te(IV) species has been reported previously in the reactions of TeF_5Cl with other nucleophiles (21, 23). The reaction of TeF_5Cl with CsF yields ClF and $CsTeF_5$ but not Te(VI) species (21). The suggested pathway for this reaction is attack by F^- on the partially positively charged chlorine ligand of TeF_5Cl (eq. [3]):

$$[3]\quad F^- + \overset{\delta^+}{Cl}\text{—}\overset{\delta^-}{TeF_5} \longrightarrow FCl + TeF_5^-$$

This pathway was first invoked to explain the attack of the hydroxyl ion on SF_5Cl, which also only yields reduced species (3).

Alternatively, TeF_5Cl may expand its coordination sphere to give a 7-coordinate intermediate (34). This intermediate can then undergo two elimination processes: in one case HF could eliminate with the formation of a Te(VI) species; in the other case ClF or HOCl could be eliminated, in addition to HF, giving rise to a Te(VI) species (eq. [4]).

$$[4]\quad H_2O + TeF_5Cl \text{——} \text{“}H_2OTeF_5Cl\text{”} \text{——} \text{Te(VI)} + \text{Te(IV) products}$$

This mechanism would therefore account for the observation of both Te(VI) and Te(IV) species as the hydrolysis products of TeF_5Cl. It could also account for both the Te(VI) and Te(IV) products in the reactions of CH_3OH and $(CH_3)_3SiOCH_3$ with TeF_5Cl. Further hydrolysis of $HOTeF_4Cl$ could proceed in the same manner, with the likelihood of HCl elimination becoming more thermodynamically favourable with the increased weakening of the Te—Cl bond as the number of F ligands substituted by OH ligands increases.

Comparison of the hydrolysis behaviour of TeF_5Cl and SF_5Cl

The hydrolysis behaviour of TeF_5Cl differs considerably from that of SF_5Cl. In the latter case, hydrolysis only occurs in the presence of alkali and leads only to S(IV) products (3). In contrast, hydrolysis of TeF_5Cl yields both Te(VI) and Te(IV) species, which can be attributed to the ability of tellurium to expand its coordination sphere to accommodate more than 6 ligands. The hydrolysis behaviour of SeF_5Cl appears to be as yet uninvestigated, although it may be anticipated that it will resemble that of SF_5Cl rather than TeF_5Cl.

Liquid junction potentials in molten salt cells

PETER J. TUMIDAJSKI

Department of Materials Engineering, The University of Western Ontario, London, Ont., Canada N6A 5B9

Received April 5, 1989

PETER J. TUMIDAJSKI. Can. J. Chem. **67**, 1506 (1989).

Liquid junction potentials were determined for fused salt concentration and galvanic cells. The results indicated that such potentials can be significant when concentration differences are large. For dilute solutions, the liquid junction potentials are within experimental uncertainty.

Key words: liquid junctions, thermodynamics, galvanic cells.

PETER J. TUMIDAJSKI. Can. J. Chem. **67**, 1506 (1989).

On a déterminé les potentiels de la jonction liquide pour diverses concentrations de sels fondus et diverses cellules galvaniques. Les résultats indiquent que de tels potentiels peuvent être importants lorsque les différences des concentrations sont grandes. Pour des solutions diluées, les potentiels de la jonction liquide sont inférieurs aux limites expérimentales.

Mots clés : jonctions liquides, thermodynamique, cellules galvaniques.

Introduction

In a recent paper (1), the thermodynamic behaviour of reactive metal chlorides in alkali chlorides was determined using cells of this type,

$$(-)\text{M}|\text{MCl}_m\text{–ACl}\|\text{asbestos diaphragm}\|\text{AgCl–ACl}|\text{Ag}(+)$$

Because of compositional differences at the steady state condition, a potential across the asbestos diaphragm develops. This potential is called the liquid junction potential. It has been generally assumed that an excess of alkali chloride on both sides of the asbestos diaphragm minimizes the liquid junction potential. However, very little fundamental work has been done to definitely determine when these potentials become significant, especially for galvanic cells. Laity (2), Blander (3), and Klemm (4) assessed the magnitudes of the liquid junction potentials for a number of molten salt solutions. However, the precise calculations of the liquid junctions is handicapped by the paucity of reliable data on transport numbers and activity coefficients of ions through the contact zone. In addition, the physical construction of the junction is important. In a paper by Wagner (5), an experimental technique was described wherein liquid junction potentials could be measured directly without neglect or hypothesis using chloride formation cells in series. To the author's knowledge, this paper represents the first attempt to determine how concentration and temperature influence the magnitude of the liquid junction potential using chloride formation cells in series.

Experimental

Liquid junction potentials were determined for fused salt concentration and galvanic cells. The variables investigated were concentration and temperature.

To determine the liquid junction potential of a concentration cell, the AgCl–KCl system was used. The liquid junction potential is given by,

[1] $$E_j = E_A - E_B$$

where E_A corresponds to the potential of the concentration cell,

$$(-)\text{Ag}|\text{AgCl}(X_1)\text{–KCl}\|\text{asbestos diaphragm}\|\text{AgCl}(X_2)\text{– KCl}|\text{Ag}(+) \quad \text{(Cell A)}$$

and E_B corresponds to the potential of two formation cells connected in series,

$$(-)\text{Ag}|\text{AgCl}(X_1)\text{–KCl}|\text{Cl}_2,\text{C}\ldots\text{C},\text{Cl}_2|\text{AgCl}(X_2)\text{–KCl}|\text{Ag}(+) \quad \text{(Cell B)}$$

For both cases, X_2 is greater than X_1.

To study the liquid junction potential in galvanic cells, the ($PbCl_2$–KCl)–(AgCl–KCl) system was employed. The liquid junction potential is calculated from

[2] $$E_j = E_C - E_D$$

E_C corresponds to the potential of the galvanic cells.

$$(-)\text{Pb}|\text{PbCl}_2\text{–KCl}\|\text{asbestos diaphragm}\|\text{AgCl– KCl}|\text{Ag}(+) \quad \text{(Cell C)}$$

E_D corresponds to the potential of two chloride formation cells connected in series,

$$(-)\text{Pb}|\text{PbCl}_2\text{–KCl}|\text{Cl}_2,\text{C}\ldots\text{C},\text{Cl}_2|\text{AgCl–KCl}|\text{Ag}(+) \quad \text{(Cell D)}$$

Results and discussion

Results of the AgCl–KCl concentration cell are given in Table 1 for 973 and 1023 K. It can be seen that the junction potentials become an appreciable contribution to the total cell potential as the concentration difference across the asbestos diaphragm becomes larger. For the larger concentration differences, the magnitude of the liquid junction potential can attain values corresponding to greater than 20% of the total cell potential. In the early work of two decades ago, liquid junction potentials were of the order of several millivolts, which did not exceed the experimental errors. Murgulescu and Popescu (6) carefully measured the free liquid junction potentials with a capillary between the electrode compartments. In agreement with the present results, they found that the free junction potentials were significant and could not be assumed to be within the experimental error over the whole concentration range. An expression for the liquid junction potential for the AgCl–KCl system, with the chloride anion as the reference component, can be derived (7),

[3] $$E_j = \frac{RT}{F}\int\left(\frac{X_{KCl}t_{Ag^+} - X_{AgCl}t_{K^+}}{X_{KCl}}\right) d\ln a_{AgCl}$$

where t represents transport numbers. It is clear from eq. [3] that the liquid junction potential approaches negligible values when

	0.2	0.281	0.272	0.009	0.285	0.223	0.062

the cation transport numbers are proportional to their mole fractions. Conradt and co-workers (8) found that none of the AgCl – alkali chloride mixtures satisfy this criteria over the entire composition range. Hence there could be a significant liquid junction potential. Furthermore, Smirnov *et al.* (9) measured the liquid junction potentials at the porous asbestos diaphragms separating alkali chloride melts of different cation compositions. It was found that cation transport numbers undergo a considerable variance with compositional changes.

In addition, Murgulescu and Popescu (6) reported that the magnitude of the diffusion potentials increases with temperature. The results of this study contradict their conclusion. Albeit liquid junction potentials were determined at two temperatures over a narrow interval, we observed a slight but discernable decrease in the magnitude of the liquid junction potential at the higher temperatures. Intuitively, this would be expected because fused salt solutions tend to become ideal as temperature is increased.

Results for the (AgCl–KCl)–($PbCl_2$–KCl) galvanic cell are given in Table 2 for 973 and 1023 K. It can be seen that there can be an appreciable junction potential especially for the more concentrated $PbCl_2$ solutions. When pure liquid $PbCl_2$ is pres-

For personal use only.

ent, there is an approximately constant value of 550 mV for the liquid junction potential regardless of the AgCl concentration in the other electrode compartment. In fact, this is a general trend. That is, it is the concentration of $PbCl_2$, and consequently, the concentration of Pb^{2+} cation, which largely determines the magnitude of the liquid junction potential. The Ag^+ cation concentration appears to have little influence on the junction potential. It is the mobility (or transport number) of the cations through the contact zone (asbestos diaphragm) which is a major contribution to the magnitude of the liquid junction potential. There are several factors which determine ionic mobilities. For the present case, it is likely that the mass and valence differences for the silver and lead cations account for the major portion of the mobility differences between the silver and lead cations. It is these effects which are observed in the present investigation and predominate in the measurement of the liquid junction. It is also worth noting that the forces developed in an electronuetrality field in the contact zone between different solutions are greater when the valence of the competing species is higher, and when the charge density is larger. A full interpretation of the liquid junction potential is not possible because the concentration and transport numbers of all species throughout the liquid junction zone are not known.

It should be emphasized that, for both cells investigated, the liquid junction potentials for dilute solutions are small and within the limits of experimental uncertainty. The result is significant because the thermodynamic results presented previously (1), can be regarded to be free of a liquid junction contribution.

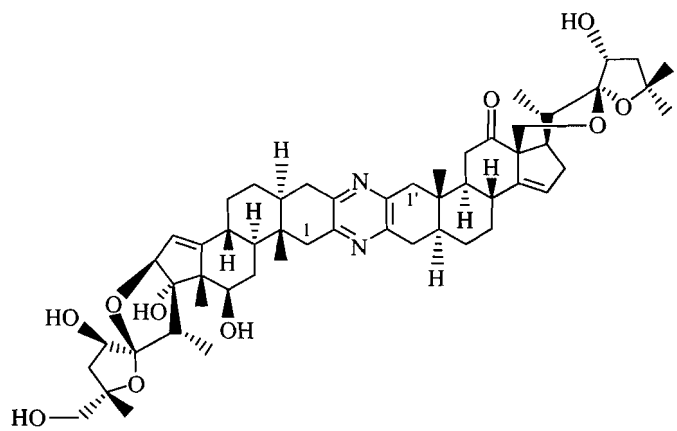
GEORGE R. PETTIT, YOSHIAKI KAMANO, CLAUDE DUFRESNE, MASUO INOUE, NIGEL CHRISTIE, JEAN M. SCHMIDT, and DENNIS L. DOUBEK. Can. J. Chem. **67**, 1509 (1989).

The Indian Ocean (South African) marine worm *Cephalodiscus gilchristi* (Hemichordata phylum) has been found to contain a series of unusual disteroidal alkaloids, designated the cephalostatins, that possess exceptionally potent lymphocytic leukemia (murine P388) cell line inhibitory activity (to ED_{50} 10^{-9} μg/mL). Two of the less prominent members with P388 ED_{50} 10^{-3} – 10^{-2} μg/mL, cephalostatins 5 (**2**) and 6 (**3**), were isolated and assigned structures based on rigorous interpretation of two-dimensional 400-MHz ^1H and ^{13}C nuclear magnetic resonance.

Key words: cephalostatins 5 and 6, disteroidal alkaloids, lymphocytic leukemia, cytostatic, *Cephalodiscus gilchristi*.

GEORGE R. PETTIT, YOSHIAKI KAMANO, CLAUDE DUFRESNE, MASUO INOUE, NIGEL CHRISTIE, JEAN M. SCHMIDT et DENNIS L. DOUBEK. Can. J. Chem. **67**, 1509 (1989).

On a trouvé que le ver marin de l'océan Indien (Afrique du sud) *Cephalodiscus gilchristi* (Hemichordata phylum) contient une série d'alcaloïdes distéroïdaux inhabituels, nommés céphalostatines, qui possèdent une activité exceptionnelle contre la leucémie lymphocitique (activité inhibitrice des cellules de murine P388 jusqu'à une ED_{50} de 10^{-9} μg/mL). On a isolé les céphalostatines 5 (**2**) et 6 (**3**), deux des membres les moins importants de la série, avec une ED_{50} de 10^{-3}–10^{-2} μg/mL, et on a déterminé leurs structures en se basant sur une interprétation rigoureuse des spectres bidimensionnels en résonance magnétique nucléaire du ^1H et ^{13}C, déterminés à 400 MHz.



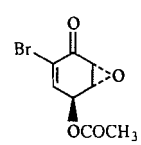
Mots clés: céphalostatines 5 et 6, alcaloïdes disteroïdaux, leucémie lymphocitique, cytostatique, *Cephalodiscus gilchristi*.

[Traduit par la revue]

Introduction

The marine worm order Cephalodiscida (Hemichordata phylum) contains two tube-living genera occurring primarily at considerable depths in the Southern hemisphere. Tubes containing colonies of these tiny marine animals are commonly found attached to, for example, bryozoans and sponges. Initial investigation of bioactive constituents in this worm class (Pterobranchia)[3] led to our discovery of the powerful murine P388 lymphocytic leukemia (PS system) cell growth inhibitor cephalostatin 1 (**1**) (1*b*) in the South African (Indian Ocean) *Cephalodiscus gilchristi*. Subsequently, we isolated and assigned structures to the related disteroidal alkaloids, cephalostatins 2, 3, and 4 (3). We now report that further bioassay (PS) guided study of *C. gilchristi* has led to the isolation of two unusual disteroidal alkaloids bearing aromatic C-rings, designated cephalostatins 5 (**2**) and 6 (**3**), that retain significant cell growth inhibition (PS ED_{50} 10^{-2} μg/mL).

Minor bioactive (PS leukemia) fractions prepared (1*b*) from a methylene chloride – methanol extract (from 166 kg of wet *C. gilchristi*) were separated by repeated gradient column chromatographic (partition on Sephadex LH-20, adsorption on silica gel, and hplc) techniques. Final purification by hplc using 30:70:0.1 hexane – ethyl acetate – methanol afforded cephalostatin 5 (**2**) as a colorless solid (5.5 mg, 3.1×10^{-5}% yield). With the X-ray crystal structure assigned cephalostatin 1 (**1**) as a reference point, and the completely interpreted nmr spectra for cephalostatins 1 (1*b*), 2, 3, and 4(3), it became possible, using detailed analysis of high field two-dimensional nmr data and the mass spectra, to unequivocally assign structures **2** and **3** respectively to cephalostatins 5 and 6.



1

The ^1H and ^{13}C nmr spectra of cephalostatins 5 and 6 proved to be almost identical except for an additional methyl doublet at 1.07 ppm in the ^1H nmr spectrum of cephalostatin 5. By mass spectral analyses, each was found to possess one more degree of unsaturation than cephalostatin 1, with cephalostatin 5 bearing an additional methyl group. Their nmr spectra were found to be similar to those of cephalostatins 1 through 4, with the exception that aromatic signals were uncovered in ^{13}C spectra.

[3]Recently, Scheuer and co-workers (2) summarized a productive study concerned with constituents of a new species of acorn worm (Enteropneusta order of the Hemichordata) found in a deep Hawaiian marine cave. A series of brominated indoles and phenols along with alicyclic derivatives were isolated. Three of the alicyclic compounds, especially **i** (ED_{50} 0.001 μg/mL), were found active against the PS cell line.

2: R = CH_3; cephalostatin 5
3: R = H; cephalostatin 6

A **B** **C** **D**

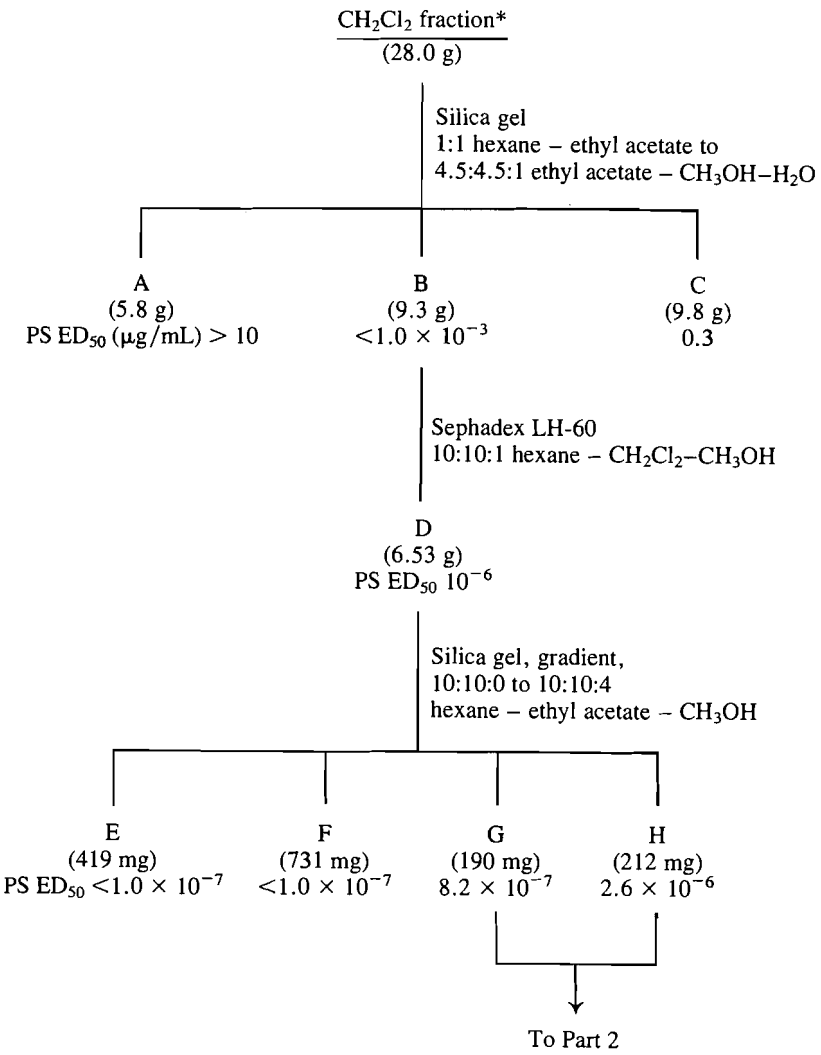
The nmr signals attributed to the "left-side" steroid unit in cephalostatins 1–4 all appeared in the spectra of cephalostatins 5 and 6, indicating that portion of the molecular skeleton remained unchanged. Subtraction of this unit from the spectra implied that the "right-side" steroid units each contained ten unsaturations, present as four double bonds and six rings. Only three spin systems, A, B, and C, were found in the right-side steroid unit, as determined by COSY and homonuclear relayed COSY (4) experiments. Spin system A was unambiguously assigned to C-4′ – C-7′. The presence of an nOe between the protons at 5.55 (H-15′ in B) and 3.09 ppm (H-7a′ in A) allowed assignment of spin system B to ring D′ and carbons 20′ and 21′ (cf. D). Location of the aromatic carbons in ring C′ was demonstrated by nOe effects between the aromatic proton at 6.93 ppm (C-11′; δ_C 111.46) and one of the C-1′ protons (3.56 ppm). The relatively high field chemical shift for the C-11′ carbon indicated the presence of an oxygen atom at C-12′, a structural feature consistent with all of the cephalostatins so far isolated. System C was attributed to side-chain carbons 23′ and 24′.

Next it remained to assign an acetal carbon (δ_C 107.35), one oxygen atom, a *gem* dimethyl group, and fragment C, while forming two rings. Using results of a sensitivity enhanced heteronuclear multiple bond correlation experiment (HMBC (5); see Table 1), and in keeping with the overall carbon skeleton deduced for cephalostatins 1–4, we were able to unambiguously assign structures **2** and **3** for cephalostatins 5 and 6 respectively. The stereochemistry at C-15′ was postulated to be *R*, assuming a biosynthetic relationship with cephalostatin 4, which bears a β epoxy group at C-14′–15′. However, it could not be assigned with certainty. The other chiral centers were assumed to correspond to their counterparts in cephalostatin 1, except for the stereochemistry at C-22′, which remains undetermined.

While naturally occurring and synthetic steroids with ring A aromatized are well known, steroids bearing an aromatic ring C are quite rare and examples of biosynthetic origin are heretofore essentially unknown. The dramatic reduction in PS cell growth inhibition displayed by cephalostatins 5 and 6 compared to 1–4 suggests that preservation of structural integrity in the right-side unit, including the C–D ring stereochemistry typical of, e.g., the steroid bufadienolides (6) and cardenolides (7), is very important to realizing powerful inhibition of the PS leukemia. The atypical C-22′ spiroketals involving C-18′ in cephalostatin 1 and C-12′ in cephalostatins 5 and 6 are also noteworthy. Doubtlessly, further pursuit of the opportunities for total syntheses and structural modifications offered by these important new leads to potent cell growth inhibition will yield important results.

Experimental

Chromatographic solvents were redistilled. Sephadex LH-20 and LH-60 (25–100 μm) employed for gel permeation and partition chromatography were obtained from Pharmacia Fine Chemicals AB, Uppsala, Sweden. Column chromatographic techniques utilizing silica gel (70–230 mesh) or silica gel 60 prepacked columns were accomplished with material supplied by E. Merck (Darmstadt, West Germany). Both the Partisil M9 10/50 and Partisil M9 10/50 ODS-2 (C-18 reverse phase) columns (9.4 mm i.d. × 500 mm) were used for hplc and obtained from Whatman, Inc., Clifton, New Jersey. Gilson FC-220 racetrack and F-80 microfractionators connected to Gilson HM uv-visible Holochrome detectors were used for chromatographic fractionation experiments. Preparative layer plates were also obtained from Whatman, Inc., and the silica gel GF Uniplates for tlc were supplied by Analtech, Inc., Newark, Delaware. The tlc plates were viewed with uv light or developed with concentrated sulfuric acid, ceric sulfate – sulfuric acid, or anisaldehyde acetic acid – sulfuric acid spray (heating at approximately 150°C for 5–10 min).



The melting points are uncorrected and were observed with a Kofler-type melting point apparatus. The uv spectra were recorded using a Hewlett–Packard 8450A uv/vis spectrophotometer equipped with a HP 7225A plotter. Optical rotation values were obtained using a Perkin–Elmer 241 polarimeter. Infrared spectral data were recorded with a Perkin–Elmer 299 IR spectrophotometer or a Nicolet MX-1 FT instrument. Mass spectra were recorded with a Kratos MS-50 spectrometer. The nmr experiments were conducted with Bruker WH-90 and Bruker WH-400 instruments employing chloroform-*d* or pyridine-d_5 as solvents and tetramethylsilane as internal standard.

Animal collection and initial experiments

The marine worm (~ 5 mm long in tube colonies) *Cephalodiscus gilchristi* (order Cephalodiscida) was collected in late 1972 by scuba (ca. −20 m) in the Indian Ocean off Southeast Africa. By 1974 methanol and water extracts of *C. gilchristi* reached the confirmed active level against the U.S. National Cancer Institute's murine P388 lymphocytic leukemia (PS system) with 32–41% life extension at 25–37.5 mg/kg.

A number of approaches to isolation of the cephalostatins were made, with re-collections of *C. gilchristi*, until the problem was eventually solved starting from a 1981 acquisition (166 kg wet weight, including Coenecium) from the same Indian Ocean location.

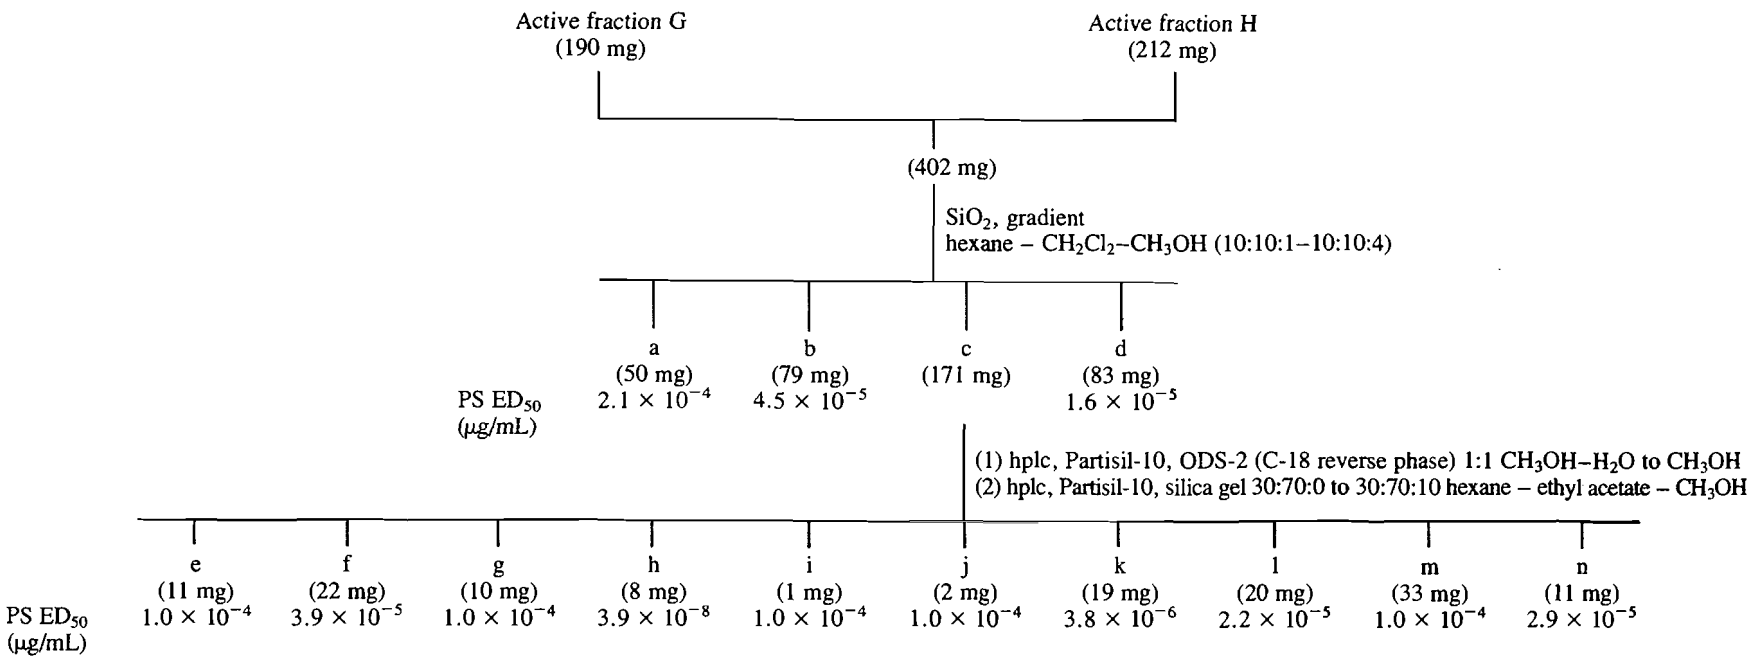
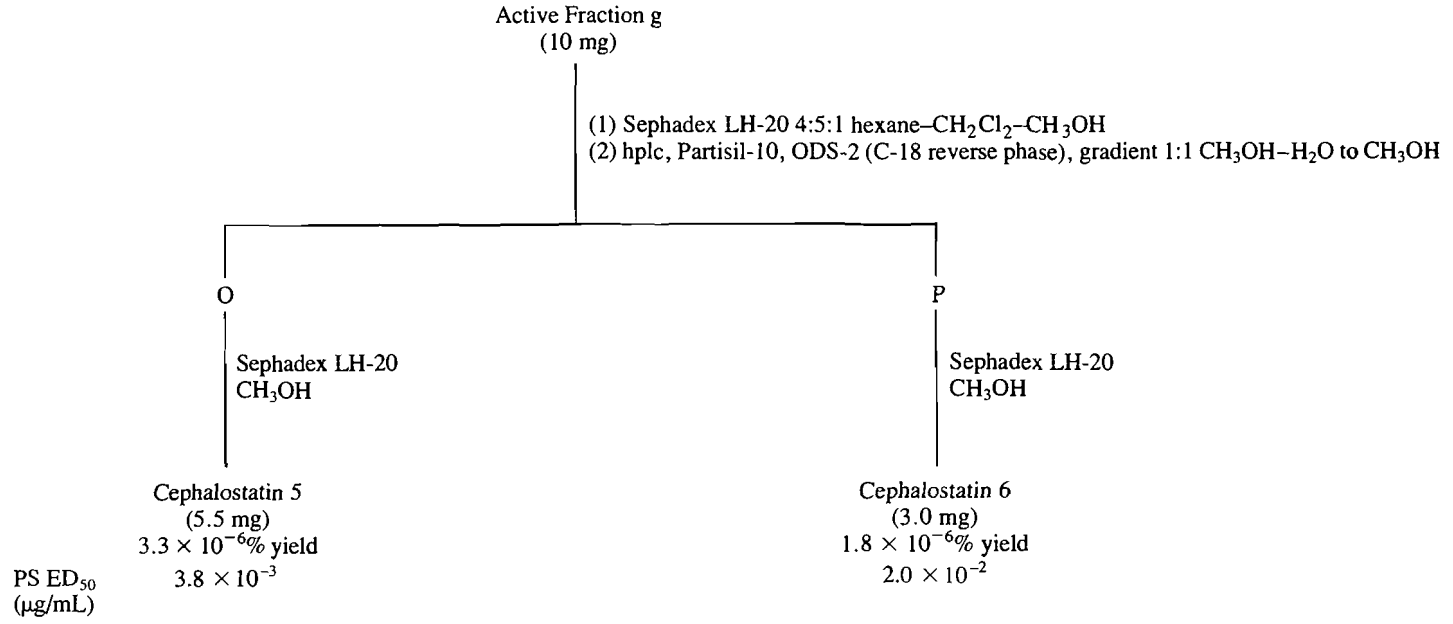
SEPARATION SCHEME 1, Part 1

*Same Scheme for the 42 g CCl_4 fraction



Animal extraction and solvent partition sequence

The marine worm (166 kg, wet weight) was extracted with methylene chloride – methanol at ambient temperature. The solvent was concentrated and the residue was partitioned between methylene chloride and water. The methylene chloride fraction was successively partitioned using the system (8) 9:1 → 4:1 → 3:2 methanol–water against hexane→carbon tetrachloride→methylene chloride, respectively. Both active methylene chloride and carbon tetrachloride fractions (28 g and 42 g respectively) were separated using a detailed (refer to Separation Scheme 1, parts 1–3) bioassay (PS) guided series of chromatographic procedures (8).



Separation of the 28 g active methylene chloride fraction was performed as outlined in Separation Scheme 1, Part 1. The active fractions, G (0.19 g; ED_{50} 8.2×10^{-7}) and H (0.21 g; ED_{50} 2.6×10^{-6}), were combined. The total amount (0.40 g) was chromatographed on a column of silica gel using gradient elution with hexane–CH_2Cl_2–CH_3OH (10:10:1→10:10:4) to give four active fractions (a,b,c, and d). Fraction c (0.17 g) was carefully separated by C-18 reversed phase hplc (Partisil-10, ODS-2) with CH_3OH–H_2O (1:1 to CH_3OH) as mobile phase, followed by normal phase hplc (Partisil-10, silica gel). Separation employing gradient elution with hexane – ethyl acetate – CH_3OH (30:70:0 to 30:70:10) provided ten active fractions (e – n). Fraction g (10 mg; ED_{50} 1.0×10^{-4}) was chromatographed on a column of Sephadex LH-20 (hexane–CH_2Cl_2-CH_3OH 4:5:1) and the resulting PS cell line active material was further separated using C-18 reverse phase hplc (Partisil-10, ODS-2: 1:1 CH_3OH-H_2O to CH_3OH). Final separation was achieved by incorporating a gel permeation step in methanol using Sephadex LH-20. By this means two pure and PS cytostatic substances were isolated: cephalostatin 5 (**2**) (5.5 mg, 3.3×10^{-6}% yield, ED_{50} 3.8×10^{-3}); mp 350°C; $[\alpha]_D$ +100° (*c* 0.02, CH_3OH); uv (CH_3OH): 290 (ε 9 500), 310 (sh) nm; SP-HRSIMS (glycerol–CF_3SO_3H), calcd. for $C_{54}H_{72}N_2O_{10}$: 908.5187; found: 908.5164 (M^+). Cephalostatin 6 (**3**) was also isolated as a colorless solid (2.5 mg, 1.8×10^{-5}% yield, ED_{50} 2.0×10^{-2}): mp > 350°C; $[\alpha]_D$ +100° (*c* 0.01, CH_3OH); uv (CH_3OH): 289 (ε 10 000), 310 (sh) nm; SP-HRSIMS (glycerol–CF_3SO_3H), calcd. for $C_{53}H_{70}N_2O_{10}$: 894.5031; found: 894.4985 (M^+). The ^1H and ^{13}C nmr assignments have been recorded in Table. 1.

New investigations of the reaction of epichlorohydrin with hindered amines: X-ray and NMR analyses

MICHEL LAGUERRE,[1] CHANTAL BOYER, JEAN-MICHEL LEGER, AND ALAIN CARPY

Laboratoire de chimie analytique, Unité associée n° 605 du Centre national de la recherche scientifique, Faculté de pharmacie, 3 Place de la victoire, 33076 Bordeaux CEDEX, France

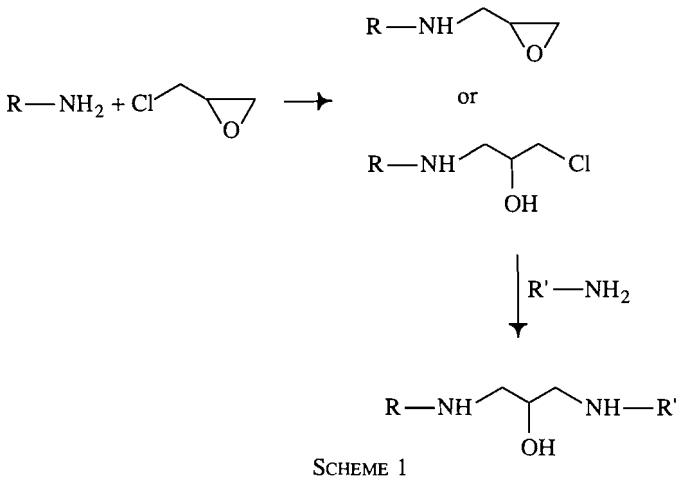
Received December 1, 1988

MICHEL LAGUERRE, CHANTAL BOYER, JEAN-MICHEL LEGER, and ALAIN CARPY. Can. J. Chem. **67**, 1514 (1989).

During the synthesis of a series of new antiarhythmic drugs, the reaction between epichlorohydrin and hindered amines was reinvestigated. With primary amines, 3-azetidinols were formed in fair yields. The X-ray structure elucidation of one of these compounds (**1**: $P2_1/n$, $a = 17.210$, $b = 6.665$, $c = 23.585$, $\beta = 102.29$, and $R = 0.064$ for 2005 observed reflections) and NMR studies led to the conclusion that both the hydroxy group and the bulky nitrogen substituent are on the same side of the azetidine ring. With secondary amines, the reaction was very complex, leading to diamino dioxane, diamino alcohols, amino alcohol ethers, and one glycol. X-ray analysis and ^1H and ^{13}C NMR studies allowed complete assignments for all compounds. All but one exhibited a slow interconversion of the nitrogen visible in the ^{13}C NMR spectra.

Key words: epichlorohydrin, hindered amines, azetidinol, adamantane, alkanol amines.

MICHEL LAGUERRE, CHANTAL BOYER, JEAN-MICHEL LEGER et ALAIN CARPY. Can. J. Chem. **67**, 1514 (1989).



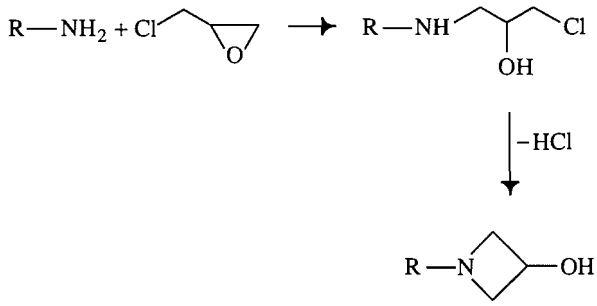
Au cours de la synthèse d'une nouvelle série d'antiarythmiques les auteurs ont été amenés à réexaminer la réaction de l'épichlorhydrine avec les amines encombrées. Avec les amines primaires, on observe la formation d'azétidinols-3 avec des rendements corrects. L'étude structurale par rayons X d'un de ces dérivés (**1** : $P2_1/n$, $a = 17{,}210$, $b = 6{,}665$, $c = 23{,}585$, $\beta = 102{,}29$ avec $R = 0{,}064$ pour 2005 réflexions observées) suivie d'une étude RMN a montré que le groupe OH et le substituant encombrant sur l'azote sont du même côté du cycle azétidine. Avec les amines secondaires, la réaction très complexe donne un diamino-dioxane, des diamino-alcools, des amino-alcools éthers et un glycol. Une analyse par rayons X et une étude complète par RMN ^1H et ^{13}C a permis, outre l'attribution de tous les dérivés, de montrer qu'ils présentaient tous (sauf un) une interconversion de l'azote visible en RMN ^{13}C.

Mots clés : épichlorohydrine, amines encombrées, azétidinol, adamantane, alkanolamines.

[Traduit par la revue]

I. Introduction

During the synthesis of a new class of antiarythmic drugs (1) the reaction of epichlorohydrin with several primary and secondary amines was reinvestigated. Our purpose was to synthesize chlorohydrins or epoxypropanes in order to react them according to Scheme 1:



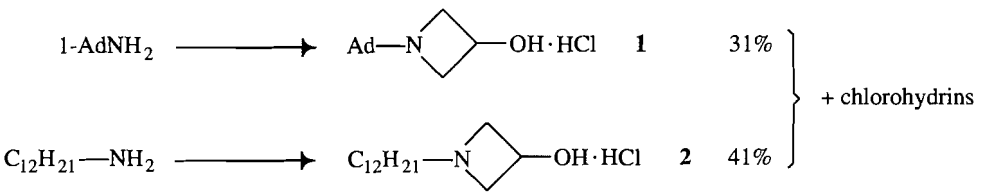
SCHEME 1

With sterically hindered amines, the reaction with epichlorohydrin follows different pathways depending on the nature of the amine.

[1]Author to whom correspondence may be addressed.

II. Primary hindered amines

Since Gaertner's work (2), it has been known that epichlorohydrin reacts with primary hindered amines and produces the corresponding 3-azetidinol by intramolecular cyclization (R must be bulky enough, i.e., R = *i*Pr, *t*Bu, cyclohexyl...) (Scheme 2).



SCHEME 2

3-Azetidinols frequently present different biological effects, such as antidepressant (3), antihypertensive (4, 5), sedative (6), and antipsoriasis (7).

In our work (1) this intramolecular cyclization occurred with R = 1-adamantyl or 1-cyclododecyl. As the purpose was the synthesis of chlorohydrins, we did not try to improve the yields of azetidinol, which were the following (absolute ethanol, 1-night reflux) (Scheme 3):

Where Gaertner (2) obtained the bases in MeOH (room temperature or reflux) or DMSO, we obtained the azetidinium salts in refluxing absolute ethanol. All formulae were confirmed by NMR, mass spectrometry, and microanalysis (see experimental section).

Compound **1** (base) has already been mentioned in the literature (5), but without any structural data. (In fact, few 3-azetidinol structures are known (8) and some questions concerning the conformation of the azetidine ring in the solid state (9) or in solution (10) were left unsolved.) Suitable crystals of **1** were obtained and the structure was determined by X-ray crystallography (Table 1).

In the crystals there are two independent molecules with slightly different geometries. The final fractional coordinates for non-hydrogen atoms are presented in Table 2. A view of molecule 1 showing the numbering of atoms and a stereo pair is shown in Fig. 1. The chemically equivalent bond lengths and angles in the independent molecules summarized in Table 3 are not very different.

Both azetidinium rings are present in a puckered form close to the puckered form of cyclobutane (11) (Table 4). Internal C—N bond lengths lie between 1.521(8) Å (molecule I) and 1.540(8) Å (molecule II), and internal C(sp^3)—C(sp^3) between 1.538(9) Å (molecule I) and 1.547(9) Å (molecule II). The corresponding C*—C(sp^3) distances in cyclobutane are in the range 1.519–1.538 Å. All θ valence angles are close to 90° with transannular distances that are shorter in molecule I than in molecule II. Consequently, the angle of pucker φ is larger in molecule I (21.6(5)°) than in molecule II (17.0(6)°). As already found in cyclobutane (12), a minimal change in θ ($\bar{\theta}$ = 89.4(5)° in II and 89.0(5)° in I) corresponds to a significant increase of the φ value (4.6°). Finally, the ring torsion angles ω are 3.3°

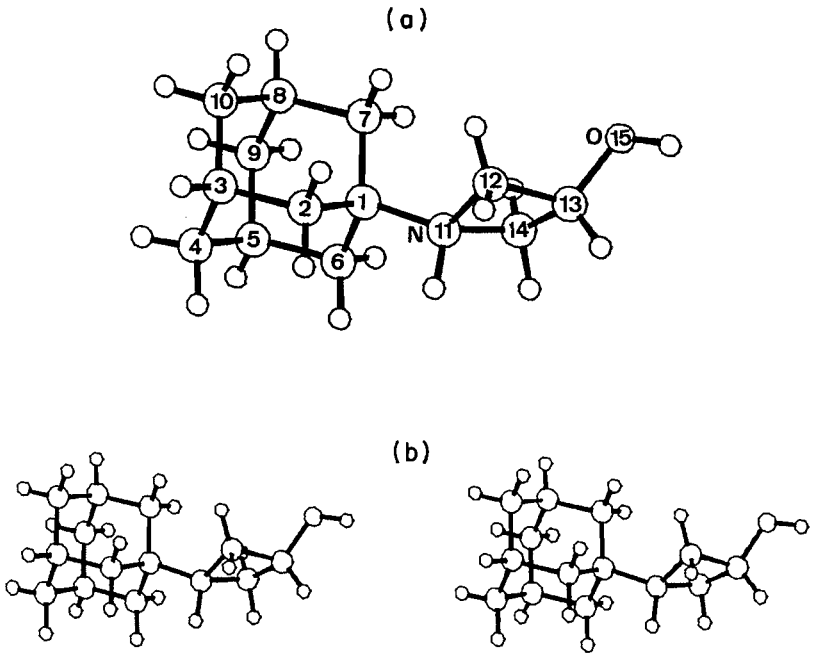

FIG. 1.(a) Projection and (b) stereoview of compound **1** (molecule I) showing the numbering of atoms.

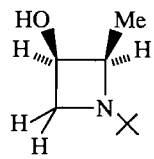
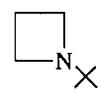
larger in molecule I than in molecule II. C(1) and C(15) are *cis* with respect to each other and are substituted on the convex side of the azetidine ring. Both the O—H groups and the N are involved in hydrogen bonding with the Cl^- anions and the water molecules.

The geometry of the adamantane ring, known for a long time (13), is as expected: all internal torsion angles are $\simeq 60(1)°$. The relative position of the two rings is defined by the torsion angle C(6)—C(1)—N(11)—C(12) = 175.6(6)° (molecule I) or C(507)—C(501)—N(511)—C(512) = −173.3(5)° (molecule II).



Both independent molecules exhibit an approximate mirror plane of symmetry passing through the atoms O(15), C(13), C(7), C(1), C(5), and C(4).

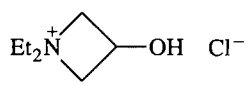
To examine the conformations of the prepared compounds in solution, the ^1H NMR spectra for both bases and hydrochlorides at 350 MHz were recorded. The chemical shifts and the coupling constants are listed in Table 5.



These data agree well with the literature. The chemical shift for H13 is fairly constant: 4.42 ± 0.06 ppm for the bases and 4.77 ± 0.03 ppm for the hydrochlorides. Depending on R, the chemical shifts vary for H12 and H14 (R = cyclododecyl close to R = cyclohexyl and R = 1-adamantyl close to R = *t*Bu). As expected, there is a downfield shift for all protons in the two hydrochlorides.

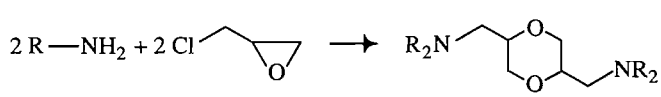
According to ref. 10*a*, lower field shifts for H12 and H14 may be assigned to protons *syn* to N-alkyl substituents, and higher field shifts to protons *anti* to this substituent. So the steric hindrance introduced by an N-alkyl substituent may account for the chemical shift dispersion in this series. It may also be deduced from these data that even in solution the OH group and R are on the same side of the molecule.

For **1** and **2** the geminal couplings ($J_{12,12'} = J_{14,14'}$) are larger than those already published: 9.8 and 9.1 Hz compared to 6–7 Hz (10). These coupling constants were assigned by irradiation of H13 after D_2O exchange of the OH group. But for compound **3** *cis*, $J_{gem14,14'}$ was found equal to −9.1 Hz, and only −7.2 Hz for the *trans* derivative (10*b*). For compound **4**, $J_{gem12,12'} = 7.45$ Hz and $J_{gem13,13'} = 10.0$ Hz (10*c*). Thus it appears that J_{gem} is very variable in this series, depending on R and presumably on the conformation.



3 *cis*

4



III. Secondary hindered amines

Until now, little work has been done in this area. In the case of diethylamine, A. T. Coscia and co-workers (14) demonstrated the formation of azetidinium **5**:

5

while D. L. Heywood and B. Philipps (15) described the formation of dioxanes (mainly with morpholine and piperidine) according to Scheme 4:

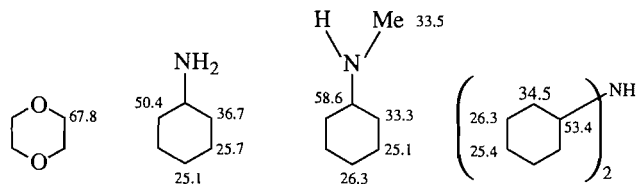
In the present work, this side reaction was found with dicyclohexylamine. Under our experimental conditions (refluxing absolute ethanol) a very complex mixture, including one dioxane, dimers resulting from the condensation of two amines with epichlorohydrin, and ethers arising from the reaction of ethanol with the intermediate epoxide or chlorohydrin, was found. The reaction mixture, containing at least 10–12 compounds, was separated by repeated chromatography on an alumina column (see experimental section).

The following derivatives have been isolated and fully

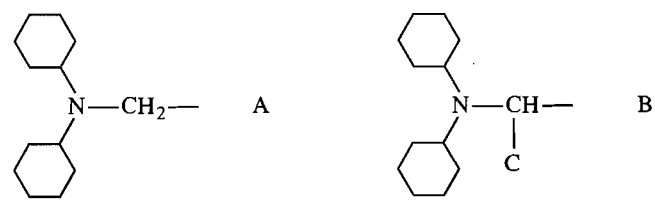
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

characterized:



SCHEME 5

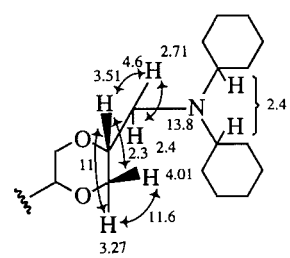
Two or three other products could not be purified enough to be unambiguously identified.



The identification of compounds **6–12** was facilitated by a single crystal X-ray analysis of compound **7**. This compound presented crystallographic problems. The Fourier maps showed a disordered hydroxypropyl unit and alternative chair conformations for the cyclohexane rings. Unfortunately it was not possible to refine properly the whole molecule. However, these observations are in agreement with a simultaneous inversion of the two nitrogen coordination tetrahedra.

After this analysis, owing to the fact that compound **7** is symmetrical, we could fully determine the ^{13}C sequence of the dicyclohexylamino fragment.

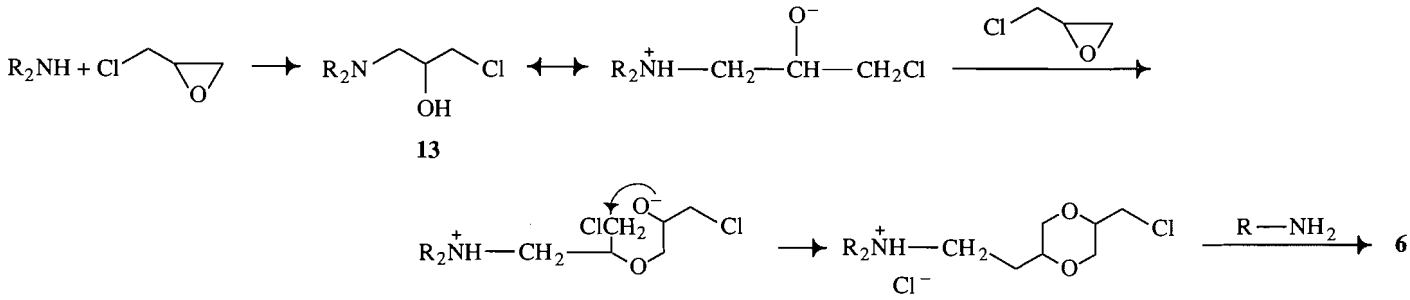
The ^{13}C chemical shifts tabled in the literature give the following data:



Differences between βCH_2 and γCH_2 in the cyclohexane rings (which have very close chemical shifts) were unambiguously established according to the relative intensity of the signals ($8CH_2\beta$ versus $4CH_2\gamma$) and by using quite long recycle delays (10–20 s depending on the compounds). In each case *two* close signals having the same intensity were recorded for $CH_2\alpha$ and in some cases for $CH_2\beta$. The results are shown in Table 6. From this table it may be deduced that for CH_{ipso} the chemical shift is 57.9 ± 0.7 ppm in fragment A and 54.0 ± 0.1 ppm in fragment B.

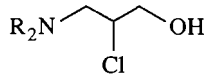
The ^{13}C chemical shift was fairly constant for $CH_2\gamma$: 25.5 ± 0.3 ppm, and for $CH_2\beta$: 26.2 ± 0.3 ppm (even if it appears as two close signals). For $CH_2\alpha$ there were always *two* different signals and for compound **8** (unsymmetrical) there were *four* signals. As compound **7** is absolutely symmetrical, a chiral center is not the fundamental reason. This fact was not mentioned for the ^{13}C spectrum of the parent dicyclohexylamine (16). According to the preliminary X-ray results for **7**, the best hypothesis may be a slow interconversion of the nitrogen atom so that the $CH_2\beta$ appears as enantiotopic. Other hypotheses, of a slow interconversion of the cyclohexane rings or the nitrogen atom being axial for one ring and equatorial for the other, can be ruled out. There was only *one* signal for ^{13}CH-N, when it is well known that in many substituted cyclohexane derivatives the α effect is different according to the axial/equatorial position of the substituent (17). For instance, in cyclohexanol derivatives, differences in δ for CH-OH axial or equatorial are about 5–6 ppm. Moreover, in 2-aminonorbornane there is a 2-ppm difference between the *endo* and the *exo* derivatives. It seems unexplained that there was not the slightest difference in δ $CH_2\alpha$ for at least one of our compounds.

To confirm the hypothetical inversion of the nitrogen, the ^1H spectra in the CH-N area were examined. But even at 500 MHz this area was so overcrowded that it was impossible to determine the coupling constants. Only the spectrum of **6** allowed some assignments to be made (but *not* in the CH-N area):



6

The assignment was performed by irradiation of the proton at 3.51 ppm, thus confirming the proposed structure.

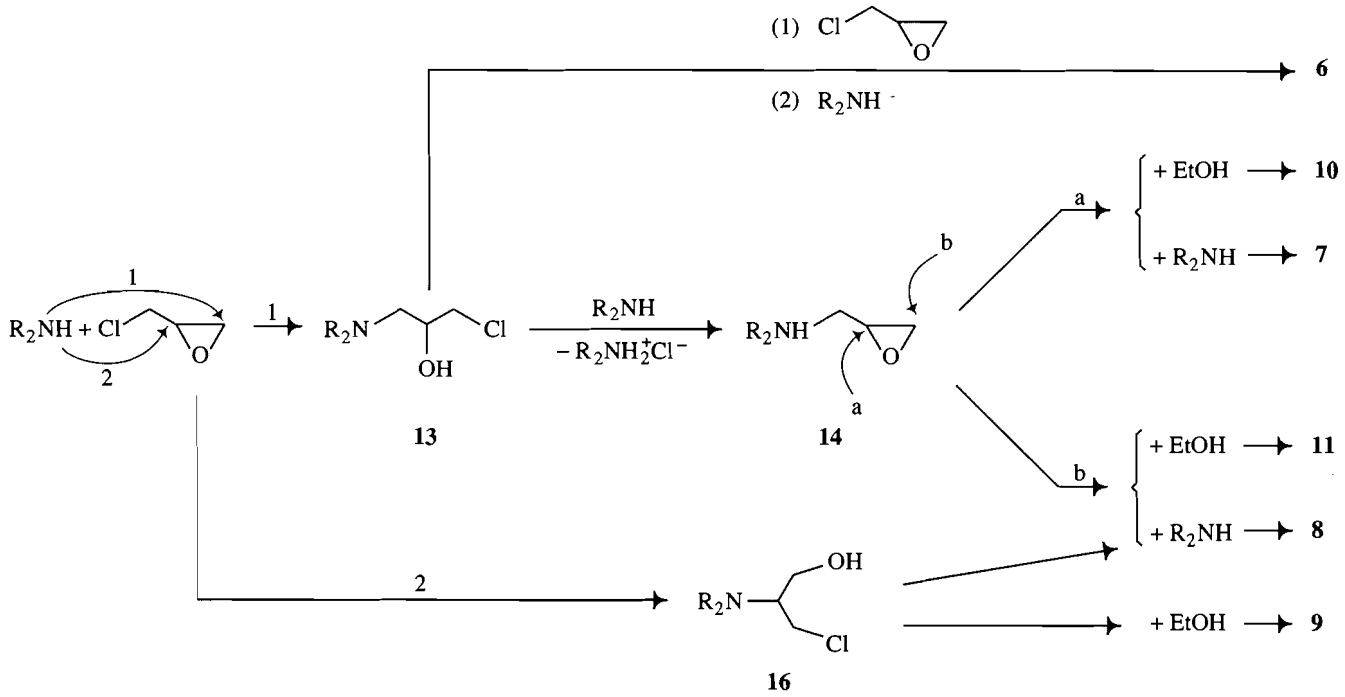


The product formation could be easily rationalized. The first product that appeared was chlorohydrin **13**. According to Heywood and Philipps (15), **6** was a product of the reaction between **13** and epichlorohydrin according to Scheme 6:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

SCHEME 6

Compounds **7**, **8**, **10**, and **11** may be formed by reaction with the corresponding epoxide **14**. Compounds **10** and **7** can also arise directly from **3** but not compounds **11** and **8**, which would arise from the isomeric chlorohydrin **15**.



15

For compound **9** it is necessary to require another isomeric chlorohydrin **16** according to Scheme 7.

So compound **8** may arise from epoxide **14** via path b or from **16**. This is only a hypothesis as **16** has not been isolated from the reaction mixture. Compound **12** obviously came from **13** or **14** by hydrolysis during basic work-up.

In conclusion, the reaction of epichlorohydrin with secondary hindered amines is rather complex, as can be seen in Scheme 7:

SCHEME 7

(Note: Buriks and Lovett (18) have recently encountered some very complex reactions between epichlorohydrin and secondary alkanolamines.)

Experimental

Melting points were taken on a Kofler apparatus and are uncorrected. The elemental analyses were carried out by the Service central d'analyses du CNRS (F-69390 Vernaison). The IR spectra were recorded on a Perkin–Elmer 157G spectrophotometer in CCl_4 solutions for solids or neat for liquids. Routine ^1H NMR spectra were recorded at 60 MHz on a Perkin–Elmer Hitachi R 24B instrument in $CDCl_3$ solution using TMS as internal standard. High-field ^1H NMR spectra were recorded at 350 MHz on a Cameca instrument and at 500 MHz on a Bruker WM-500 apparatus. ^{13}C NMR spectra were recorded at 22.63 MHz on a Bruker WM-90. All spectra were recorded in $CDCl_3$ solutions with TMS as reference.

Synthesis of ***1***

A mixture of 0.066 mol of 1-adamantylamine (10 g) and 7.6 mL of epichlorohydrin was heated at reflux in 80 mL of absolute ethanol for 24 h. After ethanol elimination, there remained 20 g of a light-brown crystalline mass, which was recrystallized in 130 mL of $C_6H_6/CHCl_3$ = 1:2 leaving 5 g of white crystals of **1** in 2 crops: mp 225–228°C, yield 31%; pure base has mp 173–174°C. Mass spectrum of base: 207 (5.6%), 150 (27.3%) adamantyl-NH^+, 135 (100%) adamantyl, 93 (12.5%), 79 (14.5%), 67 (6.5%), and 55 (5.8%). *Anal.* calcd. for hydrochloride of $C_{13}H_{22}ClNO$: C 64.05, H 9.09, N 6.56, O 5.75; found: C 64.11, H 9.13, N 6.43, O 5.61.

Synthesis of ***2***

Cyclododecylamine (0.027 mol; 5.1 g) and 3 mL of epichlorohydrin were heated at reflux in 50 mL of absolute ethanol during 24 h. After ethanol elimination there remained 8.2 g of a whitish semicrystalline mass, which was recrystallized from benzene (200 mL) giving 3 g of white crystals of **2**: mp 175°C, yield 40.5%; pure base has mp 109°C. *Anal.* calcd. for hydrochloride of $C_{15}H_{30}ClNO$: C 65.31, H 10.96, N 5.08, O 5.80; found: C 65.31, H 11.02, N 4.96, O 5.75.

Reaction of dicyclohexylamine with epichlorohydrin

A mixture of 0.05 mol of dicyclohexylamine (9.1 g or 10 mL) and 5 mL of epichlorohydrin was heated under reflux in 80 mL of absolute ethanol during 24 h. After ethanol elimination, 15.5 g of a yellowish-white pasty mass or yellowish viscous oil was obtained. This crude product was extracted with CH_2Cl_2, and washed with dilute ammonia and then with water to neutrality, leaving 12.3 g of yellow viscous oil. Part (7.5 g) of this oil was applied to a column of 300 g of alumina (Merck 90, activity II–III, 70–230 mesh) prepared in cyclohexane. The introduction was also carried out in cyclohexane and products were separated according to the following sequence of elution:

C_6H_{12}/Et_2O = 95:5	**6**, then **8**
C_6H_{12}/Et_2O = 90:10	**7**
C_6H_{12}/Et_2O = 87.5:12.5	**9**
C_6H_{12}/Et_2O = 80:20	**10**
C_6H_{12}/Et_2O = 75:25	**11**
C_6H_{12}/Et_2O = 50:50	**12**

7: mp 121–123°C, yellowish-white crystals (C_6H_{12}); IR (CCl_4): 3360, 2935, 2855, 1450, 1170, 1087, 891; ^1H NMR (500 MHz): 3.62 (m, 1H, CH-O), 2.60 (m, 8H, $2CH_2$-N + 4CH-N) and 1.83 (m, 16H), 1.65 (m, 4H), 1.27 (m, 16H), and 1.09 (m, 4H) for the four cyclohexyl groups. *Anal.* calcd. for $C_{27}H_{50}N_2O$: C 77.45, H 12.04, N 6.69, O 3.82; found: C 77.10, H 12.10, N 6.35, O 4.03.

8: mp 226–227°C, white powder (C_6H_{12}); IR (KBr disc): 3160, 2940, 2860, 1456, 1446, 1117, 1083, 1038, 887; ^1H NMR (60 MHz): 3.9–3.0 (m, 2H, CH_2-O), 2.60 (m, 7H, 5CH-N + CH_2-N), 1.50 (m, 40H) four cyclohexyl groups. *Anal.* calcd. for $C_{27}H_{50}N_2O$: C 77.45, H 12.04, N 6.69; found: C 77.17, H 12.19, N 6.56.

9: yellow oil; IR (neat): 3430, 2930, 2855, 1450, 1110, 1040, 890; ^1H NMR (60 MHz): 3.40 (m, 6H, $3CH_2$-O), 2.60 (br m, 3H, 3CH-N), 1.50 (br m, 20 H) two cyclohexyl groups, 1.15 (t, 3H, $1CH_3$). *Anal.* calcd. for $C_{17}H_{33}NO_2$: C 72.03, H 11.74, N 4.94; found: C 72.32, H 11.57, N 4.61.

10: yellow oil; IR (neat): 3430, 2930, 2860, 1450, 1120, 895; ^1H NMR (60 MHz): 3.45 (m, 5H, $2CH_2$-O + 1CH-O containing 1q at 3.5 O—CH_2—CH_3), 2.55 (m, 4H, containing an ABX system with $\delta_A \simeq 2.7$ and $\delta_B \simeq 2.25$ and J_{AB} = 12.5, J_{AX} = 4, and J_{BX} = 8.5 Hz), 1.90–1.0 (vbr m, 20 H) 2 cyclohexyl groups, 1.20 (t, 3H, CH_3). *Anal.* calcd. for $C_{17}H_{33}NO_2$: C 72.03, H 11.74, N 4.94; found: C 71.89, H 11.61, N 5.13.

11: yellow oil; IR (neat): 3420, 2920, 2840, 1450, 1110, 890; ^1H NMR (60 MHz): 3.60 (m, 5H, $2CH_2$-O + 1CH-O), 2.70 (m, 4H, CH_2-N + 2CH-N), 1.60 (vbr m, 20 H) 2 cyclohexyl groups, 1.15 (t, 3H, CH_3). *Anal.* calcd. for $C_{17}H_{33}NO_2$: C 72.03, H 11.74, N 4.94; found: C 72.16, H 11.74, N 4.69.

12: mp 80–81°C (Et_2O), white powder. IR (CCl_4): 3580, 3360, 2920, 2842, 1450, 1390, 1105, 1053, 892; ^1H NMR (60 MHz): 3.60 (m, 3H, O—CH—CH_2OH), 2.60 (m, 4H, CH_2-N + 2CH-N), 1.50 (vbr m, 20 H) 2 cyclohexyl groups. *Anal.* calcd. for $C_{15}H_{29}NO_2$: C 70.54, H 11.45, N 5.48, O 12.53; found: C 70.36, H 11.46, N 5.43, O 12.74.

Besides these products, we isolated in very small quantities, between compounds **8** and **7**, two very similar compounds having very close IR and NMR spectra. NMR spectra showed no OEt group. Data were as follows: compound A: white crystals, mp 142°C; IR (CCl_4): 2938, 2858, 1450, 1107, 890. Compound B: yellowish oil, IR (CCl_4): 2938, 2860, 1450, 1109, 890.

X-ray crystallography

Compound ***1*** was isolated from ethanol as colorless monoclinic crystals. A single crystal was selected for the collection of intensity data on an Enraf–Nonius CAD-4 diffractometer. The crystal data are summarized in Table 1. The data were collected by the ω–2θ scan technique, with variable scanning rate, using graphite monochromated CuKα radiation. Two standard reflections were measured every 5400 s of radiation time and showed no significant variation during the course of data collection. The intensities were corrected for Lorentz and polarization effects but not for absorption.

The structure was solved by direct methods using the program MULTAN 80 (19) and electron density synthesis. Difference Fourier map calculations revealed the water of inclusion and the hydrogen atoms. Block-diagonal matrix least-squares refinement was performed for the scale factor, positional, and anisotropic thermal parameters of the non-hydrogen atoms. The hydrogen atoms were included in the calculations and refined with isotropic thermal parameters. The function minimized was $\Sigma w||F_o| - |F_c||^2$ where $w = 1$ if $|F_o| < P$, $P = [F^2_{o(max)}/10]^{1/2}$; $w = (P/F_o)^2$ if $|F_o| > P$. The scattering factors used for non-hydrogen atoms were taken from the International Tables for X-ray Crystallography (20), and for hydrogens from Stewart *et al.* (21). The final atomic coordinates are given in Table 2. All calculations were performed on a Mini 6-92 CII-Honeywell Bull computer using unpublished programs from the Crystallography Laboratory, University of Bordeaux I.[2]

Compound ***7*** ($C_{27}H_{50}N_2O$; M = 418.70) was isolated from cyclohexane/ether as colorless triclinic crystals of space group $P\bar{1}$ and Z = 2. The same procedure as the one used for compound **1** was applied. The cell parameters are a = 6.340(1), b = 12.262(2), c = 17.684(3) Å, α = 102.38(2), β = 90.02(2), γ = 75.30(2)°. This compound presents crystallographic problems. During the resolution of the structure, the Fourier maps clearly indicated two conformations for the hydroxypropyl chain, with equal occupancies and single positions for both nitrogen atoms. We tried to refine the structure in the non-centrosymmetric space group $P1$ and two independent molecules but the same phenomenon occurred. We then allowed for disorder in the crystal (the low value of the calculated density D_{calcd} = 1.07, D_{obs} = 1.0 was in favour of this assumption; no solvent inclusion was identified in Fourier maps). Parallel to this, the Fourier maps revealed the four cyclohexane rings almost planar, with abnormal bond lengths and angles. Then we had to admit the existence of two conformers for

[2]A complete set of tables of hydrogen positional parameters, temperature factors, and observed and calculated structure factors may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The hydrogen atom coordinates have been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CBE 1EW, U.K.

each ring due to a simultaneous inversion of the coordination tetrahedra of the two nitrogens. What was observed was an average conformation of each cyclohexane ring, which appeared almost planar. It was possible to model the disordered hydroxypropyl unit, but unfortunately the alternative cyclohexane conformations were not clearly observed and the whole molecule could not be properly refined.

The solution structures of chiral Ti^{4+} alkoxides

PIERRE G. POTVIN,[1] ROBERT GAU, PATRICK C. C. KWONG, AND STEPHEN BIANCHET
Department of Chemistry, York University, North York, Ont., Canada M3J 1P3

Received November 14, 1988[2]

PIERRE G. POTVIN, ROBERT GAU, PATRICK C. C. KWONG, and STEPHEN BIANCHET. Can. J. Chem. **67**, 1523 (1989).

1,4-Di-*O*-methyl-L-threitol and 1,2,5,6-tetra-*O*-methyl-L-mannitol were prepared by new, more convenient, and higher yielding routes. These and 1,2;5,6-di-*O*-isopropylidene-D-mannitol formed 2:2 complexes with $Ti(O^iPr)_4$, but did not readily form 1:2 complexes in the presence of excess Ti^{4+}. ^1H and ^{13}C nuclear magnetic resonance spectra showed that the structures in solution of the 2:2 complexes were analogous to solid-state structures of tartaric acid derivatives, i.e., possessing bridging diolate oxygens. In contrast, *R,R*- and *meso*-diisopropyl tartrates, *N,N'*-dibenzyl tartramide, and *N,N'*-di(2-phenyl)ethyl tartramide behaved very differently. The tartramides formed mixtures of complexes that became dominated by 2:3 complexes in the presence of excess $Ti(O^iPr)_4$. Two tertiary tartramides failed to provide well-defined complexes. The *R,R*-tartrate formed a monocyclic (nonbridged) 2:2 complex, but an equilibrating mixture of 1:2 and 2:2 complexes with excess Ti^{4+}. The equilibrium shifted upon cooling toward a 1:2 complex possessing a bridging diolate oxygen, as did the *meso* 1:2 complex. Other temperature-dependent phenomena were also studied.

Key words: titanium(IV), chiral alkoxides, solution structures, NMR, Sharpless catalysts.

PIERRE G. POTVIN, ROBERT GAU, PATRICK C. C. KWONG et STEPHEN BIANCHET. Can. J. Chem. **67**, 1523 (1989).

Le 1,4-di-*O*-méthyl-L-thréitol et le 1,2,5,6-tétra-*O*-méthyl-D-mannitol ont été préparés avec de meilleurs rendements par des voies nouvelles et plus commodes. Ces diols et le 1,2;5,6-di-*O*-isopropylidène-D-mannitol forment des complexes 2:2 avec le $Ti(O^iPr)_4$, mais ne forment pas aisément des complexes 1:2 en présence d'excès de Ti^{4+}. D'après la spectroscopie en résonance magnétique nucléaire, les complexes 2:2 ont des structures en solution analogues à celles adoptées à l'état solide par les complexes de dérivés d'acide tartrique, possédant des ponts diolates. Cependant, les tartrates d'isopropyle *R,R* et *meso* et les *N,N'*-dibenzyl et *N,N'*-di(2-phényl)éthyl tartramides mènent à des structures très différentes. Les tartramides forment des mélanges de complexes en équilibre où les complexes 2:3 predominent en présence d'excès de $Ti(O^iPr)_4$. Deux tartramides tertiaires n'ont fourni aucun complexe charactérisable. Le tartrate *R,R* forme un complexe 2:2 monocyclique non-ponté et, en présence d'excès de Ti^{4+}, un mélange en équilibre de complexes 2:2 et 1:2 non-ponté. Ce mélange, ainsi que celui obtenu avec le tartrate *meso*, fournissent à −50°C un complexe 1:2 possédant un pont diolate. Les variations des structures avec la température ont aussi été étudiées.

Mots clés : titanium(IV), alcoxides chiraux, structures en solution, RMN, catalyseurs de Sharpless.

Introduction

The Sharpless reaction (1–3), the enantioselective epoxidation of allylic alcohols catalyzed by 1:1 complexes of Ti^{4+} with tartaric esters, clearly demonstrates the value of chiral Lewis acidic complexes as catalysts for enantioselective bond formation. The utility of Ti^{4+} complexes has been further demonstrated in other enantioslective oxidations by 2:1 (4), 4:1 (5), and 1:2 (6, 7) ligand–Ti^{4+} complexes as well as by 1:1:1 and 2:1:1 ligand–Ti^{4+}–H_2O complexes (4). Further, chiral dichlorotitanium(IV) complexes have recently been used in enantioslective Diels–Alder (8) and ene (9) reactions.

We wished to design new, general, chiral Ti^{4+} Lewis acids suited for other bond-forming reactions involving, for instance, strong nucleophiles and bases, with which the tartaric acid derivatives are incompatible. We sought sources of chirality-bearing unreactive side chains able to reproduce, as much as possible, the chiral environment that the oxidation catalysts impose with such success. The crystal structures of two Sharpless catalysts had in fact been determined (10). Both were found to be dimeric, as in solution. Both possessed tricyclic cores formed by combinations of one terminal and one bridging diolate per ligand moiety, resulting in loss of ligand-centred C_2 symmetry.

We chose to investigate C_2-symmetric vicinal diols bearing additional base- and nucleophile-stable ether-type oxygen binding sites, of which new convenient syntheses are presented. These sugar-derived ligands did not lead to highly enantioslective epoxidation,[3] yet nmr spectroscopy revealed that their 1:1 complexes with $Ti(O^iPr)_4$ had lost the ligand-centred C_2 symmetry, as expected from the crystal structures (10). On the other hand, the 2:2 complex formed from *R,R*-diisopropyl tartrate (DIPT), a typical Sharpless ligand, gave symmetrical nmr spectra. We therefore launched a study of the structures in solution of the Sharpless catalysts. In a preliminary account (12), we presented evidence that the 2:2 *R,R*-DIPT–Ti^{4+} complex adopted a ten-membered monocyclic structure in solution, while tricyclic structures, found in solid-state complexes of tartaric acid derivatives (10), were formed in solution by our ether-bearing ligands. In this report, we present further details of those findings, a reexamination of the 1:2 *R,R*-DIPT–Ti^{4+} complex and new results with *meso*-DIPT and two secondary tartramide ligands, in an effort to shed light on the structures of the precatalytic complexes involved in oxidation reactions.

Experimental

General

THF, $CHCl_3$, $CDCl_3$, and $Ti(O^iPr)_4$ were freshly distilled. Fresh ampoules of CD_2Cl_2 (Merck) were used. Optical rotations were measured on a Perkin–Elmer 110 polarimeter in a 1-dm cell. The nmr spectra were obtained on a AM-3000 Bruker instrument, at 300 MHz for ^1H spectra or at 75 MHz for ^{13}C spectra. The $CHCl_3$ peak in ^1H nmr spectra or the $CDCl_3$ peak in ^{13}C nmr spectra were at times used as internal standards. The *t*-BuOH peaks were used for spectra in D_2O. Structural assignments were made with the help of coupled ^{13}C spectra,

J-modulated spin echo, $^{13}C-^{1}H$ and $^{1}H-^{1}H$ correlation spectra, and with single-frequency hetero-decoupling (SFD) experiments using pulse sequences from the Bruker library. The ABX spin systems were analysed by computer simulation using the program NMRCALC (M. D. Johnson, Jr., University of South Florida).

Materials

1,2;3,4;5,6-Tri-*O*-isopropylidene-D-mannitol was prepared by a slight modification of the procedure of Wiggins (13), wherein three equivalents of 2,2-dimethoxypropane were added to the reaction mixture and the product was recrystallized from hexanes, with mp 70°C (lit. (13) mp 69–70°C). 3,4-*O*-Isopropylidene-D-mannitol was obtained by hydrolysis of the triacetonide according to Wiggins (13), but a shorter reaction time (1 h) provided a higher yield (77% vs. lit. 70%), mp 83°C (lit. (14) mp 85°C, (13) mp 86–87°C). 1,2;5,6-Di-*O*-isopropylidene-D-mannitol (mannitol diacetonide, MDA) was obtained by the method of Kohan and Just (15).

Diethyl 2R,3R-di-(tetrahydropyran-2-yloxy)succinate ***1***

R,R-Diethyl tartrate (2.07 g, 10 mmol) was dissolved in dry THF containing (optionally) a trace of *p*-TsOH. The solution was cooled (ice bath) and neat dihydropyran (1.23 mL, 20 mmol) was added dropwise (the reaction was exothermic). After stirring for 1 h in the cooling bath, the mixture was warmed to room temperature and allowed to stir a further 48 h. After diluting with ether and, if *p*-TsOH had been used, washing with saturated $NaHCO_3$ solution, the organic layer was dried

($MgSO_4$) and rid of solvents. The yield of crude **1**, a mobile colourless oil, was 3.75 g (100%). It was used as such in the next step; ^{1}H nmr ($CDCl_3$) δ: 4.94, 4.83, 4.74 (3dd, 2H, OCHO), 4.80, 4.58, 4.56 (3s, 2H, OCHCOOEt), 4.29–4.14 (m, 4H, CH_2CH_3), 3.53–3.42 (m, 4H, OCH_2CH_2), 1.91–1.41 (m, 12H, $OCH_2CH_2CH_2$, $OCH_2CH_2CH_2$, $OCHCH_2CH_2$), 1.30, 1.28 (2q, 6H, CH_2CH_3) ppm; ^{13}C nmr ($CDCl_3$) δ: 169.30, 169.06 (COOR), 100.81, 100.59, 96.57, 96.36 (C-2′), 78.00, 77.57, 74.41, 74.03 (C-2), 62.81, 62.25, 62.07, 61.91 (OCH_2CH_3), 61.51, 61.29, 61.09 (C-6′), 30.61, 30.06, 29.73 (C-3′), 25.38, 25.23, 25.16 (C-5′), 18.79, 18.71, 18.40, 18.25 (C-4′), 14.10, 14.03, 14.01 (CH_2CH_3) ppm.

*2,3-Di-*O*-(tetrahydropyran-2-yl)-*L*-threitol* ***2***

A suspension of $LiAlH_4$ (0.38 g, 10 mmol) in dry THF (10 mL) was treated by dropwise addition with a solution of **1** (2.68 g, 7.12 mmol) in THF (10 mL), and the mixture was heated at reflux temperature overnight. The reaction was quenched by sequential addition of H_2O (0.38 mL), 15% NaOH solution (0.38 mL), and H_2O again (1.14 mL). After the precipitate was filtered off, the filtrate was diluted with H_2O and extracted with ether. The extracts were combined, dried ($MgSO_4$), and evaporated to dryness to afford a yellow oil. Filtration through a short column of SiO_2, using 1:4 EtOAc–hexane and then 2:3 EtOAc–hexane as eluents, afforded 1.51 g of a viscous, colourless oil (73% yield), which was used as such in the next step. The ir showed no absorptions due to starting material at 1741 or 3400 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.75, 4.57, 4.52, 4.46 (4dd, 2H, OCHO), 4.00–3.44 (m, 10H, $OCHCH_2O$, $OCHCH_2O$, OCH_2CH_2), 2.50 (bs, 2H, OH), 1.84–1.74, 1.57–1.47 (2m, 12H) ppm; ^{13}C nmr ($CDCl_3$) δ: 101.76, 101.55, 101.07, 98.88 (C-2′), 82.33, 81.60, 76.49, 75.55 (C-2), 65.72, 64.80, 64.61, 63.49 (C-1), 62.46, 61.89, 60.84, 59.63 (C-6′), 31.32, 31.22, 31.36, 30.80 (C-3′), 25.17, 25.00, 24.96 (C-5′), 21.51, 20.88, 20.76, 20.00 (C-4′) ppm.

*1,4-Di-*O*-methyl-2,3-di-*O*-(tetrahydropyran-2-yl)-*L*-threitol* ***3***

A suspension of ca. 100 mg of NaH (ca. 5 mmol, previously freed of oil by hexane washes) in dry THF (15 mL) was treated, by dropwise addition under an Ar atmosphere, with a solution of diol **2** (500 mg, 1.72 mmol) in THF (10 mL) containing traces of imidazole and *n*-$Bu_4N^+Br^-$ (16). After cooling to 0°C (ice bath), 2 mL of CH_3I (32.1 mmol) was added and the mixture stirred for 2 h. After dilution with H_2O and extraction with ether, the ether solution was dried ($MgSO_4$) and evaporated to dryness *in vacuo*, providing 546 mg of viscous oily **3** (100% yield), which was used as such in the next step; ^{1}H nmr ($CDCl_3$) δ: 4.86, 4.81, 4.78, 4.71 (4dd, 2H, OCHO), 4.08–3.87 (m, 2H, $OCHCH_2O$), 3.70–3.41 (m, 8H, $OCHCH_2O$, OCH_2CH_2), 3.37, 3.36, 3.35, 3.34 (4s, 6H, OCH_3), 1.87–1.45 (m, 12H) ppm; ^{13}C nmr ($CDCl_3$) δ: 100.91, 99.83, 98.93, 97.29 (C-2′), 76.65, 76.34, 76.00, 74.26 (C-2), 72.86, 72.59, 71.63 (C-1), 62.86, 62.78, 62.13 (C-6′), 59.12, 59.02 (OCH_3), 30.95, 30.92, 30.79 (C-3′), 25.61, 25.46, 25.42 (C-5′), 19.98, 19.81, 19.34, 18.79 (C-4′) ppm.

*1,4-Di-*O*-methyl-*L*-threitol (DMT)*

Compound **3** (546 mg, 1.72 mmol) in 4:1 MeOH–H_2O (5 mL) containing 5 drops of CF_3COOH was allowed to stir overnight. An excess of Dowex IRA 400 resin (OH^- form) was then added, and after stirring 1 h, was filtered off. The neutralized reaction mixture was evaporated *in vacuo* at 30°C, using codistillation with MeOH to remove the last traces of H_2O. The mobile oily residue weighed 230 mg (90% yield); $[\alpha]_D^{22}$ −4.6° (*c* 0.05 M, MeOH) (Nanasi and Liptak (17) report $[\alpha]_D^{22}$ −9.8° (*c* 0.2, EtOH). Seebach *et al.* (18) report mp 28°C, and $[\alpha]_D$ −2.5° (*c* 2.5, MeOH)). These authors also report ir and 60-MHz ^{1}H nmr data taken in CCl_4 in agreement with ours. For ^{1}H nmr (D_2O), δ: 3.83 (m, 2H, H2), 3.62–3.51 (m, 4H, H1), 3.41 (OCH_3) ppm; ^{1}H nmr ($CDCl_3$) δ: 3.81 (X part of ABX, 2H, $J_{1a,2} = 6.0$, $J_{1b,2} = 4.0$ Hz), 3.54 (A part of ABX, 2H, $J_{1a,2} = 6.0$, $J_{1a,1b} = 9.8$ Hz), 3.52 (B part of ABX, 2H, $J_{1b,2} = 4.0$, $J_{1a,1b} = 9.8$ Hz), 3.39 (s, 6H, OCH_3) ppm; ^{13}C nmr ($CDCl_3$) δ: 74.40 (C-1), 70.35 (C-2), 59.14 (OCH_3) ppm; ^{13}C nmr (D_2O) δ: 73.17 (C-1), 69.86 (C-2), 58.28 (OCH_3) ppm.

*3,4-*O*-Isopropylidene-1,2,5,6-tetra-*O*-methyl-D-mannitol* ***5***

A solution of 3,4-*O*-isopropylidene-D-mannitol **4** (109 mg, 0.5 mmol) in dry DMSO (2 mL) was treated, under an Ar atmosphere, with 2 mL of a ca. 2 M solution of sodium dimsylate in DMSO. After stirring for 5 min, the solution was cooled to 0°C (ice bath), and CH_3I (2 mL, 32.1 mmol) was slowly added to the solidified mixture, which was then allowed to warm to room temperature and stirred for 10 min. After this period, the mixture was concentrated *in vacuo* and extracted into hexane. Washing with water, drying ($MgSO_4$), and removal of solvent afforded 83 mg (60% yield) of pure **5** as a slightly yellowish oil; $[\alpha]_D^{22}$ +31.8° (*c* 0.04 M, EtOH) (Irvine and Paterson (14) report $[\alpha]_D^{20}$ +39.1° (*c* 3.098, H_2O), +32.2° (*c* 2.865, EtOH)); ^{1}H nmr ($CDCl_3$) δ: 4.09 (X part of ABX, 2H, H3), J = 1.3, 3.2 Hz), 3.63 (A part of ABX, 2H, H1a, $J_{app} = 3.0$, 10.1 Hz), 3.53–3.41 (B part of ABX + m + s, 10H, H1b, H2, OCH_3), 3.37 (s, 6H, OCH_3), 1.39 (s, 6H, CCH_3) ppm; ^{13}C nmr ($CDCl_3$) δ: 109.73 (CCH_3), 81.34 (C-2), 77.96 (C-3), 71.89 (C-1), 59.15, 58.44 (OCH_3), 27.20 (CCH_3) ppm.

*1,2,5-6-Tetra-*O*-methyl-D-mannitol (TTM)*

Compound **5** (80 mg) was dissolved in 4:1 MeOH – 1 N HCl (5 mL) and allowed to stir at room temperature for 48 h. Work-up as with diol DMT afforded 56 mg of viscous, oily TTM (82% yield); $[\alpha]_D^{22}$ −12.6° (*c* 0.04 M, EtOH) (Irvine and Paterson (14) report $[\alpha]_D^{20}$ −13.02° (*c* 1.921, H_2O), −12.54° (*c* 1.813, EtOH)); ^{1}H nmr ($CDCl_3$) δ: 3.83 (d, 2H, H3, $J_{2,3} = 6.2$ Hz), 3.66 (A part of ABX, 2H, H1a, $J_{1a,2} = 4.4$, $J_{1a,1b} = 10.1$ Hz), 3.59 (B part of ABX, 2H, H1b, $J_{1b,2} = 4.4$, $J_{1a,1b} = 10.1$ Hz), 3.45 (X part of ABX, 2H, H2, $J_{2,3} = 6.2$, $J_{1a,2} = 4.4$, $J_{1b,2} = 4.4$ Hz), 3.47, 3.40 (2s, 12H, OCH_3) ppm; ^{13}C nmr ($CDCl_3$) δ: 80.85 (C-2), 71.66 (C-1), 69.73 (C-3), 59.23, 58.37 (OCH_3) ppm.

Nuclear magnetic resonance studies

Two methods of sample preparation were used. One involved titration at room temperature (27°C) of $CDCl_3$ solutions of $Ti(O^iPr)_4$ with $CDCl_3$ solutions of DMT, TTM, or MDA. Reverse titrations were also employed. This allowed monitoring over a wide range of stoichiometries. To preclude possible interference of adventitious H_2O, the second method involved formation of complexes at defined stoichiometries

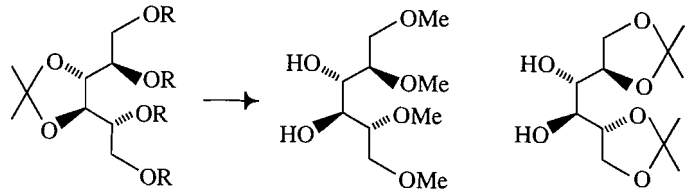
under Ar. No differences were found in the signal patterns from samples prepared by either method. Preparations at different concentrations showed no observable differences.



Results

Syntheses of DMT and TMM

1,4-Di-*O*-methyl-L-threitol (DMT) had been prepared by electrophilic (Purdie) methylation (CH_3I, Ag_2O/DMF/48 h/88.5% yield) of 2,3-*O*-isopropylidene-L-threitol, followed by hydrolysis (17). A similar methylation of the D enantiomer proceeded in 77% yield (19). Phase-transfer-catalyzed nucleophilic methylation with dimethyl sulfate (a variation on the Haworth method) proceeded in 67% yield (18). In other work in which 1,4-anhydro-L-threitol had been prepared, we had found that protection of diethyl tartrate with THP groups, needed for the cyclization of a 2,3-protected threitol, was convenient for small-scale work, proceeding quantitatively even without catalysis[4]. Thus, *R*,*R*-diethyl tartrate was protected as its di-THP derivative **1**, then reduced to the protected L-threitol **2** in 73% overall yield. In the methylation of **2**, we adapted the alcohol benzylation procedure of Czernecki *et al.* (16), in which exchange of the Na^+ counterions by the larger $^nBu_4N^+$ facilitates nucleophilic attack of CH_3I by an alkoxide. Thus, compound **3** was obtained in quantitative yield, a significant improvement over the Purdie or Haworth methods. After hydrolysis (90% yield), our overall yield of DMT was 36.5% from diethyl L-tartrate. The final product displayed the expected three-line ^{13}C nmr spectrum, the expected ABX pattern in the ^1H spectrum, and an optical rotation in agreement with literature values.

THP protecting groups find wide use in general organic work (21) but not in the carbohydrate or ribonucleoside fields (22) due to a lack of selectivity (23) or of crystallinity, to possible migration problems, and to diastereomerism. Diastereomeric THP-protected sugars have been separated in a few cases of mono-protection (24–26), but not with two THP groups (22). In our work, no attempts to separate diastereomers were made, yet there was no difficulty in verifying the structures of intermediates by ^{13}C nmr nor in monitoring the reactions by ir and tlc. The ^{13}C nmr resonances usually occurred in easily identifiable groups of four, simplified because the starting material and the product each have a C_2 axis of symmetry. However, the intermediates (particularly **3**) were not very stable in the presence of water and (or) acid, probably owing to steric congestion at the secondary positions. Trailing was also observed on tlc plates of SiO_2. The intermediates were therefore not stored and were used immediately.

We had hoped to use the same methylation procedure with mannitol 3,4-monoacetonide **4** (13) as was used in the preparation of DMT. However, the method of Czernecki *et al.* (16) failed because of the insolubility of the intermediate alkoxides. Purdie methylation of **4** had been reported, but was incomplete and required resubmission to fresh reagents for a cumulated yield of 60% (14). The yield of the subsequent hydrolysis step was not given. We found that the Hakomori polysaccharide permethylation procedure (27) (sodium dimsylate/DMSO/0°C to room temperature, then CH_3I/15 min) was fast and clean, and, after simple extraction into hexanes, afforded **5** in 60% isolated yield (Scheme 1). Thus, the Hakomori procedure presented a distinct advantage over the Purdie and Czernecki methods. After hydrolysis (82% yield), the overall yield of

5 R: Me

TMM MDA

SCHEME 1

TMM was 49%. These products displayed the expected seven- and five-line ^{13}C spectra, respectively, ^1H nmr spectra consistent with their structures, and optical rotations in agreement with literature values.

Nuclear magnetic resonance studies

Because epoxidation reactions are usually conducted at low temperatures (1), we examined several samples over a broad temperature range, down to as low as −50°C. As well, because CH_2Cl_2 is the usual solvent for epoxidation reactions (1), all of the complexes were examined in $CDCl_3$ and several were also examined in fresh, anhydrous CD_2Cl_2, with only slight differences in the nmr patterns resulting.

Complexes of DMT, TMM, and MDA

Treatment of each of the three sugar ligands DMT, TMM, and MDA with one equivalent of $Ti(O^iPr)_4$ at room temperature led to the liberation of two equivalents of HO^iPr and the disappearance of the $Ti(O^iPr)_4$ signal, according to the equation

[1] $H_2L + Ti(O^iPr)_4 \rightarrow LTi(O^iPr)_2 + 2HO^iPr$

Single species were formed in each case, as ascertained by decoupling experiments, with loss of the ligands' C_2 symmetry in the nmr spectra. In contrast with the rapid ligand equilibration reported for tartrate complexes (2, 3), these products evidently underwent no such side-chain exchange. In fact, the OCH_3 signals of the DMT complex coalesced only near 57°C, while coalescence of the central OC*H* signals was still incomplete at 62°C. Upon cooling to −23°C, only small changes in the ^1H shifts were seen. The nmr shift data and assignments appear in Tables 1 and 2. In Table 3 (entries 1–3) are reported the displacements of selected ligand signals from their positions in free ligands. Computer simulation was used to analyse the ABX pattern in the DMT complex, but similar analysis of the TMM and MDA complexes was impossible. However, the side-chain nuclei in all three complexes could be located by ^1H–^{13}C correlation experiments (see Fig. 1). Electron-impact (E.I.) mass spectra showed that, as with DBT or the tartrates (2, 3), the products were 2:2 complexes. Although a weak molecular ion was detected only with TMM, two common high-weight fragments could be assigned in each case, one owing to loss of $^iPrO^\bullet$, a fragmentation common in the E.I. spectra of tartrate ester complexes (3), and the other owing to loss of a side chain. Additionally, loss of $CH_3^\bullet$ or $CH_3O^\bullet$ occurred. For instance, the MDA complex showed Ti_2 clusters at m/z 837 ($M^{\bullet+} - CH_3^\bullet$), 793 ($M^{\bullet+} - {}^iPrO^\bullet$), and 751, coresponding to β-cleavage of one side chain, 2,2-dimethyl-1,3-dioxolane radical, which gave rise to the base peak (m/z 101). Moreover, the observed ion abundances in the cluster at 751 matched very well those calculated using formula $C_{31}H_{59}O_{14}Ti_2$ and natural isotope abundances.

At 1:2 ligand–Ti stoichiometry and even with very large excesses of $Ti(O^iPr)_4$, the mixtures clearly consisted of the 2:2

complexes and unreacted Ti(O^{i}Pr)$_4$. New species did form in minor amounts but could be seen only above room temperature with DMT, or at lower temperatures with TMM. Adding excess ligand also failed to form any new well-defined complexes. Rather, the resonances gradually became weaker and broader, and were eventually replaced with signals from the free ligands. Clearly, the sugars were reluctant to form well-defined complexes of other molecularities.

This reluctance and the lack of ligand C_2 symmetry over a broad temperature range pointed to a rigidity and a mode of stabilization particular to the asymmetric 2:2 complex. Yet side-chain binding was expected to be relatively weak, to exert little influence on the central OC*H* and OC*H* signals, and thus not expected to be the source of asymmetry. By analogy to the solid-state structure of the 2:2 DBT complex (10), the differences observed in these signals can be explained by the presence of a bridging diolate O in each ligand moiety, as in structures A*a*, *b*, *c*, with the planar tricyclic core providing the particular

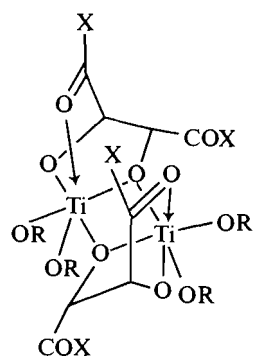
stability and rigidity observed. The other spectral data, in particular the pairs of distinct $TiOCHMe_2$ signals (and $TiOCHMe_2$ signals, with TMM), the weak coupling between central OC*H* (0–2.3 Hz), and the separate signals for each side chain, were entirely in accord with these structures.

Detailed examination of the spectra revealed two additional points. First, the most downfield side-chain carbon signal (C-4 in DMT or C-5 in the mannitols), assigned to the bound side chain, correlated to the most upfield side-chain OC*H*, and these were most closely connected to the upfield central OC*H*, assigned to the terminal diolate. Opposite assignments could also be made, but it seems most reasonable that the bridging central OCH signals should be downfield of the terminal ones. Second, the secondary ethers of the mannitols appeared to bind in preference to the primary ones. Although only small effects on adjoining nuclei were observed to result from side-chain binding, the shift differences between secondary positions were indeed larger than between the primary ones, indicating the probable binding of O5 as depicted in A*b*, *c*, even though less ring strain might be expected with O6.



Complexes of R,R-*DIPT*

In contrast to the sugars, the nmr spectra of the 1:1 DIPT–$Ti(O^iPr)_4$ mixture showed complete symmetry at room temperature. Previous solution molecular weight measurements and mass spectral data (2) had established that tartrates form 2:2 complexes with $Ti(O^iPr)_4$ at 1:1 stoichiometry. Infrared evidence (2, 3) had indicated both Ti-bound and free ester groups in 2:2 tartrate complexes at room temperature. Although no nmr data have been published, $\Delta G^{\ddagger}$ values at coalescence of between 12.8 and 15.2 kcal mol^{-1} had been calculated for various tar-

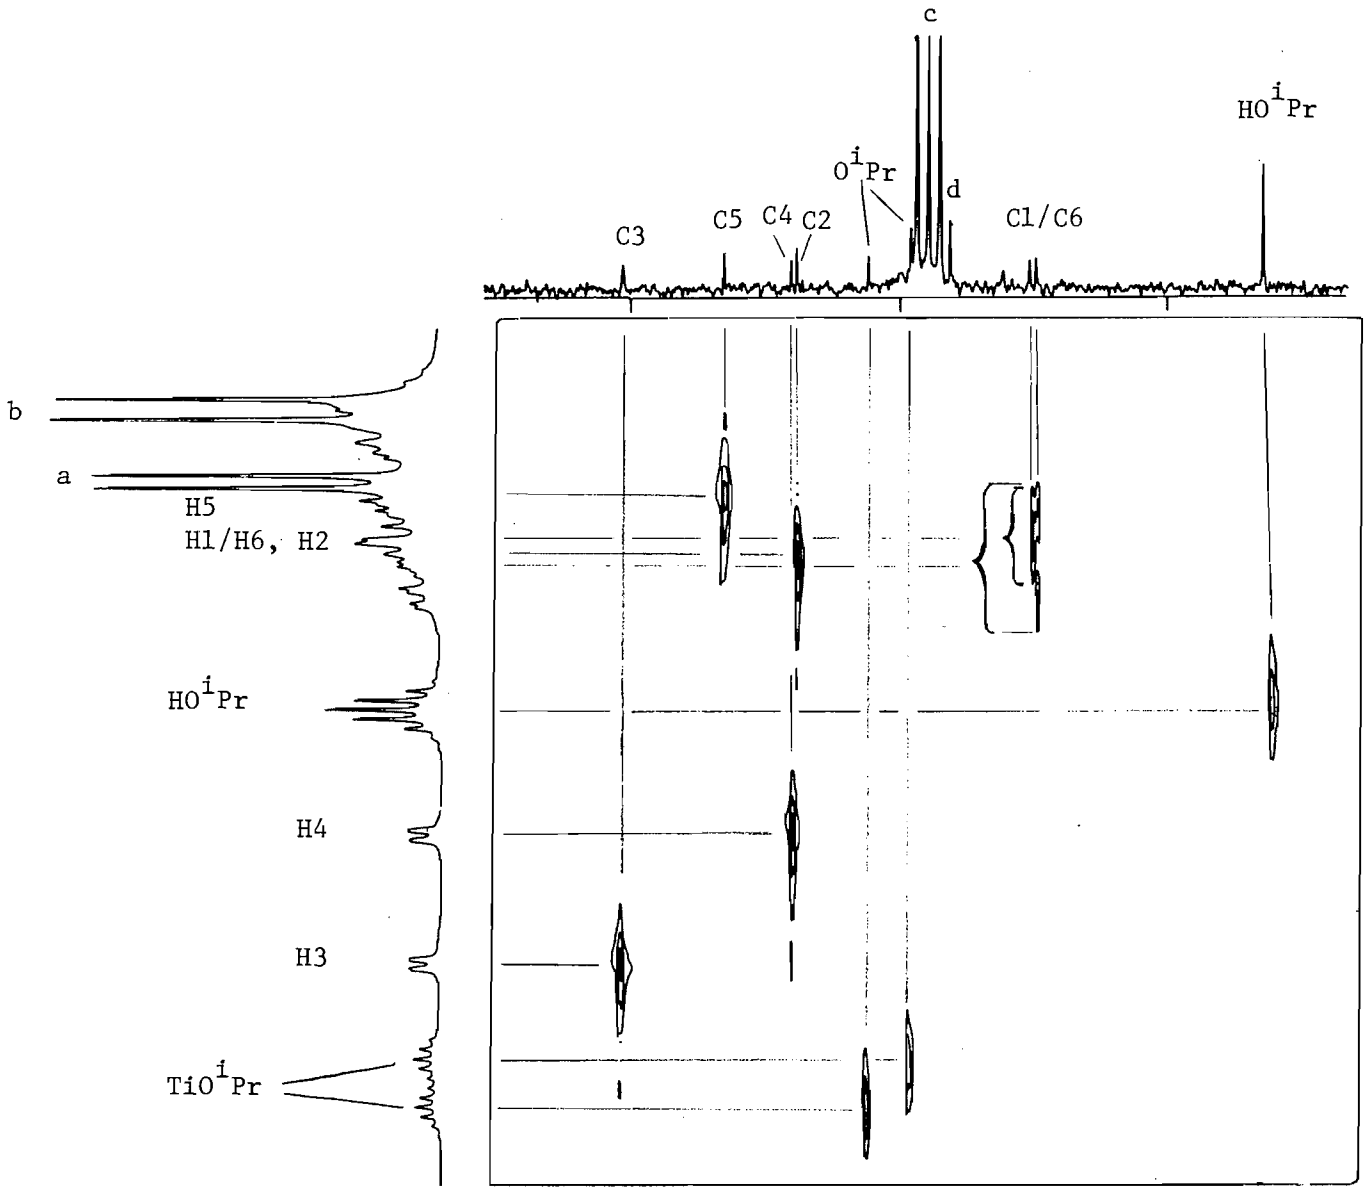

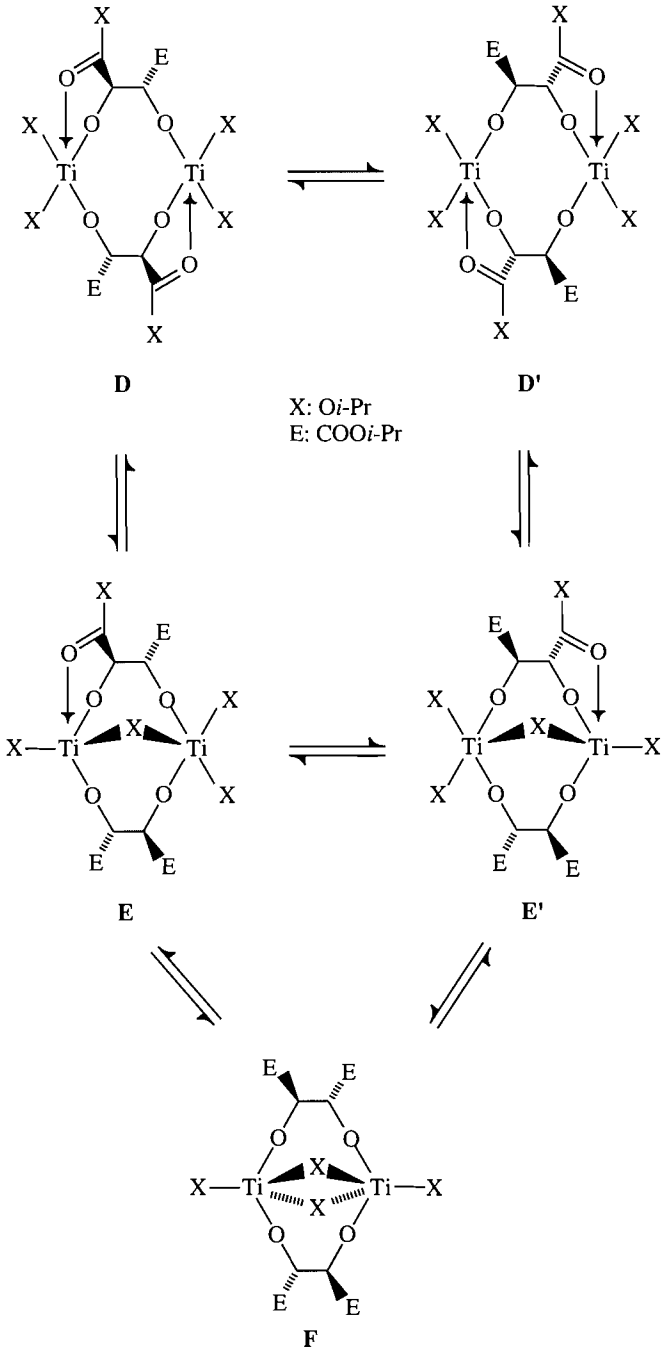

FIG. 1. OCH and OCH_2 regions of ^1H, ^{13}C and ^{13}C–^1H *J*-correlated nmr spectra of $(TMM)_2Ti_2(O^iPr)_4$ in $CDCl_3$, showing assignments. Other peaks are (a) O2-CH_3 and O5-CH_3; (b) O1-CH_3 and O6-CH_3; (c) CDCl_3; and (d) OCH from excess $Ti(O^iPr)_4$ present in ^{13}C sample.

trate–alkoxide combinations, and presumed to relate to fluxional ester interchange (2). The crystal structure of the 2:2:2 Ti – *N*-phenyl benzohydroxamate – diethyl tartrate (DET) complex (10), **B**, similar to that of the 2:2 Ti – *N*,*N*′-dibenzyltartramide (DBT) complex, **C**, in possessing a tricyclic core, would suggest that such interchange be rapid even on a rigid tricyclic framework. In view of the lack of side-chain equilibration in the sugar complexes, in which binding of the side-chain ethers was expected to be weak, the apparent symmetry in the 2:2 *R*,*R*-DIPT complex, in which binding of the side-chain ester group was expected to be much stronger, was not consistent with such a tricyclic core. The downfield shifts upon complex formation at room temperature of the single OCH and OC*H* resonances were in fact close in value to the upfield partners of the pairs seen in the sugar complexes. This suggested that both diolates were terminal and that the effect of side-chain binding on the central OCH nuclei was small compared to the effect of binding a second Ti. These suggestions were supported by data from the tartramide complexes (*vide infra*).

Detailed analysis of the nmr spectra led us back to the originally proposed (2) ten-membered monocyclic structure **D**. As shown in Fig. 2A, the room temperature ^1H nmr spectrum consisted of a broad singlet due to ligand OC*H*, overlapping broad signals for ester OC*H*, and new TiOC*H*Me_2. A weak and very broad feature near 4.7 ppm appeared to signal a second, minor kind of TiOC*H*Me_2. Single but broad ^{13}C resonances were found at room temperature for the central, ester, and HO^{i}Pr OCH, and they correlated weakly with signals due to the attached protons. Two very broad signals were at times found in the *C*=O region at room temperature, but at other times these were too broad and too weak to be detected. This might be due to rapid exchange between bound and free ester groups, but because the HO^{i}Pr signals were also broad, trans-esterification exchange was perhaps also occurring, as Ti^{4+} alkoxides are well-known trans-esterification catalysts, especially with α-hydroxy esters (1).

Cooling sharpened the spectra and arrested the side-chain exchange as well as any trans-esterification. The central OC*H*

D D' E E' F

signal split near −12°C into an apparent fine doublet (Fig. 2B), while the TiOC*H*Me_2 signal became more distinct from the ester OC*H*. The central OC*H* doublet widened into a clear AB quartet pattern (Fig. 2C) near −31°C and this persisted at least down to −43°C (at 5.08 ppm, with $\delta(H_a) - \delta(H_b) \cong 0.05$ ppm, $J_{ab} \cong 7$ Hz). Much below this temperature, the OC*H* region became more complex and detailed analysis was impossible. At the same time, the feature at 4.7 ppm gradually increased in proportion to the other signals in the OC*H* region to ca. 1:5, but remained broad. At −10°C and below, all ^{13}C signals were sharp except that for HOCMe_2. Two central OCH peaks were found, but these were very closely spaced (with $\Delta\delta = 0.2$ ppm at −50°C). This, along with the closely spaced central OC*H* signals, suggested that the diolates remained terminal at low temperatures. Two ester OCH signals could be clearly seen as well, though the downfield partner was weaker, and the C=O region contained one strong and one weak (downfield) signal. These downfield signals gradually disappeared upon cooling but had not completely disappeared even at −50°C. At this point, the TiOC*H*Me_2 signals were too weak and (or) too broad to be visible. Thus, the progressive loss of the downfield ester signals, and presumably of side-chain binding, appeared to be linked to the progressive gain in the upfield TiOC*H*Me_2 signal, while the complex remained asymmetric below −10°C. These data best fit a monocyclic structure where rapid side-chain exchange occurs at room temperature (**D** ↔ **D′**), but with loss of side-chain binding, replaced by reversible bridge formation, occurring in two steps at lower temperatures (**D** / **D′** ↔ **E** / **E′** ↔ **F**). Importantly, the bridging seemed to afford greater stability than side-chain binding.

The 1:2 DIPT–Ti(O^iPr)$_4$ mixture gave spectra at room temperature that were similar those of the 1:1 mixture. However, the presence of unreacted Ti(O^iPr)$_4$ (about one-eighth the total Ti, by integration, at 0.6 M Ti) was made evident by a broad OC*H* signal at 4.5 ppm and a OCH signal at 76.1 ppm. As well, a broad shoulder (near 5.0 ppm) on the ester OC*H* multiplet signalled a second kind of TiOC*H*Me_2 (Fig. 2D). Yet only one species was visible at −50°C (*vide infra*). Moreover, tenfold dilution sharpened the Ti(O^iPr)$_4$ and HO^{i}Pr signals and reduced the amount of unreacted Ti(O^iPr)$_4$ to about one-tenth. Clearly, *the 1:2 mixture was a mixture of complexes in rapid equilibrium*. The E.I. mass spectrum revealed the presence of both 2:2 and 1:2 complexes: a Ti_2 cluster at m/z 737 corresponded to (DIPT)$_2$Ti$_2$(O^iPr)$_4$ with loss of ^{i}PrO·, and weak clusters at m/z 681 ($M^{\bullet+}$ − H·) and 623 ($M^{\bullet+}$ − ^{i}PrO·) indicated the 1:2 complex. Further, clusters at m/z 283 ($M^{\bullet+}$ − H·), 269 ($M^{\bullet+}$ − CH_3·, base peak), and 225 ($M^{\bullet+}$ − ^{i}PrO·) confirmed the presence of Ti(O^iPr)$_4$. No significant higher mass fragments were found. Equilibrium [2] can then be postulated, with $K_2 \approx 240$. The broad feature at 5.0 ppm was therefore assigned to the 2:2 complex.

[2] $Ti_2(R,R\text{-DIPT})_2(O^iPr)_4 + 2Ti(O^iPr)_4 \overset{K_2}{\longleftrightarrow} 2Ti_2(R,R\text{-DIPT})(O^iPr)_6$

Earlier, we reported (12) that the low temperature spectra of the 1:2 mixture were also similar to those of the 1:1 mixture. That sample had been prepared by titration until disappearance of the Ti(OC*H*Me_2)$_4$ signal according to the equation

[3] $H_2L + 2Ti(O^iPr)_4 \rightarrow LTi_2(O^iPr)_6 + 2HO^iPr$

and was therefore, in light of the above, nearer 1:1 stoichiometry.

The sample used in the present work was prepared at exact 1:2 stoichiometry and showed very different spectra upon cooling. Some of the broad room temperature signals sharpened considerably. The Ti(OC*H*Me_2)$_4$ heptet progressively disappeared and new peaks due to an asymmetric complex progressively appeared and became dominant (Fig. 2E and F). The central OC*H* room temperature singlet at 5.11 ppm split, as with the 2:2 complex, into a fine doublet by −19°C, then disappeared near −30°C while being replaced, starting at least as soon as −10°C, by two new, widely separated singlets. One of these was strongly shifted upfield (to 4.74 ppm), overlapping one of the two broad LTiOC*H*Me_2 heptets that had arisen from the single room temperature heptet. The HO^{i}Pr signal remained broad throughout. These changes were paralleled in the ^{13}C spectra. At room temperature, two close broad central OCH signals were seen. The downfield partner was close to that seen in the 1:1 mixture and disappeared upon cooling, and was therefore likely due to the 2:2 species. The (upfield) room temperature partner at 84.9

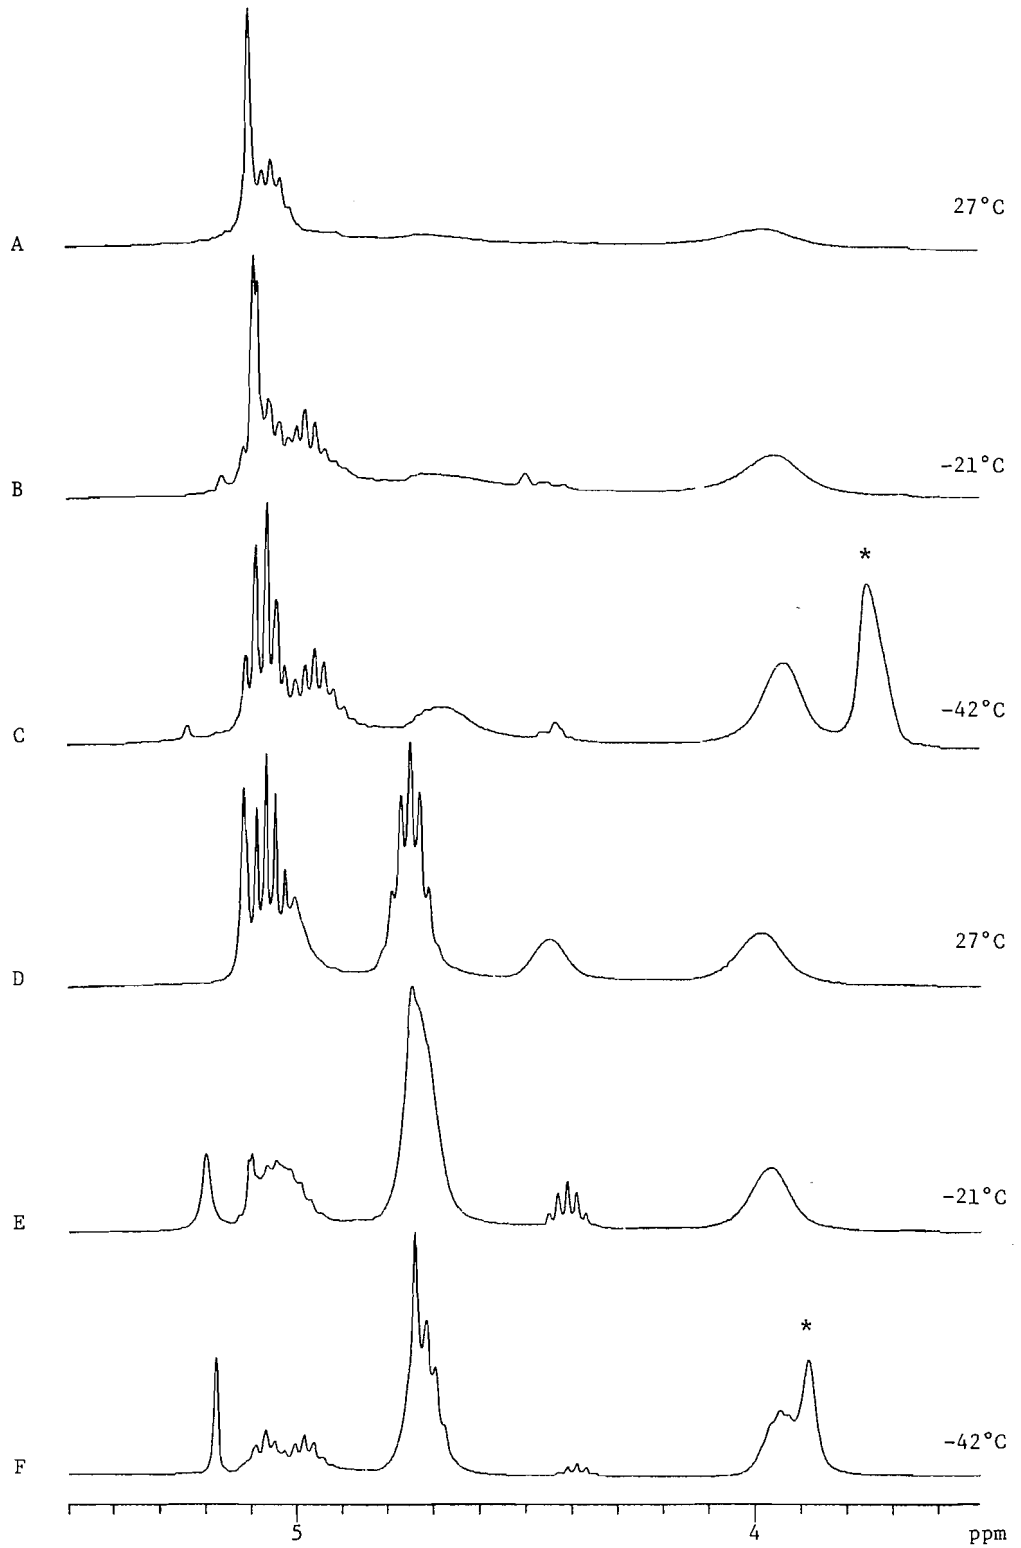

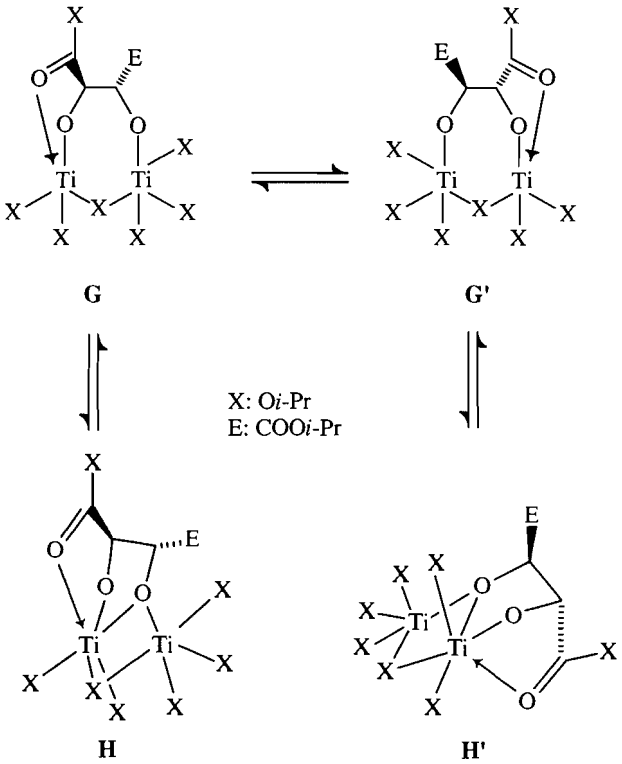

FIG. 2. OCH regions of ^{1}H nmr spectra taken at the indicated temperatures of *R*,*R*-DIPT complexes with 1 (A–C) and 2 (D–F) equivalents of $Ti(O^iPr)_4$ (refer to text). Starred peaks are due to OH, which migrate downfield upon cooling.

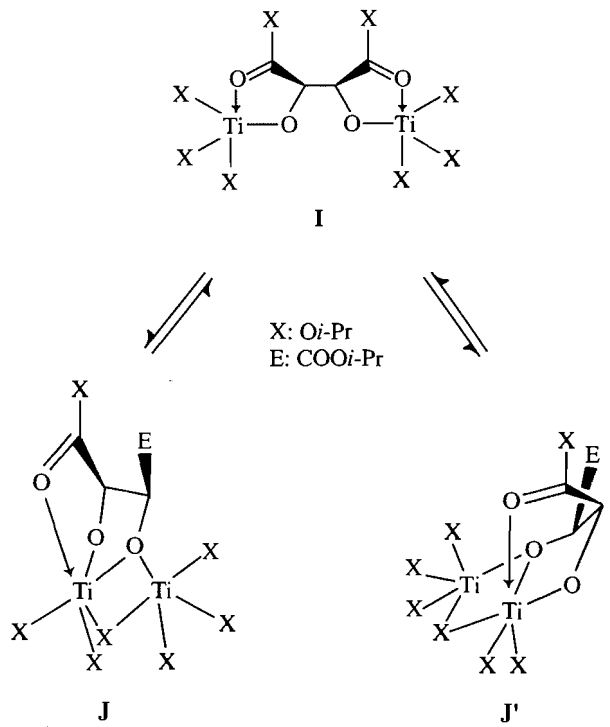
ppm was replaced at −30°C by two peaks at 86.0 and 82.6 ppm. SFD experiments at −50°C established that the former correlated to the downfield OC*H* and the latter to the upfield one. Three signals due to $LTiOCMe_2$ were found. Of these, the most upfield (at 71.1 ppm) was the smallest. Additionally, two distinct widely spaced singlets appeared in the *C*═O region, one strongly downfield (by 8.5 ppm) of the *C*═O peak in free DIPT. These data clearly indicate a radical change in structure upon cooling, from a symmetric form that resembled the 2:2 complex to a slightly asymmetric form of the same complex, and finally to a highly asymmetric complex.

Here again, combinations of bridging and terminal diolates

G G' H H'



can be postulated for the low temperature species (structures **H**/**H**′), with both bound and free side chains. Clearly, the matched pairs of ^1H and ^{13}C signals indicate that single species were formed. The asymmetry and the lack of equilibration argue for a stiffened cyclic structure. The H–H coupling constant (0 Hz) was consistent with a five-membered envelope ring in which side-chain binding brings the attached ring C out of plane, affording a ca. 90° H—H dihedral angle. On the other hand, the difference between central OC*H* signals was smaller (1.3 ppm) than in the sugar complexes (3.5–6.3 ppm). This can be interpreted to have arisen from an overall increase in electron density at the metal centres owing to the more strongly electron-donating side chains. In contrast, the relatively far upfield position of one OC*H* signal, seen only in this cold complex, can be explained by H_2 in **H** finding itself in the shielding cone of the "inward"-oriented Ti-bound C=O. No satisfactory explanation can be put forth using other structural arrangements. The presence of O^{i}Pr bridges was suggested by analogy with the sugars and with the solid-state structures (10), wherein a planar bicyclic core confers a rigidity that disallows side-chain exchange or binding of both side chains, yet allows pentacoordination at one metal centre and hexacoordination at the other. This suggestion was supported by the presence of an upfield OC*H*Me$_2$ signal. The other TiOC*H*Me$_2$ signals were downfield and reminiscent of the *axial*/*equatorial* pair seen with the sugars.

Reasonable intermediates in the **H**–**H**′ interconversion and plausible structures for the warm 1:2 complex are **G** and **G**′, formed from **H**/**H**′ by the breaking of two dative bonds. According to models, the cyclic structure of **G** precludes the simultaneous binding of both side chains. Evidence for the side-chain binding or for the O^{i}Pr bridge in **G**/**G**′ was blurred by rapid exchanges above −19°C, the presence of 2:2 complex at room temperature, and by the presence of the low temperature species below −10°C. An acyclic complex is also possible, as had been originally proposed (6, 7), with both side chains feasibly binding to one metal each (12). However, the transformation of such a structure to the low temperature species (**H**/**H**′) would involve the concerted breaking and forming of three bonds. Moreover, it cannot help explain the apparent slight instability with respect to the 2:2 complex and free Ti(O^{i}Pr)$_4$ (eq. [2]). Instead we postulate a slight instability in the seven-membered ring of **G**/**G**′. Reversible extrusion of Ti(O^{i}Pr)$_4$, or reversible ring opening and exchange with HO^{i}Pr, would lead to the 2:2 complex.

Complexes of meso-*DIPT*

The upfield shift of one OC*H* signal seen in the cold 1:2 *R*,*R* complex (**H**) was explained by a shielding by the neighbouring Ti-bound ester group. As this would only be expected with the chiral tartrate, the *meso* analogue was prepared and examined to verify this hypothesis. Indeed, an analogous complex formed and no strong upfield shift occurred. The ^1H nmr spectrum of the 1:2 *meso* complex at room temperature included a singlet OC*H* at 5.25 ppm, which was replaced upon cooling by two well-separated OC*H* doublets at 5.35 and 5.17 ppm (cf. Δδ 0.44 ppm in the *R*,*R* case) that persisted down to −50°C. Similarly, the lone ester heptet at room temperature (at 5.01 ppm) broadened, and was replaced by two heptets (at 5.02 and 4.94 ppm) over the range −10°C to −20°C. In fact, coalescence seemed to occur near 0°C, with the room temperature ^1H and ^{13}C nmr signals at rough averages of the low temperature positions.

These and other data supported the assignment of structure **J**/**J**′ to the low temperature *meso* complex, in complete analogy to structures **H**/**H**′. Well-separated *C*O peaks, one strongly

I J J'

shifted downfield of the free ligand position (none were seen at room temperature due to extensive broadening above −10°C), and the distinct ester OC*H* and OC*H* signals argued for one Ti-bound side chain per ligand moiety. Well-separated OC*H* signals (Δδ = 2.9 ppm, approaching the spread seen in the sugar complexes) were consistent with a bridging diolate. The H–H coupling (J = 4.6 Hz at −20°C) was also consistent with the ca. 30° dihedral angle expected for a five-membered envelope in which side-chain binding brings the attached diolate carbon out of plane. Additionally, four TiOC*H*Me$_2$ signals were seen at

For personal use only.

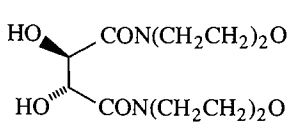
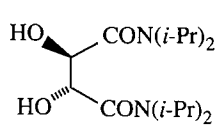
−50°C, replacing the one at room temperature, and one was significantly upfield of the others, as expected for a bridging O^{i}Pr.

The coalescence phenomenon suggested that the interconversion between **J** and **J′** may be faster than between **H** and **H′** as both side chains can bind in an analogous transitory (but undetected) intermediate **I**. A minor species was also present at room temperature but this was not due to an intermediate in the interconversion of **J** and **J′**, as its signals remained sharp at all temperatures.



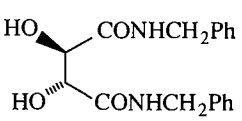
As might be expected, the 1:1 *meso*-DIPT–Ti(O^{i}Pr)$_4$ mixture gave complex spectra, featuring several doublet and AB quartet patterns in the OC*H* region. From low temperature ^{1}H and ^{13}C spectra, at least five different ligand types could be discerned and side-chain exchange was slow or absent in these, but no useful assignments could be made.

Complexes of tartramides

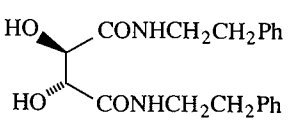


The behaviour of the tartramides was completely different from the foregoing. Little information was gained with the tertiary varieties. The $CDCl_3$-soluble *N,N,N′,N′*-tetraisopropyl tartramide (TIPT) gave an insoluble, likely polymeric, material upon treatment with Ti(O^{i}Pr)$_4$, while the $CDCl_3$-insoluble tartaryl bis-morpholide (TBM) very slowly dissolved only in the presence of two equivalents of Ti(O^{i}Pr)$_4$. Even after aging several days — tartramides form complexes more slowly than tartrates (7) — its spectra were broad, ill resolved, and uninformative.

N,N′-Dibenzyl tartramide (DBT), also $CDCl_3$-insoluble, dissolved in ca. 1 h after treatment with equimolar Ti(O^{i}Pr)$_4$, but gave similarly ill-resolved spectra (Fig. 3A), as did the 1:1 *N,N′*-di(2-phenylethyl) tartramide (DPET) mixture. The shapes of the OC*H* signals were time-, temperature-, and concentration-dependent, but prolonged aging, heating, or cooling failed to simplify the spectra (Fig. 3B) while tenfold dilution did so only temporarily (Fig. 3C). No useful assignments could be made, however. Incomplete reaction was not to blame as only a trace of unreacted Ti(O^{i}Pr)$_4$ could be detected (Fig. 3A). The ^{13}C signals were also broad, weak, and numerous. The 2:2 DBT complex had been crystallized for X-ray studies (10) by evaporation of liberated HO^{i}Pr and trituration with ether. In our hands, the solid product so obtained displayed similarly broad spectra after redissolution in $CDCl_3$. These observations suggested slowly equilibrating mixtures of species. The measured solution molecular weight (7) and the X-ray crystal structure (10) support a 2:2 molecularity for the 1:1 DBT mixture. However, this does not exclude the possibility of a concentration-dependent range of molecularities whose average molecular weight approaches that of the crystalline dimer.



When excess Ti(O^{i}Pr)$_4$ was added to the secondary amide mixtures (up to and beyond 1:2 stoichiometry), the spectra



TBM

TIPT

DBT

DPET

became progressively sharper until a dominant set of ligand resonances appeared, evidently due to a single asymmetric complex (Fig. 3D). Other smaller broad resonances persisted at room temperature but slowly disappeared upon progressive cooling. Unreacted Ti(O^{i}Pr)$_4$ was present in significant amounts, indicating that the single dominant species was not of 1:2 stoichiometry. Signal integration was difficult in the DBT case due to overlapping signals but was clearer with DPET, and revealed that the dominant species could not be a 2:2 species as it had been with the 1:2 sugar mixtures. Rather, the integration ratios more aptly fit an equimolar mixture of 2:3 complex and unreacted Ti(O^{i}Pr)$_4$, according to

[4] $2H_2L + 4\,Ti(O^iPr)_4 \rightarrow L_2Ti_3(O^iPr)_8 + Ti(O^iPr)_4 + 4HO^iPr.$

[5] $L_2Ti_2(O^iPr)_4 + Ti(O^iPr)_4 \leftrightarrow L_2Ti_3(O^iPr)_8$

Equilibrium [5] was evidently operative; the value of the equilibrium constant was large but could not be estimated by integration due to signal overlaps. Mass spectrometry was unfortunately not very instructive, only confirming the presence of Ti(O^{i}Pr)$_4$ and showing extensive fragmentation (with no ions above *m / z* 501 in the DBT case). This result does not contradict the measured solution molecular weight of the 1:2 DBT mixture (7) since the number-average molecular weight (discounting volatile HO^{i}Pr) according to eq. [4] is exactly the same as that expected for a 1:2 complex. Small amounts of 2:2 complex, as suggested by minor OC*H* resonances, would increase the average molecular weight somewhat. Indeed, the measured molecular weight (819) of the 1:2 DBT mixture exceeded that expected (7) by 42 mass units.

These apparent 2:3 complexes showed the same kind of slight asymmetry that the DIPT complexes showed at moderately low temperatures. Again, small differences in OC*H* or O*C*H shifts, with values close to the downfield OCH signals in the cold 1:2 *R,R*-DIPT complex and to the upfield OCH signals in the 2:2 sugar complexes, and the evidently strong (nonequilibrating) side-chain binding pointed to terminal diolates. Again, side-chain binding exerted only a small effect on the central nuclei.

Most of the signals changed little upon cooling to −50°C; the postulated 2:3 species remained dominant throughout. However, the central OC*H* and *C*=O signals underwent interesting changes. In the case of DPET, the central OC*H* appeared as an AB system at room temperature (Fig. 3D), but as a singlet at −30°C (Fig. 3F). Strong coupling was still evident at intermediate temperatures (Fig. 3E). A new, broad TiOC*H*Me$_2$ signal appeared just upfield of the Ti(OC*H*Me$_2$)$_4$ signal and accounted for one proton per ligand. As well, a TiOCHMe$_2$ signal upfield of Ti(OCHMe$_2$)$_4$ appeared weak and broad at room temperature, but strong and sharp at −10°C. Meanwhile, there were two *C*=O signals at room temperature, one strongly downfield of the free ligand position, but the downfield partner decreased upon cooling and disappeared entirely at −30°C. At −50°C, almost all of the signals suddenly shifted upfield while the proportion of HO^{i}Pr increased, perhaps indicating some aggregation and (or) precipitation. However, a weak downfield *C*=O signal had reappeared. The case of DBT was more dramatic: the room temperature OC*H* AB quartet similarly collapsed to a singlet over the range −10°C to −30°C, but became a new AB quartet below −42°C. Meanwhile, a broad TiOC*H*Me$_2$ had appeared upfield of Ti(OC*H*Me$_2$)$_4$ in this case as well. Similarly, the downfield *C*=O signal gradually disappeared below −10°C, was completely absent at −30°C, then started to reappear at −50°C. Yet the complexes remained asymmetric

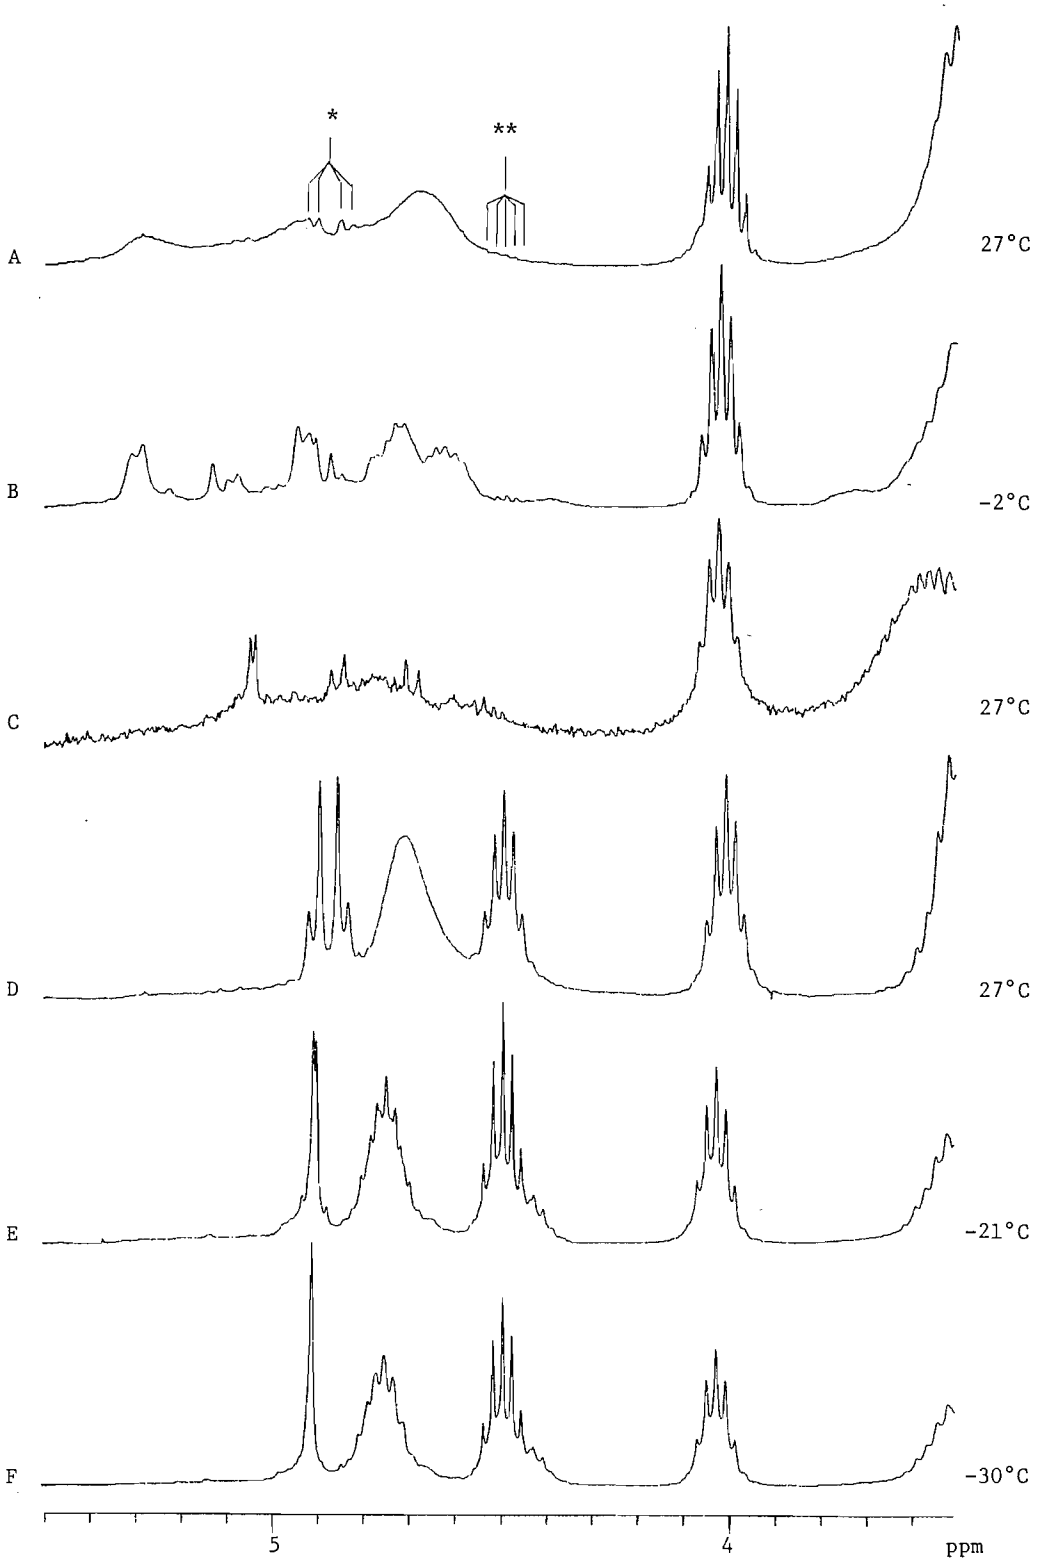

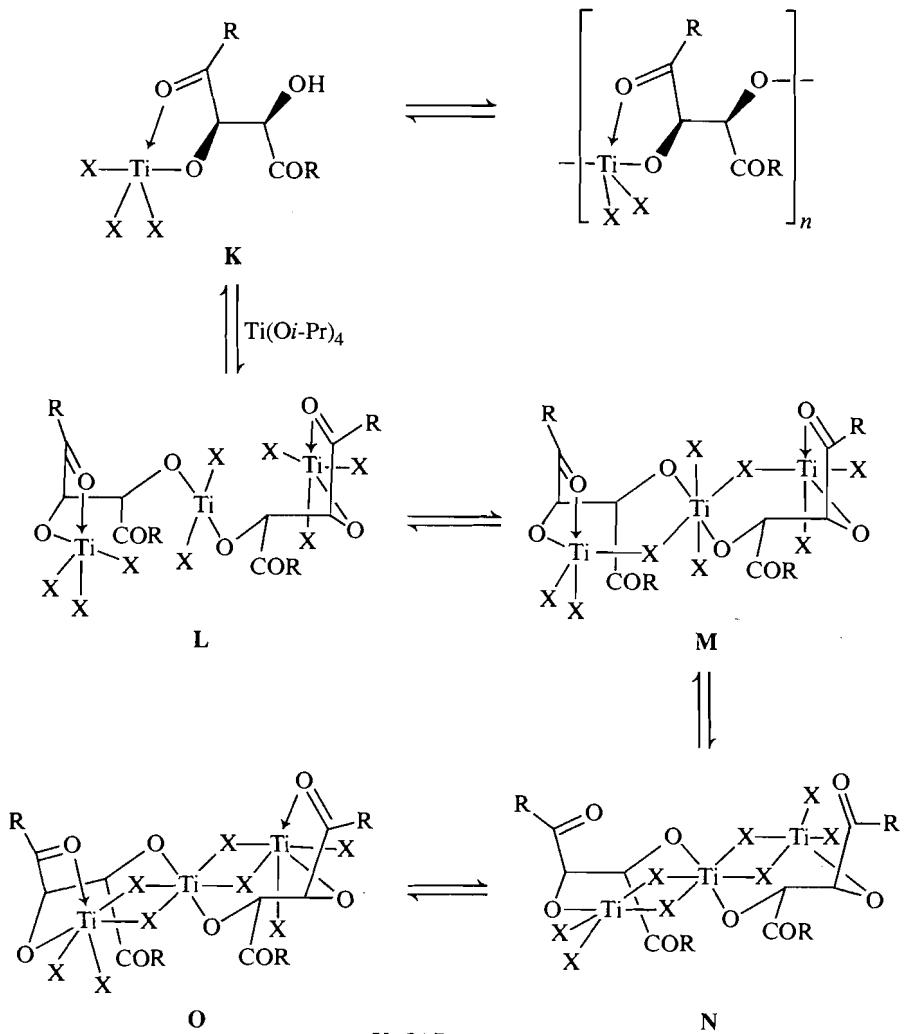

FIG. 3. OCH regions of ^{1}H nmr spectra taken at the indicated temperatures of DPET complexes with 1 (A–C) and 2 (D–F) equivalents of $Ti(O^iPr)_4$ (refer to text). Spectrum C taken approximately 15 min after tenfold dilution of the sample that gave spectrum A. Starred and double-starred patterns in spectrum A overlap with the AB pattern and the $Ti(O^iPr)_4$ heptet of spectrum D, respectively. Peaks on the far right are part of the $NHCH_2$ multiplet.

throughout, as pairs of signals were seen for all other ligand nuclei. The presence of pairs of N*H* triplets throughout indicated that no ionization of the side chains was occurring, contrary to suggestion (7). The collapse of the AB quartets was then due to a fortuitous overlap, rather than a gain in symmetry.

These observations are consistent with centro-symmetric Ti–L–Ti–L–Ti arrays that impose ligand asymmetry irrespective of the binding or nonbinding of the side chains, and support the 2:3 ligand–Ti stoichiometry deduced from signal integration. The changes observed upon cooling were suggestive of a step-

wise reorganization in which the loss of side-chain binding at an intermediate step was compensated by the formation of an O^{i}Pr bridge, as was postulated to occur in the 2:2 tartrate complex, and supported by upfield TiO*C*HMe$_2$ and TiOC*H*Me$_2$ signals.

Species **L***a*, *b*, containing tetracoordinate Ti, can explain why well-defined complexes are formed only in the presence of excess Ti(O^{i}Pr)$_4$, by the "trapping" of putative acyclic 1:1 complexes **K***a*, *b*. Tetracoordination at room temperature was suggested because an equilibrium (eq. [5]) was operative, and the formation of the 2:3 species was evidently not favoured by a strong chelate effect. Species **K** are possible components of the 1:1 mixtures because the strong side-chain binding in tartramides can kinetically and thermodynamically stabilize monomeric species like **K** relative to higher molecularities, and acyclic forms relative to cyclic ones. Upon cooling, O^{i}Pr bridges offer stabilization, forming rigid structures **M***a*, *b* by −10°C. These are formulated by analogy to the warm 1:2 *R*,*R*-DIPT complex **G**/**G**′ and the cold 2:2 complex **E**/**E**′, and involve slightly unstable seven-membered rings, as with **G**/**G**′. Upon further cooling, two-step loss of side-chain binding occurs, with new bridges forming in intermediates **N***a*, *b*, but the fortuitous overlap of central OC*H* may occur somewhat earlier on the path from **M** to **N**. Finally, further cooling of the DBT complex affords **O***a*, also in two steps.

Discussion

Prior to this work, some nmr studies on Ti^{4+} alkoxides had been published. Generally, tetraalkoxides can aggregate when the alkoxides are primary (28, 29), either in solution or neat. Secondary alkoxides remain monomeric, at least in benzene solution (30), but solid 1:1 adducts with netural electron donors are known (31–33). Dilution of a decalin solution of Ti(O^{i}Pr)$_4$ caused the OC*H* signal to shift upfield. This was interpreted in terms of a fast dimer–monomer equilibrium with rapid terminal-bridging exchange. The dimer, with a higher average coordination number, would have the more downfield position (28). An earlier study with ethanolamine complexes confirmed this (34). Opposite concentration-dependent displacements occurred in aromatic solvents (35). The ^{13}C signals of Ti(O^{i}Pr)$_4$ did not change with temperature in $CDCl_3$ (36), but the bridging-terminal exchange was frozen at −90°C in methylcyclohexane-d_{14}, whence the signal for bridging O^{i}Pr was upfield of the terminal one (37).[5] The bridging OCH_3 signals of Ti(OCH$_3$)$_4$ were found upfield (in $CDCl_3$) of those for terminal OCH$_3$ but downfield in benzene-d_6 (11), but solvent impurities may have been responsible for both the dissolution of the normally insoluble (and polymeric) Ti(OCH$_3$)$_4$ and the effects on the chemical

shift (35). Although this should alert us to possible interference by liberated HO^{i}Pr, we found no displacement of its OC*H* or O*C*H signals, only broadening indicative of its participation in exchanges with Ti-bound and ester O^{i}Pr. With some exceptions, the TiOC*H*Me$_2$ and TiO*C*HMe$_2$ signals observed in all our complexes were downfield of those in Ti(O^{i}Pr)$_4$, indicating an increase in average coordination number in each case (28, 34). Upfield TiO*C*HMe$_2$ signals were taken to indicate bridging O^{i}Pr in slow or frozen exchange with terminal O^{i}Pr.

In assigning structures in this study, the most telling data concern the chiral ligands, but little could be inferred with as much certainty about the geometries at the metal centres or about the O^{i}Pr ligands. However incomplete, the structural picture emerging from our analysis of the available nmr, ir, and ms data can account for the existence of equilibria [2] and [5] and for the lack of well-defined complexes in the 1:1 tartramide mixtures, and is consistent with the different side-chain binding abilities expected from the three classes of ligand.

Certain generalizations could then be made about chiral alkoxides as a result: (a) with mannitol skeletons, secondary ether groups bind in preference to primary ones; (b) with tartaric acid skeletons, only one side chain can bind at a time; (c) the effect on diolate shifts due to side-chain binding is small compared to that due to binding a second metal centre in forming a diolate bridge; and (d) isopropoxide bridging affords greater stabilization than does side-chain binding. Overall, the complexes studied fall into two broad categories: those that gave strongly asymmetric ligand signals, and those whose spectra were symmetrical or slightly asymmetric. Some effects on structure might be anticipated from differences in the nature of the side chains. Certainly, the steric bulk in the tertiary amides might be at the source of their reluctance to form single, well-defined, and soluble complexes at any stoichiometry. Poor side-chain binding in the sugar complexes (**A**) may explain their need to form strong diolate bridges and hexacoordinate metal centres at 1:1 stoichiometry, as well as their reluctance to form 1:2 complexes as the side chains compete poorly with the alkoxide bridges. Moderate side-chain binding by tartrates can apparently stabilize pentacoordinate Ti in a cyclic dimer, but O^{i}Pr bridging apparently affords greater stabilization at lower temperatures (**D** → **E**). It can be argued that such bridging was preferred in the 1:2 *R*,*R*-DIPT complex as well: where there was an opportunity to bind both ester side chains at two pentacoordinate Ti centres, a bridged cyclic form seemed to have formed instead with only one side-chain binding at a time (**G**). Such bridging was also preferred in the 2:3 secondary tartramide complexes, where, in addition, a second bridge seemed to form at lower temperatures to replace side-chain binding (**M** → **N**). As related above, the 1:1 tartramide mixtures may have consisted of many slowly equilibrating acyclic or cyclic structures. The insolubility and the presumed oligomeric nature of the TIPT complex and the reluctance of TBM to complex suggest that [L–Ti]$_n$ arrays may have formed with all tartramides, consistent with Ti–L–Ti–L–Ti arrays predominating with the secondary tartramides in the presence of excess Ti(O^{i}Pr)$_4$. Slowly evolving side-chain binding, with little difference in stability between the isomers, could account for the unresolved spectra. We are currently testing the hypothesis that these ligands may nevertheless form well-defined 1:1 or 2:2 complexes under conditions of kinetic control.

Some important lessons can be drawn from this work. Comparisons between complexes with similar ligands are important, because solution data can be mistakenly interpreted as being in agreement with crystal structure data (2, 3). We were fortunate in that the sugar complexes provided the spectra expected from the crystal data while the tartrate complex did not, and thereby piqued our curiosity. As well, the examination of more than one stoichiometry and of temperature dependence proved valuable in arriving at structures integrating with all of the data. More cursory study led to an erroneous conclusion (12). As well, molecular weight determinations can be misleading, as demonstrated with the 1:2 *R*,*R*-DIPT and tartramide mixtures. We therefore consider spectroscopic tools more valuable than crystal structures and molecular weight measurements.

These considerations are especially valid if mechanistic postulates concerning homogeneous catalysis are to be formulated. While this study cannot directly address the mechanism of the Sharpless reaction, especially since the structure of the active catalysts may change in the presence of the substrate and the oxidant, the current hypotheses concerning both 2:2 (3, 20) and 1:2 (7) ligand–Ti mixtures have been thrown into question. The results of epoxidations with the non-tartrate ligands and the implications of the nmr results on the mechanisms of Sharpless epoxidations will be dealt with elsewhere. Finally, the existence of mixtures of complexes in temperature-, concentration-, and time-dependent ratios, as demonstrated in 1:2 *R*,*R*-DIPT and in 2:2 tartramide complexes, clearly points to strong influences of reaction conditions and catalyst aging times on the stereochemical course.

With respect to our design goal, the sugar complexes do not reproduce the successful chiral environment of tartrate complexes. New base- and nucleophile-stable ligands are currently being studied for this purpose. Further work is also underway using mixed ligand complexes and with dichloro complexes to study the effect of electronegative substituents.

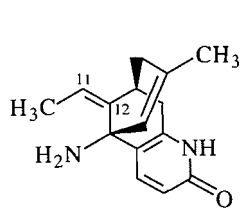
WILLIAM A. AYER, LOIS M. BROWNE, HELENA ORSZANSKA, ZDENEK VALENTA, and JIA-SEN LIU. Can. J. Chem. **67**, 1538 (1989).

Selagine, an alkaloid of *Lycopodium selago*, is shown to be identical with huperzine A (**2**). A minor alkaloid, $C_{15}H_{18}N_2O_2$, isolated from *L. selago* is found to be 6β-hydroxyhuperzine A (**4**).

Key words: huperzine A, selagine, Lycopodium alkaloids, Alzheimer's disease, acetylcholine esterase inhibitor.

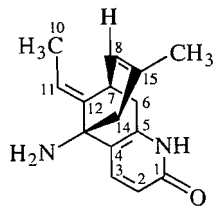
WILLIAM A. AYER, LOIS M. BROWNE, HELENA ORSZANSKA, ZDENEK VALENTA et JIA-SEN LIU. Can. J. Chem. **67**, 1538 (1989).

On a démontré que la sélagine, un alcaloïde du *Lycopodium selago*, est identique à l'huperzine A (**2**). On a trouvé qu'un alcaloïde mineur, $C_{15}H_{18}N_2O_2$, isolé du *L. selago* est la 6β-hydroxyhuperzine A (**4**).



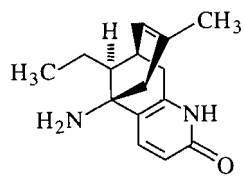
Mots clés : huperzine A, selagine, alcaloïdes Lycopodium, maladie d'Alzhéimer, agent inhibiteur d'acétylcholine estérase.
[Traduit par la revue]

Introduction



In 1960, Wiesner and co-workers proposed structure **1** for selagine, an alkaloid isolated from *Lycopodium selago* L. (1, 2). In 1986, Liu *et al.* reported the structure of huperzine A (**2**), an alkaloid isolated from *Lycopodium serratum* Thunb. (= *Huperzia serrata* (Thunb.) Trev.), a plant used in Chinese folk medicine (3). Huperzine A (**2**) shows very strong anticholinesterase activity and markedly increases efficiency for learning and memory in animals (3). The use of huperzine A (**2**) in the treatment of myasthenia gravis and Alzheimer's disease is currently under clinical investigation in China (4). Because of the structural similarity of selagine (**1**) and huperzine A (**2**), the Alberta group has reinvestigated the alkaloids of *L. selago* to obtain selagine in order to determine its anticholinesterase activity. We report herein the isolation of selagine and the finding that selagine is identical with huperzine A (**2**). The structure of a hydroxy derivative of huperzine A, originally isolated by the New Brunswick group in 1960, is also reported.

Results and discussion



Lycopodium selago was collected near Grovelsjon and near Tarna in Sweden,[2] in the Tonquin valley near Jasper, Alberta, and near Summit Lake in northern British Columbia.[3] The dried plant material was extracted with 2% aqueous tartaric acid. The crude alkaloid fraction was dissolved in chloroform and the pyridone (hydroxypyridine) alkaloids were extracted into dilute aqueous sodium hydroxide. Separation of the crude phenolic alkaloids was achieved by preparative thin-layer chromatography over silica gel. Crystallization from acetone provided a pure compound, mp 214–215°C, $[\alpha]_D$ −147°, identical with an authentic sample of selagine *and identical with* an authentic sample of huperzine A (**2**). A nuclear Overhauser enhancement (nOe) experiment confirmed the proximity of the C-10 methyl (δ 1.70) to the allylic C-7 hydrogen (δ 3.60) and spin decoupling experiments revealed that this allylic hydrogen was coupled (J = 5 Hz) to the C-8 alkenic hydrogen. This coupling was not

detected in the 60-MHz spectrum of selagine recorded by the earlier workers (1, 2). The stereochemistry at C-11 was not proposed in the original papers on selagine (1, 2) but was assigned as shown in **1** on the basis of a study of the rate of methiodide formation (5). Catalytic hydrogenation (over PtO_2) of the "selagine" isolated from *L. selago* provided the dihydro derivative **3**, identical in spectroscopic properties with 11,12-dihydrohuperzine A (**3**) (3). Observation of an nOe effect between the hydrogen at C-12 and the α-hydrogen at C-6 allows the assignment of stereochemistry at C-12.

During the search for an authentic sample of selagine among the late Prof. Wiesner's Lycopodium alkaloid samples we discovered a sample code named selagine-II.[4] High resolution mass spectrometry (hrms) indicated a molecular formula of $C_{15}H_{18}N_2O_2$ and the ultraviolet (uv) spectrum (λ_{max} 238, 302, 331 nm) was very similar to that of huperzine A (**2**). The infrared (ir) spectrum showed characteristic α-pyridone absorption (ν_{max} 1664, 1643, 1605, 1544 cm^{-1}). The ^1H nmr and ^{13}C nmr spectra indicate that this alkaloid is 6-β-hydroxyhuperzine A (**4**). The ^1H nmr spectrum shows the presence of the two alkenic methyls (doublet at δ 1.66 (J = 7 Hz), singlet at δ 1.56), the two α-pyridone hydrogens (δ 7.88 and 6.40, J = 9 Hz), the C-8 alkenic hydrogen (δ 5.56, d, J = 5 Hz), and the C-11 alkenic hydrogen (δ 5.52, q, J = 7 Hz), all with chemical shifts and couplings similar to those observed with huperzine A (3). The nOe experiments demonstrated the proximity of the C-10 methyl group to the allylic C-7 hydrogen (δ 3.74, dd, J = 5 and 5.5 Hz). The C-7 hydrogen is also coupled to a signal at δ 4.68 (d, J = 5.5 Hz), which is assigned to the benzylic carbinyl hydrogen at C-6. This result locates the position of the hydroxyl group in this alkaloid. The size of the coupling between H-6 and H-7 (5.5 Hz) indicates that the hydroxyl group has the β orientation (3). Oxidation of **4** with Jones' reagent *or* manganese dioxide provided the ketone **5** (ν_{max} 1694, 1662, 1600 cm^{-1}; λ_{max} 238, 260, 353 nm). The signal for the hydrogen at C-7 now appears as a doublet (J = 5.0 Hz) at δ 4.24. The coupling to the C-8 (δ 5.42, J = 5.0 Hz) hydrogen was confirmed by spin decoupling, confirming the position of the endocyclic double bond.

A compound assigned structure **6** and named isoselagine has been reported from *L. serratum* Thunb. var. *longipetiolatum* Spring (7). We have compared infrared, ^1H nmr, and ^{13}C nmr spectra of this alkaloid[5] with those of huperzine A and find that they are virtually identical. In veiw of this we suggest that isoselagine (lit. (7) mp 228–229°C; $[\alpha]_D$ −96°) may also be identical with huperzine A.

In view of the identity of selagine with huperzine A, we suggest that the name huperzine A be retained for the alkaloid possessing structure **2**.

Experimental

General

High resolution electron impact mass spectra (hrms) were recorded on an AEI MS-50 mass spectrometer. Unless diagnostically significant, only those peaks with an intensity of >20% of the base peak are recorded. Chemical ionization mass spectra (cims) were obtained using an AEI MS-12 mass spectrometer with ammonia as the reagent gas. The data were processed using DS-55 software and a Nova-4 computer. Fourier transform infrared (Ftir) spectra were recorded on a Nicolet 7199 FTIR interferometer. Nuclear magnetic resonance (nmr) spectra (^1H and ^{13}C) were obtained on Bruker WP-80, WH-300, and WM-360 spectrometers with either Aspect 2000 or Aspect 3000 computer systems. ^1H chemical shifts and coupling constants are reported as if they are first order. Tetramethylsilane was used as an internal standard. Ultraviolet (uv) spectra were obtained on a Hewlett Packard 8450A Diode Array spectrophotometer and optical rotations on a Perkin Elmer 241 polarimeter. Melting points are uncorrected and were determined on a Leitz Wetzler melting point apparatus. Preparative thin-layer chromatography (ptlc) was performed on E. Merck precoated 20 × 20 glass plates of silica gel 60 F-254. Analytical thin-layer chromatography (tlc) was carried out on cut sections of E. Merck precoated aluminum sheets of silica gel 60 F-254. Ultraviolet active materials were detected by visualization under a uv lamp (254 nm). All solvents were distilled prior to use.

Isolation of huperzine A (2)

Ground, dried *L. selago* (1.43 kg), collected near Summit Lake, B.C., was suspended in 2% aqueous tartaric acid (6 L) and the suspension stirred for 12 h, then filtered (cheese cloth). The process was repeated twice more. The combined extracts were filtered (Buchner funnel), concentrated to ca. one tenth volume, and extracted with chloroform (discarded). The aqueous layer was basified (aqueous ammonia) and extracted (5×) with chloroform, dried (Na_2SO_4), and concentrated to provide the crude alkaloids (8.4 g). These were dissolved in $CHCl_3$ and extracted with 1% aqueous NaOH (3×). The combined aqueous extracts were acidified (concentrated HCl) to pH ~2 and then basified with aqueous ammonia to pH ~12, then extracted with $CHCl_3$ (3×). This provided the crude phenolic alkaloids (1.77 g). Purification by ptlc afforded *huperzine A* (262 mg), which after crystallization from acetone melted at 214–215°C (lit. (3,6) mp 230°C, (1) 224–226°C); $[\alpha]_D$ −147° (*c* 0.36, CH_3OH) (lit. (3,6) $[\alpha]_D$ −150.4°, (1) −99°). The alkaloid isolated in this way was identical (^1H nmr and ^{13}C nmr, ir, tlc) with an authentic sample of huperzine A (3, 6), and with an authentic sample of selagine (^1H nmr, tlc).[6] The plant material collected near Jasper and that obtained from Sweden gave similar results.

Catalytic hydrogenation of huperzine A

Huperzine A (50 mg) in ethyl alcohol (7 mL) was stirred under hydrogen in the presence of Adams' catalyst (20 mg) at room temperature and atmospheric pressure for 2 h. The crude product was purified by ptlc over silica gel (eluent $CHCl_3$–CH_3OH (3:3)) to give a tacky oil (27 mg), which crystallized from methanol–acetone, mp 265°C (lit. (3,6) mp 269–270°C). The spectroscopic properties (ir, ^1H nmr, ^{13}C nmr, ms) are identical with those of dihydrohuperzine A (**3**) (6).

Isolation of 6β-hydroxyhuperzine A (4)[7]

The crude phenolic alkaloids (30 g) of *L. selago* (ca. 10 kg) were chromatographed over Florisil (500 g). Elution with $CHCl_3$ and $CHCl_3$–CH_3OH (up to 2% CH_3OH) provide huperzine A (as selagine, 8.6 g). Elution with $CHCl_3$–CH_3OH (19:1) gave material (3.2 g) that on crystallation from acetone provides 6β-hydroxyhuperzine A (as selagine-II, 0.58 g), mp 207–210°C after recrystallization from acetone–methanol. *Anal.* calcd. for $C_{15}H_{18}N_2O_2$: C 69.74, H 7.02, N 10.84, O 12.39%. found: C 69.88, H, 7.15, N 10.46, O 12.29%.

6β-Hydroxyhuperzine A (4): $[\alpha]_D$ −206° (*c* 0.37, CH_3OH); uv (CH_3OH) λ_{max} (log ε): 238 (3.83), 302 (3.74) nm; Ftir (KBr) ν_{max}: 3380, 1664, 1643, 1605, 1545 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.88 (1H, d, J = 9 Hz, H-3), 6.40 (1H, d, J = 9 Hz, H-2), 5.56 (1H, d, J = 5 Hz, H-8), 5.52 (1H, q, J = 7 Hz, H-1), 4.68 (1H, d, J = 5.5 Hz, H-6), 3.74

[4]The isolation of the compound, which is presented in the Experimental, is well described in the lab book of H. Yoshimura, a post-doctoral fellow with Prof. Wiesner in 1959–1960. This compound was not isolated from the *L. selago* examined in this study.

[5]Kindly provided by S. S. Lee, National Taiwan University.

[6]The only sample of selagine remaining in Prof. Wiesner's collection was in the form of a KBr pellet used for an infrared spectrum. The pellet was ground and the ground material was exhaustively washed with CH_2Cl_2. Evaporation provided sufficient material for a 360-MHz ^1H nmr spectrum. The spectrum thus obtained was identical with a spectrum of huperzine A determined on the same instrument.

[7]This is taken from the lab book of H. Yoshimura. See footnote 4.

(1H, dd, J = 5, 5.5 Hz, H-7), 2.12 (2H, bs, H-14), 1.66 (3H, d, J = 7 Hz, H-10), 1.56 (3H, s, H-16); ^{13}C nmr ($CDCl_3$) δ: 12.5 (C-10, signals assigned by multiplicity and by analogy with huperzine A (3, 6)), 22.9 (C-16), 39.9 (C-7), 49.7 (C-14), 54.9 (C-13), 71.1 (C-6), 113.5 (C-11), 118.3 (C-2), 120.3 (C-8), 123.0 (C-4), 135.7 (C-15), 140.5 (C-3), 141.3 (C-5), 145.5 (C-12), 164.8 (C-1); hrms (probe), m/z calcd. for $C_{15}H_{18}N_2O_2$ (M^+): 258.1369; found: 258.1366 (83), 243 (51), 241 (77), 212 (100, $C_{14}H_{14}NO$), 199 (25), 197 (26).

Oxidation of 6β-hydroxyhuperzine A

6β-Hydroxyhuperzine A (5 mg) was dissolved in acetone (2.5 mL), and Jones' reagent (3 drops) was added at room temperature. After 20 min the reaction mixture was diluted with water, basified with aqueous ammonia, and extracted with chloroform. Purification by ptlc (chloroform–methanol, 3:1) gave ketone **5** (2.4 mg) as a viscous oil. Ftir (film cast from $CHCl_3$) ν_{max}: 3360–3200, 1694, 1662, 1600 cm^{-1}; uv (CH_3OH) λ_{max} (log ε): 238 (3.42), 260 (3.41), 353 (3.37) nm; ^{1}H nmr ($CDCl_3$) δ: 7.98 (1H, d, J = 9 Hz), 6.76 (1H, d, J = 9 Hz), 5.64 (1H, q, J = 7 Hz), 5.42 (1H, d, J = Hz), 4.24 (1H, d, J = 5 Hz), 2.24 (2H, bs), 1.68 (3H, d, J = 7 Hz), 1.62 (3H, s); hrms (probe), m/z calcd. for $C_{15}H_{16}N_2O_2$: 256.1213; found: 256.1216 (100), 241 (48), 227 (22), 201 (18).

The same product was obtained, albeit in lower yield, when the oxidation was performed using manganese dioxide in chloroform.

Received March 17, 1989

H.-X. ZHANG, S. I. AHONKHAI, and M. H. BACK. Can. J. Chem. **67**, 1541 (1989).

Rate constants for the abstraction of hydrogen from benzene, toluene, and cyclopentane by methyl and ethyl radicals have been measured relative to the corresponding abstraction reaction from ethylene. The method is based on the effect on the rates of formation of methane and ethane of the addition of small quantities of the reactants to the thermal chain reactions of ethylene in the temperature range 650–770 K. Taking the following values of the rate constants for the reference reactions (R = 8.314 J mol^{-1} K^{-1}):

[3] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$; $\log k_3$ (L mol^{-1} s^{-1}) = 8.7 ± 0.2 − (63000 ± 3000)/2.3RT

[4] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$; $\log k_4$ (L mol^{-1} s^{-1}) = 8.2 ± 0.2 − (62200 ± 3000)/2.3RT

the following rate constants were measured:

[7] $CH_3 + C_6H_6 \rightarrow CH_4 + C_6H_5$; $\log k_7$ (L mol^{-1} s^{-1}) = 9.3 ± 0.3 − (63000 ± 5000)/2.3RT

[8] $C_2H_5 + C_6H_6 \rightarrow C_2H_6 + C_6H_5$; $\log k_8$ (L mol^{-1} s^{-1}) = 8.8 ± 0.3 − (62200 ± 5000)/2.3RT

[11] $CH_3 + C_7H_8 \rightarrow CH_4 + C_7H_7$; $\log k_{11}$ (L mol^{-1} s^{-1}) = 7.4 ± 0.5 − (29000 ± 7000)/2.3RT

[12] $C_2H_5 + C_7H_8 \rightarrow C_2H_6 + C_7H_7$; $\log k_{12}$ (L mol^{-1} s^{-1}) = 7.7 ± 0.5 − (37000 ± 7000)/2.3RT

[15] $CH_3 + c\text{-}C_5H_{10} \rightarrow CH_4 + c\text{-}C_5H_9$; $\log k_{15}$ (L mol^{-1} s^{-1}) = 8.3 ± 0.5 ± (36000 ± 7000)/2.3RT

[16] $C_2H_5 + c\text{-}C_5H_{10} \rightarrow C_2H_6 + c\text{-}C_5H_9$; $\log k_{16}$ (L mol^{-1} s^{-1}) = 8.2 ± 0.5 − (40000 ± 7000)/2.3RT

The values of the activation energies are discussed in relation to the dissociation energies of the C—H bonds in the reactants.

Key words: kinetics, abstraction, methyl, ethyl, benzene, toluene.

H.-X. ZHANG, S. I. AHONKHAI et M. H. BACK. Can. J. Chem. **67**, 1541 (1989).

On a mesuré les constantes de vitesse d'enlèvement d'hydrogène du benzène, du toluène et du cyclopentane par des radicaux méthyle et éthyle relatives à la réaction correspondante d'enlèvement à partir de l'éthylène. La méthode est basée sur l'effet, sur les vitesses de formation du méthane et de l'éthane, de l'addition de faibles quantités de réactifs à des réactions thermiques en chaîne de l'éthylène, à des températures allant de 650 à 770 K. En prenant les valeurs suivantes comme constantes de (R = 8,314 J mol^{-1} K^{-1}) :

[3] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$; $\log k_3$ (L mol^{-1} s^{-1}) = 8,7 ± 0,2 − (63000 ± 3000)/2,3RT

[4] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$; $\log k_4$ (L mol^{-1} s^{-1}) = 8,2 ± 0,2 − (62200 ± 3000)/2,3RT

on a mesuré les constantes de réaction suivantes :

[7] $CH_3 + C_6H_6 \rightarrow CH_4 + C_6H_5$; $\log k_7$ (L mol^{-1} s^{-1}) = 9,3 ± 0,3 − (63000 ± 5000)/2,3RT

[8] $C_2H_5 + C_6H_6 \rightarrow C_2H_6 + C_6H_5$; $\log k_8$ (L mol^{-1} s^{-1}) = 8,8 ± 0,3 − (62200 ± 5000)/2,3RT

[11] $CH_3 + C_7H_8 \rightarrow CH_4 + C_7H_7$; $\log k_{11}$ (L mol^{-1} s^{-1}) = 7,4 ± 0,5 − (29000 ± 7000)/2,3RT

[12] $C_2H_5 + C_7H_8 \rightarrow C_2H_6 + C_7H_7$; $\log k_{12}$ (L mol^{-1} s^{-1}) = 7,7 ± 0,5 − (37000 ± 7000)/2,3RT

[15] $CH_3 + c\text{-}C_5H_{10} \rightarrow CH_4 + c\text{-}C_5H_9$; $\log k_{15}$ (L mol^{-1} s^{-1}) = 8,3 ± 0,5 ± (36000 ± 7000)/2,3RT

[16] $C_2H_5 + c\text{-}C_5H_{10} \rightarrow C_2H_6 + c\text{-}C_5H_9$; $\log k_{16}$ (L mol^{-1} s^{-1}) = 8,2 ± 0,5 − (40000 ± 7000)/2,3RT

On discute des valeurs des énergies d'activation en relation avec les énergies de dissociation des liaisons C—H des réactifs.

Mots clés : cinétique, enlèvement, méthyle, éthyle, benzène, toluène.

[Traduit par la revue]

Introduction

Methods for the measurement of rate constants for hydrogen-transfer reactions for small radicals, represented for methyl and ethyl radicals by the following reactions,

[1] $CH_3 + RH \rightarrow CH_4 + R$

[2] $C_2H_5 + RH \rightarrow C_2H_6 + R$

have been developed and applied to a wide variety of systems during the past several decades (1, 2). Accurate and reliable values for such rate constants are important both for a fundamental understanding of the reaction and for use in the development of reaction mechanisms. For methyl and ethyl radicals in the low temperature region, <700 K, these rate

constants are generally measured relative to the rate of radical combination. In the high temperature region, >1000 K, methods for measurements of absolute values have been reported (3), but most measurements are made relative to a reference reaction, which may be a radical combination (4) or other radical reaction (5), or a thermal dissociation process (6). Values measured in these two regions are not always in agreement with an extrapolation of a simple Arrhenius expression and this problem has been discussed from different points of view (7–9). There is as yet little agreement on the most satisfactory functional form to describe the change in the rate constant with temperature or indeed whether the simple Arrhenius expression is inadequate, but all agree that more measurements are required, preferably in the range of temperature between the high and low regions. The present paper describes results that are a small step in this direction.

The method used involves the perturbation of the thermal chain reaction mechanism of ethylene by small quantities of additives at temperatures in the range 650–770 K. The method has been described previously for the systems involving ethylene with the additives hydrogen (10), ethane (11), propane, and isobutane (12) and will be only briefly summarized here. In this temperature region ethylene reacts by a complex series of chain reactions giving methane, ethane, propylene, and butene-1 as the main low molecular weight products. Studies of the kinetics of the reaction (13) showed that the saturated products, methane and ethane, were formed by the hydrogen transfer reactions,

[3] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

[4] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$

while the unsaturated products, propylene and butene-1, as well as butadiene and other higher molecular weight unsaturated products, were formed by isomerization and decomposition reactions following addition of radicals to ethylene. Addition of small quantities of a saturated hydrocarbon, such as those mentioned earlier, introduced new hydrogen transfer reactions, described by eqs. [1] and [2], and increased the rates of formation of methane and ethane, but did not affect the rates of formation of propylene and butene-1 and other products formed through addition of radicals to ethylene. On the assumption that the additive did not undergo thermal dissociation and hence increase the total radical concentration in the system, the ratio of the initial rates of formation of methane and ethane in the presence and absence of the additive were given by the following expressions:

$$[5] \quad \frac{(R^0_{CH_4})_a}{R^0_{CH_4}} = 1 + \frac{k_1[RH]}{k_3[C_2H_4]}$$

$$[6] \quad \frac{(R^0_{C_2H_6})_a}{R^0_{C_2H_6}} = 1 + \frac{k_2[RH]}{k_4[C_2H_4]}$$

It was also assumed that the additive did not alter the relative concentration of the main chain-carrying radicals or the termination steps. This is a reasonable assumption since the amount of additive was usually less than 10% and no new products were introduced.

From the measurements with the additives mentioned, ratios of k_1/k_3 and k_2/k_4 were obtained and, using the values of k_1 and k_2 corresponding to the particular additive, values for k_3 and k_4 were calculated. The present study has made use of these measurements for k_3 and k_4 to obtain values for rate constants for abstraction reactions using additives for which, particularly in this region of temperature, fewer, or, in the case of the ethyl radicals, no data have been reported. The additives used were benzene, toluene, and cyclopentane.

Experimental

The thermal reactions were performed in a conventional static pyrolysis system, similar to that described previously (14). The quartz reaction vessel (volume 0.21 L, S/V 1 cm^{-1}) was enclosed in a stainless steel cylinder and heated by a three-zone Lindberg cylindrical furnace. The temperature gradient along the length of the vessel was less than one degree and temperatures were controlled to within one degree. Mixtures of gases were prepared by admitting first a low pressure of additive followed by a high pressure of ethylene. In the spherical mixing flasks with minimum connecting tubing this procedure induced good mixing currents. Reactants were thoroughly degased in small quantities before mixing and were not condensed after mixing.

For the purpose of the present experiments analysis of only the four major products, methane, ethane, propylene, and butene-1, was necessary. Measurements of the relative rates of formation of methane and ethane in the presence and absence of the additive gave values for the ratios k_1/k_3 and k_2/k_4, while measurements of the yields of propylene and butene-1 served to show that no new initiation processes occurred in the presence of the additive. The products were analyzed by a gas chromatography using a Durapak column (phenylisocyanate on Porasil C) 3.4 m × 4 mm maintained at 30°C. Both benzene and toluene are retained for long periods of time on this column and the carrier gas was allowed to flow overnight to clean the column. Cyclopentane was eluted at the same time as butene-1 and this product was therefore not analyzed in experiments with cyclopentane as additive.

Ethylene was Research Grade reagent from Matheson Co., Whitby, Ont., L1N 5R9, and was thoroughly degassed before each experiment. The only measurable impurity was about 50 ppm ethane (amounts too small to affect the chain reaction mechanism) but correction was made to the yield of ethane produced in the reaction. Benzene and toluene were "assured ACS" grade, low in sulphur-containing compounds, purchased from BDH, Toronto, Ont. An impurity of cyclopentane, 0.3% was detected by gas chromatographic analysis in the benzene. No comparable impurities were detected in the toluene. Cyclopentane was obtained from two sources. Preliminary experiments were performed with reagent of purity 99.5% from Tridom/Fluka (Mandel Scientific, Montreal, P.Q.) while for most experiments cyclopentane of purity 99.9% from Wiley Organics, Coshocton, Ohio, was used. Impurities of concern in these reagents were compounds with an easily abstractable hydrogen atom, so that small quantities could compete with the reactant in the hydrogen transfer reactions. In the case of toluene, hydrogen transfer is very rapid and hydrocarbon impurities in small quantities should not affect the results. For benzene, the cyclopentane impurity was too low to compete significantly for reactions with methyl and ethyl radicals, although other impurities (not detected) could have contributed to the formation of methane or ethane. Such an error would yield a rate constant too large and an activation energy too low. As seen later, this does not appear to be a problem with the present results. In cyclopentane, the impurity of cyclopentene was a cause for concern, since abstraction from cyclopentene may be 50 times faster than from cyclopentane. With amounts of cyclopentene not greater than 0.1%, however, its effect on the rate of formation of methane or ethane should have been unimportant.

Results

As evident from eqs. [5] and [6] the important measurement for the determination of the ratio of rate constants is the ratio of rates in the presence and absence of the additive. Two approaches to this measurement have been adopted and have been described in previous studies (10–12). In the first method a single measurement of the rate of formation of products in pure ethylene was followed by a similar measurement on the mixture

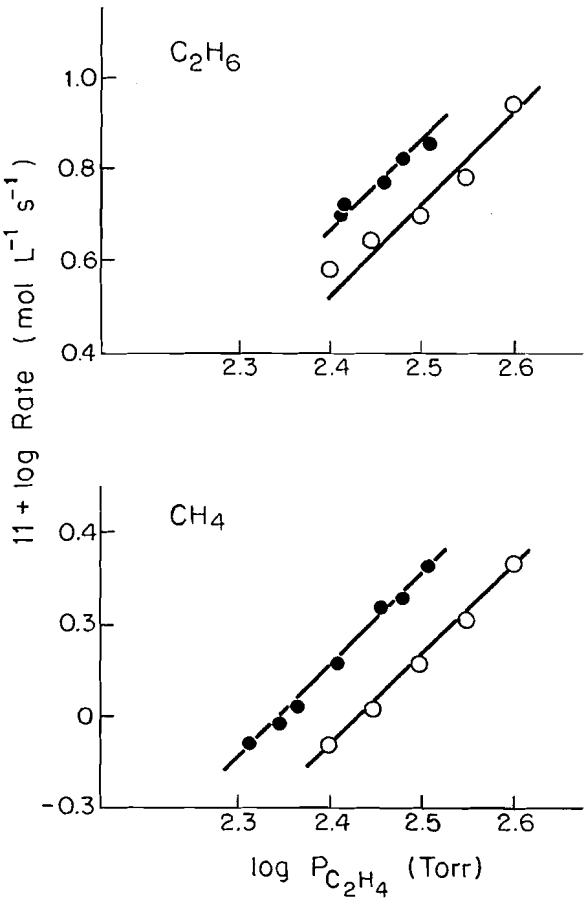

FIG. 1. Double logarithmic plots of the rates of formation of methane and ethane as a function of the initial pressure of ethylene at 683 K in the presence and absence of benzene. Lines have been drawn with slope = 2. ○: pure ethylene; ●: 12% C_6H_6.

under identical conditions of temperature and pressure of ethylene. A number of ratios were measured to obtain a final average value. This approach was used in the studies using ethane, propane, and isobutane as additives (11, 12). The second method involved a series of measurements of the initial rate of formation of products from the reaction of pure ethylene over a range of pressure, followed by a similar series with a mixture of ethylene with additive. Since the order of the rates of formation of methane and ethane was the same in the presence and absence of the additive, the ratio of rates was the same at all pressures and was obtained by interpolation. Thus several measurements were made with one mixture without the constraint of adjusting the pressure of ethylene to a particular value. This method was used with hydrogen as additive (10). In both methods measurements were made at each temperature of the yield of products as a function of time to establish the reaction time within which initial rates were measurable, before the onset of auto-catalysis. In the studies reported here the second method was used with the additives benzene and toluene, while the first method was used with cyclopentane as additive.

A. Benzene

An example of the results of measurements of the rates of formation of methane and ethane in the presence and absence of benzene as a function of pressure of ethylene are shown as double logarithmic plots in Fig. 1. Average ratios of rates were obtained for each mixture from such plots and the results are summarized in Table 1. Each ratio was obtained from a series of experiments over the approximate range of pressure of 230–380 Torr (1 Torr = 133.3 Pa). The rates of formation of propylene and butene-1 were unaffected by the addition of benzene. An example of the measurements of these products is given later for the additive toluene.

For the additive benzene, reactions [1] and [2] are expressed as follows,

[7] $CH_3 + C_6H_6 \rightarrow CH_4 + C_6H_5$

[8] $C_2H_5 + C_6H_6 \rightarrow C_2H_6 + C_6H_5$

and eqs. [5] and [6] become

$$[9] \quad \frac{(R^0_{CH_4})_a}{R^0_{CH_4}} = 1 + \frac{k_7[C_6H_6]}{k_3[C_2H_4]}$$

$$[10] \quad \frac{(R^0_{C_2H_6})_a}{R^0_{C_2H_6}} = 1 + \frac{k_8[C_6H_6]}{k_4[C_2H_4]}$$

The linearity of eqs. [9] and [10] for the rates of formation of methane and ethane is illustrated in Fig. 2A. The ratios of rate constants, k_7/k_3 and k_8/k_4, were obtained from the slopes of these plots and are included in Table 1. The Arrhenius plots for k_7/k_3 and k_8/k_4 are given in Fig. 3. Although there is some scatter in these ratios, it appears that there is no measurable difference in activation energy between reactions [7] and [3] or between [8] and [4] and the ratio of frequency factors is the same for both ratios of rate constants. The ratios of rate constants may be expressed as follows:

$$\log(k_7/k_3) = 0.60 \pm 0.01$$

$$\log(k_8/k_4) = 0.60 \pm 0.1$$

Taking the values for k_3 and k_4 reported previously (10) (R = 8.314 J mol^{-1} K^{-1}),

$$\log k_3\,(\mathrm{L\,mol^{-1}\,s^{-1}}) = 8.7 \pm 0.2 - \frac{63000 \pm 3000}{2.3RT}$$

$$\log k_4\,(\mathrm{L\,mol^{-1}\,s^{-1}}) = 8.2 \pm 0.2 - \frac{62200 \pm 3000}{2.3RT}$$

the following values were calculated for k_7 and k_8:

$$\log k_7\,(\mathrm{L\,mol^{-1}\,s^{-1}}) = 9.3 \pm 0.3 - \frac{63000 \pm 5000}{2.3RT}$$

$$\log k_8\,(\mathrm{L\,mol^{-1}\,s^{-1}}) = 8.8 \pm 0.3 - \frac{62200 \pm 5000}{2.3RT}$$

The present measurements for k_7 are shown together with previous measurements in Fig. 4. The present measurements to some extent span the measurements from the low and high temperature regions, but indicate an activation energy considerably higher than the other two values, 38.9 kJ mol^{-1} (15) and 43.1 kJ mol^{-1} (16), and also greater than the value of 46 kJ mol^{-1} recommended by Kerr and Parsonage (1). These values will be discussed later in relation to the bond dissociation energies of ethylene and the additives. No values were found in the literature for k_8.

B. Toluene

The effect of addition of toluene on the rates of formation of methane and ethane as a function of pressure of ethylene are shown as double logarithmic plots in Fig. 5. Average ratios of rates of formation of methane and ethane in the presence and absence of toluene for each mixture, obtained from these plots,

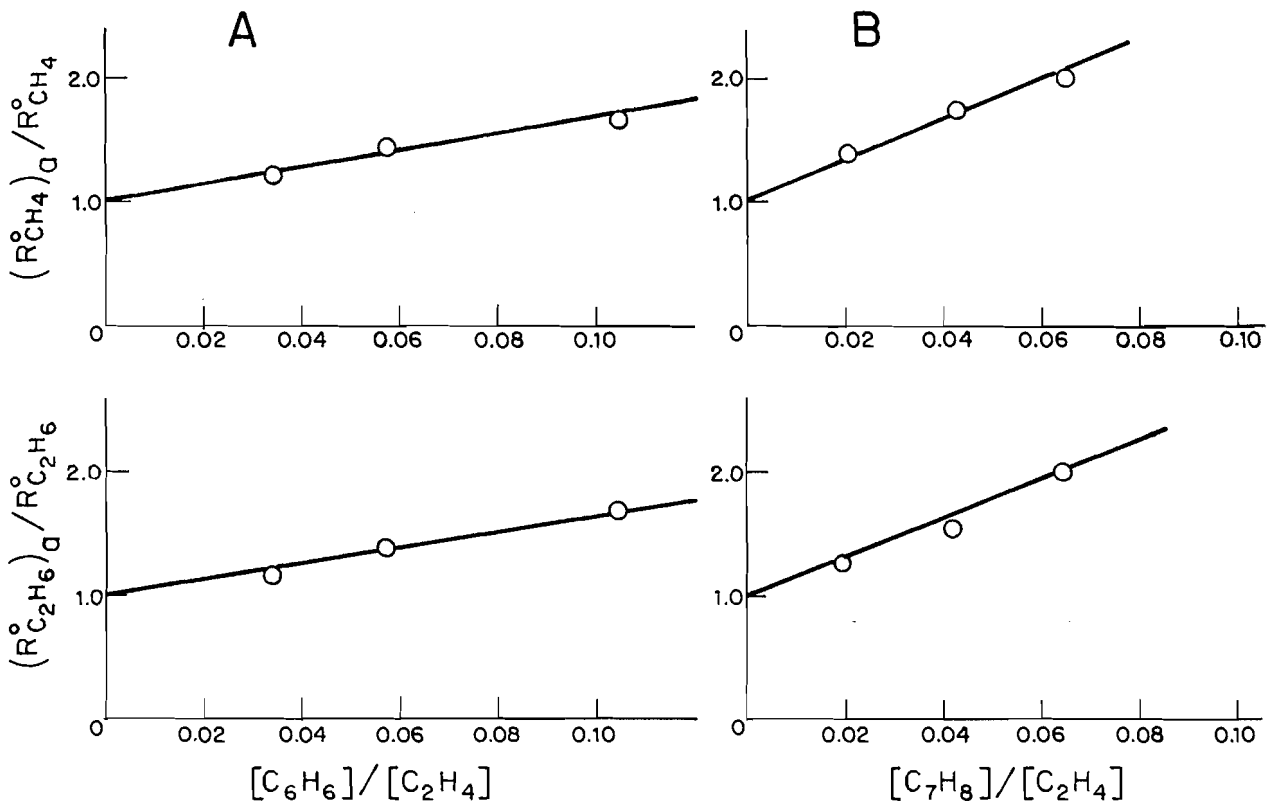

FIG. 2. Relative rates of product formation in the presence and absence of additive as a function of the ratio of additive to ethylene. A. benzene, 743 K; B. toluene, 723 K.

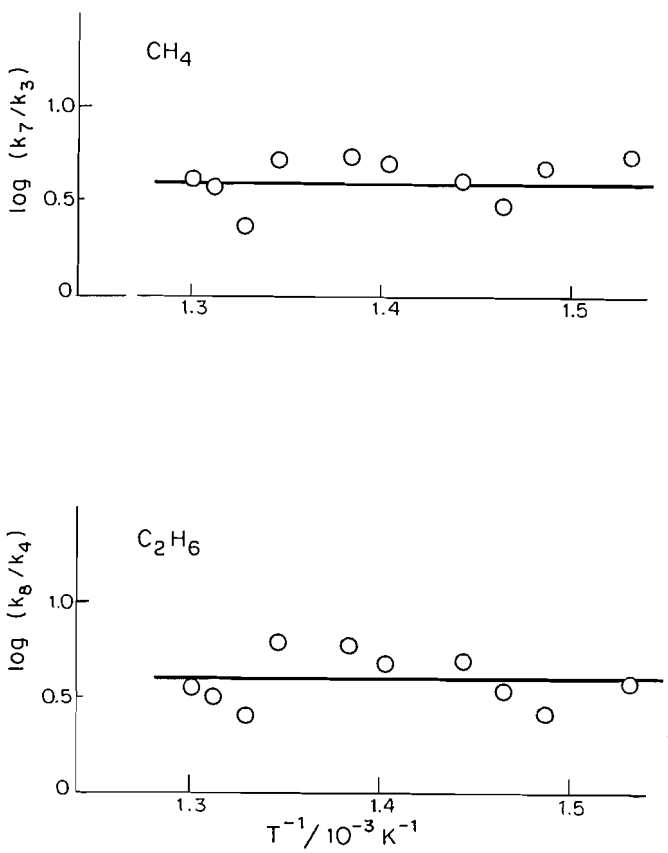

FIG. 3. Arrhenius plot of the ratios k_7/k_3 and k_8/k_4.

are summarized in Table 2. For each ratio a series of experiments was made covering a pressure range of approximately 220–360 Torr. Toluene had, within the error in the measurements, no effect on the rates of formation of either propylene or butene-1, as illustrated in Fig. 6 by the results at 743 K. Thus no new initiation processes were introduced by the addition of toluene.

In the presence of toluene, methane, and ethane are formed by the following reactions, in addition to reactions [3] and [4]:

[11] $CH_3 + C_7H_8 \rightarrow CH_4 + C_7H_7$

[12] $C_2H_5 + C_7H_8 \rightarrow C_2H_6 + C_7H_7$

In the presence of toluene, eqs. [5] and [6] become

$$[13]\quad \frac{(R^0_{CH_4})_a}{R^0_{CH_4}} = 1 + \frac{k_{11}[C_7H_8]}{k_3[C_2H_4]}$$

$$[14]\quad \frac{(R^0_{C_2H_6})_a}{R^0_{C_2H_6}} = 1 + \frac{k_{12}[C_7H_8]}{k_4[C_2H_4]}$$

Plots of the results according to these equations are shown in Fig. 2B and the ratios of rate constants k_{11}/k_3 and k_{12}/k_4 obtained from these plots are included in Table 2. Arrhenius plots for these ratios of rate constants are shown in Fig. 7. The dependence on temperature of the ratios may be expressed as follows ($R = 8.314$ J mol^{-1} K^{-1}):

$$\log (k_{11}/k_3) = -1.3 \pm 0.3 + \frac{34000 \pm 4000}{2.3RT}$$

$$\log (k_{12}/k_4) = -0.50 \pm 0.3 + \frac{25000 \pm 4000}{2.3RT}$$

With the values for k_3 and k_4 mentioned earlier the following expressions were obtained for k_{11} and k_{12}:

$$\log k_{11}(\mathrm{L\,mol^{-1}\,s^{-1}}) = 7.4 \pm 0.5 - \frac{29000 \pm 7000}{2.3RT}$$

$$\log k_{12}(\mathrm{L\,mol^{-1}\,s^{-1}}) = 7.7 \pm 0.5 - \frac{37000 \pm 7000}{2.3RT}$$

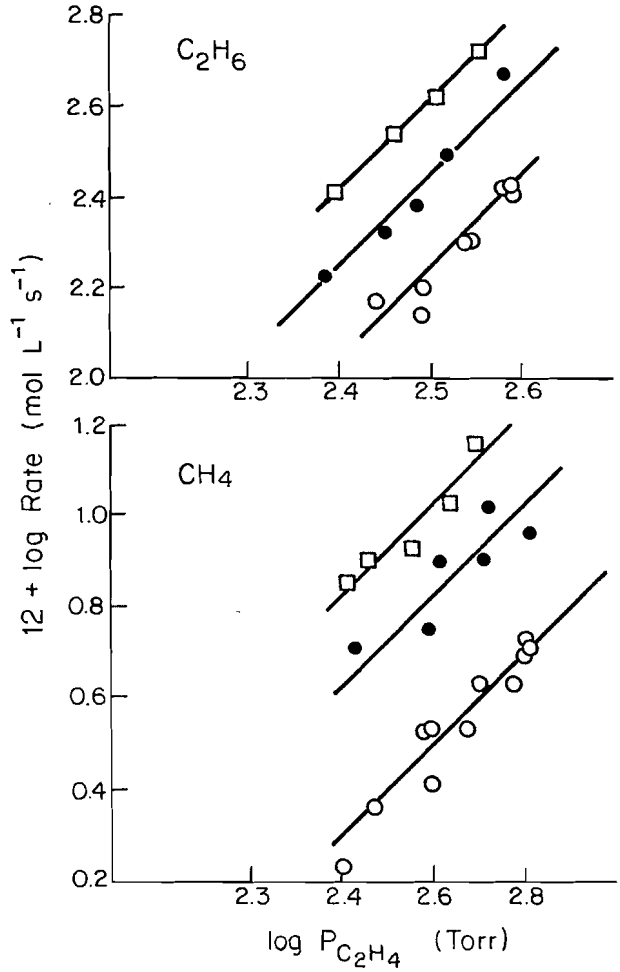

FIG. 5. Double logarithmic plots of the rates of formation of methane and ethane as a function of the initial pressure of ethylene in the presence and absence of toluene; Lines have been drawn with slope = 2. Methane: 653 K; ○: pure ethylene; ●: 3.1% toluene; □: 5.6% toluene. Ethane: 713 K; ○: pure ethylene ●: 2.5% toluene □: 4.1% toluene.

Measurements reported for k_{11} are shown together with the present results in Fig. 8. The present measurements are in agreement with the measurements of Dunlop, Kominar, and Price (17) made over a similar range of temperature but the rate constants are significantly lower than those measured at higher temperatures. The activation energy measured in the present work is also considerably lower than those values obtained at higher temperatures and lower than the value recommended by Kerr and Parsonage (1). The significance of the activation energy for this reaction will be discussed later.

The activation energy and frequency factor for reaction [12] are in good agreement with the values obtained by Price and co-workers (18, 19, 32, 33) from their studies of the thermal decomposition of alkyl metal compounds in the presence of toluene. Their activation energies were in the range 41 ± 4 kJ mol^{-1} with corresponding frequency factors in the range, and log A (L mol^{-1} s^{-1}) = 8.1 ± 0.2, the measurements covering the temperature range 465–833 K. It is interesting that the rate constants at 653 K from the present method and from the four studies of Price and co-workers lie within 15% of an average value. This is remarkable agreement between two very different methods.

C. Cyclopentane

Experiments with the additive cyclopentane were performed by the first method described earlier. Initial pressures of ethylene ranged from 190 to 377 Torr. The relatively large quantities of cyclopentane obscured the peak due to butene-1 in the analysis and prevented a reliable measurement of its rate of formation. The cyclopentane had no effect on the rate of formation of propylene and it may be concluded that no new initiation processes were occurring in the presence of this additive. The rates of formation of methane and ethane were increased in the presence of cyclopentane due to the occurrence of the following abstraction reactions:

[15] $CH_3 + c\text{-}C_5H_{10} \rightarrow CH_4 + c\text{-}C_5H_9$

[16] $C_2H_5 + c\text{-}C_5H_{10} \rightarrow C_2H_6 + c\text{-}C_5H_9$

and the ratios of the rates of formation of these products in the presence and absence of cyclopentane may be written as follows:

$$[17] \quad \frac{(R^0_{CH_4})_a}{R^0_{CH_4}} = 1 + \frac{k_{15}[c\text{-}C_5H_{10}]}{k_3[C_2H_4]}$$

$$[18] \quad \frac{(R^0_{C_2H_6})_a}{R^0_{C_2H_6}} = 1 + \frac{k_{16}[c\text{-}C_5H_{10}]}{k_4[C_2H_4]}$$

A plot of the results at 718 K according to eq. [18] is shown in Fig. 9 and the measurements are summarized in Table 3, which includes the ratios of rate constants k_{15}/k_3 and k_{16}/k_4 obtained from eqs. [17] and [18]. The Arrhenius plots for k_{15}/k_3 and k_{16}/k_4 are shown in Fig. 10, from which were derived the following expressions ($R = 8.314$ J mol^{-1} K^{-1}):

$$\log(k_{15}/k_3) = -0.4 \pm 0.3 + \frac{27000 \pm 4000}{2.3RT}$$

$$\log(k_{16}/k_4) = 0 \pm 0.3 + \frac{22000 \pm 4000}{2.3RT}$$

Using the expressions for k_3 and k_4 as in Sect. A, the following expressions for k_{15} and k_{16} were calculated.

TABLE 4. Relation of activation energies for hydrogen-transfer reactions to bond dissociation energies of the reactants

Reaction	Reference 1		Present method		Literature values	
	E, kJ mol^{-1}	D(R—H), kJ mol^{-1}	E, kJ mol^{-1}	D(R—H), kJ mol^{-1}	D(R—H), kJ mol^{-1}	Ref.
$CH_3 + C_2H_4$	45.6	426	63	445	460	25
$CH_3 + H_2$	45.8	425	55	433	435	25
$CH_3 + C_2H_6$	48.7	421			418	34
$CH_3 + C_3H_8$	40.3	408			402	34
$CH_3 + i\text{-}C_4H_{10}$	33.6	396			393	34
$CH_3 + C_6H_6$	46.2	417	63	445	464	25
$CH_3 + C_7H_8$	39.7	407	29	389	368	25
$CH_3 + c\text{-}C_5H_{10}$	39.3	406	36	401	400	34

$$\log k_{15}\,(\mathrm{L\,mol^{-1}\,s^{-1}}) = 8.3 \pm 0.5 - \frac{36000 \pm 7000}{2.3RT}$$

$$\log k_{16}\,(\mathrm{L\,mol^{-1}\,s^{-1}}) = 8.2 \pm 0.5 - \frac{40000 \pm 7000}{2.3RT}$$

Four of the five measurements reported for k_{15} (20–23) give values for the activation energy in the range 38 ± 2 kJ mol^{-1} with log A (L mol^{-1} s^{-1}) = 8.7 ± 0.3, and the present measurement falls within the range. No values for k_{16} were found in the literature.

Discussion

It is of interest to examine the activation energies for the hydrogen transfer reactions measured by the method described here, and by other methods, in relation to the bond dissociation energy of the compound RH of eq. [1]. Relations between such activation energies and bond dissociation energies have often been discussed and were recently examined in detail for small radicals such as methyl (24). The authors developed a semi-empirical procedure to calculate activation barriers for hydrogen-abstraction reactions and showed that these barriers were related to the overall energy change in the reaction. For reactions of methyl radicals of the type

$$CH_3 + RH \rightarrow CH_4 + R$$

the following relation was proposed,

[19] $$E = 0.609\,D_1 - 0.473\,D_2$$

where D_1 and D_2 are the C—H bond dissociation energies for RH and CH_4 respectively and E is the activation barrier for the reaction. Although the activation barrier is not necessarily equivalent to the experimental activation energy it will be close enough that this equation may be used to test the correlation of the measured activation energies with the bond dissociation energies of the reactants, RH. Taking the activation energies recommended by Kerr and Parsonage (1) and the values measured using the present technique, values of D_1 were calculated from this equation for several RH molecules. These are shown in Table 4 together with values from the literature (25, 34).

For the reactions with the saturated hydrocarbons ethane, propane, isobutane, and cyclopentane, the activation energies recommended by Kerr and Parsonage predict dissociation energies in reasonable agreement with the values discussed by McMillen and Golden (25). On the other hand, for the reactions with the unsaturated hydrocarbons ethylene, benzene, and toluene, the activation energies measured by the present method provide better correlation with the bond dissociation energies. For example, the C—H bond dissociation energy in ethylene is considerably stronger than that in ethane, but the activation energy for abstraction from ethylene recommended by Kerr and Parsonage is smaller than that for abstraction from ethane. Benzene and toluene provide a contrasting situation. The activation energy for abstraction from benzene measured by the present technique is considerably higher than the value recommended by Kerr and Parsonage, while the reverse is the case for toluene. In both cases the present method gives values that are more realistically related to the C—H bond dissociation energy in these molecules. The activation energies recommended by Kerr and Parsonage for these two abstraction reactions appear too close. The difference of about 6 kJ mol^{-1} suggests that the C—H bond dissociation energies in benzene and toluene are similar. In fact, the difference, according to the values recommended by McMillen and Golden, is almost 100 kJ mol^{-1}.

It should be mentioned that for the case of toluene the measured activation energy has been related to the bond dissociation energy of the C—H bond in the methyl group. In fact, the measurements do not distinguish between abstraction from the ring and from the side chain. Because the dissociation energy of the C—H bond in the methyl group is considerably less than that of the ring hydrogens, abstraction from the methyl group will be dominant at moderate temperatures. With increasing temperature, abstraction from the ring will assume increasing importance with a consequent increase in the apparent activation energy. As is evident from Fig. 8, this effect does not account for the difference in activation energy between the present results and that recommended by Kerr and Parsonage (1). Nevertheless, because of the uncertainty in the position of the abstraction, the comparison presented in Table 4 for toluene should be regarded as qualitative.

We have included in Table 4 an activation energy of 55 kJ mol^{-1} for abstraction from hydrogen. This value was not measured by the present method but was used as a reasonable average value in the temperature range of the experiments where hydrogen was the additive (10). In fact it is close to an average of the value recommended by Kerr and Parsonage, 45.8 kJ mol^{-1}, and the value proposed by Moller, Mozzhukhin, and Wagner (3), 60 kJ mol^{-1}, based on experiments in the temperature range 1200–2000 K. Use of the value of 55 kJ mol^{-1} led to a value for the activation energy for abstraction from ethylene the same as that obtained from results using ethane as additive. Thus, indirectly, the present method using measure-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

ments of relative rates strongly suggests that the activation energy for abstraction from hydrogen is at least 6 kJ mol^{-1} greater than that for abstraction from ethane, and not less, as recommended by Kerr and Parsonage. This conclusion is also in accord with the difference in bond dissociation energy between the two reactants.

In conclusion, Table 4 shows that even though the relation expressed in eq. [19] is approximate when applied to the measured activation energies, an examination of the qualitative relation between activation energy and bond dissociation energy for a particular elementary reaction may offer new insights into the results. In particular, the activation energies measured in the present study for abstraction from unsaturated hydrocarbons appear more realistic in relation to the dissociation energies of the reactants than the values recommended by Kerr and Parsonage.

Received April 4, 1989

RAMAMURTHY PALEPU and VINCENT C. REINSBOROUGH. Can. J. Chem. **67**, 1550 (1989).

Pre-micellar and micellar sodium perfluorooctanoate solutions (SPFO) were examined conductometrically with added α-cyclodextrin (α-CD), β-cyclodextrin (β-CD), and γ-cyclodextrin (γ-CD). The order of stability of the 1:1 inclusion complex was β-CD > γ-CD > α-CD determined largely by the goodness of fit of the fluorocarbon chain in the CD cavity. Sodium ion electrode studies revealed that some Na^+ ion is associated with the β-CD/SPFO complex. As shown by fluorine-19 nmr, β-CD girds the SPFO molecule snugly amidship with the terminal CF_3 group still in solution. On the other hand, SPFO manages only a weak penetration of the fluorocarbon chain into the smaller α-CD cavity.

Key words: perflurooctanoate, cyclodextrin complexes, fluorocarbon surfactant, ^{19}F nmr.

RAMAMURTHY PALEPU et VINCENT C. REINSBOROUGH. Can. J. Chem. **67**, 1550 (1989).

Faisant appel à la conductimétrie, on a étudié des solutions pré-micellaires et micellaires de perfluorooctanoate de sodium (PFOS) auxquelles on a ajouté des α- (α-CD), β- (β-CD) et γ-cyclodextrines (γ-CD). L'ordre de stabilité des complexes d'inclusion 1:1 (β-C > γ-CD > α-CD) est fortement déterminé par la facilité de la chaîne fluorocarbonée à s'adapter dans la cavité de la CD. Des études à l'aide d'une électrode sélective pour l'ion sodium ont révélé que quelques ions Na^+ sont associés avec le complexe β-CD/PFOS. La rmn du ^{19}F a permis de montrer que la β-CD entoure le milieu de la molécule de PFOS alors que le groupement CF_3 est encore en solution. Par ailleurs, la pénétration de la chaîne fluorocarbonée de la molécule de PFOS dans la cavité de l'α-CD est faible.

Mots clès : perfluorooctanoate, complexes cyclodextrines, surfactant fluorocarbone, rmn du ^{19}F.

[Traduit par la revue]

Introduction

In the inclusion of ligands by cyclodextrins in solutions, a major factor in the stability of the resultant complex is thought to be the closeness of fit of the guest molecule within the cyclodextrin cavity. Thus, for example, the binding constant for adamantanecarboxylate is 10^5 dm^3 mol^{-1} in β-cyclodextrin (β-CD) but only 10^2 dm^3 mol^{-1} in α-cyclodextrin (α-CD) and 10^3 dm^3 mol^{-1} in γ-cyclodextrin (γ-CD) (1) because the adamantane moiety with diameter 7 Å fits most snugly into the cavity of β-CD which has the same diameter. Adamantane cannot deeply penetrate α-CD of cavity diameter 5 Å and has room to spare inside γ-CD of cavity diameter 8.5 Å. Another hydrophobic entity that may demonstrate similar behavior is the fluorocarbon tail with cross-sectional diameter of 6 Å which should fit more snugly into the β-CD cavity than the α-CD cavity. Recent work has shown that fluorocarbon surfactants bind very strongly with β-CD (2, 3) with little tendency to form inclusates with α-CD (2). However, surfactant hydrocarbon chains of diameter 4.5 Å apparently are readily accommodated within the α-CD cavity because stable complexes are formed with both α-CD and β-CD (3–8). A complicating feature in the hydrocarbon chain situation is that α-CD/surfactant complexation appears to favour 2:1 complexes while 1:1 complexes predominate with β-CD (4, 8). A detailed, multi-faceted study of the inclusion of a perfluorinated surfactant by the cyclodextrins in solution was deemed appropriate to shed light on the importance of size parameters in the strength and position of binding. Binding constants and related thermodynamic data for sodium perfluorooctanoate (SPFO) inclusions with CDs were obtained through conductance measurements. Sodium ion activities were monitored by ion selection electrode techniques while environmental changes to the fluorine atoms was tracked by fluorine-19 nmr.

Experimental

Conductance measurements were performed with a Radiometer CDM83 Bridge at 25.0°C. Potentiometric and sodium ion activity measurements were peformed with an Orion Research microprocessor ion analyzer/901 with 0.1 mV sensitivity. The sodium selective electrode was an Orion 90-02 double junction electrode with the out chamber filling of KNO_3 solution replaced by 5 *M* NH_4NO_3 solution to prevent leaking of potassium ions into the test solutions. With this electrochemical cell, the response of the electrode against aqueous NaCl was linear in the concentration range investigated (10^{-3} to 5×10^{-1} mol dm^{-3}) with a slope equal to 56 mV.

Fluorine-19 nmr spectra were obtained in SPFO solutions on a Nicolet 360NB spectrometer at the Atlantic Region Magnetic Resonance Centre (Dalhousie University) with CCl_3F as reference. The cyclodextrins (Sigma) were previously dried before use while sodium perfluorooctanoate (SPFO) was obtained from the acid (Aldrich).

Results and discussion

The dependence of the conductance of SPFO on cyclodextrin concentration for α-CD, β-CD, and γ-CD is shown in Fig. 1 for some pre-micellar SPFO solutions. Clearly, the order of binding with SPFO is β-CD > γ-CD > α-CD with the last showing very little association at all. The intersection of the linear portions of the curves for the three cyclodextrins gives the stoichiometry of the main complex formed as 1:1 in agreement with findings from other surfactant systems (3–8). All pre-micellar SPFO solutions displayed the same behavior. From the change in conductivity and with reasonable assumptions about the ionic contributions to the conductivity, it is possible to derive the binding constants for the inclusion complex. A number of these relationships exists in the literature but perhaps the most versatile and computer compatible is that due to Zollinger *et al.* (9) which generates binding constants for both the 1:1 and 2:1 β-CD/inclusate

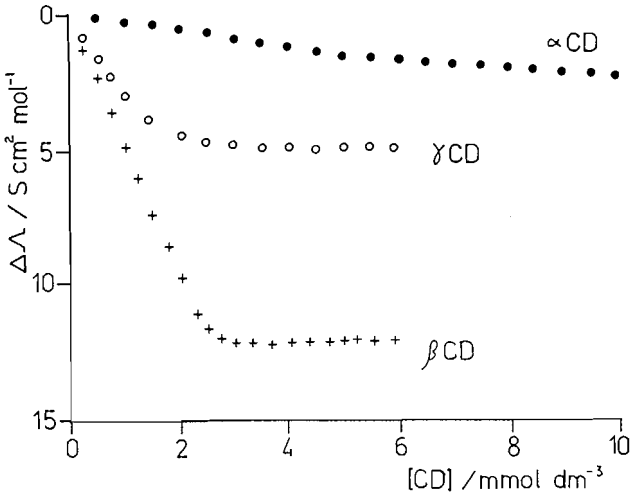

FIG. 1. Conductance decrease of SPFO solutions with added cyclodextrins. Concentration of SPFO is 5.00 mmol dm^{-3} in α-CD solutions and 2.00 mmol dm^{-3} in β-CD and γ-CD solutions.

complexes. Both complexes are generally recognized as coexisting in solution systems of this sort although one complex usually predominates. From this relationship, the value of the binding constant for the β-CD/SPFO complex was found to be 4500 dm^3 mol^{-1}, 640 dm^3 mol^{-1} for the γ-CD/SPFO complex, and essentially zero for α-CD/SPFO. The analysis revealed that no significant amounts of 2:1 complexes were present in any of the systems.

In micellar solution, the conductance of SPFO was initially little affected by additions of β-CD but beyond a certain concentration decreased rapidly (Fig. 2). With micellized hydrocarbon surfactants, the conductance behavior had been similar in concentrated β-CD solutions but in dilute β-CD solutions rose to a maximum which was identified as the amount of β-CD required to initiate micelle formation at this particular surfactant concentration (8). In other words, the latter concentration was the critical micelle concentration of SPFO in the presence of β-CD the concentration of which corresponded to the maximum in the conductivity curve. The sudden sharp drop in conductivity beyond the maximum that was common to both hydrocarbon and fluorocarbon surfactant systems is consistent with the micelles having been destroyed and with surfactant ion and perhaps also Na^+ ion being sequestered by β-CD (8, 10). One reason for the initially flat portion of the curve for micellar NaPFO solution may be that Na^+ ion was assimilated into the NaPFO complex almost as rapidly as it was released from the micellar surface region so that little net increase in the overall solution conductivity was registered. Once the micelles have been totally destroyed by β-CD addition (at the end of the flat portion of the curve), further addition of β-CD serves to bind the remaining perfluorooctanoate monomers in 1:1 complexes which in turn partly assimilate Na^+ ions from solution.

Direct evidence for the binding of Na^+ ions from solution by the β-CD/SPFO complex was provided by Na^+ ion activities measured by selective ion electrodes. Figure 3 shows the electrode potential of a Na^+ ion electrode in 5.00 mmol dm^{-3} SPFO solutions with various amounts of β-CD added. A marked drop in Na^+ ion activity acompanied β-CD addition but for stoichiometric ratios of β-CD to SPFO of unity or greater the decrease was approximately the same. Similar separate additions of β-CD or of SPFO to 5 mmol dm^{-3} NaCl solutions did not

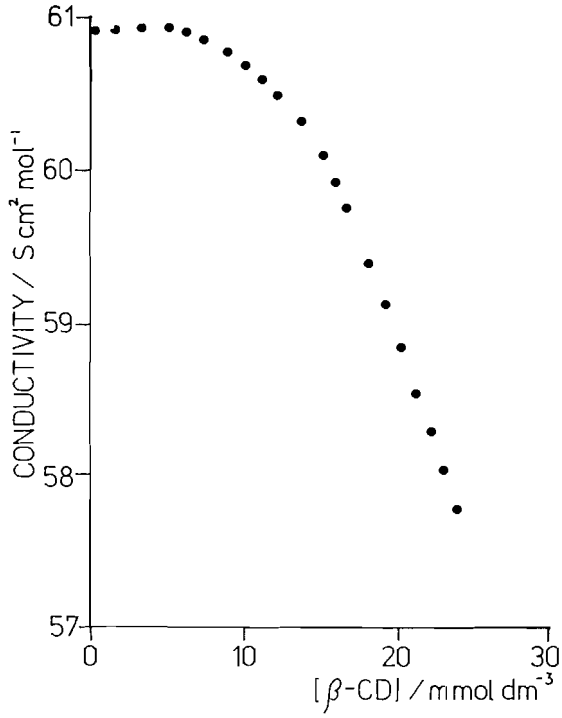

FIG. 2. Conductance of 4.00 × 10^{-2} mol dm^{-3} SPFO in β-CD solutions.

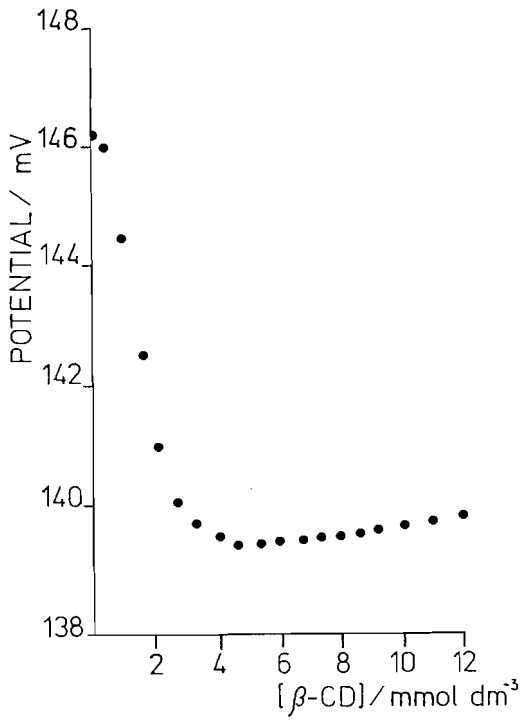

FIG. 3. Sodium ion potentials in 5.00 mmol dm^{-3} SPFO with added β-CD.

alter the observed Na^+ ion activity. Thus, it would appear that Na^+ ion was removed from solution by β-CD only when the latter was bound with SPFO. This apparent Na^+ ion association with β-CD/surfactant complexes in solution had been noted previously from our laboratory with other anionic surfactants (8) and is now being investigated more thoroughly. At this stage, the most reasonable explanation is that ion-pairing between Na^+

For personal use only.

ion and included SPFO is abetted by the hydrophilic β-CD exterior.

The molar conductivities of SPFO in several pre-micellar β-CD solutions were measured at four different temperatures to obtain estimates of ΔH^0 and ΔS^0 for the associative process. From the expansion of ΔG as a polynomial and by a plot of $\ln K$ versus $1/T$, an average value of ΔH^0 and ΔS^0 could be obtained. It was found that $\Delta H^0 = -12 \pm 1$ kJ mol^{-1} and $\Delta S^0 = 70 \pm 5$ J mol^{-1} K^{-1} for the formation of the β-CD/SPFO complex and 32 ± 3 kJ mol^{-1} and 200 ± 25 J mol^{-1} K^{-1}, respectively, for the γ-CD/SPFO complex.

Similar temperature dependence studies were conducted in sodium dodecylsulfate solutions (SDS) to obtain comparison thermodynamic data for β-CD/SDS inclusion complexes. In 2.0 mmol dm^{-3} SDS solution, ΔH^0 was endothermic at 10.5 ± 0.3 kJ mol^{-1} and ΔS^0 was 139 ± 1 J mol^{-1} K^{-1}. Measurements in three other pre-micellar SDS solutions gave similar results. It is clear from these numbers that, both for the inclusion of the hydrocarbon chain and that of the fluorocarbon chain, entropy is the significant driving force which might be expected with the solvent elimination from the cavity and the subsequent internal binding occurring with the insertion process.

Fluorine-19 nmr spectra for three 0.020 mol dm^{-3} SPFO solutions, one with only SPFO, one together with 0.020 mol dm^{-3} β-CD and one together with 0.020 mol dm^{-3} α-CD, gave rise to seven peaks as shown in Fig. 4 and Table 1. These were assigned to the fluorines of the seven carbons of the surfactant chain following the usual convention of beginning the numbering with the fluorine-less carbon of the polar head (C1). Peak assignments were taken from Muller and Simsohn (11) who, however, had relegated the fluorines of C_3, C_4, C_5, and C_6 to one complex peak. In this same region, with the better resolution possible in the present work, four peaks were easily distinguished and these have been tentatively assigned to specific carbons. The placement of peaks C_3, C_4, C_5, and C_6 may not be correct relative to each other but this is not important to the present argument.

No new peaks appeared when cyclodextrins were added to the SPFO solutions but several of the peaks underwent appreciable chemical shifts. Thus the exchange between the fluorine atoms in SPFO in solution and in the inclusion complex must be rapid. All the observed shifts in both CD systems were downfield, indicating probably a loosening of the restrictive environment fluorine atoms experience in water as compared to the situation within the CD cavity. The theoretical background for both the direction and magnitude of chemical shifts is far from resolved at the moment and the environmental constraint is but one of several factors deemed important in the relative movement of peaks. However, the situation with the strongly polarizing fluorine atoms in aqueous media may not be so complex. The association of perfluorinated surfactant monomers in aqueous solution into micelles results in upfield shifts in F-19 nmr (12). The close packing of fluorine atoms to fluorine atoms in the micelle is envisaged as being more restrictive to the observed resonant frequency than in the aqeous situation. It is well known that upfield shifts for fluorine peaks are recorded for movement from a hydrocarbon environment into a fluorocarbon one and thus passage from aqueous to fluorocarbon medium should be similarly disposed. It would appear from the present results that fluorine atoms in passing from the aqueous solution situation into the hydrophobic CD interior enter into a less constrained environment.

The pattern of the chemical shifts in both CD systems was entirely different. With β-CD, only C_2–C_6 showed noticeable shifts (peaks for C_4 and C_5 essentially coalesced and thus could be pinpointed less accurately) while peak movement was only noted with C_5–C_8 when α-CD was the complexing agent. Moreover, the most pronounced shifts with β-CD occurred with the fluorines of the middle carbons while with α-CD the fluorines of the terminal group experienced the greatest peak displacement. It is clear from this nmr study that the binding sites of the two cyclodextrins on the surfactant chain differ markedly: β-CD girds the fluorocarbon chain over the region C_3 to C_6 while α-CD is impaled on the surfactant tail. Simple geometry dictates the difference: the cavity size of β-CD allows for a snug fit over the fluorocarbon chain but the interior of α-CD is not large enough for this. Only the terminal group of the chain and a few further carbons experience environmental or conformational changes on binding with α-CD. The C_6 and C_5 peaks were assigned on the basis of diminishing chemical shift from the tail in the α-CD/SPFO spectrum and the C_3 and C_4 peaks were decided from symmetry considerations in the chemical shift pattern in the β-CD/SPFO spectrum. These assignments are clearly tentative but receive some support in their self-consistency.

The conductivity data would indicate that the inclusion of the SPFO by β-CD is much stronger than with α-CD where the binding constant could not be measured accurately by this

method. The nmr picture is entirely consistent with this in that the smaller internal diameter of the α-CD torus allows only partial penetration by the end of the fluorocarbon tail in probably loose fashion while β-CD sits tightly amidship relatively close to the polar head of the surfactant. The two configurations also would not give rise to the same loss in ion mobility when the surfactant ion was complexed and this may be the reason why the conductivity measurements failed to indicate any appreciable concentration of α-CD/SPFO complex when the F-19 nmr gave results of a different nature.

Infrared spectroscopic studies of surfactant micelles: the behaviour of aliphatic ketones as guests[1]

HECTOR L. CASAL AND ADÈLE MARTIN

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received February 20, 1989

HECTOR L. CASAL and ADÈLE MARTIN. Can. J. Chem. **67**, 1554 (1989).

Aliphatic ketones were incorporated into micelles and bilayers formed by various surfactant molecules. These ketones are used as "probe" molecules; hydrogen bonding to their carbonyl groups is easily detected by means of infrared spectroscopy. The extent of hydrogen bonding between the C=O groups and the solvent (D_2O) is monitored by a parameter which gives a relative (qualitative) measure of the volumes of different micellar environments. It is also shown that structural changes may induce translocation of the ketone probes and that there are subtle structural differences between cooling-induced and ion-induced coagels.

Key words: infrared, micelles, water penetration, bilayers, surfactants.

HECTOR L. CASAL et ADÈLE MARTIN. Can. J. Chem. **67**, 1554 (1989).

On a incorporé des cétones aliphatiques dans des micelles et dans des bicouches formées par divers agents tensioactifs. On a utilisé ces cétones comme «sondes»; grâce à la spectroscopie infrarouge, on peut facilement détecter la formation de ponts hydrogènes avec leurs groupements carbonyles. Utilisant un paramètre qui donne une mesure relative (qualitative) des volumes des divers environnements micellaires, on a évalué l'importance de la liaison hydrogène entre les groupements C=O et le solvant (D_2O). On montre que les changements structuraux peuvent induire une translocation des «sondes» cétoniques et qu'il existe des différences structurales subtiles entre des coagels induits par le froid ou par les ions.

Mots clés : infrarouge, micelles, penetration d'eau, bicouches, tensioactifs.

Introduction

The structure of micelles and other mesomorphs formed by surfactant molecules continues to be a subject of considerable interest. Recently, we investigated micelles and bilayers by using keto surfactants and aliphatic ketones as "probes" (1, 2). The infrared spectra of keto-surfactants as guests in micelles demonstrated that the extent of contact between the solvent (water) and the surfactant aliphatic chains is considerable. In fact, in the case of a short keto surfactant molecule (sodium 7-oxooctanoate) in micelles of sodium octanoate, there do not appear to be C=O groups at positions free from contact with the solvent (D_2O). However, when 5-nonanone was used as the guest, the infrared spectra demonstrated that this molecule coexists in two environments; in one there is extensive ketone:water contact while in the other there is no such contact. Therefore, from that comparison, two micellar environments were found (1).

In the work reported here, we explore the possibility of using aliphatic ketones as probes of micellar structure with particular emphasis on determining changes in the extent of contact between the solvent and the surfactant aliphatic chains. We use the infrared spectra of the guest ketones to measure the extent of hydrogen bonding to their C=O groups. In the systems studied the only source of hydrogen bond donors is the solvent (D_2O). Several different surfactant systems (forming micelles and bilayers) have been measured and the results indicate that the infrared spectra of guest ketones yield a qualitative comparison of different mesomorphs.

Aliphatic ketones such as those used in this study are incorporated into micelles and at the concentrations used here do not bring about gross structural changes (3). Malliaris (4) has determined several micellar properties of SDS[2] in the presence of ketones. For example, the cmc of SDS goes from 8 m*M* in the absence of ketones to 7 m*M* in the presence of 9.9 m*M* 6-undecanone, while the aggregation number changes from 67 to 61 (the SDS concentration was 0.04 *M*, i.e. samples of 4:1 molar ratio SDS:ketone). These results give us some confidence that the information derived from guest ketones does not come from systems grossly distorted by the probe.

Experimental

The aliphatic ketones used in this study were obtained from Aldrich or Wiley Organics and used without further purification. SDS was from BDH (especially pure grade); sodium octyl sulfate, sodium decyl sulfate, sodium tetradecyl sulfate, and sodium hexadecyl sulfate were from Lancaster Synthesis and purified by recrystallization from methanol. Triton X-100 was from Sigma. DTAC, CTAB (Eastman Kodak), and DODAC (Shelex Chemical Co.) were purified by repeated recrystallization from acetone. Sodium octanoate and sodium dodecanoate were from Nu-Check Chemical Co. and used as received.

In all cases, the mixtures of the ketones with the surfactants were prepared by adding the desired amount of ketone to a ready made solution of the detergent prepared in D_2O. After addition of the ketones, the samples were warmed to 40°C and vortexed. They were left at room temperature for 24 h prior to measurement. In all cases, the molar ratios detergent:ketone were higher than 14:1. Specific concentrations are found in the captions to the figures. D_2O was used throughout as the solvent for two reasons: H_2O has a strong absorption band at 1640 cm^{-1} which overlaps the ketone C=O stretching bands and, hydrogen bonds to D_2O induce larger frequency shifts of the C=O stretching vibration.

Infrared spectra at 2 cm^{-1} resolution were recorded on a Digilab FTS-60 Fourier transform spectrometer equipped with a DTGS detector. Curve-fitting of the C=O stretching bands was carried out with an iterative procedure, the estimated error in the band areas determined from band fitted spectra is ±10%.

Results and discussion

The C=O stretching vibrational mode, $\nu_{C=O}$, gives intense bands in the 1750 to 1650 cm^{-1} region, characteristic of carbonyl-containing compounds. When a C=O group is

engaged in hydrogen bonding, the C=O frequency decreases (5–8); this well known effect is easily and readily detected in the infrared spectra. Symons and co-workers (9–11) have investigated in detail hydrogen bonding to esters and ketones. In the particular case of acetone (9), they found three C=O stretching bands depending on the extent of hydrogen bonding to the C=O group. A band at 1717 cm^{-1} is due to the non-bonded species and bands at 1707 and 1697 cm^{-1} are due to the mono- and dihydrogen-bonded species, respectively. Thus, the different C=O stretching frequencies may be assigned to specific species. Our own experiments with ketones longer than acetone (e.g. 3-pentanone and 4-heptanone) reproduce the frequencies for the three species described for acetone. The different C=O stretching frequencies are used in this work to detect hydrogen bonding to ketones mixed with surfactants and to determine which particular species are formed.

Ketones in micelles

As an example, a typical spectrum is shown in Fig. 1*A*. In this case, the ketone is 6-undecanone and the micelles are those of SDS. There are two C=O stretching bands from the ketone at 1720 and 1698 cm^{-1}. These two bands are assigned to the "free C=O" and the "hydrogen-bonded C=O" group, respectively. These two bands arise from the ketone residing, respectively, in a micellar region completely devoid of water (D_2O in this case) and in a region where contact with the solvent is possible. The intensities of these two bands are related to the number of ketone molecules in each of these micellar regions. However, the absorptivities of these two bands are not known and without them it is not possible to use band intensities in a quantitative manner. The individual band intensities (integrated areas) are obtained by curve fitting the observed spectra, as depicted in Fig. 1*B*. While the ratio I_b/I_f gives only a qualitative idea of the relative volumes of the two micellar regions, variations in its value reflect structural micellar changes that modify the extent of contact between the solvent and the surfactant hydrocarbon chains.

Figure 2 shows a plot of I_b/I_f values obtained from spectra of 6-undecanone and 5-nonanone as guests in micelles of a series of sodium alkyl sulfates. The chain length of the surfactant molecules varies from 8 to 16. The results of this plot show that the values of I_b/I_f measured are the same for the two ketones used and that I_b/I_f decreases as the surfactant chain length increases. Since I_b/I_f decreases as the extent of ketone:solvent contact decreases, we may conclude that as the surfactant chain length increases the volume of the micellar region completely devoid of solvent increases. This observation also implies that the ketones are not located preferentially in a polar environment or that they reside outside the micelle or exclusively at the Stern layer. The decrease in the values of I_b/I_f as the micelles grow shows that the extent of hydrogen bonding to the ketones depends on the medium in which they reside, and not exclusively on the polarity of the C=O group. The plot of Fig. 2 illustrates that the infrared spectra of guest ketones gives a measure (qualitative at the moment) of the relative volumes of the two micellar regions in coexistence. Previous ^{13}C-NMR work on ketones as guest in micelles detected only one environment (highly polar) for the guest ketone (12). As pointed out earlier (1) this is due to the time scale of the NMR experiment; in the presence of "fast" chemical exchange only one "average" NMR signal is observed. In the infrared, the two environments are observed separately because the ketone signals arising from the two environments are sufficiently different and the exchange rate is "slow" compared to the infrared time scale. Nevertheless, this comparison of the results from infrared and NMR spectra shows that the guest ketones are exchanging between the two environments; and, therefore it also shows that the hydrogen bonds formed between the ketone C=O group and the solvent dissociate once the ketone migrates to a micellar region devoid of solvent.

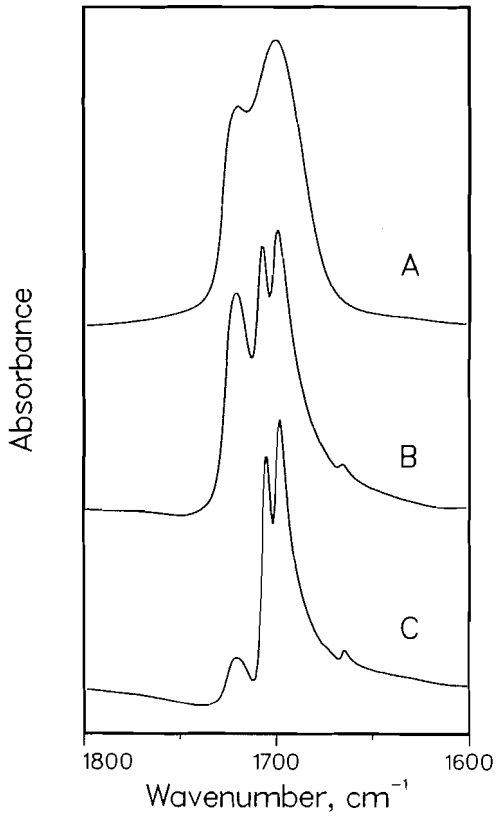

FIG. 3. Infrared spectra of 7-tridecanone (*A*); 9-heptadecanone (*B*), and 10-nonadecanone (*C*) as guests in SDS. Molar ratios SDS:ketones were 14:1 and the concentration of SDS was 0.28 *M*.

The fact that the I_b/I_f values obtained from spectra of 5-nonanone and 6-undecanone are practically identical (Fig. 2) indicates that the results are related to the micellar properties and not to some particular property of the individual ketones. However, the chain lengths of these two ketones are comparable to or less than the chain lengths of the surfactant molecules. Quite different results are obtained when the guest ketone is much longer than the surfactant molecules. Figure 3 shows spectra of 7-tridecanone, 9-heptadecanone, and 10-nonadecanone as guests in SDS micelles. The spectrum of 7-tridecanone (Fig. 3*A*) is practically the same as that of 6-undecanone (Fig. 1) and the value of I_b/I_f (≈ 3) coincides with that for 6-undecanone (Fig. 2). The spectra of 9-heptadecanone and 10-nonadecanone (Fig. 3, *B* and *C*) are completely different from those of 5-nonanone, 6-undecanone, and 7-tridecanone. In these cases, there are three C=O stretching bands instead of two. The band at 1720 cm^{-1} is clearly due to a free C=O group (i.e. not hydrogen bonded), showing that these ketones may also occupy the dry micellar region. The other two bands at 1705 and 1698 cm^{-1} are due to hydrogen-bonded C=O groups. As pointed out above these two bands are due to 1:1 and 1:2 C=O$\cdots$D$_2$O hydrogen bonds, respectively. It is interesting to note that the half widths (~ 10 cm^{-1}) of these two bands are much less than the half width of the C=O hydrogen-bonded band in the spectrum of 6-undecanone (~ 30 cm^{-1}). Two bands due to a hydrogen-bonded C=O group appear when the ketone is in direct contact with water (or D$_2$O), for example, a ketone dissolved in acetonitrile and in the presence of a large excess of water (cf. Fig. 1, ref. 2). The appearance of these two narrow bands due to hydrogen bonded C=O groups in the spectra of 9-heptadecanone and 10-nonadecanone as guests in SDS indicates that the C=O groups are in direct contact with D$_2$O. It appears that when the ketone chain length is much longer than the surfactant chain length, the ketones adopt a conformation which favours direct contact with the solvent. Furthermore, the small width of the "bound" bands suggests that in such a situation the C=O groups are restricted motionally with respect to the other cases. Therefore, in these cases where the mismatch in chain length is very pronounced, there appears to be a third micellar environment, one in which the ketone adopts a ∩ conformation and the C=O group is anchored at the Stern layer. Such a conformation has been proposed for ketones in gel phases (13) and may also be present in other lamellar phases (see below). These results, obtained with ketones much longer than the surfactant chain length, serve as a caveat for studies of micellar systems with probe molecules of greatly differing chain length.

TABLE 1. I_b/I_f values obtained from the infrared spectra of various ketones in micelles of different surfactants

Surfactant	Ketone	I_b/I_f
Na-C$_8$	5-Nonanone	8.0
SDS	5-Nonanone	3.0
NaC$_{12}$	7-Tridecanone	2.0
SDS	7-Tridecanone	3.0
SDS	6-Undecanone	3.0
CTAB	6-Undecanone	<1.0
DTAC	6-Undecanone	7.0
Triton X-100	6-Undecanone	0.8

A comparison of the I_b/I_f values determined from spectra of ketones in different surfactant systems is presented in Table 1. The values for 5-nonanone, 6-undecanone, and 7-tridecanone are the same within experimental error as already mentioned. The value of I_b/I_f for 7-tridecanone in sodium dodecanoate is smaller than that for 7-tridecanone in SDS. This demonstrates that the extent of contact between the solvent and the guest ketone is dependent on the nature of the polar group of the surfactant molecules. Menger *et al.* (14) found differences in the conformational order of the chains in these two surfactant molecules. In the case of DTAC and CTAB, I_b/I_f (determined from guest 6-undecanone) decreases as the surfactant chain length increases, the same as in the case of the series of alkyl sulfates (Fig. 2). The value of I_b/I_f for 6-undecanone in DTAC is 7 while it is only 3 for 6-undecanone in SDS. Thus, there is a pronounced difference between anionic and cationic surfactants of the same chain length. At the moment there is not enough information to conclude that this difference is a general phenomenon. But, as the extent of contact between the ketone and the solvent can be monitored by I_b/I_f, which as shown above is dependent on the "order" of the surfactant chains, these different I_b/I_f values are probably a reflection of packing differences and/or differences in the extent of solvent penetration. The value of I_b/I_f measured from the spectrum of 5-nonanone in sodium octanoate is large (8.0) compared to the others. This is undoubtedly a reflection of a very disordered micelle, one in which the water-chain contact is extensive (15). In the case of Triton X-100, the value of I_b/I_f measured from the spectrum of 6-undecanone is 0.8. This low value reflects a limited surfactant-water contact, probably a consequence of a more ordered micellar structure (16).

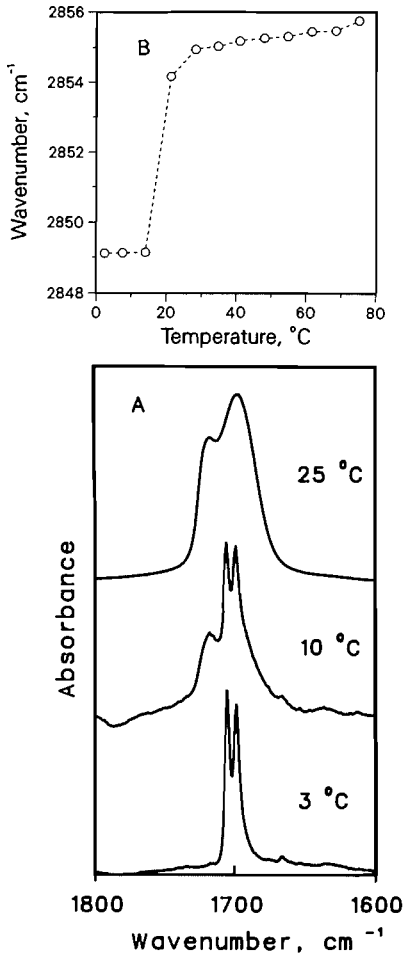

FIG. 4. *A*: Infrared spectra of 7-tridecanone (0.02 *M*) in SDS (0.28 *M*) at the indicated temperatures. *B*: temperature dependence of the wavenumber of the symmetric stretching from the methylene groups of SDS.

Effect of structural changes

One important question in this type of study is the precise location of the probe. So far, we have not addressed this question and have simply used the I_b/I_f value as a qualitative parameter to monitor the extent of contact between the solvent and guest ketones. The structure of micelles may be changed by external agents such as temperature. In the case of SDS it is well known that upon cooling a clear micellar solution, a poorly hydrated lamellar phase (coagel) forms. Several studies have determined the critical temperature of this phase transition (17–19). It is accepted that in the coagel phase the SDS alkyl chains are fully extended in the all *trans* conformation. Such changes may be easily followed by infrared spectroscopy, by monitoring the temperature dependence of the wavenumber of the methylene symmetric stretching mode, $\nu_s(CH_2)$, for example.

The C=O stretching bands of 7-tridecanone as a guest in SDS micelles at various temperatures are shown in Fig. 4*A*. The temperature dependence of the $\nu_s(CH_2)$ wavenumber of the SDS alkyl chains in the same sample is presented in Fig. 4*B*. In accord with previous work, the coagelization temperature is centered at 15°C, characterized by a large shift in the $\nu_s(CH_2)$ wavenumber. The micelle to coagel transition is complete in ≈2°C. The C=O stretching bands of the guest 7-tridecanone do change with temperature, but only below the coagelization temperature, and even then the changes are not as distinct as those of the $\nu_s(CH_2)$ mode. The C=O bands in the spectrum recorded at 25°C are those characteristic of a micellar system; there are two bands at 1718 and 1698 cm^{-1} representing the "free" and the "bound" C=O groups, respectively. The same is observed in the spectrum recorded at 14°C; that is at a temperature slightly below the coagelization temperature, the ketone C=O stretching bands have not changed.

The ketone C=O stretching bands change dramatically at lower temperatures as demonstrated in the spectra recorded at 10 and 3°C. In the 10°C spectrum there are three C=O stretching bands at 1718, 1705, and 1698 cm^{-1} while only two at 1705 and 1698 cm^{-1} are observed in the 3°C spectrum. These spectra demonstrate that as the coagel forms, there are structural changes that modify the extent of contact between the solvent and the guest ketone. The formation of the coagel seems to be complete in a narrow temperature range (≈2°C), but the changes in the ketone spectra occur in a progressive manner covering a wider temperature range. These spectral effects are a reflection of a change in location of the guest ketone. The characteristics of the ketone C=O stretching bands in the low temperature spectrum (3°C) are those expected for direct contact between D_2O and the C=O group, and as explained above, they imply that the ketone is immobilized in a region forming 1:1 and 1:2 C=O···D_2O hydrogen bonds. We propose that in the coagel, the ketone adopts the ∩ conformation exposing the C=O group. The same conformation was proposed for the long chain ketones above and also proposed by Weiss *et al.* (13) in studies of ketones in interdigitated gel phases. In such a conformation, the ketone should also serve to stabilize the lamellar coagel phase acting as a charge "separator".

In the spectrum recorded at 3°C (Fig. 4) there are no bands due to "free" C=O groups indicating that no ketone molecules remain free from contact with the solvent.

The spectral changes induced by cooling (Fig. 4) are entirely reversible but the C=O bands show some hysteresis in following the structural changes. That is, when a sample is heated from 3 to 30°C, the coagel reverts to micelles at ≈16°C but the C=O stretching bands do not change until the system is micellar. At all temperatures below 20°C there appear only two bands at 1705 and 1698 cm^{-1}. At temperatures above 18°C, the "free" C=O band at 1718 cm^{-1} appears, and its intensity grows with time such that after 2 h, the spectrum is that typical of the micellar phase.

These spectra show that the guest ketone translocates as a consequence of structural changes and that these changes are reversible. The ketone changes from a situation in which it coexists between two environments in the micelle, to one in which there is only one in the coagel. Furthermore, in the latter case it is immobilized, forming strong hydrogen bonds. On increasing the temperature and upon reformation of the micelles, the ketone C=O stretching bands indicate that it is again exchanging between the two coexisting micellar environments. This emphasizes that the C=O···D_2O hydrogen bonds may dissociate when the ketone occupies a dry micellar region.

The structure of micelles may also be changed in the presence of a large excess of added ions (20–22). In some cases there is micellar growth, while in others there are specific ion–micelle interactions such as direct association and precipitation. The values of I_b/I_f obtained from spectra of 6-undecanone in SDS in the presence of increasing quantities of several ions are shown in Fig. 5. These results point to some contrasting effects with no ready explanation.

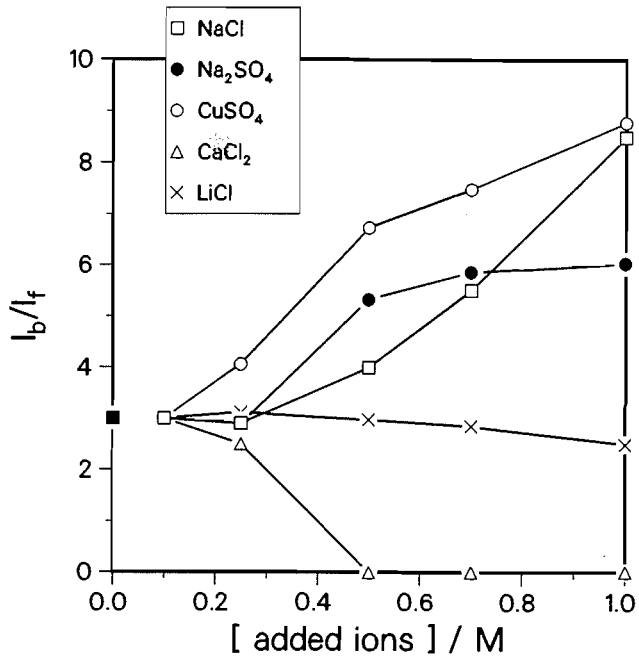

FIG. 5. The parameter I_b/I_f obtained from spectra of 6-undecanone (0.018 *M*) as guest in SDS (0.25 *M*) as a function of the concentration of added ions.

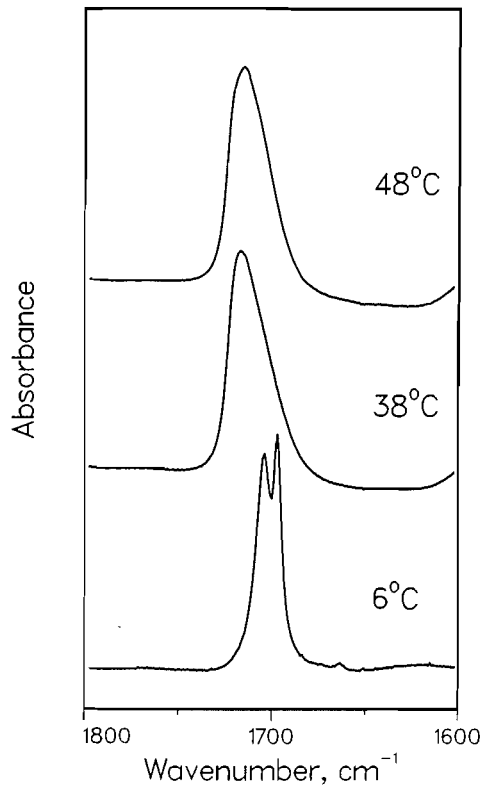

FIG. 6. Infrared spectra of 6-undecanone (0.018 *M*) mixed with DODAC (0.25 *M*) at the indicated temperatures.

Addition of increasing quantities of Ca^{2+} ions results in the disappearance of the "bound" C=O bands and therefore the I_b/I_f values decrease and tend to zero. Addition of Cu^{2+} ions has the opposite effect to that of Ca^{2+}, the I_b/I_f values increase. Both Ca^{2+} and Cu^{2+} ions associate strongly to SDS and, at the concentrations used here induce precipitation possibly forming lamellar (coagel) structures (20, 21, 23). However, there is a distinct difference between the C=O bands of the ion-induced and the cooling-induced coagels. It appears that in the ion-induced precipitation, the ketone does not adopt the ∩ conformation which allows it to come in direct contact with the solvent.

In the presence of excess Na_2SO_4, the I_b/I_f values increase slightly. Excess Na_2SO_4 induces a large increase in the aggregation number of SDS micelles (24) and in these larger micelles there is increased possibility of contact between the solvent and the probe ketones. Excess NaCl induces increases in I_b/I_f in a similar manner as with Na_2SO_4. Addition of excess LiCl does not induce significant changes in the I_b/I_f values, even though Li^+ ions interact with these surfactants inducing a lower coagelization temperature (18).

As pointed out above, there is, at present, no ready explanation for these observations at the molecular level. However, these data show that the interaction of each of these ions with micelles can alter significantly the location and/or conformation of the guest ketone, thereby affecting its ability to sample the extent of contact with the solvent.

Ketones in bilayers

In a previous report (2) of the infrared spectra of guest ketones in lipid bilayers, it was found that the I_b/I_f parameter from those spectra was lower than in the case of micelles studied here. This is a manifestation of less water penetration in bilayers as compared to micelles (25). Spectra of 6-undecanone in DODAC (21 wt.% in D_2O) at different temperatures are shown in Fig. 6. At this concentration, DODAC bilayers undergo two transitions: at room temperature it forms a coagel which transforms to a gel at 35.5°C. The gel forms a liquid crystalline phase at 45.5°C. These phase transitions have been well characterized by infrared spectroscopy (26). The C=O stretching bands of the guest 6-undecanone are at 1705 and 1698 cm^{-1} at temperatures characteristic of the coagel phase. These bands are those typical of the immobilized ketone in direct contact with the solvent. Upon formation of the gel phase (see spectrum at 38°C) the C=O bands change dramatically. The main band is at 1718 cm^{-1} with a weak shoulder at 1700 cm^{-1}; these features do not change appreciably on transition to the liquid-crystalline phase. The values of I_b/I_f measured from the spectra recorded at 38 and 48°C are 1.5 and 0.7, respectively. These spectral changes are entirely reversible; after cooling the sample back to 16°C, the C=O bands are the same as those obtained before heating.

In the coagel phase of DODAC, the alkyl chains are fully extended in the all-*trans* conformation and the polar groups are poorly hydrated (26). In this case, the ketone adopts the ∩ conformation and comes into direct contact with the solvent, possibly serving as "charge separator". Thus the DODAC coagel induces the same type of ketone location and immobilization as in the cooling-induced coagel formed by the single chain SDS. In the gel phase, the DODAC alkyl chains are also fully extended but the polar groups are hydrated (26); it is apparent that in this case the ketone is not immobilized at the solvent interface and migrates to a hydrophobic region with no possibility of contact with D_2O. The same holds for the liquid crystalline phase of DODAC. From the values of I_b/I_f it appears that in passing from the gel phase to the liquid-crystalline phase of DODAC the extent of chain–water contact decreases; a similar result was found in the case of lipid bilayers (2).

Concluding remarks

In this work, we have explored the possibility of using the infrared spectra of aliphatic ketones to study micellar properties. The approach uses ketones as probes and is based on the sensitivity of the C=O stretching vibration to hydrogen bonding. Therefore, the extent of contact between the guest ketones and the solvent (water) is readily followed. In the infrared spectra (cf. Fig. 1), there are C=O stretching bands characteristic of hydrogen-bonded C=O groups as well as bands due to non-bonded or "free" C=O groups. Thus, the guest ketones occupy at least two different micellar environments. One environment offers the possibility of contact between the ketone and water, while the other does not. The relative intensity of the "bound" and "free" C=O bands, I_b/I_f, is used as a parameter to monitor the extent of contact between water and the surfactant chains. This parameter gives a qualitative measure of the relative volumes of these two micellar environments. Variations in this parameter are used to compare different systems. It is shown that as the volume of micelles increases, I_b/I_f decreases (cf. Fig. 2) demonstrating that the volume of the micellar region devoid of solvent increases. Formation of lamellar phases of SDS induced by cooling induces a reversible translocation of the guest ketones. It is proposed that in these coagels the ketones adopt a bent conformation. A similar conformation is proposed for guest ketones in micelles when there is a pronounced mismatch between the ketone chain length and the surfactant chain length (cf. Fig. 3).

In summary, the infrared spectra of carbonyl-containing compounds dissolved in various mesomorphs yield a qualitative comparison of different systems regarding the water–chain contacts. The determination of the absorptivities of the individual C=O stretching bands coupled with "locking" of the probe molecules at known locations will help to quantitate the effects observed and to remove the uncertainties derived from probe translocations. Such work is in progress.

α-Phenylglycinamide **5** reacts with ketones to give either the Schiff base **3** or the 4-imidazolidone **4**, but reacts with boiling isobutyraldehyde to give the bicyclic compond **6**. The structure and stereochemistry of **6** have been established by ^{1}H nuclear Overhauser effect difference measurements, supported by molecular mechanics calculations.

Key words: structure, stereochemistry, nuclear Overhauser effect, molecular mechanics, α-phenylglycinamide reactions.

NING QING, LAWRENCE D. COLEBROOK, JOHN T. EDWARD, ALLAN KON et FRANCIS L. CHUBB. Can. J. Chem. **67**, 1560 (1989).

L'α-phénylglycinamide (**5**) réagit avec les cétones pour fournir soit les bases de Schiff **3** soit les 4-imidazolinones **4**; toutefois, il réagit avec l'isobutyraldéhyde bouillant pour conduire au composé bicyclique **6**. On a déterminé la structure et la stéréochimie du composé **6** à l'aide de mesures de différences d'effet Overhauser nucléaire du ^{1}H ainsi que par des calculs de mécanique moléculaire.

Mots clés : structure, stéréochimie, effet Overhauser nucléaire, mécanique moléculaire, α-phénylglycinamide.

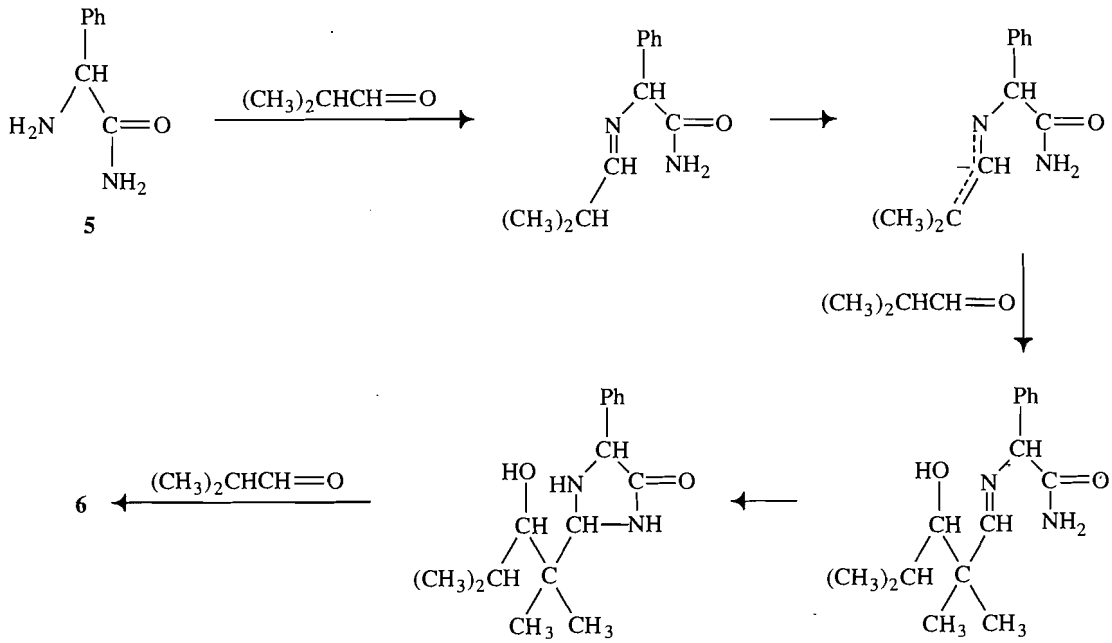
Under basic conditions, α-aminonitriles **1** react with neat acetone (**2**; $R^2 = R^3 =$ Me) to give sometimes the Schiff bases **3** ($R^2 = R^3 =$ Me) (1–4), and sometimes the isomeric 4-imidazolidones **4** ($R^2 = R^3 =$ Me) (5); on the other hand, they are reported to react with cyclohexanone (**2**; $R^2R^3 = (CH_2)_5$) to give only the imidazolidones **4** ($R^2R^3 = (CH_2)_5$) (4, 5). The isomers **3** and **4** may be distinguished by their characteristic infrared and nuclear magnetic resonance spectra (6, 7), and by differing chemistries. Thus, while the imidazolidones are sufficiently basic and sufficiently stable to form stable picrates, the Schiff bases are readily hydrolyzed and with picric acid give picrates of the α-aminoamides **5** (4).



On mechanistic grounds (6–9) it seems likely that in all the reactions cited above the Schiff bases are first formed, but that in basic solution some are readily cyclized to the imidazolidones (cf. ref. 4). To study the differing cyclization tendencies, we attempted to prepare various Schiff bases by reaction of α-amido-α-phenylacetamide (**5**; R^1 = Ph) with ketones or aldehydes in neutral solution. While acetone yielded the Schiff base **3** (R^1 = Ph, $R^2 = R^3$ = Me), cyclopentanone in refluxing absolute alcohol yielded the imidazolidone **4** (R^1 = Ph, $R^2R^3 = (CH_2)_4$), and cyclohexanone the imidazolidone **4** (R^1 = Ph, $R^2R^3 = (CH_2)_5$). However, in refluxing benzene, cyclopentanone and cyclohexanone formed the corresponding Schiff bases, which then cyclized to the imidazolidones in refluxing absolute alcohol. The order of reactivity of the Schiff bases in forming the cyclic product (**3**, R^1 = Ph, $R^2R^3 = (CH_2)_5$ > **3**, R^1 = Ph, $R^2R^3 = (CH_2)_4$ > **3**, R^1 = Ph, $R^2 = R^3$ = Me) accords with the order of reactivity of the parent ketones (10).

Commeyras and co-workers (9) found isobutyraldehyde (**2**; R^2 = *i*-Pr, R^3 = H) very effective in catalyzing the hydrolysis of α-aminopropionitrile (**1**; R^1 = Me) in basic aqueous solution to the amide **5** (R^1 = Me), and concluded that the Schiff base **3** (R^1 = Me, R^2 = *i*-Pr, R^3 = H) was first formed but readily hydrolyzed. We attempted to obtain the Schiff base **3** (R^1 = Ph, R^2 = *i*-Pr, R^3 = H) by reaction of **5** (R^1 = Ph) with boiling neat isobutyraldehyde, but obtained instead a compound shown by analysis to be formed by condensation of one molecule of α-phenylglycinamide with three molecules of isobutyraldehy-

de, with the elimination of two molecules of water. Two possible structures for this compound are **6**, formed by the route of Scheme 2 or some equivalent route, or **7**.

This structural problem presents an interesting challenge, because both **6** and **7** contain four chiral centres. Since these chiral centres form isolated spin systems, scalar ^1H–^1H coupling information that might have related them is not available. Hence their relative stereochemistry was determined using dipolar (through-space) coupling via ^1H nuclear Overhauser effect difference (NOED) spectroscopy (11–13).

6

7

The 400-MHz (C_6D_6 solution) ^1H nmr spectrum shows well-resolved aromatic proton signals, which were assigned on the basis of their multiplicities and intensities (Table 1). The NH proton shows a broad singlet at δ 8.47.

The ring protons give rise to two singlets (H-3 and H-9), and two doublets due to spin coupling to the isopropyl groups (H-5 and H-7). The singlet at δ 4.12 was broadened due to unresolved long range coupling, and hence was assigned to the benzylic proton at C-3. The remaining (sharp) singlet (δ 4.25) in this region must be due to H-9.

The geminal methyl groups at C-8 are diastereotopic since the molecule is chiral, and give rise to singlets at δ 1.04 and δ 0.82.

Similarly, the isopropyl methyl groups are diastereotopic, and give rise to four doublets, those at δ 0.85 and 0.88 being incompletely resolved. Spin-decoupling experiments identified and established the spin connectivities of the complete isopropyl and associated ring proton spin systems. Thus H-5 (δ 3.94, J = 1.5 Hz), H-10 (δ 1.44), the δ 1.14 and δ 0.88 methyl groups

form one isolated spin system, while H-7 (δ 3.14, J = 5.0 Hz), H-11 (δ 1.70), the δ 0.94 and δ 0.85 methyl groups form the other.

The relative stereochemistry at the chiral centres was established by NOED experiments. Irradiation of the benzylic ring proton (H-3) led to intensity enhancement of the signals from the *ortho* aromatic protons, H-5, H-10, but not for the NH proton signal. This demonstrates the close proximity of H-3 to H-5 and H-10, so that H-5 and H-3 must be on the same face of the ring system. The proximity of H-3 to H-5 and H-10 is consistent with structure **6**, but not **7**. Further, an NOE between the benzylic

ring proton and the NH proton would have been expected for structure **7**.

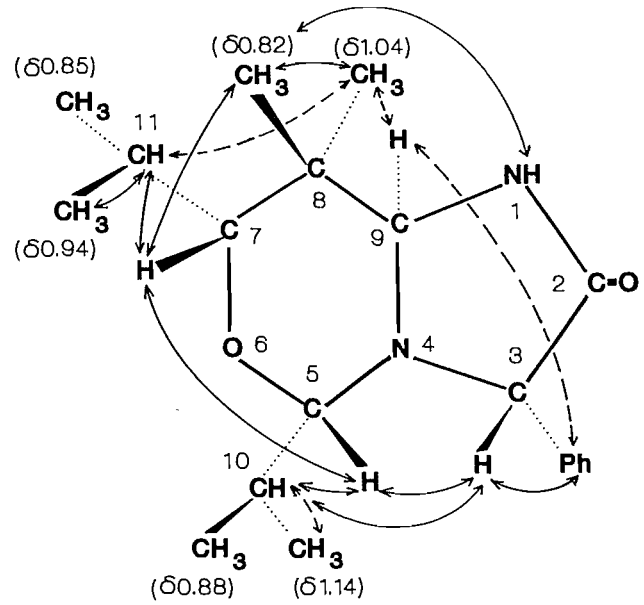
Irradiation of H-9, which produces the other ring proton singlet, enhances the signals of the *ortho* aromatic protons, the NH proton, and the δ 1.04 geminal methyl group. There is no detectable enhancement of signals from the other ring protons, indicating that H-9 is not in close proximity, and suggesting that H-9 is on the opposite side of the ring from H-3 and H-5. Detection of a relaxation pathway between H-9 and the *ortho* protons indicates that H-9 and the phenyl group are on the same face of the ring system.

Irradiation of H-5 strongly enhances the signals of H-3, H-7, and weakly enhances the signal of H-10, its vicinal neighbour. This indicates that H-5 and H-7 are in close proximity, i.e., on the same side of the molecule.

Irradiation of H-7 strongly enhances the signal of H-5 (verifying the steric relationship of H-5 and H-7), and weakly enhances the signal of H-11, its vicinal neighbour.

We note that irradiation of H-5 enhances the signals of *both* H-3 and H-7, but that the only ring proton affected by irradiation of H-3 and H-7 is H-5. This suggests that H-5 is close to both H-7 and H-3, but that H-7 and H-3 are distant from each other. Examination of a molecular model of the assigned structure shows that H-3, H-5, and H-7 have an approximately linear relationship, such that a significant NOE pathway between H-3 and H-7 is not expected.

The NOE pathway between H-3 and H-10 indicates that H-3 is close to the isopropyl group containing H-10, and that this group is in a conformation with H-10 close to H-3. A study of molecular models suggests that H-10 would be close to H-3 in the preferred conformation of the C-5 isopropyl group.



Irradiation of H-11 affects only the signal of its vicinal neighbour, H-7, and methyl groups, indicating that H-11 is remote from other ring protons.

Irradiation of the δ 1.14 isopropyl methyl group enhances the signals of H-10 and the δ 0.88 isopropyl methyl group, i.e., within the same isopropyl group, and also the *ortho* aromatic proton signals. Hence the δ 1.14 isopropyl methyl group is on the same face of the molecule as the phenyl group. Irradiation of the δ 0.94 isopropyl methyl group enhances the signals of H-11 and H-7. Hence the δ 0.94 isopropyl methyl group is on the same face of the molecule as H-7.

The NOED experiments on the geminal methyl groups permit assignment of their signals. Thus irradiation of the δ 1.04 methyl produces an enhancement of the signal of its geminal neighbour, of H-11, and of H-9. Irradiation of the δ 0.82 methyl produces enhancement of H-9, H-11, the δ 1.04 geminal methyl, the NH, and the H-7 signals. It may be inferred that the geminal methyl groups lie between C-7 (and C-11) and C-9, that the δ 0.82 methyl is on the same face of the molecule as H-7, and is close to NH, and that the δ 1.04 methyl group is on the same face as H-9. The C-7 isopropyl group must have a low energy conformation with H-11 facing the *gem*-dimethyl groups.

The ^{13}C spectrum, which shows 18 resolved signals, was assigned with the aid of the DEPT (ref. 11, Chap. 8) spectral editing sequence to classify the signals of the carbons according to the numbers of attached protons. Thus, the six signals in the range 14–24 ppm were identified as arising from methyl groups (all geminal methyl groups are diastereotopic), and nine signals (three of which were characterized by their chemical shifts as aromatic) were shown to arise from CH units. Correlation of the carbon signals with the chemical shifts of directly attached, previously assigned, protons was achieved using the CHORTLE method (14). Unequivocal assignment of all carbon signals except those at 23.21, 22.98, and 18.97 ppm was possible by this method. There is some uncertainty in the assignment of these three signals because of the small chemical shift differences of the attached protons.

Thus, the NOED data indicate that the structure of the molecule is:

(plus its enantiomer). In the preferred conformations of the isopropyl groups, H-10 faces towards H-3, while H-11 faces the *gem*-dimethyl system. The major NOE (relaxation) pathways are indicated.

Other spectral properties (e.g., ir) are in agreement with the structure **6** but of no particular value in establishing structure.

Further insight into the geometry of the molecule was obtained from molecular mechanics calculations, using an implementation of the Allinger MMP2 algorithm (15), with provision for π-electrons. The lowest energy optimized structure, based on the configuration established by the NOED measurements, was predicted with the six-membered ring in a chair conformation, with both isopropyl groups equatorial, the N-4—C-3 bond pseudo-equatorial, and the C-9—NH bond pseudo-axial (Fig. 1). Molecular mechanics calculations in which rotation about the C-5—C-10 bond is driven indicated an overall energy minimum for the conformation with H-10 facing towards the phenyl group. The three-bond $^1H-^1H$ coupling constant calculated using the Karplus equation (16) for the predicted H-5—C—C—H-10 dihedral angle (about 60°) for this conformation is consistent with the observed value of 1.5 Hz.

Similarly, energy calculations for rotation of the other isopropyl group about the C-7—C-11 bond indicated a broad low energy region centred on a H-7—C—C—H-11 dihedral angle of about 122°, with H-11 facing towards the *gem*-dimethyl group. The calculated three-bond coupling constant for this angle is consistent with the observed 5.0-Hz coupling constant.

The H-9—C—N—H dihedral angle in the calculated minimum energy conformation is 87°, corresponding to a near minimum three-bond coupling constant predicted from a Karplus-type relationship (17). This is consistent with the absence of observable coupling in the H-9 and NH signals.

This molecular conformation (Fig. 1), deduced from molecular mechanics calculations, is completely consistent with the NOED measurements.

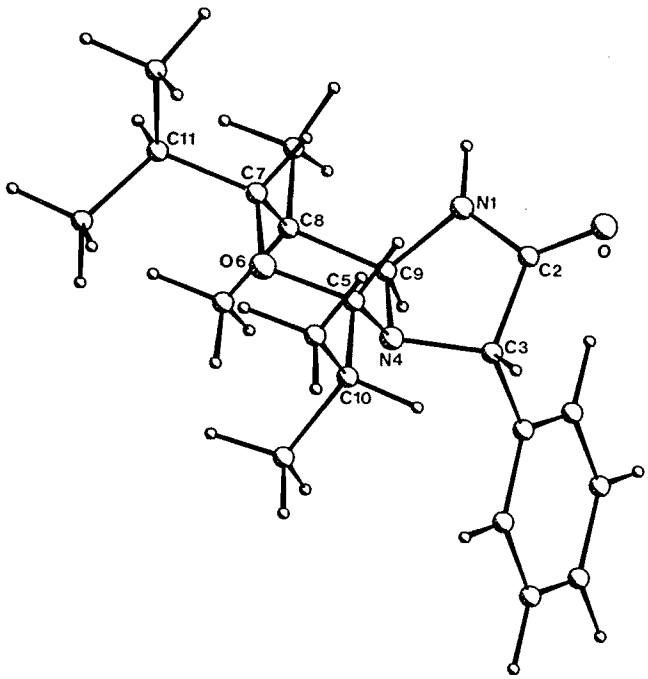


FIG. 1. Lowest energy conformation of **6**, predicted by molecular mechanics calculations for the configuration established by NOED measurements.

Experimental

The ^1H nmr spectra were recorded at 60 MHz unless otherwise noted. The ^1H nmr spectra of **6** were determined at 400.13 MHz using $CDCl_3$ and C_6D_6 solutions on a Bruker WH-400 spectrometer located at the Montreal Regional High Field NMR Laboratory. The spectra obtained in C_6D_6 solution showed better signal dispersion, so this solvent was used for spin-decoupling and NOED (11–13) measurements. The method of successive multiple irradiation of the components of multiplets described by Kinns and Sanders (13) was used for NOED experiments, with the sample not spinning. The NOED assignments were verified by the reverse irradiation experiments.

The ^{13}C nmr spectra were measured at 20.1 MHz on C_6D_6 solutions using a Bruker WP-80SY spectrometer equipped with a 10-mm broadband probe. The DEPT (ref. 11, Chap. 8) spectral editing pulse sequence was used to identify the numbers of attached protons associated with each carbon signal. The carbon signals were correlated with the previously assigned attached proton signals using the CHORTLE (14) method, with evolution times of 0.4, 1.0, 2.4, and 3.2 ms, and data processing using the program CHFIT (14) on an Olivetti M24 microcomputer. CHORTLE, which is a one-dimensional technique, has the advantage over the two-dimensional heteronuclear ($^{13}C-^1H$) method of identifying the chemical shifts of protons attached to carbon atoms with high accuracy, and so is equivalent to a two-dimensional experiment that uses a very large data matrix. It is also suitable for use with a low field ^{13}C instrument, provided that a high field ^1H spectrum, with good chemical shift dispersion, is available for signal assignment, and the ^1H spectra are approximately first order.

Molecular mechanics and coupling constant calculations were carried out on an Olivetti M24 microcomputer using the programs MMPMI and PCMODEL, obtained from Serena Software, Bloomington, Indiana, U.S.A. MMPMI is an implementation of the Allinger program MMP2 (15), which includes π calculations, and has been modified to run on IBM-compatible microcomputers. Three-bond coupling constants for the appropriate low energy geometries were calculated within PCMODEL, which uses the parameters of Haasnoot *et al.* (18). The program PCDISPLAY (Serena Software) was used for molecular graphics display.

Synthetic procedures

N-Isopropylidenephenylglycinamide

Phenylglycinamide (1 g) was heated with 50 mL acetone under reflux for 2 h. Concentration yielded 0.9 g (71%) of crude product, mp 135–139°C. A sample recrystallized from acetone had mp 142–144°C (lit. (4) mp 144°).

N-*Cyclopentylidenephenylglycinamide*

A solution of 1.5 g phenylglycinamide and 2 mL cyclopentanone in 25 mL benzene was heated under reflux with a Dean Stark trap. Separation of water occurred during 1 h. After 2.5 h the solvent was evaporated and the residue was washed with petroleum ether and filtered to yield 2.1 g (97%), mp 143–145°C, of *N*-cyclopentylidenephenylglycinamide. This was recrystallized from benzene (20 mL) and petroleum ether (20 mL) to yield 1.9 g, mp 145–147°C; ir ν_{max} (KBr): 3272 (NH_2), 3098 (aromatic CH), 2956 (aliphatic CH), 1674 (CO), 1653 (N=C); ^1H nmr ($CDCl_3$) δ: 1.55–2.58 (m, 8H, aliphatic CH), 4.73 (s, 1H, aliphatic CH), 6.25 (br s, 1H, amide H, D_2O exchangeable), 7.28 (m, 6H, reduced to 5H by D_2O, 5 aromatic CH, 1 amide H). *Anal.* calcd. for $C_{13}H_{16}N_2O$: C 72.19, H 7.46; found: C 72.35, H 7.54.

2,2-Tetramethylene-5-phenylimidazolidone-4

Procedure A: A solution of 1.5 g phenylglycinamide and 2.0 mL of cyclopentanone in 25 mL absolute alcohol was heated under reflux for 3 h. After evaporation of solvent the residue was washed with petroleum ether and filtered to yield 1.97 g (91%) of crude product, mp 128–142°C. Recrystallization from water and alcohol raised the mp to 150–153°C. An analytical sample melted at 155–157°C; ir ν_{max} (KBr): 3260, 3172 (NH_2), 3073, 3032 (aromatic CH), 2935, 2853 (aliphatic CH), 1710 (CO) 1687 (C=N); ^1H nmr ($CDCl_3$) δ: 1.33–2.00 (m, 8H, aliphatic CH), 2.22 (s, 1H, NH, exchangeable with D_2O), 4.67 (s, 1H, aliphatic CH), 7.00–7.63 (m, 5H, aromatic CH), 8.15 (s, 1H, CONH, exchangeable with D_2O). *Anal.* calcd. for $C_{13}N_{16}N_2O$: C 72.19, H 7.46; found: C 72.42, H 7.42.

Procedure B: When 1 g of *N*-cyclopentylidenephenylglycinamide was heated to reflux in 20 mL absolute alcohol for 3 h it was converted to the cyclic compound in 60% yield.

Picrate of 2,2-tetramethylene-5-phenylimidazolidone-4

The picrate was prepared by dissolving 0.22 g of the above compound and 0.23 g of picric acid in 5 mL of alcohol. On dilution with 5 mL water, 0.27 g (61%) of the picrate separated, mp 146–147°C. *Anal.* calcd. for $C_{19}H_{19}N_5O_8$: C 51.23, H 4.30; found: C 51.29, H 4.34.

N-*Cyclohexylidenephenylglycinamide*

A mixture of 3.0 g phenylglycinamide and 4 mL of redistilled cyclohexanone in 50 mL benzene was heated to reflux under a Dean Stark trap. Heating was continued until water ceased coming over (about 15 min). Evaporation of solvent left a solid residue, which was washed with petroleum ether and filtered to yield 4.3 g (93.5%) of crude product, mp 104–107°C; ir ν_{max} (KBr): 3398, 3229, 3164 (NH_2), 3085, 3071, 3027 (aromatic CH), 2947, 2933, 2857 (aliphatic CH), 1639 (CO), 1659 (C=N); ^1H nmr ($CDCl_3$) δ: 1.30–1.90 (m, 6H, aliphatic CH_2), 1.90–2.5 (m, 4H, aliphatic CH_2), 4.78 (s, 1H, aliphatic CH), 6.00 (br s, amide NH, exchangeable with D_2O), 6.73–7.40 (m, 6H, 5 aromatic CH, 1 amide NH, reduces to 5H with D_2O). *Anal.* calcd. for $C_{14}H_{18}N_2O$: C 73.01, H 7.88; found: C 73.10, H 7.86.

2,2-Pentamethylene-5-phenylimidazolidone-4

Procedure A: A solution of 2.5 g phenylglycinamide and 2.0 mL of cyclohexanone in 17 mL of absolute alcohol was heated to reflux for 2.5 h. Concentration of the solution yielded 3.1 g (81%) of the product, mp 168–171°C. Recrystallization from alcohol raised the mp to 174–176°C; ir ν_{max} (KBr): 3170, 3070 (NH), 3040 (aromatic CH), 2940, 2860 (aliphatic CH_2), 1695 (CO); ^1H nmr ($CDCl_3$) δ: 1.16–1.96 (m, 1OH, aliphatic CH_2), 2.16 (s, 1H, NH, exchangeable with D_2O), 4.71 (s, 1H, aliphatic CH), 7.20–7.68 (m, 5H, aromatic CH), 7.85 (s, amide NH, exchangeable with D_2O). *Anal.* calcd. for $C_{14}H_{18}N_2O$: C 73.01, H 7.88; found: C 72.92, H 8.02.

Procedure B: When 1.0 g of *N*-cyclohexylidenephenylglycinamide in 40 mL absolute alcohol was heated under reflux for 2.5 h, concentra-

For personal use only.

tion and crystallization of the residue from alcohol–water yielded 0.71 g (71%), mp 172–174°C, of the cyclic amide (structure confirmed by ir).

Picrate of 2,2-pentamethylene-5-phenylimidazolidone-4

2,2-Pentamethylene-5-phenylimidazolidone-4 (0.1 g) and 0.1 g picric acid were dissolved in 1 mL absolute alcohol. Dilution with petroleum ether yielded 0.16 g (80%) of the picrate, mp 146–148°C. *Anal.* calcd. for $C_{20}H_{21}N_5O_8$: C 52.29, H 4.60; found: 52.31, H 4.54.

5,7-Diisopropyl-8,8-dimethyl-2-oxo-3-phenylimidazolidino-[1,2-c]-tetrahydro-[1,3]-oxazine, 6

A solution of 2.5 g phenylglycinamide in 40 mL isobutyraldehyde was heated under reflux for 6 h. Cooling and filtering the solution yielded a crop of white crystals, which were recrystallized from ethanol to yield 1 g (18%) of product, mp 192–194°C; ir ν_{max} (Nujol): 3175 (NH), 1700 (CO). *Anal.* calcd. for $C_{20}H_{30}N_2O_2$: C 72.69, H 9.15, N 8.48; found: C 72.26, H 9.41, N 8.22.

Alternative procedure: Phenylglycinamide (2.5 g) in 40 mL isobutyraldehyde was heated under reflux for 7 h. After diluting with petroleum ether, 1.2 g of product, mp 197–199°C, crystallized from the solution. When the filtrate was extracted with 4 N HCl and the extract made basic with NaOH an additional 0.54 g of product separated, mp 187–193°C. The total yield of crude product was 1.74 g (32%). When recrystallized from alcohol, it melted at 196–198°C.

Acknowledgments

This work was supported by operating grants from the Natural Sciences and Engineering Research Council of Canada (NSERC), who also provided funding towards the purchase of the NMR spectrometers. We wish to thank Dr. G. A. Pearson for providing copies of the CHCORR pulse program for the Bruker spectrometer and the CHFIT program for data reduction.

Photoexcitation of the title compound (DMBA) in polar solvents leads to sequential formation of at least three excited species as detected by laser transient absorption spectroscopy: the lowest Franck–Condon singlet, a twisted singlet (*P*-state), and the lowest triplet states. Only the initially formed, localized singlet is emissive under our conditions. Interystem crossing to triplet occurs primarily from the twisted *P*-state in acetonitrile and in methanol. Photo-CIDNP and quantum yield measurements indicate that electron transfer occurs exclusively from the triplet in acetonitrile or methanol to sensitize decomposition of diphenyliodonium cation and to bleach DMBA. Analysis of the photochemistry is complicated by formation of a charge transfer complex of enhanced photolability. Using tris(trichloromethyl)-*sym*-triazine as the electron acceptor in hydrocarbon solvent, bleaching of DMBA again occurs, somewhat more efficiently than with the 'onium salt in polar solvent. We infer that under these conditions electron transfer occurs from the *P*-state.

Key words: photochemistry, fluorescence, electron transfer, TICT, chalcone.

La photoexcitation du composé mentionné dans le titre (DMBA), dans des solvants polaries, conduit à la formation en série d'au moins trois espèces excitées que l'on a détectées par spectroscopie d'absorption au laser des espèces transitoires : l'état singulet Franck–Condon le plus bas, un état singulet déformé (état-*P*) et l'état triplet le plus bas. Dans les conditions utilisées, le seul état à émettre est le singulet localisé qui se forme initialement. Dans l'acétonitrile ou le méthanol, il se produit un passage intersystème de l'état-*P* déformé vers l'état triplet. Des études de photo-CIDNP et des mesures de rendement quantique effectuées dans l'acétonitrile ou dans le méthanol indiquent que le transfert d'électron se produit exclusivement à partir du triplet, qu'il sensibilise la décomposition du cation diphényliodonium et qu'il décolore le DMBA. L'analyse de la photochimie est compliquée par la formation d'un complexe de transfert de charge de photolabilité accrue. Lorsqu'on utilise de la tris(trichlorométhyl)-*sym*-triazine comme accepteur d'électron dans un solvant hydrocarboné, il se produit encore de la décoloration du DMBA dont l'efficacité est plus grande qu'avec le «sel onium» dans un solvant polarie. On en déduit que dans ces conditions le transfert d'électron se produit à partir de l'état-*P*.

Mots clés : photochimie, fluorescence, transfert d'électron, TICT, chalcone.

[Traduit par la revue]

Introduction

The spectroscopic properties of bis(*p*-*N*,*N*-dimethylaminobenzylidene)acetone (DMBA) have been studied by Eisenhart and Ellis (1), who also reported its photodimerization. These investigators report a sub-ns lifetime for the fluorescent singlet excited state of DMBA, but find evidence in the dimerization kinetics for the existence of a second, longer-lived "phantom" singlet state. Given the structural relationship between DMBA and other molecules, e.g., Michler's Ketone, in which the formation of twisted internal intramolecular charge transfer (TICT) excited states have been confirmed (2), we anticipated

DMBA

that this phantom state of DMBA might be of a similar nature. Fluorescence spectroscopy (1), however, provided no evidence for a TICT state; TICT states are usually emissive (2).

One purpose of this study, therefore, was the characterization of the excited states of this interesting molecule; detailed description of the excited state dynamics is, furthermore, prerequisite to interpretation of the behaviour of DMBA as a sensitizer of electron transfer photoreactions.

Electrochemical studies[5] suggested that DMBA, $E_{ox} = +1.0$ V vs. SCE in acetonitrile, should be capable in one or more of its

excited states (4) of donating an electron to a relatively oxidizable, photolabile species, such as tris(trichloromethyl)-*sym*-triazine, $E_{ox} = -0.7$ V vs. SCE (5), or diphenyliodonium cation, $E_{red} = -0.7$ V vs. SCE,[6]. The chemistry of the latter cation has been under extensive investigation in other laboratories (7–9) as well as our own (10), especially with respect to electron transfer sensitized photolysis. We are presently interested in the question of participation of a nonlocalized excited state, either of the TICT (2) or the *P* (11) type, in such electron transfer sensitization.

As with our previous study (10) of anthracene sensitized photolysis of the diphenyliodonium cation, several lines of investigation have proved fruitful in elucidating the pathways responsible for electron transfer sensitization with DMBA: photo-CIDNP experiments; quantum yield measurements for the photobleaching of the DMBA chromophore; picosecond-resolved transient absorption spectroscopy; and kinetic analysis of the results obtained in these and the steady-state irradiations. It is thus a further intent of this paper to correlate these observations with the photophysical insights.

Experimental

Materials and methods

Bis(*trans-p-N,N*-dimethylaminobenzylidene)acetone, mp 191–192°C, was prepared according to the method of Olomucki and LeGall (12) and recrystallized from toluene.[7] Diphenyliodonium hexafluorophosphate (Aldrich), mp 136°C, was purified by recrystallization from isopropanol. The tris(trichloromethyl)-*sym*-triazine, mp 93–95°C, was prepared as previously described (13). Spectral quality, glass distilled acetonitrile (EM OmniSolv^R) was used for solution preparation. Other solvents were likewise spectral quality. Most solutions were prepared directly; solutions of DMBA in cyclohexane were prepared by appropriate dilution of aliquots of a *freshly sonicated* dispersion of DMBA, 0.0010 M in cyclohexane.

Fluorescence intensities were recorded on a Perkin Elmer MPF-44B fluorescence spectrophotometer. The data for the fluorescence quantum yields were based on emission intensities of 5×10^{-7} M solutions of DMBA, excited at λ_{max} where the optical density was accordingly ca. 0.2. Spectra for absolute quantum yield measurements were recorded in the "ratio" mode of the spectophotometer to provide correction of the data for wavelength-dependent lamp output. The quantum yields were estimated by comparison at the integrated emission intensities to that of an anthracene standard (14).

Laser flash photolyses

The instrumentation used for these experiments has already been described in detail (15). The double beam, mode-locked, Nd-YAG laser system employed a silicon intensified target Vidicon detector. Light pulses at 355 nm were obtained by frequency-stripling; typical irradiances were ca. 2 mJ per pulse focused to a 2 mm diameter spot on the face of a 2-mm quartz sample curvette. The pulse width was 30 ps (FWHM). As in the quantum yield experiments, below, the solutions were deoxygenated by dry argon purge prior to irradiation. The fluorescence lifetime of DMBA in cyclohexane was measured on a similarly excited sample; fluorescence was detected with a Hamamatsu streak camera (16). Other fluorescence lifetimes were measured on a PRA time-resolved single photon counting apparatus with Xe flash excitation.

Photo-CIDNP

The photo-CIDNP spectra were obtained using the proton probe on a Varian XL-100 magnetic resonance spectrometer, with the probe modified to allow direct irradiation of the sample at the receiver coil. Typical sample composition was 0.05 M 'onium salt and ca. 0.01 M DMBA. The light source, a 300-W Xe arc operating at full power, was focused on the receiver coil using quartz optics on an optical rail. Heating of the sample was a problem, as infrared filtration decreased the light intensity too much to observe CIDNP. Consequently, photo-CIDNP spectra were recorded in the Fourier transform mode of the XL-100, collecting two transients over ca. 5 s exposure time, during which heating was minimal. Samples (2 mL volume) were deoxygenated by nitrogen purge, and dark spectra were taken before and after irradiation. Thermal instability of the solutions of the requisite concentration precluded the photo-CIDNP experiment on DMBA with the triazine acceptor in deuterocarbon solvent.

Quantum yields

Quantum yields were measured with no more than 10% conversion of DMBA as described in the text; loss of DMBA was followed spectrophotometrically at 450 nm in AN and at 425 nm in hexane. The solutions were deoxygenated by dry argon purge, as required. Aliquots (3 mL) in a 1-cm quartz spectrophotometer cell were irradiated at 405 or 450 nm on an optical bench with light from the Xe arc lamp, passed through a monochromator with the slits adjusted to allow a 20–30 nm bandpass. The output of the source was calibrated by means of potassium ferrioxalate actinometry (17) and continuously monitored with a radiometer. Typical fluxes of 1×10^{-6} einstein min^{-1} required 2–5 min irradiation to yield ca. 10% conversion with the iodonium salt. Correspondingly shorter times were required with the triazine acceptor. Ultraviolet–visible absorption spectra were recorded on the samples in the reaction cuvette before and after irradiation.

Photophysics of DMBA

As the absorption and fluorescence spectra of DMBA are not dissimilar to those of singly chromophoric *p*-aminophenyl carbonyl compounds (2, 18, 19), we consider the molecule to comprise two identical cross-conjugated chromophores; excitation may thus reside in either aminophenylvinylcarbonyl segment of the molecule. Intramolecular rotation to convert the vertical first singlet excited state to a TICT state would accordingly occur about the C—N single bond (2); alternatively this localized singlet may decay by twisting of the vinylic double bond, to form a *P*-state, according to Hochstrasser's (11) nomenclature. This state may be either charge transfer or biradicaloid in nature. A potential energy diagram incorporating the *P*-state is shown in Fig. 1.

Studies in acetonitrile

We determined the fluorescence lifetime of DMBA in acetonitrile (AN) by time-correlated single photon counting. The emission decays as a single exponential with time constant, τ, 0.7 ns. Based on the oscillator strength of 0.89, calculated by integration of the DMBA absorption spectrum in acetonitrile, we estimated (20) the first-order fluorescence rate constant, k_f, to be 4.8×10^8 s^{-1}, consistent with the directly measured value (see below):

$$[1] \quad \phi f = k_f(k_f + k_d)$$

and

$$[1a] \quad \tau = 1/(k_f + k_d)$$

where ϕ_f is the fluorescence quantum yield and k_d is a rate constant for radiationless decay. The radiationless decay process, responsible for the deactivation of the initially formed, fluorescent, singlet excited state then occurs with a first-order rate constant, k_d, of ca. 1×10^9 s^{-1} in AN.

[6]A commonly cited reference (6) for the reduction potential of diphenyliodonium cation in this solvent has proved unreproducible in our laboratories, although the value cited in this earlier work has recently been reproduced in Prof. Timpe's laboratory (8). We thank Prof. Timpe for bringing this reference to our attention and for providing a reprint.

[7]We thank Dr. M. Z. Ali of the Graphics Research Laboratory, 3M, for the sample used in these experiments.

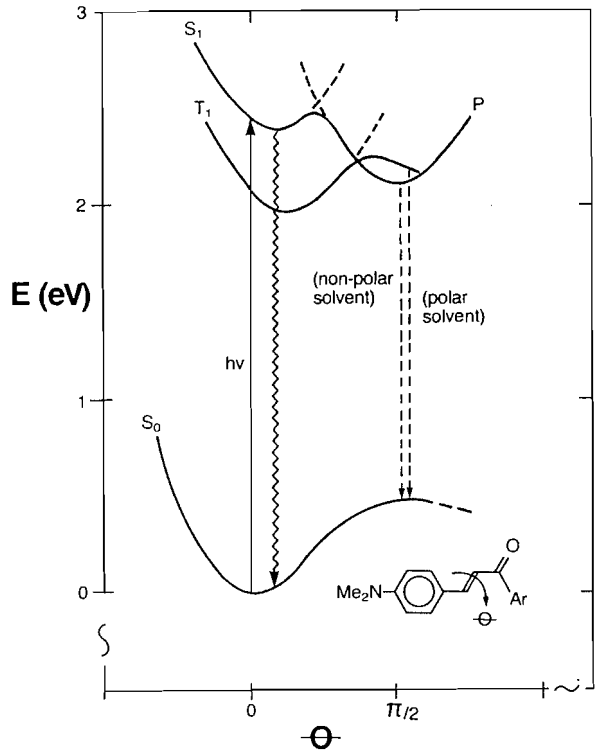

FIG. 1. Potential energy surfaces for S_0, S_1, P, and T states of DMBA as a function of torsional angle about the vinylic C—C bond.

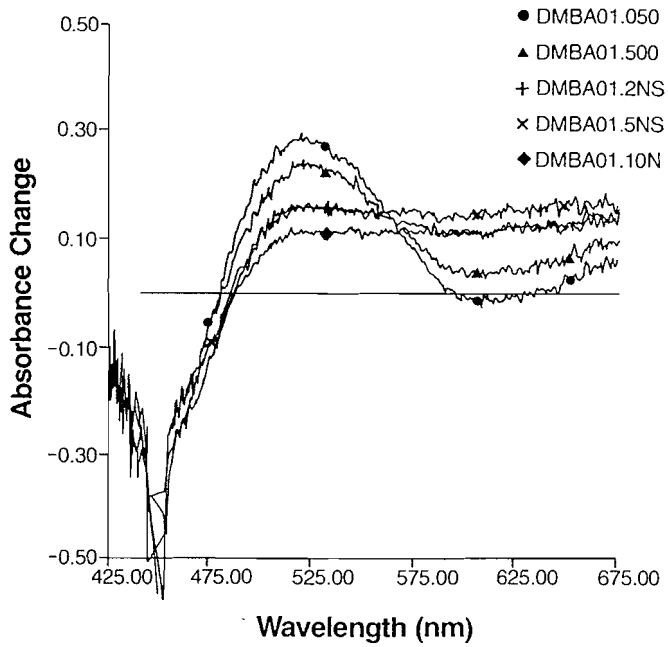

FIG. 2. Transient absorption spectra of DMBA (8×10^{-5} M in AN): (●) 50 ps, (▲) 500 ps, (+) 2 ns, (×) 5ns, and (◆) 10 ns delays after excitation with a 30-ps (FWHM) 355-nm laser pulse.

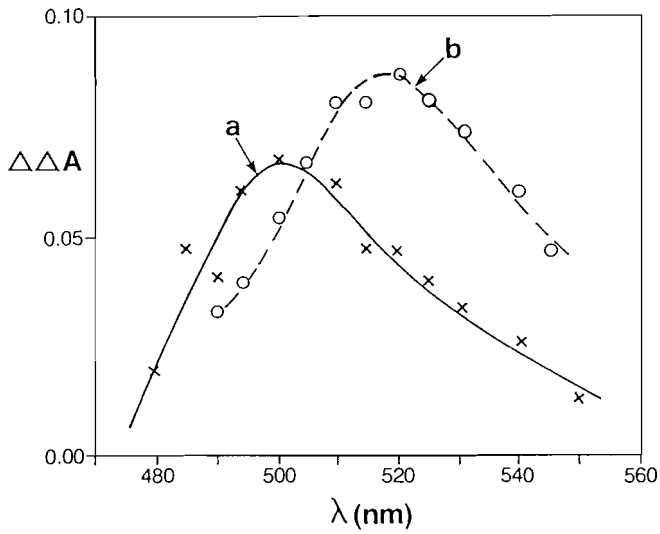

FIG. 3. Difference spectra obtained by subtracting (a) the 500-ps trace of Fig. 2 from the 50-ps trace, and (b) the 5-ns trace from the 500-ps trace.

To elucidate the nature of the radiationless decay process associated with k_d, we looked for light absorbing transients on laser irradiation at 355 nm of 8×10^{-5} M solutions of DMBA in AN. Such laser flash exposures led to transient bleaching of the 440-nm DMBA absorption, assigned by Eisenhart and Ellis (1) to the π–π^* electronic transition; no permanent changes in the absorption spectrum resulted, however. At this concentration dimerization is unimportant (raman-shifted pump radiation at 450 nm, characteristic of such experiments in acetonitrile, interferes with observation of the bleaching.) With ca. 2 mJ per excitation pulse, nearly 50% of the DMBA, 3.5×10^{-5} M, was converted to S_1, based on the intensity of bleaching.

Consequent to excitation, a new absorption occurs, apparently centered on 517 nm, assigned to an S_n–S_1 transition, with extinction coeffient 3.5×10^4 M^{-1} cm^{-1}, estimated by comparison with the extent of bleaching of the S_1–S_0 transition of known extinction coefficient (see Fig. 1). Over the lifetime of the experiment, this absorption exhibits biphasic decay, from which we infer that the S_1 state exists in two isomeric forms. Based on the time-resolved Vidicon response at 517 nm, we estimate that photo-excited DMBA surviving more than 1 ns after excitation has a lifetime in this second, phantom state of ca. 19 ± 3 ns; it represents about two-thirds of the originally excited species. This value compares with the 40-ns lifetime estimate of Eisenhart and Ellis in methylene chloride (1), based on the dimerization kinetics. The faster decaying component of the DMBA excitation corresponds to the sub-ns lifetime fluorescent species.

We illustrate that the initially formed transient of Fig. 2 actually comprises two species by taking the difference spectra between (a) the transients recorded 50 and 500 ps after the exciting pulse, and (b) the transients recorded 500 ps and 5 ns thereafter. As shown in Fig. 3, the initially formed transient has an absorption maximum at 500 nm, which subsequently red-shifts to 519 nm, characteristic of the longer-lived isomeric form of the singlet.

In AN, the ca. 20-ns lifetime state converts cleanly to a species absorbing in the red (Fig. 2). The extinction coefficient of the new transient is ca. 4.5×10^4 M^{-1}, assuming complete conversion of the first phantom state to this product. We assign it to triplet excited DMBA. In addition to the photo-CIDNP evidence, below, the rate constant for formation of this species is comparable to other intersystem crossing rate constants reported for aromatic and carbonyl compounds (20, 21).[8] Some decay of the transient is observed at 10-ns delay, despite purging with dry

[8]We thank Dr. T. S. Godfrey, Minnesota 3M Research, Harlow, England for bringing ref. 21 to our attention.

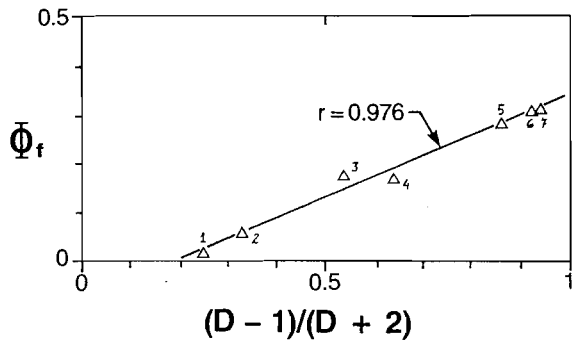

FIG. 4. DMBA fluorescence quantum yield as a function of the Debye solvent polarizability function: solvents are (1) cyclohexane (ref. 1), (2) toluene (this work and ref. 1), (3) methylene chloride (ref. 1), (4) tetrahydrofuran, (5) acetone, (6) *N*,*N*-dimethylformamide, and (7) acetonitrile (AN).

argon, suggestive again of a short triplet lifetime, which may be rationalized by the facility of isomerization about the vinylic C—C bond to provide a diabatic deactivation pathway. Sub-μs triplet lifetimes for substituted stilbenes possessing polar excited states have recently been reported (22), as well as for nitro-substituted azobenzenes (23). Similar lifetimes have also been reported for a variety of alkene triplets (24).

Solvent polarity effects

Additional experiments were accordingly undertaken to establish the nature of the secondary singlet state and elucidate the pathways for radiationless decay. The fluorescence quantum yield for DMBA correlates in non-hydroxylic solvents with the Debye solvent polarizability function $(D - 1)/(D + 2)$ (25), where D is the solvent (static) dielectric constant, as shown in Fig. 4. The plot includes data both from this work and from that of Eisenhardt and Ellis (1). The spectral energy corresponding to maximum fluorescence intensity also correlates with the same function, indicative of significant charge separation in the lowest Franck–Condon singlet.

Fluorescence rate constants, k_f, calculated as above, differ by less than a factor of two among the solvents studied; by eq. [1], k_d must therefore increase with decreasing solvent polarity. This is the opposite dependence than expected for a process that forms a charge-separated, e.g., TICT, state (28) and suggests an assignment of the non-emissive, longer-lived, singlet state as a biradicaloid *P*-state. This assignemnt is consistent with intersystem crossing therefrom, insofar as pyramidalization of the ethylenic carbons can be expected (27) to give rise to modest, but significant, spin-orbit coupling. In further support of this assignment, singlet excited 7-aminocoumarins, which contain the same chromophore as DMBA, but in which the rotation about the vinylic bond is precluded, decay (a) monoexponentially, and (b) with fluorescence as the exclusive deactivation pathway (18). That the *P*-state is biradicaloid in character is also consistent with its participation in DMBA photodimerization (1), which is accordingly orbital symmetry allowed. The biradicaloid character of the *P*-state might be expected to contribute toward the facility of intersystem crossing therefrom, as well: Caldwell *et al.* (24) have shown that pyramidalization of ethylenic carbon atoms leads to small, but significant, enhancement of spin-orbit coupling.

In cyclohexane, the least polar solvent in the series shown in Fig. 4, k_d must reach ca. 10^{12} s^{-1}, from eq. [1] and k_f, estimated as above, as 4.2×10^8 s^{-1}. Depopulation of the Franck–Condon

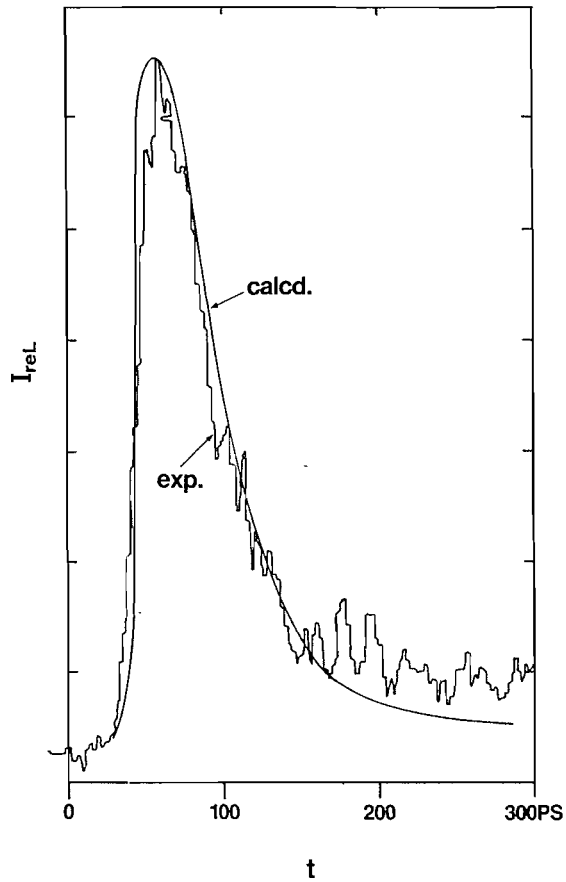

FIG. 5. Determination of fluorescence lifetime for DMBA in cyclohexane: stepped line is the trace of the streak camera as recorded, 2.2 ps per channel; smooth curve is simulation of the experimental data for 30-ps laser pulse width and 25-ps decay of fluorescence.

S_1 state on this time scale in nonpolar media was confirmed by direct measurement of the fluorescence lifetime using the 355-nm pulsed laser excitation and time-resolved fluorescence detection with a streak camera. The trace from this experiment, Fig. 5, is consistent with a ca. 25-ps lifetime for the emissive state. We also repeated the transient absorption laser flash photolysis experiment on 8×10^{-5} M DMBA dissolved in cyclohexane, as shown in Fig. 6. Despite intense bleaching of the DMBA absorption at 430 nm, no significant transient corresponding to S_2–S_1 absorption between 500 and 550 nm was observed even within the duration of the laser pulse. Ground state DMBA was, however, regenerated only to the extent of ca. 30% in 10 ns, the maximum time available in the experiment, indicating that a phantom state of up to 30-ns lifetime is, indeed, intermediate between the localized S_1 and the ground state in the nonpolar solvent, even though it is transparent to the experiment. The monotonic dependence of the relationship of Fig. 4 suggests, furthermore, that the same phantom state is involved in all solvents studied.

Solvent viscosity effects

In addition, DMBA fluorescence intensity exhibits a viscosity dependence, as shown in Fig. 7 for measurements made in a series of methanol–glycerol mixtures[9] (among which the polarizability function varied only trivially, from 0.919 to 0.936).

[9]We thank Dr. Colleen C. Nagel of these laboratories for recommending this solvent system.

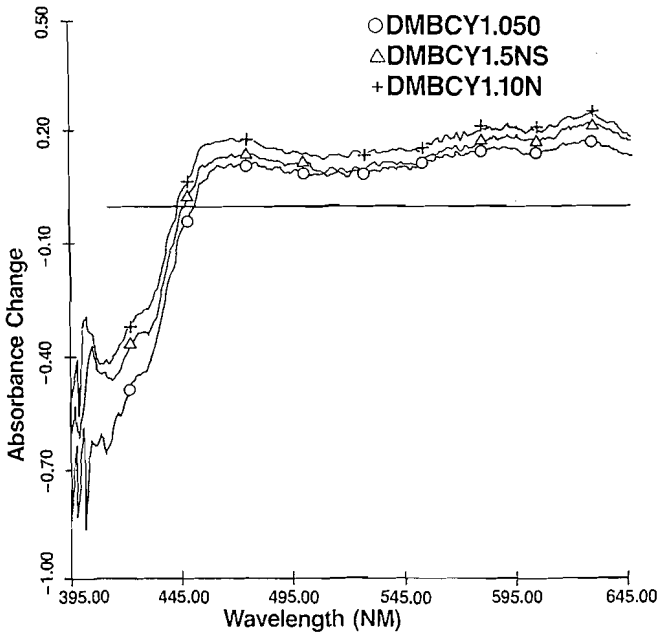

FIG. 6. As Fig. 2, in cyclohexane. Traces correspond to 50 ps (○), 5 ns (△), and 10 ns (+) after the initial 355-nm pump pulse.

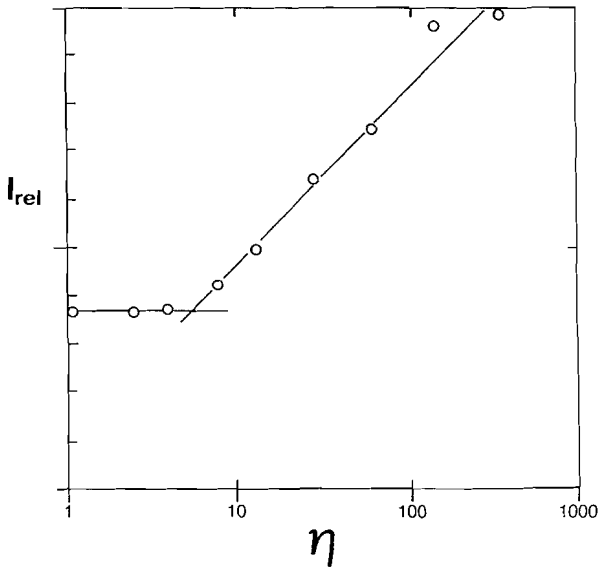

FIG. 7. DMBA fluorescence intensity as a function of solvent viscosity (cP): methanol–glycerol mixtures.

We assign the viscosity dependent radiationless decay process as isomerization to the phantom singlet state, occurring with k_d = ca. 1×10^9 s^{-1} in AN and ca. 5×10^9 s^{-1} in methanol. From Fig. 7, the rotational correlation time apparently becomes rate limiting at a viscosity of ca. 7.5 cP; at this viscosity we would then expect the correlation time to be of the order of 1 ns. At lower viscosities, the rate of formation of the phantom state is apparently limited by some intrinsic activation barrier.

The Debye formula (28) for rotational relaxation time,

$$[2] \quad t = \eta V / k_b T$$

where η is the medium viscosity, has been demonstrated to be applicable to barrierless isomerizations (2, 29). From the estimate for t when $\eta \geq 7.5$ cP and eq. [2], we estimate the sweep

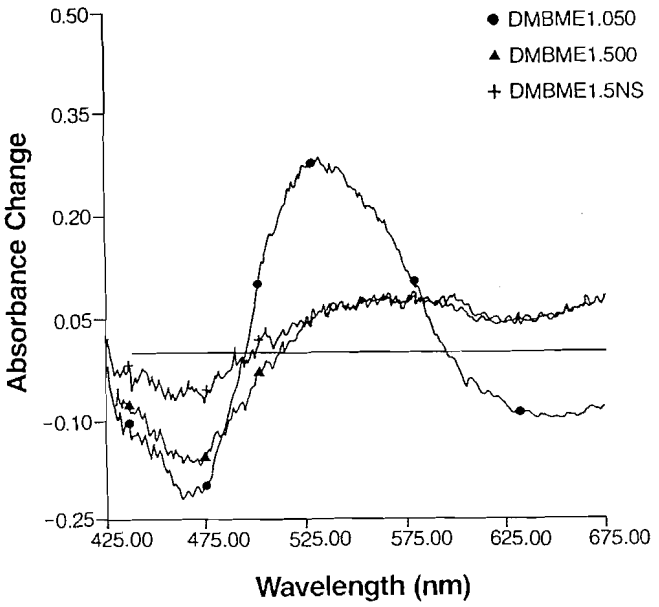

FIG. 8. As Fig. 2, in methanol. Traces shown correspond to 50 ps (●), 500 ps (▲), and 5 ns (+) after excitation; traces for intermediate delay times, used in kinetic analysis, are omitted for sake of clarity.

volume, V, of the rotating fragment to be 225 Å^3, in reasonable agreement with the volume of rotation through 90° of the *p*-dimethylaminobenzyl radical, calculated from molecular models, 192 Å^3. This correspondence is consistent with an assignment of the phantom state as a *P*-state, derived by twisting about the (ground state) vinylic double bond from a predominantly charge transfer, directly excited singlet state of DMBA, as shown in Fig. 1.

Studies in methanol

In methanol the quantum yield for fluorescence was lower, 0.06, than in aprotic solvents of comparable polarity. The fluorescence lifetime for DMBA in this solvent, measured by single photon counting, was 0.12 ns, consistent with this quantum yield and eq. [1]. Coupling of the vibrational modes of hydrogen bonded solvent is the most likely loss pathway (30); actual protonation of the carbonyl carbon is unlikely under these conditions (31).

Representative transient absorption spectra obtained following 355-nm laser flash excitation of 8×10^{-5} M DMBA in methanol are shown in Fig. 8. There are, in comparison to the AN result, several new features. First, the absorptions are slightly red-shifted in this solvent; the light absorbing transients corresponding to the initially populated localized singlet and its decay product, hypothesized to the the *P*-state, are clearly distinguishable. Second, the fluorescence is also red-shifted, so significantly negative A's are observed for wavelengths beyond 590 nm at the shortest delay times (<100 ps). Third, there is no light absorbing transient, within the wavelength regime of the experiment, that appears to be associated with the decay product of the *P*-state.

As in AN, the transient absorption assigned to S_1, with λ_{max} ca. 530 nm, decays more rapidly than the ground state is repopulated. Kinetics for the disappearance of absorption at 530 and 575 nm and its reappearance at 460 nm, obtained at 11 delay increments including those shown in Fig. 8, are plotted in Fig. 9. The rate of ground state regeneration from fluorescent singlet after pulse excitation is given by

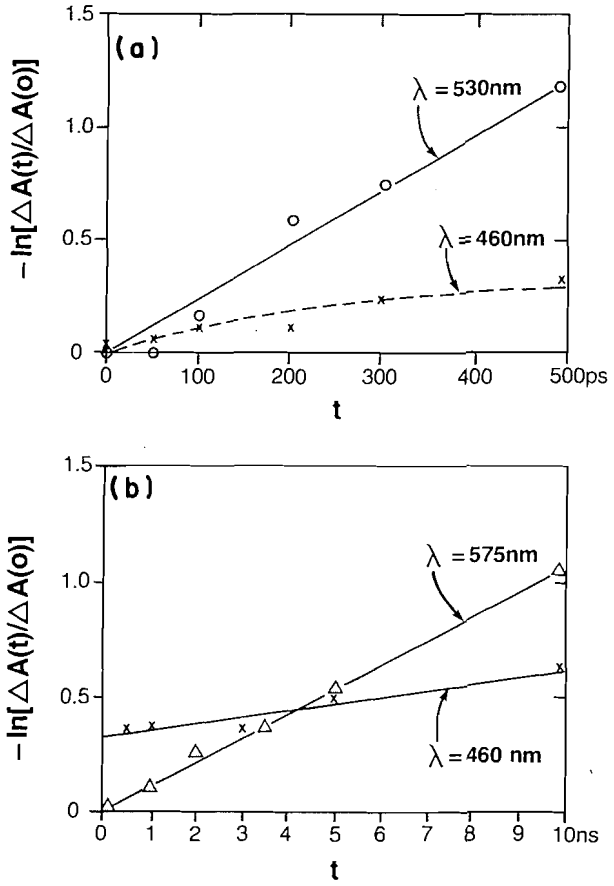

FIG. 9. First-order kinetic plots for (a) decay of 530-nm transient absorption and recovery of 460-nm absorption over the interval 0–500 ps after laser excitation, and (b) decay of 575-nm absorption and recovery of 460-nm absorption over the interval 0.5–10 ns after excitation, in the experiment of Fig. 8. Dashed line in Fig. 9a represents eq. [3] with $(k_f + k_r)$ equal to 3.3×10^9 s^{-1}.

$$[3] \quad d[DMBA]/dt = (k_f + k_r)\,[^1DMBA]_0 \cdot \exp(-t/\tau_1)$$

where $[^1DMBA]_0$ is the concentration of DMBA converted to the localized singlet state by the pump laser (3×10^{-5} M in our experiment), k_r is the rate constant for the radiationless processes *not* leading to the *P*-state, so that

$$[4] \quad \tau_1^{-1} = k_f + k_r + k_d + \ldots$$

Given our estimate of τ_1, 0.12 ns, the data for recovery of DMBA ground state could be fit by eq. [3] with $(k_f + k_r)$ equal to $(3.3 \pm 1.0) \times 10^9$ s^{-1}, as shown in Fig. 9a.

Formation of the *P*-state occurs to an extent of ca. 60% of the initially excited DMBA, based on (a) the maximum observed absorption at 575 nm, assuming the same extinction coefficient for the *P*-state as estimated in AN, and (b) the extent of recovery of ground state DMBA at 1 ns after excitation. As the quantum yield for *P*-state formation is given by $k_d\tau_1$, we estimate its formation rate constant, $k_d = (5 \pm 0.7) \times 10^9$ s^{-1}. Note that this is about fivefold faster than in the non-hydrogen bonding solvent of comparable polarizability and viscosity (AN). The sum of k_d and $(k_f + k_r)$ is then $(8.3 \pm 1.2) \times 10^9$ s^{-1}, in good agreement with the measured value (8×10^9 s^{-1}) for the disappearance of the localized singlet; no additional decay pathways need be postulated.

TABLE 1. Rate constants for interconversion of excited states of DMBA in various solvents

	Rate constant ($\times 10^{-9}$ s^{-1})		
Process	AN	Hexane	Methanol
k_f	0.48[a]	0.42[a]	0.50
k_r	—	—	2.8±1.0
k_d	1.0	1×10^3	5.0±0.7
k_{isc}	0.5	—	0.10
1/3	ca. 0.02	—	0.025

[a]Estimated from transition probabilities calculated from DMBA absorption spectra in the indicated solvents.

The species absorbing at 575 nm decays (Fig. 9b) with a first-order rate constant of 1×10^8 s^{-1}, while ground state DMBA recovers more slowly on this time scale, at ca. 2.5×10^7 s^{-1}. The *P*-state must therefore decay to a species of ca. 40 ns lifetime, which is transparent to the experiment. By analogy to the results obtained in AN (above) we assign this species as triplet DMBA. The reason for the transparency of ^{3}DMBA in methanol is not directly apparent: the transition active in AN may involve excitation of an oxygen *n*-orbital electron, which becomes involved in hydrogen bonding in methanol; alternatively the geometry of the triplet states obtaining in these two solvents may be different, planar in one case and twisted in the other. The observed and calculated rate constants for interconversion of the excited states of DMBA are summarized in Table 1.

Electron transfer photochemistry

Photolysis of DMBA in either methanol or acetonitrile, AN, in the presence of diphenyliodonium hexafluorophosphate leads both to bleaching of the DMBA and decomposition of the iodonium cation (to iodobenzene, benzene, and other minor products). The electron transfer sensitization mechanism has considerable precedent in the sensitized photochemistry of 'onium salts (8–10, 19).

A similar bleaching is observed with the triazine acceptor, in nonpolar solvents, such as toluene or cyclohexane, as well as in polar solvents. By analogy to the electron transfer photochemistry of benzyl halides (32), haloforms (8), and carbon tetrahalides (33), one-electron reduction of the triazine is expected to liberate chloride ion, leaving a neutral radical whose recombination with the DMBA radical cation results in the observed bleaching.

When the reaction is carried out with either acceptor to, e.g., 50% conversion, a ca. 10-nm blue shift in the DMBA absorption maximum is observed. This suggests that the two more-or-less independent chromophores in DMBA are bleached sequentially, and that two electron transfer events are required for the complete bleaching of the ketone.

Photo-CIDNP

Photochemically Induced Dynamic Nuclear Polarization experiments (Fig. 10) show that benzene, presumably formed by H-abstraction by the phenyl radical product of cleavage of the diphenyliodo radical, has a triplet radical pair precursor, when the iodonium salt is photolyzed in perdeutero-AN. Our inference is based on application of Kaptein's Rules (34), as embodied in the equation

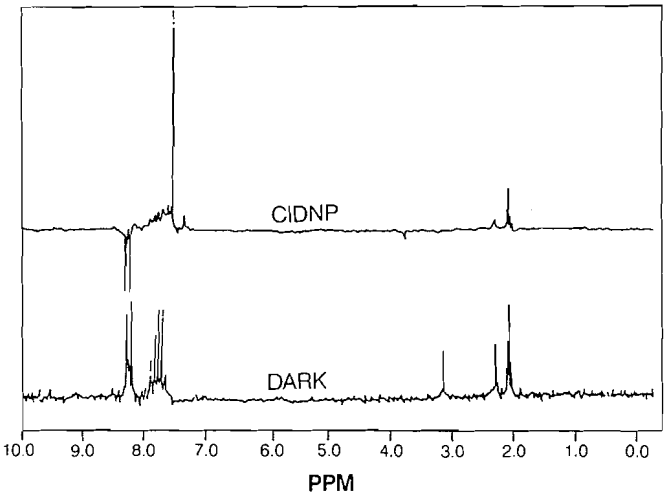

FIG. 10. Photo-CIDNP and dark proton nmr spectra of DMBA (0.01 M) with diphenyliodonium hexafluorophosphate (0.05 M) in acetonitrile.

$$[5] \quad G = \mu\epsilon\cdot\Delta g\cdot a$$

where $G < 0$ corresponds to emission and $G > 0$ corresponds to absorption in the magnetic resonance spectrum of a given product of a photoreaction. The absolute signs of three parameters in eq. [5] must be known in order to assign the fourth: the hyperfine coupling constant, a, and the difference between the g-factors of the two radicals, Δg, are experimentally measured; the other two are assigned by convention, with $\mu > 0$ for in-cage products and $\mu < 0$ for cage-escape products, and $\epsilon < 0$ or > 0 for singlet and triplet radical pair precursors of the product, respectively.

We have already established, in similar photolyses with aromatic hydrocarbon sensitizers, that benzene (emission at 7.55 ppm) is a cage-escpae product ($\mu < 0$) (10). The sign of the product, $\Delta g\cdot a$, was inferred from a similar experiment with the structurally related Michler's Ketone as the sensitizer. Owing to its high intersystem crossing quantum yield, Michler's Ketone sensitizes only by a triplet pathway ($\epsilon > 0$) (35); the observation in this case of enhanced absorption, $G > 0$, then requires $\Delta g\cdot a < 0$. Since DMBA also yields essentially an amine-centered cation radical, we infer that $\Delta g\cdot a$ is also < 0 for its photoreaction. The enhanced absorption at 7.55 ppm observed in Fig. 1 then requires that the benzene product results from a triplet radical pair precursor in this case as well.

The diphenyliodonium polarization (8.2 ppm) shows the characteristics of a special CIDNP effect, magnetic field induced $T_- - S_0$ mixing (ref. 20, pp. 273–288). In this kind of spin-sorting mechanism, only emission is observed and radical pair dissociation (hence cage-escape) is not necessary: Zeeman splitting of the triplet sublevels causes the lowest energy triplet sublevel (T_-) to become degenerate with the singlet ground state at a finite interradical distance, thus enhancing the rate of intersystem crossing from the T_- sublevel. Conservation of angular momentum requires a concomitant nuclear spin inversion from spin states aligned with the magnetic field, hence emission of *all* diphenyliodonium protons is characteristic of this effect. It is, furthermore, obtained *only* when the initial radical pair is a triplet.

Charge transfer complexation

DMBA and the diphenyliodonium cation form a one-to-one charge transfer complex reversibly in solution. No spectroscopic evidence was obtained, on the other hand, for an analogous complex with the triazine acceptor, even in the nonpolar solvents. The iodonium salt complex can be detected by optical absorption between 520 and 550 nm, along with a corresponding decrease in absorption at λ_{max}, 430 nm. These changes are illustrated by the spectra of Fig. 11. Similar spectral changes are reportedly observed for *p*-dimethylaminobenzoyl chromophores in acrylic polymers on incorporation of iodonium salts therein (19). A Benesi–Hildebrand analysis (36) of the absorptivity changes in AN at λ_{max} leads to an estimate of the formation constant for the complex in this solvent as $6 \pm 2\ M^{-1}$.

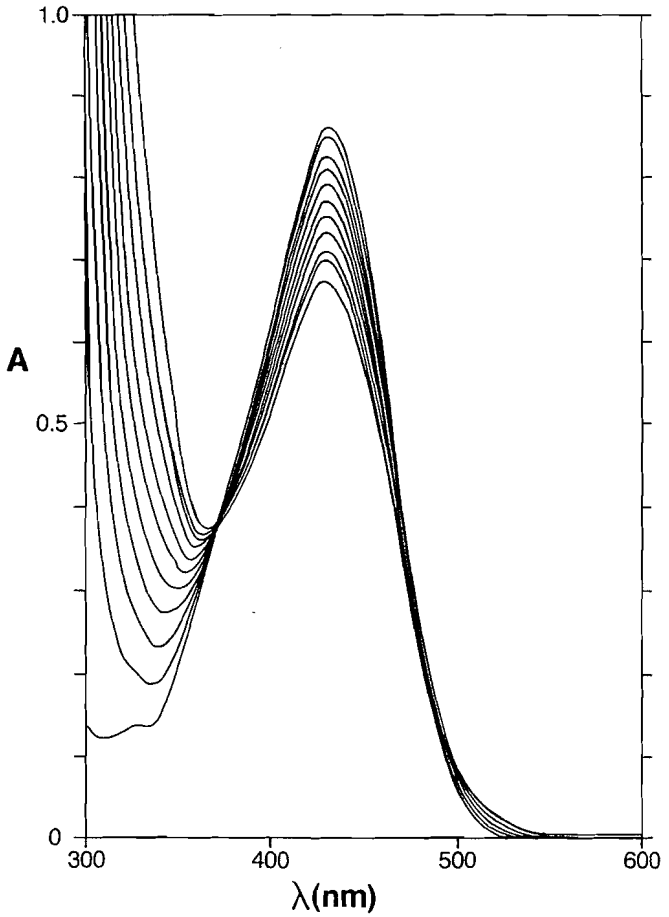

FIG. 11. Spectra changes observed on addition of diphenyliodonium hexafluorophosphate to 2×10^{-5} M DMBA in acetonitrile. Iodonium salt concentrations range from 0.001 to 0.04 M.

Electron transfer quenching of photoexcited DMBA in either a twisted singlet (P) or the triplet excited state represents a case of gated electron transfer. Statistically significant quenching of DMBA fluorescence by added diphenyliodonium hexafluorophosphate was not detectable in AN after correction of the observed emission intensity for formation of the fluorescence-inactive charge transfer complex. The fluorescent excited singlet of DMBA is too short-lived for collisional deactivation, so the electron transfer quenching is "gated" by the rotational relaxation about the vinylic C—C bond (37).

Transient absorption spectroscopy

The results of pulsed laser irradiation at 355 nm of an AN solution 8×10^{-5} M in DMBA and 0.045 M in diphenyliodonium hexafluorophosphate are shown in Fig. 12. Comparison

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12

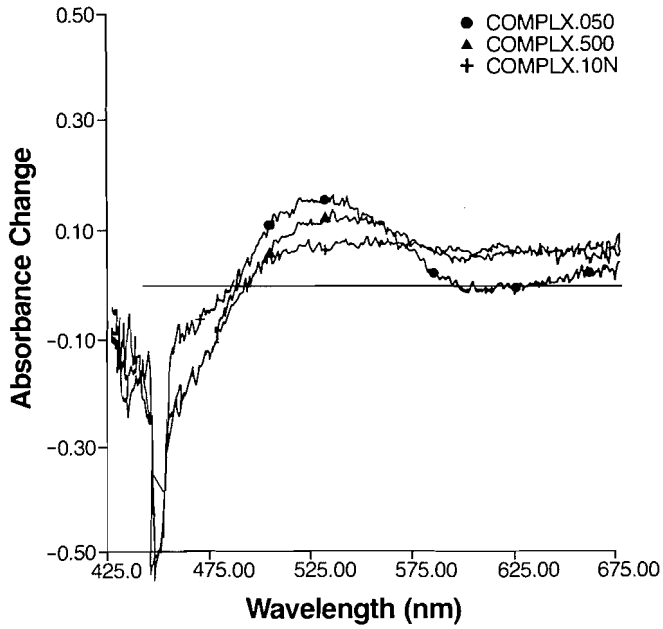

FIG. 12. Transient absorption spectra, recorded 50 ps (●), 500 ps (▲), and 10 ns (+) after initial 355-nm laser pulse excitation of DMBA in the presence of 0.045 M diphenyliodonium salt.

with Fig. 2 reveals that addition of the iodonium salt does not significantly affect the bleaching of the 430-nm transition. The 517-nm absorption was, however, significantly attenuated. Based on our estimates of the extinction coefficients for the transitions, above, 3.2×10^{-5} M DMBA was excited in the experiment, but only 2.2×10^{-5} M of the lowest singlet was formed. We relate this observation to formation of the ground state charge transfer complex, which absorbs light in the same spectral region as uncomplexed DMBA, but does not generate the light absorbing transient; 31% of the DMBA is thus inactivated, compared to a prediction of 27 ± 9% based on the experimental formation constant for the complex. The 430-nm absorption is regenerated to a comparable extent within 10 ns in this experiment, indicative of decay of the charge transfer complex to ground state on this time scale.

Intensity of the 610-nm transient indicates that the quantum yield for triplet DMBA (based on photoexcited, uncomplexed DMBA) is ca. 0.45 after 10 ns, compared with 0.42 in the absence of the iodonium salt. Thus little or none of the DMBA appears to be diverted to a photoproduct from the biradicaloid *P*-state, consistent with the photo-CIDNP observations.

Electron transfer from the *P*-state to the iodonium cation must be thermodynamically allowed insofar as we expect it to be more reducing than the electron transfer active triplet DMBA. At the same time electron transfer from the *P*-state must be strongly disfavored kinetically, since the *P*-state is not quenched by the added iodonium cation. We attribute the kinetic barrier to electron transfer from DMBA in part to a large intramolecular contribution to the reorganization energy (38); unlike the *P*-state, the minimum energy conformation of $DMBA^{\cdot+}$ ought to be planar, so as to maximize charge *delocalization*. This hypothesis implies that triplet DMBA, at least in AN, approximates the ground state conformation.

Mechanistic inferences: quantum yields

The combination of deactivation processes can be accommodated most economically by a reaction scheme comprising the following steps. Photochemical reaction, leading to decomposition of the 'onium cation and bleaching of DMBA, is presumed *a priori* to occur from both complexed and uncomplexed sensitizer. The quantum yield for formation of triplet DMBA in AN, ϕ_3, is given by $(1 - \phi_f)$, ca. 0.7 (see eq. [1]), and K is the formation constant for the ground state charge transfer complex, ca. 6 M^{-1} (above). The quantum yield of any photoproduct, ϕ_r, is then

$$\text{DMBA} + \text{Ph}_2\text{I}^+ \rightleftharpoons [\text{DMBA/Ph}_2\text{I}^+] \qquad K$$
$$[\text{DMBA/Ph}_2\text{I}^+] + h\nu \longrightarrow {}^{CT}[\text{DMBA/Ph}_2\text{I}^+]$$
$${}^{CT}[\text{DMBA/Ph}_2\text{I}^+] \longrightarrow \text{DMBA}^{\cdot+} + \text{PhI} + \text{Ph}^{\cdot} \qquad \phi_c$$
$$\text{DMBA} + h\nu \longrightarrow {}^{P}\text{DMBA}$$
$${}^{P}\text{DMBA} \longrightarrow {}^{3}\text{DMBA} \qquad k_{isc}$$
$${}^{3}\text{DMBA} \longrightarrow \text{DMBA} \qquad 1/\tau$$
$${}^{3}\text{DMBA} + \text{Ph}_2\text{I}^+ \longrightarrow {}^{3}\{\text{DMBA/Ph}_2\text{I}^+\} \qquad k_{diff}[\text{Ph}_2\text{I}^+]$$
$${}^{3}\{\text{DMBA/Ph}_2\text{I}^+\} \longrightarrow \text{DMBA}^{\cdot+} + \text{PhI} + \text{Ph}^{\cdot} \qquad \phi_p$$

SCHEME 1. Electron transfer sensitization.

$$[6] \quad \phi_r = \phi_3\phi_p f_r \cdot k_{diff}\tau\,[\text{Ph}_2\text{I}^+]/(1 + k_{diff}\tau\,[\text{Ph}_2\text{I}^+])$$

where f_r is the fraction of the products of the last step in the scheme converted to the detected photoproduct. If the observable quantum yield, ϕ_{obs}, also includes a contribution from the photoreaction of complexed DMBA, ϕ_c, then

$$[7] \quad \phi_{obs} = f_c\phi_c + (1 - f_c)\phi_r$$

where $f_c = K[\text{Ph}_2\text{I}^+]$.

The analysis was tested experimentally by observing the spectrophotometric disappearance of DMBA, ϕ_{obs}, in nitrogen-purged samples of DMBA (4×10^{-6} M) irradiated at 405 and 450 nm. The relevant data are reported in Table 2. The dependence of the quantum yield on iodonium cation concentration is represented in the form of a double reciprocal plot in Fig. 13. At 0.008 M iodonium salt, the quantum yield for DMBA disappearance was ca. 0.6 that of iodobenzene formation, estimated by quantitative gas chromatography of the reaction mixtures; iodobenzene is presumably formed in every event described by ϕ_r. This ratio, 0.6, then corresponds to f_r for DMBA disappearance, and agrees reasonably with the value of 0.5 expected on the basis of our hypothesis, above, that two electron transfer events are required for the complete bleaching of DMBA. (The two events may not occur with exactly equal probabilities.)

There are two regimes in the concentration dependence of the quantum yield in Fig. 13. At lower concentrations, at both wavelengths the plot is essentially linear, with an intercept-to-slope ratio of 1.2×10^3 M^{-1}. This ratio should be equal to $k_{diff}\tau$, if each encounter leads to electron transfer;[10] as k_{diff}, the second-order diffusional encounter rate constant in AN, is ca. 2×10^{10} s^{-1}, we estimate the lower limit lifetime of the photoactive excited state, τ, to be ca. 60 ns. This value is consistent with involvement of a short-lived triplet state of DMBA, cf. the 40-ns triplet lifetime estimated in methanol on the basis of the observed rate of ground state recovery. Quantum yields in this concentration regime decreased by ca. 30% on admission of air, also consistent with the intervention of a short-lived triplet state of the sensitizer.

The dimensionless intercept of the plot, numerically 15 ± 1 at

[10]The triplet state of Michler's Ketone is quenched by diphenyliodonium cation at much less than the diffusion controlled rate, ca. 10^7 M^{-1} s^{-1}, despite the exergonicity of the electron transfer (8).

[a]Calculated from eq. [7].

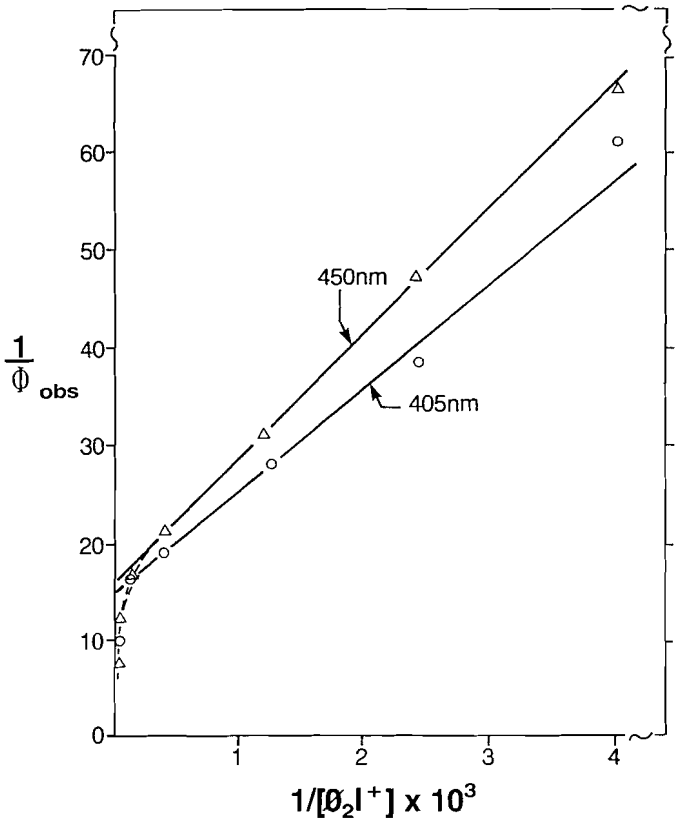

FIG. 13. Double reciprocal plot for DMBA bleaching at 405 and 450 nm in the presence of diphenyliodonium hexafluorophosphate.

both wavelengths, corresponds to $1/\phi_0$, where

[8] $\phi_0 = \phi_3 f_r \phi_p$

i.e., 0.067 ± 0.04, for $\phi_p = 0.16$. At the higher concentrations of iodonium salt, the quantum yield for disappearance of DMBA is higher than expected from extrapolation of the linear portion of the double reciprocal plot. We infer that the additional contribution to photoreaction arises from the DMBA-iodonium cation charge transfer complex, whose concentration becomes significant at these iodonium concentrations (see Table 2). Analysis according to eq. [7] allows us to estimate ϕ_c as 0.20 ± 0.03 for $\phi_p = 0.32$ from the complex.

On the basis of these quantum yield estimates, the charge transfer complex is twice as reactive as the encounter complex. This reactivity difference does not likely have an energetic basis, although electron transfer from the ^{3}DMBA is inevitably slightly less exergonic than from the complex. As Gould *et al.*

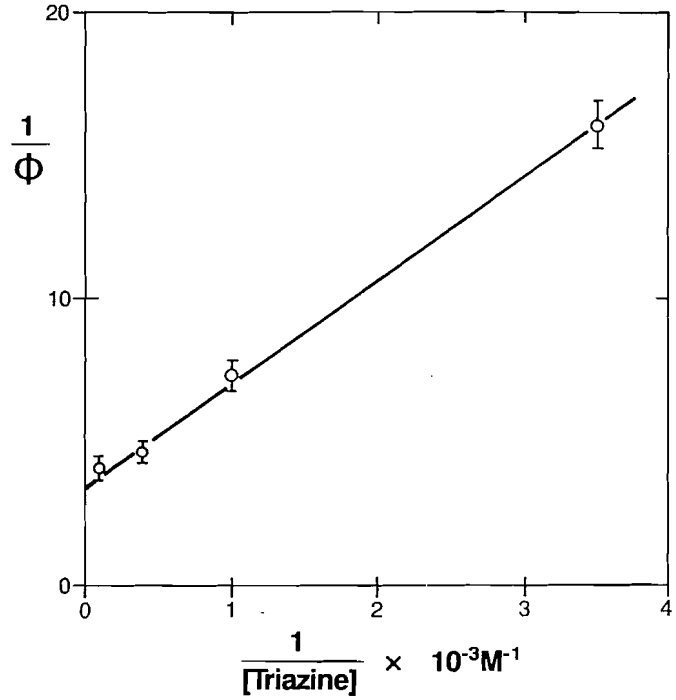

FIG. 14. As Fig. 13, for DMBA bleaching at 420 nm in cyclohexane in the presence of tris(trichloromethyl)-*sym*-triazine.

(40) have recently shown, back electron transfer may be significantly slower in the radical pair produced by photoexcitation of a charge transfer complex, than in the corresponding solvent-separated radical pair formed from an encounter complex. This interpretation is consistent with the ca. 2-ns lifetime of the excited state of the DMBA-iodonium cation charge transfer complex (see. Fig. 12). If the quantum yield for photolysis via the encounter complex reflects the competition between decomposition of the diphenyliodo radical (which occurs in ca. 250 ps (10)) and back electron transfer in the radical pair, the latter process would have to occur with a rate constant of ca. 4×10^{10} s^{-1}, i.e., in 25 ps.

The observed quantum yields for disappearance of 7×10^{-5} M DMBA in the presence of the triazine acceptor in cyclohexane (420-nm irradiation) are also presented in the form of a double reciprocal plot in Fig. 14. These data were obtained on argon-purged samples, but were entirely reproducible when the samples were exposed to air. We accordingly exclude intervention of triplet DMBA in this experiment, consistent with the abence of spectroscopic evidence for intersystem crossing from the *P*-state in this solvent. The quantum yields in cyclohexane were also unaffected by added hydroquinone (saturated, ca. 0.001 M): we thus exclude a radical chain process, such as has been proposed with other halocarbon acceptors (8). By contrast, the quantum yield for DMBA disappearance in the presence of 0.005 triazine in argon-purged AN, 0.016, drops to 0.009 on admission of air. We infer that electron transfer to the triazine in AN, like that to the iodonium cation, occurs from ^{3}DMBA; the extent of oxygen quenching is consistent with a DMBA triplet lifetime of ca. 40 ns in this solvent (see above).

The intercept of Fig. 14 indicates a limiting quantum yield, ϕ_0, of 0.28, corresponding to a quantum yield for electron transfer under these conditions of 0.56, insofar as bleaching of one DMBA molecule requires two photoinduced electron transfer events (see above). The intercept-to-slope ratio, i.e., Stern–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

Volmer slope, derived from Fig. 14 is 1.0×10^3 M^{-1}. This value requires an excited state lifetime of 50 ns, if it is quenched by the acceptor at a diffusion limited rate. The estimate is in reasonable agreement with the rate of repopulation of the ground state observed in the transient absorption experiments. We infer that the biradicaloid *P*-state is not significantly inhibited from undergoing electron transfer photochemistry in relatively nonpolar media: in the conventional dielectric continuum approximation (39) we expect the medium reorganization contribution to the activation barrier for electron transfer to be substantially reduced in a nonpolar solvent compared to, e.g., AN; at the same time the solvatochromism of DMBA suggests that its excited states may be somewhat more reducing in hydrocarbon solvent than in AN. Both of these arguments are consistent with the higher quantum yield for DMBA bleaching observed in cyclohexane compared to AN.

Conclusions

DMBA is characterized by more than one singlet excited state accessible by excitation of its lowest energy electronic transition. The shorter-lived charge transfer state is efficiently fluorescent; the longer-lived twisted *P*-state undergoes intersystem crossing in either AN or methanol, but apparently decays to ground state in cyclohexane.

The *P*-state is essentially unreactive towards diphenyliodonium cation in polar solvent, while its principal product, the DMBA triplet, reacts, albeit somewhat inefficiently, on encounter with the cation in solution. We attribute the unreactivity of the *P*-state to association of a large reorganization energy with electron transfer therefrom.

Photoreaction from triplet DMBA is an example of so-called gated electron transfer. That only the encounters with triplet DMBA yield detectable photochemistry with the iodonium cation in AN is in agreement with photo-CIDNP observations. DMBA also forms a ground state charge transfer complex with diphenyliodonium cation. Photoexcitation of this complex leads, at least twice as efficiently, to products as does capture of triplet DMBA by iodonium cation. Differences in back electron transfer rates may be responsible for the enhanced photoreactivity of the complex.

The phantom *P*-state is, however, efficiently reactive towards another electron acceptor, tris(trichloromethyl)-*sym*-triazine in hydrocarbon solvent. No evidence was obtained to suggest that either a DMBA triplet or a charge transfer complex might be involved under these conditions. The observation of oxygen quenching implicates the involvement of triplet DMBA in the photoreduction of this acceptor in AN, however.

Gas-phase measurements of the kinetics of BF_2^+-induced polymerization of olefinic monomers

LEONARD FORTE, MIN H. LIEN, ALAN C. HOPKINSON, AND DIETHARD K. BOHME
Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received February 9, 1989

LEONARD FORTE, MIN H. LIEN, ALAN C. HOPKINSON, and DIETHARD K. BOHME. Can. J. Chem. **67**, 1576 (1989).

The initial steps in the BF_2^+-induced polymerization of the monomers of ethylene, propylene, *cis*-2-butene, isobutene, and styrene have been observed in the gas phase at room temperature using the Selected-Ion Flow Tube (SIFT) technique. Rate constants and product distributions have been determined for the initiation of the polymerization in each case. All five initiation reactions were found to be rapid ($k \geq 5.0 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}). The primary product ions that propagate polymerization have been identified and sequential addition reactions have been followed in all five systems. For ethylene the energetics of the initial steps have been followed using *ab initio* molecular orbital theory. Reactions of BF_2^+ with the vapours of water and benzene have also been characterized.

Key words: ion-induced polymerization, alkenes, kinetics, gas phase ion chemistry.

LEONARD FORTE, MIN H. LIEN, ALAN C. HOPKINSON et DIETHARD K. BOHME. Can. J. Chem. **67**, 1576 (1989).

Opérant en phase gazeuse, à la température ambiante et faisant appel à la technique du tube à écoulement sélectif d'ion (SIFT), on a observé les étapes initiales de la polymérisation, induite par le BF_2^+, de monomères de l'éthylène, du propylène, du *cis*-but-2-ène, de l'isobutène et du styrène. Dans chacun des cas, on a déterminé les constantes de vitesse ainsi que les distributions des produits obtenus pour l'initiation de la polymérisation. On a trouvé que chacune de ces cinq initiations est rapide ($k < 5{,}0 \times 10^{-10}$ cm^3 molécule^{-1} s^{-1}). Dans chacun des cinq systèmes, on a identifié les ions des produits primaires qui propagent la polymérisation et on a suivi les réactions subséquentes d'addition. Dans le cas de l'éthylène, on a déterminé les énergies impliquées dans les étapes initiales en faisant appel à la théorie des orbitales moléculaires *ab initio*. On a aussi caractérisé les réactions du BF_2^+ avec les vapeurs d'eau et de benzène.

Mots clés : polymérisation induit par les ions, alkènes, cinétique, chimie des ions en phase gazeuse.

Introduction

Friedel–Crafts or Lewis acid catalysts such as the halides BF_3, $AlCl_3$, and $TiCl_4$ are widely used to initiate carbocationic polymerization in solution (1). In industry, polymerizations designed to yield high-molecular-weight polymers invariably involve Friedel–Crafts catalysts in the presence of protogenic cocatalysts. At one time cocatalysts were thought to be essential for the initiation of cationic polymerization (2), but the number of systems in which cationic polymerization has been shown to occur without the purposeful addition of a cocatalyst has grown. Compilations of such systems have recently appeared in the literature (3, 4). We note here that the mechanism of direct initiation and the nature of the species involved in the initiation remain a matter of speculation (5–7). One theory attributes initiation to the ionized form of the initiator, which becomes available in solution by self-dissociation of the initiator (8). For example, in the polymerization of isobutene by $AlCl_3$, the $AlCl_2^+$ cation formed by self-dissociation would immediately add to the double bond to give an equivalent concentration of carbenium ions (8, 9). Indirect evidence for such a mechanism based on conductivity measurements has been given by Grattan and Plesch, but direct identification of the initiating and propagating species is lacking (9, 10). The initial steps are difficult to isolate for study in solution. We show here that this is not the case in the gas phase, as we address the intrinsic features of such a mechanism with gas-phase measurements designed to mimic the initiation of cation-induced polymerization in solution (11).

We have chosen to investigate the initiation of the polymerization of ethylene, propylene, *cis*-2-butene, isobutene, and styrene by the BF_2^+ cation in the gas phase. The experiments provide both the specific rate and the product distribution of the initial step, as well as insight into the ensuing steps that propagate the polymerization. For the reaction with ethylene, quantum-chemical calculations that follow the energetics of the initial steps of polymerization are also reported. Such a combined experimental and theoretical approach can provide a detailed understanding of the intrinsic features of the initial steps in cationic polymerization.

Experimental

The experiments were performed with the selected-ion flow tube/flowing afterglow apparatus in the Ion Chemistry Laboratory at York University. The apparatus and technique have been described in detail elsewhere (12, 13). The range of the downstream mass spectrometer was ca. 260 amu. The BF_2^+ cation was generated from either pure BF_3 (Matheson, C.P. grade) or mixtures of BF_3 in helium by electron impact at energies in the range 55–80 eV. The BF_2^+ was selected from the ionized gas using a quadrupole mass filter and injected into a flow tube containing helium at ca. 0.3 Torr (1 Torr = 133.3 Pa). A typical spectrum of BF_2^+ in helium, observed downstream using a second quadrupole mass filter, is shown in Fig. 1. The ion at m/z 47 ($FBOH^+$) arises from reaction with water impurity in the helium and the ion at m/z 30 (BF^+) arises from collisional dissociation of BF_2^+. Low ion injection energies (nominally 18–24 V) were used to minimize collisional dissociation.

Ethylene, isobutene, propylene (all Matheson, C.P. grade), and *cis*-2-butene (Phillips, research grade) were used as reagent gases while styrene and benzene (both Aldrich) were used as their vapours, diluted with helium as 5 mol% and 10 mol% mixtures, respectively.

All measurements were done at a room temperature of 296 ± 2 K and a total pressure of 0.34 Torr. Helium (Matheson, high purity 99.995%) was used as carrier gas.

Theory

Closed shell *ab initio* molecular orbital calculations were carried out with the MONSTERGAUSS program (14). Geometry optimization on the ions $C_2H_4BF_2^+$ and on all smaller species was performed at the 6-31G* level (15), while the 3-21G basis

For personal use only.

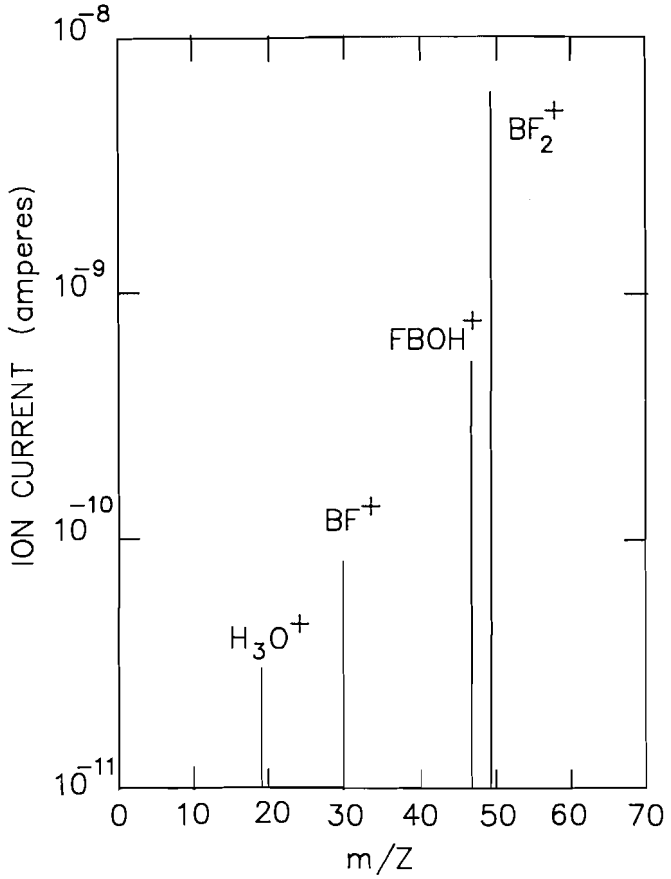

FIG. 1. Downstream SIFT spectrum for BF_2^+ derived from a mixture of BF_3 in He by electron ionization at 51 eV. The buffer gas is helium at 0.33 Torr and the ion injection energy is ca. 24 V. The background "chemical noise" arises from the collisional dissociation of BF_2^+ and from reactions with water vapour impurity in the buffer gas.

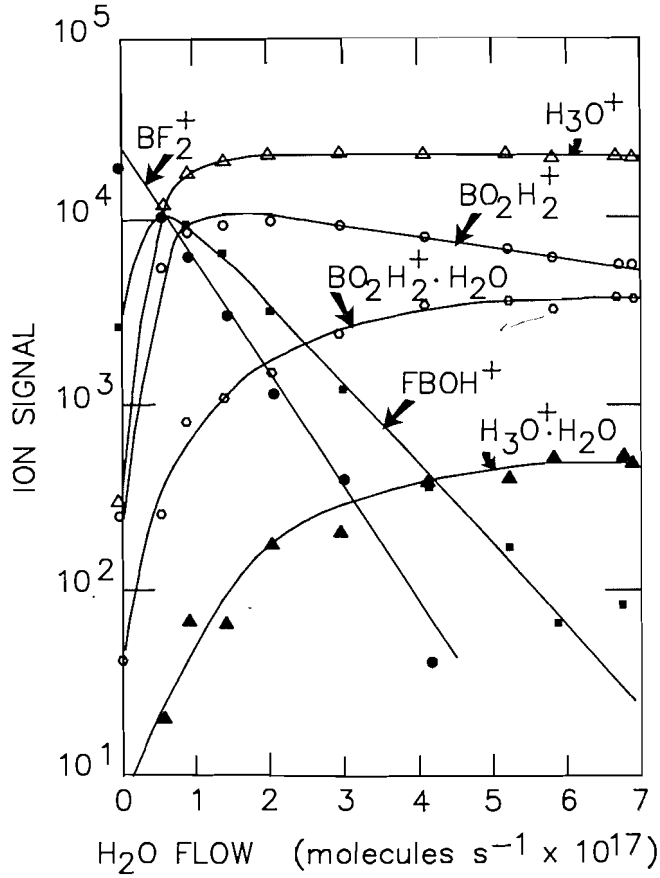

FIG. 2. The variation in ion signals observed for the addition of water vapour into the reaction region of the SIFT apparatus in which the BF_2^+ ion is initially established in helium buffer gas. P = 0.35 Torr, [He] = 1.1×10^{16} atoms cm^{-3}, $\bar{v} = 7.1 \times 10^3$ cm s^{-1}, L = 46 cm, and T = 296 K.

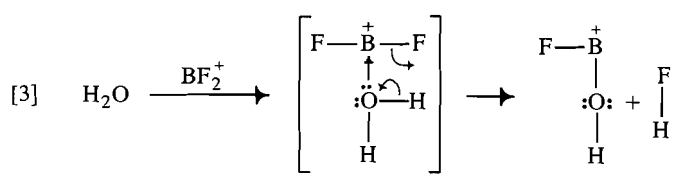
set (16) was used for preliminary work and for optimization of the ion $C_4H_7BF^+$. For the ion $C_4H_7BF^+$, single point 6-31G* calculations were performed at the 3-21G structure (these calculations are denoted as 6-31G*//3-21G).

Results and discussion

Table 1 provides a summary of the reaction rate constants and product distributions obtained in this study and a comparison with specific rates for collision. Standard enthalpy changes are also indicated for those reactions for which the required enthalpies of formation were available.

Water

The reaction of BF_2^+ with water vapour was investigated in order to elucidate the contribution to the ion spectrum observed downstream of ion–molecule reactions with the water vapour impurities in the helium carrier gas. When water vapour was deliberately added into the reaction region in which BF_2^+ was established as a dominant ion, $FBOH^+$ was observed to be produced according to reaction [1].



$$[1] \quad BF_2^+ + H_2O \longrightarrow FBOH^+ + HF$$

The $FBOH^+$ ion reacted further with H_2O by proton transfer and condensation according to reaction [2]. Both H_3O^+ and $BO_2H_2^+$

$$[2] \quad FBOH^+ + H_2O \xrightarrow{0.75} H_3O^+ + FBO$$
$$\xrightarrow{0.25} BO_2H_2^+ + HF$$

were observed to react further by adding a water molecule in what are presumed to be termolecular reactions with He as the third molecule. The observed reaction sequence initiated by BF_2^+ in H_2O is shown in Fig. 2. The semilogarithmic decay of BF_2^+ provides a measure of the rate constant for reaction [1], which was found to be $(1.5 \pm 0.5) \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}. The rate constant for reaction [2] was determined to be 1.3×10^{-9} cm^3 $molecule^{-1}$ s^{-1} from a computer fit to the growth and decay of the $FBOH^+$ ion.

Mechanistic considerations suggest that the $FBOH^+$ ion produced in reaction [1] is FB=O protonated at the oxygen, F—B^+—O—H, which may be formed directly by electrophilic attack on the oxygen of water with elimination of HF as shown in reaction [3]. The isomers F—B(H)—O^+ and H—B^+—O—F would require more bond redisposition for their formation. The secondary reaction of F—B^+—O—H with H_2O can proceed similarly to eliminate HF and produce HO—B^+—OH rather than, say, H—B^+—OOH.

The assignment of F—B^+—O—H is consistent with results of molecular orbital calculations. Calculations at the 6-31G*

TABLE 1. Summary of rate constants (in units of 10^9 cm^3 molecule^{-1} s^{-1}) and product distributions measured at 296 ± 2 K for reactions of BF_2^+ with selected olefinic monomers, with benzene, and with water vapour

Monomer	Products	Branching ratio[a]	k_{exp}[b]	k_{ADO}[c]	ΔH^0_{298}[d] (kJ mol^{-1})
$H_2C{=}CH_2$	$C_2H_3BF^+ + HF$	1.0	0.73 (0.66)	1.1	
$H_2C{=}CH(CH_3)$	$C_3H_5^+ + HBF_2$	0.80	0.50 (0.38)	1.3	−130 to −92
	$C_2H_2BF_2^+ + CH_4$	0.20			
$H_2C{=}C(CH_3)_2$	$C_2H_5^+ + C_2H_3BF_2$	0.35	0.81 (0.58)	1.4	−146
	$C_4H_7^+ + HBF_2$	0.25			−225
	$C_2H_4BF_2^+ + C_2H_4$	0.25			
	$C_3H_4BF_2^+ + CH_4$ $C_3H_5^+ + CH_3BF_2$ $C_4H_8{\cdot}BF_2^+$ (He)	0.15			
cis-2-C_4H_8	$C_2H_5^+ + C_2H_3BF_2$	0.20	0.78 (6.60)	1.3	−156
	$C_4H_7^+ + HBF_2$	0.40			−225
	$C_2H_4BF_2^+ + C_2H_4$	0.25			
	$C_3H_4BF_2^+ + CH_4$ $C_3H_5^+ + CH_3BF_2$ $C_4H_8{\cdot}BF_2^+$ (He)	0.15			
$C_6H_5CHCH_2$	$C_8H_8{\cdot}BF_2^+$ (He)	0.95	0.82 (0.43)	1.9	
	$C_8H_7BF^+ + HF$ $C_6H_7^+ + C_2HBF_2$	0.05			−74
C_6H_6 (benzene)	$C_6H_6{\cdot}BF_2^+$ (He)	0.80	0.74 (0.53)	1.4	
	$C_6H_5BF^+ + HF$	0.20			
H_2O	$FBOH^+ + HF$	1.0	1.5 (0.75)	2.0	

[a]Primary product ions that contribute 5% or more to the total product ions observed are listed. The branching ratio is rounded off to the nearest 5%.

[b]The apparent bimolecular rate constant is given in each case. All measurements were taken in helium buffer gas at a total pressure of 0.34 Torr and a number density of 1.1×10^{16} atoms cm^{-3}. The accuracy of the rate constants is estimated to be ±30%. The value given in parentheses represents the reaction efficiency, k_{exp}/k_{ADO}.

[c]Collision rate constants were derived with the combined variational transition-state theory/calculated trajectory approach of Su and Chesnavich (29).

[d]Enthalpies of formation were derived from ref. 30.

level indicated an energy for F—B=O 184 kcal mol^{-1} lower than that for B—O—F, compared to a difference of 146 kcal mol^{-1} based on calculations at the STO-4G* level reported previously (17). Protonation of FBO was also investigated at the 6-31G* level. The proton affinity of the oxygen site was found to be 90 kcal mol^{-1} higher than the proton affinity at the fluorine site. Protonation on the boron atom did not give rise to a minimum and gave rise to H-atom migration to the oxygen site in the structure optimization procedure.

Due to the presence of water vapour impurities in the helium buffer, $FBOH^+$ ions were always present in the reaction tube when BF_2^+ was selected upstream (in spite of the depletion of its precursor ion, BF_2^+, in the reaction region). The $FBOH^+$ was observed to react rapidly with benzene and with all of the olefins investigated in this study. The predominant channel in each case was proton transfer. In each case the observed decay of $FBOH^+$ was rate-limited by the depletion of its precurser ion, BF_2^+, so that only a lower limit of the rate constant equal to the rate constant for the reaction of BF_2^+ can be derived from these observations. The protonated ethylene was observed to react rapidly with ethylene to form $C_3H_5^+$ and the adduct ion, as reported previously (18). Protonated propylene produced only the adduct ion with propylene with a rate constant of 2.3×10^{-10} cm^3 molecule^{-1} s^{-1}. The two butenes, styrene, and benzene reacted only slowly with their protonated parent molecules to form adduct ions. Rate constants of 3×10^{-11}, 8×10^{-11}, $\leq 4 \times 10^{-11}$, and $\leq 1 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} were obtained for the reactions with *cis*-2-butene, isobutene, styrene, and benzene, respectively. In the case of the reaction with isobutene there is good agreement with a previous determination of 7×10^{-11} cm^3 molecule^{-1} s^{-1} using high-pressure mass spectrometry at 450 K (19).

Ethylene

BF_2^+ was found to react rapidly with ethylene in a bimolecular fashion with a rate constant of $(7.3 \pm 2.2) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} to form the $C_2H_3BF^+$ cation as shown in reaction [4].

[4] $BF_2^+ + H_2C{=}CH_2 \longrightarrow C_2H_3BF^+ + HF$

Figure 3 shows the further occurrence of several propagation steps. In total, the sequential addition of four molecules of ethylene was observed as expressed in reaction [5].

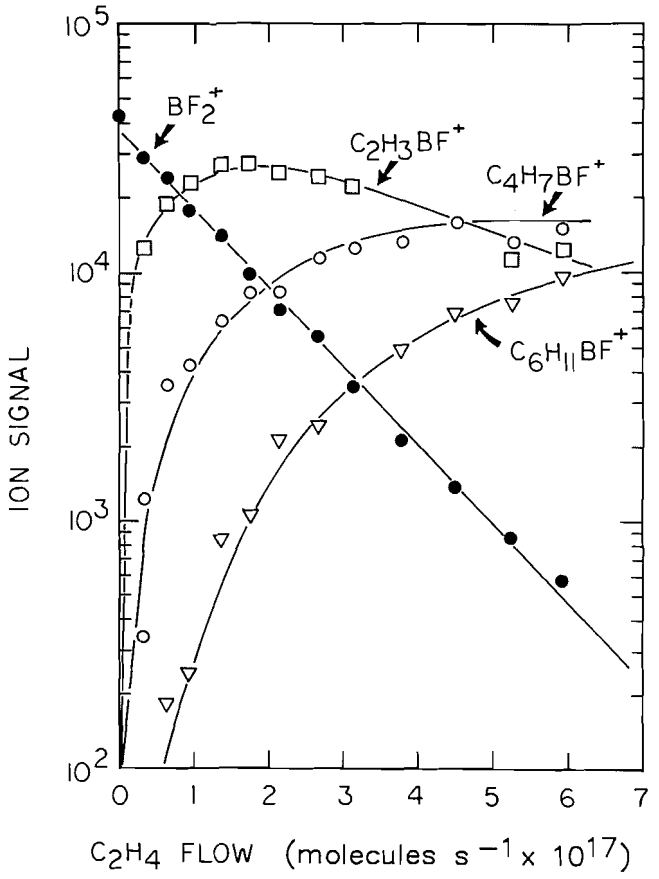

FIG. 3. SIFT measurements of the sequential ion chemistry initiated by BF_2^+ in ethylene and helium buffer gas. $P = 0.349$ Torr, [He] = 1.15×10^{16} atoms cm^{-3}, $\bar{v} = 6.5 \times 10^3$ cm s^{-1}, $L = 46$ cm, and $T = 294$ K. The solid lines represent a computer fit by the method of least squares.

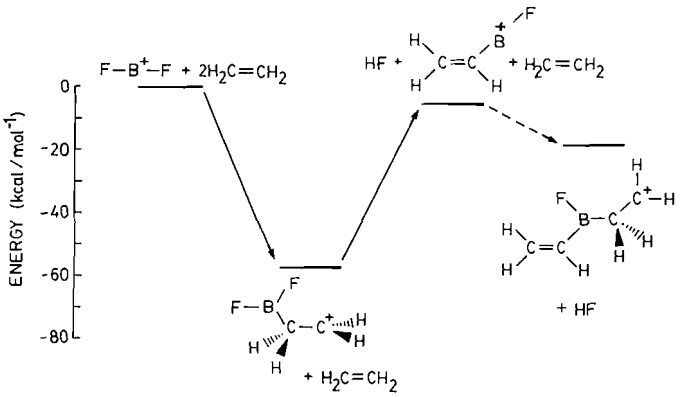

FIG. 4. Relative energies (in kcal mol^{-1}) computed at the 6-31G*//6-31G* level (**4** is at the 6-31G*//3-21G level) for combinations of BF_2^+ and two ethylene molecules.

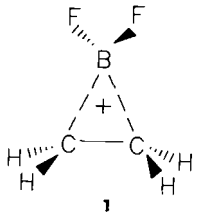
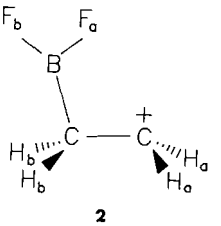
[5] $C_2H_3BF^+ \xrightarrow{C_2H_4} C_4H_7BF^+ \xrightarrow{C_2H_4} C_6H_{11}BF^+ \xrightarrow{C_2H_4}$

$C_8H_{15}BF^+ \xrightarrow{C_2H_4} C_{10}H_{19}BF^+$



The sequential additions of ethylene proceed with slightly decreasing specific rates. Rate constants were determined with a computer fit to the ion profiles using the method of least squares. One such fit is shown in Fig. 3 and it provides effective bimolecular rate constants for the first three steps in reaction [4] of 1.6, 1.3, and 1.3×10^{-10} cm^3 $molecule^{-1}$ s^{-1}. The individual steps are likely to be termolecular with helium acting as the stabilizing third body.

TABLE 2. Total energies (in hartrees) computed for the open and cyclic isomers of the adduct formed from BF_2^+ and ethylene[a]



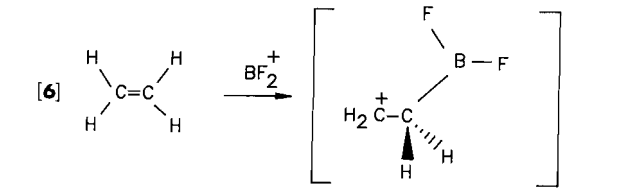
Structure	3-21G	6-31G*	MP2/6-31G*
Cyclic	−299.78534 (10.6)	−301.43044 (2.4)	−302.08957 (0)
Open	−299.80229 (0)	−301.43424 (0)	−302.07991 (6.1)

[a]Numbers in parentheses indicate relative energies (in kcal mol^{-1}).

The reaction profile for the addition of BF_2^+ to ethylene was examined using molecular orbital theory and is shown schematically in Fig. 4. At the level of theory indicated in Fig. 4 (HF 6-31G*), the most stable form of the intermediate adduct ion $BF_2^+.C_2H_4$ has an open structure, but the cyclic structure is more stable when correlation energy is included. Preliminary calculations at the 3-21G//3-21G level of theory showed the cyclic ion with structure **1** to be 10.6 kcal mol^{-1} higher in energy than the open ion with structure **2**. At the 6-31G* level of theory the energy of the cyclic ion was found to be only 2.4 kcal mol^{-1} higher, but at the MP2/6-31G* level of theory it became lower by 6.1 kcal mol^{-1}. Table 2 summarizes the energies obtained for the cyclic and open $C_2H_4BF_2^+$ isomers at the different levels of theory. Structural parameters for the 6-31G* optimized structures of the cyclic and open ions shown as **1** and **2** are given in Table 3. One structural feature is worthy of note. In **1** the C—B

1

2



distance of 1.967 Å is extremely long and compares with a formal single-bond distance of 1.533 Å in borirane (20). The 6-31G* calculated charge distribution for **1** has a charge of +0.45 on the BF_2 group and +0.55 on the ethylene fragment. The bonding between ethylene and BF_2^+ then is best described as π donation from $H_2C{=}CH_2$ to the vacant p orbital on BF_2^+ with little or no back-donation from BF_2^+ to the π^* orbital on ethylene, i.e., only two electrons are formally involved in the bonding and **1** should be considered to be a π complex and not a three-membered ring.

The addition of ethylene to BF_2^+, which is shown mechanistically in eq. [6], is computed to be exothermic by 58 kcal mol^{-1} at the 6-31G*//6-31G* level of theory and so provides sufficient energy to eliminate HF, leaving the observed ion $C_2H_3BF^+$, which can be drawn in the two resonance forms ***3a*** and ***3b***. A Mulliken population analysis showed the boron atom to carry most of the positive charge. Nucleophilic attack by another ethylene molecule may then occur, in principle, at either the terminal carbon or the boron atom, with the latter being indicated by the charge distribution. Calculations at the STO-3G level (21) showed the product of attack at boron (structure **4**) to be lower in energy (by 38 kcal mol^{-1}) than that formed by attack on carbon (structure **5**). The primary carbenium ions **4** and **5** are both at local minima in C_s symmetry. However, the barrier to rearrangement of primary carbenium ions to secondary ions by 1,2-hydride shifts is, in general, very low and it is likely that these ions will rearrange prior to reacting further with another

ethylene molecule. Therefore it is uncertain whether polymerization occurs by repeated ethylene addition at the end of the newly formed primary carbenium ion, or whether ethylene adds at secondary carbenium sites to form polymers with ($CHCH_3$) repeating units.

4

5

Propylene

A rapid reaction was observed between BF_2^+ and propylene, $k = (5.0 \pm 1.6) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. The following primary products were identified:

[7*a*] $BF_2 + C_3H_6 \xrightarrow{0.80} C_3H_5^+ + HBF_2$

[7*b*] $\xrightarrow{0.20} C_2H_2BF_2^+ + CH_4$

The preferred channel [7*a*] corresponds to hydride abstraction, which results in the formation of the $C_3H_5^+$ ion. This latter ion has several possible structures including the allyl, propenyl, and cyclopropyl structures, which decrease in thermodynamic stanbility in the order presented. The formation of all three isomers is exothermic. Channel [7*b*], which corresponds to the elimination of methane, proceeds in one of every five reactive collisions of BF_2^+ with propylene. The occurrence of a minor (≃5%) channel corresponding to the elimination of HF could not be excluded. The ion $C_3H_5BF^+$ was observed as a product but could not be attributed unambiguously to the reaction of BF_2^+. An alternative or additional source for this ion at the operating conditions of the experiment was the reaction of the impurity ion $FBOH^+$ with propylene.

Secondary and higher-order reactions were also observed. The $C_3H_5^+$ was seen to react rapidly with propylene according to reaction [8] in approximately the following proportions:

[8*a*] $C_3H_5^+ + C_3H_6 \xrightarrow{0.6} C_4H_7^+ + C_2H_4$

[8*b*] $\xrightarrow{0.4} C_6H_{11}^+$

A fit to the rise and decay of the $C_3H_5^+$ signal led to a rate constant of 5.0×10^{-10} cm^3 molecule^{-1} s^{-1} for the overall reaction. Both $C_4H_7^+$ and $C_6H_{11}^+$ were observed to add one molecule of propylene to form the adduct ions $C_7H_{13}^+$ and $C_9H_{17}^+$, respectively, presumably in a termolecular fashion by collisional stabilization. The addition reaction with $C_4H_7^+$ was rapid, $k \geq 10^{-10}$ cm^3 molecule^{-1} s^{-1}, while that with $C_6H_{11}^+$ was much slower, $k \leq 3 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}. The propylene adduct of $C_7H_{13}^+$, $C_{10}H_{19}^+$, was also observed but was formed again in a slow reaction, $k \leq 2 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}. In the absence of further work the mechanisms of reactions [8*a*] and [8*b*] are necessarily a matter of conjecture, but it is interesting to note that the $2\pi_s + 2\pi_s$ cycloaddition of allyl cations and alkenes is thermally forbidden by the Woodward–Hoffman orbital symmetry rules, so that the rapid addition of propene to the allyl cation may best be viewed as electrophilic attack by a terminal carbon of the cation on the double bond of propene, forming a secondary cation that may ring-close to the methylcyclopentyl cation. This latter ion can eliminate ethylene to form a methylcyclopropyl cation, which will ring-open without barrier to form the 1-methylallyl cation, $C_4H_7^+$. Alternatively the adduct $C_6H_{11}^+$ may be stabilized by collision. The further reaction of the methylcyclopentyl cation, $C_6H_{11}^+$, with propene is likely to be slower than the further reaction of the 1-methylallyl cation, $C_4H_7^+$, with propene as the latter can be expected to proceed with a similar mechanism and probably similar rate as the initial allyl cation.

The secondary reaction of $C_2H_2BF_2^+$ with propylene was seen to be fast, $k = 8.0 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}. While the propylene adduct ion was observed in small amounts, the main product appeared to be $C_5H_7^+$:

[9] $C_2H_2BF_2^+ + C_3H_6 \longrightarrow C_5H_7^+ + HBF_2$

The $C_5H_7^+$ did not react further, $k \leq 3 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}.

Isomeric butenes

The reaction of BF_2^+ with the isomeric butenes, *cis*-2-butene and isobutene, proved to be more complex than the others. Both reactions were equally rapid, $k = (7.8 \pm 2.4) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, and led to product ions with identical m/z as indicated by reaction [10].

[10*a*] $BF_2^+ + C_4H_8 \longrightarrow C_4H_7^+ + HBF_2$

[10*b*] $\longrightarrow C_2H_4BF_2^+ + C_2H_4$

[10*c*] $\longrightarrow C_2H_5^+ + C_2H_3BF_2$

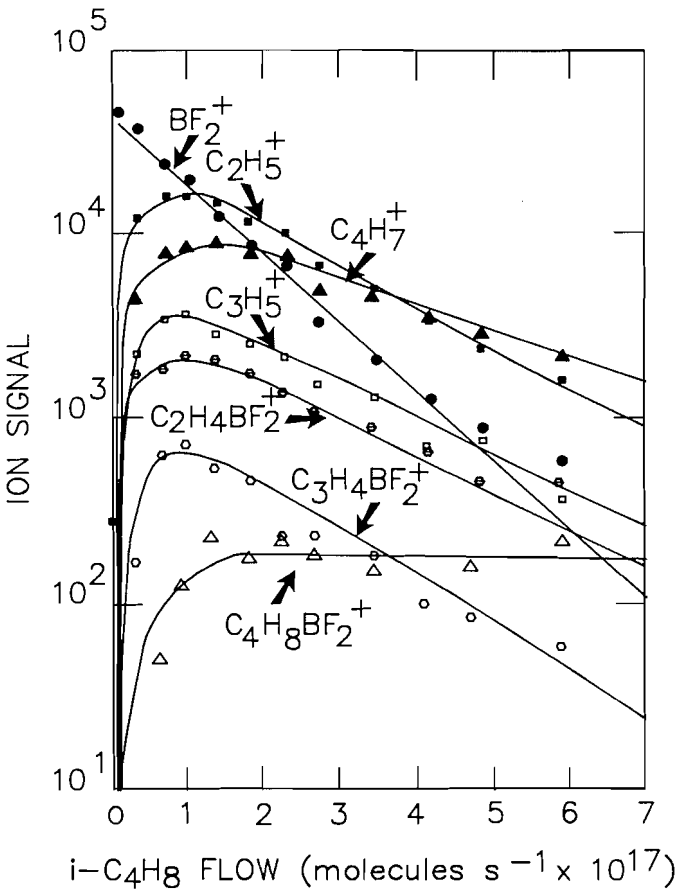

FIG. 5. The variation in ion signals observed for the addition of isobutene into the reaction region of the SIFT apparatus in which BF_2^+ is initially established in helium buffer gas. $P = 0.35$ Torr, [He] = 1.1×10^{16} atoms cm^{-3}, $\bar{v} = 6.9 \times 10^3$ cm s^{-1}, $L = 46$ cm, and $T = 294$ K. Only primary products are indicated.

$$[10d] \longrightarrow C_3H_5^+ + CH_3BF_2$$

$$[10e] \longrightarrow C_3H_4BF_2^+ + CH_4$$

$$[10f] \longrightarrow C_4H_8BF_2^+$$

Channel [10*a*] corresponds to H^- abstraction. Channel [10*b*] leads to elimination of C_2H_4 and will be preempted by channel [10*c*] if a proton is transferred before the products separate. Channel [10*d*] corresponds to CH_3^- abstraction, which may leave the allyl cation $C_3H_5^+$. Channel [10*e*] leads to elimination of methane while [10*f*] corresponds to adduct formation.

Figure 5 shows the semilogarithmic decay of BF_2^+ upon addition of isobutene, and the appearance of the product ions indicated in reaction [10]. All of the primary product ions in reaction [10], with the exception of the adduct, were observed to react further with isobutene. Several of the primary product ions were active in propagating additions of isobutene molecules, which presumably occur in a termolecular fashion. For example, the $C_4H_7^+$ cation formed primarily by H-abstraction from the isobutene, and, to some extent, by secondary reactions of $C_2H_5^+$ and $C_3H_5^+$ with isobutene, was observed to add two molecules of isobutene in sequential reactions. Other isobutene adducts observed were those of $C_3H_4BF_2^+$, $C_4H_9^+$, which is a derivative of the chemistry initiated by $C_2H_5^+$, and $C_5H_{11}^+$, which is a derivative of $C_4H_9^+$ (22). $C_4H_9^+$ is also produced by proton transfer from the impurity $FBOH^+$ to the isobutene.

Slightly different product distributions were observed for the two butene isomers. Channels [10*a*]–[10*c*] account for about

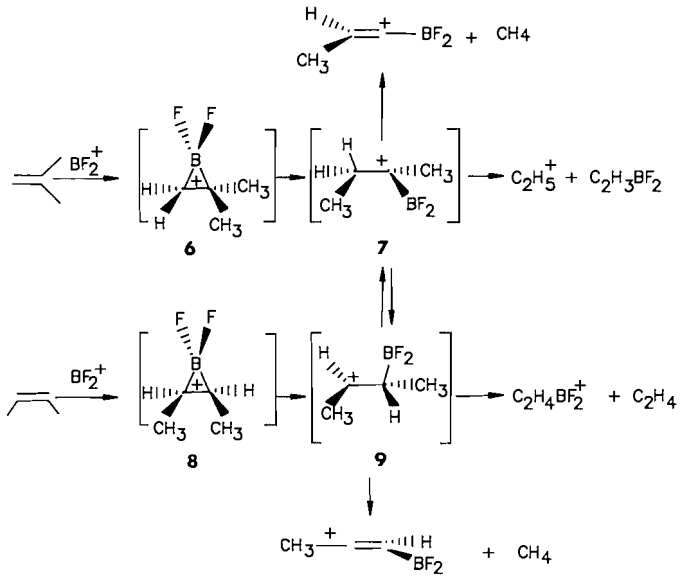

FIG. 6. Possible mechanism for the formation of the primary product ions $C_2H_5^+$, $C_2H_4BF_2^+$, and $C_3H_4BF_2^+$ from the reaction of BF_2^+ with *cis*-2-butene and isobutene.

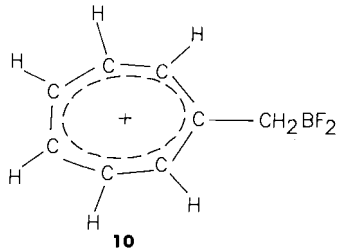
85% of the total reaction in both cases. Formation of $C_4H_7^+$ by hydride abstraction constitutes a larger channel than does formation of $C_2H_5^+$ in the case of *cis*-2-butene. The reverse is true in the case of isobutene. This may reflect differences in stabilities of the two isomeric $C_4H_7^+$ ions. Hydride abstraction from *cis*-2-butene forms the 1-methylallyl cation, whereas abstraction from isobutene yields the 2-methylallyl cation. Allyl cations are stabilized by π-electron-donating substituents on a terminal carbon, but substitution at the central carbon has little effect. The methyl group is a weak π donor and *ab initio* molecular orbitals at the HF 6-31G*//3-21G level indicate the 1-methylallyl cation to be 11.3 kcal mol^{-1} lower in energy than the 2-methylallyl cation (23). Thus when the 1-methylallyl cation is the product, hydride abstraction competes more effectively with other channels.



A mechanism for the formation of the primary products $C_2H_5^+$, $C_2H_4BF_2^+$, and $C_3H_4BF_2^+$ is proposed in Fig. 6. The reactions of the two isomeric butenes are likely to involve similar intermediates since their observed products are the same and the product distributions are not radically different. BF_2^+ and isobutene are likely to form the cyclic π complex indicated by structure **6**. Rearrangements of the type shown in Fig. 6 may then lead to structure **9**. These rearrangements involve the migration of the BF_2 group with a concomitant transfer of CH_3^- to leave structure **7**, which may undergo a 1,2 hydride transfer to leave structure **9**. Addition of BF_2^+ to *cis*-2-butene should give the cyclic π complex indicated by structure **8**, which can open to yield structure **9**. Structures **7** and **9** may decompose by 1,2 CH_4 elimination to form the vinyl cations shown in Fig. 6 or by C—C bond scission as indicated.

Styrene

The major primary product ion observed in the reaction of BF_2^+ with styrene was the adduct ion, possibly a termolecular product at our operating pressure. The observed effective bimolecular rate constant is quite large so that chemical bonding in the adduct ion is indicated. One could assume the structure of the adduct to be benzylic ($C_6H_5C^+HCH_2BF_2$) in which the positive charge is delocalized onto the phenyl group. However, other experimental evidence indicates that benzylic-type ions can rearrange to form tropylium-type ions (24, 25). It is there-

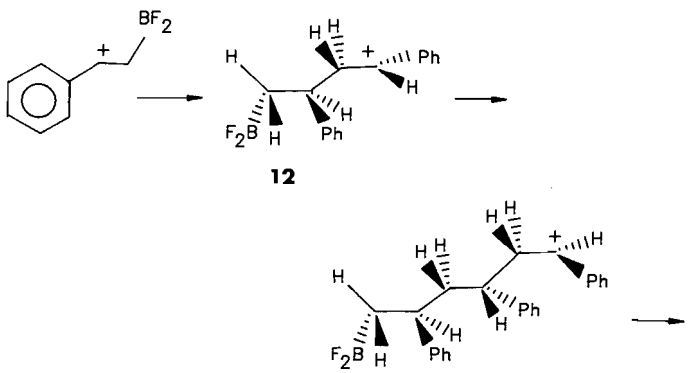
For personal use only.

fore possible that the structure of the adduct ion observed in this case is that of the tropylium-like ion shown in **10**. The other



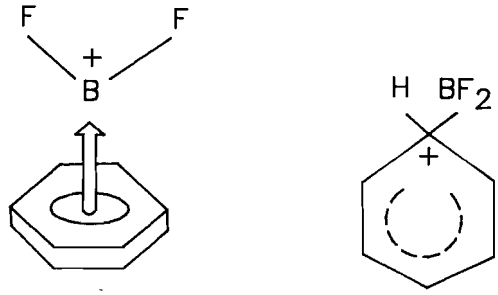
10

minor primary product ions that were observed may arise from the elimination of HF or C_2HBF_2 from the intermediate adduct ion, which is likely to leave an ion with structure **11** or protonated benzene, respectively. The identification of the source for the $C_8H_7BF^+$ ion observed at m/e 133 as the reaction of BF_2^+ with styrene and the elimination of HF was not unequivocal. Another possible source for this ion was the reaction of $FBOH^+$ with styrene and the elimination of H_2O.

11

One other styrene molecule was observed to add to the primary adduct ion. The specific rate for this addition was one half that for the primary addition, having an effective bimolecular value of 4.7×10^{-10} cm^3 molecule^{-1} s^{-1} at our operating conditions. Further additions could not be observed due to the low vapour pressure of styrene that permitted the introduction of only a limited flow of styrene molecules into the reaction region. The high specific rate of addition of the second styrene molecule is suggestive of further chemical bonding. Such bonding seems more probable if the primary adduct ion has a benzylic rather than tropylium-like structure. In the former case the second addition of styrene could occur on the benzylic carbon to yield the structure indicated in reaction [11] as **12**. Reaction [11] shows how polymerization would then be achieved by repeated styrene addition to the cationic carbon of the benzyl cations.

12



Benzene

For the reaction of BF_2^+ with styrene the question arose as to whether BF_2^+ could be adding to the benzene ring of styrene. Thus we decided to carry out the reaction of BF_2^+ with benzene. It was found to be rapid, $k = (7.4 \pm 2.2) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, and to produce two primary species according to reaction [12].

$$[12] \quad BF_2^+ + C_6H_6 \xrightarrow{0.80} BF_2^+.C_6H_6$$

$$\xrightarrow{0.20} C_6H_5BF^+ + HF$$

Adduct formation was the major channel observed. The high efficiency of this channel is again suggestive of chemical bonding. Several structures can be envisaged for a chemically bonded adduct, including a complex in which BF_2 sits on top of the benzene π cloud (structure **13***a*) as well as the σ complex **13***b*.

13*a* **13***b*

Conclusions

The results of the experiments reported in this study characterize the intrinsic chemistry that the BF_2^+ ion initiates by reacting with the olefinic monomers of ethylene, propylene, isobutene, *cis*-2-butene, and styrene, and with benzene and H_2O. They provide values for the specific rates and product distributions of the initiation steps and the early propagating steps that lead to the build-up or polymerization of the ions.

All of the initiation reactions of BF_2^+ are rapid, $k \geq 5.0 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, and efficient, and they show an interesting range in the nature of their reaction products. The major reaction pathways for the monomers selected for study are elimination of HF, CH_4, C_2H_4, or $C_2H_3BF_2$, hydride transfer, and adduct formation. HF elimination is unique to the reaction with ethylene. It is not observed with the butenes and constitutes only a very small channel with styrene and possibly propylene. Hydride transfer is an important channel in the reactions with monomers containing an allylic hydrogen. For instance, hydride transfer was observed to compete effectively with other channels in the reactions of BF_2^+ with propylene and the butenes from which stable allylic cations can be formed. Styrene and ethylene do not contain an allylic hydrogen and were not observed to react with BF_2^+ by hydride transfer. The implication of these results is that other monomers having an allylic hydrogen such as, for example, α-methylstyrene and cyclopentadiene, can also be expected to react with BF_2^+ by hydride transfer to form allylic cations that may propagate polymerization.

The results indicate that ethylene, styrene, *cis*-2-butene, and isobutene can all be polymerized in the gas phase by propagating species formed in reactions with BF_2^+. The BF or BF_2 group may or may not be retained in the propagating ion. The former (e.g., $C_2H_3BF^+$, $C_8H_8BF_2^+$) appear more reactive in propagating monomer additions and are predominant in the polymerization observed with ethylene and styrene. Carbocations are the main propagating ions produced in the initiation reactions of BF_2^+ with the two butenes.

Propylene appears to be an exception in that propagation is terminated early in the reaction sequence. A possible explanation is illustrated in Fig. 7. If an allylic structure is assumed for $C_3H_5^+$, addition of propylene should lead to the 1-methylallyl

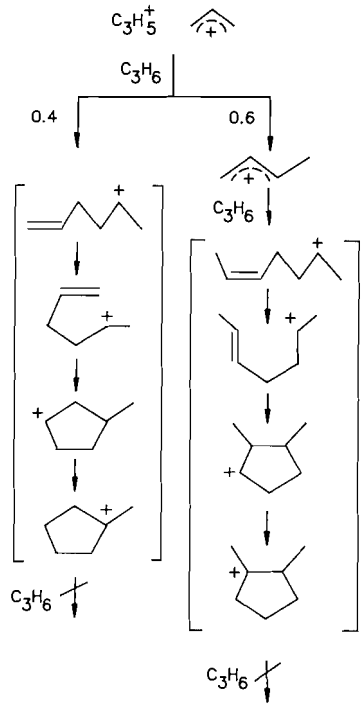

FIG. 7. Possible mechanism for the termination of the polymerization of propylene initiated by allylic $C_3H_5^+$ in the gas phase.

cation and a secondary methylcyclopentyl cation, which might undergo a 1,3 hydride shift to form the thermodynamically more stable tertiary methylcyclopentyl cation. If the further reaction of the 1-methylallyl cation with propene proceeds with a mechanism and rate similar to the initial allyl cation, we can expect the intramolecular cyclization to produce the tertiary 1,2-methylcyclooentyl cation shown in Fig. 7. Both of the methyl-substituted tertiary cyclopentyl cations should be less reactive because the attack by another propylene molecule is hindered. This is consistent with our experimental observations, which indicate further propylene additions to the tertiary cyclic cations, which proceed with rate constants that are much smaller, $k \leq 3 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}, than those for the addition of propylene to the acyclic precursor cations, $k \geq 10^{-10}$ cm^3 molecule^{-1} s^{-1}. The polymerization of propylene therefore appears to be impeded in the gas phase by intramolecular cyclization. In contrast, if solvent molecules act to hinder the cyclization, we can expect the analogous polymerization to be allowed in solution.

It is interesting to compare the cocatalytic role of water in the gas phase and solution. Water is known to act as a coinitiator in many polymerization systems in solution, including BF_3/isobutene (26), BCl_3/isobutene (27), and $TiCl_4$/diphenylethylene (28). Our gas-phase measurements indicate that water vapour acts in a cocatalytic fashion by leading to the protonated monomers $C_2H_4^+$, $C_3H_7^+$, $C_4H_9^+$, and $C_8H_9^+$ via the $FBOH^+$ ion formed by reaction of BF_2^+ with water vapour. $FBOH^+$ was observed to transfer a proton to all of the monomers investigated and also to water vapour. The latter implies that H_3O^+ may be an intermediate when $FBOH^+$ is formed in solution in the presence of water.

The interaction between other Lewis acid cations and olefinic monomers remains to be examined in the gas phase. Of special interest is the reaction of olefinic monomers with $AlCl_2^+$ derived from $AlCl_3$, perhaps the best known and most popular initiator. Gas-phase measurements of the reaction of $AlCl_2^+$ with isobutene may allow some insight into one of the oldest and most studied cationic polymerizations.

Diphosphido bridged early/late heterobimetallic complexes: synthesis and molecular structure of $Cp_2Zr(\mu\text{-}PPh_2)_2ReH(CO)_3$

PEI YAO ZHENG and DOUGLAS W. STEPHAN[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

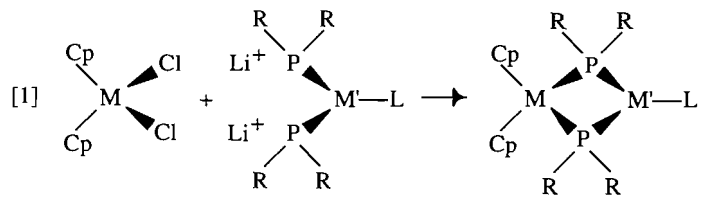
Received February 28, 1989

PEI YAO ZHENG and DOUGLAS W. STEPHAN. Can. J. Chem. **67**, 1584 (1989).

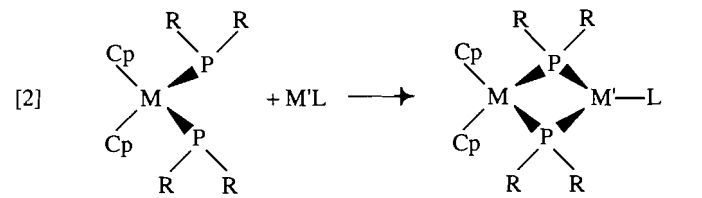
The reaction of the metal–metal bonded complex $Re_2(CO)_{10}$ with $Cp_2Zr(PPh_2)_2$ results in formation of the diphosphido bridged heterobimetallic species, $Cp_2Zr(\mu\text{-}PPh_2)_2ReH(CO)_3$, **1**. Complex **1** crystallizes in the space group $P2_1/c$ with a = 17.393(3) Å, b = 14.348(7) Å, c = 13.036(3) Å, β = 92.35(2)°, Z = 4, and V = 3250(2) Å^3. The crystallographic study confirmed that complex **1** contains two phosphido bridges between the Zr and Re centres. The Zr—P bond distances are 2.629(3) and 2.615(3) Å, while the Re—P bonds are 2.498(3) and 2.474(3) Å. The Zr—Re separation is 3.274(1) Å. The details of the geometry of the ZrP_2Re core are discussed in relation to that of other diphosphido bridged early/late heterobimetallics. The possibility of dative bonding between the electron-rich, late metal and the electron-deficient early metal centre is discussed. The data indicate that if such dative bond is present in the d^0–d^6 complex **1**, it is very weak.

Key words: rhenium, zirconium, heterobimetallic, crystal structure.

PEI YAO ZHENG et DOUGLAS W. STEPHAN. Can. J. Chem. **67**, 1584 (1989).



La réaction du complexe $Re_2(CO)_{10}$, comportant une liaison métal–métal, avec le $Cp_2Zr(PPh_2)_2$ conduit à la formation de l'espèce diphosphido hétérobimétallique pontée, $Cp_2Zr(\mu\text{-}PPh_2)_2ReH(CO)_3$, **1**. Le composé **1** cristallise dans le groupe d'espace $P2_1/c$ avec a = 17,393(3), b = 14,348(7), c = 13,036(3) Å, β = 92,35(2)°, Z = 4, et V = 3250(2) Å^3. L'étude cristallographique confirme que le complexe **1** contient deux ponts phosphido entre les centres Zr et Re. Les longueurs des liaisons Zr—P sont égales à 2,629(3) et 2,615 (3) Å alors que celles des liaisons Re—P sont égales à 2,498(3) et 2,474(3) Å. La distance entre le Zr et le Re est de 3,274(1) Å. On discute des détails de la géométrie du noyau ZrP_2Re en relation avec ceux d'autres diphospido hétérobimétalliques pontés. On discute de la possibilité de l'existence d'une liaison dative entre le métal de la fin, riche en électrons, et le centre métallique du début, déficient en électron. Les données indiquent que si une telle liaison est présente dans le complexe **1**, d^0–d^6 elle est très faible.



Mots clés : rhénium, zirconium, hétérobimétallique, structure cristalline.

Introduction

Complexes containing both early, oxophilic and late, electron-rich metal centres have been the subject of numerous studies and have been recently reviewed (1). Interest in such species is spurred by the potential applications in carbon oxide reduction chemistry. Such early/late heterobimetallic complexes combine the Lewis acidity of the early metals with the known abilities of the late metals for hydrogen activation. Interest is also prompted by the observation of strong metal–support interactions (SMSI) in heterogeneous catalytic systems (2). Direct electronic communication between the late metal centres and the early metals of the supports is presumed to be responsible for unique reactivity arising from these catalyst systems. Attempts to understand the nature of such interactions and their effects on the chemistry of the constituent metals have led to the development of numerous synthetic routes to compounds containing such early/late metal combinations. A variety of bridging ligands including thiolates (3–20) and pendent chelates (21–49) have been employed to link such metal pairs. In addition, we (50–53) and others (54–62) have described early/late heterobimetallics in which phosphido groups link early and late metal centres. For example, complexes of the form $Cp_2M(\mu\text{-}PR_2)_2M'L_n$ have been prepared via one of two synthetic routes; reaction of late metal phosphide dianions with early metal halides (54–56) ([1]) or reaction of early metal phosphides with labile late metal species (50–53, 57–61) ([2]). More recently, we have described the formation of monophosphido bridged early/late heterobimetallics from the redox reaction of $Cp_2Zr(PR_2)_2$ with $[CpM(CO)_3]_2$ [(3]) (63). In the course

of investigating other reactions of $Cp_2Zr(PPh_2)_2$ with metal–metal bonded species, we have prepared and structurally characterized the complex $Cp_2Zr(\mu\text{-}PPh_2)_2ReH(CO)_3$, **1**. This paper presents the results of our study. The structure of **1** is described and the implications of metal–metal interactions are discussed.

Experimental section

General data

The preparation was done under an atmosphere of dry O_2-free N_2. Solvents were reagent grade, distilled from the appropriate drying agents under N_2, and degassed by the freeze–thaw method at least three times prior to use. ^1H NMR spectra were recorded on a Bruker AC-300 spectrometer operating at 300 MHz. Trace amounts of protonated solvents were used as references and chemical shifts are reported relative to $SiMe_4$. $^{31}P\{^1H\}$ NMR spectra were recorded using a Bruker AC-200 NMR spectrometer operating at 81 MHz and are reported relative to external 85% H_3PO_4. Infrared absorption data were recorded on a Nicolet 5DX Fourier Transform IR spectrometer. Cp_2ZrCl_2, $Re_2(CO)_{10}$ were purchased from the Aldrich Chemical Co. $Cp_2Zr(PPh_2)_2$ was prepared by the literature method (50, 57).

Synthesis of $Cp_2Zr(\mu\text{-}PPh_2)_2ReH(CO)_3$, 1

To a solution of $Cp_2Zr(PPh_2)_2$ (0.100 g, 0.17 mmol) in 35 mL of THF was added a solution of $Re_2(CO)_{10}$ (0.055 g, 0.09 mmol) in 10 mL of THF. The mixture was stirred for 12 h. The volume of the solvent was reduced to about 10 mL under vacuum. Slow addition of *n*-hexane (50 mL) caused the precipitation of a yellow solid. The solid **1** was isolated by filtration and washed with an additional 50 mL of *n*-hexane. (Yield 0.025 g, 17%.) Crystals of **1** were obtained by slow diffusion of pentane into a THF solution of **1**. ^1H NMR (C_6D_6, δ, ppm): 4.99 (s, Cp), 4.81 (s, Cp), 8.3–8.0, 7.2–6.9 (m, Ph), −9.52 (t, H, $|J_{P-H}| = 29$ Hz). $^{31}P\{^1H\}$ NMR (C_6D_6, δ, ppm): 154.2 (s). IR (KBr, cm^{-1}): 1996, 1939, 1911, 1869.

X-ray data collection and reduction

Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation. The initial orientation matrix was obtained from 15 machine-centred reflections selected from a rotation photograph. These data were used to determine the crystal system. Partial rotation photographs around each axis were consistent with a monoclinic crystal system. Ultimately, 35 reflections ($20° < 2\theta < 25°$) were used to obtain the final lattice parameters and the orientation matrix. Machine parameters, crystal data, and data collection parameters are summarized in Table 1. The observed extinctions were consistent with the space group $P2_1/c$. $\pm h$, $+k$, $+l$ data were collected in one shell ($4.5° < 2\theta < 45.0°$) and three standard reflections were recorded every 197 reflections. Their intensities showed no statistically significant change over the duration of the data collection. The data were processed using the SHELX-76 program package on the computing facilities at the University of Windsor. A total of 3118 reflections with $F_o^2 > 3\sigma F_o^2$ were used in the refinement. An empirical absorption correction was applied to the data based on two sets of Ψ scan data.

Structure solution and refinement
