Crystallographic data for **1**, **1·EtOH**, **2**, **3**, and **4** are given in Table 1. As crystals of **1·EtOH** lose solvent on standing in air, a freshly prepared crystal of **1·EtOH** was selected and quickly coated with epoxy cement for the X-ray diffraction experiment. This procedure proved very satisfactory. In each case, the cell dimensions and crystal orientation matrix were determined on a CAD-4 diffractometer by a least-squares treatment of the setting angles of 25 reflections in the range $10° < \theta < 20°$. Intensity data were collected using graphite monochromatized Mo-Kα radiation. Intensities of three reflections measured as standards every two hours of exposure time showed no evidence of decay. Data were corrected for Lorentz and polarization factors. The data for **2** were also corrected for absorption (but this had a negligible effect on the molecular geometry, the dimensions changing by less than 1σ between the absorption-corrected and non-absorption-corrected data sets). The structures were solved with the aid of MULTAN (7). Refinement was by full-matrix least-squares calculations minimizing $\Sigma w\Delta^2$ initially with isotropic and then with anisotropic thermal parameters; in the final rounds (except for **3**) an extinction correction was also refined (Table 1). At intermediate stages in the refinements, difference maps showed maxima in the anticipated locations of all hydrogens. In subsequent refinement cycles, the hydrogens bonded to oxygen were allowed to refine with isotropic motion and all other hydrogen atoms were positioned on geometrical grounds (C—H, 0.95 Å; B_{iso} = 5 Å^2) and included (as riding atoms) in the structure factor calculations. Final difference maps were devoid of significant features. Scattering factor data and anomalous dispersion corrections (for non-hydrogen atoms) were from International Tables for X-ray Crystallography (8) and all calculations were performed on a PDP11/73 computer using SDP-Plus (9). Atomic coordinates are listed in Table 2 and details of molecular geometry conformation in Tables 3 and 4. Tables of all bond lengths and angles, calculated hydrogen coordinates, mean-plane data, anisotropic thermal parameters, and structure factors for **1**, **1·EtOH**, **2**, **3**, and **4** have been placed in the Depository of Unpublished Data.[2]

Étude cinétique de la N-chloration de la diméthylamine et de la diéthylamine en phase aqueuse

DENISE MATTE,[1] BERNARD SOLASTIOUK, ANDRÉ MERLIN ET XAVIER DEGLISE[2]

Université de Nancy I, Laboratoire de photochimie appliquée (Unité associée au Centre national de la recherche scientifique, n° 328), B. P. 239, 54506 Vandoeuvre les Nancy CEDEX, France

Reçu le 27 juin 1988

DENISE MATTE, BERNARD SOLASTIOUK, ANDRÉ MERLIN et XAVIER DEGLISE. Can. J. Chem. **67**, 786 (1989).

Nous présentons une étude des mécanismes et déterminons les constantes de vitesse des N-chlorations de la diméthylamine et de la diéthylamine en milieu aqueux, tant par l'acide hypochloreux et les ions hypochlorites (milieu neutre et basique), que le chlore moléculaire dissous (milieu acide). Les énergies d'activation des processus mis en cause ont été déterminées. Ces cinétiques rapides ont été étudiées sur spectrophotomètre à écoulement bloqué. En milieu neutre et basique, deux processus sont susceptibles de rendre compte des résultats expérimentaux.

$$R_2NH + ClOH \xrightarrow{k_1} \text{produits}$$

$$R_2NH_2^+ + ClO^- \xrightarrow{k_2} \text{produits}$$

Ces processus sont indiscernables du point de vue cinétique; ceci est dû au fait de l'existence d'un équilibre rapide entre les deux groupes de réactifs. En milieu acide, la chloration s'effectue par l'action du dichlore (Cl_2) sur l'amine non protonée; cette cinétique est limitée par la diffusion des réactifs.

$$R_2NH + Cl_2 \xrightarrow{k_{Cl_2}} R_2NCl + H^+ + Cl^-$$

Les valeurs numériques des constantes de vitesse pour chaque amine sont

$$R = CH_3 : k_1 = (1{,}2 \times 10^{11}) \exp(-17600/RT)\ M^{-1}\ s^{-1}$$
$$k_{Cl_2} = (3{,}3 \times 10^{10}) \exp(-7500/RT)\ M^{-1}\ s^{-1}$$

$$R = CH_3CH_2 : k_1 = 2{,}3\ 10^{10} \exp(-15000/RT)\ M^{-1}\ s^{-1}$$
$$k_{Cl_2} = 9{,}4\ 10^8\ M^{-1}\ s^{-1} \text{ (à 298 K)}$$

Mots clés : cinétique, N-chloration, amines, phase aqueuse.

DENISE MATTE, BERNARD SOLASTIOUK, ANDRÉ MERLIN, and XAVIER DEGLISE. Can. J. Chem. **67**, 786 (1989).

A complete kinetic study of the N-chlorination, in aqueous medium, of dimethylamine and diethylamine by a stopflow spectrophotometric method is presented. In neutral or basic medium our experimental results can be interpreted by two kinetically indistinguishable mechanisms; the reactions between protonated amine ($R_2NH_2^+$) and hypochlorite ion (ClO^-) and the reaction between R_2NH and hypochlorous acid (ClOH) are equivalent because of the fast equilibrium of proton exchange existing between the two groups of possible reactants ($R_2NH + ClOH \leftrightarrows ClO^- + R_2NH_2^+$). In acid medium, in the presence of chloride ions, we observed a reaction by aqueous chlorine (Cl_2) on the amine ($Cl_2 + R_2NH \rightarrow$ chloramine).

Key words: kinetics, N-chlorination, amines, aqueous medium.

Introduction

En milieu aqueux, les amines aliphatiques réagissent, comme l'ammoniac, avec le chlore dissous pour former des chloramines. Les cinétiques de chloration de ces amines ont été souvent suivies (2, 3) par des techniques peu adaptées à la rapidité de ces réactions et dans des domaines étroits de variation des paramètres (pH, température ...).

Grâce à la spectrophotométrie à écoulement bloqué, nous avons pu étendre cette étude à toute la gamme de pH couverte par les solutions aqueuses et déterminer l'influence de la température.

Techniques expérimentales

En milieu basique nous avons suivi la consommation de chlore à 290 nm au maximum d'absorption de l'ion ClO^-. En milieu acide il est par contre possible d'observer l'apparition de la chloramine, celle-ci absorbant seule à 270 nm. Dans tous les cas, la concentration en amine étant en large excès par rapport à celle du chlore, nous mesurons donc une constante de vitesse expérimentale du pseudo premier ordre (k_{exp}), pente de la droite $\ln(A - A_\infty)$ en fonction du temps (A est la densité optique de la solution à un instant donné).

Résultats expérimentaux et interprétation

Chloration par ClOH et ClO^-

Influence des concentrations (ordres de réaction)

Diméthylamine et diéthylamine réagissent de façon similaire avec le chlore en solution. Les figures 1 et 2 montrent pour la diméthylamine une variation linéaire de la constante de vitesse de réaction en fonction des concentrations globales de chacun des réactifs. Pour les deux molécules, dans toutes les conditions de pH, la cinétique de réaction est du second ordre, c'est à dire d'ordre un par rapport à chacun des réactifs *amine* et *chlore*.

Influence du pH et de la force ionique

En milieu neutre ou basique une solution de chlore ne contient que deux espèces prédominantes: les ions hypochlorites et l'acide hypochloreux. De la même manière, l'amine existe en solution sous formes protonée ou non, ceci selon les équilibres ci-dessous :

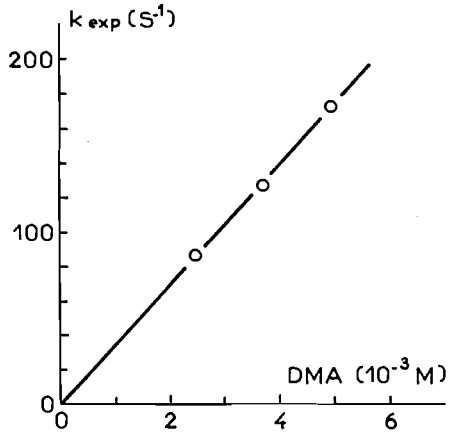

FIG. 1. Influence de la concentration en amine. T = 298 K; pH = 9,25; $Cl_t = 2{,}5 \times 10^{-4}$ M; force ionique $I = 0{,}071 \pm 0{,}003$ M; k_{exp} : pente de la droite $\ln(A - A_\infty)$ en fonction du temps.

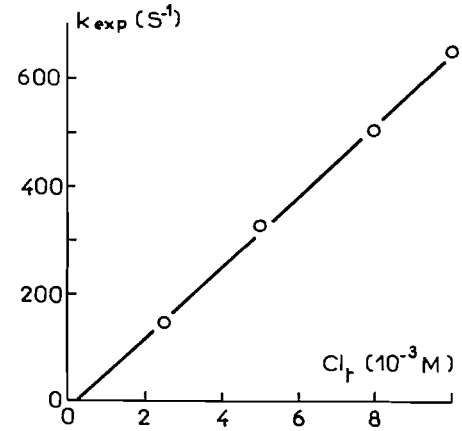

FIG. 2. Influence de la concentration en chlore. T = 298 K; pH = 4,45; $DMA_t = 7{,}5 \times 10^{-3}$ M; force ionique $I = 0{,}135 \pm 0{,}004$ M; k_{exp} : pente de la droite $\ln(A - A_\infty)$ en fonction du temps.

[I] $HOCl \leftrightarrows ClO^- + H^+$ $\quad pK_I = 7{,}54$ à 298 K (4)

[II] $R_2NH_2^+ \leftrightarrows R_2NH + H^+$ $\quad R = CH_3$, $pK_{II} = 10{,}73$ à 298 K; $R = CH_2CH_3$, $pK_{II} = 11{,}00$ à 298 K (5)

Ces équilibres sont rapides devant la cinétique de chloration; nous pouvons donc envisager quatre processus différents susceptibles de limiter la vitesse globale de réaction, compte tenu de la constatation expérimentale d'un ordre un par rapport à chacun des réactifs :

P1 : $R_2NH + ClOH \xrightarrow{k_1}$ produits

P2 : $R_2NH_2^+ + ClO^- \xrightarrow{k_2}$ produits

P3 : $R_2NH + ClO^- \xrightarrow{k_3}$ produits

P4 : $R_2NH_2^+ + ClOH \xrightarrow{k_4}$ produits

Afin de relier constante de vitesse expérimentale et constante de vitesse absolue calculée à partir de la théorie de l'état de transition, nous utilisons les relations suivantes :

$$[1] \qquad K_I = \frac{(ClO^-)(H^+)}{(ClOH)}$$

$$[2] \qquad K_{II} = \frac{(R_2NH)(H^+)}{(R_2NH_2^+)}$$

$$[3] \qquad Cl_t = [ClO^-] + [ClOH]$$

$$[4] \qquad Am_t = [R_2NH_2^+] + [R_2NH]$$

Am_t et Cl_t représentent les concentrations courantes globales des réactifs; les activités des espèces s'expriment à partir de leurs concentrations et des coefficients d'activité γ :

$$[5] \qquad (X) = \gamma_X[X]$$

La constante de vitesse expérimentale calculée à partir de la relation

$$[6] \qquad V = k_{exp}Cl_tAm_t$$

s'exprime à l'aide des relations [1]–[5] selon que l'on envisage les differents processus :

$$k_{exp}^{P1} = \frac{k_1^0 K_{II}}{\gamma_1^{\neq}}\left[\frac{(H^+)\gamma_{R_2NH}\gamma_{ClOH}\gamma_{R_2NH_2}\gamma_{ClO^-}}{[K_I\gamma_{ClOH}+(H^+)\gamma_{ClO^-}][K_{II}\gamma_{R_2NH_2}+(H^+)\gamma_{R_2NH}]}\right]$$

$$k_{exp}^{P2} = \frac{k_2^0 K_I}{\gamma_2^{\neq}}\left[\frac{(H^+)\gamma_{R_2NH}\gamma_{ClOH}\gamma_{R_2NH_2}\gamma_{ClO^-}}{[K_I\gamma_{ClOH}+(H^+)\gamma_{ClO^-}][K_{II}\gamma_{R_2NH_2}+(H^+)\gamma_{R_2NH}]}\right]$$

$$k_{exp}^{P3} = \frac{k_3^0 K_I K_{II}}{\gamma_3^{\neq}}\left[\frac{\gamma_{R_2NH}\gamma_{ClOH}\gamma_{R_2NH_2}\gamma_{ClO^-}}{[K_I\gamma_{ClOH}+(H^+)\gamma_{ClO^-}][K_{II}\gamma_{R_2NH_2}+(H^+)\gamma_{R_2NH}]}\right]$$

$$k_{exp}^{P4} = \frac{k_4^0}{\gamma_4^{\neq}}\left[\frac{(H^+)^2\gamma_{R_2NH}\gamma_{ClOH}\gamma_{R_2NH_2}\gamma_{ClO^-}}{[K_I\gamma_{ClOH}+(H^+)\gamma_{ClO^-}][K_{II}\gamma_{R_2NH_2}+(H^+)\gamma_{R_2NH}]}\right]$$

Les figures 3a et 3b représentent ces fonctions sur le domaine de pH de l'eau (pour des paramètres arbitraires). Il apparaît clairement que si les processus P3 et P4 sont facilement discernables par une simple étude de l'influence du pH sur la constante de vitesse expérimentale, il n'en est pas de même pour les processus P1 et P2 pour lesquels les variations théoriques de la constante de vitesse sont strictement identiques tant du point de vue du pH que de celui des coefficients d'activité (donc de tout paramètre, comme la force ionique par exemple, agissant sur ces coefficients).

Sur la figure 4 où nous avons porté, pour la diéthylamine, le logarithme népérien de k_{exp} en fonction du pH, nous obtenons une courbe avec maximum correspondent aux cas P1 ou P2.

Pour le vérifier (figure 5) nous avons porté $\ln(k_{exp})$ en fonction de $\ln(W)$ avec :

$$W = \left[\frac{(H^+)\gamma_{R_2NH}\gamma_{ClOH}\gamma_{R_2NH_2}\gamma_{ClO^-}}{[K_I\gamma_{ClOH} + (H^+)\gamma_{ClO^-}][K_{II}\gamma_{R_2NH_2}+(H^+)\gamma_{R_2NH}]}\right]$$

et an admettant une forme approchée par la loi limite de Debye–Hückel pour les coefficients d'activité des espèces ioniques :

$$\gamma_{R_2NH} = \gamma_{ClOH} = 1 \qquad \gamma = \gamma_{R_2NH_2} = \gamma_{ClO^-} = 10^{-0{,}5\sqrt{I}}$$

$$W = \left[\frac{(H^+)\gamma^2}{[K_I + (H^+)\gamma][K_{II}\gamma + (H^+)]}\right]$$

Pour chaque amine, nous avons obtenu une droite dont l'ordonnée à l'origine peut représenter indifféremment $\ln(k_1^0K_{II})$ ou $\ln(k_2^0K_I)$ ou même la somme des deux valeurs si les deux processus sont possibles et de vitesse équivalente.

Ce problème, remarqué pour les N-chlorations de la méthylamine et de la diméthylamine par Morris et Weil (1), est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12

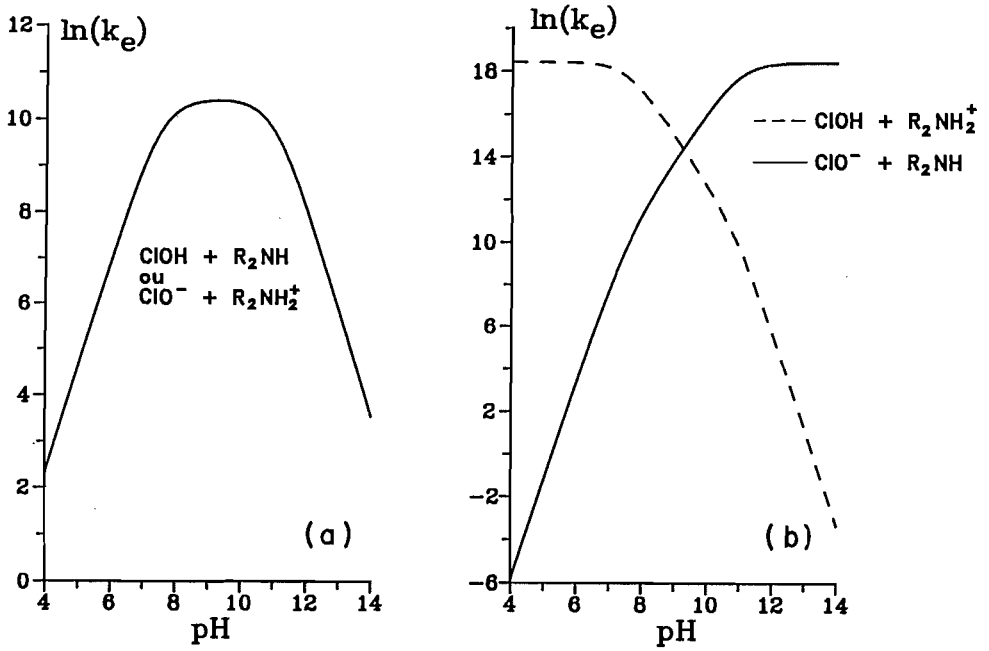

FIG. 3. Variation théoriques de la constante de vitesse expérimentale avec le pH selon le mécanisme envisagé entre acides et bases faibles en solution aqueuse.

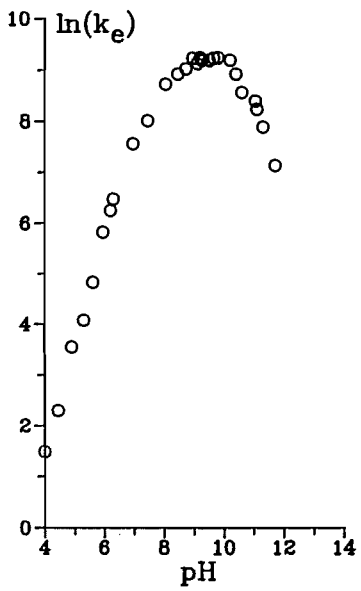

FIG. 4. Logarithme népérien de la constante de vitesse expérimentale de chloration de la diéthylamine en fonction du pH. $T = 298$ K; $DEA_t = 5 \times 10^{-3}$ M; $Cl_t = 5 \times 10^{-4}$ M; force ionique $I = 0{,}10 \pm 0{,}03$ M.

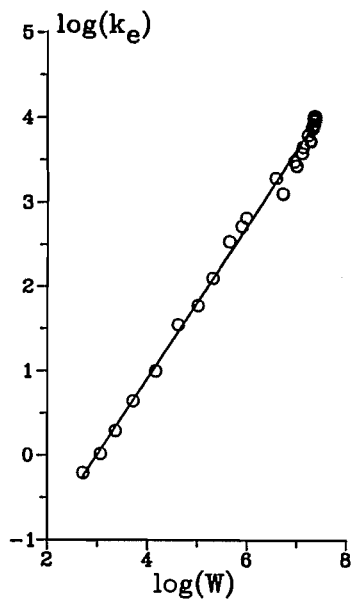

FIG. 5. Logarithme népérien de la constante de vitesse expérimentale de chloration de la diéthylamine en fonction de ln(W)

$$W = \frac{(H^+)^2}{[K_I + (H^+)][K_{II} + (H^+)]}$$

(pente = 0,9; coefficient de corrélation = 0,9895).

strictement analogue à celui analysé par Pearson et Frost (6) à propos de la conversion cyanate d'ammonium en urée en milieu aqueux. Nous observons là aussi deux processus entre acides et bases faibles conjugués, qui rendent compte des données expérimentales

$$NH_4^+ + CNO^- \rightarrow (NH_2)_2CO$$

ou

$$NH_3 + HCNO \rightarrow (NH_2)_2CO$$

Dans un tel cas chaque série de point expérimentaux conduit à deux valeurs possibles des constantes de vitesse selon que l'on fait l'hypothèse de l'un ou l'autre des processus.

Influence de la température

En milieu acide (pH = 3,35), à concentration suffisamment faible en ions chlorures pour que la chloration par le chlore moléculaire n'intervienne pas, les expressions de k_{exp} se simplifient pour les processus P1 et P2 :

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

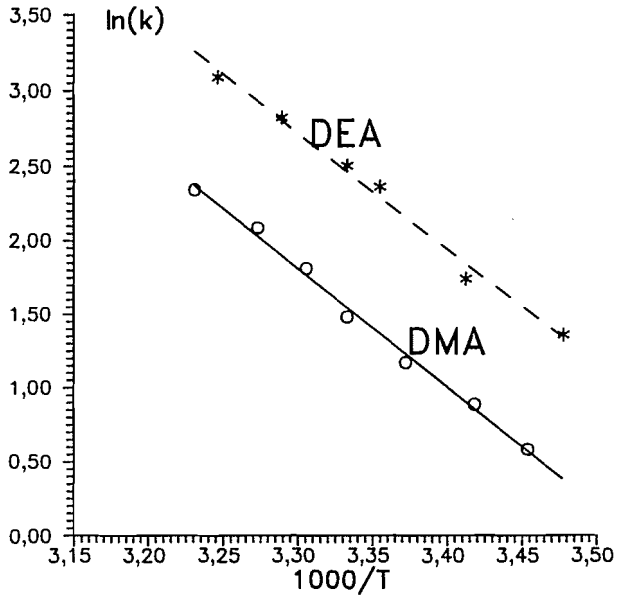

FIG. 6. Énergie d'activation globale. Diéthylamine : $\ln(k_{exp}) = -8100/T + 28{,}39$ (coeff. corr. = 0,9576); E_a = 67 kJ mol^{-1}. Diéthylamine : $\ln(k_{exp}) = -7800/T + 28{,}40$ (coeff. corr. = 0,9807); E_a = 65 kJ mol^{-1}.

$$k_{exp}^{P1} = k_1^0 K_{II}\left[\frac{\gamma_{ClOH}\gamma_{R_2NH_2}}{(H^+)\gamma_1^{\neq}}\right] \qquad k_{exp}^{P2} = k_2^0 K_I\left[\frac{\gamma_{ClOH}\gamma_{R_2NH_2}}{(H^+)\gamma_2^{\neq}}\right]$$

Soit avec les notations déjà utilisées précédemment :

$$k_{exp}^{P1} = k_1^0 K_{II}\left[\frac{\gamma}{(H^+)}\right] \qquad k_{exp}^{P2} = k_2^0 K_I\left[\frac{\gamma}{(H^+)}\right]$$

Pour chaque amine, les points $\ln(k_{exp})$ versus $1/T$ sont portés par une droite dont la pente représente les énergies d'activation globales, soit 67,1 kJ mol^{-1} pour la DMA et 64,7 kJ mol^{-1} pour la DEA (figure 6).

Dans ces conditions de pH, les énergies d'activations des processus se déduisent de la valeur de l'énergie d'activation globale à partir des relations :

$$\ln(k_{exp}) = \frac{-E_a}{RT} + C = \frac{-E_1 - \Delta H_{II}^0}{RT} + C$$

soit $E_1 = E_a - \Delta H_{II}^0$

ou

$$\ln(k_{exp}) = \frac{-E_a}{RT} + C = \frac{-E_2 - \Delta H_I^0}{RT} + C$$

soit $E_2 = E_a - \Delta H_I^0$

Avec ΔH_I^0 = 16,3 kJ mol^{-1} (4), $\Delta H_{II(DMA)}^0$ = 49,5 kJ mol^{-1} (7) et $\Delta H_{II(DEA)}^0$ = 49,7 kJ mol^{-1} (8), les énergies d'activations des processus prennent les valeurs pour le processus ionique $E_{2(DMA)}$ = 50,8 kJ mol^{-1}, $E_{2(DEA)}$ = 48,4 kJ mol^{-1} et pour le processus moléculaire $E_{1(DMA)}$ = 17,6 kJ mol^{-1}, $E_{1(DEA)}$ = 15 kJ mol^{-1}.

Chloration par Cl_2

En milieu acide, en présence de chlorures, nous observons (figure 7) une accélération de la réaction par rapport à celle due à ClO^- ou ClOH. Cet écart aux valeurs théoriquement attendues apparait dés que la concentration de Cl_2 n'est plus négligeable.

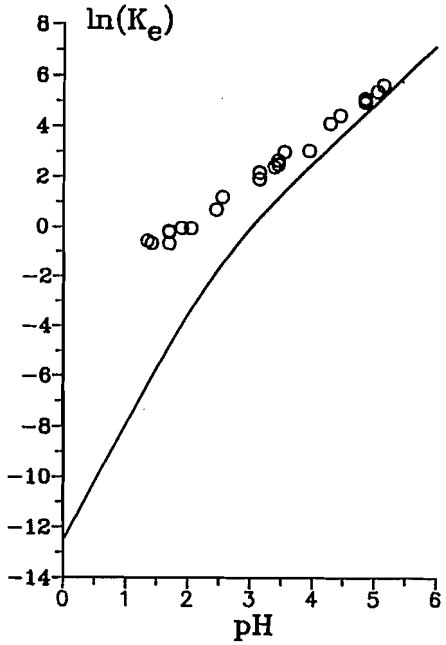

FIG. 7. Chloration par Cl_2. Logarithme népérien de la constante de vitesse expérimentale de chloration de la diéthylamine en fonction du pH. T = 298 K; $DMA_t = 7{,}5 \times 10^{-3}$ M; $Cl_t = 8 \times 10^{-4}$ M; $[Cl^-]$ = 0,2 M (en trait plein courbe théorique pour une chloration par ClOH ou ClO^- uniquement).

Dans ces conditions il faut tenir compte de deux équilibres supplémentaires.

[III] $Cl_2 + H_2O \leftrightarrows ClOH + H^+ + Cl^-$ $\quad pK_{III} = 3{,}4$ à 298 K (9)

[IV] $Cl_2 + Cl^- \leftrightarrows Cl_3^-$ $\quad pK_{IV} = 0{,}74$ à 298 K (10)

Quelques essais à pH constant et à concentration variable d'ions chlorures nous ont permis de vérifier que la chloration engage le chlore moléculaire Cl_2 et non Cl_3^-. De plus, la persistance de la décroissance de la vitesse avec le pH permet d'affirmer que la chloration se fait sur l'amine non protonée pourtant espèce très minoritaire aux pH acides.

Nous avons donc, aux pH où Cl_2 et ClOH coexistent, une vitesse globale qui s'exprime par une double contribution due à la chloration par les deux espèces :

$$V = k_{Cl_2}[Cl_2][R_2NH] + k_1[ClOH][R_2NH]$$

En milieu acide le bilan en chlore libre total devient :

[7] $\quad Cl_t = [Cl_2] + [ClOH] + [Cl_3^-]$

avec pour expression des concentrations de ClOH et Cl_2

$$[ClOH] = \left[\frac{K_{III}}{K_{III} + K_{IV}[Cl^-]^2\gamma(H^+) + [Cl^-]\gamma(H^+)}\right] Cl_t$$

$$[Cl_2] = \left[\frac{[Cl^-]\gamma(H^+)}{K_{III} + K_{IV}[Cl^-]^2\gamma(H^+) + [Cl^-]\gamma(H^+)}\right] Cl_t$$

Pour l'amine en milieu acide nous avons : $[R_2NH_2^+] \neq Am_t$ D'où l'expression simplifiée de la concentration de R_2NH :

$$[R_2NH] = K_{II}\frac{\gamma}{(H^+)} Am_t$$

À partir de ces relations et celle de la vitesse [6] nous obtenons

TABLEAU 1. Résultats numériques à 298 K

Réactions	k^0 ($M^{-1}\,s^{-1}$)	E (kJ mol^{-1})	$\Delta H^{\neq}$ (kJ mol^{-1})	$\Delta S^{\neq}$ (J $K^{-1}\,mol^{-1}$)
$(CH_3)_2NH + HOCl \rightarrow (CH_3)_2NCl + H_2O$	$9{,}8 \times 10^7$	17,6	15,1	−41
$(CH_3)_2NH + Cl_2 \rightarrow (CH_3)_2NCl + H^+ + Cl^-$	$1{,}6 \times 10^9$	7,5	5,5	−50,2
$(C_2H_5)_2NH + HOCl \rightarrow (C_2H_5)_2NCl + H_2O$	$5{,}3 \times 10^7$	15,0	12,5	−54
$(C_2H_5)_2NH + Cl_2 \rightarrow (C_2H_5)_2NCl + H^+ + Cl^-$	$9{,}4 \times 10^8$	—	—	—

pour valeur de la constante expérimentale de réaction :

$$k_{exp} = \left(\frac{k_{Cl_2}[Cl^-]\gamma(H^+) + k_1K_{III}}{K_{III} + K_{IV}[Cl^-]^2\gamma(H^+) + [Cl^-]\gamma(H^+)}\right)\frac{K_{II}\gamma}{(H^+)}$$

Pour

$$X = \frac{(H^+)\gamma[Cl^-]}{K_{III} + K_{IV}[Cl^-]^2(H^+)\gamma + (H^+)\gamma[Cl^-]}$$

et

$$Y = \frac{k_{exp}(H^+)}{K_{II}\gamma} - \frac{k_1K_{III}}{K_{III} + K_{IV}[Cl^-]^2(H^+)\gamma + (H^+)\gamma[Cl^-]}$$

nous avons, à partir de nos résultats expérimentaux, obtenu une droite $Y = f(X)$ dont la pente est une mesure de k_{Cl_2} égale à $1{,}6 \times 10^9\,M^{-1}\,s^{-1}$ pour la diméthylamine et $9{,}4 \times 10^8\,M^{-1}\,s^{-1}$ pour la diéthylamine à 298 K (figure 8).

Pour la DMA nous avons déterminé une énergie d'activation de 7,5 kJ mol^{-1}.

Les résultats numériques sont resumés dans le tableau 1.

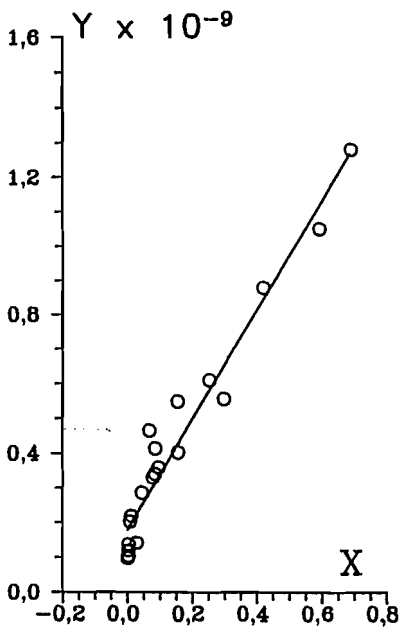

FIG. 8. Détermination de k_{Cl_2} pour la diméthylamine.

$$X = \frac{(H^+)\gamma[Cl^-]}{K_{III} + K_{IV}[Cl^-]^2(H^+)\gamma + (H^+)\gamma[Cl^-]}$$

et

$$Y = \frac{k_{exp}(H^+)}{K_{II}\gamma} - \frac{k_1K_{III}}{K_{III} + K_{IV}[Cl^-]^2(H^+)\gamma + (H^+)\gamma[Cl^-]}$$

Pente = $k_{Cl_2} = 1{,}1 \times 10^9\,M^{-1}\,s^{-1}$ (coefficient de corrélation = 0,9895).

Conclusions

Pour les deux amines la chloration par Cl_2 se fait par réaction de R_2NH et Cl_2. Ces cinétiques sont limitées par la diffusion ce qui est général pour les N-chlorations par Cl_2 en milieu aqueux (11).

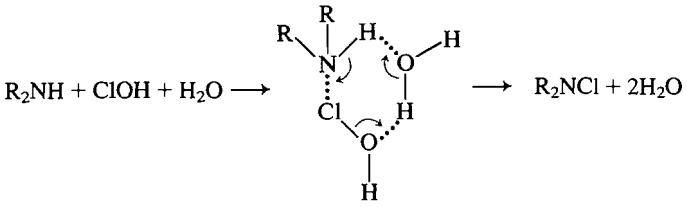
Par analogie il semblerait raisonnable d'admettre un mécanisme similaire entre ClOH et R_2NH.

Ces deux mécanismes se conçoivent facilement par une attaque nucléophile de l'amine sur un chlore :

$$R_2\bar{N}H + Cl\text{—}Cl \rightarrow R_2NClH^+ + Cl^- \rightarrow R_2NCl + Cl^- + H^+$$

$$R_2\bar{N}H + Cl\text{—}OH \rightarrow R_2NClH^+ + OH^- \rightarrow R_2NCl + H_2O$$

Toutefois l'expérience ne permet pas d'exclure une réaction de type ionique entre ClO^- et $R_2NH_2^+$.



Si l'on admet que le mécanisme de chloration moléculaire est le plus probable, les valeurs faibles des énergies d'activations liées à celui-ci (17,6 et 15 kJ mol^{-1}) sont proches des paramètres d'activation d'une cinétique limitée par la diffusion.

En fait pour les deux amines le facteur 10 entre les valeurs de k_1 et k_{Cl_2}, et le facteur 2 entre les énergies d'activation incitent à penser que la cinétique de chloration par ClOH n'est que partiellement limitée par la diffusion. En effet les valeurs proches des coefficients de diffusion de ClOH et Cl_2 dans l'eau ($D_{Cl_2} = 1{,}83\,m^2\,s^{-1}$ et $D_{ClOH} = 1{,}28\,m^2\,s^{-1}$ à 298 K (12)) ne peuvent expliquer, dans l'hypothèse de cinétiques limitées par la diffusion, cet écart entre les valeurs des constantes de vitesse.

À partir de la valeur du coefficient de diffusion de la DEA($0{,}97\,m^2\,s^{-1}$ (13)), nous obtenons dans les conditions de Smoluchovski ($k_d = 4\pi\rho_0(D_A + D_B)$, avec $\rho_0 = 10^{10}$ m), les valeurs théoriques $k_d^{Cl_2} = 2{,}1 \times 10^9\,M^{-1}\,s^{-1}$ et $k_d^{ClOH} = 1{,}6 \times 10^9\,M^{-1}\,s^{-1}$ à comparer aux valeurs expérimentales, $k_{Cl_2} = 9{,}4 \times 10^8$ et $k_1 = 5{,}3 \times 10^7\,M^{-1}\,s^{-1}$. Il apparait que pour le chlore moléculaire les valeurs sont du même ordre de grandeur, ce qui confirme un régime diffusionnel alors que pour l'acide hypochloreux, si nous admettons une situation intermédiaire, nous calculons à partir de la relation :

$$k_1 = \frac{k_1^x}{(1 + k_1^x/k_d)}$$

une valeur de k_1^x (constante de vitesse réelle du processus) de $5{,}7 \times 10^7\,M^{-1}\,s^{-1}$ soit une valeur très proche de k_1. L'influence de la diffusion apparait donc faible pour un tel processus. Par contre, le proposition (1) d'une participation d'une molécule d'eau au mécanisme avec formation d'un intermédiaire stabilisé par liaison hydrogéne :

permet d'expliquer la faiblesse relative des énergies d'activation et des constantes de vitesse par rapport à l'hypothèse d'un processus bimoléculaire simple.

Medium isotope effect for isobutyrophenone in aqueous solution. Solvent isotope effects on carbonyl group hydration

J. R. KEEFFE[1] AND A. J. KRESGE[2]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 12, 1988

J. R. KEEFFE and A. J. KRESGE. Can. J. Chem. **67**, 792 (1989).

A medium solvent isotope effect of $\Phi = 0.827 \pm 0.013$ was determined for transfer of isobutyrophenone from H_2O to D_2O. This result, in conjunction with the average solvent isotope effect on hydration of a number of carbonyl compounds, leads to $\phi = 0.987 \pm 0.009$ as the fractionation factor for the hydroxyl group hydrogens of the hydration reactions' *gem*-diol products, which is consistent with the expectation that fractionation factors for uncharged hydroxyl groups should be unity.

Key words: isobutyrophenone, fractionation factors, solvent isotope effects, deuterium oxide.

J. R. KEEFFE et A. J. KRESGE. Can. J. Chem. **67**, 792 (1989).

Pour le transfert de l'isobutyrophénone du H_2O au D_2O, on a déterminé que l'effet isotopique du solvant est $\Phi = 0{,}827 \pm 0{,}013$. Ce résultat, utilisé de concert avec la valeur moyenne de l'effet isotopique du solvant sur l'hydratation d'un certain nombre de composés carbonylés conduit à une valeur de $\phi = 0{,}987 \pm 0{,}009$ pour le facteur de fractionnement des hydrogènes des groupements hydroxyles des produits *gem*-diols obtenus par réaction d'hydratation; ce résultat est en accord avec la valeur de 1 à laquelle on s'attend pour le facteur de fractionnement de groupement hydroxyles qui ne sont pas chargés.

Mots clés : isobutyrophénone, facteurs de fractionnement, effets isotopiques du solvant, oxyde de deutérium.

[Traduit par la revue]

Fractionation factor theory (for recent reviews, see ref. 1) expresses solvent isotope effects on equilibria as the product of fractionation factors[3] for all exchangeable hydrogens in the reactants, ϕ_i^R, divided by a like product for all exchangeable hydrogens in the products, ϕ_j^P, eq. [1].

$$[1] \quad K_{H_2O}/K_{D_2O} = \Pi_i\phi_i^R/\Pi_j\phi_j^P$$

Application of this formalism at its simplest level to the hydration of carbonyl compounds in aqueous solution, eq. [2],[4]

$$[2] \quad \text{>C=O} + L_2O \underset{}{\overset{K}{\rightleftharpoons}} \text{>C(OL)(OL)}$$

leads to an expression, eq. [3], containing only the fractionation factor for the hydroxyl group hydrogen of the *gem*-diol product, ϕ_{ROL}, and that fractionation factor can thus be evaluated directly from this solvent isotope effect. When that is done using the average value of eight separate determinations of this isotope effect (2), $K_{H_2O}/K_{D_2O} = 0.849 \pm 0.009$, the result $\phi_{ROL} = 1.085 \pm 0.006$ is obtained (3).

$$[3] \quad K_{H_2O}/K_{D_2O} = 1/\phi_{ROL}^2$$

It is generally believed, however, that fractionation factors for the hydrogens of uncharged hydroxyl groups should be unity (1, 3), and it is not readily apparent why *gem*-diols would be different. The simple expression of eq. [3] cannot of course accommodate a *gem*-diol fractionation factor of unity and a solvent isotope effect different from unity, but the expression could be modified by introducing additional terms. In particular, fractionation factors might be added to allow for medium isotope effects (4). Such effects are generally produced by small differences between the water molecules of bulk solvent and those directly involved in solvating the dissolved species; the individual fractionation factors of these solvating sites are usually not very different from unity, but because several water molecules are generally involved, the aggregate effect can be appreciable. A medium isotope effect of this kind would appear to be especially likely for the carbonyl compound substrate of the present hydration reaction (eq. [2]), inasmuch as carbonyl groups are strongly dipolar. The modification of eq. [3] that this would require is shown as eq. [4],

$$[4] \quad K_{H_2O}/K_{D_2O} = \Phi_C/\phi_{ROL}^2$$

in which Φ_C is the medium isotope effect for transferring the carbonyl compound from H_2O to D_2O.[5]

To determine whether or not this is so, we have measured the medium isotope effect for a simple carbonyl compound. We chose isobutyrophenone for this purpose because it has a strong ultraviolet chromophore that facilitates accurate concentration measurements, and also because we have an interest in this molecule from the point of view of its keto–enol equilibrium (5). We determined the medium isotope effect in two independent ways: (1) by measuring the ratio of the solubilities of isobutyrophenone in H_2O and D_2O, and (2) by measuring the ratio of its partition coefficients between hexane and H_2O and hexane and D_2O.

Experimental

Solubilities

Saturated solutions of isobutyrophenone in H_2O and D_2O were prepared by adding 3.0-μL quantities of ketone to cuvettes containing 3.0-mL volumes of each solvent and shaking the mixtures mechanically for 3 h. The presence of haziness in each mixture indicated that the amount of ketone supplied was more than enough to achieve saturation. These mixtures were allowed to stand at room temperature (23–24°C) in the dark for 10 days, to ensure that all undissolved ketone had ample

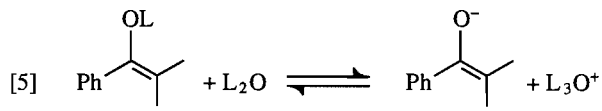
opportunity to float to the top. Absorbance measurements at $\lambda = 300$ nm were made during this time; these remained constant over the final three days. The ratio of these final absorbances gives the medium isotope effect $\Phi_C = 0.852$. Use of the extinction coefficient $\varepsilon_{300} = 285$ M^{-1} cm^{-1} also provides a saturation solubility of 4.4×10^{-3} M for isobutyrophenone in H_2O solution.

Partition coefficients

Solutions of isobutyrophenone in H_2O and D_2O that were ca. three-quarters saturated were prepared and their absorbances were measured at $\lambda = 300$ and 310 nm. Nine-millilitre aliquots of these solutions were then shaken with 1.00-mL portions of hexane and the resulting mixtures were allowed to stand for 5 h to ensure complete phase separation. Absorbance measurements of the aqueous portions were made during this time at $\lambda = 300$ and 310 nm; these remained constant over the final hour. Medium isotope effects were calculated using the relationship $\Phi_C = (A_0)_{H_2O}(A_0-A)_{D_2O}/(A_0)_{D_2O}(A_0-A)_{H_2O}$, in which A_0 and A are the absorbances measured before and after extraction respectively. The measurements at $\lambda = 300$ nm give $\Phi_C = 0.819$ and those at $\lambda = 310$ nm, $\Phi_C = 0.809$. These experiments also provide a partition coefficient of 3.4×10^{-3} for isobutyrophenone between hexane and H_2O.

Results and discussion



The three determinations of the medium isotope effect for isobutyrophenone made here are in good agreement with one another. Their average value is $\Phi_C = 0.827 \pm 0.013$.

This is a reasonable result. Carbonyl groups of simple aldehydes and ketones will be solvated in aqueous solution principally through their negatively charged oxygen atoms, inasmuch as this end of the carbonyl group dipole is more accessible to solvent molecules than is the positively charged carbon atom. These solvent molecules, moreover, will be linked to the carbonyl oxygen atom through hydrogen bonds, and hydrogen bonding is known to loosen the bonds involved and lead to lowered isotopic fractionation factors (6); water molecules solvating the hydroxide ion, for example, have $\phi = 0.7$ (1, 4, 7).

It is likely that in the present case this hydrogen bonding involves two water molecules, one bound to each of the unshared electron pairs of the carbonyl oxygen atom. The aggregate medium isotope effect is then equal to the fractionation factor for these hydrogen-bonding hydrogens raised to the second power, and the value of this fractionation factor may thus be calculated as $\phi = \sqrt{\Phi_C} = 0.0909 \pm 0.007$.

Use of the presently determined medium isotope effect in conjunction with the isotope effect on carbonyl compound hydration, $K_{H_2O}/K_{D_2O} = 0.849$ (2), leads, via eq. [4], to $\phi_{ROL} = 0.987 \pm 0.009$. This result is hardly different from unity, and that is nicely consistent with the fact that this value refers to an uncharged hydroxyl group for which a unit fractionation factor would be expected.

If a unit value of ϕ_{ROL} may be assumed to apply to the hydroxyl groups of enols as well, then the value of Φ_C determined here can be used together with the recently measured solvent isotope effect on the acid ionization of isobutyrophenone enol, eq. [5],

[5]

$(K_a^E)_{H_2O}/(K_a^E)_{D_2O} = 5.88 \pm 0.32$ (5*b*), to estimate the medium isotope effect for isobutyrophenone enolate ion, Φ_{E^-}. The fractionation factor theory expression for this acid ionization isotope effect is given by eq. [6],

$$[6] \quad (K_a^E)_{H_2O}/(K_a^E)_{D_2O} = \phi_{ROL}/(\Phi_E \cdot \ell^3)$$

in which ℓ is the fractionation factor for the hydronium ion whose value is 0.69 (1, 4); use of this plus $\phi_{ROL} = 1.00$ then leads to $\Phi_{E^-} = 0.52 \pm 0.03$. To the best of our knowledge, this is the first medium isotope effect ever reported for the enolate ion of a monofunctional carbonyl compound; it is a sensible value in that medium isotope effects for anions are expected to be less than unity (1, 4, 7). On the expectation that this isotope effect, like the medium isotope effect for the hydroxide ion, is produced by three hydrogen-bonded water molecules each attached to one unshared electron pair of the enolate oxygen atom, $\phi = (\Phi_{E^-})^{1/3} = 0.80 \pm 0.02$ may be calculated as the fractionation factor for the hydrogen-bonding hydrogens; this is consistent with $\phi = 0.7$ for the hydrogen-bonding hydrogens of the water molecules solvating the hydroxide ion (1, 4, 7).

Introduction

We recently reported (1) an investigation of chelation and non-chelation controlled organometallic addition to acrolein dimer as a route to the economically important bicyclic ketals *exo*-brevicomin **1** and *endo*-brevicomin, **2**.[2] Although diastereoselectivity of organometallic addition was quite high, the approach was beset by the difficult vinyl metalation. The present investigation was undertaken to develop an efficient route to racemic **1** and **2** from a single inexpensive intermediate. We have achieved highly diastereoselective chemical reduction of **3** (2) and its acyclic analogs **4***a* and **4***b*. The dihydroxyketones (**5** and **6**) generated in each case readily cyclize in acid to mixtures of alkylated 2,6-dioxabicyclo[3.2.1]octanes (**1** and **2**).

Results and discussion

threo-Selective chemical chemical reduction of **3**, **4***a*, or **4***b* is required to produce **1**. *threo*-Selective reduction of α- and β-oxy-carbonyl compounds is usually achieved by delivery of a hydride from the least hindered side of the carbonyl in the presence of a reagent capable of enhancing the dipolar repulsion between the carbonyl and the α-oxy function but devoid of bidentate chelating ability (non-chelation control). The *erythro*-selective chemical reduction required to produce **2** is usually achieved through use of a Lewis acid capable of coordination of both the carbonyl and α-oxy function followed by hydride delivery from the less hindered side (chelation control) (for an excellent discussion, see ref. 3). Selectride^R reagents effect *threo*-selective reductions while, owing to its superior chelating ability, zinc borohydride is the efficient reagent for *erythro*-selective reductions (4–8).

We found the reductions of **3** and its acyclic derivatives, **4***a* and **4***b*, with several hydride reducing agents are highly diastereoselective (Table 1). The stereochemical course of these reductions was followed by conversion of intermediates **5** and **6** to **1** and **2**, respectively. As previously reported (9), reduction of **3** with $NaBH_4$ in methanol did not show useful selectivity (Table 1, entry 1). Use of either lithium tetrahydridoaluminate or diisobutylaluminum hydride in the reduction of **3** gave similar low diastereoselectivity (entries 2 and 3). Addition of $CeCl_3$ as a chelating agent unexpectedly gave an increased proportion of *threo* product **1** in the reduction of **3** by $NaBH_4$ (entry 4). Neither **4***a* nor **4***b* underwent diastereoselective reduction with $NaBH_4$ (entries 5 and 6). Reduction of **3** with potassium tri(*sec*-butyl)borohydride (10*a*) (K-Selectride^R, entry 7) gave an increased proportion of *threo* product **1**, which was not significantly increased upon addition of BF_3 (entry 8). Reduction of **4***a* or **4***b* with K-Selectride^R offered no advantage in production of **1** (entries 9 and 10). The highest proportion of *threo* product (93:7) from reduction of **3** was achieved using lithium tri(*sec*-butyl)borohydride (10*b*) (Li-Selectride^R, entries 11 and 12). This reducing agent was also the most *threo* selective in reductions of **4***a* (entry 13) and **4***b* (entry 14). The lower yields obtained with BF_3 (entries 8 and 12) may be attributed to competing Lewis acid catalyzed polymerization of the substrates.

[a]Estimated by gas chromatographic analysis (please see Experimental).
[b]Unless otherwise specified, yields determined by gas chromatographic analysis (please see Experimental).
[c]Isolated yields.

Chelation controlled reduction of **3** with zinc borohydride (10*c*) afforded a *threo*:*erythro* ratio of 27:73 (entry 15). Use of K- or Li-Selectride^R with $ZnCl_2$ (entries 16 and 17, respectively) did not dramatically improve *erythro* selectivity. We reasoned that *erythro* selectivity would be increased if the α-oxygen were more available for complexation. Indeed, when **4***a* was reduced with zinc borohydride *erythro* selectivity improved significantly (entry 18).

Addition of $MgBr_2$–Et_2O effected a dramatic alteration of the stereochemical outcome of reduction of **3** by Li-Selectride^R (compare entries 7 and 20) but had little effect in the case of Li-Selectride^R (compare entries 11 and 21). In the former reaction KBr precipitates from the reaction, giving a reducing agent most probably coordinated with magnesium. Lewis acid mediated reversal of selectivity was not observed when $ZnCl_2$ was added to Li-Selectride^R reduction of **3** (compare entries 11 and 17). No improvements of selectivity were observed when **4***a* and **4***b* were reduced with Li-Selectride^R in the presence of $MgBr_2$–Et_2O (compare entries 9, 10, 22, and 23).

Experimental

The nmr spectra were recorded using Bruker WM400 and SY100 spectrometers. Infrared spectra were recorded of neat films between NaCl plates on a Perkin Elmer 599B spectrophotometer. Low resolution mass spectra were recorded on an in-house Hewlett–Packard 5985B GC/MS/DS system operating at 70 eV. Gas chromatographic analysis utilized a Hewlett–Packard 5880A operated with a J + W fused silica DB-1 capillary column (15 m × 0.25 mm), a flame ionization detector, and linear oven temperature programs initiated at 60°C (Program 1) or 100°C (Program 2) and increased at 5°C/min to 200°C. Elemental analyses were performed at the microanalytical laboratory of the Department of Biological Sciences, Simon Fraser University, on a Perkin Elmer Model 240 elemental analyzer.

Chromatography sovents were distilled before use. Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl immediately prior to use. All reactions involving air or moisture sensitive reagents were performed under an argon atmosphere.

*Preparation of 2-propionyl-6-methyl-2,3-dihydro-4*H*-pyran,* ***3***

Fractional distillation of 200 g of an aged (6 months) sample of methyl vinyl ketone afforded 88 g (44%) of methyl vinyl ketone dimer: bp 65–70°C (20 Torr; 1 Torr = 133.3 Pa), lit. (11) bp 68°C (13 Torr); ir (film): 1720 and 1684 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.83 (d, J = 1.0 Hz, 3H), 1.95 (m, 4H), 2.22 (s, 3H), 4.25 (m, 1H), 4.50 (bs, 1H).

The *N*-cyclohexyl imine of methyl vinyl ketone dimer was prepared according to the procedure of Chaquin *et al.* (2); ir (film): 1685 and 1668 cm^{-1}. This compound was treated sequentially with ethylmagnesium bromide in ether and iodomethane to give **3** in 75% overall yield from methyl vinyl ketone dimer; bp, Kugelrohr, 40°C (0.25 Torr), lit. (2) bp 83°C (14 Torr).

Preparation of **4**a

A mixture of 0.79 g (5.13 mmol) of **3**, 0.31 g (5 mmol) of ethylene glycol, and ca. 5 mg of oxalic acid monohydrate was kept stirred at 25°C for 48 h. The reaction mixture was chromatographed on 25 g of neutral activity grade 3 alumina using 10–30% ether in hexanes (v/v, gradient) to afford 0.931 g (84%) of **4***a* as a colorless, thermally unstable oil that cyclized to **3** slowly upon standing and rapidly upon attempted distillation. The oil was therefore used immediately following chromatography; ir (film): 3450, 1715 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.027 (t, J = 7.3 Hz, 3H), 1.20 (t, J = 7.2 Hz, 2H), 1.38 (s, 3H), 1.4–2.05 (m, 4H), 2.60 (m, 2H), 3.50 (m, 4H), 3.72 (br t, 1H), 4.08 (dd, J = 11.7, 3 Hz, 1H). Low resolution CIMS (isobutane) m/e: 217 ($M + H^+$). *Anal.* calcd. for $C_{11}H_{20}O_4$: C 61.09, H 9.32; found: C 61.02, H 9.25.

Preparation of **4**b

To a solution of 0.532 g (2.0 mmol) of **4***a* and 0.33 g (2.2 mmol) of *tert*-butyldimethylchlorosilane in 2.0 mL of dichloromethane were added 0.164 g (2.08 mmol) of pyridine and ca. 5 mg of DMAP and the reaction mixture was kept stirred at 25°C for 3 h. The reaction mixture was then diluted with 50 mL of ether and washed successively with 2 × 10 mL of 0.05 M KH_2PO_4 and 10 mL of H_2O, dried ($MgSO_4$), and solvents removed *in vacuo*. The residue, upon chromatography on 25 g of neutral activity grade 3 alumina using 10–30% ether in hexane (v/v, gradient) to afford 0.535 g (81%) of **4***b* as a colorless oil, was also thermally unstable and therefore must be stored in the fridge and used within a few days of purification; ir (film): 1720, 1052 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.054 (s, 6H), 0.88 (s, 9H), 1.03 (t, J = 7 Hz, 3H), 1.36 (s, 3H), 1.2–2.0 (m, 6H), 2.61 (q, J = 7 Hz, 2H), 3.52 (m, 2H), 3.75 (m, 2H), 4.23 (dd, J = 11.7, 2.5 Hz, 1H). *Anal.* calcd. for $C_{17}H_{34}O_4Si$: C 61.77, H 10.37; found: C 61.71, H 10.16.

General procedure for hydride reduction of ***3***, **4**a, *and* **4**b

In the case of reduction by $NaBH_4$ the reaction was conducted at 0°C in methanol. All other reductions were conducted in dry THF. Thus, typically, the substrate (~0.5 mmol) was dissolved in 2 mL of dry THF and maintained under an atmosphere of argon. The solution was cooled to −78°C and the accompanying salt, if any (2 equivalents), was added. Next, a twofold excess of hydride reagent was added and the reaction was allowed to stir for 1 h at −78°C, then warmed slowly to room temperature. Excess hydride was quenched by addition of a proton source. In the case of $LiAlH_4$ reductions, reaction mixtures were treated with aqueous 5 M NaOH until aluminum salts precipitated. In the case of Dibal-H reductions, reaction mixtures were treated with methanol to achieve precipitation of aluminum salts. The salts were filtered and washed with ether. The aqueous portion of each reaction was extracted with 3 × 10 mL of ether. The combined ether extracts and washings were treated with 2 mL of 2 M H_2SO_4 if this was not already part of the work-up. The ether phase was separated and dried over anhydrous $MgSO_4$ and, where isolation was pursued, these ether extracts were concentrated *in vacuo* to give mixtures of *exo*- and *endo*-brevicomin in the yields and ratios reported in Table 1. Where isolation was not pursued, yields were estimated by capillary gas

Synthesis and fast atom bombardment mass spectrometry of the coordination complexes of the ligand 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane

CINDY LEE MACLAURIN, JACK MARTIN MILLER,[1] AND MARY FRANCES RICHARDSON
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received September 19, 1988

CINDY LEE MACLAURIN, JACK MARTIN MILLER, and MARY FRANCES RICHARDSON. Can. J. Chem. **67**, 797 (1989).

Metal complexes containing the ligand 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazatetradecane were synthesized and characterized using electron impact (EI) and fast atom bombardment (FAB). The FAB mass spectra were obtained in positive and negative ion mode. FAB in the positive ion mode proved to be the most successful technique for the identification of these compounds. The majority of the FAB spectra obtained were structurally informative, although not all showed molecular (M^+) or quasimolecular ($[M + H]^+$) ions. The fragmentations observed were characteristic of the ligands and the metal, and were interpreted based on the chemical and spectroscopic properties of these compounds.

Key words: FAB mass spectroscopy, tetraazacyclotetradecane complexes.

CINDY LEE MACLAURIN, JACK MARTIN MILLER et MARY FRANCES RICHARDSON. Can. J. Chem. **67**, 797 (1989).

On a synthétisé des complexes métalliques contenant le ligand hexaméthyl-5,5,7,12,12,14 tétraaza-1,4,8,11 décane et on les a caractérisés par spectrométrie de masse sous impact électronique (IE) et par bombardement avec des atomes rapides (FAB). On a déterminé les spectres de masse par FAB tant dans le mode positif que négatif. La technique des spectres de masse par FAB dans le mode positif s'avère la plus utile pour l'identification de ces composés. Même si les spectres obtenus par cette technique ne présentaient pas tous des ions moléculaires (M^+) ou quasimoléculaires ($[M + H]^+$), la majorité d'entre eux s'est avérée utile pour la détermination des structures. Les fragmentations observées étaient caractéristiques des ligands et du métal et on les a interprétées en se basant sur les propriétés chimiques et spectroscopiques de ces composés.

Mots clés : spectrométrie de masse par FAB, complexes de tétraazacyclotétradécane.

Introduction

Fast Atom Bombardment (FAB) mass spectrometry was introduced by Barber in 1981, and has become a popular ionization technique (1). The sample is dissolved in a matrix liquid (which resulted in long-lived spectra compared to solid samples (2)) and is energized by neutral atom bombardment (in the keV energy range). Sputtered ions characteristic of the sample are produced. Some common matrices are glycerol, sulfolane, thioglycerol, and nitrophenyloctylether and 3-nitrobenzyl alcohol.

Mass spectroscopic analysis of non-volatile, thermally labile inorganic complexes has generally proved so difficult that in the past mass spectroscopy has not been a common tool of the inorganic chemist. FAB makes it possible to obtain mass spectra of organometallic, coordination, and ionic compounds that could not be analyzed previously (3, 4).

Cerny *et al.* found that FAB fragments could be useful in predicting the solution chemistry of some neutral, 1+, and 2+ cationic transition metal coordination complexes (5). They obtained both parent ion information and fragments for the 1+ complexes and generalized that monodentate ligands are lost in preference to bidentate ligands. If redox processes occur, then the spectrum is complicated with many fragment peaks, most of these fragments being formed by the reduction of a higher oxidation state to a lower one. In those compounds in which metal reduction is disfavored, simple ligand loss occurred. Further, the solution chemistry of the complex was paralleled by FAB fragmentation.

Johnstone studied crown ether complexes of metallic cations using FAB (6, 7). Molecular ions of the type $[\text{crown} + M^{n+} + A^{(n-1)-}]^+$ (where A is the anion) were observed. Competitive reactions showed that the order of preference for complex formation with 18-crown-6 in Group 1 is K > Cs > Na, which reflects the trends found in solution. This trend is different for each crown ether investigated. It was suggested that this method could be used to rapidly analyze trace metals as low as 10^{-10} *M*. Johnstone also proposed a method by which stability constants could be measured (6). In another FAB–MS study (8), $[HgCl_2(18\text{-crown-}6)]$ gave a cluster of peaks centered at *m/z* 501, corresponding to the $[HgCl(18\text{-crown-}6)]^+$ ion. This shows that the mercury ion remains associated with the crown ligand despite the weak mercury-to-oxygen bonds. Finally, FAB–MS has been used to determine the nature of mixed-ligand magnesium complexes (9); oligomeric species were identified in which the mixed ligand content was retained.

We chose to study the metal complexes of the macrocyclic ligand 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane, in order to determine the usefulness of FAB–MS in studying the chemistry of macrocyclic complexes. The ligand has two isomers, designated teta (the meso isomer) and tetb (the racemic isomer). We use the symbol L throughout this paper to represent this ligand generally, and the symbols teta and tetb when referring to a specific isomer.

Experimental

Mass spectra were obtained using a Kratos MS-30 double beam, double focusing mass spectrometer, retrofitted with a Kratos FAB source in beam 1. A resolution of 1000 and an accelerating voltage of 4 kV were used. Scan rates of 10 s/decade and 30 s/decade were used.

EI samples were introduced by a heated solids probe (beam 2) with an ionization voltage of 70 eV. The source temperature was varied between 180 and 220°C.

The samples for FAB were introduced on a stainless steel probe. The atom gun (Ion Tech) was operated at a voltage of 6–8 keV, at a source pressure of 10^{-5} Torr and a gun-current of 1–2 mA. All data collection and computation were done with a Kratos DS-55 data system with Brock modified software, including the programs BMASROS and BMASABD used for computation of isotopic multiplets and deconvolution of overlapping multiplets. Positive and negative FAB ion spectra were obtained, using Xe as the primary atom beam.

Infrared spectra were recorded on an Analect FX-6260 FTIR

spectrometer. The shift in ν(N—H) was used to determine if complexation had occurred. All IR samples were prepared as KBr pellets. Elemental analysis were done by Galbraith Laboratories Inc., and Guelph Chemical Laboratories Ltd.

The macrocyclic ligand was obtained from the Parish Chemical Co., and Strem Chemicals Inc. The Parish chemical is a mixture of teta and tetb isomers and will be referred to as L. The chemical obtained from Strem has only the teta isomer present, and will be referred to as teta. One of the Strem lots was contaminated with Cl, probably due to teta.2HCl.

(1) Cobalt complexes: Co(teta)$CoCl_4$ was prepared according to the basic procedure of Endicott and co-workers (11). The remaining cobalt complexes $[Co(teta)(NO_2)(OH)]ClO_4.H_2O$, $[Co(teta)(NO_2)_2]$-$ClO_4.(1/2)H_2O$, $[Co(teta)ClN_3]ClO_4.H_2O$, $[Co(teta)Cl_2]Cl.4H_2O$, $[Co(teta)(CN)_2]ClO_4.H_2O$, $[Co(teta)(SCN)_2]SCN.H_2O$, $[Co(L)Cl_2]ClO_4$ (where L is a mixture of teta and tetb) were synthesized by the methods of Whimp and Curtis (12).

(2) $CdCl_2(L)$: 0.40 g of cadmium chloride was dissolved in 10 mL of warm distilled water and allowed to cool. A stoichiometric amount of the ligand was dissolved in 10 mL of 1-butanol and cooled. The ligand solution was then layered on top of the cadmium solution in a separatory funnel and allowed to stand for 48 h. A large quantity of precipitate formed at the interface. A small amount of precipitate had formed in the aqueous layer and this was drawn off. The precipitate from the interface was filtered, washed with 10 mL of cold 1-butanol, and allowed to air dry.

(3) $ZnCl_2(teta).H_2O$: 0.14 g of $ZnCl_2$ was dissolved in 5 mL of ethanol, and 0.23 g of the teta ligand in another 5 mL of ethanol. Both solutions were filtered and then combined. The resulting solution clouded and a white precipitate formed. The product was recrystallized using ethanol as the solvent.

(4) $NiCl_2(teta).3H_2O$: this complex has been prepared by Ito and Toriumi (13), but our method was different, being similar to that used for the zinc complex. Both the teta and $NiCl_2.6H_2O$ were dissolved in hot 1:1 ethanol/water and combined. The characteristic orange crystals of the low-spin $[Ni(teta)]Cl_2.3H_2O$ complex were obtained. The product turned mauve at approximately 160–165°C which represents a conversion of this product to the high-spin Ni complex (13).

(5) $CuCl_2(teta).H_2O$: 0.43 g of teta was dissolved in 10 mL of absolute ethanol. A stoichiometric amount of cupric chloride was dissolved in 5 mL of absolute ethanol and added to the teta solution. The combined solution was heated for 15 min, and filtered. After 24 h a blue precipitate formed and was filtered and recrystallized from hot ethanol.

$[Ag(teta)(ONO_2)_2]$, $[Mn(teta)Cl_2]Cl.3H_2O$, and $CuL(ClO_4)_2$ were prepared by literature methods (14–16). The $(HgCl_2)_2$(tetb) had been prepared previously (10). Elemental analysis data are provided in Table 1.

The FAB samples were prepared by adding approximately 0.1 g of the complex to 0.05 mL of the matrix liquid. The following matrices were used in an attempt to produce suitable spectra: nitrophenyloctylether (NPOE), di-*t*-amylphenol (DAP), Nujol, glycerol, thioglycerol, glycerol in sulfolane, sulfolane, polyethyleneglycol (PEG), glycerol/DMF, glycerol/water, 18-crown-6(10% tetraglyme), and 3-nitrobenzylalcohol (NBA). To increase the amount dissolved and thus to improve the quality of spectra, samples were left in the matrix for 12–24 h, which greatly improved the quality of the spectra obtained. Heating the sample slightly also improved the results.

Obtaining mass spectra for a number of the cobalt complexes proved to be difficult so a doping technique was employed. The sample (0.1 g) was dissolved in glycerol and then 0.05 mL of a 0.1 *M* NH_4Cl was added to provide doping anions. However, the chloride anion did not produce useful results for cobalt compounds that contained nitrite, so for these compounds 0.1 *M* $NaNO_2$ was used.

The method of sample preparation of Zhang and Liang (17) was used on a number of the more intractable complexes. The sample is dissolved in a suitable solvent and 2 μL of this solution is transferred to the surface of the liquid matrix on the probe tip using a microsyringe. The probe is then inserted into the vacuum lock, where the solvent is evaporated. After 1–2 min the probe is inserted into the ionization chamber.

Results and discussion

A. Electron impact ionization

Previous mass spectral studies of the ligand and its complexes have been concerned with molecular weight determination only (18, 19). The spectra of teta or tetb show the parent ion peak at m/z 284, with a peak at m/z 269 corresponding to the loss of one methyl group (18). Our own results are no better. Spectra could not be obtained for many complexes: those spectra obtained were short lived (one or two scans). The inability to obtain spectra using electron impact is believed to result from the involatility and thermal lability of these compounds, in agreement with Busch's work on iron complexes of the L ligand which showed only low m/z values due to the decomposition of the complex (19).

Molecular ions were not observed even when usable EI spectra were obtained. Spectra contained peaks due only to the decomposition of the complex. The EI spectra of the dinitro and dichloro cobalt complexes had in common uninterpretable peaks at m/z 333, 315, 301, and 287, as well as peaks due to the decomposition of the ligand. It should be noted that the cobalt complexes of $[Co(teta)ClNO_3]ClO_4$ and $[Co(teta)(OH)$-$(NO_2)]ClO_4$ also gave similar spectra, but barely above the detection threshold. The Ag, Mn, and Cd compounds had peaks

TABLE 2. Major peaks in the FAB negative ion spectra of the $Me_6[14]aneN_4$ complexes

$Co(teta)(CoCl_4)$			$[Co(L)Cl_2]ClO_4$			$[Cu(L)](ClO_4)_2$			$CdCl_2(L)$		
Fragment	m/z	% (TIC)	Fragment	m/z	% (TIC)	Fragment	m/z	% (TIC)	Fragment	m/z	% (TIC)
Cl^-	35	(68.5)	Cl^-	35	(30.5)	Cl^-	35	(24.1)	$CdCl_2^-$	184	(18.8)
$CoCl_2^-$	129	(4.6)	ClO_4^-	99	(50.1)	ClO_4^-	99	(44.5)	$CdCl_3^-$	219	(45.2)
$CoCl_3^-$	164	(5.2)				$Cu(ClO_4)Cl^-$	199	(2.1)			
						$Cu(ClO_4)(ClO_3)^-$	247	(0.9)			
						$Cu(ClO_4)_2^-$	263	(4.9)			

due only to the decomposition of the ligand, teta. The mercury complex had peaks corresponding to Hg^+ and $HgCl_2^+$, as well as ligand decomposition peaks. The $CuL(ClO_4)_2$ spectrum had peaks due to the presence of $[CuL]^+$ and $[CuLClO_4]^+$, however, these peaks were of extremely low intensity. The $Ni(teta)Cl_2$ complex showed a peak due to $[Ni(teta)]^+$. The fragmentation pattern of the nickel complex is similar to the cobalt complexes, as it has the same peaks present in the 300–350 range as the cobalt complexes. The fragmentation products from the ligand are easily observed in all the EI spectra of the complexes as well as the ligand itself.

B. Negative ion FAB

Negative ion FAB was attempted for about one third of the complexes. The results were rather unproductive in terms of providing molecular ions or fragment ions containing the ligand. The complexes for which negative ion FAB results were obtained were $Co(teta)CoCl_4$, $[CoLCl_2]ClO_4$, $Cu(L)(ClO_4)_2$, and $CdCl_2(L)$. The major fragments are shown in Table 2. Results could not be obtained either for the $(HgCl_2)_2(tetb)$ or the $Ni(teta)Cl_2$ complexes.

In the $[CoLCl_2]ClO_4$ spectrum, the base peak was the perchlorate ion, followed in intensity by the peak due to the chloride ion with the remaining peaks of low intensity. The most intense peak in the $Co(L)CoCl_4$ spectrum corresponded to the chloride ion, with other peaks due to $[CoCl_2]^-$ and $[CoCl_3]^-$ ions.

The $[Cu(L)](ClO_4)_2$ spectrum was remarkably similar to the $[Co(L)Cl_2]ClO_4$ in that the anion with the greatest intensity was the perchlorate. The second most intense peak was due to the chloride ion, most likely resulting from the perchlorate species. A reasonably intense cluster of peaks was obtained around mass m/z 263, which corresponded in isotope pattern to $[Cu(ClO_4)_2]^-$. Peaks at m/z 247 and 199 corresponded to $[Cu(ClO_4)(ClO_3)]^-$ and $[CuCl(ClO_4)]^-$. Thus the perchlorate ion decomposes under FAB conditions to produce chloride ion, consistent with the reducing nature of the matrix under FAB conditions.

The loss of the counter ion ClO_4^- in the $[Co(L)Cl_2]ClO_4$ spectrum was expected in terms of what has been found by other workers (5, 18, 20). The chloride and the perchlorate anions had been used in a study by Cohen *et al.* (20). As with our present work, Cohen *et al.* found that no negative ions of any analytical significance were observed.

C. Positive ion FAB mass spectra

Figures 1 and 2 show the EI and FAB mass spectra of the ligand. The FAB spectrum is cleaner, and the total ion current (TIC) is an order of magnitude higher than in the EI spectrum. Furthermore, the highest-intensity peak in the FAB spectrum is the protonated molecular ion at m/z 285 (21% TIC), whereas the molecular ion is only 1.9% of the TIC in the EI spectrum.

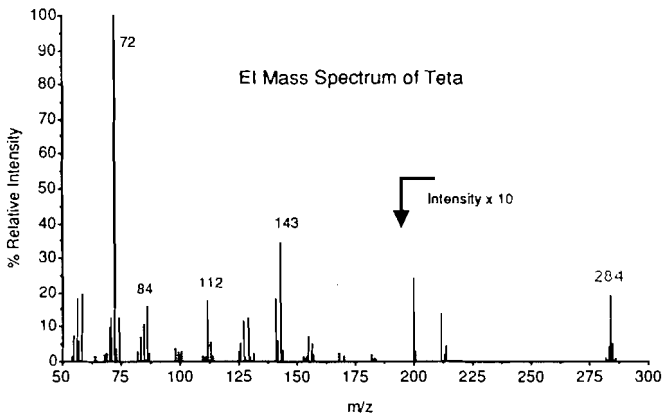

FIG. 1. EI mass spectrum of teta.

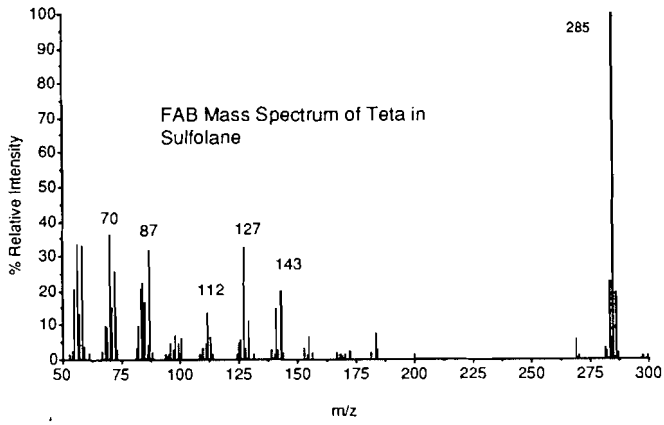

FIG. 2. FAB mass spectrum of teta in sulfolane.

(a) Studies on the cobalt complexes

Figure 3 illustrates the positive ion FAB spectra of a typical cobalt(III) compound. The matrix used was monothioglycerol, which gives a significantly more intense spectrum than that in glycerol. The principal positive ions result from the cation $[C^+]$, the subsequent loss of the anionic ligands (accompanied by reduction of the metal) followed by Co(III) loss, and the formation of ions originating from the teta ligand.

The $teta^+$ and the $[Co(teta)]^+$ species are common to all the positive ion spectra of the cobalt compounds. These observed ion clusters are complicated because of successive loss of hydrogen via ion/molecule or matrix/molecule reactions.

The spectrum of the uncomplexed ligand also had peaks due to addition and subtraction of hydrogens. The quasimolecular ion at m/z 285 was very intense, and the peaks due to hydrogen loss were of minor intensity. In the cobalt spectra the quasimolecular ion associated with the teta species is weak and the

TABLE 3. Comparison of the ion intensities in the FAB mass spectra of the $[Co(teta)Cl_2]Cl$ and $[Co(L)Cl_2]ClO_4$ complexes

	Ion intensities[a]			
	$[Co(teta)Cl_2]Cl$		$[Co(L)Cl_2]ClO_4$	
Ions observed	Glycerol	Thioglycerol	Glycerol[b]	Thioglycerol
C^+	22.3	50.8	2.2	27.1
$(C - Cl)^+$	30.0	24.1	45.2	44.5
$(C - 2Cl)^+$	45.2	23.1	45.2	28.4
$(C - 2Cl - Co)^+$	2.6	0.2	7.5	0.0

[a]Ion intensities are a percentage of the teta-containing species. Isotope cluster peak intensities of the same elemental composition are summed and included with the parent species. Peaks due to deprotonation of an elemental cluster are also summed and included with the parent peak.
[b]$C^+ = Co(teta)Cl_2^+$.

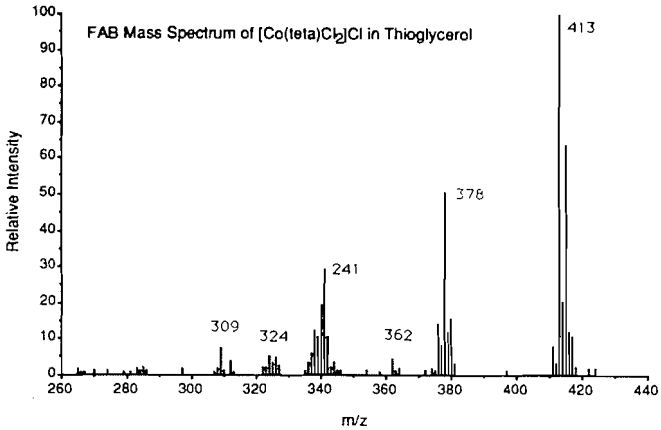

FIG. 3. FAB mass spectrum of the cobalt teta chloride complex.

surrounding peaks are more intense. The explanation for the observed dehydrogenation of these species will be discussed later.

For the cobalt(III) cationic complexes which have perchlorate as the counter ion, a peak is observed corresponding to $[Co(II)(L)ClO_4]^+$. This is interesting since the perchlorate ion is often used where an anion unlikely to coordinate is required, although if no other donor is present to compete with the perchlorate, it can behave as a donor (21). The intensity of this species is low in all the cobalt perchlorate complexes. Further there is a great difference in the intensities of the peaks that are obtained in the spectra of $[Co(L)Cl_2]ClO_4$ and $[Co(teta)Cl_2]Cl$ (Table 3), and the clusters of peaks due to dehydrogenation of the $[Co(L)]^+$ or $[Co(teta)]^+$ ions have very different patterns in the two spectra. One possible explanation for these differences is that the outer sphere ion affects the spectrum, although this is contrary to results obtained by other authors (20); it is also possible that $[Co(L)Cl_2]ClO_4$ is actually a mixture of the teta and tetb complexes, or is even just the tetb complex. This has implications for the structures of the complexes since teta prefers to coordinate in a planar fashion to give a *trans*-octahedral complex, whereas the most stable tetb coordination occurs when tetb folds and a *cis*-octahedral complex is produced (22).

Good quality spectra were obtained for the $[Co(teta)(CN)_2]ClO_4$ and the $[Co(teta)(SCN)_2]SCN$ complexes in both glycerol and thioglycerol.

Molecular cations or molecular ions could not be obtained for a number of the cobalt complexes. The $Co(teta)CoCl_4$ spectrum proved to be very difficult to analyze, and a molecular ion could not be obtained. The ions that were observed were similar to $[CoLCl_2]ClO_4$ or $[Co(teta)Cl_2]Cl$ complexes. Peaks were observed at masses which corresponded to $[Co(teta)Cl_2]^+$, $[Co(teta)Cl]^+$, $[Co(teta)]^+$, and $teta^+$. The blue $(Co(teta))(CoCl_4)$ turned pink upon dissolving in most of the matrices used, indicating destruction of the deep blue $CoCl_4^{2-}$ ion.

It was also difficult to obtain spectra of $[Co(teta)(NO_2)(OH)]ClO_4.H_2O$ and $[Co(teta)(NO_2)_2]ClO_4.(1/2)H_2O$ due to low solubility, and the ions that were observed were of low intensity. Even the doping method using NH_4Cl and $NaNO_2$ did not produce worthwhile results. The C^+ molecular ion was not obtained for the $[Co(teta)(NO_2)(OH)]ClO_4$ complex, nor was a peak observed for the $[Co(teta)(OH)]^+$ species even in a thioglycerol matrix. The cation molecular ion peak was obtained in both glycerol and thioglycerol matrices for the dinitro complex, as well as the peak created by the loss of one NO_2 group. The intensities of these species were low, particularly in glycerol.

$[Co(teta)ClN_3]ClO_4$ did not produce a C^+ parent ion. The azide was not observed in any of the peaks present in the spectrum. This is not an uncommon observation, as previous EI work done with inorganic azides had shown that these compounds show a distinct preference for N_3^- loss (23). The major peaks were $[Co(teta)]^+$ and the $[Co(teta)Cl]^+$. Other peaks included the $[Co(teta)Cl_2]^+$ and the $[Co(teta)ClO_4]^+$ ions. $[Co(teta)Cl_2]^+$ might be due to perchlorate decomposition.

(b) Studies on the complexes of metals other than cobalt

For the remaining metal complexes, the matrix did not have a great effect on the spectrum observed, as the spectra appeared the same in both glycerol and thioglycerol.

Spectra of the complexes $Ag(teta)(ONO_2)_2$ and $(HgCl_2)_2(tetb)$ proved to be extremely difficult to obtain. Both the silver and the mercury complex showed ligand-related peaks with a wide variety of matrices. The di-mercury complex gave spectra when the coprecipitation technique was employed. Methanol was the solvent used to dissolve the complex and glycerol was the matrix layered on the probe tip. The peaks at m/z 485, m/z 521, and m/z 593 were identified as the $[Hg(tetb)]^+$, $[Hg(tetb)Cl]^+$, and $[Hg(tetb)Cl_3]^+$ species, respectively.

$[Mn(teta)Cl_2]Cl.3H_2O$, $CdLCl_2$, and $Zn(teta)Cl_2.H_2O$ had the $(\mathbf{M}(teta)Cl)^+$ as the most intense peak in the spectrum (where **M** represents the metal, since M represents the molecular ion). The cluster due to the $[\mathbf{M}(teta)Cl]^+$ represented more

For personal use only.

than 35% of the TIC for these complexes in glycerol. This was also true of the Mn and Zn complexes in a thioglycerol matrix; however, the cluster was reduced to 15% for the Cd complex using thioglycerol. The only other peak of significant intensity in the spectra of the Cd and Mn complexes was the teta or L peak. The zinc complex had a peak corresponding to the $[Zn(teta) - H]^+$ species as well as the $[teta + H]^+$ species. The spectrum of $Zn(teta)Cl_2$ in glycerol also has a cluster at m/z 805 which corresponded in isotope pattern to the species $[(Zn(teta))_2Cl_3]^+$. It should be noted that these peaks are of minor intensity in comparison to the $[\mathbf{M}(teta)Cl]^+$ peak which overwhelms the spectra. Table 4 gives the intensities of the peaks obtained in the spectra of the Zn, Cd, and Mn complexes. The appearance of the $[\mathbf{M}(teta)Cl]^+$ ion as the highest-mass peak is normal for chlorinated compounds, which usually exhibit much stronger $[M - Cl]^+$ peaks than $[M]^+$ peaks (8, 9). This is to be contrasted with the Cu and Ni complexes which do not give strong $[\mathbf{M}(teta)Cl]^+$ peaks, possibly because the chloride is not coordinated, or only weakly coordinated in these complexes.

The spectra of $Cu(L)(ClO_4)_2$ and the $Cu(teta)Cl_2$ are similar. The species common to these compounds included $teta^+$, $[Cu(teta)]^+$, and $[Cu(teta)X]^+$, where X is the anion, either ClO_4^- or Cl^-. The spectrum of $Cu(teta)Cl_2$ in thioglycerol has a peak at m/z 800 which corresponds to $[(Cu(teta))_2Cl_3 - H]^+$, as well as the other common peaks.

The $Cu(teta)(ClO_4)_2$ spectrum includes a cluster of peaks due to the $[Cu(teta)Cl]^+$ species. This cluster is believed to be a result of ClO_4^- decomposition and is more predominant in thio-matrices. This is consistent with the results obtained in the negative ion FAB mass spectrum of this complex, as ions were observed which were formed as a result of the decomposition of perchlorate (Table 2). The $[\mathbf{M}(teta)Cl]^+$ ion has been observed before in cobalt complexes containing no coordinated chloride, but having perchlorate as the outersphere anion.

There is a strong correspondence between the copper complexes and the nickel complex in terms of the species obtained in the FAB spectra. The nickel complex has peaks due to $teta^+$, $[Ni(teta)]^+$, and $[Ni(teta)Cl]^+$. A peak also appears at m/z 423 whose identity is unknown; it may result from some type of matrix interaction. As in the mercury and silver complexes the protonated ligand peak at m/z 285 is the most intense peak in this spectrum.

TABLE 5. The data from the deconvolution calculation of the complex $[Co(teta)(SCN)_2]SCN$, the % composition of the dehydrogenated fragments

Fragment	% Composition[a]
Co(teta)	4.9
Co(teta)-H	26.6
Co(teta)-2H	12.0
Co(teta)-3H	22.7
Co(teta)-4H	5.4
Co(teta)-5H	15.2
Co(teta)-6H	11.1
Co(teta)-7H	1.4
Co(teta)-8H	0.4

[a]NOTE: Species with less than 1% composition are not statistically valid but are known to exist on a chemical basis.

(c) Dehydrogenation

It is common in the teta complexes to observe successive dehydrogenations of the main fragment ions. A good example is the $[Co(teta)]^+$ ion which loses up to eight hydrogens. Least squares analysis of the peak cluster associated with this ion gave the percentages of the various dehydrogenated species; Table 5 shows the results for $[Co(teta)(SCN)_2]SCN$. Five other cobalt complexes were also examined in this way. In each instance, the percent composition obtained for each fragment was comparable, confirming that the spectra are reproducible. The results for $[Co(teta)(SCN)_2]SCN$ complex in glycerol and thioglycerol are also very similar. Further, the teta complexes of Cu and Ni also display dehydrogenation of the $[\mathbf{M}(teta)]^+$ species with dehydrogenation occurring one step at a time. Hydrogen loss occurs independently of the matrix, indicating that it is not due to a specific matrix/ion reaction.

The extent of dehydrogenation is dependent on the presumed oxidation state of the metal in the fragment. For example, $[Cu(teta)Cl]^+$ and $[Ni(teta)Cl]^+$, which contain metal ions in the 2+ oxidation state, show a small amount of dehydrogenation, but this is minor compared to that observed for $[Cu(teta)]^+$ and $[Ni(teta)]^+$. Similarly, $[Co(teta)Cl_2]^+$ shows no dehydrogenation, but it is extensive in $[Co(teta)]^+$ and $[Co(teta)Cl]^+$.

These dehydrogenations are consistent with the fact that

TABLE 6. Comparison of C^+ and $(C - X)^+$ for the series of cobalt complexes $[Co(teta)X_2]Y$ in glycerol and thioglycerol

Complex	C^+	$(C-X)^+$	$C^+/(C-X)^+$
Matrix: glycerol			
$[Co(teta)Cl_2]ClO_4$	2.2	45.2	1/21
$[Co(teta)(SCN)_2]SCN$	1.2	17.6	1/15
$[Co(teta)(NO_2)_2]ClO_4$	1.9	5.6	1/3
$[Co(teta)(CN)_2]ClO_4$	3.1	6.3	1/2
Matrix: thioglycerol			
$[Co(teta)Cl_2]ClO_4$	27.1	44.5	0.6/1
$[Co(teta)(SCN)_2]SCN$	18.0	22.7	0.8/1
$[Co(teta)(NO_2)_2]ClO_4$	9.5	3.2	3/1
$[Co(teta)(CN)_2]ClO_4$	53.3	2.7	20/1

oxidative dehydrogenation is a useful synthetic technique for new macrocyclic complexes (24). The ease of oxidation is metal–ion dependent, and the proposed mechanisms involve higher oxidation states of the metal (24–26). The aliphatic rings become unsaturated as a result of the dehydrogenation (26, 27).

Our data suggest that an essential requirement for dehydrogenation in the FAB–MS is that the metal ion be in an easily oxidized oxidation state. This is consistent with the first step of the oxidative dehydrogenation mechanism, which is a $1\text{-}e^-$ oxidation of the metal (26). The overall mechanism for the production of dehydrogenated species probably involves the following processes: reduction of the parent complex during the ionization step, consistent with the fact that reduction is commonly observed in FAB spectra (5, 28); loss of one or more anionic ligands to produce a singly charged species; and rapid successive loss of hydrogens by oxidative dehydrogenation.

The solution chemistry of these complexes in the 1+ oxidation state has no parallel to the reaction observed in FAB–MS. Dehydrogenation of the 1+ oxidation state has not been observed in the electrochemistry of these complexes (29, 30). It has been noted by Busch that the overall oxidation–reduction behaviour of the macrocyclic metal complexes is a function of the degree and type of ligand unsaturation (30).

In the Cu(I) complexes it is necessary to have some degree of unsaturation in the ligand in order for Cu(I) macrocyclic complexes to exist in solution. It has been published that this behaviour is related to σ and π bonding features of the Cu(I) macrocycle (31). It is possible if unsaturation exists for Cu(I) to transfer electron density to low energy antibonding orbitals of the ligand through a π mechanism (32), and as a result stabilize the Cu(I) complex.

Similar arguments would apply to the Ni(I) and Co(I) complexes. As mentioned, the FAB spectra of the nickel and cobalt complexes show extensive dehydrogenation for fragments in which the metal is formally in the 1+ oxidation state, (and the 1+ and 2+ state for cobalt).

The case for oxidative dehydrogenation is strengthened by the results obtained in oxidizing matrices containing nitro groups such as NBA. $[Co(teta)(CN)_2]ClO_4$ and $[Cu(teta)](ClO_4)_2$ showed increased dehydrogenation of the $[\mathbf{M}(teta)]^+$ cations. Thus the oxidizing matrix may help to facilitate the oxidation of the metal, the initial step in the dehydrogenation mechanism (26).

(d) π-Acidity

We also hoped that FAB would mimic the solution chemistry of these complexes. The complexes $[Co(teta)X_2]Y$ (Y = SCN or ClO_4 and X = NO_2, SCN, CN, and Cl) were studied to see if a π-acidity trend might be discovered by FAB. Two different matrices were used for the study, glycerol and thioglycerol. In the glycerol matrix, the $[C - X]^+$ species had a more intense peak than the C^+ species. In thioglycerol, the opposite trend was observed. This type of effect is not uncommon and may be explained in terms of the reducing potential of the matrix. Pelzer investigated the oxidation–reduction chemistry of glycerol solutions under ion (SIMS) or atom (FAB) bombardment. A reduction process occurred in glycerol for both inorganics and organics (33). The reduction process occurring in glycerol solutions could be governed by a simple redox equilibrium between hydrogen atoms produced in glycerol by bombardment and the oxidized species present in solution. Meili and Seibl also investigated matrix effects in the FAB analysis of cobalamines (34). They concluded that if any metal-containing system appears to give as the highest mass ion in FAB a species corresponding to the reduction of the metal, then a slightly oxidizing matrix is advisable.

In glycerol, $[C - X]^+$ is more intense than C^+. The process involves reduction of the Co(III) center to Co(II) accompanied by the formation of an X radical; this process is favoured over X dissociation. Since glycerol enhances reduction (35), according to Meili a slightly oxidizing matrix should produce the opposite effect, i.e. increase the C^+ cation concentration. This is in fact what is observed in thioglycerol: the C^+ peak is more intense than the $[C - X]^+$ peak. Thus, the thioglycerol is sufficiently oxidizing to produce the desired molecular ion. It is clearly important that the matrix be kept constant in comparing trends among complexes. Table 6 shows the intensity of the C^+ and the $[C - X]^+$ species for the complexes of interest in both glycerol and thioglycerol. Previous workers have used a ratio of $C^+/[C - X]^+$ when making comparisons in spectra of similar complexes (36), where C^+ is the cation and $[C - X]^+$ represents the cation minus an axial ligand.

In both matrices, the trend observed is that of $CN^- > NO_2^- > SCN^- > Cl^-$ in terms of the relative intensity of the parent ion versus loss of the axial ligand. This is a familiar trend in terms of the ability of the ligand to split the *d* orbitals.

Conclusions

Molecular weights, or more correctly, cationic weights, were obtained in the majority of the spectra. There were exceptions such as the nitrite-containing cobalt complexes and the complexes containing two metal ions. The problem in producing quality spectra for these complexes was their insolubility, a prerequisite for obtaining a good spectrum being sufficient solubility in the matrix.

In those complexes which yielded good spectra, the ion with the greatest intensity at high m/z could be attributed to the complex. Peaks did occur at high m/z values which could not be attributed to the complex, but these were usually of low intensity. The cobalt complexes gave spectra containing the intact cation $[Co(teta)X_2]^+$, and the fragments from this cation. These complexes did not have ions corresponding to the (cation + anion) in positive ion FAB. Information concerning the anion could be easily obtained using negative FAB–MS. However, care had to be exercised in the interpretation of the spectra containing perchlorates, since perchlorates were both reduced and sometimes coordinated under FAB conditions.

The metal(II) complexes have the $[\mathbf{M}(teta)X]^+$ ion as the highest mass cluster in the spectrum. No other peaks could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

be identified at higher m/z values. Although this provides information concerning the metal and the anion present, it would not allow for the complete identification of the complex. The oxidation state of the metal would still be lacking for a total determination.

The information obtained through a comparison of peak heights allowed for the determination of the chemical reactivity of the complexes. A π-acidity trend was determined through a comparison of the C^+ and $[C - X]^+$ peaks which paralleled known solution behaviour.

Dielectric relaxation of acetyl- and benzoyl-acetones

R. K. KHANNA[1] AND ABHA BHATNAGAR
Microwave Laboratory, Physics Department, Government College, Ajmer-305 001, Rajasthan, India

Received May 26, 1988[2]

R. K. KHANNA and ABHA BHATNAGAR. Can. J. Chem. **67**, 804 (1989).

Dielectric absorption measurements are reported at radio and microwave frequencies (at six different wavelengths) for acetylacetone and benzoylacetone solutions in benzene, in a temperature range 25–60°C. Analysis of dielectric data in terms of Cole–Cole arc plots and multiple relaxation processes reveals that, at higher temperatures, overall molecular relaxation is the dominant relaxation mechanism in these β-diketones. The observed relaxation times, distribution parameters, and dipole moments are in reasonable agreement with the few data reported for some temperatures, in the literature. The activation energy parameters are also evaluated assuming dielectric relaxation to be a rate process. Molar polarization vs. weight fraction (concentration) plots show anomalous behaviour for acetylacetone.

Key words: dielectric properties, dielectric losses, relaxation times, dipole moment, dielectric absorption and dispersion, microwave measurements.

R. K. KHANNA et ABHA BHATNAGAR. Can. J. Chem. **67**, 804 (1989).

Opérant à des températures allant de 25 à 60°C et à six longueurs d'onde couvrant des fréquences radio et micro-ondes, on a mesuré les absorptions diélectriques des acétyl- et benzoyl-acétones en solution dans le benzène. Une analyse des données diélectriques en fonction d'une courbe de Cole–Cole et des processus de relaxations multiples révèle que, à des températures plus élevées, la relaxation moléculaire globale est le mécanisme de relaxation prédominant dans ces β-dicétones. Les valeurs observées pour le temps de relaxation, le paramètre de distribution et le moment dipolaire sont en bon accord avec les quelques données disponibles dans la littérature, pour quelques températures. En faisant l'hypothèse que la relaxation diélectrique est un processus impliquant une vitesse, on en a aussi évalué les paramètres d'activation. Dans le cas de l'acétyl acétone, les courbes de polarisation molaire en fonction de la fraction molaire exprimée en poids (concentration) présentent des anomalies.

Mots clés : propriétés diélectriques, pertes diélectriques, temps de relaxation, moment dipolaire, absorption et dispersion diélectrique, mesures micro-ondes.

[Traduit par la revue]

Introduction

Dielectric relaxation measurements can be profitably used, apart from NMR and IR absorption, to study inter- and intramolecular hydrogen bonding. These studies in solutions containing electron donor molecules can reveal valuable information, such as complex formation, extent of hydrogen bonding, and, in general, molecular motion (1–4). β-Diketones are known to form an intramolecular hydrogen bond and have been found to exist predominantly in enolic form in dilute solution. Relatively few studies have been carried out on the dielectric behaviour of β-diketones, especially acetylacetone and benzoylacetone. The excess value of the dielectric constant of binary mixtures of acetylacetone with carbon tetrachloride and tetrachloroethylene at 383.15 K has been studied by Jain *et al.* (5). Dielectric permittivity and loss measurements have been reported by Gupta *et al.* (6) for benzoylacetone and *p*-substituted benzoylacetone at a single frequency in the microwave region and at a single temperature of 40°C. Similar types of dielectric measurements have also been reported by Purohit *et al.* (7) on some β-diketones, but again at a single temperature of 35°C. In general there appear to be few, and limited, investigations on these molecules. For an accurate collection of relaxation data, dielectric measurements must be carried out at different frequencies (at least three) so as to have an even distribution of points in the Cole–Cole plot and a point at high frequency (8). Hence in the present paper dielectric measurements on β-diketone solutions in benzene are presented in the extended high frequency region (up to 67.7 GHz) and at temperatures ranging from 25 to 60°C.

Experimental

Measurements of dielectric constant (ε') and dielectric loss (ε'') were made on β-diketones in benzene solution at five different concentrations (weight fraction from 0.010 to 0.035) at 1000 MHz, 8.8 GHz, 30.5 GHz, and 67.7 GHz using four different experimental arrangements. Transmission line methods were used for the 1000-MHz, 8.8-GHz, and 30.5-GHz (plunger technique) measurements, and a free space interferometric technique was used for the 67.7-GHz measurements. The details of the apparatus and technique have been described previously (9–11). The estimated accuracy of dielectric constant and dielectric loss is 1% and 3% for the transmission line methods, and 0.5% and 1% for the free space method. In addition, the static dielectric constant was measured at 10 kHz using a dipolemeter bridge, and the value of ε_∞ from the refractive index (n) in the optical region (sodium light) was determined using an Abbé refractometer. The temperature of the solution under study was maintained within ±1°C by circulating water around the dielectric cell from a temperature controlled bath.

Analysis of data

For dilute solutions of polar solutes in a nonpolar solvent, the dielectric constant (ε') and dielectric loss (ε'') are proportional to solute concentration expressed as weight fractions (W_2) of the solute, i.e.,

$$\begin{aligned} \varepsilon' &= \varepsilon_1' + a' W_2 \\ \varepsilon'' &= a'' W_2 \\ \varepsilon_0 &= \varepsilon_{01} + a_0 W_2 \\ \varepsilon_\infty &= \varepsilon_{\infty 1} + a_\infty W_2 \end{aligned} \qquad [1]$$

The measured values of ε', ε'', ε_0, and ε_∞ for different solutions were fed into the computer as a function of ω and, from the straight line best-fit program, the coefficients a', a'', a_0, and

a_∞ were obtained. The values of these slope parameters for acetylacetone and benzoylacetone at different frequencies and temperatures are presented in Table 1. The most probable relaxation time (τ_0) and distribution parameter (α) were obtained at different temperatures by fitting the data to Cole–Cole plots represented by the equation:

$$[2] \quad \frac{(a' - ja'') - a_\infty}{a_0 - a_\infty} = \frac{1}{(1 + j\omega\tau_0)^{1-\alpha}}$$

Typical Cole–Cole plots for acetylacetone in benzene solution at different temperatures (25°C, 30°C, 40°C, 50°C, and 60°C) are shown in Fig. 1. The values of α and mean relaxation time (τ_0) are presented in Table 2. The equation for evaluating the dipole moment by Higasi's method (12) is

$$[3] \quad \mu = B(a_0 - a_\infty)^{1/2}$$

where

$$B = \frac{1}{2(\varepsilon_1 + 2)}\left[\frac{27M_2kT}{\pi N d_1}\right]^{1/2}$$

M_2 is the molecular weight of the solute, k is the Boltzman constant, d_1 is the density of the solvent, ε_1 is the dielectric constant of the solvent, and N is the Avogadro number. Calculated values of the dipole moment at different temperatures are given in Table 3. The dielectric data were also analysed in terms of overall and group rotation of the molecules. Double relaxation analysis was carried out using Bergmann's equations, which were further simplified by Bhattacharya *et al.* (13) for a straightforward calculation. Bergmann's equations are

$$[4] \quad \frac{a' - a_\infty}{a_0 - a_\infty} = A = \frac{g_1}{1 + \omega^2\tau_1^2} + \frac{g_2}{1 + \omega^2\tau_2^2}$$

$$[5] \quad \frac{a''}{a_0 - a_\infty} = B = \frac{g_1\omega\tau_1}{1 + \omega^2\tau_1^2} + \frac{g_2\omega\tau_2}{1 + \omega^2\tau_2^2}$$

and

$$g_1 + g_2 = 1$$

The simplified relation is

$$[6] \quad \frac{1 - A}{B\omega} = (\tau_1 + \tau_2) - \frac{A\omega}{B}\tau_1\tau_2$$

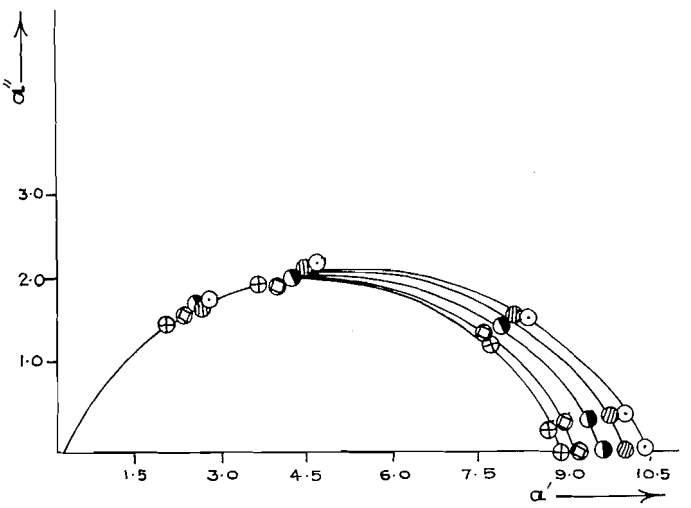

FIG. 1. Cole–Cole plots for acetylacetone in benzene solution at different temperatures: ⊙ 25°C; ◍ 30°C; ◑ 40°C; ⊘ 50°C; ⊕ 60°C.

This linear equation was solved and τ_1 and τ_2 were evaluated for different g_1 and g_2 values. The consolidated results are given in Table 4.

Results and discussion

For both the β-diketones, i.e., acetylacetone and benzoylacetone, fairly smooth depressed semicircular arc plots could be drawn between slope parameters a' and a''. Examination of the results in Table 2 shows a fairly large value of the distribution parameter (α) for both the β-diketones, while Crossley (14) found very small values for the distribution parameter for some aliphatic ketones in cyclohexane. The value of α is found to decrease with increasing temperature. This may be due to greater uniformity in the energy barrier at higher temperature, hindering molecular relaxation processes. The significant value of the distribution parameter for β-diketones indicates the presence of more than one mechanism contributing to the dielectric relaxation. The Cole–Cole plots also reveal a notable difference between ε_∞ and n^2, which further suggests the presence of an additional high frequency internal mode of vibration. A similar observation for many polar liquids has been reported and discussed by many workers (15). Data from

50	0.22	4.92	0.18	14.17
60	0.20	4.85	0.16	13.49

TABLE 3. Values of dipole moment for β-diketones in benzene obtained by different methods at different temperatures

Temperature (°C)	Acetylacetone		Benzoylacetone	
	Higasi μ (D)	Guggenheim μ (D)	Higasi μ (D)	Guggenheim μ (D)
25	3.04	2.92	3.40	3.34
30	3.03	2.90	3.35	3.23
40	3.02	2.76	3.24	3.21
50	3.01	2.75	3.22	3.20
60	3.00	2.72	3.20	3.18

Table 2 also show that the mean relaxation time (τ_0) for benzoylacetone is very large (about three times) compared to acetylacetone. This may be partly due to large molecular size and partly because of a hindrance to free rotation expected to arise from intramolecular hydrogen bonding. Such intramolecular hydrogen bonding and its effect on the dielectric relaxation mechanism of the molecules has been reported by Antony *et al.* (16) for the case of phenols. For both β-diketones, the value of the mean relaxation time (τ_0) decreases with a rise in temperature, which is normal behaviour for a polar solute in a nonpolar solvent.

Double relaxation analysis by Bhattacharya's method (13) led to values of relaxation time τ_1 of 14.1 and 26.8 ps at 30°C for acetylacetone and benzoylacetone, respectively. The value of τ_1 for acetylacetone is found to be very large compared to the only literature value (7) known to the authors (8 ps at 35°C). For the benzoylacetone no such values are available in the literature. τ_1 exhibits the temperature variation to be expected for overall molecular rotation. Again, the value of τ_2 for acetylacetone (3.8 ps at 30°C) is found to be large compared to the literature value of 0.7 ps at 35°C (7). The τ_2 value shows relatively little dependence on temperature (Table 4), as may be expected for an intramolecular process. The large value of τ_2 indicates intramolecular hydrogen bonding, hindering the free group rotation in these molecules. For both the β-diketones the value of weight factors g_1 compares well with g_2 at low temperatures ($g_1 = 0.44$ at 25°C) while at higher temperatures $g_1 \gg g_2$ ($g_1 = 0.69$ and 0.74 at 60°C for acetylacetone and benzoylacetone, respectively). The increasing value of g_1 with temperature indicates that overall molecular rotation is becoming more prominent at higher temperature. The tendency of τ_2 to become less important at higher temperature suggests that this need not result from the intramolecular segment rotation, which will be more prominent at higher temperature, but may result from an intramolecular cooperative relaxation mechanism, so that the reorientation of one segment triggers many other reorientations and consequently the rotating group does not relax independently.

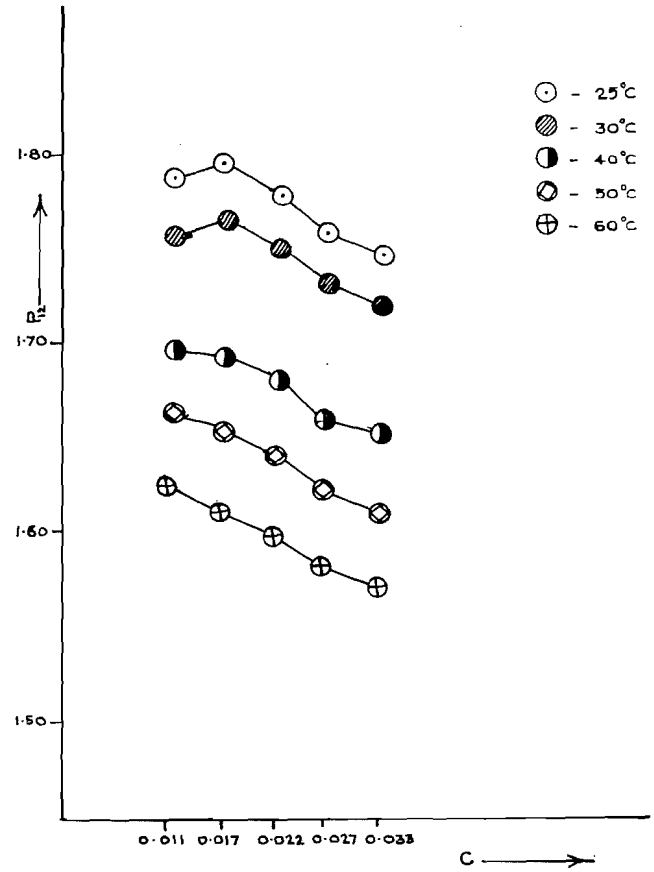

FIG. 2. Plot of log ($\tau_0 T$) vs. $1/T$ for acetylacetone and benzoylacetone.

Dipole moments of these molecules have been determined in dilute solution in benzene using Guggenheim's method at RF frequency and Higasi's method at microwave frequencies. The dipole moment values at different temperatures are listed in Table 3. Dipole moment values obtained by Guggenheim's method are found to be small compared to those obtained by Higasi's method, at all temperatures, which may be due to the difference in the square of the refractive index and dielectric constant of solution. Present values of the dipole moment for acetylacetone and benzoylacetone, i.e., 3.03 D and 3.35 D respectively at 30°C, by Higasi's method, compare well with

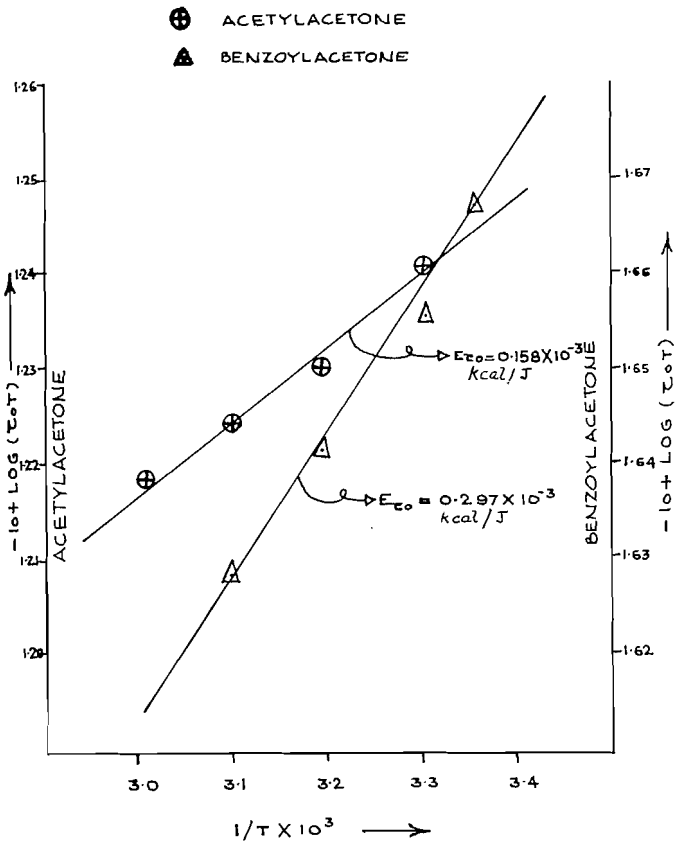

FIG. 3. Molar polarization (P_{12}) vs. concentration in wt. fraction (c) plot for acetylacetone in benzene at different temepratures.

the reported (7) values (3.00 D and 3.34 D respectively at 35°C). These values are found to be high compared to values reported by Gupta *et al.* (6) for benzoylacetone (2.68 D at 40°C). The dipole moments were also calculated theoretically by combining vectorially the group moments (17, 18), assuming the enolic form for both acetylacetone and benzoylacetone in benzene solution. The calculated value of the dipole moment for acetylacetone is 2.98 D and for benzoylacetone is 2.62 D, which are small compared to experimental results. Small deviations in these values from the experimental results may be due to neglect of hydrogen bonding and the mesomeric effect (6) in the theoretical calculations.

From the temperature variation of relaxation times (τ_0), the free energy of activation for the molecular relaxation mechanism is evaluated for both β-diketones using the Eyring equation (19), assuming it to be a rate process.

$$[10] \quad \ln(\tau_0 T) = \ln(h/k) + (E_{\tau_0}/R)T^{-1}$$

where h is Plank's constant, k the Boltzman constant, T the absolute temperature, R the gas constant, and E_{τ_0} the free energy of activation. When $\log(\tau_0 T)$ were plotted against $1/T$ for different diketones, a good linear relationship within experimental error was observed. Figure 2 gives such a linear plot along with the values of activation energy for both acetylacetone ($E_{\tau_0} = 0.158 \times 10^{-3}$ kcal/J) and benzoylacetone ($E_{\tau_0} = 0.297 \times 10^{-3}$ kcal/J) in benzene solution.

The molar polarization vs. weight fraction (concentration) curves for acetylacetone at different temperatures show anomalous behaviour (Fig. 3). In place of the decrease with increasing concentrations usually observed for an unassociated solute in nonpolar solvent, these curves show maxima and minima for acetylacetone while for benzoylacetone this anomalous behaviour is not observed. The anomalous behaviour for acetylacetone was also found to be less predominant at higher temperatures. These observations indicate complex formation and the presence of hydrogen bonding. IR absorption studies reported earlier (20) also show a similar type of behaviour for these compounds.

Solubility of nonpolar gases in 2-methylcyclohexanone between 273.15 and 303.15 K at 101.32 kPa partial pressure of gas

MARIA ASUNCION GALLARDO, MARIA DEL CARMEN LOPEZ, JOSE SANTIAGO URIETA,[1] AND CELSO GUTIERREZ LOSA
Química Física, Facultad de Ciencias, Universidad de Zaragoza, 50009-Zaragoza, Spain

Received July 22, 1988

MARIA ASUNCION GALLARDO, MARIA DEL CARMEN LOPEZ, JOSE SANTIAGO URIETA, and CELSO GUTIERREZ LOSA. Can. J. Chem. **67**, 809 (1989).

Solubility measurements of several nonpolar gases (He, Ne, Ar, Kr, Xe, H_2, D_2, N_2, CH_4, C_2H_4, C_2H_6, CF_4, SF_6, and CO_2) in 2-methylcyclohexanone at 273.15–303.15 K and a partial pressure of gas of 101.32 kPa are reported. Thermodynamic functions (Gibbs energy, enthalpy, and entropy) for the solution process at 298.15 K and 101.32 kPa partial pressure of gas are evaluated. Use is made of the Scaled Particle Theory applied to gas solubility for determining Lennard-Jones (6, 12) pair-potential parameters and temperature dependence of the effective hard-sphere diameter of the solvent. The values that this theory predicts for the solution thermodynamic functions are also calculated.

Key words: 2-methylcyclohexanone, gas solubility, thermodynamic functions of solution, Henry coefficient, scaled particle theory.

MARIA ASUNCION GALLARDO, MARIA DEL CARMEN LOPEZ, JOSE SANTIAGO URIETA et CELSO GUTIERREZ LOSA. Can. J. Chem. **67**, 809 (1989).

Opérant à des températures allant de 273,15 à 303,15 K et à des pressions partielles de gaz de 101,32 kPa, on a effectué des mesures de solubilité de plusieurs gaz non polaires (He, Ne, Ar, Kr, Xe, H_2, D_2, N_2, CH_4, C_2H_4, C_2H_6, CF_4, SF_6 et CO_2) dans la méthyl-2 cyclohexanone. On a évalué les fonctions thermodynamiques (énergie de Gibbs, enthalpie et entropie) des processus de solution à 298,15 K et à une pression partielle de gaz de 101,32 kPa. On a appliqué la théorie de la particule scalaire à la solubilité des gaz pour déterminer les paires de paramètres de potentiel de Lennard-Jones (6, 12) et la relation entre la température et le diamètre effectif de la sphère dure du solvant. On a aussi calculé les valeurs que cette théorie permet de prédire pour les fonctions thermodynamiques de solution.

Mots clés : méthyl-2 cyclohexanone, solubilité de gaz, fonctions thermodynamiques de solution, coéfficient de Henry, théorie de la particule scalaire.

[Traduit par la revue]

Introduction

In a previous paper in this same journal we presented the solubility measurements of some nonpolar gases in cyclohexanone (1). In the present work we are interested in studying the influence of the presence of methyl groups in the molecule on both solubility and thermodynamic functions, and on intermolecular interactions between the solvent molecules. We started to do so by choosing 2-methylcyclohexanone as solvent for our experiments. The Scaled Particle Theory (SPT) as applied by Pierotti to gas solubility (2) assumes a Lennard-Jones (6, 12) potential well for the interactions between molecules, and allowed us to determine the corresponding interaction parameters for 2-methylcyclohexanone. Thermodynamic functions for the solution process are also reported.

Experimental

Equipment and the procedure used for solubility measurements have been described in detail elsewhere (3, 4); the volume of gas dissolved in a known (by calibration of the solution vessel) mass of solvent at constant pressure and temperature is determined and, assuming ideality of the gas phase, the mole fraction of the solute in the liquid phase, x_2, is calculated. The apparatus is lodged in a thermostatic air bath, the temperature of which is controlled within ±0.2 K. The temperature of the solution vessel is controlled within ±0.05 K. The precision in the mole fraction x_2 is estimated to be ±0.7%, except for gases with low solubility (He and Ne) for which it is approximately ±2.0%. For CO_2, both dry gas and a slightly different procedure were used (see ref. 4), and mole fraction x_2 was calculated taking into account the nonideality of the gas by introducing the CO_2 gas virial coefficient (5).

By means of different empirical approaches (6, 7) the virial coefficients for the solvent and the mixture were estimated, and from them the mole fractions for C_2H_4, C_2H_6, and SF_6, taking into account the nonideality of the gas phase. Such estimates led to mole fractions 1%, 1.4%, and 2% higher, respectively, than when ideality is assumed. One must bear in mind that this is simply a reckoning of the error, because the lack of experimental data for 2-methylcyclohexanone and the gas mixtures studied meant that most of the values for the necessary properties and parameters (even the critical data for the solvent) were merely estimates.

Gases were from Sociedad Española del Oxígeno, except Ne and CF_4, which were from Baker, and their mole-percentage purities were as follows: He 99.995, Ne 99.9, Ar 99.9990, Kr 99.95, Xe 99.995, H_2 99.99, D_2 99.4, N_2 99.998, CH_4 99.95, C_2H_4 99.90, C_2H_6 99.0, CF_4 99, SF_6 99.5, and CO_2 99.998.

2-Methylcyclohexanone was a Merck product (better than 98%) and its purity was checked by refractive index measurements (experimental n_D (293.15 K) = 1.44766; lit. (8) n_D = 1.4483) and by glc (2-methylcyclohexanone: 98.1%). The main impurity, in a proportion of 0.6%, was found to be cyclohexanone, which has similar solubilities (differences of 25% on average). Solvent vapour pressures were determined in our laboratory in the working temperature range, and fit the equation

$$[1] \quad \ln (p/\text{kPa}) = -5552.37\,(T/\text{K})^{-1} + 18.046$$

The densities of 2-methylcyclohexanone were taken from the literature (9).

Results and discussion

Table 1 shows the experimental equilibrium mole fraction of gas, x_2, in 2-methylcyclohexanone at temperatures ranging from 273.15 to 303.15 K and at a partial pressure of gas of 101.32 kPa. The results for x_2 (101.32 kPa, T) were fitted by a least-squares routine to an equation of the form

$$[2] \quad -\ln x_2 = A_0 + A_1 T^{-1}$$

over the given temperature range. Table 1 also contains the

The changes in partial molar Gibbs free energy, $\Delta G^0_{m,2}$, partial molar enthalpy, $\Delta H^0_{m,2}$, partial molar entropy, $\Delta S^0_{m,2}$, for the solution process (10–12)

[4] Y(gas, 101.32 kPa, T)
$\rightarrow$ Y(P, T, $x_2 = 1$ but infinite dilute solution behaviour)

and Hildebrand entropy, ΔS_H (10–12) for

[5] Y(gas, 101.32 kPa, T) $\rightarrow$ Y($p_2 = 101.32$ kPa, T, x_2 but infinite dilute solution behaviour)

were evaluated from the fitting coefficients A_0 and A_1 in eq. [2], using our experimental results. Table 2 shows the values obtained for $\Delta G^0_{m,2}$, $\Delta H^0_{m,2}$, $\Delta S^0_{m,2}$, and ΔS_H at 298.15 K.

SPT applied by Pierotti (2, 13, 14) to the gas solution process can be used as a method for predicting Henry coefficients when Lennard-Jones (6, 12) pair-potential parameters for both solute and solvent are known, and can also be used in a reverse way for calculating Lennard-Jones (6, 12) pair-potential parameters of the solvent when experimental solubility data are provided and the corresponding parameters for the gases are known (1, 2, 4, 12–22).

Readers are referred to other papers for a detailed description of SPT for gases (2, 13–17, 23). According to this theory, solution can be thought of as a two-step process, the first consisting of the creation of a cavity in the solvent large enough to accommodate the solute molecule, and the second consisting of the introduction into the cavity of a solute molecule that interacts with the solvent. For the thermodynamic functions associated with the solution process the following expressions are obtained (2, 13–16, 23):

[6] $\Delta G^0_{m,2} = -RT \ln K_H = G_c + G_i + RT \ln (RT/v_1^0)$

[7] $\Delta H^0_{m,2} = [\partial(\Delta G^0_{m,2}/T)/\partial(1/T)]_p = H_c + H_i - RT + \alpha_p RT^2$

[8] $T\Delta S^0_{m,2} = H_c - RT + \alpha_p RT^2 - G_c - RT \ln (RT/v_1^0)$

TABLE 2. Experimental values for partial molar Gibbs energy, $\Delta G^0_{m,2}$, partial molar enthalpy, $\Delta H^0_{m,2}$, partial molar entropy, $\Delta S^0_{m,2}$, and partial molar Hildebrand entropy, ΔS_H, of dissolution of gases in 2-methylcyclohexanone at 298.15 K and 101.32 kPa partial pressure of gas

at 298.15 K was $\sigma_1 = 5.988 \times 10^{-10}$ m and for the energy parameter was $\varepsilon_1/k = 627$ K.

Comparison of these values with those obtained for cyclohexanone ($\sigma_1 = 5.651 \times 10^{-10}$ m, $\varepsilon_1/k = 584$ K) (1) shows an increase of both the distance and the energy parameters when a methyl group is introduced. The same behaviour was found for cyclohexane and methylcyclohexane (15, 25).

The linear coefficient of expansion of the effective hard-sphere diameter of the solvent (17), $l_1 = (1/a_1)(\partial a_1/\partial T)_P$, at 298.15 K was evaluated both by the method proposed by Pierotti (26) from solubility data of rare gases at several temperatures, $l_1 = -1.80 \times 10^{-4}$ K^{-1}, and by the method more recently suggested by Cosgrove and Walkley (23), from enthalpy solution data, $l_1 = -1.66 \times 10^{-4}$ K^{-1}. Agreement between the two values is good and similar to that obtained with other solvents (1, 23).

Once σ_1, ε_1/k, and l_1 are known, solubility and thermodynamic functions for the solution process predicted by the theory can be calculated with eqs. [6]–[8] together with the corresponding expressions for G_c, G_i, H_i, and H_c (2, 13–16, 23). Table 3 includes these theoretical values. $\Delta H^0_{m,2}$ and $\Delta S^0_{m,2}$ were calculated with $H_i = G_i$ as assumed by SPT and either using $l_1 = -1.66 \times 10^{-4}$ K^{-1} or using $l_1 = 0$. The same pattern of agreement between experimental and calculated values of $\Delta H^0_{m,2}$ and $\Delta S^0_{m,2}$ is obtained for 2-methylcyclohexanone and for cyclohexanone (1). For a further discussion on the enthalpy and entropy values predicted by SPT, the different methods of calculating them, and their agreement with experimental values, see the paper by Cosgrove and Walkley (23) and our previous paper on cyclohexanone (1).

Protium–deuterium exchange of benzo-substituted heterocycles in neutral D_2O at elevated temperatures

NICK HENRY WERSTIUK AND CHEN JU[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 14, 1988

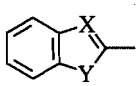
N. H. WERSTIUK and CHEN JU. Can. J. Chem. **67**, 812 (1989).

H–D exchange of 2-methylbenzofuran (**1**), 2-methylindole (**2**), 2-methylbenzimidazole (**3**), 2-methylbenzothiazole (**4**), and 2-methylbenzoxazole (**5**) has been studied in neutral D_2O at elevated temperatures. While **1**, **2**, **3**, and **4** can be specifically labelled and **4** can be perlabelled at 255°C, **5** undergoes facile hydrolysis in D_2O at 115°C to 2-acetamidophenol (**8**) with the incorporation of deuterium into the methyl group.

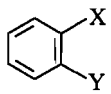
Key words: H–D exchange, heterocycles, D_2O, elevated temperatures.

N. H. WERSTIUK et CHEN JU. Can. J. Chem. **67**, 812 (1989).

Opérant à des températures élevées, dans du D_2O neutre, on a étudié les réactions d'échange H–D du méthyl-2 benzofuranne (**1**), du méthyl-2 indole (**2**), du méthyl-2 benzimidazole (**3**), du méthyl-2 benzothiazole (**4**) et du méthyl-2 benzoxazole (**5**). Les composés **1**, **2**, **3**, et **4** peuvent être marqués d'une façon spécifique et on peut perdeutérer le composé **4** en opérant à 255°C; par ailleurs, le composé **5** subit une hydrolyse facile, dans le D_2O à 115°C, qui conduit à la formation de l'acétamido-2 phénol (**8**) avec une incorporation de deutérium dans le groupement méthyle.



Mots clés : échange H–D, hétérocycles, D_2O, températures élevées.



[Traduit par la revue]

Introduction

As an extension of our research on the hydrogen-isotope exchange of aromatic compounds in neutral D_2O at elevated temperatures, we undertook a study of the H–D exchange of the benzo-substituted five-membered-ring heterocycles 2-methylbenzofuran (**1**), 2-methylindole (**2**), 2-methylbenzimidazole (**3**), 2-methylbenzothiazole (**4**), and 2-methylbenzoxazole (**5**). This work, along with our other studies (1–4), begins to detail the scope and limitations of this methodology, which may be generally useful for hydrogen isotope labelling of heterocycles. To obtain mechanistic information, 2-acetamidophenol (**8**), 2-aminophenol (**9**), phenol, and aniline were studied as well.

This publication documents the results of our study, which establishes that **1**, **2**, **3**, **4**, **5**, **9**, phenol, and aniline can be labelled with deuterium in good yield.

1 X = C, Y = O
2 X = C, Y = NH
3 X = N, Y = NH
4 X = N, Y = S
5 X = N, Y = O

6 X = NHAc, Y = NH_2
7 X = SH, Y = NHAc
8 X = OH, Y = NHAc
9 X = OH, Y = NH_2

Results and discussion

H–D exchange of 2-methylbenzofuran (1)

As shown in Table 1 (entry 1), C3-H and the hydrogens of the methyl group of **1** undergo H–D exchange at 185°C. Exchange at these sites can occur via two mechanisms: by electrophilic substitution (Scheme 1) or by ring opening to 1-(2-hydroxyphenyl)-2-propanone, which undergoes exchange, then cyclizes to **1**-d_n (Scheme 2). that the aromatic ring of **1** does not undergo H–D exchange at 185°C while phenol incorporates deuterium at temperatures as low as 130°C (entries 5 and 6, Table 2) establishes that H–D exchange of the furan ring occurs by electrophilic substitution and not by the mechanism shown in Scheme 2; if a statistical factor is included, exchange at C3 is approximately three times as fast as exchange of the methyl. It is noteworthy that **1** does not undergo ring opening at 185°C.

H–D exchange of 2-methylindole (2)

As shown in Table 1 (entry 2) **2** undergoes H–D exchange faster than **1**. The relative stabilities of the cations derived from **1** and **2** (the cation derived from **2** is expected to be more stable than the cation derived from **1**) may play a role in determining the exchange rates. That C3-H of **2** exchanges approximately five times faster than the methyl, relative to **1** in which the relative rates are 3:1, is in accord with the fact that indole exhibits a higher resonance energy than benzofuran (5); the selectivity for deprotonation from C3 of **2** is higher than from C3 of **1**.

H–D exchange of 2-methylbenzimidazole (3)

From entries 3–6 of Table 1 it is seen that the methyl group of **3** undergoes exchange at a lower temperature than the methyls of **1** and **2**. The mechanism shown in Scheme 3 accounts for the enhanced reactivity of **3**, which is in accord with the observation that the methyl groups of 2- and 4-methylpyridine undergo H–D exchange readily in D_2O at elevated temperatures (1). The higher basicity of **3** results in a higher concentration of the cationic species in this case than the imidazolinium ion in the case of **1** and **2**. Furthermore, the hydroxide ion concentration is higher as well. At higher temperatures, the aromatic ring undergoes H–D exchange by electrophilic substitution (entries 5 and 6, Table 1). This result illustrates the advantage of carrying out exchange reactions in neutral D_2O. Since the D_3O^+ and OD^- concentrations are equal, acid- and base-catalyzed processes occur without exclusion of one or the other. The expected orientation of deuteronation by the —N=C and —NH— groups accounts for the similar rates of exchange at C4, C5, C6, and C7 of the aromatic ring. That aniline undergoes exchange in D_2O at 250°C with *ortho* and *para* selectivity (entry 7, Table 2) provides support for this proposal.

Hydrolysis of **3** to 2-aminoacetanilide (**6**) via a tetrahedral

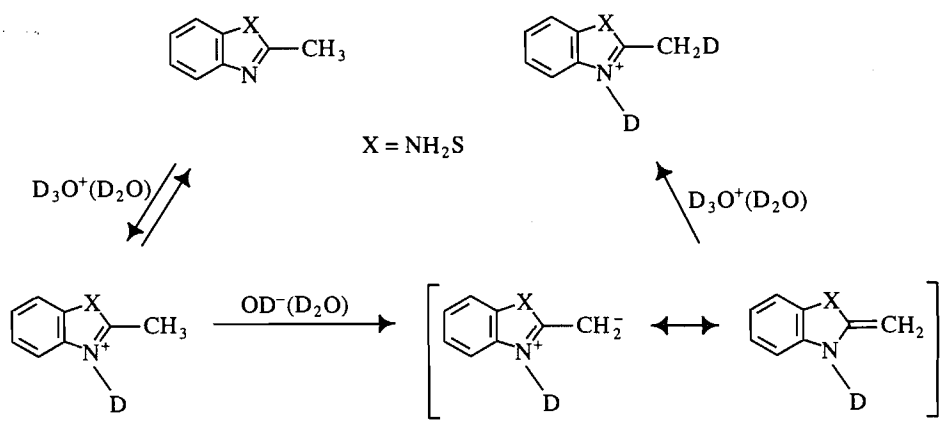
SCHEME 2

intermediate is a possibility as well. That **6** is not a product of the reaction is in keeping with the fact that Morgan and Turner have shown that **6** cyclizes to **3** in aqueous solution in the pH range 2–12.25 (6). On the basis of their study, the rate constant for cyclization of **6** at pH 7 at 50°C is 1.7×10^{-8} s^{-1}. We estimate that the rate constant for cyclization in D_2O at 145°C is in the range 10^{-3}–10^{-4} s^{-1}. That **6** is not a product establishes that cyclization is faster than hydrolysis of the amide under the conditions of the exchange reaction. In fact, imidazole **3** is very resistant to hydrolysis and yields only small amounts of *o*-phenylene diamine in strongly alkaline solutions of pH > 12.25 (6).

H–D exchange of 2-methylbenzothiazole (4)

As seen from the data in entries 7–10 (Table 1), **4** also undergoes H–D exchange of the methyl group and the aromatic ring. That the methyl group does not exchange as fast as the methyl of **3** is likely due to the fact that **4** is not as basic as **3** and consequently the equilibrium concentration of the benzothiazolinium ion is lower than the concentration of the benzoimidazolinium ion derived from **3**. It is remarkable that **4** can be perlabelled in excellent yield using only D_2O at 255°C.

As in the case of **3**, hydrolysis of **4** is a possibility as well. In this case 2-acetamidothiophenol (**7**) and 2-aminothiophenyl acetate can be formed. Studies by Collings and Morgan on the partial hydrolysis of *N*,*S*-diacyl-2-aminothiophenols in 1 N alcoholic KOH established that 2-acetamidothiophenols cyclize quantitatively to benzothiazoles. In fact, **7** cyclizes spontaneously to **4** on standing in the absence of hydroxide ion (7). Studies by Tee *et al.* (8) on the reversible ring opening of quaternary thiazolium ions established that the thiazolium ions are the stable species in the pH range 4.5–9. If **4** ring opens, the products recyclize to **4** faster than they hydrolyze. That exchange *ortho* and *para* to the sulfur is slightly faster than exchange at other sites is perhaps an indication that ring opening of **4** to **7** does occur. This thiophenol then undergoes H–D exchange via elctrophilic substitution, perhaps via deuteronation of the thiophenolate, and then cyclizes.



H–D exchange of 2-methylbenzoxazole (5)

In D_2O at 115°C, **5** hydrolyzes to 2-acetamidophenol (**8**), which incorporates 0.49 atoms of deuterium (entry 11, Table 1). Analysis of **8** by ^{1}Hmr, ^{2}Hmr, and mass spectroscopy established that within the limits of detection the deuterium is located in the methyl group. When **8** is heated in D_2O at 115° (entry 1, Table 2), it does not undergo deuterium exchange. At higher temperatures **8** hydrolyzes to 2-aminophenol (9) and acetic acid. To ensure that exchange of the methyl of **8** is not catalyzed by **9**, **8** was heated in D_2O in the presence of **9**. No detectable deuterium was incorporated into the methyl group, but **9** underwent facile exchange. Additional experiments (entries 2–4, Table 2) established that **9** can be selectively labelled *ortho* and *para* to the hydroxyl group or perlabelled. This result suggests that **9** undergoes H–D exchange by deuteronation of the phenolate anion. These experiments also establish that **5** hydrolyzes faster than the methyl group undergoes H–D exchange and that **8** does not cyclize to **5**.

In principle, the hemi-orthoamide derived from **5** can ring open in two ways to yield either **8** or 2-aminophenyl acetate. In fact, imidates generally give a mixture of two products with aminoesters being the kinetic products (9). That **8** is the only detectable product at 115°C is in keeping with the results of studies carried out by Morgan and co-workers (10) in the pH range 2–5. The ease with which **5** hydrolyzes contrasts with the stability of **3** and **4**. These researchers propose that the hemi-orthoamide decomposes via the zwitterionic form in the pH range 2–5. This proposal is consistent with the fact that **8** is the only product of the reaction; the stability of the phenolate anion leaving group overrides any stereoelectronic effects (9).

Conclusions

This study establishes that benzo-substituted heterocycles can be specifically labelled or perlabelled in good yield by heating the compounds in neutral D_2O at elevated temperatures. It

should be possible to prepare corresponding tritiated compounds simply by using tritiated water of the appropriate specific activity.

Experimental

The reagents (95–98% purity) were obtained from Aldrich Chemical Co. and were used without further purification.

Proton and deuterium magnetic resonance spectra were recorded on Bruker AM 500 (^{1}H 500-MHz, ^{2}H 76.8-MHz), WM 250 (^{1}H 250-MHz, ^{2}H 38.4-MHz), and Varian EM 390 spectrometers. Carbon tetrachloride was used as nmr solvent for **1** and **2** and acetone was used for **3**, **4**, **5**, **8**, and **9**. Deuterium assays were performed on a VG Micromass 7070 mass spectrometer at low ionization voltage (12–15 eV) and expressed as atoms of deuterium per molecule in excess of natural abundance deuterium. All samples that contained OH, SH, or NH groups were back-exchanged in H_2O before analysis.

In a typical exchange reaction, substrate (0.20 g) was added to D_2O (5 mL) in a 5/8-in. medium-walled glass tube. The mixture was degassed via three freeze–pump–thaw cycles, placed in a 600-mL Parr pressure vessel that contained water to equalize pressure, and heated at the desired temperature for an appropriate period. The deuteriated compounds were isolated by extraction with ether or by filtration.

A very short synthesis of 3-methoxyestra-1,3,5,8,14-pentaen-17-one

D. JEAN BURNELL[1] AND YONG-JIN WU

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

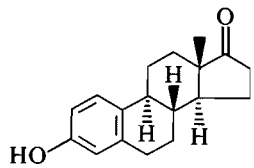
Received September 7, 1988

D. JEAN BURNELL and YONG-JIN WU. Can. J. Chem. **67**, 816 (1989).

3-Methoxyestra-1,3,5,8,14-pentaen-17-one (**4**) was prepared from 6-methoxy-1-tetralone (**8**) by an efficient two-pot procedure in which the D ring was generated by the Lewis acid catalysed reaction of 1,2-bis(trimethylsiloxy)cyclobutene (**5**) with an appropriate ketal (**10**).

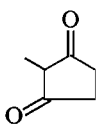
Key words: steroid, estrone, annellation.

D. JEAN BURNELL et YONG-JIN WU. Can. J. Chem. **67**, 816 (1989).



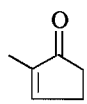
On a préparé la méthoxy-3 estrapentaène-1,3,5,8,14 one-17 (**4**) à partir de la méthoxy-6 tétralone-1 (**8**) en faisant appel à une méthode efficace en deux étapes dans lesquelles le cycle D est généré par la réaction, catalysée par un acide de Lewis, du bis(triméthylsiloxy)-1,2 cyclobutène (**5**) avec un cétal approprié (**10**).

Mots clés : stéroïde, estrone, annelation.



[Traduit par la revue]

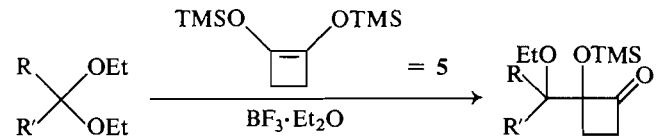
Introduction



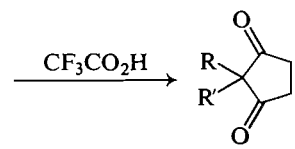
Considerable effort has gone into the total synthesis of estrone (**1**) and the other physiologically active aromatic steroids (1). In many, if not most, syntheses the D ring of the steroid has been derived from either 2-methyl-1,3-cyclopentanedione (**2**) or 2-methyl-2-cyclopenten-1-one (**3**). This paper

1

2



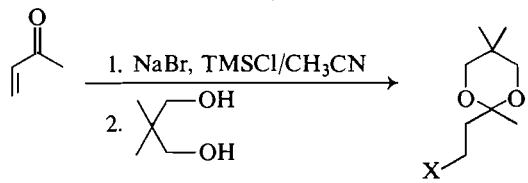
3



describes a very expedient, alternative route to the steroidal diene **4**, which is the key intermediate in the Torgov estrone synthesis (2) as well as in a number of more recent approaches (3). In our synthesis neither **2** nor **3** is used as the D ring precursor: this route serves to illustrate further the considerable synthetic utility of 1,2-bis(trimethylsiloxy)cyclobutene (**5**)[2] for the formation of a five-membered ring.

Results and discussion

Kuwajima and co-workers (5) demonstrated that under Lewis acid catalysis a dimethyl or diethyl ketal reacts with 1,2-bis(trimethylsiloxy)cyclobutene (**5**) to provide the cyclobutanone **6**, which can be rearranged in the presence of trifluoroacetic acid (TFA) to yield ultimately a 2,2-disubstituted 1,3-cyclopentanedione moiety **7**. In the course of our recent synthesis of isokhusimone (6)[3] we showed that this annellation procedure is viable with cyclic ketals, and, more importantly, that prolonged



6

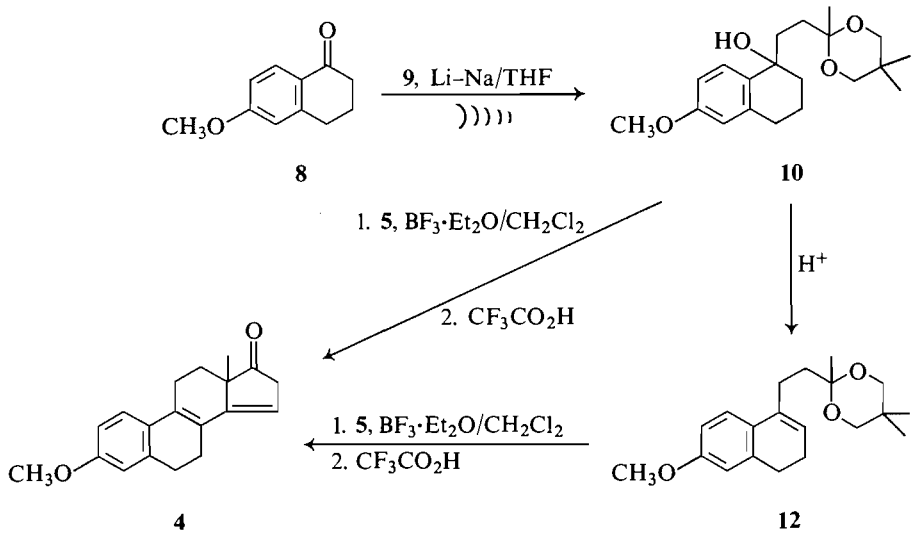
7

treatment of a ketal with **5** and a large excess of boron trifluoride etherate provides a superior yield of the cyclopentanedione **7** *directly*. Thus, our strategy for the synthesis of **4** was simply to add a ketal-containing synthon to 6-methoxy-1-tetralone (**8**), then to build a 1,3-cyclopentanedione D ring moiety, which might spontaneously cyclize to **4** in the acidic medium.

The ketal **9** was prepared from 3-buten-2-one by a procedure derived from that of Larson and co-workers (8).[4] Whereas we expected only the bromo-ketal **9***a*, we found that it was always accompanied by a lesser amount of the chloro-ketal **9***b*.[5]

9*a* X = Br
9*b* X = Cl

[1]Author to whom correspondence may be addressed.



[2]Acyloin coupling of diethyl succinate and trapping with chlorotrimethylsilane affords **5** in multigram quantities (4).

[3]Other syntheses that have employed this reaction are given in ref. 7.

[4]These workers prepared iodo-ketals and iodo-acetals derived from ethanediol and 1,3-propanediol. We prefer the bromo-ketal derived from 2,2-dimethyl-1,3-propanediol because it is more easily separated from the corresponding bromo-ketone by vacuum distillation, and it can be stored in a freezer for several months.

[5]Larson and co-workers (8*b*) reported that in a reaction to prepare a bromo-acetal the product was contaminated with 40% of an unidentified impurity. We suggest this was the corresponding chloro-acetal.

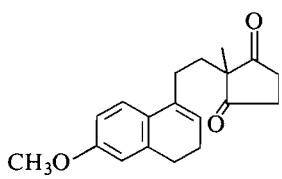
Attempts to separate these by vacuum distillation proved to be unnecessary. Reaction of the mixture of halo-ketals **9** with magnesium turnings or lithium metal was extremely sluggish even with ultrasonic irradiation. However, addition of THF solutions of **8** and an excess of **9** to lithium containing a small amount of sodium, followed by ultrasonic irradiation (9) for 4 h, provided the desired Barbier reaction product **10** in a yield of 76% accompanied by 19% recovered **8** and a small amount of the diketal **11**. (Increasing the initial amount of **9** did not increase the yield of **10**.) Dehydration of **10** occurred readily. From a sample of **10** that had been stored at room temperature for a week we recovered 64% of **10**, 30% of the unsaturated compound **12**, and 2% of the unsaturated ketone **13** by flash chromatography. The 2-D nmr spectra, i.e., COSY and ^1H–^{13}C correlation, of **12** left no doubt as to the position of the double bond in this molecule. A benzene solution of **10** was heated with a small amount of pyridinium *para*-toluenesulfonate (PPTS) and 2,2-dimethyl-1,3-propanediol to provide **12** in a yield of 96%.



Compound **12** was treated with four equivalents of **5** and 15 equivalents of boron trifluoride etherate at −78°C (6). The crude product was subjected to gc–ms analysis, which revealed that D ring annellation had occurred giving the diketone **14**,

11

13

14

but it was clear that cyclization of the C ring had not taken place. Longer reaction times and more boron trifluoride etherate resulted in some destruction of **14** but still no C ring cyclization. However, addition of TFA to a solution of crude **14** at room temperature provided **4** (91%) as a pale brown powder. Furthermore, it is not surprising that direct treatment of the alcohol-ketal **10** with **5** and boron trifluoride etherate followed by TFA also gave **4** in an excellent yield. We have witnessed considerable destruction of **4** during its rigorous purification by flash chromatography.[6] Therefore this reaction was repeated with anthracene as an internal standard, which allowed us to calculate (from gc–ms data) an actual chemical yield of 83% for the one-pot conversion of **10** to **4**. Thus, we have demonstrated that the important estrone precursor 3-methoxyestra-1,3,5,8,14-pentaen-17-one (**4**) can be produced in good yield from 6-methoxy-1-tetralone (**8**) by an efficient two-pot procedure using **5** to generate the D ring.

Experimental

Melting points (mp) were determined on a Fisher–Johns apparatus and are uncorrected. Infrared (ir) spectra were recorded on a Perkin Elmer 283 spectrophotometer. Nuclear magnetic resonance (nmr) spectra were obtained in $CDCl_3$ solution on a General Electric GE 300-NB (300-MHz) instrument. Signal multiplicities in the ^{13}C nmr data were determined from APT spectra; ^1H and ^{13}C signal assignments were aided by COSY and heteronuclear-correlation 2-D spectra. A Hewlett–Packard system (5890 gas chromatograph coupled to a 5970 mass selective detector) equipped with a Hewlett–Packard 12.5-m fused silica capillary column with cross-linked dimethylsilicone as the liquid phase was used for gc–ms analyses. Except where noted, both the low and the high resolution mass spectral data were obtained on a V.G. Micromass 7070HS instrument.

*2-(2-Bromoethyl)-2,5,5-trimethyl-1,3-dioxane (**9**a)*

3-Buten-2-one (8.1 mL, 0.10 mol) was added to a stirred suspension of sodium bromide (15.4 g, 0.15 mol) in anhydrous acetonitrile (250 mL) under an atmosphere of dry nitrogen, then chlorotrimethylsilane (19.0 mL, 0.15 mol) was introduced by syringe over a period of 5 min. Stirring was continued at room temperature overnight. 2,2-Dimethyl-1,3-propanediol (15.6 g, 0.15 mol) was added, and the mixture was stirred for a further 4 h. The mixture was poured into a flask containing petroleum ether (300 mL) and 8% aqueous Na_2CO_3 (100 mL), then stirred thoroughly and transferred to a separatory funnel: *three* layers were clearly evident. The lowest (aqueous) layer was removed, and 5% aqueous sodium thiosulfate (100 mL) was added: only two layers were visible. The organic layer was washed

[6]It is better to hydrogenate **4** using Torgov's procedure (2) before flash chromatography. In this way we obtained a 69% overall yield of pure 3-methoxyestra-1,3,5,8-tetraen-17-one from **10**.

with water (2 × 100 mL), saturated NaCl (150 mL), then dried over anhydrous $MgSO_4$. The solution was concentrated by rotary evaporation, and the residue was distilled under vacuum to provide 12.2 g (58%) of a mixture of **9***a* and **9***b* (the corresponding chloro compound) in a ratio of 77:23, respectively (by gc–ms), as a colorless liquid, bp 63–64°C/0.1 Torr (1 Torr = 133.3 Pa). For **9***a*, ^{1}H nmr δ: 0.855 (3H, s) and 1.032 (3H, s) C-5 methyls, 1.385 (3H, s, C-2 methyl), 2.279 (2H, m, -C*H*$_2$CH$_2$Br), 3.406 (2H, d, *J* = 11.4 Hz, -C*H*$_2$O-), 3.525 (2H, m, -C*H*$_2$Br), 3.581 (2H, d, *J* = 11.4 Hz, -C*H*$_2$O-); ^{13}C nmr δ: 20.0 (C-2 methyl), 22.4 and 22.8 (C-5 methyls), 27.0 (-*C*H$_2$Br), 29.8 (C-5), 42.9 (-*C*H$_2$CH$_2$Br), 70.4 (2C, C-4 and C-6), 98.4 (C-2); ms (from gc–ms) *m/z* (%): 223 (21, M$^+$), 221 (20, M$^+$), 153 (11), 151 (10), 137 (11), 135 (10), 129 (71), 107 (10), 69 (44), 56 (43), 55 (15), 43 (100), and 41 (51). For **9***b*, ^{1}H nmr as for **9***a* except δ: 1.396 (3H, s, C-2 methyl), 2.190 (2H, m, -C*H*$_2$CH$_2$Cl), 3.685 (2H, m, -C*H*$_2$Cl); ^{13}C nmr as for **9***a* except δ: 39.5 (-*C*H$_2$Cl), 42.3 (-*C*H$_2$CH$_2$Cl), 97.8 (C-2); ms (from gc–ms) *m/z* (%): 179 (10, M$^+$), 177 (35, M$^+$), 129 (54), 109 (9), 107 (23), 93 (7), 91 (21), 69 (50), 56 (54), 55 (23), 43 (100), and 41 (41).

Alcohol-ketal ***10***

A flask containing lithium metal (60.5 mg, 8.72 mmol) and sodium metal (4 mg) under vacuum was heated with a heat gun to alloy the metals. The flask was cooled and an atmosphere of dry nitrogen was introduced. Dry THF (50 mL, distilled from potassium) was added, followed by **8** (227.5 mg, 1.29 mmol) in dry THF (20 mL) and **9** (mixture of **9***a* and **9***b*, 1.80 mL, 9.77 mmol). The flask was placed in an ultrasonic cleaning bath (Branson) and irradiated at room temperature for 4 h. After concentration of the mixture by rotary evaporation, ether (30 mL) and saturated aqueous NH_4Cl (30 mL) were added. The aqueous layer was reextracted with ether (4 × 20 mL). The combined organic layers were washed with saturated NaCl (30 mL), dried over anhydrous $MgSO_4$, and the solvent was removed by rotary evaporation. Flash chromatography of the residue (3% acetone in petroleum ether) provided 326.1 mg (76%) of **10**, 42.0 mg (19%) of recovered **8**, and 30.1 mg of the diketal **11**. For **10**,[7] ir (film) ν_{max}: 3460 (br) and 1610 cm^{-1}; ^{1}H nmr δ: 0.887 (3H, s) and 1.026 (3H, s) dioxane's C-5 methyls, 1.371 (3H, s, C-18*H*$_3$), 1.6–2.05 (8H, br m), 2.20 (1H, s, -O*H*, disappears with D$_2$O shake), 2.75 (2H, m, C-6*H*$_2$), 3.433 (2H, d, *J* = 11.5 Hz, -C*H*$_2$O-), 3.559 (2H, d, *J* = 11.5 Hz, -C*H*$_2$O-), 3.780 (3H, s, -OC*H*$_3$), 6.590 (1H, d, *J* = 2.5 Hz, C-4*H*), 6.775 (1H, dd, *J* = 2.5, 8.7 Hz, C-2*H*), 7.482 (1H, d, *J* = 8.7 Hz, C-1*H*); ^{13}C nmr δ: 19.7 (C-7), 20.4 (C-18), 22.4 and 22.7 (dioxane's C-5 methyls), 29.7 (dioxane's C-5), 30.1 (C-6), 32.4, 35.6, and 35.9 (C-8, C-11, and C-12), 55.0 (-O*C*H$_3$), 70.1 (2C, -*C*H$_2$O-), 71.4 (C-9), 98.8 (C-13), 112.4 (C-2), 112.8 (C-4), 127.6 (C-1), 134.8 and 138.0 (C-5 and C-10), 158.1 (C-3); ms *m/z* (%): (no M$^+$), 316 (5, M$^+$ − H$_2$O), 175 (13), 174 (68), 172 (17), 129 (14), 85 (65), and 83 (100). Potential functions for the inner branches of diatomic potential curves

JOEL TELLINGHUISEN
Department of Chemistry, Vanderbilt University, Nashville, TN 37235, U.S.A.

Received August 31, 1988

JOEL TELLINGHUISEN. Can. J. Chem. **67**, 820 (1989).

The performance of simple three-parameter potential functions in predicting the inner branches of known diatomic potentials is tested for 35 diatomic molecular states. The Varshni III potential outperforms the Morse and Rydberg functions when the spectroscopic R_e, ω_e, and $\mathcal{D}_e$ values are used to define the potential parameters, but all three functions perform comparably well when R_e, ω_e, and $\omega_e x_e$ are used. In the latter case the 35 potentials show an average absolute value of about 0.6% for the *maximum* relative error.

Key words: diatomic molecules, potential energy curves.

JOEL TELLINGHUISEN. Can. J. Chem. **67**, 820 (1989).

On a testé la performance de fonctions de potentiel simples à trois paramètres à prédire les potentiels diatomiques connus des branches internes de 35 états moléculaires diatomiques. Lorsqu'on utilise les valeurs spectroscopiques R_e, ω_e et $\mathcal{D}_e$ pour définir les paramètres de potentiel, le potentiel de Varshni III donne de meilleures performances que les fonctions de Morse et de Rydberg; par ailleurs, si on utilise les valeurs R_e, ω_e et $\omega_e x_e$, les trois fonctions donnent des bonnes performances. Dans ce dernier cas, pour les 35 potentiels, la valeur absolue moyenne de l'erreur relative *maximale* est d'environ 0,6%.

Mots clés : molécules diatomiques, courbes d'énergie potentielle.

Potential energy curves are all-important in diatomic spectroscopy, and there are well-established methods for determining them from experimental data. The Rydberg–Kelin–Rees (RKR) method yields the classical turning points as functions of the energy via a semiclassical direct inversion process requiring as input the vibrational energy G_v and rotational constant B_v, both being functions of the vibrational quantum number v (1). The validity of the RKR potential is then of course limited to the range of v spanned by the data, although judicious extrapolations can be used somewhat beyond this range with fair reliability. For most applications, RKR potentials are fully trustworthy; however, in precision work, and especially for molecules of small reduced mass, it may be necessary to correct the RKR potential for the semiclassical errors inherent in it. For this task, too, there are established methods (2, 3).

Sometimes one can obtain a fairly complete analysis of the vibrational structure in an electronic spectrum but little or no information about the rotational constants. This is particularly true for emission spectra of heavy diatomics, where the rotational structure may be very congested. Since the vibrational information is sufficient to determine the RKR *width* of the potential, in such cases one can still obtain a fair approximation of the potential in question – provided one can somehow "guess" one branch of the potential.

Perhaps the simplest approach to this problem is to use the workhorse of diatomic potentials, the Morse function, to fix the needed "half potential." Several years ago Henderson and I (4) examined a number of fairly well-known potentials with the goal of answering the question: How well does the Morse function approximate the inner or repulsive branch of the potential? Because the inner branches of potentials rapidly become very steep with increasing energy, it is more appropriate to assess errors in R as a function of energy than vice versa. We found that the Morse curve does surprisingly well, often producing errors of less than 0.01 Å all the way to the dissociation limit.

Recently Varshni (5) has extended these comparisons to two other easily used closed-form potentials – the Rydberg potential (6) and a potential devised earlier by Varshni (7). His conclusion was that the Varshni potential (Varshni III) is the best performer of the three. While the additional comparisons constitute a useful exercise, Varshni's computational procedure has unfairly tilted the scales against the other two functions in the comparisons of his Table 2.

All three of the functions examined by Varshni are three-parameter functions. For such it is customary to use the experimental internuclear distance R_e, vibrational frequency ω_e, and dissociation energy $\mathcal{D}_e$ to fix the three parameters. In fact, if one is interested in the whole potential, this is the only choice that makes sense, since these three quantities are needed to properly locate the potential on the R-axis and give it the correct curvature near the minimum and the correct asymptotic energy. However, if one is interested in only the *inner* branch of the potential, one can use in place of $\mathcal{D}_e$ some other experimental quantity; the obvious choices are the vibrational anharmonicity $\omega_e x_e$ and the vibration–rotation coupling constant α_e. In our comparisons, Henderson and I found that Morse repulsive branches defined by R_e, ω_e, and $\omega_e x_e$ gave appreciably better agreement with known RKR potentials than curves defined by R_e, ω_e, and $\mathcal{D}_e$. Varshni has considered only the latter definition in his comparisons.

I have repeated Varshni's comparisons using both $\mathcal{D}_e$ and $\omega_e x_e$ alternately to define the three parameters needed for each potential function. For the Morse function and the Rydberg function, the use of $\omega_e x_e$ is straightforward, since the equations relating $\omega_e x_e$ to $\mathcal{D}_e$ are simple (7, 8). (Of course, one cannot use $\omega_e x_e$ in those very rare cases where it is negative, as in the alkali hydrides.) For the Varshni III function, the relations among ω_e, $\omega_e x_e$, $\mathcal{D}_e$, and R_e are more complex; and it is necessary to solve numerically for the quantity Δ in the expression relating $\omega_e x_e$ to the equilibrium rotational constant B_e and Δ (7, 8). This, however, is also easily accomplished using any good root finder, e.g. Newton's method. (There are exceptions such as $H_2(X)$, where there is no physical root to this equation.)

In my comparisons I have used the 25 molecular states considered in ref. 4, updated in accord with more recent data, plus 10 more states included in a recent study of reduced potentials (9). These 35 potentials have considerable overlap with the set used by Varshni; however, I have not included the hydrides and the interhalogens (except ICl) in my set. Many of the members

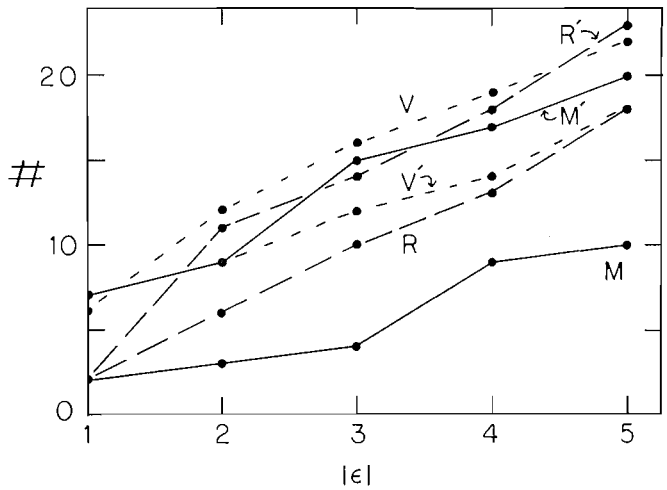

FIG. 1. Comparison of six potential forms in reproducing inner branches of known diatomic potentials. The quantity ϵ on the abscissa is defined as 1000 times the maximum relative error, $[R(\text{calc}) - R(\text{known})]/R_e$. (The maximum relative error usually occurs at the highest energy.) The quantity on the ordinate is the number of cases where the error is less than the value on the abscissa. M, R, and V refer to the Morse, Rydberg, and Varshni III functions, respectively. Primes indicate potentials determined by R_e, ω_e, and $\omega_e x_e$, while unprimed labels refer to use of $\mathcal{D}_e$ in place of $\omega_e x_e$.

of these two groups are experimentally known to less than 50% of their well depths; and in such cases it is inappropriate to extend the RKR potentials to 75–95% of well depth for the purpose of such comparisons, as Varshni has done (e.g. his Table 2).

Figure 1 gives a semiquantitative picture of the performance of these potential functions for the 35 known potentials tested here. In terms of the quantities displayed in this figure, a good performance is exemplified by a rapid rise at small $|\epsilon|$; however, from the cumulative nature of the plotted quantity, all curves must rise eventually to the total number of cases considered (here 35). The Varshni curve based on $\mathcal{D}_e$ is the best performer over much of the displayed range of $|\epsilon|$; but the $\omega_e x_e$-based Morse and Rydberg functions perform about as well, and the $\omega_e x_e$-based Varshni function is only slightly poorer. In fact, only the $\mathcal{D}_e$-based Morse function is noticeably poorer than the others over the full range of this diaplay.

Some further comparisons are given in Table 1, from which it can be seen that all three $\omega_e x_e$-based potentials show smaller average absolute values and smaller rms values of the maximum relative errors than the $\mathcal{D}_e$-based functions. It is interesting to note that all six functions show *positive* average error, which means that they are systematically too "hard." However, for the V′ potential, the systematic error is noticeably smaller than for the other five.

The comparisons of Table 1 are strongly influenced by the results for the alkali–metal dimers, for which the errors are noticeably larger for all six functions. When the 7 potentials in this group are excluded, I obtain the values given in parentheses, from which it can be seen that the V, M′, and R′ functions are comparably "good" in columns 2 and 3. From the standpoint of systematic errors, the V potential is now the best.

Henderson and I also examined the ability of the Morse potential to predict α_e, and I have repeated this check for all six forms. With double counting in cases where the calculated values are very close, the tally of best predictions is: V′(15), V(10), M′(10), R′(3), M(2), R(1). Since the Rydberg α_e value is almost always sandwiched between the other two (in each group of three), the Rydberg potential is at a disadvantage in this particular test.

TABLE 1. Average maximum error, average absolute maximum error, and rms maximum error for six functions used on 35 (28)[a] molecular states; quantities as defined in Fig. 1

Potential	$\langle\epsilon\rangle$	$\langle\|\epsilon\|\rangle$	rms ϵ
M	8.3(5.0)	9.7(6.2)	12.7(7.1)
R	5.2(2.4)	7.9(4.8)	10.6(5.8)
V	3.3(−0.2)	6.6(3.9)	9.7(5.3)
M′	3.8(2.2)	5.8(4.0)	7.8(5.2)
R′	2.6(1.1)	5.5(3.9)	7.3(5.0)
V′	0.2(−2.2)	5.8(4.8)	7.4(6.1)

[a]Values in parentheses obtained when 7 alkali-metal dimer potentials are excluded.

Varshni (5) reported a large error for NaAr(X), in discord with results of Henderson and myself (4). The correct experimental potential to use in this case is the modified Morse curve reported in eq. [8] of the original paper (10); since the rotational constants B_v were determined only for $v = 0$ and 1, and RKR calculation is inappropriate.

Schwartz and Le Roy (11) have criticized the use of the Morse function to approximate the repulsive branch on the grounds that the Morse function cannot accommodate higher-order semiclassical corrections to the potential. However, the cases where such an approximation is needed are "ignorance" situations where the rotational constants are not known. In the face of the uncertainties that this lack of information entails, higher-order semiclassical corrections pale to insignificance.

In summary, the repulsive branches of diatomic potentials are remarkably simple, permitting surprisingly reliable prediction from closed-form potentials based on equilibrium spectroscopic constants. Although the Varshni III function outperforms the Morse and Rydberg functions when R_e, ω_e, and $\mathcal{D}_e$ are used to define the potentials, the latter two functions perform comparably well when R_e, ω_e, and $\omega_e x_e$ are used. It seems likely that other potential forms will be found to perform similarly well. However, in cases where chemically analogous potentials are known experimentally, the use of reduced potentials may be preferable to these closed-form potential functions (4, 9).

The effect of temperature and salinity on the Setschenow parameters of naphthalene in seawater

GERARDO GOLD[1] AND SILVIO RODRIGUEZ
Department of Chemistry, University of the Pacific, Stockton, CA 95211, U.S.A.

Received April 12, 1988[2]

G. GOLD and S. RODRIGUEZ. Can. J. Chem. **67**, 822 (1989).

Solubility measurements of naphthalene in seawater of different salinities have been determined by the Generator Column Method in the 276.6 K to 316.8 K temperature range. The Gibbs free energy, enthalpy, and entropy of solution were evaluated at 298 K by means of the Clarke and Glew equation. The temperature dependence of the Setschenow parameters for naphthalene in seawater has been studied and compared with the values calculated using current models for the salting-out of nonpolar molecules. The Surface Tension Approach gives the best correlation with experimental values.

Key words: Setschenow parameters, solubility of naphthalene in seawater.

G. GOLD et S. RODRIGUEZ. Can. J. Chem. **67**, 822 (1989).

Opérant à des températures allant de 276,6 à 316,8 K et faisant appel à la méthode de la colonne génératrice, on a mesuré la solubilité du naphtalène dans de l'eau de mer de salinités diverses. Utilisant l'équation de Clarke et Glew, on a évalué l'énergie libre de Gibbs, l'enthalpie et l'entropie de solution. On a étudié la relation qui existe entre la température et les paramètres de Setschenow du naphtalène dans l'eau et on l'a comparée avec les valeurs calculées en utilisant les modèles actuels pour le salage des molécules non polaires. L'approche de la tension superficielle donne la meilleure corrélation avec les valeurs expérimentales.

Mots clés : les paramèters de Setschenow, la solubilité du naphtalène dans de l'eau de mer.

[Traduit par la revue]

Introduction

Although considerable progress has been made in research concerning identification and distribution of contaminants in the ocean, little is known about fundamental properties such as the effect of salinity, temperature, and pressure on the aqueous solubility of contaminant molecules. Of these compounds, polycyclic aromatic hydrocarbons (PAH) are particularly important because of their wide distribution in the environment and the carcinogenic character of some of them. A number of review articles have been published about the incidence and consequences of their presence in aquatic systems (1, 2). Solubilities of polycyclic aromatic hydrocarbons in seawater have been reported at 298 K for naphthalene (3, 4), biphenyl and phenanthrene (4), acenaphthene and pyrene (5). More recently Whitehouse has reported the aqueous solubility of phenanthrene, anthracene, 1,2-benzanthracene, and benzo(*a*)pyrene at temperatures ranging from 276.8 to 298.4 K and salinities ranging from 0 to 36.7% (6), and the abnormal solubility behaviour of some aromatic hydrocarbons in seawater (7). Estimates of the aqueous solubilities of organic hydrophobic molecules have been obtained from molecular parameters and activity coefficients (8). The presence of an electrolyte changes the activity coefficient of a dissolved nonelectrolyte and its solubility. For many electrolyte–nonelectrolyte systems the experimental results can be described by the empirical Setschenow equation

$$[1] \quad \log (S^0/S) = k_s C_s$$

where S^0 and S are the solubilities of the electrolyte in pure water and in an aqueous electrolyte solution, respectively; C_s is the concentration of the non-electrolyte, and k_s is the salting constant, also known as the Setschenow constant. Given that the aqueous solubilities of PAH are low, and self interaction terms may be considered negligible, the Setschenow constants can be identified with the true salting-out coefficients of the electrolytes. Many different models have been proposed to predict the magnitude of k_s for any given pair of electrolyte–nonelectrolyte cosolutes. It is the objective of the present work to determine the Setschenow parameters of naphthalene, the simplest PAH, in seawater of different salinities, in the temperature range 276.6 to 316.8 K. For the ideally dilute solution of the hydrocarbon, the thermodynamic parameters ΔG^0, ΔH^0, and $\Delta C_p{}^0$ for the solution process are then determined using the Clarke and Glew equation. Also, Setschenow constants have been calculated, as a function of temperature, using the different models for nonelectrolyte salting currently available.

Experimental

Naphthalene was zone refined (James Hinton, Valparaiso, FL), and methylene chloride was spectro quality (Aldrich, Gold Label). These reagents were used as received, without further purification. Natural seawater was IASOP (Institute of Oceanographic Sciences, Surrey, England) standard seawater, which is used as a salinity standard and therefore is provided with a very accurate value of its salt content. Prior to use, this water was irradiated with ultraviolet light from a medium-pressure mercury vapour lamp. Artificial seawater was prepared according to Lyman and Fleming (9).

The solubility of naphthalene in seawater, in the range from 276.6 to 316 K in temperature and 0 to 35 parts per thousand (ppt) in salinity was measured using a modified version of the Generator Column Method developed at the U.S. National Bureau of Standards (8, 10, 11). With this method it is possible to minimize the problems commonly associated with the so-called "shake-flask" method, such as supersaturation of the solution, adsorption of the solute onto the walls of the container, and interference from other compounds. Typically, naphthalene was deposited onto 60–80 mesh glass beads (Alltech Associates) by adding 20 g of the beads to 200 mL of a 0.1% w/w solution of the hydrocarbon in methylene chloride, and then evaporating the solvent in a rotary evaporator. A 60 × 0.6 cm polypropylene tube was then filled with the dry beads and placed inside a one meter water jacket connected to a thermoregulated circulator (Lauda model B-1). Each new column was conditioned by pumping distilled water at 50°C using a Bodine NSI-34RH pump. After equilibrium was reached, water or seawater at the

276.6	0.854 (0.01)	1.52 (0.03)

appropriate temperature was pumped through the column. The Generator Column technique was modified by eliminating the extraction of the saturated solution, and measuring the absorbance of the column effluent directly (12). The concentrations of naphthalene in the effluent were calculated from the absorbance at 276 nm and the extinction coefficient at that wavelength (3). All absorption spectra were recorded with a Cary 219 double beam uv–vis spectrophotometer with a nominal slit of 0.5 nm. The temperature was monitored with a digital thermometer (Bailey model BAT-12). Seawater with salinities less than 35 ppt were prepared by gravimetric dilution of the standard seawater with distilled deionized water.

Results

The solubilities of naphthalene in seawater, as a function of both temperature and salt content, are listed in Table 1. The electrolyte concentration in seawater was calculated by taking advantage of the fact that the proportion between the major constituents of seawater is constant and independent of the salinity. Results obtained with natural seawater are indistinguishable from those obtained with artificial seawater. Absorbances were corrected for temperature induced volume changes using the one-atmosphere equation of state for seawater given by Wang and Millero (13)

$$[2] \quad V_{sw} = 1.000027/(1.0 + \rho_t 10^{-3})$$

where V_{sw} is the specific volume of seawater, and ρ_t is given by

$$[3] \quad \rho_t = A_t + B_t\rho_0 + C_t\rho_0^2 + \ldots$$

where ρ_0 is a function of salinity and the coefficients A_t, B_t, C_t, ... are a function of the temperature. The corrected solubility values were then converted to the mole fraction scale. The solubility of naphthalene in pure water at 298 K reported here, 4.67×10^{-6} agrees very well with the values given recently by other authors: 4.48×10^{-6} (11) and 4.32×10^{-6} (14).

TABLE 2. Setschenow parameters for the salting-out of naphthalene in seawater as a function of temperature; σ is the standard deviation and r is the correlation coefficient

T/K	k_s/(kg/mol)	$\sigma \times 10^4$	r^2
316.8	0.267 (0.007)	0.012	0.9988
307.8	0.254 (0.009)	0.150	0.9969
298.0	0.252 (0.007)	0.067	0.9993
286.4	0.262 (0.014)	0.270	0.9947
276.6	0.270 (0.003)	0.012	0.9998

Solubilities were fitted to the Setschenow equation using least-squares. The resulting Setschenow parameters, and their uncertainties, as a function of temperature are given in Table 2. The uncertainty in the values for the slope and the correlation coefficient were calculated using standard statistical techniques. Our value for the salting-out constant of naphthalene in seawater at 298 K, 0.252 kg/mol, compares very well with the value of 0.256 kg/mol given by Gordon and Thorne (3) and is lower than the value of 0.303 kg/mol reported by Eganhouse and Calder (4). In order to calculate the thermodynamic functions for the process

$$\text{naphthalene (solid)} \Leftrightarrow \text{naphthalene (aqueous)}$$

the corrected solubilities were fitted to the Clarke and Glew equation

$$[4] \quad R \ln X = -\Delta G_\theta^0/\theta + \Delta H_\theta^0(1/\theta - 1/T) + \Delta C_{p\theta}^0 [\theta/T - 1 + \ln (T/\theta)]$$

where θ is a reference temperature, and the other symbols have their usual thermodynamic meaning. This equation does not assume the heat capacity change to be zero, and has the advantage that the adjustable coefficients are not mutually correlated (11, 15, 16). The thermodynamic functions are given in Table 3 for the process of solution of naphthalene in water and seawater. Values calculated from the data reported by May *et al.* (11) are included for comparison.

Discussion

The enthalpy of solution of hydrocarbons in water can be considered to be the result of four contributions: (*a*) the lattice enthalpy of the hydrocarbon, (*b*) an enthalpy of solvation which is negative because of a more ordered structure of the solvent around the hydrocarbon molecules in solution, (*c*) a positive enthalpy of cavity formation, which is the energy required to make a hole in the solvent for the dissolved hydrocarbon, and (*d*) an enthalpy of hydrocarbon–solvent interaction that is usually considered to be negative, and includes all the remaining solvent–solute interactions. From the results in Table 3 it can be seen that ΔH^0 of solution for naphthalene is the same for water and seawater, and the more positive value for the Gibbs free energy of solution of naphthalene in seawater, as compared to the value in pure water, can be ascribed to an entirely entropic contribution. This is usually interpreted as the predominance of water structure formation, promoted by the hydrocarbon, over the destruction of the structure induced by the electrolytes.

Many different models have been proposed to predict the magnitude of the salting-out coefficient for any given pair of electrolyte–nonelectrolyte cosolutes. In general, these models can be divided into three categories: electrostatic, statistical mechanical, and thermodynamic. Electrostatic equations usually predict k_s values that are very similar for all 1:1 electrolytes,

TABLE 3. Thermodynamic functions for the process solid naphthalene – aqueous naphthalene

Solvent	ΔG^0/(kJ/mol)	ΔH^0/(kJ/mol)	$T\Delta S^0$/(kJ/mol)	ΔC^0_p/(kJ/mol K)
Water	30.41 (0.019)	28.4 (0.1)	−2.01	0.26 (0.02)
Water[a]	30.55 (0.032)	28.6 (1.3)	−1.95	0.31 (0.17)
Seawater	31.16 (0.014)	28.4 (0.09)	−2.76	0.19 (0.02)

[a]Calculated from the experimental data of May *et al.* (11).

and in many cases fail to predict salting-in (17). Having proved unsatisfactory, electrostatic theories have received minor attention in the literature. Statistical mechanical models consider the dissolution process of a solute in a liquid as a two step process: (*1*) the creation of a cavity in the solvent, large enough to accommodate the solute, and (2) the introduction of a solute molecule into the cavity (18). At present, the best approach to calculate the free energy changes associated with these processes is the Scaled Particle Theory (SPT) (19, 20). In this theory, a fluid is considered to be formed by a system of spherical molecules obeying a pairwise additive potential into which an additional molecule, obeying the same potential, is introduced by the procedure of distance scaling. Pierotti (21, 22) applied the SPT to the solubility of gases in real liquids, and calculated the molecular parameters of water that are needed in the calculations. Shoor and Gubbins (23) applied Pierotti's results to the solubility of gases in concentrated electrolyte solutions, finding an expression for k_s. Pierotti's SPT assumes solutions to consist of hard-core spherical molecules in which solvent molecules are uniformly distributed around each molecule of solute. Masterton and Lee (24) obtained a general expression for k_s

$$[5] \quad k_s = k_\alpha + k_\beta + k_\gamma$$

where k_α is the contribution from the free energy of cavity formation, k_β is the term containing the solute–cavity interaction, and k_γ is a statistical term that becomes negligible for slightly soluble hydrocarbons. The term k_α always leads to salting-out. It is proportional to the molecular diameter of the solute and inversely proportional to the temperature. The term k_β always leads to salting-in and it decreases with increasing temperature. Masterton (25) derived an equation for salting-out in seawater in the 273 to 313 K temperature range. His equations for k_s are expressed in terms of ionic strength I_w, therefore, in order to apply the SPT to our results, the values of solubility from Table 2 were recalculated according to the equation

$$[6] \quad I_w = 0.01994S/(1 - S/1000)$$

where S is the salinity in parts per thousand (13). The calculation of k_s requires the knowledge of the Lennard–Jones parameters for the solute. These parameters were calculated using two different approaches. The first approach uses an empirical relationship between the critical properties of the compound and the Lennard–Jones parameters (26, 27). The critical constants for naphthalene were taken from the compilations by Kudchaker *et al.* (28) and Dreisbach (29). Using this method, the work function was calculated to be 394.1 K and the intermolecular distance as 6.89 Å. The value of k_s at 298 K calculated using these parameters is 0.546 kg/mol which is three times higher than the experimental result of 0.186 kg/mol, expressed in terms of ionic strength. In the second approach, the work function was calculated using the Mavroyannis–Stephen equation (24)

$$[7] \quad \epsilon/k = 2.28 \times 10^{-8} (\alpha^{3/2} E^{1/2} \delta^6)$$

where α is the molecular polarizability, E is the total number of electrons, and δ is the intermolecular distance. The molecular polarizability of naphthalene, 17.48×10^{-24} cm^3, was taken from the compilation by Miller and Savchik (30) and the intermolecular distance 6.58 Å was taken to be equal to the crystallographic diameter (29) which was calculated from the bond lengths and angles determined from X-ray diffraction data by Ponomarev *et al.* (31) and Sellers and Boggs (32). The calculated value for the work function is 169.3 K, and the calculated salting-out constant is 0.333 kg/mol, which is about two times greater than the experimental value of 0.186 kg/mol.

Although pairwise additivity seems unlikely in aqueous solution, the experimental values of the salting coefficients of simple gases in seawater are in reasonable agreement with the values calculated from the SPT (25). However, for large nonpolar solutes, the assumption of random distribution of molecules is more difficult to justify and cavity terms in seawater cannot be accurately evaluated. Moreover, the assumption that the molecules in solution have a hard-core leads to the problem of the selection of the correct diameter. Thermodynamic functions for cavity formation are very sensitive to the solvent molecular diameter. A change of only 0.1 Å in the diameter of water produces an almost 30% change in the free energy of the cavity (20).

The disagreement between experiment and theory can also be partially attributed to the magnitude of the calculated ion–solute interactions (24). Given that in this case the calculated value of the salting-out constant is higher than the experimental one, this seems to indicate that we have underestimated the effect of the interaction between the naphthalene and the surrounding ions.

Thermodynamic models were developed in their original form by McDevit and Long (33), and are based on the Tamman, Tait, and Gibson equation for electrolyte solutions (13) which assumes that the properties of an aqueous electrolyte solution are the same as those of pure water under an additional pressure, P_e, exerted by the electrolyte. This pressure is the result of an electrostriction in which the coulombic field of the ions interact with the water dipoles, thus compressing the solvent in their immediate neighborhood. McDevit and Long (33) assumed that the only significant interaction in the process of dissolving a nonelectrolyte is the work necessary to create a cavity in the solvent, without considering any solute–cavity interactions. For very low concentrations of both salt and nonelectrolyte they found

$$[8] \quad k_s = V_i^0 (V_s - V_s^0)/2.3B_0RT$$

where V_s and V_s^0 are the "liquid" volume and partial molar volume of the salt respectively; B_0 is the isothermal compressibility of water; V_i^0 is the partial molar volume of the nonelectrolyte, R and T have their usual meaning. An equivalent expression for k_s is

[9] $k_s = \lim V_i^0/2.3RTdP_e/dC_s$

where C_s is the electrolyte concentration. This equation contains explicitly the pressure exerted by the electrolyte, P_e, instead of the "liquid" volume of the salt, V_s^0, which is not clearly defined. Equations [8] and [9] correctly predict the relative change of k_s for different salts, and are in good quantitative agreement for small molecules such as O_2, H_2, and the noble gases (34). However, for larger nonelectrolytes such as benzene or naphthalene the estimated values of k_s are off by a factor of two or three. This is probably due to the neglect of nonzero distance of closest approach. The effective pressure, P_e, exerted by sea salt was calculated from

[10] $B^pV^p = 0.4343X_l(0.135\ V_w)/(B_t + P_e + P)$

where B^p is the isothermal compressibility at pressure P, V^p, and V_w are the volume of the solution at pressure P and the volume of pure water at atmospheric pressure, X_l is the number of grams of water per gram of solution, and B_t refers to the pressure exerted by pure water. The values of B^p and V^p for seawater in the salinity and temperature ranges of this work were calculated from the high pressure equation of state given by Millero *et al.* (35). The calculated value for k_s at 298 K is 0.836 kg/mol, which is about three times greater than the experimental value.

Recently, Aveyard (36) used a different approach assuming that the nonideal work of transferring a nonelectrolyte solute from water to a salt solution depends not on P_e but on the change of the surface tension of the aqueous solution when the salt is added. He assumed that the surface tension of a microscopic cavity is the same as the macroscopic value and the solute–solvent interactions are the same in water and in the aqueous electrolyte solution. For a 1:1 electrolyte Aveyard found

[11] $k_s = 3.86\ V_w^{1/3}\ V_i^{2/3}\ \Phi_s$

where Φ_s is the osmotic coefficient for a one molal solution and the volumes are given in m^3/mol. In this case, the osmotic coefficients for seawater were calculated from the equation given by Millero (37)

[12] $1 - \Phi_s = 2.303A^{1/2}(\xi/3) + BI + CI^{3/2} + DI^2 + \ldots.$

where I is the ionic strength of the solution and $A, B, C, D, \xi\ldots.$ are temperature-dependent parameters. The calculated value of k_s for naphthalene in seawater at 298 K using the Aveyard approach gives a value of 0.267 kg/mol, which is in good agreement with the experimental value of 0.252 kg/mol.

Figure 1 shows the experimental and calculated values of k_s using the TTG and ST models for naphthalene in seawater as a function of temperature. It has been pointed out that the prediction of the temperature dependence of the Setschenow parameters is a more stringent test of the models available than the prediction of k_s at a single temperature (36). As shown in this figure, Aveyard's surface tension method predicts the correct sign and order of magnitude for the temperature coefficient of the salting constant while the TTG model shows a strong temperature dependence that is not consistent with the experimental data.

By assuming that in the presence of an electrolyte the water in an aqueous solution behaves as if it was subjected to an additional pressure, the TTG model has the advantage of making no assumptions about the distribution of molecules and ions in solution or about the explicit mathematical characterization of their interactions. Nevertheless, in many cases, this approach predicts Setschenow parameters that are high by a factor of two and three (33, 36, 38).

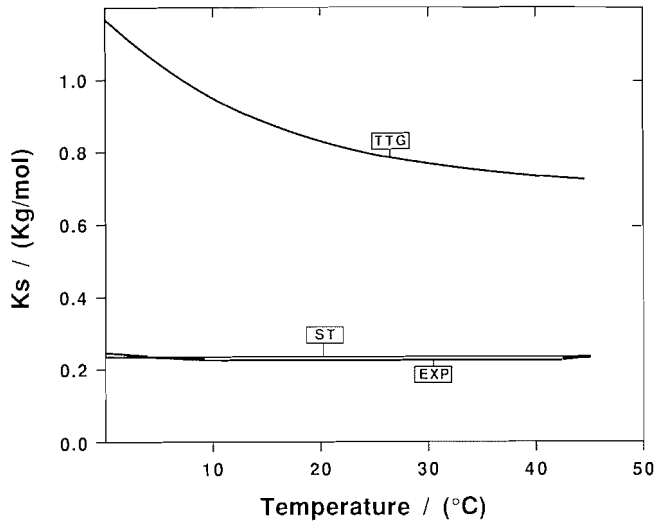

FIG. 1. Experimental and calculated values of k_s for naphthalene in seawater as a function of temperature. EXP, experimental values. TTG, values calculated by the Tamman, Tait, and Gibson model. ST, values calculated using the Surface Tension approach.

Whether the agreement we found between our experimental values and the Surface Tension approach is fortuitous or an indication of the validity of the model, it is evident that more experimental results and more theoretical work are needed in order to predict the behaviour of nonelectrolytes in aqueous electrolyte solutions.

A positive $^6J(H,CHO)$ in some *meta* derivatives of benzaldehyde. A simple model

TED SCHAEFER AND CRAIG S. TAKEUCHI
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 7, 1988

TED SCHAEFER and CRAIG S. TAKEUCHI. Can. J. Chem. **67**, 827 (1989).

^6J(H,CHO), the long-range coupling constant between the aldehydic and *para* protons in benzaldehyde, has not been detected, possibly because the $\sigma-\pi$ interaction giving rise to a negative coupling is intrinsically rather small and because the internal barrier to rotation about the C_{sp^2}—C_{sp^2} bond is large. However, ^6J(H,CHO) in some *meta* substituted derivatives is actually positive and as large as 0.09 Hz in 3,5-difluorobenzaldehyde; the barrier to internal rotation in this molecule is some 4 kJ/mol lower than in the parent molecule. The magnitude of ^6J(H,CHO) in these derivatives correlates well with $\sigma_{R,ST}$ values, a recent set of substituent constants derived from ^{13}C nuclear magnetic resonance chemical shifts of the β carbon in styrene derivatives. It is hypothesized that the substituents with negative $\sigma_{R,ST}$ values stabilize an ionic valence bond structure that has a positive ^6J(H,CHO). A brief discussion of ^4J(H,CHO) in some of these molecules is also presented.

Key words: NMR, spin coupling NMR, benzaldehyde.

TED SCHAEFER et CRAIG S. TAKEUCHI. Can. J. Chem. **67**, 827 (1989).

La constante de couplage à longue distance, ^6J(H,CHO), entre les protons aldéhydique et en *para* du benzaldéhyde n'a pas été détectée, probablement parce que l'interaction $\sigma-\pi$ qui donnerait lieu à un couplage négatif est intrinsèquement plutôt faible et parce que la barrière interne à la rotation autour de la liaison C_{sp^2}—C_{sp^2} est grande. Toutefois, le couplage ^6J(H,CHO) observé dans quelques dérivés substitués en *méta* est de fait positif; dans le cas du difluoro-3,5 benzaldéhyde, il est même de 0,09 Hz alors que la barrière interne à la rotation dans cette molécule est 4 kJ/mol plus faible que celle observée dans la molécule de base. Il existe une bonne corrélation entre l'amplitude du couplage ^6J(H,CHO) dans ces dérivés et les valeurs $\sigma_{R,ST}$, un ensemble de constantes de substituants qui a été établi à partir des déplacements chimiques observés dans les spectres en résonance magnétique nucléaire du ^{13}C pour le carbone β de dérivés du styrène. On fait l'hypothèse que les substituants avec des valeurs négatives de $\sigma_{R,ST}$ stabilisent une structure de liaison de valence ionique possédant une valeur de ^6J(H,CHO) qui est positive. On présente aussi une brève discussion des ^4J(H,CHO) dans quelques-unes de ces molécules.

Mots clés : RMN, couplage du spin, benzaldéhyde.

[Traduit par la revue]

Introduction

Positive long-range spin–spin coupling constants between *para* ring protons and α protons in the side chain of benzene derivatives are not expected. For example, $^6J(H,CH_3)$ in toluene is negative because it is a $\sigma-\pi$ coupling constant whose sign is proportional to the product of the negative hyperfine interaction, Q^H_{CH}, at the *para* C—H bond and the positive hyperfine interaction, Q^H_{CCH}, between the α C—H bond and the π electrons (1, 2). The latter interaction is proportional to $\sin^2\theta$, where θ is the angle by which the C—H bond of the methyl group twists out of the benzene plane. A ^6J(H,CH) as small in magnitude as 0.04 Hz and negative in sign is known for a highly hindered toluene derivative in which the C—H bond containing the coupled proton is strongly confined to the aromatic plane (unpublished work in this laboratory). Because of its simple conformational behaviour, ^6J(H,CH) has proved informative about side-chain orientations and about internal rotational potentials in benzene derivatives, particularly for those to which classical methods are not easily applicable (3–5). Again, ^6J(H,SH) in thiophenol derivatives (6) or, for example, $^6J(H,^{13}C)$ in derivatives of benzyl cyanide-8-^{13}C (7) have the signs expected of a $\sigma-\pi$ spin–spin coupling mechanism.

In benzaldehyde, $^6J(H,CHO) \equiv {}^6J$ has not been measured. Indeed, it must be very small (see Fig. 1, where the linewidth at half-height of the aldehyde proton peaks is about 0.02_5 Hz) and probably not more than about 0.01 Hz in magnitude. As the aldehyde group twists about the C_{sp^2}—C_{sp^2} bond the usual $\sigma-\pi$ coupling mechanism should give rise to a negative ^6J. As discussed recently (8), ^6J in 2,6-dichlorobenzaldehyde is −0.14 Hz and, in conjunction with molecular calculations, implies an unusually small magnitude of $^6J_{90}$, the coupling constant when the C—H bond of the side chain lies in a plane perpendicular to that of the benzene moiety. Thus, $^6J_{90}$ in toluene is −1.20 Hz (2) whereas it appears (8) to be only −0.3 Hz in benzaldehyde. The standard INDO MO FPT computations (9) agree closely with the experimental result for toluene, including the $\sin^2\theta$ dependence of ^6J (1), but calculate $^6J_{90}$ as −0.8 Hz in benzaldehyde (10). For rather subtle reasons, not understood (but see a suggestive discussion of $^6J(H,^{13}C)$ for acetophenone-β-^{13}C (8)), the carbonyl group hinders the transfer of nuclear spin state information via a $\sigma-\pi$ mechanism.

If $^6J_{90}$ in benzaldehyde is only 0.3 Hz in magnitude, then the assumption that the barrier (11) of 32.2 kJ/mol in dimethyl ether solution is twofold (12) implies a $\langle\sin^2\theta\rangle$ of about 0.04 at 300 K and hence a ^6J of $-0.3\langle\sin^2\theta\rangle$ or −0.01 Hz. Consequently, the unmeasurably small ^6J in benzaldehyde is rationalized.

Here we report on small positive ^6J values in some *meta* derivatives of benzaldehyde and interpret them in terms of an ionic valence bond structure; their correlation with a new set of substituent constants is also discussed.

Results and discussion

Some *meta* substituents should decrease the rotational barrier of the C_{sp^2}—C_{sp^2} bond (13) and perhaps give rise to an observable, negative ^6J in the appropriate benzaldehyde derivatives. For example, STO-3G MO computations on benzaldehyde (12) and ours on 3,5-difluorobenzaldehyde imply a decrease of 1.6 kJ/mol in the latter. Because the barrier to internal rotation in benzaldehyde is so large, however, these computations suggest that $\langle\sin^2\theta\rangle$ in the 3,5-difluoro derivative will increase by less than 10% and hence no observable ^6J would arise, it being estimated above as −0.01 Hz. Of course, an experimental

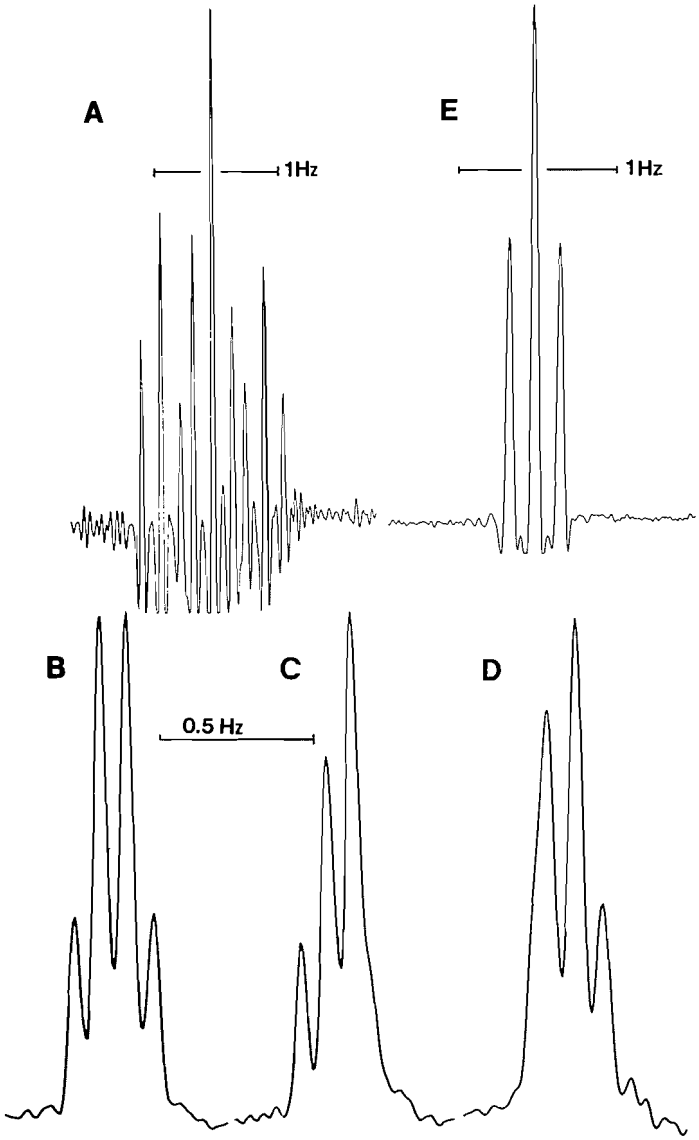

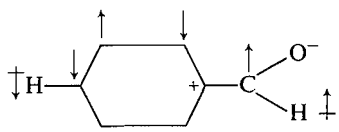

FIG. 1. In A the aldehydic ^1H nmr spectrum is shown for a 4.0 mol% solution of benzaldehyde in acetone-d_6 at a probe temperature of 300 K and 300 MHz. The digital resolution is 0.006 Hz. Severe resolution enhancement, LB −0.2 and GB 0.5, is employed in an attempt to detect ^6J(H,CHO). The linewidth is 0.02_5 Hz. The triplet of triplets arises from a ^5J(H,CHO) of 0.430(1) Hz and a ^4J(H,CHO) of −0.161(1) Hz (Table 1). In B the aldehydic ^1H nmr spectrum appears for a 3.9 mol% solution of 3,5-dimethoxybenzaldehyde. ^4J and ^6J are nearly equal in magnitude, causing the quartet structure. In C the *ortho* protons are being decoupled for one spin state of the *para* proton. Therefore one "triplet" within the spectrum collapses onto one peak of the remaining "triplet" (the couplings are not exactly the same so that these statements are only approximate, but sufficient for the purpose). In this experiment the *ortho* proton peaks at low frequency are irradiated. The triplet at low frequency of the aldehydic proton spectrum collapses. Hence ^6J(H,CHO)/^4J(H-2,H-4) > 0. ^4J(H-2,H-4) is known to be positive. These results were confirmed by further double resonance experiments. In D the *para* proton is being decoupled for a given spin state combination of the *ortho* protons, that is, the *para* proton peaks at lowest frequency are being irradiated. The irradiation intensity is not quite high enough for a clean result. Nevertheless, the two peaks at highest frequency in the aldehydic proton region are nearly collapsed into one another. Hence ^4J(H,CHO)/^4J(H-2,H-4) < 0. This result was confirmed by other experiments and also for a solution in CS_2. In E the ^1H nmr spectrum of the aldehydic proton is shown for a 6 mol% solution of 3,5-dimethylbenzaldehyde in acetone-d_6 at 300 MHz and 300 K. Again, no evidence for ^6J(H,CHO) appears. The linewidth at half-heights is about 0.04 Hz, perhaps because of very small residual coupling to the six methyl protons (the acquisition time was 41 s). Considerable resolution enhancement has caused distortions of peak intensities.

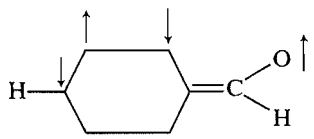
barrier height is to be preferred. For 3,5-difluorobenzaldehyde in dimethyl ether solution, an ^{19}F DNMR experiment (see below) gave $\Delta G^{\ddagger}$ as 28.0 ± 0.4 kJ/mol at 144 ± 2 K. For a twofold barrier $\langle \sin^2 \theta \rangle$ at 300 K is then 0.048 on the assumption that $\Delta S^{\ddagger}$ is negligible and that $\Delta H^{\ddagger}$ is roughly the same as V_2. Hence a ^6J of -0.01_5 Hz might exist by the above hypotheses.

In fact, for 3,5-difluorobenzaldehyde in CS_2 or acetone-d_6 solutions at 300 K, ^6J is +0.086(3) Hz. Furthermore, ^6J is +0.078(6) Hz for the 3,5-dimethoxy derivative in the same solvents and is +0.051(2) Hz for 3,5-dichlorobenzaldehyde. Analysis of the ^1H and ^{19}F nmr spectra of 3-fluorobenzaldehyde in these solvents gave ^6J as 0.047(2) Hz, while good iterative fits to the ^1H nmr spectra of 3-methoxybenzaldehyde in CS_2 and acetone-d_6 solutions could only be obtained with ^6J as +0.043(4) Hz. By way of contrast, ^6J in 3,5-dimethylbenzaldehyde is not detectable under the linewidth conditions for the aldehyde group (Fig. 1) and is probably <0.02 Hz. Similar remarks apply to the 3,5-dinitro and 3,5-bis(trifluoromethyl) derivatives, although linewidth conditions were less favourable; no evidence for significant magnitudes of ^6J was found.

A simple model



The positive sign of ^6J can be rationalized in terms of an ionic valence bond structure similar to that first proposed in connection with the transmission of electron spin density in nickel(II) aminotroponeiminates (14). In structure **1**, the usual

1

negative hyperfine interaction, Q_{CH}, at the site of the *para* C—H bond leads to a preferred parallel arrangement of the proton (crossed arrow) and the π electron. The ionic structure at the carbonyl group then ensures an antiparallel arrangement of the two protons in question and therefore a positive ^6J.

It appears that in benzaldehyde itself the contributing structure, **1**, is either not important enough to lead to a measurable positive ^6J or the hyperconjugative contribution, described above as negative and proportional to $\langle \sin^2 \theta \rangle$, happens to cancel the positive component. Another possibility involves the conjugative structure, **2**, which contributes to a

2

negative ^6J. This structure is contraindicated by ^6J(F,CHO) in 4-fluorobenzaldehyde being −0.44 Hz (8). Because Q_{CF} is positive, the ionic structure, **1**, is clearly predominant. Furthermore, the π electron donor, fluorine, must increase the

For personal use only.

contribution of the ionic structure; Q_{CF} is only about twice as large in magnitude as Q_{CH} and yet ^6J(F,CHO) is sizeable. It is also probably true that the mobile bond order of the exocyclic C_{sp^2}—C_{sp^2} bond increases in the presence of the *para* fluorine substituent, thereby causing an increase in the internal rotational barrier (15). However, the ionic structure must also increase in importance if the magnitude of ^6J(F,CHO) is to be understood.

With these considerations in mind, the ^6J values above indicate that *meta* fluorine or methoxy substituents also stabilize ionic structures at the carbonyl site, that residual π electron donation to a *meta* site is most pronounced for these substituents, and that it is roughly additive for two *meta* substituents. A nonzero π electron donation (resonance effect) for *meta* substituents is apparently somewhat problematical in the theory of substituent effects.

It is therefore of interest that a recent and novel analysis of substituent effects (16), based on ^{13}C nmr chemical shifts for the β-carbon in styrene derivatives (17), deduces so-called standard resonance substituent constants, $\sigma_{R,ST}$, whose values for the *meta* substituents of interest here are −0.30(F), −0.29(OCH_3), −0.18(Cl), −0.04(CH_3), 0.01(CF_3), and −0.05(NO_2). According to the authors (16), these nonzero values are a conceptual problem. Nevertheless, their values can rationalize the present ^6J values.

With the assumption that the *meta* substituent effects are additive, as suggested by the values of ^6J, a linear regression yields $^6J/\text{Hz} = 0.007 - 0.127\Sigma\sigma_{R,ST}$ with a correlation coefficient of 0.992 (5 points). The mean deviation between the numbers given by this equation and those measured is 0.002 Hz. The predicted ^6J values for the CH_3, CF_3, and NO_2 substituents, not included in the correlation, are 0.017, 0.004, and 0.020 Hz and are certainly compatible with the experimental linewidths of the aldehyde proton peaks for these compounds.

Other considerations

In terms of structures **1** and **2** the present correlation implies a stabilization of the ionic structure by those *meta* substituents with negative $\sigma_{R,ST}$ values (π donation). Yet, the usual interpretation has it that π donation will increase the mobile bond order of the C_{sp^2}—C_{sp^2} bond and lead to an increase in the internal barrier to rotation of the aldehyde group. Actually, the barrier in 3,5-difluorobenzaldehyde is lower than in benzaldehyde. Furthermore, the STO-3G MO calculations, although agreeing qualitatively with the barrier changes, find only an insignificant increase in the C_{sp^2}—C_{sp^2} length, 0.002 Å, for the difluoro derivative in the planar conformation. It does seem that the common interpretation of changes in barriers caused by *para* substituents, namely, that, as appropriate, their presence increases or decreases the mobile bond order of the exocyclic bond in question, cannot easily be applied to *meta* substitution. Indeed, some *ab initio* molecular orbital computations (18) on *meta* substituted phenols provide examples in which, although a decrease in the internal barrier is computed, the mobile bond order of the C—O bond is higher than in the parent molecule.

Standard INDO MO FPT computations on benzaldehyde find ^6J as −0.29 Hz for the planar molecule (10). The origin of such a sign and magnitude has been examined in some detail for styrene and its analogs (19). One important factor is the p_z spin density at the ipso carbon atom. Another is that the p_z orbital on the oxygen atom (by analogy to the discussion for styrene (19)) increases the spin polarizability of the p_z orbital on the α carbon atom. Indeed, when the p_z orbital on oxygen is removed from the coupling interaction by the PRMO (20) procedure, ^6J is computed as +0.007 Hz, in fortuitous agreement with the correlation above. Similar calculations on 3,5-difluorobenzaldehyde change ^6J from −0.36 to −0.03 Hz. Because structure **1**, unlike **2**, does not place spin density in the p_z orbital of oxygen, the computations are probably compatible with the present interpretation of the positive ^6J, particularly if the negative charge on oxygen in **1** reduces its ability to influence the spin polarizability of a p_z orbital on the neighbouring carbon atom.

Evidence that *meta* substituents do not significantly alter the double bond character of the exocyclic C_{sp^2}—C_{sp^2} bond comes from ^1J(C,C) ≡ ^1J for the carbonyl group (21). For example, a *para* methoxy substituent causes an increase of 2.5 Hz in ^1J, in line with an increased double bond character caused by π donation. A *meta* methoxy group does not change ^1J to within experimental error (21). In fact, ^1J is the same in benzaldehyde and in its 3-fluoro, 3-CF_3, and 3,5-di CF_3 derivatives (21). These data are therefore compatible with the assumptions inherent in the simple model of ^6J above.

Remarks on ^{4}J(H,CHO) ≡ ^{4}J and ^{5}J(H,CHO) ≡ ^{5}J

^4J is −0.15 Hz in benzaldehyde in CS_2 solution (see below). Computations (22) suggest that ^4J is a composite of positive σ electron and negative π electron contributions. It is interesting that ^4J remains very near this value in 3,5-dimethylbenzaldehyde, becomes −0.08 Hz in the 3,5-dimethoxy derivative, −0.05 Hz in the 3,5-dichloro, and is not detected in the 3,5-difluoro derivative. Furthermore, a precise analysis of the ^1H and ^{19}F nmr spectra of 3-fluorobenzaldehyde as a dilute solution in CS_2 yields ^4J(H-6,CHO) as −0.14 Hz whereas ^4J(H-2,CHO) is apparently not present. ^5J(H,CHO) in this molecule shows that the two conformers are presented in effectively equal proportions. All these data are consistent with the hypothesis that an electronegative substituent at the *meta* position causes an increase in the positive σ component of ^4J involving the neighbouring *ortho* C—H bond, thereby cancelling the negative π electron component; a polarization of the σ electron framework occurs at C-2 in a 3-X derivative. ^4J was not detected in the 3,5-dinitro and 3,5-di CF_3 derivatives but linewidth problems do not allow the statement that ^4J is insignificant in magnitude for these compounds.

The ^1H nmr spectrum of the aldehyde proton for 3,5-dimethylbenzaldehyde in Fig. 1E implies that ^5J in benzaldehyde must be very nearly a pure σ electron coupling constant.

Experimental

The 3,5-di X-benzaldehydes were commercial (X = OCH_3, F, Cl) or were prepared from the corresponding benzyl alcohols (X = CH_3, CF_3, NO_2). Aldrich was the source of all compounds not synthesized, as it was for the benzyl alcohols.

Samples for nmr spectral work were prepared as 2–4 mol% solutions in CS_2/C_6D_{12}/TMS/C_6F_6 and in acetone-d_6/TMS/C_6F_6 solvent mixtures. The solutions were transferred to 5 mm o.d. nmr sample tubes and were then degassed by the freeze–pump–thaw procedure; flame-sealing completed the sample preparation.

The ^1H nmr and ^{19}F nmr spectra were accumulated on a Bruker AM300 nmr spectrometer at a probe temperature of 300 K, by methods previously described (23). The $^{19}F\{^1H\}$ spectra at low temperatures were also obtained on the AM300 system by standard methods. Homonuclear partial decoupling experiments (24), meant to ascertain the signs of ^6J(H,CHO) and ^4J(H,CHO), were also performed. Figure 1 gives an example of such experiments.

The ^1H and ^{19}F nmr spectra were analyzed with the locally modified computer program NUMARIT (25). The ^1H nmr spectral parameters of benzaldehyde are found in Table 1 (see ref. 26 for an early analysis).

TABLE 1. The ^{1}H nmr spectral parameters for benzaldehyde at 300 K

Parameter	Value		Parameter	Value

[c]In Hz at 300.135$_2$ MHz to high frequency of internal TMS.
[d]Numbers in parentheses are the standard deviations in the NUMARIT analysis.
[e]No direct evidence exists for this number in the spectrum.

^4J(H,CHO) and ^6J(H,CHO) values for the *meta* derivatives have been quoted and used above. Full spectral analytical results, usually in two solvents, are available to the interested reader.

The coupling constants for benzaldehyde are larger in acetone-d_6 than in CS_2 solution in some instances. It is a common experience in this laboratory with polar benzene derivatives and is unlikely to be an artefact of the analysis. On the other hand, the values of ^6J(H,CHO) in Table 1 may well be an artefact because no direct evidence exists in the spectra for a finite value of this coupling constant. Again, with a digital resolution of 0.006 Hz, this conclusion is probably correct to about 0.01 Hz.

The ^{19}F{^{1}H} spectra of 3,5-difluorobenzaldehyde at low temperatures in dimethyl ether solution are very similar to those reported and displayed (27) for 4-bromo-2,6-difluoro-*N*-methylaniline. They were treated in the same way. In brief, the ^{19}F doublet coalesced at 144 ± 1 K, the linewidth at coalescence was 93 ± 5 Hz (conservative error estimate), and hence (28) $\Delta G^{\ddagger}$ is 28.0 ± 0.5 kJ/mol. The reference peak has a linewidth of 2.8 ± 0.4 Hz, yielding the estimate above. The total width at half-height at coalescence is the sum of the static splitting (slow rotation) and the natural width (29).

Acknowledgments

We thank Dr. G. H. Penner for the STO 3G MO computations on 3,5-difluorobenzaldehyde, Dr. R. Laatikainen for the restricted INDO computations on benzaldehyde, Mr. K. Marat for help with the ^{19}F DNMR experiments, and Mr. R. Sebastian for the datum on 3-methoxybenzaldehyde. The work was aided by financial assistance from the Natural Sciences and Engineering Research Council of Canada. A referee is thanked for helpful suggestions.

Solution and solid phase chemical synthesis of arabinonucleotides

MASAD JOSÉ DAMHA,[1] NASSIM USMAN,[2] AND KELVIN KENNETH OGILVIE[3]
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received August 29, 1988

MASAD JOSÉ DAMHA, NASSIM USMAN, and KELVIN KENNETH OGILVIE. Can. J. Chem. **67**, 831 (1989).

A fast and convenient procedure for the chemical synthesis of arabinonucleotides, which eliminates the multistep protection of the arabinonucleoside building blocks, is described. The results of these studies were successfully applied to the automated chemical synthesis of the hexanucleotide 5′-aU$_p$aA$_p$aU$_p$aA$_p$aU$_p$aA-3′. Both solution and solid phase phosphite triester procedures are described.

Key words: arabinonucleotides, arabinophosphoramidites, automated chemical synthesis, protected arabinonucleosides.

MASAD JOSÉ DAMHA, NASSIM USMAN et KELVIN KENNETH OGILVIE. Can. J. Chem. **67**, 831 (1989).

Une méthode générale et rapide a été developpée pour la synthèse chimique d'arabinonucléotides en solution et sur support solide. La méthode a été appliquée à la synthèse automatisée de l'hexanucleotide 5′-aU$_p$aA$_p$aU$_p$aA$_p$aU$_p$aA-3′.

Mots clés : arabinonucléotides, arabinophosphoramidites, synthèse chimique automatisée, arabinonucléosides protégés.

Introduction

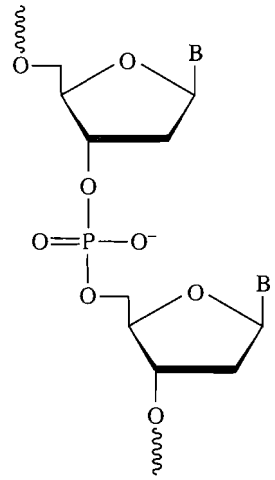
Arabinonucleosides, analogues of naturally occurring nucleosides, have been shown to possess a wide range of biological activities including antiviral and antitumor properties (1, 2). Unfortunately, the cytotoxicity, enzymic modification, and relative insolubility of these analogues (e.g., 9-β-D-arabinofuranosyladenine, aA) limit their utility for systemic administration. Some of these problems have been bypassed by chemically modifying the sugar or base moieties of these molecules (3). A different approach, which might be envisaged to improve the biological action and solubility of arabinonucleosides, is their incorporation into a nucleotide chain (4, 5). In addition to possible resistance to enzymic modifications and cleavage of the phosphodiester linkage, arabinonucleotides are expected to possess an inherent stability comparable to that of deoxyribonucleic acids (DNA). The unfavourable (*trans*) orientation of the 2′-hydroxyl function in arabinonucleotides prevents 2′-hydroxyl assisted cleavage of the vicinal 3′–5′ phosphodiester linkage (4).

The chemical synthesis of arabinonucleic acids (ANA, **1**), like that of ribonucleic acids (RNA), is difficult due to the presence of the 2′-hydroxyl function. The selective protection of the 2′-hydroxyl group is generally difficult due to its orientation towards the hindered β face of the arabinofuranosyl sugar. In the original work by Wechter (4), the 2′- and 3′-hydroxyls were left unprotected during nucleotide coupling steps, resulting in a mixture of 2′–5′- and 3′–5′-linked dinucleoside monophosphates. Smrt and Sorm (6) reported the incorporation of arabinouridine (aU) and arabinocytidine (aC) as the terminal 3′-end nucleoside of two trinucleotide diphosphates. Syntheses of aU-containing nucleotides were presented by Nagyvary and Provenzale (7), Ogilvie and Iwacha (8), and Schramm (9) but these procedures are limited to nucleosides that possess a C-2 keto function (pyrimidines) as they require formation of an O^2,2′-anhydro intermediate. Chattopadhyaya and co-workers (10) described the regiospecific, stepwise synthesis of the 3′–5′-linked nucleotides aA$_p$aA and aA$_p$aA$_p$aA but protection of the nucleoside monomers required numerous steps. Our laboratory has previously described the use of 2′-*O*-silyl-protected ribonucleosides as building blocks for the synthesis of ribonucleotides (11, 12). The successful use of the *tert*-butyldimethylsilyl group (TBDMS) in providing a rapid method for protecting the 2′-hydroxyl in ribonucleosides suggested that the same approach should be investigated in the arabinonucleoside area. Indeed, 5′-*O*-monomethoxytrityl 2′-*O*-TBDMS arabinonucleosides have been successfully prepared (13) and incorporated into nucleotide chains (5). In this report we describe a more practical and efficient procedure for the preparation of arabinonucleotide fragments. This method minimizes the protection of the arabinonucleoside units and affords 3′–5′-linked arabinonucleotide oligomers in good yields. A preliminary report of some of these results has appeared (14).

Results and discussion

Preparation of arabinonucleoside phosphoramidites

The key reagents used for the synthesis of arabinonucleotides were the nucleoside 3′-phosphoramidite derivatives **3***a* and **3***b*, which were easily prepared, in good yields, in a manner analogous to the preparation of ribonucleoside 3′-phosphoramidites (12*b*). Thus, *N*,*N*-diisopropyl-β-cyanoethylphosphonamidic chloride (1.1 equiv.) selectively reacted with the 5′-tritylated arabinonucleosides **2***a* and **2***b* (1.0 equiv.) at 0°C (2 h) to afford the corresponding 3′-phosphoramidites **3***a* and **3***b* in 90 and 60% yields, respectively (Scheme 1). The 2′,3′-*O*-bisphosphoramidites **5***a* and **5***b* were also isolated in ca. 5% yield and were easily separated from the desired 3′-*O*-phosphoramidites by silica gel chromatography. The arabinouridine 2′-*O*-phosphoramidite **4***a* was formed in ca. 3–5% yield (^{31}P NMR) and was separated from the 3′-*O*-phosphoramidite isomer **3***a* by repeated purifications on a silica gel column. The arabinoadenosine 2′-*O*-phosphoramidite **4***b* could not be detected. These results clearly indicate the marked difference in the steric environments of the 2′- and 3′-hydroxyl functions of arabinonucleosides.



Solution phase synthesis of arabinonucleotides

To evaluate the arabinonucleoside 3′-*O*-phosphoramidites as building blocks for arabinonucleotide synthesis, **3***a* (1.0 equiv.) was activated with tetrazole (4 equiv.) in THF in the presence of 2′,3′-*O*-diacetylarabinouridine (**6***a*, 1.3 equiv.). After 30 min at 20°C, the resulting 3′,5′ dinucleoside phosphite

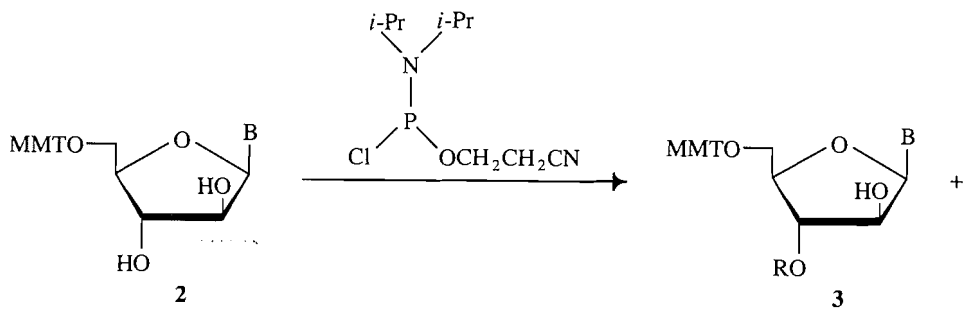
DNA

RNA

ANA, **1**



triester intermediate **7***a* was reacted *in situ* with a mixture of acetic anhydride/4-dimethylaminopyridine/collidine (5.0/0.5/7.0 equiv.) for 30 min to block the 2′-hydroxyl position. Upon completion of the capping reaction, an excess of an aqueous iodine solution was added to oxidize the fully protected phosphite intermediate (Scheme 2). Thus, activation of the nucleoside 3′-phosphoramidite with tetrazole, acetylation of the 2′-hydroxyl, and iodine oxidation were all carried out sequentially without intermediate product isolation. The work-up of the condensation reaction involved removal of excess iodine using an aqueous sodium bisulfite solution followed by purification of the product by silica gel chromatography. This procedure resulted in the isolation of phosphotriester aU_paU (**8***a*) in 78% yield based on the 3′-phosphoramidite **3***a*. The reaction of the adenosine 3′-phosphoramidite **3***b*, nucleoside **6***b*, and tetrazole by this condensation procedure gave the dinucleoside phosphotriester aA_paA (**8***b*) in 60% yield.

It is worth noting that, unlike ribonucleoside phosphite triesters (15), the phosphite triester linkage of aU_paU (**7***a*) and aA_paA (**7***b*) does not undergo 2′-hydroxyl assisted cleavage, because of the unfavourable (*trans*) orientation of the 2′-hydroxyl group.

During the coupling step one may envisage the possibility of the formation of branches at the unprotected 2′-hydroxyl of phosphite intermediates aUpaU (**7***a*) and aApaA (**7***b*). However, branched trinucleotides did not form under the condensation conditions. It appears that the ratio of nucleoside amidite **3** to nucleoside **6** employed in these couplings (1:1.3), as well as the steric hindrance of the 2′-hydroxyl group, disfavour this side reaction. Chain branching does occur in solid phase syntheses where the ratio of phosphoramidites to solid-support-bound arabinonucleoside reaches 20:1 (*vide infra*).

Solid phase synthesis of arabinonucleotides

The use of a solid phase approach eliminates the need for purification of the protected nucleotides, allows the rapid

synthesis of long sequences, and reduces the amount of (expensive) nucleoside 3′-phosphoramidite needed. Because our methodology employs the same synthetic strategy currently used for the solid phase synthesis of DNA and RNA chains, the preparation of ANA oligomers was attempted on a DNA/RNA synthesizer (12*b*).

Preparation of solid supports

To carry out the solid phase syntheses it was first necessary to prepare a suitable solid support, which avoided the preparation of a derivative of the arabinonucleosides. Thus, a support bearing a carboxylic acid would be most suitable as the carboxyl moiety could simply be esterified with one of the hydroxyl groups of compound **2**. Four different supports were evaluated: aminopropyl controlled pore glass (CPG), long chain alkylamine (LCAA) CPG, carboxyl CPG, and aminopropylsuccinylated Vydac TP silica gel. In the case of the two amino derivatized CPG supports a succinyl linker was attached according to the literature procedure (16), which resulted in supports bearing a terminal carboxylic acid. All four supports were then treated with compound **2** and DCC followed by *p*-nitrophenol (to esterify any remaining carboxyl groups). Finally, piperidine was added to convert the *p*-nitrophenyl esters to amides. None of the three CPG supports gave satisfactory results. The aminopropylsuccinylated Vydac TP silica gel gave loadings of 20–25 μmol g^{-1}. Therefore all solid phase syntheses were performed on the silica gel support (Fig. 1).

Solid phase synthesis

The first syntheses performed were those of the trimer of aU using 60- and 300-s recycle times in the cycle shown in Table 1. At the end of each coupling cycle any unreacted 5′- and all of the 2′-hydroxyls of the newly added nucleoside were acetylated using an Ac_2O solution. The average coupling yields obtained, determined by trityl cation analysis, were 94 and 115%, respectively. The coupling yield higher than 100% obtained in the latter synthesis indicated that a side reaction (i.e., chain branching) was occurring at the unprotected 2′-hydroxyl group. The formation of side products was confirmed by polyacrylamide gel electrophoresis (Fig. 2) and HPLC analyses (data not shown) of the crude products after complete deprotection. Consistent with the formation of branches during the coupling step is the observation that the amount of side product increases with increasing coupling time (Fig. 2).

To eliminate chain branching two approaches were taken. The first was to decrease the coupling time, to favour only the reaction of the amidite at the less hindered 5′-OH, and the

[a]TCA = trichloroacetic acid; DCE = dichloroethane; DMAP = 4-dimethylaminopyridine.

second was to use the amidites bearing 2′-OAc protection (**10***a* and **10***b*). In each case the sequences were deprotected (*vide infra*) and analyzed by gel electrophoresis and HPLC.

In the first approach, coupling times of 30 and 60 s were used in the synthesis of dimers and trimers of both aA and aU. The use of the 30-s recycle resulted in almost the complete elimination of the branching reactions (Fig. 2); however, the stepwise coupling yields were low, only ca. 75%. The use of a 60-s recycle suppressed the branching somewhat compared to the 300-s recycle (Fig. 2); however, there was still an unacceptable amount of branching and the average coupling yields were ca. 90%. The use of a 900-s recycle time did not increase the amount of branching relative to the 300-s recycle time; therefore it appears there is a saturating level of branching occurring at approximately 300 s.

In the second approach, compounds **10***a* and **10***b* were used, in which no branching may occur due to the presence of the 2′-OAc protecting group. These derivatives were prepared in high yields by the reaction of their corresponding 2′-hydroxyl amidites **3***a* and **3***b* with an Ac_2O/4-dimethylaminopyridine/EtN*i*Pr_2/THF solution at room temperature. A trimer of aU was prepared with compound **10***a* using a 300-s recycle time, and an average coupling yield of 96% was obtained. The isolated material after deprotection appeared as one well-defined band and, as expected, the branching reaction was entirely eliminated (Fig. 2).

From these experiments it appeared that the best approach was to use a 30-s recycle time with amidites **3** (method 1) or the 2′-OAc protected amidites **10** and a 300-s recycle time (method 2). As a test, the synthesis of 5′-aU$_p$aA$_p$aU$_p$aA$_p$aU$_p$aA-3′ was performed using the two methods. In the case of method 1 an average coupling yield of 86% was obtained and in the case of method 2, 98.5%. The overall yields following deprotection were consistent with what would be expected from the average coupling yields, 39 A_{260} units for method 1 and 57 A_{260} units for method 2. Gel electrophoresis analysis indicated some small amount of branching in the case of method 1 (data not shown). The branching reaction appeared to occur early in the synthesis (at the dimer or trimer level).

Deprotection and isolation of arabinonucleotides

All nucleotides (5′-hydroxyl free) were fully deprotected in a single treatment with 15 M aqueous ammonia in ethanol at 20°C (sequences containing aU) or 50°C (sequences containing aA) for 16 h. The crude products aU$_p$aU and aA$_p$aA (solution phase synthesis) were passed through a column of Dowex Na^+ ion exchange resin and subsequently purified by size exclusion chromatography (Sephadex G-25) and cellulose TLC. The hexanucleotide 5′-aU$_p$aA$_p$aU$_p$aA$_p$aU$_p$aA-3′ was purified by electrophoresis on a preparative polyacrylamide gel and desalted on a Sephadex G-25 column.

Characterization of arabinonucleoside phosphoramidites and arabinonucleotides

Arabinonucleoside phosphoramidites

Because the phosphoramidite derivatives represent a new class of protected arabinonucleosides it was necessary to characterize the products in detail. The chromatographic and spectroscopic properties of the phosphoramidite derivatives are presented in Table 2. The NMR data show that there is, as expected, only one pair of diastereomeric signals in the ^{31}P NMR spectra of **3** and **10**, thereby establishing the isomeric purity of these compounds.

The isomeric uridine 3′- and 2′-phosphoramidites **3***a* and **4***a* were characterized by conversion to the acetylated derivatives **10***a* and **11**, respectively. The same compounds **10***a* and **11** were prepared from the known 5′-MMT-2′- and 5′-MMT-3′-TBDMS-arabinouridine (5, 13) as shown in Scheme 3.

The position of the phosphoramidite moiety of the adenosine phosphoramidite **3***b* was established by ^{13}C NMR. In the ^{13}C spectrum of **3***b* (one diastereoisomer, Fig. 3) the C4′, C3′, and C2′ resonances are coupled to ^{31}P while that of C1′ is not. The presence of the phosphoramidite group causes shielding and deshielding of the arabinose carbon resonances relative to the corresponding signals in **2***b*, the effect being more pronounced for the carbon directly attached to the phosphoramidite group (C3′).

Protected nucleotides

The chromatographic and spectral properties of the fully protected (**8***a*, **8***b*) and 5′-unprotected (**9***a*, **9***b*) nucleotides are summarized in Table 2. The UV and ^{31}P NMR spectra are in complete agreement with the proposed structures.

Free nucleotides

The physical (UV, ^1H, ^{13}C, and ^{31}P NMR, and R_f values) properties of aU$_p$aU and aA$_p$aA (solution phase synthesis) are presented in Table 3. The ^1H and ^{13}C NMR base resonances clearly indicated the composite nature of the deprotected products. The ^1H NMR spectrum of aA$_p$aA was identical to that reported by Doornbos *et al.* (17).

As found by Wechter (4), the fully deprotected arabinonucleotides were stable to alkaline treatment (0.1 N KOH, 37°C, 16 h, HPLC analysis), conditions that degrade ribonucleotide chains. Furthermore, they were completely degraded by spleen phosphodiesterase (2′–5′-linked arabinonucleotides are not hydrolyzed by this enzyme) and snake venom phosphodiesterase to the corresponding monomer components (HPLC

analysis). This established the integrity of the 3′–5′-phosphodiester linkages.

Conclusions

The procedure described in this study permits the rapid and efficient synthesis of 3′–5′-linked arabinonucleotides with a minimum effort involved in the protection of the monomer units. This represents the first general procedure for direct conversion of arabinonucleosides to phosphoramidite derivatives, and these can be immediately incorporated into nucleotide chains. This feature, along with the facile removal of the protecting groups, makes this an attractive and efficient procedure.

Experimental

All general procedures and techniques including chromatography, UV, NMR, enzyme assays, condensation and deprotection procedures, gel electrophoresis analyses, and general reagents are as previously described (15, 12*b*). Solid phase syntheses were performed according to ref. 12.

High performance liquid chromatography (HPLC) analyses were carried out on a Spectra-Physics SP8000 HPLC equipped with a 254 nm UV detector and a chromatography data system under the following conditions: reverse phase 4.6 × 250 mm Whatman Partisil ODS-2 column (10-μm particles, Chromatographic Specialities); mobile phase, solvent A: 0.02 M KH_2PO_4 (pH = 5.5, adjusted with KOH), solvent B: methanol, gradient 0–50% solvent B in 30 min;

flow rate 2 mL/min; temperature 30°C. About one A_{260} unit (in 10 μL buffer) of crude nucleotide was injected in the HPLC column per run.

An A_{260} unit is the amount of material that will produce an absorbance of 1.0 at 260 nm, when dissolved in 1 mL of solvent, in a 1-cm cell.

Synthesis of arabinonucleosides

Derivatives **2**a *and* **2**b

The synthesis of compound **2***b* has been described (15). Compound **2***a* was prepared in 89% yield according to the procedure developed by Ogilvie *et al.* (13).

*2′,3′-*O*-Diacetylarabinouridine (***6***a)*

To a THF (15 mL) solution of 5′-*O*-monomethoxytritylarabinouridine (**2***a*) (1.9 mmol, 1.0 g), 4-dimethylaminopyridine (0.8 mmol, 98 mg), and 2,4,6-collidine (8.0 mmol, 1.1 mL), was added acetic anhydride (8.0 mmol, 750 μL) at room temperature. After stirring for 1 h, the solution was diluted with CH_2Cl_2 (75 mL) and washed with 5% $NaHCO_3$ solution (50 mL). The organic layer was dried (anhydrous Na_2SO_4) and evaporated under reduced pressure to give a gum. The monomethoxytrityl group was removed by treatment of the crude product with 80% acetic acid (40 mL) at 90°C. After 15 min, ethanol was added (50 mL) and the solvents removed under vacuum. The residue was diluted with CH_2Cl_2 (5 mL) and added to a stirred hexane solution (100 mL). The resulting precipitate was filtered and dried under vacuum to obtain derivative **6***a* as a white powder. The product crystallized (94% yield, 613 mg) from CH_2Cl_2 or CH_2Cl_2/hexanes (3:1), mp 164–165°C; TLC (methanol/$CHCl_3$, 5:95): R_f 0.24; UV (95% EtOH/H_2O): λ_{max} 262 nm, λ_{min} 232 nm; ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 8.94 (b, 1, NH), 7.63 (d, 1, H6), 6.27 (d, $J_{H1'-H2'}$ = 4.8 Hz, 1, H1′), 5.73 (d, 1, H5), 2.13 (s, 3, $COCH_3$), 2.01 (s, 3, $COCH_3$).

N^6*-Benzoyl-2′,3′-*O*-diacetylarabinoadenosine (***6***b)*

Compound **6***b* was prepared from N^6-benzoyl-5′-*O*-monomethoxytritylarabinoadenosine (**2***b*) (2.0 mmol, 1.3 g) as described for the preparation of compound **6***a*. The product was isolated on silica gel column chromatography using ethanol/ethyl acetate/CH_2Cl_2 1:50:49 as solvent. The yield of **6***b* was 78% yield (708 mg). A faster moving product identified as N^6-acetyl-N^6-benzoyl-2′,3′-di-*O*-acetylarabinoadenosine was also isolated in 13% yield (127 mg). **6***b*, TLC (methanol/$CHCl_3$ 5:95): R_f 0.26; (ethanol/ether/CH_2Cl_2 3:71:26): R_f 0.08; (ethanol/ethyl acetate/$CHCl_3$ 5:50:45): R_f 0.11; UV (95% EtOH/H_2O): λ_{max} 236, 282 nm, λ_{min} 230, 248 nm; ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 9.34 (b, 1, NH), 8.78 (s, 1, H8), 8.27 (s, 1, H2), 6.58 (d, $J_{H1'-H2'}$ = 4.6 Hz, 1, H1′), 2.12 (s, 3, $COCH_3$), 1.71 (s, 3, $COCH_3$). Physical properties of N^6-acetyl-N^6-benzoyl-2′,3′-di-*O*-acetylarabinoadenosine: TLC (methanol/$CHCl_3$ 5:95): R_f 0.34; (ethanol/ether/CH_2Cl_2 3:71:26): R_f 0.19; (ethanol/ethyl acetate/$CHCl_3$ 5:50:45): R_f 0.38; UV (95% EtOH/H_2O): λ_{max} 250, 274 nm, λ_{min} 231, 263 nm; ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 8.71 (s, 1, H8), 8.28 (s, 1, H2), 6.55 (d, $J_{H1'-H2'}$ = 5.3 Hz, H1′), 2.60 (s, 3, $COCH_3$), 2.13 (s, 3, $COCH_3$), 1.59 (s, 3, $COCH_3$).

Synthesis of arabinonucleoside phosphoramidites

*5′-*O*-Monomethoxytritylarabinouridine-3′-*O*-N,N-diisopropyl-β-cyanoethylphosphoramidite (***3***a)*

To a stirred THF (18 mL) of derivative **2***a* (6.0 mmol, 3.1 g) and diisopropylethylamine (21.8 mmol, 3.8 mL) was added dropwise, over 15 min, *N*,*N*-diisopropyl-β-cyanoethylphosphonamidic chloride (6.3 mmol, 1.34 mL) at 0°C. The reaction was then stirred for 2 h at room temperature. Ethyl acetate (100 mL, prewashed with 5% $NaHCO_3$) was added and the solution washed with saturated brine solution (3 × 100 mL). The organic phase was dried (anhydrous Na_2SO_4) and the solvent removed under vacuum to yield the crude product as a white foam. The crude product was purified (twice) by silica gel chromatography by elution with CH_2Cl_2/hexane/triethylamine, gradient: 50:45:5 to 50:40:10. After evaporation of the pooled fractions the product was coevaporated, first with 95% ethanol to remove traces of triethylamine, and then with ether to provide the product as a white foam. The purification was repeated until **3***a* was isomerically pure (^{31}P NMR). Derivative **3***a* was obtained in 90% yield (3.8 g). A faster moving product identified as 5′-*O*-monomethoxytritylarabinouridine-2′,3′-*O*-di-*N*,*N*-diisopropyl-β-cyanoethylphosphoramidite (**5***a*) was also isolated in ca. 5% yield. The chromatographic and spectroscopic properties of **3***a*, **4***a*, and **5***a* are presented in Table 2. *Anal.* calcd. for $C_{38}H_{45}N_4O_8P \cdot 1/2H_2O$: C 62.88, H 6.39, N 7.72; found: C 62.33, H 6.37, N 7.92.

N^6*-Benzoyl-5′-*O*-monomethoxytritylarabinoadenosine-3′-*O*-N,N-diisopropyl-β-cyanoethylphosphoramidite (***3***b)*

Compound **2***b* (3.0 mmol, 1.9 g) and *N*,*N*-diisopropyl-β-cyanoethylphosphonamidic chloride (3.2 mmol, 672 μL) were reacted according to the method described for the preparation of compound **3***a*. The products were separated on silica gel column chromatography using CH_2Cl_2/hexane/triethylamine 50:45:5 as solvent. The 3′-phosphoramidite and 2′,3′-bisphosphoramidite derivatives **3***b* and **5***b* were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

obtained in 66% (1.65 g) and 11% (335 mg) yields, respectively. The physical properties of these derivatives are presented in Table 2. *Anal.* calcd. for **3***b*, $C_{46}H_{50}N_7O_7P \cdot H_2O$: C 64.10, H 6.08, N 11.38; found: C 64.30, H 6.15, N 11.45.

*5′-O-Monomethoxytritylarabinouridine-2′-O-acetyl-3′-O-N,N-diisopropyl-β-cyanoethylphosphoramidite (**10**a)*

From derivative **3**a: To a THF (4 mL) solution of compound **3***a* (0.5 mmol, 358 mg), 4-dimethylaminopyridine (0.2 mmol, 25 mg), and diisopropylethylamine (4.0 mmol, 0.7 mL) was added dropwise, over 1 min, acetic anhydride (2.0 mmol, 187 μL) at room temperature. After stirring for 45 min, ethyl acetate (prewashed with 5% $NaHCO_3$) was added and the solution washed with saturated brine solution (5 × 100 mL). The organic phase was dried (anhydrous Na_2SO_4) and the solvent removed under vacuum to yield derivative **10***a* as a white foam in 95% yield (360 mg). The purity of this material judged by TLC and ^{31}P NMR was greater than 95%. The physical properties of this compound are presented in Table 2.

From 5′-O-monomethoxytrityl-3′-O-tert-butyldimethylsilylarabinouridine: (*a*) 5′-*O*-MMT-2′-*O*-acetylarabinouridine. To a THF (1.5 mL) solution of 5′-*O*-monomethoxytrityl-3′-*O*-*tert*-butyldimethylsilylarabinouridine (13) (0.23 mmol, 145 mg), 4-dimethylaminopyridine (0.07 mmol, 8 mg), and 2,4,6-collidine (0.92 mmol, 130 μL) was added acetic anhydride (0.92 mmol, 86 μL) at room temperature. After stirring for 1 h, the crude product was diluted with CH_2Cl_2 and the solution washed with saturated brine solution (50 mL) followed by water (50 mL). The organic phase was dried (anhydrous Na_2SO_4) and the solvent removed under vacuum to yield an oil. Analysis of this product by TLC showed complete conversion of the starting material (TLC: methanol/CH_2Cl_2 5:95, R_f 0.58) to a faster moving product (TLC: methanol/CH_2Cl_2 5:95, R_f 0.68). The 3′-silyl group was removed by treatment of the crude product with 1 M TBAF/THF (1.2 mmol, 1.2 mL) at room temperature. After 15 min, water was added (1 mL) and the product extracted with CH_2Cl_2 (50 mL). The organic phase was dried (anhydrous Na_2SO_4) and the solvent removed under vacuum to yield an oil. The crude product was diluted with CH_2Cl_2 (5 mL) and added to a stirred hexane solution (100 mL). The resulting precipitate was filtered and dried under vacuum to obtain 5′-MMT-2′-*O*-acetylarabinouridine in quantitative yield (155 mg); TLC (methanol/CH_2Cl_2 5:95): R_f 0.49; UV (95% EtOH/H_2O): λ_{max} 234, 262 nm, λ_{min} 227, 251 nm; ^1H NMR ($CDCl_3$, 200 MHz) δ: 6.30 (d, $J_{H1'-H2'}$ = 5.7 Hz, 1, H1′), 1.98 (s, 3, $COCH_3$).

(*b*) 5′-*O*-MMT-2′-*O*-acetyl-3′-*O*-phosphoramidite **10***a*. To a stirred THF (0.6 mL) solution of 5′-*O*-MMT-2′-*O*-acetylarabinouridine (0.20 mmol, 110 mg) and diisopropylethylamine (0.84 mmol, 144 μL) was added *N,N*-diisopropyl-β-cyanoethylphosphonamidic chloride (0.24 mmol, 51 μL) at room temperature. After stirring for 2 h, ethyl acetate (prewashed with 5% $NaHCO_3$) was added and the mixture was worked up and purified as for **3***a*. Chromatographic solvent: CH_2Cl_2/hexane/triethylamine; gradient: 50:45:5. The pure product was obtained as a white foam in 50% yield (75 mg). The chromatographic and spectral properties of this derivative are presented in Table 2.

*5′-O-Monomethoxytritylarabinouridine-3′-O-acetyl-2′-O-N,N-diisopropyl-β-cyanoethylphosphoramidite (**11**)*

Derivative **11** was prepared and purified as for **10***a* from 5′-*O*-MMT-3′-*O*-TBDMS-arabinouridine (13) (*vide supra*). Physical properties of the intermediate, 5′-*O*-MMT-3′-*O*-acetylarabinouridine: TLC (methanol/$CHCl_3$ 5:95): R_f = 0.27; UV (95% EtOH/H_2O): λ_{max} 234, 264 nm, λ_{min} 230, 252 nm; ^1H NMR ($CDCl_3$, 200 MHz) δ: 6.10 (d, $J_{H1'-H2'}$ = 4.3 Hz, 1, H1′), 2.08 (s, 3, $COCH_3$).

The chromatographic and spectral properties of **11** are presented in Table 2.

*N^6-Benzoyl-5′-O-monomethoxytritylarabinoadenosine-2′-O-acetyl-3′-O-N,N-diisopropyl-β-cyanoethylphosphoramidite (**10**b)*

To a THF (4 mL) solution of compound **3***b* (0.5 mmol, 422 mg), 4-dimethylaminopyridine (0.2 mmol, 25 mg), and diisopropylethylamine (4.0 mmol, 0.7 mL) was added dropwise, over 1 min, acetic anhydride (2.0 mmol, 187 μL) at room temperature. After stirring for 1 h, ethyl acetate (prewashed with 5% $NaHCO_3$) was added and the solution washed with saturated brine solution (5 × 100 mL). The organic phase was dried (anhydrous Na_2SO_4) and the solvent removed under vacuum to yield the crude product as a white foam. The crude product was purified by silica gel chromatography by elution with CH_2Cl_2/hexane/triethylamine 40:55:5. After evaporation of the pooled fractions the product was coevaporated, first with 95% ethanol to remove traces of triethylamine, and then with ether to provide the product as a white foam. Derivative **10***b* was isolated in 75% yield (332 mg). The physical and chromatographic properties of **10***b* are presented in Table 2. A faster moving product identified as N^6-acetyl-N^6-benzoyl-5′-*O*-monomethoxytritylarabinoadenosine-2′-*O*-acetyl-3′-*O*-*N,N*-diisopropyl-β-cyanoethylphosphoramidite was also isolated in 25% yield (116 mg); TLC (ether/CH_2Cl_2 1:1): R_f 0.83, 0.76; UV (95% EtOH/H_2O): λ_{max} 231, 271 nm, λ_{min} 227, 261 nm; ^1H NMR ($CDCl_3$, 400 MHz) δ: 8.65 (s, 1, H8), 8.63 (s, 1, H8), 8.18 (s, 1, H2), 8.16 (s, 1, H2), 6.60 (d, $J_{H1'-H2'}$ = 4.2 Hz, 1, H1′), 6.59 (d, $J_{H1'-H2'}$ = 4.2 Hz, 1, H1′), 2.59 (s, 6, $COCH_3$), 1.66 (s, 3, $COCH_3$), 1.62 (s, 3, $COCH_3$); ^{13}P NMR ($CDCl_3$, 121.5 MHz) δ: 152.0, 151.9.

Solution phase synthesis of arabinonucleotides

*Dinucleotides aU_paU (**8**a) and aU_paU (**9**a)*

To a sealed vial containing **3***a* (0.50 mmol, 359 mg), **6***a* (0.67 mmol, 219 mg), and tetrazole (2.0 mmol, 140 mg) was added THF (3.0 mL) and the solution stirred at room temperature for 45 min. At this point a mixture of 4-dimethylaminopyridine (0.26 mmol, 33 mg) and 2,4,6-collidine (3.6 mmol, 0.5 mL) in THF (2.7 mL) was added and, after 15 min, the phosphite triester intermediate aU_paU (**7***a*) was oxidized to the phosphate with an aqueous iodine solution (0.1 M in THF/water 3:1.5, excess, 5 min). The reaction mixture was diluted with CH_2Cl_2 (75 mL) and washed with an aqueous sodium bisulfite solution (2–5 mL of 5% sodium bisulfite in 200 mL water). The organic phase was washed with saturated brine (2 × 100 mL), dried (anhydrous Na_2SO_4), and evaporated under reduced pressure to yield a foam. The crude product was purified by silica gel chromatography by elution with ethanol/ethyl acetate/$CHCl_3$, gradient: 5:50:45 to 10:50:40. The pure product **8***a* was obtained in 78% yield (392 mg) and its physical properties are presented in Table 2.

It should be noted that 5′,3′,2′-*O*-triacetylarabinouridine is obtained as by-product and is easily separated during the purification step; TLC (ethanol/ethyl acetate/$CHCl_3$ 5:50:45): R_f 0.63; UV (95% EtOH/H_2O): λ_{max} 231 nm, λ_{min} 262 nm.

The monomethoxytrityl group was removed by treatment of **8***a* (0.43 mmol, 430 mg) with 80% acetic acid (10 mL) at 90°C for 15 min. At the end of this period, ethanol was added and the resulting solution was evaporated under reduced pressure to give an oil. This material was diluted with CH_2Cl_2 (5 mL) and added to a stirred hexane solution (100 mL). The resulting precipitate was filtered and dried under vacuum to obtain the 5′-deprotected dinucleotide **9***a* as a white powder in 80% yield (249 mg). The physical properties of this derivative are presented in Table 2. *Anal.* calcd. for $C_{27}H_{32}N_5O_{17}P$: C 44.45, H 4.42, N 9.60; found: C 44.32, H 4.48, N 9.13.

*Dinucleotides aA_paA (**8**b) and aA_paA (**9**b)*

Compounds **3***b* (0.61 mmol, 518 mg) and **6***b* (0.67 mmol, 373 mg) were coupled in the presence of tetrazole in dry THF as described for the preparation of **8***a*. The product **8***b* was purified as for **8***a*. The yield of **8***b* was 60% (453 mg) and its physical properties are presented in Table 2. It should be noted that N^6-benzoyl-5′,3′,2′-*O*-triacetylarabinoadenosine is obtained as by-product and is easily separated during the purification step (TLC, ethanol/ethyl acetate/$CHCl_3$ 5:50:45; R_f 0.51). *Anal.* calcd. for **8***b*, $C_{63}H_{58}N_{11}O_{16}P \cdot 3/2H_2O$: C 58.97, H 4.79, N 12.00; found: C 59.00, H 4.92, N 11.30.

Compound **8***b* (0.25 mmol, 330 mg) was detritylated and purified (silica gel column, methanol/$CHCl_3$: gradient 3–10% methanol) in a similar way as described for the preparation of compound **9***a* to give compound **9***b* (181 mg, 74%). The physical properties of this derivative are presented in Table 2.

Solid phase synthesis of arabinonucleotides

Preparation of Vydac TP silica gel supports

In a 50-mL round bottomed flask under argon, **2***a* (129 mg, 0.25 mmol) or **2***b* (161 mg, 0.25 mmol) was shaken with aminopropylsuccinylated Vydac TP silica gel (1.0 g) (16), 4-dimethylaminopyridine (25 mg, 0.20 mmol), and dicyclohexylcarbodiimide (2.06 g, 10 mmol) in anhydrous pyridine (9 mL) for 5 days. To the slurry was added *p*-nitrophenol (70 mg, 0.50 mmol) and the reaction shaken for 16 h. The support was filtered on a sintered glass funnel (M) and washed with pyridine (2 × 5 mL) and THF (2 × 5 mL). The support was then transferred to a 50-mL round bottomed flask and treated with 0.25 M Ac_2O/2,4,6-collidine/4-dimethylaminopyridine in THF (20 mL) for 18 h. The support was filtered and washed with THF. The support was then treated in a 50-mL round bottomed flask with piperidine (20 mL) for 18 h. The silica support was filtered and successively washed with acetone, EtOH, MeOH, and Et_2O. The support was dried overnight in a MeOH drying pistol. Loadings of 20.6 μmol g^{-1} and 25.3 μmol g^{-1} for the aA and aU supports respectively were obtained. Loadings were determined by detritylation of 5.0-mg samples with 5% trichloroacetic acid/dichloroethane solution (extinction coefficient used for the MMT cation = 56 $\mu mol^{-1} cm^{-1}$ mL).

Solid phase synthesis

Approximately 100 mg of derivatized solid support was used in each synthesis (ref. 12*b* for details). In each synthesis either amidite **3** or **12** was used with the cycle shown in Table 1. The time of recycle was varied (30, 60, 300, and 900 s) to examine the branching reaction when amidites **3***a* and **3***b* were used. In the case of amidites **10***a* and **10***b* a 5-min recycle time was used.

Deprotection and isolation of arabinonucleotides

*Deprotection of aU_paU (**9**a)*

This derivative (25 μmol, 18 mg) was fully deprotected in a single step by treatment with aqueous ammonia (15 M) in ethanol (3 mL: 1 mL) at room temperature for 16 h. At the end of this period, the ammonia was evaporated in a Speed-Vac concentrator to yield a white foam. This material was diluted with water (1 mL) and passed slowly through a column of Dowex Na^+ ion exchange resin and the eluant (40 mL) lyophilized. The residue was diluted with water (1 mL) and applied to a column packed with preswollen Sephadex G-25 size exclusion gel. The fractions containing the nucleotide were lyophilized to give 396 A_{260} units of aU_paU (87% yield, ca. 12 mg). The chromatographic and spectral properties of aU_paU are summarized in Table 3.

aU_paU was enzymatically degraded to aU by a mixture of snake venom and alkaline phosphatase. Degradation of aU_paU with spleen phosphodiesterase resulted in the formation of aU3′p and aU in a 1:1 ratio.

*Deprotection of aA_paA (**9**b)*

Compound **9***b* (25 μmol, 25 mg) was deprotected as for aU_paU **9***a*. The following conditions were used: (*a*) 15 M ammonium hydroxide/ethanol (3 mL: 1 mL), 55°C, 18 h; (*b*) ion exchange chromatography (Dowex Na^+, 90 mL water as eluant); (*c*) cellulose TLC (solvent F); (*d*) size exclusion (Sephadex G-25, water as eluant). A 32% yield (216 A_{260} units) of aA_paA was obtained. The chromatographic and spectral properties of aA_paA are presented in Table 3.

aA_paA was enzymatically degraded to aA by a mixture of snake venom and alkaline phosphatase. Degradation of aA_paA with spleen phosphodiesterase resulted in the formation of aA3′p and aA in a 1:1 ratio.

Deprotection of 5′-$aU_paA_paU_paA_paU_paA$-3′ (methods 1 and 2)

Silica gel (50 mg) bearing the protected sequences was placed in a sterile 5-mL polypropylene test tube to which was added aqueous ammonia (15 M) in ethanol (3:1, 3 mL) and the tube sealed with a septum (the septum was taped to the tube using commonly available electrical tape). The tube was placed in a thermostated oil bath at 55°C for 18 h to effect the concomitant decyanoethylation, removal of the sequence from the support, and the removal of the exocyclic amino benzoyl protecting groups. After cooling the tube in an EtOH/Dry Ice bath, the washings were removed with a sterile silanized pipette and placed in a sterile 15-mL test tube. The support was further washed with aqueous ammonia (15 M) in ethanol (3:1, 4 × 2 mL). The combined washings were frozen in an EtOH/Dry Ice bath and evaporated in a Speed-Vac evaporator overnight. The residue was extracted with sterile H_2O (5 × 1 mL) to yield 57 and 39 A_{260} units of 5′-$aU_paA_paU_paA_paU_paA$-3′, methods 1 and 2, respectively. Each sequence isolated from methods 1 and 2 (20 A_{260} units each) was loaded into 15 cm wide slots on a 1.5 mm × 20 cm × 20 cm 24% polyacrylamide gel for purification. The gels were visualized by UV shadowing and the desired bands cut out. The gel pieces were cut into small pieces and extracted by soaking in 0.05 M NH_4OAc, pH 7.0, at room temperature (16 h). The resulting supernatants were applied to a Sephadex G-25 column packed and run in 0.05 M NH_4OAc, pH 7.0 (12*b*). A final desalting step was carried out on Waters C18-SepPak cartridges. The final yields were 3.6 and 4.7 A_{260} units for the hexamers prepared by methods 1 and 2, respectively; UV (H_2O): λ_{max}, 262. All sequences were stored as 1 A_{260} units/10 μL aqueous solutions. Analytical gels were run with 0.5 A_{260} units of the sequence.

JOSÉE BRISSON, JOHANNE GAGNÉ, and FRANÇOIS BRISSE. Can. J. Chem. **67**, 840 (1989).

Three model compounds of poly(tetramethylene terephthalamide) or 4T Nylon have been synthesized and characterized using single crystal X-ray diffractometry, infrared spectroscopy, and ^{13}C CP/MAS nmr spectroscopy. The model compounds are the *para*-substituted *N,N'*-tetramethylene dibenzamides, where the substituents are the —OMe, —*t*Bu, —CN, and —CH_3 groups. The crystal structure determinations reveal three distinct conformations for the CO—NH—$(CH_2)_4$—NH—CO sequence of atoms. The conformation is all *trans* for OMe, *tgttt*$^-$*t* for the *t*Bu substituent, and *tsttts*$^-$*t* for the CN substituent (*t* = *trans* ≃ 180°, $g^{\pm}$ = *gauche* ≃ ±60°, and $s^{\pm}$ = *skew* ≃ ±120°). In all three derivatives, the dihedral angle between the aromatic ring and the amide plane is around 30°. The OMe and *t*Bu *para*-substituted molecules are interconnected by nearly linear hydrogen bonds of normal N...O distances. However, for the CN derivative the N...O distance is exceptionally short, 2.402(4) Å. On the basis of its infrared and solid state nmr spectra, it is proposed that *N,N'*-tetramethylene di-*para*-methyl benzamide has a crystal structure comparable to that of its unsubstituted analog. The methylenic sequence of the parent polyamide, 4T Nylon, has the *tgtttg*$^-$*t* conformation. Furthermore, the polyamide chains form sheets within which the chains, parallel to one another, are connected through hydrogen bonds.

Key words: polyamide, crystal structure, solid-state nmr.

JOSÉE BRISSON, JOHANNE GAGNÉ et FRANÇOIS BRISSE. Can. J. Chem. **67**, 840 (1989).

On a synthétisé trois composés modèles du poly(tétraméthylène téréphtalamide) (Nylon 4T) et on les a caractérisés par diffraction des rayons-X sur un cristal unique, par spectroscopie infrarouge ainsi que par rmn du ^{13}C en mode CP/MAS. Les composés modèles sont des *N,N'*-tétraméthylène dibenzamides substitués en position *para* par des groupements —OMe, —*tert*-butyle, —CN ou —CH_3. Les déterminations des structures ont permis d'identifier trois conformations distinctes pour la séquence d'atomes CO—NH—$(CH_2)_4$—NH—CO. On observe la conformation complètement *trans* avec le substituant OMe, la conformation *tgtttg*$^-$*t* avec le substituant *tert*-butyle et la conformation *tsttts*$^-$*t* avec le substituant CN (*t* = *trans* ≃ 180°, $g^{\pm}$ = *gauche* ≃ ±60° et $s^{\pm}$ = *skew* ≃ ±120°). Dans les trois dérivés, l'angle dièdre entre le plan du noyau aromatique et celui de l'amide est d'environ 30°. Les molécules substituées par des groupements OMe ou *tert*-butyle sont reliées par des liaisons hydrogènes linéaires dont les distances N...O sont normales. Toutefois, dans le cas du dérivé portant un substituant CN, la distance N...O est exceptionnellement courte, 2,402(4) Å. En se basant sur ses spectres ir et de rmn à l'état solide, on suggère que la structure cristalline du *N,N'*-tétraméthylène di-*p*-méthyl benzamide doit être comparable à celle de son analogue qui n'est pas substitué. Dans le polyamide de base, le Nylon 4T, la conformation de la séquence méthylénique est *tgtttg*$^-$*t*. De plus, les chaînes de polyamide forment des couches à l'intérieur desquelles les chaînes, parallèles les unes aux autres, sont reliées par des liaisons hydrogènes.

Mots clés : polyamide, structure cristalline, rmn état solide.

[Traduit par la revue]

Introduction

Recently we have studied the crystalline phase of various polyesters such as poly(oligomethylene terephthalates) (1–3), or poly(1,4-*trans*-cyclohexanediyldimethylenesuccinate) (4). We have also undertaken to establish the structure of the series of aromatic Nylons or *n*T Nylons which are in some ways related to the above-mentioned poly(oligomethylene terephthalates). However, the *n*T Nylons cannot be easily obtained in an oriented form, hence the X-ray diffraction patterns or films of fibers are not of a very high quality. Therefore, we have sought to gain information on the polymer's structure through other means.

Structural data were obtained from single crystal determinations of a series of related model compounds chosen for their similarity with the chemical repeat of the parent polymer. The crystal structures of the series of *N,N'*-oligomethylene dibenzamides, abbreviated *n*DBN where *n* is the number of methylene units, have been reported previously (5–10).

In the present paper, *para*-substituted *N,N'*-tetramethylene dibenzamides are studied with cyano, methyl, methoxy, and *tert*-butyl groups as substituents. These compounds are abbreviated *n*DBN-*p*-X where X is CN, Me, OMe, or *t*Bu. It is hoped that this study will bring a new understanding of the factors governing the conformation of 4T Nylon.

Infrared spectroscopy, which was used in the study of the *n*DBN, was also used in the study of this new series. We hoped to confirm our previous findings as well as to gain structural information on certain model compounds for which no single crystals suitable for X-ray diffraction have yet been obtained.

A solid state CP/MAS ^{13}C nmr study of the model compounds was also undertaken in order to correlate the chemical shifts of the methylenic carbons with the conformation of the aliphatic segments as obtained by X-ray diffraction. Our aim was to use the γ-*gauche* effect on the chemical shifts in order to deduce the conformation of the aliphatic chain of polymers and model compounds. It has been shown that the γ-*gauche* effect and the molecular packing interactions both affect to different degrees the chemical shift and we hoped to be able to quantify the factors influencing the chemical shift.

A comparison of specific absorption frequencies and ^{13}C nmr chemical shifts of the model compounds will provide structural information on those model compounds for which no single crystals are available.

Finally, we will propose a structure for the crystalline phase

of 4T Nylon that is coherent with the set of information and correlations deduced from model compounds.

Experimental

Spectroscopy

^{13}C CP/MAS nmr spectra were recorded on a Bruker CXP200 200 MHz at a frequency of 50.3 MHz. For all compounds a 1 ms contact time was used with a 10 s delay between sequences. An average number of 700 contacts was used.

Infrared spectra were recorded on a FTIR Nicolet 7199 using a HeNe class II laser. The number of scans accumulated was on the average 200, with a resolution of 2 cm^{-1} resolution. The samples were ground with KBr.

X-ray diffraction

Well-developed crystals suitable for X-ray diffractometry were obtained by slow evaporation of solutions of 4DBN-*p*-OMe and 4DBN-*p*-*t*Bu in a 50:50 mixture of isopropanol and water while 4DBN-*p*-CN was dissolved in DMSO. The unit cell dimensions were calculated from 25 reflections accurately centered on the Nonius CAD-4 diffractometer. The space groups were established from photographic investigation combined with an analysis of the intensity data. The densities were measured by the flotation method using $ZnCl_2$ aqueous solutions. The crystal data of interest are presented in Table 1. Integrated intensities were collected on the Enraf-Nonius CAD-4 diffractometer in the $\omega/2\theta$ scan mode using graphite monochromatized CuK$\bar{\alpha}$ radiation, λ(CuK$\bar{\alpha}$) = 1.54178 Å, and a scan width calculated by the relation $\Delta\omega = (1.00 + 0.14 \tan\theta)°$. The stabilities of the crystals were monitored by measuring every hour the intensities of seven reference reflections. The X-ray scattering factors used were those of Cromer and Mann (11) for all non-hydrogen atoms. The X-ray scattering factor for H atoms were those of Stewart, Davidson, and Simpson (12).

All structures were solved by direct-methods using the MULTAN80 or SHELX programs.[1] In all cases, the H atoms were found on difference Fourier syntheses. The H atoms were included in the refinement with isotropic temperature factors while all the non-hydrogen atoms were treated anisotropically. In the case of 4DBN-*p*-*t*Bu, the *t*Bu group was found to be disordered over two sites, each with an occupancy factor of 50%. The full-matrix least-squares refinement of the atomic coordinates using anisotropic temperature factors for nonhydrogen atoms and isotropic thermal parameters for H atoms, proceeded smoothly. The various criteria indicating the correctness of the structures are given in Table 2.

[1]The programs used here are modified versions of NRC-2, data reduction; NRC-3, absorption correction; NRC-10, bond distances and angles; NRC-22, mean planes (13); FORDAP, Fourier and Patterson maps; MULTAN80, multisolution program (14); SHELX program (15); NUCLS, least-squares refinement (16); ORTEP, stereoviews (17).

Results and discussion

Crystal structures

The final atomic coordinates and their standard deviations are presented in Tables 3*a*, *b*, and *c*.[2] The atomic numbering is shown in Fig. 1 and the various molecular structures are presented, as stereopairs in Fig. 2. The final bond distances and angles are compared in Table 4. There is no unusual feature among the bond distances and angles in the benzamide groups. Each six-membered ring is planar within experimental errors and so are the amide groups of atoms [C(1), C(7), N(1), O(1)]. The dihedral angles between the above two planes are very similar having values of 27.3, 27.3, and 33.7° for the *p*-OMe, *p*-*t*Bu, and *p*-CN derivatives, respectively. This compares well with the value of 30.0° reported for 4DBN (6) and is in the range of 19.0 to 34.1° observed for other *n*DBN's (9, 10).

The tetramethylene sequence

The bond distances, bond angles, and torsion angles of the —NH—$(CH_2)_4$—NH— sequence of atoms are compared in Table 5 to the corresponding quantities in 4DBN. In all four molecules there is a crystallographic center of symmetry at the mid-point of the central CH_2—CH_2 bond so that all symmetrically related (τ, τ', ϕ_1, ϕ_1') torsion angles have the same numerical value but are of opposite signs. The three torsion angles (ϕ_1, ϕ_2, ϕ_1') that define the conformation of the —NH—$(CH_2)_4$—NH— sequence are all *trans*. In other words, the atoms of the methylenic sequence are coplanar in all three compounds. What distinguishes most a compound from another is the torsion angle τ = C(7)—N(1)—C(8)—C(9). It has the values of 169.5(3) and 173.4(3)° for 4DBN and 4DBN-*p*-OMe, respectively, while τ is 79.8(2)° for 4DBN-*p*-*t*Bu and −120.0(4)° for 4DBN-*p*-CN.

[2]Structure factor tables, H atom coordinates, anisotropic thermal parameters, and the assignments of the infrared spectra may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

In this respect, 4DBN-*p*-*t*Bu resembles 2DBN, $\tau = 91.5(3)°$, 5DBN, $\tau = 71.3(2)°$ and $\tau' = 90.2(3)°$ or one end of 7DBN, $\tau = 91.6(4)°$. On the other hand, 4DBN-*p*-CN may be compared to 3DBN, $\tau = -140.3(3)°$, and to the other extremity of 7DBN, $\tau' = -105.0(4)°$.

Hydrogen bonding

The distances and angles describing the hydrogen bonding scheme are compared in Table 6. In an earlier work on *n*DBN's, the N...O distances were found in the range 2.838(2) to 3.012(3) Å while the N—H...O and N...O—C angles were within 147–168° and 125.5–166°, respectively. The corresponding quantities fall within the above limits for 4DBN-*p*-OMe and 4DBN-*p*-*t*Bu. The H bonds in all three compounds are nearly linear. However, in the case of 4DBN-*p*-CN, the N...O distance is remarkably short, 2.402(4) Å. For both 4DBN-*p*-OMe and 4DBN-*p*-CN, each molecule forms two H bonds with each of two molecules. This association results in the formation of a ribbon extending in the *b* direction.

Each 4DBN-*p*-*t*Bu molecule is H-bonded to four distinct molecules, thus forming a three-dimensional network similar to that observed for 2DBN (5). The various packing modes are shown as stereopairs in Fig. 3*a*, *b*, *c*.

Infrared spectroscopy

The assignments of the absorption bands of the infrared spectra of the various models have been deposited.

Although there is no obvious correlation between specific absorption frequencies and the conformation of the aliphatic chains, some other features of the ir spectra are useful diagnostics in identifying the type of hydrogen bonding present and assigning values to the τ torsion angles.

(1) The amide II band

It has been found that the frequency of the amide II band was dependent upon the type of hydrogen bonding in the structure. This observation is confirmed here. All the *n*DBN's which form extended ribbons through H-bonding between adjacent molecules have a strong ir absorption at around 1535 cm^{-1}. In the case of 4DBN-*p*-OMe the absorption is observed at

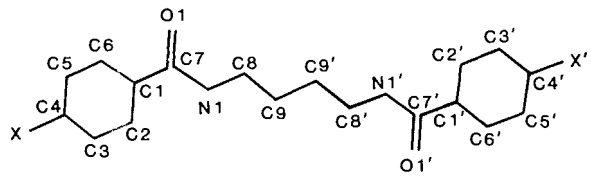

FIG. 1. Schematic representation of the molecules and atomic numbering.

1534 cm^{-1} in agreement with the observed one-dimensional ribbon-like structure (Fig. 3*a*).

The amide II band in 4DBN-*p*-*t*Bu is a doublet at 1555–1551 cm^{-1}. This value compares very well to that of 1562 cm^{-1} reported for 2DBN a molecule whose packing is identical to that of 4DBN-*p*-*t*Bu (Fig. 3*b*). In this arrangement each molecule forms one H bond with four distinct molecules (5) as opposed to the ribbon-like packing of 4DBN and 4DBN-*p*-*t*Bu where each molecule forms two H-bonds with each of two different molecules. In the case of 4DBN-*p*-CN, the amide II band is observed split at 1542–1559 cm^{-1}. Normally, one would expect an absorption band at ~1535 cm^{-1} since the hydrogen-bonded 4DBN-*p*-CN molecules form extended ribbons (Fig. 3*c*). However, the CN group is strongly electroattractive and this affects the frequency of the amide II band. It is this characteristic of the CN group which is also responsible for the extremely short N...O bond. Its length of 2.402(4) Å is significantly shorter than in the other *n*DBN's for which it is observed in the range of 2.8 to 3.0 Å.

(2) The amide V band

In a previous study (9) of non-substituted model compounds of the *n*T Nylons, it was proposed that the τ torsion angle was related to the position of the absorption of the amide V band. For $\tau \simeq 180°$, the absorption was observed in the lower frequencies, in the range 642–652 cm^{-1} while for $\tau \simeq 90°$, the absorption was shifted to the 664–675 cm^{-1} range. Since for 4DBN-*p*-OMe, the absorption of the amide V band is at 642 cm^{-1}, one may conclude that τ is near 180°. This is in good agreement with the observed τ value of 173.4(2)°. On the other hand, in the solid

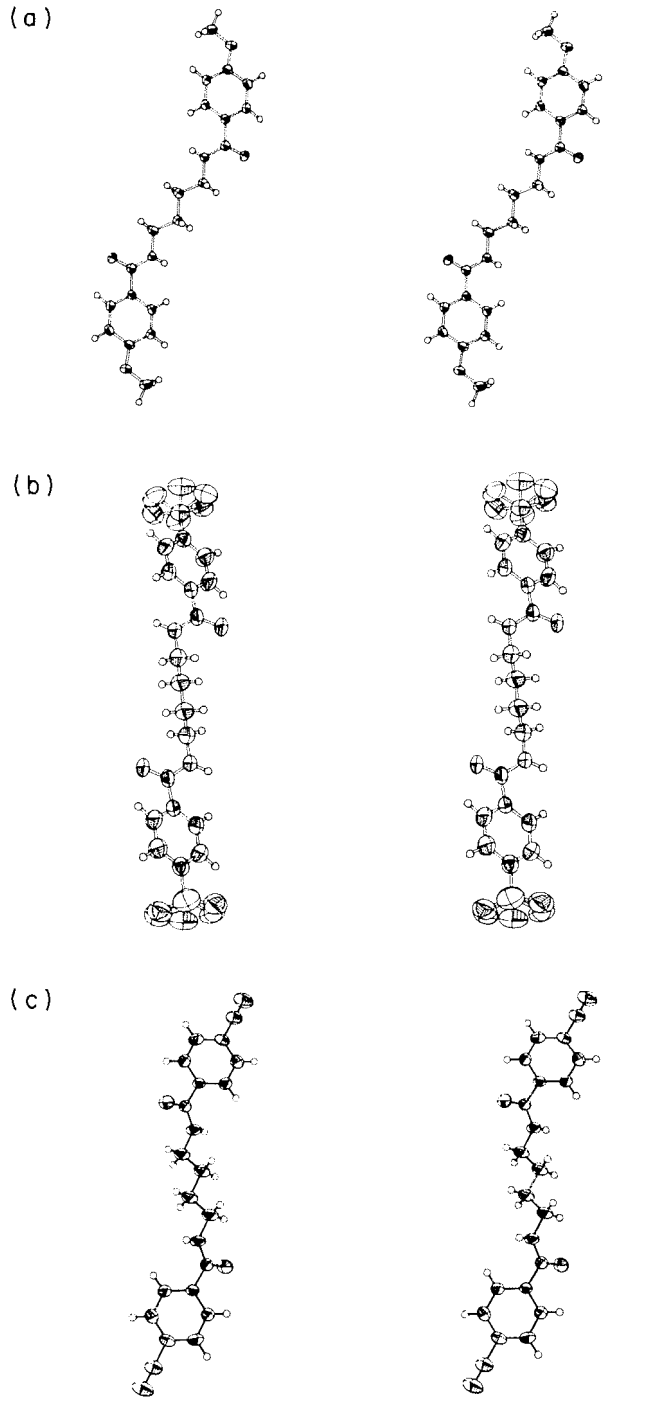

FIG. 2. Stereopairs showing the molecular conformation of (*a*) 4DBN-*p*-OMe, (*b*) 4DBN-*p*-*t*Bu, and (*c*) 4DBN-*p*-CN.

state 4DBN-*p*-*t*Bu and 4DBN-*p*-CN have τ values of 79.8(2)° and −120(4)°, respectively. The corresponding amide V frequencies should be in the 664–675 cm^{-1} range but are observed at 697 (4DBN-*p*-*t*Bu) or 690 cm^{-1} (4DBN-*p*-CN).

*(3) In the case of 4DBN-*p-*Me*, the amide II band observed at 1537 cm^{-1} points to a ribbon-like type of packing as observed for 4DBN. The amide V band is recorded at 657–662 cm^{-1}. We are unable to decide on the value of τ, since the amide V band falls in between the two above defined ranges for the τ torsion angle of 180 or 90°.

Solid-state ^{13}C nmr spectroscopy

The spectra of the model compounds studied appear in Fig. 4*A*. Since all the model compounds have a crystallographic center of symmetry at the mid-point of the aliphatic chain, only one peak is observed for each of the two symmetrically related carbon atoms. It is observed that, in most cases, C(7) of the amide group and C(8) of the aliphatic chain, which are both attached to the nitrogen atom, have doubled peaks. This is caused by the quadrupole moment of the nitrogen atom, which is not averaged out entirely by the rotation of the sample. It is also noted that the carbon signals of the methyl and *tert*-butyl groups are much more intense than those of the other carbon atoms. This is a common feature due to the rapid rotation of these specific groups in the solid state (Table 7).

(a) Chemical shift of atom C(9)

As can be seen in Fig. 4*Ba*, the chemical shift of the C(9) atom may be affected by the γ-*gauche* effect of the τ and ϕ_1' torsion angles. In their study of model compounds of 4GT, Grenier–Loustalot and Bocelli (18) reported that the γ-*gauche* effect related to a change of the torsion angle O—C(8)—C(9)—C(8′) from *trans* to *gauche* is of the order of −3 ppm. Their torsion angle is similar to our φ (and φ′) torsion angle. However, in all the *n*T Nylon model compounds whose structures have been established, the φ torsion angle is always *trans*. Thus there should not be any γ-*gauche* effect on the C(9) atom due to φ.

On the other hand, the torsion angle τ is *trans* for 4DBN and 4DBN-*p*-OMe whereas it has the values of 79.8(2) and −120.0(4)° for 4DBN-*p*-*t*Bu and 4DBN-*p*-CN, respectively (Table 5). A change of τ from ≈180° to ≈100° results in a γ-*gauche* effect of +1.8 ppm, since the chemical shifts for 4DBN and 4DBN-*p*-OMe are 27.3 and 27.6 ppm, respectively, whereas they are 29.1 and 29.4 ppm for 4DBN-*p*-*t*Bu and 4DBN-*p*-CN. In this case, the effect is towards low fields. However, it is normally found to be towards high fields as in the case of alkanes for which it has been observed in solution (19). This has been explained as resulting from a steric interaction between two methylenes in δ position from one another. In the present case, the methylene group C(9) is brought very close to the carbonyl group when τ is near 90° (Fig. 4*c*). This causes the methylene to be in the vicinity of the electron cloud circulating

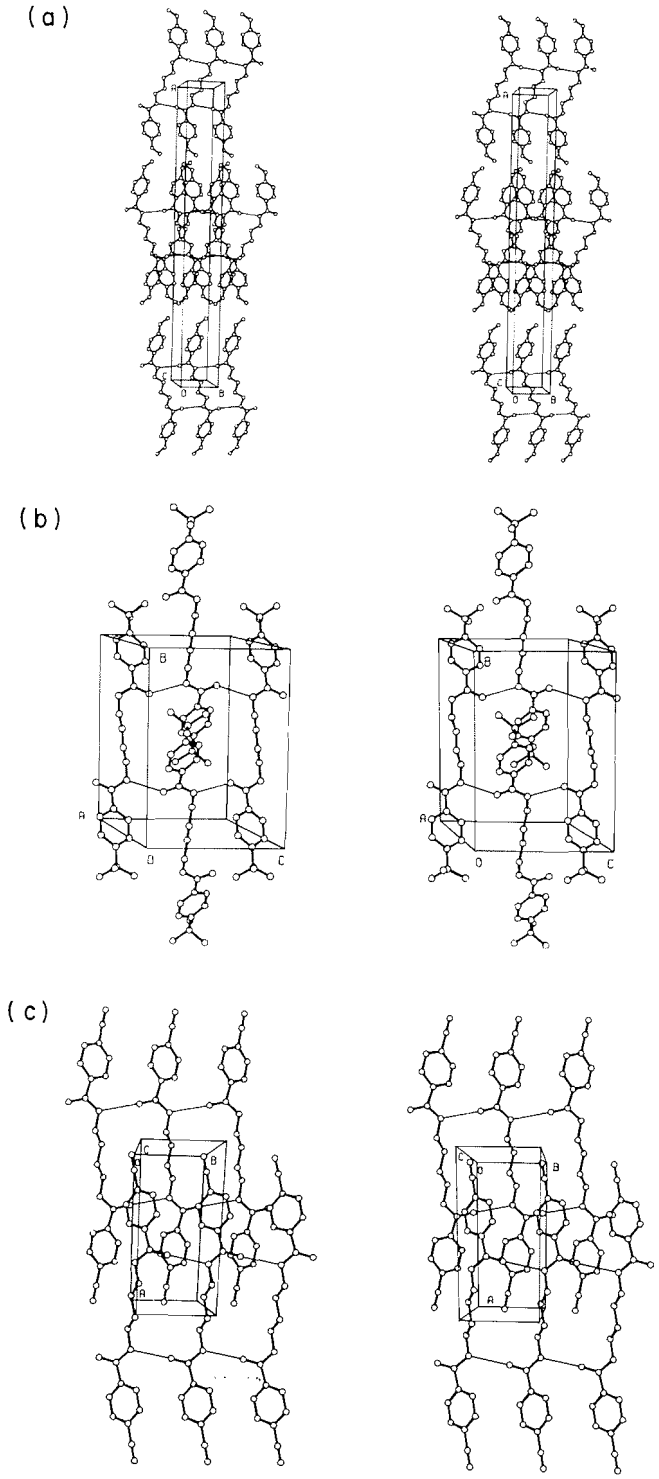

FIG. 3. Packing of the molecules. (*a*) 4DBN-*p*-OMe, (*b*) 4DBN-*p*-*t*Bu, and (*c*) 4DBN-*p*-CN.

about the amide group and could explain the deshielding γ-*gauche* effect of the τ torsion angle on the C(9) methylene group.

(b) Chemical shift of atom C(8)

The chemical shift of this atom should be affected by the γ-*gauche* effect related to the ω and ϕ_2 torsion angles. Both these angles are close to 180° in all the structures analyzed here. Consequently, if the γ-*gauche* effect were the sole factor involved, it would be expected that the chemical shift of the C(8) would remain constant. Nevertheless, the mean chemical shift of the split peak varies significantly. For 4DBN and 4DBN-*p*-OMe, it is observed at 43.3 and 44.4 ppm, but for 4DBN-*p*-CN and 4DBN-*p*-*t*Bu it is observed at 40.4 and 41.6 ppm, respectively. Since the difference is approximately 3 ppm, it can hardly be attributed to the inaccuracy of the measurements. This observation is interpreted as a molecular packing interaction effect. In a previous study of polypropylene a chemical shift difference of about 1 ppm was attributed to van der Waals interactions (20). Similarly, chemical shift differences of approximately 1 ppm have been observed between the orthorhombic and triclinic forms of polyethylene which have also been attributed to differences in intermolecular interactions (21). In the case of *n*T Nylons and of their model compounds, we must also take into account possible interactions between the electron cloud surrounding the benzamido group and the aliphatic and amide sections of neighbouring molecules.

The packing modes of 4DBN (Fig. 4*Da*) and 4DBN-*p*-OMe (Fig. 3*a*) are comparable. The molecules, assembled in ribbons, are placed in such a way that the atoms of the amide group and the aliphatic chain are far from the aromatic rings of neighbouring molecules. However, in the case of 4DBN-*p*-CN and 4DBN-*p*-*t*Bu (Fig. 3*b*,*c*), although the molecular packings differ greatly, both molecules have in common the fact that the C(7)—N—C(8) section of one molecule is facing the aromatic moiety of neighbouring molecules. It is proposed that the observed difference of +3 ppm could be due to the position of the C(8) atom in relation to the aromatic rings of adjacent molecules. This effect has been quantified in solution state and has been calculated (22) by the relation:

$$\Delta\delta(\text{ppm}) = \mu(1 - 3\cos^2\Phi)r^3$$

where μ is the equivalent dipole, Φ is the angle between the dipole axis and the atom (in degrees), and *r* is the distance (in Å) between the center of the aromatic ring and atom C(8).

In the case of 4DBN-*p*-CN where $\Phi = 15°$ and $r = 3.8$ Å, we estimated a value of $\Delta\delta$ of -1.8 ppm for this interaction using a value of μ of 27.0 (23). This compares relatively well with the observed value of $\Delta\delta$ of -2.9 ppm relative to 4DBN, since the van der Waals interactions account for the difference of 1.1 ppm observed between 4DBN-*p*-OMe and 4DBN.

(c) Chemical shift of atom C(7)

The chemical shift of atom C(7) is influenced by the value of the τ torsion angle as well as by the molecular packing, as was the case for atom C(8). However, the chemical shift is also influenced by the substitution of the aromatic ring. These combined factors make the interpretation of the chemical shifts of atom C(7) difficult.

On Fig. 4*Bc*, one can see that the chemical shift of C(7) should be influenced by the γ-*gauche* effect due to the τ torsion angle. The interchain interactions should be of the same order of magnitude as for the C(8) and N atoms. Since the γ-*gauche* effect and the interchain interactions are of similar values but of opposite signs, it is expected that the chemical shifts of C(7) should be roughly the same for the four model compounds. We observe a mean value for the doublets ranging from 168.1 ppm for 4DBN-*p*-OMe to 169.3 ppm for 4DBN-*p*-*t*Bu. However, in the case of 4DBN-*p*-CN, this mean value is of 166.7 ppm. The strongly electron-withdrawing capability of the cyano substituent, may account, in part, for the shielding of C(7).

Because of this additional factor involved in the case of the chemical shift of C(7), care should be taken when comparing the

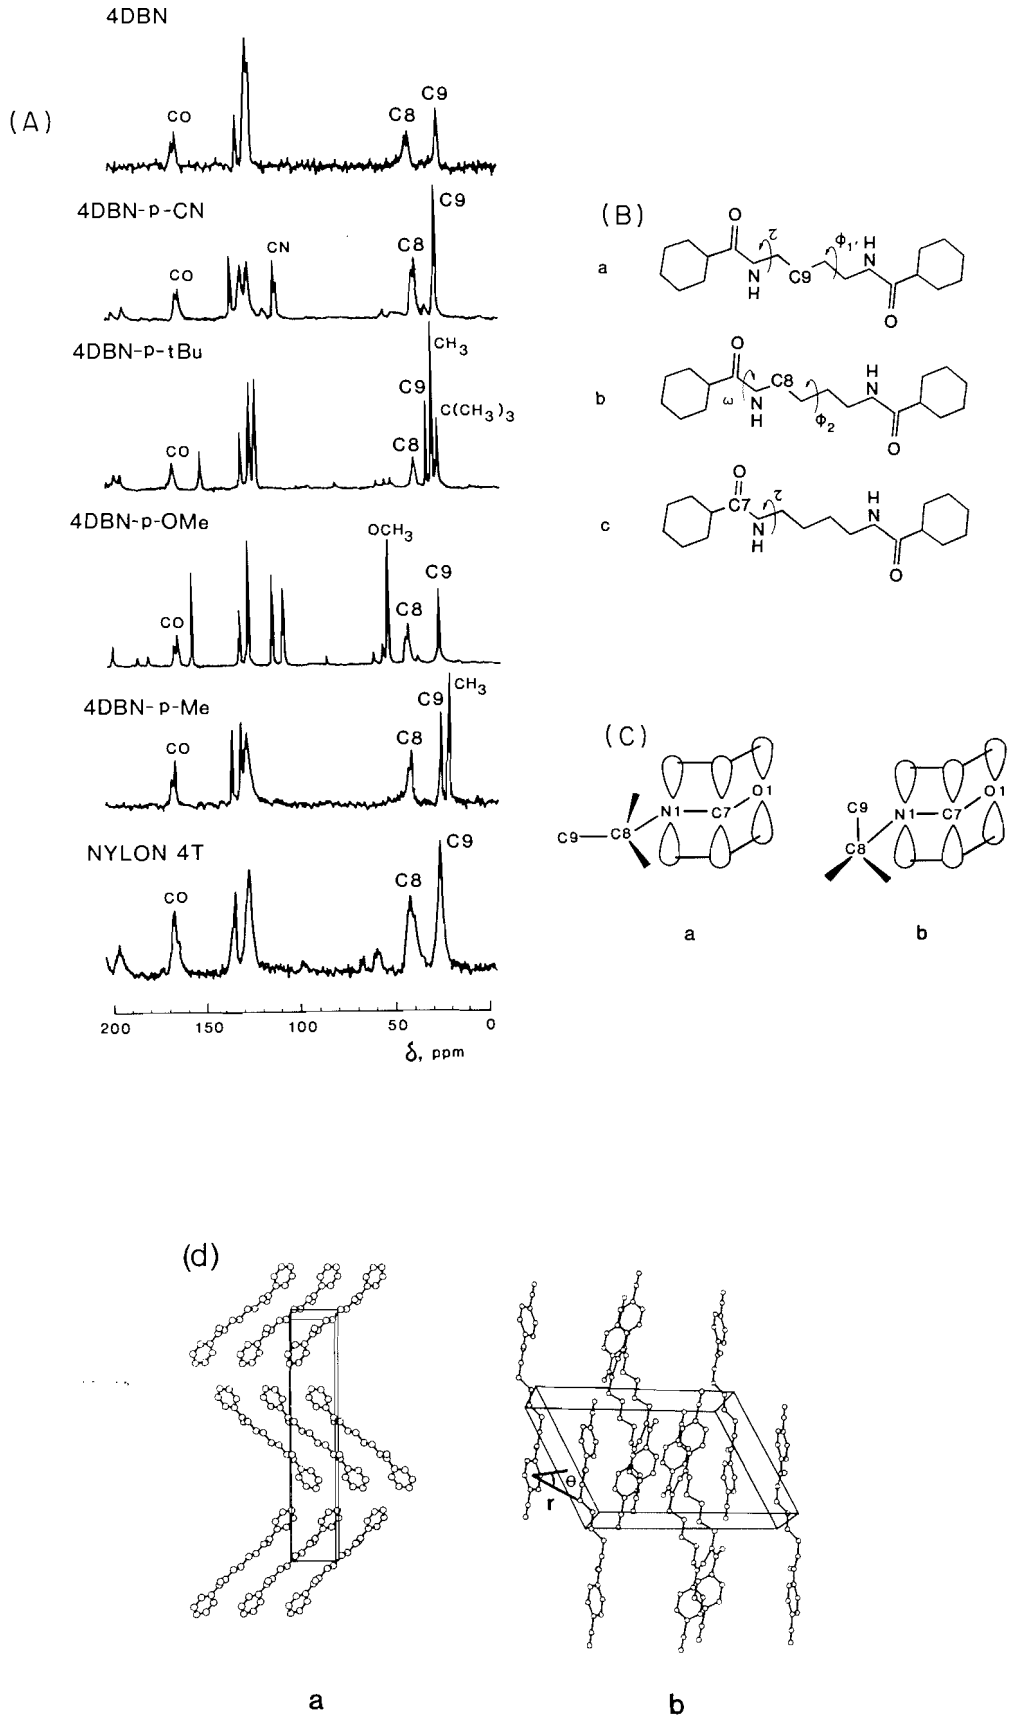

FIG. 4. (*A*) CP/MAS ^{13}C nmr spectra of 4T Nylon and its model compounds. The unidentified peaks in the 120–160 ppm region are due to the aromatic carbon atoms. (*B*) γ-*gauche* effect: (*a*) on C(9), (*b*) on C(8), (*c*) on C(7). (*C*) Relative disposition of the atoms involved in the τ torsion angle: (*a*) $\tau = 180°$, (*b*) $\tau = 90°$. (*D*) Comparison of the molecular packing of (*a*) 4DBN and (*b*) 4DBN-*p*-CN. Note the aromatic ring – methylenic chain interaction in the latter.

CP/MAS spectra of polymers to those of model compounds which have weakly interacting substituents, such as H, Me, or *t*Bu.

The structure of 4DBN-p-Me

The study of the model compounds whose structures are known has shown that: (*1*) the chemical shift of atom C(9) can be related directly to the torsion angle τ. This γ-*gauche* effect is of +2 to +3 ppm when $\tau \approx 90°$. It might also be affected by the ϕ_1' torsion angle, but this has not been quantified. It is assumed, on the basis of the study of Grenier–Loustalot and Bocelli (18) on related esters, that this effect should be approximately −3 ppm. (*2*) The chemical shift of atom C(8) is influenced by two main factors: the γ-*gauche* effect related to ϕ_2, which should be approximately −2 ppm, and the interchain interactions, more specifically the interaction of the electron cloud of the aromatic ring with C(8), which depends on the packing of the molecules.

Using this information, we should be able to determine the conformation, and possibly the type of interactions resulting from the packing mode.

The number of peaks observed for 4DBN-*p*-Me corresponds to an asymmetric unit composed of half a molecule, which implies a symmetry element in the middle of the aliphatic chain (most probably a center of symmetry as in all the model structures solved previously). Thus ϕ_2 should be near 180° and the chemical shift of C(8) should not be affected by the γ-*gauche* effect. Its mean value (43.7 ppm) is in the same range as observed for 4DBN and 4DBN-*p*-OMe, therefore corresponding to τ and ϕ_1' torsion angles in *trans* conformations. However, it must be noted that the combination of $\tau \approx 90°$ and $\phi_1' \approx 60°$ would lead to a similar chemical shift, and this hypothesis cannot be ruled out at this point.

Finally, since the substituent is not strongly electron withdrawing or donating, we can use the C(7) chemical shift. We have already established that there is no notable aromatic interaction with C(8)—N—C(7). The sole remaining effect on C(7) is the γ-*gauche* effect of τ. The mean chemical shift of this atom is 168.8 ppm, which compares well with that of 4DBN which was 169.0 ppm. This argument supports the hypothesis of τ and ϕ_1' in *trans* conformation. In conclusion 4DBN-*p*-Me has a structure similar to that of 4DBN. This is supported in part by the analysis of its infrared spectra.

Extension to the parent polyamide, 4T Nylon

The fiber diffraction pattern of 4T Nylon reveals a limited number of diffraction spots to a d_{min} value of 1.90 Å. The strongest reflections, which are well resolved, appear on the equator. There are, however, enough diffraction spots on the meridian and the upper levels to evaluate the value of the fiber repeat, p_0 = 13.2(1) Å. In this study of model compounds of 4T Nylon as well as in (10) it has been observed that ϵ, the dihedral angle between the amide group of atoms, [C(1), C(7), N(1), O(1)], and the benzene ring is always very near ±30°. The fiber repeat calculated for a chain of 4T Nylon constructed using average values of the bond distances and angles, taken from the above described model compounds, and with ϵ = 30 or −30° has a value of 13.5 Å. As it can be observed in Table 5, the ω, ϕ_1, and ϕ_2 torsion angles in the model compounds always assume values near 180°. The τ torsion angle, however, is the most flexible since it has values of about 80, 120, or 180°. The same behavior of the torsion angles has been noted for other *n*DBN's (10). Thus we have chosen to calculate the fiber repeat, p_c, as τ was varied from −180 to 180°. In this manner (Fig. 5)

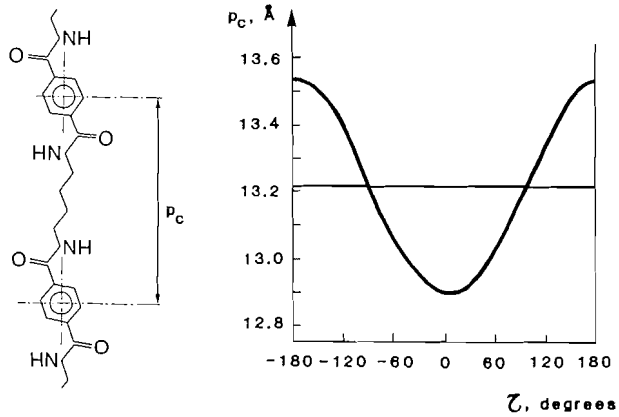

FIG. 5. Variation of p_c vs. τ for ϵ = 30°. The horizontal line corresponds to the experimental value, p_0 = 13.2 Å, of the fiber repeat.

when τ takes the values of 90° or −90°, the observed and calculated fiber repeats are perfectly matched. We conclude that the 4T Nylon structure has the conformation *tgtttg*$^-$*t*. It is indeed very reassuring that $\tau = \pm 90°$ is a very common occurrence among the *n*DBN's (10).

It is also of interest to note that the amide V band of the infrared spectra of both 4T Nylon and 4DBN-*p*-*t*Bu is observed at 700 and 697 cm^{-1}, respectively, and that the conformation of the model compound is *tgtttg*$^-$*t*, the same as that proposed here for the polyamide.

The frequency of the amide II band of 4T Nylon at 1545 cm^{-1} indicates that the polyamide chains are connected through H bonds so as to form sheets where the chains, parallel to one another, extend in one direction while they are "cross-linked" by H bonds in the perpendicular direction.

Conclusions

This series of model compounds of 4T Nylon has led to very promising conclusions. We have observed, using X-ray diffraction, that the τ torsion angle may take a value near 90°. We have also verified that the interpretation of the ir spectra of an earlier study of model compounds (10) is in agreement with the observations on *para*-substituted compounds. Finally, we have quantified two important factors affecting the chemical shift of these model compounds; the γ-*gauche* effect related to the τ torsion angle and the presence of a 2 to 3 ppm shift which is attributed to a specific interchain interaction between an aromatic ring and the C(7)—N(1)—C(8) group of atoms from a neighbouring molecule. This information, combined with that of the literature, led us to propose a structure for 4DBN-*p*-Me whose structure is not presently known.

The solid-state ^{13}C CP/MAS nmr spectroscopy is being used more and more for obtaining conformational information on the crystalline phase of various polymers. However, it must still be used with circumspection, especially in the case where aromatic rings are present. We have shown that in such cases, interchain interactions can be responsible for chemical shifts comparable in size to the γ-*gauche* interactions. This can significantly complicate the analysis of the spectra. The analysis of spectra of model compounds should enable us to quantify such effects and to use the conformation information from such a study for predicting that of polymers of unknown crystal structures.

The proposed conformation, *tgtttg*$^-$*t*, for 4T Nylon is in agreement with that obtained by infrared spectroscopy and is consistent with the X-ray data.

Effect of precipitation inhibitors on calcium phosphate scale formation

ZAHID AMJAD

The BFGoodrich Company, Specialty Polymers and Chemicals Division, Avon Lake Technical Center, Avon Lake, OH 44012, U.S.A.

Received July 12, 1988

ZAHID AMJAD. Can. J. Chem. **67**, 850 (1989).

The highly reproducible pH-stat technique was used to study the influence of various types of inhibitors on the precipitation of calcium phosphate from solution. Three types of inhibitors were evaluated: (*1*) homo- and copolymers of acrylic acid, (*2*) polyphosphate and phosphonates, and (*3*) polycarboxylic acids. Experimental variables studied included pH, temperature, and inhibitor dosage all of which were found to greatly affect the precipitation of calcium phosphate. The role of polyacrylic acid molecular weight is addressed. Comparative data for the various types of inhibitors is discussed.

Key words: precipitation inhibitors, calcium phosphate scale formation.

ZAHID AMJAD. Can. J. Chem. **67**, 850 (1989).

On a utilisé la très reproductible technique du "pH-stat" pour étudier l'influence de divers types d'inhibiteurs sur la précipitation du phosphate de calcium à partir de solutions. On a évalué trois types d'inhibiteurs: (*1*) des homo- et des co-polymères de l'acide acrylique, (*2*) du polyphosphate et des phosphonates et (*3*) des acides polycarboxyliques. On a étudié l'influence des variables expérimentales suivantes: le pH, la température et la concentration des inhibiteurs; on a trouvé que tous ces facteurs avaient une grande influence sur la précipitation du phosphate de calcium. On a aussi examiné le rôle du poids moléculaire de l'acide polyacrylique. On discute de données comparatives concernant les divers types d'inhibiteurs.

Mots clés : inhibiteurs de précipitation, formation des écailles du phosphate de calcium.

Introduction

Formation of mineral scales on equipment surfaces is a problem in many areas such as industrial water systems, secondary oil recovery utilizing water flooding techniques, desalination, and clothing washing machines. Precipitation of mineral salts such as calcium carbonate results in incrustation on clothes washed with hard water. Among the problems caused by scale deposits are obstruction of fluid flow, impedence of heat transfer, wear of metal parts, localized corrosion attack, and unscheduled equipment shutdown. The scales consist primarily of carbonates, sulfates, hydroxides, phosphates, and silicates of alkaline earth metals, particularly calcium and magnesium. The problem of scale formation is intensified at higher temperatures because of the peculiar inverse temperature – solubility characteristics of these minerals in water.

In addition to scaling problems, cooling water systems and boilers constructed of carbon steel also experience corrosion problems caused by the presence of dissolved oxygen. In the past, this corrosion problem was combated using chromate compounds. More recently, polyphosphate/orthophosphate compounds have been replacing chromates because of the toxicity problems associated with chromates. However, the use of phosphate compounds adds to scale formation of highly insoluble calcium phosphate.

Recently, the problem of calcium orthophosphate scaling in industrial water system has become increasingly important (1–3). Higher orthophosphate levels are being encountered in cooling waters due to increased water reuse, use of low quality make-up water such as waste water treatment plant effluent and the use of organic phosphonate scale and corrosion inhibitors which are degraded to orthophosphate. The increased orthophosphate levels, combined with alkaline operating conditions can lead to the formation of highly insoluble calcium phosphate scale deposits which are normally attributed to hydroxyapatite ($Ca_5(PO_4)OH$,HAP). In cooling water systems, however, it is not the HAP which is initially formed, but instead a precursor phase is obtained which is widely known as amorphous calcium phosphate.

The influence of trace amounts of polyphosphates and phosphonates on the precipitation of calcium phosphate has been the subject of numerous investigations. Results of previous studies have shown that hydroxyethane 1,1-diphosphonic acid, HEDP, is an effective inhibitor when added to barium sulfate (4), calcium fluoride (5), calcium carbonate (6), and calcium oxalate (7). However, with more soluble calcium sulfate dihydrate, this inhibitor appeared to have only a slight effect on the growth kinetics (8). Varsanik (9) reported that among various phosphonates studied in laboratory and pilot plant experiments, HEDP was the most effective inhibitor for limiting calcium phosphate scale formation. However, system pH had a dramatic effect upon inhibitor effectiveness. At neutral pH values, the performance of aminotri(methylene phosphonic acid), AMP, was comparable to that of HEDP.

The effect of trace amounts of polymeric scale inhibitors on both the rate of precipitation and crystal modification of scale forming minerals has been the subject of numerous investigations (10–12). McCartney and Alexander (10) showed that polymers containing carboxyl groups such as carboxymethyl cellulose, aliginic acid, polymethacrylic acid, and polyacrylic acid (PAA) were particularly effective as $CaSO_4 \cdot 2H_2O$ crystal growth inhibitors. Electrophoretic studies (11) suggest that the inhibitory effect of polyelectrolytes such as PAA (11), is due to the adsorption of the molecules on the surfaces of calcium sulfate crystals. Amjad (12), in a recent study on the influence of polyacrylic acids (PAAs) in controlling $CaSO_4 \cdot 2H_2O$ scale formation on heat transfer surfaces, reported that the molecular weight (mol wt) plays an important role on the inhibitory effect of PAAs on $CaSO_4 \cdot 2H_2O$ (gypsum) crystal growth from aqueous solution.

The work discussed in this paper focuses on the precipitation of calcium phosphate in the presence of PAAs of varying molecular weights over a range of temperature, pH, and polymer concentration using a pH-stat technique. The influence of functional groups originating from the monomers, other than carboxylic acid attached to the polymer backbone, on the inhibiting activity of the polymers has also been investigated.

TABLE 1. Inhibitors tested

Description	Acronym
Polymers	
Acrylic Acid (AA) homopolymers	PAA
AA/methacrylic acid (MAA) copolymer	AA/MAA
AA/carbitol acrylate (E)	AA/E
Polyphosphate and phosphonates	
Sodium pyrophosphate	PP
Aminotri (methylene phosphonic acid)	AMP
Hydroxyethane 1,1-diphosphonic acid	HEDP
Polycarboxylic acids	
Benzene hexacarboxylic acid or mellitic acid	MA
1,3,5-Benzene tricarboxylic acid (trimesic acid)	TMA
Citric acid	CA

For quantitative comparison, precipitation studies were also performed in the presence of polyphosphates, phosphonates, and polycarboxylic acids (e.g., citric acid, benzene hexacarboxylic acids, etc.). Table 1 identifies the inhibitors used in this study. As shown, the inhibitors vary appreciably in terms of both the functional group and the molecular weight. The purpose of this study was to quantify the effectiveness of these inhibitors and provide an explanation for the mechanism of inhibition of calcium phosphate precipitation in aqueous systems.

Experimental

Grade A glassware and reagent grade chemicals were used. Stock solutions of calcium chloride and disodium hydrogen phosphate were prepared using distilled water, filtered through 0.22 micron filter paper (Millipore Corp.) and analyzed for calcium and phosphate as described previously (9). Sodium pyrophosphate (PP) and citric acid (CA) were prepared from reagent grade chemicals. The AMP and HEDP used in this study were provided by The Monsanto Company. The polymeric inhibitors used were selected from commercial and experimental materials supplied by The BFGoodrich Company, Specialty Polymers and Chemicals Division. Polymer solutions were prepared on a dry weight basis. The desired concentrations were obtained by dilution.

Subsaturated calcium phosphate solutions were prepared in a double-walled glass cell maintained at constant temperature by adding stock solutions of calcium chloride and disodium hydrogen phosphate to the distilled water to attain initial calcium and orthophosphate concentrations of 140 and 9.0 parts per million (ppm), respectively. Spontaneous precipitation was induced by raising the pH of this acidic solution with 0.10 *M* NaOH. The pH of the solution was maintained at a constant value (±0.01) using a Metrohm pH stat (pH meter Model 632, dosimat Model 655, impulsomat Model 616, Brinkmann Instruments, Westbury, NY). Hydrogen ion measurements were made with a combination electrode equilibrated at the required temperature. The electrode was calibrated before and checked after each experiment using NBS standard buffer solutions. The solutions were continuously stirred with a Teflon-coated stirring bar at ~400 revolutions per minute. Experiments involving inhibitors were performed by adding the inhibitor to the subsaturated calcium phosphate solution before inducing spontaneous precipitation. Precipitation of calcium phosphate in this supersaturated solution was monitored by analyzing aliquots of the filtered (0.22 micron filter paper) solution for phosphate by spectrophotometric method (9).

Percent inhibition attained was then calculated using the following equation:

$$[1] \quad \% \text{ Inhibition} = \frac{(PO_4)_{exp} - (PO_4)_{final}}{(PO_4)_{initial} - (PO_4)_{final}} \times 100$$

where

$(PO_4)_{exp}$ = concentration of phosphate in the filtrate in presence of the inhibitor at known time

$(PO_4)_{final}$ = concentration of phosphate in filtrate in absence of the inhibitor at 20 h

$(PO_4)_{initial}$ = concentration of phosphate ion at the beginning of the experiment

Results and discussion

The initial conditions used and the results of typical precipitation experiments made in the presence of inhibitors are summarized in Table 2. The experiments reported here had good reproducibility (±6% or better). Initiation of precipitation by foreign particles, which are always present, does not seem likely, since the experiments were reproducible. Furthermore, the experiments were repeated after having filtered the solutions prior to mixing through 0.1 micron membrane filters without any change in the observed results. However, the possibility of heterogeneous nucleation on the walls of the glass vessels used cannot be precluded, although experiments were conducted in two different experimental set-ups.

Effect of concentration of polyacrylic acid

Results of precipitation experiments made in the presence of varying concentrations (5–50 ppm) of polyacrylic acid (PAA-1, mol wt 2 100), are summarized in Table 2 and shown in Fig. 1. It can be seen (Fig. 1) that the precipitation reaction in the presence of 15 ppm of PAA-1 is reduced by ~50% compared to that in the absence of PAA-1. Figure 1 further indicates that an increase in polymer concentration results in an increase in inhibition value and at 50 ppm of polymer concentration, the precipitation of calcium phosphate was completely inhibited (>95% inhibition) for at least 20 h.

Effect of polyacrylic acid molecular weight

Recently the influence of PAAs as antiscalants for controlling scale formation in industrial water systems has attracted the attention of several investigators. It has been shown that one of the factors determining the effectiveness of PAA is its mol wt (12–14). Based upon the results for similar mol wt polyelectrolytes, Smith and Alexander (15) reported that PAA was more effective than polymethacrylic acid in inhibiting the precipitation of calcium sulfate from supersaturated solutions. Furthermore, growth inhibition results for series of experiments with styrene/maleic anhydride copolymers suggest an optimum effectiveness at a mol wt of 1 600.

Precipitation experiments made in the presence of PAAs of varying mol wt (2 100 – 60 000) are summarized in Table 2. Figure 2 shows precipitation curves in the presence of 10 ppm of various PAAs. The curves in Fig. 2 show that at constant temperature and polymer concentration, the phosphate inhibition value increases with decreasing mol wt, reaches a maximum at a mol wt about 2 100, and thereafter decreases with decreasing mol wt (2 100 to 800). It is interesting to note that Amjad and Masler (14) in their study on the evaluation of PAAs (mol wt 800 – 12 000) as $CaSO_4 \cdot 2H_2O$ crystal growth inhibitors showed optimum performance with an ~2 000 mol wt PAA. Similarily, Amjad (12) in a recent study on the influence of PAA in controlling gypsum ($CaSO_4 \cdot 2H_2O$) scale formation on heat transfer surfaces, reported that the molecular weight of PAA plays an important role in the inhibition of $CaSO_4 \cdot 2H_2O$ crystal growth from aqueous solution. The amount of gypsum scale formed on heat exchanger surface was found to be higher

*See Table 1 for inhibitor acronyms. Note: the number following PAA- refers to the PAA's mol wt as follows: 1 = 2 100; 2 = 5 100; 3 = 800; 4 = 10 000; 5 = 26 000; 6 = 60 000. Experimental conditions: calcium = 140 ppm, phosphate = 9.0 ppm, pH = 8.50.

in the case of a high (240 000) mol wt PAA than that obtained on the presence of 2 100 mol wt PAA.

The phenomenon of a markedly decreasing PAA effectiveness with increasing mol wt as observed in the present study may be due to several factors including different rates and degrees of adsorption/desorption of PAA molecules on the precipitating calcium phosphate particles. Other factors such as coiling/uncoiling of the polymer molecule and the type of end groups in the polymer could also influence the adsorption processes. Adsorption studies are currently underway in our laboratories to better understand the role of PAA mol wt in inhibiting the precipitation of sparingly soluble salts from aqueous solutions.

Effect of polymer composition

The effect of polymer composition at a constant concentration of 10 ppm was studied using the pH-stat technique. The results are summarized in Table 2 and illustrated in Fig. 3. As shown in Fig. 3, the copolymer of acrylic acid/methacrylic acid (AA:MAA) shows better performance than PAA-4. For example, % inhibition values obtained for AA:MAA and PAA-4 are 5 and 15, respectively (expts. 29, 16). The slight performance increase observed for AA:MAA over PAA-4 may be attributed to the presence of additional methyl groups attached to carbon atoms between carboxylate carrying carbon atoms.

The next polymer in order of increasing inhibitor effectiveness is a copolymer of acrylic acid and an acrylate ester (carbitol acrylate) or AA/E. Compared with PAA, the acrylic acid segments for AA/E are partially substituted by a carbitol acrylate group. The carboxylic acid group concentration and thus the anionic charge density are significantly lower than PAA-4. The effectiveness of AA/E as calcium phosphate inhibitor (Table 2, expt. 22) is surprisingly better than PAA-4, suggesting that the carbitol acrylate group is more effective in improving the inhibitory activity of AA/E than the corresponding carboxyl group in PAA-4. Phosphate inhibition data (Table 2, expts. 16, 29, 22) indicate the following order of polymer effectiveness:

$$\text{AA/E} > > \text{AA/MAA} > \text{PAA}$$

Effect of temperature

The results on the effect of temperature on the inhibition of

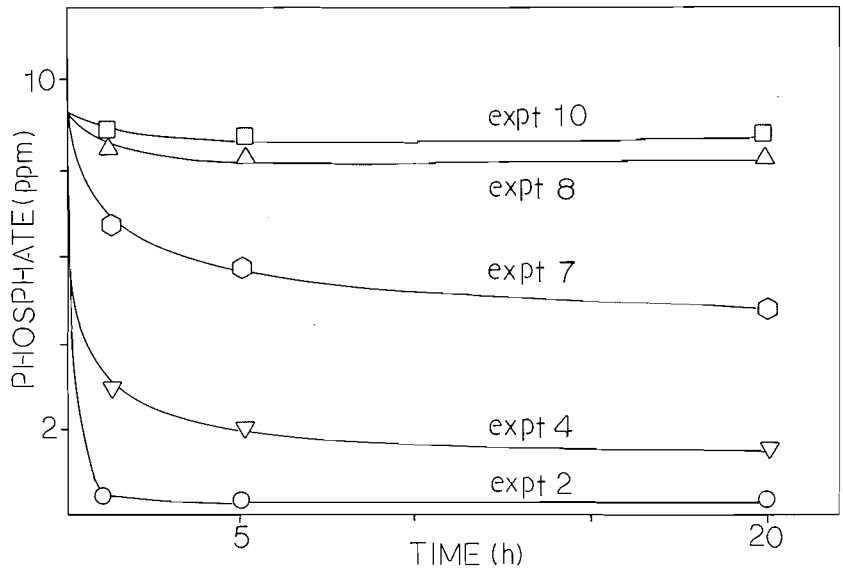

FIG. 1. Plots of phosphate concentration as a function of time at 50°C in the presence of PAA-1 of varying concentrations (ppm): (○) 0; (▽) 10; (⬡) 15; (△) 20; (□) 50.

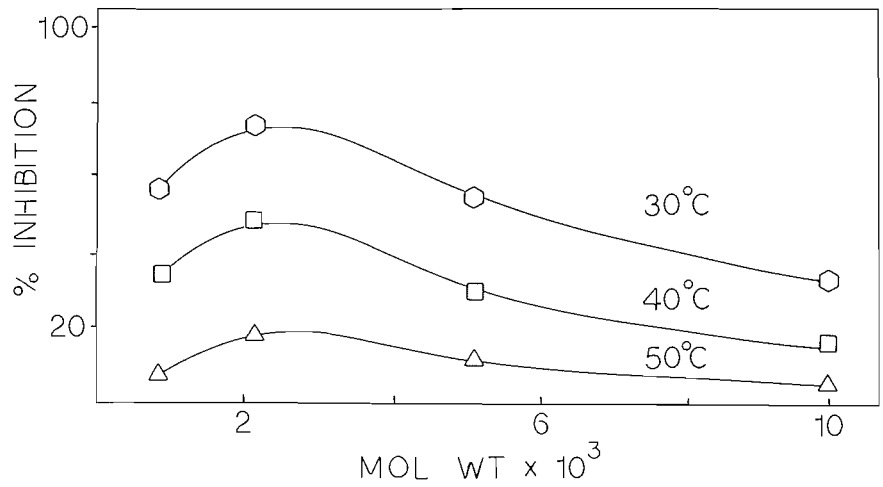

FIG. 2. Relationships of % inhibition with polyacrylic acid molecular weight for calcium phosphate inhibition at temperatures from 30–50°C.

calcium phosphate precipitation in the presence of PAAs are shown in Table 2. It can be seen (Table 2) that as the temperature is raised, there is a concomitant marked decrease in the phosphate inhibition. At a given calcium phosphate and PAA concentration, the relationship between the temperature and the phosphate inhibition can roughly be expressed quantitatively by an empirical equation:

$$[2] \quad \% \text{ Inhibition} = a(1/T) + b$$

where T is the absolute temperature; a and b are constants. The linear plots of % inhibition against $1/T$ for PAA-1 and PAA-2 are illustrated in Fig. 4.

Effect of solution pH

The influence of pH on the performance of several phosphonic acids as $CaSO_4 \cdot 2H_2O$ crystal growth inhibitors has been studied by seeded growth technique (16). Results of this study show that an increase in the pH of the crystal growth medium over a pH 4 to 9 range brings about an improvement in inhibitor performance that runs parallel to the phosphonic acid titration curve.

For polymeric inhibitors, such as polyacrylic acid and acrylic acid based copolymers, the degree of protonation should, just as phosphonate inhibitors, be considered in explaining their action. Unfortunately, their acid dissociation constants are not available. It can nevertheless be expected that the affinity of polymeric molecules towards the crystal surface should also be influenced by the solution pH due to the dissociation of carboxylic acid group.

The effect of the solution pH on the precipitation of calcium phosphate in the presence of 10 ppm of PAA-1 and AA/C polymers was studied using the spontaneous precipitation technique. Results are summarized in Table 3. Figure 5 compares phosphate inhibition values for PAA-1 and AA/E at pH 7.5, 8.0, and 9.0. As shown in Fig. 5, at pH 7.5, both polymers (Table 3, expts. 53, 55) exhibit excellent performance (>90% inhibition). However, at pH 8.5, AA/E shows 85% inhibition vs. 30% obtained for PAA-1 (Table 3, expts. 60, 61). Data presented in Table 3 also shows that increasing the solution pH to 9.0 does not significantly affect the performance of AA/E whereas a marked performance decrease occurs for PAA-1 (Table 3, expts. 62, 66).

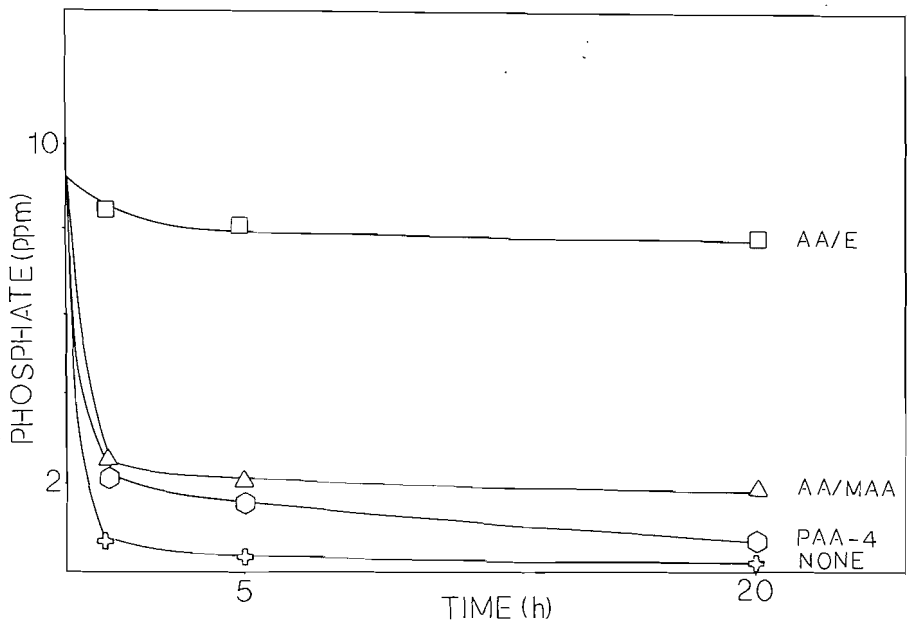

FIG. 4. Plots of phosphate concentration as a function of time at 50°C in the presence of 10 ppm of PAA-4, AA/MAA, and AA/E.

It is interesting to note that in the seeded growth study of $CaSO_4 \cdot 2H_2O$ in the presence of PAA, the inhibitory effect of PAA was found to increase with increasing solution pH (17). This is inconsistent with the results obtained in the present study. The observed difference in PAA performance for two different sparingly soluble salts as a function of solution pH may be explained in terms of differences in solubility values of calcium phosphate and calcium sulfate salts (i.e. an increase in solution pH results in an increased supersaturation in the case of calcium phosphate, whereas pH does not significantly affect the calcium sulfate supersaturation).

Effect of polyphosphate, phosphonate, benzene polycarboxylic acid, and citric acid

The inhibiting properties of condensed phosphates of both the meta- and polyphosphate types have been extensively studied in relation to scale formation and biological calcification processes. In the former case it has been shown that sodium pyrophosphate is an effective growth inhibitor when added to $CaCO_3$ (6) and $BaSO_4$ (18) systems. In biological calcification processes, pyrophosphate ion has been found to be an effective crystal growth inhibitor for calcium phosphate (19) and calcium oxalate (7) systems. A surface adsorption mechanism has been found useful in describing the effect of pyrophosphate in many of these systems.

Precipitation experiments made in the presence of pyrophosphate (PP) are summarized in Table 4. It can be seen (Table 4, expt. 47) that at 10 ppm, PP exhibits a smaller inhibiting effect compared to PAA-1 (Table 2, expt. 40). For example, % phosphate inhibition values obtained for PP and PAA-1 are 28 and 74, respectively. It is interesting to note that PP, which exhibits strong inhibitory effect for calcium oxalate (7), barium

sulfate (18), and calcium carbonate (6) systems, only has moderate inhibitory effect on calcium phosphate precipitation.

Organophosphonates such as HEDP have been found to markedly inhibit the crystallization of calcium carbonate (6), calcium oxalate (20) and barium sulfate (18). Inhibition data summarized in Table 4 show that AMP is a better inhibitor than HEDP. For example, % inhibition values obtained at 10 ppm inhibitor concentration, 30°C, and at 20 h for AMP and HEDP are 40 and 33, respectively. It is noteworthy that for HAP crystal growth in the presence of polyphosphates and phosphonates (19), the relative order of effectiveness reported was:

$$\text{HEDP} > \text{AMP} > \text{PP}$$

The above order of inhibitor effectiveness is inconsistent with the results obtained in the present study (expts. 47, 48, 49). It should be noted that for dicalcium phosphate dihydrate, (DCPD), seeded growth on DCPD seed crystals (21) in the presence of PP and phosphonates, the order of effectiveness suggested was:

$$\text{AMP} > \text{HEDP} > \text{PP}$$

The differences observed in the order of phosphonates effectiveness for HAP, DCPD, and this investigation, may be due to several factors including different rates of adsorption/desorption of inhibitors on different types of substrates.

Results summarized in Table 4 for the inhibitory effect of benzene hexacarboxylic acid (mellitic acid, MA) show that compared to PAA, MA is a moderately effective calcium phosphate inhibitor. However, under similar experimental conditions, MA exhibits a much greater effectiveness compared to citric acid (CA) but is significantly less effective than PAA-1. For example, % inhibition values obtained at 30°C for 10 ppm concentration of PAA-1, MA, trimesic acid, and CA are 74, 41, 5, and 1, respectively. These results are consistent with those reported by Coffey (22) which indicate that the best inhibitors for barium sulfate precipitation were those that imparted the most negative electrophoretic mobility to the barium sulfate particles. Similar observations have been reported in recent seeded growth studies on the effect of polycarboxylic acid on the crystal growth of calcium carbonate (23), dicalcium dihydrogen phosphate (24), and hydroxyapatite (25) from aqueous solutions.

Mechanism of inhibitor action

The results discussed above show that trace quantities of certain inhibitors markedly reduce the precipitation of calcium phosphate. The influence of these inhibitors on precipitation reaction may be explained in terms of three effects, (*a*) direct

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

complexation of inhibitor with crystal lattice ions in solution; (*b*) adsorption of inhibitor on the crystal surface either generally or at the active growth sites; (*c*) inhibitor may change the ionic strength of the solution and hence the effective solubility of the calcium phosphate.

Under the experimental conditions employed in the present investigation, the marked reduction in calcium phosphate precipitation must be attributed to surface adsorption factor rather than the calcium–inhibitor complex formation or the concomitant increase in ionic strength of the supersaturated solution in the presence of inhibitors.

If the action of the inhibitor, which stabilizes supersaturated solutions of calcium phosphate, is to be adsorbed on the crystal embryos and prevent their growth, the question arises why the nuclei do not go on forming until all the stabilizing material (i.e. inhibitor) has been used up, since the formation of nuclei involves a negligible change in the concentration of the solution. There are two possible reasons for this. Nucleation may take place only on a limited number of "stray nuclei", or it may be that the inhibitors stop development of the nuclei below the critical size and they redisperse, forcing the inhibitor to interact with other embryos. An adsorption mechanism is also indicated in many systems by an appreciable habit modification of crystals grown in the presence of impurities (12).

Summary

In the present work it has been shown that low levels of both polymeric and non-polymeric type inhibitors can significantly inhibit the precipitation of calcium phosphate from aqueous solution. The results on the performance of PAAs of varying molecular weight (800 to 60 000) suggest that optimum effectiveness for PAAs occurs at a mol wt ~2 000. The results of the present study also suggest that the inhibition of calcium phosphate precipitation strongly depends upon the concentration of polymer, solution pH, and polymer composition. In addition, it has also been shown that the presence of pyrophosphate, phosphonates, and mellitic acid at low concentrations can significantly inhibit calcium phosphate precipitation. A mechanism based upon surface adsorption has been proposed to explain the influence of inhibitors on calcium phosphate precipitation.

Hydrogen isotope exchange between D_2 and H_2O catalyzed by platinum plate

SHIN-ICHI MIYAMOTO, TETSUO SAKKA, AND MATAE IWASAKI
Institute of Atomic Energy, Kyoto University, Uji, Kyoto 611, Japan

Received May 26, 1988

SHIN-ICHI MIYAMOTO, TETSUO SAKKA, and MATAE IWASAKI. Can. J. Chem. **67**, 857 (1989).

The reaction rate of hydrogen isotope exchange between D_2 and H_2O catalyzed by platinum plate is studied. The exchange reaction is described with the kinetic model which is the modification of that for the exchange reaction catalyzed by alumina-supported platinum catalyst. For the comparison of experimental results with this model relative amount of the number of sites for hydrogen adsorption was estimated from the initial rate of hydrogen isotope exchange between H_2 and D_2 on the same surface. The results show that the kinetic model is applicable for the plate catalyst if the number of the sites for hydrogen absorption, which is very sensitive to the surface state of the catalyst, was estimated not from the macroscopic surface area but from our scheme.

Key words: hydrogen isotope exchange reaction, platinum plate as catalyst.

SHIN-ICHI MIYAMOTO, TETSUO SAKKA et MATAE IWASAKI. Can. J. Chem. **67**, 857 (1989).

On a étudié la vitesse de la réaction d'échange isotopique entre le D_2 et le H_2O, catalysée par une plaque de platine. On peut décrire la réaction d'échange grâce à un modèle cinétique qui est une modification de celui proposé pour la réaction d'échange catalysée par un catalyseur de platine supporté par de l'alumine. Pour faire une comparaison des données expérimentales avec ce modèle, on a évalué la quantité relative de sites pour l'adsorption d'hydrogène à partir de la vitesse initiale de l'échange des isotopes de l'hydrogène (H_2 et D_2) sur la même surface. Les résultats démontrent que le modèle cinétique peut être appliquer au catalyseur en plaque si on évalue le nombre de sites pour l'adsorption de l'hydrogène en se basant sur notre schéma et non pas sur la superficie de la surface macroscopique.

Mots clés : réaction d'échange des isotopes de l'hydrogène, plaque de platine comme catalyseur.

[Traduit par la revue]

I. Introduction

Catalytic behavior of platinum for hydrogen isotope exchange reaction between hydrogen and water in gas phase has been investigated by several researchers (1–7) and some related studies have been reported (8, 9). Most of the researches, however, are confined to the investigations on the supported catalyst or the powder catalyst, which are often used in practical processes. In those systems catalytic behaviors of platinum itself become ambiguous, because the effect of support and the effect of particle sizes and shapes are not negligible (1, 2). The catalytic activity of the platinum surface itself remains unclear in these investigations.

The aim of the present study is to determine the catalytic activity of the surface of a platinum plate for the hydrogen isotope exchange between H_2O gas and D_2 gas and to clarify the reaction mechanism.

Previous works (10–12) revealed that the factors for surface activity, such as microscopic roughness and contamination by oxygen, influence the catalytic reaction on platinum. It is shown that the kinetic phenomena, such as sticking rate of hydrogen or H_2/D_2 exchange reaction rate, are enhanced by the microscopic surface roughness, such as steps or kinks, in the investigation of the surface of single crystal platinum (10).

Pretreatment conditions of catalyst play an important role in the catalytic activity (12). In our experiments the obtained data varied considerably among runs performed under the same experimental conditions. This result indicates that the surface activity of the platinum plate used differs from one run to another, and it is not easy to control the surface activity by the pretreatment made in this study. We then tried to evaluate the surface activity by relative intensity of the number of the sites for the hydrogen absorption, which was estimated by measuring the exchange rate between H_2 and D_2. The evaluation of the surface activity was done before each run for the exchange reaction between D_2 and H_2O. Using these evaluated values of surface activity, we could obtain reasonable kinetic relationships for the isotope exchange between D_2 and H_2O without it being affected by the initial surface state of the platinum plate used in each run.

In Section II, the experimental procedure and experimental results are described. In Section III the model for the hydrogen exchange reaction on the surface of the platinum plate is described. The method of the estimation of the surface state and the examination of the model are also described. In Section IV, the model was examined and some parameters are obtained. Furthermore, some comments on the experimental results and on the model are described, and a comparison between supported catalyst and platinum plate catalyst is made.

II. Experimental procedure and results

The rate of the hydrogen isotope exchange between H_2O and D_2 on a platinum plate at high temperature is determined by the analysis of D_2, HD, and H_2 in a sample container using a quadrapole mass spectrometer, Nichiden Anelva model AQA-100MPX.

The apparatus used is illustrated in Fig. 1. The whole manifold of the apparatus was made of Pyrex glass, and vacuum gauge heads were isolated from the sample gas by glass cocks. As a blank test, the occurrence of the exchange reaction in the whole apparatus was examined. This test shows that no reaction occurs without the platinum plate.

Polycrystalline platinum plate (99.99% in purity, 32.0 cm^2 macroscopic surface area, obtained from Fukuda Kinzoku Hakufun Ltd.) was used. Contamination of the surface of the plate was removed by boiling in concentrated nitric acid for 20 min. The plate was set in a reaction chamber made of silica glass tubing. The volume of the chamber was 310 cm^3.

The whole system was baked at 200°C for 7 h. The base pressure of the reaction chamber was 10^{-4} Pa. The base pressure of the quadrapole mass spectrometer became 3×10^{-6} Pa by differential evacuation.

D_2 gas, 99.5% in purity, containing H_2 as main impurity was

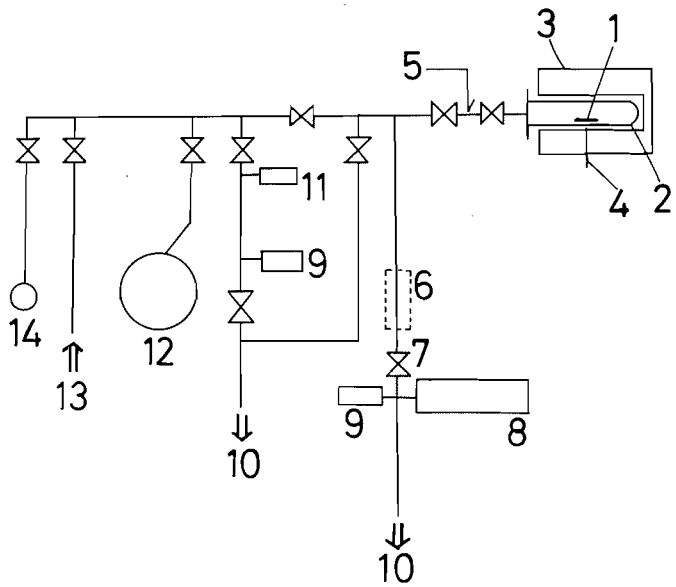

FIG. 1. Experimental setup for the measurement of the rate of hydrogen isotope exchange between D_2 and H_2O catalyzed by platinum plate. The numbers in the figure correspond to the following components: *1*, platinum plate; *2*, reaction chamber; *3*, electric furnace; *4*, chromel–alumel thermocouple; *5*, sampling room; *6*, liquid-N_2 trap; *7*, leak valve; *8*, mass spectrometer; *9*, ion gauge; *10*, diffusion pump; *11*, Pirani gauge; *12*, Macleod gauge; *13*, D_2; *14*, H_2O.

introduced to the apparatus to a given pressure. The pressure was measured with a Macleod pressure gauge. The evacuation of water sample vessel was made after freezing its water by liquid nitrogen. The pressure of the water vapor was measured with a Pirani gauge.

Finally, the gases in the apparatus other than that in the reaction chamber were evacuated. The reaction chamber was heated with an electric furnace, and its temperature was controlled with a temperature regulator with chromel–alumel thermocouple attached to the outside of the silica glass tube just below the inserted platinum plate. The heating of the reaction chamber was completed within 1 min and the time at which the temperature became the set temperature was taken as the starting time of the reaction.

During the reaction, sample gas was collected intermittently into a sampling room (Fig. 1). After water vapor was removed from sample gas with a cold trap at liquid nitrogen temperature, the residual sample gas was introduced through a variable leak valve into the quadrapole mass spectrometer, and the ratio of D_2 to whole hydrogen gas was determined. The removal of water vapor was necessary to avoid its attack on an ion source filament.

By repeating this procedure, time dependence of the isotopic ratio of the hydrogen gas was obtained. Figure 2 shows the time dependence of the fraction of D_2 during the exchange reaction. The initial concentrations of D_2 and H_2O were both 5.38×10^{-1} mol/m^3 (this corresponds to 10.0 Torr at room temperature) and the reaction temperature was 773 K. Blank tests for reaction chamber show that silica glass is a suitable material for the reaction chamber, because it has no catalytic activity, but alumina is found to be unsuitable.

The experiments were carried out specifically at the early stage of the reaction. An example is shown in Fig. 3. In this run the initial concentrations of D_2 and H_2O were both 5.38×10^{-2} mol/m^3 and the temperature was 443 K. From the series

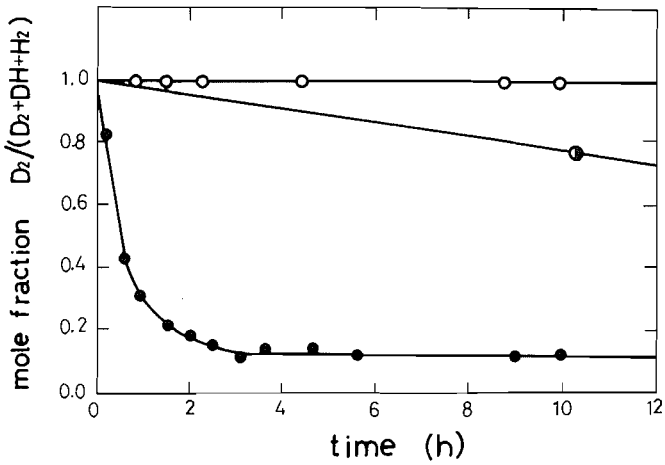

FIG. 2. Decrease in D_2 fraction by the exchange reaction between D_2 and H_2O in the alumina reaction chamber without platinum plate (half-filled circle), the silica reaction chamber without platinum plate (open circle), and the silica reaction chamber with platinum plate (filled circle) at 773 K. The initial concentrations of D_2 and H_2O were both 5.38×10^{-1} mol/m^3, which corresponds to a pressure of 10 Torr each.

of figures, of which an example is illustrated in Fig. 3, the initial rates of the exchange reaction were determined.

As will be mentioned in Section III, the number of the sites for hydrogen adsorption should be estimated before each run of the exchange reaction between D_2 and H_2O. The estimation was made through determining the initial rate of hydrogen isotope exchange between H_2 and D_2 before each run. The experimental procedure was similar to that of the reaction between D_2 and H_2O.

III. Kinetics of the exchange reaction

A. Kinetics of D_2/H_2O exchange reaction

The kinetic model for the reaction on the alumina-supported platinum catalyst proposed by Rolston and Goodale (1) is modified for the reaction on the platinum plate. The model contains five steps: the adsorption of a water molecule and the dissociative adsorption of a hydrogen molecule on the platinum surface, exchange reaction on the surface, the desorption of a water molecule and of a hydrogen molecule from the surface. It is assumed that the third step, i.e., the exchange reaction on the surface is rate controlling, and the other steps are in equilibrium. The early stage reaction process is as follows:

$$[1] \quad D_2(g) + 2S_1 \rightleftarrows 2D_{ads} \qquad K_1 = T_D^2/C_{D_2}[S_1]^2$$

$$[2] \quad H_2O(g) + S_2 \rightleftarrows H_2O_{ads} \qquad K_2 = T_{H_2O}/C_{H_2O}[S_2]$$

$$[3] \quad H_2O_{ads} + D_{ads} \xrightarrow{2k_3} HDO_{ads} + H_{ads}$$

$$[4] \quad D_{ads} + H_{ads} \rightleftarrows HD(g) + 2S_1 \qquad K_4 = C_{HD}[S_1]^2/T_D T_H$$

$$[5] \quad HDO_{ads} \rightleftarrows HDO(g) + S_2 \qquad K_5 = C_{HDO}[S_2]/T_{HDO}$$

where S_1 is the site for adsorption of dissociated hydrogen on the surface of platinum plate; S_2 is the site for physical adsorption of water; D_{ads} and H_{ads} are dissociatively adsorbed D and H, respectively; H_2O_{ads} is a physically adsorbed water molecule; K_1, K_2, K_3, and K_4 are equilibrium constants of reactions [1], [2], [3], and [4], respectively; $2k_3$ is a rate constant of the reaction [3]; C_{H_2O}, C_{HDO}, C_{D_2}, and C_{HD} are the concentrations of $H_2O(g)$, $HD(g)$, $D_2(g)$, and $HD(g)$, respectively; T_D, T_H, T_{H_2O}, and T_{HDO} are the number of D atoms, H atoms, H_2O

molecules, and HDO molecules adsorbed on the surface, respectively; and $[S_1]$ and $[S_2]$ are the number of the vacant sites on the platinum plate available for the adsorption of hydrogen atoms and water molecules, respectively. The symbol (g) means gaseous molecules. We have the following relations between the numbers of adsorbed species and the numbers of vacant sites,

$$[6] \quad [S_1]_0 = [S_1] + T_H + T_D$$

$$[7] \quad [S_2]_0 = [S_2] + T_{H_2O} + T_{HDO} + T_{D_2O}$$

where $[S_1]_0$ and $[S_2]_0$ are the overall number of the sites for the adsorption of hydrogen atoms and that for the adsorption of water molecules, respectively. We neglected the exchange reaction between the produced species, such as HDO or HD, because of their small concentration at the early stage of the reaction.

The rate of hydrogen isotope exchange between D_2 and H_2O is written as

$$[8] \quad v = -d[D_2]/dt = k_3 T_D T_{H_2O}$$

The initial rate of the reaction is

$$[9] \quad v_0 = (-d[D_2]/dt)_{t=0} = (k_3 T_D T_{H_2O})_{t=0}$$

Substituting eqs. [1] and [2] into eq. [9], we get

$$[10] \quad v_0 = k_3 K_1^{1/2} K_2 C_{D_2}^{1/2} C_{H_2O} [S_1][S_2]$$

Using eqs. [6], [1], and [4], we get

$$[11] \quad [S_1] = [S_1]_0 [1 + K_1^{1/2} C_{D_2}^{1/2} + C_{HD}/K_1^{1/2} K_4 C_{D_2}^{1/2}]^{-1}$$

and, using eqs. [7], [2], and [5], we get

$$[12] \quad [S_2] = \{[S_2]_0 - T_{D_2O}\}[1 + K_2 C_{H_2O} + C_{HDO}/K_5]^{-1}$$

Substituting eqs. [11] and [12] into eq. [10] and using the fact that at the early stage of the reaction,

$$C_{HD} = C_{HDO} = 0$$

and

$$T_{D_2O} = 0$$

we obtain

$$[13] \quad v_0 = a[S_1]_0$$

$$a \equiv k_3 K_1^{1/2} K_2 [S_2]_0 C_{D_2}^{1/2} C_{H_2O} / [1 + (K_1 C_{D_2})^{1/2}][1 + K_2 C_{H_2O}]$$

Notice that a depends on the temperature and concentrations of the reacting gases, and $[S_1]_0$ depends on the surface state of the platinum plate. Because the number of sites for the physical adsorption of water, $[S_2]_0$, is supposed to be independent of the surface state, a is independent of the surface state of the platinum plate.

B. Correction of $[S_1]_0$

For the evaluation of $[S_1]_0$ in eq. [13], we used the reaction of hydrogen isotope exchange between D_2 and H_2. Two mechanisms of this reaction are well-known: Rideal type (13) and Bonhoeffer–Farkas type (14). At high temperature the reaction proceeds in the former mechanism (15):

$$[14] \quad H_2(g) + 2S_1 \rightleftarrows 2H_{ads} \qquad K_{14} = T_H^2/C_{H_2}[S_1]^2$$

$$[15] \quad D_2(g) + 2S_1 \rightleftarrows 2D_{ads} \qquad K_{15} = T_D^2/C_{D_2}[S_1]^2$$

$$[16] \quad H_{ads} + D_{ads} \xrightarrow{k_{16}} HD(g) + 2S_1$$

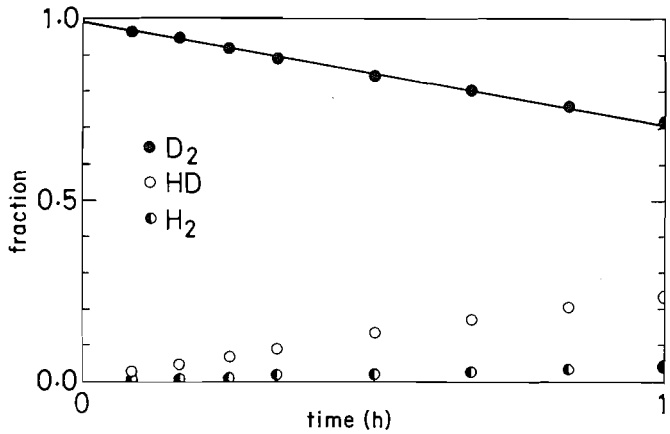

FIG. 3. An example of the figures for the determination of the initial rate of the reaction between D_2 and H_2O. In this run the initial concentrations of D_2 and H_2O were both 5.38×10^{-2} mol/m^3, which corresponds to 1 Torr each, and the temperature was 443 K.

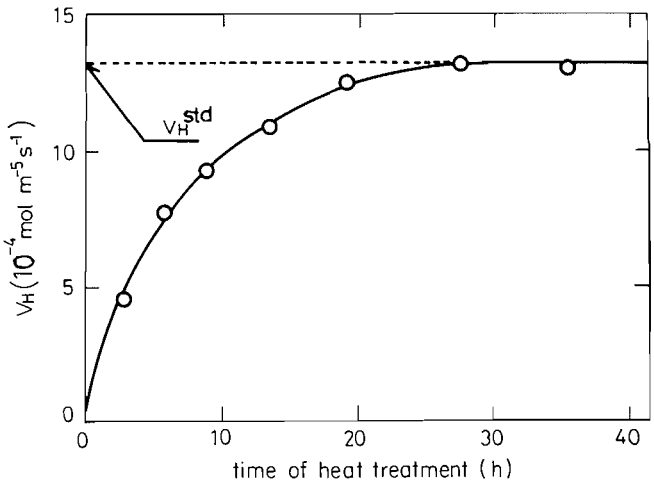

FIG. 4. Time of the heat treatment of the catalyst in hydrogen atmosphere (8.07 mol/m^3) at 973 K vs. the initial rate of exchange reaction between H_2 and D_2 at 373 K. The initial concentrations of H_2 and D_2 were both 2.69×10^{-2} mol/m^3. Using the chamber volume the unit mol/m^3 s can be converted to 3.1×10^{-4} mol/m^2 s, which is the unit of reaction rate on a unit surface.

where K_{14} and K_{15} are equilibrium constants for reactions [14] and [15], respectively, C_{H_2} is a concentration of H_2(g), and k_{16} is the rate constant for reaction [16]. We get the relation $K_{14} = K_{15} = K_1$ by neglecting the isotope effect. From eqs. [6], [14], and [15], the initial rate for reaction [16] is

$$[17] \quad v_H = k_{16} T_H T_D = b[S_1]_0^2$$

$$[18] \quad b \equiv k_{16} K_1 C_{H_2}^{1/2} C_{D_2}^{1/2} / [1 + (K_1 C_{H_2})^{1/2} + (K_1 C_{D_2})^{1/2}]^2$$

Notice that b depends on the temperature and concentration of hydrogen and deuterium gases and $[S_1]_0$ depends on the surface state of the platinum plate, as mentioned in Section IIIA.

Our experiments show that the initial rate seems to saturate by pretreatment of heating in hydrogen gas for 25 h (Fig. 4). The measurement of the saturation level seems to be reproducible within a few percent, because the measured saturation levels for v_H after treatment for 27.5 h and 35 h show good agreement. We regard the number of sites at this saturated stage as the

For personal use only.

standard number of sites, $[S_1]_0^{std}$. The experiments suggest that the catalytic activity will change delicately and that we must carefully estimate the activity of the platinum plate surface. Relative amount of the number of sites for hydrogen adsorption may be good measure for the estimation of catalytic activity of the platinum plate surface. We, therefore, estimated it by determining the initial rate, v_H, of hydrogen isotope exchange between D_2 and H_2 before each run.

From eq. [17] the initial rate of hydrogen isotope exchange between H_2 and D_2 at this stage is

$$[19] \quad v_H^{std} = b([S_1]_0^{std})^2$$

The initial rate v_H was evaluated at the same condition as that made for obtaining v_H^{std} in Fig. 4, i.e., $C_{D_2} = C_{H_2} = 2.69 \times 10^{-2}$ mol/m^3 and $T = 373$ K. Then, from eqs. [17] and [19] the number of the sites, $[S_1]_0$, is written as follows,

$$[20] \quad [S_1]_0 = [S_1]_0^{std}(v_H/v_H^{std})^{1/2}$$

From eqs. [13] and [20] the corrected initial reaction rate for hydrogen isotope exchange between D_2 and H_2O,

$$[21] \quad v_0^{cor} \equiv v_0(v_H^{std}/v_H)^{1/2}$$

is written as

$$[22] \quad v_0^{cor} = a[S_1]_0^{std}$$

Notice that v_0^{cor} can be determined experimentally using eq. [21], and that $[S_1]_0^{std}$ is independent of the surface state of the platinum plate.

C. Examination of the model

When the initial concentration of hydrogen is fixed at a value of $C^0_{D_2}$, the following relation between the initial rate and the water concentration is obtained from eqs. [22] and [13]:

$$[23] \quad 1/v_0^{cor} = (1/k_{app})(1/C_{H_2O}) + K_2/k_{app}$$

$$k_{app} \equiv k_3K_1^{1/2}K_2[S_2]_0[S_1]_0^{std}C^0_{D_2}{}^{1/2}/[1 + (K_1C^0_{D_2})^{1/2}]$$

$$= \text{constant}$$

The value of $1/v_0^{cor}$ plotted against $1/C_{H_2O}$ is expected to be linear.

Similarly, in the case that the initial concentration of water vapor is fixed at a value of $C^0_{H_2O}$, the following relation is obtained from eqs. [22] and [13].

$$[24] \quad 1/v_0^{cor} = (1/k'_{app})(1/C_{D_2}{}^{1/2}) + K_1^{1/2}/k'_{app}$$

$$k'_{app} \equiv k_3K_1^{1/2}K_2[S_2]_0[S_1]_0^{std}C^0_{H_2O}/(1 + K_2C^0_{H_2O})$$

In this case, $1/v_0^{cor}$ plotted against $1/C_{D_2}{}^{1/2}$ is expected to be linear.

IV. Results and discussion

In Fig. 5 the corrected initial reaction rates measured under the condition of a constant temperature, $T = 423$ K, and a constant water-vapor concentration, 2.69×10^{-2} mol/m^3, are plotted against the concentration of D_2. In Fig. 6 the corrected initial reaction rates are plotted against the various concentrations of water vapor. The measurement is performed under the condition that the initial concentration of D_2 is 5.37×10^{-8} mol/cm^3 and the temperatures are 463 K, 443 K, and 423 K. In these figures, each plot does not deviate from a certain curve. Our scheme of the correction of the initial rate by estimating the relative intensity of the number of sites for the adsorption of dissociated hydrogen seems to be satisfactory.

Plots of $1/v_0^{cor}$ against $1/C_{D_2}{}^{1/2}$ and $1/v_0^{cor}$ against $1/C_{H_2O}$ are described in Figs. 7 and 8, respectively. These plots show

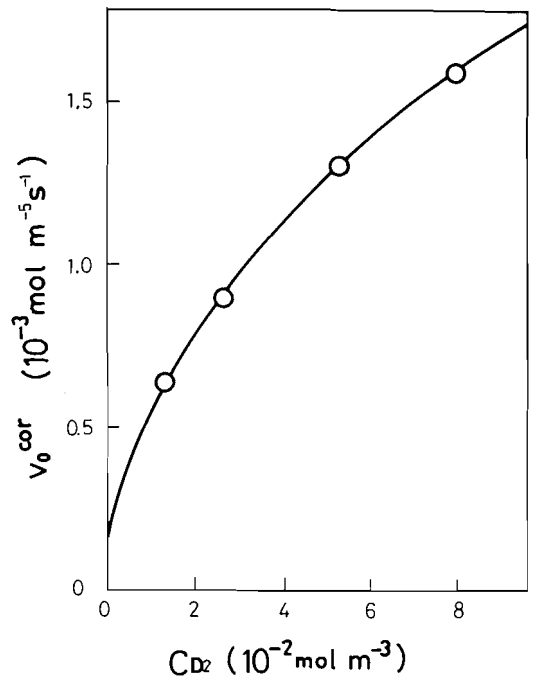

FIG. 5. The plots of corrected initial rates of the reaction against the concentration of D_2. The concentration of H_2O is 2.69×10^{-2} mol/m^3. The temperature was 423 K.

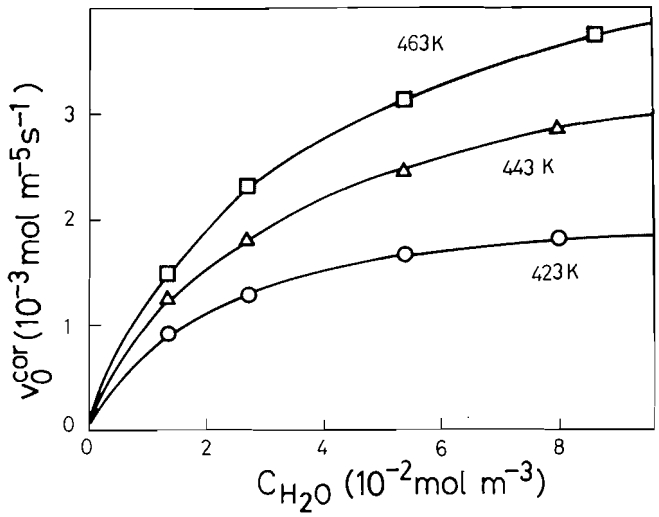

FIG. 6. The plots of corrected initial rates of reaction against the concentration of H_2O. The concentration of D_2 is 5.37×10^{-2} mol/m^3.

linearity, as predicted by eqs. [24] and [23]. The model seems to be successful in explaining the exchange reaction on the platinum plate surface.

The present study revealed that the relative number of sites for the adsorption of hydrogen atom which is obtained from the model calculation based on the exchange reaction between H_2O and D_2 can be simulated by that between H_2 and D_2. In the experiment the reproducibility of uncorrected experimental results for the initial rate of the hydrogen isotope exchange between H_2O and D_2 is not satisfactory. This seems to originate in the variation of the number of sites as a consequence of some delicate differences in the treatment of the platinum plate.

There seems to be two factors affecting the uncertainty of the number of sites for hydrogen adsorption. One is the reconstruction of surface atoms by heating or by other treatments, the

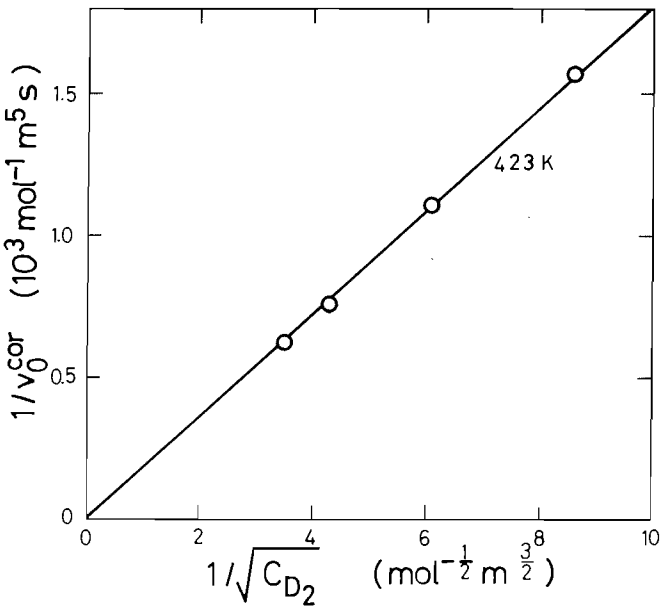

FIG. 7. The plot of $1/v_0^{cor}$ against $1/C^0{}_{D_2}{}^{1/2}$ for an examination of the model.

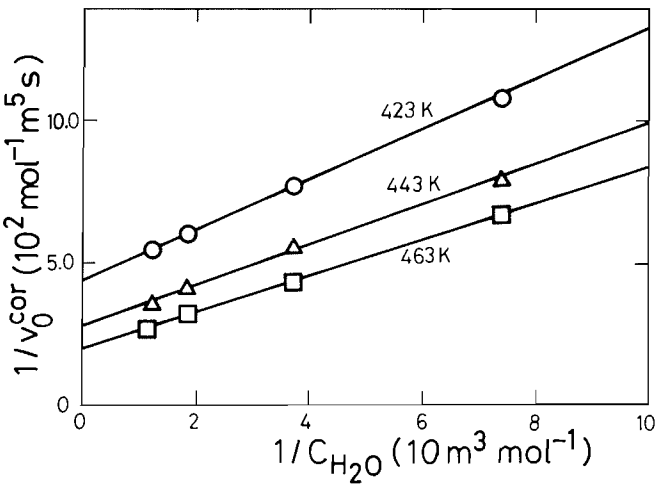

FIG. 8. The plot of $1/v_0^{cor}$ against $1/C^0{}_{H_2O}$ for an examination of the model.

possibility of which was pointed out by Nishiyama *et al.* (11). It is also pointed out by Somorjai (16) and Salmeron *et al.* (17) that the steps on the surface of single-crystal platinum will promote the reaction. The other is the site blocking by oxygen adsorbed on the surface. It has been found by Chon *et al.* (18) that the heat of hydrogen adsorption on platinum black depends considerably upon the concentration of surface oxygen.

In our experiments the effect of oxygen seems to be larger. Auger electron spectroscopy and X-ray photoemission spectroscopy have shown that the surface contamination by carbon can be removed by the heat treatment in concentrated nitric acid but oxygen cannot be removed completely. On platinum surface there seems to be two kinds of adsorbed oxygen: weakly adsorbed oxygen and strongly adsorbed oxygen at step sites (19). The adsorbed oxygen which can be titrated by hydrogen at the standard temperature (18) may be the former one. The fact that the platinum plate used in our study needed high temperature and long time to reduce (Fig. 4) suggests that the blocking of sites for hydrogen adsorption should be due to the strongly adsorbed oxygen. It may be interesting to investigate, in detail, the effect of the adsorbed oxygen upon the number of sites for hydrogen adsorption.

The reaction mechanism of the hydrogen exchange between D_2 and H_2O on a platinum powder catalyst or on a supported platinum catalyst has been investigated by several researchers. According to Rolston and Goodale (1), the rate of hydrogen isotope exchange between water and hydrogen on the alumina-supported platinum catalyst has explained by the five elementary reactions similar to those in this paper, except that alumina plays an important role in the adsorption of water in their case. Besides these reactions, it is proposed that the support plays an important role in the exchange reaction between the adsorped species (4). In this paper, we clarified, however, that the rate of hydrogen isotope exchange between D_2 and H_2O on the surface of platinum plate can be described fairly well by assuming physical adsorption of water vapor on platinum plate itself.

There are two major conclusions in the present study. One is that the relative number of the sites for hydrogen adsorption which is obtained from the model calculation based on the exchange reaction between H_2O and D_2 can be simulated by that between H_2 and D_2. The other is that the experimental results of the exchange reaction between H_2O and D_2 are successfully explained by the model in which the step of hydrogen exchange between H_2O adsorbed physically and D_2 adsorbed dissociatively on the platinum surface is rate controlling.

Acknowledgments

We would like to thank Mr. Koukichi Hotta for his assistance in experiments and Professor Ichiro Fujiwara (Otemon Gakuin University) and Dr. Nobutsugu Imanishi (Faculty of Engineering, Kyoto University) for their valuable discussions. The measurements of AES, XPS owes the kindness of Dr. Hidekazu Touhara (Faculty of Engineering, Kyoto University).

Methanation on exfoliated and supported MoS_2

GUENTER A. SCHOLZ[1] AND S. ROY MORRISON
Energy Research Institute, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received November 14, 1988

GUENTER A. SCHOLZ and S. ROY MORRISON. Can. J. Chem. **67**, 862 (1989).

The methanation reaction on MoS_2 exfoliated to a thickness of a few layers or less and adsorbed onto alumina is found to be very small. However, by calcining and resulfiding the exfoliated MoS_2 catalysts, greatly improved performance is achieved that is at least equal to the commercial catalysts based on ammonium heptamolybdate. The creation of molybdenum oxysulfide surface species therefore appears to be a necessary step toward producing significant methanation rates with exfoliated and supported MoS_2. The methanation products are almost exclusively CO_2 and CH_4, their mole ratios near unity, with otherwise only very much smaller amounts of longer chain hydrocarbons. The activation energy for methanation is generally observed to be near 100 kJ/mol, with the overall reaction being first order in the carbon monoxide concentration and third order in the hydrogen concentration. In contrast to the transition-metal catalysts, no water could be detected in the reaction products of the molybdenum based catalyst.

Key words: methanation reaction on MoS_2, exfoliated and supported MoS_2 as catalyst.

GUENTER A. SCHOLZ et S. ROY MORRISON. Can. J. Chem. **67**, 862 (1989).

On a trouvé que la réaction de méthanation, réalisée sur du MoS_2 affouillé jusqu'à une épaisseur maximale de quelques épaisseurs et adsorbé sur de l'alumine, est faible. Toutefois, si on procède à une calcination et à une resulfuration des catalyseurs de MoS_2 affouillé, on obtient des meilleures performances qui sont au moins équivalentes à celles obtenues avec des catalyseurs commerciaux basés sur l'heptamolybdate d'ammonium. Il semble donc que la création à la surface d'espèces oxysulfure de molybdène soit une étape nécessaire lorsqu'on veut obtenir des vitesses de méthanation significatives avec du MoS_2 affouillé et déposé sur un support. Les produits de méthanation sont presqu'exclusivement le CO_2 et le CH_4 accompagnés de faibles quantités d'hydrocarbures en longues chaînes. On observe généralement que l'énergie d'activation de la méthanation est d'environ 100 kJ/mol et que la réaction globale est du premier ordre en monoxyde de carbone et du troisième ordre en hydrogène. Par opposition avec ce qui est observé avec les catalyseurs de métaux de transition, on n'a pas pu détecter d'eau dans les produits de réaction obtenus à l'aide du catalyseur basé sur le molybdène.

Mots clés : réaction de méthanation sur MoS_2, MoS_2 affouillé et déposé sur un support comme catalyseur.

[Traduit par la revue]

1.0. Introduction

In attempts to convert syngas to hydrocarbon fuels, transition-metal catalysts (e.g. nickel, cobalt, etc.) have been used (1, 2). These catalysts, however, all suffer severe drawbacks because of deactivation caused by sulphur poisoning and/or build-up of carbon residues. The large scale removal of sulphur and nitrogen from a variety of petroleum feedstocks is presently accomplished with catalysts having mainly Ni—MoS_2 or Co—MoS_2 as the active components. Therefore, the search for a sulphur-tolerant methanation catalyst has recently also focussed attention on MoS_2 and to a lesser extent WS_2 (3–6). Commercial MoS_2 based catalysts are typically prepared by impregnating alumina powder with aqueous ammonium heptamolybdate $[(NH_4)_6Mo_7O_{24}\cdot 6H_2O]$ solutions followed by drying, calcining at about 800 K, and finally by sulfiding with a mixture of H_2S (typically 10%) in H_2 at about 700 K.

In studying the physical properties of layered dichalcogenides in this laboratory, it has become possible to exfoliate and subsequently separate these layer compounds along their basal planes (7, 8). The resulting crystallites are usually only a few layers thick and, recently, monolayers of the dichalcogenide sandwiches in suspension have also been produced (8). These layers are typically about 6 Å thick. If exfoliation is carried out in the presence of alumina powder, these monolayers can be made to deposit on the aluminum oxide by carefully controlling the pH of the suspension. Furthermore, promoters can be conveniently precipitated onto the dichalcogenide layers while they are still in suspension.

In this work we present a comparison between the methanation ability of MoS_2 based catalysts (*i*) derived from the above-mentioned exfoliation technique, (*ii*) those further treated by calcining and resulfiding, and (*iii*) a commercial MoS_2 catalyst. The reaction stoichiometry and the reaction order are also considered since the behaviour of MoS_2 is found to be different from those of well known transition metal catalysts like nickel.

2.0. Experimental methods

2.1. Apparatus

Quantitative analysis of feed and product gases is done in a standard way with a Varian model 6000 gas chromatograph in conjunction with a Vista 401 controller using a series-bypass arrangement (Fig. 1). A built-in nickel catalyst will allow the use of FID with its much higher sensitivity for detecting CO and CO_2. However, the presence of some sulfides in the reaction products, which will poison the nickel catalyst, is found to be unavoidable. Therefore these two gases are monitored via TCD. Feed gases are Matheson's UHP (99.999%) H_2 and Matheson grade (99.9%) CO. Whereas the former is used without further purification, the latter is first passed over copper shavings at about 500 K to decompose the nickel carbonyl that is found to be present.

Methanation is carried out at 1 atm in a continuous-flow manner in a quartz reaction tube in a single pass rather than a circulation system so that potential interference from reaction products (e.g. H_2O) will be minimized. The 12 mm i.d. reaction tube is heated with an external cylindrical heater and its temperature monitored with a chromel/alumel thermocouple. Feed and product gases can be diverted to a 0.25 mL sampling loop for quantitative analysis by the gas chromatograph.

2.2. Sample preparation

The general recipe for preparing the exfoliated catalyst, i.e. supporting the exfoliated MoS_2 layers on alumina, is described in detail

[1]Present address: Guelph–Waterloo Program for Graduate Work in Physics, Physics Department, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

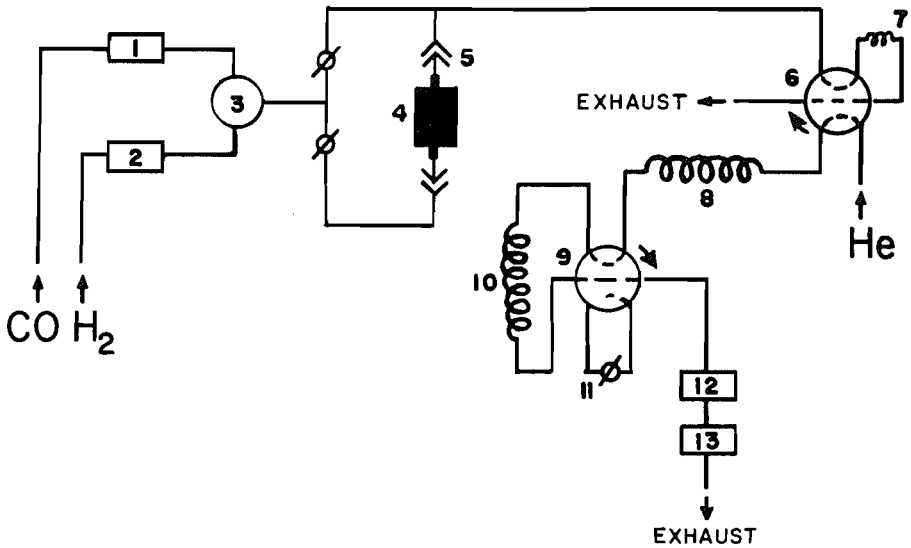

FIG. 1. Schematic of the experimental arrangement: flow meters (*1*, *2*); mixing chamber (*3*); furnace (*4*); o-ring joints (*5*); 6-way sampling valves (*6*, *9*); 1/4 mL sample loop (*7*); 4′ × 1/8″ Poropak T (*8*); 13′ × 1/8″ molecular sieve 13 × (*10*); restriction valve (*11*); TCD (*12*); FID (*13*).

in ref. 8 and involves the intercalation of lithium into powdered MoS_2 followed by immersion in water. The Li/H_2O reaction generates hydrogen which "blows" the crystallites apart into, at times, single 6.2 Å thick layers. In neutral or slightly basic pH these layers will then precipitate onto alumina without first flocculating. One would therefore expect that with an increasing MoS_2 to alumina concentration the alumina should eventually become covered with, but not exceed, one layer of MoS_2. This was experimentally confirmed in that MoS_2 suspensions cleared when the surface area (BET) of these layers is less than that of alumina, and the suspensions did not clear when the layers surface area is greater. In practice, the former occurs at concentrations of less than about 2 wt% MoS_2, and the latter at concentrations greater than about 5 wt% MoS_2. The alumina powder is obtained from Alfa Chemicals and is about 1 μm in diameter. The alumina does not appear to be porous since its BET surface area is found to be only about 5 m^2/g. The MoS_2 powder for exfoliation came from Materials Research Corp. The crystallites are from 5 to 10 μm in diameter with a surface area (BET) of about 6 m^2/g. The thickness of the MoS_2 layers deposited on the alumina is estimated by measuring the broadening of the initial (00.2) diffraction line while the layers are still in suspension.

A summary for the preparation of a series of MoS_2 based catalysts is given below. Some commercially available ammonium heptamolybdate catalysts and untreated MoS_2 are also included in order to provide reference points for the methanation ability of our exfoliated catalysts.

A: a 5 wt% mixture of MoS_2 crystallites from Materials Research Corp. and alumina; the MoS_2 crystallites are about 5 to 10 μm in diameter and BET measurements on those yield a surface area of about 6 m^2/g.

B1,B2: respectively 5% and 0.5% exfoliated MoS_2 supported on alumina; line broadening suggests that in each case the MoS_2 is about 4 layers thick.

$B2_s$: B2 sulfided at 700 K with 6 vol% H_2S in H_2 for about 12 h.

$B1_{cs}$: B1 calcined in air at 800 K for about 3 h and then resulfided with 6 vol% H_2S in H_2 at 700 K for about 1/2 h.

C: 1% exfoliated MoS_2 on alumina; some (*hk*.0) but no (00.*l*) lines are observed and indicate the presence of monolayers.

C_{cs}: C calcined in air at 800 K for about 3 h and then resulfided with 6 vol% H_2S in H_2 at 700 K for about 1/2 h.

D1,D2: 5 wt% MoS_2 on alumina; a pseudo-commercial type of catalyst prepared by impregnating alumina with an ammonium heptamolybdate solution followed by calcining in air at 800 K for about 3 h and then sulfiding with 6 vol% H_2S in H_2 at 700 K also for about 3 h.

$D2_e$: D2 subjected to the exfoliation procedure.

F: a hydrosulfurization Ni—Mo/Al catalyst (Harshaw catalyst HT 500) containing 15.5 wt% MoO_3 and 3.5 wt% NiO on alumina. The alumina has a BET surface area of 200 m^2/g.

F_s: F sulfided for about 12 h with 6 vol% H_2S in H_2 at 700 K.

The amount of catalyst in the reaction tube is near 6 g in all cases and results in a bed depth of about 4 cm. Pretreatment of the samples consisted of drying under vacuum at about 650 K for 1 day. Because the BET surface area for all the catalysts prepared by us is quite constant near 6 m^2/g, the methane yields are normalized to per gram MoS_2.

3.0. Results and discussion

The production of methane and CO_2 is given in Table 1 for a 3:1 mixture of H_2 and CO at 650 K and a total flow rate of 20 mL/min. The yields correspond to steady state conditions after several hours. The CO consumed is always less than about 1 vol%.

Primary reactions of interest are

[1] $2CO + 2H_2 \rightarrow CH_4 + CO_2$

[2] $CO + 3H_2 \rightarrow CH_4 + H_2O$

and possibly also the water-gas shift reaction

[3] $CO + H_2O \rightarrow H_2 + CO_2$

To establish a basis for comparison, in (3.1) we will first give a short discussion of the methanation rate and net reaction observed for untreated MoS_2 powder (A) and the commercial type of moly catalysts derived from impregnating alumina with an ammonium heptamolybdate solution (F, F_s, D1, D2). Then in (3.2) results for the exfoliated and supported MoS_2 catalysts (B1, B2, $B2_s$, C) are discussed. Finally in (3.3) we discuss the orders of magnitude improvement found in the methanation rates of the exfoliated catalysts subsequent to their calcining and resulfiding treatment ($B1_{cs}$, C_{cs}).

3.1. As-received MoS_2 (A) exhibited poor performance and had a negligible methane yield when normalized to either the unit area or weight of the catalyst (Table 1). A relatively large amount of CO_2 is produced ($[CH_4]/[CO_2] \equiv R$ is small) and may in part be related to the removal of active sites because of the accumulation of either carbidic or graphitic carbon on the catalyst surface ($2CO \rightarrow C + CO_2$).

A commercial hydrodesulphurization catalyst from Harshaw

TABLE 1. Catalyst performance at 650 K, 1 atm and a space velocity[a] of 250 h^{-1}

Sample[b]	wt% MoS_2	BET (m^2/g)	$[CH_4]^c$ $\left(\frac{\mu mol}{min\ g}\right)$	R^d	E_a (kJ/mol)	Comments
A	5.0	5.1	0.01	0.03	92 ± 10	Dispersed MoS_2 physically mixed with alumina
B1	5.0	5.7	<0.2	0.1	40 ± 5	Exfoliated MoS_2 (about 4 layers thick) deposited on Al_2O_3. $B2_s$ is sulfided B2 exposed to 6 vol% H_2S in H_2
$B2,B2_s$	0.5	5.7	0.2	0.02	44 ± 5	
C	1.0	5.7	<0.2	0.1	—	Monolayers of exfoliated MoS_2 deposited on Al_2O_3
D1	5.0	6.7	17	0.9	100 ± 6	Similar catalysts prepared from $(NH_4)_6Mo_7O_{24}.6H_2O$ and presulfided. Samples give extremes in methanation rates
D2	5.0	6.8	33	1.1	96 ± 5	
F	0	225	139 (>500)[e]	3.3	116 ± 10	NiO–MoO_3/Al (Harshaw HT-500) the only catalyst to produce observable amounts of H_2O
$D2_e$	5.0	6.1	1.0	0.3	96 ± 7	D2 subjected to exfoliation procedure
F_s	15.5	200	14	1.1	108 ± 7	F presulfided. Ni is poisoned so no more H_2O is observed
$B1_{cs}$	5.0	7.2	6.7	0.7	90 ± 7	B1 calcined and presulfided
C_{cs}	1.0	—	16	0.5	96 ± 10	C calcined and presulfided

[a]5 mL/min and 15 mL/min of H_2 and CO, respectively.
[b]About 6 g of catalyst.
[c]Normalized to per g MoS_2.
[d]Mole ratio of methane to carbon dioxide yield.
[e]Normalized to per g Ni.

(F) contains 3.5 wt% nickel oxide and 15.5% MoO_3 and following the reduction of nickel oxide has by far the largest methane yield and is also the only catalyst in this study to produce water as a methanation product. After sulfiding F to produce F_s, water production cannot be detected via gas chromatography and the methane and CO_2 yields decrease. Whereas the methane yield decreases by an order of magnitude from 139 to 14 μmol/min g, the CO_2 production decreases somewhat less so that R shifts near unity and the net reaction of eq. [1] appears to satisfactorily explain the products and yields observed. The lower activity of F_s and the change in reaction products is of course quite expected since the two major effects of sulfiding is the poisoning of the catalytically very active elemental nickel and the sulfiding of MoO_3. Consequently, the smaller catalytic activity of F_s can now be primarily attributed to supported molybdenum sulfide or oxysulfide species. Arrhenius plots for the two catalysts yield activation energies for methanation which are surprisingly similar (i.e. 116 ± 10 kJ/mol for F and 108 ± 7 kJ/mol for F_s; Fig. 2), in view of the differences in the active materials and reaction products.

Results for the heptamolybdate based catalysts prepared by us are summarized for D1 and D2 whose methane yield of 17 μmol/min g and 33 μmol/min g respectively, illustrate the largest spread in the observed rates. These methanation rates and the reaction products of methane and carbon dioxide with a mole ratio near unity are in general agreement with studies on heptamolybdate catalysts by Hou and Wise (6). However, the activation energies which we find to be 100 ± 6 kJ/mol and 96 ± 5 kJ/mol, respectively, are at variance with the 31 kJ/mol reported by them.

3.2. From a large number of supported catalysts prepared by the exfoliation technique, typical results for a few of these samples (i.e. B1, B2, C) are given in Table 1. Compared to the ammonium heptamolybdate based catalysts (D1, D2, F_s) the exfoliated and supported catalysts have quite disappointing methane yields of about 0.2 μmol/min g or less. Although the rates do generally increase by about one order of magnitude compared to as-received MoS_2 (A), they are still consistently more than two orders of magnitude below those of the heptamolybdate based catalysts. The order of magnitude increase in the methanation rates between the exfoliated and as-received MoS_2 catalysts may actually be the result of the latter breaking up into smaller fragments, resulting in an increased edge area, following the exfoliation procedure. Exfoliated catalysts also demonstrate a low R, in common with A, so that an accumulation of carbidic or graphitic carbon on their surfaces again appears very likely. The activation energy for methanation for the exfoliated catalysts is found to be surprisingly low at 40 ± 5 kJ/mol and 44 ± 5 kJ/mol (Fig. 2) and may well be related to the exfoliation process. To probe whether or not the small methanation rates and low activation energies are the result of a poor molybdenum/sulphur stoichiometry caused by exfoliation, B2 was sulfided at 700 K for 12 h ($B2_s$). The behaviour of $B2_s$ proved indistinguishable from B2 so that it would appear that the sulphur defect composition is not at fault. Further evidence that the exfoliation procedure may be detrimental is observed by subjecting the heptamolybdate based catalyst D2 to an exfoliation procedure ($D2_e$). Even though the activation energy for $D2_e$ remains unchanged at 96 kJ/mol, the methane yield decreases from 33 to 1.0 μmol/min g and the R value

decreases from near unity to 0.3. These rather disappointing results for our exfoliated catalysts clearly demonstrate that our exfoliation technique is either detrimental to the catalytically active sites, or is still incomplete with respect to a critical preparative step which will "activate" potential catalytic sites.

3.3. Evidence has been presented by other researchers (9–11) that the presence of molybdenum oxysulfide surface species having strong interactions with the alumina substrate may be critically important to the development of catalytically active sites for methanation. The correct environment for methanation may therefore not be produced when we simply adsorb monolayers of exfoliated MoS_2 onto alumina. In an attempt to produce an oxysulfide surface species, a number of the exfoliated MoS_2 samples are subjected to a calcining and resulfiding procedure. Calcining should promote the presence of oxysulfide surface species and establish strong interactions between these species and the alumina substrate. Subsequent to calcining, the samples are sulfided for about 1/2 h even though this vigorous reaction appears to last only a few minutes if judged by the water produced from the reduction of the oxides. The prolonged sulfiding will, however, help in reducing any lattice oxygen possibly introduced during calcining. The complete absence of oxygen is important because during the rate studies below, it will avoid ambiguities such as the formation of water in a parallel reaction. Typical results chosen from a number of calcined and resulfided samples are given in Table 1 for samples $B1_{cs}$ and C_{cs} derived from catalysts B1 and C, respectively. The dramatic increase in their methanation rates clearly establishes that calcining and resulfiding is very beneficial.[2] As with the previous MoS_2 based catalysts, there is no water observed in the methanation products. Along with the increased methanation ability, it is also interesting to note that R has moved nearer to unity and that the activation energies have increased, from 40 kJ/mol for B1 to 90 kJ/mol for $B1_{cs}$. It is therefore clear that new catalytic sites must have been activated by the calcining and resulfiding process.

An investigation of the reaction order for methanation using the calcined and resulfided catalysts is presented in Figs. 3 and 4 for C_{cs} at 670 K. Measurements are made in the usual manner using a three component gas mixture (CO, H_2, and He) by holding one of the reactants fixed and varying the other while using He as the diluent to keep the net flow rate constant. Small rate changes caused by temperature drifts in the furnace ($< \pm 4$ K) are corrected by using the already determined activation energy for C_{cs}. As mentioned earlier, because the total conversion of CO is less than 1% the reactor is in the differential mode. These rate measurements suggest that methanation is first order in the carbon monoxide concentration (Fig. 3) and third order in the hydrogen concentration (Fig. 4), i.e.

$$[4] \quad (d/dt)[CH_4] = -k[CO][H_2]^3$$

It may be of note that while the reaction products are in agreement with eq. [1], the reaction orders are in agreement with the stoichiometric coefficients of eq. [2]. The latter agreement is very likely fortuitous and, if anything, points to a relatively complex reaction mechanism for methanation. However, considering that MoS_2 does have some propensity (13) for the water-gas shift reaction (eq. [3]), and considering that the net reaction of eqs. [2] and [3] is that of eq. [1], it may be true that methanation on MoS_2 and, for example, nickel are similar in that an intermediate step in the methanation reaction on MoS_2 also produces water (eq. [2]). The fact that no water is observed in the reaction products could be accounted for by assuming a subsequent rapid water-gas shift reaction on the part of MoS_2. Some support for this hypothesis comes from the unexpectedly similar activation energies found for F (i.e. elemental nickel) and most of our other MoS_2 based catalysts, even though water is observed in the reaction products only for the former but never for the latter catalysts.

[2]Further studies have been done to investigate the effects of promoters in addition to calcining (12).

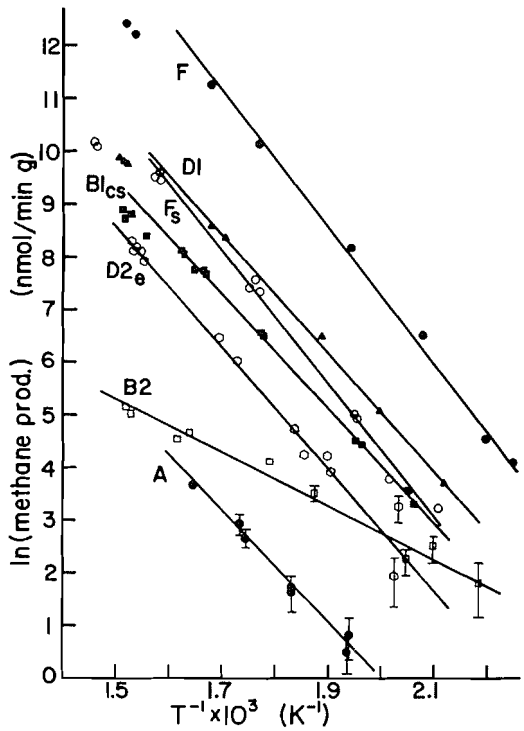

FIG. 2. Arrhenius plots for some of the catalysts listed in Table 1. The highest temperature methanation rates tend to level off and were therefore not included when determining the slope. H_2 and CO flow rates are 5 mL/min and 15 mL/min, respectively, with a resulting space velocity of about 250 h^{-1}.

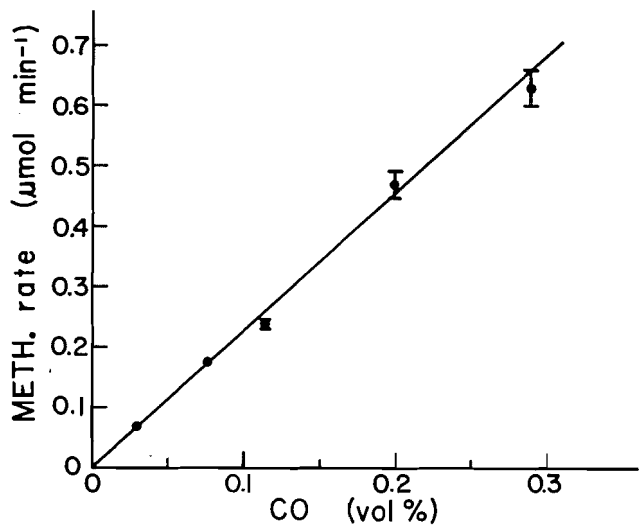

FIG. 3. Changes in the methanation rate with carbon monoxide concentration for sample C_{cs} at 670 K and 1 atm. The hydrogen concentration is 50 vol% and the space velocity is about 500 h^{-1}.

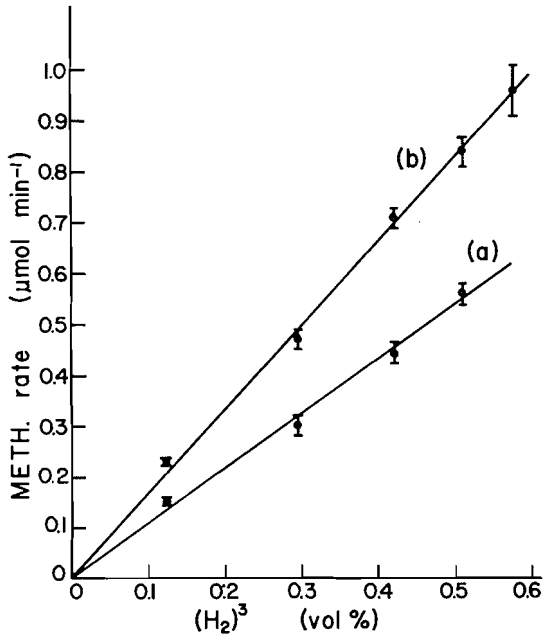

FIG. 4. Changes in the methanation rate with the cube of the hydrogen concentration for sample C_{cs} at 670 K and 1 atm. The carbon monoxide concentration is 17 vol% and the space velocity is about 375 h^{-1}. Data in (*a*) corresponds to initial rates and in (*b*) after methanation has continued for about 2 days. Although the methanation rate increases somewhat with time, the reaction order remains the same.

The rate equation for methanation determined by Hou and Wise (6) for a molysulfide catalyst is different from ours (eq. [4]). This is in part expected because they added small quantities of H_2S to the $CO/H_2/He$ feed gas in an attempt to control the sulphur defect composition of the catalyst. Strictly speaking, these rate equations are therefore not comparable. Nevertheless, it is interesting to make some limited comparisons. They find

$$[5] \quad (d/dt)[CH_4] = \frac{-k_1[H_2S]^{1/2}[CO][H_2]^{1/2}}{1 + \gamma[CO_2]}$$

The rate dependence on H_2S and CO_2 is not tested for by us. However, without any H_2S in the feed gas we observe relatively constant methanation rates over a period of days that are similar (when normalized to wt% Mo loading) to those reported by Hou and Wise. For example, Fig. 4*b* actually indicates a slight improvement in the catalysts methanation rates while it is continuously on-line for over 2 days. Therefore, we do not find the presence of H_2S in the feed gas to be a necessary condition for methanation as is implied by eq. [5]. The $[CO_2]$ dependence in eq. [5] is not a point of major difference since our use of a single pass reactor that has less than 1% conversion of CO guarantees the term $\gamma[CO_2] \ll 1$. Since we both find methanation to be first order in the CO concentration, the other major difference between the two rate equations appears to be with respect to the reaction order for H_2. A possible explanation for this might be related to pore diffusion limitations. Whereas we deposit "sheets" of MoS_2, onto a low (5 m^2/g) surface area alumina, they impregnate a high (320 m^2/g) surface area alumina, which is very likely porous, with a heptamolybdate solution. While in the former case the MoS_2 layers will "wrap" themselves around the alumina particles, in the latter case the heptamolybdate ions are free to disperse, in particular, into the pores of the alumina particles. Pore diffusion limitations could therefore become of concern and result in the apparently lower reaction orders along with the decreased activation energies observed.

Although not specifically mentioned previously, all of the MoS_2 catalysts discussed do produce small amounts of the longer chain hydrocarbons whose concentration decreases rapidly as their carbon number increases. To be more specific, at 650 K the calcined and resulfided catalysts produce ethane and propane at rates which are typically a few percent and a few permill, respectively, of the methane rate. The largest molecules detected are *i*- and *n*-pentane. Unsaturated hydrocarbons are generally not found, except in a few cases where the catalyst has a low methane yield. For those catalysts a few permill, with respect to the methane concentration, of ethylene is typically observed. The catalysts with low methane yields generally also produce proportionately higher concentrations of the longer hydrocarbons.

4.0. Conclusion

We have shown that methanation rates comparable to the ammonium heptamolybdate based catalysts can be obtained with exfoliated and separated MoS_2 layers adsorbed onto alumina after they are calcined. Since this procedure is known to result in molybdenum oxysulfide surface species, these species therefore appear to be necessary for methanation to proceed at substantial rates. Methanation is observed to be first order in the carbon monoxide concentration and third order in the hydrogen concentration. The reaction products are primarily methane and carbon dioxide at a 1:1 ratio and unlike corresponding transition-metal catalyst like nickel, water is not observed. The activation energy for methanation is near 100 kJ/mol. The overall reaction products and their concentrations are in general agreement with results by Hou and Wise; however, we find differences in the rate law and can not confirm their relatively low activation energy.

ASHIS KUMAR MUKHERJEE and S. K. SANYAL. Can. J. Chem. **67**, 867 (1989).

The thermal diffusion of aqueous solutions of methanol, ethanol, propan-1-ol, butan-1-ol, ethan-1,2-diol, and propan-1,2-diol contained in the pores of a sintered glass disc (of porosity G4) has been studied. The Soret coefficient (σ) and the heat of transport ($\hat{Q}$) values are reported in the temperature range of 25–40°C. The heat capacities of transport are ascertained at 30°C from the temperature coefficient of heat of transport values. The results are explained on the basis of changes in local entropy in the solvent (water), arising out of solute–solvent interactions. Correlations of the observed experimental values with certain relevant thermodynamic parameters, taken from the literature, have also been sought, with encouraging results.

Key words: thermal diffusion, heat of transport, entropy of hydration.

ASHIS KUMAR MUKHERJEE et S. K. SANYAL. Can. J. Chem. **67**, 867 (1989).

On a étudié la diffusion thermique de solutions aqueuses de méthanol d'éthanol, de propanol-1, de butanol-1, d'éthanediol-1,2 et de propanediol-1,2 contenus dans les pores d'un disque en verre frité (de porosité G4). On rapporte les valeurs des coefficients de Soret (σ) et des chaleurs de transport ($\hat{Q}$) pour l'intervalle de température allant de 25 à 40°C. En se basant sur le coefficient de température des valeurs des chaleurs de transport à 30°C, on a déterminé les capacités calorifiques de transport. On explique les résultats en se basant sur des changements d'entropie locale dans le solvant (eau) qui résultent d'interactions soluté–solvant. On a aussi recherché, avec des résultats encourageants, des corrélations entre les valeurs experimentales observées et certains paramètres thermodynamiques appropriés relevés dans la littérature.

Mots clés : diffusion thermique, chaleur de transport, entropie d'hydratation.

Introduction

Even though there have been many studies on thermal diffusion of electrolytes (1–5), relatively less attention seems to have been paid to the thermal diffusion of non-electrolytes. The present communication describes experiments on thermal diffusion of aqueous solutions of alcohols, contained in the pores of a coarse G4 glass diaphragm. The diffusion cell used has been described earlier (6).

Theoretical

A solution-filled pore in a highly porous non-isothermal diaphragm (e.g., a sintered G4 glass disc) may be considered to be equivalent to a porous Soret cell free from flow caused by external stirring. Thus, the relations used for thermal diffusion in a binary system (7) (and for a solvent-fixed reference frame) can be adopted in the present case with the supposition that the chemical potential of the component i(μ_i) just within the diaphragm at each of its surfaces is the same as that in the adjacent layer of free solution outside the diaphragm (8, 9). The latter holds true for the assumed equilibrium across each surface of the glass disc used in the present case, and the heat of transport of solute ($\hat{Q}$) for a solvent-fixed reference frame is given (10) by

$$[1] \quad \hat{Q} = RT^2\sigma\left(1+\frac{\mathrm{d}\ln\gamma}{\mathrm{d}\ln m}\right)_T$$

where σ is the Soret coefficient, obtained as

$$[2] \quad \sigma = -\left(\frac{\mathrm{d}\ln m}{\mathrm{d}T}\right)_{st} = -\frac{1}{\bar{m}}\left(\frac{\Delta m}{\Delta T}\right)_{st}$$

$\bar{m}$ being the mean molal concentration, γ the mean activity coefficient on the molality scale, and T the mean (absolute) temperature. Δm refers to the concentration difference between the cold and warm sides of the diaphragm at the steady state (denoted by the subscript "st" in eq. [2]), the solution in each half-cell being kept thoroughly mixed by means of magnetic stirrers (6). The thermodynamic factor

$$\left(1+\frac{\mathrm{d}\ln\gamma}{\mathrm{d}\ln m}\right)_T$$

is often given a symbol "B". The above relation, eq. [1], relating $\hat{Q}$ to σ, assumes the validity of Onsager's Reciprocity Relations between the cross-effect phenomenological (L) coefficients.

Experimental

The cell

The thermodiffusive cell used is the same as that described earlier (6). It consists of two compartments, holding the non-isothermal diaphragm sandwiched in between, and having several arrangements to monitor *in situ* concentration changes and temperatures. The details have already been reported (6).

Materials and method

The alcohols used were of high purity grade and their solutions were prepared in double distilled (deaerated) water of conductivity less than 0.5 μmho cm^{-1}. The initial concentration of each solution studied was 0.1 m.

The experimental method followed was similar to the one described in our earlier paper (6). On applying a thermal gradient across the diaphragm, the temperatures were monitored by the thermocouples, and any solvent flow was ascertained by noting the rate of development of a pressure difference between the glass capillary tubes emerging from the top and the bottom half-cells. Such solvent flow, however,

turned out to be negligible[3] after making proper correction for unequal thermal expansions in the two compartments (6).

At the steady state, suitable aliquots were withdrawn from each compartment, and the concentration difference was determined by using a Brice–Phoenix differential refractometer. The latter was previously calibrated with a number of standard pairs of solutions of each solute, having known concentration differences.

A number of tests, as described earlier (6), were applied to ensure a satisfactory operation of the cell, thereby obtaining reliable experimental data.

Results and discussion

The results are incorporated in Tables 1 and 2. The errors in the determination of σ and the heat of transport ($\hat{Q}$) are calculated as standard deviations and shown in parentheses below each value.

The values of the thermodynamic factor

$$\left(1+\frac{d\ln\gamma}{d\ln m}\right)$$

at 25°C are calculated from the appropriate activity or osmotic coefficient data available in the literature (11*a*, *b*) and are assumed constant over the experimental temperature range. In some cases (e.g., for diols), owing to unavailability of such appropriate activity or osmotic coefficient data, the variations of the latter with mean molality over the concentration range used in the present study were neglected, and the value of the thermodynamic factor (B) was thus taken to be unity. The latter appears to be a reasonably satisfactory approximation for these moderately dilute non-electrolyte solutions. The temperature variations of B have also been neglected.

Positive $\hat{Q}$ corresponds to the promotion of "local" structure (10) of water, i.e., it finds an interpretation in terms of local ordering (i.e., loss of entropy) of water adjacent to the solute molecules in dilute solutions. The gradual increase of $\hat{Q}$ from methanol to butan-1-ol (Table 1) may be ascribed to the gradually increasing hydrophobic chain length of the alcohols, which causes a lowering of entropy of neighbouring water molecules because of hydrophobic hydration effects (12–14). Introduction of a hydroxyl group, on the other hand, is seen to cause a lowering of $\hat{Q}$, e.g., from ethanol to ethanediol and from propan-1-ol to propan-1,2-diol (Table 1). This agrees well with earlier observations reported in the literature (15) and is attributed to the ability of hydroxyl groups to take part in hydrogen bonding with neighbouring water molecules, thereby increasing their entropy, and also to transmit the cluster-disruptive perturbations from solvent molecules lying outside the cluster regions formed around these largely hydrophobic solutes (10).

[3]In fact, such minute volume flow contributes not more than 0.1% towards the observed Δm values at the steady state, and the attendant error in ignoring such volume flow is thus considered negligible.

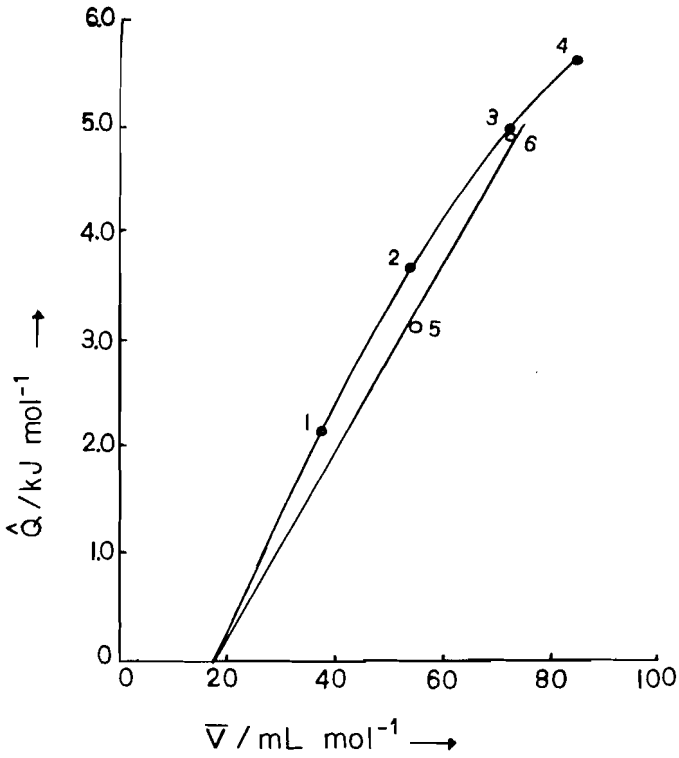

FIG. 1. Correlation between heats of transport and partial molal volumes of the solutes methanol (1), ethanol (2), propan-1-ol (3), butan-1-ol (4), ethan-1,2-diol (5), propan-1,2-diol (6), at 25°C.

The temperature dependence of $\hat{Q}$ has been described in terms of the corresponding heat capacities of transport (at 30°C) of the various non-electrolytes studied. The heat capacity of transport ($\hat{C}$) is given (10) by

$$[3]\quad \hat{C}=\left(\frac{d\hat{Q}}{dT}\right)-\frac{\hat{Q}}{T}$$

The appropriate $d\hat{Q}/dT$ values (at T = 30°C), noted from the slope of $\hat{Q}$ vs. T (and given in Table 2), as well as the corresponding $\hat{C}$ values, are both seen to be negative and may be attributed to the higher thermal energy of water molecules, especially in the bulk, as the mean temperature is raised; the latter renders structure promotion in water by the alcohols more difficult. Further, the trend to gradually increasing negative magnitudes of $\hat{C}$ with increase in chain length of the monohydric alcohols, and also a sharp fall in $\hat{C}$ for the diols (Table 2), fit in with the line of argument presented above.

It is of interest to plot the $\hat{Q}$ values (at 25°C) for the alcohols studied against the corresponding partial molal volumes. A nearly linear correlation is obtained for both the monohydric alcohols and diols (Fig. 1). This implies that the positive $\hat{Q}$ of

For personal use only.

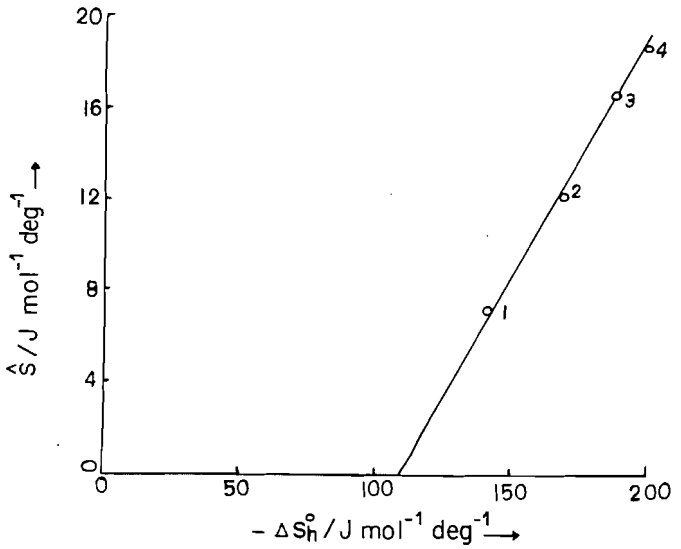

FIG. 2. Correlation between entropy of transport and standard entropy of hydration of the solutes methanol (1), ethanol (2), propan-1-ol (3), butan-1-ol (4), at 25°C.

these alcohols can be accounted for in terms of the enhanced degree of hydrogen bonding between the water molecules in the layer of water in the neighbourhood of the hydrocarbon chain. This, in turn, is a function of the size of the cavity in the aqueous solution required to accommodate the solute molecule, and thus it is not surprising that $\hat{Q}$ is related to the corresponding partial molal volumes.

A plot (Fig. 2) of the entropy of transport ($\hat{S} = \hat{Q}/T$) at 25°C of the aqueous alcohols against the corresponding standard entropies of hydration, $-\Delta S_h^0$ (quoted in Table 2), is given for those compounds for which the latter data are available from the literature (16). On the assumption of ideal gas behaviour for the vapours of the solute, such hydration entropy gives a measure of total solute–solvent interactions in dilute solutions.

Indeed, these negative hydration entropies originally led Frank and Evans (17) to postulate the "iceberg" formation through the water structure-enforcing character of the hydrocarbon chains of alcohols and other similar solutes in aqueous solutions.

It is in this context that the linear correlation between $\hat{S}$ and $-\Delta S_h^0$ (Fig. 2) is satisfactory, and is taken to highlight the importance of local interactions (i.e., of the hydrophobic hydration effects referred to above) in determining the net $\hat{Q}$ or $\hat{S}$ for diffusional transport through the given non-isothermal diaphragm.

The intercepts on the x-axes of Figs. 1 and 2 (for $\hat{Q} = \hat{S} = 0$) are seen to be rather close to the molar volume (18.05 mL) and the standard entropy of vaporization (118.7 J mol^{-1} K^{-1}) of pure water at 25°C and 1 atm pressure (101.3 kpa), respectively (for which $\hat{Q}_w = 0$). This indeed is interesting and serves to increase confidence in the present experimental results.

The chemistry of the chromotropic acid method for the analysis of formaldehyde

PARIS E. GEORGHIOU[1] AND CHI KEUNG (JIMMY) HO

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received October 14, 1988

PARIS E. GEORGHIOU and CHI KEUNG (JIMMY) HO. Can. J. Chem. **67**, 871 (1989).

Formaldehyde is present in the indoor air of many industrial and non-industrial environments. The procedure for its analysis which is commonly employed in North America is a NIOSH recommended one that uses chromotropic acid and concentrated sulphuric acid. The nature of the purple chromogen that is produced in the analytical procedure has not been fully understood until now. Using ^{1}H and ^{13}C nuclear magnetic resonance spectroscopic techniques and calibration line studies, evidence has been obtained to support the hypothesis that the chromogen has a mono-cationic dibenzoxanthylium structure and not a *para,para*-quinoidal one that is commonly cited.

Key words: Formaldehyde, formaldehyde analysis, chromotropic acid, chromogen, dibenzoxanthylium cation.

PARIS E. GEORGHIOU et CHI KEUNG (JIMMY) HO. Can. J. Chem. **67**, 871 (1989).

Le formaldéhyde est présent dans l'air ambiant de nombreux environnements industriels et non-industriels. La méthode communément utilisée en Amérique du nord pour en faire l'analyse est une méthode recommandée par NIOSH et elle est basée sur l'utilisation de l'acide chromotropique et de l'acide sulfurique concentré. Jusqu'à maintenant, on n'a pas encore bien compris quelle est la nature du chromogène violacé qui se produit au cours de cette procédure. Faisant appel à la rmn du ^{1}H et du ^{13}C ainsi qu'à des études de calibrations linéaires, on a obtenu des données suggérant que le chromogène possède une structure dibenzoxanthylium mono-cationique et non pas une structure de type quinonoïde-*para,para* comme il a souvent été proposé.

Mots clés : formaldéhyde, analyse du formaldéhyde, acide chromotropique, chromogène, cation dibenzoanthylium.

Introduction

Since its discovery in 1859 by Butlerov (1) formaldehyde has become one of the most important and widely used industrial chemicals. In recent years the presence of significant amounts of formaldehyde in domestic indoor air has been recognized. This has been a result of formaldehyde being released from a variety of sources including plywood, particleboard (2) and urea–formaldehyde foam insulation (U.F.F.I.) (3). Formaldehyde in air can be analysed by several different chemically-based procedures in which a chromogen is produced with formaldehyde-specific reagents. In North America one of the most widely used chromogen-forming reagent with formaldehyde is chromotropic acid **1** (4,5-dihydroxy-2,7-napthalenedisulphonic acid) which is used in the method recommended by the National Institute for Occupational Safety and Health (NIOSH), Method P&CAM 125 (4).

The use of chromotropic acid as a formaldehyde-specific reagent was first described by Eegriwe in 1937 (5). The nature of the chromogen and its formation by the reaction of chromotropic acid with formaldehyde has never been unambiguously proven. The most often-quoted structure (4–8) for the chromogen formed between chromotropic acid and formaldehyde has been the *para,para*-quinoidal adduct (**2**). No direct proof of this structure has ever been presented. It is based on an analogy with the reaction of formaldehyde with aromatic compounds in the LeRosen test (6). Chromotropic acid is known to form a large number of compounds with diazotised derivatives of aromatic compounds. In all of these cases, the structures presented (for which very little direct proof has been advanced) have diazo groups undergoing substitution in the position *ortho* to both the hydroxyl and sulphonic acid groups. An example is provided by Sulfonazo III (**3**) (9). The strongest evidence presented in support of its formula is that it is consistent with its chemical properties.

An alternative structure for the chromogen from the reaction of **1** and formaldehyde that has been proposed by Kamel and Wizinger (10) but which appears to have been ignored in the recent literature and for which there are only three brief citations (11–13) is **4**. This mono-cationic dibenzoxanthylium structure was proposed by analogy with the product obtained **5** when J-acid **6** (7-amino-4-hydroxy-2-naphthalenesulphonic acid) reacts with formaldehyde in concentrated sulphuric acid. Carbon, hydrogen, and sulphur analyses were consistent with the proposed structure **5** but no other direct evidence was presented. The analogous chromotropic acid – formaldehyde adduct **4** could not be isolated from the reaction mixture, since it was found to be much more water soluble than **5** thus precluding similar elemental analysis.

The work described in this paper was aimed at understanding the chemistry and establishing the structure of the chromotropic acid – formaldehyde chromogen. A better understanding of the chemistry of the reaction between chromotropic acid and formaldehyde could potentially lead to a modification of the method to avoid the use of concentrated sulphuric acid.

Experimental

^{1}H NMR spectra were recorded with the following instruments at the designated frequencies: Varian Anaspect EM 360 at 60 MHz, Bruker WP-80 at 80 MHz, and GE GN-300NB at 300 MHz. ^{13}C NMR spectra were recorded with the Bruker WP-80 at 20.1 MHz, and/or the GE GN-300NB at 75.47 MHz. The solvent used was either deuterium oxide or water as noted in the experimental details. Ultraviolet and visible spectra were determined on a Unicam SP800 Ultraviolet spectrophotometer. Calibration lines were determined with a Perkin–Elmer Hitachi–Coleman 139 grating single-beam spectrophotometer. Infrared spectra were recorded on a Perkin–Elmer 1320 infrared spectrophotometer using KBr disks.

Sephadex LH-20 purchased from Pharmacia Fine Chemicals was used for the gel permeation chromatography. Merck silica gel was used for preparative-layer chromatography using 20 × 20 cm plates of 0.75 mm thickness.

*Purification of 4,5-dihydroxy-2,7-naphthalenedisulphonic acid disodium salt (**1**)*

Purified **1** was obtained by dissolving, with heating, in 100 mL of water 20 g of 98% reagent purchased from Sigma Chemical Co.

A saturated solution of sodium chloride was added to the chromotropic acid solution until a precipitate formed. The precipitate was recrystallized from water to afford a near-colourless product: ^{1}H NMR (D_2O) δ ppm: 7.20 (d, J = 2 Hz, 1H, Ar—H), 7.92 (d, J = 2 Hz, 1H, Ar—H); ^{13}C NMR (D_2O) δ ppm (for assignments see ref. 14): 106.44 (C-3, C-6), 116.18 (C-10), 118.12 (C-1, C-8), 134.64 (C-9), 141.36 (C-2, C-7), 153.76 (C-4, C-5); uv (H_2O) λ_{max} absorbances: 316, 332, 346 nm; ir (KBr) ν_{max}: 3 500 cm^{-1} (Ar*O*—*H*), 1 200 cm^{-1} (S=O).

In-situ ^{1}H NMR studies of the reaction with 1:2 and 1:1 molar ratios of formaldehyde and ***1***

In 15 mL of deionized organic-free water 1.0 g of **1** was treated with either 1.0 or 2.0 mL of aqueous 1.32 *M* methanol-free formaldehyde and the mixture refluxed. One-mL aliquots were removed periodically and were evaporated to dryness. The residues were each redissolved in 0.3 mL of D_2O and their 60 MHz NMR spectra were recorded.

Preparation of adduct ***9***

The 1:1 chromotropic acid – formaldehyde adduct was prepared exactly in the same way as described below for **12** except that equimolar amounts of **1** and formaldehyde were used. The resulting cherry-red reaction mixture was chromatographed on Sephadex LH-20 in the same manner as for **12**. Only one major component was isolated, and its spectral properties was consistent with the structure **9**: ^{1}H NMR (D_2O) δ ppm: 8.10 (s, C_1- and C_8-protons); ^{13}C NMR (D_2O) δ ppm: 26.94 (C-11, methylene bridge carbon), 117.48 (C-10), 119.28 (C-3 and C-6), 120.01 (C-1 and C-8), 130.45 (C-9), 140.03 (C-2 and C-7), 151.52 (C-4 and C-5); uv (H_2O) λ_{max} absorbances: 320, 337, 353 nm.

Preparation of adduct ***12***

To a solution of 876 mg (2.04 mmol) of purified **1** in 10.0 mL of deionized organic-free water was added 0.87 mL (1.1 mmol) of aqueous 1.32 *M* methanol-free formaldehyde solution. The reaction mixture was heated and maintained at gentle refluxing while the formaldehyde solution was added dropwise over 40 min. After completion of the addition the mixture was refluxed for a further 20 min. The reaction mixture was cooled and concentrated to approximately 6 mL on a rotatory evaporator. This concentrate was fractionated on a 2.0 cm × 25 cm open glass column packed with 20 g Sephadex LH-20 gel in water. The eluting solvent used was deionized organic-free water at a flow rate of 2 mL/min. Approximately thirty 10-mL fractions were collected. Those fractions having similar uv–visible absorbances were combined and evaporated to dryness. Two components were isolated and characterized. Fractions 10–12 contained 235 mg (27%) of a product whose ir, uv–vis, and ^{1}H NMR spectra, and R_f on paper chromatography were identical to those of **1**. Fractions 13–16 contained 475 mg (55%) of **12**: ^{1}H NMR (D_2O) δ ppm: 5.03 (s, methylene protons), 7.00 (d, J = 2 Hz, 1H, C_3—H), 7.83 (d, J = 2 Hz, 1H, C_1—H); 8.17 (s, 1H, C_8—H); ^{13}C NMR (D_2O) δ ppm: 26.73 (C-11, methylene bridge carbon), 106.96 (C-6), 117.26 (C-10), 118.08 (C-8), 118.96 (C-3), 120.35 (C-1), 132.94 (C-9), 140.98 (C-2 and C-7), 152.21 (C-5), 153.65 (C-4); uv (H_2O) λ_{max} absorbances: 320, 337, 353 nm; ir (KBr) λ_{max}: 3 500 cm^{-1} (Ar*O*—*H*), 1 200 cm^{-1} (S=O).

Preparation of ***13****, the tetra-acetate of adduct* ***12***

In 0.033 mL of 6.1 *M* aqueous sodium hydroxide solution was dissolved 37 mg (5.0×10^{-5} mol) of adduct **12**. The mixture was cooled to 0°C and 0.019 mL (2.0×10^{-4} mol) of acetic anhydride was added with stirring. The resultant pale reddish solution was stirred with cooling for 5 min. The sodium acetate produced in the reaction was removed by precipitating it as insoluble silver acetate with an aqueous solution of silver nitrate. After the insoluble silver acetate was filtered off the filtrate was concentrated down to approximately 0.6 mL and fractionated on a 10 cm × 1 cm open-glass column packed with approximately 0.7 g of Sephadex LH-20 gel in water. The eluate was collected as thirty 0.5-mL fractions which were examined by uv–vis spectroscopy. Those fractions having similar absorbances were combined and evaporated to dryness. Seven milligrams of a product whose spectral properties were consistent with the structure **13** was obtained: ^{1}H NMR (D_2O) δ ppm: 1.97 (s, 6H), 2.08 (s, 6H), 5.13 (s, methylene protons, 2H), 7.63 (d, J = 2 Hz, 2H, C_3—H), 8.47 (d, J = 2 Hz, 2H, C_1—H); 8.73 (s, 2H, C_8—H); uv (H_2O) λ_{max} absorbances: 319, 334, 356 nm.

Calibration line determinations

(*a*). Modified NIOSH procedure. The basic NIOSH procedure was followed for the determination of calibration lines for standard formaldehyde solutions with the following modifications (15): The standard formaldehyde solutions and the aqueous chromotropic acid solutions were freshly prepared on each day that calibration lines were determined. Purified **1** was used to prepare 5% aqueous solutions in deionized organic-free water. A 1.00 L stock solution containing 4.470 g of sodium formaldehyde bisulphite was used. The standard formaldehyde solutions were prepared from a solution whose formaldehyde concentration was 10 μg/mL prepared from the stock solution. Seven standard solutions were prepared by pipetting 0.00, 0.50, 1.0, 2.0, 3.0, 4.5, and 6.0 mL of the 10 μg/mL solution into 25-mL volumetric flasks. These were made up to 25 mL with the appropriate amounts of deionized organic-free water. These solutions correspond to aqueous formaldehyde concentrations of 0.00, 0.20, 0.40, 0.80, 1.2, 1.8 and 2.4 μg/mL, respectively.

Two-mL aliquots of each of the seven standard solutions were pipetted into separate clean 25-mL glass culture tubes. To each of these solutions 300 μL of aqueous 5% chromotropic acid solution was added and thoroughly mixed by vortexing. Three mL of concentrated sulphuric acid (96%) was added to each tube cautiously in order to avoid spattering. The mixtures were thoroughly vortexed. The tubes were sealed with Parafilm and were capped loosely with Teflon-lined screw caps and were placed in a boiling water bath for 1 h. The tubes were cooled to room temperature and were again thoroughly mixed with a vortex to prevent layering prior to the removal of samples for spectrophotometric determinations. Absorbances were measured at 580 nm using 1.0 cm optical glass cells. The spectrophotometer was zeroed against analytical blanks. The analytical blanks corresponding to a 0.00 μg/mL formaldehyde solution consisted of 2.00 mL deionized organic-free water, 300 μL of aqueous 5% chromotropic acid solution, and 3.00 mL of concentrated sulphuric acid (96%). The analytical blanks were treated in an identical manner as the solutions which contained formaldehyde.

(*b*). Effect of different concentrations of sulphuric acid. The procedures described above in (*a*) were employed with the following modifications:

(*i*) 10.2 *M* solutions. Seven standard solutions were prepared by pipetting 0.0, 0.90, 1.8, 3.6, 5.4, 8.0, and 10.7 mL of the 10 μg/mL solution into 25-mL volumetric flasks. These were made up to 25 mL with the appropriate amounts of deionized organic-free water. These solutions correspond to aqueous formaldehyde concentrations of 0.00, 0.36, 0.71, 1.4, 2.1, 3.2, and 4.3 μg/mL, respectively. After treatment of the standard solutions, a calibration line slope of 0.21 AU/(μg/mL) was obtained.

(*ii*) 4.10 *M* solutions. The exact procedures described above in (*a*) were employed except that aqueous sulphuric acid (38%) was used. No colour could be formed after treatment of these solutions.

(*iii*) Reconstituted 4.10 *M* solutions. Two-mL aliquots of the chromogen-containing solutions obtained in (*i*) which are 10.2 *M* in sulphuric acid were removed and each was diluted with 3.0 mL deionized organic-free water. The mixtures were thoroughly mixed by vortexing. The resulting solutions correspond to formaldehyde concentrations of 0.00, 0.14, 0.29, 0.57, 0.89, 1.3, 1.7 μg/mL, respectively. No additional heating was conducted on these solutions. A calibration line slope of 0.21 AU/(μg/mL) was obtained.

(*iv*) Reconstituted 10.2 *M* solutions. To each of the solutions from (*ii*) which are 4.10 *M* in sulphuric acid, was added 4.15 mL of concentrated (96%) sulphuric acid. The mixtures were thoroughly mixed by vortexing. The resulting solutions correspond to formaldehyde concentrations of 0.00, 0.20, 0.40, 0.80, 1.2, 1.8, 2.4 μg/mL, respectively. A calibration line slope of 0.20 AU/(μg/mL) was obtained after heating for 1.0 h.

(*c*) Calibration line determination using adduct **12**. A 500 mL stock

aqueous solution containing 38.6 mg of a sample of **12** was prepared in a volumetric flask. The molar mass of **12** was assumed to be 740 g/mol and the equivalent formaldehyde concentration of the stock solution was calculated to be 3.12 μg/mL. Six standard diluted solutions containing the equivalent formaldehyde concentrations of 0.00, 0.20, 0.40, 0.80, 1.2, and 1.6 μg/mL, respectively, were prepared by appropriate dilutions of the stock solution with deionized organic-free water. Two-mL aliquots of each of these solutions were pipetted into separate 25-mL glass culture tubes. A duplicate set of these six solutions was also prepared. To each culture tube in the first set was added 300 μL of deionized organic-free water and the solutions thoroughly mixed by vortexing. Three mL of concentrated sulphuric acid (96%) was cautiously added to each tube and the mixtures thoroughly vortexed. To each culture tube of the second set was added 300 μL of aqueous 5% chromotropic acid solution and the solutions thoroughly mixed by vortexing. Three mL of concentrated sulphuric acid (96%) was cautiously added to each tube and all subsequent operations were conducted as described previously above in (*a*). A control set of six standard formaldehyde solutions was prepared exactly as described in (*a*) except that the highest formaldehyde concentration was 1.8 μg/mL. The calibration line slopes measured were 0.096 AU/(μg/mL) for the first set of solutions prepared from **12** which did not contain the added 5% aqueous chromotropic acid solution: 0.23 AU/(μg/mL) for the second set of solutions prepared from **12** which did contain the added 5% aqueous chromotropic acid solution; and 0.23 AU/(μg/mL) for the control set of solutions which were prepared from sodium formaldehyde bisulphite.

Results and discussion

The formation of the *para,para*-quinoidal adduct **2**, the alternative *ortho,ortho*-quinoidal adduct **7**, and/or the *ortho,para*-quinoidal adduct **8** can all be envisioned to be formed by pathways similar to those known for the condensation of formaldehyde and phenol (16).

Nuclear magnetic resonance spectroscopy appeared to be the best method for determining the exact position on **1** where condensation of formaldehyde occurs. Both the ^{1}H and ^{13}C NMR spectra of **1** were first unambiguously defined (14). During the course of these assignments, a regioselective hydrogen–deuterium exchange of the 7.20 ppm ^{1}H NMR signal was observed. The corresponding ^{13}C NMR spectrum revealed that the intensity of the signal at 106.44 ppm due to C-3 and C-6 was diminished by over 90%, all other signals remaining unchanged. Thus the C-3 (and C-6) position of **1** was the most reactive for the deuterium exchange. If the reactivity of **1** towards deuterium oxide is assumed to be similar to that towards formaldehyde, the fact that only this regioselective hydrogen–deuterium exchange occurs suggested that the chromotropic acid – formaldehyde adduct is the *ortho,ortho*-product and not **2**, or **8**. In principle, the analytical reaction could be monitored directly by NMR. These solutions, however, contain large excesses (240 – 3 000-fold) of **1** relative to formaldehyde, thereby precluding the use of even a high-resolution NMR instrument. Experiments were therefore conducted with larger concentrations of reagents which would permit direct monitoring in a 60 MHz NMR spectrometer. Molar ratios of formaldehyde to **1** of only 1:1 and 1:2 were employed.

The reactions at either molar ratio in the presence of catalytic amounts of sulphuric acid were found to be too rapid to monitor. A typical series of the low-field region of the spectra obtained when only water was used without any sulphuric acid, is presented in Fig. 1. Figure 1*b* taken after 0.5 h shows that new signals appeared in the aromatic region at 8.25 and 7.86 ppm and that there were changes in the chemical shifts and line shapes of the signals of **1**. In addition, a new signal appeared at

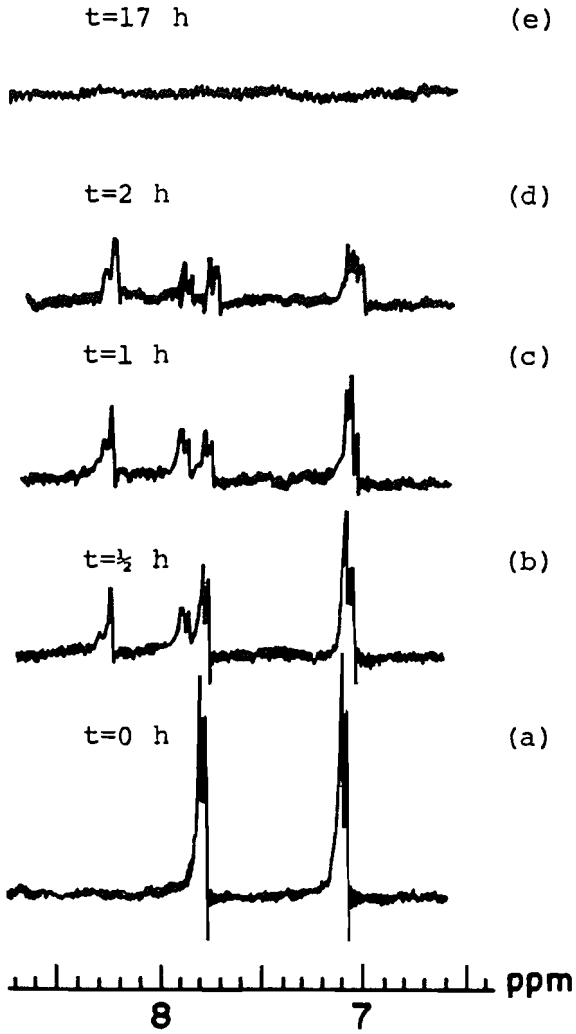

FIG. 1. Time series of nuclear magnetic resonance spectra of 1:2 molar ratio of chromotropic acid to formaldehyde in deuterium oxide.

5.40 ppm (not shown) presumably due to methylene protons. After 1.0 h the lowest field signals consisted of two singlets, a smaller one at approximately 8.30 ppm, and the larger one at 8.25 ppm. The two doublets at 7.90 and 7.80 ppm had similar coupling constants, J = 2 Hz. The signals centered at 7.10 ppm consisted of two overlapping doublets, of similar intensities and coupling constants, J = 2 Hz. No major significant changes were evident in the spectra recorded after 2.0 h up to 4.0 h. After refluxing for 17 h, however, all the aromatic region signals apparently disappeared. The high viscosity of the resulting solution, however, could account for this last observation.

When the 1:1 molar ratio of formaldehyde to **1** (or when a large excess of formaldehyde was used) was reacted and followed as above, a different series of NMR spectra was obtained. Typical low-field spectra are shown as Fig. 2. Figure 2*d* shows a spectrum recorded at 1.0 h which indicated that **1** had nearly all been consumed as the signals originally centered at 7.15 ppm had all but disappeared. The lowest field signals consisted of two singlets, as noted previously except that now the lower field singlet was the larger of the two. In addition, a methylene peak centered at 5.60 ppm (not shown) was observed. After 4.0 h all the aromatic region signals had disappeared except for a sharp singlet at 8.20 ppm. The signal due to the methylene protons was still present, but shifted

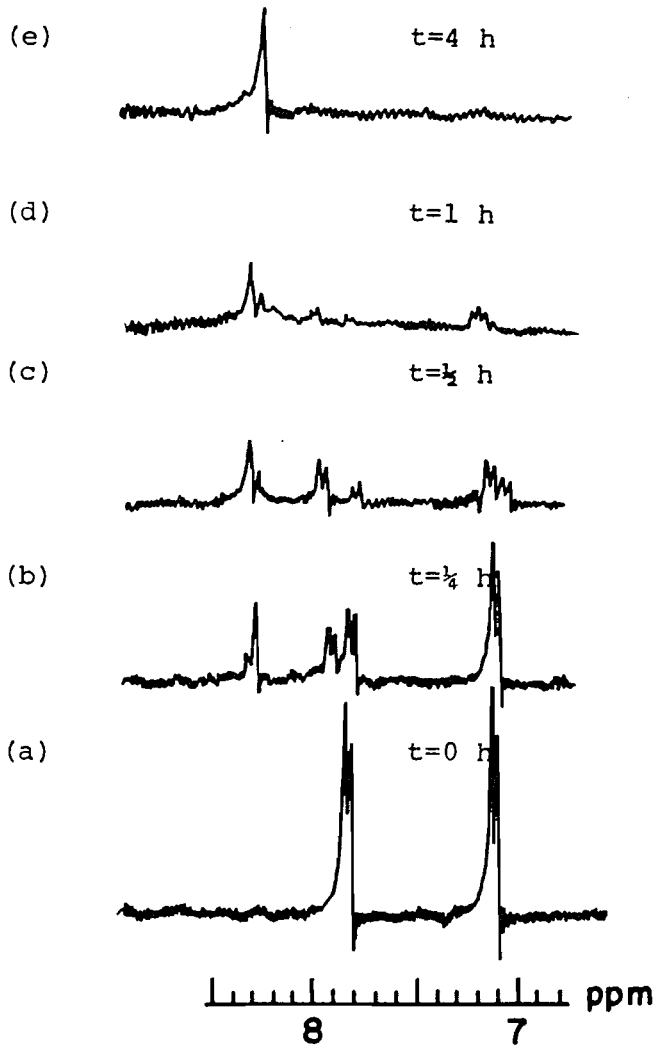

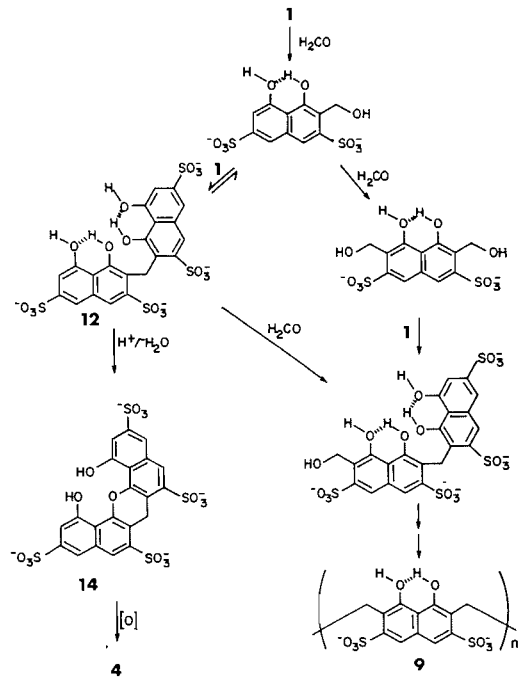

FIG. 2. Time series of nuclear magnetic resonance spectra of 1:1 molar ratio of chromotropic acid to formaldehyde in deuterium oxide.

to 4.90 ppm (not shown). It therefore appeared that cleaner reaction mixtures were being formed when the 1:1 conditions were employed. All attempts at separating the components of the reaction mixtures obtained under either sets of conditions using several different standard techniques, proved to be futile as were attempts to crystallize the product(s).

The proton-decoupled ^{13}C NMR spectrum of the crude product obtained from the 1:1 conditions showed only 7 signals. This spectrum indicated that the signal due to C-3 (and C-6) in chromotropic acid was the most affected with its chemical shift changing from 106.44 ppm in **1** to 119.28 ppm in the reaction product. The additional signal at 26.94 ppm was presumably due to a methylene carbon (17). The simplicity of the spectrum suggested that a highly symmetrical product was formed. In the 300 MHz ^1H NMR spectrum only a singlet in the aromatic region at 8.10 ppm and a singlet at 4.85 ppm was observed. This suggested that the crude product obtained was a linear polymer of formaldehyde and **1**, linked in the *ortho,ortho* positions as shown in structure **9**. The two-dimensional $^1H-^{13}C$ chemical shift correlation (18) spectrum and the attached-proton test (18) (APT) of **9** was consistent with the assigned structure.

To compare spectra with those obtained in the in-situ experiments, the mono- and dibromo derivatives **10**, **11** were

SCHEME 1

synthesized (19, 20). The ^1H NMR spectrum of **10** was similar to that of **9** but that of **11** was more revealing, showing one singlet and two doublets in the aromatic region. Its two-dimensional $^1H-^{13}C$ chemical shift correlation spectrum and the APT were also consistent with the assigned structure (14). The NMR spectra of **11** provided essential information for interpretation of the spectra obtained earlier in the in-situ experiments. These indicated that a monosubstituted chromotropic acid – formaldehyde adduct was likely being formed in the earlier stages of the reaction. Subsequently, the adduct was being converted in the presence of excess formaldehyde into the disubstituted *ortho–ortho* linear polymer **9**. Other intermediate adducts as outlined in Scheme 1 could also be formed. The in-situ spectra also indicated that after 1.0 h the optimal amounts of mono-substituted adduct could be obtained when using the 1:2 molar ratio conditions. Unreacted **1** itself was always present.

The reaction could be terminated after approximately 1.0 h by rapidly evporating the solvent and any unreacted formaldehyde under high vacuum. Some of the components of these mixtures were separated by gel permeation chromatography (21) using Sephadex LH-20. The major components that could be identified were **1** (25–30%) and a new compound **12** (55–60%). The two-dimensional $^1H-^{13}C$ chemical shift correlation spectrum and the APT of **12** was consistent with the proposed structure except that the ^{13}C NMR spectrum consisted of only ten discernable carbon signals when eleven carbon signals were predicted. Peak height comparisons in ^{13}C NMR spectra are generally unreliable (18) nevertheless, for the series of compounds that were described above, the peak heights of the ^{13}C signals due to C-4 and C-5 (those carbon atoms which are attached to the hydroxyl groups) were clearly very similar to those of the ^{13}C signal of C-2 and C-7 (those carbon atoms which are attached to the sulphonic acid groups). In the spectra of **12**, however, the combined peak heights of the carbon signals at 153.65 and 152.21 ppm assigned to C-4 and C-5 in **12** were approximately only one-half of the peak height of the signal at 140.98 ppm. This latter signal whose chemical shift is

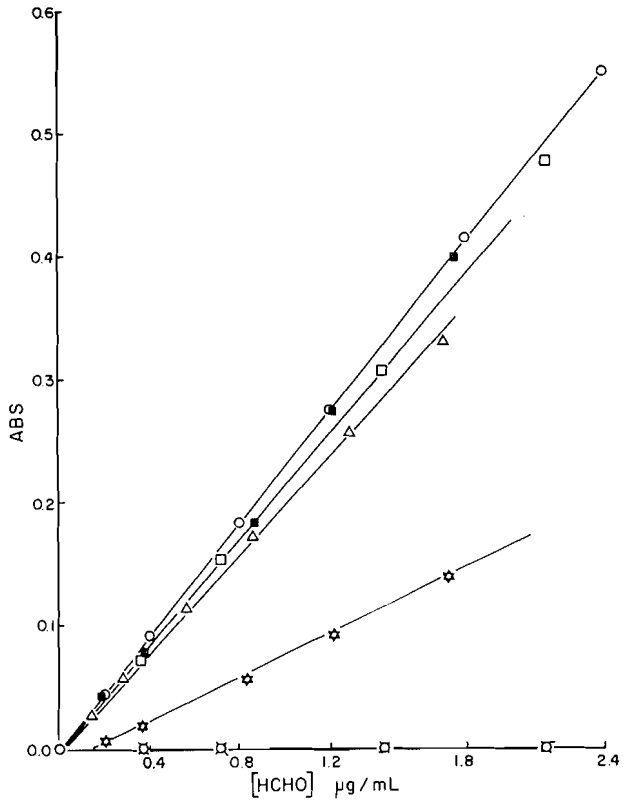

FIG. 3. Calibration lines for chromotropic acid and standard formaldehyde solutions with varying sulphuric acid concentrations; and for standard solutions derived from the adduct **12**, with concentrated sulphuric acid. □, 10.2 *M* H_2SO_4 solutions, slope = 0.21; △, 10.2 *M* H_2SO_4 solutions diluted to 4.10 *M*, slope = 0.20; ⊠, 4.10 *M* H_2SO_4 solutions, slope = 0; ○, 4.10 *M* H_2SO_4 solutions increased to 10.2 *M*, slope = 0.23; ✡, adduct **12** only, slope = 0.096; ■, adduct **12** + chromotropic acid, slope = 0.23.

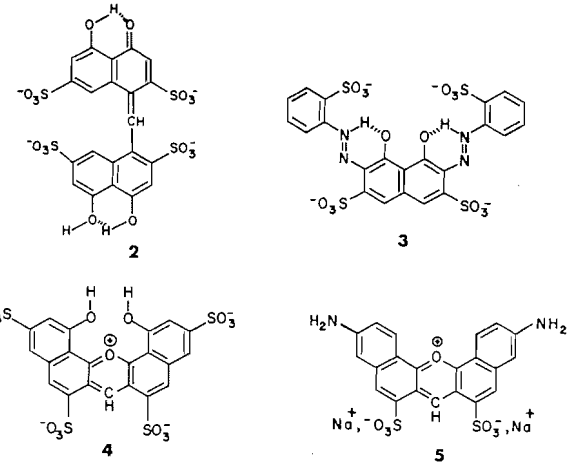

consistent with the shifts associated with C-2 and C-7 in **1** and its derivatives described above, was therefore assigned to *both* carbon atoms C-2 and C-7 in **12**. Acetylation of **12** afforded a tetra-acetoxy compound **13** whose ^1H NMR spectrum was similar to that of **12** but which in addition showed clearly two different types of acetate methyl groups. These experiments provided additional strong evidence that reaction of formaldehyde occurs at C-3 (or C-6) of **1**.

The purple chromogen could also be produced using concentrated hydrochloric acid, concentrated perchloric acid, and 85% phosphoric acid but not with glacial acetic acid. Calibration lines were determined for each of the above acids in the usual way using standard formaldehyde and 5% aqueous solutions of **1**. Concentrated sulphuric acid (96%), however, was found to give the highest calibration line slope (0.23 AU/(μg/mL)). Since sulphuric acid appeared to be the optimal acid to use, the effect of using different acidic concentrations was examined. Concentrated (96%) or diluted sulphuric acid (38%) were then compared, affording solutions which were 10.2 *M* and 4.10 *M* in sulphuric acid, respectively. After heating, only the former solutions developed the purple chromogen. The purple solutions were diluted by the addition of water in proportions such that the sulphuric acid concentrations were reduced to 4.10 *M*. The calibration line slopes derived from these diluted solutions were equivalent to those obtained before the dilution. Thus the chromogen formed originally with concentrated sulphuric acid could still exist in the 4.10 *M* sulphuric acid solutions. When concentrated sulphuric acid was added to the original 4.10 *M* sulphuric acid solutions the calibration line slopes of these reconstituted solutions were identical to the previously obtained slopes within experimental error implying that the chromogen formation was therefore not simply pH-dependent alone. These results are shown in Fig. 3.

Using chromatographically-pure **12** several attempts to isolate and characterize the polar chromogen were unsuccessful, due to its very high water solubility. The only compounds that could be recovered consistently were **1** and unreacted **12**. Nuclear magnetic resonance experiments revealed that **12** could decompose in aqueous solution to regenerate **1**. An experiment to show inferrentially that **12** was the precursor of **4** via **14** was then undertaken. An aqueous 1.04×10^{-4} *M* solution of **13** was prepared and from this solution, five aqueous solutions were prepared by appropriate dilution. One mole of formaldehyde per mole of the adduct **12** was assumed to be present, and the five solutions which were prepared had formaldehyde equivalent concentrations in the range normally employed in the analytical calibration line determinations. Two-mL aliquots of these solutions were treated with 300 μL of deionized organic-free water and 3.0 mL of concentrated sulphuric acid in a manner exactly analogous to the NIOSH procedures. As a control, the usual standard formaldehyde calibration line was also determined. The slopes were found to be different: 0.23 AU/(μg/mL) for the control solutions, and 0.096 AU/(μg/mL) for those prepared from the adduct.

The analytical solutions normally contain a large excess of **1** over the formaldehyde that is being determined. A true comparison between the absorbances measured from the solutions derived from **12** could only be made if the 300 μL of 5% aqueous **1** was also present. Therefore, replicate sets of the five solutions prepared previously from the aqueous solution of **12** were prepared and each solution was treated as before except that each now contained 300 μL of 5% aqueous **1** instead of only the 300 μL amount of water. The calibration lines were again determined in the usual way. The slopes now obtained were found to be identical to those of the controls. Typical results are included in Fig. 3. From these slopes the absorptivity for the chromogen was calculated to be $1.8 \times 10^4\ M^{-1}\ cm^{-1}$ which is two- to four-fold greater than those values reported previously (22).

All of the evidence presented above is consistent with a mono-cationic dibenzoxanthylium structure for the chromogen and not the *para,para*-quinoidal one that is commonly cited. The experimental data suggests that the first step in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

analytical reaction is the reversible formation of an adduct such as **12**. The second step involves the dehydration by a strong acid to form the dibenzoxanthene-type compound **14**. The oxidation of such a compound once formed should be facile since it can produce the mono-cationic dibenzoxanthylium species **4** which is planar and contains 22 π electrons, and satisfies the Huckel $(4n + 2)$ rule for aromaticity. The calibration line observations provided additional evidence that an equilibrium reaction exists in which the excess **1** shifts the equilibrium favourably toward the direction of the optimal chromogen formation. Scheme 1 shows a likely mechanism for the reaction.

Conclusions

The site of the reaction of formaldehyde with chromotropic acid in aqueous or aqueous acidic conditions most likely occurs on the carbon atom which is *ortho-* to both the hydroxyl and sulphonic acid groups. An adduct containing a methylene bridge formed by the coupling of a single molecule of formaldehyde between two molecules of chromotropic acid could be isolated and characterized by ^{1}H and ^{13}C NMR spectroscopy. Attempts at crystallization of this adduct were unsuccessful, however, the adduct has been shown to undergo a retro-addition equilibrium in aqueous solution. Using calibration line studies, with a large excess of chromotropic acid, the adduct was shown to be a precursor of the same chromogen that is observed in the NIOSH analytical method. Its formation is not simply a function of pH alone. It is hypothesised that a dehydration step is first required to produce a dibenzoxanthene-type compound which then undergoes facile oxidation to produce the corresponding mono-cationic dibenzoxanthylium structure. The mono-cation is planar and obeys the Huckel $(4n + 2)$ rule for aromaticity.

Finally, the often-quoted *para,para*-quinoidal structure for the chromogen appears to be very unlikely and concentrated sulphuric acid appears to be the optimal acid to use in the method. Therefore, simple modifications to the procedure would not seem to be feasible in light of the understanding of the reaction gained during this study.

Le polysaccharide naturel de l'antigène extrait du *Streptococcus* du type IV du groupe B contient du D-galactose, du D-glucose, de l'acétamido-2 désoxy-2 D-glucose et de l'acide sialique dans un rapport molaire de 2 : 2 : 1 : 1 et il est composé de l'unité de base suivante :

L'analyse de la structure de cet antigène est basée sur les résultats obtenus à l'aide de techniques de méthylation, d'hydrolyses partielles, de désaminations nitreuses et de spectroscopie en résonance magnétique nucléaire.

Mots clés : polysaccharide capsulaire, spectroscopie RMN de haute résolution, groupe B *Streptococcus*, structure du polysaccharide, dégradation du polysaccharide.

[Traduit par la revue]

Introduction

Group B *Streptococcus* (GBS) is a major cause of neonatal sepsis and meningitis. In early immunological studies, Lancefield characterized the type-specific polysaccharide antigens of GBS (1–3), which were isolated by hot hydrochloric acid extraction of the whole organisms (2, 3). While still retaining type-specificity, these acid extracted antigens are structurally and, in most cases, immunologically incomplete. They form the lower molecular weight core structures of their respective native antigens, which all contain additional terminal sialic acid residues (4–8). The structures of the types Ia, Ib, II, and III capsular polysaccharides have been elucidated (9–11), and the important role of sialic acid in the pathogenicity of GBS (12)

and in the unique formation of conformational determinants critical to the immunogenicity of many of the GBS polysaccharides has been defined (13–15).

While the majority of the GBS isolates from human neonatal infections bear one of the above four major capsular types (Ia, Ib, II, and III), a number of previously non-typable GBS isolates have recently been identified as belonging to an antigenically distinct group, type IV (16). This serogroup is also based on a capsular antigen and its isolation, purification, and immunochemical characterization have been previously described (17). We now report the structural elucidation of the type IV GBS polysaccharide.

Results and discussion

The type IV GBS capsular polysaccharide had $[\alpha]_D$ + 9.0 (*c* 0.3, in water) and contained D-glucose, D-galactose, 2-acetamido-2-deoxy-D-glucose, and *N*-acetylneuraminic acid in the molar ratio of 2:2:1:1 (Table 1). The configuration of the glycoses was established by the characteristic retention times of their acetylated (-)-2-butanol glycosides (22) on capillary glc. Methylation analysis (Table 2) indicated that the type IV polysaccharide was composed of a branched hexasaccharide repeating unit, the branch point being a β-D-galactopyranosyl residue linked at O-4 and O-6. The presence of a fully methylated sialic acid derivative is indicative of a terminal sialic acid residue, and this is consistent with the known neuraminidase sensitivity of the sialic acid residues of the type IV polysaccharide (17). The other sugar residues present in the repeating unit are two glucopyranoses, both linked through O-4, a galactopyranose residue linked through O-3, and a 2-acetamido-2-deoxy-glucopyranosyl residue linked through O-4. The ^{1}H nmr spectrum (500 MHz at 27°C and 37°C) of the native type IV GBS polysaccharide indicated the presence of five anomeric signals (Table 3), only one of them corresponding to an α-D-linked hexopyranosyl residue, and two signals of equal intensity at 2.07 and 2.03 ppm corresponding to the respective *N*-acetyl groups of the 2-acetamido-2-deoxy-D-glucopyranose and *N*-acetylneuraminic acid residues in the repeating unit. A quartet at 2.75 ppm and a triplet at 1.81 ppm are similar in chemical shift to the respective signals associated with the equatorial and axial H-3 protons of an α-linked sialic acid residue. These results together with the ^{13}C nmr spectrum (125 MHz at 37°C) shown in Fig. 1, which exhibited six anomeric signals at 104.15, 103.48, 103.16, 101.56, 100.69, and 100.35 ppm, confirm that the type IV polysaccharide is composed of a hexasaccharide repeating unit.

[a]Measured at 37°C in D_2O with acetone as internal reference (δ = 2.225 ppm).
[b]In parentheses, Hz = hertz; brs = broad singlet; brd = broad doublet.

Following mild acid treatment of the native type IV polysaccharide, another polysaccharide called the core polysaccharide was obtained and had $[\alpha]_D$ + 17.0 (*c* 0.4, in water). Sugar analysis (Table 1) indicated only the loss of the sialic acid from the native polysaccharide, and this was confirmed by the absence of the aforementioned charactistic H-3a and H-3e of sialic acid in the ^{1}H nmr spectrum of the core polysaccharide. Methylation of the core polysaccharide (Table 2) shows that the 2,4,6-tri-*O*-methyl-galactose derivative of the native polysaccharide is replaced by a new 2,3,4,6-tetra-*O*-methyl-galactose derivative; thus in the native polysaccharide sialic acid must be α-(2–3)-linked to a galactose residue. Traces of a 3,4,6-tri-*O*-methylglucosamine derivative were detected in the methylation analysis of the core polysaccharide that could have originated from the partial removal, due to the mild acid treatment, of the terminal galactopyranosyl residues from O-4 of the 2-

[b]nd, not determined.

acetamido-2-deoxy-D-glucopyranose residues. The ^{1}H nmr spectrum (500 MHz at 37°C) of the core polysaccharide exhibited five anomeric signals (Table 3), with only one of them undergoing a considerable displacement in comparison with the equivalent signals of the native type IV polysaccharide. This particular signal at 4.547 and 4.471 ppm in the spectra of the native and core polysaccharides, respectively, can be assigned to the β-D-galactopyranosyl residue in the side chain of each of the polysaccharides.

Following removal of the *N*-acetyl groups of the native type IV polysaccharide by base treatment, the *N*-deacetylated polysaccharide was deaminated with nitrous acid. A new polymeric material was again obtained, which is henceforth referred to as the backbone polysaccharide. It had $[\alpha]_D$ + 39.0 (*c* 0.4, in water) and was composed of D-glucose and D-galactose in the molar ratio of 2:1 (Table 1). Methylation analysis of the backbone polysaccharide (Table 2) indicated that it had a linear structure in which all the glycose residues were linked through O-4. The ^{1}H nmr (500 MHz at 37°C) spectrum of the backbone polysaccharide exhibited three anomeric signals and the coupling constant ($^3J_{1,2}$ = 3.5 Hz) of one of them indicated that the backbone still retained the only α-D-linked glycose reside in the native type IV polysaccharide. This sugar was identified by further ^{1}H nmr analysis. Based on 2-D COSY and relay COSY experiments it was possible to assign most of the signals in the ^{1}H nmr spectrum of the backbone polysaccharide (Table 4). The signal at 4.915 ppm was assigned to one of the two glucopyranosyl residues, which could then be identified as the glycose residue having the α-D configuration (Table 3).

The remaining information required to reconstruct the repeating unit of the type IV polysaccharide was the sequence of the glycose residues in the backbone. This was ascertained from the ^{1}H nmr nOe data and is depicted in Fig. 2. Following assignment of the proton signals of the backbone polysaccharide, the anomeric signals of its component sugars were selectively irradiated and the observed nOe's are listed in Table 5. Irradiation of H1(a) gave enhancements on H2(a), H4(b), H5(b), and H6(b), indicating that the glucopyranose residue (a) is in the α-D configuration and linked to the β-D-galactopyranose residue (b) through O-4. Irradiation of H1(b) gave enhancements on H2(b), H3(b), H4(b), H5(b), and H4(c), thus confirming the β-D configuration of (b) and confirming that (b) is linked to the remaining β-D-glucopyranose residue (c) through O-4. The configuration of (c) and the fact that it is also

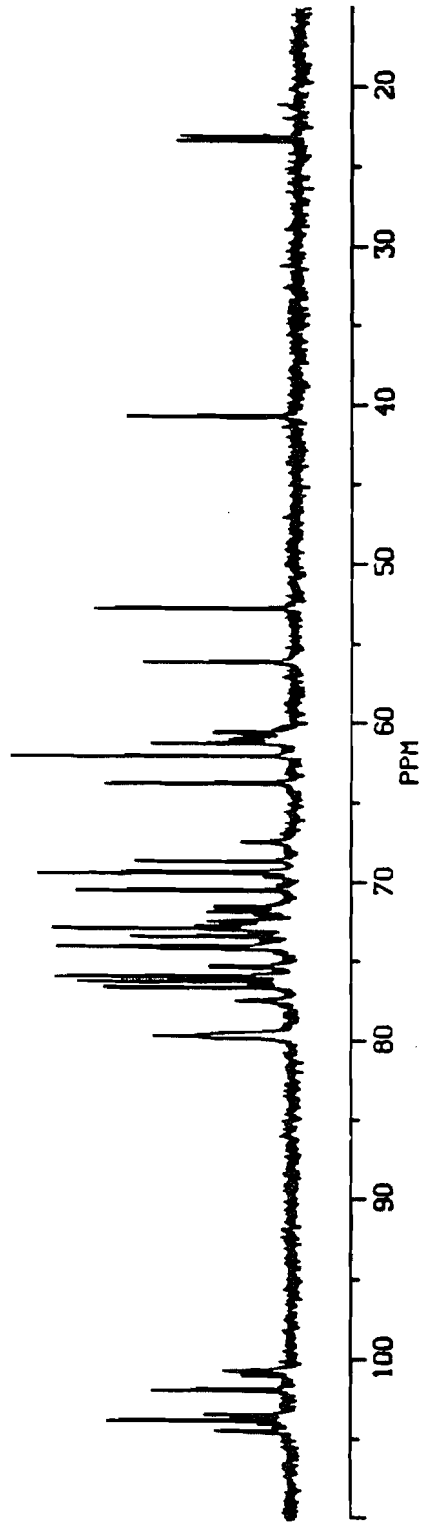

FIG. 1. The ^{13}C nmr spectrum of the native type IV GBS capsular polysaccharide.

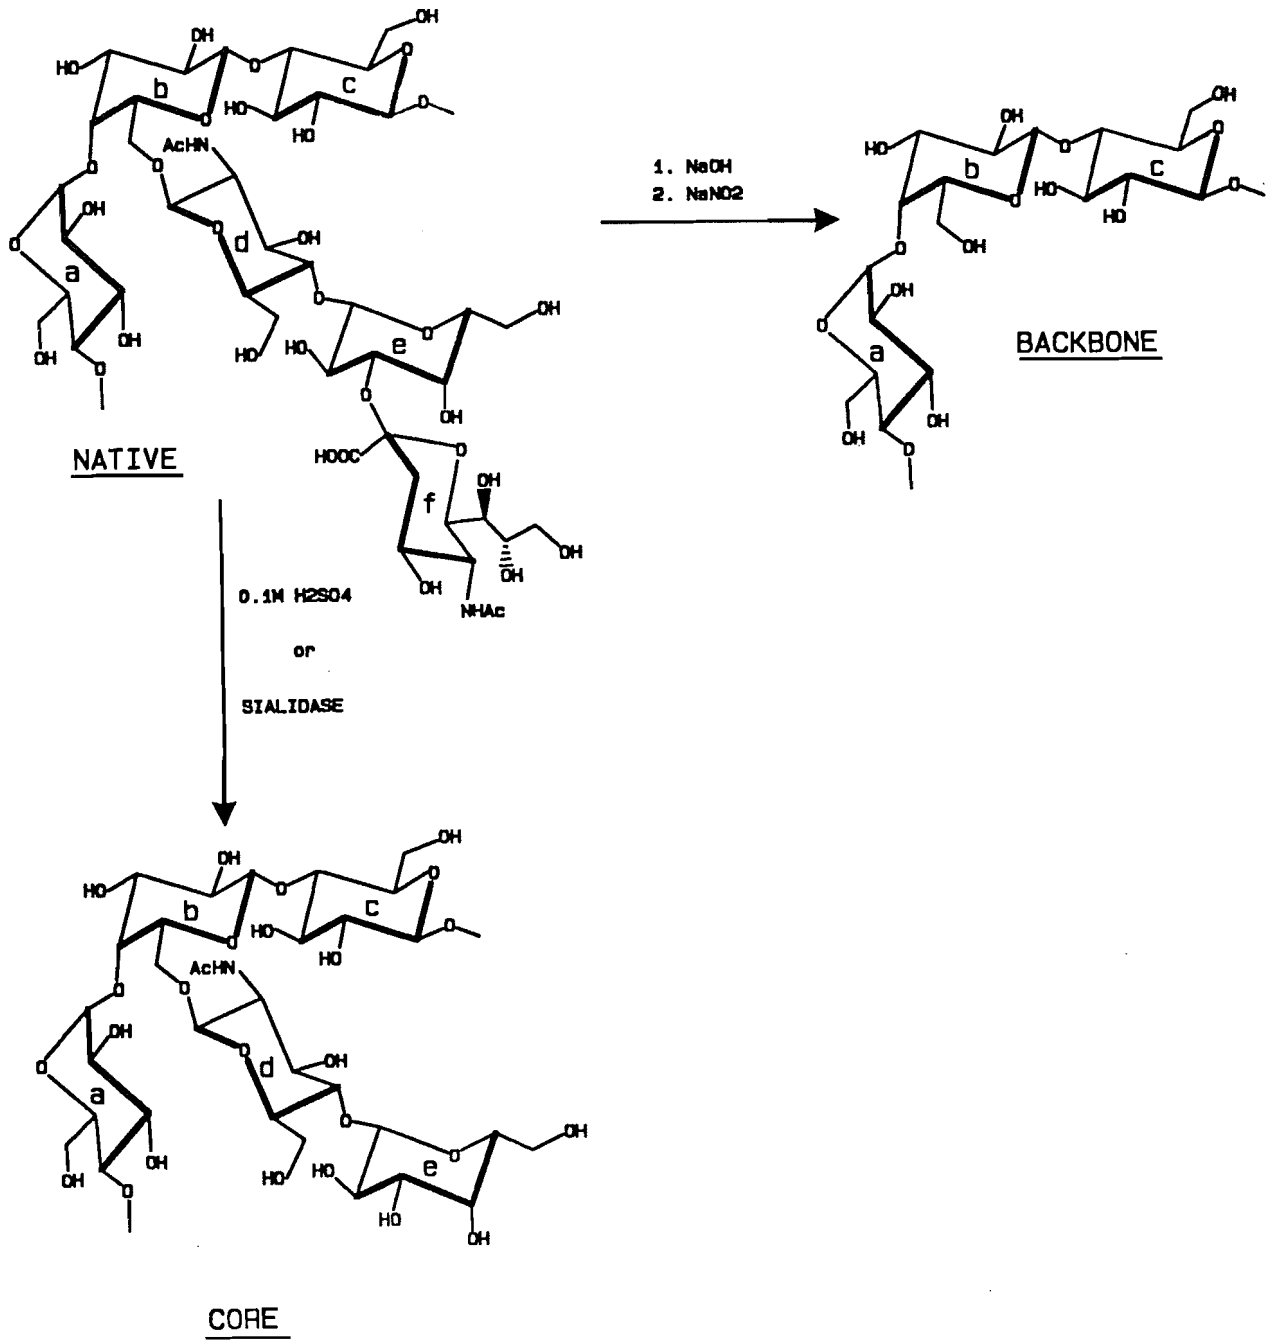

FIG. 2. Structure of the backbone and the core polysaccharide obtained by chemical and enzymatic degradations of the native antigen.

linked to O-4 of (a) was also confirmed by enhancements obtained on H2(c), H3(c), and H4(a) by irradiating H1(c).

Knowing the structure and sequence of the backbone polysaccharide, the structure of the core polysaccharide (Fig. 2) can easily be reconstructed from its glycose (Table 1), methylation (Table 2), and ^{1}H nmr (Table 3) analysis. It is obviously related to the backbone by the addition of a β-D-Galp-(1–4)-β-D-GlcpNAc branch (residues (e) and (d)) to O-6 of residue (b) of the backbone and this structure is consistent with the backbone being formed by deamination of the native polysaccharide (Fig. 2). Finally, glycose (Table 1) and methylation (Table 2) analysis of the native type IV polysaccharide indicate that it can be constructed from the core polysaccharide by the simple addition of α-linked sialic acid (f) to O-3 of its terminal β-D-galactopyranose residues (e). Thus the repeating unit of the type IV GBS polysaccharide is as depicted in Fig. 2.

The ^{13}C nmr spectrum of the type IV polysaccharide is shown in Fig. 1 and it is interesting to observe that some of the signals are sharper and hence more intense than others. This result can be explained in terms of the molecular dynamics of the polysaccharide, where the branches of the polysaccharide are much more flexible than its more rigid backbone. This was ascertained by the fact that the more intense signals, usually associated with the more flexible part of the polysaccharide (25), could all be readily assigned to the carbons in the branch consisting of residues (f), (e), and (d) (Fig. 2) as the signals had

TABLE 5. Nuclear Overhauser enhancements for the backbone polysaccharide of Type IV GBS

Proton saturated	Observed negative nOe[a]	
	Same residue	Other residues
H-1a	H-2a (4)	H-4b (5) H-5b (11) H-6b (8)
H-1b	H-2b (6) H-3b (12) H-4b (3) H-5b (4)	H-4c (9)
H-1c	H-2c (1) H-3c (6)	H-4a (14)

[a]Values in parentheses are percentage enhancements.

virtually identical chemical shifts to the corresponding signals previously assigned (26) to the free trisaccharide α-NeupNAc-(2–3)-β-D-Galp-(1–4)-β-D-GlcpNAc.

Comparison of the structure of the type IV polysaccharide with those of the other GBS polysaccharides (9–11) indicates that they are all constructed from the same glycose constituents, and all have extensive structural and sequence homology. All have terminal sialic acid linked to O-3 of β-D-galactopyranose, the closest structural homologue to the type IV polysaccharide being the type Ia polysaccharide (9). Both polysaccharides have identical trisaccharide branches and a common backbone disaccharide sequence. However, despite this extensive structural homology the type IV polysaccharide remains antigenically distinct (17). This is due in large part to the fact that the regions of structural homology in the types Ia and IV polysaccharides, and also in all the other GBS polysaccharides, are also present in human and animal tissues (14). For example, the terminal trisaccharide, α-NeupNAc-(2–3)-β-D-Galp-(1–4)-β-D-GlcpNAc, has been identified in fetuin (27, 28), M and N blood group substances (29), and human erythrocytes (30). Therefore because they are self antigens, the formation of antibodies to these structures common to the GBS polysaccharides is normally suppressed.

Another phenomenon associated with the GBS polysaccharides is that their sialic acid residues play a major role in controlling the conformations of the epitopes of the types Ia, II, and III polysaccharides (13–15). In contrast, it would appear that the type IV polysaccharide (17) resembles more that of type Ib (7, 8) in which this conformational dependence was not detected.

Experimenal

Materials

Type IV GBS strain 3139, Czechoslovak National Collection of Type Cultures (CNCTC), was kindly provided by Dr. J. Jélinková, Institute of Hygiene and Epidemiology, Prague. The growth of the organism and the isolation and purification of the capsular polysaccharide have been previously described (17).

Analytical methods

Sialic acid was determined by the method of Aminoff (18). Solutions were concentrated below 50°C under diminished pressure in a rotatory evaporator. Gel filtration was done on columns of Sephadex G-100 (2.0×80 cm), Sephadex G-50 (2.0×80 cm), and Sephadex G-15 (2.0×40 cm) (Pharmacia Fine Chemicals) at 20°C using PBS buffer (0.01 M sodium phosphate, 0.15 M sodium chloride, pH 7.0) and (or) pyridinium acetate buffer (0.05 M, pH 4.5) as the eluants.

Instrumental methods

Optical rotations were determined on a Perkin–Elmer 243 instrument with 1-dm semimicro cells at 23±1°C.

Gas–liquid chromatography (glc) was performed on a Hewlett–Packard model 5830A instrument equipped with a flame ionization detector and a model 3380A electronic integrator. The following conditions were used with a capillary column (0.32 mm×25 m) of 007 bonded phase, fused silica OV-17 (Quadrex Corp.). Program A for alditol acetates: from 180°C to 240°C at 4°C/min; program B for methylated alditol acetates: from 200°C to 240°C at 1°C/min; and program C for methylated sialic acid derivatives: isothermal at 230°C. Combined gas–liquid chromatography – mass spectrometry (glc–ms) was carried out on a Hewlett–Packard 5985B instrument using the above capillary column and employing programs A, B, and C as described above and an ionization potential of 70 eV.

The ^{13}C nmr spectra were obtained with the samples in 5 mm diameter tubes at 27°C and 37°C, with a Bruker AM500 spectrometer operating at 125 MHz, in the pulsed Fourier transform mode with complete proton decoupling. The ^{1}H nmr spectra were recorded at 27°C and 37°C with a Bruker AM200 spectrometer operating at 200 MHz or a Bruker AM500 spectrometer operating at 500 MHz, in the pulsed Fourier transform mode. The chemical shifts (δ) are quoted relative to the CH_3 signal of internal acetone at 2.225 ppm for ^{1}H and 31.07 ppm for ^{13}C. Coupling constants are expressed in hertz.

Proton homonuclear shift correlated 2-D nmr experiments, COSY (19) and related COSY (20), were performed by using the standard pulse sequences provided by Bruker (DISB87). Quadrature detection in both dimensions was employed. The initial (t_1, t_2) matrices of 256×1024 data points were zero filled to 512×2048 points, providing 1.6 Hz/point digital resolution in the second domain. Resolution enhancement in both dimensions was done by the unshifted sine bell window function prior to Fourier transformation. Magnitude spectra symmetrized about the diagonal were used to represent data.

Heteronuclear shift correlation spectroscopy was performed by the CHORTLE technique (21). A total of 4000 scans for each of the five proton evolution times of 0.16, 0.40, 1.0, 2.4, and 3.2 ms was collected and data were processed to give a table of data correlating ^{1}H and ^{13}C chemical shifts.

Glycose analysis

Polysaccharide samples (0.5–1.0 mg) were hydrolyzed with 0.25 M sulfuric acid at 100°C for 16 h. The hydrolysate was neutralized with barium carbonate, filtered, and evaporated to dryness. The residue in water (0.6 mL) was then treated with 33% acetic acid (1 mL) and 5% sodium nitrite (1 mL) for 1 h at room temperature. The solution was deionized with Dowex 50 (h^+) ion-exchange resin and lyophilized, and the residue was analyzed by glc–ms (Program A) after conversion of the glycoses into their alditol acetates. The configuration of the glycoses was established by capillary glc of their acetylated (−)-2-butyl glycosides according to the method of Leontein *et al.* (22).

Methylation analysis

Samples (1.0–2.0 mg) were methylated using sodium methylsulfinylmethanide and methyl iodide in dimethylsulfoxide according to the Hakomori procedure (23). The products were purified with C18 Sep-Pak cartridges (Waters Associates). Methylated products were hydrolyzed with 0.5 M trifluoroacetic acid at 100°C for 16 h. After evaporation the hydrolyzates were reduced with sodium borodeuteride followed by acetylation, and examined by glc–ms (Program B). The methylated sialic acid was identified by glc–ms (Program C) as the methyl ester methyl glycoside obtained by methanolysis of the permethylated polysaccharide.

Preparation of the core polysaccharide

Purified capsular polysaccharide was treated with 0.1 M sulfuric acid at 80°C for 60 min. The solution was diluted, applied to a small column of AG3-X4A (acetate form) resin, eluted with water, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

freeze-dried. The solid was dissolved in pyridinium acetate buffer and applied to a small Sephadex G-15 column. The material eluting in the void volume corresponded to the core polysaccharide.

N-Deacetylation and deamination of the capsular polysaccharide

The capsular polysaccharide (20 mg) was dissolved in 2 M NaOH (3 mL) and sodium borohydride (50 mg) was added. The solution was heated at 100°C for 5 h. After neutralization with acetic acid, the solution was dialyzed and freeze-dried. The *N*-deacetylated capsular polysaccharide was then deaminated essentially by the method of Dmitriev *et al.* (24). The *N*-deacetylated material was dissolved in water (1.2 mL) and, following the addition of 33% aqueous acetic acid (2.0 mL), the solution was treated with 5% aqueous sodium nitrite (3.0 mL) for 1.5 h at room temperature. The reaction mixture was passed through Dowex 50 (H^+) ion-exchange resin, evaporated to dryness, and applied to a small Sephadex G-50 gel permeation column eluted with pyridinium acetate buffer. The void volume was collected.

The coordinatively unsaturated binuclear rhodium hydrides $[\{Pr^i_2P(CH_2)_nPPr^i_2\}Rh]_2(\mu\text{-}H)_2$ (n = 2: **1***b*; n = 3: **1***c*; n = 4: **1***d*) react rapidly with dihydrogen to yield the fluxional binuclear tetrahydrides $[\{Pr^i_2P(CH_2)_nPPr^i_2\}RhH](\mu\text{-}H)_3[Rh\{Pr^i_2P(CH_2)_nPPr^i_2\}]$ **2***b*–*d* (n = 2–4). The dihydride **1***b* was structurally characterized by single crystal X-ray diffraction. While the tetrahydrides **2***b* and **2***c* were found to be stable only in solution in the presence of excess dihydrogen, **2***d* was stable in the solid state. Three separate exchange processes were characterized for **2***b*–*d* via ^1H and $^{31}P\{^1H\}$ NMR spectroscopy: intermolecular exchange with free dihydrogen, and two intramolecular processes exchanging the four hydride ligands. The geometry about the rhodium centres in the limiting structures involved in these processes is affected by the chelate ring size of the ancillary diphosphine ligand. A "rocking" process observed at low temperatures for each of these tetrahydrides has a $\Delta G^{\ddagger}$ of $<$7.0(5) kcal/mol, 8.6(5) kcal/mol, and 11.5(5) kcal/mol for **2***b*, **2***c*, and **2***d*, respectively. The dihydrides **1***b* and **1***c* were found to catalyze the hydrogenation of 1-hexene. Turnover numbers of 850–950 h^{-1} and 700 h^{-1} were observed for **1***b* and **1***c*, respectively, along with isomerization side reactions. Catalyst concentration studies on the hydrogenation of styrene using **1***c* as the catalyst precursor revealed a decrease in turnover frequency with increasing total metal concentration, suggesting that the active catalyst is a mononuclear species. Chemical evidence suggests that a pathway involving binuclear intermediates is also available, but that in the **1***c* system at least, a pathway utilizing mononuclear species as intermediates predominates.

Key words: binuclear rhodium hydrides, homogeneous catalysis.

MICHAEL D. FRYZUK, WARREN E. PIERS, FREDERICK W. B. EINSTEIN et TERRY JONES. Can. J. Chem. **67**, 883 (1989).

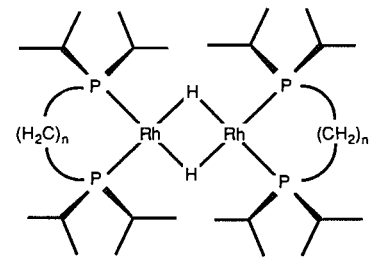
Les hydrures de rhodium binucléaires et insaturés par coordination $[\{Pr^i_2P(CH_2)_nPPr^i_2\}Rh]_2(\mu\text{-}H)_2$ (n = 2 : **1***b*; n = 3 : **1***c*; n = 4 : **1***d*) réagissent rapidement avec le dihydrogène pour fournir les tétrahydrures binucléaires de fluxion $[\{Pr^i_2P(CH_2)_nPPr^i_2\}RhH]_2(\mu\text{-}H)_3[Rh\{Pr^i_2P(CH_2)_nPPr^i_2\}]$ **2***b*–*d* (n = 2–4). On a caractérisé la structure du dihydrure **1***b* à l'aide de la diffraction des rayons-X. Les tétrahydrures **2***b* et **2***c* ne sont stables qu'en solution, en présence de dihydrogène; par ailleurs, le composé **2***d* est stable à l'état solide. En se basant sur la rmn du ^1H et du $^{31}P\{^1H\}$, on a pu caractériser trois processus différents d'échanges : un échange intermoléculaire avec le dihydrogène libre et deux processus intramoléculaires permettant l'échange des quatre ligands. Dans les structures limites impliquées dans ces processus, la géométrie autour des centres de rhodium est influencée par la grandeur du cycle chélate du ligand diphosphine ancillaire. Les $\Delta G^{\ddagger}$ du processus de «balancement» observé à basses températures pour chacun de ces tétrahydrures sont respectivement de $<$7,0(5), 8,6(5) et 11,5(5) kcal/mol pour les composés **2***b*, **2***c* et **2***d*. On a trouvé que les dihydrures **1***b* et **1***c* catalysent l'hydrogénation de l'hexène-1. On a trouvé que les activités des composés **1***b* et **1***c* sont respectivement de 850 à 900 et 700 heure^{-1} et qu'elles sont accompagnées de réactions d'isomérisations secondaires. Des études de concentration de catalyseur sur l'hydrogénation du styrène utilisant le composé **1***c* comme précurseur du catalyseur ont permis de mettre en évidence qu'une augmentation de la concentration totale du métal est accompagnée d'une diminution de l'activité; ces résultats suggèrent que le catalyseur actif est une espèce mononucléaire. Des données de nature chimique suggèrent qu'une voie réactionnelle impliquant des intermédiaires binucléaires est aussi disponible; toutefois, au moins avec le système **1***c*, la voie réactionnelle utilisant l'espèce mononucléaire comme intermédiaire prédomine.

Mots clés : hydrures de rhodium binucléaires, catalyse homogène.

[Traduit par la revue]

Introduction

Polynuclear transition metal complexes with coordinative unsaturation associated with one or more metal centres have been an attractive target in synthetic inorganic chemistry (1). Activation of small molecules, whether stoichiometrically or catalytically, requires that the substrate molecule be able to access a metal centre in the cluster. In the triosmium cluster series, the advent of the "lightly stabilized" complexes $Os_3(CO)_{10}L_2$ (L = cyclooctene, acetonitrile (2); L_2 = 1,3-cyclohexadiene (3)) greatly expanded the range of substrates for activation by simply making the metal centres more accessible as compared (4) to the parent cluster $Os_3(CO)_{12}$. The related dihydride $Os_3(\mu\text{-}H)_2(CO)_{10}$ (5), unsaturated by virtue of the bridging hydrides of the $Os_2(\mu\text{-}H)_2$ part of the cluster, has also been extremely important in developing the chemistry of osmium clusters (6).



The carbonyl-free family of polynuclear rhodium hydrides of the general formula $[L_2Rh]_n(\mu\text{-}H)_n$ (n = 2, 3, or 4, depending on the steric bulk of L) are inherently unsaturated. For example, the binuclear complexes of the formula $[L_2Rh]_2(\mu\text{-}H)_2$ are 28 electron systems; by comparison, coordinatively saturated binuclear clusters such as $Fe_2(CO)_9$ and $M_2(CO)_{10}$ (M = Mn and Re) are 34 electron species. The unsaturation of these rhodium hydride clusters is reflected by their high reactivity with a range of small molecules such as dihydrogen (7), alkenes

b n = 2 [(dippe)Rh]$_2$(μ-H)$_2$

c n = 3 [(dippp)Rh]$_2$(μ-H)$_2$

d n = 4 [(dippb)Rh]$_2$(μ-H)$_2$

1

(8), alkynes (9), dienes (10), imines (11), isonitriles (12), and carbon monoxide (13). In addition, these unsaturated clusters are active as catalyst precursors for the hydrogenation of alkenes and alkynes (7, 9).

The most intensely studied members of this family of rhodium hydride clusters are the binuclear derivatives. The complex [{(Pr^{i}O)$_3$P}$_2$Rh]$_2$(μ-H)$_2$, **1***a*, was the first derivative in this class to be reported (14) and it has provided the underpinning for the understanding of both the stoichiometric and catalytic reactivities of these 28 electron clusters. Modification of these systems by the use of chelating bidentate phosphines and phosphinites has provided complexes with enhanced reactivity as compared to **1***a* above (15). Thus complexes of the formula [{Pr$^i{}_2$P(CH$_2$)$_n$PPr$^i{}_2$}Rh]$_2$(μ-H)$_2$ (n = 2: **1***b*; n = 3: **1***c*; n = 4: **1***d*) react with dihydrogen, olefins and other unsaturated substrates under exceedingly mild conditions.

These particular bidentate ligands all have isopropyl substituents on the phosphorus donors separated by two, three, and four methylene units. The substituents are large enough to generate the binuclear structure (16) but do allow access to the unsaturated Rh$_2$(μ-H)$_2$ core by a variety of substrate molecules. However, it is the chelate ring size that dramatically affects the reactivity patterns of these hydride dimers. In this paper, we examine the addition of dihydrogen to these binuclear 28 electron complexes (**1***b*–**1***d*). Also presented is a discussion of the possible pathways for these systems to hydrogenate olefins in the catalytic mode.

Experimental

General

All manipulations were performed under prepurified dinitrogen in a Vacuum Atmospheres HE-553-2 glovebox equipped with a MO-40-2H purifier, or in standard Schlenk-type glassware. The description "reactor bomb" refers to a cylindrical, thick-walled Pyrex vessel equipped with a 5 mm Kontes needle valve and a ground glass joint for attachment to a vacuum line. Larger bombs have 10 mm Kontes valves.

Hydrated rhodium trichloride was obtained from Johnson–Matthey and used as received. The syntheses of (η^3-C$_3$H$_5$)Rh(COD) (COD = 1,5-cyclooctadiene) (7) and the binuclear complex [{Pr$^i{}_2$P(CH$_2$)$_2$-PPr$^i{}_2$}Rh]$_2$(μ-H)$_2$, [(dippe)Rh]$_2$(μ-H)$_2$, **1***b* (8) were as reported previously. Literature preparations were used to generate the bidentate ligands, Pr$^i{}_2$PCH$_2$CH$_2$CH$_2$PPr$^i{}_2$, dippp (17) and Pr$^i{}_2$PCH$_2$CH$_2$PPr$^i{}_2$, dippe (8).

Toluene and diethylether were purified by distillation from sodium-benzophenone ketyl under argon. Tetrahydrofuran (THF) and hexanes were predried by refluxing over calcium hydride followed by distillation from sodium-benzophenone ketyl under argon.

Melting points were determined on a Mel-Temp apparatus in sealed capillaries under nitrogen, and are uncorrected. Carbon, hydrogen, and halogen analyses were performed by Mr. P. Borda of this department. ^{1}H NMR spectral measurements were carried out on one of the following instruments: Varian XL-300, Bruker WP-80, or a Bruker WH-400. (All ^{1}H{^{31}P} NMR spectra were obtained on the Bruker WH-400.) ^{31}P{^{1}H} NMR measurements were carried out at 121.421 MHz on the Varian XL-300, using trimethylphosphite as an external standard (141.0 ppm). ^{13}C{^{1}H} spectra were run at 75.429 MHz, also on the Varian instrument, using internal solvent peaks as a reference (C$_6$D$_6$, 128.0 ppm). NMR solvents C$_6$D$_6$ and C$_7$D$_8$ were bought from MSD Isotopes, and dried over activated 3 Å molecular sieves and vacuum transferred, while d_8-THF was dried over sodium-benzophenone ketyl, and stored under dry nitrogen. Simulated NMR spectra were obtained using the program UBCPANIC.

The 1,4-dibromobutane used in the preparation of 1,4-bis(diisopropylphosphino)butane (dippb) was obtained from the Aldrich Chemical Co. and distilled under argon prior to use. The substrates 1-hexene and styrene (99%) were also obtained from Aldrich. 1-Hexene was dried for 8 h over activated 3 Å molecular sieves, vacuum transferred into a storage vessel, and degassed thoroughly via three freeze–pump–thaw cycles. It was then passed through neutral alumina and stored under N_2 in a glove box. Styrene was distilled under argon just prior to use.

Hydrogen gas used in the hydrogenation of 1-hexene was purified by passing through a glass tower (4″ in diameter) packed with MnO (bottom layer) and 4 Å molecular sieves separated by a plug of glass wool and a layer of glass beads. The towers were made by packing with 200 g $MnCO_3$ and 1700 mL Vermiculite (mixed) followed by the molecular sieves. Activation was accomplished by passing H_2 gas through the tower while heating at about 200°C until the brown colour of the $MnCO_3$ had turned the characteristic green of MnO. Heating was effected by passing current through a wire wrapped around the tower in spirals separated by about 1″ (18). Hydrogen gas used for the kinetic measurements on the hydrogenation of styrene was purified by passing through an Englehard Deoxo hydrogen purifier, attached to the hydrogen cylinder.

Analysis of hexenes and hexane in the hydrogenation of 1-hexene was done by gas chromatography on a Varian 6000 instrument equipped with FID detectors and a 20% tri-*o*-cresylphosphate on 60/80 chromosorb-P column (20′ × 1/8″ SS) operating at 50°C. UV/VIS spectral measurements were performed on a Perkin Elmer 552A UV/VIS spectrometer.

*Structure determination of [(dippe)Rh]$_2$(μ-H)$_2$ (**1**b).* A deep red crystal (0.12 × 0.16 × 0.24 mm) was mounted in a Lindemann glass capillary. Precession and Weissenberg photographs were used to obtain approximate unit cell dimensions and to assign the space group as $P1$ or $P\bar{1}$ (subsequent structure solution uniquely defined the space group as $P\bar{1}$). Accurate cell dimensions (Table 1) were determined by least-squares refinement of the diffractometer angles of 34 independent reflections (2θ = 35.0 − 42.8°; Mo-K$_{\alpha 1}$ = 0.70926 Å) chosen from a variety of points in reciprocal space. Data were collected, at 293 K, using a Picker FACS-I four-circle diffractometer with a graphite monochromator and a scintillation counter with pulse height discrimination. The take-off angle was 3° and symmetrical θ–2θ scans (2° min^{-1}) of (1.3 + 0.692 tan θ)° were used. Stationary crystal stationary counter counts of 10% of the scan time were formed on each reflection and the intensity and its associated error determined by the method of Grant and Gabe (19). Measurement of two standards every 70 reflections showed no significant variation in intensity.

Intensities were measured for 6213 independent reflections of which 5170 were classed observed ($I \geq 2.3\sigma(I)$). Lorentz, polarization, and absorption corrections were made (transmission coefficients varied from 0.719–0.804).

The structure was solved by Patterson and Fourier methods. The Patterson shows there to be three Rh atoms in the asymmetric unit, two of which are contained within a single dimeric molecule and the third which when considered with its symmetry equivalent (1) fives rise to a second dimeric molecule; thus there are six "C$_{14}$H$_{33}$P$_2$Rh" units per unit cell. Subsequent Difference-Fourier syntheses revealed the positions of all non-hydrogen atoms. The atoms C(61) and C(611) were found to be disordered; C(61A) and C(611A) take up one orientation while C(61B) and C(611B) take up a second with the axis along P(6)...C(612) acting as a pivot between the two arrangements. (Occupancies of 0.5 were derived for each arrangement.) Subsequent Difference-maps revealed the positions of most of the hydrogen atoms, and the positions of those not located were calculable (apart from those hydrogen atoms associated with the disordered isopropyl group).

TABLE 1. Crystal data for $C_{28}H_{66}P_4Rh_2$ (**1***b*)

a, Å	10.660(2)
b, Å	11.703(2)
c, Å	23.952(8)
α, deg	94.21(2)
β, deg	95.98(2)
γ, deg	113.10(1)
U, Å^3	2712.54
Space group	$P\bar{1}$
Mr (dimer)	732.54
μ, cm^{-1}	10.88
ρ_{obsd}[a], g mL^{-1}	1.34
ρ_{calcd}, g mL^{-1}	1.346
Final R_1[b]	0.027
Final R_2[c]	0.028

[a]Flotation in a mixture.
[b]$R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[c]$R_2 = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$.

Later stages of refinement required that the asymmetric unit be treated in two portions, viz. molecule **1**[a] and molecule **2** (see Table 2).

Alternate block-diagonal least-squares refinement of the coordinates of all non-hydrogen atoms and the majority of hydrogen atoms[b] of each molecule, with variable anisotropic temperature factors for all non-hydrogen atoms (apart from C(61A) and C(61B)) and fixed isotropic temperature factors for hydrogen atoms ($B_{iso} \propto B_{iso}$(parent carbon)) gave final agreement factors of $R_1 = 0.027$ and $R_2 = 0.028$. The final difference-map was essentially clean. Unit weights were applied. Atomic scattering factors together with anomalous dispersion terms were taken from International tables for X-ray crystallography (20). Final positional and B_{iso} thermal parameters are given in Table 2. The computer programs used here are those belonging to "The PDP-8e crystal structure system" (21).

The synthesis of $Pr^i_2P(CH_2)_4PPr^i_2$ *(dippb).* The procedure used was identical to that used for the ligand $Pr^i_2P(CH_2)_3PPr^i_2$, dippp (17). Starting with 2.22 g (0.018 mol) of $LiPPr^i_2$ and 1.05 mL (1.90 g, 0.009 mol) $Br(CH_2)_4Br$, 1.98 g (77%) of dippb was obtained. Bp: 100–102°C (0.1 mm Hg). ^{1}H NMR (C_6H_6, ppm): 1.65, $CH_2(CH_2)_2CH_2$ (br m, 4H); 1.59, $CH(CH_3)_2$ (d of sp, 4H, ^3J_H = 7.6 Hz, ^2J_P = 2.8 Hz); 1.32, $CH_2(CH_2)_2CH_2$ (br m, 4H); 1.02, 1.06, $CH(CH_3)_2$ (overlapping dd, 24H, ^3J_P = 12.9, 13.3 Hz). $^{31}P\{^1H\}$ NMR (C_6D_6, referenced to external $P(OMe)_3$ at +141.0 ppm): 2.41 (s).

Synthesis of $[(dippp)Rh]_2(\mu\text{-}H)_2$, **1***c*. To a solution of $(\eta^3\text{-}C_3H_5)$Rh-(COD) (1.00 g, 3.97 mmol) in toluene (25 mL) was added a solution of the ligand dippp (1.09 g, 3.97 mmol) in toluene (10 mL), yielding a golden yellow solution of $(\eta^3\text{-}C_3H_5)$Rh(dippp). (This compound may be isolated as yellow crystals through recrystallization from toluene/hexanes in 92% yield; see below for spectral data.) Toluene and 1,5-cyclooctadiene were removed under reduced pressure, and the yellow residues were redissolved in toluene (25 mL), and the solution was transferred to a large reactor bomb equipped with a magnetic stirring bar. The solution was degassed on a vacuum line, cooled to −196°C, and was pressurized with dihydrogen to 1 atm. The reactor was sealed and was allowed to warm to room temperature. Efficient stirring was continued for 1 day, after which the reaction vessel was repressurized with H_2 at −196°C. After a further day of stirring at room temperature, the excess of dihydrogen and the solvent were removed, leaving a black–green solid from which 1.32 g (88.0%) of **1***c* could be obtained after three recrystallizations from toluene/hexanes. Melting point 226°C. ^{1}H NMR (C_6D_6, ppm): $CH(CH_3)_2$, 1.83 (d of sp, ^2J_P = 2.2 Hz, ^3J_H = 6.9 Hz); $CH(CH_3)_2$, 1.59, 1.22 (dd, ^3J_P = 12.1 Hz); $CH_2CH_2CH_2$, 0.97 (m); Rh—H—Rh, −6.65 (br m, $^1J_{Rh}$ = 35.2 Hz). $^{31}P\{^1H\}$ NMR (C_6D_6, ppm referenced to $P(OCH_3)_3$ at 141.0): 50.3 (d, $^1J_{Rh}$ = 161.0 Hz). *Anal.* calcd. for $C_{15}H_{35}P_2Rh$: C 47.37, H 9.28; found: C 47.49, H 9.21. The deuterated analogue of **1***c*, d_2-**1***c*, was prepared in a procedure analogous to that employed for preparing the dippe dideuteride d_2-**1***b* (8). Spectroscopic data for

(η^3-C_3H_5)Rh(dippp): ^{1}H NMR (C_6D_6, ppm): H_{cent}, 4.86 (m, $^3J_{H_{syn}}$ = 7.0 Hz, $^3J_{H_{anti}}$ = 12.8 Hz, $^2J_{Rh}$ = 2.0 Hz); H_{syn}, 3.65 (d); H_{anti}, 2.19 (dd, J_P = 4.8 Hz); C*H*(CH_3)$_2$, 1.92 (br sp, ^3J_H = 7.0 Hz), 1.81 (br sp, ^3J_H = 7.0 Hz); CH(C*H*$_3$)$_2$, 1.20 (dd, ^3J_P = 14.4 Hz), 1.10 (two overlapping dd, ^3J_P = 12.9, 13.6 Hz), 1.01 (dd, ^3J_P = 12.8 Hz); $CH_2CH_2CH_2$, ~1.8, 1.2 (resonances obscured by other peaks). ^{31}P{^{1}H} NMR (C_6D_6, ppm referenced to $P(OCH_3)_3$ at 141.0): 42.9 (d, $^1J_{Rh}$ = 188.0 Hz). *Anal.* calcd. for $C_{18}H_{39}P_2Rh$: C 51.42, H 9.35; found: C 51.22, H 9.33.

*The synthesis of [(dippb)Rh]$_2$(μ-H)$_3$(H), 2*d. To a solution of (η^3-C_3H_5)Rh(COD) (0.356 g, 1.4 mmol) in toluene (5 mL) was added dropwise a solution of dippb (0.409 g, 1.4 mmol) in toluene (5 mL) with stirring. A rapid deepening of the orange colour of the solution signified that the reaction was instantaneous. The toluene was removed under reduced pressure, and the residue pumped under high vacuum to remove as much COD as possible. The residue was then redissolved in toluene (25 mL) and the resulting solution placed in a 250 mL thick-walled reactor bomb, degassed, cooled to −196°C, and exposed to 1 atm of purified dihydrogen. The reactor was sealed at this temperature and allowed to warm to room temperature. After 3 days of efficient stirring the yellow–orange to dark yellow–green colour change was complete, and the excess dihydrogen and toluene were pumped off. The dark green–brown residue was recrystallized from toluene/hexanes (1:3) at −20°C, yielding 2–3 crops of black–green plates of **2***d* (0.407 g, 73% from (η^3-C_3H_5)Rh(COD)). ^{1}H NMR (C_7H_8, ppm): ^{31}P{^{1}H} NMR (C_7D_8, referenced to external $P(OMe)_3$ at +141.0 ppm). *Anal.* calcd. for $C_{32}H_{76}P_4Rh_2$: C 48.61, H 9.69; found: C 48.49, H 9.80.

The intermediate complex (η^3-C_3H_5)Rh(dippb) may also be isolated via recrystallization from toluene/hexanes as yellow crystals in 79% yield. ^{1}H NMR (C_6H_6, ppm): 4.80, H_c (tt, $^3J_{H_a}$ = 11.6 Hz, $^3J_{H_s}$ = 7.0 Hz); 3.44, H_s (dd, $^3J_{H_a}$ = 1.1 Hz); 2.10, H_a (ddd, J_P = 5.1 Hz); 1.92, C*H*(CH_3)$_2$ (d of sp, ^3J_H = 7.0–7.4 Hz; ^2J_P ≈ 2.6 Hz); 1.45–1.85, C*H*(CH_3)$_2$, (CH_2)$_4$ (overlapping multiplets); 1.18, 1.06, 1.05, 0.98, CH(C*H*$_3$)$_2$ (overlapping dd, ^3J_P = 13.0–13.4 Hz).

*The synthesis of [(dippb)Rh]$_2$(μ-H)$_2$, 1*d. The generation and observation of **1***d* was carried out in an NMR tube. A solution of **2***d* was dissolved in C_6D_6 and placed in a sealable 5 mm NMR tube. The tube was fitted to a 180° needle valve adapter and the whole assembly attached to a vacuum line. After degassing, about 1.1 equiv. of 1-hexene were vacuum transferred into the tube and the tube was sealed with a torch. ^{1}H NMR spectra recorded immediately after the tube had warmed to room temperature showed the presence of hexane and **1***d* in nearly quantitative yield. ^{1}H NMR (C_6H_6, ppm): ^{31}P{^{1}H} NMR (C_7D_8, referenced to external $P(OMe)_3$ at +141.0 ppm): 59.8 (d, J_{Rh} = 166.2 Hz).

The reactions of [{Pr$^i_2$P(CH$_2$)$_n$PPr$^i_2$}Rh]$_2$(μ-H)$_2$ (n = 2 and 3) with dihydrogen. An appropriate amount of [(dippe)Rh]$_2$(μ-H)$_2$, **1***b*, or [(dippp)Rh]$_2$(μ-H)$_2$, **1***c* (25–30 mg) were dissolved in C_7D_8, and the solution loaded into a sealable 5 mm NMR tube. The tube was fitted with a 180° needle valve adapter, and the assembly attached to a vacuum line with access to purified dihydrogen. The sample was degassed, and H_2 was admitted to nearly 1 atm pressure. Reaction with dihydrogen was immediate as indicated by a rapid deep green to brown colour change. To ensure an excess of dihydrogen in the sample, it was cooled to −196°C before sealing with a torch. ^{31}P{^{1}H} NMR spectroscopic data obtained are discussed in the text. ^{1}H NMR (hydride region of **1***b*, −80°C, C_7H_8, ppm): −7.05, $2H_b$ (d of br m, J_P = 122.1 Hz, J_{Rh} = 20.6 Hz); −13.17, H_t/$H_{b'}$ (br m). Further cooling to −95°C results in nearly complete coalescence of this high field signal. ^{1}H NMR (hydride region of **1***c*, −90°C, C_7H_8, ppm): −2.35, $2H_b$ (d of br m, J_P = 116 Hz, J_{Rh} = 19.2 Hz); −5.50, $H_{b'}$ (br m); −11.15, H_t (br m).

Crossover experiment

The hydrogenation of 1-hexene with a mixture of [(dippe)Rh]$_2$(μ-H)$_2$ (1b) and [(dippp)Rh]$_2$(μ-H)$_2$ (1c). A toluene solution (10 mL) of **1***b* (0.080 g) and **1***c* (0.075 g) was loaded into a small thick-walled reactor bomb. After degassing, 5.0 mL of 1-hexene was syringed into the bomb under a strong flow of dihydrogen. The hydrogenation was allowed to proceed to completion by stirring overnight under an atmosphere of H_2. The volatiles were then removed and the residues examined by ^{31}P{^{1}H} NMR. The only peaks observed were the doublets characteristic of **1***b* and **1***c*.

Synthesis of the mixed dimer [(dippe)Rh](μ-H)$_2$[Rh(dippp)]. A mixture of (dippe)Rh(C_3H_5) (generated from 0.150 g Rh(COD)(C_3H_5) and 0.156 g dippe) and (dippp)Rh(C_3H_5) (generated from 0.150 g Rh(COD)(C_3H_5) and 0.164 g dippp) was dissolved in 25 mL of toluene and loaded into a 250 mL thick-walled reactor bomb. The solution was degassed and cooled to −196°C; H_2 was admitted to 1 atm of pressure. After a 2–3 day period of efficient stirring, excess dihydrogen and toluene were removed under reduced pressure. The residues were redissolved in hexanes (30 mL) and filtered through a pad of celite. Concentration of the filtrate to 10–15 mL, followed by cooling to −20°C resulted in isolation of a crop of red–black crystals (0.217 g, 49% on mass balance). Analysis by ^{31}P{^{1}H} NMR spectroscopy revealed the presence of **1***b* and **1***c* (approximately 10% in total) as well as signals expected for the AA′MM′XY spin system in the mixed dimer. ^{31}P{^{1}H} NMR (C_6D_6, referenced to external $P(OMe)_3$ at +141.0 ppm): 103.7, *P*(CH_2)$_2$*P* (d of m, J_{Rh} = 157.3); 52.7, *P*(CH_2)$_3$*P* (d of m, J_{Rh} = 150.9 Hz).

The hydrogenation of 1-hexene with [(dippe)Rh]$_2$(μ-H)$_2$ (1b) and [(dippp)Rh]$_2$(μ-H)$_2$ (1c). A 250 mL thick-walled glass bomb equipped with an efficient magnetic stir bar was charged with catalyst precursor (**1***b* or **1***c*, 0.050 g) and purified 1-hexene (10.00 g, substrate:catalyst, 1700–1800:1). **1***b* reacted immediately with the substrate, producing an orange solution, whereas **1***c* was unreactive and the intense green colour of the dihydrides was maintained. The bomb was then attached to a vacuum line with access to purified H_2 and the solution degassed thoroughly via three freeze–pump–thaw cycles. When the solution had warmed to room temperature (22–23°C), hydrogen was admitted to 1 atm. Samples were periodically removed through the bomb's Teflon needle valve port using an argon and hydrogen flushed syringe. The volatiles were vacuum transferred away from the catalyst, and analyzed by gas chromatography. Identification of the peaks in the GC trace was carried out by "spiking" with the pure materials (Aldrich).

Kinetic measurements. Kinetic measurements on the hydrogenation of styrene by **1***b* were made by following the uptake of H_2 at constant pressure. The apparatus was identical to that described by James and co-workers (22). Samples for each run were prepared from varying amounts (0.5–4.0 mL) of a stock solution of **1***b* (0.048 g in 25 mL toluene, 1.58×10^{-2} *M*). The total volume of each sample was made up to 4.0 mL with toluene. Higher concentrations of catalyst were attained by dissolving accurately weighed amounts of **1***b* (0.016, 0.024 g) in 4.0 mL of toluene. Styrene was then added (0.55 mL; substrate: catalyst ratios ranged from ≈150–3800), and the reaction vessel assemblage attached to the constant pressure uptake apparatus. The sample solution was degassed with two freeze–pump–thaw cycles, and then allowed to thermally equilibrate in an oil bath thermostatted to 30°C. Once equilibrated, shaking was begun, and H_2 admitted to 1 atm of pressure. After a brief (2 min) induction period, gas uptake was monitored by measuring the difference in levels of a liquid of negligible vapour pressure in a capilliary manometer thermostatted together with a gas burette at 25°C. Admission of H_2 to the system through a needle valve maintained a constant pressure by raising the mercury level in a calibrated tube of the burette. A travelling microscope was used to follow the change in height of this mercury column. Runs were typically allowed to go for 4–5 turnovers. The sole product in the reaction was ethylbenzene.

Results and discussion

The crystal and molecular structure of [{Pr$^i_2$P(CH$_2$)$_2$PPr$^i_2$}-Rh]$_2$(μ-H)$_2$ (1b)

A single crystal X-ray analysis of [(dippe)Rh]$_2$(μ-H)$_2$, **1***b*, was performed to establish the structural parameters of this

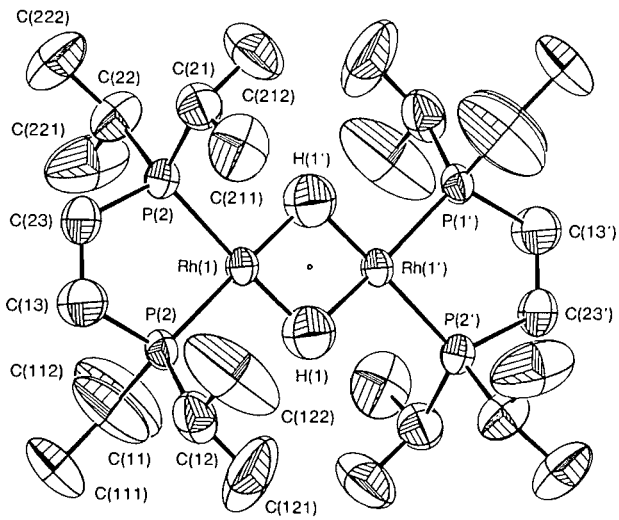

FIG. 1. ORTEP diagram of the dihydride $[(dippe)Rh]_2(\mu\text{-}H)_2$, **1***b*.

central compound in our ongoing research on the reactivity of polynuclear unsaturated clusters, Figure 1 shows the molecular structure of **1***b* along with the atom numbering scheme, and Tables 1, 2, and 3 give the crystal data, final atomic parameters, and selected bond parameters, respectively, for this compound. The structure was found to have two crystallographically separate molecules in the crystal lattice. The unit cell consisted of two dimers of molecule **1**, and one of molecule **2**.

Bond distances and angles were all within expected ranges. In particular, the Rh—Rh distances of 2.629(1) Å (molecule **1**) and 2.6266(8) Å (molecule **2**) are only slightly shorter to that found for the dimer $[\{Pr^i O)_3P\}_2Rh]_2(\mu\text{-}H)_2$, **1***a*, at 2.647 Å (23). The P—Rh—P bond angles of 85.7° are about 10° less than those found for **1***a* (94.7°) and that expected for **1***c*.[4] This small P—Rh—P angle of the dippe hydride **1***b* has the effect of "pulling back" the isopropyl groups on the phosphorus atoms, and thus exposing the $Rh_2(\mu\text{-}H)_2$ core of this molecule to a greater extent than other members of the dihydride family. While the metal centres of **1***b* still experience some steric crowding, we have observed that the dippe hydride dimer has heightened reactivity when compared to its more sterically crowded analogs, the dippp dimer **1***c* and the dippb dimer **1***d* (*vide infra*).

The reaction of $[\{Pr^i{}_2P(CH_2)_nPPr^i{}_2\}Rh]_2(\mu\text{-}H)_2$ (n = 2, 3, *and 4) with dihydrogen*

The effect of chelate ring size is apparent in the synthesis of these binuclear complexes. The standard procedure involves the reaction of the mononuclear rhodium allyl complexes $(\eta^3\text{-}C_3H_5)Rh\{Pr^i{}_2P(CH_2)_nPPr^i{}_2\}$ where n = 2 and 3, with dihydrogen to generate, respectively, the binuclear rhodium *dihydride* complexes $[(dippe)Rh]_2(\mu\text{-}H)_2$ (**1***b*) and $[(dippp)\text{-}Rh]_2(\mu\text{-}H)_2$ (**1***c*) upon workup. However, the analogous reaction of the corresponding allyl complex containing the bidentate phosphine ligand 1,4-bis(diisopropylphosphino)butane (dippb) generates the binuclear *tetrahydride* $[(dippb)Rh]_2(H)_4$ (**2***d*) under the same conditions. Further experiments established that the binuclear dihydrides **1***b* and **1***c* add one molecule of dihydrogen to generate the respective tetrahydrides **2***b* and **2***c*, but these latter tetrahydrides are unstable and lose H_2 upon removal of excess H_2. Although the dippb tetrahydride **2***d* is stable even under vacuum, we were able to synthesize the corresponding dihydride **1***d* by reaction of **2***d* with 1 equiv. (or a slight excess) of 1-hexene. This is summarized in Scheme 1. By comparison, the binuclear dihydride containing the monodentate triisopropylphosphite ligands $[\{(Pr^iO)_3P\}_2Rh]_2(\mu\text{-}H)_2$, **1***a*, also adds H_2 to generate an unstable tetrahydride $[\{(Pr^iO)_3\text{-}P\}_2Rh]_2(H)_4$, **2***a*.

All of the binuclear tetrahydrides **2***a*–**2***d* exhibit fluxional behaviour as evidenced by variable temperature ^1H and $^{31}P\{^1H\}$ NMR spectroscopy. Although the fluxional processes appear qualitatively similar, there are some important differences that depend on the particular ancillary ligand. At room temperature, solutions under H_2 of the two tetrahydrides **2***c* and **2***d*, having six- and seven-membered chelate rings, respectively, show a broad peak in the hydride region of the ^1H NMR spectrum indicative of both fast exchange of the hydrides with themselves and with free H_2 dissolved in solution. As the temperature is lowered to −20°C, the latter process effectively stops and the self exchange slows to give a doublet of broad multiplets for two equivalent bridging hydrides and a broad singlet for two terminal hydrides. As the temperature is lowered further (−80°C), the singlet for the two terminal hydrides broadens and coalesces to give two different broad singlets assignable to one bridging hydride and one terminal hydride. This pattern and temperature behaviour are nearly identical to that reported for **2***a*. Thus the structure in the slow exchange limit is consistent with the formulation $[P_2RhH](\mu\text{-}H)_3[RhP_2]$, that is, a Rh(III) centre with a terminal hydride and a Rh(I) centre separated by three bridging hydrides; at slightly higher temperatures (−80°C to −20°C), one of the bridging hydride ligands exchanges with the terminal hydride to give an averaged, excited state structure formulated as $[P_2RhH_2](\mu\text{-}H)_2[RhP_2]$. The $^{31}P\{^1H\}$ NMR of the dippp tetrahydride **2***c* at various temperatures (Fig. 2) provides clear evidence for the stereochemical arrangement about each metal centre as a function of temperature. At room temperature, two doublets were observed at 61.6 ($^1J_{Rh—P}$ = 167.3 Hz) and 67.6 ($^1J_{Rh—P}$ = 105.8 Hz) ppm (at higher temperatures these signals collapsed into one doublet).[5] The magnitudes of the $^1J_{Rh—P}$ coupling constants are consistent with a Rh(I)/Rh(III) formulation for the dimer (22). As the temperature is lowered, the doublet due to the phosphorus nuclei coupled to the Rh(I) centre coalesces and reemerges at −100°C as two doublets of doublets (an ABX spin system). A stereochemical arrangement for the ground state structure consistent with the low temperature limit is an octahedral Rh(III) centre, coupled with a trigonal bipyramidal geometry at the Rh(I) centre. As H_t and $H_{b'}$ equilibrate via the rocking motion depicted in Scheme 2, the two phosphorus nuclei on the rhodium(I) centre undergo axial/equatorial exchange, while the other two phosphorus atoms remain equivalent at all times.

Although the trigonal bipyramidal geometry would undoubtedly be highly distorted from the ideal, the square pyramidal geometry would not give rise to two inequivalent phosphorus nuclei on the Rh(I) centre in the low temperature limit. The excited state structure is therefore likely tetrahedral at the Rh(I) centre in **2***c*, although the spectra do not rule out a square planar geometry. The activation free energy (26) for this "rocking"

[4]The bite angle for the dippp ligand (8*b*), as well as other six membered chelate ligands (21*b*), is in the range 93–96°C. See, for example, ref. 24.

[5]It has been found empirically (22*b*) and calculated theoretically (22*c*) that the magnitude of $^1J_{Rh—P}$ is about 50% larger for complexes with a formal oxidation state of I than for those with an oxidation state of III (25).

SCHEME 1

process which equilibrates the two rhodium(I) phosphorus nuclei is about 8.6(5) kcal mol^{-1}, which is near the value of 9 kcal mol^{-1} reported for **2***a* (7). The $^{31}P\{^1H\}$ NMR spectra of **2***d* are qualitatively identical to those of **2***c* as a set, but are broadened and complicated by the fact that the chemical shifts for the two equivalent rhodium(III) phosphorus atoms and the downfield resonance for one of the rhodium(I) phosphorus nuclei are very nearly coincident in the low temperature limiting spectrum. Nonetheless, it is apparent that the two sets of spectra are analogous, and that the same geometries may be invoked for **2***d* as for **2***c*. The activation energy for this low temperature ("rocking") process for the larger chelate ring size dimer is about 11.5(5) kcal mol^{-1}.

As mentioned above, the tetrahydride $[\{(Pr^iO)_3P\}_2Rh]_2(H)_4$, **2***a*, behaves similarly as a function of temperature; however, a different proposal to explain this exchange process has been given based on the isolation and structure of the moderately stable related tetrahydride complex $[\{(Me_2N)_3P\}_2RhH_2](\mu\text{-}H)_2[Rh\{P(NMe_2)_3\}_2]$, **2***e* (23), since it was shown to have the structure **2***e* shown.

The molecule consists of an octahedral rhodium(III) centre and a square planar rhodium(I) centre joined by two bridging hydrides. In this tetrahydride, the phosphorus nuclei on the rhodium(III) centre are *trans* disposed across the $H_2Rh(\mu\text{-}H)_2RhP_2$ plane. Thus it was suggested that exchange of the terminal hydride with the one unique bridging hydride occurred via an excited state structure similar to **2***e*. The fact that chelating phosphines with four or fewer methylene units cannot span *trans* coordination sites precludes this type of excited state geometry for the systems reported here.

The effect of the ancillary ligand is again evident when the binuclear complex of the five-membered chelate ring diphosphine dippe is considered. The tetrahydride **2***b* presents a qualitatively different set of $^{31}P\{^1H\}$ NMR spectra (Fig. 3), characterized by two doublets which, rather than undergoing coalescence and decoalescence, show a marked dependance of chemical shift as a function of the temperature.

This is the spectral behaviour expected if the rhodium(I) centre in the structures in Scheme 2 were now square pyramidal (ground state) and square planar (excited state) in geometry

2e

(Scheme 3). In this process, the two phosphorus nuclei on each rhodium centre remain pairwise equivalent, but due to the structural changes involved, the chemical shifts of the two doublets change with temperature. This is consistent with the ^1H NMR spectra as well wherein the same low temperature limit observed for the dippp and dippb tetrahydrides, **2***c* and **2***d*, is not attained, that is, the terminal hydride signal only broadens as the temperature is lowered (to −95°C).

This observed dependance of the geometry about the rhodium(I) centre on the chelate ring size of the diphosphine ligand may be rationalized partially on the basis of steric arguments. On going from the square pyramidal to the trigonal bipyramidal geometry in the low temperature limit (ground state), steric interactions between the isopropyl groups of the opposing diphosphine ligands are relieved. Similarly, these interactions may be lessened by decreasing the bite angle of the chelating ligand which results in a "pulling back" of the isopropyl groups on phosphorus. Evidently, the contraction of bite angle by about

TABLE 4. Hydrogenation and isomerization rates[a] for the hydrogenation of 1-hexene by **1***a* and **1***b*[b]

Catalyst	Loss of 1-hexene	Products			Internal olefin hydrogenation	
		Hexane	*t*-2-Hexene	*c*-2-Hexene	*t*-2-Hexene	*c*-2-Hexene
1*b*	2600	850–950	13–1700	750–1100	520	240
1*c*	2100	280	1150	700	210	170

[a]All rates are given as the turnover frequencies in h^{-1}.
[b]Hydrogenation reactions carried out at 1 atm pressure of H_2, and 23–25°C.

10° (*vide supra*) was enough to render the change from square pyramidal to trigonal bipyramidal unnecessary for the dippe tetrahydride **2***b*. In **2***c* and **2***d* however, this change in geometry is required to stagger the isopropyl groups and relieve the steric tension. The chelate ring size also affects the activation energy for the exchange of the terminal hydride and the unique bridging hydride ligands: for the seven-membered dippb system, $\Delta G^{\ddagger} = 11.5(5)$ kcal mol^{-1}; for the six-membered dippp system, $\Delta G^{\ddagger} = 8.6(5)$ kcal mol^{-1}; and for the five-membered dippe ligand, $\Delta G^{\ddagger} = <7.0(5)$ kcal mol^{-1} (estimated).

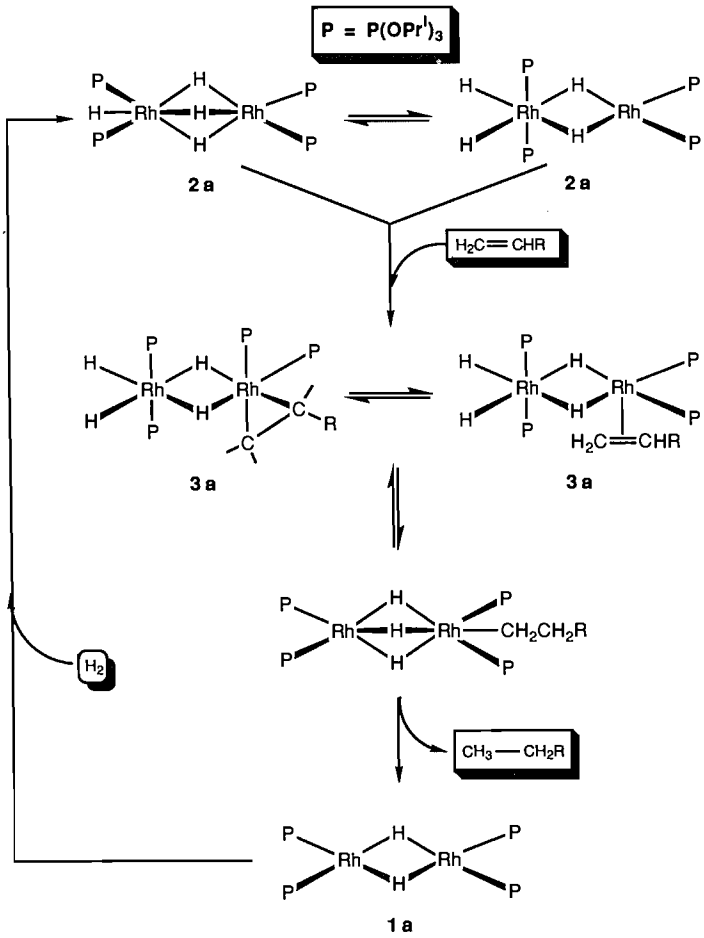
*The hydrogenation of 1-hexene using [{Pr$^i_2$P(CH$_2$)$_n$PPr$^i_2$}-Rh]$_2$(μ-H)$_2$ (**1**b: n = 2; **1**c: n = 3) as catalyst precursors*

The activity of the dimer containing triisopropylphosphite ligands, **1***a*, towards the hydrogenation of olefins (7) lead us to explore the ability of the dippe dimer **1***b* and the dippp dimer **1***c* to bring about this transformation. Neither proved to be more active than **1***a* in this capacity, but we were also interested in probing the reaction mechanistically in some detail.

The dimer **1***b* was found to be a reasonably efficient catalyst precursor for the hydrogenation of 1-hexene at ambient temperature and pressure. With a substrate/catalyst ratio arbitrarily set at about 1700, hexane was generated with a turnover rate of about 850–950 h^{-1} (Table 4). Rapid olefin isomerization steps also occurred, with production of *cis*- and *trans*-2-hexene along with hexane. The catalyst hydrogenated the terminal olefin selectively until it was used up, and then began to hydrogenate the internal olefins, producing hexane at a slightly lower turnover frequency of about 700 h^{-1}.

The dippp dimer **1***c* was also active as a catalyst precursor for this reaction, but was significantly slower under the same conditions. Turnover rates are shown in Table 4. In this reaction, some evidence for the build-up of 3-hexenes was also observed. Notably, while relative rates of isomerization were higher for **1***c*, the overall rate of hexane production was steady, probably reflecting similar rates in the hydrogenation of terminal and internal olefins, or selective hydrogenation of internal olefins only.

A cursory study of the dippb tetrahydride **2***d* showed that its activity was not significantly different from that of the dippp dimer **1***c* and it was therefore not studied in any detail.



Mechanistic studies

Chemical evidence abounds for a mechanistic pathway for hydrogenation which involves solely binuclear intermediates. The early work on the use of [{(Pr^{i}O)$_3$P}$_2$Rh]$_2$(μ-H)$_2$, **1***a*, as a catalyst precursor for the hydrogenation of olefins provided the first such mechanistic proposal as shown in Scheme 4 (7).

The reaction of this dihydride **1***a* with H_2 leads to the

SCHEME 4

tetrahydride **2***a* which adds 1 equiv. of alkene to the coordinatively unsaturated Rh(I) centre to produce **3** (in the geometry suggested by the isolation of **2***e*); a subsequent migratory insertion and reductive elimination regenerates the dimer **1***a* and produces alkane. This proposal was based on the observation of a fast dehydrogenation of the tetrahydride **2***a* by the stoichiometric addition of an alkene. In our systems, we have also observed this same dehydrogenation reaction, in fact, it is the pathway for the synthesis of the dippb dihydride **1***d* starting from the stable tetrahydride **2***d*. A modification of the catalytic cycle shown in Scheme 4 to take into account the use of chelating bidentate ligands that cannot span *trans* coordination sites requires that the binuclear alkene–tetrahydride intermediate **3'** have a structure as shown.

3'

Further chemical evidence for a binuclear hydrogenation cycle exists in a crossover experiment. When a mixture of equal amounts of **1***b* and **1***c* was used to hydrogenate a large excess of 1-hexene, the mixed dimer [(dippe)Rh](μ-H)$_2$[Rh(dippp)], expected should fragmentation/aggregation occur, was not detected after workup. This observation does not totally eliminate the possibility of crossover, but does show that (within the detection limits of $^{31}P\{^1H\}$ NMR) crossover is minimal.

This chemical evidence certainly suggests that a pathway exists which contains only binuclear intermediates. It does not, however, totally eliminate the possibility that fragmentation occurs to yield a highly reactive mononuclear species which may (or may not) be responsible for the majority of the catalysis observed. This is a long standing problem encountered in cluster catalysis (28, 29), and chemical evidence alone does not provide sufficient grounds to state firmly that catalysis by the cluster is the major mechanistic pathway in the reaction. In order to determine this with confidence it is necessary to carry out kinetic analysis on the reaction, and even then it is sometimes difficult to reach meaningful conclusions.

One of the kinetic criteria arguing for cluster catalysis is an increase in turnover frequency upon increasing catalyst concentration (29). Catalyst concentration studies were carried out using varying amounts of the dippp dimer **1***c* as the catalyst precursor. Styrene was used as the substrate to eliminate isomerization side reactions, and the dihydrogen uptake was monitored as a function of time at 30°C. A plot of the rate of dihydrogen uptake (mol s^{-1} L^{-1}) vs. the concentration of **1***c*, should be linear if no fragmentation occurs. In the plot in Fig. 4, it is clear that this is not a linear relationship, and in fact, is better represented by the plot in Fig. 5 that actually shows the reaction to be half order in the concentration of the dippp dimer **1***c*.

When the turnover frequency (TF = mole substrate consumed per mole catalyst precursor per unit time) is plotted vs. catalyst concentration (Fig. 6), it is clear that the TF decreases with increasing [**1***c*]. This is diagnostic and provides clear kinetic evidence that, in this system, fragmentation occurs such that the majority of the actual catalysis is performed by small amounts of a highly reactive mononuclear fragment.

Unfortunately, similar kinetic analysis of the reaction involving the dippe dimer **1***b* was hampered by this compound's extreme sensitivity to minor amounts of oxygen and water unavoidably included under the conditions employed. (The scatter apparent in Figs. 4–6 was likely due to this factor as well, particularly at low catalyst concentrations, but **1***c* was generally more well-behaved under the monitoring conditions.) Thus, it cannot be similarly concluded that mononuclear fragments carry out the majority of catalysis in the reaction utilizing **1***b* as a catalyst precursor. Indeed, the chemical evidence suggests that the pathway involving binuclear intermediates is the major one in the **1***b* catalyzed reaction, since we observe no crossover in the hydrogenation with a mixture of **1***b* and **1***c*. This is the expected result if only *one* of **1***b* or **1***c* were fragmenting under the hydrogenation conditions, and since **1***c* does fragment, by process of elimination, **1***b* cannot.

Based on both sets of evidence (chemical and kinetic) we propose that both binuclear and mononuclear pathways exist for the hydrogenation of alkenes by the dippp dimer **1***c* as shown in Scheme 5.

Attempts to detect fragmentation of the tetrahydride **2***c* in the absence of substrate alkenes by deviation from Beer–Lambert behaviour especially at low concentration were unsuccessful; plots of absorbance vs. [**2***c*] were linear for concentrations spanning a range of 0.14 m*M* to 0.0012 m*M*. Thus it can be concluded that the mononuclear pathway for hydrogenation is kinetically much more efficient than the binuclear one since mononuclear fragments have not yet been spectroscopically detected.

A number of features of the proposed binuclear cycle (top in Scheme 5) are different than those given in Scheme 4 (7, 28). As already mentioned, the olefin complex **3***c* has *trans* terminal hydrides on the Rh(III) centre. The migratory insertion step to form the alkyl complex **4***c* is also in contrast to that in Scheme 4; to account for the substantial and rapid olefin isomerization, a bridging, *secondary* alkyl ligand in **4***c* is invoked. Although speculative, the bridging alkyl (30) is in line with other proposals that involve dehydrogenation of the dihydride dimers **1***b* and **1***c* by olefins and dienes (10*c*). In addition, the alkyl must be secondary at some point to explain the olefin isomerization; how this occurs is not explicitly detailed, but would obviously involve a β-elimination back to **3***c* but with an *internal* olefin coordinated to the Rh(I) centre. Reductive elimination from **4***c* generates the product alkane and the dihydride **1***c*.

The bifurcation to the mononuclear cycle (bottom Scheme 5) is proposed to occur at the tetrahydride species **2***c*. Rather than bind the olefin, the tetrahydride can fragment under dihydrogen to generate the mononuclear trihydride **5***c*. This coordinatively unsaturated fragment undergoes the usual olefin binding, migratory insertion, and reductive elimination to produce olefin and the 14-electron, monohydride **8***c*. The mononuclear cycle can continue by oxidative addition of H_2 to **8***c* to regenerate **5***c*, or the monohydride monomer **8***c* can dimerize to **1***c* and thus gain entrance back into the binuclear regime.

A possible reason for the fragmentation pathway in the dippp dimer **1***c* system is again the increased steric crowding about the metal centres as compared to the dippe dimer **1***b*. The observed differences in the geometries about the rhodium(I) centre in the ground state structures of the tetrahydrides may stymie the alkene binding by **2***c*, and lead to fragmentation, while with **2***b*, the binding of the alkene is facilitated. It thus appears that contact between the catalyst and the substrate is significantly hindered in the pathway invoking dimeric intermediates for the larger chelate ring system, and that when such contact is made, fragmentation is induced and the mononuclear regime dominates. Other fragmentation points in the binuclear cycle are of course possible; for example, the dihydride **1***c* could generate **8***c* spontaneously. However, the proposal that it is the binding of the substrate to the tetrahydride that induces fragmentation is more compelling, in our opinion.

Detection at the picogram level of bis(cyclopentadienyl)ruthenium by gas chromatography – flame photometry[1]

XUN-YUN SUN AND WALTER A. AUE[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received November 2, 1988

XUN-YUN SUN and WALTER A. AUE. Can. J. Chem. **67**, 897 (1989).

Ruthenocene — bis(cyclopentadienyl)ruthenium — can be determined with surprisingly high sensitivity and selectivity by gas chromatography – flame photometry. The detector's response relies mainly on an unidentified emission system (RuH?) with major peaks at 484 and 528 nm, while some familiar atomic lines show up as well. Without interference filter, the minimum detectable amount of ruthenocene, at S/N = 2, is approximately 2 pg (or 2×10^{-13} g/s or 1×10^{-15} mol/s), the elemental selectivity ruthenium/carbon 4×10^5, and the linear range $1 : 4 \times 10^4$. These calibration characteristics place ruthenium among the strongest luminescing and best performing species in the flame photometric detector. In fact, under conditions optimized for ruthenocene, ruthenium responds stronger than other FPD-active atoms (Sn, P, Cr, S, B). Fortunately, quenching effects are very weak: for instance, it takes about 1600 ppm (v/v) of methane in the detector to reduce the ruthenocene peak height by 50%.

Key words: ruthenocene, gas chromatography, flame photometric detector, ruthenium hydride.

XUN-YUN SUN et WALTER A. AUE. Can. J. Chem. **67**, 897 (1989).

Utilisant la chromatographie en phase gazeuse couplée à la photométrie à flamme, on peut déterminer le ruthénocène — le bis(cyclopentadiényl)ruthénium — avec une grande sensibilité et une grande sélectivité. La réponse du détecteur dépend principalement d'un système d'émission qui n'a pas été identifié (RuH?), qui possède des pics importants à 484 et à 528 nm et dans lequel on remarque la présence de quelques raies atomiques familières. Sans faire appel à un filtre d'interférence, la quantité minimale de ruthénocène que l'on peut détecter, à S/N = 2, est approximativement 2 pg (ou 2×10^{-13} g/s ou 1×10^{-15} mol/s), la sélectivité élémentaire ruthénium/carbone est de 4×10^5 et la plage linéaire est $1 : 4 \times 10^4$. Sur la base de ces caractéristiques de calibration, le ruthénium s'avère être l'espèce possédant la plus forte luminescence et celle qui donne les meilleurs résultats dans un détecteur de photométrie à flamme. En fait, utilisant les conditions optimisées pour le ruthénocène, le ruthénium répond mieux que les autres atomes actifs avec cette méthode (Sn, P, Cr, S, B). Heureusement, les effets de piégeage sont très faibles : par exemple, il faut avoir 1600 ppm (v/v) de méthane dans le détecteur pour réduire la hauteur du pic du ruthénocène par 50%.

Mots clés : ruthénocène, chromatographie gazeuse, détecteur de photométrie à flamme, hydrure de ruthénium.

[Traduit par la revue]

Introduction

Recently we wanted to determine ruthenocene — bis(cyclopentadienyl)ruthenium — with high sensitivity and selectivity. This simple metallocene — as well as other, related ruthenium structures — is of interest in a variety of areas, e.g. in catalysis. The fact that ruthenocene is volatile and stable suggests the use of gas chromatography. Ruthenocene has been subjected to this technique before (1, 2); however, no conventional gas chromatographic detector is known to be selective to ruthenium.

The microwave-excited atmospheric pressure helium plasma has been used on ruthenocene (and many other organometallics) eluted from a capillary column. Spectrophotometric monitoring of the 240.3 nm Ru^+ line yielded a minimum detectable amount of 7.8 pg/s, an elemental selectivity against carbon of 1.34×10^5, and a linear range of 10^3 (3). Beyond capillary GC-MED, any of a number of "hyphenated" techniques (GC-MS, GC-ICP, GC-ETV-AS, GC-ICP-MS, etc.) could be used for a fairly sensitive and selective determination of ruthenocene. However, for reasons of simplicity, ruggedness, quantitative accuracy, and cost, a typical GC detector seemed preferable.

Among the common GC detectors, the flame photometric (FPD) stands out as a possible candidate. Although the FPD is generally used for compounds of sulfur (via S_2*) and phosphorus (via HPO*), it can respond to other hetero-atoms as well. Listed in order of decreasing sensitivity — and spanning a range of minimum detectable amounts from 5×10^{-18} to 4×10^{-13} mol/s — the elements to which the FPD has proven sufficiently sensitive to be of analytical interest are Sn, Ge, P, Cr, S, As, Se, B, Fe, and Te (4). An extensive literature review of the FPD — and other GC detectors — has recently become available (5).

The above list of responsive elements reveals no easily discernable pattern, and we known of no reports on the FPD's behaviour vis-a-vis ruthenium or any of the platinum metals.

Experimental

A Shimadzu GC-4BMPF gas chromatograph with dual-channel FPD was used with a 100 × 0.3 cm i.d. column, packed with 5% OV-101 on Chromosorb W, purged by 22 mL/min of nitrogen, and heated to 155°C. (Under these conditions ruthenocene elutes 2 min after injection.) The temperature of the injection port was 180°C, as was that of the detector base. A simple *RC* filter ($R = 10\,k\Omega$, $C = 200\,\mu F$) was inserted between the electrometer and strip chart recorder. For *analytical* purposes, the detector was usually operated under the optimized conditions of 300 mL/min hydrogen, 80 mL/min air, an additional 20 mL/min nitrogen (added to the air supply), and without the conventional quartz chimney and interference filter. Under these conditions, the only spectral discrimination was that inherent in the Hamamatsu R-268 photomultiplier tube (bialkali, 300 to 650 nm, maximum at 420 nm).

The same tube was used for *spectral* purposes in conjunction with a Jarrel-Ash 82-415 quarter-meter scanning spectrophotometer with a 1180 lines/mm grating of 500 nm blaze. To suppress any background (there was little), "spectra" were obtained by repeatedly injecting ruthenocene while manually advancing the wavelength drive.

Quenching experiments were conducted by adding methane to the hydrogen supply via an exponential dilution flask; or, for constant levels, via a very fine metering dual valve (Nupro).

The visual detection of ruthenium luminescence was carried out after

adapting the eyesight of one of us (X.Y.S.) to a darkened lab for about half an hour. The temperature at various positions in the FPD was estimated with a 0.2 mm diameter fine-wire iron–constantan thermocouple connected to a simple amplifier (Omega OMNI-AMP II-A). (Iron–constantan thermocouples made of 0.4 mm diameter wires and/or dipped into phosphoric acid prior to use gave essentially the same readings.)

Results and discussion

The variation of detector gas flow rates in Fig. 1 shows that the highest signal/noise ratios are obtained around 300 mL/min of hydrogen and 80 mL/min of air (with "noise" defined as the peak-to-peak baseline fluctuation). The hydrogen flow rate is quite high (c.f. ref. 5), but it should be noted that the flame gas volume in the detector is also somewhat larger than usual, owing to the removal of the protective (and constrictive) traditional quartz chimney. Removing the chimney produces a significantly larger signal/noise ratio (for *ruthenocene*, not necessarily for other FPD-active elements such as sulfur).

Visual observation of the ruthenocene peak was possible: The slim luminescence, green with an upper bluish tinge, appeared strongest in the flame itself, diminished gradually above it, and vanished about halfway up the viewing area — without ever significantly spreading out to the sides. (The term "flame" refers here to the minute region where a very weak glow can be visually observed under *no-analyte* conditions.) Thus the visible luminescence did by no means fill the total accessible volume — as, for instance, low concentrations of sulfur would have done.

The region where the luminescence appeared — as well as other detector regions — were measured with a fine-wire thermocouple. The temperature was obviously highest right in the central flame area (788°C) and decreased from there to values around 600°C at the upper end of the observable luminescence. The introduction of saturation amounts of ruthenocene showed no effect on the thermocouple temperature; the introduction of part-per-thousand levels of methane (see later) produced only a very minor decrease.

Although such temperature measurements are notoriously unreliable, particularly in diffusion flames, it is obvious that the system is fairly low in thermal energy. For comparison: the maximum theoretical temperature of the hydrogen-air flame is 2115°C, the highest measured values range from 2000 to 2050°C (6). The excess of hydrogen, with its very high thermal conductivity, does help to depress the temperature. Note that 300 mL of hydrogen would need 750 mL of air for a stoichiometric mixture, while the optimum flow of air is not much more than one tenth of that. Figure 2 provides an approximate drawing of the visually observable flame shapes with and without analyte, as well as a few selected thermocouple temperatures measured at flow-optimized conditions.

In the context of excitation mechanisms, it is interesting to know whether and to what extent emission rises with increasing air flow (temperature). Figure 1 displays only the signal/noise ratio and, while this criterion is of paramount importance in an analytical setting, the signal per se is of more interest in a spectral context. Figure 3 shows that the signal itself does not rise much anymore beyond the region where S/N reaches its maximum (in several cases involving other elements, both signal and noise kept right on rising with increasing air flow rates). This fact, as well as the relatively low temperature and the surprisingly high sensitivity, all point to a chemiluminescent process.

Using the optimum flow rates, the spectrum of the luminescence was determined. It is shown in Fig. 4. The emissions in the 350 to 400 nm range agree with the atomic Ru lines most prominently found, and most often used, in atomic spectroscopy (7). They are all transitions to the ground state (a^5F_5) from $z^5G_6^0$ (349.9 nm), $z^5F_5^0$ (372.8), and $z^5D_4^0$ (379.9) (8). The 349.9 nm line is the most energetic one found (3.55 eV, 342 kJ/mol). Finding an atomic line at this low a temperature

may seem unusual in the context of conventional atomic spectroscopy. However, the flame photometric detector — particularly, one assumes, because of its hydrogen-rich environment — is low in thermal but high in chemical energy. The fact that *atomic* emission is seen points to a chemical excitation process: If the process were purely thermal, it would be hard to explain why it is that many other hetero-elements do not respond at all (or, in a few cases, do not respond with commensurate strength).

The atomic lines in the 350 to 400 nm region constitute, however, only a minor part of the observed total light intensity. The larger part of the spectrum consists of two similarly shaped, complex structures, whose dominant, sharp emissions are centered at approximately 484 and 528 nm. Our search of the literature failed to locate that system (or systems). It should be noted that the peak width of the 484 and 528 nm bands as shown in Fig. 4 is likely not natural but determined by the 0.5 mm slit width (1.7 nm bandpath). We suggest that these major emissions originate from a di (or perhaps tri) atomic system. Based on their relatively open and sharp structure, and on the chemical environment whence they originate, we further suggest that they might be due to the (so far unknown but theoretically investigated (9)) ruthenium hydride. Additional, indirect support for the likelihood of RuH being the emitter comes from the great similarity of the measured spectral features with those of FeH (we are indebted to Professor John Coxon for pointing this out to us). The iron hydride emits complex bands in the blue from 486 to 497 (strongest band at 493.2257 nm) and in the green from 528 to 536 nm (strongest band at 533.6044 nm), in a King-type furnace at ca. 2600 K and 400 Torr of H_2, as well as in the sun and particular in sunspots (10). However, it should be added that, in the FPD, ruthenocene's congener ferrocene shows spectral features other than the FeH bands in the relevant wavelength region (11).

Again, it is quite likely that the driving process is chemiluminescent in nature. The wavelength 484 nm corresponds to 2.56 eV or 248 kJ/mol. Note that the ruthenocene molecule is unusually stable: Its enthalpy of formation $\Delta H_f^{298} = -782$ kJ/mol and its decomposition temperature is 610°C (12). Its break-up might involve fairly selective reactions with hydrogen atoms or other radicals (as contrasted with the general, complex pyrolysis/combustion schemes commonly associated with flames). Note that only about 10% of the hydrogen (and an unknown but perhaps small percentage of ruthenocene) is *oxi*dized, that the maximum temperature measured is below 790°C (and below 590°C at only slightly less efficient conditions, *vide infra*), and that the residence time in the hottest parts of the detector is extremely short (about a tenth of a millisecond if the "flame" volume — marked dark in Fig. 2 — is assumed to be 3 mm^3).

The calibration curves shown in Fig. 5 tally six for the analyte ruthenocene and two for the hydrocarbon standard dodecane. The unconventional showing of *six* calibration curves for a single compound is used here to point out important detector characteristics, appraise various optimization strategies, and assess the magnitude of quenching effects. Since noise levels vary among the different conditions at which these calibration curves were obtained (*vide infra*), the results are plotted as signal/noise ratios: these allow a better appreciation of potential analytical utility than conventional (signal-only) measurements.

The analytically "best" calibration curve — i.e. #1, the one farthest to the left — is obtained without interference filter and quartz chimney, and at the optimized conditions noted in the Experimental section. The minimum detectable amount of ruthenocene, as defined by a signal/noise ratio of two, is 2.2×10^{-12} g. On a peak with a base width of 20 s ($2\sigma = 10$s), 2.2 pg translates to 2.2×10^{-13} g/s or 0.95×10^{-15} mol/s. (To compare: For the two most prominent analyte heteroatoms in the FPD, phosphorus and sulfur, Dressler reports a literature range of minimum detectable mass flow rates of 1×10^{-13} to 2×10^{-12} g P/s and 2×10^{-12} to 5×10^{-11} g S/s (5) — corresponding to 3×10^{-15} to 6×10^{-14} mol P/s and 6×10^{-14} to 2×10^{-12} mol S/s.)

The selectivity against dodecane, on an (atom Ru/atom C) basis — and measured at the same conditions as the "best" ruthenocene calibration curve — is 4.2×10^5. The calibration is linear over a range of 1 to 4×10^4. (Note that, for the abstract, most of these data have been rounded off to an overall more reasonable single significant digit.)

The next best calibration curve (#2) is obtained at similar conditions, except that the additional 20 mL/min flow of nitrogen (piped into the detector's air supply) was shut off. We have not investigated the reason for this difference in response.

The next calibration curve (#3) uses a significantly smaller amount of air (50 instead of 80 mL/min). Despite the fact that the temperature measured (583°C at the bottom to ca. 420°C in the upper regions of the luminescence) is now considerably lower, the detector performance is only slightly diminished. That fact is worth mentioning (*a*) in the spectral context of earlier speculation on chemical vs. thermal excitation, and (*b*) in the analytical context of ruthenocene having to be determined

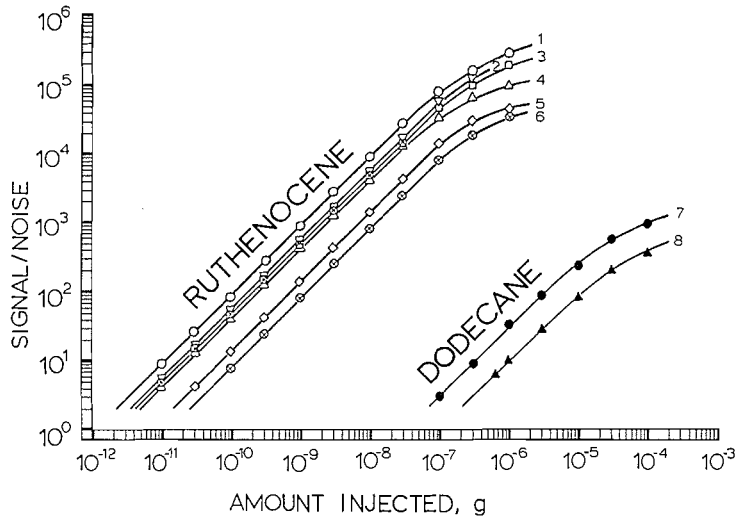

FIG. 5. Calibration curves for ruthenocene and dodecane at different conditions. See text for explanation. ○ (*1*) ruthenocene response optimized for maximum S/N ratio; ▽ (*2*) as (*1*), but no nitrogen added to detector gases; □ (*3*) as (*1*), but air flow = 50 mL/min; △ (*4*) as (*1*), but 526 nm interference filter present; ◇ (*5*) as (*1*), but quartz chimney present; ⊗ (*6*) as (*1*), but ca. 1600 ppm methane present in total detector gases; ● (*7*) dodecane response at conditions of (*1*); ▲ (*8*) dodecane response at conditions of (*4*).

in conjunction with other organometallic compounds, which may require different flame temperatures and/or compositions.

The next calibration curve (#4) is obtained at optimum conditions (like # 1), but with a 526 nm interference filter of at least 75% maximum transmission and at most 6 nm bandpass at half-height (the specifications of a typical FPD "phosphorus filter" that came as part of the original Shimadzu FPD package). Such a filter — or one for 484 nm, depending on the particular case — could be used for spectral discrimination, depending on the spectral characteristics of the sample matrix. Not surprisingly, the selectivity against dodecane is now at a higher level, i.e. at 7.4×10^5.

(The reader may in fact be surprised how *small* an improvement in selectivity the interference filter has brought about. The "dodecane" spectrum can not be procured by our spectrophotometer under these conditions; the maximum luminescence is too weak. It may be that the very strong 516 nm, 0,0 bandhead of the Swan bands, $C_2(d^3\Pi_g \rightarrow a^3\Pi_u)$, is the culprit, particularly since the filter, at a nominal 526 nm, does not quite match the peak at 528 nm.)

The next ruthenocene calibration curve (#5) simply shows what happens when the original Shimadzu quartz chimney is being put back in: The S/N value drops to one sixth of optimum. Again, the reason for this effect is unknown.

The last ruthenocene calibration curve (#6) employs optimum conditions (like # 1), but with ca. 1600 ppm CH_4 (as an example of a quencher) added to the detector gases. This large amount of methane reduces the ruthenocene peak by about one half. The calibration curve, however, shifts to the right by one full decade — owing to the effect of a drastic rise in baseline (background luminescence) on noise in the S/N measurement. Still, it remains linear.

There is good reason for running a "quenched" calibration curve: It is not unusual in FPD practice that other organic material should co-elute with the compound of interest and quench its response — be the former a chromatographic solute of the same rate of migration, or the continuously eluting twin scourges of column bleed and carrier gas contamination. This type of interference can present a major problem at the low-temperature of the FPD — as it does, for instance, in the well-known case of hydrocarbons quenching the response of sulfur compounds.

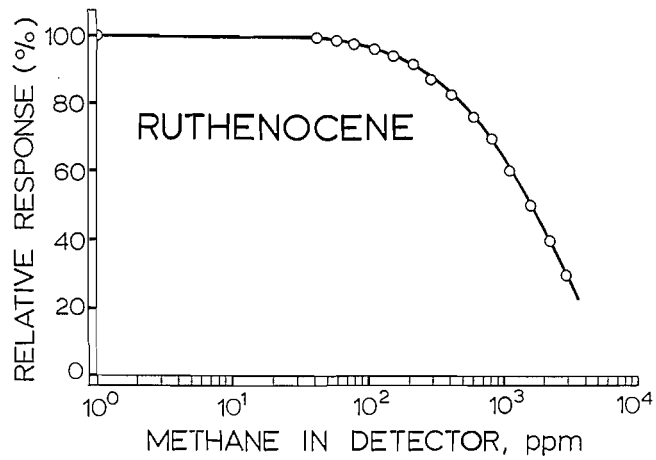

FIG. 6. Response of 3 ng ruthenocene at optimized conditions, but with varying concentrations of methane added to the hydrogen supply via an exponential dilution flask.

Figure 6 shows one of a series of experiments that use methane as a quencher and are designed to clarify the magnitude of the expected interference. (Note: methane is added to the hydrogen supply line which, in turn, joins the column effluent *prior* to reaching the flame.) It takes about 500 ppm (v/v) of methane to reduce the peak height of ruthenocene by a mere 20%. As mentioned before, to reduce the peak to one half of its former size requires about 1600 ppm CH_4.

Furthermore, the concentration of methane is calculated here on the *total* volume of detector gases (ca. 422 mL/min), not just on the nitrogen flow through the column. These 1600 ppm would correspond to about 3.1 volume percent, or 7.1×10^{-6} g/s, or 4.5×10^{-7} mol/s, of methane in the 22 mL/min of nitrogen carrier gas. That means that it takes a column flow of methane 3.6×10^6 and 4.5×10^7 times larger — on a weight and on a molar basis, respectively — than that of ruthenocene at its (quenched) minimum detectable limit, to reduce the ruthenocene peak by 50%.

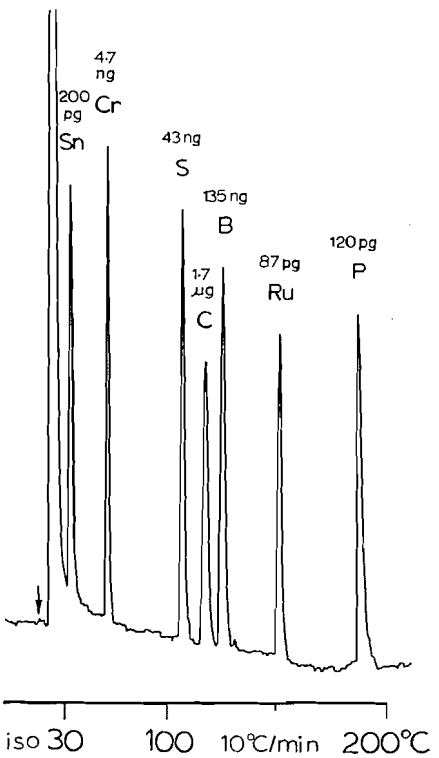

FIG. 7. Temperature-programmed chromatography. Amounts injected (in order of elution): 0.30 ng tetramethyltin, 20 ng chromium hexacarbonyl, 120 ng di-*t*-butyldisulfide, 2.0 µg dodecane, 180 ng *o*-carborane, 0.20 ng ruthenocene, 1.0 ng tri-*n*-butylphosphate. Flows in mL/min: hydrogen 300, air 80, carrier nitrogen 25, additional nitrogen 23. Detector and injector temperature 200°C.

Thus, if the quencher behaves similar to methane and is being continuously introduced (as are column bleed, carrier contamination, etc.), the quenching effect should be unobservably small in most practical cases. If the quencher behaves similar to methane but comes in the form of a peak of equal retention time, it will increase rather than decrease the ruthenocene peak at all quencher concentrations but those way beyond linear range. This can be easily visualized by comparing the dodecane response shown in Fig. 5, with the methane-quenched ruthenocene response shown in Fig. 6.

Prompted by one of the reviewers of this manuscript, we are pleased to add a chromatogram showing ruthenocene in the company of other hetero-organics. The detector gas flows are roughly optimized according to the ruthenium signal/noise ratio, hence the responses of other elements are depressed to varying extents, but the conditions are *not* optimal for obtaining the largest possible selectivity for ruthenium vis-a-vis one or more of these other elements. Further selectivity can be achieved by adjusting flow conditions and using various interference filters; however, such optimization is most effectively performed only after particulars of the sample matrix are known. For obtaining Fig. 7, no optical discrimination is used, and selectivity is reflected by the amounts of analytes necessary to produce peaks of similar height. The elemental responses, under these conditions and normalized to ruthenium on an atomic basis, are roughly Ru 1, Sn 0.6, P 0.3, Cr 1×10^{-2}, S 9×10^{-4}, B 8×10^{-5}, and C 5×10^{-6}. Note that the response of sulfur, as usual, is approximately quadratic and that tributylphosphate also exhibits minor non-linearity due to some premature decomposition. Note further that these response ratios are intended for determination of ruthenocene in the presence of other hetero-analytes: they should not be confused with a general FPD sensitivity ranking (for which each element is measured at its own, optimized conditions).

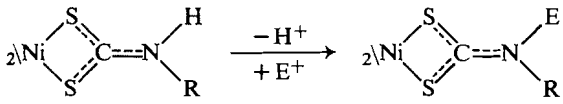
C. C. HADJIKOSTAS, G. A. KATSOULOS, M. P. SIGALAS, and C. A. TSIPIS. Can. J. Chem. **67**, 902 (1989).

Nickel(II) complexes of the general type $[Ni(S_2CN(COR')R)_2]$ have been synthesized by the reaction of the appropriate Ni(II) *N*-alkyldithiocarbamate with acetic anhydride or benzoyl chloride in the presence of triethylamine. The complexes obtained were identified and characterized by elemental analyses, conductivity measurements, and ir and electronic spectra. It was concluded that the bonding mode of the dithiocarbamato ligands to the metal ion is not altered by the acylation reaction, the chromophore remaining square-planar NiS_4. Moreover, EHMO-SCCC calculations have been used in the analysis of electronic structure, and related properties of the novel compounds. From the calculated molecular orbital description of the complexes and the frontier molecular orbital approach of chemical reactivity, plausible mechanisms of their formation reactions have been deduced.

Key words: Ni(II) amide *N*-carbodithioates, *N*-alkyldithiocarbamates, dithiocarbimates, electrophilic substitution reactions, EHMO-SCCC calculations.

C. C. HADJIKOSTAS, G. A. KATSOULOS, M. P. SIGALAS et C. A. TSIPIS. Can. J. Chem. **67**, 902 (1989).

On a synthétisé des complexes du Ni(II), du type général $[Ni(S_2CN(COR')R)_2]$, en faisant réagir les *N*-alkyldithiocarbamates de Ni(II) appropriés avec de l'anhydride acétique ou de chlorure de benzoyle, en présence de triéthylamine. On a identifié et caractérisé les complexes à l'aide d'analyses élémentaires, de mesures de conductivité et de spectres ir et électroniques. On en a conclu que le mode de liaison des ligands dithiocarbamato avec les ions métalliques n'est pas modifié par la réaction d'acylation; le chromophore demeure le NiS_4 plan carré. De plus, on a utilisé des calculs EHMO-SCCC pour faire l'analyse de la structure électronique ainsi que des propriétés apparentées des nouveaux composés. En se basant sur la description par orbitales moléculaires des complexes ainsi que sur l'approche par orbitales moléculaires frontières de la réactivité chimique, on propose divers mécanismes qui peuvent éventuellement expliquer leurs réactions de formation.



Mots clés : Amide de *N*-carbodithionates de Ni(II), *N*-alkyldithiocarbamates, dithiocarbamates, réactions de substitutions électrophiles, calculs EHMO-SCCC.

[Traduit par la revue]

Introduction

Since it was first demonstrated that dithiocarbamates, with an electron-withdrawing group and a proton on the nitrogen atom, may lose the proton to form dithiocarbimates (1, 2), there have been many studies in our laboratory concerning the reactions of Lewis bases, such as phosphines and amines, with square-planar d^8 bis(*N*-monosubstituted-dithiocarbamato)metal(II) complexes (3–9). In particular, our studies have shown (5) that reacting platinum(II) and palladium(II) *N*-alkyldithiocarbamates, $[M(S_2CNHR)_2]$, with excess tertiary phosphine, they easily afford neutral dithiocarbimato complexes, $[M(S_2C{=}NR)(PR'_3)_2]$, via a deprotonation reaction on the coordinated bidentate dithio-ligand. In this respect, the chemical behaviour of the *N*-alkyldithiocarbamato ligands is similar to that of the isoelectronic xanthates, which easily undergo dealkylation reactions (10). Moreover, the *N*-alkyldithiocarbamates of nickel triad metals, when treated with amines (e.g. NH_3) afford (6, 8) in most cases the corresponding dithiocarbimate complex anions, $[M(S_2C{=}NR)]^{2-}$. The mechanism of these reactions has been fully investigated by EH MO-SCCC quantum chemical calculations based on the frontier molecular orbital interactions which are the main factor controlling the nucleophilic substitution reactions under consideration (9). An interesting perspective of these theoretical investigations is that, for the dithiocarbimato complex, its HOMO is mainly localized on the nitrogen atom, and hence this atom should be the nucleophilic center of the complex in reactions with electrophiles. Actually, this prediction has been experimentally verified (5, 6, 8), since the dithiocarbimato complexes react with the electrophile H^+, affording the protonated products on the nitrogen atom, namely, the corresponding dithiocarbamato complexes.

Taking advantage of this labile to electrophilic attack nitrogen atom it seems reasonable to react the dithiocarbimato complexes with a variety of electrophiles (E^+), in order to prepare new classes of dithiocarbamates, according to the scheme:

The gain of such a work is that selecting electrophiles with strong electron-withdrawing groups the synthesis of carbodithioato derivatives of weak nitrogenous nucleophiles can be achieved. The direct preparation of such ligands by the reaction of the corresponding amine with carbon disulfide in alkaline media is difficult even impossible to afford, although some examples concerning the formation of *N*-formyl and *N*-methyl *N*-formyl dithiocarbamates have already been published (11–15). However, no reports on their corresponding complexes have been found by us to date. Consequently, in this paper we present our results on the synthesis and characterization of some novel nickel(II) amide *N*-carbodithioates of the general formulae $[Ni(S_2CNHR)(S_2CN(COR')R)]$ and $[Ni(S_2CN(COR')R)_2]$. Furthermore, we have utilized the EHMO-SCCC method, in relation to the frontier molecular orbital theory of chemical reactivity, to investigate the acylation reactions of nickel(II) dithiocarbamates. Particular emphasis has also been placed upon the interpretation of the observed electronic properties of these compounds with respect to their highly delocalized covalent bonding.

Experimental

Physical measurements

Infrared spectra were recorded in the 4000–250 cm^{-1} region on a Perkin-Elmer 467 spectrophotometer using KBr pellets or Nujol mulls. Electronic spectra were obtained on a Cary 17DX spectrophotometer using freshly prepared chloroform solutions at 25°C. Magnetic susceptibility measurements in solid state were done by the Faraday technique using $Hg[Co(SCN)_4]$ as the calibrant. Conductivity measurements were done on a WTW conductivity bridge using 10^{-3} *M* solutions in chloroform. Molecular weights were determined using a Perkin-Elmer molecular weight apparatus Model 115 in $CHCl_3$ solutions. Melting points were determined with a Büchi apparatus and are uncorrected. The elemental analysis of carbon, nitrogen, and hydrogen was performed on a Perkin-Elmer 240B Elemental Analyzer. Nickel was determined according to published methods (16).

Starting materials

All solvents were of reagent grade and were used without further purification in synthetic work. The bis(*N*-alkyldithiocarbamato)nickel(II) complexes were obtained from the reaction between nickel chloride and the appropriate ammonium dithiocarbamate in dimethylsulfoxide (DMSO) solution (17). The ammonium *N*-alkyldithiocarbamates were prepared and recrystallised as previously reported (8). All the other reagents were obtained commercially.

Preparation of the complexes

The (*N*-alkyldithiocarbamato)(*N*-alkyl *N*-acetyldithiocarbamato)-nickel(II) complexes, $[Ni(S_2CNHR)(S_2CN(COMe)R)]$ (R = Me, Et, Bu^i, Bz), were prepared according to the following synthetic route: A solution of 1 mmol of the appropriate $[Ni(S_2CNHR)_2]$ in 20 cm^3 of acetone was treated with 1 mmol of triethylamine and 1 mmol of acetic anhydride and the mixture was left for 1 h at room temperature under continuous magnetic stirring. In the resulted solution a solid material was formed, which on addition of 100 cm^3 of water, was quantitatively separated. The precipitate was filtered off, washed several times with water, and dried over $CaCl_2$ under vacuum. Recrystallization was carried out by dissolving the complex in acetone–chloroform (1:1) and reprecipitating with water. The yields in this procedure were about 70%.

The bis(*N*-alkyl *N*-acetyldithiocarbamato)nickel(II) complexes, $[Ni(S_2CN(COMe)R)_2]$ (R = Me, Et, Bu^i, Bz, Ph, *p*-MePh, *p*-ClPh), were prepared as follows: 1 mmol of the appropriate $[Ni(S_2CNHR)_2]$ was dissolved in 20 cm^3 of acetone and treated with 2 mmol of triethylamine and 2 mmol of acetic anhydride. The resulting clear solution was left at room temperature under continuous magnetic stirring. After a period of 1 h a reddish precipitate was formed and the precipitation was completed by addition of 100 cm^3 of water. The solid material was filtered off, washed with acetone, and dried under vacuum. Purification was achieved by dissolving the solid in chloroform and reprecipitating with ethanol (yield: 75%).

The bis(*N*-alkyl *N*-benzoyldithiocarbamato)nickel(II) complexes, $[Ni(S_2CN(COPh)R)_2]$ (R = Me, Ph), were prepared according to the following method: A solution of 1 mmol of the appropriate $[Ni(S_2CNHR)_2]$ in 20 cm^3 of acetone was treated with 2 mmol of triethylamine and 2 mmol of benzoyl chloride. The reaction mixture was stirred for 1 h at room temperature. During this period a microcrystalline solid was formed which on addition of 100 cm^3 of water was quantitatively separated. The precipitate was filtered off, washed several times with water, and dried over $CaCl_2$ under vacuum. Recrystallization was carried out by dissolving the complex in acetone and reprecipitating with water. The yields in this procedure were about 70%.

Calculations

All calculations were performed in the framework of the extended Hückel LCAO-MO method (18–20) with self-consistent charge and configuration (EHMO-SCCC) by using the FORTICON-8 computer program (21). In these iterative calculations the so-called "weighted H_{ij} formula" for the off-diagonal matrix elements (H_{ij}) was used in order to reduce the intriguing phenomenon of counterintuitive orbital mixing (COM) common in calculations of transition-metal complexes (22). Moreover, a Madelung energy correction (21, 23, 24) was applied to the diagonal matrix elements, H_{ii}. The value of 1.65 was used for the parameter *K*, as this value was found by a series of calculations to give the best agreement between the experimental and theoretical frequencies of the electronic transitions of the complexes studied, as well as over a wide range of dithio-complexes (9, 25). Orbital exponents, valence state ionization energies (VSIE), and parameters of the polyonymic charge dependence of the VSIES for all the basis AO's were those previously used (21, 25–30).

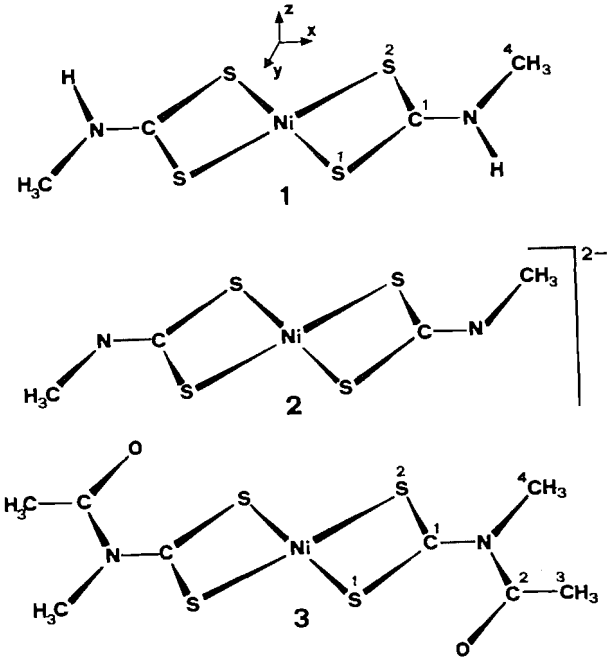

FIG. 1. Molecular geometries of the compounds studied along with the coordinate system used.

The geometries of the $[Ni(S_2CNHMe)_2]$ and $[Ni(S_2CN(COMe)Bz)_2]$ complexes were taken from already published X-ray crystal data (31, 32). In the case of $[Ni(S_2C{=}NBz)_2]^{2-}$ complex, structure parameters for the $(S_2C{=}NBz)^{2-}$ moiety were taken from the X-ray crystal data of the $[Pt(S_2C{=}NBz)(PEt_3)_2]$ complex (33), whereas optimization was carried out for the NiS_4 chromophore. For the sake of simplicity, as well as to avoid very large basis sets, the Bz substituents were replaced by methyl groups, the bond length value of C—H being 1.01 Å. The molecular geometries of the compounds studied along with the coordinate system used are displayed in Fig. 1.

Results and discussion

Reaction of acetone solutions of bis(*N*-alkyldithiocarbamato)nickel(II) complexes, $[Ni(S_2CNHR)_2]$, with acetic anhydride or benzoyl chloride in the presence of triethylamine (1:2:2 molar ratios) rapidly gave clear solutions from which solid compounds of stoichiometry $[Ni(S_2CN(COR')R)_2]$ (R' = Me, Ph) were isolated by precipitation with water. Similarly, the mixed-ligand $[Ni(S_2CNHR)(S_2CN(COMe)R)]$ complexes were prepared by the action of acetic anhydride and triethylamine on $[Ni(S_2CNHR)_2]$ in a 1:1:1 molar ratio. The above formulations have been further corroborated on the basis of spectral properties of these compounds. These novel complexes

*vs = very strong, s = strong, m = medium, w = weak.

are probably some of the first examples in the pure chemistry of the dithiocarbamato ligands which may be considered as derivatives of secondary amides. Until recently, as far as we know, only the [S_2CN(HCO)H]$^-$ and [S_2CN(HCO)CH_3]$^-$ ligands had been reported (14, 15). Moreover, the formation of [S_2CN(HCS)H]$^-$ and [S_2CN(HCS)CH_3]$^-$ ligands by the reaction of thioformamide with carbon disulfide in the presence of hydroxides had also been reported (12, 13). It should be noted, however, that all our efforts to prepare the corresponding free ligands according to the procedure described by Gattow and Gerner (14, 15) were unsuccessful, leading to unstable, easily oxidized species.

All the complexes are microcrystalline red–brown solids, quite stable both in solid and solution state. They are soluble in most of the common organic solvents, such as chloroform, acetone, and methylene chloride, but insoluble in ethanol, diethyl ether, carbon tetrachloride, and water. The low values of the molar conductivity in chloroform indicate the non-electrolyte character of the complexes, whereas their monomeric nature was established by osmometric molecular weight measurements in chloroform. Moreover, they are diamagnetic, as would be expected for d^8 species. Data from elemental analyses, decomposition temperatures, and molecular weights of the new compounds are given in Table 1.

Infrared spectra

The frequencies (cm^{-1}) of the most relevant absorption bands in the ir spectra of the studied compounds and their tentative assignments are presented in Table 2. The spectra of the mixed-ligand [Ni(S_2CNHR)(S_2CN(COMe)R)] complexes show one broad band in the 3300–3200 cm^{-1} region due to the N—H stretching frequency (34). In contrast, no such band appears in the spectra of the [Ni(S_2CN(COR′)R)$_2$] complexes, as a consequence of abstraction of the hydrogen atom in the S_2CNHR system and its substitution by a COR′ group. Moreover, the strong band found between 1730–1680 cm^{-1} in all the complexes was assigned to the C=O stretch, thereby indicating the acylation of the *N*-alkyldithiocarbamato ligands. The ν(C=N) and ν(CSS) stretching frequencies fall in the range 1590–1460 and 1010–970 cm^{-1}, respectively (35, 36).

The presence of only one strong band in the region where ν(CSS) lies strongly supports chelation of the dithiocarbamates, a doublet being expected in the region $1000 \pm 70\ cm^{-1}$ in the unchelated dithiocarbamates (37). However, the spectra did not show any peaks that could be ascribed to unidentate dithiocarbamato ligand or to thiuram disulfide (38). The bidentate bonding mode of the dithio ligands was further established by the analysis of the position of the ν(C=N) band. This band undergoes a blue shift in all the dithiocarbamato complexes, while for unidentate coordination this stretching would be shifted towards lower wavenumbers or remain unchanged at the value of the free dithiocarbamate ammonium salt (38). Finally, single peaks have been observed in the range 400–380 cm^{-1}, which are likely to be due to metal–sulphur modes according to the observed values for the dithiocarbamates of the nickel triad metals.

The ir data, the diamagnetic nature of the complexes under investigation and their stoichiometry allowed us to suggest a square-planar configuration. This conclusion is consistent with an X-ray crystal structure determination (32) of one derivative of this series, namely the $[Ni(S_2CN(COMe)Bz)_2]$.

Electronic spectra

The electronic spectra of the studied compounds are complicated, exhibiting a number of overlapping intense bands in the ultraviolet and visible region. This complicated nature of the spectra prevents any simple classification and rationalization in terms of the ligand-field model. This is a general problem encountered in any ligand-field interpretation of the electronic spectra of many nickel(II) dithiocarbamates (17). Therefore, an attempt was made to interpret the electronic spectra of the complexes under investigation by means of EHMO-SCCC quantum-chemical calculations on a representative member of the series, namely $[Ni(S_2CN(COMe)Bz)_2]$. The electronic

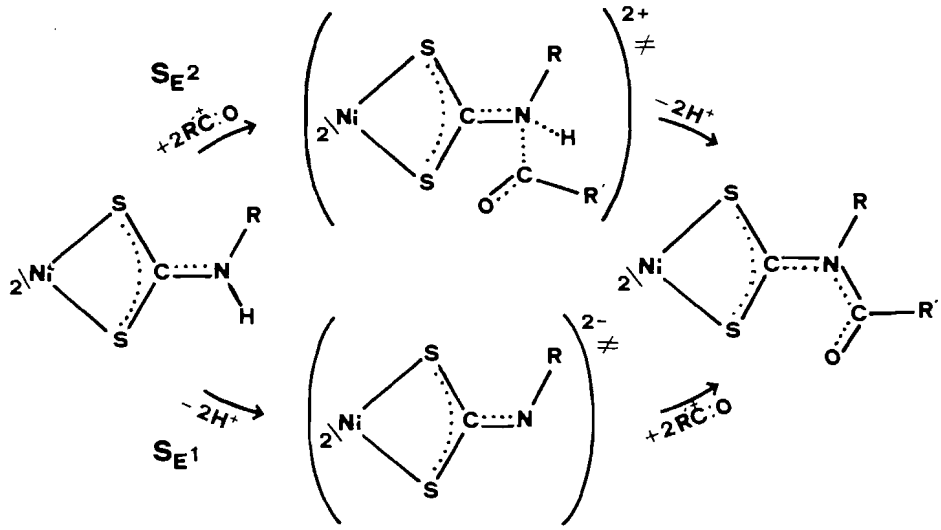

FIG. 2. Possible reaction mechanisms for the acylation of the nickel(II) dithiocarbamates.

excitation energies of the latter complex are compared with the experimental peak positions of the corresponding absorption spectrum in Table 3. Assignments were made by associating the observed bands with the transitions they most nearly match in energy. The resulting assignments of the bands were also invoked for the rest of the complexes (Table 4), whose spectra closely resemble to that of $[Ni(S_2CN(COMe)Bz)_2]$.

Furthermore, for a more precise characterization of the LF part of the spectrum the calculated one electron LF transitions were corrected for electronic repulsions (39), according to the following equations:

$$E(^1B_{1g}{}^a \leftarrow {}^1A_g) = E(xy) - E(z^2) - (4B + C)$$
$$E(^1B_{3g} \leftarrow {}^1A_g) = E(xy) - E(xz) - (3B + C)$$
$$E(^1B_{1b}{}^b \leftarrow {}^1A_g) = E(xy) - E(x^2 - y^2) - C$$
$$E(^1B_{2g} \leftarrow {}^1A_g) = E(xy) - E(yz) - (3B + C)$$

The values of the nephelauxetic parameters B and C were those found from a full AOM-CI description of the spectrum of $[Ni(S_2CNEt_2)_2]$ complex (17), and are equal to 0.28 and 1.28 kK, respectively. It must be noted also that we have considered the NiS_4 chromophore as belonging to the D_{2h} point group.

As can be seen from Table 3, the low intensity bands VI and V are assigned to the $^1B_{1b}{}^a \leftarrow {}^1A_g$ and $^1B_{3g} \leftarrow {}^1A_g$ LF excitations with a remarkably good agreement between calculated and experimentally observed energies. For the latter band a mixing with one $L(\pi^*) \leftarrow M(d)$ type excitation cannot be excluded, particularly when this band has high intensity. The other two expected LF transitions for the quadratic NiS_4 chromophore were impossible to observe, since the intense CT bands are extended up to the ligand-field part of the spectra, obscuring the weaker d–d transitions. The bands IV and III, in the region 21–27 kK, include all the calculated excitations of the $L(\pi^*) \leftarrow M(d)$ type and are reasonably assigned to MLCT transitions, in accordance with the results of previously published electronic spectral data on nickel(II) dithiocarbamato complexes (17, 40). Band II at ca. 30 kK can be assigned as a mixture of LMCT and L–L transitions, according to the calculated excitations. This fact is quite in line with the contradictory assignments (17, 40, 41) of that band in nickel(II) dithiocarbamates. Finally, band I includes all the $L(\pi^*) \leftarrow L(\pi)$ excitations and can be characterized as an intraligand L–L band.

Frontier orbital approach of chemical reactivity

In order to gain more information about the reaction of Ni(II) *N*-alkyldithiocarbamates with acetic anhydride or benzoyl chloride in the presence of triethylamine, EHMO-SCCC calculations were carried out. The experimentally verified (5, 6, 8) electrophilic substitution on the nitrogen atom of the coordinated dithiocarbamato ligand may proceed via either a unimolecular (S_E1) or a bimolecular (S_E2) mechanisms both depicted schematically in Fig. 2. It should be also noted that in the latter case the electrophile $(RC{=}O)^+$ attacks the parent dithiocarbamato complex, $[Ni(S_2CNHR)_2]$, whereas in the case of the S_E1 mechanism the deprotonated dianionic form, $[Ni(S_2C{=}NR)_2]^{2-}$, is likely to be attacked. This anion is formed during the nucleophilic substitution reaction of the Ni(II) *N*-alkyldithiocarbamates with amine nucleophiles (1, 2), in a manner analogous to the deprotonation reactions of the Pt(II) dithiocarbamates with phosphines (5, 9). Hence, the $[Ni(S_2CNHBz)_2]$ and $[Ni(S_2C{=}NBz)_2]^{2-}$ complexes were selected for the calculations, their corresponding electronic structures being depicted schematically in Fig. 3.

In terms of the frontier molecular orbital theory of chemical reactivity the aforesaid electrophilic substitution reaction requires high lying occupied MO's localized on nitrogen atoms for both the $[Ni(S_2CNHBz)_2]$ and/or $[Ni(S_2C{=}NBz)_2]^{2-}$ molecular species. However, in the case of the former complex, such MO's are the $2b_g$, and $4a_u$ π-MO's found in low energies, whereas the corresponding σ-MO's have much lower energies. Thus, energetically any interaction of these MO's with the unoccupied MO's of the electrophilic reagent is not possible. Furthermore, the net charge on the nitrogen atoms ($q_N = -0.22$) as compared with that on the sulphur atoms ($q_S = -0.30$) shows that such an interaction is not electrostatically favoured as well. However, in the case of the $[Ni(S_2C{=}NBz)_2]^{2-}$ complex the picture is quite different. Thus, beside the arising of the whole MO band in higher energies, MO's localized mainly on the nitrogen atoms, such as $4a_u$, $9b_u$, $13a_g$, and $4b_g$ were found near the HOMO's. Therefore these MO's, been of σ- and π-type, should interact with MO's of the electrophile. These frontier MO's interactions are demonstrated schematically in Fig. 4. It should be also noted that the deprotonation of the $[Ni(S_2CNHBz)_2]$ complex leads to an increasing of the net charge on the nitrogen atoms ($q_N = -0.55$; $q_S = -0.52$) showing that this reaction path is also electrostatically favoured. In conclusion, from the molecular orbital point of view, it

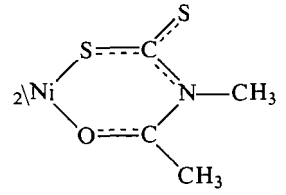
O	−0.631	N—C_4	0.646 (0.669)	−17.764 (−18.255)
C_3	−0.024	C_2—O	1.003	−27.467
C_4	0.208 (0.304)	C_2—C_3	0.813	−21.532



*Atomic numbering as in Fig. 1.
†Values in parentheses are the corresponding values for the parent $[Ni(S_2CNHBz)_2]$ complex, **1**.

seems that the acylation reaction of the bis(*N*-alkyldithiocarbamato)nickel(II) complexes in the presence of triethylamine proceeds via an S_E1 mechanism, involving as a transition state the deprotonated $[Ni(S_2C{=}NR)_2]^{2-}$ complexes.

Moreover, in an attempt to investigate the possibility of an alternative coordination of the new ligands through the S and O ligating atoms, we have performed EHMO-SCCC calculations on the model compound **4**, in both D_{2h} (square planar) and T_d (tetrahedral) coordination microsymmetry. The total energies (in 10^3 kcal mol^{-1}) of these model compounds compared with that of complex **3** are as follows:

$$\mathbf{3}(D_{2h}): -39.987 < \mathbf{4}(D_{2h}): -39.891 < \mathbf{4}(T_d): -39.659$$

Thus any O- and S-coordination should be excluded for the compounds under study in accordance with the X-ray structure found for the $[Ni(S_2CN(COMe)Bz)_2]$ complex (32). This conclusion is consistent with the two-center energy terms and overlap population data for the coordination bonds of the complex under investigation listed in Table 5. For comparison reasons the corresponding results for the parent $[Ni(S_2CNHBz)_2]$ complex are also included.

Continuous flow fast atom bombardment mass spectrometry of mononucleotides and their metal complexes

M. J. BERTRAND,[1] V. BENHAM, R. ST-LOUIS, AND M. J. EVANS

Department of Chemistry, University of Montreal, P.O. Box 6128, Station A, Montreal, P.Q., Canada H3C 3J7

Received September 7, 1988

M. J. BERTRAND, V. BENHAM, R. ST-LOUIS, and M. J. EVANS. Can. J. Chem. **67**, 910 (1989).

The mass spectra of mononucleotides and their metal adducts Na, K, Mg, Ca, Ni, Co, Cu, and Zn of guanosine 5′-monophosphate (5′-GMP) as well as H, Na, and Mg of adenosine 5′-monophosphate (5′-AMP) and H and Ni of inosine 5′-monophosphate (5′-IMP) have been obtained in low concentrations of matrix in water using continuous-flow fast atom bombardment. The results indicate that this technique is suitable for the analysis of these complexes in aqueous media and yields spectra that are highly characteristic of the compounds analyzed. Parent-molecular ions and structurally significant fragment ions are observed for all compounds studied and the different binding sites for the metal on the nucleotides can be isolated from the fragment ions. Experimental parameters influencing the quality of the spectra such as flow rate, matrix concentration, matrix nature, and analyte concentration have been studied and optimized. For the thirteen compounds studied, it appears that continuous-flow FAB is superior to conventional FAB and that good quality spectra can be obtained with as little as 0.5% of added matrix thus minimizing spectral interferences.

Key words: continuous flow FAB, FAB MS, mass spectrometry, nucleotides, metal-nucleotides.

M. J. BERTRAND, V. BENHAM, R. ST-LOUIS et M. J. EVANS. Can. J. Chem. **67**, 910 (1989).

Utilisant la technique du bombardement par atomes rapides en flux continu, on a déterminé les spectres de masse de mononucléotides et de leurs adduits métalliques (les sels de Na, K, Mg, Ca, Ni, Co, Cu et Zn de la monophosphate-5′ guanosine (5′-GMP), les adduits du H, Na et Mg de la monophosphate-5′ adénosine (5′-AMP) ainsi que les adduits H et Ni de la monophosphate-5′ inosine (5′-IMP)) présents à de faibles concentrations dans des matrices d'eau. Les résultats obtenus indiquent que cette technique est appropriée pour l'analyse de ces complexes dans des milieux aqueux et qu'elle fournit des spectres très caractéristiques des composés analysés. Pour chacun des composés étudiés, on a observé les ions moléculaires parents ainsi que des ions correspondants à des fragments importants du point de vue de la structure; en se basant sur les ions de ces fragments, on peut identifier les divers sites de liaison du métal sur les nucléotides. On a étudié et optimisé les paramètres expérimentaux qui influencent la qualité des spectres, comme la vitesse d'écoulement, la concentration matricielle, la nature de la matrice et la concentration du produit à analyser. Pour les treize composés étudiés, il semble que cette méthode soit supérieure à la méthode FAB conventionnelle et que l'on puisse obtenir des spectres de bonne qualité avec une addition minimale de 0,5% de la matrice; on minimise ainsi les interférences spectrales.

Mots clès: FAB à debit-continu, FAB MS, spectrométrie de masse, nucléotides, adduits metallique.

[Traduit par la revue]

Introduction

In life sciences, tremendous importance is attributed to nucleosides, nucleotides, and their metal adducts. Metals and their complexes are known to play a crucial role in various biological systems. Alkaline and alkaline earth metals play the role of charge carriers and activators for several enzymes. The transition metal ions are efficient in blocking active sites of metallo-enzymes in redox and oxygenation reactions. Accordingly, the structural characterization of nucleic acid derivatives and their metal adducts in biological media should pave the way for a better understanding of their behavior in different micro-organism environments.

The first applications of mass spectrometry in the characterization of nucleotides and nucleosides were reported by Biemann and McCloskey who demonstrated the use of electron ionization in the structure elucidation of the so-called low volatility nucleosides (1). They used free nucleosides and sublimed them directly in the ionizing electron beam to produce mass spectra. Further accomplishments involve the analysis of chemically modified nucleosides (2) and nucleotides (3), the sequencing of deoxyribonucleotides (4), and the use of chemical ionization, field desorption, thermospray, and other desorption–ionization techniques (5–10) for the analysis of these polar compounds. Since the introduction of fast atom bombardment (FAB) (11, 12), a desorption–ionization technique that allows the analysis of polar, thermally labile and involatile compounds, a number of publications dealing with its application to the analysis of nucleotides, nucleosides, and their derivatives have appeared in the literature (13–20).

Although FAB is known to be a relatively simple and versatile technique, its application to the analysis of nucleotides, nucleosides, and their metal adducts is often limited because of the lack of solubility and/or chemical stability of these compounds in the commonly used matrices. Furthermore, the use of liquid matrices such as glycerol and diethanolamine can modify the structures of the metal adducts and often create strong spectral interferences in the mass spectra of complexes of relatively low molecular weights. Recently, a technique known as continuous-flow FAB or dynamic FAB has been introduced (21, 22) and it appears promising for the analysis of nucleotides, nucleosides, and their metal adducts, since it allows the analysis to be conducted in aqueous media containing relatively low concentrations of added matrix. Under these conditions, it becomes possible to vary matrix conditions to increase solubility and chemical stability and consequently spectral interferences can be reduced substantially (23).

The present work reports a feasibility study on the use of continuous-flow FAB for the characterization of nucleotides and their metal adducts in aqueous media. The purine mononucleotides, Na_2-5′-GMP, H_2-5′-AMP, and H_2-5′-IMP (see Fig. 1) and some of their metal adducts with alkaline, alkaline earth, and transition metals (Na, Mg, Ca, Ni, Co, Cu, Zn) have been studied and their mass spectra have been obtained in water using a home-made continuous-flow probe. Most of the compounds studied in this work give complexes of the type $M_2L \cdot nH_2O$ and $M'L \cdot nH_2O$ where M = Na, K; M′ = alkaline earths and transi-

tion metals; and L = guanosine 5′-monophosphate (5′-GMP), adenosine 5′-monophosphate (5′-AMP) and inosine 5′-monophosphate (5′-IMP) (24, 25). In the solid phase, the alkaline and transition metals are normally bound to N(7) and indirectly interact with phosphate groups through a hydrogen bonding network (26–30). The effect of several experimental parameters that have an influence on the quality of the mass spectra recorded under dynamic FAB conditions such as pH, matrix concentration, matrix basicity, and analyte concentration have also been studied.

Experimental

Continuous-flow probe

The block diagram of the continuous-flow probe, which is similar in design to a commercially available continuous-flow probe (22), and sample delivery system that have been built and used in this study is shown in Fig. 2. The constant and continuous flow of the mobile phase, contained in a syringe reservoir, is provided by a suitable infusion pump (Harvard Apparatus Inc.) normally operated at 3–5 μL/min. The pump is connected to an adjustable probe (capped with an angled brass tip through which a 0.35 mm hole is drilled) via a Rheodyne (Model 7125) injector for samples of 5 μL and larger volumes or a Rheodyne (Model 7520) injector for submicroliter volumes. The probe is constructed from a stainless steel hollow shaft through which an electrically isolated 1.5 m long (0.08 mm id, 0.3 mm od) fused silica capillary is centered coaxially and fixed to the brass tip. The other end of the capillary is connected to the Rheodyne injection valve. The hollow shaft is continuously evacuated through a 3 mm hole in the side of the brass tip. All injections, as well as the mobile phase, are continuously filtered by appropriate line filters (see Fig. 2). In this project, the samples were dissolved in the mobile phase before they were injected.

Mass spectrometry

All mass spectral analyses presented in this study were conducted on a Kratos MS-50TC triple analyzer mass spectrometer arranged in a C-shaped geometry (EBE). The instrument was equipped with a standard Kratos FAB source operated at 8 kV and a post-acceleration detector. The xenon (Matheson 99.9%) atom beam was generated by an Iontech B-11NF saddle-field gun mounted on the FAB source and had a kinetic energy of 6 keV. Data acquisition and treatment were done using a Kratos DS-90 system and the spectra presented were obtained by averaging 6–8 scans.

Chemicals

The nucleotides H_2-5′-IMP, H_2-5′-AMP as well as Na-5′-AMP (6.8% sodium content), Na_2-5′-GMP, and K_2-5′-GMP were obtained from Sigma Chemical Company (St. Louis, MO, U.S.A.) and were used without further purification. The alkaline earth complexes Ca-5′-GMP, Mg-5′-GMP, and Mg-5′-AMP together with the transition metal complexes Ni-5′-GMP, Co-5′-GMP, Cu-5′-GMP, Zn-5′-GMP, and Ni-5′-IMP, were all prepared according to established methods (ref. 29 and references therein – ref. 31). The mobile phases used were HPLC grade water, glycerol, diethanolamine, triethanolamine, and mixtures thereof.

Results and Discussion

In spite of numerous attempts, little or no success was achieved in recording the conventional FAB spectra of a number of mononucleotides and their metal adducts presented in this work. The partial solubility and chemical instability of the compounds in commonly used FAB matrices are some of the reasons attributed to the poor results. In the case of metal adducts, the pH of the matrix and the nature of the matrix are quite important to the stability of the complexes. Some polar matrices can interact strongly with nucleotide metal adducts and compete with the nucleotides for the metal ion, thus changing the nature and chemical structure of the molecules to be studied. However, the use of a technique such as continuous-flow FAB

should eliminate several of the drawbacks described above since a water solution of variable pH can be used for the analysis, and the amount of support matrix added to water for ionization to occur can be very small. Under these experimental conditions, it should be possible to reduce the background in the spectra and to study the nature of the metal adducts of nucleotides that exist in aqueous media.

The positive ion spectra of the nucleotides Na_2-5′-GMP and Ni-5′-GMP obtained using continuous-flow FAB and conventional FAB are shown in Fig. 3. Comparison of the spectrum of Na_2-5′-GMP obtained with conventional FAB (Fig. 3*a*) by dissolving the compound in glycerol with that obtained from a 0.01 *M* aqueous solution at pH 5.9 containing 0.5% of glycerol using the continuous-flow system reveals that a much higher S/N ratio is obtained under dynamic conditions. Even if the ions (M − Na + 2H), (M + H), and (M + Na) at *m/z* 386, 408, and 430 are observed in both spectra, the spectrum recorded using water clearly shows the presence of ions (M + 2Na − H) and (M + G+ H) at *m/z* 452 and 500 that are lost in the background under conventional FAB. As another example, the spectrum of Ni-5′-GMP obtained from a 0.01 *M* aqueous solution at pH 3.5 containing 0.5% of thioglycerol using continuous-flow FAB (Fig. 3*c*) can be compared with that obtained using conventional FAB by dissolving the compound in thioglycerol (Fig. 3*d*). It can readily be observed from the spectra that ions which are characteristic of the metal adduct are present under continuous-flow conditions whereas under conventional FAB, the ions present are mostly formed from thioglycerol. The spectrum obtained under dynamic conditions (Fig. 3*c*) shows parent-molecular ions (M + H) and (M + T + H) at *m/z* 420 and 528 and fragment ions (RP + Ni + $2H_2O$ + H), (B + H), and S at *m/z* 306, 151, and 133 that are characteristic of the compound under study. In the above assignments RP, B, and S refer to the ribose-phosphate, the base, and the sugar moiety, respectively. Furthermore, it can be seen that interference from the matrix ions is very small (*m/z* 109), indicating the preferred ionization of the analyte. The spectrum recorded using conventional FAB does not show ions that are characteristic of the metal adduct. The intense ions that are present are mostly formed from thioglycerol and the only two ionic species containing Ni are (T + Ni + H) and (2T + Ni − H) at *m/z* 165 and 273 and these ions do not contain structural information. Thus, for the examples shown, the continuous-flow system is clearly advantageous.

In order to confirm the potential of the continuous-flow mode for the analysis of nucleotides and their metal adducts in aqueous solutions, a series of metal complexes and nucleotides have been analyzed. The positive ion spectra of the transition metal complexes Zn-5′-GMP, Cu-5′-GMP, Co-5′-GMP, and Ni-5′-GMP have been obtained from 0.01 *M* aqueous solutions (pH = 2–3.5) containing 0.5% of glycerol and are shown in Fig. 4. It can be seen that in all cases parent-molecular ions and characteristic fragments are observed. The parent-molecular ions (M + H) for Zn, Cu, Co, and Ni are present at *m/z* 426, 425, 421, and 420, respectively. Intense fragment ions of the type (RP + M′ + $2H_2O$ + H), (B + 2H), and (S), where M′ = metal are also observed. The (B + 2H) and (S) ions usually appear at *m/z* 152 and 133 whereas the (RP + M′ + $2H_2O$ + H) fragments are observed at *m/z* 312, 311, 307, and 306 for Zn, Cu, Co, and Ni, respectively. The fragment ions observed are of special interest because they include the different binding sites on the molecules such as the base, the sugar, and the phosphate moieties. The transition metals are usually bonded to N(7) in the solid state and interact indirectly with the phosphate moiety via the hydrogen bonding network (26–30). In water and under FAB bombardment, ions of the type (RP + M′ + $2H_2O$ + H) are intense, indicating that a metal–phosphate interaction is favored in the fragmentation. These results can be interpreted with the view that in the reaction of *cis*-diaminediaquoplatinum-(II) with disodium 5′-uridine phosphate in solution, it has been observed using vibrational spectroscopy that Pt atoms are temporarily bound to the phosphate group (31). The presence of (B + 2H) ions in the spectra is also consistent with the assumption that the metals interact strongly with the phosphate group in the ionic state. Thus the use of continuous-flow FAB not only yields mass spectra that are characteristic of the complexes but furthermore they may provide a tool by which the metal nucleotide interaction in water can be studied. Considerations related to the identification of the binding site of the metal from the spectra will be discussed furtheron.

The positive ion spectra of H_2-5′-AMP, Na-5′-AMP, Mg-5′-AMP, and H_2-5′-IMP were also recorded using aqueous solutions and continuous-flow FAB and are shown in Fig. 5. The spectra were obtained from 0.01 *M* aqueous solutions containing 0.5% of glycerol. As seen from Fig. 5*a* and *d*, both H_2-5′-AMP and H_2-5′-IMP give relatively simple spectra with parent-molecular ions (M + H) at *m/z* 348 and 349 and fragment ions (B + 2H) at 136 and 137 which are common in the spectra of nucleotides and nucleosides. The spectrum obtained for Na-5′-AMP (Fig. 5*b*) is characteristic of the compound and different from the spectrum of H_2-5′-AMP showing parent-molecular ions (M + H), (M + Na), and (M + 2Na − H) at *m/z* 370, 392, and 414. Fragment ions that are characteristic of the base are observed at *m/z* 136 and 164 and they correspond to (B + 2H) and (B + 30). The spectrum of Mg-5′-AMP shown in Fig. 5*c* has features that are indicative of the structure of this metal adduct. The parent-molecular ion (M + H) is present at *m/z* 370 and fragment ions corresponding to the base and the sugar moieties (B + 2H), (B + 44), and (S) are seen at *m/z* 136, 178, and 133. It is interesting to note that the ion at 133 corresponding to the sugar moiety is essentially present when a divalent cation is present (Cu, Ni, Co, Mg...). In this spectrum, contrary to the metal adducts of transition metals where the (RP + $2H_2O$ + H + M′) ion was intense, this type of ion is not observed for Mg but instead the fragment ions (Mg + 2B) and (Mg + BH) are observed at *m/z* 159 and 292. This may imply that with Mg the preferred site of interaction in the ionic state is the base and not the phosphate moiety as is the case for the transition metals. The magnesium complex was soluble at pH ~ 2 contrary to H_2-5′-IMP, H_2-5′-AMP, and Na-5′-AMP that were soluble at pH ~ 6.

Although most compounds yield acceptable spectra in the positive ion mode, it was not possible to obtain significant positive spectra for the compounds Mg-5′-GMP, Ca-5′-GPM, and Ni-5′-IMP and consequently these compounds were analyzed in the negative ion mode. The spectra obtained for Mg-5′-GMP (pH = 2, 0.5% glycerol) Ca-5′-GMP (pH = 2, 1% diethanolamine), and Ni-5′IMP (pH = 11, 0.5% triethanolamine) are shown in Fig. 6. In all three cases, parent-molecular ions $(M - H)^-$ are observed at *m/z* 384, 400, and 404. The common fragment ions that are present in the three spectra are B^- and $H_2PO_4^-$ at *m/z* 135 or 150 and 97. However, the spectrum of the magnesium complex differs from the two others because it exhibits ions at *m/z* 323 and 209 that can be attributed to (2B + Mg − H) and (Mg + B + $2H_2O$ − H). The latter is equivalent to the (RP + M′ + $2H_2O$ + H) ion observed for the transition metals but the ribose-phosphate moiety has been

replaced by the base moiety indicating that Mg possibly has a preferred interaction with the base moiety as observed previously for Mg-5′-AMP. If the results reflect the binding site of the metal in solution (see later) these findings differ from published results in which Mg was found to be bonded to the phosphate moiety in solutions having a pH lower than 5 (32).

The results that have been obtained for the analysis of thirteen nucleotides and metal adducts using continuous-flow FAB in the positive and negative ion modes are summarized in Table 1. The ions that are most significant and common to most compounds are given and the numbers in parentheses refer to their relative intensities in the spectra. It can be seen that most compounds yield a spectrum in both negative and positive ion modes and that ions which are specific to each part of the molecules are present, allowing structure assignment. In several cases, ions are present to isolate the possible binding sites and the nature of the metal is seen to have an important influence on the fragmentation of the molecule.

During the evaluation of the continuous-flow probe, several parameters were found to have an influence on the quality of the results and those are (*i*) flow rate, (*ii*) solute concentration, (*iii*) droplet size and shape, (*iv*) matrix concentration, and (*v*) the nature of the matrix.

Flow rate

To obtain a stable operation, it is important that the evaporation rate of the mobile phase from the probe surface be in constant equilibrium with the pumping speed of the mass spectrometer and this is to a large extent controlled by the adoption of an optimum flow rate. In this work the flow rates used were in the vicinity of 3–5 μL/min. Lower and higher flow rates resulted in freezing within the end of the capillary tip, and spattering of the liquid surface, respectively. Both these conditions lead to considerable instability in the ion current.

Solute concentration

The range of solute concentrations that can be used is limited at the higher end by the possibility of blocking the capillary with precipitation or crystallization of the sample in the capillary or at the probe surface and at the lower end by the sensitivity of the method for a particular compound. In this study, it was found that good signal-to-noise ratio and stable operation could be achieved routinely using 0.01 *M* solutions. However, reasonable spectra could be achieved with concentrations as low as 10^{-5} *M* for some nucleotides.

Matrix concentration

Since the main objective of this project was to explore the nature of the metal adducts of nucleotides in aqueous media, considerable effort was made to use the lowest possible added matrix concentration. Correspondingly, the majority of the samples were analyzed with 0.5% of added matrix in water. Smaller amounts lead to the inhibition of ionization of the analyte or freezing of the water at the probe tip. Caprioli *et al.* have used up to 25% of glycerol and thioglycerol (22) but under these conditions contamination of the spectrum at lower masses by ions generated by the matrix is substantial and not acceptable for the compounds studied in this work.

Nature of the matrix

In FAB mass spectrometry, solute, and matrix are in constant competition in scavenging the available protons and this to a large extent depends on their acidic properties (33, 34). The outcome of such a competition will have a determining effect on the intensities of the fragments observed in both the positive and negative ion modes. Since the amount of added matrix was relatively small (0.5%) in our experiments, a short study was conducted to evaluate the extent of the influence of the acidic properties of the matrix. Aqueous solutions of Na_2-5′-GMP containing 0.5% of thioglycerol, glycerol, diethanolamine, and triethanolamine were analyzed in the positive and negative ion modes and the variation of the signal-to-noise ratio was evaluated by measuring the ratios of the intensities of the parent-molecular ions to the base peak of the matrix. The negative ion spectra obtained with glycerol, diethanolamine, and triethanolamine are shown in Fig. 7 and the variations of S/N are given in Table 2. It is seen from the spectra that as the nature of the added matrix is changed, the features of the spectra remain essentially the same but that the intensities vary. The results shown in Table 2 indicate that the nature of the added matrix even at low-concentrations has a definite effect on the quality of the spectra. For positive ion spectra the more acidic matrices such as thioglycerol and glycerol yield better results whereas for negative ion spectra it is preferable to use an

Triethanolamine	0.05	0.27
Diethanolamine	—	1.1

alkaline matrix such as diethanolamine. However, under the conditions of continuous-flow FAB contrary to conventional FAB, the solubility of the analyte does not depend on the added matrix but mostly on the pH of the aqueous solution which is advantageous.

Conclusion

On the basis of the results obtained in our mass spectrometric investigation of mononucleotides and their metal adducts using continuous-flow fast atom bombardment it can be concluded that this approach is better suited than conventional FAB to analyze these compounds. Under the dynamic conditions used it appears that not only a higher signal-to-noise, reducing the background interferences, is obtained, but the spectra recorded are more reliable and reproducible. The nature of the matrix that is present in small concentration has an effect on the intensities of the parent-molecular ions but contrary to conventional FAB the solubility does not depend greatly on the added matrix. The solubility of the analyte can be augmented by varying the pH, which is an advantageous feature. The mass spectra that have been obtained using the continuous-flow approach are very characteristic of the structure of the compounds analyzed since parent-molecular ions are present and fragment ions corresponding to the base, the sugar and the phosphate are dependent on the nature of the metal in metal adducts. It thus appears that the continuous-flow approach can be useful for characterizing the structures of nucleotides, nucleosides, and their derivations directly from aqueous media.

Finally, an important question arises from the results that have been obtained and it relates to the possibility to elucidate the positions of the binding of the metal to the nucleotide from the mass spectral data. It is doubtful that a definite answer can be given from the preliminary experiments that have been conducted in this study. Since the primary objective of the work was to obtain the mass spectra of metal adduct of nucleotides, the project was not designed to answer such a question. Furthermore, since our knowledge of all the aspects involved in the production of a FAB spectrum and the phenomena of chemical reactions that can be induced by high energy particles is still incomplete (35), it is difficult to accurately predict the relation between observations made on fragments and structures that can exist in the liquid solution. However, there are some elements in the spectra of the metal adducts that indicate a definite relation between the spectrum obtained and the nature of the divalent ions. For example, the presence of an intense ions at *m/z* 133 corresponding to the sugar moiety is observed whenever a divalent cation is present in the adduct. The mass spectra of Ni, Ca, Co, and Zn complexes exhibit similar features whereas the magnesium adducts differ from them both in the positive and negative ion mode indicating that this behavior is probably structure related. Thus, although the information gathered in this work is not sufficient to answer the important question on the binding site, it is sufficient to warrant further investigation on well-characterized systems to verify if the binding sites can be determined by this technique.

Surface electrochemistry of the oxidation of glycine at Pt

DANIEL G. MARANGONI, RICHARD S. SMITH, AND SHARON G. ROSCOE[1]
Chemistry Department, Acadia University, Wolfville, N.S., Canada B0P 1X0

Received September 21, 1988

DANIEL G. MARANGONI, RICHARD S. SMITH, and SHARON G. ROSCOE. Can. J. Chem. **67**, 921 (1989).

The electrochemical oxidation of glycine at a Pt electrode was investigated in aqueous solutions at pH 1 and 13 using steady-state current–potential measurements, cyclic voltammetry, and open circuit potential decay. The capacitance behaviour and the high Tafel slopes suggest the production of free radicals at the surface of the electrode accompanied by a second reaction involving loss of CO_2 which is the rate determining step. In the electro-oxidation of glycine, it appears that the adsorbed intermediate species is either hydrolyzed anodically to formaldehyde and ammonia, or is oxidized to a carbonium ion which is subsequently hydrolyzed to formaldehyde and ammonia in solution. This behaviour differs from the dimerization process typical of the radical reactions associated with the Kolbe mechanism.

Key words: glycine, amino acid, electrochemical oxidation, surface electrochemistry, Kolbe mechanism.

DANIEL G. MARANGONI, RICHARD S. SMITH et SHARON G. ROSCOE. Can. J. Chem. **67**, 921 (1989).

Faisant appel à des mesures de potentiel du courant à l'état stationnaire, à la voltamétrie cyclique et à la dégénérescence du potentiel en circuit ouvert et opérant en solutions aqueuses, à des pH de 1 et de 13, on a étudié l'oxydation électrochimique de la glycine, au niveau d'une électrode de Pt. Le comportement de la capacitance et les courbes de Tafel élevées suggèrent qu'il y a une production de radicaux libres à la surface de l'électrode et que celle-ci est accompagnée d'une deuxième réaction, impliquant une perte de CO_2, qui détermine la vitesse de la réaction. Dans l'électro-oxydation de la glycine, il semble que l'espèce intermédiaire adsorbée est soit hydrolysée à l'anode en formaldéhyde et en ammoniac soit oxydée en un carbocation qui est subséquemment hydrolysé en formaldéhyde et en ammoniac, en solution. Ce comportement diffère du processus de dimérisation typique des réactions radicaliques associées au mécanisme de la réaction de Kolbe.

Mots clés : glycine, acide aminé, oxydation électrochimique, électrochimie de surface, mécanisme de la réaction de Kolbe.

Introduction

Several investigations of the electro-oxidation of α-amino acids were reported in the early 1930's (1–5). Fichter and Schmid (1) concluded from product analysis, that the electrolytic oxidation of α-amino acids in sulfuric acid solution produces the next lower aldehyde in the first step of the oxidation. However, Takayama (2, 3) found that oxidation at a PbO_2 anode resulted in a facile further oxidation of the aldehyde by the following:

$$RCH(NH_2)COOH \xrightarrow{[o]} RCHO + NH_3 + CO_2$$

$$RCHO \xrightarrow{[o]} RCOOH$$

Fichter and Kuhn (2) and Takayama (5) reported the formation of ammonia, formaldehyde, formic acid, carbon dioxide, and methyl, dimethyl, and trimethyl amines as products from the electrolytic oxidation of glycine. Plochl (6) has suggested that the amines probably resulted from the interaction of formaldehyde and ammonia. Takayama concluded that, from the experimental results, the first stage of the oxidation of amino acids is the aldehyde formation and that the other products either result from further oxidation (formation of carboxylic acids) or the chemical interaction of one product with another. He also concluded that the general reaction above best represents the course of the electrolytic oxidation of an α-amino acid.

The present research has been undertaken to investigate the kinetics, mechanisms, and surface effects of the electrochemical oxidation of glycine at the Pt electrode. Steady-state current–potential measurements, cyclic voltammetry, and open circuit potential decay have been used to study 0.45 *M* aqueous solutions of glycine at pH 1 and pH 13 in order to characterize these reactions with a fully protonated and fully unprotonated reactant, respectively. Anodic reactions in aqueous solutions at the Pt electrode are complicated by the electrocatalytic surface oxide film which develops on the anode metal surface. Thus, electrocatalysis occurs for such reactions as O_2 (7, 8), Cl_2 (9–13), N_2 (from N_3^-) (14–17) evolution, and the Kolbe reaction (18). Generally, in anodic reactions in aqueous media, the electrode may be considered "demetallized" (19) by its oxide film. Thus, the present work examines the influence of surface oxidation on the kinetics of anodic oxidation of glycine on well defined states of the Pt surface oxide film.

Experimental

(a) Methods

Steady-state polarization measurements were made on solutions of the amino acid at a pH of 1 and 13. A Wenking potentiostat (Fast Rise Model 6288RS) was used to control the potential of the working electrode, and the current and potential measurements were read from Keithley autoranging multimeters (model 175 and model 195), respectively. Polarization lines were determined by holding for 10 s per current-density point, at 10 mV intervals of potential. Data analysis and graphics were carried out using both the Cyber 830 and Commodore PC-10 computers.

Corrections for uncompensated solution resistance ("*iR*" drop corrections) were made to the Tafel plots. These "*iR*" corrections were determined using a mercury-wetted vacuum relay to give a clean fast break in the circuit, and the rapid potential drop was recorded on a digital storage Tektronics oscilloscope (model 5440). Potential decay transients were determined in the same manner following steady-state potentiostatic polarization. Analysis of the potential–time data was accomplished using a Commodore PC-10 computer with the Asystant data processing software.

Cyclic voltammograms were obtained using the potentiostat and a function generator (Hokuto Denko Ltd, Model HB-111) to produce a repeating triangular potential function. The potential, read directly from the working and the reference electrodes, and the current, measured by the potential across a variable resistor placed in the counter electrode circuit, were connected to a Hewlett-Packard X-Y recorder (model HP 489-5093) to give the potential–current profile.

(b) Solutions

Solutions of glycine were prepared from 99+% purity, gold label reagent (Aldrich Chemical Company) using conductivity water (Nanopure water, resistivity = 18.3 megohm cm^{-1}) which had been distilled from acid potassium permanganate to remove organic impurities. Sulfuric acid solutions were prepared from Aristar grade 98% purity reagent (BDH Chemicals Limited), while sodium hydroxide solutions were prepared from the standardized Aldrich Acculute concentrate. All solutions were prepared to a concentration of 0.45 *M* in amino acid.

(c) Electrochemical cell and electrodes

Three compartment, all glass cells, provided with glass-sleeved stopcocks as two of the compartments, were used. A specially designed gas-tight cell having a small volume was used for analysis of electrogenerated gaseous products by means of gas chromatography. Johnson Matthey and Mallory high-purity grade Pt wires were degreased by refluxing in acetone, sealed in soft glass, and electrochemically cleaned by potential cycling in 1 *M* sulfuric acid, and stored in 98% H_2SO_4. The reference electrodes used were saturated calomel electrodes made according to a standard procedure (19). Their potentials were checked frequently against a standard hydrogen electrode and compared with the literature value (20). The saturated calomel electrodes were found to be reproducible to within ±1 mV.

(d) Product analysis

A Perkin-Elmer model 226 gas chromatograph fitted with a flame ionization detector was used to detect products from electrolysed solutions of glycine at pH 1 and pH 13. The 2.5 m by 0.6 cm copper column, packed with Chromosorb 103, was maintained at 140°C. This column packing is selective for nitrogen-containing compounds, aldehydes, and some lower molecular weight alcohols. In addition, formaldehyde was quantitatively determined from electrolysed solutions of glycine maintained at carefully controlled anodic potentials, using the pentane-2,4-dione colorimetric method (21). Carbon dioxide was detected by passing the evolved gases through a saturated BaOH solution. Ammonia was determined by the Kjeldahl method (22).

Results

Tafel plots derived from the steady-state polarization experiments for each of the systems studied are shown in Figs. 1 and 2, and the numerical values for the Tafel slopes determined by least-squares analysis are presented in Table 1. The Tafel slopes for both systems are significantly higher than those normally observed for oxygen evolution in aqueous solution (i.e. $2.3(2RT/F) = 120$ mV) (23). In Fig. 2, the Tafel plots for the amino acid under acidic conditions (pH 1) showed a long linear Tafel region with a slope which was twice those observed for oxygen evolution. In a 1 *M* sulfuric acid solution, in the absence of amino acid, oxygen evolution occurs at 1.36 V, E_{SCE}. This difference in the Tafel behaviour may be attributed to the barrier layer effect observed by Conway and Dzeiciuch (24) where the oxygen evolution reaction is suppressed because of a dipole barrier due to the presence of adsorbed species on the surface of the electrode.

A different effect is observed under alkaline conditions. There is a distinct inflection observed in the Tafel slopes (Fig. 1). This is similar to that observed in the Kolbe reaction of acetate ion in aqueous solution (18) and again appears at the same potential where oxygen evolution would occur in a 1 *M* sodium hydroxide solution (i.e. 1.10 V, E_{SCE}). Thus it appears, as in the Kolbe mechanism, that the oxygen evolution reaction is suppressed by the amino acid anion. Glycine shows an unusually high Tafel slope over this potential region. The value of 363 mV corresponds to a Tafel slope of $3(2.3(2RT/F))$. It is also interesting that below the inflection region the slope is the same as those observed under acidic conditions.

Cyclic voltammograms for glycine in both alkaline and acidic solutions are shown in Figs. 3 and 4. Table 2 shows the numerical values for the charge Q_0 associated with the formation of oxide, the charge Q_r due to the reduction of the surface oxide, and the ratio Q_0/Q_r. A comparison may also be made of the charge from the oxidation process with that of the reduction process in a sulfuric acid or sodium hydroxide solution.

The results from Table 2 show that the charge Q_r due to the reduction of the oxide is very much smaller than Q_0 in all cases, suggesting that there are species other than the normal oxide adsorbed on the surface of the electrode which are not removed during the oxide reduction process. The ratio of Q_r for oxide reduction to Q_r (=210 μC cm^{-2}) for hydrogen reduction is also significant. For a sulfuric acid solution in the absence of amino acids this ratio is about 2.5 (18). For amino acids at pH 1, the ratio is about 2.1, whereas an even smaller ratio of ca. 1.0 is observed in solutions of pH 13. This indicates that adsorption by amino acids occurs at platinum causing a reduction in the

13.0	(−0.854–0.816)	2136	223	9.58
1.0	(−0.317–1.220)	1315	451	2.92

normal oxide growth due to a blocking effect by the bulkier molecules with an even stronger adsorption and diminished oxide formation occurring in the basic solutions. This is also consistent with the larger Q_0/Q_r for anodic oxidation and reduction in the basic compared with the acidic solutions. In the aqueous acid solution (Fig. 4) a blocking effect by glycine of the submonolayer film of upd (underpotential deposition) OH species occurs similar to the blocking effect of Cl^- ions adsorbed at Pt electrodes during anodic Cl_2 evolution from an aqueous solution (25–29).

Open circuit potential decay curves for glycine in basic and acidic solutions are shown in Figs. 5 and 7. Plots of potential versus log $(-dV/dt)$ were obtained from a curve-fitting routine on the potential versus time data. Multiple correlation coefficients were determined using the *F*-test. In all cases, the fit was better than 99.99%. The pseudo-capacitance (C_ϕ) was then evaluated as a function of potential (Figs. 6 and 8) (30).

These graphs indicate a rapid decrease in capacitance in the basic solution at the lower potentials to a capacitance of about

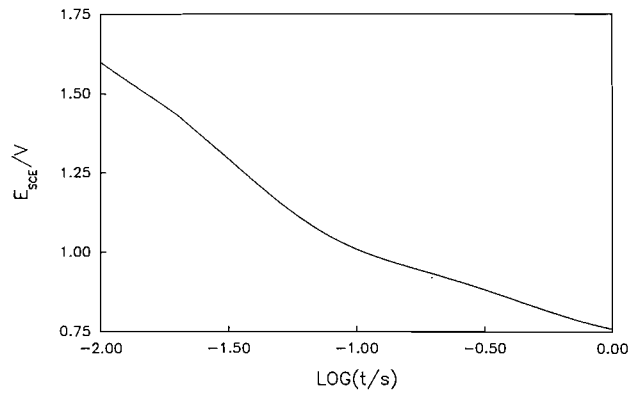

FIG. 5. Open-circuit potential decay of 0.45 *M* glycine (pH 13) at the Pt electrode.

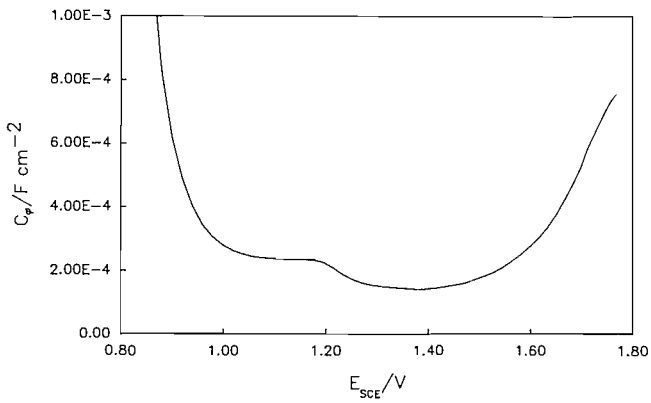

FIG. 6. Capacitance behaviour at anodic potentials of 0.45 *M* glycine (pH 13) at the Pt electrode.

250 $\mu F\,cm^{-2}$ (Fig. 5). An inflection in the capacitance is observed at potentials coincident with the inflection in the Tafel plot (Fig. 1). The capacitance decreases to a minimum of about 100 $\mu F\,cm^{-2}$ before increasing again at higher potentials, indicating that the initial coverage of adsorbed species on the electrode surface is rapidly diminished as the Faradaic process proceeds. This decrease in surface coverage corresponds to a mechanism where the initial or electron discharge step is slow, followed by fast consecutive reactions which reduce the surface coverage (31). The inflection regions in the capacitance and the Tafel plots suggest a change in the mechanism of the reaction associated with surface coverage of adsorbed species.

The potential decay curve in the acidic solution shows three linear regions with very small changes in slope (Fig. 7). These correspond to very slight inflections observed in the Tafel slope (Fig. 2). However, the plots of C_ϕ versus potential (Fig. 8) show a similar rapid decrease in capacitance followed by an increase to ca. 600 $\mu F\,cm^{-2}$ at a potential of 1.47 V. This behaviour is similar to the inflection region observed in the alkaline solution.

Qualitative analysis of the products obtained from the electrolysis of glycine agreed with those found by Fichter and co-workers (1, 2) and Takayama (3–5). The electrolysis was carried out at high current densities under controlled potentials of 2.2 V in the acidic solution and 1.8 V in the basic solution. The products identified by gas chromatographic analysis were formaldehyde and methyl and trimethyl amine in acidic solution and formaldehyde and methyl amine in the basic solution. Carbon dioxide and ammonia were also detected as products of the electrolysis. A quantitative analysis of the formaldehyde

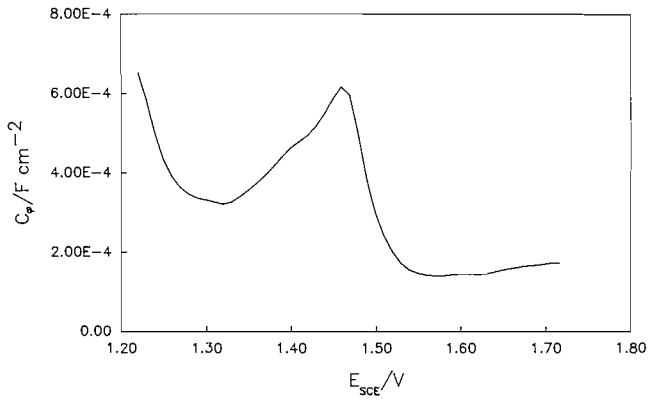

FIG. 8. Capacitance behaviour at anodic potentials of 0.45 *M* glycine (pH 1) at the Pt electrode.

formed after electrolyzing the basic solution at an anodic potential of 1.32 V, E_{SCE} using the pentane-2,4-dione colorimetric method (21) indicated an 85–90% yield. From the same experiments, analysis of ammonia using the Kjeldahl method (22) indicated ca. 83% yield. When the electrolysis was carried out at the anodic potential of 1.06 V, E_{SCE}, which is just below the inflection region, the yield of formaldehyde dropped to 60% and ammonia to ca. 55%.

Discussion

Analysis of the products of the electro-oxidation of glycine shows that formaldehyde is the main product in both basic and acidic conditions. Ammonia and carbon dioxide were also detected as products of this reaction in agreement with Fichter (1, 2). These products suggest a dissociative, adsorptive type of mechanism, with the overall reaction for the basic solution

$$CH_2(NH_2)COO^- + OH^- \rightarrow CH_2O + NH_3 + CO_2 + 2e$$

The thermodynamic potential for the basic glycine solution was calculated to be 1.33 V, E_{SCE} using the standard free energies of formation (20). A similar calculation for the acidic solution gave a value of 1.17 V, E_{SCE}. These correspond to the observed inflection regions discussed previously which are also coincident with the potentials for oxygen evolution, which suggests that oxygen evolution is suppressed by the amino acid oxidation process in a manner similar to that observed for the Kolbe reaction (24). The overall reaction must, however, be written in terms of elementary electrochemical steps because it has become well established in electrodics that it is not energetically favourable for two electrons to tunnel simultaneously between the solution and the metal surface (32). Elementary steps using single electron transfer are therefore preferred.

TABLE 3. Theoretical Tafel slopes calculated on the basis of each of the steps being rate-determining for the mechanism proposed for the electro-oxidation of glycine at Pt

RDS	Theoretical Tafel slope	Calculated Tafel slope (mV)	r_2/r_1
Step I	$2.3(2RT/F)$	120	—
Step II	$2.3(2RT/F)(r_1/(r_1 - r_2))$	180	0.33
		240	0.50
		360	0.66
Step III	$2.3(2RT/F)(r_1/(r_1 + r_2))$	90	0.33
		80	0.50
		72	0.66

The production of CO_2 in the alkaline solution may be explained by a series of steps similar to the initial two steps in the Kolbe reaction (18),

$$CH_2(NH_2)COO^- \rightarrow CH_2(NH_2)COO(M) + e$$
$$CH_2(NH_2)COO(M) \rightarrow NH_2CH_2(M) + CO_2$$

This series of steps could lead to formaldehyde and ammonia by either of two routes, a hydrolysis reaction of the adsorbed radical accompanied by an electron transfer at the surface of the electrode,

$$NH_2CH_2(M) + OH^- \rightarrow NH_3 + CH_2O + e$$

or with the formation of a carbonium ion by electron transfer (18, 33) followed by subsequent hydrolysis in solution to give ammonia and formaldehyde:

$$NH_2CH_2(M) \rightarrow NH_2CH_2^+ + e$$
$$NH_2CH_2^+ + OH^- \rightarrow NH_3 + CH_2O$$

The corresponding mechanism for the acidic solution would be

$$CH_2(NH_3^+)COOH \rightarrow CH_2(NH_3^+)COO(M) + H^+ + e$$
$$CH_2(NH_3^+)COO(M) \rightarrow (NH_3^+)CH_2(M) + CO_2$$

followed by:

$$(NH_3^+)CH_2(M) + H_2O \rightarrow NH_4^+ + CH_2O + H^+ + e$$

A carbonium ion mechanism in the acidic solution, however, is rather unlikely due to the formation of a positive charge on adjacent atoms:

$$(NH_3^+)CH_2(M) \rightarrow (NH_3^+)CH_2^+ + e$$
$$(NH_3^+)CH_2^+ + H_2O \rightarrow NH_4^+ + CH_2O + H^+$$

In order to verify these mechanisms it is necessary to compare the experimentally determined Tafel slopes with those derived from theoretical considerations (34–36). The Tafel slope is calculated separately for each possible rate determining step (Table 3).

Considering step I of the mechanisms to be rate determining, the following rate expression is obtained:

$$i_1 = zFk_1(1 - \theta_{G\cdot})C_{G+}\exp\{-(\Delta G_1^{\neq} - \beta VF + \beta r_1\theta)/RT\}$$

where the subscript G· refers to the radical species on the electrode surface, G+ the amino acid species in the bulk solution, θ the fractional surface coverage, and β the symmetry factor, which will be considered for these calculations to be equal to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

0.5, which is the value expected for most reactions (18). The possibility of very low values for β due to a barrier-layer discharge process will be discussed later. The r term is introduced in the above equation to allow for variation in the heat of adsorption with coverage.

The experimental Tafel slopes may be compared with those calculated from the rate expressions. For the case where step I is rate controlling the derivative is:

$$dV/d \log i_1 = 2.3(2RT/F)$$

If step II of the mechanisms were rate determining, the rate equation would rearrange as follows:

$$\ln i_2 = \ln zFk_2 + \ln (1 - \theta_{G1\cdot}) + \ln \theta_{G\cdot} - (\Delta G_2^{\neq} - \beta r_1\theta + (1 - \beta)r_2\theta)/RT$$

where G· refers to the initially adsorbed radical in step I and G_1· refers to the adsorbed radical after rearrangement occurs. Now if step II was rate controlling and step I was in quasi-equilibrium, and with $\beta = 0.5$, the equation may be written as

$$\ln i_2 = \ln zFk_2 + \ln (1 - \theta_{G1\cdot}) + \ln (\theta_{G\cdot}) - [\Delta G_2^{\neq} + (VF/2r_1)(r_2 - r_1)]/RT$$

Rearranging and differentiating gives

$$dV/d \ln i_2 = (2RT/F)[r_1/(r_1 - r_2)]$$

If step III of the mechanisms were rate determining

$$\ln i_3 = \ln zFk_3 + \ln \theta_{G1\cdot} - (\Delta G_3^{\neq} - \beta VF - \beta r_2\theta)/RT$$

Substituting in terms of θ and differentiating gives

$$dV/d \ln i_3 = (2RT/F)[r_1/(r_1 + r_2)]$$

The Tafel slopes obtained have factors designated as r related to the heats of adsorption. Under Temkin conditions, that is conditions of intermediate coverage, the r values become important, whereas under Langmuir conditions, either $\theta \cong 0$ or $\theta \cong 1$, these effects need not be considered. Under Temkin conditions, values must be assigned to r_1 and r_2. The high Tafel slopes may be explained by taking r_1 to be 1.5 to 2 times greater than r_2, and the Tafel slopes calculated in this way for each of the possible steps considered to be rate controlling are given in Table 3. From these results and a comparison with the Tafel slopes observed experimentally (Table 1), a mechanism consistent with step II as the rate-determining step is proposed.

For the alkaline solution of glycine, the experimental Tafel slope was 239 mV over the potential range 0.90 to 1.10 V, which is below the inflection region. This would correspond to $r_2/r_1 = 0.5$ where r_1 and r_2 represent the heats of adsorption of $CH_2(NH_2)COO\cdot$ and $NH_2CH_2\cdot$, respectively. At the inflection point, the Tafel slope increased abruptly to 363 mV which would correspond to $r_2/r_1 = 0.66$. The capacitance decreased abruptly at this point indicating a smaller surface coverage. At very high potentials the capacitance gradually increased due to the growth of thicker films of adsorbed species.

In the acidic solution of glycine, the Tafel slope of 237 mV again corresponds to a value of $r_2/r_1 = 0.5$ where r_1 and r_2 are now $CH_2(NH_3^+)COO\cdot$ and $(NH_3^+)CH_2\cdot$. An inflection region is not observed in the Tafel slope, although the capacitance behaviour shows an increase in surface coverage which maximizes and then drops as in the alkaline solution.

Similar Tafel relationships were obtained for the reaction of formate ion in 100% formic acid (36) and trifluoroacetate in 100% trifluoroacetic acid (24). The reaction mechanisms were treated in terms of a Temkin isotherm. In the case of the trifluoroacetate reaction, the value of r_1 for adsorption of the bulky polar $CF_3COO\cdot$ was considered to be greater than that for the smaller $CF_3\cdot$ groups.

If the mechanism involving formation of carbonium ions for step III proceeds as follows,

$$NH_2CH_2(M) \rightarrow NH_2CH_2^+ + e$$

followed by hydrolysis in solution to give ammonia and formaldehyde, a similar analysis for this step III as the rate-determining step results in the same theoretical Tafel slope as that obtained previously for step III (Table 3). Thus, although the mechanism may proceed via a carbonium ion intermediate formed in solution, it is not the rate-determining step for the process.

Another possibility which may be considered is the formation of the carbonium ion during the decarboxylation step, step II, although generally carbonium ion formation is considered to occur in a step following decarboxylation (18, 33).

$$CH_2(NH_2)COO(M) \rightarrow CO_2 + NH_2CH_2^+ + e$$

However, if this were the rate-determining step, the derivative would be

$$dV/d \log i_1 = 2.3(RT/2\beta F)$$

which gives a value of 60 mV for the Tafel slope if $\beta = 0.5$, which is too low a value compared to that observed experimentally.

High Tafel slopes observed in anodic oxidations of this type have also been interpreted by a change in the effective symmetry factor due to the formation of a thin moderately conducting dipole barrier-layer film of adsorbed species on the electrode (18, 24, 36). This may cause the effective symmetry factor to be less than 0.5. In order to explain the high Tafel slopes observed, the β values would have to be as low as 0.25 and 0.17 for the lower and upper Tafel slopes, respectively. However, there is evidence for strong adsorption of species as shown by the blocking of the upd OH species and the large anodic charge in the cyclic voltammograms. The capacitance behaviour shows a rapid decrease in surface coverage with increasing potential at the onset of the Faradaic process, which gives further evidence for the second step following adsorption being the rate determining step, followed by fast consecutive reactions (31). As even higher potentials are reached, the capacitance again begins to increase due to the strongly adsorbed intermediate species on the surface of the electrode. Therefore, although a barrier-layer film and consequently a modified β value may be used to explain the high Tafel slopes, there is evidence that a changing surface coverage due to adsorbed species may account for these results. It is of interest that a more normal vaue of β is actually observed for the acetate Kolbe reaction in completely anhydrous solution (18). Recently, the results of several studies of the Kolbe electrosynthesis under a variety of conditions have been attributed to the surface adsorption of radicals (37–39).

In conclusion, the mechanism of electrolytic oxidation of glycine at a platinum electrode, in both basic and acidic solution, may be accounted for by a radical mechanism for the first two steps similar to that observed for the Kolbe reaction with the loss of carbon dioxide, the second step in the mechanism being rate-determining. However, rather than the dimerization typical of those radical reactions associated with the Kolbe mechanism, it appears that the adsorbed intermediate species is either hydrolyzed anodically in these aqueous solutions to formaldehyde and ammonia, or is possibly further

oxidized to a carbonium ion which is subsequently hydrolyzed to ammonia and formaldehyde in solution.

A laser flash photolysis study of the behaviour of polyfluorophenyl ketones in solution[1]

D. R. BOATE, L. J. JOHNSTON, AND J. C. SCAIANO
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 19, 1988

D. R. BOATE, L. J. JOHNSTON, and J. C. SCAIANO. Can. J. Chem. **67**, 927 (1989).

Decafluorobenzophenone triplets, which have a triplet energy very close to that of benzophenone, are much more reactive than benzophenone in quenching reactions that involve hydrogen transfer and/or charge transfer. An excellent correlation has been observed between the rate constants for charge transfer quenching and the oxidation potential of the substrate. In the case of 2-propanol, where the reactivity can be fully accounted for by hydrogen transfer, decafluorobenzophenone is 35 times more reactive than benzophenone. Pentafluorobenzophenone shows intermediate behaviour.

Key words: laser photolysis, benzophenones, triplet states, charge transfer, photoreduction.

D. R. BOATE, L. J. JOHNSTON et J. C. SCAIANO. Can. J. Chem. **67**, 927 (1989).

Les triplets de la décafluorobenzophénone, dont l'énergie du triplet est très proche de celle de la benzophénone, sont beaucoup plus réactifs que la benzophénone dans les réactions de piégeage impliquant un transfert d'hydrogène et/ou un transfert de charge. On a observé une excellente corrélation entre les constantes de vitesse de piégeage du transfert de charge et le potentiel d'oxydation des substrats. Dans le cas du propanol-2, où on peut expliquer complètement la réactivité à l'aide d'un transfert d'hydrogène, la décafluorobenzophénone est 35 fois plus réactive que la benzophénone. Le comportement de la pentafluorobenzophénone est intermédiaire entre les deux.

Mots clés : photolyse du laser, benzophénones, états du triplet, transfert de charge, photoréduction.

Introduction

The photochemical and photophysical properties of benzophenone have been studied extensively and are rather well understood (1–5). Benzophenone (as do many other aromatic ketones) undergoes intersystem crossing rapidly and efficiently to populate its lowest triplet state, which is responsible for most of its photochemistry (1). Typical reactions of this triplet state include electronic energy transfer to suitable acceptors, charge transfer reactions where the ketone can behave as an electron donor or acceptor, addition to unsaturated systems, and hydrogen abstraction. This last process has been the subject of extensive studies, and the radical-like properties of the benzophenone triplet have been long recognized (5). Conventional and laser flash photolysis have been widely employed in the study of triplet benzophenone reactivity (3). By contrast, very little is known about the reactivity of the corresponding triplet states of polyfluorinated phenyl ketones (6–11), although the short triplet lifetime of decafluoro and pentafluorobenzophenone in cyclopentane as a reactive solvent has been reported previously (11).

In this paper we report the results of a laser flash photolysis study of the photochemistry of decafluorobenzophenone. A comparison is made with pentafluorobenzophenone and pentafluoroacetophenone.

Experimental

Materials

Decafluorobenzophenone (DFB) (Aldrich) was sublimed and benzophenone (BP) and phenol were recrystallized from ethanol and hexane, respectively. Pentafluorobenzophenone (PFB), pentafluoroacetophenone (PFA) (Aldrich), Aberchrome-540 (Aberchromics Ltd., Cardiff, U.K.), and the solvents (acetonitrile and carbon tetrachloride, spectroscopic grade) were used as received. All triplet quenchers were used as received except 1,3-cyclohexadiene (1,3-CHD) which was vacuum distilled before use in order to eliminate polymeric impurities.

General techniques

Ultraviolet–visible spectra were recorded on a HP-8451-A diode array spectrometer. Phosphorescence spectra were recorded on a Perkin-Elmer LS-5 spectrofluorimeter.

Cyclic voltammetry[2] of DFB in acetonitrile (containing 0.1 *M* tetraethylammonium perchlorate as supporting electrolyte) at a platinum disk electrode with a scan rate of 50 mV s^{-1} afforded a cathodic peak potential of −1.21 V vs. SCE.

Laser flash photolysis

The laser flash photolysis facility has been described in detail elsewhere (12). A Molectron UV-24 nitrogen laser (337 nm, ~8 ns pulses, ≦10 mJ/pulse) or a Lumonics TE-860-2 excimer laser with a Xe/HCl gas mixture (308 nm, ~5 ns pulses, ≦20 kJ/pulse) was used for excitation. All quenching studies were carried out on static samples of either DFB, PFB, or PFA (typically 10^{-2} *M*) in either acetonitrile or carbon tetrachloride with 3 × 7 mm^2 quartz cells.

The extinction coefficients for benzophenone ketyl radical (BPH) and DFB triplet in acetonitrile were measured using Aberchrome-540 actinometry (13). All experiments were performed using a flow system with 3 × 7 mm^2 quartz cells, with the same cell being used for both the actinometer and the sample. Solutions of BP (ca. 10^{-3} *M*) in ACN with 1,4-cyclohexadiene (ca. 10^{-2} *M*) or of DFB in acetonitrile and of Aberchrome-540 (ca. 10^{-4} *M*) in toluene were prepared with matched optical densities (typically 0.3 for a 3 mm optical path) at the laser wavelength (337 nm). The optical density at 494 nm following the pulse for Aberchrome was measured as a function of the laser intensity, which was adjusted with a set of calibrated neutral-density filters (evaporated metal on quartz plates). The optical densities for the samples were then measured at the corresponding transient absorption maxima, again as a function of the laser intensity.

In the case of the DFB ketyl radical (DFBH) it is straightforward to obtain the product ($\Phi_K\epsilon_{516}$) of its yield of formation (Φ_K) and its extinction coefficient (ϵ_{516}) at 516 nm (not λ_{max}) using the Aberchrome-540 technique described above. However, separating these two values requires at least one additional piece of information. To obtain this we have employed a competitive method based on the reactions of triplet BP and DFB with phenol to estimate ϵ_{516} for DFBH. This method is described in some detail in the Results section. The method requires the knowledge of ratios of extinction coefficients for each of the radicals at its own maximum and at the maximum for the other species with which it may overlap. Independent spectra of BPH,

[2]The measurement was performed by D. Wayner, N.R.C., Canada.

TABLE 1. Ratios of extinction coefficients utilized in the study of decafluorobenzophenone ketyl radical

Radical	Symbol[a]	ϵ_x/ϵ_y
$(C_6F_5)_2\dot{C}OH$	$\epsilon_{400}/\epsilon_{516}$	0.17
$(C_6H_5)_2\dot{C}OH$	$\epsilon_{400}/\epsilon_{540}$	0.09
$C_6H_5O\cdot$	$\epsilon_{516}/\epsilon_{400}$	0.226
$C_6H_5O\cdot$	$\epsilon_{540}/\epsilon_{400}$	0.248

[a]The subscripts identify the wavelengths at which the ratio was determined.

TABLE 2. Phosphorescence data and triplet energies at 77 K

Substrate	Media[a]	$\lambda_{0,0}$[b]	E_T[c]	Reference
BP	MCH	418	68.4	7
BP	EPA	413	69.3	7
DFB	MCH	424	67.4	This work
DFB	EPA	410	69.7	This work
PFB	MCH	417	68.6	This work
PFA	MCH	415	68.9	This work
Acetophenone	EPA	386	74.1	15
Acetophenone	MCH	388	73.7	15

[a]MCH = methylcyclohexane; EPA = ether:isopentane:ethanol, 5:5:2.
[b]In nm.
[c]In kcal mol^{-1}.

DFBH, and phenoxyl radicals were obtained as follows: (*a*) BPH by reaction of triplet BP with 1,4-cyclohexadiene (10^{-2} *M*) in acetonitrile; (*b*) DFBH by reaction of triplet DFB with 0.3 *M* cyclohexane in acetonitrile; and (*c*) phenoxyl by reaction of *tert*-butoxyl (from 0.2 *M* peroxide) with 0.2 *M* phenol in acetonitrile. The relevant ratios of extinction coefficients are given in Table 1.

An independent determination of the BP–DFB ketyl radical (BPH–DFBH) optical density ratio was performed in static 3 × 7 mm^2 quartz cells. Solutions of BP (ca. 10^{-3} *M*) and DFB (ca. 10^{-2} *M*) with 1,4-cyclohexadiene (ca. 10^{-2} *M*) in acetonitrile were prepared with matched optical densities at the laser wavelength. The transient optical densities were measured at 540 and 516 nm for BPH and DFBH radicals, respectively. Due to the presence of overlapping triplet ketone at the monitoring wavelength, the optical densities for both ketyl radicals were corrected by extrapolation to the time of laser excitation.

All samples except for Aberchrome-540 were deaerated with a stream of nitrogen.

Results

Phosphorescence

The 77 K phosphorescence of the various ketones examined was recorded in methylcyclohexane, and occasionally in EPA. They all show the band structure which is characteristic of n,π* triplet states (ref. 1, chap. 5). Table 2 summarizes the triplet energies derived from the 0,0 bands in the emission spectra. Quite clearly, fluorine substitution does not have any dramatic effect on the triplet energy. These triplets are known to show short phosphorescence lifetimes, in accordance with their n,π* character (7).

Figure 1 shows a comparison of the phosphorescence spectra from DFB in an EPA glass at 77 K and in acetonitrile solution at room temperature. Some of the resolution is lost at room temperature and a small shift is noted between these two solvents. The broadness and the small shift observed in the room temperature spectrum (obtained with an OMA detector) was

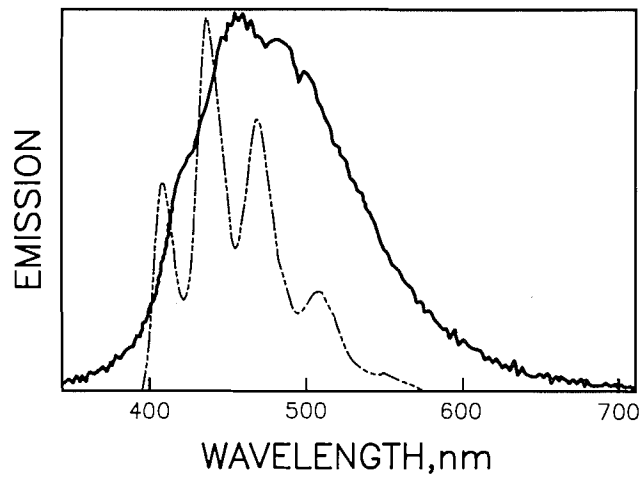

FIG. 1. Phosphorescence spectra for DFB obtained 400 ns after 337 nm excitation of 8 × 10^{-2} *M* DFB in acetonitrile at 293 K (—) and in an EPA glass at 77 K (· · – · ·).

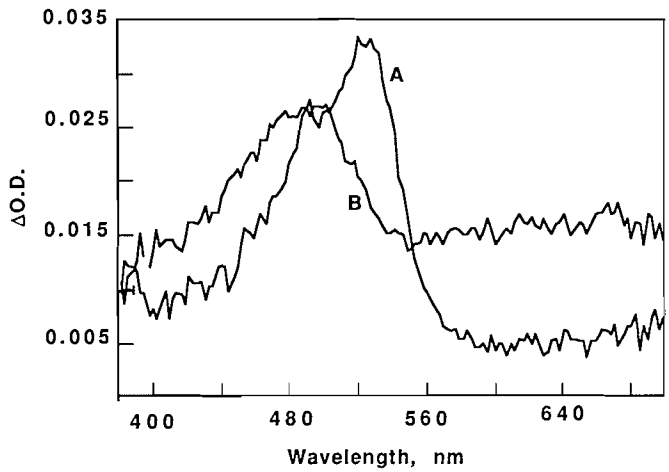

FIG. 2. Transient absorption spectra for triplet DFB (*B*) obtained by laser excitation of 9.4 × 10^{-3} *M* DFB in acetonitrile, and for its ketyl radical (DFBH) for a similar sample but containing 0.6 *M* cyclohexane (*A*). Both spectra recorded 500 ns after 337 nm excitation.

verified upon repeating the measurement (not shown) under more dilute conditions (1 × 10^{-3} *M*), with the same spectrometer as that used to obtain the 77 K spectrum.

The phosphorescence yields at 77 K have been reported to be 0.21 (in perfluorodimethylcyclohexane (8)) and 0.74 (in isooctane (16)) for DFB and BP, respectively. Intersystem crossing quantum yields are 1.0 for both ketones (8, 16).

Transient absorption spectra

The high reactivity of triplet DFB (*vide infra*) makes the selection of inert solvents rather limited. We have found that acetonitrile and carbon tetrachloride are reasonable choices, since triplet lifetimes in excess of 10 μs could be easily achieved at room temperature in these solvents. Figure 2 shows the transient absorption spectra obtained at room temperature for DFB triplet and its ketyl radical (*vide infra*). Figure 3 shows triplet spectra for BP, PFB, and PFA. Fluorine substitution leads to a blue shift in the spectra; this appears reasonable, since promoting an electron should be more difficult in the electron-deficient polyfluorinated ketones. The spectrum for triplet DFB is considerably broader than that from BP.

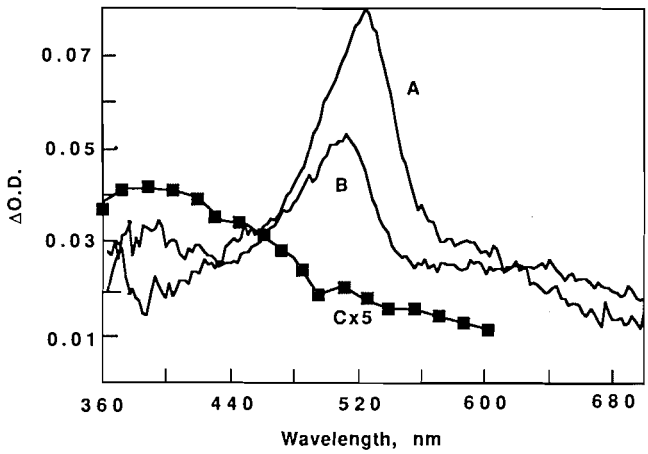

FIG. 3. Triplet–triplet absorption spectra for 7.3×10^{-3} *M* BP (*A*), 2.4×10^{-2} *M* PFB (*B*), and 3.2×10^{-2} *M* PFA (*C*) in acetonitrile. The delays after 337 nm excitation are 500, 500, and 200 ns for spectra *A*, *B*, and *C*, respectively. The ΔOD scale in spectrum (*C*) has been expanded 5 times.

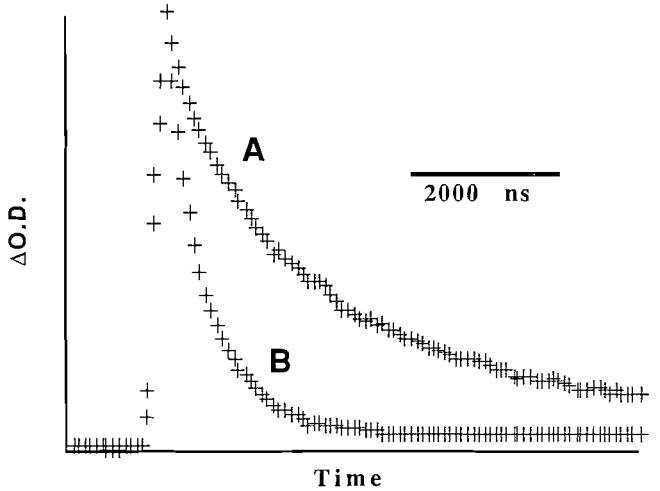

FIG. 4. Experimental decay traces for triplet DFB in the absence of quencher (*A*) at 610 nm, where only the triplet absorbs and in the presence of 6.0×10^{-3} *M* *tert*-butylbenzene (*B*), recorded at 516 nm, where both triplet and ketyl radical absorb. Note that *B* has virtually no residual absorption after triplet decay.

The triplet spectra in carbon tetrachloride (not shown) were very similar to those obtained in acetonitrile.

Kinetics of triplet quenching by various substrates

The experimental rate constants for triplet decay (k_{exptl}) were obtained by monitoring the transient absorption due to the carbonyl triplet at 600 nm for the three benzophenones, and at 400 nm for PFA. It is clear from the spectra in Figs. 2 and 3 that 600 nm is considerably removed from the triplet absorption maxima for BP, PFB, and DFB. However, at $\lambda \geqq 600$ nm the ratio of extinction coefficients for the carbonyl triplet and the corresponding ketyl radical is large (usually >10) thus making measurements of triplet decay rates more accurate. Figure 4 shows representative traces obtained in carbon tetrachloride in the absence and presence of *tert*-butylbenzene, one of the quenchers examined in this study. Each trace yields a value of k_{exptl} from a single exponential treatment of the decay data. The bimolecular rate constants, k_q, for the reaction of the triplet with quencher Q were determined by measuring k_{exptl} for different concentrations of Q and plotting according to eq. [1],

$$[1] \quad k_{exptl} = k_0 + k_q[Q]$$

where k_0 (i.e. τ_T^{-1}) is the first order rate constant for triplet decay in the absence of quencher and incorporates radiationless decay, emission, and possibly interactions with the solvent. As is frequently the case in laser flash work, the decays in the absence of quencher tend to incorporate second order contributions resulting from triplet–triplet annihilation. For this reason our quenching plots normally do not include a point at [Q] = 0. Some representative examples are shown in Fig. 5. Table 3 summarizes the rate constants obtained for DFB in this work, along with some literature values for benzophenone. Table 4 summarizes a few representative values for PFB and PFA.

Several of the quenchers used are excellent hydrogen donors (e.g. 2-propanol, cyclohexane, 1,4-cyclohexadiene, phenol). In all these cases the corresponding ketyl radical was readily detectable following triplet decay. For example, DFB in acetonitrile reacts with cyclohexane with a rate constant of $4.3 \times 10^7\ M^{-1}\ s^{-1}$. Figure 2 illustrates the observed shift in λ_{max} from 491 nm (triplet) to 526 nm (ketyl radical) when cyclohexane (0.60 *M*) is added to a solution of DFB in ACN.

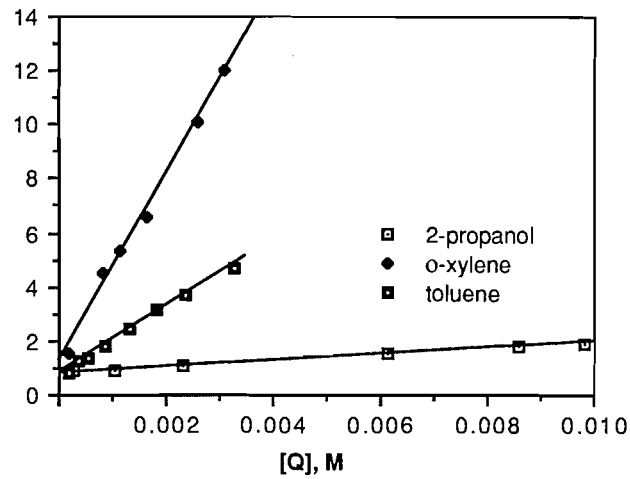

FIG. 5. Representative quenching plots for DFB triplet in acetonitrile.

With the exception of phenol, most of the aromatic quenchers listed in Tables 3 and 4 did not yield substantial amounts of ketyl radical. These results indicate that charge transfer quenching of the triplet is an important process for these ketones. In order to establish to what extent hydrogen abstraction competes with charge transfer when such a competition is possible (e.g. toluene), we measured the extinction coefficients of triplet DFB and of the ketyl radical $(C_6F_5)_2\dot{C}OH$. With these data it is possible to estimate the yields of ketyl radical formation. The experiments are presented in the following section.

Extinction coefficients and photoreduction yields for DFB

Reactions [2] and [3] illustrate the competition that would normally be responsible for the quenching rate constants of Table 3.

$$[2] \quad (C_6F_5)_2CO^* + RH \xrightarrow{k_2} (C_6F_5)_2\dot{C}OH + R\cdot$$

$$[3] \quad (C_6F_5)_2CO^* + RH \xrightarrow{k_3} \text{other quenching reactions}$$

The efficiency of ketyl radical formation will be given by:

$$[4]\quad \psi_K = \frac{k_2}{k_2 + k_3}$$

that is, ψ_K is the fraction of quenching events that lead to ketyl radical generation. If the only important mode of decay of the triplet state is by interaction with RH, then ψ_K is identical to the quantum yield for ketyl radical formation, Φ_K. Triplet DFB is sufficiently reactive than there are many cases where this criterion is met.

There are several transient actinometry techniques with which it is straightforward to determine values of $\Phi_K\epsilon_K$, the product of the quantum yield times the extinction coefficient of the transient at the monitoring wavelength. For example, for $Ph_2\dot{C}OH$ we employed the Aberchrome-540 technique (13) to obtain $\epsilon_{540} = 3000\ M^{-1}\ cm^{-1}$ in acetonitrile using 1,4-cyclohexadiene (for which $\Phi_K = 0.94$ (19)) as a hydrogen donor. In the case of $(C_6F_5)_2\dot{C}OH$, for which the values of Φ_K are not known in any solvent, separating the two values requires an approach where one of them can be measured independently, for at least one hydrogen donor. In order to achieve this, we have compared the reaction of BP and DFB with phenol, and have employed the 400 nm signals from phenoxyl radicals to compare the ketyl signals in both systems. Reactions [5] and [6] illustrate the chemistry in these systems.

$$[5]\quad Ph_2CO^* + PhOH \rightarrow PhO\cdot + Ph_2\dot{C}OH$$

$$[6]\quad (C_6F_5)_2CO^* + PhOH \rightarrow PhO\cdot + (C_6F_5)_2\dot{C}OH$$

While there is some overlap between the spectrum of PhO· and the spectra of the two ketyl radicals, this is sufficiently small that it can be readily taken into account (Table 1).

At each of the monitoring wavelengths the absorption in a ketone–phenol system is the sum of contributions from phenoxyl and ketyl radicals which can be readily separated with the coefficients given in Table 1. Since reactions [5] and [6] have a 1-to-1 stoichiometry, the initial concentrations of phenoxyl and the corresponding ketyl radical should be identical. Thus, the ratio of ketyl-to-phenoxyl optical densities is directly proportional to the extinction coefficient for the ketyl radical. Since the value for $Ph_2\dot{C}OH$ is known (*vide supra*) this analysis leads to a value for $(C_6F_5)_2\dot{C}OH$ of $1580\ M^{-1}\ s^{-1}$ at 516 nm. Combining this analysis with the measured triplet signals it is possible to obtain ψ_K values for phenol or other substrates. These are summarized in Table 5. For phenol $\psi_K = 0.66$.

A check of the estimated values of ψ_K can readily be made by comparing the measured values for the BP–DFB ketyl extinction coefficients and experimental optical densities according to:

$$[7]\quad \frac{OD_{BPH}^{540}}{OD_{DFBH}^{516}} = \frac{\epsilon_{BPH}^{540}}{\epsilon_{DFBH}^{516}} \cdot \frac{\psi_K^{BPH}}{\psi_K^{DFBH}}$$

Using values of 0.94 (19) and 0.65 for the efficiencies of ketyl formation for BP and DFB (with 1,4-cyclohexadiene) we obtained a calculated value of 2.7 which should be compared with an experimental value of 2.3 for the left term in eq. [7].

As part of these measurements we also determined an extinction coefficient for triplet DFB at 516 nm of $\epsilon_{516} = 2200\ M^{-1}\ cm^{-1}$.

Discussion

It is noteworthy that in all the examples examined (see Table 3) the triplet state of DFB is quenched faster than triplet BP, with PFB showing intermediate behaviour (Table 4). Only

in the case of 1,3-cyclohexadiene, which is a near-diffusion controlled quencher for numerous carbonyl compounds (24), are the rate constants for the various substrates comparable. The triplet energy for 1,3-cyclohexadiene is 52.3 kcal/mol (25), much lower than that for the carbonyl compounds studied in this work (see Table 2). The main mode of quenching by 1,3-cyclohexadiene must, therefore, be energy transfer. For the remaining aromatic compounds typical triplet energies are in the 80–85 kcal/mol range (25); i.e. too high for energy transfer to be an important quenching mode. The predominant mode of quenching for phenol, cyclohexane, 2-propanol, and 1,4-cyclohexadiene is hydrogen abstraction, as indicated by the ketyl yields of Table 5. These results are consistent with the efficient photoreduction which has been observed for DFB in cyclohexane ($\Phi = 0.41$ for ketone disappearance (8)). The products in this system are derived from combination and aromatic substitution of the cyclohexyl and ketyl radicals. Efficient photoreduction has also been reported in 2-propanol (9).

Since the triplet energies for both BP and the fluorinated systems are essentially the same (ca. 69 kcal/mol), the large differences in the quenching rate constants must be a direct consequence of the presence of multiple fluorine substituents in DFB and PFB. Dedinas and Regan have also reported large differences in the quenching rate constants for triplet BP and DFB by cyclohexane and benzene under conditions of lamp irradiation (8). Their values of rate constants for DFB are 7.5×10^6 and 1.6×10^8 M^{-1} s^{-1} for cyclohexane and benzene, respectively. The differences with our values (see Table 3) are likely a reflection of errors introduced by the fact that the triplet lifetimes (needed for the Stern–Volmer analysis) were not determined in the same work. Since the laser photolysis technique does not depend on assumptions of this type, this error is not incorporated in our values. The large differences in rate constants between BP and DFB were attributed to the increased inductive effect due to the fluorine substituents, which increase the degree of charge polarization of the $^3n,\pi^*$ state in the polyfluorinated ketones.

Wagner *et al.* have also observed increased rates of photoreduction in the case of α,α,α-trifluoroacetophenone (AF_3) as compared to acetophenone (26), although it should be noted that for AF_3 the lowest triplet state has π,π^* character with a close by n,π^* level, so that these results may not be directly comparable to those for DFB. In spite of these differences, substituent effects in AF_3 also demonstrate enhanced reactivity induced by electron-withdrawing groups which are in line with DFB if an appropriate allowance is made for the difference in reduction potentials (20). Wagner, Truman, and Scaiano also reported increased reactivity of substituted benzophenones towards cyclopentane when electron-withdrawing substituents are employed (11). For example, 4-carboxymethylbenzophenone is 50% more reactive than benzophenone, in spite of a decrease in triplet energy upon substitution (11).

Anisole is one of the aromatic substrates for which it is possible to compare the reactivities of the various ketones. The data in Tables 3 and 4 lead to relative reactivities of 9600:2600:1 for DFB, PFB, and BP, respectively. For comparison, Wagner and Leavitt report that AF_3 is typically 35 times more reactive than BP towards aromatic substrates (26). Rate enhancements in excess of 1000 are not uncommon between BP and DFB (Table 3) in the case of aromatic substrates.

We find that the rate constants for quenching by aromatic substrates correlate well with the energy requirements for electron transfer (Table 6). Figure 6 shows the corresponding plot; for aromatics only, the slope is −2.21 and the correlation coefficient is 0.91. From Fig. 6 it can be seen that both phenol and 2-propanol do not fit well in the plot. However, for these substrates two parallel processes appear to occur; i.e. reactive and unreactive processes take place. The reactive path involves hydrogen transfer which occurs with the yields indicated in Table 5. When the rate constant for phenol is corrected for this reactive path the point fits very well within the same plot (Fig. 6); this would suggest that hydrogen abstraction and charge transfer are parallel paths, as opposed to a possible charge transfer process that could lead to reactive or unreactive quenching. Since for 2-propanol the reaction is all hydrogen abstraction, the corrected point in this case falls below the line in Fig. 6 and must be considered only as an upper limit.

In the case of toluene no correction has been introduced, since the fraction of hydrogen abstraction (Table 5) is too small to make a significant difference in Fig. 6. The efficiency of the process (0.09) is in reasonable agreement with the reported quantum yield of ketone disappearance in toluene of 0.055 (8). Note that the solvents are different for these two measurements.

For 2-propanol we have only been able to estimate an upper limit for the rate constant for charge transfer interactions, since the efficiency data (Table 5) suggest that hydrogen abstraction

is the only significant reaction path. The fact that the measured efficiency somewhat exceeds one may in fact be significant, since reaction [8] may partially contribute to the yield measured. The process is well established for benzophenone (3) and is likely to be even more efficient for DFB.

[8] $(CH_3)_2\dot{C}OH + (C_6F_5)_2C{=}O \rightleftharpoons (CH_3)_2CO + (C_6F_5)_2\dot{C}OH$

A comparison of the rate constants for quenching of triplet DFB in acetonitrile and in carbon tetrachloride (Table 3) reveals only a small polar solvent effect. Others have noted similar results for charge-transfer quenching of benzophenone and various phenyl alkyl ketones (23, 28, 29). This is usually taken as an indication that only partial charge transfer takes place.

In summary, the spectroscopy of decafluorobenzophenone (triplet absorption and phosphorescence) is very similar to that for benzophenone, although the triplet reactivities of these two ketones are quite different. Decafluorobenzophenone shows enhanced reactivity in hydrogen abstraction and charge transfer processes; for the latter the rate constants correlate well with the oxidation potentials of the quenchers.

Received October 31, 1988

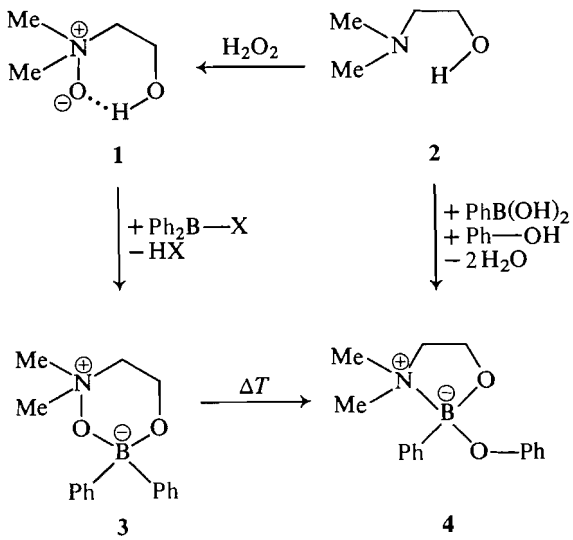
ECKARDT EBELING, WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **67**, 933 (1989).

Details of the syntheses, physical properties, and crystal structures of the title compounds are reported. Crystals of 4,4-dimethyl-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclohexane, **3**, are monoclinic, a = 6.512(1), b = 15.765(2), c = 14.342(4) Å, β = 93.170(7)°, Z = 4, space group Pn, and those of 3,3-dimethyl-2-phenoxy-2-phenyl-1-oxa-3-azonia-2-boratacyclopentane, **4**, are orthorhombic, a = 13.5829(8), b = 16.940(1), c = 6.3181(4) Å, Z = 4, space group $P2_12_12$. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to R = 0.034 and 0.034 for 1974 and 1478 reflections with $I \geq 3\sigma(I)$, respectively. The molecular structures are discussed in terms of the thermally-induced 1,2-migration of B-substituents by which **3** is converted to **4**.

Key words: crystal structures, boron compounds, organoboron compounds.

ECKARDT EBELING, WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **67**, 933 (1989).

On rapporte les détails relatifs à la synthèse, aux propriétés physiques et aux structures cristallines des composés mentionnés dans le titre. Les cristaux du diméthyl-4,4 diphényl-2,2 dioxa-1,3 azonia-4 borata-2 cyclohexane, **3**, sont monocliniques, avec a = 6,512(1), b = 15,765(2) et c = 14,342(4) Å, β = 93,170(7)°, Z = 4 et groupe d'espace Pn; ceux du diméthyl-3,3 phénoxy-2 phényl-2 oxo-1 azonia-3 borata-2 cyclopentane, **4**, sont orthorhombiques, avec a = 13,5829(8), b = 16,940(1) et c = 6,3181(4) Å, Z = 4 et groupe d'espace $P2_12_12$. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R de 0,034 et 0,034 pour 1974 et 1478 réflexions avec $I \geq 3\sigma(I)$. On discute des structures moléculaires en fonction de migrations-1,2 des substituants-B, induites d'une façon thermique et qui conduisent à la conversion de **3** en **4**.



Mots clés : structures cristallines, composés du bore, composés du organobore.

[Traduit par la revue]

Introduction

2-Dimethylaminoethanol N-oxide **1** has been found to possess an intramolecular hydrogen bond both in solution and in the solid state (1). These findings are consistent with the fact that the bridge-bonded proton in **1** can be replaced by the diphenylborenium ion (Ph_2B^+) in a reaction leading to the diphenylboron chelate **3** (2). Diarylboron chelates of this type rearrange upon heating, undergoing an intramolecular redox reaction during which the N-oxide is deoxygenated and the diarylborinic acid component is oxidized to a monoarylboronic acid (2, 3). In this thermally-induced rearrangement, the six-membered chelate **3** is converted to the five-membered ring compound **4**, formulated with an assumed intramolecular N→B coordination analogous to similar five-membered boron chelates of 2-aminoalcohols (4–6). The supposed ring contraction from **3** to **4**, an exothermic reaction with ΔH about −200 kJ mol^{-1} (7), does not only change the steric conditions but also increases the number of electron-rich donating non-carbon ligands at the boron centre.

Compound **3** can be considered as an example of an isolable intermediate in the oxidation reaction between trialkylaminoxides and organylboranes (8). This type of reaction belongs to a general class of organoborate anion rearrangements involving a 1,2-migration of B-substituents (9). The intramolecular mechanism of the 1,2-shift within the initially formed N-oxide borane adduct as the transient species appears to be established by stereochemical experiments which show retention of configuration (10) as well as by product analyses of variously substituted adducts of the type **3** (3) and by oxidation experiments with trimethylamine N-oxide and several organylboranes (11). From these experiments it has been established that the sites of cleavage and recombination for the migrating alkyl or aryl group are identical. The intermediacy of the N-oxide borane adduct has been postulated generally (9, 12) and is well proven

by stable cyclic adducts like **3** that can be transformed into the products (like **4**) of the 1,2-migration (2, 3).

Following a proposed model (11) in which the trialkylamine group leaves antiperiplanar to the migrating group during the oxidation process, the conformational requirements are represented approximately by the formulations **3'** and **4'**. In order to assess the degree of accordance with this model and to obtain precise molecular dimensions in the solid state, especially since the transformations **3**→**4** can be performed as a solid state reaction (2, 3), X-ray crystallographic analyses of both compounds have been undertaken.

3' **4'**

Compound **3** also represents a six-membered homolog of the cyclic *B*,*N*-betaine **5**, the structure of which has been determined (13), and is isomeric with the symmetrical diphenylboron chelate **6** (14) which has also been structurally characterized. **3** and **6** are examples of isomeric cyclic *B*,*N*-betaines of the same ring size that have different relative locations of the ionic centres. Compound **3** can be prepared by the known (2) synthetic pathway **2**→**1**→**3**. The rearrangement product **4** is moisture-sensitive and tends to incorporate up to one mole of water, probably by insertion into the N→B bond. To avoid this problem the synthesis can be achieved by the condensation of 2-dimethylaminoethanol **2** with phenylboronic acid and phenol in benzene or toluene solvent under anhydrous conditions (2). This method was chosen for the preparation of water-free crystals of **4**.

Experimental

4,4-Dimethyl-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclohexane, 3

This compound was prepared as described previously (2). Crystals suitable for X-ray analysis were obtained by recrystallization from acetonitrile/acetone. Melting point (corr.) 156°C. ^{1}H nmr (90 MHz, d_6-DMSO/TMS): δ (ppm) = 3.19 (s, NMe_2), 3.48 (t, J = 5 Hz, N—CH_2C), 3.98 (t, J = 5 Hz, O—CH_2C), 6.9–7.5 (m, BPh_2).

3,3-Dimethyl-2-phenoxy-2-phenyl-1-oxa-3-azonia-2-boratacyclopentane, 4

2-Dimethylaminoethanol (0.89 g, 10 mmol), phenylboronic acid (1.22 g, 10 mmol), and phenol (0.94 g, 10 mmol) were refluxed in toluene (50 mL, dried over Na before use) for 30 min, water being continuously removed using a Dean–Stark trap. The resulting clear solution is slowly cooled (stepwise over a 12 h period) down to room temperature. The formation of colorless crystals yields 1.4 g (52%) of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

4. Melting point 184°C; lit. (2) 190–192°C. ^{1}H nmr (90 MHz, d_6-DMSO/TMS): δ (ppm) = 2.32 (s, NMe_2), 2.63 (t, J = 6 Hz, N—CH_2C), 3.59 (t, J = 6 Hz, O—CH_2C), 6.6–8.0 (m, BPh and OPh); (90 MHz, $CDCl_3$/TMS): 2.50 (s, NMe_2), 3.09 (m, N—CH_2C), 3.99 (t, J = 6 Hz, O—CH_2C), 6.7–8.2 (m, BPh and OPh).

X-ray crystallographic analyses of ***3*** *and* ***4***

Crystallographic data for the two compounds are presented in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 30–41° for **3** and 34–50° for **4**) measured with Mo-$K\alpha$ radiation. The intensities of three standard reflections, measured each hour of X-ray exposure time, showed only small random variations in each case (<4%). Data were corrected[2] for Lp but not for absorption in view of the low values of μ. The systematic absences for **3** ($h0\ell$, $h+\ell$ odd) allow space groups Pn or $P2/n$, the former being suggested by the E-statistics. The structure analysis of **3** was initiated (and successfully completed) in the non-centrosymmetric space group Pn. Both structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from E-maps. Non-hydrogen atoms were refined with anisotropic thermal parameters. For **3**, hydrogen atoms were fixed in idealized positions (C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å) and their isotropic thermal parameters varied, and for **4** hydrogen atom coordinates and thermal parameters were refined. Neutral atom scattering factors of ref. 15 were used. Final positional and anisotropic thermal parameters appear in Tables 2 and 7,[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

The thermal motion in both structures has been analysed in terms of the TLS model (16). The rms errors in the temperature factors σU_{ij} (derived from the least-squares analyses) are 0.0019 and 0.0011 Å^2 for **3** and **4**, respectively. The structural subunits PhB and the six-membered ring plus all substituent atoms were separately analysed for each of the two crystallographically independent molecules of **3** (rms ΔU_{ij} = 0.0015–0.0031 Å^2) and for **4** the subunits PhO, PhB, and the five-membered ring plus substituent atoms were similarly treated (rms ΔU_{ij} = 0.0015–0.0029 Å^2). The appropriate bond distances have been corrected for libration (16, 17), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; bond angles appear in Table 4 and intra-annular torsion angles in Table 5. Hydrogen atom parameters (Table 6), bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 8–10) have been deposited.[3]

Results and discussion

The structure analysis of **3** confirms the presence of the expected six-membered chelate ring system (Fig. 1). Any open-chain intermolecular association between the N-oxide and diphenylborinate sites of the molecule can therefore be excluded from consideration. Osmometric determination of the molecular mass of this type of chelate are ambiguous (3), probably as a result of the dissociation process. Mass spectra show the presence of the peak due to the monomeric parent ion, but this peak may also be due to the rearranged product **4** which gives a nearly identical fragmentation pattern.

The crystal structure of **3** (Fig. 2) consists of discrete

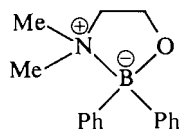
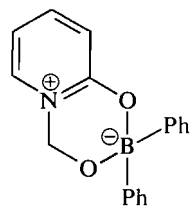
monomeric molecules, the shortest intermolecular distances between non-hydrogen atoms being O(2′)···C(3′)(1 + x,y,z) = 3.282(4) Å, O(2)···C(3)(x −1,y,z) = 3.322(4) Å, and C(3)···C(8′)(1/2 + x, 1 − y,z−1/2) = 3.341(5) Å. The two shortest of these contacts may represent weak C—H···O hydrogen bonds linking the molecules into ribbons extending along the a axis (C(3)—H(3a)···O(2), H···O = 2.44 and 2.40 Å, C—H···O = 150° and 149°, for the unprimed and primed molecules, respectively.)

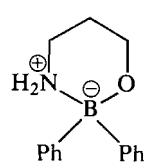


The two independent molecules of **3** have almost identical geometries, with slightly-distorted chair conformations (Table 5) for the six-membered chelate rings, similar to that observed for the isomeric compound **6** (18). The B—C bond distances involving the axial phenyl groups are longer than those involving the equatorial phenyl groups by an average of 0.014 Å in **3**, comparable to a corresponding difference of 0.020 Å in **6**. Bond length differences of this type have also been noted for (pseudo)-axial and (pseudo)-equatorial *B*-phenyl groups in seven- (19) and eight-membered (20) chelates of the type "Ph_2BO_2" and also between the corresponding B—C bond distances in compound **8** (21). Comparable but smaller differences between B—C distances have been noted for the diphenylboron chelates of acetylacetone (22), salicylaldehyde (23), and trishydroxymethylated phenylphosphine (24).

5



6



7

The significant differences between the O—B bond lengths in **3** are as expected. In general, the O—B distance involving the *N*-oxide oxygen atom is longer than that involving an alcoholate or phenolate oxygen atom within the same molecule, as in **5** (13) and other diphenylboron chelates with an *N*-oxide ligand (refs. 19, 25, 26, and references therein). The mean C—B/mean

O—B bond length ratios for the two independent molecules of **3**, 1.066 and 1.074, are similar to the corresponding value of 1.069 for compound **6** (18). These values represent a relatively strong overall bonding of the *O,O*-chelating ligand to the diphenylboron moiety when compared with the values of 1.039–1.088 (average 1.058) observed for other "Ph_2BO_2" compounds containing six-membered chelate rings (ref. 27 and references therein).

The chemical differences between the isomeric compounds **3** and **6** give rise to significant structural differences. All of the N—C bond lengths in **3** are shorter by about 0.02 Å than the corresponding distances in **6** (18). The C—O bonds[4] in **5** (1.378(9) Å) and **6** (average 1.374 Å), derived from inserted formaldehyde, are shorter than the C(1)—O bond in **3** (average 1.412 Å) which is chemically similar to those found in other boron chelates with hydroxyalkyl ligands displaying normal C—O single bond distances (refs. 4–6, 20 and references therein); cf. compounds **7** and **9** (6). The N—O bond in **3** (average

[4]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are, in general, compared with other corrected distances.

B′ —O(2′)—C(1′)—C(2′)	59.6(4)
C(1′)—O(2′)—B′ —O(1′)	−49.0(3)
N′ —O(1′)—B′ —O(2′)	43.9(3)
4	
B —O(1)—C(1)—C(2)	−6.7(3)
O(1)—C(1)—C(2)—N	−22.6(3)
B —N —C(2)—C(1)	37.6(2)
C(2)—N —B —O(1)	−40.8(2)
C(1)—O(1)—B —N	29.2(2)

1.434 Å) is longer than that in the free ligand **1** (1.38 and 1.41 Å for intra- and intermolecular hydrogen-bonded *N*-oxide groups, respectively). Five-membered diphenylboron chelates with *N*-oxide ligands like **5** (13, 25) have shorter N—O bonds than **3**: 1.409 Å for **5** (13) and 1.410 Å for a substituted derivative (25). The ligand bite in **3**, mean O(1)···O(2) = 2.471 Å, is smaller than the corresponding distance of 2.53 Å in the hydrogen-bridged free ligand **1** (1).

The crystal structure of the rearrangement product **4** (Fig. 2) consists of molecules separated by normal van der Waals distances, the shortest intermolecular contact between non-hydrogen atoms being C(14)···C(14) ($2 - x$, $1 - y$, $-z$) = 3.618(5) Å. The *N*-oxide group of **3** has been cleaved during its thermal rearrangement to **4**, the N···O(2) distance being 2.406(2) Å in the product. The exocyclic N—B—O(2) angle (100.10(15)°) is relatively small, the corresponding C—B—O angle in the diphenylboron chelate **7** (6) (involving the pseudo-axial *B*-phenyl group) being 109.7°. The overall geometry of **4** is quite similar to that of **7** although there appears to be less intramolecular steric strain in the former. The C(1)—O(1) bond in **4** (1.432 Å) is longer than the corresponding bond in **7** (1.418 Å), and the B—O(1) bond in **4** is shorter (1.446 Å) than that in **7** (1.476 Å). The N—B bond in **4** (1.682 Å), like that in **7** (1.691 Å), is longer than the N—B bonds in *N*-substituted "boroxazolidines" (4, 5) and other sterically less hindered boron chelates of aminoalcohols such as **9** (6).

The bond lengths involving the boron atom in **4** all lie within the ranges previously observed for compounds of the type "PhBN(sp^3)O_2" (ref. 28 and references therein). The sum of bond lengths at boron, 6.205 Å, is fairly small for a compound of this type (6.191–6.297, mean 6.23 Å), consistent with relatively low overall strain about the boron atom (28).

The thermally induced 1,2-migration of one *B*-phenyl substituent to the *N*-oxide oxygen atom can be assumed to involve an approach of C(11) to O(1), if the migrating group is approaching antiperiplanar to the leaving trialkylamine group (**3′**→**4′**). The

C(11)—B—O(1) angle (average 102.8°) involving the equatorial phenyl group of **3** is considerably smaller than the C(5)—B—O(1) angle (average 112.4°) involving the axial *B*-phenyl substituent. The average C(11)···O(1) and C(5)···O(1) distances in **3** are 2.474 and 2.641 Å, respectively. Thus relatively small changes have to occur during the reaction. The rearrangement of **3** seems to be sterically "conditioned" by fortuitous relative positioning of both the migrating and leaving groups, as well as bonds and lone pairs involved in the transformation. It is possible that the long N—O bond in **3** (see above) is involved in facilitating the pending 1,2-shift, thus the structure of **3** may be interpreted as an example of a "frozen" intermediate in the progress of the oxidation of organylboranes with *N*-oxides. The best molecular fit between compounds **3** and **4** is good ($\Sigma\Delta^2$ = 13.2 Å^2 for all 20 non-hydrogen atoms) and the molecular volumes differ by only 1.1%. These data are consistent with a unimolecular process in a topochemically-allowed solid state reaction, and, considering the similarity of the unit-cell parameters, suggest the possibility of a single-crystal to single-crystal transformation. However, a comparison of the packing diagrams for **3** and **4** (Fig. 2) leads to the conclusion that too great a rearrangement of the lattice is required for such a topotactic reaction (involving these particular crystal forms) to occur.

Vibrational spectroscopic studies of the phase transition behavior in solid cyclohexene

JULIAN HAINES and D. F. R. GILSON[1]

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, Que., Canada H3A 2K6

Received December 5, 1988

JULIAN HAINES and D. F. R. GILSON. Can. J. Chem. **67**, 941 (1989).

The vibrational spectra (FT-ir and Raman) of cyclohexene have been examined as functions of temperature. The phase transition behavior is complex and highly dependent upon the thermal treatment of the sample. Spectra of the stable low temperature form (phase II) are quite different from those of the other phases, and suggest that the crystal has either C_i or C_{2h} symmetry with two molecules per primitive unit cell. The asymmetric line shapes of the internal vibrational bands and the presence of broad peaks in the low frequency region of the Raman spectra of the high temperature phase indicate that the molecules undergo anisotropic rotation. The frequency of the ring inversion mode is highly phase dependent.

Key words: cyclohexene, FT-ir, Raman, phase transition.

JULIAN HAINES et D. F. R. GILSON. Can. J. Chem. **67**, 941 (1989).

On a déterminé les spectres de vibration (ir-FT et Raman) du cyclohexène en fonction de la température. Le comportement à la transition de phase est complexe et dépend beaucoup du traitement thermique de l'échantillon. Les spectres de la phase II (forme stable à basse température) sont très différents de ceux des autres phases et ils suggèrent que la symétrie du cristal est soit C_i ou C_{2h} avec deux molécules par cellule unitaire. Les formes asymétriques des raies des bandes de vibration interne ainsi que la présence de pics larges dans la région de basse fréquence des spectres Raman de la phase de température élevée indiquent que les molécules subissent une rotation anisotrope. La fréquence du mode d'inversion du cycle dépend beaucoup de la phase.

Mots clés : cyclohexène, ir-FT, Raman, transition de phase.

[Traduit par la revue]

Introduction

Organic molecular crystals, particularly pseudo-spherical cage hydrocarbons such as adamantane, often possess an order–disorder phase transition in the solid state (1). The high temperature phase is usually face-centered cubic and melts with a low entropy of fusion (less than 21 J K^{-1} mol^{-1}). The low temperature crystal structures are seldom known, but, in principle, it is possible to analyze the splittings that occur in the vibrational spectra when the crystal symmetry changes at the transition and to determine the number of molecules per unit cell and to identify possible space groups (2). These phase transitions are not limited to rigid compounds and have been observed in monocyclic compounds such as cyclohexane, and in the present study, we have examined the temperature dependence of the FT-ir and Raman spectra of the analogous compound cyclohexene. The existence of a transition in this compound has been known for many years (3, 4). Adiabatic calorimetric studies showed that a single transition occurred at 139 K, with an entropy of transition of 30.7 J K^{-1} mol^{-1}, which is much larger than the entropy of fusion of 19.4 J K^{-1} mol^{-1} at 170 K, indicating that the high temperature phase is disordered. A more recent and extensive dta and adiabatic calorimetric study by Haida and co-workers (5, 6) has shown that the behavior is more complicated and involves metastable and "glassy crystalline" states, depending on the rate of cooling and the thermal history of the sample. When cooled slowly, the high temperature phase, phase I, transforms reversibly to a metastable phase III at 112 K. Upon rapid cooling a "glassy crystal" is formed, termed phase gI, which when heated undergoes a series of overlapping transitions some of which are exothermic; gI→I→III→I→II →I→liquid at 92 K, 100 K, 115 K, 120 K, 140 K, and 170 K, respectively. The stable low temperature phase II is formed irreversibly from phase I at 120 K and could be cooled to 61 K. Phase III was also found to form a glassy crystal if cooled below 83 K. This unusual sequence of transitions was explained by Haida and co-workers using a Gibbs free energy schematic diagram.

Molecular motion is commonly observed to occur in the high temperature phases of these materials (7). El Saffar and co-workers (8) have examined the nmr second moment and spin–lattice relaxation time for cyclohexene as functions of temperature. The phase transition behavior described in this study is in agreement with that subsequently observed by Haida and co-workers for rapidly cooled samples. A decrease in second moment was observed between 100 and 110 K and attributed to rotation of the cyclohexene molecule around an axis perpendicular to the four co-planar carbon atoms. A sudden increase in second moment was observed at 110 K when the stable low temperature phase was formed irreversibly, then at 139 K, the transition to phase I occurred, with a reduction in second moment due to the above mentioned rotation in conjunction with ring inversion. Upon cooling a transition was observed at 129 K with the ring inversion process persisting down to 115 K.

The vibrational spectrum of cyclohexene has been studied previously (9), but no results on the solid phases have been reported. A study of the vibrational spectra of solid cyclohexene enables more information to be obtained on the phase transition behavior and the different solid forms.

Experimental

Cyclohexene (Aldrich Chemical Co., Purity 99%) was distilled under reduced pressure before use.

Raman spectra were recorded on a Instruments S.A. spectrometer with a Jobin-Yvon Ramanor U-1000 1.0 m double monochromator. A Spectra Physics model 164, 5 W (all lines) argon-ion laser (514.5 nm line, approximately 200 mW at the sample) was used for excitation. The resolution was typically 1 or 2 cm^{-1}. Infrared spectra (2 cm^{-1} resolution) were acquired on a Analect AQS-18 FT-ir spectrometer equipped with a triglycine sulfate (TGS) detector. The infrared spectra were measured on samples sprayed on a potassium bromide window and annealed at a temperature just below the melting point. The Raman spectra were obtained by cooling liquid samples in sealed glass capillary tubes, which were mounted on to the cold finger of a cryostat using indium foil as a conducting junction. The sample temperature was

controlled, for both FT-ir and Raman spectra, with a Cryodyne Cryocooler Model 21 cryostat (Cryogenics Technology Inc.) and measured using a silicon-diode temperature sensor attached to a Cryophysics Model 4025 controller. The sample temperature remained essentially constant (±0.5 K).

Results and discussion

Raman spectra were obtained for both the metastable phase III and the glassy phase gI, as well as those of the stable phases I and II, Figs. 1 and 2, but, due to cooling rate limitations, infrared spectra could only be obtained for phases I and III, Fig. 3. The spectroscopic results conform to the dta and calorimetric results of Haida and co-workers (5, 6), and to the nmr results of El Saffar *et al.* (8). Upon slow cooling, many of the infrared and Raman bands of phase I were found to split into doublets at the transition to phase III, but remained quite broad. For example, ν_{39} and ν_{40}, at 718 and 641 cm^{-1} in the infrared spectrum of phase I, both split into two components, Table 1. This splitting could be due to the presence of two conformers related by the ring inversion mode. Rapid cooling of phase I, leading to the formation of the glassy crystalline phase gI, gave spectra that were very similar to those of phase III. The most noticeable differences were observed for the low frequency Raman region and in the intensity distribution between the peaks of the dou-

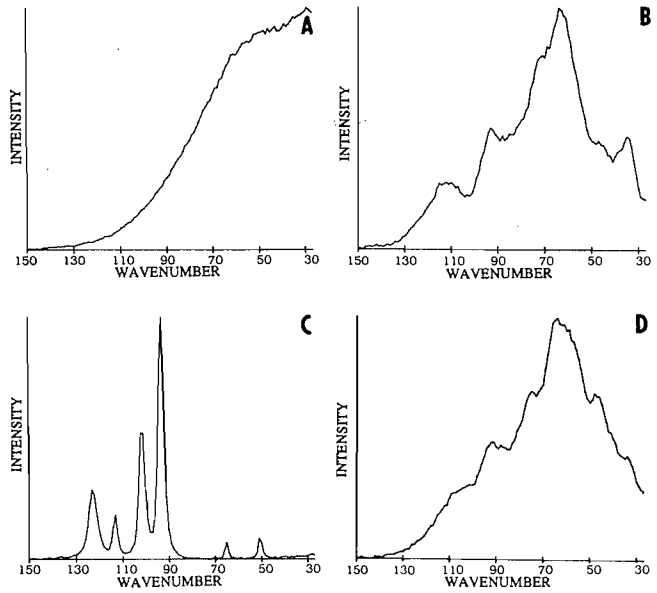

FIG. 2. Comparison of the low frequency Raman spectrum of cyclohexene: *A*, phase I at 149 K; *B*, phase III at 58 K; *C*, phase II at 61 K; and *D*, phase gI at 58 K (not to scale).

blets arising from the splittings of the internal modes, but the broad bands present in the spectra of both phases indicate that a significant degree of disorder was still present. In the low temperature stable phase II the lines in the Raman spectra were very much sharper than those in any other phase, and with some increases in relative intensities, notably for the C—H stretching region, and for ν_{11}, ν_{15} and the combination $\nu_{40} + \nu_{42}$ at 1244, 1068, and 818 cm^{-1}, respectively. These latter vibrations correspond to the CH_2 wag, the CH_2 twist and a combination of the CH wag and the ring inversion modes.

The external modes, as seen in the low frequency Raman region, Fig. 4, provide spectra which are quite characteristic of the type and behavior of each solid phase. For instance, the two overlapping broad bands in the spectrum of phase I persisted under slow cooling conditions down to 96 K, indicating that a considerable degree of motion is still present in phase III, well below the phase transition temperature. A similar conclusion was drawn on the basis of the wide line nmr results (8). At 96 K, a sudden change occurred to at least seven broad and overlapping bands. Upon heating the glassy phase (produced by rapid cooling), the transition to phase III and the subsequent transition to phase I were easily observable. The spectrum of phase I obtained by this path was identical to that obtained by cooling the liquid phase. At approximately 120 K, a sudden transformation to phase II occurred and the lattice region spectrum changed from two broad bands in phase I to six narrow bands, indicating the formation of the ordered phase. Thus the spectral evidence confirms the sequence of transitions reported by Haida *et al.* (5, 6). The temperature dependence of the lattice mode frequencies is shown in Fig. 4.

The possible site symmetries for cyclohexene, which belongs to the C_2 molecular point group, are C_1 and C_2. The presence of six external modes in the Raman spectrum of phase II, indicates that there are at least two molecules per unit cell. The absence of splitting in the Raman spectrum restricts the unit cell symmetry

to doubly occupied centrosymmetric groups under the triclinic or monoclinic system, whereby each internal mode, which is both ir- and Raman-active under the C_2 molecular point group, is split into one infrared and one Raman active component. Based on the above, a symmetry of C_i or C_{2h} with two molecules per primitive unit cell is proposed for this crystal (Fig. 5).

It is interesting to note that while most of the internal modes showed only small shifts in frequency at the various phase transitions, the transition from phase II to I produced the most pronounced changes. In most cases the shift was less than 5 cm^{-1}. The ring inversion mode, however, was strongly affected and was observed in the Raman spectrum at 185 cm^{-1} in the liquid and in phase I, at 193 cm^{-1} and 192 cm^{-1} in phases gI and III, respectively, and at 208 cm^{-1} in phase II. This band was found not to shift with temperature in phase I and the liquid, and only shifted 2 cm^{-1} from 62 K to 130 K in phase II. The shifts that occur at the phase transformations indicate that the crystal structure has a significant effect on the ring inversion process. Intermolecular forces, which are distance dependent, affect the barrier to ring inversion, therefore an increase in the frequency of the ring inversion mode is indicative of a crystal of higher density due to closer packing. This is in agreement with the arguments of Haida and co-workers (5, 6), who concluded, based on residual entropy arguments, that the energy difference between conformers in phase gI is less than in phase gIII, with the energy difference in phase II, which has no residual entropy, being so high that the lattice is rigid below the phase transition. The residual entropy in phase gI was found to be greater than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

that of phase gIII by about R ln 3, therefore the possibility of a three-fold disordering process, such as the distribution of the double bond about an axis passing through the center of the ring, could be considered. The total residual entropy of phase gI is about R ln 4, which is consistent with a four-fold disordering process. The vibrational spectra of these two glassy crystals are so similar that it is difficult to draw any conclusions on the relative degree of disorder. Both crystals are disordered and hence their spectra contain broad bands which partially obscure any splitting that might be present.

The broad bands in the low frequency Raman spectra of the high temperature phase of cyclohexene are characteristic of molecules that are undergoing anisotropic reorientation (10). In addition, the lineshapes of the internal modes are asymmetric with visible shoulders in many cases. These features are similar to those found in the spectra of the high temperature phases of cyclopentene (11), furan (12), and thiophene (13, 14), for which reorientation about an axis perpendicular to the ring was confirmed by nmr experiments (15–17). The nmr experiments (8) on cyclohexene also indicate the same motion is present along with ring inversion. A similarity is also noticed between the entropies of fusion of the four compounds, which are close to or greater than the upper limit of 2.5R which Timmermans (18) set for what he termed "plastic crystals". It should be noted that the high temperature phases of furan and thiophene are orthorhombic in contrast to the majority of "plastic crystals" which have cubic or hexagonal structures. The similarity between these two compounds and cyclopentene and cyclohexene could be due to the fact that, in the latter, the ring puckering only involves a portion of the ring as opposed to the situation in cyclobutane, cyclopentane and cyclohexane where the whole ring is affected and, consequently, a much greater degree of disorder is present in the high temperature phases.

Reçu le 23 septembre 1988

MICHEL LEBŒUF, ANDRÉ CAVÉ, ANISSA RANAIVO et HENRI MOSKOWITZ. Can. J. Chem. **67**, 947 (1989).

Au cours de l'étude de deux Lauracées néocalédoniennes, *Cryptocarya phyllostemon* et *Cryptocarya oubatchensis*, quatre alcaloïdes quaternaires à squelette dibenzopyrrocoline ont été isolés. Deux d'entre eux ont été identifiés à la cryptowoline et à la cryptaustoline, les deux seuls produits naturels de ce type structural connus jusqu'alors. Les deux autres, nommés cryptowolinol et cryptowolidine, sont nouveaux; leur structure a été déterminée et la synthèse de la cryptowolidine a été réalisée. La structure du cryptowolinol est originale par la présence inhabituelle d'un hydroxyle alcoolique sur le carbone benzylique, et sa possible origine biogénétique est discutée.

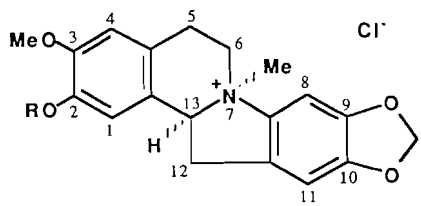
Mots clés : *Cryptocarya*, Lauraceae, alcaloïdes dibenzopyrrocolines.

MICHEL LEBŒUF, ANDRÉ CAVÉ, ANISSA RANAIVO, and HENRI MOSKOWITZ. Can. J. Chem. **67**, 947 (1989).

Four quaternary dibenzopyrrocoline alkaloids were isolated from the Neocaledonian Lauraceae *Cryptocarya phyllostemon* and *C. oubatchensis*. Two of them were identified as cryptowoline and cryptaustoline, the only natural representatives of this structural type known up to now. The other two are new products and have been named cryptowolinol and cryptowolidine; their structures were elucidated, and synthesis of cryptowolidine was perfomed. An original feature of cryptowolinol is the unusual presence of an alcoholic hydroxyl on the benzylic carbon; its putative biogenetic origin is discussed.

Key words: *Cryptocarya*, Lauraceae, dibenzopyrrocoline alkaloids.

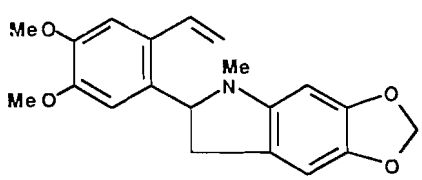
Introduction



Parmi les très nombreux alcaloïdes isoquinoléiques ou biogénétiquement apparentés actuellement connus, deux seulement, la cryptowoline et la cryptaustoline, possèdent un squelette de type dibenzopyrrocoline ou indolo[2,1-*a*]isoquinoléine (1). Depuis leur découverte il y a plus de 35 ans dans une Lauracée australienne, *Cryptocarya bowiei* (Hook.) Druce (2, 3), leur présence n'a jamais été de nouveau signalée dans une quelconque espèce végétale.

Au cours d'un travail d'ensemble portant sur le contenu alcaloïdique d'une dizaine d'espèces de *Cryptocarya* originaires d'Australie, des Nouvelles-Hébrides et de Nouvelle-Calédonie, l'étude de deux de ces dernières, *C. phyllostemon* Kost. et *C. oubatchensis* Schlechter, a permis d'isoler quatre alcaloïdes quaternaires à noyau dibenzopyrrocoline. Deux d'entre eux, présents respectivement dans *C. phyllostemon* et dans *C. oubatchensis*, ont été identifiés à la cryptowoline et à la cryptaustoline. Les deux autres, qui sont nouveaux, ont été nommés cryptowolinol et cryptowolidine; ils ont été isolés, le premier à partir des deux espèces étudiées, le second seulement à partir de *C. phyllostemon*.

L'extraction de ces alcaloïdes quaternaires a été réalisée de façon classique. La détermination structurale de ces différents produits, ainsi que la synthèse de l'un d'entre eux, la cryptowolidine, font l'objet du présent mémoire.



Résultats et discussion

L'alcaloïde quaternaire **1**, de formule brute $C_{19}H_{20}O_4N^+$, a été isolé sous forme de chlorure. Son appartenance au groupe des dibenzopyrrocolines est déduite de l'examen de son spectre de masse. Le pic moléculaire, à *m/z* 326, n'a qu'une faible intensité en ionisation chimique et est totalement absent en impact électronique; mais, sur ce dernier, toutes les fragmentations classiques des dibenzopyrrocolines quaternaires sont observées (4) et elles indiquent que l'alcaloïde **1** est substitué en 9 et 10 par un méthylènedioxyle et que le cycle A porte un méthoxyle et un hydroxyle phénolique dont les positions exactes, en 2 et en 3, restent à déterminer. La localisation des substitutions oxygénées sur le noyau est confirmée par comparaison du dérivé O-méthylé **2**, obtenu par action du diazométhane sur **1**, avec un échantillon de O-méthyl cryptowoline. Le spectre de RMN ^1H de **1** (Tableau 1) est en accord avec les données précédentes, mais il ne permet pas de placer avec certitude les substituants en 2 et 3. Une étude des effets nucléaires Overhauser (ENO) observés sur le spectre de **1**, enregistré dans CD_3OD à 500 MHz, a conduit sans ambiguïté à attribuer à cet alcaloïde la structure de la cryptowoline dans

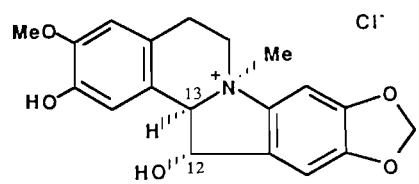
laquelle l'hydroxyle est en 2 et le méthoxyle en 3. Enfin, les spectres de RMN ^{13}C des dibenzopyrrocolines quaternaires n'ayant pas encore été décrits, celui du chlorure de cryptowoline a été enregistré; les attributions ont été faites (Tableau 2) par comparaison aux données publiées d'une part pour d'autres alcaloïdes isoquinoléiques (5, 6), d'autre part pour une dibenzopyrrocoline tertiaire synthétique tétraméthoxylée en 2, 3, 9 et 10 (7).

La cryptowoline isolée ici de *C. phyllostemon* possède la même configuration 13-*S* que celle précédemment extraite de *C. bowiei* (pouvoir rotatoire négatif, même effet Cotton négatif à 242 nm sur le spectre de dichroïsme circulaire); quant à la configuration de l'atome d'azote quaternaire, elle a été établie récemment comme étant 7-*R* (8).



Lors de la préparation de la O-méthyl cryptowoline **2**, il a été constaté que la réaction de méthylation de la cryptowoline **1** par le diazométhane en solution éthérée était particulièrement laborieuse et nécessitait, pour être complète, un temps de contact supérieur à 1 semaine. Nous avons également tenté de méthyler la cryptowoline par action de l'iodure de méthyle dans la potasse méthanolique, selon une technique déjà utilisée dans le cas d'autres alcaloïdes quaternaires phénoliques (9). Cependant, il n'a pas été obtenu dans ces conditions le dérivé **2** espéré, mais le produit vinylique **3** formé par O-méthylation et élimination spontanée de Hofmann. Sa structure a été déduite de son spectre de RMN ^{1}H qui présente en particulier les signaux caractéristiques du N-méthyle tertiaire (singulet à 2,55 ppm) et de la chaîne vinylique (trois doublets dédoublés à 5,23, 5,56 et 6,86 ppm, avec des couplages respectivement *gem* et *cis*, *gem* et *trans*, *cis* et *trans*).

La dibenzopyrrocoline quaternaire **4**, $C_{20}H_{24}O_4N^+$, a comme la précédente été isolée sous forme de chlorure. Elle a été facilement identifiée à la cryptaustoline par examen de ses spectres de masse et de RMN ^{1}H (Tableau 1) et comparaison à ceux de la cryptowoline **1** dont elle ne diffère que par la présence en 9,10 de deux méthoxyles au lieu du groupe méthylènedioxy. Le placement de l'hydroxyle phénolique en 2 et du méthoxyle en 3 résulte de la similitude des déplacements chimiques des protons aromatiques en 1 et 4 observés pour ces deux alcaloïdes.

Les deux autres dibenzopyrrocolines quaternaires isolées au cours de ce travail sont nouvelles. La première, nommée cryptowolinol, **5**, $C_{19}H_{20}O_5N^+$, cristallise sous forme de chlorure. Son spectre UV est comparable à celui des alcaloïdes précé-

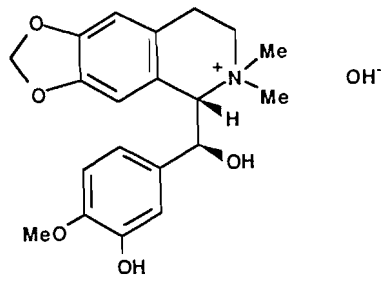
dents. Un déplacement bathochrome observé en milieu alcalin révèle la présence d'une fonction phénolique, ce qui est confirmé par l'existence d'un singulet de trois protons à 2,28 ppm sur le spectre de RMN ^1H du dérivé acétylé **6**; mais on observe également sur ce spectre la présence d'un autre singulet de trois protons, à 1,75 ppm, attribuable à un O-acétyle alcoolique. Sur le spectre de masse du cryptowolinol en ionisation chimique, le pic moléculaire n'a qu'une faible intensité (2%) et se trouve à m/z 342, soit à 16 u.m.a. de plus que pour la cryptowoline **1**, ce qui confirme la présence d'une fonction alcool supplémentaire. Les fragmentations observées sur le spectre de masse de **5** en impact électronique sont en accord avec celles des dibenzopyrrocolines portant un méthylènedioxyle en 9,10 ainsi qu'un méthoxyle et un hydroxyle phénolique sur le cycle A (4).

Le cryptowolinol est donc une dibenzopyrrocoline quaternaire du même type que la cryptowoline et portant une fonction alcool secondaire. Pour des raisons biogénétiques, cet hydroxyle alcoolique ne peut être qu'en position 5 ou 12; c'est l'interprétation du spectre de RMN ^1H, enregistré à 500 MHz dans CD_3OD (Tableau 1), qui a permis de trancher en faveur de cette seconde hypothèse. En effet, ce spectre comporte, outre les signaux provenant du N-méthyle quaternaire, du méthoxyle, du méthylènedioxyle et des quatre protons aromatiques, deux doublets de un proton chacun, à 5,16 et 5,41 ppm, $J = 6$ Hz, qui ne peuvent être attribués respectivement qu'au proton en 13 et à celui en 12, ce dernier étant géminé à la fonction alcool secondaire.



À ce stade, deux structures planes isomères peuvent être proposées pour le cryptowolinol, selon la position de l'hydroxyle phénolique et du méthoxyle en 2 et 3 sur le cycle A. L'étude des effets nucléaires Overhauser a permis d'attribuer au cryptowolinol la structure **5**. L'irradiation du doublet à 5,16 ppm (H en 13) provoque une augmentation d'intensité d'une part du singulet à 3,50 ppm (N-méthyle quaternaire), d'autre part du singulet à 6,83 ppm qui est de ce fait attribué au proton aromatique en 1. L'irradiation du doublet à 5,41 ppm (H en 12) entraîne un accroissement de l'intensité du singulet précédent, mais aussi du singulet à 7,11 ppm qui correspond donc au proton aromatique en 11. D'autre part, en irradiant le troisième singulet de proton aromatique situé à 7,41 ppm, on observe un effet sur le signal à 3,50 ppm du N-méthyle, ce qui permet de placer en 8 ce proton; il s'agit du proton aromatique le plus déblindé, ce qui est logique car il subit l'influence du N-méthyle quaternaire. Le dernier singulet d'un proton, à 6,91 ppm, est donc celui du proton en 4; ceci est confirmé par le fait qu'en l'irradiant on augmente l'intensité du multiplet à 3,10 ppm du CH_2-5; cette même irradiation augmente également l'intensité du singulet à 3,89 ppm du méthoxyle qui, par conséquent, se trouve en position 3.

Le spectre de RMN ^{13}C du cryptowolinol a été enregistré et les attributions ont été faites (Tableau 2) par comparaison à celles de la cryptowoline **1**. La présence de l'hydroxyle alcoolique se traduit par un fort déblindage (35 ppm) du C-12 qui résonne ici à 72,4 ppm, et les carbones 11a et 13, situés en *ortho*, sont faiblement déblindés. Les autres valeurs sont très voisines de celles observées pour la cryptowoline.

Le cryptowolinol **5** est donc une hydroxy-12 cryptowoline dont il reste à établir la configuration absolue. Sa courbe de DC est tout à fait semblable à celle de la cryptowoline et en particulier elle présente, comme elle, un effet Cotton négatif à 244 nm. Ces deux alcaloïdes ont donc la même configuration au niveau du C-13. La stéréochimie en 12 peut être déduite de la valeur

7 : Cryptowolidine

15

($J = 6$ Hz) de la constante de couplage observée en RMN ^1H pour les doublets des protons en 12 et en 13, qui indique un couplage de type axial-équatorial. L'examen du modèle Dreiding du cryptowolinol montre qu'une telle situation est observée lorsque l'hydroxyle en 12 est en dessous du plan moyen, du même côté que le proton en 13; dans ces conditions, le proton en 12 occupe une position pseudo-équatoriale au dessus du plan moyen de la molécule. La configuration absolue proposée pour le cryptowolinol **5** est donc 12-*S*, 13-*R*.

La dernière dibenzopyrrocoline quaternaire isolée, sous forme de chlorure, au cours de ce travail est également nouvelle et a été nommée cryptowolidine. De formule brute $C_{19}H_{20}O_4N^+$, cet alcaloïde **7** est un isomère de la cryptowoline **1** et l'examen de ses données spectrales révèle la très grande parenté des deux produits. En particulier, son spectre de masse est, aux intensités des pics près, pratiquement identique à celui de la cryptowoline, indiquant ainsi que le cycle D porte un méthylènedioxyle en 9,10 et le cycle A un hydroxyle phénolique et un méthoxyle. Il est donc logique de penser que dans la cryptowolidine le phénol est en 3 et le méthoxyle en 2; cette hypothèse a été confirmée par une étude ENO réalisée dans CD_3OD à 500 MHz. L'irradiation du triplet à 5,32 ppm (H en 13) entraîne une augmentation de l'intensité du singulet du proton aromatique résonnant à 6,91 ppm; il s'agit donc du proton en 1. Ce même singulet est également affecté par irradiation du signal à 3,88 ppm du méthoxyle, qui se trouve donc bien en position 2. Les autres signaux du spectre de RMN peuvent alors être attribués sans difficulté (Tableau 1), en particulier celui du proton aromatique en 4 à 6,72 ppm. On constate ainsi qu'en passant de la cryptowoline **1** à la cryptowolidine **7**, le proton en 1 est déblindé de 6,76 à 6,91 ppm, tandis que celui en 4 est blindé de 6,86 à 6,72 ppm; ces déplacements sont tout à fait logiques compte-tenu de la structure de ces deux alcaloïdes.

Ne disposant que d'une très faible quantité de cryptowolidine, nous avons réalisé la synthèse de cet alcaloïde, pour confirmer la structure proposée et pouvoir envisager son triage pharmacologique. Plusieurs méthodes de synthèse du noyau dibenzopyrrocoline ont été décrites (1); parmi elles, nous avons choisi la cyclisation d'une benzyltétrahydroisoquinoléine halogénée convenablement substituée, en la dibenzopyrrocoline correspondante, par l'intermédiaire d'un benzyne obtenu par

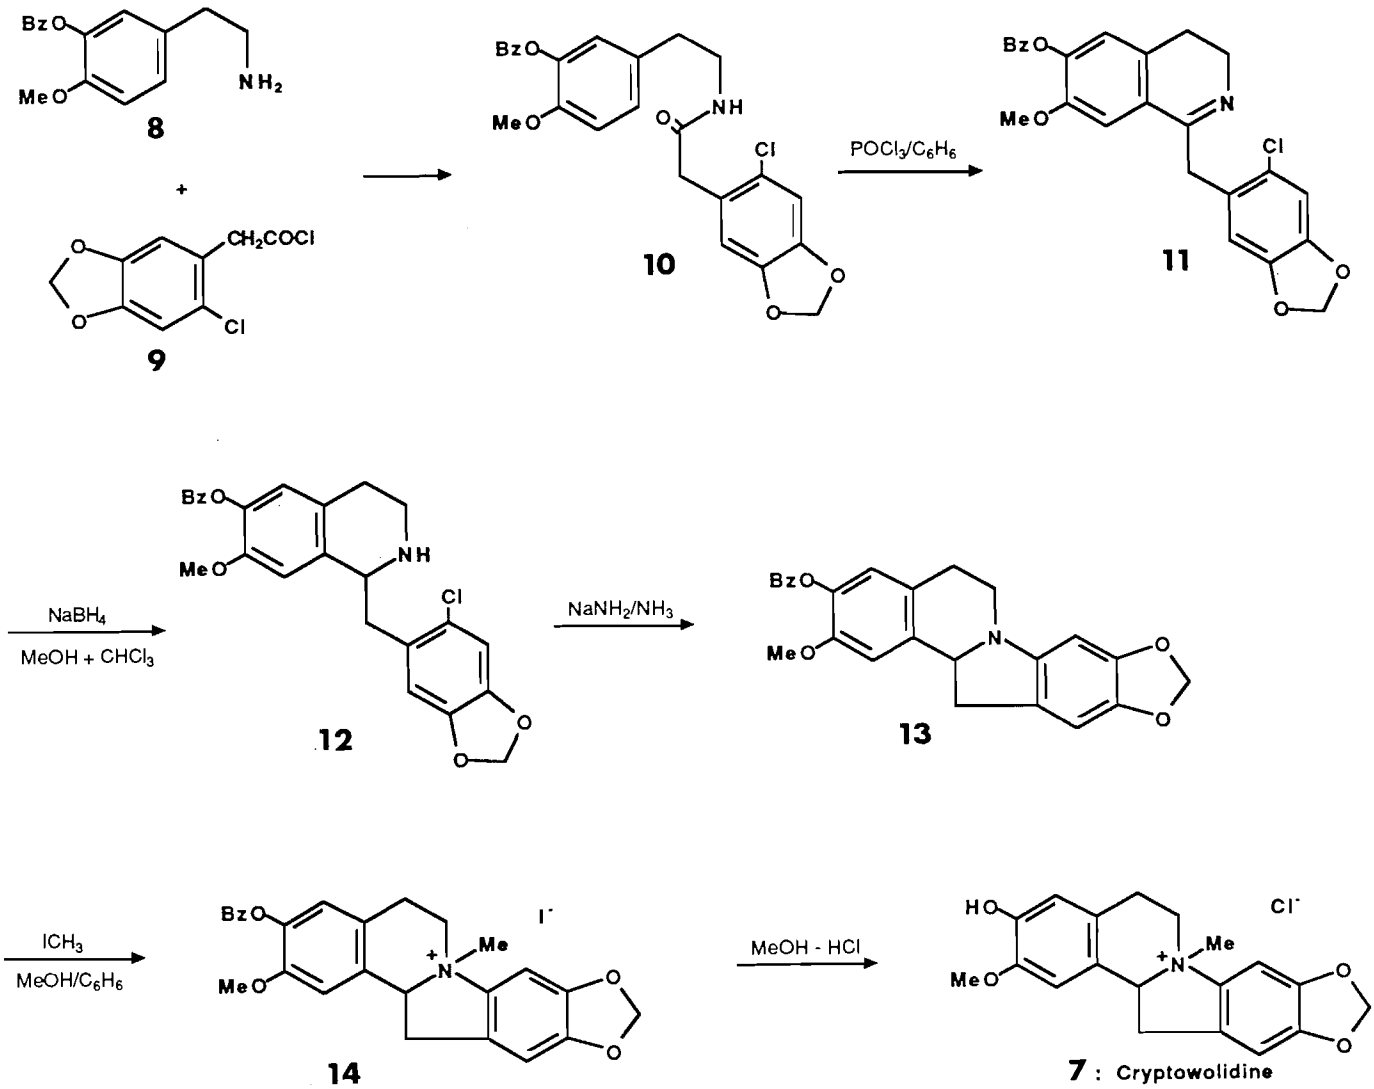


SCHÉMA 1: Synthèse de la cryptowolidine.

réaction de l'amidure de sodium dans l'ammoniac liquide (10, 11). Les étapes de la synthèse de la cryptowolidine sont représentées sur le schéma 1.

Les matières premières utilisées sont la benzyloxy-3 méthoxy-4 β-phényléthylamine **8** et le chlorure de l'acide chloro-2 homopipéronylique **9**; ces deux produits ont été préparés de façon classique, le premier (12, 13) en trois étapes à partir de l'isovanilline, le second (14, 15) en six étapes à partir du pipéronal. La condensation des deux dérivés **8** et **9** conduit à l'amide **10**. Une cyclisation de Bischler–Napieralski, réalisée sur cet amide par action de l'oxychlorure de phosphore dans le benzène à reflux, fournit la (chloro-2′ pipéronyl)-1 benzyloxy-6 méthoxy-7 dihydro-3,4 isoquinoléine **11**, dont la réduction par le borohydrure de sodium livre la benzyltétrahydroisoquinoléine correspondante **12**. La première de ces trois étapes se fait avec un rendement de l'ordre de 70% et les deux autres avec un rendement supérieur à 90%. Traitée par l'amidure de sodium dans l'ammoniac liquide selon la technique décrite par Kametani et Ogasawara (10), la benzyltétrahydroisoquinoléine chlorée **12** subit une cyclisation conduisant à la dibenzopyrrocoline tertiaire **13** qui, très instable comme cela a été déjà observé pour un produit du même type, n'est obtenue pure qu'avec un faible rendement (29%). La N-méthylation de l'amine tertiaire **13** est réalisée par action de l'iodure de méthyle à température ambiante. Enfin, la libération de la fonction phénolique de l'ammonium quaternaire **14** par débenzylation est effectuée par chauffage au bain-marie de sa solution dans un mélange méthanol – acide chlorhydrique. Chacune de ces deux dernières étapes se fait avec un rendement de 75% et on obtient ainsi le chlorure de cryptowolidine racémique, correspondant au produit naturel **7** par son R_f en CCM, ses spectres IR, UV, de masse et de RMN ^1H.

Ainsi, au cours de ce travail portant sur deux espèces néocalédoniennes de *Cryptocarya*, les deux seuls alcaloïdes à squelette dibenzopyrrocoline jusqu'alors connus, la cryptowoline et la cryptaustoline, ont été trouvés pour la seconde fois et deux autres dibenzopyrrocolines quaternaires non encore décrites, le cryptowolinol et la cryptowolidine, ont été isolées. C'est le cryptowolinol **5** qui, par la présence inhabituelle d'un hydroxyle alcoolique sur le carbone benzylique C-12, présente le plus d'originalité. D'un point de vue biogénétique, il est couramment admis, bien que non encore expérimentalement prouvé, que le squelette dibenzopyrrocoline a pour précurseur une benzyltétrahydroisoquinoléine telle que la laudanosoline qui, après oxydation du cycle benzylique, subirait une cyclisation intramoléculaire entre l'atome d'azote et le carbone-2′;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12

For personal use only.

cette hypothèse biogénétique a d'ailleurs été mise à profit pour réaliser des synthèses biomimétiques des dibenzopyrrocolines par couplage oxydatif enzymatique de la laudanosoline (16). Dans le cas du cryptowolinol, on peut s'interroger sur son mode de formation in vivo et plus précisément sur le moment de l'hydroxylation en 12 du squelette. Deux hypothèses peuvent être envisagées : ou bien l'hydroxylation est tardive et ne se produit qu'après formation du noyau dibenzopyrrocoline; ou bien cette hydroxylation est précoce et elle concerne alors une *N*-benzyltétrahydroisoquinoléine qui, après hydroxylation de son carbone benzylique C-α, subit la cyclisation en dibenzopyrrocoline. Ces considérations biogénétiques incitent à rapprocher la structure du cryptowolinol **5** de celle de la phyllocryptonine **15**, également présente dans la même espèce *Cryptocarya phyllostemon* (17); la phyllocryptonine est la première benzyltétrahydroisoquinoléine quaternaire naturelle hydroxylée sur son carbone-α. Il est possible, par conséquent, qu'un analogue proche de la phyllocryptonine puisse conduire in vivo au cryptowolinol.

Partie expérimentale

Points de fusion déterminés un tube capillaire à l'aide d'un appareil Tottoli. Pouvoirs rotatoires mesurés à l'aide d'un polarimètre Schmidt–Haensch, type Polatronic I, à la longueur d'onde de la raie D du sodium. Spectres enregistrés sur les appareils suivants : IR, Perkin–Elmer type 257; UV, Unicam SP 1800; DC, Auto-dichrograph Mark V; SM, VG Micromass 70; RMN ^{1}H, Varian T 60 à 60 MHz ou Bruker à 500 MHz; RMN ^{13}C, Varian CFT 20 à 25,2 MHz.

Matériel végétal

L'échantillon de *Cryptocarya phyllostemon* étudié est constitué d'écorces de tiges récoltées en Nouvelle-Calédonie sur les pentes du Mont Dzumac en Novembre 1977; des échantillons d'herbier sont conservés sous la référence PC NC 219 à l'Herbarium de l'ORSTOM à Nouméa.

L'échantillon de *Cryptocarya oubatchensis* consiste en feuilles et écorces de tronc récoltées en Nouvelle Calédonie, à Haute-Tchamba, en juillet 1979; l'échantillon d'herbier (référence Sévenet-Pusset 1901) est déposé au Museum National d'Histoire Naturelle de Paris.

Extraction et isolement des alcaloïdes

Les écorces de tiges broyées (600 g) de *Cryptocarya phyllostemon*, après un dégraissage par l'éther de pétrole en appareil de Soxhlet, sont épuisées dans un lixiviateur par de l'éthanol à 80%. L'extrait, concentré, est repris par une solution aqueuse d'acide citrique à 2%. La phase aqueuse, alcalinisée par NH_4OH, est extraite par $CHCl_3$. L'évaporation de la phase organique fournit un résidu constitué d'alcaloïdes non quaternaires. La phase aqueuse précédente, qui présente encore une réaction de Mayer positive, est acidifiée à pH 1 par HCl concentré et les bases quaternaires sont précipitées par addition de réactif de Mayer concentré. Les iodomercurates ainsi obtenus (84 g) représentent une teneur en bases quaternaires de 4,5%. Une partie (12 g) de ces iodomercurates est solubilisée dans 10 mL d'un mélange Me_2CO–MeOH–H_2O (6:2:1, v/v), et est transformée en chlorures par passage sur une colonne de résine Amberlite IRA 400 en phase Cl^-; 5,1 g de chlorures sont ainsi obtenus. Ils sont dissous dans un mélange $CHCl_3$–MeOH–NH_4OH (70:30:8, v/v) et chromatographiés, en utilisant le même système de solvants, sur une colonne de 200 g de Kieselgel 60 H (Merck 7736). On isole ainsi successivement, après purification par cristallisation ou par chromatographie préparative sur couche mince de gel de silice, cinq bases quaternaires parmi lesquelles la cryptowoline **1** (0,32 g, rdt 0,30% exprimé par rapport au poids de plante sèche), le cryptowolinol **5** (0,81 g, rdt 0,75%) et la crytowolidine **7** (0,09 g, rdt 0,07%). L'isolement et la structure des autres alcaloïdes seront décrits ailleurs (18).

Les alcaloïdes quaternaires de *Cryptocarya oubatchensis* ont été isolés par une méthodologie identique. La teneur en bases quaternaires est de 2,71% dans les écorces de tiges et de 0,77% dans les feuilles. Deux bases quaternaires ont été isolées à partir des écorces de tiges, la crystaustoline **4** (0,07 g, rdt 0,02%) et le cryptowolinol **5** (5,1 g, rdt 1,52%), et une seule à partir des feuilles, le cryptowolinol **5** (1,22 g, rdt 0,30%).

*(−)-Cryptowoline, **1***

$C_{19}H_{20}O_4N^+$ = 326,36. Obtenue cristallisée sous forme de chlorure; *F* 188–190°C ($CHCl_3$); $[\alpha]_D$ −200 (EtOH, *c* = 1); UV, λ_{max} (EtOH) : 210 (log ε 4,59), 222 (log ε 4,03) (épaule), 292 (log ε 3,83); EtOH + NaOH: 212, 240 (épaule), 298; DC (MeOH) : $\Delta\varepsilon_{212}$ −5,9, $\Delta\varepsilon_{225}$ −1,82, $\Delta\varepsilon_{242}$ −3,6, $\Delta\varepsilon_{270}$ 0, $\Delta\varepsilon_{282}$ +0,2, $\Delta\varepsilon_{290}$ 0, $\Delta\varepsilon_{300}$ −0,4, $\Delta\varepsilon_{340}$ 0; SM (ic, NH_3), *m/z* (%) : 326 (M^+, 9); SM (ie), *m/z* (%) : 311 (41), 310 (60), 309 (100), 294 (75), 280 (8), 278 (3), 266 (28), 250 (3); RMN ^{1}H : voir tableau 1; RMN ^{13}C : voir tableau 2.

*O-Méthyl cryptowoline, **2***

Cryptowoline **1** (50 mg), en solution dans 12,5 mL de méthanol, est traitée par 12,5 mL de diazométhane en solution éthérée. Après 1 mois de contact, le solvant est évaporé à sec. *O*-Méthyl cryptowoline **2** (25 mg) est obtenue parfaitement pure après CCM préparative sur silice 60F 254 ($CHCl_3$–MeOH 90 : 10 v/v, vapeurs d'ammoniac). Le produit obtenu est identique à un témoin de *O*-méthyl cryptowoline synthétique. $C_{20}H_{22}O_4N^+$; RMN ^{1}H, $CDCl_3$, 60 MHz, δ : 3,66 (3H, N^+-Me), 3,87 et 3,90 (2 × 3H, OMe-2 et OMe-3), 6,10 (2H, OCH_2O-9,10), 6,76 et 6,81 (2 × 1H, H-1 et H-4), 6,88 (1H, H-11), 7,47 (1H, H-8).

*O-Méthyl cryptowoline méthine, **3***

Cryptowoline **1** (26,5 mg) est dissoute dans 1 mL de potasse méthanolique 0,5 N, puis additionnée de 1 mL de CH_3I. Le mélange est chauffé à reflux pendant 1 h. Après évaporation à sec du solvant, le résidu est extrait par $CHCl_3$. Les solutions chloroformiques évaporées laissent un résidu (14,5 mg) du dérivé vinylique **3** identifié par son spectre de RMN; RMN ^{1}H, $CDCl_3$ 60 MHz, δ : 2,55 (s, 3H, N-CH_3), 3,88 et 3,91 (2s, 2 × 3H, OMe-2 et OMe-3), 5,23 (dd, J_{gem} = 2 Hz, J_{cis} = 11 Hz, 1H, CH-C*H*$_2$), 5,56 (dd, J_{gem} = 2 Hz, J_{trans} = 18 Hz, 1H, CH-C*H*$_2$), 5,86 (s, 2H, OCH_2O-9,10), 6,86 (dd, J_{cis} = 11 Hz, J_{trans} = 18 Hz, 1H, C*H*=CH_2), 6,21, 6,61, 7,01, 7,31 (4s, 4 × 1H, H aromatiques).

*(−)-Cryptaustoline, **4***

$C_{20}H_{24}O_4N^+$ = 342,40. Obtenue à l'état amorphe sous forme de chlorure; $[\alpha]_D$ −150 (EtOH, *c* = 0,45); UV, λ_{max} (EtOH) : 216 (log ε 4,72), 222 (log ε 4,21) (épaule), 288 (log ε 4,03); EtOH + NaOH : 222, 244 (épaule), 296; SM (ic, NH_3), *m/z* (%) : 342 (M^+, 4), 328 (77), 327 (100); SM (ie), *m/z* (%) : 328 (17), 327 (81), 326 (42), 325 (100), 313 (20), 312 (10), 311 (15), 310 (17), 296 (13), 294 (5), 282 (4), 266 (4); RMN ^{1}H : voir tableau 1.

*(−)-Cryptowolinol, **5***

$C_{19}H_{20}O_5N^+$ = 342,36. Obtenu cristallisé de l'acétone sous forme de chlorure; *F* 218–220°C; $[\alpha]_D$ −152 (EtOH, *c* = 1); UV, λ_{max} (EtOH) : 211 (log ε 4,60), 224 (log ε 3,91) (épaule), 230 (log ε 3,90), 293 (log ε 3,89); EtOH + NaOH : 223, 243 (épaule), 298; DC (MeOH) : $\Delta\varepsilon_{215}$ −5,6, $\Delta\varepsilon_{230}$ −2,1, $\Delta\varepsilon_{244}$ −5,2, $\Delta\varepsilon_{281}$ 0, $\Delta\varepsilon_{299}$ −0,5, $\Delta\varepsilon_{342}$ 0; SM (ic, NH_3), *m/z* (%) : 342 (M^+, 2), 310 (100), 309 (74); SM (ie), *m/z* (%) : 341 (6), 327 (1), 325 (2), 324 (9), 323 (38), 321 (16), 310 (21), 309 (100), 308 (16), 295 (15), 294 (73), 280 (10), 266 (30), 250 (6); RMN ^{1}H : voir tableau 1; RMN ^{13}C : voir tableau 2.

*O,O-Diacétyl cryptowolinol, **6***

Préparé à partir de **5** (Ac_2O/Pyr); IR, ν_{max} (KBr) : 1760 cm^{-1}; RMN ^{1}H, CD_3OD, 60 MHz, δ : 1,75 (s, 3H, OAc-12), 2,28 (s, 3H, OAc-2), 3,68 (s, 3H, N^+-Me), 3,88 (s, 3H, OMe-3), 5,68 (d, *J* = 6 Hz, 1H, H-13), 6,16 (s, 2H, OCH_2O-9,10), 6,66 (d, *J* = 6Hz, 1H, H-12), 7,06 (s, 2H, 2 protons aromatiques), 7,11 et 7,53 (2s, 2 × 1H, 2 protons aromatiques).

*(−)-Cryptowolidine, **7***

$C_{19}H_{20}O_4N^+$ = 326,36. Obtenue à l'état amorphe sous forme de chlorure; $[\alpha]_D$ négatif (EtOH); UV, λ_{max} (EtOH) : 212 (log ε 4,48), 225 (log ε 4,04) (épaule), 290 (log ε 3,86); EtOH + NaOH : 219, 240 (épaule), 298; SM (ic, NH_3), *m/z* (%) : 326 (M^+, 6), 312 (100), 311 (14); SM (ie), *m/z* (%): 326 (M^+, 1), 311 (45), 310 (63), 309 (100), 294 (2), 266 (2); RMN ^{1}H : voir tableau 1.

Synthèse de la cryptowolidine, 7

N-(Benzyloxy-3 méthoxy-4 phényléthyl)-chloro-2' homopipéronyl-amide, 10

L'acide chloro-2 homopipéronylique (5g; 0,022 mol), 5 mL de C_6H_6 anhydre et 6,4 mL de $SOCl_2$ sont chauffés à reflux pendant 2 h. Le benzène et l'excès de $SOCl_2$ sont évaporés sous pression réduite. Le résidu, constitué par le chlorure d'acide **9**, est dissous dans 5 mL d'éther anhydre et ajouté goutte à goutte sous agitation à une solution de 18 g (0,07 mol) de benzyloxy-3 méthoxy-4 β-phényléthylamine **8** dans 650 mL d'éther. Il se forme un précipité blanc qui est recueilli et lavé par de l'éther. On l'agite ensuite pendant 15 min dans de l'eau chaude (50°C) qui dissout le chlorure d'amine. L'amide **10** est alors recueilli par filtration, lavé à l'eau et séché. On obtient 7,6 g de produit brut qui est purifié par chromatographie sur colonne (silice 60 H, élution par $CHCl_3$–MeOH 98 : 2 v/v) et cristallisation dans $CHCl_3$. On isole ainsi 7,1 g de l'amide **10** pur en fins cristaux blancs (rendement 68%). $C_{25}H_{24}O_5NCl$; *F* 178–179°C; RMN ^1H, $CDCl_3$, 60 MHz, δ : 3,48 (s, 2H, CH_2-CO), 3,83 (s, 3H, OMe), 5,06 (s, 2H, OCH_2-φ), 5,91 (s, 2H, OCH_2O), 6,63–6,76 et 7,30–7,40 (2 massifs de m, 2 × 5H, 10H aromatiques).

(Chloro-2' méthylènedioxy-4',5' benzyl)-1 benzyloxy-6 méthoxy-7 dihydro-3,4 isoquinoléine, 11

Un mélange de 4,2 g (9,6 mmol) de l'amide **10**, 25 mL de C_6H_6 et 8,5 mL de $POCl_3$ est porté à reflux pendant 1 h 30. La solution devient brun clair. En refroidissant, un solide jaune pâle précipite. Filtré, lavé par C_6H_6, ce produit est dissous dans une solution hydro-méthanolique chaude. La solution est alcalinisée par NaOH 10%. Par refroidissement, l'imine **11** cristallise et l'on isole 3,97 g de produit pur en CCM (rendement 99%). $C_{25}H_{22}O_4NCl$; *F* 147–148°C; RMN ^1H, $CDCl_3$, 60 MHz, δ : 2,62 (t, *J* = 7,5 Hz, 2H, CH_2-4), 3,70 (t, *J* = 7,5 Hz, 2H, CH_2-3), 3,83 (s, 3H, OMe-7), 4,10 (s large, 2H, CH_2-α), 5,16 (s, 2H, OCH_2-φ), 5,90 (s, 2H, OCH_2O-4',5'), 6,71 et 6,80 (2s, 2 × 1H, H-5 et H-8), 6,86 (s, 1H, H-6'), 7,01 (s, 1H, H-3'), 7,40 (s large, 5H, $OCH_2C_6H_5$).

(Chloro-2' méthylènedioxy-4',5' benzyl)-1 benzyloxy-6 méthoxy-7 tétrahydro-1,2,3,4 isoquinoléine, 12

L'imine **11** étant peu soluble dans le méthanol, sa réduction est effectuée dans un mélange de MeOH et de $CHCl_3$. On dissout 3,66 g de **11** (8,4 mmol) dans 450 mL du mélange $CHCl_3$–MeOH 3 : 7 v/v. On ajoute 850 mg de $NaBH_4$ (22,5 mmol) petit à petit en agitant à température ambiante pendant 30 min, puis le mélange est chauffé à reflux pendant 30 min. Après refroidissement, le milieu réactionnel est alcalinisé par NH_4OH 10% (pH = 9). Le solvant est évaporé et le résidu est extrait par $CHCl_3$. L'extrait chloroformique, lavé, séché sur Na_2SO_4 et évaporé à sec, abandonne un résidu pur en CCM de 3,34 g de l'amine **12** (rendement 91%). $C_{25}H_{24}O_4NCl$; RMN ^1H, $CDCl_3$, 60 MHz, δ : 2,56–3,46 (m, 6H, CH_2-3, CH_2-4 et CH_2-α), 3,78 (s, 3H, OMe-7), 5,06 (s, 2H, OCH_2-φ), 5,75 (s, 2H, OCH_2O-4',5'), 6,60 et 6,68 (2s, 2 × 1H, H-5 et H-8), 6,70 (s, 1H, H-6'), 6,80 (s, 1H, H-3'), 7,28–7,36 (m, 5H, $OCH_2C_6H_5$).

Méthoxy-2 benzyloxy-3 méthylènedioxy-9,10 tétrahydro-5,6,7,13 dibenzo[b,g]pyrrocoline, 13

Une solution d'amidure de sodium dans l'ammoniac liquide anhydre est préparée à partir de 7 g de Na, 250 mL de NH_3 liquide et une pointe de spatule de nitrate de fer. À cette solution de $NaNH_2$ est ajoutée sous agitation vigoureuse une solution de 3,2 g de l'amine chlorée **12** (7,3 mmol) dans 25 mL de THF anhydre. L'agitation est maintenue 3 h. NH_4Cl (16 g) est alors ajouté par petites fractions et on laisse l'ammoniac s'évaporer pendant la nuit. Le résidu est repris par 70 mL d'eau glacée et on extrait par $CHCl_3$. La solution chloroformique, lavée à l'eau, séchée sur K_2CO_3 et évaporée, livre 3,16 g du produit cyclisé **13**, impur en CCM. Connaissant l'instabilité de ce type de produit (19), sa purification est réalisée par une simple filtration rapide sur colonne (silice 60 H, élution par $CHCl_3$). On obtient ainsi 835 mg de la dibenzopyrrocoline **13** pure (rendement 29%). $C_{25}H_{23}O_4N$; RMN ^1H, $CDCl_3$, 60 MHz, δ : 2,98–3,70 (m, 6H, CH_2-5, CH_2-6 et CH_2-12), 3,83 (s, 3H, OCH_3-2), 5,01 (s, 2H, OCH_2-φ), 5,76 (s, 2H, OCH_2O-9,10), 6,23, 6,48, 6,56, 6,63 (4s, 4 × 1H, H-4, H-1, H-11, H-8), 7,33 (s large, 5H, $OCH_2C_6H_5$).

Méthoxy-2 benzyloxy-3 méthyl-7 méthylènedioxy-9,10 tétrahydro-5,6,7,13 dibenzo [b,g]pyrrocoline, 14

En raison de l'instabilité de l'amine **13**, celle-ci est méthylée aussitôt après sa purification. On dissout 320 mg (0,8 mmol) de **13** dans MeOH additionné de C_6H_6 pour améliorer la solubilité. À cette solution est ajouté 5 mL de CH_3I et le mélange bien bouché est laissé à température ambiante pendant 1 nuit. Le solvant est alors évaporé, abandonnant un résidu de 420 mg de **14** impur. Après chromatographie sur colonne (silice 60 H, élution par $CHCl_3$–MeOH 95 : 5 v/v), on isole 365 mg de l'iodure de dibenzopyrrocolinium **14** (rendement 75%). $C_{26}H_{26}O_4N^+,I^-$; SM (ie), *m/z* (%) : 401 (M^+ − 142, 61), 400 (15), 310 (16), 309 (7), 308 (15), 279 (10), 278 (17). *Anal.* calc. % : C 57,45, H 4,79, N 2,58; tr.% : C 57,32, H 4,60, N 2,45.

Méthoxy-2 hydroxy-3 méthyl-7 méthylènedioxy-9,10 tétrahydro-5,6,7,13 dibenzo[b,g]pyrrocoline, 7: (±)-cryptowolidine

On dissout 150 mg de **14** dans un mélange de 5 mL de MeOH et de 3 mL de HCl et la solution est chauffée au bain-marie pendant 10 min. Le résidu (115 mg) obtenu par évaporation à sec est purifié par chromatographie sur colonne (silice 60 H, élution par $CHCl_3$–MeOH 85:15 v/v); 75 mg de chlorure de cryptowolidine racémique pur **7** est obtenu (rendement 75%). Ce produit est identique au produit naturel (co-CCM, SM, RMN ^1H, IR, UV).

Remerciements

Les auteurs expriment leur gratitude aux Docteurs T. Sévenet et J. Pusset (CNRS, Noumea) et P. Cabalion (Centre ORSTOM, Noumea) pour la récolte du matériel végétal. Ils remercient les Professeurs W. C. Taylor (Université de Sydney) et T. Kametani (Université de Tohoku) pour l'envoi d'échantillons de *O*-méthylcryptowoline et de cryptowoline, ainsi que les Docteurs D. Davoust (Université P. et M. Curie, Paris), J. Mahuteau (Faculté de Pharmacie de Châtenay-Malabry) et T. Bécue (S.A.M.M., Faculté de Pharmacie de Châtenay-Malabry) pour l'enregistrement des spectres de RMN et de masse.

Reçu le 5 juillet 1988[4]

DANIEL HÉTU, JAIME LARA et JACQUES E. DESNOYERS. Can. J. Chem. **67**, 953 (1989).

Les vitesses du son ont été mesurées de façon à couvrir tout le domaine de miscibilité du système eau + 2-propanol + benzène. Les compressibilités isentropiques molaires apparentes du benzène et de l'eau ont été calculées à partir de ces données. Les compressibilités molaires apparentes du benzène et de l'eau présentent respectivement de grandes variations dans les régions riches en eau et en benzène, alors que les variations deviennent plus régulières dans la région intermédiaire. Ces résultats suggèrent qu'il se produit, aux deux extrémités du diagramme de phase, des micro-transitions analogues à la formation de micelles et de micelles inverses. L'absence de transition dans la région intermédiaire est, quant à elle, conforme au modèle bi-continu de microémulsion. Plus d'attention a été portée à la région riche en eau, où les compressibilités de transfert du benzène à dilution infinie, de l'eau aux mélanges eau + 2-propanol, ont été simulées à l'aide du modèle de Roux et coll. Cette simulation tend à confirmer que l'alcool et le benzène forment des agrégats mixtes.

Mots clés : compressibilité, système ternaire, microémulsion, eau, benzène, 2-propanol.

DANIEL HÉTU, JAIME LARA, and JACQUES E. DESNOYERS. Can. J. Chem. **67**, 953 (1989).

Sound velocities have been measured over the whole miscibility domain of the water + 2-propanol + benzene system. The apparent molar isentropic compressibilities of benzene and water were calculated from these data. The apparent molar compressibilities of benzene and water present large changes in the water-rich and benzene-rich regions, respectively, whereas the changes are smooth in the intermediate region. These results suggest that microtransitions similar to the formation of micelles and inverse micelles occur at the two ends of the phase diagram. The regularity of the intermediate region is consistent with a bicontinuous model of microemulsions. For the water-rich region, the compressibilities of transfer of benzene at infinite dilution, from water to water + 2-propanol mixtures, were simulated with the model of Roux and co-workers. This simulation tends to confirm that the alcohol and the benzene form mixed aggregates.

Key words: compressibility, ternary system, microemulsion, water, benzene, 2-propanol.

Introduction

Les alcools ont longtemps été reconnus comme des agents secondaires aidant à stabiliser les microémulsions. Toutefois, depuis quelques années, le rôle des alcools dans la formation et la stabilisation des microémulsions a fait l'objet de nombreuses études (1–4). Il a ainsi été démontré qu'un alcool pouvait en fait solubiliser à lui seul d'importantes quantités d'huile dans l'eau (5–7) et que les systèmes ainsi formés présentaient des propriétés physiques typiques des microémulsions (8, 9).

De curcroît, il y a maintenant de plus en plus de preuves démontrant l'existence de micro-phases dans les simples mélanges eau–alcool (10, 11). Leurs propriétés, en particulier leurs propriétés thermodynamiques, ressemblent aussi à plusieurs égards à celles des solutions micellaires (12). D'ailleurs, afin d'expliquer les propriétés thermodynamiques des systèmes eau–alcool, Roux et Desnoyers (13) ont récemment proposé un modèle très semblable à un modèle de micellisation.

Ces dernières années, la présente équipe s'est grandement impliquée dans l'étude du comportement d'additifs dans les systèmes micellaires. Une étude précédente a révélé que les volumes et les capacités calorifiques molaires apparentes du benzène, dans tout le domaine de miscibilité du système eau + 2-propanol + benzène (14), sont très semblables à ceux du toluène dans le système toluène + eau + *n*-butanol + dodécylsulfate de sodium. Ce dernier système est reconnu pour former des microémulsions (15). Les importantes transitions observées dans les régions riches en eau et en benzène du système eau + 2-propanol + benzène ont donc été expliquées par la formation de micro-agrégats du genre micelles et micelles inverses. Une autre étude des fonctions thermodynamiques de transfert du benzène, de l'eau aux mélanges eau + 2-propanol (16), a montré que ces fonctions présentaient de grandes similitudes avec les fonctions de transfert de certains solutés hydrophobes aux systèmes micellaires (17, 18), ce qui soutient l'idée que les alcools peuvent former des agrégats mixtes avec un soluté hydrophobe.

Compte tenu que la plupart des études thermodynamiques visant à comprendre l'effet d'un soluté hydrophobe sur un système micellaire ont été effectuées en utilisant l'approche des fonctions de transfert du soluté hydrophobe, de l'eau aux mélanges tensioactif, un modèle d'équilibre chimique permettant de simuler ces fonctions a été proposé (19–21). Ce modèle a été appliqué avec succès aux volumes et aux capacités de transfert du benzène (21) et d'alcools (19, 20), les paramètres thermodynamiques extraits à l'aide de ces simulations étant, lorsque la comparaison était possible, en excellent accord avec ceux obtenus à partir d'autres modèles théoriques semblables. Le modèle a aussi été appliqué aux volumes, aux enthalpies et aux

capacités calorifiques de transfert du benzène aux solutions aqueuses d'alcools (19), mais aucune simulation de compressibilités n'a à ce jour été publiée.

Afin de compléter l'étude du système eau + 2-propanol + benzène, les compressibilités de l'eau et du benzène dans tout le domaine de miscibilité sont présentées ici. L'analyse qualitative des résultats de cette démarche est appuyée par la simulation théorique des compressibilités de transfert du benzène à dilution infinie de l'eau aux mélanges eau + 2-propanol.

Conditions expérimentales

Les compressibilités isentropiques β_S, en bar^{-1}, ont été obtenues à partir des vitesses du son μ, en m s^{-1}, en utilisant la relation suivante :

$$[1] \quad \beta_S = 100/\mu^2 d$$

où d représente la densité des solutions en g cm^{-3}. Les mesures de vitesses du son ont été effectuées avec un vélocimètre Nusonic (Mapco, modèle 6105) basé sur la méthode du «sing around» (22, 23). Les vitesses du son ont été obtenues à partir des fréquences f avec la relation :

$$[2] \quad \mu = A(1 + \alpha t)/(7/f - 10^{-6}B)$$

où A et B sont des constantes de la cellule, α le coefficient d'expansion thermique de la cellule et t, la température en °C. les valeurs de A et B ont été obtenues par calibration de la cellule avec de l'eau, en utilisant les données de Del Grosso et Mader (24). Lors des mesures, la température a été maintenue à 25.00 ± 0.01°C à l'aide d'un bain à circulation SODEV et vérifiée avec un thermomètre à quartz Hewlett–Packard. Les densités ont été mesurées à l'aide d'un densimètre à écoulement SODEV, ou obtenues par interpolation à partir des données de l'étude antérieure sur les volumes du système benzène + 2-propanol + eau (14).

Les compressibilités isentropiques molaires apparentes ϕ_{KS} du composant 3, soit l'eau (W) ou le benzène (B), ont été obtenues en prenant, selon le cas, le mélange binaire eau + 2-propanol (W + P) ou 2-propanol + benzène (P + B) comme solvant de référence, le calcul se faisant à l'aide de l'équation :

$$[3] \quad \phi_{KS} = \beta_S\phi_v + (X_1M_1 + X_2M_2)(\beta_S - \beta_{S,0})/X_3d_0$$

où ϕ_V est le volume molaire apparent du soluté 3 dans le solvant mixte de densité d_0; X, la fraction molaire; M, la masse molaire; β_S et $\beta_{S,0}$ représentant respectivement les coefficients de compressibilité des systèmes ternaires et binaires. Les indices 1 et 2 réfèrent respectivement à W et P ou à P et B.

Comme ce fut le cas pour les volumes et les capacités calorifiques (14), les solutions ont été préparées gravimétriquement de façon à couvrir tout le domaine de miscibilité. La cellule était d'abord remplie avec un mélange binaire W + P ou P + B initial et le troisième constituant, W ou B, était ajouté par quantités pesées, directement dans la cellule, jusqu'à pleine capacité.

L'eau utilisée pour la préparation des solutions ainsi que comme solvant de référence a été distillée, déionisée (Continental deionized water system), filtrée sur filtre millipore 0.22 μm type GS et dégazée. Sa conductivité était en tout temps inférieure à 5×10^{-6} cm^{-1} Ω^{-1}. Le 2-propanol (Fisher Scientific) était de qualité Certifié ACS. Il a été gardé sur tamis moléculaire 4A (Davidson Chemicals) pour être filtré sur filtre millipore 0.22 μm juste avant son utilisation. Le benzène (Fisher Scientific) a subi le même traitement que le 2-propanol, mais était de qualité spectro-analysé.

Résultats

Toutes les données originales pour les compressibilités isentropiques molaires apparentes de B ($\phi_{KS,B}$) et de W ($\phi_{KS,W}$) dans tout le domaine de miscibilité du système W + P + B sont données sous forme de tableaux condensés.[5] Sont aussi incluses

5. On peut acheter ces tableaux en s'adressant au Dépôt des données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ontario), Canada K1A 0S2.

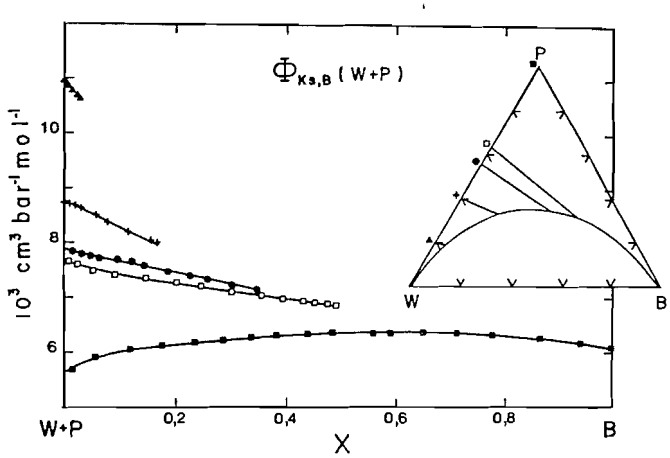

FIG. 1. Compressibilités isentropiques molaires apparentes du benzène dans le système ternaire eau–2-propanol–benzène en fonction de la concentration de benzène, à 25°C.

les données pour B à dilution infinie dans les mélanges W + P, dont les résultats ont déjà été publiés graphiquement (16). Les données de densité nécessaires pour le calcul des compressibilités sont disponibles ailleurs (14).

Les valeurs de $\phi_{KS,B}$ ont été portées en graphique en fonction de X_B à la figure 1, où les valeurs limites $\phi^0_{KS,B}$ (W + P) délimitent la fonction standard de B à dilution infinie ($X_B \rightarrow 0$) dans les mélanges W + P. Les trajets suivis dans le domaine de miscibilité sont montrés sur le diagramme de phase en surimpression, les concentrations des mélanges binaires W + P initiaux étant X_P = 1,00, 0,63, 0,56, 0,40 et 0,20. Pour ces concentrations, la solubilité de B est, relativement à la sensibilité des appareils, assez élevée pour permettre des mesures raisonnables. Compte tenu de la grande volatilité du benzène et de la difficulté à manipuler les solutions, la limitation de la précision des mesures provient donc essentiellement de la détermination de la concentration de B. Ainsi, en admettant une incertitude d'environ 1% sur X_B, l'erreur sur les valeurs de compressibilités de la figure 1 serait généralement de 1×10^{-5} cm^3 bar^{-1} mol^{-1}. L'erreur peut toutefois atteindre jusqu'à 0.2×10^{-3} cm^3 bar^{-1} mol^{-1} aux faibles concentrations de B. C'est par exemple le cas pour la détermination directe de la fonction standard de B à dilution infinie en fonction de X_P (16), où la concentration de B a été maintenue aussi faible que possible de façon à rendre l'effet de concentration de B négligeable, et où la solubilité de B à $X_P < 0,1$ devient particulièrement limitée. Compte tenu de la grandeur des changements observés, la précision des mesures est néanmoins largement suffisante.

Pour avoir un profil global du comportement du système étudié dans tout le domaine de miscibilité, les données de la figure 1 sont présentées sur un graphique tridimensionnel permettant de mettre les propriétés en relation avec le diagramme de phase. Ce type de graphique pour les propriétés apparentes de B est présenté à la figure 2. Dans ce diagramme, les valeurs de $\phi^0_{KS,B}$ (W + P) se retrouvent sur le plan gauche, les compressibilités molaires apparentes de B dans P, $\phi_{KS,B}$ (P), sur le plan de droite, la ligne pointillée de l'axe W + B représentant les compressibilités de B à la limite de la zone de miscibilité. Les lignes pâles allant de l'axe W + P vers B pur correspondent, comme à la figure 1, aux trajets suivis dans le domaine de miscibilité.

En général, les tendances observées pour les valeurs de compressibilités de la figure 2 ressemblent grandement à celles des volumes (14). Ainsi, dans la région riche en eau, les valeurs de $\phi_{KS,B}$ changent d'une façon très marquée avec X_P et X_B, attei-

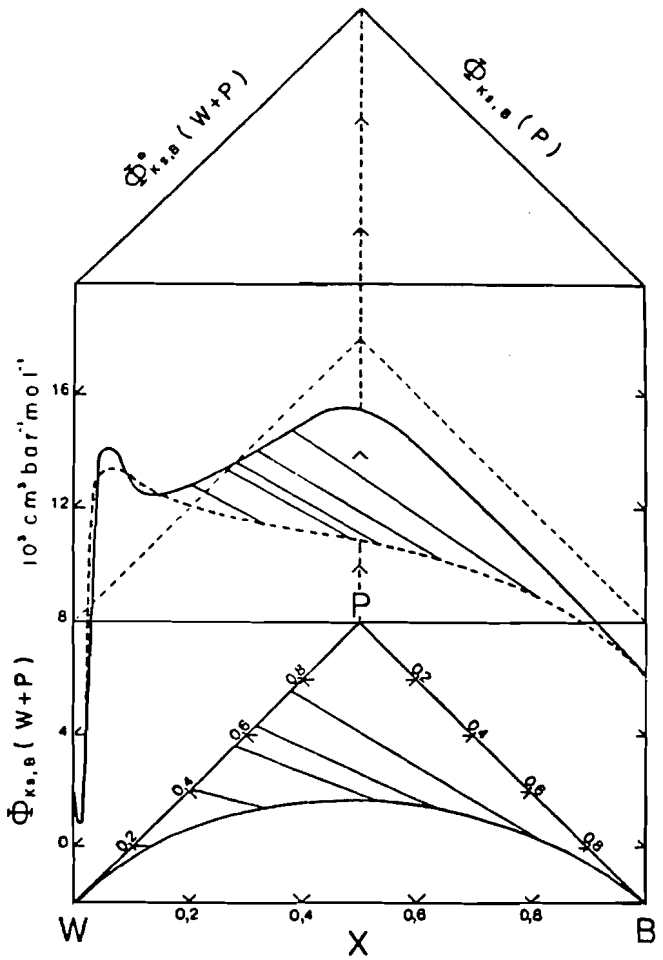

FIG. 2. Compressibilités isentropiques molaires apparentes du benzène sur toute la zone de miscibilité du système eau–2-propanol–benzène, à 25°C.

gnant un minimum aux environs de $X_P = 0{,}03$ et un maximum, particulièrement important lorsque X_B tend vers zéro, autour de $X_P = 0{,}05$. Il semble aussi exister une diminution accentuée des valeurs dans la région riche en P, mais les changements se font généralement plus réguliers dans la partie centrale du diagramme. Ainsi, sur l'axe W + B, soit le long de la limite de la zone de miscibilité, les valeurs tendent simplement vers la valeur de B pur, alors que sur l'axe B + P, les compressibilités changent presque idéalement, de la valeur standard à dilution infinie dans P pur, à la valeur molaire de B pur.

Dans la région riche en B, les valeurs de $\phi_{KS,B}$ sont peu sensibles aux changements, car les interactions sont imputées à un très grand nombre de molécules. Pour investiguer les changements structuraux de la région non-aqueuse, ce sont donc les compressibilités de l'eau, présente en petite quantité, qui sont examinées. Les résultats en fonction de la concentration d'eau, ainsi que les trajets suivis pour des mélanges initiaux P + B de concentrations $X_B = 0$, 0,09, 0,43 et 0,76 sont présentés à la figure 3.

Afin d'avoir un profil global de comportement dans tout le domaine de miscibilité, les $\phi_{KS,W}$ de la figure 3 ont, comme les $\phi_{KS,B}$, été reportés sur un diagramme en trois dimensions présenté à la figure 4. Comme dans le cas des volumes et des capacités calorifiques (14), les changements de l'axe W + P sont, comparativement aux $\phi_{KS,B}$, grandement amoindris, la seule variation d'importance se trouvant dans la région riche en

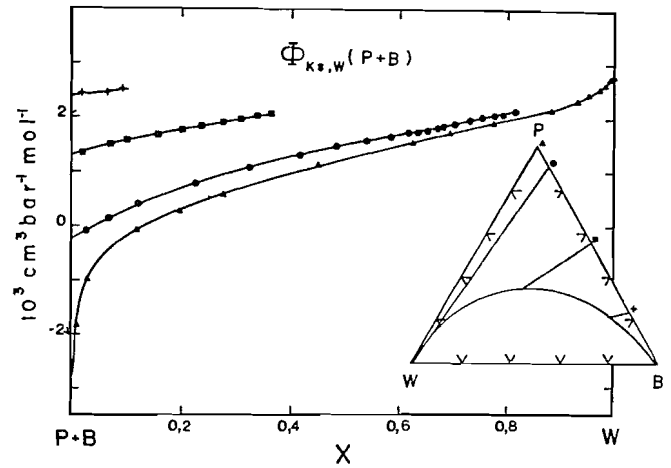

FIG. 3. Compressibilités isentropiques de l'eau dans le système ternaire eau–2-propanol–benzène en fonction de la concentration de l'eau, à 25°C.

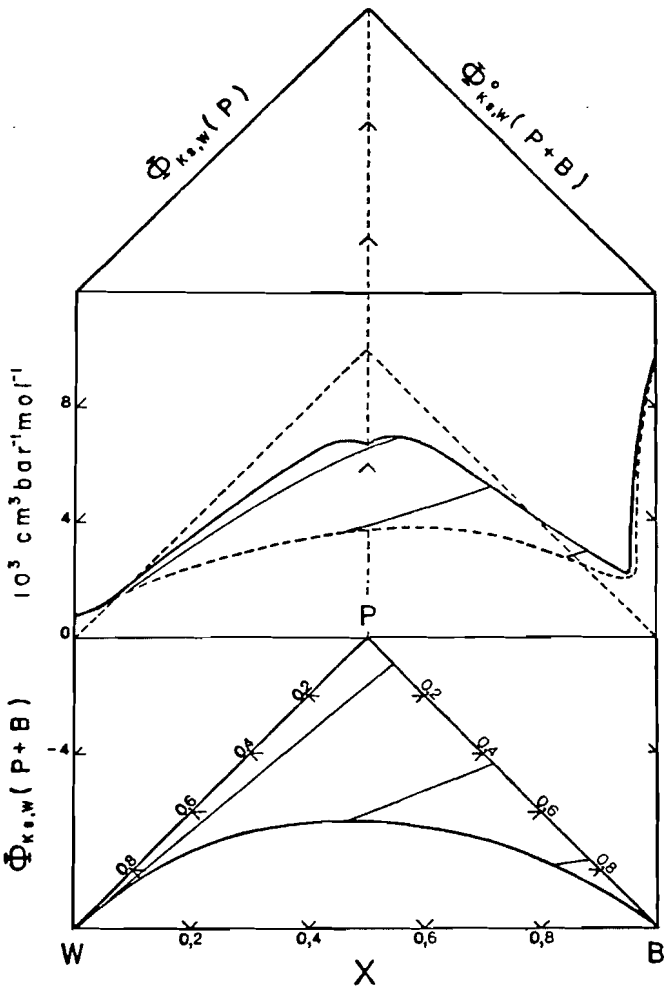

FIG. 4. Compressibilités isentropiques molaires apparentes de l'eau sur toute la zone de miscibilité du système eau–2-propanol–benzène, à 25°C.

B. Il est toutefois à noter qu'il existe encore ici une diminution accentuée des valeurs dans la région riche en P.

Discussion

En règle générale, le comportement des compressibilités mène aux mêmes conclusions que les volumes et les capacités calorifiques (14), à savoir qu'il existe d'importantes transitions

dans les régions riches en W et en B, correspondant respectivement à la formation d'agrégats de type huile dans l'eau et eau dans l'huile. De plus, en accord avec le modèle bi-continu de Scriven (25), la régularité des changements dans le reste du domaine de miscibilité tend à démontrer qu'il y a coexistence de ces deux types d'agrégats et non un changement abrupt d'une forme à l'autre à une composition donnée.

À la figure 2, il est visible que, dans les mélanges B + P, le benzène se comporte à peu près idéalement. La présence de traces d'eau dans ces mélanges aurait donc comme effet d'orienter les molécules de P, par établissement de liens hydrogène entre l'eau et les groupements −OH de P, de façon à en promouvoir l'association. Il en résulterait la formation d'agrégats de type eau dans l'huile, ce dont témoigne le signe inversé de la transition des $\phi_{KS,W}$ (P + B) de la région riche en B, figure 4, comparativement au $\phi_{KS,B}$ (W + P) de la région riche en eau, figure 2. La promotion de la structure de P par l'eau se confirme de plus par l'analyse des compressibilités de l'eau dans les mélanges binaires W + P de la région riche en alcool, dont la courbe est présentée à la figure 3. Bien que plutôt faible à la figure 2, où il n'y a qu'une légère accentuation dans la variation des valeurs de $\phi_{KS,B}$, l'accentuation dans les valeurs de $\phi_{KS,W}$ de la région riche en P est très évidente et résulte certainement de la formation d'ilots plus structurés de P au coeur du solvant. Cette interprétation est en conformité avec l'idée d'agrégats inverses, où les groupements −OH des alcools seraient orientés vers les molécules d'eau se trouvant alors enfermées au coeur de ces agrégats.

L'axe W + P de la figure 2 est celui qui est le plus affecté par les transitions. Aussi, afin d'analyser les transitions de la région riche en eau, les compressibilités de transfert standard de B de l'eau mélanges W + P, $\Delta K^0_{S,B}$ (W→W + P), ont, comme les volumes (21), été simulées à l'aide du modèle de Roux et coll. (19, 20). Ce modèle a été prévu pour décrire le comportement d'un soluté hydrophobe peu soluble dans l'eau, lorsqu'il est transféré de l'eau aux solutions aqueuses d'un tensioactif nonionique. Ceci permet ainsi de vérifier si le P a un comportement associatif analogue à celui des tensioactifs.

Selon ce modèle, l'allure générale des courbes de fonctions de transfert peut s'expliquer par trois principales contributions : (1) les interactions hydrophobes par paire entre les monomères du soluté transféré et ceux du tensioactif; (2) le partage du soluté transféré entre l'eau et les micelles du tensioactif; (3) le déplacement d'équilibre du tensioactif, induit par l'action du soluté transféré. Dans le cas des propriétés dérivées secondes de l'enthalpie libre, comme la compressibilité, la courbe est généralement plus complexe et une quatrième contribution, dite de relaxation et dépendant de la propriété dérivée première, doit aussi être considérée. Ainsi, la courbe des compressibilités de transfert peut être reproduite à partir de l'équation suivante :

$$[4]\quad \Delta K_3(\mathrm{W}\rightarrow \mathrm{W}+2) = 2\alpha\beta B_{K,AB} m_2 + (m_2/m_3)(\alpha_0-\alpha)(K_{A'}-K_A) + (1-\beta)(K_{B'}-K_B) - (m_2/m_3)\times\left(\frac{\partial\alpha_0}{\partial P}-\frac{\partial\alpha}{\partial P}\right)(V_{A'}-V_A) + (V_{B'}-V_B)\frac{\partial\beta}{\partial P}$$

Dans cette équation, m_2 et m_3 sont respectivement les molalités du soluté principal et du soluté transféré, $B_{K,AB}$ est la pente d'interaction hydrophobe par paire entre les monomères A du soluté 2 et B du soluté 3, P étant la pression. $K_{A'}$ et $K_{B'}$ représentent respectivement les compressibilités molaires des solutés 2 et 3 dans les micelles ou agrégates, K_A et K_B les compressibilités molaires dans la phase aqueuse, alors que $V_{A'}$, $V_{B'}$, V_A et V_B symbolisent les volumes molaires des différentes espèces. Finalement α et β sont les fractions de monomères des solutés 2 et 3 restant dans la phase aqueuse, le 0 en indice indiquant les valeurs pour les systèmes binaires des solutés dans l'eau. Les valeurs de α et β sont obtenues en résolvant, par itération, les deux équations suivantes conditionnant l'équilibre

$$[5]\quad -(1/n)\ln K_M = \ln \alpha m_2 - (1/n)\ln[(1-\alpha)m_2/n] + X_{B'}$$

$$[6]\quad -\ln K_D = \ln(\beta m_3/X_{B'}) + X_{B'} - 1$$

Dans ces équations, K_M représente la constante d'équilibre du processus d'aggrégation du soluté 2, K_D la constante de distribution du soluté 3 entre l'eau et les micelles ou agrégats, n le nombre d'agrégation, R la constante des gaz parfaits, T la température en Kelvin et $X_{B'}$ la fraction molaire du soluté 3 dans les agrégats, définie comme :

$$[7]\quad X_{B'} = \frac{(1-\beta)m_3}{(1-\beta)m_3 + (1-\alpha)m_2}$$

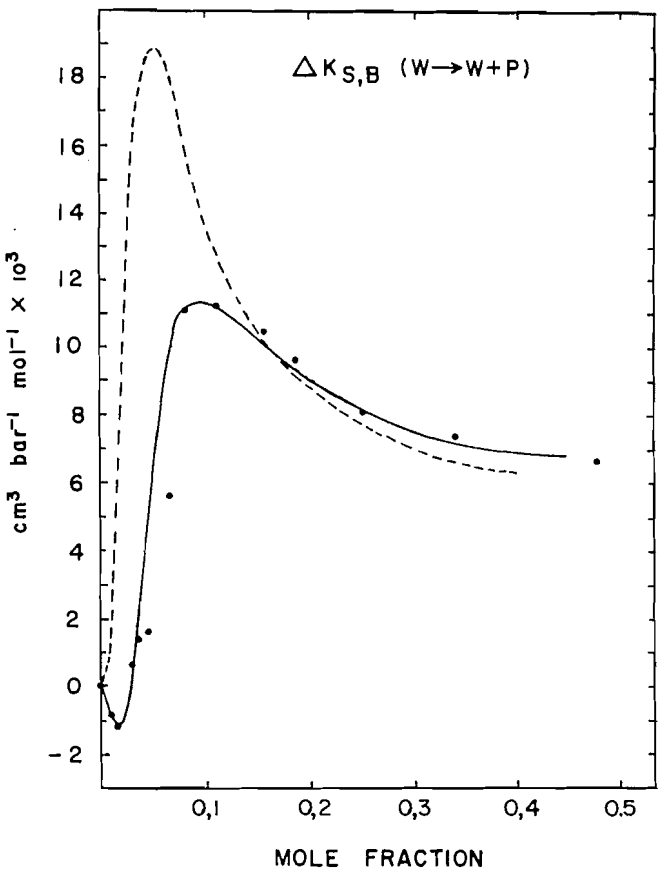

FIG. 5. Simulations des compressibilités isentropiques de transfert du benzène à dilution infinie, de l'eau aux mélanges eau–2-propanol, à 25°C. (---) simulation idéale; (—) simulation ajustée.

Les points expérimentaux et les simulations sont présentés à la figure 5. Les valeurs expérimentales de $\Delta K_{S,B}$ (W→W + P) ont été calculées en soustrayant systématiquement la valeur du $\phi^0_{KS,B}$ (W) de B à dilution infinie dans l'eau, soit (1,9 ± 0,2) × 10^{-3} cm^3 bar^{-1} mol^{-1}, des valeurs de la fonction standard de B à dilution infinie dans les mélanges W + P. Les simulations, représentées par la ligne pleine et la ligne pointillée, ont été effectuées à partir des paramètres du tableau 1, où leur prove-

nance est indiquée. Il faudrait toutefois préciser que la molalité à l'inflexion m_I et le nombre d'agrégation n du système binaire W + P ont été obtenus en simulant la courbe des volumes molaires apparents du P dans l'eau à l'aide du modèle de micellisation de Roux et coll. (28), pour les systèmes binaires eau–tensioactif, considérant que l'alcool a un comportement associatif similaire à celui d'un tensioactif. La valeur de 4 obtenue pour m_I correspond bien à ce qui est observé expérimentalement. Il faudrait cependant considérer que le nombre d'agrégation de 4 obtenu n'a qu'une signification qualitative montrant que le P n'a tendance à former que de très petits agrégats, probablement très labiles. Compte tenu du nombre d'agrégation de 10 obtenu par Quirion[6] pour le butoxy-2 éthanol, utilisant plusieurs techniques, la valeur de 4 pour le P semble néanmoins très réaliste, d'autant plus que la tendance montre que des alcools plus petits comme l'éthanol et le méthanol présenteraient des nombres d'agrégation très voisin de zéro.

La ligne pointillée représente la simulation idéale obtenue en négligeant les interactions hydrophobes par paire et en assumant que le benzène se partage, entre la phase aqueuse et les micelles, comme il le ferait entre l'eau et une phase pure de benzène. Cette simulation implique donc que la constante de distribution K_D est simplement évaluée par l'inverse de la solubilité S de B dans l'eau, alors que la compressibilité molaire de B dans les agrégats, $K_{S,B'}$, est simplement donnée par la compressibilité molaire de B pur, $K^{*}_{S,B}$. Cette simulation prédit bien l'allure générale de la courbe. Toutefois, comme le démontre son pauvre accord quantitatif avec les données expérimentales, la solution ne se comporte visiblement pas d'une façon aussi idéale que ne l'impliquent ces approximations. Aussi, afin de rendre cette analyse plus quantitative, la constante de distribution K_D et la fonction de micellisation de B $\Delta K^{M}_{S,B}$ ont été ajustées de façon à tenir compte des diverses sources secondaires de non-idéalité du processus d'agrégation. De plus, la pente initiale tenant compte des interactions hydrophobes par paire dans la phase aqueuse a été considérée, celle-ci ayant été évaluée par régression linéaire des points expérimentaux de la partie linéaire de la région diluée. La simulation obtenue, qui est représentée à la figure 5 par la ligne en trait plein, est quantitativement en accord avec les données expérimentales.

Au tableau 1, la valeur obtenue pour le $\Delta K^{M}_{S,B}$ ajusté, soit la variation entre la compressibilité de B dans les agrégats et sa compressibilité dans l'eau, est sensiblement la même que la valeur idéale. Par contre, la valeur ajustée de K_D, 4,4, est environ 10 fois plus faible que l'inverse de la solubilité, ce qui confirme bien la faible valeur de 1,8 obtenue par la simulation des volumes (21). Bien que de nature semi-quantitative, ces résultats tendent néanmoins à démontrer que le B se retrouve essentiellement dans un milieu très semblable à une phase pure de B, mais que ce milieu lui est beaucoup moins accessible qu'une phase pure. Comme l'ont démontré Abuin et Lissi (31), lorsque la fraction molaire du soluté intra-micellaire $X_{B'}$ atteint 0,5, les valeurs de K_D chutent abruptement pour tendre vers une nouvelle valeur. Ainsi, compte tenu du faible nombre d'agrégation moyen de P rapporté au tableau 1, $X_{B'}$ tendrait rapidement vers 0,5, les agrégats se saturant rapidement et restreignant ainsi l'accès à des molécules supplémentaires. Il y aurait donc formation de micro-phases de B stabilisées par quelques molécules de P, où les molécules de B seraient en grande partie en contact avec d'autres molécules de B et isolées de l'eau par les molécules de P, ce qui est caractéristique des microémulsions (32).

Conclusion

L'analyse des compressibilités isentropiques molaires apparentes de B et de W dans tout le domaine de miscibilité du système W + P + B tend, à l'instar des volumes et des capacités calorifiques, à démontrer l'existence d'agrégats mixtes de B et de P de type huile dans l'eau dans la région riche en eau du diagramme de phase et de type eau dans l'huile dans la région riche en B, le passage d'une forme à l'autre se faisant graduellement, conformément à un modèle bi-continu de microémulsion. Cette analyse est appuyée par le fait que les compressibilités de transfert de B, de l'eau aux solutions aqueuses de P, peuvent être simulées à l'aide d'un modèle destiné aux transferts de solutés hydrophobes dans les systèmes micellaires, les paramètres obtenus montrant que les agrégats formés présentent des caractéristiques de microémulsions.

Reçu le 17 octobre 1988

ABDALLAH ALBOURINE, MICHELLE PETIT-RAMEL, GERMAINE THOMAS-DAVID et JEAN-JACQUES VALLON. Can. J. Chem. **67**, 959 (1989).

Les constantes de protonation de la 1-canavanine (Can) et de son analogue structural, la 1-arginine (Arg) ont été calculées à 25°C et à force ionique $\mu = 0{,}1$ ($NaNO_3$). Dans les mêmes conditions, les constantes de stabilité des complexes binaires et ternaires formés avec le cuivre(II) ont été déterminées par potentiométrie, complétée par des mesures spectrophotométriques et de dichroïsme circulaire dans le domaine du visible. Cette étude comparative de ces deux aminoacides a permis de mettre en évidence une différence d'ordre de protonation des trois groupements fonctionnels (carboxylique, aminé et guanidyle) qui se traduit par une différence de mode de complexation avec le cuivre(II) situé dans un état de coordinence octaédrique : l'arginine se comporte comme un ligand bidenté (type glycine) alors que la canavanine se comporte comme un ligand tridenté.

Mots clés : 1-arginine, 1-canavanine, dichroïsme circulaire, coordination ternaire du cuivre, potentiométrie.

ABDALLAH ALBOURINE, MICHELLE PETIT-RAMEL, GERMAINE THOMAS-DAVID, and JEAN-JACQUES VALLON. Can. J. Chem. **67**, 959 (1989).

The protonation constants of 1-canavanine (Can) and its structural analogue 1-arginine (Arg) have been calculated at 25°C and at ionic strength $\mu = 0.1$ ($NaNO_3$). Under the same conditions, the stability constants of the binary and ternary complexes with Cu(II) have been determined by potentiometry, spectrophotometry, and by circular dichroïsm in the visible region. A comparative study of these two amino acids allows us to differentiate the order of protonation of the three functional groups (carboxylic, amino, and guanidyl), mainly by the different modes of complexation with copper(II), which is found in an octahedral coordination: arginine behaves like a bidentate ligand (glycine type) whereas canavanine behaves like a tridentate ligand.

Key words: 1-arginine, 1-canavanine, circular dichroïsm, copper ternary coordination, potentiometry.

Introduction

La qualité biologique des protéines varie avec leur teneur en acides aminés essentiels. Si les protéines animales représentent le «haut de gamme» dans cette échelle de valeur, il ne faut pas moins négliger l'apport important que constituent les protéines végétales rencontrées dans la plupart des noix, légumes et racines comestibles. Que ce soit pour l'alimentation de l'homme (soja) ou celle de l'animal (luzerne), l'utilisation des protéines végétales tend à s'amplifier au fil des années et dans ce contexte nous nous sommes intéressés à un amino acide de soja et de luzerne (alfalfa), la 1-canavanine.

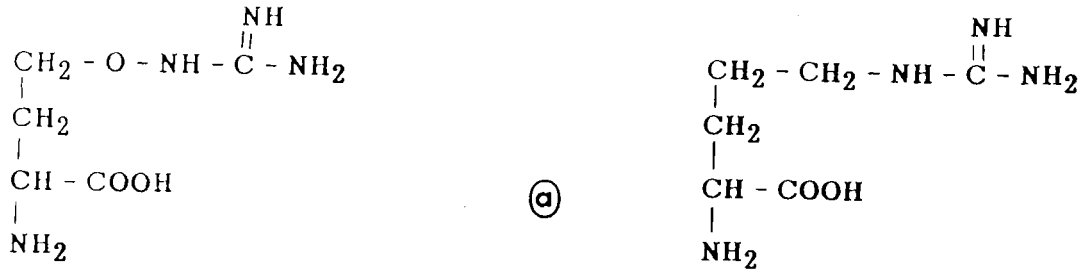
La 1-canavanine ou acide amino-2 (guanidinoxy)-4 butyrique, analogue structural de la 1-arginine (figure 1a) a été isolée en 1929 à partir de farine de «jack bean» (*Canavalia ensiformis*) par T. Tomiyama et coll. (1).

Bien que la détection de la 1-canavanine dans diverses plantes alfalfa, soja trèfle... ait intéressé de nombreux auteurs (2–4), très peu d'études fondamentales relatives à ses modes de protonation et de chélation ont été abordées (5, 6). Ceci semble d'autant plus anormal que sa ressemblance structurale avec la 1-arginine, aminoacide bien connu des chimistes de coordination, lui confère une certaine toxicité liée à deux mécanismes : inhibition des enzymes du métabolisme de l'arginine et dénaturation des propriétés fonctionnelles des protéines où elle se trouve incorporée (3, 7). Ceci justifie l'intérêt du contrôle de qualité qui devrait permettre de vérifier l'absence de la canavanine dans les protéines végétales destinées à l'alimentation humaine ou animale.

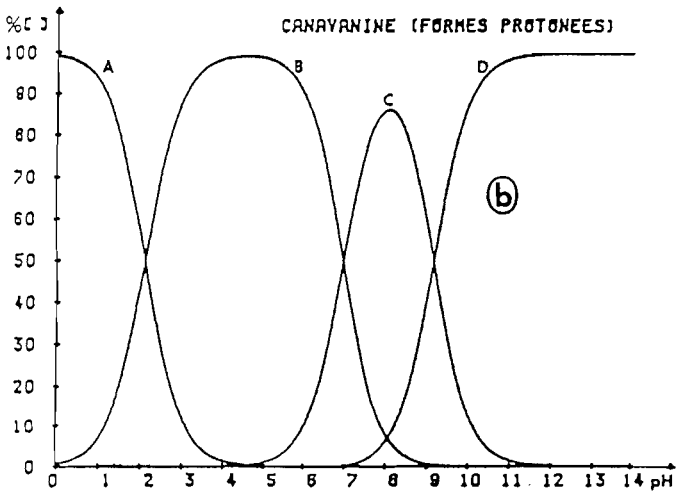
Dans le but de mettre en évidence les caractéristiques particulières de la 1-canavanine ligand, et de ses complexes avec le cuivre, nous procéderons à une étude potentiométrique complétée par des mesures d'absorbance et de dichroïsme circulaire dans le domaine du visible.

Pour chacune des techniques utilisées, nous nous attacherons à établir une comparaison avec le comportement de la 1-arginine et à dégager les paramètres caractéristiques utilisables pour une détection ultérieure. En outre, dans le cas où les deux ligands seraient extraits simultanément il nous a semblé particulièrement souhaitable de compléter cette étude par l'examen du complexe mixte ternaire qui pourrait se former avec le métal choisi à titre d'exemple.

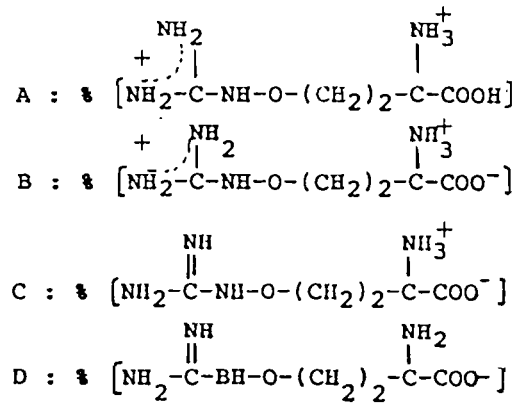
Nous définirons par β_{pqrs} la constante de stabilité globale d'une espèce complexe de formule générale : $M_pH_qL_rL'_s$ où M représente l'atome métallique central, H l'atome d'hydrogène, L et L′ les deux ligands susceptibles de complexer le métal. Cette formule est régie par l'équilibre :



$$pM + qH + rL + sL' \rightleftarrows M_pH_qL_rL'_s$$



$$[1] \quad \beta_{pqrs} = \frac{[M_pH_qL_rL'_s]}{[M]^p[H]^q[L]^r[L']^s}$$



Lors de la neutralisation nous pourrons définir le nombre moyen de protons neutralisables par mole de ligand :

$Cu(Arg)_2$	1002	13,83 (0,01)	6,39	pH 3,5–10		6,10	6,64
Cu–Can–Arg	1011	14,30 (0,08)		pH 5,5–10			

*Écart-type correspondant aux constantes.

$$[2] \quad \bar{q} = \frac{C_H - [H] - [OH]}{C_L}$$

où C_L est la concentration du ligand; [H] et [OH] sont respectivement les concentrations en H^+ et OH^- à l'équilibre; C_H est la concentration en protons telle que $C_H = qC_L - B$; B est la concentration de l'hydroxyde ajouté.

En ce qui concerne l'étude spectroscopique, la mesure d'une grandeur additive quelconque X, variable au cours de la chélation, prend en compte les contributions secondaires dues au métal et aux autres espèces libres du coordinat.

$$[3] \quad X = l(\sum_0^n X_n[ML_n] + \sum_0^p X'_p[H_pL])$$

où l est la longueur de la cuve, X_n et X_p sont respectivement les facteurs intensifs des complexes ML_n et des différentes formes du coordinat L associé, suivant sa basicité, à p protons.

Les méthodes utilisées, absorption lumineuse et dichroïsme circulaire, permettent d'éliminer partiellement ou totalement certaines contributions parasites. La mesure de l'absorption lumineuse dans le visible d'un complexe coloré permet d'annuler l'absorbance molaire du coordinat libre n'absorbant que dans l'ultra-violet (amino acide); seul subsiste le terme relatif au métal x_0[M] d'accès facile. Plus intéressant est le dichroïsme circulaire pour lequel x_0[M] inactif est nul et qui donne accès à une mesure directe de la formation du complexe.

Résultats

1. Protonation

Au regard du nombre important de travaux concernant l'arginine, il faut souligner que les quelques travaux recensés dans la littérature laissent encore très ouvert le champ des investigations fondamentales sur l'étude du ligand canavanine. Dès 1935, Tomiyama (5) avait donné des valeurs très approchées des constantes apparentes de dissociation de la canavanine sulfatée. Beaucoup plus tard, en 1981, Boyar et Marsh (6) ont recalculé ces paramètres à partir des valeurs expérimentales de Tomiyama. Cette démarche ne nous paraissant pas satisfaisante, nous avons repris ces déterminations sur la l-canavanine sulfatée d'une part et la l-canavanine «free base» d'autre part.

La transformée de la courbe de neutralisation conduit aux valeurs moyennes ($\bar{q}$) de protons neutralisables par mole de ligand. Pour les deux qualités de ligand, cette valeur tend vers 3. Ceci est en bonne concordance avec l'examen des formules précédentes qui font ressortir trois groupements fonctionnels susceptibles d'être protonés. Après affinement de 160 couples de valeurs ($\bar{q}$, pH) répartis sur plusieurs concentrations (canavanine sulfatée : 2×10^{-3} M, 10^{-3} M; canavanine free base : 2×10^{-3} M et 10^{-3} M), les constantes de protonation sont rassemblées dans le tableau 1, les courbes de répartition de chaque forme protonée apparaissent sur la figure 1b.

L'ordre de protonation est bien connu pour la l-arginine (8) et concerne successivement les groupements carboxylique, aminé et guanidyle. Alors que pour la l-canavanine, si la dissociation du groupement aminé NH_3^+/NH_2 reste situé à pH 9, le groupement guanidyle semble se déprotoner vers pH 7 en accord avec les conclusions de Boyar et Marsh (6).

2. Complexation binaire : cuivre–canavanine et cuivre–arginine

A. Mesures potentiométriques

Pour chaque système cuivre–canavanine et cuivre–arginine, deux rapports des concentrations ont été étudiés : ligand : métal = $1,92 \times 10^{-3}$ M : $7,68 \times 10^{-4}$ M d'une part et $1,92 \times 10^{-3}$ M : $4,05 \times 10^{-4}$ M d'autre part. Le tableau 1 donne les constantes de stabilité des complexes successifs ML et ML_2 par affinement des valeurs expérimentales issues des deux premières constantes de protonation dans le cas de l'arginine (le cuivre étant généralement complexé dès pH 9) et des trois constantes de protonation dans le cas de la canavanine, puisque les trois groupements se déprotonent dans le domaine de complexation du cuivre. Nous obtenons les courbes de répartition représentées sur les figures 2a et 2b.

B. Mesures spectroscopiques

Pour une solution $5{,}05 \times 10^{-3}$ M en cuivre(II) et $1{,}25 \times 10^{-3}$ M en canavanine sulfatée, nous faisons varier le pH entre 2,1 et 8,9 en enregistrant chaque fois le spectre d'absorption dans un domaine de longueur d'onde compris entre 500 et 800 nm. Le faisceau de spectres représenté sur la figure 2c montre la formation graduelle des complexes ML et ML_2 (tableau 1) avec l'accroissement du pH, le complexe ML_2, plus stable, provoquant un déplacement hypsochromique d'environ 120 nm par rapport au cuivre.

De pH 2 à pH 4, seule l'espèce ML est formée et présente une faible absorbance.

Au voisinage de pH 4,5, un point isobestique apparaît à 720 nm, ce qui confirme l'existence de deux complexes en équilibre absorbant identiquement à cette longueur d'onde. Au delà de pH 8,9 nous n'observons aucune modification des spectres; le complexe ML_2 est entièrement formé et présente pour la canavanine un maximum d'absorption à 640 nm.

En ce qui concerne le système cuivre–arginine nous pouvons citer l'étude partielle faite par Phan *et al.* (8); dans un souci d'homogénéité il nous a semblé utile de refaire et compléter ces mesures dans les conditions expérimentales utilisées pour la canavanine.

Le maximum d'absorption du complexe ML_2 pour l'arginine est situé à 620 nm et le point isobestique à 710 nm (figure 2d), ce qui concorde avec les résultats de Phan *et al.* (8).

Pour ces deux maxima : 640 nm pour la canavanine et 620 nm pour l'arginine, l'expression [4] reliant l'absorbance totale à l'absorbance molaire de chaque contribution permet de calculer par affinement les facteurs intensifs de chaque complexe (tableau 2).

$$[4] \quad X = l(\sum_{0}^{n} X_n[ML_n])$$

Les solutions étudiées par dichroïsme circulaire contiennent $2{,}5 \times 10^{-3}$ M en 1-canavanine et $1{,}01 \times 10^{-3}$ M en cuivre(II) d'une part et 5×10^{-3} M en 1-arginine et $2{,}02 \times 10^{-3}$ M en cuivre(II) d'autre part, soit un rapport ligand : métal = 2,5. Le domaine d'étude en longueur d'onde est de 400 à 800 nm (figures 2e et 2f). Nous observons deux faisceaux de spectres comparables à ceux obtenus par spectrophotométrie. Ils correspondent à la réponse directe des complexes métalliques ML et ML_2 (tableau 1) puisque le cuivre non complexé ne possède pas de dichroïsme circulaire.

Un extremum négatif apparaît à 616 nm pour la 1-canavanine alors que pour la 1-arginine, il est situé à 595 nm.

La figure 3e représente la variation du dichroïsme circulaire molaire $\lvert\Delta\varepsilon\rvert$, en fonction du pH.

En fin de complexation l'intensité dichroïque molaire du système cuivre(II)–1-canavanine est nettement supérieure à celle du système cuivre(II)–1-arginine. Le dichroïsme circulaire molaire de chaque forme complexée est représenté dans le tableau 2 et conduit à deux remarques :

(*i*) Comme ceci a déjà été montré dans le cas d'autres ligands (9), l'effet Cotton correspondant aux espèces ML est nettement inférieur à celui des espèces ML_2; l'intensité dichroïque croît notamment avec le nombre de cycles de chélation et par là-même, avec le degré de coordination du complexe.

(*ii*) D'autre part, la comparaison des dichroïsmes circulaires molaires de chaque espèce ML ($\lvert\Delta\varepsilon\rvert_{Cu-Can} = -0{,}105$ trente fois supérieur à $\lvert\Delta\varepsilon\rvert_{Cu-Arg} = -0{,}003$) laisse prévoir deux modes de coordination différents liés aux nombres de cycles (figures 4a et 4b).

3. Complexation ternaire : cuivre–canavanine–arginine

A. Mesures potentiométriques

Plusieurs rapports ont été étudiés pour le système cuivre : canavanine : arginine, 1 : 1 : 1, 1 : 2 : 2, 1 : 2 : 1 et 1 : 1 : 2. Une valeur approchée de la constante de stabilité du complexe mixte ternaire est donnée par l'expression [5] :

$$[5] \quad \log X_{11} = 2 \log \beta_{1011} - (\log \beta_{1020} + \log \beta_{1002})$$

où β_{1011} : constante globale du complexe Cu–Can–Arg; β_{1020} : constante globale du complexe $Cu(Can)_2$; β_{1002} : constante globale du complexe $Cu(Arg)_2$; $\log X_{11}$: renforcement de stabilité par chélation mixte (10). Pour les amino acides, $\log X_{11}$ est généralement voisin de 0,2 d'où $\beta_{1011} = 1{,}2 \times 10^{14}$. Cette valeur est affinée de la même manière que pour les systèmes simples et nous avons : $\beta_{1011} = 2{,}00 \times 10^{14}$ soit $\log \beta_{1011} = 14{,}30$.

Le renforcement de stabilité apparaît nettement puisque $\log \beta_{1011}$ est supérieur à $\log \beta_{1020}$ et $\log \beta_{1002}$. La répartition des espèces est donnée pour les rapports les plus favorables à l'obtention du complexe mixte : Cu : Can : Arg = 1 : 1 : 1 (figure 3a) et 1 : 2 : 2 (figure 3b).

B. Mesures spectroscopiques

L'examen des spectres d'absorption visible correspondant au rapport Cu : Can : Arg = 1 : 2 : 2 (figure 3c) permet de localiser un maximum d'absorption à 632 nm, soit une valeur intermédiaire entre les deux maxima des complexes simples : 640 nm pour $Cu(Can)_2$ et 620 nm pour $Cu(Arg)_2$. En accord avec les observations de Mecca et coll. (11) et Petit-Ramel et Pâris (12) on peut avancer que ce maximum correspond bien au complexe mixte Cu–Can–Arg dont l'absorbance molaire est donnée dans le tableau 2.

Sur la figure 3d est représenté le spectre dichroïque du complexe mixte rapport Cu : Can : Arg = 1 : 1 : 1 (B) à pH = 9,65 avec un maximum d'absorption dichroïque à 604 nm ainsi que les spectres des complexes simples : cuivre–1-canavanine

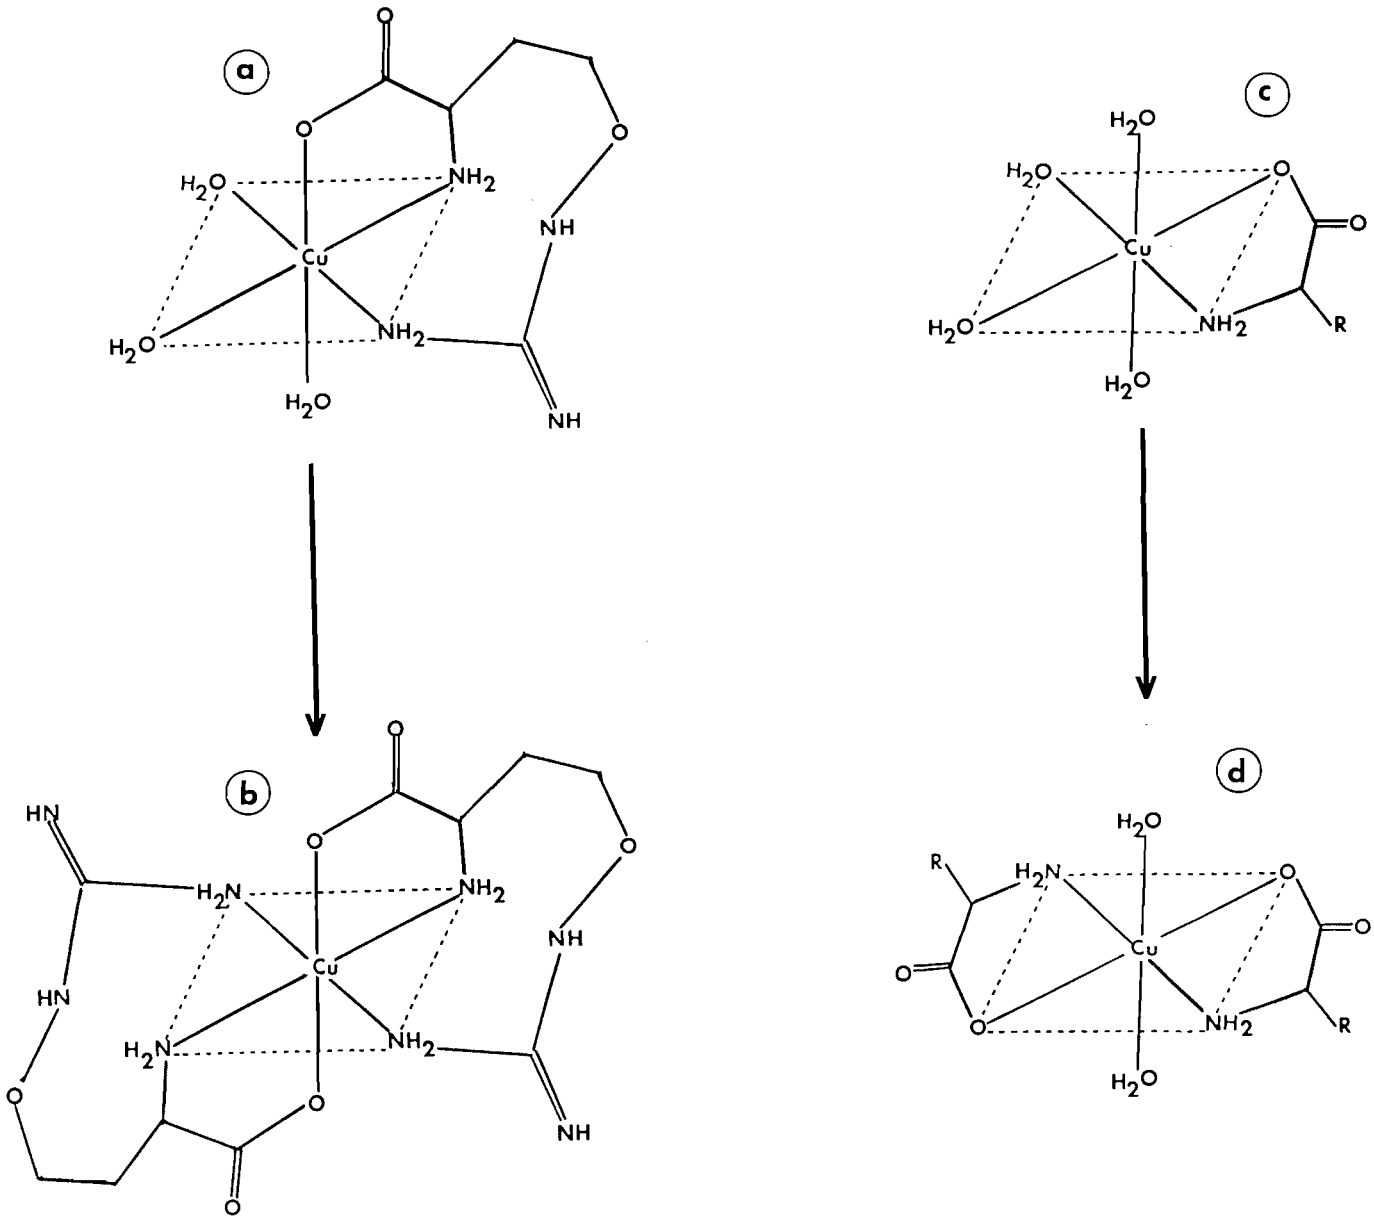

FIG. 4. Mode de complexation des systèmes 1-canavanine–cuivre(II) et 1-arginine–cuivre(II); R = $(CH_2)_3$—NH—C(=NH)—NH_2. (a) Cu–Can; (b) $Cu(Can)_2$; (c) Cu–Arg; (d) $Cu(Arg)_2$.

(C) à pH = 9,70 et cuivre–1-arginine (A) à pH = 9,72 dont les maxima sont respectivement 616 nm et 595 nm.

Comme dans le cas des mesures spectrophotométriques le maximum d'absorption dichroïque du complexe mixte Cu–Can–Arg prend une valeur intermédiaire entre les deux maxima des complexes simples correspondants. Pour ces valeurs de pH, nous sommes en présence de quatre types de complexes pour lesquels nous avons déterminé les $|\Delta\varepsilon|$ molaires à 604 nm : Cu–Can, 13%, $|\Delta\varepsilon|_{604} = 0{,}085$, $Cu(Can)_2$, 18%, $|\Delta\varepsilon|_{604} = -0{,}210$, $Cu(Arg)_2$, 24,5%, $|\Delta\varepsilon| = -0{,}122$ et Cu–Can–Arg, 44,5%. Il est donc aisé d'obtenir la valeur correspondant à l'espèce mixte (tableau 2).

Discussion

L'étude potentiométrique préalable de la 1-canavanine et de la 1-arginine a mis en évidence une différence notable au niveau de l'ordre de déprotonation des groupements guanidyle et aminé. Dans le cas de la canavanine, le groupement guanidyle se déprotone en effet avant le groupement aminé ($pK = 6{,}98$), alors que pour l'arginine, il se déprotone bien au-delà ($pK = 11{,}85$). La conséquence directe de ce phénomène se traduit par des modes de complexation différents (figure 4) vis à vis du cuivre(II) dans le domaine de pH considéré ($2 < pH < 10$). La 1-arginine se comporte comme un coordinat bidenté (type glycine), sans déprotonation du groupement guanidyle. La 1-canavanine, au contraire, se comporte comme un coordinat tridenté (type histidine) puisque le groupement guanidyle se déprotone.

La spectrophotométrie et surtout le dichroïsme circulaire illustrent encore cette différence dans le mode de chélation. La densité optique varie en effet comme la «force de covalence» de la liaison métal–coordinat (13), liée au nombre de cycles

de chélation. La comparaison des absorbances molaires, plus tranchée pour les espèces ML, met en évidence une covalence plus importante pour la 1-canavanine que pour la 1-arginine. Ce phénomène apparaît encore plus nettement avec le dichroïsme circulaire : lors de la complexation, il existe avec les amino acides un effet vicinal dû à la modification d'activité optique du ligand. L'effet Cotton correspondant dépend principalement de la mobilité conformationnelle du ligand et augmente avec le nombre de cycles de chélation (14). Nos observations recoupent parfaitement ces conclusions dans la mesure où le dichroïsme circulaire des formes complexées ML (un cycle de chélation) est toujours inférieur à celui des complexes ML_2 (deux cycles de chélation). De même le dichroïsme circulaire des complexes ML et ML_2 de la 1-arginine, bidentée (respectivement un et deux cycles de chélation) est toujours inférieur à celui des espèces ML et ML_2 formées avec la 1-canavanine tridentée (respectivement deux et quatre cycles de chélation).

En ce qui concerne la chélation mixte ternaire du cuivre(II) avec ces deux amino acides, l'étude potentiométrique, illustrée par les courbes de répartition des figures 3a et 3b montre bien l'existence d'un complexe mixte Cu–Can–Arg qui se forme majoritairement (environ 50% pour le rapport 1 : 2 : 2) au détriment des deux complexes simples $Cu(Can)_2$ et $Cu(Arg)_2$ et nous avons l'équilibre suivant

$$Cu(Can)_2 + Cu(Arg)_2 \rightleftarrows 2Cu\text{–}Can\text{–}Arg$$

Dans ce cas, la spectrophotométrie et surtout le dichroïsme circulaire présentent des maxima d'absorption dont les longueurs d'onde sont intermédiaires par rapport à celles des deux complexes binaires. Ceci confirme encore une fois les résultats obtenus par potentiométrie.

Nous avons signalé dans l'introduction que la détection de la canavanine dans les produits naturels et possible par CLHP. Les premières mesures que nous avons effectuées à l'aide de cette technique s'avèrent encourageantes notamment après extractions multiples. Mais le protocole de mesure CLHP nécessite un intermédiaire dérivé d'orthophtaldialdehyde/ethanethiol peu stable, qui peut avoir une incidence sur la reproductibilité des mesures. D'autre part les premiers spectres de dichroïsme circulaire que nous avons enregistrés sur l'extrait naturel complexé par le cuivre(II), concordent parfaitement avec les spectres dichroïques de canavanine–cuivre étudiés précédemment.

Dans un premier temps, une détection rapide peut donc être effectuée directement sur l'extrait.

L'utilisation conjointe de la CLHP et du dichroïsme circulaire devrait se traduire par une amélioration sensible de la détection de la canavanine dans les produits naturels.

Partie expérimentale

Matériel

Nous disposons d'une chaîne de mesures étalonnée avec précision :

électrode de verre | solution thermostatée | KCl saturé | électrode calomel

Le jeu d'électrodes est relié à un potentiomètre ISIS 20000 Tacussel et les mesures sont effectuées sur des solutions aqueuses thermostatées à 25 ± 0,1°C et sous atmosphère d'azote. La force ionique de chaque solution est maintenue constante à l'aide d'une solution de $NaNO_3$ 0,1 M.

Les spectres d'absorption sont tracés à l'aide d'un spectrophotomètre Varian 634 et les spectres dichroïques à l'aide du dichrographe Jobin-Yvon Mark IV. Les cuves Hellma sont en quartz et ont un trajet optique de 1 cm pour l'absorption et de 5 cm pour le dichroïsme circulaire dans le domaine du visible.

Réactifs

La canavanine utilisée est sous deux formes : 1-canavanine sulfatée (Sigma) et 1-canavanine free base (Sigma). L'arginine est sous forme free base (Sigma). Ces amino acides sont conservés constamment à basse température.

Le sel métallique est introduit sous forme de nitrate de cuivre(II) : $Cu(NO_3)_2,3H_2O$ (Prolabo) dissous dans de l'eau distillée et dont le titre est déterminé par un dosage complexométrique à l'EDTA préalablement dosé à l'aide d'une solution titrisol de zinc(II).

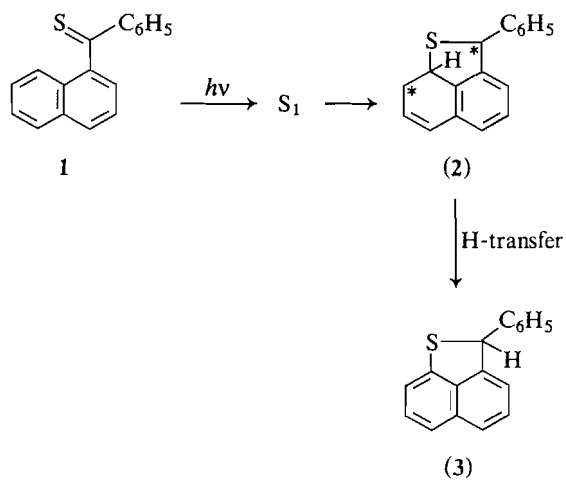
1-Thiobenzoylnaphthalene (TBN), known for its pericyclization reaction from the lowest excited singlet state (S_1), has been subjected to nanosecond and picosecond laser flash photolysis studies. The two major transients observed in the course of nanosecond laser pulse excitation are (*i*) the short-lived triplet characterized by two absorption maxima (400–410 and 740–750 nm) and submicrosecond intrinsic lifetimes (80–130 ns) and (*ii*) a relatively long-lived species (λ_{max} = 520 nm and τ = 220–240 ns). Various triplet-related photophysical data of TBN, including self-quenching and bimolecular quenching rate constants, have been determined. The existence of a photochemical path from S_1 manifests itself in low intersystem crossing quantum yields, particularly in the polar/hydrogen-bonding solvent, methanol. From the build-up of the triplet under picosecond excitation into S_1, the lifetime of the latter is estimated to be $\leq$50 ps (in benzene). The fast intrinsic decay of TBN triplet is attributable to facile intra- and intermolecular photochemistry. The 520 nm transient species could not be definitively assigned, except that it is neither a triplet nor a triplet-derived product and that it arises via photochemistry from S_1.

Key words: laser flash photolysis, triplet, transients, absorption maxima, lifetimes, quenching rate constants, photochemistry, 1-thiobenzoylnaphthalenes.

R. MINTO, A. SAMANTA et P. K. DAS. Can. J. Chem. **67**, 967 (1989).

Le thiobenzoyl-1 naphtalène (TBN), bien connu pour sa réaction de péricyclisation à partir de l'état singulet excité le plus bas (S_1), a été soumis à des études de photolyses flash au laser à la nanoseconde et à la picoseconde. Les deux intermédiaires majeurs observés au cours de l'excitation pulsée au laser à la nanoseconde sont: (*i*) le triplet de courte vie caractérisé par deux maxima d'absorption (400–410 et 740–750 nm) et des temps de vie intrinsèques inférieurs à la microseconde (80–130 ns) et (*ii*) une espèce dont la vie est relativement longue (λ_{max} = 520 nm et τ = 220–240 ns). On a déterminé diverses données photochimiques reliées à l'état triplet du TBN, dont les constantes de vitesse d'auto-piégeage et de piégeage bimoléculaire. L'existence d'une voie photochimique à partir de l'état S_1 se manifeste par des rendements quantiques faibles pour le passage entre les systèmes, particulièrement dans le méthanol, un solvant polaire pouvant former des liaisons hydrogènes. En se basant sur l'accumulation de l'état triplet dans des conditions d'excitation de l'état S_1 au niveau de la picoseconde, on peut évaluer le temps de vie de ce dernier à $\leq$50 ps (dans le benzène). On attribue la dégénérescence intrinsèque rapide du triplet du TBN à une photochimie intra- et inter-moléculaire facile. On n'a pas pu déterminer d'une façon définitive la nature des espèces intermédiaires à 520 nm; on peut toutefois affirmer qu'il ne s'agit ni d'un produit triplet ni d'un produit dérivé d'un triplet et qu'il se forme d'une façon photochimique à partir de l'état S_1.



Mots clés : photolyses flash au laser, triplet, intermédiaires, maxima d'absorption, temps, constantes de vitesse de piégeage, photochimie, thiobenzoyl-1 naphtalène.

Introduction

The photochemistry and photophysics associated with the lowest triplet (T_1) and the second excited singlet (S_2) states of thiocarbonyl compounds have received considerable attention in recent years (3–7). The T_1 states in thioketones are invariably assigned to be of (n,π^*) character. At millimolar concentrations of substrates in fluid solutions at room temperature, the triplets decay with lifetimes in the submicrosecond time domain; the major part of the shortening of T_1 lifetimes arises from diffusion-controlled self-quenching (5–17). On the other hand, the S_2 states originate from $\pi \rightarrow \pi^*$ transitions and are characterized by subnanosecond lifetimes (18–21). For a given thioketone, both S_2 and T_1 states have usually been implicated in biomolecular interactions of physical and chemical consequences.

In continuation of our interest in time-resolved behaviors of aliphatic and aromatic thione triplets as observable by nanosecond laser flash photolysis (10–16), we have carried out a study of 1-thiobenzoylnaphthalene (TBN, **1**). Discovered by de Mayo and co-workers (22), an interesting photochemical reaction of this thioketone as well as similar polycyclic aromatic thiones containing a free peri position is the photocyclization leading to thiophene derivatives. This is shown in Scheme 1. In contrast to the majority of thione photoreactions which take place from S_2 or T_1 states, de Mayo *et al.* (22) have shown that

the photocyclization in the case of **1** occurs from the lowest excited singlet state (S_1) of (n,π*) character. Furthermore, they suggested the involvement of a dipolar intermediate (**2**) in the course of the cyclization process. The main objective of the present laser flash photolysis study of TBN was to shed light on the mechanism of this interesting S_1-mediated pericyclization reaction. Furthermore, TBN provided us with an example of aromatic thiones with a substantially low triplet energy (E_T = 39 kcal mol^{-1}). It was of interest to examine in detail various triplet-related properties of TBN in the context of those of related aromatic thiocarbonyl systems studied earlier (10–16).

Experimental

1-Thiobenzoylnaphthalene (TBN), prepared by a literature procedure (23), was obtained as a gift from Dr. V. Ramamurthy. It was recrystallized from toluene. The solvents used in spectroscopy and kinetics studies were all of spectral grades. The sources and methods of purification of reagents are given in earlier papers (10–16) from the Radiation Laboratory. For removal of oxygen from solutions, high-purity argon was bubbled through them.

The steady-state absorption and emission spectra were recorded in a Cary 219 spectrophotometer (1 nm bandpass) and an SLM spectrofluorimeter (24), respectively. In the latter instrument, a right-angle geometry was used for the excitation and observation of emission. The phosphorescence spectra at 77 K were obtained from solutions taken in 3 mm × 3 mm square quartz cells immersed in liquid nitrogen contained in a finger Dewar. A red-sensitive photomultiplier tube (Hamamatsu R928) enabled emission spectral measurements at long wavelengths (≤850 nm).

For nanosecond laser flash photolysis, use was made of the following two pulsed laser sources: Molectron UV-400 nitrogen (337.1 nm, ~8 ns, 2–3 mJ/pulse), and Quanta-Ray DCR-1 Nd:YAG coupled with Quanta-Ray PDL-1 dye (355, 532, and 640 nm, ~6 ns, 5–50 mJ/pulse). The laser intensities were attenuated in accordance with the ground-state absorbance of the thioketone solutions at a given laser excitation wavelength. The details of kinetic spectrophotometers, data collection systems, and experimental procedures are available elsewhere (10–16, 24, 25).

The picosecond laser flash photolysis was carried out in a system from Quantel. The laser excitation wavelengths were 355 and 532 nm (pulse width ~18 ps). The apparatus has been described in a recent paper (26).

Results

(a) *Absorption and emission spectra*

Millimolar solutions of TBN in cyclohexane, benzene, and methanol are bluish in appearance and are characterized by four well-defined absorption band systems in the spectral region 200–700 nm. The absorption spectra in cyclohexane are shown in Fig. 1 (parts *A*, *A'*, and *A''*). The lowest-energy band system at 500–700 nm is weak in intensity (ϵ_{max} = 130–140 M^{-1} cm^{-1}), and undergoes a blue shift on going from cyclohexane (or benzene) to methanol. This band system is characteristic of thiocarbonyl compounds in general and is assignable to the lowest-lying excited singlet state (S_1) of (n,π*) origin. The next higher-lying singlet state (S_2) has its absorption maxima at 370–378 nm; calculated from the peak locations, the energy gap between S_1 and S_2 for TBN in cyclohexane is 10 898 cm^{-1}. Table 1 summarizes the wavelength maxima and extinction coefficient data of TBN in various solvents.

At room temperature, cyclohexane solutions of TBN show a weak emission at 400–550 nm (see Fig. 1*B*). The location of this emission suggests that it originates from the S_2 state (see Fig. 1). This is not uncommon; by virtue of large S_1–S_2 gaps (azulene-like), many thioketones exhibit moderately intense S_2 emissions, particularly in solvents that do not strongly interact with the S_2 state (e.g., perfluoroalkanes) (18–20). In benzene and methanol, the S_2-emission from TBN becomes too weak to be discerned under steady-state excitation in our setup; its presence, however, becomes noticeable under laser pulse excitation.

The phosphorescence spectra of TBN in 3-methylpentane glass at 77 K were measured and were found to occupy the spectral region >700 nm (see Fig. 1*C*). From the portion of the spectra we were able to monitor at 700–850 nm, two component bands are evident. The spacing between them is 1 270 cm^{-1}. The triplet energy (E_T) is estimated to be 39 kcal mol^{-1}. It should be noted that most of our data concerning absorption and phosphorescence spectra of TBN are in reasonable agreement with those reported by Cox *et al.* (22).

(b) *Nanosecond laser flash photolysis*

TBN was subjected to detailed nanosecond laser flash photol-

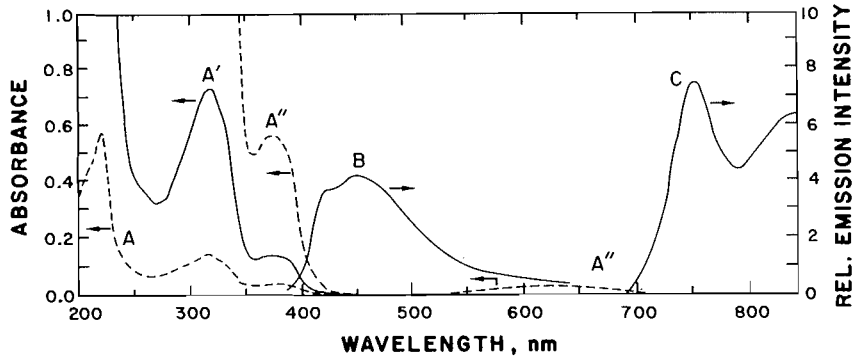

FIG. 1. Absorption (A, A', and A''), S_2-fluorescence (B), and phosphorescence (C) spectra of TBN. Solvents: cyclohexane for A, A', A'', and B, and 3-methylpentane for C. Temperatures: 295 K for A, A', A'', and B, and 77 K for C. Bandpass: 1 nm for the absorption spectra and 16 nm for both excitation and emission monochromators used for fluorescence and phosphorescence spectra. The absorption spectra A, A', and A'' were measured with 1.0, 0.25, and 0.050 nM TBN in cells of 2 mm pathlength.

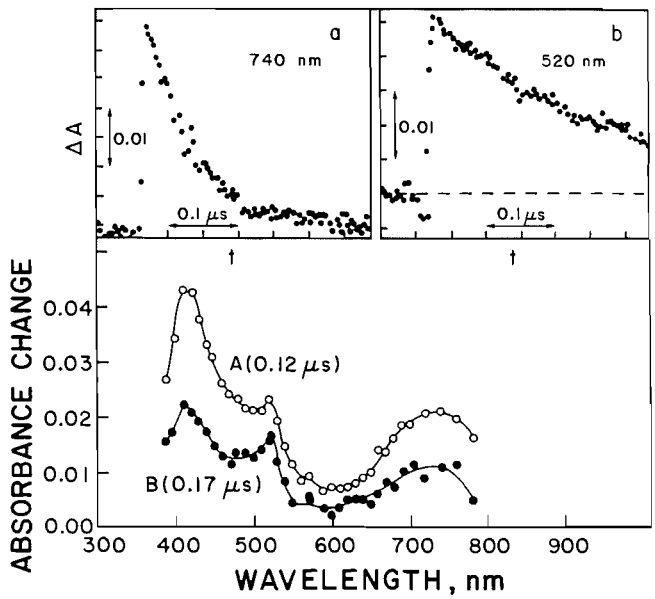

FIG. 2. Transient absorption spectra observed at (A) 0.12 and (B) 0.17 μs following 355 nm laser pulse excitation of 0.5 mM TBN in benzene. Insets: a representative kinetic traces for transient absorption decay at (a) 740 and (b) 520 nm.

ysis studies using 337.1, 355, 532, and 640 nm as laser excitation wavelengths. In the course of the pulse photoexcitation, we observed a short-lived transient species characterized by submicrosecond lifetimes and absorption spectra consisting of two maxima at 400–410 and 730–740 nm. In addition, the formation of a second species with slightly longer lifetimes and absorption maxima at 520 nm was noted. The transient spectra and representative decay traces in benzene are shown in Fig. 2. The efficient quenching of the first transient by oxygen, nitroxy radicals, ferrocene, and azulene, as well as the fact that its quenching by *all-trans*-1,6-diphenyl-1,3,5-hexatriene (DPH) led to the formation of DPH triplet, strongly suggested a triplet assignment for it. Furthermore, as expected for a thioketone triplet, this transient was quenched by TBN ground state with bimolecular rate constants in the limit of diffusion control. By following procedures described in earlier papers (12–16), we determined the triplet-related photophysical data, namely, triplet–triplet extinction coefficients (ϵ_{max}^T), intrinsic triplet lifetimes (τ_0^T), triplet yields (ϕ^T), and self-quenching rate constants (k_{SQ}^T). These data are presented in Table 1.

The bimolecular rate constants (k_q^T) for the quenching of TBN triplet in benzene by various quenchers (Q) were determined from the slopes of the linear plots of observed, pseudo-first-order rate constants (k_{obs}) vs. [Q]. These are given in Table 2. For comparison, in the same table, the corresponding data for 4,4'-dimethoxythiobenzophenone (DMTBP) and xanthione (XT) are also quoted from our previous work (10).

The effect of TBN triplet quenching by oxygen in benzene was examined in terms of singlet oxygen ($^1O_2^*$, $^1\Delta_g$) generation. In particular, the efficiency (ϕ_Δ^T) of $^1O_2^*$ production in the course of the quenching was measured under 640 nm laser pulse excitation. DMTBP was used as the reference ($\phi^T = 1$, $\phi_\Delta^T = 1$) (10) and $^1O_2^*$ was monitored via its reaction with 1,3-diphenylisobenzofuran (DPBF) leading to the bleaching of the ground state absorption of the latter. A series of benzene solutions of TBN and DMTBP, optically matched at 640 nm and containing DPBF at 0.04 mM and oxygen at varying concentrations (1.91–9.12 mM), were flash-photolyzed in 2 mm cells and the negative absorbance changes (ΔA_D^∞) due to DPBF depletion were monitored at 425 nm following the completion of the bleaching process (over ~100 μs). The double reciprocal plots of $1/\Delta A_D^\infty$ vs. $1/[O_2]$, shown in Fig. 3, were reasonably linear. If the thioketone triplets were the only photosensitizers for $^1O_2^*$ under the conditions of our experiments, the intercept-to-slope ratios of these plots were expected to give the corresponding ($k_q^T\tau_T$) values. Based on Figs. 3A and B, we obtained intercept-to-slope ratios of 150 and 170 M^{-1} for TBN and DMTBP, respectively. These results, combined with the triplet lifetimes (τ_T) of 38 and 55 ns as observed in the solutions of TBN and DMTBP respectively (under deoxygenated conditions), gave $k_{O_2}^T$ as 3.9×10^9 and 3.1×10^9 M^{-1} s^{-1}, respectively. These values are in close agreement with $k_{O_2}^T$'s measured via direct triplet quenching by O_2 (3.3×10^9 and 3.7×10^9 M^{-1} s^{-1}, respectively). Thus, the triplets are established to be the primary photosensitizing species leading to singlet oxygen. From the comparison of the reciprocals of the intercepts of the plots for the two thioketones in Fig. 3, the product ($\phi^T \cdot \phi_\Delta^T$) for TBN is estimated to be 0.8 ± 0.2. Since ϕ^T of TBN in benzene is 0.7 ± 0.1, this result indicates that the efficiency of $^1O_2^*$ sensitization by TBN triplet is essentially quantitative.

The behavior of the second transient with absorption maximum at 520 nm (see Fig. 2) was examined in various solvents. In benzene, its quenching by oxygen (≤9.1 mM) ferrocene (≤5.0 mM) and ground-state TBN (≤5.0 mM) was negligible. This ruled out the assignment of the transient as a triplet.

TABLE 2. Bimolecular rate constants for the quenching of 1-thiobenzoylnaphthalene (TBN), 4,4'-dimethoxythiobenzophene (DMTBP), and xanthione (XT) triplets in benzene at 295 K

Quencher	Maximum concentration used (m*M*)	$k_q^{T\,a}$ ($10^9\ M^{-1}\ s^{-1}$) TBN	DMTBP	XT
Oxygen	5.5	3.3	3.7	2.8
Di-*tert*-butylnitroxide	7.6	3.1	1.4	3.0
2,5-Dimethyl-2,4-hexadiene	87.5	0.23	0.27	1.4
Azulene	4.0	3.6	4.6	8.2
Ferrocene	5.1	5.6	6.7	9.8

[a] ±15%. The data for DMTBP and XT are taken from ref. 10.

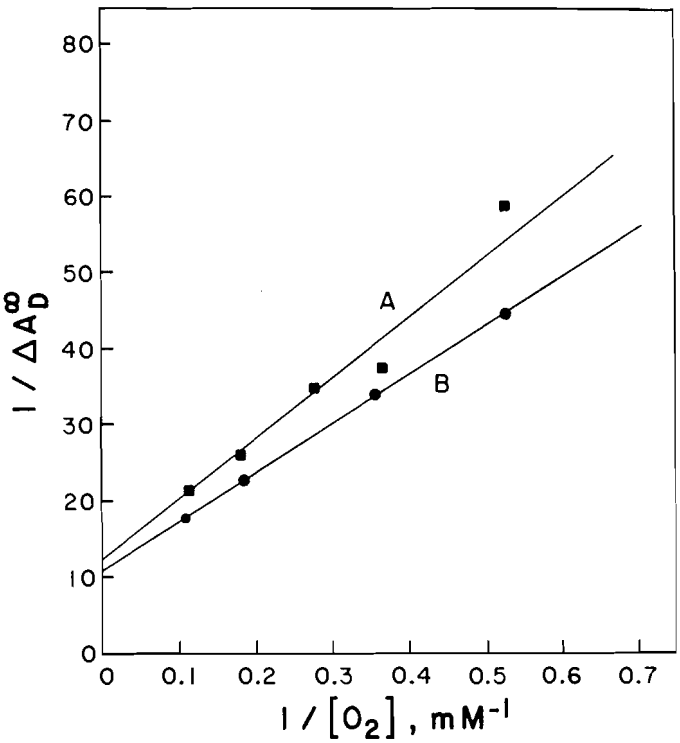

FIG. 3. Double reciprocal plots of $1/\Delta A_D^\infty$ vs. $1/[O_2]$ for (*A*) TBN and (*B*) DMTBP in benzene. ΔA_D^∞ is the absorbance change due to DPBF depletion, monitored at 425 nm, as a result of the reaction of DPBF with $^1O_2$* (see text).

Furthermore, the quenching of TBN triplet by oxygen and ferrocene did not cause a proportionate reduction in the yield of the 520 nm transient, suggesting that the latter was not a triplet-mediated product. The lifetime and relative yield of the 520 nm transient, measured in four different solvents (Table 3), were essentially independent of the nature of the solvent. Also, in methanol, it was found to be nonquenchable by perchloric acid (added up to 0.12 *M*).

Practically no residual absorption was observed following the decay of TBN triplet and the 520 nm transient in benzene, methanol, or cyclohexane. Thus, intermediate **2** (Scheme 1), if formed in high yields, could not possibly be a species with strong absorption in the visible and a lifetime longer than a microsecond.

(*c*) *Picosecond transient absorption studies*

In order to shed light on S_1 and S_2 lifetimes, benzene solutions

TABLE 3. Lifetimes and relative yields of 520 nm transient in various solvents (λ_{ex} = 337.1 nm)

Solvent	τ, ns[a]	Relative yield[b]
Benzene	230	1.0 (1.0)
Cyclohexane	220	1.1 (0.8)
Acetonitrile	230	0.9 (0.8)
Methanol	220	0.9 (0.8)

[a] ±10%.

[b] Measured in solutions (otpically matched at laser excitation wavelength) from end-of-pulse transient absorbance changes at 520 nm. The numbers in the parentheses are from 532 nm laser excitation, and those not parenthesized are from 337.1 nm excitation. ±20%.

of TBN were excited by 18 ps laser pulses at 355 and 532 nm. Note that while the latter wavelength corresponds to excitation into the S_1 band system, the former leads to absorption into the higher-energy side of S_2 band system and possibly lower vibronic levels of S_3 (see Fig. 1). Within 50–100 ps of the excitation at both wavelengths, transient absorption spectra were noted at 400–660 nm; these were comparable to those of the triplet observed in the course of nanosecond flash photolyses. Note that the short wavelength portion of the spectra (near 400 nm) in picosecond measurements was unreliable because of the low intensity of the probe light. Since the formation of the triplet was essentially complete within ~50 ps of the excitation at both wavelengths, lifetimes ≤50 ps could be associated with both S_1 and S_2 excited states of TBN in benzene. No additional prominent absorption that could be attributed to intermediate **2** (Scheme 1) was apparent in the picosecond time scale.

Discussion

(*a*) *Assignment of observed transients*

The triplet assignment for the major species with absorption maxima at ~405 and 745 nm is straightforward on the basis of its quenching behavior (see the Results section) and needs no further elaboration. In this connection, mention may be made of the laser flash photolytic observation by Cox *et al.* (22) of TBN triplet monitored at 550 nm (λ_{ex} = 353 nm). For 0.89 m*M* TBN in cyclohexane, they measured a triplet decay rate of 1.41×10^7 s^{-1}. Based on our τ_T and k_{SQ}^T data in cyclohexane (Table 1), we calculate a value of 1.3×10^7 s^{-1} for the triplet decay under the given conditions. The agreement between the data from the two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

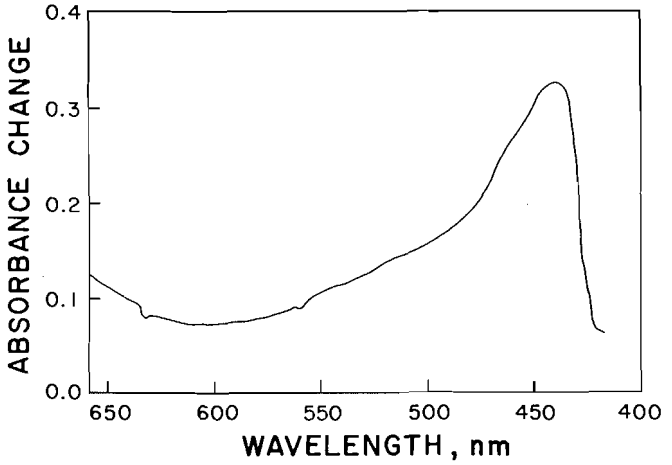

FIG. 4. Transient absorption spectrum at 50 ps following ~18 ps laser pulse excitation (532 nm) of TBN in benzene.

laboratories is satisfactory. Furthermore, in benzene, Cox *et al.* (22) measured a unimolecular triplet decay rate of $(1.0 \pm 0.1) \times 10^7$ s^{-1} and a triplet self-quenching rate constant (k_{SQ}^T) of 1.8×10^9 M^{-1} s^{-1}. While the former value is not very different from the one determined in the present work, the latter is lower (Table 1). It should be noted that as evident from the triplet absorption spectrum (Fig. 2), the monitoring wavelength of 550 nm used in ref. 22 is well removed from either of the maxima.

In view of the observed photochemistry of TBN (Scheme 1), it is tempting to assign the second transient (λ_{max} = 520 nm, Fig. 2) as the S_1-mediated photointermediate **2**. However, several experimental observations do not conform to this assignment. First, the 520 nm transient is not quenched by acids; this goes against its dipolar character (as tentatively proposed for **2** by Cox *et al.* (22)). Second, the yield of this species is not affected by the polarity of solvents (Table 3). On the contrary, the quantum yield of the photocyclization (Scheme 1) has been shown to increase on going from nonpolar to polar solvents (namely, by factors of 2 to 2.5 on going from benzene to acetonitrile and 4:1 acetonitrile:acetic-acid mixture) (22). Third, although the relatively sharp band at 520 nm is detected at an early stage following nanosecond pulse excitation into S_1 (e.g., by laser pulses at 532 nm), it is not discernible in the picosecond absorption spectra in the course of picosecond excitation at the same wavelength (Fig. 4). This rules out the 520 nm species as an S_1-derived product as primary as the triplet.

At the current level of our understanding, it is not possible to give a definitive identification for the 520 nm species, except that it arises via photochemistry from S_1.

(b) Triplet state behaviors. Comparison with other aromatic thiones

In terms of diffusion-limited self-quenching, submicrosecond triplet lifetimes, high triplet yields (in nonpolar solvents), quantitative singlet oxygen sensitization by triplet, and efficient bimolecular quenching by various quenchers, TBN triplet exhibits general similarities to aromatic and aliphatic thiocarbonyl triplets studied earlier (10–16). However, a few significant differences are also noticeable. These are discussed below.

The triplet yields of TBN, obtained by photoexcitation into S_1, are considerably less than unity. This is particularly true for the polar/H-bonding solvent, methanol, in which ϕ_T is only 0.4. Such a low ϕ_T has not been observed for any of the aromatic thiones previously studied (10, 11, 16). It seems logical to attribute the low ϕ_T to photochemistry, especially, the path described in Scheme 1. However, the quantum yields of the photocyclization have been measured (22) to be low ($(1.2–3.0) \times 10^{-3}$) in various solvents. If the photocyclization is the only photoreaction responsible for loss of quanta from S_1, then the ring opening of the intermediate **2** leading to the ground state has to be highly efficient (as proposed by Cox *et al.* (22)).

The intrinsic triplet lifetimes (τ_0^T) of TBN are much shorter than those of related aromatic thiones. In view of the fact that the solvents used are of "reactive" nature (e.g., relative to perfluoroalkanes) (9), part of the lifetime shortening is attributable to intermolecular quenching, namely, hydrogen transfer or charge transfer interactions with solvents. Since these interactions are also operative for other arylthiones in the given solvents, additional factor(s) should be sought in the case of TBN. One such factor would be the lower T_1–S_0 energy gap for TBN enhancing the related nonradiative process. However, it has been recently shown (9) that the energy gap law manifests itself in the case of thiones in terms of an increase in k_{nr} to the extent of $(4–6) \times 10^4$ s^{-1} on going from 4*H*-pyran-4-thione (E_T = 49.3 kcal mol^{-1}) to 4*H*-1-benzopyran-4-thione (E_T = 46.2) to xanthione (E_T = 43.3) in perfluoro-1,3-dimethylcyclohexane. Such a small change alone cannot account for the large decrease in τ_0^T from 1.4 μs for DMTBP (E_T = 41.1 kcal mol^{-1}) to 0.086 μs for TBN (E_T = 39 kcal mol^{-1}) in benzene. It is feasible that the intramolecular photochemistry as shown in Scheme 1 is also operative from T_1 (rendering it short-lived), although the contribution of the triplet pathway to the overall photochemistry may be negligible because of efficient reversion to the ground state in the subsequent steps.

The effect of the lowering of E_T is generally evident in the trend of the bimolecular rate constants for triplet quenching (Table 2) for XT (E_T = 43.3 kcal mol^{-1}), DMTBP (E_T = 41.1 kcal mol^{-1}), and TBN (E_T = 39 kcal mol^{-1}). Interestingly, in spite of the isoenergetic nature of the energy transfer, the quenching of TBN triplet by azulene (E_T ~40 kcal mol^{-1}) and ferrocene (E_T ~39–41 kcal mol^{-1}) is diffusion-limited. Of particular note is the fact that on going from XT to TBN, the rate constant for quenching by the nitroxide radical remains unchanged. Energy transfer quenching (1) is out of the question in the case of the low-energy TBN triplet. The unusually efficient quenching by the stable radical in this case is attributable to electron exchange (2) with the thiocarbonyl *S* atom enhancing intersystem crossing in the encounter complex.

RAOUL M'BOUNGOU, MICHELLE PETIT-RAMEL, GERMAINE THOMAS-DAVID, GÉRARD PERICHET et BERNARD POUYET. Can. J. Chem. **67**, 973 (1989).

Les constantes de protonation de l'uracile (UR), de la cytosine (CY) et de la D-valine (VA) ont été calculées à 25°C et à force ionique $\mu = 0{,}1$ ($NaNO_3$). Dans les mêmes conditions, les constantes de stabilité des complexes simples formés avec le Cu(II), le Hg(II) et le Pt(II) ainsi que celles des complexes mixtes formés entre un acide aminé, la D-valine et une série d'homologues de l'uracile : thymine, thymidine, acide orotique et cytosine avec les mêmes ions métalliques ont été déterminées par protométrie. En ce qui concerne les complexes mixtes, nous avons développé et testé une nouvelle méthode simple d'estimation de leurs constantes de stabilité.

Mots clés : coordination du Cu(II), du Hg(II) et du Pt(II), coordination ternaire, homologues de l'uracile, D-valine, méthodes protométriques.

RAOUL M'BOUNGOU, MICHELLE PETIT-RAMEL, GERMAINE THOMAS-DAVID, GÉRARD PERICHET, and BERNARD POUYET. Can. J. Chem. **67**, 973 (1989).

The protonation constants of uracil (UR), cytosine (CY), and D-valine (VA) have been calculated at 25°C and at ionic strength $\mu = 0.1$ ($NaNO_3$). In a first step the stability constants of their Cu(II), Hg(II) and Pt(II) simple complexes were determined. In a second step the mixed complexation of several uracil homologues as thymine, thymidine, orotic acid and cytosine was also investigated under the same conditions by protometric methods. Concerning the mixed complexes, a new simple method of estimating their stability constants has been developed and verified.

Key words: Cu(II), Hg(II), Pt(II) coordination, ternary coordination, uracil homologues, D-valine, protometric methods.

Introduction

Ce travail est dans le prolongement direct d'un précédent mémoire (1) concernant les interactions du Cu(II), du Hg(II) et du Pt(II) avec les formes monomère et dimère de la thymine, de la thymidine et de l'acide orotique.

Depuis les travaux de Rosenberg *et al.* (2, 3), le cis-dichlorodiamineplatine(II) ou cis-platine est utilisé en chimiothérapie pour ses propriétés antitumorales bien connues, mais sa faible solubilité dans l'eau et sa toxicité vis à vis du rein limitent son utilisation dans certains traitements anticancéreux (4–6). Par contre, les nombreuses combinaisons de substitution des groupes aminés ou des groupes chlorés par des amino-acides (7), des amines (8), des amino-acides et amines (9–14), des molécules d'eau (2, 8, 15), des acides alcools (16) ou des diacides (17) ont permis d'obtenir des produits à la fois plus solubles et moins toxiques. Enfin la découverte des complexes bleus des dérivés de la purine et la pyrimidine, les «platin-blues», solubles dans l'eau, peu toxiques, élargit notablement le domaine d'application des composés du platine(II) (15, 18–24). Dans ce but, nous avons étudié les complexes binaires du platine(II) avec la D-valine (figure 1a), l'uracile (figure 1b) et la cytosine (figure 1c) ainsi que les espèces ternaires obtenues avec la D-valine d'une part, la thymine (figure 1d), la thymidine (figure 1e), l'acide orotique (figure 1f), l'uracile, la cytosine d'autre part.

En outre, d'un point de vue purement structural, il est utile de comparer les complexes binaires et ternaires du Pt(II) avec, d'une part ceux du Hg(II), en liaison avec une réponse photochimique possible (25), et d'autre part ceux du Cu(II), qui demeure un métal de référence intéressant dans la complexation des amino-acides.

Nous rappelons brièvement le protocole développé dans les mémoires précédents (1, 26) pour la mise en évidence des espèces protonées puis des espèces complexes simples $M_pH_qL_r$, ainsi que le calcul de leurs constantes de stabilité β_{pqr} :

(*i*) examen des courbes de formation $\bar{n} = f(pL)$ où n représente le nombre moyen de ligands L déprotonés fixés par métal.

(*ii*) affinement par minimisation d'écart-type sur les points expérimentaux et calculés, des transformées de courbes de titration, $\bar{q} = f(pH)$, rendues linéaires où q est le nombre de protons neutralisables par mole de ligand.

En ce qui concerne l'affinement des espèces complexes mixtes, la difficulté essentielle réside dans une appréciation convenable de la valeur initiale de la constante de stabilité (27–29*a*). Nous avons développé et testé sur une dizaine d'exemples une nouvelle méthode simple d'estimation de la constante du mixte. Soit une espèce complexe mixte de formule générale $M_pH_qL_1L_2$ où M représente l'atome métallique central, H l'atome d'hydrogène, L_1 et L_2 les deux ligands, dont la formation est régie par l'équilibre :

$$[1] \quad pM + qH + L_1 + L_2 \rightleftarrows M_pH_qL_1L_2$$

avec q le nombre global des protons neutralisables tel que :

$$[2] \quad q = q_1 + q_2$$

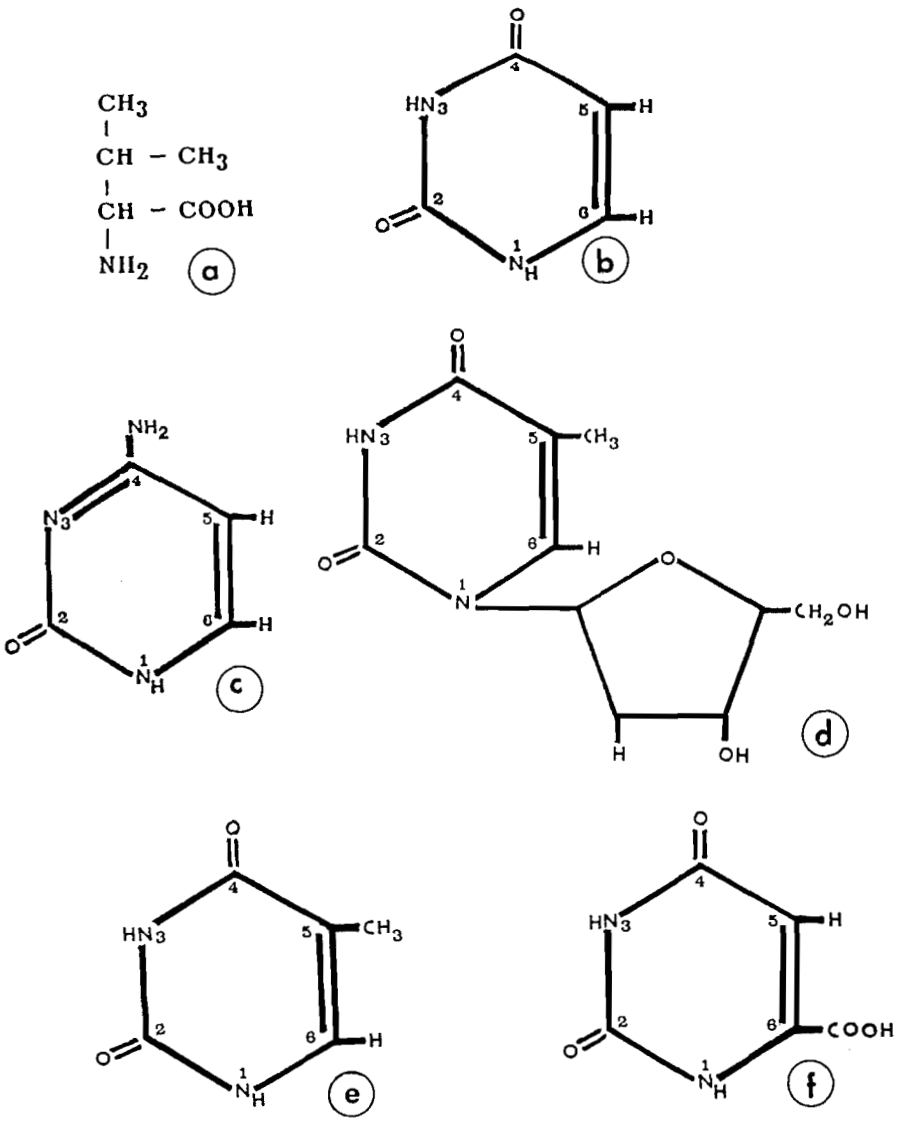

FIG. 1. (a) D-Valine, (b) uracile, (c) cytosine, (d) thymidine, (e) thymine, (f) acide orotique.

q_1 et q_2 sont respectivement le nombre de protons neutralisables du ligand L_1 et du ligand L_2.

En considérant l'ensemble des deux ligands L_1 et L_2 de concentration totale respective C_{L_1} et C_{L_2} dans l'espèce mixte comme un seul ligand L, nous avons, si C_L est la concentration totale en ligand L :

$$[3] \quad C_L = C_{L_1} + C_{L_2}$$

Dans ces conditions, l'équilibre [1] devient par analogie avec un complexe binaire :

$$[4] \quad pM + qH + L \rightleftarrows M_pH_qL$$

Pour $p = 1$, en faisant abstraction des espèces hydroxydées et protonées, nous pouvons calculer un degré de formation défini par Bjerrum :

$$[5] \quad \bar{n} = \frac{[ML]}{C_M}$$

où [ML] est la concentration de l'espèce mixte sous la forme ML; C_M est la concentration en métal telle que :

$$[6] \quad C_M = [M] + [ML]$$

La concentration en ligand total est définie par :

$$[7] \quad C_L = \sum_1^q [H_qL] + [ML] + [L]$$

Alors

$$[8] \quad [ML] = C_L - [L] - \sum_1^q [H_qL]$$

où

$$[9] \quad \sum_1^q [H_qL] = \sum_1^q [H]^q[L]\beta'_{q1}$$

avec β'_{q1}, le paramètre de stabilité protonique relatif au ligand global L, tel que :

$$[10] \quad \beta'_{q1} = \beta_{q10} + \beta_{q01}$$

où β_{q10} et β_{q01} représentent respectivement les constantes de stabilité protonique du premier et du second ligand. L'expression [5] devient en combinant les relations [8] et [9] :

$$[11] \quad \bar{n} = \frac{C_L - [L] - \sum_1^q [H]^q[L]\beta'_{q1}}{C_M}$$

La courbe de formation du système ternaire est donc obtenue en représentant graphiquement $\bar{n} = f(p[L])$.

D'autre part, nous pouvons relier graphiquement le paramètre de formation du mixte β'_{101} et ce même degré de formation

*Écarts-types correspondants aux constantes.

en combinant les expressions [5] et [6].

$$[12] \quad \bar{n} = \frac{[L]\beta'_{101}}{1 + [L]\beta'_{101}}$$

Il est clair qu'il existe une relation entre la courbe de formation et la constante de stabilité de «l'espèce ternaire» ML. Sans entrer dans les développements mathématiques de Bjerrum, nous utiliserons une méthode approchée pour déterminer la constante de stabilité du mixte β'_{101}, ou mieux β_{1011}, d'après l'équilibre [1] en traçant sur la même figure les courbes de formation relatives aux systèmes binaires ML_1 et ML_2 et au système ternaire ML_1L_2. Nous distinguons les cas suivants :

(a) Les courbes de formation des systèmes ML_1L_2 et ML_1 (ou ML_2) sont confondues pour toutes les valeurs de $\bar{n}$: il n'y a pas formation d'espèce mixte.

(b) Les courbes de formation des systèmes ML_1L_2 et ML_1 (ou ML_2) sont confondues pour chaque valeur de $\bar{n}$ comprise entre 0 et 1 ou pour toutes les valeurs de $\bar{n}$ supérieures ou égales à 1,5, ou encore ne sont pas confondues quel que soit $\bar{n}$: la valeur de β_{1011} est estimée comme pour le cas d'un simple MA_2 (avec $\beta_{1011} = K_1 \cdot K_2$).

(c) Les courbes de formation des systèmes ML_1L_2 et ML_1 (ou ML_2) sont confondues pour toutes les valeurs de $\bar{n}$ supérieures ou égales à 1 : la valeur de β_{1011} est estimée pour $\bar{n} = 0,5$.

La constante du mixte étant ainsi estimée, elle est affinée à l'aide d'un programme basic développé dans notre laboratoire.

Résultats

Les valeurs définitives des constantes affinées par la méthode de «pit mapping» sont rassemblées dans les tableaux 1 et 2.

1. Systèmes binaires

1. D-Valine H_2^+(VA)

Bien que la D-valine ait déjà été étudiée (29, 30), nous avons recalculé ses constantes de protonation ainsi que les constantes de stabilité des complexes du cuivre pour donner le maximum d'homogénéité à nos résultats (figure 2).

(a) Interactions avec le cuivre. Les deux chélates $[Cu(VA)]^+$ et $[Cu(VA)_2]$ répondent aux équilibres connus :

$$Cu^{2+} + H_2^+(VA) \rightleftarrows [Cu(VA)]^+ + 2H^+$$

$$Cu^{2+} + 2H_2^+(VA) \rightleftarrows [Cu(VA)_2] + 4H^+$$

(b) Interactions avec le mercure. Les interactions D-valine–mercure n'ont pas donné lieu, à notre connaissance à une évaluation précise de la constante de stabilité des complexes obtenus. Pour notre part, le traitement des données potentiométriques relatives à ce système fait apparaître deux espèces complexes $[Hg(VA)]^+$ et $[Hg(VA)_2]$ correspondant aux équilibres :

$$Hg^{2+} + H_2^+(VA) \rightleftarrows [Hg(VA)]^+ + 2H^+$$

$$Hg^{2+} + 2H_2^+(VA) \rightleftarrows [Hg(VA)_2] + 4H^+$$

(c) Interactions avec le platine. Si l'état solide et particulièrement l'étude cristallographique des complexes platine–valine ont retenu l'attention des chercheurs (9, 14), les interactions en solution ne semblent pas avoir été étudiées systématiquement. Cela tient sans doute à la transformation préalable obligée du cis-platine dans lequel il est nécessaire de libérer une ou deux positions de coordination en substituant les groupements chlorures. En solution dans l'eau, le cis-platine donne lieu aux

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

réactions d'hydrolyse suivantes (15) :

$$\text{cis-}[PtCl_2(NH_3)_2] + H_2O \rightleftarrows \text{cis-}[PtCl(H_2O)(NH_3)_2]^+ + Cl^-$$

$$\text{cis-}[PtCl(H_2O)(NH_3)_2]^+ + H_2O \rightleftarrows \text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + Cl^-$$

Nous avons identifié deux espèces complexes cis-$[Pt(VA)(NH_3)_2]^+$ et cis-$[Pt(VA)_2(NH_3)_2]$ répondant aux équilibres :

$$\text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + H_2{}^+(VA) \rightleftarrows \text{cis-}[Pt(VA)(NH_3)_2]^+ + 2H^+ + 2H_2O$$

$$\text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + 2H_2{}^+(VA) \rightleftarrows \text{cis-}[Pt(VA)_2(NH_3)_2] + 4H^+ + 2H_2O$$

Il a été montré (12, 31) que dans le cas de la plupart des amino-acides, l'espèce ML, cis-$[Pt(VA)(NH_3)_2]^+$ présente un cycle de chélation, le platine étant lié par les groupements carboxylique et aminé. Pour la seconde espèce ML_2, cis-$[Pt(VA)_2(NH_3)_2]$, le cycle de chélation disparaît et le complexe présente deux liaisons Pt – groupement aminé de l'amino-acide (8–13, 31).

2. Uracile H(UR), cytosine $H_2{}^+(CY)$ et thymidine H(TY)

En ce qui concerne la thymidine, les constantes de protonation ainsi que les constantes de stabilité des complexes du cuivre et mercure ont déjà été publiées dans un mémoire précédent (1). Nous ne donnerons que les équilibres relatifs aux complexes du platine.

(a) Protonation. Bien qu'il y ait dans chaque molécule d'uracile deux possibilités d'échange relatives aux hydrogènes portés par les fonctions amines N1 et N3, seule la déprotonation N3 (32, 33) est observable dans le domaine de pH envisagé (tableau 1).

En ce qui concerne la cytosine, la forme cationique $H_2{}^+(CY)$ prédomine en milieu acide et la protonation de l'atome d'azote N3 (34–36) induit préférentiellement la fixation d'ions métalliques. Comme l'indique la majorité des références bibliographiques (33, 37–40), les valeurs de la constante d'acidité de l'hydrogène lié à l'azote N3 sont homogènes. Par contre, la disparité des valeurs collectées pour la constante d'acidité relative à la déprotonation N1 (32, 41–44) nécessite un calcul complet et précis bien que cette position ne soit pas un site de coordination privilégié.

(b) Interactions avec le cuivre. L'existence de deux complexes d'uracile $[Cu(UR)]^+$ et $[Cu(UR)_2]$ a été signalée par Taqui Khan *et al.* (32, 37, 45*a*). Bien que Tan et Beck aient identifié uniquement l'espèce $[Cu(UR)]^+$ (46), nous avons aisément mis en évidence deux espèces successives $[Cu(UR)]^+$ et $[Cu(UR)_2]$ répondant aux équilibres :

$$Cu^{2+} + H(UR) \rightleftarrows [Cu(UR)]^+ + H^+$$

$$Cu^{2+} + 2H(UR) \rightleftarrows [Cu(UR)_2] + 2H^+$$

Dans ce cas, il y a coordination par l'intermédiaire de l'azote N3 (46, 47).

Pour la cytosine, nous avons identifié les complexes successifs $[Cu(CY)]^+$ et $[Cu(CY)_2]$ selon les équilibres de formation :

$$Cu^{2+} + H_2{}^+(CY) \rightleftarrows [Cu(CY)]^+ + 2H^+$$

$$Cu^{2+} + 2H_2{}^+(CY) \rightleftarrows [Cu(CY)_2] + 4H^+$$

Ces espèces complexes obtenues sous forme cristalline (47, 48) chélatent le métal par l'azote N3 et l'oxygène adjacent O2 afin de respecter la coordinence quadrangulaire plane du cuivre.

(c) Interactions avec le mercure. Les quelques données bibliographiques relatives aux complexes du système mercure–uracile concernent surtout l'état solide (49–51) et ponctuellement la détermination de la stabilité de l'espèce $[HgCl_2(UR)]$ qui relève de la complexation ternaire avec les ions chlorures peu labiles (52). Plus directement, le cas de complexation binaire que nous étudions en utilisant le nitrate mercurique, $Hg(NO_3)_2$, porte sur la formation de deux espèces complexes $[Hg(UR)]^+$ et $[Hg(UR)_2]$ répondant aux équilibres :

$$Hg^{2+} + H(UR) \rightleftarrows [Hg(UR)]^+ + H^+$$

$$Hg^{2+} + 2H(UR) \rightleftarrows [Hg(UR)_2] + 2H^+$$

La cytosine est comme nous l'avons annoncé précédemment un diacide faible protoné en N3 et N1. Ferreira *et al.* (53) ont montré l'existence de l'espèce $[Hg(CY)_2]$; ceci procède d'une démarche incomplète puisque seule la déprotonation en N3 a été considérée. En ce qui nous concerne, la prise en compte des deux déprotonations conduit aux équilibres suivants :

$$Hg^{2+} + H_2{}^+(CY) \rightleftarrows [Hg(CY)]^+ + 2H^+$$

$$Hg^{2+} + 2H_2{}^+(CY) \rightleftarrows [Hg(CY)_2] + 4H^+$$

Pour les deux ligands envisagés, les complexes du mercure présentent une géométrie linéaire (53); il y a coordination par l'intermédiaire de l'azote N3, site de liaison préférentiel (30, 36*b*).

(d) Interactions avec le platine. Comme dans le cas de la valine, plusieurs auteurs (18–20, 22, 23, 54–61) ont préparé les complexes platinés de l'uracile, de la cytosine et ses dérivés sous forme cristalline, leur stabilité en solution demeurant inconnue. Les complexes cis-$[Pt(UR)(H_2O)(NH_3)_2]^+$, cis-$[Pt(UR)_2(NH_3)_2]$, cis-$[Pt(CY)(H_2O)(NH_3)_2]^+$ et cis-$[Pt(CY)_2(NH_3)_2]$, dont nous avons montré l'existence, répondent aux équilibres :

$$\text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + H(UR) \rightleftarrows \text{cis-}[Pt(UR)(H_2O)(NH_3)_2]^+ + H^+ + H_2O$$

$$\text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + 2H(UR) \rightleftarrows \text{cis-}[Pt(UR)_2(NH_3)_2] + 2H^+ + 2H_2O$$

$$\text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + H_2{}^+(CY) \rightleftarrows \text{cis-}[Pt(CY)(H_2O)(NH_3)_2]^+ + 2H^+ + H_2O$$

$$\text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + 2H_2{}^+(CY) \rightleftarrows \text{cis-}[Pt(CY)_2(NH_3)_2] + 4H^+ + 2H_2O$$

La thymidine ne réagit pas directement avec le cis-platine (62, 63). Nous avons donc procédé, comme dans le cas de la valine, à la substitution des chlorures par des molécules d'eau et obtenu les espèces successives suivantes :

$$\text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + H(TY) \rightleftarrows \text{cis-}[Pt(TY)(H_2O)(NH_3)_2]^+ + H^+ + H_2O$$

$$\text{cis-}[Pt(H_2O)_2(NH_3)_2]^{2+} + 2H(TY) \rightleftarrows \text{cis-}[Pt(TY)_2(NH_3)_2] + 2H^+ + 2H_2O$$

II. Systèmes ternaires

Dans un premier temps, nous calculons la valeur approchée de la constante de stabilité de l'espèce ternaire par la méthode d'estimation décrite en introduction. L'affinement des constantes de stabilité du complexe ternaire MLL′ converge ainsi aisément et conduit aux courbes de répartition de l'ensemble des espèces (figures 3 et 4).

Seuls le cuivre et le platine donnent naissance à des espèces ternaires. Le mercure provoque une précipitation immédiate de la solution contenant les deux ligands quels que soient les rapports envisagés.

(c) Cytosine : (▲▲) $[H_2^+ CY] = 10^{-3}$ M; $[Hg^{2+}] = 2{,}027 \times 10^{-4}$ M; (--) $[H_2^+ CY] = 10^{-3}$ M; $[Cu^{2+}] = 1{,}99 \times 10^{-4}$ M; (—) $[H_2^+ CY] = 10^{-3}$ M; $[Pt^{2+}] = 5 \times 10^{-4}$ M. 1, Hg^{2+}; 2, $[Hg(CY)]^+$; 3, $[Hg(CY)_2]$; 4, Cu^{2+}; 5, $[Cu(CY)]^+$; 6, $[Cu(CY)_2]$; 7, cis-$[Pt(H_2O)_2(NH_3)_2]^{2+}$; 8, cis-$[Pt(CY)(H_2O)(NH_3)_2]^+$; 9, cis-$[Pt(CY)_2(NH_3)_2]$.

(d) Thymidine : (—) $[HTY] = 2 \times 10^{-3}$ M; $[Pt^{2+}] = 4 \times 10^{-4}$ M; 1, cis-$[Pt(H_2O)_2(NH_3)_2]^{2+}$; 2, cis-$[Pt(TY)(H_2O)(NH_3)_2]^+$; 3, cis-$[Pt(TY)_2(NH_3)_2]$.

1. Complexation ternaire avec le cuivre

Récemment, les systèmes cuivre–histidine–cytosine (40) et cuivre–glycine–thymine (64) ont été étudiés. Pour notre part, nous avons identifié les espèces suivantes (figure 3) : [Cu(VA)(TM)], [Cu(VA)(TY)], $[Cu(VA)(OM)]^+$, [Cu(VA)(UR)] et [Cu(VA)(CY)].

2. Complexation ternaire avec le platine

Seul, B. Lippert (61) a signalé l'existence des complexes mixtes du cis-platine par combinaison deux à deux des quatre principales bases de l'ADN (adénine, cytosine, guanine et thymine). La complexation ternaire entre un acide aminé d'une part, et une quelconque de ces bases, n'a par contre jamais été abordée à notre connaissance. Notre choix s'est donc porté sur la D-valine entrant dans la préparation de différents produits anticancéreux et les homologues de l'uracile étudiés précédemment.

Comme pour les systèmes binaires, l'ion platine est sous forme cis-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ et conduit à la formation d'espèces ternaires que l'on pourrait qualifier en terme limite «d'espèces quaternaires» (figure 4), cis-[Pt(VA)(TM)$(NH_3)_2$], cis-[Pt(VA)(TY)$(NH_3)_2$], cis-$[Pt(VA)(OM)(NH_3)_2]^+$, cis-[Pt(VA)(UR)$(NH_3)_2$] et cis-[Pt(VA)(CY)$(NH_3)_2$].

Conclusion

Les tableaux 1 et 2 regroupent tous les résultats obtenus. Les répartitions des différentes espèces simples et mixtes sont consignées dans les figures 2, 3 et 4. Cette étude de stabilité appelle plusieurs remarques.

1. Complexation binaire

D-Valine

Les complexes simples de la D-valine avec le cuivre(II) sont des chélates (29, 30), tandis que ceux du platine(II) sont de deux types : chélate (figure 5a) dans des composés de formule ML

*Écarts-types correspondants aux constantes.

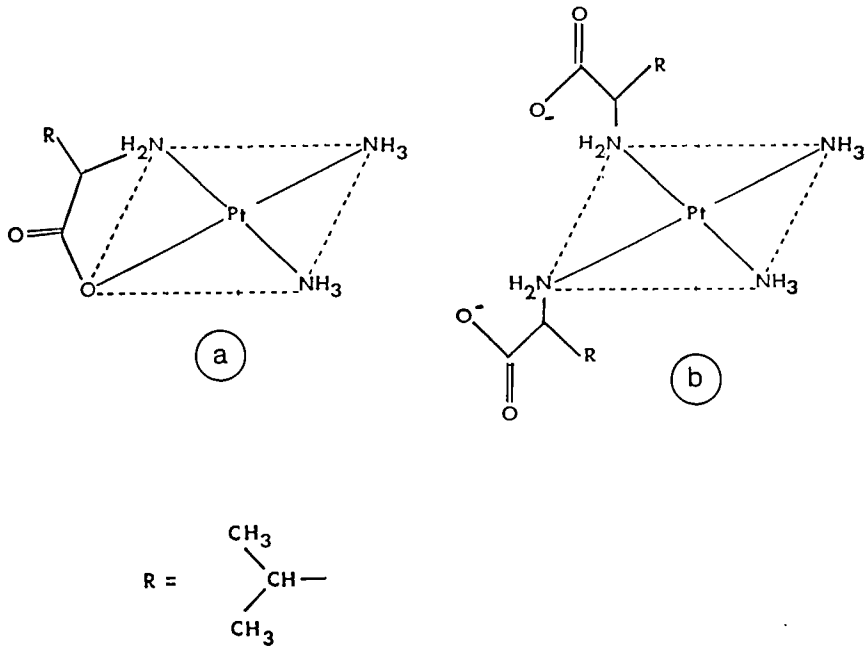

FIG. 5. (a) Espèce ML. (b) Espèce ML_2.

(12, 31) ou complexe non chélaté (figure 5b) dans lequel la liaison métal–ligand passe par l'azote du groupement amino de l'acide aminé, comme l'ont montré les études de certains autres (8–11, 13, 31) pour les complexes de formule ML_2. Ceci nous incite à penser que les sites de liaisons dans les complexes de mercure avec la D-valine sont les mêmes que ceux de l'espèce ML_2 du platine(II) avec la D-valine.

Uracile

Dans le domaine de pH envisagé ($2 < pH < 12$), l'uracile est monodentate. Le site de complexation avec le platine et le cuivre est N3 (21, 32, 45, 46, 65), quelquefois N1, avec possibilité de conversion entre les deux sites (22, 53); la liaison platine–N1 serait alors plus stable en milieu acide que la liaison platine–N3. Les complexes dont nous avons montré l'existence se forment dans la zone de pH où se produit la déprotonation de l'hydrogène lié à N3, ce qui laisse prévoir, dans ce cas, une complexation préférentielle avec l'azote N3. Ceci a été confirmé par Flynn *et al.* (21) par la non formation de platin-blue en utilisant un homologue de l'uracile auparavant substitué en position N3.

Cytosine

La cytosine et ses dérivés sont soit des coordinats monodentates dont le site de liaison est N3 (58, 59, 62, 67, 68) et parfois l'azote du groupement amino déprotoné porté par le carbone C4 (66, 69), soit des ligands bidentates dans certains chélates du platine, du mercure et du cuivre. Dans ce dernier cas, il y a chélation des ions métalliques par l'azote N3 et l'oxygène O2 (46*b*–48, 63, 70–72), ou par l'azote N3 et le groupement amino déprotoné porté par C4 (57, 60, 67). Cependant les études de RMN sur les complexes de la cytidine (nucléoside de la cytosine) avec le mercure et le platine (73, 74) ont montré que le site de liaison est N3 tout en excluant la possibilité de fixation d'ions métalliques sur l'azote du groupement amino. Nos complexes appartiennent simultanément à ces deux modes de complexation dans lesquels la cytosine est monodentate vis à vis du mercure et du platine dans les espèces ML et ML_2 (le site de liaison étant l'azote N3), bidentate pour le cuivre dans les chélates de formule ML et ML_2 avec chélation du cuivre par l'oxygène O2 et l'azote N3.

Thymidine

Comme nous l'avons déjà montré pour la thymine (1), l'ion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

hydraté cis-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ a une bonne réactivité vis à vis de la thymidine (nucléoside de la thymine) et le site de liaison évident reste l'atome d'azote N3 (65).

2. Complexation ternaire

La bonne et rapide convergence des processus d'affinement relatifs à toutes nos espèces ternaires confirme bien la validité de la méthode d'estimation exposée.

Au cours de cette étude, nous constatons que la plupart des espèces mixtes sont plus stables que les espèces complexes simples et à l'aide des valeurs obtenues, nous avons pu vérifier la règle bien connue de renforcement de stabilité ionique résultant de la dissymétrie de la chélation mixte (28, 75).

Considérons l'équilibre $ML_2 + ML'_2 \rightleftarrows 2MLL'$; nous pouvons définir sa constante χ_{1011} par la relation :

$$\log \chi_{1011} = 2 \log \beta_{1011} - (\log \beta_{1020} + \log \beta_{1002})$$

Toutes les valeurs de $\log \chi_{1011}$ sont consignées dans le tableau 2. Ce renforcement ne s'est pas vérifié dans le cas du mixte cis-$[Pt(VA)(CY)(NH_3)_2]$ pour lequel la valeur de la constante de stabilité de l'espèce simple cis-$[Pt(CY)_2(NH_3)_2]$ ($\log \beta_{1011} = 13{,}89$) est plus élevée que celle de l'espèce mixte, cis-$[Pt(VA)(CY)(NH_3)_2]$ ($\log \beta_{1011} = 12{,}33$) pour les mêmes rapports de concentration. Ceci se traduit dans les courbes de répartition par un faible pourcentage de l'espèce mixte comparé aux espèces simples (figure 4e).

Complexes mixtes du cuivre. Dans ces espèces, la D-valine, la cytosine et l'acide orotique sont des coordinats bidentates tandis que les autres ligands sont monodentates (1, 29, 30, 46*b*, 47, 48).

Complexes mixtes du platine. Il a été montré que dans les espèces mixtes du cis-platine avec le tertiobutylamine et certains amino-acides, le groupement carboxylique de ces derniers ne participe pas à la liaison; ils sont monodentates (9–11). Il en est de même des complexes ternaires que nous avons étudiés dans lesquels la D-valine n'est liée que par le groupement amine : le platine est alors entouré uniquement d'atomes d'azote. Cette configuration lui confère l'ensemble de ses propriétés antitumorales.

Cette étude permet de mettre en évidence les deux modes de complexation, monodentate et bidentate, de la valine et de la cytosine selon le métal envisagé.

Partie expérimentale

Une chaîne de mesure, convenablement étalonnée, permet de mesurer le pH dans un large domaine ($2 < pH < 12$) :

électrode de verre | solution thermostatée | NaCl saturé | électrode au calomel

Le jeu d'électrodes est relié à un potentiomètre ISIS 20 000 Tacussel et les mesures sont effectuées sur des solutions aqueuses thermostatées à 25 ± 0,1°C et sous atmosphère d'azote. La force ionique de chaque solution est maintenue constante à l'aide d'une solution de $NaNO_3$ 0,1 M.

Sels métalliques

Les sels de cuivre et de mercure sont préparés par dissolution de $Cu(NO_3)_2,3H_2O$ et $Hg(NO_3)_2,H_2O$ Prolabo dans l'eau déminéralisée et dosés par complexométrie à l'EDTA notamment à l'aide d'une électrode réversible aux ions Hg^{2+} couplée à une électrode de référence au sulfate mercureux pour le mercure.

La solution de cis-$[Pt(H_2O)_2(NH_3)_2]^{2+}$ est préparée à partir de cis-$[PtCl_2(NH_3)_2]$ R. Bellon par substitution stoechiométrique des ions Cl^- effectuée à l'aide d'une solution titrée de nitrate d'argent (16, 20, 65). Une triple centrifugation du chlorure d'argent permet de garantir la reproductibilité de l'échange qui n'affecte en rien la liaison Pt—N (76).

Coordinats

La D-valine, la thymine, la thymidine, l'acide orotique, la cytosine et l'uracile proviennent respectivement des laboratoires Chemische Fabrik, Merck, Boehringer Mannhein GMBH, Sigma Chemical Company, Janssen Chimica et Merck.

Pour chaque système nous avons suivi la titration par la soude Prolabo 0,2 N, des solutions correspondant à deux rapports de concentration ligand : ion métallique (~2 et ~5) pour les systèmes simples et ligand 1 : ligand 2 : ion métallique (~1 : 1 : 1 et ~2 : 2 : 1) pour les systèmes mixtes, soit environ 100 points expérimentaux.

Remerciements

Nous remercions vivement les laboratoires Roger Bellon, 159 avenue du Roule, 92200 Neuilly sur Seine, de nous avoir fourni gracieusement le cis-$[PtCl_2(NH_3)_2]$.

New trends in differential scanning calorimetry

H. TACHOIRE
Laboratoire de Thermochimie, Université de Provence, F-13331 Marseille CEDEX 03, France

AND

V. TORRA
Departament de Fisica, Universitat de les Illes Balears, E-07071 Palma de Mallorca, Spain

Received January 26, 1989

This paper is dedicated to the memory of Professor James A. Morrison

H. TACHOIRE and V. TORRA. Can. J. Chem. **67**, 983 (1989).

Recent applications of differential scanning calorimetry in the study of solid–solid transformations are presented. The importance of the deconvolution of the thermograms and of the modelling of the calorimetric equipment is stressed.

Investigations of the phase transformations of the martensitic type in shape-memory alloys have made clear the influence of thermomechanical treatment of the material and have evaluated the influence of defects on the dynamics of transformation. A combination of calorimetric and acoustical observations has demonstrated irreversibilities, even in the so-called thermoelastic transitions.

Key words: martensitic transformation, differential scanning calorimetry, entropy production, thermomechanical treatments, acoustic emission.

H. TACHOIRE et V. TORRA. Can. J. Chem. **67**, 983 (1989).

On présente de récentes applications de l'analyse calorimétrique différentielle dans l'étude des transformations solide–solide. L'importance de la modélisation des instruments et de la déconvolution de leur réponse est clairement mise en évidence.

Une étude des transformations de phase de type martensitique dans les alliages à mémoire de forme permet de montrer l'influence d'un traitement thermomécanique du matériau et celle des défauts sur la dynamique de la transformation. Le couplage d'observations calorimétriques et acoustiques prouve l'existence d'irréversibilités même au cours de transformations réputées thermoélastiques.

Mots clés : transformation martensitique, analyse calorimétrique différentielle, production d'entropie, traitements thermomécaniques, émission acoustique.

Introduction

Calorimetric equipment with thermal fluxmeters are stable instruments. Equipped with semiconductor elements, they possess a high sensitivity (about 400 mV W^{-1} at ambient temperature). The response of these instruments contains the energy production of the phenomena studied, deformed by the inertia of the apparatus. The techniques of acquisition and processing of data allow compensation for this inertia. In certain cases, it is possible to link to the calorimeter other techniques of measurement and/or observation leading to the simultaneous determination of several parameters and hence to a better understanding of the phenomenon under study (1).

In our application, we observed a change in the dynamics of the instrumental response during the course of manipulation. Therefore, for solid–solid transitions, it is necessary to model the instrumental response and to reconstitute the true evolution of heat, thermogenesis $P(t)$, using appropriate algorithms such as inverse filtering.

Knowledge of the thermogenesis of the process allows either the development of phenomenological interpretations or the modelling of processes which develop within the laboratory cell.

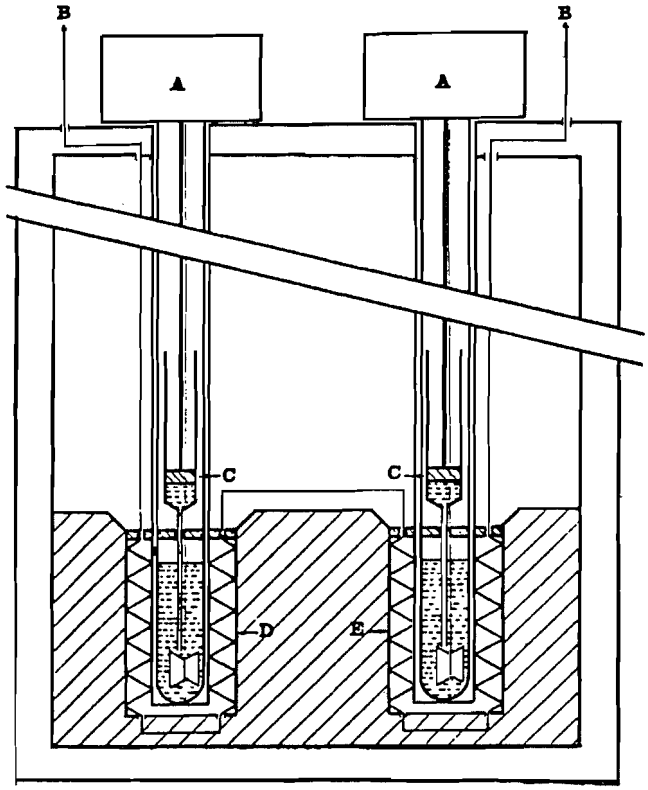
In this paper, we describe the application of techniques developed for the study of the dynamics of a martensitic-type transformation induced by a programmed temperature change in shape-memory alloys. Using thermomechanical treatments, it is possible to describe the influence of the initial state of the samples and of the subsequent development of defects, surface polishing, cycling effects, ... on the transformation process (2).

Calorimeters and heat-transfer equations

A system of N first order differential equations allows the description of experimental equipment having a classical laboratory cell (Fig. 1 top) or in which a sample under investigation is in contact with thermocouples (Fig. 1, middle section). When this is the case, one adopts a model with localised constants composed of N thermal capacities. This approach is obviously only valid for linear experimental systems. The conditions of linearity are always checked in the normal region of use of the heat conduction calorimeters (constant mass and temperature).

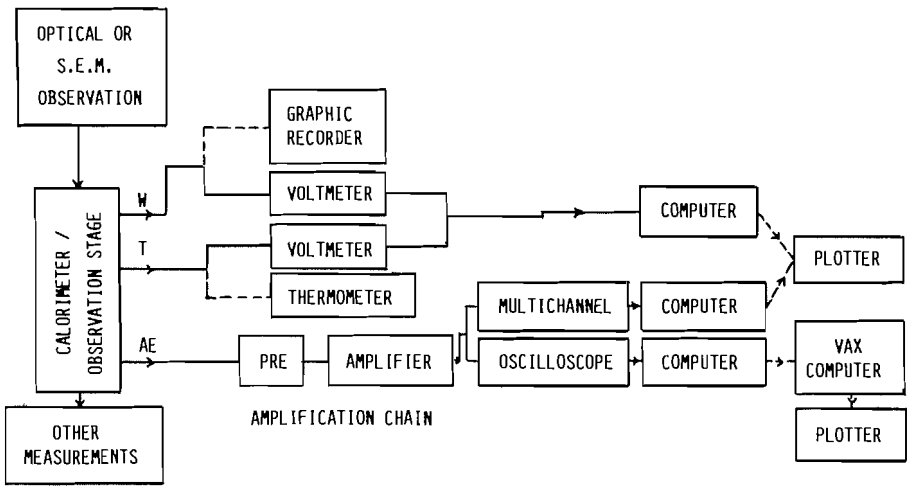
In the case where the thermal evolution $P(t)$ occurs in a single capacity, the system of N linear equations takes the following form, since the calorimetric response $s(t)$ (the amplitude of the thermogram) is proportional to the temperature differences (3),

$$[1]\quad P(t) + a(\mathrm{d}P(t)/\mathrm{d}t) + \ldots + m(\mathrm{d}^M P(t)/\mathrm{d}t^M) = A(\mathrm{d}^N s(t)/\mathrm{d}t^N) + B(\mathrm{d}^{N-1} s(t)/\mathrm{d}t^{N-1}) + \ldots \quad (\text{with } M < N)$$



When the temperature of these systems changes slowly with time, the coefficients of the preceding equation also change. It is possible to extend the application of this formalism and to obtain the thermogenesis, $P(t)$, of the phenomena from experimental thermograms using appropriate calibration.

In this simple case, in which temperature T is a function of time t (4), one obtains



$$[2]\quad \text{Energy}\Big\}_{t_1}^{t_2} = \int_{t_1}^{t_2} \{s(t)/S(T)\}\mathrm{d}t$$

CALORIMETRIC AND ACOUSTIC SET-UP

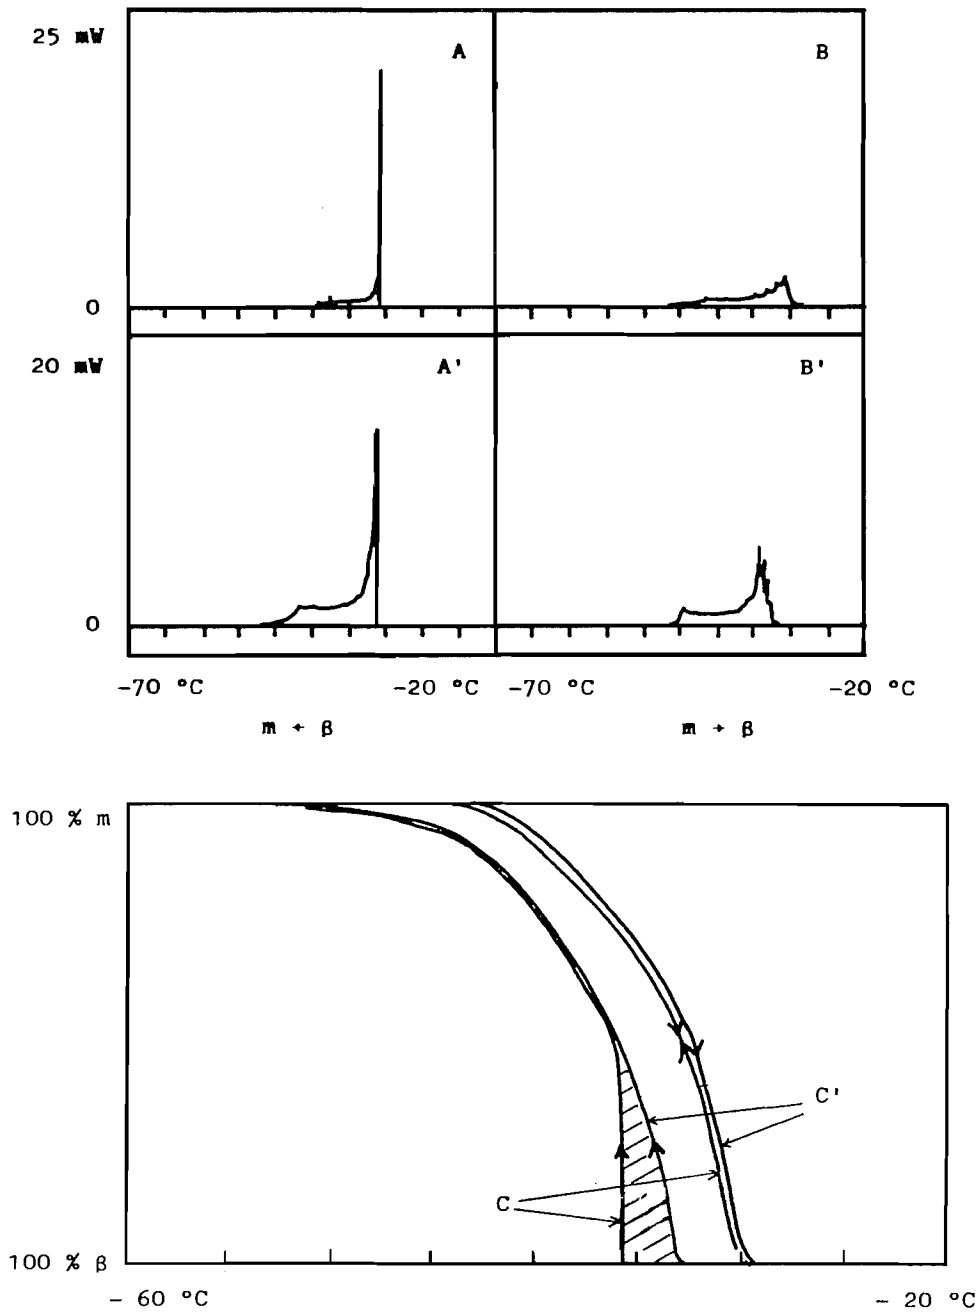

FIG. 2. Influence of centres for nucleation on a transformation of the type phase β → martensite in an alloy Cu 74.4 wt.% – Al 7.41% – Zn 18.18%. Graphs *A*, *B*, *C* refer to the first thermal cycle, graphs *A'*, *B'*, *C'* refer to the second thermal cycle. Graphs *C* and *C'* represent the hysteresis of each cycle and are obtained by integration of the thermogenesis from graphs *A* and *B*, and *A'* and *B'*. The hachured area corresponds to the nucleation process related to the first cycle.

FIG. 1. (*Top*) Vertical cross-section of a differential heat-conduction calorimeter. Diagram to show the principle of the calorimetric system for measuring heats of mixing or heats of dilution (1). *A*, stirrer and mixing system; *B*, to amplifier; *C*, syringe; *D*, measurement cell; *E*, reference cell. Equipment designed for the simultaneous experiments in thermosonimetry and calorimetry (1), (2). (*Middle*) Data processing scheme. (*Bottom*) Calorimetric system: *a*, thermoelectric sensor; *b*, sample and reference material; *c*, piezoelectric sensor; *d*, thermometric sensor.

The thermobatteries (Melcor FC 0.6-66-05L) consist of an ensemble of thermoelectric couples made from two elements of semiconductor (bismuth telluride) placed between two square ceramic plates (11.2 × 11.2 mm) separated 2.4 mm. Their temperature range is limited to between −150 and +110°C, which results in the same limitation for the temperatures at which the calorimeter can operate.

The acoustic emission transducers are pill-shaped piezolectric crystals PHILIPS PXE5 (ϕ 5 mm, different thicknesses from 0.5 mm to 2 mm). Their resonance frequency centres around 500 kHz.

Using this configuration and detectors, the main features of the calorimeter are its high sensitivity, between 100 and 360 mV W^{-1} in the whole temperature range, and a first time constant $\tau_1 \approx 12$ s.

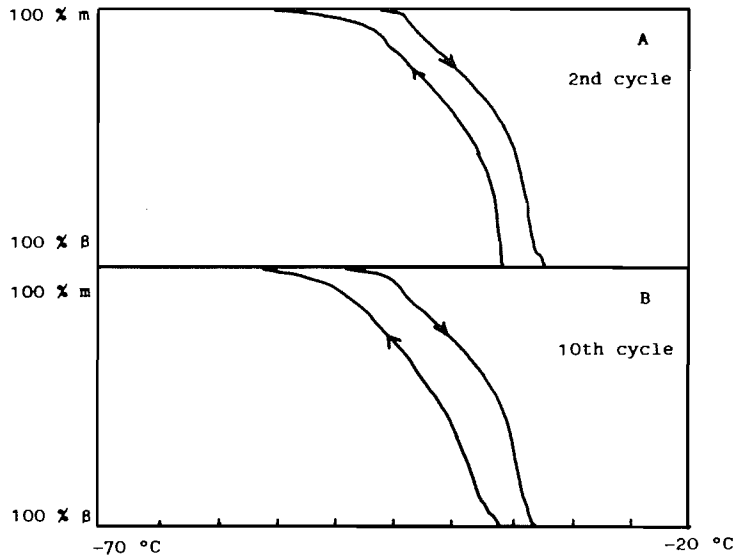

FIG. 3. Change of the hysteresis of the transformations with the number of thermal cycles applied to a sample identical in composition to that of Fig. 2. Graph *A*, 2nd cycle; graph *B*, 10th cycle.

The sensitivity $S(T)$ is obtained by fitting to the experimental values S_1, S_2, ... corresponding to temperatures T_1, T_2, ...

When the mass of the contents of the experimental cell changes with time (as in calorimetric titration) there are corresponding changes in the coefficients of eq. [1]. In modelling these variable systems by comparing the predictions of the models with the experimental results, routines can be established which allow the determination of the instantaneous power associated with a continuous mixing or dilution process (3, 5–7).

In both cases, the inverse filtering permits the compensation of the influence of the most important time constants of the calorimetric equipment (6, 7).

Description of martensitic-type transformations in shape-memory alloys

The properties of these materials make them interesting. They adapt to the conditions imposed on them with several interesting effects (one and two shape-memory effects, pseudo-elasticity, rubber effect, etc). These effects are accompanied by the production of martensitic variants corresponding to the external stress. Alloys of this type include the titanium–nickel system (Nitinol) and copper alloys. The copper–aluminium–zinc and copper–aluminium–nickel alloys are easier to fabricate and produce than the titanium–nickel alloy and their cost is only about 1% of the latter.

There is much current interest in the study of the fundamental properties of these materials with the aim of delaying their ageing, that is, minimising the change in their properties (8).

From calorimetric studies (1, 6, 9), thermograms are obtained which are representative of the complete transformation and these can be used to show how the transformation is influenced by the properties of the material and the treatment imposed upon it. Our experimental results clearly show a change in the transformation depending on the state of the surface (whether or not it favours nucleation) (Fig. 2), the number of thermal cycles (Fig. 3), and the concentration of defects resulting, for example, from quenching in water. Such quenching promotes the appearance of microtransformations at a temperature about 20 K over the normal transformation (10).

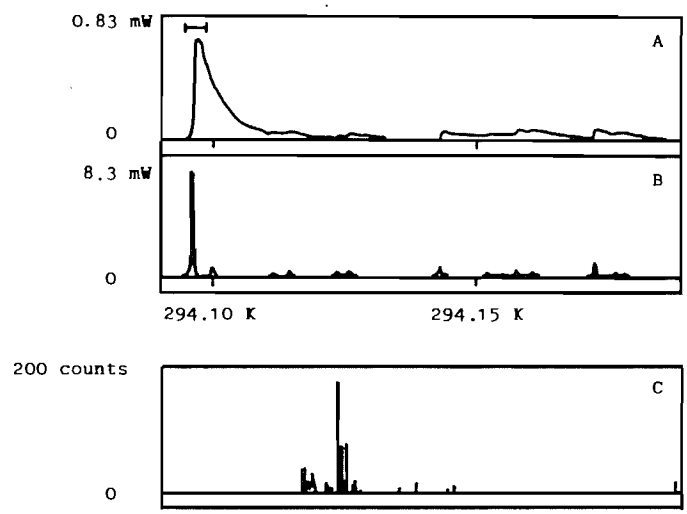

FIG. 4. Transformation of the type martensite → phase β experienced by an alloy Cu, 81.2 wt.% – Al, 11.8% – Mn, 6.8% – Fe, 0.2%. *A*, experimental thermogram; *B*, thermogenesis obtained by deconvolution of the preceding graph; *C*, acoustic emission obtained in the window indicated on graph *A*. Graph shows the ringdown counts as a function of time. (The ringdown counting gives the number of times that the acoustic emission signal crosses a preselected threshold voltage).

Figure 2 relates to changes observed in a sample of the copper–aluminium–zinc alloy (Cu 74.41 wt.% – Al 7.41% – Zn 18.8%). The transformation, phase β → martensite has been studied calorimetrically over the temperature range −20°C to −70°C and the inverse transformation from −70°C to −20°C. The initial sample (about 450 mg) is electrolytically polished before being subjected to the first thermal cycle to which the graphs A, B, and C correspond. Graphs A′, B′, and C′ relate to the second cycle applied to the sample.

In the initial sample, there are very few centres for nucleation and hence the "explosive" nature of the first transformation, phase β → martensite (graph A) is justified. In the second transformation, this characteristic is largely attenuated by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

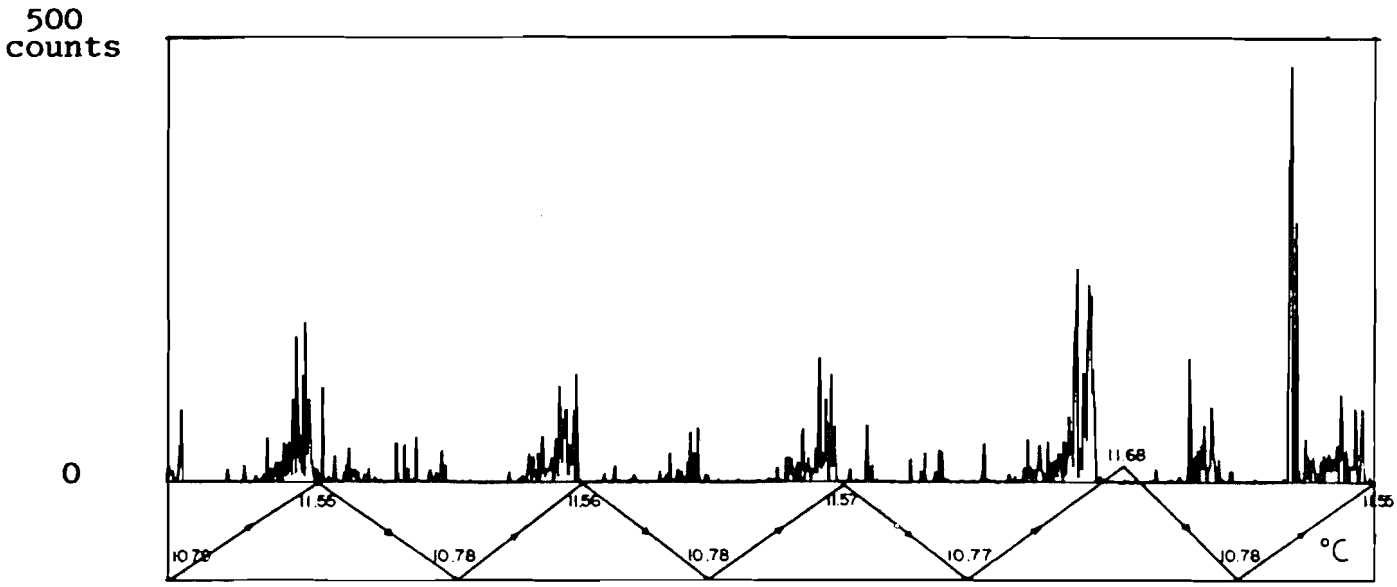

FIG. 5. Change of acoustic emission during thermal cycling for a sample (about 450 mg) of alloy Cu, 68.5 at.% – Al, 16.6% – Zn, 14.9% not subjected to stress. Note the very small changes at the extreme temperatures of the cycle (cycling controlled to about ± 0.01 K).

presence of centres for nucleation created during the first thermal cycle (graph A′).

Figure 3 concerns the same type of sample and shows changes in the hysteresis of the transformation with the number of thermal cycles applied to the material. A broadening of the width of the hysteresis cycle is observed. This is due to a progressive increase in the number of defects promoted by the successive thermal cycles, the transformations gradually becoming more and more complex with increasing number of cycles.

The study of the hysteresis cycles thus provides complementary information since their form is influenced by the characteristics of the material: their breadth is related to the influence of friction, their temperature-dependent extension indicates the existence and importance of the interactions between the variants of martensite. The area of the cycle in temperature–entropy diagram indicates, on the other hand, the importance of the energy losses caused by the thermal cycling associated to the motion of interfaces; the increase of area indicates the increase of friction as a result of defects developed during the cycle.

The thermograms obtained show the complexity of the dynamics of the transformations. This complexity is confirmed by the simultaneous study of the acoustic emission and/or by optical observations (11). In particular, acoustic emission shows evidence of the fine structure of the transformations which from calorimetry appear to be instantaneous and thus elementary.

Figure 4 relates to the inverse transformation martensite → phase β experienced by a sample (about 450 mg) of the alloy Cu 81.2 wt.%, Al 11.8%, Mn 6.8%, Fe 0.2%. The programmed temperature change was very slow (0.01 K min^{-1}). Graph A represents the raw thermogram; graph B is the thermogenesis obtained by deconvolution of the preceding thermogram in the same temperature region; graph C is the acoustic emission (the ringdown histogram versus time) observed in the window, the position and length of which are indicated on graph A. This figure clearly shows that the simultaneous study of acoustic emission describes the fine structure of events which might

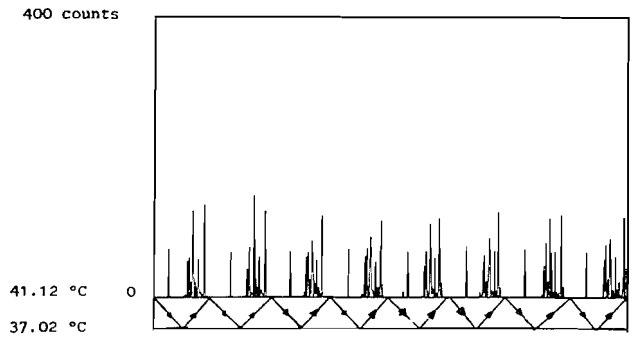

FIG. 6. Change of acoustic emission during thermal cycling in the presence of an external stress for a sample of identical composition to that of Fig. 5.

be assimilated into the elementary transformation or internal stresses reorganization.

When studying the "elementary" transformations in a limited temperature region (less than 5 K for example), a stochastic uncontrolled change of acoustic emission is again observed as seen in Fig. 5. This figure shows the change in acoustic emission observed in the course of several successive thermal cycles applied to a sample of the alloy Cu 68.5 atm.%, Al 16.6%, Zn 14.9%. The stochastic nature of the transformations is apparent in this sample which is not subjected to any stress. The transformation is such that the sum of the internal stresses is minimised. It is therefore evident that there are several orientations of the variants of martensite, that is, several orientations of the independent domains of martensite. These are the parts of the crystal which are transformed by internal adaptation of internal stresses and the local temperature differences induced by (dT/dt) effects.

On the other hand, when the material is subjected to mechanical stress, a completely reproducible process is observed even when measured by acoustic emission. The mechanical stress produces a favoured axis of transformation which results in the appearance of a simple variant of martensite (12). Since the number of degrees of freedom of the material is reduced, a

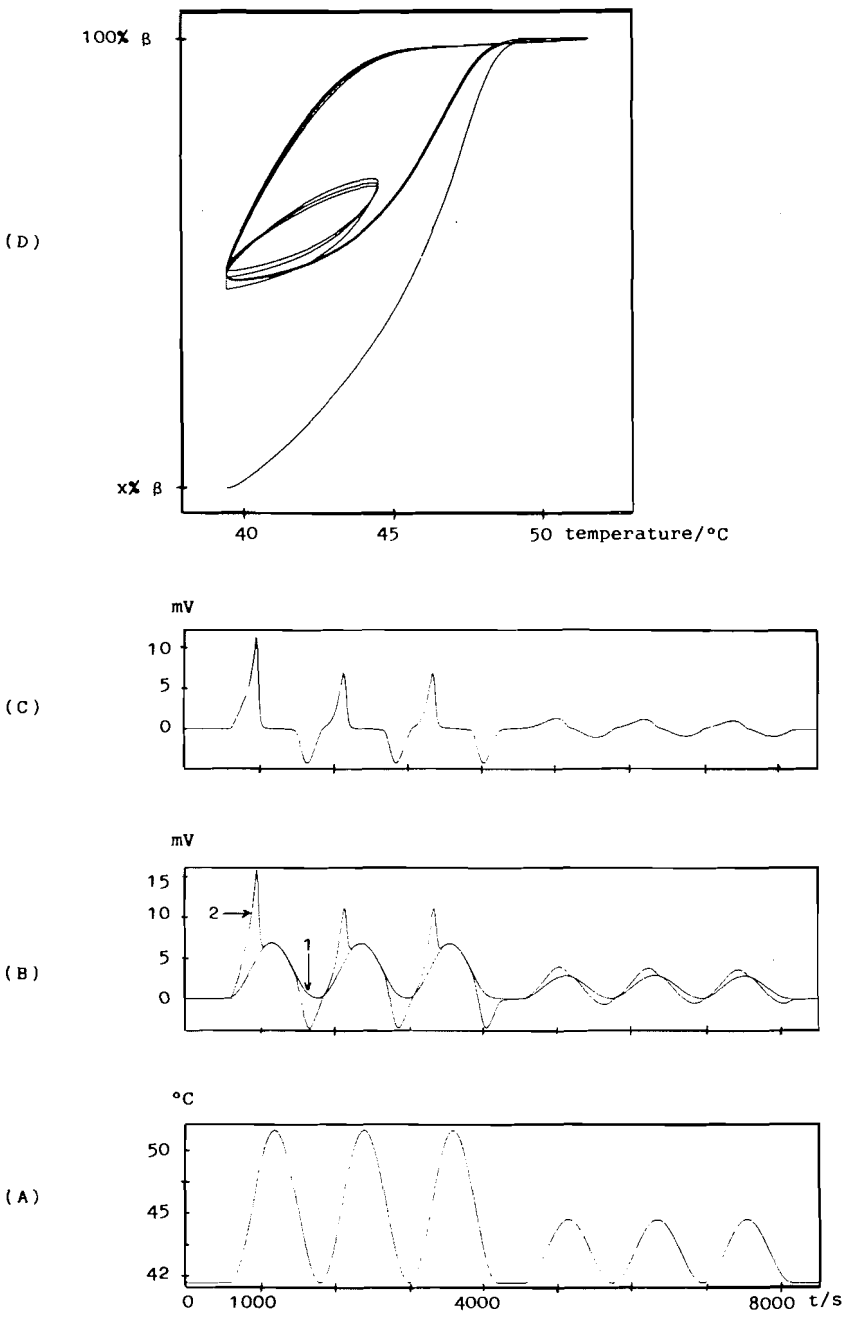

FIG. 7. Partial hysteresis cycle associated with a transformation of the type phase β → martensite experienced by a shape-memory alloy (Cu, 76.99 wt.% – Al, 8.24% – Zn, 14.77%). (*A*): Temperature change of a calorimetric block containing the samples. (*B*): (*1*), Base line of the calorimetric equipment determined in a temperature region where all the material is in its β phase; (*2*), raw thermogram. (*C*) Thermogram obtained after "subtraction" of the base line *1* from thermogram *2*. (*D*) Partial hysteresis cycles obtained by integration of graph *C*.

temperature control of about ±0.01 K is seen to be sufficient for this system.

Figure 6 emphasises the reproducibility of the acoustic emission observed during a thermal cycle (controlled to about ±0.01 K) applied to a sample subjected to mechanical stress. The transformation is favoured by the presence of the external stress and a single variant of martensite is produced. The peaks observed in the acoustic emission with the aid of a multichannel oscilloscope are identical.

These results show that the existence of instantaneous elementary transformations is not indicative of changes in the material. As a parameter of change, one is therefore inclined to use the global entropy increase uniquely associated with the instantaneous process (burst process) and its change during thermal cycling.

The basis of the calculation is the implication that the burst processes produce locally, within the sample, a temperature increase associated with the phase change. The heat conduction in the material and that towards the external thermostat produce an increase in the global entropy, $\Delta S_u(T)$, such that

$$[3] \quad \Delta S_u(T) = \Sigma \Delta S_i = \Sigma Q_i \{(1/T) + (1/(T_m - T))\} \ln (T/T_m)$$

Q_i represents the quantity of heat produced at the time of the elementary transformation, T_m is the temperature of the

region i immediately after the preceding loss, and T is the initial temperature of the material. ΔS_u represents the increase in entropy of the universe associated to temperature internal gradients.

We have also studied the entropy production associated with successive thermal cycles experienced by a sample of a copper–aluminium–zinc alloy of similar composition to that of the material described in Fig. 2. This electrolytically polished sample initially contained few defects since it had been air quenched.

The study of successive cycles (between 280 and 230 K) showed a pronounced tendency for a decrease of entropy production as seen from Table 1.

This entropy production was associated with an increase in the number of defects developed in the course of each cycle. Positron absorption (13) and transmission electron microscopy (14) show evidence for this phenomenon. The observed transformations were less of the burst-like type and more "spreaded" in this temperature region.

The identification and deconvolution techniques allowed the samples to be subjected to a very sophisticated temperature programme whilst at the same time studying the resultant changes in the partial hysteresis cycles. Figure 7 shows the power of the technique developed: graph A represents the temperature change to which the calorimetric block containing the sample under investigation (shape-memory alloy Cu 76.99 wt.% – Al 8.24% – Zn 14.77%) was subjected. This change, which was numerically displayed, had a reproducibility (from one cycle to another) greater than one-hundredth of a degree. Graph B shows the base line of the calorimetric equipment (determined within a temperature region where all the material was in its β phase) and the raw thermogram. Graph C represents the thermogram after "subtraction" of the base line. An excellent signal/noise ratio was obtained after filtering-out the effects of fluctuation of the Peltier current produced by the temperature-controlling system (noise 1 μV).

Total and partial investigation of graph C allows the automatic recording of the global and partial hysteresis curves experienced by the shape-memory alloy, cycles which are of fundamental interest for the macroscopic characterisation of the material (graph D). These cycles define the instantaneous state of the alloy which is of interest both for practical applications and for simulation of its behaviour (15).

The detailed observation of the displacement of an interface caused by temperature change showed evidence of the existence of an intrinsic hysteresis cycle (of width of about 0.5 K) and of the effects of pinings and unpinnings of the interface which (in the case of unpinnings) produced acoustic emission (15–18).

Figure 8 concerns the free displacement of an interface under the influence of temperature as given by optical observation (video). The position of the interface was measured to ±1 μm. The global hysteresis represented by the figure corresponds to a total displacement of 60 μm.

A similar study showed that this cycle possessed several components, including an intrinsic component probably associated with the shuffling of atoms. Interactions with the surface and/or precipitates as well as other interactions with network defects (frictions and observable pinnings) may also occur (15, 18).

Examination of the partial cycle observed even at the centre of the transformation region shows that the reproducibility was satisfactory when the temperature was correctly programmed.

TABLE 1. Entropy production associated with successive thermal cycles

Thermal cycle	Entropy production/(J K^{-1} kg^{-1})
1	0.320
2	0.182
3	0.156
4	0.147

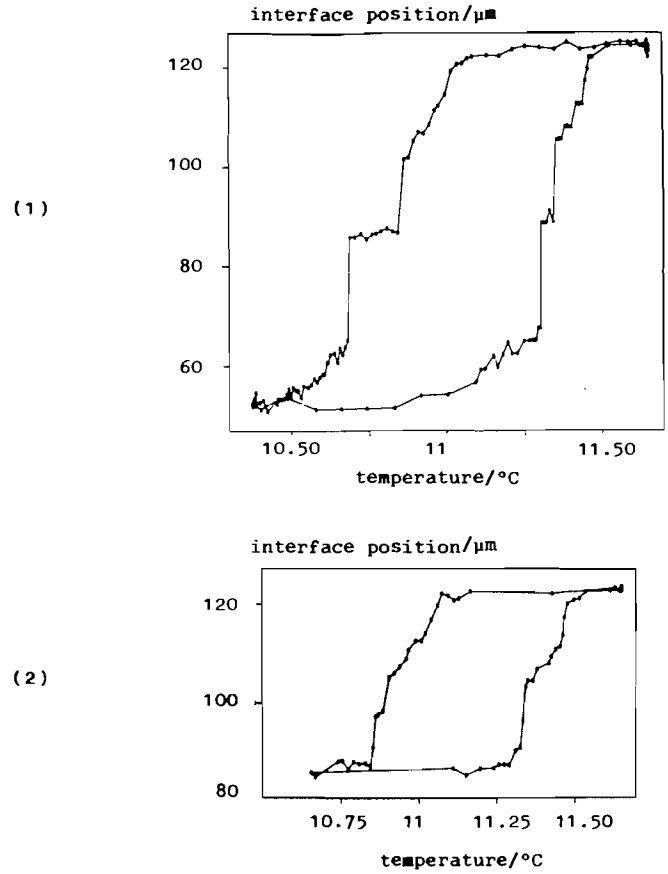

FIG. 8. Transformation of the type β-phase → martensite experienced, in the absence of strain, by a shape-memory alloy (Cu, 76.99 wt.% – Al, 8.24% – Zn, 14.77%). Displacement of an interface under the influence of temperature.

Maximum temperature rate of the sample 8.55 mK s^{-1}.

Hysteresis cycles corresponding to the displacement of an interface (position located optically to ±1 μm). Partial cycle 2 shows the existence of an intrinsic cycle.

The width of a macroscopic hysteresis cycle greatly exceeded that of an intrinsic cycle of a so-called "thermoelastic" material. There are probably interactions between the various variants, frictions, coupling between the interfaces and stabilization effects of β and martensite phases (19) which are responsible for this width (about 3 K).

Conclusions

The modelling of calorimetric equipment (variable or invariant) allows for the establishment of algorithms for the deconvolution of the thermograms and the determination of the dynamic energy (thermogenesis) of the phenomenon under investigation. Our studies have entailed an increase of the area of application and of the degree of resolution of differential scanning calorimeters.

In the study of phase transformations of the martensitic type, a calorimetric study makes clear the influence of thermomechanical treatment of the material and allows the evaluation of the influence of defects on the dynamics of transformation.

By combining calorimetric and acoustical observations, the change in the dynamics of the transformations demonstrates the existence of irreversibilities even in the so-called thermoelastic transitions (transitions produced in limited temperature regions).

When the materials are subjected to mechanical stresses and when the temperature is rigorously controlled, these irreversibilities do not induce any structural changes in these materials. On the other hand, during spontaneous transformation, changes in the medium may be characterized by the production of entropy as inferred from the calorimetric results.

A. C. HOPKINSON and M. H. LIEN. Can. J. Chem. **67**, 991 (1989).

Ab initio molecular orbital calculations at the 6-31G* level have been used to optimise structures for ions SiX^+, $HSiX^{+\cdot}$, and H_2SiX^+, and for neutrals HSiX (singlets), $H_2SiX^\cdot$, and H_3SiX, where X is H, CH_3, NH_2, OH, F, CN, and NC. Single point calculations at the MP4(SDTQ)/6-31G* level were used to calculate substituent stabilisation energies.

The amino group is the strongest π-donor and also is the most stabilising group in the cations, the silylenes, and the silyl radicals. Stabilisation is greatest in ions SiX^+. Ions $HSiX^{+\cdot}$ and H_2SiX^+ are stabilised by similar but smaller amounts, although CN and NC are destabilising in these ions. Substituent stabilisation energies in radicals $H_2SiX^\cdot$ are almost zero. There is a linear relationship between the stabilisation energies of ions H_2SiX^+ and the ionisation potentials of radicals $H_2SiX^\cdot$, but a similar plot correlating stabilisation energies for ions $HSiX^{+\cdot}$ with the ionisation potential of HSiX (singlet) shows considerable scatter.

Key words: silications, silyl radicals, stabilisation energies.

A. C. HOPKINSON et M. H. LIEN. Can. J. Chem. **67**, 991 (1989).

On a utilisé des calculs d'orbitales moléculaires ab initio au niveau 6-31G* pour optimiser les structures des ions SiX^+, $HSiX^{+\cdot}$ et H_2SiX^+ ainsi que des composés neutres HSiX (singulets), $H_2SiX^\cdot$ et H_3SiX dans lesquels X est égal à H, CH_3, NH_2, OH, F, CN ainsi que NC. Afin de calculer les énergies de stabilisation des substituants, on a utilisé des calculs au niveau MP4(SDTQ)/6-31G*.

Le groupement amino est le meilleur donneur π; il est le plus stabilisant des cations et des radicaux silyle et silylènes. Sa stabilisation est maximale dans les ions SiX^+. Les ions $HSiX^{+\cdot}$ et H_2SiX^+ sont stabilisés de la même manière, mais un peu moins; toutefois, dans ces ions, les groupements CN et NC sont déstabilisants. Les énergies de stabilisation des substituants dans les radicaux $H_2SiX^\cdot$ sont pratiquement égales à zéro. Il existe une relation linéaire entre les énergies de stabilisation des ions H_2SiX^+ et les potentiels d'ionisation des radicaux $H_2SiX^\cdot$; dans le cas de la courbe équivalente reliant les énergies de stabilisation des ions $HSiX^{+\cdot}$ avec le potentiel d'ionisation du HSiX (singulet), on note toutefois une dispersion importante.

Mots clés : des cations et des radicaux silyle, les énergies de stabilisation des substituants.

[Traduit par la revue]

Carbenium ions are common intermediates in organic reactions and many are sufficiently stable to be long-lived in strong acid solutions. Silicon is more electropositive than carbon and carries a positive charge more easily, but silicenium ions R_3Si^+ have proved to be elusive species in solution and only recently has there been good experimental evidence for their existence (1–4). Silicenium ions are more commonly observed in the gas phase (5–8) and in this phase carbenium ions abstract hydride or alkyl anions from silanes to form silicenium ions (8). Also *ab initio* molecular orbital calculations have shown that carbenium ions with a silyl or trimethylsilyl group in the α-position undergo a 1,2-shift of hydrogen or methyl, with little or no barrier, to form the lower energy silicenium ions (4, 9). Clearly then, in the absence of solvent, silicenium ions are thermodynamically more stable than the isomeric carbenium ions.

π-Donation from an α-substituent is strongly stabilising in carbenium ions (10–14), but less so in silicenium ions (15, 16). The decreased stabilisation in silicenium ions is attributed to the higher intrinsic ability of silicon to carry a positive charge and to the poor overlap between the π-donating 2*p*-orbital on nitrogen and oxygen with the vacant 3*p*-orbital on silicon (15, 16). Better overlap with silicon can be achieved by using donor elements from the second row, but PH_2 is less effective at stabilising silicenium ions than NH_2, and this has been attributed to the higher energy required to take the pyramidal PH_2 group into the more planar conformation required for π-donation. Some unsaturated molecules containing silicon are known e.g.

$$\rangle Si{=}C\langle \ (17),\quad \rangle Si{=}O\ (18, 19),\quad \text{and}\quad \rangle Si{=}Si\langle \ (20, 21)$$

but, in general, compounds with multiple bonds to silicon are very reactive and rarely encountered in the laboratory. Several such molecules are, however, either known or predicted to exist in interstellar space. SiO and SiS are believed to be present in interstellar space. SiO and SiS are believed to be present in interstellar clouds (22, 23) and lines in the spectrum from interstellar space have been tentatively assigned to HSiN (24) and $HSiC_2$ (25). *Ab initio* molecular orbital calculations cast doubt upon the existence of these last two structures. The $HSiC_2$ radical was assigned to be $^2\Sigma$ whereas theory shows the ground state to be $^2\Pi$ (26), and radical HSiN is at least 55 kcal/mol above the isomeric HNSi (27–31). Also the latter molecule is expected to be formed easily from Si^+ (^2P) and NH_3, both of which are abundant in interstellar clouds, followed by proton transfer from $SiNH_2^+$, possibly to NH_3 (31). The reactions of Si^+ with a variety of small molecules have been shown to form several ions SiX^+ (5, 32, 33).

Previously, we have compared the role of substituents in carbocations and carbenes with formally different amounts of electron deficiency at carbon (13). In all these species NH_2, the most potent π-donor, has the largest stabilising effect, while the CN group, normally both σ- and π-electron withdrawing, functions as a π-donor but is destabilising in carbocations and weakly stabilising in carbenes. For the smallest cations CX^+, it is not possible to draw a reasonable resonance structure in

which the carbon atom has a complete octet and these ions then have the largest positive charges on carbon and have the largest

$$:\overset{+}{C}—X \leftrightarrow :C{=}X^+$$

substituent stabilisation energies. Radical cations $CHX^{+\bullet}$ (again formally lacking an octet in any resonance structure) and methyl cations CH_2X^+ have smaller, but similar, stabilisation energies. Singlet carbenes, like carbocations, formally have a vacant *p*-orbital and are strongly stabilised by π-donors. Singlet carbene substituent stabilisation energies, then, are similar to those of methyl cations and are much larger than those of triplet carbenes (34–36).

In silicenium ions (4, 15, 16) and silylenes (30, 37) π-donating α-substituents are stabilising, but less so than in their carbon analogues. Here we extend the study of substituent effects in silacations to ions which are of current interest in interstellar chemistry, ions SiX^+ and $SiHX^{+\bullet}$ which are formally more electron-deficient at silicon than the silicenium ions SiH_2X^+. We have also re-examined the silicenium ions SiH_2X^+ at the same high level of theory (MP4SDTQ/6-31G*) as used in the recent work on silylenes (30). Finally, in order to calculate ionisation energies, we have also included calculations on the silyl radicals $SiH_2X^\bullet$. The unsubstituted SiH_n and SiH_n^+ (where *n* takes values from 1 to 4) have previously been studied at the 6-21G level of theory (38).

Computational methods

All molecular geometries were fully optimised with the 6-31G* basis set (39) initially using the Monstergauss program (40). The Gaussian 82 program (41) was used to construct the force constant matrix and all structures were shown to be at minima (i.e. no negative eigenvalues). Singlet spin states were calculated by using closed-shell spin-restricted Hartree–Fock theory (RHF) (42) and doublets were calculated with spin-unrestricted theory (UHF) (43). Post-Hartree–Fock calculations were performed at the fourth-order Møller–Plesset level (44) (MP4SDTQ) on the structures previously optimised at the 6-31G* level (such calculations are denoted by MP4/6-31G*//HF/6-31G*).

Results and discussion

(a) Structures

The HF/6-31G* and post-Hartree–Fock energies for all the monosubstituted silicon-containing molecules are listed in Table 1. The structural parameters of greatest interest, the Si—X bond lengths and the angles HSiX are reported in Table 2, along with the net-charges on the silicon atom and, in the planar cations and the silylenes, the populations of the formally vacant 3*p*-orbital on silicon. The triplet states are higher in energy than the singlets (41) and only the singlets are included in Table 2.

Several structural features are worthy of comment. The ions have Si—X bond lengths which are dependent only on X and not on the coordination number of silicon, i.e. the bond lengths of SiX^+, $HSiX^{+\cdot}$, and H_2SiX^+ are almost identical, regardless of the extent of electron-deficiency at silicon. Similarly in the neutrals HSiX (singlets), $H_2SiX^{\cdot}$, and H_3SiX, the Si—X distances are almost identical, but are longer than in the cations. Comparing ions with the neutrals from which they are generated by ionisation, then in the parent system the bond length of $SiH_3^{\cdot}$ is only 0.022 Å longer than that of SiH_3^+, but the differences are considerably larger when X is a π-donor. For example, in $H_2SiX^{\cdot}$ when X is NH_2 and NC the Si—N bond lengths are both 0.095 Å longer than in H_2SiX^+, while the more unsaturated system $HSiNC^{+\cdot}$ has an Si—N bond length 0.112 Å shorter than in singlet HSiNC.

Ionisation of $H_2SiX^{\cdot}$ and HSiX (singlet) formally replaces Si with Si^+ and the Mulliken population analysis shows that more than half the positive charge is added to the silicon. This increases the electronegativity of the silicon and results in the Si—H bonds being shorter in the cations. The β-linkages in the substituent (heteroatom-H, or C—H) are the least affected by ionisation and these all increase slightly except when X is CN.

(b) Stabilisation energies

The effect of the substituent X in the silacations relative to that in silanes can be assessed from the isodesmic bond-separation reactions in eqs. [1]–[3].

[1] $SiX^+ + SiH_4 \rightarrow SiH^+ + H_3SiX$

[2] $HSiX^{+\cdot} + SiH_4 \rightarrow SiH_2^{+\cdot} + H_3SiX$

[3] $H_2SiX^+ + SiH_4 \rightarrow SiH_3^+ + H_3SiX$

Equation [3] can be modified for silyl radicals by replacing the superscript positive sign by an electron dot. A positive energy difference for these reactions indicates that the substituent is more stabilising in the cation (or radical) than in the silane (where interactions are assumed to be minimal). The stabilisation energies for SiX^+, $HSiX^{+\cdot}$, H_2SiX^+, HSiX (singlet), and $H_2SiX^{\cdot}$ are given in Table 3, along with those for the identically substituted carbon analogues.

Several trends emerge from the stabilisation energies of the silacations. In cations SiX^+ all substituents are stabilising and the stabilisation energies are considerably larger than in $HSiX^{+\cdot}$ and H_2SiX^+. As with the analogous carbocations the stabilisation energies of the latter two ions are almost identical.

The ability of substituents to stabilise silacations follows the order $NH_2 > OH > CH_3 > F > NC > CN$. Fluorine is strongly stabilising in SiF^+, but has little effect in $HSiF^{+\cdot}$ and H_2SiF^+. Isocyano is somewhat less stabilising in $SiNC^+$ and is weakly destabilising in $HSiNC^{+\cdot}$ and in H_2SiNC^+. The cyano group is only weakly stabilising in $SiCN^+$ and is strongly destabilising in $HSiCN^{+\cdot}$ and H_2SiCN^+. For substituents with a lone pair of π-symmetry there is a rough correlation between the stabilisation energy and the amount of π-donation. For a given substituent X the Si—X distance is almost the same in all ions and the amount of π-donation from substituent to Si^+ is also the same. The amino group is the strongest π-donor and even the cyano group, normally a π-acceptor in neutral molecules, also functions as a weak π-donor in the cations. The order of

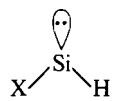
π-donation is $NH_2 > OH > F \approx NC > CH_3 > CN$ i.e. substituents formally carrying lone pairs are better π-donors than groups which delocalise through unsaturated bonds or hyperconjugation. Clearly then the amount of π-donation is a poor indicator of the methyl group's ability to stabilise silacations.



In the carbocations CH_nX^+ for a given X the C—X bond length increases with n and, somewhat surprisingly, the amount of π-donation to C^+ also increases (13). The donor orbitals have better overlap with the vacant 2p-orbital on carbon than with the 3p-orbital on silicon and consequently all the substituents are better π-donors in CH_nX^+ than in SiH_nX^+.

Stabilisation energies again roughly follow the amount of π-donation and are much larger for carbocations than for silacations. The cyano group is somewhat anomalous; in the carbocations it is a strong π-donor but is destabilising, while in $SiCN^+$ it is a weak π-donor, but also weakly stabilising.

Both the radical cations $HSiX^{+\bullet}$, **1**, and the singlet silylenes HSiX, **2**, are, in principle, stabilised by the same mechanism, π-donation to the vacant 3p-orbital in silicon.

1

2

There is larger π-donation in the more electron-deficient silacations and for potent donors NH_2 and OH π-stabilisation dominates and the cation stabilisation is larger than that of the silylenes. When X is a weaker π-donor and a stronger σ-withdrawing group (X = F, CN, and NC) then the singlet silylene is weakly stabilised but in the cations σ-withdrawal dominates and the result is destabilisation.

(c) Ionisation energies and stabilisation energies

The following thermochemical cycle has been used to relate the stabilisation energies of cations (SE^+) with the ionisation potentials of the radicals (45).

$$H_2SiX^+ + SiH_4 \xrightarrow{SE^+} H_3SiX + SiH_3^+$$
$$\downarrow -I_{H_2SiX_2^\bullet} \qquad \uparrow I_{SiH_3^\bullet}$$
$$XSiH_2^\bullet + SiH_4 \xrightarrow{SE^\bullet} H_3SiX + SiH_3^\bullet$$

Formally the stabilisation of the cation is given by eq. [4].

$$[4]\quad SE^+ = SE^\bullet + I_{SiH_3^\bullet} - I_{H_2SiX^\bullet}$$

From Table 3 the stabilisation energies of the radicals ($SE^\bullet$) are small, varying from 2.1 kcal mol^{-1} for NH_2 to −1.7 kcal mol^{-1} for F. If $SE^\bullet$ is taken to be zero then SE^+ is linearly related to the ionisation potential of $H_2SiX^\bullet$. Ionisation potentials were calculated at the MP4/6-31G*//HF/6-31G* level of theory by taking the difference in energy between $H_2SiX^\bullet$ and H_2SiX^+ (including zero-point energy). Further improvement in theory should favour the radical and the ionisation potentials may therefore be slightly too small. However, any error is likely to be common to all ionisation potentials and the plot of stabilisation versus ionisation potential shows a good linear correlation (Fig. 1).

The ionisation potentials of the radicals can also be estimated by using the orbital energies of the highest occupied molecular orbitals (Koopmans' theorem). This more approximate method does not allow for the increased binding in the cation and leads to an overestimation of the ionisation potential. Nevertheless, a plot of the stabilisation energies of SiH_2X^+ against the HOMO of the radicals $SiH_2X^\bullet$ produces a linear plot (Fig. 1), but with more scatter.

Silylenes are ground state singlets and a plot of stabilisation energies of $HSiX^{+\bullet}$ versus the ionisation potential of HSiX (determined by taking the difference between the energies of HSiX and $HSiX^{+\bullet}$) shows considerable scatter (Fig. 2(*a*)). The two points which deviate furthest from the line are for the methyl and hydrogen (parent) substituted ions, i.e., the stabilisation energies of both these ions are too small. The largest positive deviation is for the amino-substituted ion. Hydrogen is not a π-donor and the methyl group is the weakest π-donor, while the amino group is the strongest donor. The ability of the substituent to function as a π-donor, then, dictates whether the stabilisation energy for a substituent will fall above or below the line in Fig. 2(*a*).

The scatter in Fig. 2(a) arises from the stabilisation energy of the singlet. For the same type of thermochemical cycle as used above, but involving the radical cation and silylene, $SE^{+\bullet}$, is given by equation 5.

$$[5]\quad SE^{+\bullet} = SE(\text{silylene}) + I_{SiH_2} - I_{HSiX}$$

A plot of $SE^{+\bullet}$ against I_{HSiX} will be linear only if the

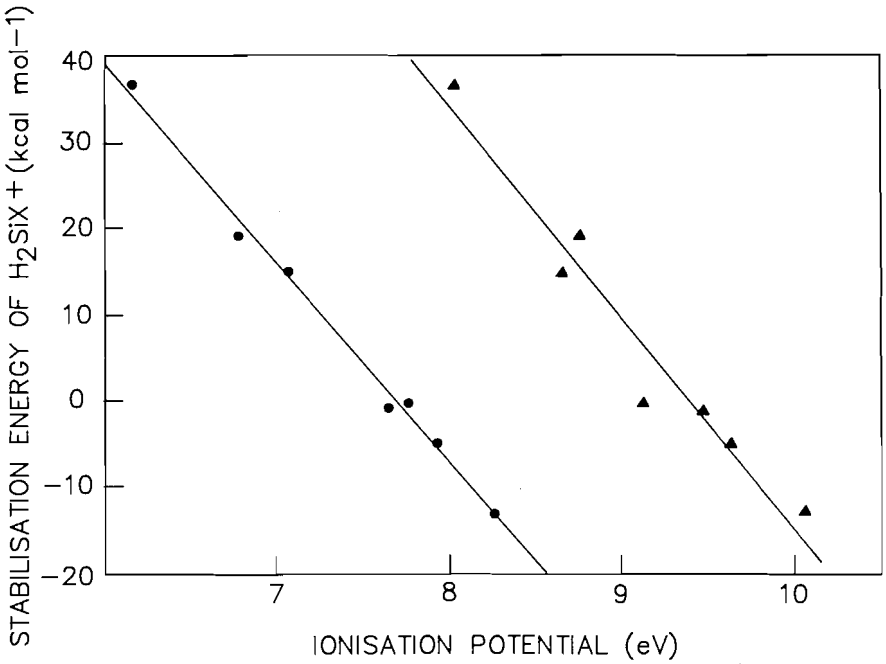

FIG. 1. Plot of stabilisation energies for ions H_2SiX^+ against the ionisation potential of the radicals $H_2SiX^{\cdot}$; ● indicates ionisation potential taken from ($E_{H_2SiX^{\cdot}} - E_{H_2SiX^+}$); ▲ indicates energy of radical HOMO.

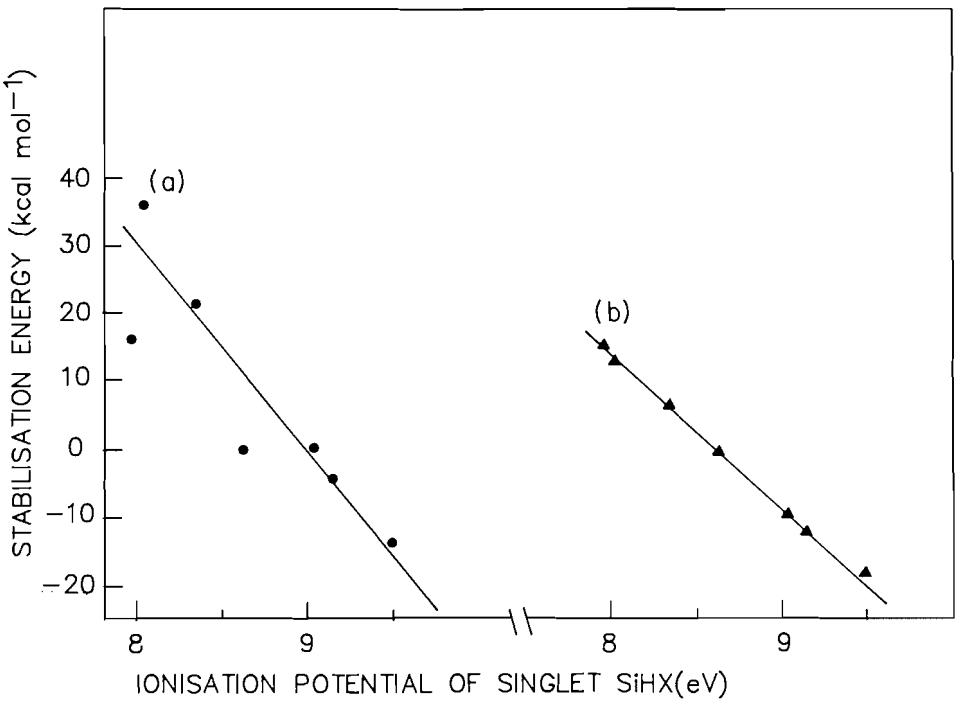

FIG. 2. (*a*) Plot of stabilisation energies for ions $HSiX^{+\cdot}$ against the ionisation potential of singlet silylenes HSiX; (*b*) plot of difference in stabilisation energies of cations $HSiX^{+\cdot}$ and singlet silylenes HSiX against ionisation potentials of silylenes.

stabilisation energy of the silylene is constant. In Table 3 the stabilisation energies of silylenes are shown to vary, from 14.7 kcal mol^{-1} for NH_2 to zero for H, and hence there is considerable scatter in Fig. 2(*a*). However, a plot of [$SE^{+\cdot}$ − SE(silylene)] against I_{HSiX} should be linear and this is found to be the case (Fig. 2(*b*)).

$$\begin{array}{ccc} HSiX^{+\cdot} + SiH_4 & \xrightarrow{SE^{+\cdot}} & H_3SiX + SiH_2^{+\cdot} \\ \Big\downarrow -I_{HSiX} & & \Big\uparrow I_{SiH_2} \\ HSiX + SiH_4 & \xrightarrow{SE(silylene)} & H_3SiX + SiH_2 \end{array}$$

(d) Proton affinities of silylenes and carbenes

The proton affinity of a silylene is the negative of the enthalpy of the reaction described in eq. [6]. At the MP4/6-31G* level of theory, including zero-point energies, the proton affinity of the parent singlet silylene (X = H) is 193.9 kcal mol^{-1}.

[6] $HSiX + H^+ \rightarrow H_2SiX^+$

TABLE 4. Proton affinities (kcal mol^{-1}) of singlet silylenes and singlet carbenes

X	Silylenes HF/6-31G*	Silylenes MP4/6-31G* + ZPE	Carbenes HF/6-31G*
H	206.5	193.9	224.6
CH_3	220.7	208.9	244.3
NH_2	220.5	209.0	256.5
OH	210.7	198.4	234.0
F	195.9	184.1	212.7
CN	187.1	176.8	203.8
NC	197.6	181.8	219.0

In singlet silylenes the bond angle at silicon is close to 90°, indicating that the bonds have mainly *p*-orbital character with the lone pair having a high percentage *s*-character (30). Protonation of singlet silylenes to generate a trigonal geometry at the silicon atom then involves promotion of these 3*s* electrons into a bonding pair. In contrast, the bond angles in singlet carbenes are somewhat larger and the lone pair has more *p*-character. Protonation of singlet carbene then is more exothermic than protonation of silylene (by 18 kcal mol^{-1} at the 6-31G* level).

Stabilisation by π-delocalisation is important in singlet silylenes but is larger in the product of the protonation reaction, the silicenium ions. When X is CH_3, NH_2, and OH the proton affinities of silylenes are larger than that of the parent (Table 4). Conversely, silylenes which contain substituents that are destabilising in silicenium ions (X = F, CN, and NC) have lower proton affinities than SiH_2. The proton affinities of singlet carbenes show a very similar substituent dependence to that found in the silylenes (13).

(e) Relative energies of cyanides and isocyanides

Organonitriles are generally lower in energy than the isomeric isonitriles (46). However, the isonitrile group is a better π-donor than cyano and in α-X-substituted carbocations, the isocyano-substituted carbocations are lower in energy. When CN and NC are attached to silicon the effect is less pronounced but somewhat similar. In five neutral species, SiX$^{\bullet}$ (47), HSiX (singlet), HSiX (triplet), $H_2SiX^{\bullet}$, and H_3SiX the cyano-substituted molecules have the lower energy (Table 5), but the differences are smaller than in the carbon analogues. When adjacent to Si^+ the isocyano group acts as a π-donor, resulting in a shortening of the Si—N bond and a slight lengthening of N—C. These structural changes are consistent with appreciable contribution from valence bond structure **3***b*.

$$H_nSi^{+}—N^{+}\equiv C^{-} \longrightarrow H_nSi=N^{+}=C$$

3*a* **3***b*

A similarly situated cyano group is a much weaker π-donor and the net-result is that isocyano-substituted silacations are lower in energy than the isomeric cyano-substituted ions. The difference is most pronounced in the most unsaturated ion, SiX^+ and smallest in H_2SiX^+.

Inclusion of correlation energy consistently favours cyano-substituted molecules and ions over the isomeric isocyanides. This appears to be a general phenomenon as it has previously (47–49) been observed for SiCN/SiNC, HCN/HNC, LiCN/LiNC, BCN/BNC, CH_3CN/CH_3NC, and NH_2CN/NH_2NC.

TABLE 5. Relative energies[a] of RCN and RNC[b]

Species		6-31G*	MP4/6-31G*

Conclusions

Substituent stabilisation energies in silacations are largest in ions SiX^+, and smaller but similar in $SiHX^{+\bullet}$ and SiH_2X^+. Substituents have little or no effect in radicals. The substituent dependence of silacations and silaradicals, then, is very similar to that of the carbon analogues, although the effects at silicon are smaller in magnitude. For cations SiH_2X^+ and $SiHX^{+\bullet}$ the stabilisation energies are linearly related to the ionisation potentials of $SiH_2X^{\bullet}$ and SiHX, respectively. A similar relationship has recently been reported for the methyl cations CH_2X^+.

Using standard heats of formation for the hydride transfer reaction in eq. [7] (X = H) ΔH^0_{298} is 57 kcal mol^{-1}, indicating

[7] $CH_3X + SiH_2X^+ \rightarrow SiH_4 + CH_2X^+$

that the parent silyl cation intrinsically supports the positive charge more easily than the methyl cation. However, substituents overlap more effectively with orbitals on carbon and all the substituents are more stabilising, or less destabilising, in the carbocations CH_nX^+ than in the silacations SiH_nX^+. In all the cations, π-donation to the vacant *p*-orbital at the cation centre has the strongest stabilising effect and the amino group is the most effective donor. Stabilisation at carbon by the amino group is so strong that for eq. [7] when X is NH_2 the calculated ΔE^0_0 is −36 kcal mol^{-1} (at the 6-31G* level), i.e., the intrinsic ability of silicon to support a positive charge relative to carbon has been more than overcome by the stabilisation endowed by the amino group.

The biosynthesis of ephedrine

GUNNAR GRUE-SØRENSEN[1] AND IAN D. SPENSER[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 28, 1988

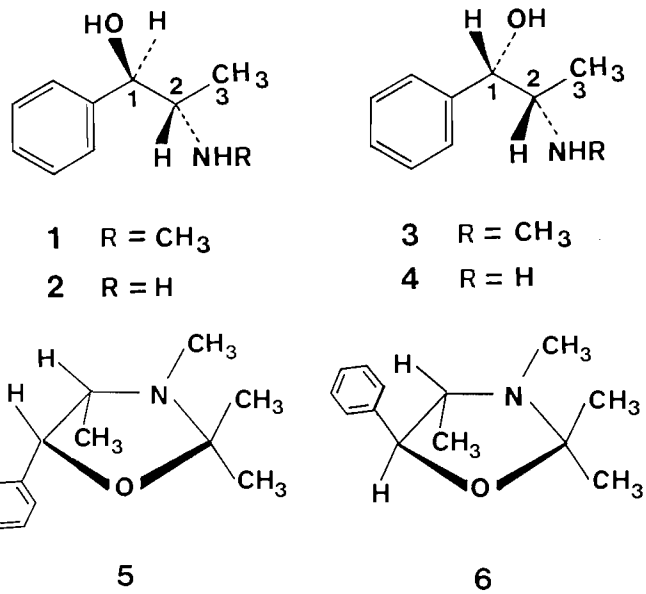
GUNNAR GRUE-SØRENSEN and IAN D. SPENSER. Can. J. Chem. **67**, 998 (1989).

It is shown by ^{13}C nuclear magnetic resonance spectroscopy that the labelled C_2 fragment of [2,3-$^{13}C_2$]pyruvic acid is transferred intact into the C-methyl group and the adjacent carbon atom of the Ephedra alkaloids, norephedrine, ephedrine, norpseudoephedrine, and pseudoephedrine, in growing plants of *Ephedra gerardiana*. This finding serves to identify pyruvate as the elusive precursor of the aliphatic C_2 terminus of the skeleton of the alkaloids. In earlier experiments with ^{14}C-labelled substrates, label from [3-^{14}C]pyruvic acid was incorporated mainly, but not exclusively, into the C-methyl group of ephedrine, and label from [2-^{14}C]pyruvate was incorporated similarly into the carbon atom adjacent to the C-methyl group. A C_6–C_1 unit related to benzaldehyde or benzoic acid has long been known to generate the benzylic fragment of the carbon skeleton of the Ephedra alkaloids. It is likely that the carbon skeleton of ephedrine is generated from pyruvate and either benzaldehyde or benzoic acid, by a reaction analogous to the formation of acetoin or diacetyl from pyruvate and acetaldehyde or acetic acid, respectively.

Key words: biosynthesis of ephedrine, Ephedra alkaloids, ^{13}C NMR spectra, ephedrine, biosynthesis of pyruvic acid, incorporation into ephedrine ^{13}C NMR spectra.

GUNNAR GRUE-SØRENSEN et IAN D. SPENSER. Can. J. Chem. **67**, 998 (1989).

Utilisant la résonance magnétique nucléaire du ^{13}C, on a démontré que, dans les plants d'*Ephedra gerardiana* en croissance, le fragment en C_2 de l'acide pyruvique-[$^{13}C_2$-2,3] est transféré tel quel au groupement C-méthyle et à l'atome de carbone adjacent de la norépédrine, de l'éphédrine de la norpseudoéphédrine et de la pseudoéphédrine, des alcaloïdes de l'Ephedra. Sur la base de ces résultats, on peut identifier le pyruvate comme le précurseur de la portion aliphatique en C_2 du squelette des alcaloïdes. Dans des expériences antérieures réalisées à l'aide de substrats marqués au ^{14}C, le marqueur provenant de l'acide pyruvique-[^{14}C-3] avait été incorporé principalement, mais pas exclusivement, dans le groupement C-méthyle de l'éphédrine alors que le marqueur du pyruvate-[^{14}C-2] s'était lui aussi incorporé dans l'atome de carbone adjacent au groupement C-méthyle. Ou sait depuis longtemps que l'unité C_6–C_1 reliée au benzaldéhyde ou à l'acide benzoique génère le fragment benzylique du squelette de carbone des alcaloïdes de l'Ephedra. Il est probable que le squelette carboné de l'éphédrine est généré, à partir du pyruvate et du benzaldéhyde ou de l'acide benzoique, par une réaction analogue à celle conduisant à la formation de l'acétoine ou du diacétyle à partir du pyruvate et respectivement de l'acétaldéhyde ou de l'acide acétique.



Mots clés : biosynthèse de l'éphédrine, alcaloïdes de l'Ephedra, RMN du ^{13}C, éphédrine, biosynthèse de l'acide pyruvique, incorporation dans les spectra RMN du ^{13}C de l'éphédrine.

[Traduit par la revue]

Introduction

(−)-Ephedrine (**1**) is the active principle of the herb "Ma Huang," which has been used in Chinese medicine for centuries (1). The compound has received much attention by pharmacologists because of its action on the central nervous system (2), but despite its simple chemical structure the biosynthetic origin of its carbon skeleton is still not established. In plants of the genus *Ephedra* (−)-ephedrine is usually found together with (−)-norephedrine (**2**), (+)-pseudoephedrine (**3**), and (+)-norpseudoephedrine (**4**) (1, 3), and it is likely that the phenylpropanoid skeleton of these four alkaloids is derived from common precursors. *Catha edulis*, a plant of an unrelated genus, which is used as a stimulant in many parts of the Middle East (4), contains (+)-norpseudoephedrine (**4**). It was shown some 30 years ago (5) that, in this plant, radioactivity from the benzylic carbon atom of phenylalanine was transferred into the benzylic carbon atom of (+)-norpseudoephedrine (**4**), and that, in *E. distachya*, the N-methyl group of **1** is derived from the S-methyl group of methionine (6).

It was originally thought that the aminophenylpropanoid system of ephedrine was derived directly from phenylalanine (7) or by reaction of a phenylalanine-derived phenethylamine with a formate-derived one-carbon unit (8–10). These views had to be abandoned when it was found (11, 12) that label from [2-^{14}C]phenylalanine did not enter ephedrine, and that label from [2,3-^{14}C]phenylalanine was found solely at the benzylic carbon atom, C-1, of ephedrine (from [3-^{14}C]phenylalanine) but not at C-2, the site predicted for entry of label from [2-^{14}C]phenylalanine. It thus became evident that phenylalanine supplies neither the intact phenylpropanoid system of the alkaloids, nor a C_6–C_2 moiety, but merely a C_6–C_1 unit. Benzoic

acid and benzaldehyde, whose side-chain carbon atom enters the benzylic carbon atom of ephedrine (11, 12), are presumably intermediates on the route from phenylalanine into the C_6–C_1 unit of the alkaloids.

The origin of the C_2 unit, C-2,-3, of ephedrine remained unknown. None of a wide range of ^{14}C-labelled substrates ([2-^{14}C]glycine (12), [U-^{14}C]alanine (12), [U-^{14}C]serine (12), [U-^{14}C]aspartic acid (12), [2-^{14}C]propanoic acid (12), [^{14}C]formic acid (8, 12), [6-^{14}C]glucose (12)) delivered radioactivity preferentially into this unit.

We have investigated the origin of this C_2 unit. Experiments with ^{14}C-labelled substrates did not lead to unequivocal results. It was only with the advent of high field ^{13}C nmr spectroscopy that definitive proof emerged that the nonbenzylic C_2 unit of the Ephedra alkaloids is derived intact from pyruvic acid.[3]

Methods and results

Specifically ^{14}C-labelled samples of serine (in admixture with [ring-^{3}H]phenylalanine), of pyruvic acid, and of acetic acid were administered to *Ephedra gerardiana* and *E. distachya* plants by infusion into their stems through cotton wicks or by external application (Table 1, Expts. 1–8). Extraction of the plants yielded a mixture of the diastereomeric alkaloids, (−)-ephedrine ((1*R*,2*S*)-2-methylamino-1-phenylpropan-1-ol) (**1**) and (+)-pseudoephedrine ((1*S*,2*S*)-2-methylamino-1-phenylpropan-1-ol) (**3**). Separation was achieved by conversion into the corresponding acetonides, (4*S*,5*R*)-2,2,3,4-tetramethyl-5-phenyloxazolidine (**5**) and (4*S*,5*S*)-2,2,3,4-tetramethyl-5-phenyloxazolidine (**6**), which were separated by liquid chromatography and reconverted into the alkaloids by acid hydrolysis.

The *Ephedra* species used were *E. distachya* (Expts. 1–6) and *E. gerardiana sikkimensis* (Expts. 7–9). The early experiments (Expts. 1–6), with mature plants, were performed in the greenhouse at McMaster University. Radioactive tracers, dissolved in glass distilled water, were administered by the wick method and were kept in contact with the plants for 4–5 days before harvesting (see Table 1). For the more recent experiments (Expts. 7–9) small plants were used, which were grown from one year old cuttings, obtained from The Geographic Garden, Kolding, Denmark. In these experiments a solution of the tracers was painted onto the growing aerial parts of the plants over a period of 3–5 days. The plants were in contact with the tracer for a total of 7–8 days before being harvested (see Table 1). Only the aerial parts of the plants were extracted.

The procedures for the isolation of the alkaloids varied to some extent from experiment to experiment. In Expts. 1–3 the plant material was dried (50°C, 1 week) before extraction with methanol, whereas in Expts. 4–9 the fresh plant material was extracted immediately with methanol. In Expts. 1–8 a Soxhlet apparatus was used for the extraction and in Experiment 9 methanol was percolated through a column containing the plant material until extraction was complete.

In Expts. 1–6 the methanolic extracts were evaporated *in vacuo*, whereas in Expts. 7–9 the methanolic extracts were acidified with hydrochloric acid before evaporation of solvent.

After the usual work-up, with acid/base partitioning between water and ether, the crude alkaloids were purified in several ways.

In Expts. 1–3 the Ephedra bases were treated with acetone/silica gel (14) to convert ephedrine (**1**) and pseudoephedrine (**3**) into their acetonides **5** and **6**, respectively. Facile separation of **5** and **6** by liquid chromatography followed by acidic demasking gave ephedrine and pseudoephedrine as their hydrochlorides (see Table 2). The radioactive (−)-ephedrine was further purified by recrystallization after addition of unlabelled (−)-ephedrine hydrochloride. In Expts. 4–8 addition of radioinactive (−)-ephedrine hydrochloride to the crude mixture of alkaloid hydrochlorides, followed by repeated recrystallization, gave radiochemically pure (−)-ephedrine hydrochloride. In Expts. 2 and 3 (−)-ephedrine hydrochloride was converted to (−)-ephedrine sulfate via the free base.

It is apparent from Table 2 that both the amount of isolated (−)-ephedrine as well as the relative amounts of (−)-ephedrine and (+)-pseudoephedrine isolated from individual experiments varied from experiment to experiment. Whether this reflects a natural variation or is a consequence of different work-up procedures is not known, but some loss of (−)-ephedrine during standard isolation procedures has been observed (15). In most cases (−)-ephedrine was the more abundant alkaloid. The amount of either alkaloid isolated was too small for the chemical manipulation required to determine the distribution of radioactivity. Carrier dilution was thus essential to obtain enough material for a complete degradation. Since, of the two alkaloids, (−)-ephedrine invariably had the higher specific activity, this compound was chosen for carrier dilution and degration.

Even so, the carrier dilution that was required to obtain sufficient material for determination of the sites of labelling within an alkaloid sample was such that the degradation experiments had to be performed with samples whose specific radioactivity (cpm per mg above background) was close to the limits of detectability. As a result, the confidence limits of the values for the molar specific activity (dpm per mmol) of the individual degradation products were unusually wide.

The distribution of label within (−)-ephedrine derived from radioactive precursors (Expts. 1–8) was determined by a degradation sequence (Schemes 1 and 2) that permitted individual assay of activity at C-1, C-2, C-3, N-methyl, and at the phenyl group. Dehydration with 50% (v/v) sulfuric acid[4] at 110°C gave, within 15 min, a mixture of ephedrine and pseudoephedrine (ca. 1:1 by ^{1}H nmr) (Scheme 1) that on standing 24 h was converted almost quantitatively into methylamine, isolated by conversion into the *N*-phthaloyl derivative (**9**), and 1-phenyl-2-propanone (**7**), which was recovered as the semicarbazone (**8**) in unexpectedly poor yield.

Chromic acid oxidation of 1-phenyl-2-propanone (**7**), or of ephedrine (**1**) itself (12), gave a mixture of benzoic acid and acetic acid. A portion of this mixture was converted into a mixture of the corresponding 1-acylaminonaphthalenes (**10**, **11**), which were then separated by liquid chromatography. Another portion of the mixture of benzoic and acetic acids was reacted with azide in concentrated sulfuric acid (8) at 25°C for 3 h to give aniline (isolated as its hydrochloride) (aromatic C-atoms), or at 100°C for 2 h to give methylamine (C-3) (isolated as *N*-methylphthalimide (**9**)). The degradation sequence is shown in Scheme 2.

The sample of (−)-ephedrine obtained from plants that had been fed with a mixture of L-[3-^{14}C]serine and L-[ring-2,6-^{3}H]phenylalanine (Expt. 1) showed a much higher incorpora-

[3]An account of the conclusive experiment has appeared (13).

[4]More concentrated sulfuric acid (e.g., 85% (v/v)) (cf. ref. 8) led to sulfonation in the *para* position of the aromatic nucleus, as shown by the appearance of an AB system in the aromatic region of the ^{1}H nmr spectrum of the reaction mixture.

tion of ^{14}C than of ^{3}H (Table 2). Both the benzoic acid and the acetic acid obtained on degradation contained ^{14}C (Table 3), but more than half of the ^{14}C was located within the N-methyl group (ephedrine minus (benzoic plus acetic acid)). Tritium was confined to the benzoic acid (Table 4).

The sample of (−)-ephedrine from the experiment with [1-^{14}C]acetic acid (Expt. 4) was essentially inactive (Table 2).

The results of the degradation of the samples of ephedrine obtained from the experiments with [2-^{14}C]- and [3-^{14}C]pyruvic acid (Expts. 2, 3, 5–8) are summarized in Table 3. In each case, the acetic acid obtained by degradation, representing the C-methyl group of (−)-ephedrine and the adjacent carbon atom, contained between one and two thirds of the activity of the intact ephedrine, the N-methyl group contained ca. one tenth, and the C_6–C_1 unit accounted for a significant portion ranging from one quarter to more than one half of the total activity.

The distribution of the activity within the acetate differed in the experiments with [3-^{14}C]- and those with [2-^{14}C]pyruvic

SCHEME 2

acid. In the former case (Expts. 3, 6, and 8) the greater part of the activity (approximately three quarters) was recovered in *N*-methylphthalimide representing the C-methyl group of (−)-ephedrine. In the latter case (Expts. 2, 5, and 7) the greater part of the activity (approximately three quarters) was located in the carboxyl group of acetate, i.e., within the carbon of (−)-ephedrine adjacent to the C-methyl group.

The distribution of label within the four Ephedra bases **1**–**4**, derived from plants to which [2,3-$^{13}C_2$]pyruvic acid had been administered (Expt. 9), was determined by ^{13}C nmr.

To facilitate the analysis of the ^{13}C nmr spectrum of the mixture of ^{13}C-enriched alkaloid hydrochlorides, the individual natural abundance ^{13}C nmr spectra of the four compounds were determined under similar conditions (Table 5). Spectra of three of the compounds had previously been reported and assigned (16–18).[5]

The ^{13}C nmr spectrum of the mixture of alkaloid hydrochlorides from plants to which sodium [2,3-$^{13}C_2$]pyruvate had been administered (Expt. 9) (see Fig. 1 and Table 2) shows that the sample consists of pseudoephedrine (**3**), ephedrine (**1**), norpseudoephedrine (**4**), and norephedrine (**2**), in the molar ratio 52:35:10:3 (based on the peak integrals of the central lines of the C-methyl signals). The C-methyl signal (C-3) of each of the four alkaloids consists of a central line (δ 12.49 (**1**), 14.39 (**3**), 15.24 (**2**), and 17.36 (**4**) ppm) straddled by a doublet (J = 37 Hz). A similar pattern is discernible in each of the signals due to C-2 (δ 54.95 (**2**), 55.51 (**4**), 62.61 (**3**), and 62.69 (**1**) ppm). The benzylic carbon atoms (C-1) (δ 74.16 (**1**), 75.69 (**2**), 76.81 (**3**), and 77.55 (**4**) ppm) and the phenyl carbon atoms (δ 128–142 ppm) give signals that appear as singlets. The relative intensity of all singlet signals was identical with that in the spectra of authentic non-labelled alkaloids. This indicates that all detectable ^{13}C enrichment in the nmr spectrum of the four alkaloids from Expt. 9 originates from intact $^{13}C_2$ units. The average specific incorporation of C-2,3 of sodium [2,3-$^{13}C_2$]pyruvate into norephedrine (**2**), norpseudoephedrine (**4**), ephedrine (**1**), and pseudoephedrine (**3**) was 1.4, 1.0, 0.32, and 0.22%, respectively (see Table 6).

Discussion

It was shown by Leete (5) and by Shibata and his students (11, 12) that the benzylic fragment of the carbon skeleton of the Ephedra alkaloids originates from a C_6–C_1 unit derived from phenylalanine. In plant cuttings, radioactivity from DL-[3-^{14}C]phenylalanine entered C-1 and no other sites of (+)-norpseudoephedrine (5) and of (−)-ephedrine (11, 12), and label from DL-[ring-^{3}H]phenylalanine entered the benzylic fragment of (−)-ephedrine (11, 12). Label from DL-[2-^{14}C]phenylalanine was not incorporated (11, 12).

Similarly, label from [3-^{14}C]cinnamic acid, from [carboxyl-^{14}C]benzoic acid, and from [carbonyl-^{14}C]benzaldehyde also entered C-1 of (−)-ephedrine (11, 12). Thus, it is likely that a C_6–C_1 unit related to benzaldehyde or benzoic acid and derived from L-phenylalanine by the phenylalanine ammonia lyase route (22) is the direct precursor of the benzylic fragment of the Ephedra alkaloids (see Scheme 3).

The search for the source of the remaining C_2-unit of the alkaloid skeleton had so far proved fruitless. Less than one third of the total activity within the samples of (−)-ephedrine derived

[5]The assignment of two signals (C-2′,6′ and C-3′,5′) in the spectra has not been settled (cf., refs. 16–18). Assignment is now made on the basis of the following considerations:

Comparison of the chemical shifts of the signals in the spectrum of benzyl alcohol (19) with those of the substituted benzyl alcohols, **1**–**4**, permits the prediction that the signals due to C-2′,6′ be 1–2 ppm upfield from those due to C-3′,5′. The observed chemical shift differences between C-2′,6′ and C-3′,5′ are (**1**) 2.73, (**2**) 2.51, (**3**) 2.00, and (**4**) 2.12 ppm (see Table 5). Secondly, the magnitude of two-, three-, and four-bond carbon–proton coupling constants in monosubstituted benzenes permits a distinction to be made between C-2′,6′ and C-3′,5′ (20, 21). It is predicted that, for C-2′,6′, the numerical values of two of the carbon–proton coupling constants ($J_{2',3'}$ and $J_{2',5'}$) would be <2 Hz and two ($J_{2',4'}$ and $J_{2',6'}$) would be 4.5–8 Hz. For C-3′,5′, the numerical values of three of the carbon–proton coupling constants ($J_{3',2'}$,$J_{3',4'}$, and $J_{3',6'}$) are predicted to be <2 Hz and one ($J_{3',5'}$) to be 7–9 Hz.

The assignments shown in Table 5 are the only ones consistent with these predictions.

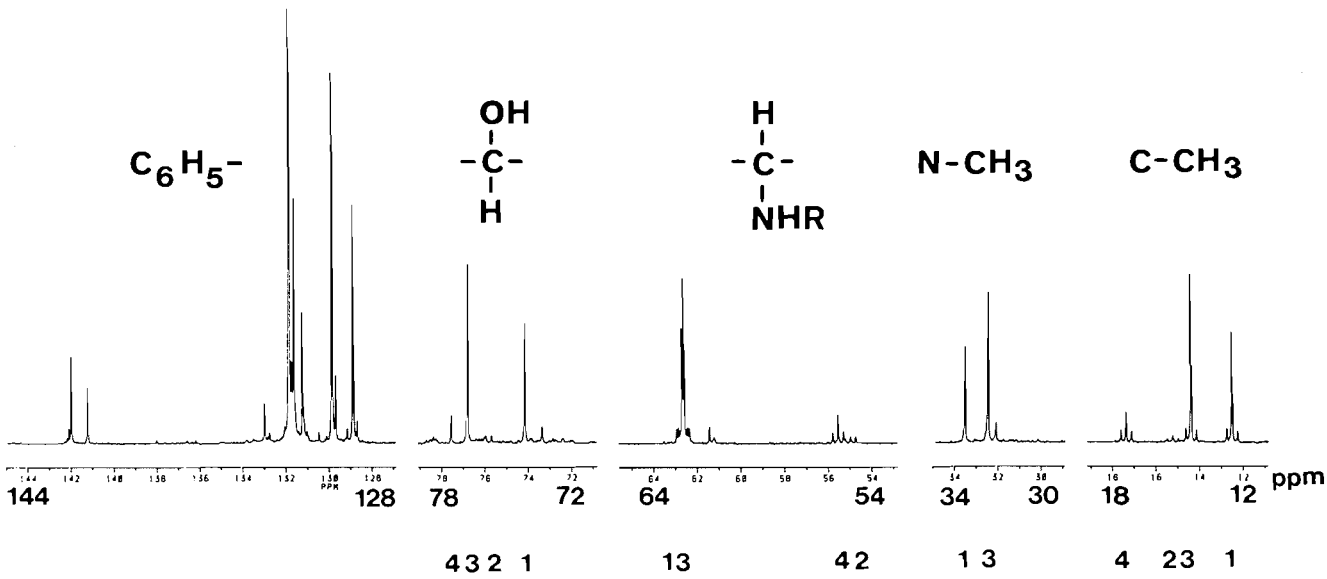

FIG. 1. Proton noise decoupled ^{13}C nmr spectrum (75.47 MHz, 5000 transients) of alkaloid hydrochlorides (57 mg in 0.6 mL D_2O) obtained from plants of *Ephedra gerardiana* after administration of sodium [2,3-$^{13}C_2$]pyruvate. The spectrum was recorded on a Bruker AC 300 spectrometer under standard conditions, with sodium 2,2,3,3-tetradeuterio-3-(trimethylsilyl)propionate (δ 0.00 ppm) as internal reference. The numbers below the δ (ppm) scale show assignments of the signals to the four compounds **1**–**4**.

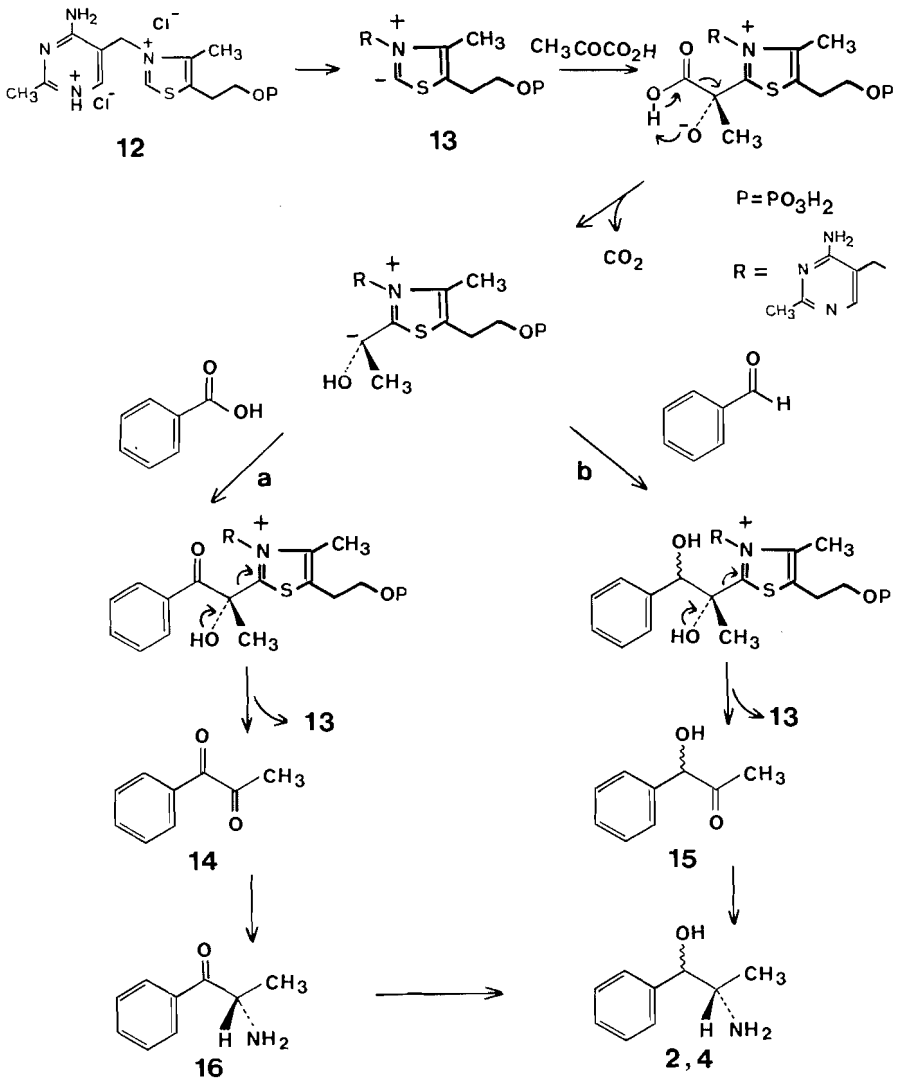

from a variety of radioactive substrates was present within this unit; 70% or more of the label was distributed over the rest of the molecule.

The multicarbon substrates that delivered the highest fraction (ca. 25%) of the total activity of ephedrine into the C_2 unit were D-[6-^{14}C]glucose, and L-[U-^{14}C]aspartic acid and L-[U-^{14}C]alanine, two amino acids closely related to the tricarboxylic acid cycle. But in each case at least an equal fraction of label entered the C_6–C_1 unit and twice as much was incorporated into the N-methyl group (12).

[2-^{14}C]Glycine and L-[U-^{14}C]serine delivered ca. 75% of activity into the N-methyl group, 20% into the benzylic fragment, and only ca. 5% into the C_2 unit (12). This distribution of label was maintained (see Tables 2 and 3) when L-[3-^{14}C]serine was administered in the presence of L-[ring-^{3}H]phenylalanine ($^3H/^{14}C$ ratio 13:1) (Expt. 1). Even though the ephedrine that was isolated showed a $^3H/^{14}C$ ratio 3:1, indicating that ^{14}C (i.e., serine) had been incorporated almost four times as efficiently as ^3H (i.e., phenylalanine), the presence of phenylalanine had not caused a redirection of ^{14}C from the C_6–C_1 into the C_2 unit.

Evidently, in all the above experiments metabolic fragmenta-

[b]Average specific incorporation of ^{13}C from sodium [2,3-$^{13}C_2$]pyruvate into C-2 and C-3 of the *Ephedra* alkaloids = (E_E/E_P) × 100%, where E_E = average enrichment above natural abundance (at.% ^{13}C) at C-2 and C-3 = [(*R*(C-2) + *R*(C-3))/2] × 1.1% and E_P = average at.% ^{13}C at C-2 and C-3 of sodium [2,3-$^{13}C_2$]pyruvate = 99%.

tion of the precursors had occurred prior to incorporation of label into the alkaloid. Glycine and serine are known to participate in one-carbon metabolism (23). Another one-carbon donor, [^{14}C]formic acid (9, 12), supplied 50% of the total activity into the N-methyl group and ca. 20% into the phenyl nucleus. In this instance the C_2 unit contained 30% of the total activity. Most of this activity was present in the C-methyl group (9).

The scrambling of label and, in particular, the predominant presence of label in the N-methyl group that was observed in every one of the above experiments points to rapid metabolic turnover in the course of the feeding experiments. The distribution of label observed in these experiments tended to obscure rather than to illuminate the origin of the C_2 fragment.

Since the carbon skeleton of the Ephedra bases does not appear to be derived directly from an amino acid, it is likely that the nitrogen atom is introduced at a late stage of biosynthesis. Indeed, the stereospecific transfer of the amino group of L-glutamic acid into (±)-1-hydroxy-1-phenyl-2-propanone (**15**), to yield a mixture of (−)-norephedrine (**2**) as the major and (+)-norpseudoephedrine (**4**) as the minor product, is catalyzed by transaminases that have been obtained from several plant species (24). The same enzyme system catalyzes the reverse reaction, converting (−)-norephedrine into (−)-1-hydroxy-1-phenyl-2-propanone.

The latter compound has been reported to be the major product when yeast (*Saccharomyces cerevisiae*) is incubated with benzaldehyde (25–35) in the presence of fermentable sugars (25, 27, 30, 33–35), pyruvic acid (25, 29, 31, 32), or acetyl phosphate (31). The relative amounts of (*S*)- and (*R*)-1-hydroxy-1-phenyl-2-propanone that are formed are determined by the stereoselectivity of this reaction.

The reaction is catalyzed by "α-carboxylase" (E.C. 4.1.1.1,

For personal use only.

2-oxo acid carboxylyase, pyruvate decarboxylase), and requires thiamin as a cofactor (31, 32). The course of the reaction (Scheme 3) is evidently analogous to that of the carboxylase-catalyzed formation of acetoin from acetaldehyde and pyruvate (36–38).

If the carbon skeleton of the Ephedra alkaloids were generated in Ephedra plants by a reaction analogous to the formation of 1-hydroxy-1-phenyl-2-propanone in yeast, the stereoselectivity of the process would ultimately determine the relative amounts of (1*R*) alkaloids ((−)-norephedrine (**2**) and (−)-ephedrine (**1**)) and (1*S*) alkaloids ((+)-norpseudoephedrine (**4**) and (+)-pseudoephedrine (**3**)) present in the plants.

The primary objective of this investigation was to test whether, in analogy with the condensation reaction that takes place in yeast, the C_2 unit of the Ephedra alkaloids is derived from pyruvate.

Samples of sodium [2-^{14}C]pyruvate (Expts. 2, 5, 7) and sodium [3-^{14}C]pyruvate (Expts. 3, 6, 8) were administered to plants of two different Ephedra species by two different methods, under various conditions (Table 1). In some cases (Expts. 5, 6) thiamin and sodium benzoate were administered 3 days before the solution containing the pyruvate was applied, in an attempt to enhance the condensation reaction (thiamin) and to suppress incorporation of label into the benzylic fragment of the alkaloid (benzoic acid). The yield of ephedrine, the per cent incorporation, and the specific incorporation of radioactivity into the alkaloid (Table 2) as well as the distribution of label over the three fragments, N-methyl, C_6–C_1, and C_2, within the alkaloid (Table 3) varied from experiment to experiment and no consistent pattern was evident. As in the earlier experiments, label was heavily scrambled over the three fragments, indicating rapid metabolic turnover of pyruvate (Table 3).

Even though label from [2-^{14}C]- and [3-^{14}C]pyruvate did not necessarily enter the C_2 unit predominantly, the distribution of activity within this C_2 unit showed a strong trend (Table 3): In each of the three experiments with [3-^{14}C]pyruvate most of the label (ca. 75%) within the C_2 unit was located at the C-methyl group (C-3) of ephedrine (recovered as methylamine by Schmidt degradation of the Kuhn–Roth acetate), whereas in each of the three experiments with [2-^{14}C]pyruvate most of the label (ca. 75%) within the C_2 unit was located at the adjacent carbon atom, C-2 (Kuhn–Roth acetate minus Schmidt methylamine). Even though this distribution of label tends to be in accord with that expected if pyruvate were the source of the C_2 unit (Scheme 3), these results could not be regarded as conclusive evidence in support of the proposition that the C_2 unit was generated from an acetyl unit derived from pyruvate by decarboxylation.

Incorporation of radioactivity into ephedrine from acetate itself (Expt. 4) was too low to attempt the chemical degradation required to determine the distribution of label. This was not altogether surprising. The kinases required to convert acetate into its biologically active species, acetyl CoA or acetyl phosphate, are absent from many biological systems. The conversion of pyruvate into acetyl CoA, on the other hand, takes place in most living species. Thus, for example, pyruvate served as the direct precursor of the non-tyrosine derived C_2 unit of anhalonidine and pellotine, alkaloids of the peyote cactus (39), whereas acetate was incorporated only indirectly, with scrambling of label (40). In yeast, acetate did not serve as a precursor of the nonbenzylic C_2 unit of 1-hydroxy-1-phenyl-2-propanone, whereas acetyl phosphate or pyruvate did (31). Even so, in the present instance the experiments with ^{14}C-labelled samples of pyruvate (Expts. 2, 3, 5–8), while indicative, were inconclusive, since label from these substrates was not confined to the predicted sites.

Conclusive evidence was obtained, almost 10 years after our first experiments with ^{14}C-labelled precursors, by means of an experiment with [2,3-$^{13}C_2$]pyruvic acid. The distribution of label within the four alkaloids, **1**–**4**, derived from this precursor in *E. gerardiana sikkimensis*, is evident from the high field ^{13}C nmr spectrum of the mixture of alkaloid hydrochlorides (Fig. 1). The signals due to the C-methyl group and the adjacent carbon atom of each of the four alkaloids show satellites, due to ^{13}C–^{13}C coupling, a clear demonstration of the incorporation of the intact $^{13}CH_3$–^{13}CO unit of the precursor into each of the four alkaloids. A full interpretation of the spectrum has appeared (13).

The question arises why the experiments with [^{14}C]pyruvate gave results that were inconclusive whereas the experiment with [$^{13}C_2$]pyruvate gave an unequivocal result, even though the sensitivity of detecting ^{14}C within the product[6] is approximately 3 orders of magnitude greater than that of detecting ^{13}C (cf. ref. 41).[7]

It is probable that it is this sensitivity which permitted the detection of radioactivity in all parts of the ephedrine molecule, when [^{14}C]pyruvate served as the substrate, indicating rapid metabolic turnover of pyruvate. There is no reason to think that in the experiment with [$^{13}C_2$]pyruvate a similar rapid turnover did not also occur. But since such turnover would have led to enrichment at all carbon atoms of ephedrine, leading to a small increase in the height of every peak in the ^{13}C nmr spectrum of the product, these increases were not detectable.

What was detectable were the satellites due to intact transfer

---

[6]Radioactivity of carrier free ^{14}C-labelled precursor: Specific activity = ca. 62 mCi per mmol, i.e., ca. 1.4×10^{11} disintegrations per minute per mmol, i.e., ca. 1.2×10^{11} counts per minute per mmol, when radioactivity is assayed in a modern liquid scintillation counter at ca. 90% efficiency. Radioactivity of a product of MW 200 (say), determined on a weighed sample of 0.1 mg (say) to be 50 counts per minute above background (say). Specific activity of product is 1.0×10^5 counts per minute per mmol, i.e., 1.1×10^5 disintegrations per minute per mmol. Thus a dilution of radioactivity of six orders of magnitude is detectable.

[7]To detect, in unequivocal fashion, incorporation of ^{13}C from a singly ^{13}C-labelled substrate, the peak height of the ^{13}C nmr signal due to the enriched carbon atom of the product must show an enhancement of at least 20–30% over that of the corresponding signal of a sample containing only natural abundance ^{13}C. This enhancement, which corresponds to an incorporation of 0.2–0.3% ^{13}C above natural abundance (1.1%), must be determined relative to the peak height of signals due to unenriched carbon atoms in the sample containing the enriched carbon.

Thus the maximum permissible dilution of ^{13}C of a precursor containing 100% ^{13}C at a single position, en route to a biosynthetic product, is less than three orders of magnitude.

If the ^{13}C-labelled substrate is enriched in ^{13}C at a pair of contiguous carbon atoms, i.e., the substrate is "bond-labelled", and if this enriched C_2 unit is transferred intact into a product, detection of incorporation no longer depends on observing the increase in peak height of a single signal in the ^{13}C nmr spectrum, but on the appearance of signal satellites due to ^{13}C–^{13}C coupling. The use of such bond-labelled substrates thus permits much greater dilution of the administered precursor.

The limit of detection of these satellites depends less on the per cent incorporation of ^{13}C than on the field strength of the spectrometer and the quality of the probe used in recording the spectrum. The field strength controls the signal dispersion while the quality of the probe determines the signal-to-noise ratio of the spectrum, for a given amount of sample.

For personal use only.

of pairs of contiguous carbon atoms from substrate into each of the products.

Thus the less sensitive tracer technique provided an unequivocal result whereas the more sensitive technique gave information that was not readily interpretable.

A further difference between the experiments with ^{14}C and ^{13}C-labelled pyruvate is the enhanced specific incorporation of label into the alkaloids in the latter case (Expt. 9) (10^3-fold) compared to that in the ^{14}C-pyruvate experiments (Expts. 7, 8), in the same *Ephedra* species (Table 1). This may be related to the fact that, whereas in the ^{14}C experiments (Expts. 7, 8) only tracer amounts of sodium pyruvate (ca. 1 mg) were administered, in the ^{13}C experiment (Expt. 9) a massive dose of substrate (500 mg) was applied.

The final question that must be raised concerns the status of 1-hydroxy-1-phenyl-2-propanone (**15**) in the biosynthesis of the Ephedra alkaloids. Attempts to trap this compound in the plant extracts from our tracer experiments, or to demonstrate specific incorporation into ephedrine, of label from ^{14}C-labelled samples of 1-hydroxy-1-phenyl-2-propanone by means of feeding experiments with *E. distachya*,[8] did not meet with success.

There is thus no experimental evidence supporting the intermediacy of this compound in ephedrine biosynthesis. The supposition that it is implicated is based entirely on chemical analogy (28, 33, 35).

A closely related compound, (*S*)-(−)-2-amino-1-phenyl-1-propanone ((−)-cathinone) (**16**) is a major constituent of *Catha edulis* Forsk., where it occurs together with (+)-norpseudoephedrine (**4**) and (−)-norephedrine (**2**) (42, 43). It is, of course, possible that (−)-cathinone (**16**) is derived from (+)-norpseudoephedrine or (−)-norephedrine by enzymic dehydrogenation. However, it is also conceivable that (−)-cathinone might, in fact, serve as the substrate for stereospecific enzymic reduction and represent the precursor of (+)-norpseudoephedrine and of (−)-norephedrine (42). If so, the compound from which the alkaloids are derived would not be 1-hydroxy-1-phenyl-2-propanol (**15**) but 1-phenyl-1,2-propandione (**14**).

This compound, which has been detected in *Catha edulis* (42), in turn would be generated in the presence of thiamin by the carboxylase-catalyzed reaction of pyruvate with benzoic acid (rather than with benzaldehyde) (Scheme 3), analogous to the carboxylase-catalyzed formation of butan-2,3-dione (diacetyl) (44, 45).

Such a biosynthetic sequence would be consistent with the apparent lack of participation of 1-hydroxy-1-phenyl-2-propanone in ephedrine biosynthesis. It would also explain the observation that benzoic acid as well as benzaldehyde serves as the precursor of the C_6–C_1 unit of the Ephedra alkaloids (12). Whereas the biological oxidation of benzaldehyde to benzoic acid is likely to be a facile process (46), the reverse reaction, reduction of benzoic acid to benzaldehyde, does not appear to have been observed in higher plants (46).

Experiments are in hand to examine the possible intermediacy of 1-hydroxy-1-phenyl-2-propanone (**15**), 1-phenyl-1,2-propandione (**14**), and cathinone (**16**) in the biosynthesis of the Ephedra alkaloids.

Experimental

Labelled compounds

The labelled compounds employed in the nine feeding experiments were obtained from commercial suppliers (see Table 1).

[8]K. Yamasaki. Personal communication.

Tracer experiments

Administration of labelled compounds to Ephedra distachya *L. and* E. gerardiana sikkimensis

Experiments 1–6

Stocks of *Ephedra distachya* L. were obtained from Hillier Nurseries, Winchester, England. The plants were propagated in the greenhouse at approximately 24°C. Large stocks were split in the spring. Labelled compounds were administered to actively growing plants by the wick method. The plants were kept in contact with tracer for 4–5 days. Alkaloids were isolated from the plants as described below.

Experiments 7–9

Plants of *E. gerardiana sikkimensis* were propagated in a greenhouse at 25–30°C for 1 year, from cuttings obtained from The Geographic Garden, Kolding, Denmark. Labelled compounds were administered in an aqueous solution of Tween 80 (1% w/v). This solution (1.0 mL per day) was applied to the light green shoots with a fine paint brush. After administration of tracer the plants were painted with 1.0 mL of water per day (see Table 1). In Experiment 9 a total of 500 mg sodium [2,3-$^{13}C_2$]pyruvate (99 at.% ^{13}C per position) was administered over 5 days.

Details of the feeding experiments are summarized in Table 1.

Isolation of ephedrine and pseudoephedrine

Extraction of the alkaloid mixture

Expts. 1–3: The aerial parts of the plants were cut into pieces (approximately 1 cm long) and dried at 50°C for 1 week. The weight loss was 60–65%. The dry plant material was finely ground in a blender and extracted with methanol in a Soxhlet extractor until the extract was no longer coloured (ca. 8 h). Expts. 4–8: The fresh aerial parts of the plants were ground in a blender and extracted with methanol in a Soxhlet apparatus. Experiment 9: The fresh aerial parts of the plants were ground in a blender and extracted with methanol at 20°C. In each case the extraction of the alkaloids was considered complete when chlorophyll had been completely extracted from the plant material.

In Expts. 1–6, the extract was then concentrated *in vacuo*, sulfuric acid (0.1 M, 70 mL) was added to the oily residue, the mixture was extracted with ether (4 × 35 mL), and the ether extract discarded. The aqueous phase was basified to pH 10 with solid potassium carbonate and then extracted with ether (5 × 30 mL). In Expts. 7–9, the methanol extracts were acidified with hydrochloric acid (4 M, 3 mL) before concentration *in vacuo*. Hydrochloric acid (0.1 M, 50 mL) was added to the residue and the aqueous mixture was washed with ether (4 × 50 mL), basified with potassium carbonate, and extracted with ether (4 × 50 mL).

In Expts. 1–3, the ether extract was dried (anhydrous sodium sulfate) and concentrated *in vacuo* to yield an oily residue that contained the crude alkaloids, which were then separated via the acetonides (*vide infra*). In Expts. 4–9, the ether extracts were extracted with hydrochloric acid (1 M, 2 × 5 mL) and the aqueous phase was evaporated to dryness *in vacuo* to yield a mixture of crude alkaloid hydrochlorides. In Expts. 4–8, radioinactive (−)-ephedrine hydrochloride (60–220 mg) was then added as carrier and the product was recrystallized from ethanol/ether, mp 217°C (lit. (12) mp 220°C). In Expt. 9 the 75.5-MHz ^{13}C nmr spectrum (see Fig. 1) of the mixture of alkaloid hydrochlorides (57 mg) showed that the sample consisted of the hydrochlorides of pseudoephedrine (**3**), ephedrine (**1**), norpseudoephedrine (**4**), and norephedrine (**2**) in the molar ratio 52:35:10:3 (see Table 2). An analysis of the ^{13}C nmr spectrum is presented in Tables 5 and 6.

Separation of ephedrine and pseudoephedrine via their acetonides ***5*** *and* ***6*** *(Expts. 1–3)*

The residue containing the crude alkaloids was dissolved in acetone (50 mL). Silica gel 60 (60–200 mesh, 700 mg) and a few boiling chips were added, the mixture was refluxed 20 h, filtered, and concentrated *in vacuo* (14). The oily residue was dissolved in a mixture of ethyl acetate (2.5 mL) and petroleum ether (bp 30–60°) (2.5 mL), and residual solid was removed by centrifugation. The supernatant liquid was applied to a column (Merck Silica Gel 60, prepacked, size B) and eluted with a mixture of ethyl acetate and petroleum ether (bp 30–60°C) (1:1 v/v). The ultraviolet absorption of the effluent was monitored continuously at 254 nm. The fractions containing the two products, (4*S*,5*R*)-2,2,3,4-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

tetramethyl-5-phenyloxazolidine (i.e., (−)-ephedrine acetonide (**5**)) and (4*S*,5*S*)-2,2,3,4-tetramethyl-5-phenyloxazolidine (i.e., (+)-pseudoephedrine acetonide (**6**)) were collected separately (tlc (ethyl acetate:petroleum ether (bp 30–60°C) 1:1, v/v): R_f 0.6 and 0.5, respectively) and concentrated *in vacuo*.

Each acetonide was hydrolyzed without further purification. Each residue was dissolved in ethanol (1 mL) and hydrochloric acid (0.25 M, 1 mL), and the solution kept 1.5 h at 70°C. Each solution was evaporated *in vacuo*, the residue was dried over P_2O_5, an inactive sample of (−)-ephedrine hydrochloride or (+)-pseudoephedrine hydrochloride, respectively, was added as carrier, and the products were recrystallized from ethanol/ether: (−)-ephedrine hydrochloride, mp 217°C (lit. (12) mp 220°C: (47*a*) mp 218°C; (+)-pseudoephedrine hydrochloride, mp 180–181°C (lit. (48) mp 179–181°C; (47*a*) mp 182–182.5°C).

(−)-Ephedrine sulfate

A sample of (−)-ephedrine hydrochloride (50 mg) was dissolved in water (3 mL), solid potassium carbonate was added (to pH 10), and the solution was continuously extracted with ether (20 h). Ether was evaporated and sulfuric acid (0.1 M) was added dropwise to the residue (to pH 4). The solution was concentrated and the solid residue recrystallized (water/ethanol/ether) to give (−)-ephedrine sulfate (44 mg, 0.10 mmol, 83%); mp 259°C (lit. (48) mp 257°C).

Determination of radioactivity

Radioactivity was assayed by liquid scintillation counting (Mark 1 liquid scintillation computer, Model 6860, Nuclear Chicago (Expts. 1–6) or Beckman LS 9000 liquid scintillation system (Expts. 7, 8). Activity due to ^3H and ^{14}C was determined simultaneously, by external standardization counting with ^{133}Ba.

Samples (0.5–1.0 mg) were dissolved in ethanol or water, and the solution dispersed in Aquasol (New England Nuclear). The incorporation of the radioactive precursors into the alkaloids (Expts. 1–8) is summarized in Table 2.

Degradation of labelled ephedrine

The radioactively labelled samples of ephedrine (Expts. 1–8) were degraded by the reactions outlined below. The purity of all labelled samples was checked by thin-layer chromatography and melting point determination. All samples were recrystallized to constant specific activity. The molar specific activities of the samples of ephedrine and its degradation products, obtained from individual tracer experiments, are summarized in Tables 3 and 4. Confidence limits shown in Tables 3 and 4 are standard deviation from the mean.

Carbon atoms 1–3 and the aromatic carbon atoms as 1-phenyl-2-propanone semicarbazone

(−)-Ephedrine sulfate (27 mg, 0.06 mmol) or an equivalent quantity of the hydrochloride was dissolved in sulfuric acid (50% (v/v), 0.5 mL), and kept 24 h in a sealed flask at 110°C. Water (1 mL) was added and the mixture was extracted with ether (3 × 1 mL). The ether extract was washed with water (2 × 1 mL) and concentrated in a stream of nitrogen. The residue was dissolved in a solution of potassium acetate (20 mg, 0.20 mmol) in ethanol (0.5 mL). A solution of semicarbazide hydrochloride (20 mg, 0.18 mmol) in water (0.5 mL) was added, the mixture was heated 1 min on a steam bath, solvent was removed *in vacuo*, and the residue was sublimed at 140°C and 0.027 Torr. The sublimate was applied to a column (Merck Silica Gel 60 prepacked, size A), which was eluted with ethanol. The fraction containing *1-phenyl-2-propanone semicarbazone* (detected by continuous monitoring of the effluent at 254 nm) (tlc (ethanol) R_f 0.7) was concentrated *in vacuo*. Yield 3 mg (0.02 mmol, 25%); mp 181°C (from ethanol) (lit. (49) mp 177°C).

This degradation of ephedrine to 1-phenyl-2-propanone was a modification of an established method (8).

The N-methyl group of ephedrine as N-methylphthalimide

(−)-Ephedrine sulfate (71 mg, 0.16 mmol) or an equivalent quantity of the hydrochloride was dissolved in sulfuric acid (50% (v/v), 1 mL) and kept 24 h in a sealed flask at 110°C. The flask was cooled and a solution of potassium carbonate (2.0 g) in water (6 mL) was added. The mixture was heated until 4 mL distillate had been trapped in hydrochloric acid (1 M, 0.5 mL). The acidified distillate was concentrated to dryness *in vacuo*. The crystalline residue of methylamine hydrochloride was redissolved in water (0.5 mL), the solution was basified with solid sodium carbonate (to pH 9), and *N*-carboethoxyphthalimide (62 mg, 0.28 mmol) was added. The reaction mixture was stirred until precipitation of N-*methylphthalimide* was complete (15 min). The product was sublimited at 70°C and 0.025 Torr and recrystallized (methanol/water). Yield 11 mg (0.07 mmol, 44%), mp 133°C (lit. (47*b*) mp 133–134°C; (50) mp 134°C)).

Carbon atoms 2 and 3 as acetic acid and carbon atom 1 and the aromatic carbons as benzoic acid (isolated as 1-acylaminonaphthalenes)[9] (12)

(−)-Ephedrine hydrochloride (50 mg, 0.25 mmol) was dissolved in a solution of chromium trioxide (750 mg, 7.5 mmol) in concentrated sulfuric acid (0.7 mL) and water (10 mL). The mixture was distilled, with simultaneous addition of water to maintain constant volume, until 50 mL distillate had been collected. The distillate was neutralized with dilute sodium hydroxide and the solution was divided in two portions in a ratio of 1:3. Both portions were concentrated to dryness *in vacuo*. The larger portion was kept for a Schmidt degradation of benzoic acid and acetic acid (*vide infra*).

The smaller portion was dissolved in water (2 mL) and 1-naphthylamine hydrochloride (53 mg, 0.34 mmol) and *N*-ethyl-*N'*-[3-(dimethylamino)propyl]carbodiimide hydrochloride (170 mg, 0.89 mmol) were added and the solution stirred for 1 h. Hydrochloric acid (1 M, 1 mL) was then added and the mixture was extracted with ether (3 × 3 mL). The ether extracts were dried (sodium sulfate) and evaporated to dryness *in vacuo* and the residue was chromatographed on silica gel 40 (70–230 mesh, 15 g) with ether as eluent. The fractions containing 1-benzamidonaphthalene and 1-acetamidonaphthalene were collected (tlc (ether) R_f 0.8 and 0.4, respectively) and evaporated, and the products were recrystallized. 1-Benzamidonaphthalene, yield 5 mg (0.02 mmol, 32%), mp 162–163°C, after sublimation at 135°C and 0.025 Torr, and recrystallization from benzene/hexane (lit. (47*c*) mp 162°C; (52) mp 157–159°C). 1-Acetamidonaphthalene, yield 7 mg (0.04 mmol, 61%), mp 158–159°C, after sublimation at 95°C and 0.025 Torr, and recrystallization from benzene/hexane (lit. (47*c*) mp 160°C; (53) mp 159–160°C).

The C-methyl group of ephedrine (C-3) as methylamine (isolated as N-methylphthalimide) and the aromatic carbon atoms as aniline hydrochloride

The solid residue containing the sodium salts of benzoic acid and acetic acid obtained from the major portion of the distillate from the chromic acid oxidation, which had been kept for a Schmidt degradation (*vide supra*), was dissolved in concentrated sulfuric acid (1.8 mL). Sodium azide (120 mg, 1.85 mmol) was added. When a homogeneous solution was obtained the mixture was divided into two equal portions.

One portion was kept 3 h at 25°C. The mixture was added to water (8 mL) and solid sodium hydrogen carbonate was added, to pH 8. The mixture was extracted with ether (3 × 3 mL) and the extracts were dried (sodium sulfate). Hydrochloric acid (1 M, 0.5 mL) was added and the mixture was concentrated to dryness *in vacuo*. Recrystallization from ethanol/ether gave aniline hydrochloride: 3 mg (0.02 mmol, 34%), mp 194°C (lit. (54) mp 198°C).

[9]These simple compounds do not appear to have a unique name assigned to them: IUPAC nomenclature rules (51) permit any one of four alternative names: (*i*) IUPAC rule C-824-1: *N*-1-naphthalenylacetamide and -benzamide. This is the nomenclature used in Chem. Abstr. (registry numbers 575-36-0 and 634-42-4, respectively). (*ii*) IUPAC rule C-824-2: 1-acetyl- and 1-benzoylaminonaphthalene or, since the name 1-naphthylamine is permissible for 1-aminonaphthalene (see rule C-812), acetyl- and benzoyl-1-naphthylamine. These are the names found in the Dictionary of Organic Compounds (47*c*). (*iii*) IUPAC rule C-824-3: 1-acetamido- and 1-benzamidonaphthalene. Furthermore, IUPAC rule C-823-1 refers to either (*ii*) or (*iii*), but not to (*i*). So much for uniformity of chemical nomenclature.

The second portion was heated on a steam bath for 2 h. After cooling, the mixture was added to water (10 mL). Solid sodium hydroxide was then added to pH 13. The mixture was heated until 5 mL distillate had been collected in hydrochloric acid (1 M, 2 mL). The acidified distillate was concentrated to dryness *in vacuo* and the solid residue of methylamine hydrochloride was converted to *N*-methylphthalimide, as described above. Yield: 5 mg (0.03 mmol, 47%).

Asymmetric induction in Diels–Alder reactions of α-alkoxyorthoquinodimethanes

JAMES L. CHARLTON, GUY L. PLOURDE, AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 23, 1988

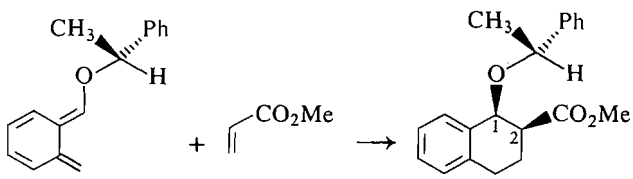
JAMES L. CHARLTON, GUY L. PLOURDE, and GLENN H. PENNER. Can. J. Chem. **67**, 1010 (1989).

It has been shown that dienophiles cycloadd selectively to one face of *o*-quinodimethanes (*o*-QDMs) bearing chiral α-alkoxy groups. The face selectivity (diastereoselectivity) increases for the series of chiral groups -OCH(Ph)CH_3, -OCH(Ph)$CH(CH_3)_2$, and -OCH(Ph)$C(CH_3)_3$. A similar effect on the face selectivity of the Diels–Alder reactions of chiral alkoxy vinyl ethers for the same series of chiral groups has been noted previously by others. A mechanism has been proposed to explain the face selectivity in the cycloaddition reactions of the alkoxy *o*-QDMs. *Ab initio* molecular orbital calculations with geometry optimization on vinyl 1-phenylethyl ether to determine its lowest energy conformations support the proposed mechanism. The absolute stereochemistries of the *o*-QDM cycloadducts have been determined to verify the predictions of the model.

Key words: *o*-quinodimethanes, asymmetric, Diels–Alder, cycloaddition.

JAMES L. CHARLTON, GUY L. PLOURDE et GLENN H. PENNER. Can. J. Chem. **67**, 1010 (1989).

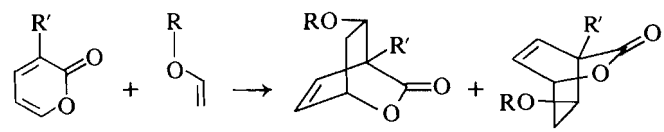
On a démontré que les diénophiles peuvent donner lieu à une cycloaddition qui est sélective pour une face des *o*-quinodiméthanes (*o*-QDM) portant des groupements α-alcoxy chiraux. La sélectivité faciale (diastéréosélectivité) augmente dans la série des groupements chiraux -OCH(Ph)CH_3, -OCH(Ph)$CH(CH_3)_2$ et -OCH(Ph)$C(CH_3)_3$. Un effet semblable a déjà été observé antérieurement, par d'autres, dans le cas de la sélectivité faciale de réactions de Diels–Alder d'éthers vinyliques comportant la même série de groupements alcoxy chiraux. On propose un mécanisme pour expliquer la sélectivité faciale observée lors des réactions de cycloadditions des alcoxy *o*-QDM. Des calculs d'orbitales moléculaires *ab initio*, comportant une optimisation de la géométrie, ont été effectués sur l'éther de vinyle et de phényl-1 éthyle dans le but de déterminer ses conformations d'énergies minimales; ces calculs supportent le mécanisme proposé. Dans le but de vérifier les prédictions du modèle, on a déterminé les stéréochimies absolues des cyclo-adduits des *o*-QDM.



Mots clés : *o*-quinodiméthanes, asymétrique, Diels–Alder, cycloaddition.

[Traduit par la revue]

Introduction



The Diels–Alder reaction, and more recently, the asymmetric Diels–Alder reaction, has proven to be a popular synthetic tool (1). While the Diels–Alder reactions of *ortho*-quinodimethanes (*o*-QDMs) have also received extensive study, less work has appeared on the asymmetric cycloaddition reactions of *o*-QDMs (2). Asymmetric control of these versatile reactions would open up the possibility for enantioselective synthesis of a large number of interesting and important compounds.

In preceding publications we have described initial studies of asymmetric induction in the Diels–Alder reaction of *o*-quinodimethanes (2–5) and, while the results of these studies have now been successively applied to an asymmetric synthesis of (+)-isolariciresinol (5), the exact mechanism of the induction is still unknown. The reactions in question involve the cycloaddition of achiral dienophiles to *o*-QDMs that bear an α chiral alkoxy group. As an example, in the conversion of **1** to **2**, it was

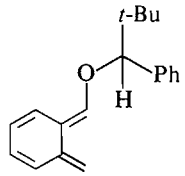
found that an (*R*)-1-phenylethoxy group directed addition of methyl acrylate to the upper face of **1** (*si* face at the α center) such that the major product had the (1′*R*,1*S*,2*S*) configuration.

A mechanism to explain the face selectivity, based on π-stacking of the chiral auxiliary to the *o*-QDM, has been shown to be inconsistent with product stereochemistry (3, 4, 6) and it was proposed that reaction from the conformation shown

3 R′ = -SO_2Tol **4** **5**

	R	%de
a	-CH(Ph)Me	66
b	-CH(Ph)*i*-Pr	84
c	-CH(Ph)*t*-Bu	90

in **1** might explain the face selectivity due to the difference in size of the phenyl and methyl groups (4). Results from a study by Posner and Wettlaufer seemed to be inconsistent with the above proposal (7). They studied the conversion of **3***a–c* to **4** and **5**.



They found that the face selectivity of the reaction increased as the bulk of the alkyl group in the chiral auxiliary increased. The question then arises as to whether the same increase in face selectivity would be observed in the reactions of **1** as methyl is changed to isopropyl and *tert*-butyl. Such an increase would be inconsistent with the face selectivity being due to a conformation of the *o*-QDM as shown in **1**. It is also necessary to determine at which face the *o*-QDM reacts for each of the chiral auxiliaries by determining the configurations of the newly formed chiral centers in the cycloaddition products relative to that of the chiral auxiliary.

In this paper we describe the preparation of the *o*-QDMs **1**, **6**, and **7**, a study of their reactions with dimethyl fumarate, and a comparison of the diastereoselectivities in these reactions. We also describe *ab initio* molecular orbital calculations on **3***a*, which were carried out with geometry optimization to determine the conformational preferences of this molecule and, by inference, the conformational preferences of the *o*-QDM **1**.

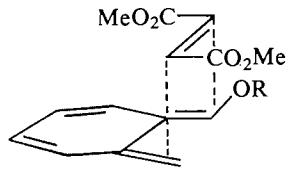
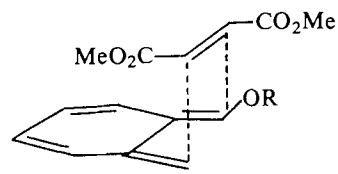
7



Results and discussion

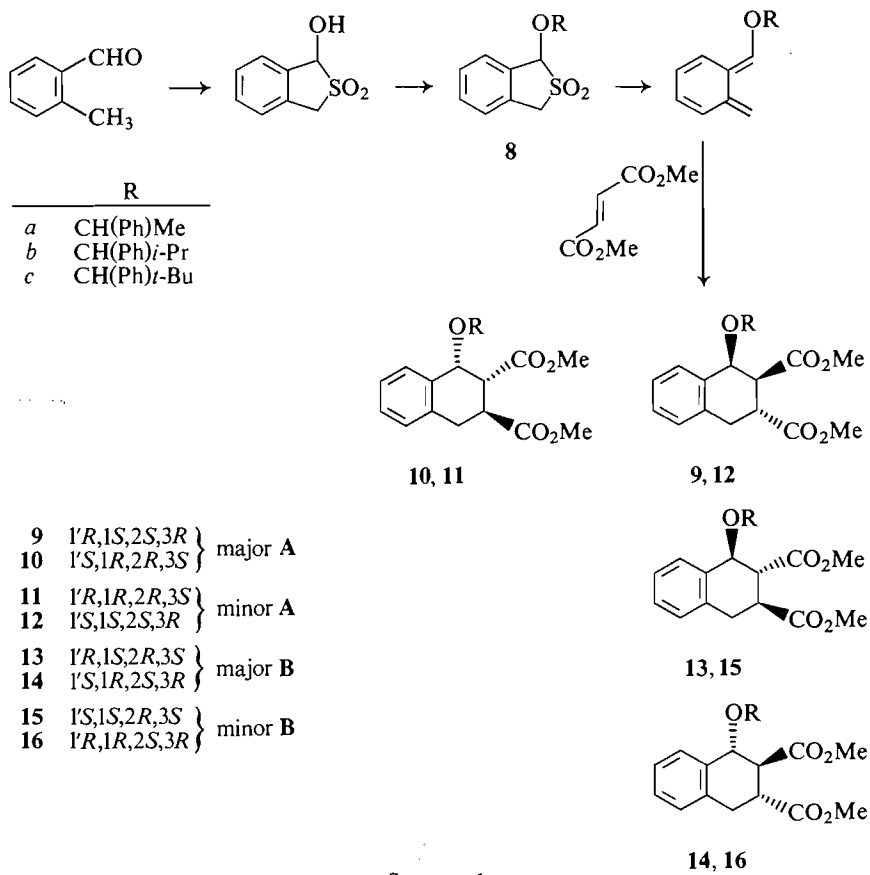
The *o*-QDMs **6** and **7** were generated and reacted with dimethyl fumarate using the procedure (illustrated in Scheme 1) previously described for **1** (3, 4).



For comparison purposes the *o*-QDM **1** was generated and reacted with dimethyl fumarate. As well as the racemic form, **1** was also generated in the optically pure *S* form. **6** was generated in both the racemic and the *R* forms while only the racemic form of **7** was prepared. In all cases, reaction with dimethyl fumarate led to one major and three minor diastereomers (**9/10**, **11/12**, **13/14**, **15/16**), which were each characterized by nmr. These four products made up more than 95% of the crude reaction mixture and the major product was 60 ± 5% of the total for all three starting *o*-QDMs.

The major isomer could be crystallized from the product mixture from racemic **1**, racemic **7**, and optically pure (*R*)-**6** and totally freed from the minor isomers in each case. In the case of optically pure (*S*)-**1**, the major adduct **10***a* cocrystallized with the minor isomer **12***a* but could be enriched to 85% by column chromatography. The minor isomers could not be separated and were characterized using difference nmr techniques. However, treatment of the crude cycloadduct mixtures with toluenesulfonic acid in refluxing toluene converted all of the stereoisomeric adducts to the single elimination product **17** in high yield in each case (see Table 1), thereby confirming the stereoisomeric nature of the minor products.

Dimethyl fumarate is known to add to *o*-QDMs through the two transition states **A** and **B** with the major products (*r*-1,*c*-2,*t*-3) arising from **A** (8, 9).



A

B

For *o*-QDMs bearing a chiral auxiliary, two diastereomers can arise from each transition state, one from addition to each face of the *o*-QDM. In this study the major **A** diastereomer was assigned the structure **9/10** by nmr. The minor **A** isomer, **11/12**, was identified by the similarity of its spectrum to that of the major isomer. The two **B** isomers (*r*-1,*t*-2,*c*-3, **13/14** and **15/16**) were easily distinguished from the **A** isomers by their nmr spectra. The product yields and isomer ratios for the **A** isomers are given in Table 1. As can be seen from the data in Table 1, the diastereoselectivity (face selectivity) of the addition did indeed increase as the alkyl group in the chiral auxiliary was changed from methyl to *tert*-butyl.

In two previous studies we have shown that the (*R*)-1-phenylethyl chiral auxiliary partially blocks the *re* face of the *o*-QDM towards cycloaddition reactions and therefore the *S* chiral auxiliary would block the *si* face (4, 5). Thus the

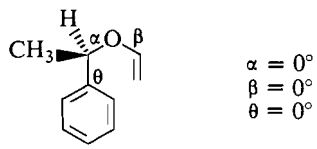
[d]After chromatography.

reaction of *o*-QDM (*S*)-**1** with dimethyl fumarate gives the (1′*S*,1*R*,2*R*,3*S*)-cycloadduct (**10***a*) as the major product. Treating this adduct (containing 15% **12***a*) with toluenesulfonic acid in refluxing toluene produced the (*S*)-2,3-dicarbomethoxy-3,4-dihydronaphthalene (*S*)-**17** ($[\alpha]_D = -92°$). Subjecting the adduct from the pure (*R*)-**6** to the elimination reaction produced (*R*)-**17** ($[\alpha]_D = +124°$). To confirm the absolute configuration of (*R*)-**17** it was also synthesized from the recently reported lactone **18** whose structure has been unambiguously established by X-ray crystallography (10). **18** was hydrolysed in methanolic KOH and the intermediate acid **19** esterified with CH_2N_2 to yield (*R*)-**17**, which had a specific rotation of +128°. Thus the cycloadduct from *R*-**6** has the configuration (1′*R*,1*S*,2*S*,3*R*) (**9***b*) and the *R* chiral auxiliary must partially block the *re* face in **6**, as was found for **1**.

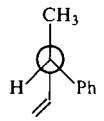


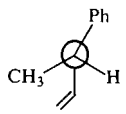
We were unable to obtain the chiral auxiliary for **7** in an optically pure form and therefore the relative configurations of the chiral centers in this cycloadduct were assigned on the basis of the nmr spectrum of the racemic material. In the cases of **1** and **6** there are distinct differences between the nmr spectra of the major and minor **A**-type cycloaddition products, with the H1 and H2 in the major isomer both appearing downfield of the protons in the minor isomer. This pattern was also true in the racemic cycloadduct **7**, leading us to the conclusion that the relative configurations of the chiral centers in **7** were the same as that in **1** and **6**. Therefore the major cycloadduct from the racemic **7** was assumed to be a racemic mixture of **9**/**10***c*. This being the case, an *R* chiral auxiliary in **7** also partially blocks the *re* face of the *o*-QDM.

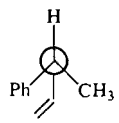
It is expected that *o*-QDM cycloadditions are relatively exothermic with early transition states (Hammond postulate), and that the conformation of the *o*-QDM will not change substantially on entering the transition state. In such cases, face selectivity might be predicted by determining the preferred conformation of the *o*-QDM. Predictions of face selectivity based on conformational preferences of the diene or dienophile have been very successful for other asymmetric Diels–Alder reactions (1*b*).

Molecular orbital calculations were carried out on **3***a* as a model for **1**, to reduce computational requirements. The appropriateness of using **3***a* as a model is discussed below. *Ab initio* calculations were carried out at the STO-3G level with optimization of bond lengths and bond angles, with the constraint that the ring carbons in the phenyl group were held planar as were the carbons in the vinyl group. The ring carbons of the phenyl were also constrained to a hexagonal geometry. Calculations were performed on an Amdahl 470/V8 system using the program MONSTERGAUSS (11).

The conformation of the molecule can be described by the use of the three dihedral angles θ, α, and β, which are defined in structure **20**. Rotation about any of the three bonds from zero degrees (eclipsed) to a positive torsion angle is a rotation in which the atom in the foreground is rotated counterclockwise relative to the atom in the background.







20

To probe the conformational preferences of **3***a*, calculations were carried out starting at several different combinations of angles for α, β, and θ. The first general observation resulting from these calculations is that β always optimizes to a value near 180° or 0°. This is presumably due to the conjugation of the double bond with the lone pair electrons on the ether oxygen. Such a conformational preference in unsaturated ethers has been noted previously (12). The two structures **21** and **22** represent the two extremes in β (180° and 0° respectively).

Since these calculations are a model for the *o*-QDM **1**, conformations with β near 0° are not of interest because this conformation is sterically impossible for **1**. Thus we concentrated further calculations on only those conformations that had β near 180°. Within this domain we found three low energy conformations with respect to rotation about the α axis, corresponding roughly to the three possible staggered conformations about α. The optimized angles of α, β, and θ and the relative energies of the three conformations are given in Table 2. It can be seen that the lowest energy conformer is that which roughly corresponds to structure **21** (illustrated more accurately in the ORTEP drawing, which is oriented to better display the orientation around α, β, and θ). We expect the conformational preferences of *o*-QDM **1** to be similar to that of **3***a* and that the most stable conformer of **1** is approximately that shown by structure **23**.

Face selectivity in cycloaddition reactions of **23** will arise due to the difference in steric bulk of the phenyl and hydrogen substituents. This differs slightly from the conformation previously proposed (see structure **1**) to account for the diastereo-

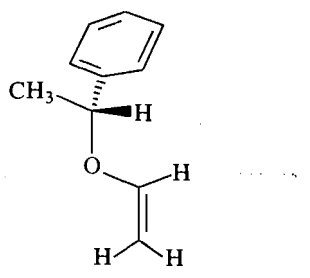


TABLE 2. Conformers of **3***a*

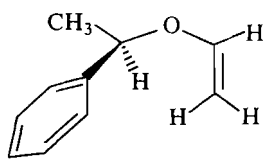
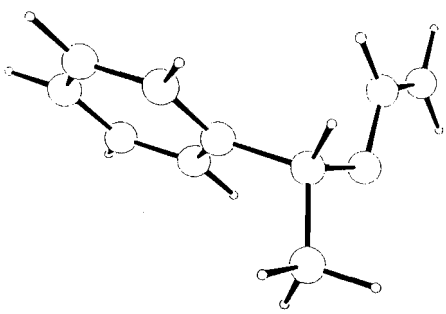
Conformation	Angles (°) α	β	θ	Energy (relative) (kJ/mol)
	70	184	37	0.0
	164	161	35	2.78
	300	187	119	2.30



selectivity, where face selectivity depended on the relative bulk of the phenyl and methyl substituents. Proposing that reaction occurs from conformer **23** is more consistent with the experimental data since exchanging the methyl group for an isopropyl (**6**) or *tert*-butyl (**7**) group would improve the diastereoselectivity (as observed) by increasing the preference for conformation **23**, which conformation provides the most room for the alkyl substituent.

Posner and Wettlaufer (7) proposed no mechanism for the asymmetric induction observed in their work since the relative configurations of all chiral centers in **4** and **5**, and the face at which the chiral vinyl ether reacted, were unknown. While it is tempting to predict that the *R* chiral auxiliary blocks the *re* face, as in this work, the fact that conformations of the vinyl ether with $\beta \approx 0°$ may be populated makes such a prediction uncertain.



Based on the above observations and calculations it would appear that further improvement in face selectivity in Diels–Alder reactions of *o*-QDMs will require the conformation of the chiral auxiliary to be more rigidly locked. Strategies such as putting a substituent onto the alkyl group of the chiral auxiliary, which can hydrogen bond to the ether oxygen and thereby lock the conformation, are being pursued.

23

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AM-300 instrument using tetramethylsilane as internal standard. The ir spectra were recorded on a Perkin Elmer 881 spectrometer. Merck Kieselgel 60 was used for all chromatography. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada. Melting points were measured on a hot stage instrument and are uncorrected. Optical rotations were recorded on a Rudolph Research Corporation Autopol III instrument.

1-Hydroxy-1,3-dihydrobenzo[c]thiophene-2,2-dioxide

This compound was prepared from *o*-methylbenzaldehyde (7.6 g) using the method previously described (8, 13) to yield 3.7 g (32%). Traces of *o*-toluic acid were removed by trituration with a small amount of carbon tetrachloride at room temperature.

1-Alkoxy-1,3-dihydrobenzo[c]thiophene-2,2-dioxide, 8

The alkoxysulfones **8** were prepared by refluxing, for 5–6 h, a methylene chloride solution of hydroxysulfone, the alcohols (1.5:1 molar ratio) *rac*-1-phenylethanol, *rac*-2-methyl-1-phenyl-1-propanol, *rac*-2,2-dimethyl-1-phenyl-1-propanol, (*S*)-(−)-1-phenylethanol, and (*R*)-(+)-2-methyl-1-phenyl-1-propanol, and a trace of toluenesulfonic acid, filtering the mixture through a short silica gel column (5 cm × 1.5 cm) with methylene chloride, and evaporating to give a mixture of diastereomers. Crude yields were typically 90–100%. The residual oil was further purified by chromatography on silica gel using 10% ethyl acetate/hexane as eluant to isolate the major stereoisomer whose properties are given below.

rac-***8***a: ^{1}H nmr ($CDCl_3$) δ: 1.61 (d, J = 6.5, CH_3), 4.20 (d, J = 15.7, H-3A), 4.46 (d, J = 15.7, H-3B), 5.20 (s, H-1), 5.23 (q overlapping with s at 5.20, J = 6.5, H-1′), 7.23–7.47 (m, aromatics).

*Alkoxy-2,3-dicarbomethoxy-1,2,3,4-tetrahydronaphthalene, **9/10, 11/12, 13/14, 15/16***

The cycloadducts were prepared by refluxing a toluene solution (20 mL) of alkoxy sulfone **8** (200–400 mg), four equivalents of dimethyl fumarate, and 100–200 mg of zinc oxide powder for 3–5 h. The solution was filtered through a silica gel column (5 cm × 1.5 cm) with methylene chloride, evaporated to dryness, then heated to 100°C at high vacuum to remove the excess fumarate. Crude yields were typically 75–85%. The major diastereomer from the reaction of *rac*-**1**, *rac*-**7**, and (*R*)-**6** could be obtained by crystallization from hexane or pentane. The major **A** isomer from (*S*)-**1** was obtained as an 85:15 mixture with the minor **A** isomer by chromatography on silica gel using 5% ethyl acetate in benzene as eluant. The remaining minor isomers were also partially separated by a similar chromatography and their nmr spectra determined using difference nmr techniques.

*(S)-****17***: Prepared from an 85:15 mixture of ***10a*** and ***12a***; ^1H nmr ($CDCl_3$) identical to that of *rac*-**17**; $[\alpha]_D^{20}$ −92° (*c* 0.33, $CHCl_3$).

*Preparation of (R)-****17*** *from lactone* ***18***

The lactone **18** (10) (67.5 mg, 0.22 mmol) was dissolved in methanolic KOH (0.2 M, 10 mL) and the solution refluxed for 2 h. The solution was concentrated to one half volume by evaporation, diluted with 5% aqueous $NaHCO_3$, and extracted with ethyl acetate. The aqueous portion was acidified (HCl), extracted with ethyl acetate, dried ($MgSO_4$), and evaporated to give an oil. The oil was dissolved in ethyl ether (5 mL) and an excess of CH_2N_2 in ether added. After 15 min at room temperature the solvent was removed by evaporation to leave an oil (47.4 mg, 87%). Chromatography on silica gel using 15% ethyl acetate/hexane as eluant gave a clear oil (37 mg, 65%) identical by nmr to the material produced above; $[\alpha]_D^{20}$ +128° (*c* 0.58, $CHCl_3$).

STO-3G MO computations, with substantial geometry optimization, are reported for benzyl alcohol. They are performed at 15° intervals for the angle by which the C—O bond twists out of the plane of the phenyl group, as well as for 30° intervals for the HCOH dihedral angle. The ensuing conformational energies are used to estimate expectation values of these two angles as well as of functions of these angles. The latter are compared with those obtained from long-range proton–proton coupling constants for dilute solutions in CS_2 and acetone-d_6. At infinite dilution in CS_2 these coupling constants give a distribution for motion about the C(1)—C_{sp^3} bond that happens to agree with the theoretical results for the free molecule. The latter are used to derive the dihedral angle dependence of ^3J(HCOH), the coupling constant between the hydroxyl and methylene protons. This dependence is compared with the observed coupling constants in benzyl alcohol in the gas phase at 422 K and with those measured for the 2,6-difluoro and 2,6-dichloro derivatives of benzyl alcohol. Infinite dilution shifts are reported for the latter two compounds and for α,α-dimethylbenzyl alcohol. The first self-association complex of any significance for benzyl alcohol in CS_2 at 300 K is most likely a trimer. Between zero and 2.5 mol% in CS_2, all five proton chemical shifts of this molecule are linearly proportional to one another, four of them becoming less shielded at decreasing concentrations. Some nuclear magnetic resonance data are also reported for 3,5-dichlorobenzyl alcohol.

On a effectué des calculs d'OM STO-3G, avec optimisation importante de la géométrie de l'alcool benzylique. Ces calculs ont été réalisés à des intervalles des 15° pour l'angle de torsion C—O hors du plan du groupement phényle ainsi que pour des intervalles de 30° pour l'angle dièdre HCOH. On a utilisé les énergies conformationnelles ainsi obtenues pour évaluer l'ordre de grandeur de ces deux angles ainsi que les grandeurs qui varient en fonction de ces angles. On a comparé les valeurs ainsi déterminées avec celles qui ont été obtenues expérimentalement à partir de constantes de couplage proton–proton à longue distance, pour des solutions diluées dans le CS_2 ou l'acétone-d_6. À dilution infinie dans le CS_2, ces constantes de couplage donnent une distribution du mouvement autour de la liaison C(1)—C_{sp^3} qui est en accord avec les résultats théoriques pour la molécule libre. On utilise ces derniers pour obtenir la relation qui existe entre l'angle dièdre et ^3J(HCOH), la constante de couplage entre les protons hydroxyle et méthylènes. On compare cette dépendance avec les constantes de couplage observées pour l'alcool benzylique en phase gazeuse, à 422 K, ainsi que pour celles mesurées pour les dérivés difluoro-2,6 et dichloro-2,6 de l'alcool benzylique. On a déterminé les déplacements chimiques à dilution infinie pour ces deux composés ainsi que pour l'alcool α,α-diméthylbenzylique. Le premier complexe d'auto-association significatif de l'alcool benzylique, dans le CS_2, à 300 K, est probablement un trimère. À des concentrations allant de 0 à 2,5 mol%, dans le CS_2, les cinq déplacements chimiques des protons de cette molécule sont proportionnellement linéaires les uns aux autres; quatre d'entre eux deviennent moins blindés avec des diminutions de concentrations. On rapporte aussi quelques données de résonance magnétique nucléaire pour l'alcool dichloro-3,5 benzylique.

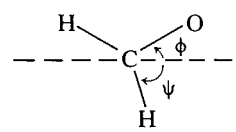
Mots clés: conformations de l'alcool benzylique, RMN du ^{1}H de l'alcool benzylique, calculs d'OM STO-3G de l'alcool benzylique.

[Traduit par la revue]

Introduction

The conformational behaviour of benzyl alcohol has been much discussed in recent years, particularly from the viewpoint of intramolecular hydrogen bonding of the hydroxyl group to the aromatic π system, (θ behaviour in **1**) but also in terms of the motion about the exocyclic C—C bond (ϕ motion).

1



$\theta = 0°$ } as shown
$\phi = 0°$ } in **1**

endo: $\theta = 60°$ or 300°

exo: $\theta = 180°$

Electron diffraction patterns for gaseous benzyl alcohol (1) are most consistent with a conformation in which ϕ is 54° (see **2**). Presumably this angle represents an average over the potential surface. Because the hydrogen atom adds only small contributions to the scattering intensities, its position is uncertain, although it appears (1) that the *endo* forms (θ in **1** assumed to be 60° or 300°) are more stable than the *exo* form (θ is 180° in **1**).

On the basis of ^3J(HCOH) ≡ ^3J, the vicinal proton–proton coupling constants in the side chain of benzyl alcohol, measured at a concentration of 0.02 M in CCl_4 solution at 296 K, it is concluded that the *endo* conformer is about 10 times as abundant as the *exo* conformer (2). The relative concentrations deduced in this way depend on the values assumed for ^3J at $\theta = 60°$ and 180°. Again, the ^{1}H nmr chemical shift of the

For personal use only.

hydroxyl proton at infinite dilution in CCl_4 (2) is consistent with an *endo* conformer having $\phi = 60°$ but also with free rotation about the exocyclic C—C bond (ϕ motion). The geminal coupling constant, $^2J(H,H)$, deduced from $^2J(^1H,^2H)$ in α-deuterobenzyl alcohol (2), gives the same consistency. The probability of a rather low barrier to rotation about the C—C bond is indicated by early STO-3G MO computations (3), albeit with a standard (unrelaxed) geometry.

The stability of the *endo* conformers has been attributed, not to O—H$\cdots\pi$ hydrogen bonding (4) but, more recently (5–8), to repulsive forces between the lone-pair electrons on the oxygen atom and the π electrons. This interpretation is in line with a recent theoretical investigation of allyl alcohol (9), in which the most stable conformer about the allylic C—O bond is attributed to a minimization of the repulsion between the lone pairs on the oxygen atom and the π bond. The latest infrared and nmr data (10) are also interpreted in this way.

The many infrared studies of benzyl alcohol and related compounds have been reviewed (4). The latest of these (4) concludes that, in CCl_4 and CS_2 solutions, at least two conformers are present, defined by $\phi = 0°$ and 60°. The conformer with $\phi = 90°$ cannot be excluded, however (4). It is stated that a distinction between attractive O—H$\cdots\pi$ and repulsive lone-pair $\cdots\pi$ forces cannot be made on the basis of stretching frequencies.

Now, if the barrier to rotation about the C—C bond is rather small compared to thermal energies, as is also suggested by the long-range proton–proton coupling constants in 3,5-dichlorobenzyl alcohol (11), then a discussion in terms of only a few conformations appears inappropriate. A more detailed potential surface is required for comparison with experimental data. STO-3G MO computations, with extensive geometry optimization, are reported here for many combinations of θ and ϕ. Computations with larger basis sets are too time consuming at present. It may be noted that the minimal basis set appears to give reasonable conformational predictions for some benzyl derivatives, such as the fluoride and chloride (12, 13).

The computations yield expectation values of θ, ϕ, and of functions of these angles. These can be compared with those deduced from electron diffraction patterns and from long-range coupling constants reported here for benzyl alcohol in CS_2 and acetone-d_6 solutions. In addition, measurements of ^3J are reported for some diortho-substituted benzyl alcohols. These measurements represent an attempt at testing values of ^3J for the *exo* and *endo* conformers.

Experimental

Benzyl alcohol and its derivatives came from Aldrich. Samples for nmr analysis of benzyl alcohol were prepared as 0.5, 1.0, and 2.5 mol% solutions in CS_2 and as a 2.5 mol% solution in acetone-d_6 (see the tables for details of the solvent composition) and were transferred to 5 mm o.d. sample tubes. The tubes were degassed by several freeze–pump–thaw cycles and were then flame-sealed. The nmr sample tubes contained a few pellets of Linde 3A molecular sieve (Alfa products), meant to remove residual water. Solutions of varying and low concentrations were also prepared in CS_2/C_6D_{12}/TMS of benzyl alcohol and its α,α-dimethyl, 2,6-difluoro, and 2,6-dichloro derivatives.

The ^1H nmr spectra were accumulated on an AM 300 spectrometer in the manner previously described in detail (12). The ^1H nmr spectra of α,α-dimethylbenzyl alcohol and of 3,5-dichlorobenzyl alcohol (in a number of solvents) were recorded on a WH 90 FFT nmr spectrometer. STO-3G MO computations (14) were performed with the program GAUSSIAN 82 (15) on an Amdahl 5870 system.

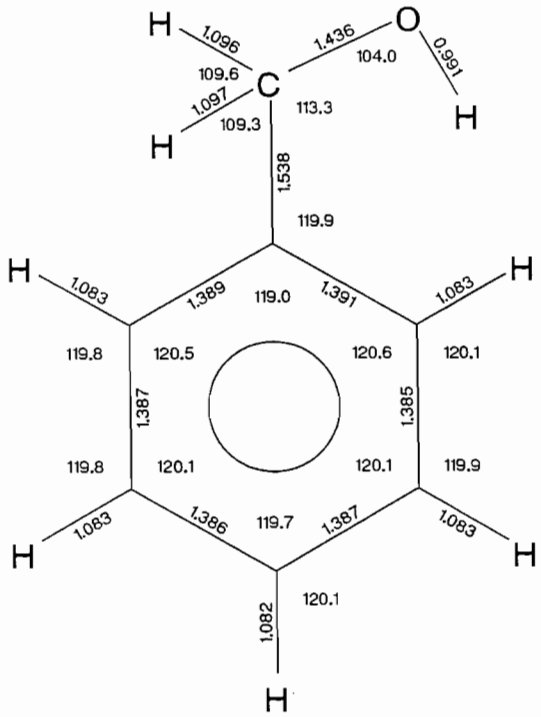

FIG. 1. The geometry-optimized STO-3G MO structure of lowest energy, −340.302247 au, is shown and can be used as a starting point for computations with larger basis sets. The angle ϕ is 42.9° and θ is 60.2° (see **1** in the text), the molecule being in the *endo* conformation. The C(1)—C(α) bond bends by 0.4°, C(α) lying below the plane of the phenyl group, which was actually constrained to have its nuclei in a plane. The deviations of the internal angles of the phenyl moiety from 120° are in qualitative agreement, but somewhat smaller in magnitude than those caused by a methyl group (46–48).

Results and discussion

The stable STO-3G MO structure

Figure 1 displays the computed structure with the minimum energy of −340.302247 au. It has the *endo* conformation. The angle ϕ is 42.9°, θ is 60.2° (see **1**), and the exocyclic C—C bond makes an angle of 0.4° with the extension of the C(1)–C(4) line. Optimization of the bond angles within the benzene ring has reduced the total energy by 0.4 kJ/mol but has not changed the geometry of the side chain significantly, e.g., ϕ changes from 42.8 to 42.9°. Because of the computing time involved (58.4 h for the cpu time in the computations given in Table 1), the ensuing calculations constrained the carbon skeleton of the benzene ring to a regular hexagon.

As expected (16), the exocyclic C—C and the C—O bond lengths are computed about 0.01–0.02 Å longer than anticipated on the basis of those known for related molecules. The COH angle of 104.0° in Fig. 1 is about 4° smaller than measured in methanol (17). However, it does not follow that the relative energies of the various conformers in Table 1 will therefore be computed incorrectly (18, 19). Naturally, geometry optimization procedures are requisite.

The STO-3G MO populations at 300 K

Table 1 contains the computed energies of the geometry-optimized conformations of benzyl alcohol for $0° \leq \theta \leq 180°$ and $0° \leq \phi \leq 180°$. The intervals are 15° in ϕ and 30° in θ (see **1**). The energies are given relative to the conformation defined by $\phi = 45°$ and $\theta = 60°$. This conformation has an energy

[a]In kJ/mol relative to $\phi = 45°$, $\theta = 60°$.
[b]The *exo* conformers are taken as those with $\theta > 120°$, although, of course, those with $\theta = 180°$ are the stable ones.
[c]See structure **1** in the text for definitions of φ and θ.

insignificantly different from that with $\phi = 42.8°$ (0.04 kJ/mol). The energies of the conformers described by $180° < \phi < 360°$ can, of course, be obtained from those in Table 1. The presentation in Table 1 is, in our opinion, preferable to a contour diagram because it is the quantitative base for the calculation of populational distributions that a reader may want to perform. The eye also easily follows various energetic pathways in such a table.

For example, the *exo* conformer is that one with $\theta = 180°$; the barrier to rotation about the C—C bond (φ motion) is 1.4 kJ/mol, very similar to that computed for benzyl fluoride (12). It may be that, for values of θ near 180°, an attractive force exists between the C^+–O^- and the *ortho* C^-–H^+ dipole. The interatomic distances involved for conformations not far from $\phi = 0°$ are just those for which attractive intramolecular C—H···O interactions have been detected in the solid state (20, 21). If so, then the postulated lone-pair···π repulsive forces at a φ near 90° are not strikingly large, less than those necessary to cause a barrier of 1.4 kJ/mol. Note that the most stable *endo* conformer, at $\phi \sim 45°$, has the O—H bond pointing in such a manner that the 1*s* orbital lies rather near the $2p - \pi$ orbital on the *ipso* carbon atom.

The data in Table 1 can be converted into populational distributions over a grid of some 90 points. The populations are found from the data in Table 1 via the Boltzmann expression ($T = 300$ K) and simple statistical weights (entropy corrections) for equivalent conformations are applied. This procedure is not rigorous because the populations are determined by free energies whereas the energies in Table 1 are internal energies, which can be equated to enthalpies if the volume differences between conformers are small. A proper calculation of a classical partition function would account for entropy terms arising from the shape of the potential energy surface defined by θ and φ. Such calculations are beyond our resources and, in common with many other workers, we write $\langle x \rangle = \Sigma_i p_i x_i$, where p_i is the fractional population of conformer *i* as obtained in the simple way above; note that the conformational grid is reasonably fine. Furthermore, these averages are also compared below with experimental quantities obtained for the solution state, adding a further uncertainty to that contributed by the approximate averages, themselves based on an approximate theoretical model. The reasonable agreement between the model and the experimental data may therefore be fortuitous.

At 300 K, $\langle\phi\rangle$, the average value of φ, is computed as 48.2°. The electron diffraction patterns correspond to a nozzle temperature of about 383 K (1) and are best fit by a φ of 53.7°. The value of $\langle\phi\rangle$ at 383 K actually decreases by a degree for the energies in Table 1. Of course, a distribution of φ values with very similar energies is expected on the basis of Table 1.

From the viewpoint of the nmr data to follow, other averages from Table 1 are also of interest. If the *exo* forms are taken as those with $\theta > 120°$, then their fractional populations add to 0.27 at 300 K, leaving 0.73 as the populations of the *endo* conformers. Furthermore, $\langle\sin^2\phi\rangle$ is found to be 0.538 and $\langle\sin^2\psi\rangle$ is 0.481 (see **2**). The latter number will be compared with that found from long-range proton–proton couplings below.

^{1}H nuclear magnetic resonance spectra of benzyl alcohol

Table 2 presents the ^{1}H nmr spectral parameters of benzyl alcohol in CS_2 and acetone-d_6 solutions at 300 K. Although the spectral extent of the ring protons is small, giving rise to some significant parameter correlations, the crucial parameter, $^6J(H,CH_2)$, is available with some precision. $^6J(H,CH_2) \equiv {}^6J$ is proportional to $\langle\sin^2\psi\rangle$. The proportionality constant is $^6J_{90}$, the value of ^6J when ψ is 90°. $^6J_{90}$ is known reliably from very detailed investigations of the conformational behaviour of salicyl alcohol and its monoethylated derivatives (22). Its value is −1.02 Hz. Hence $\langle\sin^2\psi\rangle$ for benzyl alcohol in CS_2 solution is $0.503/1.02 = 0.493$. This number is indeed in satisfactory agreement with the 0.481 obtained from the computations for the free molecule.

The question of solvent and self-association effects on the conformational distribution is naturally of interest. At a concentration of 2.5 mol%, appreciable intermolecular hydrogen bonding is expected. How the conformational distribution is perturbed by the presence of hydrogen bonded trimers (see below) is problematical. Intuitively, one might expect higher proportions of the *exo* conformers in such a situation. Indeed, for the acetone-d_6 solution, in which considerable populations of benzyl alcohol – acetone complexes should occur, the magnitude of ^6J rises to −0.552 Hz, yielding a $\langle\sin^2\psi\rangle$ of 0.542. A higher value of $\langle\sin^2\psi\rangle$ is expected as the population of *exo* conformers increases because fewer unfavorable O—H, *ortho* C—H interactions occur. Hence φ values near 0° and 180°, and therefore ψ values near 60° or 120°, become more probable.

Dilution to 0.5 mol% in the CS_2 solvent mixture causes a hydroxyl proton chemical shift of 1.39 ppm. Because this chemical shift is 1.07 ppm at infinite dilution (see below) and because the association shift must be *at least* 3.38 ppm, the value at a concentration of 2.5 mol%, it follows that not less than about 90% of the benzyl alcohol is in monomeric form at a concentration of 0.5 mol% and 300 K. It is therefore interesting that the long-range coupling constants between the methylene and ring protons, particularly $^6J(H,CH_2)$, are invariant to concentration between 0.5 and 2.5 mol%. The most simple explanation of this fact has it that association into trimers and probably into higher polymers as well (23), which must be substantial at 2.5 mol%, does not alter the distribution of φ values. In other words, the internal potential controlling the motion about the

[g]^3J(HCOH) is 6.07 ± 0.01 Hz at concentrations of 0.12_5, 0.06_3, 0.03, and 0.01_6 mol%.

C_{sp^2}—C_{sp^3} bond has not altered significantly. The lifetime of intermolecular hydrogen bonds in solution at ambient temperatures is certainly less than 10^{-7} s (24, 25). In fact, the depolarized light scattering spectrum of liquid benzyl alcohol and dielectric relaxation data for the liquid (26) are consistent with a lifetime of about 50 ps near room temperature. The present results suggest that the present extent of self-association, viewed as a solvent effect, is no more effective in perturbing the internal rotational potential in benzyl alcohol than are the molecules of CS_2 and C_6D_{12} surrounding the monomer in the dilute solution.

In a statistical mechanical treatment of gaseous and liquid alkyl alcohols (27) it is found that the molecules in the liquid make close to two hydrogen bonds per molecule. The conformational energy wells for rotation about the C—O bonds become narrower, that is, *gauche* and *trans* conformers become better defined at 298 K in the liquid. Furthermore, the change in conformational populations is rather small as the gas condenses. For example, the *trans* population of ethanol changes by only 2% and similar alterations are found for 1-propanol and 2-propanol (27). These results are taken to indicate that a comparison between computations on free benzyl alcohol molecules and measurements in CS_2 solutions have some validity.

Finally, in a study of the orientational ordering of benzyl alcohol in some phospholipid bilayers (28), it was concluded that the aromatic ring is preferentially coplanar with the hydroxyl group. In that event the computations in Table 1 imply a stabilization of this conformer ($\phi = 0°$) by at least 4 kJ/mol, presumably by an interaction (29) with the head group and glycerol moiety in the backbone region of the bilayer membrane.

exo *and* endo *populations from* ^{3}J*(HCOH)* $\equiv$ ^{3}J

The deduction of the *exo/endo* equilibrium constant in benzyl alcohols has been based on the assumption that each conformer is characterized by a definite ^3J, namely, a ^3J_g or *gauche* coupling constant for the *exo* form and a $(^3J_g + {}^3J_t)/2$, or the mean of *gauche* and *trans* coupling constants, for the *endo* form (2, 30–32). A range of ^3J_g and ^3J_t values has been employed in discussions of alcohols, covering 2.0–3.0 Hz for ^3J_g and 11.0–12.5 Hz for ^3J_t. Clearly, the equilibrium constant and the derived conformational energy difference depend significantly on the assumed values of ^3J_g and ^3J_t. At infinite dilution in CS_2 solution at 300 K, ^3J in 2,6-dichlorobenzyl alcohol is 7.27 ± 0.01 Hz (see below), while in 2,6-difluorobenzyl alcohol it is 6.89 ± 0.02 Hz. In a CCl_4/C_6D_{12} solution containing 0.1 w/v% of 2,6-dimethoxybenzyl alcohol, ^3J is 7.02 ± 0.01 Hz (22). At infinite dilution in CS_2 solution, ^3J in 2-chloro-6-fluorobenzyl alcohol is 7.09 ± 0.02 Hz at 305 K. On the assumption that ^3J depends only on the *exo/endo* equilibrium, these results suggest a lower limit of 14.5_4 Hz for $^3J_g + {}^3J_t$.

The approach outlined above assumes rigid conformations. The average values of the trigonometric functions of the Karplus equation (33) are needed for a more rigorous treatment. In other words, an equation of the type $^3J = A\langle\cos^2\gamma\rangle + B\langle\cos\gamma\rangle + C$ is required, angular brackets indicating expectation values and γ being the dihedral angle for the HCOH fragment. These expectation values are not available in general.

As an example, suppose that the STO-3G MO results for benzyl alcohol hold for the dilute solution in CS_2 at 300 K, in which ^3J is 6.07 ± 0.01 Hz. At 300 K, the data in Table 1 yield a $\langle\cos^2\gamma\rangle$ of 0.517_3 and $\langle\cos\gamma\rangle$ as -0.064_2. The equation, $^3J/\text{Hz} = 11.0\,\langle\cos^2\gamma\rangle - 1.9\,\langle\cos\gamma\rangle + 0.25$, then has ^3J as 6.06 Hz. ^3J_t and ^3J_g ($\gamma = 60°$) are now 13.1_5 and 2.0_5 Hz, respectively. The largest ^3J_t values in the literature appear to be 12.1 and 12.5 Hz (34, 35) and, of course, are expected to be smaller than the true ^3J_t because of torsional motions in the

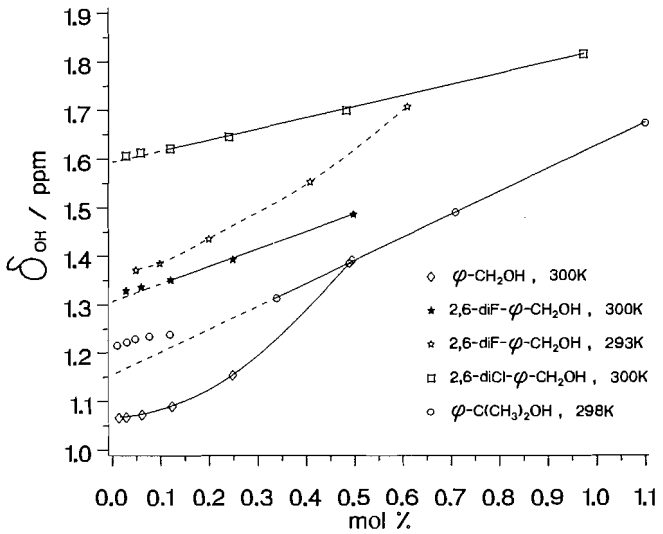

FIG. 2. The hydroxyl proton chemical shifts, relative to internal tetramethylsilane, are plotted as a function of concentration in units of mol% for dilute solutions in CS_2, which also contains 10 mol% of C_6D_{12} and 0.5 mol% TMS. For benzyl alcohol, ϕ-CH_2OH, δ(OH) is 1.394, 1.1569, 1.0923, 1.0744, 1.0693, and 1.0684 at concentrations of 0.50, 0.25, 0.12_5, 0.06_3, 0.03_1, and 0.01_6 mol%, respectively. ^3J(HCOH) is 6.06_9 and 6.06_7 Hz at 0.06_3 and 0.01_6 mol%, respectively. The shift at infinite dilution appears to be 1.067_5 ppm. See Table 2 for δ(OH) at 1.0 and 2.5 mol%. A plot of δ(OH) between 0.01_6 and 2.5 mol%, not shown here, displays the characteristic shape of a monomer–trimer equilibrium (40). Infinite dilution shifts and ^3J(HCOH), when applicable, are given in the text for the other compounds.

reference molecule. For the 2,6-disubstituted benzyl alcohol derivatives above, potential surfaces are required, to estimate ^3J from the present equation. Qualitatively it is clear that the 2,6-dichloro compound comes closest to a pure *endo* form in CS_2 solution at infinite dilution and 300 K. The rigid *endo* conformer would now have a ^3J of 7.6_0 Hz, only 0.1 Hz larger than in a recent discussion (22).

^3J is reported as 5.94 ± 0.05 Hz for benzyl alcohol in the gas phase at a pressure of 100 Torr (1 Torr = 133.3 Pa) and at 422 K (36). The data in Table 1 translate into a $\langle\cos^2\gamma\rangle$ of 0.499 and a $\langle\cos\gamma\rangle$ of −0.002 at 422 K. Hence the equation above yields ^3J as 5.75 Hz (the computed population of the *exo* form has increased to 31% at 422 K from 27% at 300 K). The dipole moment in the vapor phase at 463 K is 1.70 ± 0.01 D for benzyl alcohol (37), equal to that measured at 298 K in benzene, benzene–hexane, and in CCl_4 solutions (37–39). However, the computed dipole moment of the *exo* form is only 5% larger than that of the *endo* form, so that these data do not provide a sensitive measure of populational changes with temperature.

The population of the *endo* conformer in benzyl alcohol and its diortho-substituted derivatives increases in the order H < F < OCH_3 < F-2, Cl-6 < Cl, from 73% in the parent molecule to 94% in the dichloro derivative, assuming the new values of ^3J_g and ^3J_t. Of course, this treatment assumes the same dihedral angle in a given conformer for all the molecules (22).

Hydroxyl proton shifts in dilute solutions

(*i*) *Benzyl alcohol and its 3,5-dichloro derivative*

In Fig. 2 the plot of δ(OH) versus concentration in the CS_2/C_6D_{12}/TMS mixture (see figure caption) shows remarkable curvature between 0.01_6 and 0.49_6 mol% (roughly 0.003–0.08 molar) and, as already noted by Abraham and Bakke (2) for CCl_4 solutions at concentrations as low as 0.02 M, displays a rapidly decreasing slope at the lowest concentrations. At 300 K the shift at infinite dilution is 1.067_5 ppm. This number is very similar to the 1.09 ppm quoted for the CCl_4 solution at 298 K.[4] As is well known (23, 40), these results strongly indicate that a polymer higher than dimer is predominant at low concentrations. It is also true that the determination of the associative equilibria from δ(OH) alone is beset by uncertainties (40) and will not be attempted here.

^3J(HCOH) is 6.07(1) Hz at concentrations of 0.12_5, 0.06_3, 0.03, and 0.01_6 mol%, so that this number is also that at infinite dilution in the CS_2/C_6D_{12}/TMS mixture at 300 K. At 298 K, ^3J(HCOH) is 5.79 Hz for a 0.02 M solution in CCl_4 (2). In an experiment with 3,5-dichlorobenzyl alcohol, we find ^3J as 5.99(2) Hz for a 0.1 mol% solution in CS_2/C_6D_{12}/TMS and as 5.85(1) Hz at a concentration of 0.1 mol% in acetone-d_6, while it is 6.23(1) Hz at the same concentration in benzene-d_6. δ(OH) is 1.319, 4.470, and 0.623 at 298 K for the three solutions, in that order.[5]

(*ii*) *α,α-Dimethylbenzyl alcohol*

The investigations of associative equilibria for *tert*-butyl alcohol in CCl_4 solutions set an upper limit of 0.25 M^{-1} for the dimerization constant, but a much smaller, perhaps vanishingly small, value applies in hexadecane solution (23). δ(OH) is a linear function of concentration between 0.05 and 0.2 M in CCl_4 at 294 K (23, 40) and changes by 1.07 ppm between 0 and 0.2 M.

In Fig. 2, δ(OH) for α,α-dimethylbenzyl alcohol in CS_2 varies by only 0.46 ppm over roughly the same range of concentration but at 300 K, the lowest concentration being 0.01_2 mol% or roughly 0.002 M. Consequently, a small dimer concentration will be more easily detected for this compound because, clearly, the trimer concentration is smaller than for *tert*-butyl alcohol. This point is also emphasized by the difference of 0.06_5 ppm between the extrapolated shift and the true shift at infinite dilution in Fig. 2. This difference, whose magnitude is related to the trimer concentration for the dilute region, is as large as 0.17 ppm for *tert*-butyl alcohol (23, 40). The distribution of points in Fig. 2 suggests the presence of dimer at the lowest concentrations (limiting finite slope), followed by the rapid onset of polymer formation above about 0.05 mol% or roughly 0.008 M. An estimate of the dimerization constant, K_2, demands a value of δ(OH) for the dimer. A rough estimate of 5 ppm for this number, noting that δ(OH) for the monomer is 1.214 ppm, gives K_2 as ca. 0.2 M^{-1}.

(*iii*) *2,6-Difluorobenzyl alcohol*

The high sensitivity of δ(OH) to temperature is demonstrated by the plots in Fig. 2 at 293 and 300 K. Again, at 300 K the decreasing slope at low concentrations is evident. ^3J(HCOH) is 6.89(2) Hz for the four solutions ranging from 0.25 to 0.03 mol% in the alcohol, giving its value at infinite dilution. The increase of 0.8 Hz relative to the parent molecule is plausibly attributable to an increase in the *endo* population. The δ(OH) at infinite dilution at 300 K is less than 1.331 and greater than 1.321.

[4] At 422 K and 100 Torr, δ(OH) is 0.802.

[5] The assumption that ^3J_t is 13.1_5 Hz and that ^3J_g is 2.0_5 Hz (see the equation in the previous section) leads to 24% as the population of the *exo* conformer in the benzene solution at 298 K. This approximation may be compared with that of 30% for 4-chlorobenzyl alcohol in benzene at 308 K obtained from dipole moments (41). In the solid, 4-chlorobenzyl alcohol forms intermolecular hydrogen bonds, which cause it to exist in the *exo* form only (42).

(iv) 2,6-Dichlorobenzyl alcohol

At infinite dilution, δ(OH) is greater than 1.604 at 300 K and less than 1.608. Between 0.24 and 0.03 mol%, ^3J(HCOH) is 7.27(1) Hz. The decreased shielding of the hydroxyl proton in the 2,6-dihalobenzyl alcohols is perhaps partly caused by intramolecular hydrogen bonding (δ(OH) is 2.08 for 2-nitrobenzyl alcohol at infinite dilution in CCl_4 and is 1.63 for 2-methoxybenzyl alcohol (2)). Judging by the δ(OH) plots in Fig. 2, formation of polymers, probably mainly trimers at these low concentrations (23, 40), is most pronounced for benzyl alcohol and least pronounced for 2,6-dichlorobenzyl alcohol. For sufficiently hindered molecules, such as 2,4-dimethyl-3-ethyl-3-pentanol, only dimer formation occurs (43), so that at least part of the present observations is accounted for by the greater congestion near the site of the hydroxyl group in the benzyl alcohol derivatives.

(v) Caveats

The existence of sharp multiplets in the hydroxyl proton spectra of benzyl alcohol and its dihalo derivatives at low concentrations demonstrates the absence of rapid intermolecular proton exchange. However, it does not prove the absence of water in the nmr samples, even though the presence of molecular sieve will reduce the concentration of water significantly. Thus, it is conceivable that some of the alcohol monomers or polymers at the lowest concentrations actually exist as species in which a water molecule is hydrogen bonded to the alcohol. Peaks due to water were not observed in the spectra. In one experiment, the CS_2/C_6D_{12}/TMS mixture was shaken with water. The ^{1}H nmr spectrum of the nonaqueous layer displayed no obvious peak attributable to water. One very small peak near the residual peak due to the 0.5% residual protons in the 99.5% deuterated cyclohexane, if indeed it arose from water, represented a concentration of less than 0.015 mol%. For the α,α-dimethylbenzyl alcohol solutions there is no large ^3J(HCOH), so that some ambiguity arises; it is possible that the linear portion of the plot at low concentrations in Fig. 1 is caused by exchange with water protons whose chemical shift is less than 1.2 ppm. However, we have no evidence for this exchange.

The ring proton shifts in CS_2 solution

Compared to the quoted dilution shifts of aromatic protons in monosubstituted benzene derivatives (44), those of the ring protons in benzyl alcohol are larger by about an order of magnitude (Table 2). Plots of these shifts as a function of concentration in the CS_2 solvent mixture are curved and, unfortunately, below 0.5 mol% spectral analytical difficulties do not allow their extraction from the very tightly coupled spectra. However, the chemical shifts of all five types of protons are proportional to each other, correlation coefficients being 0.999 or better. Thus, for six concentrations between 0.016 and 0.50 mol%, one has $\delta(CH_2) = 4.6660 - 0.09685\delta(OH)$ with $r = 0.999_1$. Again, for the three concentrations at which ring proton chemical shifts are available one has, for example, δ(H-3) = 7.2503 − 0.02718δ(OH) with $r = 0.999_9$. Correlations of this kind allow the conclusion that, at infinite dilution and 300 K, $\delta(CH_2)$ = 4.563(3), δ(H-2) = 7.224(2), δ(H-3) = 7.223(1), and δ(H-4) = 7.149(1); these numbers are based on a δ(OH) of 1.067_5 at infinite dilution.

The methylene and ring protons are increasingly deshielded as the concentration decreases. The changes in chemical shifts between zero and 2.5 mol% are in the ratio of 1:2.1:3.5:6.1 for H-4, H-3, H-2, CH_2 respectively. This means that the hydrogen bonded complexes, probably mainly trimers in this concentration range, have a structure in which, on average, these protons lie in the shielding region arising from the diamagnetic anisotropies of the other phenyl groups involved in the complex. Furthermore, although the shielding depends on angular as well as distance parameters (45) and therefore a unique average structure is unlikely to be ascertainable from the chemical shifts, the ratio above is consistent with the idea that the structure has the methylene protons of one molecule placed nearest to the phenyl rings of the partners in the complex. A structure in which two phenyl groups are stacked is unlikely, for example, because of the ratio given above.

The ratio of the change in δ(OH) to that of δ(H-4) in this concentration range is −77:1, so that δ(OH) is dominated by the deshielding caused by the O—H···O interactions. However, δ(OH) also contains a term of unknown sign and magnitude originating in the diamagnetic anisotropies of the other phenyl groups in the self-complex.

Finally, it is of interest that the $\delta(CH_2)$ of 4.563(3), at 300 K and at infinite dilution in the CS_2 solvent mixture, is rather near that of 4.585 in the vapor at 422 K (36). At 296 K, $\delta(CH_2)$ is 4.598 at infinite dilution in CCl_4(2).

Internal motion in benzylidene diacetate and its 2,6-dibromo derivative by DNMR and the *J* method

TED SCHAEFER AND CRAIG S. TAKEGUCHI
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 17, 1988

TED SCHAEFER and CRAIG S. TAKEGUCHI. Can. J. Chem. **67**, 1022 (1989).

The ^{1}H nuclear magnetic resonance spectral parameters are reported for benzylidene diacetate in CS_2 and acetone-d_6 solutions. The long-range spin–spin coupling constant over six formal bonds, ^6J, is used to derive apparent twofold barriers to rotation about the exocyclic C(1)—C bond in the two solutions. The conformation of lowest energy has the α C—H bond in the benzene plane. The barrier is higher in CS_2 than in acetone-d_6 solution, in contrast to a molecule like benzyl chloride. In the 2,6-dibromo derivative, the free energy of activation for reorientation about the bond in question is 36 kJ/mol at 165 K in dimethyl ether solution. Such a high barrier implies a very small six-bond proton–proton coupling constant for this derivative because ^6J is proportional to the expectation value of $\sin^2\theta$. The angle θ is zero when the α C—H bond lies in the benzene plane. ^6J is −0.051 Hz in acetone-d_6 solutions; its sign is determined by double resonance experiments. The question of an angle-independent component of ^6J, that is, whether ^6J is finite at $\theta = 0°$, is addressed. A maximum magnitude of 0.02 Hz may be present at $\theta = 0°$ for the 2,6-dibromo derivative, although a zero magnitude is also compatible with the experimental data. In a compound with a higher internal barrier, α,α,2,6-tetrachlorotoluene, the experimental results are best in accord with a negligibly small ^6J at $\theta = 0°$.

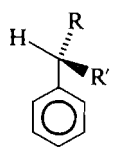
TED SCHAEFER et CRAIG S. TAKEGUCHI. Can. J. Chem. **67**, 1022 (1989).



On a rapporte les paramètres des spectres rmn du ^{1}H du diacétate de benzylidène, mesurés en solutions dans le CS_2 et l'acétone-d_6. On a utilisé les constantes de couplage spin–spin à longue distance à travers six liaisons formelles, ^6J, pour déterminer les barrières binaires, apparentes, à la rotation autour de la liaison exocyclique C(1)—C, dans les deux types de solutions. Pour la conformation d'énergie plus basse, la liaison C—Hα se trouve dans le plan du benzène. Par opposition à ce qui a été observé avec le chlorure de benzyle, la barrière est plus élevée dans le CS_2 que dans l'acétone-d_6. Dans le dérivé dibromo-2,6, en solution dans l'éther diméthylique, à 165 K, l'énergie libre d'activation pour la réorientation autour de la liaison en question est de 36 kJ/mol. Puisque la valeur de ^6J est proportionnelle à la valeur attendue pour $\sin^2\theta$, une barrière aussi élevée implique que la constante de couplage proton–proton à longue distance est très faible. L'angle θ est égal à zéro lorsque la liaison C—H α se trouve dans le plan du benzène. En solution dans l'acétone-d_6, la valeur de ^6J est −0,051 Hz; on a déterminé son signe grâce à des expériences de double résonance. On discute de la question relative à la possibilité que la valeur de ^6J soit différente de zéro lorsque $\theta = 0°$. Même si une amplitude de zéro est compatible avec les données expérimentales obtenues avec le dérivé dibromo-2,6, on établit à 0,02 Hz l'amplitude maximale présente dans ce système, lorsque $\theta = 0°$. Dans l'α,α,2,6-tétrachlorotoluène, un composé possédant une barrière interne plus élevée, les résultats expérimentaux s'accordent mieux avec une valeur négligeable de ^6J pour $\theta = 0°$.

[Traduit par la revue]

Introduction

The deduction of the internal barrier to rotation about the bond between a benzene ring and a side chain from motionally averaged long-range spin–spin coupling constants (*J* method) depends on a knowledge of the coupling mechanisms and of the extrema in the magnitudes of the coupling constants (1–4). For example, in **1** the coupling constant over six bonds between the proton in the side chain and that at the *para* position has

1

been written as in eq. [1], where θ is the angle by which the

$$[1] \quad {}^6J(\mathrm{H,H}) = {}^6J_{90} \sin^2\theta$$

C—H bond rotates out of the benzene plane and $^6J_{90}$ is the value of ^6J at $\theta = 90°$ (1). If the latter is known, then a measurement of ^6J yields the expectation value of $\sin^2\theta$, which, in turn, can be related to the internal barrier by a hindered rotor model (1) or by a classical averaging procedure (5). In toluene, $^6J_{90}$ is −1.20 Hz (6) but electronegative substituents can alter this magnitude (1, 3, 4), thereby introducing some uncertainty into the use of the *J* method. A further possible source of error originates in the suspicion that there occurs an angle-independent term in eq. [1], ^6J_o, analogous to that in the Heller-McConnell relationship for β-hyperfine interactions in radicals (7).

Nevertheless, the *J* method is one of the few available for the estimation of small barriers in solution and is most reliable for barrier magnitudes much smaller than those accessible to dynamic nuclear magnetic resonance (DNMR) procedures. Consequently it is worthwhile to devise tests of its reliability. One such test involved the overlap of the *J* method and DNMR in 2,6-difluoroisopropyl benzene (2), but was not entirely successful, the barrier lying in a range for which both methods were somewhat insensitive. The present work describes another attempt at an overlap of the two methods. Again, the results are not without some ambiguity, although they are compatible with the non-existence of a second term on the right of eq. [1]. The nmr spectral data were obtained for benzylidene diacetate (R = R′ = $OCOCH_3$ in **1**) (α,α′-diacetoxytoluene) and for its 2,6-

[b]In the absence of decoupling of the methyl protons.
[c]Decoupling of the methyl protons.
[d]In Hz at 300.135$_2$ MHz to high frequency of internal TMS.
[e]Numbers in parentheses are standard deviations in the last significant figure.
[f]For the ring and methine protons, ignoring the methyl protons.
[g]Ring protons only.
[h]Ring and methine protons. The two analyses were independent in that they were performed some months apart in a "blind" sense. The Bloch–Siegert shift is observed for the ring protons during decoupling of the methyl protons and amounts to 0.024 Hz in column 3.
[i]For a 4.8 mol% solution in CS_2, containing also 10.0 mol% of C_6D_{12} and 0.5 mol% of TMS.

dibromo derivative, **2**; α,α,2,6-tetrachlorotoluene was also examined.

Experimental

The synthesis (8) of **2** used 1.01 g of 2,6-dibromotoluene (Lancaster Synthesis), dissolved in a precooled mixture of 10 mL acetic anhydride, 10 mL of glacial acetic acid, and 3 mL of concentrated H_2SO_4. At a solution temperature of 5°C, 1.7 g of CrO_3 was added slowly so as to keep the temperature below 10°C, stirring the while. Stirring ceased 0.5 h after the addition was complete. The flask contents were poured into a 400-mL beaker that had been one-third filled with crushed ice. Cold water was added to give a volume of 200 mL. Filtration and washing with cold water until the washings were colorless was followed by a wash with cold 2% Na_2CO_3 solution and, finally, with 10 mL of ethanol.

1 came from 2.01 g of benzaldehyde and 0.044 g of *p*-toluenesulfonic acid, which were added to 10 mL of acetic anhydride in a 100-mL round-bottom flask. The mixture was stirred overnight. The isolated solid was dried on a vacuum line to remove acetic anhydride and was then air-dried, yielding a white crystalline product.

Approximately 2–3 mol% solutions of **1**, **2**, and of 2,6-dibromotoluene were prepared in CS_2/C_6D_{12}/TMS and acetone-d_6/TMS mixtures (see tables). These were transferred to 5 mm o.d. nmr sample tubes; the latter were degassed by numerous freeze–pump–thaw cycles and were then flame-sealed. A dilute (<5 mol%) solution of **2** in dimethyl ether was sealed off in a 5 mm o.d. sample tube and was stored in a freezer before use.

The ^{1}H nmr spectra were accumulated on an AM300 Bruker nmr spectrometer by methods previously described (6). Linewidths at half-height of less than 0.04 Hz could be attained for **2** and of about 0.05 Hz for **1**. The DNMR experiments on **2** in dimethyl ether were performed by the usual procedures (2) in this laboratory, also on the AM300 instrument.

Results and discussion

Spectral analyses

These were performed with the computer program NUMARIT (9), as revised in this laboratory by R. Sebastian. The ^{1}H nmr spectral parameters are given in Tables 1 and 2. For the benzylidene diacetate, **1**, in acetone-d_6 solution, two independent analyses were made, one in which the spectrum under analysis was single resonance, the other of a spectrum for which the methyl protons had been decoupled. Comparison of the spectral data in Table 1 suggests that the standard deviations are good measures of precision (note also the Bloch–Siegert shifts for the ring protons).

The sign of ^6J in **2** for the acetone-d_6 solution was determined by weak irradiation experiments (10). ^6J is −0.051(0) Hz. See Fig. 1 for an adumbration.

*^{6}J and the internal barrier in **1***

^6J is −0.263(10) Hz in acetone-d_6 solution, the standard deviation being taken as the sum of the standard deviations for the two analyses in Table 1. Were $^6J_{90}$ in eq. [1] that in toluene, −1.20 Hz, then $\langle\sin^2\theta\rangle$ would follow as 0.219(8). The assumption of a twofold barrier hindering rotation about the exocyclic C_{sp^2}—C_{sp^3} bond and a hindered rotor model (1) would then yield a V_2 of 7.0 ± 0.3 kJ/mol. A classical averaging procedure would and did give the same result at 300 K. The measured value of ^6J shows that the conformation of lowest energy has the methine C—H bond in the benzene plane.

However, the electronegativity of the acetoxy group is effectively that of the methoxy group (11). The latter reduces the magnitude of $^6J_{90}$ to 1.02 Hz (12). It is unlikely that a second acetoxy group is as effective as the first (saturation effect). The assumption of additivity will therefore yield a maximum in $\langle\sin^2\theta\rangle$ and a lower limit to a V_2. A $^6J_{90}$ of −0.84 Hz (additivity assumption) has $\langle\sin^2\theta\rangle$ as 0.313(12) and an apparent V_2 as 4.1 ± 0.4 kJ/mol. An alternative, that $^6J_{90}$ is −0.93 Hz, the second acetoxy group being now half as effective as the first in magnitude reduction, has the apparent V_2 as 4.9 ± 0.4 kJ/mol. It seems safe to conclude that, if the barrier is twofold, then it lies between 4 and 5 kJ/mol.

In CS_2 solution, ^6J is −0.223(6) Hz. The procedure above leads to an apparent V_2 lying between 5 and 6 kJ/mol, an increase of about 1 kJ/mol relative to that in acetone-d_6 solution. It may be that the perpendicular conformer of **1**, that with $\theta = 90°$, is stabilized by the polar solvent. This stabilization occurs in benzyl chloride, for which the acetone solvent stabilizes that conformer in which the C—Cl bond lies in a plane perpendicular to the benzene plane. In benzyl chloride, however, the perpendicular conformer lies at the bottom of the

For personal use only.

internal rotational potential well, so that the acetone solvent *increases* the internal barrier (13); that is, ^6J is smaller in magnitude in the acetone solution. On the other hand, for both benzyl chloride and **1**, the coupling constants within the ring are in general larger in acetone-d_6 than in CS_2 solution. Consequently, it is reasonable to conclude that the solvent dependence of ^6J in **1** implies a solvent dependence of the internal barrier and is not simply an indication of an intrinsic solvent perturbation.

The barrier magnitudes seem reasonable by comparison with those deducible from ^6J for 2-phenyl-1,3-dioxane and the analogous dioxolane (14), for which the present approach with a $^6J_{90}$ of −0.93 Hz yields apparent V_2 values of 1.5 ± 0.3 and 3.1 ± 0.4 kJ/mol, respectively. It should be noted that molecular mechanics (15) and calorimetric techniques (16) indicate an essentially free internal rotation in the phenyldioxane. Of course, in these two compounds the relative motion of the phenyl and saturated rings implies nearest approaches of the *ortho* C—H bonds of the phenyl group and of the oxygen atoms in the saturated moiety, the rest of the latter being held distant by virtue of its cyclic structure. Models of **1** clearly indicate that, the lowest energy corresponding to a conformation with the α C—H bond in the benzene plane (as shown by the magnitude of ^6J), the acetyl groups must point away from the phenyl group during internal rotational motion. However, whatever the value of $^6J_{90}$, the ^6J values in the three compounds under discussion show that the barrier is **1** is rather higher than in the other two. This seems reasonable because the excursions of the acetyl group must be significant in **1** and should therefore lead to a higher barrier to motion about the C_{sp^2}—C_{sp^3} bond.

Now, because of the reasonable agreement between the calorimetric and J measurements of the internal barrier in the phenyl dioxane and because the J measurement assumes a twofold barrier, it is reasonable that the twofold component is indeed dominant, at least for the two-ring molecules. For **1**, the presence of the librating groups in the side chain might introduce substantial magnitudes of higherfold terms into the internal rotational potential. Assume $\langle \sin^2 \theta \rangle$ to be 0.283 in acetone-d_6 solution, corresponding to a $^6J_{90}$ of −0.93 Hz. Such a value at 300 K also corresponds to a V_2, V_4 combination of 4.0 and 2.0 kJ/mol, instead of a V_2 of 4.9 kJ/mol; or, if V_2 and V_4 have opposite signs, then, among other combinations, V_2 and V_4 could typically be 11.5 and −7.3 kJ/mol, respectively, or 10.5 and −6.6 kJ/mol. These magnitudes of V_4 may be considered as rather high, yet they cannot be excluded on the basis of ^6J.

Finally, the presence of an angle-independent term in eq. [1] would introduce further complications. Such a term, apparently negative and about 0.1 Hz in magnitude, is thought to exist in styrene (17). Consequently, the following measurements on **2** become of interest.

2,6-Dibromobenzylidene diacetate, 2, and ^6J_o

The free energy barrier to internal rotation in **2** comes from the DNMR data for the dimethyl ether solution. At 150 K the chemical shift difference between H-3 and H-5 is 12 ± 2 Hz at 300 MHz. The coalescence temperature is 165 ± 3 K. Assuming a transmission coefficient of unity, $\Delta G^{\ddagger}_{165}$ follows as 36.2 ± 0.9 kJ/mol. It is bootless (18) to attempt a reliable decomposition of $\Delta G^{\ddagger}$ into $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for such a small difference in chemical shift for H-3 and H-5 because the temperature range over which the line shape is sensitive to the pre-exchange lifetime is too small. The apparent V_2 should be compared roughly with $\Delta H^{\ddagger}$ and not with $\Delta G^{\ddagger}$ (2).

^6J is −0.045(0) and −0.051(0) Hz for **2** in CS_2 and acetone-d_6 solutions, respectively (Table 2). Perturbations of $^6J_{90}$ by the bromine substituents are indicated by the ^6J of −0.627(1) and −0.637(0) Hz for 2,6-dibromotoluene in these two solvents. ^6J is −0.602(2) Hz in toluene (6).

Because the internal barrier to rotation in **2** cannot be infinite, $|^6J_o| < 0.05$ Hz. If $\Delta S^{\ddagger}$ is zero, then $\Delta H^{\ddagger} = \Delta G^{\ddagger}$ and is 36 ± 1 kJ/mol in ether solution. With the assumptions that $\Delta G^{\ddagger}$ is

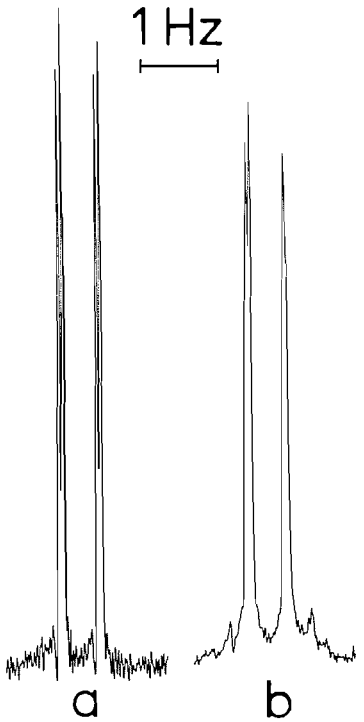

FIG. 1. In (a) four peaks of the nmr spectrum of H-4 in 2,6-dibromobenzylidene diacetate, **2**, are shown for a 3.1 mol% solution in acetone-d_6 at 300 K and 300 MHz. The small splitting of 0.051 Hz corresponds to $^6J_{AX}$ in the spectrum arising from an AB_2X spin system (see Table 2 for the spectral parameters). The doublet on the left represents the two transitions of H-4 for which the B_2 (H-3 and H-5) protons are in antisymmetric spin states (vanishing spin magnetic moment for the B_2 protons). The two pairs of doublets would coincide in frequency were the spin system describable as AM_2X. In (b) the doublets in (a) are again shown, but under conditions in which a very weak radiofrequency field is constantly applied while co-adding (24) 32 F1Ds with acquisition times of 42 s. The weak irradiation is applied to one transition in the B_2 region, corresponding to a given spin state of the X (methine) proton. The peak at low frequency in the right-hand doublet in (b) has been perturbed (the "antisymmetric" transitions on the left must be "unaware" of the second radiofrequency field under these conditions and therefore provide a good reference for resolution conditions as well as peak frequencies). Because the second field is applied at "high" frequency, the experiment indicates that J_{AX} and J_{BX}, i.e., ^6J and ^5J, have opposite signs. This indication was confirmed by three further experiments during which the second field was applied to three other transitions in the B_2 region. Because ^5J is positive (25), it follows that ^6J is $-0.051(0)$ Hz, the number in parentheses being the standard deviation given by the analysis of the single resonance spectrum.

the same in all three solvents, that the barrier is twofold, that $0.88 \leq |^6J_{90}| \leq 1.02$ Hz, that ^6J_o vanishes, and that $^6J = -0.048(3)$ Hz (being the mean of ^6J in CS_2 and acetone-d_6 solutions), $\langle \sin^2\theta \rangle$ is then 0.051(7) and V_2 is $26.5^{+4.0}_{-3.0}$ kJ/mol. If ^6J_o is -0.01 Hz, V_2 follows as $33.5^{+6.5}_{-5.0}$ kJ/mol. Of course, if the α substituents did not alter $^6J_{90}$, then (Table 2) it would be $-1.26(1)$ Hz and a ^6J of 0.048(3) Hz with a vanishing ^6J_o would correspond to a V_2 of 35.4 ± 2.1 kJ/mol. However, it is very unlikely that $^6J_{90}$ is not of the lower magnitude indicated above.

$\Delta S^{\ddagger}$ is not necessarily zero. In 2,6-difluoroisopropylbenzene, $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$ are -21 ± 4 J/mol K and 25.5 ± 0.4 kJ/mol (2), whereas in α,α,2,4,6-pentabromotoluene they are -2 ± 2 J/mol K and 80 ± 1 kJ/mol (19).

If the former value of $\Delta S^{\ddagger}$ applies to **2**, then $\Delta H^{\ddagger}$ is 33 ± 2 kJ/mol, which again is compatible with a ^6J_o of -0.01 Hz.

The presence of a fourfold component, V_4, must also be considered. A negative V_4 allows freer oscillation about the C(1)—C_{sp^3} bond than if only V_2 is present. A negative V_4 therefore leads to a larger value of $\langle \sin^2\theta \rangle$ for a given V_2, the latter being the measure of the barrier height. Consequently, the existence of a negative V_4 implies a ^6J_o of less than 0.01 Hz in magnitude.

However, the available data imply a small positive V_4 for a related compound. Thus, for α,α-diiodo-2,6-dichlorotoluene, molecular mechanics computations (20) of the internal energy of the molecule agree with the measured free energy of activation of 89 kJ/mol for internal rotation and imply that $V_4 < 0.1\,V_2$. In such a situation V_2 yields the barrier height. If V_2 is 36 kJ/mol in **2** and V_4 is 4 kJ/mol, then $\langle \sin^2\theta \rangle$ is 0.026 at 300 K; a V_2 of 33 kJ/mol and a V_4 of 3 kJ/mol yield $\langle \sin^2\theta \rangle$ as 0.030. Because the measured value of the latter is 0.051(7), ^6J_o would follow as ca. -0.02 Hz.

These illustrative arguments show that a vanishing ^6J_o cannot be established with the available information.

Turning to molecules with a higher internal rotational barrier, in CS_2 solution $\Delta H^{\ddagger}$ for α,α,2,4,6-pentachlorotoluene is 57.3 ± 1.1 kJ/mol (21) and is expected (19, 21, 22) to be much the same in α,α,2,6-tetrachlorotoluene. For a dilute solution of the latter in CS_2, containing also a smaller amount of α,2,6-trichlorotoluene, the outer peaks of H-4 correspond to αα and ββ spin states of H-3 and H-5. Hence these peaks are not broadened by the internal rate process. The peak at lowest frequency has a linewidth at 300 K of 0.06 Hz, whereas the triplets of H-4 in α,2,6-trichlorotoluene possess one of 0.03_3 Hz. The larger linewidth is attributed to an unresolved ^6J(H,H) in the α,α-dichlorotoluene derivative. Simulations, which allow for the partially Gaussian character of the resolution-enhanced experimental peaks, show that a ^6J(H,H) of just over 0.025 Hz, but certainly less than 0.030 Hz, in magnitude will account for the shapes of the measured peaks.

$^6J_{90}$ in benzyl chloride is -1.06 Hz (13). The assumption of additivity implies $^6J_{90}$ as -0.92 Hz in benzal chloride. In 2,6-dichlorotoluene, $^6J(H,CH_3)$ is $-0.630(1)$ Hz, implying $^6J_{90}$ as -1.26 Hz, compared to -1.20 Hz in toluene. A reasonable $^6J_{90}$ for α,α,2,6-dichlorotoluene appears to be -0.98 Hz, assuming additivity, or perhaps -1.05 Hz if the second α chlorine substituent is only half as effective as the first in reducing the magnitude of $^6J_{90}$. An estimate of $\langle \sin^2\theta \rangle$ as 0.027(3) follows from all these considerations. A hindered rotor approach, using 51 basis functions and a V_2 of 57.3 kJ/mol, has $\langle \sin^2\theta \rangle$ as 0.030 at 300 K. A molecular mechanics calculation (23) yields 55.2 kJ/mol for the barrier height in α,α,2,6-tetrachlorotoluene and implies a small fourfold component of the internal potential. If it is as large as 10% of V_2, then $\langle \sin^2\theta \rangle$ follows as 0.024. For this molecule, at least, ^6J_o appears to be negligibly small. There is no *a priori* reason why the situation should be any different in **1** or **2**.

^{1}H nuclear magnetic resonance and molecular orbital studies of the conformations of 3-fluoroanisole

TED SCHAEFER AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

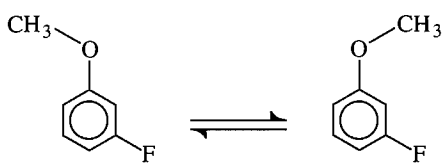
Received November 29, 1988

TED SCHAEFER and RUDY SEBASTIAN. Can. J. Chem. **67**, 1027 (1989).

The proximate spin–spin coupling constant between the methyl protons and the ring protons, $^5J(H,OCH_3)$, is extracted from a full analysis of the ^{1}H and ^{19}F nuclear magnetic resonance spectra of 3-fluoroanisole in CS_2 and acetone-d_6 solutions. The values of $^5J(H,OCH_3)$ imply that the less polar *cis* conformer is slightly more stable at 300 K than the more polar *trans* conformer in both solvents, in agreement with geometry-optimized STO-3G MO computations for the free molecule. The latter also find a higher barrier to internal rotation of the methoxy group for 3-fluoroanisole than for the parent molecule. The present results are compared with other measurements of the conformer ratio for the vapor and for solutions. The STO-3G and 6-31G structures of the *cis* and *trans* conformers are compared. The C—F bond length is computed more reliably with the minimal basis set, as is the COC bond angle. The internal angles of the benzene moiety are, of course, found more accurately with the 6-31G basis. The computations indicate additivity of the substituent effects on the internal angle, as found experimentally for a variety of benzene derivatives.

Key words: ^{1}H NMR of fluoroanisole, conformations of fluoroanisole, molecular orbital calculations for fluoroanisole.

TED SCHAEFER et RUDY SEBASTIAN. Can. J. Chem. **67**, 1027 (1989).



En se basant sur les spectres rmn du ^{1}H et du ^{19}F du fluoro-3 anisole, déterminés dans des solutions de CS_2 et d'acétone-d_6, on a déterminé les constantes de couplage spin–spin entre les protons du méthyle et les protons du cycles, $^5J(H,OCH_3)$. Ces valeurs impliquent que, à 300 K et dans chacun des solvants, le conformère *cis* qui est le moins polaire est légèrement plus stable que le conformère *trans* qui est plus polaire; ces résultats sont en accord avec des calculs d'OM STO-3G effectués sur la molécule libre à l'aide de géométries optimisées. Ces calculs ont aussi permis d'évaluer que la barrière à la rotation interne du groupement méthoxy est plus élevée dans de fluoro-3 anisole que dans la molécule parente. On compare les résultats obtenus au cours de cette étude avec ceux obtenus par d'autres méthodes pour le rapport des conformères en phase vapeur ainsi qu'en solution. On compare aussi les structures des conformères *cis* et *trans* auxquelles ont arrive par des calculs STO-3G et 6-31G. Les valeurs les plus fiables pour la longueur de la liaison C—F ainsi que pour l'angle de la liaison COC sont obtenues à l'aide de l'ensemble avec la base minimale. Par ailleurs, les angles internes de la portion benzénique les plus précis sont obtenus à l'aide de l'ensemble 6-31G. Comme on l'a noté sur la base des données expérimentales pour un grand nombre de dérivés du benzène, les calculs indiquent qu'il existe une additivité des effets des substituants.

Mots clés : RMN du ^{1}H du fluoroanisole, conformations du fluoroanisole, calculs d'OM sur le fluoroanisole.

[Traduit par la revue]

Introduction

The *cis–trans* equilibrium for 3-fluoroanisole has been investigated in solution and in the gas phase, with different results. Two bands in the infrared, at 940 and 915 cm^{-1}, displayed changes in their optical densities between 23 and 100°C for liquid 3-fluoroanisole (1). From these changes, the enthalpy difference between the two isomers was estimated as 2.4 ± 0.6 kJ/mol. The *trans* conformer was assigned as the more stable. In another investigation, a liquid sample gave vibrational bands from two conformers (2). On cooling to 93 K, the vibrational spectrum simplified significantly and was assigned to one conformer. From the intensities of the vibrational bands for 3-fluoroanisole in CCl_4 solution at ambient temperatures (3) the *cis* conformer was assigned a fractional population of 0.72.

trans *cis*

The microwave spectrum in the gas phase detected (4) the *trans* form only, possibly because it has by far the larger dipole moment (see below). The electronic spectrum of a supersonic free jet of 3-fluoroanisole showed that the *cis* conformer was the more stable (5), but the proportions of the conformers was not given; both conformers were present. Geometry-optimized STO-3G MO computations (see below) predict the *cis* form to be 0.45 kJ/mol lower in energy than the *trans*.

These data suggest that the more polar *trans* conformer is being stabilized in the liquid or in polar solvents. Because the long-range spin–spin coupling constant between the *ortho* and methyl protons in anisole and its derivatives is stereospecific (6–9) and should allow an estimate of the *cis–trans* equilibrium, its extraction is described here for CS_2 and acetone-d_6 solutions of 3-fluoroanisole. It seems that the proportions of *cis* and *trans* forms in these solutions are very nearly equal, the *cis* form being slightly more abundant.

Experimental

The 3-fluoroanisole (Aldrich) was prepared as 3.0 mol% solutions in $CS_2/C_6D_{12}/TMS/C_6F_6$ and acetone-d_6/TMS/C_6F_6 solvent mixtures; the tables below give the composition of these mixtures. The solutions were transferred to 5 mm o.d. nmr sample tubes and were degassed by several cycles of the freeze–pump–thaw procedure. The sample tubes were then flame-sealed so as to produce symmetrical tops.

The ^{1}H nmr and ^{19}F nmr spectra were accumulated on an AM 300 Bruker spectrometer, precisely in the manner described previously for benzyl fluoride (10).

STO-3G and 6-31G MO computations employed the computer program Gaussian 82 (11) on an Amdahl 5870 system. The constraint in the geometry optimization procedure was that the nuclei of the aromatic ring remain in a plane.

TABLE 1. ^1H and ^{19}F nuclear magnetic resonance spectral parameters for 3-fluoroanisole at 300 K

Parameter	Value		Parameter	Value	
$\nu(CH_3)^c$	1114.407(1)[a]	1138.958(0)[b]	$^5J_{25}$	0.300(1)[a]	0.305(1)[b]
ν_2	1939.859(1)	2006.677(1)	$^5J_{36}$	−0.488(1)	−0.426(1)
ν_4	1953.438(1)	2001.395(1)	$^5J(2,CH_3)$	−0.152(1)	−0.163(1)
ν_5	2130.391(1)	2182.870(0)	$^5J(6,CH_3)$	−0.145(1)	−0.141(0)
ν_6	1967.598(1)	2024.066(1)	$^6J(5,CH_3)$	0.061(1)	0.054(0)
ν(F-3)[d]	14476.464(1)	14436.205(1)	$^6J(F,CH_3)$	±0.074(1)	±0.074(0)
$^3J_{23}$	10.704(1)[e]	11.315(1)[f]	$^7J(4,CH_3)$	−0.019(8)	−0.024(1)
$^3J_{34}$	8.140(1)	8.627(1)[f]	Calculated transitions	608	665
$^3J_{45}$	8.245(1)	8.282(1)	Assigned transitions	525	581
$^3J_{56}$	8.342(1)	8.382(1)	Peaks observed	250	282
$^4J_{26}$	2.408(1)	2.417(1)	Largest difference	0.017	0.016
$^4J_{24}$	2.404(1)	2.446(1)	Root mean square		
$^4J_{45}$	0.880(1)	0.850(1)	deviation	0.006	0.005
$^4J_{35}$	6.740(1)	6.959(1)			

[a]3.0 mol% in CS_2, containing also 10 mol% of C_6D_{12}, 0.5 mol% of TMS, and a small drop of C_6F_6 in 0.5 mL of solution.
[b]3.0 mol% in acetone-d_6 containing also 0.5 mol% of TMS and a tiny amount of C_6F_6.
[c]In Hz at 300.135$_2$ MHz to high frequency of internal TMS.
[d]In Hz at 282.363 MHz to high frequency of internal C_6F_6.
[e]Numbers in parentheses are standard deviations of the last significant figure.
[f]The solvent dependence of ^nJ(H,F) has precedents (38); the generally larger ^nJ(H,H) values for the protons within the ring in the more polar solvent are a frequent result in this laboratory.

Results and discussion

Spectral analysis

The ^1H nmr and ^{19}F nmr spectra were analyzed with the computer program Numarit (12), as reworked in this laboratory by R. Sebastian. The spectral parameters are given in Table 1. Figure 1 shows a small part of the ring proton spectrum to illustrate the spectral quality.

$^3J(H,OCH_3) \equiv {}^5J$ and the conformational equilibrium

For anisole in CS_2 and acetone-d_6 solutions, ^5J is −0.152(0) and −0.155(0) Hz, respectively, at 300 K (9). ^5J is −0.288(1) Hz for a 5 mol% solution of 2-methoxyphenol in benzene-d_6 at 305 K (13). Again, ^5J is −0.28(1) Hz for a solution of 1,2-dimethoxybenzene in benzene-d_6 at 305 K (6). These data suggest that ^5J has a large magnitude only when the methyl group lies *cis* to the *ortho* C—H bond containing the coupled proton. Indeed, a detailed set of computations (6, 7) implies that ^5J is dominated by a through-space or proximate mechanism in which the sizeable coupling magnitudes occur when the bonds carrying the coupled nuclei are rather near each other. The computations yield ^5J as −0.292 Hz for a *cis* and 0.037 Hz for a *trans* orientation.

These considerations lead to the following application of the ^5J values in Table 1. Assume that ^5J_t, the coupling constant for the *trans* orientation, vanishes. Then ^5J_c, that for the *cis* arrangement, is −0.297(2) Hz for 3-fluoroanisole in the CS_2/C_6D_{12} solution and is −0.304(1) Hz in the acetone-d_6 solution. The fractional population of *cis* conformer follows as 0.54 in the latter and as 0.51 in the former solution.

Alternatively, a small nonzero ^5J_t can be accommodated as follows. In acetone-d_6 solution, ^5J is −0.155 Hz for anisole. Assume ^5J_t to be as large as 0.05 Hz. Then ^5J_c is −0.36 Hz. The two ^5J values for 3-fluoroanisole in acetone-d_6 solution therefore yield the fractional population of the *cis* conformer as 0.52 or 0.53. The same procedure, but with ^5J_t as −0.05 Hz, gives these populations as 0.54 or 0.57. In other words, the *cis* conformer is *slightly* preferred in both acetone-d_6 and CS_2 solutions at 305 K. For a 5 mol% solution in CCl_4, ^5J of 3,5-dichloroanisole is 0.158(7) Hz, implying a negligible intrinsic perturbation of ^5J by electronegative *meta* substituents (7).

The values of $^6J(H,OCH_3) \equiv {}^6J$ for 3-fluoroanisole are consistent with the very similar stabilities of the two conformers. For example, ^6J in the acetone-d_6 solution is 0.054(0) Hz whereas, in the same solvent, ^6J is 0.049(0) Hz for anisole (9). ^6J appears to be sizeable only when the *meta* C—H bond is arranged *cis* to the methoxy group (9), and is 0.095(14) Hz in 2,3,4-trichloroanisole.

The usual rule, that a polar solvent stabilizes that conformer with the higher dipole moment, does not appear to hold for 3-fluoroanisole. Indeed, ^5J indicates that, if anything, the *cis* conformer is more stable in acetone than in CS_2 solutions. Of course, the two dipolar centers are somewhat remote from one another in this molecule. By way of contrast, the long-range coupling constant, ^5J(OH,F), of 3-fluorophenol indicates that the more polar *trans* form is favored by more than 2 kJ/mol in free energy at 305 K for solutions in CCl_4, CS_2, C_6D_6, and $CDCl_3$ (14). The electronic spectra of 3-fluorophenol in a supersonic free jet also suggest (5) a somewhat greater stability of the *trans* conformer.

Molecular orbital results

Figure 2 displays the STO-3G MO potential energy curve for the rotation of the methoxy group in 3-fluoroanisole. The figure caption gives the computed energies at 15° intervals of the internal rotational angle, θ. The relative energies can be fit to a function consisting of six terms, also given in the caption; the solid line of the figure represents this function.

The rotational barrier is dominated by a twofold term, in $\sin^2\theta$, of 8.3 kJ/mol and by a fourfold term, in $\sin^2 2\theta$, of 2.5 kJ/mol. These terms are somewhat higher than for similar calculations on anisole (15), being 5.8 and 2.4 kJ/mol (see notes to Table 1 of ref. 15). It is noteworthy that the twofold term, no doubt a reflection of the decreased π electron conjugation at θ = 90°, has increased by 2.5 kJ/mol in 3-fluoroanisole, rather larger than the decrease of about 1 kJ/mol

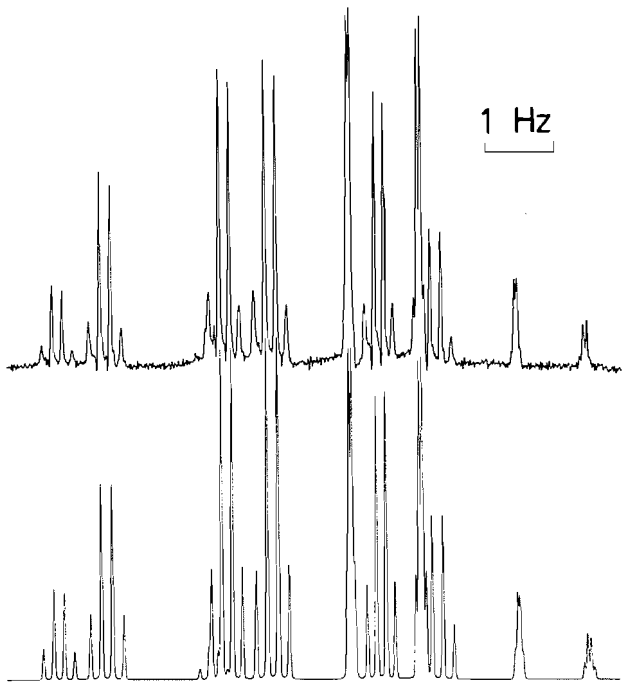

FIG. 1. The parts at high frequency of the ^{1}H nmr spectrum of H-2 and H-4 are shown for 3-fluoroanisole in acetone-d_6 solution at 300 MHz and 300 K (see Table 1 for spectral parameters). The quartets with the large splittings of 0.16 Hz arise from H-2 and those with the small splittings of 0.02 Hz originate with H-4 (in a first-order approximation). The computed spectrum has a linewidth at half height of 0.03 Hz.

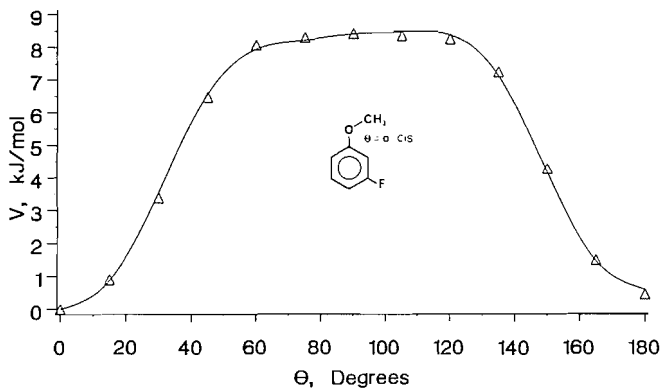

FIG. 2. The relative energies of 3-fluoroanisole at the STO-3G level of molecular orbital theory are plotted as a function of θ, the angle of the out-of-plane twist of the methoxy group. The total energy of the *cis* conformer, with θ = 0°, is −437.772194 au. Relative to this energy, the energies of the other conformers in kJ/mol (θ, degrees) are 0.92(15), 3.40(30), 6.49(45), 8.10(60), 8.35(75), 8.46(90), 8.40(105), 8.30(120), 7.27(135), 4.28(150), 1.52(165), and 0.46(180). These energies are given as triangles in the figure. The solid line is given by $V(\theta)/\text{kJ mol}^{-1} = 0.69 \sin^2(\theta/2) + 8.32 \sin^2\theta - 0.10 \sin^2(3\theta/2) + 2.50 \sin^2 2\theta - 0.17 \sin^2 3\theta - 0.28 \sin^2 4\theta$. Clearly, the internal rotational potential is dominated by the twofold term, 8.32 kJ/mol, and the fourfold term, 2.50 kJ/mol.

computed for 4-fluoroanisole (15). The torsional frequencies of the liquids have been interpreted to mean that the internal barrier in 3-fluoroanisole is 4 kJ/mol higher than in anisole (1). Rather dramatic increases in V_2 have been measured for *meta* derivatives of thiophenol and thioanisole (16, 17), in qualitative agreement with STO-3G MO computations. Qualitatively, therefore, the increased, computed rotational barrier in 3-fluoroanisole is very likely correct. Of course, the internal barrier in anisole is state dependent (18–20) and, although its value in the vapor, as well as in solution, is unknown, there is little doubt that it is substantially higher in solution than in the gas phase or than the value computed (20). By way of contrast, the onefold component computed for 3-fluoroanisole, that is, the energy difference of 0.46 kJ/mol between the two planar conformers, happens to agree with that obtainable from the $^5J(H,OCH_3)$ values in CS_2 and in acetone-d_6 solutions. At 300 K, the computed difference in energy indicates a fractional *cis* population of 0.55, very close to those deduced above from $^5J(H,OCH_3)$.

The dipole moments computed with the minimal basis set are 0.69 D for the *cis* conformer and 2.13 D for the *trans* conformer. The dipole moment of 3-fluoroanisole appears not to be available. Judging from the STO-3G MO dipole moments of anisole and fluorobenzene (21), the values above are somewhat too low. Split-valence basis sets yield dipole moments larger than measured (21). At the 6-31G level, the *cis* conformer was here computed to have a dipole moment of 1.54 D, and 4.13 D was calculated for the *trans* conformer. Comparison of the computations for the monosubstituted benzenes at the two levels of MO theory with experiment (21) suggests that a 1:1 mixture of the two conformers of 3-fluoroanisole will have a dipole moment of 2.3 ± 0.2 D. This number represents the mean of numbers at the STO-3G and 6-31G levels of computation. In this connection it might be noted that the dipole moment of 3-bromoanisole is 2.05 D in benzene solution at 298 K (22) and that the dipole moments of fluorobenzene and bromobenzene are nearly equal (23). $^5J(H,OCH_3)$ for 3-bromoanisole in acetone-d_6 solution at 300 K implies that the fractional population of the *cis* conformer is 0.49 ± 0.03 (8). The infrared intensity measurements in CCl_4 solution yield this number as 0.50(3).

In a recent study of 20 monosubstituted benzenes (24) it was concluded that minimal basis computations, in general, give a better account of π electron transfer and related experimental data than do split-valence calculations, such as 4-31G, for example. Indirect support for such a conclusion comes from a good correlation of σ and π electron densities, calculated from STO-3G wavefunctions, with the variations of the internal angles in such compounds (25–27). It does not follow, however (28–32), that the angles themselves will be reproduced satisfactorily by the minimal basis set. Thus, Figs. 3 and 4 display the STO-3G and 6-31G structures of the *cis* and *trans* conformers, respectively, of 3-fluoroanisole, and the following comparisons may well be of interest.

First, the computed geometry at the methoxy group may be compared with that found by averaging (33) over values for 212 crystal structures, that is, for planar anisole derivatives. The COC angle is 117.7(1.2)°, the number in parentheses being the standard deviation. Neither basis set reproduces this number, although the STO-3G value is somewhat more satisfactory, it being also computed as 115.2° in anisole itself (34). The large CCO angle has an average value of 124.5(9)°. The STO-3G values have an average of 125.9° whereas the 6-31G number is 123.8° in Figs. 3 and 4. The C_{sp^3}—O length in the crystal structures is 1.425(16) Å; both computations are satisfactory. The C_{sp^2}—O average is 1.371(15) Å, the 6-31G value falling very close to this.

The C—F bond length is computed more reliably by the minimal basis set, judging by the microwave substitution

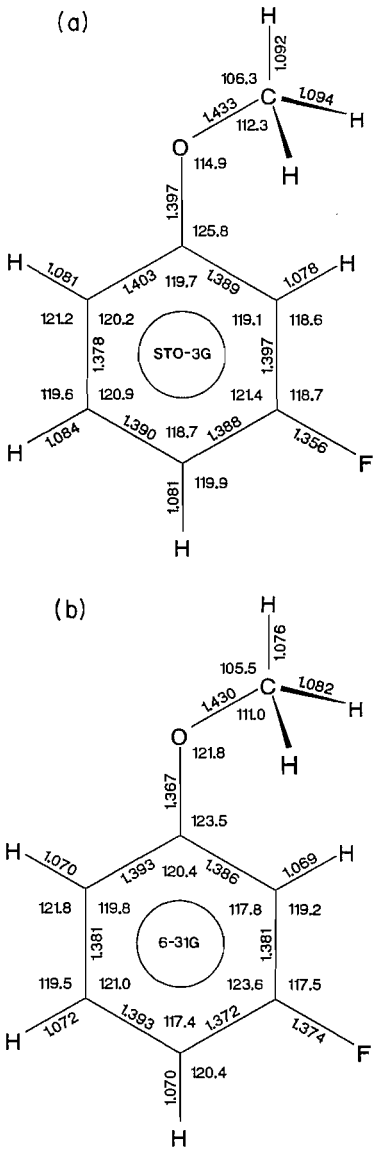

FIG. 3. The STO-3G and 6-31G MO structures of the *cis* conformer of 3-fluoroanisole are shown. During the optimization procedure the nuclei of the benzene moiety were constrained to lie in a plane. The total energies are −437.772194 and −443.275538 au, respectively, and the dipole moments are 0.69 and 1.54 D. The bond angles and lengths given in degrees and angstroms are discussed in the text.

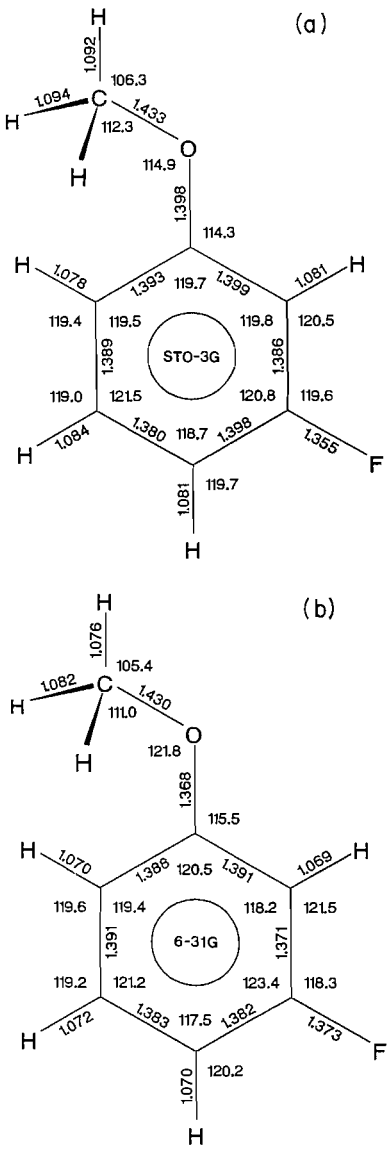

FIG. 4. The STO-3G and 6-31G MO structures of the *trans* conformer of 3-fluoroanisole are displayed. They are computed to be 0.46 and 0.85_5 kJ/mol less stable than the *cis* conformer structures, respectively, and the dipole moments are 2.13 and 4.13 D. These properties and the bond angles and lengths are discussed in the text and compared with the available experimental data.

structures of fluorobenzene and its 2- and 3-fluoro derivatives; these three have an average C—F length of 1.351 ± 0.005 Å (35). The so-called (28) "basis set offset" is therefore probably very near −0.02 Å at the 6-31G level for 3-fluoroanisole.

It is quite clear that internal bond angles in monosubstituted benzene derivatives are much better reproduced with the 6-31G than with the minimal basis (29–32). If those for fluorobenzene and phenol (anisole is not available) are superimposed, then the averages of the 6-31G angles for the two conformers of 3-fluoroanisole are reproduced with a mean deviation of 0.15°. The additivity of substituent effects on internal bond angles has been noted experimentally (26, 36), but there are some noticeable exceptions (37). In fact, the bond angle deformations assigned to fluorine and methoxy substituents (Tables 5 and 8 of ref. 26) reproduce the averaged internal angles of the two 6-31G structures to within a mean deviation of 0.3°, the largest deviation being 0.4°. The angular parameters come from polysubstituted benzenes as derived from an additivity scheme. The effect of thermal motion on these parameters is apparently less than 0.1°. A number of other comparisons of the structural parameters in Figs. 3 and 4 could be made. The present remarks are sufficient, however, to demonstrate that, even within the same molecule, a correct choice of basis set for the prediction of a particular parameter depends on experience (of course, given unlimited computing time, such experience would be unnecessary).

The 6-31G basis has the *cis* as 0.85_5 kJ/mol more stable than the *trans* conformer, corresponding to a 58% abundance of the former at 300 K.

Received August 30, 1988

THOMAS G. BACK, KURT BRUNNER, M. VIJAYA KRISHNA, and ENOCH K. Y. LAI. Can. J. Chem. **67**, 1032 (1989).

(22*S*,23*E*)-6β-Methoxy-3α,5-cyclo-5α-ergost-23-en-22-ol (**2**), an intermediate in the synthesis of brassinolide (**1**) and related compounds, was synthesized by a new approach. (20*S*)-6β-Methoxy-3α,5-cyclo-5α-pregnane-20-carboxaldehyde (**5**) was converted to the corresponding 22*S* and 22*R*-24-yn-22-ol derivatives **6***a* and **6***b* by treatment with 3-lithio-1-trimethylsilylpropyne, followed by tetra-*n*-butylammonium fluoride. The products were subjected to selenosulfonation, base-catalyzed isomerization, and selenoxide elimination to afford the respective 22*S* and 22*R* allenic sulfones **9***a* and **9***b*. The 22*S* isomer **9***a* underwent addition with lithium diisopropylcuprate – dimethyl sulfide complex, followed by reductive desulfonylation with magnesium in methanol, to afford **2**, as well as smaller amounts of its 24(28) isomer **11***a* and (22*E*)-6β-methoxy-3α,5-cyclo-5α-ergosta-22,24(28)-diene (**12**). Similar treatment of **9***b* afforded **13**, the 22*R* isomer of **2**, as the principal product, as well as its 24(28) isomer **11***b*, and diene **12**.

Key words: brassinolide, (22*S*,23*E*)-6β-methoxy-3α,5-cyclo-5α-ergost-23-en-22-ol, selenosulfonation, allenic sulfones.

THOMAS G. BACK, KURT BRUNNER, M. VIJAYA KRISHNA et ENOCH K. Y. LAI. Can. J. Chem. **67**, 1032 (1989).

Utilisant une nouvelle approche, on a réalisé la synthèse du méthoxy-6β cyclo-3α,5 5α-ergostène-23 ol-22 (22*S*,23*E*) (**2**), un intermédiaire dans la synthèse du brassinolide (**1**). En faisant réagir le méthoxy-6β cyclo-3α,5 5α-pregnanecarboxaldéhyde-20 (**5**) avec le lithio-3 triméthylsilyl-1 propyne, puis avec le fluorure de tétra-*n*-butylammonium, on obtient les dérivés correspondants yne-24 ol-22 (22*S* et 22*R*) (**6***a* et **6***b*). Ces produits, soumis successivement à une réaction de sélénosulfonation, à une isomérisation catalysée par les bases et à une élimination de sélénoxyde, fournissent respectivement les sulfones alléniques 22*S* et 22*R* (**9***a* et **9***b*). Lorsqu'on soumet l'isomère 22*S* (**9***a*) à une addition du complexe de diisopropylcuprate de lithium/sulfure de diméthyle puis à une désulfonylation réductrice par le magnésium et le méthanol, on obtient le composé **2** ainsi que de faibles quantités de l'isomère 24(28) (**11***a*) et du méthoxy-6β cyclo-3,5α 5α-ergostadiène-22,24(28) (**12**). Soumis aux mêmes réactions, le produit principal obtenu à partir du composé **9***b* est le composé **13**, l'isomère 22*R* du produit **2**, ainsi que son isomère 24(28) (**11***b*) et le diène **12**.

Mots clés : brassinolide, méthoxy-6β cyclo-3α,5 5α-ergostène-23 ol-22 (22*S*,23*E*), sélénosulfonation, sulfones alléniques.

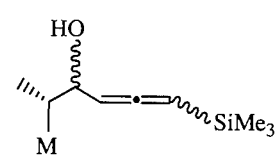
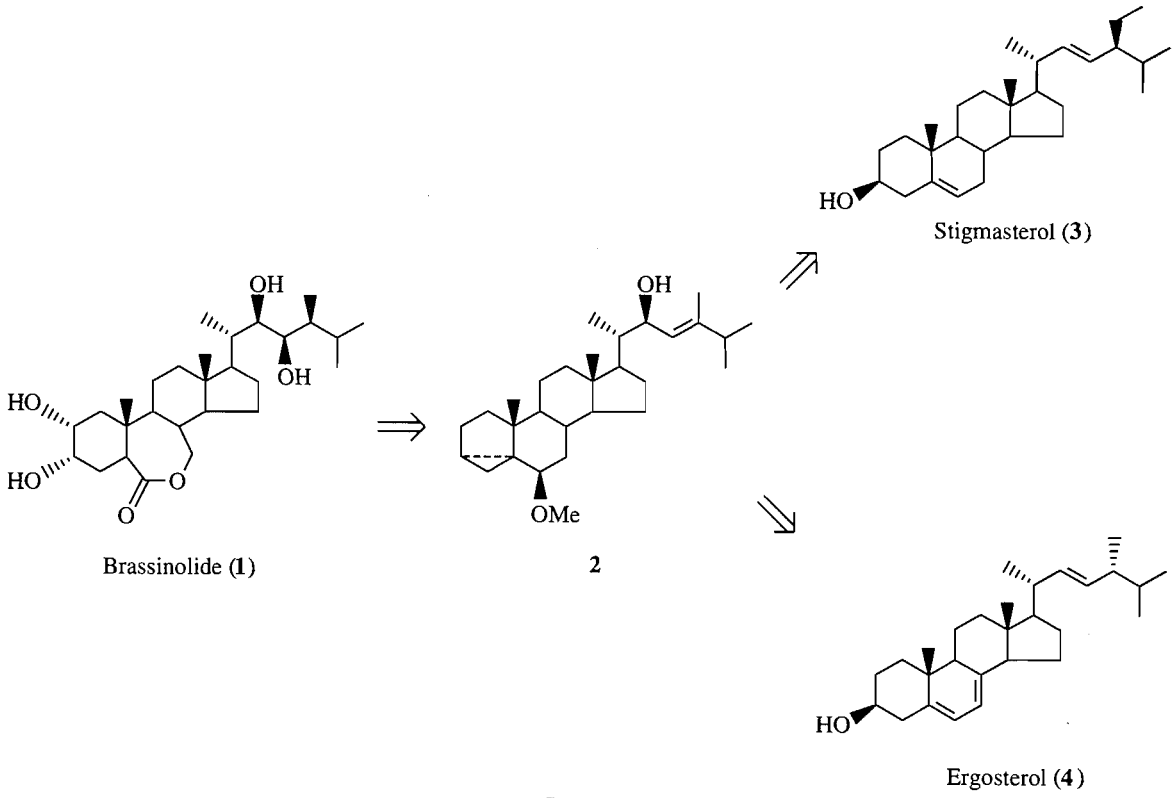
Introduction

Brassinolide (**1**) is a potent plant-growth promoter that was first isolated in minute quantities from the pollen of *Brassica napus* L. (1). Its biological activity and unusual structure have made it a challenging synthetic target (for reviews, see ref. 2; for previous syntheses, ref. 3). The allylic alcohol (22*S*,23*E*)-6β-methoxy-3α,5-cyclo-5α-ergost-23-en-22-ol (**2**) was employed as a key intermediate in the first synthesis of brassinolide by Fung and Siddall (3*a*), who prepared it from stigmasterol (**3**). Moreover, **2** is a potential precursor of other structurally related steroids such as dolicholide (3*f*, 4), typhasterol (3*c*, 5), and castasterone (3*c*, 3*f*), some of which also display plant growth-promoting activity (3*g*, 6). An alternative synthesis of **2** from ergosterol (**4**) was later described by Fiecchi and co-workers (7) (Scheme 1).

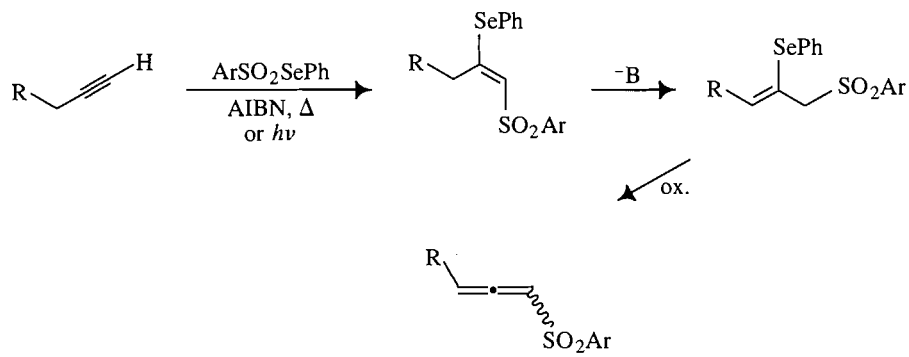


We recently demonstrated that acetylenes can be converted to allenic sulfones by a simple protocol involving selenosulfonation, base-catalyzed isomerization, and selenoxide elimination (8) (Scheme 2). A related selenosulfonation-based method was previously employed for the synthesis of the marine sterols 24,28-dehydroaplysterol, xestosterol, and ostreasterol (9). We now report a new synthesis of the allylic alcohol **2**, using the novel addition of an organocuprate to an allenic sulfone obtained via the method shown in Scheme 2 as the key step in the elaboration of the steroid side chain.



[1]Author to whom correspondence may be addressed.

Results and discussion

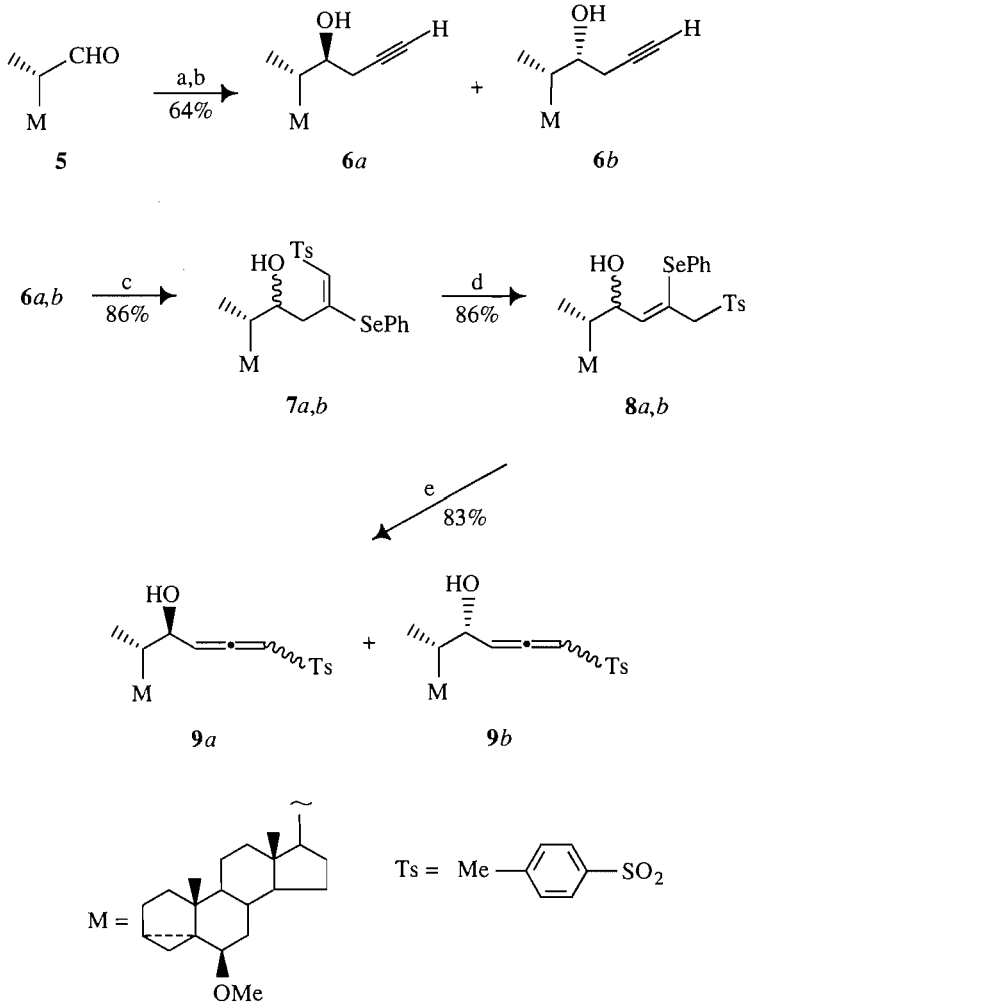


The synthesis of the required allenic sulfone precursor of the allylic alcohol **2** is summarized in Scheme 3. The aldehyde **5**, readily available from stigmasterol by a literature method (10), was treated with 3-lithio-1-trimethylsilylpropyne (11) to afford a 1.32:1 mixture of the epimeric C-22 alcohols **6***a* and **6***b*, obtained in 64% yield[2] after desilylation with tetra-*n*-butylammonium fluoride. The mixture of **6***a*,*b* was subjected to free-radical selenosulfonation with Se-phenyl *p*-tolueneselenosulfonate to afford, as expected (12), exclusively the products of *anti* addition **7***a*,*b*, respectively. The two C-22 epimers could be separated chromatographically at this stage, and elaborated further independently. However, it proved more convenient to postpone the separation until a later point in the synthesis (*vide infra*). Base-catalyzed isomerization of **7***a*,*b* produced the allylic sulfones **8***a*,*b*, tentatively depicted with the

[2]The ratio is based on the isolated yields of the corresponding C-22 epimers **7***a* and **7***b* obtained after selenosulfonation. The addition of 3-lithio-1-trimethylsilylpropyne to **5** also produced 22–24% of the corresponding allene stereoisomers:

SCHEME 1

SCHEME 2



Z configuration. Oxidation of **8***a*,*b*, followed by selenoxide *syn*-elimination, was induced with *tert*-butyl hydroperoxide (13),[3] cleanly providing the allenic sulfones **9***a*,*b*, and no significant quantities of their corresponding acetylenic sulfone regioisomers. The regioselectivity of the selenoxide elimination can be attributed to either the activating effect of the sulfone group, or the *Z* configuration of **8***a*,*b*, which would preclude acetylene formation because of the unavailability of a *cis* vinylic hydrogen required for the *syn*-elimination. Furthermore, since the allene moiety is chiral, each C-22 epimer of **9***a*,*b* was formed as a mixture of two diastereomers. The epimers **9***a* and **9***b* could be easily separated by flash chromatography at this point, but attempted separation of the two allene diastereomers of each epimer was unsuccessful, and fortunately unnecessary.

[3]For the previous use of this oxidant in selenoxide eliminations, see ref. 13*a*; for the formation of other allenes via selenoxide elimination, see ref. 13*b*.

The further transformations of the latter products are shown in Scheme 4. The mixtures of allene stereoisomers of the C-22 epimers **9***a* and **9***b* were individually treated with lithium diisopropyl cuprate – dimethyl sulfide complex (i-$Pr_2CuLi \cdot SMe_2$) to afford the allylic sulfones **10***a* and **10***b*, in yields of 52% and 56%, respectively. Whereas organocuprate additions to vinyl sulfones are known (14), this represents, to our knowledge, the first example of such an addition to an allenic sulfone. The olefin geometry was established in each case by ^{1}H nmr nOe difference spectroscopy. Evidently, addition of the cuprate occurs with high selectivity to the sulfone-substituted π-bond from the less hindered side (Scheme 5), resulting in products with the 23*Z* configuration. The unmasked C-22 hydroxyl group does not appear to play a role in determining the direction of addition by complexing with the cuprate reagent, as evidenced by the formation of only the (*Z*) isomer from either of the C-22 alcohol epimers.

To complete the synthesis of the desired allylic alcohol **2**,

SCHEME 5

allylic sulfone **10***a* was subjected to reductive desulfonylation. Although a number of methods are reported to be effective for the desulfonylation of various types of unsaturated sulfones (15), the best results in the present case were obtained with magnesium in methanol (16). Sulfone **10***a* thus afforded **2** as the principal product, along with its isomer **11***a* and diene **12**, the product of reductive elimination. Similarly, the C-22 epimer **10***b* furnished allylic alcohol **13**, its isomer **11***b*, and diene **12**. Products **2**, **12**, and **13** had physical and spectral properties consistent with those reported in the literature (3*a*, 7). The structures of **2** and **13** were further confirmed by ^{1}H nmr nOe difference spectroscopy. Since **2** has been previously converted to brassinolide (**1**) (3*a*), these results constitute a formal synthesis of the latter sterol.

Experimental

Melting points were determined on an A. H. Thomas hot-stage apparatus and are uncorrected. The ir spectra were recorded on a Nicolet 5DX spectrometer as thin films. The ^{1}H and ^{13}C nmr spectra were recorded on a Bruker ACE 200 or a Bruker AM 400 spectrometer, operating at 200 and 400 MHz, respectively, in deuteriochloroform solvent with either chloroform or tetramethylsilane as the internal standard. Mass spectra were recorded on a Kratos MS80 or a VG 7070 spectrometer. Optical rotations were measured on a Rudolph Autopol III polarimeter in chloroform solution. Elemental analyses were obtained by Dr. W. S. Lin, using the analytical facilities of the Department of Chemical Engineering, courtesy of Mr. L. Dornan. Preparative tlc was carried out on Analtech 20 × 20 cm glass plates coated with 1 mm of silica gel GF. Flash chromatography was performed on Merck silica gel, 60–200 mesh. A Rayonet RMR-500 reactor equipped with four 254-nm lamps was employed for selenosulfonations.

THF was distilled from $LiAlH_4$ prior to use, and air- or moisture-sensitive materials were handled under argon. Aldehyde **5** was obtained by a literature method (10), as was Se-phenyl *p*-tolueneselenosulfonate (17). All other reagents were purchased from commercial sources and purified by standard methods as required.

*6β-Methoxy-3α,5-cyclo-5α-26,27-dinorcholest-24-yn-22-ol (**6**a,b)*

n-Butyllithium in hexane (9.00 mmol) was added to a solution of 1-trimethylsilylpropyne (1.33 mL, 9.00 mmol) in 20 mL of THF at 0°C. After 10 min, the solution was cooled to −78°C and aldehyde **5** (2.00 g, 5.81 mmol) in 30 mL of THF was added dropwise. The mixture was stirred at −78°C for 3 h, quenched with aqueous NH_4Cl solution, and warmed to room temperature. The product was diluted with ether, washed with aqueous NaCl solution, dried (anhydrous $MgSO_4$), and evaporated *in vacuo*. Flash chromatography (elution with 5% ethyl acetate – hexane) afforded 1.70 g (64%) of a mixture of C-22 epimers of the silylacetylene as a viscous oil; ir: 3434, 2175, 1249, 1099, 842, 759 cm^{-1}; ^{1}H nmr (400 MHz) δ: 3.85 (m, 1H), 3.32 (s, 3H), 2.76 (m, 1H), 1.02 (s, 3H), 0.91 (two overlapping d each with J = 6.7 Hz, total 3H), 0.74 and 0.73 (two s, total 3H), 0.15 (s, 9H); mass spectrum, *m/e* (relative intensity, %): 456 (M^+, 4), 441 (M^+ − Me, 4), 424 (16), 43 (100).

The preceding product (1.485 g, 3.25 mmol) and tetra-*n*-butylammonium fluoride (6.5 mL of a 1 M THF solution, 6.5 mmol) were stirred in 40 mL of THF at 0°C for 25 min. The solution was then diluted with ether, washed with aqueous NaCl solution, dried (anhydrous $MgSO_4$), and evaporated *in vacuo* to afford 1.25 g (100%) of the title compound **6***a,b* (mixture of C-22 epimers) as a viscous oil of sufficient purity for further use; ir: 3419, 3310, 2119, 1098, 733 cm^{-1}; ^{1}H nmr (200 MHz) δ: 3.90 (m, 1H), 3.33 and 3.32 (two s, total 3H), 2.77 (m, 1H), 1.02 (s, 3H), 0.93 and 0.92 (two overlapping d each with J = 6.8 Hz, total 3H), 0.74 and 0.73 (two s, total 3H); mass spectrum, *m/e* (relative intensity, %): 384 (M^+, 12), 369 (27), 352 (27), 329 (55), 41 (100).

*(24E)-6β-Methoxy-24-(phenylseleno)-25-(*p*-toluenesulfonyl)-3α,5-cyclo-5α-26,27-dinorcholest-24-en-22-ol (**7**a,b)*

The mixture of **6***a,b* (113 mg, 0.29 mmol) produced in the preceding experiment and Se-phenyl *p*-tolueneselenosulfonate (110 mg, 0.35 mmol) were dissolved in 2 mL of benzene and irradiated with uv light for 4.5 h. The products were purified by flash chromatography (elution with 15% ethyl acetate – hexane) to afford 175 mg (86%) of the unseparated epimers **7***a,b*. When the reaction was performed similarly with 6.09 mmol of **6***a,b*, the products **7***a,b* were obtained in 82% yield. A portion of this mixture was separated by preparative tlc (25% ethyl acetate – hexane) to provide **7***a* and **7***b* in the ratio of 1.32:1. Compound **7***a* (22*S*) was a pale yellow oil, R_f 0.52; ir: 3507, 1596, 1588, 1316, 1302, 1289, 1144, 1085, 733 cm^{-1}; ^{1}H nmr (200 MHz) δ: 7.68 (d, J = 8.3 Hz, 2H), 7.57–7.27 (complex, 7H), 6.00 (s, 1H), 3.99 (m, 1H), 3.46 (dd, J = 14.0, 10.0 Hz, 1H), 3.33 (s, 3H), 2.78 (m, 1H), 2.42 (s superimposed on dd at δ 2.48, J = 14.0, 2.7 Hz, total 4H), 1.03 (s, 3H), 0.99 (d, J = 6.3 Hz, 3H), 0.73 (s, 3H). *Anal.* calcd. for $C_{39}H_{52}O_4SSe$: C 67.30, H 7.55; found: C 67.31, H 7.39. Compound **7***b* (22*R*) was a pale yellow oil, R_f 0.44; ir: 3512, 1596, 1575, 1314, 1303, 1289, 1143, 1084, 733 cm^{-1}; ^{1}H nmr (200 MHz) δ: 7.68 (d, J = 8.4 Hz, 2H), 7.56–7.27 (complex, 7H), 6.01 (s, 1H), 4.02 (m, 1H), 3.44 (dd, J = 14.1, 10.9 Hz, 1H), 3.32 (s, 3H), 3.10 (d, J = 8.0 Hz, 1H, exchanged in D_2O), 2.77 (m, 1H), 2.42 (s superimposed on dd at δ 2.36, J = 14.2, 1.95 Hz, total 4H), 1.03 (s, 3H), 1.01 (d, J = 6.4 Hz, 3H), 0.76 (s, 3H). *Anal.* calcd. for $C_{39}H_{52}O_4SSe$: C 67.30, H 7.55; found: C 66.57, H 7.60.

*6β-Methoxy-24-(phenylseleno)-25-(*p*-toluenesulfonyl)-3α,5-cyclo-5α-26,27-dinorcholest-23-en-22-ol (**8**a,b)*

The mixture of **7***a,b* (2.39 g, 3.43 mmol) was refluxed for 35 h in a mixture of 30 mL of triethylamine and 50 mL of toluene. Evaporation of volatile material, followed by flash chromatography (elution with 50% ethyl acetate – hexane), produced 2.06 g (86%) of the mixture of epimers **8***a,b*. The reaction was repeated separately with pure **7***a* and **7***b* to afford pure **8***a* and **8***b*, respectively. Compound **8***a* (22*S*) was a solid foam; ir: 3476, 1598, 1579, 1318, 1303, 1137, 1086 cm^{-1}; ^{1}H nmr (200 MHz) δ: 7.68 (d, J = 8.3 Hz, 2H), 7.35–7.24 (complex, 7H), 6.25 (d, J = 7.3 Hz, 1H), 4.65 (crude d, J = 7.6 Hz, 1H), 3.86 (AB quartet, J = 14.5 Hz, 2H), 3.33 (s, 3H), 2.78 (m, 1H), 2.47 (s, 3H), 1.04 (s, 3H), 0.895 (d, J = 6.3 Hz, 3H), 0.73 (s, 3H). *Anal.* calcd. for $C_{39}H_{52}O_4SSe$: C 67.30, H 7.55; found: C 67.29, H 7.81. Compound **8***b* (22*R*) was a solid foam; ir: 3502, 1597, 1578, 1319, 1303, 1137, 1086 cm^{-1}; ^{1}H nmr (200 MHz) δ: 7.71 (d, J = 8.3 Hz, 2H), 7.36–7.26 (complex, 7H), 6.20 (d, J = 8.8 Hz, 1H), 4.59 (dd, J = 8.8, 3.5 Hz, 1H), 3.91 (AB quartet, J = 14.5 Hz, 2H), 3.34 (s, 3H), 2.80 (m, 1H), 2.48 (s, 3H), 1.035 (s, 3H), 1.02 (d, J = 6.4 Hz, 3H), 0.76 (s, 3H). *Anal.* calcd. for $C_{39}H_{52}O_4SSe$: C 67.30, H 7.55; found: C 67.17, H 7.69.

*6β-Methoxy-25-(*p*-toluenesulfonyl)-3α,5-cyclo-5α-26,27-dinorcholesta-23,24-dien-22-ol (**9**a,b)*

The mixture of **8***a,b* (2.06 g, 2.96 mmol) and *tert*-butyl hydroperoxide (25 mL of ca. 90% solution in *tert*-butanol) was stirred for 8 h in 50 mL of chloroform. The solution was then evaporated and the residue was separated by flash chromatography (elution with 10% ethyl acetate – hexane) to afford 0.76 g (47.4%) of the less polar 22*S* epimer **9***a* (mixture of allene diastereomers), followed by 0.57 g (35.4%) of the more polar 22*R* epimer **9***b* (mixture of allene diastereomers).

Compound **9***a* was a pale yellow oil;[4] ir: 3504, 1956, 1597, 1320, 1303, 1146, 1085, 733 cm^{-1}; ^1H nmr (200 MHz) δ: 7.80 (d, J = 8.3 Hz, 2H), 7.34 (d, J = 8.4 Hz, 2H), 6.34 (m, 1H), 5.89 (m, 1H), 4.47 (m, 1H), 3.33 (s, 3H), 2.78 (m, 1H), 2.44 (s, 3H), 1.03 (s, 3H), 0.72 (s, 3H). Compound **9***b* was a pale yellow oil;[4] ir: 3508, 1958, 1598, 1324, 1304, 1146, 1086, 755 cm^{-1}; ^1H nmr (200 MHz) δ: 7.80 (d, J = 8.3 Hz, 2H), 7.34 (d, J = 8.3 Hz, 2H), 6.28 (m, 1H), 5.88 (m, 1H), 4.41 (m, 1H), 3.33 and 3.32 (two s, total 3H), 2.44 (s, 3H), 1.02 (s, 3H), 0.75 and 0.74 (two s, total 3H).

*(22S,23Z)-6β-Methoxy-28-(p-toluenesulfonyl)-3α,5-cyclo-5α-ergost-23-en-22-ol (**10**a)*

Isopropyllithium (2.06 mmol) in petroleum ether (bp 30–60°C) was added to a stirred suspension of cuprous bromide – dimethyl sulfide complex (212 mg, 1.03 mmol) in 10 mL of THF at −78°C. After 45 min, the allenic sulfone **9***a* (111 mg, 0.206 mmol) in 1 mL of THF was added and stirring at −78°C was continued for 14 h. The reaction was then quenched with aqueous NH_4Cl solution, dried (anhydrous $MgSO_4$), filtered through Celite, and evaporated *in vacuo*. The residue was separated by preparative tlc in 28% ethyl acetate – hexane to afford 62 mg (52%) of **10***a* as a pale yellow oil,[4] R_f 0.52; ir: 3508, 1597, 1316, 1303, 1143, 1086, 733 cm^{-1}; ^1H nmr (200 MHz) δ: 7.78 (d, J = 8.3 Hz, 2H), 7.36 (d, J = 8.0 Hz, 2H), 5.72 (d, J = 7.0 Hz), 4.27 (crude d, J = 6.3 Hz, 1H), 4.02 (AB quartet, J = 13.5 Hz, 2H), 3.33 (s, 3H), 2.78 (m, 1H), 2.46 (s, 3H), 2.24 (m, 1H), 1.02 (s, 3H), 1.02 (d, J = 7 Hz, collapsed to s with double irradiation at δ 2.24, 3H), 0.98 (d, J = 7 Hz, collapsed to s with double irradiation at δ 2.24, 3H), 0.95 (d, J = 6.3 Hz, 3H), 0.71 (s, 3H). Irradiation of the vinylic proton at δ 5.72 produced nOe enhancement of the signals at δ 1.02 and 0.98 assigned to the *i*-propyl group, but not of the AB quartet at δ 4.02 assigned to the C-28 methylene protons.

*(22R,23Z)-6β-Methoxy-28-(p-toluenesulfonyl)-3α,5-cyclo-5α-ergost-23-en-22-ol (**10**b)*

The 22*R* epimer **10***b* was prepared in 56% yield from **9***b* according to the preceding procedure. The product was purified by preparative tlc in 28% ethyl acetate – hexane, to afford a pale yellow oil,[4] R_f 0.39; ir: 3511, 1597, 1316, 1303, 1145, 1086, 733 cm^{-1}; ^1H nmr (400 MHz) δ: 7.80 (d, J = 8.3 Hz, 2H), 7.37 (d, J = 8.0 Hz, 2H), 5.81 (d, J = 9.2 Hz, 1H), 4.28 (m, 1H), 3.99 (AB quartet, J = 13.5 Hz, 2H), 3.32 (s, 3H), 2.75 (m, 1H), 2.46 (s, 3H), 2.09 (m, 1H), 1.04 (d, J = 6.7 Hz, 3H), 1.01 (s superimposed on d, J = 6.7 Hz, total 6H), 0.95 (d, J = 6.8 Hz, 3H), 0.74 (s, 3H). Irradiation of the vinylic proton at δ 5.81 produced nOe enhancement of the signals at δ 1.04 and 1.01 assigned to the *i*-propyl group, but not of the AB quartet at δ 3.99 assigned to the C-28 methylene protons.

*(22S,23E)-6β-Methoxy-3α,5-cyclo-5α-ergost-23-en-22-ol (**2**)*

Magnesium turnings (265 mg, 11 mg-atom) were warmed to 45–50°C in 6 mL of methanol. When hydrogen evolution commenced, the allylic sulfone **10***a* (100 mg, 0.172 mmol) was added in 1 mL of THF. The mixture was stirred at room temperature for 2.5 h. The mixture was concentrated; 5 mL of 20% aqueous NH_4Cl was added, and the product was extracted three times with ether, dried (anhydrous $MgSO_4$), and evaporated *in vacuo*. Flash chromatography (elution with 5% ethyl acetate – hexane) afforded, in order of elution, 15 mg (21%) of diene **12**, 20 mg (27%) of the 24(28) isomer **11***a*, and 33 mg (45%) of the title compound. Diene **12** had mp 72–76°C (from methanol) (lit. (7) mp 79–81°C), and spectra in close agreement with the literature (7). Compound **11***a* was a pale yellow oil; ir: 3459, 1638, 1099, 892, 734 cm^{-1}; ^1H nmr (200 MHz) δ: 4.89 (crude s, 1H), 4.79 (crude s, 1H), 3.81 (m, 1H), 3.33 (s, 3H), 2.77 (m, 1H), 2.20 (m, 1H), 1.06 (d, J = 6.8 Hz, 3H), 1.03 (d, J = 6.8 Hz, 3H), 1.02 (s, 3H), 0.94 (d, J = 6.3 Hz, 3H), 0.73 (s, 3H); mass spectrum *m/e* (relative intensity, %): 428 (M^+, 1.4), 343 (35), 312 (85), 83 (100). Product **2** had R_f 0.65 (silica gel, 30% ethyl acetate – hexane),[5] mp 128–130°C (from moist methanol) (lit. (3*a*) mp 127–129°C); $[\alpha]_D$ +34° (lit. (7) $[\alpha]_D$ +37°); and an ^1H nmr spectrum in close agreement with the literature (3*a*, 7). In addition, the 23*E* configuration was confirmed by nOe experiments, where irradiation of the vinylic methyl signal resulted in enhancement of the signal assigned to the C-22 proton. ^{13}C nmr δ: 142.9 (s), 125.1 (d), 82.6 (d), 70.7 (d).

*(22R,23E)-6β-Methoxy-3α,5-cyclo-5α-ergost-23-en-22-ol (**13**)*

Allyl sulfone **10***b* (146 mg, 0.25 mmol) was reduced and the products were separated by flash chromatography (elution with 10% ethyl acetate – hexane) as described in the preceding procedure. The products obtained were, in order of elution, 22 mg (21%) of diene **12**, 21 mg (20%) of the 24(28) isomer **11***b*, and 57 mg (53%) of **13**. Diene **12** was identical to the sample obtained in the previous procedure in all respects. Compound **11***b* was a pale yellow oil; ir: 3464, 1639, 1099, 757 cm^{-1}; ^1H nmr (200 MHz) δ: 4.93 (s, 1H), 4.83 (s, 1H), 3.75 (m, 1H), 3.33 (s, 3H), 2.77 (m, 1H), 2.20 (m, 1H), 1.08 (d, J = 6.0 Hz, 3H), 1.05 (d, J = 7.2 Hz, 3H), 1.03 (s, 3H), 0.95 (d, J = 6.7 Hz, 3H), 0.76 (s, 3H); mass spectrum, *m/e* (relative intensity, %): 428 (M^+, 2.0), 343 (30), 312 (78), 83 (100). Product **13** had R_f 0.50 (silica gel, 30% ethyl acetate – hexane);[5] ir: 3460, 1665, 1099, 1016, 734 cm^{-1}; ^1H nmr (200 MHz) δ: 5.29 (crude d, J = ca. 9.5 Hz, 1H), 4.42 (dd, J = 9.7, 3.6 Hz, 1H), 3.32 (s, 3H), 2.76 (m, 1H), 2.27 (m, 1H), 1.69 (d, J = 1.3 Hz, 3H), 1.04–0.99 (complex, overlapping resonances from *i*-Pr, C-21 and C-19 methyl groups, total 12H), 0.73 (s, 3H). Irradiation of the vinylic methyl signal at δ 1.69 resulted in nOe enhancement of the signal assigned to the C-22 proton at δ 4.42; ^{13}C nmr δ: 146.5 (s), 120.5 (d), 82.4 (d), 69.6 (d).

[4]The viscous, oily nature of compounds **9** and **10** precluded satisfactory analyses, presumably due to the retention of traces of solvent. High resolution mass spectra for these compounds could not be obtained because of their failure to display molecular ions.

[5]Fung and Siddall (3*a*) reported that the 22*R* epimer **13** is less polar than the 22*S* epimer **2**, whereas Fiecchi and co-workers (7) noted the reverse. Our observations are in accord with the latter authors.

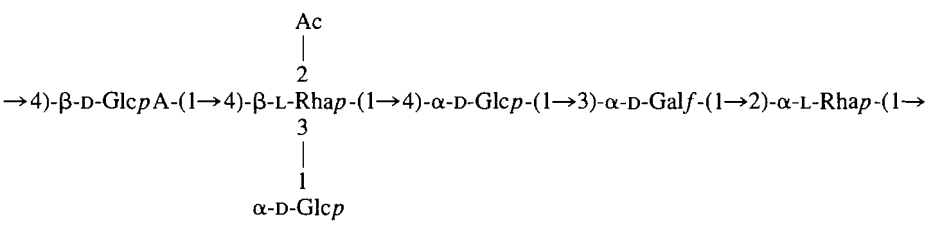
Received December 5, 1988

JAMES C. RICHARDS, MALCOLM B. PERRY, and PETER J. KNISKERN. Can. J. Chem. **67**, 1038 (1989).

The structure of the specific capsular polysaccharide produced by *Streptococcus pneumoniae* type 22F (American type 22) was investigated by high-field ^1H and ^{13}C nuclear magnetic resonance spectroscopy, composition, methylation analysis, and periodate oxidation studies. The polysaccharide was found to be a high molecular weight acidic polymer composed of D-glucose, D-galactose, D-glucuronic acid, and L-rhamnose residues to form a regular repeating hexasaccharide unit having the structure



in which the β-L-rhamnopyranosyl residues were substituted by *O*-acetyl groups in 80% of the repeating units. The ^1H and ^{13}C nmr resonances of the *O*-deacetylated type 22F polysaccharide were completely assigned by application of two-dimensional homo- and heteronuclear chemical shift correlation techniques.

Key words: *Streptococcus pneumoniae* polysaccharide, NMR analysis.

JAMES C. RICHARDS, MALCOLM B. PERRY et PETER J. KNISKERN. Can. J. Chem. **67**, 1038 (1989).

Faisant appel à des études par résonance magnétique nucléaire du ^1H et du ^{13}C, d'analyses de composition et de méthylation ainsi que par des oxydations periodiques, on a étudié la structure du polysaccharide capsulaire spécifique produit par le *Streptococcus pneumoniae* de type 22 (américain de type 22). On a trouvé que le polysaccharide est un polymère acide de poids moléculaire élevé, composé de résidus de D-glucose, de D-galactose, d'acide D-glucuronique et de L-rhamnose formant une unité hexasaccharide régulière de structure

dans laquelle les résidus β-L-rhamnopyrannosyles ont été substitués par des groupements acétyles dans 80% des unités qui se répètent. En se basant sur des techniques de corrélations des déplacements chimiques homo- et hétéro-nucléaires bi-dimensionnels, on a pu attribuer toutes les raies observées dans les spectres rmn du ^1H et du ^{13}C du polysaccharide de type 22F *O*-désacétylé.

Mots clés : Polysaccharide de *Streptococcus pneumoniae*, analyse RMN.

[Traduit par la revue]

Introduction

The cell surface capsular polysaccharides of *Streptococcus pneumoniae* are the type specific immunological determinants of these microorganisms and have received considerable attention because of their successful use as vaccines for the prevention of pneumococcal pneumonia (1, 2). Eighty-four serologically defined types of *S. pneumoniae* are recognized, of which the pneumococcal vaccine currently in use in North America contains the capsular polysaccharides of 23 serotypes (3, 4). Within the group 22 *S. pneumoniae*, two serotypes, 22F and 22A, are recognized from the use of factor serum (3). Type 22F accounts for 99% of pneumococcal infections caused by the group 22 organisms and the capsular polysaccharide of *S. pneumoniae* type 22F is included as a component of the current 23-valent human pneumococcal vaccine (4).

The structural analysis of the 22F pneumococcal polysaccharide was undertaken to provide information on the relationship of its molecular structure to its immunobiological activities and cross-serological properties, and to establish physical and chemical criteria for the determination of its purity in commercial biologicals.

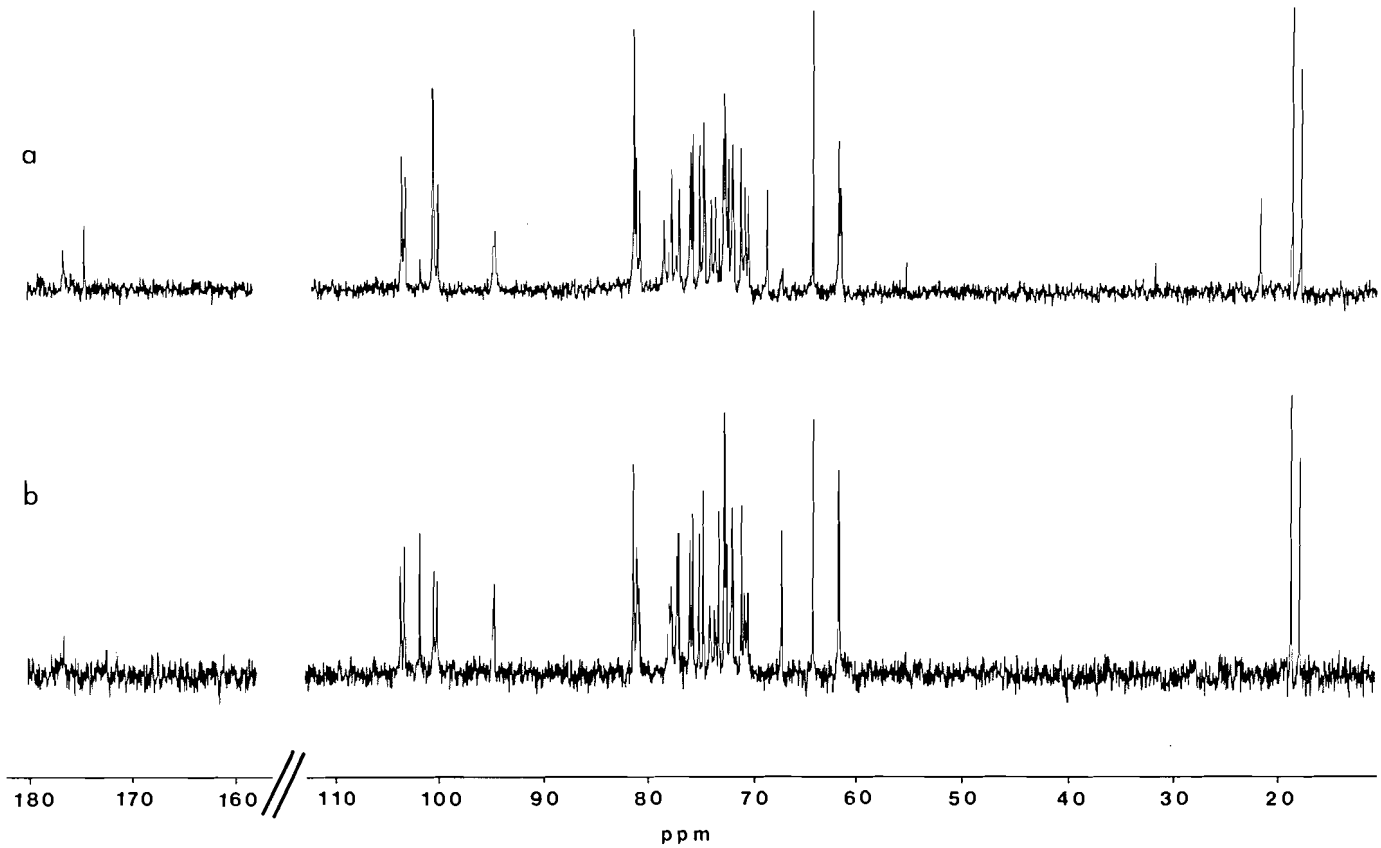

FIG. 1. Proton decoupled ^{13}C nmr spectra of the type 22F pneumococcal polysaccharide recorded at 310 K. (a) Native polysaccharide. (b) *O*-Deacetylated polysaccharide.

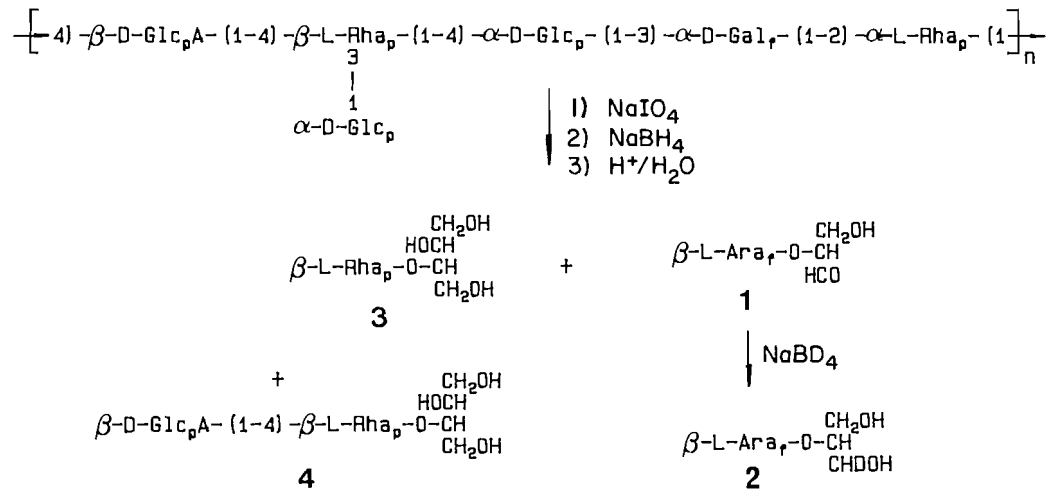
Previous structural analyses of the 22F polysaccharide made by Chatterjee *et al.* (5, 6) led to a proposed structure of a repeating unit composed of 21 glycose units containing D-galactopyranosyl, D-glucopyranosyl, L-arabinofuranosyl, L-rhamnopyranosyl, and D-glucopyranosyluronic acid residues as well as a phosphodiester unit. Our present studies have led to the unambiguous conclusion that the 22F polysaccharide is composed of a repeating hexasaccharide unit that is unrelated to the previously reported structure.

Results and discussion

The type 22F specific capsular polysaccharide was obtained from the spent growth medium of *S. pneumoniae* type 22F and was purified via its insoluble cetyltrimethylammonium salt (7). Ion exchange chromatography of the capsular material on DEAE-Sephacel afforded the specific polysaccharide as a sharp peak at the beginning of the salt gradient (0.02 M NaCl), which was homogeneous with respect to glycose composition and positive reaction with 22F type specific antiserum. The purified polysaccharide was indicated to be a high molecular weight polymer since it eluted as the void volume fraction on a Sephadex G-200 gel filtration system. All subsequent analyses were made on this material.

Complete acid hydrolysis of the capsular polysaccharide afforded the component glycoses, which were identified as D-galactose, D-glucose, D-glucuronic acid, and L-rhamnose by glc–ms of the derived acetylated or trimethylsilylated *R*-(−)-2-butyl glycosides (8–10). Quantitative analysis of the reduced and acetylated hydrolysis products on glc (program A) indicated that the neutral glycosyl components, identified as 1,2,3,4,5-penta-*O*-acetyl-L-rhamnitol (T_{GA} 0.51), 1,2,3,4,5,6-hexa-*O*-acetylgalactitol (T_{GA} 0.95), and 1,2,3,4,5,6-hexa-*O*-acetyl-D-glucitol (T_{GA} 1.00), were present in the molar ratio 1.9:1.0:2.2. When a sample of the capsular polysaccharide was treated with methanolic HCl (100°C, 15 h) and the product reduced with sodium borodeuteride prior to the quantitative analysis procedure, the aforementioned acetylated alditols were obtained in the molar ratio 2.0:1.0:2.9 in which the D-glucuronic acid component, detected as 1,2,3,4,5,6-hexa-*O*-acetyl-D-glucitol-6,6-d_2 (by ms), represented ≈30% of the derived D-glucitol hexaacetate.

The ^1H and ^{13}C nmr data for the native polysaccharide indicated the presence of an *O*-acetyl substituent. Comparison of the relative signal area of the *O*-acetyl methyl protons (2.18 ppm) to those of the methyl signals from the two L-rhamnosyl residues (1.38 and 1.26 ppm) indicated that the polymer was substituted by *O*-acetyl groups to the extent of 0.8 mol per repeating unit. In the ^{13}C nmr spectrum of the native polysaccharide (Fig. 1a), resonances at 174.10 ppm and 20.90 ppm were characteristic of the carbonyl and methyl carbons of the acetate ester. Removal of the *O*-acetyl groups by treatment of the polysaccharide with dilute alkali resulted in the loss of these signals (Fig. 1b).



Diagnostic ^{13}C signals were observed in the spectrum of the native polysaccharide (Fig. 1a) at 103.20 (1C), 102.85 (1C), 100.14 (2C), 99.68 (1C), and 94.20 ppm (1C) from the anomeric carbon atoms, at 17.90 and 17.00 ppm from the methyl carbons of the two L-rhamnosyl residues, and at 176.20 ppm from the carboxyl carbon of the D-glucuronic acid residue. The methylene carbon resonances due to the hydroxymethyl groups (C-6) of the D-galactosyl and the two D-glucosyl residues were readily identified at 63.86, 61.47, and

SCHEME 1

61.30 ppm from a ^{13}C DEPT experiment (11). In the spectrum of the *O*-deacetylated polymer (Fig. 1b), six resonances from the anomeric carbon atoms of the constituent monosaccharides were observed between 95 and 105 ppm, clearly indicating that the polysaccharide is composed of a regular hexasaccharide repeating unit.

Methylation analysis of the 22F polysaccharide gave the results recorded in Table 1. Since the hydrolysis products derived from the methylated native polysaccharide contained equal molar amounts of 3,4-di-*O*-methyl-L-rhamnose, 2,3,4,6-tetra-*O*-methyl-D-glucose, 2-*O*-methyl-L-rhamnose, 2,5,6-tri-*O*-methyl-D-galactose, and 2,3,6-tri-*O*-methyl-D-glucose, it can be concluded that the polysaccharide is composed of the following structural units: →2)-L-Rha*p*-(1→, D-Glc*p*-(1→, →3,4)-L-Rha*p*-(1→, →3)-D-Gal*f*-(1→, and →4)-D-Glc*p*-(1→. In addition, carboxyl reduction of the permethylated polysaccharide, by treatment with $NaBD_4$ prior to hydrolysis, gave a molar equivalent of 2,3-di-*O*-methyl-D-glucose-6,6-d_2, which establishes the presence of 1,4-linked D-glucuronic acid residues in the repeating unit.

The combined analytical evidence indicates that the 22F polysaccharide is a high molecular weight polymer composed of a branched hexasaccharide repeating unit in which one of the D-glucosyl residues forms the non-reducing end group and a L-rhamnopyranosyl unit is a di-*O*-substituted branch point. To determine the sequence of the glycosyl residues within the repeating unit, chemical fragmentation of the polymer was investigated by taking advantage of the anticipated resistance of the 1,3-linked L-rhamnopyranosyl and D-galactofuranosyl ring systems to periodate oxidation.

As expected, periodate oxidation of the *O*-deacetylated 22F polysaccharide followed by reduction and total acid hydrolysis afforded L-rhamnose and L-arabinose (1:1) as the only detectable neutral glycoses. Mild acid hydrolysis of the reduced periodate-oxidized type 22F polysaccharide (Smith degradation) with dilute aqueous acetic acid (1%, 100°C, 3 h) followed by fractionation of the products on a Bio-Gel P2 column afforded two neutral disaccharides, **1** and **3**, and an acidic trisaccharide **4**, which were fully characterized by nmr and ms analyses (Scheme 1).

The fraction containing oligosaccharide **1** was reduced with sodium borodeuteride and rechromatographed on Bio-Gel P2 to afford disaccharide **2**. The disaccharide **2** on hydrolysis gave L-arabinose and glycerol-1-*d* (1:1). The peracetylated derivative of **2** gave a protonated molecular ion in its ci ms at m/z 436. The ^1H nmr spectrum of **2** showed a single anomeric proton doublet at 5.186 ppm ($J_{1,2}$ = 3.7 Hz) and eight resonances were observed in the ^{13}C nmr spectrum in which those corresponding to the glycosyl residue could be readily assigned (Table 2) by comparison with data reported (12) for methyl β-L-arabinofuranoside. The chemical shifts of the remaining signals were consistent with O-2 substitution of the glycerol moiety (13). The assignment of the β-L-configuration for the arabinofuranosyl residue was consistent with the observed high specific optical

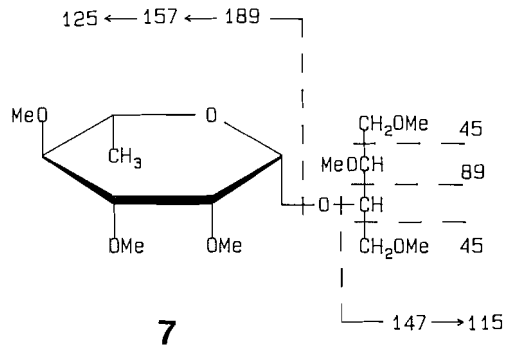
[a]Chemical shifts for the β-D-Glc*p*A-(1→ residue.
[b]Chemical shifts for the →4)-β-L-Rha*p*-(1→ residue.
[c–f]Assignments may be reversed.

rotation ($[\alpha]_D$ +107.3°) of **2** (14). Methylated **2** gave an ei ms fragmentation pattern consistent with 2-*O*-(2,3,5-tri-*O*-methyl-β-L-arabinofuranosyl)-1,3-di-*O*-methylglycerol-1-*d* (**5**).

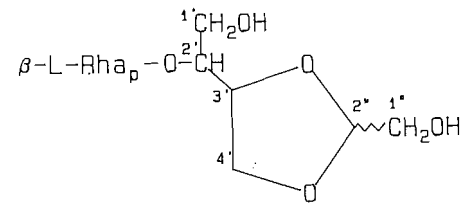
5



The combined evidence permits **2** to be identified as 2-*O*-β-L-arabinofuranosyl-D-glycerol-1-*d* and **1** to be assigned to the corresponding 2-*O*-substituted glyceraldehyde derivative. From the identification of a β-L-arabinofuranosyl end group in **1**, it can be inferred that it was derived from the 1,3-linked α-D-galactofuranosyl residue by periodate cleavage of the C-5—C-6 bond. Since the glyceraldehyde moiety can only arise from an O-2 substituted glycose residue in the intact polymer, it follows that the disaccharide fragment, **6**, forms part of the repeating unit.

→3)-α-D-Gal*f*-(1→2)-L-Rha*p*-(1→

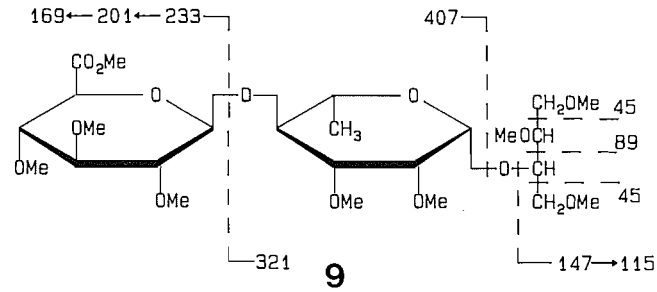
6



The oligosaccharides **3** and **4** were each obtained pure by preparative tlc. The disaccharide **3** was composed of L-rhamnose and erythritol (1:1). The ^{1}H nmr spectrum of **3** showed characteristic signals at 4.785 (d, $J_{1,2}$ = 1.2 Hz) and 1.321 ppm (d, $J_{5,6}$ = 6.0 Hz) due to the anomeric and 6-deoxy methyl protons of the L-rhamnopyranosyl component, respectively. The rhamnopyranosyl residue was assigned the β-L configuration from its specific optical rotation ($[\alpha]_D$ +58.5°, water) (15) and from analysis of its ^{13}C nmr spectrum (Table 2) (13). The methylated derivative (**7**) of **3** gave an ei ms fragmentation pattern that was consistent with **3** being 2-*O*-β-L-rhamnopyranosyl-D-erythritol, the erythritol moiety arising from the 4-*O*-substituted D-glucopyranosyl residue of the 22F polysaccharide.

In addition to oligosaccharide **3**, in which the aglycon was erythritol, the corresponding 2-*O*-substituted 3,4-*O*-(2-hydroxyethylidene)-D-erythritol analog (**8**) was obtained as a minor product (ca. 30% by ^{1}H nmr).

7



The cyclic derivative **8** was characterized from analysis of its ^{1}H and ^{13}C nmr spectra (see experimental section), the magnitude of the ^{1}H–^{1}H vicinal (^3J = 4.9, 6.6 Hz) and geminal (^2J = 8.5 Hz) coupling constants of the ring methylene protons (C-4′) being indicative of the 1,3-dioxolane ring system (16, 17). 3,4-*O*-(2-Hydroxyethylidene) derivatives have previously been reported as minor products (10–25%) obtained from the Smith degradation of polysaccharides containing O-4-linked α-D-hexopyranosyl residues having the *gluco* or *galacto* configuration (18, 19); they arise from acetal migration during the mild acid hydrolysis step (18).

8

The acidic trisaccharide **4** was composed of D-glucuronic acid, L-rhamnose, and erythritol (1:1:1). Two equal intensity anomeric proton signals were observed in the ^{1}H nmr spectrum of **4**: a singlet at 4.786 ppm corresponding to the L-rhamnosyl residue, and a doublet ($J_{1,2}$ = 7.8 Hz) at 4.769 ppm indicating that the D-glucopyranosyluronic acid residue has the β configuration. In the ^{13}C nmr spectrum of the trisaccharide (Table 2), characteristic signals at 175.50 and 17.72 ppm were diagnostic for the carboxyl carbon of the glucuronic acid and of the methyl carbon of the rhamnose residue, respectively. Comparison of the ^{13}C chemical shifts with those reported (13, 20) for the corresponding mono- and unsubstituted methyl glycosides

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

9

suggested that the β-D-glucopyranosyluronic acid was present as a non-reducing end group and that the β-L-rhamnopyranosyl group was substituted at the O-4 position. Methylation of **4** and subsequent glc–ms analysis confirmed the presence of a terminal glucuronic acid residue. The fragmentation pattern in the ei ms spectrum of the methylated derivative (**9**) showed primary fragment ions at m/z 233 [aA_1] (fragment ions labelled according to Kochetkov and Chizov (21)), 201 [aA_2], and 233 [aA_3], indicative of a permethylated hexopyranosyluronate end group (22). In addition, reduction of the methyl ester by treatment of the permethylated trisaccharide with sodium borodeuteride followed by hydrolysis gave 2,3,4-tri-*O*-methyl-D-glucose-6,6-d_2 and 2,3-di-*O*-methyl-L-rhamnose (1:1). Thus, the combined evidence leads to **4** being assigned the structure *O*-β-D-glucopyranosyl uronic acid-(1→4)-β-L-rhamnopyranosyl-(1→2)-D-erythritol.

The characterization of the oligosaccharides **3** and **4** indicates that part of the 22F polysaccharide structure contains the trisaccharide unit **10** in which the β-L-rhamnosyl residue forms the branch point, as indicated by methylation analysis of the native polysaccharide, and is therefore O-3 and O-4 disubstituted.

→4)-β-D-Glc*p*A-(1→4)-β-L-Rha*p*-(1→4)-D-Glc*p*-(1→

10

With the identification of the structural units **6** and **10**, several possibilities can still be envisaged for the arrangement of the glycosyl residues within the repeating unit of the 22F polysaccharide. The survival of the 1,4-linked D-glucuronic acid residue in the course of periodate oxidation of the *O*-deacetylated polysaccharide to give **4** probably results from its protection via hemiacetal formation with proximal aldehydo groups arising from more readily oxidizable residues (23). The terminal non-reducing D-glucopyranosyl residues identified as forming part of the repeating hexasaccharide unit (Table 1) would be expected to be most susceptible to periodate oxidation (24) and could afford protection to the D-glucuronic acid residues if they were positioned at either the O-4 position of the uronic acid or O-3 of the di-*O*-substituted L-rhamnopyranosyl residues. A detailed nmr analysis of the 22F capsular polysaccharide led to a unique structure.

Complete and unambiguous assignment of the ^1H and ^{13}C nmr spectra of the *O*-deacetylated 22F polysaccharide was made using two-dimensional (2D) homo- and heteronuclear chemical shift correlation techniques. Analysis of the connectivities observed between directly coupled protons in the 2D homonuclear chemical shift correlation (COSY) spectrum (Figs. 2 and 3) permitted the ^1H resonances to be grouped into subspectra corresponding to each of the component glycosyl ring systems (25). The ^1H chemical shift data and the ^1H–^1H coupling constants, determined from the appropriate cross-peaks in the COSY spectrum (cf. Fig. 3) or from a 2D homonuclear *J*-resolved spectrum (26), are recorded in Table 3. Comparison of the chemical shift data and the vicinal coupling constants with values reported in the literature (27, 28) led to the identification of the respective subspectra. Assignment of the ^{13}C resonances of the *O*-deacetylated polysaccharide was then achieved by correlation with the corresponding ^1H resonances from a 2D heteronuclear $^1H/^{13}C$ shift correlation map (Fig. 4) (29).

The anomeric proton (H-1) resonances, which were readily identified from their single vicinal proton couplings, in the low field region of the spectrum (5.3–4.7 ppm) provided a convenient starting point for this analysis and were labelled **A**1, **B**1, **C**1, **D**1, **E**1, and **F**1 in order of decreasing chemical shifts (Fig. 2). Delineation of the connectivity relationships defined by the cross-peaks led to the assignment of most of the ^1H resonances associated with the individual monosaccharide components (residues **A**, **B**, **C**, **D**, **E**, and **F**). This analysis was relatively straightforward and the connectivity pathway corresponding to residue **A** is shown in Fig. 3. Seven ^1H resonances could be associated with this subspectrum from the related cross-peaks and, from the magnitude of the vicinal ring proton coupling constants ($J_{1,2} \leq 4$ Hz, $J_{2,3} \approx J_{3,4} \approx J_{4,5} \approx$ 10 Hz), the residue **A** was identified as a D-glucopyranosyl unit having the α configuration. Analogously, the subspectra corresponding to residues **C** and **F** were attributed to pyranose residues having the *gluco* configuration. Residue **C** also had the α-anomeric configuration ($J_{1,2}$ = 3.8 Hz) and was assigned to the second D-glucopyranosyl unit, while residue **F**, which gave a spin system composed of only five ^1H resonances, could be assigned to the β-D-glucopyranosyluronic acid residue. The latter assignment was confirmed from the observed pH dependence of the H-4 and H-5 resonances of residue **F**, which showed downfield shifts of ≈0.1 and ≈0.4 ppm, respectively, when the spectrum of the *O*-deacetylated polysaccharide was recorded at pD ≈ 2 (Table 3).

Residues **D** and **E** were identified as the L-rhamnopyranosyl residues since the two high-field methyl doublets at 1.398 ($J_{5,6}$ = 5.7 Hz) and 1.294 ppm ($J_{5,6}$ = 6.1 Hz) could be readily associated with the respective connectivity pathways through cross-peaks to the H-5 resonances of **D** (3.550 ppm) and of **E** (4.051 ppm) in the full-scale COSY spectrum. The low intensity of the cross-peaks relating H-1 and H-2 of these residues (Fig. 2), which is particularly apparent in the case of residue **D** (**D**12), can be attributed to the small values (ca. 1 Hz) for the scalar couplings, $J_{1,2}$, which, together with small values for $J_{2,3}$ (≤3 Hz), are indicative of the *manno* configuration (28). Due to the axial disposition of the C-2 hydroxyl group of the L-rhamnopyranosyl residues, the anomeric configurations were not evident from the $J_{1,2}$ values (28). The configurations were determined from the magnitude of their corresponding one-bond ^{13}C–^1H coupling constants ($^1J_{C,H}$) (30). The $^1J_{C,H}$ values (Table 4) for the anomeric carbon (C-1) resonances of the L-rhamnopyranosyl units **D** (159 Hz) and **E** (172 Hz) were characteristic (30) of the two residues having the β and the α configurations, respectively.

The magnitudes of the ring proton vicinal coupling constants (Table 3) were consistent with the constituent monosaccharides, **A**, **C**, **D**, **E**, and **F** being present in the corresponding pyranosyl ring forms with the $^4C_1$ (D-enantiomer) or the $^1C_4$ (L-enantiomer) chair conformations (28). On the other hand, the $J_{1,2}$ (≈4 Hz), $J_{2,3}$ (≈8 Hz), $J_{3,4}$ (≈7 Hz) values measured for residue **B** were consistent (31) with that residue being the α-D-galactofuranosyl unit. Corroborative evidence for this assignment was obtained from a comparison of the respective ^{13}C chemical shifts (Table 4) with data for the corresponding

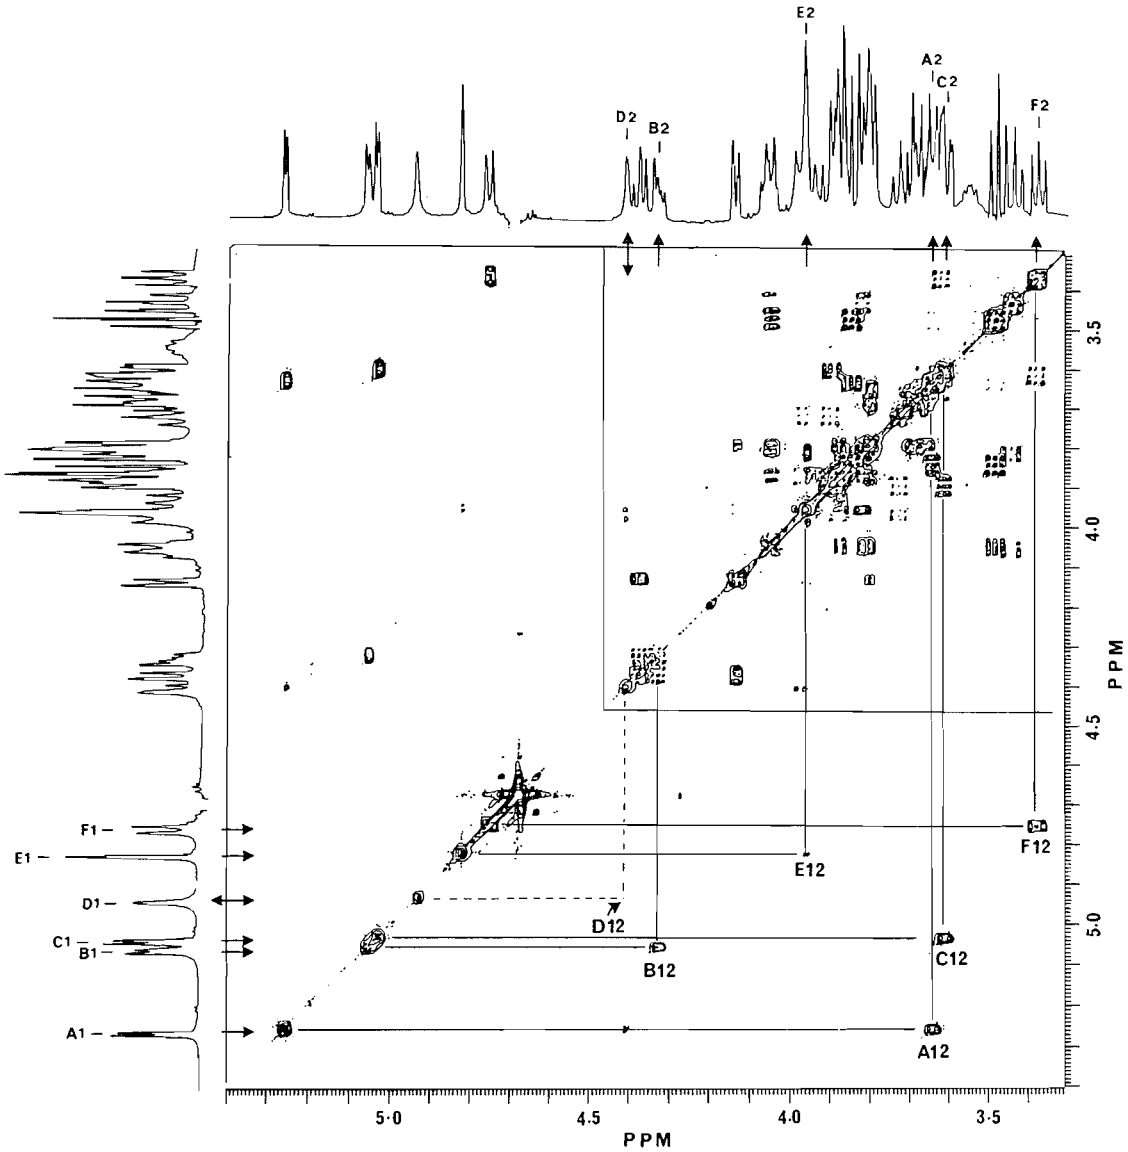

FIG. 2. Contour plot of the ring proton region (5.4–3.3 ppm) of the COSY spectrum of the *O*-deacetylated type 22F pneumococcal polysaccharide at 310 K. The spectrum was measured using a narrow sweep width and 512 × 2048 data points (see experimental section). Resonance assignments are shown for H-1 and H-2 of each of the component monosaccharides (**A**–**F**).

methyl furanosides of galactose, arabinose, and 3-*O*-methyl arabinose (12, 32), in which the chemical shift of C-1 (103.19 ppm) was diagnostic for the α-D configuration.

The arrangement of the six glycosyl residues within the repeating unit of the 22F polysaccharide was unequivocally determined from *inter*residue nOe measurements (33, 34). A 2D nOe experiment (NOESY) was carried out on the *O*-deacetylated 22F polysaccharide (Fig. 5). The 2D experiment provided the best method for nOe determination since the H-1 resonances corresponding to residues **B** and **C** were not completely resolved from one another in the 1D ^{1}H nmr spectrum.

*Inter*residue nOe's (Table 5) were observed between protons **B**1 and **E**2, and between protons **F**1 and **D**4, and **D**1 and **C**4, which provides verification of the sequences of the two structural units, **B**–**E** (**6**) and **F**–**D**–**C** (**10**), deduced from the periodate oxidation studies. The relationship between these units is indicated from the observed nOe's between H-1 of residue **C** and H-3, H-4, and H-5 of the α-D-galactofuranosyl residue (**B**), which, together with the *inter*residue effect between protons **E**1 and **F**4, establishes the linear sequence of glycoses as **F**–**D**–**C**–**B**–**E**–**F**. Thus, the main chain of the polymer is composed of the repeating pentasaccharide unit **11** in which the β-L-rhamnopyranosyl residue provides the branch point.

Nuclear Overhauser effects relating the anomeric protons with other protons within the same ring system provided additional confirmation for the anomeric configurations of the glycopyranosyl residues (Table 5). *Intra*residue effects between only H-1 and H-2 were indicative of the α configuration

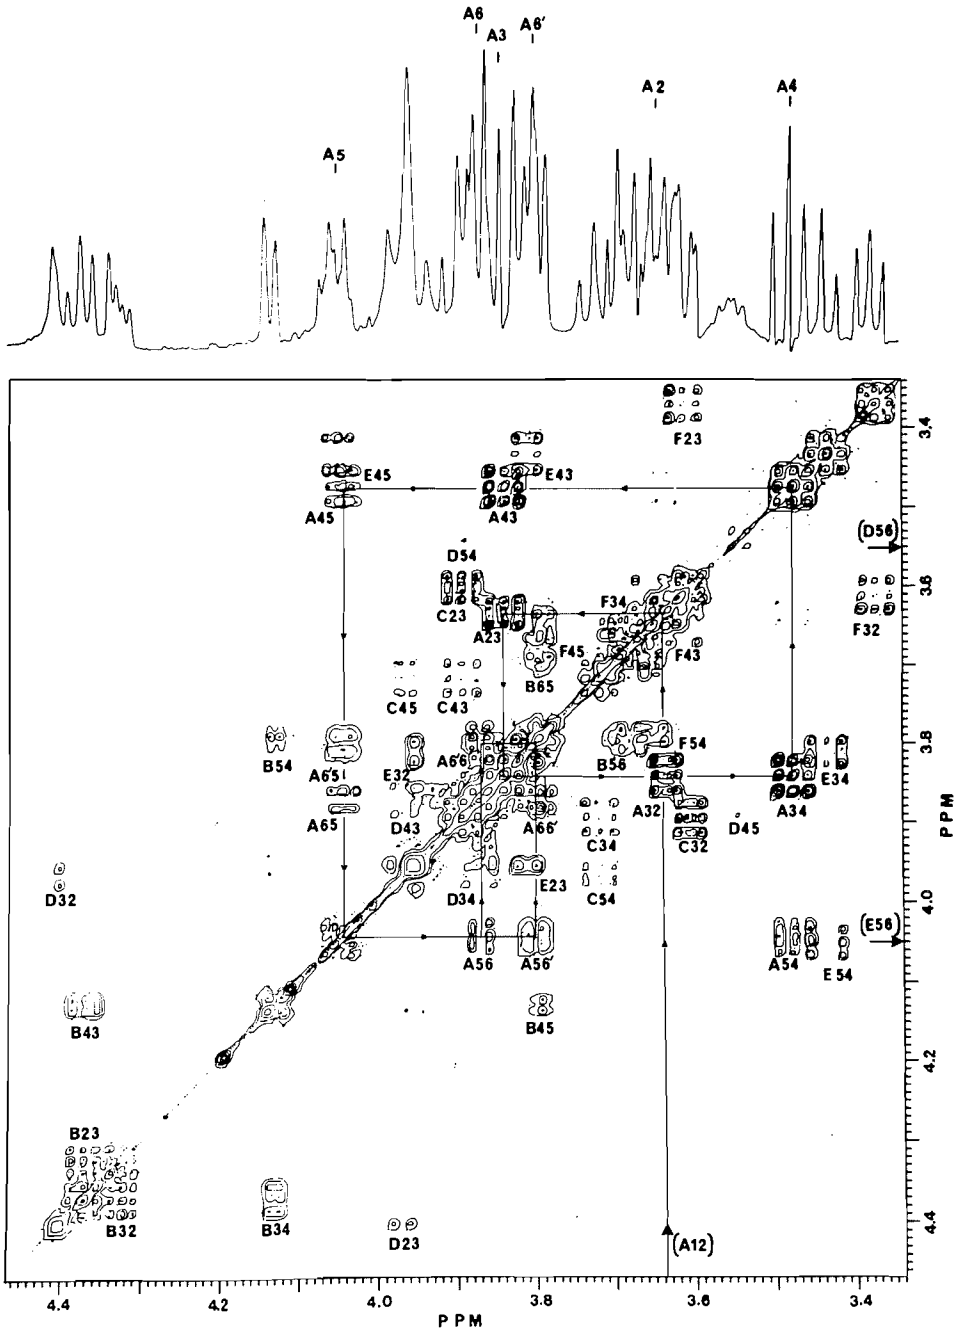

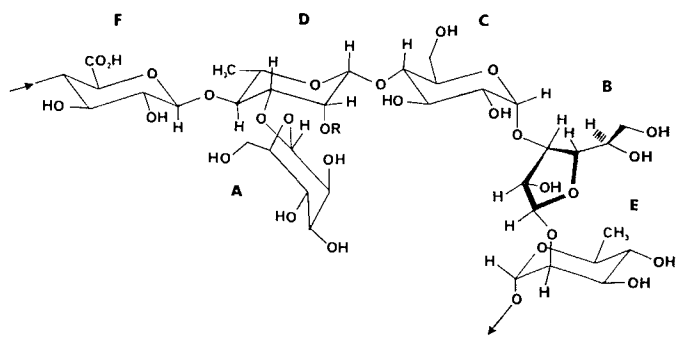

FIG. 3. Expansion (4.47–3.34 ppm) of the COSY contour plot shown in Fig. 2. Assignments of the cross-peaks are shown and the connectivity pathway corresponding to the residue **A** subspectrum is indicated by the solid line.

(residues **A**, **C**, and **E**), while *intra*residue nOe's between H-1 and H-3 and between H-1 and H-5 were diagnostic of the β-linked residues **D** and **F**.

In accord with the results of methylation analysis, the nOe data (Table 5) clearly indicate that residue **A** is the non-reducing α-D-glucopyranosyl end group. The occurrence of *inter*residue nOe's between H-1 of residue **A** and H-2 and H-3 of residue **D** establishes that the terminal non-reducing α-D-glucopyranosyl unit is 1,3-linked to the 3,4-di-*O*-substituted β-L-rhamnopyranosyl residue, and it follows that the hexasaccharide repeating unit of the *O*-deacetylated 22F polysaccharide has the structure **12**.

As indicated in Table 5, the occurrence of nOe's between the

[a]Determined from the 2D NOESY experiment (cf. Fig. 5).

anomeric and aglyconic protons of contiguous glycosyl residues can provide, in addition to the sequence, the positions of the glycosidic linkages (35). However, since the nOe is dependent on the conformation about the glycosidic bond, the largest *inter*residue nOe need not necessarily occur between the anomeric and aglyconic proton pair (36, 37). This is evident from the occurrence of significant *inter*residue nOe's between H-1 of the terminal α-D-glucopyranosyl unit (**A**) and both H-2 and H-3 of the β-L-rhamnopyranosyl unit (**D**), which, as predicted from potential energy calculations using the HSEA method (38), is a consequence of the conformation about the α-1,3 glycosidic linkage of the **A**–**D** disaccharide unit (cf. structure **12**). Similar effects have been observed for this disaccharide unit, which is also part of the pneumococcal type 7F polysaccharide repeating unit (39).

The location of the *O*-acetyl substituent, present in the native 22F polysaccharide, was determined from a comparison of its ^{13}C nmr spectrum with that of the *O*-deacetylated polysaccharide (Fig. 1). The anomeric carbon regions (95–105 ppm) of the two spectra were similar except that the signal intensity of the resonance at 101.33 ppm due to C-1 of the β-L-rhamnopyranosyl residue (**D**) was considerably reduced in the spectrum of the native polysaccharide, while the intensity of the signal at 99.98 ppm was almost twice that observed in the spectrum of the *O*-deacetylated polysaccharide, indicating that the introduction of the *O*-acetyl group leads to an upfield shift of the **D**1 resonance by almost 1.4 ppm. The C-2 resonance (**D**2) corresponding to the β-L-rhamnosyl residue was shifted downfield by ≈1.6 ppm in the spectrum of the native polysaccharide. Since replacement of an hydroxy group by an *O*-acetyl substituent in glycosides is known to lead to downfield shifts (0.7–3.5 ppm) of the substituted carbon and to upfield shifts (1.2–2.8 ppm) of the adjacent carbon resonances (40), it can be concluded that the O-2 position of the 3,4-di-*O*-glycosylated β-L-rhamnopyranosyl residues carry *O*-acetyl groups in the native polysaccharide. Moreover, the low-field position of the H-2 resonance of the β-L-rhamnopyranosyl residue in the ^1H nmr spectrum of the native polysaccharide (5.739 ppm) compared to the chemical shift of that resonance in the *O*-deacetylated polymer (4.407 ppm) is also in accord with the β-L-rhamnopyranosyl units being 2-*O*-acetylated (40).

The combined chemical and nmr evidence therefore permits the repeating hexasaccharide unit of the pneumococcal type 22F capsular polysaccharide to be assigned to the structure **13** in which the *O*-acetyl groups are present in ≈80% of the repeating units.

Experimental

Type 22F pneumococcal polysaccharide

Type 22F polysaccharide was obtained by ethanol precipitation from the growth medium of *S. pneumoniae* type 22F, after digestion with trypsin, ribonuclease, and deoxyribonuclease, and fractional precipitation with 2-propanol with serological probing (7). The capsular polysaccharide was further purified via its insoluble cetyltrimethylammonium complex (41).

Purified 22F polysaccharide (100 mg) was converted to its sodium salt by passing an aqueous solution (2.0 mL) through a column (0.5 × 2.0 cm) containing Rexyn 101 (Na^+ form) ion exchange resin followed by lyophilization of the eluate: $[\alpha]_D$ +90.8° (*c* 0.52, water). *Anal.* found: C 43.42, H 6.24, N nil, ash 2.10%.

O-Deacetylation

A solution of the purified type 22F polysaccharide (100 mg) in 5% (v/v) aqueous ammonia (5 mL) was stirred at 35°C for 3 h, the solution lyophilized, and the product converted to its sodium salt (as above).

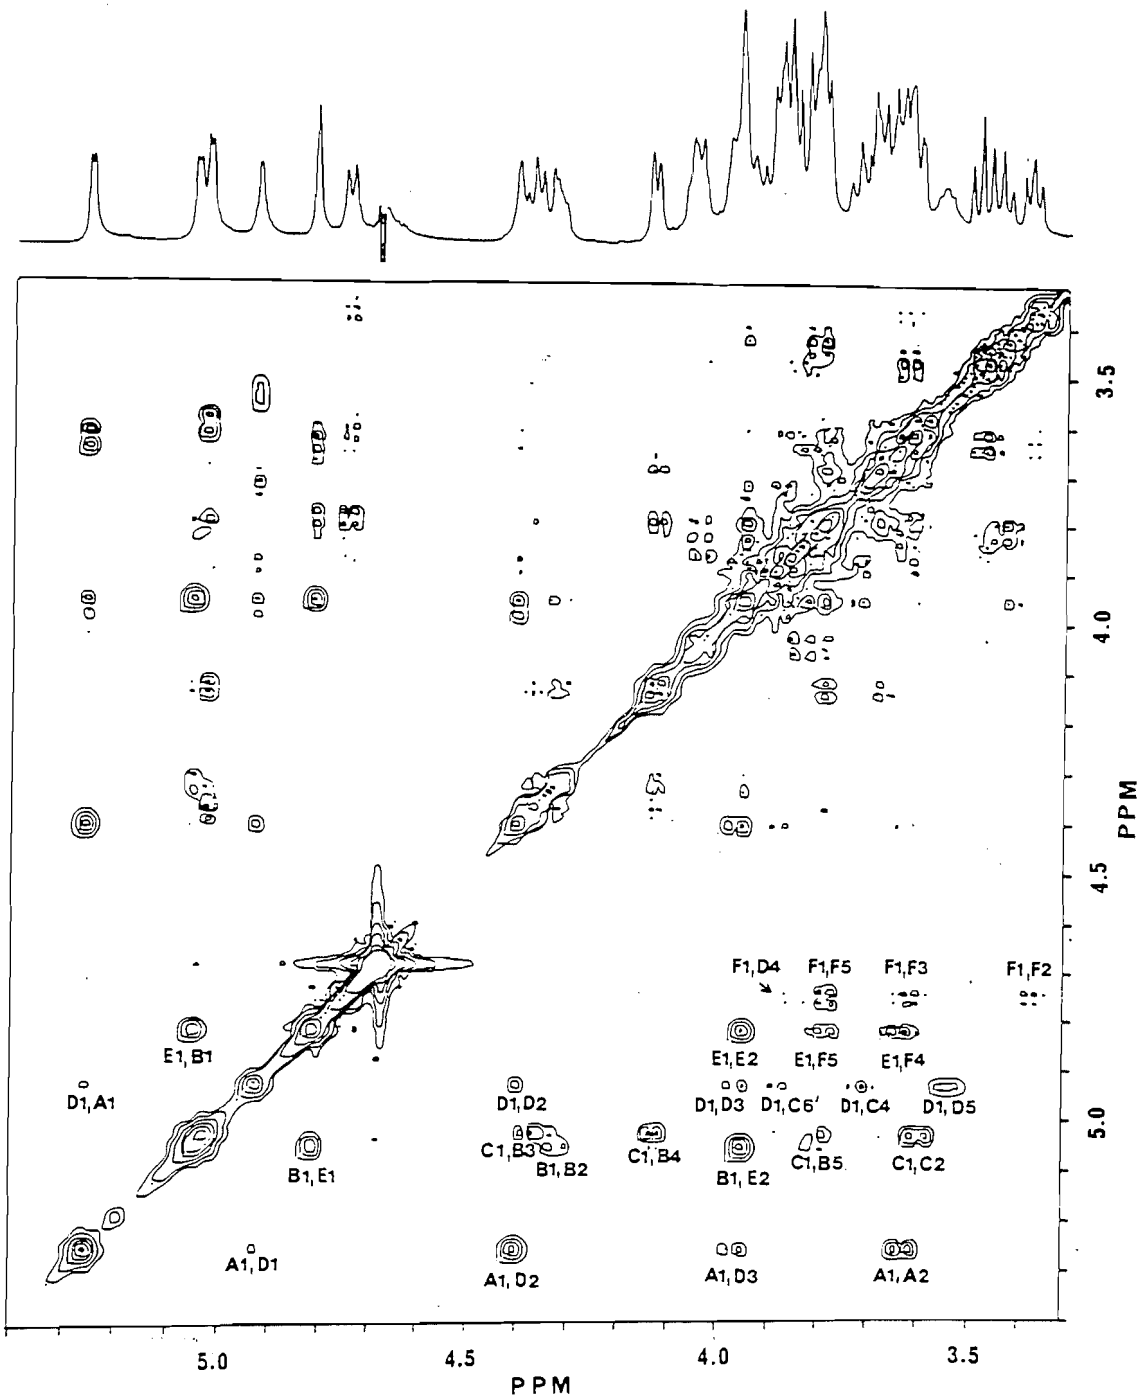

FIG. 5. Contour plot of the ring proton region (5.4–3.3 ppm) of the NOESY spectrum of the *O*-deacetylated type 22F pneumococcal polysaccharide at 310 K. Cross-peaks arising from nOe's involving the anomeric proton resonances are indicated.

Chromatography

Samples (6 mg) of polysaccharide were subjected to chromatography on columns (1.2 × 40 cm) of Sephadex G-200 eluted with 0.05 M pyridinium acetate (pH 4.5), and of DEAE-Sephacel (Pharmacia) eluted with 0.05 M Tris-HCl (pH 7.2) (25 mL) followed by a buffered 0–0.5 M sodium chloride gradient. Fractions (1 mL) were collected and assayed for neutral glycose (42) and hexuronic acid (43).

Analytical methods

Quantitative colorimetric methods used for the analysis of column chromatography eluates were (*i*) phenol – sulfuric acid for neutral glycoses (42), (*ii*) *m*-hydroxydiphenyl – sulfuric acid method for hexuronic acids (43), and (*iii*) the method of Nash (44) for the determination of formaldehyde liberated by periodate oxidation.

Gas–liquid chromatography (glc) was done with a Hewlett Packard model 5710A gas chromatograph fitted with a hydrogen flame detector and a model 3380A electronic integrator using the following conditions: A, glass column (2 mm × 180 cm) packed with 3% (w/w) SP2340 on Supelcoport (80–100 mesh) and the temperature program, 180°C (for 2 min) – 240°C at 4°C/min; B, the foregoing column and the temperature program, 190° (for 2 min) – 220°C at 1°C/min; C, glass column (2 mm × 60 cm) packed with 1% (w/w) Dexsil 300 on Supelcoport (100–120 mesh) and the temperature program, 130°C–340°C at 10°C/min; D, fused silica capillary column (0.3 mm × 25 m)

containing 3% (w/w) OV17 and the temperature program, 180°C (for 2 min) – 240°C at 2°C/min. The carrier gas was dry nitrogen and retention times are given relative to those of D-glucitol hexaacetate (T_{GA}), 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-glucitol (T_{GM}), or permethylated cellobiitol (T_{CM}).

The glc–ms data were obtained using a Hewlett Packard 5958B system employing the glc program conditions A–D by electron impact (ei) with an ionization potential of 70 eV, or by chemical ionization (ci) with isobutane as the reagent gas.

Glycoses were determined by glc of their alditol acetates (45) using inositol as internal standard. Samples (0.2–0.5 mg) were hydrolyzed in sealed glass tubes with 1 M sulfuric acid (0.5 mL) for 15 h at 100°C followed by neutralization with barium carbonate, filtration, and concentration to obtain the free glycosides. For the estimation of hexuronic acid, samples (0.5 mg) suspended in methanolic hydrogen chloride (3%, w/v, 1 mL) were heated at 100°C in sealed glass tubes for 15 h. Excess methanolic HCl was removed *in vacuo* and the residues in water (1 mL) were treated with sodium borodeuteride (15 mg) for 6 h at 22°C. Following neutralization with aqueous acetic acid (10%, w/v), the reaction mixtures were decationized with Rexyn 101 (H^+ form) ion exchange resin (1.5 mL), concentrated *in vacuo*, and borate was removed by repeated distillation from methanol (5 × 5 mL). The products were then hydrolyzed in 3 M HCl (1 mL) for 3 h at 100°C followed by concentration *in vacuo*. The liberated glycoses were reduced ($NaBH_4$) and acetylated (Ac_2O) (46) prior to glc analysis using program A.

Absolute configurations of the glycoses were determined by glc–ms (program D) of the corresponding acetylated or trimethylsilylated *R*-(−)-2-butyl glycoside derivatives (8–10). The identity of the glycose derivatives was established by comparison of their glc retention times and mass spectra with those of authentic reference compounds.

Methylation analysis

Polysaccharide samples (2 mg) were methylated with methyl iodide in dimethyl sulfoxide containing an excess of sodium methylsulfinylmethanide according to the Hakomori procedure (47) and the products were purified by dialysis against distilled water followed by concentration of the aqueous dialyzate. Oligosaccharide samples (0.5–1.0 mg) were methylated by the above procedure, and the products were recovered by extraction into dichloromethane and analyzed by glc–ms using program C. The methylated products were hydrolyzed, reduced with sodium borodeuteride, and acetylated as previously described (46). Methylated products containing uronic acid residues were subjected to carboxyl reduction before hydrolysis by treatment with $NaBD_4$ in tetrahydrofuran (12 h, 50°C) and analysis by glc–ms (program B).

Nuclear magnetic resonance spectroscopy

Measurements were made at 310 K on solutions (0.4 mL) in deuterium oxide with a Bruker AM-500 spectrometer equipped with an Aspect 3000 computer, operating in the pulsed Fourier transform mode with quadrature detection using standard Bruker software.

Proton nmr spectra were recorded at 500 MHz using a spectral width of 2.5 kHz, a 16 K data block, and a 90° pulse. For quantitative measurement of signal area, a 45° pulse and a fixed delay of 3 s was employed. Prior to Fourier transformation, resolution enhancement was achieved by the Gaussian line shape transformation (48) with typical values of −2.0 to −4.0 Hz for the line broadening factor and a Gaussian broadening factor of +0.1 or +0.2. Chemical shifts are expressed relative to that of internal acetone (0.1%, 2.225 ppm).

Broad-band proton decoupled carbon-13 spectra were obtained at 125 MHz using a spectral width of 25 kHz, a 32 K data block, and a 90° pulse employing WALTZ decoupling (49). Heteronuclear $^1J_{C,H}$ coupling constants for the anomeric carbons were measured using gated decoupling (50). DEPT spectra (11) were obtained with broad-band proton decoupling by using a 135° proton pulse and a 3.3-ms delay between pulses. Chemical shifts are referenced to that of 1,4-dioxane (67.40 ppm).

Two-dimensional homonuclear COSY (41), NOESY (52, 53), and *J*-resolved (54) experiments were measured using the conventional pulse sequences on a D_2O solution (25 mg/mL) of the *O*-deacetylated polysaccharide (sodium salt, pD ≈ 7). COSY and NOESY data were measured using data sets ($t_1 \times t_2$) of 256 × 1024 points for a spectral width of 2203 Hz, a recycle delay of 1.5 s, and 32 or 96 transients for each value of the incrementable delay. A mixing time of 200 ms was employed for the NOESY experiment. The data matrices were zero filled to 512 × 2048 points and, following resolution enhancement in both dimensions by a non-shifted sine bell function, were processed to give magnitude spectra with symmetrization. The COSY was also carried out over a narrow spectral width (1200 Hz) using a data set of 512 × 2048 points that was zero filled to 1024 × 2048 points, and the data were processed as described above. The *J*-resolved spectrum was acquired using a 32 × 2048 point data set and spectral widths of 1200 Hz and ±18.7 Hz in the chemical shift (F_2) and the coupling constant (F_1) domains, respectively. A recycle delay of 1.5 s was used and 32 transients were collected for each of 32 experiments. The data matrix was zero filled to 128 × 2048 points, a non-shifted sine bell function was applied to both time domains, and the transformed data were tilted 45° and symmetrized.

A two-dimensional heteronuclear $^1H/^{13}C$ chemical shift correlation experiment (29, 55) was carried out on a concentrated solution (100 mg/mL) of the *O*-deacetylated polysaccharide (sodium salt). The experiment was performed using a data matrix of 128 × 1024 points and spectral widths of 12 500 and 2500 Hz for the respective carbon-13 (F_2) and proton (F_1) chemical shift domains. A recycle delay of 1.5 s was employed and the fixed delays, τ_1 and τ_2, were set at 3.2 and 1.6 ms, respectively, to select for all multiplicities. Composite broad-band proton decoupling was employed during the acquisition of 1000 transients for each of the 128 increments. The data matrix was zero filled to 256 × 2048 points and, following resolution enhancement in both dimensions by means of a Lorentz-to-Gauss transformation, the data were processed to give a power spectrum.

Smith degradation (ref. 56)

To a solution of the *O*-deacetylated type 22F polysaccharide (80 mg) in water (50 mL) was added an aqueous solution of 0.04 M sodium *meta*-periodate (50 mL). The solution was kept in the dark at 4°C for 96 h and, following the destruction of excess periodate by the addition of ethylene glycol (0.1 mL), the oxidized polymer was reduced by addition of sodium borohydride (500 mg). After stirring for 15 h at 22°C, excess borohydride was decomposed by the slow addition of aqueous acetic acid (10%, w/v) to the cooled solution, and the solution was dialyzed and lyophilized to yield the periodate-oxidized and reduced polymer (60 mg). The periodate-oxidized and reduced polysaccharide was hydrolyzed with dilute aqueous acetic acid (1%, v/v, 10 mL) at 100°C for 3 h, and the reaction mixture was concentrated to dryness. The hydrolysis products were chromatographed on a column (1.5 × 95 cm) of Bio-Gel P2, jacketed at 50°C, with water as the eluant to give three major oligosaccharide containing fractions, I (20 mg), II (13 mg), and III (10 mg).

Oligosaccharide 2

Fraction I, which eluted in the monosaccharide region of the Bio-Gel P2 column, was treated with sodium borodeuteride (25 mg) in water (2 mL) at 22°C for 3 h. Excess borodeuteride was decomposed by addition of acetic acid and the neutralized solution (pH 7) was passed through a bed of Rexyn 101 (H^+ form) ion exchange resin (2 mL). The eluate was repeatedly concentrated with methanol (5 × 10 mL) to yield a mixture of alditols (20 mg). A portion (ca. 0.5 mg) of the mixture was acetylated by heating an acetic anhydride solution (1 mL) containing anhydrous sodium acetate (0.5 mg) at 115°C for 3 h; glc–ms analysis showed unlabeled and glycerol-1-*d* triacetate (T_{GA} 0.13) (30%), L-arabinitol-1-*d* pentaacetate (T_{GA} 0.66) (18%), and 2-*O*-arabinofuranosyl-glycerol-1-*d* (**2**) pentaacetate (T_{GA} 1.50) (52%). Peracetylated **2** gave ms (ei), *m/z* (relative intensity): 259 (26.3), 170 (17.2), 160 (49.2), 157 (10.2), 139 (41.1), 128 (14.9), 115 (9.5), 97 (19.3), 69 (6.5), 68 (5.3), 43 (100); ms (ci), *m/z*: 436 (M + 1).

The remainder of the reduced fraction (19 mg) was rechromatographed on Bio-Gel P2 as described above and the fraction eluting in

For personal use only.

the disaccharide region was collected and lyophilized to give pure **2** (7 mg): $[\alpha]_D$ +107.3 (*c* 0.22, water); ^{1}H nmr, δ (partial): 5.186 (d, 1H, $J_{1,2}$ = 3.7 Hz); ^{13}C nmr, Table 2. Hydrolysis, reduction, and acetylation of **2** gave (by glc–ms, program A) glycerol-1-*d* triacetate (T_{GA} 0.13) and L-arabinitol pentaacetate (T_{GA} 0.66) (1:1). Permethylated **2** gave a single peak on glc (program C) having T_{CM} 0.20; ms (ei), *m/z* (relative intensity): 175 (4.9) [aA_1], 164 (9.9) [J_1], 143 (10.7) [aA_2], 115 (9.3), 111 (4.9) [aA_3], 104 (5.6), 101 (100), 89 (4.7), 71 (6.4), 46 (22.3), 45 (46.1).

Oligosaccharides 3 and 8

Fraction II eluted in the disaccharide region of the Bio-Gel P2 column and showed ^{1}H nmr, δ (partial): 5.039 (t, 0.3H, $J_{1,2}$ = 3.2 Hz), 4.785 (d, ca. 0.7H, $J_{1,2}$ = 1.2 Hz), 4.780 (d, ca. 0.3H, $J_{1,2}$ = 1.2 Hz), 1.322 (d, 3H, $J_{5,6}$ = 6.0 Hz); ^{13}C nmr, δ: 104.4, 100.5, 100.0 (0.4:1.0:0.4). Thin-layer chromatography (silica gel) developed with ethyl acetate – acetic acid – methanol–water (12:3:3:5) showed two components that were subsequently separated by preparative tlc to give oligosaccharides **3** (7 mg, R_f 0.29) and **8** (3 mg, R_f 0.38).

Oligosaccharide **3** had $[\alpha]_D$ +58.5 (*c* 0.11, water); ^{1}H nmr, δ (partial, β-L-rhamnopyranosyl residue): 4.785 (d, 1H, $J_{1,2}$ = 1.2 Hz, H-1), 4.048 (d of d, 1H, $J_{1,2}$ = 1.2 Hz, $J_{2,3}$ = 3.3 Hz, H-2), 3.604 (d of d, 1H, $J_{2,3}$ = 3.3 Hz, $J_{3,4}$ = 9.3 Hz, H-3), 3.405 (d of q, ca. 1H, $J_{4,5}$ = 9.2 Hz, $J_{5,6}$ = 6.0 Hz, H-5), 3.383 (d of d, 1H, $J_{3,4}$ = 9.3 Hz, $J_{4,5}$ = 9.2 Hz, H-4), 1.321 (d, 3H, $J_{5,6}$ = 6.0 Hz, H-6); ^{13}C nmr, Table 2. The glc–ms (program A) of a hydrolyzed, reduced, and acetylated sample of **3** showed erythritol tetraacetate (T_{GA} 0.36) and L-rhamnitol pentaacetate (T_{GA} 0.51) (1:1). The methylated derivative (**7**) of the disaccharide gave a single peak on glc (program C) (T_{CM} 0.35); ms (ei), *m/z* (relative intensity): 207 (29.5) [J_1], 189 (5.9) [aA_1], 157 (3.0) [aA_2], 147 (13.0), 129 (7.2), 125 (3.4) [aA_3], 115 (27.8), 101 (31.1), 89 (22.7), 88 (100), 71 (24.7), 59 (27.1), 45 (99.5). Hydrolysis, reduction ($NaBD_4$), and acetylation of methylated **3** gave on glc–ms (program B) 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methyl-L-rhamnitol-1-*d* (T_{GM} 0.89).

Oligosaccharide **8** gave ^{1}H nmr, δ: 5.032 (t, 1H, $J_{1'',2''}$ = 3.2 Hz, H-2″), 4.777 (d, 1H, $J_{1,2}$ = 1.2 Hz, H-1), 4.287 (d of t, 1H, $J_{3',4a'}$ = 4.9 Hz, $J_{3',4b'}$ = 6.6 Hz, H-3′), 4.157 (d of d, 1H, $J_{3',4a'}$ = 4.9 Hz, $J_{4a',4b'}$ = 8.5 Hz, H-4a′), 4.052 (d of d, 1H, $J_{3',4b'}$ = 6.6 Hz, $J_{4a',4b'}$ = 8.5 Hz, H-4b′), 4.021 (d of d, 1H, $J_{1,2}$ = 1.2 Hz, $J_{2,3}$ = 3.4 Hz, H-2), 3.882 (m (unresolved), ca. 1H, H-2′), 3.867 (d of d, ca. 1H, $J_{1a',2'}$ = 3.2 Hz, $J_{1a',1b'}$ = 13.2 Hz, H-1a′), 3.712 (d of d, 1H, $J_{1b',2'}$ = 5.6 Hz, $J_{1a',1b'}$ = 13.2 Hz, H-1b′), 3.680 (m, 2H, H-1a″, H-1b″), 3.590 (d of d, 1H, $J_{2,3}$ = 3.2 Hz, $J_{3,4}$ = 9.6 Hz, H-3), 3.375 (m (unresolved), ca. 1H, H-5), 3.362 (m (unresolved), ca. 1H, H-4), 1.320 (d, 3H, $J_{5,6}$ = 6.0 Hz, H-6); ^{13}C nmr, δ: 104.05 (C-2″), 99.70 (C-1), 79.75 (C-2′), 75.74 (C-3′), 73.52 (C-3), 72.95 (C-4, C-5), 71.69 (C-2), 68.20 (C-4′), 61.97 (C-1″), 61.14 (C-1′), 17.46 (C-6). The glc–ms of hydrolyzed, reduced, and acetylated **8** was similar to that of **3**, showing erythritol tetraacetate (T_{GA} 0.36) and L-rhamnitol pentaacetate (T_{GA} 0.51) (1:1).

Oligosaccharide 4

Fraction III, which contained hexuronic acid, eluted at the void volume of the Bio-Gel P2 column and was further purified by preparative tlc using the above-mentioned conditions to afford oligosaccharide **4** (6 mg, R_f 0.10). The oligosaccharide emerged in the trisaccharide region of a Sephadex G-15 column (1.7 × 95 cm). The trisaccharide had $[\alpha]_D$ 0° (*c* 0.12, water); ^{1}H nmr, δ (partial): 4.786 (s, 1H), 4.769 (d, 1H, $J_{1,2}$ = 7.8 Hz); ^{13}C nmr, Table 2. Glycose analysis of **4** gave erythritol tetraacetate (T_{GA} 0.36), L-rhamnitol pentaacetate (T_{GA} 0.51), and D-glucitol-6,6-d_2 hexaacetate (T_{GA} 1.00) (1:1:1). The permethylated trisaccharide (**9**) gave a single peak on glc (program C) (T_{CM} 1.92); ms (ei), *m/z* (relative intensity): 407 (0.2), 321 (0.6), 233 (7.1) [aA_1], 207 (44.5) [J_1], 201 (100.0) [aA_2], 169 (19.4) [aA_3], 157 (14.0), 147 (22.2), 141 (25.0), 129 (10.7), 115 (39.1), 101 (43.4), 89 (32.1), 88 (64.5), 85 (26.9), 71 (16.0), 59 (27.2), 45 (65.2). Following reduction of the methyl ester ($NaBD_4$), hydrolysis, reduction, and acetylation gave on glc–ms (program B) 1,4,5-tri-*O*-acetyl-2,3-di-*O*-methyl-L-rhamnitol-1-*d* (T_{GM} 0.98) and 1,5,6-tri-*O*-acetyl-2,3,4-tri-*O*-methyl-D-glucitol-1,6,6-d_3 (T_{GM} 1.98) (1:1).

Immunodiffusion

Double diffusion studies (57) were made at 4°C in 1% (w/w) agarose gels containing 0.8% (w/w) sodium chloride using 1 mg/mL concentrations of the polysaccharides. Precipitin lines were allowed to develop over 48 h. Type 22F factor serum was supplied by Dr. J. Henrichsen, Statens Serum Institut, Copenhagen.

General methods

Commercial reagents and solvents were analytical grade. Concentrations were made under reduced pressure at bath temperatures below 40°C. Optical rotations were determined at 22°C in 10-cm microtubes using a Perkin–Elmer 243 polarimeter.

Acknowledgments

We thank Mr. F. P. Cooper for glc–ms analyses and Dr. J. Henrichsen for providing us with type 22F pneumococcal factor sera.

Bis(imidazol-2-yl)phosphinic acid hemihydrate, $[(C_3H_3N_2)(C_3H_4N_2)PO_2].(1/2)H_2O$

HELEN E. HOWARD-LOCK, COLIN J. L. LOCK,[1] SARAH PENNY, AND MARY A. TURNER
Laboratories for Inorganic Medicine, Departments of Chemistry and Pathology, McMaster University, ABB 426, Hamilton, Ont., Canada L8S 4M1

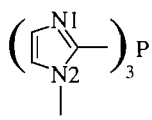
Received September 17, 1988

HELEN E. HOWARD-LOCK, COLIN J. L. LOCK, SARAH PENNY, and MARY A. TURNER. Can. J. Chem. **67**, 1051 (1989).

The title compound was obtained as the major product of our handling of the literature preparation of tris(imidazol-2-yl)phosphine. The compound was characterized by ^{1}H NMR, mass and vibrational spectroscopy. The structure was determined by single crystal X-ray diffraction. Crystals were triclinic, $P\bar{1}$, a = 7.677(1), b = 12.658(2), c = 10.072(2) Å, α = 91.18(1), β = 114.44(1), γ = 99.49(1)°, Z = 4. Intensities were measured on a Syntex $P2_1$ diffractometer with MoKα radiation and 3088 reflections were used to determine the structure. R = 0.0698, R_w = 0.0534. The phosphinic acid exists in the solid as the zwitterionic form and bond lengths and angles are normal.

Key words: tris(imidazol-2-yl)phosphine, X-ray structure, bis(imidazol-2-yl)phosphinic acid hemihydrate.

HELEN E. HOWARD-LOCK, COLIN J. L. LOCK, SARAH PENNY et MARY A. TURNER. Can. J. Chem. **67**, 1051 (1989).



En répétant la préparation de la tris(imidazolyl-2)phosphine décrite dans la littérature, on a obtenu le composé mentionné dans le titre comme produit principal. On l'a caractérisé par RMN du ^{1}H ainsi que par spectrométrie de masse et par spectroscopie vibrationnelle. On a déterminé sa structure à l'aide de la diffraction des rayons-X sur un cristal unique. Les cristaux sont tricliniques, $P\bar{1}$, avec a = 7,677(1), b = 12,658(2) et c = 10,072(2) Å, α = 91,18(1), β = 114,44(1) et γ = 99,49(1)° et Z = 4. On a mesuré les intensités à l'aide d'un diffractomètre Syntex $P2_1$ et de la radiation MoKα; on a utilisé 3088 réflexions pour déterminer la structure. R = 0,0698 et R_w = 0,0534. L'acide phosphinique existe dans le solide sous la forme zwitterionique et les longueurs des liaisons ainsi que les angles sont normaux.

Mots clés : tris(imidazolyl-2)phosphine, structure par rayons-X, hémi-hydrure d'acide phosphinique bis(imidazolyl-2).

Introduction

As part of our studies of metal complexes of ligands with two types of binding site, one soft and the other relatively hard (1), we became interested in tris(imidazol-2-yl)phosphine, **A**. In one of its substituted forms it has been used to bind zinc as a model for the protein carbonic anhydrase (2) and this zinc complex does act as a catalyst for the CO_2/HCO_3^- reaction (3). In this ligand there are three types of potential binding site, the

A

phosphorus atom, N1 and N2. The metal binding capabilities of N1 and N2 are very pH dependent since they will not bind metals when protonated. We attempted to prepare the ligand by a minor modification of the literature method (4), but the major product we obtained was not the desired compound and the fact that a copper(II) complex was neutral suggested the ligand was charged. We have investigated the product and identified it as bis(imidazol-2-yl)phosphinic acid. We describe this work here.

Experimental section

Imidazole orthoformate

The procedure was a modification of that of Curtis and Brown (4). The product was distilled under vacuum to give a clear colourless liquid (bp 90°C at 1 mm Hg).

Bis(imidazol-2-yl)phosphinic acid hemihydrate

The literature procedure for tris(imidazol-2-yl)phosphine was followed with minor modification (4). The procedure is described in full because of the different product obtained by us. *N*-butyllithium (1.6 *M* in hexane, 28.8 mL, 0.046 mol) was added with a syringe to dry ether (100 mL) in a round bottom flask, with a pressure equalized dropping funnel, at −78°C, under N_2. Imidazole orthoformate (7.86 g, 0.046 mol), dried over molecular sieves, was added by syringe to dry ether (10 mL) in the dropping funnel. The imidazole orthoformate was added slowly to the *n*-butyllithium and the solution was stirred for 15 min. This produced the lithium anion of the protected imidazole orthoformate. The dropping funnel was washed twice with ether (10 mL). PCl_3 (1.34 mL) was added by syringe to dry ether (10 mL) in the dropping funnel. The PCl_3 solution was added slowly to the lithium anion. When the addition of PCl_3 was complete the solution was stirred and allowed to warm up overnight. The round bottom flask was cooled in an ice bath and concentrated NH_4OH (100 mL) was added. The solution was stirred for 15 min. The ether layer was removed and dried over Na_2SO_4. The ether was then removed *in vacuo*. The residue was refluxed for 5 h in H_2O (10 mL) and acetone (100 mL). The white solid which separated was collected by filtration. Recrystallization was done from water (yield ~20%). Instead of the expected tris(imidazol-2-yl)phosphine, this white solid was found to be bis(imidazol-2-yl)phosphinic acid, mp 230°C, ^{1}H NMR (D_2O solvent) 7.25 ppm. In another attempt to prepare the desired tris(imidazol-2-yl)phosphine, we modified the literature procedure but this attempt was not successful. The following modifications in ratios and temperatures were made. The imidazole orthoformate was used in a 5:1 ratio with the PCl_3 rather than 3:1, and the reaction was carried out at 0°C, rather than at −78°C. When the residue was refluxed with water and acetone no solid appeared. The solvent was then removed *in vacuo* to produce an oil. Mass spectra and ^{1}H NMR revealed that the oil was a complex mixture.

Spectral measurements

Proton NMR spectra were recorded at 500.137 MHz on a Bruker AM-500 spectrometer with use of D_2O as an internal lock. Spectra were recorded over a 5 kHz sweep in 32K data points (3.277 s acquisition time). Suppression of the HDO resonance was achieved by pre-saturation during the 1.0 s delay before acquisition. Sample temperature was maintained at 30 ± 1°C by a Bruker B-VT1000 variable temperature unit. The free induction decays were processed using Gaussian multiplication for resolution enhancement. Chemical shift values are reported relative to TMS.

The FAB mass spectrum was recorded on a VG ZAB-E spectro-

[a] $R_{int} = \left[\frac{\Sigma\{Nx\Sigma[w(\langle F\rangle - F)^2]\}}{\Sigma(N-1)\Sigma wF^2}\right]^{1/2}$.

[b] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.

[c] $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2}$.

meter. The sample was dissolved in a thioglycerol/5% trifluoroacetic acid matrix and submitted to bombardment by Xe atoms (8 keV).

Infrared spectra were recorded on a Perkin-Elmer 283 grating spectrometer over the range 4000–200 cm^{-1}. The samples were prepared as KBr pellets. Spectra were calibrated against polystyrene. Raman spectra from powder samples were excited by the λ = 514.5 nm radiation of a Coherent Radiation Argon Laser Model 52 and measured over the range 3000–50 cm^{-1} on a Spex Spectrometer Model 14018. The wavenumber readout is accurate to ± 2 cm^{-1}. Spectral calibrations were made with the use of $HgCl_2$.

X-ray diffraction studies

The crystal used for diffraction studies was a colourless plate. Precession photographs showed the crystal to be triclinic and a Delaunay reduction showed no hidden symmetry. Cell parameters were obtained by least-squares refinement of the setting angles of 15 automatically centred reflections (21.7° < 2θ < 29.9°) measured on a Syntex $P2_1$ diffractometer with use of graphite-monochromated MoKα radiation (λ = 0.71069 Å). Crystal data and other information related to data collection are given in Table 1. Intensities were measured with a θ(crystal)–2θ(counter) scan. The density of the crystal was measured by suspension in a chloroform/bromoform mixture. Intensities were corrected for Lorentz-polarization effects, but not for absorption. This will cause a maximum error in F_o of <0.65%.

Although the correct space group is $P\bar{1}$, the structure was solved in $P1$. The strongest peak in the Patterson map was interpreted as a phosphorus atom and its centrosymmetrically related atom. Although difference syntheses revealed part of the structure, refinement ceased at R_w = 0.18. The structure was converted to $P1$ with one phosphorus atom placed at the origin. A series of refinements and difference syntheses revealed all the atoms. It became apparent that there were two molecules in the asymmetric unit and that the true space group was $P\bar{1}$. The initial problem was caused by the incorrect interpretation of the strongest peak in the Patterson map as that arising from a

*Atoms are related to those given in Table 2 by the relationships *a*: $1 - x, 1 - y, 1 - z$; *b*: $1 - x, 1 - y, -z$; *c*: $-x, -y, -z$; *d*: $x, 1 + y, z$.

pair of centrosymmetrically related atoms. The water molecule was located, and subsequent full-matrix least-squares refinement of all parameters (except the hydrogen temperature factors), which minimized $\Sigma w(|F_o| - |F_c|)^2$, was terminated when Δ/σ fell below 0.1. Reflections with $3\sigma_I \geq I \geq -3\sigma_I$ were treated by the method of French and Wilson (5). Scattering curves were taken from the International tables (6) and a correction for anomalous dispersion was made to the curve for phosphorus (7). No correction was necessary for secondary extinction. The atomic positional parameters are given in Table 2.[2]

Results and discussion

Molecule **1** is shown in Fig. 1 and selected interatomic distances and angles are given in Table 3.[3] Both molecules of the compound exist in the zwitterionic form such that there are both protonated and unprotonated imidazole rings attached to the phosphorus atom in each molecule. The P—O bond lengths in a given molecule are insignificantly different, but the mean distances in molecule **1** appear to be shorter than those in molecule **2** and the shortest P—O distance in molecule **1** is

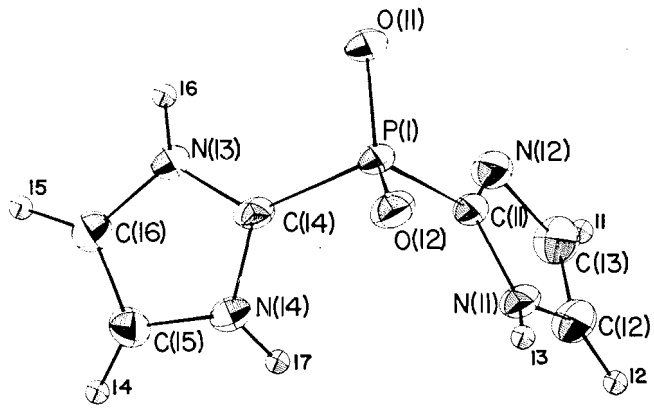

FIG. 1. Molecule **1** showing the atom numbering. The atoms in molecule **2** are numbered similarly, but the first affix is changed from **1** to **2**. Hydrogen atoms are given by affixes only in smaller print.

[2]The program DATRDN from the XTAL program (8) was used for preliminary data treatment. The structure was solved with use of SHELX (9). Planes calculations were made with LSQPL (10). Molecule and cell packing diagrams were obtained from SNOOPI (11).

[3]Tables of anisotropic temperature factors, hydrogen atom positional parameters, interatomic distances and angles involving hydrogen atoms, best planes and dihedral angles, and the moduli of F_o and F_c have been deposited. They may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

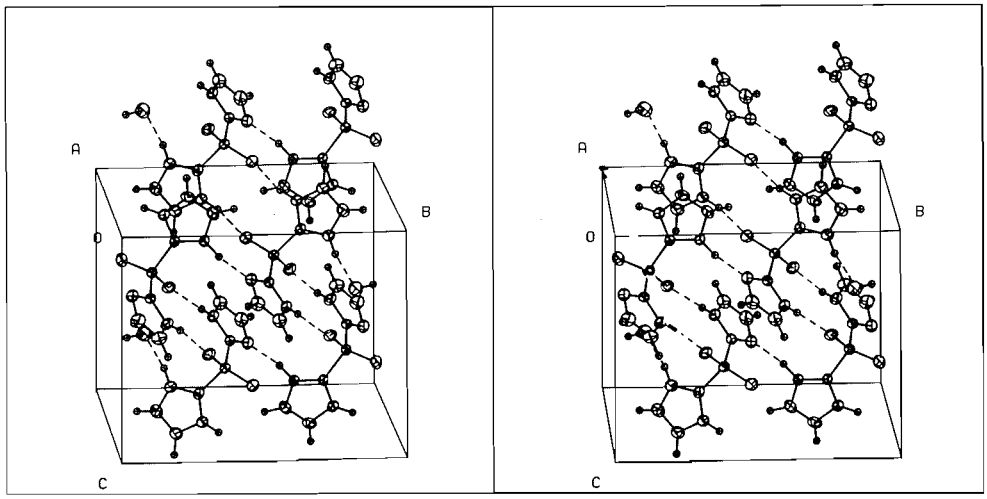

FIG. 2. The packing of the molecules in the unit cell. Hydrogen bonding is shown by broken lines. Molecule **1** is the left-hand one at the bottom of the figure and molecule **2** is the right-hand one.

significantly shorter than the longest P—O distance in molecule **2** ($\Delta = 4.94\sigma$). The difference is not caused by hydrogen bonding; the hydrogen bonds to the oxygen atoms in molecule **1** are stronger than those in molecule **2** (2.658(3), 2.761(3) Å vs. 2.812(3), 2.732(3) Å). The longer P—O distances in molecule **1** compared to molecule **2** are clearly related to the stronger P—C bonds in molecule **1**. The differences in P(1)—C(11) and P(2)—C(21) ($\Delta = 2.59\sigma$) and P(1)—C(12) and P(2)—C(22) ($\Delta = 3.06\sigma$) are significant at the 90% confidence level and may be related to changes in overlap of the *d* orbitals of the phosphorus atom and a π-system. Angles about the phosphorus atom are very roughly tetrahedral, the biggest variation being the O—P—O angles which are large (123.5(1), 121.8(1)°) because of the repulsion of the multiply bonded oxygen atoms; the O...O distances (2.57 Å, **1**; 2.60 Å, **2**) are shorter than the van der Waals distance (12). The C—P—C angles are correspondingly smaller than the tetrahedral angle (101.9(1), 104.6(1)°).

Protonation causes some significant changes in the bond lengths and angles in the imidazole group. While there are significant differences in the averages of C(*i*1)—N(*i*1) and C(*i*1)—N(*i*2), N(*i*1)—C(*i*2)—C(*i*3) and C(*i*2)—C(*i*3)—N(*i*2) (4.0°) and C(*i*2)—N(*i*1)—C(*i*1) and C(*i*3)—N(*i*2)—C(*i*1) (2.4°) ($i = 1, 2$) in the imidazole group these are removed on protonation. Protonation causes an increase in the internal ring angle at the protonated nitrogen atom (~4°) and consequent decreases in the adjacent angles at the carbon atoms (~3°) and a small increase in the angles at the opposite nitrogen atoms (~1°). Changes of this type on protonation of aromatic ring nitrogen atoms have been observed previously (13). Changes in bond lengths within the ring are hardly significant, although there is apparently a change in the lengths of bonds to the nitrogen atom opposite to the protonation site. N(*i*3)—C(*i*4) is longer (~0.02 Å) and N(*i*3)—C(*i*3) is shorter (~0.02 Å) than the corresponding bonds in the unprotonated imidazole. The surprising change is the significant lengthening of the P—C bonds to the protonated rings (average 0.033 Å). The dihedral angles between the two rings in each molecule are very similar (82.8(2)°, **1**; 77.1(2)°, **2**).

The packing is shown in Fig. 2 and is dominated by π–π interactions between imidazole rings and an extensive hydrogen bonding network. The two independent molecules form a pair such that each molecule lies roughly in the same orientation and pairs are hydrogen bonded together through the water molecule (N14—H...O3—H...O22). There are π–π interactions between pairs of centrosymmetrically related molecules (molecule **1**, ring 1, inversion centre at 1/2, 1/2, 1/2; molecule **2**, ring 1, inversion centre at 0 0 1/2) and between pairs of independent molecules (molecule **1**, ring 2 – molecule **2**, ring 2). There are hydrogen bonds between other centrosymmetrically related pairs (molecule **1**, N13...O11, inversion centre 0, 1/2, 1/2, molecule **2**, N23...N22, inversion centre 0, 0, 0) and between independent molecules (N24...N12, N21...O12, N11...O21). The remaining hydrogen bond is from O3...O21. This results in chains of molecules interacting through π–π interactions which lie roughly along [1 1 2]. Interactions between chains in the *a* direction are primarily van der Waals with the hydrogen bonds lying very roughly along [0 1 1].

TABLE 4. Mass spectrum of $(C_3H_3N_2)(C_3H_4N_2)PO_2$

M/Z	*I*	Assignment
595	6	$P_3 + H^+$
419	6	$P_2 + Na^+$
397	31	$P_2 + H^+$
237	5	$P + K^+$
221	16	$P + Na^+$
199	100	$P + H^+$
131	11	$P^+ - C_3H_3N_2$

Only a single proton nmr peak is observed at 7.25 ppm. No signal is seen for the protons attached to the nitrogen atoms because of exchange with the aqueous solvent and the exchange makes the protons attached to the carbon atoms equivalent.

The mass spectrum is given in Table 4. All peaks except one are derived from the parent ion plus a cation, as expected for a FAB spectrum. Higher peaks corresponding to two and three parent molecules plus a cation are of lower intensity. A peak at $m/z = 131$ corresponded to a parent ion which has lost an imidazole molecule.

The bis(imidazole)phosphinic acid spectra have been assigned by comparison with the imidazole spectra with the addition of bands associated with the P—C and P=O modes (14).

The vibrational spectra of imidazole have been assigned previously on the basis of a C_{2v} molecular model. The splitting

[b]ν = stretching frequency, δ = deformation.

of the νNH stretching band as well as the fact that there are two bands assignable to δNH deformations can be accounted for in C_{2v}, with protons equidistant from the two nitrogen atoms (15). The infrared spectrum of imidazole observed by us is similar. The broad absorption 2800–2600 cm^{-1} is typical of five-membered heteroaromatic rings with more than one nitrogen. There are strong interactions of force constants and a large amount of mixing among the mid-region frequencies.

The major product obtained by us was not that reported for the same reaction in the literature (4). By coincidence, the ^1H NMR parameters and melting points of the two compounds were identical, but there is no doubt about the nature of the compound described in the literature, since it was also characterized by analysis and mass spectrometry (16). The reason we obtained the phosphinic acid rather than the phosphine is probably because we used the general procedures for synthesizing the phosphines given in ref. 4 in which the hydrolysis step was carried out under reflux for 5 h in a water (10 mL)/acetone (100 mL) mixture, since we did not obtain any product when the mixture was stirred at room temperature. The room temperature reaction, given in a footnote, suggests the mixture did not *require* heating. In light of our experience the procedure should probably be modified to state the mixture should not be heated (4). The hydrolysis/oxidation does not occur on the recrystallization step even though we had to use water rather than methanol for recrystallization. The mass spectrum of the powder before recrystallization is identical to that of the crystals use for the X-ray study, with a parent ion m/z of 198, rather than the expected 232. The hydrolysis–oxidation reaction has been observed before in the preparation of a zinc complex (17). In this case, it was postulated that the zinc ions catalysed the hydrolysis–oxidation reaction, but no metal ions were present in our reaction so the reaction is obviously more facile than had previously been anticipated.[4]

The nature of selenium dissolved in hydrobromic acid containing selenium dioxide

JOHN MILNE
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received September 29, 1988

JOHN MILNE. Can. J. Chem. **67**, 1056 (1989).

Elemental selenium dissolves in solutions of selenium dioxide in hydrobromic acid. In 8.72 *M* HBr, there is complete reaction to give Se_2Br_2 and $SeBr_4^{2-}$ as shown by solubility studies and Raman spectroscopy. When the Se_2Br_2 concentration exceeds 0.0116 *M*, insoluble Se_2Br_2 is formed. The equilibrium constant for the reaction,

$$Se_2Br_2 + 2Br^- \rightleftharpoons SeBr_4^{2-} + Se^0$$

has been determined, $K = 0.025\ (\pm 0.002)\ mol^{-2}\ L^2$.

Solutions of SeO_2 and Se^0 in 4.8 *M* HBr contain Se(IV), Se(II), and Se(I) in equilibrium,

$$3SeBr_4^{-2} + H_2O \rightleftharpoons Se_2Br_2 + SeOBr_3^- + 7Br^- + 2H^+$$

The equilibrium constant for this reaction is $10.0\ (\pm 0.7) \times 10^{12}\ mol^8\ L^{-8}$. The solubility of Se_2Br_2 at saturation in 4.8 *M* HBr is 0.0052 *M*.

Key words: selenium bromides, bromoselenates, hydrobromic acid, solution equilibria, solubility.

JOHN MILNE. Can. J. Chem. **67**, 1056 (1989).

Le sélénium se dissout en solution du dioxyde de sélénium dans l'acide bromohydrique. L'étude de la solubilité et de la spectroscopie Raman de ces solutions ont montré que dans l'acide bromohydrique, 8,72 *M*, la réaction est complète et donne Se_2Br_2 et $SeBr_4^{2-}$. Quand la concentration de Se_2Br_2 dépasse 0,0116 *M*, le Se_2Br_2 devient insoluble. La constante d'équilibre de la réaction,

$$Se_2Br_2 + 2Br^- \rightleftharpoons SeBr_4^{2-} + Se^0$$

a été determinée, $K = 0{,}025\ (\pm 0{,}002)\ mol^{-2}\ L^2$.

Les solutions de SeO_2 et Se^0 en HBr, 4,80 *M*, contiennent Se(IV), Se(II) et Se(I) en équilibre,

$$3SeBr_4^{2-} + H_2O \rightleftharpoons Se_2Br_2 + SeOBr_3^- + 7Br^- + 2H^+$$

la constante d'équilibre pour cette réaction est $10{,}0\ (\pm 0{,}7) \times 10^{12}\ mol^8\ L^{-8}$. La solubilité de Se_2Br_2 au point de saturation en HBr, 4,80 *M*, est 0,0052 *M*.

Mots clés: bromures de sélénium, bromosélénates, acide bromhydrique, équilibres en solution, solubilité.

Introduction

Amongst the selenium chlorides and bromides only the diselenium dihalides, Se_2X_2, and the tetrahalides, SeX_4, are found as isolable substances. The dihalides, SeX_2, have been detected in vapour state (1, 2) and in non-aqueous solution (3, 4) but have not been prepared as pure compounds. Elemental selenium dissolves in hydrochloric acid containing SeO_2 and this has been accounted for by the formation of Se_2Cl_2 (5). Recently, however, it has been shown that such solutions contain significant concentrations of $SeCl_2$ or chloroselenate(II) (6). It was of interest to extend these studies to hydrobromic acid, where higher concentrations of Se(II) may be possible in view of the greater stability of $SeBr_2$ compared to $SeCl_2$ in acetonitrile (4).

Experimental section

Hydrobromic acid (Fisher, 48%) was analyzed for acid strength by titration against sodium carbonate and, for free bromine content, by iodimetry, against sodium thiosulfate. Acid strength was 8.72 *M* and free bromine content was 0.00125 *M*. Selenium dioxide (Aldrich) was analyzed by potentiometric acid base titration. Elemental selenium (Baker analyzed, pellets) was freshly ground before use.

Solutions of SeO_2 and HBr were saturated with elemental selenium by shaking for several hours in closed containers. Complete saturation was achieved for the SeO_2 concentrations studied, in 4 h. All experiments and measurements were carried out at room temperature (20°C). Initial SeO_2 concentrations were corrected to allow for the Se(IV) produced by oxidation of Se by free bromine in the HBr. No evidence of photooxidation in the timeframe of the experiments was noted. The concentration of dissolved elemental selenium (c_0) was determined by dilution in distilled water (1 in 4 minimum) and weighing of the precipitated selenium. The degree of dilution necessary for complete precipitation was determined by stepwise dilution to the point where no further precipitation occurred. Analysis for total Se content confirmed the stoichiometry,

$$c(\text{total Se}) = c_{IV} + c_0$$

where c_{IV} represents the initial SeO_2 concentration in HBr. Below the point of Se_2Br_2 saturation, elemental selenium was nearly twice as soluble, for the same c_{IV}, in 8.48 *M* HBr as in 11.80 *M* HCl (6).

Spectrophotometric measurements were made with a Varian DMS 90 UV-visible spectrophotometer using 1 cm and 1 mm path length quartz cells. All measurements were blanked against water.

Raman spectra were taken using a Jobin-Yvon spectrometer with PAR photon counting. The spectra were excited by a Spectra Physics Krypton Ion laser operating at 647.1 nm.

The preparation of $SeBr_4^{2-}$ salts from the solutions studied, with the addition of potassium or tetraethylammonium bromides, was attempted. The solids obtained were mixtures with crystals varying from orange to black in colour. Raman spectra showed them to consist mainly of hexabromoselenate(IV) and diselenium dibromide.

Results and discussion

When elemental selenium is dissolved in HBr solutions containing SeO_2, they turn from pale orange to dark orange. At low SeO_2 concentrations Se^0 is the insoluble phase but at higher SeO_2 concentrations, the insoluble phase becomes liquid Se_2Br_2. This is the basis of a preparative method for Se_2Br_2 (7).

8.72 M *HBr solutions*

The solubilities of elemental selenium in solutions of 8.72 *M* HBr containing various concentrations of SeO_2 are given in Table 1. A plot of c_0 against c_{IV}, Fig. 1, shows a straight line dependence of c_0 on c_{IV} up to $c_{IV} = 0.0165\,M$, followed by a plateau limit for which $c_0 = 0.0287\,M$. The insoluble phase for these latter solutions consisted of liquid Se_2Br_2 and solid selenium. The UV–visible spectra of the supernatant solutions were measured. The spectrum consists of an absorbance, increasing towards the UV from 600 nm with a shoulder at 385 nm, corresponding to a peak in the spectrum of Se_2Br_2 in carbon tetrachloride (3) and acetonitrile (4). The absorbances at 385 nm are listed in Table 1 and plotted in Fig. 1. The nature of the dependence of A_{385} on c_{IV} parallels that of c_0.

Elemental selenium is insoluble in pure HBr and the observed solubility must be due to reaction with Se(IV) to form species of intermediate oxidation state. The mean oxidation states (MOS) calculated from c_0 and c_{IV} by

$$[1] \qquad \text{MOS} = \frac{4 \times c_{IV}}{c_{IV} + c_0}$$

for the solutions studied are given in Table 1. Up to $c_{IV} = 0.0121$, the MOS remains constant at 1.49 ± 0.02. The apparent mean oxidation state then increases as part of the Se(IV) is used to produce insoluble Se_2Br_2. The constant MOS and the linear dependence of A_{385} on c_{IV} indicate that there is complete reaction with Se(IV) to give lower selenium bromides. Since the MOS is greater than unity, both Se_2Br_2 and some Se(II) species must be formed.

The Raman spectrum of a 0.05 *M* SeO_2 solution in 8.72 *M* HBr, saturated with Se, Fig. 2, exhibits three clearly distinguishable peaks at 103, 165, and 250 cm^{-1}. The two strongest peaks in the Raman spectrum of Se_2Br_2 are at 105 and 254 cm^{-1} (8), which accounts for the highest and the lowest bands observed. The remaining peak at 165 cm^{-1} cannot be due to $SeBr_2$, which has no peak at this frequency (4). The $SeBr_3^-$ and $SeBr_4^{2-}$ anions have bands at 159 and 162 cm^{-1} (9), respectively, and may be present in the solution. An additional band for $SeBr_3^-$ at 258 cm^{-1} may be hidden by the strong Se_2Br_2 peak at 254

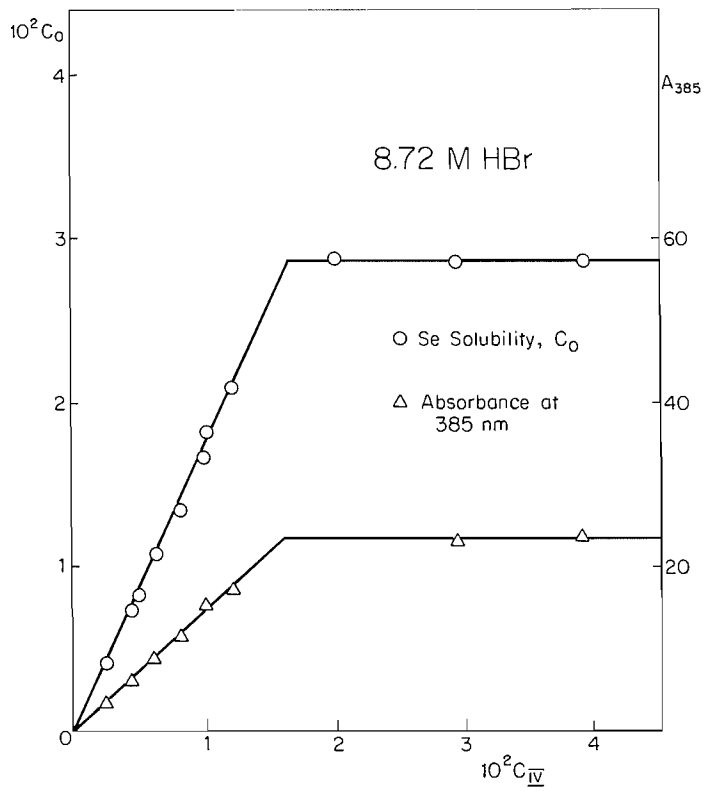

FIG. 1. Selenium solubilities and absorbances at 385 nm for 8.72 *M* HBr solutions of SeO_2.

cm^{-1}. However, in view of the high bromide ion concentration and the favourable formation constant for $SeBr_4^{2-}$ in acetonitrile (9), it is probable that $SeBr_4^{2-}$ is formed in these HBr solutions. Thus, the reactions which occur when Se is added to a solution of SeO_2 in 8.72 *M* HBr are

$$[2] \qquad SeBr_6^{2-} + 3Se \rightarrow 2Se_2Br_2 + 2Br^-$$

$$[3] \qquad 2Br^- + SeBr_6^{2-} + Se \rightarrow 2SeBr_4^{2-}$$

From the MOS in Table 1, the constant, K, for the equilibrium,

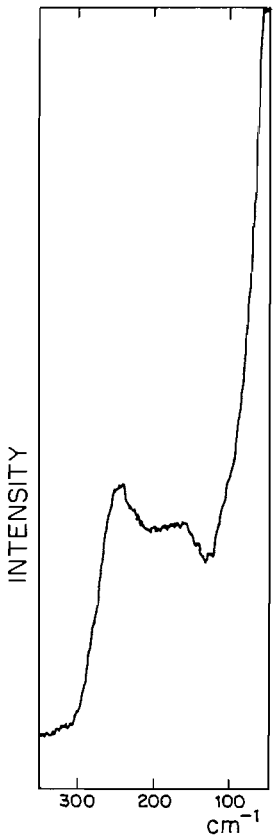

FIG. 2. The Raman spectrum of a 0.05 M solution of SeO_2 in 8.72 M HBr saturated with Se. Resolution, 10 cm^{-1}.

[4] $2Br^- + Se_2Br_2 \rightleftharpoons SeBr_4^{2-} + Se$

may be calculated, using the following equations,

[5] $$c_0 = \frac{[SeBr_4^{2-}]}{2} + \frac{3[Se_2Br_2]}{2}$$

[6] $$\frac{2[Se_2Br_2] + 2[SeBr_4^{2-}]}{c_{IV} + c_0} = MOS$$

[7] $$K = \frac{[SeBr_4^{2-}]}{[Se_2Br_2][Br^-]^2}$$

[8] $$[Br^-] = 8.72 - 4[SeBr_4^{2-}] - 2[Se_2Br_2]$$

The constant, K, is not a true thermodynamic equilibrium constant in as much as no allowance for activity coefficients has been made. The activity coefficient for Se_2Br_2 may be safely assumed to be unity but coefficients for the ionic species are unknown. However, the molar activity coefficient ratio, $y(SeBr_4^{2-})/y(Br^-)^2$, is expected to be nearly constant within the very small change in ionic strength over the range of c_{IV} and c_0 studied in the presence of such a large concentration of HBr. The equilibrium constant, K, is therefore a product of the true thermodynamic equilibrium constant, K_{th}, and the inverse of the activity coefficient factor. The value of this composite equilibrium constant and the concentration of Se_2Br_2, $SeBr_4^{2-}$, and Br^- for each solution are given in Table 1. The average value of K ($= K_{th} \times y(Br^-)^2/y(SeBr_4^{2-})$) is 0.025 ($\pm$0.002) $L^2\,mol^{-2}$. The measured absorbance of these solutions at 385 nm, A_{385}, is also shown in Table 1. Because the ratio $[Se_2Br_2]/[SeBr_4^{2-}]$ changes only slightly over the c_{IV} range studied and the absorbances are not sufficiently accurately determined, it was not possible to determine the extinction coefficients of the two species from the data.

From the plateau region of c_0 in Fig. 1, the solubility of Se_2Br_2 in 8.72 M HBr may be calculated. The average c_0 above $c_{IV} = 0.0165\,M$ is 0.0287 M. Using eqs. [5], [7], and [8] and $K = 0.025\,L^2\,mol^{-2}$, the saturation concentration of Se_2Br_2 in 8.62 M HBr is found to be 0.0116 M.

4.80 M *HBr solutions*

Table 2 gives c_0 and A_{385} values for solutions of SeO_2 in 4.8 M HBr, saturated with elemental selenium. Figure 3 shows the dependence of c_0 and A_{385} on c_{IV}. Below $c_{IV} = 0.100\,M$, the insoluble phase is Se^0 but above that concentration of SeO_2, the insoluble phase is Se_2Br_2 and Se^0. The MOS, given in Table 2, shows that the solutions contain Se(IV) species and the shoulder at 385 nm in the spectra of the solutions indicates the presence of Se_2Br_2. The curvature in the A_{385} and c_0 vs. c_{IV} plots shows that there is an equilibrium between Se(IV) and lower valent Se species. The principle Se(IV) species present at these concentrations in 4.80 M HBr is $SeOBr_3^-$ (10). Because of low concentrations, it is not possible to identify the lower valent Se species by Raman spectroscopy. If it is assumed that $SeBr_4^{2-}$ and Se_2Br_2 are formed as in the 8.72 M HBr solutions, the disproportionation equilibrium involved is

[9] $3SeBr_4^{2-} + H_2O \rightleftharpoons Se_2Br_2 + SeOBr_3^- + 7Br^- + 2H^+$

which is governed by the constant,

[10] $$K' = \frac{[Se_2Br_2][SeOBr_3^-][Br^-]^7[H^+]^2y^4}{[SeBr_4^{2-}]^3a}$$

where y is the mean molar ionic activity coefficient for HBr and a is the water activity. Since selenium solute concentration is small, y and a for pure HBr solutions may be used (11). The constant, K', is not a thermodynamic equilibrium constant, since no allowance for the activity coefficients of the selenium species and free Br^- ("non-HBr" Br^-) has been made. The activity coefficient for Se_2Br_2 may be assumed to be unity but the other ionic coefficients are unknown. The constant in eq. [10] may be expressed as,

[11] $$K' = K_{th} \times \frac{y(SeBr_4^{2-})^3}{y(SeOBr_3^-) \times y(Br^-)^5}$$

where K_{th} is the thermodynamic equilibrium constant and the y(ionic species)'s represent molar activity coefficients. The activity coefficient factor is expected to be nearly constant with the very small change in ionic strength over the range of c_{IV} and c_0 studied in the presence of the large HBr concentration. Therefore, K' is expected to be nearly constant.

The 4.8 M HBr solutions will contain four Se(IV) species, $HSeO_2Br$, $SeOBr_3^-$, $SeBr_5^-$, and $SeBr_6^{2-}$, the concentrations of which are governed by known equilibrium constants (10).

[12] $$K_2 = \frac{[SeOBr_3^-]a}{[HSeO_2Br][H^+][Br^-]^2y^2} = 9.5 \times 10^{-4}\,L^3\,mol^{-3}$$

[13] $$K_3 = \frac{[SeBr_5^-]a}{[SeOBr_3^-][H^+]^2[Br^-]^2y^4} \frac{y(SeBr_5^-)}{y(SeOBr_3^-)} = 8 \times 10^{-8}\,L^4\,mol^{-4}$$

[14] $$K_4 = \frac{[SeBr_6^{2-}]}{[SeBr_5^-][Br^-]} \frac{y(SeBr_6^{2-})}{y(SeBr_5^-) \times y(Br^-)} = 0.3\,L\,mol^{-1}$$

where the activity coefficient factors for Se species and "non-HBr" Br^- in [13] and [14] were assumed to be unity (10) (or the equilibrium constants are a composite of the thermodynamic equilibrium constant and an activity coefficient factor as above). The equilibrium constant of the disproportionation, K', may be determined by an iterative procedure from equations [5], [7], [12], [13], [14], the mass balance for Br,

$$[15]\quad c_{HBr} = 4.80 = [Br^-] + 2[Se_2Br_2] + 4[SeBr_4^{2-}] + [HSeO_2Br] + 3[SeOBr_3^-] + 5[SeBr_5^-] + 6[SeBr_6^{2-}]$$

the valence balance for selenium,

$$[16]\quad 4c_{IV} = 2[Se_2Br_2] + 2[SeBr_4^{2-}] + 4[HSeO_2Br] + 4[SeOBr_3^-] + 4[SeBr_5^-] + 4[SeBr_6^{2-}]$$

and the charge balance

$$[17]\quad [H^+] = 2[SeBr_4^{2-}] + [SeOBr_3^-] + [SeBr_5^-] + 2[SeBr_6^{2-}] + [Br^-]$$

The K' values calculated in this way are listed in Table 2 along with the concentrations of all Se species and Br^-. The predominant Se species in these solutions are $SeOBr_3^-$, $HSeO_2Br$, and Se_2Br_2 but significant amounts of $SeBr_4^{2-}$, containing selenium in the unusual 2+ oxidation state, are also present.

The saturation solubility of Se_2Br_2 in these 4.80 M HBr solutions may be estimated from the plateau c_0 value (0.0092 M) at c_{IV} above ca. 0.1 M using eqs. [5] and [7] and assuming $[Br^-] = 4.58\ M$, the bromide concentration of the highest c_{IV} concentration solution, before saturation, studied. This gives an estimated saturation concentration of Se_2Br_2 in 4.58 M HBr of 0.0052 M, which is lower than the solubility in 8.61 M HBr, 0.0116 N. This direct dependence of Se_2Br_2 solubility on HBr concentration parallels the normal solubility behaviour of non-electrolytes in concentrated strong acids (12) and is opposite to the normal "salting-out" effect on solubility at low electrolyte concentrations.

The extinction coefficients of Se_2Br_2 and $SeBr_4^{2-}$ at 385 nm may be determined from the measured absorbance of a solution of known composition in 4.80 M and 8.72 M HBr and the known extinction coefficients of $HSeO_2Br$ (0.0 cm^{-1} mol^{-1} L), $SeOBr_3^-$ (40 cm^{-1} mol^{-1} L), $SeBr_5^-$ (1450 cm^{-1} mol^{-1} L), and $SeBr_6^{2-}$ (1300 cm^{-1} mol^{-1} L) (10). From the absorbances for the 4.80 M HBr solution with $c_{IV} = 0.0283\ M$ and the 8.72 M HBr solution with $c_{IV} = 0.00636\ M$, the molar extinction coefficient of Se_2Br_2 is found to be 934 cm^{-1} mol^{-1} L and that of $SeBr_4^{2-}$, 564 cm^{-1} mol^{-1} L. From these extinction coefficients and those for Se(IV) species, the absorbance at 385 nm for the 4.80 and 8.72 M solutions may be calculated from the known concentrations of all species. These calculated absorbances are listed in Tables 1 and 2 and they compare reasonably well with the observed absorbances, which supports the interpretation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

the 4.80 *M* HBr results in terms of Se_2Br_2 and $SeBr_4^{2-}$ as the lower valent Se species present.

Conclusion

The $SeBr_4^{2-}$ ion has been characterized in solid and in acetonitrile solution (9) and the crystal structure of $[P(C_6H_5)_4]_2SeBr_4$ has been determined (13). The present study shows that this unique anion is present in aqueous HBr solutions as well. The concentrations of Se(II) species in HBr are higher than in HCl solution (6), which parallels the behaviour in acetonitrile (4). While it is possible to prepare $SeBr_4^{2-}$ salts from aprotic solvents, if a sufficiently large cation is chosen, preparation from aqueous HBr is not possible because of the low solubility of Se_2Br_2 and of the corresponding $SeBr_6^{2-}$ salt, which arise from disproportionation of the Se(II) species.

Carbon tetrabromide as an electron acceptor in heterogeneous photocatalysis[1]

H. AL-EKABI,[2] A. M. DRAPER,[3] AND P. DE MAYO

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 8, 1988

This paper is dedicated to Professor Sir Derek Barton on the occasion of his 70th birthday

H. AL-EKABI, A. M. DRAPER, and P. DE MAYO. Can. J. Chem. **67**, 1061 (1989).

Three reactions: the CdS-mediated valence isomerization of hexamethyldewarbenzene to hexamethylbenzene, the cycloreversion of dianthracene, and the TiO_2-mediated *cis–trans* isomerization of stilbene are known to be suppressed when the semiconductor excitation takes place in the absence of oxygen. The oxygen, when present, is presumed to trap the electron delaying electron–hole recombination. It has been found that CBr_4 may replace oxygen and functions in a similar way. In addition, the concomitant formation of oxidation products in the TiO_2-mediated aerobic reaction is avoided. The mechanism is discussed.

Key words: cadmium sulphide, carbon tetrabromide, dianthracene, heterogeneous photocatalysis, hexamethyldewarbenzene, titanium oxide.

H. AL-EKABI, A. M. DRAPER et P. DE MAYO. Can. J. Chem. **67**, 1061 (1989).

Il est connu que trois réactions (l'isomérisation de valence, sous l'influence du CdS, de l'hexaméthyldewarbenzène en hexaméthylbenzène; la cycloréversion du dianthrène ainsi que l'isomérisation *cis–trans* du stilbène sous l'influence du TiO_2) sont supprimées lorsque l'excitation semiconductrice a lieu en l'absence d'oxygène. Il est supposé que, lorsque l'oxygène est présent, il piège l'électron et retarde ainsi la recombinaison de l'électron dans le trou. On a trouvé que le CBr_4 peut remplacer l'oxygène et qu'il remplit les mêmes fonctions. De plus, on évite la formation concomitante de produits d'oxydation dans la réaction aérobique provoquée par le TiO_2. On discute du mécanisme.

Mots clés : sulfure de cadmium, tétrabromure de carbone, dianthracène, photocatalyse hétérogène, hexaméthyldewarbenzène, oxyde de titanium.

[Traduit par la revue]

Introduction

The recombination of photogenerated holes and electrons is an important process in the use of semiconductors. Rectification, transistor function, and photoconductivity all depend on the lifetime of the mobile carriers. This recombination rate is of paramount importance in heterogeneous photocatalysis with semiconductors if transformations of interest to the organic chemist are to be achieved. Recent studies on colloidal samples have indicated that these recombination processes occur on the ps–ns time scale (1–8). However, the trapping of either the conduction band electron by suitable electron acceptors, or the "hole" by suitable electron donors could, in principle, delay the energetically wasteful collapse.

Molecular oxygen has been found to enhance the rate of many semiconductor-mediated reactions (9–17). As an electron acceptor, adsorbed on the semiconductor surface, it traps the electron as superoxide ion. The latter has been detected as the spin adduct with 5,5-dimethyl-1-pyrroline 1-oxide (18, 19). The disadvantage of the use of oxygen is that accelerated reaction may be accompanied by oxidation. Whilst in certain cases oxidation may be a desired process (20–23), in many others it is not. For instance, the semiconductor photoinduced *cis–trans* isomerization of stilbenes in the presence of oxygen is usually associated with oxidation product formation (20, 24). Accordingly, we recognized the need for an electron trap which would not produce other complex by-products.

Carbon tetrabromide is known to be a good electron acceptor ($E^{red} = -0.3$ V vs. SCE (25)) and that the derived radical anion CBr_4^- dissociates rapidly at room temperature into $CBr_3^{\cdot}$ and bromide ion (26–32).[4] Provided the rate of reaction of D^+, obtained by oxidation of the donor (D) by the "hole", is slower than the rate of decomposition of CBr_4^- to radical and ion, then CBr_4 would act as an "irreversible" electron acceptor. We report below the results of our preliminary studies in this area.

Experimental

Chemicals

Methylene dichloride was of spectroscopic grade (BDH). HMDB (Aldrich) was purified by passage rapidly through a very short column (4 × 0.5 cm) of dry silica gel (Merck, 230–400 mesh). *cis*-Stilbene (Aldrich) was purified by fractional distillation and *trans*-stilbene (Kodak) was used without further purification. Dianthracene was prepared as previously described (33). Carbon tetrabromide (Aldrich) was crystallized from ethyl acetate.

General techniques

Irradiation sources used throughout this work: 150 W and 1000 W PRA xenon arcs. While the 150 W was used for CdS-mediated HMDB and dianthracene reactions the 1000 W was used for TiO_2-mediated stilbene reactions. For both lamps compressed air was used as collant and water filters were used to remove IR radiation. Prior to irradiation the mixture of the reactant and the semiconductor in methylene dichloride was sonicated for 10 min and was constantly stirred during the course of the irradiation. Except for the oxygen-free experiments, the reaction vessels were open to the atmosphere via a reflux condenser. For the oxygen-free experiments argon saturated with methylene dichloride was bubbled through the mixture for 15 min before starting the irradiation and was kept running during the irradiation. After irradiation, the semiconductor was removed by filtration. The filtrate, except in the case of the dianthracene reaction, was analyzed by a Varian 3700 gas chromatograph equipped with a flame ionization detector which was connected to a Hewlett Packard 3390 Å integrator. Analysis was performed on 2 m/2 mm column packed with OV-101 (10%) on chromosorb W(HP) 80–100 mesh. The yields of the oxida-

TABLE 1. Some physical properties of different CdS samples

CdS supplier	Purity (%)	Surface area[a] (m^2/g)	Crystalline structure[a]
Strem (lot no. 16027-S_1)	≥99.99	44	Polytype
Aldrich (lot no. 1721 PJ)	99.999	1.2	α
Aldrich (lot no. 053087)	98.8	7	β

[a]See ref. 43.

tion products of stilbene were determined by NMR. For dianthracene cycloreversion, the reaction (anthracene formation) was followed spectroscopically.

Valence isomerization of HMDB

Typically, 0.057 *M* of HMDB in methylene dichloride (6 mL) in the presence of CdS (50 mg) was irradiated at $\lambda > 400$ nm for 15 min using 150 W PRA xenon lamp. The reaction was conducted with three different CdS samples (see Table 1 for their physical properties) in the presence and absence of oxygen and/or carbon tetrabromide. Adequate removal of oxygen is important for reproducibility in CBr_4 experiments.

Cycloreversion of dianthracene

Solutions of dianthracene (6 mL; 0.001 *M*) in methylene dichloride in the presence of CdS (50 mg) were irradiated at $\lambda > 400$ nm using 150 W PRA xenon arc. The reaction was conducted, with two different CdS samples, in the absence of oxygen and the presence of various concentrations of carbon tetrabromide.

Isomerisation of cis*-stilbene*

Typically, 0.057 *M* of *cis*-stilbene in methylene dichloride (6 mL) in the presence of TiO_2 (25 mg) was irradiated at $\lambda > 380$ nm using a 1000 W PRA xenon arc. The reaction was conducted in the absence of oxygen and presence of different concentrations of carbon tetrabromide.

Results and discussion

The CdS-mediated valence isomerization of hexamethyldewarbenzene (HMDB) to hexamethylbenzene (HMB)

The above-named reaction has been reported (13, 16) and a cation radical chain mechanism proposed: a quantum yield greater than unity was obtained (13). It has also been reported (16) that the presence of oxygen is essential for efficient reaction. That this is so may be seen from the results in Table 2 using three different commercial samples of CdS (described in Table 1). For instance, the chemical yield with Strem CdS increased from 3% under argon to 20% in the presence of oxygen under defined conditions. With the same CdS sample under argon but in the presence of 0.0026 *M* CBr_4 the yield increased to 70%, indicating that CBr_4 is acting as an electron acceptor. In the presence of both oxygen and CBr_4 an intermediate yield was obtained, suggesting that bound CBr_4 is more effective than bound molecular oxygen, but that, in competition, O_2 is preferentially bound to the surface sites.

The effect of varying the concentration of CBr_4 on the yield of HMB obtained under specific defined conditions, is shown in Fig. 1. There is an increase with increasing concentration of CBr_4 which levels off at about $[CBr_4] \simeq 0.0005$ *M*. This is less, by two orders of magnitude, than the initial concentration of HMDB, and suggests that the CdS surface is then saturated with CBr_4 at the concentration of HMDB used. The resemblance to the Langmuir isotherm suggests that only CBr_4 molecules preadsorbed on the surface will accept the conduction band electron. Such a pathway has been proposed (the Langmuir–Hishelwood pathway) as one of two contributors to the overall

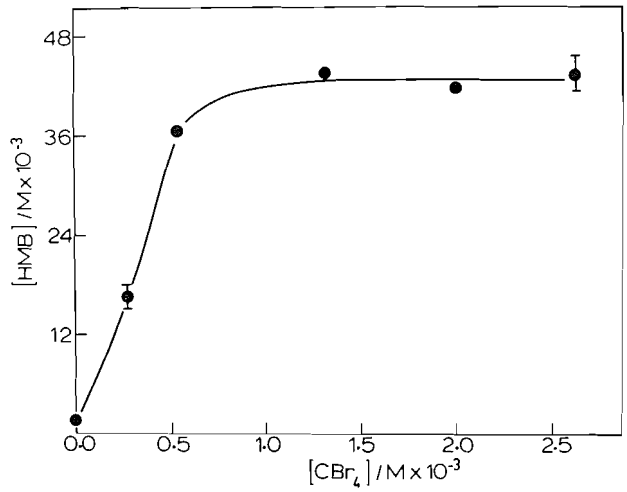

FIG. 1. Effect of CBr_4 concentration on yields of HMB formation. Each sample was irradiated at $\lambda > 400$ nm under argon for 15 min with a 150 W xenon lamp. [HMDB] = 0.057 *M*, CdS = 50 mg.

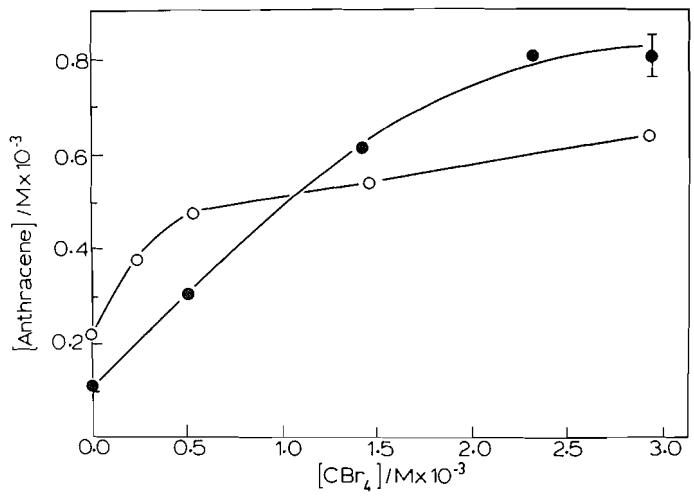

FIG. 2. Effect of CBr_4 concentration on yields of anthracene formation using two different CdS samples. Experiments conducted with Aldrich CdS sample (●) were irradiated for 30 min at $\lambda >$ 400 nm under argon with a 150 W xenon lamp while those with strem CdS sample (○) were irradiated for 2 h under similar conditions. [Dianthracene] = 0.001 *M*, CdS = 50 mg.

process, the second being the Eley–Rideal pathway. In principle, the lifetime of the reactive species (hole, electron, cation radical) bound to the surface determines the contribution of each pathway. In the present reaction, if our interpretation of Fig. 1 is correct, the lifetime of the conduction band electron appears to be too short to allow CBr_4 molecules in the bulk of the solution to diffuse to the surface and react (Eley–Rideal pathway). Recent studies (6, 7) have indicated that reduction of methyl viologen (MV^{2+}) by conduction band electron occurs on the surface within 100 ps of excitation of the colloidal CdS samples.

The CdS-mediated cycloreversion of dianthracene

This also has been shown (17) to proceed via a radical cation mechanism. The effect of CBr_4 concentration on the rate of anthracene formation was examined with two CdS samples: the Strem and Aldrich 99.999% (Table 1). The results are presented in Fig. 2. With the Strem the yield of anthracene obtained

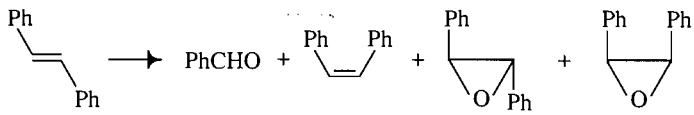
TABLE 2. Valence isomerization of HMDB to MMB under different conditions[a]

CdS supplier	Chemical yield (%) of HMB (±10%)			
	Ar[b]	Atm[c]	Atm + CBr_4[d]	Ar + CBr_4[d]
Strem (lot no. 16027-S_1)	3	20	28	70
Aldrich (lot no. 1721 PJ)	4	10	18	38
Aldrich (lot no. 053087)	2	9	23	35

[a]HMDB in CH_2Cl_2 (0.057 *M*; 6 mL) were irradiated for 15 min in the presence of CdS (50 mg), $\lambda > 400$ nm, 150 W xenon lamp.
[b]Reaction mixtures were purged with argon (saturated with CH_2Cl_2) for 15 min prior to irradiation and during the irradiation.
[c]Reaction mixtures are open to atmosphere via a reflux condenser.
[d]$[CBr_4] = 0.0026$ *M*.

under specific defined conditions, low in the absence of CBr_4 increased with increasing $[CBr_4]$ reaching, as was found with HMDB, a plateau at $[CBr_4] \simeq 0.0005$ *M*. The initial concentration of dianthracene was 0.001 *M*.



Since using the Strem CdS the initial concentration of HMDB is higher, by a factor of 57, than that of the dianthracene, but both achieve surface saturation with CBr_4 at the same concentration, one may tentatively suggest that the active sites at which CBr_4 is adsorbed are different from those utilized by HMDB and dianthracene.

Using the Aldrich CdS the same behaviour was observed except that the plateau was reached at ~0.0025 *M* CBr_4; higher, by a factor of five than found with the Strem. This is contrary to what would be expected on the basis of surface areas (Table 1) and is, presumably, to be attributed to their different crystalline form. Significantly, four times the irradication time was required for the Strem CdS to produce a comparable yield of anthracene as from the Aldrich CdS.

The TiO_2-mediated cis–trans *isomerisation of stilbene*

The results obtained with HMDB and dianthracene demonstrate the efficacity of CBr_4 as an electron acceptor with a semiconductor. However, these reactions are not associated with oxidation product formation even in the presence of oxygen. One reaction so associated is the *cis–trans* isomerization of stilbene in the presence of illuminated TiO_2.

Fox and Chen (20) have reported that when a suspension of TiO_2 in acetonitrile containing *trans*-stilbene **1** was irradiated ($\lambda = 350 \pm 30$ nm) in the presence of oxygen, four products **2–5** were obtained.

1 **2**:32% **3**:14% **4**:43% **5**:11%

More recently Tokumaru *et al.* (24) have reported that when a suspension of CdS or TiO_2 in acetonitrile containing **1** was irradiated (CdS, $\lambda > 430$ nm; TiO_2, $\lambda > 350$ nm) in the presence of oxygen **2** and **4** were obtained. Starting with **3** they obtained **1**, along with **2** and **4**. Further, under argon only **3** → **1** has been observed, the reverse process being barely discernible. We have also found that in the CdS-mediated *cis–trans* isomerization of stilbene, the photostationary state lies heavily on the side of the *trans*-isomer (34, 35). We have proposed, based on quenching data with methoxybenzenes, a cation radical mechanism (see refs. 36–38, however).

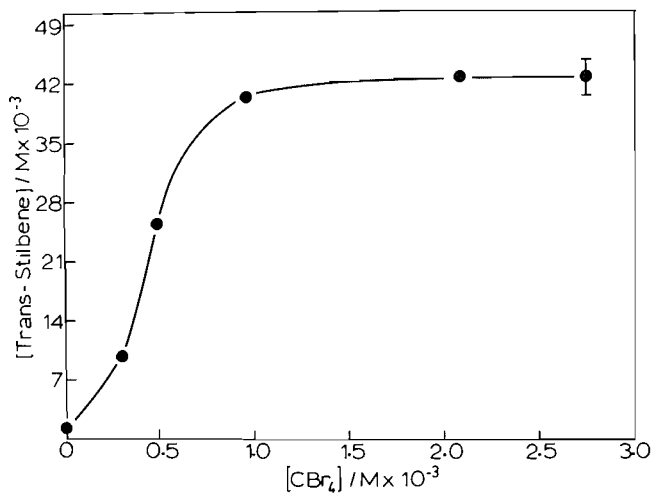


FIG. 3. Effect of CBr_4 concentration on yields of *trans*-stilbene formation. Each sample was irradiated at $\lambda > 380$ nm under argon for 30 min with a 1000 W xenon lamp. [*cis*-Stilbene] = 0.057 *M*, TiO_2 = 25 mg.

We have irradiated ($\lambda > 380$ nm) TiO_2 (Degussa P-25) in methylene chloride containing 0.057 *M* **1** for 1 h in an open system. Products **2** and **4** were formed in a total yield of 30% together with a trace of *cis*-stilbene. When the same experiment was performed in the presence of **3**, **1** was a major product (75%) with **2** and **4** in a total yield of 25%. In the absence of oxygen the isomerization of **3** was extremely slow. Addition of CBr_4 (0.0026 *M*) led to rapid isomerization and **1** was the only product.

Because of the reported **1** → **3** mentioned above (20) we took advantage of the facilitated process to determine the photostationary state. Approached from both sides we obtained **1**:**3** = 99.6:0.4. This is consistent with previous results (34, 35) obtained with CdS (>99:<1) and approximates the thermodynamic equilibrium (39). Accordingly, the formation of 14% **3** formed in TiO_2/MeCN may be attributed either to inadvertent direct irradiation or to sensitization by benzaldehyde a product of the experiment, or both.

The effect of CBr_4 concentration on the yield of **1**, obtained under specific defined conditions, was determined and is reported in Fig. 3. The plateau is reached ~0.001 *M* which is less by a factor of ~50 than the initial concentration of **3** (0.05 *M*); an observation which suggests that CBr_4 is strongly adsorbed on the TiO_2 surface. However, our attempt to determine the adsorption isotherm of CBr_4 on TiO_2 was not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12

successful as the sensitivity of the flame ionization detector to CBr_4 is very low.

Reversible or non-reversible trapping

It is generally known that substances such as CCl_4 (31, 40–42) or CBr_4 (26–31) accept an electron with dissociative attachment to give $CX_3^{\cdot}$ and X^-, but it appears not to known whether such a process can occur on the ps–ns time scale, i.e., whether CX_4 is a reversible or non-reversible trap. The problem can be tentatively discussed in terms of the unimolecular process $D \rightarrow P$, as outlined in Scheme 1. If step [*e*] be faster than any other process available to CBr_4^-, then the trapping is irreversible. If, on the other hand, step [*f*] can compete there is quenching without consumption of CBr_4. Step [*g*] permits product formation, if it can compete with [*e*] and there is no destruction of CBr_4. To our knowledge the occurrence of a step such as [*f*] and [*g*] in competition with [*e*] has not been unambiguously demonstrated, but evidence for its possible intrusion has been provided (see, for example, ref. 32).

[*a*] $SC \rightleftharpoons h^+ + e^-$

[*b*] $CBr_4 + e^- \rightarrow CBr_4^-$

[*c*] $D + h^+ \rightarrow D^{\ddagger}$

[*d*] $D^{\ddagger} \rightarrow P^{\ddagger}$

[*e*] $CBr_4^- \rightarrow CBr_3^{\cdot} + Br^- \left(\rightarrow \begin{matrix} C_2Br_6 \\ + \\ CHBr_3 \end{matrix} \text{ ref. 32}\right)$

[*f*] $CBr_4^- + D^{\ddagger} \rightarrow CBr_4 + D$

[*g*] $CBr_4^- + P^{\ddagger} \rightarrow CBr_4 + P$

[*h*] $D^{\ddagger} + e^- \rightarrow D$

[*i*] $P^{\ddagger} + e^- \rightarrow P$

SCHEME 1

If such a process be participating in the reactions under discussion, then the amount of CBr_4 decomposed during irradiation of the semiconductor in the presence of reactant D should be less than in its absence. Experimentally, it was found that irradiation of TiO_2 (argon) in methylene chloride containing CBr_4 (0.0026 *M*) for 1 h using a 1000 W lamp led to the decomposition of 15% CBr_4. However, when the mixture was 0.05 *M* in **3** the amount of CBr_4 decomposed decreased to 5%.

DANIEL BUR, MARCEL A. LUYTEN, HLA WYNN, LOUIS R. PROVENCHER, J. BRYAN JONES, MARVIN GOLD, JAMES D. FRIESEN, ANTHONY R. CLARKE, and J. JOHN HOLBROOK. Can. J. Chem. **67**, 1065 (1989).

The potential utility of the L-lactate dehydrogenase of *Bacillus stearothermophilus* (BSLDH) for stereospecific, preparative-scale reductions of α-keto acids to (*S*)-α-hydroxy acids of >99% ee has been demonstrated. BSLDH is a stable, thermophilic, enzyme whose gene has been cloned into a high-expression vector to assure its plentiful supply. Its specificity for keto acid substrates possessing straight- and branched-chain alkyl, cyclopropyl, or phenyl groups has been evaluated in preparative and kinetic terms, and compared with that of the mammalian pig heart enzyme (PHLDH). The specificities of BSLDH and PHLDH are similar, with branched alkyl-chain keto acids being poor substrates for both enzymes.

Key words: enzymes in organic syntheses, lactate dehydrogenase, asymmetric synthesis.

DANIEL BUR, MARCEL A. LUYTEN, HLA WYNN, LOUIS R. PROVENCHER, J. BRYAN JONES, MARVIN GOLD, JAMES D. FRIESEN, ANTHONY R. CLARKE et J. JOHN HOLBROOK. Can. J. Chem. **67**, 1065 (1989).

On a démontré que la déshydrogénase L-lactique du *Bacillus stearothermophilus* (DHLBS) peut être utile pour effectuer des réductions stéréospécifiques, à l'échelle préparative, d'acides α-cétoniques en (*S*)-α-hydroxyacides >99% ee. La DHLBS est un enzyme stable et thermophile dont on a reproduit les gènes en lignées afin de s'assurer de leur grande disponibilité. On a évalué sa spécificité, tant cinétique que préparative, par rapport à des substrats céto-acides possédant des chaînes alkyles linéaires et ramifiées ainsi que des groupements cyclopropyles et phényles et on l'a comparée à celle de l'enzyme cardiaque du cochon (DHLCC). Les spécificités des DHLBS et DHLCC sont semblables et, pour chacun de ces enzymes, les céto-acides portant des chaînes ramifiées sont de mauvais substrats.

Mots clés : enzymes en synthèses organiques, déshydrogénase lactique, synthèse asymétrique.

Introduction

The application of enzymes for the generation of chiral synthons for asymmetric synthesis is well documented (2). Alcohol dehydrogenases, which catalyze C=O ⇄ CH(OH) interconversions and in whose preparative applications we have been involved (1), have been especially widely exploited. We have selected the L-lactate dehydrogenase of *Bacillus stearothermophilus* (BSLDH)[3] as a model system in connection with our interest in exploiting further the applicability of the oxidoreductase group of enzymes in organic synthesis. BSLDH is an excellent candidate for such exploratory studies since it is a very stable, thermophilic, enzyme of known protein sequence (4*a*, *b*) and its properties have already been the subject of several studies (4–7). Its gene has been cloned (4*c*, 5) and the protein very efficiently overexpressed (5), thereby enabling large quantities of BSLDH to be produced inexpensively from small fermentation volumes. Furthermore, the feasibility of altering the specificity of the native enzyme by site-directed mutagenesis of key active-site amino acid residues has just been established (8).

Lactate dehydrogenases (LDH's) are nicotinamide coenzyme-dependent enzymes whose in vivo function (9) is to catalyze pyruvate (**1***a*) – lactate (**2***a*) oxidoreductions as shown in eq. [1].

[1] $$\underset{\mathbf{1}}{\text{RCOCOOH}} + \text{NADH} + \text{H}^+ \rightleftharpoons \underset{\mathbf{2}}{\text{RCH(OH)COOH}} + \text{NAD}^+$$

b: R = CH_2CH_3
c: R = $CH_2CH_2CH_3$
d: R = $CH(CH_3)_2$
e: R =
f: R = $CH_2C_6H_5$

While the natural LDH substrates **1**, **2***a* are small molecules possessing only a methyl side chain, LDH's from various mammalian and bacterial sources can tolerate a significant diversity in the structures of their 2-keto or 2-hydroxy acid substrates (10). In fact, sevral LDH's have already been applied in preparative-scale reactions (10*g*, 11) and in NADH recycling systems (12).

As the first step towards our evaluation of BSLDH, we examined its substrate specificity towards the 2-keto acids **1***a–f* in both preparative and kinetic terms. To provide a benchmark comparison of the BSLDH, the kinetic data of the mesophilic L-lactate dehydrogenase from pig heart (PHLDH) (13) were also determined for the same substrates.

Results

The keto acids **1***a–d*,*f* were commercially available and the

(±)-**3***f*	0.00	0.20

[a]At 400 MHz in $CDCl_3$.

cyclopropyl substrate **1***e* was prepared by the literature (14) method. BSLDH was readily obtained using the cloned gene of Barstow *et al.* (5), and employing a hydrophobic chromatographic purification procedure. PHLDH was commercially available material.

Preparative-scale reductions of **1***b–f* to the corresponding (2*S*)-hydroxy acids **2***b–f* were performed using BSLDH as catalyst, and employing formate/formate-dehydrogenase (FDH) recycling of NADH (10*g*, 12*e*, 15). The results are summarized in Table 1.

The (2*S*) absolute configurations of the product acids were assigned on the basis of their known rotations for **2***b* (16), **2***d* (17), and **2***f* (18), and by correlating the ^{1}H nmr chemical shifts of the methoxyl groups of the Mosher esters of **2***c* and **2***e* with the configuration of **2***b* (19).

For the enantiomeric excess (ee) determinations, the hydroxy acids (2*S*)-**2***b–f* were first converted to the corresponding methyl esters with diazomethane, and the C-2 hydroxyl groups then esterified with (*S*)-(+)-MTPA chloride (20) to give the Mosher ester derivatives (2*S*)-**3***b–f*. The ee values of these esters were obtained from ^{1}H nmr examinations of their methyl ester and methoxyl protons, using the Mosher esters "(±)"-**3***b–f*, prepared from the racemic acids (±)-**2***b–f*, as reference standards. The corresponding Δδ values for the latter are recorded in Table 2. In addition, capillary glc analyses of "(±)"-**3***b–f* showed base-line separations of the two diastereomers, with the (2*S*) diastereomers having the higher retention times. The glc analyses of (2*S*)-**3***b–f* confirmed the >99% ee values determined by nmr.

The kinetic parameters k_{cat} and K_M for **1***a–f* were evaluated under steady-state conditions for both BSLDH and PHLDH. The values are recorded in Table 3.

Discussion

The selection of BSLDH as a potentially useful enzyme for preparative-scale asymmetric syntheses was based on several criteria. It is an enzyme composed of two (at low concentrations) or four (at high concentrations or when allosterically activated by FDP) identical subunits (21*a*) and a great deal is known about its catalytic mechanism (7, 21). Of prime importance is the fact that it is a very stable enzyme of high activity and, being a thermophile (4*c*,*d*), can, if necessary, operate at the elevated temperatures often required in organic synthesis. Furthermore, a plentiful supply is assured as a result of the highly successful cloning of its gene into the pKK223-3 vector (5). When this is expressed in *Escherichia coli* TG1, BSLDH is produced in amounts of up to ~35% of the soluble proteins, from which it is easily purified, thereby enabling large quantities of the enzyme to be prepared from small fermentation volumes.

As the first step in our synthetic applications programme, we elected to evaluate the specificity and preparative-scale viability of BSLDH against that of a representative and well-documented mammalian enzyme (9, 10*g*, 13), PHLDH.

The reduction direction of eq. [1] was selected since, being an enantiotopically face-specific process, it is of more asymmetric synthetic interest than that of the reverse, oxidation, reaction. Also, on the preparative scale, reductions are easier to effect, being thermodynamically heavily favored (9), and with good methods for recycling of the nicotinamide coenzyme available (12, 15).

Despite the wide variation in activities of BSLDH towards the Table 1 substrates, the enzyme performed satisfactorily under preparative-scale conditions. The reactions were carried out on the 1–3 mmol scale and gave good yields of enantiomerically pure (2*S*) hydroxy acids (Table 1). Pyruvate itself was not subjected to preparative-scale reduction since its LDH-catalyzed conversion to L-lactic acid is so well documented (9). Product inhibition by the cyclopropyl acid **2***e* (11*e*) was not a problem with this enzyme. For 2-oxo-3-methylbutanoate (**1***d*), with a K_M of 17 mM, FDP was used to activate the BSLDH allosterically, thereby lowering the K_M (22). The purification of the hydroxy acid product **2***d* was not affected by the presence of FDP. We estimate that any substrate of BSLDH with a $k_{cat}/K_M \geq 10$ will be a satisfactory synthetic-scale candidate.

The kinetic measurements were carried out to provide a quantitative basis for comparison of the effects of the structural differences in **1***a–f* on the rates of reduction between the bacterial (BSLDH) and the well-known mammalian pig heart (PHLDH) enzyme. The kinetic parameters for the two enzymes (Table 3), which are in generally good agreement with the literature values available, show some interesting contrasts.

For the natural substrate pyruvate (**1***a*), the reduction is very fast and k_{cat} and K_M are about the same for both enzymes. For all the non-natural substrates **1***b–f*, the reduction processes are less facile to a greater or lesser extent, with k_{cat} lowered and K_M increased in each case.

For **1***b* and **1***c*, the next higher homologues of pyruvate, there is a marked decrease in activity of ~(2–8) × 10^2-fold within the series **1***a–c*, which is accounted for by the progressive increase in size of the alkyl substituents.

Branching at the 3-position of 2-keto acid substrates is seen to lower the enzyme activity dramatically. For **1***d*, the presence of the isopropyl group results in a reduction of the pyruvate k_{cat}/K_M value by ~10^5-fold for both enzymes. The highly deleterious effect of the 3-methyl substituent is also very clearly

TABLE 3. Kinetic parameters for BSLDH-catalyzed reductions of **1***a–f*[a] (values for PHLDH in parentheses)[a]

Substrate	k_{cat} (s^{-1})		K_M (mM)		k_{cat}/K_M (M^{-1} s^{-1})	
1*a*	188	(203)	0.04	(0.03)	4.76×10^6	(6.34×10^6)
1*b*	155	(101)	0.34	(0.43)	4.55×10^5	(2.33×10^5)
1*c*	44	(11)	2.38	(1.45)	1.85×10^4	(7.63×10^3)
1*d*	0.49	(0.65)	17	(3.9)	2.91×10^1	(1.66×10^2)
1*e*	5.0	(7.3)	1.74	(1.67)	2.87×10^3	(4.37×10^3)
1*f*	81	(5.4)	0.67	(1.47)	1.21×10^5	(3.67×10^3)

[a]At 25°C, pH 6.0 in triethanolamine-HCl buffer (20 mM) with [FDP] 5 mM, [S] $0.2K_M$–$6K_M$, [NADH] 0.2 mM, and [E] (0.2–5000) $\times 10^{-9}$ M.
[b]At same conditions as described under *a* but at pH 7.0 in phosphate buffer (100 mM) without FDP.

demonstrated by the 6×10^2-fold (BSLDH) and 50-fold (PHLDH) lowering of k_{cat}/K_M for **1***d* compared with its structurally isomeric parent 2-oxopentanoate (**1***c*).

The C-3 substituent effect is significantly ameliorated if the branching is part of a small ring. This is demonstrated by the results for the cyclopropyl substrate **1***e* for which the specificity constants are only slightly lower than for the isomeric 2-oxopentanoate (**1***c*) substrate.

When the branching is at the 4-position and is part of a planar phenyl ring, as in **1***f*, the two enzymes perform significantly differently, with **1***f* being much better tolerated by BSLDH (33-fold) than by PHLDH. In fact, the specificity constant for the BSLDH-catalyzed reduction of phenyl pyruvate (**1***f*) is even higher than that for the much less bulky 2-oxopentanoate (**1***c*).

2-Hydroxy acids have been widely recognized as useful chirons (23). This has stimulated many investigations of chemical (24) and fermentation (25, 26) methods for their preparation in enantiomerically pure forms. Enzyme-based approaches have also been demonstrated to be very powerful (10*g*, 11, 27). The initial results reported here with BSLDH show that this enzyme is an excellent choice as a catalyst for the preparation of a broad structural range of enantiomerically pure α-hydroxy acid chirons (23*a*). We are now exploring further the tolerance of the enzyme towards structural variations in its substrates, and the synthetic potential of predetermining the specificity of the enzyme in a controlled manner via the site-directed mutagenesis techniques of protein engineering (8, 28).

Experimental

Melting points were measured in an electrothermal capillary apparatus, and are uncorrected. The ir spectra were recorded on a Nicolet 5DX FT-IR system as liquid films, or in KBr if solid. Proton nmr spectra were obtained in $CDCl_3$, unless noted otherwise, using Varian T60, XL200, or XL400 spectrometers. Optical rotations were measured with a Perkin–Elmer 141 polarimeter. The glc analyses were performed on a Varian Aerograph 3400 fitted with a capillary DB wax column (25 m × 0.25 mm) and flame ionization detectors. The pH-stat used was a Metrohm 655 instrument.

NAD^+ was purchased from the Kyowa Hakko Kogyo Co. The pig heart L-lactate dehydrogenase (EC 1.1.1.27) used for kinetics was the H_4 enzyme from Boehringer Mannheim (batch no. 10525921-14). Formate dehydrogenase (from yeast, EC 1.2.1.2) was obtained in lyophilized form from Boehringer Mannheim (batch no. 10978222-78). (*R*)-(+)-Methoxytrifluoromethylphenylacetic acid ((*R*)-(+)-MTPA) was purchased from Aldrich.

Substrates

Except for **1***e*, all 2-oxo acids **1***a–f* were purchased from Sigma Chemical Co., and were used as received. 2-Cyclopropyl-2-oxoacetic acid (**1***e*) was prepared as its potassium salt, as described by Basnak and Farkas (14), in 65% yield; mp 260°C (dec.) (lit. (14) mp 258°C (dec.); ir: 2990, 1690, 1620, 1361 cm^{-1}; ^1H nmr (DMSO-d_6): 0.81 (4H, m) and 2.23 (1H, m) ppm.

Preparation of BSLDH

The gene, cloned into a pKK223-3 plasmid, was expressed in *E. coli* TG1 as described by Barstow *et al.* (5). Cells were grown overnight (16 h) in YT (2×) medium (16 g Bactotryptone, 10 g yeast extract, 5 g NaCl per litre) supplemented with ampicillin and harvested by centrifugation (10 min at 4000*g*). The cells were resuspended in 10 mM sodium phosphate buffer pH 6.3, lysed by sonication, and the cell debris removed by centrifugation (10 min at 9000*g*). The supernatant was heated for 90 min at 65°C with occasional swirling, and the denatured proteins removed by centrifugation (15 min at 14 000*g*). The supernatant was brought to 25% ammonium sulfate saturation and loaded onto a phenyl-Sepharose column (Pharmacia, 5.5 mL/g of wet cells) previously equilibrated with 25% saturated ammonium sulfate in 10 mM sodium phosphate buffer pH 6.3. A step gradient down to 0% ammonium sulfate saturation in the above phosphate buffer removed bulk proteins. The LDH protein was eluted with 2 column volumes of a linear gradient of ethylene glycol (0–50%) in 10 mM phosphate buffer pH 6.3 and yielded ~250 mg (120 000 units) of LDH per litre of overnight culture. Fractions were assayed by the method of Schaer and Zuber (4*d*). Those with LDH activity were dialyzed against 10 mM sodium phosphate buffer pH 6.3 and were >95% pure as judged by polyacrylamide gel electrophoresis in SDS (29). This level of purity was satisfactory for all the preparative scale reductions. The enzyme was stored in 2 M ammonium sulfate at 4°C.

Preparative scale BSLDH catalyzed reductions of ***1*** b–f

BSLDH and FDH were assayed prior to the experiments by the literature methods (refs. 4*d*, 30*a* for PHLDH, and 30*b* for FDH).

The same basic procedure was used for all preparative-scale LDH-catalyzed reactions, as follows: the keto acid substrate and 1.2 equivalents of sodium formate were dissolved in Tris-HCl buffer (5 mM, pH 6.0) and the solution deoxygenated with bubbling nitrogen for 30 min. The enzyme-catalyzed reaction, carried out under positive nitrogen atmosphere at 23°C, was initiated by adding NAD^+, dithiothreitol (0.5 μM), FDH, and BSLDH. The gently stirred solution was kept at a constant pH of 6.0 by adding hydrochloric acid (0.1 or 0.5 M) using a pH-stat. After 1 equivalent of acid had been added, the solution was acidified to pH 2 with 6 M hydrochloric acid, filtered through a Hyflo SuperCel-packed sintered funnel, and extracted with ethyl acetate (3×). The organic phases were dried ($MgSO_4$) and the solvent rotoevaporated. The hydroxy acid products were then recrystallized.

The individual reactions gave the following results.

BSLDH-catalyzed preparations of ***2*** b–f

*(S)-2-Hydroxybutanoic acid (**2** b)*

2-Oxobutanoic acid (**1***b*, 101.8 mg, 1 mmol), NAD^+ (5.1 mg), BSLDH (400 U), FDH (8.4 mg, 4.3 U), Tris-HCl buffer (10 mL), reaction time 15 h, recrystallization from $CHCl_3$, gave **2***b* (90.6 mg,

88%, >99% ee); mp 48–49°C (lit. (16) mp 52.7–53.5°C (dec.)); $[\alpha]_D^{25}$ +6.4° (*c* 2.63, $CHCl_3$) (lit. (16) $[\alpha]_D^{21}$ +6.4° (*c* 11.03, $CHCl_3$); ir (KBr): 1131, 1735, 2938, 2973, 3402, 2600–3676 cm^{-1}; ^1H nmr (400 MHz) δ: 0.99 (3H, t, J = 7 Hz), 1.74 (1H, m), 1.88 (1H, m), 4.24 (1H, dd, J = 7 Hz, J' = 5 Hz), and 5.95 (2H, br s, OH and COOH) ppm.

*(S)-2-Hydroxypentanoic acid (***2**c*)*

2-Oxopentanoic acid, sodium salt (**1***c*, 138.3 mg, 1 mmol), NAD^+ (5.1 mg), BSLDH (430 U), FDH (8.9 mg, 4.5 U), Tris-HCl buffer (10 mL), reaction time 35 h, recrystallization from CCl_4, yielded **2***c* (105.7 mg, 89%, >99% ee); mp 52–55°C (lit. (10*g*) mp 57.8–58.5°C); $[\alpha]_D^{25}$ +5.9° (*c* 1.25, $CHCl_3$), $[\alpha]_D^{25}$ −3.3° (*c* 1.0, H_2O) (lit. (31) $[\alpha]_D^{25}$ −2.7° (*c* 1–5%, H_2O); ir (KBr): 1131, 1215, 1728, 2959, 3367, 2400–3711 cm^{-1}; ^1H nmr (400 MHz) δ: 0.94 (3H, t, J = 7 Hz), 1.46 (2H, m), 1.66 (1H, m), 1.79 (1H, m), 4.25 (1H, dd, J = 7 Hz, J' = 4 Hz), and 5.40 (2H, br s, OH and COOH) ppm.

*(S)-2-Hydroxy-3-methylbutanoic acid (***2**d*)*

3-Methyl-2-oxobutanoic acid, sodium salt (**1***d*, 414 mg, 3 mmol), NAD^+ (15 mg), BSLDH (3000 U), FDH (23.6 mg, 12 U), Tris-HCl buffer (20 mL), FDP (60.5 mg, 0.11 mmol), reaction time 42 h, recrystallization from CCl_4, afforded **2***d* (305 mg, 86%, >99% ee); mp 66°C (lit. (17) mp 65°C); $[\alpha]_D^{25}$ +17.2° (*c* 1.85, $CHCl_3$) (lit. (17) $[\alpha]_D^{14}$ +16.9° ± 2° (*c* 1.85, $CHCl_3$); ir (KBr): 1032, 1707, 2973, 3423, 2400–3600 cm^{-1}; ^1H nmr (400 MHz) δ: 0.91 (3H, d, J = 7 Hz), 1.05 (3H, d, J = 7 Hz), 2.14 (1H, m), 4.13 (1H, d, J = 3 Hz), and 7.3 (2H, s, br) ppm.

*(S)-2-Hydroxy-2-cyclopropylethanoic acid (***2**e*)*

2-Cyclopropyl-2-oxoethanoic acid, potassium salt (**1***e*, 304 mg, 2 mmol), NAD^+ (10 mg), BSLDH (1000 U), FDH (15.7 mg, 8 U), Tris-HCl buffer (20 mL), reaction time 42 h, recrystallization from CCl_4, produced **2***e* (206 mg, 89%, >99% ee); mp 98°C (lit. (10*g*) mp 97–98.5°C); $[\alpha]_D^{25}$ +44° (*c* 0.87, $CHCl_3$); ir (KBr): 1075, 1264, 1721, 3430, 2400–3600 cm^{-1}; ^1H nmr (400 MHz) δ: 0.50 (4H, m), 1.15 (1H, m), 3.81 (1H, d, J = 7 Hz), and 6.20 (2H, br s, OH and COOH) ppm.

*(S)-2-Hydroxy-3-phenylpropanoic acid (***2**f*)*

2-Oxo-3-phenylpropanoic acid (**1***f*, 301 mg, 1.84 mmol), NAD^+ (10.3 mg), BSLDH (800 U), FDH (22.1 mg, 11.3 U), Tris-HCl buffer (20 mL), reaction time 2.1 days, recrystallization from $CHCl_3$, yielded **2***f* (276 mg, 90%, >99% ee); mp 125–126°C (lit. (18) mp 124–125°C); $[\alpha]_D^{25}$ −24.7° (*c* 3.2, H_2O) (lit. (18) $[\alpha]_D^{25}$ −19.9° (*c* 3.2, water)); ir (KBr): 1735, 2600, 3451, 2500–3600 cm^{-1}; ^1H nmr (200 MHz) δ: 2.98 (1H, dd, J = 14 Hz, J' = 8 Hz), 3.11 (1H, dd, J = 14 Hz, J' = 4 Hz), 4.50 (1H, dd, J = 7 Hz, J' = 4 Hz), 5.90 (2H, v br s, OH and COOH), and 7.25 (5H, m) ppm.

*Synthesis of racemic 2-hydroxy acids (±)-***2**b–f *as reference standards*

*(±)-2-Hydroxy-3-methylbutanoic acid ((±)-***2**d*)* was obtained from Aldrich as a calcium salt. For **2***b*, *c*, *e*, *f* the same basic preparative procedure was used. The following is representative.

*(±)-2-Hydroxybutanoic acid ((±)-***2**b*)*

To a stirred solution of potassium cyanide (6.5 g, 0.1 mol) in EtOH-free diethyl ether (40 mL) and distilled water (20 mL) at 0°C was added simultaneously propanal (3.48 g, 0.06 mol) and glacial acetic acid (5.72 mL, 0.1 mol). The mixture was stirred vigorously at 0°C, and stirring was continued while it was allowed to warm to room temperature during 2 h. The ether layer was then separated and the aqueous layer extracted with more ether (3 × 50 mL). The combined ether extracts were dried ($MgSO_4$), filtered, and concentrated by rotoevaporation to give (±)-2-hydroxybutanonitrile (3.91 g, 77%); ir (film): 3430, 2249 cm^{-1}; ^1H nmr δ: 1.18 (3H, dt, J = 6 Hz, J' = 1 Hz), 1.95 (2H, dq, J = 7 Hz, J' = 1 Hz), 2.98–4.25 (1H, br s), and 4.50 (1H, t, J = 6 Hz) ppm. The above cyanohydrin (3.8 g, 45 mmol) in distilled water (15 mL) was slowly poured into a precooled (0°C) solution of hydrochloric acid (12 M, 36 mL). Methanol (6 mL) was used to rinse the flask and was added to the reaction. The mixture was stirred for 12 h, during which period it was allowed to warm from 0 to 20°C. It was then heated at reflux for 1 h, cooled, and rotoevaporated at 60–70°C. The residue was dissolved in water (30 mL), extracted with ethyl acetate (3 × 50 mL), and the organic extracts dried ($MgSO_4$), filtered, and concentrated. Kugelrohr distillation gave 2-hydroxybutanoic acid ((±)-**2***b*, 2.3 g, 56%); bp 110°C (0.5 Torr; 1 Torr = 133.3 Pa) (lit. (16) bp 140°C (14 Torr)); ir and ^1H nmr for all the racemic hydroxy acids are the same as described for the (*S*) isomers.

The remaining (±)-2-hydroxy acids **2***c–f* were prepared by the same method, as follows:

*(±)-2-Hydroxypentanoic acid ((±)-***2**c*)*

Butanal (Aldrich) (4.32 g, 0.06 mol) yielded its cyanohydrin (5 g, 84%); ir (film): 3430 (strong), 2249 cm^{-1}; ^1H nmr δ ($CDCl_3$/DMSO-d_6): 0.95 (3H, br t, J = 6 Hz), 1.80 (4H, m), 4.45 (1H, m (dt)), and 5.98 (1H, d, J = 6 Hz, disappeared upon D_2O exchange) ppm. This cyanohydrin (3.5 g, 0.035 mol) yielded (±)-**2***c* (3.46 g, 75%), which solidified after distillation, mp 34–35°C (lit. (3) mp 34°C).

*(±)-2-Hydroxy-2-cyclopropylacetic acid ((±)-***2**e*)*

To a solution of hydroxymethylcyclopropane (5 g, 0.069 mol) in dry dichloromethane (50 mL) under a nitrogen atmosphere was added pyridinium chlorochromate (Aldrich, 16.5 g, 0.076 mol) at 0°C, and the mixture stirred for 2 h. Filtration through silica gel and evaporation of the solvent gave formylcyclopropane (2.7 g, 56%); ir (film): 2839, 1707 cm^{-1}; ^1H nmr δ: 1.05 (4H, distorted d), 1.75 (1H, m), 8.90 (1H, d, J = 6 Hz). This aldehyde (2.6 g, 0.037 mol) was converted to its cyanohydrin (3.6 g, 100%); ir (film): 3409 (strong), 2249 cm^{-1}; ^1H nmr (60 MHz) δ: 0.60–0.90 (4H, distorted d), 1.42 (1H, m), 3.78–4.48 (1H, br s), and 4.27 (1H, d, J = 6 Hz) ppm. The cyanohydrin (3.6 g, 0.037 mol), recrystallized from CCl_4:hexane (1:1), gave (±)-**2***e* (2 g, 47%), mp 76–78°C (lit. (32) mp 77–78°C).

*(±)-2-Hydroxy-3-phenylpropanoic acid ((±)-***2**f*)*

Phenylacetaldehyde (Aldrich, 3.0 mL, 0.026 mol) gave its cyanohydrin (3.7 g, 98%); ir (film): 3437, 2249 cm^{-1}; ^1H nmr δ: 2.79 (1H, d, J = 6 Hz), 3.15 (2H, d, J = 6 Hz), 4.60 (1H, td, J = 6 Hz, J' = 6 Hz), and 7.23 (5H, s) ppm. This cyanohydrin (3.48 g, 0.024 mol) yielded (±)-**2***f* (3.1 g, 80%); mp 97–98°C (lit. (16) mp 98°C).

Enantiomeric excess determinations

The ee's were determined by the Mosher ester method (20). The enzyme-derived acids **2***b–f* were first converted in quantitative yields to their methyl esters with diazomethane in THF at 0°C, and these then reacted with (*S*)-(+)-MTPA chloride (freshly prepared from (*R*)-(+)-MTPA with excess thionyl chloride) in the presence of a catalytic amount of 4-dimethylaminopyridine to give the corresponding Mosher esters (20). The % ee's were determined by integrations of the well-separated ^1H nmr -OCH_3 and -$COOCH_3$ signals, using the similarly prepared Mosher esters of racemic (±)-**2***b–f* as reference standards. In the capillary glc analyses, the *S*-**2***b–f*-derived MTPA-esters had longer (by 2.73–5.04 min) retention times than those of the *R* enantiomers. The results confirmed the >99% ee's of *S*-**2***b–f* determined by ^1H nmr.

The ^1H nmr (400 MHz) spectral data for the Mosher esters of the methyl esters of (*S*)-**2***b–f* are as follows:

(S)-2-O(MTPA)-butanoic acid methyl ester: δ: 0.99 (3H, t, J = 7.4 Hz), 1.94 (2H, m), 3.55 (3H, br s), 3.73 (3H, s), 5.13 (1H, dd, J = 7.0 Hz, J' = 5.2 Hz), and 7.40–7.60 (5H, m) ppm.

(S)-2-O(MTPA)-pentanoic acid methyl ester: δ: 0.92 (3H, t, J = 7.38 Hz), 1.41 (2H, m), 1.82 (2H, m), 3.55 (3H, br s), 3.73 (3H, s), 5.17 (1H, t, J = 6.42 Hz), and 7.40–7.63 (5H, m) ppm.

(S)-2-O(MTPA)-3-methylbutanoic acid methyl ester: δ: 0.95 (3H, d, J = 6.83 Hz), 1.02 (3H, d, J = 7.08 Hz), 2.33 (1H, m), 3.54 (3H, br s), 3.74 (3H, s), 5.00 (1H, d, J = 4.1 Hz), and 7.40–7.56 (5H, m) ppm.

(S)-2-O(MTPA)-2-cyclopropylacetic acid methyl ester: δ: 0.44–0.75 (4H, m), 1.31 (1H, m), 3.57 (3H, br s), 3.75 (3H, s), 4.58 (1H, d, J = 8.74 Hz), and 7.4–7.6 (5H, m) ppm.

(S)-2-O(MTPA)-3-phenylpropanoic acid methyl ester: δ: 3.10 (1H, dd, J = 14 Hz, J' = 10 Hz), 3.33 (1H, dd, J = 14 Hz, J' = 4 Hz),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

3.33 (3H, br s), 3.77 (3H, s), 5.42 (1H, dd, J = 10 Hz, J' = 4 Hz), and 7.19–7.41 (10H, m) ppm.

Absolute configuration assignments

The absolute configurations of the LDH-produced hydroxy acids **2***b–f* were confirmed as *S* from comparison of their optical rotations with the known values of *S*-**2***b* (16), -**2***d* (17), and -**2***f* (18). For **2***c* and **2***e* the ^{1}H nmr chemical shifts for one to three characteristic protons of each (*R*)-(+)-MTPA derivative were correlated with the *S* configuration by the scheme described by Yamaguchi (19).

LDH kinetic studies

BSLDH was prepared as described above for the preparative studies, but with additional purification by affinity chromatography on *N*-(6-aminohexyl)oxamate-Sepharose 4B according to Schaer and Zuber (4*d*), and with the procedure being slightly modified to give a highly concentrated enzyme solution (33). The gel was prepared by coupling AH-Sepharose 4B (Pharmacia) with oxalic acid in the presence of (1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide.[4] The column was equilibrated with triethanolamine-HCl buffer (20 mM, pH 6.0) containing NaCl (500 mM), 2-mercaptoethanol (5 mM), FDP (5 mM), and NADH (750 μM). Five millilitres (containing 15 mg) of the above purified enzyme solution was brought to 500 mM in NaCl, 5 mM in 2-mercaptoethanol, 5 mM in FDP, and 750 μM in NADH, incubated for 1 h, and applied to the column (0.5 mL gel). The inactive proteins were washed out with 5 mL of the equilibration buffer and the enzyme was eluted with triethanolamine-HCl (20 mM, pH 9.0) containing 2-mercaptoethanol (5 mM) (33). Fractions with LDH activity (6) were dialyzed against triethanolamine-HCl (20 mM, pH 6.0) buffer containing mercaptoethanol (1 mM) and EDTA (1 mM). Concentrations were determined spectrophotometrically at 280 nm assuming an absorption coefficient of 0.91 for 1 mg/mL enzyme (7*b*). The molecular weight of the monomeric enzyme was taken to be 34 862 daltons (5).

For kinetic measurements the pig heart H_4 (PHLDH) enzyme suspension in ammonium sulfate was centrifuged and redissolved in phosphate buffer (100 mM, pH 7.0). Concentrations were determined spectrophotometrically using E_{A280} = 1.37 cm^{-1} mg^{-1} (34).

Kinetic studies

All measurements were done under steady-state conditions at 25°C. Triethanolamine-HCl buffer (20 mM, pH 6.0) and saturating conditions of FDP (5 mM) and NADH (0.2 mM) were used for the assays with BSLDH. The kinetics measurements with PHLDH were carried out on the H_4 enzyme in phosphate buffer (100 mM, pH 7.0), without FDP. Typically, enzyme concentrations between 6×10^{-9} and 6×10^{-7} M (BSLDH) and 5×10^{-10} and 5×10^{-6} M (PHLDH) were used. The reactions were initiated by addition of a substrate solution (3–500 mM) to give a final concentration between $0.1K_M$ and $5.0K_M$ in a 1-mL, 1 cm pathlength, cuvette. Reactions were recorded on a Shimadzu UV-240/PR1 spectrophotometer equipped with a constant temperature cell holder. The reactions were followed by monitoring the decrease in the NADH absorbance at 340 nm. The extinction coefficient of NADH was taken to be 6220 L^{-1} M^{-1} cm^{-1} (35). All experiments were done in duplicate and individual data points were determined in triplicate. Michaelis constants (K_M) and turnover numbers (k_{cat}) were determined by Lineweaver–Burk plots (36) and least-squares analyses. Correlation coefficients were higher than 0.995 in each case. A minimum of six substrate concentrations between $0.1K_M$ and $5K_M$ were used except for **1***b* ($0.1K_M$–$1.5K_M$) and **1***g* ($0.1K_M$–$2.5K_M$) for BSLDH where substrate inhibition occurred. The results are recorded in Table 3.

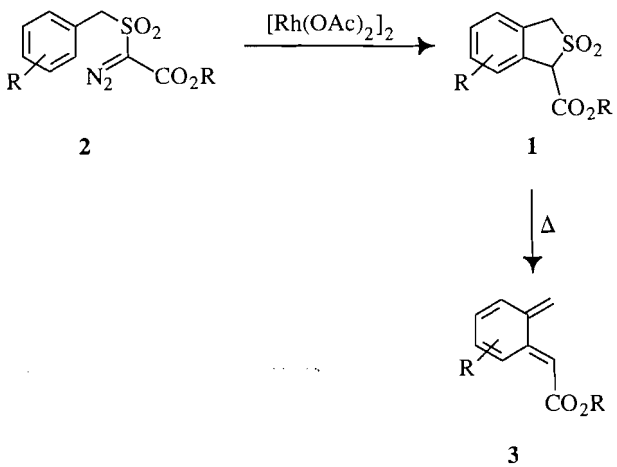
Received June 28, 1988[2]

SURESH D. BABU, MICHAEL D. HRYTSAK, and TONY DURST. Can. J. Chem. **67**, 1071 (1989).

The preparation of 1-carboalkoxy-1,3-dihydrobenzo[*b*]thiophene 2,2-dioxides via rhodium acetate or rhodium trifluoroacetate catalyzed decomposition of α-diazo-β-arylmethanesulfonyl esters is described. The reaction has been extended to yield 1,3-dihydrothiophene 2,2-dioxides fused to the 2,3 position of thiophene and indole, but not of furans. In the latter case products derived from the opening of the furan ring were obtained.

Key words: synthesis, 1-carboalkoxy-1,3-dihydrobenzo[*b*]thiophene 2,2-dioxides, intramolecular carbenoid insertions, rhodium acetate catalysis.

SURESH D. BABU, MICHAEL D. HRYTSAK et TONY DURST. Can. J. Chem. **67**, 1071 (1989).

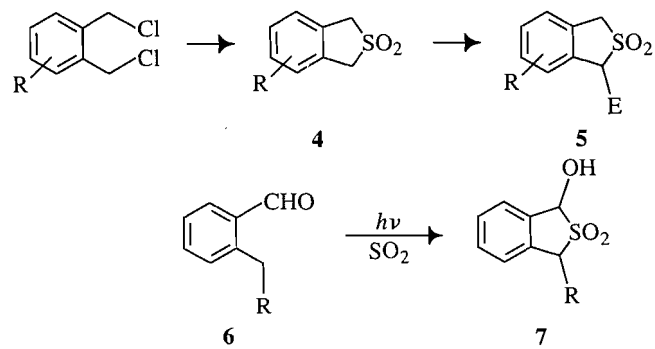


On décrit la préparation des dioxydes-2,2 des carboalcoxy-1 dihydro-1,3 benzo[*b*]thiophènes par le biais de décompositions, catalysées par l'acétate ou le trifluoroacétate de rhodium, d'esters α-diazo β-arylméthanesulfoniques. On a étendu le champ d'application de cette réaction de façon à pouvoir obtenir des dioxydes-2,2 de dihydro-1,3 thiophènes condensés aux positions 2,3 du thiophène ou de l'indole, mais pas des furannes. Dans ces derniers cas, on obtient plutôt des produits provenant de l'ouverture des noyaux furannes.

Mots clés : synthèse, dioxydes-2,2 des carboalcoxy-1 dihydro-1,3 benzo[*b*]thiophènes, insertions intramoléculaires de carbénoïdes, catalyse par l'acétate de rhodium.

[Traduit par la revue]

Introduction



We have reported in a preliminary publication the preparation of 1-carboalkoxy-1,3-dihydrobenzo[*b*]thiophene 2,2-dioxides **1** (1) via the rhodium acetate catalyzed decomposition of α-diazo-β-arylmethanesulfonyl esters of the type **2**. Compounds such as **1** are of interest as synthetic intermediates since they undergo thermal extrusion of sulfur dioxide to yield *o*-quinodimethanes, **3**.

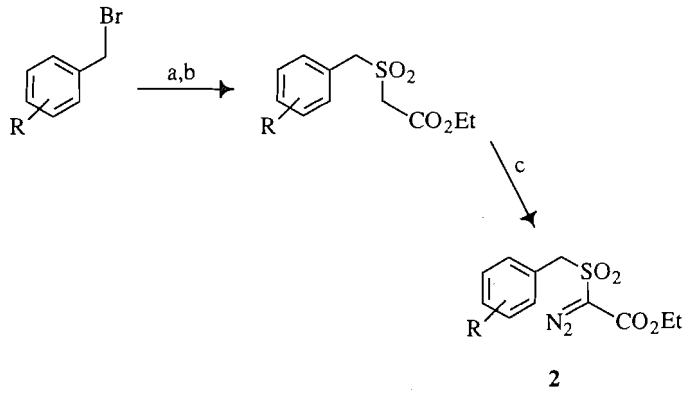
2 **1** **3**

The use of these reactive dienes as intermediates in the synthesis of natural products was first championed by Kametani and Nemoto (2*a*) and Oppolzer (2*b*). The field has recently been reviewed by Charlton and Alauddin (3).

1,3-Dihydrobenzo[*b*]thiophene 2,2-dioxides have been prepared by the reaction of *o*-dihalomethylbenzenes with sodium sulfide followed by oxidation (4), or by photolysis of *o*-substituted benzaldehydes **6** in the presence of SO_2 to yield α-hydroxy sulfones **7** (5). Compounds such as **5**, which are substituted in the heterocyclic ring, can be obtained via formation of an α-sulfonyl carbanion derived from **4** followed by addition of an electrophile (4*c*–*e*). Potential problems concerning regiochemistry can arise in the above reaction when substituents are also present in the aromatic ring.

4 **5** **6** **7**

The rhodium acetate catalyzed route from **2** to **1** represents a new route to these sulfones. Rhodium carboxylate decomposition of the diazo compounds bearing electron-withdrawing groups have been extensively investigated during the past decade. Typical reactions observed for the intermediate carbenoid include OH, NH, SH, and both aliphatic and aromatic CH insertions, and cyclopropanations. Recent reviews by Doyle and Mass are available (6). The required α-diazo-β-sulfonyl esters are readily prepared from commercially available benzylic alcohols or halides via mercaptoacetates and zinc iodide or mercaptoacetate and sodium hydroxide, respectively, followed by oxidation and diazo transfer using tosyl azide and base (7). Compounds such as **1** can be modified in the heterocyclic ring at either C-1 or C-3 via the C-1 anion or the C-1, C-3 dianion. Examples of this methodology and extensions of the carbenoid insertion to form 1,3-dihydrothiophene rings fused to thiophene and indole are also described in this paper. Furan analogs could not be prepared by this route. Their attempted preparation resulted in opening of the furan ring to give α,β-unsaturated aldehydes.



Results and discussion

The α-diazo-β-sulfonyl esters used in this study were prepared by standard procedures outlined below (Scheme 1).

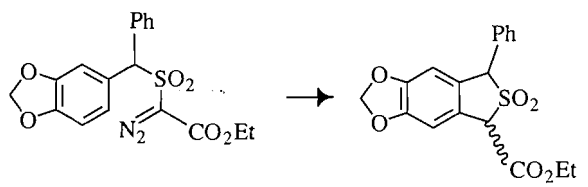
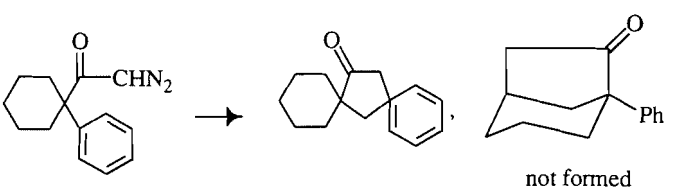


SCHEME 1. (a) $NaSCH_2CO_2Et$; (b) MCPBA; (c) TsN_3/base.

The yields in the various steps were generally excellent with the exception of the diazo transfer reaction, which rarely afforded the desired product in higher than 50% yield despite extensive variations in the diazotization conditions (tosyl azide, NaH/THF; tosyl azide, EtOH/KOH; tosyl azide, CH_2Cl_2/NEt_3) (7). The key α-diazo sulfones were characterized by the strong peak near 2120 cm^{-1} in the infrared and by their nmr spectra. These data are reported in the experimental section.

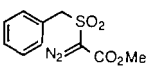
The decomposition of the various diazo sulfones was initially studied with $(Rh(OAc)_2)_2$ in methylene chloride at room temperature. Under these conditions the yields of the insertion product of the type **1** derived from the substituted benzenes or substituted thiophenes were generally in the 40–50% range. Near the end of this investigation it was found that the use of rhodium trifluoroacetate (8) improved the insertion yields to the more useful 70–80% range. The results are collected in Table 1.

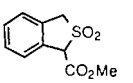
The cyclic sulfones were readily characterized by their nmr spectra, which showed the C-1 hydrogen as a singlet at δ 4.95–5.25 ppm and the C-3 methylene group as an AB quartet centred near δ 4.4 ppm. When the diazosulfone bore an additional substituent at the benzylic carbon, for example a phenyl group, compound **8**, and entries 10 and 11 in Table 1, a 1:1.5 to 1:2 mixture of diastereomers of **9** was obtained as judged by the appearance of two sets of singlets near δ 5 and 4.4 ppm respectively, each set equal to 1H. The stereochemical assignment of the individual isomers was not made.

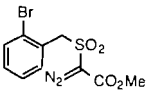


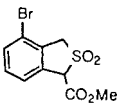
8 **9**

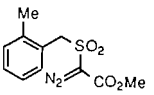
Inspection of Table 1 reveals that the aromatic C—H insertion is tolerant of an *ortho*-methyl or bromine, but not an *ortho*-methoxy substituent. In the former case, the rhodium carbenoid insertion would require a 7-membered ring transition state for aliphatic C—H insertion compared to a 6-membered ring for the aryl C—H insertion. Nakatani (9) has reported a preference for a formyl aryl C—H insertion when compared to insertion into an equidistant aliphatic C—H bond.

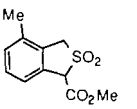


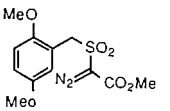


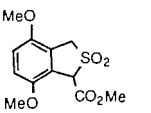


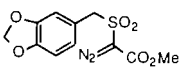


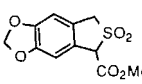


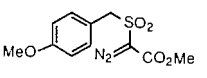


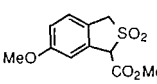


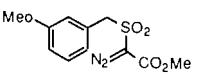


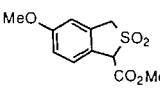


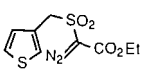


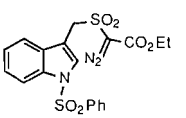


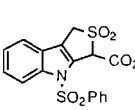


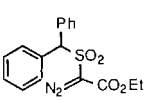


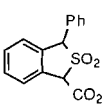


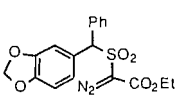


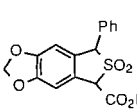


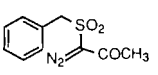


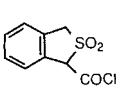






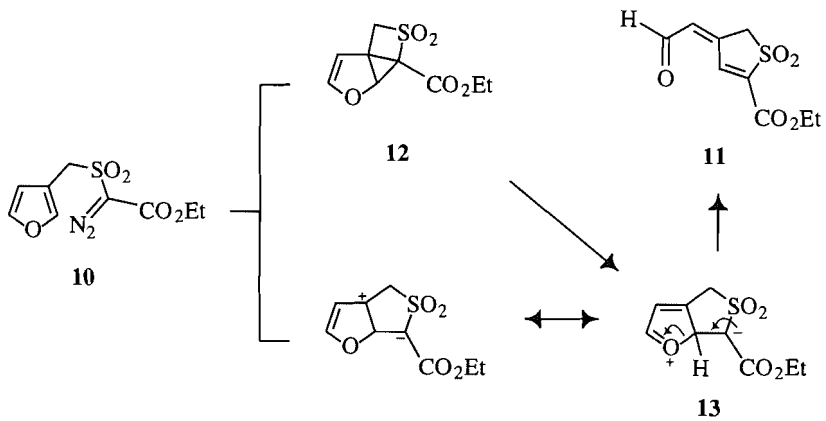






Reaction of the 2,5-dimethoxybenzyl substituted sulfone (entry 4, Table 1) led to a complex mixture (tlc) from which no pure product was isolated. A considerable amount of literature exists concerning the formation of oxygen ylids upon reaction of carbenes or carbenoids with ether oxygens (10). A variety of products are typically obtained from such intermediates.

The regiochemistry of the insertion reaction is predictable if one assumes an electrophilic characteristic for the rhodium carbenoid, coupled with a steric effect. The preference for



not formed

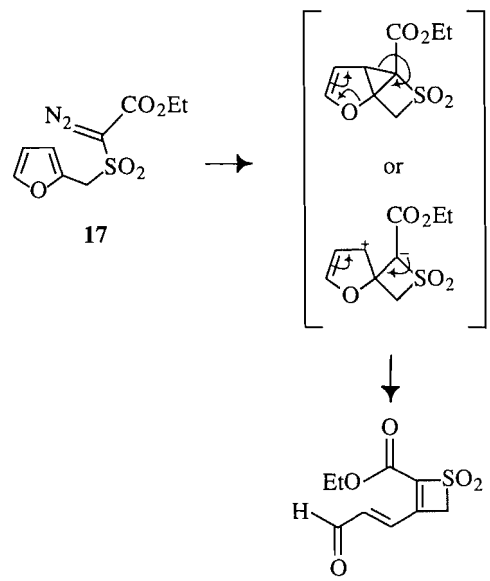
insertion into the more activated methylenedioxy substituted aryl ring as compared to a phenyl ring, i.e., conversion of **8** to **9**, is as expected. The aromatic insertion reaction is also applicable to the preparation of 2,5-dihydrothiophene sulfones fused onto the 2,3-position of thiophene and indole, see entries 8 and 9 in Table 1.



Attempts to extend the insertion reaction to furans failed. Thus the reaction of **10** with rhodium acetate in methylene chloride at room temperature for 2 h afforded the unsaturated aldehyde **11** in >95% crude yield. The nmr spectrum (200 MHz) (δ: 1.40, (t, J = 7 Hz, 3H), 4.24 (d, J = 1.3 Hz, 2H), 4.43 (q, J = 7 Hz, 2H), 6.30 (dd, J = 6, 1.3 Hz, 1H), 8.50 (s, 1H), 10.16 (d, J = 6 Hz, 1H)), was consistent with the assigned structure. The formation of this product is readily rationalized as resulting from either fragmentation of the strained cyclopropane intermediate **12** or, more directly, via the zwitterion **13**, which is due to an electrophilic attack of the carbenoid on the furan ring.

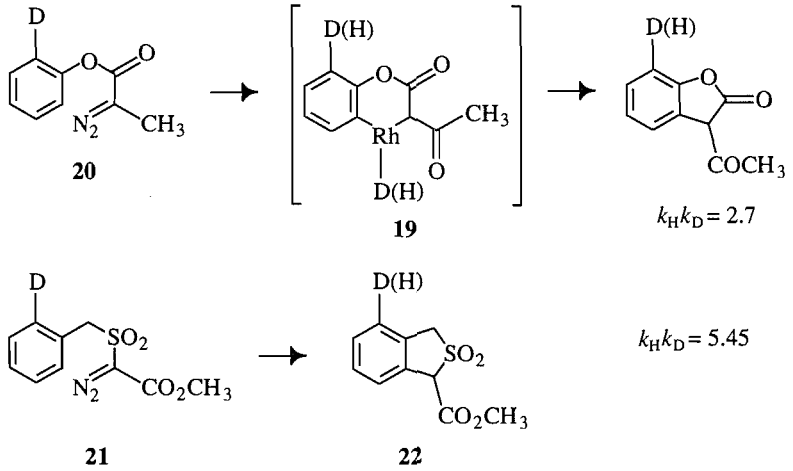
Padwa *et al.* (11) have obtained the unsaturated aldehyde **14** in 86% yield from the reaction of the diazoketone **15** with rhodium acetate. These authors have postulated the cyclopropane **16** as the intermediate in the conversion of **15** to **14**. Cyclopropanation products have been isolated from the intermolecular reaction of rhodium carbenoids with furans (12).

15 **16** **14**

Reaction of the diazo compound **17**, bearing a 2-furyl substituent, with $[Rh(OAc)_2]_2$ led to the formation of **18** as the only product after filtration of the reaction mixture and evaporation of the solvent. The 200-MHz nmr spectrum of this unusual product showed, in addition to the ethyl group, a 2H singlet at δ 4.81 assigned to the methylene group of the thiete sulfone ring, a doublet of doublets at δ 6.45 (J = 12, 6.3 Hz), a doublet δ 7.68 (J = 12 Hz), and a doublet at δ 10.16 (J = 6.3 Hz) due to the *trans*-α,β-unsaturated aldehyde unit. Attempts to purify either **11** or **18** via silica gel chromatography resulted in extensive decomposition. Two possible mechanisms for the formation of **18** are shown below. It is interesting to speculate whether cyclobutenones could be prepared from the keto analog of **17**.

Mechanistic aspects

A number of mechanistic possibilities can be proposed to explain the formal insertion products described in this paper. These include (*i*) the formation of an unstable norcaradiene intermediate, (*ii*) electrophilic attack on the carbenoid by the aromatic ring, and (*iii*) C—H insertion via a 6-membered metallocycle e.g., **19**.



These aspects were considered in an earlier publication (13) dealing with the insertion reaction of the carbenoid derived from the diazo ester **20**. The observation of a significant isotope effect (k_H/k_D = 2.7) in that reaction indicated that the aromatic C—H bond was broken in the rate-determining step. This was interpreted as being most consistent with the aromatic C—H insertion process. A significant hydrogen–deuterium isotope effect (k_H/k_D = 5.45) has been observed for the diazo sulfone **21**.

1,3-Dianion chemistry in the thiopheen series (Compound **23**)

As mentioned in the introduction, the insertion products ought to be amenable to regio-controlled introduction of electrophilic reagents in the dihydrothiophene ring via mono- and 1,3-dianions such as **24** and **24***a*. These intermediates could indeed be generated by treatment of **23** in THF with one or two equivalents of *n*BuLi.

Thus, reaction of **24** with excess CH_3I afforded a 60% yield of **25**, while treatment of **24***a* with one equivalent of alkylating agent gave a mixture of diastereomers of **26** in 32% isolated

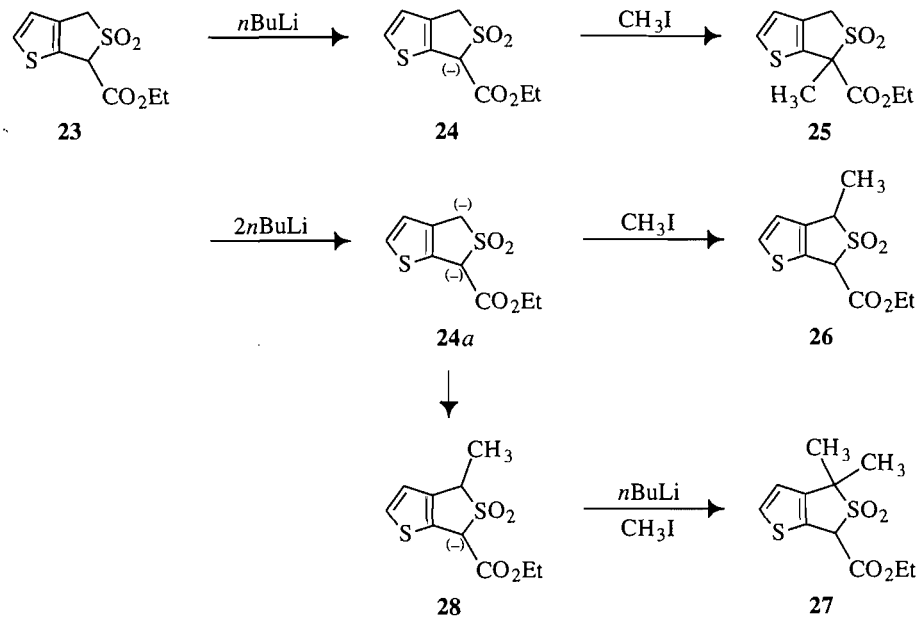
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

yield. The structures of these products were readily established by nmr spectroscopy. For example, **25** showed singlets for both the newly introduced methyl and the remaining methylene group α to the sulfone at δ 1.90 and 4.33 ppm, respectively, while **26** showed two methyl doublets near δ 1.66 ppm, and two methine singlets at δ 5.14 and 5.17 ppm (2:1 ratio) due to the hydrogen α to both the carboethoxy and the sulfone group; the remaining methine hydrogen in **26** overlapped with the methylene group of the ethyl ester.

Finally, reaction of **23** with 3 equivalents of *n*BuLi followed by 2 equivalents of CH_3I afforded the α,α-disubstituted products **27** (41%). The mass spectrum (CI) showed a small molecular ion at the expected $m/e = 274 + 1$ with the base peak at $M - 64$ due to facile extrusion of SO_2. The nmr spectrum of **27** (60 MHz) featured, in addition to the ethyl group, a 6H singlet (δ 1.67), a 1H singlet (δ 5.05), and two doublets at δ 6.88 and 7.43 ppm due to the remaining thiophene hydrogens. The formation of **27** presumably involves rapid initial monomethylation of **24***a* to **28**, dianion formation due to the third equivalent of *n*BuLi, and a further methylation at the more reactive α′ centre. The possibility that **27** is formed via an α,α,α′ trianion has been suggested by a referee but it is considered less likely by the authors.

Experimental

"Usual work-up" indicates that the reaction mixture was diluted with an appropriate volume of saturated NH_4Cl solution and extracted with ether or methylene chloride. The organic extracts were dried over anhydrous $MgSO_4$ and the solvent evaporated. The nmr spectra, unless stated otherwise, were recorded using a Varian EM 360 spectrometer in $CDCl_3$ solution. Chromatography was carried out using hexane – ethyl acetate solvent mixtures.



Preparation of benzylic sulfides. General procedures

Method A

To a solution of 1 equiv. of benzylic bromide in ethanol (4 mL/mmol) was added 1 equiv. of KOH dissolved in ethanol. The resulting solution was stirred under a nitrogen atmosphere for about 2 h. The reaction mixture was poured into an equal volume of saturated NaCl solution and extracted with ether. The ether layer was dried over $MgSO_4$ and the solvent evaporated to give crude sulfide (78–90%), of sufficient purity for subsequent manipulation.

Method B

To a solution of methyl or ethyl mercaptoacetate (1 equiv.) and benzylic alcohol (1 equiv.) in CH_2Cl_2 (2 mL/mmol of alcohol) under N_2 at room temperature was added 0.5 equiv. of powdered zinc iodide. The mixture was stirred for 45 min and then washed with water. The organic phase was dried over $MgSO_4$ and evaporated to give the crude benzylic sulfide. This material was filtered through a silica gel column

with 1:1 ethyl acetate – hexane to give 85–95% of sulfide of sufficient purity for further manipulation. The crude sulfides were characterized by their nmr spectrum. The key features were the CH_2 group α to the aromatic ring found in the δ 3.7–3.9 ppm range and the methylene group α to the ester at δ 2.9–3.1 ppm. Most of the ethyl esters of the following sulfides have been previously reported. The data for the non-ester nmr peaks agree closely with our data (14).

Mercaptobenzylacetone

Powdered KOH (23 mmol) was dissolved in 50 mL of ethanol under N_2. Benzyl mercaptan (21.3 mmol) was added, followed by chloroacetone (33 mmol). The reaction mixture was stirred for 30 min at room temperature and the solvent evaporated on a rotary evaporator. The residue was taken up in CH_2Cl_2 and the solution washed with 10% NaOH solution. Evaporation of the organic phase afforded 3.75 g (98%) of the title compound (15); nmr: 2.23 (s, 3H), 3.03 (s, 2H), 3.63 (s, 2H), 7.23 (s, 5H).

Oxidation of benzylic sulfides to the corresponding sulfones. General procedures

The crude or semipurified sulfides were oxidized to the corresponding sulfones using either 2 equiv. of MCPBA in CH_2Cl_2 at 0°C for 45 min (method A) or excess 30% H_2O_2 in acetic acid for 1–2 days (method B). Work-up consisted of washing the organic phase successively with 10% $Na_2S_2O_3$ and 5% $NaHCO_3$ solution, then drying and evaporating the resultant solutions. The sulfones were thus obtained in 60–90% yield. The sulfones were purified either by recrystallization and (or) by silica gel chromatography. Data concerning individual sulfones are given using the following format: entry number, relating to the table; preparation method, A or B; yield; mp (°C); chemical shift of the methylene groups α to the ester and aromatic rings.

Diazo transfer reactions

Method A

To a sulfone in dry ethanol (5 mL/mmol) cooled in an ice bath was added 1.2 equiv. of powdered KOH (A1), NaH using THF as the reaction solvent (A2), or triethylamine (A3), and then, dropwise, tosyl azide (1.1 equiv.) dissolved in a minimum quantity of ethanol or THF. The mixture was stirred at room temperature for 40 min and then evaporated to dryness. The residue was taken up in ether, washed with 10% KOH solution, and then worked up in the usual manner to afford the crude diazo compounds. These were further purified by chromatography on silica gel using 3:1 hexane – ethyl acetate as eluant.

Method B

To a solution of sodium methoxide in methanol (1 mmol/2 mL) was added an ice-cold solution of 1 equiv. of sulfone (1 mmol/2 mL) in methanol. The solution thus obtained was stirred for 5 min and treated with 1 equiv. of methyl formate, followed 5 min later by 1 equiv. of tosyl azide. The reaction mixture was stirred at room temperature for 2.5 h and the solvents were evaporated. Work-up of the product was carried out as in method A above. Data concerning the individual α-diazosulfones are given in the following format: entry number relating to the table; yield; mp (°C); chemical shift of the benzylic methylene singlet (ppm).

Rhodium carboxylate catalyzed cyclizations of the α-diazosulfones. General procedure

A solution of the diazo sulfone in dry CH_2Cl_2 (1 mmol/4 mL) was stirred at room temperature and treated with 5 mol% of rhodium acetate or rhodium trifluoroacetate in one portion. Gas evolution occurred slowly. The progress of the reaction was monitored by tlc. When the reaction was judged complete, the green solution was filtered through a cotton plug and the solvent was evaporated. The desired bicyclic sulfones were purified via silica gel chromatography. Yields refer to isolated, purified products. Data concerning these compounds are presented below according to the following format: entry number; mp (°C); hrms for the molecular ion peak unless otherwise indicated, calculated, found; chemical shift of methine singlet α to the ester at C-1, and the remaining hydrogens at C-3 (ppm). All compounds showed the expected ester peak near 1740 cm^{-1} and the symmetric sulfone stretching frequency near 1335 cm^{-1}.

Reaction of the furan substituted diazo compounds with rhodium acetate

A solution of the diazosulfone **10** (260 mg, 10 mmol) in 10 mL of dry CH_2Cl_2 was stirred with $(Rh(OAc)_2)_2$ for 1 h. Thin-layer chromatographic analysis showed the absence of starting material and the formation of one major product. The reaction mixture was filtered through a cotton plug and the solvent was evaporated to afford 230 mg of crude unsaturated aldehyde **11**; nmr: (200 MHz) δ: 1.40 (t, J = 7 Hz, 3H), 4.24 (d, J = 1.3 Hz, 1H), 4.43 (q, J = 7 Hz, 2H), 6.37 (dd, J = 1.3 Hz, 1H), 8.50 (s, 1H), 10.16 (d, J = 6 Hz, 1H) ppm. Attempted chromatography on silica gel led to decomposition. The EI mass spectrum of **11** failed to show a molecular ion peak at m/e 230. The highest m/e peak occurred at M − OC_2H_5 = 185. A hrms of this peak gave 184.9943; calculated for $C_7H_5O_4S$: 185.0092.

The diazo sulfone **17** was treated as above for compound **10** with 20 mg of rhodium acetate. The crude product, 130 mg (81%) of **18** as a colorless oil, had nmr (200 MHz) peaks at δ 1.31 (t, J = 7 Hz, 3H),

4.30 (q, J = 7 Hz, 2H), 4.81 (s, 2H), 6.45 (dd, J = 12 Hz, 6.3 Hz, 1H), 7.68 (d, J = 12 Hz, 1H), and 10.16 (d, J = 6.3 Hz, 1H) ppm. Attempted further purification via silica gel column chromatography resulted in extensive decomposition.

Methylation of sulfone ***23***

(a) To a solution of 0.6 mmol of sulfone **23** in 12 mL of THF at −78°C was added 0.6 mmol of *n*BuLi, followed after 30 min by 0.6 mmol of CH_3I. The reaction mixture was stirred for 30 min at −78°C and then warmed to room temperature for 2 h prior to quenching with saturated NH_4Cl solution. The usual work-up followed by chromatography afforded 100 mg (64%) of the monomethyl derivative **25** as a colorless solid, mp 88°C.

(b) Sulfone **23** (0.28 mmol) was dissolved in THF at −78°C and reacted with 3.3 equiv. of *n*BuLi for 1 h at −78°C and 1 h at room temperature. The reaction mixture was recooled to −78°C and 0.62 mmol (2.2 equiv.) of CH_3I was added. The mixture continued to be stirred at −78°C for 30 min and then at room temperature for 1 h prior to quenching with saturated NH_4Cl solution. The usual work-up followed by chromatography afforded 35 mg (41%) of the 3,3-dimethyl derivative **27** as a colorless solid, mp 82°C; nmr δ: 1.4 (t, J = 7 Hz, 3H), 1.7 (s, 6H), 4.3 (q, J = 7 Hz, 2H), 5.1 (s, 1H), 6.68 (d, J = 6 Hz, 1H), 7.43 (d, J = 6 Hz, 1H); ms m/e (rel.%): 210 (M − 64) (49), 137 (100).

(c) To a THF solution of sulfone **23** (0.6 mmol) in THF at −78°C was added 2.2 equiv. of *n*BuLi. The anion-forming reaction was allowed to proceed for 30 min at −78°C and 1 h at room temperature; the resultant solution was reacted with 0.6 mmol of CH_3I for 20 min at −78°C and 1 h at room temperature. The usual work-up followed by chromatography afforded 56 mg (36%) of the methylated sulfone **26** as a mixture of isomers, mp 91°C.

Some new Lycopodium alkaloids

WILLIAM A. AYER[1] AND GERTRUDE C. KASITU
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 4, 1989

WILLIAM A. AYER and GERTRUDE C. KASITU. Can. J. Chem. **67**, 1077 (1989).

The alkaloids of the club moss *Lycopodium obscurum* L., collected in Northern Alberta, have been investigated. The known alkaloids lycopodine, lycodine, clavolonine, dihydrolycopodine, *O*-acetyldehydrolycopodine, flabelliformine, β-lofoline, lycofoline, and des-*N*-methyl-α-obscurine were isolated and identified, as were the known compounds des-*N*-methyl-β-obscurine and acrifolinol. α-Obscurine and β-obscurine were not detected. The structures of the previously unreported alkaloids hydroxypropyllycodine (**9***a*), lyconnotinol (**11***a*), lobscurinol (**19***a*), epilobscurinol (**19***b*), and acetyllobscurinol (**19***c*) are presented. Hydroxypropyllycodine (**9***a*) is the first 19-carbon Lycopodium alkaloid reported to date. Its possible biogenetic significance is discussed. The isolation of obscurinine (**14**) and isoobscurinine (**15**) are reported and the preparation of obscurinine (**15**) by treatment of lobscurine (**18**) with ammonia is described. It is suggested that obscurinine and isoobscurinine are artefacts produced during the isolation process.

Key words: alkaloids, Lycopodium alkaloids, obscurinine, *Lycopodium obscurum*, biogenesis.

WILLIAM A. AYER et GERTRUDE C. KASITU. Can. J. Chem. **67**, 1077 (1989).

On a étudié les alcaloïdes de lycopodes en massue, *Lycopodium obscurum* L., récoltés dans le nord de l'Alberta. On a isolé et identifié les alcaloïdes connus lycopodine, lycodine, clavolonine, dihydrolycopodine, *O*-acétyldéhydrolycopodine, flabelliformine, β-lofoline, lycofoline et des-*N*-méthyl-α-obscurine ainsi que la des-*N*-méthyl-β-obscurine et l'acrifolinol. Par ailleurs, on n'a pas détecté la présence des α- et β-obscurines. On a déterminé les structures des alcaloïdes suivants qui n'avaient pas été rapportés antérieurement : l'hydropropyllycodine (**9***a*), le lyconotinol (**11***a*), le lobscurinol (**19***a*), l'épilobscurinol (**19***b*) et l'acétyllobscurinol (**19***a*). L'hydroxypropyllycodine (**9***a*) est le premier alcaloïde du Lycopodium à 19 atomes de carbones à être rapporté. On discute de sa signification biologique éventuelle. On décrit aussi l'isolement des obscurinine (**14**) et isoobscurinine (**15**) ainsi que la préparation de l'obscurinine (**15**) par traitement de lobscurine (**18**) avec de l'ammoniac. On suggère que la présence de l'obscurinine et de l'isoobscurinine est due à un artefact résultant de la méthode d'isoler les produits.

Mots clés : alcaloïdes, alcaloïdes Lycopodium, obscurinine, *Lycopodium obscurum*, biogenèse.

[Traduit par la revue]

Introduction

The club moss *Lycopodium serratum* Thumb. has been used in Chinese traditional medicine in the treatment of myasthenia gravis and conditions of senile memory loss now recognized as symptoms of Alzheimer's dementia (AD) (1). The alkaloids huperzine A (**1**) and huperzine B (**2**), isolated from this plant (2), show pronounced anticholinesterase activity and are under clinical investigation in China for the treatment of myasthenia gravis and senile memory loss (1, 2). Another report of the use of a club moss in an AD-related disorder dates back to the late forties when powdered *L. selago* was investigated as a substitute for pilocarpine and eserine in treating glaucoma (3). *Lycopodium selago* is the source of the alkaloid selagine, which has been assigned structure **3** (4). In 1960 we reported the structures of α-obscurine (**4**) and β-obscurine (**5**), the first of the α-pyridone containing Lycopodium alkaloids (5). The obscurines (**4** and **5**) were first isolated in 1944 by Manske and Marion (6) from *L. obscurum* L. They also reported the presence of lycopodine (**6***a*) and three alkaloids designated L13, L16, and L17. In our earlier work on *L. obscurum* we isolated lycopodine (6), the obscurines (**4** and **5**), lycodine (**7**), and several other alkaloids (5). Because of the current interest in the α-pyridine alkaloids **1** and **2** we have recently reexamined the alkaloidal content of *L. obscurum*, which we collected in northern Alberta, to obtain more of the obscurines for pharmacological testing and to search for other pyridone-type alkaloids. During this study we have isolated several new alkaloids, which are the subject of this report.

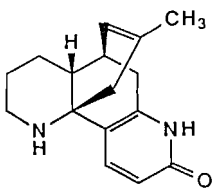
Results and discussion



Finely ground *L. obscurum* was extracted with aqueous 2% tartaric acid (7). The extract was concentrated, washed with chloroform to remove neutral and acidic material, basified with aqueous ammonia, and extracted with ether and then chloroform. The combined extracts were examined by gas chromatography – mass spectrometry (gc–ms) (8), which revealed the presence of at least 20 components, the major ones being lycopodine (**6***a*), clavolonine (**6***b*), lycodine (**7**), and an unidentified compound $C_{17}H_{24}N_2O$ described below. Subsequent isolation of these compounds confirmed the gc–ms result. Surprisingly, no α- or β-obscurine was detected in the gc–ms scan and none was obtained during the isolation studies. Both des-*N*-methyl-α-obscurine (**4***b*) and des-*N*-methyl-β-obscurine (**5***b*) were, however, detected and isolated. Other known compounds detected and isolated include dihydrolycopodine, *O*-acetyldihydrolycopodine, flabelliformine (**6***c*), β-lofoline (**6***b* with carbonyl reduced to β-OH), lycofoline (**6***b* with carbonyl reduced to β-OH and containing $\Delta^{11,12}$ double bond), and flabellidine (**8**). The identity of the known compounds was established by direct comparison of spectral data with those obtained from authentic samples. Des-*N*-methyl-β-obscurine (**5***b*) has not previously been reported as a natural product, but has been prepared from β-obscurine (9).

The crude alkaloids from *L. obscurum* were first separated

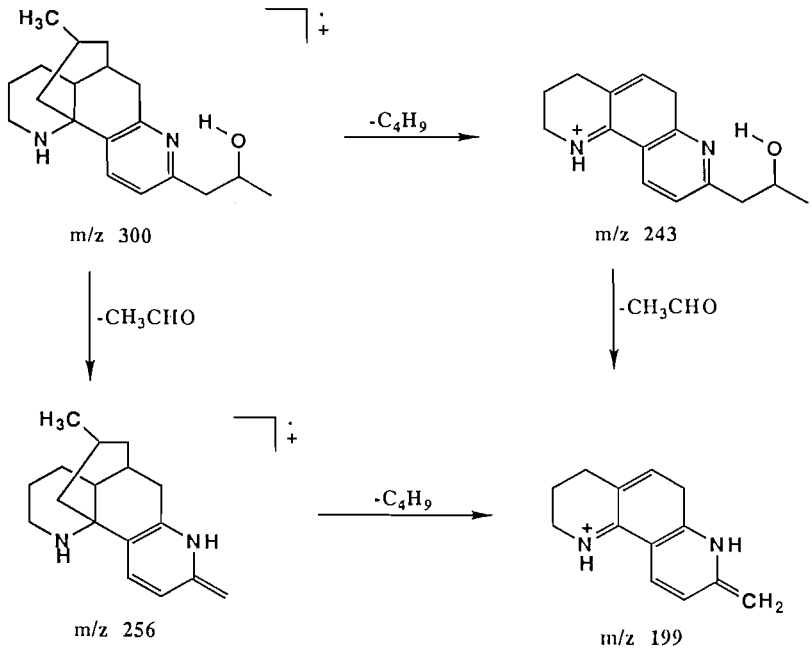
into seven fractions by gradient (methanol in dichloromethane) elution chromatography over alumina. These fractions were further separated by elution chromatography over alumina, flash chromatography over silica gel, or preparative thin-layer chromatography (ptlc) over silica gel as described in the Experimental. Each of the new compounds is described below.



*Hydroxypropyllycodine (**9**a)*

This alkaloid was obtained as an opaque solid and was shown by high resolution electron impact mass spectrometry (hreims) and chemical ionization mass spectrometry (cims) to possess the molecular formula $C_{19}H_{28}N_2O$. The ultraviolet (uv) spectrum suggested the presence of a substituted pyridine ring (λ_{max} 272, 280 (sh) nm) and the ^{13}C nuclear magnetic resonance (nmr) spectrum showed that the ring was trisubstituted (δ 157.6 (s), 157.3 (s), 134.0 (d), 133.7 (s), 121.4 (d)). Comparison of the ^1H nmr and ^{13}C nmr spectra (see Table 1) of lycodine (**7**) and hydroxypropyllycodine (**9***a*) reveals many similarities. The presence of a 2-hydroxypropyl group in **9***a* is apparent from the ^1H nmr spectrum. On irradiation of the signal for the hydrogen (δ 4.21) *geminal* to the hydroxyl group, the non-equivalent *geminal* methylene hydrogens at δ 2.89 (dd, J = 15, 3 Hz) and 2.71 (dd, J = 15, 9 Hz) each collapse to a doublet (J = 15 Hz), while the methyl signal (δ 1.27, d, J = 6 Hz) collapses to a singlet. Comparison of the ^{13}C nmr spectrum of **9***a* with that of lycodine (**7**) reveals that the hydroxypropyl group is located at C-1. In lycodine, C-1 appears as a doublet at δ 147.0, while in **9***a* it appears as a singlet at δ 157.6. This is consistent with the observed coupling (J = 8 Hz) of the aromatic hydrogens, since in pyridines $J_{\alpha,\beta}$ is normally ca. 5 Hz, while $J_{\beta,\gamma}$ is 7–9 Hz (10). This also follows from a comparison of the uv spectra (lycodine (**7**) λ_{max} 268 nm, hydroxypropyllycodine 272 nm) since α substitution in pyridines causes a bathochromic shift, γ substitution a hypsochromic shift (11). Analysis of the COSY 90 spectrum of hydroxypropyllycodine provides further evidence for structure **9***a*. This reveals long range coupling between the hydrogens of the methylene group of the 2-hydroxypropyl group and H-2 and H-3. These are in turn coupled to the C-6 methylene hydrogens (δ 3.09 and 2.66), which are further coupled to H-7 (δ 2.06). H-7 is coupled to a pair of H's (C-8), which are both coupled to the hydrogen (H-15) that is coupled to the methyl group at δ 0.76. In a similar manner, H-7 may be traced through the C-12, C-11, and C-10 hydrogens to the downfield (δ 2.43, 2.27) hydrogens of the C-9 methylene group.

The hreims of hydroxypropyllycodine (**9***a*) (Scheme 1) shows the base peak at m/z 243 corresponding to the loss of the "bridging" carbons C-14, C-15, C-8, a common fragmentation pathway in related Lycopodium alkaloids (12). An ion at m/z 256 is due to the loss of acetaldehyde (McLafferty rearrangement) from the molecular ion, and a prominent peak at m/z 199 corresponds to the loss of both acetaldehyde and the bridging carbons, as illustrated in Scheme 1.

Acetylation (acetic anhydride – triethylamine) of hydroxypropyllycodine (**9***a*) gives the diacetyl derivative **9***b*, which shows both ester (1737 cm^{-1}) and amide (1656 cm^{-1}) absorption in the ir. Significant downfield shifts are observed in the ^1H nmr spectrum for the hydrogens at C-18 (δ 4.21 to δ 5.27) and C-9 (δ 2.77 and 2.43 to δ 3.03 and 2.91). A signal at δ 3.17 is assigned to the equatorial hydrogen at C-14. This signal appears as a broadened doublet (J = 12 Hz), which collapses to a sharp doublet when the hydrogen at C-15 (δ 1.18) is irradiated. We attribute the deshielding of this hydrogen to the anisotropic effect of the N-acetyl carbonyl group. In the ^{13}C nmr spectrum (Table 1), C-14 shows an upfield shift. The rela-

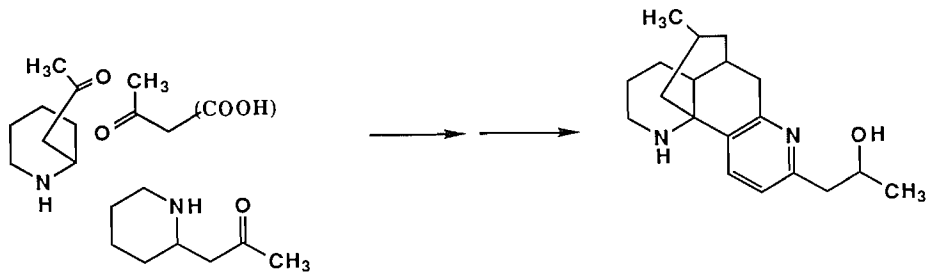
[a,b,c]Carbon assignments may be interchanged.

tive (and absolute) stereochemistry of hydroxypropyllycodine (**9***a*) is assumed to be the same as in lycodine (**7**). The stereochemistry at C-18 has not been assigned.



Hydroxypropyllycodine (**9***a*) is the first Lycopodium alkaloid encountered possessing a 19-carbon skeleton. The biogenetic origin of the Lycopodium alkaloids still is not completely clarified.[2] It has been shown that carbons 9–16 in lycopodine (**6***a*) and, by implication, lycodine (**7**) are derived from lysine and acetoacetate via pelletierine (**10**). Carbons 1–5 are derived from lysine and carbons 6, 7, and 8 from acetate, without the intermediacy of pelletierine (**10**) (13). As illustrated in Scheme 2, the 19-carbon skeleton of hydroxypropyllycodine can be constructed from two pelletierine units and one acetoacetate unit.

*Lyconnotinol (**11**a)*

This alkaloid was isolated by repeated chromatography of one of the more polar fractions from the initial separation. Lyconnotinol (**11***a*), $C_{16}H_{25}NO_2$, mp 173–175°C, is most easily separated from accompanying polar components in the form of the monoacetyl derivative **11***b*. Lyconnotinol (**11***a*) itself does not show a molecular ion in the hreims, although the protonated form of the molecular ion can be detected in the cims. Monoacetyllyconnotinol (**11***b*) does show a molecular ion in the hreims. The base peak in the mass spectra of both **11***a* and **11***b* occurs at *m/z* 190, corresponding to the ion **12** formed by loss (α-cleavage) of the four-carbon side chain. The ^1H nmr spectrum of monoacetyllyconnotinol (**11***b*) indicates the presence of an acetylated primary alcohol (δ 3.87 and 3.71, shifted from δ 3.43 and 3.28 in lyconnotinol itself), a secondary alcohol (δ 4.10), and three olefinic hydrogens (δ 6.20, 5.68, and 5.49). The uv spectrum (λ_{max} 235 nm) suggests a conjugated diene system. The ^1H nmr spectra and the ^{13}C nmr spectra (Table 2) of **11***a* and **11***b* are very similar to those of the known alkaloid lyconnotine (**13**) (14), except for the signals associated with C-8. Reduction of lyconnotine with lithium aluminum hydride gave the diol **11***a*, identical with the compound isolated from *L. obscurum*. The configuration at C-15 in lyconnotinol (**11***a*) has not been determined. Lyconnotinol (**11***a*) is only the second representative of this particular skeleton among the Lycopodium alkaloids, the other being lyconnotine (**13**).

[2]Reference 13 provides an informative and up to date summary of the biosynthetic studies and biogenetic theories in this field.

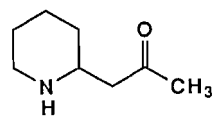
*Obscurinine (**14**)[3] and isoobscurinine (**15**)*

Obscurinine (**14**), $C_{17}H_{24}N_2O$, mp 128–130°C, and isoobscurinine, mp 106–107°C, have R_f values very similar to those of lycopodine (**6***a*) and lycodine (**7**), from which they were separated by flash chromatography over silica gel. Both compounds show cyclopentanone absorption in the ir (**14** at 1731 cm^{-1}, **15** at 1734 cm^{-1}) and in the ^{13}C nmr spectrum (**14**, δ 220.3; **15**, δ 220.6), but only **14** shows conjugated imine (233 nm) absorption (17) in the uv. The 2D COSY spectrum of isoobscurinine (**15**) shows the presence of two isolated spin systems, one for the C-9, C-10, and C-11 hydrogens similar to that in obscurinine (16), the other including C-1 to C-8 and C-14, C-16. The methylene hydrogens at C-14 (δ 3.00 and 2.92) are coupled to the olefinic hydrogen (δ 5.54) and the alkenic methyl hydrogens (δ 1.78). The olefinic hydrogen is in turn correlated with a methine hydrogen at δ 2.67 (H-7), which is coupled to the C-6 methylene hydrogens (δ 2.44 and 1.87). One of the C-6 H's shows a small (2 Hz) coupling to a hydrogen (C-4) at δ 3.81, and this in turn is coupled (3 Hz) to the C-3 methine hydrogen (δ 4.21), and so on to C-1. The ^{13}C nmr spectrum of **15** (Table 3) shows the expected similarities with (and differences from) that of obscurinine (**14**). Treatment of isoobscurinine (**15**) with warm 10% hydrochloric acid brings about isomerization to obscurinine (**14**).

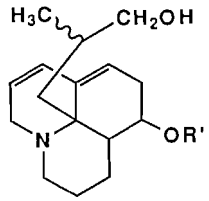
The location of the imino nitrogen in obscurinine and isoobscurinine is not consistent with a biogenetic origin from lysine as is envisioned for the other dinitrogenous Lycopodium alkaloids (e.g., lycodine (**7**), cernuine (**16**), phlegmarine (**17**)) (13). It seemed possible that obscurinine (**14**) and isoobscurinine (**15**) are artefacts derived by addition of ammonia to an appropriate (e.g., **18**) fawcettimine-type precursor. To test this hypothesis, lobscurinol (**19***a*, structure *vide infra*) was oxidized to lobscurine (**18**). Treatment of a chloroform solution of **18** with aqueous ammonia led to the formation of obscurinine (**14**) in virtually quantitative yield. Since we had exhausted our supply of plant material, we have not yet been able to show that lobscurine (**18**) is present in *L. obscurum* and obscurinine (**14**) is not. However, the fact that lobscurinol (**19***a*) and epilobscurinol (**19***b*) are both isolated from the plant (*vide infra*), and since lobscurine (**18**) reacts readily with aqueous ammonia, we feel that obscurinine (**14**) may well be an artefact of the isolation process. Chandler and co-workers (15) also used aqueous ammonia in their study.

*Lobscurinol (**19**a), epilobscurinol (**19**b), and acetyllobscurinol (**19**c)*



These three minor alkaloids are uv active and thus readily detected on tlc. Lobscurinol (**19***a*), the most abundant of the three, has an R_f very similar to that of the much more abundant β-lofoline and was obtained pure only after extensive chromatography. More lobscurinol (**19***a*) was obtained in the form of the much less polar naturally occurring acetyl derivative **19***c*. Epilobscurinol (**19***b*) is eluted from alumina after lobscurinol and is most readily purified as its acetyl derivative **19***d*.

The hreims spectrum of lobscurinol (**19***a*) indicated a molecular formula $C_{17}H_{25}NO_2$ and did not show the $M^+ - C_4H_9$ peak characteristic of the lycopodine and lycodine type alkaloids (12). The base peak appears at *m/z* 84, attributed to ion 20, similar to the case of paniculatine (**21**) (18). The oxygen atoms are present as a carbonyl (ir, 1658 cm^{-1}; ^{13}C nmr, δ 200.2 (s)) and a secondary hydroxyl (ir, 3400 cm^{-1}; ^{13}C nmr, δ 72.2 (d)) group. The ^{13}C nmr spectrum (Table 4) shows the presence of four other sp^2 carbons and the uv spectrum (λ_{max} 234 nm) is consistent with the α,β-unsaturated ketone. The ^1H nmr spectrum shows two olefinic hydrogens (δ 5.95 and 5.82), an allylic carbinyl hydrogen (δ 4.36), and two methyl groups (δ 2.33 ($N-CH_3$), δ 1.92 (alkenic methyl)). Analysis of the COSY 90 ^1H nmr spectrum again revealed an isolated spin



[3]During the course of our studies, Chandler and co-workers (15) reported the isolation and X-ray crystallographic structure determination of this compound, which they have named obscurinine. We independently arrived at the same structural assignment based on extensive nmr, ir, and uv studies. These studies are described in detail in ref. 16. We will present evidence herein that obscurinine is probably an artefact formed during the isolation process.

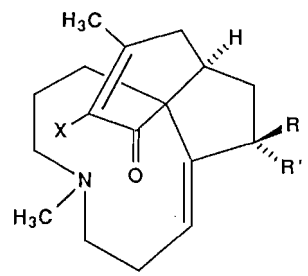
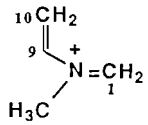
system corresponding to carbons 9, 10, and 11 and another correlating H-14 with the alkenic methyl and on through the C-8 hydrogens all the way to C-2 as summarized in Fig. 1.

The relative stereochemistry at C-5 in lobscurinol (**19***a*) is assigned on the basis of extensive decoupling of ^1H nmr spectra and by nOe difference spectroscopy. The hydrogen at C-5 appears as a doublet of doublets ($J_{3,5}$ = 1 Hz, $J_{5,6\beta}$ = 5 Hz, $J_{5,6\alpha}$ = 0 Hz). The chemical shifts of the C-6 hydrogens (Fig. 1) were established by the 2D COSY experiment mentioned above.



The α and β assignments[4] are based on the observed coupling constants, i.e., the hydrogen showing the large *vicinal* coupling (13 Hz) with H-7 is assigned as *antiperiplanar* to H-7. It is this hydrogen at C-6 which shows the 5-Hz coupling with H-5 (dihedral angle approaching 0°). In the nOe experiment, irradiation of H-5 causes a 9% enhancement of H-6β, no enhancement of H-6α. Acetylation of lobscurinol (**19***a*) afforded acetyllobscurinol (**19***c*), identical with the naturally occurring compound. The ^1H nmr spectral data obtained for **19***a* and **19***c* are very similar to those reported for lycoplegmarine (**19***e*) and acetyllycoplegmarine (19).

Epilobscurinol (**19***b*) was obtained in very small amounts (~1 mg), and was characterized as its acetyl derivative **19***d*. The hreims spectrum of acetylepilobscurinol is very similar to that of **19***c*. The ^1H nmr spectrum of **19***d* is remarkably similar to that of **19***c* except for the signals associated with H-5. This signal appears slightly downfield (δ 5.45 vs. 5.40) from that in acetyllobscurinol (**19***c*) and shows *vicinal* coupling with both C-6 hydrogens (7 Hz, 7 Hz), allylic coupling (2 Hz) with H-3, and W plan coupling (3 Hz) with H-7, consistent with its α-orientation. Due to the limited availability of **19***d*, the ^{13}C nmr spectrum was not obtained.



[4]Substituents on the same side as the C-13, C-14 bond are arbitrarily designated β, those on the opposite side are designated α.

23

Acrifolinol (22)

The fractions containing lyconnotinol (**11***a*) afforded two minor, isomeric alkaloids, acrifolinol (**22**) and the known alkaloid lycofoline (**23**). To the best of our knowledge, acrifolinol (**22**), a reduction product of acrifoline (**24**) (20) has not been reported previously as a natural product. To confirm the structural assignments, acrifoline (**24**) was reduced with sodium borohydride in the presence of sodium hydroxide (21) to give the C-15 epimers, acrifolinol (**22**) and lycofoline (**23**).

Experimental

High resolution electron impact mass spectra (hreims) were recorded on an AEI MS-50 mass spectrometer coupled to a DS-50 computer. Data are reported as *m/z* (formula, relative intensity). Unless diagnostically significant, peaks with intensities less than 20% of the base peak are omitted. Chemical ionization mass spectra (cims) were recorded on an AEI MS-12 mass spectrometer with ammonia as the reagent gas. Gas chromatography – mass spectra (gc–ms) were recorded on a Varian Vista 600 equipped with a mass spectrometry detector 7070E. Fourier transform infrared (ftir) spectra were recorded (thin film cast from $CHCl_3$ solution unless otherwise noted) on a Nicolet FT 7199 interferometer. Ultraviolet (uv) spectra were recorded on a Hewlett Packard 8450A or a Unicam SP 1700 spectrophotometer. Optical rotations were recorded on a Perkin Elmer 141 polarimeter. The ^1H and ^{13}C nuclear magnetic resonance (nmr) spectra were measured (in $CDCl_3$ unless otherwise noted) on Bruker WH-200, WH-300, WH-360, or WH-400 spectrometers. Chemical shifts are reported in parts per million (δ value) from tetramethylsilane (TMS). For ^1H nmr, residual $CHCl_3$ in $CDCl_3$ was employed as the internal standard (assigned as 7.26 ppm downfield from TMS). For ^{13}C nmr, $CDCl_3$ was employed as the internal standard (assigned as 77.0 ppm downfield from TMS). Melting points are uncorrected and were measured on a Zeitz–Wetzlar or a Thomas model 40 melting point apparatus.

Reagent grade solvents were distilled prior to use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C. Analytical grade diethyl ether was used without further purification. Pyridine was distilled from NaOH and stored over NaOH. Acetic anhydride was dried over P_2O_5 and distilled over sodium acetate.

Woelm (activity III/20 mm) and Brockman (activity I and II) neutral alumina were used for column chromatography. E. Merck silica gel 60 (230–400 mesh) was used for flash column chromatography. Pharmacia Sephadex LH20 and G10 were used for gel filtration chromatography. Analytical thin-layer chromatography (tlc) was carried out on silica gel precoated tlc plates (E. Merck DC-Alufolien, Kieselgel 60 F-254 0.2 mm thickness) and on alumina precoated tlc plates (E. Merck DC-Alufolien, Aluminumoxide 60 F-254 neutral type E 0.2 mm thickness). The chromatograms were examined under ultraviolet light (254 or 350 nm). Visualization was completed by spraying with Dragendorf's reagent (solution A: 1.7 g of basic $Bi(NO_3)_3 \cdot 5H_2O$ in 100 mL of water:acetic acid, 4:1; solution B: 40 g of KI in 100 mL of water; spray solution: 20 mL of solution A, 5 mL of solution B, and 70 mL of water) or by dipping in a 3% phosphomolybdic acid solution (3 g of $20MoO_3 \cdot 2H_3PO_4 \cdot 48H_2O$, 0.5 g of $H_4Ce(SO_4)_4$ in 100 mL of 3% (v/v) sulphuric acid).

Molecular formulae were established by hreims. Each new compound reported gave a single spot on tlc on both alumina and silica gel and showed no spurious peaks in the ^1H and ^{13}C nmr spectra.

Plant collection and extraction

Lycopodium obscurum was collected in September and October at

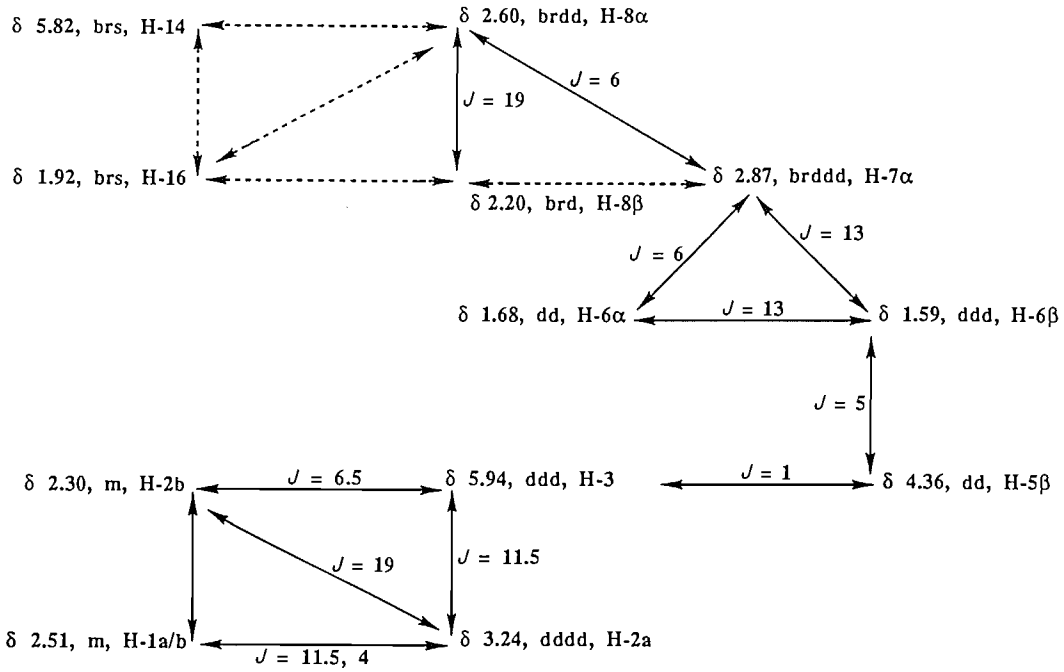

FIG. 1. ^1H–^1H chemical shift correlations obtained from the COSY 90 spectrum of lobscurinol (**19***a*). Chemical shifts in δ values, coupling constants (*J*) in Hz. Full arrows indicate measurable couplings, broken arrows indicate correlations where coupling constants were too small to be measured.

Pine Tree campgrounds, Fox Creek, Alberta, and 125 km south of Grande Prairie, Alberta, off forestry road 734. Specimens (nos. 91186, 92370, 92311) have been deposited in the herbarium, Department of Botany, University of Alberta. The whole plant was air-dried for three weeks, ground (Wiley mill), and suspended in 2% aqueous tartaric acid contained in 4-L Erlenmeyer flasks fitted with stopcocks at the bottom. Each flask contained 1 L aqueous tartaric acid and 0.5 kg ground plant. The mixture was stirred at room temperature for 24 h. The suspension was allowed to settle, the solution drained and then filtered. The extraction was repeated three times; then the clarified aqueous solution was concentrated to half volume *in vacuo* at 50°C. A white solid (negative to Dragendorf reagent) was removed by filtration and the filtrate was washed with chloroform (3×) and made basic to pH 11) with aqueous ammonia. The basic solution was extracted with ether and then chloroform. Each of the ether and chloroform layers were washed with water, dried ($MgSO_4$), and concentrated. The two extracts were combined to give the crude alkaloids (4.29 g from 4.7 kg plant material).

Isolation and characterization of the new alkaloids[5]

The crude alkaloid mixture (5.1 g) was partitioned into seven fractions by chromatography over neutral alumina (Woelm, 400 g) using methanol in dichloromethane as the eluant: fraction A, 0.3% methanol (0.5 L), 2.42 g; B, 0.5% methanol (0.5 L), 0.78 g; C, 1.0% methanol (1 L), 0.17 g; D, 1.0% methanol (1 L), 0.76 g; E, 2.0% methanol (1 L), 0.20 g; F, 3% methanol (0.5 L), 0.24 g; G, 5% methanol (1 L), 20% methanol (1 L), 0.43 g.

*Hydroxypropyllycodine (9*a)

Fraction D (0.60 g) was chromatographed over neutral alumina (100 g) eluting with 0.2, 0.5, 1.0, and 2.0% methanol in dichloromethane. The fraction that eluted with 1% methanol was subjected to ptlc over silica gel (eluent 3% methanol in ether saturated with ammonia). Hydroxypropyllycodine (**9***a*) was obtained as an opaque solid: $[\alpha]_D$ +11° (*c* 0.39, methanol); λ_{max} nm (log ε): 272 (3.7), ca. 280 (shoulder); ftir ν_{max} cm^{-1}: 3320 (br, NH and OH), 1650, 1590, 1570; ^1H nmr (see Table 5); ^{13}C nmr (see Table 1); hreims: *m/z* calcd. for $C_{19}H_{28}N_2O$: 300.2203; found: 300.2199 (19, M^+), 285 (2), 256 ($C_{17}H_{24}N_2$, 3), 243 ($C_{15}H_{19}N_2$, 100), 199 ($C_{13}H_{15}N_2$, 19), 171 (4).

*Acetylation of hydroxypropyllycodine (9*a)

Hydroxypropyllycodine (**9***a*, 2 mg), Ac_2O (1 mL), and Et_3N (5 drops) were stirred at room temperature overnight. Excess Ac_2O was decomposed by dropwise addition of water, the solvent was evaporated azeotropically with benzene *in vacuo*, and the residue was purified by preparative tlc (silica gel: 1% methanol in ethyl acetate – ammonia vapours; alumina: ethyl acetate:Skellysolve B, 1:4) to afford **9***b* (ca. 2 mg): ftir ν_{max} cm^{-1}: 1737, 1656, 1242; ^1H nmr (Table 5); ^{13}C nmr (Table 1); cims: *m/z* 385 (100 M^+ + 1); hreims: *m/z* calcd. for $C_{23}H_{32}N_2O_3$: 384.2415; found: 384.2405 (71, M^+), 341 (100), 327 (13), 325 (74), 324 (26), 298 (21), 285 (15), 267 (58), 225 (35).

*Acetyllyconnotinol (11*b)

A 1:1 mixture (by ^1H nmr, 3 mg) of lyconnotinol (**11***a*) and an unidentified alkaloid was obtained by chromatography of fraction F over alumina (eluent 2% methanol in CH_2Cl_2) followed by ptlc over silica gel (3% CH_3OH in CH_2Cl_2 saturated with ammonia). The mixture was acetylated (acetic anhydride, overnight at room temperature) and purified by filtration through alumina (pipette) in ethyl acetate to give monoacetyllyconnotinol (**11***b*) (1.5 mg). Additional material was obtained by similar treatment of other fractions from the chromatography of fraction F. A total of 5 mg of monoacetyllyconnotinol (**11***b*) was obtained as a viscous liquid from fraction F: ftir ν_{max} cm^{-1}: 3200 (OH), 2810, 2720, 2660 (Bohlmann bands), 1736, 1247, 1214, 1162, 1097, 1060, 1033; uv (ethanol) λ_{max} nm (log ε): 234 (3.72); ^1H nmr (400 MHz): 6.20 (1H, brd, *J* = 10 Hz, H-11), 5.68 (1H, brddd, *J* = 10, 5, 2 Hz, H-10), 5.49 (1H, t, *J* = 4 Hz, H-7), 4.10 (1H, ddd, 7.5, 3.4, 3.3 Hz, H-5 eq), 3.87 (1H, dd, *J* = 10.6, 5.2 Hz, H-8a), 3.71 (1H, dd, *J* = 10.5, 7 Hz, H-8b), 3.20 (1H, brd, *J* = 18 Hz, H-9 eq), 3.09 (1H, brdd, *J* = 18, 5 Hz, H-9 ax), 2.79 (1H, brddd, *J* = 20, 7.5, 4 Hz, H-6 ax), 2.68 (1H, ddd, *J* = 11.5, 11.5, 4.4 Hz, H-1 ax), 2.58 (1H, dt, *J* = 11.5, 2, 2 Hz, H-1 eq), 2.27 (1H, brd, *J* = 20.4 Hz, H-6 eq), 2.04 (3H, s, CH_3CO_2-), 1.98 (3H, m, H-15), 1.80–1.66 (6H, m), 1.52 (1H, brdm, *J* = 15 Hz, H-3a), 1.38 (1H, brd, 3.3, -O*H*), 0.89 (1H, d, *J* = 7 Hz); ^{13}C nmr: see Table 2; hreims: *m/z* calcd. for $C_{18}H_{27}NO_3$: 305.1992; found: 305.1988 (0.6, M^+), 190 (100), 172 (3), 144 (3).

[5]A complete description of the isolation of all of the alkaloids, including the identification of the known compounds, may be found in ref. 16.

For personal use only.

Acetyllyconnotinol (**11***b*) was further characterized as its crystalline methiodide, mp 192–193°C (from acetone).

Reduction of lyconnotine (13) to lyconnotinol (11a)

Lyconnotine (**13**) (119 mg) and $LiAlH_4$ (117 mg) in dry ether (10 mL) were heated under reflux for 4 h. Excess $LiAlH_4$ was decomposed by careful addition of acetic acid in ether, the mixture was diluted with ether, and filtered. The filtrate was diluted with water (5 mL), the ether and aqueous layers were separated, and the aqueous layer was extracted with chloroform (3 × 10 mL). The combined ether and chloroform extracts were concentrated *in vacuo*, then filtered through alumina (2% methanol in chloroform) to afford lyconnotinol (**13**) (100 mg). Lyconnotinol crystallizes from methanol–acetone as off-white prisms, mp 173–175°C; $[\alpha]_D$ +103° (*c* 0.43, methanol); uv (ethanol) λ_{max} nm (log ε): 235 (3.72); ftir ν_{max} cm^{-1}: 3340 (br, OH), 3027, 3013, 3006 (olefinic CH), 2880, 2824, 2789, 2773, 2763, 2747 (Bohlmann bands), 1642, 1099, 1081, 1062, 1033; ^1H nmr (400 MHz): 6.19 (1H, brd, *J* = 10 Hz, H-11), 5.71 (1H, brdd, *J* = 10, 5 Hz, H-10), 5.49 (1H, t, *J* = 4 Hz, H-7), 4.09 (1H, brs, $W_{1/2}$ = 16 Hz, H-5 eq), 3.43 (1H, dd, *J* = 10.4, 5 Hz, H-8a), 3.28 (1H, dd, *J* = 10.4, 6.3 Hz, H-8b), 3.23 (1H, brd, *J* = 18 Hz, H-9 eq), 3.12 (1H, brdd, *J* = 18, 5 Hz, H-9 ax), 2.80 (1H, brdd, *J* = 20, 7, 4 Hz, H-6 ax), 2.74 (1H, ddd, *J* = 12, 12, 4.5 Hz, H-1 ax), 2.58 (1H, brd, *J* = 12 Hz, H-1 eq), 2.27 (1H, brd, *J* = 12 Hz, H-6 eq), 1.93–1.66 (7H, m), 1.52 (1H, brdm, *J* = 15 Hz, H-3a), 1.45 (1H, brs, OH), 0.90 (3H, d, *J* = 6.4 Hz, H-16); ^{13}C nmr: see Table 2; cims: *m/z* 264 (100, M^+ + 1); hreims: *m/z* calcd. for $C_{16}H_{25}NO_2$: 263.1887 (not observed); 190 ($C_{12}H_{16}NO$, 100), 172 ($C_{12}H_{14}N$, 3), 144 ($C_{10}H_{10}N$, 3).

Acetylation of lyconnotinol (11a)

Lyconnotinol (84 mg), Ac_2O (10 mL), and Et_3N (5 drops) were stirred at room temperature for 15 h. Excess Ac_2O was decomposed with water and most of the solvent was removed by azeotropic distillation with benzene *in vacuo*. The mixture was diluted with water (10 mL), made basic (10% NaOH), and extracted with chloroform (5 × 10 mL). The organic solution was concentrated *in vacuo* and separated by chromatography over alumina (Skellysolve B:ethyl acetate, 1:1) into 3 fractions **a**–**c** containing diacetyllyconnotinol (**11***c*) (8 mg), a mixture of mono and diacetyllyconnotinol (58 mg), and monoacetyllyconnotinol (18 mg), respectively. Fraction **b** was separated by preparative tlc (3% methanol in ethyl acetate saturated with ammonia vapours) to afford **11***b* and **11***c* (50 mg and 3.8 mg, respectively). Monoacetyllyconnotinol (**11***b*) thus obtained is identical with the sample from natural sources. Diacetyllyconnotinol (**11***c*): ftir ν_{max} cm^{-1}: 2800, 2720, 2660 (Bohlmann bands), 1737, 1248, 1238, 1086, 1061, 1034; ^1H nmr (400 MHz): 6.17 (1H, brd, *J* = 10 Hz, H-11), 5.70 (1H, brdd, *J* = 10, 5 Hz), 5.48 (1H, t, *J* = 4 Hz, H-7), 5.17 (1H, dd, *J* = 7.9, 4.2 Hz, H-5 eq), 3.87 (1H, dd, *J* = 10.7, 5.2 Hz, H-8a), 3.72 (1H, dd, *J* = 10.7, 6.8 Hz, H-8b), 3.19 (1H, brd, *J* = 19 Hz, H-9 eq), 3.10 (1H, brdd, *J* = 19, 5 Hz, H-9 ax), 2.86 (1H, ddd, *J* = 21, 7.9, 5 Hz, H-6 ax), 2.64 (1H, ddd, *J* = 12, 12, 4 Hz, H-1 ax), 2.57 (1H, brd, *J* = 12 Hz, H-1 eq), 2.21 (1H, brd, *J* = 21 Hz, H-6 eq), 2.06 (3H, s, CH_3CO_2-), 2.05 (3H, s, CH_3CO_2-), 1.94–1.84 (2H, m), 1.79–1.63 (5H, m), 0.92 (3H, d, *J* = 6.7 Hz, H-16). The methiodide melts at 176–177°C (from acetone–ether).

Obscurinine (14) and isoobscurinine (15)

The portion of fraction D eluted with 0.5% methanol (see isolation of hydroxypropyllycodine above) was separated by flash chromatography (eluent acetone–CH_2Cl_2 (1:1)) to give lycopodine (**6***a*), isoobscurinine (**15**, 4 mg), and obscurinine (**14**, 85 mg). *Isoobscurinine* (**15**) crystallizes from Skellysolve B – acetone as off-white plates, mp 106–107°C; $[\alpha]_D$ +107° (*c* 1.1, methanol); ftir ν_{max} cm^{-1}: 2964, 2924, 2853, 2838, 2786 (Bohlmann bands) 1734, 1649, 1605; ^1H nmr: see Table 5; ^{13}C nmr: see Table 3; hreims: *m/z* calcd. for $C_{17}H_{24}N_2O$: 272.1890; found: 272.1888 (100, M^+), 271 (5), 257 (15), 189 (5), 173 (20), 172 (21), 98 (36), 84 (51), 72 (66), 71 (64), 70 (30), 58 (88), 57 (30).

Obscurinine (**14**) crystallizes from Skellysolve B – acetone as off-white plates, mp 128–130°C (lit. (15) mp 124–125.2°C); $[\alpha]_D$ +242° (*c* 0.5, methanol); uv (ethanol) λ_{max} nm (log ε): 233 (4.0); ftir ν_{max} cm^{-1}: 3029, 3006 (CH, olefinic), 2963, 2944, 2936, 2912, 2838, 2809, 2801, 2792, 2765, 2719, 2708 (Bohlmann bands), 1733, 1646, 1627, 1603; ^1H and ^{13}C nmr: see Tables 5 and 3; cims: *m/z* 273 (100, M^+ + 1); hreims: *m/z* calcd. for $C_{17}H_{24}N_2O$: 272.1890; found: 272.1886 (100, M^+), 271 (3), 257 (15), 189 (10), 172 (10), 98 (18), 84 (34), 72 (61), 71 (62), 70 (22), 58 (39), 57 (18).

Obscurinine (14) from lobscurinol (19a)

Lobscurinol (1.8 mg) dissolved in dichloromethane (0.2 mL) was added to a suspension of pyridinium chlorochromate (5 mg) in dichloromethane (0.4 mL) at 0°C. The mixture was stirred at 0°C for 30 min, then warmed to room temperature for 3 h. The reaction mixture was filtered through a pipette containing alumina and washed with chloroform. The organic solution was evaporated under reduced pressure to afford *lobscurinine* (**18**) (1 mg); ftir ν_{max} cm^{-1}: 1722, 1663, 1643; ^1H nmr (400 MHz): 6.95 (1H, dd, *J* = 11.7, 7.3 Hz, H-3), 5.92 (1H, brs, $W_{1/2}$ = 5.6 Hz, H-14), 3.33 (1H, dddd; *J* = 14, 11.7, 11.7, 2 Hz, H-2), 2.35 (3H, s, -NCH_3), 2.23 (1H, d, *J* = 17.3 Hz, H-8β), 1.98 (3H, s, H-16), 1.83 (1H, ddd, *J* = 15.2, 6.6, 2.5 Hz); ^{13}C nmr: see Table 4; cims: *m/z* 274 (100, M^+ + 1); hreims: *m/z* calcd. for $C_{17}H_{23}NO_2$: 273.1730; found: 273.1721 (13, M^+), 258 (34), 190 (5), 85 (20), 84 (100), 70 (14), 57 (50). A few drops of aqueous NH_3 were added to lobscurinine (**18**) dissolved in a minimum amount of chloroform. The mixture was stirred at room temperature overnight. Concentration under reduced pressure gave a single compound, identified (^1H nmr, ir, tlc) as obscurinine (**14**), in quantitative yield.

Lobscurinol (**19***a*) (2 mg) was obtained as a colourless oil from fraction E by chromatography (alumina, methanol in dichloromethane, 0.5% to 1%) and further purification by two successive preparative tlc's (methanol in dichloromethane 3% and 5%, atmosphere of ammonia); ftir ν_{max} cm^{-1}: 3600–3200 (br, OH), 1658; ^1H nmr: see Table 5; ^{13}C nmr: see Table 4; hreims: *m/z* calcd. for $C_{17}H_{25}NO_2$: 275.1887; found: 275.1881 (17, M^+), 192 (20), 85 (21), 84 ($C_5H_{10}N$, 100), 83 (22), 58 (28), 57 (44).

Epilobscurinol (19b)

Relatively pure epilobscurinol (**19***b*) (1 mg) was obtained from fraction E where it eluted after lobscurine (**19***a*, see above). It was further purified by preparative tlc (5% methanol in dichloromethane, atmosphere of ammonia), and then transformed to its acetyl derivative **19***d*. The acetylation (Ac_2O–pyridine) product was purified by preparative tlc (3% methanol in dichloromethane, atmosphere of ammonia); ^1H nmr: see Table 5; hreims: *m/z* calcd. for $C_{19}H_{27}NO_3$: 317.1992; found: 317.1991 (47, M^+), 302 (5), 258 (68), 215 (23), 85 (20), 84 ($C_5H_{10}N$, 100), 83 (21), 70 (25), 58 (57), 57 (37).

Acetyllobscurinol (19c)

Acetyllobscurinol (**19***c*) (3.5 mg) was obtained as a colourless opaque solid from fraction D by flash chromatography (acetone:dichloromethane, 1:4, 1:1, and 1% methanol in dichloromethane presaturated with ammonia) and by preparative tlc (3% methanol in ether in an atmosphere of ammonia); $[\alpha]_D$ +110° (*c* 0.16, methanol); uv (ethanol) λ_{max} nm (log ε): 234 (3.3); ftir ν_{max} cm^{-1}: 2956, 2925, 2854, 1735, 1659, 1240; ^1H and ^{13}C nmr: see Tables 5 and 4; cims: *m/z* 318 (100, M^+ + 1); hreims: *m/z* calcd. for $C_{19}H_{27}NO_3$: 317.1992; found: 317.1985 (18, M^+), 274 (5), 258 ($C_{17}H_{24}NO$, 100), 257 (8), 215 (39), 84 (38), 83 (10), 70 (12), 58 (39), 57 (21).

Des-N-methyl-β-obscurine (5b)

Trituration of fraction G left a residue (70 mg) that was purified by flash chromatography over silica gel (eluent 3% CH_3OH in CH_2Cl_2 saturated with ammonia) to give des-*N*-methyl-β-obscurine (**5***b*); mp 290–293°C; $[\alpha]_D$ −34° (*c* 0.21, methanol); ^1H nmr (400 MHz): 7.57 (1H, d, *J* = 9 Hz, H-3), 6.44 (1H, d, *J* = 9 Hz, H-2), 2.91 (1H, brdd, *J* = 19, 7 Hz, H-6 ax), 2.76 (1H, dm, *J* = 13 Hz, H-9 eq), 2.43 (1H, brddd, *J* = 13, 13, 2 Hz, H-9 ax), 2.40 (1H, brd, *J* = 19 Hz, H-6 eq), 2.10 (1H, brsext, *J* = 3 Hz, H-7 eq), 1.70 (1H, brdm, *J* = 12 Hz, H-8 eq), 1.60–1.35 (5H, m, H-12, H-14 eq, 2 H-10, H-15), 1.30–1.20 (3H, m, H-8 ax, 2 H-11), 1.03 (1H, dd, *J* = 11, 11 Hz, H-14 ax), 0.80 (3H, d, *J* = 6.5 Hz, H-16); hreims: *m/z* calcd. for $C_{16}H_{22}N_2O$: 258.1734; found: 258.1733 (14, M^+), 201 (100). The spectra (ir, ^1H and ^{13}C nmr) were identical with those of an authentic sample (9).

*Des-*N*-methyl-α-obscurine (4b)*

An uv-active material (1.3 mg), showing a single spot on tlc, was obtained from the chromatography described above and was identified (gc–ms) as a mixture of lobscurinol and des-*N*-methyl-α-obscurine. The mixture was acetylated (excess Ac_2O, 5 drops Et_3N, overnight). The reaction mixture was concentrated *in vacuo* and separated by preparative tlc (3% methanol in dichloromethane) to afford acetyllobscurinol (**19***b*) and acetyl des-*N*-methyl-α-obscurine (**4**, R = Ac); ^{1}H nmr (400 MHz): 6.49 (1H, brs, $W_{1/2}$ = 9 Hz, N*H*), 3.64 (1H, brd, J = 13.5 Hz), 3.14 (1H, brd, J = 10 Hz), 2.70 (1H, brddd, J = 13.5, 12, 3 Hz), 2.13 (3H, s, -NCOC*H*$_3$), 2.08 (1H, m, H-15), 1.92 (1H, brs, $W_{1/2}$ = 14 Hz), 0.91 (3H, d, J = 6.5 Hz); hreims: *m/z* calcd. for $C_{18}H_{26}N_2O_2$: 302.1996; found: 302.1997 (39, M^+), 245 (100). The spectra (ir, nmr) were identical with those of an authentic sample (9).

Acrifolinol (22) and lycofoline (23)

These alkaloids were obtained from fraction F after several chromatographic separations (16). They were compared with samples that were prepared from acrifoline (**24**) in the following manner: acrifoline hydrobromide (57 mg) and sodium borohydride (0.12 g) were added to a solution of sodium hydroxide (0.5 g) in 80% aqueous ethanol (10 mL). The reaction mixture was heated under reflux for 2 h, excess $NaBH_4$ was destroyed by the dropwise addition of acetic acid, and most of the alcohol was removed at the pump. The residue was diluted with water, basified (10% NaOH), and extracted with chloroform. The products were separated by ptlc (eluent 5% methanol in ether, atmosphere of ammonia) to give acrifolinol (**22**, 19 mg) and lycofoline (**23**, 6 mg), identical with the alkaloids isolated from *L. obscurum*.

HERMAN LAM, SEBASTIAN M. MARCUCCIO, POLINA I. SVIRSKAYA, SHAFRIRA GREENBERG, A. B. P. LEVER, CLIFFORD C. LEZNOFF, and RONALD L. CERNY. Can. J. Chem. **67**, 1087 (1989).

Three different binuclear phthalocyanines were prepared and characterized. Two of the binuclear phthalocyanines are cofacially linked by rigid naphthalene and anthracene spacers, while the third consists of a direct linkage between two phthalocyanine rings. The dicobalt, dicopper, and dizinc derivatives were prepared by inserting the metal into the metal-free species. The synthesis and the physical and spectroscopic properties of the precursor bisphthalonitriles are also included.

Key words: phthalocyanines, cofacial, binuclear, bisphthalonitriles.

HERMAN LAM, SEBASTIAN M. MARCUCCIO, POLINA I. SVIRSKAYA, SHAFRIRA GREENBERG, A. B. P. LEVER, CLIFFORD C. LEZNOFF et RONALD L. CERNY. Can. J. Chem. **67**, 1087 (1989).

On a préparé et caractérisé trois phtalocyanines binucléaires différentes. Deux d'entre elles sont liées d'une façon cofaciale par le biais de noyaux naphtalène et anthracène qui agissent comme rondelle d'espacement; dans le cas de la troisième, il s'agit d'un lien direct entre deux cycles phtalocyanines. On a préparé les dérivés comportant deux atomes de cobalt, de cuivre ou de zinc en insérant les métaux dans des espèces ne contenant pas de métal. On décrit aussi la synthèse ainsi que les propriétés physiques et spectroscopiques des bisphtalonitriles qui sont les précurseurs des phtalocyanines.

Mots clés: phtalocyanines, cofacial, binucléaire, bisphtalonitriles.

The use of porphyrins and phthalocyanines in electrocatalysis has been the subject of intensive research (1).

Four-electron reductions of oxygen to water using cofacial dicobalt porphyrins have been reported by different groups of researchers (2, 3). The cofacial structures have been achieved either by using a cyclophane type of framework (2) or by covalently linking two porphyrins on rigid spacers, via the 1,8-positions of anthracene and biphenylene (3). Some of these binuclear porphyrins are sensitive to light, oxygen, or both (2). To overcome this problem, we have synthesized metal-free binuclear phthalocyanines covalently linked by one (4), two (5), four (5), five (6), and "−1" (7) atom bridges and some of their metallated derivatives. In general these phthalocyanines are very stable towards light and oxygen. The dicobalt derivatives of these binuclear phthalocyanines catalyze the two-electron reduction of oxygen to hydrogen peroxide but the four-electron process has not been observed (8). The lack of a permanent cofacial interaction between the two phthalocyanine rings may be one of the reasons for not achieving the goal of a four-electron reduction. We wished to prepare phthalocyanine derivatives analogous to the cofacial porphyrins that catalyze the four-electron reduction of oxygen to water. Methods were developed to link phthalonitrile units to rigid spacer molecules to form the bridging bisnitriles, which can be converted to binuclear phthalocyanines.

We report herein the synthesis of three examples of binuclear phthalocyanines and their dicobalt, dicopper, and dizinc derivatives. In the direct linked binuclear phthalocyanines, the two phthalocyanine rings are joined as two phenyl groups in biphenyl derivatives, while in the cofacial systems the two phthalocyanine rings are linked via the 1,8-positions of naphthalene (9) and anthracene. With these new binuclear phthalocyanines, we have now synthesized a series of binuclear phthalocyanines in which the covalent bridging linkages range from five to "−1" atoms.

Synthesis of directly linked binuclear phthalocyanines

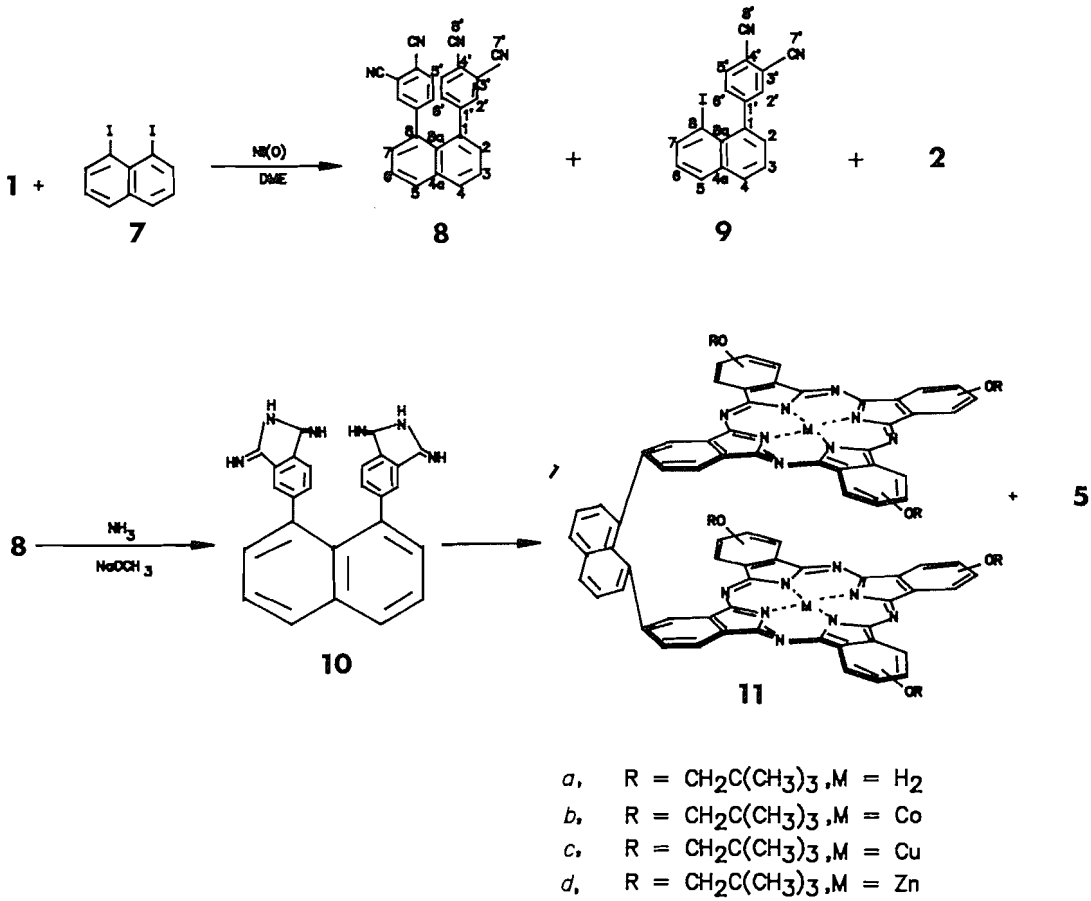
By a previously described method (10), elemental nickel was generated by reduction of nickel iodide with lithium in dry glyme in the presence of naphthalene. The activated nickel powder catalyzed the self-coupling of 4-iodophthalonitrile (**1**) to give 3,3′,4,4′-tetracyanobiphenyl (**2**) in 78% yield. Compound **2** was converted into its 1,3-diiminoisoindoline (**3**) (5, 6). Condensation of **3** with 5-neopentoxy-1,3-diiminoisoindoline (**4**) (5, 6) was carried out in 2-*N*,*N*-dimethylaminoethanol for 36 h. The resulting dark blue solution was purified by flash chromatography (11) to give the mononuclear 2,9,16,23-tetraneopentoxyphthalocyanine (**5**) and the binuclear 2,2-bi-(9,16,23-trineopentoxyphthalocyanine) (**6***a*) in 55 and 33% yield respectively. We can refer to **6***a* as the zero atom bridged binuclear phthalocyanine. The binuclear phthalocyanine **6***a* was converted to its dicobalt **6***b* and dicopper **6***c* derivatives by refluxing **6***a* in toluene/2-methoxyethanol with $CoCl_2$ and $Cu(OAc)_2$ respectively (5, 6). Compounds **2** and **6***a*–*c* were fully characterized by spectroscopic data and elemental analysis (see Experimental). Some spectroscopic data of **6***a* but not its synthesis or characterization have been previously mentioned (12).

Synthesis of binuclear phthalocyanines covalently bridged by naphthalene

Treatment of **1** and 1,8-diiodonaphthalene (**7**) with elemental nickel (10) at room temperature for 3.5 h gave 1,8-bis(3,4-dicyanophenyl)naphthalene (**8**), 1-iodo-8-(3,4-dicyanophenyl)-naphthalene (**9**), and 3,3′,4,4′-tetracyanobiphenyl (**2**) in 15.5, 2.5, and 42.5% yield respectively. Compound **8** was converted to its 1,3-diiminoisoindoline (**10**) as previously described (5, 6).

SCHEME 1

Condensation of **10** and **4** in 2-*N*,*N*-dimethylaminoethanol for 44 h gave a dark green solution. Purification by flash chromatography (11) followed by vacuum liquid chromatography (13) gave the mononuclear **5** and the binuclear **11***a* in 45 and 8.7% yield respectively. The binuclear **11***a* was converted to its dicobalt **11***b*, dicopper **11***c*, and dizinc **11***d* derivatives by refluxing **11***a* in toluene/2-methoxyethanol with $CoCl_2$, $Cu(OAc)_2$, and $Zn(OAc)_2$ respectively. Although **11***a–d* and **8** have been reported in a communication (9), the full details are reported here (see Experimental). The binuclear phthalocyanines **11***a–d* exhibit parent ion clusters in their fast atom bombardment (FAB) mass spectra (14). More importantly, no evidence of partially or half-metallated species of **11***b–d* were observed. The ultraviolet–visible (uv) spectrum of **11***a* gave a single broad (symmetric shape) absorption at the Q band region that had not been observed before in other metal-free binuclear phthalocyanines (7, 12). A more detailed ^1H nmr analysis of **8** than previously reported (9) indicates that the compound exists as a mixture of two rotamers at room temperature in a 1:1 ratio. The existence of rotamers suggests that there is a rotation barrier sufficiently higher than that of the unsubstituted 1,8-diphenylnaphthalene (15). The ^{13}C nmr of **8** also indicates the presence of rotamers at room temperature.



These rotamers did not separate by chromatographic methods. Although the two rotamers of **8** could be observed on the nmr time scale, their ultimate use in the formation of phthalocyanines at high temperatures, resulting in their subsequent equilibration again, removed any incentive to resort to heroic efforts to isolate the rotamers of **8**. After condensation, the binuclear phthalocyanine **11***a* should also exist as two isomers due to restriction in the rotation of the phthalocyanine rings. The two possible isomers of **11***a* were isolated as one fraction by chromatography. Construction of molecular models of **11***a* has shown substantial overlap of the two phthalocyanine rings in each isomer, and this may be the reason that these almost identical isomers are not separable by column chromatography. Separation of these isomers of **11***a* using high performance liquid chromatography (hplc) on a silica gel column was also not successful.

Synthesis of binuclear phthalocyanines covalently bridged by anthracene

The coupling reaction of aromatic halides using elemental nickel works well only with reactive halides such as iodides. The 1,8-diiodoanthracene is unknown. Even though 1,8-dichloroanthracene is readily available (16), it is not active enough to undergo the desired cross-coupling reaction.

Less electropositive arylzinc derivatives can tolerate various electrophilic functional groups such as nitriles and esters (17). These organometallic reagents readily undergo cross-coupling reactions with aryl halides (18), making arylzinc derivatives the reagents of choice in our synthesis. In general, direct attack

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12

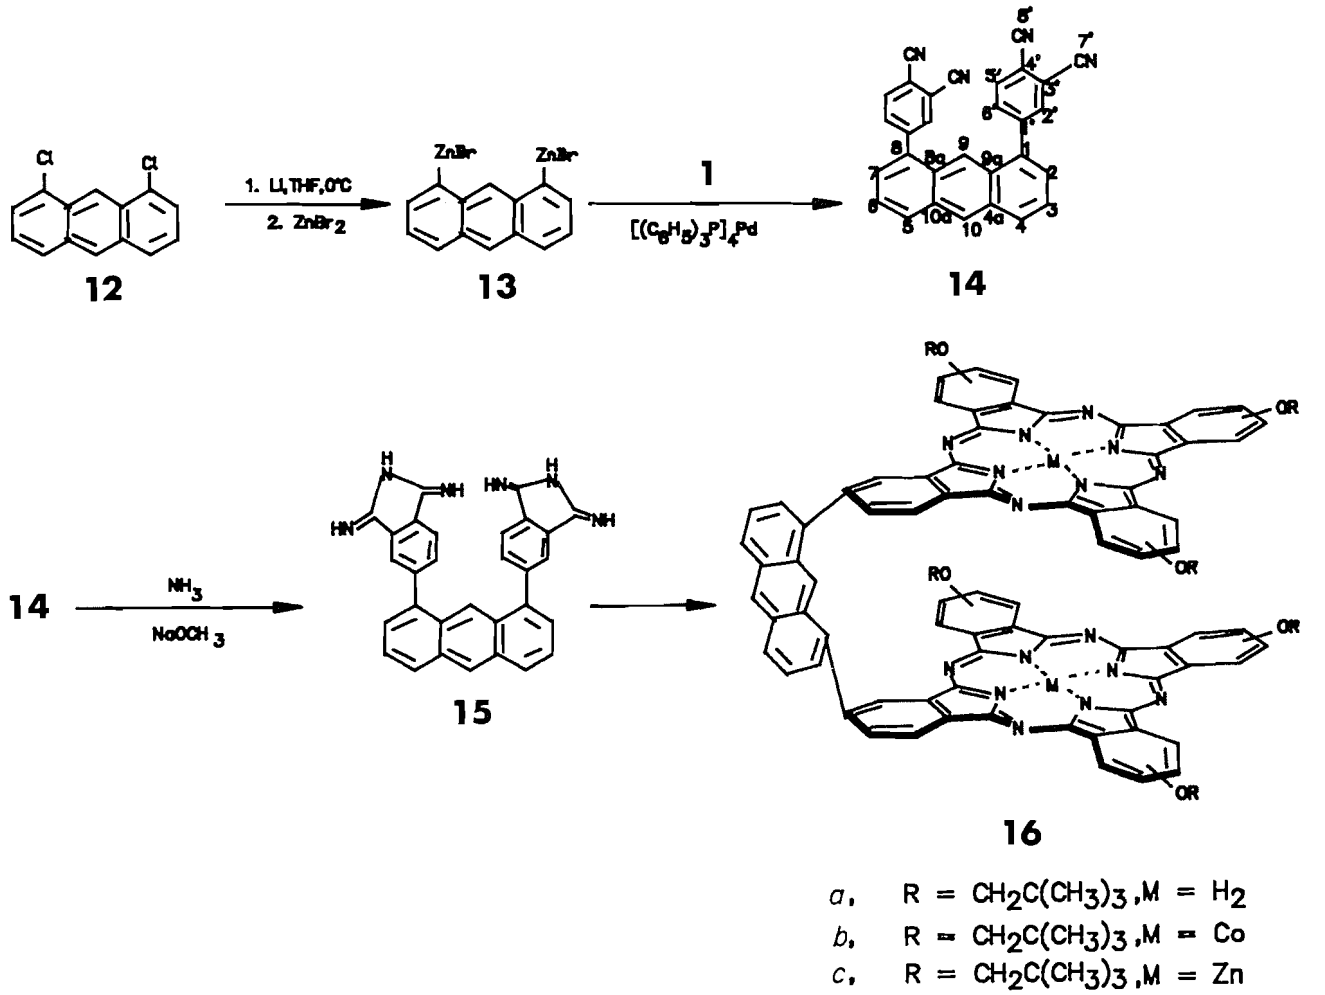
SCHEME 2



of aryl halide by zinc metal is difficult and the organozinc reagents are usually obtained by a two-step process from organolithium or Grignard reagents and the zinc halides (19). Instead of using an alkyllithium/aryl halide reaction to generate the organolithium intermediate, the organolithium can be generated conveniently by reacting the aryl halide directly with lithium metal in tetrahydrofuran (THF) using ultrasonic irradiation without any noticeable side reaction (20).

Treatment of 1,8-dichloroanthracene (**12**) with lithium and zinc bromide in dry THF at 0°C with ultrasonic activation for 2 h generated the 1,8-organozinc intermediate (**13**) (21). A cross-coupling reaction between **1** and **13** catalyzed by tetrakis-(triphenylphosphine)palladium (17, 18) gave 1,8-bis(3,4-dicyanophenyl)anthracene (**14**) in 9.9% yield. Compound **14** was converted to its 1,3-diiminoisoindoline (**15**) and condensed with **4** in 2-*N*,*N*-dimethylaminoethanol to give a dark green mixture. Upon dilution with water the mixture gave a blue colored residue. The mixture was purified by flash chromatography (11) to give a mixture of mononuclear phthalocyanine **5** and binuclear phthalocyanine **16***a*. A trace of the mononuclear phthalocyanine **5** was removed by gel permeation chromatography (22) to give the binuclear **16***a* in 12% yield. Metal-free binuclear phthalocyanine **16***a* was converted to its dicobalt (**16***b*) and dizinc (**16***c*) derivatives by standard procedures.

Unlike **8**, bisnitrile **14** does not exist as a mixture of rotamers, as shown by its simpler ^{1}H and ^{13}C nmr spectra, because of the low rotation barrier between the two phenyl rings in the 1,8-anthracene system (23). The uv spectrum of binuclear phthalocyanine **16***a* exhibits broad symmetric absorption similar to **11***a*. Parent ions were exhibited in the (FAB) mass spectra of **16***a–c* and no evidence for partially metallated species for **16***b* and *c* was observed.

Attempts to apply a similar organozinc procedure to 1,8-diiodonaphthalene did not give the desired product **8** (17–19). The products isolated were found to be 1-(3,4-dicyanophenyl)-naphthalene (**18**) and **2**. Due to the close proximity of the 1,8-positions on naphthalene, the formation of a monozinc-naphthalene intermediate **17** may be favoured over the naphthalene-1,8-dizinc species, although a dimer of **17** cannot be excluded. Reaction of **1** and **17** with zinc dissociated from naphthalene after reaction may explain the formation of **18**. The elemental nickel used in the cross-coupling reaction is not a true catalyst since it is not regenerated after the reaction (10). Large amounts of nickel iodide (more than 1:1 ratio) have been used for satisfactory results. Thin-layer chromatography of the reaction mixture has shown that the cross coupling between the organozinc derivatives and 4-iodophthalonitrile (**1**) is faster than the homo-coupling of **1** itself. In this regard, the cross-coupling reaction of organometallics and aryl halides catalyzed by transition metal complexes is superior to the mixed coupling between different aryl halides catalyzed by elemental nickel. The cross-coupling product is expected to be the major product in the case of the organometallic/aryl halide reaction, whereas the homo-coupling product is expected to be the major product in the elemental nickel catalyzed aryl halides coupling. The low yield of 1,8-bis(3,4-dicyanophenyl)naphthalene (**8**) is predictable because the 1,8-diiodonaphthalene has to react twice with 4-iodophthalonitrile to form the product, and has to compete against the homo-coupling reaction. The poor yield of 1,8-bis(3,4-dicyanophenyl)anthracene, which is obtained via a

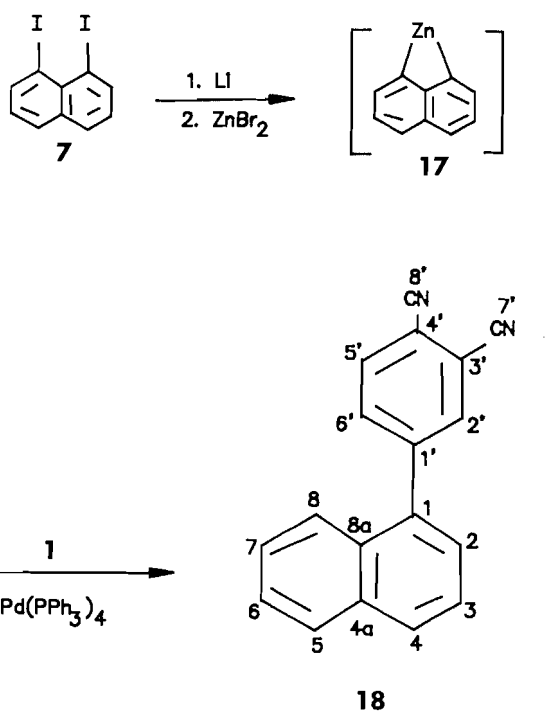
For personal use only.



SCHEME 3

different coupling, may be due to incomplete formation of the 1,8-dilithiated intermediate. Half of the 1,8-dichloroanthracene was recovered. Also, the possible formation of polymeric organozinc in which the zinc atom acts as a bridge to link up adjacent anthracene molecules may decrease the yield.

Physical and spectroscopic properties of the phthalonitriles

Phthalonitriles **2**, **8**, **14**, and **18** all have melting points higher than their unsubstituted parent compounds (16, 24) and exhibit characteristic CN absorption in the infrared region at 2240 cm^{-1}. Phthalonitriles **8** and **9** have the same molecular weight of 380. High resolution mass spectra of **8** and **9** were obtained to check their elemental composition. Together with elemental analysis data, phthalonitrile **8** was clearly identified as the symmetrical 1,8-disubstituted product.

The proton nmr spectra of the bisphthalonitriles all showed complicated patterns in the aromatic region. Chemical shift assignments were achieved for **2**, **8**, **9**, **14**, and **18** with additional coupling information obtained from correlation nmr and homo-decoupling experiments (Table 1). Carbon/proton correlation experiments have been done on the more soluble phthalonitriles (Table 2). The ^1H nmr and ^{13}C nmr of **2** are relatively simple. Selective irradiation of H2′, H5′, and H6′ in **2**, which resulted in changes in signal intensity in the ^{13}C spectra due to the nOe effect, helps to identify the chemical shifts of the carbons (26, 27).

[a]The numbering of the carbon atoms in the compounds listed follows that given for these structures in the schemes and does not follow from the names of the compounds.
[b]These values may be interchanged.
[c]These values may be interchanged.
[d]Data taken from ref. 27.
[e]The two given values correspond to the two rotamers **8***a* and **8***b* and may be interchanged.
[f]The chemical shift values for carbons 9 and 10 are 128.45 and 119.00 respectively.
[g]The chemical shift values for carbons 9 and 10 are 128.08 and 120.82 respectively.

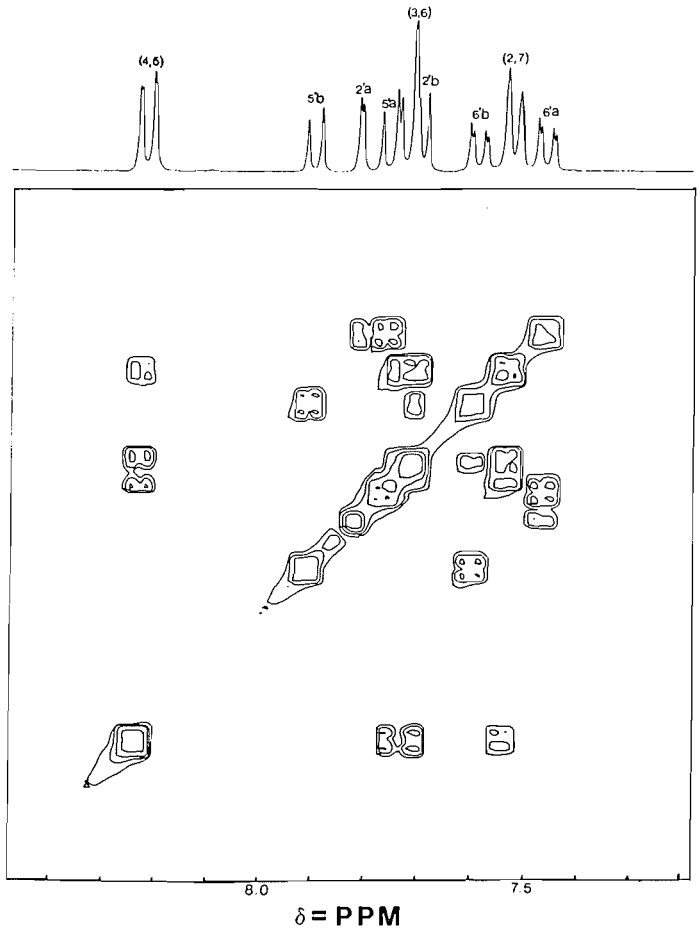

FIG. 1. ^{1}H homonuclear correlation (COSY) of a mixture of **8***a* and **8***b* in DMSO-d_6 at 25°C.

For the 1,8-disubstituted naphthalene systems, the two parallel phenyl rings are at an angle of about 70° to the plane of the naphthalene ring, to relieve some of the strain in the molecule (25). The distance between the 1,8-positions on the naphthalene ring is about 2.45 Å (24), which is too small for free rotation of the 3,4-dicyano-substituted phenyl rings at room temperature. The ^{1}H nmr of **8** at room temperature showed evidence that there is a sufficiently high rotation barrier between the two phenyl rings and **8** exists as two rotamers. The rotamer with two sets of cyano groups on the same side of the naphthalene plane is referred to as **8***a* and the other rotamer with cyano groups on the opposite side is referred to as **8***b*. Proton/proton correlation experiments clearly established the coupling relationship of the protons in the rotamers. The correlation spectrum indicated the protons on the phenyl rings of **8***a* and **8***b* as separate systems (Fig. 1). The chemical shifts for protons on the naphthalene ring do not seem to be affected by the different orientations of the phenyl rings. A model based on the different resultant dipoles pointed in different directions for **8***a* and **8***b* can help to assign the chemical shifts for the protons on the phenyl rings (Fig. 2). The orientation of the resultant dipoles may influence the localization of electron density over the ring and hence the deshielding effect of the π cloud. For **8***a*, the resultant influence is located between C3′ and C4′, which may have roughly equal effects on H2′ and H5′ and less effect on H6′. The expected chemical shifts are therefore H2′ = H5′ > H6′. For **8***b*, the resulting influence is concentrated around C4′, affecting H5′, H2′, and H6′ in decreasing order. The

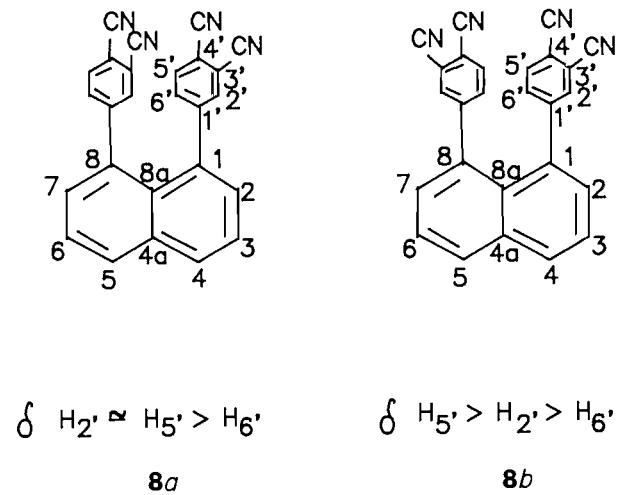

FIG. 2. 1,8-Bis(3,4-dicyanophenyl)naphthalene rotamers **8***a* and **8***b*.

expected chemical shifts are therefore H5′ > H2′ > H6′. The strongest influence will be experienced by H5′ in **8***b* due to the close distance between H5′ and the net dipole as shown in Fig. 2. With this model, the sequence of the predicted chemical shifts of the phenyl protons is found to be matched with the observed sequence. The nitrile groups cause the phenyl protons to shift downfield, which offsets the upfield shifting effect observed in the 1,8-diphenylnaphthalene, in which the ten phenyl protons resonate at 6.85 ppm in carbon tetrachloride (24). A carbon nmr spectrum of **8** at room temperature showed 18 peaks. If only one rotamer is present, 14 peaks are expected. At 100°C in DMSO-d_6 the spectrum consisted of 14 peaks as expected (see Experimental).

The proton spectrum of **9** is much simpler than that of **18** even though these compounds have similar structures. The chemical shifts of H2′ and H5′ of **9** are more downfield shifted than H6′. The characteristic C—I carbon appeared at 92.07 ppm. The distance between the 1,8-positions on anthracene is about 4.8 Å (16). The energy barrier of rotation of the phenyl rings at the 1,8-positions is quite small (23). In fact, ^{1}H nmr and ^{13}C nmr of **14** did not indicate the presence of rotamers at room temperature. Again, H2′ and H5′ are further downfield than H6′ and are consistent with the chemical shifts in the naphthalene systems.

Spectroscopic properties of the phthalocyanines

The infrared spectra of all metal-free phthalocyanines exhibited characteristic NH absorption at 3300 and 1020 cm^{-1}, which disappeared upon formation of their metallated derivatives. All phthalocyanines exhibited parent ions or ion clusters in their FAB mass spectra (14). All phthalocyanines gave satisfactory C, H, N analyses, while metal analyses were also good except for **6***b*, which was slightly low.

The double Q band seen in the mononuclear metal-free phthalocyanines as a consequence of D_{2h} symmetry is further split due to coupling in the binuclear phthalocyanines (12). Coupling in general can be expected to occur either through space in the close cofacial conformation, or via conjugation through the unsaturated bridge, or both. For binuclear phthalocyanines with low symmetry, transitions to higher and lower energy combinations are allowed, resulting in both blue and red shifts with respect to the mononuclear species (12). In fact, the zero linked binuclear phthalocyanine **6***a* and the previously reported

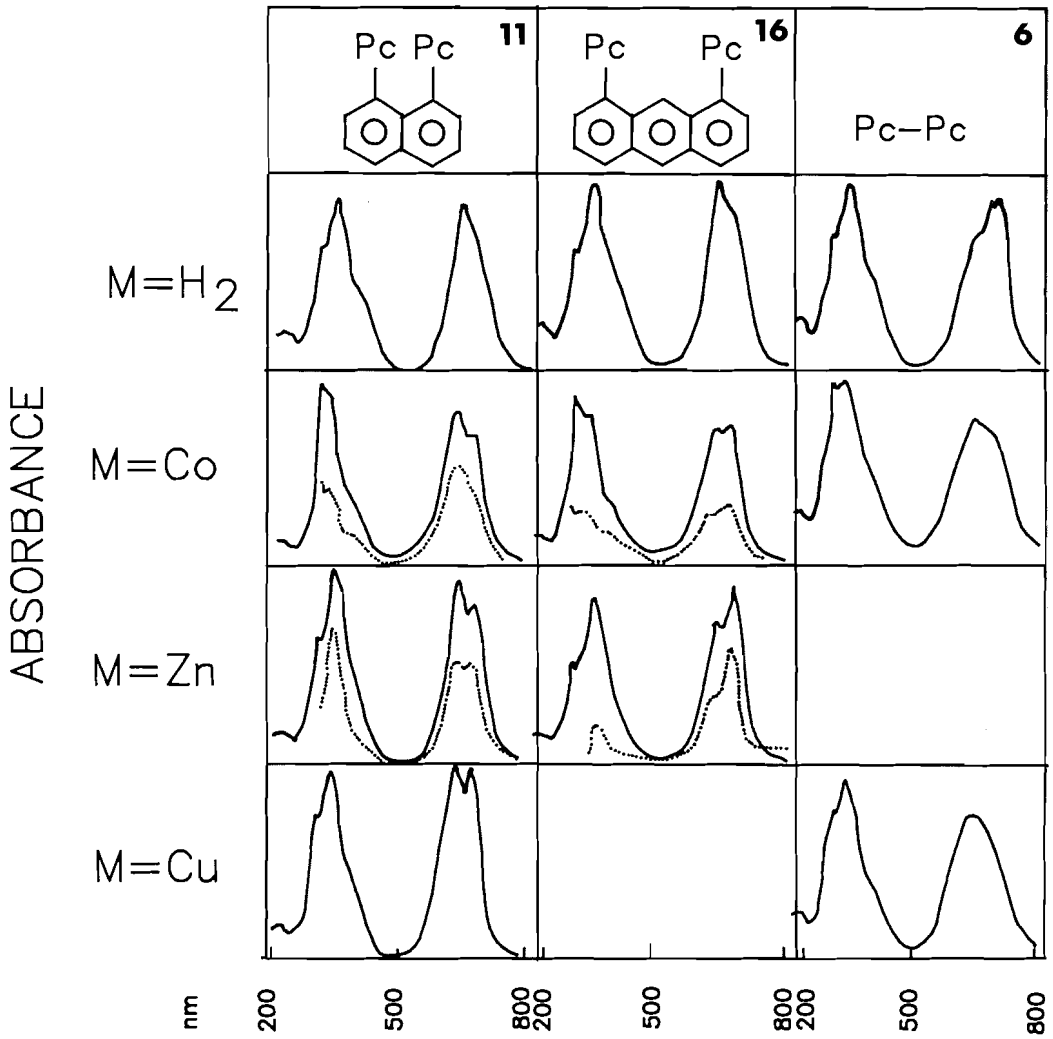

FIG. 3. Absorption spectra of metal-free and metallated binuclear phthalocyanines in *o*-dichlorobenzene at room temperature ([PcM], (---) $\sim 1 \times 10^{-5}$ M; (···) $\sim 5 \times 10^{-7}$ M).

binuclear phthalocyanines (4–6), except the negative linked binuclear phthalocyanine (7), show such splitting patterns. However, the electronic spectra of metal-free binuclear phthalocyanines **11***a* and **16***a*, which closely resembled one another, exhibited a single broad Q band absorption at 648 nm but with some evidence of splitting in the spectrum of **16***a* (Fig. 3).

Indeed, the spectra of **11***a* and **16***a* looked similar to the deprotonated spectrum of the five-atom bridged binuclear phthalocyanine (12), which is able to assume a close cofacial D_{4h} configuration. The similarity suggests that the two phthalocyanine rings in **11***a* and **16***a* are very close together and the four internal hydrogens are equivalent, which raises the symmetry of the molecules effectively to D_{4h}. For phthalocyanine with D_{4h} symmetry, the π–π^* transition is not split. There are large blue shifts in the Q band absorption in the metal-free cofacial D_{4h} binuclear phthalocyanines **11***a* and **16***a* (Table 3) relative to mononuclear metal-free phthalocyanines, indicative of the extensive electronic coupling between the cofacial rings (28, 29).

In general, all the metallated cofacial binuclear phthalocyanines showed two Q-band absorptions, the relative intensity varying with concentration. The absorption centered around 680 nm corresponds to the expected transition for uncoupled metallated phthalocyanines, whereas the 640-nm transition resulted from aggregated species (30). For cofacial systems, aggregation may be both intermolecular and intramolecular. Intermolecular aggregation is expected to be concentration dependent, while intramolecular aggregation should be concentration independent. When the concentration is sufficiently reduced, the spectrum becomes concentration independent and the remaining absorption near 640 nm arises from intramolecular coupling (aggregation) due to the cofacial arrangement (Fig. 3).

The proton nmr spectra of the binuclear phthalocyanines exhibited absorption peaks typical of the neopentoxy group and very weak aromatic signals. The NH absorption of **6***a* occurred around −3 ppm. The NH absorption of the binuclear phthalocyanines **11***a* and **16***a* occurred at higher field. Binuclear phthalocyanine **11***a* gives two sets of broad NH signals at −5 and −6 ppm. The two sets of signals may correspond to the two configurational isomers. The isomer which is exactly cofacial is related to the bisnitrile **8***a*. The other isomer is related to bisnitrile **8***b* in which the two rings are slightly away from each other but still have some degree of overlap in a cofacial manner. The broadening of all of the peaks is due to the positional isomers arising from the neopentyl substituents. The NH protons for the anthracene linked binuclear phthalocyanine **16***a* were observed at −6.5 ppm and are much sharper. The sharpening of the signal may be due to increased separation between the rings so that the neopentyl groups contribute less influence

[a]The concentration of the binuclear phthalocyanines was $\sim 1 \times 10^{-5}$ M.

on the overall configuration and hence less variation in the orientation of the two phthalocyanine rings. The upfield shift of the internal NH signal is very characteristic of a cofacial configuration. It is a result of the ring current effect of the two phthalocyanine rings being held closely in a cofacial arrangement. Similar upfield shifts for NH protons in cofacial porphyrins are well documented (2, 28). The NH signal disappeared in the ^{1}H nmr spectra of the zinc derivatives of **11***a* and **16***a*.

Experimental

Matheson high purity argon was used to maintain inert atmosphere conditions. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs. Nuclear magnetic resonance (nmr) spectra for protons and carbons were recorded on a Bruker AM300 nmr spectrometer. The position of signals is reported in δ units. (The splitting of the signals is described as singlets (s), doublets (d), triplets (t), quartets (q), doublets of doublets (dd), or multiplets (m).) The ^{1}H nmr spectra of 10^{-4} M solutions of the phthalocyanines were obtained by averaging 500–3000 scans over the absorption range. The ultraviolet–visible spectra (uv) were recorded on a Hewlett Packard HP8451A diode array spectrophotometer. Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode. The FAB spectra were obtained with a Kratos MS-50 triple analyzer mass spectrometer equipped with a FAB ion source of standard Kratos design and Ion Tech atom gun. The sample was dissolved in chloroform and a microlitre of the resulting solution added to a microlitre of *m*-nitrobenzyl alcohol on the probe tip. The spectra of the molecular ions of the binuclear phthalocyanines were obtained by signal averaging up to 256 scans over the appropriate mass range. The number in parentheses after the indicated ion shows the percentage of the base peak represented by that ion. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Flash chromatography was performed using silica gel of particle size 20–45 μm. All reactions, except the one that required sonication, were stirred with a magnetic stirrer. Ultrasound activation was carried out using a Branson 1200 sonicator. All solvents were freshly distilled before use. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario. Thin-layer chromatography (tlc) was performed using silica gel G as the absorbant.

3,3′-4,4′-Tetracyanobiphenyl (2)

By a previously described method (10), nickel iodide (dried for 4 h at 60–70°C/0.5 Torr; 1 Torr = 133.3 Pa) (4.53 g, 14.5 mmol), lithium (0.248 g, 35.7 mmol), and naphthalene (0.186 g, 1.45 mmol) in 30 mL of fresh distilled dry glyme were stirred at room temperature for 12 h. To the nickel powder, precipitated as a bulky black slurry, was added 1.0 g (3.9 mmol) of 4-iodophthalonitrile (**1**) dissolved in 5 mL of dry glyme. The reaction mixture became warm (30–35°C) and after 2 h the reaction was completed (tlc benzene/acetonitrile (9:1)). The reaction mixture was poured into 100 mL of ice-water; the solid was filtered and washed twice with ice-water. The resulting product was washed very slowly with benzene to remove most of the naphthalene. It was then extracted with ethyl acetate, dichloromethane, and acetonitrile (three times 30–40 mL portions for each solvent). The ethyl acetate, dichloromethane, and acetonitrile solutions were combined and dried over $MgSO_4$. The solvent was evaporated to give 0.5 g of crude product. The crude product was chromatographed by flash chromatography (11) using benzene, benzene/dichloromethane (1:1), and acetonitrile/dichloromethane (5:100) as eluants to give, in 78% yield, 0.39 g of **2** as white crystals, mp 291–293°C; ir (cm^{-1}): 2240 (CN), 1600, 1480, 1380, 1210, 910, 860, 840; uv (CH_2Cl_2) λ_{max} (log ε): 242 (4.16), 270 (4.18), 290 (4.14sh) nm; ^{1}H nmr and ^{13}C nmr: see Tables 1 and 2; ms *m/z*: 254 (M^+, 100), 227 (M^+ − HCN, 38), 220 (M^+ − 2HCN, 20). *Anal.* calcd. for $C_{16}H_6N_4$: C 75.60, H 2.36, N 22.04; found: C 75.54, H 2.07, N 21.98.

2,2-Bi-(9,16,23-trineopentoxyphthalocyaninyl) (6a)

By a previously described method (5, 6), the two crude diiminoisoindolines **3** and **4** were obtained from 0.273 g (1.10 mmol) of **2** and 6.0 g (28 mmol) of 4-neopentoxyphthalonitrile respectively. Compounds **3** and **4** were heated at 150°C (oil bath) in 20 mL of 2-*N*,*N*-dimethylaminoethanol and 10 mL of dimethylformamide (DMF) for 36 h under an argon atmosphere. After cooling to room temperature, the dark blue mixture was diluted with water, and the residue filtered and washed thoroughly with water until the filtrate was colorless. Preliminary purification of the product was achieved by flash chromatography using a 5 cm diameter column in which the crude product was preadsorbed on silica and eluted with hexane (200 mL), hexane/toluene (1:1) (1.5 L), and then hexane/toluene (1:2) until all the monomeric 2,9,16,23-tetraneopentoxyphthalocyanine (**5**) (3.3 g, 55% yield) was eluted. Further elution with toluene/2-methoxyethanol (200:5) (1.5 L) gave, after solvent evaporation, a portion of the dimer contaminated with traces of the monomer **5**. A second portion obtained by continued elution with toluene/2-methoxyethanol (200:5) (1 L) was contaminated with some green material. The latter portion was purified by evaporating the solution to dryness; the resultant solid was suspended in dry acetone, filtered, and washed with acetone until the filtrate was colorless. Finally, the product was purified by flash chromatography using silica gel and toluene/2-methoxyethanol (200:5) as eluant to give 565 mg (33% yield) of the product as a very dark blue shining solid; ir (cm^{-1}): 3300 (NH), 1615, 1240, 1100, 1015 (NH), 750; uv: see Table 3; ^{1}H nmr δ: 3.50 (br, CH_2O), 1.40–1.20 (m, $(CH_3)_3C$); ^{13}C nmr δ: 31.92, 27.13, 26.49; ms *m/z*: 1543.8 (M^+). *Anal.* calcd. for $C_{94}H_{94}N_{16}O_6$: C 73.13, H 6.14, N 14.15; found: C 73.50, H 6.39, N 14.60.

2,2-Bi-(9,16,23-trineopentoxyphthalocyaninyl) dicobalt(II) (6b)

A mixture of **6***a* (57.5 mg, 0.037 mmol), anhydrous cobalt(II) chloride (50 mg, 0.38 mmol), 2-methoxyethanol (3 mL), and toluene (7 mL) was heated at 110°C (oil bath) for 27 h under an argon atmosphere.

The product was purified by flash chromatography using a 1.5 × 8 cm column by direct application of the refluxing mixture to the column. Elution with hot toluene gave, after solvent evaporation, 24 mg of **6***b*. Continued elution with hot toluene/THF (1:1) yielded an additional 12 mg of **6***b*. The combined 36 mg of dimer **6***b* was washed with acetone to remove very minor fluorescent impurities (detected by tlc), leaving 32.4 mg (52% yield) of pure **6***b* as a very dark blue solid; ir (cm^{-1}): 1615, 1240, 1100, 750; uv: see Table 3; ms *m/z*: 1657.7, (M^+). *Anal.* calcd. for $C_{94}H_{90}N_{16}O_6Co_2$: C 68.11, H 5.47, N 13.52, Co 7.11; found: C 68.35, H 5.86, N 13.50, Co 6.40.

*2,2-Bi-(9,16,23-trineopentoxyphthalocyaninyl) dicopper(II) (**6**c)*

A mixture of **6***a* (100 mg, 0.065 mmol), anhydrous copper(II) acetate (100 mg, 0.550 mmol), 2-methoxyethanol (3 mL), and toluene (7 mL) was heated at 110°C for 24 h under an argon atmosphere. The solvent was removed and the mixture continuously extracted with toluene. Evaporation of toluene under reduced pressure gave **6***c* (57 mg) in 53% yield as a very dark blue shining solid; ir (cm^{-1}): 1620, 1245, 1070, 755; uv: see Table 3; ms *m/z*: 1667.6, (M^+). *Anal.* calcd. for $C_{94}H_{90}N_{16}O_6Cu_2$: C 67.73, H 5.44, N 13.44, Cu 7.62; found: C 67.72, H 5.26, N 13.15, Cu 7.55.

*1,8-Bis(3,4-dicyanophenyl)naphthalene (**8**) and 1-iodo-8-(3,4-dicyanophenyl)naphthalene (**9**)*

To 30 mL of freshly distilled dimethoxyethane (DME), 23.0 g (73 mmol) of anhydrous nickel iodide, 1.0 g (144 mmol) of lithium, and 0.8 g (6.25 mmol) of naphthalene were added. The mixture was stirred at room temperature for 12 h. To the resulting black slurry, 4-iodophthalonitrile (**1**) (4.0 g, 15 mmol) and 1,8-diiodonaphthalene (**7**) (25) (2.0 g, 5.26 mmol) were added. The mixture was allowed to react for 3.5 h. The resulting mixture was filtered through Celite using a sintered glass funnel and the residue was washed with ethyl acetate. The combined filtrate was washed with saturated sodium thiosulfate and water. The organic fraction was collected and dried over anhydrous magnesium sulphate. Evaporation of the solvent gave a yellowish brown solid. The crude material was purified by flash chromatography using benzene as the eluting solvent to remove naphthalene and unreacted 4-iodophthalonitrile (1.30 g). Elution with EtOAc/$CHCl_3$ (1:9) gave 50 mg of 1-iodo-8-(3,4-dicyanophenyl)naphthalene (**9**) in 2.5% yield. Recrystallization of **9** from EtOAc/hexane gave slightly brown crystals, mp 178–180°C; ir (cm^{-1}): 3060, 2240 (CN), 1595, 1490, 830, 780; uv (CH_2Cl_2) λ_{max} (log ε): 244 (4.13), 268 (4.15), 310 (4.19) nm; ^1H nmr and ^{13}C nmr: see Tables 1 and 2; hrms, *m/z* calcd. for $C_{18}H_9N_2I$ (M^+): 379.9809; found: 379.9802. *Anal.* calcd. for $C_{18}H_9N_2I$: C 56.86, H 2.38, N 7.37; found: C 57.21, H 2.89, N 7.89.

Further elution with the same solvent system gave 310 mg of 1,8-bis(3,4-dicyanophenyl)naphthalene (**8**) in 15.5% yield. Recrystallization of **8** from EtOAc/hexane gave white crystals, mp 284–285°C; ir (cm^{-1}): 3060, 2240 (CN), 1600, 1490, 835, 780; uv (CH_2Cl_2) λ_{max} (log ε): 238 (4.34), 265 (4.23sh), 340 (4.04) nm; ^1H nmr and ^{13}C nmr: see Tables 1 and 2; ^{13}C nmr (DMSO-d_6, 100°C) δ: 147.28, 134.67, 134.39, 134.35, 134.26, 132.52, 131.11, 130.01, 127.10, 125.22, 114.67, 114.46, 113.51, 111.62; hrms, *m/z* calcd. for $C_{26}H_{12}N_4$ (M^+): 380.10619; found: 380.10580. *Anal.* calcd. for $C_{26}H_{12}N_4$: C 82.09, H 3.18, N 14.73; found: C 82.00, H 3.34, N 14.80.

Further elution with 5% acetonitrile/dichloromethane gave 850 mg of **2** in 42.5% yield.

*Preparation of the bis-1,3-diiminoisoindoline (**10**)*

The bis-1,3-diiminoisoindoline (**10**) was prepared as previously described (5, 6). Bisphthalonitrile **8** (380 mg, 1.00 mmol) was added to 20 mL of a 1:1 mixture of methanol/dioxane containing 15 mg of sodium. Ammonia was bubbled into the solution at 80°C. The reaction was over in 3 h. The solution was evaporated to give crude **10**, which was used directly in the condensation reaction without further purification.

*1,8-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)naphthalene (**11**a)*

The two crude diiminoisoindolines **4** and **10** obtained from 6.0 g (28.00 mmol) of 4-neopentoxyphthalonitrile and 380 mg (1.00 mmol) of **8** respectively, in 25 mL of 2-*N*,*N*-dimethylaminoethanol, were heated to 150°C for 44 h. The reaction mixture was allowed to cool and then poured into 200 mL of water. The resulting mixture was filtered and washed with water until the filtrate became clear. The residue was washed again with methanol and then dried overnight in the oven at 60°C. Flash chromatography of the crude material using a 5 cm diameter column and eluting with toluene gave a mixture of mononuclear **5** and binuclear **11***a*. This mixture was chromatographed further using toluene/hexane (1:1) to give 2.70 g of **5** in 45% yield. Further elution using 2-methoxyethanol/toluene (2:100) gave a fraction consisting of mainly binuclear **11***a*. The final purification was achieved by vacuum liquid chromatography using toluene as the eluting solvent followed by gradual increase of 2-methoxyethanol/toluene (2:100) to give 139 mg of binuclear phthalocyanine **11***a* in 8.7% yield as a dark blue solid; ir (cm^{-1}): 3300 (NH), 1015, 1245, 1100, 1020 (NH), 750; uv: see Table 3; ^1H nmr (C_6D_6) δ: 7.0–8.5 (br, aromatic), 3.3–3.8 (br, CH_2O), 1.0–1.6 (br, $(CH_3)_3C$), −5 to −7 (br, NH); ms *m/z*: 1670 (M^+). *Anal.* calcd. for $C_{104}H_{100}N_{16}O_6$: C 74.72, H 6.03, N 13.42; found: C 74.71, H 5.76, N 13.15.

*1,8-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)naphthalene dicobalt(II) (**11**b)*

A mixture of 33 mg (0.02 mmol) of **11***a* and 60 mg (0.46 mmol) of anhydrous cobalt(II) chloride in 10 mL of a 1:4 mixture of 2-methoxyethanol/toluene was heated to 120°C for 20 h under an argon atmosphere. Flash chromatography of the crude reaction mixture using a 1 cm diameter column and eluting with 2-methoxyethanol/toluene (1:50) gave 30 mg of **11***b* in 85% yield as a dark blue shining solid; ir (cm^{-1}): 2940, 1610, 1240, 1090, 750; uv: see Table 3; ms *m/z*: 1782 (M^+). *Anal.* calcd. for $C_{104}H_{96}N_{16}O_6Co_2$: C 70.00, H 5.43, N 12.57, Co 6.61; found: C 70.50, H 5.50, N 12.32, Co 6.52.

*1,8-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)naphthalene dicopper(II) (**11**c)*

A mixture of 53 mg (0.032 mmol) of **11***a* and 57 mg (0.32 mmol) of anhydrous copper(II) acetate in 10 mL of a 1:4 mixture of 2-methoxyethanol/toluene was heated to 120°C for 20 h under argon. The crude reaction mixture was chromatographed as described above to give 37.2 mg of **11***c* in 70% yield as a dark blue solid; ir (cm^{-1}): 2940, 1610, 1235, 1090, 740; uv: see Table 3; ms *m/z*: 1793.6 (M^+ + 1, 100). *Anal.* calcd. for $C_{104}H_{96}N_{16}O_6Cu_2$: C 69.64, H 5.39, N 12.50, Cu 7.09; found: C 70.14, H 5.20, N 12.69, Cu 7.08.

*1,8-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)naphthalene dizinc(II) (**11**d)*

A mixture of 50 mg (0.030 mmol) of **11***a* and 100 mg (0.54 mmol) of anhydrous zinc acetate in 10 mL of a 1:4 mixture of 2-methoxyethanol/toluene was heated to 120°C for 20 h under argon. The crude reaction mixture was chromatographed as described for **11***b* to give 44 mg of **11***d* in 86% yield as a dark blue solid; ir (cm^{-1}): 2950, 1610, 1100, 740; uv: see Table 3; ^1H nmr ($CDCl_3$) δ: 7.5–8.5 (br, aromatic), 3.3–4.3 (br, CH_2O), 1.0–1.6 (br, $(CH_3)_3C$); ms *m/z*: 1797.6 (M^+ + 1.100). *Anal.* calcd. for $C_{104}H_{96}N_{16}O_6Zn_2$: C 69.50, H 5.38, N 12.48, Zn 7.28; found: C 69.25, H 5.73, N 12.60, Zn 7.46.

*1,8-Bis(3,4-dicyanophenyl)anthracene (**14**)*

To 60 mL of freshly distilled THF in a two-necked round-bottom flask, 2.0 g (8.1 mmol) of 1,8-dichloroanthracene (**12**) and 5.49 g (24 mmol) of anhydrous zinc bromide were added. The solution was cooled to 0°C. With a strong stream of argon flowing through the flask, 0.24 g (36 mmol) of lithium wire was cut into small pieces and dropped into the solution. The mixture was sonicated with ultrasound at 0°C for 1 h under argon and allowed to warm up to room temperature. The dark solution containing the zinc organometallic intermediate **13** was transferred with a syringe to another round-bottom flask containing 4.0 g (16 mmol) of **1** and 0.8 g (4 mol%) tetrakis(triphenylphosphine)palladium. The resulting solution was stirred under argon at room temperature for 3 h. Ethyl acetate and water were added to the reaction mixture, and the cloudy mixture was filtered through Celite. The filtrate separated into an aqueous and an organic layer. The organic

For personal use only.

layer was collected and dried over anhydrous $MgSO_4$. Evaporation of the solvent gave a brownish crude material. The crude material was purified by flash chromatography using chloroform as the eluting solvent. The first fraction contained mostly unreacted starting material. Further elution gave 34.5 mg of 1,8-bis(3,4-dicyanophenyl)anthracene (**14**) in 10% yield. Recrystallization of **14** from acetonitrile/EtOAc gave yellow crystals, mp 345–346°C; ir (cm^{-1}): 3060, 2230 (CN), 1590; 1490, 880, 745; uv (CH_2Cl_2) λ_{max} (log ε): 284 (4.05), 268 (4.06), 386 (3.99), 405 (3.96); ^1H nmr and ^{13}C nmr: see Tables 1 and 2; ms *m/z*: 430 (M^+, 100) 330 (20). *Anal.* calcd. for $C_{30}H_{14}N_4$: C 83.69, H 3.28, N 13.02; found: C 83.42, H 3.46, N 13.15.

*Preparation of the bis-1,3-diiminoisoindoline (**15**)*

Bisphthalonitrile **14** (430 mg, 1.0 mmol) was added to 50 mL of a 1:1 mixture of methanol/dioxane containing 15 mg of sodium. Ammonia was bubbled into the solution under reflux at 80°C for 2 h. The solution was evaporated to give the crude bis-1,3-diiminoisoindoline (**15**), which was used directly in the condensation reaction without further purification.

*1,8-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)anthracene (**16**a)*

The two crude diiminoisoindolines **15** and **4** (5, 6), obtained from 430 mg (1.0 mmol) of **14** and 6.0 g (28.0 mmol) of 4-neopentoxyphthalonitrile respectively in 25 mL of 2-*N*,*N*-dimethylaminoethanol, were heated to 160°C for 44 h. The reaction mixture was allowed to cool and then poured into 200 mL of water. The resulting mixture was filtered and washed with water until the filtrate became clear. The residue was washed again with MeOH and then dried in the oven at 60°C overnight. Flash chromatography of the crude material using toluene as eluting solvent gave a mixture of mononuclear **5** and binuclear **16***a*. Rechromatography of the mixture using toluene/hexane (1:1) did not give a good separation. The binuclear fractions were still contaminated with large amounts of **5**. The mixed binuclear fraction was rechromatographed using a gel permeation column (Bio-Beads SX-1, 200–450 mesh) with THF as the eluting solvent. The front running binuclear fractions were combined and rechromatographed on a silica gel column using 2-methoxyethanol/toluene (2:100) as the eluting solvent to give 210 mg of 1,8-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)anthracene (**16***a*) in 12% yield as a dark blue solid; ir (cm^{-1}): 3300 (NH), 1610, 1240, 1100, 1020 (NH), 750; uv: see Table 3; ^1H nmr (C_6D_6) δ: 7.0–8.5 (br, aromatic), 3.5–3.7 (br, CH_2O), 1.0–1.6 (br, $(CH_3)_3C$), −6 to −7 (NH); ms *m/z*: 1719 (M^+, 100%). *Anal.* calcd. for $C_{108}H_{102}N_{16}O_6$: C 75.39, H 5.98, N 13.03; found: C 75.18, H 6.33, N 12.65.

*1,8-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)anthracene dicobalt(II) (**16**b)*

A mixture of 52 mg (0.030 mmol) of **16***a* and 60 mg (8.46 mmol) of anhydrous cobalt(II) chloride in 10 mL of a 1:4 mixture of 2-methoxyethanol/toluene was heated to 120°C for 20 h. The crude reaction mixture was flash chromatographed using 2-methoxyethanol/toluene (1:80) and gave 56 mg of **16***b* in 95% yield; ir (cm^{-1}): 2940, 1610, 1240, 1090, 750; uv: see Table 3; ms *m/z*: 1832 (M^+). *Anal.* calcd. for $C_{108}H_{98}N_{16}O_6Co_2$: C 70.71, H 5.38, N 12.23, Cu 6.43; found: C 70.90, H 5.88, N 11.83, Co 6.40.

*1,8-Bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninyl)anthracene dizinc(II) (**16**c)*

A mixture of 56 mg (0.0325 mmol) of **16***a* and 100 mg (0.54 mmol) of anhydrous zinc acetate in 10 mL of a 1:4 mixture of 2-methoxyethanol/toluene was heated to 120°C for 20 h. The crude reaction mixture was flash chromatographed using 2-methoxyethanol/toluene (1:50) to give 58 mg of **16***c* in 97% yield; ir (cm^{-1}): 2950, 1610, 1240, 1090, 750; uv: see Table 3; ^1H nmr (C_6D_6) δ: 7.5–8.5 (br, aromatic), 3.3–4.3 (br, CH_2O), 1.0–1.6 (br, $(CH_3)_3C$); ms *m/z*: 1847 (M^+). *Anal.* calcd. for $C_{108}H_{98}N_{10}O_6Zn_2$: C 70.22, H 5.35, N 12.14, Zn 7.08; found: C 70.72, H 5.65, N 11.60, Zn 7.45.

*1-(3,4-Dicyanophenyl)naphthalene (**18**)*

Following a previously described procedure (17, 18), 1.0 g (2.63 mmol) of 1.8-diiodonaphthalene and 1.78 g (7.9 mmol) of anhydrous zinc bromide were added to a two-necked flask containing 60 mL of freshly distilled THF. The solution was cooled to 0°C. Lithium (0.09 g, 0.013 mmol) was cut into small pieces and added into a flask flushed with a vigorous stream of argon. The mixture was sonicated with ultrasound at 0°C for 1 h under argon and allowed to warm to room temperature. The resulting solution was transferred with a syringe to another round-bottom flask containing 1.33 g (5.26 mmol) of **1** and 0.8 g (~4 mol%) tetrakis(triphenylphosphine)palladium. After stirring this mixture at room temperature for 3 h, water was added, followed by ethyl acetate. The cloudy mixture was filtered through Celite. The filtrate separated into aqueous and organic layers. The organic layer was collected and dried over anhydrous $MgSO_4$. Evaporation of the solvents gave a brownish colored crude material. The crude material was purified by flash chromatography using chloroform. The first fraction contained mostly starting material. Further elution gave 200 mg of **18** in 30% yield as white crystals, mp 148–149°C; ir (cm^{-1}): 3060, 2230 (CN), 1600, 1485, 1390, 910, 770; uv (CH_2Cl_2) λ_{max} (log ε): 242 (3.67), 282 (3.42), 324 (3.41) nm; ^1H nmr and ^{13}C nmr: see Tables 1 and 2; ms *m/z*: 254 (M^+) (100%), 233 (15%). *Anal.* calcd. for $C_{18}H_{10}N_2$: C 83.69, H 3.28, N 13.02; found: C 83.42, H 3.46, N 13.15.

The initial stages of lead oxidation in pH 9 to 14 aqueous solutions

V. I. BIRSS[1] AND W. WAUDO
Chemistry Department, University of Calgary, Calgary, Alta., Canada, T2N 1N4

Received January 21, 1988[2]

V. I. BIRSS and W. WAUDO. Can. J. Chem. **67**, 1098 (1989).

The initial stages of lead oxidation in a range of alkaline solutions of varying pH and ion content have been investigated with the use of cyclic voltammetry and potential step techniques. In both carbonate and borate buffered solutions (pH > 9), and in more alkaline solutions, Pb oxidation commences at a potential of ca. 140 mV vs. RHE. The initial product is considered to be $Pb(OH)_2$, due to the proximity of this potential with the theoretically predicted one, and due to its invariance (vs. RHE) with pH. In pH 14 solutions, $Pb(OH)_2$ is soluble, producing $Pb(OH)_3^-$ and only a small amount of a stable surface film. At lower pH's, $Pb(OH)_2$ is not predicted to be soluble, and in borate-buffered solutions, a stable, reducible film appears to form. In carbonate-buffered solutions, the surface film is very difficult to remove electrochemically. Although XPS analyses show the film to be essentially free of carbonate, it is clear that carbonate must be involved in some way in inhibiting film reduction.

Key words: lead, lead hydroxide, lead oxide, surface films, carbonate solutions, borate solutions, alkaline solutions, cyclic voltammetry.

V. I. BIRSS et W. WAUDO. Can. J. Chem. **67**, 1098 (1989).

Utilisant des techniques de voltamétrie cyclique et opérant dans des solutions alcalines de pH et de contenus ioniques divers, on a étudié la nature des étapes initiales de l'oxydation du plomb. Dans des solutions tamponnées avec des ions carbonate ou borate (pH > 9) ainsi que dans des solutions plus alcalines, l'oxydation du plomb commence à un potentiel d'environ 140 mV vs. RHE. En se basant sur le fait que ce potential est très proche de celui prédit sur une base théorique ainsi que sur le fait qu'il ne varie pas (vs. RHE) avec le pH, on considère que le produit initial est du $Pb(OH)_2$. Dans des solutions de pH 14, le $Pb(OH)_2$ est soluble et il conduit à la formation de $Pb(OH)_3^-$ ainsi qu'à une très faible quantité d'une couche superficielle stable. A des pH plus bas, il n'est pas prévu que le $Pb(OH)_2$ soit soluble et, dans des solutions tamponnées au borate, il semble se former une couche stable qui peut être réduite. Dans des solutions tamponnées au carbonate, il est très difficile d'enlever la couche superficielle d'une façon électrochimique. Méme si des analyses par XPS démontrent que la couche superficielle ne contient essentiellement pas de carbonate, il est évident que le carbonate doit être impliqué d'une façon quelconque dans l'inhibition de la couche superficielle.

Mots clés : plomb, hydroxyde de plomb, oxyde de plomb, couches superficielles, solutions de carbonate, solutions de borate, solutions alcalines, voltamétrie cyclique.

[Traduit par la revue]

Introduction

Quite a number of studies concerning the electrochemical behaviour of lead have been carried out in the past (1–3), with emphasis on acidic environments. Lead has a variety of applications in industry, particularly as a lining and piping material because of its good corrosion resistance in acidic media (4). It has also played a major role in the development of electrical power sources, e.g. in lead–acid batteries (5).

Relatively little has been reported in the literature regarding the fundamental electrochemistry of lead in alkaline media. Early research (6) concerning the anodic behaviour of lead in alkaline solutions, carried out under galvanostatic conditions, has indicated that lead can be dissolved to form Pb^{2+} at low applied current densities. At higher current densities, a PbO_2 film is expected to form at the electrode surface, with the subsequent evolution of oxygen. A more recent study carried out by Ptitsyn *et al.* (7), using potentiostatic and potentiometric methods, has indicated that the oxidation of lead in alkaline solutions involves first the formation of $Pb(OH)_2$, which subsequently dissolves as $Pb(OH)_3^-$, with the latter dissolution step being rate determining.

More recently (8), it has been suggested on the basis of results obtained with cyclic voltammetry as well as steady state and transient potentiostatic techniques, that the first stage in the anodic oxidation of lead in 1 *M* NaOH solutions involves the formation of a surface intermediate, PbOH, followed by the deposition of a thin $Pb(OH)_2$ film on the Pb electrode surface, as shown in reactions [1] and [2]. The $Pb(OH)_2$ film then dissolves to form a soluble species, $Pb(OH)_3^-$ (reaction [3]), as was also suggested by Ptitsyn *et al.* (7).

[1] $Pb + OH^- \rightarrow (PbOH)_{ads} + e^-$

[2] $(PbOH)_{ads} + OH^- \rightarrow Pb(OH)_2 + e^-$

[3] $Pb(OH)_2 + OH^- \rightarrow Pb(OH)_3^-$

Following reaction [3], it has been suggested (9) that a PbO film forms at higher potentials, both by the dehydration of $Pb(OH)_2$ and also via a nucleation and growth process at the free Pb surface, according to reactions [4] and [5], respectively. PbO is also thought to be somewhat soluble (reaction [6]).

[4] $Pb(OH)_2 \rightarrow PbO + H_2O$

[5] $Pb + 2OH^- \rightarrow PbO + H_2O + 2e^-$

[6] $PbO + OH^- \rightarrow HPbO_2^-$

These suggested reactions pathways and products are supported by thermodynamic calculations (8–10) which indicate that $Pb(OH)_2$ is predicted to form at a potential more negative than that for PbO formation.

The electrochemistry of lead in somewhat less alkaline solutions has also been investigated recently (11, 12). In borate buffered solutions (pH 9.0), it has been suggested (11) that the initial stage of Pb oxidation involves the formation of a lead borate surface film, followed by PbO deposition. In carbonate solutions (pH 10 to 12), a small anodic peak preceding the main peak in cyclic voltammetric experiments has been attributed to the formation of a lead hydroxy–carbonate surface compound (12). It has been suggested that within the potential range of this small peak, some Pb dissolution may also occur, possibly via a

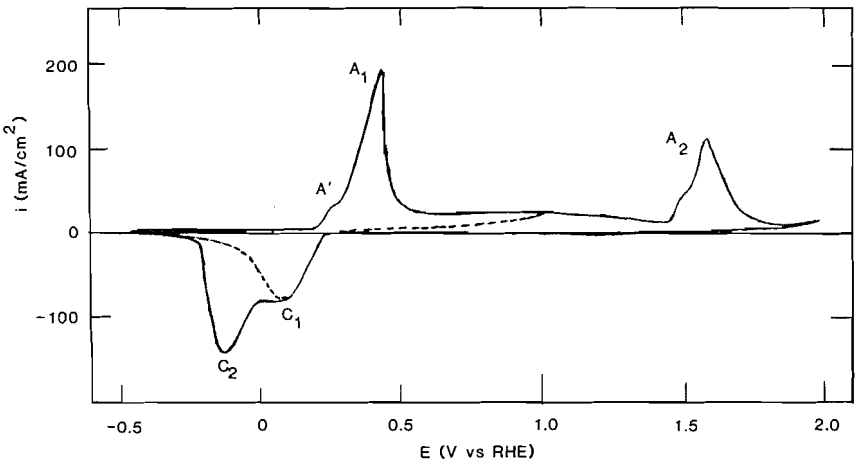

FIG. 1. Cyclic voltammogram of Pb chip electrode (0.015 cm^2) in 1 *M* NaOH at $s = 20$ mV/s.

surface intermediate, while at higher anodic potentials, further surface film formation occurs and the rate of dissolution diminishes.

Interest in the behaviour of lead in alkaline carbonate-containing solutions is growing due to the possible use of lead to precipitate ^{14}C-containing carbonate ions, a radioactive contaminant produced in CANDU D_2O-containing nuclear reactors (13). Lead may also be used as a storage material for nuclear waste in deep underground vaults in the future (14).

This paper focuses on the initial stage of lead oxidation in a number of alkaline solutions. These include NaOH (pH 14) solutions, as well as buffered (primarily pH 9 to 10) carbonate and borate solutions. It will be shown that the initial step in the oxidation process in all of these solutions is likely to involve the formation of the same species, i.e. $Pb(OH)_2$, as seen partly from the fact that the potential at which Pb oxidation commences (vs. the RHE) is independent of the nature of the electrolyte and the solution pH.

Experimental

Cyclic voltammetry (CV) and chronoamperometry (I/t) experiments were carried out using standard three electrode circuitry and an EG&G PARC 173 potentiostat coupled to an EG&G PARC 175 function generator. The current (I) vs. potential (E) profiles were plotted on a HP 7045B X/Y recorder at slow potential sweep rates (s), while all I/t data, and I/E curves at sweep rates greater than ca. 300 mV/s, were monitored on a Nicolet 3091 digital oscilloscope, and then transferred to the X/Y recorder.

A three compartment electrochemical cell was used in all of this work. The electrolytic contact between the working electrode (WE) and the reference electrode (RE) compartments was maintained via a luggin capillary. The counter electrode (CE), a large area platinum gauze, was placed in the third compartment. The RE was either a platinized Pt/hydrogen electrode placed in the same solution as that in the main compartment of the cell (RHE) or a saturated calomel electrode (SCE). All potentials are given with respect to the RHE in this work.

The WE consisted of either a Pb chip (from a Pb rod, 99.99% purity; Johnson and Matthey), having a geometrical area of ca. 1.5 to 3.0 mm^2, embedded in epoxy in a Pyrex tube, or a Pb disc (ca. 0.385 cm^2) press-fitted into a Teflon holder. In some of this work, the WE surface was mechanically polished in stages with various grades of emery paper (250 to 600 grit), then with 0.1 alumina paste on a polishing cloth, ultrasonically cleaned in acetone, and then finally rinsed with distilled water. The true surface area of the WE could be obtained from double layer capacitance measurements in 0.1 *N* Na_2SO_4 solutions (15), in order to compare the surface areas of different electrodes. However, because Pb is roughened by repeated oxidation/reduction cycles in high pH (>13) solutions, all current and charge densities are given with respect to the apparent electrode surface area in this work.

All solutions used were prepared from Analar grade chemicals and triply distilled water, and all experiments were carried out at room temperature. The solutions were deoxygenated by bubbling argon through the cell prior to, and over the cell solution, during the electrochemical experiments. Several runs were also carried out in carbonate-free NaOH, but no differences were seen in these results vs. those obtained in normal NaOH solutions.

X-ray photoelectron spectroscopy (XPS) analyses were carried out with a VG ESCA III instrument at the Alcan International Limited laboratories in Kingston, Ontario.

Results and discussion

(i) General behaviour of lead in 1 M *NaOH solutions*

Figure 1 shows a typical CV obtained with a mechanically polished Pb chip electrode in 1 *M* NaOH at a sweep rate of 20 mV/s. When the potential is extended positively towards the oxygen evolution reaction (OER) at ca. 2.0 V, and then negatively towards the range of hydrogen evolution (HER), two main anodic peaks (A_1 and A_2) and corresponding cathodic peaks (C_I and C_2) are observed. A shoulder (A′) is also seen on the cathodic side of peak A_1.

(a) Shoulder, A′

In earlier work (8), it was proposed that this shoulder, A′, is related to $Pb(OH)_2$ film formation and its subsequent dissolution, as shown by reactions [1]–[3]. A recent thermodynamic calculation has shown (8, 9) that $Pb(OH)_2$ can be expected to form at ca. 115 mV vs. RHE, while PbO is not predicted to form until ca. 255 mV (10, 16). At a higher current scale sensitivity than in Fig. 1, the potential at the foot of shoulder A′ is seen to be ca. 150 mV, which is at only a small overpotential relative to the theoretical value for $Pb(OH)_2$ formation. It should be noted that when a positive going potential sweep (at $s < 200$ mV/s) is reversed in the region of A′, very little cathodic current is seen (8). This evidence for the dissolution of the product formed in the anodic reaction (i.e. $Pb(OH)_3^-$, reaction [3]) under the conditions of these experiments was also supported by the results of ring-disc electrode experiments (9, 10).

To confirm $Pb(OH)_2$ dissolution in this potential range and in pH 14 solutions, new experiments were focussed on the use of high potential sweep rates and small area Pb electrodes. It should be noted that a small electrode area was chosen for the present work primarily to maintain low cell currents and thereby

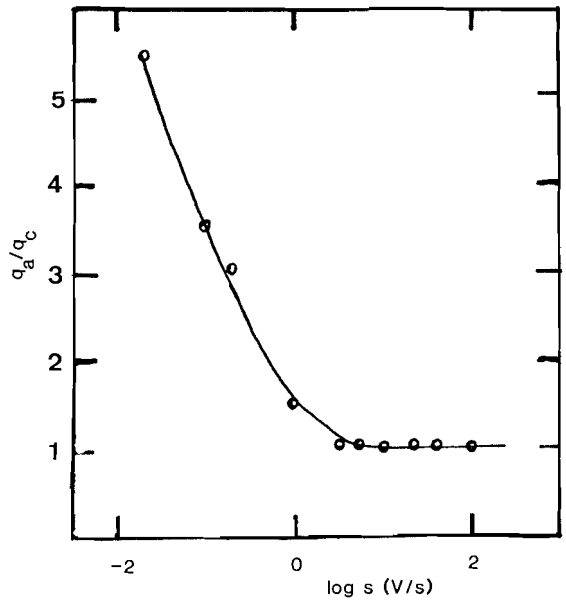

FIG. 3. Ratio of anodic to cathodic charge densities passed in the region of A′/C′ in 1 *M* NaOH as a function of potential sweep rate.

minimize *IR* drops and distributed potential effects (18), which were present in our prior work (8, 9).

The first series of experiments involved the use of high potential sweep rates as a test of the suggested reaction mechanism (reactions [1]–[3]) in pH 14 solutions. Figure 2 shows the CV response obtained in the region of A′ at high sweep rates (2 to 10 V/s) at a Pb chip electrode. With increasing sweep rates, the potential at the positive end of the scan had to be incremented somewhat in order to reach all of A′ in each scan.

In contrast to the large q_A/q_C ratios observed at low sweep rates (Table 1), it can be seen that as the sweep rate is increased, the anodic (A′) and cathodic (C′) charge densities become similar in value (Fig. 3). The charge density passed in A′ and C′ is ca. 2.3 ± 0.2 mC/cm^2 at high sweep rates, i.e. a charge density equivalent to ca. 5 to 10 monolayers of $Pb(OH)_2$ (19, 20), assuming a surface roughness factor (true surface area/apparent surface area) of unity. The similarity of the anodic and cathodic charge densities at high sweep rates indicates that insufficient time is available for any dissolution of $Pb(OH)_2$ (reaction [3]) to occur, so that only the formation and reduction of $Pb(OH)_2$ is monitored in A′/C′. Table 1 summarizes the principal features of A′/C′, including the charge densities and the potential at the foot of A′, as a function of potential sweep rate.

(b) Peaks A_1 and A_2

The potential obtained by extrapolating the current to the foot of peak A_1 in Fig. 1 is ca. 220 mV. Since this potential is reasonably close to the calculated potential for PbO formation (255 mV), it was suggested (8, 9) that peak A_1 depicts the formation of a PbO surface film, while peak C_1 reflects its reduction. When the potential is extended to peak A_2, considered to represent PbO_2 film formation, peak C_2 begins to develop (Fig. 1), while peak C_1 then decreases somewhat. This indicates that PbO_2 is reduced in peak C_2, and that more PbO is converted to PbO_2 in peak A_2 than is formed along with PbO_2 in

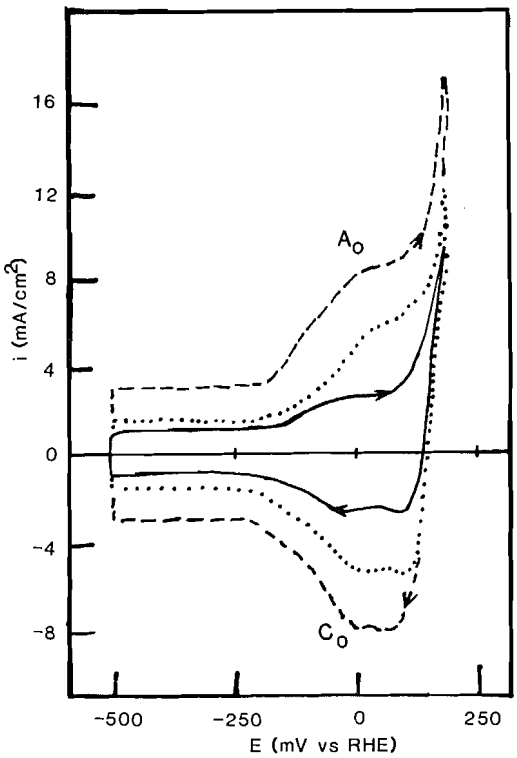

FIG. 4. Cyclic voltammograms of Pb chip electrode (0.02 cm^2) at high sweep rates after several hours of electrochemical experimentation in 1 *M* NaOH. s = 10 V/s (—), 20 V/s (···), and 30 V/s (---).

the potential range of peak A_2. The reduction of PbO (C_1) at a potential positive of that for the reduction of PbO_2 (C_2) is unusual, and may indicate that film reduction occurs first at the metal/inner film (PbO region) interface and then moves outward towards the outer film (PbO_2)/solution interface.

(c) *Peaks A_0/C_0*

After several hours of experimentation with a Pb electrode in the same 1 *M* NaOH solution, a new phenomenon was seen to develop in the potential range just negative of A′. Figure 4 shows that at high sweep rates, a matching pair of small peaks (A_0/C_0) appear, centred at a potential of ca. 0 V vs. RHE, i.e. at an underpotential of ca. 115 mV relative to the calculated potential for $Pb(OH)_2$ formation. An analysis of the relationship between the peak current densities of peaks A_0 and C_0 and the potential sweep rate reveals a linear dependence between these parameters (Fig. 5 depicts the case for peak A_0). The charge density contained in the peaks in Fig. 4 is ca. 40 $\mu C/cm^2$, if the apparent electrode area is again assumed. If the electrode area is higher by a factor of 2 or 3, which would be more realistic, the charge density would be still smaller than this.

It should be noted that the formation of a monolayer of $Pb(OH)_2$ would be expected to be seen at an underpotential. Also, a linear i_p/s relationship would be consistent with monolayer formation and removal. However, a single monolayer of $Pb(OH)_2$, having the same density as the bulk material, would be expected to involve a charge density of ca. 220 $\mu C/cm^2$ (19, 20). As the charges are sufficiently less than this, peaks A_0/C_0 may represent the formation of a two-dimensional layer of $Pb(OH)_2$ on only part of the electrode surface, or the deposition of two-dimensional $Pb(OH)_2$ having a very open structure (lower density than phase $Pb(OH)_2$ over the entire electrode surface).

Peaks A_0/C_0 may also reflect the adsorption of OH^- on the Pb surface, as suggested in reaction [1], followed by a partial

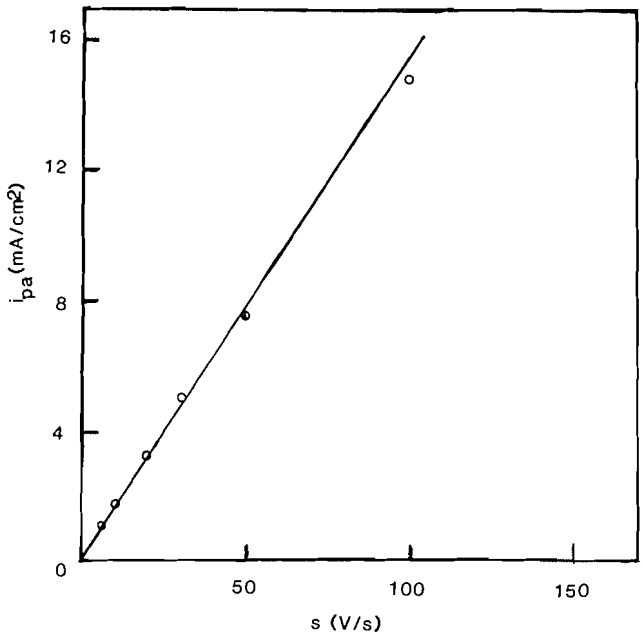

FIG. 5. Relationship between anodic peak current density of A_0 and potential sweep rate in 1 *M* NaOH.

charge transfer reaction (21). This type of process could also be observed at an underpotential, and would be expected to involve a lower charge density than that for the formation of a monolayer of $Pb(OH)_2$ film. These two possibilities cannot be distinguished from the data presented here. In a study of the electrochemistry of Ag electrodes in chloride-containing solutions (22), a similar difficulty was encountered in distinguishing adsorption with partial charge transfer from the formation of a low density monolayer.

The fact that peaks A_0/C_0 are only seen after some time of experimentation, during which many sweeps of potential are made to positive potentials, was originally thought to indicate that the Pb electrode had become activated, perhaps by an etching process, with time of potential cycling in these alkaline solutions. However, the appearance of peaks A_0/C_0 with time may also be related to the gradual deposition of high energy Pb nuclei on the Pb electrode surface by the reduction of $Pb(OH)_3^-$ at negative potentials. It is reasonable to suggest that Pb sites of this kind would be more active towards either two-dimensional film formation and/or anion (OH^-) absorption, as they would be likely to have a different surface energy from the original Pb electrode surface.

The suggestion that the newly deposited Pb nuclei, rather than a surface etching process, are responsible for the gradual appearance of peaks A_0/C_0 is supported by the following observation. A fresh Pb electrode, placed into a solution which had been studied previously, and therefore would be expected to contain dissolved Pb, probably in the form of $Pb(OH)_3^-$, rapidly developed peaks A_0/C_0. In contrast, a fresh Pb electrode placed in a fresh 1 *M* NaOH solution required several hours of continuous potential cycling before peaks A_0/C_0 appear. As the rate of Pb surface etching should depend only on time spent in the solution (and the potential), this result rules out an etching process as the cause of the development of peaks A_0/C_0.

(ii) Behaviour of Pb in less alkaline solutions

The cyclic voltammetric response obtained with lead in pH 9.6 bicarbonate and borate solutions is shown in Figs. 6*a* and *b*,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

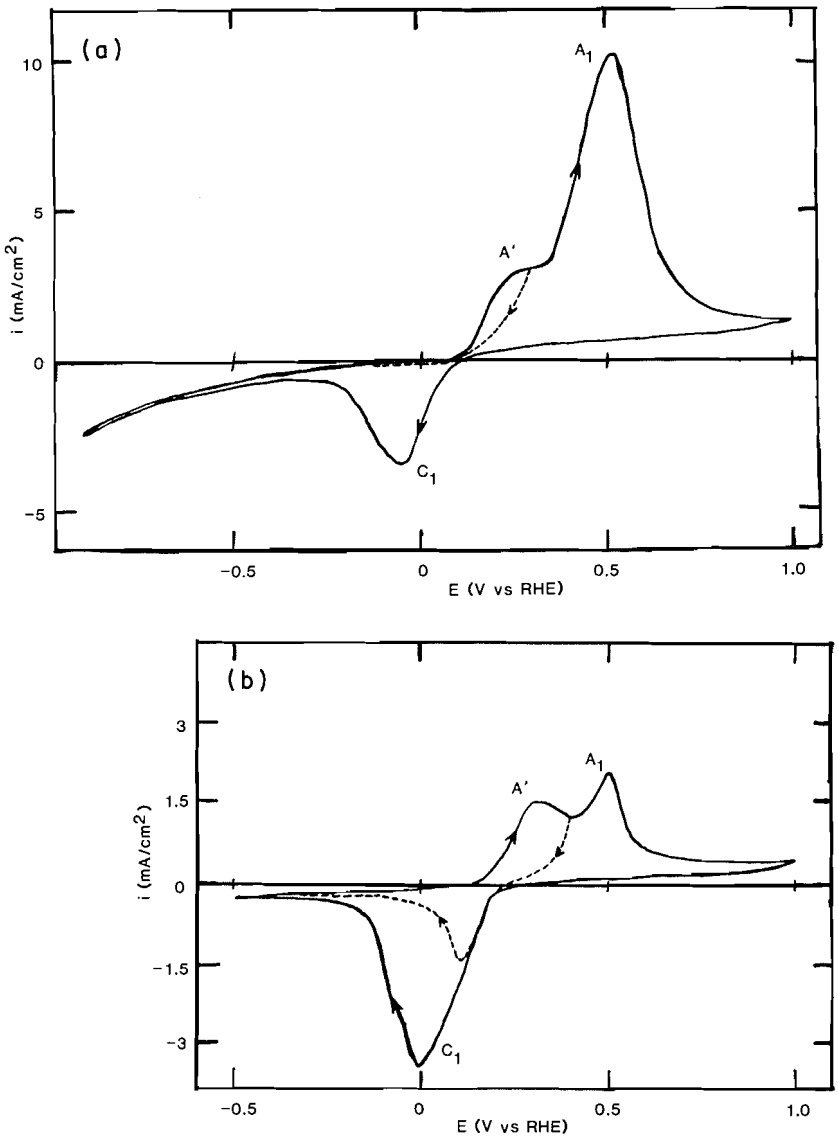

FIG. 6. Cyclic voltammograms obtained with Pb chip electrode in buffered pH 9.6 solutions: (*a*) 0.05 *M* sodium bicarbonate at s = 50 mV/s; (*b*) 0.025 *M* sodium borate at s = 20 mV/s.

respectively. In these experiments, the positive potential limit has been extended to only ca. 1.0 V. The general appearance of the CVs in these pH 9.6 solutions is similar to that at pH 14, although A′ now appears as a more distinct peak rather than a shoulder, and peak A_1 is significantly smaller at pH 9.6 than at pH 14. This indicates that the extent of PbO formation (A_1) is diminished at lower OH^- concentrations.

The similarity of the CVs in the carbonate and borate solutions is striking, lending support to a common reaction sequence and products. One noticeable difference in Figs. 6*a* vs. 6*b*, however, is that the anodic charge is substantially greater than the cathodic charge in carbonate solutions, while in the borate medium, the charges are similar. Figures 6*a* and *b* display this more clearly when the potential is reversed just positive of A′. In the carbonate solution, almost no cathodic charge is observed under the conditions of this experiment, while in borate solutions, the charges are very similar. It will be shown below that this difference in the anodic and cathodic charges in the carbonate solution is not the result of Pb dissolution, but rather the incomplete removal of the oxidation products from the electrode surface during each cathodic sweep. In fact, the electrochemistry of Pb in these dilute carbonate solutions is very complex, in that the magnitude of the anodic peaks, as well as their response to sweep rate, depends significantly on the electrochemical history of the electrode (23). Also, the ease of film reduction depends on both the upper potential limit utilized and the time of oxidation (23). A detailed mechanistic analysis of the oxidation of lead in pH 9 to 10 carbonate-buffered solutions will be presented in a future publication.

Despite these complexities, it is of interest to note that the onset of A′ occurs at ca. 140 mV vs. RHE under all conditions in the carbonate solutions and also in the borate-containing solutions investigated in this work (Table 1). This value is very similar to the potential at the foot of A′ in pH 14 solutions. The charge passed in peaks A′/C′ in borate solutions and also in carbonate solutions after numerous cycles of potential, are also given in Table 1, for comparison with the pH 14 case. It can be seen that the charge densities are of a similar order at pH 9.6 at low sweep rates to those in pH 14 solutions at high sweep rates. It should also be noted that $Pb(OH)_2$ is not expected to be very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

soluble at pH 9.6 (8, 10), consistent with the matching anodic and cathodic charge densities in Fig. 6*b*.

A′ was also seen to commence at a similar potential (vs. RHE) over the range of pH from ca. 10 to 14, and with either (or neither) carbonate/bicarbonate or borate ions present. This is strong evidence for the formation of the same phase in A′ in all of these solutions, i.e. at least in the early stages of A′. As A′ has been correlated with $Pb(OH)_2$ formation in pH 14 solutions (from thermodynamic calculations), it is therefore assumed that the first step of Pb oxidation in these dilute borate and carbonate solutions also involves $Pb(OH)_2$ formation.

Our hypothesis that the same phase, i.e. $Pb(OH)_2$, is formed initially in a range of alkaline solutions is similar to that made in recent studies of the Zn electrode (24). During the oxidation of Zn in various alkaline solutions, using a range of buffer solutions, the potential at the onset of Zn oxidation was also found to be independent of the nature of the electrolytes used. It was therefore proposed that the initial stage of Zn oxidation must also involve the formation of the same oxide phase, i.e. $Zn(OH)_2$, in all solutions.

Our suggestion that peak A′ reflects $Pb(OH)_2$ formation, at least initially, is in partial disagreement with two prior studies in the literature. Shoesmith *et al.* (12) have recently studied the oxidation of lead in carbonate solutions (1 *M* carbonate, pH 12). At this comparitively high pH, the CV response appears quite similar to our results at pH 14, including the presence of an anodic shoulder (A′) preceding the main anodic peak (A_1). It was suggested in their work that the formation of a hydroxycarbonate complex of lead (e.g. plumbonacrite (PN) or hydrocerussite (HC), $Pb_{10}O(OH)_6(CO_3)_6$ or $Pb_3(OH)_2(CO_3)_2$, respectively) occurs in A′, as determined by XRD analyses after long times of oxidation. However, the potential obtained by extrapolating to the foot of peak A′ in their data also yields a potential of ca. 130 to 150 mV vs. RHE, as is observed in both carbonate and borate-buffered solutions in our work.

If a PN or HC phase is indeed the equilibrium phase formed in peak A′ in pH 12, 1 *M* carbonate solutions, it is possible that the initial step in the reaction is still the formation of $Pb(OH)_2$, hence defining the thermodynamic conditions, and that $Pb(OH)_2$ subsequently transforms to the carbonate/Pb oxide phase after reaction with carbonate. The high carbonate concentrations (ca. 1 *M*) used in their work would favor such a process. It is also feasible that the free energy of formation of the PN or HC phase is similar to that of $Pb(OH)_2$ in these carbonate-containing solutions, and that this is the case of the similar potentials observed in their work as in our solutions.

In a study of the electrochemical behavior of Pb in 0.1 *M* sodium borate solutions (11), the foot of the first anodic peak observed (very similar to peak A′ in Fig. 6*b*) was also observed at a potential of ca. 150 mV vs. RHE, while the second anodic peak was considered to reflect PbO film formation. In this paper (11), peak A′ was attributed to the formation of a lead borate surface film, although no supporting evidence (eg. surface analysis) was provided for this assignment. Under certain conditions during the reduction of this film, two cathodic peaks were seen, thought to depict two forms of Pb borate formation and reduction. We have carried out a series of experiments to determine the pH dependence of A′ in borate solutions, and have found that when the borate concentration was held constant, while the pH was varied from ca. 9.5 to 12, peaks A′ and A_1 both moved negatively with increasing pH in an identical manner. On the basis of all of our results, we believe it is more likely

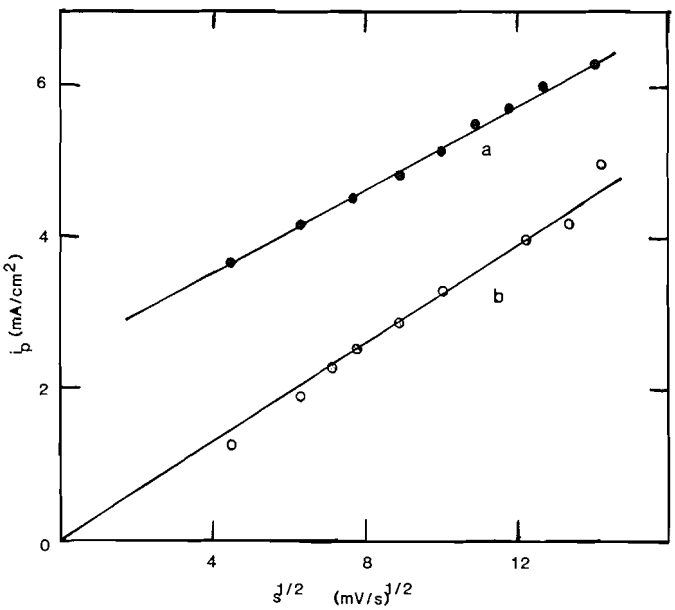

FIG. 7. Dependence of the peak current density of A′ on sweep rate in pH 9.6 bicarbonate (*a*) and borate (*b*) solutions.

that the first peak (A′) in borate solutions reflects $Pb(OH)_2$ deposition, followed by PbO formation in peak A_1.

Further support for the hypothesis that $Pb(OH)_2$ is formed in peak A′ in carbonate solutions comes from the results of XPS analyses. In a typical experiment, a Pb electrode, which had been oxidized in a single sweep from −1.0 V to 0.35 V in a pH 9.6 carbonate solution, was removed from the solution at the positive potential limit, and was examined by XPS. The nature of the surface film was assessed by comparing the binding energy shift for Pb(4*f*) and the O(1*s*)/Pb(4*f*) intensity ratios of the electrode surface with a number of standard materials, e.g. various lead oxides. As $Pb(OH)_2$ is not an equilibrium phase, it could not be produced as a standard material. Nevertheless, the results showed that the binding energy and intensity ratios of the surface film were essentially equivalent to that of PbO. This would be the likely dehydration product of $Pb(OH)_2$ after transferring the electrode into a vacuum chamber. Some carbon was observed at the electrode surface, but no more than at the PbO standard. Sputtering through the material at the electrode surface showed a sharp drop in carbon, and no evidence was obtained for carbonate at any points in the film. This result implies that an oxide film forms in A′ in pH 9 to 10 carbonate-buffered solutions, and by inference, this supports the same conclusion in borate-buffered solutions.

An analysis of the sweep rate dependence of peak A′ in carbonate (first sweep after holding the potential at the negative limit for controlled periods of time) and borate solutions was carried out to further probe similarities in the identity and nature of the surface products. This type of analysis could not be done in pH 14 solutions, as A′ did not form as a peak in this solution, even at high sweep rates (Fig. 2). Figure 7 demonstrates a generally similar behavior in the two solutions, although the non-zero intercept on the current density axis in Fig. 7 (curve *a*) is consistent with the more complex electrochemistry of Pb in the bicarbonate vs. borate solutions. These plots cannot be interpreted as being indicative of simple diffusion control by a species in solution. This is because the peak currents are essentially independent of solution stirring, and also as the diffusion

coefficients obtained from the slopes of these plots are anomalously large. It is perhaps more likely that the linear $i_p/s^{1/2}$ behavior is indicative of rate control by transport of species within pores of a surface film (25).

When the potential is reversed at ca. 0.35 V (see Fig. 6*a*), almost no cathodic charge passes, even at high sweep rates. An analysis of the solution after several hours of cycling of the potential between ca. −1.0 and 0.3 V revealed that virtually no Pb had dissolved during this time. The electrode surface, however, appeared to be covered with a grey, porous coating. Therefore, in pH 9.6 carbonate solutions, it appears that peak A′ initially involves the formation of $Pb(OH)_2$, which then interacts with carbonate species in some way so that the surface films are very difficult to reduce, as compared to the ease of reduction (in peak C′) of the material formed in A′ in borate solutions.

Overall, it is proposed that the initial step in the oxidation of lead in the range of pH from ca. 9 to 14, i.e. in solutions containing low concentrations of borate or carbonate ions as the buffering species, involves $Pb(OH)_2$ formation, as seen primarily by the common potential at the foot of peak A′ in all solutions. Also, the XPS result obtained for surface films formed in pH 9.6 carbonate solutions showed the presence of only oxide species, and essentially no carbonate was observed in the surface films. In pH 14 solutions, $Pb(OH)_2$ is soluble and repeated cycling of the potential in these solutions leads to the redeposition of lead on the electrode surface at negative potentials. A new pair of peaks is observed at an underpotential on such a lead electrode surface, perhaps reflecting OH^- adsorption with partial charge transfer, or the formation of a dilute monolayer of Pb hydroxide.

Summary

An investigation of the electrochemistry of Pb in three types of alkaline solutions of varying pH and ion content show a strong similarity in the initial stages of Pb oxidation. This is seen from cyclic voltammetry experiments, where a shoulder (A′) in pH 14 solutions occurs at the same potential (vs. the RHE) as the small peak (A′) in borate and carbonate solutions of lower pH. The potential at the onset of this shoulder (or peak) is ca. 140 ± 10 mV vs. RHE in all solutions. As the shoulder in pH 14 solutions has been suggested previously to be due to $Pb(OH)_2$ formation, it is proposed that the same reaction occurs in all of these solutions. The surface film formed in peak A′ in carbonate solutions was found by XPS to be an oxide film, containing essentially no carbonate. In pH 9.6 solutions, significantly less dissolution of $Pb(OH)_2$ is observed than at pH 14. In borate-buffered solutions, the $Pb(OH)_2$ surface film can be reversibly removed, while in carbonate solutions, the $Pb(OH)_2$ film must interact in some way with carbonate species in solution, making it difficult to remove electrochemically.

Excess properties of the binary liquid systems dimethylsulfoxide + isopropanol and propylene carbonate + isopropanol

GEORGE RITZOULIS

Laboratory of Physical Chemistry, Aristotelian University of Thessaloniki, 54006 Thessaloniki, Greece

Received August 29, 1988[1]

GEORGE RITZOULIS. Can. J. Chem. **67**, 1105 (1989).

The dielectric constants, viscosities, densities, and refractive indices of the binary solvent mixtures dimethylsulfoxide–isopropanol and propylene carbonate–isopropanol were measured at 25, 30, and 35°C over the entire mole fraction range. Excess dielectric constant, excess molar polarization, and excess viscosity were calculated. For both binary systems the variation of the Kirkwood correlation factor has been examined.

Key words: propylene carbonate, acetonitrile, correlation factor, excess properties, dielectric constant.

GEORGE RITZOULIS. Can. J. Chem. **67**, 1105 (1989).

Opérant à 25, 30 et 35°C et sur l'ensemble des concentrations, on a mesuré les constantes diélectriques, les viscosités, les densités et les indices de réfraction de mélanges binaires des solvants diméthylsulfoxyde/isopropanol et carbonate de propylène/isopropanol. On a calculé les constantes diélectriques en excès, les polarisations molaires en excès et les viscosités en excès. Pour les deux systèmes binaires, on a examiné la variation du facteur de corrélation de Kirkwood.

Mots clés : carbonate de propylène, acétonitrile, facteur de corrélation, propriétés en excès, constante diélectrique.

This work is a continuation of our previous studies (1) of thermodynamic and physicochemical properties of various binary liquid systems which are of special interest in chemical and electrochemical processes.

The binary systems chosen for investigation are the dimethylsulfoxide (DMSO)–isopropanol (*i*-prOH) and propylene carbonate (PC) – isopropanol (*i*-prOH). These binary liquid systems are good media for many chemical and electrochemical reactions and the fact that isopropanol is very often used as a substitute for ethanol extends the area of their applications.

The components dimethylsulfoxide and propylene carbonate belong to the so-called "high-energy reaction solvent" having a wide range of applications (2, 3). Moreover, there are many chemical reactions which are accelerated or retarded by dimethylsulfoxide and propylene carbonate. In many cases, the addition of alcohol changes the rate of these reactions and it is possible to control them by regulating the amount of added alcohol.

In the present paper densities, dielectric constants, viscosities, and refractive indices for the systems dimethylsulfoxide–isopropanol and propylene carbonate – isopropanol are measured over the entire mole fraction range at 25, 30, and 35°C. From the above experimental data the excess dielectric constant (ϵ^E), excess viscosity (η^E), and the excess molar polarization (P^E) are calculated. The variation of the Kirkwood correlation factor g_k as a function of mole fraction for the above-mentioned systems is also studied.

Experimental

Dimethylsulfoxide (Carlo Erba 99.5%) was dried for a week over 4A molecular sieves, followed by fractional distillation and collection of the middle fraction. The value of the specific conductance was 1×10^{-8} to 2×10^{-8} ohm^{-1} cm^{-1}.

Propylene carbonate (Merk zur synthese 99%) was dried over 4A molecular sieves and fractionally distilled under vacuum. The middle fraction was collected. The value of the specific conductance was less than 10^{-8} ohm^{-1} cm^{-1}.

Isopropanol (Fluka AG, puriss p.a.) was dried over 5A molecular sieves followed by two distillations. The value of the specific conductance was between $2 \times 10^{-8} - 3 \times 10^{-8}$ ohm^{-1} cm^{-1}.

Dielectric constants were measured with a dipolmeter employing the heterodyne beat method (Model WTW DM-01, Wissenshaftlich-Technische Werkstatten GmbH). The measurements were made at 2 MHz. The cell was thermostated (±0.02°C) by circulating the water of a constant temperature bath. The reproducibility of the measurement was approximately equal to 0.2 unit of dielectric constant.

Refractive indices were measured by means of a thermostated (±0.02°C) Abbe refractometer. The instrument was calibrated with benzene. The reproducibility was 0.0001 unit. Values were obtained for Na-D light.

Viscosity measurements were carried out with an Ubbelohde-type suspended-level viscometer with flow time 180 s for water at 25°C. Flow times were measured to 0.01 s with an electronic stopwatch. The standard deviations for more than five measurements did not exceed 0.05 s. Temperature control during the viscosity measurements was better than 0.01°C. The viscometer was standardized with conductivity water $\eta(H_2O, 25°C) = 0.008903$ P and $\eta(H_2O, 20) = 0.01002$ P. Kinetic energy corrections were made to the viscosity data.

Densities were measured with a Sprengel–Ostwald pycnometer having a volume of about 25 mL. Temperature control was 0.01°C.

Results

The experimental data for the binary systems dimethylsulfoxide–isopropanol and propylene carbonate – isopropanol are given in Table 1 at various mole fractions and at 25, 30, and 35°C.

The functions ϵ^E and η^E are calculated from the following equations

$$\epsilon^E = \epsilon - (\epsilon_1 x_1 - \epsilon_2 x_2)$$

$$\eta^E = \eta - (\eta_2 x_1 - \eta_2 x_2)$$

where x_1 and x_2 are the mole fractions; ϵ, ϵ_1, and ϵ_2 are the dielectric constant of the mixtures and of the pure (1) and (2) components; η, η_1, and η_2 are the viscosities of the mixtures and of the pure components.

The molar volume V is defined by the relationship

$$V = (x_1 M_1 + x_2 M_2)/d$$

where M_1 and M_2 are the molecular weights of the pure substances and d is the density of the mixture.

The linear correlation factor of the dielectric polarization g_k,

is a parameter which provides useful information regarding intermolecular interactions, in particular the dipole association in the liquids.

Modifying the following equation proposed by Onsager and Kirkwood (4, 5)

$$\epsilon - \epsilon_\infty = \left(\frac{3\epsilon}{2\epsilon + \epsilon_\infty}\right)\left(\frac{\epsilon_\infty + 2}{3}\right)^2 \left(\frac{4\pi N \mu_i^2 g_k}{3kTV}\right)$$

where ϵ is the static dielectric constant, ϵ_∞ is the dielectric constant at high frequency, N is Avogadro's number, k is Boltzmann's constant, μ_i is the dipole moment of substance i, and g_k is the Kirkwood factor, given the following expression:

$$g_k = \frac{(\epsilon - \epsilon_\infty)(2\epsilon + \epsilon_\infty)}{\epsilon(\epsilon_\infty + 2)^2} \frac{9kT}{4\pi Nd} \frac{(M_1 x_1 + M_2 x_2)}{(\mu_1 x_1 + \mu_2 x_2)^2}$$

The quantity P defined by the following expression

$$P = \frac{(\epsilon - \epsilon_\infty)(2\epsilon + \epsilon_\infty)}{\epsilon(\epsilon_\infty + 2)^2} \frac{M_1 x_1 + M_2 x_2}{d}$$

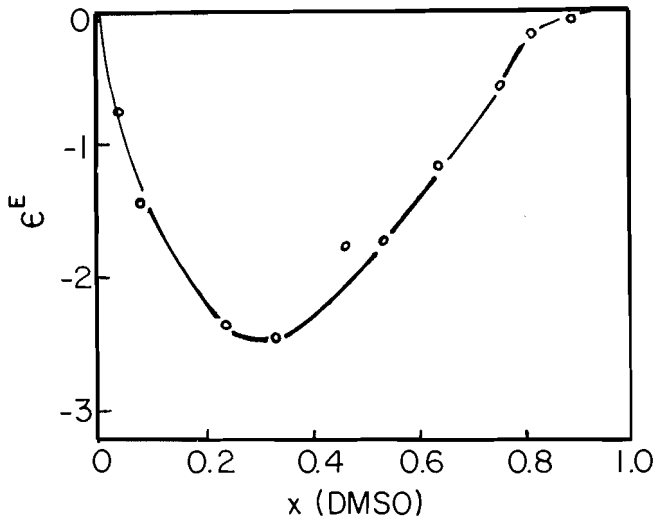

FIG. 1. Variation of ϵ^E vs. x for the system DMSO – i-prOH at 25°C.

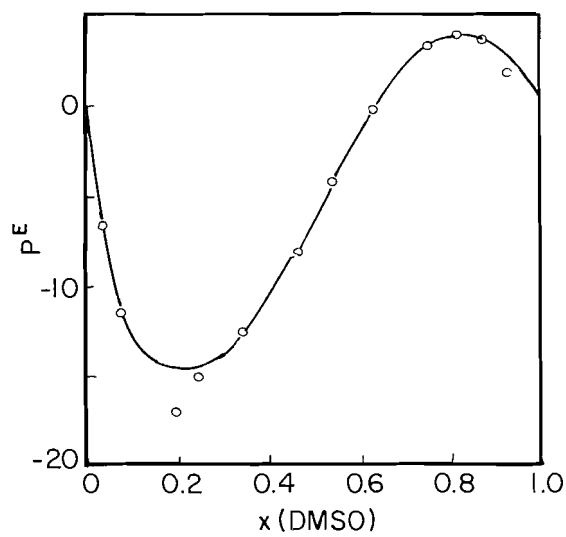

FIG. 2. Variation of P^E vs. x for the DMSO – i-prOH mixture at 25°C.

has been named the "molecular polarization" (6) of the mixture. The excess polarization is calculated by the expression

$$P^E = P - (P_1x_1 + P_2x_2)$$

During the calculations ϵ_∞ was set equal to n^2, where n is the refractive index of the mixture.

Discussion

The excess dielectric constant gives an estimate of the dipole–dipole interactions and the hydrogen bonded complexes (7). In the case of the system dimethyl sulfoxide – isopropanol, the excess dielectric constant shows negative deviations from ideal behaviour (Fig. 1), and is not sensitive to temperature. The curve ϵ^E vs. x shows a minimum at the dimethylsulfoxide mole fraction ~0.33.

In the case of propylene carbonate – isopropanol there are no significant deviations from the linear dependence of ϵ^E on mole fraction at the different temperatures. This does not mean that this binary liquid system can be considered an ideal mixture, because other properties show large deviations from ideality.

Excess molar polarizations are negative for both systems. Figure 2 shows the variation of excess molar polarization vs. x for the dimethylsulfoxide–isopropanol mixtures. The shape of the curve P^E vs. x for the system propylene carbonate – isopropanol is similar. One must notice the slightly different x values at which the minima ϵ^E and P^E appear. If we consider the variations of P^E in terms of temperature, a decrease of the extrema as the temperature increases is observed. This means that there is a reduction of the interactions between the different molecules as a consequence of the temperature increase.

The excess viscosity gives an estimation of the intermolecular interactions. According to Ford and Moor, positive values of η^E due to strong specific interaction causes complex formation and negative values of excess viscosity are observed for systems of different molecular size in which the dispersion forces are dominant (8, 9). In our case the excess viscosity is negative (Fig. 3) through the entire composition range at temperatures 25, 30, and 35°C for both binary mixtures under investigation. The values of mole fraction where the minimum is observed is at x(DMSO) ≃ 0.33 for the system dimethyl sulfoxide – isopropanol and x(PC) ≃ 0.50 for the system propylene carbonate – isopropanol (Fig. 4). In order to explain

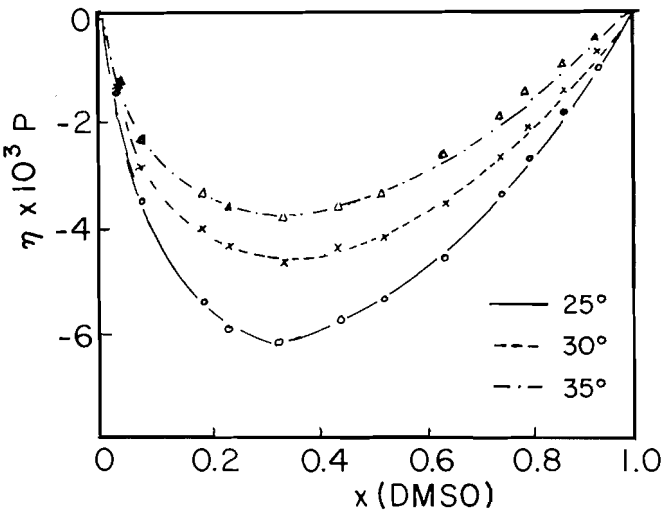

FIG. 3. Variation of η^E vs. x for the DMSO – i-prOH mixture.

this negative deviation we accept that the hydrogen bonds are broken and new species are formed. These new species consist of molecules having different geometrical configuration.

Increase of the temperature decreases the value of η^E extrema, implying that the intermolecular forces between different molecules becomes less strong.

The correlation factor g_k is an important parameter introduced by Kirkwood. It measures the correlation between the orientations of neighbouring molecules resulting from hindered rotation. The correlation factor is greater than unity for systems in which the dipole–dipole interactions give antiparallel orientation. It is less than unity when the dipole–dipole interactions give parallel orientation and g_k equals unity for a normal polar liquid. Hence the values of g_k provide a measure of the extent of the association in polar liquid (10).

The variation of g_k vs. mole fraction for both investigated binary liquid systems is shown in Fig. 5.

For the system dimethylsulfoxide–isopropanol, the correlation factor increases slowly as the concentration of dimethylsulfoxide decreases up to mole fraction x(DMSO) ≃ 0.33. From this point the correlation factor increases more rapidly. The value of g_k for pure dimethylsulfoxide is nearly unity,

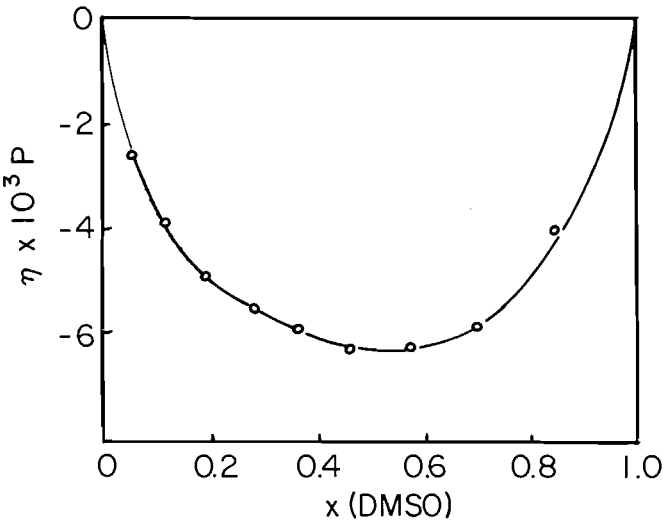

FIG. 4. Variation of η^E vs. x for the PC – *i*-prOH mixture at 25°C.

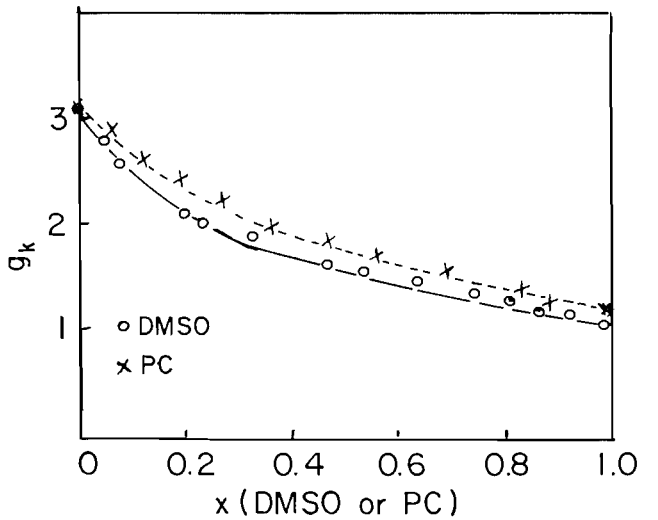

FIG. 5. Variation of η^E vs. x for the DMSO – *i*-prOH and PC – *i*-prOH mixtures.

which means that no specific dipole–dipole interactions exist. The value of g_k for pure isopropanol is much greater than unity. This observation indicates the existence of a chain of molecules with parallel dipole orientation. Addition of isopropanol to dimethylsulfoxide increases the value of g_k. This phenomenon in connection with the variation of ϵ^E and η^E can be explained by accepting the formation of a 2(*i*-prOH)·DMSO complex.

For the binary liquid system propylene carbonate – isopropanol, the molecular association through specific forces was also investigated by calculating the Kirkwood correlation factor g_k. The variation of g_k vs. x is shown in Fig. 5. The resultant g_k values for pure propylene carbonate at 25°C are close enough to unity and are in good agreement with the value reported by Simeral and Amey (11) at the same temperature (taken by extrapolation). This means that propylene carbonate is a relatively unstructured liquid. Thus its physical properties are due to the large molecular dipole moment and there are strong but not specific dipole–dipole forces.

The values of g_k increase gradually, up to mole fraction $x(\mathrm{PC}) \simeq 0.50$ and then the increase becomes more rapid. From the variation of η^E and the change of the increasing rate of g_k one can conclude that the formation of an 1:1 complex takes place. The ability of dimethylsulfoxide and propylene carbonate to associate with substances and to form aggregates, containing species of different kinds of molecules of liquid, has been reported by many authors. Thus the binary liquid system dimethylsulfoxide–water was examined in several laboratories. Experimental data on excess volume, excess viscosity, and excess heat of mixing indicate that these properties show large deviations from ideality (12–15). The deviations show extremum values at about $x \simeq 0.66$ of mole fraction of water. The latter implies that a complex containing a ratio of two molecules of water for each one of dimethylsulfoxide formed. Formation of similar complexes of dimethylsulfoxide with phenol, *p*-cresol, and picric acid is observed (16, 17). Association of dimethylsulfoxide with methanol, ethanol, and acetic acid is also reported (18, 19).

The propylene carbonate – water system shows a miscibility gap between 30 and 90 mol% of water at 25°C. In the area where the two components are miscible the excess dielectric constant shows negative deviation from ideality. Negative deviation in excess dielectric constant shows also the systems propylene carbonate – diethyl carbonate and ethylene carbonate – methanol (20).

It should be mentioned that the Trouton's constants of propylene carbonate and dimethylsulfoxide, which are higher than the value 21 corresponding to nonassociated liquid, are 23 and 29.5, respectively (21).

Dioxygen reduction at a graphite electrode modified by mononuclear tetraneopentoxyphthalocyaninatocobalt(II) and related polynuclear species

PAVEL JANDA, NAGAO KOBAYASHI, PAMELA R. AUBURN, HERMAN LAM, CLIFFORD C. LEZNOFF, AND A. B. P. LEVER[1]

Department of Chemistry, York University, North York, Ont., Canada M3J 1P3

Received October 6, 1988

PAVEL JANDA, NAGAO KOBAYASHI, PAMELA R. AUBURN, HERMAN LAM, CLIFFORD C. LEZNOFF, and A. B. P. LEVER. Can. J. Chem. **67**, 1109 (1989).

Potentiodynamic data were obtained under argon for the mononuclear species tetraneopentoxyphthalocyaninatocobalt(II) species adsorbed on glassy carbon (GC), ordinary pyrolytic graphite (OPG), and highly oriented pyrolytic graphite (HOPG). Comparative data show that the most convenient material to use is HOPG whereon a limiting monolayer is apparently achieved. Data were also presented for the mononuclear and polynuclear analogues on HOPG under both argon and dioxygen. Comparison is made of the potential data obtained in water and in organic solvent. A pH dependence study shows that the dioxygen reduction potential tracks the Co(II)TNPc/Co(I)TNPc redox couple with a slope of approximately −65 mV/pH for the mononuclear species, in the acid regime, but substantially less than −65 mV/pH for the polynuclear species. There is no pH dependence in the alkaline regime. Possible mechanisms are discussed.

Key words: phthalocyanine, electrochemistry, dioxygen reduction, pH dependence, graphite electrode, cobalt phthalocyanine.

Opérant sous de l'argon, on a déterminé des données potentiodynamiques pour des espèces mononucléaires du tétranéopentoxyphtalocyaninatocobalt(II) adsorbées sur du charbon vitreux (CV), sur du graphite pyrolytique ordinaire (GPO) et sur du graphite pyrolytique hautement orienté (GHPO). Des données comparatives ont permis de démontrer que le matériau le plus commode à utiliser est le GPHO sur lequel il semble possible se déposer une monocouche. On présente aussi des données relatives aux analogues mononucléaires et polynucléaires, sur le GPHO, tant sous un atmosphère d'argon que d'oxygène moléculaire. On a établi une comparaison des potentiels obtenus dans l'eau et dans un solvant organique. Une étude effectuée dans le but de déterminer l'influence du pH a permis de démontrer que, en milieu, le potentiel de réduction des espèces mononucléaires par l'oxygène moléculaire coupe le couple redox Co(II)TNPc/Co(I)TNPc avec une pente d'environ −65 mV/pH, valeur beaucoup plus faible que la valeur de −65 mV/pH qui est observée avec les espèces polynucléaires. En milieu alcalin, il n'y a aucune variation en fonction du pH. On discute des divers mécanismes qui pourraient être impliqués.

Mots clés : phtalocyanine, électrochimie, réduction de l'oxygène moléculaire, relation avec le pH, électrode de graphite, phtalocyanine de cobalt.

Introduction

Macrocyclic complexes of iron and cobalt have proven useful in the development of a better dioxygen reduction catalyst for a fuel cell (1) cathode (2–45). In this regard phthalocyanine species are of particular interest (2–4, 7–9, 16, 17). Recently we have reported (30) data for a series of binuclear cobalt phthalocyanine complexes whose electrocatalytic activity exceeds that of the mononuclear control molecule [3,9,16,23-tetra(neopentoxy)phthalocyanato]cobalt(II),[2] **1** by an amount proportional to the degree of molecular electronic coupling within the binuclear system. During these studies, control data were collected for mononuclear complex **1** on various graphite substrates over a range of pH. The earlier work on the binuclear phthalocyanines was undertaken by depositing the phthalocyanine onto ordinary pyrolytic graphite (OPG) (30), but at that time no variable pH data were obtained. To obtain pH dependence data, this study was repeated on highly oriented pyrolytic graphite (HOPG) which is much more efficient to use since its surface can be prepared (renewed) much more readily than that of OPG. A tetranuclear species (46) was also studied. These data are now reported. Possible mechanisms for dioxygen reduction are discussed.

[1]To whom all correspondence should be addressed.

[2]For simplicity one isomer of species **1**, and of its analogues are labelled here; however, recognize that due to different neopentoxy group substitution patterns, there will be several isomers which are generally inseparable.

Experimental

Equipment

Potential scans (cyclic voltammetry) for dioxygen reduction were performed with a Pine Instruments RD3 potentiostat and the rotation studies with a Pine Instruments PIR rotator.

Materials

o-Dichlorobenzene (DCB) (Aldrich, Gold Label) was used as supplied. Tetrabutylammonium perchlorate (TBAP) (Kodak) was recrystallized from absolute ethanol and dried at 50°C under vacuum for 2 days. Water was purified by double distillation over $KMnO_4$, followed by passage through a Barnstead organic removal cartridge and two Barnstead mixed resin ultrapure cartridges. Fisher certified 1 *N* sodium hydroxide was used for pH 14 aqueous dioxygen reduction studies. Potassium hydrogen phosphate buffers were made up as required for other pH values and checked against a Beckman pH meter. Dilute H_2SO_4 was used for pH 0.7 and 1.0.

Argon gas (Linde) was purified by passage through preheated copper filings, anhydrous $CaSO_4$ (Drierite), molecular sieves (BDH type 3A), and glass wool. Oxygen gas (Linde) was purified by passage through anhydrous $CaSO_4$, NaOH pellets (AnalaR analytical grade), anhydrous $CaSO_4$, molecular sieves, and glass wool.

[3,9,16,23-tetra(neopentoxy)phthalocyanato]cobalt(II), **1** (47, 48), metal-free 3,9,16,23-tetra(neopentoxy)phthalocyanine, **2** (47, 48), and the polynuclear complexes were prepared by literature methods. The polynuclear complexes were 1,2-bis[2′-(9′,16′,23′-trineopentoxyphthalocyanino) cobalt(II)]ethane, C(2)[CoTrNPc]$_2$ (**3**) (49) two cobalt trineopentoxyphthalocyanine rings linked via —CH_2CH_2—; bis-[2′-(9′,16′,23′-trineopentoxyphthalocyanino) cobalt(II)] ether, O(1)[CoTrNPc]$_2$ (**4**) (50) two cobalt trineopentoxyphthalocyanine

rings linked via a single dioxygen (ether) bridge; Ethylmethylbis-[2′-(9′,16′,23′-trineopentoxy phthalocyaninoxymethyl) cobalt(II)]-methane, EtMeO(5)[CoTrNPc]$_2$ (**5**) (47, 48) two cobalt trineopentoxyphthalocyanine rings linked via —$OCH_2C(Me)(Et)CH_2O$—; 1,2-bis-[2′-(9′,16′,23′-trineopentoxyphthalocyaninoxy) cobalt(II)]benzene, Cat(4)[CoTrNPc]$_2$ (**6**) (49) two cobalt trineopentoxyphthalocyanine rings linked via —O—C_6H_4—O— (*o*-catechol). These complexes are henceforth abbreviated by the label appearing before the square bracket immediately above, namely C(2), O(1), EtMeO(5), and Cat(4), the numeral representing the number of atoms in the bridge. The study also included the tetranuclear spiro species, 1,1,1,1-tetrakis[2′-(9′,16′,23′-trineopentoxyphthalocyaninoxymethyl) cobalt(II)] methane, [Co(II)TrNPc(−2)]$_4$ (**7**) (46), abbreviated Tet.

Electrodes

Ordinary pyrolytic graphite (OPG), and highly oriented pyrolytic graphite (HOPG), sometimes called stress annealed pyrolytic graphite (SAPG) were obtained from Union Carbide. The OPG was mounted in Teflon to expose a circular area of 0.493 cm^2. The glassy carbon (GC) electrode, of area 0.07 cm^2, was purchased from Tokai Carbon Ltd., Japan.

Electrodes fabricated from OPG, GC, and Pt were cleaned by polishing with 1.0, 0.3, and 0.05 μM alumina suspended in water. The cell for the adsorption experiments employed an SCE electrode, a graphite working electrode, and a platinum wire counter electrode.

The HOPG was similarly mounted in a Teflon holder to expose a circular area of 0.44 cm^2. The basal plane of the graphite was perpendicular to the axis of the electrode. This enables a fresh surface of electrode material to be exposed when a piece of Scotch brand "Magic Transparent" tape is momentarily pressed onto the surface and then gently lifted off. Usually at least two layers are removed between each adsorption study. The new surface thus revealed is used within a few minutes of exposure.

Catalyst coated electrodes were prepared by immersing and rotating (ca. 400 rpm) (on open circuit) the freshly prepared graphite surface in DCB solutions of a phthalocyanine of concentration approximately 5 $\times 10^{-5} M$ (varied from $1 \times 10^{-7} M$ to $5 \times 10^{-5} M$ in the case of **1**). The coated electrode was washed with ethanol and distilled water and dried under reduced pressure.

The time required to achieve a steady state surface concentration of a designated phthalocyanine may be conveniently monitored by cyclic voltammetry (v = 100 mV/s). For these experiments, solutions containing the desired phthalocyanine were made 0.1 M in TBAP and the state of the adsorbed layer was monitored at 5 min intervals, until the peak current corresponding to a redox reaction of the adsorbed catalyst remained constant. Redox processes corresponding to the adsorbed and bulk species occur at different potentials and are thus easily distinguished. The adsorption equilibrium (as evidenced by constant first CV scan) was established in $10^{-7} M$ **1** in about 40 min and in about 10 min (or less) in the case of $5 \times 10^{-5} M$ solution. Unlike the situation with similarly active (11) tetrasulfonated phthalocyanines (TSPc) (12) well-defined voltammetric peaks were obtained without cycling of the electrode during the adsorption step. Indeed, continuous cycling during adsorption, in any potential range, significantly decreased the amount of **1** adsorbed at the surface.

Data in non-aqueous solution were referenced to SCE via incorporation of ferrocene as an internal calibrant (51).

Note that for good reproducibility of the dioxygen reduction data, the catalyst surface was renewed for every individual experiment, *i.e.*, for every scan. Successive scans, under dioxygen, using the same surface show variations (shift in potential, loss of current etc.) which may be due to loss of catalyst and/or some catalyst decomposition.

Results and discussion

*(i) Adsorption of **1** on GC, OPG, and HOPG*

Since it is feasible to study dioxygen reduction by laying down one or more layers of catalyst upon various types of graphitic surface, especially OPG, HOPG, and GC, the best conditions to prepare electrodes modified by **1** were first investigated.

Phthalocyanines applied to the electrode by simple evaporation of their solution in an organic solvent can form uneven multi-layer films which are often microcrystalline. In addition, only a fraction of the film may be electrochemically active, leading to problems of reproducibility. The slow diffusion of oxygen (and counter ions) from the solution into the film, and the potential drop caused by the resistance of the film and hence potential shift of the votammetric curve also provide complicating factors (52, 53). While vapour deposition provides a convenient method (54) for film preparation especially where insoluble, but volatile, phthalocyanines are concerned, adsorption is a simpler procedure for organic solvent soluble metallophthalocyanines. A monolayer of the catalyst formed at the electrode surface by adsorption yields much better electrochemical results under the conditions where adsorption is highly irreversible and the bare surface of the electrode shows minimal electrocatalytic activity toward dioxygen reduction. Such layers were laid down according to the procedures outlined in the experimental section.

No adsorption was found on a Pt electrode. In the case of OPG and especially HOPG strong adsorption was observed (Fig. 1). Essentially the same results were seen with **2**, thus adsorption does not seem to involve metal ion interaction with defects on the surface. Low coverage and weak adsorption were observed on amorphous GC (Fig. 1*D*) which does not have the oriented graphitic structure of other electrodes.

On the OPG surface, the phthalocyanine surface concentration calculated to be present varies with the cleaning procedure. An OPG electrode polished by alumina, and washed only by distilled water yields a lower coverage (Fig. 1*B*) than an electrode in which the surface after the alumina treatment is further cleaned using a clean wet polishing cloth or ultrasonic cleaner. In the former case a highly hydrophilic surface is formed, presumably covered by alumina particles which can block the adsorption of TNPc. The surface cleaned using the second method is hydrophobic, as judged qualitatively from the water contact angle, and the amount of adsorbed TNPc is higher (Fig. 1*A*). Thus the degree of coverage is variable and dependent upon the details of cleaning (55, 56). Moreover, there is a relatively large residual current from the OPG surface, hindering the observation of waves of low faradaic current. Thus this material provides an unsatisfactory surface for routine and reproducible study of the electroactivity of supported phthalocyanines. The HOPG surface was undoubtedly the preferred surface with a low residual current and high reproducibility. When the bare electrode is rotated in a *ca.* $10^{-5} M$ DCB solution of **1**, the cyclic voltammogram rapidly reaches an equilibrium current maximum. This maximum, adopting the macroscopic area of the electrode, and assuming a one-electron redox couple (see below), corresponded approximately to an average surface concentration of a 6×10^{-11} mol/cm^2. It is conceivable that the phthalocyanine molecules lie flat and form π–π bonds with the graphite lattice yielding an area of about 200 Å^2. Other aromatic molecules similarly show high affinity for graphite (54, 56). The coverage, Γ, then approaches a monolayer (Fig. 1*C*). Compounds **2**–**7** may be similarly adsorbed but no evidence was collected to determine their detailed surface behaviour.

The limit of one monolayer for **1** is instructive. If the molecules are lined up perpendicular to the surface with a smaller effective area (e.g. as suggested for tetrasulfonated cobalt phthalocyanine (13)), then the amount of charge, C_p, would correspond to an incompletely covered surface and further adsorption would have been anticipated.

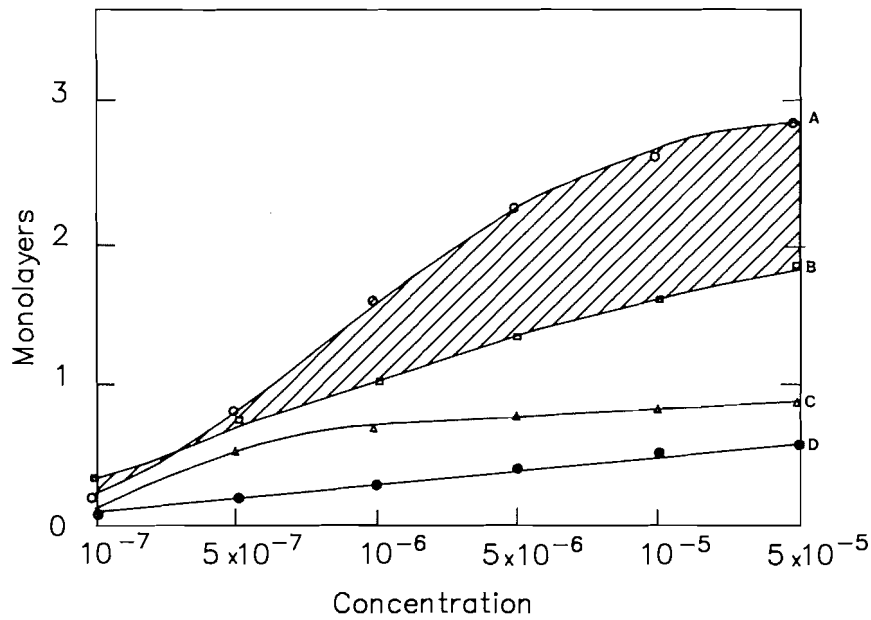

FIG. 1. Adsorption isotherms for Co(II)TNPc, **1**. Number of monolayers versus concentration of Co(II)TNPc in depositing solution (0.1 *M* TBAP/DCB) at 20°C. (*A*) OPG hydrophobic surface, (*B*) OPG hydrophilic surface, (*C*) HOPG, (*D*) GC. The shaded region shows a continual gradation between highly hydrophobic and highly hydrophilic surfaces.

TABLE 1. Charge under the Co(II)TNPc/Co(I)TNPc redox couple of complex **1** as a function of scan rate[a]

Scan rate (V/s)	Current (μA) i_p	Charge (μC) C	i_p/C
0.15	8.5	7.64	1.13
0.125	6.0	6.31	0.93
0.1	5.0	6.80	0.75
0.075	4.0	7.20	0.54
0.05	2.0	6.10	0.34

[a]Plot of i_p/C versus scan rate, including the origin point, yields a least-squares slope of 7.58 (for $nF/4RT$) corresponding to n = 0.78 and with a regression coefficient of 0.998.

The assumption that the redox couples observed under argon were one-electron in nature, was checked using eq. [1]. Thus:

$$i_p = n^2F^2\Gamma v/4RT$$

and since

$$C_p = nF\Gamma$$

then:

[1] $$i_p/C_p = nFv/4R$$

where i_p and C_p are the current and charge densities, respectively. Thus a plot of the ratio of these quantities against scan rate v, provides a measure of n, the number of electrons (14). Experimentally, using the Co(II)TNPc(−2)/[Co(I)TNPc(−2)]$^-$ redox couple of **1**, a value of n = 0.78 is obtained (Table 1).

Alternatively, if a Langmuir isotherm is assumed to be valid to describe the adsorption of the catalyst on the surface (see refs. 30, 57 for detailed discussion), then the number of electrons, n, is related to the half-bandwidth of the cyclic voltammetric peak, $W_{1/2}$, by

[2] $$n = 2RT[\ln (3 + 2\sqrt{2})/FW_{1/2}]$$

This yields a n value of 1.1–1.2 electrons for the several voltammetric peaks involved, using **1**. The deviation from unity probably reflects some deviation from true Langmuir isotherm behaviour, *i.e.* probably some interaction between adjacent molecules. Note, however, that the use of any isotherm requires a dynamic equilibrium between surface and solution, and the absence of any phthalocyanine catalyst in solution precludes such an equilibrium here.

In the HOPG case, the true surface area of the electrode and that measured macroscopically are not likely to be very disparate. A significantly higher coverage on OPG seems to be caused by a higher roughness factor of the OPG surface which is also confirmed by a higher residual current, *i.e.* the true microscopic surface area is larger than the macroscopically measured area.

Comparative CV data taken in DCB and in water show that the catalyst layer survives the transfer to the water medium.

(ii) Electrochemical behaviour of an HOPG electrode covered by a monolayer of ***1***

Under argon

The redox peaks of a monolayer of catalyst on the surface, under argon, can readily be observed in water solutions (Fig. 2*a*). A pair of voltammetric peaks in the region negative of 0 V vs. SCE, under argon, correspond to the [Co(II)TNPc(−2)]/[Co(I)TNPc(−2)]$^-$ couple, by analogy with a wealth of data collected in solvent media (58–67). They are adsorption peaks having a current proportional to the scan rate (not its square root) (68), and approach more reversible behaviour in acidic solution, the separation between the anodic and cathodic components decreasing with pH (Table 2). The half-wave potential for the [Co(II)TNPc(−2)]/[Co(I)TNPc(−2)]$^-$ couple in the alkaline range, near −700 mV vs. SCE, is essentially the same as that observed in the aprotic organic solvents such as DCB (67) (Table 3), but distinctly more negative than either CoPc or CoTsPc under the same adsorption conditions. A second reduction peak at more negative potentials arises from the [Co(I)TNPc(−2)]$^-$/[Co(I)TNPc(−3)]$^{2-}$ redox process.

The catalyst oxidation peaks are seen near (+475) − (+720) mV, vs. SCE (Fig. 2*a*) and are composite, at some pH showing two clear cathodic components. Solution studies (67) reveal

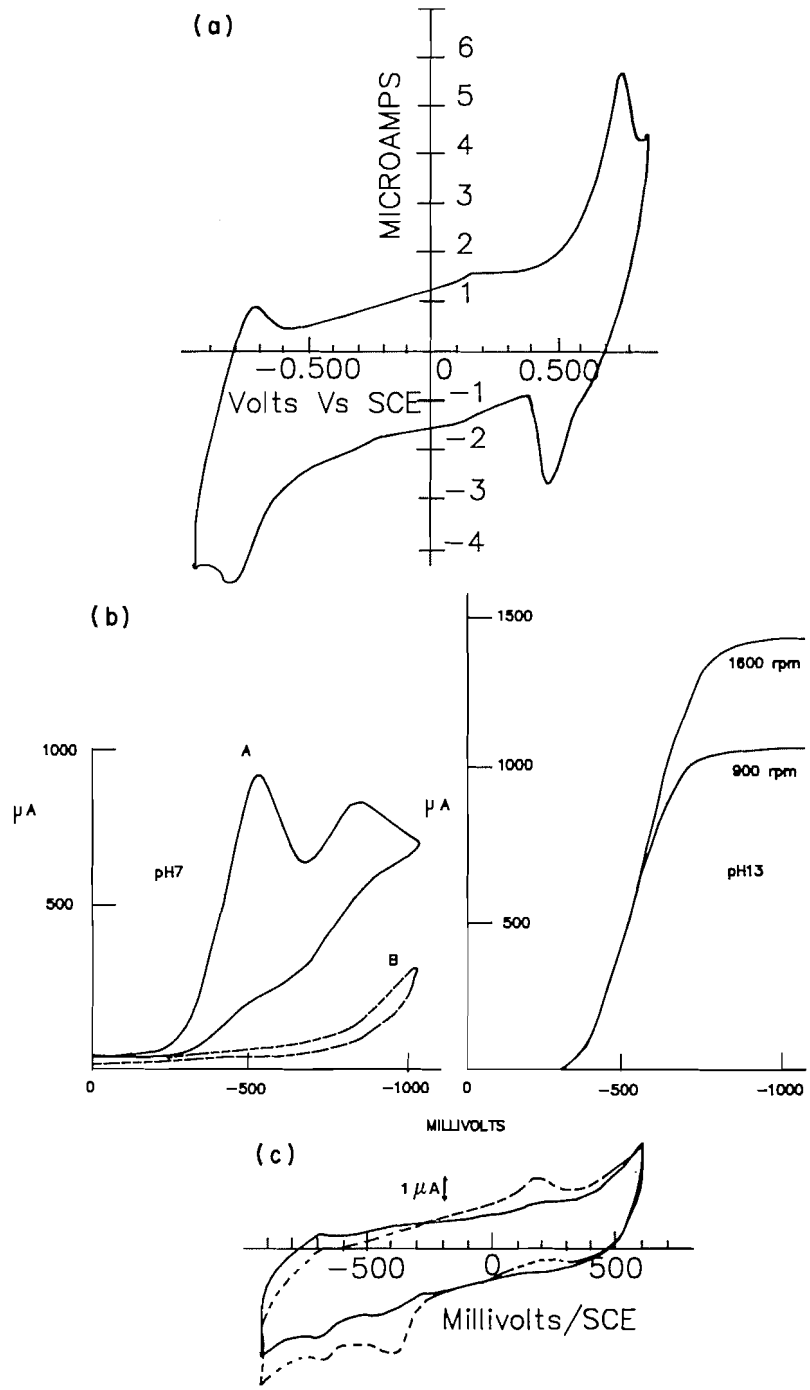

FIG. 2. (*a*) Cyclic voltammogram for Co(II)TNPc (**1**) layer deposited from a TBAP/DCB solution onto a HOPG electrode, and immersed in 0.1 *M* aq. phosphate buffer at pH 7, under argon. The left-hand couple is Co(II)TNPc(−2)/[Co(I)TNPc(−2)]$^-$, while the right-hand couple is probably an overlap of the Co(III)/Co(II) and Pc(−1)/Pc(−2) couples. (*b*) Left-hand plot: (A) Cyclic voltammogram for Co(II)TNPc (**1**) layer deposited from a TBAP/DCB solution onto a HOPG electrode, and immersed in 0.1 *M* aq. phosphate buffer at pH 7, saturated with dioxygen at 20°C. (B) as (A) but a bare unmodified HOPG surface. Right-hand plot: rotating disc electrode study of a Co(II)TNPc (**1**) layer deposited from a TBAP/DCB solution onto a HOPG electrode, and immersed in 0.1 *M* aq. NaOH at pH 13, saturated with dioxygen at 20°C. The lower scan is observed at 900 rpm and the upper at 1600 rpm. (*c*) Cyclic voltammogram for Co(II)TNPc (**1**) layer deposited from a TBAP/DCB solution onto a HOPG electrode, and immersed in 0.1 *M* NaOH at pH 13, under argon. Solid line — as described; hatched line with addition of 0.5 mL of 1×10^{-3} *M* O_2 dissolved in 0.1 *M* NaOH. The new peak at −420 mV in the second spectrum corresponds to dioxygen reduction while the new peak at +170 mV corresponds to hydrogen peroxide oxidation.

that the [Co(II)TNPc(−1)]$^+$/Co(II)TNPc(−2) and [Co(III)-TNPc(−2)]$^+$/Co(II)TNPc(−2) oxidation couples are likely to be close together and critically dependent upon potentially ligating groups in solution (or on the surface). In the absence of clearly defined behaviour for these couples their discussion will be postponed for later study.

Under dioxygen

It is very convenient that the bare HOPG surface also has a low catalytic activity towards dioxygen reduction in water solutions, allowing one to measure the electrocatalytic activity of the catalyst without interference of the bare surface (Fig. 2*b*).

An HOPG electrode surface modified with a layer of the

[c]Half-wave potential of rotating disc electrode peak, under dioxygen.

metal free **2** does not show any electrocatalytic activity. However, the cobalt complex **1** is active. In Fig. 2*c* are shown the cyclic voltammograms for the **1** modified HOPG electrode in water solution at pH 13, under argon, to which has been added 0.5 mL of solution containing 10^{-3} *M* dioxygen. The appearance of a signal due to dioxygen reduction can clearly be observed at a potential positive of the catalyst reduction peak (Table 2). The hydrogen peroxide re-oxidation wave can also be observed at +170 mV (Fig. 2*c*).

As shown in Fig. 2*b*, with excess dioxygen, the anodic peak (observed under argon) corresponding to the re-oxidation of $[Co(I)TNPc(-2)]^-$ completely disappears since the $[Co(I)TNPc(-2)]^-$ has already been oxidized by dioxygen to Co(II)TNPc(−2).

(a) Cyclic voltammetry

The current exhibited by the dioxygen reduction wave is proportional to the square root of the scan rate and is therefore a diffusion wave (68). The dioxygen reduction wave occurs positive of the catalyst Co(II)/Co(I) redox couple, by about 250 mV in the alkaline regime decreasing to about 100 mV in the acid regime (Table 2, Fig. 2*b*).

The pH dependence of the dioxygen reduction potential for **1** parallels that of the $Co(II)TNPc(-2)/[Co(I)TNPc(-2)]^-$ couple with a slope, in the acid region, of −66 mV/pH. We return to this issue below.

At a more negative potential, a second reduction wave is observed (Table 2), which corresponds to the successive reduction of hydrogen peroxide to water. Scanning positively again after the first reduction peak yields a hydrogen peroxide re-oxidation wave at about 0.2 V (Fig. 2*c*). Further proof was obtained by adding microlitre quantities of dioxygen-free hydrogen peroxide to the electrochemical cell and observing an increase in the height of this second wave, relative to the first. The pH dependence of the second reduction wave is not very clearly defined since it is observed very close to the solvent limit and is therefore subject to some error. This behaviour is very similar to that observed with a crown phthalocyanine cobalt species (69–71) where a well-defined pH dependence was observed (71). Previous studies of the two-electron reduction of dioxygen to hydrogen peroxide, have noted the existence of a second reduction process ascribed to hydrogen peroxide reduction (4, 23, 31, 72). In acid solution, under argon, the second reduction process, namely $[Co(I)TNPc(-2)]^-/[Co(I)TNPc(-3)]^{2-}$ occurring very close to the $Co(II)TNPc(-2)/[Co(I)TNPc(-2)]^-$ couple (12), may catalyse the hydrogen peroxide reduction to water. In alkaline solution, this couple moves dramatically more negative (12), explaining why the hydrogen peroxide to water reduction process is not observable in alkaline solution.

(b) Rotating disc and ring disc electrode (RDE and RRDE) studies

The magnitude of the limiting current, i_L, in the RDE dioxygen reduction wave depends linearly on the square root of the rotation rate in the range of 400–2500 rpm and is in agreement with the two-electron reduction of dioxygen to peroxide throughout the pH range studied. The halfwave potential $E_{1/2}$ of the dioxygen reduction wave tracks the $Co(II)TNPc(-2)/[Co(I)TNPc(-2)]^-$ pH dependence (Fig. 3*a*).

The standard expression for the limiting current of a diffu-

sion limited RDE plateau is given by (68)

[3] $i_L = 0.620nFAD_0^{2/3}\Omega^{1/2}v^{-1/6}C_{ox}$

where $\Omega = 2\pi f/60$ (f in rpm). The terms $D_0^{2/3}v^{-1/6}C_{ox} = 1.77 \times 10^{-9}$ mol cm^{-2} s$^{-1/2}$ calibrated with a platinum electrode assumed to be well behaved (73) and to provide a four-electron limiting wave, and the kinematic viscosity, v, $= 9.97 \times 10^{-3}$ cm^2/s. The expression yields a limiting two-electron current of 1066 μA at 900 rpm compared with an experimental value of 1075 μA (complex **1**) (Fig. 2*b*).

Logarithmic analysis of the current, i, *i.e.*, a plot of potential versus log $[i/(i_L - i)]$ yields a value falling between −110 and −130 mV/pH unit (Tafel slope) through the pH range from ca. 1.0 to 13, with a regression coefficient generally of 0.999. This corresponds to a charge transfer coefficient, $\alpha = 0.5$ and a one-electron rate-determining step, a common observation with cobalt macrocycle catalysts which reduce dioxygen to hydrogen peroxide (14, 74). Similar results are obtained for the binuclear and polynuclear species described immediately below.

Finally, a rotating ring disc experiment (RRDE, OPG, gold ring), with the ring polarised to oxidise any hydrogen peroxide which may be formed, provides additional proof of the generation of hydrogen peroxide in this experiment (at pH 9.2, Fig. 4).

(iii) Binuclear and tetranuclear species, 3–7, adsorbed on to HOPG

Figure 3*b–f* illustrates the pH dependence of the Co(II)/Co(I) couple under argon, and the dioxygen reduction peak potentials, as a function of pH, for complexes **3–7**. In all cases, and similar to the monomeric species **1** the Co(II)/Co(I) couple has a ca. −(60–70) mV/pH unit dependence in the acid regime, between pH 1 and ca. 5.0, and then becomes pH independent.[3]

The dioxygen reduction wave appears at some 200–250 mV more positive a potential than the Co(II)/Co(I) wave, in the alkaline range, dropping to about 50 mV more positive in the acid range. However, there is characteristic difference between the polynuclear species and the control species **1**. In the latter, the slope of the dioxygen reduction wave is ca. −65 mV/pH in the acid range, but for the polynuclear species it is invariably significantly smaller (Table 4). Indeed, the dioxygen reduction wave and Co(II)/Co(I) wave in these polynuclear species will occur at essentially the same potential near pH 0 (see intercept in Table 4).

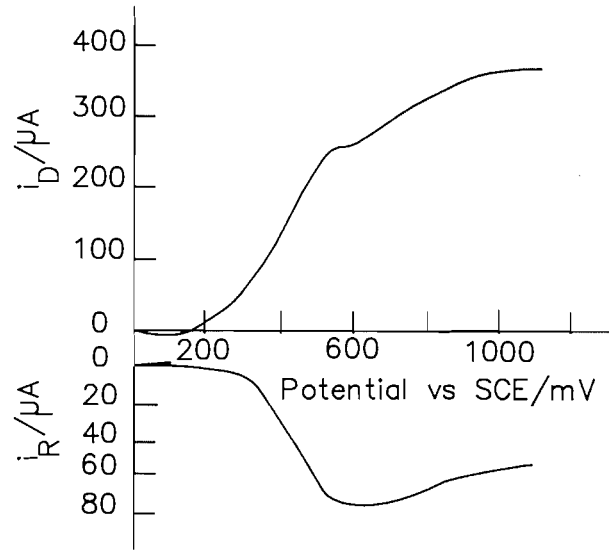
(iv) Mechanism and pH dependence

The −65 mV/pH unit dependence of the Co(II)TNPc(−2)/[Co(I)TNPc(−2)]$^-$ couple, seen with all the species investigated here, implies that the reduced and negatively charged [Co(I)TNPc(−2)]$^-$ species binds a proton, probably to a peripheral nitrogen atom (12). This pH dependence is very similar to that observed with the TsPcM(II)/[TsPcM(I)]$^-$ redox couples (M = Co, Fe) (12) and differs from that generated by the TsPcM(III)/TsPcM(II) redox couple (M = Co, Fe) where the pH dependent region lies above 7 rather than below 7.

There have been a number of studies of the role of pH on the dioxygen reduction potential of macrocyclic catalysts (3, 14, 18, 20, 23, 25, 27, 29, 37, 38, 76, 77) including a similar study of the pH dependence of the unsubstituted cobalt phthalocyanine in its Co(II)/Co(I) redox couple (3, 77).

Ni and Anson have (28) discussed the relative potentials for reduction of the adsorbed species, for various cobalt macrocyclic catalysts under argon and under dioxygen. They note that where the Co(III)/Co(II) couple of an adsorbed catalyst is involved, reduction of dioxygen often occurs at a potential *considerably more negative* than the Co(III)/Co(II) couple. The mechanism is perceived to be a "CE catalytic" mechanism where Co(II) is formed and subsequently reacts with dioxygen

[3]The data for the mononuclear species **1** were obtained at York, while the data for the polynuclear species were obtained by the same procedure in Prague, but using a different electrode and different equipment. These latter data are more scattered than the York data, with a probable error of at least ±20 mV. The reason for this scatter is not known, but it does not invalidate the general conclusions.



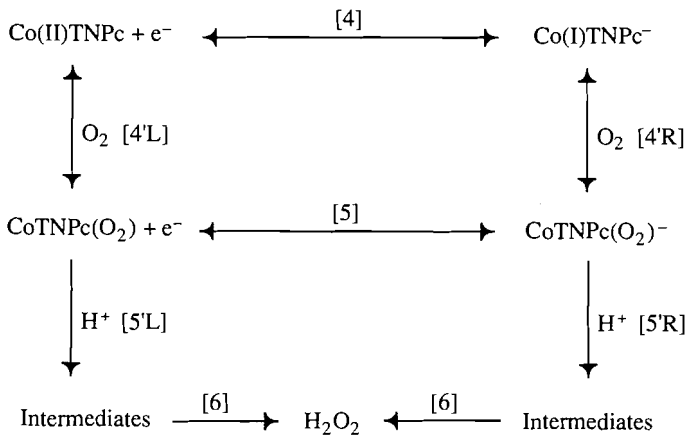


FIG. 4. A rotating ring disk experiment with Co(II)TNPc (**1**). Gold ring — OPG disk (0.18 cm^2 area) response for adsorbed **1** immersed in 0.1 *M* phosphate buffer at pH 9.2, saturated with dioxygen at 20°C. The upper curve shows reduction of dioxygen at the disk, and the lower response, re-oxidation of hydrogen peroxide at the ring (polarised at +1.0 V). Rotation rate is 400 rpm, and scan rate is 10 mV/s.

TABLE 4. Line equations in the acidic range[a]

Complex	Couple	Slope (mV/pH)	Intercept[b] (mV)	Correlation coefficient
Monomer	Co[c]	−53	−359	0.99
	O_2[d]	−58	−239	0.98
Binuclears				
O(1)	Co	−83.4	−224	0.98
	O_2	−41	−252	0.98
C(2)	Co	−73.6	−247	0.975
	O_2	−48.1	−253	0.985
Cat(4)	Co	−63.4	−299	0.97
	O_2	−32.5	−288	0.95
EtMeO(5)	Co	−65.1	−290	0.98
	O_2	−45.7	−247	0.99
Tet	Co	−69.2	−263	0.99
	O_2	−49.3	−239	0.97

[d]Refers to the dioxygen reduction couple.

SCHEME 1

(the C step) prior to eventual electron transfer with reduction of dioxygen (the E step) (28, 78). This is construed to differ from other systems where the reduction of the catalyst drives the dioxygen reduction immediately in an "EC catalytic" mechanism. This occurs both in homogenous solution (4, 25, 29, 39, 42, 43, 79) and for some adsorbed catalysts (25, 27, 29, 39, 41, 42, 76, 77), where the dioxygen reduction occurs at, or slightly negative of, the catalyst redox couple.

However, dioxygen reduction may occur at a potential positive of the catalyst redox process. This may be a consequence of an EC mechanism where the chemical and E step are so fast (80, 81) that dioxygen reduction can occur to a significant extent at a potential positive of the half-wave potential of the catalyst redox process, where a nernstian-determined small concentration of the active reduced form of the catalyst will occur.

However, if this process occurs some 250 mV or more positive of the catalyst redox wave, the quantity of reduced catalyst (e.g. Co(I)Pc here) is so small that the rate constant for dioxygen reduction needs to be excessively if not impossibly high (25, 29, 78, 80–86). Thus this likelihood is discounted, i.e., even though the dioxygen reduction tracks the Co(II)/Co(I) couple, it is not Co(I)Pc which is the primary active species. This conclusion is further supported by the observation of dioxygen reduction some 800 mV positive of the Co(II)Pc/Co(I)Pc wave at pH 14 using a newly investigated system (87).

A general set of relevant equations may be written as in Scheme 1. It is generally assumed that Co(III)TNPc species are not involved in dioxygen reduction.

Dioxygen reduction catalysis is not a consequence of activation by Co(I)TNPc, at least at the higher potentials (positive of the Co(II)/Co(I) wave). Thus the right-hand channel ([4], [4'R], [5'R]) is not important until very close to or beyond the Co(II)-TNPc/$[Co(I)TNPc]^-$ redox potential. Thus reaction must occur with Co(II)TNPc species.

Then the reaction mechanism may be written following [4'L], [5'L]. Equilibrium [4'L] lies well to the top since, at room temperature, there is little tendency to form a dioxygen adduct with Co(II)Pc. Such species are, however, observed at reduced temperatures (88). A significant overpotential is required to drive the reaction towards hydrogen peroxide. The Co(III)Pc/Co(II)Pc couple is pH independent in the acid regime (89) emphasizing that the pH dependence seen for dioxygen reduction in the acid regime must involve the irreversible binding of a proton to the coordinated di-oxygen as a first step towards hydrogen peroxide formation (85, 90); the fact that it appears to track the Co(II)/Co(I) wave is then fortuitous.

It is significant that the slope of the dioxygen reduction potential versus pH plot is less than −65 mV/pH for all the polynuclear species (Table 4), but is close to −65 mV/pH for dioxygen reduction at the mononuclear species, and for the Co(II)TNPc/Co(I)TNPc couple for the mononuclear and polynuclear species. That the dependence is about −65 mV/pH for this latter couple in the polynuclear species shows that the reduction of each Co(II) is unconcerted, *i.e.*, the reduction of one Co(II) moiety has no detectable electrochemical consequence for the other even though the electronic spectra of the polynuclear Co(II)TrNPc species shows evidence of some electronic coupling (46, 91).

A slope of less than −65 mV/pH can arise through the inclusion partially or wholly of a concerted two-electron dioxygen reduction process in the polynuclear species. That this is observed with the polynuclear species and not the mononuclear is quite credible. Consider, for example, the concerted process [7], [8]

[7] $\text{Bridge}[Co(II)TrNPc]_2 + O_2 \rightleftharpoons \text{Bridge}[TrNPcCo(III)(O_2^{2-})Co(III)TrNPc]$

[8] $\text{Bridge}[TrNPcCo(III)(O_2^{2-})Co(III)TrNPc] + H^+ + 2e^- \dashrightarrow O_2H^- + \text{Bridge}[Co(II)TrNPc]_2$

It is not at all unreasonable that the formation of a most likely bridged peroxo derivative in at least those polynuclear CoTrNPc species capable of cofacial configurations in one or more of their conformations could lead to some concerted character in the dioxygen reduction and re-formation of the starting polynuclear Co(II) species. We see no direct evidence in these complexes for such a binuclear peroxo species which need, however, only be present to a small equilibrium degree to give rise to the observed electrochemical behaviour. In the cofacial crown phthalocyanine cobalt species, however, there is much more direct evidence for the formation of such a dioxygen adduct (69, 75).

Excess molar volumes of mixtures containing methyl alkanoates (acetate, propanoate, and butanoate) with normal alkanols (from ethanol to pentan-1-ol)

J. ORTEGA AND P. SUSIAL

Cátedra de Termodinámica y Fisicoquimica, Escuela Superior de Ingenieros Industriales, Polytechnic University of Canarias, 35071-Las Palmas, Spain

Received November 21, 1988

J. ORTEGA and P. SUSIAL. Can. J. Chem. **67**, 1120 (1989).

Measurements of v^E for binary mixtures of $C_mH_{2m+1}CO_2CH_3$ (m = 1, 2, 3) + $C_nH_{2n+1}(OH)$ (n = 2, 3, 4, 5) are reported. The results have been determined by using the densities obtained in a vibrating tube densimeter at 298.15 K, they are positive for all these systems. The data have also been compared with available literature values with a discussion on these mixtures.

Key words: excess molar mixtures, methyl alkanoates, normal alkanols.

J. ORTEGA et P. SUSIAL. Can. J. Chem. **67**, 1120 (1989).

On rapporte des mesures de v^E pour des mélanges binaires de $C_mH_{2m+1}CO_2CH_3$ (m = 1, 2, 3) + $C_nH_{2n+1}(OH)$ (n = 2, 3, 4, 5). On a déterminé les résultats, à 298,15 K, à l'aide d'un densimètre à tube vibrant et ils sont positifs pour tous les systèmes. On a aussi comparé les résultats ainsi obtenus avec ceux disponibles dans la littérature et on présente une discussion concernant ces mélanges.

Mots clés : mélanges molaires en excès, alcanoates de méthyle, alcanols normaux.

Introduction

With a view to extending our previous study (1) of the binary systems methyl alkanoates with normal alkanols from hexan-1-ol to decan-1-ol, we report here the excess molar volumes of a further twelve systems formed by the same methyl esters and four other normal alkanols, from ethanol to pentan-1-ol. Although the v^E of the systems involving alkyl esters + methanol were presented in several reports (2–4), we later decided to undertake a separate study since these mixtures present a net effect of volume contraction, giving negative v^E values. The presence of methanol causes some type of specific interaction for several reasons, two of which are singled out for mention: on the one hand, the formation of hydrogen bridges and, on the other, the better interstitial accommodation of the small molecules of methanol among the molecules of the ester. The determination of other physico-chemical magnitudes will help to verify accurately this behaviour.

After the presentation of data, an analysis will be made of the effects caused by the increase in chain length of the ester and the *n*-alkanol on the v^E, verifying the indications made in other works.

Theoretical and experimental interest has increased in recent years in the thermodynamic properties of liquid mixtures containing associated compounds. The majority of the theoretical models, generally based on a rigid lattice concept, are not suitable for the prediction of volumetric properties such as v^E. Thus, the model of Nitta *et al.* (5) permits the prediction of several properties of pure compounds and mixtures, simultaneously, including v^E, and confirming that, an increase in the predictive capacity of a model causes a decrease in the capacity of representation or reproduction of experimental data. Therefore, the Nitta model does not offer a good prediction of v^E for mixtures. However, in recent years, Heintz (6) and Treszczanowicz and Benson (7) in particular have developed other models with specific applications to systems involving alkanols + alkanes that allow g^E, h^E, and v^E to be calculated simultaneously. Their extension to another type of systems requires previous knowledge of a large number of experimental data that confirm the models developed. This necessity arises when applying any of the models chosen.

Experimental

All the products employed were of the best quality commercially available (Fluka AG). The characteristics of the methyl esters have been reported previously (1). The normal alkanols, and likewise the esters, were used without further purification; however, prior to use, they were degassed with ultrasound and dried with a molecular sieve, type 4A by Fluka. After this treatment and to verify the purity of components used, the physical properties n_D and ρ were determined at 298.15 K, with comparable literature values shown in Table 1. Refractive indices of pure components were measured with a Bausch and Lomb refractometer with an accuracy of ±0.0001 unit. All measurements were made for a wavelength of 5893 Å for the sodium-D line, having been checked with pure water at 298.15 K. Measurements of densities for pure components and their mixtures were made with a DMA-55 densimeter (Anton Paar, Graz, Austria) with a reproductibility of ±0.01 kg m^{-3} and calibrated with doubly distilled and degassed wter, ρ(298.15 K) = 997.04 kg m^{-3}, and *n*-nonane (Fluka 74252 purum), ρ(298.15 K) = 713.85 kg m^{-3}. The densities of water and *n*-nonane offer a wide interval and are much closer to those of the majority of organic products, which recommends their joint use as substances for calibration purposes.

Both the digital densimeter and the refractometer were thermostated by a Heto Birdkerod ultrathermostat which controlled the temperature within ±0.01 K using a precision thermometer Anton Paar DT-100, whose performance was checked in accordance with the IPTS-68 norms.

All the mixtures were prepared by weighing in hermetically sealed 2.5 cm^3 glass vials, injecting the products with a hypodermic syringe to avoid evaporation. The mole fractions were calculated with an imprecision smaller than 5×10^{-5}.

From the densities, ρ_i, and molar masses, M_i, of the pure liquids (i = 1 for methyl alkanoates, 2 for *n*-alkanols) and the density ρ of the mixture, the molar excess volumes are given by

$$[1] \quad v^E/(\text{cm}^3\ \text{mol}^{-1}) = xM_1(\rho^{-1} - \rho_1^{-1}) + (1 - x)M_2(\rho^{-1} - \rho_2^{-1})$$

where x is the mole fraction of methyl alkanoate.

The results for v^E are estimated to be accurate to better than

TABLE 1. Physical properties ρ and n_D of pure normal alkanols obtained experimentally at 298.15 K and their comparison with literature data

Compound	ρ/(kg m^{-3})		n_D

± 0.001 cm^3 mol^{-1}. The accuracy of the technique described was checked by measuring the v^E data for the test binary mixture benzene + cyclohexane at 298.15 K and the results agree satisfactorily with those of other authors.

Results and discussion

The excess molar volumes of the twelve systems studied are summarized in Table 2. The said results can be satisfactorily represented by a fitting equation, such as

$$[2] \quad v^E/(\text{cm}^3\ \text{mol}^{-1}) = x[1 - x]\Sigma A_i\{x/[x + k[1 - x]]\}^i \qquad i = 0, 1, 2, \ldots$$

where x is the mole fraction of the methyl ester. Table 3 shows the A_i coefficients determined by a least-squares method and the standard deviations, $s(v^E)$, of the fits. With these values and those of k, the curves in Fig. 1 could be plotted for all the systems studied. The best values of k were achieved upon optimizing the corresponding correlation of the set of values of each system, bearing in mind that k will always have positive values since, if $k < 0$, the term between brackets in eq. [2] will present a discontinuity in $x = k/(1 + k)$.

Of the twelve systems studied, data have only been found in the literature for methyl propanoate + ethanol (11). Although the representation of these data are qualitatively rather similar, quantitatively there exists a difference, at $x = 0.5$, between our data and those reported in ref. 11 of -0.02 cm^3 mol^{-1}. We attribute this to the major imprecision of their picnometric technique in measurements of small excess volumes.

The same effects on the volumetric behaviour of these systems, already described in earlier papers (1–4), can be observed in the curves plotted in Fig. 1. On the one hand, the negative effect on v^E due to the increase in the chain of the methyl ester and, on the other, the quasi-linear increase of v^E with the increase in length of the n-alkanol chain, when interacting with any one ester. This latter effect can be noted perfectly upon plotting v^E, at $x = 0.5$, for the binary systems methyl alkanoate + $C_nH_{2n+1}(OH)$ as a function of n. However, the proportionality indicated is clear for values of $n > 4$,

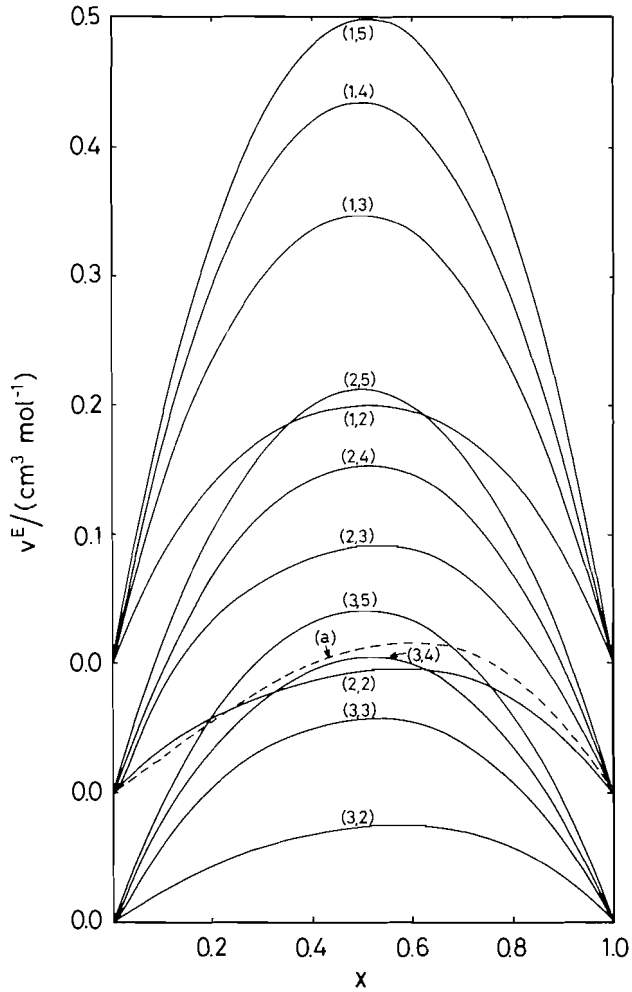

FIG. 1. Representation of the v^E curves using eq. [1] for the binary systems indicated by the pair (m, n): $\{xH_{2m+1}C_mCO_2CH_3$ $(m = 1, 2, 3) + (1 - x)C_nH_{2n+1}(OH)$ $(n = 2, 3, 4, 5)\}$. The dash line indicates the curve obtained by Polak and Lu (11) for the system (2,2).

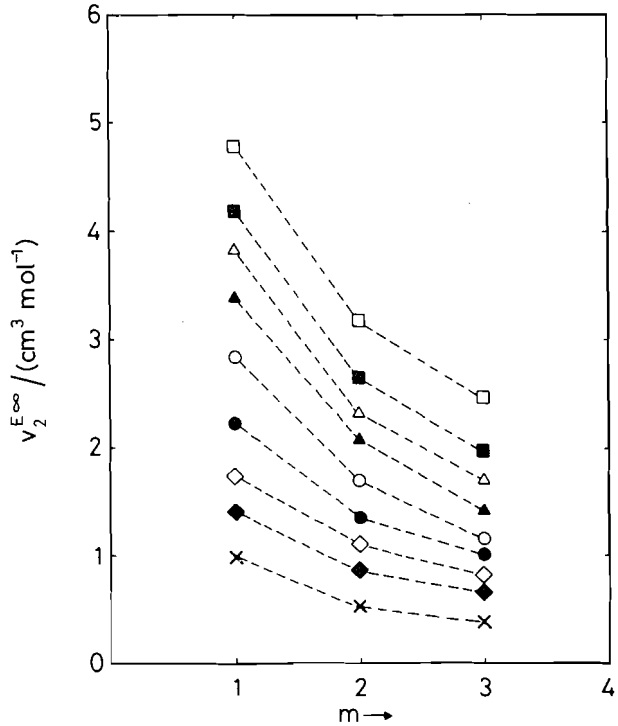

FIG. 2. Representation of $v_2^{E\infty}$ for normal alkanols $C_nH_{2n+1}(OH)$ diluted in methyl alkanoates, $H_{2m+1}C_mCO_2CH_3$ (m = 1, 2, 3), as a function of m; ×, n = 2; ◆, n = 8; ◇, n = 4; ●, n = 5. The other points correspond to the values derived from ref. 1 for n-alkanols, from hexan-1-ol to decan-1-ol.

falling abruptly for $n < 4$, to produce contractions of volume in the case of methanol.

To complete the earlier paper (1), the curves of the partial molar volumes were also determined by means of eq. [2]. In particular, the values at infinite dilution were determined by means of $v_2^{E\infty} = \Sigma A_i$ (i = 0, 1, 2, ...) for the four n-alkanols, being represented in Fig. 2 as a function of the number of carbon atoms, m, of the methyl ester $C_mH_{2m+1}COOCH_3$, and together with the data of the previous paper for the remaining normal alkanols (from hexan-1-ol to decan-1-ol).

A general qualitative interpretation of the results of the excess molar volumes of the mixtures of esters + n-alkanols is that they are the result of different factors which may be resumed as follows. First, a positive effect on the v^E due to the destruction of polymers and to the steric effect of the molecular groups of the pure compounds. However, added to these effects are others having opposite consequences on v^E, such as interstitial accommodation and especially the appearance of specific interactions with the formation of new polymers ester + n-alkanol. These act negatively in mixtures of ester with alkanols in addition to the effect of changes in the free volume. These negative effects may even predominate over the first ones, with the v^E taking on negative values as the number of carbon atoms of the n-alkanol decreases.

RÉMY TULOUP, RENÉE DANION-BOUGOT, DANIEL DANION, JEAN-PAUL PRADÈRE et LOÏC TOUPET. Can. J. Chem. **67**, 1125 (1989).

Le cycle pyrazoline est utilisé à la fois comme groupe masquant, groupe stéréodirecteur et groupe formyle latent dans une synthèse d'amino-7 formyl-4 céphèmes à partir de 6*H*-thiazines-1,3.

Mots clés : thiazine, céphème, pyrazoline, anhydride benzèneséléninique.

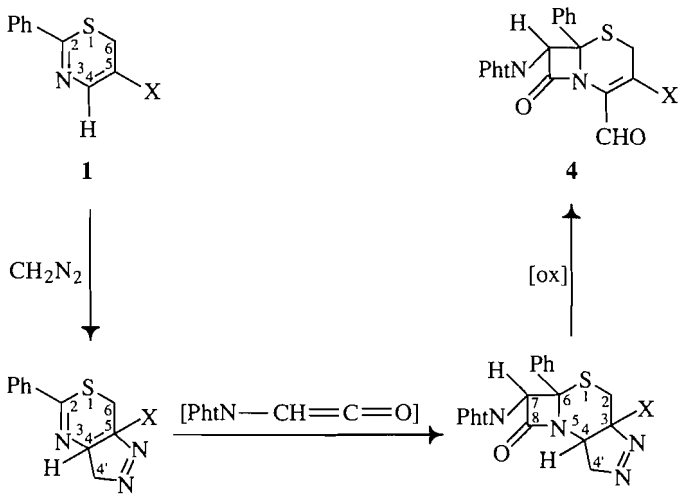
RÉMY TULOUP, RENÉE DANION-BOUGOT, DANIEL DANION, JEAN-PAUL PRADÈRE, and LOÏC TOUPET. Can. J. Chem. **67**, 1125 (1989).

A pyrazoline ring is used as a masking, a stereodirecting, and a latent formyl group in the synthesis of 7-amino-4-formyl cephems from 6*H*-1,3-thiazines.

Key words: thiazine, cephem, pyrazoline, benzeneseleninic anhydride.

Introduction

Les 6*H*-thiazines-1,3 **1** sont des intermédiaires de synthèse facilement accessibles par réaction de Diels–Alder (1). Leur valorisation comme précurseurs de céphèmes implique une réaction de lactamisation avec un équivalent synthétique d'aminocétène et l'introduction d'une fonction acide carboxylique potentielle en position 4.



Ces réactions ne sont pas réalisables avec les thiazines **1**. D'une part, la fonction imine est trop peu réactive vis à vis des cétènes à cause de la conjugaison; d'autre part, il est très difficile d'introduire un groupement fonctionnel en position 4. Les réactifs nucléophiles attaquent en 2 ou 6 (2), les réactifs électrophiles attaquent en 3.[2]

Nous décrivons dans ce mémoire une méthodologie permettant d'atteindre ces objectifs. Elle fait appel à un cycle pyrazoline intermédiaire (schéma 1).

1. Addition du diazométhane

Les résultats d'un calcul MNDO, effectué sur une thiazine modèle[3] (géométrie optimisée selon la méthode inhérente au programme), montrent que les réactions de cycloaddition dipolaire avec le diazométhane sont susceptibles d'avoir lieu sélectivement sur la liaison C4—C5. On note, en particulier, une BV basse en énergie, avec des coefficients importants en C4 et C5 (schéma 2).

Comme nous l'avons montré dans un travail préliminaire (3), le diazométhane réagit lentement, mais de façon quantitative, avec les thiazines **1***a* et **1***b*. Les pyrazolines **2***a* et **2***b*, obtenues de façon régio et stéréosélective, sont stables jusqu'à 100°C.

X = CO_2CH_3 (composés *a*) ou $COCH_3$ (composés *b*)

SCHÉMA 1

2. Réactions de lactamisation

L'introduction du cycle pyrazoline permet un masquage temporaire de la double liaison C4—C5 et rend possible la réaction de lactamisation (4). Les réactions sont effectuées avec le système chlorure de l'acide phtalimidoacétique – triéthylamine dans le dichlorométhane, à la température ambiante (5).

Les pyrazolinothiazines **2** conduisent aux lactames **3***a* et **3***b* avec des rendements supérieurs à 80%, contrairement aux thia-

SCHÉMA 3

zines **1** qui ne réagissent pas. Comme attendu, le cycle pyrazoline a un effet stéréodirecteur très important. La réaction conduit à un seul stéréoisomère, dont la configuration a été établie sans difficulté par radiocristallographie X; l'étude a été réalisée sur la pyrazoline-2 *5a* (isomérisation de *3a* en présence de triéthylamine) (schéma 3).

Les cycles β-lactame et pyrazoline sont disposés en *trans*, de même que le groupe phtalimido et le noyau thiazine. Ce résultat est en bon accord avec un contrôle stérique de la réaction.

3. Préparation de méthyl-4 céphèmes et étude de leur oxydation allylique

La conversion des pyrazolinocéphames **3** en formyl-4 céphèmes **4** a été réalisée selon deux approches convergentes. La première méthode est basée sur la préparation du dérivé méthylé **6**, qui est ensuite oxydé selon des techniques déjà utilisées pour les méthyl-3 ou hydroxyméthyl-3 céphèmes (déacétoxy ou déacétyl céphalosporines) (6, 7) (schéma 4).

La thermolyse des pyrazolines **3** a fait l'objet d'un travail préliminaire (3). Elle conduit de façon exclusive aux céphèmes méthylés **6**. L'oxydation allylique a été réalisée sur le seul composé **6***a* (X = CO_2CH_3).

L'action de la *N*-bromosuccinimide, à la température ambiante dans le dichlorométhane, donne dans de bonnes conditions le bromométhyl-4 céphème **7**, qui peut être converti en composé **8** par action du nitrate d'argent dans l'acétonitrile.

L'hydrolyse du composé **7**, en présence de nitrate d'argent, conduit à la lactone **9**. Le composé **8** donne lieu à une élimination d'acide nitreux par traitement à la triéthylamine. Dans ces conditions, il se forme, à l'équilibre, un mélange du formyl-4 céphème **4** et d'un composé tautomère **10** auquel nous avons attribué une structure Δ-2 céphème sur la base des données de

SCHÉMA 5

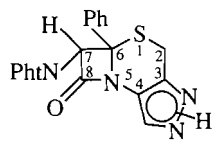
RMN. Ce type d'isomérisation en milieu basique est fréquemment rencontré en série céphème (6, 7).

Ces résultats nous ont conduits à privilégier une seconde approche, plus rapide, et qui permet de s'affranchir des milieux basiques.

4. Oxydation des pyrazolinocéphames par l'anhydride benzènesélénique

La mise au point d'une technique d'ouverture oxydante du cycle pyrazoline nous a conduits à étudier de façon systématique sur les pyrazolines-2 de formule **5** l'action des principaux oxydants utilisés pour le clivage des hydrazones (8). Une majorité de réactifs conduisent à des produits de N ou C substitution, stables dans le cas des pyrazolines étudiées (schéma 5).

La formation de ces deux types de composés s'interprète bien si l'on admet que la réaction peut être sous contrôle cinétique ou thermodynamique.



N-substitution

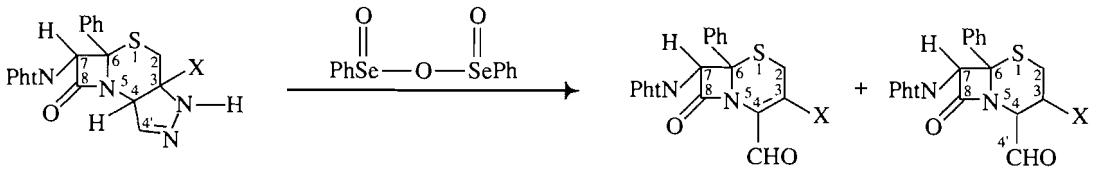
Il s'agit de la réaction la plus classique (alkylation ou acylation des pyrazolines-2) (9). Nous l'avons observée lors de la nitrosation de **5***b*, conduisant à **11***b*.

C-substitution

Cette réaction, sous contrôle thermodynamique, est observée lorsque les réactifs donnent des liaisons fragiles avec l'azote. La *N*-bromosuccinimide, en milieu eau/acétone, conduit à **12***a* et **12***b*. De même, le chlorure de benzènesélénényle donne lieu à la formation de **13***a*.

Les essais d'ouverture de ces pyrazolines substituées **11** ou **12** n'ont permis d'isoler que le pyrazole **14**, dans le cas où il n'y a pas dégradation du noyau céphame.

14



Action de l'anhydride benzènesélénique

Ce réactif, préconisé par Barton *et al.* pour réaliser le clivage des hydrazones encombrées (10), permet l'ouverture oxydante du cycle pyrazoline dans des conditions très douces. La réaction est générale et elle a fait l'objet d'une note préliminaire (11). Appliquée à la pyrazoline-2 **5***a*, elle conduit à un mélange de formyl-4 céphème **4** et de formyl-4 céphame **15** (schéma 6).

Un contrôle assez satisfaisant des proportions des deux produits est obtenu par le choix de la température. Lorsque l'oxydation est effectuée à l'ébullition du toluène, le céphème **4** est isolé à l'état pur avec un rendement de 50%. Sous l'action de la triéthylamine à la température ambiante, il s'isomérise en quelques minutes, en donnant un mélange identique à celui obtenu à partir du composé **8**.

Une autre réaction a été mise en évidence : lorsque la pyrazoline-2 bromée **16***a* (isomérisation de **12***a* par Et_3N) est soumise à l'action de l'anhydride benzènesélénique, le produit isolé est le 4-*H* céphème **17** (schéma 7).

SCHÉMA 6

16a **17**

SCHÉMA 7

Compte tenu de l'instabilité des azocomposés cycliques α-carbonylés (12), le mécanisme le plus vraisemblable est la formation d'un ester séléninique intermédiaire, qui conduit à une oxo-3 pyrazoline-1. Une rétrocycloaddition [2σ + 2σ + 2σ] permet alors d'expliquer la formation de l'alcène **17**.

L'introduction de groupes carbonylés sur des modèles plus élaborés de thiazines ou de céphèmes (13) sera envisagée ultérieurement. D'autre part, ce travail montre que les pyrazolines peuvent être utilisées comme intermédiaires pour la formylation d'alcènes. L'application synthétique de ce résultat est actuellement en cours de développement (11).

Partie expérimentale

Les spectres de RMN sont enregistrés sur des solutions dans $CDCl_3$ (sauf indication contraire) à l'aide d'appareils Bruker WP 80 CW (80 MHz; ^1H), WP 80 DS à transformée de Fourier (20,115 MHz; ^{13}C) ou AM WB 300 (300,113 MHz pour ^1H; 75,472 MHz pour ^{13}C); les deux derniers appareils sont du Centre Régional de Mesures Physiques de l'Ouest (C.R.M.P.O.). Les déplacements chimiques δ sont exprimés en ppm/TMS et les constantes de couplage J en hertz (les signaux correspondant aux groupements phényles ne seront pas donnés). Un spectrophotomètre Perkin Elmer 1420 est utilisé pour les déterminations infrarouges; les échantillons sont examinés en suspension dans le Nujol; les fréquences de vibration caractéristiques sont exprimées en cm^{-1}. Les spectres de masse sont enregistrés soit à l'aide d'un appareil Varian MAT 311 du C.R.M.P.O. (énergie du faisceau électronique 70 eV, intensité du courant d'émission 300 μA et tension d'accélération des ions 3 kV), soit à l'aide d'un appareil Varian MAT 112 de l'Université de Nantes (énergie du faisceau électronique 70 eV, intensité dans le filament 1,5 mA). Les points de fusion sont déterminés à l'aide d'un banc chauffant Kofler ou sur une platine chauffante équipée d'un microscope. Les analyses élémentaires sont effectuées par le Service Central de Microanalyse du C.N.R.S.

Les 6-*H* thiazines-1,3 **1** (1*b*, 1*c*) et le diazométhane (14) sont préparés selon les méthodes décrites dans la littérature.

1. *Synthèse des pyrazolinothiazines* **2**

Une solution de 2×10^{-2} mol de thiazine **1** dans 20 cm^3 de dichlorométhane est additionnée d'une solution éthérée (6×10^{-2} mol dans 150 cm^3) de diazométhane (14). Le mélange réactionnel est abandonné 8 jours à la température ambiante, à l'abri de la lumière. Après élimination du solvant, la pyrazoline **2** cristalline.

4. *Analyse cristallographique du composé* **5**a

$SO_5N_4C_{25}H_{18}$ M_r = 462.5

Orthorhombique, *Pbca*, a = 14,689(4), b = 16,243(4), c = 18,118(9) Å, V = 4322,6(6) Å^{-3}, Z = 8, D_x = 1,42 (Mg m^{-3}), λ (MoKα) = 0,71073 Å, μ = 1,8 cm^{-1}, F(000) = 1920, T = 296 K. L'étude a été réalisée à l'aide d'un diffractomètre automatique Enraf–Nonius: Les paramètres de la maille ont été déterminés et affinés à partir d'un ensemble de 25 réflections à angle élevé. L'échantillon, taillé à 0,15 × 0,23 × 0,26 mm, a fourni 4251 réflexions ($2\theta_{max}$ = 50°) dont 1044 indépendantes avec $I > \sigma(I)$: domaine analysé h (0 → 17) k (0 → 19) l (0 → 21), balayage $\omega/2\theta$ = 1, vitesse de balayage variable (t_{max} = 60 s), variation de 1,5% sur les contrôles d'intensité.

La structure a été résolue à l'aide des Méthodes Directes qui permettent de localiser tous les atomes non-hydrogène. L'ensemble du motif est affiné en mode isotrope (R = 0,084) puis en mode anisotrope (R = 0,072). À ce stade, les atomes d'hydrogène sont définis à l'aide d'une différence de Fourier (entre 0,57 et 0,19 e Å^{-3}).

Le meilleur affinement par matrice complète de l'ensemble de la molécule (x, y, z, β_{ij} atomes non-hydrogène et x, y, z atomes d'hydrogène) donne pour 1525 observations: R = 0,059; R_w = 0,058; S_w = 2,2; Δe = 0,15 e Å^{-3}.

5. *Synthèse des méthyl-4 céphèmes* **6**

Une solution de 10^{-3} mol de pyrazolino-1 céphame **3** dans 30 cm^3 de toluène est portée à reflux pendant 72 h. Après élimination du solvant, le résidu est cristallisé dans 10 cm^3 d'éthanol.

6*a*: *F* = 244°C; Rdt = 85%; IR ν: 1790 (C=O lactame), 1724 (C=O ester); RMN ^{1}H (80 MHz) δ: 2,87 et 3,77 (système AB, J = 15,0; H2); 2,95 (s; $=CCH_3$); 3,75 (s; CO_2CH_3); 5,60 (s; H7); RMN ^{13}C δ: 18,0 (q, ^1J = 131; $=CCH_3$); 25,7 (t, ^1J = 141; C2); 51,8 (q, ^1J = 147; CO_2CH_3); 65,1 (d, ^1J = 152; C7); 70,0 (s; C6); 108,1 (s large; C3); 144,7 (s large; C4); 161,0 (s; C8); 166,9 (s large; CO_2CH_3). *Anal.* calc. pour $C_{23}H_{18}N_2O_5S$: C 63,59, H 4,15, S 7,37; tr.: C 63,09, H 4,12, S 7,22%.

6*b*: *F* = 240°C; Rdt = 85%; IR ν: 1785 (C=O lactame), 1718 (C=O acétone); RMN ^{1}H (80 MHz) δ: 2,34 (s; $COCH_3$); 2,92 et 3,66 (système AB, J = 17,0; H2); 2,86 (s; $=CCH_3$); 5,58 (s; H7); RMN ^{13}C δ: 18,2 (q, ^1J = 130; $=CCH_3$); 26,4 (t, ^1J = 143; C2); 30,6 (q, ^1J = 127; $COCH_3$); 65,1 (d, ^1J = 152; C7); 69,9 (s; C6); 116,8 (s large; C3); 142,2 (s large; C4); 165,9 (s; C8); 198,2 (s large; $COCH_3$). Spectrométrie de masse (Varian Mat 112): $[M]^+$ = 418. *Anal.* calc. pour $C_{23}H_{18}N_2O_4S \cdot H_2O$: C 63,30, H 4,59, N 6,42; tr.: C 63,89, H 4,38, N 6,48%.

6. *Synthèse du bromométhyl-4 céphème* **7**

Du *N*-bromosuccinimide (3×10^{-3} mol) est ajouté à une solution de 2×10^{-3} mol de céphème **6***a* dans 15 cm^3 de dichlorométhane et le mélange est maintenu 6 h à reflux. Après lavage à l'eau et séchage sur $MgSO_4$, le solvant est éliminé. Le résidu est recristallisé à froid dans le mélange acétate d'éthyle/éther de pétrole; *F* = 198°C; Rdt = 91%; IR ν: 1795 (C=O lactame), 1727 (C=O ester); RMN ^{1}H (80 MHz) δ: 2,91 et 3,82 (système AB, J = 18,4; H2); 3,80 (s; CO_2CH_3); 5,14 et 5,41 (système AB, J = 10,4; CH_2Br); 5,62 (s; H7). *Anal.* calc. pour $C_{23}H_{17}N_2O_4SBr$: C 53,80, H 3,34, S 6,25; tr.: C 53,69, H 3,44, S 6,37%.

7. *Synthèse du composé* **8**

Du nitrate d'argent (7×10^{-4} mol) est ajouté, sous agitation magnétique, à une solution de 7×10^{-4} mol de bromométhylcéphème **7** dans 10 cm^3 d'acétonitrile anhydre. Le mélange est abandonné sous agitation pendant 24 h à la température ambiante et à l'abri de la lumière. Le solvant est alors éliminé et le résidu repris avec du dichlorométhane, puis lavé à l'eau. Après séchage sur $MgSO_4$, le dichlorométhane est éliminé et le produit obtenu recristallisé à froid dans le mélange acétate d'éthyle/éther de pétrole; *F* = 179°C; Rdt = 89%; IR ν: 1805 (C=O lactame), 1727 (C=O ester); RMN ^{1}H (80 MHz) δ: 2,82 et 3,70 (système AB, J = 19,2; H2); 3,69 (s; CO_2CH_3); 5,53 (s; H7); 5,91 et 6,24 (système AB, J = 12,4; CH_2ONO_2). Spectrométrie de masse (Varian Mat 112): $[M]^+$ = 495. *Anal.* calc. pour $C_{23}H_{17}N_3O_8S \cdot 1/2H_2O$: C 54,76, H 3,57, S 6,35; tr.: C 54,77, H 3,52, S 6,37%.

8. *Synthèse de la lactone* **9**

À une solution de 4×10^{-4} mol de bromométhylcéphème **7**, dans 20 cm^3 d'acétone, est ajoutée 8×10^{-4} mol de fluoroborate d'argent (celui-ci, soluble dans l'eau et dans l'acétone, est préparé par action de 2 mol de HBF_4 sur 1 mol de $AgCO_3$, lui-même obtenu par action de $NaHCO_3$ sur une solution de $AgNO_3$). Le mélange est maintenu à reflux sous agitation magnétique, pendant 24 h, à l'abri de la lumière, puis concentré au 1/4. Du dichlorométhane (100 cm^3) et 200 cm^3 d'eau sont alors ajoutés. La phase organique est épuisée au dichlorométhane, séchée et le solvant éliminé. Le produit ainsi obtenu est recristallisé dans l'éthanol; *F* = 260°C; Rdt = 92%; IR ν: 1815 (C=O lactame), 1770 (C=O lactone); RMN ^{1}H (80 MHz; $CDCl_3/CF_3CO_2H$, 90:10) δ: 3,15 et 3,40 (système AB, J = 16,0; H2); 5,50 (s large; CH_2 lactone); 5,84 (s; H7). Spectrométrie de masse (Varian Mat 311):

For personal use only.

pour $[M]^{+}$, masse calculée : 418,062; trouvée : 418,063. *Anal.* calc. pour $C_{22}H_{14}N_2O_5S$: C 63,16, H 3,35, N 6,70; tr. : C 62,65, H 3,29, N 6,64%.

9. *Essai d'obtention du formyl-4 céphème* ***4*** *à partir du composé* ***8***

De la triéthylamine ($6,4 \times 10^{-4}$ mol) est ajoutée à une solution de $3,2 \times 10^{-4}$ mol de composé **8** dans 20 cm^3 de chloroforme. Le mélange est abandonné 15 min à la température ambiante, puis versé dans 10 cm^3 d'acide chlorhydrique molaire. Après épuisement au dichlorométhane et séchage sur $MgSO_4$, le solvant est éliminé et le résidu analysé par RMN ^{1}H. C'est un mélange de formyl-4 céphème **4** (20%) et d'un isomère (80%) auquel nous avons attribué la structure Δ-2 céphème énolisée **10**; les caractéristiques de ces deux produits seront données plus loin.

10. *Synthèse du nitrosopyrazolino-2 céphame* ***11***b

À une solution de 5×10^{-4} mol de pyrazolino-2 céphame **5***b* dans 2 cm^3 d'acide trifluoroacétique, portée à 0°C, est ajoutée $2,5 \times 10^{-3}$ mol de nitrite de sodium en solution dans 2 cm^3 d'eau, sous vive agitation magnétique. Cette agitation est maintenue pendant 5 min, puis le mélange est versé dans 20 cm^3 d'eau. Après essorage, le produit obtenu est recristallisé dans l'acétone; F = 235°C; Rdt quantitatif; IR ν : 1789 (C=O lactame), 1710 (C=O cétone); RMN ^{1}H (80 MHz) δ : 2,22 (s; $COCH_3$); 3,55 et 3,72 (système AB, J = 15,8; H2); 5,99 (d, ^3J = 2,0; H4); 6,08 (s; H7); 7,85 (d, ^3J = 2,0; H4′). Spectrométrie de masse (Varian Mat 112) : ion fragment $[M - COCH_3 - NO]^{+}$ = 402.

11. *Synthèse des bromopyrazolino-1 céphames* ***12***

Du *N*-bromosuccinimide ($3,3 \times 10^{-3}$ mol) est ajouté, sous agitation magnétique, à une solution de 3×10^{-3} mol de pyrazolino-2 céphame **5** dans 100 cm^3 d'acétone. Le mélange est abandonné 1 h à la température ambiante et le solvant éliminé. Le résidu est repris par 50 cm^3 de dichlorométhane, puis lavé successivement par une solution saturée d'hydrogénosulfite de sodium, une solution saturée d'hydrogénocarbonate de sodium et à l'eau. Après séchage sur $MgSO_4$ et élimination du solvant, le résidu est recristallisé dans l'éthanol.

12*a* : F = 188°C (déc.); Rdt = 87%; IR ν : 1790 (C=O lactame), 1730 (C=O ester); RMN ^{1}H (80 MHz) δ : 3,26 et 3,63 (système AB, J = 16,0; H2); 3,94 (s; CO_2CH_3); 5,35 (d, ^3J = 6,0; H4); 5,75 (s; H7); 6,25 (d, ^3J = 6,0; H4′); RMN ^{13}C δ : 28,1 (t, ^1J = 148; C2); 54,2 (q, ^1J = 148; CO_2CH_3); 58,8 (d, ^1J = 152; C4); 68,5 (d, ^1J = 153; C7); 71,6 (s large; C6); 79,9 (d, ^1J = 168; C4′); 93,0 (s large; C3); 166,0 (s; C8); 166,7 (s large; CO_2CH_3). *Anal.* calc. pour $C_{23}H_{17}N_4O_5SBr$: C 51,02, H 3,14, N 10,35; tr. : C 51,18, H 3,30, N 10,23%.

12*b* : F = 195–200°C (déc.); Rdt = 89%; IR ν : 1787 (C=O lactame), 1725 (C=O cétone); RMN ^{1}H (80 MHz) δ : 2,59 (s; $COCH_3$); 3,53 (s large; H2); 5,39 (d, ^3J = 5,0; H4); 5,87 (s; H7); 6,35 (d, ^3J = 5,0; H4′); RMN ^{13}C δ : 26,6 (q, ^1J = 129; $COCH_3$); 27,5 (t, ^1J = 146; C2); 55,4 (d, ^1J = 151; C4); 68,1 (d, ^1J = 155; C7); 70,7 (s large; C6); 79,5 (d, ^1J = 171; C4′); 98,8 (s large; C3); 165,7 (s; C8); 199,9 (s large; $COCH_3$). *Anal.* calc. pour $C_{23}H_{17}N_4O_4SBr$: C 52,57, H 3,24, N 10,66; tr. : C 52,47, H 3,45, N 10,79%.

12. *Synthèse du phénylsélénopyrazolino-1 céphame* ***13***a

Du chlorure de benzènesélénényle (10^{-3} mol) est ajouté à une solution de 10^{-3} mol de pyrazolino-2 céphame **5***a* dans 50 cm^3 de dichlorométhane. Le mélange est maintenu 18 h à reflux. Après élimination du solvant, le résidu est recristallisé dans l'acétone; F = 236°C; Rdt = 95%; IR ν : 1791 (C=O lactame), 1733 (C=O ester); RMN ^{1}H (80 MHz) δ : 3,13 et 3,56 (système AB, J = 15,4; H2); 3,72 (s; CO_2CH_3); 5,06 (d, ^3J = 6,8; H4); 5,69 (s; H7); 5,82 (d, ^3J = 6,8; H4′); RMN ^{13}C δ : 28,1 (t, ^1J = 145; C2); 53,8 (q, ^1J = 148; CO_2CH_3); 55,1 (d, ^1J = 150; C4); 66,3 (d, ^1J = 153; C7); 71,4 (s large; C6); 85,6 (d, ^1J = 156; C4′); 91;6 (s large; C3); 165,9 (s large; CO_2CH_3); 167,0 (s; C8). Spectre de masse (Varian Mat 311) : pour $[M]^{+}$, masse calculée : 590,041; trouvée : 590,041. *Anal.* calc. pour $C_{29}H_{22}N_4O_5SSe \cdot H_2O$: C 54,80, H 3,78, N 8,81; tr. : C 55,12, H 3,55, N 8,96%.

13. *Obtention du pyrazole* ***14***

À une solution de 3×10^{-4} mol de bromopyrazolino-1 céphame **12**, dans 40 cm^3 de méthanol, est ajoutée 3×10^{-4} mol de potasse en solution dans le minimum de méthanol. Le mélange est maintenu 20 min sous agitation magnétique, à la température ambiante, puis additionné de 25 cm^3 d'acide chlorhydrique 0,5 M. Après extraction au dichlorométhane, la phase organique est lavée à l'eau, puis séchée sur $MgSO_4$ et le solvant éliminé. Les cristaux obtenus après addition de 20 cm^3 d'éther sont recristallisés dans l'éthanol; F = 260°C; Rdt = 87%; IR ν : 3260, large (NH), 1795 (C=O lactame); RMN ^{1}H (80 MHz; $CDCl_3/CF_3CO_2H$, 90 : 10) δ : 3,50 et 4,21 (système AB, J = 18,4; H2); 5,78 (s; H7); 8,49 (s; H pyrazole). Spectrométrie de masse (Varian Mat 112) : $[M]^{+}$ = 402.

14. *Oxydation avec l'anhydride benzènesélénique*

(a) Synthèse des formyl-4 céphème 4 et formyl-4 céphame ***15***

Une solution de 2×10^{-3} mol de pyrazolino-2 céphame **5***a* dans 100 cm^3 de toluène est portée à reflux sous vive agitation. Sont alors ajoutées 10^{-2} mol d'hydrogénocarbonate de sodium en poudre, puis $2,2 \times 10^{-3}$ mol d'anhydride benzènesélénique. Le mélange est maintenu 5 min à reflux sous vive agitation magnétique, puis lavé avec 2 fois 50 cm^3 d'eau, séché sur $MgSO_4$ et le solvant éliminé. Le produit brut, analysé en RMN ^{1}H, montre la formation des composés **4** (68%) et **5** (32%). Il est repris par un mélange de tétrachlorure de carbone (20 cm^3) et d'acétone (10 cm^3). Le milieu, abandonné à l'air libre, laisse déposer les aldéhydes, qui sont séparés par recristallisation à chaud dans l'acétate d'éthyle.

4 : F = 241°C; Rdt = 50%; IR ν : 1808 (C=O lactame), 1735 (C=O ester), 1729 (C=O aldéhyde); RMN ^{1}H (80 MHz) δ : 2,98 et 3,82 (système AB, J = 19,2; H2); 3,79 (s; CO_2CH_3); 5,55 (s; H7); 10,25 (s; CHO); RMN ^{13}C δ : 26,0 (t, ^1J = 147; C2); 53,0 (q, ^1J = 148; CO_2CH_3); 65,6 (d, ^1J = 153; C7); 69,0 (s; C6); 117,8 (s large; C3); 141,3 (s large; C4); 159,5 (s; C8); 165,2 (s large; CO_2CH_3); 184,9 (d, ^1J = 199; CHO). *Anal.* calc. pour $C_{23}H_{16}N_2O_6S$: C 61,61, H 3,57, N 6,25; tr. : C 61,50, H 3,48, N 6,32%.

15 : F = 229°C; Rdt = 10%; IR ν : 1800 (C=O lactame), 1733 (C=O ester), 1726 (C=O aldéhyde); RMN ^{1}H (300 MHz) : système ABCX analysé par découplage successif des différents protons, δ : 2,82 (A) (H2); 3,06 (C) (H3); 3,17 (B) (H2); 5,56 (X) (H4); J_{AB} = 14,5; J_{AC} = 11,4; J_{BC} = 2,7; J_{BX} = 0,8; J_{CX} = 5,2; $J_{H3H4'}$ = 1,1; δ : 3,70 (s; CO_2CH_3); 5,54 (s; H7); 9,78 (d, $J_{H4'H3}$ = 1,1; H4′); RMN ^{13}C δ : 24,3 (t, ^1J = 143; C2); 40,2 (d, ^1J = 125; C3); 52,4 (q, ^1J = 148; CO_2CH_3); 57,5 (d, ^1J = 138; C4); 69,1 (d, ^1J = 156; C7); 71,0 (s; C6); 163,5 (s; C8); 169,3 (s large; CO_2CH_3); 193,7 (d, ^1J = 184; CHO). Spectrométrie de masse (Varian Mat 311) : pic moléculaire correspondant à $C_{23}H_{18}N_2O_6S$ (M = 450) trop faible pour mesurer la masse exacte; ion fragment $[M - OCH_3]^{+}$, masse calculée : 419,070; trouvée : 419,071.

(b) Obtention du Δ-2 céphème ***10***

De la triéthylamine (10^{-3} mol) est ajoutée à une solution de 2×10^{-4} mol de céphème **4** dans 15 cm^3 de dichlorométhane anhydre. La solution se colore immédiatement et, après 5 min à la température ambiante, elle est versée dans 25 cm^3 d'acide chlorhydrique 0,2 M. Après extraction au dichlorométhane, la phase organique est séchée sur $MgSO_4$, puis le solvant est éliminé. L'analyse en RMN ^{1}H montre que le produit obtenu est un mélange des composés **4** (20%) et **10** (80%). La recristallisation, à chaud dans l'acétate d'éthyle, permet d'isoler **10** pur; F = 230°C; Rdt = 75%; IR ν : 1795 (C=O lactame), 1720 (C=O ester); RMN ^{1}H (80 MHz) δ : 3,75 (s; CO_2CH_3); 5,61 (s; H7); 7,12 (s imbriqué dans les signaux du noyau phényle) et 7,73 (s) (H2 et =$CHOH$); le signal relatif au proton énolique n'est pas détecté; RMN ^{13}C δ : 52,3 (q, ^1J = 148; CO_2CH_3); 65,2 (d, ^1J = 156; C7); 68,2 (s; C6); 110,7 (s) et 118,3 (s large) (C3 et (ou) C4); 126,5 (d, ^1J = 180; C2); 141,4 (d, ^1J = 190; =$CHOH$); 161,0 (s; C8); 163,2 (s large; CO_2CH_3). Spectrométrie de masse (Varian Mat 311) : pour $[M]^{+}$ ($C_{23}H_{16}N_2O_6S$) masse calculée : 448,072; trouvée : 448,072.

*(c) Obtention du 4-*H *céphème* ***17*** *à partir du bromopyrazolino-1 céphame* ***12***a

(1) *Synthèse des bromopyrazolino-2 céphames* ***16*** : 10^{-2} mol de triéthylamine est ajoutée à une solution de 3×10^{-3} mol de bromopyrazolino-1 céphame **12** dans 30 cm^3 de dichlorométhane et le mé-

lange est maintenu au reflux pendant 2 h. Après élimination du solvant et de la triéthylamine, le produit obtenu est recristallisé dans l'éthanol.

MICHEL MPASSI, GÉRALD GUILLAUMET, GÉRARD COUDERT, MADELEINE TISSIER et JEAN JUILLARD. Can. J. Chem. **67**, 1132 (1989).

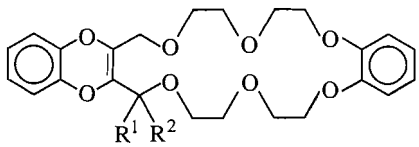
La synthèse de deux nouvelles séries de macrocycles polyoxygénés, **1** et **2**, a été réalisée. Ces dérivés présentent en commun une structure benzodioxinique 1,4 et sont apparentés aux éthers-couronnes, aux éthers-couronnes benzo et aux éthers-lassos. L'étude de la complexation des cations sodium et potassium par les différents composés préparés a été effectuée par potentiométrie dans le méthanol; ces résultats sont comparés aux données de la littérature concernant d'autres composés macrocycliques polyoxygénés.

Mots clés : macrocycles polyoxygénés, benzodioxine-1,4, éthers-lassos, complexes du sodium et du potassium, solvant méthanol.

MICHEL MPASSI, GÉRALD GUILLAUMET, GÉRARD COUDERT, MADELEINE TISSIER, and JEAN JUILLARD. Can. J. Chem. **67**, 1132 (1989).

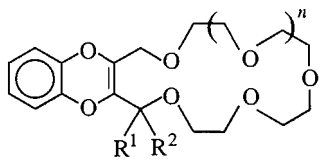
The synthesis of two new series of polyoxygenated macrocyclic derivatives, **1** and **2**, was realised. All these compounds have a 1,4-benzodioxinic moiety and are related to crown ethers, benzocrown ethers, and lariat ethers. The complexing properties of sodium and potassium ions were studied using potentiometry in methanol; results thus obtained are compared to data, previously reported in the literature, for classical polyoxygenated macrocyclic compounds.

Key words: polyoxygenated macrocycles, 1,4-benzodioxin, lariat ethers, sodium and potassium complexes, solvent methanol.



Introduction

Depuis la découverte quelque peu fortuite des éthers-couronnes effectuée par C. J. Pedersen il y a 20 ans (1) un nombre considérable de travaux ont été réalisés dans ce domaine. Après la synthèse des premiers composés cycliques polyoxygénés, des ligands organiques cycliques neutres incorporant des atomes de soufre (2), d'azote (3) ou de phosphore (4) ont aussi été préparés; l'ensemble de ces dérivés sont regroupés sous le terme de coronands. Parallèlement aux recherches réalisées en série monocyclique, Lehn a développé un nouveau groupe de composés, celui des cryptands (5), ligands bi- ou tri-cycliques oxygénés et azotés caractérisés par l'existence d'une cavité tridimensionnelle de taille modulable. Des travaux visant à l'obtention de dérivés à chaîne ouverte apparentés soit aux coronands soit aux cryptands (6) ont également été réalisés.



Tous ces composés, du fait de leur structure et de leur aptitude à complexer les cations, constituent des modèles potentiels des ionophores naturels. Cependant, le pouvoir complexant et la sélectivité observés dans le cas des coronands se révèlent souvent trop faibles, alors que les cryptands, ligands puissants et sélectifs des cations, présentent l'inconvénient de conduire à des complexes, les cryptates, souvent trop stables. On pouvait dès lors estimer qu'un compromis favorable du point de vue topologique devait être réalisé entre ces deux types de ligands avec les éthers-lassos (lariat-ethers) élaborés tout d'abord par Gokel *et al.* (7).

Il est souvent difficile de fixer des chaînes latérales sur des cycles polyoxygénés dans des conditions définies; trois d'entre-nous ont proposé, pour ce faire, une méthode originale utilisant comme structure de base le motif benzodioxine (8). Lors de cette synthèse il est aisé d'introduire en α du cycle benzodioxinique un ou deux bras susceptibles de participer ou non à la complexation des cations par le macrocycle. Ce travail a été développé et le pouvoir complexant des molécules obtenues systématiquement testé.

Nous avons préparé deux types de composés, **1** possèdant une chaîne latérale de nature et taille variable et un motif catéchol comme moyen de fermeture, et **2** comportant une cavité de taille variable et quelques bras représentatifs. Les groupements R^1 et R^2 peuvent être soit des chaînes alkyle ou aryle, soit des groupes porteurs de sites de complexation supplémentaires susceptibles, comme dans le cas des éthers-lassos simples, de participer à

la capture du cation. Quelques produits du type **1** préparés précédemment ont déjà été décrits (8).

Tous sont ici étudiés en ce qui concerne leur aptitude à complexer les cations sodium et potassium. Cette étude est effectuée dans le méthanol par une méthode potentiométrique utilisant des électrodes de verre sélectives à ces deux cations; beaucoup des données similaires concernant les macrocycles polyoxygénés ont été obtenues dans ce solvant, ce qui doit permettre de comparer les performances de nos produits à celles d'autres composés obtenus par d'autres auteurs.

Méthodes et résultats

Synthèse des macrocycles polyoxygénés 1 et 2

Les schémas 1 et 2 rendent compte de la stratégie adoptée pour préparer de tels composés à partir du carboxy-2 benzodioxine-1,4 **3**.

La première étape de cette séquence réactionnelle est constituée par la fonctionnalisation de la position 3 du cycle benzodioxinique par action du dianion de l'acide **3** sur des électrophiles appropriés (9). Cette réaction permet très aisément de faire varier la nature des substituants R^1 et R^2 et ainsi de moduler les caractéristiques topologiques et physico-chimiques des composés recherchés. De surcroît, le mode de fermeture du cycle polyoxygéné permet de faire varier la taille de la cavité et le nombre d'atomes d'oxygène impliqués dans le processus de complexation.

Nous avons déjà décrit le mode de préparation des composés **1***a–k* pour lesquels la fermeture du cycle est assurée par un noyau catéchol ainsi que les caractéristiques physiques et spectrales de **1***e–k* (8). Dans tous les cas le nombre d'atomes d'oxygène du macrocycle est égal à six.

Nous avons par ailleurs réalisé la préparation des macro-

SCHÉMA 2. (h) $ClCH_2CH_2OCH_2CH_2Cl$, NaOH 50%, $nBu_4N^+HSO_4^-$; (i) catéchol, NaOH, butanol; (j) NaH, $TsO(CH_2CH_2O)_nTs$.

cycles **2** dans lesquels la fermeture du cycle est assurée par une chaîne polyéthylèneglycol de longueur variable. Les composés **2**c ont été préparés en fixant la nature des substituants R^1 et R^2 ($R^1 = R^2 = CH_3$) et en faisant varier la taille de la cavité. Les dérivés **2***e* ($R^1 = CH_3$; $R^2 = CH_2CH_2OCH_2Ph$) et **2***l* ($R^1 = CH_3$; $R^2 = CH_2CH_2(OCH_2CH_2)_2OCH_2Ph$) sont du type ethers-lassos et font apparaître au contraire une cavité de taille fixe, la longueur de la chaîne latérale étant variable et incorporant un ou trois atomes d'oxygène susceptibles d'intervenir dans le processus de complexation.

La cyclisation des diols **7***c*, **7***e*, et **7***l* est réalisée au sein du tétrahydrofuranne en utilisant l'hydrure de sodium comme base. Les macrocycles **2** sont isolés après purification sur colonne de silice avec des rendements compris entre 45 et 55%.

Complexes avec le sodium et le potassium

L'étude potentiométrique utilisant une électrode sélective, soit au sodium, soit au potassium, a permis de mettre en évidence une possible formation de deux complexes EM^+ et E_2M^+, entre l'éther couronne E et le cation métallique M^+, selon les réactions successives [1] et [2] :

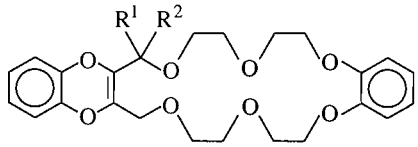
[1] $E + M^+ \rightleftarrows EM^+$

[2] $EM^+ + E \rightleftarrows E_2M^+$

Le plus souvent, la formation de E_2M^+ est négligeable. Elle n'est appréciable que pour les interactions entre l'ion potassium et des composés de type **2** où $n \geq 4$. Dans ce cas les deux constantes K_1 et K_2 ont été déterminées conjointement. Les résultats sont reportés sur les tableaux 1 et 2.

Discussion

Couronnes cyclisées par les polyéthylèneglycols (composés **2**c_1–**2**c_6*)*



Si l'on compare les constantes de formation des complexes EM^+ à celles obtenues avec les couronnes (10, 11) et les benzocouronnes simples (12, 13) de même nombre d'atomes d'oxygène dans le macrocycle, il apparaît qu'elles sont beaucoup plus faibles pour les produits benzodioxiniques (10–100 fois). D'autre part, le fort maximum de complexation observé pour des cycles à 6 oxygènes (fig. 1) est perdu. Un petit maximum apparaît cependant ici pour les cycles à 7 oxygènes. Les constraintes stériques imposées par la liaison éthylénique conduisent à un rétrécissement *de facto* du macrocycle, les deux atomes d'oxygène de ce dernier les plus proches de la double liaison se révélant par ailleurs à l'examen des modèles CPK peu utilisables lors du processus de complexation. De ce fait, les performances de ces composés n'approchent celles des couronnes et benzocouronnes à même nombre d'oxygène dans le cycle que pour un nombre élevé d'atomes d'oxygène (fig. 1).

La sélectivité $S = K_1 (K^+) : K_1 (Na^+)$ est en faveur du potassium de façon à peu près similaire pour les cycles de 6 à 10 oxygènes, **2**c_2–**2**c_6 ($10 < S < 20$). Elle est plus faible, $S \simeq 3$, pour le cycle à 5 oxygènes **2**c_1. Une tendance analogue avait été observée avec les couronnes simples pour lesquelles la sélectivité potassium/sodium est forte pour 18-couronne-6 (10) et 21-couronne-7 (11), $S \simeq 60$. Celle de 24-couronne-8 (11), $S = 15$, est de l'ordre de celle mise ici en évidence pour les composés **2**c_2–**2**c_6. La sélectivité est faible pour 12-couronne-4, $S = 1{,}3$, et 15-couronne-5, $S = 3$; une inversion est même observée, $S = 0{,}65$, pour benzo-15-couronne-5 (12).

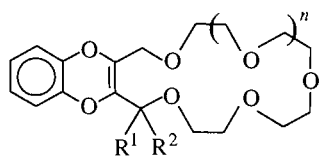
Couronnes cyclisées par le catéchol (composés **1**a–**1**d*)*

Le composés $\mathbf{2c}_2$ ne diffère du dérivé **1***c* que par la présence d'un noyau aromatique. La constante de formation du complexe avec le sodium croît lors du passage de $\mathbf{2c}_2$ à **1***c*, celle du complexe avec le potassium décroît; de ce fait, la sélectivité potassium/sodium décroît fortement, de 15 à 2. Le même phénomène a été observé lors du passage des couronnes aux dibenzocouronnes; la sélectivité diminue, elle est même inversée, $S = 0,6$ pour le dibenzo-15-couronne-5 (12).

La présence d'un noyau aromatique **1***b* ou d'un cycle spiranique **1***d* aboutit à une forte restriction de la cavité; ceci induit un abaissement de la complexation notable dans le cas du sodium, important dans le cas du potassium. Ce phénomène entraîne pour ces deux composés une inversion de la sélectivité favorable ici au sodium.



Ethers-lassos (composés **1**e–**1**k, **2**c *et* **2**l*)*

L'adjonction des divers bras et, en particulier, polyoxyéthylèniques sur l'un des carbones du cycle a conduit à des améliorations plus ou moins notables des propriétés complexantes de 15-couronne-5, pour le sodium et donc, dans certains cas, à un accroissement sensible de la sélectivité sodium/potassium (14, 15).

Dans le cas des composés **1** étudiés ici, aucune des chaînes latérales greffées n'améliore, par rapport au produit **1***c*, les propriétés complexantes vis à vis du potassium; elles les diminuent plus ou moins vis à vis du sodium. Ceci est sans doute dû à un mauvais positionnement de la chaîne latérale par rapport au macrocycle. Dans le cas des éthers-lassos simples la présence d'un groupement méthyle sur carbone pivot favoriserait une orientation correcte du bras (16, 17). Les conformations sont ici très différentes, la présence du carbone pivot au voisinage du cycle benzodioxinique introduit en effet une forte rigidification, la chaîne latérale entraînant plutôt une gêne stérique déterminant une restriction de la cavité complexante.

Par contre, dans le cas des composés **2***e* et **2***l* la cavité complexante se trouve agrandie du fait de la présence d'un maillon oxyéthylène supplémentaire, et les chaînes latérales

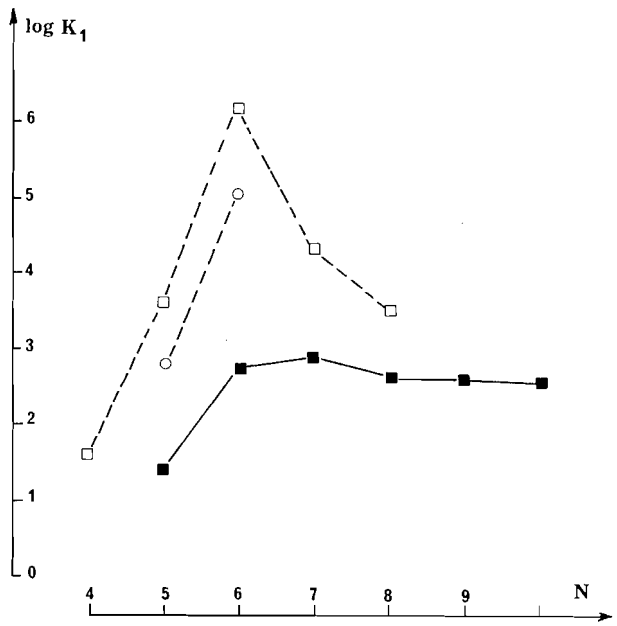

FIG. 1. Constantes de formation K_1 dans le méthanol à 25,0°C des complexes avec le potassium de quelques polyéthers cycliques en fonction du nombre N d'atome d'oxygène dans le cycle. □ éthers-couronnes (d'après les références 10 et 11); ○ éthers-couronnes benzo (d'après les références 12 et 13); ■ nos produits n° $\mathbf{2c_1}$–$\mathbf{2c_6}$.

favorisent légèrement la complexation du potassium et par contre défavorisent fortement celle du sodium.

La présence d'un carbone asymétrique dans un certain nombre de composés doit entraîner pour chaque stéréoisomère des variations notables des propriétés complexantes. Cependant, les études de complexation n'ont pas conduit à des résultats suffisamment convaincants pour qu'ait été entreprise la synthèse énantiosélective ou spécifique des dérivés **1** et **2**.

À la lumière des résultats obtenus il semble que les performances recherchées : augmentation de la complexation et de la sélectivité, pourraient être améliorées en adaptant la longueur et le nombre de sites de la chaîne latérale. Il est de surcroît indéniable que la nature du substituant R^1 détermine la position du bras R^2 et influe de ce fait de façon considérable sur le processus de complexation.

Partie expérimentale

Mesures physiques

Les spectres de résonance magnétique nucléaire (rmn) ont été enregistrés à l'aide de spectromètres Perkin Elmer R 12B (60 MHz) et Bruker AM 300 (300 MHz) en utilisant le tétraméthylsilane comme référence interne. Les spectres infra-rouge (ir) ont été tracés sur des appareils Perkin Elmer 297 et 580 B. Les spectres de masse (sm) ont été réalisés sur un appareil Nermag R.10.10C.

Les points de fusion ont été déterminés sur un banc de Kofler et ne sont pas corrigés.

Les chromatographies sur couche mince (ccm) ont été effectuées sur gel de silice 60 F_{254} (Merck). Toutes les analyses centésimales sont en accord avec les valeurs calculées à ±0,35% près.

*Préparation des composés carbonylés **4**, **5** et **6***

Le dianion de l'acide **3** (18) est obtenu par action de 17,5 mmol de diisopropylamidure de lithium sur 8 mmol de l'acide **3**. La réaction est réalisée sous atmosphère inerte, à −78°C, au sein de 30 mL de THF.

Au bout de 4 h à −78°C, on additionne 12 mmol du composé électrophile approprié (chloroformiate d'éthyle, aldéhyde benzoïque ou cétones) en solution dans 10 mL de THF. On laisse en contact 2 h supplémentaires à −78°C, puis on hydrolyse. Après extraction à l'éther en milieu basique, la phase aqueuse est acidifiée, puis extraite au chlorure de méthylène. La phase organique est séchée sur $MgSO_4$, puis évaporée sous vide.

Dans le cas du chloroformiate d'éthyle et du benzaldéhyde les produits bruts sont estérifiés par traitement au diazométhane, puis purifiés sur colonne de silice.

Dans le cas où les électrophiles sont des cétones, les produits bruts sont lactonisés après dissolution dans 30 mL de dioxanne par action de 30 mL d'une solution HCl à 10%. Les lactones sont purifiées sur colonne de silice.

CH_2CH_2O, J = 5,2 Hz), 3,30–3,65 (m, 10H, OCH_2CH_2O), 4,38 (s, 2H, OCH_2Ar), 6,68 (s, 4H, aromatiques), 7,08 (s, 5H, aromatiques).

Réduction des composés carbonylés ***4***, ***5*** *et* ***6***

Réduction du diester ***4***

Après avoir dissous 4 mmol du diester **4** ou de l'ester alcool **5** dans 10 mL de THF, la solution est refroidie à 0°C; puis on additionne goutte à goutte 16 mL d'une solution 1,0 M de DIBAL dans le toluène. Après 3 h d'agitation à 0°C, le milieu réactionnel est hydrolysé par l'eau, filtré sur Célite, puis extrait à l'éther. La phase organique est séchée sur $MgSO_4$, puis évaporée sous vide pour conduire aux diols **7***a* ou **7***b* qui sont purifiés sur colonne de silice.

1,4-Benzodioxin-2,3-diméthanol **7***a* (83%); F = 152°C; ir (KBr) : 3750–3100, 1710 cm^{-1}; rmn ^1H (acétone d_6) δ : 3,99 (s, 4H, CH_2OD), 6,50–7,00 (m, 4H, aromatiques).

α-Phényl-1,4-benzodioxin-2,3-diméthanol **7***b* (95%); F = 141–142°C; ir (KBr) : 3650–3000, 1710 cm^{-1}; rmn ^1H (acétone d_6) δ : 4,29 (s, 2H, CH_2OD), 5,62 (s, 1H, CHOD), 6,55–6,95 (m, 4H, aromatiques), 7,20–7,70 (m, 5H, aromatiques).

Réduction des lactones ***6***

Après dissolution de 4 mmol de lactone dans 20 mL d'éther anhydre on additionne par petites fractions $LiAlH_4$ à température ambiante. L'évolution de la réaction est suivie en ccm. La réaction est hydrolysée après disparition de la lactone de départ, les sels sont filtrés sur Célite et la phase organique séchée sur $MgSO_4$. Après évaporation des solvants les diols sont purifiés sur colonne de silice en utilisant un mélange éther – éther de pétrole (6 : 4).

α,α-Diméthyl-1,4-benzodioxin-2,3-diméthanol **7***c* (90%); F = 147–148°C; ir (KBr) : 3700–3000, 1700 cm^{-1}; rmn ^1H (DMSO d_6) δ : 1,37 (s, 6H, CH_3), 4,29 (s, 2H, CH_2OD), 6,60–6,90 (m, 4H, aromatiques).

3-(1-Hydroxycyclohexyl)-1,4-benzodioxin-2-méthanol **7***d* (85%); F = 98–99°C; ir (KBr) : 3600–3100, 1680 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,10–2,10 (m, 10H, $-(CH_2)_5-$), 4,39 (s, 2H, CH_2OD), 6,50–7,00 (m, 4H, aromatiques).

α-Méthyl-2-[2-(phénylméthoxy)éthyl]-1,4-benzodioxin-2,3-diméthanol **7***e* (90%); huile; ir (film) : 3600–3100, 1680 cm^{-1}; rmn ^1H (CCl_4) δ : 1,42 (s, 3H, CH_3), 1,80–2,15 (m, 2H, CH_2CH_2O), 3,50–3,90 (m, 2H, CH_2CH_2O), 4,22 et 4,29 (2s, 4H, OCH_2Ph et CH_2OD), 6,45–6,85 (m, 4H, aromatiques), 7,13 (s, 5H, aromatiques).

α-Méthyl-α-[2-[(2-méthoxyphényl)méthoxy]éthyl]-1,4-benzodioxin-2,3-diméthanol **7***f* (70%); huile; ir (film) : 3600–3200, 1680 cm^{-1}; rmn ^1H (CCl_4) δ : 1,37 (s, 3H, CH_3), 1,80–2,10 (m, 2H, CH_2CH_2O), 3,50–3,90 avec forte résonance à 3,71 (m, 5H, OCH_3 et CH_2CH_2O), 4,18 et 4,41 (2s, 4H, OCH_2Ar et CH_3OD), 6,40–7,35 (m, 8H, aromatiques).

α-Méthyl-α-[2-[(3-méthoxyphényl)méthoxy]éthyl]-1,4-benzodioxin-2,3-diméthanol **7***g* (85%); huile; ir (film) : 3600–3100, 1680 cm^{-1}; rmn ^1H (CCl_4) δ : 1,38 (s, 3H, CH_3), 1,80–2,10 (m, 2H, CH_2CH_2O), 3,30–3,85 avec forte résonance à 3,67 (m, 5H, OCH_3, CH_2CH_2O), 4,20–4,45 (m, 4H, OCH_2Ar et CH_2OD), 6,40–7,30 (m, 8H, aromatiques).

α-Méthyl-α-[2-[(4-méthoxyphényl)méthoxy]éthyl]-1,4-benzodioxin-2,3-diméthanol **7***h* (73%); huile; ir (film) : 3600–3200, 1680 cm^{-1}; rmn ^1H (CCl_4) δ : 1,36 (s, 3H, CH_3), 1,80–2,10 (m, 2H, CH_2CH_2O), 3,30–3,80 avec forte résonance à 3,71 (m, 5H, OCH_2CH_2O), 4,10–4,40 (m, 4H, OCH_2Ar et CH_2OD), 6,50–7,20 (m, 8H, aromatiques).

α-Méthyl-α-[2-[(2,3-diméthoxyphényl)méthoxy]éthyl]-1,4-benzodioxin-2,3-diméthanol **7***i* (62%); huile; ir (film) : 3600–3100, 1680 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,41 (s, 3H, CH_3), 1,80–2,15 (m, 2H, CH_2CH_2O), 3,70–4,05 avec forte résonance à 3,78 (m, 8H, OCH_3 et CH_2CH_2O), 4,29 et 4,45 (2s, 4H, OCH_2Ar et CH_2OD), 6,60–7,20 (m, 7H, aromatiques).

α-Méthyl-α-[2-[(3,4-diméthoxyphényl)méthoxy]éthyl]-1,4-benzodioxin-2,3-diméthanol **7***j* (67%); huile; ir (film) : 3600–3100, 1680 cm^{-1}; rmn ^1H (CCl_4) δ : 1,36 (s, 3H, CH_3), 1,70–2,10 (m, 2H, CH_2CH_2O), 3,20–3,90 avec forte résonance à 3,69 (m, 8H, CH_3O et CH_2CH_2O), 4,23 et 4,32 (2s, 4H, OCH_2Ar et CH_2OD), 6,40–6,80 (m, 7H, aromatiques).

α-Méthyl-α-[(2-méthoxy)éthyl]-1,4-benzodioxin-2,3-diméthanol **7***k* (66%); huile; ir (film) : 3600–3200, 1680 cm^{-1}; rmn ^1H (CCl_4) δ : 1,38 (s, 3H, CH_3), 1,80–2,10 (m, 2H, CH_2CH_2O), 3,20–3,80 avec forte résonance à 3,24 (m, 5H, CH_3O et CH_2CH_2O), 4,28 (s, 2H, CH_2OD), 6,40–6,90 (m, 4H, aromatiques).

α-Méthyl-α-[2-[2-[2-(phénylméthoxy)éthoxy]éthoxy]éthyl]-1,4-benzodioxin-2,3-diméthanol **7***l* (60%); huile; ir (film) : 3600–3200, 1680 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,31 (s, 3H, CH_3), 1,70–2,10 (m, 2H, CH_2CH_2O), 3,30–3,60 (m, 12H, OCH_2CH_2O), 4,31 (s, 2H, OCH_2Ar), 6,30–6,80 (m, 4H, aromatiques), 7,01 (s, 5H, aromatiques).

Préparation des dérivés dichlorés ***8***

Le mode de préparation de ces composés ainsi que les caractéristiques spectrales de **8***e*, **8***f*, **8***g*, **8***h*, **8***i*, **8***j* et **8***k* ont déjà fait l'objet d'une description détaillée (8).

2,3-Bis[[2-(2-chloroéthoxy)éthoxy]méthyl]-1,4-benzodioxin **8***a* (57%); huile; ir (film) : 1710, 1100 cm^{-1}; rmn ^1H (CCl_4) δ : 3,50–3,75 (m, 16H, OCH_2CH_2O), 4,01 (s, 4H, CH_2O), 6,60–6,90 (m, 4H, aromatiques).

2-[[2-(2-Chloroéthoxy)éthoxy]méthyl]-3-[[2-(2-chloroéthoxy)éthoxy]phénylméthyl]-1,4-benzodioxin **8***b* (55%); huile; ir (film) : 1700, 1090 cm^{-1}; rmn ^1H (CCl_4) δ : 3,30–3,90 (m, 16H, OCH_2CH_2O), 4,12 (s, 2H, CH_2O), 5,12 (s, 1H, PhC*H*O), 6,40–6,85 (m, 4H, aromatiques), 7,10–7,60 (m, 5H, aromatiques).

2-[[2-(2-Chloroéthoxy)éthoxy]méthyl]-3-[1-[2-(2-chloroéthoxy)-éthoxy]-1-méthyléthyl]-1,4-benzodioxin **8***c* (66%); huile; ir (film) : 1690–1100 cm^{-1}; rmn ^1H (CCl_4) δ : 1,41 (s, 6H, CH_3), 3,30–3,85 (m, 16H, OCH_2CH_2O), 4,19 (s, 2H, CH_2O), 6,40–6,85 (m, 4H, aromatiques).

2-[1-[2-(2-Chloroéthoxy)éthoxy]cyclohexyl]-3-[[2-(2-chloroéthoxy)éthoxy)]méthyl]-1,4-benzodioxin **8***d* (58%); huile; ir (film) : 1690–1100 cm^{-1}; rmn ^1H (CCl_4) δ : 1,10–2,00 (m, 10H, $-(CH_2)_5-$), 3,30–3,85 (m, 16H, OCH_2CH_2O), 4,18 (s, 2H, CH_2O), 6,40–6,90 (m, 4H, aromatiques).

Préparation des macrocycles ***1***

La synthèse de ces dérivés et les caractéristiques spectrales de **1***e*, **1***f*, **1***g*, **1***h*, **1***i*, **1***j* et **1***k* ont déjà fait l'objet d'une description détaillée (8).

6,8,9,11,12,19,20,22,23,25-Décahydro-[1,4]benzodioxino[2,3-*i*][1,4,7,12,15,18]-benzohexaoxacycloeicosin **1***a* (40%); F = 118°C; ir (KBr) : 1710, 1100 cm^{-1}; rmn ^1H acétone d_6 δ : 3,70–4,30 avec forte résonance à 3,75 et 4,15 (m, 20H, CH_2O), 6,60–7,00 (m, 8H, aromatiques); sm (m/z) : 444 (M^+). *Anal.* calc. pour $C_{24}H_{28}O_8$: C 64,85, H 6,35; trouvé : C 64,71, H 6,47.

Préparation des macrocycles ***2***

Mode opératoire général

On soumet 4 mmol de diol en solution dans 30 mL de THF à l'action de 4,4 mmol de NaH. Après 2 h de contact à reflux on additionne 4 mmol du bistosylate du polyéthylèneglycol approprié en solution dans 70 mL de THF. On laisse à reflux pendant 24 h. Après retour à température ambiante, on hydrolyse, extrait à l'éther et sèche la

Détermination potentiométrique des constantes de complexation des ions sodium et potassium par les produits préparés

Celle-ci est effectuée à l'aide d'un millivoltmètre Orion 701/A. La détermination des constantes est basée sur la mesure de la tension réversible d'une cellule galvanique formée d'une électrode spécifique au cation étudié et d'une électrode de référence. L'électrode de mesure est une électrode de verre sensible soit aux ions sodium (Jena^{er} glass), soit aux ions potassium (Tacussel type pKV3).

L'électrode de référence est une électrode au calomel saturé dans le méthanol munie d'une jonction constituée par une solution 0,08 mol dm^{-3} de perchlorate de tétraéthylammonium dans le méthanol. Lors des mesures, les solutions sont maintenues à 25,0°C et une agitation magnétique est assurée en permanence.

Les chlorures de potassium et de sodium sont des produits Merck Suprapur, le méthanol utilisé est aussi un produit Merck «Réactif pour analyse» de teneur en eau inférieure à 0,01%.

À un certain volume de méthanol pur, placé dans la cellule, sont ajoutées des quantités croissantes d'une solution concentrée du chlorure alcalin dans le méthanol, ce qui réalise l'étalonnage. Nous ajoutons alors des aliquotes successives d'une solution concentrée de l'éther couronne dans le méthanol.

Les réactions [1] et [2] sont isoélectriques. La correction d'activité peut donc être négligée. La constante de formation de EM^+, K_1, est calculée pour les divers rapports éther : cation. Les valeurs obtenues sont le plus souvent, compte-tenu de la précision, invariables. Dans le cas contraire, où une variation systématique de K_1 avec le rapport éther : cation est observée, nous prenons en compte la formation du second complexe E_2M^+ et utilisons alors, pour traiter les résultats, la méthode de calcul de Leden.

Azide ion trapping and lifetime in aqueous solution of a primary carbenium ion stabilized by a 2-imidazoyl ring

JUDY L. BOLTON AND ROBERT A. MCCLELLAND
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 5, 1988

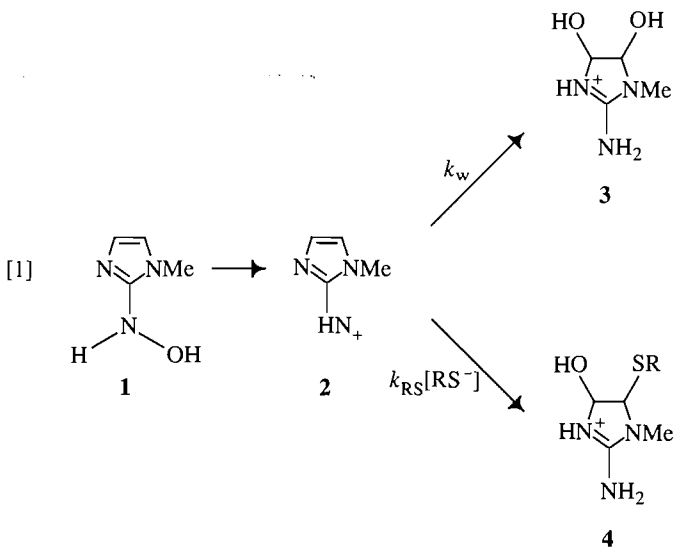
JUDY L. BOLTON and ROBERT A. MCCLELLAND. Can. J. Chem. **67**, 1139 (1989).

2-Chloromethyl-1-methylimidazole undergoes a pH-dependent aqueous hydrolysis with the neutral substrate being the reactive species, and the imidazole-protonated form ($pK_a = 5.7$) unreactive. Addition of sodium chloride retards the hydrolysis, evidence that there is a free carbenium ion intermediate (the common ion effect). The rate constant ratio k_{Cl}/k_w for the reactions of this cation with the added chloride and with the solvent is 7.4 M^{-1}. Further evidence for a free cation is the observation of the 2-azidomethyl product when the hydrolysis is carried out with sodium azide present, but with no change in the rate constant. The k_{az}/k_w ratio as determined by product analysis is 1.1×10^2 M^{-1}. With the assumption that k_{az} represents a diffusion-controlled reaction and has a value of 7×10^9 M^{-1} s^{-1}, the rate constant k_w for the reaction of the cation with solvent is 6×10^7 s^{-1}. A comparison with azide–water selectivity ratios reported for other cations shows that the imidazole-stabilized primary cation of this study is relatively long-lived. A possible explanation for this is given, in terms of the extensive resonance delocalization of the positive charge in this cation.

Key words: solvolysis, carbenium ion, heterocycle.

JUDY L. BOLTON et ROBERT A. MCCLELLAND. Can. J. Chem. **67**, 1139 (1989).

Le chlorométhyl-2 méthyl-1 imidazole subit une hydrolyse aqueuse qui dépend du pH et dans laquelle l'espèce réactive est le substrat neutre et l'espèce qui n'est pas réactive est la forme protonée de l'imidazole ($pK_a = 5,7$). L'addition de chlorure de sodium retarde l'hydrolyse; ce résultat indique l'existence d'une ion carbénium libre comme intermédiaire (effet d'ion commun). Le rapport des constantes de vitesse k_{Cl}/k_w pour les réactions de ce cation en présence de chlorure additionné et avec le solvant est de 7,4 M^{-1}. La formation d'un produit azidométhyl-2, sans changement de la constante de vitesse de la réaction, lorsqu'on opère l'hydrolyse en présence d'azoture de sodium est une preuve additionnelle de l'existence d'un cation libre. Le rapport k_{az}/k_w, tel que déterminé par analyse des produits, est égal à $1,1 \times 10^2$ M^{-1}. En faisant l'hypothèse que k_{az} correspond à la vitesse de la réaction contrôlée par la diffusion et que sa valeur est 7×10^9 M^{-1} s^{-1}, la constante de vitesse k_w de la réaction avec le solvant est égale à 6×10^7 s^{-1}. Une comparaison des rapports de sélectivité azoture–eau rapportés pour d'autres réactions indique que la durée de vie du cation primaire stabilisé par l'imidazole et examiné dans cette étude est relativement longue. Ces propriétés seraient le résultat d'une délocalisation importante par résonance de la charge positive de ce cation.



Mots clés : solvatation, l'ion carbénium, hétérocycle.

[Traduit par la revue]

Introduction

2-Hydroxylaminoimidazoles **1** undergo nitrogen–oxygen bond cleavage in water (1, 2) resulting in resonance-stabilized cationic intermediates that are nitrenium ions if written in the form of the resonance contributor **2**. The overall reaction, a heterocyclic analog of the Bamberger rearrangement (3–5), results in ring-substituted products such as **3** and **4** (1, 2).

More recent experiments have revealed high nucleophile:solvent selectivity ratios ($k_{RS}/k_w = 10^5$–10^6 M^{-1}) obtained by analyzing products when the reactions are carried out in the presence of added thiol anions (6). These results imply a first-order rate constant k_w of less than 10^4–10^5 s^{-1} for the reaction of the cation with water, since the thiol anion can react no faster than the diffusion limit ($\sim 10^{10}$ M^{-1} s^{-1}). In comparison with the 2,6-dimethylphenylnitrenium ion, a phenyl-stabilized analog, for which k_w has been estimated to be $\sim 10^9$ s^{-1} (7), imidazole-stabilized nitrenium ions are thus suggested to be relatively long-lived intermediates in water in the absence of other nucleophiles.

The effects of structure on relative nucleophilic selectivity and lifetime have seen more extensive investigations with carbenium ions, and we were therefore interested in seeing whether the stabilizing effect of the imidazole ring extends to this type of intermediate, or whether it is a particular feature of the Bamberger-type rearrangement of the hydroxylamino derivatives. Accordingly an investigation has been carried out, of a reaction that in principle at least would proceed through a carbenium ion analog of **2**, the aqueous hydrolysis of 2-chloromethyl-1-methylimidazole. The intermediate involved here is a primary carbenium ion, and indeed we find evidence that it forms in water as a free ion, with a significant lifetime for such a species.

Experimental

2-Hydroxymethyl-1-methylimidazole and 2-chloromethyl-1-methylimidazole were prepared as described by Jocelyn (8).

2-Azido-1-methylimidazole was prepared by the addition of solid 2-chloromethyl-1-methylimidazole to a solution of 0.5 M sodium azide

in 50 mL of water at pH 7. After 10 min stirring at ambient temperature the pH was adjusted to 8 with the addition of sodium hydroxide, and the solution was extracted with 200 mL of methylene chloride. After drying over anhydrous $MgSO_4$, the solvent was removed and the resulting liquid was purified by distillation at reduced pressure; bp 95–100°C, 15 Torr (1 Torr = 133.3 Pa); ^{1}H NMR ($CDCl_3$) δ: 3.70 (3H, s), 4.44 (2H, s), 6.91 (1H, br s), 7.00 (1H, br s); MS, *m/e*: 137 (M^+). *Anal.* calcd. for $C_5H_7N_5$: C 43.80, H 5.11, N 51.09; found: C 43.92, H 5.09, N 51.05.

Kinetic experiments with 2-chloromethyl-1-methylimidazole were carried out with a Varian 2390 spectrophotometer and, for faster reactions, with a Durrum–Gibson stopped-flow spectrophotometer. Data analyses were performed with Apple IIe (Varian) and Tektronix 4051 (Durrum–Gibson) microcomputers interfaced to the spectrophotometers. Experiments with the Varian apparatus were carried out by addition of 10 μL of a solution of the substrate (0.03 M) in dry acetonitrile to 3 mL of the appropriate aqueous solution, which had prior temperature equilibration in the UV cuvette. Stopped-flow experiments were carried out by preparing a substrate solution (2×10^{-4} M) in 0.1 M HCl, where the half-life is 10 h, and mixing this solution with the appropriate buffers of higher pH. Experiments were carried out by monitoring the spectral change, a decrease in absorbance, which occurs at 230 nm. First-order rate constants were calculated using a Varian Associates PLUS Kinetics Calculations Program, which fits the experimental absorbance–time data to the exponential equation via an iterative procedure, and with the stopped-flow apparatus, as the slopes of plots of ln $(A - A_\infty)$.

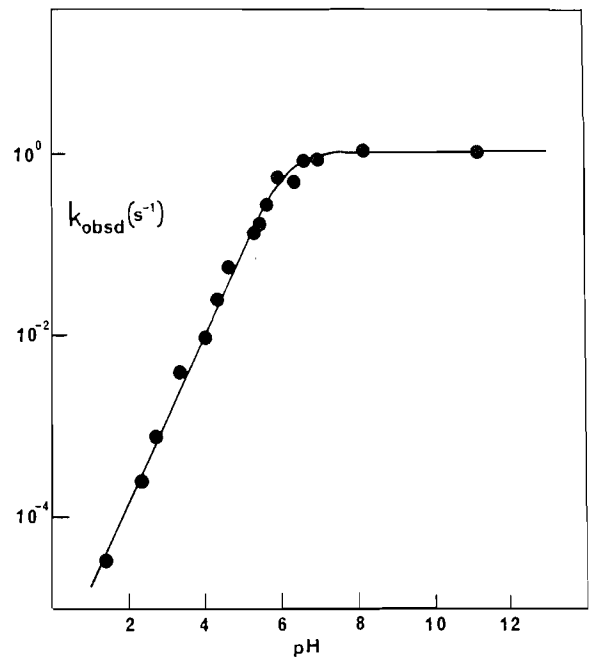
Product analyses for the hydrolysis in the presence of azide were carried out by addition of solid substrate (0.01 mmol) to 100 mL of an acetate buffer (pH 4.7, 0.005 M sodium acetate and 0.005 M acetic acid) containing varying amounts of sodium azide. After 10 min of vigorous stirring, the water was removed by lyophilization, and the resulting solids taken up in D_2O. The ^{1}H NMR spectra were immediately recorded with a Varian XL-400 NMR spectrophotometer. Ratios of alcohol product to azide product were obtained from the relative integrations of the N-methyl singlets at 3.81 and 3.85 ppm.

The dissociation constant of the conjugate acid of 2-hydroxymethyl-1-methylimidazole was determined by recording 400-Mz ^{1}H NMR spectra of 0.01 molar solutions of the compound in D_2O. A series of buffers in D_2O of Na_2DPO_4:NaD_2PO_4 were prepared at ionic strength 1.0 with the ratios of the components ranging from 1:10 to 10:1. The pD values of these solutions were obtained from the relationship (9): pD = pH(meter) + 0.40, where pH(meter) were the values recorded with a pH meter. Spectra in 0.01 M DCl and in 0.01 M NaOD were also recorded, to establish the chemical shifts of the conjugate acid (δ_{BH}) and conjugate base (δ_B) forms. The acidity constant was calculated as the average value obtained with the equation $K_a = [D^+](\delta_{BH} - \delta)/(\delta - \delta_B)$, where δ is the chemical shift in the solutions of intermediate pH. The signals of one of the aromatic protons and the N-methyl group undergo significant changes (0.2 ppm) with changing pH and both were analyzed. The acidity constant in H_2O was estimated by subtracting 0.5 from the value obtained in D_2O. This factor is the difference in the values obtained with imidazole itself in the two solvents (10).

Results and discussion

Rate–pH profile

2-Chloromethyl-1-methylimidazole undergoes hydrolysis in aqueous solutions, producing the expected alcohol, 2-hydroxymethyl-1-methylimidazole, as the only product. This species was isolated from the hydrolysis solution, and exhibited a 400-MHz ^{1}H NMR spectrum consistent with its structure being substituted on the exocyclic methylene. This hydrolysis is accompanied by changes in the UV spectra at 200–240 nm; first-order rate constants were obtained by monitoring a decrease at 230 nm. At a given pH these rate constants were found to be independent of the concentration of added buffers. There was, however, a dependency on pH, which is depicted in Fig. 1. In



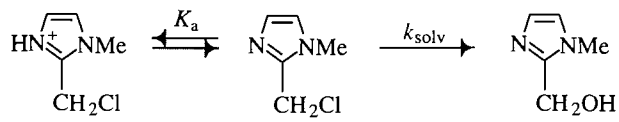


FIG. 1. The pH dependency of the first-order rate constants for the hydrolysis of 2-chloromethyl-1-methylimidazole, at 25°C and an ionic strength of 1.0 as maintained with $NaClO_4$. The points are experimental; the line is calculated according to eq. [3] with the constants given in the text.

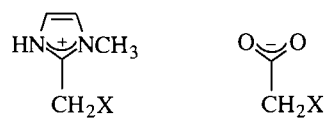
acidic solutions the rate constants were found to be inversely proportional to H^+ concentration; there was a break at pH 5–6 and in neutral and basic solutions the rate constants became independent of pH. A mechanism that accounts for this behavior has the neutral imidazole as the solvolytically reactive species, with the imidazolium ion unreactive.



[2] 

With the assumption of a rapid equilibrium between the neutral and protonated forms, we may write

$$[3] \quad k_{obsd} = \frac{k_{solv}K_a}{(K_a + [H^+])}$$

The best fit of the experimental data to this equation, shown by the solid line in Fig. 1, has $k_{solv} = 1.0\ s^{-1}$ and $pK_a = 5.7$.

To place this acidity constant in perspective, the corresponding value for the alcohol product of the hydrolysis was also measured, in this case from the pH dependency of the ^{1}H NMR chemical shifts; a value for 1,2-dimethylimidazole is available from the literature (11). These are summarized in Table 1. The conclusion is that the effects of substitution in a 2-methyl group attached to an imidazole are very similar to the effects of the same substitutions in acetic acids. Although there are differences in the charges, this result is perhaps not surprising since in each case the substituent is located at a distance the same number of atoms removed from a delocalized system.

Common ion rate depression

The question that we address here concerns the details of the mechanism of the hydrolysis of the neutral imidazole. The possibility that this is a stepwise S_N1 reaction can be investigated by studying the solvolysis in the presence of significant concentrations of the leaving group (12). As shown in Table 2 the addition of sodium chloride does have a significant rate-retarding effect. This behavior is good evidence for the formation of free ions in the solvolysis (13, 14) and the following reaction scheme can therefore be written,

$$[4] \quad ImCH_2Cl \underset{k_{Cl}}{\overset{k_{ion}}{\rightleftarrows}} \overset{+}{Im}CH_2 + Cl^-$$

$$[5] \quad \overset{+}{Im}CH_2 + H_2O \xrightarrow{k_w} ImCH_2OH + H^+$$

where Im = 1-methyl-2-imidazoyl. This then produces the equation

$$[6] \quad k_{obsd} = \frac{k_{ion}}{1 + (k_{Cl}/k_w)[Cl^-]}$$

defining k_w as a first-order rate constant. The data in Table 2 can be treated in the normal fashion, by plotting the reciprocal of k_{obsd} versus the concentration of chloride ion. This gives the two parameters $k_{ion} = 0.25\ s^{-1}$ and $k_{Cl}/k_w = 7.4\ M^{-1}$.

Azide ion trapping

A second way of demonstrating S_N1 solvolysis is through the observation of products derived from added nucleophiles, with no change in the rate constant for disappearance of the substrate. Azide ion has been extensively used in this regard (15–19) and, as shown in Fig. 2, this criterion is satisfied in experiments carried out with the substrate of this study in the presence of

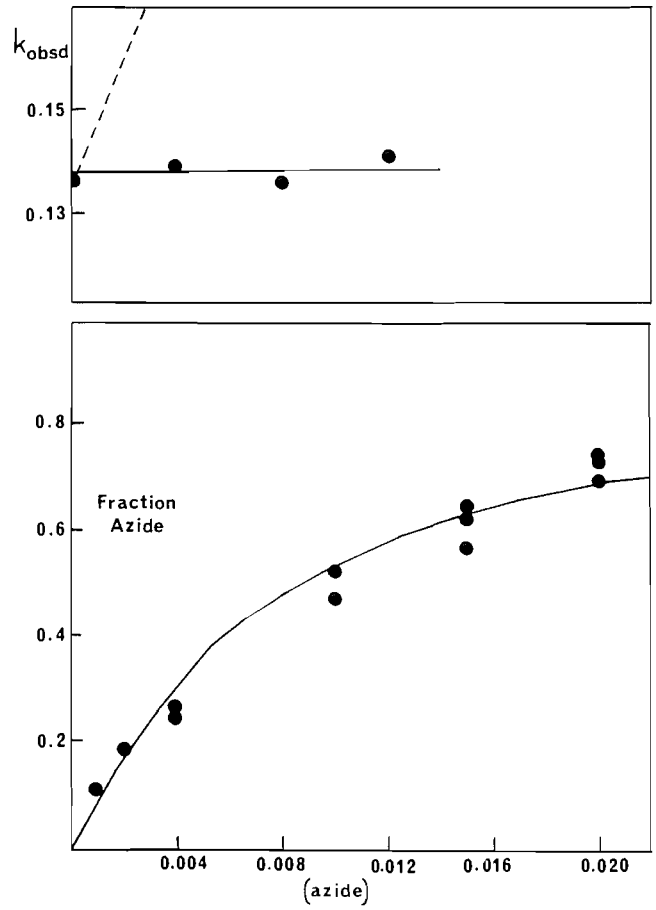

FIG. 2. First-order rate constants and the fraction of the total product that is the azidomethyl-substituted imidazole ($[RN_3]/([RN_3] + [ROH])$) for the hydrolysis of 2-chloromethyl-1-methylimidazole in the presence of sodium azide. The dashed line drawn in the top panel represents the behavior calculated from the product ratios if azide ion were to be reacting directly with the substrate in a bimolecular S_N2 fashion.

sodium azide. Thus, for example, the addition of 0.01 molar sodium azide resulted in approximately 50% of the azido-substituted product, but, within experimental error, there was no increase in the rate constant for the reaction. The azido-methyl product was also isolated, in this case from a reaction carried out in the presence of 0.5 M sodium azide. This material also had an ^1H NMR spectrum consistent with substitution at the exocyclic methylene.

[7]

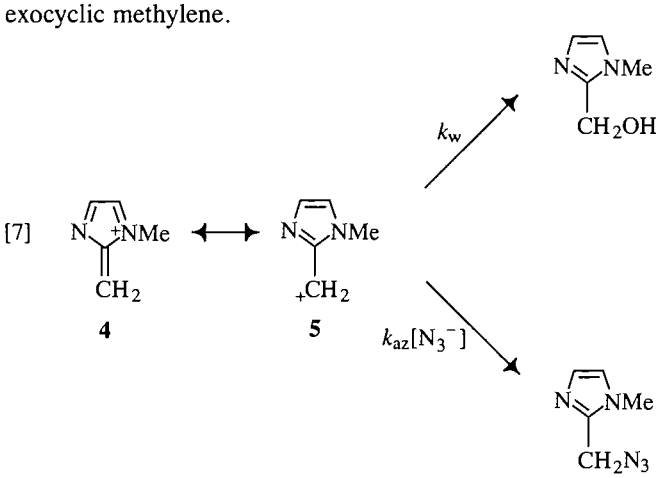

TABLE 3. Azide: water selectivities and rate constants for the reactions of cations with water

Substrate	k_{az}/k_w (M^{-1})	k_w (s^{-1})
2-(Chloromethyl)-1-methyl-imidazole	1.1×10^2	6×10^7
p-Methoxyphenethyl carboxylates[a]	4.9×10^1	1.4×10^8
Phenethyl chloride	1.8^b	$\sim 10^{11}$ [c]

[a]Reference 17.
[b]Reference 31. Reaction with azide is S_N2.
[c]Reference 17, estimated by extrapolation.

The product data can be treated in the normal way, through a plot of the inverse of the fraction azide product versus the inverse of the azide concentration. This produces a linear plot (not shown), with an intercept of unity as required by a simple competition model (eq. [7]). The inverse of the slope of this plot gives the azide selectivity factor $k_{az}/k_w = (1.1 \pm 0.1) \times 10^2$ M^{-1}.

Carbenium ion lifetime

The absolute value of the rate constant k_w for the reaction of the carbenium ion with water can be estimated from the k_{az}/k_w ratio with the assumption that the combination with azide ion is diffusion controlled (17–21). Direct proof of the validity of this approach has recently been provided through the measurement using laser flash photolysis of individual k_{az} and k_w for a series of diarylmethyl cations (22). Previously a value of 5×10^9 M^{-1} s^{-1} was taken for the diffusion-controlled k_{az} (18, 19); the direct measurements suggest that, in 20% acetonitrile in water, a value of 7×10^9 M^{-1} s^{-1} is more appropriate (22). Taking the latter value, k_w for the imidazole carbenium ion is then calculated as 6×10^7 s^{-1}. From the common ion experiments this in turn provides $k_{Cl} = 4 \times 10^8$ M^{-1} s^{-1}. The latter number obviously does not reflect diffusion control, a feature that is evident in a comparison of literature k_{Cl}/k_w ratios (23) with k_{az}/k_w ratios (17) obtained for the same cations.

A comparison of azide:water selectivities for three cations is presented in Table 3. The number for the *p*-methoxyphenethyl ion is that for 100% water, taken from Table V of ref. 17 and based on the "azide clock" method with k_{az} at 7×10^9. The entry for the parent phenethyl cation is also from ref. 17, this value estimated through an extrapolation of a correlation of log k_w for more stable cations with σ^+ and σ^0 substituent parameters. Estimates of lifetimes of simple primary cation analogs of the phenethyl cations appear not to be available. There have been studies of *p*-methoxybenzyl systems, but these have usually been carried out in less polar solvents where ionization is slow, and under these conditions it appears as if azide ion reacts principally via the S_N2 mechanism (24–26). Examination of the extensive compilation of Ta-Shma and Rappoport of azide:water selectivities (17) shows two examples suggestive of free primary carbenium ions, those derived from solvolyses of 6-(chloromethyl)benzo[*a*]pyrene and of 9-(chloromethyl)anthracene, where polycyclic aromatic hydrocarbons are the stabilizing groups (27).

Noyce and Stone previously analyzed the stabilizing influence of various heterocyclic rings through an examination of rate constants for solvolysis reactions of secondary derivatives (28). Their approach involved the generation of a log $k_{ion} - \sigma^+$ correlation line for a series of substituted 1-phenethyl *p*-nitrobenzoates. The k_{ion} value for the analogous heterocyclic system was then placed on this line, generating a group substituent constant for the heterocycle σ^+_{Ar}. The value obtained in this way for a 1-methyl-2-imidazoyl group was −0.82. This number implies that this group is slightly more stabilizing for an adjacent carbenium being formed than a *p*-methoxyphenyl group, for which σ^+_{Ar} is simply the σ^+ value of the substituent, −0.78. The results for the cation reacting with water are consistent with this, although with the present data the comparison is not perfect since the *p*-methoxyphenyl number is for a secondary cation.

Ab initio computations for an N-1 unsubstituted 2-imidazoyl carbenium ion suggest that the structure is better written as the resonance contributor **4** of eq. [7], rather than as **5** (29). This delocalization obviously accounts for the inherent stability of this type of cation, and may also explain the significant lifetime in water. As demonstrated now in two cases (19, 30), in a reaction of the type

[8] $R^+ + H_2O \rightleftarrows \neq \rightleftarrows ROH + H^+$

there is an imbalance in the transition state in the extent of development of the polar and resonance effects. In particular in the forward direction of eq. [8], where the cation is reacting with water, a large fraction of the resonance delocalization must be destroyed to reach the transition state. This has the consequence that a cation with a high degree of resonance stabilization, such as the carbenium ion adjacent to the imidazole ring, appears more kinetically stabilized in a reaction that starts at the fully formed cation than in a reaction that forms the cation.

1-Chloromethyl-3,5-dimethylpyrazole hydrochloride. A useful synthetic intermediate

ALAN R. KATRITZKY[1] AND JAMSHED N. LAM
Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

Received October 13, 1988

ALAN R. KATRITZKY and JAMSHED N. LAM. Can. J. Chem. **67**, 1144 (1989).

1-Chloromethyl-3,5-dimethylpyrazole hydrochloride readily undergoes nucleophilic displacement with O-, N-, or S-nucleophiles. 1-Phenylthiomethyl-3,5-dimethylpyrazole can be lithiated at the CH_2 group and reacted with alkyl halides and carbonyl compounds. Desulfurization of the products affords a novel method of preparing N-substituted pyrazoles.

Key words: pyrazole, lithiation, chloromethylazoles, desulfurization.

ALAN R. KATRITZKY et JAMSHED N. LAM. Can. J. Chem. **67**, 1144 (1989).

Sous l'influence de nucléophiles comportant des O, N ou S, le chlorhydrate du chlorométhyl-1 diméthyl-3,5 pyrazole subit une substitution nucléophile facile. Le phénylthiométhyl-1 diméthyl-3,5 pyrazole peut être lithié sans difficultés au niveau du groupement CH_2 et réagir alors avec les halogénures d'alkyles et les composés carbonylés. La désulfurisation des produits ainsi obtenus fournit une nouvelle méthode de préparation des pyrazoles N-substitués.

Mots clés : pyrazole, lithiation, azoles chlorométhyles, désulfurisation.

Many heterocycles with a ring ·NH· group react with formaldehyde to yield addition products of type ·N(CH_2OH)·, which can be converted (1) into the corresponding derivatives ·N(CH_2Cl)·. The synthetic utility of some of these derivatives has been previously explored (1, 2).

Most previous N-substituted pyrazoles have been made either (*i*) by ring closure using N-substituted hydrazines (3) or (*ii*) by alkylation, etc. of an N-unsubstituted pyrazole (4). Relatively few procedures are known for the elaboration of N-substitution in the pyrazole series.

Hüttel and Jochum (5) showed that a variety of C-substituted, N-unsubstituted pyrazoles react with formaldehyde to give the corresponding *N*-hydroxymethyl derivatives, including 3,5-dimethylpyrazole (**2**), the preparation of which was repeated by Dvoretzky and Richter (6). The conversion of **2** into the chloromethyl hydrochloride **5**, first reported in the patent literature (7), was studied by Rüfenacht (8) as a precursor to various thiophosphates for use as insectides. Similar work has been reported for other pyrazoles (9–12), but apparently no attempts have been made to use 1-chloromethylpyrazoles as general intermediates for the preparation of more complex N-substituted pyrazoles. The present paper describes a variety of transformations of **5**, illustrating its potential as a synthetic intermediate.

Treatment with sodium ethoxide readily afforded the ethoxy compound **7***a*. The reaction of **5** with 2-pyridone in THF yielded solely the N-substituted 2-pyridone **8***a*; however, in two cases where the pyridone N-atom was hindered by a 6-phenyl group, the reaction with **5** gave mixtures of the corresponding N-substituted 2-pyridone (**8***b*,*c*) and the 2-(pyrazol-1-ylmethoxy)pyridine (**7***b*,*c*). The use of DMF as a solvent, treating with sodium salt of the corresponding pyridones with **5** or varying the temperature, still gave in all cases mixtures of the N-substituted derivatives (**8***b*,*c*) and the O-substituted analogs (**7***b*,*c*).

The chloromethyl hydrochloride **5** reacted readily with the appropriate S-nucleophiles to give **3**, **4**, and **6**. Attempts to cleave off the benzothiazole ring of **4** with butyllithium (cf. ref. 13) failed, but we found that the methylene group in **6** can be smoothly lithiated, and in this way prepared derivatives **9***a*,*b* by alkylation, and the hydroxythioether **12***a* by reaction of the lithium compound with 4-methylbenzaldehyde.

Further alkylation of **9***a* with benzyl bromide was effected via a second lithiation. Compounds **9***b*, **11**, and **12***a* were all desulfurized by treatment with Raney nickel, and the products **14***a*,*b*,*c* illustrate the potential of this novel way of synthesizing N-substituted pyrazoles.

The phenylthiomethyl derivative **6** was easily converted into its sulfoxide (**10**). Lithiation of **10** with LDA or *n*-BuLi followed by alkylation with benzyl bromide led directly to **15**. The intermediate **13** is formed at −78°C (as monitored by tlc) but decomposes readily to the styryl derivative **15** on warming to room temperature. With 4-methylbenzaldehyde as the electrophile, the alcohol **12***b* was isolated in 55% yield.

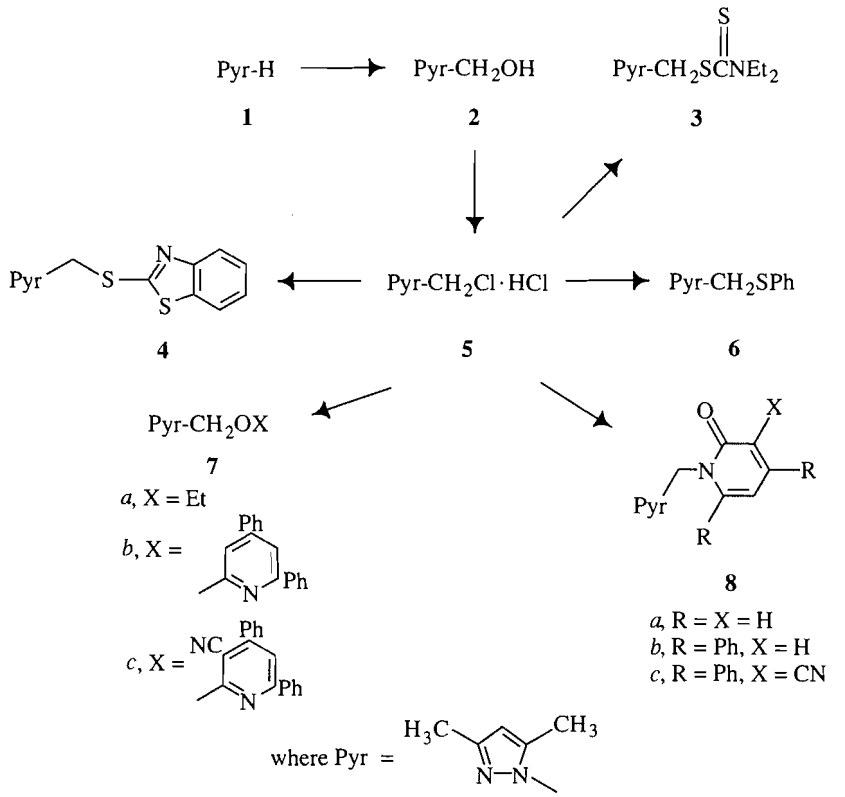
Experimental

Melting points were determined on a Kofler hot-stage microscope and are uncorrected. Spectra were recorded with the following instruments: ^{1}H nmr with a Varian model EM 360 L or a Varian XL-200 (FT mode) spectrometer with Me_4Si as internal standard; ^{13}C nmr with a JEOL model JNM-FX 100 (25 MHz) and on a Varian XL-200 (50 MHz) spectrometer, referring to the center signal of $CDCl_3$ (77.0). Mass spectra were obtained at 70 eV on a AEI MS 30 spectrometer operating with a DS-55 data system. Elemental analyses were performed under the supervision of Dr. R. W. King of this department.

Tetrahydrofuran (THF) was dried by distillation from sodium benzophenone ketyl.

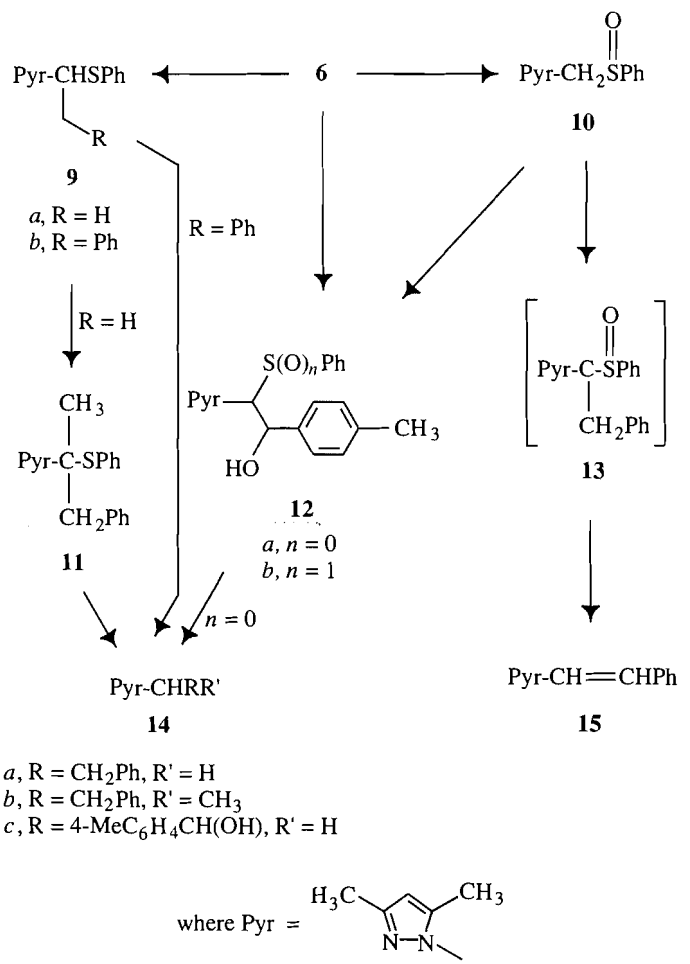
All lithiations were carried out in a dry argon atmosphere.

Column chromatography was carried out with MCB silica gel (230–400 mesh).



The following compounds were prepared by known literature methods: 3,5-dimethyl-1*H*-pyrazole (**1**), mp 106–108°C (lit. (14) mp 105–108°C); 1-hydroxymethyl-3,5-dimethyl-1*H*-pyrazole (**2**), mp 105–107°C (lit. (6) mp 108–109°C); 1-chloromethyl-3,5-dimethyl-1*H*-pyrazole hydrochloride (**5**) (8); δ_H: 16.13 (1H, s), 6.50 (3H, s), 2.66 (3H, s), and 2.59 (3H, s); 4,6-diphenyl-2-pyrone, mp 137–139°C (lit. (15) mp 139–140°C); 3-cyano-4,6-diphenyl-2-pyridone, mp 318–319°C (lit. (16) mp 318–320°C).

4,6-Diphenyl-2-pyridone



4,6-Diphenyl-2-pyrone (15) (10 g, 40 mmol) and ammonium acetate (31 g, 400 mmol) were heated at 150°C for 60 h. On cooling, chloroform (100 mL) was added and the organic layer washed with saturated sodium bicarbonate (2 × 25 mL), water (2 × 25 mL), dried ($MgSO_4$), and the solvent removed to afford tan microcrystals (8.11 g, 82%), mp 205–207°C (lit. (16) mp 207–208°C).

SCHEME 2

*1-Ethoxymethyl-3,5-dimethyl-1*H*-pyrazole (7*a*)*

To a solution of 1 N sodium ethoxide (60 mL, 60 mmol) was added slowly 1-chloromethyl-3,5-dimethyl-1*H*-pyrazole hydrochloride (**5**) (5.0 g, 27.6 mmol). The reaction mixture was then heated under reflux for 12 h. The solvent was then removed *in vacuo* and to the residue was added chloroform (50 mL). The mixture was washed with water (3 × 20 mL), dried ($MgSO_4$), and the solvent removed to leave behind a pale yellow oil. Distillation under vacuum gave a colorless liquid (2.96 g, 70%), bp 98°C/31 Torr (1 Torr = 133.3 Pa); δ_H: 6.03 (1H, s), 5.50 (2H, s), 3.61 (2H, q, *J* 7 Hz), 2.36 (3H, s), 2.28 (3H, s), and 1.16 (3H, t, *J* 7 Hz); δ_C 147.4, 139.4, 106.0, 77.3, 63.5, 14.3, 13.0, and 10.1. $C_8H_{14}N_2O$ requires M^+, *m/z*: 154.1106; found: 154.1103.

*General procedure for the reaction of 1-chloromethyl-3,5-dimethyl-1*H*-pyrazole hydrochloride (**5**) with pyridones*

Method A

To a suspension of NaH (60% in mineral oil) (55 mmol) in tetrahydrofuran (150 mL) was added the corresponding pyridone (27.5 mmol). After stirring at ambient temperature for 30 min, 1-chloromethyl-3,5-dimethyl-1*H*-pyrazole hydrochloride (**5**) (25 mmol) was added slowly, and the mixture allowed to react further. The solvent was then removed *in vacuo* and the residue treated with water (75 mL). The organic material was extracted with chloroform (3 × 50 mL), dried ($MgSO_4$), and the solvent removed to give the crude product.

The following reactions were thus carried out:

Reaction with 2-pyridone

The reaction mixture was heated under reflux for 48 h, followed by the general work-up to give the crude product as a brown wax. Crystallization from ethyl acetate afforded *1-(pyrid-2-on-1-yl)methyl-3,5-dimethyl-1*H*-pyrazole* (**8***a*) as brown needles (32%), mp 131–132°C; δ_H: 7.9–7.3 (2H, m), 6.8–6.1 (4H, m), 6.00 (1H, s), 2.43 (3H, s), and 2.23 (3H, s); δ_C: 161.5, 149.2, 140.5, 139.9, 138.7, 136.3, 120.6, 106.3, 105.9, 102.7, 57.5, 13.2, and 10.5. *Anal.* calcd. for $C_{11}H_{13}N_3O$: C 65.01, H 6.45, N 20.68%; found: C 65.21, H 6.59, N 20.35%.

Reaction with 4,6-diphenyl-2-pyridone

The reaction mixture gave, after 18 h at ambient temperature and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

general work-up, a mixture of two compounds A and B purified by column chromatography (chloroform:hexanes 3:1). Compound A (R_f = 0.53), isolated as a colorless oil and characterized as *1-(4,6-diphenylpyrid-2-yl)oxymethyl-3,5-dimethyl-1*H*-pyrazole* (**7***b*), (44%), δ_H: 8.3–8.1 (2H, m), 7.8–7.2 (9H, m), 7.06 (1H, s), 6.50 (2H, s), 6.00 (1H, s), 2.36 (3H, s), and 2.30 (3H, s); δ_C: 162.5, 155.0, 152.4, 149.4, 140.6, 138.8, 138.3, 129.0, 128.6, 126.9, 126.8, 112.7, 107.4, 106.6, 72.4, 13.5, and 10.8. $C_{23}H_{21}N_3O$ requires M^+, *m/z*: 355.1676; found: 355.1685.

Compound B (R_f = 0.19) and characterized as *1-(4,6-diphenylpyrid-2-on-1-yl)methyl-3,5-dimethyl-1*H*-pyrazole* (**8***b*), colorless needles (21%), mp 160–161°C; δ_H: 7.6–7.5 (4H, m), 7.5–7.3 (6H, m), 6.76 (1H, d, *J* 2 Hz), 6.37 (1H, d, *J* 2 Hz), 5.95 (2H, s), 5.68 (1H, s), 2.22 (3H, s), and 2.10 (3H, s). *Anal.* calcd. for $C_{23}H_{21}N_3O$: C 77.72, H 5.96, N 11.82%; found: C 77.78, H 6.03, N 11.71%.

Reaction with 3-Cyano-4,6-diphenyl-2-pyridone

3-Cyano-4,6-diphenyl-2-pyridone (14) and **5** gave, after work-up, a mixture of two products, which were purified by column chromatography (chloroform:hexanes 3:1). The first product isolated (R_f = 0.41) was characterized as *1-(3-cyano-4,6-diphenylpyrid-2-yl)oxymethyl-3,5-dimethyl-1*H*-pyrazole* (**7***c*), colorless needles (35%), mp 153–154°C; δ_H: 8.4–8.1 (2H, m), 7.8–7.3 (9H, m), 6.57 (2H, s), 6.00 (1H, s), 2.43 (3H, s), and 2.27 (3H, s); δ_C: 162.9, 157.9, 157.0, 149.3, 140.9, 136.9, 136.0, 130.6, 130.0, 128.9, 128.8, 128.3, 127.4, 114.6, 114.4, 107.1, 93.6, 73.5, 13.4, and 10.8. *Anal.* calcd. for $C_{24}H_{20}N_4O$: C 75.76, H 5.30, N 14.73%; found: C 75.98, H 5.45, N 14.50%. Fraction 2 (R_f = 0.14), *1-(3-cyano-4,6-diphenylpyrid-2-on-1-yl)methyl-3,5-dimethyl-1*H*-pyrazole* (**8***c*), colorless microcrystals (20%), mp 198–200°C; δ_H: 7.9–7.4 (10H, m), 6.40 (1H, s), 6.00 (2H, s), 5.80 (1H, s), 2.33 (3H, s), and 2.13 (3H, s); δ_C: 161.0, 159.0, 154.1, 148.9, 141.3, 135.3, 133.6, 130.7, 130.1, 129.2, 128.8, 128.6, 128.1, 115.7, 110.0, 105.3, 101.0, 56.2, 13.7, and 10.7. *Anal.* calcd. for $C_{24}H_{20}N_4O$: C 75.76, H 5.30, N 14.73%; found: C 75.55, H 5.28, N 14.42%.

Method B

Sulfur nucleophiles: To a solution of 1 N sodium ethoxide (150 mL, 150 mmol) at 0°C was added the corresponding sulfur nucleophile (75 mmol). After 30 min, 1-chloromethyl-3,5-dimethyl-1*H*-pyrazole hydrochloride (**5**) (70 mmol) was added slowly and the mixture stirred at ambient temperature for 3 h. Work-up was carried out as described in Method A.

The following compounds were prepared in this manner:

*1-(Benzothiazol-2-ylthio)methyl-3,5-dimethyl-1*H*-pyrazole (**4**)*

From 2-mercaptobenzothiazole and **5**, a red solid that was crystallized from ethanol/water to give tan plates (71%), mp 96–98°C; δ_H: 8.1–7.6 (2H, m), 7.6–7.3 (2H, m), 6.10 (2H, s), 5.90 (1H, s), 2.36 (3H, s), and 2.26 (3H, s). *Anal.* calcd. for $C_{13}H_{13}N_3S_2$: C 56.7, H 4.8, N 15.3%; found: C 56.62, H 4.70, N 15.02%.

*1-(Phenylthio)methyl-3,5-dimethyl-1*H*-pyrazole (**6**)*

Thiophenol and **5** gave a pink oil, which was purified by distillation to give a pale yellow oil (72%), bp 138–140°C/0.85 Torr; δ_H: 7.7–7.3 (5H, m), 5.93 (1H, s), 5.43 (3H, s), 2.26 (3H, s), and 1.93 (3H, s); δ_C: 148.2, 139.4, 133.5, 132.8, 128.8, 128.0, 105.8, 53.4, 13.3, and 10.4. $C_{12}H_{14}N_2S$ requires M^+, *m/z*: 218.0877; found: 218.0861.

*1-(N,N-Diethyldithiocarbamyl)methyl-3,5-dimethyl-1*H*-pyrazole (**3**)*

To a solution of sodium diethyldithiocarbamate trihydrate (9.75 g, 43.5 mmol) in ethanol (150 mL) was added 1-chloromethyl-3,5-dimethyl-1*H*-pyrazole hydrochloride (**5**) (3.75 g, 20.7 mmol), and the mixture stirred overnight at ambient temperature. The solvent was then removed *in vacuo* and the residue treated with water (100 mL). The organic material was extracted with chloroform (3 × 25 mL), dried ($MgSO_4$), and the solvent removed to afford the crude mixture as an oil. Purification by chromatography (chloroform:hexanes 2:1) gave **3** as a yellow oil (4.62 g, 87%); δ_H: 5.95 (2H, s), 5.81 (1H, s), 4.01 (2H, q, *J* 7 Hz), 3.70 (2H, q, *J* 7 Hz), 2.34 (3H, s), 2.21 (3H, s), and 1.26 (6H, t, *J* 7 Hz); δ_C: 192.3, 149.1, 140.2, 106.1, 55.2, 49.2, 46.7, 13.4, 12.4, 11.3, and 11.2. *Anal.* calcd. for $C_{11}H_{19}N_3S_2$: C 51.33, H 7.44%; found: C 51.27, H 7.47%.

*3,5-Dimethyl-1-(phenylsulfinyl)methyl-1*H*-pyrazole (**10**)*

To a solution of 3,5-dimethyl-1-(phenylthio)methyl-1*H*-pyrazole (**6**) (5.45 g, 25 mmol) in methylene chloride (150 mL) at −20°C was added *m*-CPBA (80%; 5.93 g, 27.5 mmol) in small portions. The reaction mixture was stirred at that temperature for 4 h. Water (50 mL) was then added and the layers separated. The organic layer was washed with 10% aqueous Na_2CO_3 (2 × 25 mL), saturated NaCl (1 × 25 mL), dried ($MgSO_4$), and the solvent removed to give a pale yellow oil that solidified on trituration with hexanes. Crystallization from benzene/hexanes afforded the sulfoxide **10** as colorless needles (4.85 g, 83%), mp 75–76°C; δ_H: 7.51 (5H, s), 5.80 (1H, s), 5.09 (1H, AB, J_{AB} 12.7 Hz), 4.89 (1H, AB, J_{AB} 12.7 Hz), 2.20 (3H, s), and 2.01 (3H, s); δ_C: 149.6, 141.3, 141.0, 131.5, 129.1, 124.0, 106.4, 71.2, 13.2, and 10.4. *Anal.* calcd. for $C_{12}H_{14}N_2$: C 61.51, H 6.02, N 11.96%; found: C 61.36, H 5.99, N 11.88%.

General procedure for lithiation with n*-butyllithium and subsequent treatment with electrophiles*

To a solution of the corresponding precursor (**6** or **10**) (10 mmol) in dry THF (100 mL) at −78°C was added dropwise *n*-butyllithium (2.5 M in hexanes, 4.4 mL, 11 mmol), and the resulting solution stirred at that temperature for 2 h. To the solution of the corresponding lithio derivative was added a solution of the electrophile (10.5 mmol) in dry THF (10 mL). In the case of the sulfides (**6**, **9***a*), the resulting solution was stirred at −78°C for 6 h and at ambient temperature for 12 h. For the sulfoxide (**10**), the resulting solution was stirred at −78°C for 4 h. The reaction mixture was then poured into saturated aqueous ammonium chloride (75 mL) and the layers separated (it might be necessary to add a little water to dissolve any inorganic precipitate). The aqueous layer was washed with Et_2O (3 × 25 mL), the combined organic extracts washed with water, dried ($MgSO_4$), and the solvent evaporated to give the crude product, which was then purified.

The following compounds were prepared in this manner:

*2-(3,5-Dimethyl-1*H*-pyrazol-1-yl)-1-(4-methylphenyl)-2-(phenylthio)ethanol (**12**a)*

4-Methylbenzaldehyde and **6** afforded the alcohol as colorless microcrystals from *n*-pentane (55%), mp 123–124°C; δ_H: 7.57 (5H, s), 7.26 (4H, s), 6.3–6.0 (1H, m, OH), 5.73 (1H, s), 5.6–5.4 (2H, m), 2.33 (6H, s), and 1.30 (3H, s). *Anal.* calcd. for $C_{19}H_{20}N_2S$: C 70.97, H 6.55, N 8.28%; found: C 70.90, H 6.81, N 8.12%.

*1-(3,5-Dimethyl-1*H*-pyrazol-1-yl)-1-(phenylthio)ethane (**9**a)*

Obtained from **6** and methyl iodide as a colorless oil purified by column chromatography (chloroform:hexanes 2:1) (66%); δ_H: 7.20 (5H, m), 5.65 (1H, s), 5.40 (1H, q, *J* 7 Hz), 2.25 (3H, s), 1.91 (3H, d, *J* 7 Hz), and 1.70 (3H, s); δ_C: 148.2, 139.5, 135.1, 132.3, 128.6, 105.0, 61.4, 21.2, 13.6, and 10.3. *Anal.* calcd. for $C_{13}H_{16}N_2S$: C 67.20, H 6.94%; found: C 67.06, H 6.99%.

*1-(3,5-Dimethyl-1*H*-pyrazol-1-yl)-2-phenyl-1-(phenylthio)ethane (**9**b)*

Benzyl bromide and **6** gave **9***b* as colorless needles from *n*-pentane (74%), mp 69–70°C; δ_H: 7.3–7.1 (8H, m), 7.0–6.9 (2H, m), 5.52 (1H, s), 5.28 (1H, dd, *J* 4.5 Hz, 9.8 Hz), 3.71 (1H, dd, *J* 9.8 Hz, 13.6 Hz), 3.36 (1H, dd, *J* 4.5 Hz, 13.6 Hz), 2.30 (3H, s), and 1.36 (3H, s). *Anal.* calcd. for $C_{19}H_{20}N_2S$: C 73.98, H 6.54, N 9.08%; found: C 74.06, H 6.78, N 8.94%.

*2-(3,5-Dimethyl-1*H*-pyrazol-1-yl)-1-phenyl-2-(phenylthio)propane (**11**)*

9*a* and benzyl bromide gave the product as a colorless oil that slowly solidified. Crystallized from *n*-pentane as colorless plates (72%), mp 64–66°C; δ_H: 7.3–7.1 (6H, m), 7.05–6.95 (2H, m), 6.95–6.85 (2H, m), 5.83 (1H, s), 4.03 (1H, d, *J* 14 Hz), 3.21 (1H, d, *J* 14 Hz), 2.36 (3H, s), 2.15 (3H, s), and 1.73 (3H, s). *Anal.* calcd. for $C_{20}H_{22}N_2S$: C 74.49, H 6.88, N 8.69%; found: C 74.51, H 7.12, N 8.33%.

*3,5-Dimethyl-1-styryl-1*H*-pyrazole (**15**)*

10 and benzyl bromide gave the intermediate adduct **13**, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

readily decomposed at room temperature to give a pale yellow oil. Purification by column chromatography (chloroform:hexanes, 1:2) afforded a colorless oil (1.2 g, 60%); δ_H: 7.5–7.1 (7H, m), 5.89 (1H, s), 2.30 (3H, s), and 2.28 (3H, s); δ_C: 149.9, 139.2, 135.7, 128.6, 126.9, 125.9, 122.5, 116.3, 106.9, 13.5, and 10.8. $C_{13}H_{14}N_2$ requires M^+, m/z: 198.1157; found: 198.1150.

*2-(3,5-Dimethyl-1H-pyrazol-1-yl)-1-(4-methylphenyl)-2-phenylsulfinylethan-1-ol (**12**b)*

10 and 4-methylbenzaldehyde afforded a crude mixture that was purified by column chromatography (ethyl acetate:hexanes, 1:2) to afford the alcohol **12***b* as colorless needles (1.13 g, 55%), mp 155–157°C; δ_H: 7.4–7.2 (7H, m), 7.06 (2H, AB, J_{AB} 8 Hz), 6.05 (1H, bs, OH), 5.89 (1H, d, J 6 Hz), 5.60 (1H, s), 4.93 (1H, d, J 6 Hz), 2.29 (3H, s), 2.18 (3H, s), and 1.47 (3H, s); δ_C: 149.2, 142.5, 141.3, 137.5, 136.7, 130.8, 128.9, 128.6, 126.3, 124.8, 105.6, 83.1, 72.3, 21.1, 13.5, and 10.2. *Anal.* calcd. for $C_{20}H_{22}N_2O_2S$: C 67.77, H 6.26, N 7.90%; found: C 67.91, H 6.17, N 7.83%.

General procedure for the Raney nickel desulfurization

To a solution of the corresponding sulfide (2 mmol) in ethanol (20 mL) was added Raney nickel (ca. 3 g). The mixture was heated under reflux for 12 h. The Raney nickel was then filtered off and the solvent removed *in vacuo* to give the crude product. Purification by column chromatography (chloroform:hexanes, 1:1) afforded the pure products.

The following compounds were prepared in this manner:

*1-(3,5-Dimethylpyrazol-1-yl)-2-phenylethane (**14**a)*

A yellow liquid (17) (68%); δ_H: 7.4–7.0 (5H, m), 5.73 (1H, s), 4.16 (2H, t, J 7 Hz), 3.06 (2H, t, J 7 Hz), 2.30 (3H, s), and 1.86 (3H, s).

*2-(3,5-Dimethylpyrazol-1-yl)-1-phenylpropane (**14**b)*

A yellow oil (70%); δ_H: 7.2–7.1 (3H, m), 6.9–6.8 (2H, m), 5.61 (1H, s), 4.3–4.1 (1H, m), 3.18 (1H, dd, J 9, 13.2 Hz), 2.92 (1H, dd, J 5.3, 13.2 Hz), 2.26 (3H, s), 1.72 (3H, s), and 1.54 (3H, d, J 7 Hz); δ_C: 146.9, 138.7, 138.6, 128.8, 128.0, 126.1, 103.9, 55.2, 43.4, 20.7, 13.5, and 10.6. *Anal.* calcd. for $C_{14}H_{18}N_2$: C 78.46, H 8.47%; found: C 78.37, H 8.52%.

*1-(4-Methylphenyl)-2-(3,5-dimethylpyrazol-1-yl)ethan-1-ol (**14**c)*

Colorless microcrystals (68%), mp 125–126°C; δ_H: 7.18 (2H, AB, J_{AB} 8.4 Hz), 7.11 (2H, AB, J_{AB} 8.4 Hz), 5.74 (1H, s), 5.01 (1H, m), 2.32 (3H, s), 2.19 (3H, s), and 1.98 (3H, s). *Anal.* calcd. for $C_{14}H_{18}N_2O$: C 73.01, H 7.88%; found: C 73.10, H 7.89%.

Remarks on the barrier to rotation about the C_{sp^2}—O bond in anisole

TED SCHAEFER AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

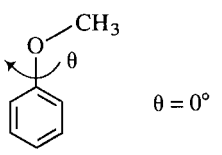
Received February 13, 1989

TED SCHAEFER and RUDY SEBASTIAN. Can. J. Chem. **67**, 1148 (1989).

Molecular orbital computations with the basis set 6-31G are reported for seven values of θ, the torsion angle about the C_{sp^2}—O bond in anisole. All bond angles and lengths are optimized but the atoms of the phenyl group are constrained to a plane. The relative energies are fit by $V(\theta)/\text{kJ mol}^{-1} = 7.78(5)\sin^2\theta + 2.41(5)\sin^2 2\theta - 0.54(5)\sin^2 3\theta$, where θ is zero when the heavy-atom skeleton is planar. Computations with the basis set 6-31G*(5D) for three values of θ can be reproduced by $V(\theta)/\text{kJ mol}^{-1} = 6.07\sin^2\theta + 2.68\sin^2 2\theta$. These results are compared with experimental gas phase data from the literature. The analysis of the ^{1}H nuclear magnetic resonance spectrum of anisole-α-^{13}C in a CS_2/C_6D_{12}/TMS solvent mixture yields a value of $^6J(^1\text{H}, ^{13}\text{C})$, the long-range spin–spin coupling constant between the ^{13}C nucleus in the methyl group and the *para* proton. Because this coupling constant is proportional to $\sin^2\theta$, it is shown, together with previous dynamic nmr measurements, that the barrier to rotation about the C_{sp^2}—O bond in solution cannot be purely twofold. The internal potential must also contain a fourfold term of the same sign as that of the twofold component. If the V_2/V_4 ratio given by the various molecular orbital computations holds in solution, then V_2 is 15.0 ± 2.0 kJ/mol and V_4 is 5.6 ± 2.2 kJ/mol. The apparent doubling of the internal barrier in solution is perhaps unprecedented for such a simple molecule.

Key words: anisole, internal barrier in solution, anisole-α-^{13}C, ^{1}H NMR, conformational behaviour, MO computations.

TED SCHAEFER et RUDY SEBASTIAN. Can. J. Chem. **67**, 1148 (1989).



Utilisant un ensemble de base 6-31G, on a effectué des calculs d'orbitales moléculaires pour sept valeurs de θ, l'angle de torsion autour de la liaison C_{sp^2}—O de l'anisole. On a optimisé tous les angles ainsi que toutes les longueurs; on a toutefois contraint le groupement phényle dans un plan. Les énergies relatives peuvent être représentées par l'équation $V(\theta)/\text{kJ mol}^{-1} = 7{,}78(5)\sin^2\theta + 2{,}41(5)\sin^2 2\theta - 0{,}54(5)\sin^2 3\theta$, dans laquelle θ est égal à zéro lorsque le squelette de l'atome lourd est plan. Les calculs effectués à l'aide de l'ensemble 6-31G* (5D) pour trois valeurs de θ peuvent être reproduits par l'équation $V(\theta)/\text{kJ mol}^{-1} = 6{,}07\sin^2\theta + 2{,}68\sin^2 2\theta$. On compare ces résultats avec les données expérimentales en phase gazeuse qui sont rapportées dans la littérature. L'analyse des spectres rmn du ^{1}H de l'anisole-α-^{13}C, dans un mélange de solvant CS_2/C_6D_{12}/TMS, fournit une valeur de $^6J(^1\text{H}, ^{13}\text{C})$, la constante de couplage spin–spin à longue distance entre le ^{13}C du groupement méthyle et le proton en *para*. Cette constante de couplage étant proportionnelle à $\sin^2\theta$, on démontre, en se basant aussi sur des mesures rmn dynamiques antérieures, que la barrière à la rotation autour de la liaison C_{sp^2}—O, en solution, ne peut pas être purement binaire. Le potentiel interne doit aussi contenir un terme quaternaire du même signe que la composante binaire. Si le rapport de V_2/V_4 obtenu par les divers calculs d'orbitales moléculaires s'applique aussi en solution, V_2 est alors égal à 15,0 ± 2,0 kJ/mol et V_4 à 5,6 ± 2,2 kJ/mol. Il est probable que la multiplication par deux de la valeur de la barrière interne en solution n'a pas de précédent pour une molécule aussi simple.

Mot clés : anisole, barrière interne en solution, anisole-α-^{13}C, RMN du ^{1}H, comportement des conformations, calculs d'OM.
[Traduit par la revue]

Introduction

The barrier to rotation about the C_{sp^2}—O bond is uncertain. Its magnitude apparently ranges from 6 to 48 kJ/mol, depending on the experimental or theoretical methods used to assess its magnitude as well as on the state in which the molecule is examined. Compilations of references are available (1–3). Of immediate interest to the present investigations are the following summaries.

In the gas phase, the electron diffraction pattern (4) and the microwave spectrum (5) are consistent with a planar heavy-atom skeleton at 328 and 260 K, respectively, although slightly better agreement between experimental and computed intensities of the diffraction patterns is evident at a dihedral angle of 10° in **1**. At 523 K, the electron diffraction data are well represented on the basis of a θ of 40° (4); an unsuccessful fit to these data assumes a twofold barrier of 9.6 or 25.1 kJ/mol (4). Coupling of torsional modes complicates the interpretation of the infrared spectrum, but a twofold barrier of 15.1 kJ/mol is tentatively deduced (6). Molecular mechanics calculations (1) yield 7.9 kJ/mol for the barrier. Most quantum mechanical approaches also find a barrier of less than 8 kJ/mol *if* extensive geometry optimization procedures are employed (2, 7, 8).

θ = 0°

1

The barrier to rotation about the C_{sp^2}—O bond in anisole is apparently much larger in the liquid or in solution that in the vapour. On the assumption that it is twofold, its magnitude is estimated as 25.3 kJ/mol from the torsional frequencies measured on the liquid (6). However, dynamic ^{13}C nmr measurements on a dimethyl ether solution imply a barrier height of less than 19.7 kJ/mol and relaxation measurements in the rotating frame suggest a barrier of less than 18.4 kJ/mol for the same solution (9). Infrared intensities give 10.9 kJ/mol for the internal barrier in CCl_4 solution (10). Another approach to motion about the C_{sp^2}—O bond in solution uses the long-range spin–spin coupling constant over six bonds, $^6J(^1\text{H}, ^{13}\text{C})$, a σ–π coupling and therefore proportion to $\sin^2\theta$ (9). However, on a Bruker WH90 FT nmr spectrometer and for CS_2/C_6D_{12} or acetone-d_6 solutions, $^6J(^1\text{H}, ^{13}\text{C})$ is not apparent in the ^{13}C nmr spectrum of anisole-α-^{13}C (9) and must be <0.05 Hz in magnitude. Because $^6J(^1\text{H}, ^{13}\text{C})$ at θ = 90° is at least 0.6 Hz in magnitude (9), it follows that the expectation value of $\sin^2\theta$ is less than 0.08 at 300 K and therefore that a purely twofold

[f]$^1J(H,^{13}C)$ = 142.899(1), $^4J(H,^{13}C)$ = 0.000(1), $^5J(H,^{13}C)$ = 0.113(1) Hz. Simulation of the H-4 spectral region with all these parameters, and a linewidth at half-height of 0.038 Hz, gives $^6J(H,^{13}C)$ as ±0.030 ± 0.005 Hz.

barrier must be greater than about 18 kJ/mol (as obtained from classical or quantum mechanical averages). The presence of a term in V_4 in the internal rotational potential, of the same sign as V_2, will reduce the magnitude of the barrier height compatible with such a value of $\langle\sin^2\theta\rangle$. Again, $^5J(^{13}C, ^{13}C)$ is not detectable for the acetone-d_6 solution (11), this coupling constant also being indicated as proportional in $\sin^2\theta$. While both long-range coupling constants are consistent with a predominantly planar conformation of anisole in solution, it is unsatisfying that their presence is not evident in the available spectra.

For solid anisole, the Raman spectra imply a barrier height of 48.2 kJ/mol (12). Dielectric loss studies of anisole dispersed in an *o*-terphenyl glass yield an enthalpy of activation of 11.0 ± 0.5 kJ/mol for the rotation about the C_{sp^2}—O bond (13). As stated by Konschin (3), the torsion is to be regarded as a motion of large amplitude that affects the spatial and structural preferences of the molecule in different aggregation states. Because the methoxyphenyl group is a constituent of a variety of useful and (or) interesting chemical moieties, such as lignin, and psychotomimetic entities as well as of mesogenic materials (14, 15), it is unfortunate that the quantitative data above are so disparate.

The results below present new molecular orbital calculations on anisole, of interest to structural work in the gas phase, as well as $^6J(^1H, ^{13}C)$ measurements, of interest in the assessment of the fourfold component of the barrier to rotation about the C_{sp^2}—O bond in solution.

Results and discussion

The ^{1}H nmr spectral parameters

The results of the NUMARIT (16) analyses of the ^{1}H nmr spectra of anisole and anisole-α-^{13}C at 300 MHz in CS_2/C_6D_{12}/TMS solutions at 300 K are given in Table 1. This solvent mixture is chosen because, unlike in acetone-d_6 solution (17), the spectral region of H-4 is relatively well separated from the H-2 and H-3 regions; this is an essential condition for the determination of a small $^6J(^1H, ^{13}C)$. It is also essential that the spectra of the two molecules be available for comparison because, apart from the ensuing comparison of the precision of the spectral parameters, the presence of a $^7J(H, CH_3)$, comparable in magnitude to $^6J(^1H, ^{13}C)$, entails spectral simulations with and without a contribution from $^6J(^1H, ^{13}C)$. By such procedures (footnotes in Table 1) it is established that $^6J(^1H, ^{13}C)$ is ±0.030 ± 0.005 Hz in the ^{13}C-enriched molecule. Comparison of the coupling constants for the two molecules suggests that the standard deviations are a reasonable estimate of the accuracy in the analyses. Another comparison is for $^5J(^1H, ^{13}C)$, 0.113(1) Hz in Table 1 and 0.116(2) Hz from the ^{13}C nmr spectrum obtained on a different spectrometer (9). Figure 1 displays parts of the ^{1}H nmr spectra of H-4 for anisole and anisole-α-^{13}C.

The long-range coupling constants involving the methyl protons have been discussed as to their magnitudes and coupling mechanisms (17).

6J(^1H, ^{13}C) and the internal barrier in solution

The ratio of $^6J(^1H, ^{13}C)$, as measured, to its value when θ = 90° in **1**, yields $\langle\sin^2\theta\rangle$, which in turn is determined by the potential governing motion about the C_{sp^2}—O bond. In 2,6-dichloroanisole, $^6J(^1H, ^{13}C)$ is 0.603(5) Hz in magnitude, and is 0.625(7) Hz for the corresponding bromine derivative (9). These numbers hold for benzene-d_6 solutions at 300 K. For 2,6-dimethylanisole, $^6J(^1H, ^{13}C)$ has a magnitude of 0.62$_2$ Hz (11). In the crystal of 2,3,5,6-tetrachloro-1,4-dimethoxybenzene, θ is 84.0° (18), implying that $\langle\sin^2\theta\rangle$ is perhaps within 1% of its maximal value of unity. We assess the value of $^6J(^1H, ^{13}C)$ as 0.625(5) Hz for a θ of 90°. Hence $\langle\sin^2\theta\rangle$ for anisole-α-^{13}C at 300 K in the CS_2 solvent mixture follows as 0.048(8). Were the barrier purely twofold, this number would mean that V_2 is $28.0^{+5.5}_{-3.9}$ kJ/mol. Therefore, because of the dynamic nmr measurements (9), it follows that a positive V_4 must be present. No negative V_4 values compatible with these measurements are, however, compatible with the above value of $\langle\sin^2\theta\rangle$; the latter is consistent with a range of V_2 and V_4 numbers of the same sign.

Figure 2 displays the V_4 and V_2 values consistent with a $\langle\sin^2\theta\rangle$ of 0.048(8) at 300 K. In principle, with the exception of combinations excluded by the dynamic nmr data, all combinations to left of the vertical line are possible. However, the 6-31G and 6-31G*(5D) computations, described below, imply that V_4 is not larger than 0.44 V_2. If the solvent does not alter the V_2/V_4 ratio drastically, then the V_2 and V_4 values in the hatched area of

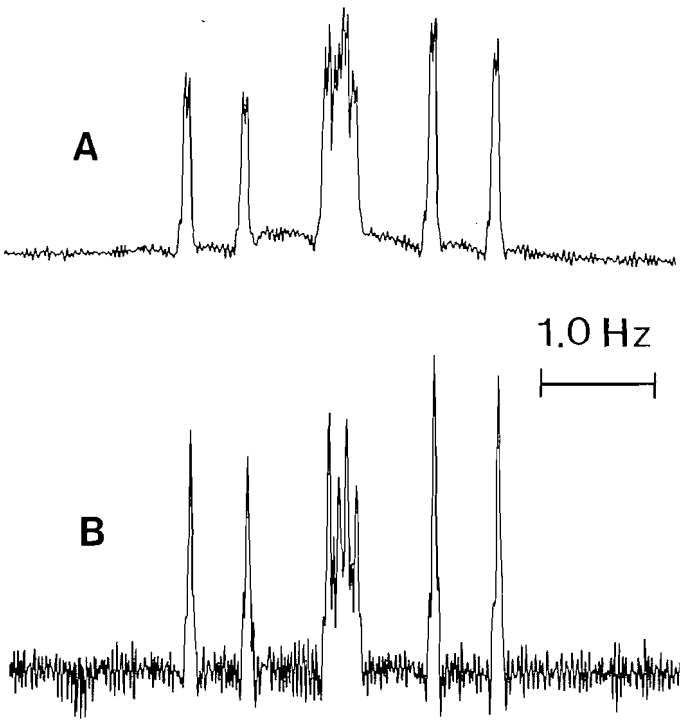

FIG. 1. In A, a part of the ^{1}H nmr spectrum of H-4 of anisole, that near the chemical shift position at 2037 Hz to high frequency of internal TMS, is shown for a 2.5 mol% solution in the CS_2/C_6D_{12}/TMS solvent mixture (see Table 1 and its footnotes). The smallest splittings arise from ^7J(H-4, CH_3). This coupling constant is rather better resolved in the methyl proton region (17) because the peaks in the latter region have a somewhat lower linewidth at half height, ca. 0.03 Hz, than do the peaks from H-4. ^7J(H-4, CH_3) is $-0.042(1)$ Hz (17). In B, the same spectral region is displayed as in A, but for anisole-α-^{13}C dissolved in the same solvent mixture. The presence of $^6J(^1H, ^{13}C)$ has altered the spectral appearance. A full analysis of the ^{1}H nmr spectrum for anisole gives the parameters in Table 1. There is a large coupling of 0.11 Hz between the α ^{13}C nucleus and the *meta* protons in anisole-α-^{13}C, but none discernible for the *ortho* protons. Analysis of the *ortho* and *meta* proton spectrum is followed by simulation of the *para* proton spectrum with various magnitudes of $^6J(^1H, ^{13}C)$, with the result that this coupling constant is $\pm 0.030 \pm 0.005$ Hz.

Fig. 2 are most likely, yielding V_2 as 15.0 ± 2.0 and V_4 as 5.6 ± 2.2 kJ/mol. These numbers are considerably larger than the theoretical values computed for the free molecule. The upper limit to the barrier *height* is 18.6 kJ/mol, just below the value tested by the dynamic nmr experiments (9). The lower limit is 13.0 kJ/mol.

*The internal potential according to 6-31G and 6-31G**

The relative energies computed (geometry optimization) for seven values of the torsion angle, θ, with the 6-31G basis set are reproduced by eq. [1], the standard error in the fit being shown in parentheses. The total energy at $\theta = 0°$ is $-344.450\,628$ au. The barrier height is very similar to that found (7) with the basis 4-31G. Inclusion of polarization functions (5 D per heavy atom) leads to relative energies at $\theta = 0, 45, 90°$, fit by eq. [2]. The barrier height is lowered to 6.5 kJ/mol and is very similar to that found with the minimal basis set, STO-3G (7, 8). The energies are plotted in Fig. 3 as a function of θ.

$$[1]\quad V/\text{kJ mol}^{-1} = 7.78(5)\sin^2\theta + 2.41(5)\sin^2 2\theta - 0.54(5)\sin^2 3\theta$$

$$[2]\quad V/\text{kJ mol}^{-1} = 6.07\sin^2\theta + 2.68\sin^2 2\theta$$

It may well be of interest that, at 523 K, the temperature of measurement for one set of electron diffraction data (4), the use of the potential in eq. [2] yields 31° as the expectation value of θ; alternatively, arc $\sin(\sin^2\theta)^{1/2}$ is 34°. The electron diffraction pattern was fit well with a *fixed* θ of 40°. A fit of that pattern with the potential of eq. [2] is indicated by this comparison.

The geometry of the stable, planar form of anisole is shown in Fig. 4, as computed with the polarized basis set. The geometry of the $COCH_3$ moiety agrees rather well with that quoted in connection with the diffraction data (4), but rather less well with that used and partially deduced in a microwave study (5). Of course, the external geometry changes significantly as θ increases from zero; the interested reader may ask for details.

Solvent perturbations of the barrier

Qualitatively, all the available experimental evidence indicates an increase in the internal barrier about the C_{sp^2}—O bond if anisole moves from the vapour phase into solution.

The present values, $V_2 = 15.0 \pm 2.0$ and $V_4 = 5.6 \pm 2.2$ kJ/mol, for the internal rotational potential in the CS_2/C_6D_{12}/TMS solvent mixture are reliable only if the solvent does not alter significantly the ratio of V_2 to V_4. In this connection, an excellent correlation exists between $^6J(^{13}C, ^{19}F)$ for 4-fluorophenyl OR (R = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$) in solution and ΔI^V_{31} for the parent molecules in the gas phase (19). $^6J(^{13}C, ^{19}F)$ is proportional (19) to $\langle\sin^2\theta\rangle$ and ΔI^V_{31} represents the conjugative interaction between the lone pairs on oxygen and the π electrons of the phenyl group (20). Among other things, this correlation ($r = 0.998$ and significant at the 98% confidence level) suggests that the qualitative nature of the internal rotational potential in the gas phase is not severely altered in solution, although the magnitudes of the *n*-fold components must increase in solution. Of course, it is still true that the numbers above depend on the assessment of V_2/V_4 provided by the various basis sets. Possible reasons for a finite V_4 have been discussed (8, 17).

The reason for the large increase in the barrier in solution is also problematic. A continuum model (21, 22), which takes electrostatic, dispersion, and cavitation energies into account, has reproduced the increase in internal barrier in benzaldehyde in solution (23). The same model appears to fail when applied to anisole (24). The recent intersecting-state model (25) evidently interprets the increased solution barrier for benzaldehyde as a consequence of an interaction of the lone-pair electrons on oxygen with solvent molecules; this interaction changes the "transition state bond order" found for the isolated molecule. The solvent effect on the barrier might therefore be said to be the consequence of specific molecular interactions, in contrast to the continuum model. The barrier in benzaldehyde is experimentally and theoretically almost purely twofold (26), unlike anisole, and it is not known how well the intersecting-state model applies to anisole.

It may be relevant that a comparison of experiment and molecular orbital computations suggests the independence of solvent of the barrier to rotation about the C_{sp^2}—C_{sp^3} bond in ethylbenzene and that the barrier may be slightly smaller in solution than in the gas phase (27). The magnitude of the barrier is computed as very similar in magnitude to that for anisole, although, of course, the conformation of lowest energy has θ as 90°. The sign of V_4 is the same (27) as that for anisole, however, and is computed as amounting to about 20% of the magnitude of V_2. The molecular volumes of anisole and ethylbenzene cannot differ greatly. The dipole moment of anisole in various environ-

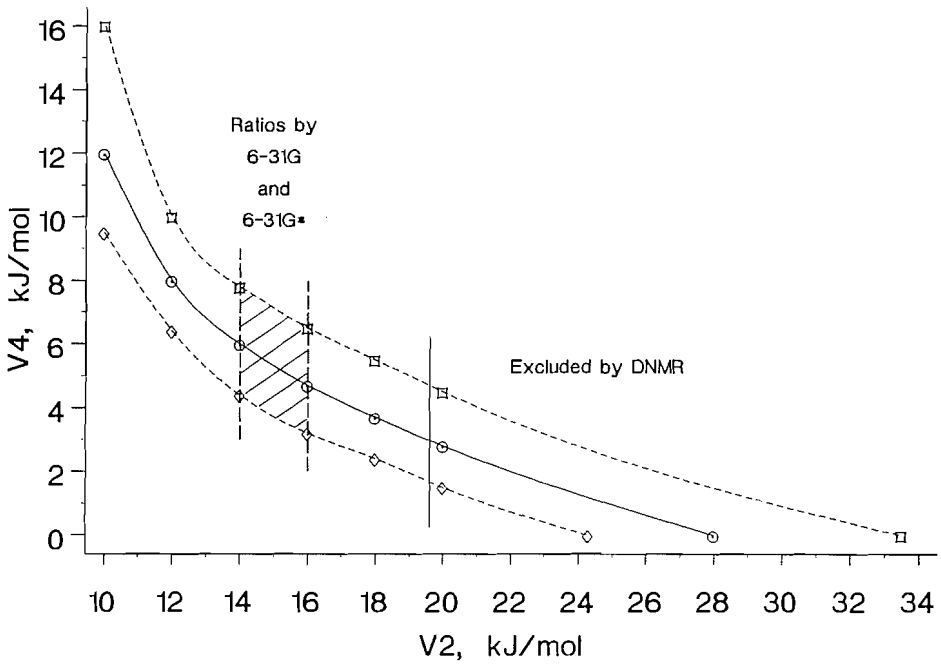

FIG. 2. The various combinations of the twofold component, V_2, and the fourfold component, V_4, of an internal potential, hindering rotation about the C_{sp^2}—O bond in anisole, are plotted. These combinations are compatible with a $\langle \sin^2 \theta \rangle$ of 0.048(8) as determined from $^6J(^1H, ^{13}C)$ in anisole-α-^{13}C and discussed in the text. The hatched area is that compatible with the V_2/V_4 ratios given by 6-31G and 6-31G*(5D) molecular orbital computations and also discussed in the text. The region to the right of the vertical solid line is excluded by dynamic ^{13}C nmr measurements (9).

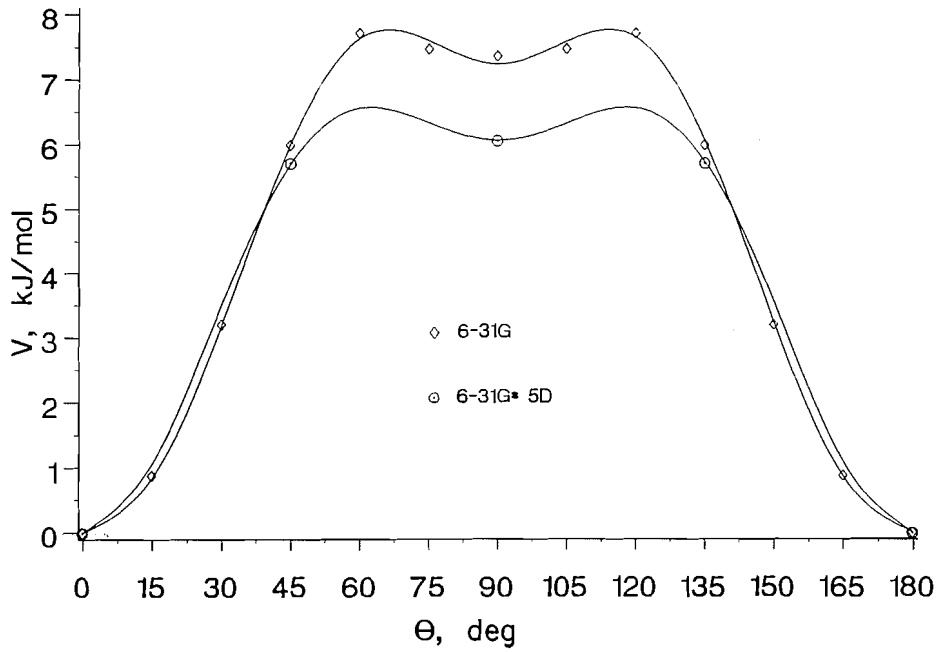

FIG. 3. The relative energies of various conformations of anisole, as computed with 6-31G and 6-31G*(5D) basis sets, are plotted as a function of θ, the angle of rotation about the C_{sp^2}—O bond. At θ = 0° the heavy-atom skeleton is planar. The solid lines represent the potential functions, $V(\theta)/\text{kJ mol}^{-1} = 7.78(5) \sin^2 \theta + 2.41(5) \sin^2 2\theta - 0.54(5) \sin^2 3\theta$ for the 6-31G results, and $V(\theta)/\text{kJ mol}^{-1} = 6.07 \sin^2 \theta + 2.68 \sin^2 2\theta$ for the three 6-31G*(5D) results.

ments is 1.25 ± 0.1 D (28). The 6-31G computations have the dipole moment as 1.18 D at θ = 0° in **1**, rising to only 1.35 D at θ = 90°. To a first approximation, therefore, the electrostatic term in the continuum model should act to decrease slightly the barrier in solution. The approximate doubling of the barrier in solution is therefore something of an anomaly; that of benzaldehye increases by only bout 50% in solution.

Experimental

The anisole-α-^{13}C was prepared as previously decribed (11). Solutions of anisole and anisole-α-^{13}C in the CS_2/C_6D_{12}/TMS solvent mixture, at concentrations given in Table 1, were transferred to 5 mm o.d. nmr sample tubes. Degassing of the tubes by a number of freeze–pump–thaw cycles was followed by flame-sealing of the evacuated tubes. The detailed procedures for accumulation of highly resolved

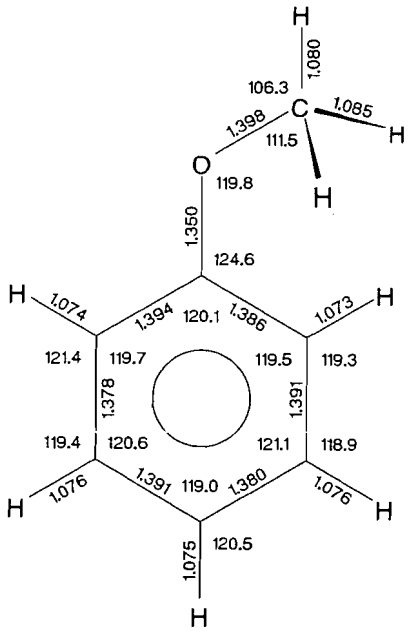

FIG. 4. The structure of the conformation of lowest energy, that with all heavy atoms in a plane, is shown and is that computed with the basis 6-31G*(5D). All bond angles, given in degrees, and bond lengths, given in angstroms, are optimized; the constraint is that the atoms of the phenyl group of anisole remain in a plane. The total energy is −344.582 089 au. The computed structure is quite similar to that assumed in the study of the electron diffraction patterns of anisole (4) but unlike that used in the work (5) on the microwave spectrum.

spectra on the Bruker AM 300 spectrometer have been described (29). These procedures were followed in the acquisition of ^{1}H nmr spectra of anisole-α-^{13}C at a probe temperature of 300 K.

The 6-31G and 6-31G* molecular orbital computations used the program GAUSSIAN 86 (30) and an Amdahl 5870 system. During these computations all bond angles and lengths were optimized, with the constraint, however, that the atoms of the phenyl group remain in a plane.

Received January 10, 1989

JOHN F. SMITH and LOREN G. HEPLER. Can. J. Chem. **67**, 1153 (1989).

We have made new measurements of the enthalpies of adding cyclohexane to mixtures of chloroform + triethylamine + cyclohexane at 25°C. The results of these measurements have been analysed in terms of the ideal associated solution model to obtain ΔH^θ for the dissociation of the chloroform–triethylamine complex. Our value of ΔH^θ is in excellent agreement with a published value that was obtained from results of measurements on binary mixtures of chloroform + triethylamine. This agreement indicates that it is usefully accurate to treat mixtures of chloroform + triethylamine + cyclohexane as ideal mixtures of chloroform, triethylamine, cyclohexane, and chloroform–triethylamine complex. This result has important implications for studies of associated systems dissolved in "inert" solvents and helps to provide a connection between complex formation in dilute solutions and in binary systems (A + B, no solvent).

Key words: ideal associated solution model, chloroform, triethylamine, inert solvent, hydrogen bonded complex.

JOHN F. SMITH et LOREN G. HEPLER. Can. J. Chem. **67**, 1153 (1989).

On a effectué de nouvelles mesures des enthalpies d'addition, à 25°C, du cyclohexane à des mélanges de chloroforme + triéthylamine + cyclohexane. Afin de déterminer les valeurs de ΔH^θ pour la dissociation du complexe chloroforme-triéthylamine, on a analysé ces résultats en fonction du modèle de la solution associée idéale. Notre valeur de ΔH^θ est en excellent accord avec une valeur publiée qui a été obtenue à partir de mesures sur des mélanges binaires de chloroforme + triéthylamine. Cet accord indique qu'il est correct et utile de traiter des mélanges de chloroforme + triéthylamine + cyclohexane comme des mélanges idéaux de chloroforme, de triéthylamine, de cyclohexane et du complexe chloroforme + triéthylamine. Les implications de ce résultat sont importantes pour les études de systèmes associés dissous dans des solvants «inertes» et il fournit un moyen de relier la formation de complexes en solutions diluées et dans des systèmes binaires (A + B, sans solvant).

Mots clés : modèle de la solution associée idéale; chloroforme; triéthylamine, solvant inerte, complexe avec liaison hydrogène.

Introduction

It has recently been shown (1–9) that for some non-electrolyte solutions in which chemical reactions are expected (or known) to occur all of the observed deviations from ideality may appropriately be attributed to the formation of new chemical species. That is, contributions to non-ideality arising from differences in size, shape, and polarity of the components (often called "physical" contributions and usually accounted for by activity coefficients) are negligible compared with the chemical contributions. Since the physical contributions are assumed to be unimportant, the activity coefficients of all species are set equal to unity at all compositions and temperatures. The solution is, therefore, considered to be an ideal solution of all the species present at equilibrium. This is known as the ideal associated solution model (10–12).

The studies cited above show that the ideal associated solution model can be applied successfully to binary mixtures (no solvent) of two associating components. However, associated non-electrolyte systems (A + B = AB) are often studied as dilute solutions in some more or less inert solvent. For such investigations there are two ways of choosing standard states and evaluating activity coefficients. First, we may choose standard states for A, B, and AB based on Henry's law, which means that activity coefficients for all species that are sufficiently dilute are taken to be unity. An advantage of this choice is that it avoids the need to specify any particular model or theory of activity coefficients, but there are important difficulties. The first difficulty arises from the practical necessity of working with solutions that contain a reasonable concentration of complex. Many complexes are not formed in an appreciable amount in very dilute solution. Therefore, investigators are forced to work with reasonably concentrated solutions for which activity coefficients based on Henry's law may not be equal to unity, which then leads to the need for some further model or theory of activity coefficients. A second difficulty is that there is no straightforward way to compare K, ΔG^θ, and ΔS^θ values based on a Henry's law standard state with K, ΔG^θ, and ΔS^θ values based on Raoult's law, which is the usual standard state for binary mixtures of A + B (no solvent).

The second approach to solutions of A + B in an "inert" solvent is to choose standard states of all species based on Raoult's law. Compositions are expressed in terms of mole fractions and all activity coefficients are set equal to unity at all temperatures and compositions. This approach is equivalent to extending the ideal associated solution model from binary mixtures of A + B to solutions of A + B in an "inert" solvent and has the advantage that it permits direct comparison of results obtained for binary mixtures of A + B with results obtained for solutions of A + B in a solvent. If this approach is valid, then values of the equilibrium constant (K) and the standard enthalpy (ΔH^θ) for A + B = AB will be the same whether they are determined from the results of investigations of binary A + B (no solvent) or from the results of investigations of solutions of A + B in an inert solvent.

TABLE 1. Mass balance for A + B = AB mixed with an inert solvent S

Species	Stoichiometric amount/mol	Stoichiometric mole fraction	Equilibrium amount/mol[a]	Equilibrium mole fraction[b]
A	N_A	x_A	$(N_A - n_{AB}) = n_A$	$(x_A - r)/(1 - r) = z_A$
B	N_B	x_B	$(N_B - n_{AB}) = n_B$	$(x_B - r)/(1 - r) = z_B$
AB	—	—	n_{AB}	$r/(1 - r) = z_{AB}$
S	N_S	x_S	$N_S = n_S$	$x_S/(1 - r) = z_S$

[a]Total number of moles at equilibrium is $(N_A + N_B + N_S - n_{AB})$.
[b]$r = n_{AB}/(N_A + N_B + N_S)$.

To examine the validity of the extension of the ideal associated solution model to solutions of A + B in an inert solvent we have investigated the chloroform + triethylamine + cyclohexane system at 25°C. Chloroform + triethylamine was chosen as the complexing pair because the complex formed between chloroform and triethylamine is quite stable ($K = 2.6$ at 25°C) and because the ideal associated solution model has been shown (8) to work well for this binary system. Cyclohexane was chosen as the "inert" solvent because of its common use as a solvent in spectroscopic and thermodynamic studies of non-electrolyte solutions. In addition, cyclohexane has no obvious chemical reactivity towards either chloroform or triethylamine.

The enthalpies of adding known amounts of cyclohexane to both dilute and concentrated solutions of chloroform + triethylamine in cyclohexane were measured. To the extent that the model is applicable to the binary mixtures of chloroform + triethylamine and also to the solutions in cyclohexane, the results of these measurements will be consistent with the previously reported (8) values of K and ΔH^θ that were established on the basis of measurements of vapour pressures and excess enthalpies of binary A + B mixtures.

Treatment of speciation

The formation of a 1:1 complex, AB, between unlike molecules, A and B, can be represented by

[1] $A + B = AB$

When N_A moles of A are mixed with N_B moles of B and N_S moles of inert solvent, S, the equilibrium composition of the solution (expressed in terms of the equilibrium mole fractions, z_i) can be related to the stoichiometric composition (expressed in terms of the stoichiometric mole fractions, x_i). The relationship is derived from the mass balance considerations presented in Table 1, where r represents extent of reaction.

In the ideal associated solution model the activity coefficients of all species are taken to be unity at all compositions. Therefore, the equilibrium constant for reaction [1] can be expressed in terms of the equilibrium mole fractions, z_i:

[2] $$K = z_{AB}/z_A z_B$$

Substituting the expressions for the equilibrium mole fractions of each species, z_i, from the last column of Table 1 into eq. [2], we obtain an expression for the equilibrium constant in terms of the extent of reaction (r) and the stoichiometric mole fractions, x_A and x_B:

[3] $$K = r(1 - r)/(x_A - r)(x_B - r)$$

Rearrangement of eq. [3] yields

[4] $$r = \frac{[K(x_A + x_B) + 1] - \{[K(x_A + x_B) + 1] - 4(K + 1)Kx_Ax_B\}^{0.5}}{2(K + 1)}$$

Therefore, the value of r can be calculated for any given mixture of A, B, and S for which the equilibrium constant of association is known. The value of r can then be used in the expressions (obtained from Table 1)

[5] $$z_A = (x_A - r)/(1 - r)$$
$$z_B = (x_B - r)/(1 - r)$$
$$z_{AB} = r/(1 - r)$$
$$z_S = x_S/(1 - r)$$

to evaluate the equilibrium mole fraction of each species in the solution. The equilibrium amount of the complex, n_{AB}, can also be calculated from the extent of reaction using

[6] $$n_{AB} = r(N_A + N_B + N_S)$$

The equilibrium amounts of A and B, n_A and n_B, can then be calculated from the expressions

[7] $$n_A = N_A - n_{AB}$$
$$n_B = N_B - n_{AB}$$

that are derived in Table 1. The amount of solvent is unchanged by the formation of AB and hence the equilibrium amount of S, n_S, equals the stoichiometric amount of S:

[8] $$n_S = N_S$$

Thus, for any mixture of A, B, and S for which the stoichiometric amount of each species and the equilibrium constant of association are known, the equilibrium speciation can be calculated.

Experimental

Calorimetric measurements were made using an isoperibol calorimeter. The calorimeter consists of a Dewar flask (capacity 370 cm^3) reaction vessel clamped inside a sealed brass can. The brass can is fitted with an inlet port through which a liquid can be admitted to the reaction vessel by an automatic titrator. Changes in the temperature of the mixture in the reaction vessel are monitored with a thermistor and a resistance bridge. A calibration heater mounted on the inside of the lid of the can is positioned near the bottom of the reaction vessel when the vessel is sealed inside the can. The calorimeter is described in full in ref. 13.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

To begin an experiment the reaction mixture is weighed into the reaction vessel. The reaction vessel is then clamped inside the can and the can is sealed and placed in a constant temperature water bath. The reaction mixture is stirred continuously and the change in resistance of the thermistor with time is recorded. When the resistance of the thermistor reaches a value that has been shown previously to correspond to the temperature of the water bath, a known volume of the liquid in the titrator is admitted to the reaction vessel. The titration leads to a change in temperature of the reaction mixture and a corresponding change in resistance of the thermistor. The change in resistance of the thermistor with time is recorded. When the rate of change in resistance of the thermistor with time has been constant for several minutes the calibration heater is switched on. The current through the heater, I_h, the voltage across the heater, V_h, and the time of the heating, t, are recorded. The heater is then switched off and the change in resistance of the thermistor with time is again recorded.

The resistance changes due to the titration and the electrical calibration are calculated by standard methods (14). The ratio of these resistance changes is equal to the ratio of the energy changes associated with the two processes. Since the electrical energy of the calibration, Q_c, is known (from $Q_c = I_h V_h t$), the energy associated with the titration can be calculated.

When the electrical calibration is finished, the mixture in the reaction vessel is heated (or cooled) until the resistance of the thermistor is $\sim 4\Omega$ above the resistance corresponding to the temperature of the water bath. The calorimetric experimental process (titration followed by calibration) is then repeated. The number of repetitions is limited only by the capacity of the reaction vessel. By this method several calorimetric experiments can be performed without changing the starting mixture in the reaction vessel.

In this work we have measured the heat associated with adding a known volume of cyclohexane to mixtures of chloroform, triethylamine, and cyclohexane at 25°C. Experiments were performed with two types of mixture in the reaction vessel. The first type of mixture contained concentrated chloroform + triethylamine with a maximum mole fraction of cyclohexane of 0.0971. The second type of mixture contained dilute chloroform + triethylamine with a minimum mole fraction of cyclohexane of 0.7345. For both types of mixture three ratios of chloroform to triethylamine were investigated: 3:1, 1:1, and 1:3. There were, therefore, six different starting mixtures, three concentrated and three dilute.

For each of the concentrated mixtures six additions of approximately 5 cm^3 of cyclohexane were made and the heat associated with each of these additions was measured. For the dilute mixtures the heat associated with each of four additions of 25 cm^3 of cyclohexane was measured.

Chloroform (Caledon) was washed five times with doubly distilled water, dried over anhydrous calcium chloride, and fractionally distilled twice. The middle fraction from each distillation was retained. At all stages of the process the chloroform was protected from light. The purified chloroform was stored under nitrogen in the dark and was used within 3 days of purification. Triethylamine (Fluka) was refluxed for 2 h over potassium hydroxide pellets and then distilled from the potassium hydroxide. The middle fraction of this distillation was collected and redistilled. The middle fraction was again collected and was stored under nitrogen. Cyclohexane (Caledon) was dried over molecular sieve (4A), distilled, and stored under nitrogen.

Results and analysis

The results of the calorimetric measurements described in the preceding section are given in Table 2 (concentrated mixtures) and Table 3 (dilute mixtures). Both tables list results of three sets of measurements, each set corresponding to a different ratio of chloroform to triethylamine. For each set of measurements the stoichiometric amounts of chloroform and triethylamine are invariant and are given above the results to which they relate. The first two columns of Tables 2 and 3 list the amount of cyclohexane in the reaction vessel before an experiment and the amount of cyclohexane added during the experiment. The third columns list the heat absorbed when this amount of cyclohexane is introduced to the reaction vessel. The uncertainty in these measured enthalpies is estimated to be less than 2%.

The fourth columns of Tables 2 and 3 list the heat arising

[a]Average molar enthalpy of complex dissociation, based on six experiments for concentrated solutions and four experiments for dilute solutions.
[b]One standard deviation of the set of enthalpies from the listed average enthalpy.

from complex dissociation. The heat of complex dissociation was calculated by subtracting the heat due to chloroform + cyclohexane interactions, $Q(CHCl_3/C_6H_{12})$, and the heat due to triethylamine + cyclohexane interactions, $Q(TEA/C_6H_{12})$, from the measured heat:

$$[9] \quad Q_{diss} = Q_{meas} - Q(CHCl_3/C_6H_{12}) - Q(TEA/C_6H_{12})$$

That the interactions of cyclohexane with chloroform and with triethylamine make significant contributions to the measured heat is consistent with treatment of the chloroform + triethylamine system by the ideal associated solution model. Although the model assumes that all physical contributions to the deviations from ideality are negligible, this assumption applies only to those species involved in association. The model contains no requirement that other species (e.g., "inert" solvent) be treated in any particular way. Therefore, we must evaluate the contributions to the measured heat arising from chloroform + cyclohexane and triethylamine + cyclohexane interactions from separate experiments. These contributions can then be subtracted from the measured heat to obtain the heat due to complex dissociation as described by eq. [9].

The last two terms in eq. [9] were evaluated for each experiment from equations of the form

$$[10] \quad Q(J/S) = [2z_J z_S \Delta H^*(J/S)](n_J + n_S)$$
$$J = CHCl_3 \text{ or TEA}, \; S = C_6H_{12}$$

where $2z_J z_S$ represents the probability of a J/S interaction in a random mixture of J and S and $\Delta H^*(J/S)$ represents the binary interaction enthalpy of J with cyclohexane. The equilibrium mole fraction (z_i) and equilibrium amount (n_i) of each species was found using the method described in the second section of this paper. A value of $K = 2.6$ for the equilibrium constant of association between chloroform and triethylamine as determined by Hepler *et al.* (8) from studies of the binary (no inert solvent) chloroform + triethylamine system was used in the speciation calculations. A value of $\Delta H^*(CHCl_3/C_6H_{12}) = 1.40$ kJ mol^{-1} was found by fitting an equation of the type represented by eq. [10] to the data of Findlay, Keniry, Kidman, and Pickles (15) for the excess enthalpies of the chloroform + cyclohexane system. A similar fit to the data of Murakami and Fujishiro (16) for excess enthalpies of mixing in the triethylamine + cyclohexane system led to a value of 0.55 kJ mol^{-1} for $\Delta H^*(TEA/C_6H_{12})$. The maximum residual in the fit to the chloroform + cyclohexane data was 26 J mol^{-1} while the maximum residual in the fit to the triethylamine + cyclohexane data was 33 J mol^{-1}.

The enthalpy of complex dissociation was calculated by dividing the enthalpy of dissociation from an experiment by the amount of complex dissociated, n_{diss}, during that experiment:

$$[11] \quad \Delta H_{diss} = Q_{diss}/n_{diss}$$

The amount of complex dissociated is the difference in amount of complex before and after a titration.

$$[12] \quad n_{diss} = n_{AB}(\text{before}) - n_{AB}(\text{after})$$

We estimate the uncertainty in each of our enthalpies of complex dissociation to be around 3%. For each set of experiments the values of ΔH_{diss} were averaged and these average enthalpies of complex dissociation together with the standard deviations of the averages are given in Table 4.

Earlier work (2) has shown that it is possible to apply the ideal associated solution model to the results of measurements of excess enthalpies to evaluate simultaneously the equilibrium constant and the standard enthalpy of association reactions. In principle, the calorimetric results presented in this paper could be treated in a similar way. We could then compare the values of *both* the association equilibrium constant and the standard enthalpy of association for chloroform + triethylamine with the values determined by other workers. In practice, analysis of our calorimetric results in this manner is complicated by the need for corrections due to chloroform/cyclohexane and triethylamine/cyclohexane interactions and leads to large uncertainties in the values of K and ΔH^θ. We have, therefore, chosen to assume that the value of $K = 2.6$ (8) is correct and to calculate the molar enthalpy of association as described above.

Discussion

Table 4 shows that the values of the molar enthalpy of chloroform–triethylamine complex dissociation determined in this work are independent of both the ratio of chloroform to triethylamine and the amount of cyclohexane in the mixture within the uncertainties of the calculations and the measurements. Our average value of the average enthalpy of complex dissociation is $\Delta H^\theta = 16.7 \pm 0.6$ kJ mol^{-1}. This average enthalpy is in excellent agreement with $\Delta H^\theta = -17.0 \pm 0.5$ kJ mol^{-1} that Hepler *et al.* (8) obtained for the enthalpy of complex association in the binary (no solvent) chloroform + triethylamine system from results of calorimetric experiments and the ideal associated solution model. This agreement shows that the same thermodynamic quantities ($\Delta H^\theta = 17$ kJ mol^{-1}, $K = 2.6$) can be used to describe the chloroform + triethylamine system both as a pure binary system and as a binary system dissolved in cyclohexane (and by inference, other "inert" solvents). We therefore conclude that the ideal associated

For personal use only.

solution model can provide a useful approach to the analysis of data for A + B = AB systems when these systems are dissolved in some inert solvent.

That the model can provide a good approximation to associated systems in dilute solutions in an "inert" solvent is fortunate because there exists a large body of spectroscopic work in which dilute solutions of associated systems have been studied. The results of these studies are almost always analysed according to the ideal associated solution model. That is, it is assumed that physical interactions between the components are unimportant compared with the chemical interactions. A second assumption is then usually made: the thermodynamic properties of associated systems in dilute solution are the same as those that would be observed in binary mixtures (A + B = AB, no solvent). In this paper we have shown that, at least in the case of chloroform + triethylamine in cyclohexane, both assumptions are justified. Further experimentation is necessary to ascertain whether these assumptions are valid in general or are valid only for certain specific cases.

Received July 20, 1988[2]

GERALD BERNARDINELLI, DIANE DEGUENON, REGIS SOULES, and PAULE CASTAN. Can. J. Chem. **67**, 1158 (1989).

The synthesis and magnetic data of four copper(II) complexes obtained from squaric acid and bipyridyl or imidazole as ligand are described. $Cu(C_4O_4)(imidazole)_2 \cdot 2H_2O$ (compound **I**) is made of chains of squarato-1,3-bridged Cu(II) ions. The compound crystallizes in the monoclinic system, space group $P2_1/n$, and lattice parameters $a = 7.455(2)$ Å, $b = 8.196(2)$ Å, $c = 11.235(2)$ Å and $\beta = 100.55(2)°$. $R_F = 0.067$ for 1076 observed reflections. $[Cu_2(bipyridyl)_2(C_4O_4)(H_2O)_4](C_4O_4H)_2 \cdot 4H_2O$ (compound **II**) is a $C_4O_4H^-$ salt of a squarato-1,3 bridged centrosymmetric Cu(II) dimeric cation. The compound crystallizes in the triclinic system, space group P-1 and lattice parameters $a = 9.021(2)$ Å, $b = 9.017(2)$ Å, $c = 12.581(4)$ Å, $\alpha = 98.58(2)°$, $\beta = 106.81(2)°$, and $\gamma = 106.03(2)°$. $R_F = 0.038$ for 2376 reflections. Each copper atom is pentacoordinated in a distorted square-based pyramidal and is linked by two nitrogen atoms of the bipyridyl, one oxygen atom of the squarato bridge, and one oxygen atom of a water molecule in the plane and one water molecule out of plane. $[Cu_2(bipyridyl)_2(C_4O_4)(H_2O)_2Br_2]$ (compound **III**) is a squarato-1,3 bridged copper(II) dimer. The compound crystallizes in the monoclinic system, space group $P2_1/n$, and lattice parameters $a = 10.480(4)$ Å, $b = 8.503(1)$ Å, $c = 14.590(2)$ Å, and $\beta = 99.75(2)°$. $R_F = 0.048$ for 1423 reflections. Each copper atom is pentacoordinated in a distorted square-based pyramidal and is linked by two nitrogen atoms of the bipyridyl, one oxygen atom of the squarato bridge and one oxygen atom of a water molecule in the plane, and one bromine atom out of the plane.

In complexes **I**, **II**, and **III**, the magnetic susceptibility data could be best described by neglecting the exchange coupling. The magnetic data of $[Cu(bipyridyl)(C_4O_4) \cdot 4H_2O]_n$ (**IV**) are best explained in terms of an alternating Heisenberg ferromagnet. The epr spectra ratify results obtained from magnetic and crystallographic measurements.

Key words: squaric acid, 3,4-dihydroxy-3-cyclobutene-1,2-dion, copper(II) dimers, copper(II) chains, magnetic properties.

GERALD BERNARDINELLI, DIANE DEGUENON, REGIS SOULES et PAULE CASTAN. Can. J. Chem. **67**, 1158 (1989).

Nous décrivons la synthèse et les propriétés magnétiques de quatre complexes du cuivre(II), de l'acide squarique agissant comme ligand pontant entre deux atomes de cuivre et du bipyridyle ou de l'imidazole. La structure radiocristallographique de trois d'entre eux a été obtenue. Le complexe $Cu(C_4O_4)(imidazole)_2 \cdot 2H_2O$ (complexe I) est composé de chaînes dans lesquelles l'anion squarate ponte les atomes de cuivre par ses positions 1,3. Le composé cristallise dans le système monoclinique, groupe d'espace $P2_1/n$, les paramètres de la maille étant $a = 7{,}455(2)$ Å, $b = 8{,}196(2)$ Å, $c = 11{,}235(2)$ Å et $\beta = 100{,}55(2)°$. $R_F = 0{,}067$ pour 1076 réflexions observées. Le complexe $[Cu_2(bipyridyle)_2(C_4O_4)(H_2O)_4](C_4O_4H)_2 \cdot 4H_2O$ (complexe **II**) est un sel de $C_4O_4H^-$ et d'un cation centrosymétrique ou deux atomes de cuivre sont pontés par un ion $C_4O_4^{2-}$. Ce composé cristallise dans le système triclinique, avec un groupe d'espace P-1 et les paramètres de maille suivants : $a = 9{,}021(2)$ Å, $b = 9{,}017(2)$ Å, $c = 12{,}581(4)$ Å, $\alpha = 98{,}58(2)°$, $\beta = 106{,}81(2)°$ et $\gamma = 106{,}03(2)°$. $R_F = 0{,}038$ pour 2376 réflexions. Chaque atome de cuivre se trouve dans un environnement de pyramide à base carrée déformée. La coordination dans le plan est assurée par deux atomes d'azote du bipyridyle, un atome d'oxygène du pont squarate et un oxygène d'une molécule d'eau. La seconde molécule d'eau occupe la position axiale. Le complexe $[Cu_2(bipyridyle)_2(C_4O_4)(H_2O)_2Br_2]$ (complexe **III**) est aussi un dinucléaire du cuivre, où l'ion squarate agit comme pont. Le composé cristallise dans le système monoclinique, groupe d'espace $P2_1/n$, les paramètres de la maille étant $a = 10{,}480(4)$ Å, $b = 8{,}503(1)$ Å, $c = 14{,}590(2)$ Å et $\beta = 99{,}75(2)°$. $R_F = 0{,}048$ pour 1423 réflexions. Chaque atome de cuivre se trouve dans un environnement de pyramide à base carrée déformée. La coordination dans le plan est la même que celle du complexe **II** et un atome de brome occupe la position axiale. Dans les complexes **I**, **II** et **III**, aucun couplage magnétique n'est observé entre les atomes de cuivre. Le comportement magnétique du complexe **IV** $[Cu(bipyridyle)(C_4O_4) \cdot 4H_2O]_n$ ne peut être justifié qu'en utilisant le modèle d'une chaîne alternée d'Heisenberg. L'étude epr est en accord avec les données cristallographiques et les résultats de l'étude magnétique.

Mots clés : acide squarique, 3,4-dihydroxy-3-cyclobutene-1,2-dione, dimères du cuivre(II), chaînes de cuivre(II), propriétés magnétiques.

[Traduit par la revue]

Introduction

Squaric acid gives rise to a wide variety of complexes with transition metal compounds. The squarate anion $(C_4O_4)^{2-}$ does not behave like a chelating ligand but rather like a bridge between two or more metal atoms as uni- or multimonodentate ligand. In all the cases described so far, each site of coordination of squaric acid is coordinated to a different metal atom and either mono-dimensional chain or bi-dimensional or tri-dimensional polymers are obtained.

Moreover, interaction between paramagnetic metal ions in coupled systems has been extensively studied for many years. As early as 1977, Hendrickson and co-workers (1) have focussed on Cu(II) dimers bridged by small molecules and have described oxalate-bridged complexes exhibiting large antiferromagnetic exchange interaction. Keeping in mind analogies between squarate

and oxalate ions, some copper squarate complexes have been investigated but not structurally identified (1, 2). We report here the study of some copper complexes obtained from copper(II) and squaric acid as ligand. From this work, it may be underlined that in such chemistry, it is very hazardous to postulate some "interesting magnetic properties" from a study of amorphous compounds since three hardly different complexes may be isolated from the same synthesis. In the present paper, the crystal structures of three copper complexes of squaric acid and bipyridyl or imidazole are reported.

Experimental

Synthesis

Compound ***I****, catena-poly-diaquabis(imidazole)copper(II)-μ-squarato(1,3)*

Transparent green–blue crystals of $Cu(C_4O_4)(imidazole)_2 \cdot 2H_2O$ were slowly grown from a mixture of $CuCl_2 \cdot 2H_2O$ in water (10 cm^3; 0.01 mol dm^{-3}), $H_2C_4O_4$ in water (10 cm^3, 0.01 mol dm^{-3}), and imidazole in water (10 cm^3, 0.02 mol dm^{-3}). The solution rapidly turned green. After 2 h, a green microcrystalline precipitate appeared and was filtered off. Green needles could be isolated from the resulting solution. The two fractions obtained have the same analysis. *Anal.* calcd. for $[Cu(C_3N_2H_4)_2(C_4O_4)(H_2O)_2]_n$: C 34.53, H 3.45, N 16.11, Cu 18.28; found: C 34.58, H 3.49, N 15.36, Cu 18.01.

Compound ***II****, $[Cu_2(C_{10}H_8N_2)_2(C_4O_4)(H_2O)_4](C_4O_4H)_2 \cdot 4H_2O$, [μ-squarato(1,3)-bis(diaqua(2,2'-bipyridyl)copper(II))] bis(hydrogenosquarate) tetrahydrate, and* ***III*** *$[Cu_2(C_{10}H_8N_2)_2(C_4O_4)(H_2O)_2Br_2]$, μ-squarato(1,3)-bis(aquabromo(2,2'-bipyridyl)copper(II))*

A solution of 0.001 mol of bipyridyl dissolved in 10 mL of ethanol was slowly added to a water solution of $CuBr_2$ (0.001 mol in 10 mL). The resultant solution was added to a solution of squaric acid (0.001 mol in 10 mL of $EtOH/H_2O$ 50/50). After about 1 week, emerald green crystals were separated (compound **II**). Shortly after, slightly darker crystals appeared (compound **III**). The two compounds could be unambiguously assigned by EDAX spectroscopy since compound **II** only contains copper as heavy atoms while compound **III** has a Cu/Br ratio close to 1. *Anal.* calcd. for $[Cu(C_{10}H_8N_2)(C_4O_4)_{0.5}(H_2O)_2]_2(C_4O_4H)_2 \cdot 4H_2O$ (compound **II**): C 41.69, H 3.72, N 6.08; found: C 41.75, H 3.67, N 6.02. *Anal.* calcd. for $[Cu(C_{10}H_8N_2)(C_4O_4)_{0.5}Br \cdot H_2O]_2$ (compound **III**): C 38.57, H 2.70, N 7.50; found: C 38.56, H 2.66, N 7.43.

Compound ***IV****, $[Cu(C_{10}H_8N_2)(C_4O_4) \cdot 4H_2O]_n$, catena-poly-tetraaqua(2,2'-bipyridyl)copper(II)-μ-squarato(1,3)*

Copper(II) squarate $\cdot 2H_2O$ was prepared following the procedure of West and Niu (3). This product (1×10^{-3} mol) was suspended in 20 mL of $EtOH/H_2O$ (50/50). A solution of 0.001 mol of bipyridyl dissolved in 10 mL of ethanol then was added slowly under stirring and gentle warming (60°C) until copper squarate dissolved. From this solution, compound **IV** crystallized with time as thin needles. *Anal.* calcd. for $Cu(C_4O_4)(C_{10}H_8N_2) \cdot 4H_2O$ (compound **IV**): C 41.64, H 3.99, N 6.94, Cu 15.74; found: C 41.61, H 3.41, N 6.88, Cu 15.62.

Measurements

Pertinent data about the crystals used and the measurement of diffraction intensities are summarized in Table 1. Intensity data for compounds **I** and **III** were collected on a Philips PW 100 diffractometer, those for compound **II** on an Enraf-Nonius CAD-4 diffractometer. The structures were solved by direct methods using the program MULTAN 80 (4) for complex **I** and MULTAN 84 (5) for complexes **II** and **III**. Anisotropic temperature factors were used for the non-hydrogen atoms. All hydrogen atoms were located on a Fourier difference map for compound **II**, but only those of water molecules for compounds **I** and **III** while the other ones were introduced into the calculations with common isotropic thermal parameters. The functions minimized were $\Sigma\omega[|F_o| - |F_c|]^2$.

Routine ir spectra were recorded on a Perkin Elmer 577 spectrophotometer using KBr pellets.

Magnetic susceptibility data were collected on powdered samples of the compounds using a Faraday-type magnetometer with mercury tetrakis(thiocyanato)cobaltate (susceptibility at 20°C, 16.44×10^{-6} cm^3 mol^{-1}) as susceptibility standard. Data were corrected for dimagnetism of the ligands estimated from Pascal constants (6).

Electron paramagnetic resonance spectra of powdered samples were recorded on a Bruker 200TT spectrometer at 77 K (sample immersed in liquid nitrogen) and room temperature using X-band frequencies.

Results and discussion

Description and discussion of the crystal structures

ORTEP drawings of the complexes showing the atom numbering scheme are given in Fig. 1. The final fractional atomic coordinates with estimated standard deviations are presented in Table 2 (compound **I**), Table 3 (compound **II**), and Table 4 (compound **III**). Selected interatomic bond distances and valence angles are given in Table 5. Hydrogen bonds are reported in Table 6.

Figure 1 shows that the crystal structure of complex **I** consists of chains, running parallel to the *b* axis, built up of *trans* squarato bridged copper(II) ions. Within each chain, each metal atom is octahedrally coordinated by two water molecules, two imidazole ligands, and two oxygen atoms of two different squarato ligands.

The chains of copper(II) are held together by strong hydrogen bridges between the water molecules and the noncoordinating squarato oxygen atoms on the one hand, and between the imidazole hydrogen atoms and the squarato coordinated oxygen atoms on the other hand (see Table 6).

This chain looks like the one observed in the homologous nickel(II) complex (NISIA) studied by Reedijk *et al.* (7). However, an important difference may be underlined in the squarae ring since in NISIA the carbon–carbon bond lengths (1.463 and 1.470 Å) are close to the value reported for $NiC_4O_4(H_2O)_2$ while in the copper complex (CUSIA), the carbon–carbon bond lengths of the squarato anion are 1.55 and 1.50 Å, respectively. To our knowledge, these are the longest bond lengths observed for such an anion, although the bond lengths in $[Pt_2(C_4O_4)_4]^{4+}$ are quite long (*i.e.* 1.533 and 1.463 Å, respectively) (8). Keeping in mind the 1.56 Å bond lengths in cyclobutane (9), it seems that this oxocarbon dianion is non-aromatic although the squarato anion is almost planar. The π-electron distributions are different in CUSIA and in the squarate ion, the greatest C—C bond lengths implying shorter C—O bond lengths (1.241 and 1.228 Å in CUSIA, 1.260 Å in potassium squarate monohydrate) (10). The C—C—C angles are very close to 90°. The geometry of the imidazole ligand is similar to that of reported data and therefore will not be discussed more in detail.

In contrast with compound **I** where Ni(II) and Cu(II) complexes are quite isostructural, the reaction of squaric acid with copper salts in the presence of bipyridyl does not give rise to linear chains with metal atoms cis-bridged squarate as for Ni(II) (11). This type of chain is only obtained by reaction of copper(II) squarate previously isolated (3) with bipyridyl (complex **IV**). Compounds **II** and **III** are two dinuclear complexes.

In compound **II**, two copper(II) ions are bridged by a squarato ion in a *trans* mode. Thus, each copper(II) is five-coordinated. The four equatorial donor atoms, *i.e.*, two nitrogen atoms from 2,2'-bipyridine, one oxygen atom of a water molecule, and one oxygen atom of the squarate ion are almost planar (maximum deviation = 0.044 Å for N(1)). The Cu atom is located at 0.169 Å above this mean plane.

Square-planar copper(II) has a decided tendency to extend its coordination sphere to five, the so-called (4 + 1) geometry

(12), or to six (4 + 2) geometry. In complex **II**, the coordination sphere is extended to five by an axial water molecule, the Cu—O(w2) bond length of which is 0.222 Å smaller than the Cu—O(w1) bond of water in the plane.

The metal-bonded squaric dianion exhibits bond lengths and angles similar to those observed in squaric complexes. The O—C—C angles vary between 132.5 and 135.30° and the C—C—C angles are very close to 90° as in $CuC_4O_4(H_2O)_2$ where they are equal to 85.54 and 90.56°, respectively (13). In complex **II**, charge equilibrium is obtained by a non-bonded monoacidic squaric ion (HSq^-) and the bond lengths within the HSQ^- ion do not deviate greatly from those found in H_2Sq (14). The average C—O hydroxylic bond (1.305 Å) is similar to that observed in H_2Sq (1.291 Å) and little longer than that of $LiHSq\cdot H_2O$ (1.285 Å) (15). The average C—O bonds in the diketonic group (1.221 to 1.245 Å) are also in agreement with those found in $LiHSq\cdot H_2O$ (1.232 Å) or in H_2Sq (1.229 Å). Very small deviations are observed for the C—C bonds, the nearly "double" and "single" bonds being recognizable (1.428 Å and 1.492 Å, respectively). We have to note that even in HSq^-, carbon–carbon bond lengths are significantly shorter than in the bonded squarate of complex **I**. The molecular packing is fixed by a network of hydrogen bonds involving all potential donors (see Table 6).

The internal geometry of the bipyridine ligand is normal and will not be discussed further.

As already noticed, complexes **II** and **III** are obtained from the same preparative batch and their structures are very similar. Again the copper complex is dinuclear with the two metallic centers bonded by a squarate ligand. Bond lengths in the squarate entity are quite similar, as evidenced by Table 5. Here again, the square planar copper extends its coordination to five but in complex **III** a bromide ion changes places with the axial water molecule, allowing charge equilibrium. No hydrogen bonds or short interatomic contacts was observed for compound **III**. We have been informed[3] that a similar complex has

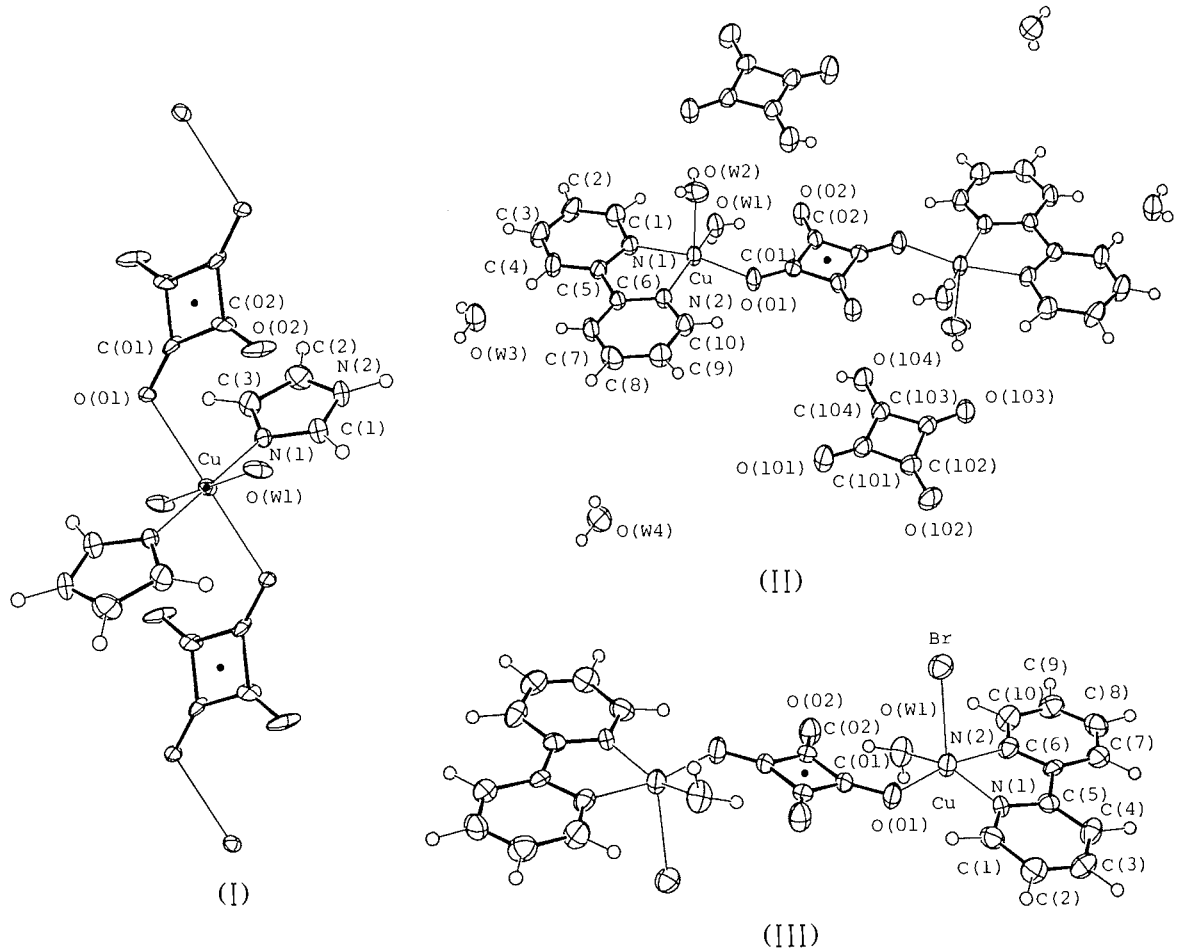

FIG. 1. Perspective view of compounds **I**, **II**, and **III** (■ indicates the position of the center of inversion).

recently been obtained with the bromide ion substituted by a NO_3^- ion. The structure of complex **IV** has not been determined, but from powder diffraction data show it is assumed to be the homologous Ni(II) complex already described as an infinite chain with squarato entities bonding metal atoms in a *cis* mode (11).

Spectroscopic data

As already discussed, the interpretation of the infrared spectra of squaric containing molecules is not straightforward. The infrared spectrum of complex **I** displays a broad and intense band located around 3100–2900 cm^{-1}. This observation agrees with structural data, pointing to the presence of strong hydrogen bonds. These bands may be attributed to the OH group of the water molecules. By contrast, complex **II** exhibits two bands in the same region (at 3150 and 3200 cm^{-1}, respectively), corresponding to O—H stretching vibrations of water molecules. In the same region, the C—H bands of the aromatic ring of bipyridyl may be identified. For complex **III**, the ir spectrum in the 3000 cm^{-1} region is almost identical to that of complex **II**.

All three complexes exhibit a very strong and extremely broad band near 1500 cm^{-1}. This type of absorption is characteristic of salts of $C_nO_n^{2-}$ ions (16) and was observed in $K_2C_4O_4$. This large band is slightly splitted, suggesting when compared to $K_2C_4O_4$ that symmetry is lower than D_{4h}, as evidenced by the X-ray investigation. In complex **II** a strong sharp band appears at 1780 cm^{-1} which is not present in the other two spectra. Our infrared studies show that this band appears at 1805 cm^{-1} for the $NaHC_4O_4$ molecule and at 1804 cm^{-1} in a complex of platinum, $[Pt(ethylenediamine)_2](C_4O_4H)_2$.[4] This band is attributed to a free non-coordinated carbonyl of the squaric entity.

In the far ir spectra, all the complexes exhibit two well-resolved absorption bands in the 400 cm^{-1} region (complex **I**: 400–380; complex **II**: 388–375; complex **III**: 410–375; complex **IV**: 419–370). Since metal–oxygen vibration bands are more intense compared to metal–nitrogen ones, these absorptions have been attributed to metal–oxygen. While Cu—Ow occurs generally near or higher than 400 cm^{-1}, the first band is attributed to the Cu–Ow stretching vibration while the other one is attributed to the Cu—Osq vibration. Since M—O stretching vibrations are metal-sensitive and are shifted to higher frequencies in the order Ni(II) < Cu(II) (17), the assignments may favorably compare with those proposed for NISIA (7), the homologue of complex **I**, viz. 400 ($\nu_{Ni—Ow}$) and 369 ($\nu_{Ni—Osq}$), respectively.

Magnetic susceptibility

The $1/\chi$ versus temperature curves for compounds **I**, **II**, and **III** are not reproduced here since the χ_M values obey the Curie–Weiss law, i.e. $\chi_M = (C/T) - \theta$. Table 7 reports the C, θ, and g values which correspond well to a Cu(II) ion without any interaction between metallic centers. The negative value of θ

Mean values (deg) for the noncoordinated squarate of complex **II**:
O—C—C = 135.0 C—C—C = 90.0

*The primed atoms are generated through the center of inversion. The Cu atom of the complex **I** and the coordinated squarate of the complexes **I**, **II**, and **III** are located on a center of inversion.

for compound **I** suggests the occurrence of a weak antiferromagnetic interaction, as expected for a two-dimensional interchain interaction caused by the hydrogen bonds between the water molecule and the oxygen of the squarate ion.

Generally, in the least-squares fitting, it is best to use the *g* value obtained for epr measurements. However, in order to obtain a satisfactory fit to the magnetic data the average *g* value had to be adjusted. As for compound **II** it was necessary to fix *g* at 2.26 in order to get the best least-squares fit of the data.

Magnetic susceptibility data for compound **IV** are given in Fig. 2. The maxima in the susceptibility curves provide evidence for antiferromagnetic interactions. The data follow the Curie–Weiss law above 30 K, yielding $C = 0.45$ emu K/mol ($g = 2.19$) and $\theta = -29.47$ K. Below 30 K, there is a marked

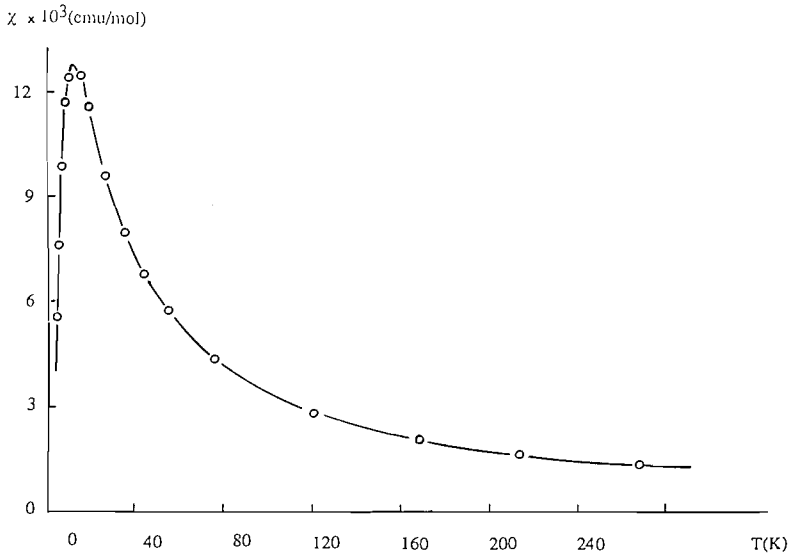

FIG. 2. Molar susceptibility versus T for complex **IV**. The drawn line represents the theoretical values, calculated with the susceptibility expression of an Heisenberg alternating chain, $J = 7.1\,cm^{-1}$, $g = 2.05$, $\alpha = 0.63$.

No hydrogen bond was observed below 3.2 Å.			

deviation from Curie–Weiss behavior and the susceptibility appears to tend to zero as the temperature approaches zero.

Since it has been proved that this compound is analogous to Ni(bipyridyl)(sq^{2-})·$2H_2O$ already described, attempts were made to fit magnetic data with the 1-D Heisenberg chain model. Bonner and Fischer (18) have performed exact calculations on small systems of $S = 1/2$ Heisenberg spins and have been able to extrapolate the infinite 1-D limit.

Furthermore, the fit of the Bonner–Fischer curve to the following rational function of $|J|/kT$ has been proposed (19):

$$\chi \approx [(N^2g^2\beta^2)/kT][(0.25 + 1.14995X + 0.30094X^2) \times (1.0 + 1.9862X + 0.68854X^2 + 6.0626X^3)]$$

where $X = |J|/kT$.

Agreement between susceptibilities calculated by the above equation and experimental data is excellent up to 30 K, with an exchange constant J near $-7\,cm^{-1}$. Below 30 K, the agreement is not as good and the susceptibility does not tend to zero at lower temperatures.

Actually, it is well known that the behavior expected for an infinite chain is that susceptibility tends to a non-zero value as the temperature reaches zero. In contrast, in small clusters containing even multiples of $S = 1/2$, the susceptibility tends to zero as the temperature tends to zero (18).

Consequently, we have used the model of an isolated Heisenberg dimer of $S = 1/2$ ions to analyze the data. The susceptibility of this model (20) has been shown to be:

$$\chi \approx [(Ng^2\beta^2)/kT][e^x/(1 + 3e^x)]$$

where $x = -2J/kT$.

This expression predicts the antiferromagnetic exchange constant to be related to the temperature of the maximum susceptibility (T_{max}) as $J/k = -0.801T_{max}$. Since T_{max} is 15 K for this compound, the exchange constant should be close to −12 K ($-8.3\,cm^{-1}$) if this is the appropriate model. A very good fit is obtained with this model with a J value of $-8\,cm^{-1}$ and $g = 1.94$.

A magnetic study of a copper complex described as $[Cu_2(phen)_4sq](ClO_4)_2$ has been published without X-ray structural investigation (2). Temperature-dependence studies of the magnetic susceptibility of this compound indicate antiferromagnetic exchange interaction. Susceptibility vs. temperature maxima occur at 17.2 K in this complex and a good fit has been obtained with $J = -10.1\,cm^{-1}$ with a dimer model.

To this point, it may be underlined that for compound **IV**, a similar model gives a good fit with experimental data while it seems that, in view of X-ray powder study, this compound is best described as an infinite chain.

In many exchange-coupled transition metal compounds with linear-chain structure, attempts to fit the magnetic data by the uniform Heisenberg-chain model have failed. This is the case for $Cu(NO_3)_2·2.5H_2O$ (21), a compound which has a ladder-like structure at room temperature (22). The magnetic properties of this compound, which is the most thoroughly studied example, may only be explained with an alternating Heisen-

berg chain structure model. Other examples of copper compounds which have alternating-chain structures and attendant magnetic properties have been described as pyrazine-bridged binuclear copper acetate chains (23). X-ray structural studies at room temperature on a single crystal of Cu(N—Me-imidazole)$_2$Br$_2$ reveal a uniform chain (24). However, magnetic data have suggested that this material is an alternating Heisenberg antiferromagnet (25). For catena-di-μ chloro-bis(4-mefylpyridine)copper(II) (26), dielectric measurements provide evidence for structural transformations near 50 K, in agreement with the hypothesis of the alternating linear chain model. It may be underlined that, in such a model, the susceptibility tends to zero as the temperature tends to zero, like in dimers or even short clusters.

With this in view, the magnetic data for compound **IV** have been analyzed in terms of the alternating chain model. The Hamiltonian for the Heisenberg alternating chain may be written as:

$$H = 2J \sum_{i=1}^{n/2} [S_{2i}S_{2i-1} + \alpha S_{2i}S_{2i+1}]$$

where J is the exchange integral between a spin and its neighbor on the right, and αJ is the exchange integral between a spin and its neighbor on the left. The model is particularly interesting for antiferromagnetic exchange ($J < 0$) and for $0 \leq \alpha \leq 1$. This model has been largely studied by Duffy and Barr (27) and we have used the parameters proposed by Hatfield *et al.* (25) fitted for ten alternating chain cases.

With the values $J = -7.1\,\text{cm}^{-1}$, $g = 2.05$, and $\alpha = 0.63$, a good fit is obtained between calculated and experimental data, as viewed in Fig. 2.

While apparently structural studies for compound **IV** reveal a uniform chain structure, this remains a fascinating puzzle which certainly deserves room temperature and low temperature structural studies.

Electron paramagnetic resonance spectroscopy

Copper(II) complexes are particularly amenable to examination by epr since two types of information can be obtained. The pattern of g values for a given complex allows us to get insight into the coordination geometry around the copper(II) ion. Moreover, particularly in the case of dinuclear complexes, spectral features characteristic of magnetic exchange between the copper(II) ions may be observed. In a Cu(II) dimer, each Cu(II) ion has one unpaired electron in a d-type orbital, and to first order, the antiferromagnetic interaction reflects the level of spin–spin interactions.

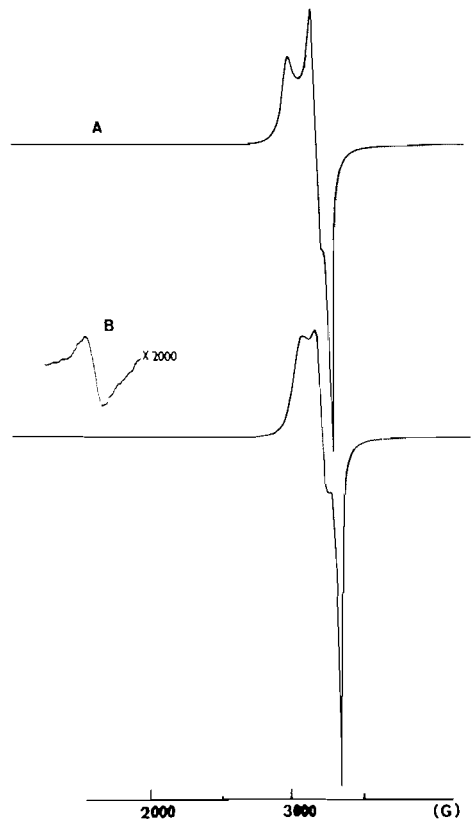

FIG. 3. Liquid-nitrogen X-band epr spectra: *A*, compound **I**; *B*, compound **III**.

The four complexes prepared in this study were investigated by epr spectroscopy at X-band frequencies both at room temperature and *ca.* 90 K. The spectra do not change when the temperature changes and only a slightly better resolution of signals is observed at the lower temperature.

For complexes **I**, **II**, and **III**, the epr data bear out the results of magnetic susceptibility studies. Each of the three compounds shows an asymmetric signal of *ca.* 3200 G in its X-band spectrum that is characteristic of a lone copper(II) ion. No hyperfine splitting was obtained. The asymmetric signal is characteristic either of a paramagnetic Cu(II) monomer or of a polymer without metal interactions (Fig. 3).

A formally forbidden transition, $\Delta m_s = 2$, is also observed for compounds **II** and **III** at "half-field" (1600 G) but at an intensity of 5×10^{-3} times the full-field transition.

In the epr spectra some points are of interest and may be underlined. The spectrum is strongly nonaxial, which reflects a noticeable distortion of the geometries. The values of g_1, g_2, and g_3 do not allow to precise geometry. First of all, the high field signal at $g = 2.09–2.07$, i.e. >2.04, will be consistent either with an elongated rhombic–octahedral geometry, which is the case for complex **I**, or for a distorted square-based pyramidal stereochemistry, which is the case for the two dimers (28, 29).

Actually, complexes structurally quite different such as an infinite chain with each copper atom in a quasi octahedral surrounding and a dinuclear with a penta-coordinated metal offer strongly similar epr spectra. In these two cases, the one-electron ground state is $d_{x^2-y^2}$.

The room temperature epr spectra of complex **IV** show only one broad uninterpretable signal with a pronounced hump at $g = \sim 2.04$ and apparent g values of 2.25 and 2.08. No additional information could be obtained upon decreasing the temperature of the sample to 77 K.

L. GIROUX, M. H. BACK, and R. A. BACK. Can. J. Chem. **67**, 1166 (1989).

The photolysis of ethylene has been studied at pressures from 50 to 3000 Torr using a pulsed ArF excimer laser at 193.3 nm. Major products were acetylene, *n*-butane, 1-butene, ethane, and 1,3-butadiene, with smaller amounts of propane, propene, methane, and allene. Quantum yields varied with pressure and reaction time; the latter dependence is ascribed to secondary photolysis of butene and butadiene. The reaction products are accounted for by three primary processes:

[1] $C_2H_4 + h\nu \rightarrow C_2H_2 + H_2$

[2] $\rightarrow C_2H_2 + H + H$

[3] $\rightarrow C_2H_3^{\ddagger} + H$

followed by reactions of H, C_2H_3, and C_2H_5 radicals. The vibrationally excited $C_2H_3^{\ddagger}$ radical can decompose to H + C_2H_2 or can be stabilized by collision. The pressure dependence of the quantum yields of the primary processes [1]–[3] is complex, and a photodissociation mechanism involving several intermediates and excited states of ethylene is presented to account for the present results and previous measurements at 185 nm.

Key words: ethylene, uv photolysis.

L. GIROUX, M. H. BACK et R. A. BACK. Can. J. Chem. **67**, 1166 (1989).

On a étudié la photolyse de l'éthylène à l'aide d'un laser excimère ArF pulsé à 193,3 nm et en opérant à des pressions allant de 50 à 3000 Torr. Les produits principaux sont l'acétylène, le *n*-butane, le butène-1, l'éthane, le butadiène-1,3 ainsi que des quantités plus faibles de propane, de propène, de méthane et d'allène. Les rendements quantiques varient avec la pression et la durée de la réaction; cette dernière dépendance est attribuée à des photolyses secondaires du butène et du butadiène. On explique la formation des produits réactionnels à l'aide de trois processus primaires :

[1] $C_2H_4 + h\nu \rightarrow C_2H_2 + H_2$

[2] $\rightarrow C_2H_2 + H + H$

[3] $\rightarrow C_2H_3^{\ddagger} + H$

qui sont suivis de réactions avec des radicaux H, C_2H_3 et C_2H_5. Le radical $C_2H_3^{\ddagger}$ peut se décomposer en H + C_2H_2 ou être stabilisé par collision. La relation entre la pression et les rendements quantiques des processus primaires [1] à [3] est complexe; afin d'expliquer les résultats actuels ainsi que les mesures faites antérieurement à 185 nm, on propose un mécanisme de photodissociation impliquant plusieurs intermédiaires et des états excités de l'éthylène.

Mots clés : éthylène, photolyse uv.

[Traduit par la revue]

Introduction

The photolysis of ethylene in the far UV has been studied many times in a number of laboratories. The most thorough work and most relevant to the present paper has been done at 185 nm with a mercury resonance lamp (1–4), but results have also been reported at a number of shorter wavelengths. The photolysis was reviewed by McNesby and Okabe (5) and more recently by Collin (6). Three primary processes have been demonstrated to occur:

[1] $C_2H_4 + h\nu \rightarrow C_2H_2 + H_2$

[2] $\rightarrow C_2H_2 + 2H$

[3] $\rightarrow C_2H_3 + H$

with the relative yields showing some dependence on wavelength. Few measurements have been reported at wavelengths longer than 185 nm. Potzinger *et al.* did one or two experiments with a weak carbon-resonance lamp at 193 nm (2), and there is a brief unpublished report by Irion (7) of the photolysis with an ArF laser at 193 nm. The present paper describes a systematic study of the photolysis with an ArF laser at 193 nm.

Experimental methods

The photolysis vessel was a short cylinder, 0.5 cm long and 2.0 cm in diameter, made from a brass annulus 0.5 cm thick with plane Suprasil quartz windows cemented to each side with Apiezon W black wax. Two small-bore tubes through the annulus led with minimum dead space to valves which permitted attachment to a vacuum line for pumping or filling, or connection as the sample loop of a gas chromatograph, so that the entire contents of the vessel could be injected for analysis.

The light source was a pulsed ArF excimer laser (Lumonics 820 Series) with pulse energies typically between 15 and 30 mJ, operating at a pulse rate of 1 Hz. The beam was unfocussed and stopped down to a diameter of 1.04 cm to avoid striking the vessel walls. Care was taken to minimize heating of the front window and to avoid any build-up of solid material which could lead to local heating, and windows were cleaned or replaced whenever traces of a deposit became evident. Incident and transmitted power or pulse energy were measured with a Scientech Model 36-0001 disc calorimeter. Absorption by ethylene

TABLE 1. Quantum yields of products from the photolysis of ethylene, at 193 nm and 760 Torr, vs. number of laser pulses

Product	Initial extrapolated value	Yield when number of pulses = 10	25	50	100	250
C_2H_2	0.42	0.42	0.42	0.41	0.42	0.41
n-C_4H_{10}	0.069	0.071	0.075	0.076	0.081	0.084
1-C_4H_8	0.096	0.089	0.088	0.078	0.069	0.049
C_2H_6	0.047	0.048	0.051	0.052	0.055	0.061
1,3-C_4H_6	0.025	0.019	0.013	0.0092	0.0057	0.0028
C_3H_8	0.00	—	—	0.0065	0.010	0.020
C_3H_6	0.0050	0.0059	0.0089	0.0090	0.011	0.016
CH_4	0.0007	0.0012	0.0019	0.0027	0.0044	0.0069
C_3H_4	0.00	0.00037	0.00079	0.0011	0.0016	0.0021

followed Beer's Law, and a value of the molar decadic absorption coefficient of 5.63 (±0.14) M^{-1} cm^{-1} was obtained for the ArF laser radiation, which had a central wavelength of 193.3 nm and a band width (FWHM) of about 0.5 nm. For quantum yield measurements, the transmitted energy was monitored during the experiment, and the absorbed energy was calculated from the absorption coefficient, making allowance for window losses and back reflection.

Ethylene was Matheson Research-grade, used after rigorous degassing but no other purification. Trace impurities present were C_2H_2 and C_2H_6, each about 13 ppm; these were measured by GC in suitable blank experiments and corrections applied to the observed yields of these products. A variety of columns were employed for analysis; products were identified by comparison with standard mixtures and by mass spectrometry, and quantitative calibrations were made with synthetic mixtures similar in composition to the reagent–product mixture.

Results and discussion

Products and time dependence of their quantum yields

The major products observed, in approximate order of decreasing importance, were C_2H_2, n-C_4H_{10}, 1-butene, C_2H_6, and 1,3-butadiene. Minor products were C_3H_8, propene, CH_4, and allene. At higher conversions, traces of 2-butene and methylcyclopropane were observed, and some C_4 and C_5 hydrocarbons were tentatively identified, including 1,2-butadiene, diacetylene, 1,4-pentadiene, 1-pentene, and n-pentane. Hydrogen, known from previous work to accompany C_2H_2 in reaction [1], was also undoubtedly a major product but was not measured. Quantum yields of products from the photolysis at 760 Torr of C_2H_4 are shown in Table 1 as a function of the number of laser pulses, with incident pulse energies between 19 and 22 mJ; these data are also shown in Figs. 1 and 2. Of the major products, the quantum yield of C_2H_2 is constant, those of C_2H_6 and n-C_4H_{10} increase somewhat, while those of 1-butene and 1,3-butadiene decrease, the latter quite sharply, with increasing number of pulses (i.e., time of photolysis). The quantum yields of all the minor products increase markedly with time from initial values close to zero, and are all clearly secondary in origin. Because of these dependences on photolysis time, the data have been extrapolated to give initial values, primary quantum yields, as shown, and these will be used to assess the photolysis mechanism in its simplest initial stages.

The mechanism of the photolysis

The primary products of the photolysis can be accounted for by the three primary photodissociation reactions, [1], [2], and [3] followed by a sequence of reactions of hydrogen atoms and

TABLE 2. Product ratios and secondary quantum yields in the photolysis of ethylene at 193 nm and a pressure of 760 Torr vs. the number of laser pulses

Product ratio	Initial extrapolated value	Value when number of pulses = 10	25	50	100	250
$C_2H_6/(n\text{-}C_4H_{10} + 1\text{-}C_4H_8)$	0.28	0.30	0.31	0.34	0.37	0.46
$(1\text{-}C_4H_8)^2/(n\text{-}C_4H_{10})(1,3\text{-}C_4H_6)$	5.3	5.9	7.9	8.7	10.3	10.2
$n\text{-}C_4H_{10}$ (secondary)	0	2.0×10^{-3}	6.0×10^{-3}	7.0×10^{-3}	12×10^{-3}	15×10^{-3}
C_2H_6 (secondary)	0	1.0×10^{-3}	4.0×10^{-3}	5.0×10^{-3}	8.0×10^{-3}	14×10^{-3}
C_2H_6 (secondary, corrected for reaction 4)	0	0.9×10^{-3}	3.4×10^{-3}	4.3×10^{-3}	6.9×10^{-3}	12×10^{-3}
$(C_3H_8)^2/4(n\text{-}C_4H_{10})$	0	—	—	0.14×10^{-3}	0.31×10^{-3}	1.2×10^{-3}

ethyl and vinyl free radicals similar to that suggested previously (1–4):

[4] $H + C_2H_4 \xrightarrow{+M} C_2H_5$

[5] $2C_2H_5 \longrightarrow n\text{-}C_4H_{10}$

[6] $\longrightarrow C_2H_6 + C_2H_4$

[7] $C_2H_5 + C_2H_3 \longrightarrow 1\text{-}C_4H_8$

[8] $\longrightarrow C_2H_6 + C_2H_2$

[9] $\longrightarrow 2C_2H_4$

[10] $2C_2H_3 \longrightarrow 1,3\text{-}C_4H_6$

[11] $\longrightarrow C_2H_2 + C_2H_4$

[12] $H + C_2H_5 \longrightarrow [C_2H_6{}^*]$

[13] $[C_2H_6{}^*] \xrightarrow{+M} C_2H_6 + M$

[14] $\longrightarrow 2CH_3$

[15] $2CH_3 \longrightarrow C_2H_6$

[16] $CH_3 + C_2H_5 \longrightarrow C_3H_8$

[17] $\longrightarrow CH_4 + C_2H_4$

To test this mechanism and to evaluate the quantum yields of the primary photodissociation reaction, the following values were assumed for the several disproportionation/combination reactions involved: $k_6/k_5 = 0.14$ (8); $k_8/k_7 = 0.12$ (9); $k_9/k_7 = 0.03$ (9), and $k_{11}/k_{10} = 0.02$ (10). If C_2H_6 were formed only by reactions [6] and [8], and n-butane and 1-butene only by reactions [5] and [7], respectively, the ratio $C_2H_6/(n\text{-}C_4H_{10} + 1\text{-}C_4H_8)$ should have had a value between 0.14 and 0.12. In Table 2 it is seen that this ratio had an initial extrapolated value of 0.28, indicating an additional primary source of ethane. The combination of CH_3 radicals can be ruled out, since reaction [16] rather than [15] should be the predominant fate of CH_3 in the presence of excess C_2H_5 radicals, and the absence of C_3H_8 as a primary product shows that CH_3 was not a significant primary species. Reaction [13] in fact appears to be the most probable source of the extra primary C_2H_6; it can be shown that the required yield is compatible with estimates of the concentrations of H and C_2H_5 following the laser pulse, within the considerable uncertainties in the calculations.

The second ratio of interest included in Table 2 is (1-butene)^2/(n-butane)(1,3-butadiene), which should have a value of about 4 if these three products were formed by random combination of ethyl and vinyl radicals, reactions [5], [7], and [10]. The initial extrapolated value of this ratio is 5.3, and it rises to a value of 10.2 with increasing conversion. This rise is due to the sharp fall in 1,3-butadiene (Fig. 1), partly compensated by the decrease in 1-butene and the increase in n-butane. Given the uncertainties in the initial extrapolations, particularly for 1,3-butadiene, the initial extrapolated value of 5.3 is close enough to the expected value of 4 to support the conclusion that n-butane, 1-butene, and 1,3-butadiene were formed by radical combination.

Quantum yields of the primary photodissociation processes

If reactions [4] to [11] are assumed to account for all the primary products (i.e., neglecting C_2H_6 formation by reaction [13]), the quantum yields for reactions [1], [2], and [3] can be estimated from the following expressions:

$$\Phi(1) = \Phi(C_2H_2) - \Phi(2)$$

$$\Phi(2) = \tfrac{1}{2}\{2\Phi(n\text{-}C_4H_{10})(1 + k_6/k_5) + \Phi(1\text{-}C_4H_8)[1 + (k_8 + k_9)/k_7] - \Phi(3)\}$$

$$\Phi(3) = 2\Phi(1,3\text{-}C_4H_6)(1 + k_{11}/k_{10}) + \Phi(1\text{-}C_4H_8)[1 + (k_8 + k_9)/k_7]$$

It is seen that $\Phi(1)$ is given by the total yield of C_2H_2 minus that formed in reaction [2]; $\Phi(2)$ is equal to the total yield of C_2H_5 radicals (which in turn is a measure of the H atom yield), minus the H atoms formed in [3]; $\Phi(3)$ is given by the yield of C_2H_3 radicals found in the products. Values of these primary photodissociation quantum yields calculated in this way, using initial extrapolated product yields, are shown in Table 3.

If the formation of "extra" C_2H_6 noted earlier can be attributed to reaction [13], as seems probable, the quantum yield of this reaction should be added to $\Phi(2)$, and the value of $\Phi(1)$ should be reduced by a similar amount. These corrected values are also listed in Table 3.

Secondary processes

The variations in quantum yields with time evident in Table 1 and Figs. 1 and 2 occur at times when depletion of C_2H_4 is negligible, and must therefore arise from secondary reactions of products. The most striking variations are those of 1-butene and 1,3-butadiene, and their large absorption coefficients at 193 nm ($\sim$500 and $\sim10^4$ M^{-1} cm^{-1} respectively (11)) suggest that secondary photolysis was responsible for the observed decrease in yields. To test this hypothesis, the data were fitted to a simple expression, $\Phi = \Phi_0[1 - \exp(-KN)]/KN$, in which N = number of pulses and K is a constant, which corresponds to constant rate of formation of a product and its first-order loss by secondary photolysis. Best-fit calculated curves are compared with experiment in Fig. 3, and from the values of K and knowledge of the absorption coefficients and radiation fluence,

TABLE 3. Quantum yields of primary photodissociation processes in the photolysis of C_2H_4 at 193 nm and 760 Torr, based on initial extrapolated values

Quantum yield	Neglecting reaction [13]	Assuming extra C_2H_6 from reaction [13]
$\Phi(1)$	0.37	0.34
$\Phi(2)$	0.05	0.08
$\Phi(3)$	0.16	0.16
$\Phi(1 + 2 + 3)$	0.58	0.58

values for the required quantum yields of disappearance of 1-butene and 1,3-butadiene were found to be 0.31 and 0.15, respectively. These are reasonable values for an ethylene pressure of 760 Torr, as some collisional quenching has been observed with both molecules (12, 13). The deviation of the data for 1,3-butadiene above the curve at longer times is probably due to diffusion of product out of the laser beam, which did not fill the photolysis vessel.

The sharp increase with time of the minor products from initial yields close to zero, and the significant increases in the primary products, C_2H_6 and n-C_4H_{10}, are also probably largely the result of the secondary photolyses of 1-butene and 1,3-butadiene. The parallel increases in C_2H_6 and n-C_4H_{10} (Fig. 1) suggest a common cause, an increase in C_2H_5 radicals presumably caused in turn by an increased production of H atoms. The appearance of C_3H_8 indicates the presence of CH_3 radicals which combined with C_2H_5 (reaction [16]), and some of the CH_4 observed will have been formed in the accompanying disproportionation reaction, [17]. The yield of CH_4 is in fact higher than expected from this, and the balance may be a molecular product of a secondary photolysis or may be formed by abstraction of H from 1-butene by CH_3. Methyl radicals, H atoms, allyl radicals and allene are all known products of the photolysis of 1-butene (12), while CH_3 and perhaps H are also probably generated in the photolysis of 1,3-butadiene (13). Thus the secondary products C_3H_8, CH_4, and allene, and the secondary formation of C_2H_6 and C_4H_{10} can be accounted for. The secondary C_2H_6 is larger than expected from reaction [6]. In Table 2 are shown values of the secondary yields of n-C_4H_{10} and C_2H_6 obtained by subtracting the initial extrapolated values from the total yields. Also shown are yields of secondary C_2H_6 in excess of that expected from reaction [6] (i.e., (secondary C_2H_6) $-$ (k_6/k_5) (secondary C_4H_{10})), and finally are shown values of $(C_3H_8)^2/4C_4H_{10}$, which for statistical combination of C_2H_5 and CH_3 should be a measure of C_2H_6 expected from reaction [15]. It is clear that the secondary C_2H_6 cannot be accounted for by reactions [6] and [15]; some of the excess may come from reaction [12], and some may be formed by abstraction of H from 1-butene by ethyl radicals.

The minor product, propene, is not so easy to explain. Simple extrapolation of the data (Fig. 2) indicates a small primary yield of 0.005, but it is difficult to devise a plausible means for its formation as a primary product. It is possible that propene is entirely secondary (the dashed extrapolation in Fig. 2), with the curve bending over sharply with time due to secondary photolysis, which can be expected ($\epsilon_{193} = \sim 300\ M^{-1}\ cm^{-1}$ (11)); the resulting curve then reflects a balance between secondary formation and secondary destruction. The mechanism of formation is again not obvious. Propene is a known product of the photolysis of 1-butene, but it is formed there by

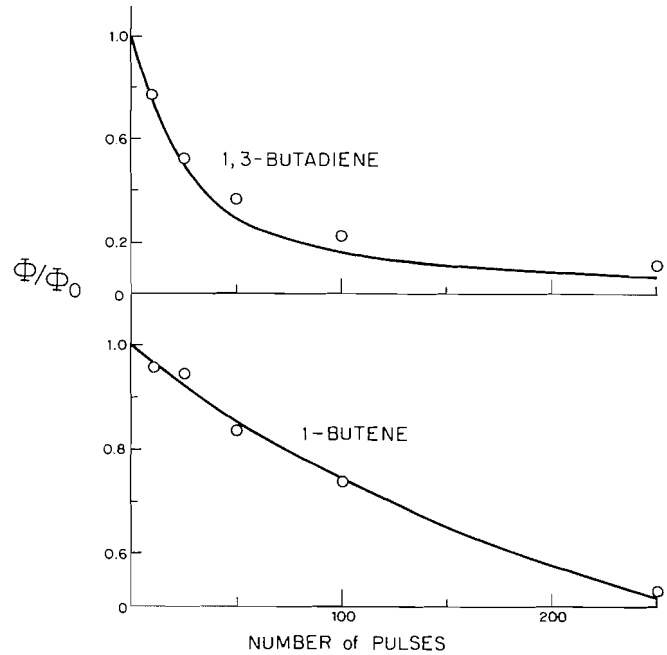

FIG. 3. The dependence of the quantum yields of 1,3-butadiene and 1-butene on number of pulses (i.e., photolysis time). Φ_0 is the initial extrapolated value at zero time. Curves are calculated, points measured; see text.

addition of H atoms to 1-butene followed by decomposition of a "hot" *sec*-butyl radical (12), a sequence of events doubly unlikely in the presence of 760 Torr of C_2H_4. A possible mechanism of formation is the reaction of electronically excited 1-butene and C_2H_4 to form a "hot" C_6H_{12} species which decomposes into 2 propenes via a sequence of two internal H-atom transfers, but further speculation is unwarranted.

The pressure dependence of the photolysis

Figures 4 and 5 show the quantum yields of the six most important products from a series of 10-pulse experiments with average incident energy per pulse of 29 ($\pm$2) mJ at C_2H_4 pressures from 50 to 3000 Torr. The quantum yield of C_2H_2 decreased from 0.47 at 50 Torr to 0.37 at 3000 Torr. That of 1-butene remained constant at 0.086, that of n-C_4H_{10} decreased from 0.082 to 0.067, while that of C_2H_6 increased from 0.037 to 0.059. The quantum yield of 1,3-butadiene increased while that of propene decreased markedly.

Values of the quantum yields of the three primary processes [1], [2], and [3] have been calculated as before, assuming that "extra" C_2H_6 was formed by reaction [13], and are shown in Fig. 6 as a function of C_2H_4 pressure. Reaction [1], the molecular elimination of H_2, is the main process at all pressures, although its yield declines slowly between 50 and 3000 Torr. Reaction [2] decreases while reaction [3] increases in the same pressure range. The observed decrease in the total quantum yield (Fig. 4) from a value of 0.58 at 50 Torr to 0.52 at 3000 Torr is almost entirely accounted for by the decrease in $\Phi(1)$ since the changes in $\Phi(2)$ and $\Phi(3)$ largely compensate one another. The observed decrease in $\Phi(C_2H_2)$ with pressure is thus attributable to the decreasing importance of both primary processes [1] and [2]. The decrease in process [2] and the compensating increase in [3] point to collisional stabilization of the vinyl radical as suggested previously (3, 14, 15) or possibly to vibrational de-excitation of a precursor. In the photolysis of ethylene at 185 nm, both Potzinger and co-workers (2) and

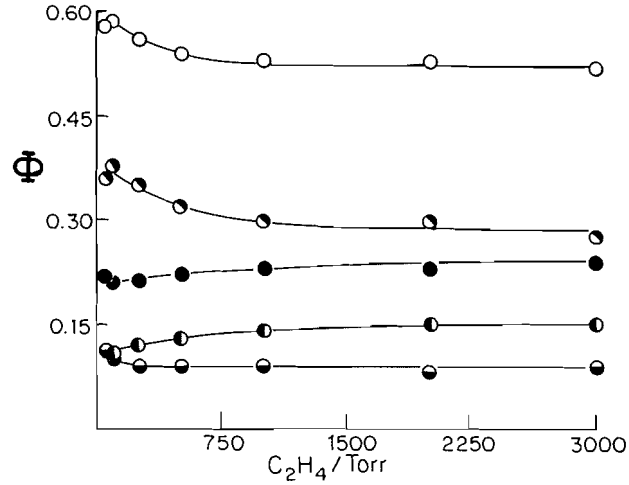

FIG. 5. Quantum yields of primary processes in the photolysis of ethylene at 193 nm, vs. pressure of ethylene. Based on data from Fig. 4. ○ = $\Phi_1 + \Phi_2 + \Phi_3$; ◔ = Φ_1; ● = $\Phi_1 + \Phi_2$; ◐ = Φ_3; ◒ = Φ_2.

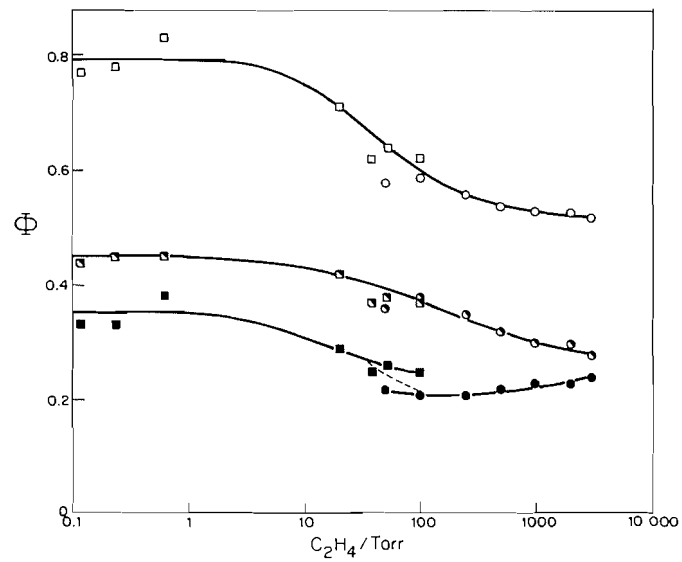

FIG. 6. Quantum yields of primary processes in the photolysis of ethylene. Squares are the data of Potzinger *et al.* at 185 nm (2); circles are the present work at 193 nm. Top curve = $\Phi_1 + \Phi_2 + \Phi_3$; middle curve = Φ_1; bottom curve = $\Phi_2 + \Phi_3$.

Borrell *et al.* (1) also observed a decrease in the acetylene quantum yield, and proposed collisional quenching of several different excited states of ethylene. A constant quantum yield of 1-butene was also reported by Potzinger *et al.* (2) at 185 nm between ethylene pressures of 0.1–100 Torr; they also found a decrease in $\Phi(n\text{-}C_4H_{10})$ from 0.24 to 0.18. The decrease in *n*-butane in the present work, and probably in the earlier studies, can be attributed to the decrease in process [2] and thence in the yield of H-atoms and C_2H_5 radicals. The increase in $\Phi(C_2H_6)$ is probably best explained by the enhancement of reaction [12] due to the higher concentrations of H· and C_2H_5· at higher pressures, and by increased stabilization of the C_2H_6* produced. The increasing trend in $\Phi(1,3\text{-}C_4H_6)$ can be attributed to increase in $\Phi(3)$ with increasing pressure.

Table 4 shows the ratios $C_2H_6/(n\text{-}C_4H_{10} + 1\text{-}C_4H_8)$ and $(1\text{-}C_4H_8)^2/(n\text{-}C_4H_{10})(1,3\text{-}C_4H_6)$, both as a function of pressure. As before, the first ratio exceeds 0.13, the value expected if ethane were all formed by disproportionation, and increases with increasing pressure, further evidence for an increase in reaction [12] with increasing pressure. The second ratio, which should be equal to about 4 for a random combination of ethyl and vinyl radicals, is appreciably larger. As before, this is probably due to loss by secondary photolysis of 1,3-butadiene, which was appreciable even at 10 pulses (Figs. 2 and 3). The decrease of this ratio with increasing pressure is probably due to collisional stabilization of the photo-excited butadiene and perhaps to some optical screening effects of the high pressure of C_2H_4.

Because the photon energies at 185 and 193 nm differ only by 27 kJ/mol, and because both wavelengths appear to excite cleanly into the V-state of C_2H_4, it is useful to compare the primary quantum yields obtained by Potzinger *et al.* at 185 nm (2) with the present results; this is done in Fig. 6. Within the experimental scatter, values of $\Phi(1)$ and $\Phi(2 + 3)$ at the two wavelengths can be reasonably well fitted by single smooth curves. The only major difference between the two sets of data appears in the ratio $\Phi(3)/\Phi(2)$ (Fig. 7); while this increased with increasing pressure at both wavelengths, its absolute value at 185 nm was smaller by a factor of about 5 at pressures from 50 to 100 Torr common to both studies. Some of this difference reflects a higher level of vibrational excitation of the vinyl radicals produced at 185 nm, and some can be attributed to loss of 1-butene and 1,3-butadiene (the latter was not observed at all)

TABLE 4. Product ratios from the photolysis of ethylene at 193 nm with 10 laser pulses

Product ratio	Value when C_2H_4 pressure (Torr) =						
	50	100	250	500	1000	2000	3000
$C_2H_6/(n\text{-}C_4H_{10} + 1\text{-}C_4H_8)$	0.23	0.24	0.27	0.31	0.33	0.36	0.38
$(1\text{-}C_4H_8)^2/(n\text{-}C_4H_{10})(1,3\text{-}C_4H_6)$	13.0	11.0	10.8	7.2	6.3	4.9	4.4

at the higher conversions of the earlier work. The significant loss of these compounds by secondary photolysis (Figs. 1 and 2) sets in at times corresponding to less than 0.1% decomposition of C_2H_4.

The mechanism of the photodissociation

To account for the dependence of processes [1], [2], and [3] on wavelength and pressure, Potzinger *et al.* (2) proposed a scheme involving several excited states of C_2H_4. The present work extends the measurement of primary dissociation yields to higher pressures and to 193 nm, and a modified scheme to account for the combined results at 185 and 193 nm is suggested:

We assume that only the V-state is excited originally and that its lifetime is such that there is no collisional quenching at 3000 Torr, since the total quantum yield of dissociation remains constant from 1000 to 3000 Torr of C_2H_4. This implies a lifetime less than ~100 ps; in fact the diffuse character of the absorption spectrum indicates a lifetime at least 100 times shorter than this. Seven reaction channels [A] to [G] are postulated for the V-state, with quantum yields indicated in parentheses.

Reaction [A] is needed to account for the loss without product formation of about 20% of the molecules originally excited at 185 nm, even at a pressure as low as 0.12 Torr. This must involve a long-lived intermediate X^* that can be completely deactivated by collisions at this pressure and eventually reverts to ground state C_2H_4 with insufficient energy to decompose or react. There is no obvious candidate for X. The known behaviour of the triplet state and the vibrationally-excited ground-state in the mercury-photosensitized decomposition (16) rule these out. Ethylidene is an interesting possibility because of its heat of formation, estimated to be 324 and 279 kJ/mol above that of C_2H_4 for the singlet and triplet, respectively (17). If it were totally relaxed by collision before reverting to C_2H_4, its energy would be below an estimated threshold of ~350 kJ/mol for decomposition to $C_2H_2 + H_2$

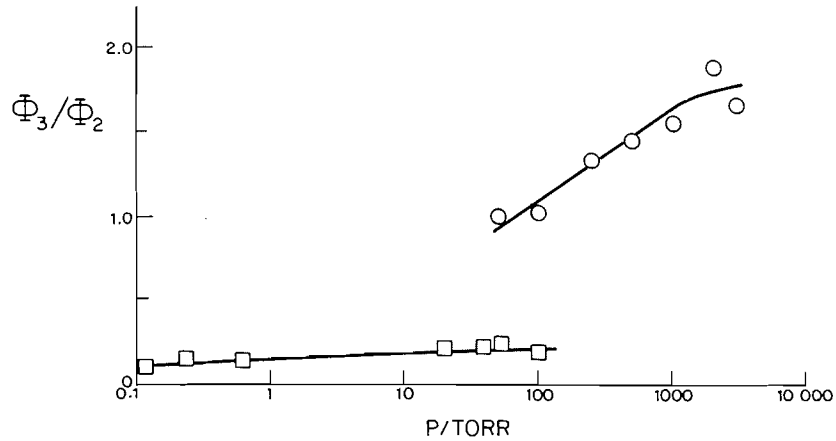

FIG. 7. The ratio of primary processes [3] and [2] in the photolysis of ethylene plotted against the log of ethylene pressure. □ = data of Potzinger *et al.* at 185 nm (2); ○ = present data at 193 nm.

(18). It is not clear, however, whether ethylidene is sufficiently unreactive towards C_2H_4 to permit such deactivation without reaction; the very small quantum yields of methylcyclopropane ($\leq 10^{-4}$) suggest that this may be so.

Reactions [B], [C], and [D] account for the formation of $C_2H_2 + H_2$ (process [1]), which has a complex pressure dependence. Potzinger *et al.* (2) found $\Phi(H_2)$ to be unaffected by pressure up to 100 Torr, but found $\Phi(1)$, based on hydrocarbon analysis, to decline from about 0.45 to 0.37 between 0.12 and 100 Torr (Fig. 6). It would be interesting to know whether this difference continued at higher pressure and at 193 nm, but the present experiments were not designed to measure H_2. Reaction [B] is suggested to account for this difference, since Laufer (19) showed that H_2CC, vinylidene, is an intermediate in the system and is relatively long-lived, and might be lost by reaction with C_2H_4; no products of such a reaction were observed in the present work, but yields would have been small and they may not have been detected in our analysis. The decline in $\Phi(1)$ with increasing pressure continues in our experiments, falling from about 0.37 at 50 Torr to 0.28 at our highest pressure (Figs. 5, 6). Stern–Volmer plots indicate two quenching processes, an efficient one (reaction [B]) at low pressure (<50 Torr) and a less efficient one between 50 and 100 Torr for which we suggest reaction [C] proceeding through an unspecified intermediate Y. The yield of process [1] of 0.28 unquenched at 3000 Torr we attribute to direct dissociation of the V-state, reaction [D].

Reactions [E], [F], and [G] are postulated to account for primary processes [2] and [3] and their pressure dependence. The formation of vibrationally "hot" vinyl radicals which decompose at low pressure but can be stabilized by collision was suggested in earlier photolysis studies (3, 14, 15). The present data indicate complete stabilization of $C_2H_3^{\ddagger}$ by about 2000 Torr, evident in the plot of $\Phi(3)$ in Fig. 5 which leads to $\Phi(F) = 0.15$, while $\Phi(E)$ is similarly given by the high-pressure limit of $\Phi(2)$, corresponding to direct formation of $C_2H_2 + 2H$. Reaction [G] is suggested to explain the decrease in $\Phi(2 + 3)$ from ~0.35 at low pressure to ~0.25 at 100 Torr; the decrease in fact occurred entirely in $\Phi(2)$ while $\Phi(3)$ remained constant. Values of $\Phi(2 + 3)$ in the present study lie slightly lower than the initial extrapolated values of Potzinger *et al.* (2). Reaction [G] requires the formation of an intermediate, Z, with a quantum yield of about 0.10 which is fully quenched at ~100 Torr and which can decompose to $C_2H_2 + 2H$ at low pressure. A lifetime of ~16 μs can be estimated for Z from a Stern–Volmer plot. The identity of Z is unknown, but the triplet state is a possible candidate; the vibrationally excited ground state is less likely, as some molecular dissociation to $C_2H_2 + H_2$ might be expected although perhaps Y and Z are in fact the same excited state, decomposing by two channels having different quenching probabilities.

Summary

The present work shows that the photochemistry of C_2H_4 excited to the V-state at 193 nm is well accounted for, as at shorter wavelengths, by three primary processes followed by simple reactions of H, C_2H_3, and C_2H_5. The pressure dependence confirms earlier conclusions that a surprisingly complex photodissociation mechanism underlies the photochemistry, involving several excited states and intermediates, a conclusion also reached in a recent review of the photolysis (6) and in a theoretical study (20) of the photodissociation.

Several points need experimental clarification. Careful measurements of quantum yields at low pressures, at both 185 and 193 nm, are needed to establish whether $\Phi(1 + 2 + 3)$ has indeed a low-pressure limit of about 0.8 as found at 185 nm, or whether it approaches unity, and thus whether reaction [A] is really required. Measurements of both H_2 and hydrocarbon products are also needed to determine whether the difference between $\Phi(1)$ and $\Phi(H_2)$ observed at 185 nm is real and if it persists at 193 nm and at higher pressures, and thus whether reaction [B] is needed. To be useful, these experiments demand accurate actinometry and must be done at very low conversions to avoid loss of 1-butene and 1,3-butadiene by secondary photolysis.

Thermal instability of germacrone: implications for gas chromatographic analysis of thermally unstable analytes

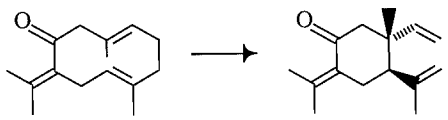
PAUL B. REICHARDT,[1] BARBARA J. ANDERSON, THOMAS P. CLAUSEN, AND L. CLARON HOSKINS
Department of Chemistry, University of Alaska, Fairbanks, AK 99775-0520, U.S.A.

Received October 3, 1988

PAUL B. REICHARDT, BARBARA J. ANDERSON, THOMAS P. CLAUSEN, and L. CLARON HOSKINS. Can. J. Chem. **67**, 1174 (1989).

The rearrangement of germacrone (**1**) to β-elemenone (**2**) is common during gas chromatographic (GC) analysis, with the conversion taking place in the injector port at temperatures above 250°C as well as on the column. While production of **2** in the injector is evident from the gas chromatographic trace, **2** produced from **1** during its migration down the column is difficult to detect because of the diffuse nature of the chromatographic peak produced by this process. A mathematical model and kinetic parameters ($A = (1.35 \pm 0.03) \times 10^{13}\,s^{-1}$; $E_a = 137 \pm 4\,kJ\,mol^{-1}$) determined from the reaction in solution can be used to estimate the degree of conversion of **1** to **2** for chromatographic runs (including temperature-programmed analyses). The results of these calculations verify that substantial amounts of **1** are converted to **2** under conditions that are commonly used for the analysis. The method for modeling thermally induced rearrangements in nonisothermal processes represents the first approach to quantitatively assessing their importance in GC analyses of thermally labile substances.

Key words: kinetics, gas chromatography, thermal rearrangement, germacrone, β-elemenone.



PAUL B. REICHARDT, BARBARA J. ANDERSON, THOMAS P. CLAUSEN et L. CLARON HOSKINS. Can. J. Chem. **67**, 1174 (1989).

La transposition de la germacrone (**1**) en β-élémènone (**2**) se produit régulièrement au cours d'analyses par chromatographie en phase gazeuse (CG); la conversion se produit tant dans l'injecteur, à des températures au-dessus de 250°C, que sur la colonne. Alors que la formation du composé **2** dans l'injecteur est évidente sur le chromatogramme, la formation du composé **2** à partir du composé **1** au cours de sa migration sur la colonne est plus difficile à détecter à cause de la nature diffuse du pic chromatographique qui résulte de ce processus. On peut utiliser une modèle mathématique et des paramètres cinétiques ($A = (1{,}35 \pm 0{,}03) \times 10^{13}\,s^{-1}$; $E_a = 137 \pm 4\,kJ/mol$) déterminés à partir de la réaction en solution pour évaluer le degré de conversion du composé **1** en **2** au cours de chromatographies (y compris des analyses avec une variation programmée de la température). Les résultats de ces calculs confirment que des quantités importantes du composé **1** sont transformées en **2** dans des conditions qui sont couramment utilisées pour l'analyse. La méthode développée pour faire un modèle des transpositions induites d'une façon thermique dans des processus qui ne sont pas isothermes représentes la première approche à une détermination quantitative de leur importance dans des analyses de CG de substances thermiquement labiles.

Mots clés : cinétique, chromatographie en phase gazeuse, transposition thermique, germacrone, β-élémènone.

As part of a program designed to probe the chemical facets of plant defenses against herbivores, we require an analytical method for quantifying the volatile metabolites of Labrador tea (*Ledum groenlandicum*). Von Schantz and Hiltunen employed a gas chromatographic (GC) method for this purpose and found germacrone (**1**) to be a major component of the essential oil of this plant (1). Similar GC analyses of germacrone-containing essential oils of other plants have also been reported (e.g., refs. 2–7), but it is clear that the known propensity of **1** to thermally isomerize to β-elemenone (**2**; refs. 2, 8) poses problems for quantifying **1** by this method and casts doubt on the authenticity of reports (2, 4–7) of **2** as a metabolite of germacrone-containing plants.

1 **2**

Although **1** can be analyzed by high performance liquid chromatography (see below), normally it has been analyzed as only one of several volatile metabolites of a plant. Thus GC has been, and is likely to remain, the standard method for the analysis of **1**. Assessment of the validity of previous reports of the concentrations of **1** and **2** in plants as well as development of improved analytical methods require quantitative evaluation of the rearrangement of **1** to **2** during GC analysis.

The study reported here was initiated with two goals in mind. We desired to develop (1) a method that would provide the information needed to quantitatively interpret GC analyses of **1** and **2** in plant material and (2) a general kinetic technique for extracting quantitative information from GC analyses of thermally unstable substances.

Results and discussion

Our initial GC analyses of the steam distillable fraction of *Ledum groenlandicum* confirmed the previous finding that **1** is the major volatile metabolite of this species (1), but they also indicated the presence of **2** and exhibited a "hump" in the baseline between the retention times for **1** and **2** (Fig. 1).

HPLC analysis of the steam distillate revealed the presence of **1** but no detectable **2**, implying that **2** detected by GC is entirely an artifact. The sharpness of the β-elemenone GC peak suggested that it was generated in the injection port (high temperature and short residence time). This idea was supported by analyses of purified **1** in which column conditions were held constant but the injector temperature varied (Fig. 2).

Varying the column temperature, flow rate, or temperature program altered the relative size of the "hump" in GC traces of **1** (Fig. 1b; Table 1). From these results it is clear that increased

retention times and higher column temperatures lead to greater relative areas of the hump, as would be expected if **2** were produced from **1** *during migration through the column*.

To verify that both the β-elemenone peak and hump are artifacts of the analytical method and to calculate the amounts of **1** that were actually in the samples before injection into the GC,

TABLE 1. Observed and calculated effects of GC program on conversion of **1** to **2** on-column

we conducted a kinetic analysis of the conversion of **1** to **2**. Over the temperature range 140–160°C, in bis(2-ethoxyethyl) ether, **1** converted to **2** with clean first-order kinetics. No products other than **2** were chromatographically detected (HPLC, GC), although minor decomposition was visually apparent (darkening) in some samples. Analyses at three half-lives indicated that **1** and **2** accounted for more than 90% of **1** originally in the sample. At ten half-lives the sample contained no detectable **1**, suggesting the conversion of **1** to **2** is irreversible (8).

Standard treatment of the kinetic data (Table 2) gave $E_a = 137 \pm 4\,kJ\,mol^{-1}$ and $A = (1.35 \pm 0.03) \times 10^{13}\,s^{-1}$, values that are similar to those determined for other Cope rearrangements (9).

These parameters and eq. [1] can be used to calculate the concentration (C) of **1** experiencing first-order decomposition

$$[1] \quad \frac{dC}{C} = -k\,dt = -A \exp(-E_a/RT)\,dt$$

to **2** at temperature T. However, eq. [1] must be modified for modeling the conversion during periods of temperature variation (temperature-programmed GC analysis, for example). As temperature rises at a constant rate, the temperature (T) at any time (t) can be expressed as $T = T_0 + rt$, where T_0 is the initial temperature and r is the temperature ramp rate (K/s). Substituting this relation into eq. [1] and integrating from a concentration C_0 to a final concentration C_f at time t_f yields

$$[2] \quad \ln \frac{C_f}{C_0} = -A \int_0^{t_f} \exp\{-E_a/[R(T_0 + rt)]\}\,dt$$

If we define $u = E_a/[R(T_0 + rt)]$, then eq. [2] can be transformed to

$$[3] \quad \ln \frac{C_f}{C_0} = \frac{AE_a}{Rr} \int_{u_0}^{u_f} e^{-u} u^2\,du$$

where $u_0 = E_a/RT_0$ and $u_f = E_a/RT_f$. The integral in eq. [3] can be evaluated using series or by numerical integration.

For computational purposes we chose to evaluate eq. [2] as

$$[4] \quad \ln \frac{C_f}{C_0} = -\tau A \sum_{i=0}^{n-1} e^{-E_a/RT_i}$$

where C_f = concentration of analyte at end of GC run; C_0 = concentration of analyte at beginning of GC run; τ = time increment per calculation; T_0 = initial temperature (K) of GC run; $T_i = T_0 + i\tau r$; r = temperature ramp rate (K/s); n = total time of GC run $\times \tau^{-1}$.

The activation parameters determined in solution can be used to model the conversion of **1** to **2** at any temperature, and eq. [4] can be used to model the conversion during a period of regular temperature change. The method can be applied to temperature-programmed GC analyses if one assumes the reactions in the gas phase and the GC stationary phase have the same activation parameters as the reaction in bis(2-ethoxyethyl) ether.

Attempts to use eq. [1] to calculate the degree of conversion of **1** to **2** in the injection port were thwarted by our inability to estimate a residence time. The problem is that the flow rate in the injector cannot be approximated due to the pressure rise associated with rapid solvent evaporation (T. Brown, personal communication). However, calculated $t_{1/2}$'s of 30 μs for the conversion at 300°C and 6 s at 200°C are consistent with the effect of injector temperature on the relative size of the β-elemenone peak (Fig. 2).

Using time increments (τ) of about 6 s and the temperature/time relationships defined by the GC temperature programs allowed calculation (eq. [4]) of the percent on-column conversion of **1** to **2** expected for several GC analyses (Table 1). The model makes only moderately good quantitative predictions about on-column conversions, presumably due to effects of the media on reaction rates (10) or small errors in the value of E_a. However, the calculations verify that the hump in the chromatographic traces can result from on-column conversion of **1** to **2** and that the fraction of **1** reaching the detector can be approximated by our model.

The value of this kinetic approach to modeling thermally induced reactions can be exemplified by its application to two long-standing problems in germacrone analysis. First, the kinetic parameters reported here indicate that at least trace quantities of **2** can be produced from **1** during steam distillation (about 2 h are calculated to be required for conversion of 1% of **1** to **2** at 100°C). Secondly, the method can be used to assess the validity of GC-based literature reports of **1** and **2** as natural products. Examination of several such reports indicates that generally the injection port temperatures used (e.g., refs. 1 and 4) are not high enough to cause substantial production of **2** from **1**, although in some cases this may be a problem (2). However, it does appear that typical GC conditions for analyzing germacrone-containing essential oils (e.g., refs. 1, 2, 4, 5, and 7) can result in significant underestimation of the concentration of **1** due to on-column conversion of **1** to **2** (Table 1). Conclusive statements about individual reports are not possible because authors have not given retention times and operating conditions in enough detail to mathematically model the analyses.

The method described here suggests a useful approach to modeling a reaction under nonisothermal conditions if appropriate kinetic parameters are known. Its application to GC analyses allows distinction between transformations that occur in the injector and on-column, and it provides an estimate of the extent of on-column transformation. It can be used to evaluate the reliability of analyses that have already been conducted and as a predictive tool for developing GC conditions for new analyses.

Experimental

Gas chromatographic analyses were conducted on a Perkin Elmer 8410 gas chromatograph equipped with a 30 m × 0.53 mm bonded FSOT RSL-200 column (Alltech). Unless otherwise specified the injector and detector were held at 300°C, the He flow rate was 6.0 mL/min, and the temperature program was 60°C for 1 min, 60–180°C at 10°/min, 180°C for 5 min, 180–260°C at 30°/min. HPLC analyses were conducted on a 4.6 mm × 25 cm silica gel column (5 μm) eluted with hexane–ether (95:5) at a rate of 2 mL/min and detection by UV at 255 nm. HPLC data collection and processing were accomplished using Chromatochart software.

The nmr spectra ($CDCl_3$ solvent) were recorded on a JEOL FX-90Q instrument.

*Isolation of germacrone (**1**)*

Ledum groenlandicum steam distillate (1.8 g) was separated by silica gel flash chromatography (11) using dichloromethane – petroleum ether (55:45) solvent. Fractions that appeared to be pure **1** by TLC (silica gel, dichloromethane) were combined (0.69 g) and the solid residue recrystallized from ethanol (−20°C) to give **1** (0.36 g); mp 54–56°C (lit. (12) mp 54–55°C); ^1H and ^{13}C nmr spectra were identical to those previously reported for **1** (12).

*Preparation of β-elemenone (**2**)*

1 (26 mg) was sealed in an ampoule under a nitrogen atmosphere and heated at 200°C for 3 h. The light brown reaction product was chromatographed using the system described above to give purified **2** (20 mg; oil) with an ^1H nmr spectrum identical to that reported for **2** (13).

Kinetics

Ampoules were charged with 100 μL of a bis(2-ethoxyethyl) ether solution of **1** (6.0 mg/mL) and fluoranthene (0.39 mg/mL; internal standard). Ampoules were sealed and immersed in a thermostated (±0.1°C) silicone oil bath. The temperature of each kinetics run was monitored with a calibrated thermometer (0.1°C). Ampoules were periodically removed, immersed in an ice water bath, and stored at −20°C until analysis. At least 12 ampoules removed over three half-lives were utilized for each kinetics run.

The contents of each ampoule were diluted with 1.0 mL of bis(2-ethoxyethyl) ether and analyzed by HPLC. The ratio of fluoranthene to germacrone peak areas was utilized to quantify the disappearance of **1**, and a first-order kinetics program (CONINFIN) was used to calculate rate constants.

Calculations of expected germacrone isomerization during GC analysis

Equation [1] was evaluated for several GC runs using a program written for an Apple II^+ computer. Each run was modeled by selecting successively smaller time increments (τ) until the calculated percentage rearrangement of **1** no longer responded to the magnitude of τ. Given the amount of **1** reaching the detector and the temperature/time profile in the GC run, the program calculates the amount of **1** that exited the injector.

Characterization of thermal modulation of electrical conductivity: a small volume absorbance measurement technique

ROBERT MCLAREN AND NORMAN J. DOVICHI[1]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 21, 1988

ROBERT MCLAREN and NORMAN J. DOVICHI. Can. J. Chem. **67**, 1178 (1989).

Laser-induced thermal modulation of electrical conductivity is a new photothermal method for the measurement of minute absorbance in sub-nanoliter liquid samples. In this paper, a model is presented for the technique. This model is based upon the interaction of a Gaussian laser beam with a cylindrical, homogeneous electrolytic resistor. Particularly simple results are produced if the laser beam spot size is much smaller than the diameter of the electrodes. The theory is verified with respect to the electrode spacing and to the laser power, spot size, and chopping frequency; the highest sensitivity occurs with low chopping frequency, high laser power, and small electrode spacing. The signal is independent of laser spot size, as long as the beam does not illuminate the electrode surface. The precision of the measurement is dominated by shot noise in the current flow through the electrolytic resistor. One point absorbance detection limits of 5.5×10^{-6} measured across the 76-μm diameter electrode wires are obtained in aqueous solution with a 5-mW helium–neon laser. With this instrument, the difference in the absorbance of water and deuterated water is easily determined at 632.8 nm.

Key words: thermal modulation of electrical conductivity.

ROBERT MCLAREN et NORMAN J. DOVICHI. Can. J. Chem. **67**, 1178 (1989).

La modulation thermique induite au laser de la conductivité électrique est une nouvelle méthode photothermique permettant de mesurer de très faibles absorbances dans des échantillons liquides de volumes plus faibles que le nanolitre. Dans ce travail, on présente un modèle pour cette technique. Ce modèle est basé sur l'interaction d'un faisceau gaussien de laser avec une résistance électrolytique homogène et cylindrique. On obtient des résultats particulièrement simples si la grosseur du rayon laser est beaucoup plus petite que le diamètre des électrodes. La théorie se vérifie par rapport à l'espacement entre les électrodes, à la puissance et à la grosseur du rayon laser et à la fréquence de modulation; la meilleure sensibilité est obtenue avec une faible fréquence de modulation, une grande puissance du rayon laser et un faible espacement entre les électrodes. En autant que le rayon n'illumine pas la surface de l'électrode, le signal est indépendant de la grosseur du rayon laser. La précision des mesures est dominée par le bruit de fond dans le flot de courant à travers la résistance électrolytique. Opérant en solution aqueuse, avec un laser d'hélium-néon de 5-mW, on a obtenu des limites de détection de $5{,}5 \times 10^{-4}$ pour des mesures faites à travers des fils d'électrodes d'un diamètre de 76-μm. Avec cet instrument on peut facilement mesurer la différence d'absorbance de l'eau et de l'eau lourde, à 632,8 nm.

Mots clés : la modulation thermique de la conductivité électrique.

[Traduit par la revue]

Introduction

Photothermal techniques produce high sensitivity absorbance determination by measurement of the heat deposited within a sample following absorbance of light. This heat may be detected directly with a liquid helium cooled bolometer in molecular beam experiments (1) or the heat may be detected indirectly as a temperature rise with a thermocouple (2), as a pressure wave with a piezoelectric or microphonic transducer (3), as a variation in electron capture cross-section for gaseous samples (4), or as a refractive index disturbance with the variety of thermo-optical techniques (5). The latter class of thermo-optical techniques probably is the best developed analytical photothermal method for absorbance determination of liquid samples. In all cases, because the heat deposited within the sample following absorbance is directly proportional to the excitation energy, the absorbance of dilute and highly transparent materials may be measured by use of a high energy or high intensity light source.

Recently, we presented a preliminary report of a photothermal technique based upon the change in electrical conductivity with the temperature of an ionic solution (6). The principle of the measurement is rather simple. Small changes in the temperature of a volume of solution will result in relatively large changes in the viscosity of the solution because of the high thermal coefficient of viscosity for most liquids. The change in viscosity can be conveniently monitored by measuring the conductance of the solution because of the inverse relationship between conductance and viscosity. In this paper, the conductance is measured by employing miniature, 76-μm diameter platinum electrodes that define the geometry for a small volume electrolytic resistor. A modulated laser beam intersects the electrolytic resistor. When an absorbing analyte is present and the beam is on, the temperature increases, causing a decrease in the viscosity of the solution and an increase in the current through the electrolytic resistor. When the beam is off, the solution cools and the current decreases. The current (or conductivity) signal can be demodulated at the chopping frequency of the laser by a lock-in amplifier. The amplitude of the demodulated signal is proportional to the absorbance of the solution whereas the phase is related to thermal diffusion within the sample.

Small volume absorbance measurements are of importance in a number of technological fields, including detection for the chromatographic and electrophoretic analysis of biological materials. Although a number of thermo-optical techniques have been developed for small volume absorbance determinations (7), the thermally modulated electrical conductivity (TMEC) technique appears to offer the greatest promise for analysis of aqueous samples.

Theory

The coordinate system used in the model is shown in Fig. 1. A laser beam, aligned along the Z axis of a Cartesian system, intersects the cylindrical electrolytic resistor centered on the X axis and defined by the radius of the electrode, r, and the

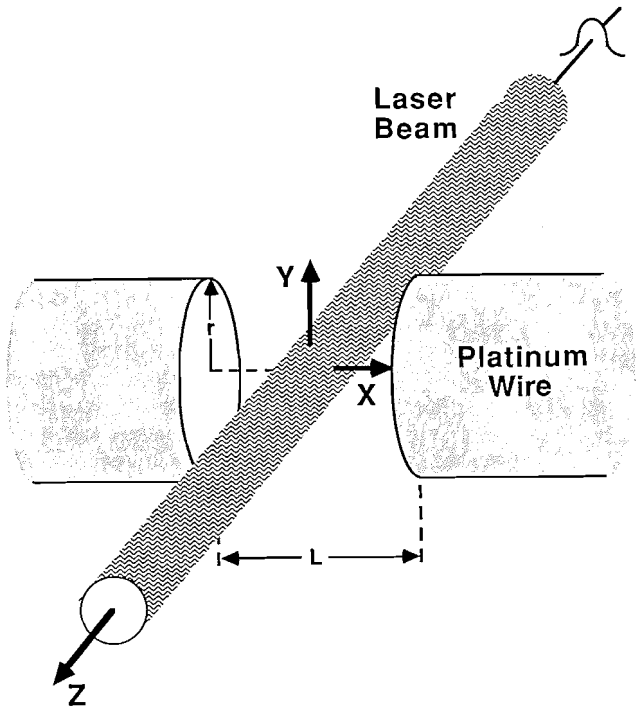

FIG. 1. Interaction of the beam with a cylindrical electrolytic resistor.

distance between the electrodes, L. Normally, the beam is aligned to intersect the center of the resistor. The change in current as a function of time following a pulse of light has been derived in Appendix 1. This impulse response function may be simplified greatly if the laser beam spot size is much smaller than the radius of the wire. In this case, the impulse function takes on a simple form

$$[1] \quad \Delta I_{\text{impulse}} \begin{bmatrix} \text{small spot} \\ \text{limit} \end{bmatrix} = \frac{2.303 E \epsilon C I}{\pi r L} \left[\frac{-1}{\rho C_p \eta} \frac{d\eta}{dT} \right]$$

where E is the energy of the laser pulse, ϵ is the molar absorptivity of the analyte, C is analyte concentration, and I is the average current passing through the resistor. The term in brackets is the solvent constant that is a function of the solvent density ρ, heat capacity C_p, viscosity η, and the derivative of the viscosity with respect to temperature $d\eta/dT$. The solvent constant, Table 1, changes by about a factor of three for the different solvents listed (5, 8–10). Interestingly, water has a solvent constant which is within a factor of two of the best solvent listed, ethanol. Of course, the low dielectric constant of most organic liquids presents difficulty in preparation of high ionic strength solutions required for high precision measurements.

The small spot size limit of the impulse response function is quite remarkable. The signal is predicted to be independent of time, undergoing no decay. Time independence results because the thermally modulated electrical conductivity signal is a function of the average temperature rise in the volume between the electrodes. A decay in the impulse signal will occur only when the thermal energy diffuses to the bulk solution or to some other heat sink. Assuming that the radius of the wire is less than the separation between the electrodes, the thermal decay is characterized by a diffusion time

$$[2] \quad t_{\text{diffusion}} \approx \frac{r^2}{D}$$

TABLE 1. Physical constants of solvents[a]

Solvent	Density (g/mL)	Heat capacity (J/g °C)	Viscosity η (cP)	$d\eta/dT$ (cP/°C)	$10^3 \times$ Solvent constant[b] (mL/J)
Water	0.998	4.18	1.002	−0.0245	5.86
Methanol	0.791	2.46	0.597	−0.0076	6.54
Ethanol	0.789	2.36	1.200	−0.0232	10.4
Acetonitrile	0.786	2.17	0.360	−0.0030	4.89
Acetone	0.790	2.18	0.326	−0.0021	3.74

[a]All constants are at 20°C. Obtained from refs. 5, 8–10.
[b]The solvent constant = $(-\eta\rho C_p)^{-1}\, d\eta/dT$.

where the thermal diffusivity of the solution, D, is given by

$$[3] \quad D = \frac{k}{C_p \rho}$$

where k is the thermal conductivity of the solution. For time shorter than the diffusion time, no decay in the impulse signal is predicted. Also, the signal is predicted to be independent of the laser beam spot size. This observation is understandable, given the dependence of the signal on the thermal energy contained between the electrodes. The signal is predicted to be inversely related to the radius of the electrode, r, and the electrode spacing, L. The former observation arises because the average temperature rise of the solution will depend inversely upon the volume of the electrolytic resistor; an inverse second power dependence is not observed because the laser beam crosses perpendicular to the electrolytic resistor. Integration over the beam path results in the observed inverse first power dependence on the wire radius. The inverse dependence of the signal upon both the wire radius and the electrode spacing is important for application of this technique to small volume absorbance determinations; the signal increases as the sample volume decreases, essentially because the thermal energy is contained within a smaller sample volume.

To obtain the change in current passing through the electrode for an arbitrary excitation waveform, it is necessary to convolute the impulse response function with the appropriate excitation function. For example, the current response obtained at time t after the start of a step excitation by a light source of power P is simply given by

$$[4] \quad \Delta I_{\text{step}} \begin{bmatrix} \text{small spot} \\ \text{limit} \end{bmatrix} = \frac{2.303 P \epsilon C I}{\pi r L} \left[\frac{-1}{\rho C_p \eta} \frac{d\eta}{dT} \right] t$$

The current change is expected to increase linearly with time following illumination with a continuous wave light source. Again, the approximation will be valid for time less than $t_{\text{diffusion}}$.

Experimental

Figure 2 presents a block diagram of the cell used to characterize the technique. The electrodes were constructed by drawing glass tubing over 76-μm diameter platinum wire. The finished electrodes had an outer diameter of 530 (±10) μm. The ends of the electrodes were polished progressively using coarse polishing cloth, 6 μm diamond polishing compound, 3 μm alumina, and finally 1 μm alumina. The cell was machined from a Teflon block with an inner chamber volume of ca. 0.3 mL. A "V" groove was cut across the front of the block in which the electrodes could sit to a depth such that they remained flush with the front face of the block. A quartz window presses firmly against the front of the block and is held in place by a thick Teflon ring. The laser beam enters the cell through the front window and

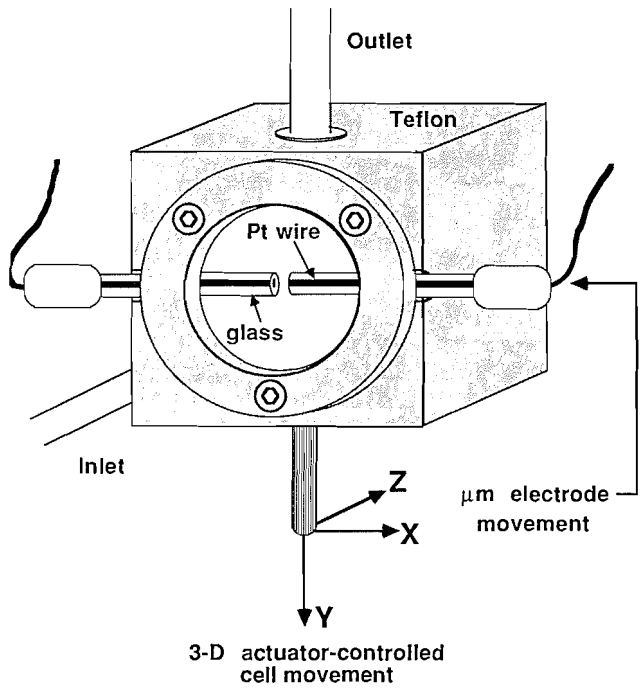

FIG. 2. Diagram of the cell used for characterization of TMEC.

exits through a second window at the back of the cell. The distance the beam travels in solution before it passes the electrode central axis is about 265 μm. One of the electrodes is held stationary while the other is driven along its axis using a translation stage-micrometer assembly. In this way the electrode spacing could be varied accurately while maintaining the platinum faces of the electrodes directly opposite each other in a parallel plate configuration. The entire cell–electrode assembly was mounted on translation stages for movement in three dimensions by computer controlled actuators.

The conductance of the solution between the electrodes is measured using an ac method. The electronics used are similar to those described previously (6). Briefly, a 40 kHz frequency carrier wave is applied to the electrodes. The ac current passing through the cell is amplified, half-wave rectified and smoothed using a four pole low-pass active filter with 300 Hz cutoff frequency. The resultant dc signal is linear with the conductivity of the solution for cell impedances of >10 kΩ; for typical solutions and electrode spacing, the cell impedance was greater than 100 kΩ. It was found that, with the present electrode configuration, a carrier wave frequency of 40 kHz was needed in order to minimize the impedance due to double layer capacitance; the system acts as a high pass filter with a cut-on frequency of about 10 kHz. In addition, there are three parallel capacitive impedances that should be made as large as possible in order to reduce any non-electrolytic current flow (11). They are (*i*) cell capacitance, (*ii*) contact and lead capacitance, and (*iii*) physical electrode capacitance (due to the parallel plate configuration). The cell capacitance was minimized by grounding the metal inlet and outlet ports of the cell. The contact and lead capacitance was reduced by careful construction. The physical electrode capacitance is dependent on the dielectric material and the electrode dimensions. In total, the current flow due to all three of these capacitances was typically <10% of the electrolytic current flow. This value would be unacceptable for an absolute conductance measurement but is quite acceptable for the differential measurement of conductance in this photothermal technique.

A block diagram of the experiment is presented in Fig. 3. A 5 mW, linearly polarized He–Ne laser beam (632.8 nm) passes through an optical chopper. Mirrors are used to manipulate the beam through a 2-mm diameter aperture that acts to reduce stray light. A 10×, 16 mm focal length lens focuses the beam to a small spot between the electrodes in the cell. The light exiting the cell strikes a photocell that generates a reference signal for the two-channel lock-in amplifier. The conductivity circuit described above provides the signal for the lock-in amplifier. The lock-in measures both the amplitude and phase of the thermally modulated conductivity signal simultaneously.

For the purpose of beam positioning and for generating X–Y scans, an 855C Newport programmable controller and actuators were used to control the movements of the cell with respect to the laser beam. The controller is capable of 0.1 μm movements although such resolution was not needed in this application. A computer was used to communicate with the controller and to store data from the lock-in as incremental movements were made.

Chemicals

Aqueous solutions were typically 0.01 *M* NaCl. Fast Green FCF dye (Aldrich, 96%), which has a strong absorbance at the He–Ne wavelength, was used for the experiments without further purification. The visible spectrum of the dye was recorded in water as a function of its concentration, NaCl concentration, and pH with a HP 8451A diode array spectrophotometer. A 0.01 *M* salt concentration was found not to have any effect on the spectrum. The dye behaves as an acid–base indicator, changing from violet in strongly alkaline solutions, to aqua in neutral solutions, to green in acidic solutions. The spectrum is relatively constant as the concentration of the dye is increased in neutral solutions up until about 10^{-5} *M*. Above this concentration, the intensity of the main α band centered at 624 nm starts to decrease in intensity. This decrease in intensity is not due to a change in pH that occurs as the dye concentration is increased but instead appears to be due to aggregation of the dye molecules (12).

Results and discussion

The cell–electrode arrangement was first characterized with respect to conductivity detection. For a 0.01 *M* NaCl solution, the current through the cell was measured for various electrode separations. As expected, the current was found to be inversely proportional to the electrode separation ($R = 0.998$, $n = 15$) in the range of 40 to 3000 μm at a constant applied voltage. A small positive intercept was observed in the data that is attributable to the parallel capacitances mentioned previously. The current through the cell was also found to be linear with the applied voltage ($R = 0.9991$, $n = 12$) in the range of 0 to 3 V rms. Above this voltage, resistive heating of the solution between the electrodes led to positive curvature. The upper limit to the voltage that may be applied to the electrodes is determined by the effects of resistive heating. Heating of the solution between the electrodes could result in convection currents, which would presumably lead to additional noise in the system; the current was found to be more stable over a long period of time with lower applied voltages. For this reason, voltages of less than 1 V rms were used for most subsequent experiments.

Two sources of modulated electrical conductivity are expected: that due to absorbance of the sample and that associated with stray light which illuminates the electrodes. To characterize the latter signal, the thermally modulated electrical conductivity signal was measured as the laser beam was moved with respect to the cell. Figure 4 shows the lock-in amplitude as a function of position near the electrodes in the X–Y plane of Fig. 1, using a blank solution and a chopping frequency of 200 Hz. Individual pixels in the plot are 10 μm on a side. An image of the wire is observed as two hills separated by a valley of weakly absorbing blank solution. The signal drops off quite quickly as the laser spot moves along the wire away from the resistor region. Because the resistance of the wire is negligible in comparison to that of the electrolytic resistor, it appears that the background signal associated with the illuminated wire arises as heat diffuses through the wire to the solution within the electrolytic resistor volume. As the laser beam illuminates

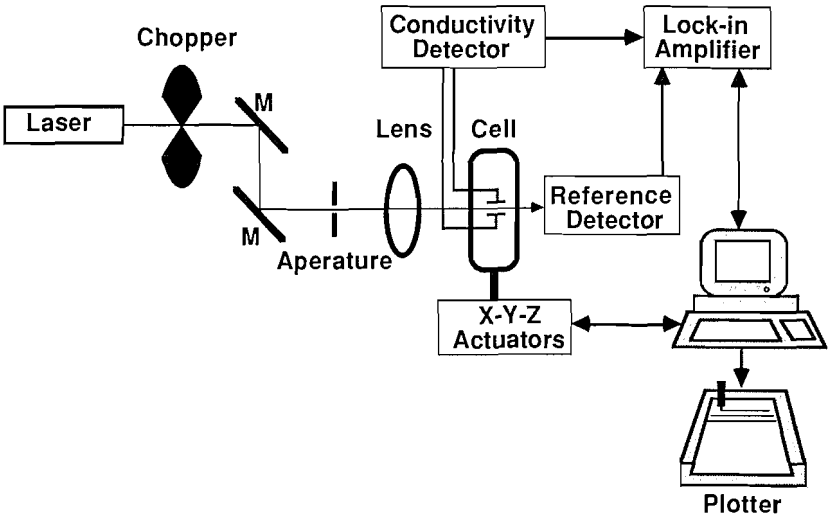

FIG. 3. Schematic diagram of the experiment.

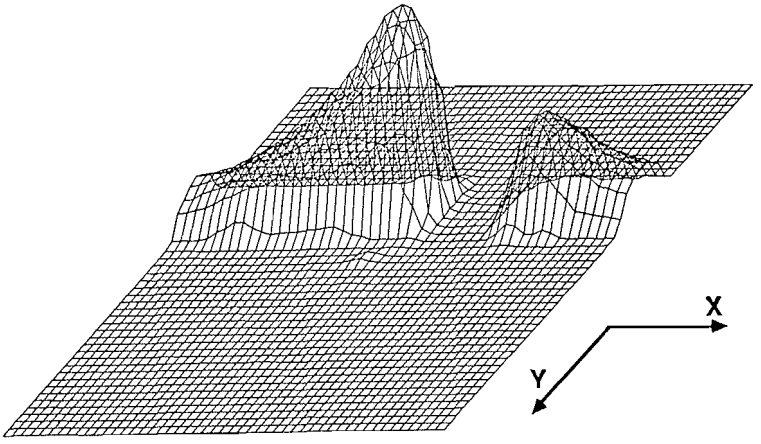

FIG. 4. A laser scan (X–Y) of the signal generated in the vicinity of the electrodes for a non-absorbing solution. The signal due to conductance of heat along the wire into the resistor region has generated a "picture" of the electrodes. TMEC absorbance measurements are made by aligning the beam to pass between the electrodes. Each pixel is 10 μm on a side.

the wire at larger distances from the electrolytic resistor, less heat is transported to the solution during each chopper cycle and an exponential decrease in signal is observed.

Absorbance measurements of a sample are generated when the laser illuminates the valley region between the electrodes. Figure 5 shows three close-up scans of the region between the electrodes using step sizes of 2.5 μm. Figure 5*a* shows the scan using a blank solution. The edges of the wire are observable as sharp rises in signal on the left and right sides of the scan. Any residual signal on the valley floor constitutes a background signal for the absorbance measurement. The magnitude of the background signal has been greatly reduced in this study as compared to our preliminary report (6). This decreased background signal results from careful minimization of beam reflections from the windows, use of polished electrode surfaces, and use of platinum as an electrode metal, which has a lower absorption than many other metals including copper (8). Figures 5*b* and 5*c* show scans of the same region with a dye concentration in solution of $4.0 \times 10^{-5} M$ for chopping frequencies of 10 Hz and 200 Hz, respectively. The signal maximizes between the electrodes and then falls off gradually in the radial direction. This signal, generated when the laser is shining in the region outside the resistor volume, is due to diffusion of heat into the resistor region. During the 50 ms illumination period during each chopping cycle, heat will diffuse approximately 100 μm — similar to the distance over which an appreciable hump is observed in Fig. 5*b*. At a chopping frequency of 200 Hz, Fig. 5*c*, heat will travel about 20 μm during the chopper cycle and little signal is generated in the solution outside of the electrolytic resistor.

With 20 μm spatial resolution provided by the 200 Hz chopping frequency, the signal strength generated between the electrodes reflects the local sensitivity of the measurement and not the effects of heat flow. A dip in the signal between the electrodes along the X axis in Fig. 5*c* is not due to increased background signal at the electrodes, see Fig. 5*a*, but rather may arise from increased sensitivity near the electrodes. The origin of this increased sensitivity would be associated with the higher current density near the electrode face compared with the region in the center of the electrolytic resistor. To test this idea, the magnitude of the electric field along the axis between two parallel, circular electrodes is derived in Appendix 2. The magnitude of the electric field vector pointing along the electrode axis is given by

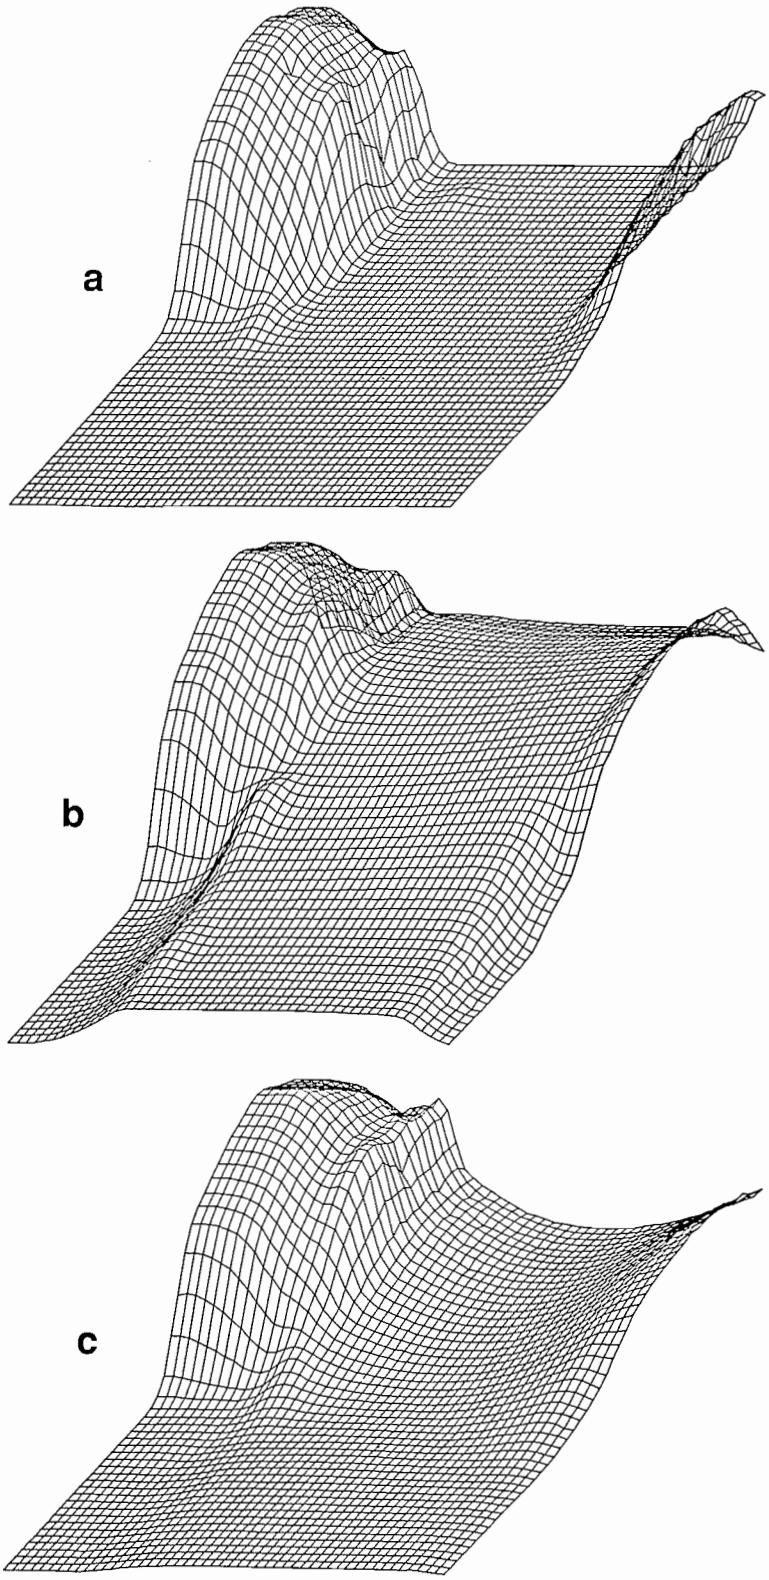

FIG. 5. Closeup scans (X–Y) of the signal in the resistor region using 2.5 μm pixels: (*a*) blank solution in the cell; (*b*) strongly absorbing solution with a chopping frequency of 10 Hz; (*c*) strongly absorbing solution with a chopping frequency of 200 Hz. The variation of the magnitude of the electric fields along the resistor axis become apparent at this higher chopping frequency. A "U" shape results for the TMEC absorbance signal in the X direction between the electrodes.

$$[5] \quad E = \frac{\sigma}{K\epsilon_0}\left[1 - (1/2)\left(\left[\frac{1}{1 + \{R/(0.5 + \beta)\}^2}\right]^{1/2} + \left[\frac{1}{1 + \{R/(0.5 - \beta)\}^2}\right]^{1/2}\right)\right]$$

where K is the dielectric constant of the medium, ϵ_0 is the permittivity of free space, R is the ratio of the wire radius r to the electrode separation L, and β is the distance from the electrode face divided by the electrode separation. Equation [5] is plotted as a function of β for various values of the dimensionless parameter R in Fig. 6. As R approaches ∞, corresponding to small electrode separations and large values of r, the electric field along the axis becomes uniform and approaches that given for a parallel plate configuration, $|E_{pp}| = \sigma/K\epsilon_0$ (13). The electric fields in the diagram are presented as a fraction of this value. As R decreases, the electric field along the axis of the resistor decreases: the magnitude of the field at the electrode surface asymptotically approaches a limit of $E_{pp}/2$ and the electric field at the center of the resistor approaches zero. The curve marked with squares has a R value of 0.381, corresponding to the particular r:L ratio used for the data in Fig. 5. The shape of the squared line in Fig. 6 qualitatively matches the shape of the dip between the electrodes in Fig. 5*c*. Higher sensitivity is achieved near the electrode face due to the greater magnitude of the electric fields there. To quantitatively compare Figs. 5*c* and 6, it is necessary to integrate the nonuniform electric field strength with the volume of the laser beam.

With the laser beam focused at the center of the electrolytic resistor, with a 100 μm electrode spacing, and utilizing a weakly absorbing solution, the dc current and the lock-in signal were measured as the voltage was increased from 0.0 to 3.0 V rms. The lock-in signal was found to be linear with the current (R = 0.9998, n = 12) as predicted from the theory. For all other data, the voltage applied to the electrodes was held at 1.0 V.

A linear polarizer was used to vary the laser power and a power meter was used to measure the power of the beam at the entrance to the cell. Using an electrode spacing of 50 μm, the lock-in signal increased linearly with the power (R = 0.9998, n = 7). However, the noise was constant to the maximum power of 5 mW. This constant noise and linear dependence of signal on laser power suggests that increasing the power further will result in increased sensitivity and improved detection limits.

The noise in the system appears to be associated with the conductivity of the electrolytic resistor. In fact, the noise appears to be due to shot noise in the current passing through the resistor. The current fluctuation associated with shot noise is given by (14)

$$[6] \quad I_{noise}(\text{rms}) = (2eIB)^{1/2}$$

where e is the electron charge, I is the average current through the cell, and B is the bandwidth of the measurement. Typical ac currents through the cell are 2.5 μA rms and the frequency bandwidth of the lock-in is given by $(1/8)T_c$ using the time constant T_c. Taking amplification into account, the expected shot noise appearing at the lock-in was 0.5 μV. Depending on the day, the noise that was measured was anywhere from one to six times this fundamental limit for chopping frequencies of 10 to 100 Hz. Using a resistor of 300 kΩ in place of the cell resulted in noise that was consistently within a factor of two of the shot noise limit.

Sensitivity was measured as a function of the electrode spacing, L, and chopping frequency, f, under constant current conditions for the ranges L = 50 to 200 μm and f = 10 to 100 Hz. The results are shown graphically in Fig. 7. The signal increases with a decrease in the chopping frequency at all electrode separations; lower chopping frequencies allow more heat to be deposited within the electrolytic resistor during each chopping cycle and, hence, a larger modulated signal. Of course, the temperature can not increase without bound between the electrodes. Eventually, heat will diffuse to the electrodes or other heat sinks, limiting the maximum signal produced at low chopping frequency. The signal also increases with a decrease in the electrode spacing; a small volume solution will heat faster than a larger volume. Equations [1] and [4] predict that the signal is inversely proportional to the electrode spacing. However, as the electrodes come close together, heat flow to the electrodes will decrease the sensitivity of the measurement and light scatter onto the electrodes will increase the background

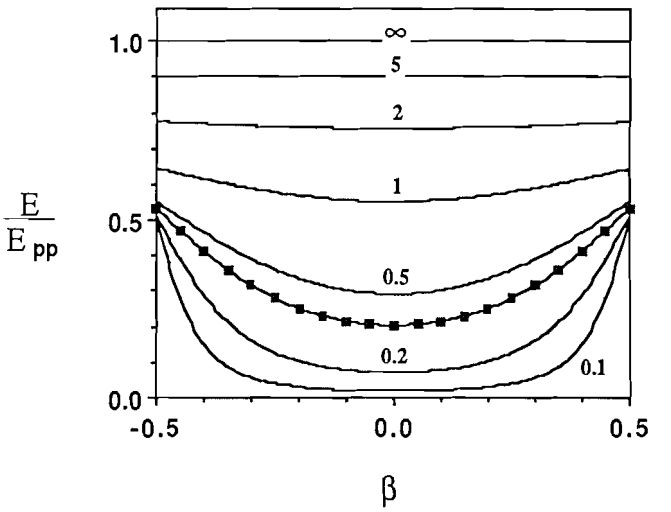

FIG. 6. Plotted are the calculated curves (eq. [11]) for the variation of the magnitude of the electric field on axis due inside a cylindrical parallel plate configuration. β is the fractional distance along the x axis between the electrodes and each curve represents a particular R value: the ratio of the wire radius to the electrode separation. E_{pp} is the field inside a parallel plate capacitor, achieved as R approaches infinity. The squared line represents the fields for an R ratio of 0.381, that used in the scans of Fig. 5.

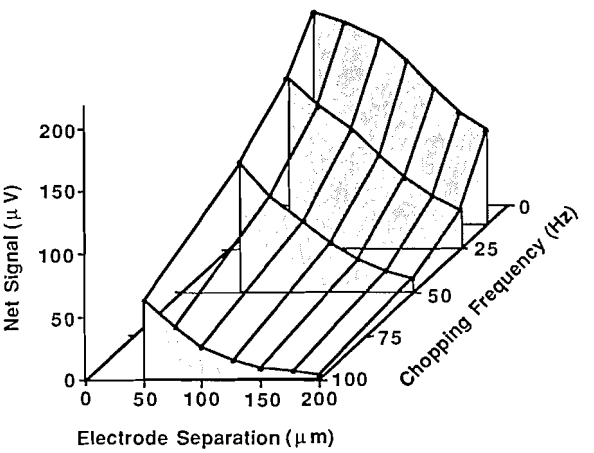

FIG. 7. Variation of the absorbance signal as a function of the electrode separation and chopping frequency. Greater sensitivity is achieved by using small electrode separations and low chopping frequencies.

signal. In this instrument, the background signal increases when the electrode spacing is less than 50 μm. Highest sensitivity is produced at low chopping frequency and small electrode spacing.

To study the variation in signal with laser beam spot size, a relatively large electrode separation, 125 μm, was used to allow a wide range of spot sizes to be studied. The spot size was varied by moving the lens, which focuses the beam, with respect to the cell using a micrometer. The spot size of the beam between the electrodes was estimated by recording the background signal as the laser beam was moved from the solution onto the resistor. The background signal gave a good approximation to an error function for the overlap of the Gaussian beam with the electrodes and the spot size was estimated from this data. The signal observed when the laser beam was centered in the electrolytic resistor varied by less than two standard deviations as the laser beam spot size changed from 9 μm to 40 μm and at a chopping frequency of both 10 Hz and 50 Hz. Despite the fact that the spot sizes are relatively large, this spot size independence is as predicted from eqs. [1] and [4]. This independence of signal upon spot size is important because it suggests that relatively large beams from incoherent light sources could be used to generate the thermally modulated signal.

A calibration curve was generated with an electrode separation of 50 μm and a chopping frequency of 10 Hz for aqueous Fast Green dye ranging from $1.0 \times 10^{-8} M$ to $4.0 \times 10^{-5} M$ and 0.01 *M* NaCl. Two blank solutions were prepared; one in H_2O and the other in D_2O. The noise measured during the calibration was 3.6 times the shot noise limit. The calibration curve was linear ($R = 0.9998$, $n = 14$) over three orders of magnitude from the one point detection limit (3σ) of $6.9 \times 10^{-9} M$ to $1.0 \times 10^{-5} M$ dye concentration. At higher concentrations, the calibration curve shows negative deviation because of a change in the spectrum of the dye due to self-association and a decrease in the laser power reaching the electrodes due to absorbance of the beam through the 260 μm distance from the window to the electrodes.

The blank signal was not zero, even though the laser beam passed through the center of the electrolytic resistor. This background signal has two origins, one from light scatter on the electrodes and the other from the finite absorbance of H_2O at 632.8 nm. The effect of each contribution may be determined by comparing the background signal observed with 0.01 *M* NaCl in water and that observed with 0.01 *M* NaCl prepared in D_2O. Although the light scatter background for the two solvents should be similar, because the refractive index of the two solvents is similar, the absorbance of D_2O is much less than that of H_2O at 632.8 nm. The absorbance of water in the red portion of the spectrum is associated with overtones of infrared transitions; the higher mass of deuterium results in lower frequency infrared transitions and, hence, lower absorbance in the visible portion of the spectrum. The Fast Green – H_2O calibration line intercepts the D_2O blank signal level at a negative dye concentration of $-1.31 \times 10^{-8} M$. The absorbance of a positive amount of dye of this concentration should thus be interpreted as the difference in absorbance between H_2O and D_2O at a wavelength of 632.8 nm. The experimental value for this difference is $\Delta\epsilon C(H_2O - D_2O) = 1.3 \times 10^{-3}\,cm^{-1}$. The datum is in excellent agreement with the literature value of $1.22 \times 10^{-3}\,cm^{-1}$ determined using pulsed photoacoustic spectroscopy in a long path length cell (15).

The absorptivity–concentration product (ϵC) detection limit for the calibration was $7.2 \times 10^{-4}\,cm^{-1}$, made over a path length given by the diameter of the wire, 76 μm. Using this path length, the absorbance detection limit is 5.5×10^{-6}, made in a volume of only 230 pL, estimated by the full resistor volume. The amount of analyte between the electrodes at the detection limit is only 1.6 attomoles or about a million molecules. Thermal modulation of electrical conductivity is a useful technique for the determination of absorbance within sub-nanoliter volumes of aqueous samples.

This excellent performance is achieved using a low power and low cost 5 mW laser. Of course, an increase in the laser power will result in a proportional increase in the sensitivity and decrease in the detection limit. For example, a 250-mW laser could produce detection limits on the order of 1×10^{-7} for aqueous samples, a significant advance in the state of the art. These detection limits are not likely to be exceeded with this particular cell geometry. Shot noise in the current flowing through the electrolytic resistor limits the precision of the conductivity technique. One approach to decrease the relative shot noise would be to increase the size of the electrodes which would increase the current through the increased electrolytic resistor. Unfortunately, the sensitivity of the measurements is predicted to scale inversely with the radius of the wire. Increasing the wire diameter will improve the precision of the measurement while decreasing the sensitivity of the measurement. It may prove necessary to investigate alternative cell geometries to improve further the performance of the technique.

Appendix 1

In this appendix, a derivation is presented for the change in the current through a cylindrical electrolytic resistor induced by a pulsed Gaussian laser beam. The derivation of the impulse response involves a description of the current through a thermally non-homogeneous resistor, the temperature field produced by the laser and, finally, the change in the current.

The current through a cylindrical homogeneous resistor can be derived by calculating the current density in the resistor due to the movement of ions. The ions have a particular ion mobility and are subjected to a force from the electric field present in the resistor (16). Ignoring the complications from ion–ion forces, the current is given by

$$[7] \quad I = \sum_i \frac{M_i N z_i^2 e^2 \pi r^2 V}{6\pi\eta r_i L}$$

where M_i is the molarity of the ith ionic species, z_i is the ionic charge number, r_i is the radius of the ion, e is the electron charge, N is Avogadro's number, V is the voltage applied to the electrodes, η is the viscosity of the medium, r is the radius of the resistor, and L is its length. The summation is over the current carrying ionic species in the solution. The current through a thermally non-homogeneous resistor can be described by a weighted average of the current in small volume elements of the resistor

$$[8] \quad \bar{I} = \frac{\int_{vol} I(x,y,z)\,dx\,dy\,dz}{\int_{vol} dx\,dy\,dz}$$

where the integral is evaluated over the cylindrical resistor volume. With the assumption that only the viscosity changes with temperature and defining the resistor volume, vol $= \pi r^2 L$, the current is given by

$$[9] \quad \bar{I} = \sum_i \frac{M_i N z_i^2 e^2 V}{4\pi r_i L^2} \int_{vol} \frac{1}{\eta(x,y,z)}\,dx\,dy\,dz$$

where $\eta(x,y,z)$ is the local viscosity of the solution at a point. Equation [9] converges to eq. [7] for a homogeneous viscosity between the electrodes. The thermally induced current change, ΔI, is then given by differentiating with respect to temperature. Over the small temperature rise induced by absorbance of the laser beam, the viscosity will be inversely proportional to the temperature of the solvent. Collecting variables and simplifying

$$[10] \quad \Delta I = \frac{\partial I}{\partial T} \times \Delta T = \frac{\bar{I}}{vol}\left(\frac{-1}{\eta}\frac{d\eta}{dT}\right)\int_{vol} \Delta T\,dx\,dy\,dz$$

The current change is proportional to the temperature rise, ΔT, integrated over the resistor volume. The temperature rise excited by a pulsed Gaussian TEM_{00} laser within a homogeneous absorbing sample has been derived (17) and, in the coordinate system of Fig. 1, is given by

$$[11] \quad \Delta T_{impulse}(x,y,t) = \frac{2.303E\epsilon C}{2\pi k t_c(1 + 2t/t_c)} \times \exp\left[\frac{-2(x^2 + y^2)}{\omega^2(1 + 2t/t_c)}\right]$$

where k is the *thermal* conductivity of the solvent, ω is the spot size of the beam, t is the time after the pulse, and t_c is the time constant of the solvent.

$$[12] \quad t_c = \frac{\omega^2 \rho C_p}{4k}$$

Here, ρ is the solvent density and C_p is its thermal capacity. The impulse response of the current, $\Delta I_{impulse}$, is then given by substituting eq. [11] into eq. [10].

Taking the resistor center as the origin, the overlap integral of the temperature field with the resistor of eq. [10] may be evaluated using rectangular coordinates

$$[13] \quad \int_{vol} \Delta T_{impulse}\,d\tau = \frac{2.303E\epsilon C}{2\pi k t_c(1 + 2t/t_c)} \int_{-r}^{r} \int_{-\sqrt{r^2-Z^2}}^{\sqrt{r^2-Z^2}} \int_{-L/2}^{L/2} \times \exp\left[\frac{-2(X^2/\omega^2)}{(1 + 2t/t_c)}\right] \exp\left[\frac{-2(Y^2/\omega^2)}{(1 + 2t/t_c)}\right] dX\,dY\,dZ$$

The integration with respect to x is separable and yields an error function

$$[14] \quad \int_{-L/2}^{+L/2} \exp\left[\frac{-2x^2}{\omega^2(1 + 2t/t_c)}\right] dx = \left[\frac{\pi\omega^2(1 + 2t/t_c)}{2}\right]^{1/2} \mathrm{erf}\left(\left[\frac{L^2}{2\omega^2(1 + 2t/t_c)}\right]^{1/2}\right)$$

The remaining integrals can not be expressed in terms of simple functions. Instead, we make the approximation that the spot size of the laser beam is much less than the radius of the wire. Under this condition, the limits of integration in the Y direction become $\pm\infty$

$$[15] \quad \int_{vol} \Delta T_{impulse}\,d\tau = \frac{2.303E\epsilon C\omega}{2\sqrt{2\pi}kt_c\sqrt{(1 + 2t/t_c)}} \times \mathrm{erf}\left(\left[\frac{L^2}{2\omega^2(1 + 2t/t_c)}\right]^{1/2}\right) \times \int_{-r}^{r} \int_{-\infty}^{\infty} \exp\left[\frac{-2(Y^2/\omega^2)}{(1 + 2t/t_c)}\right] dY\,dZ = \frac{2.303E\epsilon Cr}{\rho C_p} \mathrm{erf}\left(\left[\frac{L^2}{2\omega^2(1 + 2t/t_c)}\right]^{1/2}\right)$$

Collecting all together, the modulated current is given by

$$[16] \quad \Delta I = \frac{2.303E\epsilon C\bar{I}}{\pi rL}\left(\frac{-1}{\rho C_p \eta}\frac{d\eta}{dT}\right) \times \mathrm{erf}\left(\left[\frac{L^2}{2\omega^2(1 + 2t/t_c)}\right]^{1/2}\right)$$

Last, if the laser beam spot size is much less than the electrode spacing, the current is found to be

$$[17] \quad \Delta I_{impulse}\begin{bmatrix}\text{small spot}\\ \text{limit}\end{bmatrix} = \frac{2.303E\epsilon C\bar{I}}{\pi rL}\left(\frac{-1}{\rho C_p \eta}\frac{d\eta}{dT}\right)$$

Assumptions

Various approximations have been made in the derivation of the impulse response of eq. [17]. These are listed below:

(*i*) The ions and absorbing analyte are homogeneously distributed between the electrodes.

(*ii*) In the derivation of the current of eq. [1], Stokes approximation has been invoked for the frictional coefficient of a spherical particle of radius r_i particle moving through a viscous medium: $f = 6\pi\eta r_i$ (16).

(*iii*) The electric field between the electrodes is of magnitude

$\boldsymbol{E} = V/L$ — inside the cylindrical resistor volume (V = applied voltage)

$\boldsymbol{E} = 0$ — elsewhere

This approximation will hold in the limit of small electrode spacing. An accurate model would account for the variation in electric field strength throughout the sample volume. Appendix 2 presents the variation in the axial electric field between the electrodes. A uniform axial electric field is achieved if the radius of the wire is more than five times the distance between the electrodes.

(*iv*) The voltage drop across the double layer capacitance is assumed to be zero. This is achieved by using a sufficiently high ac frequency to eliminate the double layer impedance.

(*v*) The spot size of the laser is assumed constant over the diameter of the electrolytic resistor.

(*vi*) The effects of heat sinks such as quartz windows and platinum wires have been ignored.

(*vii*) The background signal associated with scattered light striking the electrodes is ignored.

(*viii*) The modulation frequency of the conductivity measurement is sufficiently low so that eq. [7] holds.

Appendix 2

This appendix presents a derivation for the magnitude of the electric field at a point on the axis of a cylindrical parallel plate capacitor. The calculation involves summing all the contributions to the field at point P to all charge on the surface of the electrode faces as shown in Fig. 8.

A charge density $+\sigma$ exists on the left electrode surface and an equal and opposite charge density exists on the right electrode surface. An incremental electric field vector, $d\boldsymbol{E}$, at point P is calculated from Coulombs law (13)

$$[18] \quad d\boldsymbol{E} = \frac{1}{4\pi K\epsilon_0}\frac{dq}{l^2}\boldsymbol{l}$$

where dq is the element of surface charge a distance l away from point P and $\boldsymbol{l}$ is a vector pointing along the line from the surface charge to point P. When calculating the field on axis due to a thin circular ring of surface charge on an electrode face, the vector components perpendicular to the x axis can be ignored due to cancellation by symmetry. Thus, the field at P due to a charged ring of radius ζ and thickness $d\zeta$ on the left electrode face is given by

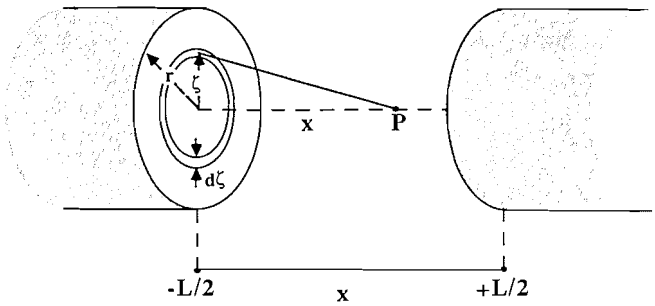

FIG. 8. Calculation of the magnitude of the electric fields on axis due to cylindrical parallel plate configuration. X is distance measured from the center of the electrode.

$$[19] \quad d\boldsymbol{E} = \frac{1}{4\pi K\epsilon_0}\frac{2\pi\zeta\, d\zeta\, \sigma}{[(L/2+x)^2+\zeta^2]}\frac{(L/2+x)}{\sqrt{(L/2+x)^2+\zeta^2}}\boldsymbol{x}$$

$$= \frac{(L/2+x)\sigma}{2K\epsilon_0}\frac{\zeta\, d\zeta}{[(L/2+x)^2+\zeta^2]^{3/2}}\boldsymbol{x}$$

The total field at point P due to the left electrode is obtained by integrating with respect to ζ

$$[20] \quad d\boldsymbol{E}_{\text{LEFT}} = \frac{(L/2+x)\sigma\boldsymbol{x}}{2K\epsilon_0}\int_0^r \frac{\zeta}{((L/2+x)^2+\zeta^2)^{3/2}}\, d\zeta$$

Substituting $y = \zeta^2$, the integral yields

$$[21] \quad \boldsymbol{E}_{\text{LEFT}} = \frac{\sigma\boldsymbol{x}}{2K\epsilon_0}\left(1 - \left[\frac{1}{1+\{r/(L/2+x)\}^2}\right]^{1/2}\right)$$

The field at P due to charge on the right electrode can be calculated in a similar fashion and will add to the field calculated above. It is convenient to use the fractional distance between the electrodes; $\beta = x/L$ and to calculate the field for a particular ratio of the wire radius r to the electrode separation L; $R = r/L$. The final expression for the magnitude of the field at P using these substitutions is

$$[22] \quad \boldsymbol{E}(\beta, R) = \frac{\sigma}{K\epsilon_0}\left[1 - (1/2)\left(\left[\frac{1}{1+\{R/(0.5+\beta)\}^2}\right]^{1/2} + \left[\frac{1}{1+\{R/(0.5-\beta)\}^2}\right]^{1/2}\right)\right]$$

Nitrosyl complexes of rhenium. 3. The synthesis and substitution reactions of $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ derived from the reaction of $ReH_2(NO)(PPh_3)_3$ with $HClO_4$. Members of the series $ReHX(NO)(PPh_3)_3$

JULIE Y. CHEN, KEVIN R. GRUNDY,[1] AND KATHERINE N. ROBERTSON
The Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received August 18, 1988[2]

JULIE Y. CHEN, KEVIN R. GRUNDY, and KATHERINE N. ROBERTSON. Can. J. Chem. **67**, 1187 (1989).

$ReH_2(NO)(PPh_3)_3$ reacts with alcoholic $HClO_4$ to yield the solvated cation, $[ReH(ROH)(NO)(PPh_3)_3]ClO_4$ (R = CH_3, C_2H_5) which can be isolated as an explosive solid (R = CH_3 only). In the solid state, the perchlorate counter ion is hydrogen bound to the ligated alcohol, as observed for $[ReH(CH_3OH)(CO)(NO)(PPh_3)_2]ClO_4$. This latter complex also results from the reaction of $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ with CO under ambient conditions. On reaction with *p*-tolylisocyanide (RNC), however, substitution is also accompanied by dihydrogen elimination to give $[Re(OR)(NO)(CNR)_2(PPh_3)_2]ClO_4$, irrespective of the mole ratio of the reactants. In contrast, $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ reacts with coordinating anions with loss of methanol to give air-sensitive $ReHX(NO)(PPh_3)_3$ (X = OCH_3, F, Cl, Br, I, N_3, NCO, SCN), of which only those with X = Cl, Br, N_3 were characterized in solution. The compounds $ReHX(NO)(PPh_3)_3$ are similar to their osmium analogues in having a labile third phosphine. Thus, reaction with neutral ligands such as CO or RNC leads to the series of neutral rhenium hydrido nitrosyls $ReHX(L)(NO)(PPh_3)_2$. Prior to this work, the only known examples from this series were those with L = CO, X = H, F, OCH_3. Interestingly, the isomer of $ReHF(CO)(NO)(PPh_3)_2$ isolated in this work differs from that previously isolated (from the reaction of $[ReF(CO)(NO)(PPh_3)_3]^+$ with BH_4^-) in having F *trans* to NO. All structural assignments have been made on the basis of elemental analyses, infrared spectroscopy, ^1H and ^{31}P nmr spectroscopy and deuteration studies, where appropriate.

Key words: hydrido, nytrosyl, rhenium, complexes.

JULIE Y. CHEN, KEVIN R. GRUNDY et KATHERINE N. ROBERTSON. Can. J. Chem. **67**, 1187 (1989).

Le $ReH_2(NO)(PPh_3)_3$ réagit avec le $HClO_4$ en solution alcoolique pour fournir le cation solvaté, $[ReH(ROH)(NO)(PPh_3)_3]ClO_4$ (R = CH_3, C_2H_5), que l'on peut isoler sous la forme d'un solide explosif (R = CH_3 seulement). A l'état solide, une liaison hydrogène relie le contre-ion perchlorate à l'alcool agissant comme ligand; un résultat semblable a aussi été observé avec le $[ReH(CH_3OH)(CO)(NO)(PPh_3)_2]ClO_4$. Ce dernier composé est aussi formé par la réaction du $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ avec du CO dans des conditions ambiantes. Lors de la réaction avec l'isocyanure de *p*-tolyle, la substitution est toutefois accompagnée d'une élimination d'hydrogène moléculaire conduisant à la formation de $[Re(OR)(NO)(CNR)_2(PPh_3)_2]ClO_4$, quel que soit le rapport molaire des réactifs. Par ailleurs, la réaction du $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ avec des anions pouvant donner lieu à une coordination conduit à une perte de méthanol et à la formation de $ReHX(NO)(PPh_3)_3$ (X = OCH_3, F, Cl, Br, I, N_3, NCO, SCN) qui sont sensibles à l'air et dont seulement les dérivés contenant X = Cl, Br et N_3 ont été caractérisés en solution. Les composés $ReHX(L)(NO)(PPh_3)_2$, comme leurs analogues contenant de l'osmium, portent une troisième phosphine qui est labile. Par réaction avec des ligands neutres comme le CO et le RNC, ils conduisent donc à la formation d'une série de nitrosyl hydrido rhénium neutres $ReHX(L)(NO)(PPh_3)_2$. Avant ce travail, les seuls exemples connus dans cette série étaient ceux comportant un L = CO et X = H, F ou OCH_3. Il est intéressant de noter que l'isomère du $ReHF(CO)(NO)(PPh_3)_2$ qui a été isolé au cours de ce travail est différent de celui qui avait été isolé antérieurement (par réaction du $[ReF(CO)(NO)(PPh_3)_3]^+$ avec le BH_4^-); le F est trans par rapport au NO. Toutes les attributions de structures ont été faites en se basant, suivant le cas, sur des analyses élémentaires, les spectroscopies infrarouge et rmn du ^1H et ^{31}P ainsi que des éudes de deutération.

Mots clés : hydrido, nitrosyl, rhénium, composés.

[Traduit par la revue]

Introduction

In the second paper of this series (1), we described the reaction of $ReH_2(NO)(PPh_3)_3$ with alcoholic $HClO_4$ in the presence of CO to give $ReH(OR)(CO)(NO)(PPh_3)_2$ and numerous derived compounds, most of which took the form $ReXY(CO)(NO)(PPh_3)_2$. Like their isoelectronic osmium counterparts $OsXY(CO)_2(PPh_3)_2$, however, the reactivity of these mixed carbonyl nitrosyl derivatives of rhenium is limited by the lack of a labile ligand. $OsHCl(CO)(PPh_3)_3$ does not suffer from this limitation since the third phosphine *trans* to the hydride ligand is quite labile, making this material arguably the most versatile synthon available in osmium chemistry. It was obviously in our best interest, therefore, to synthesize $ReHCl(NO)(PPh_3)_3$, or some closely related species, and investigate its usefulness as a synthon for non-carbonyl containing Re(I) nitrosyl derivatives.

This paper describes the reaction of $ReH_2(NO)(PPh_3)_3$ with $HClO_4$ in the absence of CO to give the highly unstable, solvated species $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$, analogous to previously reported $[ReH(CH_3OH)(CO)(NO)(PPh_3)_2]ClO_4$ (1). The extreme instability of the title compound somewhat limits its utility but simple substitutions either of the coordinated solvent or the third phosphine do allow the synthesis of a variety of both new and previously reported Re(I) derivatives, including the original target compound, $ReHCl(NO)(PPh_3)_3$.

Experimental section

CAUTION! THESE COMPOUNDS SHOULD BE TREATED WITH THE EXTREME CAUTION NORMALLY AFFORDED ORGANOMETALLIC PERCHLORATE SALTS, WHICH ARE POTENTIALLY EXPLOSIVE (2). IN THIS RESPECT THE TITLE COMPOUND $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ IS PARTICULARLY HAZARDOUS, BEING SUBJECT TO VIOLENT, EXPLOSIVE DECOMPOSITION. To minimize the hazards associated with these perchlorate complexes the following precautions should be observed: (*i*) Keep reaction scales to <0.5 g, or <0.25 g for the title compound, (*ii*) avoid the use of metal spatulas, and (*iii*) use the complexes when

prepared and refrain from storing samples, especially near sources of heat or in sealed containers.

General experimental details and instrumental methods were as outlined previously (1). Infrared and ^1H and ^{31}P nmr data are summarized in Tables 1 and 2.

Reaction of $ReH_2(NO)(PPh_3)_3$ with $HClO_4$ in methanol. Synthesis of $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ (1)

$ReH_2(NO)(PPh_3)_3$ (0.20 g, 0.20 mmol) was combined with enough methanol to barely suspend the solid (0.5 mL) and 3 drops of perchloric acid (0.04 mL, 70% w/v) at 0°C. Dichloromethane (0.5 mL) was then added dropwise to the stirred suspension until a visible reaction had begun. A bright, yellow–orange solution formed as the original solid was consumed, accompanied by gas evolution. The product was precipitated immediately by the addition of diethyl ether (30 mL). After stirring for a further 5 min at 0°C, the pale yellow needles were collected by vacuum filtration under nitrogen and washed with diethyl ether. The product could neither be recrystallized nor sent for analysis because of its instability (0.22 g, 97%); mp 97–98°C expl.

Reaction of $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ with CO. Synthesis of $[ReH(CH_3OH)(CO)(NO)(PPh_3)_2]ClO_4$

A mixture of dichloromethane and methanol (40 mL, 1:1 v/v) was saturated with CO by bubbling for 20 min. To the solution was added freshly prepared $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ (0.1 g, 0.09 mmol) suspended in 10 mL of methanol. The resultant pale yellow solution was stirred under CO for a further 30 min and then reduced to 2–3 mL under reduced pressure. (*Note*: Do not evaporate to dryness or an explosion may result.) The viscous, dark gold oil was diluted with diethyl ether (100 mL) and stirred for 10 min to induce precipitation of a small amount of material. On further reducing the solvent volume to 10 mL the remainder of the product precipitated. The beige–yellow needles of $[ReH(CH_3OH)(CO)(NO)(PPh_3)_2]ClO_4$ were filtered and recrystallized from dichloromethane/methanol/diethyl ether (0.06 g, 80%). Characterization was by comparison with an authentic sample (1).

Reaction of $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ with p-tolylisocyanide. Synthesis of $[Re(OC_2H_5)(NO)(C_7H_7NC)_2(PPh_3)_2]PF_6$ (2)

To 20 mL of ethanol was added 6.1 mL of *p*-tolylisocyanide solution (10 mg mL^{-1}, 2.4 equiv.) in ethanol followed by freshly prepared $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ (0.25 g, 0.22 mmol) suspended in 10 mL methanol. After stirring for 5 min, solid $NaPF_6$ (0.1 g) was added to the bright yellow solution and stirring continued for a further 30 min. No gas evolution could be observed under these conditions. Evaporation under reduced pressure to 2–3 mL yielded a thick golden-orange oil which was dissolved in dichloromethane (15 mL) and filtered through Celite to remove excess $NaPF_6$. The resultant bright yellow solution was diluted with an equal volume of ethanol and the volume reduced to 2–3 mL. Crystallization was initiated by scratching the vessel and completed by the addition of diethyl ether (40 mL) in several small portions. After stirring for a further 5 min, the pale yellow product was removed by filtration and recrystallized in the above manner from dichloromethane/ethanol/diethyl ether in the form of small needles (0.21 g, 82%); mp 177–179°C dec. *Anal.* calcd. for $C_{54}H_{49}N_3F_6O_2P_3Re$: C 55.67, H 4.24, N 3.61; found: C 55.79, H 4.38, N 3.63.

Prepared in similar fashion using methanol and/or $NaClO_4$ where appropriate were $[Re(OC_2H_5)(NO)(C_7H_7NC)_2(PPh_3)_2]ClO_4$ (**2***a*) (81%, mp 182–183°C dec.), $[Re(OCH_3)(NO)(C_7H_7NC)_2(PPh_3)_2]PF_6$ (**3**) (59%, mp 195–198°C dec.), and $[Re(OCH_3)(NO)(C_7H_7NC)_2(PPh_3)_2]ClO_4$ (**3***a*) (70%, mp 183°C dec.).

Reaction of $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ with anions. Synthesis of $ReHX(NO)(PPh_3)_3$ (4–9)

Method A: $ReH_2(NO)(PPh_3)_3$ (0.20 g, 0.20 mmol) was converted to $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ as described above. The yellow solid was immediately suspended in methanol (5 mL) and 1.1 equiv. of the required solid salt were washed into it with a second 5 mL portion of methanol. The original solid dissolved rapidly with stirring as the product precipitated. After a further 5 to 10 min, the product was collected by filtration under nitrogen. All $ReHX(NO)(PPh_3)_3$ derivatives proved air-sensitive and were used immediately. Characterization was limited to infrared and nmr spectroscopy, and derivatization. Prepared in this manner were $[ReH(OCH_3)(NO)(PPh_3)_3]$ (**4**) (0.5 mL, 0.5 *M* $NaOCH_3$ in methanol, pale yellow, 49%, mp 104–107°C dec.), $ReHF(NO)(PPh_3)_3$ (**5**) ($KF.2H_2O$, yellow, 64%, mp 175–176°C dec.), and $ReH(NCO)(NO)(PPh_3)_3$ (**9**) (KNCO, golden orange, 72%, mp 171–174°C dec.).

Method B: $ReH_2(NO)(PPh_3)_3$ (0.20 mmol) was converted to $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ as described above. While still on the filter stick, the yellow solid was washed with a minimum of degassed dichloromethane into a solution of 2 equiv. of the appropriate salt in 30 mL of methanol at 0°C. Precipitation of the bright yellow products began immediately. After stirring for 20 min, the crystals were collected under nitrogen and washed with methanol and hexane. Prepared in this manner were $ReHCl(NO)(PPh_3)_3$ (**6**) (LiCl, bright yellow, 68%, mp 165–170°C dec.), $ReHBr(NO)(PPh_3)_3$ (**7**) (NaBr, golden orange, 74%, mp 160–165°C dec.), and $ReH(N_3)(NO)(PPh_3)_3$ (**8**) (NaN_3, yellow, 67%, mp 133–134°C dec.).

Reaction of $ReHX(NO)(PPh_3)_3$ with CO. Synthesis of $ReHX(CO)(NO)(PPh_3)_2$. (10–15)

A mixture of dichloromethane and ethanol (40 mL, 1:1 v/v; methanol was used for X = OCH_3) was saturated with CO by bubbling for 20 min. While maintaining the flow of CO, a freshly prepared sample of $ReHX(NO)(PPh_3)_3$, suspended in 10 mL of the appropriate alcohol was added. Any solid remaining was dissolved by the addition of dichloromethane to give a bright yellow solution which quickly lightened to a pale yellow or gold as stirring under CO was continued for a further 30 min. Evaporation under reduced pressure precipitated the product which was recrystallized from dichloromethane and the appropriate alcohol. All derivatives are air- and solution-stable crystalline solids.

Prepared in this manner were $ReH(OCH_3)(CO)(NO)(PPh_3)_2$ (**10**) (pale yellow needles, 89%, characterized by comparison with an authentic sample (1). $ReHF(CO)(NO)(PPh_3)_2$ (**11**) (pale yellow, 93%, mp 186–188°C dec.) *Anal.* calcd. for $C_{37}H_{31}NO_2FP_2Re$: C 56.34, N 1.78, O. 4.06; found: C 56.38, N 1.75, O 4.16. $ReHCl(CO)(NO)(PPh_3)_2$ (**12**) (pale yellow, 85%, mp 205–208°C dec.). *Anal.* calcd. for $C_{37}H_{31}NClO_2P_2Re$: C 55.19, H 3.88, N 1.74; found: C 54.60, H 3.91; N 1.71. $ReHBr(CO)(NO)(PPh_3)_2$ (**13**) (pale yellow needles, 91%, mp 211°C dec.). $ReH(N_3)(CO)(NO)(PPh_3)_2$ (**14**) (pale yellow needles, 93%, mp 178–180°C dec.). $ReH(NCO)(CO)(NO)(PPh_3)_2$ (**15**) (pale yellow–gold needles, 92%, mp 209–212°C dec.).

Prepared in similar fashion using the appropriate precursors were $ReHI(CO)(NO)(PPh_3)_2$ (**16**) (pale yellow needles, 92%, mp 224–227°C dec.). $ReH(SCN)(CO)(NO)(PPh_3)_2$ (**17**) (golden orange, 90%, mp 173–177°C dec). *Anal.* calcd. for $C_{38}H_{31}N_2O_2P_2SRe$: C 55.13, H 3.77, N 3.38; found: C 55.02, H 3.78, N 3.37.

Reaction of $ReHX(NO)(PPh_3)_3$ with p-tolylisocyanide. Synthesis of $ReHX(C_7H_7NC)(NO)(PPh_3)_2$ (18–23)

To 20 mL of 1:1 dichloromethane/ethanol (methanol in the case X = OCH_3) was added 2.6 mL of *p*-tolylisocyanide solution (10 mg mL^{-1} in the appropriate alcohol, 1.1 equiv. based on original amount of $ReH_2(NO)(PPh_3)_3$ used at the start of the sequence, 0.25 g). To this solution was added the freshly prepared $ReHX(NO)(PPh_3)_3$ slurried in 10 mL of the appropriate alcohol. A further 10 mL of dichloromethane was added to generate a bright yellow solution which, after 30 min stirring, was evaporated under reduced pressure to give crystals of the product. Recrystallization was from dichloromethane/alcohol plus several drops of the isocyanide solution. All derivatives are air- and solution-stable, crystalline solids.

Prepared in this manner were $ReH(OCH_3)(C_7H_7NC)(NO)(PPh_3)_2$ (**18**) (pale yellow needles, 98% based on $ReH(OCH_3)(NO)(PPh_3)_3$ used, mp 179–180°C dec.). *Anal.* calcd. for $C_{45}H_{41}N_2O_2P_2Re$: C 60.73, H 4.64, N 3.15; found: C 60.76, H 4.77, N 3.17. $ReHF(C_7H_7NC)(NO)(PPh_3)_2$ (**19**) (pale yellow needles, 87%, mp 196–197°C dec.). $ReHCl(C_7H_7NC)(NO)(PPh_3)_2$ (**20**) (bright yellow needles, 85%, mp 221°C dec.). *Anal.* calcd. for $C_{44}H_{38}N_2ClOP_2Re$: C 59.09, H

4.28, N 3.13; found: C 58.57, H 4.35, N 3.09. $ReHBr(C_7H_7NC)(NO)(PPh_3)_2$ (**21**) (bright yellow needles, 77%, mp 223–225°C dec.). $ReH(N_3)(C_7H_7NC)(NO)(PPh_3)_2$ (**22**) (bright yellow needles, 87%, mp 208–209°C dec.). $ReH(NCO)(C_7H_7NC)(NO)(PPh_3)_2$ (**23**) (pale yellow needles, 94%, mp 196–197°C dec.).

Prepared in similar fashion using the appropriate precursors were $ReHI(C_7H_7NC)(NO)(PPh_3)_2$ (**24**) (yellow–green needles, 90%, mp 216–218°C dec.). $ReH(SCN)(C_7H_7NC)(NO)(PPh_3)_2$ (**25**) (bright yellow crystals, 83%, mp 188°C dec.). *Anal.* calcd. for $C_{45}H_{38}N_3OP_2SRe.(CH_2Cl_2)_{0.25}$: C 57.93, H 4.14, N 4.48; found: C 57.51, H 4.22, N 4.44.

Results and discussion

The reader's attention is drawn to the warning in the Experimental section concerning the instability of the percholorate complexes described in this paper. To date our efforts directed at eliminating the need for the use of perchloric acid have been unsuccessful so that, unfortunately, the only currently available synthetic route to compounds **4–25** is through the highly unstable title complex, $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$.

As mentioned in the Introduction, the previous paper in this series examined the reaction of $ReH_2(NO)(PPh_3)_3$ with alcoholic $HClO_4$ in the presence of CO. In order to rationalize the dependence of the observed products on the nature of the alcohol used in their preparation, we proposed the initial formation of $[ReH(ROH)(NO)(PPh_3)_3]ClO_4$ as a common intermediate. At that time we also reported that unstable materials could be isolated from this system by eliminating the addition of CO. It was apparent that, if these materials were as we thought, the presence of two labile ligands should make them useful precursors to a wide range of hydrido nitrosyl complexes of rhenium(I). Such proved to be the case, but on looking further into the nature of these intermediate complexes, it quickly became apparent that it was futile to attempt to either characterize or use the material obtained from ethanol, since its decomposition at room temperature is very rapid. From methanol, however, relatively stable samples can be obtained, provided solvent volumes are kept to a minimum. Thus, if $ReH_2(NO)(PPh_3)_3$ is suspended in a minimum of ice-cold methanolic $HClO_4$ (0.5 mL for 200 mg of solid) and 0.5 mL of dichloromethane is added to the suspension, the solid quickly goes into solution accompanied by gas evolution. Flooding the resultant yellow–orange solution immediately with diethyl ether affords a yellow crystalline precipitate of $[ReH(CH_3OH)(NO)(PPh_3)_3]ClO_4$ (**1**), in excellent yield.

As mentioned earlier, this compound is thermally unstable and prone to violent or explosive decomposition at any time, or on heating above about 90°C. In solution, decomposition can also be rapid and unpredictable, even at low temperatures. For example, even at −80°C under nitrogen, sufficient decomposition usually takes place to give poorly defined ^1H nmr spectra. Thus, a typical spectrum would show a poorly resolved multiplet in the aromatic region, a broad singlet at 3.40 ppm attributable to methanol and a featureless lump at 1.6 ppm, presumably arising from the hydride ligand. Although the presence of the hydride could not be unequivocally established through ^1H nmr spectroscopy, the proton coupled ^{31}P nmr spectrum exhibited evidence of coupling between the hydride ligand and the *trans*-phosphine of 53 Hz. Unfortunately, the lines were too broad to discern any *cis* H—P or P—P couplings. On proton decoupling, the lines were still too broad to resolve P—P coupling, which for members of the series $ReHX(NO)(PPh_3)_3$, were typically around 8 Hz.

The ir spectrum of **1** exhibits bands due to νReH and νNO at 1993 and 1700 cm^{-1}, respectively. Evidence for the methanol ligand is seen in absorptions at 2810 and 3138 cm^{-1}, the former of which is diagnostic of the OCH_3 group (3) and the latter due to ν(O—H—O). On reacting $ReH_2(NO)(PPh_3)_3$ with $DClO_4$ in CH_3OD, $[ReH(CH_3OD)(NO)(PPh_3)_3]ClO_4$ (**1***a*) was obtained which had essentially the same spectrum as **1** but for ν(O—D—O) which appeared at 2326 cm^{-1}. That the perchlorate counterion is hydrogen bound to the methanol ligand is further supported by the appearance of five absorptions at 1122, 1031 (ν_3), 921 (ν_1), 616 (ν_4), and 448 (ν_2) cm^{-1}. These and other nmr and ir data are summarized in Tables 1 and 2. Further support for the proposed formulation is provided by the fact that **1** reacts with CO in dichloromethane–methanol solution to give good yields of previously characterized $[ReH(CH_3OH)(CO)(NO)(PPh_3)_2]ClO_4$ (1).

Unlike CO, however, *p*-tolylisocyanide reacts with **1** via a quite different pathway, giving instead the cations $[Re(OR)(NO)(RNC)_2(PPh_3)_2]^+$ (R = CH_3 or C_2H_5, depending on the alcohol used), isolable as both PF_6^- and ClO_4^- salts (**2**, **2***a*: R = C_2H_5; **3**, **3***a*, R = CH_3). These compounds have been fully characterized by the usual techniques and both ir and nmr data establish a *trans* arrangement for the isocyanide ligands. This reaction involves the formal elimination of dihydrogen, although the presence of elemental dihydrogen was not demonstrated, and is strongly reminiscent of the reaction of $[ReH(CH_3OH)(CO)(NO)(PPh_3)_2]ClO_4$ with anions to generate $ReH(OCH_3)X(CO)(NO)(PPh_3)_2$ (1). Most probably, the first step in the reaction of **1** with RNC involves replacement of the labile third phosphine, which we believe to be *trans* to the hydride ligand (*vide infra*), to generate $[ReH(CH_3OH)(RNC)(NO)(PPh_3)_2]ClO_4$. Having an excellent donor ligand such as *p*-tolylisocyanide *trans* to hydrogen in this manner should promote dihydrogen loss by making this ligand even more hydridic in nature. Certainly dihydrogen loss must be more rapid than the initial substitution since reaction of **1** with one equivalent of RNC yields only a mixture of **1** and **2** or **3**. It is interesting to note that **2** and **3** can also be synthesized by reacting $[ReH(CH_3OH)(CO)(NO)(PPh_3)_2]^+$ with excess RNC in the appropriate alcohol. Here, the initial reaction presumably involves substitution of the carbonyl group which, although unusual, is perhaps not too surprising in view of the relative weakness of the Re—CO bonding, manifested by a rather high νCO value of 2040 cm^{-1} in the starting material.
