Non-hydrogen atomic scattering factors were taken from the literature tabulations (64–66). The Zr and Re atom positions were determined using direct methods. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least squares techniques on F, minimizing the function $w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of refinement all the non-hydrogen atoms were assigned anisotropic temperature factors. Hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. In the case of the carbon bound hydrogen atoms, contributions were calculated, but not refined. The hydride was not located and its contribution was omitted in the final cycles of least squares. The final values of R and R_w are given in Table 1. The maximum Δ/σ on any of the parameters in the final cycles of the refinement and the location of the largest peaks in the final difference Fourier map calculation are also given in Table 1. The residual electron densities were of no chemical significance. The following data are tabulated: positional parameters (Table 2) and selected bond distances and angles (Table 3). Thermal parameters (Table S1), hydrogen atom parameters (Table S2), and values of 10 $|F_o|$ and 10 $|F_c|$ (Tables S3) have been deposited as supplementary material.[2]

TABLE 1. Crystallographic parameters

Formula	$C_{37}H_{31}O_3P_2ReZr$
Crystal colour, form	Yellow blocks
a (Å)	17.393(3)
b (Å)	14.348(7)
c (Å)	13.036(3)
β (deg)	92.35(2)
Crystal system	Monoclinic
Space group	$P2_1/c$
Volume (Å^3)	3250(2)
Density (g cm^{-3}) calcd.	1.76
Z	4
Crystal dimensions (mm)	0.31 × 0.42 × 0.21
Absorption coefficient, μ(cm^{-1})	39.54
Radiation, λ(Å)	Mo Kα (0.71069)
Temperature (°C)	24
Scan speed (deg/min)	2.0–5.0 (θ/2θ scan)
Scan range (deg)	1.0 below Kα1 1.0 above Kα2
Background scan time ratio	0.5
Data collected	4476
No. of unique data $F_o^2 > 3\sigma(F_o^2)$	3118
No. of variables	349
R (%)	5.23
R_w (%)	5.33
Largest Δ/σ in the final least-squares cycle	0.010
Maximum residual electron density (e/A^3)	2.5
Atom associated	Re

Results and discussion

The reaction of two equivalents of $Cp_2Zr(PPh_2)_2$ with $Re_2(CO)_{10}$ in THF results in a gradual colour change from red–black to yellow over a 12 h period. Monitoring of the reaction by $^{31}P\{^1H\}$ NMR spectroscopy implies the formation of numerous phosphorus containing products including the species **1** that exhibits a single resonance at 154.2 ppm. In addition, chemical shifts indicate that other products include P_2Ph_4, PPh_2H, and several uncharacterized species containing coordinated phosphine or phosphido moieties. Fractionation of the products with pentane and fractional crystallization of the pentane insoluble residue from THF/pentane led to isolation of yellow crystals of the complex **1**, in relatively low yield (17%). The $^{31}P\{^1H\}$ NMR spectrum of **1** shows a resonance at 154 ppm. The similarity of this chemical shift to that seen for $Cp_2Zr(\mu\text{-}PPh_2)_2W(CO)_4$ (56) suggests the presence of bridging phosphido groups between Zr and Re. ^1H NMR data for **1** show reso-

[2]Tables of thermal and hydrogen atom parameters, bond distances and angles, and values of $10F_o$ and $10F_c$ (15 pages) have been deposited. †Distances are given in Å, angles in degrees.
‡Report is prelinminary and thus full details are not available.

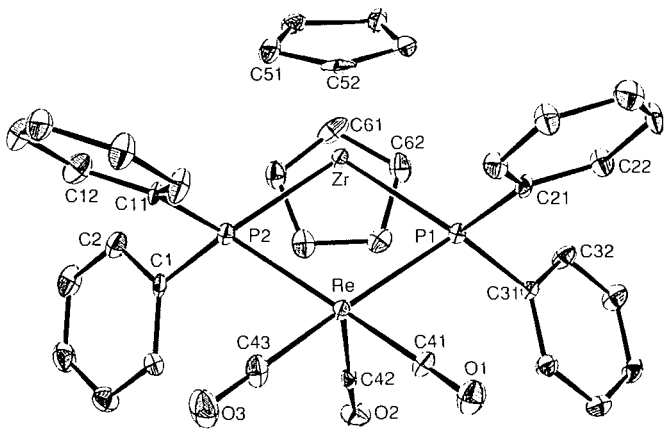

FIG. 1. ORTEP drawing of molecule **1**, 20% thermal ellipsoids are shown. Hydrogen atom are omitted for clarity.

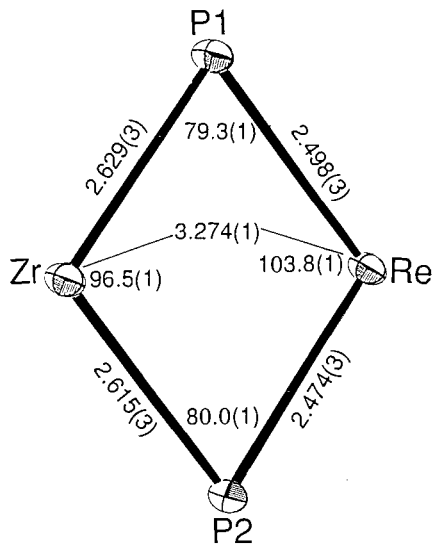

FIG. 2. Structural details of the core of **1**.

nances attributable to the phenyl rings of the phosphido groups, as well as, two inequivalent cyclopentadienyl groups. A triplet at −9.52 ppm is attributable to a Re bound hydride. The $|J_{P—H}|$ value suggests the coordination of a hydride *cis* to two equivalent phosphorus atoms. Infrared data are consistent with the presence of carbonyl groups and a hydride bound to Re. Thus, these spectroscopic data suggest the formulation of **1** as $Cp_2Zr(\mu\text{-}PPh_2)_2ReH(CO)_3$. This formulation was confirmed by X-ray crystallography (*vide infra*).

As mentioned above, numerous species appear to form during the course of the reaction, consequently, the mechanism of **1** formation is not understood. One might speculate that substitution reactions and heterolytic cleavage of the Re—Re bond gives an intermediate of the form $[Cp_2Zr(\mu\text{-}PPh_2)_2Re(CO)_3]^-$. Related heterobimetallic anions are known to be efficient proton scavengers (67), and thus the formation of this proposed intermediate would readily lead to the formation of **1** in the presence of a proton source. As it is necessary to perform the synthesis of **1** in the strict absence of H_2O, the source of proton in the present reaction is unknown, but is the subject of ongoing research.

Crystals of **1** are made up of unit cells each containing four discrete molecules. The closest non-bonding distance between molecules in the unit cell is 2.327 Å (H33—H26). Selected interatomic distances and angles are given in Table 3. An ORTEP drawing of the molecule is shown in Fig. 1. The study confirmed the general formulation of **1** as given above. The coordination sphere of Zr is best described as pseudo-tetrahedral. Two π-bonded cyclopentadienyl rings are bound to Zr with two diphenylphosphido groups completing the Zr coordination sphere and bridging to Re. Three terminal carbonyl moieties are also bonded to Re. Two of the carbonyl moieties are *trans* to the phosphido group, while the third cabonyl is *cis* to the phosphides. Although not located in the X-ray study, the geometry of the Re coordination shell is consistent with the location of a hydride *cis* to the phosphido groups. Thus, the coordination shell of Re is best described as pseudo-octahedral. The M—C bond distances in the Cp_2Zr fragments average to a typical value of 2.50(1) Å (50), while the Re—C distances range

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

from 1.91(1)–1.97(2) Å. The slightly longer Re—C42 bond length is consistent with the proposed location of the hydride *trans* to C42. The C—O bond distances average 1.16(2) Å and are typical of terminal carbonyl moieties (50, 56, 57). The bond distances and angles within the PPh_2 and Cp fragments are also typical (50, 57) and thus warrant no further comment.

The structural details of the ZrP_2Re core are shown in Fig. 2. The four atoms are essentially coplanar. The Zr—P distances of 2.615(3) and 2.629(3) Å, the Zr—P—Re angles of 79.3(1) and 80.0(1)° and the P—Re—P angle of 103.8(1)° are similar to corresponding values found in $Cp_2Zr(\mu\text{-}PPh_2)_2M(CO)_4$(M = Mo, W) (50, 56). The P—Zr—P angle of 96.5(1)° is substantially smaller than the angle found in the Zr/Mo or Zr/W heterobimetallics, while it is greater than the P—Zr—P angle found in the Zr/Rh heterobimetallic, $Cp_2Zr(\mu\text{-}PPh_2)_2RhH(CO)PPh_3$ (53). In a similar trend, the Re—P distances of 2.498(3) and 2.474(3) Å and the Re—Zr distance of 3.271(1) Å are intermediate between the corresponding values for $Cp_2Zr(\mu\text{-}PPh_2)_2M(CO)_4$ (M = Mo, W) (50, 56) and $Cp_2Zr(\mu\text{-}PPh_2)_2RhH(CO)PPh_3$ (53). The trend in the M—P distances for this series of Mo, Re, and Rh species corresponds to that expected on the basis of decreasing covalent radii. These trends suggest that increased electron density on the late metal centre enhances back bonding, resulting in stronger M—P bonds. As the M—P shortens, the angle subtended at Zr decreases, as does the Zr—M separation.

The question of dative bonding between the electron-rich, late metal centre and electron-deficient, early metal centre has been previously discussed for other early/late heterobimetallics (13–16, 50–53, 60–62, 69). Table 4 lists the pertinent structural parameters for all of the crystallographically characterized diphosphido bridged early/late heterobimetallics. These data show that the complexes that contain d^8 and d^{10} metal centres exhibit angles at P (i.e., M—P—M′) that are significantly less than 80°. This has been previously cited (13–16, 50–53, 61, 62) as a criterion indicative of metal–metal bonding. The P—M′—P angles in the d^8 and d^{10} complexes exceed 110°, indicative of dative donation to the early metal centre. The relatively long M—P (M = Zr, Hf, Th) bond lengths and relatively short M—M′ distances are further evidence of acceptance of electron density from the late metal centre by the early metal centre. For the d^6 complexes of the form, $Cp_2M(\mu\text{-}PR_2)_2M(CO)_4$ as well as complex **1**, the angles at P are only slightly less than 80°, while the P—M′—P angles are less than 103.8(1)°. The M—P bond distances are relatively short and the metal–metal separation exceeds 3.271(1) Å. Furthermore, the planarity of the ZrP_2M cores in the d^6 complexes suggests little perturbation of the bonding involving the metal centres. This is in contrast to that seen for $Cp_2M(\mu\text{-}PPh_2)_2RhH(CO)PPh_3$ and $Cp^*_2Th(\mu\text{-}PPh_2)_2PtPMe_3$[3] where a "butterfly" distortion of the core atoms accommodates a shorter metal–metal separation. Although the cause of such distortions is not clear, metal–metal interactions and crystal packing effects have been suggested (53, 61). Thus, the structural data for these species support the notion that direct dative bonding between the late and early metal centres is present for d^0–d^8 and d^0–d^{10} heterobimetallics. This conclusion is also supported by molecular orbital calculations (62, 68). However, the structural data also suggest that if such metal–metal bonding is present in d^0–d^6 species, it is at best very weak.

[3]Report is preliminary and thus full structural details are not available.

Stereochemistry of hydrogen loss during C-21 dehydroxylation of tetrahydrodeoxycorticosterone by *Eubacterium lentum*

HERBERT L. HOLLAND, RONALD W. NINNISS, AND FRANCES M. BROWN
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 1Y3

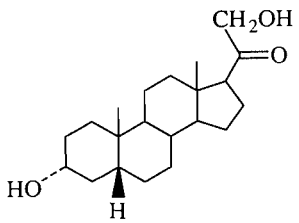
Received April 5, 1989

HERBERT L. HOLLAND, RONALD W. NINNISS, and FRANCES M. BROWN. Can. J. Chem. **67**, 1590 (1989).

The loss of hydrogen from the C-21 position of 5β-pregnane-3α,21-diol-20-one (tetrahydrodeoxycorticosterone, THDOC) during reductive removal of the 21-hydroxy group by the anaerobic bacterium *Eubacterium lentum* has been shown to be selective for the pro-*S* position by the use of THDOC labelled with deuterium at the C-21 pro-*S* and C-21 pro-*R* positions. The labelled substrates were obtained by using the bacterium *Clostridium paraputrificum* to reduce chemically prepared C-21 labelled samples of pregn-4-en-21-ol-3,20-dione (deoxycorticosterone, DOC) at C-3 and C-4 (5). The stereochemistry of deuterium label introduced by chemical means at C-21 of DOC was determined by comparison with a sample of 21-(*R*)-DOC-21-d_1 produced by reduction of the corresponding aldehyde pregn-4-en-21-al-3,20-dione, 21-*d* by the enzyme 21-hydroxysteroid NAD oxidoreductase from beef liver.

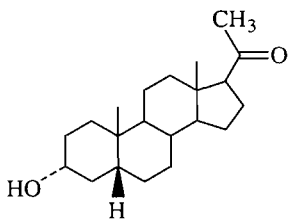
Key words: *Eubacterium*, *Clostridium*, steroids, tetrahydrodeoxycorticosteroids.

HERBERT L. HOLLAND, RONALD W. NINNISS et FRANCES M. BROWN. Can. J. Chem. **67**, 1590 (1989).



Utilisant des THDOC marquées aux deutérium dans les positions C-21-pro-*S* et C-21-pro-*R*, on a démontré que la perte d'un hydrogène de la position C-21 de la 5β-pregnane-3α,21-diol-20-one (tétrahydrodésoxycorticostérone, THDOC) au cours de l'enlèvement réducteur du groupement 21-hydroxy par la bactérie anaérobique *Eubacterium lentum* est sélective pour la position pro-*S*. On a obtenu les substrats marqués en réduisant, à l'aide de la bactérie *Clostridium paraputrificum*, les positions C-3 et C-4(5) d'échantillons de pregn-4-en-21-ol-3,20-dione marqués en C-21 et préparés d'une façon chimique. On a déterminé la stéréochimie du deutérium introduit en C-21 par des méthodes chimiques en procédant à une comparaison avec un échantillon de 21-(*R*)-DOC-21-d_1, préparé par réduction de l'aldéhyde correspondant pregn-4-en-21-al-3,20-dione, 21-*d* par l'enzyme oxydoréductase 21-hydroxystéroïde NAD provenant du foie de boeuf.

Mots clés : *Eubacterium*, *Clostridium*, stéroïdes, tétrahydrodésoxycorticostérones.

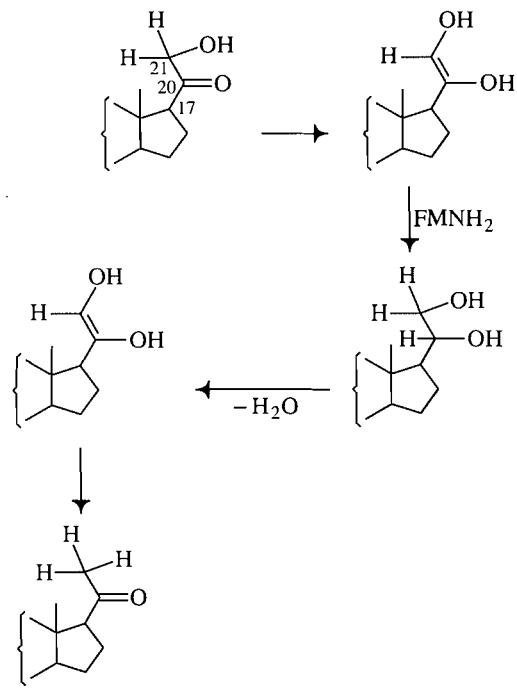


[Traduit par la revue]

Those 21-hydroxycorticosteroids that are reabsorbed into the liver after passage through the intestines can be excreted as derivatives in which the hydroxyl group at C-21 has been replaced by hydrogen (1). This process is performed by the anaerobic bacterium, *Eubacterium lentum*, present in the intestines (2).

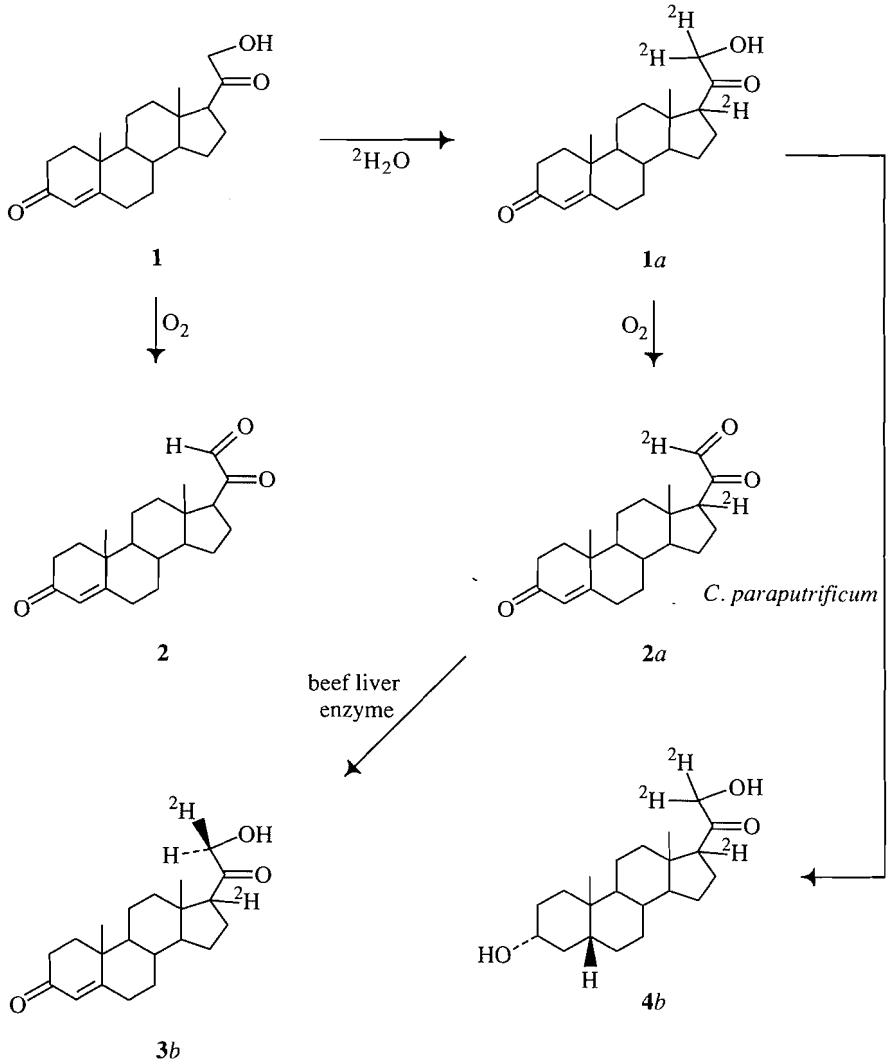
In an earlier paper (3) we examined the conversion of the 21-hydroxycorticosteroid 5β-pregnane-3α,21-diol-20-one (tetrahydrodeoxycorticosterone, THDOC, **6**) to 5β-pregnan-3α-ol-20-one (**7**) by *E. lentum*, and determined that the enzymic

6



7

removal of the C-21 hydroxy group proceeds with retention of hydrogen at C-17, but with loss of one of the two hydrogen atoms originally present at C-21. A consideration of the cofactor (2, 4) and substrate (1) requirements for the 21-dehydroxylase enzyme, together with the primary kinetic hydrogen/deuterium isotope effect at C-21 (3), led us to propose the mechanism for the action of this enzyme shown in Scheme 1.



We have now extended our study of this enzyme by the use of substrates with asymmetric deuterium labelling at C-21, and report that the loss of hydrogen from C-21 in the first step of Scheme 1 is specific for the pro-*S* position.

The substrates required for our study were the 21-(*S*) and 21-(*R*) deuterium labelled tetrahydrodeoxycorticosteroids, **4** and **4***a*, respectively. In view of the high cost of THDOC as a starting material for synthetic procedures, the stereoselective introduction of deuterium label at C-21 was carried out by reduction of the readily available 21-aldehydes **2** and **2***a*, the 4-ene-3-keto functionality of ring A being subsequently reduced by *Clostridium paraputrificum* (5) to the 3α-ol-5β stereochemistry required by *E. lentum* (3).

SCHEME 1. Proposed route for C-21 dehydroxylation by *E. lentum*.

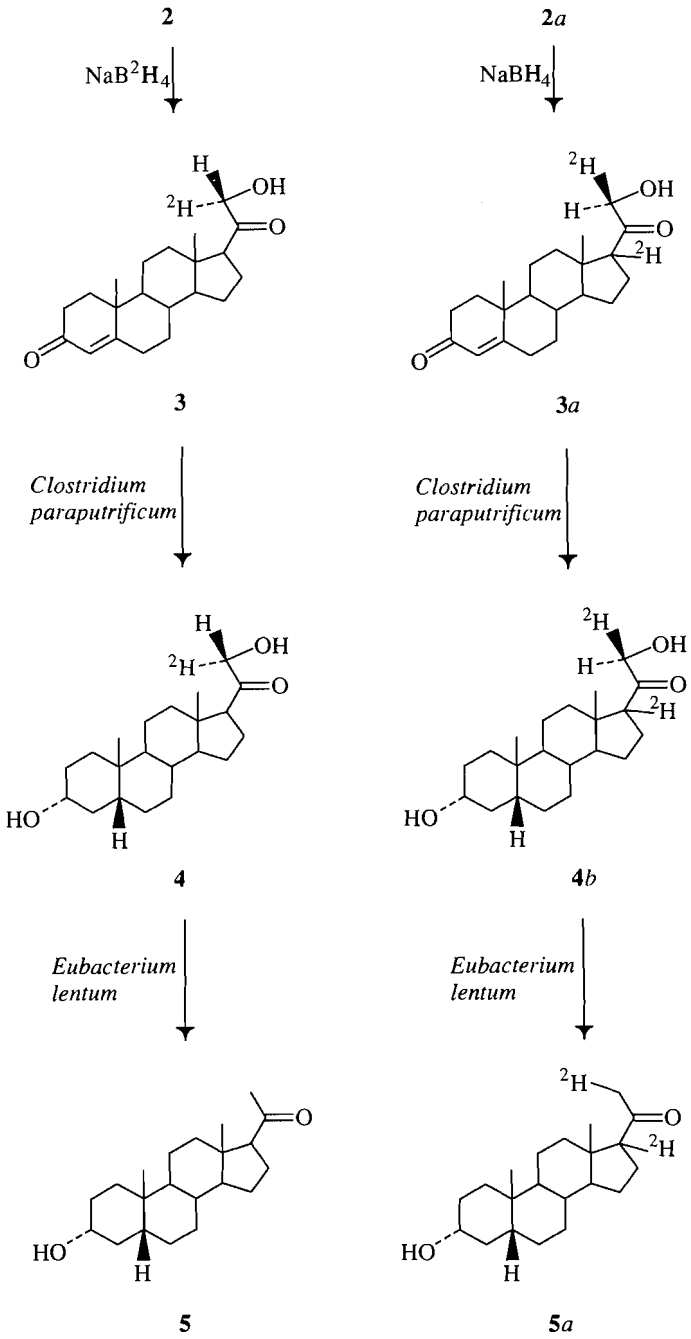
SCHEME 2

In two parallel synthetic routes, pregn-4-ene-3,20-dion-21-ol (deoxycorticosterone, DOC, **1**), and its analogue labelled at C-17 and -21 (**1***a*), were first converted by copper catalysed air oxidation (6–8) to the corresponding 21-aldehydes **2** and **2***a* (Scheme 2). To facilitate the analysis of the stereochemistry of reduction of **2** and **2***a*, the labelled aldehyde **2***a* was reduced at C-21 by the enzyme 21-hydroxysteroid NAD oxidoreductase, isolated from beef liver (9). This enzyme is specific for delivery of hydrogen to the pro-*S* position at C-21 (8, 10), giving in the present case the 21-(*R*) labelled DOC **3***b* (Scheme 2).



At 500 MHz the proton nmr spectrum of DOC shows the prochiral hydrogens at C-21 as a well-resolved AB quartet centered at δ 4.12 and 4.18 ppm, and in the C-21 deuterium labelled samples these signals are shifted to 4.10 and 4.16 ppm (see Experimental). The ^1H nmr spectrum of **3***b* derived from enzymic reduction of **2***a* shows a large singlet at δ 4.10 ppm, with a very minor peak at δ 4.16, confirming the assignment of the prochiral C-21 hydrogen absorptions as pro-*S*: upfield at δ 4.10/4.12; pro-*R*: downfield at δ 4.16/4.18 ppm. Using these assignments it is possible to assign the stereochemistry of the products resulting from the sodium borodeuteride reduction of the aldehyde **2** and the sodium borohydride reduction of the deuterium labelled aldehyde **2***a* (Scheme 3) as 21-(*S*) and 21-(*R*) respectively. The same stereoselectivity has been observed in the hydride reduction of 21-aldehydes in 17α-hydroxysteroids (8). The stereochemistry of chemical reduction at the C-21 aldehyde group therefore parallels the enzymic reduction, with preferential delivery of hydride or deuteride at the pro-*S* position.

Analysis of the 500-MHz proton nmr spectra of the C-21 chirally labelled DOC samples **3** and **3***a* was performed as outlined above and in the experimental section to determine the stereochemical integrity of labelling: the 21-(*S*) isomer **3** was found to be a 3:1 mixture of the (*S*) and (*R*) configurations at C-21, while the 21-(*R*) isomer was a 2:1 mixture of (*R*) to (*S*). Both samples were essentially completely labelled at C-21, as evidenced by the virtual absence of the AB quartet at δ 4.12 and 4.18 characteristic of C-21 unlabelled material.

Accurate estimation of the deuterium content of the side chain in 21-hydroxy-20-ketopregnanes by mass spectrometry is difficult: electron impact spectra show very weak molecular ions, fragmentation of which invariably occurs by loss of the side chain, and FAB spectra are difficult to use for precise deuterium determination in view of the presence of M + H and M − H ions. However, the FAB mass spectra of **3** and **3***a* were recorded (see Experimental) and qualitatively confirm the results of the high resolution nmr analysis.

To establish that reduction of ring A could be carried out by

For personal use only.

SCHEME 3

Clostridium paraputrificum without the loss of stereochemical integrity at C-21, the C-21 labelled DOC **1***a* was converted to the labelled 3α-hydroxy-5β-steroid **4***b* (Scheme 2). Some loss of label from C-21 was observed, the product containing 0.2 hydrogens at C-21 by ^{1}H nmr analysis compared with 0.05 hydrogens present in **1***a*. However, integration of the resulting signals at δ 4.10 and 4.16 ppm showed that this loss did not occur in a stereoselective manner. This was confirmed following analysis of the labelled THDOC samples **4** and **4***a* derived from reduction of **3** and **3***a* respectively using *C. paraputrificum* (Scheme 3). As determined by high resolution ^{1}H nmr analysis and outlined in the experimental section, these products had the same *R*:*S* ratios at C-21 as the starting materials from which they were derived.

The labelled THDOC samples **4** and **4***a* were then converted to 5β-pregnan-3α-ol-20-one (**5** and **5***a* respectively) by *E. lentum* as outlined in Scheme 3. The analysis of these experiments is presented in Tables 1 and 2. Table 1 predicts the deuterium content at C-21 that would result from loss of hydrogen/deuterium from the pro-*R* or the pro-*S* positions of THDOC, while Table 2 presents the experimentally determined values.

TABLE 1. Predictions of deuterium content arising from loss of the pro-*R* or pro-*S* hydrogen/deuterium atoms of THDOC on conversion to 5β-pregnan-3α-ol-20-one by *Eubacterium lentum*

		Predicted D content of product			
		pro-*R* loss		pro-*S* loss	
Substrate	Composition (%)	C21-*d*	ΣD	C21-*d*	ΣD
4	21-*S* (63) 21-*R* (21) 21-unlabelled (16) Total D = 0.84 C-21-D = 0.84	0.73	0.73	0.34	0.34
4*a*	21-*S* (30) 21-*R* (58) 21-unlabelled (12) Total D = 1.55 C-21-D = 0.88	0.46	1.13	0.71	1.38

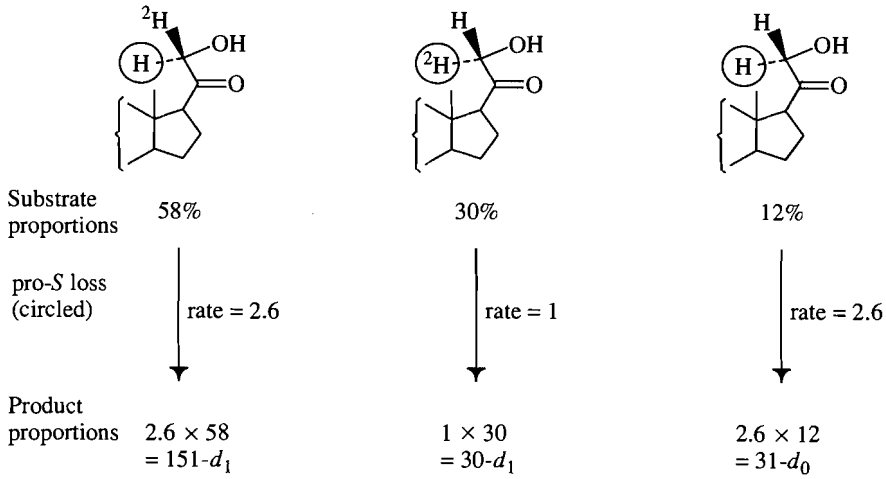

TABLE 2. Deuterium content of 5β-pregnan-3α-ol-20-one arising from C-21 dehydroxylation of 21-(*R*)- and 21-(*S*)-THDOC by *Eubacterium lentum*

		Deuterium at C-21		Total deuterium	
Substrate	Product	MS	NMR	MS	NMR
4	**5**	0.30	0.38	0.30	0.38
4*a*	**5***a*	—	0.78	1.42	—

The values in Table 1 were calculated starting from the isotopic compositions of the substrates **4** and **4***a*, as determined by 500-MHz ^{1}H nmr and FAB MS analysis (see Experimental for details), with the assumption of a primary kinetic isotope effect, k_H/k_D, of 2.6 for the conversion to **5** and **5***a* (3). The calculation for substrate **4***a* is detailed in Scheme 4. To avoid complications arising from changes in isotopic composition of substrate as the reactions proceeded, incubations with *E. lentum* were carried out only to the point of 10% conversion to product. Recovered starting material at this stage was essentially identical to isotopic content and stereochemistry with starting material analysed before exposure to *E. lentum*.

The values for isotopic content of the products **5** and **5***a* are presented in Table 2. The deuterium contents at C-21 in both **5** and **5***a* were estimated by integration of the signal from the C-21 methyl group in their 500-MHz ^{1}H nmr spectra, in which the signals from all three methyl groups of the product are cleanly resolved to the baseline. The values obtained (**5** = 38%, **5***a* = 78% d_1; predicted for pro-*S* loss **5** = 34%, **5***a* = 71% d_1) clearly indicate that loss has occurred from the pro-*S* position. In the case of **5**, the deuterium content at C-21 could also be obtained directly from mass spectral analysis, as the method of synthesis ensured that any label present must be located at the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

Therefore total product $d_0 = 30 + 31 = 61$
total product $d_1 = 151$
deuterium content of **5***a* = 151/212 = 0.71

Substrate total *d* content at C-21 = 0.58 + 0.30 = 0.88
Product total *d* content at C-21 = 0.71
Predicted loss from C-21 = 0.88 − 0.71 = 0.17*d*

SCHEME 4. Calculations used to predict the deuterium content in **5***a* resulting from pro-(*S*) loss of hydrogen or deuterium from 21-(*R*)-THDOC **4***a*.

C-21 position. The value obtained (d_1 = 30%) also supports a loss from the pro-*S* position of **4** (predicted deuterium content for pro-*S* loss = 34%).

In the case of **5***a*, however, the presence of deuterium elsewhere in the molecule precluded direct determination of the deuterium content at C-21 by mass spectrometry. Mass spectral analysis of **5***a* nevertheless indicated the presence of a total of 1.42 deuteriums per molecule (see Experimental and Table 2), thus permitting the deuterium loss for the conversion of **4***a* to **5***a* to be estimated by comparison with the total deuterium content of **4***a* (1.55 deuteriums) as 0.13 deuterium atoms per molecule, a value in reasonable agreement with the loss of 0.17 deuteriums per molecule predicted for loss of the pro-*S* atom from C-21 of **4***a*. The ms data are thus supportive of the conclusions reached from nmr analysis, namely that conversion of 5β-pregnane-3α,21-diol-20-one (**6**) into 5β-pregnan-3α-ol-20-one (**7**) by *Eubacterium lentum* proceeds with stereospecific loss of the pro-*S* hydrogen from C-21.

This finding now opens possibilities for the synthesis of C-21 pro-*S* substituted deoxycorticosteroids whose metabolic deactivation by anaerobic C-21 dehydroxylation may be blocked.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Proton nmr spectra were determined at 80 MHz on a Bruker WP80CW, at 200 MHz on a Bruker AC200, or at 500 MHz on the Bruker AM500 at McMaster University, using deuterochloroform as solvent and chloroform as internal standard. Deuterium nmr spectra were obtained at 30.7 MHz using the Bruker AC200 instrument with chloroform as solvent and deuterochloroform as internal standard. Electron impact (EI) mass spectra were obtained with an AEI MS30 interfaced to a Kratos DS55 data system, and fast atom bombardment (FAB) spectra were obtained with the same machine fitted with an Ion Tech saddle field gun operating at 7 keV using a glycerol matrix. Deuterium content was estimated following repetitive analyses and application of the appropriate corrections for natural isotopic abundances, and is accurate to ± 2% (EI) or ± 5% (FAB). Centrifugation was done using either a Sorvall RC5 with a GSA head or an IEC B20A with an IEC 870 head. Liver homogenates were obtained from fresh commercial beef liver using a Waring blender. Flash column chromatography was performed on silica gel (Merck 230–400 mesh or equivalent), thin-layer chromatography on Merck silica gel 60F-254 (0.2 mm), and preparative layer chromatography on 2.0-mm Merck F-254 silica gel plates.

Maintenance of micro-organisms

Eubacterium lentum ATCC 25559 was maintained on a medium of cysteine supplemented brain heart infusion broth (sBHIB) as previously described (3). *Clostridium paraputrificum* ATCC 25780 was also maintained on sBHIB using identical techniques. Cultures were maintained by transfers to fresh medium at intervals of 7 days.

Isolation of 21-hydroxysteroid NAD oxidoreductase

This enzyme was isolated from fresh commercial beef liver using the published procedure (9) to the point of the supernatant fluid from the 55°C heat treatment. The resulting preparation was stored at 4°C and used within 2 weeks.

Reduction of **2**a *with 21-hydroxysteroid NAD oxidoreductase*

The above enzyme preparation (5 mL) was diluted to 100 mL with 0.1 M phosphate buffer, pH 7.4, and NADH (50 mg) dissolved in this solution. A solution of pregn-4-en-21-al-3,20-dione, 17,21-d_2 (25 mg) in 95% ethanol (1.5 mL) was then added, and the mixture stirred at room temperature for 2 h. The aqueous solution was then extracted with ethyl acetate, and the extract dried and evaporated to give a residue (20 mg). Crystallization from ethyl acetate/hexane afforded 21-(*R*)-pregn-4-ene-3,20-dion-21-ol, 17,21-d_2 (**3***b*), identified by comparison with an authentic sample of unlabelled material. The ^{1}H nmr included δ 4.12 (s, C-21 pro-*S* H) and 4.16 (s, C-21 pro-*R* H) ppm in the ratio 25:1.

Synthesis of substrates

Pregn-4-ene-3,20-dion-21-ol, 17,21,21-d_3 *(DOC-*d_3*,* **1***a*)

This was prepared from unlabelled material using the method previously described for the preparation of 5β-pregnane-3α,21-diol-20-one, 17,21,21-d_3 (3). A solution of unlabelled **1** (1.5 g) in methanol-OD (15 mL) was added to a solution of Tris base (3.15 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

previously exchanged with deuterium oxide and vacuum dried) in methanol-OD (50 mL) and deuterium oxide (50 mL). Following exchange and work-up of the reaction mixture, the residue (1.63 g) was resubmitted to the exchange procedure, and the resulting material purified by chromatography to give **1***a* (1.2 g), identical in physical properties (mp, tlc) to unlabelled starting material. Using the C-4 ^{1}H nmr signal at δ 5.68 ppm as an internal standard of 1.0 hydrogens allowed the residual ^{1}H content at C-21 (δ 4.15 ppm) to be estimated as 0.05H; ^{2}H nmr: δ 2.4, 4.14 ppm (no detectable signal at δ 5.68 ppm). Using the C-21 ^{2}H signal at δ 4.14 ppm as an internal standard of 1.94 deuteriums, the total signal at δ 2.4 ppm corresponded to 1.59 deuteriums. FAB MS showed a molecular ion cluster at *m/e* 330–336.

Pregn-4-en-21-al-3,20-dione (2)

Following the procedure outlined (6), a solution of cupric acetate in dry methanol (100 mL, 0.005 M) was added to a solution of **1** (1.2 g) in dry methanol (100 mL), and the resulting mixture stirred with aeration at the rate of one bubble per second for 45 min. A solution of disodium EDTA (200 mg) in water (12 mL) was then added, and stirring continued for a further 15 min. The solvent was then removed by evaporation, water (200 mL) added, and the resulting mixture extracted with methylene chloride (3 × 50 mL). The yellow extract was washed with 5% aqueous sodium bicarbonate and water, then dried and evaporated to give a residue (1.2 g), which was used directly in the preparation of **3**. As noted by others (7, 8) this product is a mixture of the aldehyde **2** (^{1}H nmr including signals at δ 0.65 (C-18H), 1.18 (C-19H), 5.68 (C-4H), and 9.1 (C-21H) ppm), and the 21 hydrate (^{1}H nmr including a signal at δ 4.70 (C-21H)). FAB MS showed ions at *m/e* 347 (M^+ hydrate + H, 15) and 329 (M^+ aldehyde + H, 64) relative to 307 (M − CHO or $CH(OH)_2$, 100).

*Pregn-4-en-21-al-3,20-dione, 17,21,21-*d$_3$ *(2*a*)*

This was prepared from DOC-d_3 (**1***a*) (1.2 g) by the method described above for the preparation of **2**, with extension of the reaction time to 105 min as a consequence of tlc monitoring. Work-up as described above gave the title compound (1.19 g) as a yellow solid, identical on tlc with unlabelled material; ^{2}H nmr: δ 2.4 (C-17 ^{2}H), 4.82 (C-21 $C^2H(OH)_2$), and 9.2 (C-21 C^2H) ppm.

*21-(*S*)-Pregn-4-ene-3,20-dion-21-ol, 21-*d *(3)*

Sodium borodeuteride (38 mg) was added in one portion to a stirred solution of pregn-4-en-21-al-3,20-dione (**2**) (1.2 g) in dry pyridine (24 mL) at −5°C. Stirring was continued for 15 min, and the solution then poured into water (50 mL) and extracted with ethyl acetate (4 × 100 mL). The extract was washed with 2 M tartaric acid (3 × 50 mL) and water, and then dried and evaporated to give a residue (1.0 g) that was purified by chromatography (benzene/ether gradient elution) to give the title compound (0.76 g), crystallized from ethyl acetate/hexane. The product showed physical and spectral data identical with those of authentic unlabelled material with the following exceptions: ^{13}C nmr: triplet at δ 69.0, J = 21 Hz (C-21); ^{1}H nmr (500 MHz): included δ 4.12 (s, C-21 pro-*S* H) and 4.16 (s, C-21 pro-*R* H) ppm in the ratio 1:3.1. FAB MS: *m/e* (%) 332 (100), 331 (24). Comparison with unlabelled material indicated the presence of >90% d_1 labelled material.

*21-(*R*)-Pregn-4-ene-3,20-dion-21-ol, 17,21-*d$_2$ *(3*a*)*

This was prepared by the procedure described for compound **3**, using sodium borohydride (35 mg) and the labelled aldehyde **2***a* (1.2 g). The crude product (0.93 g) was purified as described above to give a total of 0.2 g of the desired product, identical on spectral analysis with authentic unlabelled material, with the following exceptions: ^{1}H nmr (500 MHz): included δ 4.12 (s, C-21 pro-*S* H) and 4.16 (s, C-21 pro-*R* H) ppm in the ratio 2.0:1. FAB MS: *m/e* (%) 333–335, comparison with unlabelled material indicating approximately equal amounts of d_2 and d_3 labelled material.

Incubations with Clostridium paraputrificum *ATCC 25780*

Pregn-4-ene-3,20-dion-21-ol (DOC, 1)

To 1.5 L of sBHIB growth medium, prepared as described (3), was added 10 mL of an overnight culture of *C. paraputrificum*, followed by a solution of DOC (150 mg) in 95% ethanol (7.5 mL). The culture was maintained at 37°C for 7 days, and then worked up as described (3) to give a residue (1.13 g) that, following chromatography, afforded 0.12 g of 5β-pregnane-3α,21-diol-20-one (THDOC, **6**), identical in all respects with an authentic sample.

*Pregn-4-ene-3,20-dion-21-ol, 17,21,21-*d$_3$ *(DOC-*d$_3$*, 1*a*)*

Using the procedure described above, incubation of **1***a* (25 mg) with *C. paraputrificum* gave, after purification, 17.5 mg of 5β-pregnane-3α,21-diol-20-one, 17,21,21-d_3 (**4***b*). The ^{1}H nmr (200 MHz) showed the presence of a signal at δ 4.13 (0.20H) in addition to the signals expected for THDOC-d_3. At 500 MHz, signals at δ 4.10 (0.1H, C-21 pro-*S* H) and 4.16 (0.1H, C-21 pro-*R* H) ppm were observed; ^{2}H nmr: δ 2.90 (C-17 ^{2}H), 4.10 (C-21 ^{2}H) ppm.

*21-(*S*)-Pregn-4-ene-3,20-dion-21-ol, 21-*d *(3)*

Incubation of **3** (200 mg) with *C. paraputrificum* (2 L culture) as described above gave, following chromatography of the extract, 21-(*S*)-5β-pregnane-3α,21-diol-20-one, 21-*d* (**4**) (120 mg), identical in all respects with authentic unlabelled material **6** with the following exceptions: ^{1}H nmr (500 MHz) included δ 4.10 (s, C-21 pro-*S* H) and 4.16 (s, C-21 pro-*R* H) ppm in the ratio 1:3.0, together with 4.12, 4.18 ppm (ABq, total 0.32H, unlabelled C-21H). FAB MS *m/e* (%) 336 (74), 335 (34) relative to 318 (100). Comparison with the spectrum of unlabelled material indicated the isotopic composition to be d_0 22%, d_1 78%.

*21-(*R*)-Pregn-4-ene-3,20-dion-21-ol, 17,21-*d$_2$ *(3*a*)*

Incubation of **3***a* (200 mg) with *C. paraputrificum* as described above gave, following chromatography, 21-(*R*)-5β-pregnane-3α,21-diol-20-one, 17,21-d_2 (**4***a*) (95 mg), identical in all respects with an authentic sample of unlabelled material **6** with the following exceptions: ^{1}H nmr (500 MHz) included signals at δ 4.10 (s, C-21 pro-*S* H) and 4.16 (s, C-21 pro-*R* H) in the ratio 1.9:1, together with 4.12, 4.18 (ABq, total 0.25H, unlabelled C-21H). FAB MS *m/e* 335–338: comparison with the spectrum of unlabelled material indicated the isotopic composition to be d_0 19%, d_1 26%, d_2 36%, d_3 19%, corresponding to a total of 1.55 deuteriums per molecule (0.26 + 0.36 × 2 + 0.19 × 3).

Incubations with Eubacterium lentum *ATCC 25559*

Incubations with *E. lentum* were performed exactly as described (3), using an incubation period of 140 h.

*21-(*S*)-5β-Pregnane-3α,21-diol-20-one, 21-*d *(21-(*S*)-THDOC-21-*d*, 4)*

Incubation of **4** (100 mg) with a mixed *E. lentum/E. coli* culture gave, following extraction and chromatography, 5β-pregnan-3α-ol-20-one (**5**, 9 mg), identified by comparison of spectral properties with those of an authentic sample of unlabelled material. The ^{1}H nmr (500 MHz) included signals at δ 0.56 (3H, s, C-18H), 0.89 (3H, s, C-19H), and 2.09 (2.62H, s, C-21H) ppm. EIMS *m/e* (%) 319 (21), 318 (44) relative to 301 (100); *d* content d_0 71.3%, d_1 29.7%. Also obtained was recovered substrate **4** (77 mg) identical in all respects with the sample of **4** described above.

*21-(*R*)-5β-Pregnane-3α,21-diol-20-one, 17,21-*d$_2$ *(21-(*R*)-THDOC-17,21-*d$_2$*, 4*a*)*

Incubation of **4***a* with *E. lentum/E. coli* gave an extract that, following chromatography, afforded 5β-pregnan-3α-ol-20-one (**5***a*, 11 mg), identified as described above for **5**; ^{1}H nmr (500 MHz) included signals at δ 0.56 (3H, s, C-18H), 0.89 (3H, s, C-19H), and 2.09 (2.22H, s, C-21H) ppm. EIMS *m/e* 318–321, indicating the isotopic composition to be d_0 20%, d_1 35%, d_2 28%, d_3 17% for a total of 1.42 deuteriums (0.35 + 0.28 × 2 + 0.17 × 3). Also obtained was recovered substrate (75 mg) identical in all respects with the initial substrate **4***a*.

The dissociation constant and acid hydrolysis rate of hydroxysulfamic acid

DAVID LITTLEJOHN, ABIGAIL R. WIZANSKY, and S. G. CHANG[1]

Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720, U.S.A.

Received August 29, 1988

DAVID LITTLEJOHN, ABIGAIL R. WIZANSKY, and S. G. CHANG. Can. J. Chem. **67**, 1596 (1989).

The acid dissociation constant and hydrolysis rate of hydroxysulfamic acid (HSA) in acid aqueous solutions have been studied. The acid dissociation constant was determined to be $K = 1.5 \pm 0.5\ M$ at 298 K. The hydrolysis rate, R, was found to be $R = k[H^+][HSA]$, where $k = 6.2 \times 10^{12} \exp(-26\,300/RT)\ M^{-1}\ s^{-1}$ at $\mu = 1.0\ M$ and [HSA] is the concentration of all forms of hydroxysulfamic acid.

Key words: hydroxysulfamic acid, hydrolysis, acid dissociation.

Introduction

Reactions between nitrite ions and bisulfite ions occur in aqueous solutions and may be involved in the acid rain formation from SO_2 and NO_x in aqueous aerosols. These reactions can also be important in solution-based flue gas scrubbing systems. Knowledge of the chemistry of these compounds is needed to predict their behavior in aqueous solutions. Most of the chemistry associated with the nitrogen sulfonate products of these reactions is fairly well understood (1). An exception is the

decomposition of hydroxysulfamic acid (HSA) in acidic conditions. Ackermann and Powell (2, 3) have investigated the akaline hydrolysis and oxidation by oxygen of HSA. The only quantitative study of the acid hydrolysis of HSA was done by Candlin and Wilkins (4), who performed a limited number of hydrolysis runs in their studies of nitrogen–sulfur compounds. It is unclear whether they deaerated their solutions. They noted a decreasing yield of hydroxylamine as a product at higher pH conditions, which could be due to oxidation of the HSA. As part

of our studies of the chemistry of nitrogen–sulfur compounds (5–7), we have investigated the acid dissociation constant of HSA. While working with HSA it was decided to make a determination of the acid hydrolysis rate.

Experimental

HSA was prepared in aqueous solution by hydrolyzing dissolved potassium hydroxyimidodisulfate (HIDS). HIDS is prepared by reacting nitrite ion with bisulfite ion at 0°C (8). The synthesis of potassium HIDS is more straightforward than for HSA (8, 9), and higher yields and purity can be obtained. HIDS hydrolyzes much more quickly than HSA, and did not interfere in the studies. The potassium IDS was stored in a refrigerated dessicator to retard decomposition. Reagent grade compounds were used in the HIDS synthesis and in the solutions used for this study.

The acid dissociation constant for HSA was determined by observing solutions of HSA with varying concentrations of perchloric acid using Raman spectroscopy. Quantitative measurements of the concentrations of compounds above about 0.01 M in solution by Raman spectroscopy can be obtained by use of a reference compound. At higher concentrations (about 0.5 M or higher), scan-to-scan reproducibility is generally better than ±5% when the peaks are free of interference. Raman spectra of the HSA – perchloric acid solutions were obtained immediately after preparation to avoid problems with the hydrolysis of HSA. The solutions were prepared under a nitrogen atmosphere. The heights of the Raman peaks for the two forms of HSA were compared with each other and the ClO_4^- peak to determine the dissociation constant. Since the peaks of the two forms of HSA overlap, reference spectra of the two forms were scaled to yield a flat baseline on subtraction to determine the concentrations. The spectra were corrected for the presence of HSO_4^-, which slightly overlapped the HSA peaks. These corrections introduced some uncertainty into the results. All measurements were made with deaerated solution.

The hydrolysis of HSA was studied using ion chromatography to monitor the decay of HSA and the growth of the sulfate product (10). Solutions were prepared by adding the HIDS salt to a deaerated perchloric acid solution. The solutions were kept under a nitrogen atmosphere in a water bath of the desired temperature. The ionic strength of the solutions was adjusted with sodium perchlorate when necessary. When the HIDS had completely hydrolyzed, as determined by Raman spectra of the solution, it was placed in a controlled-temperature bath. Aliquots were then taken periodically and diluted for analysis by ion chromatography. The ion chromatograph has a linear response to HSA and sulfate at concentrations up to $10^{-4}\ M$, so solutions were diluted to ensure that the HSA and sulfate ions were below this level.

Results and discussion

For the determination of the acid dissociation constant of HSA, Raman spectra were obtained of 0.01 M HSA solutions with perchloric acid concentrations ranging from 0.001–5.1 M over a temperature range of 288–338 K. The spectra obtained at the lowest acid concentrations had only the deprotonated form of HSA present, with a Raman peak at 1056 cm^{-1}. These spectra were used to determine the amount of deprotonated HSA in other solutions and correct their spectra, so that the peak due to

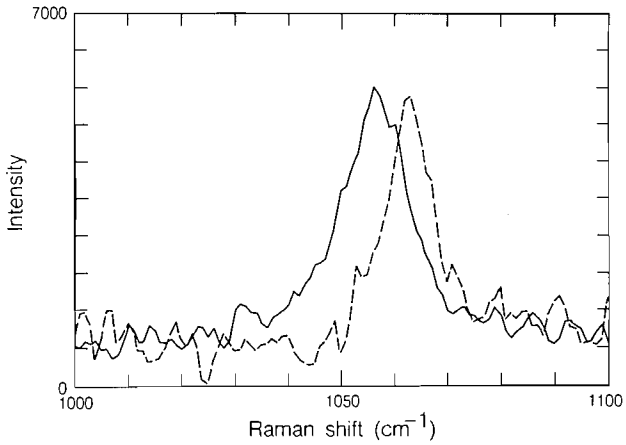

FIG. 1. Raman spectra of the anion (1056 cm^{-1}) and the acid (1063 cm^{-1}) forms of HSA.

protonated HSA at 1063 cm^{-1} could be measured. From these measurements, it was found that the HSA acid and the HSA anion had Raman scattering efficiencies of 0.50 and 0.48 respectively, compared to the 980 cm^{-1} sulfate peak at 298 K. Raman spectra of the two peaks are shown in Fig. 1. These Raman peaks are due to the SO_3 stretch in the molecules (11). The small shift in the stretch frequency observed on protonation suggests that the hydrogen ion is attaching to the nitrogen (structure **I**) rather than the SO_3 group (structure **II**).

I

II

There was a significant amount of HSA anion present in the 5.1 *M* perchloric acid solution. From the measured concentrations of the two forms of HSA and the hydrogen ion concentration, the acid dissociation constant was calculated. The average value obtained was $K = 1.5 \pm 0.5\ M$ at 298 K. The uncertainty is due largely to the noise in the Raman spectra. Within the uncertainty, no significant temperature dependence of the dissociation constant was observed over a temperature range of 288–338 K. Work done by Hall and Sprinkle (12) suggests that there should be a relatively small change in the equilibrium constant with temperature. The ionic strengths of the solutions studied were not controlled. Most of the solutions were in the range of $\mu = 1$ to 5 *M*.

To determine the hydrolysis rate of HSA, measurements were made on HSA solutions over a range of conditions. Perchloric acid concentrations varied from 0.03 to 2.0 *M* and HSA concentrations varied from 3×10^{-4} to $3 \times 10^{-2}\ M$. Ionic strengths of these solutions ranged from 0.03 to 2.1 *M*. The hydrolysis was studied over a temperature range of 298 to 358 K. Most of the hydrolysis runs were done at perchloric acid concentrations of 0.10 and 1.0 *M*.

The dependence of the hydrolysis rate on hydrogen ion concentration was determined with a series of runs at 348 K in which $[H^+]$ was varied from 0.03 to 1.0 *M* at [HSA] = 0.01 *M* and $\mu = 1.0\ M$. The effective rate exhibited first order dependence on $[H^+]$. A run done at $[H^+] = 2.0\ M$ was corrected for ionic strength and its rate was found to be in agreement with the results obtained at lower acidities. The hydrolysis rate dependence on HSA concentration was determined from runs done with 0.1 *M* $HClO_4$ at 348 K and $\mu = 0.13$–$0.18\ M$. The rate showed first order dependence on [HSA] for concentrations from 1×10^{-3} to $3 \times 10^{-2}\ M$.

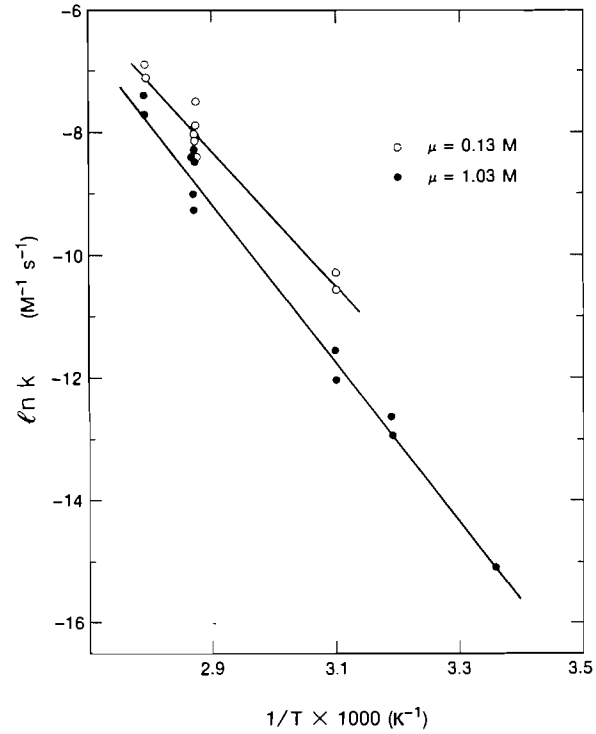

FIG. 2. Arrhenius plot of the rate constant for the hydrolysis of HSA at $\mu = 0.13\ M$ ($[H^+] = 0.1\ M$) and $\mu = 1.03\ M$ ($[H^+] = 1.0\ M$). [HSA] = 0.01 *M* for both conditions.

The rate constants were calculated from the experimental results using the expression of rate = $k[H^+][HSA]$, where [HSA] is the sum of the concentrations of the protonated and deprotonated forms of HSA. The ionic strength dependence was determined from a plot of log *k* vs. $\mu^{1/2}/(1 + \mu^{1/2})$ for runs at 348 and 358 K. At both temperatures, the results yielded a slope of −1, within the uncertainty of the data. This is what would be expected for a reaction of HSA with a 1− charge with H^+. Candlin and Wilkins obtained a slightly lower slope, possibly due to interference by oxygen. Extrapolating the 358 K data to $\mu = 0$ leads to a value of $k = 1.63 \times 10^{-3}\ M^{-1}\ s^{-1}$, close to the value of $1.75 \times 10^{-3}\ M^{-1}\ s^{-1}$ obtained by Candlin and Wilkins. The temperature dependence of the rate constant can be expressed as $k = A \exp(-E_a/RT)$, where *A* is the pre-exponential factor, E_a is the activation energy, *R* is the gas constant and *T* is the absolute temperature. Plots of ln *k* vs. $1/T$ for $\mu = 0.13\ M$ and $\mu = 1.03\ M$ are shown in Fig. 2. The lines are least-squares fits to the data, which give $A = 1.3 \times 10^{10}$ ($\ln A = 23.3 \pm 2.5$) and $E_a = 21.7 \pm 0.7$ kcal mol^{-1} for $\mu = 0.13\ M$, and $A = 6.2 \times 10^{12}$ ($\ln A = 29.5 \pm 1.4$) and $E_a = 26.3 \pm 1.0$ kcal mol^{-1} for $\mu = 1.03\ M$. Candlin and Wilkins obtained a rate expression of $k = 3.2 \times 10^{10} \exp(22\ 800/RT)\ M^{-1}\ s^{-1}$ at 1 *M* H^+. Both expressions for the rate constant at $\mu = 1\ M$ give similar values of the rate constant in the temperature range of 323 to 358 K.

The results indicate that HSA is fairly stable in moderately acid solutions (pH 2–4) where other nitrogen–sulfur compounds hydrolyze. The results indicate that significant amounts of HSA could accumulate in aqueous aerosols exposed to SO_2 and NO_x. In an acidic environment, oxidation by O_2 is fairly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

slow (3). Since the acid hydrolysis is also slow, except under highly acidic conditions, the oxidation and acid hydrolysis pathways will be competitive. Under these conditions, HSA may have time to react to form other compounds if other reactive species are present.

Spectrophotometric determination of sulfanilic acid and sulfonamides in pharmaceutical samples with potassium 1,2-naphthoquinone-4-sulfonate

A. PUNTA CORDERO, F. J. BARRAGÁN DE LA ROSA, and A. GUIRAUM

Department of Analytical Chemistry, Faculty of Chemistry, University of Sevilla, 41012-Sevilla, Spain

Received February 1, 1989

A. PUNTA CORDERO, F. J. BARRAGÁN DE LA ROSA, and A. GUIRAUM. Can. J. Chem. **67**, 1599 (1989).

An accurate and simple method is proposed for the determination of sulfanilic acid in the presence of sulfonamides. This method is based on measuring the intensity of the red colour that develops when sulfanilic acid is allowed to react with potassium 1,2-naphthoquinone-4-sulphonate (NS) in a chloroaceticchloroacetate buffer at pH 3.4. Colour development reaches completion after 2 h, allowing sulfanilic acid to be quantified spectrophotometrically at 470 nm ($\epsilon = 4.7 \times 10^3$ L mol^{-1} cm^{-1}). The main product causing colour formation, potassium 1,2-naphthoquinone-4-(N-aminophenylen-4-sulphonate) (NSSA), was isolated and characterized. When samples also contain sulfonamides an extraction into chloroform must be performed. Sulfanilic acid in binary mixtures with sulfanilamide, sulfacetamide, or sulfathiazole can be determined either by direct measurement of the aqueous phase after extraction at 470 nm or by subtracting from the absorbance of the aqueous phase before extraction the absorbance of sulfonamide as determined by measuring the extracted chloroform phase at 345 nm. Sulfadiazine, sulfamethoxipyridazine, and sulfamethoxazole interferences are prevented by their extraction into chloroform at pH 7.2; these species cannot be determined. The effects of pH, reagent concentration, time, and temperature on colour formation were investigated. In all cases the standard addition method gave more accurate results. The method was applied to several pharmaceutical samples.

Key words: spectrophotometry, sulfanilic acid, sulfonamides, potassium 1,2-naphthoquinone-4-sulphonate.

A. PUNTA CORDERO, F. J. BARRAGÁN DE LA ROSA et A. GUIRAUM. Can. J. Chem. **67**, 1599 (1989).

On propose une méthode précise et simple pour déterminer l'acide sulfanilique en présence de sulfonamides. La méthode est basée sur la mesure de l'intensité de la couleur rouge qui se développe lorsqu'on fait réagir de l'acide sulfanilique avec le 1,2-naphtoquinone-4-sulfonate de potassium (NS) dans un tampon d'acide chloroacétique-chloroacétate, à un pH de 3,4. La couleur est complètement développée après deux heures et l'on peut alors quantifier l'acide sulfanilique d'une façon spectrophotométrique à 470 nm ($\epsilon = 4{,}7 \times 10^3$ L mol^{-1} cm^{-1}). On a isolé et caractérisé le produit principal responsable de la couleur, le 1,2-naphtoquinone-4-(N-aminophénylène-4-sulfonate) de potassium (NSSA). Lorsque les échantillons contiennent aussi des sulfonamides, on doit procéder à une extraction au chloroforme. L'acide sulfanilique en mélanges binaires avec la sulfanilamide, la sulfacétamide ou le sulfathiazole peut être déterminée soit par une mesure directe de la phase aqueuse à 470 nm après extraction soit en soustrayant l'absorbance de la sulfonamide, telle que déterminée par une mesure à 345 nm de la phase chloroformique extraite, de l'absorbance de la phase aqueuse avant extraction. On peut prévenir les interférences de la part de la sulfadiazine, de la sulfaméthoxipyridazine et du sulfaméthoxazole en procédant à leur extraction dans le chloroforme à un pH de 7,2; on ne peut déterminer ces espèces. On a examiné les effets du pH, de la concentration des réactifs, du temps et de la température sur la formation de la couleur. Dans tous les cas, la méthode standard d'addition a fourni les meilleurs résultats. On a appliqué la méthode à de nombreux échantillions pharmaceutiques.

Mots clés : spectrophotométrie, acide sulfanilique, sulfonamides, 1,2-naphtoquinone-4-sulfonate.

[Traduit par la revue]

Introduction

Sulfonamides are pharmaceuticals used extensively as antibacterial compounds. They have, in general, very high chemotherapeutic coefficients, so that overdosage can cause digestive or renal accidents. Sulfonamides can rupture under the action of mineral acids at the S—N bond, producing sulfanilic acid (1). Sulfanilic acid exhibits a still greater toxicity than sulfonamides. It is therefore of interest to detect its presence in drugs.

The voltammetric behaviour of sulfanilic acid and sulfonamides has been studied, and selected mixtures have been analyzed by differential pulse voltammetry (2). It is difficult to obtain quantitative results using this approach, however, since the peaks of different compounds are not well resolved. Therefore, the method is proposed only for detection after high-performance liquid chromatography. On the other hand, the spectrophotometric determination of primary arylamines, including sulfonamides, sulfanilic acid, and aniline derivatives, with metol in the presence of *N*-bromosuccinimide has been proposed (3). Nevertheless, these compounds are usually determined by colourimetry based on the Bratton–Marshal procedure (4), which involves diazotation of the amine and coupling to a coloured dye. Since these methods are tedious, it is of interest to find less complicated procedures.

The present study is a method for the determination of sulfanilic acid, sulfonamides, and binary mixtures of the two based on condensation with potassium 1,2-naphthoquinone-4-sulphonate (NS) and separation of the resulting sulfonamide adducts by extraction into chloroform. The derivative of sulfanilic acid remains in the aqueous phase owing to its higher polarity. A few publications on the use of NS for detecting sulfonamides have appeared (5–7), but the proposed methods have been applied only to the pure amines, with no attempt to resolve mixtures in real samples.

In this paper we also report a study of the pure derivative of sulfanilic acid with NS (NSSA) (8) by UV–visible, IR, ^{1}H- and ^{13}C-NMR, and mass spectroscopy including the determination of its acid dissociation contant.

Experimental

Apparatus

Perkin Elmer 1310 and Varian XL 200 spectrometers were used for recording IR and NMR spectra. A Perkin Elmer 554-UV–visible spectrophotometer with matched glass cells of 1.00 cm path was employed. The mass spectrum was obtained with a Kratos MS8RFA apparatus under 70 eV as ionisation voltage and 300°C as the temperature of the source. A Beckman model-70 pH-meter was used.

Chemicals and pharmaceuticals

Amberlite CG-50 I cation exchange resin (Merck) was digested with

*Abbreviations: s, strong; m, medium; w, weak; v, very.

1 *M* KOH, and then placed in a 1-cm diameter ion exchange column to a depth of 10 cm. The column was washed with water until the pH of the eluate was 5 to 6. Sulfanilic acid was analytical grade (Merck-Schuchard), and 1,2-naphthoquinone-4-sulfonic acid, potassium salt (NS) was technical grade (Ega-Chemie). Sulfamethoxazole, sulfamethoxipirydazine, sulfadiazine, sulfanilamide (sodium salt), sulfacetamide, and sulfathiazole were pharmaceutical grade (Acofarma Tarrasa, Barcelona), and were utilized as working standards as received. Distilled-deionised water and spectroscopic grade chloroform were used throughout. Abactrim was an antibacterial chemotherapeutic suspension (Roche) containing 40 mg of trimetoprime and 200 mg of sulfamethoxazole per 5 mL; Bio Exazol Simple was an antibacterial tablet (Andreu–Barcelona) containing 125 mg of erythromycine base, 125 mg of sulfamethoxipyridazine total, and 150 mg of dimethylchlorotetracycline chlorhydrate per tablet; Amidrin was an antibacterial antiseptic solution (Fardi–Barcelona) containing 4 mg of sulfanilamide, 8 mg chlorhydrate of efedrine, and 5 mg of chlorobutanol per mL; and colirio Oculos was a sedative antiseptic solution (Frumtost-Zyma S.A. Barcelona) containing 100 mg of sulfacetamide sodium salt, 4 mg of tetracaine chlorhydrate, 6 mg of carbamide, and 0.4 mg of naphazoline per mL.

Synthesis and purification of NSSA

A solution of sulfanilic acid (0.7 g) in 60% ethanol–water (v:v) was added to an aqueous solution of 1,2-naphtoquinone-4-sulphonate (NS) (1.0 g). The mixture was refluxed for 30 min, then cooled and passed through an Amberlite CG-50 I column at a rate not exceeding 3 mL min^{-1}. The resin was washed with 200 mL of water and the eluates (about 400 mL) concentrated to approximately 40 mL. The solution upon cooling yielded a deep red violet product. The product when recrystallized from water showed only one spot in TLC tests on silica gel (R_f = 0.72 for chloroform–ethanol 75:25 and R_f = 0.30 for acetone–methanol 90:10). Melting point >300°C. *Anal.* Calcd. for $C_{16}H_{10}NSO_5K$: C 52.30, H 2.74, N 3.81, S 8.72; found: C 51.89, H 2.78, N 3.76, S 8.45. The assignments made for the IR, ^1H- and ^{13}C-NMR spectra of the product are showed in Tables 1 to 3. The calculated values of the ionization constant of the product are collected in Table 4. The molecular peak in the mass spectrum at m/z 368 is close to the calculated molecular weight of the compound (367.1 g mol^{-1}).

Reagent solutions

Sulfanilic acid and sulfonamide stock solutions

Dissolve in 250 mL of water an accurately weighed each of the following: for sulfanilic acid about 39.5 mg, sulfanilamide sodium salt about 44 mg, sulfacetamide about 49 mg, sulfathiazole about 49 mg, sulfamethoxipyridazine about 49 mg, sulfamethoxazole about 231 mg, and sulfadiazine about 200 mg. Working standard solutions are prepared by diluting with water as necessary.

NS stock solution

Dissolve 0.2012 g of potassium 1,2-naphthoquinone-4-sulphonate (Ega-Chemie) in 50 mL of water and dilute to 100 mL with water. This NS solution must be prepared daily.

Chloroacetic acid – chloroacetate (sodium salt) buffer, 0.1 *M* (total concentration), pH = 3.42.

Imidazole – hydrochloric acid buffer, 0.1 *M* (total concentration), pH = 7.20.

Prepared pharmaceutical samples

To accurately weighed amounts of Abactrim, Bio Exazol Simple, Amidrin, and Colirio Oculos an accurately weighed amount of sulfanilic acid was added. The samples were then dissolved in water and diluted to give the compositions shown in Table 5. The samples so prepared were starting materials for the analyses.

Assay procedure

Transfer 5 mL of a prepared pharmaceutical sample solution into a 25-mL calibrated flask and add 0, 1, 3, or 5 mL of sulfanilic acid or sulfonamide working standard solution to construct a standard additions graph (see Table 6). Add 5 mL of chloroaceticchloroacetate solution buffer and 5 mL of NS solution. Mix thoroughly and dilute to volume with water. Let stand for 2 h, then measure the absorbance at 470 nm (A_0) in a 1-cm cell against a blank. Subsequently carry out the separation of sulfonamides into chloroform using either technique A or B.

(A) For samples containing sulfamethoxipyridazine, sulfamethoxazole, or sulfadiazine

Adjust the pH of a 10-mL aliquot of prepared solution to 7.2 by adding 10 mL of imidazole–HCl buffer. Transfer 10 mL of this sample into a separatory funnel and extract twice for 2 min each time with 5 mL of chloroform. Discard the extracts and measure the absorbance of the aqueous phase at 470 nm (A_a) against blanks prepared under the same conditions, but using 5 mL of water instead of sample solution.

The intercept value in a plot of A_a vs. mg of added sulfanilic acid gives the sulfanilic acid concentration in the prepared pharmaceutical sample.

(B) For samples containing sulfanilamide, sulfacetamide or sulfathiazole

Place a 5-mL aliquot of prepared solution from the 25-mL calibrated flask in a separatory funnel and extract twice for 2 min each time with 5 mL of chloroform. Collect the extracts and measure the absorbance of the chloroform phase at 345 nm (A_b) against a blank.

The intercept value of a plot of $(A_0 - \epsilon_{470}/\epsilon_{345} \times A_b)$ vs. mg of added sulfanilic acid gives the sulfanilic acid concentration in the pharmaceutical sample. In the above expression ϵ_{470} and ϵ_{345} are the apparent molar absorptivities for the sulfonamide in the aqueous phase (λ_{max} 470 nm) and chloroform phase (λ_{max} 345 nm), respectively.

The intercept value of the graphic representation of A_b vs. mg of added sulfonamides gives the sulfonamide concentration in the prepared pharmaceutical sample.

Construction of calibration graphs

The calibration graphs to determine the molar absorptivities were not prepared from pure substances, but with binary mixtures of sulfanilic acid and sulfonamides, prepared by diluting and mixing aliquots of the stock solutions to give a series of suitable concentrations. Linearity is maintained over the range 7 to 28 μg mL^{-1} for sulfanilic acid; 7 to 15 μg mL^{-1} for sulfanilamide, sulfacetamide, or sulfathiazole; and 0 to 45 μg mL^{-1} for sulfamethoxipyridazine, sulfamethoxazole, or sulfadiazine. Sulfamethoxipyridazine, sulfamethoxazole, and sulfadiazine are not determinable because they develop little colour in the organic phase; their interference with the sulfanilic acid determination is eliminated by extraction at pH 7.20.

Determination of the stoichiometry of the sulfanilic acid – NS species

Job's method of continuous variations in equimolar (9) and in non-equimolar (10) conditions was employed. Standard aqueous solutions of sulfanilic acid (1.09×10^{-3} *M* to 2.30×10^{-3} *M*) and NS (2.20×10^{-3} *M* to 0.82×10^{-3} *M*) were used. A series of standard solutions of sulfanilic acid and NS in complementary proportions totalling 12 mL (from 0 to 12 and 12 to 0 inclusive) were prepared in 25-mL calibrated flasks. To each was added 5 mL of chloroacetic acid – sodium chloroacetate solution buffer. After 2 h the absorbance of each solution was measured at 470 nm against blanks prepared under the same conditions, but replacing the sulfanilic acid with an equal volume of water.

Yoe and Jones' method of molar ratios was also applied (11). Into a

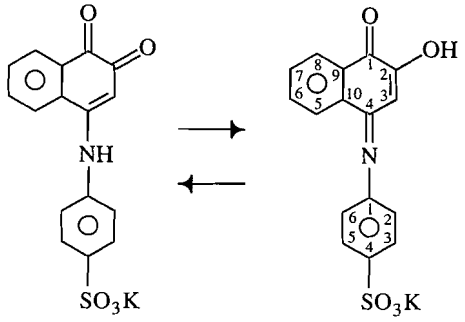
series of 25-mL calibrated flasks were placed 5 mL of chloroacetic acid – sodium chloroacetate solution buffer, 4 mL of sulfanilic acid (1.09×10^{-3} *M*) and variable amounts of NS solution (6.20×10^{-3} *M*). After 2 h the absorbances at 470 nm were measured against blanks.

Results and discussion

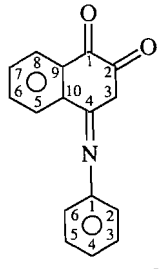


(A) Study of the NSSA adduct

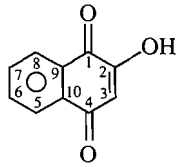
Infrared, NMR, and UV–visible spectra

The use of several spectroscopic techniques permits one to establish the nature of the adduct formed between sulfanilic acid and 1,2-naphthoquinone-4-sulphonate (potassium salt). Two tautomers could be present (**I**, 4-arylamino-1,2-naphthoquinone; and **II**, 4-arylamino-2-hydroxy-naphthoquinone).

The infrared spectrum of the derivative (potassium bromide disk) is complicated; the main bands and their assignments are given in Table 1. The characteristic strong C=N band at 1620 cm^{-1} and the presence of a C=O band at 1670 cm^{-1} confirm the coupling of sulfanilic acid at position 4 of the NS molecule.



The most relevant features of ^{1}H- and ^{13}C-NMR spectra in d_6-dimethylsulphoxide are summarized in Tables 2 and 3. For



Tautomer I Tautomer II

comparison we synthesized substances **III** and **IV** by the method of Fieser (12, 13).

The most characteristic signal for this type of substance in the ^{1}H-NMR spectrum (Table 2) is a singlet at δ = 6.2 ppm

corresponding to the proton attached at C_3. The peak at 9.29 ppm disappears on deuteration. The δ-value lies between those of —NH in **III** and —OH in **IV**, suggesting the tautomeric character of this proton.

The number of ^{13}C-NMR signals, Table 3, are 16 as expected and their positions agree well with those of corresponding carbons in the comparison compounds. The APT technique (14) shows no inversion for the C_1, C_2, and C_4 signals, in accordance with the quaternary character of these atoms. The presence in the NSSA spectrum of a single signal around 182 ppm (assigned to C=O) and one signal for C=N at 168.4 ppm is consistent with the tautomer **II** structure. On the other hand, for product **IV** two signals for C=O (C_1 and C_4) appear but the C=N signal is not present.

Ultraviolet–visible spectra at various pH values in water (Fig. 1) show a band at 270 nm and a shoulder at 340 nm, both assigned to $\pi \rightarrow \pi^*$ transitions, and a wide band with a maximum at 470 nm characteristic of 1,2-naphthoquinone nuclei bounded with arylamines at position 4. The chromophoric system changes beyond pH 11 and the maximum at 470 nm shifts to 525 nm. This may be explained by considering that in alkaline medium the 2-keto group is converted to a —OH group (transformation of form **I** to form **II**, producing maxima at 253 and 280 nm, typical for 1,4-naphthoquinones) which then deprotonates go give the corresponding anion. An analogous change in the molecular structure of other NS arylamine derivatives does not appear in alkaline media, but only in strong acids (pH ≤ 0.8) due to protonation of the 2-keto group (15). Weakly acidic or alkaline solutions contain 4-arylamino-1,2-naphthoquinone as the more important form. The fact that NSSA in strong acids does not undergo transformation from form **I** to form **II** could be attributable to the presence of the $-SO_3^-$ group, which precludes protonation of the 2-keto group.

Equilibria of NSSA with protons

The spectra of aqueous solutions of NSSA are pH-dependent

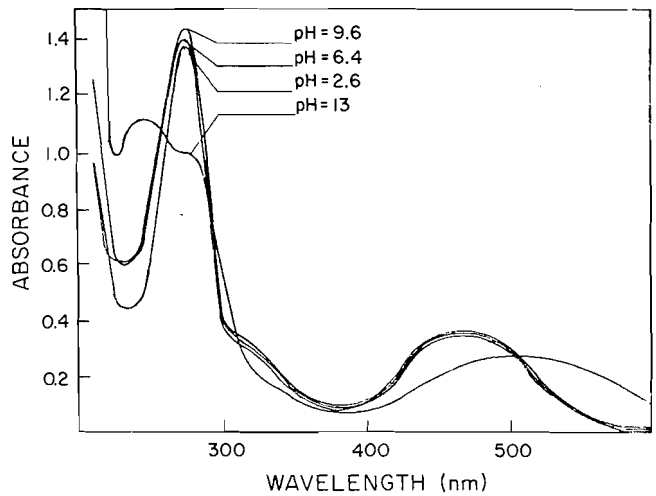

FIG. 1. Ultraviolet absorption spectra of NSSA ($c = 6.4 \times 10^{-5}$ mol L^{-1}) at different pH values.

(Fig. 2). The NSSA spectrum over pH 1 to 11 is attributed to the charged species RH^-, with an absorption maximum in the visible region at 470 nm which in strong acids may be converted to a fully protonated species (RH_2). We did not study this pK_a because we found that protonation of the $-SO_3^-$ group, if it occurs, is not reflected by any change in the spectrum of NSSA when a large amount of acid is present. Moreover, this pK_a lacks practical interest. The major species above pH 11 is the anion R^{2-}, which has an absorption maximum in the visible region at 525 nm.

Graphical analysis of A vs. pH curves (Fig. 2*A*) over the appropriate wavelengths yielded a pK_{a2} value. The Maroni–Calmon and Romain–Colleter methods were used. Deprotonation is shown by the absorbance step that appears for each wavelength in the basic region, with an inflection point dividing the steep part of the graph into two sections.

Maroni and Calmon (15) developed two techniques which permit one to obtain the pK_{a2} value and the molar absorptivity $\epsilon_{R^{2-}}$. In the first technique (method of parallel straight lines) A vs. $|A_{HR^-} - A|[H^+] \times 10^{12}$ is plotted (Fig. 2*B*); in the second one $1/|A - A_{HR^-}|$ vs. $[H^+] \times 10^{12}$ is plotted (Fig. 2*C*). In both cases the inverse of the slope yields the pK_{a2} value.

The Romain–Colleter method (16) was started with an initial pK_{a2} value of 10.3 (estimated from Maroni–Calmon's method) to obtain a more refined value. Budesinky's technique (17) to calculate the number of protons implicated in the ionization reaction was applied to the A vs. pH curves. It was found that only one proton participated in the reaction.

Potentiometric titration of a NSSA solution (0.0016 mol / L)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

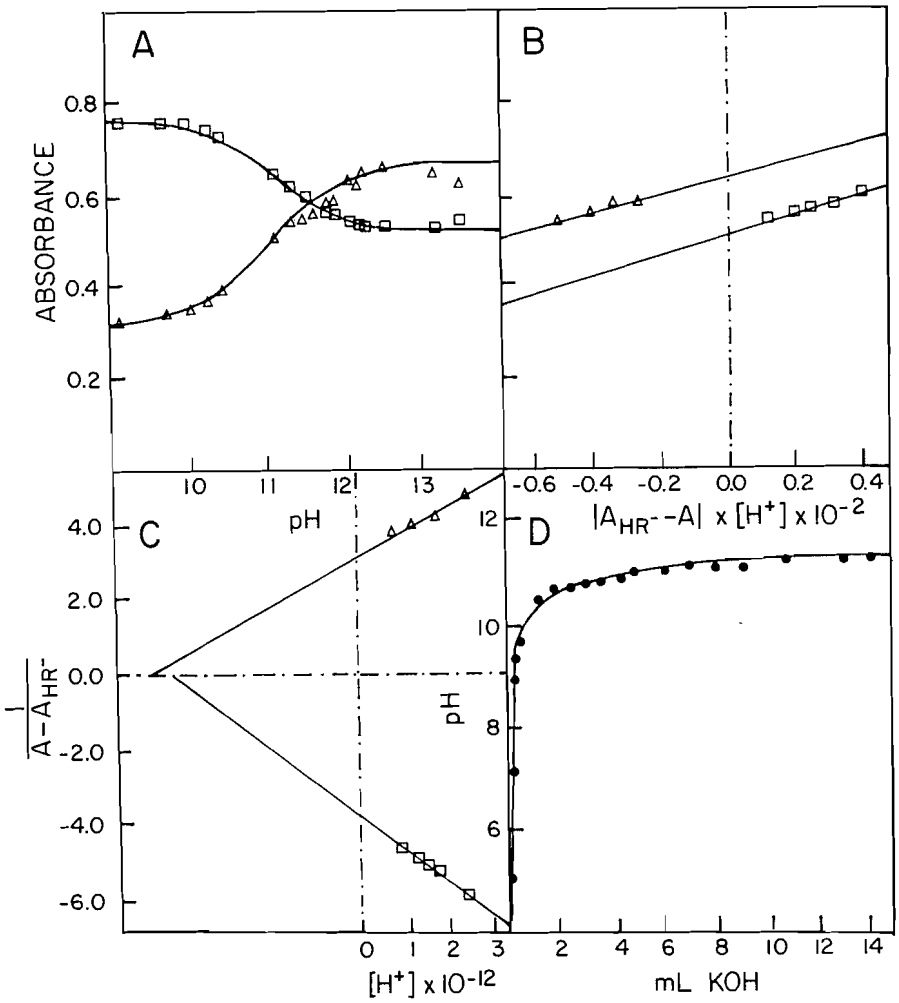

FIG. 2. Determination of pK_{a2} of NSSA: (*A*) absorbance vs. pH curves; (*B*) parallel straight lines method; (*C*) concurrent straight lines method; (*D*) potentiometric method.

with 0.0185 mol / L KOH in water under nitrogen while keeping temperature and ionic strength constant was also carried out (Fig. 2*D*). A pK_{a2} determination from the potentiometric measurements was made using Schwarzenbach's method (18).

The pK_{a2} and arithmetic mean values obtained by all these methods are summarized in Table 4.

Stability and behaviour against reducing and oxidizing agents

NSSA is very stable in the pH 4 to 9 range, but out of this range it suffers rapid decomposition. Both reducing and oxidizing agents at 1% (w / v) concentration alter the absorption spectra of NSSA in water, the material being more unstable against oxidizing than reducing agents. The decomposition products were not identified.

(B) Reaction of sulfanilic acid with NS and determination of sulfanilic acid and sulfonamides

A characteristic red colour with an absorption maximum at 470 nm develops when sulfanilic acid reacts with NS in the chloroacetic acid – chloroacetate (sodium salt) buffer. The reaction can be used to determine this acid. NS is yellow in aqueous solution, but its color does not affect sulfanilic acid determintions if blanks with the same concentration of NS are used.

The reaction of NS with six sulfonamides was studied. Sulfanilamide, sulfacetamide, and sulfathiazole also show intense red colouration when treated with NS in the presence of chloroaceticchloroacetate buffer, both in aqueous medium and after extraction into chloroform. In chloroform quantitative measurements can be undertaken.

Preliminary studies revealed the additivity of the absorbance caused by sulfanilic acid and by the other sulfonamides studied. Hence, we attempted to resolve the several binary mixtures by mathematical analysis of the spectroscopic data, as well as by derivative spectroscopy. The results were not satisfactory, however, because the absorption maxima and molar absorptivities were very close. Extraction into chloroform to prevent the interference of sulfanilamide, sulfacetamide, and sulfathiazole with the sulfanilic acid determination was, however, successful. Moreover, simultaneous determinations are possible. To determine sulfanilic acid in these mixtures a simple absorbance measurement of the aqueous layer at 470 nm can be employed, but results are more precise if the equation described under the Assay Procedure is used. This equation corrects the total absorbance of the aqueous phase before extraction by subtracting the sulfonamide contribution (obtained from measurement of the chloroform phase at 345 nm). Sulfamethoxiazole, sulfamethoxipyridazine, and sulfadiazine form so little colour with NS that they cannot be quantitatively determined; instead they are extracted into chloroform from an imidazole buffer to eliminate their slight interference in the aqueous phase.

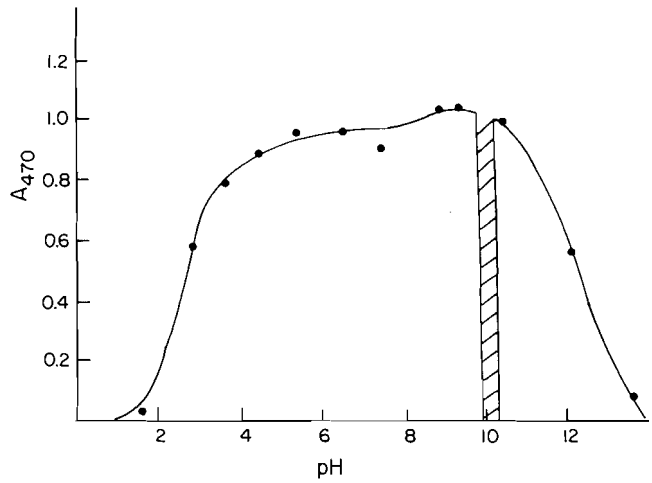

FIG. 3. Absorption intensity of the chromogen as a function of pH. Concentration of sulfanilic acid 43 μg mL^{-1}. The cross-hatched zone represents precipitation of NS in the samples.

Optimisation of variables

The optimisation of several variables influencing the reaction between sulfanilic acid and NS was studied. Maximum colour intensity was obtained after 90 min at 20 ± 5°C. The colour was stable for a further 24 h. The optimum pH range using an equimolar solution of both compounds is 3.3 to 8.0 (Fig. 3). A pH value of 3.5, adjusted with chloroacetic acid – sodium chloroacetate buffer, is recommended. The optimum concentration of NS leading to maximum intensity of colour was found to be 15-fold that of the sulfanilic acid concentration in the final solution. The amount of buffer solution, ionic strength, addition order, and temperature did not affect the results. A modified simplex method (19) was used to optimize pH and relative amount of NS reagent to sulfanilic acid in addition to the classical approach for optimisation. The result obtained by the simplex method was the same as that obtained by the classical one.

Quantification, linearity of Beer's law plot, accuracy, and precision

A linear correlation ($r = 0.9997$) was found between absorbance at 470 nm and concentration of sulfanilic acid in the range 3.1 to 31.0 μg mL^{-1}. The apparent molar absorptivity was found to be 4.7×10^3 L mol^{-1} cm^{-1}. The reproducibility of the procedure was determined by running replicate samples, each containing 15.8 μg mL^{-1} of sulfanilic acid in the final test solution. At this concentration level the relative standard deviation did not exceed 0.4% for twelve separate samples.

Sensitivity and specificity

The optimum range for measurement of sulfanilic acid with NS was determined by Ringbom's method (20) to be in the range from 8 to 25 μg mL^{-1}. This indicates good sensitivity for the reaction, and thus the present method can be recommended for the detection of trace amounts of sulfanilic acid in drugs. The influence of numerous cations and some amines on sulfanilic acid quantification was tested. Cations do not interfere except for Cu(II) and Al(III) at molar ratios higher than 1:10 (sulfanilic acid:cation). Hydrazides, semicarbazides, and some aminopyridines interfer by forming precipitates with NS. Aniline and sulfonamides give coloured products with NS in aqueous medium, but can be separated by extraction into organic solvents.

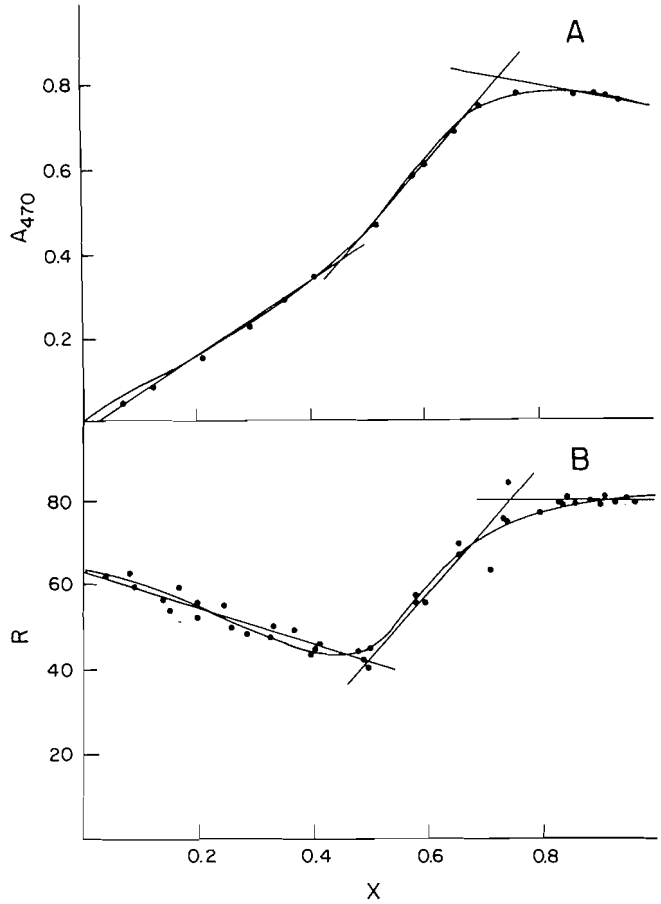

FIG. 4. Sulfanilic acid to NS ratio in the chromogen: (*A*) molar ratio method; (*B*) plot of data from investigation in non-equimolar conditions. *X* is the molar fraction of NS $C_{NS} / (C_{NS} + C_S)$.

Sulfanilic acid to NS ratio in the chromogen

A continuous molar variation study of sulfanilic acid and NS showed that interaction between them does not occur on a equimolar basis. Hence we applied the continuous variation method in non-equimolecular solutions according to Ramanathan and Walvekar (10) to a set of experimental curves obtained at different molarities of the reactants. This study suggested the possible presence of more than a single complex if a large excess of NS is present, even though the isolated adduct obtained under experimental conditions of equal molar amounts of both reactants corresponds clearly to a 1:1 stoichiometry.

To evaluate more precisely the combining ratios of sulfanilic acid and NS, we used the molar ratio method (11) with a fixed amount of sulfanilic acid (Fig. 4*A*), and also the data from an investigation under non-equimolar conditions (Fig. 4*B*).

Plots of *R* (relative percentage of adduct to total amount of minor component in sulfanilic–NS mixtures) against *X* (molar fraction of NS in the sulfanilic acid – NS mixtures) are shown in Fig. 4*B*. *R* is calculated on the assumption that the absorbance limit at each end of the studied range corresponds to different species involving sulfanilic acid and NS. If these species are called **I** and **II**, $C_{\mathbf{I}}$ and $C_{\mathbf{II}}$ are calculated from $\epsilon_{\mathbf{I}}$ and $\epsilon_{\mathbf{II}}$ at each point and thus situation (*A*) occurs when $C_S \geq C_{NS}$, $R = (C_{\mathbf{I}} / C_{NS}) \times 100$, and (*B*) when $C_S \leq C_{NS}$, $R = (C_{\mathbf{II}} / C_S) \times 100$. In the above expressions C_S and C_{NS} are the concentrations of sulfanilic acid and NS in the samples. Situation *A* reflects predominance of sulfanilic acid, and *B* when NS predominates.

TABLE 7. Assay of sulfanilic acid and some sulfonamides in pharmaceuticals by the NS method

Sample	Sulfonamide assay: Amount present (mg mL^{-1}) I[b]	II[c]	Recovery, %[a] I	II	Sulfanilic acid spike recovery: Amount added (mg mL^{-1})	Recovery, %[a]
Abactrim	—	—	—	—	7	93±1.5
Bio exazol simple	—	—	—	—	22[d]	109±1.3
Amidrin	4	—	98±2.1	—	7	96±1.3
Colirio oculos	—	100	—	89±2.0	152	113±1.2

[a]All averages are based on the three determinations; uncertainties are one standard deviation. Theoretical recovery is 100%.
[b]**I** = sulfanilamide.
[c]**II** = sulfacetamide.
[d]In mg/tablet.

The graph R vs. X should be monotonic if only one complex is involved, but the presence of two points of discontinuity demonstrates that, in agreement with the molar ratio method, there is an initial combining ratio of 1:1 (sulfanilic acid – NS) and a second above a 1:3 ratio.

The first ratio indicates formation of the equimolar adduct that was isolated and characterised in this work. The second inflection point is not easy to interpret. We conclude that the red colour produced when sulfanilic acid reacts with a large excess of NS is due to a mixture of a 1:1 complex and a second complex of undefined higher stoichiometry.

Application to pharmaceuticals

The suggested method was applied to the quantitative determination of spiked sulfanilic acid, and to sulfonamides in pharmaceuticals. The data in Table 7 indicate the suitability of the method for routine quality control analysis.

Conclusions

The nature of the species formed between sulfanilic acid and 1,2-naphthoquinone-4-sulphonate has been established by elemental and spectroscopic analysis. The adduct has two tautomers: 4-arylamino-1,2-naphthoquinone (form **I**) and 4-arylimine-1,4-naphtoquinone (form **II**). Form **I** is present in acidic and slightly basic aqueous solutions. Deprotonation of this form leads to form **II** (pK_a = 11.3).

Although several methods are described in the literature for the determination of sulfonamides, all have serious limitations. The photometric Bratton–Marshal method for amines, which uses diazotation and coupling of the formed azo dye, is tedious. Acid–base titrimetry in dimethylformamide with tetramethylammonium hydroxide of the sulfonamide group (—SO_2—NH—) presents problems from interferences by other substances in the sample. Moreover, relatively high concentrations are needed. In this study we propose a new simple procedure for the determination of sulfanilic acid and sulfonamides. Furthermore, binary mixtures can be resolved. Sulfanilic acid can be determined in the presence of a two-fold molar excess of sulfanilamide, sulfacetamide, and sulfathiazole and vice versa. The method also tolerates sulfamethoxazole, sulfamethoxipyridazine, and sulfadiazine at molar concentrations five- to eight-fold greater than sulfanilic acid, but these sulfonamides could not be quantified in the mixtures.

Although direct analysis is feasible, use of a standard additions method is recommended to obtain more precise results. When the amines are alone the direct procedure is more advantageous.

Results of application of the method to several samples are in general satisfactory and deviations from theoretical recovery of 100.0% are minimal (Table 7).

Received March 10, 1989

JEAN-LOUIS KRAUS, SOPHIE MICHEAU, PHILIPPE PERNICE, and MADELEINE CASTAING. Can. J. Chem. **67**, 1606 (1989).

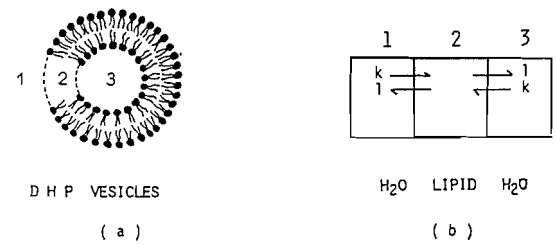
New substituent constants π_p, derived from permeation coefficients, of membrane model vesicles have been evaluated for fifteen functional groups. The excellent correlation found between the new substituent constants and the values derived from partition coefficients in octanol–water system leads one to consider this new parameter and the technique used for its evaluation as new promising tools for quantitative structure–activity relationship studies and for hydrophobic properties measurement.

Key words: permeation coefficients, model membrane, dihexadecyl-phosphate vesicles.

JEAN-LOUIS KRAUS, SOPHIE MICHEAU, PHILIPPE PERNICE et MADELEINE CASTAING. Can. J. Chem. **67**, 1606 (1989).

Les coefficients de perméation π_p de quinze groupements chimiques fonctionnels ont été évalués à l'aide de membranes de vésicules de dihexadecyl phosphate. L'excellente corrélation trouvée entre ces coefficients de perméation π_p et les coefficients de partition π mesurés dans le système octanol–eau d'une part et la simplicité de la nouvelle technique d'évaluation de π_p d'autre part, permettent d'envisager leur utilisation dans des études de relation structure-activité et pour des mesures d'hydrophobicité.

Mots clés : coefficients de perméation, modèle membrane, vésicules de dihexadecyl phosphate.



[Traduit par la revue]

Introduction

For a drug to be absorbed from the intestine to the interior of a cell, it has to penetrate cell membranes. The factors that determine the permeability of cell membranes to drugs are of interest to medicinal chemists and biochemists (1–7).

In attempting to rationalize the correlation between the chemical structure of a drug and its biological activity, Hansch and co-workers focused on the hydrophobic character of drugs (refs. 8, 9 and references therein). They used, for an operational representation of the capacity of molecules to form hydrophobic bonding, the values for the octanol–water partition coefficient of drugs, expressed as log P (P is the octanol–water partition coefficient of the unionized molecule) (10), and showed good correlation between the hydrophobic character of the drugs and various biological responses (9, 11). The fundamental basis underlying these results was the assumption that the rather orderly shell of water molecules surrounding an organic compound in an aqueous solution would disintegrate when this compound is transferred into a non-polar phase. The entropic change associated with this process appears to be one of the most important contributing factors to "hydrophobic bonding".

Following the considerable work of Hansch and co-workers, other substituent constants for organic compounds were proposed in the field of structure-activity relationship, the most widely used being the Hammett constants (12), and their extension by Taft, Brown, and Charton (13). In this work we proposed a new method for the determination of a new substituent parameter which can be easily determined whatever the chemical structure of a drug. This constant was derived from permeation coefficient of dihexadecyl phosphate vesicles. Indeed, using a model membrane made of dihexadecyl phosphate bilayers, it has been possible to determine permeation values which directly reflect the hydrophobic character of the organic molecules. As is well known, single compartment vesicles made of dihexadecyl phosphate (DHP) offer a realistic model for permeability investigations, as like living cells, their membrane is made of bilayers.

SCHEME 1

Scheme 1 shows that the DHP vesicle (*a*) can be visualized as a lipid barrier separating two aqueous compartments (*b*). Let k be the rate constant for the passive movement of a given marker from the aqueous phase towards the lipid phase, and l the same but for the reverse process, the value for the partition coefficient P of this marker is equal to the ratio of the rate constants ($P = k/l$). In the present study the marker encapsulated in the vesicle cavity (compartment 3) was the tris(2,2′-bipyridyl)ruthenium(II) chloride hexahydrate ($Ru(bpy)_3^{2+}$).

The magnitude of the leakage of $Ru(bpy)_3^{2+}$ ions through the membrane of DHP vesicles, when induced by various organic molecules, was quantified. The permeation properties of these drugs were determined by monitoring the outflux of $Ru(bpy)_3^{2+}$ ions from the vesicles (compartment 3 to compartment 1) using electronic absorption. Defining $PD50_H$ and $PD50_X$ as the respective concentrations of $CH_3(CH_2)_4CH_3$ and $CH_3(CH_2)_4CH_2X$ required to decrease the $Ru(bpy)_3^{2+}$ content of the vesicles to 50% of its initial value, a new substituent constant expressed by the equation $\pi_p = \log PD50_X - \log PD50_H$ can be calculated. The purpose of this work was therefore to evaluate π_p values of various compounds of the hexane series using a model membrane of bilayers and to establish a correlation between these π_p values and those derived from Hansch's partition coefficients.

TABLE 1. Substituent parameter values derived from permeation coefficients in the hexane series $CH_3(CH_2)_4$—CH_2X

Compound	X	PD50 $M\,L^{-1}$	π_p[e,f]	π according to Hansch (17)[a]
Hexane, $CH_3(CH_2)_4CH_3$	—H[b]	0.83×10^{-2}	0	0
1-Chlorohexane, $CH_3(CH_2)_5Cl$	—Cl	0.30×10^{-2}	−0.48±0.05	+0.71±0.03
1-Bromohexane, $CH_3(CH_2)_5Br$	—Br	0.18×10^{-2}	−0.66±0.03	+0.86±0.02
1-Iodohexane, $CH_3(CH_2)_5I$	—I	0.14×10^{-2}	−0.76±0.05	+1.01±0.01
Heptane, $CH_3(CH_2)_5CH_3$	—CH_3[b]	0.30×10^{-2}	−0.45±0.02	+0.56±0.02
Octane, $CH_3(CH_2)_6CH_3$	—CH_2CH_3[b]	0.325×10^{-2}	−0.40±0.02	+1.02±0.02
Heptanoic acid, $CH_3(CH_2)_5CO_2H$	—COOH	4.4×10^{-2}	+0.72±0.04	−0.28±0.02
Heptanoamide, $CH_3(CH_2)_5CONH_2$	—$CONH_2$	29.2×10^{-2}	+1.61±0.04	−1.49±0.02
Hexylcyanide, $CH_3(CH_2)_5CN$	—CN	7.8×10^{-2}	+0.96±0.03	−0.57±0.02
Hexylamine, $CH_3(CH_2)_5NH_2$	—NH_2[c]	0.19×10^{-2}	−0.64±0.04	−1.23±0.02
1-Nitrohexane, $CH_3(CH_2)_5NO_2$	—NO_2	1.50×10^{-2}	+0.26±0.07	−0.28±0.02
Hexanal, $CH_3(CH_2)_4CHO$	—CHO[d]	2.30×10^{-2}	+0.44±0.11	−0.65±0.02
1-Hexyltetrazole, $CH_3(CH_2)_4CN_4H$	—CN_4H[d]	7.20×10^{-2}	+0.94±0.03	—
Hexyl alcohol, $CH_3(CH_2)_5OH$	—OH	3.95×10^{-2}	+0.68±0.02	−0.67±0.01
1-Hexanethiol, $CH_3(CH_2)_5SH$	—SH	0.31×10^{-2}	−0.43±0.03	+0.39±0.02

[a]The values reported in this column correspond to those reported by Hansch (17) in the case of benzene system. The function X is placed in position 4 of the aromatic ring.
[b]The following values for PD50 have been determined in using DMSO as indicated in the Materials and Methods section.
[c]This value does not verify the linear relationship shown in Fig. 1 (see Discussion).
[d]The π values for these substituents were not available in the benzene system reported by Hansch (ref. 17).
[e]The error values refer to the standard deviation.
[f]π_p was calculated according to the equation $\pi_p = \log PD50_X - \log PD50_H$.

Experimental

Most of the tested compounds used in this work were stated to be 99% pure or more, manufactured by Aldrich Chemicals. Hexyltetrazole has already been described in a previous paper (14). The other chemicals dimethylsulfoxide (DMSO), $Ru(bpy)_3Cl_26H_2O$ were purchased from Aldrich Chemicals. The analytical grade cation exchange resin AG 50W-X2 (100–200 mesh, hydrogen form) was purchased from Biorad Laboratories.

Preparation of DHP vesicles

The present experiments were performed on vesicles made of DHP since they are known to be highly stable (a few months). The entrapment of $Ru(bpy)_3Cl_26H_2O$ ions into such vesicles has been extensively studied by Tricot *et al.* (15). Based on their data, the optimal concentration of DHP was estimated to be $2 \times 10^{-3}\,M\,L^{-1}$, while that of $Ru(bpy)_3Cl_26H_2O$ ions would reach $3.3 \times 10^{-4}\,M\,L^{-1}$, and the pH at sonication a value of 5.7.

Vesicles were prepared by heating the required amount of DHP dissolved in double distilled deionized water for 60 min at 80°C. The solution was then alkalinized to the required pH by NaOH addition and the $Ru(bpy)_3Cl_26H_2O$ injected to the mixture. A sonication was then performed for approximately 45 min at 80°C. After cooling, the vesicle suspension was filtered to remove the titanium particles released by the sonicating probe. The suspension contained single-compartment vesicles with $Ru(bpy)_3Cl_26H_2O$ ions adsorbed within the outer and inner surfaces of their membrane. Further details on DHP vesicles preparation are available in the data reported by Tricot and Fendler (16).

PD50 calculation

The optical density (OD) of $Ru(bpy)_3Cl_26H_2O$, at approximately 455 nm, was determined by recording the visible absorption spectra of the samples with a 860 KONTRON Spectrometer (KONTRON/Instrument Division). The experimental procedure was as follows. First, the DHP vesicles suspension was passed over a cation-exchange resin, and therefore, the free $Ru(bpy)_3Cl_26H_2O$ ions of the sample, as well as those adsorbed at the outer surface of the membranes, were exchanged with the H^+ ions of the resin. The OD value of this suspension, when corrected from the contribution of vesicles with no entrapped marker molecules, was taken to be "standard OD" (OD_S). Secondly, the perturbing agent was added to the eluted vesicles suspension. This induced a membrane perturbation and $Ru(bpy)_3Cl_26H_2O$ leakage from the inside of the vesicles. These ions were removed from the sample, as explained above, using a cation-exchange resin, and the absorption spectrum was recorded. The OD value determined now, when corrected from vesicles contribution, was taken to be the "measured OD" (OD_M). The value of the OD_M/OD_S ratio was then equal to the percentage of $Ru(bpy)_3Cl_26H_2O$ ions remaining entrapped in the vesicles after the action of a given perturbing agent, at a given concentration. The permeation dose at 50%, i.e. PD50 was defined as the concentration of the perturbing agent required to induce a 50% decrease in the value of the initial $Ru(bpy)_3Cl_26H_2O$ ion concentration. In other words, PD50 corresponds to a OD_M/OD_S ratio equal to 0.50. This provided a useful means to compare the action of the various perturbing agents.

It must be emphasized that because of their low hydrophilicity, the perturbing agents were dissolved in DMSO. An equivalent amount of DMSO was added to the standard vesicles suspensions previous to the recording of their absorption spectra allowing the calculation of the standard OD_S. In addition we ascertained that the perturbing effect of DMSO on the vesicles membranes could be neglected as the PD50 determined for this solvent was higher than 7 *M*.

All experiments were carried out at 25°C. We ensured that the incubation time was long enough to reach the equilibrium state which corresponds to the maximum leakage of $Ru(bpy)_3^{2+}$ from the inner to the outer surface of the vesicles.

Results and discussion

The results reported in Table 1 show that the hexane congeneric compounds behave as perturbing agents of DHP vesicles. Their PD50 values are within the range 10^{-3} to $0.5\,M\,L^{-1}$. The new substituent parameter has been calculated from the equation

$$\pi_p = \log PD50_X - \log PD50_H.$$

Figure 1 illustrates the correlation between the new substituent parameter π_p and Hansch's substituent constant derived from partition coefficients. The correlation equation is as follows:

$$[1]\quad \pi_p = -0.99\pi(\pm 0.08) + 0.17(\pm 0.07)$$
$$r = 0.9189 \qquad n = 12 \qquad p < 0.001$$

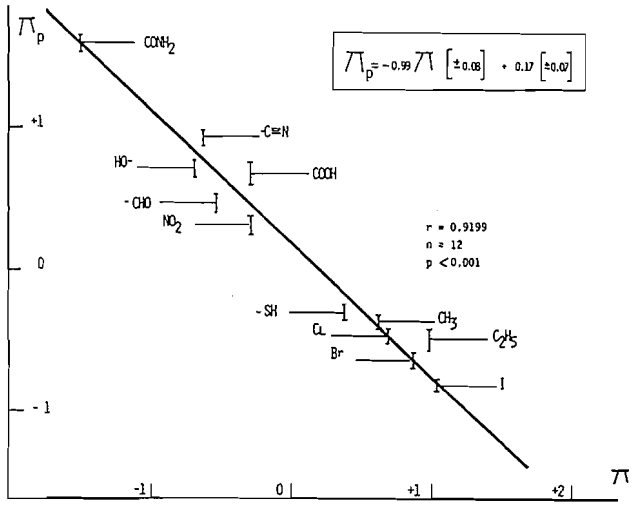

FIG. 1. Correlation between π_p values derived from permeation coefficients of model membrane vesicles and π values derived from partition coefficients according to Hansch (17).

In eq. [1] π is the partition coefficient constant according to Hansch's data (17); π_p is the permeation coefficient derived from the present experimental data, r is the correlation coefficient, n represents the number of data points used and this linear regression was highly significant: $p < 0.001$. S.E.M. values are given in parentheses.

Let us start by pointing out the selection of the hexane series for this study, because of our recent results (14). In this work, we have showed that carboxylic acids having a carbon chain length from 5 to 8 carbon atoms induced vesicle membrane perturbations the magnitude of which is controlled by two parameters — carbon chain length and the carboxylic function while for carboxylic acids having a carbon chain length of more than 10 carbon atoms, the perturbing effect is mainly under the control of the carbon chain length, the contribution of the functional group to the perturbing effect is very low and not suitable for the purpose of this work.

Our second question is that: are partition coefficients representative enough in quantitative structure–activity relationships? As stated in the Experimental section, PD50 values reported are easy to determine and are available for all types of chemical functions using DMSO to overcome eventual solubility problems. Moreover, single-compartment vesicles represent a more realistic model for the study of membrane permeability than the partition coefficients in octanol–water, since like real membranes, single-compartment vesicles are made from bilayers. Finally, a point of concern to us is that the determination of partition coefficients in the octanol–water system requires the presence of an aromatic moiety in the chemical structure of the drug. This aromatic part could interact with the rest of the molecule bearing the chemical group. Such an interaction of the side-chain dipole with the electrons of the aromatic ring could result in a folding of the molecule that can modify the intramolecular hydrophobic bonding (for comprehensive examples see ref. 10). On the other hand, permeation coefficients as determined in this study exclude the participation of π electrons as a governing factor in the permeability properties.

In the case of the primary amino group, whose co-ordinates do not significantly verify the linear relationship shown in Fig. 1, a possible explanation could be found in considering the electrical effects of an amino group in an anilin system which are widely different from that of a primary aliphatic amine such as hexylamine. This point is illustrated in comparing the pK_a of the two compounds.

The permeation induced by the hexane congeners is a very fast kinetic process, the mechanism of which remains unclear. It is possible that the interaction between the permeant molecules and the lipid head groups of the outer interface of the vesicles would slightly affect the bridging of the water molecules within the membrane, allowing therefore, the formation of pores and the release of $Ru(bpy)_3^{2+}$ ions.

Since Hansch and co-workers have provided powerful tools of physical organic chemistry in introducing hydrophobic substituent constants which represent the linkage between the dynamic effects of substituent (hydrogen bonding power, degree of polarization, and Van der Waals forces) and the biological response for a set of congeners, biological chemical structure–activity problems have made remarkable improvements. Related to these problems we believe that the introduction of new substituent constants π_p derived from permeation coefficients of membrane model vesicles could be of interest, since the latter are closely representative of the hydrophobic properties of substituents.

Moreover, the fact that no aromatic ring is involved in the determination of π_p made the use of this new substituent parameter a very attractive one. Finally if one considers that π_p values can be determined for any type of function, we can postulate the permeation coefficients could be used for numerical analysis of biochemical structure–activity studies.

Synthesis and transannular Diels–Alder reaction of a *cis–trans–trans* and a *trans–cis–cis* 13-membered macrocyclic trienone

ANNE MARINIER,[1] KURT BAETTIG, CAROL DALLAIRE,[1] RITA PITTELOUD, AND PIERRE DESLONGCHAMPS[2]

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received April 25, 1989

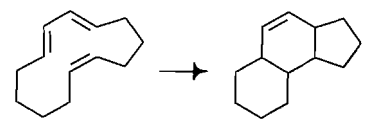
ANNE MARINIER, KURT BAETTIG, CAROL DALLAIRE, RITA PITTELOUD, and PIERRE DESLONGCHAMPS. Can. J. Chem. **67**, 1609 (1989).

The synthesis of the *cis–trans–trans* **5** and *trans–cis–cis* **6** macrocyclic trienones from cyclohexene is described. Upon heating at 300°C, trienone **5** underwent 1,5-H shift and transannular Diels–Alder reaction to give adducts **33**, **34**, and **35** while trienone **6** provided tricyclic ketone **37**.

Key words: transannular Diels–Alder reaction.

ANNE MARINIER, KURT BAETTIG, CAROL DALLAIRE, RITA PITTELOUD et PIERRE DESLONGCHAMPS. Can. J. Chem. **67**, 1609 (1989).

La synthèse des triénones macrocycliques *cis–trans–trans* **5** et *trans–cis–cis* **6** à partir du cyclohexène est décrite. En chauffant à 300°C, la triénone **5** subit un réarrangement sigmatropique-1,5 et une réaction Diels–Alder transannulaire pour donner les adduits **33**, **34** et **35**, alors que la triénone **6** conduit à la cétone tricyclique **37**.



Mots clés : réaction Diels–Alder transannulaire.

During the last decade, chemists have become increasingly interested in the synthesis of macrocarbocyclic molecules. Many naturally occurring compounds contain medium or large rings (1) and their syntheses require good methods for the preparation of these rings. The cyclization of long chains of carbons was first shown to be possible by direct processes (2). It was also recently demonstrated through a systematic study that the introduction of unsaturation in the carbon chain greatly helped the cyclization process by improving the yields considerably (3).

The reactivity of macrocarbocycles has also been studied. Chemists have shown that intermolecular reactions of these molecules can be carried out with high chemo-, regio-, and stereoselectivity (4, 5). Some examples of the transannular reactions of macrocycles have also been reported (6), demonstrating the facility with which these processes can take place. Transannular reactions, however, have rarely been used as cornerstones in specific syntheses.[3] In 1984, we pointed out (8) that transannular processes of macrocycles[4] represent a powerful approach for the development of new strategies for the construction of complex polycyclic molecules. From this perspective, the transannular Diels–Alder reaction of macrocycles, i.e., **1** → **2** or **3** → **4** has the potential to be a good synthetic approach to polycyclic systems. Recent communications from our laboratory (10) and from Takahashi *et al.* (11) demonstrate promise for the synthesis of diterpenes, triterpenes, steroids, etc., by the transannular Diels–Alder methodology.

We wish to report here our first detailed preliminary studies on the transannular Diels–Alder methodology. We describe the synthesis and the Diels–Alder reactivity of two 13-membered macrocyclic trienones, i.e., the *cis–trans–trans* (CTT) **5** and *trans–cis–cis* (TCC) **6** trienones.

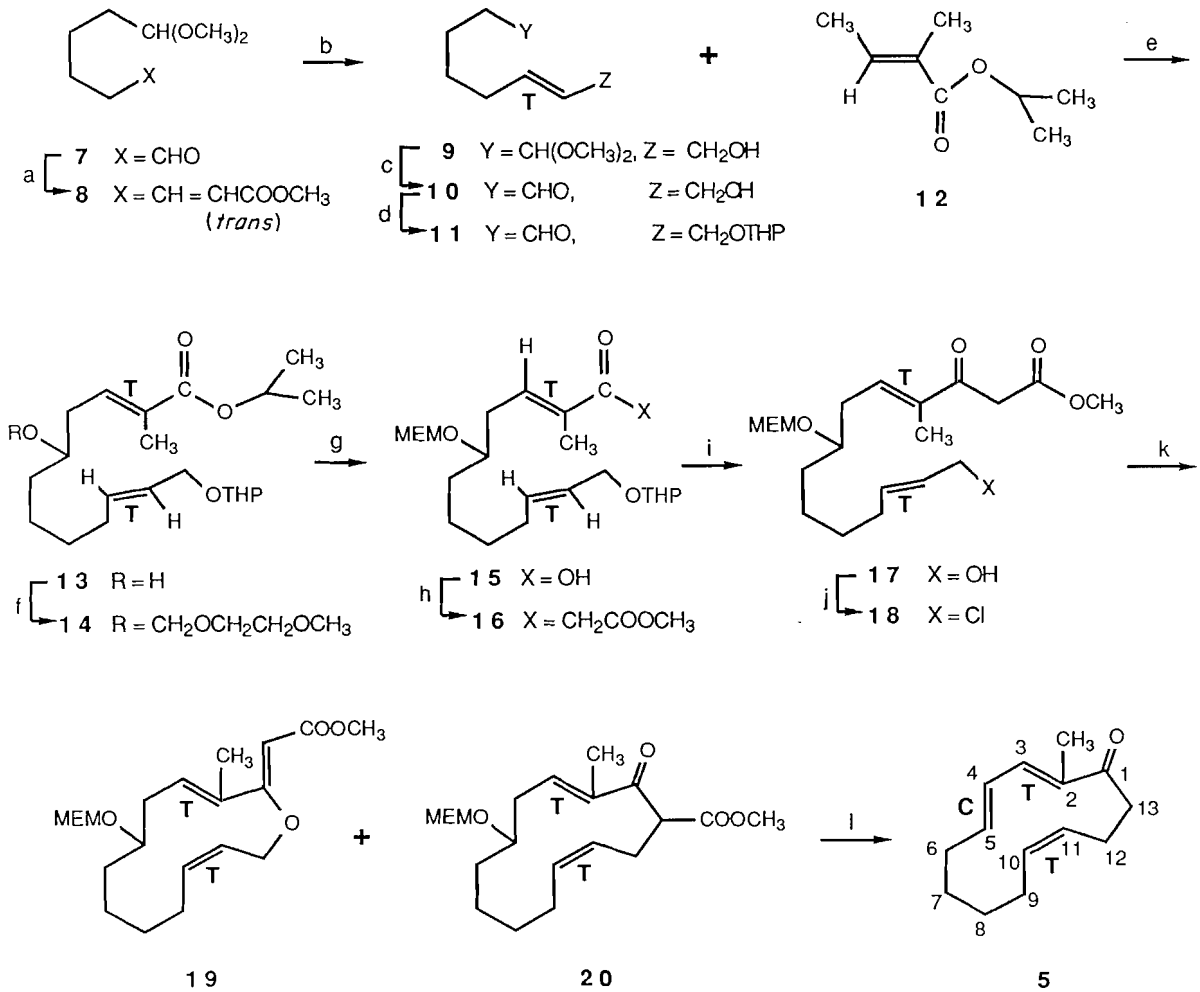
1 **2**

3 **4**

Synthesis of trienones 5 and 6

Dimethoxy acetal aldehyde **7** prepared from cyclohexene by the method of Schreiber *et al.* (12) was used as starting material for the synthesis of the two trienones **5** (Scheme 1) and **6** (Scheme 2). Horner–Emmons condensation (13) of **7** with trimethyl phosphonoacetate provided unsaturated *trans* ester **8** (69%), which was reduced with diisobutylaluminium hydride (89%). The resulting dimethoxyalcohol **9** was hydrolyzed under acidic conditions to liberate the aldehyde moiety and protected (14) with dihydropyran to give aldehyde **11** in 55% overall yield. Condensation (15) with the lithium dienolate of isopropyl tiglate **12** produced the *trans–trans*-γ-coupling aldol product **13** (67%), which was converted into the methoxyethoxymethyl (MEM) ether derivative **14** (16) (88%).

Basic hydrolysis of **14** with lithium hydroxide (60% to **15**) followed by treatment with carbonyldiimidazole and reaction with the magnesium salt of monomethylmalonic acid (17) provided the β-ketoester **16**. Removal of the tetrahydropyrannyl protecting group afforded **17** (81% from **15**) from which subsequent halogenation gave the allylic chloride **18** in 89% yield.



Macrocyclization was carried out by slow addition of allylic chloride **18** to a suspension of cesium carbonate (18) in tetrahydrofuran-*N*,*N*-dimethylformamide and produced macrocycles **19** and **20** in 9% and 77% isolated yields respectively after

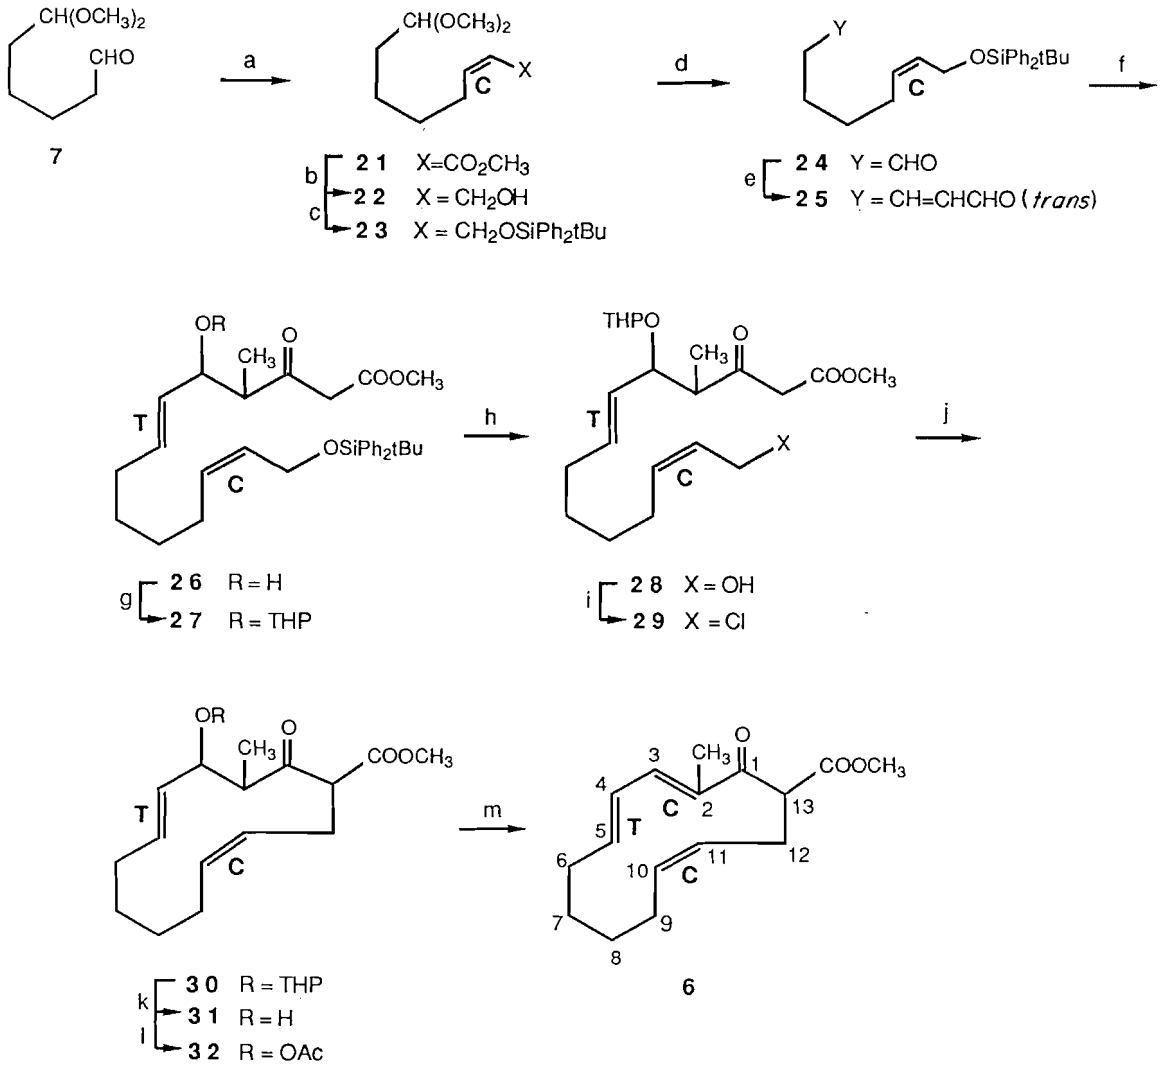
(d) DHP, PPTS, CH_2Cl_2, 2 h, r.t. (55% from **5**) (ref. 13); (e) LDA, THF, HMPA, **12**, 20 min, −78°C; add **11**, 30 min, 0°C (67%); (f) $MeOCH_2CH_2OCH_2Cl$, diisopropylethylamine, CH_2Cl_2, 4 h, 0°C (88%); (g) LiOH, DME–H_2O (15:85), reflux, 12 h (60%); (h) **15**, carbonyldiimidazole, THF, 1 h, 50°C; add to a solution of $MeO_2CCH_2CO_2H$, $Me_2CHMgCl$, THF–CH_2Cl_2 (1:1), 10 min, −10°C and 15 min, r.t.; (i) PPTS, MeOH–H_2O (95:5), reflux, 4 h (81% from **15**); (j) $MeSO_2Cl$, $(C_2H_5)_3N$, CH_2Cl_2, 10 min, 0°C; LiCl, HMPA, 1 h, r.t. (89%); (k) Slow addition of **18** in THF to Cs_2CO_3, DMF–THF (1:1), 26 h, chromatography (**19** = 9%, **20** = 77%); (l) KOH (0.26 N), *tert*-butanol–H_2O (9:1), reflux, 12 h (59%)

SCHEME 1

chromatography. Subsequent treatment of **20** with potassium hydroxide in *tert*-butanol and water provided the CTT macrocyclic trienone **5** (59%). The CTT olefin geometries were assigned on the basis of spectroscopic data of **5** ($J_{5,4}$ = 11.6 Hz, $J_{10,11}$ = 15.2 Hz, $J_{3,4}$ = 10.8 Hz, and $J_{3,Me}$ = −1.3 Hz)[5] and that of its acyclic precursors.

Dimethoxyacetal aldehyde **7** was condensed with methyl-bis(trifluoroethyl)phosphonoacetate following Still's procedure (19) to give unsaturated *cis* ester **21** in 79% isolated yield. Reduction with diisobutylaluminum hydride (72% to **22**), silylation (20) (95% to **23**), and acidic hydrolysis gave aldehyde **24** (88%), which was treated with (formylmethylene)triphenylphosphorane (21). The resulting *trans* unsaturated aldehyde **25** (65% from **24**) underwent aldol condensation (22) with the lithium dianion of methyl 3-oxo-pentanoate to provide β-ketoester **26** as a diastereoisomeric mixture in 72% yield. The alcohol moiety of **26** was immediately converted into its tetrahydropyranyl ether derivative (14) **27** (88%). Removal of the silyl protecting group (23) (88% to **28**) followed by halogenation provided a diastereoisomeric mixture of allylic chlorides **29** (87%).



Macrocyclization in refluxing acetone with sodium iodide and potassium carbonate produced *trans–cis* macrocycle **30** as a diastereoisomeric mixture in 74% yield. Deprotection (90%) followed by transformation of the resulting alcohols **31** into acetates (93% to **32**) provided, after treatment with 1,8-diazabicycloundecene in refluxing benzene, the macrocyclic trienone **6** in 50% yield. The olefin geometries were again assigned on the basis of spectroscopic data of **6** ($J_{5,4}$ = 15.4 Hz, $J_{4,3}$ = 10.5 Hz, and $J_{3,Me}$ = 1.2 Hz)[5] and that of its acyclic precursors. Furthermore, a nuclear Overhauser effect was noted between H-C3 and CH_3-C2 by an nOe difference experiment, proving the *cis* geometry of the olefin formed.

Diels–Alder reactivity of 5

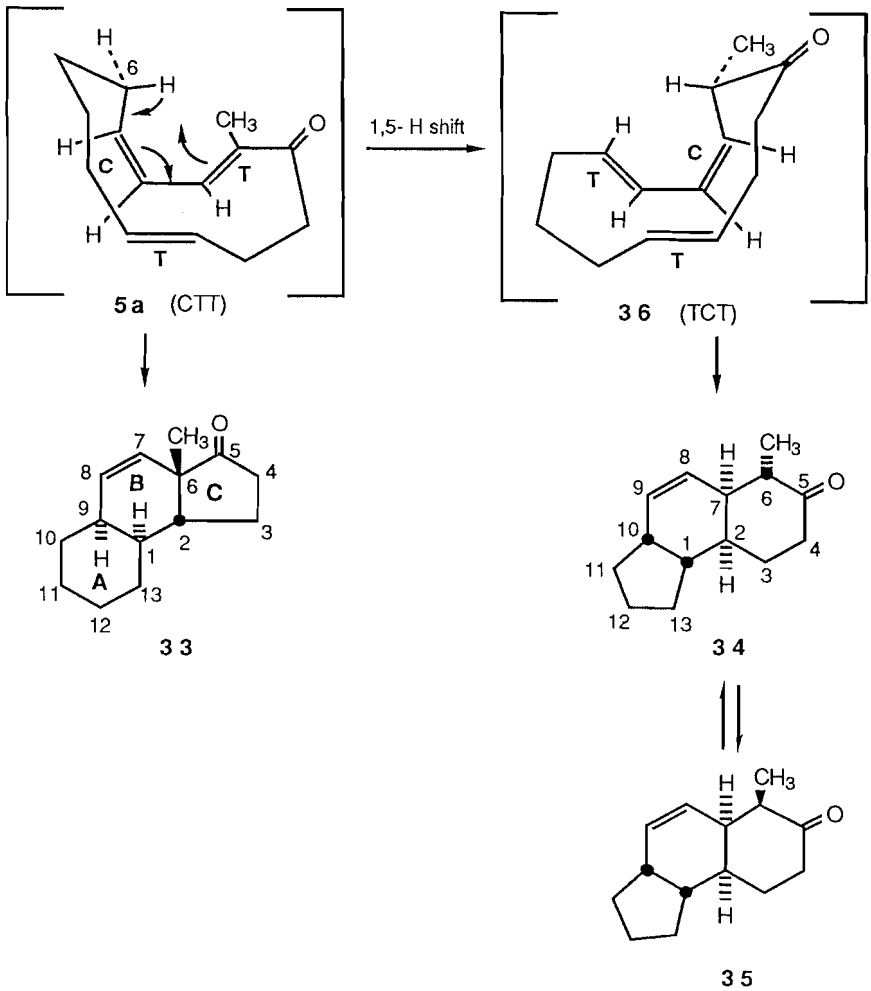
(a) HMDSK, toluene, THF, $(CF_3CH_2O)_2POCH_2CO_2Me$, 0.5 h, −78°C, chromatography (*cis* ester = 79%, *trans* ester = 15%); (b) Dibal-H, cyclohexane, CH_2Cl_2, 15 min, −78°C (72%); (c) imidazole, *t*-$BuPh_2SiCl$, DMF, 2 h, 0°C to r.t. (85%); (d) HCl 5%, THF (1:1), 24 h, r.t. (88%); (e) $Ph_3PCHCHO$, benzene, CH_2Cl_2 (7.5:3) reflux, 40 h (65%); (f) NaH, methyl 3-oxopentanoate, THF, 30 min, *n*-BuLi, hexane, 30 min, −50°C; add **25** in THF, 5 min, −5°C (72%); (g) DHP, PPTS, CH_2Cl_2, 2 h, r.t. (88%); (h) $(Bu)_4NF$, THF, 2 h, r.t. (88%); (i) $MeSO_2Cl$, $(C_2H_5)_3N$, CH_2Cl_2, 0.5 h, 0°C; LiCl, HMPA, 1.5 h, r.t. (87%); (j) K_2CO_3, NaI, acetone, reflux, 72 h (74%); (k) PPTS, MeOH–H_2O (9.5:0.5), reflux, 1.5 h, (90%); (l) $(MeCO)_2O$, $(C_2H_5)_3N$, dimethylaminopyridine, CH_2Cl_2, 9 h, 0°C, (93%); (m) DBU, benzene, reflux, 12 h (50% after crystallization)

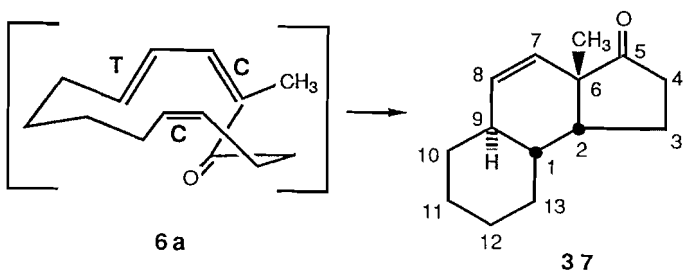
SCHEME 2

macrocyclic trienone **5** was transformed into a mixture of three products **33**, **34**, and **35** (Scheme 3) in a ratio of 1.8:2:1 respectively (90% yield). These compounds were separated by chromatography and were converted into their 2,4-dinitrophenylhydrazone (2,4-DNP) derivatives.[6]



The structure of the minor adduct **35** was rigorously established by X-ray crystallography of its 2,4-DNP derivative. Similarities in the spectral data of **34** and **35** suggested that the former was simply the epimer of the latter. This assumption was confirmed by the interconversion of compounds **34** and **35** in the presence of sodium methoxide in methanol. It was further demonstrated that tricycles **34** and **35** can be thermally isomerized at 300°C, suggesting that one isomer might have been formed selectively in the course of the cycloaddition process.

The formation of these three tricyclic products can be explained in the following way. The Diels–Alder reaction must take place via a boat-like transition state (10*d*). With this requirement in mind, molecular models show that CTT trienone **5** can undergo Diels–Alder reaction only via conformer **5***a* (Scheme 3) to produce a tricycle having the *cis–anti–cis* (CAC) relative stereochemistry. However, the planar cisoid conformation that the diene moiety must take up is quite hindered because the C6 methylene and the methyl group are very close to each other (cf. **5***a*). The steric repulsion generated must raise considerably the energy of the transition state for the Diels–Alder reaction. To relieve this stress, a competing suprafacial 1,5-sigmatropic hydrogen shift could take place. This would produce the nonconjugated trienone **36** having *trans–cis–trans* (TCT) olefin geometry, which could then give the CAC tricycle **34** via a transannular Diels–Alder reaction. Compound **34** could then undergo thermally induced equilibration with its less stable epimer **35** via the formation of an enol.



The structure of tricycle **33** was deduced on the basis of its spectroscopic data. However, the CAC relative stereochemistry

SCHEME 3

SCHEME 4

was not rigorously established. By chemical shift comparison of the C18 methyl ^{1}H nmr signal in steroids (24) (0.86 ppm for the 14-α steroids and 1.08 ppm for the 14-β steroids) with that of **33** (1.18 ppm), it was supposed that the junction between ring B and ring C was *cis*. As **4***a* is the sole possible transition state conformer of macrocycle **5**, there should be only one Diels–Alder adduct of CAC relative stereochemistry (10*d*). However, it is also conceivable that CTT trienone **5** could undergo a thermally induced isomerization of the *cis* olefin to produce a *trans–trans* (TTT) macrocyclic trienone. For this trienone, molecular models predict the formation of two Diels–Alder products, i.e., a *cis–anti–trans* (CAT) and (or) a *trans–anti–cis* (TAC) tricycle (10*d*).

Diels–Alder reactivity of **6**

On heating at 300°C for 2.5 h, macrocycle **6** was transformed into tricyclic ketone **36** by transannular Diels–Alder reaction with concomitant decarbomethoxylation (90%) (Scheme 4). The chemical structure and the *trans–syn–cis* (TSC) relative stereochemistry of **37** was established spectroscopically and by X-ray diffraction analysis of its 2,4-dinitrophenylhydrazone derivative.[7] This result is readily explained since molecular models indicate that trienone **6** can only produce TSC tricycle **37** by Diels–Alder reaction of conformer **6***a*.

In conclusion, this preliminary investigation demonstrates that transannular Diels–Alder reaction of macrocycles is possible, and in some cases is a high yield process, even with nonactivated dienes and dienophiles. This reaction shows good promise for the synthesis of natural products. Work in this direction is currently underway in our laboratory.

Experimental

All reactions were carried out under an argon atmosphere. The infrared spectra (ir) were taken on a Perkin–Elmer 681 spectrophotometer. Proton nmr spectra were recorded on a Bruker WM-250 instrument. Chemical shifts are reported in δ values relative to chloroform as internal standard. Abbreviations used are m: multiplet, s: singlet, t: triplet, d: doublet, q: quartet, sp: septuplet. Mass spectral assays (ms *m*/*e*) and peak matching were obtained using a VG Micromass ZAB-1F spectrometer. Chromatographic separations were done using Merck silica gel 230–400 mesh ASTM. High pressure liquid chromatography was carried out on a Waters instrument using μPorasil Waters column of 7.8 mm by 30 cm.

α,β-*Unsaturated* trans *ester* ***8***

To a stirred suspension of sodium hydride (3.36 g, 140 mmol, 1.4 equiv.) in tetrahydrofuran (600 mL) was added dropwise at −78°C trimethylphosphonoacetate (22.8 mL, 141 mmol, 1.41 equiv.). After the addition, the resulting mixture was allowed to warm to room temperature and then stirred for 20 min. A solution of aldehyde **7** (16.0 g, 100 mmol) in tetrahydrofuran was added to the cooled (−78°C) reaction mixture. After stirring at −78°C for 15 min, the resulting mixture was allowed to warm to room temperature, poured over a saturated solution of ammonium chloride, and extracted three times with ether. The combined organic layers were dried over magnesium sulfate, filtered, and concentrated to give an oily residue that was purified by column chromatography (5% to 15% ethyl acetate in hexane) affording ester **8** (14.8 g, 69%); ir (neat): 2990, 2950, 2830, 1725, 1628, 1440 cm^{-1}; nmr ($CDCl_3$) δ: 7.0 (1H, dt, J = 15.6 Hz and 7Hz, $-CH_2-CH{=}CH-$), 5.8 (1H, dt, J = 15.6 Hz and −1.6 Hz, $-CH_2-CH{=}CH-$), 4.35 (1H, t, J = 5.7, $-CH_2-CH(OCH_3)_2$), 3.7 (3H, s, $-CO_2CH_3$), 3.3 (6H, s, $-CH-(OCH_3)_2$), 2.2 (2H, dtd, J = 7.0 Hz, and −1.6 Hz, $-CH_2-CH_2-CH{=}CH-$), 1.25–1.55 and 1.55–1.65 (6H, m, $-CH_2-CH_2-CH_2-CH(OCH_3)_2$).

Allylic alcohol ***9***

To a stirred solution of ester **8** (16.4 g, 76 mmol) in dichloromethane at −78°C was added dropwise a solution of diisobutylaluminium hydride in cyclohexane (1 M, 167 mL, 167 mmol, 2.2 equiv.). After stirring for 20 min at −78°C, sodium sulfate decahydrate (17.9 g, 56 mmol, 0.73 equiv.) was added and the resulting stirred mixture was allowed to warm to room temperature. The mixture was then filtered and the solid was rinsed with acetone several times. After concentration of the filtrate the resulting residue was purified by column chromatography (20% to 40% ethyl acetate in hexane) giving alcohol **9** (12.7 g, 89%); ir (neat): 3420, 1227, 2940 cm^{-1}; nmr ($CDCl_3$) δ: 5.65 (2H, m, $-CH{=}CH-$), 4.35 (1H, t, J = 5.7 Hz, $-CH(OCH_3)_2$), 4.1 (2H, m, $-CH{=}CH-CH_2OH$), 3.3 (6H, s, $-CH(OCH_3)_2$), 2.05 (2H, m, $-CH_2-CH_2-CH{=}CH-$), 1.65–1.55 and 1.5–1.3 (7H, m, $-CH_2-CH_2CH_2-CH-(OCH_3)_2$ and -OH)); ms m/e (70 eV): 188 (M^+), 171 (M^+-OH), 157 ($M^+ - OCH_3$).

Aldehyde ***11***

To a stirred solution of dimethoxyalcohol **9** (12.7 g, 67.6 mmol) in ether was added a 5% aqueous solution of hydrochloric acid (120 mL). The two-phase solution was vigorously stirred at room temperature for 18 h. The organic layer was then separated and the aqueous layer was extracted three times with ether. The combined organic layers were washed with an aqueous solution of sodium bicarbonate (10%), dried with magnesium sulfate, filtered, and concentrated to provide crude aldehyde-alcohol **10** (9.1 g).

Without any purification this oily residue was dissolved in dichloromethane (250 mL), and dihydropyran (18.5 mL, 3 equiv.) followed by pyridinium *para*-toluenesulfonate (200 mg) were added. After stirring for 2 h, the resulting mixture was poured over water and extracted three times with dichloromethane. The combined organic layers were dried with magnesium sulfate, filtered, and concentrated to give an oily residue that was purified by column chromatography (5% to 20% ethyl acetate in hexane) affording aldehyde **11** (8.4 g, 55%); ir CH_2Cl_2): 3060–3000, 3000–2800, 2730, 2660, 1740, 1460, 1030 cm^{-1}; nmr ($CDCl)_3$ δ: 9.76 (1H, t, J = 1.8 Hz, $-CHO$), 5.78–5.53 (2H, m, $-CH{=}CH-$), 4.63 (1H, dd, J = 4.2 Hz and 2.7 Hz, -O-CH-O-), 4.25–4.15 and 3.97–3.85 (2H, m, $-CH{=}CH-CH-CH_2-O$), 3.95–3.83 and 3.55–3.45 (2H, m), 2.43 (2H, dt, J = 1.8 Hz, 7.3 Hz, $-CH_2-CH_2-CH_2-CHO$), 2.1 (2H, dt, J = 6.5 Hz and 6.5 Hz, $-CH_2-CH_2-CH{=}CH-$), 1.9–1.4 (10H, m); ms m/e (70 eV): 227 (MH^+).

δ-*Hydroxy-ester* ***13***

To a stirred solution of diisopropylamine (2.62 mL, 18.7 mmol, 1.1 equiv.) in tetrahydrofuran at 0°C was added a 1.6 M solution of butyllithium in hexane (11.7 mL, 18.7 mmol, 1.1 equiv.). The solution was stirred for 10 min and was cooled to −78°C. Hexamethylphosphoramide (3.3 mL) was added and, after stirring for 10 min, a solution of isopropyltiglate **12** (2.66 g, 18.7 mmol, 1.1 equiv.) in tetrahydrofuran (2 mL) was added. Additional stirring was continued for 20 min at −78°C and a solution of aldehyde **11** (3.83 g, 17 mmol) in tetrahydrofuran (2 mL) was added to the resulting solution. After stirring for 30 min at 0°C, the mixture was treated with a saturated aqueous solution of ammonium chloride and extracted 3 times with ether. The combined organic layers were washed with water, dried with magnesium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (10% to 14% of ethyl acetate in hexane) affording ester **13** (4.21 g, 67%); ir ($CHCl_3$): 3610, 3460, 3008, 2940, 2870, 1700, 1650, 1270, 1110 cm^{-1}; nmr ($CDCl_3$) δ: 6.8 (1H, tq, J = 7.5 Hz and −1.5 Hz, H-C3), 5.8–5.5 (2H, m, H-C10 and H-C11, 5.05 (1H, sp, J = 6.3 Hz, $-O-CH(CH_3)_2$), 4.63 (1H, dd, J = 4.0 Hz and 2.5 Hz, -O—CH—O-), 4.2 and 3.9 (2H, m, H-C12), 3.9–3.8 and 3.55–3.45 (2H, m), 3.8–3.7 (1H, m, H-.C5), 2.4–2.3 (2H, m, H-C4), 2.1–2.0 (2H, m, H-C9), 1.84 (3H, d, J = −1.5 Hz, CH_3-C3), 1.7–1.3 (15H, m), 1.2 (6H, d, J = 6.3 Hz, $-O-CH(CH_3)_2$; ms m/e (70 eV): 368 (M^+), 285 (MH^+ − DHP).

Methoxyethoxymethyl ether ***14***

To a stirred solution of δ-hydroxy-ester **13** (2.50 g, 6.79 mmol) in dichloromethane (20 mL) was added dropwise at 0°C *N,N*-diisopropylethylamine (2.6 mL, 13.6 mmol, 2.2 equiv.) followed by methoxyethoxymethyl chloride (1.6 mL, 13.6 mmol, 2 equiv.). After stirring for 4 h at −40°C, the resulting solution was poured over water and extracted 3 times with dichloromethane. The combined organic layers were washed with brine, dried with magnesium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (10% to 20% ethyl acetate in hexane) affording ether **14** (2.72 g, 88%); ir ($CHCl_3$): 2935, 1708, 1650, 1110, 1025 cm^{-1}; nmr ($CDCl_3$) δ: 6.75 (1H, tq, J = 6.6 Hz and −1.5 Hz, H-C3), 5.65 (2H, m, H-C10 and H-C11), 5.05 (1H, sp, J = 6.3 Hz, $-O-CH-(CH_3)_2$), 4.75 (2H, s, -O-CH_2-O-), 4.6 (1H, dd, J = 4.1 Hz and 2.7 Hz, -O—CH—O-), 4.2 and 3.9 (2H, m, H-C12), 3.9–3.5 (7H, m, H-C5, $-O-CH_2-CH_2-O-$ and $-CH_2-CH_2-O-$ cyclic), 3.4 (3H, s, $-CH_2-OCH_3$), 2.4 (2H, dd, J = 6.6 Hz and 6.6 Hz, H-C4), 2.4 (2H, m, H-C9), 1.83 (3H, s, CH_3-C2), 1.6–1.3 (13H, m), 1.25 (6H, d, J = 6.3 Hz, $-O-CH(CH_3)_2$; ms m/e (70 eV): 457 (MH^+).

Carboxylic acid ***15***

To a stirred solution of ester **14** (1.54 g, 3.38 mmol) in 85% aqueous dimethoxyethane (100 mL) was added lithium hydroxide (275 mg, 11.8 mmol, 3.5 equiv.). The resulting mixture was heated under reflux for 12 h and then allowed to cool to room temperature. The solution was neutralized and concentrated to give a residue that was poured over water, acidified to pH 2, and extracted 3 times with dichloromethane. The combined organic layers were washed with water, dried with magnesium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (20% to 30% ethyl acetate in hexane) affording acid **15** (855 mg, 61%); ir ($CHCl_3$): 3600–2420, 2930, 1688, 1645 cm^{-1}; nmr ($CDCl_3$) δ: 6.94 (1H, tq, J = 6 Hz and −1.1 Hz, H-C3, 5.8–5.5 (2H, m, H-C16 and H-C10), 4.75 (2H, s, -O-CH_2-O-), 4.63 (1H, dd, J = 4.2 Hz and 2.7 Hz, -O—CH—O-), 4.2 and 3.9 (2H, m, H-C12), 3.9–3.5 (7H, m, H-C5, $-O-CH_2-CH_2-O-$ and $-CH_2-CH_2-O-$ and $-CH_2-CH_2-O-$ cyclic), 3.4 (3H, s, $-CH_2-OCH_3$), 2.44 (2H, dd, J = 6 Hz and 6Hz, H-C4), 2.05 (2H, m, H-C9), 1.85 (3H, d, J = −1.1 Hz, CH_3-C2), 1.7–1.3 (14H, m); ms m/e (70 eV): 415 (MH^+), 331 (MH^+ −DHP).

β-*Ketoester* ***17***

To a stirred solution of carboxylic acid **15** (2.12 g, 5.12 mmol) in tetrahydrofuran (20 mL) was added carbonyldiimidazole (1.1 g, 6.8 mmol, 1.33 equiv.). The resulting clear solution was stirred for 1 h at 50°C. A solution of monomethylmalonic acid (1.21 g, 10.24 mmol, 2 equiv.) in dichloromethane (20 mL) was placed in a second two-necked flask. A solution of isopropylmagnesium chloride 1.15 N in tetrahydrofuran (17.8 mL, 20.48 mmol, 4 equiv.) was added to this ice-cooled solution. After stirring for 10 min at 0°C, the solution was allowed to cool to −10°C. To this solution, the previously prepared imidazolide solution was added dropwise and the resulting mixture was stirred for 15 min at −10°C and an additional 15 min at room temperature. This mixture was poured over a 1N aqueous solution of hydrochloric acid and extracted 3 times with dichloromethane. The combined organic

layers were washed with a saturated aqueous solution of sodium bicarbonate, dried with magnesium sulfate, filtered, and concentrated to give crude β-ketoester **16** (2.36 g).

Without any purification, the crude β-ketoester **16** was dissolved in 95% aqueous methanol (100 mL) and pyridinium *para*-toluenesulfonate (400 mg) was added. The resulting solution was heated under reflux during 3 h. After cooling, the solution was concentrated and the resulting residue was poured over water and extracted 3 times with dichloromethane. The combined organic layers were washed with brine, dried with magnesium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (25% to 50% of ethyl acetate in hexane) affording alcohol **17** (1.6 g, 81%); ir ($CHCl_3$): 3460, 2930, 1745, 1670, 1642 cm^{-1}; nmr ($CDCl_3$) δ: 6.7 (1H, tq, J = 6 Hz and −1.1 Hz, H-C3), 5.65 (2H, m, H-C10 and H-C11), 4.75 (2H, s, -O-CH_2-O-), 4.1 (2H, dd, J = 4.5 Hz and −1.1 Hz, H-C12), 3.75 (2H, s, H-C13), 3.7 (3H, s, -COOCH_3), 3.8–3.5 (5H, m, H-C5, -O-CH_2-CH_2-O-), 3.4 (3H, s, -CH_2-OCH_3), 2.5 (2H, dd, J = 6 Hz and 6 Hz, H-C4), 2.05 (2H, m, H-C9), 1.8 (3H, d, J = −1.1 Hz, CH_3-C2), 1.6–1.3 (6H, m, H-C6, H-C7, and H-C8); ms m/e (70 eV): 279 (M^+ − $MEMOH_2$).

*Allylic chloride **18***

To a stirred solution of alcohol **17** (1.55 g, 4 mmol) in dichloromethane (15 mL) at −10°C were added triethylamine (0.84 mL, 6 mmol, 1.5 equiv.) and methanesulfonyl chloride (0.48 mL, 4.8 mmol, 1.2 equiv.). The resulting mixture was allowed to warm to 0°C and stirred for 10 min. Hexamethylphosphoramide (1.4 mL, 8 mmol, 2 equiv.) and dry lithium chloride (0.51 g, 12 mmol, 3 equiv.) were then added and the mixture, warmed to room temperature, was stirred for 1 h. The solution was poured over water and extracted 3 times with dichloromethane. The combined organic layers were washed with brine, dried with magnesium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (10% and 25% ethyl acetate in hexane) affording chloride **18** (1.45 g, 89%); ir ($CHCl_3$): 2930, 1745, 1670, 1640 cm^1; nmr ($CDCl_3$) δ: 6.6 (1H, tq, J = 6 Hz and −1 Hz, H-C3), 5.85–5.55 (2H, m, H-C10 and H-C11), 4.75 (2H, s, -O-CH_2-O-), 4.02 (2H, d, J = 6.8 Hz, H-C12), 3.75 (2H, s, H-C13), 3.7 (3H, s, -COOCH_3), 3.8–3.5 (5H, m, H-C_5 and -O-CH_2-CH_2-O-), 3.4 (3H, s, -CH_2-OCH_3), 2.5 (dd, J = 6 Hz and 6.2 Hz, H-C_4), 2.05 (2H, m, H-C9), 1.8 (3H, d, J = −1 Hz, CH_3-C2), 1.6–1.25 (6H, m, H-C6 and H-C8); ms m/e (70 eV): 331 (M^+ − CH_2COOCH_3), 329 (M^+ − $OCH_2CH_2OCH_3$).

*Macrocycles **19** and **20***

To a stirred mixture of cesium carbonate (537 mg, 1.65 mmol, 1.3 equiv.) in *N*,*N*-dimethylformamide (200 mL) and tetrahydrofuran (200 mL) was added a solution of allylic chloride **18** (513 mg, 1.27 mmol) in tetrahydrofuran (15 mL) over 26 h. After the addition, the resulting mixture was stirred for an additional 14 h. A saturated aqueous solution of ammonium chloride was then added and the solvants were evaporated. The resulting residue was extracted 3 times with ether and the combined organic layers were dried with magnesium sulfate, filtered, and concentrated to give a residue. After purification by column chromatography, this residue afforded macrocycles **19** (49 mg, 9%) and **20** (361 mg, 77%); ir $CHCl_3$) **20**: 2938. 1750, 1660, 1650, 1040 cm^{-1}; nmr ($CDCl_3$) δ **19**: 6.3 (1H, tq, J = 7 Hz and −1 Hz, H-C3), 5.75–5.4 (2H, m, H-C10 and H-C11), 5.4 (1H, s, -C═CH-CO_2CH_3), 4.8 (2H, s, -O-CH_2-O-), 4.7–4.55 (2H, m, H-C12), 3.85 (1H, m, H-C5), 3.7 (3H, s, -COOCH_3), 3.75–3.55 (4H, A_2B_2, -O-CH_2-CH_2-O-), 3.4 (3H, s, -CH_2-OCH_3), 2.55–2.3 (2H, m, H-C4), 2.1 (2H, m, H-C9), 1.75 (3H, d, J = −1 Hz, CH_3-C2), 1.6–1.2 (6H, m); nmr ($CDCl_3$) δ **20**: 6.8–6.5 (1H, m, H-C3), 5.4–5.2 (2H, m, H-C10 and H-C11), 4.78 (2H, s, -O-CH_2-O-), 4.25 (1H, t, J = 11.1 Hz, 11.5 Hz, H-C13), 3.95 (1H, m, H-C5), 3.7 (3H, s, -COOCH_3), 3.55 (4H, A_2B_2, -O-CH_2-CH_2-O-), 3.4 (3H, s, -CH_2-OCH_3), 2.8–2.4 (4H, m, H-C4 and H-C12), 2.1–1.95 (2H, m, H-C9), 1.85 (3H, d, J = −1.2 Hz, CH_3-C2), 1.6–1.1 (6H, m); ms m/e **19**: 368 (M^+); ms m/e (70 eV) **20**: 368 (M^+).

*Trienone **5***

The macrocycle **20** (210 mg, 0.57 mmol) was dissolved in a solution of 0.26 N potassium hydroxide in 90% aqueous *tert*-butanol (68 mL). The resulting stirred mixture was heated under reflux for 12 h. Then the mixture was poured over water, neutralized with an aqueous solution of hydrochloric acid 10%, and extracted 3 times with ether. The combined organic layers were washed with water, dried with magnesium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (3% to 10% ethyl acetate in hexane) affording trienone **5** (68 mg, 59%); mp 19–20°C; ir ($CHCl_3$): 3030, 2930, 2855, 1650, 1628 cm^{-1}; nmr ($CDCl_3$) δ: 7.35 (1H, ddq, $J_{3,4}$ = 10.8 Hz, $J_{3,5}$ = −1.4 Hz, $J_{3,Me}$ = −1.3 Hz, H-C3), 6.35 (1H, ddt, $J_{4,5}$ = 10.6 Hz, $J_{4,3}$ = 10.8 Hz, $J_{4,6}$ = −1 Hz, H-C4), 6.05 (1H, dtd, $J_{5,6}$ = 8.3 Hz, $J_{5,4}$ = 10.6 Hz, $J_{5,3}$ = −1.4 Hz, H-C5), 5.65–5.35 (2H, m, $J_{10,11}$ = 15.2 Hz, $J_{9,10}$ = 7.3 Hz, $J_{11,12}$ = 7.4 Hz, $J_{10,12}$ = −1.3 Hz, $J_{9,11}$ = −1.4 Hz, H-C10 and H-C11), 2.7 (2H, m, H-C13) 2.4 (2H, m, H-C12), 2.2 (4H, m, H-C6, H-C9), 1.8 (3H, d, $J_{3,Me}$ = −1.3 Hz, CH_3-C2), 1.55–1.3 (4H, m, H-C7 and H-C8); ms m/e (70 eV): 204 (M^+).

*Tricycles **33**, **34**, and **35***

Trienone **5** (30 mg, 0.14 mmol) was dissolved in anhydrous toluene (2 mL) and was heated in a sealed tube for 4.5 h. After cooling, the resulting solution was concentrated to give a residue that was analyzed by capillary gc affording 35% of tricycle **33**, 42% of **34**, and 20% of **35**. This residue was then purified by column chromatography (1% to 4% ethyl acetate in hexane) to afford tricycles **33** (9.5 mg, 32%), **34** (3.4 mg), and a mixture of **34** and **35** (14 mg, 58%); ir (neat) **33**: 3017, 2955, 2855, 1740, 1447 cm^{-1}; ir (CH_2Cl_2) **34**: 3020, 2970, 2945, 2930, 1705 cm^{-1}; nmr ($CDCl_3$) **33** δ: 5.6 (1H, dtd, $J_{8,7}$ = 9.9 Hz, $J_{8,9}$ = 3.4 Hz, H-C8), 5.47 (1H, dd, $J_{7,8}$ = 9.9 Hz, $J_{7,9}$ = −2.1 Hz, H-C7), 2.35–2.25 (3H, m, H-C9 and H-C4), 2.15 (1H, q apparent, J = 7 Hz), 2.05–1.85 (2H, m, H-C3), 1.85–1.7 (2H, m), 1.7–1.3 (7H, m), 1.18 (3H, s, -CH_3); nmr ($CDCl_3$) **34** δ: 5.8–5.6 (2H, m, H-C7 and H-C8), 2.5–2.2 (4H, m, H-C9, H-C10), and H-C11), 2.15 (1H, m, H-C6), 2.1–1.6 (6H, m), 1.55–1.2 (4H, m), 1.1 (3H, d, $J_{10,Me}$ = −6.6 Hz, CH_3-C10); ms m/e (70 eV) **33**: 204 (M^+); ms m/w (70 eV) **34**: 204 (M^+).

Partial epimerization of a 1:4 mixture of compounds **34** and **35** using a 0.45 M solution of sodium methoxide in methanol afforded a mixture of **34** and **35** in 2:1 ratio after 23 h. Evidence was established by thermally induced isomerization of heating in a sealed tube over 2 h at 300°C; the ratio of **34**:**35** changed from 89.11 to 72.28 and from 34:66 to 58:42 in separate experiments.

*2,4-Dinitrophenylhydrazone derivative of **33***

To a stirred solution of tricycle **33** (2 mg, 0.01 mmol) in ethanol (1.5 mL) and *N*,*N*-dimethylformamide (0.5 mL) were added 2,4-dinitrophenylhydrazine (4 mg, 0.029 mmol, 3 equiv.) and a drop of dilute hydrochloric acid. When the reaction was completed (≈ 2 h), the resulting mixture was filtered on silica gel with dichloromethane as eluant and the filtrate was concentrated to give a residue that was purified by preparative chromatography (15% ethyl acetate in hexane). Despite considerable effort, crystallization of the resulting derivative (1.5 mg) was not possible, attempts giving powder and (or) flakes; nmr ($CDCl_3$) δ: 10.8 (1H, s, -NH-), 9.1 (1H, d, J = 2.6 Hz, >C═C(NO_2)-CH═C(NO_2)-), 8.28 (1H, dd, J = 9.6 Hz, 2.6 Hz, >C═CH-CH═C(NO_2)-), 7.95 (1H, d, J = 9.6 Hz, >C═CH-CH═(NO_2)-), 5.75 (1H, dd, J = 9.9 Hz and 1.4 Hz, H-C7), 5.65 (1H, dd, J = 9.9 Hz and 4.0 Hz, H-C8), 5.6–5.5 (2H, m, H-C4), 2.25–1.95 (4H, m, H-C3, H-C2, and H-C9), 1.85–1.75 (1H, m), 1.7–1.2 (7H, m), 1.34 (3H, s, CH_3-C5).

*2,4-Dinitrophenylhydrazone derivative of **34** and **35***

To a stirred solution of mixture of epimers **34** and **35** in ethanol (2 mL) and *N*,*N*-dimethylformamide (1 mL) were added 2,4-dinitrohenylhydrazine (10.8 mg, 0.055 mmol, 1.1 equiv.) and a drop of dilute hydrochloric acid. When the reaction was completed (≈ 15 min), the resulting mixture was filtered on silica gel with hexane – ethyl acetate (3:1) as eluant and the filtrate was concentrated to give a residue that was purified by successive recrystallizations from dichloromethane and hexane. The derivative of **35** was the first to crystallize and later the derivative of **34** was obtained (20 mg, 100%); mp, derivative of **35**: 204–205°C; nmr $CDCl_3$) derivative of **34** δ: 11.2 (1H, -NH-), 9.1 (1H, d, J = 2.6 Hz, -C(NO_2)═CH-C(NO_2)═CH-), 8.15

(1H, dd, J = 9.6 Hz, 2.6 Hz, >C=CH-C*H*=C(NO_2)-), 8.0 (1H, d, J = 9.6 Hz, =C-C*H*=CH-C(NO_2)<), 5.6 (2H, m, H-C7 and H-C8), 2.6–2.45 (3H, m, H-C10 and H-C12), 2.27–2.1 (2H, m), 2.0–1.6 (6H, m), 1.55–1.3 (4H, m), 1.3 (3H, d, J = 6.9 Hz, CH_3-C10); nmr $CDCl_3$) derivative of **35** δ: 11.2 (1H, -N*H*-), 9.1 (1H, d, J = 2.6 Hz, -C(NO_2)=C*H*-C(NO_2)-), 8.3 (1H, dd, J = 9.6 Hz and 2.6 Hz, >C=CH-C*H*=C(NO_2)-), 8.0 (1H, d, J = 9.6 Hz, >C=C*H*-CH=C(NO_2)-), 5.5 (2H, m, H-C7 and H-C8), 2.8 (1H, ddd, J = 14.2 Hz, 4.2 Hz, and 3.1 Hz), 2.7–2.6 (2H, m, H-C10), 2.55–2.45 (1H, m), 2.15–2.0 (3H, m), 1.85–1.6 (3H, m), 1.55–1.25 (3H, m), 1.3 (3H, d, J = 6.5 Hz, CH_3-C10).

α,β-*Unsaturated* cis *ester* ***21***

To a stirred solution of methylbis(trifluoroethyl)phosphonoacetate (4.220 g, 13.3 mmol, 1.2 equiv.) in tetrahydrofuran (72 mL) was added dropwise a solution of potassium bis(trimethylsilyl)amide in toluene (0.657 M, 20.2 mL, 13.3 mL, 1.2 equiv.) at −78°C. The resulting solution was stirred for 15 min and a solution of aldehyde **7** (1.771 g, 11.1 mmol) in tetrahydrofuran (3 mL) was then added. After stirring for an additional 15 min, the mixture was allowed to warm to room temperature, poured over a saturated aqueous solution of ammonium chloride, and extracted 3 times with ether. The combined organic layers were washed with brine, dried with magnesium sulfate, filtered, and concentrated to afford an oily residue that was purified by column chromatography (5% to 25% ethyl acetate in hexane) affording *cis* ester **21** (1.874 g, 79%); ir ($CHCl_3$): 3005, 2945, 1718, 1645, 1440, 1200, 1137 cm^{-1}; nmr ($CDCl_3$) δ: 1.34–1.55 and 1.57–1.67 (6H, m, -CH_2-CH_2-CH_2-CH(OCH_3)$_2$, 2.66 (2H, tdd, J = 7.5 Hz, 7.5 Hz, and 1.7 Hz, -CH_2-CH_2-CH=CH-), 3.31 (6H, s, -CH(OCH_3)$_2$), 3.70 (3H, s, -CO_2CH_3), 4.35 (1H, t, J = 5.7 Hz, -CH_2-CH(OCH_3)$_2$), 5.77 (1H, dt, J = 11.5 Hz and 1.7 Hz, -CH_2-CH=C*H*-), 6.22 (1H, dt, J = 11.5 Hz, 7.5 Hz, -CH_2-C*H*=CH-); ms m/e (70 eV): 215 (M^+ −H), 185 (M^+ −OCH_3).

Allylic alcohol ***22***

To a stirred solution of ester **21** (14.044 g, 65.0 mmol) in dichloromethane (200 mL) at −78°C was added dropwise a solution of diisobutylaluminum hydride in cyclohexane (1 M, 143 mL, 143.0 mmol, 2.2 equiv.). The resulting mixture was stirred for 15 min and methanol, followed by a saturated aqueous solution of ammonium chloride, was added. The mixture was then allowed to warm to room temperature, stirred for 2 h, and extracted 4 times with dichloromethane. The combined organic layers were washed with brine, dried with sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (10% to 25% ethyl acetate in hexane) affording alcohol **22** (7.936 g, 65%); ir ($CHCl_3$): 3610, 3450, 3005, 2940, 1450, 1383, 1363, 1128, 1050 cm^{-1}; nmr ($CDCl_3$) δ: 1.29–1.48 and 1.55–1.68 (6H, m, -CH_2-CH_2-CH_2-CH(OCH_3)$_2$), 2.02–2.26 (2H, m, -CH_2-CH=CH-), 3.31 (6H, s, -CH(OCH_3)$_2$), 4.00–4.11 (1H, m, -CH_2OH), 4.18 (2H, d, J = 6.3 Hz, -CH_2OH), 4.34 (1H, t, J = 5.7 Hz, -CH_2-CH(OCH_3)$_2$), 5.45–5.67 (2H, m, -CH=CH-).

Silyl ether ***23***

To a stirred ice-cooled solution of alcohol **22** (442 mg, 2.3 mmol) in *N*,*N*-dimethylformamide (1.7 mL), were added imidazole (240 mg, 3.5 mmol, 1.5 equiv.) and *tert*-butylchlorodiphenylsilane (730 μL, 2.8 mmol, 1.2 equiv.). The resulting solution was allowed to warm to room temperature, stirred for 2 h, poured over a 10% aqueous solution of hydrochloric acid and extracted 3 times with ether. The combined organic layers were washed with brine, dried with sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (10% ethyl acetate in hexane) affording silyl ether **23** (851 mg, 85%); ir ($CHCl_3$): 3075, 3010, 2930, 2860, 1471, 1462, 1428, 1110, 1080 cm^{-1}; nmr ($CDCl_3$) δ: 1.04 (9H, s, -OSiC(CH_3)$_3$$Ph_2$), 1.23–1.34 and 1.49–1.59 (6H, m, -CH_2-CH_2-CH_2-CH(OCH_3)$_2$), 1.81–1.92 (2H, m, -CH_2-CH=CH-), 3.29 (6H, s, -CH(OCH_3)$_2$), 4.24 (2H, dd, J = 6.1 Hz and 1.5 Hz, -CH=CH-CH_2-), 5.34–5.41 and 5.54–5.66 (2H, m, -CH=CH-), 7.34–7.45 and 7.67–7.75 (10H, m, -OSiPh_2C(CH_3)$_3$).

Aldehyde ***24***

To a stirred solution of silyl ether **23** (708 mg, 1.7 mmol) in tetrahydrofuran (3.5 mL) was added a 5% aqueous solution of hydrochloric acid (3.5 mL). The resulting solution was stirred for 24 h at room temperature, then diluted in water and extracted 3 times with ether. The combined organic layers were washed with brine, dried with sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (hexane to 50% ethyl acetate in hexane) affording aldehyde **24** (557 mg, 88%); ir ($CHCl_3$): 3010, 2930, 2860, 2725, 1472, 1462, 1428, 1110, 1080 cm^{-1}; nmr ($CDCl_3$) δ: 1.04 (9H, s, -OSiPh_2C(CH_3)$_3$), 1.21–1.37 and 1.49–1.52 (4H, m, -CH_2-CH_2-CH_2-CHO), 1.88 (2H, td, J = 7.3 Hz and 7.3 Hz, -CH_2-CH=CH-), 2.35 (2H, td, J = 7.4 Hz and 1.8 Hz, -CH_2-CHO), 4.24 (2H, dd, J = 6.1 Hz and 1.5 Hz, -CH=CH-CH_2-), 5.33–5.45 and 5.58–5.69 (2H, m, -CH=CH-), 7.34–7.44 and 7.64–7.72 (10H, m, -OSiPh_2C(CH_3)$_3$), 9.71 (1H, t, 1.8 Hz, -CHO).

α,β-*Unsaturated* trans *aldehyde* ***25***

To aldehyde **24** (453 mg, 1.19 mmol) was added a solution of (formylmethylene)triphenylphosphorane (600 mg, 1.97 mmol, 1.7 equiv.) in benzene (7.5 mL) and dichlormethane (3 mL). The resulting mixture was heated under reflux for about 40 h. After cooling, the solution was concentrated and the resulting residue was purified by column chromatography (2.5% ethyl acetate in hexane) to afford aldehyde **25** (316 mg, 65%); ir ($CHCl_3$): 3005, 2930, 2860, 2740, 1687, 1637, 1470, 1428, 1110 cm^{-1}; nmr ($CDCl_3$) δ: 1.04 (9H, s, -OSiPh_2C(CH_3)$_3$), 1.19–1.50 (4H, m, -CH_2-CH_2-CH=CH-CHO), 1.88 (2H, td, J = 7.0 Hz, and 7.0 Hz, -CH_2-CH=CH=CH_2OSiPh_2*t*-Bu), 2.40 (2H, tdd, J = 7.4 Hz, 7.4 Hz and 1.1 Hz, -CH_2-CH=CH-CHO), 4.24 (2H, dd, J = 6.1 Hz and 1.5 Hz, -CH_2OSiPh_2*t*-Bu), 5.33–5.45 and 5.58–5.70 (2H, m, -CH=CH_2OSiPh_2*t*-Bu), 6.08 (1H, ddt, J = 16.3 Hz, 8.0 Hz, 1.2 Hz, -CH=C*H*-CHO), 6.79 (1H, dt, J = 16.3 Hz, 7.5 Hz, -CH=CH-CHO), 7.34–7.45 and 7.66–7.72 (10H, m, -OSiPh_2C(CH_3)$_3$), 9.48 (1H, d, J = 7.9 Hz, -CHO); ms m/e (70 eV): 349 (M^+ −*t*-Bu).

β-*Ketoester* ***26***

To a stirred suspension of sodium hydride (61 mg, 1.52 mmol, 3.1 equiv.) in tetrahydrofuran (1.5 mL) was added methyl 3-oxopentanoate (185 μL, 1.474 mmol, 3 equiv.) at −5°C. After stirring for 30 min, a solution of butyllithium in hexane (1.68 M, 821 μL, 1.38 mmol, 2.8 equiv.) was added and the resulting solution was stirred for an additional 30 min at −5°C. A solution of aldehyde **25** (198 mg, 0.49 mmol) in tetrahydrofuran (0.5 mL) was finally added to the mixture, which was then allowed to stir for 5 min, poured over an aqueous saturated solution of ammonium chloride, and extracted 3 times with dichloromethane. The combined organic layers were dried with magnesium sulfate, filtered, and concentrated to give a residue that was rapidly purified by column chromatography (25% ethyl acetate in hexane) affording β-ketoester **26** (188 mg, 72%). The product was immediately converted into its tetrahydropyranyl derivative; ir ($CHCl_3$): 3592, 3005, 2930, 2860, 1740, 1710, 1438, 1428, 1111 cm^{-1}; nmr ($CDCl_3$) δ: 1.04 (9H, s, -OSiPh_2C(CH_3)$_3$), 1.11 (3H, d, J = 7.1 Hz, -CHOH-CHCH_3-CO-), 1.17–1.37 (4H, m, -CH_2-CH_2-CH_2-CH=CH-CH_2-OSiPh_2*t*-Bu), 1.76–1.91 and 1.92–2.08 (4H, m, -CH=CH-CH_2-(CH_2)$_2$-CH_2-CH=CH-), 2.70–2.86 (1H, m, -CHOH-CHCH$_3$-CO-), 3.56 (2H, s, -CO-CH_2-CO_2Me), 3.73 (3H, s, -CO_2CH_3), 4.23 (2H, d, J = 6.2 Hz, -CH_2-OSiPh_2*t*-Bu), 4.33–4.44 (1H, m, -CHOH-CHCH$_3$-), 5.33–5.46 (2H, m, -CH=CH-CH_2OSiPh_2*t*-Bu), 5.53–5.65 (2H, m, -CH=CH-CHOH-), 7.33–7.44 and 7.65–7.73 (10H, m, -OSiPh_2C(CH_3)); ms m/e (70 eV): 461 (M^+ −H_2O−*t*-Bu).

Tetrahydropyrannyl ether ***27***

To a stirred solution of alcohol **26** (1.86 g, 3.47 mmol) in dichloromethane (35 mL) were added dihydropyran (3.16 mL, 34.6 mmol, 10 equiv.) and pyridinium *para*-toluenesulfonate (37 mg, 0.147 mmol, 0.04 equiv.) After stirring for 2 h, the resulting mixture was poured over water and extracted 3 times with dichloromethane. The combined organic layers were washed with brine, dried with sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (10% to 25% ethyl acetate in hexane) affording ether

27 (1.901 g, 88%); ir $CHCl_3$): 3005, 2930, 2860, 1745, 1712, 1425, 1111 cm^{-1}; nmr ($CDCl_3$) δ: 0.84–1.11 (3H, m, -CHOTHP-CHCH_3), 1.04 (9H, s, -OSiPh_2C(CH_3)$_3$), 1.18–1.38 (4H, m, -(CH_2)$_2$-CH_2-CH=CH-CH_2OSiPh_2*t*-Bu), 1.41–1.64 (6H, m, -(CH_2)$_3$-CH_2-O-), 1.77–1.91 and 1.92–2.05 (4H, m, -CH=CH-CH_2-(CH_2)$_2$-CH_2-CH=CH-),2.77–3.02 (1H, m, -CHOTHP-C*H*CH$_3$-CO-), 3.34–3.87 (4H, m,-CH_2-CH_2-O- and -CO-CH_2-CO_2CH_3), 3.71, 3.72, 3.73, 3.74 (3H, s, -COOCH_3), 3.91–4.20 (1H, m, -C*H*OTHP-CHCH$_3$-), 4.24 (2H, d, J = 6.2 Hz, -CH_2OSiPh_2*t*-Bu), 4.54, 4.62, 4.70 (1H, t, J = 3.8 Hz, -O-C*H*-O-), 4.98–5.45 and 5.54–5.74 (4H, m, -C*H*=C*H*-(CH_2)$_4$-C*H*=C*H*-), 7.34–7.45 and 7.66–7.73 (10H, m, -OSi*Ph*$_2$*t*-Bu); ms *m/e* (70 eV): 563 (M^+ − *t*-Bu).

Allylic alcohol ***28***

To an ice-cooled stirred solution of silyl ether **27** (2.30 g, 3.71 mmol) in tetrahydrofuran (45 mL) was added a solution of tetrabutylammonium fluoride in tetrahydrofuran (1 M, 4.45 mL, 4.45 mmol, 1.2 equiv.). After stirring for 2 h at room temperature, the resulting mixture was poured over water and extracted 3 times with dichloromethane. The combined organic layers were washed with brine, dried and sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (25% ethyl acetate in hexane) to afford alcohol **28** (1.200 g, 88%); ir ($CHCl_3$): 3610, 3450, 3010, 2935, 2855, 1745, 1712, 1652, 1629, 1452, 1438, 1020, 1008 cm^{-1}; nmr ($CDCl_3$) δ: 0.96, 0.99, 1.06, 1.09 (3H, d, J = 7.1 Hz, 7.0 Hz, 6.9 Hz, and 6.9 Hz, -CHOTHP-CHCH_3-CO-), 1.29–1.44 (4H, m, -(CH_2)$_2$-CH_2-CH=CH-CH_2OH), 1.44–1.86 (6H, m, -(CH_2)$_3$-CH_2-O-), 1.96–2.13 (4H, m, -CH=CH-CH_2-(CH_2)$_2$-CH_2-CH=CH-), 2.76–3.06 (1H, m, -CHOTHP-C*H*CH$_3$-CO-), 3.34–3.88 (4H, m, -CH_2-C*H*-O- and -CO-CH_2-CO_2CH_3), 3.71, 3.72, 3.73, 3.74 (3H, s, -COOCH_3), 3.91–4.24 (1H, m, -C*H*OTHP-CHCH$_3$-), 4.12–4.22 (2H, m, -CH=CH-CH_2OH), 4.51–4.56, 4.61–4.65 and 4.68–4.75 (1H, m, -O—C*H*-O-), 4.98–5.76 (4H, m, -C*H*=C*H*-(CH_2)$_4$-C*H*=C*H*-); ms *m/e* (70 eV): 383 (M^+).

Allylic chloride ***29***

To a stirred solution of alcohol **28** (201 mg, 0.526 mmol) in dichloromethane (3 mL) were added triethylamine (110 μL, 0.789 mmol, 1.5 equiv.) and methanesulfonyl chloride (49 μL, 0.633 mmol, 1.2 equiv.) at −10°C. The resulting mixture was allowed to warm to 0°C and stirred for 30 min. Hexamethylphosphoramide (201 μL, 1.161 mmol, 2.2 equiv.) and lithium chloride (49 mg, 1.156 mmol, 2.2 equiv.) were added to the ice-cooled mixture, which was then allowed to warm to room temperature, stirred for 1.5 h, poured over brine, and extracted 3 times with ether. The combined organic layers were dried with sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (5% ethyl acetate in hexane) affording chloride **29** (183 mg, 87%); ir ($CHCl_3$): 3015, 3005, 2852, 1745, 1712, 1650, 1480, 1452, 1440, 1020, 1008 cm^{-1}; nmr ($CDCl_3$) δ: 0.95, 0.98, 1.07 and 1.09 (3H, d, J = 7.6 Hz, 7.1 Hz, 6.9 Hz, and 6.9 Hz, -CHOTHP-CHCH_3-), 1.30–1.44 (4H, m, -(CH_2)$_2$-CH_2-CH=CH-CH_2Cl), 1.44–1.90 (6H, m, -(CH_2)$_3$-CH_2-O-), 1.97–2.20 (4H, m, -CH=CH-CH_2-(CH_2)$_2$-CH_2-CH=CH-), 2.79–3.03 (1H, m, -CHOTHP-C*H*CH$_3$-), 3.34–3.90 (4H, m, -CH_2-CH_2-O- and -CO-CH_2-COOCH$_3$), 3.71 and 3.72 (3H, s, -COOCH_3), 3.91–4.26 (1H, m, -C*H*OTHP-CHCH$_3$-), 4.05–4.12 (2H, m, -CH_2Cl), 4.51–4.57, 4.60–4.66, and 4.67–4.75 (1H, m, -O-C*H*-O-), 4.98–5.45 and 5.53–5.76 (4H, m, -C*H*=C*H*-(CH_2)$_4$-C*H*=C*H*-); ms *m/e* (70 eV): 369 (M^+ −OCH$_3$), 365 (M^+ − Cl). *Exact Mass* (M^+ − Cl) calcd.: 365.2335; found: 365.2335.

Macrocycle ***30***

To a stirred solution of chloride **30** (104 mg, 0.260 mmol) in dry acetone (120 mL) were added potassium carbonate (107 mg, 0.774 mmol, 3 equiv.) and sodium iodide (116 mg, 0.774 mmol, 3 equiv.). The heterogeneous mixture was heated under reflux for 72 h. After cooling, the mixture was poured over a saturated aqueous solution of ammonium chloride and concentrated. The resulting residue was then poured over a 1:1 mixture of dichloromethane and water and extracted **3** times with dichloromethane. The combined organic layers were washed with brine, dried with sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (5% to 10% of ethyl acetate in hexane) to afford macrocycle **30** (69 mg, 74%); spectra of one diastereoisomer only: ir ($CHCl_3$): 2922, 2855, 1742, 1712, 1455, 1447 cm^{-1}; nmr ($CDCl_3$) δ: 1.27 (3H, d, J = 6.7 Hz, CH$_3$-C2), 1.01–2.27 (14H, m, H-C6, H-C7, H-C8, H-C9, and -(CH_2)$_3$-CH_2-O-), 2.29–2.43 and 2.51–2.64 (2H, m, H-C12), 3.09 (1H, dq, J = 10.0 Hz, 6.7 Hz, H-C2), 3.45–3.56 and 3.79–3.90 (2H, m, -(CH_2)$_3$-CH_2-O-), 3.73 (3H, s, -COOCH_3), 3.55 (1H, dd, J = 9.9 Hz, 3.6 Hz, H-C13), 4.03 (1H, dd, J = 10.0 Hz, 7.5 Hz, H-C3), 4.68 (1H, t, J = 3.1 Hz, -O—C*H*-O-), 5.21 (1H, ddt, J = 15.0 Hz, 7.5 Hz, 1.8 Hz, H-C4), 5.44–5.69 (3H, m, H-C5, H-C9, and H-C11); ms *m/e* (70 eV): (M^+). *Exact Mass* (M^+) calcd.: 364.2250; found: 364.2253.

Alcohol ***31***

To a stirred solution of macrocycle **30** (71 mg, 0.195 mmol) in 95% methanol (10 mL) was added pyridinium *para*-toluenesulfonate (37 mg, 0.147 mmol, 0.75 equiv.). The mixture was heated under reflux for 1.5 h, then poured over brine and extracted 3 times with dichloromethane. The combined organic layers were dried with sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (10% to 25% ethyl acetate in hexane) affording alcohol **31** (49 mg, 90%); spectra of one diastereoisomer only: ir ($CHCl_3$): 3525, 3020, 2930, 2855, 1747, 1702, 1455, 1438, 1261 cm^{-1}; nmr ($CDCl_3$) δ: 1.24 (3H, d, J = 6.6 Hz, CH$_3$-C2), 1.04–2.23 (8H, m, H-C6, H-C7, H-C8, and H-C9), 2.33–2.61 (2H, m, H-C12), 2.97 (1H, dq, J = 9.4 Hz and 6.7 Hz, H-C2), 3.56 (1H, dd, J = 10.0 Hz and 3.7 Hz, H-C13), 3.74 (3H, s, -COOCH_3), 4.02 (1H, dd, J = 9.8 Hz and 6.8 Hz, H-C3), 5.42-5.75 (4H, m, H-C4, H-C5, H-C10, and H-C11); ms *m/e* (70 eV): 280 (M^+), 262 (M^+ − H_2O). *Exact Mass* (M^+) calcd.: 280.1674; found: 280.1673.

Acetate ***32***

To an ice-cooled stirred solution of alcohol **31** (43 mg, 0.154 mmol) in dichloromethane (3.5 mL) were added triethylamine (42 μL, 0.30 mmol, 2 equiv.) acetic anhydride (29 μL, 0.307 mmol, 2 equiv.), and dimethylaminopyridine (1 crystal). The resulting mixture was stirred for 9 h, then poured over a 5% aqueous solution of hydrochloric acid and extracted 3 times with dichloromethane. The combined organic layers were washed with a saturated aqueous solution of sodium bicarbonate, dried with magnesium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (25% ethyl acetate in hexane) affording acetate **32** (46 mg, 93%); spectrum of one diastereoisomer only: nmr ($CDCl_3$) δ: 1.14 (3H, d, J = 6.7 Hz, CH$_3$-C2), 1.05–1.24 (8H, m, H-C6, H-C7, H-C8, and H-C9), 2.07 (3H, s, -OCOCH_3), 2.33–2.66 (2H, m, H-C12), 3.14 (1H, dq, J = 9.8 Hz and 6.7 Hz, H-C2), 3.57 (1H, dd, J = 9.5 Hz and 4.0 Hz, H-C13), 3.74 (3H, s, -COOCH_3), 5.18 (1H, dd, J = 9.8 Hz and 7.0 Hz, H-C3), 5.32–5.76 (4H, m, H-C4, H-C5, H-C10, and H-C11).

Trienone ***6***

To an ice-cooled stirred solution of acetate **32** (46 mg, 0.143 mmol) in benzene (11 mL) was added 1,8-diazabicyclo[5.4.0]undec-7-ene (63 μL, 0.421 mmol, 3 equiv.). The resulting solution was heated under reflux for 12 h, then poured over a 5% aqueous solution of hydrochloric acid and extracted 3 times with ether. The combined organic layers were washed with a saturated aqueous solution of sodium bicarbonate, dried with sodium sulfate, filtered, and concentrated to give a residue that was purified by column chromatography (5% to 10% ethyl acetate in hexane) affording impure trienone **6** (27 mg, 72%). The product was recrystallized from a mixture of hexane–dichloromethane at −20°C to afford pure trienone **6** (17.1 mg, 46%); mp 68–70°C; ir (CH_2Cl_2): 3010, 2925, 2885, 1745, 1685, 1432, 1222 cm^{-1}; nmr ($CDCl_3$) δ: 1.12–2.45 (8H, m, H-C6, H-C7, H-C8, and H-C9), 1.91 (3H, d, J = 1.2 Hz, CH$_3$-C2), 2.58–2.65 (2H, m, H-C12), 3.71 (3H, s, -COOCH_3), 3.94 (1H, dd, J = 7.5 Hz, 7.5 Hz, H-C13), 5.60–5.66 (2H, m, H-C11 and H-C12), 5.83 (1H, dt, $J_{5,4}$ = 15.4 Hz, $J_{5,6}$ = 7.6 Hz, H-C5), 6.15 (1H, dd, $J_{4,5}$ = 15.2 Hz, $J_{4,3}$ = 10.5 Hz, H-C4), 6.37 (1H, d, J = 10.3 Hz, H-C3); ms *m/e* (70 eV): 262 (M^+), 247 (M^+ − CH_3), 244 (M^+ − H_2O), 231 (M^+ − OMe). *Exact Mass* (M^+) calcd: 262.1569; found: 262.1567.

Tricycle 37

A solution of trienone **6** (8.3 mg, 0.032 mmol) in toluene (0.5 mL) was heated in a sealed tube at 300°C for 1.25 h. After evaporation of the solvent, the residue was purified by column chromatography (10% ethyl acetate in hexane) to give tricycle **37** (3.9 mg, 60%) and non-reacted trienone **6** (2.7 mg, 33% recovered). The trienone **6** in toluene (0.5 mL) was heated again in a sealed tube at 300°C for 2.5 h. After evaporation of the solvant and column chromatography, tricycle **37** was obtained (2.1 mg, 100%, total yield = 93%); mp 88–89°C; ir (CH_2Cl_2): 3030, 2920, 2850, 1732, 1477, 1454 cm^{-1}; nmr ($CDCl_3$) δ: 1.12 (3H, s, CH_3-C6), 1.15–2.49 (15H, m, H-C1, H-C2, H-C3, H-C4, H-C9, H-C10, H-C11, H-C12, and H-C13), 5.20 (1H, ddd, J = 10.0 Hz, 2.5 Hz, and 1.3 Hz, H-C7), 5.50 (1H, dd, J = 10.0 Hz and 1.7 Hz, H-C8); ms m/e (70 eV): 204 (M^+), 189 ($M^+ - CH_3$). *Exact Mass* (M^+) calcd.: 204.1514; found: 204.1514.

2,4-Dinitrophenylhydrazone derivative of 37

To a stirred solution of impure tricycle **37** (5.1 mg, 0.025 mmol) in ethanol (3.8 mL) and *N*,*N*,-dimethylformamide (1.2 mL) were added 2,4-dinitrophenylhydrazine (25 mg, 0.126 mmol, 5 equiv.) and a drop of 5% aqueous solution of hydrochloric acid. When the reaction was completed (≈ 0.5 h), the resulting mixture was filtered on silica gel with dichloromethane as eluant and the filtrate was concentrated to give a residue that was purified by preparative chromatography (10% ethyl acetate in hexane) and by high pressure liquid chromatography (0.75% of tetrahydrofuran in hexane) to afford derivative of **37** (2.9 mg, 30%); mp 172–177°C (dec.); ir (CH_2Cl_2): 3050, 2930, 2880, 1615, 1590, 1520, 1420, 1340, 1320, 1160 cm^{-1}; nmr ($CDCl_3$) δ: 1.34 (3H, s, CH_3-C6), 1.13–2.12 (12H, m), 2.23–2.46 (2H, m), 2.69 (1H, dd, J = 8.4 Hz and 17.6 Hz), 5.33 (1H, d, J_{AB} = 9.5 Hz, H-C7), 5.44 (1H, d, J_{AB} = 9.5 Hz, H-C8), 7.99 (1H, d, J = 9.7 Hz, >C=C*H*-CH=C(NO_2)-), 8.30 (1H, dd, J = 9.7 Hz and 2.6 Hz, >C=CH-C*H*=C(NO_2)-), 9.13 (1H, d, J = 2.5 Hz, >C=C(NO_2)-C*H*=C(NO_2)-), 10.83 (1H, s, =N-N*H*-Ar); ms m/e (70 eV): 384 (M^+). *Exact Mass* (M^+) calcd.: 384.1797, found: 384.1793.

ALAA S. ABD-EL-AZIZ, ADAM PIÓRKO, CHOI CHUCK LEE, and RONALD G. SUTHERLAND. Can. J. Chem. **67**, 1618 (1989).

Nucleophilic substitution reactions of the (η^6-*o*-, -*m*-, or -*p*-chloronitrobenzene)(η^5-cyclopentadienyl)iron cation (**2***a*, **2***b*, or **2***c*, respectively) with aniline, *n*-butylamine, or pyrrolidine as nucleophile were investigated. It was found that only selective displacement of the nitro group occurred for reactions with aniline. For reaction with *n*-butylamine or pyrrolidine, *o*-isomer **2***a* resulted in the selective displacement of only the chloro group, giving rise to the (η^6-*o*-*n*-butylaminonitrobenzene)(η^5-cyclopentadienyl)iron cation (**5***a*) or the (η^6-*o*-nitro-*N*-pyrrolidinylbenzene)(η^5-cyclopentadienyl)iron cation (**7***a*), respectively. With the *m*- or *p*-isomer **2***b* or **2***c*, reaction with *n*-butylamine or pyrrolidine gave a mixture of substitution products from competitive displacements of both chloro and nitro groups, the major product from the *m*-isomer being derived from displacement of the chloro group while the major product from the *p*-isomer resulted from displacement of the nitro group. Possible interpretations of these results on the basis that the basicity of the nucleophile and the combined inductive effects of the nitro and chloro substituents would play important roles are presented.

Key words: (η^6-*o*-, -*m*-, and -*p*-chloronitrobenzene)(η^5-cyclopentadienyl)iron cations, nucleophilic substitution reactions, aniline, *n*-butylamine, pyrrolidine.

ALAA S. ABD-EL-AZIZ, ADAM PIÓRKO, CHOI CHUCK LEE et RONALD G. SUTHERLAND. Can. J. Chem. **67**, 1618 (1989).

On a étudié les réactions de substitutions nucléophiles des cations (η^6-*o*-, -*m*- ou -*p*-chloronitrobenzène)(η^5-cyclopentadiényl)fer (respectivement **2***a*, **2***b* ou **2***c*) avec l'aniline, la *n*-butylamine ou la pyrrolidine. On a trouvé que, avec l'aniline, il ne se produit qu'un déplacement sélectif du groupement nitro. Pour les réactions de la *n*-butylamine ou de la pyrrolidine avec l'isomère *ortho*, **2***a*, on n'observe que le déplacement sélectif du groupement chloro conduisant respectivement aux cations (η^6-*o*-*n*-butylaminonitrobenzène)(η^5-cyclopentadiényl)fer (**5***a*) ou (η^6-*o*-*n*-nitro-*N*-pyrrolidinylbenzène)(η^5-cyclopentadiényl)fer (**7***a*). Avec les isomères *méta* ou *para* (**2***b* ou **2***c*), les réactions avec la *n*-butylamine ou la pyrrolidine conduisent à des mélanges de produits de substitution provenant des réactions de substitutions compétitives des groupements chloro et nitro; le produit majeur obtenu à partir de l'isomère *méta* provient de la substitution du groupement chloro alors que le produit majeur obtenu à partir de l'isomère *para* provient de la substitution du groupement nitro. On présente des interprétations possibles de ces résultats qui sont basées sur les basicités relatives des nucléophiles et sur l'hypothèse que les effets inductifs combinés des substituants nitro et chloro joueraient un rôle important.

Mots clés : cations (η^6-*o*-, -*m*- ou -*p*-chloronitrobenzène)(η^5-cyclopentadiényl)fer, réactions de substitutions nucléophiles, aniline, *n*-butylamine, pyrrolidine.

[Traduit par la revue]

The displacement of the chloro group in the (η^6-chlorobenzene)(η^5-cyclopentadienyl)iron cation (**1***a*) by a number of nucleophiles was first reported by Nesmeyanov *et al.* in 1967 (1) and it was estimated that the "mobility" of the chloro group in **1***a* was similar to that in 2,4-dinitrochlorobenzene (2). Similar displacement reactions with **1***a* were carried out with the hydroxide or hydrosulfide ion as nucleophile in 1979 (3), and with the azide ion to give the cyclopentadienyliron (CpFe) complexed azidobenzene in 1981 (4). Subsequently, nucleophilic substitution reactions with **1***a* and related systems, such as the CpFe complexed *o*-, *m*-, and *p*-chlorotoluenes and *o*-, *m*-, and *p*-dichlorobenzenes, with a variety of nucleophiles, were studied in our laboratory (5–11) and by a former colleague, U. S. Gill, in his post-doctoral work (12–14). We have also shown that CpFe complexes of nitroarenes, as those of chloroarenes, could undergo nucleophilic substitution reactions (7, 15). In the present work, substitution reactions of the (η^6-*o*-, -*m*-, or -*p*-chloronitrobenzene)(η^5-cyclopentadienyl)-iron cation (**2***a*, **2***b*, or **2***c*, respectively), as its hexafluorophosphate, with aniline, *n*-butylamine, or pyrrolidine as nucleophile, were investigated to determine whether a selective displacement of either the chloro or nitro group would take place or if competitive substitutions of both chloro and nitro groups would occur.

Cations **2***a*, **2***b*, and **2***c*, isolated as their hexafluorophosphate salts, were prepared from the oxidation of the corresponding CpFe complexed *o*-, *m*-, and *p*-chloroanilines (**3***a*, **3***b*, and **3***c*) with H_2O_2 in CF_3COOH (5), while the aniline complexes, **3***a*, **3***b*, and **3***c*, were obtained from reaction of the CpFe complexed *o*-, *m*-, and *p*-dichlorobenzenes (16) with NH_3 as previously described for the same reaction with the *o*-isomer to give **3***a* (8). The ^1H and ^{13}C nmr data for **2***a–c* and for **3***b* and **3***c*, which have not been prepared previously, are given in Tables 1 and 2.

Reaction of **2***a*, **2***b*, or **2***c* with aniline resulted solely in the selective displacement of the nitro group, giving rise to **4***a*, **4***b*, or **4***c*, respectively, as its hexafluorophosphate. It has been reported (17) that chlorobenzene complex **1***a* did not give a nucleophilic substitution reaction with aniline. On the other hand, we have found in the present work that the (η^6-nitrobenzene)(η^5-cyclopentadienyl)iron cation (**1***b*) readily reacted with aniline to give a 70% yield of substitution product **4***d*, also obtained as its hexafluorophosphate. It is, therefore, not surprising that reactions of chloronitrobenzene complexes **2***a*, **2***b*, and **2***c* with aniline resulted only in the displacement of the nitro group to give **4***a*, **4***b*, and **4***c*. Incidentally, diphenylamine complex **4***d* was prepared previously by a ligand exchange reaction between diphenylamine and ferrocene (18), but the yield was only 6%.

In contrast to the results obtained for reactions with aniline, *o*-isomer **2***a* reacted with *n*-butylamine or pyrrolidine solely by selective displacement of the chloro group, giving rise to

8*c*, Y = *p*-Cl

The ^{1}H and ^{13}C nmr spectral data in support of the structures assigned to all of the above substitution products are summarized in Tables 3 and 4. It may be pointed out that in the reactions that gave mixtures of products, **5***b* and **6***b* or **5***c* and **6***c* from reaction of **2***b* or **2***c* with *n*-butylamine, and **7***b* and **8***b* or **7***c* and **8***c* from reaction with pyrrolidine, one component of each product mixture, namely, **6***b*, **6***c*, **8***b*, or **8***c*, was previously prepared from reactions of the CpFe complexed *m*- or *p*-dichlorobenzene with *n*-butylamine and with pyrrolidine (11). The spectral data of these known compounds together with those for the product mixtures allowed the nmr spectra of **5***b*, **5***c*, **7***b*, and **7***c* to be deduced and the relative ratios of the two components in the product mixtures to be estimated.

In nucleophilic aromatic substitutions following the S_NAr mechanism as depicted in eq. [1] (19), both inductive and resonance effects of substituent Y would each exert its influence (20). In a 1978 review on nucleophilic displacement of aromatic nitro groups (21), examples were cited that under different experimental conditions for various substrates, selective displacement of the nitro or chloro group, or competitive displacement of both nitro and chloro groups, could take place, but

9 **10** **11**

no detailed mechanistic explanations were presented. More recently, it was reported that under appropriate conditions, reaction of the methyl ester of 3-chloro-2-nitrobenzoic acid (**12***a*) with benzylamine resulted in the selective displacement of only the nitro group (22, 23), while a similar reaction with amide derivative **12***b* gave selective displacement of the chloro group (23), and it was suggested that conjugative effects involving the lone pair of electrons on the amide N of **12***b* could play an important role (23). The results from the present studies on complexed cations **2***a*, **2***b*, and **2***c*, however, appear to indicate that conjugative or resonance effects may be of lesser importance. Possibly because adduct **13**, analogous to **10** of eq. [1], is a neutral species with no negative charge to be delocalized by Y, there would be a relatively minor role for the resonance effect.

Utilizing the addition–elimination mechanism of the S_NAr reaction and assuming that inductive effects would be the major factor in governing the course of reaction of **2***a–c*, the present results could be qualitatively interpreted. With aniline, a weak base (pK_b = 9.4 (24)), as nucleophile, *ipso* addition could take place only at the carbon bearing the strongly electron-withdrawing nitro group, and subsequent elimination of the nitro group would give the overall substitution product. No *ipso*

12*a*, X = CH_3
12*b*, X = $N(CH_3)_2$

addition with aniline was possible at the carbon containing the less electron-withdrawing chloro substituent. Hence there was no S_NAr reaction between aniline and chlorobenzene complex **1***a*, but such a reaction occurred readily with nitrobenzene complex **1***b* to give **4***d*, and with **2***a*, **2***b*, and **2***c* to give **4***a*, **4***b*, and **4***c*, respectively, from selective displacement of the nitro group.

With a stronger base, *n*-butylamine (pK_b = 3.3 (24)) or pyrrolidine (pK_b = 2.7 (24)), nucleophilic addition with *o*-isomer **2***a* took place solely at the *ipso* position containing the chloro substituent and *ortho* to the strongly electron-withdrawing nitro group, thus leading to the selective displacement of the chloro group to give substitution product **5***a* or **7***a*. It may be of interest to note that in a study on product distributions in the nucleophilic addition of the hydride ion to 15 CpFe complexed substituted benzenes (25), only the nitrobenzene complex **1***b*, with its strongly electron-withdrawing nitro substituent (σ_{para} = +0.78 (26)), gave rise exclusively to the *ortho*-addition product, while the other complexed substituted benzenes containing a substituent ranging from dimethylamino (σ_{para} = −0.83 (26)) to cyano (σ_{para} = +0.66 (26)) all gave various mixtures of *o*-, *m*-, *p*-, and (or) *ipso*-adducts. Apparently, the combined electron-withdrawing inductive effects of the chloro and the *o*-nitro groups in **2***a* led to the addition of *n*-butylamine or pyrrolidine at the carbon containing the chloro group and *ortho* to the nitro group, thus leading to the observed selective displacement of the chloro group in the formation of **5***a* or **7***a* from **2***a*.

With *m*-isomer **2***b*, the strongly electron-withdrawing effect of the nitro group would be less pronounced on the *m*-chloro position than the analogous effect on the *o*-chloro position of **2***a*. Thus *ipso* addition of the nucleophile occurred at both positions containing the chloro and the nitro substituents, giving rise to a mixture of products from competitive displacement of the chloro as well as the nitro groups. Apparently, the combined inductive effects of the chloro group and the *m*-nitro group led to a greater extent of *ipso* addition at the position containing the chloro substituent, giving rise to the formation of **5***b* or **7***b* as major product.

For the reaction of *p*-isomer **2***c* with *n*-butylamine or pyrrolidine, however, the major product obtained was **6***c* or **8***c*, respectively, derived from displacement of the nitro group. These results again would fit in with the suggestion that inductive effects played a dominant role. For **2***c*, the nitro group would exert the least inductive effect on the *p*-position in comparison to the *m*- and *o*-positions, thus leading to more *ipso* addition at the site containing the strongly electron-withdrawing nitro group, giving rise to **6***c* or **8***c* as major product. It may also be pointed out that if resonance effects were to play an important role, one would anticipate similar behavior for the *o*- and *p*-isomers **2***a* and **2***c*, but this was not the case, with **2***a* giving rise solely to the selective displacement of the chloro group, while **2***c* resulted in a competitive displacement of both nitro and chloro groups with the minor product derived from displacement of the chloro group.

Experimental

*(η^6-m- and -p-Chloroaniline)(η^5-cyclopentadienyl)iron hexafluorophosphate (**3**b-PF_6 and **3**c-PF_6, respectively)*

Using the same procedure as previously described for the reaction of (η^6-*o*-dichlorobenzene)(η^5-cyclopentadienyl)iron hexafluorophosphate with concentrated NH_4OH to give (η^6-*o*-chloroaniline)(η^5-cyclopentadienyl)iron hexafluorophosphate (**3***a*-PF_6) (8), reaction of the CpFe complexed *m*- or *p*-dichlorobenzene with concentrated NH_4OH gave the *m*- or *p*-chloroaniline complex as the hexafluorophosphate (**3***b*-PF_6 or **3***c*-PF_6) in 76 or 81% yield, respectively. Their ^1H and ^{13}C nmr data are summarized in Tables 1 and 2. *Anal.* calcd. for $C_{11}H_{11}NClFePF_6$: C 33.58, H 2.82, N 3.56; found: C 33.17, H 2.85, N 3.60 for **3***b*-PF_6 and C 33.20, H 2.88, N 3.47 for **3***c*-PF_6. For these and other compounds reported in the present work, the nmr data were obtained using a Bruker AM300 spectrometer. The elemental analyses were done in the analytical laboratory of the University of Saskatchewan.

*(η^6-o-, -m-, and -p-Chloronitrobenzene)(η^5-cyclopentadienyl)iron hexafluorophosphates (2*a*-PF_6, 2*b*-PF_6, and 2*c*-PF_6)*

Oxidation of *o*-, *m*-, or *p*-chloroaniline complex **3***a*-PF_6, **3***b*-PF_6, or **3***c*-PF_6 with H_2O_2 in CF_3COOH as previously described for the preparation of nitrobenzene complex **1***b* from the CpFe complexed aniline (5) gave the hexafluorophosphate of **2***a*, **2***b*, or **2***c* with a yield of 50, 56, or 57%, respectively. *Anal.* calcd. for $C_{11}H_9O_2NClFePF_6$: C 31.20, H 2.14, N 3.31; found: C 31.35, H 2.17, N 3.54 for **2***a*-PF_6, C 31.37, H 2.20, N 3.42 for **2***b*-PF_6, and C 31.20, H 2.10, N 3.35 for **2***c*-PF_6.

Reactions with aniline

A mixture of 1.0 mmol of the hexafluorophosphate of nitrobenzene complex **1***b* or the *o*-, *m*-, or *p*-chloronitrobenzene complex **2***a*, **2***b*, or **2***c*, 102 mg (1.1 mmol) of aniline, and 345 mg (2.5 mmol) of K_2CO_3 in 10 mL of THF was heated under reflux and under N_2 for 6 h. The resulting material was filtered into 10 mL of 10% HCl and a solution of 163 mg (1.0 mmol) of NH_4PF_6 in 20 mL of H_2O was added. The product was recovered by extraction with CH_2Cl_2 (3 × 20 mL). The combined extract was dried over $MgSO_4$ and, after removal of the solvent, the residue was washed with ether and then crystallized from CH_2Cl_2–ether to give a 70% yield of the hexafluorophosphate of diphenylamine complex **4***d* from **1***b*, or the hexafluorophosphate of the *o*-, *m*-, or *p*-chlorodiphenylamine complex **4***a*, **4***b*, or **4***c* with a yield of 70, 40, or 70%, respectively, from **2***a*, **2***b*, or **2***c*. *Anal.* calcd. for $C_{17}H_{15}NClFePF_6$: C 43.48, H 3.22, N 2.98; found: C 43.58, H 3.40, N 2.92 for **4***a*-PF_6, C 43.62, H 3.37, N 3.09 for **4***b*-PF_6, and C 43.40, H 3.43, N 2.87 for **4***c*-PF_6.

Reactions with n-butylamine and with pyrrolidine

A mixture of 423 mg (1.0 mmol) of **2***a*-PF_6, **2***b*-PF_6, or **2***c*-PF_6, 73 mg (1.0 mmol) of *n*-butylamine or 71 mg (1.0 mmol) of pyrrolidine, and 345 mg (2.5 mmol) of K_2CO_3 in 10 mL of a 1:1 mixture of THF–DMSO was heated under reflux and under N_2 for 6 h. The resulting material was worked up as described above for the reactions with aniline except that in the final stages most of the solvent was removed from the dried CH_2Cl_2 extract and the product was precipitated upon addition of ether. For the reaction of *o*-isomer **2***a*-PF_6 with *n*-butylamine, a 73% yield of the hexafluorophosphate of *o*-*n*-butylaminonitrobenzene complex **5***a* was obtained. *Anal.* calcd. for $C_{15}H_{19}O_2N_2FePF_6$: C 39.50, H 4.20, N 5.26; found: C 39.15, H 4.16, N 5.29. Similarly, the reaction of **2***a*-PF_6 with pyrrolidine gave a 75% yield of the hexafluorophosphate of *o*-nitro-*N*-pyrrolidinylbenzene complex **7***a*. *Anal.* calcd. for $C_{15}H_{17}O_2N_2FePF_6$: C 39.67, H 3.77, N 5.29; found: C 39.45, H 3.87, N 5.23.

From the reaction of *m*-isomer **2***b*-PF_6 with *n*-butylamine or pyrrolidine, respectively, the products obtained were a 61% yield of a 4:1 mixture of the hexafluorophosphate of *m*-*n*-butylaminonitrobenzene complex **5***b* and the known hexafluorophosphate of *m*-*n*-butylaminochlorobenzene complex **6***b* (11) or a 52% yield of a 3:1 mixture of the hexafluorophosphate of *m*-nitro-*N*-pyrrolidinylbenzene complex **7***b* and the known hexafluorophosphate of *m*-chloro-*N*-pyrrolidinylbenzene complex **8***b* (11), the product ratios being obtained from the ^1H nmr spectra of these mixtures.

In the reactions with *p*-isomer **2***c*-PF_6, a 58% yield of a 2:3 mixture of the hexafluorophosphate of *p*-*n*-butylaminonitrobenzene complex **5***c* and the known hexafluorophosphate of *p*-*n*-butylaminochlorobenzene complex **6***c* (11) was obtained from reaction with *n*-butylamine, while reaction with pyrrolidine gave a 63% yield of a 1:2

mixture of the hexafluorophosphate of *p*-nitro-*N*-pyrrolidinylbenzene complex **7***c* and the known hexafluorophosphate of *p*-chloro-*N*-pyrrolidinylbenzene **8***c* (11). Again the product ratios were determined from the ^{1}H nmr spectra.

The conductance behaviour of $NaBPh_4$ in acetonitrile–toluene mixtures at 15, 25, and 35°C

N. PAPADOPOULOS

Laboratory of Physical Chemistry, Department of Chemistry, Aristotelian University of Thessaloniki, Greece

Received August 29, 1988[1]

N. PAPADOPOULOS. Can. J. Chem. **67**, 1624 (1989).

The limiting molar conductances and association constants for $NaBPh_4$ have been evaluated in acentonitrile–toluene mixtures at 15, 25, and 35°C. Experimental data have been analysed by the Lee–Wheaton conductance equation. The thermodynamic parameters of the non-coulombic interaction have been evaluated.

Key words: conductance, association constant, Lee–Wheaton equation, acetonitrile–toulene.

N. PAPADOPOULOS. Can. J. Chem. **67**, 1624 (1989).

Opérant a 15, 25 et 35°C, dans des mélanges d'acétonitrile–toluène, on a évalué les conductivités et les constantes d'association molaires limites du $NaBPh_4$. On a analysé les données expérimentales à l'aide de l'équation de conductance de Lee–Wheaton. On a évalué les paramètres thermodynamiques de l'interaction non-coulombique.

Mots clés : conductivitès, constant d'association, l'équation de Lee–Wheaton, acétonitrile–toulène.

[Traduit par la revue]

Introduction

A complete theory of the phenomena of solution chemistry will become a reality only when solute–solvent interactions are completely elucidated. Theoretical treatments of these processes have been hampered by incomplete knowledge of the electrostatic forces in the immediate vicinity of solvated ions.

Various similar but not identical equations have been published in the literature (1, 2) trying to correlate the association constant of an electrolyte in a solution to parameters such as the size of the ions and the dielectric constant of the solvent. However, in addition to the electrostatic forces, solvation forces also exist which are completely system-specific and their contribution to association cannot be predicted.

Conductimetry is one of the most direct methods to study the behaviour of ions in solution. In this work, the conductances of $NaBPh_4$ in toluene–acetonitrile mixtures are reported at 15, 25, and 35°C.

Experimental

Sodium tetraphenyl boride (Merck p.a. 99.5%) was recrystallized from acetone and dried under vacuum over P_2O_5. The purification of the solvent was carried out as described previously (3). Details of the experimental procedure have been reported elsewhere (4). The physical constants of acetonitrile–toluene mixtures have been reported previously (3).

Results and discussion

The measured molar conductivities at various concentrations are given in Table 1. The experimental results have been analysed according to the method of Pethybridge and Taba (5) who use the Lee–Wheaton conductance equation (6, 7). This equation is different from the previous conductance equations, most of which are based on the "primitive" model (8).

Lee and Wheaton envisage three regions around the ion itself which is treated as a rigid, conducting sphere. In region 1, all the solvent molecules are aligned by the ion's field and there is dielectric saturation. In region 2 the solvent's structure is still modified by the ion's field though to a lesser extent, and in region 3 the solvent retains its bulk properties. The resulting equation is complicated in the general case of a single, associated symmetrical electrolyte. Details for the analysis of the experimental results have been given previously (9).

The analysis of conductivity data can provide three parameters: the value of equivalent conductance at infinite dilution Λ_0, the value of the association constant K_A, and the distance of the closest approach of the ions R. The values of Λ_0 and K_A calculated from the experimental results are given in Table 2. In all cases a sharp minimum was observed in the $\sigma\%-R$ plot (Fig. 1) at 11 ± 1 Å. The minimum was sharper the higher the proportion of toluene in the toluene–acetonitrile solvent mixture. The center-to-center distance of $NaBPh_4$ is about 6 Å (10, 11). The diameter of the acetonitrile molecule was calculated from the formula $d = 1.183\ (m/\rho)^{1/3}$ (12) and was found to be equal to 4.4 Å. The value of 11 ± 1 Å suggests that the ions that are formed in this solvent mixture are solvent-separated ion pairs. It is reasonable to accept that each ion pair is separated by one molecule of acetonitrile because acetonitrile is a much more polar solvent than toluene.

The conductance of solutions of $NaBPh_4$ in acetonitrile at 25°C has also been measured by Kay *et al.* (14) who obtained $\Lambda_0 = 134.1$ and $K_A = 0$. They analysed their experimental data with a conductance equation based on the primitive model. Conductance data of sufficient precision with the exception of the work of Kay *et al.* do not exist in the literature. Consequently, direct comparison for this electrolyte between the values of Λ_0 and K_A calculated from the equations based on the "primitive" model are not possible. In two previous papers (14, 15), conductance data for many other systems from the literature have been analysed with the Lee–Wheaton conductance equation. In all cases a much better fit of the conductance data to the Lee–Wheaton equation than to the equations based on the "primitive" model has been observed. The values of Λ_0 calculated from the previous conductance equations do not differ significantly from the value of Λ_0 calculated from the Lee–Wheaton conductance equation. The values of K_A calculated with the Lee and Wheaton equation are generally higher. The older conductance equations gave a distance of a closest approach that was very low. The experimental data of Kay *et al.* were reanalysed with the Lee–Wheaton conductance equation and the results $\Lambda_0 = 134.4$ and $K_A = 8.3$ were obtained. These values are in good agreement with our results. The association constant of a pure electrolyte is largely influenced by the radius

of the compound under investigation and the dielectric constant of the solvent. There is, however, considerable evidence that the ions are solvated (1), i.e. that each ion is surrounded on the average by a number of solvent molecules which accompany the ion in solution. Consequently the value of the association constant will also depend on the non-electrostatic interaction between the solvent medium and the electrolyte. In solvent media of medium and low dielectric constant, the attractive electrostatic forces between the ions become large and ion pairs that will be reasonably stable will tend to form. There exists a number of equations that have been proposed in order to predict the non-coulombic part (16–18) of the free energy of association. In this work the "Fuoss 75" (18) equation has been used for the evaluation of the nonelectrostatic free energy in the form:

$$K_A = (4\pi n/1000) \exp(-\Delta G^0/RT) \int_a^R r^2 \exp(\beta/r) dr$$

where $\beta = e/DkT$ and a = the center-to-center distance of an ion pair.

The non-Coulombic forces are taken into account in this equation by the factor $\exp(-\Delta G^0/RT)$ where ΔG^0 is the non-electrostatic free energy of association. The ΔG^0 values at 25°C calculated from the above equation are given in Table 2. The ΔH^0 value was found to be equal to about zero for all the compositions of the solvent system. Thus ΔG^0 arises solely to

entropic effects. It can be concluded that the ion pairs that are formed are solvated with acetonitrile molecules in their vicinity better than the ions with a resultant lowering of the entropy of the system. As the solvent is enriched in toluene, the ΔG^0 values of the non-electrostatic interaction are lower, indicating that the bulk competes with the ion pairs for the acetonitrile molecules. The inverse behaviour has been observed for Bu_4NI and Pr_4NI in the same solvent system. For these electrolytes desolvation of the ion pair occurred as the solvent mixture was enriched in toluene (14, 15).

Electron affinities of aza-substituted polycyclic aromatic hydrocarbons

GLEN W. DILLOW AND P. KEBARLE
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 7, 1989

GLEN W. DILLOW and P. KEBARLE. Can. J. Chem. **67**, 1628 (1989).

Electron affinities for aza-substituted polycyclic aromatics were determined from measurements of electron transfer equilibria in the dilute gas phase with a pulsed electron high pressure mass spectrometer (PHPMS). These are (in kcal / mol): quinazoline (12.7), quinoxaline (15.8), cinnoline (16.0), acridine (20.3), benzo[*c*]cinnoline (20.6), pyrido[2,3-*b*]pyrazine (22.5), phenazine (29.5). Solvation energies of the corresponding radical anions in acetonitrile and dimethylformamide are derived from the gas phase data and literature on electron reduction potentials in solution. An observed linear relationship between the electron affinities and the reduction potentials allows estimates of electron affinities to be made for 12 aza compounds whose EA's are too low to be measured with the present method.

Key words: aza-substituted aromatic hydrocarbons, electron affinities, electron transfer, radical anions, reduction potentials, solvation energies of radical anions, stabilities of radical anions.

GLEN W. DILLOW et P. KEBARLE. Can. J. Chem. **67**, 1628 (1989).

En se basant sur des mesures d'équilibre de transfert d'électron en phase gazeuse diluée et effectuées à l'aide d'une spectromètre de masse à haute pression et à électrons pulsés, on a déterminé les affinités électroniques de dérivés aromatiques polycycliques dans lesquels on a remplacé des carbones par des azotes. Les valeurs obtenues sont les suivantes (en kcal / mol) : quinazoline (12,7), quinoxaline (15,8), cinnoline (16,0), acridine (20,3), benzo]*c*]cinnoline (20,6), pyrido[2,3-*b*]pyrazine (22,5) et phénazine (29,5). En se basant sur des données en phase gazeuse et des données de la littérature relatives aux potentiels de réduction électronique en solution, on a obtenu les énergies de solvatation des radicaux anions correspondants dans l'acétonitrile ainsi que dans le diméthylformamide. Sur la base de la relation linéaire qui a été observée pour les affinités électroniques et les potentiels de réduction, on peut évaluer les affinités électroniques de 12 autres composés aza dont les affinités électroniques sont trop faibles pour être mesurées par la méthode actuelle.

Mots clés : hydrocarbures aromatiques substitués par de l'azote, affinités électroniques, transfert d'électron, radicaux anions, potentiels de réduction, énergies de solvatation de radicaux anions, stabilités de radicaux anions.

[Traduit par la revue]

Introduction

We have recently used pulsed high pressure mass spectrometry (PHPMS) (1) to determine equilibrium constants of electron transfer equilibria [1] in the dilute gas phase. With these one can obtain gas phase electron affinities (EA's) of organic molecules (2–4). The method is applicable only when stable negative ions are formed, i.e., when the EA's are positive. The previous work included a few unsubstituted polycyclic aromatic hydrocarbons (2*b*), but no aza-substituted aromatics.

[1] $A^- + B = A + B^-$

It was determined previously (5), by electron transmission spectroscopy, that aza-substitution of benzene to yield pyridine stabilizes the LUMO and thus increases the EA by ~12 kcal/mol. The LUMO energies for benzene and pyridine are relatively high, so that no stable negative ions are formed in the gas phase; i.e., the EA's are negative, $EA(C_6H_6) \approx -26.4$ kcal/mol and $EA(C_5H_5N) \approx -14.1$ kcal/mol) (5, 6). A stabilization of the aromatic LUMO and the valence electron MO's by replacement of C with N is expected, due to the greater electronegativity of the nitrogen atom. Therefore, for example, in simple Hückel MO theory the value of the coulomb integral α is taken to be lower when heteroatoms of higher electronegativity are part of the aromatic system. Successful predictions of the EA of a number of aza-substituted aromatics have been obtained by Compton and co-workers (7) on the basis of LUMO energies evaluated with the Pariser–Parr–Pople approximation to the Hartree–Fock equation, where variable β–γ were used to empirically account for the different electronegativities of heteroatoms. Compton and co-workers (7) compared their results with EA's from electron transmission spectroscopy, when the EA's were negative, but essentially no experimental data for aza-substituted aromatics with *positive* EA's were available at the time.

Indirect information on electron affinities is available from one-electron reduction potentials measured in solution. Since solvation stabilizes the ion very significantly, stable radical anions in solution can be formed even when the gas phase EA is negative. Reduction potentials for a number of aza-substituted aromatics are available (8, 9) and these include compounds whose EA's are both negative and positive. The present work, which provides electron affinities for seven aza-substituted di- and tri-cyclic aromatics, is thus of significance not only to disciplines where gas phase negative ions occur, such as the electron capture detector, chemical ionization mass spectrometry, and gas phase ion chemistry, but also provides numerical data for comparison with results of future quantum chemical calculations as well as a cross-check to the assumed reversibility of the one-electron reductions in solution. Furthermore, when the reduction potentials are reversible, the gas phase electron affinities can be combined with the solution reduction potentials to obtain solvation energies of the radical anions in the given solvents.

Results and discussion

Results

Values for: $\Delta G_1^0 = -RT \ln K_1$ were determined from the electron transfer equilibria, see reaction [1]. These measurements were made under conditions similar to those used in previous work (1–4): ion-source temperature 150°C, total ion source pressure 5 Torr (1 Torr = 133.3 Pa), mTorr pressures of the neutral reactants. The ΔG_1^0 values obtained are shown in Fig. 1. The reference compounds whose electron attachment free energies, see eq. [2], were determined in earlier work (2) are shown on the left side of Fig. 1.

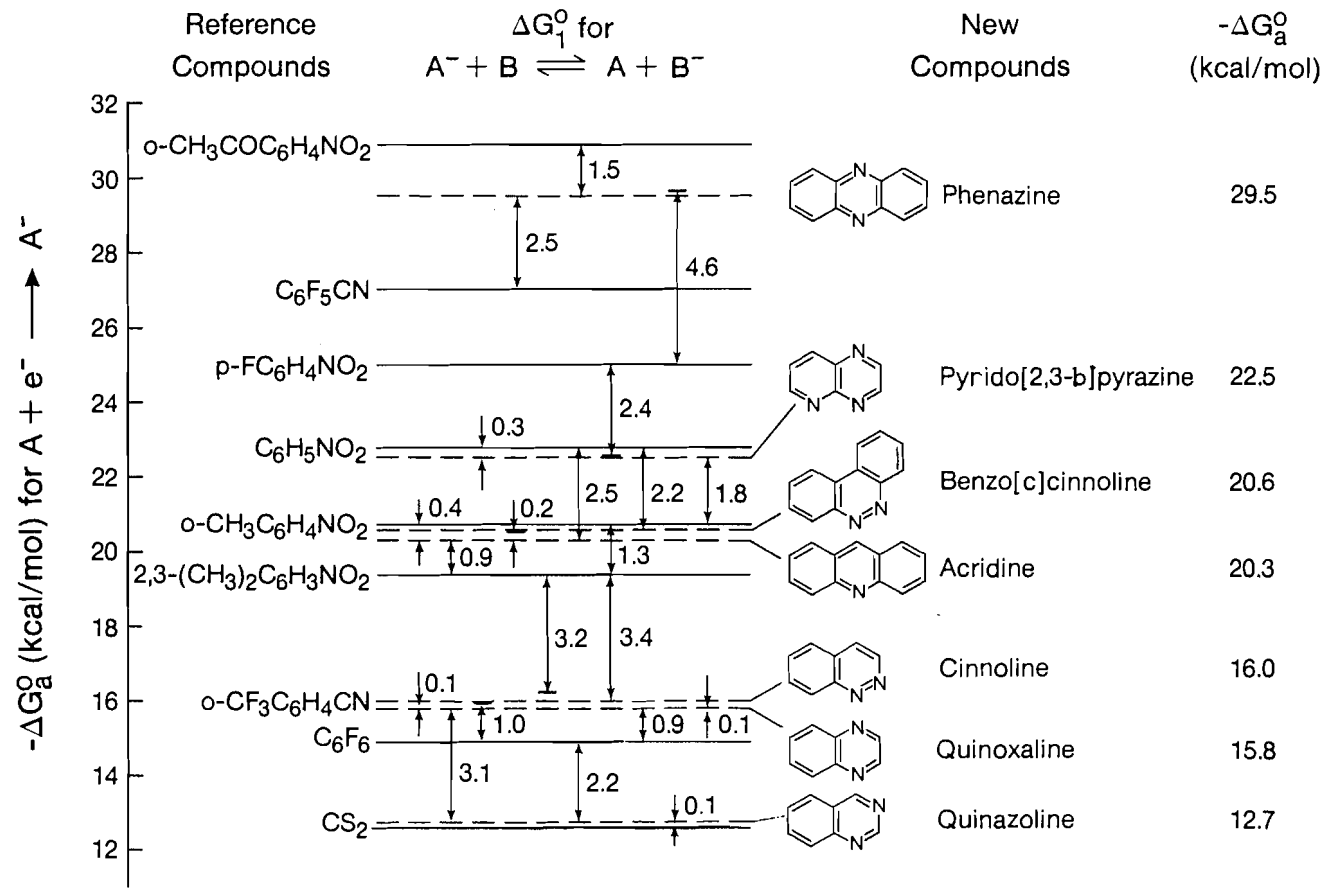

FIG. 1. Scale constructed from experimentally determined $\Delta G_1^0 = -RT \ln K_1$, obtained for electron transfer equilibria [1]: $A^- + B = A + B^-$. Scale is converted to electron capture free energies $\Delta G_a^0(B)$ by calibrating scale to known $\Delta G_a^0(A)$ of reference compounds (temperature 150°C).

[2] $e + A = A^-$ $\Delta G_a^0(A)$

Combination of the ΔG_1^0 with the known $\Delta G_a^0(A)$ of the reference compounds leads to the attachment free energies for the aza compounds shown in Fig. 1 and given in Table 1. In earlier work (*2a*) it was shown that the ΔG_a^0 values are close to the ΔH_a^0 values and that $-\Delta H_a^0 \approx$ EA. The relative values for the ΔG_a^0 of the polycyclic aromatics used should be particularly close to the relative electron affinities, since the LUMO's for these systems are delocalized over the whole molecule and, therefore, only minimal changes of geometry are to be expected between the neutral and negatively charged molecule.

Discussion of EA of aza compounds

The electron affinities of the aza-substituted benzenes, naphthalenes, and anthracenes are shown in Fig. 2, plotted versus the number of nitrogen atoms. The values for benzene, pyridine, and naphthalene are from electron transmission spectroscopy (5, 6), while that for quinoline was estimated from the electrochemical data as discussed later. Two trends are evident in Fig. 2.

1. The increase in EA, in a given series, with increasing number of nitrogens is approximately additive. This trend is particularly evident for the naphthalene series, for which most data are available. Overall, the addition of N to any of the molecules in the benzene, naphthalene, and anthracene series causes an increase of EA of ~10 kcal/mol per nitrogen atom.

2. The effect on the EA's of added nitrogens is attenuated only slightly as the size of the aromatic system increases, i.e., from benzene to anthracene.

TABLE 1. Free energy change for electron attachment to the aza-substituted polycyclic aromatic hydrocarbons

$M + e^- \rightleftharpoons M^-$ $\Delta G^0 = \Delta G_a^0$

Compound	$-\Delta G_a^0$ (kcal/mol)[a]

Acridine	20.3
Benzo[*c*]cinnoline	20.6
Pyrido[2,3-*b*]pyrazine	22.5
Phenazine	29.5

[a]Data from Fig. 1.

Both of the above effects are very similar to the field effects of substituents added onto, rather than into, the aromatic system. It was observed in earlier work that the field effects on the EA's are approximately additive in multiple substitution and attenuate only slowly with increasing molecular size (*2b*, 3, 4).

Comparison of electron affinities with reduction potentials in solution

The electrochemical reduction potentials of a variety of aza-substituted PAH's in solution have been reported (8, 9). These

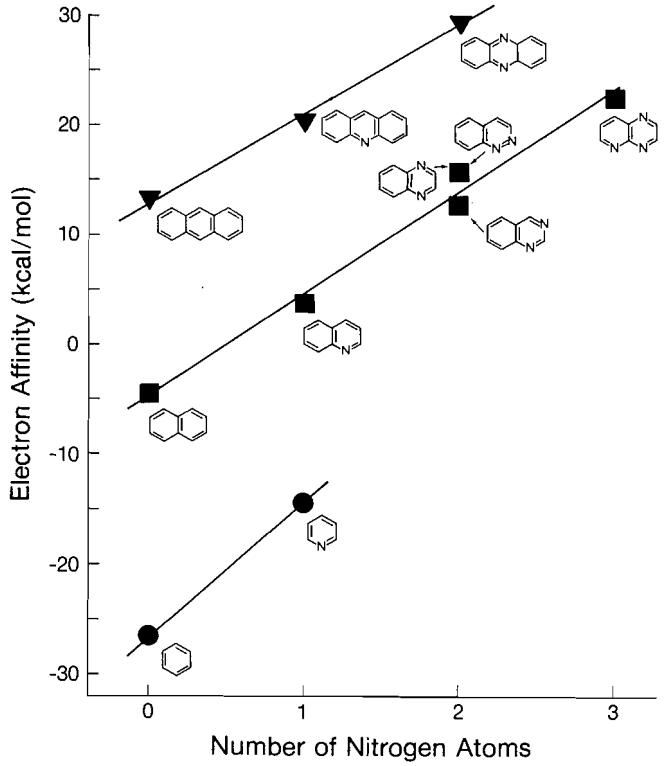

FIG. 2. Plots of electron affinities for aza-substituted polycyclic aromatics. EA for benzene, pyridine, and naphthalene from electron transmission spectroscopy (5, 6). EA for quinoline (1-azanaphthalene) estimated, see Table 2 and text. Remaining data from Fig. 1.

studies included most of the compounds used in the present study. Typically, the first reduction step in solution involves the reversible addition of an electron (from the electrode) to the molecule and is thus the solution equivalent of electron attachment.

Shown in Fig. 3 is a plot of the gas phase attachment free energies ΔG_a^0 versus reduction potentials in acetonitrile solution (8). The reduction potentials used are actually the polarographic halfwave potentials $E_{1/2}$, which for reversible processes are close to the reduction potentials. A similar plot is shown in Fig. 4 where now the $E_{1/2}$ are for dimethylformamide solution (9). In both plots, pyridine was included to extend the range of the data. Both sets of solution data were obtained with 0.1 M tetraethylammonium perchlorate as supporting electrolyte, and were measured versus the SCE reference electrode.

A very good linear correlation is obtained in Fig. 3, correlation coefficient 0.997, while the correlation in Fig. 4 has somewhat more scatter, correlation coefficient 0.985. The very good correlations indicate that all the reduction potentials involved are due to reversible one-electron reduction reactions.

From the plots in Figs. 3 and 4 one can estimate $-\Delta G_a^0$ for a number of molecules for which reduction potentials are available (8, 9) but ΔG_a^0 are difficult to measure. Measurements with the PHPMS electron transfer equilibrium method are difficult for molecules whose $-G_a^0$ are less than ~12 kcal/mol. For such systems thermal electron detachment (10) occurs above 100°C. Furthermore, often minor impurities with higher $-\Delta G_a^0$ become the dominant ions. Table 2 lists $-\Delta G_a^0$ for 12 aza compounds estimated on the basis of the linear plots of Figs. 3 and 4.

The slopes in Figs. 3 and 4 are similar, 0.72 for acetonitrile

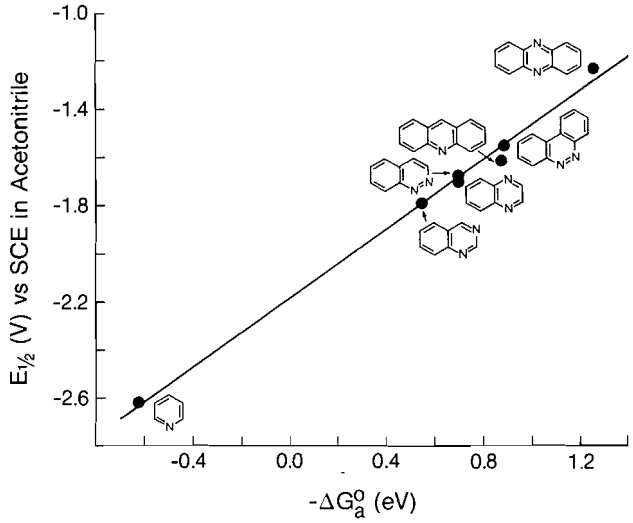

FIG. 3. Plots of $-\Delta G_a^0$ (gas phase) versus polarographic halfwave reduction potentials in acetonitrile from ref. 8. $-\Delta G_a^0$ (pyridine) based on EA of Nenner and Schulz (5).

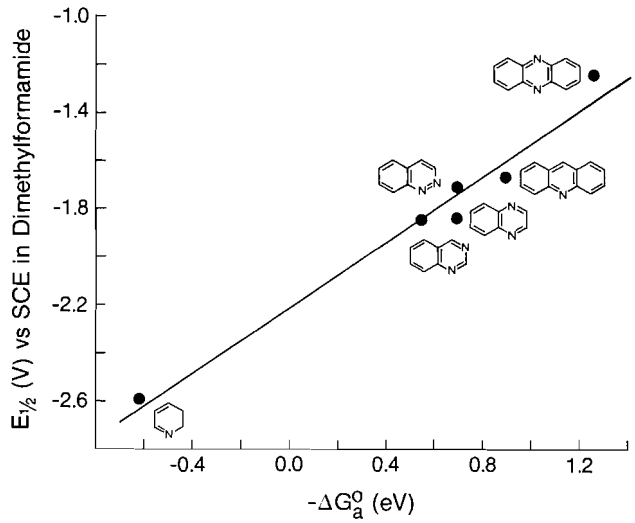

FIG. 4. Same as in Fig. 3 but $E_{1/2}$ for dimethylformamide (9).

and 0.69 for dimethylformamide. Less than unit slopes were observed in earlier comparisons (2–4) of reduction potentials with $-\Delta G_a^0$ values and are attributed to an approximately linear decrease of solvation exoergicity of the negative ions with increasing electron affinities ($-\Delta G_a^0$). The same explanation should hold also in the present cases. Increases in the electron affinities of the aza systems used are achieved by increasing delocalization of the negative charge and charge delocalization leads to decreasing exoergicity for the solvation of the ion.

In earlier work (2*d*, 2*c*, 11) approximate solvation free energies were evaluated with eq. [3]. For the origin of the equation and numerical constants see ref. 2*d*.

$$[3]\quad \Delta G_{sol}^0(B^-) - \Delta G_{sol}^0(B) = -108.6 - 23.06\,E_{1/2}(B) - \Delta G_a^0(B)$$

The numerical constant −108.6 is adjusted for answers in kcal/mol when $E_{1/2}$ is introduced in volts and ΔG_a^0 in kcal/mol. The reference electrode (SCE) potential is included in the constant. Substitution of available ΔG_a^0 and $E_{1/2}$, from ref. 8, for the

aza compounds leads to the solvation free energies in acetonitrile and dimethylformamide given in Table 3. Since the solvation energies of the neutral compounds, $-\Delta G^0$(B), are relatively much smaller than those for the negative ions, $-\Delta G^0(B^-)$ (2*d*, 2*e*, 11), it can be assumed that the $\Delta\Delta G^0$ data in Table 3 correspond largely to the solvation energies of the negative ions. The energies for acetonitrile and DMF are quite similar, a result that conforms to previous observations (2*d*, 2*e*, 11). The smallest ion, pyridine$^-$, has the highest solvation exothermicity (−63 kcal/mol). On the other hand the tricyclic phenzaine, for which the charge is also partially dispersed over two nitrogens, has the lowest solvation energy (−50 kcal/mol). These results can be compared with $\Delta\Delta G^0$ data for other radical anions: −59 kcal/mol (nitrobenzene) versus −48 kcal/mol (1,4-dinitrobenzene) in acetonitrile (11) and −54 kcal/mol (1,4-benzoquinone) versus −52 kcal/mol (9,10-anthraquinone) in acetonitrile (2*d*). The much smaller spread for the quinones can be attributed to the facts that most of the charge is expected to be on the electronegative oxygens and that the number of oxygens does not increase for this pair.

Spectroelectrochemical behaviour of the trinuclear $[Ru_3O(O_2CCH_3)_6(isonicotinamide)_3]$ cluster

HENRIQUE E. TOMA[1] AND CARLOS J. CUNHA

Instituto de Quimica, Universidade de São Paulo Caixa Postal 20780, São Paulo, SP, Brazil

Received January 19, 1989

HENRIQUE E. TOMA and CARLOS J. CUNHA. Can. J. Chem. **67**, 1632 (1989).

The $[Ru_3O(OOCCH_3)_6(isonicotinamide)_3]$ cluster exhibits reversible electrochemical and spectroelectrochemical behaviour in acetonitrile solutions, associated with a series of successive μ-oxo $Ru^{IV}Ru^{IV}Ru^{III}/Ru^{IV}Ru^{III}Ru^{III}/.../Ru^{II}Ru^{II}Ru^{II}$ redox couples with E^0 = 2.16, 1.21, 0.19, −0.98, and −1.4 V versus SHE. The metal-isonicotinamide and metal–metal charge-transfer transitions shift to lower energies as the oxidation states of the ruthenium ions decrease. In alkaline aqueous solution, the μ-oxo $Ru^{III}Ru^{III}Ru^{II}$ cluster can be reversibly reduced to the μ-oxo $Ru^{III}Ru^{II}Ru^{II}$ product (E^0 = −0.85 V); however, below pH 4, the reduction proceeds according to two successive steps, yielding $Ru^{II}Ru^{II}Ru^{II}$ species with loss of the central oxygen ion. These species can be reoxidized in the reverse potential scan, regenerating the μ-oxo $Ru^{III}Ru^{III}Ru^{II}$ complex.

Key words: ruthenium–acetate clusters, cluster spectroelectrochemistry, cluster electrochemistry, ruthenium–isonicotinamide complex, trinuclear cluster.

HENRIQUE E. TOMA et CARLOS J. CUNHA. Can. J. Chem. **67**, 1632 (1989).

En solutions dans l'acétonitrile, l'agrégat de $[Ru_3O(OOCCH_3)_6(isonicotinamide)_3]$ présente un comportement électrochimique et spectroélectrochimique réversible associé avec une série de couples rédox successifs μ-oxo $Ru^{IV}Ru^{IV}Ru^{III}/Ru^{IV}Ru^{III}Ru^{III}/.../Ru^{II}Ru^{II}Ru^{II}$ avec des E^0 = 2,16, 1,21, 0,19, −0,98 et −1,4 V vs SHE. Les transitions des transferts de charge métal–isonicotinamide et métal–métal se déplacent vers les énergies plus basses avec une diminution des états d'oxydation des ions ruthénium. En solution alcaline aqueuse, on peut réduire réversiblement l'agrégat μ-oxo $Ru^{III}Ru^{III}Ru^{II}$ en produit μ-oxo $Ru^{III}Ru^{II}Ru^{II}$ (E^0 = −0,85 V); toutefois, à des pH inférieur à 4, la réduction se produit par le biais de deux étapes successives et elle fournit des espèces $Ru^{II}Ru^{II}Ru^{II}$ avec une perte de l'ion oxygène central. Un balayage de potentiel inverse permet de réoxyder ces espèces et de régénérer le complexe μ-oxo $Ru^{III}Ru^{III}Ru^{II}$.

[Traduit par la revue]

Introduction

This work deals with the electrochemical and spectroelectrochemical behaviour of the $[Ru_3O(OOCCH_3)_6(isonic)_3]$ cluster (isonic = isonicotinamide) in aqueous and acetonitrile solutions. This complex is a typical example of ruthenium trinuclear cluster exhibiting a triangular structure strongly held by acetate bridges and a central μ-oxo bridge (1–6), as well as by extended metal–metal bonds (Fig. 1). A large number of oxidation states is accessible for this type of trinuclear cluster; however, detailed spectroelectrochemical studies have never been reported up to the present time.

Experimental section

The $[Ru_3O(OOCCH_3)_6(isonic)_3]A$ (A = PF_6^- or BF_4^-) cluster was synthesized according to the procedure previously reported in the literature for the 2-methyl pyrazine analogue (4). *Anal.* calcd. for $Ru_3C_{30}H_{36}N_6O_{16}PF_6$: C 30.4, H 3.1, N 7.1; found: C 28.9, H 3.1, N 7.4. *Anal.* calcd. for $Ru_3C_{30}H_{36}N_6O_{16}BF_4$: C 31.9, H 3.3, N 7.5; found: C 30.1, H 3.6, N 7.6.

Cyclic voltammetry was carried out with a Princeton Applied Research (PAR) instrument, consisting of a model 173 potentiostat and a model 175 universal programmer. Platinum (A = 0.09 cm^2) or glassy carbon electrodes (A = 0.23 cm^2) were employed for the measurements, using the conventional Luggin capillary arrangement with the Ag/AgCl (I = 1 mol dm^{-3} KCl) reference electrode (E^0 = 0.222 V vs, SHE) in aqueous solution (0.5 mol dm^{-3} KCl), or the $Ag/AgNO_3$ (0.01 mol dm^{-3}) reference electrode (E^0 = 0.503 V vs, SHE) (7) in acetonitrile solution containing 0.100 mol dm^{-3} tetraethylammonium perchlorate. A platinum wire was used as the auxiliary electrode.

The electronic spectra of the complexes were recorded on a Cary 17, or a Hewlett–Packard model HP 8451-A diode-array spectrophotometer. Spectral deconvolution was carried out using a local variation of the SPECSOLV (8) program. For the spectroelectrochemical measurements, the PAR-173 potentiostat was used in parallel with the Cary 17 or HP 8451-A spectrophotometers. A three-electrode system was designed for a rectangular quartz cell of 0.020 cm internal optical pathlength. A gold minigrid was used as a transparent working electrode, in the presence of a small Ag/AgCl reference electrode and a platinum auxiliary electrode.

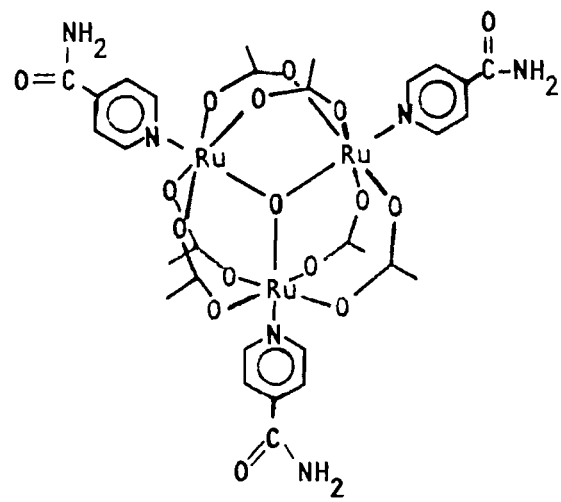

FIG. 1. The $[Ru_3O(OOCCH_3)_6(isonicotinamide)_3]$ cluster employed in this work.

Results and discussion

Cyclic voltammentry in acetonitrile solution

The cyclic voltammograms for the $[Ru_3O(OOCCH_3)_6(isonic)_3]$ cluster in acetonitrile exhibited five sucessive redox waves in the range of potentials from −1.5 to 2.3 V (Fig. 2). The electro-

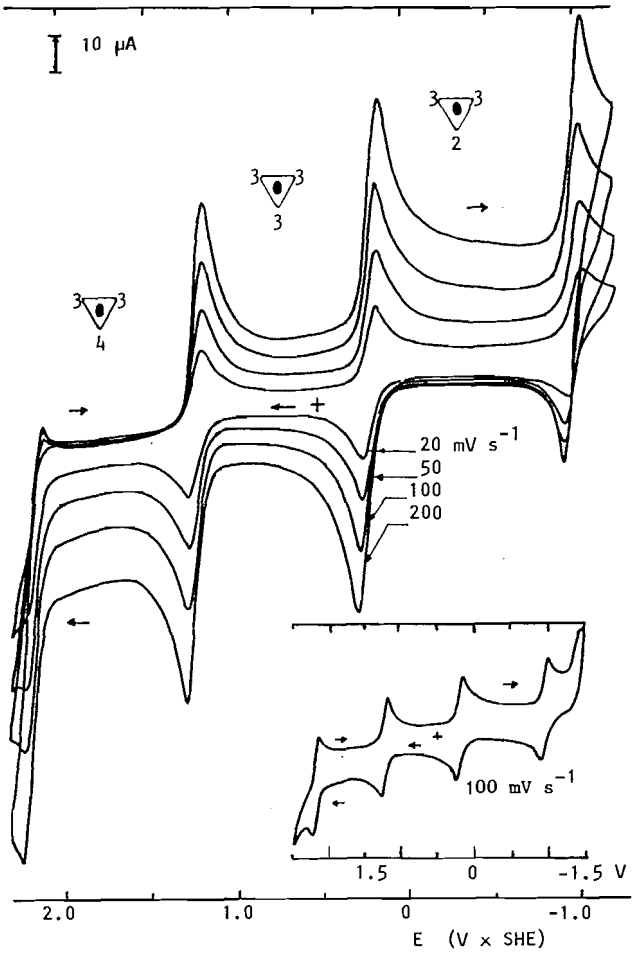

FIG. 2. Cyclic voltammograms of the $[Ru_3O(OOCCH_3)_6(isonic)_3]$ cluster (2 mmol dm^{-3}) obtained at several potential scan rates, in acentonitrile, $[NEt_4ClO_4] = 0.100$ mol dm^{-3}, 298 K, using a platinum working electrode; a fifth wave is shown at -1.4 V in the inserted voltammogram.

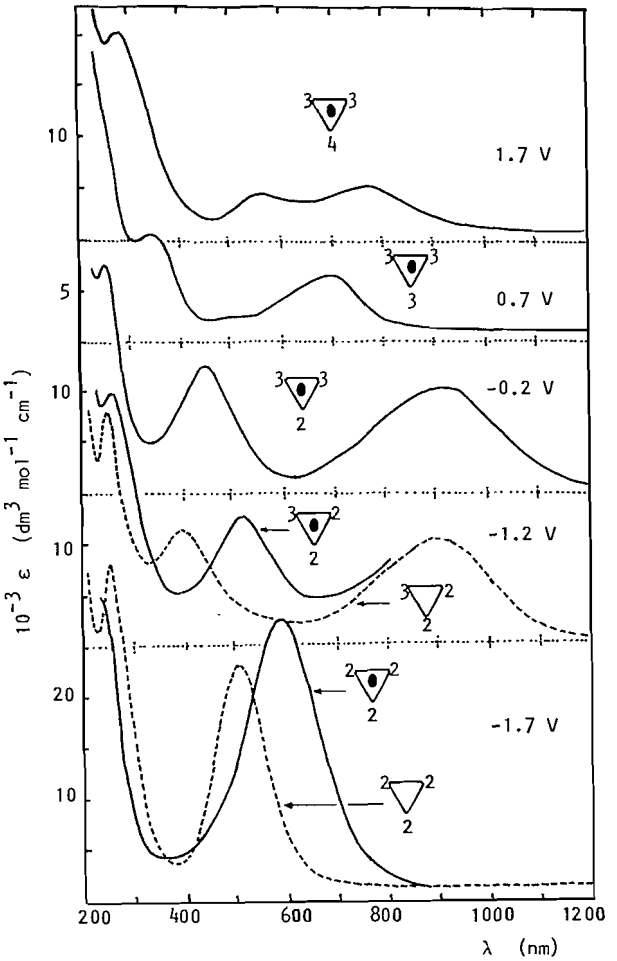

FIG. 3. Spectroelectrochemical behaviour of the $[Ru_3O(OOCCH_3)_6(isonic)_3]$ cluster in acetonitrile at several applied potentials (V versus SHE), $[NEt_4ClO_4] = 0.100$ mol dm^{-3} (acetonitrile), 298 K, showing the μ-oxo species (solid lines) before the loss of the central oxygen ion (---) which occurs below -1 V.

chemical behaviour was practically reversible (9), with the ratio of the anodic and cathodic peak currents very close to unity. The separation between the anodic and cathodic peak potentials was approximately 60 mV at low potential scan rates (e.g. 20 mV s^{-1}), increasing up to 70 mV at 200 mV s^{-1}. The assignment of the formal redox couples was proposed based on related examples from the literature (4):

$E^0(Ru^{IV}Ru^{IV}Ru^{III}/Ru^{IV}Ru^{III}Ru^{III}) = 2.16$ V vs. SHE
$E^0(Ru^{IV}Ru^{III}Ru^{III}/Ru^{III}Ru^{III}Ru^{III}) = 1.21$ V
$E^0(Ru^{III}Ru^{III}Ru^{III}/Ru^{III}Ru^{III}Ru^{II}) = 0.19$ V
$E^0(Ru^{III}Ru^{III}Ru^{II}/Ru^{III}Ru^{II}Ru^{II}) = -0.98$ V
$E^0(Ru^{III}Ru^{II}Ru^{II}/Ru^{II}Ru^{II}Ru^{II}) = -1.4$ V

The difference between the redox potentials of the $Ru^{IV}Ru^{IV}Ru^{III}/Ru^{IV}Ru^{III}Ru^{III}/.../Ru^{III}Ru^{II}Ru^{II}$ redox couples is as large as 1 V, indicating that the changes in the oxidation states of each metal ion have a pronounced influence on the electrochemical behaviour of the neighboring ions. This fact is consistent with a strong interaction between the ruthenium ions in the trinuclear centre.

Spectroelectrochemistry in acetonitrile solution

In order to characterize the chemical species involved in the electrochemical processes, spectroelectrochemical measurements were carried out for the $[Ru_3O(OOCCH_3)_6(isonic)_3]$ cluster in acetonitrile solutions, as illustrated in Fig. 3. The spectroelectrochemical behaviour was typically reversible, except for the μ-oxo $Ru^{III}Ru^{II}Ru^{II}$ and $Ru^{II}Ru^{II}Ru^{II}$ clusters, which can only be detected as transient species using a diode-array spectrophotometer. These species react with trace amounts of water, converting into the corresponding products without the oxygen bridge, as previously reported by Spencer and Wilkinson for the pyridine analogue (1, 2).

The assignment of the electronic transitions can be discussed based on the qualitative molecular orbital scheme proposed by Cotton and Norman (3) and by Baumann *et al.* (4) for the triangular Ru_3O centre, as shown in Fig. 4. The symmetry assumed is D_{3h}. The central oxygen atom is considered to be sp^2 hybridized leaving a single p orbital to interact with the d_{yz} orbitals of the three ruthenium ions, in order to generate one e'' and two a_2'' molecular orbitals. Metal–metal bonding involving the combination of the neighboring $Ru(d_{xz})$ orbitals leads to the $1e'$ and a_2' molecular orbitals. The remaining $d_{x^2-y^2}$ orbitals are separated by a considerable distance, but can interact weakly via a through-space interaction, giving rise to the $2e'$ and a_1' molecular orbitals.

According to the molecualr orbital scheme, the $[Ru_3O(OOCCH_3)_6(isonic)_3]^+$ complex can be formally de-

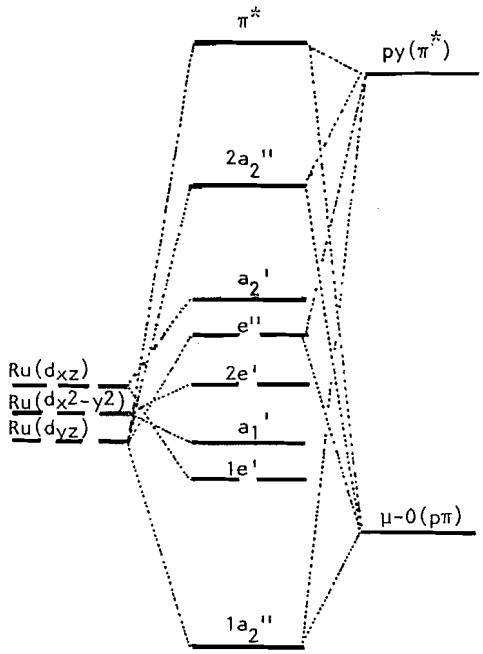

FIG. 4. Qualitative molecular orbital scheme for the $[Ru_3O(OOCCH_3)_6(isonic)_3]$ cluster in D_{3h} symmetry.

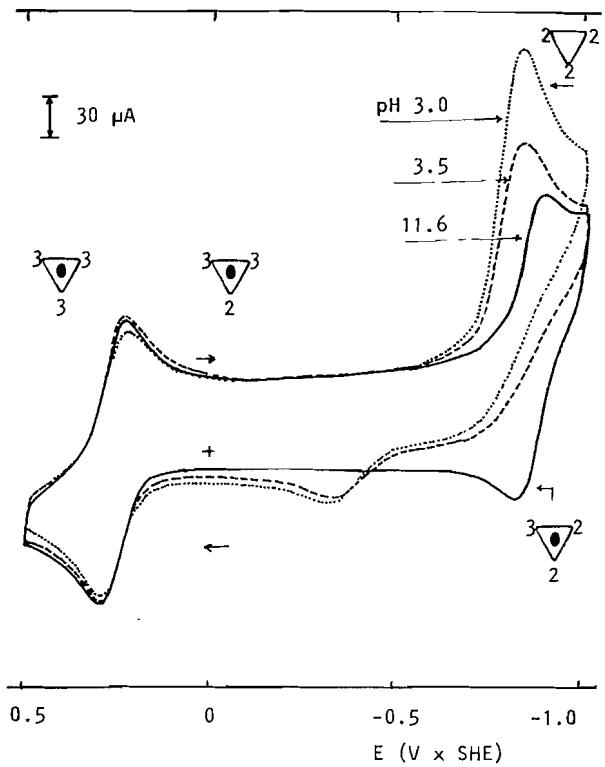

FIG. 5. Cyclic voltammogram of the $[Ru_3O(OOCCH_3)_6(isonic)_3]$ cluster (2.4 mmol dm^{-3}) in aqueous solution, obtained at several pHs, 100 mV s^{-1} KCl = 0.100 mol dm^{-3}, 298 K, using a glassy carbon working electrode.

scribed as $Ru^{III}Ru^{III}Ru^{III}$, exhibiting the electronic configuration $(1a_2'')^2(1e')^4(a_1')^2(2e')^4(e'')^4(a_2')$, leaving an empty $2a_2''$ orbital. Deconvolution of the absorption band at 710 nm leads to three Gaussian components at 707, 614, and 481 nm, ascribed to the symmetry-allowed $e'' \rightarrow a_2''$ and $a_1' \rightarrow a_2''$ transitions, and to the e' (1) $\rightarrow a_2''$ electric dipole-forbidden transition, as in the anaogous pyridine complex (4). The corresponding transitins in the $Ru^{IV}Ru^{III}Ru^{III}$, and $Ru^{III}Ru^{III}Ru^{II}$ clusters were located at 588, 481, 420 and 943, 797, and 632 nm, respectively. The optical energies display a linear correlation with the oxidation states, indicating a gradual increase of energy of the occupied metal d_π levels with the increasing number of electrons. In the case of the $Ru^{II}Ru^{II}Ru^{II}$ clusters, the d_π orbitals are completely filled and no metal–metal band is observed. In contrast, the $Ru^{IV}Ru^{III}Ru^{III}$ cluster exhibits three vacant levels, and an additional metal–metal band is observed at 778 nm, arising probably from the $1e' \rightarrow a_2'$ transition.

The isonicotinamide ligands have π^* orbitals of appropriate symmetry to interact with the ruthenium d_π molecular orbitals, particularly those of e'' and a_2'' symmetry if one assumes a planar configuration. The absorption band in the ultraviolet region, around 260 nm, is also observed in the free isonicotinamide ligand, and can be ascribed to π–π^* transitions in the aromatic ring. The band of intermediate energy is strongly sensitive to the oxidation states, moving from 310 nm in the $Ru^{IV}Ru^{III}Ru^{III}$ complex to 600 nm in the completely reduced $Ru^{II}Ru^{II}Ru^{II}$ form, with a great increase of intensity (Fig. 3). This band can be ascribed to a charge-transfer transition from occupied ruthenium(II) d_π orbitals of e'' symmetry, to the lowest unoccupied π^* orbitals of the isonicotinamide ligands.

Cyclic voltammetry in aqueous solution

Above pH 8, the waves associated with the μ-oxo $Ru^{IV}Ru^{III}Ru^{III}/Ru^{III}Ru^{III}/Ru^{III}Ru^{III}Ru^{II}/Ru^{III}Ru^{II}Ru^{II}$ redox couples are typically reversible (Fig. 5), with $E_{1/2}$ = 1.22, 0.27, and −0.85 V, respectively. The reduction of the $Ru^{III}Ru^{III}Ru^{II}$ cluster is pH dependent. Below pH 4, as one can see in Fig. 5, the cathodic peak moves from −0.88 to −0.84 V and becomes broader. The net charge involved is two times that observed above pH 4, being consistent with the transfer of two electrons, in a successive way, involving intermediarily a proton-dependent step. By reversing the potential scan, the starting μ-oxo bridged $Ru^{III}Ru^{III}Ru^{II}$ complex is regenerated. The electrochemical process can be repeated many times, in a cyclic way, with no evidence of decomposition of the trinuclear cluster.

Spencer and Wilkinson (1, 2) have shown that the $[Ru^{III}Ru^{III}Ru^{III}O(OOCCH_3)_6(pyridine)_3]^+$ cluster can be reduced by hydrogen at 2 atm pressure, in aqueous solution, in the presence of platinum oxide catalyst yielding the corresponding $Ru^{II}Ru^{II}Ru^{II}$ end product with loss of the central μ-oxo ion. This species can be oxidized, in a reversible way, without changing the overall structure of the triangular cluster.

Considering the elecrochemical behaviour in acetonitrile solutions, and the results reported by Spencer and Wilkinson (1), the pH-dependent step observed in aqueous solution can be associated with the elimination of the central oxygen ion in the μ-oxo $Ru^{III}Ru^{II}Ru^{II}$ species. Above pH 4 these μ-oxo bridged species are stable. However, as the pH decreases, the elimination of the central oxygen ion is favored, leading to an $Ru^{III}Ru^{II}Ru^{II}$ intermediate which undergoes further reduction to the $Ru^{II}Ru^{II}Ru^{II}$ end product, at the applied potentials. The overall process is illustrated in the scheme of Fig. 6. In the reverse scan, below pH 4, the reoxidation of the $Ru^{III}Ru^{II}Ru^{II}$ intermediate can be detected at approximately −0.3 V (Fig. 5). Scan rate dependence studies for the peak currents at −0.3 V were carried out at pH 4.20. The plots of the logarithm of the peak currents divided by $v^{1/2}$ (v = scan rate) against time were linear, leading to an observed rate constant of 0.02 s^{-1}. This

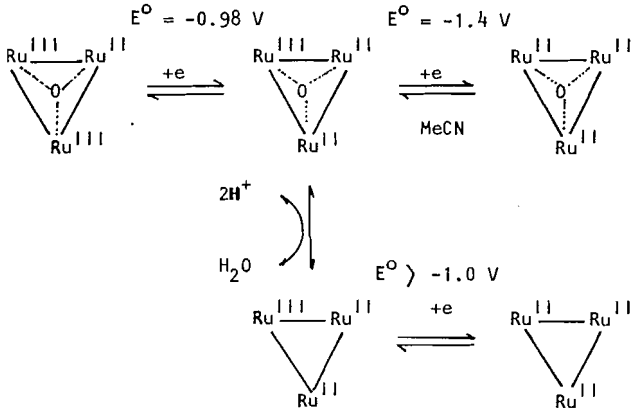

FIG. 6. Mechanistic scheme proposed for the electrochemical reduction of the $[Ru_3O(OOCCH_3)_6(isonic)_3]$ cluster in aqueous and acetonitrile solutions.

value provides a relative time scale for simple reoxidation versus oxide loss in the μ-oxo $Ru^{III}Ru^{II}Ru^{II}$ cluster.

According to the molecular orbital diagram of Fig. 4 the central oxygen ion plays an important role in the stabilization of the ruthenium(III) or (IV) species, by donating π-eletrons to the empty d_{yz} orbitals. When the cluster is completely reduced, the d_{yz} orbitals become saturated and this type of interaction is no more possible, facilitating the transfer of the oxygen ion to the proton donor species in the solvent.

WOLFGANG KLIEGEL, MAHMOOD TAJERBASHI, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **67**, 1636 (1989).

Details of the syntheses, physical properties, and crystal structures of the title compounds are reported. Crystals of 4-(*N*-methoxymethylimino)-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalene, **4**, are monoclinic, a = 9.8072(5), b = 9.6217(7), c = 19.6793(12) Å, β = 94.871(5)°, Z = 4, space group $P2_1/c$, and those of 4-diethylimino-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalene, **9**, are orthorhombic, a = 17.0593(7), b = 16.1372(6), c = 14.3753(5) Å, Z = 8, space group *Pbca*. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to R = 0.046 and 0.038 for 2198 and 2969 reflections with $I \geq 3\sigma(I)$, respectively. In both structures the *N*,*N*-dialkylsalicylamidate ligands coordinate the diphenylboron moieties via the phenolate oxygen and amide oxygen atoms, forming six-membered O—B—O chelate rings. The O(ar)—B, O(amide)—B, and mean C—B bond lengths (corrected for libration) are as follows: 1.490(3), 1.549(4), and 1.612 Å for **4** and 1.494(2), 1.550(2), and 1.612 Å for **9**.

Key words: crystal structures, boron compounds, organoboron compounds.

On rapporte les détails relatifs à la synthèse, à la détermination des propriétés physiques et aux structures cristallines des composés mentionnés dans le titre. Les cristaux du 4-(*N*-méthoxyméthylimino)-2,2-diphényl-1,3-dioxa-2-borata-1,2,3,4-tétrahydronaphtalène, **4**, sont monocliniques, groupe d'espace $P2_1/c$ avec a = 9,8072(5), b = 9,6217(7) et c = 19,6793(12) Å, β = 94,871(5)° et Z = 4 alors que ceux du 4-diméthylimino-2,2-diphényl-1,3-dioxa-2-borata-1,2,3,4-tétrahydronaphtalène, **9**, sont orthorhombiques, groupe d'espace *Pbca*, avec a = 17,0593(7), b = 16,1372(6) et c = 14,3753(5) Å et Z = 8. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R respectives de 0,046 et 0,038 pour 2198 et 2969 réflexions avec $I \geq 3\sigma(I)$. Dans chacune de ces structures, les ligands *N*,*N*-dialkyl-salicylamidates effectuent des coordinations avec les portions diphénylbores par le biais des atomes d'oxygène du phénolate et de l'amide en donnant lieu à la formation de cycles de chélates O—B—O à six chaînons. Les longueurs moyennes des longueurs des liaisons O(ar)—B, O(amide)—B et C—B (corrigées pour la libration) sont les suivantes: 1,490(3), 1,549(4) et 1,612 Å pour le compsé **4** et 1,494(2), 1,550(2) et 1,612 Å pour le composé **9**.

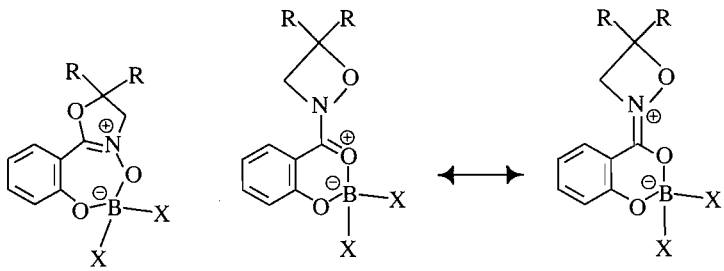
[Traduit par la revue]

Introduction



In the course of the analysis of the boron chelates **1** (X = C_6H_5 or F) an isomeric compound **2** was included in the discussion as a possible result from an intramolecular cyclization of a particular salicylhydroxamic acid derivative (1). Structure **2** would represent an example of the O—B—O boron chelate structure of an *N*,*O*-bisalkylated salicylhydroxamic acid. To obtain more information about this hitherto unknown type of compound, *N*-methoxy-*N*-methylsalicylamide **3** has been synthesized and reacted with oxybis(diphenylborane) to yield a crystalline product with the elemental composition indicating the expected diphenylboron chelate **4**, or the isomeric compounds **5** and **6**. Chelate **5**, with the hydroxylamine oxygen atom serving as ligand, would have the same ring size and sequence of ring-member atoms as found in **1** (1), whereas **6** would be an equal ring size "rotamer" of **4** having the hydroxylamine nitrogen atom bonded to boron. General considerations, in particular the well-known (2) predominant coordination of the carbonyl oxygen atom of amide groups to Lewis acids, favor the structure **4** with the carbonyl oxygen atom bonded to boron. Infrared and ^{1}H nmr spectra, however, did not allow for an unambiguous decision betwen the structures **4**, **5**, and **6**. Thus an X-ray crystallographic study was undertaken to resolve this ambiguity.

By replacing the weakly basic (pK_a = 4.75) (3) *N*,*O*-dimethylhydroxylamine component in **6** by the strong base (pK_a = 11.04) (3) diethylamine leading to **7**, the possibility of realizing such a N—B coordinated ring system via increasing the ligand basicity at the nitrogen site could be explored. Reaction of *N*,*N*-diethylsalicylamide **8** with oxybis(diphenylborane) gave crystals which show an elemental composition consistent with the structures **7** or **9**. N—B coordination as in **7** has already been discussed for products or intermediates in the reaction of *N*,*N*-dimethylsalicylamide with boric acid in a spectrophotometric study of complexing ability and ester formation of boric acid with different salicylamide derivatives (4). The alternative possibility of coordination with the amide carbonyl group, as formulated in structure **9**, was also mentioned in that work. N→B coordination has been suggested for derivatives of *o*-boronophenylacetamide (5). Some dialkylboron chelates of *N*,*N*-dimethyl- and *N*,*N*-diphenylamides of 3-oxobutyric acid

[a]Temperature 294 K, Enraf-Nonius CAD4-F diffractometer, Cu-K_α radiation ($\lambda_{K\alpha_1}$ = 1.540562, $\lambda_{K\alpha_2}$ = 1.544390 Å), nickel filter, takeoff angle 2.7°, aperture (2.0 + tan θ) × 4.0 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = C + 2B + [0.04(C - B)]^2$ (C = scan count, B = normalized background count), function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for R, R_w, and S are based on those reflections with $I \geq 3\sigma(I)$.

have been reported to form N—B bonds, and in one case an O—B bond between the amide group and boron (6). The diphenylboron chelate of (*N*-unsubstituted) salicylamide has been synthesized and studied by mass spectrometry (7), but the structure could not be assigned by this method.

Scale models of **7** demonstrate some steric strain (F-strain) between the dimethylamino and diphenylboron groups, but do not rule out a N—B bond for steric reasons. The ethyl groups, however, would each be fixed in a different neighborhood, which would appear in the ^{1}H nmr spectrum as separate ethyl signals. The free rotation of the diethylamino group about the N—C(O) bond in **9** should be hindered by the amide resonance ($a \leftrightarrow b$) and also could cause the two ethyl signals in the ^{1}H nmr spectrum to be inequivalent. There are some examples in the literature of boron chelates with *N*,*N*-dialkylamide groups displaying two different *N*-alkyl signals in their ^{1}H nmr spectra. This has been associated with the barrier to rotation about the amide C—N bond and therefore complexation through the amide oxygen atom (7–10). The signal separation appears at room temperature and has even been observed at temperatures ranging from 50 to 120°C (9). Compound **7**/**9**, dissolved in $CDCl_3$, produces only one sharp triplet (at 1.32 ppm) for both methyl groups, and one slightly broadened quartet (at 3.64 ppm) for both N—CH_2—groups at room temperature. The signals separate into two triplets and two quartets upon cooling to 3°C, indicating magnetically inequivalent *N*-ethyl groups. This temperature dependence is consistent with the structure **9** which would allow full rotation of the diethylamino group without breaking the N—B bond; but not conclusive because of the possibility of fast N—B bond breaking, *N*-inversion, rotation of the diethylamino group, and reformation of the N—B bond in **7**, similar to the processes believed to occur in cyclic N—B complexes of amines (11, 12). For clarification of this general problem, an X-ray crystallographic study was undertaken.

Experimental

4-(N-Methoxymethylimino)-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalene, ***4***

N-Methoxy-*N*-methylsalicylamide, prepared by acylation of *N*,*O*-dimethylhydroxylamine (13) (0.36 g, 2 mmol), is dissolved in ethanol, oxybis(diphenylborane) (0.35 g, 1 mmol) added, and the mixture heated for 10 min under reflux. Crystallization occurs upon concentration of the solution *in vacuo*. Colorless crystals (0.61 g, 88%) were collected, mp 133–134°C (from ethanol). Infrared (KBr): 1615 cm^{-1} (C=O / C=N$^+$). ^{1}H nmr (90 MHz, $CDCl_3$ / TMS): δ (ppm) = 3.41 (s, NCH_3), 3.43 (s, OCH_3), 6.44–7.91 (m, BPh_2 and C_6H_4). Mass spectrum (70 eV, 80°C): m/e (relative intensity) = 268 (100, M − C_6H_5),

236 (30), 133 (23). *Anal.* calcd. for $C_{21}H_{20}BNO_3$: C 73.07, H 5.84, N 4.06; found: C 73.03, H 5.85, N 3.97. Crystals suitable for X-ray analysis were obtained by recrystallization from absolute ethanol.

4-Diethylimino-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalene, 9

N,N-Diethylsalicylamide (0.57 g, 3 mmol) and oxybis(diphenylborane) (0.51 g, 1.5 mmol) are dissolved in ethanol and refluxed for 10 min. During concentration of the solution *in vacuo* crystallization occurs. Yield: 0.92 g (86%). mp 183°C (from ethanol). Infrared (KBr): 1615 cm^{-1} (C═O / C═N^+). ^1H nmr (90 MHz, $CDCl_3$ / TMS, 36°C): δ (ppm) = 1.32 (t, J = 7 Hz, 2 CH_3), 3.64 (q, J = 7 Hz, 2 NCH_2), 6.50–7.95 (m, BPh_2 and C_6H_4); ($CDCl_3$ / TMS, 3°C): δ (ppm) = 1.35 and 1.37 (2 t, J = 7 Hz, 2 CH_3), 3.59 and 3.67 (2 q, J = 7 Hz, 2 NCH_2), 6.50–7.92 (m, BPh_2 and C_6H_4). Mass spectrum (70 eV, 100°C): m/e (relative intensity) = 280 (100, M − C_6H_5), 121 (14). *Anal.* calcd. for $C_{23}H_{24}BNO_2$: C 77.33, H 6.77, B 3.03, N 3.92; found: C 77.54, H 6.81, B 3.13, N 3.81. Crystals suitable for X-ray analysis were obtained by recrystallization from absolute ethanol.

X-ray crystallographic analyses of 4 and 9

Crystallographic data for the two compounds appear in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ / λ values for 25 reflections (2θ = 60–91° for **4** and 80–92° for **9**) measured with Cu-$K\alpha_1$ radiation. Data were corrected[3] for Lp, absorption, and, for **4**, non-uniform decay (14). Both structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps and those of the hydrogen atoms from subsequent difference Fourier syntheses. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms with isotropic thermal parameters; neutral atom scattering factors and anomalous dispersion corrections were taken from ref. 15. Isotropic Type I extinction corrections (Thornley-Nelmes definition of mosaic anisotropy with a Lorentzian distribution) were applied in both cases (16–18), the final values of g being 0.25(8) × 10^4 for **4** and 3.27(12) × 10^4 for **9**. Final positional and anisotropic thermal parameters for the non-hydrogen atoms are given in Tables 2 and 7[4], respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data[4].

The thermal motion for both structures has been analysed in terms of the TLS model (19). The rms errors in the temperature factors σU_{ij} (derived from the least-squares analyses) are 0.0019 and 0.0011 Å^2 for **4** and **9**, respectively. The structural subunits PhB and the fused-ring system plus O(3) and N were separately analysed for **4** (rms ΔU_{ij} = 0.0025–0.0026 Å^2); PhB and the fused-ring system plus N, C(8), and C(10) for **9** (rms ΔU_{ij} = 0.0016–0.0022 Å^2). The appropriate bond lengths have been corrected for libration (19, 20). Bond lengths, bond angles, and intra-annular torsion angles are listed in Tables 3–5, respectively. Hydrogen atom parameters (Table 6), bond lengths and angles involving hydrogen, and a complete listing of torsion angles (Tables 8–10) have been deposited.[4]

Results and discussion

Both diphenylboron chelates (Fig. 1) show O—B coordination involving the amide carbonyl oxygen atom as depicted by canonical formulae **4** and **9**. The molecular geometries of the two compounds are very similar, thus there are no significant structural differences which would indicate amide groups of different basicity in the two boron complexes. The crystal structure of **4** consists of well-separated molecules, the only intermolecular contact between non-hydrogen atoms shorter than 3.6

Å being O(1)···C(8) ($1 - x$, $1/2 + y$, $1/2 - z$) = 3.268(5) Å. The shortest intermolecular contacts between non-hydrogen atoms in the structure of **9** are C(3)···C(3) ($-x$, $-y$, $-z$) = 3.328(4) Å and C(14)···O(1) (x, $1/2 - y$, $z - 1/2$) = 3.484(2) Å, the latter possibly representing a weak C—H···O interaction (H···O = 2.53(2) Å, C—H···O = 163(2)°). Each of the structures also contains intramolecular C—H···O interactions (for **4**: C(3)—H(3)···O(3), C(8)—H(8a)···O(2), and C(8)—H(8b)···O(2); C···O = 2.813(5), 2.677(5), and 2.677(5) Å; H···O = 2.17(3), 2.36(5), and 2.38(4) Å; C—H···O = 125(2), 98(4), and 80(3)°; respectively; and for **9**: C(10)—H(10b)···O(2) and C(19)—H(19)···O(2), C···O = 2.606(2) and 2.882(4) Å, H···O = 2.26(2) and 2.47(2) Å, C—H···O = 97(1) and 106(2)°, respectively).

The four substituents about the amide C—N bond are qualitatively coplanar in both compounds (mean and maximum deviations from the six-atom mean planes are 0.067 and 0.215(5) Å for **4**, 0.054 and 0.133(2) Å for **9**), consistent with a reasonable degree of double bond character for the C—N bond. The π-bond order of the amide C—N bonds in both **4** and **9** can be estimated as 0.75 (21) or 0.65 (22) from plots of bond length vs. MO π-bond order. The double bond character of the amide C—O bonds is reduced to about 50% in both **4** and **9** (1.294(3) and 1.297(2) Å, respectively)[5], as derived from the plot of C—O bond length vs. π-bond order reported for compounds having NC/CO π-systems (22). The resonance structures **4**(*b*) and **9**(*b*), therefore, are the most important contributors to the overall mesomeric systems. The nomenclature employed for these compounds reflects this point.

Another resonance structure (*c*) for both compounds **4** and **9** must also be considered on the basis of the observed molecular geometry. The C(3)—C(4) and C(5)—C(6) bonds (1.369–1.378 Å) are shorter than the C(2)—C(3), C(2)—C(7), and C(6)—C(7) bonds (1.395–1.413 Å) within the aromatic ring systems. The C(7)—O(1) phenolate bonds (1.342 and 1.346 Å) are relatively short when compared to average C(ar)—O bond lengths of 1.364 Å in phenols, 1.370–1.381 Å in phenolate ethers, and 1.401 Å in phenolate esters (23); and the C(1)—C(2), C(ar)—C(amide) bonds (1.457 and 1.474 Å) are shorter than the average value of 1.503 Å reported for this type of bond (23).

[5]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and those involving the boron atom are compared with similarly treated (19) distances unless otherwise stated.

The contribution of the resonance structures (*c*) to the overall structures of **4** and **9** could also explain the results of the variable temperature ^{1}H nmr spectra of **9** which show a lower barrier to rotation about the amide C—N bond than observed for other boron-chelated *N*,*N*-dialkylamide functions (7–12). A similar lowering of the rotational barrier about the amide C—N bond has been reported for both *N*,*N*-dimethyl- (24) and *N*,*N*-diethylsalicylamide (25). This has been attributed to the effect of an intramolecular hydrogen bond in a hydrogen-bridged chelate structurally comparable to **4** and **9**. In these boron chelates the diphenylborenium ion (Ph_2B^+) replaces H^+ in the intramolecular hydrogen bridge which is generally believed to exist in solutions of *N*,*N*-dialkylsalicylamides (26). It is not known whether any *N*,*N*-dialkylsalicylamides contain intramolecular hydrogen bonds in the solid state. The structure of salicylamide itself (27) does contain an intramolecular hydrogen bond from the phenolic OH group to the amide carbonyl oxygen atom, whereas crystalline salicylhydroxamic acid (28) and other *N*-monosubstituted salicylamides (29) have the reverse conformation with intramolecular N—H···O hydrogen bonds between the amide NH and phenol oxygen atoms. The amide C—N bond is shortest in salicylamide (27), 1.309 Å; compared with corresponding distances of 1.316 Å in salicylhydroxamic acid (28), 1.344 Å in salicylanilide (29*a*), and 1.359 Å in a substituted salicylhydrazide (29*b*).

In each compound, **4** and **9**, the O—B bond from the carbonyl oxygen atom to boron is about 0.06 Å longer than that from the phenolate oxygen atom. This is consistent with a corresponding

difference of 0.07 Å observed in the structure of the diphenylboron chelate of salicylaldehyde (30). The difference between the O—B distances suggests stronger donation from the phenolate oxygen atom, possibly by O—B $pp(\pi)$ interaction as symbolized by the resonance form (*d*). In consideration of these observations, the delocalization of electron density in **4** and **9** is best summarized by the overall mesomeric general formulae (*a*–*d*) (ignoring interactions between the boron atom and the *B*-phenyl groups). The B—C(phenyl) distances are similar to those reported for other diphenylboron O—B—O chelates. The small differences between the B—C distances in **4** and **9** (0.009 and 0.012 Å, respectively) are typical for Ph_2B chelates having (pseudo)axial and (pseudo)equatorial *B*-phenyl substituents (30–36) and were also observed in the structure of **1** (X = Ph) (1). As observed in every case, the pseudo-axial B—C bond is longer than the pseudo-equatorial B—C bond. The mean C—B / mean O—B bond length ratios of 1.061 for **4** and 1.059 for **9** are near the average value of 1.059 observed for other "Ph_2BO_2" chelates containing six-membered chelate rings (refs. 36, 37, and references therein), indicating an intermediate overall binding strength of the *O,O*-chelating ligand to the Ph_2B moiety.

The reaction of *N,N'*-diethyloxalohydroxamic acid with oxybis(diphenylborane) yields the title compound. Crystals of 4,8-diethyl-2,2,6,6-tetraphenyl-1,3,5,7-tetraoxa-4,8-diazonia-2,6-diborata-1,2,3,5,6,7-hexahydronaphthalene are monoclinic, $a = 14.3405(9)$, $b = 14.3053(5)$, $c = 14.9301(8)$ Å, $\beta = 116.136(4)°$, $Z = 4$, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.038$ and $R_w = 0.038$ for 3501 reflections with $I \geq 3\sigma(I)$. The molecule has a novel bis-six-membered binuclear chelate structure, the Ph_2B moieties each being coordinated by (N)O and (C=)O oxygen atoms from different hydroxamate groups. The mean libration-corrected bond distances (C=)O—B, 1.587 Å, (N)O—B, 1.511 Å, and B—C, 1.602 Å, represent the weakest overall binding strength of an *O,O*-chelating ligand with respect to the Ph_2B moiety yet observed for a six-membered O—B—O chelate.

Key words: crystal structure, boron compound, organoboron compound.

WOLFGANG KLIEGEL, MAHMOOD TAJERBASHI, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **67**, 1644 (1989).

La réaction de l'acide *N,N'*-diéthyloxalohydroxamique avec l'oxybis(diphénylborane) fournit le composé mentionné dans le titre. Les cristaux du 4,8-diéthyl-2,2,6,6,-tétraphényl-1,3,5,7-tétraoxa-4,8-diazonia-2,6-diborata-1,2,3,5,6,7-hexahydronaphtalène sont monocliniques, groupe d'espace $P2_1/n$, avec $a = 14,3405(9)$, $b = 14,3053(5)$ et $c = 14,9301(8)$ Å, $\beta = 116,136(4)°$ et $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0,038$ et $R_w = 0,038$ pour 3501 réflexions avec $I \geq 3\sigma(I)$. La molécule possède une nouvelle structure de chélate binucléaire à deux cycles à six chaînons dans laquelle les portions Ph_2B sont toutes les deux coordonnées à des atomes d'oxygène (N)O et (C=)O de groupements hydroxamates différents. Les longueurs moyennes, corrigées pour la libration, des liaisons (C=)O—B, 1,587 Å, (N)O—B, 1,511 Å et B—C, 1,602 Å correspondent à la plus faible force globale observée jusqu'à maintenant pour la liaison d'un ligand chélatant-*O,O* par rapport à la portion Ph_2B d'un chélate à six chaînons O—B—O.

Mots clés : structure cristalline, composés du bore, composé du organobore.

[Traduit par la revue]

Introduction

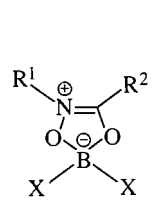
In the course of our investigation of hydroxamic acids as bidentate ligands in the formation of boron chelates (1–5), the general structures **1** and **2** have been established by X-ray structure analysis and support the *B,N*-betaine formulation as rationale for these five-membered chelate rings. Blocking of the carbonyl oxygen atom of the hydroxamate function by alkylation, in addition to offering an intramolecular phenolate ligand, led us to the seven-membered chelate type **3** (R + R = —$(CH_2)_5$—), the structure of which has been established by an X-ray crystallographic analysis (6). The simplest bishydroxamic acids are derived from oxalic acid and are of interest because of the two neighbouring hydroxamate functions. The literature reports some *N,N*-diaryloxalohydroxamic acids as coordinating ligands for organotin (7) and ruthenium compounds (8). *N,N*-Dialkyloxalohydroxamic acids and chelates thereof, to our knowledge, have not been reported.

From a series of newly synthesized (9) *N,N*-dialkyloxalohydroxamic acids, we chose the *N,N*-diethyl derivative **4** and reacted it with oxybis(diphenylborane). The crystalline reaction product has the elemental composition of a bis(diphenylboron) chelate. Infrared and ^1H nmr spectra are consistent with a two-fold chelate formation, but cannot differentiate between structure **5**, having the "normal" hydroxamate complex arrangement (10), and structure **6**, displaying an alternative binuclear chelate system with both hydroxamate groups mutually contributing one oxygen donor to each of the adjacent six-membered chelate rings.

Structure **5** is derived from the well-established (1–5) formula **1** for boron chelates and is consistent with the formulation of the binuclear ruthenium complex of *N,N*-diphenyloxalohydroxamic acid (8) which, however, is not based on solid evidence. Structure **6** would be the very first example of this type of hydroxamate complex formation. The third possible isomer, **7**, incorporates a five-membered boron chelate of the type well known from the reaction of ethanediamides with bromodimethylborane (11), and a seven-membered ring resembling that in **3**. Although **7** seems unlikely on the basis of symmetry arguments, it cannot be definitively excluded from consideration. In order to resolve any ambiguities, an X-ray crystallographic analysis was undertaken.

Experimental

*4,8-Diethyl-2,2,6,6-tetraphenyl-1,3,5,7-tetraoxa-4,8-diazonia-2,6-diborata-1,2,3,5,6,7-hexahydronaphthalene, **6***



N,N'-Diethyl-*N,N'*-dihydroxyethanediamide, **4** (9) (0.18 g, 1 mmol), and oxybis(diphenylborane) (0.35 g, 1 mmol) are dissolved in ethanol and refluxed for 20 min. Crystallization starts during concentration of the reaction mixture *in vacuo*. After complete crystallization,

0.44 g (86%) of colorless crystals are obtained; mp 173–174°C (from ethanol). Infrared (KBr): 1625 cm^{-1} (C=O / C=N$^+$). ^{1}H nmr (90 MHz, $CDCl_3$ / TMS): δ (ppm) = 1.31 (t, J = 6 Hz, 2 CH_3), 3.92 (q, J = 6 Hz, 2 NCH_2), 7.20–7.90 (m, 2 BPh_2). *Anal.* calcd. for **6**: C 71.47, H 6.00, N 5.55; found: C 71.25, H 5.94, N 5.36. Crystals suitable for X-ray analysis were obtained by stepwise (approximately 0.5°C / h over 2–3 days) cooling of a saturated ethanol solution from 50°C to 10–20°C using a cryostat with electronic temperature control.

X-Ray crystallographic analysis

A crystal bounded by the six faces (followed by the distances in mm between parallel faces): {0 1 1}, 0.28–0.37, and {2 0 −1}, 0.37, was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ / λ values for 25 reflections (2θ = 55–80°) measured on a diffractometer with Cu-$K\alpha$ radiation (λ($K\alpha_1$) = 1.540562, λ($K\alpha_2$) = 1.544390 Å). Crystal data at 22°C are:

$C_{30}H_{30}B_2N_2O_4$ fw = 504.20

Monoclinic, a = 14.3405(9), b = 14.3053(5), c = 14.9301(8) Å, β = 116.136(4)°, V = 2749.6(3) Å^3, Z = 4, ρ_c = 1.218 Mg m^{-3}, F(000) = 1064, μ(Cu-$K\alpha$) = 6.0 cm^{-1}. Absent reflections: $h0l$, $h + l$ odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/n$ (C_{2h}^5, No. 14).

Intensities were measured with nickel-filtered Cu-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.2–10.0° min^{-1} over a range of (0.80 + 0.14 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 3600 s throughout the data collection, showed only small (<3.5%) random variations. Of the 5642 independent reflections measured and processed,[3] 3501 (62.1%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.03(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of all 38 non-hydrogen atoms being determined from an E-map. After refinement of the non-hydrogen atoms with anisotropic thermal parameters, the hydrogen atoms were positioned from a difference Fourier synthesis and were subsequently refined with isotropic thermal parameters. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 12. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over

ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of 464 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type 1 extinction correction (Thornley-Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (13–15). The final value of g was $1.42(6) \times 10^4$. Convergence was reached at $R = 0.038$ and $R_w = 0.038$ for 3501 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.016 and 0.35σ respectively. The mean error in an observation of unit weight was 0.852. A final difference map showed maximum fluctuations of −0.17 to +0.18 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 6,[4] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (16). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0018 Å^2. The structural subunits PhB and the central fused-ring system plus the α-carbons of the *N*-ethyl groups were separately analysed (rms ΔU_{ij} = 0.0019–0.0029 Å^2). The appropriate bond distances have been corrected for libration (16, 17), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; bond angles appear in Table 3 and intra-annula torsion angles in Table 4. Hydrogen atom parameters (Table 5), bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 7–9) have been deposited.[4]

Results and discussion

The crystal structure of 4,8-diethyl-2,2,6,6-tetraphenyl-1,3,5,7-tetraoxa-4,8-diazonia-2,6-diborata-1,2,3,5,6,7-hexahydronaphthalene consists of well-separated molecules, the shortest intermolecular distances between non-hydrogen atoms being C(2)···C(17) $(1 - x, -y, 1 - z)$ = 3.497(4) Å. The molecule (Fig. 1) has the bis-six-membered binuclear chelate structure **6** rather than the "normal" bishydroxamate structure **5**. To the best of our knowledge, this is the first fully characterized example of this type of hydroxamate complex, involving a neighboring hydroxamate ligand in chelate formation. Other examples of metal complexes of hydroxamic acids with a second ligand function adjacent to the hydroxamic acid group involve *N*-unsubstituted hydroxamate derivatives: Ni(II) (18) and Cu(II) complexes (19) of glycinehydroxamic acid exhibit chelation by the amide nitrogen and α-amino nitrogen atoms while other metal chelates of glycinehydroxamic acid form "normal" hydroxamate complexes (20).

In structure **6** the conformation of the oxalohydroxamic acid moiety differs from that of free oxalohydroxamic acid in the crystalline state (21), which has the *N*-hydroxy group and the carbonyl oxygen in a *cis* orientation with respect to the HO—N—C—O segment of the molecule **8**. The formulation of **6** as a cyclic *B*,*N*-betaine is justified by the considerable double bond character of the C=N bond. The mean C=N distance[5] of 1.301 Å is very similar to the uncorrected value of 1.302 Å in the alkylidene iminium ion $Me_2C{=}NMe_2^+$ (22). From plots of bond lengths vs. π-bond order, the MO π-bond order of the C=N bonds is estimated as 0.8 (22) or 0.75 (23). The hydroxamate C=N bond lengths in **1** (X = F), 1.298 Å, **1** (X = C_6H_5), 1.300 Å, **3** (X = F), 1.294 Å, and **3** (X = C_6H_5), 1.306 Å, are very similar to that in **6**. Compared with uncorrected C=N bond lengths of 1.328 Å (24), 1.332 Å (25), and 1.374 Å (26) reported for free *N*-alkylhydroxamic acids, the shorter C=N bonds observed for **6** and **1** (1, 2) are indicative of increased

[4]The structure factor table, Table 6 (anisotropic thermal parameters), and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[5]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (16) distances unless otherwise stated.

double bond character in the boron chelates. The nitrogen lone pair delocalization into the carbonyl function, increasing the negative charge density at the carbonyl oxygen atom, has also been discussed for Fe(III) complexes of *N*-alkylhydroxamic acids (27).

The carbonyl C=O bond, however, still retains appreciable double bond character. The π-bond order of the C=O bond in **6** (mean 1.288 Å) can be estimated as 0.55 from a plot of π-bond order vs. C=O bond length for N—C/C—O containing π-systems (23). This is less double bond character than found in the C=O bonds of free *N*-alkylhydroxamic acids with uncorrected C—O bond lengths of 1.241 Å (24) and 1.246 Å (25). The unsubstituted oxalohydroxamic acid **8** has uncorrected C—O bond lengths of 1.232 Å (21). The C—N and C—O bond distances in **6** are similar to those reported for dimethylboron O—B—N and O—B—O chelates of *N*-substituted diamides of oxalic acid (11). The short C—N and C—O bonds in these compounds were also ascribed to significant double bond character. The shorter and stronger C—N bond in amide functions has recently been discussed in terms of a higher electron population at the nitrogen atom, and a more ionic character of the C—N bond in the planar conformers, deduced from calculations of the structures and energies of formamide rotamers (27).

The nearly planar arrangement of both hydroxamate moieties in **6**, having partial double bond character in both the C—N and C—O bonds, allows an overall formulation **9** for the mesomeric structure of **6**. This is consistent with the central C(1)—C(2) bond length of 1.492 Å, corresponding to a C(sp^2)—C(sp^2) single bond. This distance is comparable to the sample median of 1.491 Å for *o*-substituted biphenyls (28) but shorter than the corresponding uncorrected distances of 1.526 Å in oxalohydroxamic acid (21) and 1.542 Å in oxalic acid (29). In spite of the shorter C—C bond in **6**, the two amide groups are not coplanar (angle between normals to the mean amide planes = 27.9°). This represents a twisting of the hydroxamate moieties with respect to the C(1)—C(2) bond, the mean O—C—C—N torsion angle being −24.7°.

The relatively weak donation from the carbonyl oxygen atom to boron, symbolized in formula **9** by a dotted line, gives rise to an unusually long O—B bond (mean 1.587 Å). This is the

For personal use only.

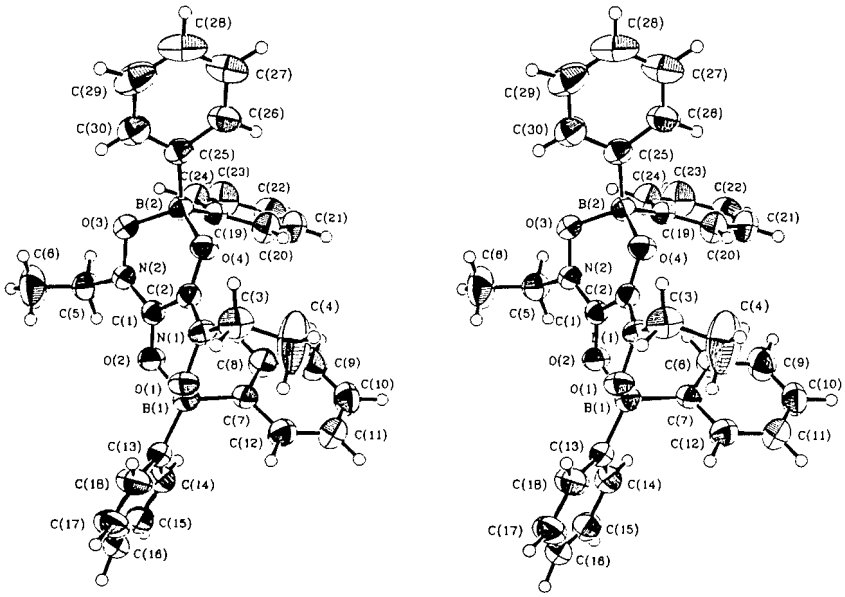

FIG. 1. Stereoscopic view of 4,8-diethyl-2,2,6,6-tetraphenyl-1,3,5,7-tetraoxa-4,8-diazonia-2,6-diborata-1,2,3,5,6,7-hexahydronaphthalene; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

longest O—B distance yet observed for a six-membered diphenylboron chelate; however, longer O—B distances of the type (C=)O—B have been reported for the five-membered diphenylboron chelates (maltolato)diphenylboron (30), 1.600 Å, and (3-hydroxy-2-methyl-4-pyridinonato)diphenylboron (31), 1.650 Å. The other O—B bond in **6**, (N)O—B (mean 1.511 Å), is shorter by an average of 0.076 Å. Differences between O—B bond lengths in O—B—O chelates of Ph_2B where one of the bonds is of the type (C=)O—B range from 0.067 to 0.153 Å (30–32). The mean C—B / mean O—B bond length ratio of 1.035 for **6** is the smallest yet reported for a six-membered O—B—O chelate of diphenylboron (33), thus the overall binding strength of the *O,O*-chelating ligand with respect to the Ph_2B moiety is the weakest yet observed. The mean N—O distance in **6** (1.383 Å) is longer than the corresponding distances of 1.331–1.343 Å in the five-membered chelates **1** (1, 2) and **2** (5), and 1.369 Å in the seven-membered chelate **3** (6), but shorter than the uncorrected distance of 1.388 Å in free oxalohydroxamic acid (21). The two six-membered chelate rings in **6** have slightly distorted 1,3-diplanar ("twist-envelope") conformations (see Table 4).

Based on the ease of preparation of five-membered boron chelates of *N*-substituted hydroxamic acids (**1** and **2**) (1–5), the formation of **6** (instead of **5**) could be due to steric factors. From molecular scale models it can be seen that there is less strain in the six-membered ring isomer. Thus **6** would be the thermodynamically preferred structure, compared with both **5** and **7**, the latter showing some strain in the five-membered ring but none in the seven-membered ring.

Synthesis and crystal structure of an octahedral nickel(II) complex derived from pentaerythrityl tetraamine

A. McAuley,[1] S. Subramanian, and T. W. Whitcombe
Department of Chemistry, University of Victoria, P.O. Box 1700, Victoria, B.C., Canada V8W 2Y2

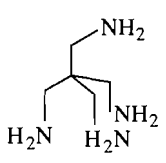
Received July 25, 1988[2]

A. McAuley, S. Subramanian, and T. W. Whitcombe. Can. J. Chem. **67**, 1650 (1989).

The Ni(II) complex, $Ni(Htam)_2^{4+}$ (tam = pentaerythrityl tetraamine), has been prepared under controlled conditions. In this ion, three of the four amino groups of each ligand are coordinated to yield an octahedral structure which shows tetragonal and trigonal distortion. The fourth amino group is protonated in each case and binds strongly to the counter ion SO_4^{2-}. The crystal structure (triclinic, $P\bar{1}$, a = 8.913(3), b = 9.775(2), c = 7.505(3), α = 102.61(4)°, β = 106.28(4)°, γ = 96.40(3)°) has been refined, converging to final values of R = 0.0347 and R_w = 0.0386. The three dimensional nature of the hydrogen bonding in the crystal structure has been described. Differences in Ni—N bond lengths are observed. A transient nickel(III) species is generated chemically or electrochemically. The esr spectrum is consistent with a low spin d^7 centre and is axial in nature.

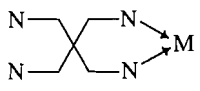
Key words: nickel, pentaerythrityl tetraamine, hydrogen bonding, oxidation.

A. McAuley, S. Subramanian et T. W. Whitcombe. Can. J. Chem. **67**, 1650 (1989).



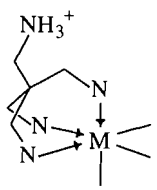
Opérant dans des conditions contrôlées, on a préparé le complexe de Ni(II), $Ni(Htam)_2^{4+}$ (tam = pentaérythrityl tétraamine). Dans cet ion, trois des quatre groupements aminés de chacun des ligands sont coordonnés pour donner une structure octaédrique qui présente une distorsion tétragonale et trigonale. Dans chaque cas, le quatrième groupement aminé est protoné et il se lie fortement au contre-ion SO_4^{2+}. On a affiné la structure cristalline (triclinique, $P\bar{1}$, a = 8,913(3), b = 9,775(2) et c = 7,505(3) Å, α = 102,61(4), β = 106,28(4) et γ = 96,40(3)°) jusqu'à des valeurs finales de R = 0,0347 et R_w = 0,0386. On décrit la nature tridimensionnelle des liaisons hydrogènes dans la structure cristalline. On a observé des différences dans les longueurs des liaisons Ni—N. Il y a génération chimique ou électrochimique d'une espèce transitoire de Ni(III). Le spectre rpe est en accord avec un centre d^7 de faible spin et de nature exiale.

Mots clés : nickel, pentaérythrityl tétraamine, liaison hydrogène, oxydation.



[Traduit par la revue]

Introduction



Although the ligand 2,2-bis(aminomethyl)-1,3-diaminopropane (**I**) (tam), was first prepared fifty years ago (1), there have been relatively few reports on its coordination chemistry. This is surprising, since several coordination geometries are possible and have been postulated. In the case of complexes involving nickel(II) and copper(II), the potential binucleating ability of the ligand has been described (2), leading to the formation of polymeric entities with extended square planar arrays. In such arrangements, two primary amines would be coordinated to each metal centre (**II**). In general, such species are rather ill characterised (2). For example, complexes of the metals described are viewed as isostructural from powder patterns and the polymeric species $\{[Ni(tam)_{1.5}]Cl_2\}_x$ was considered as exhibiting a three dimensional array of octahedral nickel(II) centers. The magnetic moment was consistent with such an observation. However, preparation of an aquated form provided a species with a significantly different uv–visible spectrum. An alternate perspective suggests that three of the four amine groups be disposed such that three primary nitrogens could occupy the face of an octahedron, leading to six-coordinate bis-complexes $M(HL_2)^{n+}$ in which one of the amine moieties is protonated (**III**). Such a configuration has been proposed from solution studies (3). Free ligands of this type are "globular" and in the case of the fully protonated amines, $(H_4tam)^{4+}$, crystallographic studies have been made for both the chloride and sulfate salts (4) in an investigation of hydrogen bonding associated with a compact, quadruply charged cation.

I

II

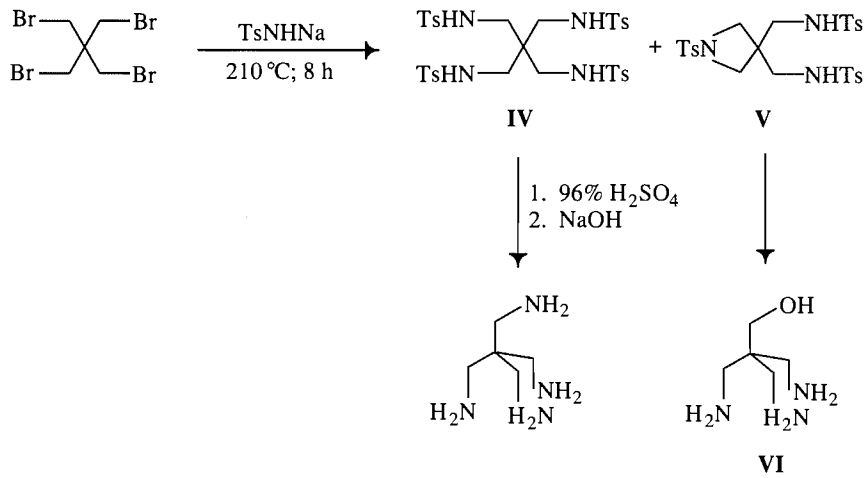
III

Our interest in such ligands stems from their possible use as building blocks for octaamines (5, 6) and C-spiro macrocycles (7) where the tetraaza systems are joined at a single quaternary carbon. Elaborations lead to dinuclear complexes (e.g. with $(H_2NCH_2CH_2NHCH_2)_4C$) which may be viewed as extended forms of the ligand 2,3,2-tet, $(H_2N(CH_2)_2NH(CH_2)_3NH(CH_2)_2NH_2)$, a species well studied in its interaction with metal ions (8, 9).

In this paper, we report a ready synthesis, under controlled conditions, of a hexa-coordinate nickel(II) ion related to some of the polymeric species described previously. The complex is of interest in that the X-ray structure provides evidence for different Ni—N bond lengths. Also, electrochemical and chemical oxidations are consistent with a transient Ni(III) complex. This is believed to be the first example of a species of this type generated from six primary amines in the inner coordination sphere.

Experimental

Synthesis



Pentaerythrityl tetrabromide was prepared by literature methods (10). The tam tetratosylate was prepared by a modification of the procedure described by Litherland and Mann (1).

*Preparation of tam tetratosylate (**IV**)*

A 500 mL three-necked reaction flask, equipped with a mechanical stirrer and a thermometer, was heated in an oil bath to 210°C. Pentaerythrityl tetrabromide (38.8 g 0.1 mol) was ground well with 95.0 g 0.5 mol) of the sodium salt of *p*-toluene sulphonamide and added in four (equal) amounts to the pre-heated reaction vessel while stirring. The reaction mixture formed a viscous melt within 40 min. The melt

SCHEME 1

was maintained under stirring at 210°C for 8 h. Pentaerythrityl tetrabromide subliming on the cooler parts of the reaction flask was melted down occasionally by pumping hot oil or blowing hot air. The reaction mixture was cooled to 180°C under stirring and then allowed to cool to room temperature. Acetic acid (150 mL, 70% V / V) was added to the reaction flask equipped with a reflux condensor and the contents refluxed until the hard reaction mixture disintegrated into a fine white suspension. The mixture was filtered while hot and the filtrate was set aside to recover the tritosylate (**V**) (Scheme 1). The residue was washed several times with hot water to remove sodium bromide and *p*-toluene sulphonamide. The resulting white crystalline powder weighed 50 g and was found to be pure tetratosylate of tam. Melting point: 248°C (lit. 248°C). ^{1}H nmr in $CDCl_3$: 7.25–7.99 (m) aromatic protons, 5.8 (5) —NH— protons, 2.75 (d) C—CH_2—N protons, 2.4 (s) CH_3—Ar— protons. Mass spectroscopy (methane chemical ionisation) $M^+ = 748$.

Isolation of tritosylate (V)

The mother liquor obtained after the removal of tetratosylate of tam was processed as described (1) to recover the tritosylate. Yield: 25 g. Melting point: 214°C (lit. 214°C). ^{1}H nmr in $CDCl_3$: 7.25–7.99 (m) aromatic protons, 5.08 (t) —NH— protons, 3.36 (s) —CH_2— protons of the azetidine ring, 2.86 (d) —CH_2—NHTs protons, 2.5 (s) and 2.4 (s) CH_3—Ar— protons. Mass spectrometry (methane chemical ionisation) $M^+ = 577$. This species may be detosylated with ring opening to yield the tripodal ligand (**VI**).

Detosylation of tetratosylate of tam

Concentrated sulphuric acid (150 mL) was taken in a three-necked flask equipped with a mechanical stirrer and heated to 160°C in an oil bath. Powdered tosylate (82 g, 0.108 mol) was added in small lots over 40 min. The tosylate dissolved immediately to form a clear solution and the temperature rose to 180°C. The reaction mixture was maintained at 180°C for 30 min. After cooling to room temperature and pouring into 30% V / V ethanol, the white crystalline solid formed was allowed to settle. The supernatant was decanted off and the precipitate recovered by filtration under suction. This precipitate was dissolved in minimum amount of 10% sodium hydroxide and filtered to remove any insoluble material. The filtrate was neutralized and made just acidic with 50% sulfuric acid. On standing, pure white crystals of the sulfate salt of protonated 2,2′-bis(aminomethyl)-1,3-diaminopropane were deposited. Yield: 28.6 g, approximately 80%. Melting point: 303°C (lit. 303°C), melted into a clear liquid and charred at 306°C.

A sample of free anhydrous amine was prepared by neutralising the sulfate salt of tam in 40% sodium hydroxide and extracting with pyridine. The extract was dried over potassium hydroxide and pyridine distilled off under vacuum to yield the anhydrous amine, soluble in chloroform. ^{1}H nmr in $CDCl_3$: 2.5 —CH_2— protons, 1.07 —NH_2 protons. ^{13}C nmr in $CDCl_3$: 44.60 —CH_2— carbon, 43.8 quarternary carbon.

Preparation of $[Ni(tamH)_2]\cdot(SO_4)_2\cdot 4H_2O$

Amine sulphate (0.328 g, 0.001 mol) was suspended in 10 mL of water containing 0.131 g (0.0005 mol) of $NiSO_4\cdot 6H_2O$. Anhydrous sodium carbonate (0.159 g, 3 mole equivalents) was added, and the solution warmed to 40°C. Reaction produced a clear pink-coloured solution. On standing, pink crystals suitable for X-ray structure determination were formed. Yield: 0.244 g, 83%. A second crop of crystals could be octained on concentrating the mother liquor. *Anal.* calcd.: C 19.69, H 7.09, N 18.6, Ni 10.3: found: C 20.38, H 7.1, N 19.0, Ni 9.9. 3500–3000, br; 2080, m; 1600, br; 1465, s; 1180–1100, br; 950, m; 770, s; 610, m.

Infrared spectra were obtained as KBr discs using a Perkin Elmer 283 grating spectrometer. High field ^{1}H and ^{13}C nmr spectra were obtained using a Bruker WM 250 instrument. All chemical shifts are reported relative to tetramethylsilane (TMS).

Electron spin resonance spectra were measured using a Varian E6S spectrometer (77 K) with dpph (diphenylpicrylhydrazyl, g = 2.0037) as reference standard.

Ultraviolet–visible spectra were run on either a Cary 17 or a Perkin Elmer Lambda 4B dual beam spectrophotometer.

Elemental analyses were performed by Canadian Microanalytical Services, Vancouver, B.C.

Electrochemical measurements were made using a Princeton Applied Research Model 273 Potentiostat / Galvanostat. Pt working and counter electrodes were used while the reference electrode was a saturated calomel linked to the cell via a saturated KCl bridge.

Structure determination

Crystals were obtained by slow growth from aqueous SO_4^{2-} media. The crystal was mounted inside a Lindemann tube and photographed using Weissenberg and precession cameras. The final lattice parameters were obtained from a least-squares refinement of 15 accurately centred reflections over the range 14–48° in 2θ. The data were collected on a Picker four circle diffractometer, automated with a PDP11 / 10 computer. Intensity measurements were made using Zr-filtered Mo radiation, λ = 0.71069 Å by scanning in the 2θ mode by using 152 steps of 0.01° in 2θ counting for 0.25 s per step. Background counting was for 19 s at each end of the scan. A set of three standard reflections preceded each batch of 50 measurements. Pertinent crystallographic data are given in Table 1. Solution of the phase problem was achieved using the direct methods package of SHELX (11). Neutral atom scattering factors were taken from the compilation of Cromer and Mann (12*a*), and correction for the real component of anomalous dispersion was taken from the table of Cromer and Libermann (12*b*). The Ni *f* curve was from the International tables (13). The absorption correction was made by numerical integration using an 8 × 8 × 8 Gaussian grid. The program (14) was modified locally for the axis system of the monochromator. The nickel was located on a special position and other

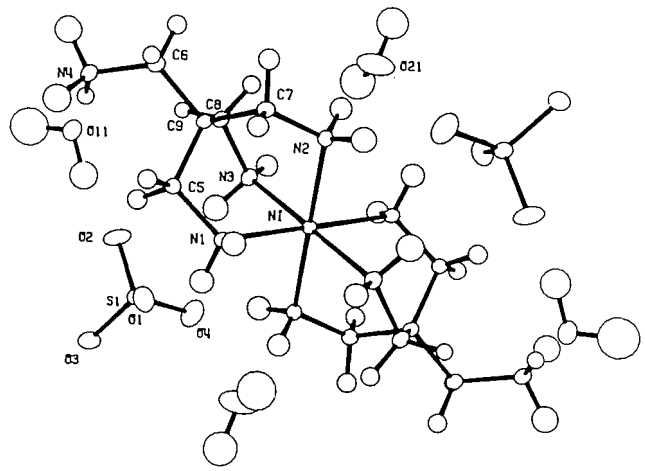

FIG. 1. ORTEP diagram of $Ni(Htam)_2(SO_4)_2(H_2O)_4$ complex, showing 25% thermal ellipsoids.

atoms were obtained from the Fourier difference maps following least-squares refinement. The hydrogen atoms were locatable from the difference map after all other atoms had been found and were included in the final stages of refinement. With this procedure the reported N—H distances were in the range 0.79–0.85 Å with an unacceptably low O—H value at 0.67 Å. The N—H and O—H distances were therefore constrained to 1.02 Å (DFIX) and the refinement repeated. All non-hydrogen atoms were refined anisotropically. A weighting scheme was employed in the latter stages of refinement, with $R_w = (\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2)^{1/2}$ where $w = 0.0606/(\sigma^2|F| + 0.001F^2)$. The refinement converged with $R = 0.0347$ and $R_w = 0.0386$. The ORTEP diagram is shown in Fig. 1, together with the atomic labelling scheme for all the atoms except the hydrogens. The hydrogen atoms are labelled in the following manner: N_1 has associated H_{11}, H_{12}, N_2 with H_{21}, H_{22}, etc., N_4, H_{41}, H_{42}, H_{43}. O_{11} has associated H_{111} and H_{112}.

Results and discussion

Preparation of ligands

There are only two relevant methods for the preparation of tam available in the literature (1, 15). The drastic experimental conditions and the tedious nature of the preparatory method of Litherland and Mann (1) often yield products of poor quality even though it is the reasonable method for the preparation of substantial amounts of the tetratosylate. Fleischer's method (15) is not generally advisable considering the explosive nature of the tetraazide intermediate. In the present investigation, it was found that many of the problems associated with the former procedure can be overcome conveniently by very slight modification. Under the experimental conditions suggested previously, the reaction mixture often charred and non-homogenity of the reaction mixture led to lower yields of products. In our procedure, homogeneity of the reactions mixture was maintained by mechanical stirring and occasionally melting down the subliming starting materials. Reaction time was shorter and hence yielded products of good quality and quantity. Also, 5, not 4 moles, of sodium salt of *p*-toluene sulfonamide were used to minimize the formation of by-product aminetosylate (**V**). Although the yield was found to be variable in the range of 40–60%, the procedure was reliable for large scale preparations.

Preparation of the nickel(II) complex

Previous authors (2) used the free amine to form complexes with metal ions. This procedure leads to polymeric products. In the present method the Ni^{2+} complex was prepared by reacting the metal ion and the ligand salt in 1:2 ratio and neutralizing only 3 equiv. of the amine, thereby preventing the formation of polymers. Under basic conditions (pH greater than 10) on refluxing, only an insoluble polymeric complex of nickel is obtained as described by Bailar and Oekhme (2).

Crystallography

The crystal structure of $[Ni(tamH)_2](SO_4)_2(H_2O)_4$ is shown in Fig. 1 together with the atomic labelling scheme for all of the atoms except the hydrogens. The fractional coordinates, bond lengths and bond angles are given in Tables 2–5, respectively. All other tables are available as supplemental material (S1–S4).[3]

The nickel atom occupies an inversion centre in the unit cell giving half the molecule as the asymmetric unit. The molecule is thus symmetric with respect to nickel. However, the molecular geometry is not perfectly octahedral. The coordination environment has three of the four primary animes of each ligand coordinated to the metal, and may be described as both tetragonally distorted owing to the elongation of the Ni—N bonds, and, as trigonally distorted due to the closing of the chelate angles. The Ni—N1 bond is significantly longer (2.140(2) Å) than the remaining two bonds (2.121(2) Å; 2.120(2) Å). It is of interest to compare the present system with other NiN_6 systems. Somewhat greater differences in axial and equatorial bond lengths (2.12 and 2.22 Å, respectively) are observed for the *bis* triamine complex of 3-axapentane-1,5-diamine where the three nitrogens of each ligand are disposed meridionally about the distorted octahedron (16). For the cyclic triamine complex (17) with a facially disposed N_3 system, $Ni([9]\text{-aneN}_3)_2^{2+}$, ([9]-aneN$_3$: 1,4,7-triazacyclononane) all bond lengths are equivalent within experimental error at 2.10 Å, slightly shorter than in the present system. An identical value has been reported (18) in the case of

[3]Tables S1 through S4 contain fractional atomic coordinates, anisotropic temperature parameters, interatomic distances, and bond angles involving the hydrogen atoms; Tables 5 list calculated and observed structure factors. A complete set of material may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]The symmetry positions are for the second atom; they are defined: 1 = X, Y, Z. A negative symmetry position denotes inversion. The translations (T) are applied after any symmetry operation has been applied.

the Ni(sepulchrate)$^{2+}$ ion (sepulchrate = 1,3,6,8,10,13,16,19-octa-azabicyclo-[6.6.6]eicosane), and for the Ni(en)$_3^{2+}$ (en = ethylenediamine) (19) the length is 2.12 Å. The trigonal distortion observed in the present complex is confirmed by the N—Ni—N angles where the six-membered chelating rings are smaller than the 90° angle anticipated for a regular octahedron. The average angle observed is 86.5° and is typical of the N—Ni—N angle for six-membered chelating rings as exemplified by nickel trispropylenediamine, Ni(pn)$_3^{2+}$ where an average of 87.5° is observed (20). In Ni(non)$_2^{2+}$ these angles (17) at 82.6° represent a significant distortion. Deviations from trigonal symmetry may be observed with one Ni—N bond shorter than the others. However, the magnitude of the distortion is much less in the present complex in keeping with the more tightly bound ring. Unlike a number of other hexacoordinated amine complexes (21, 22) there is no significant twist to the structure around the nominal C_3 axis.

The crystal structure also describes a number of hydrogen bonding interactions between the cation, the anion, and the waters of crystallization. There are present 13 H atom donors (nine from amines and two each from the waters). All N—H and O—H hydrogen atoms are used in the bonding with the exception of one hydrogen on N3 where contacts are considered very long for bonding. The number of acceptor positions is 12 on the sulfate oxygens and two each of O11 and O21. All interactions may be accounted for by strong (O11—O2, 2.714 Å and O11—O3, 2.731 Å) and weaker bonding (e.g., O11—O2, 3.488 Å and O21—O4, 3.339 Å). In other instances the bond lengths are significantly less than 3.0 Å. The longest bond required for complete description was O3—N4 at 3.556 Å. The depiction of the hydrogen bonding scheme requires a minimum of six complete molecules. Interactions extend through the crystal structure in the x, y, and z directions. A stereo projections of the hydrogen bonding arrangement is provided in Fig. 2. There is a

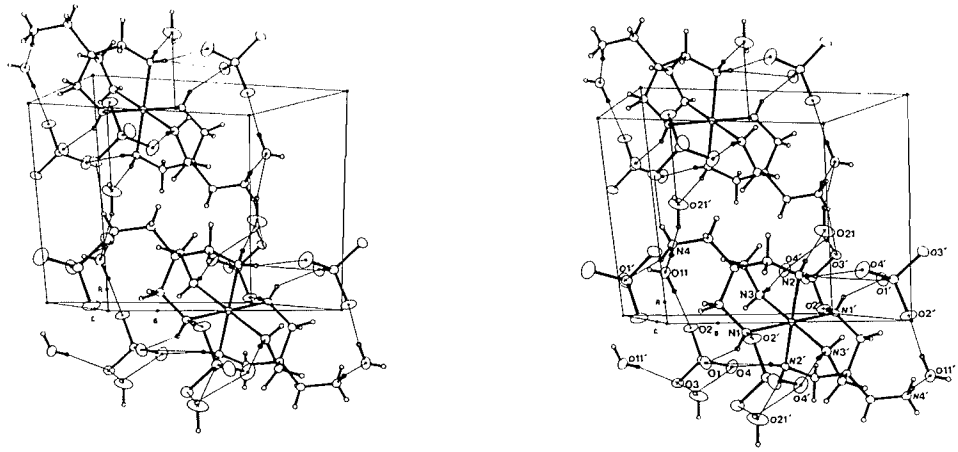

FIG. 2. Stereo projection of the hydrogen bonding arrangement.

ribbon of hydrogen bonding which links together the sulfate and water fragments. Oxygen atoms O2 and O3 of one SO_4^{2-} group bind to centrosymmetrically related O11 molecules which link back to the O2 and O3 atoms of a related sulfate. Also, O3 links a similar pair of O21 water molecules back to a symmetrically related SO_4^{2-}. The weak bonds (i.e., O3—H211 = 2.30 Å) provides linking for the crystal lattice. The short distance (1.78 Å) between O2 and H111 is indicative of a very strong interactions, and indeed, this is seen through the distension of this hydrogen from O11. Presumably this interaction tends to neutralize the positive charge present on the protonated amine through dipolar interactions. The sulfate also interacts with H112 of an adjacent molecular through O3 (1.75 Å).

The protonated nitrogen, N4, interacts with one of the waters of crystallisation (O11) through a strong hydrogen bond. This is seen in the close N4—O11 distance (2.81 Å) and the shorter O11—H43 distance (2.00 Å). There are also attachments to O1 and O3, thus providing the linking for the crystalline lattice, with additional bonding between N2 and O4, N2, and O21 and N1—O1.

The positioning of the sulfate allows for a strong interaction between this anion and all the amines through hydrogen bonding interactions with the oxygens. Short bonds are observed (<2.2 Å) between O1—H41, O2—H11, O3—H42, and O4—H31. It can be seen from these distances that the sulfate is situated over one of the "faces" of the octahedral cation and forms links between adjacent cations within the crystalline structure. It is also of interest to note that the sulfate does not interact more strongly with N1 than with the remaining nitrogens and is thus not the source for the distortion of the Ni—N1 bond length. However, among the chelated nitrogen atoms, N1 forms two of the three shortest N—O contacts. This could be the source of the elongation of the Ni—N bond.

Ultraviolet–visible studies

Owing to the protonated amines, the overall 4+ charge on the nickel complex leads to ion-pair formation and imparts poor solubility to the species. In water, the uv–visible spectrum is consistent with the maintenance of the pseudo-octahedral structure in solution. The principal features at λ = 331.7 nm (ϵ = 8.5 M^{-1} cm^{-1}), 519.0 nm (ϵ = 6.9 M^{-1} cm^{-1}), 795 nm (sh) and 850 nm (ϵ = 7.0 M^{-1} cm^{-1}) are typical of six-coordinate Ni(II). It is of interest that these wavelengths are close (335 nm (ϵ = 16.6) and 522 nm (ϵ = 14.2) to those described previously (2) under similar conditions. Owing to the differences in preparation, there may be a mixture of species present in the latter study since the extinction coefficients are significantly higher than those anticipated for species of this type. For $Ni(en)_3Cl_2$ (23) features at 345 and 545 nm have ϵ = 8.6 and 6.7 M^{-1} cm^{-1}, respectively. The more symmetrical $Ni(sep)^{2+}$ exhibits features (18) at 316 and 510 nm (ϵ = 11.2 and 8.0 M^{-1} cm^{-1} respectively) which may be due to the macrocyclic nature of the ion. The value of 10 Dq deduced for the present complex (11 695 cm^{-1}) indicates a strong field for the tricoordinate system which is only slightly weaker than the facially coordinated bis(1,4,7-triazacyclononane) nickel(II) ion (10 Dq = 12 500 cm^{-1}) (24). The present complex retains its integrity in the pH range 6–10. At higher pH's, precipitation of $Ni(OH)_2$ is observed and below pH 3 and the H_4tam^{4+} salt is formed, leaving Ni(II) in solution.

Addition of sodium persulfate at low temperature (≈0°C) leads to the formation of a green Ni(III) complex. The features of this ion are similar to those observed previously (25, 26) with an absorption band centred at 540 nm and overlapping features at 341 and 305 nm. Owing to the unstable nature of the complex, extinction coefficients could not be measured with any reasonable accuracy.

Electrochemical studies

Cyclic voltammetric studies of the complex were made in 1 M Li_2SO_4 solutions at various pH's. At pH ≈7 a quasi-reversible wave was observed for the Ni(II) / (III) couple with a peak–peak separation consistent with a $1e^-$ process. The observed $E_{1/2}$ = 0.89 V against NHE. At pH ≈10 there appears to be partial deprotonation of the terminal ammonium ion, leading to the formation of two species with features at 0.84 and 0.99 V respectively with respect to NHE.

$$[Ni(tamH)_2]^{4+} \overset{OH^-}{\rightleftharpoons} [Ni(tam)_2]^{2+}$$

However, these waves are much less well defined and, as identified earlier, rearragnements to polymeric entities are also possible.

It is of interest to note that the $E_{1/2}$ value for $Ni(tamH)_2^{5+/4+}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12

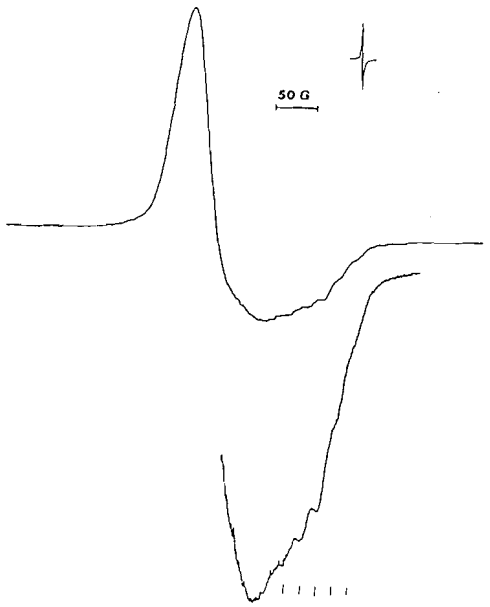

FIG. 3. Frozen solution esr spectrum of $[Ni(III)(Htam)_2]^{5+}$ ion at 77 K in aqueous media. Oxidation carried out using persulfate ion at 273 K.

is less than that observed for $Ni([9]aneN_3)_2^{3+/2+}$. The structural differences between the two molecules around the Ni(II) cation are not very great and hence, the lower $E_{1/2}$ value is presumably a result of the primary amines in the coordination sphere.

Electron spin resonance of Ni(III) species

Confirmation of the Ni(III) centre in the oxidation by persulfate is provided by the esr spectrum (Fig. 3). This is characteristic of a low spin d^7 ion $g_\perp = 2.13$, $g_\parallel = 2.028$ ($A_\parallel = 20$ G) (77 K). The spectrum shows significant tetragonal distortion with hyperfine coupling in the parallel feature consistent with the maintenance of axial *N*-coordination. There was little change observed over the pH range 6–9. However, outside these values the Ni(III) species was not stable.

This complex is of interest in that it is considered to be the first example of a Ni(III) ion with a NiN_6 chromophore involving primary amine coordination of sufficient stability to permit identification at room temperature. Previous examples, e.g. $Ni(en)_3^{3+}$, have been monitored only under pulse radiolytic conditions (27). The ion $Ni(en)_2Cl_2^+$ has been identified previously (28) and is stable only in acidic media, pH = 1, probably as a result of the axially coordinated chlorides. At pH > 2, the decay of Ni(III) is rapid. This ion, on exposure to moisture, gradually changes in the solid state to a black mixed-valence Ni(II)—Ni(IV) chloro-bridged dimer (29). The present finding of a more stable Ni(III) species in solution at pH ~6, may be due to the tripodal nature of the ligand resulting in facial coordination. In sulfate media, there is evidence for ion-pairing which is partly responsible for the non-isotropic nature of the esr spectrum. An NiN_6^{3+} chromophore of high symmetry would be expected to show features with $g_\perp$ close to $g_\parallel$, but where ion pairs are formed (30), the asymmetry imparted to the ion is such as to produce a more axial spectrum. The hyperfine coupling constant $A_\parallel$ (≈20 G) is similar to that observed where secondary amine coordination is involved. For $Ni(9\text{-}aneN_3)_2^{3+}$ (30, 31) $A_\parallel$ = 23.7 G and with $Ni(bipy)_3^{3+}$, the corresponding value is 18.6G (32). There appears to be little difference between primary and secondary amines on the residence time of the electron on the N-donor atom.

Conclusion

The tetraamine tam forms an octahedral complex with Ni^{2+} ion in which three of the four nitrogen atoms from each tam moiety are involved. Axial elongation consistent with Jahn–Teller distortion is seen in the crystal structure of the Ni^{2+} species. Electron spin resonance spectra of the oxidised ion are consistent with a low spin d^7 Ni(III) centre which shows extensive ion-pairing. The quasi-reversible nature of the $Ni^{2+/3+}$ redox couple is in keeping with retention of the primary coordination sphere upon electron transfer.

Isolation and characterization of polydentate ligands derived from the reaction of pentaerythrityltetrabromide and ethylenediamine

A. McAuley,[1] K. Beveridge, S. Subramanian, and T. W. Whitcombe
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

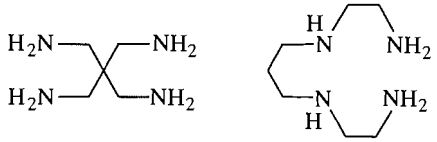
Received August 29, 1988[2]

A. McAuley, K. Beveridge, S. Subramanian, and T. W. Whitcombe. Can. J. Chem. **67**, 1657 (1989).

Reaction of pentaerythrityltetrabromide with ethylenediamine yields three product amines. These have been isolated by separation of the corresponding Ni^{2+} complexes. The free amine hydrochlorides have been obtained by acid hydrolysis of the Ni^{2+} species and have been characterized by nuclear magnetic resonance and mass spectroscopy. The crystal structures have been determined for the hexahydrochloride salt of polyamine ligand L_1, $[H_6(L_1)]Cl_6 \cdot 4H_2O$ ($L_1 = C_{11}H_{28}N_6$, 6,6-bis(4-amino-2-azabutyl)-1,4-diazacycloheptane) ($C2/c$, $a = 15.975$) Å, $b = 10.723$ (1) Å, $c = 14.686$(1) Å, $\beta = 99.40(1)°$, $Z = 4$), and for the octahydrochloride salt of L_2, $[H_2(L_2)]Cl_8 \cdot 2H_2O$ (L_2 = 5,5-bis(4-amino-2-azabutyl)-1,9-diamino-3,7-diazanonane) ($Pccn$, $a = 12.834(2)$ Å, $b = 16.691(1)$ Å, $c = 14.167(1)$ Å, $Z = 4$). Both crystals exhibit strong N—H...Cl,O,N bonding, although in the latter compound the waters of crystallization do not participate in the apparent hydrogen bonding interaction. Both these species are of interest since they represent the precursors to square planar Ni^{2+} complexes that incorporate the MN_4 chromophore. Ring closure of both the free amines L_1 and L_2 by reaction with diethyl malonate leads to cyclized products that are related to the cyclam ([14-aneN_4) tetraaza macrocylic ligands.

Key words: pentaerythrityl, amine, spiro ligand hydrochlorides.

A. McAuley, K. Beveridge, S. Subramanian et T. W. Whitcombe. Can. J. Chem. **67**, 1657 (1989).



La réaction du tétrabromure de pentaérythrityle avec l'éthylènediamine fournit trois produits aminés. On les a séparés sous la forme des complexes correspondants du Ni^{2+}. On a obtenu les chlorhydrates des amines libres par hydrolyse acide des complexes de Ni^{2+} et on les a caractérisés par spectroscopies de résonance magnétique nucléaire et de masse. On a déterminé les structures cristallines de l'hexachlorohydrate du ligand polyamine L_1, $[H_6(L_1)]Cl_6 \cdot 4H_2O$ ($L_1 = C_{11}H_{28}N_6$, 6,6-bis(4-amino-2-azabutyl)1,4-diazacycloheptane) ($C2/c$, $a = 15,975(1)$, $b = 10,723(1)$ et $c = 14,686(1)$ Å, $\beta = 99,40(1)°$ et $Z = 4$), et de l'octachlorhydrate du ligand L_2, $[H_8(L_2)]Cl_8 \cdot 2H_2O$ (L_2 = 5,5-bis(4-amino-2-azabutyl)-1,9-diamino-3,7-diazanonane) ($Pcnn$, $a = 12,834(2)$, $b = 16,691(1)$ et $c = 14,167(1)$ Å et $Z = 4$). Les deux cristaux présentent de fortes liaisons N—H...Cl,O,N même si, dans le dernier composé, les molécules d'eau de cristallisation ne participent pas aux interactions hydrogènes apparentes. Ces deux espèces sont intéressantes parce qu'elles représentent les précurseurs des complexes plans carrés du Ni^{2+} qui comprennent le chromophore MN_4. La cyclisation des deux amines libres L_1 et L_2, par réaction avec le malonate de diéthyle, conduit à des produits qui sont reliés aux ligands tétraaza macrocycliques ([14-aneN_4).

Mots clés : pentaérythrityle, amine, chlorohydrates du ligand spiro.

[Traduit par la revue]

Introduction

The mode of formation of tetrasubstituted pentaerythritol species and their use as starting materials in synthesis has been an ongoing theme in organic chemistry. Several studies have been made in characterizing extended molecules in which all of the hydroxy groups are replaced (1). The convenient large scale synthesis of the tetraamine, tetrakis(aminomethyl)methane (tam), was first achieved by Litherland and Mann (2). However, crystallographic characterization of the molecule as a tetraammonium salt was reported only recently by Cameron *et al.* (3). This structural investigation revealed $[H_4tam]^{4+}$ to exist as a

tam

2,3,2-tet

highly compact quadruply charged cation with extensive hydrogen bonding interactions in the solid state. The utilization of tam in the complexation of metal ions has been examined by Bailar and Oehmke (4) and Zompa and Bogucki (5). A recent study[3] in our laboratory has shown that tam may form a bis-monoprotonated complex ion with Ni^{2+}, $[Ni(Htam)_2]^{4+}$, in which three of the four primary amines are coordinated onto the faces of an octahedral complex (NiN_6 chromophore) whilst the fourth amino group is protonated. However, because of the presence of the coordinated primary amino groups, this species is of limited stability in acidic media.

An ongoing theme in our research is the extension of the pentaerythrityl moiety to provide a synthetic route into bicyclo-macrocyclic complexes (6), where the cyclic ligands are fused at a spiro or quaternary carbon. This paper describes the synthesis and characterization of the precursor amines, which may be viewed as structural extensions of 1,9-diamino-3,7-diazanonane (2,3,2-tet), a ligand that has been examined extensively (7) in its metal complexes.

Investigation of the crystal structures of the amine hydrochlorides has shown evidence of extensive hydrogen bonding in the solid state and the present studies provide an extension of such data. In addition, characterization of the ligands forms a basis for the comparison of structural changes occurring in the organic framework upon complexation by metal ions. This latter aspect will be discussed elsewhere.[4]

Experimental

Pentaerythrityltetratosylate, tetrabromide and tetraiodide were prepared by literature methods (8). Ethylenediamine (anhydrous) from

CHART 1. Alphabetic representation of carbon atoms in ligands (see Scheme 2 for structure).

either Fisher Scientific Co. or Aldrich Chemical Co. was used as received. All other chemicals used were of reagent grade.

The uv–vis were recorded on a Perkin–Elmer Lambda 4 spectrometer at 25°C in H_2O. The ir spectra of complexes were obtained as KBr discs using a Perkin–Elmer 283 grating spectrometer. The ^1H and ^{13}C nmr spectra were obtained using a Bruker WM 250(FT) instrument. ^{13}C chemical shifts in D_2O were monitored relative to the nitrile group of CH_3CN used as internal reference (*C*N = 118.2 ppm relative to TMS). ^{13}C and ^1H chemical shifts in $CDCl_3$ were measured relative to TMS as internal standard. The nmr resonances were assigned on the basis of comparison with known systems such as pentaerythrityl tetraamine and related amines. The various ^1H and ^{13}C resonances are described alphabetically as shown in Chart 1.

The labelling starts from the quaternary carbon (spiro carbon) and proceeds towards the middle methylene carbon in the propylene chain of the tetraaza unit in cyclic ligands L_4, L_5, L_6, and L_7 and towards the carbon bearing the primary amino group in the open chain ligands L_1, L_2, and L_3. In the diazacycloheptyl rings in ligands L_1, L_4, and L_6, the methylene carbon bonded to the quaternary carbon is denoted by C_g and the methylene carbon of the ethylene bridge by C_h respectively. In ligand L_3 the carbons in the chain —CH_2—NH—CH_2—CH_2—NH—CH_2—, bridging the two hexaaza units —C—(—CH_2—NH—CH_2—CH_2—NH_2)$_3$, do not differ distinctly from the rest of the carbons in the molecule.

The mass spectra of free amines were recorded with a Finnegan 330 gc–ms instrument by electron impact or by methane / isobutane chemical ionization methods as indicated. Ligands (oils) that proved difficult to purify or crystallize were complexed with Ni^{2+} ions, recrystallized, and the complexes analysed. Elemental analyses were performed by Canadian Microanalytical Services, Vancouver, B.C., Canada.

Structure determination

The crystals were mounted with epoxy resin inside Lindemann tubes and photographed using Weissenberg and precession cameras. The final lattice parameters were obtained from the accurate centering of 25 high angle reflections on an Enraf–Nonius CAD4 diffractometer, prior to the collection of the data set. For $[H_6(L_1)]Cl_6 \cdot 4H_2O$, the range of 2θ values of reflections for centering was 28°–50° and for $[H_8(L_2)]Cl_8 \cdot 2H_2O$, 8°–29°. The corresponding crystal sizes were 0.40 × 0.47 × 0.76 mm (μ = 7.4 cm^{-1}) for $[H_6(L_1)]Cl_6 \cdot 4H_2O$ and 0.50 × 0.08 × 0.05 mm (μ = 7.64 cm^{-1}) for $[H_2(L_2)]Cl_8 \cdot 2H_2O$ respectively. Three intensity standards were measured after each hour of exposure time, with no significant loss in intensity observed. Following corrections for absorption effects, based on the CAD4 EMPABS absorption curve, both structures were solved using the direct methods package in SHELX (9). The chlorine atoms were obtained initially, with the remaining atoms being located from subsequent Fourier difference maps. A unit weighing scheme was used and the least-squares refinement with all non-hydrogen atoms anisotropic gave the *R* values shown in Table 1. The hydrogen atoms were not found from the final difference maps. For both compounds, the maximum residual peak height was 0.5 e / Å^3. The neutral atom scattering factors were obtained from the usual source (10).

Synthesis

The ligands L_1, L_2, and L_3 prepared by reaction of pentaerythrityltetrabromide with anhydrous ethylenediamine were separated via Ni^{2+} complexation (see Scheme 1) and cyclized using the methods outlined in Scheme 2. This approach involves modification of the methods reported by Philip (11) and Gahan *et al.* (12) for the preparation of ligand L_2.

Preparation and isolation of ligands L_1, L_2, and L_3

Pentaerythrityltetrabromide (38.8 g, 0.1 mol) suspended in anhydrous ethylenediamine (500 g, 8.0 mol) was refluxed (72 h) with stirring at 145°C in a CO_2- and moisture-free N_2 atmosphere. After cooling the reaction mixture, most of the excess ethylenediamine was removed under vacuum. The resulting viscous oil, containing residual ethylenediamine and the product amines, weighed approximately 95 g.

Excess ethylenediamine was removed in the following manner: 60 g of this mixture, dissolved in 1 L H_2O, was adsorbed onto a pre-acid-washed Dowex 50X8 cation exchange resin (100–200 mesh) (500 g, column dimensions: 60 × 5 cm). the column was eluted with 2 L H_2O to remove all the hydrobromic acid liberated during the adsorption onto the column. Subsequent elution with 8–10 L of 2.25 M HCl yielded, on concentration, ethylenediamine dihydrochloride (65 g) (equivalent weight 79–81). Further elution with 8–10 L of 4.0 M HCl yielded, on concentration, 46 g of a mixture containing the hydrochloride salts of L_1, L_2, and L_3 (equivalent weight 85–86) (87% yield based on the pentaerythrityltetrabromide). Pentaerythrityltetratosylate and tetraiodide gave products with approximately the same composition but in lower yields (see discussion). The only method for satisfactory separation of the individual amines was via complexation using Ni^{2+}.

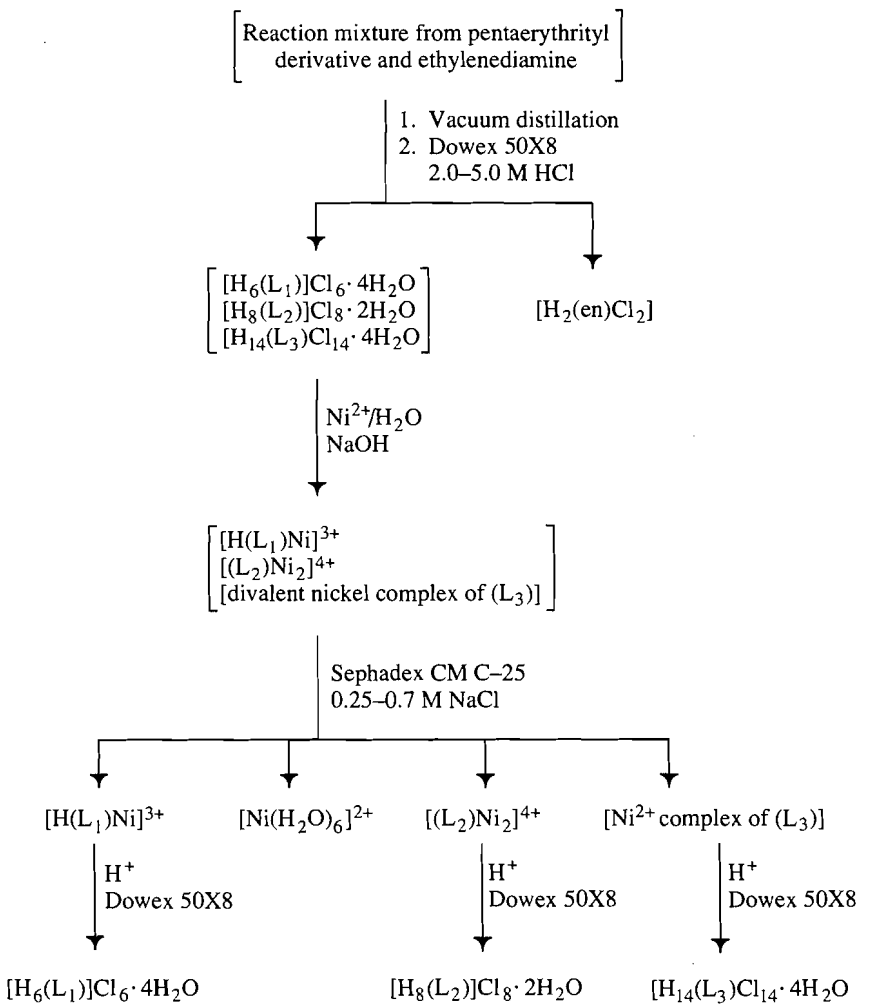
Preparation of Ni^{2+} complexes

Twenty grams of the amine hydrochloride mixture was dissolved in 250 mL H_2O and a solution of NaOH (10 g in 100 mL) was added. Following the addition of a solution of 16 g $NiCl_2 \cdot 6H_2O$ in 150 mL H_2O, the mixture was heated to nearly boiling and then diluted to 1 L. The complexes formed were adsorbed onto a Sephadex CM C-25 cation exchange column (60 g Sephadex, column dimension: 60 × 5 cm) to form a dark violet band. Gradient elution with 0.25–0.7 M NaCl yielded four distinct bands.

Elution of the first fraction with 0.25 M NaCl (2–3 L), followed by evaporation of the fractions to dryness and successive washing with 90% ethanol to remove the sodium chloride, resulted in a violet coloured ethanolic solution that yielded crystals (5.4 g) of the complex $[Ni(H(L_1))]Cl_3$ (where $H(L_1)$ is the monoprotonated (one N of the diazacycloheptyl ring) form of the amine L_1); ir: 3300(br), N—H; 1600(sh); 1455(sh); 965(sh); 640(m); uv–vis (in H_2O) (λ_{max} in nm (ε(M^{-1} cm^{-1}) at 25°C)): 384.7(7.1), 448.4(2.5), 537(3.8), 746.8(3.5), 790.3(3.3). *Anal.* calcd. (found) for $C_{11}H_{29}N_6NiCl_3$: C 32.18(31.9), H 7.07(7.29), N 20.48(19.98), Cl 25.94(25.36)%. A somewhat better analysis is provided if the complex is considered a hemihydrate, i.e., $[Ni(H(L_1))]Cl_3 \cdot 1/2H_2O$ yield C 31.5, H 7.16, N 20.04, Cl = 25.40%.

The second band eluted with 0.4 M NaCl (1–2 L) was identified as $[Ni(H_2O)_6]^{2+}$.

The third major band, pale violet in colour, was eluted with 0.45–0.5 M NaCl (4–5 L), concentrated, and sodium chloride removed as described previously. To the concentrated ethanolic solution was added, saturated aqueous $NaClO_4$ and the solution allowed to stand overnight, yielding yellow crystals of the perchlorate salt of $[Ni_2(L_2)]^{4+}$ (12.6 g); ir: 3250(br), N—H; 1600(sh), 1450(br), 1100(br), ClO_4; 620(sh); uv–vis (in H_2O) (λ_{max} in nm(ε(M^{-1} cm^{-1}) at 25°C)): 345.2(17.4), 448.4(9.2), 537.0(9.9), 741.9(8.2), 787.1(7.5). *Anal.* calcd. (found) for $C_{13}H_{36}N_8Ni_2Cl_4O_{16}$: C 19.8(19.6), H 4.41(4.39), N 13.87(13.9)%.



On prolonged standing the mother liquor deposited dark brown crystals of composition [(Ni) (Ni(Cl) (H_2O)) (L_2)] $(ClO_4)_3 \cdot 3H_2O$ (*vide infra*).

Small amounts of a final violet band were derived after elution with 0.5–0.7 M NaCl. A violet ethanolic solution was obtained but, owing to insufficient quantities available, the Ni(II) complex of L_3 was not isolated. However, nmr characterization of the amine hydrochloride was achieved (*vide infra*).

Decomplexation and isolation of ligand hydrochlorides

Isolation of $[H_6(L_1)]Cl_6 \cdot 4H_2O$

$[Ni(H(L_1))]Cl_3$ (4.1 g) was dissolved in 250 mL of water. Addition of 25 mL concentrated HCl induced acid hydrolysis of the Ni^{2+} complex. The solution was charged onto a Dowex 50 × 8 cation exchange column. The $[Ni(H_2O)_6]^{2+}$ was removed using a 2 M HCl and the ligand hydrochloride eluted with 5 M HCl (2–3 L). After concentration of the eluate to 50 mL, ethanol was added until the solution turned just cloudy. On standing, the hydrochloride salt crystallized in near quantitative yield (5.3 g) as the tetrahydrate; ^{1}H nmr (amine L_1 in $CDCl_3$): H_h = 2.84(s), H_g = 2.72(s), H_b = 2.46(s), H_c = 2.76(m), H_d = 2.63(t), N—H = 1.4(br); ^{13}C nmr ($(H_6(L_1))]Cl_6$ in D_2O): C_a = 38.2(s), C_b = 45.2(t), C_c = 44.5(t), C_d = 35.2(t), C_g = 50.6(t), C_h = 49.0(t); (amine L_1 in $CDCl_3$): C_a = 44.4(s), C_b = 53.5(t), C_c = 54.8(t), C_d = 41.6(t), C_g = 55.9(t), C_h = 54.2(t); ms of free amine(methane chemical ionisation), *m / e*: 244. *Anal.* calcd. (found) for the hydrochloride salt $C_{11}H_{42}N_6O_4Cl_6$: C 24.68(23.99), H 7.8(7.56), N 15.7(15.2), Cl 39.78(39.16).

Isolation of $[H_8(L_2)]Cl_8 \cdot 2H_2O$

$[Ni_2(L_2)](ClO_4)_4$ (6.0 g) was dissolved in 500 mL of water and 50 mL concentrated HCl was added to hydrolyse the complex. Separation of the $[Ni(H_2O)_6]^{2+}$ (2 L of 2 M HCl) and isolation of hydrochloride (4 L of 5 M HCl) was achieved as outlined above (yield 4.3 g); ^{1}H nmr (amine L_2 in $CDCl_3$): H_b = 2.57(s), H_c = 2.76(m), H_d = 2.62(t), N—H = 1.4(br); ^{13}C nmr ($[H_8(L_2)]Cl_3$ in D_2O): C_a = 37.8(s), C_b = 49.1(t), C_c = 44.8(t), C_d = 34.9(t); (amine L_2 in $CDCl_3$): C_a = 41.5(s), C_b = 54.5(t), C_c = 53.3(t), C_d = 41.3(t); ms of free amine (isobutane chemical ionization), *m / e* (relative intensity): 306(58), 307(92), 308(100), 309(83), 310(47), 311(22) (Mol. wt. 304). *Anal.* calcd. (found) for the hydrochloride salt $C_{13}H_{48}N_8O_2Cl_8$: C 24.7(25.01), H 7.65(7.52), N 17.72(17.67), Cl 44.86(45.37).

Isolation of $[H_{14}(L_3)]Cl_{14} \cdot 4H_2O$

Using the procedure as above, white microcrystals of the hydrochloride were obtained from the final band eluted from the Sephadex column; ^{13}C nmr ($[H_{14}(L_3)]Cl_{14}$ in D_2O): C_a = 37.9(s), C_b = 49.6(t), C_c = 45.0(t), C_d = 35.2(t); ms of free amine (isobutane chemical ionization): $(M + 1)^+$ = 549.

Preparation of anhydrous amines L_1, L_2, and L_3

In a typical experiment, the octahydrochloride of amine L_2 (6.0 g) was dissolved in 150 mL of 40% NaOH. The free amine liberated as an oil was extracted into pyridine (3 × 50 mL) and the combined extracts were allowed to stand over KOH pellets. The viscous aqueous layer was removed and the pyridine solution again allowed to stand over KOH pellets for 24 h. After removal of any residual aqueous phase, the pyridine extract was roto-evacuated to dryness. Final traces of pyridine were removed under vacuum overnight. The resulting viscous oil (3.0 g) was completely soluble in chloroform without any cloudiness. Satisfactory ^{13}C nmr and mass spectroscopic data were obtained on the free amines (see isolation of aminehydrochlorides). However, for ease of storage, the hydrochloride salts were preferred.

Cyclization of L_1 and L_2

Cyclization of these amines was carried out according to the method of Tabushi *et al.* (13). Excess diethylmalonate was used and the unreacted ester was removed under high vacuum at room temperature. The products obtained were characterized by ^{13}C nmr and mass spectroscopy and were reduced without further purification.

Preparation of L_5

The anhydrous amine L_2 (3.0 g, 0.0098 mol) dissolved in 2.5 L 100% ethanol was mixed under stirring with significant excess of diethylmalonate (4.5 g, 0.028 mol) present in 500 mL of 100% ethanol. The reaction mixture was refluxed with stirring in a CO_2- and moisture-free N_2 atmosphere at 82°C for 7 days. The outlet of the condensor was protected with a NaOH pellet trap. On completion of the reaction, the mixture was concentrated to a viscous oil. Most of the unreacted ester was removed under vacuum and the residual sticky solid was digested in 100 mL of dry THF for about 30 min. A colourless microcrystalline solid was obtained. This was filtered and washed with ether and dried under vacuum. Yield 3.0–3.2 g (70%); mp 248–250°C; ^{13}C nmr (L_5 in D_2O): C_a = 37.3(s), C_b = 47.2(t), C_c = 38.9(t), C_d = 44.3(t), C_e = 168.5(s), C_f = 51.5(t); ms, *m / e* (relative intensity): 441(100) (isobutane chemical ionization).

Preparation of L_4

In an experiment similar to the above, amine L_1 (1.5 g, 0.006 mol) in 1.0 L of ethanol containing 1.5 g diethylmalonate was refluxed gently for 7 days under N_2 atmosphere. The reaction mixture was processed as before to get a hygroscopic white solid. Yield 0.2 g (23% see discussion); ^{13}C nmr (L_4 in D_2O): C_a = 37.1(t), C_b = 47.6(t), C_c = 41.6(t), C_d = 50.7(t), C_e = 168.6(s), C_f = 53.5(s), C_g = 52.8(t), C_h = 52.2; ms (methane chemical ionization), *m / e* (relative intensity): 313(90).

Reduction of cyclic lactams L_4 and L_5

Both compounds were reduced to the saturated macrocyclic ligand in a similar manner using BH_3 / THF as reducing agent. In a typical experiment a well-dried sample of L_5 (2.2 g, 0.005 mol) was treated with an appropriate amount of the reagent (8.0 mol equivalent of BH_3 / THF per mol of lactam) and refluxed for 24 h. Excess reductant was destroyed by dropwise addition of water and any white sublimate from the inner walls of the condensor was washed into the round-bottom flask with a minimum amount of 10% NaOH. The reaction mixture was taken to dryness in a rotary evaporator. This solid was suspended in 100 mL of 10% HCl and refluxed for 30 min. The resulting mixture was neutralized, the pH adjusted to 12–13, and the mixture then extracted with $CHCl_3$ in a continuous liquid–liquid extractor for 6 h. The chloroform layer was dried over anhydrous sodium sulfate and concentrated to dryness. Traces of chloroform were removed under vacuum and the resulting oil (1.34 g, approximately 70% yield), on standing, slowly solidified to a semisolid; ^{1}H nmr: H_b = 2.55(s), H_c, H_d, H_e = 2.63(m), H_f = 1.67(m), N—H = 2.4(br); ^{13}C nmr (L_7 in $CDCl_3$): C_a = 40.7(s), C_b = 55.4(t), C_c = 50.1(t), C_d = 49.4(t), C_e = 48.8(t), C_f = 29.2(t); ms (methane chemical ionization), *m / e* (relative intensity): 384 (electron impact); $M + 1$ = 385(100%), $(M - 1)$ = 383(91%).

Material obtained from amine L_1 did not lead to pure products (see discussion). The crude ligand was used for metal complexation and the metal complex purified on a Sephadex CM C-25 column. The isolation and characterization of the Ni^{2+} and Ni^{3+} complexes will be reported in a forthcoming publication.[5]

Results and discussion

Synthesis

In similar earlier studies, Philip (11) first reported the isolation of amine L_2 together with its Cu^{2+}, Ni^{2+}, and Pd^{2+} complexes. Recently Gahan *et al.* (12) have extended the reaction to prepare derivatives of propylenediamine and have characterized the Cu^{2+} complex of L_2 by X-ray crystallography. No detailed account has been given of the complete isolation and characterization of all the reaction products. In this study an attempt has been made to separate and isolate the product amines, providing a complete mass balance of the products.

The isolation method described herein does not involve conditions such as fractional distillation under vacuum at high temperatures, which often leads to decomposition and charring of polyamines. Hence the method described here has been found to be readily reproducible and accounts for the overall composition of the products obtained. Better yields of the amine L_2 have been identified together with significant amounts of the hitherto unreported amine L_1.

Pentaerythrityltetratosylate and tetraiodide were used as substrates in the place of pentaerythrityltetrabromide. Identical conditions were maintained and the reaction mixture processed in a similar manner. Comparison of results indicated that the

For personal use only.

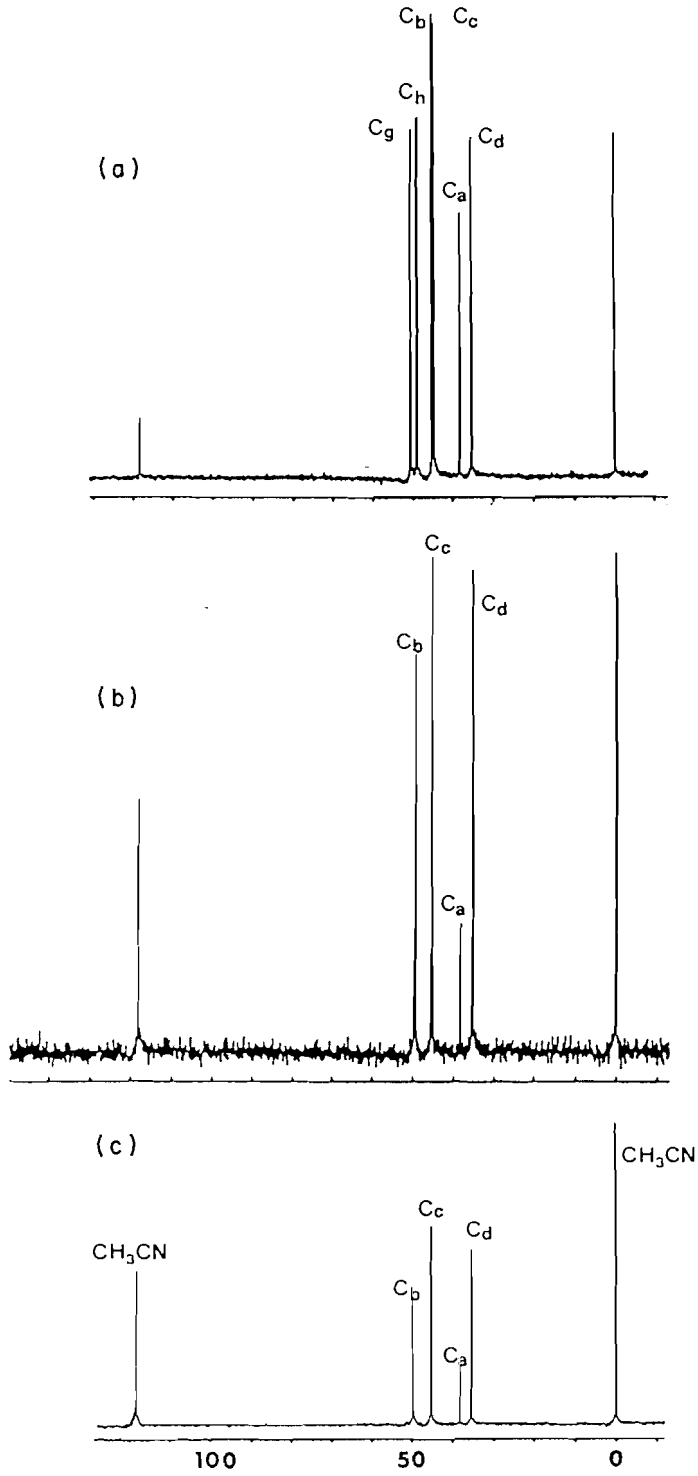
relative ratios of products obtained from all the three substrates did not vary significantly. The tetraiodide was not stable under reaction conditions and evolved iodine on prolonged heating. In the case of the tetratosylate the reaction was sluggish, presumably due to steric effects, and complete conversion of the tetratosylate to the amines did not occur. About 10–20% of unreacted tetratosylate was recovered. Hence, the overall conversion of the pentaerythrityl moiety into product amines was much higher in the case of pentaerythrityltetrabromide (up to 87%) compared to the tetratosylate and tetraiodide, where only 60% conversion was observed. Varying the mole ratio of ethylenediamine in the range of 4–10 moles per mole of pentaerythrityl derivative did not affect the ratio of products significantly. In all these experiments the products varied in the range of 30–40% for L_1, 50–60% for L_2, and 2–5% for L_3.

In the present procedure, the excess ethylenediamine was separated from the products by cation exchange resin chromatography. The presence of this diamine often leads to formation of mixed ligand amine species. Also the formation of large quantities of $[Ni(en)_3]^{2+}$ complicates the efficiency of separation of the nickel complexes. The isolation of the amines L_1–L_3 on a Dowex cation exchange resin column by gradient elution with 0.25–0.5 M HCl solutions often gives only mixtures of the products, as is evident from the ^{13}C nmr spectra of the different fractions. A similar method has been used effectively by Geue and Searle (14) for other polydentate ligands.

The amines under consideration may be compared with 2,3,2-tet. All form a sequence of 5,6,6-membered metal chelate rings around the metal ion and this arrangement of chelate rings has been shown to impart significant thermodynamic stability (15) as measured by the equilibrium constant (for example, log $K[Ni(2,3,2\text{-tet})]^{2+} = 15.9$). As a result, the structural integrity of metal complexes such as those of Ni^{2+} renders the species suitable for separation. Also, the noncyclic amine complexes containing primary amines that undergo protonation are readily hydrolysed by mineral acids to provide the ligand salts, which may then be separated from the metal ions (14). Products derived from propylenediamine and pentaerythrityl derivatives are comparable with 3,3,3-tet (3,3,3-tet: 1,5,9,13-tetraazatridecane). These form a sequence of 6,6,6-membered chelate rings, which are thermodynamically much less stable. Studies carried out in our laboratory aimed at separating such amine products using Ni^{2+} ions failed to provide pure amine hydrochlorides. Recrystallization of Ni^{2+} amine complexes of L_1–L_3 represents a good route to the amine salts, which are analytically pure.

The ^{13}C nmr spectra of the amine hydrochlorides are shown in Fig. 1(a–c). In amines L_1 and L_2 all the carbons are distinctly different in their environment, with six and four carbon resonances respectively. In the case of amine L_3, owing to the symmetry and identical chemical environment of some of the carbon centres, only four carbon signals were observed. However, comparison of the spectra of hydrochlorides of amines L_2 and L_3 showed only very slightly different chemical shifts and relative intensities (see Fig. 1). Mass spectra of the free amines confirm the identity of the products. For L_3, apart from the $(M + 1)$ ion observed at $m/e = 549$, the major fragment observed had an $e/e = 304$ corresponding to the amine fragment L_2, which could arise through loss of an N_6-containing fragment from amine L_3.

Equivalent weights of the amine hydrochlorides were determined by elution of a known amount of the solution of amine hydrochlorides through a Dowex 50 × 8 analytical column and determination of the liberated acid. By this method the equivalent weights of the hydrochlorides of amines were found to be 81.2 for amines L_2 and L_3 and 88.2 for amine L_1. Equivalent weights thus obtained compared well with the composition of the hydrochlorides of the amines and provided a quick assay of the products before their cyclization. Similar determination of equivalent weights of pure ethylenediamine dihydrochloride and the crude amine hydrochlorides obtained after the removal of ethylenediamine gave values of 79–81 and 85–86 respectively. Even though the values obtained for the hydrochlorides of



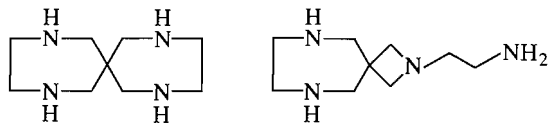


FIG. 1. The ^{13}C nmr spectra of hydrochloride salts of amines (a) L_1, (b) L_2, and (c) L_3 in D_2O with CH_3CN as internal reference.

amines L_1, L_3, and ethylenediamine are not too distinctly different, the observed values were found to be consistent when the reaction was repeated several times. However, the anhydrous amine salts gave distinctly different values.

The amine hydrochlorides were quite stable and could be stored indefinitely without any deterioration. The amine L_2, refluxed in concentrated HCl, and at pH 14, did not show any sign of decomposition, as indicated by the ^{13}C nmr spectrum. The amine L_1 was quite stable in acidic conditions but the free amine in nonaqueous media (for example in ethanol) showed signs of decomposition. The major decomposition product identified showed a m/e = 184, indicating the loss of an ethylenediamine moiety. The ^{13}C nmr spectra indicated this decomposition product to be **II** rather than **I**. This finding explains the impure product mixture obtained during cyclization and subsequent reduction of the lactam obtained in the case of amine L_1. Cyclization of amine L_1 carried out at room temperature over long periods of standing has provided better yields of the products.

I II

Crystal structures

Although there were limitations in the data sets, the basic structural features of the molecules were exhibited and confirmed. Both $[H_6(L_1)Cl_6]\cdot 4H_2O$ and $[H_8(L_2)Cl_8]\cdot 2H_2O$ provided weak data sets with somewhat poor residuals. However, the X-ray results are complementary to the other chemical observations reported. The structures of ions $[H_8(L_2)]^{8+}$ and $[H_6(L_1)]^{6+}$ are shown with the atomic labelling scheme in Figs. 2 and 3 respectively. The fractional coordinates are provided in Tables 2 and 3 respectively. Details of bond lengths and angles and intermolecular distances are given in Supplementary Tables S1–S6.[6]

The quaternary or "spiro" carbon, C(4), of the ion $[H_8(L_2)]^{8+}$ occupies a special position in the unit cell, lying on a twofold axis. Thus, the asymmetric unit consists of one half of the molecular or two of the arms. The bond lengths from C(4) to C(3) and C(5) are typical of C—C single bonds but one of the two sets of internal angles is slightly larger than the tetrahedral value (114(2)° vs. 109.4°), as has been seen in fully extended aliphatic chains. As can be seen from Fig. 2, the ion is essentially shaped like a flat cross with two of the arms above and below the plane containing the C(4). The distension in the C(3)—C(4)—C(5) (114(2)°) angle serves to move the arms further away from this plane than would be dictated by tetrahedral geometry. This is reflected in the C(5)—C(4)—C(5)′ (101(2)°) and C(3)—C(4)—C(3)′ (99(2)°) angles, which are less than the tetrahedral value. Presumably this distortion serves to lengthen the distance between the secondary amines, N(2) and N(3), and lessen any electrostatic interactions.

A structurally related ion is the protonated amine, tetrakis-(aminomethyl)methane $[H_4(tam)]^{4+}$, reported by Cameron *et al.* (3). This cation is described as adopting a planar rather than globular geometry, with the cation and anions occupying narrow "slabs" within the unit cell. In both the structure of $[H_4(tam)]^{4+}$ and $[H_8(L_2)]^{8+}$, the pentaerythrityltetraamine fragment adopts a very similar geometry. In $[H_8(L_2)]^{8+}$, the aminoethyl groups provide a further extension of this type of geometrical arrangement, lying essentially in the same plane as the central core. The unit cell for $[H_8(L_2)]Cl_8\cdot 2H_2O$ is provided in Fig. 4 and may be viewed as the stacking of flat cations along the twofold axes with the chloride and water molecules dispersed interstitially.

The crystal packing forces arise from the interactions in an

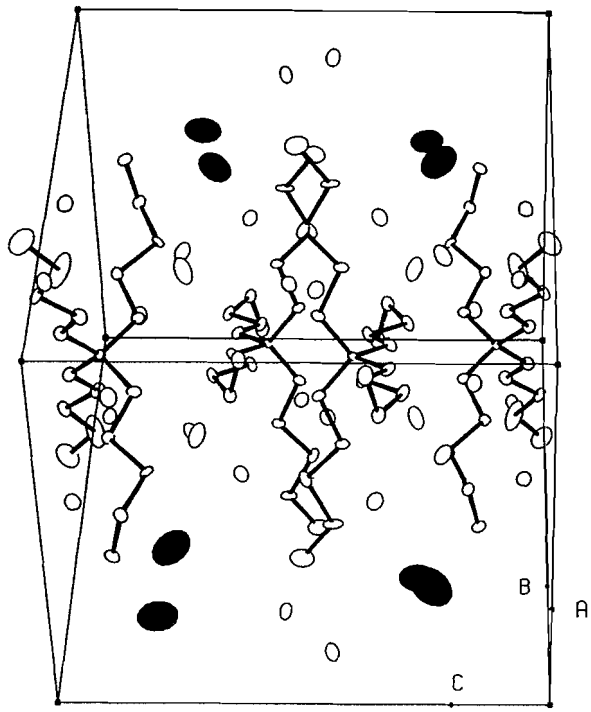

FIG. 4. Unit cell diagram of $[H_8(L_2)]Cl_8 \cdot 2H_2O$ showing stacks of cations and anions in layers. Filled and open ellipses represent oxygen and chlorine atoms respectively.

extensive array of hydrogen bonds. The absence of locatable hydrogens from the crystal structure necessitates that the information on hydrogen bonding be derived from the distances between the atoms (A--B) rather than the distance between the proton and the donor atom (H--B) (16).

Within the lattice, there are a number of short intermolecular contacts. Of particular note are the distances N(2)--Cl(1) (3.09(2) Å), N(2)--Cl(2) (3.08(3) Å), N(3)--Cl(3) (3.10(3) Å), and N(3)---Cl(4) (3.09(3) Å), which are significantly shorter than the sum of the van der Waals (17) radii (3.3 Å) for N and Cl. These distances are typical of hydrogen bonding interactions in $[H_4(tam)]Cl_4$ where the shortest N—H--Cl distance is 3.15 Å and in Et_3N—H---Cl with a distance of 3.10 Å (18). Indeed, the distances are considerably shorter than the 3.2 Å observed in $NH_2OH \cdot HCl$ (19). Several other slightly longer N---Cl distances linking the remaining amines are listed in Supplementary Table S2.

Of particular note in this structure is the absence of hydrogen bonding between the water of crystallization and the nitrogens of the cation. The O(1) atom has only very long interactions with the chlorides, the shortest of which is to Cl(2) with a distance of 3.31(2) Å. This is in contrast to the crystal structure of $[H_6(L_1)]Cl_6 \cdot 4H_2O$ (*vide infra*).

The structure of $[H_6(L_1)]^{6+}$ is shown in Fig. 3. The quaternary carbon is located on a twofold axis within the unit cell that bisects the seven-membered ring, and thus the asymmetric unit is one-half of the cations and anions. The cations are oriented within the unit cell into planes with a head-to-tail arrangement. That is, within the planes of cations, the arms of one cation are overlapped with the rings of the adjacent molecular ions. In addition, the different planes are staggered to provide the head-to-tail overlap. Also, the anions and waters of crystallization occupy sites within the planes rather than being dispersed interstitially. A diagram of the unit cell is provided in Fig. 5.

The quaternary carbon has essentially the same distorted tetrahedral structure in both the ions $[H_6(L_1)]^{6+}$ and $[H_4tam]^{4+}$, with the interior angle separating the two arms being slightly larger than the ideal tetrahedral angle (116.7(1.3)° vs. 109.4°). This distortion serves to increase the distance between N(2) and N(2)′, decreasing electrostatic interactions. Within the seven-membered ring, the C(5)—C(4)—C(5)′ angle is 110.2(1.2)°, which is typical of the value expected for a cyclic compound and indicates very little distortion of the bonding within the ring. This is to be anticipated since the rigidity of the cyclic structure would prevent large distortions in the bonding. Further evidence for the distortion of the tetrahedral structure is provided by the C(3)—C(4)—C(5) angle, which is 102.4(6)°. Essentially, the geometry of the spiro carbon implies a close similarity of structure between the three cations $[H_6(L_1)]^{6+}$, $[H_8(L_2)]^{8+}$, and $[H_4(tam)]^{4+}$.

The crystal packing forces are provided by an extensive network of hydrogen bonding interactions within the lattice. Information on hydrogen bonding was derived from the interatomic distances as given above, with distances of 2.9 Å for the N--O and 3.2 Å for the Cl--O interactions (16).

Within the lattice, there are a number of short intermolecular contacts. The positioning of the O(2) atom is of particular interest as it serves to bridge N(2) with its symmetry generated partner N(2)′. The bridge is asymmetric with one N(2)--O(2) distance being 2.76(3) Å and the other 3.40(3) Å. The latter distance is slightly longer than might be anticipated but the positioning of the water molecule would certainly suggest that it interacts with both nitrogens. Also, N(2) has a very short contact distance (3.00(3) Å) with Cl(1).

In addition to the binding of O(2), the water molecule incorporating O(1) is bound to N(3) (2.81(3) Å) and to N(1) (3.22(3) Å) of a different cation. This arrangement is facilitated by the head-to-tail arrangement of the cations within the planes. A number of other close contacts are observable within the unit cell and these are included in the intermolecular distances given in Supplementary Table S5.

Of particular interest in this structure is the absence of strong interactions between the adjacent planes of cations / anions. The closest approach is a long interaction between N(3) and Cl(1) at 3.43(3) Å. This suggests that the planes within the unit cell are

predominantly internally bonded and the stacking of the planes is a result of other interactive forces, with the closest approach being the van der Waals surfaces.

Conclusion

Interest in these polydentate amine ligands comes from their preparation and characterization prior to their use in the synthesis of metal complexes.

The amine L_1 and its cyclized derivatives form mononuclear complexes with transition metal ions. In the seven-membered ring of the ligand L_1, one of the nitrogen atoms is protonated while the metal complexes are formed. This cationic moiety acts as an anion binding site close to the metal centre. Redox reactions involving perchlorate anion and divalent nickel complexes have been reported recently by Fabbrizzi and co-workers (20) in the case of *N*-aminoethylcyclam. Ni^{2+} complexes of amines L_1 and L_2 have been found to exhibit such redox activity, and the trivalent nickel complex has been isolated in the case of ligand L_6 and characterized crystallographically[5].

Ligands L_3, L_5, and L_7 are binucleating. Homo- and heterobinuclear complexes of ligand L_7 have been prepared and characterized (21). The binuclear Ni^{2+} complex of ligand L_2 crystallizes in several forms depending upon the counteranion. X-ray crystallographic studies have shown that both Ni^{2+} centres can exist either in low spin square planar form or as a mixed low spin – high spin form depending upon the nature of the counteranion. Recently, in a polyketo system (biacetylacetone) of a binuclear nickel complex, Fukuda and Mafune (22) have shown the geometry around the nickel centres to be variable. Crystal structures and detailed reactivity studies of the complexes of the ligands L_1–L_7 have been made and will be reported elsewhere.

Molecular structure and relative proton and electron affinities of isomeric nitroimidazoles

SALIM F. FARAH, ROBERT A. MCCLELLAND, MICHAEL R. PETERSON, AND IMRE G. CSIZMADIA
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

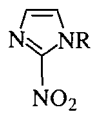
Received February 21, 1989

SALIM F. FARAH, ROBERT A. MCCLELLAND, MICHAEL R. PETERSON, and IMRE G. CSIZMADIA. Can. J. Chem. **67**, 1666 (1989).

The isomeric 2-nitro, 4-nitro, and 5-nitroimidazoles have been studied in their planar ground state, C—NO_2 rotational transition state, 3-H protonated conjugate acid and radical anion forms, with *ab initio* computations at the split-valence 3-21G basis set level. The stabilities of the parent compounds follow the order 5-NO_2 ~ 4-NO_2 > 2-NO_2. In solution 4-nitro is more stable than 5-nitro; the calculations suggest that this is a solvation effect, since the 4-nitro isomer has a considerably higher dipole moment. Barriers for nitro group rotation range from 10 to 16 kcal/mol. However, the relative change in dipole moment during the rotation is small, suggesting that dipole moments of nitroimidazoles are determined mainly by inductive effects, with resonance interactions being relatively unimportant. This conclusion is supported by calculations of molecular electrostatic potentials of the planar and rotated forms. Electron affinities follow the order 2-NO_2 > 5-NO_2 >> 4-NO_2, closely matching the order of biological effectiveness of nitroimidazole radiosensitizers. This is consistent with suggestions that the "nitro:nitro radical anion" redox cycle is an important determinant of biological activity.

Key words: nitroimidazole, *ab initio* computation, rotational barrier, proton affinity, electron affinity.

SALIM F. FARAH, ROBERT A. MCCLELLAND, MICHAEL R. PETERSON et IMRE G. CSIZMADIA. Can. J. Chem. **67**, 1666 (1989).



Opérant au niveau de l'ensemble de base 3-21G, on a effectué des calculs *ab initio* sur les 2-nitro, 4-nitro et 5-nitroimidazoles dans leur état fondamental pla, dans leur état de transition de rotation du C-NO_2 ainsi que sous les formes acide conjugué et radical anionique de la forme protonée en 3-H. Les stabilités relatives des composés de base suivent l'ordre suivant : 5-NO_2 ~ 4-NO_2 > 2-NO_2. En solution, le 4-nitro est plus stable que le 5-NO_2; les calculs indiquent que cette situation est le résultat d'un effet de solvatation dû au moment dipolaire beaucoup plus élevé du 4-nitro. Les barrières à la rotation du groupement nitro varient de 10 à 16 kcal/mol. Toutefois, le changement relatif du moment dipolaire au cours de la rotation est faible; ce résultat suggère que les moments dipolaires des nitroimidazoles sont principalement déterminés par des effets inductifs alors que les interactions de résonance ne sont pas très importantes. Cette conclusion est supportée par des calculs de potentiels électrostatiques moléculaires des formes planes et celles ayant subi une rotation. Les affinités électroniques sont dans l'ordre 2-NO_2 > 5-NO_2 >> 4-NO_2; cet ordre ressemble beaucoup l'ordre observé pour l'efficacité biologique des nitroimidazoles comme radiosensibilisateurs. Cette conclusion est en accord avec les suggestions suivant lesquelles le cycle rédox de l' «anion radical nitro:nitro» est un déterminant important de l'activité biologique.

Mots clés : nitroimidazole, calcul *ab initio*, barrière à la rotation, affinité protonique, affinité électronique.

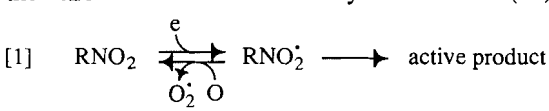
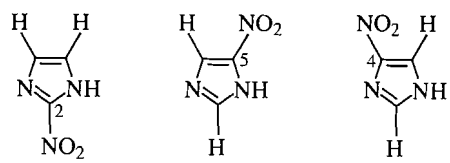
A class of drugs which has seen active investigation over the past few years is the nitroaromatics. Solid tumors develop regions where the cells are hypoxic (deficient in oxygen), and because of this are resistant to radiation therapy. Nitroaromatics function as sensitizers (1–4), selectively enhancing the response of these hypoxic cells to radiation, and the 2-nitroimidazoles misonidazole (5) and SR-2508 (6) are currently in clinical trial in this respect.



R = $CH_2CHOHCH_2OCH_3$ (Misonidazole)

R = $CH_2CONHCH_2CH_2OH$ (SR-2508)

The development of these particular drugs arose from observations that more powerful oxidizing agents were more efficient sensitizers (7). The sensitizing effect is believed to be related to an interaction of the nitro compound with electron excess or free radical centers on DNA with the concomitant formation of nitro radical anions (8). Thus there is a direct correlation between radiosensitizing ability of nitroaromatics and their one-electron reduction potential (9).

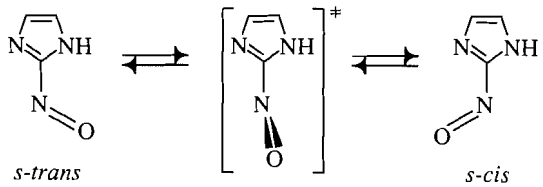


The 2-nitroimidazoles have also been found to be selectively toxic towards hypoxic tumor cells, that is, preferentially killing cells which are oxygen deficient (10). The model for this has the nitro radical anion as the key intermediate (11).

[1] $RNO_2 \underset{O_2\ O}{\overset{e}{\rightleftharpoons}} RNO_2^{\cdot} \longrightarrow$ active product

In this case, the radical anion species is produced in the cell by electron transfer to the nitro compound from cellular nitroreductase enzymes. When high concentrations of oxygen are present, the radical anion simply transfers its extra electron to the more electron affinic oxygen, a process known as "futile reduction" (3) which regenerates the parent nitro compound. At low concentrations of oxygen further reduction can occur. The toxicity observed under these conditions is believed to arise from the action of one or more of these further reduction products (active product), and indeed a synthetic 2-nitrosoimidazole has recently been found to be very biologically active (12).

In this paper we address at the theoretical level the question of the geometry, conformation, electron affinity, and proton affinity of the parent 2-, 4-, and 5-nitroimidazoles.



An understanding of various aspects of the chemistry and related biological effects were the objectives of this research. For example, the experimental electron affinity decreases in the order 2-NO_2 > 5-NO_2 > 4-NO_2, which also represents the order of biological activity (3). Additionally some nitroimidazoles show enhanced radiosensitization when there is also present a group which is protonated at physiological pH (13,

14). On their own, nitroimidazoles are, however, weak bases with pK_a values (for the conjugate acids of 1-methyl derivatives) of −0.5, +0.6, and +2.3 for 2-nitro, 4-nitro, and 5-nitro, respectively (15). Finally, in a previous communication (16) 2-nitrosoimidazole was examined at the theoretical level, the calculations revealing that planar *s-cis* and *s-trans* forms were stable minima, with the *s-trans* 2.5 kcal/mol lower in energy. The transition state for rotation of the C—NO bond was found to have a twisting angle of 93.3°, with the barrier to rotation from the *s-trans* form of 13.0 kcal/mol.

[2] 

Methods

The internal coordinates (bond lengths and bond angles) of the nitroimidazoles, and the transition states for rotation of the nitro group were geometry optimized using the split-valence 3-21G basis set within the Restricted Hartree–Fock formalism (17–19) (Unrestricted Hartree–Fock in the case of the anions) using the analytic gradient of the SCF energy with respect to the internal geometrical parameters. The optimally conditioned (OC) algorithm (20) was employed to determine the optimal geometry. Geometries were regarded as converged when the internal coordinate derivatives of the parameters were less than 0.001 Å for bond lengths or 0.01° for bond angles, and the parameter gradient lengths fell below 5×10^{-4} mdyn. This is generally sufficient to give bond lengths within 0.0001 Å and bond angles within 0.01° of the true minimum. Once a converged geometry had been obtained for a given conformation, it was determined by finite differences of gradients using the minimization of the sums of squares algorithm VAO5AD (21) whether or not this structure represented a minimum on the potential energy surface. The order of minima must be zero, while transition states must have an order of one. All computations were performed on the Gould 32/9705 computer system at the University of Toronto using the MONSTERGAUSS *ab initio* programme (22).[1]

Results and discussion

Computations in this study were generally performed at the 3-21G basis set level. This sees wide applicability to molecules of moderate size, and while it has the same number of primitives as the minimal STO-3G basis set (23), it contains nearly twice the number of contracted basis set functions per atom. The 3-21G basis set has been shown to be superior to STO-3G as a means for determining equilibrium geometries and force constants, for comparing geometries with experimental studies and for assessing relative molecular energies (24). Energies of the three parent neutral compounds were also calculated using the more extensive 6-31G* basis set, using the planar optimal geometries obtained at the 3-21G level. As shown in Table 1 the differences in the total energies of the parent nitroimidazoles were nearly the same in the two basis sets.

Geometry and conformation of nitroimidazoles

The initial estimate for the geometry of 2-nitroimidazole was based upon a previously optimized geometry for 2-nitrosoimidazole (16). However, the SCF failed to converge at the 3-21G basis set level, both in the planar ground state and in the torsional transition state. Thus the conformations were first optimized at the STO-3G basis set level, the molecular coefficients were extracted from these geometries, and these were employed via coefficient matrix projection to initiate the optimizations in the 3-21G basis set. In the case of the 4- and 5-nitroimidazoles, initial guesses were based upon the optimized geometries for the 2-nitroimidazole obtained in the 3-21G basis set and no problems were encountered in the SCF convergence. All optimized geometries were order-checked using the minimization of the sum of squares VAO5AD (21). Within this programme, there exists the option of determining second derivatives for all parameters or only for those of particular interest, such as parameters whose perturbation would break the symmetry of the molecule. In this study, the second option was chosen since all molecules possess a plane of symmetry allowing optimization within the C_S symmetry. For the torsional transition state structures, all orders were found to be equal to unity, while for the other structures orders were found to be zero.

The bond lengths and angles obtained with the planar ground states and the transitions state for carbon—nitro group rotation are shown in Fig. 1, with the rotational barriers and torsion angles in the transition state given in Table 2. The latter is very close to 90° in case of the 2-nitro isomer, and is about 7° off the perpendicular for the other two. One interesting feature of the data for the 2-nitroimidazole is that the barrier, 12.4 kcal/mol, is very similar to that previously obtained, 13.0 kcal/mol for the 2-nitrosoimidazole analog (16). These barriers arise through the interaction in the fully planar forms of the electron-rich π electrons of the imidazole ring and the π electrons of the nitro and nitroso substituents. The conclusion is that these two substituents are affected in a very similar way. It is also interesting to note that the barrier to rotation calculated for nitrobenzene, 8.5 kcal/mol (6-31G basis set) (25), is not that much smaller than those obtained here.

Dipole moments

Table 3 lists dipole moments for the three isomers obtained

from the 3-21G calculations. For both the planar and torsional forms, these show an order 5-NO_2 < 2-NO_2 < 4-NO_2. This order does not match that observed for biological effects of nitroimidazoles, with the implication that with this class of agents the polarity of the parent drug is a relatively unimportant factor in determining its efficiency. The order does, however, correctly predict the experimental order of melting points. In general, as the dipole moment of a series of isomers increases, the melting point increases, and this is the case here as well. The pattern is most clearly seen with the melting points for the 1-methyl substituted nitroimidazoles. The parent 2-nitro- and 4-nitroimidazoles also show the correct order, but there is no experimental number for the 5-nitroimidazole. This is due to the fact that in condensed phases 5-nitroimidazole spontaneously tautomerizes to its 4-nitro isomer (30).

The usual argument is that the 4-nitro isomer is more stable because it has better resonance interactions between the nitro group and the aromatic ring. Our calculations, however, indicate that there is very little difference in energy between 4-nitroimidazole and 5-nitroimidazole, the 5-nitro isomer being 0.07 kcal/mol lower in energy at the 3-21G level and 0.19 kcal/mol higher in energy at the 6-31G* level (Table 1). These calculations of course can only be directly compared to gas phase experimental results, while in fact the above conclusion about the position of equilibrium refers to condensed phases, in particular polar solvents. We suggest that the favoring of the 4-nitro tautomer observed in the latter case is principally a solvation phenomenon. The calculated dipole moments (Table 3) indicate that the 4-nitroimidazole is considerably more polar, and thus will be more strongly solvated in polar solvents. There are in fact a number of heterocyclic tautomerizations with dramatic changes in the position of equilibrium between the gas phase and solution associated with polarity differences between the two isomers (31).

With each nitroimidazole the dipole moment is seen to decrease on proceeding from the planar ground state to the torsional transition state (Table 3). This is expected since rotating the nitro group out of the plane of the ring prevents the conjugation of the type shown below for the 2-nitro isomer.

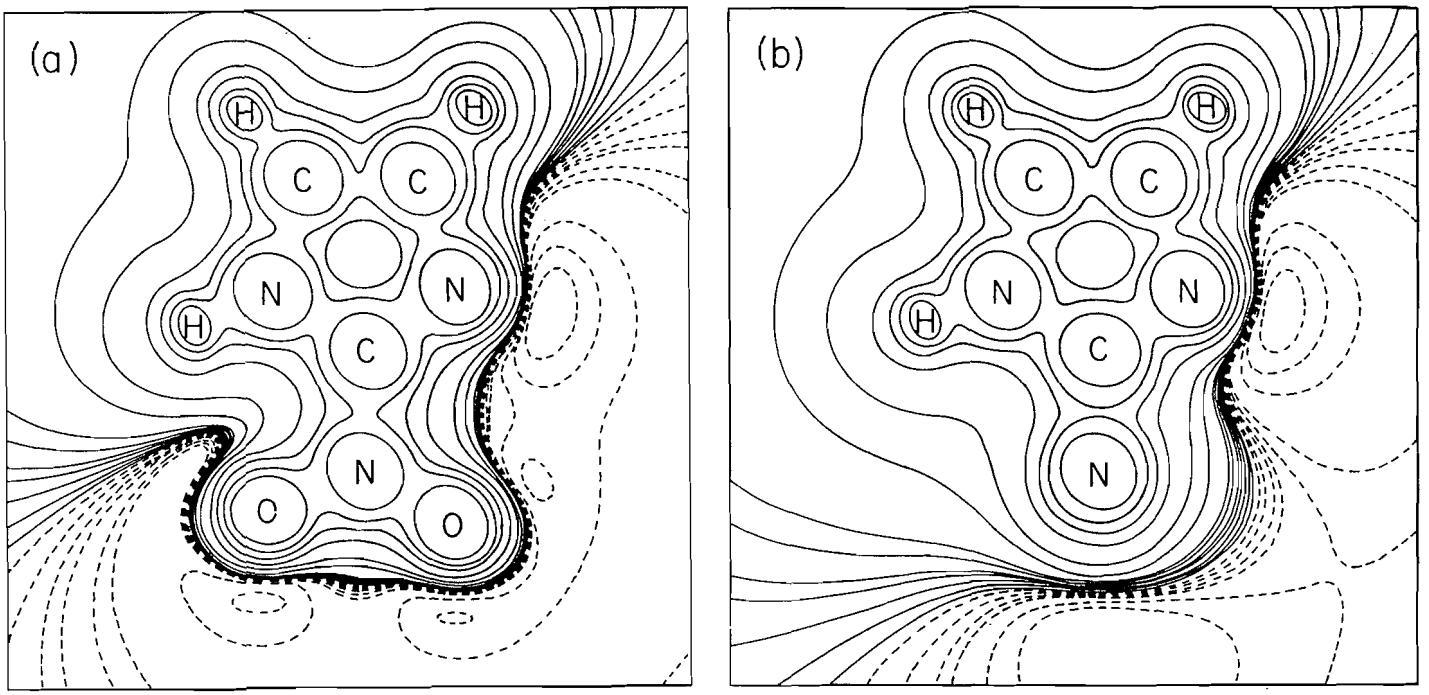

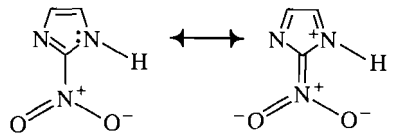

FIG. 2. Calculated electrostatic potentials of the planar (*a*) and rotated (*b*) forms of 2-nitroimidazole in the plane of the imidazole ring. Dashed contours correspond to negative potentials.

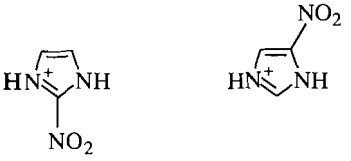
Consistent with this idea, it is observed that with each nitroimidazole a small increase in the length of the carbon—nitro bond in the transition state as compared to the ground state (Table 4). Interestingly, however, the changes in both the dipole moments and the bond lengths for each nitroimidazole are rather small. This would suggest that the resonance interaction has a minor effect, and that the principal contribution of the nitro group to the dipole moment is inductive, that is an interaction which is not affected by the loss of conjugation in the rotated form. The relative unimportance of the resonance interaction of nitro groups attached to benzene rings has been noted previously, nitro for example having a large value for its σ_I substituent constant but a small σ_R (32). What is somewhat surprising in the present case is that the imidazole ring is a π electron-rich system, capable, for example, of interacting with adjacent carbenium ion centers more strongly than a *p*-methoxyphenyl ring (33). However, even the imidazole–nitro combination does not apparently result in a greater resonance effect. This lack of importance of resonance would also explain why the barriers of rotation in nitroimidazoles and nitrobenzene are similar. Strong resonance interactions would predict greater barriers in the former.

Electrostatic potentials



The relatively small degree of conjugation in nitrobenzene has also recently been established by Politzer and co-workers, through a computational analysis of the planar and rotated forms (25). One indicator used by these authors was the similarity in the electrostatic potentials of the two forms. We have carried out similar calculations for the nitroimidazoles. The results for the 2-nitro derivative are presented in Fig. 2; similar profiles are found with the other isomers. In the molecular planes of the planar forms there are apparent large regions of negative potential which can be attributed to the lone pairs of the oxygens of the nitro group and the ring nitrogen σ lone pair of electrons. The most negative values (local minima) of the potential are −83.6, −86.7, and −86.5 kcal/mole for the 2-nitro-, 4-nitro-, and 5-nitroimidazole, respectively. In the transition state when the nitro is ~90° rotated, these large negative regions remain associated with the lone pairs, and there is little change in the absolute magnitude of the potential, the most negative values being −81.7, −83.9, and −87.6, respectively. These relatively small changes are further indicators of the unimportance of the resonance interaction.

TABLE 4. Carbon–nitrogen (NO_2) bond lengths (Å) of planar and torsional transition state nitroimidazoles (3-21G basis set)

	Bond length (Å)		
Form	2-Nitro	4-Nitro	5-Nitro
Planar form	1.4117	1.4079	1.3916
Transition state	1.4342	1.4316	1.4303

Relative proton affinities

Geometry optimization of the N-3 protonated nitroimidazoles was achieved at the 3-21G basis set level. The protonated forms were in each case about 220 kcal/mol more stable than their neutral conjugate base. (Note that 4-nitroimidazole and 5-nitroimidazole have the same conjugate acid.) The additional stability of the protonated forms is due to the extra N—H bond created during protonation.

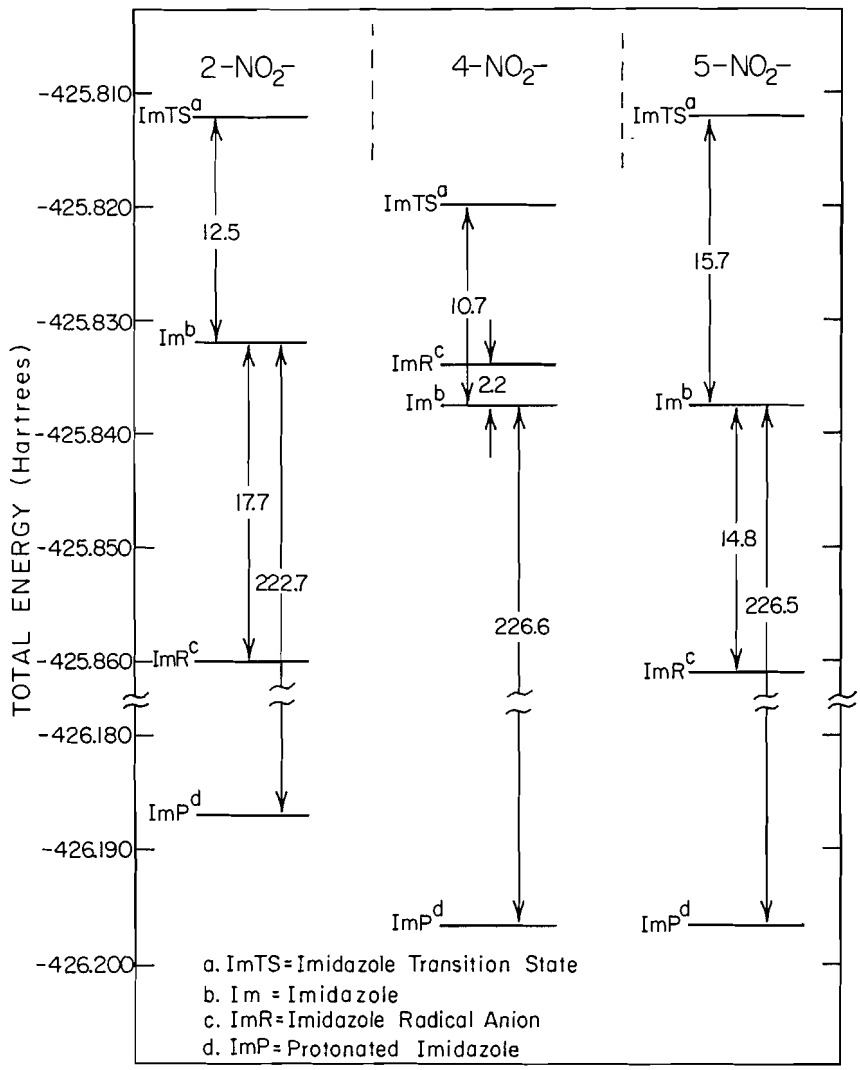

FIG. 3. Total energies of nitroimidazoles (Im), torsional transition states (ImTS), radical anions (ImR), and 3-H protonated conjugate acids (ImP).

Energies of the neutral and conjugate acid forms are compared in Table 5. The 4(5)-nitroimidazolium ion is calculated to be about 7 kcal/mol more stable than the 2-nitroimidazolium isomer, while the relative gas phase proton affinities of the neutral nitroimidazoles follow the order 4-NO_2 ~ 5-NO_2 > 2-NO_2. As illustrated in the last row of Table 5 in aqueous solution the basicity order is 5-NO_2 > 4-NO_2 > 2-NO_2. We have previously suggested that there may be solvation differences on the neutral nitroimidazoles, and this could be behind the differences between gas phase and solution.

Relative electron affinities

The radical anions of the three nitroimidazoles have been SCF geometry optimized in the 3-21G basis set within the

$E(ImNO_2^-) - E(ImNO_2)$	−18.69	+2.23	−14.80

(UHF/RHF) formalism. The energies are summarized in Table 6. Recognizing that without Configuration Interaction calculations, the absolute electron affinities must be regarded as being uncertain, the relative electron affinities are probably reasonably accurate as no electron pairs are formed or destroyed during the process of electron capture. These follow the order 2-NO_2 > 5-NO_2 > 4-NO_2, with a particularly large gap between 5-NO_2 and 4-NO_2. These numbers do correlate with the relative biological activities of differently substituted nitroimidazoles, which follow an order in both radiosensitization and hypoxic cytotoxicity of 2-NO_2 slightly more effective than 5-NO_2, with both significantly better than 4-NO_2. As discussed in the Introduction, the biological effects of nitroimidazoles are believed to be closely related to the "nitro:nitro radical anion" redox cycle, and the relationship of biological activity with theoretical electron affinity is therefore not surprising. This excellent correlation does suggest, however, that theory might provide useful new information in predicting biological effects to aid in the design of new drugs. A neurotoxic side reaction is limiting the clinical effectiveness of nitroimidazoles as radiation sensitizers, and there is considerable interest in finding new molecules of similar electron affinity but lacking the nitro group.

Summary

Figure 3 graphically compares the total energies of the species calculated in this work. The relative stability of the parent planar nitroimidazoles is 5-NO_2 ~ 4-NO_2 > 2-NO_2, and this is independent of the basis set (3-21 versus 6-31G*). The similar energy of the 5-NO_2 and 4-NO_2 isomers in the gas phase does not extend to solution, where the 4-NO_2 is more stable. The calculations, however, indicate that this isomer has a significantly higher dipole moment, and it is suggested that a solvation effect is behind the solution order. A comparison of the relative dipole moments of the planar compounds and the torsional transition states indicates that the dipole moments are largely determined by inductive effects, with resonance interactions between the nitro group and the imidazole ring being relatively unimportant. The same conclusion is reached through the analysis of bond angle and electrostatic potential differences between the two forms. The relative electron affinities correlate well with the order of biological activities (2-NO_2 > 5-NO_2 > 4-NO_2). This is consistent with suggestions that the relative stability of the radical anion is an important factor in determining the biological effectiveness of nitroimidazole drugs.

Volumetric studies on binary mixtures of some furan derivatives with benzene, chlorobenzene, and bromobenzene at 298.15 K

HOMENDRA NAOREM AND S. K. SURI[1]

Department of Chemistry, Indian Institute of Technology, Delhi, New Delhi – 110016, India

Received February 3, 1989

HOMENDRA NAOREM and S. K. SURI. Can. J. Chem. **67**, 1672 (1989).

Molar excess volumes for the binary mixtures of tetrahydrofuran, furan, furfural, and furfuryl alcohol with benzene, chlorobenzene, and bromobenzene have been calculated from precise experimental density data at 298.15 K over the entire composition range. The results have been discussed in light of unlike n–π interactions between the π-electron cloud of the aromatic ring and the oxygen atom of the heterocyclic ring. The substitution of a halogen atom in the aromatic ring activates the molecule for n–π interactions in tetrahydrofuran and furan solutions and deactivates the molecule in furfural and furfuryl alcohol solutions.

Key words: furan derivatives, binary mixtures, excess volumes, n–π interactions, π–π interactions.

HOMENDRA NAOREM et S. K. SURI. Can. J. Chem. **67**, 1672 (1989).

Utilisant des données expérimentales précises relatives aux densités de mélanges à 298,15 K, on a calculé les volumes molaires en excès pour des mélanges binaires formés d'une part de tétrahydrofurane, de furane, de furfural et d'alcool furfurylique et d'autre part de benzène, de chlorobenzène et de bromobenzène. On discute des résultats à la lumière d'interactions différentes n–π entre le nuage d'électrons π du noyau aromatique et l'atome d'oxygène du noyau hétérocyclique. La substitution du noyau aromatique par un halogène active la molécule pour les interactions n–π dans les solutions de tétrahydrofurane et de furane et désactive la molécule dans les solutions de furfural et d'alcool furfurylique.

Mots clés : dérivés du furane, mélanges binaires, volumes en excès, interactions n–π, interactions π–π.

Introduction

Our recent studies on binary mixtures of tetrahydrofuran (1–3), furan (4), furfural (5, 6), and furfuryl alcohol (7) with a variety of organic liquids revealed a strong n–π interaction between the π-electron cloud of the aromatic ring and the oxygen atom of the heterocyclic ring in tetrahydrofuran (THF) and furan. These interactions were found to be highly influenced by geometric factors and exhibited a significant change on going from furan to furfural to furfuryl alcohol (FA). As an extension of these studies, it was considered worthwhile to examine the effect of electronegative halogen atoms in the aromatic ring on the solution properties of the binary mixtures. In this paper we report the results of our studies on the excess molar volumes for binary mixtures of THF, furan, furfural, and FA with benzene, chlorobenzene, and bromobenzene at 298.15 K.

Experimental

Analytical reagent grade sample of THF (E. Merck, India) was refluxed over stannous chloride for about 8 h, filtered, stored over anhydrous calcium chloride for about 48 h, and then distilled. The sample of furan (Ferak, Germany) was refluxed over potassium hydroxide and distilled over sodium. Laboratory reagent grade samples of furfural and FA (SRL, India) were distilled under reduced pressure and the middle fractions collected (5, 6). The samples of the chlorobenzene and bromobenzene (AG-Fluka) were purified by shaking repeatedly with portions of sulfuric acid until the acid was no longer colored. It was washed with water and then with dilute potassium carbonate solution. The decanted liquid was dried over calcium chloride for 24 h before the sample was finally subjected to fractional distillation (8). Spectroscopic grade sample of benzene (Fluka) was used as such without further purification. All liquids were stored in brown bottles and fractionally distilled immediately before use. The densities of THF, furan, furfural, FA, benzene, chlorobenzene, and bromobenzene samples purified by us were 0.88193, 0.93163, 1.15473, 1.12499, 0.87352, 1.10069, and 1.48811 g cm^{-3}, respectively, at 298.15 K. These values are in close agreement with the reported literature values 0.88195, 0.93095, 1.15450, 1.12615, 0.87370, 1.10090, and 1.48820 of the liquids, respectively (8, 9).

The excess molar volumes of mixing, V^E, have been computed from the experimental density data. The solutions for the measurement of densities were prepared by weight and corrections for buoyancy were applied. The details of the experimental technique for the preparation of solutions have been described elsewhere (10).

The densities were measured with a vibrating tube digital density meter Model DMA 602/DMA 60 (Anton Paar, Austria). Water from a thermostated bath was circulated through the metal block of the density meter at a flow rate of ~3 dm^3 min^{-1}. The temperature of the water bath was controlled to $\pm 1 \times 10^{-3}$ K using a Tronac PTC-40 proportional temperature controller. The density meter was calibrated with dried air and degassed ion-exchanged water. The density of water was taken to be 0.9970429 g cm^{-3} at 298.15 K (11). Duplicate densities of liquids and liquid mixtures studied agreed to within 5×10^{-5} g cm^{-3}. This propagates a maximum uncertainty of about ± 0.005 cm^3 mol^{-1} in the V^E values. For solutions containing furan experimental uncertainties were slightly higher. However, the reported V^E values for these mixtures are expected to be uncertain by not more than ± 0.008 cm^3 mol^{-1}.

Results and discussion

The V^E values for the binary mixtures at 298.15 K are recorded in Table 1 and plotted as a function of solution composition in Fig. 1. Each set of the results were fitted into a polynomial of the type:

$$[1] \quad V^E = x(1-x)[A_0 + A_1(2x-1) + A_2(2x-1)^2 + A_3(2x-1)^3]$$

where x is the mole fraction of THF, furan, furfural, or FA in the binary mixture and A_i's are constants. The values of the constants as determined by the least-squares method (unweighted) along with the standard deviation $\sigma(V^E)$ of the fit are listed in Table 2. Since the $\sigma(V^E)$ values for all the systems

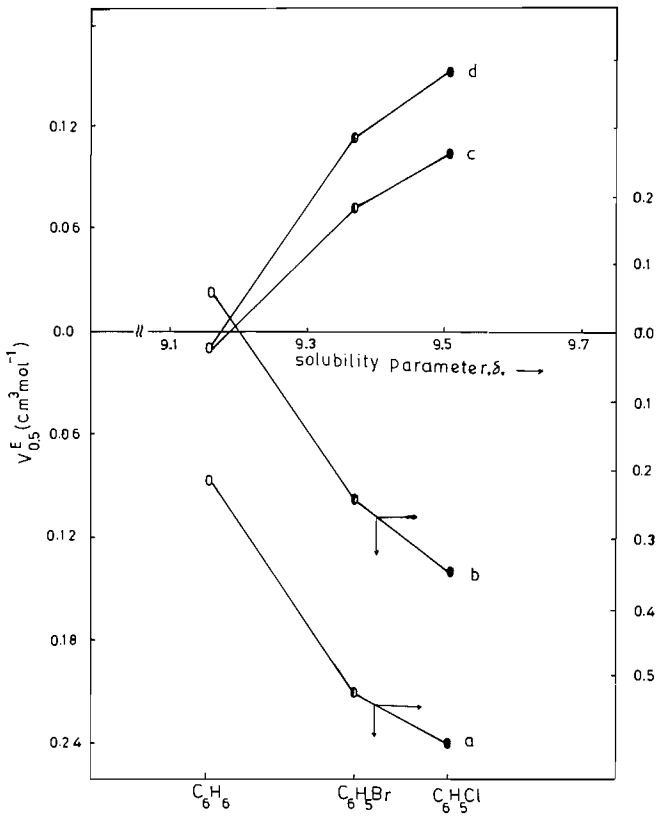

FIG. 2. Plot of $V^E_{0.5}$ against Hildebrand's solubility parameter, δ, for the binary mixtures containing (*a*), THF; (*b*), furan; (*c*), furfural, and (*d*), FA.

or FA (except for the mixtures containing benzene) were found to be positive over the entire composition range. The binary mixtures containing furan and benzene exhibited a positive V^E and those containing furfural or FA and benzene exhibited negative V^E. Our V^E values for the binary mixtures containing THF and benzene are in good agreement with those reported by Meyer and co-workers (12), the maximum difference being $\sim 0.009\ cm^3\ mol^{-1}$ over the composition range $x \approx 0.4$ to 0.6. To the best of our knowledge, no V^E data at 298.15 K have been reported in the literature for other binary mixtures considered in this paper.

For the binary mixtures containing THF or furan the molar excess volumes at equimolar concentration $V^E_{0.5}$ was found to follow the order benzene > chlorobenzene > bromobenzene. When a halogen atom is introduced into the aromatic ring, it brings about a change in the π-electron density around the aromatic ring and also a change in the shape and size of the resultant molecule. Both these factors are likely to contribute to the overall volumetric effects in the mixtures. Bromobenzene makes the molecule more asymmetric, resulting into a higher free volume in solution and in view thereof a relatively larger positive contribution to V^E is expected as compared to the mixtures containing chlorobenzene. However, it is observed that V^E for the binary mixtures containing bromobenzene are more negative than those containing chlorobenzene, whereby indicating the presence of strong intermolecular interactions. The decrease in V^E on going from benzene to chlorobenzene to bromobenzene appears to be a consequence of increased polarizability of the molecule due to the introduction of a halogen atom in the aromatic ring. For the binary mixtures of cyclohexane with benzene, chlorobenzene and bromobenzene a similar behavior has been reported (13–15).

The V^E values for the binary mixtures containing furan are observed to be consistently larger than those containing THF (Fig. 1). This may be ascribed to the presence of strong π–π interactions in furan molecules (16). Breaking this π–π interactions on addition of a hydrocarbon would lead to a positive contribution to V^E. The presence of π-electron clouds in furan molecule is also likely to restrict the participation of n-electron of the oxygen atom of furan molecule for the n–π interactions in the mixtures and hence a smaller contribution to volumetric effects arising from intermolecular interactions are anticipated (4). The $V^E_{0.5}$ for the binary mixtures containing furfural and FA follow the order benzene < chlorobenzene < bromobenzene. In pure state, the molecules of furfural are known to be associated through dipole–dipole interactions (17, 18). Also, the unusually higher viscosity value of FA (4.63 cps at 298.15 K) is indicative of the fact that the molecules of FA, like aliphatic alcohols, are self associated through hydrogen bonding in the pure state. The addition of a liquid to furfural or FA would, therefore, tend to break the molecular aggregates in pure furfural or FA resulting in an increase in V^E. These effects would, however, be counteracted by the unlike n–π interactions which would lead to a decrease in V^E. In view of the observed V^E for the mixtures, it is apparent that with the introduction of a halogen atom in the benzene ring, the "structure breaking" effects becomes more predominating in the mixtures. The relatively larger V^E values for mixtures containing FA as compared to those containing furfural (Fig. 1) suggest that the molecules of FA are associated to a larger extent

than the furfural molecules. Strictly speaking, more work is required to be done to reach a definite conclusion in this regard.

It is interesting to observe that $V^E_{0.5}$ for these mixtures varies almost linearly with the Hildebrand solubility parameter, δ (Fig. 2). A similar behavior has been observed for the binary mixtures of cyclohexanone with substituted benzenes (19) and is attributed to the presence of dipoles in the mixtures.

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

J. RAMÓN LEIS, M. ELENA PEÑA, and JOHN H. RIDD. Can. J. Chem. **67**, 1677 (1989).

The kinetic equation for the nitrous acid catalysed nitration of naphthalene in aqueous mixtures of sulphuric acid and acetic acid has at least two kinetic terms: one first order with respect to naphthalene and one second order with respect to naphthalene. The orders with respect to nitrous acid and nitric acid vary with the conditions in the way characteristic of the electron transfer mechanism of this reaction. The second-order term with respect to naphthalene is considered to derive from the formation of the dimeric radical cation $(ArH)_2^{+\bullet}$. The acidity dependence of the rate coefficients and the absence of a normal isotope effect in the reaction of naphthalene-d_8 are consistent with this interpretation.

Key words: naphthalene, nitration, nitrous acid.

J. RAMÓN LEIS, M. ELENA PEÑA et JOHN H. RIDD. Can. J. Chem. **67**, 1677 (1989).

L'équation cinétique de la réaction de nitration du naphtalène, réalisée dans des mélanges aqueux d'acides sulfurique ou acétique et catalysée par l'acide nitreux, comporte au moins deux termes cinétiques : un du premier ordre par rapport au naphtalène et un autre du deuxième ordre par rapport au naphtalène. Les ordres par rapport à l'acide nitreux et à l'acide nitrique varient suivant les conditions de la réaction et ils sont caractéristiques du mécanisme de transfert d'électron de cette réaction. On considère que le terme du deuxième ordre par rapport au naphtalène provient de la formation d'un cation radicalaire dimère $(ArH)_2^{+\bullet}$. La relation entre les coefficients de vitesse et l'acidité ainsi que l'absence d'effet isotopique normal dans la réaction du naphtalène-d_8 sont en accord avec cette interprétation.

Mots clés : naphtalène, nitration, acide nitreux.

[Traduit par la revue]

Introduction

A considerable amount of evidence has appeared in recent years to show that the nitrous acid catalysed nitration of many substrates is a radical reaction initiated by the oxidation of the aromatic compound to a cation radical or, with phenols, to a phenoxy radical. The unusual kinetic forms observed in the nitration of *para*-nitrophenol (1) have been interpreted in this way (2) and the conclusion is supported by the observation of ^{15}N CIDNP (chemically induced dynamic nuclear polarisation) effects in the nitrous acid nitration of *para*-nitrophenol (3), mesitylene (4), and durene (5). The nitrous acid catalysed nitration of *para*-methylphenol also shows ^{13}C CIDNP effects (6). The nitrous acid catalysed nitration of phenol shows the kinetic forms characteristic of this radical reaction but there also appears to be a small contribution from the "classical" mechanism involving nitrosation followed by oxidation (7).

Kinetic studies are not available on all of the above reactions but in those that have been carried out the order with respect to the aromatic compound is unity. However, in 1983, Ross, Moran, and Malhotra showed that the nitrous acid catalysed nitration of naphthalene in aqueous sulphuric acid appeared to have an order of 1.5 in the aromatic compound (8). They showed that the reaction gave a quantitative yield of nitronaphthalenes with an α/β ratio of 25. They did not provide a detailed interpretation of their results but suggested that a chain reaction involving electron transfer could explain the unusual order. The use of aqueous sulphuric acid severely limits the range of concentrations that can be used because of the low solubility of naphthalene. In the present work, we have reinvestigated this reaction using aqueous mixtures of sulphuric acid and acetic acid since naphthalene is more soluble in these media; the results support those published in the preliminary account of this work (9).

Results

The reaction has been followed by the same method (uv spectroscopy) as used previously (8) and, as before, a large excess of nitric acid has been used so that, providing the concentration of nitrous acid can be taken as constant, the observed order of the reaction is that with respect to the naphthalene. However, probably because some of our studies have used considerably greater concentrations of naphthalene, our work indicates that the order with respect to naphthalene changes from one to about two as the concentration of naphthalene is increased. This change in the form of the kinetic runs is shown in Fig. 1 for two runs carried out with very different concentrations of naphthalene: at low concentrations, good first-order kinetics are obtained but, when the initial concentration of naphthalene is high, the second-order plot is more nearly linear.

The change in the kinetic order from first to second also leads to an increase in the rate of reaction above that expected for the first-order form. The change has therefore been represented as the incursion of an additional kinetic term as shown in eq. [1]:

$$[1] \quad \text{Rate} = k_1[\text{ArH}] + k_2[\text{ArH}]^2$$

A number of kinetic runs have been carried out using intermediate concentrations of naphthalene and many of these have been fitted to eq. [1] using a computer program. For this calculation to yield reasonably accurate results for both rate coefficients, it is necessary that the two kinetic terms should be of approximately similar magnitude; almost all the values quoted refer therefore to runs in which the contribution of the first-order term at the start of the reaction is between 17 and 70% of the total rate. These percentages are given in the final columns of the tables. The runs are grouped into sets depending

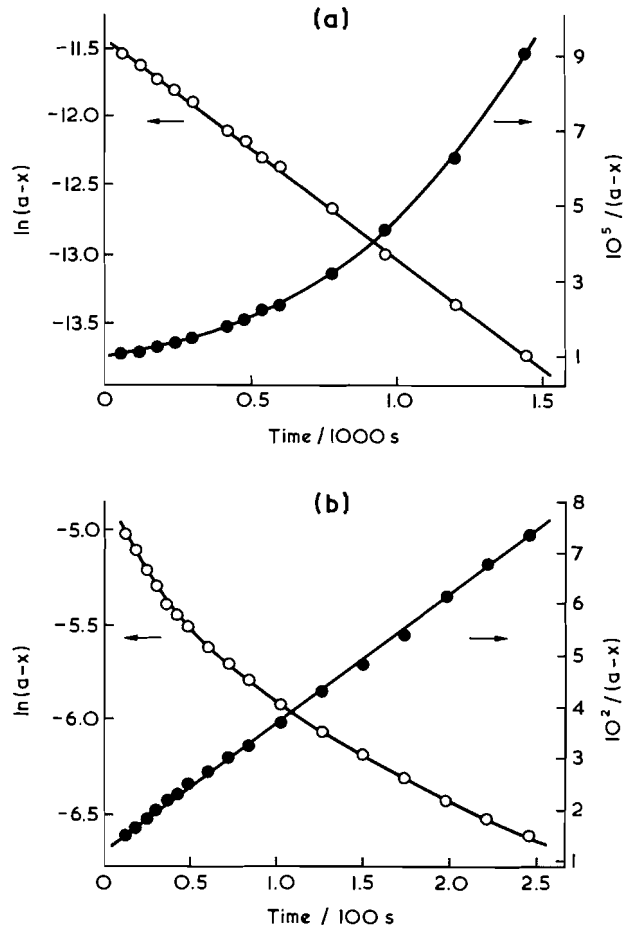

FIG. 1. First-order (open circles) and second-order (dots) plots for two kinetic runs carried out with very different concentrations of naphthalene. (a) [ArH] = 1.17×10^{-5} mol dm^{-3}; other conditions as shown in Table 1. (b) [ArH] = 7.8×10^{-3} mol dm^{-3}; other conditions as shown in Table 2.

on the other conditions used and the resulting rate coefficients and half-lives are shown in Tables 1–3. The first-order rate coefficients obtained in this way accord well with those obtained by applying a first-order equation to the runs with very low concentrations of naphthalene (Table 1) but the second-order rate coefficients from eq. [1] are significantly lower than those obtained by applying a second-order equation to the runs with high concentrations of naphthalene (Tables 2 and 3). This is presumably because the relative importance of the first-order component in eq. [1] increases during a kinetic run as the concentration of naphthalene falls.

The different sets of runs in Tables 1–3 differ in the concentrations of the other components, and it is necessary to consider whether these changes influence the apparent order with respect to naphthalene. Evidence on this is provided by the logarithmic plot of the half-lives against the concentration of naphthalene in Fig. 2. The solid lines indicate the experimental results; the broken line indicates the consequence of displacing the plobs (b) and (c) so as to form a continuous curve with plot (a). Since the curve produced has no sharp changes of slope, it would appear that the effective order with respect to naphthalene is determined primarily by the concentration of naphthalene, as implied by eq. [1]. The broken curve is drawn to have a final slope of -1; the results therefore accord with the transition between first-order and second-order kinetics.

In principle, the kinetic form of these reactions could be markedly influenced by any side reactions that led to an increase or decrease in the amount of nitrous acid present. We have therefore checked the above conclusions by a study of how the instantaneous rate at a point near the start of reaction varies with the concentration of naphthalene. If eq. [1] is correct, then a plot of Rate/[ArH] against [ArH] should be linear with an intercept equal to k_1 and a slope equal to k_2. The complete set of these

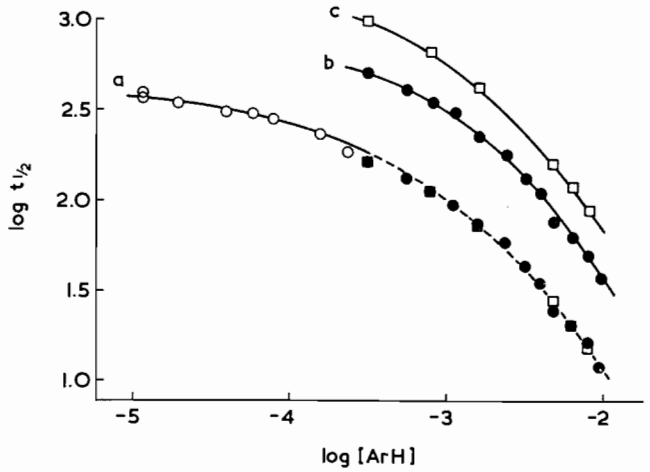

FIG. 2. Logarithmic plots of the half-life against the concentration of naphthalene for the kinetic runs in (a) Table 1; (b) Table 2; and (c) Table 3. The broken line indicates the plot obtained by displacing sets (b) and (c) to form a continuous curve with the points in set (a).

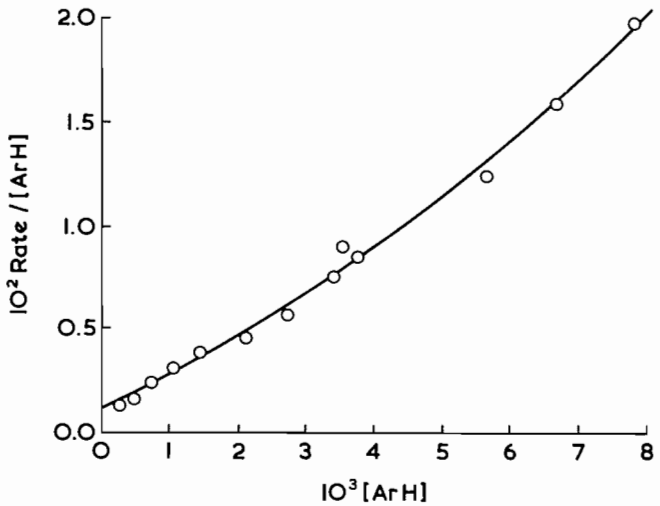

FIG. 3. A plot of the instantaneous rate of reaction divided by the concentration of the aromatic compound against the concentration of the aromatic compound. The data derive from the initial points of the kinetic runs in Table 2.

results and two related figures are given in the Supplementary Data Section (Tables 1S–3S, Figs. 1S and 2S)[3] but the results for the most extensive set of data are shown in Fig. 3. Rather unexpectedly, the plot shows slight upward curvature and accords with the presence of a third-order term in the rate equation as shown in eq. [2].

$$[2] \quad \text{Rate} = k_1[\text{ArH}] + k_2[\text{ArH}]^2 + k_3[\text{ArH}]^3$$

From the fit of the plot in Fig. 3 to a quadratic equation, the values of the rate coefficients in eq. [2] are k_1, 1.15×10^{-3} s^{-1}; k_2, 1.54 mol^{-1} s^{-1} dm^3; k_3, 1.03×10^{-2} mol^{-2} s^{-1} dm^6. However, if the last three points in Fig. 3 are omitted, the remainder give a good approximation to a linear plot and the corresponding values of the rate coefficients become k_1, 7.6×10^{-4} s^{-1}; k_2, 2.1 mol^{-1} s^{-1} dm^3. These values are very close

to those obtained from the analysis of the individual kinetic runs under the same conditions (Table 2).

Some work has been done on the variation of the first-order and second-order rate coefficients with the concentrations of nitrous acid and nitric acid. The results for nitrous acid are in Table 4 and those for nitric acid are in Table 5; both sets of data are shown as logarithmic plots in Fig. 4. The variation of these rate coefficients with acidity has also been studied (Table 6); a comparison of the results with the variation of the concentration of the nitrosonium ion with acidity[4] is shown in Fig. 5.

The deuterium isotope effect has also been measured (Table 7). A small inverse isotope effect appears to be present in k_1, k_2, and the half-life of the reaction.

Discussion

The studies described above have concentrated mainly on the order with respect to naphthalene, partly because this is the first example of such a second-order process in aromatic nitration and partly because this is also the area of our partial disagreement with the earlier work (where the order was believed to be 1.5 (8)). There is no doubt over the high order with respect to naphthalene: the decrease in the half-life by a factor of 13 when the concentration of naphthalene is increased by a factor of 30 (Table 2) cannot be missed. There is some doubt over whether eq. [1] is satisfactory representation of this kinetic form. The complete logarithmic plot of the half-lives in Fig. 2 is drawn to have a final slope of -1 but the fit of the points to a quadratic equation gives a slightly greater final slope (-1.3) and this hint of an order greater than 2 is supported by the slight curvature of the instantaneous rate plot in Fig. 3. However, even the kinetic runs corresponding to the last three points in Fig. 3 fit the integrated form of eq. [1] (see Experimental) with correlation coefficients >0.999 and so eq. [1] appears to be a good approximation to the kinetic form observed.

Under the conditions listed in Table 4, the order with respect to nitrous acid as calculated from the values of k_1 is 0.83 when $[HNO_2] = 1 \times 10^{-4}$ mol dm^{-3}, decreasing to 0.43 when $[HNO_2] = 1 \times 10^{-3}$ mol dm^{-3}. The corresponding values calculated from the variation of k_2 are 1.09 and 0.22 (see Fig. 4). The results for the order with respect to nitric acid (Table 5) show considerably more scatter (Fig. 4) but, from the variation of k_1, the order appears to change from 0.3 to 0 as the concentration of nitric acid is increased. From the variation of k_2, the corresponding change is from 0.5 to 0.

Such changes in the orders with respect to nitrous acid and nitric acid (as calculated from the variation of k_1) have been observed previously in nitrous acid catalysed nitration (2, 7) and have been ascribed to the electron transfer pathway shown in Scheme 1. The initial electron transfer may occur through the intermediate formation of a Wheland intermediate. The middle reaction of this scheme is shown within brackets because it is considered to represent only the stoichiometry of the process; the mechanism must be more complex (2). Provided that the electron transfers involved in the middle reaction are considered to be fast, this scheme leads to the kinetic form shown in eq. [3] (2).

$$[3] \quad \text{Rate} = \frac{b[\text{ArH}][HNO_2]}{c + d([HNO_2]/[HNO_3])}$$

In this equation, the concentration terms are considered to be the stoichiometric concentrations and the terms b, c, and d should be constant at a given acidity. This equation has two limiting forms: one first order with respect to nitrous acid and zero order with respect to nitric acid and the other first order with respect to nitric acid and zero order with respect to nitrous acid. These two forms correspond to the rate-determining electron transfer and the rate-determining formation of the Wheland intermediate (Scheme 1, stages 1 and 3). The variation of k_1 in Fig. 4 shows that the present work provides examples of runs near the first limiting form and covers part of the range towards the second limiting form.

The mechanism shown in Scheme 1 provides a basis for an explanation of the high order with respect to naphthalene observed in the present work, for naphthalene radical cations are known to be stabilised by complex formation with another naphthalene molecule (10) and the esr spectrum of the dimeric radical cation has been observed following the oxidation of naphthalene by nitrosonium ions (11). The resulting equilibrium (eq. [4]) has been studied in acetone solution (10) and an extrapolation of the results obtained then gives an equilibrium constant of 326 mol^{-1} dm^3 at 25°C. However, it is not sufficient merely to introduce this equilibrium since the mixed order

$$ArH + NO^+ \rightleftharpoons ArH^{+\bullet} + NO^\bullet$$

$$(NO^\bullet + NO_2^+ \rightleftharpoons NO^+ + NO_2^\bullet)$$

$$ArH^{+\bullet} + NO_2^\bullet \longrightarrow ArNO_2 + H^+$$

SCHEME 1

$$ArH + NO^+ \rightleftharpoons (ArH...NO)^+$$

$$(ArH...NO)^+ + ArH \rightleftharpoons (ArH)_2^{+\bullet} + NO^\bullet$$

$$(NO^\bullet + NO_2^+ \rightleftharpoons NO^+ + NO_2^\bullet)$$

$$(ArH)_2^{+\bullet} + NO_2^\bullet \longrightarrow ArNO_2 + ArH + H^+$$

SCHEME 2

kinetics with respect to the aromatic compound are also observed under conditions where the initial electron transfer appears to be rate determining. The results can be explained if the second naphthalene molecule is considered to facilitate the initial electron transfer as shown in Scheme 2. In this scheme, the reactants are considered to be brought together by initial π-complex formation between a nitrosonium ion and a naphthalene molecule followed by reaction with another naphthalene molecule. An alternative pathway in which the nitrosonium ion reacts with a pair of naphthalene molecules cannot be excluded but is considered less probable since we agree with the previous workers (8) that there is no evidence from Beer's Law for the association of naphthalene molecules in these solutions.

[4] $ArH^{+\bullet} + ArH \rightleftharpoons (ArH)_2^{+\bullet}$

If the reaction paths in Schemes 1 and 2 could be considered to be independent, the full kinetic equation for reaction at a given acidity would have the additional term shown in eq. [5].

$$[5]\quad \text{Rate} = \frac{b[ArH][HNO_2]}{c + d([HNO_2]/[HNO_3])} + \frac{e[ArH]^2[HNO_2]}{f + g([HNO_2]/[HNO_3])}$$

However, this is almost certainly an oversimplification because of the equilibrium shown in eq. [4]. A more complete analysis of the expected kinetic form has been carried out but it is unnecessary to consider this in detail since most of the kinetic runs described here refer to conditions where the initial oxidation stage appears to be essentially rate determining. Under these conditions and at a given acidity, both the complete kinetic analysis and eq. [5] reduce to the form of eq. [1] and hence accord with the experimental results.

The comparison of the acidity dependence of k_1 and k_2 with the fraction of nitrous acid present as the nitrosonium ion (Fig. 5) is consistent with the representation of the nitrosonium ion as the oxidising agent in Schemes 1 and 2. Exact agreement between the slopes of the logarithmic plots cannot be expected because the studies of the nitrosonium ion equilibria refer to aqueous sulphuric acid without the presence of acetic acid. Comparison with studies of the nitration of naphthalene by the nitronium ion (12) shows that this reaction cannot contribute significantly, even at the highest acidity used.

Nitrosation reactions normally give rise to conventional deuterium isotope effects (13) and when nitrous acid catalysed nitration occurs through nitrosation followed by oxidation such isotope effects remain in the overall reaction (7). The absence of such isotope effects in the present reaction (Table 7) suggests therefore that the classical mechanism for nitrous acid catalysed nitration makes no significant contribution to the reaction considered here.

Experimental

Kinetic studies

The sulphuric acid, acetic acid, sodium nitrite, sodium nitrate, and naphthalene were AnalaR or "Gold Label" reagents and were used without further purification. Naphthalene-d_8 (98+ atom% D) was from Aldrich. The naphthalene was initially dissolved in acetic acid. Mixtures of this solution with aqueous sulphuric acid and, where necessary, water and further acetic acid were prepared and brought to 25°C. Reaction was started by the addition of small volumes (50–100 μL) of aqueous solutions of sodium nitrate and then sodium nitrite. The small amount of sulphuric acid involved in the liberation of nitrous acid and nitric acid from these salts was ignored in the specification of the percentage composition by weight of these solutions.

The amount of naphthalene remaining $(a - x)$ at time t was calculated from the change in the absorbance (A_t) with time (eq. [6]) using a Perkin–Elmer 554 UV–VIS spectrometer with the cells maintained at 25°C. The initial reading (A_0) was taken from equivalent solutions not containing nitric acid. The final reading (A_∞) was taken when no further change could be detected. For a number of runs, the absorbance was also checked on the following day but no further change was found.

$$[6]\quad (a - x) = a(A_\infty - A_t)/(A_\infty - A_0)$$

For concentrations of naphthalene below 4×10^{-4} mol dm^{-3}, the wavelength used was 350 nm; for concentrations above this value, the wavelength used was in the range 410–430 nm. The final absorbance ($\epsilon(ArNO_2)_{350} = 4000$) agreed with that observed previously (8) for the mixture of nitronaphthalenes formed.

The earlier observation (8) that both nitric acid and nitrous acid needed to be present for a detectable amount of reaction to occur within the time intervals considered was confirmed. Passing nitrogen through the solutions before reaction to remove any dissolved oxygen does not appear to change the reaction rate.

Analysis of the results

The calculations of the rate coefficients k_1 and k_2 were based on the integrated form of eq. [1] (14), which may be written as eq. [7] (where $r = k_1/k_2$).

$$[7]\quad \ln \frac{(ra + a(a - x))}{((r + a)(a - x))} = k_1 t$$

The values of r and k_1 giving the best (least-squares) fit to a straight line were determined by a computer program. The values of the instantaneous rates were calculated by fitting the first 4–6 points of each kinetic run to a quadratic equation and determining the slope at the time of the first point. The half-life was determined by a similar procedure using the 4–6 points about this time and solving for $x = a/2$.

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

A. C. LEGON and D. J. MILLEN. Can. J. Chem. **67**, 1683 (1989).

A simple point-charge model is presented for some molecules B which assigns charges to atom centres and to nonbonding pairs, those for the latter placed at distances r along directions α as conventionally envisaged. The magnitude δ of the charge assigned to the nonbonding pairs is chosen so that the variation of the electrostatic interaction energy between B and HF with the angular position of HF agrees with that calculated on the basis of a more complete description (DMA) of the electrostatic charge distribution of B. The charges δ in the three molecules explored (B = H_2O, H_2CO, and H_2S) prove to be only a few hundredths of an electron at distances r comparable with bond distances in B.

Key words: nonbonding pairs, point-charge model, hydrogen bond, Gillespie–Nyholm model, electron localization.

A. C. LEGON et D. J. MILLEN. Can. J. Chem. **67**, 1683 (1989).

On présente un modèle de charge ponctuelle simple, pour quelques molécules B, qui attribue des charges aux atomes centraux et aux paires non liées, dont les atomes sont placés à des distances r selon des directions α conventionnelles. On a choisi l'ordre de grandeur δ de la charge attribuée aux paires non liées de telle sorte que la variation d'énergie électrostatique entre B et HF avec la position angulaire de HF s'accorde avec celle calculée à partir d'une description plus complète (DMA) de la distribution de charge électrostatique de B. Les charges δ dans les trois molécules étudiées (B = H_2O, H_2CO et H_2S) s'avèrent être seulement qu'une centaine d'électrons situés aux distances r comparable aux distances de liaison dans B.

Mots clés: paires non liées, modèle de charge ponctuelle, liaison hydrogène, modèle Gillespie–Nyholm, localisation d'électron.

Introduction

We have discussed recently (1) a set of rules for predicting the angular geometries of a wide range of hydrogen-bonded dimers B···HX. As originally presented, these rules were generalizations from some observations made on a carefully selected but limited subset of dimers. Subsequent expansion of the experimental observations further established the validity of the rules (2), which are as follows:

(*i*) *The axis of the HX molecule coincides with the supposed axis of a nonbonding electron pair on the acceptor atom of B as conventionally envisaged,*

or, if B has no nonbonding electron pairs but does have π-bonding pairs,

(*ii*) *the axis of the HX molecule intersects the symmetry axis of the atoms forming the π-bond and is perpendicular to the plane of symmetry of the π-bond.*

Rule (*i*) is definitive when B has both nonbonding and π-bonding electron pairs. These rules appear to apply quite generally when only a single hydrogen bond occurs, and even when two hydrogen bonds occur in a given dimer (as in H_2CO, HCCH (3)) the geometry appears to be determined in a manner that can still be rationalized in terms of the rules.

The rules are readily understood on the basis of a simple electrostatic model (2) in which the angular variation of the potential at appropriate distances from B is considered. As a result of examining the electrostatic potential due to B it was possible to enunciate the following:

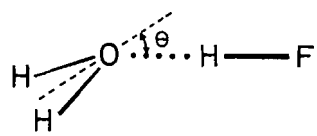

FIG. 1. Definition of the angle θ in the dimer $H_2O\cdots HF$.

(*iii*) *A corollary to rules (i) and (ii): as long as the hydrogen bond in B···HF is sufficiently weak that the electric charge distributions of B and HF are essentially unperturbed, the HF axis acts as a probe for the direction of a nonbonding (or π-bonding) pair on B.*

The explanation underlying this corollary is that the electric charge distribution of HF can be represented in good approximation by a simple extended dipole $\overset{\delta^+}{H}—\overset{\delta^-}{F}$, where $\delta^+ = 0.54e$ and $\delta^- = -0.54e$ (e is the proton charge). Starting, for example, with this model of the HF molecule lying along the C_2 axis of H_2O ($\theta = 0°$, where θ is defined in Fig. 1) and allowing the HF molecule to roll around the oxygen atom in the vertical symmetry plane of H_2O (i.e., θ increases from zero, see Fig. 1), the angular variations of the potential energies $V_H(\theta)$, $V_F(\theta)$, and $V_H(\theta) + V_F(\theta)$ are as shown in Fig. 2. These potential energies have been calculated using the distributed multipole analysis (4) of the electric charge distribution of water given by Buckingham and Fowler (5) and are being used with the implicit assumption that the dominant term in describing the angular variation of the potential energy is the electrostatic one (6, 7). The important

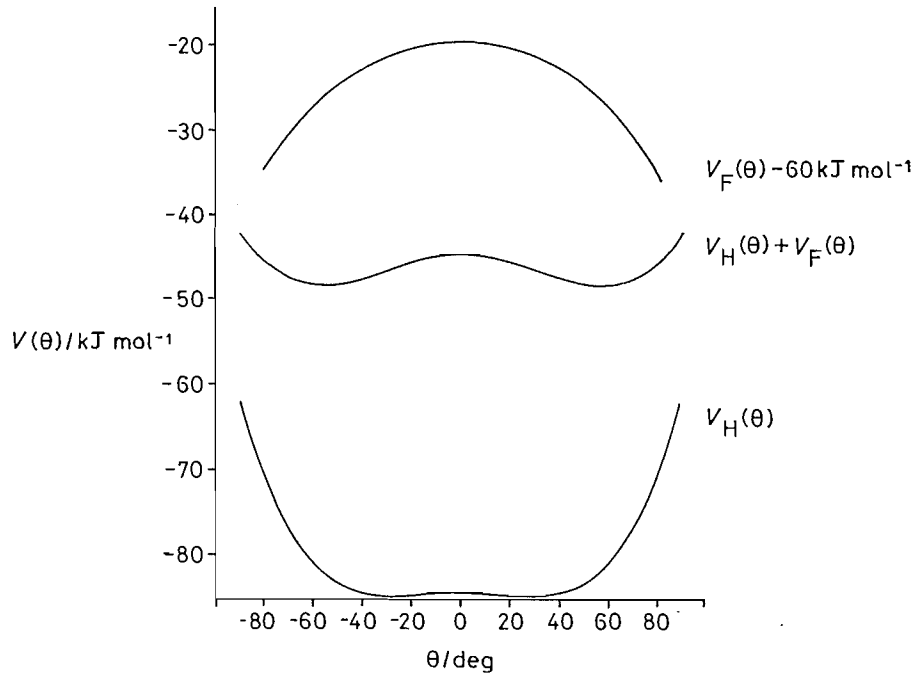

FIG. 2. Variation of the potential energy $V_H(\theta)$ and $V_F(\theta)$ of point charges $0.54e$ at H and $-0.54e$ at F, respectively, with the angle θ in $H_2O\cdots HF$ calculated using the full DMA description of the H_2O charge distribution. The total potential energy of interaction $V_H(\theta) + V_F(\theta)$, which is then that of the extended dipole model of HF with H_2O, is also shown. For convenience the curve for $V_F(\theta)$ is displaced downwards by 60 kJ mol^{-1}.

result is that the potential energy $V_H(\theta) + V_F(\theta)$ of the above extended dipole model of HF in the vicinity of B at the correct distance has a shape and barrier height in satisfactory agreement with experiment (8). Similar agreement with experiment (9) is obtained when such a model is applied to $H_2CO\cdots HF$.[1]

In this paper, we seek to interpret the rules in the simplest possible manner, i.e., a point-charge representation of the electric charge distribution of B together with the extended dipole model of HF. In particular, we show that, to obtain agreement with experiment and with calculations based on more detailed charge distributions for B, it is necessary to place only small fractional electronic charges at physically reasonable distances along the directions of nonbonding pairs as conventionally envisaged. This model has obvious parallels with the valence-shell-electron-pair repulsion model of Gillespie and Nyholm (10) and the partial localization of electron density along nonbonding pair directions discussed by Bader, Gillespie, and MacDougall (11). It is therefore a pleasure to be able to contribute such a relevant paper to this special issue of the Canadian Journal of Chemistry in honour of Professor R. J. Gillespie.

The model

Several electrostatic descriptions of the interaction between molecules B and, e.g., HF have been discussed (5, 12). The most important contribution to the electrostatic energy is the interaction between the distributed charges assigned to B by the model with those of HF. Thus, the simplest possible model consists of point charges placed on atoms and implies a spherical charge distribution centred on each nucleus. Such a model is quite good for obtaining the electrostatic interaction energy but fails completely to predict the correct angular geometry of dimers such as $H_2O\cdots HF$, $H_2CO\cdots HF$, and $H_2S\cdots HF$. The latter can be reproduced by, for example, placing in addition point dipoles and quadrupoles on the atoms according to the distributed multipole analysis (DMA) of B due to Stone (4). This approach has been used successfully by Buckingham and Fowler (5) to calculate electrostatic energies and find their minima with respect to the angular variations of HX about the molecule B. An alternative model, which is developed here, leaves the DMA point charges on the atoms but accounts for the deviations from sphericity about atom centres by translating small fractions of the point charge on the acceptor atom of B away from the atom centre and along directions conventionally associated with nonbonding pairs.

The procedure for constructing the model is to begin with point charges on the atoms of, for example, H_2O, which for convenience are taken from the DMA given in ref. 5 but could be generated in other ways, such as use of the molecular electric dipole moment (12). Small fractional point charges δ are then removed from the DMA charge on the acceptor atom (e.g., O in H_2O) and translated through a distance r along the directions α normally associated with the axes of nonbonding electron pairs in, for example, the Gillespie–Nyholm VSEPR model, as shown in Fig. 3. The point charges q_i appropriate to the DMA's of H_2O and HF are recorded in Table 1, which also includes those for H_2CO and H_2S to be used in the discussion later. Then the potential energy $V(\theta) = V_H(\theta) + V_F(\theta)$ of the HF molecule is calculated at the experimental (8) distance $r(O\cdots F) = 2.662$ Å for the range of angle $\theta = 0$–$90°$ (see Fig. 1). This procedure is repeated for various sets of values δ, r, α and that set chosen which best reproduces the potential energy barrier calculated by using the full DMA of B (see Fig. 2).

We find that physically reasonable solutions are obtained for only a limited range of values of δ and r in the region of $0.04e$ and 1 Å, respectively. Indeed, for $r \approx 0.5$ Å the double

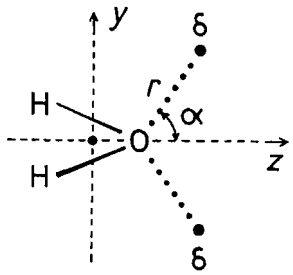

FIG. 3. Definition of the parameters δ, r, α describing the point-charge model of nonbonding electron pairs in H_2O.

TABLE 1. Distributed point charges and their coordinates for H_2O, H_2CO, H_2S, and HF[a]

Molecule	Atom	x	z	q
H_2O	O	0	0.123	−0.802
	H	1.432	−0.986	0.401
H_2CO	O	0	1.135	−0.542
	C	0	−1.138	0.679
	H	1.766	−2.231	−0.068
H_2S	S	0	0.103	0.033
	H	1.808	−1.637	−0.016
HF	F	—	0.087	−0.540
	H	—	−1.645	0.540

[a]Coordinates x, z and charges q are in atomic units and are taken from ref. 5.

TABLE 2. Position (r, α) and magnitude (δ) of point negative charges representing nonbonding pairs in acceptor molecules B and barrier heights (h) calculated for B···HF[a]

Quantity		H_2O···HF	H_2CO···HF	H_2S···HF
r(Å)		1.0	1.0	1.75
δ(au)		0.038	0.05	0.025
α(deg)		54.0	60	90
h(kJ mol^{-1})	This model:	6.9	12	35
	Full DMA:	6.6	11	36
θ_{min}(deg)	This model:	45	50	90
	Full DMA:	55	65	80

[a]See Figs. 3–5 and text for definition of r, α, and δ. h is the height of the potential energy barrier $V(\theta_{max}) - V(\theta_{min})$ calculated by the present model (see text) and also using the full DMA for B. θ is defined in Fig. 1.

minimum apparent in the full calculation (Fig. 2) is not obtained from our model and when r is in the region of 1.5 Å, the barrier height becomes very large for even very small δ. Physical acceptability therefore constrains r to be in the region of 1 Å, which we note is similar to the O—H bond length in H_2O. The important conclusion is that δ is found to be a relatively small fraction of the electronic charge. The results for δ and α when r = 1 Å, which reproduce the barrier height and θ_{min} of the full DMA, are given in Table 2.

We have also carried out a similar analysis for H_2CO···HF

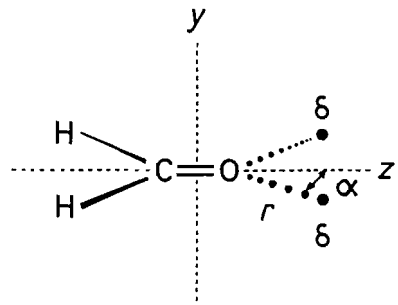

FIG. 4. Definition of the parameters δ, r, α describing the point-charge model of nonbonding electron pairs in H_2CO.

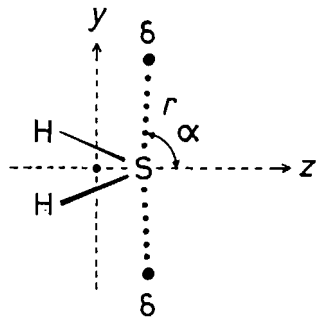

FIG. 5. Definition of the parameters δ, r, α describing the point-charge model of nonbonding electron pairs in H_2S.

(see Fig. 4) and H_2S···HF (see Fig. 5) at the appropriate experimental distances (13, 14) with the results shown in Table 2. For H_2CO···HF the angles α and θ are defined in a similar way but lie in the molecular plane rather than the perpendicular plane. We note that again reasonable solutions are obtained only when $\delta \approx 0.04e$ and $r \approx 1$ Å for H_2CO···HF, while for H_2S···HF longer distances r of δ from the S atom are required. This is not inconsistent with the notion that the H_2S molecule is generally more extensive than the H_2O molecule. Again for both H_2S and H_2CO, δ is found to be only a few per cent of the full electronic charge.

Discussion

We have presented in this paper a very simple model for the electric charge distributions of a few prototype molecules, which not only allows the electrostatic interaction within pairs such as H_2O···HF, H_2CO···HF, and H_2S···HF to be calculated very easily but also leads to observed angular geometries and reasonable angular variation of the potential energy of interaction. The main advantages of this model are that it is easily visualized and is consonant with the valence-shell–electron-pair repulsion model and the convention of nonbonding pairs. The difference from many earlier methods of representing nonbonding pairs with point charges is that our model requires relatively tiny charges (e.g., a few hundredths of an electron) at reasonable distances ($r \approx 1$ Å). These small charges arise quite naturally from the requirement that the "observed" barrier heights (e.g., those from the full DMA calculation or from experiment in the case of H_2O···HF and H_2CO···HF) are reproduced. In fact, similar 5-point charge models were discussed for H_2O and H_2S by Kollman (15) but were deduced without the advantage of the recent experimental or theoretical estimates of the barrier heights in the intermolecular potential energy functions of H_2O···HF, H_2CO···HF, and H_2S···HF.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

Another advantage of the model introduced here is that it is consistent with the generally accepted nearly spherical nature of the electronic charge distribution in H_2O (16) in which there are only very small deviations from hemisphericity at oxygen. Moreover, such a model is very easy to use in situations where large clusters are being discussed, for the electrostatic calculations involve only point charges rather than higher poles. Finally, we note that the model accords well with the ideas recently advanced by Bader, Gillespie, and MacDougall (11), who show that a small localization of electron density along the VSEPR nonbonding pair directions results from the ligand field operating in concert with the Pauli exclusion principle. Geometries of hydrogen-bonded dimers prove to be strongly dependent on these local concentrations of charge and our model gives a measure of such local concentrations.

The crystal structure of $Te(N_3)_3SbF_6$ containing the first binary tellurium–nitrogen cation, triazidotellurium(IV) ($Te(N_3)_3^+$), has been determined by X-ray crystallography. Single crystals of $Te(N_3)_3SbF_6$ are monoclinic, space group $P2_1/c$ with a = 9.201(6), b = 8.445(4), c = 13.582(7) Å, β = 100.36(5)°, Z = 4, final R_1 = 0.036 for 1286 observed reflections. The structure consists of discrete $Te(N_3)_3^+$ cations and distorted octahedral SbF_6^- anions, with some cation–anion interactions. The average Te—N_α—N_β—N_γ bond distances in $Te(N_3)_3^+$ are Te—N_α, 1.994(7); N_α—N_β, 1.237(11); and N_β—N_γ, 1.116(12) Å. The average bond angles about the Te, N_α, and N_β atoms are 94.1(3)°, 116.5(6)°, and 173.7(9)°. Structural correlations with other TeX_3^+ species have yielded an estimate of the electronegativity of the N_3^- group to be 3.1 ± 0.1.

Key words: tetratellurium (2+) cation, triazidotellurium(IV) cation, electronegativity, azide.

JAMES P. JOHNSON, GREGORY K. MACLEAN, JACK PASSMORE et PETER S. WHITE. Can. J. Chem. **67**, 1687 (1989).

Faisant appel à la diffraction des rayons-X, on a déterminé la structure cristalline du $Te(N_3)_3SbF_6$ qui est le premier complexe contenant le cation binaire du tellure et de l'azote, le triazidotellure(IV) ($Te(N_3)_3^+$). Les cristaux uniques du $Te(N_3)_3SbF_6$ sont monocliniques et ils cristallisent dans le groupe d'espace $P2_1/c$ avec a = 9,201(6), b = 8,445(4) et c = 13,582(7) Å, β = 100,36°, Z = 4 et une valeur finale de R_1 de 0,036 pour 1286 réflexions observées. La structure comporte des cations $Te(N_3)_3^+$ individuels, des anions SbF_6^- de forme octaédrique déformée et quelques interactions cation–anion. Les longueurs moyennes des liaisons Te—N_α—N_β—N_γ dans le cation $Te(N_3)_3^+$ sont TeN_α, 1,994(7); N_α—N_β, 1,237(11) et N_β—N_γ, 1,116(12) Å. Les angles moyens de liaisons des atomes de Te, N_α et N_β sont 94,1(3)°, 116,5(6)° et 173,7(9)°. En se basant sur des corrélations de structure avec d'autres espèces TeX_3^+, on a pu évaluer que l'électronégativité du groupement N_3^- est égale à 3,1 ± 0,1.

Mots clés : cation du tétratellure (2+), cation triazidotellure(IV), électronégativité, azoture.

[Traduit par la revue]

Introduction

The S_2N^+ cation, in S_2NAsF_6 (1) has a rich chemistry, and is an important building block in the systematic synthesis of other sulfur–nitrogen-containing compounds (2–9). It would be of interest to prepare the selenium and tellurium analogues, Se_2NAsF_6 and Te_2NAsF_6, as they should also have extensive chemistries, because they are of interest in their own right and because very few isolated selenium–nitrogen or tellurium–nitrogen species exist. These include Se_4N_4 (10), Te_4N_4 (11), and Te_3N_4 (12). Binary anionic or cationic species have not been characterized. The most convenient preparation of S_2NAsF_6 (1) is given in eq. [1].

$$[1]\quad S_4N_4 + \tfrac{1}{2}S_8 + 6AsF_5 \xrightarrow[\text{Trace } Br_2]{\text{Liquid } SO_2} 4S_2NAsF_6 + 2AsF_3$$

The analogous reactions leading to Se_2NAsF_6 and Te_2NAsF_6 would involve the use of explosive Se_4N_4 (10) and Te_4N_4 (11), which we wished to avoid. An alternative synthesis of S_2NAsF_6, but in lower yield, is that of $S_8(AsF_6)_2$ and NaN_3 in liquid SO_2 (1). We therefore attempted analogous reactions of azides and homopolyatomic cations of selenium, Se_4^{2+} (13), Se_{10}^{2+} (14), and tellurium, Te_4^{2+} (13, 15). Subsequently, the reaction between $Te_4(SbF_6)_2$ and KN_3 yielded, as one of the products, the compound $Te(N_3)_3SbF_6$, which was identified from its infrared spectrum and by X-ray crystallography. The compound $Te(N_3)_3SbF_6$ contains the triazidotellurium(IV) cation, $Te(N_3)_3^+$, and contains the first example of a binary tellurium–nitrogen cation. An account of this work is given below.

Experimental

Reagents and general procedures

Except where stated, the apparatus and chemicals were as previously described (16). The $Te_4(AsF_6)_2$ (13, 15, 17), $Te_4(SbF_6)_2$ (15), and $Se_{10}(AsF_6)_2$ (14) salts were prepared as described in the literature. The $Se_4(AsF_6)_2$ was prepared using a trace of bromine at room temperature (18). The salts NaN_3 (Fisher) and KN_3 (Pfaltz and Bauer) were vacuum dried before use. The SO_2 (Matheson) was dried and stored over CaH_2.

The glass reaction vessels either (A) consisted of two bulbs separated by a coarse or medium glass frit and equipped with a Teflon-in-glass J. Young Valve (15), or (B) consisted of a similar vessel with the valve attached to an evacuable condenser containing a coarse or medium glass frit and a pressure-equalizing tube (a drawing of such a vessel is given in ref. 19). Infrared spectra of Nujol mulls between KBr plates were obtained on a Perkin–Elmer model 683 grating spectrometer. Spectra were calibrated using indene (20). Mass spectra were obtained via the direct inlet port at 110°C on a Hitachi Perkin–Elmer RMU6D mass spectrometer with an ionizing voltage of 70 eV.

Reaction of $Te_4(SbF_6)_2$ with KN_3[2]

In a typical reaction, an excess of KN_3 (0.41 g, 5.05 mmol) was

[2]A 1:1 reaction between $Te_4(SbF_6)_2$ and NaN_3 in one bulb of a two-bulb glass vessel (A) yielded a colorless solid and a small amount of a yellow species. Attempted removal of the product with a nickel spatula resulted in an explosion.

We believe that $Te(N_3)_3SbF_6$ is not itself explosive but, if care is not taken in its preparation, other products that are yellow or orange in color are also formed. These materials are highly shock and friction sensitive. They may be neutral or anionic tellurium–nitrogen-containing compounds and, if formed, should be considered dangerous and highly explosive and disposed of appropriately. The method reported here successfully yielded $Te(N_3)_3SbF_6$, without the explosive impurities.

	266(1)	δN—Te—N or $\nu_5 SbF_6^-$

[a]Tentative assignments were made by comparison of species such as N_3^- (25), SbF_6^- (21*a*), $TeCl_3N_3$ and $TeCl_2(N_3)_2$ (26), TeF_3^+ (27, 28), $SbCl_5N_3^-$ (29, 30), and $SbCl_4(N_3)_2^-$ (31). Standard definitions (21*b*) of abbreviations (s, as, ν, α, δ).

[b]Shoulder on KBr cutoff.

placed onto the coarse sintered glass frit in the refluxing condenser of vessel B and the $Te_4(SbF_6)_2$ (6.00 g, 6.11 mmol) was added into the bulb of the two-bulb glass vessel below the refluxing condenser. The SO_2 (25.00 g, 390.2 mmol) was then condensed onto the $Te_4(SbF_6)_2$. The stirred $Te_4(SbF_6)_2/SO_2$ slurry was held at ~30°C, which caused SO_2 to condense on the inside walls of the water-cooled condenser and to slowly dissolve the KN_3 and thus wash down slowly into the reaction bulb holding the $Te_4(SbF_6)/SO_2$ solution. This slow addition of KN_3 to the $Te_4(SbF_6)_2$ was continued until the initial red coloration of the $Te_4(SbF_6)_2/SO_2$ solution had just disappeared (approximately 9 days). The yellowish solution was then filtered into the second bulb and the brown-gray insoluble solids (4.77 g) were washed twice with liquid SO_2. The SO_2 was slowly condensed back into the first bulb by placing it in a cold water bath. This produced colorless crystals (<0.5 g) suitable for X-ray analyses in the second bulb. The SO_2, and a noncondensible gas, were then removed by evacuation. The infrared spectrum of the brown-grey insoluble solids showed only peaks attributable to the SbF_6^- anion (21*a*). The infrared spectrum of the bulk crystals is given in Table 1. The Raman spectrum of a single colorless crystal is also given in Table 1. The mass spectrum of the colorless crystals gave peaks only attributable to HN_3^+ (rel. int. = 59) and N_2^+ (rel. int. = 100).

A colorless oil was sublimed from a mixture of pale-yellow-colored products obtained from a similar reaction to that in footnote 2, but between $Te_4(AsF_6)_2$ and NaN_3. The mass spectrum of this oil gave peaks at (*m/e* (rel. int.) assigned species) 233(<1) $TeF(N_3)_2^+$, 220(1) $AsF(N_3)_3^+$, 210(3) $TeF_2N_3^+$, 197(8) $AsF_2(N_3)_2^+$, 187(31) TeF_3^+, 174(16) $AsF_3N_3^+$, 168(6) TeF_2^+, 155(4) $AsF_2N_3^+$, 151(8) AsF_4^+, 149(2) TeF^+, 146(2) AsF_3N^+, 136(3) $AsFN_3^+$, 132(5) AsF_3^+, 130(2) Te^+, 113(22) AsF_2^+, 108(2) $AsFN^+$, 94(6) AsF^+, 89(1) AsN^+, 75(3) As^+, 47(1) N_2F^+, 43(71) HN_3^+, 42(13) N_3^+, 28(100) N_2^+. Only the ion fragments containing the ^{130}Te isotope are included above. Ion fragments containing the other tellurium isotopes were observed in their appropriate abundances.

X-ray crystal structure crystal data

$Te(N_3)_3SbF_6$ $M = 489.4$

Monoclinic, space group $P2_1/c$, $a = 9.201(6)$, $b = 8.445(4)$, $c = 13.582(7)$ Å, $\beta = 100.36(5)°$, $U = 1038$ Å^3, $Z = 4$, $D_c = 3.13$ Mg m^{-3}, $F(000) = 880$, $\mu = 5.48$ mm^{-1}, λ(MoKα) = 0.71073 Å, crystal size = 0.5 × 0.3 × 0.2 mm, $T = 293$ K.

A suitable crystal was mounted under dry nitrogen in a rigorously dried (evacuated at 250°C) capillary tube. Preliminary precession photographs provided space group information and approximate unit cell dimensions, after which the crystal was mounted on a Picker FACS-I diffractometer equipped with graphite monochromated MoKα radiation. Unit cell parameters and an orientation matrix were refined by least squares using the centered coordinates of 27 reflections with $30° \leqq 2\theta \leqq 37°$. Intensity data were collected using an ω–2θ at a scan rate of 2°(2θ) min^{-1}. Backgrounds were estimated by standing counts of 1/10 scan time at each end of the scan. If the reflection had a significant intensity ($I \geqq 3\sigma(I)$) the profile of the peak was analyzed and those portions of the scan that were not part of the peak were included in the background estimate. Data were collected in the range $5 \leqq 2\theta \leqq 50°$, resulting in 1805 unique reflections of which 1286 were considered observed ($I \geqq 3\sigma(I)$) and included in the subsequent calculations. Three standard reflections, monitored every 150 reflections throughout the data collection, showed no significant deviations from their mean values.

The structure was solved by locating the position of the Te and Sb atoms from inspection of the three-dimensional Patterson function. Least-squares refinement using SHELX-76 (22) of the scale, positional, and isotropic thermal parameters gave an R_1 of 0.26. The Te positional parameters were assumed to be correct and a least-squares refinement followed by difference Fourier synthesis revealed the correct Sb positional parameters, which were shifted by 0.2 Å along *b*. Refinement of scale, positional, and isotropic thermal parameters gave an R_1 of 0.20, indicating a significant improvement over the original solution. The remaining atoms were located from a subsequent difference Fourier synthesis. A DIFABS (23) absorption correction was applied. Anisotropic thermal parameters were used for all the atoms and the function minimized was $\Sigma(w)(\Delta F)^2$ with $w = [\sigma(F)^2 + kF_o^2]^{-1}$ where $k = 0.0023$ and $\sigma(F)$ was derived from counter statistics. The final refinement resulted in $R_1 = \Sigma|\Delta F|/\Sigma|F| = 0.036$ and $R_2 = \Sigma w|\Delta F|^2/\Sigma w|F|^2 = 0.039$ (0.064 and 0.050, respectively, when all reflections are included). Scattering factors for neutral atoms were taken from the International tables for X-ray crystallography (24) and corrected for anomalous dispersion. Table 2 gives the final atomic coordinates.[3]

Results and discussion

The reaction of $Te_4(SbF_6)_2$ and KN_3 leading to $Te(N_3)_3SbF_6$

The reaction of a 1:1 mixture of $Te_4(SbF_6)_2$ and NaN_3 in SO_2 led to the formation of both a colorless and a yellow solid, which exploded on attempted removal using a nickel spatula. It is possible, in view of the identification of $Te(N_3)_3SbF_6$ in a similar reaction, that the explosive component was the unknown

[3]Listings of calculated and observed structure factors, as well as anisotropic thermal parameters for the $Te(N_3)_3SbF_6$ structure have been deposited, and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

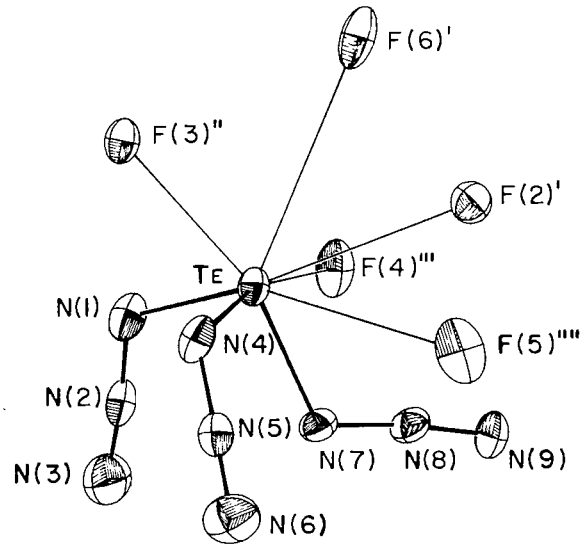

FIG. 1. Stereoscopic views of the $Te(N_3)_3SbF_6$ unit cell.

$Te(N_3)_4$ or alternatively Te_4N_4 (11) or Te_3N_4 (12). To minimize the chance of the formation of $Te(N_3)_4$, a related reaction was carried out such that the red Te_4^{2+} was always present. This was done by washing the sparingly soluble KN_3 into $Te_4(SbF_6)_2$, and stopping the reaction as soon as the solution became colorless. This in effect is a titration of the red Te_4^{2+} by N_3^-. Several single crystals of the soluble product were shown to be $Te(N_3)_3SbF_6$ by single crystal X-ray diffraction. In addition, the Raman spectrum (Table 1) of a single crystal is consistent with the presence of $Te(N_3)_3SbF_6$. The infrared spectrum of the bulk material (Table 1) appears to be more complex but it certainly contains $Te(N_3)_3[SbF_6]$. It possibly also contains other species (e.g., $Te(N_3)_2F[SbF_6]$). This suggestion is supported by the results of the related reaction of $Te_4(AsF_6)_2$ and NaN_3 in a 1:1 ratio in liquid SO_2. A yellowish oil was produced on removal of SO_2, from which was condensed a colorless oil. The mass spectrum of this oil (see experimental section) showed peaks attributable to $Te(N_3)_{3-x}F_x^+$ ($x = 1$–3) and $As(N_3)_xF_{4-x}^+$ ($x = 0$–3) arising from the dissociation of $Te(N_3)_{3-x}F_x^+$ $As(N_3)_xF_{6-x}^-$ by fluoride ion transfer from the anion to the cation, and loss of F^- from the neutral fragments on ionization. This clearly shows some ligand scrambling has occurred in the $Te_4(AsF_6)_2/NaN_3$ reaction. The infrared spectrum of the colorless oil from the $Te_4(AsF_6)_2/KN_3$ reaction is similar to that of the solid from the $Te_4(SbF_6)_2/KN_3$ but is more complex with some overlapping bands suggesting the presence of a mixture of related species. This is further evidence that fluoride–azide exchange is more extensive in the AsF_6^- reaction. The greater simplicity of the $Te_4(SbF_6)_2$ system may relate to the manner in which it was carried out, and (or) to the greater Lewis basicity of the AsF_6^- anion, leading to greater cation–anion interaction and greater azide–fluoride cation–anion exchange. The mass spectrum of $Te(N_3)_3SbF_6$ showed peaks only attributable to N_2 (and HN_3 presumably given by hydrolysis), indicating that decomposition is occurring preferentially to fluoride ion transfer.

The reaction of $Te_4(SbF_6)_2$ and KN_3 is very different from that of $S_8(AsF_6)_2$ and NaN_3 leading to ca. 30% yield of S_2NAsF_6 (1). Presumably the tellurium reaction proceeds as indicated by eq. [2], leading to the formation of the unstable azide derivative of Te_4^{2+}, $Te_4N_3^+$, which may disproportionate as indicated by eq. [3]. The unstable intermediate $Te_{11}(SbF_6)_2$ may then disproportionate according to eq. [4].

[2] $Te_4(SbF_6)_2 + KN_3 \rightarrow KSbF_6\downarrow + \text{“}Te_4N_3SbF_6\text{”}$

[3] $3Te_4N_3SbF_6 \rightarrow Te(N_3)_3SbF_6 + \text{“}Te_{11}(SbF_6)_2\text{”}$

[4] $\text{“}Te_{11}(SbF_6)_2\text{”} \rightarrow Te_6(SbF_6)_2\downarrow + 5Te\downarrow$

The insoluble dark brown $Te_6(SbF_6)_2$ (32) may be one of the observed products, or may further react with KN_3 by related reactions leading to elemental tellurium and $Te(N_3)_3SbF_6$.

The reactions of the homopolyatomic cations $Se_4(AsF_6)_2$ and $Se_{10}(AsF_6)_2$ with alkali azides were also attempted but yielded no evidence for the formation of a Se–N containing species in either the soluble or insoluble products (ir). A brown product was observed in the Se_4^{2+}/N_3^- reaction, which appeared to be $CsAsF_6$ (ir) mixed with $Se_{10}(AsF_6)_2$ (14) (solubility and color of the material). A much darker brown product was formed in the Se_{10}^{2+}/N_3^- reaction, which appeared to be unreacted $Se_{10}(AsF_6)_2$ mixed with elemental selenium (black) and $NaAsF_6$ (ir). All of these selenium reactions yielded nearly quantitative amounts of nitrogen gas.

The lack of success at preparing a new selenium–nitrogen cation may relate to the instability of the selenium–nitrogen bond. Thus, although a large number of thermally stable =N—TeF_5 compounds are known (33–37), attempts to prepare the analogous selenium compounds have been unsuccessful (38). The analogous Se(IV) compounds containing the —N=SeX_2 (X = F, Cl) (34, 39) and —N=Se=N— (40) groups, as well as compounds of the type Cl_2ArSe—N=SeArCl (Ar = aryl) (41), are thermally unstable under ambient conditions. On the other hand, cations containing selenium–nitrogen bonds have been prepared of salts that are stable at room temperature. These include $(Se_2N_2S)_2(AsF_6)_2$ (42), $Se_3N_2(AsF_6)_2$, $Se_3N_2(AsF_6)$ (43), and $Se_2N_2S(AsF_6)_2$ (43, 44) containing the $\overline{NSeSeNS}^+$, $\overline{NSeSeNSe}^+$, $\overline{NSeSeNSe}^{2+}$, and $\overline{NSeSeNS}^{2+}$ rings respectively.

The X-ray crystal structure of $Te(N_3)_3SbF_6$

The structure of $Te(N_3)_3SbF_6$ consists of discrete $Te(N_3)_3^+$ and SbF_6^- ions, with some cation–anion interactions. The contents of a unit cell are illustrated in Fig. 1. The $Te(N_3)_3^+$

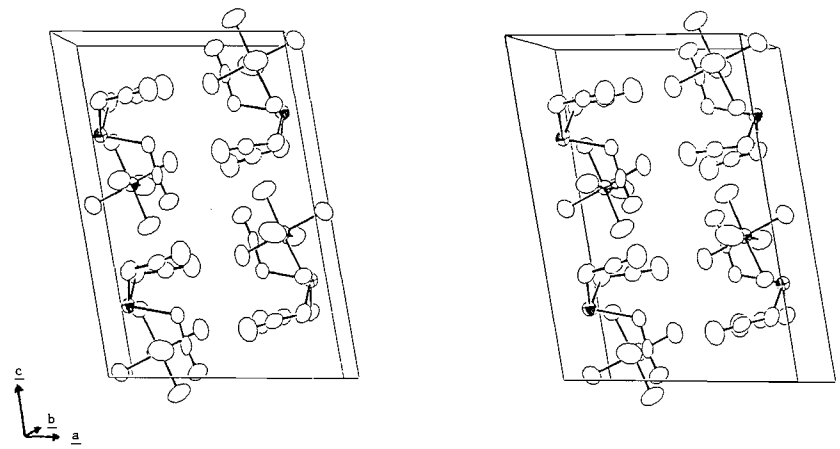

FIG. 2. The $Te(N_3)_3^+$ cation, with tellurium–fluorine contacts.

cation, with contacts to antimony fluorine atoms, is shown in Fig. 2. The bond distances and angles, within the $Te(N_3)_3^+$ cation, and the interionic contacts are given in Table 3 (a and b), and bond distances and angles within the SbF_6^- anion are given in Table 4.

The triazidotellurium(IV) cation, $Te(N_3)_3^+$, is the first binary tellurium–nitrogen cation to be prepared and structurally characterized. The related species, $TeCl_3N_3$ and $TeCl_2(N_3)_2$, have however, been reported (26). The average Te—N bond distance in $Te(N_3)_3^+$ is 1.994(7) Å, which is approximately equal to the single bond distance (1.99 Å) calculated by the Schomaker–Stevenson equation (45) (eq. [5]), where r_{AB} is the calculated single bond distance (Å), r_A and r_B are the covalent single bond radii (Å) for the elements (Te = 1.37 Å, N = 0.70 Å (46)), and χ_A and χ_B are their respective Pauling's (47) electronegativities for nitrogen (3.0) and tellurium (2.1). The electronegativity of the azide group has been estimated (2.95 ± 0.09) (48) to be very similar to that of nitrogen itself (3.0) (47), which was used in our estimate of the tellurium–nitrogen distance.

$$[5] \quad r_{AB} = r_A + r_B - 0.09|\chi_A - \chi_B|$$

The observed bond distances in all MX_3^+ cations (M = chalcogen, X = Cl, Br, I) are also very similar (within 0.01 Å) to values estimated by the Schomaker–Stevenson equation (49). As far as we are aware, the only other Te^{IV}—N bond distance reported is that in $(p\text{-}CH_3OC_6H_4)_2Te—NSO_2C_6H_4CH_3\text{-}p$ (1.980(3) Å) (50), rather similar to that in $Te(N_3)_3^+$. The compounds $(C_6H_5)_3Te(NCS)$ (51), $(C_6H_5)_3Te(NCO)$ (52), and $[(C_6H_5)_2Te(NCS)]_2O$ (53) have tellurium–nitrogen distances of 3.099(7), 2.986(10), and 2.400(10) Å respectively; these species are largely ionic. A relatively large number of other tellurium(IV) nitrogen-containing compounds have been prepared (26, 54) but their structures have not been determined. The tellurium(VI)–nitrogen distances in $F_5TeNWCl_4$ (34) (1.98(3) Å) and in $Hg[N(CF_3)TeF_5]_2$ (36) (2.01(3) Å) are not significantly different from that (1.994(7) Å) in $Te(N_3)_3^+$. However, the tellurium–nitrogen distance in F_5TeNCO (35) (1.859(21) Å) is significantly shorter, which may possibly be due to some π bonding.

The overall shape of $Te(N_3)_3^+$ is similar to one half of the $Sn(N_3)_6^{2-}$ anion (55). The N—N bond distances (average of $N_\alpha—N_\beta$ = 1.237(11) Å and $N_\beta—N_\gamma$ = 1.116(12) Å) and near linearity (average $N_\alpha—N_\beta—N_\gamma$ = 173.7(9)°) of the azide groups in $Te(N_3)_3^+$ are similar to those found in other azide species (56), and in HN_3 ($N_\gamma—N_\beta$ = 1.237(2) Å, $N_\beta—N_\gamma$ = 1.133(2) Å, $N_\alpha—N_\beta—N_\gamma$ = 180°) (57). This implies that the bonding in the TeN_3 fragments is covalent and similar to that in HN_3. The average Te—N_α—N_β bond angle (116.5(6)°) is also similar to the corresponding angle in related species (56) and HN_3 (114.1(5)°) (57).

The average XTeX angles in TeX_3^+ (X = F, Cl, Br, I) for a

TABLE 3. Bond distances and angles, including interionic contacts, for the $Te(N_3)_3^+$ cation, with estimated standard deviations in parentheses

(a) Bond distances and angles

Bond	Distance (Å)	Bonds	Angle (deg)
Te—N(1)	1.988(7)	N(1)—Te—N(4)	97.3(3)
N(1)—N(2)	1.219(11)	N(1)—Te—N(7)	93.0(3)
N(2)—N(3)	1.117(12)	N(4)—Te—N(7)	91.9(3)
Te—N(4)	2.006(7)	Te—N(1)—N(2)	116.4(6)
N(4)—N(5)	1.243(10)	Te—N(4)—N(5)	115.9(6)
N(5)—N(6)	1.104(11)	Te—N(7)—N(8)	117.2(5)
Te—N(7)	1.987(7)	N(1)—N(2)—N(3)	174.3(10)
N(7)—N(8)	1.248(12)	N(4)—N(5)—N(6)	174.3(9)
N(8)—N(9)	1.127(14)	N(7)—N(8)—N(9)	172.5(8)

(b) Interionic contacts[a]

Contact	Distance (Å)	Contacts	Angle (deg)[b]
Te—F(2)	3.001(6)	F(2)—Te—N(1)	139.8(2)
Te—F(3)	2.596(6)	F(2)—Te—N(4)	122.8(2)
Te—F(4)	2.805(5)	F(2)—Te—N(7)	85.1(2)
Te—F(5)	3.261(6)	F(3)—Te—N(1)	77.4(3)
Te—F(6)	3.436(7)	F(3)—Te—N(4)	75.7(2)
N(1)—F(3)	2.905(9)	F(3)—Te—N(7)	163.0(2)
N(4)—F(3)	2.861(9)	F(4)—Te—N(1)	79.6(3)
N(4)—F(3′)	3.035(9)	F(4)—Te—N(4)	165.7(2)
N(5)—F(3)	3.012(8)	F(4)—Te—N(7)	74.4(2)
N(5)—F(6)	3.004(10)	F(5)—Te—N(1)	154.7(2)
N(6)—F(6)	3.014(13)	F(5)—Te—N(4)	72.6(2)
N(7)—F(5)	3.014(8)	F(5)—Te—N(7)	65.0(2)
N(8)—F(2)	2.991(8)	F(6)—Te—N(1)	119.6(2)
N(8)—F(4)	2.821(9)	F(6)—Te—N(4)	116.4(2)
N(8)—F(5)	2.906(9)	F(6)—Te—N(7)	130.9(3)

[a]All interionic contacts shown for Te---F ≦ 3.55 Å, and N---F ≦ 3.05 Å (vdW Te---F = 3.53 Å, and N---F = 3.02 Å (61)).

[b]Only the interionic contact angles about the tellurium atom are given.

TABLE 4. Bond distances and angles for the SbF_6^- anion of $Te(N_3)_3SbF_6$, with estimated standard deviations in parentheses

Bond	Distance (Å)	Bonds	Angle (deg)
Sb—F(1)	1.848(6)	F(2)—Sb—F(1)	177.8(3)
Sb—F(2)	1.851(5)	F(3)—Sb—F(1)	88.2(3)
Sb—F(3)	1.889(6)	F(3)—Sb—F(2)	90.1(2)
Sb—F(4)	1.867(5)	F(4)—Sb—F(1)	89.3(3)
Sb—F(5)	1.850(5)	F(4)—Sb—F(2)	89.2(2)
Sb—F(6)	1.826(7)	F(4)—Sb—F(3)	87.7(2)
		F(5)—Sb—F(1)	90.7(3)
		F(5)—Sb—F(2)	90.2(2)
		F(5)—Sb—F(3)	88.0(2)
		F(5)—Sb—F(4)	175.7(3)
		F(6)—Sb—F(1)	94.0(3)
		F(6)—Sb—F(2)	87.7(3)
		F(6)—Sb—F(3)	177.7(3)
		F(6)—Sb—F(4)	91.4(2)
		F(6)—Sb—F(5)	92.8(3)

related series of weakly basic AsF_6^- and $Sb_2F_{11}^-$ salts decrease as the electronegativity of X increases, as expected by a V.S.E.P.R. model (58). In fact a plot of the electronegativity of the X atom against the X—Te—X bond angle (X = Cl, Br, I) falls on a reasonably straight line (correlation coefficient $r = 0.990$). The corresponding average N_α—Te_α—N_α angle (94.1(3)°) in $Te(N_3)_3^+$ then gives an electronegativity for N_3^- as 3.23 on the Pauling scale (47). This value is higher than the corresponding values for chlorine (3.0), nitrogen (3.0), and an older estimated value (2.95 ± 0.09), Pauling scale (48), for N_3^-. The strength of the tellurium–fluorine cation–anion contacts increases as the electronegativity of the halogen in TeX_3^+ increases (49). The extent of this interaction can be estimated by summing the Te---F bond valences as defined by Brown (59), in all TeX_3^+ salts. A plot of the sum of the Te---F bond valences (0.85 valence units in $Te(N_3)_3SbF_6$) against the electronegativity of the X atom (X = Cl, Br, I) also yields a reasonably straight line (correlation coefficient $r = 0.998$). This plot gives the electronegativity for N_3^- as 3.03 on the Pauling scale (47). Therefore we estimate the electronegativity of the N_3^- group to be 3.1 ± 0.1. Incorporation of this value for N_3^- in eq. [5] yields a calculated Te—N bond distance of 1.98 Å, again not significantly different than that found in $Te(N_3)_3^+$.

There are three tellurium–fluorine contacts with F(3), F(4), and F(5) that are approximately *trans* to tellurium–nitrogen bonds (163.0(2), 165.7(2), 154.7(2)° respectively), giving the tellurium atom a distorted octahedral AX_3Y_3E geometry (60). The contact Te—F(3) is significantly stronger (2·596(6) Å) than the other two (2·805(5), 3·261(6) Å) and presumably cation–anion exchange would proceed by donation of F(3) to tellurium. The strongest of the cation–anion contacts, Te—F(3), also affects the observed bond distances in the SbF_6^- anion, with the Sb—F(3) bond (1·889(6) Å) being the longest, and the opposite Sb—F(6) bond (1·826(7) Å) being the shortest. The Sb—F(4) bond (1·867(5) Å) is also lengthened due to the relatively strong Te—F(4) contact. In addition, the contacts Te—F(2) (3·001(6) Å) and Te—F(6) (3·436(7) Å) are also less than the sums of the corresponding van der Waals radii (3·53 Å) (61) and each cap a face of the octahedron, with the longer Te—F(6) contact approaching the anticipated position of the lone pair, giving an overall $AX_3Y_3Y'_2E$ geometry (60) about the tellurium atom. There are also a large number of anionic fluorine contacts to the nitrogen atoms of $Te(N_3)_3^+$ (see Table 3) but no significant correlation can be made between the number or the strength of these contacts and the observed N—N bond distances.

Reçu le 27 janvier 1989

Cet article est dédié au Professeur Ronald J. Gillespie à l'occasion de son 65e anniversaire

MOHIEDDINE FOURATI, MONCEF CHAABOUNI, JEAN LOUIS PASCAL et JACQUELINE POTIER. Can. J. Chem. **67**, 1693 (1989).

La réaction de Cl_2O_6 avec un excès de $GeCl_4$ conduit, à température ambiante, à un liquide incolore, mélange complexe. Par distillation fractionnée on peut séparer $GeCl_3ClO_4$ et $GeCl_2(ClO_4)_2$. Avec un défaut de $GeCl_4$ on prépare $(ClO_2)_2Ge(ClO_4)_6$, un solide jaune orange, qui se sublime dès 32°C pour donner des cristaux très instables. La spectroscopie de vibration montre que, dans tous ces complexes, le ligand ClO_4 est monodenté et fortement lié au métal. Ge est dans un environnement tétraédrique dans $GeCl_3ClO_4$ et octaédrique dans les deux autres composés. $GeCl_3ClO_4$ et $(ClO_2)_2Ge(ClO_4)_6$ forment des entités discrètes tandis que $GeCl_2(ClO_4)_2$ est un polymère avec des ponts Ge–Cl–Ge. $(ClO_2)_2Ge(ClO_4)_6$ a une structure analogue à celle de $(ClO_2)_2Sn(ClO_4)_6$: des groupements ClO_4 monodentés entourent l'atome central, certains d'entre eux interagissent avec ClO_2^+ définissant ainsi un nouveau mode de coordination pour le groupement ClO_4.

Mots clés : germanium, trioxyde de chlore, synthèse, perchlorato, spectroscopie de vibration.

MOHIEDDINE FOURATI, MONCEF CHAABOUNI, JEAN LOUIS PASCAL, and JACQUELINE POTIER. Can. J. Chem. **67**, 1693 (1989).

Reaction of Cl_2O_6 with an excess of $GeCl_4$ at room temperature yields a colorless liquid, a complex mixture. Fractional distillation leads to $GeCl_3ClO_4$ and $GeCl_2(ClO_4)_2$. $(ClO_2)_2Ge(ClO_4)_6$, a yellow-orange solid, is obtained by reacting excess Cl_2O_6 with $GeCl_4$. It sublimes into unstable crystals above 32°C. Vibrational spectroscopy shows mainly unidentate perchlorato groups strongly bonded to Ge in the three compounds characterized. Ge is tetrahedrally surrounded in $GeCl_3ClO_4$ while it is octahedrally surrounded in the other complexes. $GeCl_2(ClO_4)_2$ and $(ClO_2)_2Ge(ClO_4)_6$ are individual entities while $GeCl_2(ClO_4)_2$ has a polymeric structure with Ge–Cl–Ge bridges. The structure of $(ClO_2)_2Ge(ClO_4)_6$ is analogous to that found for $(ClO_2)_2Sn(ClO_4)_6$. Six unidentate perchlorato groups surround the core atom; some of them interact with ClO_2^+, defining a new mode of coordination for ClO_4 groups.

Key words: germanium, chlorine trioxide, perchlorato, syntheses, vibrational spectroscopy.

Introduction

Depuis ces dernières années la chimie du ligand ClO_4, base faible conjuguée de l'acide très fort $HClO_4$, s'est largement développée (1), cependant parmi les éléments du bloc p, seuls les complexes de la colonne IIIB [13] ont été bien caractérisés (2). Il est donc apparu important de poursuivre ces travaux en préparant des complexes des éléments de la colonne IVB [14]. On a abordé, en premier lieu, l'étude des complexes du germanium, élément frontière entre la chimie organique et inorganique. Les agents perchloratants se comportent essentiellement comme des oxydants vis à vis de C(3) et Si(4) (pour ce dernier seul est bien connu Ph_3SiClO_4 (5)). Il semblait également intéressant d'identifier les complexes pouvant être formés avec le germanium afin de les comparer avec ceux de la famille du titane(IV). Ces derniers présentent la particularité de stabiliser des entités monomères où le ligand ClO_4 est bidenté et chelatant; est ce une propriété générale pour les éléments M(IV) ou est-elle limitée à Ti(IV) (3), Zr(IV) (6) ou Hf(IV) (7) ? C'est en partie pour répondre à cette question qu'a été entrepris ce travail.

Jusqu'à maintenant la connaissance des complexes perchlorato non solvatés du germanium(IV) était limitée aux synthèses : (*i*) d'un produit cristallisé obtenu par réaction de $HClO_4$ à 72% sur $GeCl_4$ à haute température (8); (*ii*) de $Ge(CH_3)_3ClO_4$ (9).

Dans les lignes suivantes sont présentées la synthèse et l'analyse structurale par spectroscopie de vibration ir et Raman de trois complexes perchlorato du germanium(IV), $GeCl_3ClO_4$, $GeCl_2(ClO_4)_2$ et $(ClO_2)_2Ge(ClO_4)_6$.

Partie expérimentale

Attention : le trioxyde de chlore et les composés préparés au cours de ce travail sont des réactifs très puissants, plus particulièrement $(ClO_2)_2Ge(ClO_4)_6$. Les consignes de manipulation déjà signalées doivent être rigoureusement respectées (1).

Produits de base

Cl_2O_6 est préparé et purifié suivant des méthodes déjà décrites (1). $GeCl_4$ (Merck pour la synthèse >99%) est stocké sous azote U (<5 ppm en H_2O ou O_2) dans des ampoules munies de robinets Rotaflo; il est distillé, sous vide, dans les réacteurs de synthèse.

Analyses chimiques

Les ions ClO_4^- sont dosés par potentiométrie à l'aide d'une électrode spécifique à perchlorate Orion (1). Les ions ClO_2^+ s'hydrolysent en solution en donnant des ions ClO_3^- qui sont réduits en Cl^- par Fe^{2+}, l'excès de Fe^{2+} est déterminé par manganimétrie (1). Le germanium(IV) est dosé par le Service d'analyse du CNRS (Vernaison, Rhône). Remarquons que l'analyse du sel de chloryle est délicate; on

doit tenir compte de la dismutation de ClO_3^- et de la décomposition de ClO_4^- (13).

Analyses structurales

Les appareils d'analyses ir, Raman ainsi que leur étalonnage ont été présentés par ailleurs (2*a*). Les spectres Raman de $GeCl_3ClO_4$ et de $GeCl_2(ClO_4)_2$ sont enregistrés à température ambiante. Ces composés sont contenus dans des tubes en Pyrex de 5 mm de diamètre scellés sous vide. Il en est de même pour $(ClO_2)_2Ge(ClO_4)_6$. Pour ce dernier, afin d'éviter toute décomposition, on effectue les enregistrements à −160°C.

Les échantillons ir de $GeCl_3ClO_4$, sous forme de verre, sont obtenus par projection du liquide sur une face en Si refroidie à −180°C et supportée par une cellule déjà décrite (10).

Synthèse

(a) $GeCl_3ClO_4$ et $GeCl_2(ClO_4)_2$

L'action de Cl_2O_6 (2 g) sur un excès de $GeCl_4$ (6 g) sous agitation, suivie d'une élimination sous vide des gaz de décomposition (Cl_2, ClO_2) et de l'excès de $GeCl_4$, conduit à un liquide incolore dont l'analyse chimique et la spectroscopie Raman montrent qu'il est constitué d'un mélange de chloro et d'oxochloroperchlorato complexes.

Placé sous vide dynamique (ca. 1,33 Pa), à température ambiante, ce mélange laisse distiller, en premier lieu, un liquide incolore ayant une forte tension de vapeur et dont l'analyse chimique est en accord avec la stœchiométrie $GeCl_3ClO_4$ (Ge 26,85 (26,07); ClO_4 34,90 (35,72); Cl 37,60 (38,20)).

Le résidu liquide après élimination de Cl_3GeClO_4, sous contrôle Raman, à une stœchiométrie proche de $GeCl_2(ClO_4)_2$ (Ge 22,64 (21,20); ClO_4 56,85 (58,09); Cl 20,51 (20,71)). La présence, sur le spectre Raman, d'une raie à 447 cm^{-1}, proche de ν_s GeO_2 (11), indique la formation, par oxydation, soit de GeO_2, soit d'un oxochlorogermanium.

Les tentatives de purification de $GeCl_2(ClO_4)_2$, par entrainement sous vide, conduisent à l'oxyder. Il se forme des complexes de compositions variables mais pouvant s'écrire : $Ge_6O_4Cl_x(ClO_4)_{16-x}\cdot nGeO_2$. La constitution de ponts Ge–O–Ge s'accompagne de la libération de Cl_2O_7 comme l'indiquent les spectres Raman (raies caractéristiques à 287 (ρ_r), 709 (ν ClO_p) et 1058 cm^{-1} (ν_s ClO_t) (12)).

(b) $(ClO_2)_2Ge(ClO_4)_6$

Obtenu par réaction d'un excès de Cl_2O_6 sur $GeCl_4$, il n'est pas très stable. À température ambiante, il se décompose, au bout de 10 h, en donnant un mélange d'oxoperchlorates et de GeO_2. Il est, de plus, oxydé par un contact prolongé avec Cl_2O_6. Cette dernière remarque conduit à proposer le protocole de synthèse suivant :

À 10°C sous agitation, on ajoute Cl_2O_6 à $GeCl_4$ par petites fractions successives. Les temps de contact sont limités à 4 min. Après élimination, sous vide, des gaz de décomposition et de l'excès de Cl_2O_6, on obtient une poudre homogène, jaune orange, dont la composition est celle de $(ClO_2)_2Ge(ClO_4)_6$ (Ge 9,01 (9,02); ClO_4^- 75,05 (74,21); ClO_2^+ 15,93 (16,77)).

$(ClO_2)_2Ge(ClO_4)_6$ se sublime sous vide dynamique (1,33 Pa) dès 25°C. Il est possible d'obtenir de beaux cristaux à 32°C, mais leur instabilité a rendu toute analyse aux rayons X impossible. À pression atmosphérique et à 59°C il y a décomposition totale et brutale en GeO_2.

NOTE : Il n'a pas été possible, dans le cadre de ce travail, d'isoler $Ge(ClO_4)_4$. La dégradation thermique du sel de chloryle n'obéit pas aux règles classiques (14). Les réactions, en quantités stœchiométriques, de $GeCl_4$ avec $(ClO_2)_2Ge(ClO_4)_6$ ou Cl_2O_6 conduisent à des oxochloroperchlorate et à GeO_2. Par ailleurs, il est impossible d'extraire Cl_2O_6 de $(ClO_2)_2Ge(ClO_4)_6$ avec $HClO_4$ anhydre. De plus avec $GeCl_4$, cet acide donne une démixtion. Elle disparait vers 60°C mais, à cette température, $HClO_4$ se décompose rapidement. $AgClO_4$ est peu actif; tout au plus donne-t'il $GeCl_3ClO_4$ en solution dans $GeCl_4$.

Résultats et discussion

Approche structurale par spectroscopie de vibration

L'influence des modes de coordination sur le ligand ClO_4

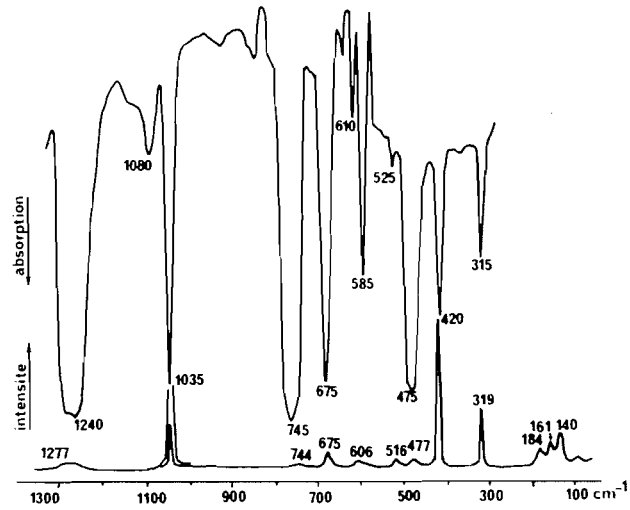

FIG. 1. Spectres infrarouge (a) et Raman (b) de $GeCl_3ClO_4$.

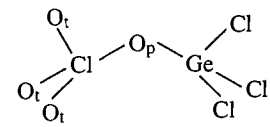
a fait l'objet, ces dernières années, d'études systématiques par rayons X (3), Extended X-ray Absorption Fine Structure (EXAFS) (2*c*) et spectroscopie de vibration ir et Raman (1). L'analyse des spectres obtenus, au cours de ce travail, reposera donc sur ce faisceau de connaissances.

(a) $GeCl_3ClO_4$



Les spectres sont reproduits sur la figure 1.

(*i*) La présence de trois bandes et raies à 1250, 1035 et 745 cm^{-1}, fréquences voisines de celles notées pour $HClO_4$ anhydre (15), est compatible avec l'existence de groupements ClO_4 monodentés.

(*ii*) La raie intense à 420 cm^{-1}, à une fréquence proche de celle observée pour ν_s GeCl dans le composé $GeCl_4$ (397 cm^{-1}) (16), est l'indication de liaisons GeCl terminales.

Ces faits conduisent à proposer une structure monomère dans laquelle Ge est dans un environnement tétraédrique. Elle diffère de la structure polymère trouvée pour $GaCl_2ClO_4$ dans laquelle les groupements ClO_4 sont bidentés pontants (10).

$GeCl_3ClO_4$, représenté selon le schéma suivant,

a une symétrie maximum C_s. Il s'apparente aux composés de types X_2Y_7 tels Cl_2O_7, $Ga_2X_7^-$ (X = Cl, Br), $P_2O_7^{4-}$, $S_2O_7^{2-}$, $Cr_2O_7^{2-}$ et Mn_2O_7.

On attend 21 vibrations actives en ir et Raman, leur description s'effectuera par analogie avec ce qui a été trouvé par ailleurs (12). Mis à part les 2 torsions de faible intensité et de faible énergie (<100 cm^{-1}), les 19 autres vibrations attendues se répartiront dans les 15 groupes de bandes ou raies observées (tableau 1).

Les attributions, données dans le tableau 1, sont effectuées sans problème pour les groupements ($OClO_3$) et ($GeCl_3$). Pour le premier, on tient compte de celles notées pour différents perchlorato complexes (1) et, pour le second, des observations effectuées pour $GeCl_4$ (16) ou $HGeCl_3$ (11). Il est, par contre, délicat de localiser la vibration de valence ν GeO.

Si l'on se réfère aux corrélations $dMO = f(R)$ où R est le rayon ionique effectif (1), on remarque que, avec un environnement tétraédrique pour Ge, la liaison Ge—O peut adopter une longueur voisine de celles signalées dans GeO_2 (≈1,88 Å) (17).

141 (25)		δ_s $GeCl_3$ (A′)
100 (5)		δ GeOCl (A′)

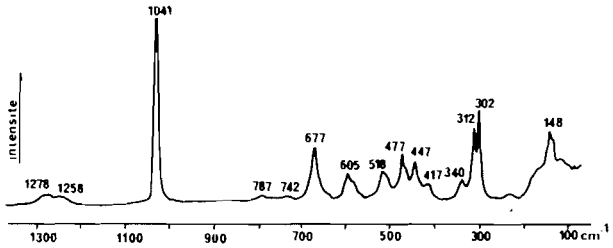

FIG. 2. Spectre Raman de $GeCl_2(ClO_4)_2$.

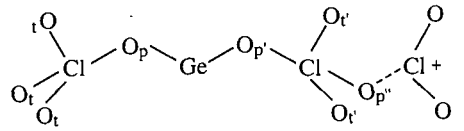
ν GeO doit être attendu à une fréquence proche de celle observée pour ν moyen Ge—O dans GeO_2 : 656 cm^{-1}.

Sur le spectre ir apparait, dans le domaine des vibrations de déformation ClO_4, une bande intense vers 670 cm^{-1}, fréquence convenable pour ν Ge—O(ClO_3). Elle diffère de celle donnée pour ν GeO dans $(CH_3)_3GeNO_3$ (18) mais est voisine de celle trouvée dans $(CH_3)_3GeOH$ (19).

NOTE : dans le tableau 1 ne figurent pas un certain nombre de bandes ir de faible intensité à 1125, 1080, 950, 830, 640 et 570 cm^{-1}. Elles correspondent à des harmoniques ou des combinaisons facilement détectables sur un spectre ir d'un composé vitreux.

(b) $GeCl_2(ClO_4)_2$



On remarque la grande similitude de son spectre Raman (fig. 2) et de celui de $GeCl_3ClO_4$ dans le domaine des modes de vibrations internes de ClO_4. En particulier, la présence d'une raie intense à 1041 cm^{-1}, due à ν_s ClO_3, conduit à admettre, dans ce complexe, la présence de groupes ClO_4 monodentés. La fréquence moyenne ν ClO_p (765 cm^{-1}) révèle que ClO_4 est moins fortement lié à Ge que dans $GeCl_3ClO_4$ (741 cm^{-1}).

Par ailleurs, on note : (*i*) l'absence de la raie très intense à 420 cm^{-1} due à ν_s GeCl dans $GeCl_3ClO_4$; (*ii*) l'apparition autour de 322 cm^{-1} de deux nouvelles composantes (340 cm^{-1} et 302 cm^{-1}). Ceci indique que, dans $GeCl_2(ClO_4)_2$, les atomes de chlore sont donc des atomes pontants avec ν_{as} $GeCl_p$: 340 cm^{-1} et ν_s $GeCl_p$ soit 312 soit 302 cm^{-1} (l'une de ces raies correspondant à ρ_r ClO_3).

Ces observations permettent d'envisager, pour $GeCl_2(ClO_4)_2$, une forme polymère comme pour $SnCl_2(ClO_4)_2$ (20). Dans ces complexes, l'élément central est dans un environnement octaédrique : cependant, avec le germanium, ce sont les atomes de chlore qui sont pontants alors que, avec l'étain, ce sont les groupes perchlorate. Les attributions principales sont analogues à celles données pour $GeCl_3ClO_4$. Les deux nouvelles raies à 447 et 417 cm^{-1} (fig. 2), bien que proches respectivement de ν_s GeO dans GeO_2 et ν_s GeCl dans $GeCl_3ClO_4$, pourraient correspondre aux vibrations ν GeO(ClO_3).

(c) $(ClO_2)_2Ge(ClO_4)_6$

Ce sel est comparable à $(ClO_2)_2Sn(ClO_4)_6$ déjà caractérisé (20). Par rayons X, il a été montré que $Sn(ClO_4)_6^{2-}$ est un anion discret où 6 groupements monodentés ClO_4 entourent l'atome d'étain; cependant certains de ces groupements sont en forte interaction avec ClO_2^+. Un tel phénomène a déjà été observé dans $ClO_2^+ClO_4^-$ (10, 21). Cette interaction anion–cation assure un environnement pseudo tétraédrique à l'atome de chlore de ClO_2^+ et confère aux groupements ClO_4 correspondants un caractère pseudo bidenté. Les différents modes de coordination des groupements ClO_4 sont schématisés ci-dessous.

Sur la figure 3 sont reproduits les spectres ir et Raman des sels d'étain et de germanium; on constate une très grande similitude. On peut donc faire, pour le complexe du germanium, une analyse sur la base d'une structure similaire de celle observée pour $(ClO_2)_2Sn(ClO_4)_6$.

Les attributions sont reportées dans le tableau 2. Comme pour le complexe de l'étain (20), les vibrations des deux types de ClO_4 sont nettement individualisées. Celles relatives au groupement ClO_4 monodenté classique $O_{3t}ClO_p$ sont observées aux fréquences habituelles (1). Celles correspondant au groupement ClO_4 interagissant avec ClO_2^+ sont plus proches d'un groupement ClO_4 bidenté pontant. La fréquence moyenne ν ClO_p (745 cm^{-1}) est de 31 cm^{-1} plus basse que celle relevée pour le complexe de l'étain (776 cm^{-1}). Ceci traduit une interaction métal–$OClO_3$ plus grande pour le germanium que pour l'étain; cette différence pourrait être due aux rayons ioniques respectifs de ces deux éléments.

Le domaine de basse fréquence (<400 cm^{-1}) où apparaissent les vibrations du squelette GeO_6, le balancement (ρ_r) de $O_{3t}ClO_p$ et la vibration de valence de la liaison longue, $ClO_{p''}\cdots ClO_2^+$, méritent quelques commentaires.

Par analogie avec les fréquences observées pour des squelettes MO_n dans des complexes perchlorato (1), on attribue la raie à 284 cm^{-1} et le doublet à 266 cm^{-1}, en Raman, et la bande en ir à 320 cm^{-1}, aux modes ν GeO_6. La fréquence moyenne (298 cm^{-1}) traduit un affaiblissement de la liaison métal–oxygène, par rapport à l'interaction observée dans $GeCl_3ClO_4$. On note, aussi, un renforcement de la liaison M—O par rapport à celle du complexe de l'étain ($\bar{\nu}$ 273 cm^{-1}). À ρ_r $OClO_3$ correspond logiquement le doublet à 210 et 219 cm^{-1}. L'évolution des fréquences de ce mode de vibration en fonction du composé : 319 cm^{-1} : $GeCl_3ClO_4$; 279 cm^{-1} : Cl_2O_7; est assez délicate à expliquer.

La vibration de valence ν $(ClO_3)O\cdots ClO_2^+$ correspondant à l'interaction anion–cation peut être assimilée à une vibration de réseau; elle doit donc apparaître à basse fréquence. La comparaison des spectres Raman de $ClO_2^+ClO_4^-$ (21) et de $(ClO_2^+)_2Ge(ClO_4)_6^{2-}$ montre que, dans le premier, existe

une raie à 227 cm^{-1} absente dans le second; corrélativement apparaissent, dans ce dernier, deux raies à 190 et 183 cm^{-1}. Il semble logique de les attribuer à $\nu\ (ClO_3)O\cdots ClO_2^+$. Le déplacement vers les basses fréquence est dû à la différence de masse entre les deux anions.

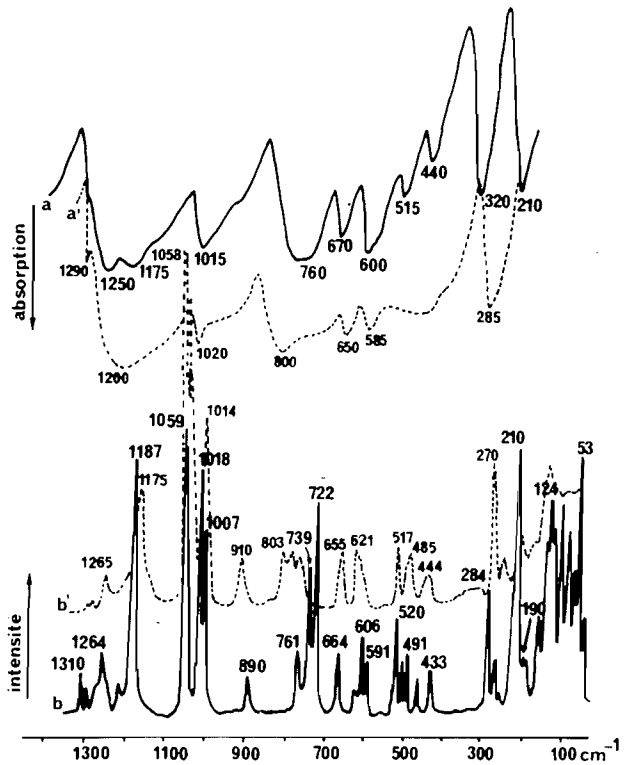

FIG. 3. Spectre infrarouge (a) et Raman (b) de $(ClO_2)_2Ge(ClO_4)_6$ en traits pleins, comparés a ceux de $(ClO_2)_2Sn(ClO_4)_6$ en traits pointillés.

Conclusion

Au cours de ce travail, il a été montré que Ge(IV), comme Ti(IV) et Sn(IV), conduit à des chloroperchlorato complexes, des oxochloroperchlorato complexes et à un sel de chloryle. Cependant, à la différence de Ti ou Sn, il n'a pas été possible d'isoler le perchlorato complexe neutre : $M(ClO_4)_4$.

Aux rares perchlorates covalents stables, liquides à température ambiante, $HClO_4$ (15), Cl_2O_7 (15), $ClOClO_3$ (22), $BCl_2(ClO_4)$ (2*a*), $GaCl_2ClO_4$ (23), $CrO_2(ClO_4)_2$ (24) sont venus s'ajouter $GeCl_3ClO_4$ et $GeCl_2(ClO_4)_2$.

Remarquons que, pour le germanium comme pour le bore ou le gallium, la substitution d'un seul atome de chlore par un groupe ClO_4 conduit à un environnement de l'élément central analogue à celui qu'il y a dans MCl_x (x = 3, 4). Dès la substitution d'un second atome de chlore, le germanium comme le gallium adopte un environnement octaédrique. Cet environnement se retrouve dans le sel de chloryle.

Par ailleurs il faut souligner que, à la différence de l'étain et du titane, le germanium a tendance à stabiliser des ligands ClO_4 monodentés.

On peut se demander pourquoi il n'a pas été possible d'isoler $Ge(ClO_4)_4$; c'est encore un des mystères de la chimie des perchlorato complexes.

Remerciements

À l'occasion de la célébration du 65e anniversaire du Professeur R. J. Gillespie, les auteurs sont heureux de lui adresser leurs sincères félicitations pour sa contribution au développement des connaissances de la Chimie.

Les aides matérielles du CNRS (France) et de la DRST (Tunisie) ont permis aux auteurs d'effectuer les recherches décrites dans cet article. Ils remercient ces organismes.

The conversion of a divinyldi-μ-methylene-dirhodium complex into a μ-ethylidene-μ-methylene-dirhodium complex

JESUS MARTINEZ, JOHN B. GILL, HARRY ADAMS, NEIL A. BAILEY, ISABEL M. SAEZ, AND PETER M. MAITLIS[1]
Department of Chemistry, The University, Sheffield, S3 7HF, U.K.

Received February 22, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

JESUS MARTINEZ, JOHN B. GILL, HARRY ADAMS, NEIL A. BAILEY, ISABEL M. SAEZ, and PETER M. MAITLIS. Can. J. Chem. **67**, 1698 (1989).

The dichloro-μ-ethylidene-μ-methylene-dirhodium complex, $[(C_5Me_5Rh)_2(\mu\text{-CHMe})(\mu\text{-}CH_2)Cl_2]$ (**2**) was the main product of the reaction of the divinyl-di-μ-methylene-dirhodium complex $[(C_5Me_5Rh\text{-}\mu\text{-}CH_2)_2(CH{=}CH_2)_2]$ (**1**), with HCl in toluene at −78°C. It was identified by an X-ray crystal structure determination and spectroscopically.

Key words: vinyl, μ-methylene, μ-ethylidene, rhodium, X-ray.

JESUS MARTINEZ, JOHN B. GILL, HARRY ADAMS, NEIL A. BAILEY, ISABEL M. SAEZ et PETER M. MAITLIS. Can. J. Chem. **67**, 1698 (1989).

Le complexe dichloro-μ-éthylidène-μ-méthylène-dirhodium $[(C_5Me_5Rh)_2(\mu\text{-CHMe})(\mu\text{-}CH_2)Cl_2]$ (**2**) est le produit majoritaire de la réaction du complexe divinyl-di-μ-méthylène-dirhodium $[(C_5Me_5Rh\text{-}\mu\text{-}CH_2)_2(CH{=}CH_2)_2]$ (**1**), avec HCl dans le toluène à −78°C. On a identifié le complexe **1** par détermination de structure cristalline aux rayons X et par spectroscopie.

Mots clés : vinyl, μ-méthylène, μ-éthylidène, rhodium, rayons-X.

Although many μ-methylene-dimetal complexes have now been made (for useful recent references, see ref. 1), an almost unique feature of the rhodium systems, $[(C_5Me_5Rh\text{-}\mu\text{-}CH_2)_2(R)_2]$ (2), is the facility with which the coupling of the R and one or two CH_2 ligands takes place to give organic products (3). Expansion of this chemistry has so far been hampered by a lack of success in making μ-homologues of such complexes. However, we now report the conversion of the divinyl-di-μ-methylene-dirhodium complex (**1**) (4) into the dichloro-μ-ethylidene-μ-methylene complex (**2**, 65% yield), by reaction with HCl (3:1 molar ratio) in toluene at −78°C. The major organic product from this reaction is propene. The dibromo analogue of **2** was formed (50% yield) when **1** was reacted with HBr in pentane.

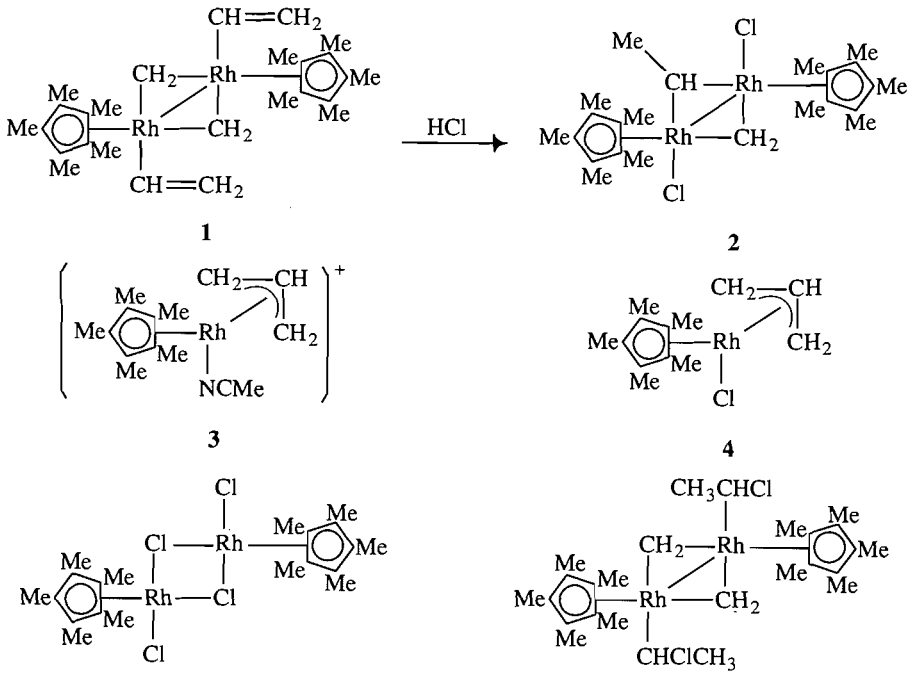
$$[(C_5Me_5Rh\text{—}\mu\text{—}CH_2)_2(CH{=}CH_2)_2] + HX =$$

1

$$[(C_5Me_5Rh)_2(\mu\text{—}CHMe)(\mu\text{—}CH_2)X_2]$$

2

The new complex was identified as the *trans*-dichloro-μ-ethylidene-μ-methylene (**2**) by a single crystal X-ray structure determination,[2] and by nmr spectroscopy.[3] The molecule of complex **2** (Fig. 1) comprises two inequivalent rhodium atoms, each bearing an η^5-C_5Me_5 ring and a Cl, and joined by one μ-CH_2 and one μ-CHMe. The Rh—Rh distance, 2.678(3) Å, is a little greater than in other complexes of this series, (cf. 2.659(1) Å in $[(C_5Me_5Rh\text{-}\mu\text{-}CH_2)_2(CO)_2]^{2+}$ and 2.588(2) Å in $[(C_5Me_5Rh)_2(\mu\text{-}CH_2)_2(CH{=}CH_2)_2]$), but is still well within bonding range, as required for a diamagnetic complex of Rh(IV). The bridging ligands are disordered across the crystallographic inversion centre, and thus no detailed comparison can be made between their bridging geometries, but they appear very similar to those in the di-μ-methylene complexes. The ^{1}H nmr spectrum is consistent with the X-ray results, and the absence of a centre of symmetry in a single molecule is shown in particular by two different signals for the two μ-CH_2 hydrogens.



The reactions of **1** with acids are very complex and depend on the precise conditions. Thus, treatment of **1** with *p*-toluenesulphonic acid in acetonitrile, in the presence of KPF_6, gave the η^3-allyl cation **3**, which was also formed by reaction of **1** with $AgPF_6$. Reaction of **1** with low molar proportions of HCl in chloroform gave the η^3-allyl chloro complex **4**, but this readily

[2]*X-ray structure determination.*
Crystal data:
$C_{23}H_{36}Cl_2Rh_2$ $M = 589.25$
Orthorhombic, space group *Pccn* (D_{2h}^{10}, No. 56), $a = 18.485(19)$, $b = 14.357(17)$, $c = 9.233(6)$ Å, $U = 2451(4)$ Å^3, $D_c = 1.597$ g cm^{-3}, $Z = 4$, Mo-K_α radiation ($\lambda = 0.71069$ Å; $\mu = 15.53$ cm^{-1}), crystal dimensions 0.30 × 0.25 × 0.175 mm. X-ray data $3.5 < 2\theta < 50°$ on Nicolet R3 four-circle diffractometer to give 1571 independent reflections, $|F|/\sigma(|F|) > 3.0$, corrected for Lorentz and polarisation effects, and for absorption by analysis of azimuthal scans. The structure was solved by Patterson and Fourier techniques and refined by blocked cascade least-squares methods. The two bridging ligands are disordered between their centrosymmetrically related sites; thus the composite model was refined with constrained geometry with C(11) common to the two ligands. Hydrogen atoms were placed in predicted positions with isotropic thermal parameters related to those of the supporting atom. Refinement converged at a final R 0.0750, with allowance for the thermal anisotropy of all non-hydrogen atoms with the exception of the half-occupancy C(12). The atomic coordinates are being filed with the Director of the Cambridge Crystallographic Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, England. Any request should be accompanied by the full literature citation for this communication. FIG. 1. The structure of complex **2**. (Because of disorder C11 and C11′ are equivalent crystallographically.)

reacted further with more HCl to give $[(C_5Me_5RhCl_2)_2]$ (**5**) (72%) and propene (71%).

While reactions of a number of cationic η^1, η^2 (i.e., bridging) vinyl complexes with hydride to yield μ-ethylidene complexes are known (5), there does not appear to have been any report of the transformation of terminal vinyls, and by protonation, into μ-ethylidene ligands. We suggest that the reaction of **1** to **2** proceeds via primary protonation of the terminal vinylic carbons, and that the intermediate terminal ethylidene so formed migrates to a bridging position (or possibly exchanges with the μ-CH_2). In support of this, a sparingly soluble orange solid, **6**, with analysis corresponding to $[(C_5Me_5Rh(\mu\text{-}CH_2)(CHClMe))]_2$, was obtained from reaction of **1** with HCl gas in pentane. The ir ν(C=C) at 1559 cm^{-1}, characteristic of the vinyls in **1**, had disappeared and we suggest that **6** has two chloroethylrhodiums (Rh—$CHClCH_3$) arising from addition of HCl to the double bonds. The solid **6** was converted into a 1:1 mixture of **2** and **5** on reaction with HCl in C_6D_6 at 20°C.

This work shows that vinyl–transition metal compounds have much potential in synthesis.

Hexafluoro antimonates(V) of divalent metals, synthesis and properties

M. S. R. CADER AND F. AUBKE[1]

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received February 8, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

M. S. R. CADER and F. AUBKE. Can. J. Chem. **67**, 1700 (1989).

Solvolysis of metal(II) fluorosulfates in liquid antimony(V) fluoride according to:

$$M(SO_3F)_2 + 6SbF_5 \xrightarrow{25-60°C} M(SbF_6)_2 + 2Sb_2F_9SO_3F$$

with M = Sn, Ni, Pd, Cu, or Ag, is found to be a clean, efficient route to the hexafluoro antimonates of the corresponding metals. Two of the compounds reported here display unusual features: $Pd(SbF_6)_2$ is, like its fluorosulfate precursor, paramagnetic with the Pd^{2+} ion in a $^3A_{2g}$ ground state, and an analysis of the ligand field spectrum is presented; $Ag(SbF_6)_2$ is, unlike a recently reported paramagnetic, blue, valence isomer, diamagnetic and nearly white in color. Formulation as a mixed valency compound $Ag(I)Ag(III)(SbF_6)_4$ is suggested. Low temperature magnetic susceptibility measurements (where appropriate), Raman, and IR data are reported. The hexafluoro antimonates of Ni, Pd, and Cu show antiferromagnetic exchange at very low temperatures. $Pd(SbF_6)_2$ shows very weak ferromagnetism below 10 K.

Key words: fluoroantimonates of divalent metals, synthesis and solvolysis in SbF_5, vibrational spectra, magnetic susceptibility measurements.

M. S. R. CADER et F. AUBKE. Can. J. Chem. **67**, 1700 (1989).

On a trouvé que la solvolyse de fluorosulfonates de métal(II) dans le fluorure d'antimoine(V) liquide, suivant la réaction :

$$M(SO_3F)_2 + 6SbF_5 \xrightarrow{25-60°C} M(SbF_6)_2 + 2Sb_2F_9SO_3F$$

et dans laquelle M = Sn, Ni, Pd, Cu ou Ag, est une méthode propre et efficace de préparer les hexafluoro antimonates des métaux correspondants. Deux des composés ainsi préparés présentent des caractéristiques particulières : comme son précurseur fluorosulfonate, le $Pd(SbF_6)_2$ est paramagnétique avec l'ion Pd^{2+} dans un état fondamental $^3A_{2g}$ et on présente une analyse du spectre de champ de ligand; par ailleurs, contrairement à ce qui a été rapportée récemment pour un isomère de valence, bleu et paramagnétique, le $Ag(SbF_6)_2$ est diamagnétique et d'une couleur pratiquement blanche. On propose que sa formule correspond à celle d'un composé de valence mixte $Ag(I)Ag(III)(SbF_6)_4$. On rapporte des données relatives à l'IR, au Raman et à des mesures de susceptibilité magnétique à basse température (lorsque c'est approprié). À des températures très basses, les hexafluoro antimonates de Ni, de Pd et de Cu présentent des échanges antiferromagnétiques. À des températures inférieures à 10 K, le $Pd(SbF_6)_2$ présente un très faible ferromagnétisme.

Mots clés : fluoroantimonates de métaux divalents, synthèse et solvolyse dans le SbF_5, spectres de vibration, mesures de susceptibilité magnétique.

[Traduit par la revue]

Introduction

Antimony(V) fluoride, SbF_5, is commonly regarded as the strongest molecular Lewis acid (1). Conversely the anions SbF_6^- and the related $Sb_2F_{11}^-$ are extremely weak nucleophiles (2), capable of stabilizing a wide range of electrophilic cations, both in solid compounds or in HF–SbF_5 superacid solution (3, and references therein).

The objective of this study is the synthesis and characterization of SbF_6^- salts formed by divalent metal cations. The synthetic route chosen is the solvolysis of metal fluorosulfates in liquid SbF_5 according to the general route:

[1] $$M(SO_3F)_2 + 6SbF_5 \rightarrow M(SbF_6)_2 + 2Sb_2F_9SO_3F$$

with M = Sn, Ni, Pd, Cu, *or* Ag.

Early work by Gillespie and Rothenbury (4) and a subsequent investigation by us (5) into the antimony–fluoride–fluorosulfate system form the basis of this reaction, focussing attention on $Sb_2F_9SO_3F$ as the most volatile component in this system, which allows ready removal of the SO_3F group from the reaction mixture. Initial uses of the solvolysis reaction in SbF_5 have involved the stabilization of nonmetallic cations, such as ClO_2^+ (6), a series of triatomic interhalogen cations (7), or the dihalogen cations Br_2^+ and I_2^+ (8) in solid compounds. Use of this method in the synthesis of the first stage graphite salt C_8SbF_6 (9) and stabilization of the dimethyltin(IV) cation as $(CH_3)_2Sn(Sb_2F_{11})_2$ (10) illustrate its versatility.

There have been a variety of alternative methods used for the synthesis of hexafluoro antimonates of divalent metals, and some of the compounds discussed here (e.g., $Ni(SbF_6)_2$ (11, 12) and $Sn(SbF_6)_2$ (13)) had been prepared when this study was started. All methods have the use of SbF_5 in common, even though the routes vary. Metal oxidation by either elemental fluorine or by SbF_5 in SO_2 solution has allowed the synthesis of $Ni(SbF_6)_2$ (11, 12) as well as of $Fe(SbF_6)_2$ and $Mn(SbF_6)_2$ (12). There are obvious limitations to this approach. Where higher oxidation states are accessible, direct fluorination may result in oxidation beyond the +2 state, unless the reaction conditions are well understood and carefully controlled. Oxidation by SbF_5 fails for metals, with higher oxidation potentials than provided for by the Sb(V)/Sb(III) couple. Quantitative separation of the reduced product, solid $SbF_3 \cdot SbF_5$, may prove difficult, and finally mixed fluoride–hexafluoro antimonates like $CoF(SbF_6)$ (12) may form instead.

Fluoride abstraction from MF_2 by SbF_5 in SO_2 or anhydrous HF may be more versatile (13, 14), but here another problem surfaces: the MF_2 lattice may be incompletely broken up under the reaction conditions. With $MF(Sb_2F_{11})$, a structural isomer

of $M(SbF_6)_2$, chemical analysis becomes inconclusive. When moving from ionic SbF_6^- to coordinated SbF_6^- in these compounds, vibrational spectra become more complex and are less readily interpreted. As a consequence, in a recent publication, formulation as $MF_2 \cdot 2SbF_5$ is employed for materials obtained in this manner (14).

There has been a fair amount of evidence for cations of the type $[MF]^+$, $[M_2F_3]^+$, and $[MF^+]_n$ when AsF_6^- is used as a counteranion (15, 16), and a crystal structure obtained on $AgF_2 \cdot AsF_5$ (17) had shown a chain-type cation $[AgF^+]_n$ with AsF_6^- as counteranion. In $AgF_2 \cdot 2SbF_5$, however, a true Ag^{2+} appears to be present and the crystal structure supports formulation as $Ag(SbF_6)_2$ (14).

The advantages of the $M(SO_3F)_2$ solvolysis in excess SbF_5 are: (*i*) $M(SO_3F)_2$ precursors are readily available either from the solvolysis of $SnCl_2$ or $NiCl_2$, or the corresponding Ni(II) or Cu(II) benzoates in HSO_3F (18), or by the use of $S_2O_6F_2$ in case of $Pd(SO_3F)_2$ (19) and $Ag(SO_3F)_2$ (20); (*ii*) in all instances further oxidation by SbF_5 appears unlikely; (*iii*) vibrational spectra allow monitoring of the reaction by probing the absence of SO_3F vibrations; and (*iv*) reactions may be carried out in glass and followed by weight.

Our reasons for selecting these five $M(SbF_6)_2$ compounds for our study, with M = Sn, Ni, Pd, Cu, or Ag, are twofold: (*i*) To avoid structural ambiguities of the type observed above, it became necessary to obtain a ^{119}Sn Mössbauer spectrum on a sample of $Sn(SbF_6)_2$ prepared by a different route and compare it to the spectrum reported previously (13). (*ii*) We had recently (21) observed significant ferromagnetism in the fluorosulfates of Pd^{2+} and Ag^{2+} with a weaker manifestation of this interesting coupling phenomenon in the Ni^{2+} and Cu^{2+} analogues. It became interesting to study the magnetic properties of the four transition-metal SbF_6^- derivatives at temperatures below 80 K. Since $Ni(SbF_6)_2$ had been obtained previously by all three methods (11, 12, 14) discussed above, its formation by solvolysis in liquid SbF_5 is viewed as a test case. A final point of interest concerns the palladium(II) compound. Pd^{2+} in the fluorosulfate is found in an unusual octahedral coordination environment, resulting in a paramagnetic $^3A_{2g}$ ion ground state. It was hoped a $Pd(SbF_6)_2$ would exhibit parmagnetism as well.

Experimental

Chemicals

The fluorosulfates $Ni(SO_3F)_2$ (18), $Cu(SO_3F)_2$ (18), $Sn(SO_3F)_2$ (18), $Pd(SO_3F)_2$ (19), and $Ag(SO_3F)_2$ (20) were all synthesized according to published methods. Antimony(V) fluoride (Ozark Mahoning) was purified by repeated distillation as described (5, 8) and transferred *in vacuo* into the reaction vessels. $AgSbF_6$ and AgF_2 were obtained from Aldrich Chemicals.

Instrumentation

Infrared spectra were obtained with a Nicolet 5DX FT-IR instrument, internally calibrated with a He/Ne laser. Samples were pressed between AgCl or AgBr windows and run as thin films without a mulling agent. Raman spectra were obtained with a Spex Ramalog-5 spectrophotometer, equipped with an argon ion laser. The 514.5-nm line was used for excitation. UV–VIS–NIR spectra were recorded on a Cary 14 spectrophotometer. Samples were run as mulls in either SbF_5 or Fluorolube oil (Halocarbon Corp.) as mulling agent in a cell fitted with quartz windows. The Mössbauer spectrometer and details regarding the recording and calibration of ^{119}Sn Mössbauer spectra have been described before (22). A P.A.R. model 155 vibrating sample magnetometer was used to obtain magnetic susceptibilities between ~2.0 and 82 K. Again, details on the instrument have been published (23). Magnetic fields of 7501 and 9225 G were used, and diamagnetic corrections were made using Pascal constants. Samples were packed into Kel-F (Fluoro-chlorocarbon polymer) capsules.

All moisture-sensitive solids were handled in a Vacuum Atmospheres Corp. Dri-Lab model no. He-493, filled with purified dry nitrogen and equipped with a Dri-Train circulating unit. The reactions were performed in Pyrex reaction vessels of about 50-mL capacity made from round-bottom flasks fitted with Kontes Teflon stem valves and equipped with Teflon-coated spin bars. The reactions were monitored by weight. Chemical analysis was carried out by the Analytische Laboratorium, Gummersbach, West Germany. Differential scanning calorimetry (DSC) studies were made by using a Mettler DSC 20 cell and a Mettler TC 10 TA processor.

Synthetic reactions

A general reaction scheme was applied to the solvolysis reactions in liquid SbF_5. Approximately 500 mg of the $M(SO_3F)_2$ compound was transferred inside the inert-atmosphere box into a preweighed reaction vessel. Approximately 10 mL of freshly purified SbF_5 was added subsequently by vacuum distillation. The reaction vessel was warmed up, initially to room temperature, and subsequently to 50–60°C in an oil bath. Detailed temperatures and reaction times are given below. Only the reactions of $Pd(SO_3F)_2$ (purple → light-grey) and $Ag(SO_3F)_2$ (black-brown → yellow-green → off-white) involved perceptible color changes of the solid reactant and the mixture remained heterogeneous throughout. The initially very viscous antimony(V) fluoride became somewhat more mobile after about 24 h and the mixture could be stirred effectively with a magnetic stirrer. Volatiles were removed in a dynamic vacuum.

Physical properties and analyses

Both $Ni(SbF_6)_2$ (11, 12, 14) and $Sn(SbF_6)_2$ (13) are known compounds. Their identity is ascertained by weight and by infrared spectroscopy. Formation of both $Ni(SbF_6)_2$ and $Sn(SbF_6)_2$ requires reaction times of 14 and 2 days at 60 and 50°C, respectively. The IR frequencies observed for $Ni(SbF_6)_2$ are listed in Table 1. For $Sn(SbF_6)_2$ the following IR bands are found (estimated intensities are in parentheses): 700 (s, sh), 678 (s), 648 (s), 620 (m), 595 (ms), 571 (ms), 520 (m, sh), 477 (m), 432 (w).

$Cu(SbF_6)_2$, reaction time 10 days, reaction temperature 50°C, white hygroscopic solid that is thermally stable up to 210°C. *Anal.* calcd. for $CuSb_2F_{12}$: Cu 11.88, Sb 45.51, F 42.61; found: Cu 11.65, Sb 45.75, F 42.47. Total: 99.87.

$Pd(SbF_6)_2$, reaction time 14 days, reaction temperature 50°C, light-grey solid, very hygroscopic and thermally stable up to 250°C. *Anal.* calcd. for $PdSb_2F_{12}$: Pd 18.62, Sb 42.14, F 39.45; found: Pd 18.35, Sb 41.90, F 39.18. Total: 99.43.

β-$Ag(SbF_6)_2$, reaction time 10 days, reaction temperature 25°C, creamy white, hygroscopic solid, melts at 180–182°C to clear liquid. *Anal.* calcd. for $AgSb_2F_{11}$: Ag 19.25, F 37.25, Sb 43.45; calcd. for $AgSb_2F_{12}$: Ag 18.62, F 39.35, Sb 42.03; found: Ag 18.65, F 39.06, Sb 42.30. Total: 100.01.

Alternate routes to β-$Ag(SbF_6)_2$: (a) 0.323 g of $AgSbF_6$ is allowed to react with an excess of $S_2O_6F_2$ at room temperature. The white color of $AgSbF_6$ changes immediately to black-brown. The $S_2O_6F_2$ is removed *in vacuo* and subsequently replaced by an excess of SbF_5. The mixture is kept at room temperature for 2 days, then heated at 60°C for 2 h. β-$Ag(SbF_6)_2$ is isolated by removing the excess SbF_5 *in vacuo* and is identified by its IR spectrum. (b) 0.436 g of AgF_2 is loaded inside the dry box into a Kel-F reactor together with 4.5 g of SbF_5. About 6.5 mL anhydrous HF is distilled onto this mixture *in vacuo*. After warming to room temperature under magnetic stirring, a light-yellow solid forms immediately. The solution's initial color, which fades quickly, is light blue. Removal of all volatiles yields pure β-$Ag(SbF_6)_2$ as a cream-colored solid.

Results and discussion

Synthesis

As noted previously (6–10), solvolysis reactions of fluorosulfates in a large excess of SbF_5 proceed smoothly and

frequently without any colour change of the solid reactant. Hence, rather long reaction times are chosen to ensure complete conversion. Two indications that a reaction takes place are a noticeable decrease in the viscosity of SbF_5 after about 1 day, and a slight increase in vapour pressure above the reaction mixture. Both observations may be attributed to the formation of $Sb_2F_9SO_3F$ (7).

To reduce the viscosity even further in order to stir the heterogeneous mixture more effectively, slightly elevated reaction temperatures are chosen. Removal of all volatiles proceeds easily in a dynamic vacuum, with the reaction flask at room temperature.

It is noteworthy that, after pumping overnight, the correct weight for $M(SbF_6)_2$ is obtained. Previous use of this synthetic method by us (6–8, 10) had in all instances led to products where molecular cations are stabilized by $Sb_2F_{11}^-$, and in one case (8) even by $Sb_3F_{16}^-$. For the spherical, less electrophilic M^{2+} cations, SbF_6^- appears to be the more suitable counteranion, allowing formation of layered materials as discussed below. In any event, neither product weights on isolation, nor chemical analyses, nor vibrational spectra give any indication of $Sb_2F_{11}^-$ containing intermediates or by-products.

Of the resulting compounds, $Ni(SbF_6)_2$ (11) and $Sn(SbF_6)_2$ (13) are identified by their weights and their previously reported IR spectra. The ^{119}Sn Mössbauer spectrum of $Sn(SbF_6)_2$ shows a single broad line (Γ = 1.35 mm s^{-1}) caused by unresolved quadrupole splitting. The isomer shift is found at 4.39 mm s^{-1} relative to SnO_2, in excellent agreement with the previously reported value (13). This poses an interesting problem: we had previously concluded, based on ^{119}Sn Mössbauer parameters, that both SbF_6^- and $Sb_2F_{11}^-$ are extremely weakly basic and the least nucleophilic anions when stabilizing the cation $(CH_3)_2Sn^{2+}$ with a linear C—Sn—C group (2). We had expected the SbF_6^- anion to be ideally suited to stabilize the "bare" Sn^{2+} ion equally well. For such a species with a stereochemically inactive, spherically distributed $5s^2$ pair, a single line is expected and calculations suggest a value of 4.84 mm s^{-1} relative to SnO_2 for the isomer shift (24). The results, with identical ^{119}Sn Mössbauer parameters regardless of methods of preparation, and an isomer shift about 0.45 mm s^{-1} lower than suggested by calculations for Sn^{2+}, indicate that steric factors rather than low nucleophilicity of the counteranion may be important. The list of stannous compounds with single-line ^{119}Sn Mössbauer spectra and isomer shifts higher than the ones observed for $Sn(SbF_6)_2$ provides a clue. $Sn[Sn(SO_3F)_6]$, 4.48 (25); $Sn(ClO_4)_2$(15-crown-5)$_2$, 4.53 (26); $Sn(SbF_6)_2 \cdot 2AsF_3$, 4.66 (27); and $Sn[Sn(SO_3CF_3)_6]$ 4.69 mm s^{-1} relative to SnO_2 (28) all approach a true Sn^{2+} more closely than $Sn(SbF_6)_2$ and all involve sterically more demanding ligands than SbF_6^-. A crystal structure for $Sn(SbF_6)_2 \cdot 2AsF_3$ (27), where the Lewis base AsF_3 is coordinated as well to tin, indicates 9-coordinate tin. The use of crown ether ligands (26) also supports the view that steric factors play an important role in stabilizing the bare Sn^{2+} ion.

The solvolysis of $Ag(SO_3F)_2$ is expected to lead to the recently reported blue $Ag(SbF_6)_2$. The X-ray diffraction study had revealed a true Ag^{2+} ion in a distorted octahedral environment (14). However, the course of the solvolysis and the final product are surprising. The initial black-brown color of $Ag(SO_3F)_2$ quickly disappears and a greenish-blue solid slowly changes color to yellow. Ultimately a cream-colored, diamagnetic solid is isolated, which melts at ~180°C, without decomposition, to a clear, colorless liquid. The magnetic behavior, the color, and the observed lack of solubility in anhydrous HF (29) suggest the possible presence of univalent silver. An alternative formulation of the reaction product as

$AgSb_2F_{11}$ is, however, not supported by the weight change during reaction, a complete chemical analysis (see experimental section), the vibrational spectrum, or the chemical behavior of the material. Besides, with paramagnetic divalent silver well established in $Ag(SO_3F)_2$ (20), the other reactant, SbF_5, can hardly be regarded as a reducing agent. A possible reductive decomposition of the reaction product appears unlikely since, besides excess SbF_5, $Sb_2F_9SO_3F$ is the only volatile reaction product obtained.

The chemical behavior of $Ag(SbF_6)_2$ is not consistent with the presence of Ag^+ in the reaction product. Unlike other silver(I) salts, the material will not undergo further oxidation by $S_2O_6F_2$ in the presence or the absence of HSO_3F. On the other hand, $AgSbF_6$ is immediately oxidized by $S_2O_6F_2$ alone, to give a black-brown solid, with the increase in weight consistent with the composition $Ag(SbF_6)(SO_3F)$. Subsequent solvolysis of this material in SbF_5 proceeds in an identical manner to the solvolysis of $Ag(SO_3F)_2$, suggesting a viable alternative synthetic route to $Ag(SbF_6)_2$.

Strong evidence for the presence of silver in an oxidation state higher than +1 comes from the hydrolysis of $Ag(SbF_6)_2$ in aqueous KI solution. The reaction proceeds very vigorously and I_2 and O_2 are produced. Formation of I_2 may in part be due to oxidation by Sb(V) in an acidic environment (30), but evolution of O_2 can only be caused by Ag(II) or Ag(III) (31) in our product.

In summary, all evidence suggests that the material obtained in the solvolysis of $Ag(SO_3F)_2$ in SbF_5 is β-$Ag(SbF_6)_2$, a valence isomer of the previously reported α-$Ag(SbF_6)_2$ (14).

Attempts to synthesize this α form using the published method (14)

$$[2]\quad AgF_2 + 2SbF_5 \xrightarrow{HF} Ag(SbF_6)_2$$

are only partially successful if a slight excess of SbF_5 (ratio SbF_5:AgF_2 = 2.32) over the stoichiometric amount is used. Even here a fair amount of solid β-$Ag(SbF_6)_2$ forms in addition to a blue solution, from which crystalline α-$Ag(SbF_6)_2$ is obtained by slow evaporation of the volatiles. When a larger excess of SbF_5 is used (SbF_5:AgF_2 = 6.01), β-$Ag(SbF_6)_2$ is the only product. The blue color of the HF solution quickly fades within an hour. Removal of HF and the excess SbF_5 yields pure β-$Ag(SbF_6)_2$.

It appears that formation of α-$Ag(SbF_6)_2$ in HF represents an acid–base titration with both the cation $Ag^{2+}_{(solv)}$ and the final product α-$Ag(SbF_6)_2$ stable in, and isolable from, anhydrous HF. Similar behavior is reported for all other transition-metal hexafluoro antimonates of the $M(SbF_6)_2$ or $MF_2 \cdot 2SbF_5$ type (14). On the other hand, β-$Ag(SbF_6)_2$ is insoluble in anhydrous HF, suggesting structural differences.

The observed diamagnetism is best explained by assuming a mixed-oxidation-state compound of the composition Ag(I)-Ag(III)$(SbF_6)_4$. To account for the diamagnetism, Ag^{3+} should be in a square planar, or at least in a tetragonally elongated, octahedral environment. Argentic oxide, AgO, represents a precedent, according to neutron diffraction studies on this compound (31). The black-brown color, also found for the recently reported oxides Ag_2O_3 (32) and Ag_3O_4 (33), is seemingly common to binary oxides and oxy salts of di- or trivalent silver, e.g., the sulfonates $Ag(SO_3F)_2$ (20) or $Ag(SO_3CF_3)_2$ (34), and may possibly be due to a charge transfer transition (35). On the other hand, alkali metal salts containing the $[AgF_4]^-$ ion are reported to be yellow (31, 36), while AgF_2 and many Ag(II) fluoro derivatives are blue (37), just like α-$Ag(SbF_6)_2$ (14).

It appears, then, that all our observations support formulation of the β form as Ag(I)Ag(III)$(SbF_6)_4$; however, our inability to oxidize Ag^+ further is not consistent with an ionic formulation as silver(I) tetrakis(hexafluoroantimonato)argentate(III), Ag^+-$[Ag(SbF_6)_4]^-$.

We are not aware of any other valence isomeric pair of the Ag(II) vs. Ag(I)Ag(III) type. The above mentioned AgO is reported to be Ag(I)Ag(III)O_2 (31), but a true Ag(II)O appears to be still missing. The crystal structure of Ag_3O_4 (33) shows both Ag(II) and Ag(III) in square planar coordination sites, however, and mixed-oxidation-state compounds of the type Pd(II)Pd(IV)X_6, with X = F (38) or SO_3F (19), are known for palladium, the neighboring element in the 4*d* series, with Pd(III)X_3 so far unknown.

Observations made during the course of this study suggest that α-$Ag(SbF_6)_2$ may be irreversibly converted to the β-valence isomer. This conversion occurs at room temperature, if SbF_5 is present in an excess, either in the presence or absence of HF. It is therefore not surprising that all our attempts to synthesize pure α-$Ag(SbF_6)_2$ from AgF_2 and SbF_5 in anhydrous HF (14) produce β-$Ag(SbF_6)_2$ as well, as an insoluble precipitate in addition to the blue solution. Removal of the solvent at −78°C in a dynamic vacuum affords a mixture of the two valence isomers.

Heating the isomeric mixture allows transformation to the pure β form. Following this conversion by differential scanning calorimetry indicates two endothermic events, a sharp peak at 100°C, and a broad peak at 139–140°C. The latter peak coincides with the melting point, where a colorless liquid forms. The β form melts at ~180°C, consistent with differential scanning calorimetry. Absence of the peak at 100°C suggests interpretation of this thermal event as a phase transition from α-$Ag(SbF_6)_2$ to β-$Ag(SbF_6)_2$.

It appears that electron transfer between two Ag^{2+} ions to give Ag^+ and Ag^{3+} is mediated by an antimony(V) fluoro species (SbF_5 or SbF_6^-). Considering our observations regarding the relative stability of the two valence isomers, it is surprising that β-$Ag(SbF_6)_2$ has not been reported while the α form has.

The solvolysis of $Pd(SO_3F)_2$ in SbF_5, on the other hand, does not appear to involve a change in the electronic structure of the Pd^{2+} ion. The resulting material of the composition $Pd(SbF_6)_2$ is paramagnetic. The electronic spectrum of the mull exhibits three broad bands: ν_1 at 840 nm ($^3A_{2g} \rightarrow {}^3T_{2g}$), ν_2 at 550 nm ($^3A_{2g} \rightarrow {}^3T_{1g}(F)$), and ν_3 at 375 nm ($^3A_{2g} \rightarrow {}^3T_{1g}(P)$). Analysis of the observed ligand-field spectrum according to Figgis (39) suggests a $10Dq$ value of 12 400 cm^{-1}, B = 587 cm^{-1} and B/B_0 = 0.707. Very similar parameters are reported for $Pd(SO_3F)_2$ with $10Dq$ = 11 770 and B = 633 cm^{-1} (19). This in turn suggests a structural similarity between both compounds. For $Pd(SO_3F)_2$ (19), as for most fluorosulfates of divalent metals (18), a layer structure based on the $CdCl_2$ prototype is postulated. The same structural type is reported for α-$Ag(SbF_6)_2$ (14) and implicitly also for $Ni(SbF_6)_2$ (11). From a comparison of the Dq and B values for the two Pd(II) compounds, it appears that in this case the tridentate SbF_6^- group ranks slightly higher in both the spectrochemical and nephelauxetic ligand series (34) than does the O-tridentate fluorosulfate group.

[a]Denotes ref. 14.

Paramagnetic Pd^{2+} complexes with fluorometallate anions have precedents. Complexes of the general type $Pd[MF_6]$, with M = Pd, Pt, Ge, or Sn, have been known for almost 25 years (38), and their magnetic susceptibility measurements have been reported down to 80 K. The presence of MF_6^{2-} anion would suggest a different structural type, but the coordination environment of Pd^{2+} should again be octahedral.

Vibrational spectra

The infrared spectra obtained for $Ni(SbF_6)_2$, $Pd(SbF_6)_2$, $Cu(SbF_6)_2$, and β-$Ag(SbF_6)_2$, together with the Raman spectra for the latter two compounds, are summarized in Tables 1 and 2. Also included are the previously reported Raman spectra for $Ni(SbF_6)_2$ (11) and α-$Ag(SbF_6)_2$ (14) as well as an approximate band description, also proposed previously (11). However, this description pertains only to the Ni^{2+}, Pd^{2+}, and Cu^{2+} compounds in Table 1. The Raman spectrum of β-$Ag(SbF_6)_2$ is illustrated in Fig. 1. Attempts to obtain a Raman spectrum of $Pd(SbF_6)_2$ result in partial sample decomposition. Apparently the excitation line of the Ar^+ laser falls within ν_2 of the electronic spectrum of $Pd(SbF_6)_2$.

Agreement with the previously reported IR and Raman spectra for $Ni(SbF_6)_2$ (11) is very good with only a minor exception: we do not observe an IR band at 583 cm^{-1} attributed to ν_{as} out of phase for the bridging SbF_3 group. This band does not have a counterpart in the Raman spectrum, and may be spurious. We have amended the band description in Table 1 slightly. There is only a partial comparison possible with the vibrational spectra reported for $NiF_2 \cdot 2SbF_5$ (14). The limited number of bands listed, six Raman and four IR bands with five non-coincidences, suggests an incomplete listing. Nevertheless, the Raman bands reported for $NiF_2 \cdot 2SbF_5$ (14) are all observed with similar relative intensities in the Raman spectrum of $Ni(SbF_6)_2$ (11). Since the reported X-ray powder data have the principle lines in common (11, 14), it is reasonable to conclude that both compounds are identical.

This is possibly not the case for $Cu(SbF_6)_2$ reported here, or for $CuF_2 \cdot 2SbF_5$ (14). Very intense Raman and IR bands at ~725 cm^{-1} (see Table 1) are apparently not observed for $CuF_2 \cdot 2SbF_5$ (14). However, the case for polymorphism is by no means as strong as in the case of the two forms of $Ag(SbF_6)_2$.

The available structural information on $M(SbF_6)_2$ compounds facilitates a discussion of the vibrational data shown in Table 1. A common $CdCl_2$-type layer strucure is proposed for $Ni(SbF_6)_2$, based on X-ray powder diffraction data (11), and evident for α-$Ag(SbF_6)_2$ from the X-ray single crystal diffraction study (14). The structure for $Ni(SbF_6)_2$ is deduced, starting from the well-known $LiSbF_6$ structure (40) by placing Ni^{2+} into every second, nearly octahedral Li^+ site (11). In α-$Ag(SbF_6)_2$, Ag^{2+} is situated in a tetragonally elongated octahedral site, resulting almost in square planar coordination, similar to the coordination in AgF_2 (41). SbF_6^- acts as a tridentate bridging group, with the bridging fluorines, F^b, and the terminal fluorines, F^t, in *fac*-octahedral positions. Unlike the SbF_3^b unit, the corresponding SbF_3^t-trigonal pyramid is remarkably regular with two $d_{Sb-F^t} \approx 1.836$ Å and one slightly longer at 1.846 Å. The vibrational assignment for $Ni(SbF_6)_2$ by Christe *et al.* (11), adopted by us in this study, suggests a useful subdivision into $Sb-F_3^t$ stretching modes found above ~660 cm^{-1} and $\nu_{Sb-F_3^b}$ below ~635 cm^{-1}. Each set is further divided into symmetric and asymmetric in-phase and out-of-phase modes. The basic difference between both sets, SbF_3^b and

SbF_3^t, is that the former belong to a filled, and the latter to an unoccupied, octahedral hole in the $M(SbF_6)_2$-layer structure.

The data summarized in Table 1 for $M(SbF_6)_2$, with M = Ni, Pd, and Cu, indeed show a common group of four strong vibrations, some small band splittings for $Cu(SbF_6)_2$ notwithstanding, which are assigned as ν_{Sb-F^t} vibrations. Most prominent among them is a Raman band at ~670 cm^{-1}, which is clearly the strongest band in the respective spectra. Interestingly, this band is found as well for a number of additional $M(SbF_6)_2$ compounds with M = Mg, Zn, Fe, Co, and Cu (14), in the same position, and always of the highest intensity. This is altogether not too surprising, since the reported X-ray powder diffraction data had indicated the existence of two structurally related triads, consisting of the hexafluoro antimonates of Mg, Zn, and Ni, and those of Fe, Co, and Cu (14). However, the structural differences between the two triads appear to be so small that they do not seriously affect the positions of the $\nu_{Sb-F_3^t}$ bands. In the Raman data, the 670-cm^{-1} band is attributed to a symmetric in-phase $Sb-F_3^t$ stretching mode, which suggests a common SbF_3^t grouping in both triads as well as in $Cu(SbF_6)_2$ reported by us. A corresponding IR band of medium intensity is observed in all instances as well. This band is found for $Pd(SbF_6)_2$ at 667 cm^{-1}. In addition, there is a rather close correspondence between $Ni(SbF_6)_2$ and $Pd(SbF_6)_2$, in both IR band positions and intensities, to suggest isostructural compounds.

The remaining $M(SbF_6)_2$ compounds reported by Gantar *et al.* (14), with M = Cr, Pb, and Cd, differ slightly in both vibrational spectra and X-ray powder diffraction data. The highest intensity Raman band is now found at about 650 cm^{-1}. Even for these compounds, as for all the others (14), formulation as $M(SbF_6)_2$ is suggested. None of the vibrational data reported here or published previously (11, 14) suggest the presence of the anion $Sb_2F_{11}^-$, by comparison to published precedents (13, 42, 43).

The vibrational data for both forms of $Ag(SbF_6)_2$ in Table 2 show interesting differences. Both have two very intense Raman bands, rather than one, in the $\nu_{Sb-F_3^t}$ region, at 668 and 658 cm^{-1} for α-$Ag(SbF_6)_2$ and at 682 and 659 cm^{-1} for the β form (see Fig. 1). In each case the band with the largest Raman shift also has the highest intensity, and yet in spite of the incomplete band listing for α-$Ag(SbF_6)_2$, there appears to be some structural similarity between the two forms. Only a rather general band description is suggested because there may be some band overlap for β-$Ag(SbF_6)_2$, while the listing for the α form appears, as stated above, to be incomplete.

The distorted layer structure formed for α-$Ag(SbF_6)_2$, with all tetragonally elongated octahedral holes occupied by Ag^{2+} and concomitant tetragonally compressed vacant sites (14), provides a suitable model for the valence isomer as well. Regular occupation of half of the compressed holes by Ag^+ and half of the elongated holes by Ag^{3+} would allow retention of the layer structure, where Ag^+ achieves linear and Ag^{3+} square planar coordination. Conversely, two types of vacant sites are formed, with two sets of $Sb-F^t$ vibrations and different band positions for the $Sb-F^b$ stretching modes as well, consistent with observations.

Ultimately, structural proof will have to come from a single-crystal X-ray diffraction study, and our efforts are currently aimed in this direction. The lack of solubility in HF and the high reactivity of β-$Ag(SbF_6)_2$ present obstacles.

Low temperature magnetic susceptibility measurements

Magnetic susceptibilities over the temperature range of ~2 to 80 K are recorded for $Ni(SbF_6)_2$, $Pd(SbF_6)_2$, and $Cu(SbF_6)_2$ on a P.A.R. vibrating sample magnetometer. Relevant data are summarized in Table 3 and the plot of the magnetic moments vs. temperature for all three compounds is shown in Fig. 2.

As discussed in the experimental section, we have not been able to obtain pure α-$Ag(SbF_6)_2$ in quantities large enough for a bulk magnetic measurement. The results of measurements made, on what is obviously a mixture of the two valence isomeric forms, allow only limited conclusions, since the small amount of paramagnetic material in the sample did not permit us to extend the measurements to temperatures higher than 65 K. Usually, for paramagnetic materials with one or two unpaired electrons, the vibrating sample magnetometer is useful to ~90 K. In the temperature range of 65–3 K the magnetic moment calculated for α-$Ag(SbF_6)_2$ appears to be independent of temperature with a shallow maximum at ~6 K before falling off. It is unclear whether the observed dilute magnetic behavior is due to α-$Ag(SbF_6)_2$, or is caused by β-$Ag(SbF_6)_2$ acting as a dilutant.

The diamagnetism of β-$Ag(SbF_6)_2$ is confirmed by measurements made at room temperature, using the Gouy technique. The measured susceptibility of -68×10^{-6} cm^3 mol^{-1} is less than the sum of Pascal constants of -128×10^{-6} cm^3 mol^{-1}; however, the Gouy balance used is insufficiently sensitive for a more accurate determination of diamagnetic susceptibilities. In addition, a trace amount of α-$Ag(SbF_6)_2$ could be responsible for the slight discrepancy, as well as some temperature independent paramagnetism (TIP).

Of the remaining three compounds, $Ni(SbF_6)_2$ presents the clearest picture. As seen in Fig. 2, the magnetic moment decreases gradually before a steep decline becomes apparent at ~10 K, indicative of strong antiferromagnetic ordering. Both $Pd(SbF_6)_2$ and $Cu(SbF_6)_2$ also show strong antiferromagnetic coupling when approaching 4 K, but in both instances, most noticeably for $Pd(SbF_6)_2$, a very slight increase of the magnetic moment is observed, just before antiferromagnetic ordering dominates. This increase is rather small for $Cu(SbF_6)_2$ and the discussion will concentrate on the palladium(II) case. The observed weak effect is reproducible and two possible interpretations are suggested: (a) a phase transition occurs at ~10 K, and (b) very weak ferromagnetism is responsible for the small effect.

We tend to favor the latter explanation because there are a number of precedents for simultaneous ferromagnetic and antiferromagnetic ordering in fluoro derivatives of palladium(II). Very weak ferromagnetism is observed for PdF_2 (44), which has a rutile structure (45), and for the ternary fluorides $Pd(II)Pd(IV)F_6$ and $Pd(II)Pt(IV)F_6$ (46). According to a recent crystal structure reported for the latter compound (47), there may even be a close structural relationship: $Pd(II)Pt(IV)F_6$ has a $LiSbF_6$ structure. For $Pd(II)(SbF_6)_2$ a layer structure is suggested, which, as discussed above, is also derived from the $LiSbF_6$ prototype, with half of the octahedral holes occupied by Pd^{2+} compared to all holes filled for $Pd(II)Pt(IV)F_6$ (47).

Some similarity in magnetic behavior is also evident from the μ_{eff}^{80} values, which are for the ternary palladium(II) fluorides in the range of 2.7–~3.0 μ_B for the series $Pd(II)M(IV)F_6$, with M = Pd, Pt, Ge or Sn (38*a*), while 3.09 μ_B are found for $Pd(SbF_6)_2$, where Pd^{2+} is slightly more dilute.

Substantially higher magnetic moments (3.30–3.60 μ_B) are found for the corresponding fluorosulfato complexes of palladium(II) (19*b*), where the bulkier fluorosulfate groups appear to prevent antiferromagnetic exchange. It is interesting to note that

TABLE 3. Magnetic properties of $M(SbF_6)_2$ compounds, M = Ni, Cu, Pd

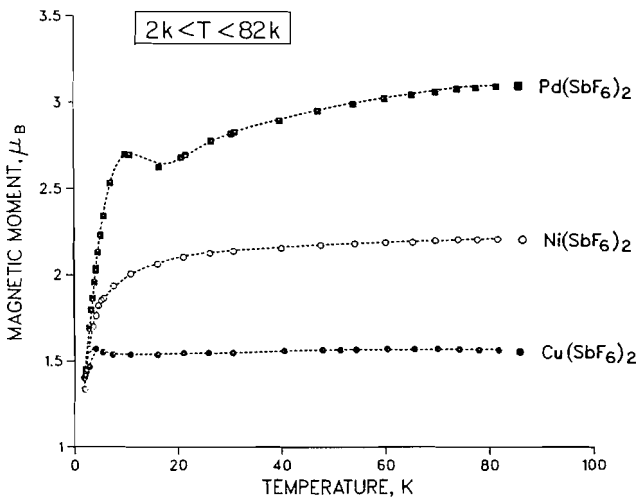

FIG. 2. Magnetic moment vs. temperature of $M(SbF_6)_2$ (M = Ni, Cu, Pd).

at low temperatures (~20 K) significant ferromagnetism has been observed for two members of this group, $Pd(SO_3F)_2$ and $Pd(II)Pd(IV)(SO_3F)_6$. The former, like $Pd(SbF_6)_2$, has a layer structure, derived from the $CdCl_2$ type, and both appear to have the Pd^{2+} ion in very similar electronic environments at room temperature, as reflected in their respective electronic mull spectra discussed above.

Finally it should be pointed out that the magnetic moments obtained for $Cu(SbF_6)_2$ are unusually low for Cu^{2+} (48) with values well below the spin-only value of 1.73 μ_B, and for the most part down to ~4 K, invariant with temperature. This behavior clearly rules out antiferromagnetic coupling as a possible cause for the low moments. With the composition of the material well established by a complete analysis, the possible presence of a diamagnetic mixed valency compound $Cu(I)Cu(III)(SbF_6)_4$ must be considered likely. A number of square-planar diamagnetic complexes of Cu(III) have been studied (48); however, the only fluorocomplex $K_3[CuF_6]$ is paramagnetic, with $\mu_{eff} = 2.80\ \mu_B$ (49). The unusual Raman spectrum of $Cu(SbF_6)_2$ has been discussed above, and it seems that a further, more detailed investigation into a possible second, perhaps less pronounced, case of valence isomerism, affecting again with $Cu^{2+}(d^9)$ a "Jahn-Teller ion", is indicated.

Conclusions

Even though a number of seemingly simpler synthetic routes to compounds of the type $M(SbF_6)_2$ are known, the solvolysis of metal fluorosulfates in excess SbF_5 is found to be a very useful addition. This is evidenced by $Pd(SbF_6)_2$ with interesting spectroscopic and magnetic properties and more so by the new diamagnetic valence isomer β-$Ag(SbF_6)_2$. Since a fair number of transition-metal fluorosulfates are known, there appears to be a wide synthetic potential for this route.

One-pot synthesis of *N*-substituted-3-hydroxy-4-pyridinone chelate complexes of aluminum, gallium, and indium

ZAIHUI ZHANG, T. L. THOMAS HUI, AND CHRIS ORVIG[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC, Canada V6T 1Y6

Received January 24, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

ZAIHUI ZHANG, T. L. THOMAS HUI, and CHRIS ORVIG. Can. J. Chem. **67**, 1708 (1989).

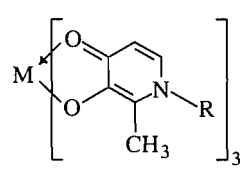
A series of tris(3-hydroxy-2-methyl-4-pyridinonato)metal(III) and tris(3-hydroxy-6-hydroxymethyl-4-pyridinonato)-metal(III) complexes have been prepared in water by one-pot synthesis directly from maltol and kojic acid, respectively, and the metal ion (M = Al, Ga, In) with an appropriate amine. The pyridinones have substituents at the ring nitrogen atom (CH_3, C_2H_5). The tris(3-hydroxy-4-pyronato)metal(III) complexes are formed *in situ* and these undergo nucleophilic attack by the primary amine; the appropriate tris(3-hydroxy-4-pyridinonato)metal(III) complexes are obtained. This method bypasses the sequential syntheses of ligand and metal complex, and has improved the yields of the tris(ligand)metal complexes, in particular by making them much more easily accessible. The electronic effects of binding the pyrone to the metal ions and of the substituents on the pyrone ring on the reactivity are discussed.

Key words: 3-hydroxy-4 pyridinone complexes, group 13 metal ions, one-pot synthesis.

ZAIHUI ZHANG, T. L. THOMAS HUI et CHRIS ORVIG. Can. J. Chem. **67**, 1708 (1989).

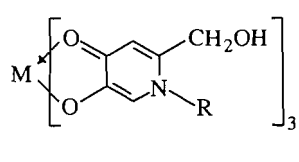
Utilisant des réactions de type «pot au feu» impliquant respectivement du maltol et de l'acide kojique, l'ion métallique (M = Al, Ga et In) et une amine appropriée, on a préparé une série de complexes tris(hydroxy-3 hydroxyméthyl-6 pyridinato-4)métal(III) dans l'eau. Les pyridinones portent des substituants sur l'atome d'azote du cycle (CH_3, C_2H_5). Les complexes tris(hydroxy-3 pyronato-4)métal(III) se forment *in situ* et ceux-ci subissent une attaque nucléophile par l'amine primaire; on obtient les complexes tris(hydroxy-3 pyridinonato-4(métal(III) appropriés. La méthode évite de passer par les synthèses en série du ligand et du complexe et conduit à de meilleurs rendements des complexes tris(ligand)métal, en particulier en les rendant beaucoup plus accessibles. On discute de l'influence que les effets électroniques de la liaison de la pyrone aux ions métalliques et des substituants présents sur le cycle pyrone peuvent avoir sur la réactivité.

Mots clés : complexes hydroxy-3 pyridinone-4, ions métallique du groupe 13, synthèse de type « pot au feu ».



[Traduit par la revue]

Introduction



Group IIIA (13) metal complexes of certain 3-hydroxy-4-pyrones and *N*-substituted-3-hydroxy-4-pyridinones are neutral, water-soluble, and lipophilic (1–5). The pyridinone complexes are thermodynamically stable (overall formation constants β_3 of 10^{32} to 10^{37}) and they strongly resist hydrolysis because the tris(ligand) species predominate between pH 4 and pH 9 (6, 7). Burgeoning interest in the bioinorganic chemistry of Al, Ga, and In has necessitated the investigation of compounds of these elements (such as those with the *N*-substituted-3-hydroxy-4-pyridinone ligands) that are soluble and stable under physiological conditions (6).[2]

The syntheses of these complexes have been reported previously (2, 4, 5); however, in these reports the metal complexes were prepared from the ligands, which were synthesized separately in other work (9). It has become obvious that the development of simple methods to synthesize the pyridinone ligand complexes is of considerable importance. 3-Hydroxy-4-pyridinones are usually prepared by amination of the analogous 3-hydroxy-4-pyrone (5, 9–16). Two common methods have been used to achieve this conversion process. The oldest method uses methyl-, benzyl-, or glucosyl-protected pyrones (9–15) as the precursors; recently, in a second procedure, workers have found that the hydroxypyrone can be converted directly (5, 16). Three steps are involved in the former method: protection of the ring hydroxyl group with methyl, benzyl, or glucosyl groups, conversion via the amine insertion reaction, and deprotection to give the pyridinone. The multistep reactions are, of course, time consuming and rigorous. Control of the pH is vital to success with the second method (5). A suitable and more general method was sought that would allow the direct preparation of tris(3-hydroxy-4-pyridinonato)metal(III) complexes; this is reported here.

Reactions of ligands coordinated to metal ions have been used frequently in the synthesis of organic compounds and, more frequently, in the preparation of their metal complexes (17–21). The preparation of macrocyclic metal complexes in high yield via the metal template effect is but one application of reactions of coordinated ligands. This knowledge of previous work on the reactions of coordinated ligands stimulated an interest in prepared tris(3-hydroxy-4-pyridinonato)metal(III) complexes by this simple route. We report the one-pot synthesis of group IIIA (complexes **1** and **2** pyridinones derived from maltol (3-hydroxy-2-methyl-4-pyrone) and kojic acid (5-hydroxy-2-hydroxymethyl-4-pyrone), respectively.

Experimental

Materials and methods

The materials used were as previously detailed (3, 9); maltol (Aldrich) and kojic acid (Sigma) were used as received. ^{1}H NMR spectra were recorded with a Bruker WH-80; infrared spectra were obtained on a Perkin–Elmer PE 783 spectrometer and were referenced to polystyrene. Characterization of the products was accomplished by

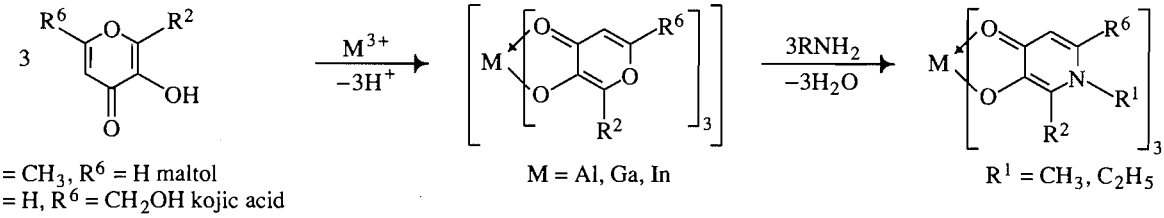

FIG. 1. Scheme for the one-pot synthesis of tris(3-hydroxy-4-pyridinonato)metal(III) complexes.

comparing infrared and ^1H NMR spectral data with those for authentic samples prepared by literature methods (2, 4, 5),[3] as well as by elemental analysis where necessary. Representative preparative details are given below and yields are presented in Table 1.

Tris(3-hydroxy-1,2-dimethyl-4-pyridinonato)aluminum(III), Al(dpp)$_3$

Maltol (2.51 g, 19.9 mmol) and $AlCl_3 \cdot 6H_2O$ (1.64 g, 6.8 mmol) were dissolved in 25 mL distilled deionized water, and methylamine (40% aqueous, 25 mL) was added. The pH of this solution was adjusted to 11.0 and the reaction mixture was transferred to a 100-mL flask in which it was refluxed for 6.5 h. The excess amine was removed under reduced pressure and the volume of the solution was reduced to 5 mL. The solution was stored in the refrigerator overnight; the light pink crystals that formed were collected by filtration and recrystallized in hot water. The recrystallized product was dried *in vacuo*, giving 2.63 g of product (90% yield based on maltol).

Tris(6-hydroxymethyl-3-hydroxy-1-methyl-4-pyridinonato)-aluminum(III), Al(hmp)$_3$

Kojic acid (1.98 g, 13.9 mmol) was dissolved in 60 mL distilled deionized water, and methylamine (40% aqueous, 10.8 mL) was added. $AlCl_3 \cdot 6H_2O$ (1.05 g, 4.35 mmol) was then added to this solution. The pH was adjusted to 11.0 and monitored regularly during 2 days of refluxing. The reaction mixture was subsequently cooled to room temperature, its volume was reduced *in vacuo*, and it was then cooled in the refrigerator overnight. A yellowish solid precipitated from the solution; it was collected by filtration, recrystallized from hot water, and dried *in vacuo*, giving 1.27 g of product (57% based on Al).

Results and discussion

A series of *N*-substituted tris(3-hydroxy-4-pyridinonato)- and tris(6-hydroxymethyl-3-hydroxy-4-pyridinonato) complexes of aluminum(III), gallium(III), and indium(III) are prepared in good yield by the one-pot synthesis method from commercially available starting materials. In this preparation, the metal–pyrone complex is first formed *in situ* and then undergoes the insertion of the primary amine into the pyrone ring to form the appropriate 3-hydroxy-4-pyridinone complex under pH control. The general synthetic scheme is outlined in Fig. 1. Neither the metal–pyrone complexes nor the product ligands were isolated because the aim of this work is the *direct* preparation; however, the conditions are completely compatible with those used in their formation (3, 4).[3]

The accepted mechanism for the preparation of a 4-pyridinone by conversion of an appropriate 4-pyrone is nucleophilic attack by a primary amine, followed by ring opening, elimination of water, and ring closure to give the 4-pyridinone (23). The nucleophilic attack is an important step in this process. Any factor that affects the electron density on the pyrone ring (especially next to the in-ring oxygen atom at C2 or C6) influences the nucleophilic attack step and therefore the whole conversion reaction. The reactivity of the pyrone ring towards the entering nucleophile varies with the substituents on the ring as well. Electron-withdrawing groups should enhance the reactivity of the ring while electron-donating groups should have the opposite effect.

TABLE 1. The yields of tris(ligand)-metal(III) complexes via the one-pot synthesis reaction

	R^1	1	2
Al	CH_3	90	57
	C_2H_5	46	21
Ga	CH_3	85	49
	C_2H_5	61	32
In	CH_3	82	54
	C_2H_5	63	63

Complex formation between a trivalent metal and the pyrone enhances the reactivity of the coordinated pyrone in two ways. In the pyrone amination reaction, the charge localization on the ring plays a crucial role in determining the effectiveness of the reaction. Deprotonation of the hydroxyl group on the pyrone ring gives an anionic hydroxyl oxygen, which hinders the formation of the 4-pyrone reasonance hybrid most susceptible to nucleophilic attack. As well, protonation of the primary amine will stop the nucleophilic attack. Complexation of the hydroxyketone oxygen atom prevents the undesired deprotonation process; in addition, the metal ion causes polarization of the ligand through an electron-withdrawing effect. This phenomenon results in increased acidity of the coordinated ligands upon conjugation and the coordinated pyrone will be more susceptible to the nucleophilic attack than the uncoordinated pyrone. Conversion reactions of the coordinated pyrones to the appropriate pyridinones should be easier. Group IIIA(13) metals are strong Lewis acids and they form stable complexes with maltol and kojic acid (1, 3, 4, 24). They should strongly polarize the coordinated pyrone and make the nucleophilic attack by a primary amine much easier. The conditions of conversion reactions should then be improved and the yield of the tris-ligand complexes should be increased.

The results (Table 1) show that the yields of the complexes are quite reasonable by this one-pot synthesis method, verifying the hypotheses as outlined. The yields for the metal complexes **1** where $R^1 = CH_3$ compare very favorably with literature results for the ligand (51% in three steps via protection (9); 70% (5) or 50% (16) directly) followed by complex preparation (79% for Al, Ga (2)). For **1** ($R^1 = C_2H_5$), the one-pot synthesis compares less favorably (ligand, 58% (5, 8) or 24% (16) directly; complex >80% (5, 8)); however, the ease of the one-pot method is not factored into the yield results, naturally.

Maltol and kojic acid were compared to investigate the effect of different substituents on the pyrone ring. Substituents

influence the reactivity by changing the electron density on the pyrone ring and, consequently, the basicity of pyrones (22). Electron-donating groups, such as the methyl group on maltol, increase the electron density on the pyrone ring and hinder the nucleophilic attack while increasing the basicity of the pyrone. Accordingly, more stable complexes with metal ions are formed. Electron-withdrawing groups, like the hydroxymethyl group on kojic acid, decrease the electron density on the pyrone ring, facilitating nucleophilic attack. This decreased electron density decreases the basicity of the pyrone, however. That kojic acid ($pK_a = 7.6$) is a stronger acid than maltol ($pK_a = 8.4$ (22, 24) illustrates these arguments. These two effects are seen to compete during the reaction process. Upon complexation, the electron-withdrawing effect of the positively charged metal ions should be much more drastic than that of the ring substituents. The relative stability of the complexes would be important in determining which effect is dominating during the reaction. The more stable the complex, the more pronounced the effect on the electron density should be. Even though electron-donating groups could impede the nucleophilic attack process, the enhanced stability of the metal complexes would compensate for this negative effect. The conversion reaction would be easier for the electron-donating substituted pyrones than for the electron-withdrawing substituted ones. The results in Table 1 show that the conversion reaction of maltol is a higher yield process than that of kojic acid.

In conclusion, the one-pot synthesis of tris(3-hydroxy-4-pyridinonato)metal(III) has proven to be a useful example of the reaction of a coordinated pyrone, and its general applicability to all R^1N substituents is currently under study.

Bis(tertiary amine)dihaloboron cations and related species: nuclear magnetic resonance and fast atom bombardment mass spectrometry studies

MELVIN J. FARQUHARSON AND J. STEPHEN HARTMAN[1]

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received January 31, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

MELVIN J. FARQUHARSON and J. STEPHEN HARTMAN. Can. J. Chem. **67**, 1711 (1989).

The formation of four-coordinate haloboron cations from aliphatic tertiary amine adducts of the mixed boron trihalides by heavy halogen displacement has been systematically studied by ^{19}F and ^{11}B nuclear magnetic resonance and positive ion fast atom bombardment mass spectrometry (FAB). Low-steric-hindrance donor molecules readily displace bromide ion from tertiary amine – bromodifluoroborane adducts, $D \cdot BF_2Br$, to form difluoroboron cations $D_2BF_2^+$ and $DD'BF_2^+$, but the corresponding dibromofluoroborane and tribromoborane adducts are highly resistant to bromide ion displacement. Bis(tertiary amine)dichloroboron and -chloroiodoboron cations can be obtained by selective iodide displacement from $D \cdot BCl_2I$ and $D \cdot BClI_2$. Fast atom bombardment mass spectrometry selectively detects the haloboron cations in preference to the neutral adducts in mixtures, and is a valuable complement to nmr in monitoring formation of the haloboron cations as well as any ionic by-products.

Key words: difluoroboron cations, dihaloboron cations, NMR, ^{11}B, ^{19}F, fast atom bombardment (FAB), ligand substitution, redistribution reactions.

MELVIN J. FARQUHARSON et J. STEPHEN HARTMAN. Can. J. Chem. **67**, 1711 (1989).

Faisant appel à la résonance magnétique nucléaire du ^{19}F et du ^{11}B ainsi qu'à la spectrométrie de masse des ions positifs par bombardement avec des atomes rapides (FAB), on a étudié d'une façon systématique la formation des cations halogénobores tétra-coordonnés à partir d'adduits d'amines tertiaires aliphatiques sur des trihalogénures mixtes du bore par déplacement des halogènes lourds. Des molécules de faible empêchement stérique pouvant agir comme donneur déplacant facilement l'ion brome d'adduits amine tertiaire – bromodifluoroborane, $D \cdot BF_2Br$, pour conduire à la formation de cations difluorobore, $D_2BF_2^+$ et $DD'BF_2^+$; toutefois, les adduits correspondants du dibromofluoroborane et tribromoborane sont très résistants à tous déplacements de l'ion bromure. On peut obtenir les cations bis(amine tertiaire) dichlorobore et chloroiodobore par déplacement sélectif de l'iodure des composés $D \cdot BCl_2I$ et $D \cdot BClI_2$. La spectrométrie de masse par bombardement avec des atomes rapides détecte les cations halogénobores d'une façon sélective par rapport aux adduits neutres présents dans les mélanges; cette méthode s'avère utile comme complément à la rmn pour détecter la formation des cations halogénobores ainsi que de leurs sous-produits ioniques.

Mots clés : cations difluorobores, cations dihalogénobores, RMN, ^{11}B, ^{19}F, bombardement avec des atomes rapides (FAB), substitution de ligands, réactions de redistribution.

[Traduit par la revue]

Introduction

Following original studies in Gillespie's laboratory (1), halogen redistribution about four-coordinate boron has been under study in this laboratory since 1968, and has been shown to give rise to mixed boron trihalide adducts (2, 3) and mixed tetrahaloborate anions (4). Rates and equilibria of halogen redistribution are highly dependent on the donor ligand and the halogen atoms present. It is well known that boron–halogen bond strengths decrease in the order $F \gg Cl > Br > I$ (5), and thus not surprising that boron–halogen bonds involving the heaviest halogens are the most easily displaced. However, one intriguing observation from our earlier studies is that the presence of fluorine on the same boron atom makes heavier halogens far more labile than they would otherwise be (3, 4). The effect is increased as more fluorines are present, and the BF_3X^- ions (X = Cl and especially Br) are particularly susceptible to rapid chemical exchange involving breaking and re-forming of the boron – heavy halogen bond (4).

The effect of fluorine in selectively labilizing boron – heavy halogen bonds provides a systematic route to formation of fluoroboron cations by displacement of heavy halide ion from mixed boron trihalide adducts of tertiary amines by neutral donors:

[1] $D \cdot BF_2X + D' \longrightarrow DD'BF_2^+ + X^-$

[2] $D \cdot BFX_2 + D' \longrightarrow DD'BFX^+ + X^-$

$\downarrow D'$

$DD'_2BF^{2+} + X^-$

In a preliminary report (6) we noted that reaction [1] occurs readily, provided that D' is a tertiary amine of sufficiently low steric hindrance, and that the reactions [2] do not occur to any appreciable extent under the same conditions. We now report our detailed studies of these systems.

Cationic boron species are a topic of current interest and a number of 3-coordinate and even 2-coordinate (7) boron cations have been reported in recent years (8), as have polyboron complex cations (9). Tetrahedral four-coordinate boron cations $D_2BH_2^+ \cdot X^-$ (where D represents the donor ligand) are well known (10), but relatively few fluoroboron cations have been reported. Hydrogen substitution in already formed $D_2BH_2^+$ gives a range of products, but the use of elemental fluorine is required to obtain difluoroboron cations by this route (11). A few chelating ligands LL give $(LL)BF_2^+ \cdot BF_4^-$ directly on reaction with BF_3 (12), but others do not (13). In solution, tetramethylurea$\cdot BF_3$ and hexamethylphosphoramide$\cdot BF_3$ are in equilibrium with a small proportion of the ionic

form of the adduct $D_2BF_2^+ \cdot BF_4^-$ (14), but few BF_3 adducts behave in this way.

Experimental

Materials

Moisture-sensitive materials were normally handled under dry nitrogen using glove bag and Schlenk line methods. Boron trifluoride and boron trichloride (Matheson) were used directly from lecture bottles with no further purification. Boron tribromide (Alfa Inorganics) was treated with metallic mercury to remove bromine (orange discoloration), and trap-to-trap distilled into glass ampoules. The sealed ampoules, containing 0.5–3 mL of colorless liquid, were stored in the dark. Boron triiodide (Alfa Inorganics) was used without further purification; some iodine (pink discoloration) was evident. Solutions (0.5–2.5 M) of boron tribromide and boron triiodide were prepared in solvents such as $CDCl_3$ and stored at temperatures below −20°C to minimize decomposition.

Quinuclidine (Aldrich) was recrystallized from acetone. Me_3N (Matheson), Me_2NEt, $MeNEt_2$, and *i*-Pr_2NEt (Aldrich), Et_3N (British Drug Houses), and *n*-Pr_3N (Eastman) were used as supplied, as were a number of other reagent grade Lewis bases. Pyridine and 2-methylpyridine were stored over NaOH following fractional distillation. Methyl benzoate (Eastman), $(Me_2N)_3P{=}O$ (Aldrich), and $(Me_2N)_3P$ (BDH) were distilled before use. Deuterated chloroform (Norell) and reagent grade chloroform (BDH) were stored over Linde 4A molecular sieves before use. Methylene chloride (BDH), 1,1,2,2-tetrachloroethane (Eastman), and methylene bromide (BDH) were purified by fractional distillation and stored over Linde 13X molecular sieves, Linde 4A molecular sieves, and in the dark, respectively. Reagent grade 1,1,2,2-tetrabromoethane (BDH) was used without further purification. Hexane was dried over sodium wire.

Hexafluorobenzene (Whittaker) was used without further purification as an internal secondary ^{19}F reference. $BF_3 \cdot OEt_2$, the external primary ^{11}B reference, was prepared by reaction of BF_3 with diethyl ether and fractional distillation of the liquid adduct.

Amine – boron trihalide adducts

BF_3 or BCl_3 gas was bubbled through a mechanically stirred 0.3 M solution of the amine in dry hexane, while cooling in an ice bath and maintaining positive nitrogen pressure. The adduct precipitated from the hexane solvent, and normally the solvent was removed using syringe/septum methods. Fine precipitates that formed an emulsion-like slurry were separated using a Schlenk vessel containing a fritted glass filter. The precipitated adducts, many of which are very hygroscopic, were washed twice with dry hexane and stored under nitrogen.

In a few cases oils were obtained instead of precipitates of BF_3 adducts. Lowering the donor concentration and slowing the rate of Lewis acid addition eliminated most, but not all, oiling problems. The few oils that could not be crystallized were subjected to vacuum to remove traces of hexane. The ^{19}F nmr spectra of the oils indicated a small proportion of BF_4^- impurity. Reactions initiated with the oils were not noticeably different from those using BF_3 adducts that were crystalline white precipitates.

Difluoroboron cation formation in solution

The preparation of difluoroboron cations requires $D \cdot BF_2X$ intermediates, which form readily by halogen redistribution between $D \cdot BF_3$ (or $D \cdot BCl_3$) and an uncomplexed boron trihalide BX_3. Equilibration at room temperature for 30 min of a mixture of 0.5–1.0 M solutions of $D \cdot BF_3$ adducts with 0.5–2.5 M BX_3 (X = Br or I), both in $CDCl_3$, gave equilibrated mixtures containing all of the possible $D \cdot BF_nX_{3-n}$ and BF_nX_{3-n} (n = 0–3) species (2). To maximize the proportion of the $D \cdot BF_2Br$ adduct relative to the other adducts in the $D \cdot BF_3 + BBr_3$ system, about 0.5 mmol of BBr_3 should be added per mmol of $D \cdot BF_3$. $D \cdot BF_nCl_{3-n}$ adducts were formed by direct addition of gaseous boron trichloride to solutions containing $D \cdot BF_3$.

Reaction occurs similarly in other chlorinated and brominated solvents, but lower solubility and (or) greater ease of decomposition can be problems. Chlorinated solvents (chloroform, methylene chloride, and 1,1,2,2-tetrachloroethane) give adequate adduct solubility but allow Cl/Br exchange. Brominated solvents eliminate this problem but generate others. Decomposition occurs readily in methylene bromide. Adduct solubilities are low in 1,1,2,2-tetrabromoethane. Bromoform is a fairly good solvent and its use should be further explored. Typically though, fluoroboron cation formation reactions that do not succeed in chloroform also do not succeed in bromoform. Although solubilities are low in toluene, difluoroboron cations do form and may precipitate, facilitating isolation as their bromide salts. Elimination of solvent, i.e., placing $D \cdot BF_nBr_{3-n}$ adducts directly in liquid amines (e.g., Me_2NEt) was ineffective.

The solutions of mixed boron trihalide adducts plus uncomplexed Lewis acids were transferred to 5-mm nmr tubes and cooled to 0°C or below, and uncomplexed donor was added by syringe. Initially the donor quenches the rapid halogen exchange reactions by complexation with the uncomplexed boron trihalide, as can be monitored by ^{19}F nmr. Further donor (which can be either the same species D or a different Lewis base D′) may attack the $D \cdot BF_2X$ species, displacing X^- to form a cation of type $D_2BF_2^+$ or $DD'BF_2^+$.

Most halide displacement reactions were carried out directly in nmr tubes at temperatures up to 100°C using a constant temperature oil bath. Typically the tubes were capped and wrapped with Parafilm rather than sealed, so temperatures above 70°C required solvents of higher boiling point than $CDCl_3$, such as $CHBr_3$ or toluene. Stronger heating of a few samples of $D \cdot BF_nBr_{3-n}$ systems in $CHBr_3$, sealed in medium-wall nmr tubes, was also carried out; in these the reactions occur at pressures considerably greater than atmospheric. Reaction with water can cause major contamination if capped nmr tubes are allowed to stand over long periods of time. This gives rise to $DH^+ \cdot X^-$ (X = Cl, Br, BF_4), which is readily detected by FAB peaks corresponding to D_2H^+, $(DH)_2X^+$, and sometimes $(D_2BF_2)(DH)X^+$.

Where the initial donor D in the $D \cdot BF_nX_{3-n}$ adducts and the further donor added are not the same species, mixed boron trihalide adducts of the second donor D′ are also formed. To minimize these, the solutions containing $D \cdot BF_nX_{3-n}$ and BF_nX_{3-n} were reacted with sufficient of the initial donor to complex with most of the free boron trihalide. Therefore little of the second donor is consumed by reaction with uncomplexed boron trihalides, and almost all is available to displace heavy halide ion.

Isolation of $D_2BF_2^+$ salts

Precipitation conditions differ considerably for each type of $D_2BF_2^+$ and counterion. The best procedures follow. The "mother solution" referred to is the solution (normally in $CHCl_3$ solvent) containing the difluoroboron cation and the various boron trihalide adducts. To determine the amounts of precipitating reagents required, the amounts of difluoroboron cation present were determined from ^{19}F nmr peak areas. Elemental analyses for carbon, hydrogen, and nitrogen were consistently satisfactory but those for fluorine were erratic, some being satisfactory and others being in error by several percent, perhaps due to interference by boron. Only the satisfactory fluorine analyses are given.

(Quinuclidine)$_2BF_2 \cdot Br$

Method A: Extraction of the mother solution with water removed the ionic species, leaving the covalent adducts behind. The water was removed under vacuum and the residue of crude $Q_2BF_2 \cdot Br$ redissolved in chloroform. Benzene was slowly added down the wall of a narrow tube, so that two layers of solvent were present. Slow diffusion of benzene into chloroform led to crystallization of the salt, which is stable in water, ethanol, and dimethylformamide.

Method B: Hexane or petroleum ether was added to the mother solution to precipitate all the adducts as well as the ionic species. In most cases an oil rather than a solid precipitate formed. This was separated and residual solvent removed under vacuum, leaving a solid residue that was dissolved in absolute ethanol by gentle heating. Cooling to below 0°C led to precipitation of $Q_2BF_2 \cdot Br$, while the covalent adducts remained in solution. A second recrystallization in absolute ethanol was then carried out.

(Quinuclidine)$_2BF_2 \cdot BPh_4$

The mother solution was diluted with an equal volume of absolute ethanol, and 1.5 equivalents of $NaBPh_4$ in a saturated solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

in ethanol were slowly added while vigorously stirring. White $Q_2BF_2 \cdot BPh_4$ precipitated immediately. The precipitate was filtered, washed with water to remove sodium salts, washed with chloroform to remove adducts and excess donor, and recrystallized from 1:1 acetone/ethanol. *Anal.* calcd.: C 77.38, H 7.86, N 4.75, F 6.44; found: C 77.21, H 8.19, N 4.82, F 6.72.

(Quinuclidine)$_2BF_2 \cdot PF_6$

The mother solution was evaporated to dryness under vacuum. Water was added, and the residue not dissolving at 50°C was removed by filtration. To the filtrate was added 1.5 equivalents of $NH_4 \cdot PF_6$ as a saturated aqueous solution. White $Q_2BF_2 \cdot PF_6$ precipitated immediately. The precipitate was recrystallized from 1:1 acetone/water by allowing the acetone to evaporate on standing. *Anal.* calcd.: C 40.41, H 6.30, N 6.73, F 36.53; found: C 40.65, H 6.27, N 6.60, F 36.90.

(Quinuclidine)$_2BF_2 \cdot BF_4$

Shaking the mother solution with two portions of saturated aqueous NH_4BF_4, followed by addition of hexane in a 1:1 ratio, precipitated the compound, which was recrystallized from 1:1 chloroform/hexane. *Anal.* calcd.: C 46.97, H 7.32, N 7.83; found: C 47.10, H 7.39, N 8.07.

$(Me_3N)_2BF_2 \cdot Br$

The mother solution was diluted with an equal volume of toluene and cooled to 0°C. The white $(Me_3N)_2BF_2 \cdot Br$ that precipitated was filtered and washed with toluene. $Me_3N \cdot BF_3$ was a minor contaminant in this precipitate; it was removed by dissolution in chloroform, followed by reprecipitation by addition of toluene. This salt is extremely hygroscopic, and is slowly decomposed by ethanol. It has not been obtained pure. *Anal.* calcd.: C 29.18, H 7.38, N 11.34, Br 32.36; found: C 27.47, H 7.31, N 10.84, Br 34.10.

$(Me_3N)_2BF_2 \cdot BPh_4$

The bromide salt described above was dissolved in CH_3CN, and 1.5 equivalents of $NaBPh_4$, as a saturated solution in CH_3CN, was then added. The resulting white precipitate was washed with toluene. The salt is soluble in water and insoluble in CH_3CN, acetone, and toluene.

$(Me_3N)_2BF_2 \cdot PF_6$

The isolation technique was identical to that for $Q_2BF_2 \cdot PF_6$. *Anal.* calcd.: C 28.10, H 5.81, N 8.98; found: C 28.16, H 5.76, N 8.76.

$(Me_2NEt)_2BF_2 \cdot BPh_4$

The isolation technique was identical to that for $Q_2BF_2 \cdot BPh_4$. *Anal.* calcd.: C 74.58, H 8.22, N 5.44, F 7.57; found: C 75.33, H 8.69, N 5.33, F 8.80.

Chloroboron cations

The formation of the non-fluorine-containing boron cations $D_2BCl_2^+$ and D_2BClI^+ as their I^- salts from $D \cdot BCl_3$ adducts (D = trimethylamine, quinuclidine) and BI_3 was carried out in methylene chloride solvent, by a procedure essentially identical to that described above. Iodide ion displacement is less favoured in $D \cdot BClI_2$ than in $D \cdot BCl_2I$. Salts of these cations have not yet been isolated in pure form.

Nuclear magnetic resonance instrumentation

^{19}F spectra were obtained at 56.45 MHz on a Bruker WP-60 FT nmr spectrometer, using a fixed frequency probe and quadrature detection. Typically a spectral width of 3800 Hz with a 1.08-s acquisition time was used to obtain an 8K FID. Fifty to 2000 scans were accumulated using 30° pulses and the PAPS sequence, and transformed using 0.5-Hz line broadening into 4K spectra. ^{19}F chemical shifts are accurate to ±0.1 ppm and were internally referenced to C_6F_6 as a secondary standard (−162.7 ppm from $CFCl_3$). $^{11}B-^{19}F$ coupling constants are accurate to within ±1 Hz. Most spectra were obtained at ambient temperature.

^{11}B spectra were obtained from three instruments, but primarily from a Bruker WH-400 multinuclear Fourier Transform nmr spectrometer operating at 128.38 MHz. A spectral width of 10 000 Hz was used to obtain an 8K FID. The FIDs with 8K of zero filling were transformed with 0.5 Hz of line broadening into 8K spectra. ^{11}B chemical shifts are accurate to ±0.1 ppm and were referenced to external $Et_2O \cdot BF_3$. ^{11}B spectra were also obtained on the WP-60 FT instrument operating at 19.25 MHz, using a fixed-frequency probe. However, peak overlap, especially of multiplets due to coupling to ^{19}F, made interpretation difficult. A Bruker CXP-200 instrument operating at 64.27 MHz gave intermediate chemical shift dispersion, so that most multiplets were distinguishable. 8K FIDs were accumulated by 200–1000 30° pulses covering a 5000-Hz range. These were transformed with 8K of zero filling and 0–1 Hz of line broadening into 8K spectra. The ^{27}Al nmr spectra were obtained at 104.18 MHz on the Bruker WH-400 instrument.

"Pairwise interaction" parameters (15, 16) for chemical shifts and coupling constants were calculated on a Burroughs B7900 computer, using a least-squares fitting program written by J. M. Miller and modified by A. G. Basile. The pairwise parameters were calculated from a data set including all available nmr data for boron trihalide adducts and haloboron cations involving only Q, Me_3N, pyridine, and 2-methylpyridine as donors, and the tetrahaloborate anions. The halogen,halogen and Me_3N,halogen pairwise terms ($\eta_{i,j}$) calculated from this data set are very similar to those reported previously (16). Chemical shifts calculated from the pairwise interaction parameters agreed well with experimental values, and were helpful in assigning haloboron cation resonances.

Fast atom bombardment mass spectrometry (17)

FAB analyses were carried out on an AEI MS-30 (Kratos Ltd., Manchester, U.K.) mass spectrometer fitted with a saddle field atom gun (Ion Tech Ltd.) and a Kratos FAB source with a rear entry probe. Samples were run at 4-kV accelerating voltage, 1000 resolving power, xenon gas (7–8 kV energy), and using glycerol as a matrix. Data were stored and worked up on a DS-55 Kratos data system. Spectra and mass intensity data were plotted on a Hewlett–Packard 2631G printer. Each spectrum is an average of five or more scans. Subtraction of peaks due to glycerol was automatically done for all spectra except where these peaks were of minimal intensity. The BMASROS program, written by D. Rosenburg and modified by D. Hoskins, J. M. Miller, and T. R. B. Jones to run on the Kratos, was utilized for calculation of isotope cluster patterns.

Results

(Quinuclidine)$_2BF_2^+$: reactions of $Q \cdot BF_nX_{3-n}$ (X = Cl, Br, I)

$Q \cdot BF_2Br$ (Q = quinuclidine, 1-azabicyclo[2.2.2]octane]), incorporating a low steric hindrance donor of high basicity, undergoes reaction [1] with no major side reactions, and was chosen for detailed study. Figure 1 shows ^{11}B nmr spectra of a $CDCl_3$ solution of the $Q \cdot BF_nBr_{3-n}$ (n = 0–3) adducts in the presence of excess Q. At ambient temperature or above, the 1:2:1 triplet of $Q \cdot BF_2Br$ disappears and is replaced by a new triplet assigned to $Q_2BF_2^+$. The total peak area of these two triplets remains constant as one grows at the expense of the other, and the multiplets of the other adducts remain unaffected. In the ^{19}F spectrum (Fig. 2) a new 1:1:1:1 quartet at −161.5 ppm grows at the expense of the $Q \cdot BF_2Br$ quartet. $Q_2BF_2^+$ has been isolated as its bromide, tetraphenylborate, hexafluorophosphate, and tetrafluoroborate salts and is stable in water, ethanol, and dimethylformamide as well as in chloroform.

The positive ion Fast Atom Bombardment (FAB) mass spectrum of $Q_2BF_2^+Br^-$, obtained in a glycerol matrix, is shown in Fig. 3. Its high-abundance peaks at m/z 271 ($Q_2BF_2^+$), 160 ($Q \cdot BF_2^+$), 112 (QH^+), and 111 (Q^+) confirm the difluoroboron cation structure. All other peaks are of much lower intensity. (Peaks at m/z greater than 280 in Fig. 3 are enhanced by a factor of ten.) Note the ion cluster peak at m/z 621, which corresponds to two cations and an anion. This was not readily detectable at lower ion current, such as was used to obtain the spectrum reported in our preliminary communication (6). Such peaks allow identification of the anion as well as the cation in positive ion FAB spectra of ionic compounds. The identity of the $Q_2BF_2^+$ and $[(Q_2BF_2)_2Br]^+$ peaks has been confirmed by analysis of these ions' isotope cluster patterns.

Attempts to form Q_2BFBr^+ and (or) Q_3BF^{2+} from $Q \cdot BFBr_2$

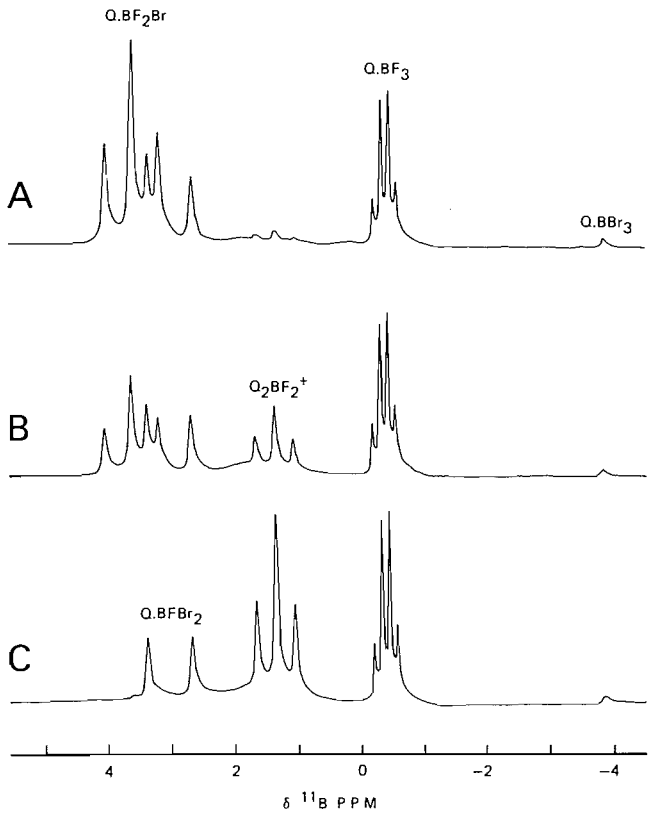

FIG. 1. 128.4 MHz ^{11}B nmr spectra of the quinuclidine·BF_nBr_{3-n} adduct system in $CDCl_3$. A, freshly prepared; B, after 14 min at 50°C; C, plus 18 h at 25°C.

according to eq. [2] have been unsuccessful under a range of conditions including large excess of quinuclidine, high temperatures, and (or) changing the solvent from chloroform to toluene or bromoform. In one sample that gave a broad ^{19}F impurity peak at −152 ppm after sufficient standing at 35°C to react all of the Q·BF_2Br (Fig. 4A), heating at 55°C for 3 days led to shrinkage of the Q·$BFBr_2$ ^{19}F quartet and appearance of Q·BFClBr and Q·BF_2Cl quartets and further unidentified broad peaks (Fig. 4B), as well as some precipitate formation. The Q·BF_3 and $Q_2BF_2^+$ signals remained essentially unchanged. Q·BFClBr no doubt arises from Cl/Br exchange with the solvent, but the source of Q·BF_2Cl is less clear; it could not arise from halogen exchange with Q·BF_2Br, which had long since been converted to $Q_2BF_2^+$, but might perhaps arise from attack of solvent-derived chloride on $Q_2BF_2^+$.

When water was added to the Q·BF_nBr_{3-n} system in $CDCl_3$, two broad unidentified peaks at −147 and −140 ppm and a BF_4^- peak appeared at the expense of Q·BF_2Br (Fig. 5). On further reaction the BF_4^- peak remained small while the broad peaks increased in intensity. Changes in chemical shift of these peaks between Figs. 5A and 5B may indicate a solvent shift due to extraction of the hydrolysis products into a minor water-rich phase. Although all B—Br bonds are highly susceptible to hydrolysis, water reacts selectively with Q·BF_2Br rather than with the other adducts (Fig. 5B).

Relative rates for halide ion displacement in Q·BF_2X in eq. [1] are I >> Br >> Cl. Less than 10% of Q·BF_2Cl reacts after a month at 48°C. The reactivity of Q·BF_2I is far greater than that of Q·BF_2Br but this species is difficult to obtain, due to the low yield of D·BF_2I (and D·BFI_2) in the halogen redistribution reaction of tertiary amine adducts D·BF_3 with BI_3, as a result of an unfavourable equilibrium (2, 3). Also, BI_3 adducts are less soluble. Neither of the mixed Q·BF_nI_{3-n} adducts could be observed by ^{19}F nmr in $CDCl_3$ solution, perhaps due to their small proportions and (or) rapid fluorine exchange among the adducts. The poor resolution of the Q·BF_3 peak was consistent with rapid fluorine exchange. After the addition of uncomplexed Q a small amount of $Q_2BF_2^+$ could be detected by ^{19}F nmr, providing indirect evidence for the intermediate existence of Q·BF_2I. With toluene as solvent it was possible to observe very low intensity ^{19}F signals for these adducts: Q·BF_2I, −119.8 ppm, J_{BF} 66.1 Hz; Q·BFI_2, −108.8 ppm, J_{BF} 114.3 Hz, consistent with nmr parameters of other tertiary amine·BF_nI_{3-n} adducts (2). Bromide displacement from R_3N·BF_2Br is clearly the most suitable route to difluoroboron cations containing aliphatic tertiary amines.

The high reactivity of D·BF_nI_{3-n} systems led to hopes for Q_2BFI^+ and (or) Q_3BF^{2+} formation from the reaction of Q·BFI_2 with excess Q (eq. [2]). Instead only a broad ^{19}F singlet at −152 ppm was observed (a frequently observed decomposition product; see Fig. 4) in addition to the $Q_2BF_2^+$ and Q·BF_3 quartets, and some precipitate appeared.

In attempts to facilitate formation of $Q_2BF_2^+$ or possibly the three-coordinate Q·BF_2^+ cation from Q·BF_2Br, Al_2Br_6 was added to extract bromide ion. Instead of cation formation this gave rapid Cl/Br exchange with the solvent, leading to all of the possible F,Cl,Br-containing boron trihalide adducts of quinuclidine. ^{11}B (Fig. 6A) and ^{19}F nmr peaks of Q·BF_2Br, Q·BF_2Cl, and Q·BF_3 were broad, indicative of rapid chemical exchange. These narrowed at temperatures below ambient, the Q·BF_2Cl peaks sharpening first, consistent with chemical exchange involving this species being slower than chemical exchange involving Q·BF_2Br. Addition of sufficient quinuclidine to complex with the Al_2Br_6 stopped the ambient-temperature chemical exchange and gave sharp ^{11}B (Fig. 6B) and ^{19}F peaks. The involvement of Al_2Br_6 in halogen exchange was confirmed by ^{27}Al nmr, which showed the presence of the known species $AlCl_2Br_2^-$ and $AlClBr_3^-$ in addition to $AlBr_4^-$ (18).

Other $(R_3N)_2BF_2^+$ species

In addition to Q, Me_3N and Me_2NEt are the only aliphatic tertiary amines that have formed $(R_3N)_2BF_2^+$ (i.e., both R_3N groups the same) from R_3N·BF_nBr_{3-n} under our conditions. The nmr parameters are given in Table 1. $(Me_3N)_2BF_2^+$ forms at ambient temperature somewhat more slowly than $Q_2BF_2^+$, whereas $(Me_2NEt)_2BF_2^+$ forms only on prolonged heating at 60°C. More sterically hindered systems (D = $MeNEt_2$, Et_3N, *n*-Pr_3N, *i*-Pr_2NEt) have undergone prolonged heating, in the presence of large excesses of the uncomplexed amine, to no avail. Instead, on heating, D·BF_2Br exchanges halogen with chlorinated solvents to form D·BF_2Cl, and D·$BFBr_2$ forms D·BFClBr. In brominated or non-halogenated solvents halogen exchange cannot give rise to chlorine-containing species, but solubility tends to be less, and no additional bis(tertiary amine)difluoroboron cations were formed. Tertiary amine·BF_nI_{3-n} systems, which have the potential to force difluoroboron cation formation in reluctant systems involving higher-steric-hindrance amines (2), are more difficult to work with and have not yet been studied systematically.

The behaviour of the (diisopropylethylamine)·BF_nBr_{3-n} system is unique. Immediately after addition of sufficient free amine to stop rapid halogen redistribution and allow well-resolved ^{19}F spectra, about half of both mixed-halogen adducts had already been converted to the chlorinated analogues.

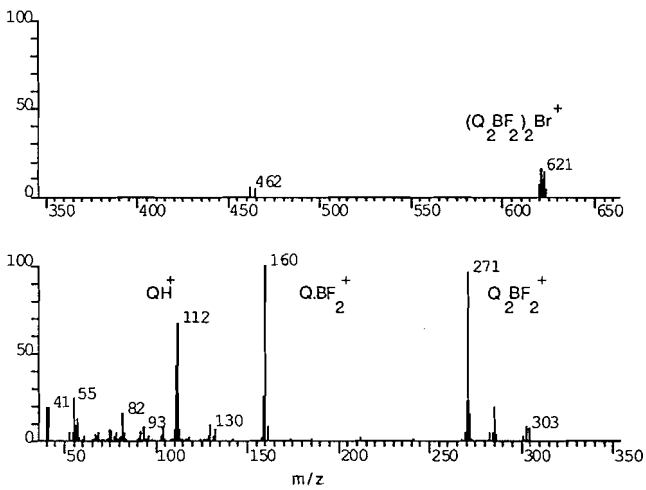

FIG. 3. Positive ion fast atom bombardment mass spectrum of $(quinuclidine)_2BF_2^+$. Peaks at m/z greater than 280 are enhanced by a factor of 10.

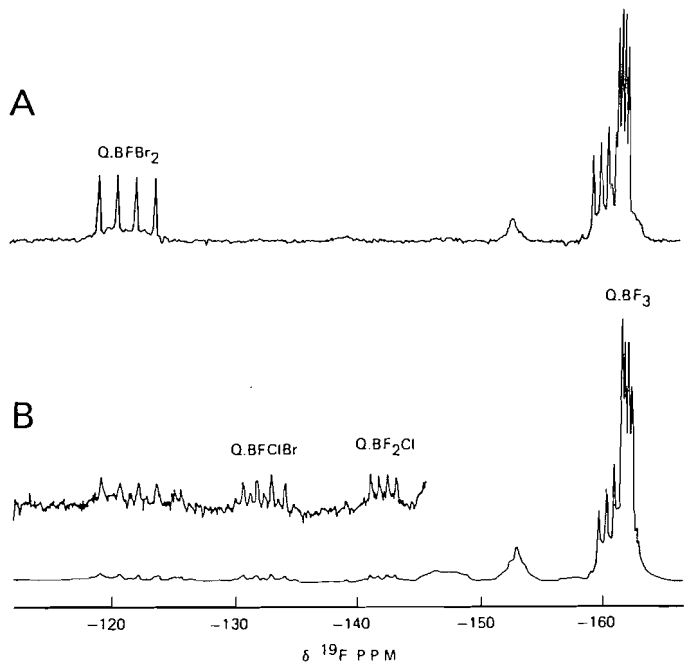

FIG. 4. 56.4 MHz ^{19}F spectra showing reaction of Q·$BFBr_2$ in $CDCl_3$ on prolonged heating. A, after complete reaction of Q·BF_2Br at 35°C; B, after 3 days at 55°C.

Anomalous behaviour of this adduct system has been attributed to very high amine steric hindrance (2).

$D_2BF_2^+$ formation by bromide displacement, when it occurs, normally goes essentially to completion if sufficient time is allowed. However, the reaction can be reversed under forcing conditions. Following completion of $(Me_2NEt)_2BF_2^+$ formation from $Me_2NEt·BF_2Br$ at 60°C in chloroform, the sample was heated to 160°C, evaporating solvent and excess Me_2NEt. Addition of fresh solvent gave a ^{19}F spectrum with no $D_2BF_2^+$ quartet and a large $D·BF_2Br$ quartet. This is consistent with Me_2NEt displacement from $(Me_2NEt)_2BF_2^+$ by bromide counterion and loss of the displaced Me_2NEt by volatilization at high temperature.

Non-fluorine-containing $D_2BX_2^+$ ions from $D·BCl_nI_{3-n}$ (D = Q, Me_3N)

$D·BCl_nBr_{3-n}$ adduct systems in chloroform and methylene chloride were unreactive to halide displacement by excess donor. No adduct ^{11}B nmr peaks changed in intensity, and no new peaks were evident, after 8 h at 30°C. In contrast, $D·BCl_nI_{3-n}$ systems (D = Q, Me_3N) underwent iodide displacement under these conditions, as shown by disappearance

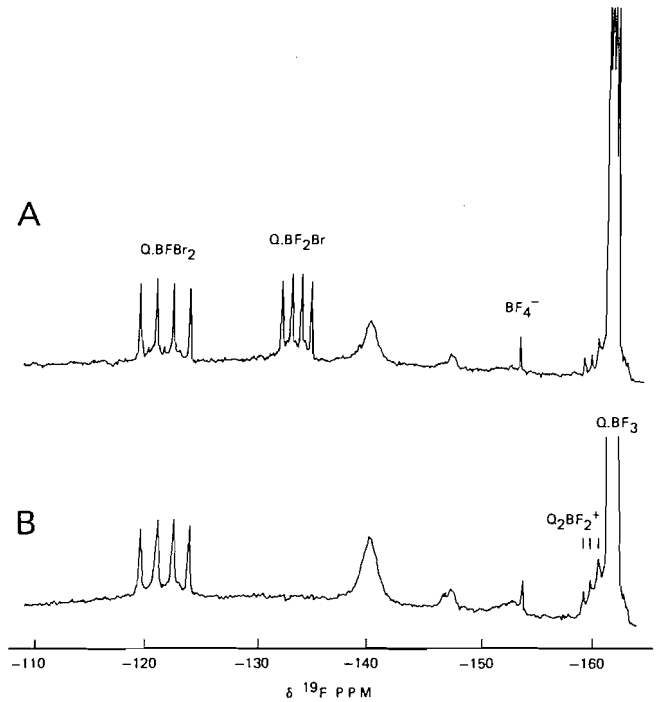

FIG. 5. 56.4 MHz ^{19}F nmr spectra of the $Q \cdot BF_nBr_{3-n}$ system in $CDCl_3$, in the presence of water. A, 30 min at 22°C; B, plus 7 h at 40°C.

of the ^{11}B signal of $D \cdot BCl_2I$ and the appearance of a new peak close to the $D \cdot BCl_3$ peak, which we assign to $D_2BCl_2^+$ (Fig. 7). Also a small singlet appeared, which we assign to D_2BClI^+. ^{11}B chemical shifts of the non-fluorinated bis(tertiary amine)haloboron cations and of the corresponding $D \cdot BCl_nI_{3-n}$ adducts are given in Table 2, along with values calculated from pairwise interaction nmr parameters (16) that support our assignments.

FAB spectra confirm the existence of the $D_2BCl_2^+$ ions but show that they are not the major ionic product. Figure 8 shows the FAB spectrum of material obtained from reaction of the $Me_3N \cdot BCl_nI_{3-n}$ adducts with excess Me_3N in methylene chloride. The assignment of the isotope cluster pattern at m/z 199 in Fig. 8 to $(Me_3N)_2BCl_2^+$ has been confirmed by calculation using the BMASROS program. However, the most intense peak in Fig. 8, at m/z 108, arises from $Me_3NCH_2Cl^+$ formed by Me_3N attack on the methylene chloride solvent. This is not too surprising in view of the extreme reactivity of systems containing B—I bonds, and emphasizes the value of FAB in identifying unexpected ionic products. Perhaps CH_2ClI, formed by halogen exchange, is an intermediate. Note the factor of 10 increases in the vertical scale of Fig. 8 above m/z 150; the dichloroboron cation parent-ion cluster has only about 5% of the intensity of the most abundant species. FAB also shows the presence of cluster ions (two cations and a chloride ion) of both $(Me_3N)_2BCl_2^+$ and $Me_3NCH_2Cl^+$, and the mixed cluster including both of these. (Note the further factor of two increase in vertical scale above m/z 300 in Fig. 8.) The counterion is chloride rather than iodide, consistent with the predominance of chloride displacement from solvent over iodide displacement from $Me_3N \cdot BCl_2I$. This predominance of a side reaction illustrates the difficulties of working with highly reactive BI_3-containing adduct systems, which often give precipitates on standing (2).

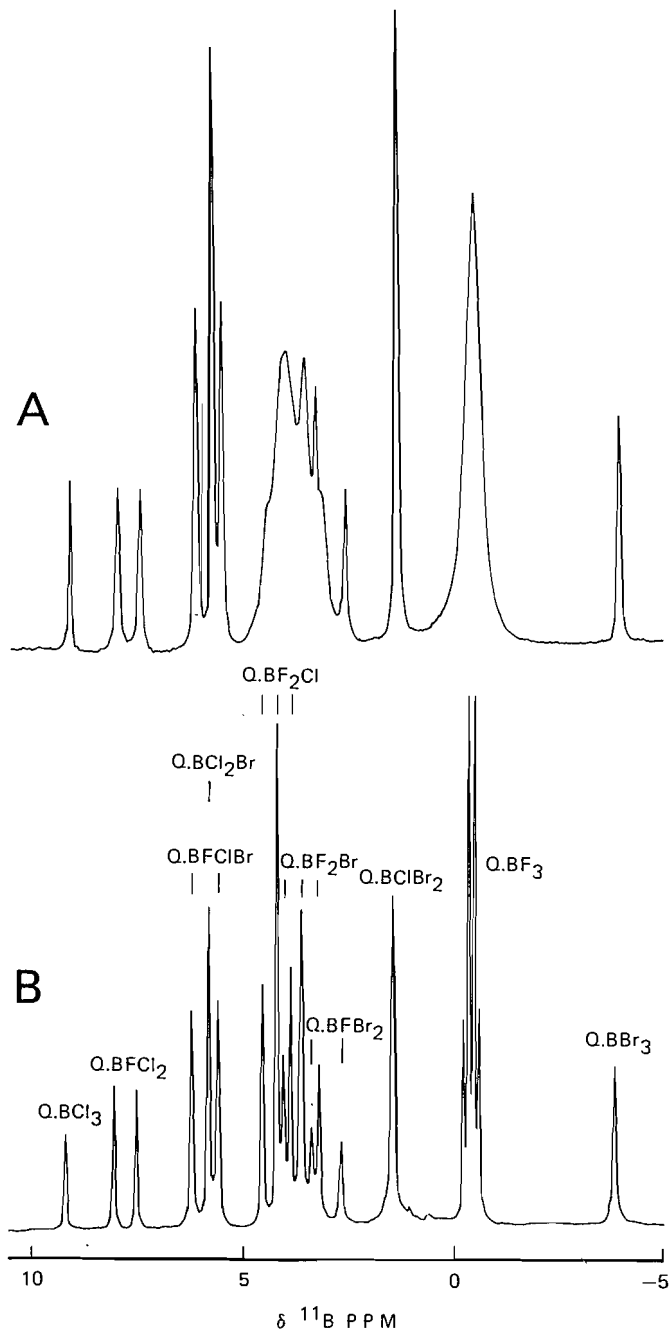

FIG. 6. 128.4 MHz ^{11}B nmr spectrum of $Q \cdot BF_nBr_{3-n}$ with Al_2Br_6 in $CDCl_3$, before (A) and after (B) addition of uncomplexed Q to react with the excess Lewis acid. Peaks of all the possible $Q \cdot B(F,Cl,Br)_3$ adducts are present.

Interestingly, D_2BClI^+ formed from $D \cdot BClI_2$ before all of the $D \cdot BCl_2I$ was converted into $D_2BCl_2^+$. Thus there is not as great a selectivity, for loss of the heaviest halogen from the adduct containing two of the lightest halogens, as occurs in the F/Br adducts. It may be possible to obtain D_3BCl^{2+} from D_2BClI^+ by further iodide displacement.

Attempts to prepare $D_2BBr_2^+$ species from $Q \cdot BBr_3$ were unsuccessful. Only the $Q \cdot BBr_3$ ^{11}B nmr peak could be detected after refluxing in toluene with an excess of either quinuclidine or trimethylamine. Perhaps $D_2BI_2^+$ cations could be obtained from $Q \cdot BI_3$ by this method.

Formation of mixed-donor difluoroboron cations $DD'BF_2^+$, and competing exchange reactions

A wide range of mixed-donor difluoroboron cations $(R_3N)D'BF_2^+$ have been prepared in solution through bromide displacement by low-steric-hindrance donors D'. The nmr parameters are included in Table 1. Of the aliphatic tertiary amines, only Q, Me_3N, and Me_2NEt are effective as attacking groups D', but many other low-steric-hindrance donors are effective as well, e.g., pyridines, *N,N*-dialkylamides, dimethylsulfoxide, etc. Steric hindrance is the dominant factor in determining the effectiveness of D'; no correlation of reactivity with D' base strength is evident.

Steric effects for the already attached amine in $D \cdot BF_2Br$ are much less stringent. Even tertiary amines such as Et_3N that are too bulky to displace Br^- can be incorporated into difluoroboron cations if present in the $D \cdot BF_2Br$ precursor and reacted with a low-steric-hindrance D'. However, amine exchange prevented the formation of certain mixed-donor cations, e.g., in the case of $Me_2NPh \cdot BF_2Br$ with Q or Me_3N. Substitution of the D' amine for Me_2NPh in the BF_2Br adduct was so much more effective than bromide displacement that only the $D'_2BF_2^+$ cation could be detected. *i*-Pr_2NEt as well was too readily displaced from its BF_2Br adduct.

Reaction of a $D \cdot BF_nX_{3-n}$ system with a second donor D' led to the additional complexity of D' for D exchange as well as halogen exchange with the solvent, giving a mixture of cations and adducts involving both donors. This is illustrated by the ^{19}F spectrum of the *n*-$Pr_3N \cdot BF_nBr_{3-n}$ + quinuclidine system (Fig. 9). The desired mixed-donor $Q(n\text{-}Pr_3N)BF_2^+$ quartet is present. In addition, however, quinuclidine had displaced *n*-Pr_3N from practically all of its BF_3 adduct and from much of its BF_2Br adduct, but not from its $BFBr_2$ adduct. Also *n*-$Pr_3N \cdot BF_2Cl$ and $Q \cdot BF_2Cl$ had formed by halogen exchange with the solvent. There is also a $Q_2BF_2^+$ quartet. On further standing for several weeks at ambient temperature with excess Q, *n*-Pr_3N was displaced entirely from the mixed-donor cation leaving $Q_2BF_2^+$ as the only difluoroboron cation present. Even then there was no evidence for Q displacement of *n*-Pr_3N in the $BFBr_2$ adduct. This example illustrates the complexities of redistribution reactions about boron (3). Reaction rates are difficult to reproduce and may be affected by traces of moisture, but the relative reactivities of the different adduct types remain as described.

FAB spectra of mixed-donor difluoroboron cations include major peaks corresponding to DH^+, $D'H^+$, DBF_2^+, $D'BF_2^+$, and $DD'BF_2^+$ and there is normally a dication cluster peak of much lower intensity. This is illustrated in Fig. 10 for $(Me_3N)(2\text{-}MePyr)BF_2^+$. The peak at m/z 489 corresponds to $[(Me_3N)(2\text{-}MePyr)BF_2]_2BF_4^+$.

Neutral and negatively charged donors of a range of structural types displace bromide to give cationic and neutral $(R_3N)D'BF_2$ species, respectively. Table 1 includes nmr parameters of various mixed-donor $(R_3N)(D')BF_2^+$ species. As when low-steric-hindrance tertiary amines are the D' species, the original D may be displaced giving $D'_2BF_2^+$. The ^{19}F spectrum of the $Q \cdot BF_nBr_{3-n}$ system after reaction with dimethylsulfoxide (DMSO; Fig. 11) illustrates this. Not only $(Q)(DMSO)BF_2^+$ but also $(DMSO)_2BF_2^+$ appears to be present. Previous attempts in this laboratory to obtain $(DMSO)_2BF_2^+$ directly from $DMSO \cdot BF_nX_{3-n}$ adducts were unsuccessful due to insolubility of all $DMSO \cdot BX_3$ adducts except $DMSO \cdot BF_3$ in the usual solvents.

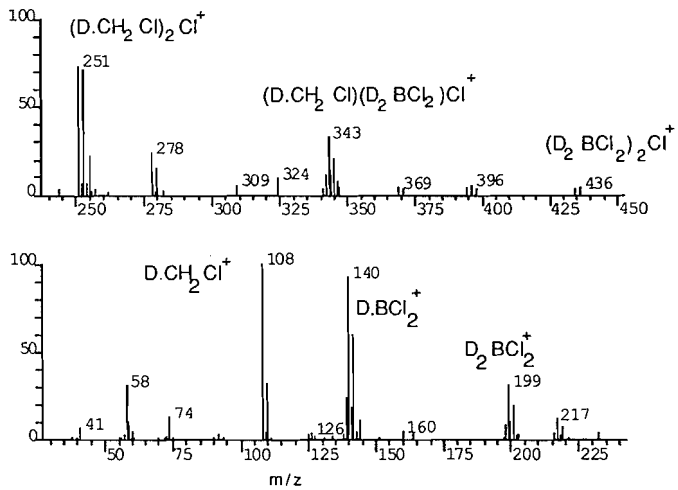

FIG. 8. Positive ion FAB mass spectrum of ionic material obtained from a CH_2Cl_2 solution of the $Me_3N \cdot BCl_nI_{3-n}$ adduct system. Peaks at m/z greater than 150 are enhanced by a factor of 10, and peaks at m/z greater than 300 are enhanced by a further factor of 2 (D = Me_3N).

Not all attempts to prepare $(R_3N)(D')BF_2^+$ ions with non-amine donors were successful. Et_2O and dihydrofuran as well as the "soft" sulfur donors Me_3PS and Me_2S did not displace Br^- from $Q \cdot BF_2Br$. (However, the soft isonitrile *t*-BuNC was successful in displacing Br^-.) Me_2O caused decomposition, not surprisingly in view of its reactivity in the presence of B—Br bonds (19). In contrast, hexamethylphosphoramide (HMPA) was such a good donor and so reactive that donor-for-donor exchange occurred in many $D \cdot BF_nBF_{3-n}$ systems (D = MeEtNBz, pyr, and 2-Mepyr) resulting in $(HMPA)_2BF_2^+$ formation exclusively. We have previously reported the formation of this species by disproportionation of $HMPA \cdot BF_3$ (14*b*). The nmr spectra of systems with HMPA and tetramethylurea (TMU) as D′ are complex and suggest that D_2BFX^+ (X = Cl, Br) and D_3BF^{2+} ions may be formed in these systems.

Addition of the potentially chelating 2:2′-bipyridyl to $D \cdot BF_2Br$ (D = Q, Me_3N) solutions gave some precipitate but no new nmr signals. Addition of acetylacetone to $Q \cdot BF_nBr_{3-n}$

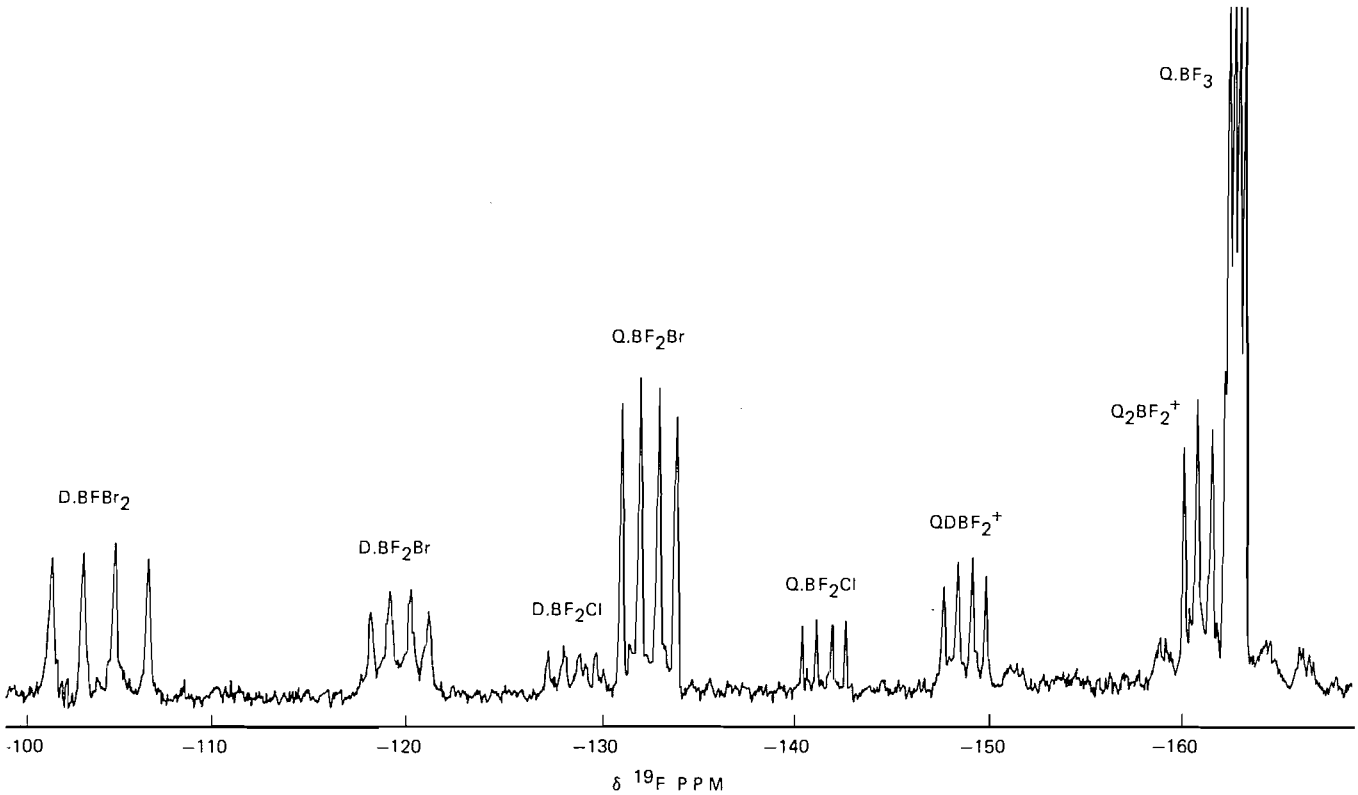

FIG. 9. 56.4 MHz ^{19}F nmr spectrum of the n-$Pr_3N \cdot BF_nBr_{3-n}$ adduct system in $CDCl_3$, following the addition of quinuclidine (D = n-Pr_3N).

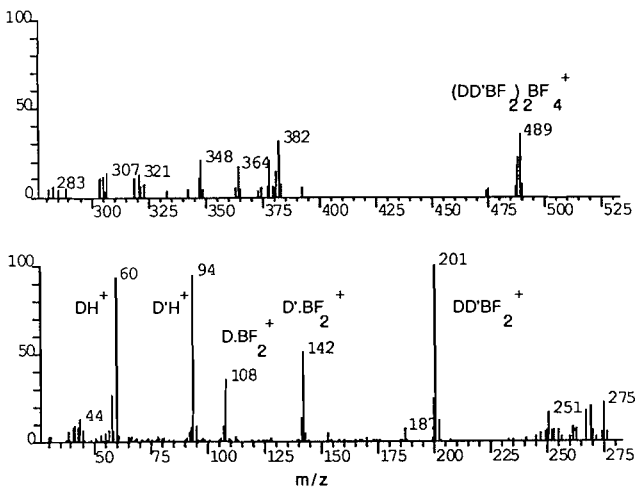

FIG. 10. Positive ion FAB mass spectrum of (Me_3N)(2-methylpyridine)$BF_2^+ \cdot BF_4^-$. Peaks at m/z greater than 250 are enhanced by a factor of 20 (D = Me_3N; D′ = 2-methylpyridine).

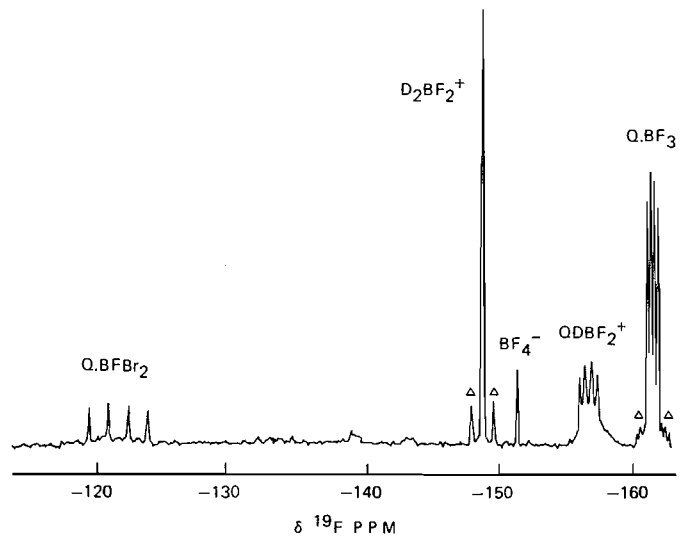

FIG. 11. 56.4 MHz ^{19}F nmr spectrum of the quinuclidine$\cdot BF_nBr_{3-n}$ adduct system in $CDCl_3$, following the addition of DMSO. The peaks marked △ are spinning sidebands (D = DMSO).

gave a large ^{19}F singlet at −139.4 ppm, consistent with the formation of (acac)BF_2 (lit. (20) −139.1 ppm). Neutral chelated LL$\cdot BF_2$ species such as this are well known (20, 21).

The displacement of X^- from D$\cdot BF_2X$ by an anion Y^- to form D$\cdot BF_2Y$ is no different in principle than displacement by a neutral D′ to form $DD'BF_2^+$, and it is not surprising that D$\cdot BF_2Br$ reacts readily with many anions, notably oxoanions, to give products that are apparently neutral D$\cdot BF_2Y$ species (Table 3). Their ^{19}F nmr parameters are consistent with those of other (R_3N)(O-donor)BF_2 species (Table 1). Addition of OH^- to D$\cdot BF_2Br$ (D = both Me_3N and Q) resulted in the same ^{19}F nmr quartet (−153.1 ppm; J_{BF} 12.1 Hz) in both cases. Instead of the intended D$\cdot BF_2OH$, this species is apparently BF_3OH^- (22). Cyanide, iodide, and acetate could not displace bromide but chloride could, giving Q$\cdot BF_2Cl$. This is consistent with earlier work (23) showing that heavier-halogen $R_3N \cdot BX_3$ adducts form mixed boron trihalide adducts by reaction with lighter-halogen tetraalkylammonium halide salts.

Discussion

General

This is the first systematic study of the simple but elusive bis(amine)difluoroboron cations, and the first easy method of preparation. It is remarkable that, in spite of extensive continuing studies of amine – boron trihalide adducts (24), these simple derivatives have been missed. They may occur more widely than is currently recognized, and their existence might explain a number of anomalies in the literature. There are a number of adduct studies in which their existence has been postulated but not confirmed (see for example ref. 25). Amine·BF_3 adducts are important catalysts, in for example epoxy resin curing (26, 27). Happe *et al.* conclude that an unidentified highly reactive species in commercial $EtNH_2 \cdot BF_3$ is probably $(EtNH_2)_2BF_2^+ \cdot BF_4^-$ (26). Primary- and secondary-amine difluoroboron cations would be expected to be far more reactive than our tertiary-amine cations because they can also function as Bronsted acids, and thus could be highly effective catalysts. Preparation of primary- and secondary-amine difluoroboron cations by methods similar to ours would be of interest, but complications could arise due to reactivity of N—H and B—Br bonds, splitting off HBr.

The mode of initiation of cationic polymerization by Lewis acids such as Al_2Cl_6 and BF_3 remains an active and controversial area of investigation (28). Some investigators, but not all, believe that a key step of Al_2Cl_6-catalysed initiation requires that Al_2Cl_6 dissociate to give $AlCl_2^+$ and $AlCl_4^-$. Characterization of difluoroboron cations may help to support an analogous mode of action of BF_3 in catalysing cationic polymerization. Three-coordinate BF_2 cations, a logical further development of our work that might be accessible by using highly hindered donors, would be highly relevant.

This work illustrates the value of using fast atom bombardment mass spectrometry in tandem with nmr to confirm the identity of the haloboron cations and to monitor cation synthesis. Nuclear magnetic resonance and FAB are complementary techniques. The haloboron cations volatilize readily in the FAB source and give well-defined spectra. FAB spectra of mixtures of haloboron cations and neutral adducts strongly discriminate against the neutral adducts (which give no parent ion peaks) and allow monitoring of haloboron cation formation in the presence of many neutral adducts, without the need for separation. Application of FAB to studies of catalysis by BF_3 adducts (26, 27) could be very fruitful.

A problem with FAB has recently been recognized: significant ion–molecule reactions can take place in the gas phase (29), so that some FAB peaks might not correspond to species present in the original sample. Recent work in this laboratory has shown that a protic matrix liquid, 3-nitrobenzyl alcohol, inhibits gas phase ligand substitution reactions involving difluoroboron cations (30). Since glycerol, which is an even more effective proton donor than 3-nitrobenzyl alcohol in FAB, was the matrix liquid for all FAB spectra reported in this work, we can discount the occurrence of appreciable gas phase reactions.

Increased D and D′ steric hindrance shifts the difluoroboron cation ^{19}F resonances to lower field and increases the magnitude of the $^{11}B-^{19}F$ coupling constant (Table 1), the same trends as observed previously for mixed boron trihalide adducts of trialkylamines (2). There is no evident relationship of these parameters to amine base strength. ^{11}B chemical shifts vary only slightly. $^{11}B-^{19}F$ coupling constants diminish in magnitude when an oxygen donor is present, consistent with the low steric hindrance of the carbonyl donors involved. Comparison of nmr parameters across the series $Q_2BF_2^+$, $QD'BF_2^+$, $D'_2BF_2^+$ (Table 4) is possible since several of the $D'_2BF_2^+$ ions have been reported previously (14, 31). The variations are fairly regular. Extrapolation predicts fairly small but non-zero $J_{^{11}B-^{19}F}$ values in $(O\text{-donor})_2BF_2^+$ cations, and often the ^{19}F signals of such species do not show splittings due to $^{11}B-^{19}F$ coupling. This is probably a result of rapid ^{11}B quadrupole relaxation as well as small J values. Similar trends in coupling constants are observed in neutral chelated BF_2 complexes as the donor atoms change from nitrogen to oxygen, and here too most $(O\text{-donor})_2BF_2$ species give unsplit ^{19}F signals (20). The absence of splittings renders peak identification less certain (e.g., the proposed $(DMSO)_2BF_2^+$ peak at −149.5 ppm in Fig. 11). A number of unsplit ^{19}F signals have been observed in Q/acetone, Q/MeO^-, Q/*i*-PrO^-, Me_3N/MeO^-, etc. systems. These probably arise from $QD'BF_2$ and D'_2BF_2 species, but await confirmation. FAB spectra should be conclusive in identifying the cationic species such as $Q(acetone)BF_2^+$.

The neutral $Q \cdot BF_2Y$ species, where Y is a range of oxyanions and Y^- must donate through an oxygen atom, have ^{19}F chemical shifts and $^{11}B-^{19}F$ coupling constants (Table 3) consistent with those of the oxygen-donor $QD'BF_2^+$ cations.

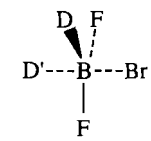
Chemical shifts of various nuclei, which are not linearly additive with respect to the substituent groups, have been shown to be "pairwise additive" in a number of cases, and the same can be true for coupling constants between directly bonded atoms (15). In other words, chemical shift or coupling constant can be expressed as a sum of pairwise terms $\eta_{i,j}$, associated with substituents i and j and independent of all other substituents. The sum is taken over all possible pairs of substituents about the central atom, excluding the nucleus being observed in the nmr experiment. We have previously shown that pairwise additivity applies to chemical shifts and coupling constants of the mixed tetrahaloborate anions (4), and extended this to a wide range of mixed boron trihalide adducts (16). This empirical relationship is useful in predicting chemical shifts of unknown species including (with the addition of donor,donor $\eta_{i,j}$ terms) haloboron cations. Sets of ^{19}F and ^{11}B chemical shift and $J_{^{11}B-^{19}F}$ pairwise interaction parameters based on all adduct and cation nmr data for Q, Me_3N, pyridine, and 2-methylpyridine together with tetrahaloborate anion data gave halogen–halogen pairwise terms very similar to those determined previously (16). Calculated and observed values are compared in Table 2 for the $D{\cdot}BCl_nI_{3-n}$ (D = Q, Me_3N) adducts and the dichloroboron and chloroiodoboron cations derived from these donors. Agreement for the cations is as good on average as for the neutral boron trihalide adducts, and confirms our chemical shift assignments.

Selectivity of bromide displacement

The high selectivity of bromide displacement from $R_3N{\cdot}BF_n{\cdot}Br_{3-n}$, with displacement occurring only for $n = 2$ and not for $n = 1$ or 0, could be rationalized in thermodynamic or kinetic terms. Some reactions can be very slow (e.g., displacement of chloride from $Q{\cdot}BF_2Cl$) and we cannot be sure that our unreactive adducts are in fact at equilibrium. Complete substitution of bromine even in a BBr_3 adduct to give D_4B^{3+} is possible, but only under forcing conditions with a low-steric-hindrance pyridine donor (32). We cannot disentangle thermodynamic and kinetic factors without kinetic studies on rigorously dry systems. We discuss here two rationalizations for the high selectivity observed, which apply if based on assumptions that we are observing (*i*) near-equilibrium systems, or (*ii*) kinetic effects favouring certain reactions in systems that may be far from equilibrium. Both aspects may come into play in specific cases, so elements of both explanations may be valid. Rates of halogen redistribution about boron can be extremely variable, and where rates are known to be rapid, equilibria of halogen redistribution can be far from statistical (3, 33).

Reactivity of $R_3N{\cdot}BF_2Br$ with "hard" donors to lose Br^- should be thermodynamically favourable, provided steric hindrance is low, according to the "Symbiotic Principle" of Pearson and Songstad (34): hard bases tend to cluster together on a central atom, as do soft bases, whereas a system with both hard and soft ligands is less stable. Major deviations from statistical redistribution equilibria do occur in, for example, $Me_2S{\cdot}BF_nX_{3-n}$ (X = Cl, Br, I) adduct systems, with the mixed F,Br and F,I adducts not being detectable although equilibration is rapid (33). These are precisely the halogen pairs that would be predicted to be the least compatible according to the Symbiotic Principle. Against this explanation we must note that the rapid $R_3N{\cdot}BF_3 + BBr_3$ halogen redistribution reaction that forms the mixed boron trihalide adducts does give large amounts of the BF_2Br and $BFBr_2$ adducts. Nitrogen and oxygen donors would, however, be more compatible with the fluorine substituents than would bromine, according to the Symbiotic Principle, and displacement of the single bromine by such donors should be thermodynamically favoured.



Kinetic factors must, however, be important since higher-steric-hindrance amines such as Et_3N cannot attack $D{\cdot}BF_2Br$, but the desired $DD'BF_2^+$ complex is readily formed by attacking $Et_3N{\cdot}BF_2Br$ with the low-steric-hindrance amine. We now consider possible mechanisms.

A dissociative mechanism, $D{\cdot}BF_2Br$ giving $D{\cdot}BF_2^+$ and Br^-, would have the advantage of maximizing F—B π bonding in the trigonal planar intermediate, stabilizing the intermediate. (This is analogous to bond stabilization in BF_3 by fluorine-to-boron π bonding, which makes BF_3 the weakest Lewis acid of the BX_3 series (5).) This should selectively lower the activation energy when fluorine is present, and to a greater extent when two fluorines rather than one are present.

However, we can probably discount a dissociative mechanism for a number of reasons. (*i*) The highly reactive three-coordinate cation should react readily with D′ amines such as Et_3N, and reaction rates should not depend much on D′ steric hindrance. (*ii*) Although no systematic study has yet been carried out, reaction rates in at least some systems increase when D′ concentrations increase. (*iii*) There is no evidence for the presence of appreciable amounts of any three-coordinate boron species, which would be expected to cause rapid halogen redistribution in all species including the solvent. (*iv*) The ability of iodine-containing boron trihalide adducts of Me_3N to form three-coordinate ionic complexes was proposed by some (35, 36), but has been questioned by others (23, 37); loss of bromide seems far less likely than loss of iodide.

We should note, however, the special case of $i\text{-}Pr_2NEt{\cdot}BF_n{\cdot}Br_{3-n}$ adducts. Especially rapid halogen exchange with the solvent occurs with this highly hindered system, consistent with dissociation to give either $D{\cdot}BX_2^+$ or BX_3. We have not, however, been able to form any fluoroboron cations containing $i\text{-}Pr_2NEt$.

Thus the evidence seems strong against dissociation to give a three-coordinate reactive intermediate in our typical adduct systems. A typical S_N2 transition state (trigonal bipyramidal) seems more plausible, provided that this is lowered in energy by a maximization of fluorine-to-boron π bonding when the $D{\cdot}BF_2$ unit becomes planar:

As in the three-coordinate intermediate, the effect would be greater as the number of fluorines increases, and could account for the high selectivity.

Trialkylamines, being already four-coordinate when bonded to boron as D, cannot contribute to the stabilization of the transition state by π bonding to boron, but pyridines could, and would further stabilize the structure. In accord with this possibility, the formation of the mixed $(R_3N)(pyr)BF_2^+$ ions occurs more rapidly when R_3N is added to the $pyr{\cdot}BF_nBr_{3-n}$ system, than when pyr is added to the $R_3N{\cdot}BF_nBr_{3-n}$ system. The enhancement of these reactions when D is pyridine rather than R_3N is dramatic, and our work on the formation of haloboron cations in $pyr{\cdot}BF_nX_{3-n}$ (X = Cl, Br) systems will be reported separately (38).[2]

Our mixed-donor systems are complicated by D′ for D exchange. These reactions too are highly selective, and the selectivity could be related to a similar transition state to the above. D for D′ exchange is faster when at least two fluorines are present (Fig. 9).

Once formed, $D_2BF_2^+$ ions are stable even in water. This is likely a kinetic rather than a thermodynamic effect, similar to the stability of BF_4^- to hydrolysis. The stability of the bulky $D_2BF_2^+$ cations suggests their use as large cations for precipitating large anions, much as cobalticinium ion is used.

The reactions of the non-fluorine-containing cations have not yet been studied. $DD'BClI^+$ may undergo replacement of the second iodine to give doubly charged cations of type $DD'D''BCl^{2+}$. Bis(R_3N)haloboron cations of the types D_2BFX^+ (X = Cl, Br, I) and D_3BF^{2+} have not been reported in the literature, but we have observed cations of these types in the more reactive pyridine (38) and *N*,*N*,*N*′-trialkylamidine (39)[3] systems.

There have been a number of recent observations of cation formation from neutral main group halide compounds via displacement of halide by a neutral donor: e.g., about aluminum (40), tin (41), titanium (42), and tantalum (43), as well as additional examples about boron, in some cases leading to three-coordinate cations (44). HMPA, which we find to be exceptionally effective in displacing other donors, is the only one of a wide range of donors that gives cationic complexes $D_3TiX_3^+ \cdot X^-$ (X = Cl, Br); all the rest give only neutral complexes D_2TiX_4 under the same conditions (42). Much remains to be learned about such reactions. Fluoride abstraction from *mer*-Ph_3TeF_3 by PF_5 gives $Ph_3TeF_2^+ \cdot PF_6^-$ (45), from which it might be possible to prepare $D \cdot TePh_3F_2^+$ cations. Fluoro- and chlorosilicon cations $(bipyridyl)_2SiX_2^{2+}$ can be obtained by a different route (46). $(THF)_2AlCl_3$ can exist as the molecular complex but can also be isolated as the ionic isomer $(THF)_4AlCl_2^+ \cdot AlCl_4^-$ (47), just as our $D_2BF_2^+ \cdot BF_4^-$ compounds are ionization isomers of the corresponding molecular $D \cdot BF_3$ complexes.

Conclusions

The wide range of R_3N-containing dihaloboron cations described here demonstrates their ready availability under mild conditions from simple starting materials. Particularly striking is the need for one heavy and two light halogens (normally fluorine) on boron, to maximize the ease of displacement of the heavy halogen. The most plausible explanation for this involves stabilization of the transition state or reactive intermediate by π bonding from fluorine to boron. Positive ion FAB mass spectrometry is shown to be a potent technique, in tandem with nmr spectroscopy, in monitoring dihaloboron cation formation and identifying the ions. Continuing work has shown that mixed boron trihalide adducts of pyridines and amidines are even more reactive than those of aliphatic tertiary amines and give a wider variety of cationic haloboron species; these systems will be described elsewhere.

Acknowledgements

We thank Mr. T. R. B. Jones for technical assistance, Dr. J. M. Miller for helpful discussions and for suggesting the use of FAB in this work, Mr. A. G. Basile for modifications to the computer program for calculating pairwise interaction parameters, Mr. J. Nye, Ms. C. L. MacLaurin, and Mr. R. Théberge for running FAB spectra, and the Natural Sciences and Engineering Research Council of Canada for financial support. We also thank Prof. A. F. Janzen and Prof. K. E. Russell for helpful discussions, on reaction mechanisms and cationic polymerization respectively. High-field nmr spectra were obtained with the assistance of Dr. R. E. Lenkinski and Mr. W. Klimstra at the South Western Ontario High Field NMR Centre, funded by a Major Installation Grant from NSERC.

Superacid-induced ring-opening reactions of fluorinated heterocycles[1]

STEFAN P. KOTUN AND DARRYL D. DESMARTEAU[2]

Department of Chemistry, Howard L. Hunter Laboratory, Clemson University, Clemson, SC 29634-1905, U.S.A.

Received March 15, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

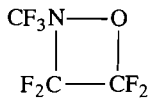
STEFAN P. KOTUN and DARRYL D. DESMARTEAU. Can. J. Chem. **67**, 1724 (1989).

HF/AsF_5 and HF/SbF_5 superacid mixtures react with fluorinated small-ring heterocycles such as 1,2-oxazetidines and oxetanes with consequent addition of HF to give alcohol and amine ring-opened products in high yield. Excess HF serves as solvent and reactant. Ring compounds containing both nitrogen and oxygen as heteroatoms protonate predominantly on nitrogen; a case with competing O-protonation arises in the case of a chloro-substituted oxazetidine. In general, rings containing two heteroatoms retain the heteroatom–heteroatom bond and it is a carbon–heteroatom bond that opens. The resulting OH and NH functional groups are not protonated and lost in the superacid medium due to the instability of the highly fluorinated cations that would be left behind. Most of the heterocycles react at or below room temperature, although the very weakly basic 2,2-bis(trifluoromethyl)-3,3,4,4-tetrafluorooxetane requires the stronger HF/SbF_5 superacid system and more severe conditions.

Key words: superacids, hydrogen fluoride, ring opening, fluorinated oxazetidines, fluorinated oxetanes.

STEFAN P. KOTUN et DARRYL D. DESMARTEAU. Can. J. Chem. **67**, 1724 (1989).

Les mélanges de superacides HF/AsF_5 et HF/SbF_5, réagissent avec les petits hétérocycles fluorés, comme les 1,2-oxazétidines et oxétanes, par additions de HF qui conduisent à des alcools et à des amines en chaîne ouverte avec d'excellente rendements. Le HF en excès sert de solvant et de réactif. Les composés cycliques contenant de l'azote ainsi que de l'oxygène comme hétéroatomes se protonent principalement sur l'azote; dans le cas des oxazétidines substituées par un chlore, on observe aussi une protonation sur l'oxygène. En général, avec les cycles contenant deux hétéroatomes, la liaison hétéroatome–hétéroatome est conservée alors que la liaison carbone–hétéroatome s'ouvre. Les groupements fonctionnels OH et NH qui en résultent ne sont pas protonés, ainsi ils ne sont pas perdus, dans le milieu superacide à cause de l'instabilité des cations hautement fluorés qui seraient laissés en arrière. La plupart des hétérocycles réagissent à la température ambiante ou à des températures plus basses; toutefois, pour faire réagir le 2,2-bis(trifluorométhyl)-3,3,4,4-tétrafluorooxétane qui est très faiblement basique, on doit utiliser le système de superacide HF/SbF_5 qui est plus fort ainsi que des conditions plus vigoureuses.



Mots clés : superacides, fluorure d'hydrogène, ouverture de cycle, oxazétidines fluorées, oxétanes fluorés.

[Traduit par la revue]

Introduction

Superacid chemistry has achieved a position of high visibility in the past several years (1). Mixtures of anhydrous hydrogen fluoride and Lewis acids such as NbF_5, BF_3, TaF_5, AsF_5, or SbF_5 constitute an important class of superacids. Among the more recent reports are those of O'Donnell on the acidity of HF (2) and on the equilibria of the HF/AsF_5 system (3) while Gillespie and Liang's particularly definitive measurements (4) now establish HF itself as one of the most acidic single-component systems known and show HF/SbF_5 mixtures to have the highest acidity values ever observed, with HF/AsF_5 about 1.3 orders of magnitude behind. X-ray crystal structures of the active protonating species, H_2F^+ and $H_3F_2^+$, have also recently been determined (5).

We wish to report here synthetic uses of HF/AsF_5 and HF/SbF_5 superacid mixtures with excess HF as solvent in the preparation of fluorinated amines and alcohols. Our initial goal in this area involved insertion of tetrafluoroethylene into the N—O bond of the 2-trifluoromethyl-3,3,4,4-tetrafluoro-1,2-oxazetidine **1** for possible conversion to polymers in which the

1

N—O bond, which limits the thermal applications of nitroso rubbers (6), would no longer be present. One part of this investigation consisted of superacid protonation in the expectation of obtaining a stable cyclic ammonium salt in analogy to previous open-chain cases such as H_2O (7), H_2S (8), HNF_2 (9), $(CF_3)_2NCF{=}NCF_3$ (10), and the more closely related conversion of $CF_3N(H)—OCF_3$ to $CF_3N^+(H)(H)—OCF_3\ AsF_6^-$ (11).

The volatile product from **1**, however, is $CF_3N(H)—OCF_2CF_3$, isolated in excellent yield and arising via opening of the N—C bond and formal addition of HF. We here show this to be a synthetically useful transformation for several fluorinated small-ring heterocycles.

Experimental

Caution! We have not encountered any difficulties with the starting materials, reagents, or products in this work; users should, however, familiarize themselves with their properties and hazards. HF and SbF_5 are very corrosive toward tissue and materials of construction; AsF_5 is, in addition, very toxic and a strong oxidizer. Some of the reactions occur at elevated pressures. The reactants and products containing N—O bonds seem to be quite thermally stable, but adequate shielding is advisable.

Manipulation of volatile materials

Volatile compounds were handled in vacuum lines constructed of Pyrex with glass/Teflon® valves and of types 304 and 316 stainless steel. Amounts of volatiles were determined by PVT techniques, assuming ideal gas behavior, using a Wallace & Tiernan series 1500 differential pressure gauge. Materials with significant nonideality (anhydrous HF) or low vapor pressure (SbF_5) were vacuum-transferred but determined by direct weighing. Low-temperature trap-to-trap distillations were performed under dynamic vacuum. AsF_5 may be handled in glass vacuum systems under sufficiently dry conditions. SbF_5,

while also safe in dry glass, was generally vacuum-transferred through a short stainless steel connector external to the metal line, as was HF.

Reagent and starting materials

SbF_5 (PCR), BF_3 and octafluorocyclobutane (Matheson), and NaF (Aldrich) were used as received. Anhydrous HF (Air Products) was usually dried in an FEP reactor (see below) with SbF_5; dry HF was removed by vacuum transfer at −40°C (7). Arsenic pentafluoride was used for this purpose in some early work, but this produces uncertainties in reaction stoichiometries due to subsequent vacuum transfer of unreacted AsF_5 with the dry HF. Christie *et al.* have pointed out (12) that BiF_5 should be the most convenient drying agent in this regard. $H_3O^+AsF_6^-$ (7), $CF_3\overline{N—O—CFXCF_2}$ where X = F (13), Cl (14), and H (15), and $\overline{C(CF_3)_2—O—CF_2CF_2}$ (16, 17) were prepared by literature methods. AsF_5 was prepared from As_2O_5 and F_2 (18, 19).

Reaction vessels

Reactors for superacid ring-openings were constructed from Teflon® -FEP tubing of $\frac{1}{16}$ in. wall thickness and either $\frac{1}{2}$ in. or $\frac{5}{8}$ in. o.d. The tube was heat-sealed at one end, fitted with a 316 stainless insert at the other, and connected to a Nupro SS-4JBR valve by means of Swagelok 316 SS tube fittings and Teflon® ferrules. Neutralizations of the superacid mixtures with NaF were conducted in 75- or 150-mL 304 SS Hoke bombs, also with the above Nupro valve.

Instrumentation

Infrared spectra were recorded in the gas phase on a Perkin–Elmer 1430 instrument equipped with a P–E 7500 data station. IR cells were 10 cm in length with KCl plates secured using Halocarbon 1500 wax. ^1H and ^{19}F NMR spectra were obtained on an IBM NR/200AF spectrometer at 200.13 and 188.31 MHz, respectively, and were referenced to internal $Si(CH_3)_4$ and $CFCl_3$. Chemical shifts upfield from these are reported as negative. Mass spectra were run on a Hewlett–Packard 5985A at 70 eV. CH_4 was the CI gas. Samples were introduced by direct gas insertion.

*Reaction of $CF_3\overline{N—O—CF_2CF_2}$, **1**, with HF/AsF_5*

An FEP reactor of internal volume 39.5 mL was evacuated, weighed, and cooled to −196°C. Anhydrous HF (0.97 g, 48 mmol) was condensed in by vacuum transfer on the steel vacuum line. The reactor was weighed, cooled again, and 10.00 mmol AsF_5 condensed in. The mixture was warmed to room temperature with a water bath to form a homogeneous solution and then frozen again in liquid nitrogen. Oxazetidine **1** (5.00 mmol) was condensed in and the reactor was warmed with agitation under a stream of running water. A vigorous reaction began as soon as the mixture began to melt (mp HF = −83°C). The reactor was allowed to stand at 23°C for 18 h. After degassing (freeze–pump–thaw) on the metal line the contents of the reactor were vacuum-transferred into a 150-mL bomb cooled to −196°C, containing several steel balls and 12.22 g (291 mmol) NaF powder to remove HF and AsF_5. A solid began to form as the volatiles were removed from the FEP reactor; this solid was somewhat volatile and with some heating and agitation nearly all of it could be transferred to the NaF bomb. The crude product was allowed to stand over the NaF for 2.5 h at 23°C with occasional shaking; it was then pumped into a glass U-trap cooled with liquid nitrogen and purified by trap-to-trap distillation using traps at −70, −95, and −196°C. The −95°C trap retained the product **1***a*, $CF_3N(H)—OCF_2CF_3$ (4.84 mmol, 97% yield).

1*a* was characterized as follows: mp −66.8°C; vapor pressure curve measured from −33.4 to +18.4°C: $\log_{10}P$ (Torr; 1 Torr = 133.3 Pa) = 6.544 − 724.735/T − 121255.969/T^2, ΔH = 6942.07 cal/mol, ΔS = 22.68 eu, extrapolated bp +32.9°C; IR (3 Torr): 3342 ($\nu_{N—H}$, m), 1483 (sh, w), 1453 (s), 1399 (w), 1313 (vs), 1275 (sh, m), 1236 (vs), 1197 (vs), 1170 (vs), 1107 (vs), 1028 (w), 969 (w), 919 (m), 863 (m), 814 (w), 741 (m), 679 (w), 620 (w), 569 (w) cm^{-1}; NMR $CF_3^AN(H)—OCF_2^BCF_3^C$, δ ^1H ($CDCl_3$): 6.56 (br q); δ ^{19}F ($CDCl_3$): A, −70.6 (3F, dt); B, −95.3 (2F, qq); C, −84.9 (3F, t) ppm; J_{HA} = 8.6, J_{AB} = 3.8, J_{BC} = 1.7, J_{HB} = J_{HC} = J_{AC} = 0 Hz; MS, major *m/z* [EI]: 219 (M^+), 200 ($M - F^+$), 180 ($M - F - HF^+$), 130 ($M - HF - CF_3^+$), 119 ($CF_3CF_2^+$), 69 (CF_3^+); major *m/z* [CI]: 220 (MH^+), 200 ($MH - HF^+$), 180 ($MH - 2HF^+$), 130 ($M - HF - CF_3^+$), 119 ($CF_3CF_2^+$).

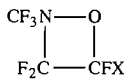
*Reaction of $CF_3\overline{N—O—CFClCF_2}$, **2**, with HF/AsF_5*

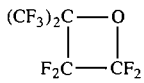
The procedure of compound **1** was followed using a 40-mL FEP reactor, 1.45 g (72.5 mmol) dried HF, 10.00 mmol AsF_5, and 5.00 mmol oxazetidine **2**. The reaction, less energetic than for **1**, stood for 16 h at 24°C and was then vacuum-transferred with heating and agitation onto 15.22 g (362 mmol) NaF powder in a 150-mL bomb containing several steel balls. After 3.5 h at 24°C the product was pumped out and fractionated through traps cooled to −58, −80, and −196°C. The −80°C trap contained 4.12 mmol of crude **2***a*, $CF_3N(H)—OCFClCF_3$, with some AsF_3. The yield of **2***a* was determined by ^{19}F NMR to be 45 mol% of the sample or 1.86 mmol of pure compound (37% yield). The −58°C trap contained 1.34 mmol (27% yield) of the known (20, 21) hydroxylamine **2***b*, $CF_3N(OH)—CF_2CF_2Cl$.

2*a* was characterized as follows: IR (4 Torr): 3333 ($\nu_{N—H}$, m), 1489 (sh, w), 1450 (s), 1336 (s), 1308 (vs), 1279 (sh, m), 1228 (vs), 1206 (sh, s), 1149 (s), 1126 (s), 1093 (vs), 1022 (m), 993 (s), 918 (m), 874 (w), 839 (m), 654 (w), 604 (w), 563 (w) cm^{-1}; NMR $CF_3^AN(H)—OCF^BClCF_3^C$, δ ^1H ($CDCl_3$): 6.63 (br q); δ ^{19}F ($CDCl_3$): A, −69.9 (3F, dd); B, −81.3 (1F, qq); C, −83.1 (3F, d) ppm; J_{HA} = 8.5, J_{AB} = 4.1, J_{BC} = 2.4, J_{HB} = J_{HC} = J_{AC} = 0 Hz; MS, major *m/z* [EI]: 200 ($M - Cl^+$), 180 ($M - Cl - HF^+$), 135/137 ($CFClCF_3^+$), 85/87 (CF_2Cl^+), 69 (CF_3^+); major *m/z* [CI]: 236/238 (MH^+), 216/218 ($MH - HF^+$), 200 ($M - Cl^+$), 180 ($M - Cl - HF^+$), 135/137 ($CFClCF_3^+$).

The previously reported compound **2***b* was not well examined in the original publication (20); we report its characterization as follows: IR (4 Torr): 3600 ($\nu_{O—H}$, sharp, m), 1390 (m), 1320 (s), 1277 (vs), 1250 (vs), 1211 (vs), 1185 (vs), 1115 (s), 1043 (m), 984 (s), 873 (s), 833 (s), 753 (m), 683 (m), 661 (w), 630 (w), 585 (w) cm^{-1}; NMR $CF_3^AN(OH)—CF_2^BCF_2^CCl$, δ ^1H ($CDCl_3$): 5.88 (s); δ ^{19}F ($CDCl_3$): A, −67.2 (3F, br t); B, −106.0 (2F, qt); C, −69.0 (2F, tq) ppm; J_{AB} = 12.9, J_{AC} = 1.4, J_{BC} = 2.8, J_{HA} = J_{HB} = J_{HC} = 0 Hz; MS, major *m/z* [EI]: 200 ($M - Cl^+$), 180 ($M - Cl - HF^+$), 150 ($M - CF_2Cl^+$), 135/137 ($CF_2CF_2Cl^+$), 85/87 (CF_2Cl^+), 69 (CF_3^+), 50 (CF_2^+); major *m/z* [CI]: 236/238 (MH^+), 216/218 ($MH - HF^+$), 200 ($M - Cl^+$), 150 ($M - CF_2Cl^+$).

*Reaction of $CF_3\overline{N—O—CHFCF_2}$, **3**, with HF/AsF_5*





The same procedure was followed as for compound **1**, using an FEP reactor of 35 mL volume. Amounts of reactants were 1.73 g (86 mmol) HF, 10.00 mmol AsF_5, and 5.00 mmol oxazetidine **3**. The initially exothermic reaction was allowed to stand at 23°C for 24 h and was then vacuum-transferred with heating and agitation onto 18.16 g (432 mmol) NaF powder in a 150-mL bomb containing several steel balls, where it was allowed to remain for 36 h at 23°C with occasional shaking. Trap-to-trap fractionation through traps cooled to −65, −90, and −196°C gave 3.20 mmol (64% yield) of $CF_3N(H)—OCHFCF_3$, **3***a*, in the −90°C trap.

3*a* was characterized as follows: IR (3 Torr): 3335 ($\nu_{N—H}$, m), 2989 ($\nu_{C—H}$, w), 1478 (sh, w), 1433 (s), 1409 (w), 1344 (w), 1291 (vs), 1214 (vs), 1191 (vs), 1127 (vs), 1088 (s), 1021 (w), 989 (sh, w), 923 (m), 904 (m), 830 (w), 725 (m), 700 (m), 609 (w), 563 (w) cm^{-1}; NMR $CF_3^AN(H^B)—OCH^CF^DCF_3^E$, δ ^1H ($CDCl_3$): B, 6.75 (1H, br q); C, 5.66 (1H, dq); δ ^{19}F ($CDCl_3$): A, −71.2 (3F, dd); D, −144.8 (1F, dqq); E, −82.6 (3F, dd) ppm; J_{AB} = 8.4, J_{AD} = 2.2, J_{CD} = 57.6, J_{CE} = 3.2, J_{DE} = 5.9, J_{AC} = J_{AE} = J_{BC} = J_{BD} = J_{BE} = 0 Hz; MS, major *m/z* [EI]: 201 (M^+), 182 ($M - F^+$), 162 ($M - F - HF^+$), 132 ($M - CF_3^+$), 112 ($M - CF_3 - HF^+$), 101 (CF_3CHF^+), 100 (CF_3CF^+), 69 (CF_3^+); major *m/z* [CI]: 202 (MH^+), 182 ($MH - HF^+$).

*Reaction of $\overline{C(CF_3)_2—O—CF_2CF_2}$, **4**, with HF/SbF_5*

Into a 12-mL FEP reactor was vacuum-transferred 2.07 g (9.55 mmol) SbF_5 followed by 2.21 g (110 mmol) dried HF. The superacid mixture was then warmed to room temperature and agitated to form a homoge-

neous solution. Oxetane **4** (9.55 mmol) was then condensed in; upon warming, the reactants formed two liquid phases and did not appear to react. The reactor was placed in an oil bath and heated to 55°C (**Caution! High pressure!**) for 17 h, by which time the reaction mixture had become homogeneous. Nearly all the material was vacuum-transferred with heating (no solid formation was observed) onto 23.19 g (553 mmol) NaF powder in a 150-mL bomb containing several steel balls. After 4 h at 23°C with occasional shaking, the product was pumped out and fractionated through traps cooled to −40, −80, and −196°C; the product, 9.20 mmol (96% yield) of the known (22, 23) $CF_3CF_2C(CF_3)_2—OH$, **4***a*, collected in the −80°C trap.

Only the boiling point and ^{19}F NMR chemical shifts have been reported (22) for **4***a*; we report additional characterization as follows: IR (1 Torr): 3620 ($\nu_{O—H}$, m), 1376 (sh, w), 1342 (w), 1274 (s), 1249 (vs), 1227 (s), 1142 (m), 1071 (w), 966 (m), 955 (sh, w), 880 (m), 736/725 (d, m), 660 (w), 621 (w) cm^{-1}; NMR $CF_3^ACF_2^BC(CF_3^C)_2—OH$, δ ^1H ($CDCl_3$): 3.56 (s); δ ^{19}F ($CDCl_3$): A, −80.5 (3F, sept); B, −119.6 (2F, sept); C, −73.3 (6F, tq) ppm; J_{AC} = 5.7, J_{BC} = 10.9, J_{AB} = J_{HA} = J_{HB} = J_{HC} = 0 Hz; MS, major *m/z* [EI]: 247 ($M - F - HF^+$), 217 ($M - CF_3^+$), 197 ($M - CF_3 - HF^+$), 167 ($M - C_2F_5^+$), 147 ($M - C_2F_5 - HF^+$), 119 ($C_2F_5^+$), 100 (CF_3CF^+), 97 (CF_3CO^+), 69 (CF_3^+); major *m/z* [CI]: 305 ($MH + H_2O^+$), 287 (MH^+), 267 ($MH - HF^+$), 247 ($MH - 2HF^+$), 217 ($M - CF_3^+$), 197 ($M - HF - CF_3^+$), 167 ($M - C_2F_5^+$), 150 ($CF_3CCF_3^+$), 147 ($M - HF - C_2F_5^+$), 119 (C_2F_5), 100 (CF_3CF^+).

Results and discussion

Synthetic results of this investigation are summarized in Table 1. The ring-opening reactions reported here exhibit several noteworthy, although completely reasonable, features. The first is that for **1**–**3** the normally fragile N—O bond remains intact; these reaction systems do not involve radicals and, even if the N—O bond were to cleave through a more ionic mechanism, the result would be a thermodynamically unfavorable N—F or O—F compound.

The other feature is that the >NH and —OH functional groups of these highly fluorinated products are not "protonated off" (protonated and removed as initially neutral leaving groups) in the superacid media to give cations, as is often observed in hydrocarbon superacid chemistry, for example, the cleavage of secondary oxonium ions (protonated ethers) to give alkyl cations (ref. 1, pp. 82, 182–184). The product **4***a*, for instance, would produce the corresponding carbocation $CF_3CF_2C^+(CF_3)_2$, the perfluoroalkyl substituents of which would be very destabilizing (25), even relative to fluorine substituents, since inductive withdrawal is still present but resonance stabilization of the type in eq. [1] is lacking.

[1] $>C^+—F \leftrightarrow >C{=}F^+$

These reactions are similar to the use of $(HF)_x\cdot$ pyridine or trialkylamine complexes in the ring opening of cyclopropane (26), hydrocarbon epoxides (27), aziridines (28–31), and azirines (28, 29); X-ray structures of $(HF)_x\cdot$py have recently been determined (32). The fluorinated heterocycles in this work, however, should be much less basic than the above examples and it is unlikely that $(HF)_x\cdot$py would be sufficiently acidic to protonate them. The oxetane **4**, in fact, requires the strongest system available to produce good yields. Recent work has also

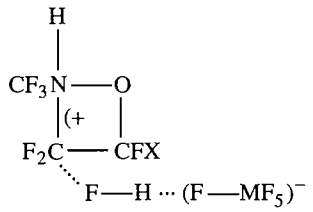

FIG. 1. Proposed solvent interaction leading to ring opening of a protonated 1,2-oxazetidine.

appeared (33) concerning the ring-opening of partially fluorinated oxetanes with $AlCl_3$. Likewise, others in our laboratory have found (34) that a Lewis acid alone (SbF_5) converts **1–3** to dimers and trimers, presumably through a fluoride-ion abstraction mechanism; this should not contribute in the current Brönsted–Lowry acid work since the amount of molecular SbF_5 in an HF mixture is negligible (4). A significant, temperature-dependent concentration of AsF_5 exists in HF solution, however, as free AsF_5 (3).

Since the reagent in this work is a protic superacid it seems reasonable to assume that the reaction is initiated by protonation of the most basic site of the substrate. Highly fluorinated, weakly basic molecules such as these require a heteroatom to provide sufficient basicity; otherwise, even a superacid will not react. An attempted reaction of octafluorocyclobutane with HF/AsF_5 at room temperature resulted in quantitative recovery of the starting material. We have not checked the stronger HF/SbF_5. The "weak" superacid HF/BF_3 undergoes only a trace of reaction with **1** (see Table 1). Possible catalytic effects from water (wet HF) were excluded by testing **1** with a sample of $H_3O^+AsF_6^-$ (7) (the result of wet HF plus AsF_5) alone; no reaction was observed.

We have not looked for discrete carbocation intermediates of the form $CF_3N(H)—OCF_2CF_2^+$, for example, which could be involved in the opening of the ring after protonation. A lower-energy "solvent-assisted" pathway seems more reasonable, where an interaction of the type shown in Fig. 1, for instance, leads to $CF_3N(H)—OCFXCF_3$. Competing protonation on oxygen would lead to fluoride-ion donation to the other ring carbon, giving a hydroxylamine as observed for **2**. The reason for this pattern of product variation with substituent X is not entirely clear. It cannot be an inductive (electronegativity) effect, because if the appropriate hydroxylamine is not observed for X = F (**1**) but is for X = Cl (**2**), then X = H (**3**) would be expected to yield even more hydroxylamine; instead, none is found. This implies a resonance effect and suggests, in the limit of the free carbocations $CF_3N(OH)—CF_2—FXC^+$, that X = Cl is more stabilizing than X = F, perhaps through the resonance form $CF_3N(OH)—CF_2—FC{=}X^+$, a contributor that is not possible for X = H. This goes against the well-known ability of α-fluorine to stabilize carbocations by back-donation of lone-pair electrons (refs. 1, p. 114, and 25) and also contradicts the known trend of Lewis acidities of the isoelectronic boron halides: $BBr_3 > BCl_3 > BF_3$. The trifluoride is the weakest Lewis acid precisely because the $2p$–p overlap is *more* effective for fluorine than for the other halogens. That is, resonance structures of the form $X_2B^-{=}X^+$ are more significant for X = F with the accompanying stronger negative charge on boron acting to reduce the acidity of BF_3 relative to the other trihalides.

Hine and Lee, however, have reported kinetic data (35, 36) for solvolysis reactions of side-chain halogenated toluenes; their rate constants, when interpreted in terms of a primarily S_N1 (carbocation) mechanism, show a superior tendency for α-chlorine relative to α-hydrogen or -fluorine to activate the departure of a chloride leaving group. Solvolysis in 50% aqueous acetone of $PhCF_2—Cl$, $PhCH_2—Cl$, and $PhCCl_2—Cl$, for example, gave rate constants in a ratio of 1:5.3:2600 respectively. While this situation is clouded by probable deviations from the extreme S_N1 case and by ground state stability differences, the trend matches the observation that in the current oxazetidine ring-opening work only the chloro-substituted **2** produces any hydroxylamine. As discussed above in the S_N1 limit, the oxygen functionality would be considered a leaving group whose departure is not sufficiently activated by X = H or F substituents. Although useful as a formalism, the purely dissociative mechanism cannot, of course, represent the initiation of the ring-opening reaction itself to a significant degree since this would predict complete reaction using HF alone without the benefit of added Lewis acid. It does, however, provide a viewpoint for following the course of the ring opening subsequent to or simultaneous with protonation.

The ring opening of oxetane **4** is regiospecific since the only product is ***4a*** and no $C(CF_3)_2F—CF_2C(O)F$ is observed. The acid fluoride would arise from spontaneous dehydrofluorination of $C(CF_3)_2F—CF_2CF_2OH$, the other possible ring-opening product. Again, in the limit of free carbocations derived from HO^+—C bond cleavage, the positive charge would prefer to develop on a carbon with substituents of F, F, R_f[3] ($HOC(CF_3)_2$-$CF_2CF_2^+$) rather than on a carbon bearing two CF_3 and one longer perfluoroalkyl group ($C^+(CF_3)_2CF_2CF_2OH$), as mentioned previously and implied by the failure of hexafluoroacetone to protonate in $HOSO_2F/SbF_5$ ("Magic Acid") (25).

An important consequence of the heteroatom basicity is that if the ring protonates and opens, then the resulting product may also be protonated. This could explain the formation of volatile solids as the superacid mixture evaporates and is vacuum-transferred onto NaF following ring-opening reactions with the nitrogen heterocycles. That is, products of the form $CF_3N(H)—OCFXCF_3$ are likely to be protonated to $CF_3N^+(H)(H)—OCFXCF_3$. Precedent for this resides in the independent synthesis of $CF_3N^+(H)(H)—OCF_3$ AsF_6^- and $CF_3N^+(H)(H)—OCF(CF_3)_2$, which exhibit dissociation pressures of 50 and 10 Torr, respectively, at 22°C (11). While the ring-opening reactions should in principle be catalytic in Lewis acid, examination of the yields of ***1a*** in Table 1 as a function of equivalents of AsF_5 used also suggests that much of the AsF_5 becomes unavailable for further reaction. The 2:1 molar ratio of AsF_5: ring necessary for optimum yields under these conditions means that most of the counterion associated with the protonated product should be $As_2F_{11}^-$. The existence of equilibria in the HF/AsF_5–AsF_6^-–$As_2F_{11}^-$ system (3) and between protonated and unprotonated product (11), however, makes the observed yield dependence somewhat surprising. Another possible answer is that the solid is the salt of the protonated unopened ring, which was an original goal of this research, and that ring opening occurs mostly upon heating via donation of fluoride from the anion to the protonated ring. The observed yield data, when interpreted in the light of such a hypothesis, would indicate that $As_2F_{11}^-$ is more effective in donating fluoride to open the ring than is AsF_6^-. Occasionally, when an FEP reactor is allowed to stand for a few days after vacuum-transferring most of its contents onto NaF, colorless crystals will sublime onto

[3] R_f is a perfluoroalkyl group.

the sides of the FEP tube. These crystals sublime away when the reactor is cut open in a drybox, and fume in moist air. An X-ray diffraction and Raman study would help to answer these mechanistic and structural questions. Standard elemental analyses on such corrosive samples would present formidable challenges and were not attempted. It should be possible, however, to determine arsenic and antimony in aqueous solution using X-ray fluorescence spectroscopy.

Yields of **1***a* using SbF_5 are lower, due, we feel, to difficulties in removing the much more strongly protonated product from the viscous SbF_5 matrix using the current experimental technique. For the less basic oxygen in oxetane **4** the HF/AsF_5 system is simply not strong enough and the use of SbF_5 is necessary. At 55°C the reaction is still slow but the use of equimolar SbF_5:**4** gives an excellent yield, indicating that product protonation is easily reversible and not a problem. No solids are observed as the reaction mixture is transferred out of the FEP reactor, so **4***a* is formed before the heating/transfer step. That is, the protonated oxetane cannot wait until being heated for the counterion to donate F^-, opening the ring as described in the second scenario for the oxazetidines. If this second mechanism were true for **4** there would probably be volatile solid formed during the transfer. The fact that there is none means either that the protonated ring–counterion pair collapses very easily or that it no longer exists at that time, lending credence to the belief that the oxazetidine solids are protonated product and not protonated starting material.

Synthetic chemistry using superacids should be capable of producing many more interesting and unusual compounds. Fluorinated oxazetidines (37, 38) and oxetanes (ref. 33 and references therein) can be made in large variety. We are investigating other ring systems, especially with regard to size, and exploring the chemistry of the amine products reported here.

Reaction of RuO_4 with KrF_2: A clear-cut method to prepare ruthenium oxide tetrafluoride

LAURENT MEUBLAT, MONIQUE LANCE, AND ROLAND BOUGON[1]

Département d'étude des lasers et de la physico-chimie, Service de chimie moléculaire — Unité de recherche associée n° 331, Centre national de la recherche scientifique, Commissariat à l'énergie atomique — Centre d'études nucléaires de Saclay, 91191 Gif sur Yvette CÉDEX, France

Received January 10, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

LAURENT MEUBLAT, MONIQUE LANCE, and ROLAND BOUGON. Can. J. Chem. **67**, 1729 (1989).

The fluorination of ruthenium tetroxide RuO_4 was attempted by using either fluorine or krypton difluoride KrF_2 in HF solution. Of the two fluorinating agents, only KrF_2 was found to be powerful enough to react with RuO_4 and to transform it into ruthenium oxide tetrafluoride $RuOF_4$. This oxide fluoride of ruthenium VI was characterized by elemental analysis, X-ray powder diffraction, and infrared absorption spectroscopy.

Key words: ruthenium tetroxide, ruthenium oxide tetrafluoride, krypton difluoride, fluorination.

LAURENT MEUBLAT, MONIQUE LANCE et ROLAND BOUGON. Can. J. Chem. **67**, 1729 (1989).

La fluoration du tétroxyde de ruthénium RuO_4 a été recherchée en utilisant le fluor ou le difluorure de krypton en solution HF. Des deux agents fluorants, seul KrF_2 s'est révélé suffisamment puissant pour réagir avec RuO_4 et le transformer en oxytétrafluorure de ruthénium $RuOF_4$. Cet oxyfluorure de ruthénium VI ainsi préparé a été caractérisé par l'analyse élémentaire, la diffraction des rayons X sur poudre et la spectroscopie d'absorption infrarouge.

Mots clés : tétroxyde de ruthénium, oxytétrafluorure de ruthénium, difluorure de krypton, fluoration.

Introduction

Studies on the volatile species of ruthenium are of interest both for academic research and for the nuclear industry, for the latter especially because of problems caused by the radioactive ^{106}Ru element.

The volatile species may include, in particular, the two oxide fluorides $RuOF_3$ and $RuOF_4$, for which there have been few properties reported.

Ruthenium oxide trifluoride $RuOF_3$ was reported quite recently (1) as being obtained from the reaction of ruthenium dioxide RuO_2 with F_2 at 300–320°C. The first mention of the synthesis of $RuOF_4$ appeared in 1963, when the compound was reported (2) to have been obtained by the reaction of an equimolar mixture of bromine and bromine trifluoride on ruthenium metal. The nature of the reactor, made of Pyrex glass (3), probably accounted for the assumed presence of oxygen in the final product. The suggestion (4) that an oxide film on the metal was the source of oxygen has to be ruled out since the authors (2) had treated the ruthenium metal with hydrogen at a dull-red heat before use. The F and Ru contents of the compound were in agreement with those expected for $RuOF_4$, and several properties were given. However, the X-ray powder pattern was reported to be complex and different from that of RuF_5. The presence of oxygen in the stable, pale, otherwise colorless solid so prepared, containing a small amount of green impurity, was inferred mainly from its vapor pressure and magnetic susceptibility, which were both found to be in agreement with those expected for an oxide tetrafluoride. Later on, a yellowish-green $RuOF_4$ was reported (5, 6) to have been obtained from the reaction of RuO_2 with F_2 at temperatures higher than 400°C. The compound was characterized by its mass spectrum, which displayed the molecular ion $RuOF_4^+$ as the heaviest species; chemical analysis, which gave a value of 4.0 ± 0.1 for the F/Ru molar ratio; and the release of oxygen identified by mass spectrometry. An infrared spectrum of the material was also given; however, the properties of this product differed from those reported by the first authors (2). In particular, the compound prepared by Sakuraï and Takahashi (5, 6) was reported to be unstable at room temperature and to decompose into ruthenium tetrafluoride and oxygen.

The work reported in the present paper, which was initially aimed at preparing new oxide fluorides of ruthenium in its high oxidation states, led in fact to a new and clear-cut method of preparation of $RuOF_4$.

Experimental

Materials

Commercial fluorine (from Union Carbide), helium (from l'Air Liquide), and ruthenium oxide hydrate, $RuO_2 \cdot xH_2O$, containing 60% of ruthenium by weight (from Merck) were used as received. The synthesis of RuO_4 was made according to the method described in the literature (7, 8), which consists of treating $RuO_2 \cdot xH_2O$ alternately with F_2 and a stream of helium saturated with water. These treatments were repeated until 90% of the black starting material was volatilized and condensed in a trap at −196°C. The ruthenium tetroxide was purified by fractional vaporization to remove SiF_4, and by passage through P_2O_5 and NaF to remove H_2O and HF, respectively. Ruthenium tetroxide was identified by the visible and infrared absorption spectra of its vapor, which were found to be identical with those published (7, 9–11). The solubility of RuO_4 in anhydrous HF was found to be 0.1 mol L^{-1} at room temperature, and the Raman spectrum of the solution showed three characteristic bands at 884, 920, and 320 cm^{-1}, assigned to $\nu_1(A_1)$, $\nu_3(F_2)$, and $\nu_2(E)$ and (or) $\nu_4(F_2)$, respectively (7).

The fluorine used for the preparation of KrF_2 was passed over NaF to remove HF, and krypton (from l'Air Liquide) was used without purification. The synthesis of KrF_2 was as previously described (12). Anhydrous HF (from Union Carbide) was dehydrated on bismuth pentafluoride before use (13). The sample of ruthenium pentafluoride used for comparison of the X-ray powder pattern of $RuOF_4$ with that of RuF_5 was prepared as described in the literature (2) using commercial fluorine and ruthenium powder (from Union Carbide and Cie des métaux Précieux, respectively).

Apparatus

Volatile materials used in this work were manipulated in a Monel Teflon–FEP vacuum system. Prior to handling of the moisture-

[b]Calculated from the crystal structure parameters given in ref. 16.

sensitive compounds, the part of the system used was passivated with ClF_3 and (or) hot fluorine. The syntheses were achieved either in Monel vessels equipped with CaF_2 or sapphire windows, or in Teflon–FEP or sapphire tubes equipped with Monel or Teflon–FEP valves. It was noticed that cracks rapidly developed when Kel-F valves were used for handling mixtures of KrF_2, HF, and RuO_4, so that the use of this chlorofluoropolymer had to be ruled out. Moisture-sensitive nonvolatile materials were handled in the dry nitrogen atmosphere of a glove box.

X-ray diffraction patterns, spectra, and analyses

The Debye–Scherrer powder patterns of the samples sealed in 0.3 mm o.d. glass or quartz capillaries were obtained by using a Phillips camera (diameter 11.46 cm) using Ni-filtered CuKα radiation. Infrared spectra were recorded in the range 4000–200 cm^{-1} on a Perkin Elmer model 283 spectrophotometer. Spectra of solids were obtained by using dry powders pressed between AgCl or AgBr windows in an Econo press (Barnes Engineering Co). Spectra of gases were obtained by using a Monel cell of 10-cm path length equipped with AgCl or polyethylene windows. Raman spectra were recorded on a Coderg model T 800 spectrophotometer using the 514.5-nm exciting line of an Ar ion model 165 Spectra-Physics laser filtered with a Coderg premonochromator. Solutions were examined in a Teflon–FEP or sapphire reaction tube. The electronic absorption spectrum of RuO_4 in the gaseous phase was recorded on a Beckman model UV 5270 spectrophotometer. The cell was identical with that used for the IR spectra except for the windows, which consisted of CaF_2 discs. Elemental analyses were performed by Mikroanalytische Laboratorien Elbach, West Germany.

Reaction of RuO_4 with F_2 in HF solution

An amount of hydrogen fluoride (0.87 g) saturated with RuO_4 (ca. 0.08 mmol) was condensed at liquid nitrogen temperature into a Teflon–FEP tube. Fluorine was then admitted to the tube kept at liquid nitrogen temperature so that the partial pressure of F_2 over the HF solution was calculated to be 2 atm (1 atm = 101.3 kPa) at room temperature, and to correspond to ca. 0.22 mmol.

The mixture was stirred and allowed to react for 1 day at room temperature. The resulting solution remained yellow and its Raman spectrum showed only the three characteristic signals mentioned above for RuO_4 in HF solution.

Reaction of RuO_4 with KrF_2 in HF solution

Hydrogen fluoride (7.527 g) was distilled into a sapphire reaction tube, then 0.1275 g of RuO_4 (0.772 mmol) and 0.4453 g of KrF_2 (3.656 mmol) were condensed at liquid nitrogen temperature into the reactor. The mixture was left at room temperature for a few hours during which the solution, initially yellow colored, turned dark orange and a brown orange solid was formed. The Raman spectrum of the slightly orange colored solution over the precipitate showed only the characteristic ν_1 line of KrF_2 at 464 cm^{-1} (14); the lines associated with RuO_4 had disappeared. The mixture was cooled to −196°C and the volatile materials put in contact with silicon powder contained in a Monel reactor in liquid nitrogen. Fluorine is known (15) to react with

silicon at temperatures as low as −196°C to yield SiF_4, which is nonvolatile at these temperatures, so that F_2 is thus normally easily removed from a gaseous mixture. However, due to the diluting effect of the other gases (Kr and O_2), several cycles of condensation and warming up were necessary to convert all the fluorine into SiF_4. The amount of F_2 in the initial gaseous mixture was deduced from the decrease of pressure measured at room temperature in the same volume. The O_2, Kr, SiF_4 mixture was then trapped at −210°C with a liquid nitrogen slush, and the oxygen pumped off. Its amount was deduced from the decrease of pressure measured at room temperature in the same volume and was found to correspond to 2.9 ± 0.2 oxygen atoms per initial Ru atom, indicating that one oxygen atom per Ru atom remained in the solid residue. The determination of the amounts of Kr and F_2 was not accurate enough to distinguish between the KrF_2 that had just been decomposed (with or without intermediary reaction with RuO_4) and that which had effectively fluorinated RuO_4. The excess of KrF_2 and HF was pumped off at −30°C, and the brown residue analysed for its Ru and F contents. *Anal.* calcd. for $RuOF_4$: Ru 52.35, F 39.36; found: Ru 52.35, F 39.15%.

Results and discussion

Fluorine was found to be not powerful enough to fluorinate RuO_4 at room temperature in HF solution, and a fluorinating agent as strong as KrF_2 had to be used.

The composition of the solid obtained was clearly identified as being $RuOF_4$. The compound is brown and very moisture sensitive. No significant rate of decomposition was observed after storage for a few hours at room temperature in a sapphire tube. The compound is not volatile at 0°C, and only slightly volatile at 20°C.

As expected, the X-ray powder pattern of $RuOF_4$ was found to be closely related to that of RuF_5 and the patterns of the two compounds are listed in Table 1.

The infrared spectrum of solid $RuOF_4$ was recorded and the region of the fundamental vibrations is shown in Fig. 1. Contrary to the spectrum reported by previous authors (5), a strong band appears at 900 cm^{-1} and is assigned to the Ru–O stretching vibration. The strong bands at 685 and 630 cm^{-1} are assigned to $Ru–F_{terminal}$ stretching vibrations, and the two bands at 540 and 514 cm^{-1} to $Ru–F_{bridged}$ stretching vibrations. Probably owing to the color of the compound, its Raman spectrum could not be recorded.

The structural unit of RuF_5 was shown (16) to consist of $(RuF_5)_4$ tetramers with the Ru ions occupying the corners of a rhombus. It may be inferred from the present observations that $RuOF_4$ has the same type of tetrameric unit. The ruthenium–oxygen stretching vibration, which is in the range expected (17) for a double bond, favors a fluorine-bridged type of arrangement in the tetramer.

In conclusion, the reaction between RuO_4 and KrF_2 in HF solution led to a compound that was unambiguously identified as $RuOF_4$. It should be stressed that both the X-ray powder pattern and the infrared spectrum of $RuOF_4$ were found to be different enough from those of RuF_5 to rule out the assumption that the product of the reaction consisted of a mixture of crystalline RuF_5 and noncrystalline RuO_4. Furthermore, as attested by the Raman spectra, the reaction, which was achieved in the presence of an excess of KrF_2, went to completion as far as RuO_4 is concerned, and no RuF_5 or RuF_6 derivatives such as $KrF^+RuF_6^-$, or $KrF^+Ru_2F_{11}^-$ (18) were observed. The formal reduction of ruthenium from the oxidation states +8 to +6 probably implies some intermediary ruthenium oxide fluoride in the oxidation states +8 or +7. Further studies on the system, especially regarding the reaction mechanism and the properties of $RuOF_4$, are now in progress.

Ethanol and ethylene both convert to gasoline over the pentasil zeolite catalyst, H-ZSM-5, at 250°C, but yields are lower for ethanol. Adding benzene produces different arrays of alkylbenzenes for the two feeds, propylbenzene being absent using ethanol feed but present using ethylene feed. Neither feed gives rise to toluene or xylene yield increments on adding benzene, showing methylating intermediates to be absent. Hence methylation of C_2 species is ruled out as a route to C_3 intermediate production, and cracking of built-up molecules must be invoked. These results may be understood by postulating stronger sorption of ethanol than of ethylene on the catalyst surface, blocking both carbon chain lengthening sites and cracking sites.

Key words: conversion, ethanol, ethylene, sequestration by benzene, H-ZSM-5.

DESMOND V. DASS et ALLAN L. ODELL. Can. J. Chem. **67**, 1732 (1989).

L'éthanol et l'éthylène se transforment en essence par passage sur un catalyseur zéolite pentasile H-ZSM-5 à 250°C, mais les rendements sont plus faibles dans le cas de l'éthanol. L'addition de benzène produit différents types d'alkylbenzènes dans les deux cas; il se forme du propylbenzène avec l'éthylène mais pas avec l'éthanol. Dans les deux cas, l'addition de benzène provoque une augmentation des rendements en toluène ou en xylène, prouvant ainsi l'absence d'une méthylation des intermédiaires. On a alors écarté la possibilité d'une méthylation des espèces en C_2 comme moyen d'accès aux composés intermédiaires en C_3, et on doit envisager le cracking des molécules formées. On peut comprendre ces résultats en envisageant une sorption plus forte de l'éthanol que de l'éthylène à la surface du catalyseur, bloquant à la fois les sites d'élongation des chaînes carbonées et les sites de cracking.

Mots clés : conversion, éthanol, éthylène, séquestration par le benzène, H-ZSM-5.

Introduction

Since 1986 synthetic gasoline has been produced on an industrial scale in New Zealand using the "Mobil" process. This process utilizes a synthetic pentasil zeolite catalyst, H-ZSM-5, which catalyses the conversion of methanol to a high octane gasoline in one process. The study of the steps in this complex reaction has given rise to an extensive literature. An exhaustive review (1) up to 1982 and a more recent survey in the form of Proceedings of a Symposium in Methane Conversion (2) (1988) provide an introduction to this field, which includes conversion studies on a variety of small molecules over H-ZSM-5.

Fort and Davis have shown (3) that when ethanol is converted over H-ZSM-5 in the presence of added benzene there is a large increase in the yield of ethylbenzene compared to the yield without benzene. They state "... benzene serves as an excellent trap for one or more precursors for chain growth." Our studies on the effect of adding benzene to converting systems led us to similar conclusions, and we have developed this method into the Benzene Sequestration Test (4) for reactive intermediates.

Novakova *et al.* (5, 6) have also utilized sequestration effects of benzene, as well as ethane, propane, and ethylene, to trap reactive intermediates in their temperature programmed desorption studies of methanol and ethanol transformations over zeolite catalysts.

While using the Benzene Sequestration Test to study conversion of C_2 feeds, we noticed interesting differences in product distributions when changing from ethylene feed to ethanol feed.

[1]Author to whom correspondence may be addressed.

Experimental

Mixtures of ethylene (MHSV 0.4 h^{-1}) and benzene (MHSV 0.1 h^{-1}) and of ethanol (MHSV 0.4 h^{-1}) and benzene (MHSV 0.1 h^{-1}) were converted over H-ZSM-5 using a range of temperatures in an apparatus previously described (7, 9).[2]

Yields of the major components in the resulting gasolines were measured by gas–liquid chromatography, and yields of alkylbenzenes with and without added benzene were recorded.

Results

Results, expressed as Δ_B values (increase in wt.% yield of various alkylbenzenes on adding benzene) are shown in Fig. 1 for ethylene feed and in Fig. 2 for ethanol feed, and yields of other products are reported in the text. All wt.% data exclude benzene. Results may be summarized as follows.

1. Conversion

Ethylene converts in the absence of benzene at 250°C to yield a typical gasoline mixture with a yield of 51.3 wt.% (excluding ethylene) leaving residual ethylene 48.7 wt.%.

Ethanol, under similar conditions, gives a smaller gasoline yield of 23.5% (excluding ethylene), an ethylene yield of 76.5 wt.%, and zero residue of ethanol.

2. Effect of adding benzene

(a) Ethylene feed

Little change was found in the yield of gasoline except for

[2]MHSV = Mass Hourly Space Velocity in grams of feed per gram of catalyst per hour.

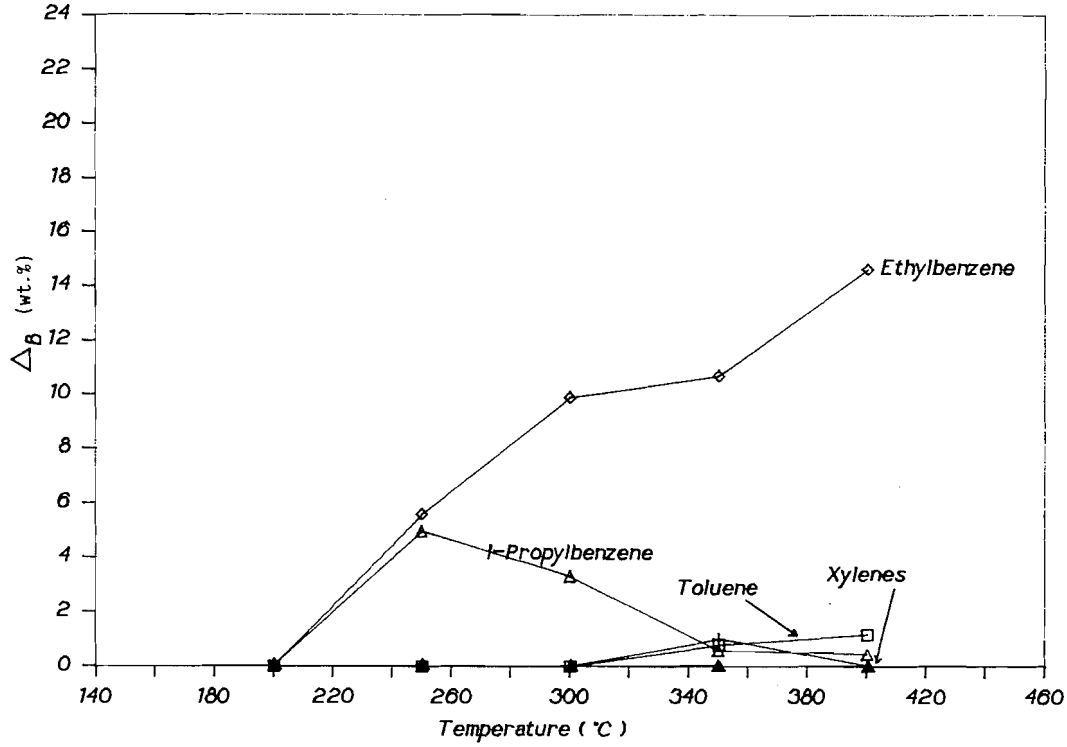

FIG. 1. Ethylene conversion with added benzene: aromatic yield increase vs. temperature.

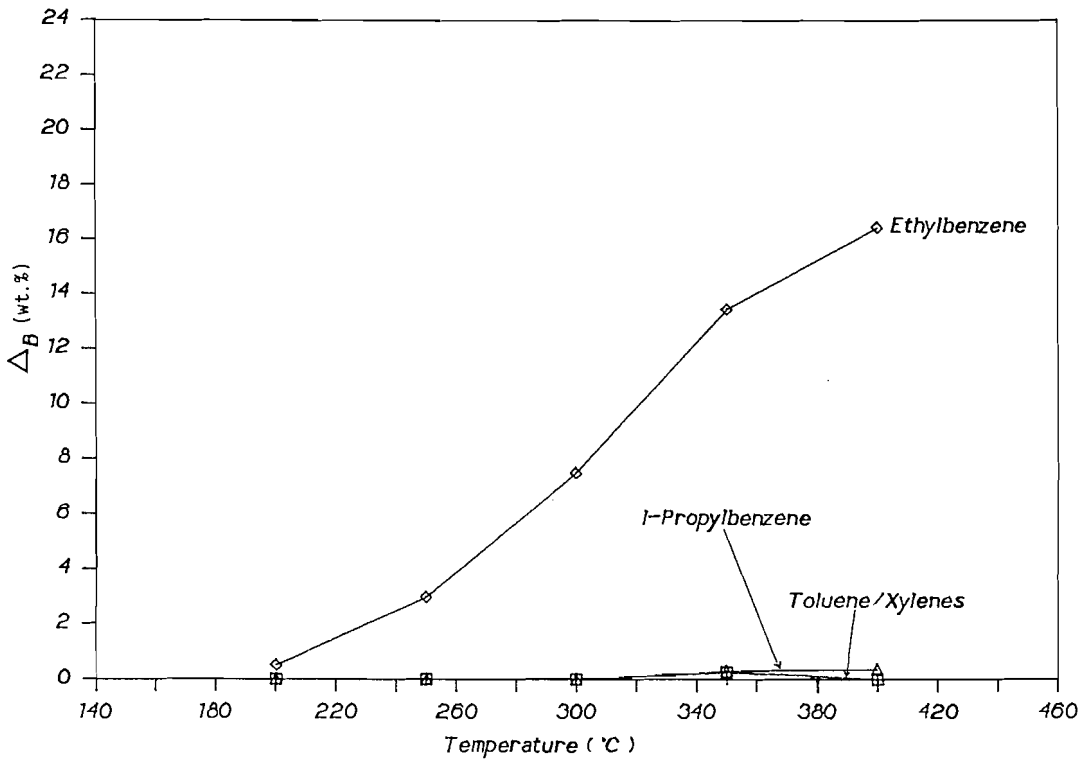

FIG. 2. Ethanol conversion with added benzene: aromatic yield increase vs. temperature.

the two components ethylbenzene and *i*-propylbenzene (see 3 below). Small changes were found in relative selectivities of other components of the resulting gasoline.

(b) Ethanol feed

A lowering of yields of gasoline components to between one half and two thirds of the yields found from benzene-free feed, except for ethylbenzene and *i*-propylbenzene (see 3 below). Small changes were found in relative selectivities of other components of the resulting gasoline.

3. Benzene Sequestration Test

(a) Ethylene feed

Large increments in yields of ethylbenzene and *i*-propylben-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

zene, i.e., large values for Δ_B (ethylbenzene) and Δ_B (*i*-propylbenzene).

(b) Ethanol feed

Large values for Δ_B (ethylbenzene) but Δ_B (*i*-propylbenzene) = 0. Small but measurable values for Δ_B (diethylbenzene).

These studies were extended to cover a range of temperatures from 140 to 400°C and results are shown in Figs. 1 and 2.

Discussion

Important features of these results are (*i*) the large value of Δ_B (ethylbenzene) found for both ethylene and ethanol feeds, showing abundance of a reactive C_2 intermediate, which increases with temperature. We shall refer to this species as C_2*; (*ii*) the contrast between the high values observed for Δ_B (*i*-propylbenzene) from ethylene feed and the zero values observed using ethanol feed.

As usual (4), Δ_B (*i*-propylbenzene) values fall off sharply above 300°C due to the instability of *i*-propylbenzene in the presence of the catalyst at such temperatures. Clearly, a C_3* type intermediate is abundant in the conversion of ethylene at least below 300°C, and possibly above this temperature also. Such a species is absent during the conversion of ethanol.

Another interesting feature is the absence of any "one carbon" reactive intermediate, C_1*, as shown by the fact that Δ_B values for toluene and for xylenes are zero at temperatures up to 300°C for both ethylene and ethanol feeds and very small above this temperature for both feeds. We conclude that methylation is absent in this system and that the C_3* intermediate found in ethylene conversion is not produced by methylation of C_2* or of any other C_2 species. Indeed, the increase in yield of *i*-propylbenzene observed on adding benzene to converting ethylene must be attributed to the production of C_3* by the cracking of larger molecules in the product mixture (10), rather than to methylation of C_2 species, since methylation is absent.

While yields of such built-up products are certainly lowered when benzene is added to converting ethanol (see 2(*b*) above), they are not lowered to zero. Hence some C_3* would be expected from cracking of these products. None is found.

Furthermore, high yields of ethylene found in converting ethanol (74 wt.% at 250°C) would be expected to give products obtained from the conversion of ethylene, including *i*-propylbenzene after the addition of benzene. That this species is not seen calls for a more specific explanation than a small general lowering of yields when benzene is added to converting ethanol.

We suggest that these effects may be accounted for by supposing that the more polar ethanol blocks sites on the catalyst used for chain lengthening or those used for cracking larger molecules in a manner not found in the conversion of ethylene. This blocking of chain lengthening sites must be partial since, in the case of ethanol feed, yields of gasoline components are lowered to only about one half of those found for ethylene conversion. Blocking of cracking sites, however, appears to be virtually complete if the zero values for Δ_B (*i*-propylbenzene) in ethanol conversion are to be understood. Above 300°C, however, some small amount of cracking appears.

It is interesting to recall that it has been argued (8) that information concerning reaction paths utilized by converting alkenes may be obtained working from experiments carried out on the corresponding alcohols. In the case of ethylene, at least, it is now clear that it is not safe to assume (8) that the alcohol is instantly dehydrated to the corresponding alkene and that all features of ethylene conversion will be the same as those of ethanol conversion. Not only are yields different, but some reactive intermediates, revealed by the Benzene Sequestration Test in conversion of the alkene, are entirely absent in the case of the converting alcohol. This principle may well apply to the higher alcohols.

These results illustrate something of the usefulness of the Benzene Sequestration Test.

A number of dithiocarbamate derivatives $Ph_2Te[S_2CNR_2]_2$, where R = Me, Et, and $Ph_2TeCl[S_2CNR_2]$, where R = Me, Et, *i*-Pr, have been prepared and characterized initially by analysis and vibrational spectroscopy. Three crystal structures have been completed that allow for comparisons of the effect of the change in the nature of R and of the presence of a chlorine atom. The dithiocarbamate groups are monodentate (or anisobidentate) and the geometry about tellurium is consistently that of a distorted sawhorse structure. Examples of both inter- and intra-molecular Te...S interactions are observed as well as an intermolecular Te...Cl interaction. The crystal structures of $Ph_2Te[S_2CNMe_2]_2$ **1**, $Ph_2TeCl[S_2CNEt_2]\cdot\frac{1}{2}CS_2$ **4** and $Ph_2TeCl[S_2CN(i\text{-}Pr)_2]$ **5** were determined. The cell parameters for **1** are a = 20.158(5) Å, b = 8.632(2) Å, c = 12.727(4) Å, β = 92.70(2)°, V = 2212(1) Å^3, Z = 4, R = 0.0221, and R_w = 0.0243; for **4** are a = 11.198(4) Å, b = 13.974(4) Å, c = 13.812(5) Å, α = 99.56(2)°, β = 103.08(3)°, γ = 87.39(3)°, V = 2076(1) Å^3, Z = 4, R = 0.0363, and R_w = 0.0398; and for **5** are a = 12.736(3) Å, b = 8.397(1) Å, c = 21.961(1) Å, β = 117.36(1)°, V = 2086(7) Å^3, Z = 4, R = 0.0266, and R_w = 0.0312. NMR spectra are not simple and indicate that several species are present in solution.

Key words: structure, tellurium, chloro, diphenyl, dialkyldithiocarbamato.

JANE H. E. BAILEY, JOHN E. DRAKE, ANIL B. SARKAR et MARIA L. Y. WONG. Can. J. Chem. **67**, 1735 (1989).

On a préparé une série de dérivés dithiocarbamates $Ph_2Te[S_2CNR_2]_2$, où R = Me, Et et $Ph_2TeCl[S_2CNR_2]$, où R = Me, Et, *i*-Pr, et on les a caractérisés initialement par analyse et par spectroscopie vibrationnelle. On a complété trois structures cristallines qui tiennent compte de l'effet des changements dans la nature de R et de la présence d'un atome de chlore. Les groupes dithiocarbamates sont monodentates (ou anisobidentates) et la géométrie autour du tellure est essentiellement celle d'une structure déformée de type chevalet. On a relevé des exemples d'interactions inter et intramoléculaires Te...S aussi bien que des interactions intermoléculaires Te...Cl. On a déterminé les structures cristallines du $Ph_2Te[S_2CNMe_2]_2$ **1**, $Ph_2TeCl[S_2CNEt_2]\cdot\frac{1}{2}CS_2$ **4** et du $Ph_2TeCl[S_2CN(i\text{-}Pr)_2]$ **5**. Le composé **1** a les paramètres de maille suivants : a = 20,158(5) Å, b = 8,632(2) Å, c = 12,727(4) Å, β = 92,70(2)°, V = 2212(1) Å^3, Z = 4, R = 0,0221 et R_w = 0,0243; le composé **4** a les paramètres suivants : a = 11,198(4) Å, b = 13,974(4) Å, c = 13,812(5) Å, α = 99,56(2)°, β = 103,08(3)°, γ = 87,39(3)°, V = 2076(1) Å^3, Z = 4, R = 0,0363 et R_w = 0,0398; les paramètres du composé **5** sont a = 12,736(3) Å, b = 8,397(1) Å, c = 21,961(1) Å, β = 117,36(1)°, V = 2086(7) Å^3, Z = 4, R = 0,0266 et R_w = 0,0312. Les spectres de RMN ne sont pas simples et indiquent la présence de plusieurs espèces en solution.

Mots clés : structure, tellure, chloro, diphényl, dialkyldithiocarbamato.

[Traduit par la revue]

Introduction

Dithiocarbamate complexes have been extensively studied (1–7). The dithiocarbamate group frequently acts in a bidentate fashion (3–7), and examples can be cited both for transition metals such as cobalt in $Co[S_2CNMe_2]NO$ (8), and copper in $Cu_4[S_2CNEt_2]_4$ (9), as well as for main group elements such as tin in $C_4H_9Sn[S_2CNEt_2]_2$ (10). Examples of monodentate dithiocarbamates are relatively fewer in transition metal chemistry, where they usually occur in mixed ligand complexes such as $Pt[S_2CN(i\text{-}Bu)_2]_2[P(Me_2)Ph]_2$ (11). We have reported on several dithiocarbamates of germanium in which monodentate (or anisobidentate) bonding is consistently found (12–15). In some instances changes in mode of attachment have been noted with variation of the alkyl group of the dithiocarbamate, as illustrated by $Zn[S_2CNMe_2]_2$ in which the dithiocarbamate groups are both bidentate and bridging (16), and $Zn[S_2CNEt_2]_2$ where both of the dithiocarbamate groups are bidentate and the molecule is monomeric (17).

We have prepared the tellurium dithiocarbamate derivatives $Ph_2Te[S_2CNR_2]_2$, where R = Me, Et, and $Ph_2TeCl[S_2CNR_2]$, where R = Me, Et, *i*-Pr. All compounds were characterized by elemental analysis and vibrational spectroscopy and several structural determinations were completed by X-ray crystallography.

Experimental

Materials

$TeCl_4$, Ph_4Sn, NaS_2CNMe_2, NaS_2CNEt_2, diisopropylamine, toluene, diethyl ether, and petroleum ether were obtained from Aldrich. All but toluene, which was distilled, were used as supplied. Carbon disulfide (BDH) was distilled from P_4O_{10} prior to use, whereas ethanol and methylene chloride were used as supplied by BDH.

Synthesis of $NaS_2CN(i\text{-}Pr)_2$

Sodium hydroxide (3.96 g) was dissolved in ethanol (15 mL) followed by the addition of distilled CS_2 (3.67 g). Diisopropylamine (9.61 g) was introduced slowly at the rate of 2 drops/s, while nitrogen gas was bubbled through the mixture at a rate of 3 bubbles/s. The system was heated at 20°C for 1 h. The desired product, sodium *N*,*N*-diisopropyldithiocarbamate (8.47 g; 42.56%) was filtered, washed with cold diethyl ether, and dried in vacuum (1).

Synthesis of Ph_2TeCl_2

An equimolar mixture of tetraphenyltin (4.56 g) and tellurium tetrachloride (2.87 g) in toluene (20 mL) was refluxed at 60°C for 12 h and worked up in the manner previously described (18).

*Synthesis of diphenylbis(*N,N*-dialkyldithiocarbamato)tellurium(IV)*

Typically, sodium *N,N*-dimethyldithiocarbamate (0.25 g), which had been previously well dried *in vacuo* for 3–4 days, was added to an excess of carbon disulfide (approximately 12 mL). Diphenyltellurium dichloride (0.62 g) was added to the solution, which was then refluxed at 45°C for 3 h while nitrogen gas bubbled through at a rate of 3 bubbles/s. The solution was filtered to remove sodium chloride and any unreacted materials. A few drops of petroleum ether were added to the solution before it was left in the refrigerator to crystallize. After approximately 3 days, the product, $Ph_2Te[S_2CNMe_2]_2$, was filtered, washed with cold *n*-hexane, and dried in vacuum; 0.73 g; 79% yield; yellow crystals; mp 132°C. *Anal.* calcd. for $C_{18}H_{22}N_2S_4Te$: C 41.40, H 4.25, N 5.36; found: C 41.99, H 4.35, N 5.96%. Similarly was formed $Ph_2Te[S_2CNEt_2]_2$, pale yellow crystals; mp 140°C. *Anal.* calcd. for $C_{22}H_{30}N_2S_4Te$: C 45.69, H 5.25, N 4.84; found: C 45.56, H 5.25, N 4.93%).

*Synthesis of chlorodiphenyl(*N,N*-dialkyldithiocarbamato)tellurium(IV)*

Typically, an equimolar mixture of sodium *N,N*-dimethyldithiocarbamate (0.13 g), which had been previously dried as described above, and diphenyltellurium dichloride (0.62 g) was refluxed in excess of methylene chloride or carbon disulfide (approximately 10 mL) at 41°C for 3 h. Nitrogen gas was bubbled through at a rate of 3 bubbles/s during the reflux. The solution was then filtered to remove any excess material and placed in the refrigerator to crystallize. The ethyl and isopropyl derivatives were obtained in a similar manner: $Ph_2TeCl[S_2CNMe_2]$, pale green crystals, mp 124°C. *Anal.* calcd. for $C_{15}H_{16}ClNS_2Te$: C 41.18, H 3.69, N 3.20; found: C 41.07, H 3.60, N 3.17%; $Ph_2TeCl[S_2CNEt_2]\cdot\frac{1}{2}CS_2$, pale green crystals; mp 95°C. *Anal.* calcd. for $C_{17.5}H_{20}ClNS_3Te$: C 41.74, H 4.00, N 2.78; found: C 42.03, H 3.98, N 2.98%; and $Ph_2TeCl[S_2CN(i\text{-}Pr)_2]$, yellow crystals: mp 144°C. *Anal.* calcd. for $C_{19}H_{24}ClNS_2Te$: C 46.24, H 4.90, N 2.84; found: C 46.21, H 4.71, N 3.05%.

Physical measurements

All solvents were dried and distilled prior to use. The elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario. Density measurements were performed by the flotation method in CCl_4/CH_3I. The infrared spectra were recorded on a Nicolet 5DX FT spectrometer as CsI pellets. Samples for Raman spectrometry were sealed in capillary tubes and the spectra recorded on a Ramanor U-1000 spectrometer using the 4880 Å exciting line. The ^{1}H NMR spectra were recorded on a Bruker AC 300 spectrometer in CS_2 or $CDCl_3$ solutions using tetramethylsilane as internal standard. The same instrument was used to record the $^{13}C\{^1H\}$ NMR spectra. The melting points were determined on a Fisher–Johns apparatus.

X-ray crystallographic analysis

X-ray diffraction data were collected on a Syntex $P2_1$ diffractometer by the procedure already described in detail (13). In each case the crystal was sealed in a capillary and mounted along the largest dimension. The least-squares refinement of the setting angles of 35 high-angle reflections ($15° > 2\theta > 30°$) led to the cell dimensions given in Table 1. The appropriate space group was used in each case and later assumed correct because of successful refinement of the data. During data collection, the intensities of three monitor reflections measured after 200 reflections decreased in the range of approximately 2–4% and the appropriate scaling factor was applied. Each set of data was corrected for Lorentz and polarization effects, and an empirical absorption correction was applied but resulted in no significant changes

in refinement. The ranges of absorption correction factors were 0.945–0.993 for **1** and 0.937–0.957 for **5**. A summary of crystal and refinement data is given in Table 1.

The position of the tellurium atom was determined by a sharpened Patterson synthesis using SHELX, and difference maps revealed the remaining atoms. Tellurium, sulfur, nitrogen, and, where appropriate, chlorine atoms were refined anisotropically. Limitations on data in two cases allowed the anisotropic refinement of carbon atoms other than those in the phenyl rings. Hydrogen atoms were included at the idealized positions (C—H = 0.95 Å; HCH and CCH (for ethyl and isopropyl) = 109.5°; CCH = 120° (for phenyl rings)) with isotropic U values set at approximately 0.01 Å^2 greater than the corresponding carbon atom. Complete refinement by full-matrix least-squares methods minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ converged satisfactorily in all three cases at $R = 0.0221$ and $R_w = 0.0243$ for **1**; $R = 0.0363$ and $R_w = 0.0398$ for **4**; and $R = 0.0266$ and $R_w = 0.0312$ for **5**. A weighting scheme of the form $w = 1/\Sigma[\sigma^2(F) + pF_2]$ was employed with final p values of 0.00048 for **1**; 0.00036 for **4**; and 0.00001 for **5** respectively. No evidence was found of reflections being affected by secondary extinctions.

The final fractional coordinates for non-hydrogen atoms of **1**, **4**, and **5** are listed in Tables 2, 3, and 4 respectively. Anisotropic (Te, S, N, Cl, and all C atoms not in the phenyl ring) and isotropic (C) thermal parameters for non-hydrogen atoms are listed in Tables 5, 6, and 7 respectively for **1**, **4**, and **5**. All molecules were thus subjected to the same degree of refinement and in all cases NP/P was greater than 9. Important bond lengths and angles are given in Tables 8 and 9. The molecular structures of each of the compounds are given in Figs. 1–3. Tables of final fractional coordinates and thermal parameters of hydrogen atoms as well as tables of observed and calculated structure factors have been deposited.[2]

Results and discussion

The diphenyltellurium(IV) derivatives are made by the reaction of diphenyltellurium dichloride with the sodium salt of the appropriate *N*,*N*-dialkyldithiocarbamic acid.

$$Ph_2TeCl_2 + NaS_2CNR_2 \rightarrow Ph_2TeCl[S_2CNR_2] + NaCl$$

(R = Me, Et, *i*-Pr)

$$Ph_2TeCl_2 + 2NaS_2CNR_2 \rightarrow Ph_2Te[S_2CNR_2]_2 + 2NaCl$$

(R = Me, Et)

With the sodium salt added in equimolar amounts, the chlorodiphenyl(*N*,*N*-dialkyldithiocarbamato)tellurium(IV) derivatives can be isolated in yields of up to 75%. The methyl and ethyl derivatives form pale green crystals, while those of the isopropyl derivative have a more yellow tinge. With an excess of sodium salt the diphenylbis(*N*,*N*-dialkyldithiocarbamato)tellurium(IV) compounds are also prepared in up to 75% yields for the methyl and ethyl derivatives, whose crystals are best described as yellowish. Attempts to prepare pure samples of the bis isopropyl derivative were not successful even with larger excesses of the sodium salt.

The crystal structure of $Ph_2Te[S_2CNMe_2]_2$ *1*

This compound crystallizes as discrete molecular units in the space group $C2/c$, containing a crystallographic twofold axis (Fig. 1). The geometry about tellurium can be described as being that of a distorted sawhorse structure based on a distorted trigonal bipyramid in which a lone pair occupies an equatorial position. The structure bears a strong resemblance to that of $Ph_2Te[S_2P(OMe)_2]_2$ (19), in that the sulfur-containing groups are monodentate with the bonding sulfur atoms occupying the axial positions. The S1—Te—S1′ angle in **1** is 172.0(1)°, comparable to 171.8(1)° in the dithiophosphate. In **1**, the Te—S bond length of 2.621(1) Å is essentially the same as those reported for the dithiophosphate (19). The carbon atoms of the two phenyl groups attached to tellurium occupy two of the equatorial positions with a C—Te—C angle of 99.4(1)° and a Te—C distance of 2.140(5) Å in **1**, again comparable to the angle of 98.5(2)° and length of 2.133(5) and 2.136(5) Å in the dithiophosphate.

The two dithiocarbamate groups are positioned in such a way that the nonbonded sulfur atoms approach the tellurium atom at a distance of 3.186(2) Å. This distance is shorter than the previously reported Te—S distances of a similar type such as 3.383(2) and 3.362(2) Å in $Ph_2Te[S_2P(OMe)_2]_2$ (19), 3.225(3) Å in $(PhN_2C_6H_4)Te(S_2CNMe_2)$ (20), and 3.228(4) Å in $PhTe[S_2CNEt_2]_3$ (21), and is also considerably shorter than the sum of the van der Waals distances of 4.05 Å. This type of linkage is probably better described as being anisobidentate rather than simply monodentate. However, as with $Ph_2Te[S_2P(OMe)_2]_2$, the suggestion that these secondary interactions complete a distorted octahedral geometry around the tellurium atom is less attractive when it is noted that these secondary sulfur atoms are considerably above and below the plane formed by the two carbon atoms and the tellurium atom by approximately 1.86 Å. Thus, the secondary bonds appear to be formed in positions to allow them to avoid a stereochemically active lone pair.

The similarities to a Ph_2TeL_2 species with a different sulfur ligand are striking when comparisons are drawn with $PhTe[S_2CNEt_2]_3$ with the same family of ligands (21). In $PhTe[S_2CNEt_2]_3$, the tellurium atom is described as being bonded to all six sulfur atoms, leading to a distorted pentagonal bipyramidal configuration (21). Two dithiocarbamate groups are bidentate with all four sulfur atoms in the equatorial plane, giving similar Te—S bond lengths of 2.701(3), 2.797(3),

2.816(3), and 2.657(3) Å. The shortest of these is longer, but not considerably longer, than the Te—S distances of 2.621(1) Å for the axial bonds in **1**. There is a fifth sulfur atom in the equatorial plane of $PhTe[S_2CNEt_2]_3$ giving the shortest Te—S bond of 2.606(3) Å. The second sulfur atom of this third ligand lies in an approximately axial position with a Te—S distance of 3.228(4) Å, which is longer than, but of the same order as, the secondary bonding distance of 3.186(2) Å in the anisobidentate ligands of **1**. Interestingly, the C—Te—S angle to the secondary bonded sulfur atom in $PhTe[S_2CNEt_2]_3$ is 144.6(2)°, which is very similar to the corresponding angle in **1** of 144.4(1)°. Similarly, the C—Te—S angles to the bonded sulfur atoms in **1** are 83.3(1) and 91.5(1)°, values that are close to those in $PhTe[S_2CNEt_2]_3$, which range from 84.2(2) to 93.7(3)°.

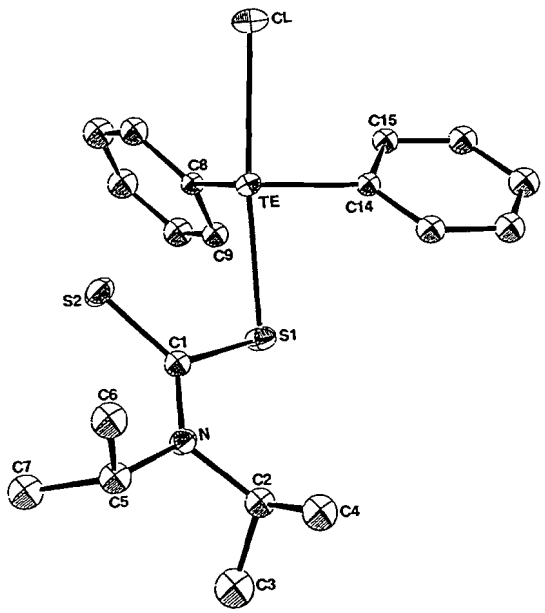

FIG. 3. ORTEP plot of the molecule $Ph_2TeCl[S_2CN(i\text{-}Pr)_2]$ **5**. The atoms are drawn with 20% probability ellipsoids. Hydrogen atoms are omitted for clarity.

The structure of a tellurium(II) compound, $(PhN_2C_6H_4)Te(S_2CNMe_2)$, that contains a dimethyldithiocarbamate group has been reported (20). The dimethyldithiocarbamate group is again anisobidentate with Te—S distances of 2.568(2) and 3.225(3) Å. The sums of the two Te—S linkages of this type are thus 5.807 Å in **1**, 5.834 Å in $PhTe[SCNEt_2]_3$, and 5.793 Å in $C_6H_4N_2PhTeS_2CNMe_2$. The S—Te—S bite angle is 61.0(1)° in **1**, which is similar to the corresponding angle of 60.9(1)° in the tellurium(II) compound and that of the anisobidentate ligand in the tris compound of 60.5(1)°. All the bite angles are larger in the fully bidentate ligands in $PhTe[S_2CNEt_2]_3$, being 64.76(9) and 65.04(8)° (21).

The C1—S1 and C1—S2 distances of 1.738(5) and 1.678(5) Å respectively in **1** are as expected for an anisobidentate or monodentate ligand and are comparable to the values of 1.73(2) and 1.67(1) Å for the anisobidentate ligand in $PhTe[S_2CNEt_2]_3$ (21) and of 1.736(9) and 1.679(9) Å in the tellurium(II) compound (20). However, the two different C—S bond lengths are also observed in one of the bidentate ligands in $PhTe[S_2CNEt_2]_3$ where values of 1.748(9) and 1.69(1) Å were reported, although in the other bidentate ligand the two C—S distances are essentially identical at 1.721(9) and 1.722(9) Å (21). The same lack of clear differential between monodentate and bidentate ligand appears to extend to the partially double

[c]Probably overlapping with the phenyl ring vibration (p).
[d]For the "bis" species, there are both *sym* and *asym* modes.

C···N bond. In all cases it is of course shorter than the single C—N bond. In the anisobidentate ligands in **1**, the tellurium(II) compound, and $PhTe[S_2CNEt_2]_3$ the C···N bond is 1.333(6), 1.34(1) Å (20), and 1.39(1) Å (21) respectively with the C—N single bonds being 1.432(7) and 1.471(8) Å, 1.46(1) and 1.47(1) Å (20), 1.49(2) and 1.61(2) Å (21) respectively. However, the bidentate ligand bond lengths in $PhTe[S_2CNEt_2]_3$ are very similar, being 1.34(1) and 1.33(1) Å for N···C and 1.48(1), 1.52(2), 1.49(1), and 1.48(1) Å for the C—N single bonds (21).

*The crystal structures of $Ph_2TeCl[S_2CNEt_2]\cdot\frac{1}{2}CS_2$ **4** and $Ph_2TeCl[S_2CN(i\text{-}Pr)_2]$ **5***

The ethyl derivative crystallizes out with CS_2 contained in the lattice so that the two derivatives are in different crystal systems and space groups, triclinic and $P\bar{1}$ for **4** and monoclinic and $P2_1/c$ for **5**. However, the two independent molecules in **4** and the molecular unit of **5** have the same distorted sawhorse structure about tellurium described for **1** with a Te—Cl bond replacing an axial Te—S bond. The Te—Cl bond is considerably longer than the Te—S bond in these molecules. The Te—Cl bonds, 2.638(1) and 2.616(2) Å in the two independent molecules in **4** and 2.661(2) Å in **5**, are also considerably longer than has been generally observed in R_2TeCl_2 species (22), where for seven species with six different R groups the shortest Te—Cl bond was 2.47(1) and the longest was 2.576(3) Å (22).

In **4** the molecules are packed together in such a way that there is no secondary Te···Cl interaction with an adjacent molecule. However, in **5** the chlorine atom is only 3.305 Å from the tellurium atom of an adjacent molecule and this may account for the longer Te—Cl primary bond. The Cl—Te—S bond angles of 172.0(1), 168.7(1)° in **4** and 173.2(1) in **5** compare well with the corresponding S—Te—S angle of 172.0(1)° in **1**.

In both compounds the dithiocarbamate groups are anisobidentate as they are in **1**. The Te—S bond distances of 2.516(1) and 2.513(2) Å in **4** and 2.484(2) Å in **5** are considerably shorter than those observed in **1**, $PhTe[S_2CNEt_2]_3$, or the tellurium(II) compound. The shorter bond is not unexpected when comparing a Te(IV) to a Te(II) compound (20), and the closer approach compared to the tris compound could be associated with the relative crowding in the latter where the five Te—S bonds are essentially in one plane and two of the ligands are bidentate (21). The association of the longer Te—Cl bond with the shorter Te—S bond in **5** could be a reflection of the degree to which the compounds are approaching a structure of the form $[Ph_2Te(S_2CNR_2)]^+Cl^-$.

The Te—C bond lengths of 2.114(6) and 2.124(6) Å in **4** and 2.137(5) Å in **5** are also slightly shorter than in **1**. The C—Te—C angles of 98.2(2) and 98.5(2)° in **4** and 96.0(2)° in **5** are comparable to that of **1**. The secondary Te···S interactions at 3.112(2) and 3.184(1) Å for **4** and 3.149(2) Å for **5** are similar to those in **1**. The sum of the Te—S and Te···S distances for each linkage is 5.628 and 5.697 Å for **4** and 5.633 Å for **5**, which is less than, but of the same order as, that noted for **1**, so that the bonding, around tellurium as a whole, does appear to be slightly tighter in the chlorinated derivatives. The bite angles of each of the anisobidentate ligands are similar, being 62.5(1) and 61.8(1)° for **4**, 62.0(1)° for **5**, and 61.0(1)° for **1**. In addition, the C—Te···S angles, which were noted in **1** to be 144.4(1)°, are 146.7(1), 145.1(2)° in **4** and 147.1(1)° in **5**. The secondary S atom is again well out of the plane formed by tellurium and the two carbon atoms attached to it by approximately 1.71 and 1.82 Å in **4** and 1.67 Å in **5** comparable to 1.86 Å in **1**. The position occupied by the second secondary-bonded S atom in **1** is approximately the position taken up by a secondary-bonded S atom of an *adjacent* molecule in **4** at a distance of 3.825(2) and 3.656(2) Å respectively for the two independent molecules. The four atoms Te1—S2—Te1″—S2″ or Te2—S4—Te2″—S4″ form planes with S2—Te1—S2″ or S4—Te2—S4″ angles of 83.8(1)° or 86.2(1)° respectively and Te1—S2—Te1″ or Te2—S4—TeS2″ angles of 96.2(2)° or 93.8(2)° respectively. By contrast, in **5**, as mentioned above, the closest interaction between molecules involves the chlorine atoms rather than a sulfur atom.

The C—S (bonded) distances in the two chlorinated derivatives of 1.760(6), 1.763(5) Å for **4** and 1.788(6) Å for **5** are all longer than found in **1** or in the anisobidentate and bidentate ligands in $PhTe(S_2CNEt_2)_3$ (21), or the tellurium(II) compound (20). However, the C—S (secondary-bonded) distances are very similar to those reported for the other compounds, being close to the value of 1.68 ± 1 at 1.669(6), 1.675(5) Å for **4** and 1.660(6) Å for **5**, the C···N bond lengths of 1.325(7), 1.319(7) Å in **4** and 1.329(7) Å in **5** are slightly shorter than those in **1** and previously reported compounds, reflecting the tighter bonding associated with the chloro derivatives. Indeed, the presence of chlorine indicates some sort of trend whereas changing R groups in the dithiocarbamate does not.

Vibrational spectra

Features that are considered characteristic of dithiocarbamate derivatives are listed in Table 10. The well-known phenyl vibrations (23) are of course excluded from the table but their presence makes the spectra very "busy". The N···C stretching vibration is typically assigned to a feature in the region of

TABLE 11. ^1H and ^{13}C chemical shifts in the NMR spectra of compounds **1–5**[a]

	C_6H_5	N–C*H*	C–CH_3	C_6H_5	N–*C*H	C–*C*H$_3$
$Ph_2Te[S_2CNMe_2]_2$ **1**	8.0,7.4m(10H)	3.5b(12H)	—	135.8,130.0,129.6	43.9	—
$Ph_2TeCl[S_2CNMe_2]$ **2**	8.2,7.7m(10H)	3.8b(6H)	—	133.0,130.6,129.0	44.8	—
$Ph_2Te[S_2CNEt_2]_2$ **3**	7.8,7.3m(10H)	3.7b(8H)	1.2m(12H)	135.6,130.0,129.8	48.7	13.0
$Ph_2TeCl[S_2CNEt_2]$ **4**	7.9,7.4m(10H)	3.7b(4H)	1.2m(6H)	135.0,130.8,129.8	49.1	12.9
$Ph_2TeCl[S_2CN(i\text{-}Pr)_2]$ **5**	7.9,7.3m(10H)	n.o.[b](2H)	1.4b(12H)	134.9,130.6,129.6	n.o.	20.5

[a]Number of hydrogen atoms given in parentheses; m = multiplet, b = broad.
[b]n.o. = not observed.

1450–1550 cm^{-1}. It appears that the compounds containing a Te—Cl bond generally show the band at a higher wave number than the related bis compound. This is consistent with the shorter C···N bond being found in **4** and **5**. There is no obvious dependence in any of the characteristic features in the spectra on the nature of R in the R_2NCS_2 group. Any shifts in the positions of ν(C—S) are more probably associated with vibrational interactions than with structural effects. The ν(Te—S) region is very distinctive, as is typical for many metal–sulfur bonds, and well separated from other vibrations. The values of ν(Te—S) in the Raman effect at 365, 375, and 389 cm^{-1} respectively for **1**, **4**, and **5** correspond to Te—S bond lengths of 2.621(1) Å in **1**, 2.516(1) and 2.513(2) Å in **4**, and 2.484(2) Å in **5**. The assignment of the Te—Cl stretching vibration to 212, 199, and 189 cm^{-1} in **2**, **4**, and **5** respectively is at an unusually low wave-number region but is consistent with the presence of the very long Te—Cl bonds of 2.638(1) and 2.616(2) Å in **4** and 2.661(2) Å in **5**. These results can be compared to the assignments of the ν(Te—Cl) symmetric and asymmetric modes in Me_2TeCl_2 at 281 and 248 cm^{-1} (24), and Ph_2TeCl_2 at 287 and 267 cm^{-1} (25), where the Te—Cl bond lengths are reported to be much shorter, within the range of 2.48–2.54 Å (23).

The NMR spectra of all compounds gave results inconsistent with the existence of one compound in solution. The compounds are not particularly soluble but attempts were made to record the spectra in $CDCl_3$ and CS_2. The latter solvent seemed more appropriate because this was the medium from which the pure crystals were recrystallized. Typically for the $Ph_2Te[S_2CNR_2]_2$ species, the predominant peaks in the ^1H and ^{13}C NMR spectra were consistent with the presence of Ph_2Te and the dimer of the ligand, $[S_2CNR_2]_2$, rather than the complex $Ph_2Te[S_2CNR_2]_2$, particularly if there was any time lapse between making up the solution and recording the spectra. However, it was possible to also identify the peaks attributable to $Ph_2Te[S_2CNR_2]_2$ species, particularly when the spectra were recorded immediately after they were made up. While it is clear that the $Ph_2Te[S_2CNR_2]_2$ species ultimately decompose to form Ph_2Te and $[S_2CNR_2]_2$, the spectra suggest that a second isomeric form of the bis-ligated compound could be an intermediate. For the $Ph_2TeCl[S_2CNR_2]_2$ species, the NMR spectra are even more complex because disproportionation to Ph_2TeCl_2 and $Ph_2Te[S_2CNR_2]_2$ is obviously also taking place, along with the subsequent decomposition of the bis-ligand compound.

Protium–deuterium exchange of alkylated benzenes in dilute acid at elevated temperatures

NICK HENRY WERSTIUK AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received March 16, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **67**, 1744 (1989).

Benzene (**1**), toluene (**2**), *o*-xylene (**3**), *m*-xylene (**4**), *p*-xylene (**5**), 1,2,3-trimethylbenzene (**6**), 1,2,4-trimethylbenzene (**7**), 1,3,5-trimethylbenzene (**8**), 1,2,3,4-tetramethylbenzene (**9**), 1,2,3,5-tetramethylbenzene (**10**), 1,2,4,5-tetramethylbenzene (**11**), pentamethylbenzene (**12**), hexamethylbenzene (**13**), hexaethylbenzene (**14**), ethylbenzene (**15**), and tetralin (**16**) have been labelled with deuterium by the high temperature – dilute acid (HTDA) method. In dilute DCl/D_2O (0.14–0.27 M) at temperatures of 250–285°C, the ring hydrogens of these compounds equilibrate with the deuterium pool. At temperatures above 250°C the methyl groups of **3**, **4**, **5**, **6** and **11** undergo slow H/D exchange; the methyl groups of **8**, **9**, **10**, and **13** undergo exchange much more readily and hexamethylbenzene (**13**) can be readily perlabelled. Hexamethylbenzene exhibits a lower reactivity than **13** at the benzylic sites.

Key words: deuterium, exchange, alkyl groups, benzenes, acid-catalyzed.

NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **67**, 1744 (1989).

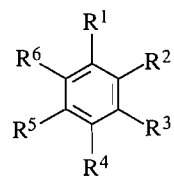
Utilisant la méthode faisant appel à un acide dilué et à une température élevée (ADTE), on a marqué les molécules suivantes avec du deutérium : la benzène (**1**), la toluène (**2**), les *o*- (**3**), *m*- (**4**) et *p*- (**5**) xylènes, les 1,2,3- (**6**), 1,2,4- (**7**) et 1,3,5- (**8**) triméthylbenzènes, les 1,2,3,4- (**9**), 1,2,3,5- (**10**) et 1,2,4,5- (**11**) tétraméthylbenzènes, le pentaméthylbenzène (**12**), l'hexaméthylbenzène (**13**), l'hexaéthylbenzène (**14**), l'éthylbenzène (**15**) et la tétraline (**16**). À des températures allant de 250 à 285°C, dans du DCl/D_2O (0,14–0,27 M), les hydrogènes des cycles de ces composés s'équilibrent avec le bassin de deutérium. À des températures supérieures à 250°C, les hydrogènes des groupements méthyles des composés **3**, **4**, **5**, **6** et **11** subissent un échange lent des H/D; les groupements méthyles des composés **8**, **9**, **10** et **13** subissent des échanges beaucoup plus rapides et l'hexaméthylbenzène (**13**) peut facilement être perdeutéré. Les sites benzyliques de l'hexaméthylbenzène présentent une réactivité qui est plus faible que celle du composé **13**.

Mots clés : deutérium, échange, groupements alkyles, benzènes, catalyse acide.

[Traduit par la revue]

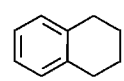
Introduction

In our continuing investigation of hydrogen isotope exchange by the high temperature – dilute acid (HTDA) method, we undertook a study of a group of alkylated benzenes to establish its scope and limitations (1–9). Our goal was to determine whether the HTDA method can be used to label alkyl substituents with deuterium (or tritium). In this paper, we document the results of this study; it is clear that the HTDA method is useful for labelling alkyl groups of substituted benzenes with deuterium (or tritium).



Results

The deuterium incorporations for each substrate including benzene are listed in Table 1. In all cases, the ring hydrogens equilibrate with the deuterium pool. At temperatures above 250°C, the methyl groups of **2**–**13** and the benzylic methylene groups of **14**, **15**, and **16** undergo H–D exchange to varying degrees. While the methyl groups of the xylenes **3**, **4**, and **5** incorporate only a small amount of deuterium, the methyl groups of **13** are equilibrated with the deuterium pool at 285°C. H–D exchange β to the aromatic ring in **15** and **16** occurs much more slowly than exchange at the benzylic sites.



Discussion

H–D exchange of methyl-substituted benzenes

The ease of exchange of the methyl groups depends on the degree of substitution of the benzene ring, the position of the methyl groups, and on statistical factors for deprotonation of the intermediate cyclohexadienyl cations. For example, deuteronation of *m*-xylene (**4**) at C2 or C4 yields cyclohexadienyl

1 $R^{1-6} = H$
2 $R^{1} = CH_3, R^{2-6} = H$
3 $R^{1,2} = CH_3, R^{3-6} = H$
4 $R^{1,3} = CH_3, R^{2,4-6} = H$
5 $R^{1,4} = CH_3, R^{2,3,5,6} = H$
6 $R^{1-3} = CH_3, R^{4-6} = H$
7 $R^{1,2,4} = CH_3, R^{3,5,6} = H$
8 $R^{1,3,5} = CH_3, R^{2,4,6} = H$
9 $R^{1-4} = CH_3, R^{5,6} = H$
10 $R^{1,2,3,5} = CH_3, R^{4,6} = H$
11 $R^{1,2,4,5} = CH_3, R^{3,6} = H$
12 $R^{1-5} = CH_3, R^{6} = H$
13 $R^{1-6} = CH_3$
14 $R^{1-6} = Ch_2CH_3$
15 $R^{1} = CH_2CH_3, R^{2-6} = H$

16

cations **17** and **18**, which are inductively and hyperconjugatively stabilized by two methyl groups. In the case of the cyclohexadienyl cations generated from **3** and **5**, only one methyl group is positioned to provide maximal hyperconjugative stabilization. Also, while cations **17** and **18** can be deprotonated at either methyl group, the cations derived from **3** and **5** can only be deprotonated at a single methyl. On the basis of these factors, **4** is expected to undergo H–D exchange of the methyls faster than **3** or **5**. In fact, the exchange rates roughly correlate with the pK_b's of **3**, **4** and **5** (−5.3, −3.2, and −5.7, respectively) obtained at low temperatures (10).

[a]DCl in D_2O.
[b]The recoveries of deuteriated compounds were generally greater than 90%. Incorporations of ≥95% correspond to equilibration with the deuterium pool.
[c]Temperatures are ±5°C.
[d]Deuterium content was determined by mass spectrometry at low ionizing voltage (10–15 eV).
[e]The reaction was agitated and decalin was used as a cosolvent.
[f]Value is for methylene; trace of D in methyl.
[g]Value is for α-CH_2s.
[h]Value is for β-CH_2s.

The same rationale can be used to account for the fact that the methyl groups of 1,3,5-trimethylbenzene (**8**) undergo exchange faster than the methyl groups of its isomers **6** and **7**. Deuteronation of **8** can occur at either of three identical sites to yield a cyclohexadienyl cation (**19**) maximally stabilized by three methyl groups. In the case of **19**, deprotonation can occur from either of three methyls to form a triene, in competition with deprotonation (dedeuteronation) to form **8**; in the case of the cations derived from **6** and **7**, deprotonation can occur from two methyl groups. Consequently, **8** should undergo exchange approximately 1.3 times faster than **6** due to a statistical factor. This coupled with the fact that **8** is more basic than **6** or **7** (pK_b: **6** (−2.9), **7** (−2.8), **8** (−0.4) (ref. 10)), accounts for the enhanced rate of exchange of the methyls of **8** relative to **6** and **7**. It should be possible to perlabel **8** simply by increasing the reaction time.

That 1,2,3,5-tetramethylbenzene (**10**) undergoes exchange of the methyl groups faster than its isomers **9** and **11** is again in accord with the relative basicities of these compounds (pK_b: **9** (−1.9), **10** (0.1), **11** (−2.2) (ref. 10)). It is not exactly clear why **10** incorporates less deuterium than **8** even though **10** is slightly more basic than **8**. This may be due to the fact that the solubility of the substrates in D_2O decreases as the number of alkyl substituents increases. At 270°C, **10** incorporates 2.67

[a]Calculations were carried out on the protio species and the geometries were fully optimized.

deuterium atoms in the methyl groups. Analysis of the 73.4-MHz ^2H nmr spectrum of the deuteriated sample obtained using enhanced resolution established that the C1 and C3 methyls undergo H–D exchange slightly faster than the other methyls. To gain information on the source of this selectivity, AM1 (11) calculations were carried out on the isomeric cyclohexadienyl cations **20**, **21**, **22**, and **23** and the heats of formation are given in Table 2. According to AM1, **21** is the most stable cation; this is in accord with low temperature protonation studies, which established that protonation at carbons bearing hydrogens in benzene derivatives is preferred over protonation at alkylated carbons by a factor of 10–20 (10). In an attempt to predict which methyl of **21** deprotonates preferentially, AM1 calculations were also carried out on isomeric trienes **24**, **25**, and **26** derivable from **21**; the heats of formation are given in Table 2. On the basis of these computational studies, and on the assumption that there are no differential kinetic effects, deprotonation should occur preferentially at the C1 and C3 methyls; this prediction is in accord with the experimental results.

24 **25** **26** **27**

28 **29** **30**

Pentamethylbenzene (**12**) undergoes exchange of the methyls at a rate comparable to **10** and the methyls equilibrate with the deuterium pool after 48 h at 285°C. That hexamethylbenzene (**13**) can be perlabelled in good yield in a single reaction is remarkable (entry 17, Table 1).

H–D exchange of hexamethylbenzene

As seen from the data in entries 16 and 18 of Table 1, **14** undergoes exchange at the benzylic sites more slowly than **13**. There are two reasons for this. In comparison with the cation formed from **13**, there is a statistical factor of 0.66 for the deprotonation at a methylene group relative to ring deprotonation of the cyclohexadienyl cation derived from **14**. More importantly, the activation energy for formation of **27** by deprotonation at a methylene of the hexaethylcyclohexadienyl cation is expected to be higher than the activation energy for the analogous deprotonation of the cation derived from **13**. A steric interaction between the incipient vinyl methyl and ethyl groups precludes optimal alignment of the methylene C-Hs with the π system of the hexaethyl cyclohexadienyl cation.

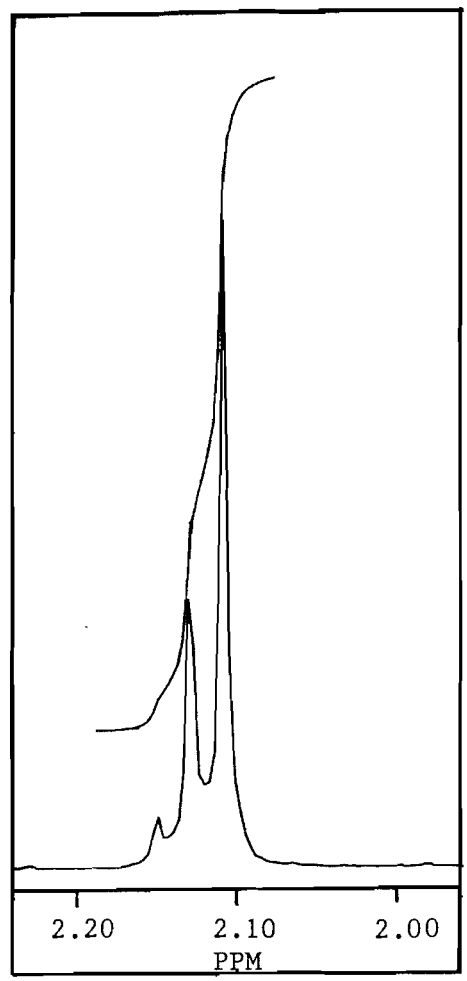

FIG. 1. The ^2H nmr spectrum (76.77 MHz, CCl_4) of deuteriated **13**.

H–D exchange of ethylbenzene and tetralin

Exchange of ethylbenzene (**15**) and tetralin (**16**) was also carried out under forcing conditions. While considerable deuteriation of the methylene of **15** (entry 19) is observed, only a trace of deuterium is incorporated in the methyl group. Tetralin (**16**) incorporates more deuterium in the α-methylene positions and a significant amount in the β-methylene positions (entry 20). A small amount of exchange at the β-methylene indicates that triene **28** (assuming that deuteronation of **16** occurs initially at C5) is deuteronated at C6 to yield cation **29**, which can return to **28** or **28**-*d* or deprotonate at C3 to yield **30**. A similar scheme is possible if **16** is deuteronated initially at C6. That exchange occurs to a greater degree in **16** than in **15** may be due to a number of factors: tetralin (**16**) is expected to be more basic than **15**; deprotonation of the α-methylene group of the first-formed cyclohexadienyl cation is expected to compete more effectively with deprotonation at C5 for **16** than for **15**. This is so because a more highly substituted double bond is formed in the former case; deprotonation of **29** at C3, which is β to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

incipient aromatic ring, competes more effectively with deprotonation at C6 because a more highly substituted double bond is formed than is the case for **15**.

^2H nuclear magnetic resonance studies

We have shown previously (12) that geminal deuterium isotope effects on deuterium chemical shifts can be determined by obtaining high field ^2H nmr spectra. In this study, for certain cases, separate resonances were observed for methyls bearing one, two, or three deuterium atoms. For example, the high field portion of the 73.4-MHz ^2H spectrum of **13**-$d_{15.42}$ (entry 16, Table 1) is shown in Fig. 1. The resonances at 2.110, 2.131, and 2.153 ppm correspond to the CD_3 (63.5%), CHD_2 (31.1%), and CH_2D (5.4%) groups respectively. The geminal deuterium isotope shifts on the deuterium resonances are 21.0 ppb. In the case of **13**-$d_{17.22}$ (entry 17, Table 1), based on the analysis of the ^2H nmr spectrum, the methyls are dideuteriated (14.9%) and trideuteriated (85.9%).

Experimental

The ^1H and ^2H nmr spectra were recorded on a Bruker AM500 spectrometer using CCl_4 as solvent and TMS as the standard. Mass spectra were performed on a VG Micromass 7070 spectrometer at low ionizing voltage (9–12 eV) to minimize fragmentation. Gas chromatographic analyses were done on a 6 ft × ⅛ in. stainless steel 3% OV-1 on Chromosorb W column in a Tracor 560 chromatograph. Preparative chromatography was carried out on a 6 ft × ¼ in. stainless steel 15% SE-30 on Chromosorb W column in a Varian Aerograph 200 chromatograph.

General exchange procedure

The substrate (0.02 g) and 0.27 M DCl/D_2O (5 mL) were sealed under vacuum in a medium-walled glass tube after degassing via three freeze–pump–thaw cycles. The tube was then heated for the prescribed time and temperature in a Parr high pressure autoclave containing water to equalize pressure. Solid products were filtered from the reaction mixture and liquids were extracted with ether (3 × 5 mL). Yields were generally quantitative; however, the gas chromatogram of 1,2,3,4-tetramethylbenzene (**9**) showed several side product peaks (12.9, 2.0, 1.0%) and after collection by preparative gc the yield was 52%.

A modification of this procedure was used for ethylbenzene (**15**) and tetralin (**16**); these reactions were run using decalin as an inert cosolvent and the mixing of the reagents was achieved through a rocking motion of the autoclave.

Received March 16, 1989

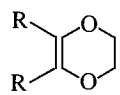
This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

ALWYN G. DAVIES, CHARLES J. SHIELDS, JEFFREY C. EVANS, and CHRISTOPHER C. ROWLANDS. Can. J. Chem. **67**, 1748 (1989).

The electron spin resonance spectra of the radical cations of dioxene (**1***a*), 2,3-dimethyldioxene (**1***b*), 2,3-diphenyldioxene (**1***c*), and benzodioxane (**2**) in fluid solution have been observed and analysed, with the help of ENDOR spectroscopy in the case of **1***c*. It is concluded that in **1***c* the molecule has overall C_2 molecular symmetry. In all four compounds, the pseudo-axial and pseudo-equatorial protons of the methylene groups in the half-chair dioxene rings are distinguished by different hyperfine coupling constants, and simulation of the spectra over a range of temperatures has given the Arrhenius parameters for the ring inversion of **1***a*, **1***b*, and **2**.

Key words: ESR spectra, radical cation, 1,4-dioxene, inversion barrier.

ALWYN G. DAVIES, CHARLES J. SHIELDS, JEFFREY C. EVANS et CHRISTOPHER C. ROWLANDS. Can. J. Chem. **67**, 1748 (1989).



On a déterminé les spectres en résonance paramagnétique électronique des radicaux cations du dioxène (**1***a*), du 2,3-diméthyldioxène (**1***b*), du 2,3-diphényldioxène (**1***c*) et du benzodioxane (**2**) en solutions fluides et, dans le cas du composé **1***c*, on a aussi analysé le spectre à l'aide de la spectroscopie ENDOR. On en conclut que le composé **1***c* possède une symétrie moléculaire globale C_2. Dans les quatre composés, des constantes de couplage hyperfin différentes permettent de distinguer les protons pseudo-axiaux et pseudo-équatoriaux des groupements méthylènes des cycles demi-chaises du dioxène; de plus, une simulation des spectres sur une plage importante de températures a permis d'évaluer les paramètres d'Arrhénius pour les inversions des cycles **1***a*, **1***b* et **2**.

Mots clés : spectres RPE, cation radical, 1,4-dioxène, barrière à l'inversion.

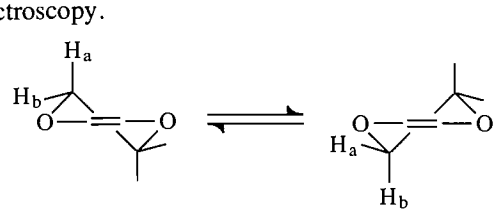
The electron spin resonance (esr) spectra of some acyclic alkoxyalkene (vinyl ether) radical cations have recently been identified (1), but there appear to be no reports in the literature of the esr spectra of the related dioxene radical cations ($\mathbf{1}^{+\cdot}$).



1

a R = H
b R = Me
c R = Ph

2

These species are interesting because in the half-chair conformation of the parent dioxenes, the axial and equatorial protons of the methylene groups can be distinguished in the nmr spectra by different chemical shifts (2, 3). Similarly in the esr spectra of the radical cations, H_{ax} and H_{eq} should be distinguished by different hyperfine coupling constants, and in principle it should be possible to examine the effect of one-electron oxidation on the conformational inversion (4) illustrated in eq. [1], by variable temperature nmr and esr spectroscopy.

[1] 

[1]Author to whom correspondence may be addressed.

Indeed the esr spectrum of the 2,3-benzodioxane radical cation $\mathbf{2}^{+\cdot}$ (which is better regarded as a 1,2-dialkoxybenzene than a dioxene) was recorded at room temperature in 1976 by Dixon and Murphy (5), and it showed an alternating line width effect characteristic of conformational inversion.

We report here the generation of the radical cations of dioxene (**1***a*), 2,3-dimethyldioxene (**1***b*), 2,3-diphenyldioxene (**1***c*), and benzodioxane (**2**) in fluid solution, and a study of their esr spectra at varying temperatures (for a preliminary note, see ref. 6).

Results

The dioxenes **1***a*, **1***b*, and **1***c* (7) were prepared by condensation of the appropriate diol and acyloin under acid conditions. This is analogous to the method used by Gelas and Petrequin (8) for preparing **1***b*, and provides a more convenient route to **1***a*, which is usually prepared by dehydrogenation/dehydration of bis(2-hydroxyethyl)ether over a copper chromite/potassium hydrogen sulphate catalyst at 230–250°C (9).

The esr spectrum of $\mathbf{1}b^{+\cdot}$ could readily be observed without photolysis when 2,3-dimethyldioxene (**1***b*) was dissolved in concentrated sulphuric acid, or in trifluoroacetic acid containing mercury trifluoroacetate, or in liquid sulphur dioxide containing fluorosulphonic acid. At 296 K, the spectrum consisted of a septet of quintets with some alternating line width effect (Fig. 1c); hyperfine coupling constants are listed in Table 1.

In SO_2/FSO_3H (10), the spectrum could be studied at low temperatures. At around 230 K, the second and fourth lines of the quintets were lost (Fig. 1b), then at near 200 K the couplings to the methylene protons resolved into a triplet of triplets

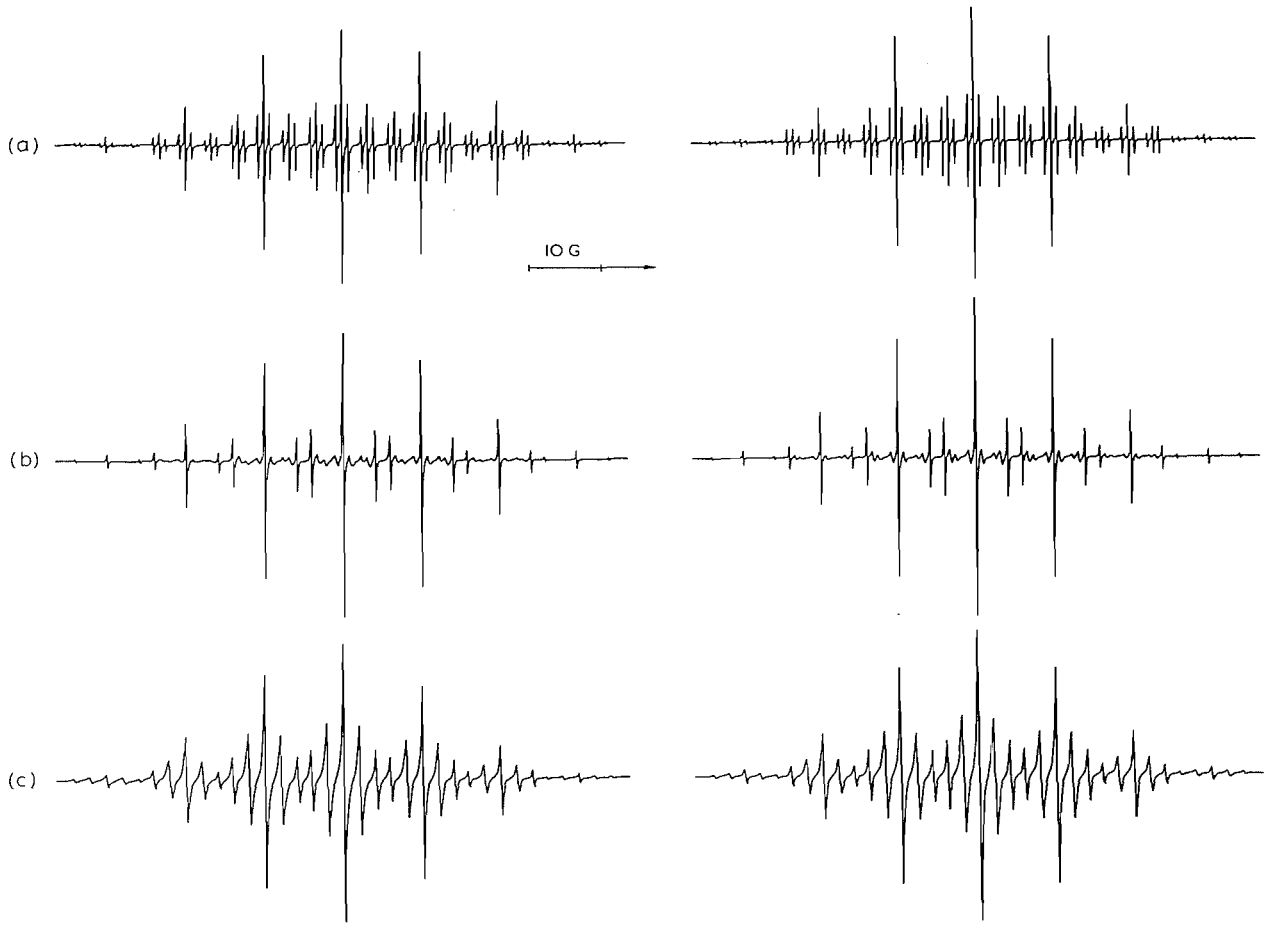


FIG. 1. The esr spectra (left) and simulations (right) of the 2,3-dimethyldioxene radical cation $\mathbf{1}b^{\dot{+}}$ in SO_2/FSO_3H at (a) 200 K, (b) 230 K, and (c) 296 K.

(Fig. 1a and Table 1), resulting from nonequivalent axial and equatorial methylene protons. Simulation of the spectra over the temperature range 175–300 K gave the Arrhenius plot shown in Fig. 2, and the values of A and E for the conformational equilibrium (eq. [1]) that are given in Table 2.

Dixon and Murphy oxidized benzodioxane (**2**) using cerium(IV) and concentrated sulphuric acid in a flow system (5). We found it difficult to obtain satisfactory spectra in a static system. In trifluoroacetic acid containing thallium(III) trifluoroacetate at 263 K, **2** showed a spectrum similar to that reported by Dixon and Murphy, superimposed on a second weaker spectrum. In

FIG. 3. The esr spectra and simulations of the benzodioxane radical cation $\mathbf{2}^{\dot{+}}$ (a) in SO_2/FSO_3H at 175 K, and (b) the wing lines, in SO_2ClF/FSO_3H at 205 K.

TABLE 2. Arrhenius parameters for reaction [1]

	log A	E (kJ mol^{-1})
$\mathbf{1}a^{\dot{+}}$	12.8±0.7	22.6±2.2
$\mathbf{1}b^{\dot{+}}$	13.7±0.7	31.4±2.5
$\mathbf{2}^{\dot{+}}$	15.1	34.7

dichloromethane containing aluminium chloride at 189 K it showed this second spectrum, which became much stronger when oxygen was admitted; a similar but weaker spectrum was obtained in the dark below 193 K with SO_2/FSO_3H. This spectrum could be simulated using the coupling constants a(4H) 2.15, a(2H) 0.875, a(2H) 0.26 G, g 2.0038, but the origin of the spectrum is not obvious.

However, photolysis with Pyrex-filtered light of a solution of **2** in SO_2/FSO_3H at 175 K showed a strong spectrum (Fig. 3), with the hyperfine coupling constants given in Table 1. Dixon and Murphy reported a(2H) 0.40, a(2H) 4.65 G, and from the illustration of their spectrum the sum of $a(H_{ax})$ and $a(H_{eq})$ can be estimated to be 5.13 G, in line with our figures.

Above 203 K, the spectrum of $\mathbf{2}^{\dot{+}}$ became contaminated in the centre with that of another radical, but the wing multiplets remained clear and could be simulated for determining the kinetics of the inversion process (Fig. 3). A rather more stable spectrum at higher temperatures was obtained by photolysis of a solution of SO_2ClF/FSO_3H, and by using these two solvents the Arrhenius plot shown in Fig. 4 could be obtained over the range 175–215 K, giving the values of A and E in Table 2.

As only the ring multiplets are being considered in the simulation, the probable errors in A and E are likely to be larger than they are for $\mathbf{1}a^{\dot{+}}$ and $\mathbf{1}b^{\dot{+}}$.

Simulation of the spectrum illustrated in Dixon and Murphy's paper gives a rate constant, at an assumed 290 K (their room temperature), that is within 5% of that given by our Arrhenius plot.

We found it much more difficult to oxidize dioxene itself ($\mathbf{1}a$) than 2,3-dimethyldioxene ($\mathbf{1}b$), and satisfactory spectra could be obtained only over the range 252–309 K in $CF_3CO_2H/Hg(OCOF_3)_2$ (Fig. 5). A low enough temperature could not be reached to measure $a(H_{ax})$ and $a(H_{eq})$ directly, but their average (2.91 G) could be obtained at the higher temperatures. The ratio of $a(H_{ax})/a(H_{eq})$ is the same in $\mathbf{1}b^{\dot{+}}$ (4.226) and $\mathbf{2}^{\dot{+}}$ (4.221) and we assumed this ratio would also be 4.22 in $\mathbf{1}a^{\dot{+}}$. From this we calculate $a(H_{ax})$ to be 4.70 G, and $a(H_{eq})$ 1.11 G.

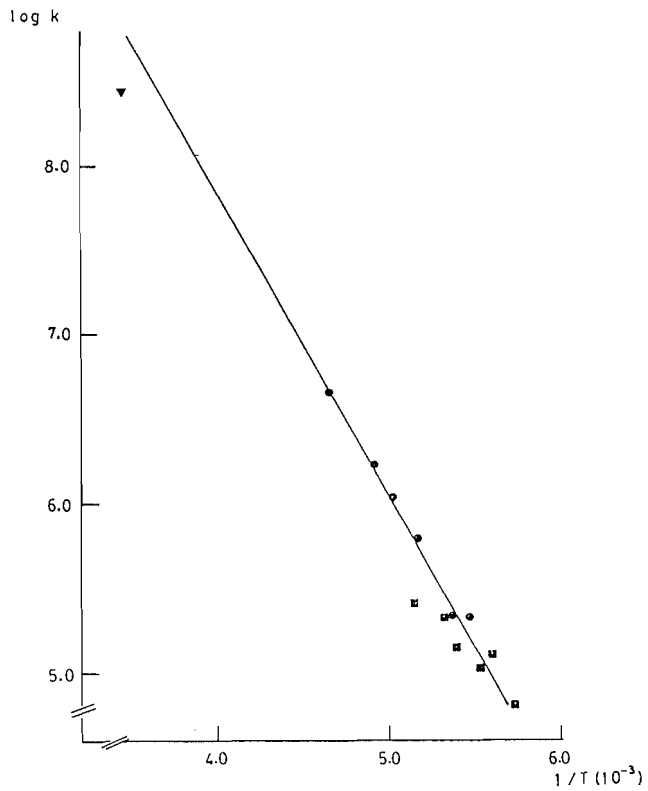

FIG. 4. Arrhenius plot for the conformational inversion of $\mathbf{2}^{\dot{+}}$, ■ in SO_2/FSO_3H, ● in SO_2ClF/FSO_3H, ▼ taken from ref. 5.

Using these values good simulations of the spectra were obtained (Fig. 5), giving the Arrhenius plot illustrated in Fig. 6, and the values of A and E listed in Table 1.

Strong esr spectra were obtained in the dark from a solution of 2,3-diphenyldioxene ($\mathbf{1}c$) in $CF_3CO_2H/Hg(OCOCF_3)_2$, or by photolysis of a solution of $\mathbf{1}c$ in $CH_2Cl_2/AlCl_3$, and under these second conditions the spectrum persisted indefinitely in the dark at 193 K. Schaap *et al.* (1) have reported detecting esr signals of some 2,3-diaryldioxenes by electrochemical oxidation or by oxidation with tris(*p*-bromophenyl)aminium tetrafluoroborate, but details of the spectra have not been published.

Our spectrum (Fig. 7) was too complicated to be analysed by inspection, but the ENDOR spectrum at 188 K provided the hyperfine coupling constants given in Table 1, which gave a good simulation of the esr spectrum.

The observation of seven different hyperfine coupling con-

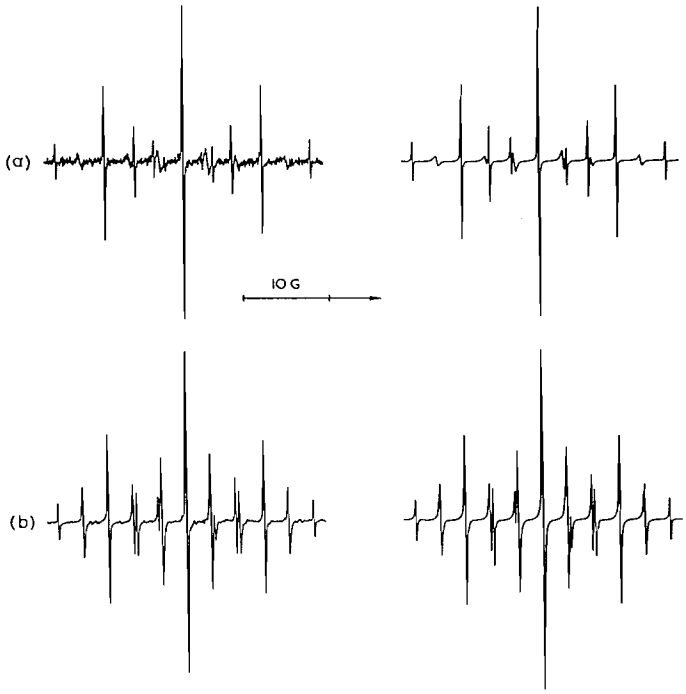

FIG. 5. The esr spectra (left) and simulations (right) of the dioxene radical cation $\mathbf{1}a^{+\cdot}$ in $CF_3CO_2H/Hg(OCOCF_3)_2$ at (a) 252 K, and (b) 309 K.

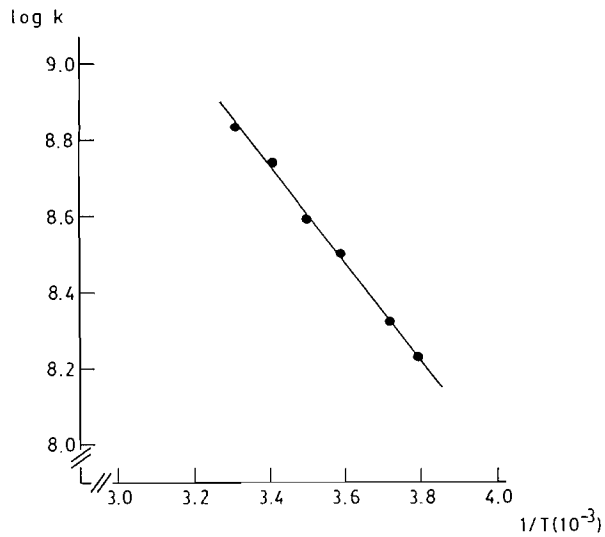

FIG. 6. Arrhenius plot for the conformational inversion of $\mathbf{1}a^{+\cdot}$.

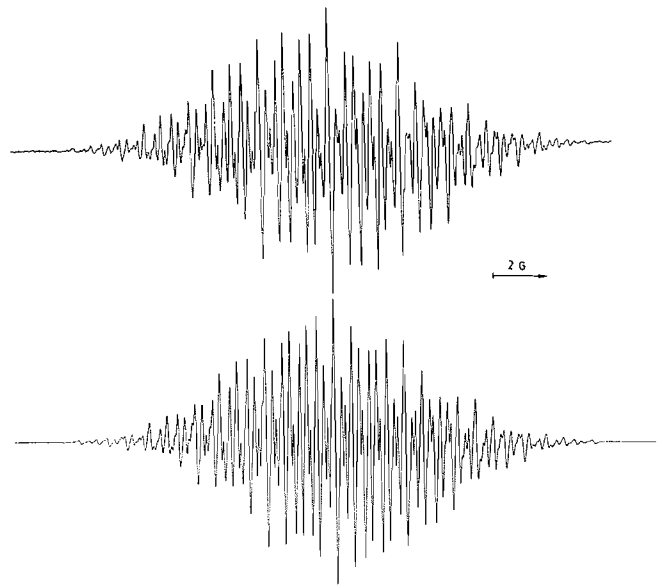
stants (which would give 2187 lines in the esr spectrum) implies that the two *ortho* and the two *meta* protons in each phenyl ring are nonequivalent, that is, that the phenyl groups are not freely rotating, nor coplanar with, nor orthogonal to the dioxene ring, but twisted as illustrated in **3**, as they are in other compounds related to *cis*-stilbene (12–14).

Presumably this twisted conformation results from a compromise between maximization of the π-overlap and minimization of *ortho* interactions. Gerson has observed the same phenomenon in the esr spectra of various radical anions containing the π-system of *cis*-stilbene (e.g., *cis*-stilbene itself (12), and 1,2-diphenyl-cyclobutene (12), -cyclopentene (13), and -cyclohexene ($\mathbf{4}^{-\cdot}$) (14); this last compound is conformationally closely related to our diphenyldioxene $\mathbf{1}c^{+\cdot}$). A similar



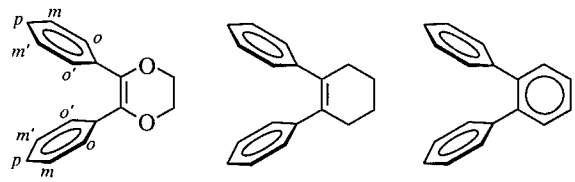


FIG. 7. The esr spectrum (top) and simulation (bottom) of the diphenyldioxene radical cation $\mathbf{1}c^{+\cdot}$ in SO_2/FSO_3H at 188 K.

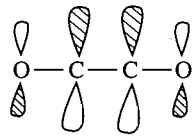
effect is observed in the *ortho*-triphenyl radical anion $\mathbf{5}^{-\cdot}$ (4, 15), and we have recently identified it also in the corresponding radical cation $\mathbf{5}^{+\cdot}$.[2]

3 **4** **5**

The tentative assignment of the hyperfine coupling constants in $\mathbf{1}c^{+\cdot}$ is based on the assumption that $a(H_{ax})/a(H_{eq}) =$ ca. 4.2 (here it is 4.2), and on Gerson's analysis of the spectra of the radical anions related to *cis*-stilbene, particularly his argument that, in this context, steric hindrance leads to a reduction in the absolute value of an α-proton coupling constant (12–14).

We were unable to determine the inversion barrier (eq. [1]) for the 1,2-diphenyldioxene radical cation $\mathbf{1}c^{+\cdot}$ because variation of the temperature caused a change not only in the hyperfine coupling constants of the axial and equatorial methylene protons, but also in those of the protons of the phenyl groups. Gerson and Martin studied the esr and ENDOR spectrum of the 1,2-diphenylcyclohexene radical anion $\mathbf{4}^{-\cdot}$ over the temperature range 173–293 K (14), but even at the highest temperature they could not observe exchange between the axial and equatorial protons, and they concluded that the inversion barrier was considerably raised by the introduction of the two phenyl groups.



Discussion

The Hückel model predicts that the HOMO of 1,4-dioxene and of its radical cation should have a node between the terminal atoms of the O—C=C—O system, with the electron density concentrated on the carbon atoms as shown in **3**.

This is supported by an *ab initio* (STO-3G) calculation, which predicts also a low ionization potential of 8.43 eV, close

3

to the value of 8.48 ± 0.02 eV that is found by photoelectron spectroscopy (16).

On the basis of infrared and Raman spectroscopy, two transition states were identified for the inversion of 1,4-dioxene (**1***a*). The first (31.99 ± 2.51, or 34.59 kJ mol^{-1}) (17, 18) had a bent half-chair conformation, and the second (78.09 ± 9.04, or 81.65 kJ mol^{-1}) (17, 18) was planar. Larkin and Lord (2) studied the ring inversion by variable temperature (−150°C to room temperature) proton nmr and found an activation energy to inversion of 31.90 ± 0.63 kJ mol^{-1}.

Allinger and co-workers (19) calculated the barrier to ring inversion in **1***a* by the molecular mechanics (MM2) method. They were unable to locate the nonplanar transition state, and for the planar structure they calculated a barrier of 25.04 kJ mol^{-1}. They proposed that the situation could best be interpreted in terms of the existence of only one barrier represented by the planar structure, and although the calculation may have too low a value, the errors in the experiments were thought to have been underestimated.

The ready formation of the radical cations $\mathbf{1}a^{\dot{+}}$ and $\mathbf{1}b^{\dot{+}}$, and the hyperfine coupling constants that we observe, are in accord with the MO calculations. Particularly noticeable is the substantial coupling at the central carbon atoms (e.g., *a*(2Me) 10.80 G in $\mathbf{1}b^{\dot{+}}$) compared with that in butadiene radical cations (e.g., *a*(2Me) 4.2 G in hexamethylbutadiene (20)), reflecting the different orbital occupancy. These hyperfine coupling constants, and the *g*-values that we observe in the dioxene radical cations $\mathbf{1}a^{\dot{+}}$ and $\mathbf{1}b^{\dot{+}}$ are close to those we reported for the acyclic 1,2-di-*tert*-butoxyalkene radical cations (e.g., *E*/*Z*-Bu^{t}OCH=CHOBu^t$^{\dot{+}}$, *a*(2H) 8.25 G, *g* 2.0049; *Z*-Bu^{t}OCMe=CMeOBu^t$^{\dot{+}}$, *a*(2Me) 9.69 G, *g* 2.0040) (1).

The barrier to inversion (eq. [1]) that we find in the dioxene radical cation $\mathbf{1}a^{\dot{+}}$ (22.6 ± 2.2 kJ mol^{-1}) is smaller than that measured by Larkin and Lord (2) by nmr for the parent molecule **1***a* (though it is close to that (25.04 kJ mol^{-1}) calculated by Allinger (19) for a planar transition state). If the transition state is planar, the inversion process involves twisting about the terminal O—C bonds where the wave function (**3**) is locally antibonding, and also about the central C—C bond where the wave function is locally bonding. The former element would increase the activation energy for achieving the transition state, and the latter element would reduce it. If we accept Larkin and Lord's results, removal of an electron from the orbital apparently reduces the activation energy, and this would be consistent with the sum of the π-bond orders in the two O—C bonds being greater than the bond order in the C—C bond. Any changes in bond lengths and bond angles, and in solvation, which will accompany ionization, however, may of course also contribute to changes in activation energy. The introduction of the two methyl groups in $\mathbf{1}b^{\dot{+}}$ increases the inversion barrier, and fusion of the dioxene and benzene rings in $\mathbf{2}^{\dot{+}}$ similarly increases the rigidity of the dioxene ring.

Experimental

The esr spectra were obtained using a Varian E109 spectrometer fitted with a 500-W high pressure mercury arc focussed on the cavity. Temperatures were measured with a calibrated thermocouple placed alongside the esr tube, and are corrected for the heating effect of the uv light on the sample. Spectra were simulated using the ESRXN programme.

*1,4-Dioxene (**1**a)*

Glycolaldehyde dimer (Aldrich; 1.5 g) was converted into the monomer by heating it in ethylene glycol (65 cm^3) at 100°C for 15 min. *p*-Toluenesulphonic acid was then added, and a mixture (ca. 1:1) of the dioxene and 2-methyl-1,3-dioxolane was distilled off through a reflux air condenser (30 min). Purification by preparative glc gave 1,4-dioxene as a colorless liquid, ^{1}H nmr ($CDCl_3$): 4.15 (s, 4H, CH_2) and 5.9 (s, 2H, =CH—).

*2,3-Dimethyl-1,4-dioxene (**1**b)*

Acetoin dimer (Aldrich; 4.4 g) was converted into the monomer by heating it in ethylene glycol (120 cm^3) for 15 min. *p*-Toluenesulphonic acid (0.1 g) was then added, and the product was distilled off through a reflux air condenser (100 min). Redistillation gave the dioxene (4.2 g, 74%) as a yellow liquid, bp 74°C/80 Torr; 1 Torr = 133.3 Pa); ^{1}H nmr ($CDCl_3$): 1.75 (s, 6H, Me), 4.0 (s, 4H, CH_2). A small sample was purified by preparative glc, giving the dioxene as a colourless liquid that turned yellow again within ca. 2 h. Both the colourless and the yellow samples showed the same nmr and esr spectra.

2,3-Diphenyl-1,4-dioxene (**1***c*) was prepared from benzoin and ethylene glycol by Summerbell and Berger's method (7), and benzo-1,4-dioxane (**2**) was a commercial product (Aldrich).

Thermolysis of 2-acyloxy-Δ^3-1,3,4-oxadiazolines. Evidence for a preferred sense of cycloreversion to carbonyl ylides and for fast 1,4-sigmatropic ylide rearrangement

MICHAEL W. MAJCHRZAK AND JOHN WARKENTIN[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 27, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

MICHAEL W. MAJCHRZAK and JOHN WARKENTIN. Can. J. Chem. **67**, 1753 (1989).

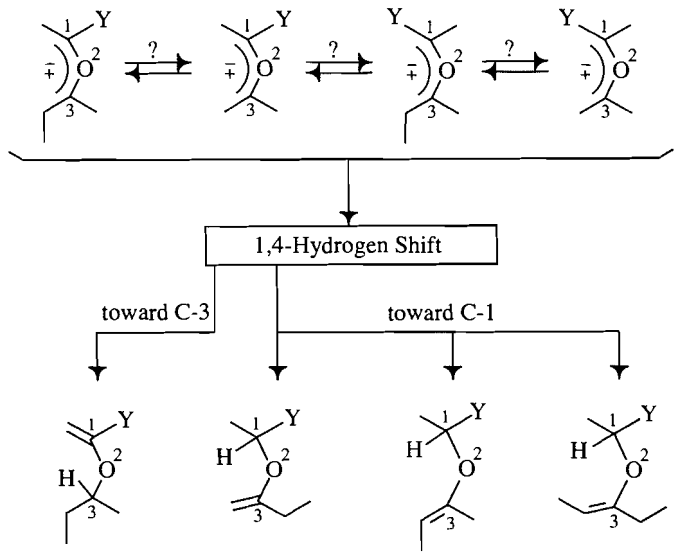
Thermolysis of 2-acyloxy-2,5,5-trialkyl-Δ^3-1,3,4-oxadiazolines in benzene solution at 80°C furnishes acyloxy-substituted enol ethers (hemiacylals) in high yield. Mixtures of *cis*:*trans* isomers of such oxadiazolines afford mixtures of isomeric hemiacylals in nearly the same ratio. Those and other results are rationalized in terms of cycloreversion of the oxadiazolines to carbonyl ylides that are not equilibrated during their lifetimes and undergo primarily 1,4-sigmatropic H-migration. Some fragmentation of the ylides to anhydrides and carbenes was also observed. A consistent mechanistic account includes concerted suprafacial ($4\pi + 2\pi$) cycloreversion in the sense that places a large ylide substituent at C-1 or at C-3, preferentially *exo*. A smaller preference for the cycloreversion that places the acetoxy group at C-1 in the *endo* position, when the steric effect of the alkyl group at C-1 is small, can be inferred. The possibility that the overall 1,4-H shift is the result of sequential 1,7-antarafacial and 1,4-suprafacial shifts, in some cases, is considered.

Key words: carbonyl ylide; 1,4-sigmatropic rearrangement; cycloreversion, thermal, of oxadiazolines; ylide, carbonyl; oxadiazoline, thermolysis of.

MICHAEL W. MAJCHRZAK et JOHN WARKENTIN. Can. J. Chem. **67**, 1753 (1989).

La thermolyse des 2-acyloxy-2,5,5-alkyl-Δ^3-1,3,4-oxadiazolines, en solution dans le benzène à 80°C, fournit des éthers énoliques substitués par des groupements acyloxy (hémiacylals) avec un excellent rendement. Les mélanges *cis*:*trans* de telles oxadiazolines fournissent des mélanges d'hémiacylals isomères qui sont dans le même rapport. On rationalise ces résultats ainsi que d'autres en fonction d'une cycloréversion des oxadiazolines en ylures de carbonyles qui ne s'équilibrent pas durant leur existence et qui subissent principalement des migrations sigmatropiques-1,4 d'hydrogène. On a aussi observé quelques fragmentations des ylures en anhydrides et en carbènes. Un mécanisme cohérent comporte une cycloréversion ($4\pi + 2\pi$) suprafaciale concertée dans le sens qui permet de placer un substituant ylure volumineux en positions C-1 ou C-3, d'une façon préférentielle *exo*. On peut supposer qu'il existe aussi une préférence plus faible pour la cycloréversion qui place le groupement acétoxy en position *endo* en C-1, où l'effet stérique du groupement alkyle en C-1 est faible. On considère qu'il est possible, dans quelques cas, que le déplacement global 1,4 d'hydrogène puisse être le résultat des déplacements successifs antérafacial-1,7 et suprafacial-1,4.

Mots clés : carbonyle ylure; transposition sigmatropique-1,4; cycloréversion, thermique, d'oxadiazolines; ylure, carbonyle; oxadiazoline, thermolyse de.



[Traduit par la revue]

Introduction

1,4-Sigmatropic H-migrations (1) in ylides, including azomethine ylides (2–4) and carbonyl ylides (5–7), are well known. Many details of those rearrangements, however, are poorly understood. First, there is the question of whether ylide equilibration, by rotation about one or both carbon–heteroatom bonds, is faster or slower than sigmatropic rearrangement. Second, the preferred geometry (*E* or *Z*) about the newly formed double bond of the product of H-migration is not known. Third, the sense of sigmatropic rearrangement (toward C-1 or C-3) in unsymmetric systems is not established for a variety of cases. Finally, there is little information in the literature concerning substitution patterns that cause suppression of the sigmatropic rearrangement in favour of alternative unimolecular processes such as fragmentations to carbonyl compounds and carbenes.

These questions are illustrated in Scheme 1 for a simple carbonyl ylide to which they would apply.

We now report the synthesis and thermolysis of a series of 2-acetoxy-2,5,5-trialkyl-Δ^3-1,3,4-oxadiazolines (**2** and **5**). Systematic changes of the alkyl substituents and a study of *cis*/*trans* mixtures provided information concerning some of the questions posed above.

SCHEME 1

Methods and results

Oxadiazolines **2** were prepared by oxidation of acyl hydrazones (**1**) of ketones with lead tetraacetate (LTA) in methylene chloride (1), eq. [1]. That method afforded *cis*:*trans* mixtures

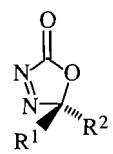
[a]All isomer ratios were estimated by integration of the ^{1}H nmr spectra.
[b]Yields were estimated by analysis of the nmr spectra of the crude pyrolysates after identification of the major components, and are not subject to losses incurred during separations.
[c]Errors in the isomer ratios were estimated to be no more than 5%. Errors in product yields were estimated to range from about 5% to 20% of the values quoted, depending on their actual magnitude.
[d]Additional products, usually minor, are mentioned in the Experimental.



of **2***b*, **2***d*, and **2***f* in which the *trans* isomer predominated (Table 1). Oxadiazolines **2***b* and **2***d* were also obtained from 2-oxooxadiazolines **3**, by the alkylation/acylation sequence of eq. [2]. Compounds **3** were prepared by the oxidative cyclization/hydrolysis sequence of eq. [3], from semicarbazones **4**. The procedure of eq. [2] afforded *cis*/*trans* mixtures of **2** in which the *cis* isomer predominated. These two synthetic approaches permitted the assignment of the *trans* structure to the major product of the synthesis according to eq. [1] and of the *cis* structure to the major product of the synthesis according to eq. [2]. Finally the oxadiazoline **5** was prepared from **2***c* by the deacylation/reacylation sequence illustrated with eq. [4].

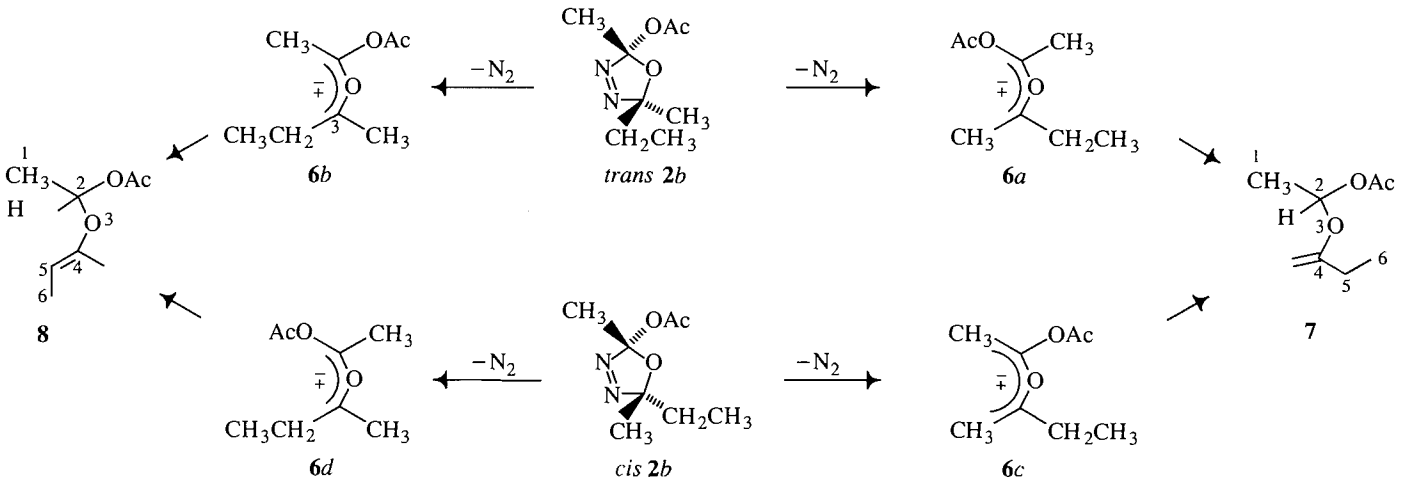
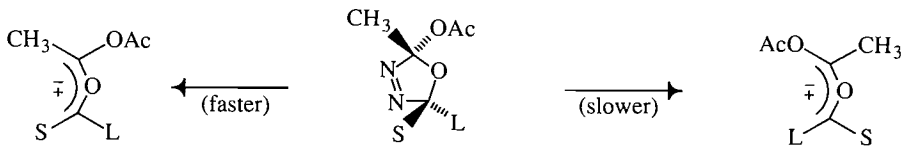
Separation of the geometric isomers of the oxadiazolines by hplc was not successful and they are too unstable to survive glpc conditions. Selective deacylation of one of the isomers by treatment of the mixture **2***b* (*trans*:*cis* = 2.3:1) with half an equivalent of methyllithium at −78°C was not promising. The *trans*:*cis* ratio in recovered **2***b* was only slightly different from that in the starting material. It was therefore necessary to use the different mixtures of isomers of **2***b* and of **2***d*, from the two synthetic approaches (eqs. [1], [2]), to infer the selectivities of the cycloreversion step and of the subsequent 1,4-sigmatropic hydrogen atom shifts, illustrated for the case of **2***b* with Scheme 2.



A striking result is the fact that a mixture (*trans*:*cis* = 2.3:1) of the isomers **2***b* afforded a product mixture in which the ratio **7**:**8** was 2.2:1. Similarly, when the isomer ratio for **2***b* was *trans*:*cis* = 1:1.9, the product ratio was **7**:**8** = 1:1.6, suggesting a substantial overall memory effect. An immediate conclusion from those results is that the geometric isomers (**6***a*–*d*) of the carbonyl ylide intermediate are not equilibrated by rotation about the bonds to the central oxygen atom during their lifetimes. Equilibration would require a product ratio independent of the ratio of isomers in the starting material.

The fact that carbonyl ylides **6***a*–**6***d* are not equilibrated during their lifetimes means that it is possible, in principle, to discover which ones are formed preferentially by the cycloreversions of *trans*- and *cis*-**2***b*. Because stereochemical information is lost in the 1,4-hydrogen atom shifts that convert the transient ylides to stable products, it was necessary to use an indirect probe. The probe chosen relies on the assumption that the cycloreversion transition states are sufficiently productlike to reflect steric effects on product stability. That is, a transition state leading to an ylide with the larger substituents *endo* will, other factors being equal, be of higher energy than a transition state leading to an isomeric ylide with the larger substituents *exo*, Scheme 3.



The assumption that large groups cannot be accommodated well in the *endo* position of a planar carbonyl ylide received strong support from the results of thermolysis of **2***d* (Scheme 4). A sample of **2***d* (*trans*:*cis* = 3:1) gave **10** and **12** in 4:1 ratio. Isomer **11** was not formed. Similarly, a sample of **2***d* (*trans*:*cis* = 1:2.6) gave **10** and **12** in 1.2:1 ratio and, again, **11** could not be detected. In both cases the combined yields of **10** and **12** accounted for more than 90% of the original isopropyl groups. Although there was a preference for formation of **12** in each case, the carbonyl ylides from **2***d* are clearly only partially equilibrated during their lifetimes and the sense of equilibration is most likely to be **9***b* → **9***c* and **9***d* → **9***a* (Scheme 4). Fragmentation presumably competes quite effectively with those rotational equilibrations, to afford **12** and 1-acetoxyethylidene (**13**), which rearranges to biacetyl **14**.

Further support for the presumed crowding experienced by *endo* isopropyl substituents of carbonyl ylides came from the

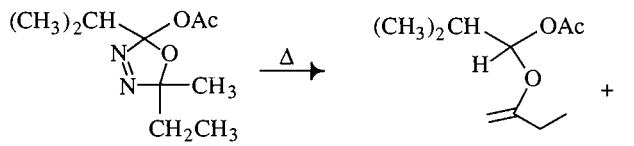
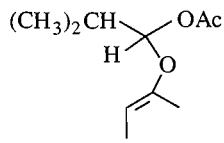
[5] 



2e 15

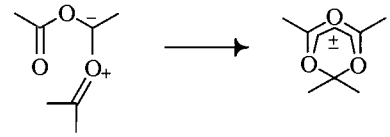


16 17

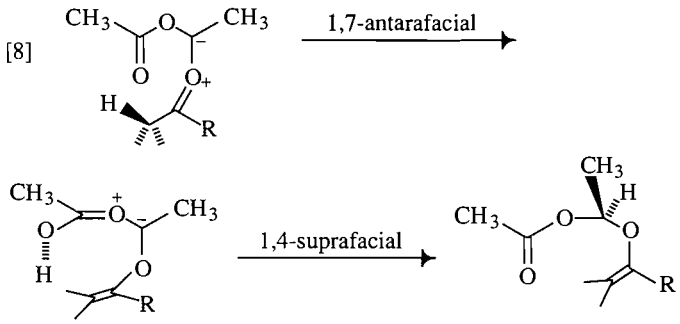
finding that **2***e* afforded none of the product of 1,4-sigmatropic rearrangement in the normal sense but only products from fragmentation (**14** and **16**) and, in approximately 10% yield, the product (**17**) of 1,4-sigmatropic rearrangement from the methyl group at C-1 (eq. [5]). Presumably the ylide **15** cannot readily adopt the conformation (8) required for sigmatropic migration of methine hydrogen and is constrained instead to a conformation in which the methine hydrogen of the *endo* isopropyl group lies in the ylide plane, or to nonplanar conformations of the ylide. The alternative migration, toward C-3, which is not competitive in other 1-acetoxy or 1-alkoxy carbonyl ylides, therefore becomes observable.

The evidence that *endo* isopropyl conformations of carbonyl ylides are probably unstable, presumably because they cannot adopt the 0°,0° geometry that is the ground state (9), was used to prepare a carbonyl ylide with an *endo* acetoxy substituent. Oxadiazoline **2***g* (*trans*:*cis* = 2.5:1) gave **18** and **19** in the ratio 2.0:1 in good yield (85%) on thermolysis, eq. [6]. Again

[6] 



2g 18



19

only partial equilibration of ylides occurred and the overall 1,4-hydrogen atom transfer took place efficiently from the "acetoxy *endo*" conformation, the "isopropyl *endo*" geometry presumably being too hindered, as was discussed above.

From the evidence that the *endo* acetoxy conformation is sufficient for sigmatropic rearrangement toward C-1 to occur, it does not follow that *endo* acetoxy is the kinetically preferred mode of cycloreversion. It also does not follow that the sigmatropic rearrangement toward C-1 is particularly facile if the acetoxy group is in the *endo* position. Nevertheless, there are reasons for believing that both of the preferences referred to above may be real. First, a carbonyl ylide must have a considerable net dipole bisecting the ylide COC angle and having the negative end in the *endo* region. Stabilizing dipole–dipole and dipole – induced dipole interactions between a substituent and the ylide framework can therefore be expected to be largest if the substituent is close to the main dipole by lying in an *endo* position. An extreme representation of internal solvation is the imagined cyclization shown in eq. [7].

[7] 

Second, a sigmatropic rearrangement in an *endo* acetoxy carbonyl ylide *could* be unusually easy because an initial 1,7-antarafacial sigmatropic shift, from carbon to oxygen to form a new ylide with a strong O—H bond, is possible. The new ylide could then undergo a suprafacial 1,4-shift (eq. [8]).

[8] 

Although the two-step process is stereochemically different from a one-step rearrangement, there is no simple test available for distinguishing between the mechanisms. We mention the hypothesis of a 1,7-antarafacial initial step as an intriguing possibility. The fact that acetoxy carbonyl ylides such as **2***b* afford products of 1,4-sigmatropic rearrangement in good yield whereas corresponding methoxy carbonyl ylides afford analogous products in low yield, except in the case of gas phase thermolysis (10), may be used to support the hypothesis.

In summary, many acyloxy-substituted carbonyl ylides undergo 1,4-sigmatropic H-migrations faster than ylide isomerization by rotations. The calculated rotational barrier[2] for the parent (unsubstituted) carbonyl ylide is 14 kcal mol^{-1} and experimental barriers of 8–13 kcal mol^{-1} have been reported for 1-cyano-1,3-diphenyl carbonyl ylide (11). It is very likely then that the free energy of activation for the observed sigmatropic rearrangement is less than 14 kcal mol^{-1}. Conformations of 1-acetoxy carbonyl ylides in which the acetoxy group is *endo* may actually rearrange by sequential 1,7-antarafacial and 1,4-suprafacial H-shifts, but the evidence for two steps is not compelling.

In those cases where sigmatropic rearrangement generated a trisubstituted double bond, the *E* isomer was formed, as predicted from a consideration of steric factors in the transition structure for the rearrangement. Sigmatropic migration of methine hydrogen from an isopropyl group was not observed. Fragmentation is the major fate of those ylides that would have to place an isopropyl group *endo* in order to be planar.

Experimental

General

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Proton NMR spectra were recorded on a Bruker AM-500 or an EM-390 spectrometer using TMS or residual ^1H signals from $CDCl_3$ or C_6D_6 as internal standards. ^{13}C NMR spectra were recorded with the Bruker AM-500 machine. Centrifugal chromatography was carried out on silica (Merck Kieselgel $60PF_{254}$) coated plates (coating 2 mm thick) spinning in a Chromatotron model 17924T apparatus. Plastic-backed, Merck Kieselgel $60F_{254}$, 0.2-mm silica plates were used for analytical thin-layer chromatography (TLC). Commercially available solvents and reagents were purified by standard procedures.

Acetylhydrazones of ketones (1)

Most of these were prepared by refluxing solutions of equimolar amounts of acetylhydrazine and of the appropriate ketone in benzene until all water was removed (Dean–Stark trap, 5–15 h). The solvent was removed under vacuum and the residue was recrystallized. The acetyl hydrazone of pinacolone (**1***e*) was obtained by refluxing a solution of acetylhydrazine in excess pinacolone for 20 h. Excess pinacolone was distilled off and the residue was recrystallized (12). New acetylhydrazones are reported below.

*1-Acetyl-2-(2,4-dimethyl-3-pentylidene)hydrazine (1*e*)*

The yield of **1***e* was 75%, mp 75–77°C (Et_2O/petroleum); ^{1}H NMR (90 MHz, $CDCl_3$) δ: 8.85 (br s, 1H, NH), 2.87 (sept, J = 6.9 Hz, 1H), 2.62 (sept, J = 6.9 Hz, 1H), 2.22 (s, 3H), 1.06 (d, J = 6.9 Hz, 6H), 1.04 (d, J = 6.9 Hz, 6H).

*1-(2-Methylpropanoyl)-2-(2-butylidene)hydrazine (1*g*)*

The general procedure afforded **1***g* in 70% yield, mp 60–68°C (Et_2O/EtOH); ^{1}H NMR (90 MHz, $CDCl_3$) δ: 8.62 (br s, 1H, NH), 3.42 (sept, J = 6.9 Hz, 1H), 2.37 (q, J = 7.5 Hz, 2H), 1.84 (s, 3H), 1.18 (d, J = 6.9 Hz, 6H), 1.12 (t, J = 7.5 Hz, 3H).

*1-(2-Methylpropanoyl)-2-(3-methyl-2-butylidene)hydrazine (1*h*)*

Yield 75%, mp 85–87°C (petroleum ether/benzene); ^{1}H NMR (90 MHz, $CDCl_3$) δ: 8.40 (br s, 1H, NH), 3.38 (sept, J = 6.9 Hz, 1H), 2.51 (sept, J = 6.9 Hz, 1H), 1.82 (s, 3H), 1.23 (d, J = 6.9 Hz, 6H), 1.17 (d, J = 6.9 Hz, 6H).

2-Acetoxy-2,5,5-trialkyl-Δ^3-1,3,4-oxadiazolines (2) by the route of eq. [1]

The lead tetraacetate oxidation of acylhydrazones of ketones was carried out as described previously (13). The products, purified by vacuum distillation, are described below. Some chemical shift assignments of methyl signals in ^{13}C NMR spectra are tentative.

*2-Acetoxy-5-ethyl-2,5-dimethyl-Δ^3-1,3,4-oxadiazoline (2*b*)*

The *trans*:*cis* ratio was 2.2:1; bp 44–45°C (0.5 Torr; 1 Torr = 133.3 Pa); ^{1}H NMR of *trans* isomer (500 MHz, C_6D_6) δ: 1.88 (s, 3H, Ac), 1.67–1.58 (m, 2H), 1.57 (s, 3H), 1.31 (s, 3H), 0.64 (t, J = 7.5 Hz, 3H); ^{1}H NMR of *cis* isomer (500 MHz, C_6D_6) δ: 1.82 (s, 3H, Ac), 1.76–1.67 (m, 2H), 1.58 (s, 3H), 1.19 (s, 3H), 0.77 (t, J = 7.5 Hz, 3H); ^{13}C NMR of *trans* isomer (125.76 MHz, C_6D_6) δ: 167.10 (CO), 130.19 (C-2), 126.27 (C-5), 30.90 (CH_2), 23.15 (Me at C-5), 22.24 (CH_3CO), 21.27 (Me), 7.62 (Me); ^{13}C NMR of *cis* isomer (125.76 MHz, C_6D_6) δ = 167.06 (CO), 130.49 (C-2), 126.66 (C-5), 30.39 (CH_2), 22.28 (CH_3CO), 22.21 (Me), 21.17 (Me), 8.08 (Me).

*2-Acetoxy-5,5-diethyl-1-methyl-Δ^3-1,3,4-oxadiazoline (2*c*)*

This compound was obtained in 75% yield, bp 53–54°C (0.4 Torr); ^{1}H NMR (90 MHz, $CDCl_3$) δ: 2.25–1.55 (m, 10H), 0.90 (t, J = 7.5 Hz, 3H), 0.77 (t, J = 7.5 Hz, 3H).

*2-Acetoxy-5-(1-methylethyl)-2,5-dimethyl-Δ^3-1,3,4-oxadiazoline (2*d*)*

The product, obtained in 75% yield, was a mixture, *trans*:*cis* ratio = 3:1; bp 53–55°C (0.5 Torr); ^{1}H NMR of *trans* isomer (500 MHz, C_6D_6) δ: 1.90–1.81 (m), 1.87 (s, 3H), 1.68 (s, 3H), 1.25 (s, 3H), 0.84 (d, J = 6.9 Hz, 3H), 0.73 (d, J = 6.9 Hz, 3H); ^{1}H NMR of *cis* isomer (500 MHz, C_6D_6) δ: 1.90–1.81 (m), 1.80 (s, 3H), 1.70 (s, 3H), 1.18 (s, 3H), 0.92 (d, J = 6.9 Hz, 3H), 0.76 (d, J = 6.9 Hz, 3H). The total integral for the overlapping signals in the region δ 1.90–1.81 was satisfactory. ^{13}C NMR of *trans* isomer (125.76 MHz, C_6D_6) δ: 167.11 (CO), 129.81 (C-2), 128.52 (C-5), 35.41 (CH), 21.81 (CH_3CO), 21.42 (2-CH_3), 20.04 (5-CH_3), 17.18 (CH_3), 16.93 (CH_3); ^{13}C NMR of *cis* isomer (125.26 MHz, C_6D_6) δ: 167.01 (CO), 130.37 (C-2), 129.21 (C-5), 35.27 (CH), 23.01 (CH_3CO), 21.29 (2-CH_3), 19.28 (5-CH_3), 17.77 (CH_3), 17.21 (CH_3).

*2-Acetoxy-5,5-di-(1-methylethyl)-2-methyl-Δ^3-1,3,4-oxadiazoline (2*e*)*

Oxadiazoline **2***e* was obtained in 72% yield; bp 58–60°C (0.1 Torr); ^{1}H NMR (90 MHz, C_6D_6) δ: 2.42–2.00 (m, 2H, CH), 1.98 (s, 3H, Ac), 1.62 (s, 3H), 0.97–0.59 (m, 12H).

*2-Acetoxy-5-(1,1-dimethylethyl)-2,5-dimethyl-Δ^3-1,3,4-oxadiazoline (2*f*)*

Mixture **2***f* was obtained in 70% yield; *trans*:*cis* ratio = 14.5:1; bp 53–55°C (0.3 Torr); mp 36–37°C (petroleum ether); ^{1}H NMR of *trans* isomer (500 MHz, C_6D_6) δ: 2.04 (s, 3H, Ac), 1.54 (s, 3H), 1.23 (s, 3H), 0.87 (s, 9H); ^{1}H NMR of *cis* isomer (500 MHz, C_6D_6) δ: 1.89 (s, 3H, Ac), 1.60 (s, 3H), 1.12 (s, 3H), 0.91 (s, 9H); ^{13}C NMR of *trans* isomer (125.76 MHz, C_6D_6) δ: 167.07 (CO), 130.68 (C-2), 129.89 (C-5), 37.27 (CMe_3), 25.45 (2-Me), 21.31 (CH_3CO or 5-Me), 21.06 ((CH_3)$_3$), 19.11 (5-Me or CH_3CO).

*2-Acetoxy-5-ethyl-2-(1-methylethyl)-5-methyl-Δ^3-1,3,4-oxadiazoline (2*g*)*

The yield was 60%, bp 65–66°C (0.3 Torr); *trans*:*cis* ratio 2.5:1; ^{1}H NMR of *trans* isomer (500 MHz, $CDCl_3$) δ: 2.84 (sept, J = 6.9 Hz, 1H), 2.05 (s, sum of two Ac integrals), 1.77–1.66 (m, 2H, CH_2), 1.52 (s, 3H), 1.12 (d, J = 6.9 Hz, 3H), 1.10 (t, J = 7.5 Hz, 3H), 1.02 (d, J = 6.9 Hz, 3H); ^{1}H NMR of *cis* isomer (500 MHz, $CDCl_3$) δ: 3.02 (sept, J = 6.9 Hz, 1H), 2.05 (s, sum of two Ac integrals), 2.00–1.90 (m, 2H, CH_2), 1.55 (s, 3H), 1.15 (d, J = 6.9 Hz, 3H), 1.00 (t, J = 7.5 Hz, 3H), 0.93 (d, J = 6.3 Hz, 3H); ^{13}C NMR of *trans* isomer (125.76 MHz, $CDCl_3$) δ: 167.39 (CO), 133.21 (C-2), 125.52 (C-5), 32.70 (CH), 30.48 (CH_2), 21.46 (5-Me), 20.70 (CH_3CO), 16.62 (CH_3), 16.32 (CH_3), 8.05 (CH_3); ^{13}C NMR of *cis* isomer (125.76 MHz, $CDCl_3$) δ: 167.39 (CO), 133.68 (C-2), 126.20 (C-5), 31.87 (CH), 30.55 (CH_2), 21.42 (5-Me), 20.83 (CH_3CO), 16.77 (CH_3), 16.08 (CH_3), 8.05 (CH_3). This last signal was assigned by analogy because one CH_3 signal of one isomer is superimposed on a CH_3 signal of the other isomer.

*2-Acetoxy-2,5-di-(1-methylethyl)-5-methyl-Δ^3-1,3,4-oxadiazoline (2*h*)*

Mixture **2***h* was formed in 65% yield; bp 66–68°C (0.3 Torr); *trans*:*cis* ratio = 2.4:1; ^{1}H NMR of *trans* isomer (500 MHz, $CDCl_3$) δ: 2.84 (sept, J = 6.9 Hz, 1H), 2.04 (s, 3H, Ac), 1.78 (sept, J = 6.9 Hz, 1H), 1.42 (s, 3H), 1.24 (d, J = 6.9 Hz, 3H), 1.10 (d, J = 6.9 Hz, 3H), 1.05 (d, J = 6.9 Hz, 3H), 1.04 (d, J = 6.9 Hz, 3H); ^{1}H NMR of *cis* isomer (500 MHz, $CDCl_3$) δ: 3.08 (sept, J = 6.9 Hz, 1H), 2.05 (s, 3H, Ac), 1.89 (sept, J = 6.9 Hz, 1H), 1.47 (s, 3H), 1.17 (d, J = 6.9 Hz, 3H), 1.16 (d, J = 6.9 Hz, 3H), 0.95 (d, J = 6.9 Hz, 3H), 0.90 (d, J = 6.9 Hz, 3H); ^{13}C NMR of *trans* isomer (125.76 MHz, $CDCl_3$) δ: 167.24 (CO), 133.04 (C-2), 127.86 (C-5), 35.44 (CH), 32.72 (CH), 18.10 (CH_3CO), 17.19 (CH_3), 16.90 (CH_3), 16.64 (CH_3), 16.39 (CH_3); ^{13}C NMR of *cis* isomer (125.76 MHz, $CDCl_3$) δ: 169.24 (CO), 133.50 (C-2), 128.76 (C-5), 35.66 (CH), 31.61 (CH), 21.39 (CH_3CO), 17.93 (CH_3), 17.10 (CH_3), 16.85 (CH_3), 16.02 (CH_3).

*2-Acetoxy-2,5,5-trialkyl-Δ^3-1,3,4-oxadiazolines, 2*b *and 2*d*, by the route of eq. [2]*

The reaction of **3***b* or **3***d* with methyllithium was carried out as described previously (14). Acetyl chloride in ethyl ether was used at the end of the reaction to trap the lithium alkoxide. The temperature during addition was kept at −40°C; then the cooling bath was removed and, while stirring, the reaction mixture was allowed to come to room temperature (2 h). Next it was quenched with water and extracted with ethyl ether (3 × 50 mL). The ether extracts were washed with 5% sodium bicarbonate solution (3 × 10 mL) and dried ($MgSO_4$). The drying agent was filtered off, and the filtrate was concentrated under vacuum and distilled. The oxadiazoline **2***b* obtained by this method was a 1.9:1 (*cis*:*trans*) mixture of isomers. The isomer ratio (*cis*:*trans*) of oxadiazoline **2***d* was 2.7:1.

*5-Ethyl-5-methyl-2-oxo-Δ^3-1,3,4-oxadiazoline (2*b*)*

This compound was prepared as described in the literature (14); ^{1}H NMR (90 MHz, $CDCl_3$) δ: 2.16 (q, J = 7.5 Hz, 2H), 1.72 (s, 3H), 0.80 (t, J = 7.5 Hz, 3H).

*5-(1-Methylethyl)-5-methyl-2-oxo-Δ^3-1,3,4-oxadiazoline (2*d*)*

This compound was prepared as described earlier (14); ^{1}H NMR (90 MHz, $CDCl_3$) δ: 2.27 (sept, J = 6.9 Hz, 1H), 1.69 (s, 3H), 1.10 (d, J = 6.9 Hz, 3H), 0.90 (d, J = 6.9 Hz, 3H).

5,5-Diethyl-2-(2-methylpropanoyloxy)-2-methyl-Δ^3-1,3,4-oxadiazoline (5)

To a stirred solution of 2-acetoxy-5,5-diethyl-2-methyl-Δ^3-1,3,4-oxadiazoline **2***c* (5 g, 0.025 mol) in THF (35.0 mL) under argon was added, dropwise at −50°C, methyllithium (0.055 mol, 37 mL of 1.5 M

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

solution). The reaction mixture was stirred at this temperature for 0.5 h and then for 1 h at −20°C before it was recooled to −60°C. At this temperature isobutyryl chloride (5.33 g, 0.05 mol) in THF (10 mL) was added dropwise. The cooling bath was removed and stirring was continued for another 3 h. After this time the solvent was removed under vacuum, the residue was dissolved in methylene chloride (50 mL), washed with saturated NaCl (2 × 10 mL), and dried ($MgSO_4$). The drying agent was filtered off, the solvent was evaporated under vacuum, and the residue was distilled to afford 3 g (53% yield) of **7**, bp 54–56°C (0.7 Torr); ^{1}H NMR (90 MHz, $CDCl_3$) δ: 2.57 (sept, J = 6.9 Hz, 1H), 2.17 (s, 3H), 2.18–1.68 (m, 4H), 1.21 (d, J = 6.9 Hz, 3H), 1.19 (d, J = 6.9 Hz, 3H), 0.95 (t, J = 7.5 Hz, 3H), 0.82 (t, J = 7.5 Hz, 3H).

Thermolysis of oxadiazolines

An oxadiazoline (40 mg) dissolved in benzene-d_6 (0.5 mL) was placed in a thick-walled NMR tube, which was put through three freeze–pump–thaw cycles (vacuum line pressure 10^{-2} Torr) prior to sealing. Thermolysis at 80.0 ± 0.2°C was monitored by taking the NMR spectrum, and was completed after 3 days. The tubes were opened after freezing in liquid nitrogen and the reaction mixture was analysed by gc, ms, and by nmr spectroscopy.

*Thermolysis of 2-acetoxy-5-ethyl-2,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**2**b)*

The mixture of **2***b* (*trans*:*cis* ratio 2.2:1) gave in 90% yield a 2.2:1 mixture of 2-acetoxy-4-methylene-3-oxahexane (**7**) and *E*-2-acetoxy-4-methyl-3-oxahex-4-ene (**8**), respectively. A 1.9:1 (*cis*:*trans*) mixture of the isomers of **2***b* gave upon thermolysis, in 90% yield, a 1.6:1 mixture of **8** and **7**, respectively. ^{1}H NMR of **7** (500 MHz, C_6D_6) δ: 6.45 (q, J = 5.2 Hz, 1H, H-2), 4.13 (d, J = 2.5 Hz, 1H, *E*-methylene), 4.04–4.00 (m, 1H, *Z*-methylene), 2.03 (J = 7.5 Hz, 2H, H-5), 1.63 (s, 3H, Ac), 1.30 (d, J = 5.2 Hz, 3H, H-1), 0.96 (t, J = 7.5 Hz, 3H, H-6); ^{13}C NMR (125.76 MHz, C_6D_6) δ: 169.21 (CO), 162.21 (C-4), 91.79 (C-2), 83.62 (sp^2-methylene), 28.05 (C-5), 20.47 (C-1), 20.21 (CH_3CO), 11.38 (C-6); MS (ci, NH_3), *m*/*e*: 159; calcd. for $(C_8H_{14}O_3 + H)^+$: 159. ^{1}H NMR of **8** (500 MHz, C_6D_6) δ: 6.40 (q, J = 5.2 Hz, 1H, H-2), 4.76 (q, J = 6.8 Hz, 1H, H-5), 1.67–1.65 (m, 3H, 4-*Me*), 1.64 (s, 3H, Ac), 1.40 (d of q, J = 6.8 Hz and 0.9 Hz, 3H, H-6), 1.32 (d, J = 5.2 Hz, 3H, H-1); ^{13}C NMR (125.76 MHz, C_6D_6) δ: 169.22 (CO), 150.43 (C-4), 97.72 (C-5), 91.94 (C-2), 20.68 (CH_3CO), 20.58 (C-6), 15.29 (4-Me), 11.89 (C-1); MS (ci, NH_3), *m*/*e*: 159; calcd. for $(C_8H_{14}O_3 + H)^+$; 159.

*Thermolysis of 2-acetoxy-5,5-diethyl-2-methyl-Δ^3-1,3,4-oxadiazoline (**2**c)*

Thermolysis of **2***c* furnished, in 88% yield, *E*-2-acetoxy-4-ethyl-3-oxahex-4-ene (**20**). Diethyl ketone (**21**), butane-2,3-dione (**14**), and acetic anhydride (**22**) were detected as minor products.

E-*2-Acetoxy-4-ethyl-3-oxahex-4-ene (**20**)*: ^{1}H NMR (500 MHz, C_6D_6) δ: 6.26 (q, J = 5.2 Hz, 1H, H-2), 4.59 (q, J = 6.9 Hz, 1H, H-5), 2.14–2.08 (q, J = 7.5 Hz, 2H, CH_2), 1.91 (s, 3H, Ac), 1.51 (d, J = 6.9 Hz, 3H, H-6), 1.41 (d, J = 5.2 Hz, 2H, H-1), 1.02 (t, J = 7.5 Hz, 3H); ^{13}C NMR (125.76 MHz, C_6D_6) δ: 170.01 (CO), 155.50 (C-4), 96.79 (C-2), 92.64 (C-5), 22.81 (CH_2), 21.13 (CH_3CO), 20.71 (C-6), 11.93 (C-1), 11.63 (Me); MS (ci, NH_3), *m*/*e*: 173; calcd. for $(C_9H_{16}O_3 + H)^+$: 173.

*Thermolysis of 2-acetoxy-5-(1-methylethyl)-2,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**2**d)*

Thermolysis of a 3:1 mixture (*trans*:*cis*) of **2***d* furnished a 4:1 mixture of 2-acetoxy-5-methyl-4-methylene-3-oxahexane (**10**) and 3-methylbutan-2-one (**12**) in 86% yield. A 2.6:1 mixture (*cis*:*trans*) of **2***d* gave a 1.2:1 mixture of **12** and **10**, respectively, in 82% yield. 1,1-Diacetoxyethane (**23**), acetic anhydride (**22**), and biacetyl (**14**) were detected as minor products. ^{1}H NMR of **10** (500 MHz, C_6D_6) δ: 6.43 (q, J = 5.2 Hz, 1H, H-2), 4.04 (d, J = 2.6 Hz, 1H, vinyl), 4.00 (d, J = 2.6 Hz, 1H, vinyl), 2.24 (sept, J = 6.9 Hz, 1H, H-5), 1.65 (s, 3H, Ac), 1.29 (d, J = 5.2 Hz, 3H, H-1), 1.02 (d, J = 6.9 Hz, 3H, H-6), 1.00 (d, J = 6.9 Hz, 3H, H-6); ^{13}C NMR (125.76 MHz, C_6D_6) δ: 169.18 (CO), 165.84 (C-4), 91.88 (C-2), 82.28 (sp^2-methylene), 33.54 (C-5), 20.79 (C-6), 20.68 (CH_3CO), 20.43 (CH_3), 20.21 (C-1).

*Thermolysis of 2-acetoxy-5,5-di-(1-methylethyl)-2-methyl-Δ^3-1,3,4-oxadiazoline (**2**e)*

The crude pyrolysate showed, in the ^{1}H nmr spectrum (C_6D_6), a pair of doublets at δ 4.52 and 4.14 (J = 2.2 Hz) attributed to the terminal methylene group of **17**. The ^{13}C spin-sort spectrum gave a positive signal at δ 81.61 (H_2C=C of the enediol system). Analysis by gc/ms gave *m*/*e* 199.1332; calcd. for $C_{11}H_{19}O_3$: 199.1329 $(M - H)^+$.

*Thermolysis of 2-acetoxy-5-(1,1-dimethylethyl)-2,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**2**f)*

Thermolysis of a 14.5:1 mixture (*trans*:*cis*) of **2***f* furnished almost exclusively 2-acetoxy-5,5-dimethyl-4-methylene-3-oxahexane **24**. Minor products were 1,1-diacetoxyethane (**23**) and pinacolone (**25**) in less than 5% yield. ^{1}H NMR of **24** (500 MHz, C_6D_6) δ: 6.43 (q, J = 5.2 Hz, 1H, H-2), 4.15 (d, J = 2.9 Hz, 1H, vinyl), 4.10 (d, J = 2.9 Hz, 1H, vinyl), 1.62 (s, 3H, Ac), 1.25 (d, J = 5.2 Hz, 3H, H-1), 1.10 (s, 9H); ^{13}C NMR (125.76 MHz, C_6D_6) δ: 169.17 (CO), 168.10 (C-4), 92.14 (C-2), 81.67 (CH_2), 35.79 (C-5), 28.30 (C-6), 20.40 (CH_3CO), 20.18 (C-1).

*Thermolysis of 2-acetoxy-5-ethyl-5-methyl-2-(1-methylethyl)-Δ^3-1,3,4-oxadiazoline (**2**g)*

A 2.5:1 mixture (*trans*:*cis*) of **2***g* furnished a 2:1 mixture of 3-acetoxy-2-methyl-5-methylene-4-oxaheptane (**18**) and *E*-3-acetoxy-2,5-dimethyl-4-oxahept-5-ene (**19**), respectively.

*3-Acetoxy-2-methyl-5-methylene-4-oxaheptane (**18**)*: ^{1}H NMR (500 MHz, C_6D_6) δ: 6.29 (d, J = 4.9 Hz, 1H, H-3), 4.30 (d, J = 2.3 Hz, 1H, vinyl), 4.01 (d, J = 2.3 Hz, 1H, vinyl), 2.02 (q, J = 7.5 Hz, 2H, C-6), 1.99–1.92 (m, H-2; superimposed on the same multiplet from **19**), 1.66 (s, 3H, Ac), 0.99–0.87 (m, ~9H, CH_3; superimposed on the Me signals of **19**); ^{13}C NMR (125.76 MHz, (C_6D_6) δ: 170.12 (CO), 162.89 (C-5), 97.10 (C-3), 84.35 (=CH_2), 33.51 (C-2), 28.68 (C-6), 20.92 (CH_3CO), 17.32 (CH_3), 17.10 (CH_3), 12.50 (C-7).

E-*3-Acetoxy-2,5-dimethyl-4-oxahept-5-ene (**19**)*: ^{1}H NMR (500 MHz, C_6D_6) δ: 6.20 (d, J = 4.9 Hz, 1H, H-3), 4.91 (q, J = 6.9 Hz, 1H, H-6), 1.95–1.92 (m, 1H, H-2), 1.68 (s, 3H, Ac), 1.62 (s, 3H, 5-Me), 1.41 (d, J = 6.9 Hz, 3H, H-7), 0.99–0.87 (m, 6H, CH_3); ^{13}C NMR (125.76 MHz, C_6D_6) δ: 170.19 (CO), 151.17 (C-5), 99.08 (C-3), 97.32 (C-6), 21.09 (C-2), 20.93 (CH_3-CO), 17.47 (C-7), 17.23 (CH_3), 16.93 (CH_3), 15.66 (CH_3).

*Thermolysis of 2-acetoxy-2,5-di-(1-methylethyl)-5-methyl-Δ^3-1,3,4-oxadiazoline (**2**h)*

A 2.4:1 mixture (*trans*:*cis*) of isomers of **2***h* furnished, after thermolysis, 3-acetoxy-2,6-dimethyl-5-methylene-4-oxaheptane (**26**) and methyl isopropyl ketone (**12**) in 2:1 ratio. The yield of these products was 90%. 4-Methylpentane-2,3-dione (**27**) as detected as a minor product.

*3-Acetoxy-2,6-dimethyl-5-methylene-4-oxaheptane (**26**)*: ^{1}H NMR (500 MHz, C_6D_6) δ: 6.23 (d, J = 4.9 Hz, 1H, H-3), 4.19 (d, J = 2.6 Hz, 1H, vinyl), 4.00 (d, J = 2.6 Hz, vinyl), 2.24 (sept, J = 6.9 Hz, 1H, methine), 1.95 (d of sept, J = 6.9 and 4.9 Hz, 1H, H-2), 1.69 (s, 3H, Ac), 1.02 (d, J = 6.9 Hz, 3H, Me), 1.01 (d, J = 6.9 Hz, 3H, Me), 0.90 (d, J = 6.9 Hz, 3H, Me), 0.89 (d, J = 6.9 Hz, 3H, Me); ^{13}C NMR (125.76 MHz, C_6D_6) δ: 169.48 (CO), 165.78 (C-5), 96.38 (C-3), 82.24 (=CH_2), 32.74 (C-6), 32.97 (C-2), 20.79 (CH_3CO), 20.75 (CH_3), 20.35 (CH_3), 16.79 (CH_3), 16.46 (CH_3).

*Thermolysis of 5,5-diethyl-2-(2-methylpropanoyloxy)-2-methyl-Δ^3-1,3,4-oxadiazoline (**5**)*

Thermolysis of this oxadiazoline gave the 2-(2-methylpropanoyloxy)-4-ethyl-3-oxahex-4-ene, presumably the *E* isomer (**28**), in 91% yield; ^{1}H NMR (500 MHz, C_6D_6) δ: 6.43 (q, J = 5.2 Hz, 1H, H-2), 4.66 (q, J = 6.8 Hz, 1H, H-5), 2.34 (sept, J = 6.9 Hz, 1H, CH-CO), 2.07 (q, J = 7.5 Hz, 2H, CH_2), 1.42 (d, J = 6.8 Hz, 3H, H-6), 1.33 (d, J = 5.2 Hz, 3H, H-1), 1.04–0.98 (m, 9H, CH_3); ^{13}C NMR (125.76 Hz, C_6D_6) δ: 175.88 (CO), 155.86 (C-4), 96.53 (C-2), 92.38 (C-5), 34.70 (*C*HCO), 23.31 (CH_2), 21.00 (CH_3), 19.36 (CH_3), 19.14 (CH_3), 12.36 (CH_3), 11.85 (CH_3).

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

RAMESH KAPOOR, POONAM WADHAWAN, VANDANA KATYAL, VIJAY RANI SOOD, and PRATIBHA KAPOOR. Can. J. Chem. **67**, 1760 (1989).

The compounds trichloroselenium(IV) and trichlorotellurium(IV) sulfonates, $MCl_3(XSO_3)$ (M = Se and Te; X = CF_3, CH_3, and p-$CH_3C_6H_4$), have been prepared and characterized by elemental analysis and infrared spectroscopy. Infrared spectra suggest that the XSO_3^- group acts as a monodentate ligand in the Se compounds and as a tridentate ligand in the Te compounds. $MCl_3(CF_3SO_3)$ (M = Se and Te) are found to act as $CF_3SO_3^-$ ion acceptors, and compounds $(C_2H_5)_4N[MCl_3(CF_3SO_3)_2]$ have been isolated. Some other reactions involving ligand substitution and complex formation have also been investigated. Reactions of potassium tellurate(IV) with trifluoromethane-, methane-, and paratoluenesulfonic acids are seen to yield $K_2[Te(CF_3SO_3)_6]$, $K_2[Te(CH_3SO_3)_6]$ and $K_2[TeO(p\text{-}CH_3C_6H_4SO_3)_4]$, respectively.

Key words: trichloroselenium(IV) sulfonates, trichlorotellurium(IV) sulfonates, tetraethylammonium trichlorobis(trifluoromethanesulfonato)selenate(IV), tetraethylammonium trichlorobis(trifluoromethanesulfonato)tellurate(IV), IR spectra.

RAMESH KAPOOR, POONAM WADHAWAN, VANDANA KATYAL, VIJAY RANI SOOD et PRATIBHA KAPOOR. Can. J. Chem. **67**, 1760 (1989).

On a préparé les sulphonates de trichlorosélénium(IV) et de trichlorotellure(IV), $MCl_3(XSO_3)$ (M = Se et Te; X = CF_3, CH_3 et p-$CH_3C_6H_4$) et on les a caractérisés en faisant appel à l'analyse élémentaire et à la spectroscopie infrarouge. Les spectres infrarouges suggèrent que le groupe XSO_3^- agit comme un ligand monodentate dans le composé du sélénium et comme un ligand tridentate dans le dérivé du tellure. On a trouvé que les composés $MCl_3(CF_3SO_3)$ (M = Se et Te) agissent comme accepteurs d'ions $CF_3SO_3^-$ et on a isolé les composés $(C_2H_5)_4N[MCl_3(CF_3SO_3)_2]$. On a également étudié quelques autres réactions impliquant une substitution et une formation de complexes. Les réactions du tellurate(IV) de potassium avec les acides trifluorométhanesulfonique, méthanesulfonique et paratoluènesulfonique semblent donner respectivement les complexes suivants : $K_2[Te(CF_3SO_3)_6]$, $K_2[Te(CH_3SO_3)_6]$ et $K_2[TeO(p\text{-}CH_3C_6H_4SO_3)_4]$.

Mots clés : sulphonates de trichlorosélénium(IV) et de trichlorotellure(IV), tétraéthylammonium trichlorobis(trifluorométhanesulphonato)sélénate(IV), tétraéthylammonium trichlorobis(trifluorométhanesulfonato)tellurate(IV), spectres IR.

[Traduit par la revue]

Introduction

There are no previous reports in the literature on the synthesis of selenium(IV) and tellurium(IV) salts of sulfonic acids (1, 2). Seleninyl bis(trifluoromethanesulfonate), $SeO(CF_3SO_3)_2$, has been shown by X-ray crystallography to contain a 9-coordinated Se (3). In this paper we report the preparation and characterization of $MCl_3(XSO_3)$, $(C_2H_5)_4N[MCl_3(CF_3SO_3)_2]$ (M = Se and Te; X = CF_3, CH_3, and p-$CH_3C_6H_4$), $K_2[Te(CF_3SO_3)_6]$, $K_2[Te(CH_3SO_3)_6]$, and $K_2[TeO(p\text{-}CH_3C_6H_4SO_3)_4]$, and some reactions of the $MCl_3(XSO_3)$ compounds.

Experimental

Both metal(IV) chlorides were prepared by methods reported in the literature (4). Potassium tellurate(IV) (BDH) was dried at ≃100°C *in vacuo* for several hours before use. Trifluoromethanesulfonic acid (Fluka AG) was fractionally distilled through a glass column packed with small glass rings and the fraction distilling at 161–162°C was collected (5). Methanesulfonic acid (Fluka AG, 98%) was made anhydrous by equilibrating with methanesulfonic acid anhydride for about 4–6 h at 70°C and then distilling it under reduced pressure (bp 165°C at 2 Torr; 1 Torr = 133.3 Pa). Paratoluenesulfonic acid monohydrate was made anhydrous by removing water as the toluene–water azeotrope (6). Trifluoromethane- and methanesulfonic acid anhydrides were prepared by mixing P_4O_{10} with the appropriate acid in equimolar amounts. Trifluoromethanesulfonic acid anhydride was obtained by distilling the equilibrated mixture at 81–82°C (745 Torr) and methanesulfonic acid anhydride was obtained as a white crystalline solid, mp 68–70°C, by distilling the equilibrated mixture at 110°C (10^{-2} Torr). Silver sulfonates, $Ag^I(XSO_3^-)$ (X = CF_3, CH_3, and p-$CH_3C_6H_4$) were prepared by the reaction of Ag_2O (BDH) with an aqueous solution of the appropriate acid. All solvents were distilled before use. Tetramethylammonium bromide and tetraethylammonium trifluoromethanesulfonate were dried at ≃100°C *in vacuo*.

Preparations

All the compounds discussed in this paper are sensitive to moisture and thus required handling in dry nitrogen atmosphere, dry box, or *in vacuo*.

Trichloroselenium(IV) and trichlorotellurium(IV) sulfonates, $MCl_3(XSO_3)$ (M = Se and Te; X = CF_3, CH_3, and p-$CH_3C_6H_4$)

These compounds were obtained when equimolar amounts of the metal(IV) chloride and the appropriate silver sulfonate, in carbon tetrachloride for the selenium derivatives and in nitromethane for the tellurium derivatives, were magnetically stirred for 8–10 h at room temperature. Silver chloride was filtered off, and pale-yellow Se and light-grey Te compounds recovered by distilling off the solvent *in vacuo* at room temperature. $TeCl_3(CF_3SO_3)$ and $TeCl_3(CH_3SO_3)$ were also prepared by the solvolyses at $TeCl_4$ in trifluoromethane- and methanesulfonic acids, respectively. Reactions of $TeCl_4$ with acid anhydrides, i.e., $(CF_3)_2S_2O_5$ and $(CH_3)_2S_2O_5$, also gave the monosubstituted products.[1] Any unreacted CF_3SO_3H or $(CF_3)_2S_2O_5$ was distilled off by keeping the compound *in vacuo* for several hours. Methanesulfonic acid or its anhydride was removed by washing the compound with an 80:20 mixture of *n*-hexane and diethyl ether. The compounds did not undergo any further substitution, even under drastic conditions (i.e., use of a large excess of the acid or its anhydride and heating the contents to about 100°C).

[1]Report of $SeCl_4$ with CF_3SO_3H or $(CF_3)_2S_2O_5$ did not yield any definite compound.

*Required values are given in parentheses.

Tetraethylammonium trichlorobis(trifluoromethanesulfonato)selenate(IV)/tellurate(IV), $(C_2H_5)_4N[MCl_3(CF_3SO_3)_2]$ (M = Se and Te)

To a solution of 0.37–0.42 g (1.1 mmol) of $MCl_3(CF_3SO_3)$ in carbon tetrachloride was added 0.65 g (≈2.2 mmol) of $(C_2H_5)_4N^+$-$(CF_3SO_3^-)$. The mixture was stirred for 4–6 h at room temperature. Any unreacted tetraethylammonium trifluoromethanesulfonate was removed by filtration and the white products were recovered by distilling off the solvent *in vacuo*.

Tetramethylammonium tribromotrichloroselenate(IV)/tellurate(IV), $[(CH_3)_4N]_2[MCl_3Br_3]$ (M = Se or Te)

To a solution of ≈0.3–0.4 g (1 mmol) of $MCl_3(XSO_3)$ in methanol (10 mL) was added a solution of 0.9 g (≈6 mmol) of $(CH_3)_4NBr$ in 20 mL of the same solvent. A yellow-coloured compound immediately precipitated out. The mixture was magnetically stirred for about 3 h and then filtered. The precipitates were washed with methanol and dried *in vacuo*. The products were air stable.

Ammonium trichlorobis(isothiocyanato)trifluoromethane/methanesulfonatotellurate(IV), $(NH_4)_2[TeCl_3(XSO_3)(NCS)_2]$ (X = CF_3, CH_3)

To a solution of 0.38 g (1 mmol) of $TeCl_3(CF_3SO_3)$ in 1,2-dimethoxyethane (10 mL) was added a solution of 0.3 g (4 mmol) of NH_4CNS in 25 mL of the same solvent. A white precipitate immediately appeared. The mixture was stirred for 2–3 h, and the product was filtered and dried *in vacuo*. Reaction with $TeCl_3(CH_3SO_3)$ was carried out in a similar fashion.

Pyridine complexes

Addition compounds of $MCl_3(CF_3SO_3)$ (M = Se and Te) with pyridine were prepared by adding an excess of pyridine to an ice-cold solution of the sulfonate derivative in CCl_4, with constant stirring. The voluminous precipitate was filtered, washed several times with CCl_4, and finally dried *in vacuo*.

Analyses

Selenium and tellurium in these compounds were determined gravimetrically as elemental selenium and tellurium by reducing a known weight of the compound with hydrazine hydrate and a saturated solution of SO_2. Sulfur and chlorine were determined gravimetrically as $BaSO_4$ and AgCl, respectively. Carbon, hydrogen, and nitrogen were determined microanalytically on a Carlo Erba Strumentazione elemental analyzer model 1106. Table 1 summarizes the analytical results of the complexes prepared above.

Infrared spectra were recorded on a Perkin–Elmer 1430 ratio recording spectrophotometer in Nujol and hexachlorobutadiene mulls between NaCl/KBr and polyethylene plates. The ^{19}F nmr spectra were recorded on a Varian EM 390 instrument with reference to $CFCl_3$ as external standard. Thermal analysis was carried out on a Paulik, Paulik and Erdey type MOM Budapest Derivatograph.

Results and discussion

Metathetical reactions between $SeCl_4$ (or $TeCl_4$) and silver sulfonates in 1:1 stoichiometry yield $MCl_3(XSO_3)$ salts (M =

*See Table 1 for identification of compounds.

Se or Te; X = CF_3, CH_3, and p-$CH_3C_6H_4$). Solvolysis of tellurium(IV) chloride in trifluoromethane- and methanesulfonic acids or their anhydrides also yield the monosubstituted compounds, $TeCl_3(XSO_3)$ (X = CF_3 and CH_3). Further substitution of chlorine by XSO_3^- in $TeCl_3(XSO_3)$ could not be effected even when drastic conditions were used. Salts of $SeCl_3^+$ and $TeCl_3^+$ in the presence of chloride ion acceptors or donor solvents are quite well known (7).

All six sulfonates, $MCl_3(XSO_3)$ (M = Se and Te; X = CF_3, CH_3, and p-$CH_3C_6H_4$) are highly sensitive to moisture, and fume in moist air. The $SeCl_3(XSO_3)$ salts are reduced to elemental selenium, and are soluble in common organic solvents such as CCl_4, C_6H_6, CH_2Cl_2, CH_3NO_2, $C_6H_5NO_2$, CH_3CN, etc. The analogous tellurium compounds dissolve only in polar organic solvents such as CH_2Cl_2, CH_3NO_2, CH_3CN, etc. Millimolar solutions of all six compounds in CH_3NO_2 and CH_3CN are nonconducting, thus suggesting that the XSO_3^- group is covalently bonded to the metal atom. The ^{19}F nmr spectra of $SeCl_3(CF_3SO_3)$ and $TeCl_3(CF_3SO_3)$ show single peaks at −74 and −80 ppm, respectively, from $CFCl_3$. This resonance occurs in a region characteristic for trifluoromethanesulfonates (8). TG-DTG studies of $TeCl_3(CF_3SO_3)$ and $TeCl_3(CH_3SO_3)$ show that both compounds on heating decompose at 50°C and in a single step lose their entire mass to give TeO_2 as the final residue. The weight loss values, 57.9% for $TeO_2/TeCl_3(CF_3SO_3)$ and 51.2% for $TeO_2/TeCl_3(CH_3SO_3)$, are in good agreement with the expected values, 58.3 and 51.5%, respectively. $TeCl_3(CF_3SO_3)$ and $TeCl_3(CH_3SO_3)$ melt at 145 and 90°C, respectively. The molecular weight of $TeCl_3(CH_3SO_3)$ could not be determined by the freezing point method since an elevation, rather than a lowering, of the freezing point of nitrobenzene was observed on addition of the compound. This unusual behaviour has been observed for compounds that can interact chemically with the solvent and are salted out on freezing along with the solvent (9).

The ir data for $MCl_3(XSO_3)$ salts (M = Se and Te; X = CF_3, CH_3, and p-$CH_3C_6H_4$) are reported in Tables 2 and 3. Earlier vibrational studies on sulfonate ligands provided information on ionic XSO_3^- groups (10–12), covalently bonded monodentate -OSO_2X groups (13–15), and bidentate bridging and tridentate XSO_3 groups (16–18). Band assignments have been made assuming that the C_{3v} local symmetry for the CSO_3 moiety (or tridentate XSO_3^- group), which would be responsible for six fundamentals, three E ($\nu_{as}(SO_3)$, $\delta_{as}(SO_3)$, and $\rho_r(SO_3)$) and three A ($\nu_s(SO_3)$, ν(S—C), and $\delta_s(SO_3)$) modes of ir-active vibrations, is lowered to local C_s (or C_1) on monodentate type

of coordination. With this lowering of symmetry the three E modes are split to give six bands, and a total of nine ir active bands may be expected.

The ir spectra of the $SeCl_3(XSO_3)$ compounds are quite identical, indicating strong structural similarity between them. The number and the position of the sulfur–oxygen stretching bands suggest that the XSO_3^- group in these compounds is acting as a monodentate ligand. Bands at 1395, 1205, and 795 cm^{-1} for $SeCl_3(CF_3SO_3)$ may be assigned to sulfur–oxygen stretching modes of a monodentate trifluoromethanesulfonate group, primarily on the basis of their similarity to the corresponding bands for this group in $Rb[I(CF_3SO_3)_4]$ (14). The remaining bands in this region at 1240, 1150, and 1100 cm^{-1} may be assigned to CF_3 stretching modes. The ir spectra of the $TeCl_3(XSO_3)$ compounds (Table 3) are quite simple and are distinctly different from those obtained for the $SeCl_3(XSO_3)$ compounds. Band positions are very close to the observed frequencies for ionic XSO_3^- ions (10–12), suggesting C_{3v} local symmetry for the CSO_3 moiety in these compounds. The presence of the ionic XSO_3^- group is, however, ruled out on the basis of molar conductance values. The ir data may be interpreted in terms of XSO_3^- ions acting as tridentate bridging ligands in which the three oxygens are involved in coordination to the central tellurium atom.

Complexes of $MCl_3(CF_3SO_3)$ (M = Se and Te) with $(C_2H_5)_4N^+(CF_3SO_3^-)$

The interaction of $SeCl_3(CF_3SO_3)$ and $TeCl_3(CF_3SO_3)$ with $(C_2H_5)_4N^+(CF_3SO_3^-)$ yields 1:1 salts of the type $(C_2H_5)_4N[MCl_3(CF_3SO_3)_2]$. The evidence that these products are not simple mixtures of $(C_2H_5)_4N^+(CF_3SO_3^-)$ and $MCl_3(CF_3SO_3)$, but definite compounds, is evident from their preparation and vibrational spectra (Table 2). The observed frequencies for $(C_2H_5)_4N[TeCl_3(SO_3CF_3)_2]$ are distinctly different from those seen for $TeCl_3(CF_3SO_3)$ (Table 3) and the $CF_3SO_3^-$ ion (10). The ir spectra of $TeCl_3(CF_3SO_3)$ and $CF_3SO_3^-$ are interpreted in terms of local C_{3v} symmetry for the CSO_3 moiety. The CSO_3 group in $(C_2H_5)_4N[TeCl_3(CF_3SO_3)_2]$ has symmetry reduced below C_{3v} as suggested by a splitting of both ν_4 and ν_5 bands. This reduction in symmetry results from a change of coordination of the $CF_3SO_3^-$ group from tridentate (C_{3v}) in $TeCl_3(CF_3SO_3)$ to monodentate (C_s) in $(C_2H_5)_4N[TeCl_3(CF_3SO_3)_2]$. As expected, the ir spectrum of $(C_2H_5)_4N[SeCl_3(CF_3SO_3)_2]$ does not show any significant change in the S—O stretching region from the corresponding bands for $SeCl_3(CF_3SO_3)$ since the $CF_3SO_3^-$ group retains the same functionality in both the compounds.

Complexes of $MCl_3(XSO_3)$ (M = Se and Te; X = CF_3, CH_3, and p-$CH_3C_6H_4$) with $(CH_3)_4N^+Br^-$

Tetramethylammonium bromide reacts instantaneously with $MCl_3(XSO_3)$ compounds to give salts of the type $[(CH_3)_4N]_2[MCl_3Br_3]$ in which the sulfonate groups have been replaced by bromo groups. Their ir spectra do not show any band in the S—O stretching region.

Complexes of $MCl_3(SO_3CF_3)$ (M = Se and Te) with pyridine

Both $SeCl_4$ and $TeCl_4$ are known to form complexes with donor molecules, and on the basis of electrical conductivity and vibrational spectra these complexes have been suggested to have the structure $[L_2MCl_3]^+Cl^-$ (7). It was of interest to find out whether or not the metal atom in these compounds is coordinately saturated. Both $SeCl_3(CF_3SO_3)$ and $TeCl_3(CF_3SO_3)$ form 1:2 addition compounds with pyridine. These complexes are insoluble in all common organic solvents. Their ir spectra are very complex due to a large number of bands for coordinated pyridine (19). However, bands at 1285, 1030, and 640 cm^{-1} and 1240 and 1160 cm^{-1}, which are present in the spectrum of $SeCl_3(CF_3SO_3)\cdot 2C_5H_5N$ (Table 3) and assigned to S—O and C—F stretching modes respectively, are in close agreement with the corresponding bands observed for ionic $CF_3SO_3^-$ (10, 11). The $CF_3SO_3^-$ ion had a monodentate mode of coordination in the parent compound, $SeCl_3(CF_3SO_3)$ (Table 2). The ir spectrum of $TeCl_3(CF_3SO_3)\cdot 2C_5H_5N$ does not exhibit any change in the S—O and C—F stretching region with the corresponding bands for $TeCl_3(CF_3SO_3)$ (Table 3). The CSO_3 groups in both these compounds have C_{3v} local symmetry, although the $CF_3SO_3^-$ group has different functionality in the two compounds. It acts as a tridentate ligand in $TeCl_3(CF_3SO_3)$ but is probably present in ionic form in the pyridine complex. The findings agree with the presence of an ionic $CF_3SO_3^-$ ion in the two pyridine complexes and may be represented as $[MCl_3(Py)_2]^+CF_3SO_3^-$.

Complexes of $TeCl_3(XSO_3)$ (X = CF_3 and CH_3) with NH_4CNS

Ammonium thiocyanate reacts with $TeCl_3(XSO_3)$ to give mixed ligand complexes of the type $(NH_4)_2[TeCl_3(NCS)_2(XSO_3)]$ (X = CF_3 and CH_3). Bands at ≃2070 (C—N stretch), ≃780 (C—S stretch), and ≃470 cm^{-1} (N—C—S bending modes) in these complexes suggest that the thiocyanate ligand binds to the Te through the N atoms (20). The presence of bands at 1370, 1220, and 830 cm^{-1} for the S—O stretching modes in the compound $(NH_4)_2[TeCl_3(NCS)_2(CF_3SO_3)]$ suggests a monodentate mode of coordination for the $CF_3SO_3^-$ ion (14) (Table 2). Both ν_4 and ν_5 bands are split for the complex $(NH_4)_2[TeCl_3(NCS)_2(CH_3SO_3)]$ (Table 2), indicating a lowering of the symmetry of the CSO_3 moiety from C_{3v} in $TeCl_3(CH_3SO_3)$ to C_s in the complex.

Potassium hexakis(trifluoromethane)/methanesulfonatotellurate(IV), $K_2[Te(XSO_3)_6]$ (X = CF_3 and CH_3), and potassium oxotetrakis(paratoluenesulfonato)tellurate(IV), $K_2[TeO(p\text{-}CH_3C_6H_4SO_3)_4]$

Potassium tellurate(IV) reacts with trifluoromethane-, methane-, and paratoluene-sulfonic acids to yield $K_2[Te(CF_3SO_3)_6]$, $K_2[Te(CH_3SO_3)_6]$, and $K_2[TeO(p\text{-}CH_3C_6H_4SO_3)_4]$, respectively. These compounds are insoluble in all common organic solvents. Their ir spectra (Table 2) show split ν_4 and ν_5 modes and are assigned to the presence of monocoordinated sulfonate groups in these salts. The incomplete solvolysis of potassium tellurate(IV) by paratoluenesulfonic acid may be attributed to the lower acidity of paratoluenesulfonic acid vis-à-vis the other two sulfonic acids considered here.

An NMR study of the Lycopodium alkaloids, annotinine and annotine: verification of the annotine structure

DONALD W. HUGHES,[1] ROBERT V. GERARD, AND DAVID B. MACLEAN[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received March 17, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

DONALD W. HUGHES, ROBERT V. GERARD, and DAVID B. MACLEAN. Can. J. Chem. **67**, 1765 (1989).

The Lycopodium alkaloids, annotinine and annotine, were examined by ^{1}H and ^{13}C NMR spectroscopy. Proton spectra were assigned by the application of double-quantum filtered phase-sensitive COSY and nuclear Overhauser enhancement difference spectra. These and other data confirmed the structure previously assigned to annotine. The ^{13}C chemical shifts were consistent with the structural data derived from the proton spectra. The NMR data showed a good correlation with structures determined from molecular mechanics (MMX) calculations.

Key words: Lycopodium alkaloids ^{1}H and ^{13}C NMR, annotinine, annotine, structure of Lycopodium alkaloids, NMR alkaloids.

DONALD W. HUGHES, ROBERT V. GERARD et DAVID B. MACLEAN. Can. J. Chem. **67**, 1765 (1989).

On a étudié des alcaloïdes du Lycopodium, l'annotinine et l'annotine, par RMN du ^{1}H et du ^{13}C. On a attribué les raies des spectres du proton par l'application de spectres de différence eOn et COSY, sensibles à la phase et doublement filtrés d'un point de vue quantique. Ces données ainsi que d'autres confirment la structure attribuée antérieurement à l'annotine. Les déplacements chimiques du ^{13}C sont en accord avec les données structurales obtenues à partir des spectres du proton. Les données de la RMN présentent une bonne corrélation avec les structures déterminées à l'aide de calculs MMX basés sur la mécanique moléculaire.

Mots clés : RMN ^{1}H et ^{13}C des alcaloïdes du Lycopodium, annotinine, annotine, structure des alcaloïdes du Lycopodium, RMN d'alcaloïdes.

[Traduit par la revue]

Introduction

The structure assigned to annotine (1, 2) (Fig. 1), a minor component of the alkaloids of *Lycopodium annotinium L.*, is unique among the more than 100 alkaloids of established structure of the Lycopodium family (3). The structural elucidation was based upon degradation experiments, spectroscopic examination (IR, ^{1}H NMR, and MS) of annotine and a number of its derivatives, and on biogenetic considerations. In the latter context, annotine and a related alkaloid, lyconnotine (4, 5), are the only members of the family isolated thus far that cannot be directly accommodated into the biogenetic schemes that apply consistently to the other members of the family (3). Because of this biogenetic anomaly and because the structure was assigned tentatively in the initial investigation, a reexamination of the structure of the alkaloid was undertaken. Here we report an NMR investigation of annotine using refinements of previously used procedures and new methods that were not available at the time of the original study.

In a parallel study we have reexamined the NMR spectra of annotinine (Fig. 1), another member of this family of alkaloids bearing a lactone function, whose structure and stereochemistry had been verified by an X-ray analysis of its bromohydrin derivative (6). Rings A and C of annotine and annotinine were expected to be conformationally similar, despite the different functionality of ring A in the two systems. Accordingly, we undertook a comprehensive examination of the ^{1}H and ^{13}C NMR spectra of annotinine and used the information so obtained as a model to interpret the annotine spectra and thereby to test the structure previously assigned.

Experimental

All NMR spectra were recorded on a Bruker AM-500 spectrometer. Proton spectra were acquired at 500.135 MHz using a 5 mm dual frequency $^{1}H/^{13}C$ probe. Spectra were obtained in 48 scans in 32K data points over a 2.000 kHz spectral width (8.192 s acquisition time) for annotinine and a 2.747 kHz spectral width (5.964 s acquisition time) for annotine. Sample temperature was maintained at 30°C by a Bruker BVT-1000 variable temperature unit. The free induction decays were processed using Gaussian multiplication for resolution enhancement and were zero-filled to 64K before Fourier transformation.

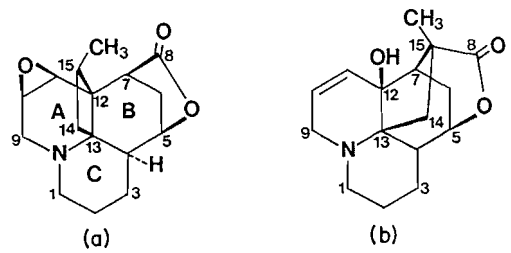

FIG. 1. Structure and numbering of (a) annotinine and (b) annotine.

The inversion–recovery experiments used the standard pulse sequence 180°–τ–90°–ACQ in which the delay τ was adjusted to selectively invert methine proton signals. The 90° ^{1}H pulse width was 18.6 μs. The relaxation delay was 5.0 s and the delay τ was 1.05 s for annotinine and 0.8 s for annotine. Free induction decays were acquired in 16 scans and processed with exponential multiplication (line broadening: 0.2 Hz) before Fourier transformation.

Nuclear Overhauser enhancement (nOe) difference spectra were obtained by subtraction of the off-resonance control FID from the on-resonance FID. The signal of interest was selectively saturated for 5.0 s and the decoupler was gated off during acquisition. This saturation period also served as the relaxation delay. Either 8 or 16 scans were acquired for each irradiation with the cycle of irradiations repeated 4–10 times. Free induction decays were processed using exponential multiplication (line broadening: 4–5 Hz) before Fourier transformation. Samples were not degassed.

Double-quantum filtered COSY 2-D NMR spectra were acquired in the phase-sensitive mode using the pulse sequence: 90°–t_1–90°–τ–90°–ACQ. Phase-sensitive data were obtained using time-proportional

phase incrementation (TPPI) (7, 8). The fixed delay τ was 3.0 μs. In the F2 dimension 4K data points were used during the acquisition of the 512 FIDs. The annotinine spectra were acquired in 48 scans over a 2.000 kHz spectral width using a 2.0 s relaxation delay while the annotine data were recorded in 64 scans over a 2.747 kHz spectral width using a 1.5 s relaxation delay. Zero-filling in the F1 dimension produced a 2K × 512 data matrix after 2-D Fourier transformation of the phase-sensitive data. This resulted in an F2 digital resolution of 0.977 Hz/point for annotinine and 1.341 Hz/point for annotine. During the 2-D Fourier transformation a sine-bell window function shifted by $\pi/2$ was applied to both dimensions. The transformed data was not symmetrized. The digital resolution of the F2 cross sections was improved by performing an inverse Fourier transform to regenerate the FID of the particular row. This was followed by zero-filling to 32K and then Fourier transformation.

COSY 2-D NMR spectra optimized for long-range couplings were recorded in the absolute value mode using the pulse sequence: $90°-t_1-90°-\tau-$ACQ. The fixed delay τ was set to 0.278 s and was determined from the calculation of $1/4J$ with J = 0.9 Hz. A 1.0 s relaxation delay was used for both samples. Spectra were acquired in 96 scans for annotinine and 128 scans for annotine for each of the 256 FIDs that contained 2K data points in F2 over the previously mentioned spectral widths. Zero-filling in F1 produced a 1K × 1K data matrix with a digital resolution of 1.953 Hz/point for annotinine and 2.683 Hz/point for annotine in both dimensions. During 2-D Fourier transformation a sine-bell squared window function was applied to both dimensions. The transformed data was then symmetrized.

Carbon-13 spectra were recorded at 125.759 MHz using the 5-mm dual frequency $^1H/^{13}C$ probe. The spectra were acquired over a 30.0 kHz spectral width in 32K data points (0.557 s acquisition time) using the standard J-modulated spin sort or DEPT pulse sequences for editing. The ^{13}C 90° pulse width was 6.4 μs while the ^1H 90° pulse width through the decoupler channel was 18.8 μs. A 1.0 s relaxation delay was used. The FIDs were processed using exponential multiplication (line broadening: 2.0 Hz).

The $^{13}C-^1H$ 2-D chemical shift correlation spectra were acquired using the standard pulse sequence incorporating the BIRD pulse during the evolution period for $^1H-^1H$ decoupling in F1 (9–11). The spectra in F2 were recorded over the aliphatic carbon spectral range of 8.0–9.5 kHz in 4K data points. The 256 FIDs in F1 were obtained over the ^1H spectral widths stated above. The fixed delays in the pulse sequence were a 1.0 s relaxation delay, BIRD pulse and polarization transfer delays ($1/2\,^1J_{CH}$) of 0.003571 s, and a refocussing delay ($1/4\,^1J_{CH}$) of 0.001786 s. The data were processed using exponential multiplication (line broadening: 4.0 Hz) in F2 and unshifted sine bell in F1. Zero-filling in F1 resulted in a 2048 × 512 data matrix.

Spectra simulations were performed using the commercially available Bruker Aspect 3000 PANIC program.

Energy-minimized structures were generated using MMX force field calculations derived from MM2 (available from Quantum Chemistry Program Exchange, Chemistry Department, Indiana University, Bloomington, IN 47405, U.S.A.). The calculations were carried out using the program PCMODEL (available from Dr. K. Gilbert, Serena Software, P.O. Box 3076, Bloomington, IN 47402-3076, U.S.A.). Vicinal coupling constants measured from these structures were calculated using a modified Karplus equation that takes into account substituent electronegativity (12).

The compounds used in this study were isolated and purified according to the procedures given in ref. 1. Samples were dissolved in C_6D_6 (MSD Isotopes) to an average concentration of 0.14 M. Chemical shifts for the ^1H and ^{13}C spectra are reported in ppm relative to TMS using the residual solvent signals at 7.15 and 128.0 ppm as internal references.

Results and discussion

NMR experiments were initially performed on annotinine since the stereochemistry of this molecule had been previously established (6). The proton chemical shifts and coupling constants are presented in Tables 1 and 2, respectively. Assignment of the annotinine ^1H spectrum shown in Fig. 2a was accomplished by a combination of one- and two-dimensional NMR methods. Protons that could be assigned in this spectrum included H-5 at 3.811 ppm, H-15 at 3.304 ppm, since the signal from this proton contained a quartet component within its multiplet structure, and the CH_3 doublet at 1.492 ppm. The remaining proton resonances were found in two sections of the spectrum. Between 2.0 and 3.0 ppm the methylene protons on C-1, C-9, and C-14 were located as well as the epoxide ring protons H-10 and H-11. The region from 0.8 to 1.6 ppm contained signals from the C-2, C-3, and C-6 methylene protons and the ring junction methine H-4.

14*c*	2.059	1.899
15	3.304	
16-CH_3	1.492	1.693

Following this preliminary analysis a series of inversion–recovery experiments were carried out to differentiate methylene from methine resonances. These experiments exploit the fact that the methine protons should have a longer spin-lattice relaxation time. Multiplets that remained inverted after the application of the inversion–recovery pulse sequence were at 3.811, 3.304, 2.683, 2.252, 2.289, and 1.004 ppm. The results confirmed the assignment of the lowest field resonances as the methine protons H-5 and H-15. The three signals between 2.2 and 2.7 ppm were considered to arise from H-10, H-11, and H-7 but could not be specifically assigned. Based on its high field position, the multiplet at 1.004 ppm was tentatively assigned to H-4.

Most of the chemical shift assignments in Table 1 were obtained from a double-quantum filtered phase-sensitive COSY 2-D NMR spectrum. This version of the COSY pulse sequence was used because it not only reduced diagonal peak intensity but also produced pure 2-D absorption lineshapes, which resolved spin couplings within cross-peaks and provided more accurate measurement of chemical shifts (13–16). Correlations among the annotinine protons were established by examining the connectivities to the methine protons and the CH_3 group. The A-ring epoxide methine protons H-10 and H-11 and the C-9 methylene protons were difficult to analyze because of the overlap of the signals at 2.683 and 2.676 ppm (Fig. 2).

Upon completing the analysis of the connectivities in the COSY spectrum it was then necessary to determine the individual chemical shift assignments of the nonequivalent methylene protons. These protons are designated using the α,β

[a]Coupling was not observed in the 1-D ^1H spectrum but was detected by the long-range COSY experiment.

terminology. A β proton, for example H-1β in Fig. 3a, is located on the same side of the molecule as the lactone ring. The C-14 methylene protons are designated as H-14*c* and H-14*t*, which indicated that they are *cis* or *trans*, respectively, to the CH_3 group.

The nOe difference experiments were the most effective technique for providing both methylene proton chemical shift assignments and structural data. The information derived from these experiments was examined in relation to an energy-minimized structure determined from molecular mechanics (MMX) calculations (Fig. 3a). Proton internuclear distances, measured from the calculated structure, were found to agree favourably with the spatial relationships indicated in the nOe difference spectra.

The nOe experiments began with the saturation of H-15, which produced an enhancement of the CH_3 doublet and the C-14 proton resonance at 1.911 ppm. This H-14 multiplet was assigned to the proton *trans* to the CH_3. Assignment of H-14*t* also aided in the discrimination of the C-1 methylene protons because irradiation of the C-1 proton at 2.921 ppm resulted in an nOe of the H-14*t* signal. The 2.921 ppm multiplet was therefore assigned to H-1β. This result was consistent with the 2.3 Å distance between the H-1β and H-14*t* in the energy-minimized structure. Other signals enhanced during this experiment were identified as H-1α (2.022 ppm) and H-2β (0.842 ppm). Methylene protons on C-6 and C-3 were also assigned by nOe difference spectra when H-7 and H-5, respectively, were saturated.

The nOe difference spectra that provided key structural data involved the irradiation of the protons on C-11 and C-9. Prior to this experiment the doublet of doublets at 2.252 ppm could not be unambiguously assigned to either H-10 or H-11. Saturation of the resonance at 2.252 ppm not only produced the expected enhancement of the adjacent epoxide proton at 2.683 ppm but also resulted in an nOe being observed on the H-6α doublet at 0.961 ppm. Examination of the annotinine structure in Fig. 3a revealed that the only epoxide proton capable of producing an nOe on the axial H-6α was H-11. The internuclear distance from H-11 to H-6α in the calculated structure was found to be 2.8 Å. Proton 11 was therefore assigned to 2.252 ppm. This particular experiment provides a means of characterizing the geometry of the C-12 substituents because the observed nOe between H-11 and H-6α can only result if the C-11 to C-12 bond is axial to ring B. This observation should prove useful in the examination of other alkaloids in this series.

The final nOe experiment on annotinine involved the saturation of the C-9 proton at 2.540 ppm. As expected, there was an enhancement of the H-9 signal at 2.676 ppm. The most surprising result was the nOe observed on H-4. From Fig. 3a it is evident that the C-9 proton labelled H-9α is directed underneath ring C toward H-4, which must have an axial geometry for the nOe to be observed. In fact the internuclear distance between these protons in the minimized structure was 2.0 Å. This particular nOe experiment may be used to probe the stereochemistry at C-4 provided that the N—C9 bond is axial to ring C in other Lycopodium alkaloids.

The coupling constants in Table 2 were indicative of the distinct conformations for each of the rings of annotinine. A considerable distortion of the B-ring conformation (Fig. 3a) was evident from the absence of any observable coupling between H-6α and H-7 and H-5. To accommodate the five-membered lactone, C-6 must be puckered well below the plane formed by carbons 1, 2, 4, and 13. Because of this distortion, the dihedral angles between H-6α and H-5 and H-7 lie in the range 80°–90°. A small coupling between H-6α and H-5 and H-7 was detected by the observation of cross-peaks between these protons in a COSY experiment optimized for long-range couplings. The COSY experiment also detected a four-bond coupling between H-5 and H-7, indicating that the intervening bonds must be in planar W structure.

The C-ring protons displayed couplings that were characteristic of a chair conformation (Table 2). Signals from H-2α,β and H-3α,β were the most difficult to interpret because of the numerous vicinal as well as long-range couplings contributing to their multiplet structure and the partial overlap of H-2α and H-3β (Fig. 1a). Some of these couplings were resolved by examining cross sections in the F2 dimension through the cross-peaks in the phase-sensitive COSY spectrum, while others were obtained by spin decoupling or computer simulation.

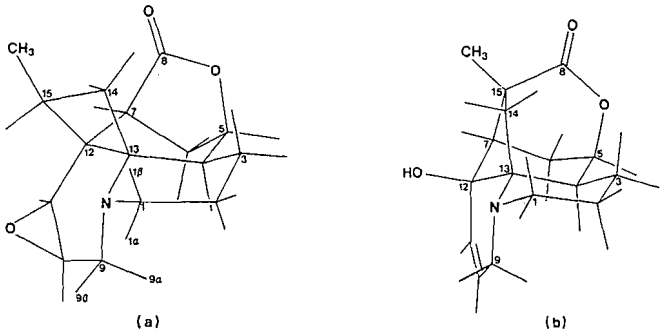

FIG. 3. Energy-minimized structures of (a) annotinine and (b) annotine obtained from MMX force field calculations.

Long-range couplings were also detected between the C-ring protons. In particular, a four-bond coupling of 1.5 Hz was observed between the equatorial protons H-1α and H-3α, indicating the planar W arrangement of the bonds in the coupling pathway.

The A-ring protons 10 and 11 displayed a 4.0 Hz vicinal coupling typical of *cis* protons in an epoxide structure (17). The C-9 protons had nearly identical couplings with H-10 (Table 2), suggesting similar dihedral angles. Molecular modelling indicated that the A ring could best accommodate the cyclobutyl and epoxide rings if it adopted a boatlike conformation (Fig. 3a). When viewed along the C-9 to C-10 bond, H-10 in this conformation appears equidistant between H-9α and H-9β and this would account for the similar vicinal couplings. Several unresolved long-range couplings were detected on the A-ring protons during the long-ranged COSY experiment. These included four-bond coupling between the C-9 protons and both H-11 and H-1β, and five-bond couplings between H-11 and H-14*t*, and H-9β and H-14*c*.

The vicinal coupling constants for H-15 and the C-14 protons (Table 2) were in the range reported for cyclobutyl compounds (17). Proton 15 was long-range coupled through four and five bonds to H-7 and H-6β, respectively.

The annotinine vicinal coupling constants measured from the ^{1}H NMR spectra corresponded to within 1–3 Hz of those calculated from the energy-minimized structure. These results, along with the nOe data and the structural constraints imposed by the long-range couplings, indicated that the calculated structure in Fig. 3a was a reasonable representation of the annotinine structure in solution.

With the analysis of the annotinine data completed, we then applied the same techniques to assign the ^{1}H spectrum of annotine to determine whether the structure and relative stereochemistry previously assigned were correct. The most obvious changes in the annotine ^{1}H spectrum (Fig. 2b) relative to that of annotinine were the presence of the olefinic protons 10 and 11, the absence of H-15, and the appearance of a singlet for the CH_3 at 1.693 ppm. Tentative assignments were made for some methine and methylene protons on the basis that their chemical shifts and multiplet patterns were similar to the corresponding annotinine protons. However, several annotine ^{1}H signals were shifted upfield and in two cases there was a reversal in position of the resonances for the α and β protons of a methylene group. An additional complication in the annotine spectrum was the overlap of the multiplets in the 1.1–1.5 ppm region (Fig. 2b). The methine signal (H-4) at 1.164 ppm was obscured by an overlapping H-6 resonance and could only be resolved by the use of the inversion–recovery pulse sequence. This experiment also resulted in the selective inversion of the olefinic protons, the H-5 multiplet at 3.608 ppm and the methine signal from H-7 at 1.816 ppm, which had undergone a 0.5 ppm upfield shift relative to annotinine. The remaining chemical shift assignments (Table 1) were determined from the COSY and nOe difference spectra.

The contour plot of the annotine double-quantum filtered phase-sensitive COSY experiment could not be used to distinguish between olefinic protons 10 and 11 since they both showed correlations to the C-9 protons at 2.876 and 2.686 ppm. The H-5 signal had cross-peaks to the H-6 proton at 1.415 ppm and the overlapped H-4 and H-6 protons near 1.1 ppm. A cross-peak between H-5 and H-7 was also observed. The multiplet at 2.409 ppm was tentatively assigned to H-1β because of the similarity in both chemical shift and multiplet structure to the corresponding proton in annotinine. This proton was correlated with H-1α at 2.171 ppm and the C-2 methylene protons at 0.828 and 1.439 ppm. By comparison with the annotinine spectrum, the H-2 multiplet at 0.828 ppm was assigned to H-2β. Proton 2β displayed other cross-peaks to H-2α (1.439 ppm) and the H-3 proton at 1.540 ppm while the cross-peaks to H-1α and the H-3 proton at 1.089 ppm were of lower intensity. Finally, a correlation was detected between the geminal coupled C-14 methylene protons at 1.899 and 2.182 ppm. A result that provided the first indication of the geometry of the C—H bond at position 4 was the cross-peak between the H-14 proton at 1.899 ppm and H-4.

In addition to the connectivity data, the phase-sensitive COSY experiment provided a means for obtaining coupling constants from overlapping multiplets. As stated in the annotinine discussion, the analysis of the protons of ring C, H-2α,β and H-3α,β, was difficult because of the large number of coupling interactions. The annotine spectrum was further complicated by the overlap of H-2α with both H-3β and H-6β (Fig. 2b). The problem of measuring the coupling constants for H-2α was solved by examining the cross-peaks in the phase-sensitive COSY spectrum. To illustrate this procedure, Fig. 4 presents a section of the contour plot containing the diagonal peak of H-1β and the cross-peaks to H-1α, H-2α, and H-2β. The cross section at the bottom of the diagram was selected from the row in the F2 dimension indicated by the arrow. It can be readily seen that the H-2α multiplet is completely resolved without the interference of other overlapping resonances.

The other advantage of the technique is that the active coupling that gives rise to the cross-peak can be identified by the antiphase transitions (13–16). All other couplings to H-2α, designated as the passive couplings, appear in-phase superimposed on the antiphase transitions (Fig. 4). The active coupling between H-1β and H-2α was measured from the point at the centre of the pair of inverted or in-phase triplets to the centre of the multiplet where the phase change occurs. The reason for this is that the geminal and *trans* diaxial couplings were nearly identical (Table 2). In the absence of all other couplings H-2α would appear as a doublet of doublets overlapped at the central transition. This pseudo triplet in the phase-sensitive COSY spectrum would have its central transition cancelled because the transition intensities of an antiphase triplet must be −1, 0, and +1 (13–16). A more straightforward example is the H-1α cross-peak in which the antiphase transitions are separated by the geminal coupling.

These examples demonstrated that cross-peaks arising from multiplets with large geminal and *trans* diaxial couplings could be readily analyzed because the individual transitions were well

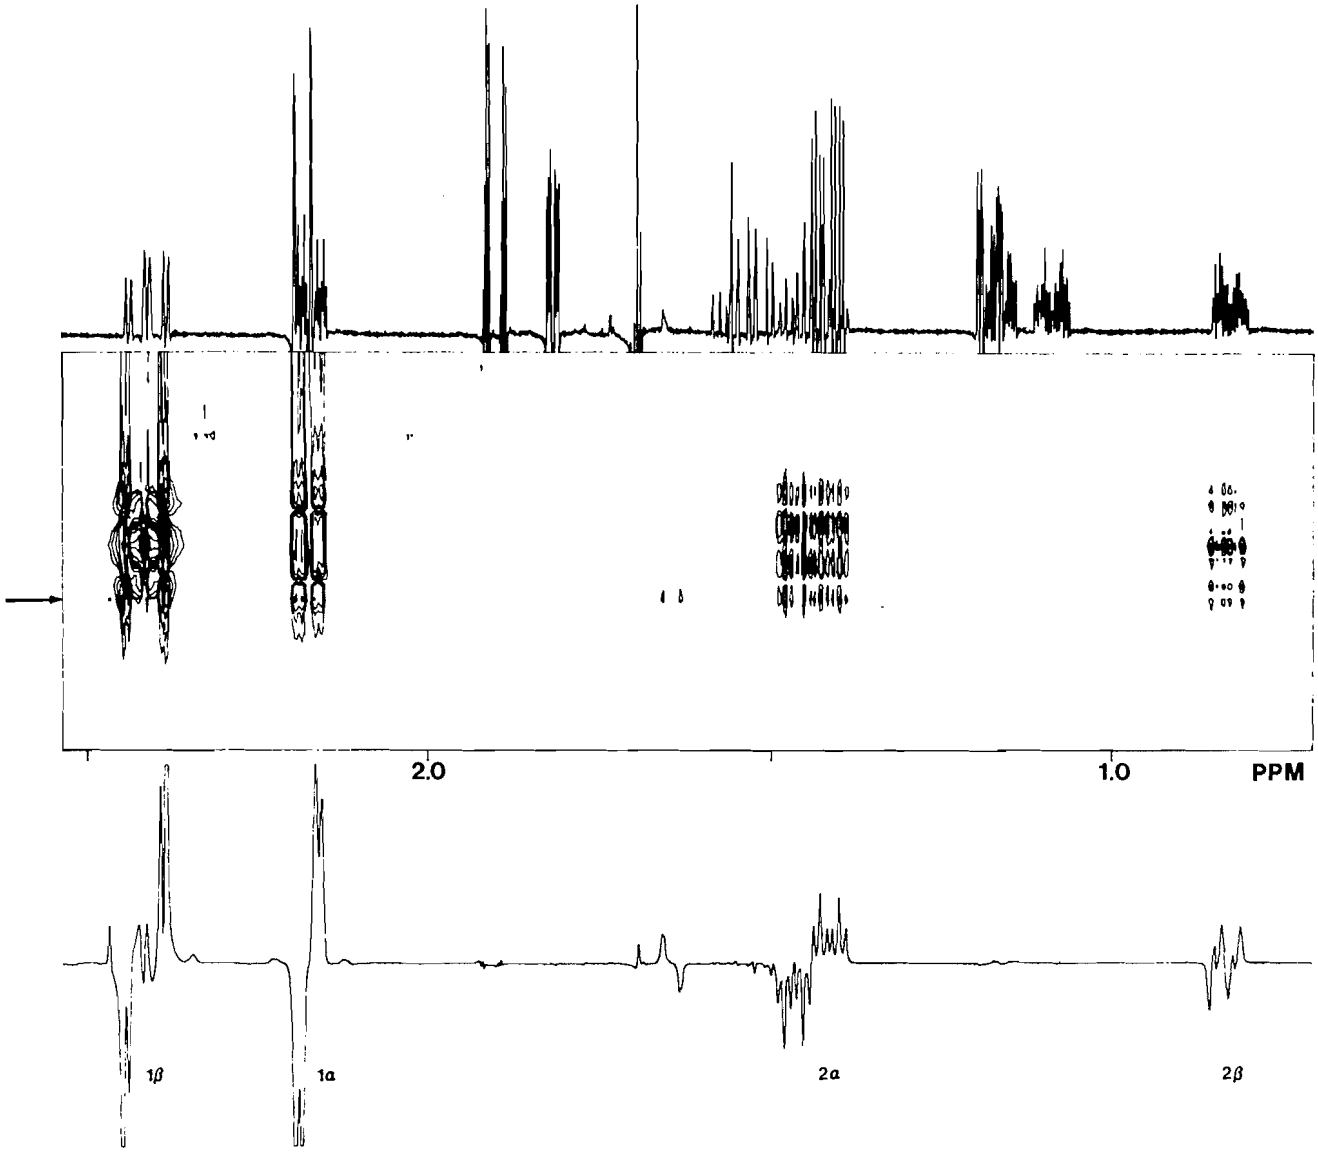

FIG. 4. Contour plot and cross section of the H-1β diagonal peak and cross-peaks to H-1α, H-2α, and H-2β of annotine.

separated. This technique was less effective for protons such as the equatorial H-2β. The H-2β multiplet was composed of many closely spaced transitions that could only be resolved in the higher resolution 1-D spectrum. In the COSY spectrum these transitions would cancel each other when they became antiphase, resulting in the loss of coupling information and lower intensity cross-peaks. Other techniques such as spin decoupling and heteronuclear shift correlation were applied to obtain the coupling information.

The nOe difference spectra were then recorded to assign the methylene protons and to examine the relative stereochemistry at C-4 and C-12. The nOe data were also compared with the ^1H distances measured from an energy-minimized structure of annotine (Fig. 3b). These experiments began by saturating the CH_3 singlet, which produced an enhancement of H-14*c* at 1.899 ppm and the H-7 signal. Irradiation of H-14*t* enhanced both H-14*c* and the H-3 multiplet at 1.540 ppm. This C-3 proton was therefore assigned to H-3β, which was separated by 2.2 Å from H-14*t* in the calculated structure. A reverse experiment in which H-3β was saturated confirmed the H-14*t* result and also produced an nOe at H-3α (1.087 ppm) and H-2β (0.828 ppm). This experimental verification of the H-2β resonance enabled us to confirm the assignment of H-1β by irradiating the 2.409 ppm multiplet. An enhancement of both H-1α (2.171 ppm) and H-2β was observed. In ring B the methylene protons at C-6 were differentiated by irradiation of H-7. The signal at 1.415 ppm experienced the nOe and was assigned to the equatorial H-6β. An additional result of this experiment was the enhancement of the lowest field olefinic proton at 5.656 ppm. On the basis of interproton distances this signal was assigned to H-11.

With the assignment of H-11 confirmed it was now possible to probe the geometry of the C-11,C-12 bond. Saturation of H-11 enhanced the *cis* olefinic proton H-10 as well as H-7. The definitive result was the nOe observed on the 1.180 ppm multiplet assigned to H-6α (Fig. 5b). This nOe to the axial C-6 proton indicated an axial orientation of the bond between carbons 11 and 12 with the C-12 hydroxyl group being equatorial. Therefore the relative stereochemistry at C-12 was identical with that of annotinine and the majority of other Lycopodium alkaloids (3). The internuclear distance from H-11 to H-6α in the calculated structure was 2.4 Å, which was smaller than the annotinine separation. This result implied that

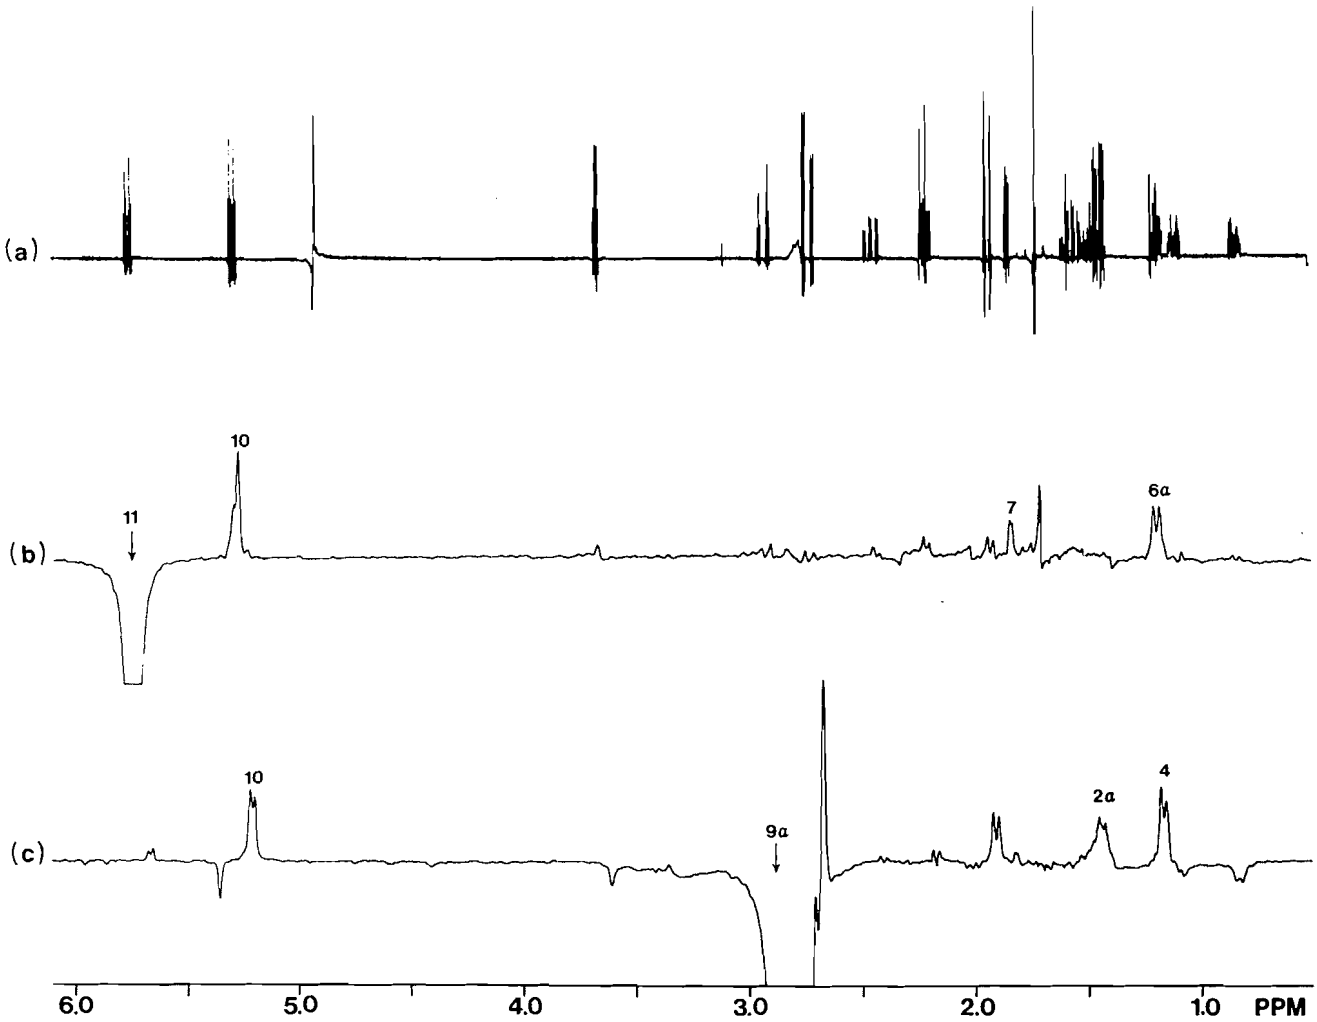

FIG. 5. Comparison of the (a) 500 MHz ^{1}H spectrum with the nOe difference spectra obtained by saturation of (b) H-11 and (c) H-9α of annotine.

changes in the conformations of the A and B rings relative to annotinine, such as those shown in Fig. 3b, would bring H-11 closer to both H-7 and H-6α.

The relative stereochemistry of the C—H bond at position 4 of annotine was determined by irradiating the C-9 protons. Saturation of the lower field H-9 proton at 2.876 ppm resulted in the enhancement of H-4 (Fig. 5c) and therefore confirmed the axial geometry of the C—H bond at carbon 4. Thus the relative stereochemistry of annotine at C-4 is also the same as annotinine. The interproton distance between H-9α and H-4 in the calculated structure was 2.5 Å, which was larger than the annotinine distance. This nOe experiment also produced an enhancement of H-2α, H-9β, and H-10.

With the spatial relationships of the annotine protons determined by the nOe experiments, the ring conformations were then examined using the ^{1}H–^{1}H coupling constants (Table 2). In contrast to annotinine, the axial H-6α in ring B of annotine showed couplings of 2.7 and 1.1 Hz to H-5 and H-7, respectively. This indicated that the B ring was adopting a more chairlike conformation (Fig. 3b) than in annotinine since the dihedral angles from these coupling constants would be in the range of 50°–70°. There is less distortion of the B ring since the lactone forms a six-membered ring and the two-carbon unit bridging C-7 and C-13 is accommodated within a five-membered ring structure involving carbons 7, 12, 13, 14, and 15. The conformation of ring B was further defined by the 1.7 Hz four-bond coupling between H-5 and H-7.

The chair conformation of ring C remained similar to that of annotinine. There were minor changes in the dihedral angles about the C—C bonds that were reflected in the variation in some of the vicinal coupling constants (Table 2). Long-range coupling was observed between H-1α and H-3α. The four-bond coupling between H-14*c* and H-4 also defined the orientation of the C—H bond at C-4. The structure in Fig. 3b shows that with an axial H-4 the bonds to H-14*c* form the planar W pathway required for the four-bond coupling.

Ring A underwent a change in conformation relative to annotinine owing to the presence of the double bond between carbons 10 and 11. This was first indicated by the substantial increase in magnitude of the H-9α,β geminal coupling constant (Table 2). The change in geminal coupling was caused by the nodal plane of the π system being oriented such that it bisects the angle between the C-9 methylene protons (17–19). Carbons 9, 10, and 11 must have a planar geometry for this to occur. From the energy-minimized structure (Fig. 3b) it can be seen that the nitrogen and all the carbon atoms except C-13 were planar, resulting in a sofa conformation.

The A-ring protons also displayed long-range couplings. A four-bond coupling was detected between H-9α and H-1β in the long-range COSY spectrum. Five-bond couplings were

15	32.1	46.3
16-CH_3	12.7	25.0
C=O	177.9	176.4

observed between H-11 and H-14*t*, and H-10 and H-1β (Table 2). The ^1H NMR data derived from the nOe experiments and the coupling constants showed a good correlation with the energy-minimized structure in Fig. 3b.

This study concluded with an examination of the ^{13}C NMR spectra of annotinine and annotine. The ^{13}C chemical shifts are presented in Table 3. Assignment of the chemical shifts initially involved the identification of carbon types from the *J*-modulated spin sort spectra. In the case of annotine, DEPT spectra were required to suppress the benzene solvent signal in order to observe the olefinic carbon resonances at 127.7 and 128.1 ppm. These signals were assigned to carbons 10 and 11, respectively, by performing selective ^1H decoupling during the acquisition of the DEPT spectra. Some preliminary assignments for the aliphatic carbons were made by combining the results of the edited spectra with ^{13}C data reported for other Lycopodium alkaloids (20). The lowest field methine signal near 80 ppm was assigned to C-5. Methine carbon signals from the epoxide group in annotinine appeared near 50 ppm. The methylene carbons adjacent to the nitrogen were located in the region 44–48 ppm. The highest field methylene carbon resonances were attributed to carbons 2 and 3. Assignment of the quaternary carbons, 12 and 13, was made on the basis of their chemical shifts. In the annotinine spectrum C-13 (58.2 ppm) was deshielded relative to C-12 (44.6 ppm) because C-13 was bonded to the nitrogen. These carbon resonances were reversed in annotine since C-12 (77.9 ppm) was directly bonded to the hydroxyl group. Carbon 13 was also deshielded in annotine relative to annotinine due to the change in ring size as well as to the β substituent effect of the hydroxyl group at C-12.

The definite assignment of the protonated carbon chemical shifts relied on the ^1H–^{13}C chemical shift correlation experiment. The pulse sequence used the BIRD pulse (21) during the evolution period to remove homonuclear ^1H couplings in the F1 dimension. Carbon atoms directly bonded to nonequivalent methylene protons produced two signals that still retained their geminal coupling. This feature of the shift correlation spectrum was especially useful for resolving the overlapping methylene proton resonances H-3β, H-2α, and H-6β of annotine. From the F1 cross sections through carbons 2, 3, and 6 a good estimate was obtained for the methylene proton chemical shifts and geminal coupling constants. These results helped to confirm the analysis of the ^1H spectrum. In the ^{13}C spectra it was difficult to distinguish C-1 and C-9 because of their similar chemical shifts. Assignment of these carbons was achieved by their correlation with the directly bonded protons H-1α,β and H-9α,β, which appeared as well-resolved multiplets in the ^1H spectra.

A comparison of the ^{13}C data of these two alkaloids indicated that the methyl resonance of annotinine had a high field chemical shift of 12.7 ppm. Similar results were also reported for the methyl groups of *cis*-1,2-dimethylcyclobutane (22). The shielding of the annotinine methyl was caused primarily by steric interactions with C-7, which is both *cis* and γ relative to the methyl. In the X-ray structure the methyl was found to be pointed in the direction of the carbonyl oxygen (6). This additional steric interaction would also contribute to the shielding of the methyl carbon. The chemical shift of C-4 in both alkaloids was essentially the same, indicating no significant difference in the structure around this carbon. Carbons 2 and 6 were both shielded in annotine relative to annotinine (Table 3). This was due to the γ steric effect of carbons 9 and 11. The change in the A-ring conformation to the sofa form shown in Fig. 3b forces the bonds between the nitrogen and C-9, and between C-11 and C-12 to become completely axial to ring B. This factor, combined with the reduced distortion of the B- and C-ring chair conformations, resulted in more effective γ interactions.

Conclusions

The application of both high field NMR and one- and two-dimensional techniques has permitted the complete assignment of the ^1H and ^{13}C NMR spectra of the Lycopodium alkaloids, annotinine and annotine. The nOe difference spectra established that the relative stereochemistry at C-4 and C-12 of annotine was identical with that of annotinine. The double-quantum filtered phase-sensitive COSY experiment has been shown to be an effective method for analyzing natural products spectra. This pulse sequence was able to provide both connectivity and coupling constant information in regions of the ^1H spectrum containing complicated overlapping multiplets. Both the ^1H and ^{13}C data indicated that the A ring of annotine has a sofa conformation. The complete assignment of both the annotinine and annotine ^{13}C spectra will be useful to those engaged in biosynthetic studies on these alkaloids.

Ligand substitution reactions of pentacyanoferrate(II) complexes with *N*-heterocyclic cations in aqueous solution

DONAL HUGH MACARTNEY[1] AND LAUREN JEAN WARRACK
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received January 31, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

DONAL HUGH MACARTNEY and LAUREN JEAN WARRACK. Can. J. Chem. **67**, 1774 (1989).

Kinetic and spectroscopic studies have been carried out in aqueous solution on the formation (from $Fe(CN)_5OH_2^{3-}$) and dissociation of pentacyanoferrate(II) complexes containing 1-(4-pyridyl)pyridinium and the neutral, protonated, and *N*-methylated forms of 4,4′-bipyridine (BPY), 1,2-bis(4-pyridyl)ethane (BPA), and *trans*-1,2-bis(4-pyridyl)ethylene (BPE). The pH dependences of the formation kinetics have been analyzed in terms of the specific rate and acid dissociation constants for these ligands. The rate constants (25.0°C, $I = 0.10$ M) for the formation of the dinuclear complexes $(NC)_5FeLFe(CN)_5^{6-}$ have been determined for BPY (50 M^{-1} s^{-1}), BPA (66 M^{-1} s^{-1}), BPE (95 M^{-1} s^{-1}), and pyrazine (10 M^{-1} s^{-1}), and are compared with the respective rate constants for the formation of $(NC)_5FeLCo(NH_3)_5$. The relationships between the formation rate constants and the size of the ligand, the number of donor sites, and the magnitude and position of charges on the ligand are discussed in terms of an ion-pair dissociative mechanism.

Key words: pentacyanoferrate(II) complexes, *N*-heterocycles, ligand substitution, kinetics.

DONAL HUGH MACARTNEY et LAUREN JEAN WARRACK. Can. J. Chem. **67**, 1774 (1989).

Opérant en milieu aqueux, on a effectué des études cinétiques et spectroscopiques sur la formation (à partir de $Fe(CN)_5OH_2^{3-}$) et sur la dissociation de complexes de pentacyanoferrate(II) contenant du (pyridyl-4)-1 pyridinium ainsi que les formes neutres, protonées et *N*-méthylées de la bipyridine-4,4′ (BPY), du bis(pyridyl-4)-1,2 éthane (BPA) et du bis(pyridyl-4)-1,2 éthylène-*trans* (BPE). La relation qui existe entre le pH et la cinétique de formation a été analysée en fonction de la vitesse spécifique et des constantes de dissociation acide de ces ligands. On a déterminé les constantes de vitesse (25,0°C, $I = 0{,}10$ M) de formation des complexes dinucléaires $(NC)_5FeLFe(CN)_5^{6-}$ du BPY (50 M^{-1} s^{-1}), du BPA (66 M^{-1} s^{-1}), du BPE (95 M^{-1} s^{-1}) et de la pyrazine (10 M^{-1} s^{-1}) et on les a comparées avec les constantes de vitesse respectives pour la formation des complexes $(NC)_5FeLCo(NH_3)_5$. Pour discuter des relations qui existent entre les constantes de vitesse de formation et le volume du ligand, le nombre de sites du donneur et l'importance et la position des charges sur le ligand, on fait appel à un mécanisme dissociatif de paires d'ion.

Mots clés : complexes de pentacyanoferrate(II), *N*-hétérocycles, substitution du ligand, cinétique.

[Traduit par la revue]

Introduction

The properties and reactions of substituted pentacyanoferrate(II) complexes have been of considerable interest in the past 15 years (1). The formation of substituted $Fe(CN)_5L^{3-}$ complexes from the aqua species (eq. [1]) has been shown to follow an ion-pair dissociative mechanism (2–5), with a dependence of k_f on the charge of the entering ligand.

$$[1] \quad Fe(CN)_5OH_2^{3-} + L^{n+} \underset{k_d}{\overset{k_f}{\rightleftharpoons}} Fe(CN)_5L^{(3-n)-} + H_2O$$

An interesting aspect of the dependences of k_f on the nature of the entering ligand has been the effects of the position(s) of the charge(s) within the ligand with respect to the available coordination sites. Using a series of amino acid derivatives as entering ligands in the substitution of water on $Fe(CN)_5OH_2^{3-}$, Toma *et al.* (5) observed an increase of ≈ 30 M^{-1} s^{-1} with every additional C—C bond (≈ 1.3 Å) separating the coordination site from the carboxylate group. The rate constants for the reactions of $Fe(CN)_5OH_2^{3-}$ with a series of $Co(NH_3)_5L^{3+}$ complexes (L is a bridging *N*-heterocycle) depend on the distance between the free nitrogen site and the Co(III) metal center (6–10).

In this paper the results of kinetic and spectroscopic studies on the ligand substitution reactions of pentacyanoferrate(II) complexes with a series of *N*-heterocyclic cationic ligands in aqueous solution are reported. The ligands employed in this study include the neutral, protonated, and *N*-methylated forms of 4,4′-bipyridine (BPY), 1,2-bis(4-pyridyl)ethane (BPA), and *trans*-1,2-bis(4-pyridyl)ethylene (BPE). These species have been used frequently as bridging ligands in homo- and heterobinuclear complexes containing $Fe(CN)_5^{n-}$ (11, 12), $M(NH_3)_5^{n+}$ (M = Co(III) (9), Rh(III) (13), Ru(II) and (III) (14)), and $M(CO)_5$ (M = Mo, W (15)) centers. The kinetics of the formation and dissociation of $Fe(CN)_5(L—X)^{n-}$, where L is BPY, BPE, or BPA and X is a lone pair, H^+, CH_3^+, or $Fe(CN)_5^{3-}$, have not, however, been reported in detail previously. The rate and activation parameters determined in this study are discussed in relation to the magnitude and distribution of charges on the entering ligand, in terms of an ion-pair dissociative mechanism.

Experimental

Materials

Sodium amminepentacyanoferrate(II), $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$, was prepared by a reported procedure (16) and recrystallized from concentrated ammonia. Solutions of the aquapentacyanoferrate(II) ion ($\lambda_{max} = 444$ nm, $\varepsilon = 660$ M^{-1} cm^{-1} (5)) were produced by dissolving the solid $Na_3[Fe(CN)_5NH_3)]\cdot 3H_2O$ in nitrogen-saturated distilled water containing a slight excess of ascorbic acid. Low concentrations of the ion ($< 2 \times 10^{-5}$ M) were generally used to minimize dimerization. The ligands pyrazine (pyz), 4,4′-bipyridine (BPY), 1-(4-pyridyl)pyridinium chloride hydrochloride ($pyrpyr^+$), 1,2-bis(4-pyridyl)ethane (BPA), and *trans*-1,2-bis(4-pyridyl)ethylene (BPE) were used as received (Aldrich). The quaternary salts 1-methyl-4-(4′-pyridinyl)pyridinium iodide (CH_3BPY^+), 1-methyl-4-[2-4′-pyridinyl)ethyl]pyridinium iodide (CH_3BPA^+), and 1-methyl-4-[*trans*-2-4′-pyridinyl)ethenyl]pyridinium iodide (CH_3BPE^+) were prepared by treating the appropriate ligand with methyl iodide in benzene (17). The

melting points and ^1H nmr spectra of $[CH_3BPY]I$ and $[CH_3BPE]I$ were in agreement with reported data (11, 18). The ^1H nmr spectrum (Varian HX-60) of $[CH_3BPA]I$ in D_2O displayed peaks at (δ vs. TSP) 3.03 (m 4H), 4.06 (s 3H), 6.80 (d 2H), 7.03 (m 2H), 7.83 (m 2H), and 8.06 (d 2H). Solutions of the substituted pentacyanoferrate(II) complexes were prepared by adding an excess of the ligand (10^{-3} M) to a nitrogen-saturated solution of aquated $Fe(CN)_5NH_3^{3-}$ (10^{-4} M).

Kinetic measurements

Kinetic measurements were performed using both stopped-flow and conventional mixing techniques. The formation reactions were carried out using a TDI Model IIA (Cantech Scientific) stopped-flow apparatus and data acquisition system interfaced to a Zenith ZF-151 microcomputer. Pseudo-first-order conditions of excess ligand were employed and plots of ln $(A_\infty - A_t)$ against time were linear for at least three half-lives. The first-order rate constants were determined from the average of four to six replicate experiments. The kinetics of the ligand dissociation reactions, along with uv–visible spectra of the substituted pentacyanoferrate(II) complexes, were measured using Bausch and Lomb Spectronic 2000 and Hewlett–Packard 8452A diode–array spectrophotometers, with cell blocks thermostatted by means of an external water bath.

The ionic strength of the reaction solutions was maintained at 0.10 M with added sodium chloride. The pH of the solutions was controlled using phthalate, acetate, or phosphate buffers, or by additions of appropriate amounts of hydrochloric acid.

Results

The reactions of the $Fe(CN)_5OH_2^{3-}$ ion with an excess of an *N*-heterocyclic ligand (L^{n+}), such as 4,4′-bipyridine, result in substitution of the aqua ligand, and the formation of highly coloured $Fe(CN)_5L^{(3-n)-}$ species in solution. The absorption maxima ($t_{2g} \rightarrow L\pi^*$ metal-to-ligand charge transfer (MLCT) band) and molar absorptivity coefficients (Table 1) for a number of the complexes in this study have been reported previously (9, 12, 19, 20). The shift in λ_{max} upon protonation or methylation of the remote pyridine nitrogen depends on the extent of conjugation to the coordinated pyridine ring. In the BPY and BPE ligands (as also seen for pyrazine) a bathochromic shift is oberved, while for the BPA ligand, where the pyridine rings are insulated from each other by the saturated $-CH_2CH_2-$ linkage, little change in the MLCT energy is observed.

The acid dissociation constant for the protonated complex $Fe(CN)_5(HBPE)^{2-}$ was determined by a spectrophotometric pH titration. The λ_{max} shifts from 466 nm to 520 nm when the solution is acidified below a pH of 6.5, and a pK_a of 5.1 ± 0.1 was determined at 25°C and I = 0.10 M. Gaswick and Haim (6) report a pK_a of ≈5.3 (ionic strength not stated) for the $Fe(CN)_5(HBPY)^{2-}$ complex. The pK_a for the $Fe(CN)_5(HBPA)^{2-}$ complex is assumed to be very similar to that for the free ligand (H_2BPA^{2+}). At lower pH these complexes may be protonated at a cyanide ligand (pK_a of $(HNC)(NC)_4Fe(L)^{2-}$ is ≈2 (19, 20)), resulting in an increase in the MLCT energies.

Kinetic studies

The kinetics of the ligand substitution reactions of $Fe(CN)_5OH_2^{3-}$ with a series of *N*-heterocyclic L^{n+} ligands were investigated in aqueous solution (I = 0.10 M, pH 7) at 25.0°C. The reactions were carried out under pseudo-first-order conditions of excess ligand concentrations ($[L^{n+}] = (1–10) \times 10^{-4}$ M, $[Fe(CN)_5OH_2^{3-}] = 1 \times 10^{-5}$ M) by following the formation of the $Fe(CN)_5L^{(3-n)-}$ product at its visible maximum (Table 1). The rate of formation may be expressed as in eq. [2]

$$[2] \quad \frac{d[Fe(CN)_5L^{(3-n)-}]}{dt} = k_f[Fe(CN)_5OH_2^{3-}][L^{n+}]$$

with $k_{obs} = k_f[L^{n+}]$. Linear plots of k_{obs} against $[L^{n+}]$ were observed for each ligand employed in the study. The second-order rate constants, k_f, and the corresponding activation parameters are presented in Table 2.

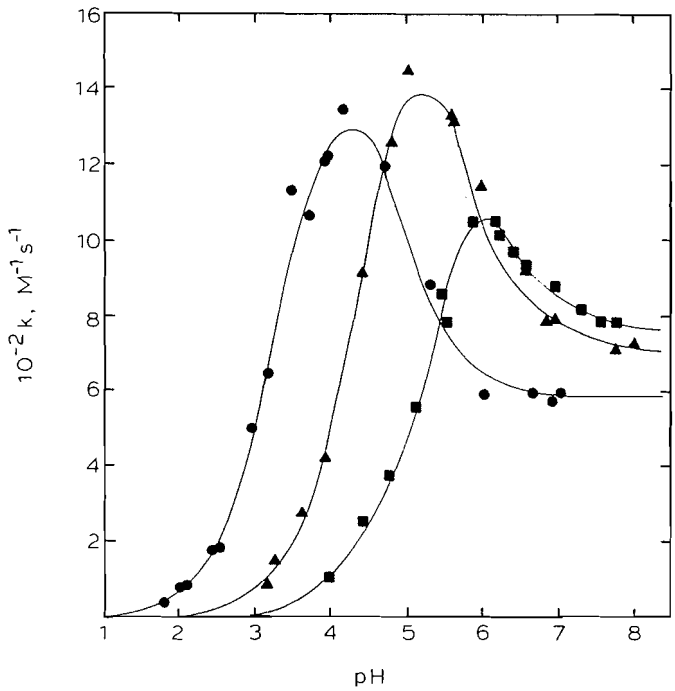

FIG. 1. The dependences of k on pH for the ligand substitution reactions of the $Fe(CN)_5OH_2^{3-}$ ion with the ligands BPY (●), BPE (▲), and BPA (■) at 25.0°C, I = 0.10 M. The solid curves represent the fits of the data to eq. [8].

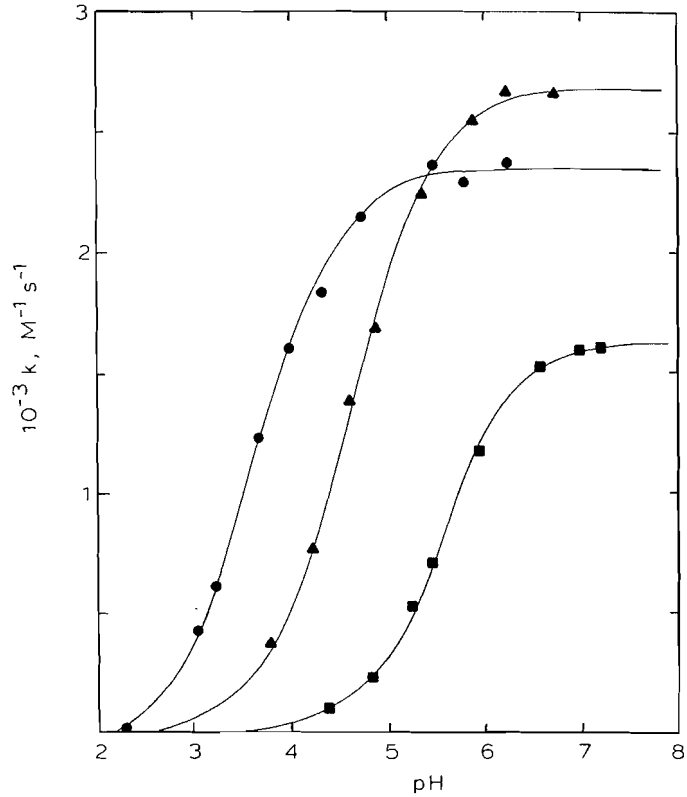

FIG. 2. The dependences of k on pH for the ligand substitution reactions of the $Fe(CN)_5OH_2^{3-}$ ions with the ligands CH_3BPY^+ (●), CH_3BPE^+ (▲), and CH_3BPA^+ (■) at 25.0°C, I = 0.10 M. The solid curves represent the fits of the data to eq. [9].

The pH dependences of the kinetics of the substitution reactions of the $Fe(CN)_5OH_2^{3-}$ ion with the BPY, BPE, and BPA ligands were investigated at 25.0°C and an ionic strength of 0.10 M (NaCl). Substantial decreases in the formation rate constants at low pH have been observed in a number of studies (4, 21, 22) and have been attributed to the greatly reduced lability of the aqua ligand in the protonated species $(HNC)Fe(CN)_4OH_2^{2-}$ (pK_m = 2.63, I = 0.10 M (21)). The rate of formation of the substituted complexes is also affected by the degree of protonation of the entering ligand. Addition of the first proton to produce HL^+ is expected to change its formation rate constant in two opposing ways: an increase owing to the increased charge on the ligand, and a decrease resulting from the loss of one potential coordination site. Protonation of both nitrogens to give H_2L^{2+} will render the ligand unreactive towards substitution on $Fe(CN)_5OH_2^{3-}$.

The acid dissociation constants K_1 (H_2L^{2+}) and K_2 (HL^+) have been reported for BPY (pK_1 = 2.69 (23) (3.31 in ref. 24) and pK_2 = 4.77 (23) (4.85 in ref. 24)) and BPE (pK_1 = 4.49 ± 0.04 and pK_2 = 5.92 ± 0.02 (25)) at 25.0°C and an ionic strength of 0.10 M. The pK values for the BPA ligand have not been determined but the pK_2 value is likely to be about 6, by comparison with analogous 4-methyl- (pK_a = 6.04) and 4-ethylpyridine (pK_a = 6.06) compounds (26). The dependences of the second-order rate constants k_H on pH for the three ligands are illustrated in Fig. 1. Each of the curves shows an increase in the rate constant as the pH is lowered below pH 8, followed by a decrease at lower pH. The positions of the maximum rate constants and the decreases in rate constant for the three ligands in Fig. 1 may be related to the acid–base equilibria of the entering species as depicted in the reaction scheme in eqs. [3]–[7].

$$[3] \quad (HNC)Fe(CN)_4OH_2^{2-} \overset{K_m}{\rightleftharpoons} Fe(CN)_5OH_2^{3-} + H^+$$

$$[4] \quad H_2L^{2+} \overset{K_1}{\rightleftharpoons} HL^+ + H^+$$

$$[5] \quad HL^+ \overset{K_2}{\rightleftharpoons} L + H^+$$

$$[6] \quad Fe(CN)_5OH_2^{3-} + HL^+ \xrightarrow{k_1} Fe(CN)_5(HL)^{2-} + H_2O$$

$$[7] \quad Fe(CN)_5OH_2^{3-} + L \xrightarrow{k_2} Fe(CN)_5L^{3-} + H_2O$$

The extent of protonation of the $Fe(CN)_5L^{n-}$ products has been determined by spectrophotometric pH titrations (see above). The observed second-order rate constant, k_f, may be expressed in terms of the specific rate constants and acid-dissociation constants in eq. [8].

$$[8] \quad k_H = \frac{k_1K_1K_m/[H^+]^2 + k_2K_1K_2K_m/[H^+]^3}{(1 + K_1/[H^+] + K_1K_2/[H^+]^2)(1 + K_m/[H^+])}$$

A non-linear least-squares fit (Simplex optimization program (27)) of the experimental data to eq. [8] produced the rate parameters and acid dissociation constants for the three systems. The k_1 and k_2 values are presented (k_f) in Table 2. The pK_1 value for BPY (pK_2 = 4.77) and the values of pK_1 and pK_2 for BPA were allowed to float, as the literature values are absent or uncertain. A pK_1 value of 3.07 was found for BPY, in good agreement with the reported values. The derived pK_1 value of 5.31 (pK_2 = 6.05) for BPA is 0.74 pK units lower than the pK_2 value, only a slightly larger difference than 0.60 based solely on statistical factors (K_1/K_2 = 4). This is also an indication of the lack of electronic communication between the two heterocyclic N-donor sites on the BPA ligand (ΔpK_a = 1.7 for BPY, 1.4 for BPE).

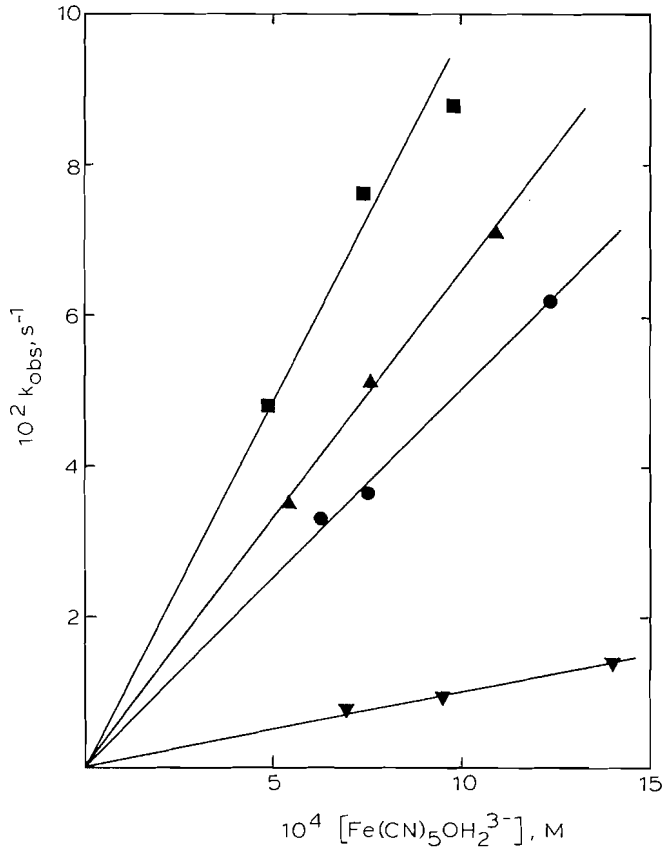

FIG. 3. The dependences of k_{obs} on $[Fe(CN)_5OH_2^{3-}]$ for the formation of $(NC)_5FeLFe(CN)_5^{6-}$ at 25.0°C, pH 7.0, and $I = 0.10$ M, where L = BPE (■), BPA (▲), BPY (●), and pyrazine (▼) ($[Fe(CN)_5L^{3-}] = 5 \times 10^{-5}$ M).

The pH dependence of the kinetics of the formation reactions of CH_3BPY^+, CH_3BPE^+, and CH_3BPA^+ were also investigated at 25.0°C ($I = 0.10$ M). In these reactions protonation of the free *N*-donor atom would render the ligands unreactive towards substitution on $Fe(CN)_5OH_2^{3-}$, and a study of the pH rate dependence would permit the determination of the pK_a values for the $(H)CH_3L^{2+}$ species. The pK_a for $(H)CH_3BPY^{2+}$ has been reported (28) to be 3.5 ± 0.1 at 25.0°C ($I = 0.10$ M), while analogous values have not been reported for $(H)CH_3BPE^{2+}$ or $(H)CH_3BPA^{2+}$. The dependences of k_H on pH are depicted in Fig. 2 for these three ligands. A fit of the data to eq. [9]

$$[9] \quad k_H = \frac{k_3 K_3 K_m/[H^+]^2}{(1 + K_3/[H^+])(1 + K_m/[H^+])}$$

yielded pK_3 values of 3.6 ± 0.1 for $(H)CH_3BPY^{2+}$, 4.6 ± 0.2 for $(H)CH_3BPE^{2+}$, and 5.6 ± 0.1 for $(H)CH_3BPA^{2+}$. The differences between pK_3 and pK_1 (H_2L^{2+}) for the three species are found to be in the range of 0.1–0.3. A slight increase (≈0.3 pK units) in pK_3 with respect to pK_1 is expected purely on statistical grounds as there are two sites of deprotonation on H_2L^{2+} and only one site on $(H)CH_3L^{2+}$.

With the potential bridging ligands BPY, BPE, BPA, and pyrazine, the addition of an excess of $Fe(CN)_5OH_2^{3-}$ to a solution of $Fe(CN)_5L^{3-}$ results in the coordination of the remote nitrogen and the formation of a bimetallic species, $(NC)_5FeLFe(CN)_5^{6-}$ (12).

$$[10] \quad Fe(CN)_5L^{3-} + Fe(CN)_5OH_2^{3-} \rightarrow (NC)_5FeLFe(CN)_5^{6-}$$

[e]$I = 1.0$ M.

The MLCT bands of the dimer display bathochromic shifts with respect to the monomer, with energy shifts decreasing in the order pyrazine > BPY > BPE > BPA (Table 1). This trend follows the order observed for protonation or methylation of the remote nitrogen on $Fe(CN)_5L^{3-}$.

The kinetics of the formation of the dimer species were studied by reacting the monomer (prepared in solution by the addition of a slight excess of $Fe(CN)_5OH_2^{3-}$ to the ligand) with a pseudo-first-order excess of a freshly prepared $Fe(CN)_5OH_2^{3-}$ solution. The first-order dependences of k_{obs} on $[Fe(CN)_5OH_2^{3-}]$ at 25.0°C ($I = 0.10$ M, pH 7) are displayed in Fig. 3 and the second-order rate constants are presented in Table 3.

The rate and activation parameters for the dissociation of L^{n+} from $Fe(CN)_5L^{(3-n)-}$ were determined in the presence of 0.1–0.2 M dimethylsulphoxide at an ionic strength of 0.10 M. The ligand DMSO is employed in the role of the entering species as it forms a very stable, colourless $Fe(CN)_5(DMSO)^{3-}$ complex (29). At these high concentrations, the limiting dissociation rate constant, k_d, is measured (3, 5, 20). The rate and activation parameters for the ligand dissociation reactions of $Fe(CN)_5L^{(3-n)-}$ are presented in Table 4.

Discussion

The kinetic and activation parameters determined for the formation of $Fe(CN)_5L^{(3-n)-}$ complexes in this study (Table 2) support a dissociatively activated ligand substitution process, as postulated previously for the reactions of the $Fe(CN)_5OH_2^{3-}$ ion (1). The neutral ligands BPY, BPE, and BPA form complexes with rate constants in the range of 580–780 $M^{-1}\,s^{-1}$, while the values for the protonated and methylated derivatives, along with pyrpyr$^+$ and CH_3pyz^+, fall in the range of 1500–2800 $M^{-1}\,s^{-1}$. The rate constants for the reactions with BPY, BPE, and BPA are about twice the value determined for pyridine, due to the presence of two coordination sites on the ligands. The trend in the formation rate constants, pyz < BPY < BPE < BPA, reflects the separation distance between the two donor sites, with BPA behaving kinetically as if it were two pyr molecules. The enthalpies and entropies of activation for the ligands in this study also fall in relatively narrow ranges of 14–17 kcal mol^{-1} and 5–12 cal $K^{-1}\,mol^{-1}$, respectively.

The dependence of the rate of complexation of $Fe(CN)_5OH_2^{3-}$ by L^{n+} on the charge of the entering ligand is consistent with an ion-pair dissociative mechanism (eqs. [11]–[13]).

$$[11]\quad Fe(CN)_5OH_2^{3-} + L^{n+} \underset{}{\overset{K_{OS}}{\rightleftharpoons}} [Fe(CN)_5OH_2,L]^{(3-n)-}$$

$$[12]\quad [Fe(CN)_5OH_2,L]^{(3-n)-} \xrightarrow{k_{-w}} [Fe(CN)_5,L]^{(3-n)-} + H_2O$$

$$[13]\quad [Fe(CN)_5,L]^{(3-n)-} \xrightarrow{\text{fast}} Fe(CN)_5L^{(3-n)-}$$

The rate-determining loss of the coordinated water molecule (k_{-w}) is preceded by an outer-sphere ion-pair association, for which K_{OS} is dependent on the size and charge of L^{n+} and on the ionic strength of the reaction medium. The expression for the observed formation rate constant reduces to $k_f = k_{-w}K_{OS}$ in this study as $K_{OS}[L^{n+}] \ll 1$ and the rate of ligand dissociation from $Fe(CN)_5L^{(3-n)-}$ is very small (Table 3).

The value of the association constant is frequently calculated using the Eigen–Fuoss expression (5)

$$[14]\quad K_{OS} = (4\pi N\sigma^3/3000)\exp(-\omega(\sigma)/RT)$$

where

$$[15]\quad \omega(\sigma) = \frac{Z_M Z_L e^2}{D_s\sigma(1 + \beta\sigma I^{1/2})}$$

In these expressions σ is the sum of the radii of the reactants, Z_M and Z_L are the charges on the reactants, D_s is the solvent dielectric constant, and $\beta = (8\pi Ne^2/1000D_skT)^{1/2}$. Toma (17) has determined the outer-sphere ion-pair association constants for the interactions of the substitution inert $Fe(CN)_6^{4-}$ ion with *N*-heterocyclic cations, such as CH_3pyz^+ (K_{OS} = 10–13 M^{-1}), and dications such as *N*,*N*′-dimethyl-4,4′-bipyridine (K_{OS} = 30–40 M^{-1}). The K_{OS} values for the ion pairs between $Fe(CN)_5OH_2^{3-}$ and the HL^+ and CH_3L^+ ligands in this study are likely to be similar in magnitude, with the effects of reducing Z_M and increasing σ cancelling each other out to some extent. If k_{-w} is taken to be 300 s^{-1} (an average value from k_f/K_{OS} for neutral ligands for which $K_{OS} \approx 1\,M^{-1}$ (1)), values of K_{OS} in the range of 5–10 M^{-1} are suggested by the k_f parameters for HL^+ and CH_3L^+. The use of σ = 6.5–12.0 Å in eqs. [14] and [15] yields ion-pair constants in this range and, with a radius of 4.5 Å for the $Fe(CN)_5OH_2^{3-}$ ion (5), an effective radius of 2–7 Å is calculated for the cationic ligands. This is a reasonable range of values for these ligands (17), which vary in size from the small CH_3pyz^+ ion to large CH_3BPE^+ or CH_3BPA^+ species.

For substitution reactions of $[Fe(CN)_5OH_2]^{3-}$ it has been observed that in addition to the total charge on the ligand, the positions of the charge(s) have an effect on the complexation rate constant (4, 5). The rate constants for the formations of the bimetallic complexes, $(NC)_5FeLFe(CN)_5^{6-}$, fall in the range of 10–95 $M^{-1}\,s^{-1}$, depending on the nature of the bridging ligand L (Table 4). The smallest value was observed for pyrazine, with the rate constants increasing with the increase in the distance between the iron center and the free *N*-donor atom on the $Fe(CN)_5L^{3-}$ ligand. The observed range of formation rate constants is comparable to the values reported for a number of monoanionic ligands, such as the cysteinate (4) and glycinate (3) anions. A similar trend has been reported (13) using $Co(CN)_5L^{2-}$ as the entering ligand, with k_f = 0.5 $M^{-1}\,s^{-1}$ for L = pyz and 3.0 $M^{-1}\,s^{-1}$ for L = BPY (I = 0.50 M). The trend in the rate constants for the $Fe(CN)_5L^{3-}$ ligands is opposite to that found for the same ligands in the set of $Co(NH_3)_5L^{3+}$ complexes (Table 4). In the former complexes the rate constants increase as the distance between the 3− center and the available *N*-donor atom increases, reducing the electrostatic repulsions. As the distance between the 3+ center and the available *N*-donor atom increases in the latter complexes the electrostatic attraction towards $Fe(CN)_5OH_2^{3-}$ decreases, as does the rate constant of formation of the bimetallic complex. The results of this study suggest that the most favourable ion-pair conformation may not be the most appropriate for ligand substitution, if it places the ligand donor atom at some distance from the site of eventual coordination on the metal. Kinetic and spectroscopic studies on the substitution reactions of $Fe(CN)_5OH_2^{3-}$ with novel bis(*N*-heterocyclic) dications of the types $pyz(CH_2)_npyz^{2+}$ (30), $BPY(CH_2)_nBPY^{2+}$, and $BPE(CH_2)_nBPE^{2+}$ (n = 1–10) are in progress in this laboratory to further investigate the nature and stabilities of the ion-pair precursor conformations.

The ligand dissociation rate constants for the $Fe(CN)_5L^{(3-n)-}$ complexes in this study (Table 4) are found in the relatively narrow range of (0.6–3.3) × $10^{-3}\,s^{-1}$. The complexes containing the protonated or methylated ligands displayed somewhat larger values of k_d than were observed for the corresponding neutral ligand complexes. An increase in the rate of dissociation upon ligand protonation has also been reported for $Fe(CN)_5L^{(3-n)-}$ complexes containing alkane-α,ω-diamines (31), nicotinic acid and isonicotinohydrazine (32), amino acid derivatives (4), and anions such as cyanide and sulphite (33). This observation has been attributed to the relative basicities of the leaving ligands and the greater ease of transfer of the protonated (or *N*-methylated) ligands to the bulk solvent, with the effect ($k_d(L^+)/k_d(L)$) becoming more pronounced when the positive charge on the terminal nitrogen is closer to the $Fe(CN)_5^{3-}$ center (31). The solvation and basicity effects would be offset to varying degrees by the attraction of the cationic ligand to the negatively charged metal center and, in the case of the *N*-heterocycles, by the increase in the Fe–L π-back bonding (as reflected in the MLCT energies) upon protonation or *N*-methylation. These effects are evident in the smaller value of k_d found for CH_3pyz^+ compared with that for pyrazine. For the ligands in this study the rate constants and activation parameters for the dissociations of neutral and cationic species would likely be affected by each of these factors. The similarities and uncertainties in the values, however, do not readily allow for a dissection of the differences in terms of the offsetting effects.

The oxidation of dimethyl sulphide, trimethylamine, and trimethylphosphine by solvated copper(II) or thallium(III) hexafluorometallates in acetonitrile

RANA M. SIDDIQUE AND JOHN M. WINFIELD[1]

Department of Chemistry, University of Glasgow, Glasgow G12 8QQ, Scotland, U.K.

Received February 2, 1989

This article is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

RANA M. SIDDIQUE and JOHN M. WINFIELD. Can. J. Chem. **67**, 1780 (1989).

Dimethyl sulphide, trimethylamine, and trimethylphosphine are oxidized by solvated copper(II) hexafluorophosphate or solvated thallium(III) hexafluorouranate(V) in acetonitrile at room temperature. The reactions are all very similar and spectroscopic studies suggest that the oxidized products are the dinuclear, non-metal cations $[Me_2SSMe]^+$, $[Me_3NNMe_2]^+$, and $[Me_3PPMe_3]^{2+}$. The compound $[Me_3PPMe_3][PF_6]_2$ is obtained from the oxidation of PMe_3 by diiodine in MeCN, followed by treatment with nitrosonium hexafluorophosphate. Coloured intermediates observed in the reactions of solvated Cu^{II} are formulated as redox-active cations $[CuL_x(NCMe)_y]^{2+}$, L = SMe_2, NMe_3, or PMe_3, and a generalized reaction scheme is proposed.

Key words: copper(II), thallium(III), acetonitrile, oxidation, fluorometallate.

RANA M. SIDDIQUE et JOHN M. WINFIELD. Can. J. Chem. **67**, 1780 (1989).

On a oxydé le sulfure de diméthyle, le triéthylamine et la triméthylphosphine avec l'hexafluorophosphate de cuivre(II) solvaté ou avec l'hexafluorouranate(V) de thallium(III) solvaté dans l'acétonitrile à la température ambiante. Les réactions sont très voisines et les études spectroscopiques suggèrent que les produits d'oxydation sont les cations non métalliques dinucléaires : $[Me_2SSMe]^+$, $[Me_3NNMe_2]^+$ et $[Me_3PPMe_3]^{2+}$. L'oxydation du composé PMe_3 par l'iode dans le MeCN, suivie de la réaction avec l'hexafluorophosphate de nitrosonium conduit au composé $[Me_3PPMe_3][PF_6]_2$. On considère les intermédiaires colorés, observés dans les réactions du cuivre(II) comme étant des cations $[CuL_x(NCMe)_y]^{2+}$, L = SMe_2, NMe_3 ou PMe_3 actifs dans des réactions d'oxydo-réduction et on propose un mécanisme général de réaction.

Mots clés : cuivre(II), thallium(III), acétonitrile, oxydation, fluorométallate.

[Traduit par la revue]

Introduction

Mononuclear cations, solvated by acetonitrile, of several elements can be prepared readily under anhydrous conditions by taking advantage of the good oxidizing and Lewis acid abilities that many hexa- and penta-fluorides have in acetonitrile (1). The cations are ideal starting points for investigation of the coordination chemistry of the elements involved and we have recently reported the behaviour of simple N- and P-donor ligands towards iron(II) in this solvent (2). An extension of this work to a study of reactions occurring between dimethyl sulphide, trimethylamine, or trimethylphosphine and solvated copper(II) or thallium(III) cations is now reported.

There is abundant evidence that the copper(I) cation is effectively solvated by MeCN (3), consequently the solvated copper(II) cation is a moderately strong oxidizing agent in MeCN (4). The thallium(III) cation appears to be more effectively solvated by MeCN than is the thallium(I) cation (5), nevertheless electrochemical measurements indicate that solvated Tl^{III} is a stronger oxidizing agent than Cu^{II} in MeCN (4). Redox reactions between Cu^{II} and thiourea derivatives (6, 7) or tertiary phosphines (8) in several solvents are well documented and similar behaviour was expected for reactions involving SMe_2 and PMe_3. A redox reaction between anhydrous $CuCl_2$ and NMe_3 at 348 K has been reported (9) as has the spontaneous reduction of Cu^{II} to Cu^{I} in the presence of 3,6-bis(2-pyridylthio)pyridazine (10).

A great advantage of carrying out the reactions under rigorously anhydrous conditions is that it has been possible to obtain evidence for cations containing S—S, P—P, or N—N bonds, which are formed as a result of the redox reactions. In two cases evidence for the formation of redox-active Cu^{II}–ligand complexes has been obtained.

Results

Oxidation of dimethyl sulphide by solvated copper(II) or thallium(III) cations

Neither solvated copper(I) nor thallium(I) cations, counter-anions hexafluorophosphate and hexafluorouranate(V) respectively, reacted with dimethyl sulphide in acetonitrile at room temperature but the copper(II) and thallium(III) cations reacted readily. Addition of SMe_2 to a solution of copper(II) hexafluorophosphate in MeCN at room temperature led to the immediate formation of a dark-green solution, $\tilde{\nu}_{max}$ 14 300 and 24 300 cm^{-1}. Both bands decayed rapidly when a large excess, tenfold, of SMe_2 was used but spectral changes could be followed by conventional means providing the concentration ratio $[Cu^{II}]$:$[SMe_2]$ was less than 1:5. With the concentration ratio $[Cu^{II}]$:$[SMe_2]$ = 1:4 and with initial $[Cu^{II}]$ = 5.0×10^{-4} mol dm^{-3} the low energy band was unobservable after 0.5 h but 3 h were required for the high energy band to become unobservable.

Mixing solutions of SMe_2 and thallium(III) hexafluorouranate(V) at room temperature resulted in a transient yellow colour but otherwise the solutions were pale green, characteristic of the UF_6^- anion. When the concentration ratio $[Tl^{III}]$:$[SMe_2]$ was 1:1, ^{205}Tl nmr resonances due to both Tl^{III} and Tl^{I} were observed after mixing but only a Tl^{I} resonance was observed when the ratio used was 1:4.

Small quantities of ethane were produced from both reactions. Colourless or pale-green solids isolated from reactions that employed a large molar excess of SMe_2 were identified from their ^1H nmr and ir spectra as mixtures of $[Me_2SSMe][MF_6]$, M = P or U, and $[Cu(NCMe)_4][PF_6]$ or $TlUF_6$. Salts of the dimethyl(thiomethyl)sulphonium cation are well known and the crystal structure of the $SbCl_6^-$ salt has been described (11). The compound $[Me_2SSMe][BF_4]$ was prepared by methylation of dimethyl disulphide with trimethyloxonium tetrafluoroborate

[a] δ(^{13}C) 31.7 and 27.5 ppm.

(12) and its ^1H nmr spectrum (Table 1) consisted of two singlets, relative intensity 2:1, rapid exchange being observed between the Me_2S moiety and added Me_2S as reported previously (12). Very similar behaviour was observed in the ^1H nmr spectra of the products from reactions between SMe_2 and fully deuteriated solvated Cu^{II} or Tl^{III} cations (Table 1) although the exact chemical shift values depended on the nature of the anion.

The ir spectrum of solid $[Me_2SSMe][BF_4]$ (Table 2) was very similar to that of the Tl^{III} reaction product. The spectrum of the Cu^{II} product contained bands due to the cation $[Cu(NCMe)_4]^+$ and those attributable to $[Me_2SSMe]^+$, in particular a band, $\tilde{\nu}_{max}$ 280 cm^{-1}, cf. Table 2. The assignment proposed for ν(SS) in the $[Me_2SSMe]^+$ cation is not unreasonable in view of the value of 276 cm^{-1} suggested for ν(SS) in the transient radical cation $[Me_2SSMe_2]^{\cdot+}$ (13).

The behaviour observed is consistent with reactions described by

[1] $2Cu^{2+}_{(solv.)} + 4SMe_2 \rightarrow 2Cu^{+}_{(solv.)} + 2[Me_2SSMe]^{+}_{(solv.)} + C_2H_6$

[2] $Tl^{3+}_{(solv.)} + 4SMe_2 \rightarrow Tl^{+}_{(solv.)} + 2[Me_2SSMe]^{+}_{(solv.)} + C_2H_6$

Oxidation of trimethylamine by solvated copper(II) or thallium(III) cations

In both cases ethane was produced and reduction of solvated Cu^{II} or Tl^{III} to Cu^{I} or Tl^{I} occurred at room temperature. The decay of the dark-green intermediate, $\tilde{\nu}_{max}$ 14 400 and 24 400 cm^{-1}, formed in the Cu^{II} reaction was similar to that in the reaction with SMe_2 and could be followed spectroscopically when the ratio $[Cu^{II}]$:$[NMe_3]$ was 1:4 and the initial $[Cu^{II}]$ was 5.0×10^{-4} mol dm^{-3}. The behaviour observed with a 1:3 ratio was similar, but using lower ratios, 1:1 or 1:2, reduction of Cu^{II} was incomplete even after 12 h. Reduction was complete within the time of mixing when $[Cu^{II}]$:$[NMe_3]$ was 1:10.

Two products were isolated from the Tl^{III} reaction, pale-green, insoluble $[Tl(NMe_3)_2][UF_6]$, which was also prepared from NMe_3 and $TlUF_6$ in MeCN, and a pale-green, soluble solid that decomposed readily on standing at room temperature. Its electronic spectrum in MeCN indicated the presence of UF_6^-, and from this and its ^1H nmr spectrum it was formulated as pentamethylhydrazinium(+1) hexafluorouranate(V), $[Me_3NNMe_2][UF_6]$. Tentative assignments of the bands in its ir spectrum (Table 3) were made by comparison with the spectra of the $N_2H_5^+$ cation (14).

Complexation of Cu^{I} by NMe_3 in MeCN was not observed and the ir spectrum of the colourless solid obtained from the

reaction between solvated Cu^{II} and NMe_3 was consistent with it being a mixture of $[Cu(NCMe)_4][PF_6]$ and $[Me_3NNMe_2][PF_6]$, $\tilde{\nu}_{max}$ 980 and 315 cm^{-1}, cf. Table 3. Similarly the ^1H nmr spectrum of the product from NMe_3 and deuteriated, solvated Cu^{II} was consistent with the presence of the $[Me_3NNMe_2]^+$ cation (Table 1). The reactions observed therefore appear to be

[3] $2Cu^{2+}_{(solv.)} + 4NMe_3 \rightarrow 2Cu^{+}_{(solv.)} + 2[Me_3NNMe_2]^{+}_{(solv.)} + C_2H_6$

[4] $Tl^{3+}_{(solv.)} + UF_6^- + 6NMe_3 \rightarrow [Tl(NMe_3)_2][UF_6] + 2[Me_3NNMe_2]^{+}_{(solv.)} + C_2H_6$

Oxidation of trimethylphosphine by solvated copper(II) or thallium(III) cations

The reaction between solvated Cu^{II} and trimethylphosphine in MeCN at room temperature involved the formation and very rapid decay of a pink intermediate. Ethane was not detected and the product was an off-white, involatile solid. Comparison with the $^{31}P\{^1H\}$ nmr and ir spectra of the compound $[Cu(PMe_3)_4][PF_6]$, obtained by reaction between PMe_3 and $[Cu(NCMe)_4][PF_6]$ in MeCN, indicated that this was a component of the mixture. The other component was shown to be hexamethylbis(phosphonium) hexafluorophosphate, $[Me_3PPMe_3][PF_6]_2$, by comparison with an independently synthesized and characterized sample.

Although the bis(phosphonium), $\equiv\overset{+}{P}—\overset{+}{P}\equiv$, moiety is probably best stabilized by the use of bridging groups (15), the compounds $[R_3PPR_3][I_3]_2$, R = alkyl, have been reported as the products from the alkylation of red phosphorus by alkyl iodides or from the oxidation of trialkylphosphines with I_2, molar ratio = 2:3, in refluxing MeCN (16). Using the latter route, but at room temperature and with an excess of PMe_3, led

to a colourless involatile solid formulated as $[Me_3PPMe_3][I]_2$, the iodide anion of which was oxidized to I_2 by $NOPF_6$ in MeCN to leave colourless, soluble $[Me_3PPMe_3][PF_6]_2$. The $^{31}P\{^1H\}$ nmr spectrum due to the cation was a singlet, $\delta(^{31}P)$ 27.8 ppm; the coupled spectrum was a complex multiplet that was not analysed. Details of the ir spectra of the two salts, together with tentative band assignments, are given in Table 4. In comparison, the $^{31}P\{^1H\}$ nmr spectrum of the solvated Cu^{II} reaction product contained a singlet $\delta(^{31}P)$ 27.5 ppm and its ir spectrum contained a band $\tilde{\nu}_{max}$ 330 cm^{-1}, cf. Table 4.

The course of the reaction between solvated Tl^{III} and PMe_3 was very similar to that with NMe_3 except that ethane was not detected. The pale-green, insoluble product was formulated as $[Tl(PMe_3)_2][UF_6]$ and the soluble product, which decomposed readily at room temperature, as $[Me_3PPMe_3][UF_6]$, in both cases on the basis of their spectra. The ^{31}P nmr chemical shift of the latter compound was $\delta(^{31}P)$ 65.0 ppm, possibly a result of the paramagnetic anion. Pronounced concentration effects on the ^{205}Tl nmr chemical shifts in MeCN solutions of Tl^I hexafluoromolybdate(V) or hexafluorouranate(V) have been interpreted on the basis of ion pairing involving the paramagnetic anions (5). The ^{31}P chemical shift in $[Me_3PPMe_3][I_3]_2$ is $\delta(^{31}P)$ 46.3 ppm (17), possibly also an indication of some degree of cation–anion interaction.

The reactions between the solvated cations and PMe_3 are formulated as

$$[5]\quad 2Cu^{2+}_{(solv.)} + 10PMe_3 \rightarrow 2[Cu(PMe_3)_4]^+_{(solv.)} + [Me_3PPMe_3]^{2+}_{(solv.)}$$

$$[6]\quad Tl^{3+}_{(solv.)} + UF_6^- + 4PMe_3 \rightarrow [Tl(PMe_3)_2][UF_6] + [Me_3PPMe_3]^{2+}_{(solv.)}$$

Discussion

The reactions reported are all very similar and a number of generalizations can be made. The use of acetonitrile as the solvent and weakly basic hexafluorometallates as counter-anions favours the formation of mononuclear copper(I) cations, although only trimethylphosphine is a good enough ligand to compete with MeCN. Coordination of organic bases to thallium(I) is characteristically weak (18), and the isolation of Tl^I salts containing ligated trimethylamine or PMe_3 probably owes more to the low solubilities of the compounds than to any other reason. In both cases the ligands are lost readily from the solids on pumping at room temperature.

Reactions between solvated copper(II) and SMe_2, NMe_3, or PMe_3 involve the formation of coloured intermediates whose lifetimes depend on the nature of the ligand used. Precedents for this type of behaviour in MeCN are the reactions between Cu^{II} and trimethyl phosphite (19) or tetramethylthiourea (tmtu) (20), which give rise to short-lived and long-lived Cu^{II}–ligand complexes respectively. Using water as solvent it has been possible to isolate and structurally characterize the intermediate $CuCl_2(tmtu)_2$ (6). The electronic spectra of the intermediates in MeCN are compared with those of Cu^{II} redox-inactive complexes in Table 5.

The spectra of the redox-active systems are all very similar but show a trend to increasing energy with the expected order of increasing ligand strength. Both bands in a given system are considered to be due to Cu^{II} d–d transitions on the basis of their intensities estimated immediately after mixing. In all cases the intensity of the high frequency band is the greater and it is possible that in some cases its strength is due to intensity-borrowing from an adjacent charge transfer band (19). That the higher energy band arises from a purely organic species is inconsistent with its absence in the spectra of the Tl^{III} reactions. In addition the electronic spectrum of $[Me_2SSMe_2]^{\cdot+}$, $\tilde{\nu}_{max}$ 21 500 cm^{-1} (21), which might be a possible intermediate in the SMe_2 reaction, is significantly different from the bands observed (Table 5).

Electronic spectra of redox-inactive systems are characterized by a single band in each case, which occurs at higher energy with increasing $[Cu^{II}]$:[L] up to a limiting value, for example 1:4 for Cu^{II} versus pyridine (py) or NH_3 in MeCN (22) or 1:2 versus NMe_3 in methanol (23). Formation constants for $[Cu(NMe_3)]^{2+}$ and $[Cu(NMe_3)_2]^{2+}$ have been determined in MeOH (23) and, assuming that the values are similar in MeCN, the major species in solution under the conditions used will be di- and mono-ligand complexes, $[Cu(NCMe)_6]^{2+}$ and free NMe_3. We tentatively suggest that the lower energy band, whose $\tilde{\nu}_{max}$ is little different from that of $[Cu(NCMe)_6]^{2+}$, $\tilde{\nu}_{max}$ 13 500 cm^{-1}, arises from species $[Cu(NMe_3)_x(NCMe)_{6-x}]^{2+}$, where $x \leqslant 2$. These species are in equilibrium with the redox-active complexes for which $x > 2$. The concentration of the latter will be very small but its spectrum is observable possibly due to intensity-borrowing from the nearby charge transfer band. Similar arguments can be made for solvated Cu^{II} reacting with SMe_2 and possibly also with tmtu. A redox-active Cu^{II}—$P(OMe)_3$ cation has been proposed previously to account for the redox behaviour observed in this system (19). Precise descriptions of the individual species present in each case cannot be given on the basis of the available data, neither can any inferences be drawn as to their structures.

It is suggested that the primary oxidation products from the reactions are the monomeric radical cations $Me_2S^{\cdot+}$, $Me_3N^{\cdot+}$, and $Me_3P^{\cdot+}$, formed, at least in the Cu^{II} reactions, by an inner sphere electron transfer, and that these species undergo further reactions to give the observed products. Dimeric radical cations, $R_2SSR_2^{\cdot+}$, derived from dialkyl sulphides and identified by epr spectroscopy, have been widely reported and are believed to be the result of reactions between $R_2S^{\cdot+}$ and SR_2 (13, 21, 24). The loss of C_2H_6 from $Me_2SSMe_2^{\cdot+}$ has not been reported previously but the decomposition pathway of this radical cation in protic media may be more complex than that in an aprotic solvent. The formation of $[Me_3NNMe_2]^+$ is suggested to occur by an analogous route from $Me_3N^{\cdot+}$. Alkyliminium radical cations, $R_3N^{\cdot+}$, have been observed or inferred as transient intermediates in a number of redox reactions (25), but normally undergo further reactions to give $[R_2N{=}CR_2']^+$ or R_3NH^+ cations. The previous studies of NMe_3 oxidation by VCl_4 (26) or $CuCl_2$ (9) reported the

formation of Me_3NH^+ and $[Me_2N{=}CH_2]^+$ rather than the $[Me_3NNMe_2]^+$ cation obtained here.

The formation of the $[Me_3PPMe_3]^{2+}$ cation from the oxidation of PMe_3 implies that dimerization of the short-lived $Me_3P^{\cdot+}$ radical cation (27) is more favoured than a reaction between $Me_3P^{\cdot+}$ and PMe_3. This is not unreasonable, since the concentration of free ligand in solution would be expected to be smaller than is the case for the weaker ligands SMe_2 and NMe_3. The available evidence indicates that the behaviour of PMe_3 towards Cu^{II} is very like that of tmtu (6).

Experimental

All operations were performed in a Pyrex vacuum line or N_2-atmosphere glove box ($H_2O < 5$ ppm) using techniques, instrumentation, and reagent purification procedures that have been described elsewhere (1, 2, 5). The solvated metal cation, fluoroanion salts $[Cu(NCMe)_5][PF_6]_2$, $[Cu(NCMe)_4][PF_6]$ (28), $[Tl(NCMe)_5][UF_6]_3$, and $TlUF_6$ (4, 5) were prepared as described previously. The ^1H and ^{13}C nmr chemical shifts are with respect to Me_4Si and ^{31}P with respect to 85% H_3PO_4, low field shifts being positive.

Reactions of [Cu(NCMe)$_4$][PF$_6$]

A mixture of $[Cu(NCMe)_4][PF_6]$ (0.5 mmol), PMe_3 (2.5 mmol), and MeCN (5 cm^3) was allowed to warm from 77 K to room temperature and gave a colourless solution from which an off-white solid was isolated on removal of volatile material. The solid was identified as tetrakis(trimethylphosphine)copper(I) hexafluorophosphate. *Anal.* calcd. for $C_{12}H_{36}CuF_6P_5$: C 28.1, H 7.0, Cu 12.5, F 22.2, P 30.2%; found: C 28.1, H 6.9, Cu 12.6, F 22.1, P. 30.0. $^{31}P\{^1H\}$ nmr spectrum: $\delta(^{31}P)$ −41.5 and −144.9 ppm; $^1J(^{31}P{-}^{63}Cu)$ 795, $^1J(^{31}P{-}^{65}Cu)$ 851, $^1J(^{19}F{-}^{31}P)$ 707 Hz. The ir spectrum of the solid is given in Table 6.

The salt $[Cu(NCMe)_4][PF_6]$ was recovered unchanged after reactions with SMe_2 or NMe_3 under similar conditions.

Reactions of [Cu(NCMe)$_5$][PF$_6$]$_2$ in MeCN

Mixtures of $[Cu(NCMe)_5][PF_6]_2$ (0.3 mmol), SMe_2 or NMe_3 (3.0 mmol), and MeCN (5 cm^3) were allowed to warm slowly from 77 K. A deep-green colour developed as SMe_2 or NMe_3 melted and flowed into the frozen solution. The colour faded slowly but disappeared rapidly if the mixture was agitated. The fraction volatile at 183 K was identified by gas chromatography as ethane. Removal of the remaining volatile material at room temperature left a colourless solid, which was identified as described in the Results section.

The reactions were also studied by electronic spectroscopy with $[Cu^{II}] = 5.0 \times 10^{-4}$ mol dm^{-3} and $[SMe_2]$ or $[NMe_3]$ varied between 5.0×10^{-4} and 5.0×10^{-3} mol dm^{-3}. Copper(II) solutions were loaded in the glove box into reaction vessels that were sealed to 10-mm Spectrosil cells. A frangible ampoule containing the appropriate quantity of ligand was added to each vessel, the solutions were degassed, and a spectrum of the Cu^{II} solution recorded after equilibrating the solution at 298 K. The ampoules were broken, the solutions allowed to mix, and spectra of the mixtures obtained over a period of several hours using a thermostated cell holder.

TABLE 6. The ir spectrum of solid $[Cu(PMe_3)_4][PF_6]$

$\tilde{\nu}_{max}$ (cm^{-1})	Suggested assignments

665 (m)	C—P sym. str.
560 (vs)	PF_6^- (ν_4)

A mixture of $[Cu(NCMe)_5][PF_6]_2$ (0.3 mmol), PMe_3 (3.0 mmol), and MeCN (5 cm^3) developed a pink colouration as it was allowed to warm from 77 K. This decreased rapidly even below 230 K and an off-white solid was isolated after removal of volatile material at room temperature. The identification of the solid is described in the Results section.

Similar behaviour was observed from the reaction between $[Cu(NCMe)_5][PF_6]_2$ and tetramethylthiourea, tmtu, under identical conditions. In this case, however, it was possible to record the electronic spectrum of the intermediate at 233 K by injecting a solution of tmtu into the Cu^{II} solution via a septum cap. $[Cu^{II}]$ was 0.5×10^{-2} and [tmtu] was 2.5×10^{-2} mol dm^{-3}. In a separate experiment coordination of tmtu to Cu^I in MeCN was demonstrated by isolation of a solid complex and recording its ir and ^1H nmr spectra.

Reactions of TlUF$_6$ in MeCN

Addition of NMe_3 (5.0 mmol) to a solution of $TlUF_6$ (0.5 mmol) in MeCN (5 cm^3) at room temperature resulted in the formation of a pale-green precipitate. The solid was identified as bis(trimethylamine)-thallium(I) hexafluorouranate(V). *Anal.* calcd. for $C_6H_{18}F_6N_2TlU$: C 10.6, H 2.6, N 4.1%; found: C 10.3, H 2.4, N 3.8. On pumping the solid at room temperature NMe_3 was evolved. The ir spectrum of the solid contained bands due to coordinated NMe_3, $\tilde{\nu}_{max}$ 3220, 1475, and 1055 cm^{-1} (2), and to UF_6^-, $\tilde{\nu}_{max}$ 520 cm^{-1} (4).

Similar behaviour was observed between $TlUF_6$ and PMe_3 under identical conditions and led to the isolation of an insoluble blue-green solid that readily lost PMe_3 *in vacuo* and was formulated as $[Tl(PMe_3)_2][UF_6]$; ir, $\tilde{\nu}_{max}$: 1305, 950, 726, and 665 cm^{-1} due to coordinated PMe_3 (cf. Table 6 and ref. 2) and 520 cm^{-1} due to UF_6^-.

The salt $TlUF_6$ was recovered unchanged from a reaction with SMe_2 under identical conditions.

Reactions of [Tl(NCMe)$_5$][UF$_6$]$_3$ in MeCN

A mixture of $[Tl(NCMe)_5][UF_6]_3$ (0.5 mmol), SMe_2 (5.0 mmol),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

and MeCN (5 cm^3) had a lemon-yellow colour when it was allowed to warm to room temperature but this rapidly faded to give a pale-green solution. A product volatile at 183 K was identified by gas chromatography as C_2H_6 and a pale-green solid isolated after removal of the remaining volatile material at room temperature was identified by its ^1H, $^{13}C\{^1H\}$, and ^{205}Tl nmr, electronic, and ir spectra as a mixture of $TlUF_6$ and $[Me_2SSMe][UF_6]$. The ^{205}Tl nmr chemical shifts obtained were similar to those reported previously for Tl^I and Tl^{III} UF_6^- salts in MeCN (5).

The reaction between $[Tl(NCMe)_5][UF_6]_3$ and NMe_3 in MeCN, carried out under identical conditions, was similar except that insoluble $[Tl(NMe_3)_2][UF_6]$ precipitated from solution and could be separated from soluble $[Me_3NNMe_2][UF_6]$. Similarly insoluble $[Tl(PMe_3)_2][UF_6]$ and soluble $[Me_3PPMe_3][UF_6]_2$ were identified by their spectra from the reaction between $[Tl(NCMe)_5][UF_6]_3$ (0.5 mmol) and PMe_3 (5.0 mmol) in MeCN (5 cm^3) at room temperature. No transient colour was observed in this reaction and C_2H_6 was not detected.

Preparation of $[Me_2SSMe][BF_4]$ (12)

The reaction between trimethyloxonium tetrafluoroborate (0.2 mmol) and dimethyl disulphide (0.6 mmol) in MeCN (5 cm^3) at room temperature for 0.25 h led to a colourless solid after removal of volatile material. The solid was identified by its ^1H nmr spectrum and reaction with SMe_2 (Table 1). The data obtained were in good agreement with those reported previously (12). Its ir spectrum is given in Table 2.

Preparation of $[Me_3PPMe_3][PF_6]_2$

A solution of I_2 (0.2 mmol) in MeCN (5 cm^3) was prepared *in vacuo* and PMe_3 (0.6 mmol) was added to the frozen solution. On warming the mixture to room temperature, a colourless precipitate formed, which was identified as hexamethyldiphosphonium diiodide. *Anal.* calcd. for $C_6H_{18}I_2P_2$: C 17.6, H 4.4, I 62.6, P 15.4%; found: C 17.4, H 4.5, I 62.9, P 15.3. Its ir spectrum is given in Table 4.

A solution of $NOPF_6$ (0.2 mmol) in MeCN was added to a portion of solid $[Me_3PPMe_3][I]_2$ at room temperature. A colourless gas, presumed to be NO, was immediately evolved and the solid dissolved giving a brown solution. An off-white solid was isolated on removal of MeCN and I_2 and was identified as hexamethyldiphosphonium hexafluorophosphate. *Anal.* calcd. for $C_6H_{18}F_{12}P_4$: C 16.3, H 4.1, P 28.0%; found: C 16.1, H 4.3, P 27.9. Its $^{31}P\{^1H\}$ nmr spectrum consisted of a signal due to PF_6^- and a singlet $\delta(^{31}P)$ 27.8 ppm. Its ir spectrum is given in Table 4.

Acknowledgements

We thank Professor W. McFarlane and colleagues, City of London Polytechnic, for obtaining the ^{205}Tl nmr spectra under the auspices of the SERC nmr service, and Dr. D. S. Rycroft and Mr. J. Gall for help in obtaining the other nmr spectra. The award of a Government of Pakistan scholarship to R.M.S. is gratefully acknowledged.

Synthesis of a new unsaturated 16-membered heterocycle with alternating CC and NS building blocks

JÖRG SUNDERMEYER, HERBERT W. ROESKY,[1] AND MATHIAS NOLTEMEYER

Institut für Anorganische Chemie der Universität, Tammannstrasse 4, 3400 Göttingen, Federal Republic of Germany

Received January 19, 1989

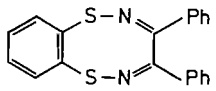
This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

JÖRG SUNDERMEYER, HERBERT W. ROESKY, and MATHIAS NOLTEMEYER. Can. J. Chem. **67**, 1785 (1989).

The reaction between $C_6H_4(SCl)_2$ **3** and $(PhC{=}NSiMe_3)_2$ **4** leads to the 16-membered heterocycle $(SC_6H_4SN{=}CPhCPh{=}N)_2$ **5**. The X-ray structure analysis of **5** shows a nonplanar macrocyclic system with alternating CC and NS units.

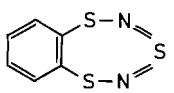
Key words: 16-membered heterocycle, X-ray structure, sulfur–nitrogen.

JÖRG SUNDERMEYER, HERBERT W. ROESKY et MATHIAS NOLTEMEYER. Can. J. Chem. **67**, 1785 (1989).



La réaction du $C_6H_4(SCl)_2$ **3** avec le $(PhC{=}NSiMe_3)_2$ **4** donne l'hétérocycle à 16 chaînons $(SC_6H_4SN{=}CPhCPh{=}N)_2$ **5**. L'analyse de la structure de **5** à l'aide de rayons-X montre un système macrocyclique que n'est pas plan avec des unités de construction CC et NS alternates.

Mots clés : hétérocycle à 16 chaînons, structure à l'aide de rayons-X, soufre–azote.



Introduction

The synthesis and electronic structure of planar carbon–sulfur–nitrogen rings continue to attract the attention of research groups (1). Many of the novel 10π- and 14π-aromatic CNS heterocycles discovered recently can formally be derived from the well-known planar dication $S_4N_4^{2+}$ (2) by substitution of sulfur or thiazyl units by isoelectronic carbocyclic fragments (3).

In this context we were interested in the target molecule **1** since, if planar, this 1,4,5,8-benzodithiadiazocine is expected to show properties of a 14π electron system, similar to the known 1,3,5,2,4-benzotrithiadiazepine **2** (4).

1

2

As a possible synthetic approach, we studied the reaction between the two bifunctional reagents 1,2-bis(chlorothio)-benzene **3** and benzil-bis(trimethylsilyl)imine **4** in dilute CH_2Cl_2 solution, and obtained (by elimination of trimethylchlorosilane) and air-stable yellow crystalline precipitate in good yield. This was separated by filtration and recrystallized from hot 1,1,2,2-tetrachloroethane (TCE) or boiling dioxane.

Experimental

The reaction was carried out under an atmosphere of nitrogen using dried solvents. The following spectrometers were used: ir spectra: Perkin Elmer 180; ^1H and ^{13}C nmr spectra: Bruker AM250; mass spectra: Finnigan MAT System 8230. Elemental analysis: Mikroanalytisches Laboratorium Beller, Göttingen. 1,2-Bis(chlorothio)benzene (5) and benzil-bis(trimethylsilyl)imine (6) were prepared by literature methods.

Preparation of the macrocycle **5**

The solutions of **3** (6.33 g, 30 mmol) in CH_2Cl_2 (100 mL) and **4** (10.56 g, 30 mmol) in CH_2Cl_2 (100 mL) were simultaneously dropped into refluxing CH_2Cl_2 (150 mL) over a period of 3 h. After 1 h a yellow crystalline material began to precipitate. After another 24 h of stirring at room temperature it was isolated by filtration and washed with CH_2Cl_2 (80 mL) to give pure **5** (yield: 7.8 g, 75%), mp 288°C. **5** can be recrystallized from boiling dioxane or hot TCE; ir (Nujol): 3050, 1570, 1495, 1440, 1430, 1320, 1300, 1255, 1230, 1182, 1025, 925, 910, 795, 770, 750, 740, 715, 705, 685, 580, and 495 cm^{-1}; ^1H nmr (250 MHz, $CDCl_3$) δ: 7.23–7.89 m; ^{13}C nmr (63 MHz, $CDCl_3$) δ: 161.6, 139.4, 134.4, 130.3, 129.4, 128.9, 127.6, and 126.6 ppm; FD–MS *m/z*: 692 (M, 100%); EI–MS *m/z*: 692 (M, 10%), 346 ($\frac{1}{2}$M, 15%), 314 ($\frac{1}{2}$M − S, 10%), 238 ($\frac{1}{2}$M − C_6H_4S, 25%), 192 ($\frac{1}{2}$M − $C_6H_4S_2N$, 100%). *Anal.* calcd. for $C_{40}H_{28}N_4S_4$: C 69.3, H 4.1, N 8.1; found: C 68.9, H 4.2, N 7.9.

Single crystals suitable for X-ray analysis were obtained by slow diffusion of pentane vapour into a saturated solution of **5** in TCE. The crystals contained half a mole of TCE per mole of **5**. The space group is $C2/c$ with cell constants a = 2389.4(9); b = 1064.9(7); c = 2992.0(9) pm; β = 102.2(1)°; V = 7.4413 nm^3, Z = 8, d_{calc} = 1.387 g/cm^3. 6165 reflections ($2\theta < 45°$) were measured on a STOE four-circle diffractometer with MoK_α radiation; 4847 reflections were independent but only 2759 observed with $F > 3\sigma(F)$. The poor quality of the data set results from the weakly diffracting crystal of size 0.2 × 0.2 × 0.5 mm^3 with strongly anisotropic reflection profiles. The structure was solved by SHELXS86 and refined by SHELX76. Because of the bad reflection-to-parameter ratio and to keep the refinement stable, rigid phenyl groups were introduced (391 parameters). From difference syntheses during the later refinement cycles, disorder of a solvent molecule TCE about the twofold axis, 0, y, $\frac{1}{4}$ was evident. Only two general peaks for chlorine appeared in the map, and weak indications for carbon atoms C(71) and C(72) lying 52 and 47 pm away from the axis. These peaks satisfied the geometrical requirements for TCE (excluding hydrogen atoms). Refinement of these locations was, however, unstable, so that thermal ellipsoids fixed on the axis with occupancies equal to 0.5 represent a dynamic inversion of the C atoms between relatively well-defined chlorine atoms, which also obey the twofold symmetry. $wR = [\Sigma w\Delta F^2/\Sigma wF_o^2]^{1/2}$ converged at 0.082 and $R = \Sigma\Delta F/\Sigma F_o$ at 0.11 ($w = [\sigma^2(F_o) + 0.0004F_o^2]^{-1}$).[2] Fractional atom coordinates are given in Table 1 and selected bond lengths and angles in Table 2.[3]

Discussion

The room temperature ^{13}C nmr of a saturated $CDCl_3$ solution of the yellow crystalline material showed eight signals. This result is consistent with the assumed structure **1** or any higher symmetric oligomer. Signals of a second oligomer could not be detected. FD mass spectroscopic experiments showed a molecular ion $M^{+\bullet}$ with m/z 692 as the only detectable peak

3 **4**

5

under these conditions. This result is consistent with a 2:2 macrocyclic oligomer **5**.

The X-ray analysis (Fig. 1) confirmed the conclusions from the ^{13}C nmr and mass spectroscopic results. Furthermore we found that the macrocycle is not planar (Fig. 2). The conformation of **5** is mainly determined by the two rigid *o*-dimercaptophenylene units, which are close to planar. The torsion angles are 12.0° (S4—C51—C56—S1) and 5.2° (S2—C61—C66—S3). The remarkably high values for the torsion angles in the α-diimino units (93.1° (N3—C3—C4—N4) and 94.6°

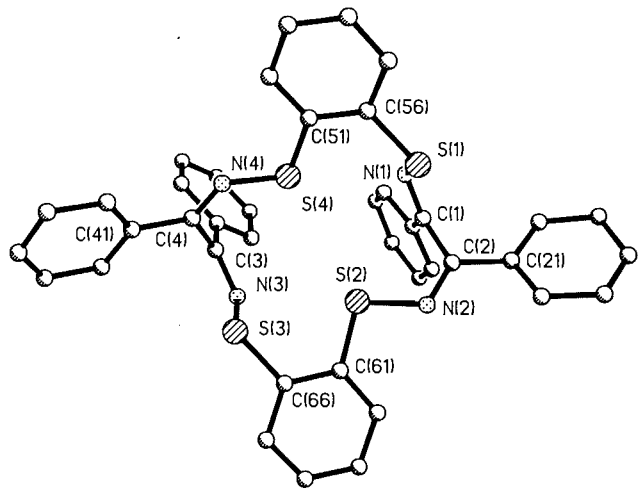

FIG. 1. **5** viewed perpendicular to the least-squares plane.

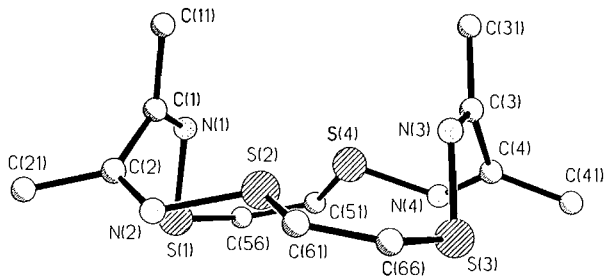

FIG. 2. The macrocyclic skeleton of **5** viewed along the least-squares plane. The fused six-membered rings (not shown) are inclined to each other at 38°, whereas the phenyl rings (also not shown) fill space irregularly.

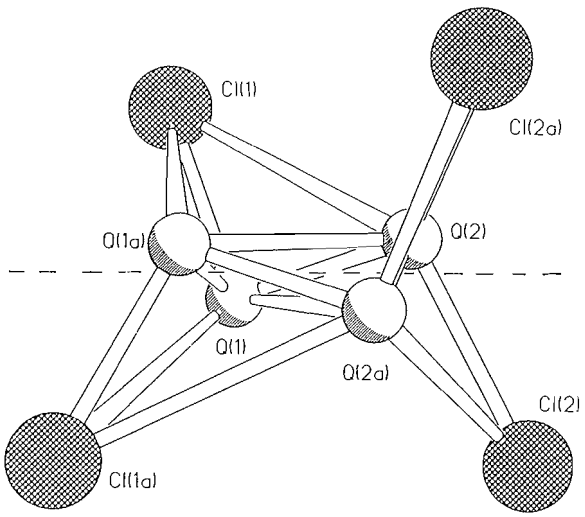

FIG. 3. Disorder of TCE shown in a difference Fourier synthesis calculated without the listed fixed positions C(71) and C(72): the peaks Q1 and Q2 are 52 and 47 pm away from the axis 0, y, $\frac{1}{4}$ ("a" refers to symmetry equivalent positions and dashes represent axis).

(N1—C1—C2—N2)) rule out *p*-conjugation, as also observed in the 2,1,3-benzothiadiazole (7). The average bond lengths for the SN bonds (169.2 pm) and CN bonds (129.3 pm) are typical for SN single and CN double bonds in nonaromatic heterocycles (see, for example, ref. 8). Due to the poor quality of the available crystals a more detailed discussion of the structure is inappropriate.

The macrocycle **5** does not possess C_1 crystallographic symmetry in the solid state conformation. However, as mentioned before, the ^{13}C nmr in $CDCl_3$ solution shows only signals for eight equivalent carbon atoms. This result is indicative of a facile change of conformation in solution.

We believe that steric factors (ring torsion) are mainly responsible for our not being able to detect any of the 1:1 ring compound **1** (Fig. 3).

A future research project should show whether **5** can be oxidized to a dicationic species, which then may be a planar 18π electron system.

Received February 3, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

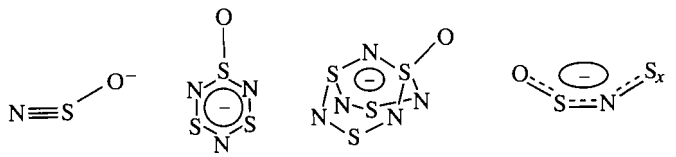
TRISTRAM CHIVERS, KENNETH J. SCHMIDT, DEANE D. MCINTYRE, and HANS J. VOGEL. Can. J. Chem. **67**, 1788 (1989).

The reaction of $(Me_2N)_3S^+NSO^-$ with sulphur has been investigated by ultraviolet–visible, infrared, Raman, and ^{14}N, ^{17}O, and ^{33}S nuclear magnetic resonance spectroscopies. The red species (λ_{max} 501 nm) formed initially is tentatively identified as $SSNSO^-$. This anion is thermally unstable with respect to the formation of S_4N^- and sulphur oxyanions. Previously reported salts of the "NSO_2^-" ion have been reinvestigated by infrared, Raman, and ^{14}N nmr spectroscopies, which indicate that the major component of these salts is the NSO^- ion. The reaction of $(Me_2N)_3S^+NSO^-$ with S_4N_4 is shown by ^{14}N nmr spectroscopy to produce both $S_3N_3O^-$, the major product, and $S_3N_3^-$.

Key words: nitrogen–sulphur–oxygen (N–S–O) anions, ^{14}N NMR spectroscopy.

TRISTRAM CHIVERS, KENNETH J. SCHMIDT, DEANE D. MCINTYRE et HANS J. VOGEL. Can. J. Chem. **67**, 1788 (1989).

Faisant appel aux méthodes spectroscopiques ultraviolet–visible, infrarouge, Raman et résonance magnétique nucléaire du ^{14}N, ^{17}O et ^{33}S, on a étudié la réaction du $(Me_2N)_3S^+NSO^-$ avec le soufre. En première approximation, on a attribué la structure $SSNSO^-$ aux espèces rouges (λ_{max} de 501 nm) qui se forment initialement. Cet anion est thermiquement stable par rapport à la formation d'ions S_4N^- et d'oxyanions du soufre. Utilisant les méthodes spectroscopiques ir, Raman et rmn du ^{14}N, on a réexaminé la structure de l'ion «NSO_2^-» dont la formation avait été rapportée antérieurement; ces résultats indiquent que la composante principale de ces sels est l'ion NSO^-. En se basant sur la rmn du ^{14}N, on démontre que la réaction du $(Me_2N)_3^+NSO^-$ avec le S_4N_4 conduit à la formation tant de $S_3N_3O^-$, le produit principal, que de $S_3N_3^-$.



Mots clés : anions de nitrogène–soufre–oxygène (N–S–O), spectroscopie RMN du ^{14}N.

[Traduit par la revue]

Introduction

Several nitrogen–sulphur–oxygen (N–S–O) anions that contain a sulphoxy group have been characterized. These include the acyclic species NSO^-, **1** (1–3), the ring system $S_3N_3O^-$, **2** (4), and the cage anion $S_4N_5O^-$, **3** (5). Recently we discovered that electrochemically generated solutions of **1** in acetonitrile (ca. 0.3 mM) react with elemental sulphur to give a red anion (λ_{max} 496 nm) tentatively identified as S_xNSO^- (**4***a*, $x = 1$; **4***b*, $x = 2$) (6). This species is an oxy analogue of the known binary anions $SNSS^-$ ($x = 1$) (7) or $SSNSS^-$ ($x = 2$) (8) in which a terminal sulphur is replaced by oxygen. In this investigation, the reaction of NSO^- with *cyclo*-S_8 has been carried out on a preparative scale and monitored by uv–visible, ^{14}N, ^{17}O, and ^{33}S nmr, and vibrational spectroscopies to elucidate the course of the reaction and the identities of the final products. In addition, the previously reported salts of the "NSO_2^-" anion (9) have been reinvestigated by ^{14}N nmr, ir, and Raman spectroscopies. The spectra of such salts, prepared by following the literature procedure (9), indicate the presence of **1** as the predominant anion.

Electrochemically generated solutions of **1** (ca. 0.3 mM) react with S_4N_4 to give **2** (6), which may also be prepared in ca. 40% yield by the controlled aerial oxidation of $S_3N_3^-$ (4). The latter synthesis also produces the cage anions **3** and $S_4N_5^-$. Consequently, the reaction of NSO^- with S_4N_4 has been performed on a preparative scale to evaluate this route as a specific, high-yield synthesis of **2**.

1 **2** **3** **4***a*, $x = 1$; **4***b*, $x = 2$

Experimental

Reagents and general procedures

Solvents were dried and distilled before use: CH_3CN ($CaH_2/P_4O_{10}/CaH_2$), CH_2Cl_2 (P_4O_{10}), THF (Na/benzophenone), diethyl ether (Na/benzophenone). Anhydrous DMSO (Aldrich gold label) was used without purification. All manipulations were carried out under an atmosphere of dry N_2. The following reagents were prepared by the literature procedures: S_4N_4 (10), $Cs^+NSO_2^-$ (9), $PPN^+NSO_2^-$-[PPN^+=$(Ph_3P)_2N^+$] (9), PPN^+Cl^- (11), $PPN^+S_4N^-$ (8), $[PPN]_2S_2O_3$ (12), $[PPN]_2SO_4$ (12), $PPN^+S_4N_5O^-$ (4, 5) K^+NSO^- (1), TAS^+-NSO^- [TAS^+=$(Me_2N)_3S^+$] (3). 18-Crown-6 (Aldrich) was dried by recrystallization from CH_3CN and then twice dissolved in THF and pumped to dryness to remove residual CH_3CN. S_8 (sublimed, Fisher) was used without further purification.

Instrumentation

The ir spectra of solids were recorded as Nujol mulls (CsI windows) on a Nicolet 5-DX FTIR spectrometer (4000–400 cm^{-1}) and on a Perkin–Elmer model 457 grating spectrometer (400–250 cm^{-1}). Subtractive ir spectra were obtained on CH_3CN solutions ((3–4) × 10^{-2} M) in a specially designed 303 stainless steel cell (13), using KBr windows (0.5 mm pathlength) and Viton O-rings, on a Nicolet 8000A FTIR spectrometer using an MCT (HgCdTe) liquid nitrogen-cooled detector (4000–400 cm^{-1}). The reaction of TAS^+NSO^- with sulphur

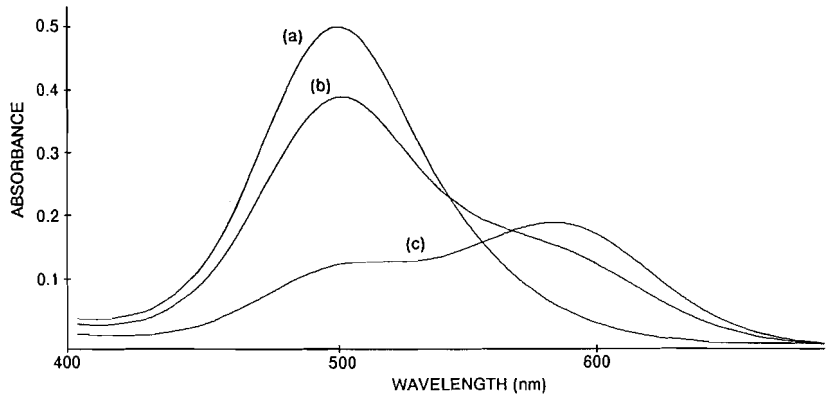

FIG. 1. Ultraviolet–visible spectra of the reaction of TAS^+NSO^- with sulphur in CH_3CN after (a) 5 min; (b) 3 h; (c) 14 h.

was performed directly in the ir cell. An ir spectrum of TAS^+NSO^- in CH_3CN was subtracted from the spectra so obtained. This procedure removed the bands due to TAS^+ and the weaker CH_3CN vibrations. The bands due to reaction products appear as positive peaks while bands attributable to reagents that are being consumed show up as negative peaks.

Raman spectra (1500–100 cm^{-1}) were recorded on a Jarrel–Ash model 25-100 double monochromator calibrated with CCl_4. The monochromator was interfaced to an IBM-PC microcomputer to permit multiple scanning and data manipulation. A Coherent Radiation CR4 argon ion laser fitted with an Innova plasma tube was used to obtain exciting radiation at 488 and 514.5 nm and to pump a Coherent Radiation model 590-03 dye laser to obtain exciting radiation at 600 nm. Low temperature Raman spectra were obtained by using sealed 5-mm glass tubes, which contained a fine frit to suspend solid S_8 near the top of the reaction solution (ca. 2×10^{-1} M) and to keep the solid out of the laser beam. A laser power of 400 mW was used. The tubes were cooled to −45°C in a thermostatted glass Dewar by the evaporation of liquid nitrogen. The laser beam was directed through the bottom of the glass Dewar and up through the bottom of the 5-mm tube into the cooled solutions to give Raman scattering that was collected through the Dewar walls at 90° to the incident beam. Raman spectra of air-sensitive solids were obtained on pressed pellets (1 cm diameter) mounted in a push-top glass vial sealed with epoxy glue. Samples were spun at ca. 1000 rpm to prevent thermal decomposition, and laser powers of 250 mW were used.

Ultraviolet–visible spectra were obtained on a Cary 219 spectrophotometer using either 0.01, 0.1, or 1 cm pathlength quartz cells. The reaction of TAS^+NSO^- (5×10^{-3} to 1.5×10^{-2} M) with elemental sulphur in CH_3CN was carried out in the uv–visible cells, which were fitted with rubber septa to exclude air.

All nmr experiments were performed on Bruker AM-400 nmr spectrometers operating at 28.915 MHz for ^{14}N, 54.244 MHz for ^{17}O, and 30.690 MHz for ^{33}S. Both a 10-mm broad-band probe and a 15-mm solenoidal coil probe were used to obtain the ^{14}N spectra, while only the former was used for ^{17}O and ^{33}S experiments. Typical parameters for ^{14}N were an acquisition time (AQ) of 0.07 s, a relaxation delay (RD) of zero, a sweep width (SW) of 30 000 Hz, and a data collection size (TD) of 4K, which was zero-filled to 16K before transformation. At least 3000 scans were collected. The signal from dissolved N_2 gas was used as an internal standard for all ^{14}N nmr spectra (15). For ^{17}O, AQ = 0.025 s, RD = 0 s, SW = 84 000 Hz, TD = 4K. For ^{33}S, AQ = 0.02 s, SW = 50 000 Hz, TD = 2K. In both cases the FIDs were zero-filled to 16K before transforming and at least 100 000 scans were collected. The RIDE (14) pulse sequence was used to reduce the effect of probe ringing for ^{33}S spectra. All reactions that were monitored by nmr spectroscopy were carried out directly in the nmr tubes using at least 1 M concentrations of reagents.

Reaction of TAS^+NSO^- with sulphur

A mixture of TAS^+NSO^- (0.55 g, 2.4 mmol) and S_8 (0.15 g, 0.59 mmol) in acetonitrile (10 mL) was stirred at 23°C. The solution became bright red immediately, then purple after 1 h and finally dark blue after 24 h. The volume of the solution was reduced to 2 mL under vacuum and then the addition of cold diethyl ether (30 mL) produced a sticky blue solid, which was recrystallized from CH_3CN/diethyl ether to give $TAS^+S_4N^-$ identified by ir, Raman, visible, and ^{14}N nmr spectra (8) (see Results and discussion for details).

Reaction of TAS^+NSO^- with S_4N_4

A solution of TAS^+NSO^- (1.25 g, 5.52 mmol) in CH_3CN (10 mL) was added dropwise to a stirred slurry of S_4N_4 (0.50 g, 2.71 mmol) in CH_3CN (30 mL) at −35°C. The solution became red within 1 min. The mixture was stirred at −35°C for 16 h and then solvent was removed under vacuum to give a red solid (1.45 g), which was shown by ^{14}N nmr, uv–visible, and ir spectra to be a mixture of $TAS^+S_3N_3O^-$ (4) and $TAS^+S_3N_3^-$ (16, 17) (see Results and discussion for details).

Results and discussion

Reaction of NSO^- with sulphur

The reaction of the soluble salt TAS^+NSO^- with elemental sulphur in acetonitrile produces a series of colour changes. The initially bright yellow solution of TAS^+NSO^- turns intensely red immediately upon the addition of sulphur. The solution then becomes purple after ca. 1 h and finally turns dark blue within a day. This transformation was followed by uv–visible spectroscopy (Fig. 1), which showed that the red species was associated with a visible absorption band at 501 nm (cf. λ_{max} 496 nm for S_xNSO^- (6)) and the blue species had an absorption band at 582 nm (cf. λ_{max} 582 nm for S_4N^- (8)). The absence of an isosbestic point indicates the involvement of an intermediate in the conversion of S_xNSO^- to S_4N^-. The red anion $SSNO^-$, a linkage isomer of **4***a*, has λ_{max} 448 nm (18) and therefore can be ruled out as a possible candidate for the red species. Attempts to isolate the red species by carrying out the reaction at low temperatures always gave a mixture of the red and blue products. When the reaction was allowed to go to completion at 23°C the final blue product was isolated and identified as $TAS^+S_4N^-$ by ir, Raman, and ^{14}N nmr spectra (*vide supra*).

Further characterization of the 501-nm species was achieved by ^{14}N nmr and vibrational spectra. The ^{14}N nmr spectra of the reaction of TAS^+NSO^- with 2 equivalents of sulphur are illustrated in Fig. 2 and the nmr parameters for relevant species are summarized in Table 1. Several recent publications have demonstrated the value of ^{14}N nmr spectroscopy for monitoring the solution behaviour of small S–N molecules (14, 19, 20), and N–S–O anions fall into this category. The ^{14}N nmr spectrum of NSO^- exhibits a relatively sharp peak at +139 ppm. Upon addition of sulphur to a solution of TAS^+NSO^- in acetonitrile a new signal appears at +45 ppm, which is attributed to the

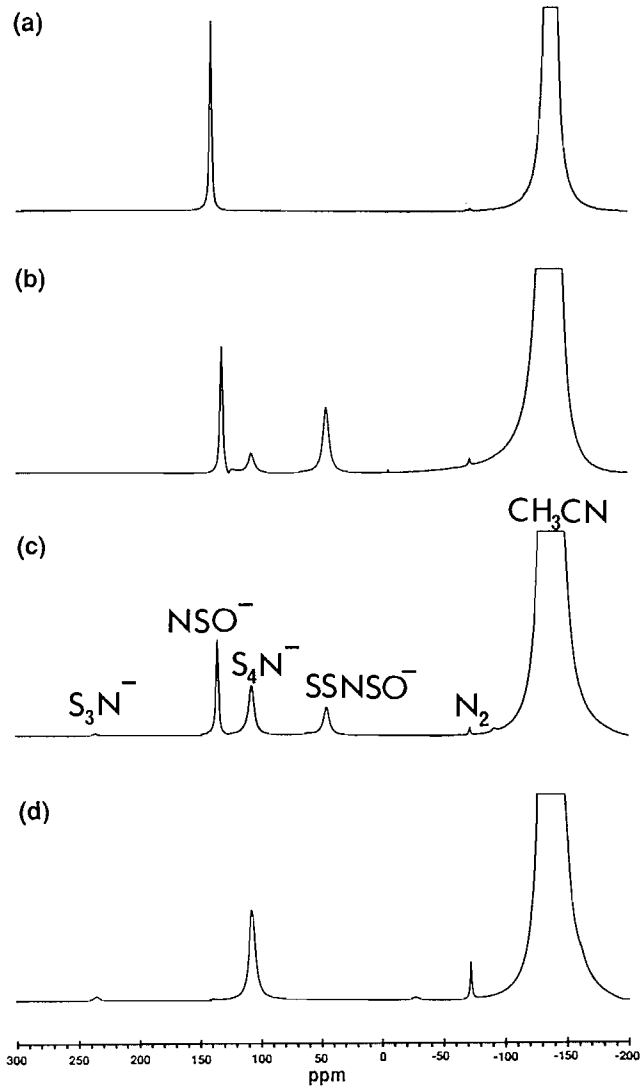

FIG. 2. The ^{14}N nmr spectra of the reaction of TAS^+NSO^- with sulphur in CH_3CN: (a) TAS^+ NSO^-; (b) after 40 min; (c) after 11 h; (d) after 16 weeks. The intensities of the signals in spectra (b), (c), and (d) are three times those of spectrum (a).

501-nm species. The new signal grows gradually at the expense of the signal due to NSO^-, which is shifted to higher field by ca. 10 ppm during the course of the reaction, and after ca. 40 min a third peak is evident at +107 ppm. This resonance was shown to be due to the S_4N^- ion by comparison with the chemical shift of an authentic sample of PPN^+ S_4N^- (Table 1). The transformation of NSO^- to the 501-nm species and the subsequent disproportionation of the red species to give S_4N^- continues over a period of several weeks until only the peak due to S_4N^- is observed (Fig. 2d). Apart from a very small amount of S_3N^-, which is known to be in photochemical equilibrium with S_4N^- (21, 22), and $S_3N_3^-$, no other nitrogen-containing products are evident from the ^{14}N nmr spectra. To rule out the possibility that peak(s) due to other nitrogen-containing product(s) are obscured by the broad CH_3CN signal, the $TAS^+NSO^-/2S$ reaction was also carried out in DMF and the reaction of KNSO with two equivalents of sulphur in the presence of 18-crown-6 was performed in THF. Both of these reactions gave S_4N^- as the only detectable nitrogen-containing species among the final products. If the TAS^+NSO^-/S reaction is carried out using a 1:1 stoichiometry, unreacted NSO^- remains even after 22 weeks. Thus 2 equivalents of S are necessary to ensure complete consumption of NSO^-, indicating that the red species is $SSNSO^-$ rather than $SNSO^-$ (cf. the rapid reaction of $SNSS^-$ with sulphur to give $SSNSS^-$ (7)).

Vibrational spectra provide some support for this conclusion (see Table 2). The blue species is clearly identified as S_4N^- by comparison of the ir and Raman spectra of the isolated product with those of $PPN^+S_4N^-$ (8). The bands at ca. 570 and ca. 595 cm^{-1} are attributed to S–S stretching vibrations and the weak band at ca. 890 cm^{-1} and the very strong band at ca. 710 cm^{-1} in the Raman spectra are assigned to ν_{as}(SNS) and ν_s(SNS), respectively (8). By analogy with the spectral assignments for $SSNSS^-$, the strong bands at 575 cm^{-1} in the Raman spectrum and at 574 cm^{-1} in the ir spectrum of red solutions of $TAS^+NSO^-/2S$ are tentatively attributed to an S–S stretching vibration and the Raman bands at ca. 705 vs and 815 w cm^{-1} are assigned to ν_{as}(SNS) and ν_s(SNS), respectively. Thus the vibrational spectra also indicate that the red species is $SSNSO^-$ rather than $SNSO^-$.

The $SSNSO^-$ can be viewed as a thionylimide derivative and such compounds are known to eliminate SO_2 readily in the presence of a base (23). Although evidence for the formation of SO_2 was not apparent from ir spectra, bands that might be attributed to sulphur oxyanions were observed for the final blue solutions. Consequently, the $TAS^+NSO^-/2S$ reaction was monitored by ^{17}O and ^{33}S nmr spectroscopies in an attempt to identify the sulphur oxyanion(s) formed. Table 3 gives the ^{17}O and ^{33}S nmr chemical shifts for NSO^- and the more common sulphur oxyanions. An ^{17}O signal at ca. 300 ppm, which is observed in the early stages of the reaction and disappears after 24 h, is attributed to $SSNSO^-$. A signal at 194 ppm, which appears after 7 h, is tentatively assigned to SO_3^{2-} (see Table 3). However, this signal also disappears after 24 h and two new peaks are observed at 178 and 220 ppm. Although these chemical shifts are in the range observed for sulphur oxyanions, we have been unable to identify the species responsible for them. The ^{33}S nmr spectra were less informative, since the signals for the intermediates were too broad to be detected. The final blue solution did, however, give a ^{33}S nmr signal at ca. 0 ppm. The width of this peak ($\Delta\nu_{1/2} \sim 1000$ Hz) is much greater than that of SO_4^{2-} (see Table 3), so it is likely due to a closely related sulphur oxyanion of lower symmetry. The $S_2O_3^{2-}$ ion is a possible candidate for the species that gives rise to the 220-ppm signal in the ^{17}O nmr spectrum, but no evidence for the formation of $S_2O_3^{2-}$ is provided by the ^{33}S nmr spectrum.

Spectroscopic characterization of the "NSO_2^-" ion

The "NSO_2^-" ion has been obtained as a cesium salt by the reaction of wet CsF with $Me_3SiNSNSiMe_3$ (9). This anion was characterized primarily on the basis of field desorption mass spectra of the Ph_4P^+ and PPN^+ salts, which exhibited molecular ion peaks with 1% of the intensity of the base peaks. The X-ray structure of the Ph_4P^+ salt could not be solved due to disorder (9*b*, 24).

We have repeated the literature preparation of "$Cs^+NSO_2^-$" to determine whether the NSO_2^- ion was one of the products of the decomposition of $SSNSO^-$. However, $Cs^+NSO_2^-$ shows ir and Raman bands characteristic of the NSO^- ion (see Table 4). We note that the strong bands at 1260–1270 and ca. 990 cm^{-1} are also present in the published ir spectra of "$PPN^+NSO_2^-$" and "$Ph_4P^+NSO_2^-$". Additional bands are apparent in the ir

and Raman spectra of $Cs^+NSO_2^-$ that can be attributed to the presence of $Cs^+S_3N_3^-$ (16). The ^{14}N nmr spectrum of $Cs^+NSO_2^-$ in a variety of solvents shows a strong signal at 138–140 ppm (cf. 139 ppm for NSO^-). A signal was also observed for $S_3N_3^-$ at −232 ppm (see Table 1) and minor peaks at −92 and −155 ppm can be attributed to a small amount of $S_3N_3O^-$ (formed by the air oxidation of $S_3N_3^-$ (4)). The PPN^+ salt of NSO_2^- was prepared from $Cs^+NSO_2^-$ and PPN^+Cl^- and

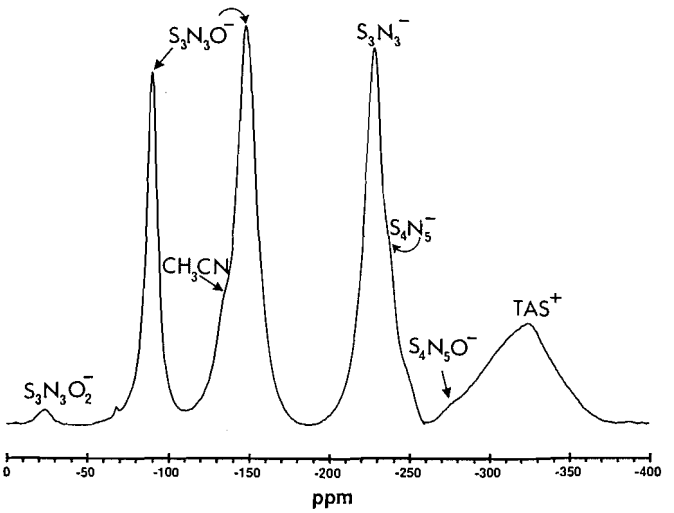

FIG. 3. The ^{14}N nmr spectrum of a DMSO solution of the products from the reaction of TAS^+NSO^- with S_4N_4 in CH_3N.

the ^{14}N nmr spectrum of the crude product revealed the presence of $S_3N_3^-$ in addition to the major signal at 138 ppm attributed to NSO^-. A recrystallized sample of $PPN^+NSO_2^-$ showed only the NSO^- peak. Thus we conclude that the major component of the product from the reaction of $Me_3SiNSNSiMe_3$ with wet CsF is Cs^+NSO^- rather than $Cs^+NSO_2^-$ as previously claimed (9). We note that the published analytical data (C, H, N, and S) for the Ph_4P^+ and PPN^+ salts are not sufficiently accurate to distinguish between NSO_2^- and NSO^- salts (9). This finding may also explain the unexpected conversion of NSO_2^- to the NSO^- ligand in the reaction of $Cs^+NSO_2^-$ with $RhH(CO)(PPh_3)_3$ to give *trans*-$Rh(CO)(NSO)(PPh_3)_2$ (25).

Reaction of NSO^- with S_4N_4

The reaction of S_4N_4 with nucleophiles, e.g., N_3^-, S^{2-}, is known to promote ring contraction to give $S_3N_3^-$ (26) probably via a 1,3-nitrogen shift (27). Six-membered rings may also

TABLE 3. The ^{17}O and ^{33}S nmr chemical shifts and line widths of N–S–O and S–O anions

be obtained in high yields from S_4N_4 by 1,4-cycloaddition reactions, e.g., with P═N— bonds (28). The formation of **2** from the reaction of electrochemically generated NSO^- with S_4N_4 (6) may also result from the latter reaction pathway. We have, therefore, performed this reaction on a preparative scale in the hope that it would provide a specific, high-yield synthesis of **2**.

The reaction of TAS^+NSO^- with S_4N_4 in acetonitrile at −35°C occurs rapidly to give a dark red solution. However, the ^{14}N nmr spectrum of this solution (see Fig. 3) shows that $S_3N_3^-$ is formed in significant amounts, in addition to the major product, **2**. From the integrated intensities of the nmr signals the approximate ratio $S_3N_3O^-$:$S_3N_3^-$ is 3:2 and very small amounts of $S_4N_5^-$, $S_4N_5O^-$, and $S_3N_3O_2^-$ are also present. The presence of $S_4N_5O^-$, which was difficult to ascertain from the ^{14}N nmr spectrum due to overlap with the signals for $S_3N_3^-$, $S_4N_5^-$, and $(Me_2N)_3S^+$, was confirmed by both ^{17}O and ^{33}S nmr spectra (see Table 3). Thus the reaction of NSO^- with S_4N_4 occurs predominantly via 1,4-cycloaddition to give **2**, but, even at low temperatures, a significant amount of ring contraction to produce $S_3N_3^-$, via a 1,3-nitrogen shift (27), also takes place (see Fig. 4).

Thermolysis of $S_3N_3O^-$

The thermolysis of $S_3N_3^-$ in CH_3CN at reflux produces $SSNSS^-$ (8). The formation of the latter ion is thought to occur via initial loss of N_2S from $S_3N_3^-$ to give SNS^-, which reacts rapidly with sulphur to give S_4N^-. By analogy, the thermolysis of $S_3N_3O^-$ might be expected to give $SSNSO^-$ (via $SNSO^-$). In the context of the present study of the reaction of NSO^- with sulphur (*vide infra*), it is significant that an investigation of the thermolysis of $PPN^+S_3N_3O^-$ revealed $PPN^+S_4N^-$ as the only identifiable product (29).[2] The results described here indicate that, under the conditions of the thermolysis, $SSNSO^-$ would disproportionate rapidly to give S_4N^- and sulphur oxyanions.

[2]We are grateful to Professor R. T. Oakley (University of Guelph) for this unpublished information.

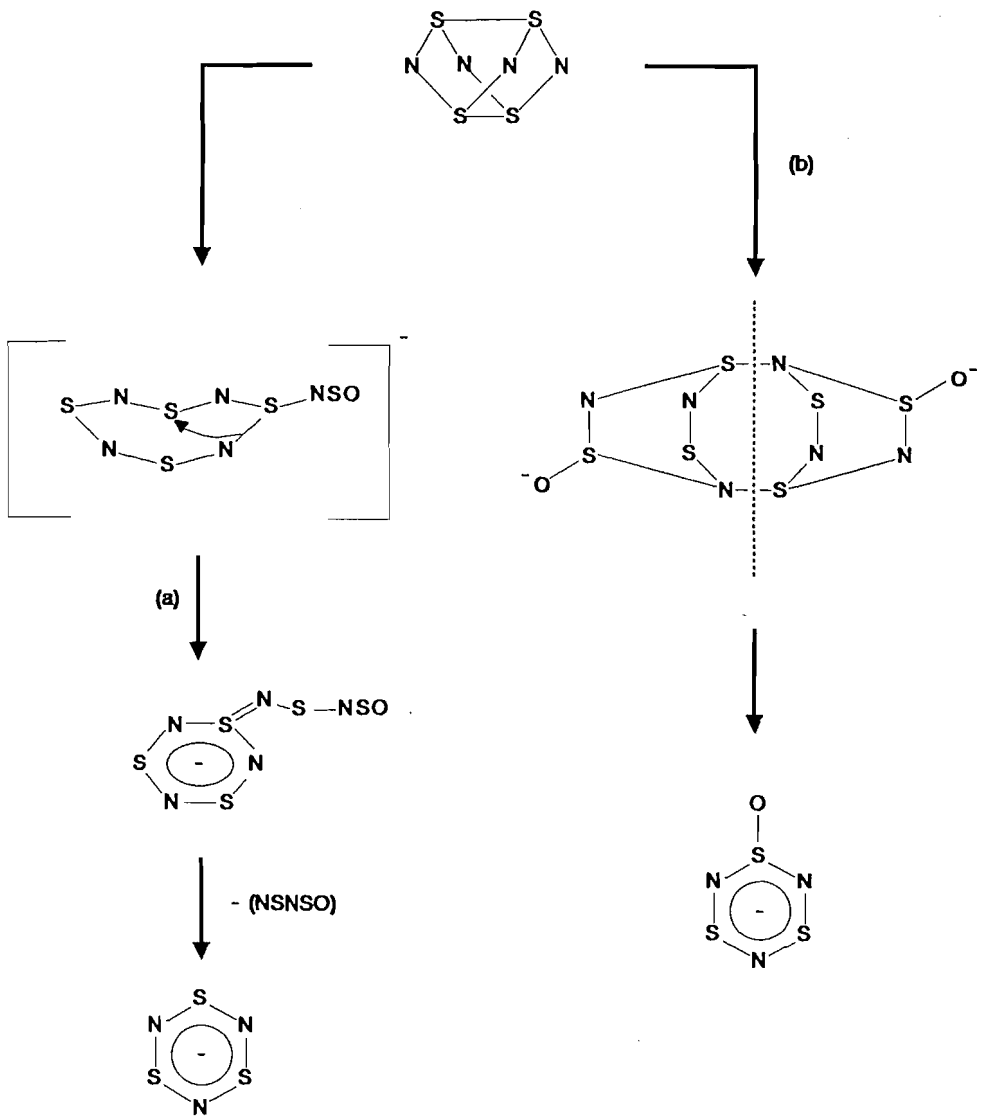

FIG. 4. Pathways for the reaction of NSO^- with S_4N_4: (a) 1,3-nitrogen shift; (b) 1,4-cycloaddition.

Conclusions

This study of the reactivity of NSO^- has demonstrated the usefulness of ^{14}N nmr spectroscopy for the analysis of solutions containing complex mixtures of N–S–O (and N–S) anions. The formation of $SSNSO^-$, rather than $SNSO^-$, from NSO^- and sulphur is consistent with the rapid conversion of $SNSS^-$ into $SSNSS^-$ via reaction with itself (or another source of sulphur). The low thermal stability of $SSNSO^-$ was unexpected and may be related to the ease of intramolecular elimination of SO_2. The formation of both $S_3N_3O^-$ and $S_3N_3^-$ from NSO^- and S_4N_4 provides a unique example of a dual reaction pathway for the cleavage of S_4N_4 by nucleophiles. The treatment of $Me_3SiNSNSiMe_3$ with wet CsF gives Cs^+NSO^- as the major product, rather than $Cs^+NSO_2^-$ as previously claimed, and alternative routes to the NSO_2^- ion should be considered.

Synthesis of fluorinated phosphonic, sulfonic, and mixed phosphonic/sulfonic acids

DEBAO SU, WENBIAO CEN, ROBERT L. KIRCHMEIER, AND JEAN'NE M. SHREEVE[1]
Department of Chemistry, University of Idaho, Moscow, ID 83843, U.S.A.

Received February 3, 1989

This article is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

DEBAO SU, WENBIAO CEN, ROBERT L. KIRCHMEIER, and JEAN'NE M. SHREEVE. Can. J. Chem. **67**, 1795 (1989).

The acids $(HO)_2P(O)CFHSO_3H$, $(HO)_2P(O)(CF_2)_4O(CF_2)_2SO_3H$, $H(CF_2)_2O(CF_2)_2P(O)(OH)_2$, $H(CF_2)_2O(CF_2)_4P(O)(OH)_2$, $(HO)_2P(O)(CF_2)_2O(CF_2)_4H$, and the acid precursor $(C_2H_5O)_2P(O)CF(SO_3Na)_2$ have been synthesized. Elemental analysis, ^{19}F, ^1H, and ^{31}P NMR, and mass spectroscopy were used for characterization of these materials. They are very strong acids, and exhibit a high degree of stability in aqueous solution at elevated temperature, which makes them attractive candidates for use as electrolytes in fuel cells.

Key words: fluorinated phosphonic acids; fluorinated sulfonic acids; ^1H, ^{19}F, ^{31}P NMR.

DEBAO SU, WENBIAO CEN, ROBERT L. KIRCHMEIER et JEAN'NE M. SHREEVE. Can. J. Chem. **67**, 1795 (1989).

On a synthétisé les acides $(HO)_2P(O)CFHSO_3H$, $(HO)_2P(O)(CF_2)_4O(CF_2)_2SO_3H$, $H(CF_2)_2O(CF_2)_2P(O)(OH)_2$, $H(CF_2)_2O(CF_2)_4P(O)(OH)_2$, $(HO)_2P(O)(CF_2)_2O(CF_2)_4H$ ainsi que de leur précurseur acide $(C_2H_5O)_2P(O)CF(SO_3Na)_2$. Pour la caractérisation de ces composés, on a fait appel à l'analyse élémentaire, à la RMN du ^{19}F, du ^1H et du ^{31}P ainsi qu'à la spectrométrie de masse. Ces composés sont des acides très forts et ils sont très stables en solution aqueuse, à température élevée; ces caractéristiques en font d'excellents candidats comme électrolytes dans des cellules à combustible.

Mots clés : acides phosphoniques fluorés; acides sulfoniques fluorés; RMN du ^1H, du ^{19}F et du ^{31}P.

Introduction

Many fluorinated sulfonic and phosphonic acids exhibit properties that make them potentially useful as electrolytes in fuel cells. They are much stronger acids than their nonfluorinated analogues, and are generally more stable. In addition, oxygen solubility is greatly enhanced, and volatility at elevated temperatures may be lower. In fuel cell applications, these factors combine to provide increased conductivity, enhanced oxygen reduction kinetics, and longer term system stability when compared to phosphoric acid as the electrolyte.

The primary acid used in fuel cells today is H_3PO_4. However, it has many drawbacks, including low oxygen solubility and anion adsorption on the catalyst surface. There is a need to develop new compounds that have the desirable properties of H_3PO_4 but fewer of the less desirable ones, in order to enhance the usefulness of fuel cells as alternative energy sources.

Fluorocarbon electrolytes have the ability to lower the surface tension of water. This effect is in part due to several structural factors: (1) terminal grouping; (2) chain-length; and (3) the presence of heteroatoms in the chain. For example, a CF_3 terminal group attached to a CF_2 chain will have a greater surface tension lowering effect than a HCF_2 terminal group attached to a similar chain. The solubility of oxygen in fluorocarbon systems is dependent on the boiling point, density, molecular weight, and viscosity of the fluorocarbon. These properties in turn are dependent in part on the structural factors and composition mentioned above.

At low temperature trifluoromethanesulfonic acid has been found to be superior to H_3PO_4 with respect to electrode kinetics. However, the acid hydrate is too volatile for extended use at the operating temperature of fuel cells (>100°C), and in addition it tends to wet the Teflon surface of the electrodes used (1). A variety of other partially fluorinated or perfluoroalkylsulfonic and disulfonic acids (1–5) as well as phosphonic acids (6–8), mixed sulfonic or phosphonic/carboxylic acids (9), and a mixed sulfonic/phosphonic acid (10) have been synthesized for evaluation as potential fuel cell electrolytes.

To further the evaluation of structure and composition factors effective for fuel cell electrolytes, we have prepared a number of additional partially fluorinated and perfluoro mixed sulfonic/phosphonic, and phosphonic acids. Electrochemical testing of these acids in model fuel cells should provide valuable information in this regard.

Results and discussion

The starting material for the preparation of the mixed acid $(HO)_2P(O)(CF_2)_4O(CF_2)_2SO_3H$ is the iodide $I(CF_2)_4O(CF_2)_2SO_2F$, which was prepared by the literature method (11).

$$I(CF_2)_4O(CF_2)_2SO_2F + (C_2H_5O)_2POP(OC_2H_5)_2 + (CH_3)_3COOC(CH_3)_3 \xrightarrow[120\,^\circ C,\ 3\ h]{CF_2ClCFCl_2}$$

$$(C_2H_5O)_2P(CF_2)_4O(CF_2)_2SO_2F \xrightarrow[-10 \rightarrow -5\,^\circ C,\ 2\ h]{(CH_3)_3COOH/CH_3OH}$$

$$(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_2F \xrightarrow[N_2,\ 85\,^\circ C,\ 2\ h]{Na_2S_2O_4/NaHCO_3,\ H_2O/CH_3CN}$$

$$(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_2Na \xrightarrow[25\,^\circ C,\ 12\ h]{30\%\ H_2O_2} \mathbf{1}\ (90\%)$$

$$(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_3Na \xrightarrow[120\,^\circ C,\ 6\ h]{HCl} \mathbf{2}\ (93\%)$$

$$(HO)_2P(O)(CF_2)_4O(CF_2)_2SO_3Na \xrightarrow[resin]{acid} \mathbf{3}\ (88\%)$$

$$(HO)_2P(O)(CF_2)_4O(CF_2)_2SO_3H \quad \mathbf{4}\ (76\%)$$

For personal use only.

Removal of inorganic impurities from **1** was found to be necessary for the successful synthesis of **2**, **3**, and **4**. Compound **3** is converted to **4** by passing an aqueous solution of **3** through a 20 mm × 30 cm long column packed with Amberlite IR-120 resin at an approximate flow rate of 2 mL/min. Purification was accomplished by repetitive dissolution of **1** in acetonitrile, followed by filtration. Attempts to simplify the synthesis of **4** by replacing the starting material $I(CF_2)_4O(CF_2)_2SO_2F$ with $I(CF_2)_4O(CF_2)_2SO_2Cl$ or $I(CF_2)_4O(CF_2)_2SO_3Na$ were unsuccessful. The sulfonyl chloride reacted vigorously with tetraethylpyrophosphite in the absence of di-*tert*-butylperoxide to give a complex mixture. No suitable solvent for the reaction of the sodium sulfonate with tetraethylpyrophosphite could be found.

Conversion of $I(CF_2)_4O(CF_2)_2SO_2F$ or $I(CF_2)_2O(CF_2)_2SO_2F$ to the respective diiodide

$$I(CF_2)_nO(CF_2)_2SO_2F \xrightarrow[H_2O/CH_3CN,\ 25\,^\circ C,\ 8\ h]{K_2SO_3} I(CF_2)_nO(CF_2)_2SO_2K \quad \begin{matrix} n=2 & (80\%) \\ n=4 & (71\%) \end{matrix}$$

$$\xrightarrow[CH_3CN\ 80\,^\circ C,\ 7\ h]{I_2} I(CF_2)_nO(CF_2)_2I \quad \mathbf{5}\,(n=2)\ (39\%) \text{ and } \mathbf{6}\,(n=4)\ (37\%)$$

provided the starting materials for the synthesis of $H(CF_2)_2O(CF_2)_4P(O)(OH)_2$, $(HO)_2P(O)(CF_2)_2O(CF_2)_4H$, and $H(CF_2)_2O(CF_2)_2P(O)(OH)_2$.

$$I(CF_2)_2O(CF_2)_2I + (C_2H_5O)_2P{-}O{-}P(OC_2H_5)_2$$
5

$$\xrightarrow{(CH_3)_3COOC(CH_3)_3} H(CF_2)_2O(CF_2)_2P(OC_2H_5)_2$$

$$\xrightarrow[MeOH]{(CH_3)_3COOH} H(CF_2)_2O(CF_2)_2P(O)(OC_2H_5)_2$$
7

$$\mathbf{7} + BrSi(CH_3)_3 \xrightarrow[2d]{25\,^\circ C} H(CF_2)_2O(CF_2)_2P(O)[OSi(CH_3)_3]_2$$
8

$$\mathbf{8} + H_2O \longrightarrow H(CF_2)_2O(CF_2)_2P(O)(OH)_2$$
9

However, the product of the tetraethylpyrophosphite reaction with **6** is a mixture of $H(CF_2)_4O(CF_2)_2P(OC_2H_5)_2$ and $(C_2H_5O)_2P(CF_2)_4O(CF_2)_2H$. This intermediate mixture was separated by distillation under reduced pressure prior to conversion to the corresponding acids $H(CF_2)_4O(CF_2)_2P(O)(OH)_2$ **10** and $(HO)_2P(O)(CF_2)_4O(CF_2)_2H$ **11**. No evidence for the formation of any other products, i.e., ether-containing diphosphonic acids, was obtained.

(Sulfomonofluoromethyl)phosphonic acid, $(HO)_2P(O)CFHSO_3H$, was prepared as described below from triethylphosphite and tribromofluoromethane.

$$(C_2H_5O)_3P + CFBr_3 \xrightarrow[4\ h]{0\,^\circ C} (C_2H_5O)_2P(O)CFBr_2$$
12 (77%)

$$\mathbf{12} + Na_2S_2O_4 \xrightarrow[25\,^\circ C,\ 4\ h]{NaHCO_3} (C_2H_5O)_2P(O)CFBrSO_2Na$$
13 (64%)

$$\mathbf{13} + H_2O_2 \xrightarrow[5\ h]{0 \rightarrow 25\,^\circ C} (C_2H_5O)_2P(O)CFBrSO_3Na$$
14 (75%)

$$\mathbf{14} + Zn \xrightarrow[(2)\ H_2O]{(1)\ 60\,^\circ C,\ 6\ h,\ THF} (C_2H_5O)_2P(O)CFHSO_3Na$$
15 (49%)

$$\mathbf{15} + HCl \xrightarrow[10\ h]{125\,^\circ C} (HO)_2P(O)CFHSO_3Na$$
16 (59%)

Compound **16** was then converted to the final acid product utilizing Amberlite IR-120 acid resin.

$$\mathbf{16} \xrightarrow[resin]{acid} (HO)_2P(O)CFHSO_3H$$
17 (80%)

Alternatively, treatment of **14** with sodium dithionite results in the formation of the disodium salt **18**.

$$\mathbf{14} \xrightarrow[NaHCO_3\ 0\,^\circ C,\ 4\ h]{Na_2S_2O_4} (C_2H_5O)_2P(O)CF(SO_3Na)(SO_2Na)$$
18 (80%)

The corresponding di(sodium sulfonate) is then obtained by oxidation with hydrogen peroxide.

$$\mathbf{18} \xrightarrow[-15\,^\circ C,\ 1\ h]{H_2O_2} (C_2H_5O)_2P(O)CF(SO_3Na)_2$$
19 (32%)

It was not possible to convert this salt to the acid by using HCl_{aq}. Other methods for conversion to this interesting disulfonic/phosphonic acid are under study.

Titration of aqueous solutions of either **17** or **4** with sodium hydroxide (0.0508 N) gave rise to two inflection points, one for 2 equivalents (the sulfonic acid proton and one phosphonic acid proton) and one for 1 equivalent (the second phosphonic acid proton) of the acid. The total titre for **17** gives 97% of a tribasic acid based on an anhydrous molecular weight of 194 g/mol. For **4** the total titre gives 100% of a tribasic acid based on an anhydrous molecular weight of 478 g/mol.

When **4** is dissolved in isopropyl alcohol and titrated with a toluene/methanol solution of tetrabutylammonium hydroxide (TBAH, 0.0392 N), two equivalence points are observed at approximately equal volumes of titrant. Addition of a slight excess (~10%) of TBAH after the second inflection point was followed by the addition of 10 mL (~15%) of H_2O. When the electrode had stabilized, the titration with TBAH was continued to a third inflection point. The three acid protons are easily resolved by this combination of nonaqueous/aqueous titration.

In summary, successful routes to a variety of mixed phosphonic/sulfonic acids, and partially fluorinated phosphonic acids have been developed. Study of several of these acids in

fuel cell systems should provide valuable insights regarding the effects of particular structural moieties on the performance of fluorinated *electrolytes*.

Experimental

Materials

The literature method was used to prepare $I(CF_2)_4O(CF_2)_2SO_2F$ (11). Other chemicals were obtained as follows: $Na_2S_2O_4$, CH_3CN, and HCl (Merck); $NaHCO_3$, H_2O_2 (30%), and K_2SO_3 (J. T. Baker); charcoal (activated "Norit" SGII) (MCB).

General procedures

The ^{19}F NMR spectra were obtained on a JEOL FX-90Q Fourier transform NMR spectrometer operating at 84.26 MHz. Chloroform-*d*, D_2O, CD_3CN, or DMSO-d_6 was used as solvent with $CFCl_3$ as external reference. ^{31}P NMR spectra were obtained at an operating frequency of 36.20 MHz with H_3PO_4 as an external reference. ^1H NMR spectra were recorded at 89.56 MHz. Mass spectra were recorded with a VG 7070HS mass spectrometer with FAB at 3.9, 4.8, or 10 V. Elemental analyses were performed by Beller Mikroanalytisches Laboratorium, Göttingen, Federal Republic of Germany.

Preparation of $(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_2F$

A mixture of $I(CF_2)_4O(CF_2)_2SO_2F$ (20.3 g, 38 mmol) and tetraethyl pyrophosphite (9.55 g, 57 mmol) in $CF_2ClCFCl_2$ (83 mL) with di-*tert*-butylperoxide (2.8 g, 19 mmol) was heated at 120°C for 3 h in a 150-mL autoclave. After reaction the mixture was placed in a glass flask fitted with a dropping funnel. The flask was cooled to −10°C under nitrogen and a solution of *tert*-butylhydroperoxide (138 mmol) in methanol (46 mL) was added slowly via the dropping funnel. After addition was complete at −10 to −5°C, stirring was continued at 0°C for 1 h.

The solution was washed with water (50 mL × 3) and volatile materials were removed *in vacuo*. The residue was distilled under reduced pressure to give 9.83 g of $(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_2F$ (yield 48%); bp 133°C/1.1 Torr (1 Torr = 133.3 Pa). Spectral data are ^{19}F NMR, Φ: 44.48m SO_2F, −82.99m CF_2, −83.92m CF_2, −113.05m CF_2, −121.80m CF_2, −123.45dt CF_2 (J_{P-F} = 83.58 Hz, J_{F-F} = 14.6 Hz), −126.08t CF_2; ^{31}P NMR, δ: −1.58t; ^1H NMR, δ: 1.19t CH_3 (J_{H-H} = 6.96 Hz), 4.18m CH_2; MS (CI, *m/e* (species) %): 537 ($M^+ + 1$) 64, 509 ($M^+ + 1 - C_2H_4$) 40, 495 ($M^+ + 1 - C_3H_6$) 36, 481 ($M^+ + 1 - C_4H_8$) 83, 397 ($(CF_2)_2O(CF_2)_4(O)(OH)_2P^+$) 25, 137 ($(C_2H_5O)_2(O)P^+$) 60, 109 ($C_2H_5O(O)(OH)P^+$) 100, 81 ($(HO)_2(O)P^+$) 46. *Anal.* calcd. for $C_{10}H_{10}F_{13}O_6PS$: C 22.40, H 1.88, F 46.06, P 5.78, S 5.98; found: C 22.38, H 1.71, F 46.4, P 5.88, S 6.03.

Preparation of $(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_2Na$, 1

In a 50-mL three-necked round-bottomed flask were placed 9.3 mmol $(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_2F$, 18.6 mmol $Na_2S_2O_4$, 18.6 mmol $NaHCO_3$, 8 mL H_2O, and 4 mL of CH_3CN. Under a stream of nitrogen, the contents were stirred vigorously at 85°C for 2 h. After cooling, the reaction mixture was filtered. The filtrate was evaporated to dryness under reduced pressure to give a white solid that was purified by repetitive extraction with CH_3CN. Finally 4.5 g (8.3 mmol) of **1** was obtained in 90% yield. Spectral data are ^{19}F NMR, Φ: −82.53m CF_2, −82.99m CF_2, −120.70m CF_2, −121.57dt CF_2 (J_{P-F} = 74.78 Hz, J_{F-F} = 14.01 Hz), −125.22t CF_2, −133.26s CF_2; ^{31}P NMR, δ: −4.73t; ^1H NMR, δ: −1.13t CH_3 (J_{H-H} = 6.97 Hz), 3.87m CH_2.

Preparation of $(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_3Na$, 2

Into a 30-mL flask were placed 8.3 mmol of $(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_2Na$ and 5 mL of water. At 0°C, a 3:1 mole ratio of hydrogen peroxide (30%) was added dropwise. The mixture was then stirred at room temperature for 12 h. After reaction, solvent was removed under reduced pressure, and the residue was dried to give 4.3 g of **2** (93% yield). Spectral data are ^{19}F NMR, Φ: −82.06m CF_2, −83.17m CF_2, −118.03s CF_2, −120.81m CF_2, −121.83dt CF_2 (J_{P-F} = 73.24 Hz, J_{F-F} = 14.6 Hz), −125.16t CF_2; ^{31}P NMR, δ: −4.61t; ^1H NMR, δ: 1.15t CH_3 (J_{H-H} = 7.33 Hz), 3.93m CH_2.

Preparation of $(HO)_2P(O)(CF_2)_4O(CF_2)_2SO_3Na$, 3

A mixture of 4.3 g of $(C_2H_5O)_2P(O)(CF_2)_4O(CF_2)_2SO_3Na$ (7.7 mmol) and 4.5 g of hydrochloric acid (12 N) were stirred vigorously at 120°C for 6 h and the reaction mixture was filtered. The filtrate was evaporated to dryness under vacuum to give 3.4 g (6.8 mmol) of **3** in 88% yield. Spectral data are ^{19}F NMR, Φ: −83.28m CF_2, −84.09m CF_2, −118.85s CF_2, −121.51m CF_2, −124.12d CF_2 (J_{P-F} = 79.18 Hz), −126.14m CF_2; ^{31}P NMR, δ: −3.27.

Preparation of $(HO)_2P(O)(CF_2)_4O(CF_2)_2SO_3H$, 4

An aqueous solution of 2.3 g of $(HO)_2P(O)(CF_2)_4O(CF_2)_2SO_3Na$ (4.6 mmol) was passed through an Amberlite IR-120 ion exchange resin at an approximate flow rate of 2 mL/min. The resulting solution was evaporated to dryness under reduced pressure. The crude product was dissolved in water and 0.15 g charcoal was added. The mixture was stirred at room temperature for 2 h. After the charcoal was removed by filtration, the filtrate was evaporated at reduced pressure at a temperature of 100°C to give 1.7 g **4** (3.5 mmol, 76% yield). The acid is a white solid, mp 91–92°C, and is very hygroscopic. Spectral data are ^{19}F NMR, Φ: −81.89m CF_2, −82.99m CF_2, −118.03s CF_2, −120.70m CF_2, −123.16dt CF_2 (J_{P-F} = 79.18 Hz, J_{F-F} = 14.01 Hz), −125.16t CF_2; ^{31}P NMR, δ: −3.76t; ^1H NMR, δ: 9.62s; MS (CI, *m/e* (species) %): 479 ($M^+ + 1$) 16, 281 ($(HO)_2P(O)CF_2CF_2CF_2CF_2^+$) 16, 231 ($(HO)_2P(O)CF_2CF_2CF_2^+$) 11, 181 ($(HO)_2P(O)CF_2CF_2^+$) 8, 131 ($(HO)_2P(O)CF_2^+$) 38, 111 ($HO_3PCF^+$) 11, 100 ($C_2F_4^+$) 68, 81 ($(HO)_2P(O)^+$) 46, 65 ($(HO)_2P^+$) 100. *Anal.* calcd. for $C_6H_3F_{12}O_7PS \cdot H_2O$: C 14.52, H 1.02, F 46.0, P 6.24, S 6.46; found: C 14.79, H 1.02, F 45.4, P 6.25, S 6.37.

Preparation of $I(CF_2)_4O(CF_2)_2SO_2K$

In a 250-mL three-necked round-bottomed flask were placed 15 g of $I(CF_2)_4O(CF_2)_2SO_2F$ (28.5 mmol), 13.6 g of K_2SO_3 (86 mmol), 60 mL water, and 40 mL CH_3CN. Under a stream of nitrogen the contents were stirred vigorously at room temperature for 10 h. The reaction mixture was filtered and the filtrate was evaporated to dryness under reduced pressure to give a white residue. Inorganic impurities were removed by repetitive extraction with CH_3CN. Finally, the solid was dried under vacuum at 70°C for 4 h to give 11.1 g (71% yield) of $I(CF_2)_4O(CF_2)_2SO_2K$ (20.3 mmol). Spectral data are ^{19}F NMR, Φ: −64.29m CF_2, −83.24m CF_2, −83.86m CF_2, −114.44m CF_2, −125.22m CF_2, −134.36s CF_2.

Preparation of $I(CF_2)_4O(CF_2)_2I$, 6

Under a stream of nitrogen, a mixture of 11.1 g $I(CF_2)_4O(CF_2)_2SO_2K$ (20.3 mmol), 6.8 g I_2 (26.8 mmol), and 30 mL of CH_3CN was stirred vigorously at 80°C for 7 h. A saturated $NaHSO_3$ aqueous solution was added to the reaction mixture to remove excess I_2 at room temperature. The mixture was filtered and the filtrate was dissolved in 50 mL of ether. The ether solution was washed with water repeatedly. After drying, 4.3 g of colorless liquid **6** (7.5 mmol) was obtained and purified by distillation (bp 60°C/10 Torr). The yield is 37%. Spectral data are ^{19}F NMR, Φ: −64.64m CF_2, −70.13s CF_2, −84.61m CF_2, −86.64m CF_2, −114.50m CF_2, −125.33m CF_2.

Preparation of $H(CF_2)_4O(CF_2)_2P(O)(OC_2H_5)_2$ and $H(CF_2)_2O(CF_2)_4P(O)(OC_2H_5)_2$

A mixture of 4.3 g of $I(CF_2)_4O(CF_2)_2I$ (7.5 mmol) and 5.8 g of tetraethylpyrophosphite (22.5 mmol) in 20 mL of $CF_2ClCFCl_2$ with 1.1 g of di-*tert*-butylperoxide (7.5 mmol) was heated at 120°C for 3 h in a 75-mL autoclave. After reaction, the mixture was placed into a glass flask fitted with a dropping funnel. The flask was cooled to −10°C under a nitrogen atmosphere and a solution of *tert*-butylhydroperoxide (60 mmol) in 20 mL of methanol was slowly added via the dropping funnel. After complete addition at −10 to −5°C, stirring was continued at 0°C for 1 h. The solution was washed with water (15 mL × 3) and volatile materials were removed *in vacuo*. The residue was distilled under reduced pressure to give 0.75 g of $H(CF_2)_4O(CF_2)_2P(O)(OC_2H_5)_2$ (1.65 mmol) and 0.25 g of $H(CF_2)_2O(CF_2)_4P(O)(OC_2H_5)_2$ (0.55 mmol). The combined yield is 29%. Spectral data for $HCF_2CF_2CF_2CF_2OCF_2CF_2P(O)(OC_2H_5)_2$ (bp 97°C/0.5 Torr) are ^{19}F NMR,

Φ: −83.45m OCF_2, −124.64d CF_2 (J_{P-F} = 87.97 Hz), −127.07m CF_2, −129.79m CF_2, −137.11d CF_2H (J_{F-H} = 53.71 Hz); ^{13}P NMR, δ: −0.36t; ^1H NMR, δ: 1.40t CH_3 (J_{H-H} = 6.96 Hz), 4.34m CH_2, 6.16tt CF_2H (J_{F-H} = 53.71 Hz, J_{F-H} = 5.5 Hz). Spectral data for $HCF_2CF_2OCF_2CF_2CF_2CF_2P(O)(OC_2H_5)_2$ (bp 126°C/0.5 Torr) are ^{19}F NMR, Φ: −84.27m CF_2, −84.79m CF_2, −123.94d CF_2 (J_{P-F} = 87.97 Hz), −126.61m CF_2, −130.77m CF_2, −139.75d CF_2H (J_{F-H} = 48.83 Hz); ^{31}P NMR, δ: −1.09t.

Preparation of $H(CF_2)_2O(CF_2)_2P(O)(OC_2H_5)_2$, 7

The method of preparation is the same as that described for $HCF_2CF_2CF_2CF_2OCF_2CF_2P(O)(OC_2H_5)_2$ and $HCF_2CF_2OCF_2CF_2$-$CF_2CF_2P(O)(OC_2H_5)_2$ above. The overall yield is 16%. Spectral data are ^{19}F NMR, Φ: −83.80m CF_2, −88.44m CF_2, −124.87d CF_2 (J_{P-F} = 87.89 Hz), −137.49d CF_2H (J_{F-H} = 52.40 Hz); ^{13}P NMR, δ: 0.12t (J_{P-F} = 87.89 Hz); ^1H NMR, δ: 1.33t CH_3 (J_{H-H} = 7.15 Hz), 4.37m CH_2, 5.83tt CF_2H (J_{F-H} = 2.94 Hz); MS (CI, *m/e* (species) %): 355 ($M^+ + 1$) 84, 335 ($M^+ - F$) 12, 327 ($M^+ + 1 - C_2H_4$) 82, 299 ($M^+ + 1 - C_4H_8$) 100, 279 ($M^+ + 1 - C_4H_9F$) 60, 137 ($(C_2H_5O)_2(O)P^+$) 50, 109 ($(HO)(O)P(OC_2H_5)^+$) 71.

Preparation of $H(CF_2)_4O(CF_2)_2P(O)(OH)_2$, 10

A mixture of 0.30 g $H(CF_2)_4O(CF_2)_2P(O)(OC_2H_5)_2$ (0.66 mmol) and 1.0 g Me_3SiBr (6.5 mmol) was stirred vigorously at room temperature for 24 h and at 50°C for 8 h. After reaction all volatiles were removed under vacuum. One millilitre of water was added, and the mixture was stirred vigorously at room temperature for 16 h followed by extraction with ether. Excess water was removed *in vacuo* to give the crude product. The product was dissolved in water and stirred with a small amount of charcoal at room temperature for 2 h to remove color. Finally, the solution was filtered, and evaporated *in vacuo* at 70°C to give 0.21 g of colorless viscous oil **10** (0.38 mmol). The yield is 58%. Spectral data are ^{19}F NMR, Φ: −84.32m OCF_2, −127.36d CF_2 (J_{P-F} = 79.17 Hz), −127.88m CF_2, −130.77m CF_2, −139.31d CF_2H (J_{F-H} = 53.71 Hz); ^{31}P NMR, δ: −4.00t; ^1H NMR, δ: −6.48tt CF_2H (J_{F-H} = 5.31 Hz), 8.61s $P(O)(OH)_2$; MS (CI, *m/e* (species) %): 399 ($M^+ + 1$) 100, 379 ($M^+ - F$) 33, 181 ($(OH)_2P(O)CF_2CF_2^+$) 71, 81 ($(HO)_2P(O)^+$) 57.

Preparation of $H(CF_2)_2O(CF_2)_4P(O)(OH)_2$, 11, and $H(CF_2)_2O$-$(CF_2)_2P(O)(OH)_2$, 9

The method of preparation is the same as that described above for **10**. Spectral data for **11** are ^{19}F NMR, Φ: −82.47m OCF_2, −122.47d CF_2 (J_{P-F} = 79.18 Hz), −124.81m CF_2, −128.69m CF_2, −138.18d CF_2H (J_{F-H} = 48.83 Hz); ^{31}P NMR, δ: −4.61t; ^1H NMR, δ: 7.13tt CF_2H (J_{F-H} = 5.50 Hz), 9.15s $P(O)(OH)_2$; MS (CI, *m/e* (species) %): 399 ($M^+ + 1$) 63, 181 ($(HO)_2P(O)CF_2CF_2^+$) 31, 81 ($(HO)_2P(O)^+$) 100. Spectral data for **9** are ^{19}F NMR, Φ: −84.44m CF_2, −89.42m CF_2, −127.30d CF_2 (J_{P-F} = 87.89 Hz), −139.46d CF_2H (J_{F-H} = 48.83 Hz); ^{31}P NMR, δ: −1.82t; ^1H NMR, δ: 6.21tt CF_2H (J_{H-F} = 2.94 Hz), 11.03s $P(O)(OH)_2$; MS (CI, *m/e* (species) %): 299 ($M^+ + 1$) 100, 279 ($M^+ - F$) 50, 181 ($(HO)_2P(O)CF_2CF_2^+$) 90, 81 ($(HO)_2P(O)^+$) 51.

Preparation of $(C_2H_5O)_2P(O)CFBr_2$, 12

Tribromofluoromethane (27.1 g, 0.1 mol) was slowly added to triethylphosphite (16.6 g, 0.1 mol) at 0°C under a nitrogen atmosphere and then stirred continuously at 0°C for 4 h. The reaction mixture was distilled under reduced pressure to yield 25.24 g (76.9%) of diethyl-dibromofluoromethylphosphonate (bp 86–87°C/0.7 Torr). Spectral data are ^{19}F NMR, Φ: −75.98d (J_{F-P} = 78.12 Hz); $^{13}P\{H\}$ NMR, δ: 1.51d; ^1H NMR, δ: 1.38t (3H, J_{H-H} = 6.96 Hz), 4.32q (1H), 4.41q (1H) (J_{H-P} = 8.03 Hz); MS (FB^+, solv. glycerol, *m/e* (species) %): 331 ($M^{81+} + 1$) 5.4, 329 ($M^{81}M^{79+} + 1$) 10.5, 327 ($M^{79+} + 1$) 6.02, 250 ($M^{81+} + 1 - Br^{81}$) 1.83, 248 ($M^{79+} + 1 - Br^{79}$) 1.5, 193 ($CFBr_2^{81+}$) 6.9, 189 ($CFBr_2^{79+}$) 6.9, 168 ($(C_2H_5O)P(O)CF^+$) 1.1, 149 ($(C_2H_5O)_2P(O)C^+$) 6.7, 137 ($(C_2H_5O)_2P(O)^+$) 29.4, 112 ($CFBr^{81+}$) 2.4, 110 ($CFBr^{79+}$) 3.0, 65 ($H_2O_2P^+$) 100, 63 (PO_2^+) 4.9. All other fragments are consistent with the isotope ratio expected for **12**.

Preparation of $(C_2H_5O)_2P(O)CFBrSO_2Na$, 13

In a 50-mL three-necked round-bottomed flask were placed 10.04 g (57.6 mmol) of $Na_2S_2O_4$, 4.84 g (57.6 mmol) of $NaHCO_3$, and 16 g (48 mmol) of $(C_2H_5O)_2P(O)CFBr_2$. Ten millilitres of water and 10 mL of CH_3CN were added. Under a stream of nitrogen, the contents were stirred vigorously at room temperature for 4 h. The reaction mixture was evaporated to dryness under reduced pressure to give a white product that was extracted with acetonitrile. The extract was filtered to remove solids, and the filtrate was evaporated to dryness under reduced pressure to give 13.8 g (84.4% yield) of **13**. Spectral data are ^{19}F NMR, Φ: −136.36d (J_{F-P} = 83.01 Hz); $^{31}P\{H\}$ NMR, δ: 9.76d; ^1H NMR, δ: 1.43t (3H, J_{H-H} = 6.96 Hz), 4.37q (1H), 4.46q (1H) (J_{H-P} = 8.03 Hz); MS (FB^+, solv. H_2O, *m/e* (species) %): 354 ($M^{81+} + H_2O$) 0.7, 353 ($M^{81}M^{79+} + H_2O$) 7.2, 352 ($M^{79+} + H_2O$) 0.4, 336 (M^{81+}) 0.5, 334 (M^{79+}) 0.3, 249 ($M^{81+} - SO_2Na$) 2.0, 247 ($M^{79+} - SO_2Na$) 1.7, 149 ($(C_2H_5O)_2P(O)C^+$) 13.9, 137 ($(C_2H_5O)_2P(O)^+$) 5.3, 87 ((SO_2Na^+) 1.9, 65 ($PO_2H_2^+$) 100, 63 (PO_2^+) 13.7. All other fragments are consistent with the isotope ratio expected for **13**.

Preparation of $(C_2H_5O)_2P(O)CFBrSO_3Na$, 14

A sample of 5 g (14.9 mmol) of $(C_2H_5O)_2P(O)CFBrSO_2N$ and 5 mL of water were placed in a 25-mL flask. Then 2.95 g of hydrogen peroxide (30%) (molar ratio $(C_2H_5O)_2P(O)CFBrSO_2Na:H_2O_2$ = 1:1.75) was added at 0°C. The mixture was stirred at room temperature for 5 h and then filtered. The filtrate was evaporated under reduced pressure to give the crude product. After repetitive extraction with acetonitrile and filtering to remove small amounts of solids, the filtrate was evaporated to dryness under reduced pressure to give 3.92 g of $(C_2H_5O)_2P(O)CFBrSO_3Na$ (74.8% yield). Spectral data are ^{19}F NMR, Φ: −128.46d (J_{F-P} = 78.13 Hz); $^{31}P\{H\}$, δ: 6.30d; ^1H NMR, δ: 1.43t (3H, J_{H-H} = 6.96 Hz), 4.41q (1H), 4.49q (1H) (J_{H-P} = 7.14 Hz); MS (FB^+, solv. glycerol, *m/e* (species) %): 375 (M^{81+} + Na) 66.6, 374 ($M^{81}M^{79+}$ + Na) 4.5, 373 (M^{79+} + Na) 66.3, 149 ($(C_2H_5O)_2P(O)C^+$) 10.3, 137 ($(C_2H_5O)_2P(O)^+$) 5.5, 121 ($SO_3Na\cdot H_2O^+$) 2.0, 109 ($C_2H_6O_3P^+$) 10.2, 103 (SO_3Na^+) 2.0, 65 ($PO_2H_2^+$) 100, 63 (PO_2^+) 17.3.

Preparation of $(C_2H_5O)_2P(O)CFHSO_3Na$, 15

Activated zinc dust and 5.95 g of **14** (16.9 mmol) were reacted in dry tetrahydrofuran for 6 h at 60°C under dry nitrogen. After THF was removed from the reaction mixture under reduced pressure, the residue was hydrolyzed with water at room temperature for 4 h. An aqueous solution of **15** was obtained. The solvent was evaporated under reduced pressure to give a white solid. After washing with acetonitrile and acetone, the white solid was dried under vacuum at 70°C for 2 h to yield 2.24 g of **15** (48.6% yield). Spectral data are ^{19}F NMR, Φ: −197.96dd (J_{F-P} = 73.24 Hz, J_{F-H} = 43.94 Hz); $^{31}P\{H\}$, δ: 10.43d; ^1H NMR, δ: 1.42t (6H, J_{H-H} = 7.15 Hz), 4.32q (2H), 4.41q (2H) (J_{H-P} = 7.85 Hz), 5.72dd (1H) (J_{H-P} = 5.5 Hz); MS (FB^+, solv. glycerol H_2O, *m/e* (species) %): 295 (M^+ + Na) 100, 289 ($M^+ + H_2O$ − 1) 1.5, 273 ($M^+ + 1$) 16.8, 149 ($(C_2H_5O)_2P(O)C^+$) 1.9, 137 ($(C_2H_5O)_2P(O)^+$) 4.6, 65 ($PO_2H_2^+$) 14.7, 63 (PO_2^+) 3.9.

Preparation of $(HO)_2P(O)CFHSO_3Na$, 16

A mixture of 2.24 g of $(C_2H_5O)_2P(O)CFHSO_3Na$ (8.2 mmol) and 5 g of hydrochloric acid (12 N) were stirred vigorously at 120°C for 10 h. The reaction mixture was filtered and the filtrate was evaporated to dryness under vacuum to obtain a crude product that was taken up in CH_3CN. A small quantity of solid was removed by filtration. After removal of the solvent under vacuum, a white solid was obtained. This process was repeated twice. The product was taken up in water, and methylene chloride was added. The mixture was stirred vigorously for 1 h. The water phase was collected and evaporated under reduced pressure at 80°C to yield 1.07 g of **16** (59.4% yield). Spectral data are ^{19}F NMR, Φ: −194.25dd (J_{F-P} = 68.85 Hz, J_{F-H} = 48.82 Hz); $^{31}P\{H\}$ NMR, δ: 6.91d; ^1H NMR, δ: 4.90dd CH (J_{H-P} = 5.13 Hz), 8.58s OH; MS (FB^+, glycerol, *m/e* (species) %): 215 ($M^+ - 1$) 19.9, 193 ($M^+ - Na$) 79.9, 175 ($M^+ - Na - H_2O$) 29.3, 113 ($M^+ - SO_3Na$) 9.1, 112 ($(HO)_2P(O)CF^+$) 1.5, 111 ($CHFPO_3^+$) 4.4, 91 (CPO_3^+)

46.2, 81 ($PO_3H_2^+$) 18.5, 64 (PO_2H^+) 12.0, 63 (PO_2^+) 33.1, 59 ($P(O)C^+$) 100.

*Preparation of $(HO)_2P(O)CFHSO_3H$, **17***

An aqueous solution of 0.8 g of $(HO)_2P(O)CFHSO_3Na$ (3.7 mmol) was passed through an Amberlite IR-120 ion exchange resin at a flow rate of approximately 2 mL/min. The volume of the aqueous acid was reduced by evaporation, and the crude product was dried under reduced pressure at 50–80°C for 4 h. The product was dissolved in water and 0.1 g of charcoal was added. The mixture was stirred at 50°C for 2 h. Charcoal was removed by filtration, and the filtrate was evaporated under vacuum at 80°C for 4 h to yield 0.57 g of $(HO)_2P(O)CFHSO_3H$ (79.2% yield). The solid melts at 115–116°C, and is very hygroscopic. Spectral data are ^{19}F NMR, Φ: −193.67dd (J_{F-P} = 68.36 Hz, J_{F-H} = 48.83 Hz); $^{31}P\{H\}$ NMR, δ: 6.55d; ^1H NMR, δ: 4.89dd CH (J_{H-P} = 5.13 Hz), 12.18(s) OH; MS (CI^+, *m/e* (species) %): 213 ($M^+ + H_2O + 1$) 0.3, 113 ($M^+ - SO_3H$) 1.0, 81 (SO_3H^+ or $(HO)_2P(O)^+$) 52.7, 80 (PO_3H^+) 1.5, 79 (PO_3^+) 3.1, 65 ($PO_2H_2^+$) 100, 64 (PO_2H^+) 4.1, 59 ($P(O)C^+$) 1.5. *Anal.* calcd. for CH_4FO_6PS: C 6.19, H 2.06, F 9.79, S 16.52; found: C 6.20, H 2.10, F 9.90, S 16.36.

*Preparation of $(C_2H_5O)_2P(O)CF(SO_3Na)(SO_2Na)$, **18**, and $(C_2H_5O)_2P(O)CF(SO_3Na)_2$, **19***

In a 25-mL three-necked, round-bottomed flask were placed 1.49 g of $Na_2S_2O_4$ (8.6 mmol), 0.72 g of $NaHCO_3$ (8.6 mmol), 2 g of $(C_2H_5O)_2P(O)CFBrSO_3Na$ (5.7 mmol), 6 mL of water, and 6 mL of CH_3CN. Under a stream of nitrogen, the contents were stirred vigorously at 0°C for 4 h. The reaction mixture was filtered and the filtrate was evaporated to dryness under reduced pressure to give crude $(C_2H_5O)_2P(O)CF(SO_3Na)(SO_2Na)$. Spectral data are ^{19}F NMR, Φ: −165.78d (J_{F-P} = 73.24 Hz); $^{31}P\{H\}$, δ: 9.76d; ^1H NMR, δ: 1.41t (3H, J_{H-H} = 6.96 Hz), 4.32q (1H), 4.40q (1H) (J_{H-P} = 7.23 Hz); MS (FAB, solv. glycerol, *m/e* (species) %): 395 ($M^+ + 1 + 2H_2O$) 1.3, 376 ($M^+ + H_2O$) 1.6, 330 ($M^+ + 1 - C_2H_5$) 3.3, 313 ($M^+ + 1 - 2Na$) 4.1, 271 ($M^+ - SO_2Na$) 4.1, 255 ($M^+ - SO_3Na$) 0.9, 168 ($((C_2H_5O)_2P(O)CF^+$) 5.3, 149 ($((C_2H_5O)_2P(O)C^+$) 29.2, 137 ($((C_2H_5O)_2P(O)^+$) 18.9, 108 ($C_2H_5O_3P^+$) 8.3, 105 ($SO_2Na\cdot H_2O^+$) 13.1, 103 (SO_3Na^+) 2.2, 64 (PO_2H^+) 100, 63 (PO_2^+) 36.2.

Crude $(C_2H_5O)_2P(O)CF(SO_3Na)(SO_2Na)$ and 5 mL of water were placed in a 25-mL flask. Then hydrogen peroxide (30%) (molar ratio **18**:H_2O_2 = 1:1) was added at −15°C, and the mixture was stirred for 1 h. After concentrating and cooling, the inorganic solid impurities were removed by filtration. The filtrate was evaporated under reduced pressure to give crude **19**. The crude product was extracted with acetone three times. The acetone extract was collected and evaporated at reduced pressure to give 0.71 g (32%) of pure $(C_2H_5O)_2P(O)CF(SO_3Na)_2$. Spectral data are ^{19}F NMR, Φ: −151.82d (J_{F-P} = 73.24 Hz); $^{31}P\{H\}$ NMR, δ: 7.82d; ^1H NMR, δ: 1.39t (3H, J_{H-H} = 6.97 Hz), 4.32q (1H), 4.41q (1H) (J_{H-P} = 8.04 Hz); MS (FAB, solv. glycerol, *m/e* (species) %): 410 ($M^+ + 2H_2O$) 3.0, 330 ($M^+ + 1 - OC_2H_5$) 8.1, 271 ($M^+ - SO_3Na$) 2.5, 168 ($M^+ - 2SO_3Na$) 4.0, 149 ($(C_2H_5O)_2P(O)C^+$) 24.9, 137 ($((C_2H_5O)_2P(O)^+$) 14.5, 121 ($SO_3Na^+ + H_2O$) 2.2, 109 ($C_2H_6O_3P^+$) 14.3, 103 (SO_3Na^+) 3.1, 65 ($PO_2H_2^+$) 1.4, 64 (PO_2H^+) 100, 63 (PO_2^+) 55.3.

Titration

Titration of the acids was monitored utilizing an Orion model 701A digital Ionalyzer and Corning combination pH electrode. Sodium hydroxide was standardized with primary standard potassium acid phthalate. Tetrabutylammonium hydroxide in toluene/methanol solution was prepared from tetrabutylammonium iodide (12) and standardized against primary standard benzoic acid in dimethyl formamide.

A route to trinuclear platinum–gold clusters

G. J. ARSENAULT AND R. J. PUDDEPHATT[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 17, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

G. J. ARSENAULT and R. J. PUDDEPHATT. Can. J. Chem. **67**, 1800 (1989).

New A-frame cluster complexes have been prepared by addition of electrophilic gold fragments to the Pt—Pt bond of $[Pt_2Cl_2(\mu\text{-dppm})_2]$, dppm = $Ph_2PCH_2PPh_2$. For example, $[AuCl(SMe_2)]$ gave $[Pt_2Cl_2(\mu\text{-AuCl})(\mu\text{-dppm})_2]$ and $[Au(NO_3)(PPh_3)]$ gave $[Pt_2Cl_2(\mu\text{-AuPPh}_3)(\mu\text{-dppm})_2]NO_3$. The complexes $[(CH_2)_n(PPh_2AuBF_4)_2]$ reacted with $[Pt_2Cl_2(\mu\text{-dppm})_2]$ to give $[Pt_2Cl_2(\mu\text{-AuPPh}_2(CH_2)_nPPh_2AuCl)(\mu\text{-dppm})_2]BF_4$ when $n = 1$ or 2, but the bridged bis(A-frame) cluster complex $[\{Pt_2Cl_2(\mu\text{-dppm})_2(\mu\text{-AuPPh}_2CH_2)\}_2CH_2](BF_4)_2$ when $n = 3$. In contrast, CuCl reacted with $[Pt_2Cl_2(\mu\text{-dppm})_2]$ to give $[Pt_2Cl(CuCl_2)(\mu\text{-dppm})_2]$. Attempts to synthesize A-frame clusters containing Pt_2Ag, Pt_2Cu, Pd_2Au, or PdPtAu units were unsuccessful, and it is concluded that these units are considerably weaker than the analogous 3-center 2-electron bond of the Pt_2Au unit. The AuCl unit is displaced from $[Pt_2Cl_2(\mu\text{-AuCl})(\mu\text{-dppm})_2]$ on reaction with diazomethane, with formation of $[Pt_2Cl_2(\mu\text{-CH}_2)(\mu\text{-dppm})_2]$.

Key words: platinum, gold, cluster, copper, silver.

G. J. ARSENAULT et R. J. PUDDEPHATT. Can. J. Chem. **67**, 1800 (1989).

On a préparé un nouveau cadre-À de complexes agglomérés, en ajoutant des fragments d'or électrophiles à la liaison Pt—Pt du complexe $[Pt_2Cl_2(\mu\text{-dppm})_2]$, dppm = $Ph_2PCH_2PPh_2$. Par exemple le composé $[AuCl(SMe_2)]$ donne le complexe $[Pt_2Cl_2(\mu\text{-AuCl})(\mu\text{-dppm})_2]$ et le composé $[Au(NO_3)(PPh_3)]$ donne le complexe $[Pt_2Cl_2(\mu\text{-AuPPh}_3)(\mu\text{-dppm})_2]NO_3$. Les complexes $[(CH_2)_n(PPh_2AuBF_4)_2]$ réagissent avec le $[Pt_2Cl_2(\mu\text{-dppm})_2]$ pour donner le complexe $[Pt_2Cl_2(\mu\text{-AuPPh}_2(CH_2)_nPPh_2AuCl)(\mu\text{-dppm})_2]BF_4$ lorsque $n = 1$ ou 2, mais donne le complexe aggloméré bis(cadre-À) ponté : $[\{Pt_2Cl_2(\mu\text{-dppm})_2(\mu\text{-AuPPh}_2CH_2)\}_2CH_2](BF_4)_2$ lorsque $n = 3$. Le CuCl au contraire réagit avec le $[Pt_2Cl_2(\mu\text{-dppm})_2]$ pour donner le complexe $[Pt_2Cl(CuCl_2)(\mu\text{-dppm})_2]$. On a essayé sans succès de préparer des groupements de cadre-À contenant du Pt_2Ag, du Pt_2Cu, du Pd_2Au ou du PdPtAu, et on en arrive à conclure que ces unités sont considérablement plus faibles que leur analogue Pt_2Au ayant une liaison à trois centres et deux électrons. La réaction du complexe $[Pt_2Cl_2(\mu\text{-AuCl})(\mu\text{-dppm})_2]$ avec le diazométhane déplace le AuCl en donnant le complexe $[Pt_2Cl_2(\mu\text{-CH}_2)(\mu\text{-dppm})_2]$.

Mots clés : platine, or, agglomérat, cuivre, argent.

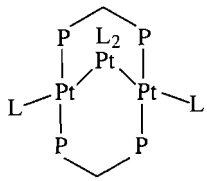
Heteronuclear cluster compounds containing the coinage metals are currently attracting considerable interest (1–9) and now constitute a well-established class of compounds, especially when the coinage metal is gold. However, relatively few reports have appeared on mixed-metal cluster complexes containing platinum and one of the coinage metals (4, 5).

The reactivity of the metal–metal bond of $[Pt_2Cl_2(\mu\text{-dppm})_2]$, **1***a*, to insertion reactions with small organic molecules and to addition of electrophilic reagents has been studied (6). These reactions often give "A-frame" complexes, such as $[Pt_2Cl_2(\mu\text{-CH}_2)(\mu\text{-dppm})_2]$ by reaction with CH_2N_2 and $[Pt_2Cl_2(\mu\text{-H})(\mu\text{-dppm})_2]^+$ by reaction with H^+. However, there has been less work on the reactions of **1** with metal moieties that are isolobal to CH_2 or H^+. $SnCl_2$ does not add to the Pt—Pt bond but inserts into the Pt—Cl bond to give $[Pt_2Cl(SnCl_3)(\mu\text{-dppm})_2]$ (7). Reaction with the nucleophilic metal carbonyl anion $[Fe(CO)_4]^{2-}$ disrupts the skeleton of **1** to give a triangulo-Pt_2Fe complex (8) and other carbonylmetallates may behave similarly. Thus, prior to the initiation of this work (11) no A-frame cluster complexes had been synthesized directly by addition of a metal fragment to the Pt—Pt bond of **1***a*. Such complexes appear to have good stability since two examples, **2** (9) and **3** (10), have been prepared indirectly, and the complex $[Pt_2Cl_2(\mu\text{-HgCl}_2)(\mu\text{-dppm})_2]$ was prepared recently by direct addition of $HgCl_2$ to **1***a* (12).



Herein, we report the reactions of complexes **1** with several electrophilic gold fragments that are isolobal with H^+. Complex **1***a* gives A-frame complexes containing Pt_2Au units by addition of the gold moeity across the Pt—Pt bond of **1***a*. However, **1***b* and **1***c* fail to give the corresponding A-frame complexes containing Pd_2Au or PdPtAu units. Reaction of **1***a* with similar copper or silver fragments also does not give A-frame complexes.

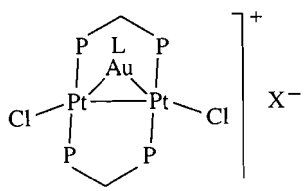
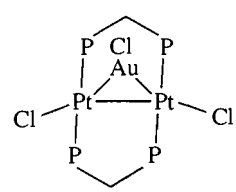
in dichloromethane solution gave $[Pt_2Cl_2(\mu\text{-}AuPPh_3)(\mu\text{-dppm})_2]NO_3$, as an air-stable yellow solid in analytically pure form (Table 1). The structure of **4***a* was readily deduced from its ^{1}H, ^{31}P, and ^{195}Pt NMR spectra (Tables 2, 3, and 4).



The ^{31}P NMR spectrum of **4***a* contains only two resonances, which are attributable to the $[Pt_2Cl_2(\mu\text{-dppm})_2]$ and Ph_3PAu phosphorus atoms respectively (Fig. 1). The dppm resonance had the typical appearance of a symmetrical A-frame complex (6–9) and the Ph_3PAu resonance appeared as 1:8:18:8:1 quintet, due to ^2J(PtP) coupling, indicating that the gold fragment is coordinated symmetrically to the Pt—Pt bond of **1***a*. Further evidence for a symmetrical structure is shown in the ^{195}Pt NMR spectrum, in which a single resonance is observed with the expected multiplicity due to ^{31}P coupling. In the ^{1}H NMR spectrum of **4***a*, the methylene protons of the dppm ligand appear as an AB spin system, as anticipated for an A-frame structure. The isolobally related complex $[Pt_2Cl_2(\mu\text{-H})(\mu\text{-dppm})_2]^+$ undergoes an easy A-frame inversion process (14) since an intermediate with a linear ClPtHPtCl unit is readily accessible. No such inversion process occurs for **4***a* or related complexes since it is obviously not possible for the bulky $AuPPh_3$ unit to pass between the platinum atoms.



The spectroscopic data for **4***a* do not prove that the nitrate ion is not coordinated. The corresponding complex **4***b* was therefore prepared from Ph_3PAuBF_4, and the ^{1}H and ^{31}P NMR spectra were shown to be identical to those of **4***a*. Since the BF_4^- ion does not coordinate, the nitrate group in **4***a* is also not coordinated. The structures of **4***a* and **4***b* are like that for **2***b*, which has been established crystallographically (9, 11).

When a solution of **1***a* in CD_2Cl_2 was treated with two equivalents of $[Ph_3PAuNO_3]$, the ^{31}P NMR spectrum of the reaction mixture showed resonances attributable to **4***a* and to $[Ph_3PAuNO_3]$. This shows, as expected, that only one mole of gold(I) can add to **1***a* and that an exchange of Ph_3PAu units between **4***a* and $[Ph_3PAuNO_3]$ either does not occur or is at least very slow on the NMR time scale.

The reaction of **1***a* and $[AuCl(SMe_2)]$ gave the A-frame cluster $[Pt_2Cl_2(\mu\text{-AuCl})(\mu\text{-dppm})_2]$, **5**, which could be isolated as air-stable red crystals, and free SMe_2 was also formed. The structure of **5** was assigned on the basis of its ^{1}H, ^{31}P, and ^{195}Pt NMR spectra, which are very similar to those of **4**.

It is interesting to compare the magnitudes of the coupling constants ^1J(PtPt) for the cluster complexes with that of the parent complex, **1***a* (Table 5). The magnitude of ^1J(PtPt) can be determined from the ^{31}P or ^{195}Pt NMR spectra by analysis of the

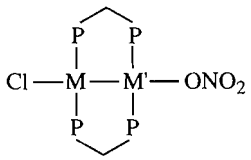
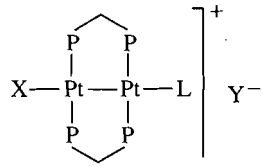
weak peaks arising from the $^{195}Pt_2$ isotopomers (13). The A-frame complexes all have lower ^1J(PtPt) values than in the parent complex **1***a*. This is not surprising since a lengthening of the Pt—Pt distance is expected and found on formation of A-frame complexes by addition of electrophiles such as H^+ or isolobal species such as AuCl or $AuPPh_3^+$. Increasing the *trans* influence of the terminal ligands on platinum leads to a great decrease in ^1J(PtPt) as expected (compare ^1J(PtPt) values of 6200 and 2060 Hz for **5** and **2***b* respectively). In contrast, increasing the *trans* influence of the ligand on gold leads to an increase in the magnitude of ^1J(PtPt) ((compare values of ^1J(PtPt) = 6100 and 6980 Hz for **5** and **4***a* respectively). We suggest that a ligand on gold having a strong *trans* influence weakens the AuPt interactions and hence leads to a stronger Pt—Pt interaction. This conclusion is tentative at this stage, since it is based only on the NMR parameters, and further X-ray studies are needed to confirm the effect.



Although the Pt_2Au cluster complexes have good thermal stability, the gold fragment can be displaced. For example, reaction of **5** with diazomethane gave [$Pt_2Cl_2(\mu$-$CH_2)(\mu$-dppm$)_2$] and "AuCl".

Attempted synthesis of Pt_2Ag and Pt_2Cu A-frame clusters



Since the above Pt_2Au complexes were very stable, attempts were made to synthesize A-frame complexes with the other coinage metals. However, in contrast to the ease of formation of the Pt_2Au complexes, it has not yet been possible to prepare similar derivatives of copper and silver.

For example, the reaction of **1***a* with Ph_3PAgNO_3 gave a

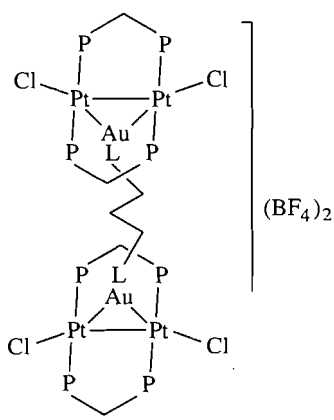
8

precipitate of AgCl and a yellow solid, characterized as $[Pt_2Cl(PPh_3)(\mu\text{-dppm})_2]NO_3$, **7***a*, by the ^1H and ^{31}P NMR data, which were identical to those of the known hexafluorophosphate salt (15). Pt—Ag complexes have only been isolated when no halides were present (16) or when unusual stabilization of the heteronuclear complex prevented the precipitation of AgCl (4).

Similarly, attempts to prepare Pt_2Cu A-frame clusters were unsuccessful. Reaction of **1***a* with $Cu(PPh_3)_2NO_3$ gave complex **7***a*, while reaction with one or two equivalents of $[Cu(MeCN)_4]BF_4$ gave CuCl and **7***b* or **8** respectively. The similar complex **7***c* had been characterized previously (17), and the characterization of the new compounds **7***b* and **8** was therefore straightforward.

A 1:1 adduct of complex **1***a* and CuCl was prepared by stirring the reagents together, using excess copper(I) chloride in dichloromethane. The adduct was thermally stable in the solid state but a solution in acetone slowly deposited CuCl and complex **1***a* was regenerated. This slow decomposition in solution has frustrated attempts to grow single crystals suitable for X-ray structure determination (crystals could be grown but all were twinned), and so the structure was deduced from NMR studies. At low temperature (−70°C), two resonances were observed in both the ^{195}Pt and the ^{31}P NMR spectra, and so the symmetrical A-frame structure analogous to complex **5** is immediately ruled out. The coupling constant $^1J(PtPt)$ from the ^{195}Pt NMR spectrum was 10 330 Hz, a value *higher* than for the parent **1***a*. Again this is inconsistent with an A-frame structure and indicates that a strong Pt—Pt bond is present. The CH_2P_2 resonance in the ^1H NMR spectrum at low temperature appeared as an AB quartet due to $^2J(HH)$ coupling, showing that there was no plane of symmetry containing the $Pt_2(\mu\text{-dppm})_2$ unit. At room temperature, a single CH_2P_2 resonance was observed in the ^1H NMR and a single ^{31}P resonance was also observed. The activation energy obtained from either ^1H or ^{31}P NMR spectra was 55 ± 4 kJ mol^{-1}, indicating a single fluxional process. We tentatively suggest that the structure of the complex is **9**, with a weakly coordinated $CuCl_2^-$ ligand and a strong Pt—Pt bond, and that the fluxional process involves exchange between $CuCl_2^-$ and Cl^- ligands on platinum, though the mechanism of this process cannot be determined. The "AB" pattern for the $CH^aH^bP_2$ protons of the dppm ligands is expected only if the $CuCl_2^-$ ligand is bound as shown in **9** and is unable to rotate about the Pt—Cl axis due to steric hindrance by the phenyl substituents.



9

Synthesis and characterization of bridged bis(A-frame) cluster complexes

Attempts were made to prepare bis(A-frame) cluster complexes by using the digold reagents $[(AuNO_3)_2\{\mu\text{-}Ph_2P(CH_2)_n\text{-}PPh_2\}]$ or $[(AuBF_4)_2\{\mu\text{-}Ph_2P(CH_2)_nPPh_2\}]$ with two equivallents of **1***a*. When n = 1 or 2, only the complexes **4***c*–**4***e* were formed and, for the nitrate derivatives, complex **6***a*. Complex **4***d* was an oil, which was characterized only spectroscopically, but **4***c* and **4***e* were solids obtained in analytically pure form. It seems that the first electrophilic gold atom can add to the Pt—Pt bond of **1***a* to give an A-frame cluster but then the second gold atom abstracts chloride from the second equivalent of **1***a* to give **4***c* or **4***d* and **6***a*. The complexes **4***c* and **4***d* could also be prepared by reaction of $[NO_3AuPPh_2(CH_2)_nPPh_2AuCl]$ with an equimolar amount of **1***a*, and in this case no side product **6***a* is formed. Complex **4***f*, n = 3, was prepared in the same way.

It was considered that, after addition of the first gold atom of the digold reagents to the Pt—Pt bond of **1***a*, the bulky A-frame substituent probably prevented approach of the second gold atom of the reagents to the Pt—Pt bond of the second equivalent of **1***a*, and so halogen abstraction took place instead to give **4***c*–**4***e*. The reaction of two molar equivalents of **1***a* with the longer chain diphosphine derivative $[BF_4AuPPh_2(CH_2)_3PPh_2AuBF_4]$ was therefore attempted, since the above type of steric hindrance should decrease with chain length. The bis(A-frame) complex **10** was obtained in high yield and was readily characterized by NMR spectroscopy. Thus in the ^{31}P NMR spectrum, single resonances, with the expected multiplicities, were observed in a 4:1 intensity ratio for the dppm and $Ph_2P(CH_2)_3PPh_2$, dppp, ligands as expected for a symmetrical bridged bis(A-frame) cluster complex. In the ^1H NMR spectrum, the expected "AB" resonance due to $CH^aH^bP_2$ protons of the dppm ligands and two resonances in a 2:1 ratio for the CH_2 protons of the bridging dppp ligand were observed. Complex **10** appears to be the first bis(A-frame) complex of any kind to be reported.

10

Attempted synthesis of Pd_2Au and PdPtAu A-frame complexes

To our knowledge, no examples of PdAu bonded complexes have been reported, and it was therefore of interest to attempt the synthesis of the dipalladium analogues of complexes **4** and **5**.

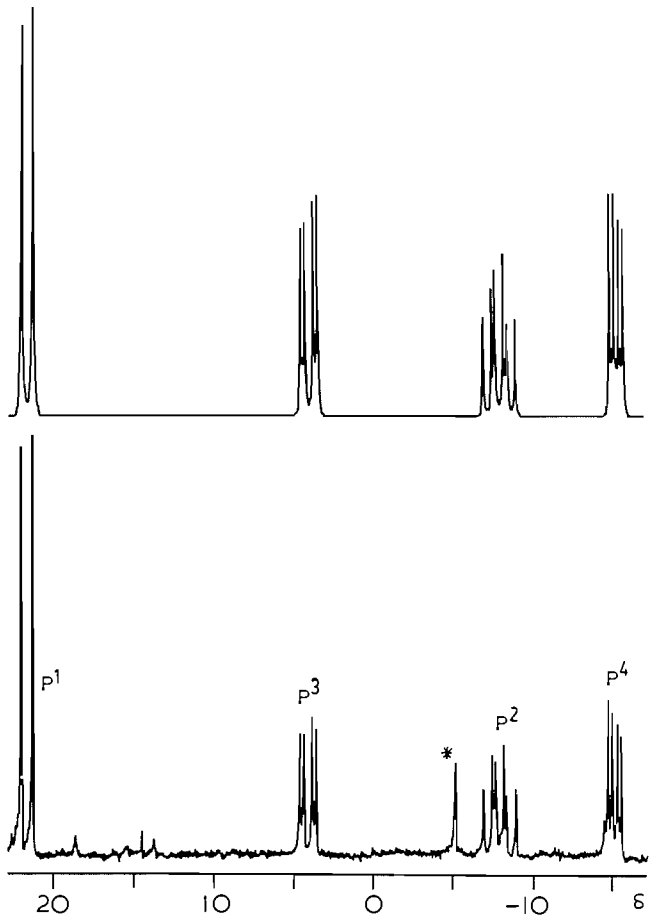

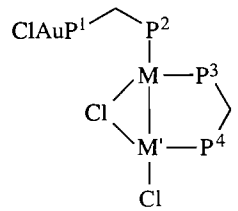

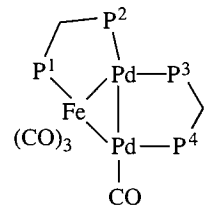

FIG. 2. The ^{31}P NMR spectrum (121 MHz) of **11***a*. The observed spectrum is shown below and the simulated spectrum above.

Reaction of $[Pt_2Cl_2(\mu\text{-dppm})_2]$, **16**, with $[AuCl(SMe)_2]$ in dichloromethane at −80°C gave a red solution. The ^{31}P NMR spectrum (Fig. 2, Table 6) at this temperature contained four equal intensity resonances. The spectral parameters resemble those for **12** (8), except for the absence of long range P^1P^3 and P^1P^4 couplings, and suggest an analogous metal–phosphorus skeleton but without PdAu bonds. We tentatively suggest structure **11***a*, though only the metal–phosphorus skeleton is characterized with confidence.

The coupling $^2J(P^2P^3)$ is less than 100 Hz and so indicates that these phosphorus atoms are mutually *cis* as shown in **11***a*. The CH_2P_2 protons of each dppm ligand gave a separate broad triplet resonance on the ^1H NMR spectrum. Braunstein *et al.* have independently studied the reaction of $[Pd_2Cl_2(\mu\text{-dppm})_2]$ with $[AuCl(SEt_2)]$ and have observed this same complex, but they too have not been able to obtain X-ray quality crystals (18). The complex decomposed to $[PdCl_2(dppm)]$ and $[Au_2Cl_2(\mu\text{-dppm})]$ and other unidentified complexes at room temperature or on attempted crystallization at low temperature. Reaction of **11***a* with PPh_3 gave $[AuCl(PPh_3)]$ and **1***b* in almost quantitative yield, as monitored by ^{31}P NMR spectroscopy.

11*a*, M = Pd, M' = Pd
11*b*, M = Pt, M' = Pd
11*c*, M = Pd, M' = Pt

12

Reaction of **1***b* with $[Au(NO_3)(PPh_3)]$ gave only $[AuCl(PPh_3)]$ and complex **6***b*. Thus, no evidence for A-frame cluster formation was obtained in any of the reactions of **1***b*, a result which has been independently obtained by Braunstein *et al.* (18).

Very similar results were obtained on reaction of the Pd—Pt bonded dimer **1***c*. Thus reaction with $[AuCl(SMe_2)]$ gave **11***b*, formed by selective cleavage of a Pd—P rather than a Pt—P bond (17). The latter reaction would have given **11***c*, which was not consistent with the spectroscopic data (Tables 4 and 6). Thus, both the ^{31}P NMR and the ^{195}Pt NMR spectra show that platinum remains bonded to two phosphorus atoms. Again it is emphasized that structure **11** is tentative. The complex decomposed rapidly at room temperature to give $[PdCl_2(dppm)_2]$, $[PtCl_2(dppm)]$, and $[Au_2Cl_2(\mu\text{-dppm})]$ and reacted cleanly with PPh_3 to give $[AuCl(PPh_3)]$ and **1***c*. Similarly, reaction of **1***c* with $[Au(NO_3)(PPh_3)]$ gave only halogen abstraction with formation of $[AuCl(PPh_3)]$ and **6***c* (19).

Conclusions

The addition of electrophilic gold fragments to metal–metal bonds is now a well-established reaction, especially with

Ph_3PAu^+ units adding to metal cluster complexes. The reactions lead to 3-centre 2-electron $[M_2AuPPh_3]^+$ units analogous to $[M_2(\mu\text{-}H)]^+$ units formed by addition of a proton to the metal–metal bond. This work has shown that such reactions occur readily with the diplatinum(I) complex **1***a* to give the A-frame cluster complexes **4***a* and **4***b*. Further, it is shown that $[AuCl(SMe_2)]$ can act as a precursor to the neutral fragment AuCl, which is also isolobal with H^+. From this reagent, the neutral A-frame cluster complex **5** was prepared and it is probable that many neutral cluster complexes containing AuCl units could be prepared by reaction of $[AuCl(SMe_2)]$ with metal–metal bonded complexes.

There is clearly a fine balance between whether an electrophilic metal fragment will add to the metal–metal bond of the complexes **1** or give other reactions. Indeed A-frame cluster formation is restricted to the case of the diplatinum(I) complex **1***a* and electrophilic gold fragments. Similar copper or silver fragments do not give A-frame clusters, but usually give halogen abstraction instead, yielding only the substituted diplatinum(I) complexes **6** or **7**. Reaction of electrophilic gold fragments with **1***b* or **1***c* also failed to give Pd_2Au or PdPtAu A-frame cluster complexes, but addition of gold to a dppm ligand occurred instead. The Pt_2Au A-frame complexes thus appear to have unique stability.

Experimental

Elemental analyses were performed by Guelph Chemical Laboratories Limited, Guelph, Ontario. NMR spectra were recorded on Varian XL-200 (^1H) and Varian XL-300 (^{31}P and ^{195}Pt) spectrometers. Chemical shifts are quoted with respect to $Me_4Si(^1H)$, trimethylphosphate (^{31}P), and K_2PtCl_4 (^{195}Pt).

Published methods were used to prepare the compounds: $[Pt_2Cl_2(\mu\text{-}dppm)_2]$ (13), $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ (20), $[PdPt_2Cl_2(\mu\text{-}dppm)_2]$ (20), Ph_3PAuNO_3 (21), $(SMe_2)AuCl$ (22), $[Au_2Cl_2(\mu\text{-}dppm)_2]$ (22), $(Ph_3P)_2CuNO_3$ (23), $[Cu(CH_3CN)_4]BF_4$ (24), and $[Pt_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ (25, 26).

Synthetic routes to Pt_2Au A-frame complexes

$[Pt_2Cl_2(\mu\text{-}AuPPh_3)(\mu\text{-}dppm)_2]NO_3$, **4**a

To a solution of **1***a* (29.7 mg, 0.0241 mmol) in CH_2Cl_2 (10 mL) was added a solution of Ph_3PAuNO_3 (14.0 mg, 0.0269 mmol) in CH_2Cl_2 (5 mL) and the mixture was stirred for 14 h at ambient temperature. The resulting solution was concentrated to 1 mL and addition of hexane (5 mL) gave an air-stable yellow precipitate. The solvent was decanted and the solid product **4***a* was washed with hexane and dried *in vacuo* (36.1 mg, 86% based on **1***a*).

In a similar experiment, 2 equivalents of Ph_3PAuNO_3 were added to a solution of **1***a* in dichloromethane. The ^{31}P NMR spectrum of the reaction mixture at ambient temperature showed resonances due to **4***a* and to free Ph_3PAuNO_3 (δ 29.0).

$[Pt_2Cl_2(\mu\text{-}AuPPh_3)(\mu\text{-}dppm)_2]BF_4$, **4**b

In a similar way, 1 equivalent of Ph_3PAuBF_4 was added to a solution of **1***a*. After stirring for 30 min, the resulting solution was concentrated and addition of excess hexane gave an air-stable yellow solid that was identified as **4***b*.

$[Pt_2Cl_2(\mu\text{-}AuCl)(\mu\text{-}dppm)_2]$, **5**

To a solution of **1***a* (49.0 mg, 0.0398 mmol) in CH_2Cl_2 (20 mL) was added a solution of $(SMe_2)AuCl$ (11.8 mg, 0.0401 mmol) in CH_2Cl_2 (2 mL) and the mixture was stirred for 16 h at ambient temperature. The solvent was removed to give a red solid, which was then crystallized from dichloromethane/diethyl ether to give red microcrystalline needles and plates. These were dried under vacuum (50.1 mg, 86%) and identified as **5**.

Reaction of **5** *with CH_2N_2*

To a solution of **5** (8 mg, 0.005 mmol) in CH_2Cl_2 (10 mL) at 0°C was added CH_2N_2 (0.1 mmol, ether solution). An immediate reaction occurred and metallic gold was precipitated. After 10 min, the solution was filtered, the solvents evaporated, and the product was identified as $[Pt_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ by its ^1H and ^{31}P NMR spectra (25).

$[Pt_2Cl_2(\mu\text{-}AudppmAuCl)(\mu\text{-}dppm)_2][NO_3]$, **4**c

To a solution of $dppm(AuCl)_2$ (14.8 mg, 0.0174 mmol) in CH_2Cl_2 (20 L) was added a solution of $AgNO_3$ (2 equiv.) in aqueous ethanol. The mixture was stirred for 1 h, the white precipitate was filtered off, and the solvent was removed to give $dppm(AuNO_3)_2$. This was immediately dissolved in CH_2Cl_2 (5 mL), and the solution was filtered and added to a solution of **1***a* (42.8 mg, 0.0340 mmol) in CH_2Cl_2 (15 mL). After stirring for 16 h, the solvent was removed to give an orange-red solid. The ^{31}P NMR spectrum of this solid showed resonances attributable to **4***c* and **6***a*. Crystallization from dichloromethane/hexane gave clusters of red needles. These were dried under vacuum (30.0 mg, 42%) and identified as **4***c*.

The above experiment was repeated except that only 1 equivalent of $AgNO_3$ was used. Crystallization of the reaction mixture from dichloromethane/diethyl ether gave red needles (28 mg, 50%) identified as **4***c*.

$[Pt_2Cl_2(\mu\text{-}AudppeAuCl)(\mu\text{-}dppm)_2]NO_3$, **4**d

This was prepared similarly from $dppe(AuCl)_2$ (19.4 mg, 0.0225 nmol) and 2 equivalent $AgNO_3$. Thus, after $dppe(AuNO_3)_2$ and **1***a* (55.5 mg, 0.0451 mmol) were combined and stirred for 18 h in dichloromethane (30 mL), the solvent was removed to give a yellow-orange solid. The ^{31}P NMR spectrum of the reaction mixture, in$CDCl_3$, gave resonances attributable to **4***d*, **6***a*, and $dppe(AuCl)_2$ (δ 29.1). This reaction mixture could not be induced to crystallize.

In a similar experiment, $dppe(AuCl)_2$ (44.6 mg, 0.0517 mmol) was treated with 1 equivalent $AgNO_3$ to give $dppeAu_2ClNO_3$, which was combined with **1***a* (61.7 mg, 0.0502 mmol) and stirred for 30 min in dichloromethane (30 mL). The solvent was removed to give a yellowish-red solid. The ^{31}P NMR spectrum of the reaction mixture gave resonances attributable to one major component, **4***c*, with trace amounts of $dppe(AuCl)_2$ and unreacted **1***a*. Complex **4***c* could not be induced to crystallize.

$[Pt_2Cl_2(\mu\text{-}AudppeAuCl)(\mu\text{-}dppm)_2]BF_4$, **4**e

This was prepared similarly except that $dppeAu_2ClBF_4$ (30.7 mg, 0.0356 mmol) was prepared instead of $dppeAu_2ClNO_3$. The digold reagent was stirred in dichloromethane (35 mL) in the presence of **1***a* (42.1 mg, 0.0342 mmol) for 30 min at ambient temperature. Evaporation of the solvent gave a yellow solid that was identified as **4***e* and was contaminated with small amounts of $dppe(AuCl)_2$ as evidenced by NMR spectroscopy. Complex **4***e* was purified by precipitation out of a dichloromethane solution with diethyl ether. Complex **4***f* was prepared similarly.

$[\{Pt_2Cl_2(\mu\text{-}dppm)_2(\mu\text{-}AuPPh_2CH_2)\}_2CH_2][BF_4]_2$, **10**

To a solution of $dppp(AuCl)_2$ (16.9 mg, 0.0193 mmol) in 20 mL of dichloromethane were added 2 equivalents of $AgBF_4$ in 95% aqueous ethanol (2 mL). This solution was stirred for 5 min, the white precipitate (AgCl) was filtered off and then immediately added to a solution of **1***a* (47.0 mg, 0.0382 mmol) in dichloromethane (15 mL). After stirring for 15 min, the solvent was removed to give a yellow solid, which was redissolved in a minimum amount of dichloromethane and excess hexane was added to precipitate complex **10** (54.9 mg, 85%) as a yellow solid.

Reaction of **1**a *with Ag(I) and Cu(I) complexes*

$AgNO_3$: To a solution of **1***a* (33.2 mg, 0.0270 mmol) in 15 mL CH_2Cl_2 was added a solution of $AgNO_3$ (4.5 mg, 0.0265 mmol) in aqueous ethanol. After stirring for 30 min, the solution was filtered and the solvent removed to give a yellow solid that was identified as **6***a* by ^{31}P NMR spectroscopy.

Ph_3PAgNO_3: Triphenylphosphine (11.6 mg, 0.0442 mmol) and $AgNO_3$ (6.9 mg, 0.0406 mmol) were dissolved in dichloromethane/95% ethanol and stirred for 20 min at ambient temperature. The solvent was removed to give a clear oil that was redissolved in CH_2Cl_2 (4 mL). To this solution was added **1***a* (51.5 mg, 0.0419 mmol) dissolved in CH_2Cl_2 (10 mL). After stirring for 1 h, the reaction mixture was filtered and the solvent removed to give a yellow solid (57.9 mg, 91%) that was identified as **7***a* by NMR spectroscopy.

$(Ph_3P)_2CuNO_3$: To a solution of **1***a* (66.6 mg, 0.0542 mmol) in 15 mL CH_2Cl_2 was added a solution of $(Ph_3P)_2CuNO_3$ (36.3 mg, 0.0558

mmol) in CH_2Cl_2 (3 mL). After stirring for 19 h, the solvent was removed to give a yellow solid (77.4 mg, 94%) that was identified as **7***a* by NMR spectroscopy.

$Cu(CH_3CN)_4BF_4$: To a solution of **1***a* (85.8 mg, 0.0698 mmol) in CH_2Cl_2 (30 mL) was added $Cu(CH_3CN)_4BF_4$ (22.2 mg, 0.0706 mmol), which dissolved and was immediately replaced by a fine white precipitate (CuCl). After stirring for 18 h, the solvent was removed and the residue was crystallized from dichloromethane/hexane to give a light yellow cluster of crystals, which was dried *in vacuo* for 3 h (86.7 mg, 94%) and identified as **7***b* (IR(Nujol)ν(MeCN): 2328 cm^{-1}).

Copper(I) chloride: To a solution of **1***a* (31 mg) in CH_2Cl_2 (10 mL) was added CuCl (4.5 mg). The mixture was stirred at ambient temperature for 20 h, then filtered and the solvent evaporated to give the product **9** (30 mg). Good crystals could be grown from CH_2Cl_2/ether by diffusion, but all crystals examined were twinned.

Reaction of **1**b *with gold reagents*

To a solution of **1***b* (68.6 mg, 0.0652 mmol) in CH_2Cl_2 (5 mL) at 0°C was added $(SMe_2)AuCl$ (22.7 mg, 0.771 mmol) in CH_2Cl_2 (5 mL). An immediate color change from light to dark red was observed. The solvent was removed after stirring for 1 h, giving a dark red solid. Examination of this reaction mixture by NMR spectroscopy in $CDCl_3$ indicated that one major compound **11***a* (see Table 6) was present along with trace amounts of $dppm(AuCl)_2$ (^{31}P NMR δ: 24.1 ppm), and other unidentified compounds. Attempted crystallization of **11***a* in CH_2Cl_2/hexane resulted in the decomposition of **11***a* to give a metal mirror (Pd° and (or) Au°), $dppm(AuCl)_2$, $dppmPdCl_2$, and other identifiable products as observed by NMR spectroscopy. This experiment, with minor changes, was repeated several times and gave similar results.

Reaction of **1**c *with gold reagents*

To a solution of **1***c* (39.2 mg, 0.0321 mmol) in CH_2Cl_2 (25 mL) was added $(SMe_2)AuCl$ (15.2 mg, 0.0516 mmol). As the gold reagent dissolved, an immediate color change from orange to dark red was observed. After stirring for 5 min at ambient temperature, the solvent was removed giving a dark red oil. This residue was dissolved in CD_2Cl_2 and the ^1H, ^{31}P, and ^{195}Pt NMR spectra were determined and gave resonances attributable to **11***b* (see Table 6), and to small amounts of dppm(AuCl). Attempted crystallization from several solvents resulted in the decomposition of **11***b* to metal, $dppm(AuCl)_2$, $dppmPdCl_2$, $dppmPtCl_2$ (δ −69.7 ppm), and other unidentified species as determined by ^{31}P NMR spectroscopy.

A solution of **11***b* was prepared as above, from **1***c* (39.2 mg, 0.0321 mmol) with $(SMe_2)AuCl$ (9.7 mg, 0.0329 mmol) in CH_2Cl_2 (20 mL) at 0°C for 10 min. Triphenylphosphine (8.6 mg, 0.0328 mmol) was added and an immediate color change from dark red to yellow was observed. The solvent was removed after stirring for 15 min and the ^1H and ^{31}P NMR spectra of the dark red residue in $CDCl_3$ gave resonances due to **1***c* and Ph_3PAuCl.

One-electron transfer processes in the reaction of elemental gallium, indium, and tin with tetrahalogeno-*ortho*-benzoquinones

THEODORE A. ANNAN AND DENNIS G. TUCK[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received February 8, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

THEODORE A. ANNAN and DENNIS G. TUCK. Can. J. Chem. **67**, 1807 (1989).

Tin reacts with tetrahalogeno-*o*-benzoquinones $X_4C_6O_2$ (X = Cl, Br) in refluxing toluene to give the tin(IV) catecholato species $Sn(O_2C_6X_4)_2$, and neutral and anionic derivatives have also been obtained. A mixture of Sn + $X_4C_6O_2$-*o* + I_2 + 1,10-phenanthroline (phen) yields $SnI_2(O_2C_6X_4)$phen. With gallium or indium (= M), the corresponding experiments give derivatives of M^{II} (e.g., $[M(O_2C_6X_4)phen]_2$), or M^{III} (e.g., $MI(O_2C_6X_4)$phen). Intermediate paramagnetic species were detected in the case of In/$Cl_4C_6O_2$-*o*/$\frac{1}{2}I_2$, and a reaction mechanism involving one-electron transfer processes is proposed on the basis of these results. Solvated crystals of the compound $InCl(O_2C_6Cl_4)(C_6H_7N)_3$ were obtained from CH_2Cl_2 solution, and the structure of this molecule has been determined by X-ray crystallographic methods.

Key words: gallium, indium, tin, benzoquinones, oxidation.

THEODORE A. ANNAN et DENNIS G. TUCK. Can. J. Chem. **67**, 1807 (1989).

En solution dans le toluène au reflux, l'étain réagit avec les tétrahalogéno *o*-benzoquinones ($X_4C_6O_2$ (X = Cl, Br) pour donner des espèces catécholato-étain(IV) $Sn(O_2C_6X_4)_2$ ainsi que des dérivés neutres et anioniques. Un mélange de Sn + *o*-$X_4C_6O_2$ + phénanthroline-1,10 (phen) fournit du $SnI_2(O_2C_6X_4)$phen. Lorsqu'on réalise la même expérience avec du gallium ou de l'indium (= M), on obtient les dérivés correspondants du M^{II} (e.g., le $[M(O_2C_6X_4)phen]_2$) ou du M^{III} (e.g., $MI(O_2C_6X_4)$phen). Dans le cas de la réaction du In/*o*-$Cl_4C_6O_2$/$\frac{1}{2}I_2$, on a détecté la présence d'intermédiaires paramagnétiques et, sur la base de ces résultats, on propose un mécanisme réactionnel impliquant des processus de transfert par un électron. En utilisant une solution de CH_2Cl_2, on a isolé des cristaux solvatés du $InCl(O_2C_6Cl_4)(C_6H_7N)_3$ et, faisant appel à des méthodes de diffraction des rayons-X, on a déterminé la structure de cette molécule.

Mots clés : gallium, indium, étain, benzoquinones, oxydation.

[Traduit par la revue]

Introduction

Recent papers from this laboratory have described the reactions between *ortho*-quinones and the halides of tin(II) or indium(I), processes which correspond formally to oxidative addition. In the case of the tetrahalogeno-*o*-benzoquinones $X_4C_6O_2$ (X = Cl, Br), the products are the corresponding tin(IV) or indium(III) catecholato compounds, as has been established by a variety of preparative, spectroscopic, and structural investigations (1, 2). More detailed mechanistic studies were possible when the oxidant was 3,5-di-*tert*-butyl-*ortho*-benzoquinone (TBQ), since the use of electron spin resonance spectroscopy demonstrated the importance of the appropriate semi-quinonate complexes as intermediates (ref. 3 and footnote 2). The general conclusion is that these reactions involve two successive one-electron transfer processes, rather than the two-electron transfer reactions generally assumed to occur in Main Group redox chemistry.

In a related study, we have shown that indium metal reacts with TBQ in refluxing toluene to give a solution of the indium(I)-semiquinone complex (TBSQ·)In, whose chemistry has been investigated (5). We have now carried out analogous studies of the oxidation of elemental gallium, indium, and tin by tetrahalogeno-*o*-benzoquinones, and find significant differences between the present results for indium and those reported earlier for TBQ. It is worth noting that direct oxidation of indium and tin can also be achieved by reaction with nonaqueous solutions of diphenyl disulphide or diselenide to give the appropriate $M(EPh)_n$ species (E = S, Se) (6), and it may well be that such simple reactions are of wider application than has been generally believed to be the case.

Experimental

General

Tin, indium, and gallium metals, tetrahalogeno-*o*-benzoquinones, 1,10-phenanthroline (phen), and 2,2′-bipyridine (bpy) (Aldrich) were used as supplied; 4-methyl pyridine (γ-picoline) (Aldrich) was stored over molecular sieves. Solvents were dried by conventional methods, and stored over drying agents. All reactions were carried out in an atmosphere of dry nitrogen.

Metal analysis was carried out by using atomic absorption spectrophotometry, with an IL 151/251 instrument and samples decomposed by aqueous nitric acid; microanalysis was by Guelph Chemical Laboratory Ltd. Halogen analysis by the Volhard method proved to be unreliable due to the presence of the strongly coloured *o*-quinone in the acidified aqueous solution. The ^1H and ^{13}C nmr spectra were recorded on a Bruker AC 300L instrument. Infrared spectroscopy involved the use of samples in KBr pellets with a Nicolet 5DX spectrometer. Conductivities were measured in a standard platinum electrode cell, standardized with 1 M aqueous KNO_3. Mass spectra of samples dissolved in 3-nitrobenzyl alcohol were recorded on a VG-ZAB-HF instrument, operating in the FAB mode, and electron spin resonance (esr) studies on a Varian E12 spectrometer, which was calibrated with an nmr gaussmeter.

Preparative

1. In the synthesis of substituted catecholato complexes of tin(IV), indium(II), and gallium(II), the general method used involved refluxing the finely divided metal (ca. 1 g) with a toluene solution of the *o*-quinone in a 1:1 (M = In, Ga) or 1:2 (M = Sn) molar ratio for 24 h. The mixture obtained at the end of this period was filtered, and any unreacted metal was collected, washed, dried, and weighed, which allowed the amount of metal consumed, typically ca. 85%, to be measured. The calculated equimolar amount of neutral donor ligand

[a]bipy = 2,2′-bipyridine; phen = 1,10-phenanthroline; pic = 4-$CH_3C_5H_4N$; tol = toluene.

(phen, bpy) was dissolved in toluene and added to the filtrate. Precipitation of the product occurred upon complete addition of the ligand; the resultant mixture was stirred at room temperature for 2 h, after which the precipitate was collected by filtration, washed with petroleum ether (2 × 20 mL), and dried *in vacuo*. Addition of petroleum ether to the filtrate caused further precipitation of the product, which was isolated in a similar manner; the two products were found to be identical on the basis of elemental and spectroscopic analyses. When γ-picoline was used as the neutral donor, the product only precipitated when the volume of the solution was reduced by 50%, followed by the addition of petroleum ether (50 mL), yielding a brown product that was washed with petroleum ether and dried *in vacuo*. Analytical results are presented in Table 1. Yields were typically ca. 90%, based on the quantity of metal consumed.

2. The compounds $MI(O_2C_6Cl_4)$·phen (M = Ga, I) were prepared by either of two related procedures. In the first, a suspension of $M(O_2C_6Cl_4)$·phen in toluene was treated with a half-molar quantity of iodine in the same solvent, added over 30 min; the mixture was stirred at room temperature for 2 h, by which time the colour of iodine had completely discharged, and the product that precipitated on the slow addition of petroleum ether (ca. 20 mL) was collected and dried *in vacuo*. In the second method, gram quantities of the metal, *o*-quinone, and iodine (I_2), in the molar ratio 2:2:1, were refluxed in toluene for 24 h; addition of 1,10-phenanthroline in toluene then led to the precipitation of the product in the form of the brown phenanthroline adduct. The isolation procedure was that described above. A DMF-solvate was obtained when $InI(O_2C_6Cl_4)$·phen was recrystallized from this solvent. In the case of indium, a deep blue colour developed in the solution after about 2 h, and the mixture became red only on complete consumption of the metal. A sample of this blue solution exhibited a very strong esr signal (see below).

3. The compound $SnI_2(O_2C_6Cl_4)$·phen was prepared by refluxing tin metal (0.40 g, 2.4 mmol), iodine (0.86 g, 3.4 mmol, calculated as I_2), and quinone (0.83 g, 3.4 mmol) in toluene for 3 h, by which time the tin had dissolved completely. An equimolar amount of 1,10-phenanthroline was added to the resultant pale-green solution, and refluxing stopped. The mixture was stirred for 1 h as it cooled to room temperature, and the orange solid which deposited was collected by filtration and isolated as above.

4. The compound $In(O_2C_6Cl_4)$·pic·0.25 toluene was obtained when a twofold excess of γ-picoline was used in the reaction described in 1. The resultant solution was slowly evaporated *in vacuo* to give colourless crystals, which were collected and redissolved in hot methylene chloride; X-ray quality crystals were formed as this solution slowly cooled. Spectroscopic and elemental analysis, and a subsequent X-ray crystallographic study, showed that this product was the methylene chloride solvate $InCl(O_2C_6Cl_4)(C_6H_7N)_3 \cdot nCH_2Cl_2$; the material submitted for elemental analysis appears to have corresponded to the hemisolvate, whereas that used in the X-ray studies in the presence of excess CH_2Cl_2 (see below) proved to be the monosolvate. The source of the chloride ligand in this molecule is discussed below.

5. Salts containing the anionic complexes $[SnX(O_2C_6Cl_4)_2]^-$ were made by the dropwise addition of one equivalent of Et_4NBr or Ph_4PCl, dissolved in the minimum amount of acetonitrile, to a toluene solution of $Sn(O_2C_6Cl_4)_2$ (see 1). As the halide solution was added, a light-brown material began to deposit. After complete addition, the reaction mixture was stirred at room temperature for 2 h; addition of diethyl ether (20 mL) precipitated a solid, which was collected by filtration and dried *in vacuo*. The yield was almost quantitative. The molar conductivities (millimolar solution) of $Ph_4P[SnCl(O_2C_6Cl_4)_2]$ and $Et_4N[SnBr(O_2C_6Cl_4)_2]$ in DMF are 72 and 85 $ohm^{-1}\,cm^2$ respectively, to be compared with the normally accepted value of 70–90 $ohm^{-1}\,cm^2\,mol^{-1}$ (7) for 1:1 electrolytes in this solvent.

X-ray crystallographic analysis

A single crystal of $InCl(O_2C_6Cl_4)(C_6H_7N)_3 \cdot CH_2Cl_2$ was sealed in a capillary tube containing a drop of methylene chloride; experience showed that in the absence of this solvent, loss of crystallinity occurred and the solid turned to a powder. The crystal was mounted along its largest dimension, and the cell parameters were obtained from 15 strong reflections in the range $15° < 2\theta < 25°$. Data were collected on a Syntex $P2_1$ diffractometer following the procedures described previously (8). The intensities of three monitored reflections did not change significantly during data collection. The data were corrected for Lorentz and polarization effects; no absorption correction was deemed necessary because of low absorption coefficient. The space group $P\bar{1}$ was used and later assumed to be correct due to successful refinement. Details of the X-ray data collection are given in Table 2.

The position of the indium atom was obtained from a sharpened Patterson synthesis using SHELX-76. Fourier synthesis gave positions for the remaining non-hydrogen atoms, including one molecule of methylene chloride per $InCl(O_2C_6Cl_4)(C_6H_7N_3)_3$. Refinement was carried out by using full-matrix least-squares methods, with scattering factors taken from ref. 9. In the final cycles of least-squares refinement, the In, Cl, O, and N atoms were refined with anisotropic thermal coefficients, while the remaining atoms were refined with isotropic coefficients. This refinement converged at $R = 0.0726$ and $R_w = 0.0782$. All hydrogen atoms were included in idealized positions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12

For personal use only.

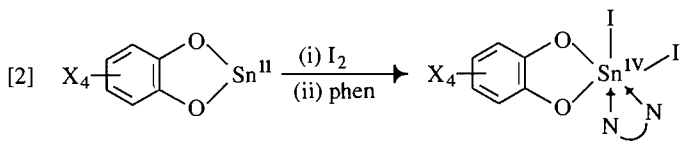
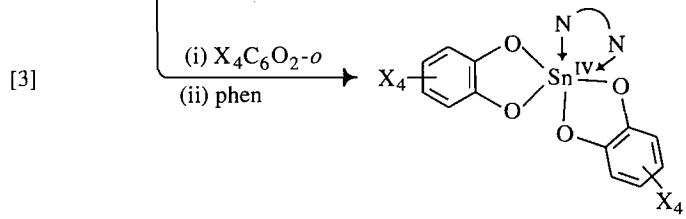
(C—H = 0.95 Å and CCH = 109.5°). Isotropic thermal parameters were assigned values 0.01 U (Å^2) greater than those for the adjacent (bonded) carbon atoms. After six more cycles of refinement, convergence was achieved with the final R = 0.0632 and R_w = 0.0678 and 2226 unique "observed ($I > 3\sigma(I)$)" reflections. The solvated methylene chloride molecule was found to be slightly disordered, and the C—Cl bond distances were therefore constrained at 1.760 Å. The quantity $\Sigma_w(|F_o| - |F_c|)^2$ was minimized during the least-squares refinement; in the final cycles a weighting scheme of the form $w = 1/[\sigma^2(F) + \rho F^2]$ was employed, with a final ρ-value of 0.00001. Final difference Fourier map calculations did not reveal any peaks of chemical significance. There was no evidence of any secondary extinction.

The final atomic coordinates for non-hydrogen atoms are given in Table 2, and important bond distances and angles in Table 3. Tables of structure factors, anisotropic thermal parameters, and fractional coordinates for hydrogen atoms are available as supplementary material.[3] The structure is shown in Fig. 1.



Results and discussion



The reaction of $X_2C_6O_2$-o with tin

The reaction of metallic tin with the substituted *o*-quinones can be understood in terms of reactions already reported in other papers from this laboratory. Both $Cl_4C_6O_2$-*o* and $Br_4C_6O_2$-*o* are strongly oxidizing species, and the initial reaction involves two successive one-electron transfer processes, giving a tin(II) species as the primary product:

[1] 

The justification for step (i) lies in the analogous reaction between indium metal and TBQ (5), which has been shown to give rise to a stable (TBSQ·)In^I species in solution. The internal one-electron transfer (ii) depends on the fact that the compounds $X_4C_6O_2$-*o* are stronger oxidizing agents than TBQ (10); it is reasonable to conclude that the $X_4C_6O_2$· semiquinones are similarly more strongly oxidizing than is TBSQ·, and it follows that the reaction of tin with $X_4C_6O_2$-*o* will yield the tin(II) species rather than a derivative of the unknown tin(I)-semiquinone. We return to the difference between indium and tin in the next section. The formation of the tin(II)-catecholato compound in this reaction is in keeping with the known stability of such substances, which can be conveniently synthesized by the one-step electrochemical oxidation of tin anodes in nonaqueous solutions of aromatic diols (11). These latter compounds are stable in the solid state but can be oxidized, and it is especially appropriate that oxidation of (say) $Sn(O_2C_6H_4)$ by I_2 gives $SnI_2(O_2C_6H_4)$, and that reaction with $Br_4C_6O_2$-*o* yields $Sn(O_2C_6H_4)(O_2C_6Br_4)$. In both cases, these tin(IV) compounds were isolated as stable 1:1 adducts with 2,2′-bipyridine, so that the previous results are congruent with the one-step syntheses reported in paragraphs 1 and 3 of the preparative work in the experimental section. These latter experiments then involve the *in situ* oxidation of $Sn^{II}(O_2C_6X_4$-*o*) formed in reaction [1] via eqs. [2] and [3]:

[2] 

[3] 

In summary, the mechanism of the reaction of metallic tin with $X_4C_6O_2$-*o* can be readily understood in the context of previous work. The infrared and nmr spectra, which were essentially identical to those of the indium and gallium products discussed below, confirm the presence of tetrahalogenocatecholate and 1,10-phenanthroline in the final products.

The reactions of $X_4C_6O_2$-o with gallium or indium

As noted above, the reaction of indium metal with TBQ in refluxing toluene gives the indium(I)-semiquinone compound (TBSQ·)In, whose chemistry includes both the formation of adducts, and oxidation by reagents such as I_2, Ph_2S_2, or $Cl_4C_6O_2$-*o* to the appropriate indium(III)-semiquinone product. These oxidation reactions bring about substantial changes in the

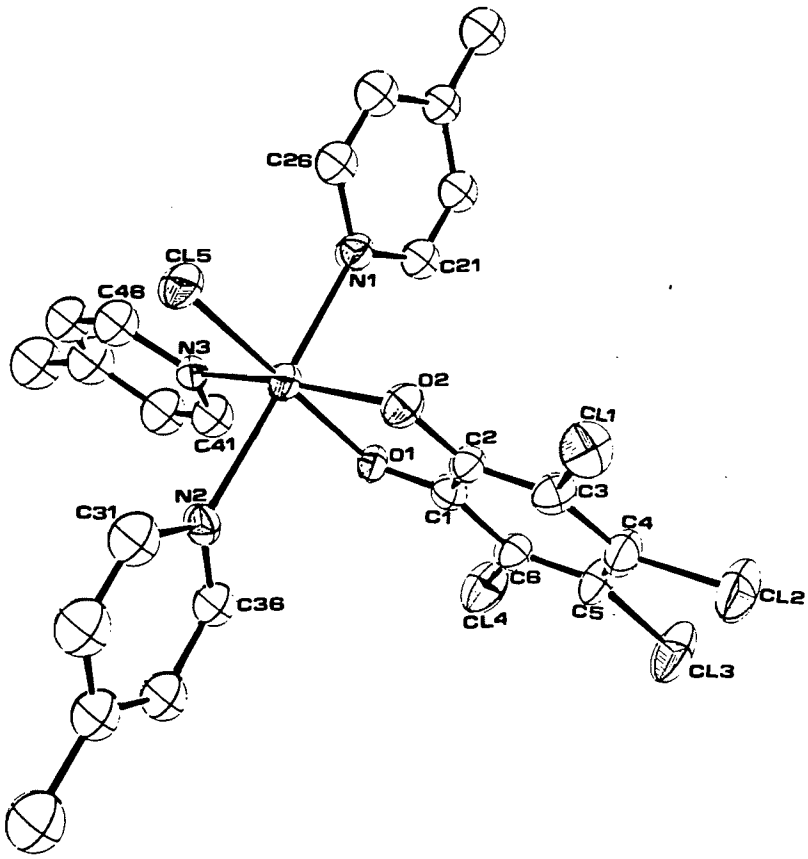

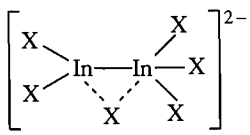

FIG. 1. Molecular structure of $InCl(O_2C_6Cl_4)(C_6H_7N)_3$, showing the atomic numbering scheme; ORTEP diagram, with 50% probability ellipsoids. Hydrogen atoms have been omitted for the sake of clarity.

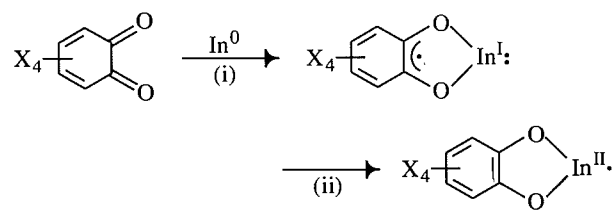
esr hyperfine coupling constant A_{In}, which is ca. 9–11 G for indium(I) compounds, and 6–7 G for the indium(III) derivatives (5). In the present case, the products of the reaction of either gallium or indium metal with $X_4C_6O_2$-*o* are identified as the M(II)-catecholato derivatives, prepared as the neutral adducts. When iodine is present in the reaction mixture, one obtains adducts of the M(III) compounds $MI(O_2C_6X_4)$, in keeping with the known oxidation $L_nM^{II} + \frac{1}{2}I_2 \rightarrow L_nM^{III}I$, a characteristic reaction in indium(II) chemistry (12).



It is well established that the M^{II} compounds of gallium and indium, as exemplified by the halides, may be either the mixed oxidation state dimers $M^I[MX_4]$ or the M—M bonded species X_2MMX_2. While no simple halides are in fact known in this latter form, a number of neutral ($M_2X_4L_2$) and anionic ($M_2X_6^{2-}$) complexes are known, and in some cases crystal structure determinations have confirmed the formulation (13, 14). An important reaction of such molecules is disproportionation to indium(I) + indium(III), a process that can be seen as an internal halide transfer, e.g.,

[4] $X_3InInX_3^{2-} \rightleftharpoons$ 

[5] $In^IX_2^- + In^{III}X_4^-$

The arguments in favour of this mechanism, which is equally applicable in its reverse mode to the formation of indium(II) halide derivatives by the oxidative insertion of InX into an In—X bond of InX_3, have been discussed elsewhere (15). Similar behaviour has been identified for the corresponding gallium(II) halides (14).

On the basis of these previous results, we propose the following reaction scheme, set out here in the case of indium. The initial reaction between the metal and $X_4C_6O_2$-*o* is presumed to give the indium(I)-semiquinone by analogy with the In/TBQ system (5), but one must also accept the possibility of a further internal electron transfer process to yield the indium(II)-catecholate monomer

[6] 

Given the electrophilic nature of the X_4C_6 group, it seems reasonable to assume that the catecholato-indium(I) form may indeed make a significant contribution. Scheme 1 shows a set of reactions that then readily explain the preparative and spectroscopic results obtained. Treatment of the semiquinone $(X_4C_6O_2\cdot)In^I$: with a strong bidentate base such as 1,10-phenanthroline (eq. [7]) produces the adduct of the indium(II)

U_{eq} for all non-carbon atoms except C(11)–C(16) is calculated from the refined anisotropic thermal parameters ($U_{eq} = \frac{1}{3}\Sigma_i\Sigma_j u_{ij} a_i^* a_j^* \cdot a_i a_j$). The remaining carbon atoms are refined isotropically.

catecholate $(X_4C_6O_2)In\cdot phen$, by a process that parallels that observed in the SnX_2/TBQ system. The driving forces for this process are twofold; the addition of electron density by coordination tends to make the indium atom electron-rich, and the electrophilic nature of the $X_4C_6O_2\cdot$ ligand aids the internal electron transfer. Dimerization of this monomer then obviously gives the In—In bonded species, which was obtained in this work as the appropriate neutral adduct $[(X_4C_6O_2)In\cdot phen]_2$ (eq. [8]), which cannot undergo internal ligand transfer (cf. eq. [4]) since there is no labile monodentate ligand. The infrared and nmr spectroscopic evidence summarized below confirm this structure, but unfortunately we were not able to identify the diagnostic ν(In—In) mode in the Raman spectrum because of high fluorescent emission from each of these compounds. An additional piece of evidence was provided by the mass spectrum of $[Ga(O_2C_6Cl_4)phen]_2$; this showed prominent ions identified as $[Ga(O_2C_6Cl_4)phen]^+$ (m/e = 675) and $[Ga(O_2C_6Cl_4)]^+$ (m/e = 495) and, in the latter case, the experimental and computer-simulated isotopic distribution patterns were in good agreement. Given that the products are diamagnetic, there is little doubt that these are indeed the M^{II}–M^{II} bonded catecholates as formulated in Scheme 1. The coordination at the indium centre in such molecules gives an InO_2N_2In' kernel, similar to the InX_2N_2In' core identified in other indium(II) dimeric species (16).

When the reaction mixture involves $X_4C_6O_2$-*o* + M + $\frac{1}{2}I_2$, the products obtained are the $MI(O_2C_6X_4)$ species, again stabilized against ligand redistribution reaction by adducts with neutral nitrogen donors (see Table 1). These molecules are clearly identical with, or related to, those obtained previously from the reaction of $X_4C_6O_2$-*o* + InX (2), as demonstrated by the spectroscopic results (see below).

The present system gives additional information not available in the earlier work, in that we were able to obtain and analyze the esr spectrum of an intermediate species. The reaction mixture $Cl_4C_6O_2$-*o* + $In_{(s)}$ + $\frac{1}{2}I_2$ is initially dark red, becomes deep blue as the reaction proceeds, and finally shows the red-wine colour of the indium(III) product. A sample of the blue solution was

SCHEME 1

abstracted, so as to remove any unreacted metal, and the esr spectrum recorded (Fig. 2). Computer simulation showed that this is the spectrum of a mixture of two species, each involving a semiquinone radical bonded to an indium atom. There is no evidence of an interaction between the unpaired electron and the chlorine atoms of the ring. The hyperfine coupling constants derived from Fig. 1, 9.8 and 7.2 G, established the presence of indium(I) and indium(III) species, and the reaction pathway by which these could arise is shown in Scheme 1. We propose that the reaction proceeds via a monomeric indium(II) $(X_4C_6O_2\cdot)In\cdot I$ molecule, which dimerizes (eq. [11]) to the corresponding In—In bonded species. This can disproportionate by halide transfer (eq. [13]), parallel to the process described above (eqs. [4] and [5]), to give an equimolar mixture of $(X_4C_6O_2\cdot)In^{I}$ and $(X_4C_6O_2\cdot)In^{III}I_2$, whose hyperfine coupling constants are those quoted above. This mechanism of dimerization and disproportionation is parallel to that proposed for the reaction of TBQ with both SnX_2 (3) and InX.[2] Similarly, the reaction of the $(X_4C_6O_2\cdot)In\cdot I$ species with a strong neutral donor stabilizes the adduct in the indium(III) form $(X_4C_6O_2)In^{III}I\cdot phen$, and the arguments in favour of this have been set out elsewhere (2, 3, and footnote 2).

The hyperfine constants for these species can be compared with the values of 9.83 and 6.44 G derived for $(TBSQ\cdot)In^{I}$ and $(TBSQ\cdot)InI_2$ in toluene. The difference between these values and those found in the present work indicates a lower electron density at the metal centre, which can be readily related to the change of ring substituents from $Bu^t_2H_2$ to Cl_4, a change that increases the electrophilic nature of the ring system.

Spectroscopic results

None of the complexes prepared show the infrared active ν(C=O) bond stretching frequency observed at ~1700 cm^{-1} in the parent tetrahalogeno-*o*-quinones, and instead ν(C—O) modes appear at ~1450 cm^{-1} in the catecholato derivatives. These changes are identical with those observed in studies of the reaction of the same *o*-quinones with SnX_2 (1) and InX (2). The ir spectra also confirmed the presence of coordinated bipy, phen, and γ-picoline in the appropriate compounds.

These compounds have appreciable solubility in DMSO, and hence the ^1H and ^{13}C nmr spectra were recorded at room temperature. The ^1H nmr spectra complemented the ir spectra by confirming the presence of the donor ligands in the appropriate region of the spectra. The ^{13}C nmr spectra on the

other hand also showed the significant shift of the resonance observed at ~170 ppm and assigned to *C*=O in the parent quinone, to ~150 ppm, assignable to *C*—O in the catecholato derivative. The numerical values were essentially identical with those reported earlier (1, 2). Finally, we may note that the sharpness of the spectral lines for the $[(X_4C_6O_2)InL]_2$ compounds confirms that these compounds are diamagnetic, and hence must be dimeric.

Crystallographic studies

As reported in the experimental section, an attempt to recrystallize $[In(O_2C_6Cl_4)pic]_2$ from hot CH_2Cl_2 gave crystals subsequently identified as $InCl(O_2C_6Cl_4)(pic)_3$, CH_2Cl_2 solvate. This indium(III) species is clearly the result of an oxidation reaction, with the chloride ligand being derived from the solvent. There is little experimental evidence on which to discuss the mechanism of such a reaction, except to note earlier and continuing studies of the reactions of indium halide molecules with dihalogenomethanes (17).

The crystallographic results confirm that the compound is indeed an indium(III)-catecholate derivative, and are therefore important in supporting the formulations given above. The In—Cl bond length of 2.430(3) Å is in good agreement with the distances reported previously for other six-coordinate indium(III) complexes, for which values between 2.538(5) and 2.394(1) Å are known. The factors that can affect the length of this bond, and the actual experimental results, have been reviewed elsewhere (18). The In—O distance, average 2.128(7) Å, is best compared with those in $InCl_2(acac)(bipy)$, for which the values are 2.124(3) Å *cis* to chlorine, and 2.164(3) Å *trans* to chlorine (4), although in the present case there is no discernible difference in the two In—O bonds. For

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

the In—N bonds, that *trans* to oxygen (In—N3) is substantially shorter (2.265(9) Å) than the other two, which are virtually identical (average 2.324(12) Å), and these distances are again close to those reported for other complexes in which an indium(III) ion is coordinated to neutral heterocyclic *N*-donor ligands (cf. ref. 18). The bond angles are those expected in an octahedral complex with distortion due to the presence of a bidentate ligand, for which the O—In—O bite angle of 78.2(3)° is close to that in other catecholato complexes (cf. refs. 1 and 3).

From the mean plane calculations (set out in the supplementary material), we found all the rings in the compound to be planar, with negligible deviations from planarity. The plane through the atoms Cl(1), Cl(2), Cl(3), Cl(4), C(11)–C(16) had an average deviation of 0.025 Å; that through the atoms N(1), C(21)–C(26) had a deviation of ±0.005 Å; for N(2), C(31)–C(36) the value was 0.022 Å; and that through N(3), C(41)–C(46) had an average deviation of 0.05 Å. The angles between the normal to these planes show that the *trans*-picoline ligands are almost perpendicular to each other, and the same relationship exists between the equatorial picoline and the two apical (*trans*) ligands.

The other bond lengths and angles call for little comment, except for the significant C—O bonds of the tetrachlorocatecholato ligand, for which the average value of 1.34(1) Å is typical of that in catecholato rather than semiquinone or *o*-quinone ligands, in complete agreement with the conclusions of the spectroscopic studies.

Synthesis and thermal study of tris(ammonium) hexafluoro metallates(III) of some rare earths

S. J. PATWE, B. N. WANI, U. R. K. RAO,[1] AND K. S. VENKATESWARLU
Water Chemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay 400 085, India

Received January 31, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

S. J. PATWE, B. N. WANI, U. R. K. RAO, and K. S. VENKATESWARLU. Can. J. Chem. **67**, 1815 (1989).

Fluorination of oxides of rare earths using ammonium hydrogen fluoride at room temperature gave new compounds $[NH_4]_3MF_6 \cdot nH_2O$, where M = Y, La, Nd, and Pr. In the case of cerium, $[NH_4]_4CeF_8$ is formed. The course of thermal decomposition of all these compounds is studied by thermogravimetry/differential thermal analysis (TG/DTA) and X-ray powder diffraction (XRD).

Key words: hexafluoro metallates, rare earths, ammonium hydrogen fluoride, thermal decomposition, X-ray diffraction.

S. J. PATWE, B. N. WANI, U. R. K. RAO et K. S. VENKATESWARLU. Can. J. Chem. **67**, 1815 (1989).

La fluoration d'oxydes de terres rares à l'aide du fluorure d'ammonium, à la température ambiante, fournit de nouveaux composés, du type $[NH_4]_3MF_6 \cdot nH_2O$ dans lesquels M = Y, La, Nd et Pr. Dans le cas du cérium, il se forme du $[NH_4]_4CeF_8$. On a étudié la décomposition thermique de ces composés à l'aide de la TG/DTA et de la diffraction de rayons-X sur des poudres.

Mots clés : métallates hexafluoro, terres rares, fluorure d'ammonium, décomposition thermique, diffraction des rayons-X.

Ammonium ytterbium/yttrium fluoride was believed to be an intermediate compound in the formation of ytterbium/yttrium trifluoride (1, 2). Bukhalov and Babaeva (1) prepared the ammonium complex by dissolving ytterbium nitrate in 48% HF in the presence of ammonium carbonate. This complex gave ytterbium trifluoride on heating. According to Thoma *et al.* (2), by heating a mixture of Y_2O_3 and NH_4HF_2 in a 1:6 mole ratio to 150°C an ammonium complex was formed, which on further heating at 300–400°C gave YF_3. In the first case 48% HF was used as fluorinating agent whereas in the second case ammonium hydrogen fluoride was used, but in neither case was the ammonium complex isolated or characterized. In this communication, we describe the synthesis and characterization of ammonium hexafluoro metallates(III) of rare earths and their pyrolytic behaviour.

In our earlier communications (3–6), ammonium hydrogen fluoride was used to fluorinate the corresponding oxides to prepare several oxyfluoride compounds such as $NH_4VO_2F_2$, $[NH_4]_3NbOF_6$, $[NH_4]_3VF_6$, $[NH_4]_4UF_8$, $[NH_4]_4ThF_8$, and $[NH_4]_3UO_2F_5$. By physical mixing of the oxide and ammonium hydrogen fluoride together at room temperature or close to room temperature, one gets the above oxyfluoride complexes. Fluoride was believed to be incorporated in the complex superconducting oxide $YBa_2Cu_3O_{6+\delta}$ by using ammonium hydrogen fluoride (7, 8) as fluorinating agent. It was our aim to prepare the title compounds starting from ammonium hydrogen fluoride and M_2O_3 (M = Y, La, Ce, Nd, Pr, and Gd) according to the following scheme:

[1] $M_2O_3 + 6NH_4HF_2 \rightarrow 2[NH_4]_3MF_6 \cdot 1.5H_2O$

Experimental

The rare earth oxides used in this study, viz., Y_2O_3, La_2O_3, Nd_2O_3, $PrO_{1.83}$, Gd_2O_3, and CeO_2 were preheated to ≈700°C to remove absorbed moisture. Ammonium hydrogen fluoride used was of BDH LR grade dried at 80–100°C prior to mixing. All the metal oxides except CeO_2 were of BARC make with purity of 99.9%. The CeO_2 used was from EMERC.

The reactants (a few hundred milligrams) in the stoichiometric ratio as given in eq. [1] were ground together for half an hour inside a polythene bag instead of in a mortar and pestle to avoid the reaction of ammonium hydrogen fluoride with the mortar and pestle. The powder X-ray diffraction (XRD) pattern of the resultant mixture showed the presence of oxide along with the ammonium hydrogen fluoride. Some additional new reflections were also seen in the XRD pattern. The mixture was kept in a polythene bag at room temperature in a desiccator over $CaCl_2$. After keeping for 3 days, completion of reaction was ascertained from the absence of reflections due to reactants in the X-ray powder pattern. Compared to the reaction with oxides of vanadium, thorium, and uranium, this reaction was very slow. The reaction can be completed within 10 min if the mixture is heated at 100°C with a slight excess of ammonium hydrogen fluoride. The final product was characterized using the powder XRD technique. The instrument used was a Philips PW-1050 wide-angle goniometer mounted on a Philips PW-1009 X-ray generator with Ni-filtered Cu-Kα radiation (λ = 1.5418 Å). In the cases of Y, La, Nd, and Pr, the reaction proceeded according to eq. [1]. In case of CeO_2, when it was mixed with ammonium hydrogen fluoride in 1:3 mole ratio the reaction did not go to completion, as was seen from the XRD pattern, which showed some new lines in addition to those of unreacted CeO_2. These new lines were those characteristic (9) of $[NH_4]_4CeF_8$. Hence a new mixture was prepared by mixing CeO_2 and ammonium hydrogen fluoride in 1:4 mole ratio just as in the case of UO_2 studied by us (6) recently.

[2] $CeO_2 + 4NH_4HF_2 \rightarrow [NH_4]_4CeF_8 + 2H_2O$

The XRD pattern of the product matches well with that reported (9) for the octafluoro compound. The above complex had been prepared earlier by Penneman and Rosenzweig (10) using 48% HF as a solvent. If the physical mixture is heated at 100°C, the reaction proceeds more quickly.

In the case of gadolinium oxide, even at the end of 4 days after mixing, the reaction did not go to completion and the XRD pattern of the product showed lines due to unreacted Gd_2O_3 along with the new lines. Heating the mixture at 100°C did not hasten the reaction.

The simultaneous TG/DTA instrument was an Ulvac Sinku Riko TGD model 7000 RHP. The heating/cooling rate was 8°C/min. The atmosphere used was static air and the sample size ≈35 mg.

Results and discussion

Powder XRD

The XRD patterns of tris(ammonium) hexafluoro metallates-(III) of all rare earths except cerium are identical. They are

[a]Orthorhombic. $a = 14.798 \pm 0.006$ Å; $b = 12.706 \pm 0.004$ Å; $c = 8.713 \pm 0.002$ Å.

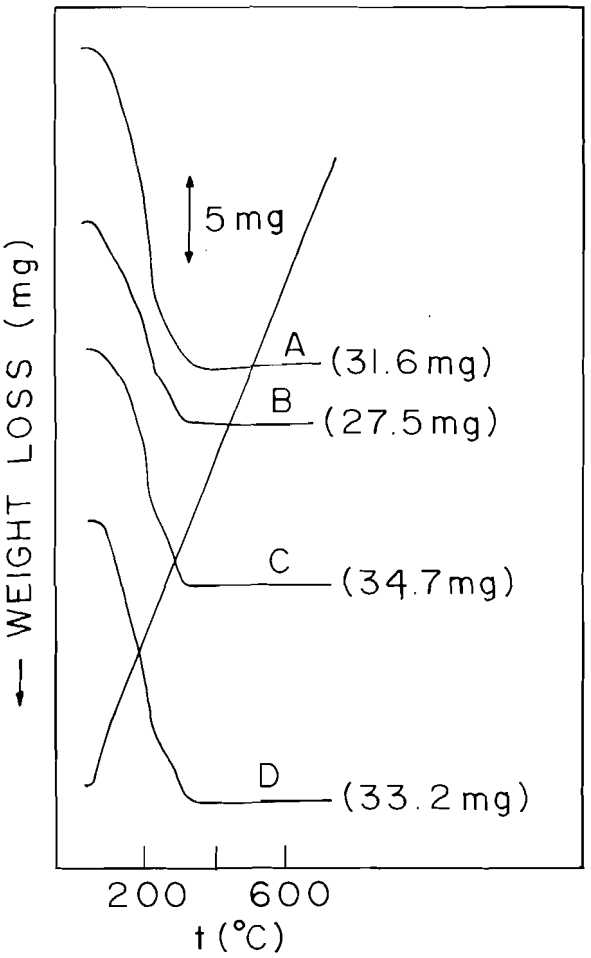

FIG. 1. TG curves of (a) $[NH_4]_3YF_6 \cdot nH_2O$, (b) $[NH_4]_3LaF_6 \cdot 1.5H_2O$, (c) $[NH_4]_3PrF_6$, and (d) $(NH_4)_3NdF_6 \cdot 2H_2O$ in air.

isostructural in the case of Y, La, Pr, and Nd. Since the nature of preparation involves reaction by physical mixing of two powdered components, the product could only be polycrystalline material. The question of obtaining a single crystal does not arise in this method. Table 1 gives a fit of the XRD powder pattern of the lanthanum compound based on an orthorhombic unit cell along with the cell dimensions. The

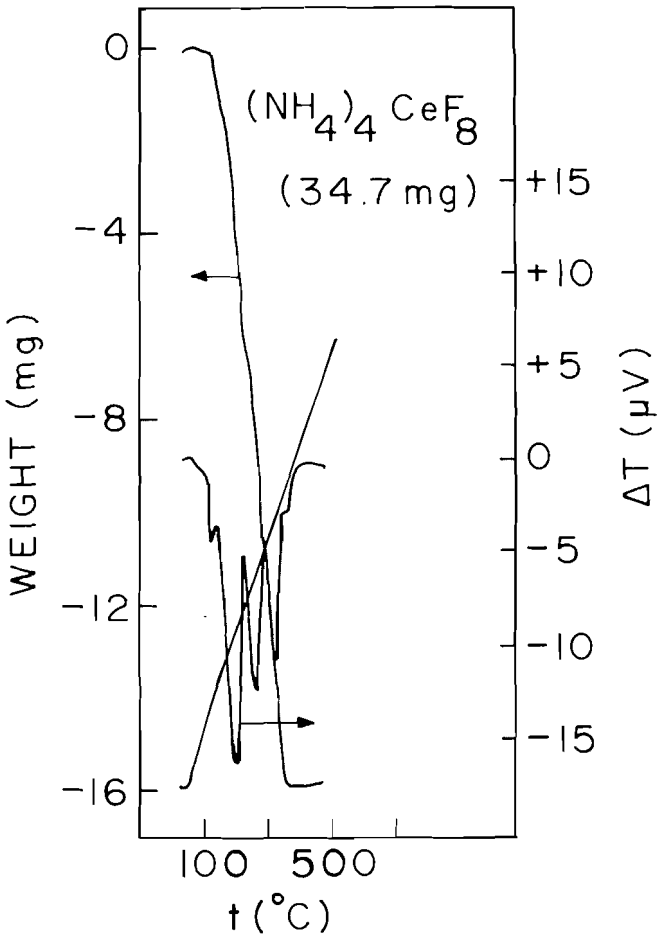

FIG. 2. Simultaneous TG/DTA curves of $[NH_4]_4CeF_8$ in air.

XRD of the complex of cerium matches well with that reported for $(NH_4)_4CeF_8$.

Thermogravimetry

TG curves of $[NH_4]_3MF_6 \cdot nH_2O$ (M = Y, La, Pr, and Nd) and $[NH_4]_4CeF_8$ are shown in Figs. 1 and 2. In all cases weight loss commences at 70°C and levels off at 320°C. The residues obtained at 320°C were the respective trifluorides, identified by XRD. The weight loss in the TG curves is consistent with the formation of MF_3 (Table 2). These TG curves indicate a single-step loss but exhibit change in slope at one or two temperatures. Since the steps overlap, one has to take recourse to simultaneous DTG or DTA to get the stepwise information. The overall decomposition is as follows:

[3] $[NH_4]_3MF_6 \cdot nH_2O \rightarrow MF_3 + 3NH_4F + nH_2O$

[4] $[NH_4]_4CeF_8 \rightarrow CeF_3 + 4NH_4F + \frac{1}{2}F_2$

Differential thermal analysis

Figure 3 shows DTA curves of the above ammonium fluoro complexes. Even though TG curves show one single-step loss in weight in all cases, the DTA shows multistep decomposition (Table 2). Similar behaviour was earlier observed in case of $[NH_4]_3VO_2F_4$ and, by a DTA analysis of different possible intermediates, the detailed thermal degradation path was delineated (3). Going from the Y to the Nd complexes, even though the TG and XRD patterns are the same, the nature of

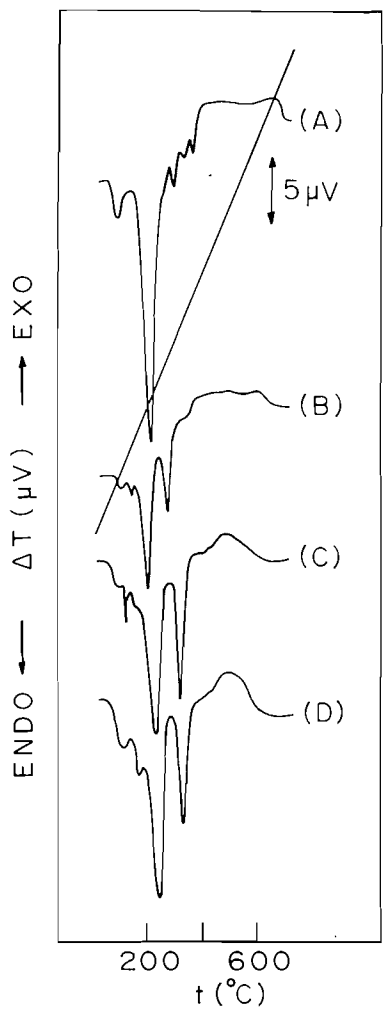

FIG. 3. DTA curves of (a) $[NH_4]_3YF_6 \cdot nH_2O$, (b) $[NH_4]_3LaF_6 \cdot 1.5H_2O$, (c) $[NH_4]_3PrF_6$, and (d) $(NH_4)_3NdF_6 \cdot 2H_2O$ in air.

decomposition is different. The first endotherm at 80°C in all cases is attributed to the removal of water of reaction.

In the case of yttrium all three ammonium fluorides are lost in one single step, as indicated by one endotherm in its DTA. In the case of lanthanum the DTA exhibits two endotherms of relative intensities 2 and 1, suggesting that two molecules of ammonium fluoride are lost in the first step and one more in the second step. This is further corroborated by the weight loss considerations as well as temperatures of inflection in the TG (Table 2). The thermal degradation of the octafluoro complex of cerium proceeds in three distinct steps, as seen in three DTA peaks with area ratio of 2:1:1 and a residue of CeF_3 above 270°C. In the case of Pr and Nd complexes, just as in the case of lanthanum, ammonium fluoride is lost in two steps. In the first step two molecules are lost, and in the second one molecule. The course of decomposition of each compound may thus be shown as follows:

$$1.\ [NH_4]_3YF_6 \cdot nH_2O \xrightarrow{80\text{–}320^\circ C} YF_3 + 3NH_4F + nH_2O$$

$$2.\ [NH_4]_3LaF_6 \cdot 1.5H_2O \xrightarrow{70\text{–}150^\circ C} [NH_4]_3LaF_6 + 1.5H_2O$$

$$[NH_4]_3LaF_6 \xrightarrow{150\text{–}225^\circ C} NH_4LaF_4 + 2NH_4F$$

$$NH_4LaF_4 \xrightarrow{225\text{–}320^\circ C} LaF_3 + NH_4F$$

$$3.\ [NH_4]_4CeF_8 \xrightarrow{70\text{–}220^\circ C} [NH_4]_2CeF_6 + 2NH_4F$$

$$[NH_4]_2CeF_6 \xrightarrow{220\text{–}290^\circ C} NH_4CeF_5 + NH_4F$$

$$NH_4CeF_5 \xrightarrow{290\text{–}370^\circ C} CeF_3 + NH_4F + \tfrac{1}{2}F_2$$

The cerium compound, when formed at room temperature, has two molecules of water as product of reaction occluded by the solid octafluoride. The fluorine evolved during decomposition of the octafluoride can thus react with water to yield HF and O_2. Analysis for the gaseous products was not attempted.

Inner-shell electron energy loss spectra (ISEELS) of gaseous selenophene and 3-methylselenophene in the regions of Se 3*d*, Se 3*p*, Se 3*s*, and C 1*s* are presented and analyzed. The ISEELS spectra are compared to the C 1*s* near-edge X-ray absorption fine structure (NEXAFS) spectra of the corresponding polymers deposited electrochemically onto Pt, both with and without doping, to form the electrically conducting state. Methyl substitution at the 3-position of the selenophene ring is found to have little effect on the intensity of the C $1s \rightarrow \pi^*$ transition, suggesting that the π manifold is relatively unaffected. The C 1*s* NEXAFS of thin polyselenophene and poly-3-methylselenophene films confirms that (1) the polymeric chain is composed of the same structural units as the monomers and (2) doping enhances electrical conductivity via a narrowing of the $\pi-\pi^*$ band gap.

Key words: core excitation, ISEELS, NEXAFS, conducting polymers.

A. P. HITCHCOCK, G. TOURILLON et W. BRAUN. Can. J. Chem. **67**, 1819 (1989).

Les spectres de perte d'énergie d'électrons en couches internes (ISEELS) du sélénophène et du 3-méthyl sélénophène en phase gaz et aux seuils Se 3*d*, Se 3*p*, Se 1*s* et C 1*s* sont présentés. Ces spectres ISEELS sont comparés aux spectres d'absorption X (NEXAFS) obtenus avec les polymères correspondants déposés électrochimiquement en films minces sur une surface de Pt. La substitution en position 3 d'un hydrogène par un groupement méthyl affecte très peu l'intensité de la transition C $1s \rightarrow \pi^*$, suggérant que les orbitales π et π^* ne sont pas modifiées. Les spectres NEXAFS des films minces polymériques confirment que (1) les chaînes polymériques sont composées des mêmes unités structurales que les monomères et que (2) le dopage de ces films vers l'état conducteur s'accompagne d'un rétrécissement de la bande interdite $\pi-\pi^*$.

Mots clés : excitation de coeur, ISEELS, NEXAFS, polymères conductant.

1. Introduction

Polymers of unsaturated heterocyclic compounds such as pyrrole, thiophene, and selenophene can be doped to form conducting materials (1). The magnitude and mechanism of conduction, the stability and mechanisms of decomposition, and the control of processibility all need to be better understood to develop practical applications of these materials. Recent studies of polythiophene by near-edge and extended X-ray absorption fine structure (NEXAFS, EXAFS) and by inverse photoemission (2) have shown that the ring structures are not changed by doping but that the π and π^* levels shift with doping such that the $\pi-\pi^*$ gap decreases considerably. The influence on the electrical properties and electronic structure of methyl substitution at the 3-position of the thiophene ring has also been studied (1). Companion studies of the core edge spectra of both gas phase monomer and thin film polymer specimens of a series of alkyl-substituted thiophenes have recently been carried out (3, 4).

It is useful to derive spectral assignments from comparison of free and condensed monomer spectra in order to take advantage of the individual strengths of the two inner-shell excitation spectroscopies we have employed. These are inner-shell electron energy loss spectroscopy (ISEELS) (5), which examines, with good energy resolution, the unoccupied electronic structure of monomers of known molecular structure in the gas phase; and NEXAFS (6), which examines doped and undoped thin film polymers and can provide additional information toward spectral assignments through polarization dependence in the case of oriented films. The combination of the two spectroscopies constitutes a powerful probe of both the electronic and geometric structures of materials such as conducting organic polymers. Studies of this nature have been carried out for polythiophene (2, 7) and polypyrrole (8) but not as yet for polyselenophene. In recent NEXAFS studies of 3-alkyl polythiophenes (3) the spectra were interpreted to indicate that the intensity of the C $1s \rightarrow \pi^*$ transition decreases with increasing length of the alkyl side chain, suggesting that the electron distribution in the π and π^* orbitals is modified by the alkyl substitution. However, the ISEEL spectra of the gas phase monomers, along with a reanalysis of the polymer NEXAFS (4), suggest that the C $1s \rightarrow \pi^*$ intensity is essentially independent of the length of a 3-alkyl side chain. Thus a motivation of the present study was to examine the effect of alkyl substitution on the π-electronic structure of heterocyclic rings in a different system, namely selenophene and 3-methylselenophene. All core excitations below 350 eV are reported

for the gas phase monomers, which have not been studied previously to our knowledge. The C 1*s* NEXAFS spectra of the doped and undoped polymers are compared to the gas phase monomer C 1*s* ISEEL spectra. Information relating to the conduction mechanism of doped heterocyclic polymers is derived.

Selenophene is a planar molecule with C_{2v} symmetry and a high degree of aromaticity. The selenium atom provides two $p\pi$ electrons, which, in addition to the four $p\pi$ electrons from the carbon atoms, makes a six-electron aromatic system. In an LCAO-MO description these five p_z atomic orbitals combine to produce five molecular orbitals, three of which ($1b_1\pi$, $2b_1\pi$, and $1a_2\pi$) are occupied and two of which ($3b_1\pi^*$ and $2a_2\pi^*$) are unoccupied in the neutral ground state (9). The highest occupied level ($1a_2\pi$) and the lowest unoccupied level ($3b_1\pi^*$) both have pure carbon character. There are no theoretical calculations available for the energies of π-bonding and π^*-antibonding orbitals formed upon polymerization of selenophene. However, we expect, as for polythiophene (10), a broadening and shift toward the Fermi level E_f of the π and the π^* bands associated with the coupling of the monomers. The polymer has a band gap of 2.5 eV, as determined by UV–visible spectroscopy (11). In addition to the π bands, there are unoccupied levels of σ symmetry associated with both the C—Se and C—C bonds [7].

2. Experimental

2.1. ISEELS

The electron energy loss spectra were recorded at McMaster with an ISEEL spectrometer using 2.5 keV final electron energy, 2° scattering angle, and 0.7 eV FWHM resolution. Under these experimental conditions electric dipole transitions dominate the inelastic scattering and thus the spectra are similar to the corresponding X-ray absorption spectra, aside from kinematic factors that, relative to photoabsorption, produce a gradual downward tilt in the spectra towards higher energy loss. The procedures used to synthesize the selenophene and 3-methylselenophene samples have been published elsewhere (12). The energy loss spectra were calibrated in the C 1*s* region relative to the C $1s \rightarrow \pi^*$ transition in CO at 287.40 eV (13), while the other spectral regions were calibrated internally relative to the calibrated C $1s \rightarrow \pi^*$ feature of the selenophene species. The C 1*s* spectra were converted to absolute oscillator strength scales by kinematic correction and normalization at 315 eV to $n \times 0.0078\ \text{eV}^{-1}$, where n is the number of carbon atoms per molecule and $0.0078\ \text{eV}^{-1}$ is the oscillator strength of a single carbon atom at 25 eV above the ionization threshold. This procedure of normalizing to atomic values in the far continuum has been developed and tested previously (14).

2.2. NEXAFS of polymer films

Films of polyselenophene and poly-3-methylselenophene were electrochemically deposited onto a Pt electrode immersed in an acetonitrile medium composed of 0.5 M $LiClO_4$ – 0.5 M monomer (11). The electrode was first polarized at +1.35 V/SCE (saturated calomel electrode) for the 3-methylselenophene and at +1.85 V for selenophene to obtain doped films and then at −0.2 V/SCE to obtain the films in the undoped state. Film thicknesses were in the range of 500 Å. The deposited films were rinsed in acetone, dried in air, and then inserted into a vacuum chamber at 10^{-8} Torr (1 Torr = 133.3 Pa). NEXAFS experiments were carried out at the electron storage ring BESSY-Berlin using the high energy TGM1 beam line with a resolution of 0.5 eV at the C K-edge (15). The incident photon beam I_0 was monitored by measuring the total electron yield from a high transmission metal grid freshly coated with gold. The total electron yield from the sample (I) was then normalized with respect to I_0. The background at the C K-edge was estimated from the yield of a clean Pt surface in the C K-edge region. Spectra recorded at grazing and normal incidence were found to be identical, indicating random orientation of the polymer at these film thicknesses. The NEXAFS spectra presented were recorded with X-rays incident at 40° relative to the surface.

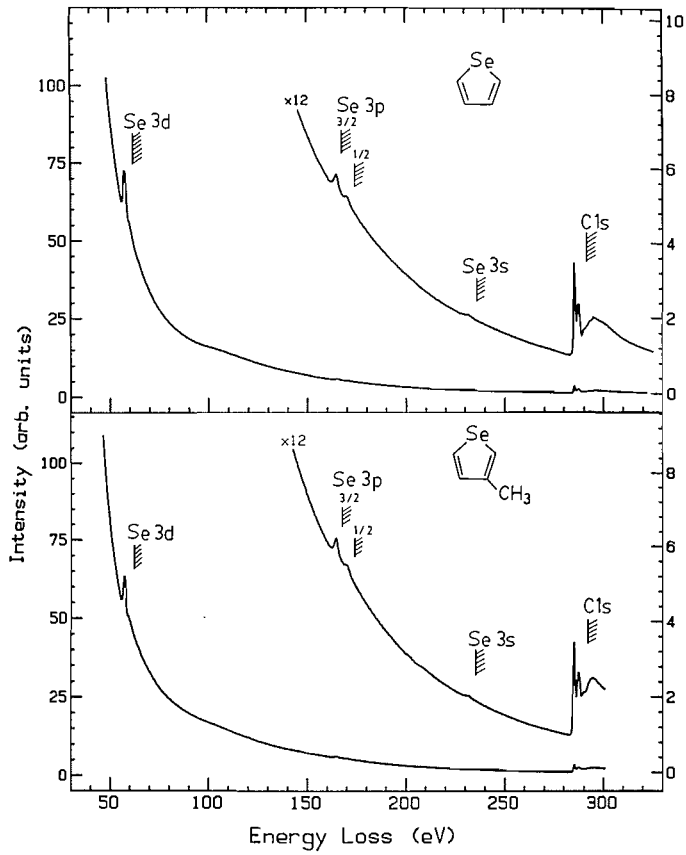

FIG. 1. Long range electron energy loss spectra of gas phase selenophene and 3-methylselenophene showing the Se 3*d*, Se 3*p*, Se 3*s*, and C 1*s* edges. Each spectrum is a composite of two spectra matched at 130 eV. All of the ISEEL spectra were recorded using 2.5 keV final electron energy, 2° scattering angle, and 0.7 eV FWHM resolution. The hatched lines indicate the estimated locations of the ionization potentials (IPs).

3. Results and discussion

A. Gas-phase ISEELS of selenophene and 3-methylselenophene

Long range spectra of selenophene and 3-methylselenophene throughout the energy loss region studied are shown in Fig. 1. As in all of the spectra presented throughout this paper, the hatched lines indicate the onset of the inner-shell ionization continua as deduced from the IPs of related species determined by X-ray photoelectron spectroscopy (16). The rapid decline in intensity with increasing energy loss arises partly because of the intrinsic falloff in photoionization cross section with increasing transition energy and partly because of additional damping of large energy-loss inelastic scattering processes relative to photoabsorption. The Se 3*p* and Se 3*s* signals are particularly weak. For each spectral region the pre-edge continuum was least-squares fitted to $a(E - b)^c$, where a, b, and c were adjusted for best fit, in order to extrapolate the background and isolate the signal associated with each core edge. The background subtracted spectra of selenophene and 3-methylselenophene in the region of each core-excitation edge are shown in Figs. 2, 3, and 4 for the C 1*s*, Se 3*d*, and Se 3*p*/3*s* respectively. The Se 3*d*, Se 3*p*, and C 1*s* spectra of selenophene are compared in Fig. 5 on a common term value scale by aligning the spectra at the ⟨Se $3d$⟩, Se $3p_{3/2}$, and C 1*s* estimated

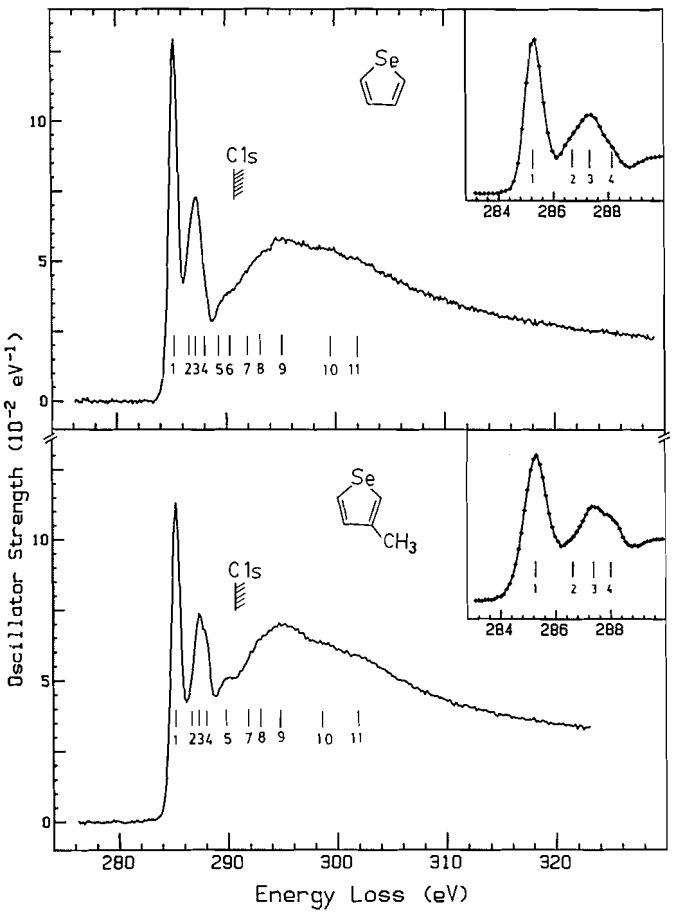

FIG. 2. The oscillator strengths for C 1*s* excitation in selenophene and 3-methylselenophene derived from dipole regime ISEELS. The insert is an expansion that shows the shoulders of the second band more clearly.

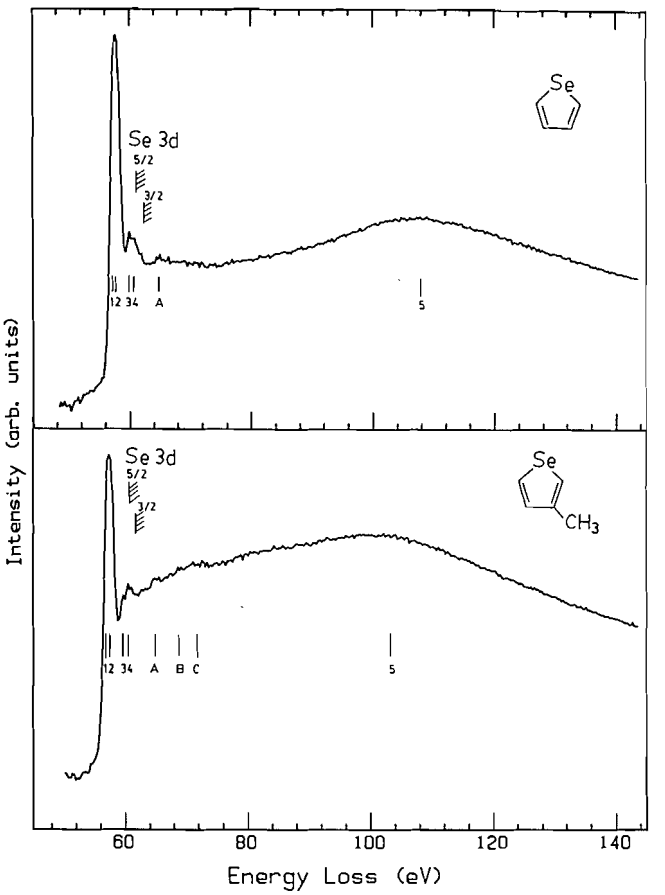

FIG. 3. The Se 3*d* ISEEL spectra of selenophene and 3-methylselenophene, after background subtraction. Features A, B, and C are Br 3*d* signals from an impurity.

IPs, where ⟨Se 3*d*⟩ is the average of the Se $3d_{5/2}$ and Se $3d_{3/2}$ IPs. Within a frozen orbital approximation, excitations to the same upper orbital from different core orbitals should have the same term value. A similar comparison for 3-methylselenophene is presented in Fig. 6. The spectral features, confirmed by observation in several independently recorded spectra, are indicated by numbered tics. Their energies, estimated term values, and proposed assignments are listed in Table 1 (C 1*s*), Table 2 (Se 3*d*), and Table 3 (Se 3*p*, 3*s*).

A.1. C 1s spectra

The C 1*s* ionization potentials (IPs), which are useful in detailed spectral analysis, were estimated by considering the following: the C 1*s* IP of $(CH_3)_2Se$ (290.9 eV (16)); extrapolation of the C 1*s* IPs of furan and thiophene, which indicates a C 1*s* IP of 290.3 eV for the ring carbons in selenophene; and the addition of 6.5 eV to the XPS value for solid thiophene (17), giving 290.7 eV. We have used 290.7 eV, an average of these estimates for the C 1*s* IP of the ring carbons and 290.3 eV as an estimate of the methyl carbon IP in 3-methylselenophene. The assignments of the spectral features in selenophene (Table 1) are guided by comparison to the C 1*s* spectrum of thiophene, where the assignments are supported by MS-Xα calculations and by comparison of solid, oriented monolayer, and gas phase spectra (7). The assignment of the C 1*s* spectrum of 3-methylselenophene is guided by comparison to the C 1*s* spectra of the 3-alkyl thiophenes (4).

The most intense peak, that at lowest energy, is clearly the C $1s \rightarrow \pi^*(3b_1)$ transition. The broad band centred at 287 eV is attributed to overlap of the C $1s \rightarrow \pi^*(2a_2)$, C $1s \rightarrow \sigma^*$(C—Se), C $1s \rightarrow \sigma^*$(C—H), and C $1s \rightarrow 3s$ Rydberg transitions. There are low and high energy shoulders on this band, which are most clearly seen in the spectrum of 3-methylselenophene (see inserts to Fig. 2). Proposed assignments of these shoulders are given in Table 1. A third low-intensity broad band around 290 eV likely arises from the overlap of unresolved Rydberg transitions leading up to the IP. The C 1*s* continuum exhibits several broad structures, with rather poorly defined low- and high-energy shoulders. The occurrence of several C $1s \rightarrow \sigma^*$(C—C) shape resonances in the near continuum of aromatic ring systems has been noted in several recent studies (7, 8, 18, 19). In the ISEEL spectra of the selenophenes these overlap to form a rather ill-defined structure. We note that the near continuum region is somewhat sharper in the NEXAFS spectra of the corresponding polymers (Fig. 7). This has been observed in several recent comparisons of gas phase ISEELS and condensed phase NEXAFS of related systems. It may be associated with preferential enhancement of continuum shape resonances in partially oriented materials because of the strong polarization dependence of X-ray absorption.

The C 1*s* spectra of selenophene and 3-methylselenophene (Fig. 2) are generally very similar. The main modifications associated with addition of the methyl group are an increase of the continuum intensity relative to that of the π^* peak, an increased intensity around 288 eV (associated with σ^*(C—H)

C				72.			Br 3d impurity	

[a]Calibration: selenophene: −227.6(2) eV; 3-methylselenophene: −227.6(2) eV relative to first C 1s peak.

[b]The Se 3d IP were obtained by adding 6.5 eV to the tabulated IP of solid Se (17). This estimate is in good agreement with the average value reported for the Se 3d IP of $(CH_3)_2Se$ (61.5 eV (16)).

levels), and an increase and shift to lower energy of the principal σ^*(C—C) continuum maximum (that around 295 eV). These modifications are those expected from consideration of the C 1s spectra of alkanes (20). Similar but more pronounced changes are observed in the C 1s spectra of the 3-alkyl thiophene series (R = methyl to decyl) (4). Of perhaps greater interest in the context of the conduction mechanism of polyselenophenes is the question of the relative energies and intensities of the C 1s → π^* transitions in these two molecules. There is no detectable shift in position (<0.05 eV) and the integrated oscillator strengths are very similar. On visual inspection it appears that there is a considerable reduction in intensity since the peak oscillator strength of the C 1s → π^* feature falls from 0.123 to 0.111 with alkylation. However, there is a simultaneous increase in the peak width, from 0.92 to 0.98 eV, according to least-squares fits to Gaussian lines. Thus the integrated peak intensity decreases by only 5%, from 0.118(3) to 0.112(5), a smaller amount than suggested by a simple visual inspection of Fig. 2. It is perhaps inappropriate to make conclusions with regard to the effect of 3-alkyl substitution on the π manifold on the basis of this comparison alone. However, the absence of any significant effect of alkylation on the π^* oscillator strength is consistent with the recent results for the 3-alkyl thiophenes, where the examination of species with much longer alkyl side chains led to the conclusion that the ring π and π^* electronic structure is not significantly affected by alkylation, at least in the monomers (4).

*A.2. Se 3*d *spectra*

The Se 3d spectra of selenophene and 3-methylselenophene (Fig. 3) are very similar. The difference in the ratio of the main discrete peak to the continuum intensity is most likely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

an artefact of the background subtractions rather than a real difference in the cross sections. The difficulties of deriving a unique extrapolated background can be appreciated in view of the very steep decline of the underlying valence ionization continuum (Fig. 1). The Se 3*d* signal in these two compounds is expected to be very similar since the methyl group is remote from the Se atom. The only likely influence of methyl substitution, via modification of the π-system, is indicated to be small by the C 1*s* results. In any case the main peak in each Se 3*d* spectrum is attributed mainly to Se $3d \rightarrow \sigma^*$(C—Se) transitions with, at most, only minor contribution from Se $3d \rightarrow \pi^*(2a_2)$ transitions. The Se $3d_{5/2}$ and Se $3d_{3/2}$ IPs are separated by only 1.0 eV (6) and thus it is difficult to resolve excitations associated with each ionization limit at our experimental resolution. Since the intrinsic Se 3*d* natural linewidth is small, additional structure may be revealed at higher resolution. However, it is also possible that the dominant Se $3d \rightarrow \sigma^*$(C—Se) transitions are broad due to a dissociative potential curve of the excited state, in which case higher resolution spectra would turn out to be rather similar to those presented in Fig. 3. On the basis of the orbital spatial distributions, the Se $3d \rightarrow \sigma^*$(C—Se) excitation should be more intense while the Se $3d \rightarrow \pi^*$ transition should be much weaker, relative to their intensity in the C 1*s* spectra. Comparison of the Se 3*d* and C 1*s* edge structure on a common term value scale (Figs. 5 and 6) shows that the main Se 3*d* peak is aligned with the *second* band in the C 1*s* spectra, consistent with its assignment to a σ*(C—Se) resonance. Our assignments of the pre-edge features to Se 3*d* excitations to σ*(C—Se) and *np* Rydberg orbitals are supported by the similarity of the Se 3*d* term values to those of corresponding C 1*s* transitions.

The near-edge Se 3*d* spectrum of 3-methylselenophene is very similar to that of selenophene. The dominant peak at 58 eV is attributed to Se $3d \rightarrow \sigma^*$(C—Se) transitions, broadened by spin-orbit interaction. Weaker features above this peak are assigned as higher energy Se $3d \rightarrow np$ Rydberg transitions. Although the lower energy structure in the Se 3*d* spectrum of 3-methylselenophene is very similar to that of selenophene, additional peaks (labelled A, B, C) and continuum intensity are found between 68 and 95 eV. These are Br 3*d* excitation features from a Br-containing organic impurity, probably CH_3Br, which was used in the synthesis (9).

Although it is not very visible in Fig. 1, the background subtraction (Fig. 3) reveals a broad maximum (feature 5) in the Se 3*d* continuum of each species, peaking around 105(3) eV. This broad maximum is a Se $3d \rightarrow \varepsilon f$ atomic-like shape resonance, which is associated with the energy at which the photoelectron final state exceeds the $l = 3$ centrifugal barrier and penetrates into the inner-well region where the Se 3*d* orbital is localized. Similar features are well known in the 3*d* spectrum of atomic Kr (21) and are calculated to occur in the 3*d* continua of neighbouring atoms (22). Connerade and Mansfield (23) have reported that the Se 3*d* spectrum of molecular Se_2 contains only a continual rise to higher energies up to 160 eV. We believe this result is an artefact, possibly associated with an inadequate correction for the incident photon flux. Morin and Nenner have studied the Br 3*d* spectra of HBr and CH_3Br (24) and found continuum shapes very similar to those reported for Kr (21) and expected for atomic Br (25). Careful comparison of atomic and molecular 3*d* continuum shapes is of interest with regard to possible molecular effects on "atomic-like" shape resonances (25).

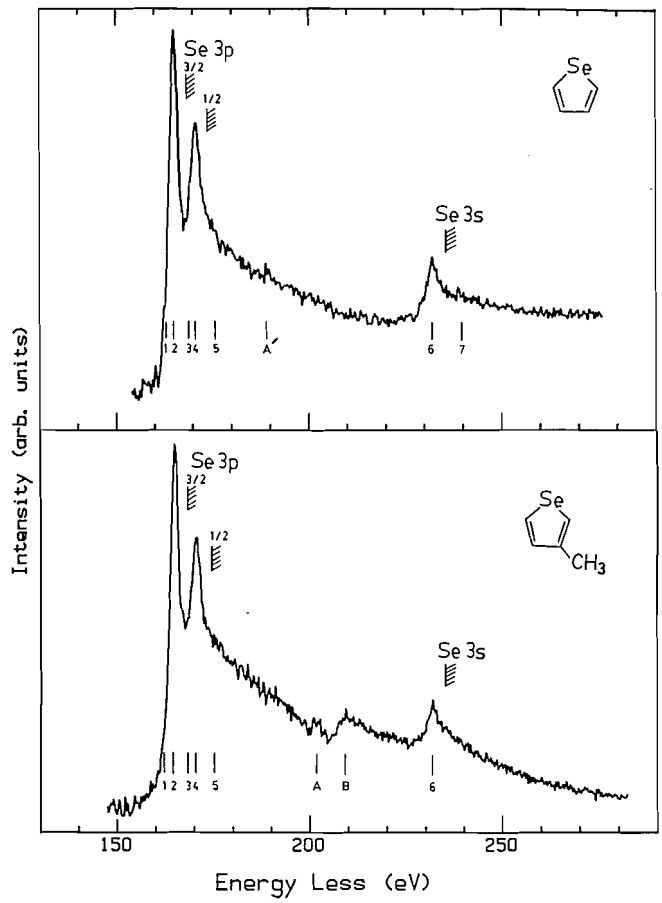

FIG. 4. The background-subtracted ISEEL spectra of selenophene and 3-methylselenophene in the Se 3*p* and Se 3*s* region. Features A and B in the spectrum of 3-methylselenophene are Cl 2*p* signals from an impurity.

A.3. Se 3p and Se 3s spectra

Although the noise level is somewhat high on account of the very weak signal, the Se 3*p* and Se 3*s* spectra of selenophene and 3-methylselenophene are readily detected (Fig. 4). The spectra are consistent with the expectation that the strongest features will correspond to excitations to orbitals localized on Se, i.e., weak Se $3p \rightarrow \pi^*$ and strong Se $3p \rightarrow \sigma^*$(C—Se) transitions. The main peaks at 165.0 and 170.6 eV are assigned to excitations to (Se $3p_{3/2}$, σ*(C—Se)) and (Se $3p_{1/2}$, σ*(C—Se)) states, since they have similar term values to those of the features attributed to Se $3d \rightarrow \sigma^*$(C—Se) and Se $3d \rightarrow$ σ*(C—Se) excitations. Weak Se $3p \rightarrow \pi^*$ transitions also appear to contribute as low energy shoulders to the 165 and 170.6 eV peaks. Se $3p \rightarrow 5s$ Rydberg transitions may also contribute to the breadth of these peaks (see Figs. 5 and 6). The Se 3*p* assignments are somewhat less certain than those for the C 1*s* and Se 3*d* features, partly because of the poor definition of the spectrum, but also because the Se 3*p* IPs are difficult to estimate accurately. Adding 6.5 eV to the tabulated value for solid Se (17) gives Se 3*p* IPs that are 1.1 eV below those derived from combining the estimated Se 3*p* IP of SeF_6 (26) with the difference in the S 2*p* IPs of SF_6 and thiophene. This latter procedure is very indirect but it was selected since it gives term values that provide a good alignment of the Se $3p_{3/2} \rightarrow$ σ*(C—Se) feature with the Se 3*d* and C 1*s* excitations to σ*(C—Se) (Figs. 5 and 6).

TABLE 3. Energies (E, eV), estimated term values (T, eV), and proposed assignments of features in the Se $3p$ and Se $3s$ spectra of selenophene and 3-methylselenophene

(b) Se $3s$

	Selenophene		3-Methylselenophene		
No.	E	T	E	T	Assignment
6	232.0	4.2	231.8	4.4	σ^*(C—Se), $\pi^*(2a_2)$
3s	236.2[c]		236.2[c]		IP
7	240	−4			σ^*(C—C)

[a]Calibration: selenophene (Se $3p$): −120.3(3) eV; 3-methylselenophene (Se $3p$): −120.3(2) eV relative to the first C $1s$ peak.

[b]The Se $3p$ IPs were obtained from the estimated Se $3p_{3/2}$ IP of SeF_6 (179.1 eV (ref. 26)) minus the difference between the S $2p$ IPs of SF_6 and thiophene (10.8 eV (ref. 16)).

[c]The Se $3s$ IP was obtained by adding 6.5 eV to the tabulated value for solid Se (17).

Although Se $3p \rightarrow 4d$ resonances might be expected to be prominent features by analogy to the prominent $2p \rightarrow 3d$ resonances in the S $2p$ spectra of many compounds, the Se $3p$ continuum does not appear to contain features of this character. This point was made recently in a dramatic fashion through comparison of the Se $3p$ spectrum of SeF_6 with the S $2p$ spectra of SF_6 and SF_5Cl (26). The weakness of the Se $3d \rightarrow 4d$ resonances was attributed to changes of the nodal pattern between the $3d$ and $4d$ orbitals, which apparently leads to much poorer $\langle 3p|\mu|4d\rangle$ than $\langle 2p|\mu|3d\rangle$ dipole overlap.

The relative prominence of the Se $3p \rightarrow \sigma^*$(C—Se) features and limited contributions from Se $3p \rightarrow \pi^*$ transitions suggest that the Se $2p_{3/2}$ edge (1440 eV) may be a more sensitive probe than the C $1s$, Se ns, or Se $3d$ edges for studying possible changes in the C—Se bond length with polymer formation or doping. However, the energies of σ^*(S—X) (X = C, O, F) orbitals as probed from S $1s$ excitation are much less sensitive to bond length changes than the energies of σ^*(O—X) orbitals (27), suggesting that the σ^*(C—Se) orbital energy, accessed by C $1s$, Se $3d$, or Se np core excitation, may also be a rather insensitive probe of C—Se bond length.

As with the Se $3d$ region, the Se $3p$ near-edge features of 3-methylselenophene are essentially identical to those of selenophene. This is not surprising, given that excitation from the Se core levels is localized at the Se atom, and thus the Se core excitation features can only be modified by second-order changes in the optical orbitals resulting from shifts in the electron density at Se as a result of methyl substitution at a relatively distant site. In contrast to the Se $3d$ spectra, the continuum shape (aside from the impurity signals marked with letters) is very similar in these two compounds. The difference between the Se $3p$ and Se $3d$ edges in this regard is the more gentle slope of the background in the $3p$ region (Fig. 1). The additional features (A, B) observed around 200–210 eV in the Se $3p$ continuum of 3-methylselenophene are most likely Cl $2p$ features of an impurity. Given the intrinsically weak intensity of Se $3p$ excitation (Fig. 1) as compared to Cl $2p$ excitation, the amount of Cl-containing impurity is very small.

The Se $3s$ spectra (Figs. 1, 4) are very weak, in part because of the large Coster–Kronig broadening of this edge. The single broad peak below the estimated Se $3s$ IP has a term value consistent with contributions from Se $3s$ excitations to both $\pi^*(2a_2)$ and σ^*(C—Se) orbitals. A similar conclusion was drawn with regard to the single, broad peak observed in the S $2s$ and S $1s$ spectra of thiophene (7).

B. NEXAFS of polymer thin films of selenophene and 3-methylselenophene

B.1. C 1s spectra of undoped polymers

The C K-edge NEXAFS spectra of 500 Å thick films of undoped polyselenophene and poly-3-methylselenophene grafted onto Pt (Fig. 7) exhibit very similar features to those observed in the ISEEL spectra of the gas phase monomer (Fig. 2). This confirms that the subunits of the polymeric chains have the same basic structure as the monomer. All of the NEXAFS spectra have had the underlying valence continuum subtracted and are normalized to the same relative intensity at 325 eV since the nonresonant continuum at this energy should be "atomic-like". We note that, although this normalization is valid if there are the same number of carbon atoms in the depth of the polymer film

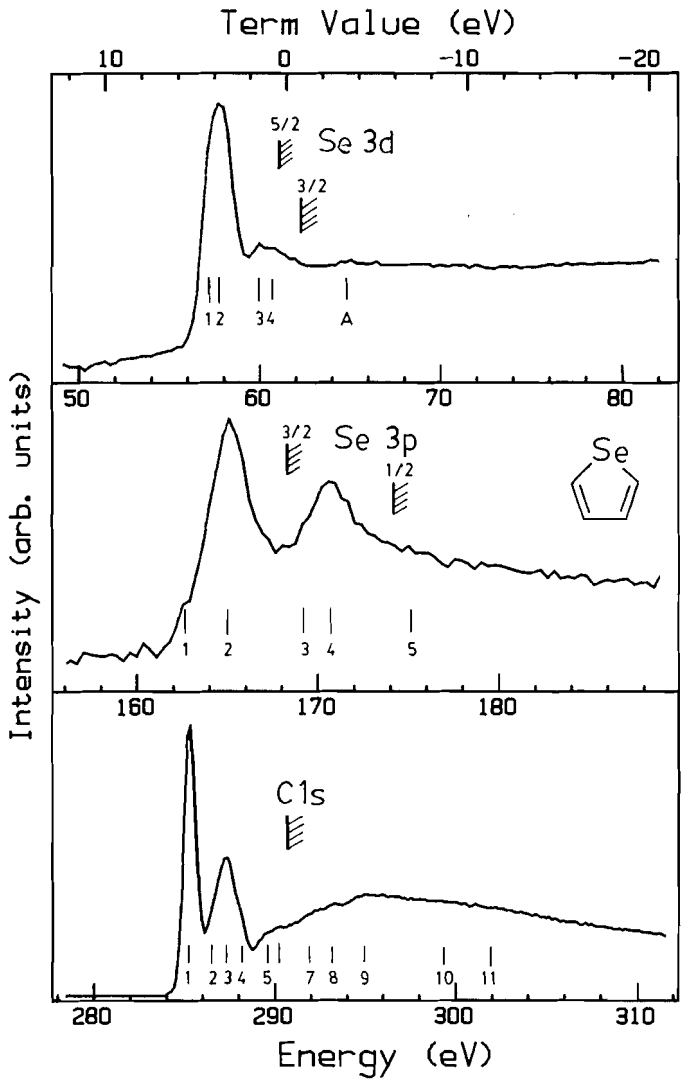

FIG. 5. Comparison of the Se $3d$, Se $3p$, and C $1s$ spectra of selenophene on a common term value scale. The spectra are aligned at the estimated ⟨Se $3d$⟩, Se $3p_{3/2}$, and C $1s$ IPs.

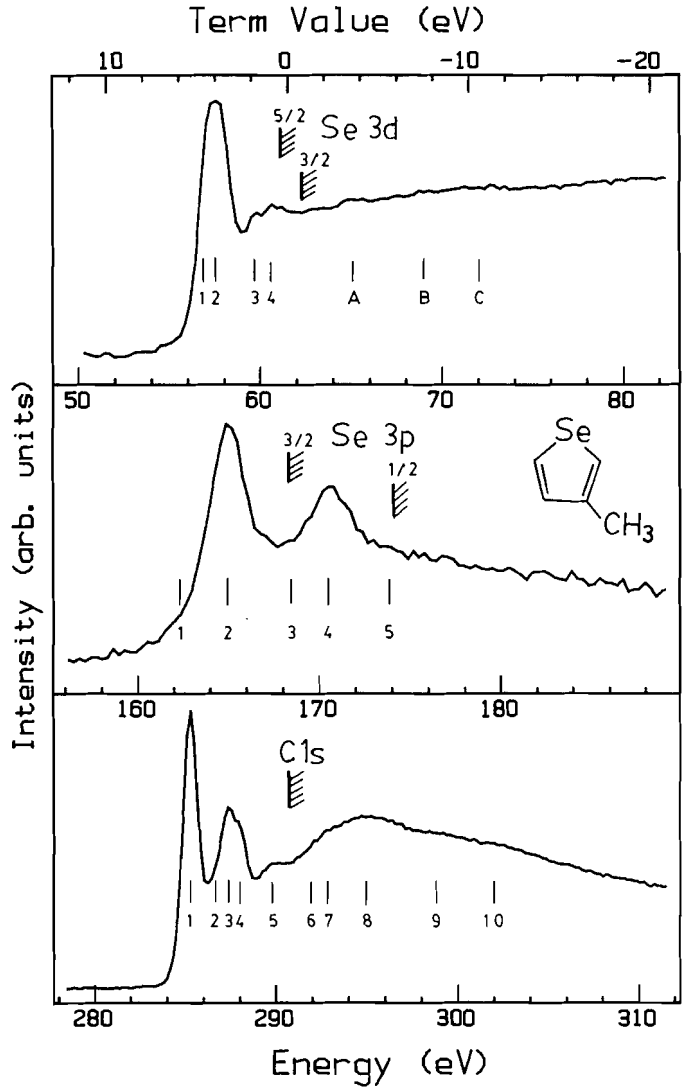

FIG. 6. Comparison of the Se $3d$, Se $3p$, and C $1s$ spectra of 3-methylselenophene on a common term value scale. The spectra are aligned at the estimated ⟨Se $3d$⟩, Se $3p_{3/2}$, and C $1s$ IPs.

sampled by the electron yield detection scheme used, it does not give spectra directly comparable to the gas phase monomer results since it does not correct for the additional methyl carbon atom in 3-methylselenophene. The normalization to constant continuum intensity explains why the C $1s \rightarrow \pi^*(3b_1)$ peak appears smaller in 3-methylselenophene than in selenophene. The consequences of different normalization treatments of the gas and surface data have been discussed in detail in connection with the 3-alkyl thiophene study (4).

Six transitions are clearly observed in the C $1s$ NEXAFS spectra of the polymers. Their energies and proposed assignments are summarized in Table 4. With reference to polythiophene (3), selenophene in the gas phase, and the Xα computations of selenophene reported by Modelli *et al.* (28), we assign the first transition to the $1s \rightarrow \pi^*(3b_1)$ bound state transition. The Xα results also predict the existence of a second $\pi^*(2a_2)$ orbital, 1.8 eV higher in energy. This is in good agreement with assignment of feature 3 (288.4 eV) to C $1s \rightarrow \pi^*(2a_2)$ transitions. Peak 2 at 287.1 eV is associated with the σ*(C—Se) shape resonance, which is consistent with observation of an opposite angular dependence for the first and the second peaks in oriented thin films of polyselenophene (29). Peaks 4 and 5 are attributed to σ*(C—C) shape resonances, in agreement with the C $1s$ ISEEL spectra of gas phase selenophene, thiophene (7), and the NEXAFS of polythiophene (3). The origin of the last transition at 302 eV, observed in essentially all aliphatic compounds (20, 30), is not well understood but may arise from a higher energy σ*(C—C) resonance or from multiple scattering of the outgoing photoelectron by several C atoms (which may be alternate descriptions of the same physical process).

B.2. C 1s NEXAFS of doped polyselenophene and poly-3-methylselenophene

When polyselenophene and poly-3-methylselenophene are doped into the conducting state with ClO_4^-, the σ*(C—Se) and σ*(C—C) shape resonances are observed at the same energy as in the spectra of the undoped polymer films (Fig. 8), suggesting that the bond lengths are not modified during the doping process. However, the C $1s \rightarrow \pi^*$ band in the polymer NEXAFS is greatly affected as evidenced by the decrease in intensity and shift in the $\pi^*(3b_1)$ band by 0.3 eV to lower energy. Additionally, a new transition, denoted 1′, appears at low energy, with an onset at 283 eV. (Note that the onset of 1′ is considered the characteristic energy of interest for this feature

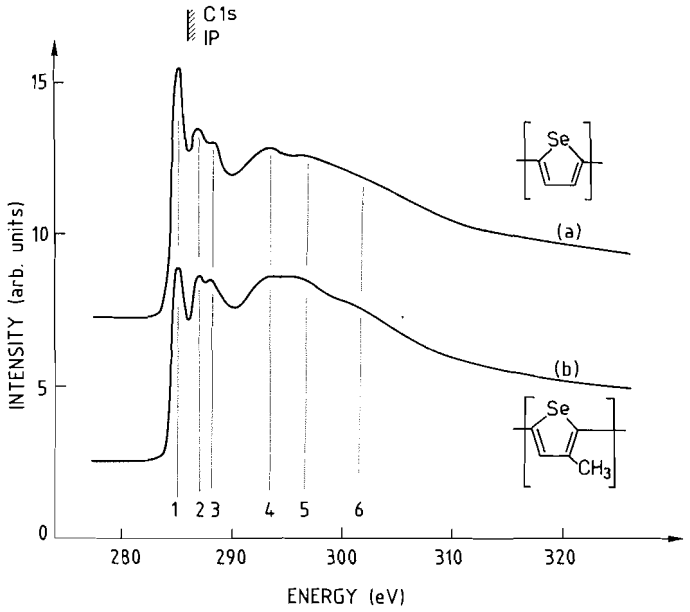

FIG. 7. C 1*s* edge NEXAFS spectra recorded at 40° X-ray incidence for 500 Å thick undoped films electrochemically deposited on a Pt surface: (a) polyselenophene; (b) poly-3-methylselenophene. The spectra do not depend on the angle of X-ray incidence.

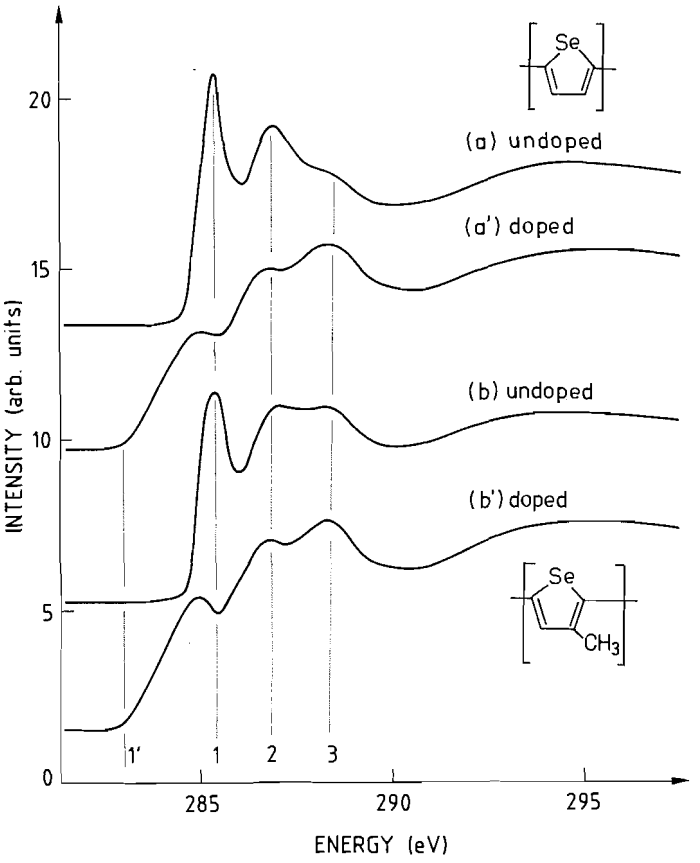

FIG. 8. C 1*s* edge NEXAFS spectra of 500 Å thick films recorded at 40° X-ray incidence: (a) and (a′) are the NEXAFS spectra of the undoped and doped states of polyselenophene respectively while (b) and (b′) are NEXAFS spectra characteristic of the undoped and doped forms of poly-3-methylselenophene.

since the edge of the "π*-conduction band" as sampled by C 1*s* excitation is defined by the onset rather than the peak. An underestimate of the band edge by about 0.3 eV will then arise because of the finite instrumental resolution.) The intensity of 1′ increases with the doping level. These additional empty states are observed in doped polyselenophenes, independent of the nature of the dopant (ClO_4^-, BF_4^-, or $SO_3CF_3^-$). Moreover, similar changes in the C 1*s* NEXAFS have been observed on doping polythiophene and poly-3-methylthiophene (3). This suggests that there is a common conduction mechanism for these polymers of five-membered heterocycles.

Several models have been proposed to explain the large increase of conductivity during the electrochemical oxidation of these polymers:

(*i*) Formation of a degenerate semiconductor associated with extraction of electrons from the π bonding band and a shift of the Fermi level below the valence band (31). With this scheme, the C K-edge NEXAFS spectra would exhibit a peak followed by a sharp threshold 2.5 eV higher in energy (the band gap of polyselenophene) due to transitions to the π* conduction band. Moreover, the intensity of this last transition should be constant during the doping process since the π* antibonding density of states would not be affected. Evidently the NEXAFS characteristics do not agree with this model.

(*ii*) Formation of local distortions in the polymeric chain around localized charges associated with the evolution of the ring system from an aromatic to a quinoid structure. In the bipolaron model (32) doping should lead to the development of *two* localized empty levels in the band gap. Structural

modifications are thus expected, especially in the C—C bond lengths of the polymeric backbone, so energy variations of peaks 5, 6, and possibly 2 should be observed (33). This is not the case experimentally. Moreover, the NEXAFS spectra would show two new peaks at low energy corresponding to the C 1*s* excitations to the bipolaron bands. The evolution of the C K-edge NEXAFS characteristics, combined with Se K-edge dispersive-EXAFS results obtained during an *in situ* doping–undoping electrochemical cycle that again do not reveal any modification in the C—Se bond length (34), are not in agreement with the bipolaron predictions.

(*iii*) Finally, if the conducting state corresponds to a metal-like behaviour, a simple step-like absorption edge would be observed 1.3 eV below the π^* band edge (mid-gap value) (31). In the fully doped state, the C 1*s* $\rightarrow$ π^* resonance observed in the undoped form of polyselenophene or poly-3-methylselenophene has almost vanished and the absorption threshold has shifted 3.4 eV to lower energy. Thus the NEXAFS characteristics suggest a closed-gap metallic state.

As with the conduction mechanism deduced for polythiophene (3), we conclude that dopant oxidation of polyselenophene and poly-3-methylselenophene proceeds through extraction of electrons from the π bonding band and a narrowing of the π–π^* gap. XPS and UPS experiments are underway which seek to confirm this scheme.

Summary

The electron energy loss spectra of selenophene and 3-methylselenophene in the regions of Se 3*d*, Se 3*p*, Se 3*s*, and C 1*s* have been recorded and analyzed. The C 1*s* spectra have been compared to the C 1*s* NEXAFS results of the corresponding polymers. The spectra of these two speices are very similar at all inner-shell edges. Only the C 1*s* spectra show minor differences that are consistent with additional σ^*(C—H) and σ^*(C—C) intensity in 3-methylselenophene, which occur at expected energies (33).

The similarity of the C 1*s* spectra of the monomers and their corresponding polymers strongly suggests that the polymer subunits have essentially the same structure as the monomers. The effect of doping on the NEXAFS of the polymer thin films is consistent with a narrowing of the band gap and the development of metal-like behaviour. Finally, doping produces modifications of the C 1*s* NEXAFS similar to those observed upon doping polythiophene (3). This indicates that the conduction mechanism is similar for these two poly-penta-heterocycles.

Chlorine can be made to disproportionate to chlorine monofluoride and chloride, taking advantage of Le Chatelier's principle in several different ways. It will disproportionate to form insoluble silver chloride and chlorine monofluoride when silver fluoride is present. It will disproportionate in a melt of alkali metal fluorides to form alkali metal chlorides and chlorine monofluoride. The alkali metal chlorides will react with hydrogen fluoride to regenerate the metal fluorides and hydrogen chloride. Chlorine will also disproportionate in hydrogen fluoride containing antimony pentafluoride to yield antimony pentafluoride adducts of chlorine monofluoride and of hydrogen chloride. These adducts are readily decomposed to yield the disproportionation products and the original antimony pentafluoride.

Key words: hydrogen fluoride, disproportionation, chlorine, waterlike, solvent system.

MARIO GAMBARDELLA, SANTAD KONGPRICHA, JAMES J. PITTS et ALBERT W. JACHE. Can. J. Chem. **67**, 1828 (1989).

En mettant à profit le principle de Le Chatelier, on peut amener le chlore à donner une réaction de dismutation conduisant au monofluorure et au chlorure de chlore. En présence de fluorure d'argent, il donne une réaction de disproportionation conduisant à la formation de chlorure d'argent insoluble. Dans des fluorures de métaux alcalins fondus, la réaction conduit à la formation de chlorures de métaux alcalins et de monofluorure de chlore. Les chlorures de métaux alcalins réagissent avec le fluorure d'hydrogène pour régénérer les fluorures métalliques et le chlorure d'hydrogène. En présence de fluorure d'hydrogène contenant du pentafluorure d'antimoine, la réaction de disproportionation du chlore fournit des adduits de pentafluorure d'antimoine avec soit du monofluorure de chlore ou de chlorure d'hydrogène. Ces adduits se décomposent facilement pour donner les produits de disproportionation et le pentafluorure d'antimoine original.

Mots clés : fluorure d'hydrogène, dismutation, chlore, semblable à l'eau, septème de solvant.

[Traduit par la revue]

Introduction

Over two decades ago, a program investigating chemistry in and of anhydrous hydrogen fluoride and interhalogen fluorides was undertaken in the research laboratories of Olin Mathieson Chemical Corporation, now Olin Corp. Part of the work involved investigations of the parallels between chemistry in water and that in hydrogen fluoride.

During the course of the work, it was shown that the relationship between IO_2^+, IO_2F, and $IO_2F_2^-$ could be explained on the basis of amphoterism (1). The concentration of fluoride controls the loss or gain of fluoride in a manner analogous to the manner in which the loss of gain of isoelectronic hydroxide in the aqueous chemistry of Al^{3+} is controlled by hydroxide ion concentration or pH.

$$[1] \quad \begin{aligned} IO_2^+ + F^- &= IO_2F \\ IO_2F + F^- &= IO_2F_2^- \end{aligned}$$

Investigations involving the chemistry of phosphorus in hydrogen fluoride showed that parallels with water chemistry exist here also (2). Phosphorus at temperatures above 280°C behaves as a metal in its reaction with water (for primary references, see ref. 3).

$$[2] \quad P_4 + 16H_2O(g) \rightarrow 10H_2 + 4H_3PO_4\ (OP(OH)_3)$$

In boiling basic aqueous solution it undergoes disproportionation.

$$[3] \quad P_4 + 3OH^- + 3H_2O \rightarrow PH_3 + 3H_2PO_2^-$$

It was shown that in the absence of intentionally added metal fluorides phosphorus reacts as a metal with hydrogen fluoride to form hydrogen and phosphorus trifluoride

$$[4] \quad P_4 + 12HF \rightarrow 6H_2 + 4PF_3$$

Small amounts of alkali or alkaline earth fluorides catalyze the reaction. The metal fluorides are generally ultimately converted to metal hexafluorophosphates. When larger amounts of fluoride are added, given sufficient time, much of the phosphorus is found as metal hexafluorophosphate. Apparently, disproportionation of the trifluoride to phosphorus (which may undergo further reaction) and phosphorus pentafluoride occurs. The phosphorus pentafluoride is tied up with the metal fluoride as a hexafluorophosphate, thus, in accordance with Le Chatelier's principle, shifting the position of equilibrium.

$$[5] \quad 10PF_3 + 6MF \rightarrow P_4 + 6MPF_6$$

The efficacy of catalysis of reaction [4] by metal fluorides and of bringing about reaction [5] can be correlated with properties that can be correlated with charge/size ratio of the metal ion (e.g., radii, lattice energy of fluoride, solubility of fluoride in HF).

While chlorine will slowly liberate oxygen from water, it primarily disproportionates in water. The degree of disproportionation is enhanced by increased basicity. Although the equilibria involved are complicated and are much influenced by kinetics (4), under ordinary conditions one sees primarily

$$[6] \quad Cl_2 + H_2O \rightarrow HOCl + HCl$$

The analogous reaction in hydrogen fluoride is

$$[7] \quad Cl_2 + HF \rightarrow FCl\ (ClF) + HCl$$

Since the heat and free energy of formation of chlorine monofluoride (negative) is much less than the (negative) difference between the heats and free energies of formation of hydrogen chloride and hydrogen fluoride, one would not expect reaction

[7] to go spontaneously as written. Indeed, the reverse reaction goes spontaneously, even in hydrogen fluoride solutions saturated with cesium fluoride. However, it seemed worthwhile to attempt to accomplish disproportionation by taking advantage of Le Chatelier's principle. Success in this endeavour was reported only in the patent literature (5) at the time, since there was then some interest in potential commercial applications. Although a decade later much of this information was presented at the 8th International Symposium on Fluorine Chemistry (6), it seems particularly appropriate to publish this work now in a journal issue honoring Professor Gillespie, whose many accomplishments include exciting work in highly acidic, fluorine-containing media.

Experimental

General

Infrared spectra were generally obtained with a Perkin–Elmer model 137 Infracord spectrometer using a 10-cm AgCl-window gas cell with a Monel body. Vapor phase chromatography was performed using an all-metal (Monel and nickel) unit at room temperature. The column was packed with Kel-F No. 1 oil on Fluor-Pak. A gas density balance was used as a detector. The AgF was obtained from Harshaw Chemical Co. and the $AgBF_4$ from the Ozark-Mahoning Co., while the SbF_5 was an Allied Chemical Corp. product.

Reactions involving antimony pentafluoride

Reactions were, in general, carried out in a Kel-F reaction vessel, which could be sealed and attached to an all-metal (copper and Monel) vacuum manifold. The reaction vessel contained a Teflon-covered magnetic stirring bar.

Antimony pentafluoride (18.5 g; 85 mmol) was poured, under a dry nitrogen blanket, into the reaction vessel, which was then evacuated on the vacuum manifold. When chlorine monofluoride (12 g; 220 mmol) was bled slowly into the system, the solution first became yellow-green, then orange-red, and finally dark maroon as the ClF was absorbed over a period of 6 h. At this time the total pressure was about 1 atm at room temperature (1 atm = 101.3 kPa). A trichloroethylene – Dry Ice bath was placed around the reaction vessel. The vapor pressure dropped to about 300 Torr (1 Torr = 133.3 Pa) and a tan-yellow solid formed. Gaseous ClF was taken from the system. The solid product exhibited no appreciable vapor pressure until, on warming, the temperature reached −40°C. The solid darkened and melted to a maroon liquid between −20 and −15°C. Extrapolated vapor pressure indicated that the vapor pressure of ClF would be 1 atm at 25°C. Elemental analysis of the solid showed a chlorine content of 16.3%. Theoretical content for Cl_2FSbF_6 is 21.8%; for $Cl_2FSb_2F_{11}$ or $ClSbF_6$ is 13.1%.

When ClF was introduced over a solution of SbF_5 (15 g; 69 mmol) in 20 mL of liquid HF at −78°C the ClF was taken up by the solution and a yellow precipitate appeared. After 12 g (22 mmol) of ClF had been added the system was closed and the pressure in the system remained constant at 1 atm. The system was then opened to a liquid nitrogen-cooled Monel cylinder until the vapor pressure in the −78°C vessel was essentially zero. When the vessel containing the solution and precipitate was warmed toward room temperature the solution started to turn red, the solid slowly disappearing at approximately −20°C. At 0°C there was no solid, the solution was orange-red, and the vapor pressure above the solution was 150 Torr. At room temperature the pressure was close to atmospheric. A sample of the vapor was collected in a liquid nitrogen-cooled Monel cylinder. Vapor pressure chromatography showed the presence of ClF and HF.

Antimony pentafluoride (30 g; 138 mmol), under a blanket of dry nitrogen, was placed in the Kel-F reactor, along with the stirring bar attached to the vacuum system, and evacuated. The SbF_5 froze when the vessel was cooled to −78°C. After HF (32 g; 1.62 mol) was distilled into the reactor the SbF_5 dissolved to give a colorless solution at −78°C. Chlorine (7 g; 99 mmol) was slowly condensed into the reactor solution with stirring, the temperature being maintained with the trichloroethylene – Dry Ice bath. A yellow solution with some droplets of liquid chlorine and a yellow precipitate resulted. Stirring was continued and the vessel warmed to −35°C. The pressure was 1 atm. The vessel was opened to a liquid nitrogen-cooled Monel cylinder and the gaseous products condensed in the cylinder until the vapor pressure in the vessel was reduced to zero. Two grams of gas were collected (condensed) in the cylinder. Vapor phase chromatography showed that the gas which had been condensed in the cylinder contained Cl_2, HF, and ClF. The reaction vessel and contents were then allowed to warm further. The yellow solid dissolved at about −20°C. The vapor coming off was condensed into a liquid nitrogen-cooled Monel cylinder as the vessel temperature was between 0 and 15°C. Vapor phase chromatography showed a large amount of ClF along with some HF and Cl_2.

Reactions involving silver salts

Silver fluoride (41 g; 0.32 mol) was placed in a 150-mL Monel cylinder equipped with a 1/4-in. Monel dip tube and outlet. The outlet was connected to a copper trap maintained at Dry Ice temperature. The outlet of the trap was connected to a 10-cm Monel body cell for the purpose of "on-stream" infrared spectrometric analysis of gaseous products. The outlet of the cell led to a Kel-F oil bubbler and an anhydrous calcium sulfate filled drying tube. The infrared cell could be bypassed. The reactor was heated by a vertical tube furnace. After the system was evacuated, Cl_2 was passed through the AgF, heated to 220°C, for 9 h. On-stream infrared analysis of the gaseous stream showed the presence of ClF. The solid residue in the reaction vessel consisted of AgCl and unreacted AgF.

A 240-mL Monel autoclave, previously passivated with chlorine trifluoride, was charged with AgF (45 g; 0.359 mol), Cl_2 (23 g; 0.324 mol), and HF (16 g; 0.80 mol), heated to 200°C, and shaken. A pressure of 49.9 atm gradually developed and remained constant throughout the heating period of 5 h. The autoclave was cooled and the gaseous products were removed to a Monel cylinder. Only 28.5 g was recovered. Vapor phase chromatography retention time and oxidizing power identified HF, Cl_2, and ClF in the gaseous products. The solid residue left in the autoclave contained 20.5% AgCl, consistent with about an 18.5% conversion of Cl_2 to ClF.

Silver tetrafluoroborate was loosely packed into 3/8-in. o.d. copper tubing connected to traps and an on-line infrared cell. After the system was evacuated, Cl_2 was passed through the $AgBF_4$ heated to 150°C. After 3 h of reaction time ClF and some ClF_3 were seen by infrared spectroscopy. They were also formed at 200 and at 250°C. Boron trifluoride was also seen. The solid residue in the copper tubing consisted of unreacted $AgBF_4$, AgF, and AgCl.

Reaction with alkali metal fluorides

A well-mixed mixture of NaF (5 g), LiF (10 g), and KHF_2 (60 g) was placed in a 150-mL Monel cylinder having a 1/4-in. o.d. nickel dip tube and outlet for gaseous products. The outlet was connected to three copper traps maintained at Dry Ice temperature, liquid nitrogen temperature, and room temperature, respectively. The system was protected from the atmosphere by a mercury seal at the end of the train. The reactor was heated, with an electric furnace, to 725°C while nitrogen was bubbled through the molten salt for about an hour. Then a stream of Cl_2 was bubbled through the molten salt for 5 h, consuming 32 g of Cl_2. The contents of the liquid nitrogen-cooled trap, about 20 g, was transferred into a Monel cylinder. Infrared spectroscopic analysis showed the presence of ClF along with some ClF_3. The solid residue in the reactor contained chloride, as evidenced by the precipitation of silver chloride upon the addition of silver ion. The aqueous filtrate from the precipitated silver chloride oxidized starch iodide solution.

Discussion and results

At the time this work was done the existence of an adduct of ClF with SbF_5 had not been established. When this work led to the conclusion that such an adduct could be made by reacting SbF_5 with ClF either neat or in HF solution, we initially and tentatively considered it to be $ClSbF_6$ admixed with $ClSb_2F_{11}$. We were uncomfortable with this since it suggested a bare positive chlorine, and the chlorine content did not fit well. When

other workers (7–9) identified and characterized Cl_2FAsF_6 and Cl_2FBF_4, we realized that our adduct must have been a Cl_2F^+ compound. Hence the likely reactions were

[8] $2ClF + SbF_5 \rightarrow Cl_2FSbF_6$

and

[9] $2ClF + 2SbF_5 \rightarrow Cl_2FSb_2F_{11}$

While it is clear that chlorine will not, by itself, disproportionate in hydrogen fluoride to a significant extent, this work shows that disproportionation can be brought about by tying up one or both disproportionation products. Both products are tied up when Cl_2 disproportionates in HF solution containing SbF_5, the ClF as the adduct discussed above, and HCl as $HSbF_5Cl$.

[10] $2Cl_2 + 3SbF_5 + 2HF \rightarrow Cl_2FSbF_5 + 2HSbF_6Cl$

Upon warming to about −20°C the ClF adduct decomposes, yielding ClF and SbF_5.

[11] $Cl_2FSbF_6 \rightarrow 2ClF + SbF_5$

At higher temperature the HCl (10) is liberated.

[12] $2HSbF_5Cl \rightarrow 2HCl + 2SbF_5$

The starting SbF_5 is regenerated. Equations [10], [11], and [12] combine to give twice eq. [7]. Overlap of the reactions shown in eqs. [11] and [12] will lead to the reverse of [7], thus accounting for some of what appeared to be unreacted chlorine. That HF is necessary for the disproportionation to occur (eq. [10]) is attested by nonreaction of Cl_2 with SbF_5 when reactions were attempted.

The low solubility of AgCl in HF (and water), contrasted with the high solubility of AgF in these solvents, might lead one to expect that the presence of Ag^+ would shift equilibria involving Cl^- in the direction of formation of Cl^- since AgCl would precipitate in the presence of significant, but low, concentrations of Cl^- and Ag^+. Hence it is not completely unexpected to note that Cl_2 will react with silver fluoride under a variety of conditions to give chloride, which is tied up as the silver salt. The other product has to be something formally oxidized. Hence ClF (and ClF_3) are likely products. Probably one of the factors that limit extent of reaction with solid AgF is a coating of chloride, which inhibits the attack of Cl_2.

[13] $Cl_2 + AgF \rightarrow ClF + AgCl$

Reactions involving $AgBF_4$ probably occur according to reaction [13] since loss of BF_3 results in AgF. One is tempted to invoke tying up of the interhalogen as a BF_3 adduct (BF_4^- species) when one speculates about intermediates, especially since some ClF_3 is observed when $AgBF_4$ is used. However, the temptation is resisted upon observation that reaction temperatures are above the decomposition temperature of the ClF_3 adduct.

Were reaction [13] a general one, where any metal (Li, Na, K, etc.) could substitute for Ag,

[14] $MF + Cl_2 \rightarrow ClF + MCl$

one could consider a scheme whereby the metal fluoride could be regenerated by reaction with HF

[15] $MCl + HF \rightarrow MF + HCl$

since this reaction, [15], occurs with most metal chlorides. Unfortunately it does not with silver chloride, probably for the same reason that [13] does. The net reaction (sum of [14] and [15] would be [7] were they to occur. In all cases where M is an alkali metal, the standard free energy (also enthalpy change) for the reaction is quite positive since the free energy of formation of ClF is not more negative than the difference between that of the metal fluoride and that of the metal chloride. However, the differences between the free energies of formation of the fluoride and chloride of given metals become less as one goes down the periodic table. This is a reflection of lattice energies showing less sensitivity to identity of the halide as the cation radius increases. Upon subtraction of lattice energies from the free energies or heats of formation one gets what might be called residual free energies or residual heats. These are the free energies or heats of formation were the metal halides liquid in their standard states. Obviously they are not liquids in their standard states and their melting points are well above room temperature. However, it was hoped that these data might give some guidance with respect to experiments in molten fluorides. It turns out that in all cases considered, the difference between the residual free energies (or enthalpies) of formation of the fluoride and chloride and the free energy of formation of ClF were less negative than is the free energy (or enthalpy) of formation of ClF. The difference in free energy of formation for the lithium halides is −204.6 kJ/mol; for the sodium halides, −161.0 kJ/mol; for the potassium halides, −130.2 kJ/mol; and for the cesium fluorides, −110.0 kJ/mol, while the difference in lattice energy of the halides is, for the lithium salts, 196 kJ/mol; sodium salts, 145 kJ/mol; potassium salts, 109 kJ/mol; and for the cesium salts, 100 kJ/mol. The residual free energy differences (negative) are then Li, 8.6 kJ/mol; Na, 16.0 kJ/mol; K, 21.2 kJ/mol; and Cs 11.0 kJ/mol. In all cases this is less than the free energy of formation of ClF, −57.7 kJ/mol, thus leading to a negative free energy change for the desired reaction were the salts liquid at room temperature. This encouraged the possibility that one could carry out the reaction by passing Cl_2 into a molten Group I halide melt, allowing the gaseous ClF product to escape from the melt (Le Chatelier's principle). Of course these conditions are far from the standard state. The fact that, when Cl_2 was bubbled through molten LiF–NaF–KF, ClF exited and chloride was formed in the melt demonstrates that, at least in this case, imprecise use of thermodynamic data gives useful guidance. It is unfortunate that the work was inadvertantly carried out at as high a temperature as it was, since it probably would have worked at temperatures down to the melting point of the mixture and thus minimized the corrosion of the apparatus that occurred.

That some ClF_3 is observed along with the ClF in some cases may be explained by the known equilibrium between ClF, ClF_3, and Cl_2 or by further disproportionation of ClF.

[16] $3ClF = ClF_3 + Cl_2$

Several years after this work was completed a study of Br_2 reactions in HF solutions containing AgF and of I_2 reactions in the same kind of medium was carried out and reported (11). While thermodynamic considerations predict that the halogen would disproportionate to halide (silver halide) and halogen monofluoride, further considerations underline the likely recovery of BrF_3 and IF_5, since these monofluorides are unstable with respect to disproportionation to halogen and the trifluoride and, in the case of iodine, to the pentafluoride. This is, except in the case of sufficient excess of Br_2, what is experimentally observed.

The trend, then, as one goes down the halogen group is to find primarily ClF, BrF_3, and IF_5 in the disproportionation products. This is pleasing to those of us who take pleasure in noting trends in the periodic table.

Chlorine, then, in ionic fluorine-containing media can be caused to undergo disproportionation when one or both of the products is tied up. The reduced product ends up in basic media as chloride and in acidic media as SbF_5Cl^-. The oxidized product is Cl_2F^+ in acidic media and as volatile ClF in basic media.

Examples exist of other kinds of waterlike behaviour (12) in hydrogen fluoride media. Drawing analogies with aqueous chemistry continues to be useful.

Synthesis and X-ray structure determination of the Ir–Ag–Ir donor–acceptor metal–metal bonded complex $[\{(\eta^5\text{-}C_5Me_5)(CO)_2Ir\}_2Ag][BF_4]$

FREDERICK W. B. EINSTEIN, RICHARD H. JONES, XIAOHENG ZHANG,[1] AND DEREK SUTTON[2]

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 1, 1989

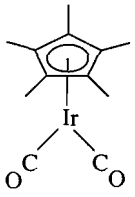
This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

FREDERICK W. B. EINSTEIN, RICHARD H. JONES, XIAOHENG ZHANG, and DEREK SUTTON. Can. J. Chem. **67**, 1832 (1989).

The title complex (**2**) has been synthesized from the reaction of $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ (**1**) with $AgBF_4$. Complex **2** crystallizes in the monoclinic space group $P2_1/c$ with a = 12.355(2) Å, b = 13.713(2) Å, c = 16.672(3) Å, β = 97.70(1)°, and Z = 4. The structure was solved by using 3131 observed reflections ($I \geq 2.5\sigma(I)$) in the range $0° < 2\theta < 50°$ to final discrepancy indices of R_F = 0.032 and R_{wF} = 0.038. The cation may be described as consisting of two molecules of **1** bound to Ag^+ by donor–acceptor Ir → Ag bonds. The Ir—Ag—Ir skeleton is nearly linear (angle 173.67(6)°). The Ag—Ir bond lengths are equal (2.659(1) Å), and the two molecules of **1** are disposed mutually *trans*, to give the cation approximate (noncrystallographic) C_{2h} symmetry.

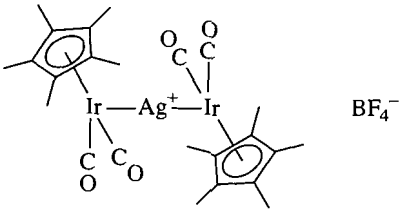
Key words: complex, iridium, silver, metal-metal bond, X-ray, crystal, structure, carbonyl, donor-acceptor, pentamethylcyclopentadienyl.

FREDERICK W. B. EINSTEIN, RICHARD H. JONES, XIAOHENG ZHANG et DEREK SUTTON. Can. J. Chem. **67**, 1832 (1989).



On a préparé le composé $[\{(\eta^5\text{-}C_5Me_5)(CO)_2Ir\}_2Ag][BF_4]$ (2) en faisant réagir le composé $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ (**1**) avec $AgBF_4$. Le complexe **2** cristallise dans le groupe d'espace monoclinique $P2/c$ avec a = 12,355(2) Å, b = 13,713(2) Å, c = 16,672(3) Å, β = 97,70(1)° et Z = 4. On a résolu la structure en faisant appel à 3131 réflexions observées ($I \geq 2{,}52\sigma(I)$ dans l'intervalle $0° < 2\theta < 50°$ jusqu'à des valeurs finales de R_F = 0,032 et de R_{wF} = 0,038. On peut décrire le cation comme étant constitué de deux molécules du composé **1** liées à l'ion Ag^+ par la liaison Ag → Ir donneur–accepteur. Le squelette Ir—Ag—Ir est quasi linéaire (angle 173,67(6)°). Les longueurs de liaison Ir—Ag sont de 2,659(1) Å, et les deux molécules du composé **1** sont mutuellement en position *trans*, pour donner le cation de symmétrie approximative (non cristallographique) C_{2h}.

Mots clés : complexe, iridium, argent, liaison métal–métal, rayons X, cristal, structure, carbonyle, donneur–accepteur, pentaméthylcyclopentadiényle.



[Traduit par la revue]

Introduction

There is considerable current interest in heteronuclear metal–metal bonded complexes (1), and one subset includes those which can be formulated in a simplistic way to contain a heteropolar (or dative), metal–metal bond that is not "supported" by the presence of concurrent bridging ligands (i.e., M → M′) (see, for example, ref. 2). Recently, two X-ray structures have been published involving complexes with unbridged Ir → Ag bonds (3), and in this paper we describe the synthesis and X-ray structure of a further example, $[\{(\eta^5\text{-}C_5Me_5)(CO)_2Ir\}_2Ag][BF_4]$ (**2**).

2

Results

Synthesis and characterization

The addition of $AgBF_4$ to the iridium complex $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ (**1**) in acetone solution in 1:2 ratio readily affords $[\{(\eta^5\text{-}C_5Me_5)(CO)_2Ir\}_2Ag][BF_4]$ (**2**), which is isolated as a pale yellow, air-stable crystalline solid. Compound **2** is soluble in common polar solvents such as acetone, chloroform, or dichloromethane to give stable solutions, but is insoluble in benzene, hexane, and diethyl ether. The crystals decompose above 220°C.

The infrared spectrum (acetone) exhibits two ν(CO) absorptions, at 2033 and 1984 cm^{-1}. This is consistent with a C_{2h} structure for the cation with *trans* $\eta^5\text{-}C_5Me_5$ groups (where only the A_u and B_u ν(CO) modes are infrared active) but not with a *cis* structure of C_{2v} symmetry. However, two infrared active ν(CO) bands would also be anticipated if the two $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ moieties are not vibrationally coupled, and only the local ν(CO) vibrations of this unit are effective. As expected, both ν(CO) absorptions are shifted to higher wavenumber by comparison with $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ (**1**) itself. In the ^1H NMR spectrum, the $\eta^5\text{-}C_5Me_5$ resonance is at δ 2.37 ppm, shifted downfield by comparison with **1**. Both effects are consistent with the withdrawal of electron density from Ir as a result of the formation of formal Ir → Ag^+ donor–acceptor bonds.

The fast-atom-bombardment (FAB) technique employing a thioglycerol matrix and xenon bombardment gave an excellent mass spectrum (FABMS) of the parent cation (Fig. 1) with the appropriate isotopic cluster for the presence of one Ag and two Ir atoms; some fragmentation of the trimetallic cation occurred under these conditions, giving ions $[(\eta^5\text{-}C_5Me_5)(CO)_2IrAg]^+$, $[(\eta^5\text{-}C_5Me_5)(CO)IrAg]^+$, and $[(\eta^5\text{-}C_5Me_5)Ir(CO)_2]^+$.

X-ray structure

The structure consists of discrete $[\{(\eta^5\text{-}C_5Me_5)(CO)_2Ir\}_2Ag]^+$ cations and $[BF_4]^-$ anions with no unusually short interionic contacts. A view of the structure of the cation is given in Fig. 2. The cation features two crystallographically distinct $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ moieties bound to Ag^+ such that the

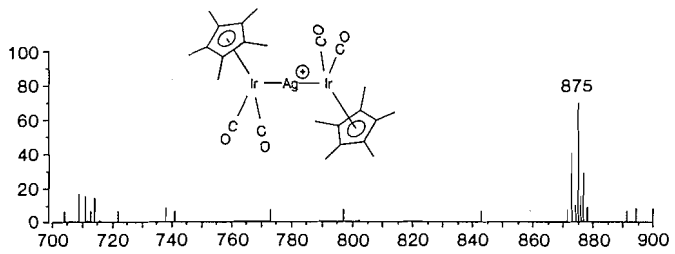

FIG. 1. Fast-atom bombardment mass spectrum (xenon gas, thioglycerol matrix) for the parent cation of **2**. Abscissa, m/z; ordinate, arbitrary intensity.

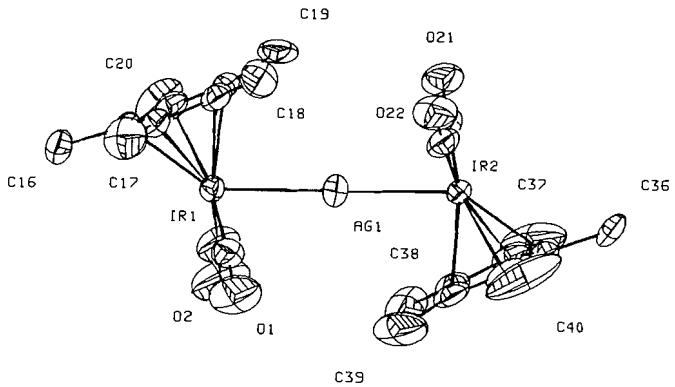

FIG. 2. View of the structure of the cation in **2** with atom numbering.

Ir—Ag—Ir skeleton is near linear (angle = 173.67(6)°) and the set of ligands on one Ir atom is disposed mutually *trans* to the set on the other Ir to give a noncrystallographic centrosymmetric (C_{2h}) ideal structure. The torsion angle Cp(1)—Ir(1)—Ir(2)—Cp(2) is 178.4° (where Cp(1) and Cp(2) are the centroids of the η^5-C_5Me_5 rings. The two Ag—Ir bond lengths are equal at 2.659(1) Å. This value may be compared with a previously determined Ag—Ir bond length of 2.683(1) Å in $IrCl(CO)(PPh_3)_2 \cdot Ag(B_{11}CH_{12})$, which also has an unbridged Ag—Ir bond and is therefore a good comparison (3*a*), and with bond lengths of 2.808(4) Å and 2.764(4) Å in $[(Ph_3P)_3Ir(\mu_3\text{-}H)(\mu\text{-}H)_2Ag_2(OSO_2CF_3)(H_2O)][CF_3SO_3]$ where, however, the Ag—Ir bonds have hydrogen bridges (3*b*). A somewhat larger value (2.87 Å) was observed for the Ag—Ir bond in a triazenide-bridged compound (4). The sum of empirical covalent radii of Ir and Ag may be estimated at 2.61 Å (5).

A notable feature of the structure is the acute angle Ag—Ir—C formed between the Ag—Ir and Ir—CO bonds in each case, ranging from 81°–83°. Thus, the CO groups appear to lean over the Ag—Ir bond toward the Ag to some extent; however, the observed Ir—C—O skeletons are close to linear, and there are no short contacts from Ag to carbonyl group carbon or oxygen atoms. This leaning is evident because each $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ group is minimally distorted from the regular structure that **1** itself is expected to possess, by comparison with the structure of $(\eta^5\text{-}C_5Me_5)Co(CO)_2$ (6*a*). (Note, however, that no determination of the X-ray structure of **1** has been reported.) Thus, the sum of the angles Cp(1)—Ir(1)—C(1), Cp(1)—Ir(1)—C(2), and C(1)—Ir(1)—C(2) is 358°, as is the sum of the corresponding angles around Ir(2). So, it appears that the presence of the Ir—Ag bond seems to be accompanied by little reorganization of each $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ moiety; the carbonyl groups have not moved away from this bond to generate the more regular three-legged piano-stool geometry typical of $(\eta^5\text{-}C_5Me_5)ML_3$ structures. Whether the CO groups assume these positions in **2** on account of some bonding interaction with the Ag^+ we cannot say at this time. Recently determined structures of related derivatives of $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ such as $(\eta^5\text{-}C_5Me_5)(CO)_2\text{-}IrW(CO)_5$ (6*b*) and $[(\eta^5\text{-}C_5Me_5)(CO)_2IrCH_2Cl]^+$ (6*c*) show somewhat greater reorganization of the carbonyl groups, to accommodate the extra ligand, than is observed here.

Discussion

The ability to form direct covalent metal–metal bonds between silver and transition metals has been known for over 50 years. Indeed a compound formulated as $[AgCo(CO)_4 \cdot xH_2O]$ was reportedly the first heteronuclear metal–metal bonded complex to be synthesized (refs. 1, p. 765, and 7*a*, *b*). In a study of the reactions of nucleophilic organometallic anions such as $[CpM(CO)_3]^-$ (M = Cr, Mo, W; Cp = η^5-C_5H_5) with $AgNO_3$, Hackett and Manning (7*c*) synthesized a series of anionic complexes $[\{Cp(CO)_3M\}_2Ag]^-$ that presumably have linear structures with two-coordinated Ag, related to the present example. The closest structural parallel that we can find to the one presented here (i.e., a discrete cationic complex of Ag with a cobalt-group metal) is the complex $[\{Cp(CO)(PPh_3)Rh\}_2Ag][PF_6]$ (**3**) synthesized by Connelly *et al.* (8). Several related mixed-metal silver complexes are known that are of different structure (4, 9).

The structure of complex **3** and that of **2** have many common features despite the different metal atom and the presence of PPh_3 ligands in the former. Thus the Ag—M distances are comparable (Ag—Ir = 2.659(1) Å in **2**, Ag—Rh = 2.651(1) and 2.636(1) Å in **3**); the M—Ag—M framework is close to linear (angle = 173.7(1)° in **2** and 171.0° in **3**); the structure adopted is *transoid* in both cases; and the M—C—O groups lean toward the Ag atom resulting in acute Ag—M—(CO) angles (80.6(4)°–83.0(5)° in **2** and 77.1(2)°, 84.3(2)° in **3**). These add further examples of carbonyl groups leaning toward metal–metal bonds to those observed previously in similar unbridged systems (2, 10).

The iridium complex **1** exhibits basic properties as, for example, in its ability to be protonated (11) to give $[(\eta^5\text{-}C_5Me_5)IrH(CO)_2]^+$. It is therefore convenient to view complex **2** as a complex with donor–acceptor $Ir \rightarrow Ag^+$ bonds, formed directly from the reaction of the Lewis base **1** with the Lewis acid Ag^+, though undoubtedly this is a gross oversimplification of the charge distribution in the final complex. For complex **3**, Connelly (8) has suggested that an alternative description as a silver(0)-stabilized source of the radical cation $[(\eta\text{-}C_5H_5)Rh(CO)(PPh_3)]^+$ provides a rationalization of the reactions of **3** with NO and NO_2. While we have not examined this possibility in detail for complex **2**, there may indeed be a parallel. Thus, we have found that addition of $AgBF_4$ and **1** to the dinuclear complex $[(\eta^5\text{-}C_5Me_5)_2Ir_2(CO)_3Cl][BF_4]$ does not yield any tri-iridium species that might be anticipated from simple chloride abstraction and coordination of a further $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$; instead, the product is $[(\eta^5\text{-}C_5Me_4\overline{CH_2})(CO)_2Ir—Ir(CO)(\eta^5\text{-}C_5Me_5)][BF_4]$ where possibly the dehydrochlorination and metal–carbon bridge-bond formation occurs by a radical process. The details of this chemistry will be the subject of a future publication.[3]

Experimental

General procedures

Reactions were carried out under dry nitrogen using standard Schlenk techniques. Infrared spectra were recorded on a Perkin–Elmer 983G spectrometer, NMR spectra on Bruker WM-400 (at 400 MHz) and 100-SY (at 100 MHz) spectrometers, and mass spectra were recorded on a Hewlett–Packard HP 5985 instrument equipped with a Phrasor Scientific Inc. fast atom bombardment accessory. Microanalyses were performed by M. K. Yang of the SFU microanalysis laboratory. $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ was synthesized by a modification of the published procedure (12).[4]

Synthesis of $[\{(\eta^5\text{-}C_5Me_5)(CO)_2Ir\}_2Ag][BF_4]$ (2)

$AgBF_4$ (15 mg, 0.078 mmol) was added to a stirred bright-yellow solution of $(\eta^5\text{-}C_5Me_5)Ir(CO)_2$ (**1**) (60 mg; 0.157 mmol) in dry acetone, under nitrogen. The colour became pale yellow and the reaction was followed by IR spectroscopy until absorptions from **1** were no longer present. The solvent was removed under vacuum and **2** was recrystallized from acetone–ether as a yellow solid, mp above 220°C (dec.). Yield (recrystallized) 60.6 mg; 80.8%. IR (acetone, cm^{-1}): 2033 s, 1984 s (ν(CO)); ^{1}H NMR ($CDCl_3$) δ: 2.37 (C_5Me_5); FABMS (xenon–thioglycerol) m/z (cation): 875 (M^+), 491 (M^+ − $Cp^*Ir(CO)_2$), 463 (M^+ − $Cp^*Ir(CO)_2$ − CO), 384 ($Cp^*Ir(CO)_2^+$) (values are for the most abundant mass in the isotopic pattern). *Anal.* calcd. for **2**: C 29.97, H 3.12; found: C 30.02, H 3.08%.

X-ray structure determination for 2

A suitable crystal of **2** was mounted on the end of a glass fibre and transferred to an Enraf–Nonius CAD4F diffractometer equipped with graphite monochromated Mo-K$_\alpha$ radiation. The unit cell was obtained from the accurate setting angles of 25 reflections ($25 < 2\theta < 35°$). Three standard reflections measured every two hours showed no appreciable variation with time (1.25%). The data were corrected for Lorentz polarization and analytically for absorption effects (13). Pertinent crystallographic and experimental parameters are given in Table 1.

The structure was solved by heavy atom methods, and refined by full-matrix least squares. During the course of the refinement it became apparent that the tetrafluoroborate anion was disordered and two orientations of this group were included in the refinement. Restraints were applied to the B—F bond lengths and the F—B—F bond angles (14). In addition, the sum of the occupation numbers of the two disordered sites were constrained to unity. The locations of most of the hydrogen atoms were found in difference Fourier maps but it was

decided to geometrically place these and allow them to "ride" on the carbon atoms to which they were bonded. The variables included in the final cycles of refinement were scale, extinction, positional and anisotropic thermal parameters for the silver, iridium, carbon, and oxygen atoms, positional parameters of the boron atom and fluorine atoms, one occupation parameter for the disordered site ($F(1,\text{occ}) = 0.499(22)$), an isotropic thermal parameter for the boron atoms, one overall isotropic thermal parameter for the fluorine atoms, and two overall thermal parameters for the hydrogen atoms (one for each ring).

The final residuals were $R = 0.032$, $R_w = 0.038$, and the goodness of fit was 1.070. Refinement was by full-matrix least squares minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where w was calculated from a three-term Chebyshev series so that $w = [1.709t_0(x) + 2.239t_1(x) + 0.898t_2(x)]^{-1}$, where $x = F_o - F_{max}$ (15). The refinement was considered complete when the ratio of all shifts to esd's was less than 0.1. The highest peak in the final difference map was 1.06(3) e $Å^{-3}$ and was situated 1.183 Å from Ir(1). Complex neutral atom scattering factors were taken from International Tables for Crystallography (16). Calculations were carried out on a Microvax II computer with use of the NRC VAX Crystal Structure System (17) and the CRYSTALS suite of programs (18). Positional parameters are given in Table 2. Selected bond distances and angles are listed in Table 3. Anisotropic thermal parameters, hydrogen atom coordinates, and tables of calculated and observed structure factors are available as supplementary material.[5]

Polyfluoroaralkyl amines. Further studies on the reactivity of 4,5,6,7-tetrafluoroindole

ROBERT FILLER, SARAH M. WOODS, AND WILLIAM L. WHITE
Department of Chemistry, Illinois Institute of Technology, Chicago, IL 60616, U.S.A.

Received February 20, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

ROBERT FILLER, SARAH M. WOODS, and WILLIAM L. WHITE. Can. J. Chem. **67**, 1837 (1989).

4,5,6,7-Tetrafluoroindole **1** undergoes electrophilic formylation and aminoalkylation at C-3 to give compounds that can be readily converted to a variety of products, including the skatole, tryptamine, and tryptophan. **1** reacts with ethyl diazoacetate to yield 4,5,6,7-tetrafluoroethyl-3-indole acetate. The Grignard reagent of **1** offers a direct route to the versatile substituted acetonitrile **10** via C-3 alkylation with chloroacetonitrile.

Key words: tetrafluoroindole, tetrafluorotryptamine, tetrafluoroindolyl magnesium bromide, tetrafluorotryptophan.

ROBERT FILLER, SARAH M. WOODS et WILLIAM L. WHITE. Can. J. Chem. **67**, 1837 (1989).

Le 4,5,6,7-tétrafluoroindole (**1**) subit des formylation et des aminoalkylation en C-3 qui fournissent des produits qui peuvent facilement être transformés en une variété de composés comprenant le skatole, la tryptamine et le tryptophane. Le composé **1** réagit avec le diazoacétate d'éthyle pour conduire au 4,5,6,7-tétrafluoroindole-3-acétate d'éthyle. Le réactif de Grignard du composé **1**, par le biais d'une alkylation en C-3 à l'aide du chloroacétonitrile, offre une voie d'accès directe vers l'acétonitrile substitué **10** qui est très versatile.

Mots clés : tétrafluoroindole, tétrafluorotryptamine, bromure de tétrafluoroindylmagnésium, tétrafluorotryptophane.

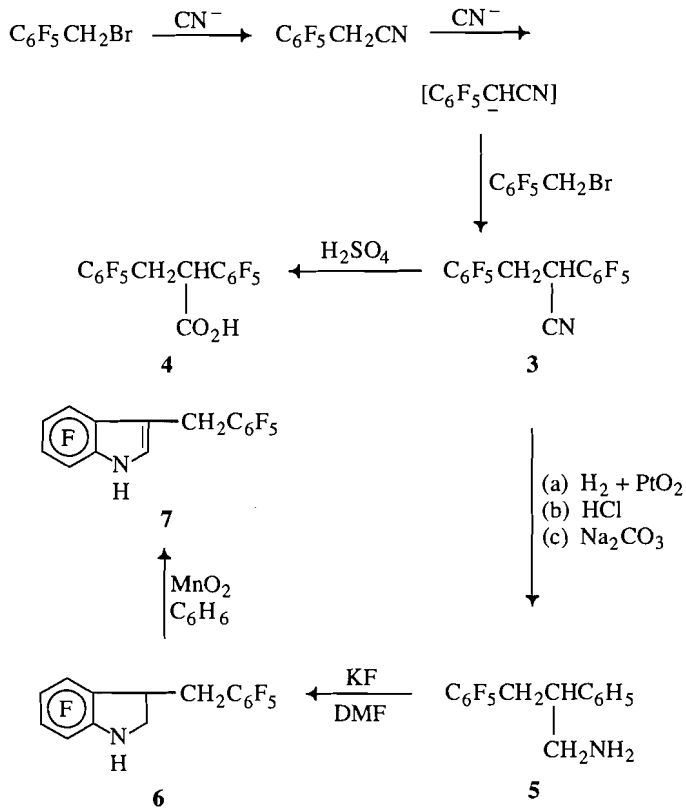
In previous papers (1–3), we reported the chemistry of polyfluoroaralkyl amines, including the facile synthesis of 4,5,6,7-tetrafluoroindole **1** (3). This compound and other fluorine-containing amines are of interest as potential bioactive molecules, especially as central nervous system agents. Although Yakobson and co-workers (4–7) and Fujita and Ojima (8) have previously described some reactions of **1** and substituted analogs, we wish to report new observations that extend the chemistry of this heterocyclic system. Compound **1** was readily prepared by aromatization of the indoline **2**, which was obtained by fluoride-catalyzed nucleophilic cyclization of 2-pentafluorophenylethylamine (Scheme 1) (3).

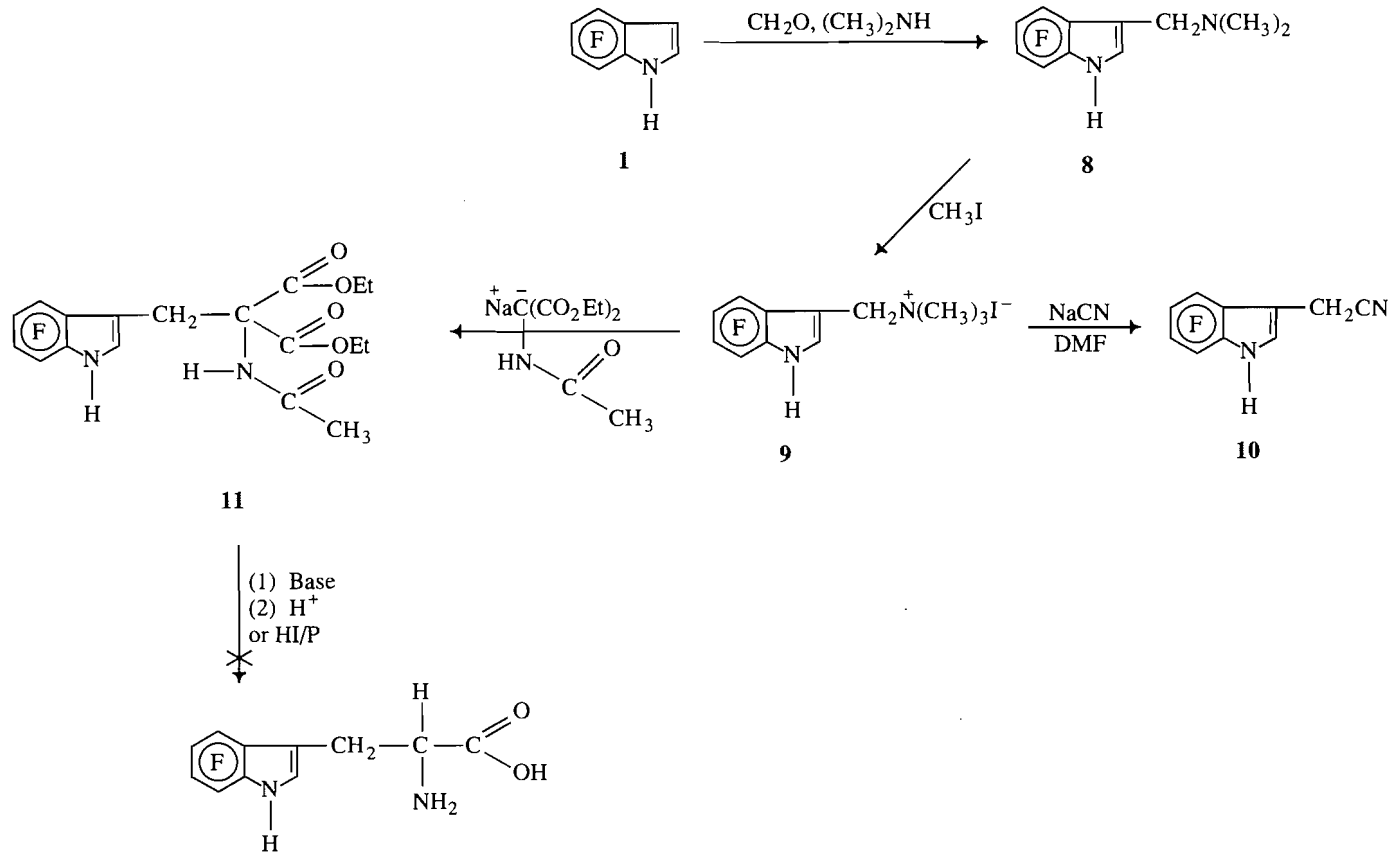


The 3-substituted tetrafluoroindole **7** was similarly obtained (Scheme 2). A by-product of this synthesis was the previously unreported carboxylic acid **4**.

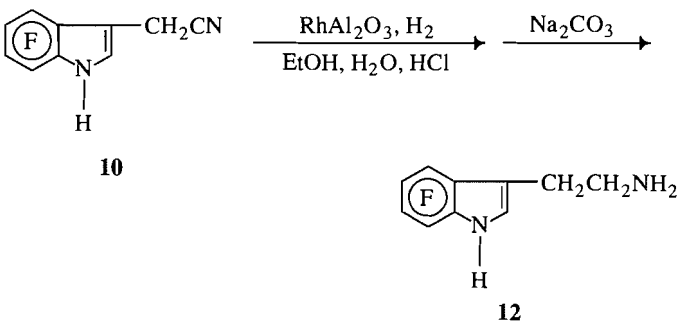
Electrophilic reactions of 4,5,6,7-tetrafluoroindole

The Mannich reaction of **1** afforded the gramine **8**, which readily formed the methiodide **9**. The 3-cyanomethyl compound **10** was obtained on reaction of **9** with NaCN. Sodiodiethylacetamidomalonate and **9** gave **11**, which we were unable to convert to the tetrafluorotryptophan (Scheme 3).

SCHEME 1



SCHEME 2



Catalytic hydrogenation of **10** afforded a low yield of the tryptamine **12**, which was unstable on standing, probably owing to intermolecular displacement of fluoride by the free amine.

Vilsmeier formylation of **1** readily yielded the 3-carboxaldehyde **13**, from which the skatole **14**, carboxylic acid **15**, and *N*-acetylazlactone **16** were easily prepared (Scheme 4). A small quantity of tetrafluorotryptophan **17** was obtained via compound **16**.

Printed in Canada / Imprimé au Canada

SCHEME 3

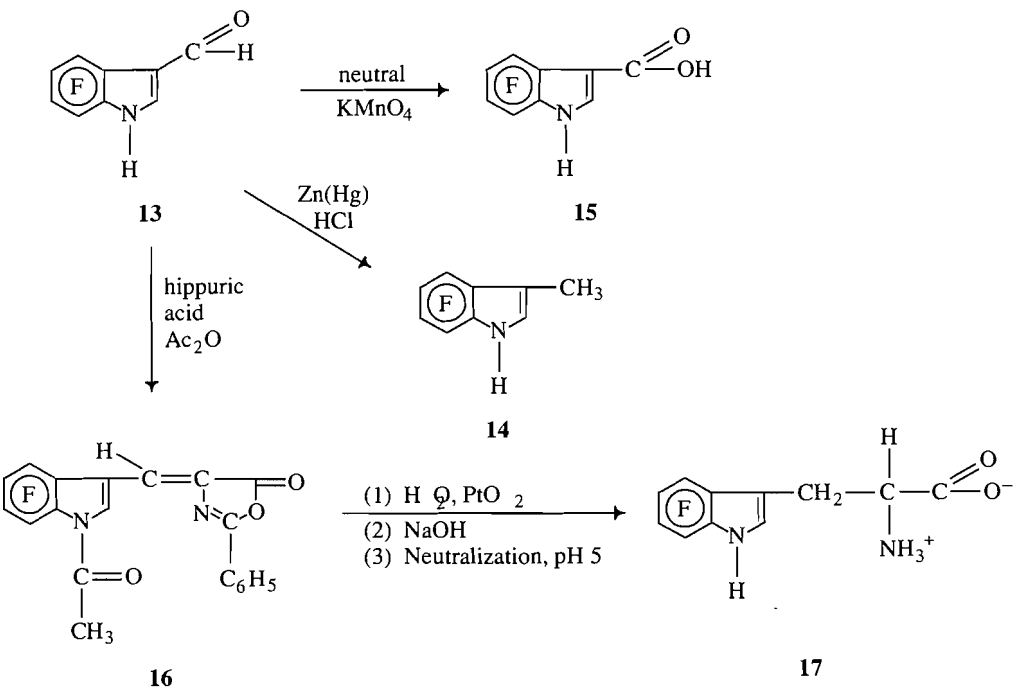
The reaction of **1** with an electrophilic carbenoid species is illustrated by the facile formation, using ethyl diazoacetate, of the corresponding ethyl 3-indole acetate **18**.

The Grignard reagent derived from **1** was easily prepared by reaction with ethyl magnesium bromide in tetrahydrofuran solvent. C-3 alkylation with chloroacetonitrile then gave a 50% yield of **10** as the sole isolable product. This method offers a much more direct route to **10** than the nucleophilic displacement reaction.

Experimental

2-Cyanodecafluorodibenzyl (3)

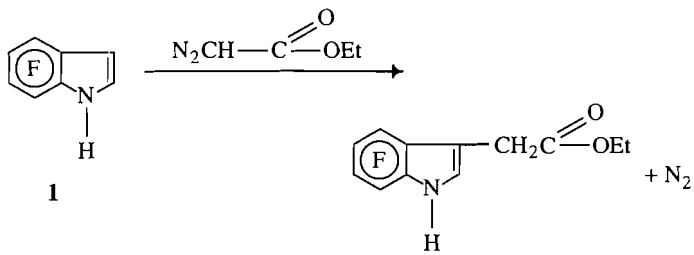
A mixture of 53.0 g (0.203 mol) of 2,3,4,5,6,-pentafluorobenzyl bromide (9) and 14.1 g (0.21 mol) of potassium cyanide in 140 mL of ethanol was heated with stirring at 75–80°C for 45 min. Work-up and fractionation of the residual oil through a 10-cm Vigreux column gave 32.47 g (78% yield) of 2,3,4,5,6-pentafluorophenylacetonitrile, bp 98–101°C (13 Torr; 1 Torr = 133.3 Pa) and 7.5 g (19% yield) of the dibenzyl. The dibenzyl compound appeared as a white sublimate in the Vigreux column as soon as the boiling point began to drop. Heating was continued, with warm water flowing through the condenser, until about 3.5 g of this material was collected. The dark solid remaining in the flask was dissolved in hot 95% ethanol and treated with decolorizing carbon. Light tan prisms were isolated, mp 125°C. The crystallized material was combined with the sublimate and all of the material was sublimed at 120°C/6 Torr to give a purified sample, mp 132°C; ir (hexachlorobutadiene mull): 2825, 2920 (s, CH_2 and CH_3), 2250 (s, CN), 1500 and 1140 (s, CF), 1610 and 1570 (s, aromatic); ^{1}Hmr (acetone-d_6) δ: 3.78 (d, fine structure, 2, CH_2), 5.13 (t, fine structure, 1, CH); mass spectrum (70 eV) *m/e*: 387 (M^+); calcd.: 387. *Anal.* calcd. for $C_{15}H_3F_{10}N$: C 46.53, H 0.77, N 3.62; found: C 46.18, H 0.71, N 3.42.



2,3-Bis(pentafluorophenyl) propionic acid (4)

2-Cyanodecafluorodibenzyl (1.0 g, 2.57 mmol) was placed in a 50-mL round-bottom flask and wet thoroughly with a chilled mixture of 2.4 g concentrated H_2SO_4 (25 mmol) and 1.8 mL of water. The mixture was heated rapidly, using a bunsen burner through a small (ca. 2 cm) hole in an asbestos sheet. The boiling was continued for 5 min. After allowing the mixture to cool to room temperature, it was diluted with ice-cold water. The precipitate was filtered on a Buchner funnel and washed several times with cold water. The yield of this crude material was 1.06 g (100%). After several recrystallizations from acetone using decolorizing carbon, a white crystalline substance was obtained, mp 167°C; ir (hexachlorobutadiene mull): 3540–3000 (br, OH), 2920, 2844 (CH), 1730 (s, C=O), 1640, 1520, 1450 (aromatic), 1500, 1150 (CF) cm^{-1}; mass spectrum (70 eV) *m/e*: 406 (M^+); calcd.: 406. *Anal.* calcd. for $C_{15}H_4F_{10}O_2$: C 44.17, H 0.99, N 0.00; found: C 44.18, H 0.78, N trace.

2-Pentafluorophenyl-2-pentafluorobenzylethylamine (5)



2-Cyanodecafluorodibenzyl (**3**) (7.74 g, 20 mmol) was dissolved in 150 mL of ethyl acetate in a 500-mL Parr flask. To this solution was added 50 mL of water containing 7 mL of concentrated hydrochloric acid and 0.10 g of platinum oxide. The two-phase mixture was cooled below 20°C and shaken on a Parr hydrogenation apparatus until hy-

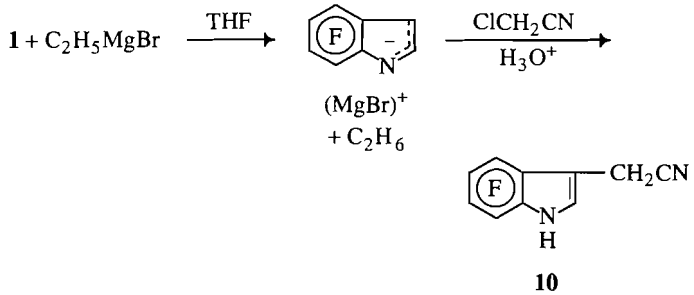

SCHEME 4

1 18

drogen uptake ceased. The light tan crystals that precipitated during the hydrogenation were collected on a filter. The filtrate, after concentration on a rotary evaporator, yielded 0.5 g of additional product. The solids were combined and washed on the filter with anhydrous ether, then with acetone, and dried. The combined mass was 7.0 g (82%), mp 220°C (dec.); mass spectrum (70 eV) *m/e*: 392, 427 (M^+); calcd.: 427. *Anal.* calcd. for $C_{15}H_8F_{10}NCl$: C 42.13, H 1.87, N 3.27; found: C 42.06, H 1.64, N 3.27.

Six grams (14 mmol) of the amine hydrochloride were dissolved in a chilled solution of sodium carbonate. The basic aqueous cold solution was extracted with several portions of ether. The combined ethereal layers were washed with water and dried over anhydrous $MgSO_4$. A white solid remained after evaporation of the ether *in vacuo*. The yield was 3.0 g (55%). The solid was recrystallized from CCl_4, using Norite as a decolorizing agent, and dried. The material was light-sensitive and reddened rapidly; ir (CCl_4): 3500–3000 (br, NH), 2940, 2800 (CH), 1650 (s, NH), 1540, 1450 (aromatic), 1500, 1130 (vs, CF) cm^{-1}; ^{1}Hmr

10

(CCl_4–acetone-d_6) δ: 4.73 (m, 1, C*H*), 3.66 (m, 4 C*H*), 2.2 (s, 2, N*H*). *Anal.* calcd. for $C_{15}H_7F_{10}N$: C 45.90, H 1.79, N 3.58; found: C 45.54, H 1.29, N 3.43.

3-Pentafluorobenzyl-4,5,6,7-tetrafluoroindoline (6)

For this preparation, the amine formed from 3.35 g (10 mmol) of **3** was not isolated. The ethereal layer was stripped *in vacuo*, until about 10 mL of solution remained. A 250-mL one-necked flask was fitted with an adapter for condenser, carrying a calcium chloride tube and nitrogen inlet tube. After the addition of 150 mL of dry DMF and 1.5 g of anhydrous potassium fluoride, the contents were stirred magnetically and refluxed for 3 h. The DMF was removed by distillation at 10 Torr. The residue remaining was transferred to a sublimator and sublimed at 60°C (0.5–1.5 Torr). After 4 days, 1.5 g of a white solid had sublimed, melting range 72–110°C; ^{1}Hmr δ: 3.3 (m), 3.6 (m); mass spectrum (70 eV) *m/e*: 419 (very small) M^+; base peak 372, which is the molecular mass of the indoline **6**; *Anal.* calcd. for $C_{15}H_6F_9N$: C 48.30, H 1.44, N 4.02; found: C 46.61, H 1.07, N 3.67.

Pentafluorobenzyl-4,5,6,7-tetrafluoroindole (7)

Several batches of impure indoline were combined to total 1.8 g (5 mmol). Seven grams of MnO_2 and 50 mL of dry benzene were added to it in a 125-mL round-bottom flask. The mixture was cooled to 20°C and placed on a wrist-action shaker for 24 h. After filtration through a Celite filter and on a Buchner funnel, the solid was extracted in a Soxhlet for 7 h. Solvent was removed from the combined solutions by vacuum distillation. The addition of water to the residue in the flask caused the formation of white crystals. The crystals were filtered, dried, and sublimed twice at 80°C, 0.7–1.0 Torr. One gram (60%) of this material was obtained, mp 115°C; ^{1}Hmr (acetone-d_6) δ: 8.75 (br, m, 1, N*H*), 6.90 (m, 1, C*H*), 4.20 (s, 2, CH_2); mass spectrum (70 eV) *m/e*: 369 (M^+); calcd.: 369. *Anal.* calcd. for $C_{15}H_4F_9N$: C 48.80, H 1.08, N 3.79; found: C 48.74, H 1.02, N 3.68.

3-Dimethylaminomethyl-4,5,6,7-tetrafluoroindole (4,5,6,7-tetrafluorogramine) (8)

To 0.85 mL of 5.2 N aqueous dimethylamine (ca. 0.25% solution, 4.42 mmol), cooled in an ice bath, was added first 0.60 g (10.0 mmol) of cold glacial acetic acid and, secondly, 0.34 g of cold 37% aqueous formaldehyde (6.3 mmol). To the resulting solution was added 0.75 g (3.98 mmol) of 4,5,6,7-tetrafluoroindole (**1**). After the indole had partially dissolved, the mixture was allowed to warm to room tempera-

ture and stirred magnetically overnight or placed on a wrist-action shaker. A solution of 0.55 g of sodium hydroxide in 10 mL of water, cooled to 0°C, was added with vigorous stirring and, after the mixture was cooled for about 2 h in an ice bath, the resulting precipitate was broken up, filtered, washed with three 10-mL portions of cold water, and dried to constant weight *in vacuo* at 50°C. The yields of crude material were suitable for subsequent reactions. An analytical sample was prepared by three recrystalliztions from $CHCl_3$, mp 133°C; ir ($CHCl_3$): 3460 (s, NH_2), 2942, 2860, 2820, 2790 (br, CH), 1600, 1530, 1480, 1420 (aromatic), 1010 (CF) cm^{-1}; ^{1}Hmr (acetone-d_6-DMSO-d_6) δ: 9.03 (b, 1, N*H*), 7.33 (s, 1, C*H*) 3.5 (s, 2, CH_2), 2.17 (s, 6, N-(CH_3); mass spectrum (70 eV) *m/e*: 246 (M^+); calcd.: 246. *Anal.* calcd. for $C_{11}H_{10}F_4N_2$: C 53.63, N 3.71, N 11.07; found: C 53.41, H 3.82, N 11.22.

*4,5,6,7-Tetrafluorogramine methiodide (**9**)*

To 18.0 g (0.127 mmol) of purified CH_3I, contained in a glass bottle chilled in ice, was added slowly 0.71 g (2.9 mmol) of 4,5,6,7-tetrafluorogramine. The mixture was stirred magnetically during the addition, and for 45 min afterwards. The solid gramine did not dissolve completely. The container was capped and placed in a refrigerator at 10°C for 6 h, then shaken on a wrist-action shaker for 24 h. The resulting solid was filtered, air-dried, and desiccated over $CaCl_2$. The crude material weighed 1.00 g (99.0% yield) and was recrystallized by dissolving in 8 mL of warm methanol, cooling, and adding hexane until a slight turbidity was observed. This suspension was placed in a refrigerator until crystallization occurred. After three recrystallizations, the material was dried in an Abderhalden flask with refluxing acetone at 2 Torr. The yellowish crystals melted at approximately 270°C; ir (hexachlorobutadiene mull): 3400, 3320 (m, br. NH), 3120 (s), 3020, 2980, 2840, 1580, 1500, 1450 (aromatic), 1010 (CF) cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 8.33 (m, ~1, N*H*), 7.6 (m, 1, C*H*), 5.1 (m, 2, CH_2), 3.2 (m, 9, N(CH_3)$_3$); mass spectrum (70 eV) *m/e*: 388 (M^+); calcd.: 388. *Anal.* calcd. for $C_{12}H_{13}F_4N_2I$: C 37.13, H 3.75, N 7.16; found: C 37.78, H 3.54, N 6.88.

*3-Cyanomethyl-4,5,6,7-tetrafluoroindole (**10**)*

To 0.393 g (10 mmol) of 4,5,6,7-tetrafluorogramine methiodide, in a 50-mL three-necked flask fitted with a reflux condenser, nitrogen inlet tube, and stopper, were added 25 mL of DMF and 9.8 mg (2.0 mmol) of reagent grade sodium cyanide, with magnetic stirring. The gramine methiodide did not dissolve entirely in this amount of solvent. The mixture was refluxed for 2 h, cooled, reduced to a volume of about 10 mL by vacuum distillation, transferred to a 50-mL separatory funnel, and extracted with three 8-mL portions of ether. The ethereal extracts were dried over anhydrous $MgSO_4$, filtered, and evaporated to dryness on a rotary evaporator. The 13 mg of solid (60% yield) was transferred to the sublimation apparatus and the purified material collected at 95°C and 0.7 Torr. After three sublimations the material melted at 133°C (lit. (4) mp 134°C); ir (hexachlorobutadiene mull): 3400–3120 (br, but sharp, NH), 3120, 3080, 2940, 2900 (w, CH), 2260 (s, CN), 1580, 1490, 1440 (aromatic), 1000 (CF) cm^{-1}; ^{1}Hmr (CCl_4) δ: 11.8 (s, 1, N*H*), 7.62 (m, 1, C*H*), 4.05 (m, 2, CH_2).

*Reaction of **9** with sodiodiethylacetamidomalonate*

A three-necked round-bottom flask fitted with a condenser, a nitrogen inlet tube, and a pressure equalizing dropping funnel was flamed and continuously purged with a positive nitrogen pressure. In this apparatus was placed 5.0 g (22 mol) of sodiodiethylacetamidomalonate, 17 mL of purified dry DMF, and 1.0 g (3 mmol) of 4,5,6,7-tetrafluorogramine methiodide. By use of an oil bath, the mixture was kept at 55°C for 22 h, by which time the reaction mixture had become maroon in color. The solution was poured into 40 mL of water at 0°C with stirring. The resulting crystals were filtered off and recrystallized from 80% ethanol to give 0.58 g of product (41%), mp 200°C becoming mp 205°C, after repeated recrystallizations and sublimation at ca. 180°C (0.7–2 Torr); ^{1}Hmr (acetone-d_6, CCl_4) δ: 7.7 (m, 1, N*H*), 7.12 (m, 1, C*H*), 5.2 (s, 1, N*H*), 4.17 (q, 4, CH_2), 3.73 (s, 3, CH_2) 3.4 (s, 2, CH_2), 1.21 (t, 6, CH_3). *Anal.* calcd. for $C_{18}H_{18}O_4F_4N_2$: C 51.37, H 4.53, N 6.67; found: C 51.37, H 4.28, N 6.47.

4,5,6,7-Tetrafluorotryptamine hydrochloride

To 0.85 g (3.72 mmol) of 3-cyanomethyl-4,5,6,7-tetrafluoroindole dissolved in 100 mL absolute ethanol was added 20 mL of water containing 4 mL of 12 N HCl and 0.2 g of Rh–Al_2O_3 catalyst. The mixture was reduced on a Parr apparatus. Only one half of the theoretical amount of hydrogen reacted. The mixture was filtered and concentrated on a rotary evaporator until yellow needles precipitated. These were filtered, washed with anhydrous ether, and dried to give 0.29 g (32%), mp 240°C; ^{1}Hmr (D_2O) δ: 7.60 (m), 3.50 (complex multiplet).

*4,5,6,7-Tetrafluorotryptamine (**12**)*

To 10 mL of a chilled aqueous solution of sodium carbonate was added 0.29 g (1.1 mmol) of the tryptamine hydrochloride. The resulting solution was extracted with several portions of ether and the combined ethereal extracts were washed with water and dried over anhydrous $MgSO_4$. The ether was removed *in vacuo* to give 100 mg (49%) of white solid, mp 125–130°C. Chromatography on 5 g of neutral alumina yielded a white substance. Before a melting point was determined, the material began to turn blue.

*3-Formyl-4,5,6,7-tetrafluoroindole (**13**)*

In a 150-mL round-bottom three-necked flask fitted with a nitrogen inlet tube, a drying tube containing calcium chloride, and a 50-mL dropping funnel was placed 7.24 g (10.2 mmol) of freshly distilled dimethylformamide. The flask and contents were cooled in an ice–salt bath and stirred magnetically for about half an hour. Freshly distilled phosphorus oxychloride (4.5 g, 23 mmol) was added dropwise over a period of 15 min. The mixture turned yellow. The first dropping funnel was replaced with a second charged with 1.0 g (5.3 mmol) of 4,5,6,7-tetrafluoroindole dissolved in 7.24 g (10.2 mmol) of DMF. The mixture was added dropwise over a period of 0.5 h and the temperature not allowed to rise above 10°C during the addition. The mixture was heated with stirring to 35°C and maintained at this temperature for 3 h. Crushed ice (30 g) was added and a solution of 2.2 g NaOH in 6 mL water was added dropwise to the reaction mixture. The mixture was then heated rapidly to boiling and the flask placed in the refrigerator overnight. The precipiate was collected, suspended in water, filtered, and washed. The precipitate was air-dried and sublimed twice at 110°C and 0.7 Torr; 1.02 g (89%); ir ((KBr): 3040 (s, NH), 3180 (s), 3140, 2920, 2820, 2770 (CH), 1680–1640 (br, sharp, C=O), 1550, 1480 (aromatic), 1500, 1000 (CF) cm^{-1}; mass spectrum (70 eV) *m/e*: 217 (M^+); calcd.: 217. *Anal.* calcd. for $C_9H_3F_4ON$: C 49.79, H 1.38, N 6.45; found: C 49.63, H 1.42, N 6.33.

*3-Methyl-4,5,6,7-tetrafluoroindole (**14**)*

In a three-necked 100-mL flask fitted with a 50-mL dropping funnel and reflux condenser was placed 1.0 g of freshly prepared amalgamated zinc. Concentrated hydrochloric acid (5 mL) was added dropwise. The contents were stirred magnetically and heated to gentle reflux. 95% Ethanol (15 mL) containing 0.3 g (1.5 mmol) of 4,5,6,7-indole-3-carboxaldehyde was added dropwise and the mixture refluxed for 30 min. The cooled mixture was decanted from the unreacted zinc, taken up in carbon tetrachloride, and neutralized with sodium bicarbonate. The organic layer was washed with water, dried over anhydrous $MgSO_4$, filtered, and concentrated *in vacuo* to give white crystals, which were purified by sublimation at 35°C and 0.8 Torr, mp 94–95°C; ^{1}Hmr (CCl_4) δ: 7.67 (very broad, 1, N*H*), 6.83 (m, 1, C*H*), 2.40 (s, 3, fine structure, CH_3). *Anal.* calcd. for $C_9H_5F_4N$: C 53.20, H 2.41, N 6.89; found: C 53.60, H 2.49, N 6.72.

*4,5,6,7-Tetrafluoroindole-3-carboxylic acid (**15**)*

A solution of 0.503 g (3.08 mmol) of potassium permanganate in 15 mL of water was added with stirring to 0.5 g (2.5 mmol) of the aldehyde **13** dissolved in 15 mL of acetone. The temperature was maintained between 30 and 40°C. After 5 min the purple color of potassium permanganate disappeared and the brown precipitate of MnO_2 formed. The mixture was filtered on a Buchner funnel using Celite filter aid. The filtrate was concentrated on a steam bath and a white precipitate formed after addition of six drops of 6 N hydrochloric acid. The precipitate was dissolved in sodium bicarbonate, reprecipitated with a few drops of 6 N HCl, and dried, mp 233°C, 0.537 g (90%); ir (hexachlorobutadiene

mull): 3400 (s, NH), 3260 (w), 2920, 2840 (CH), 1720–1650 (s, C═O), 1580, 1540, 1440 (aromatic), 1500, 1000 (CF) cm^{-1}; ^{1}Hmr (acetone-d_6) δ: 8.33, 8.15, 6.67; mass spectrum (70 eV) *m/e*: 233 (M^+); calcd.: 233. *Anal.* calcd. for $C_9H_3F_4O_2N$: C 46.33, H 1.29, N 6.49; found: C 46.07, H 1.11, N 6.29.

*Azlactone of 4,5,6,7-tetrafluoroindole-3-carboxaldehyde (**16**)*

A mixture of 0.35 g (2.4 mmol) of hippuric acid and 0.20 g (2.5 mmol) of anhydrous sodium acetate, 0.5 g (2.4 mmol) of 4,5,6,7-tetrafluoroindole-3-carboxaldehyde, and 6.12 g (9.2 mmol) of freshly distilled acetic anhydride was warmed in a loosely corked 25-mL Erlenmeyer flask with magnetic stirring until solution was complete. A deep orange suspension formed immediately. After filtration, the material was recrystallized from benzene and dried, mp 254–256°C, yield 89%; mass spectrum (70 eV) *m/e*: 402 (M^+); calcd.: 402. *Anal.* calcd. for (N-acetylated compound) $C_{20}H_{10}N_2O_2F_4$: C 59.72 H 2.45, N 6.98; found: C 59.56, H 2.42, N 6.95. After hydrolysis in dilute sodium hydroxide a white solid formed and was removed by filtration. The filtrate was concentrated *in vacuo* and the total solid (0.42 g, 50% yield) was taken up in 25 mL of ethyl acetate, 3 drops of concentrated HCl added, and 0.1 g platinum dioxide added to the mixture. The mixture was reduced on a Parr apparatus until hydrogen uptake ceased. The mixture was neutralized, separated from the water phase, and the ethyl acetate removed on a rotary evaporator. Infrared analysis suggests that the substance is 4,5,6,7-tetrafluorotryptophan, **17**; ir (hexachlorobutadiene mull): 3450 (s, NH), 3300 (br, OH in CO_2H), 2960, 2840 (CH), 1770–1670 (br, C═O, 1600, 1540, 1440 (aromatic), 1500, 1000 (CF) cm^{-1}.

*Ethyl-3-(4,5,6,7-tetrafluoroindolyl) acetate (**18**)*

In a 50-mL three-necked flask fitted with a 125-mL pressure equalizing dropping funnel, a condenser carrying a calcium chloride drying tube at the top, and a nitrogen inlet tube was placed 1.0 g (5.7 mmol) of 4,5,6,7-tetrafluoroindole and 2.62 g (22.8 mmol) of ethyl diazoacetate (10). The mixture was stirred magnetically and heated for 5 h at 140°C, using an oil bath. The contents of the flask were then dissolved in ether, washed with water, dried, and sublimed at 60°C and 0.7 Torr to give 0.50 g of a crystalline material, mp 91°C. This material was unreacted indole. The remainder of the material, 1.50 g (80% yield), was transferred to a 50-mL flask fitted with a condenser and refluxed with a mixture of 0.74 g (1.0 mmol) of methanesulfonic acid and 1.0 g (22 mmol) of formic acid for 5 h to give a bright red mixture. This mixture was extracted with several portions of ether and aqueous Na_2CO_3. The aqueous layer yielded no crystals when acidified. The combined ethereal layers were washed with water and dried over anhydrous $MgSO_4$. Concentration *in vacuo* left a red viscous oil. Chromatography on 5 g of Al_2O_3 using ether–hexane provided no separation. Spectral characterization showed no hydrolysis had occurred; ir (neat): 3460 (w, NH), 3300 (s, NH), 2980, 2940, 2860 (s, CH), 1780, 1670, 1550, 1480, 1440 (aromatic), 1490, 1000 (CF) cm^{-1}; ^{1}Hmr (CCl_4) δ: 9.4 (1, N*H*), 7.10 (m, 1, C*H*), (q, 2, CH_2), 3.80 (s, 2, CH_2), 1.3 (t, 3, CH_3).

Preparation of the 4,5,6,7-tetrafluoroindole Grignard reagent

Two grams (10.6 mmol) of 4,5,6,7-tetrafluoroindole dissolved in 20 mL of anhydrous THF was added dropwise to a 100-mL 3-necked flask containing ethyl bromide (0.952 g, 8.9 mmol) dissolved in 40 mL of THF, and magnesium turnings (0.312 g, 13 mmol), in a nitrogen atmosphere. The mixture was allowed to reflux for 0.5 h.

Reaction of 4,5,6,7-tetrafluoroindole Grignard reagent with chloroacetonitrile

Chloroacetonitrile (0.09 g, 13.24 mmol) was dissolved in 5 mL of dry THF and added dropwise to the Grignard reagent. The mixture was heated, using an oil bath, for 0.5 h. After cooling, the material in the flask was worked up. Crystals formed, mp 132°C. The product was 4,5,6,7-tetrafluoroindolylacetonitrile, obtained in 50% yield. Its ^{1}Hmr was superimposable with that of **10**.

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

PRESTON J. MACDOUGALL, MICHAEL B. HALL, RICHARD F. W. BADER, and JAMES R. CHEESEMAN. Can. J. Chem. **67**, 1842 (1989).

The Laplacian of the electronic charge density demonstrates the presence of local concentrations of charge in the valence shell of an atom in a molecule. These local maxima faithfully duplicate in number, location, and size the spatially localized electron pairs of the VSEPR model. Thus the Laplacian of the charge density provides a physical basis for the Lewis and VSEPR models. The VSEPR model can fail to predict the observed geometry when a transition metal is the central atom in the system. In such a case there is no basis within the model itself to predict the existence of the nonbonded pair or pairs of electrons whose presence would account for the observed geometry. By appealing to the Laplacian of the charge density in one such system, namely $VOCl_3$, one observes that the penultimate shell of charge concentration of this transition metal atom exhibits nonbonded concentrations of charge with the locations and properties required to account for the observed geometry of the molecule. Thus the properties of the Laplacian distribution, which are model independent, can be used to extend the applicability of the VSEPR model to those cases where the usual arguments fail to account for the number and type of charge concentrations that exist within the outer shell of an atom.

Key words: Laplacian of the charge density, VSEPR model, transition metal.

PRESTON J. MACDOUGALL, MICHAEL B. HALL, RICHARD F. W. BADER et JAMES R. CHEESEMAN. Can. J. Chem. **67**, 1842 (1989).

La distribution de Laplace de la densité de la charge électronique démontre qu'il existe des concentrations locales de charges dans la couche de valence d'un atome d'une molécule. Ces maxima locaux sont une réplique exacte du nombre, de la position et de la grandeur des paires d'électrons localisées dans l'espace du modèle VSEPR. La distribution de Laplace de la densité de charge fournit donc une base physique pour les modèles de Lewis et VSEPR. Lorsque l'atome central d'un système est un élément de transition, il existe des cas où le modèle VSEPR ne permet pas de prédire la géométrie observée. Dans un tel cas, il n'existe pas de base dans le modèle pour prédire l'existence de la paire non-liée ou des paires d'électrons dont la présence pourrait expliquer la géométrie observée. En faisant appel à la distribution de Laplace de la densité de charge d'un tel système, à savoir le $VOCl_3$, on peut observer que l'avant-dernière couche de la concentration de charge de cet élément de transition présent des concentrations de charge non-liées dont les positions et les propriétés correspondent à celles requises par la géométrie observée pour la molécule. Les propriétés de la distribution de Laplace, qui sont indépendantes du modèle, peuvent donc être utilisées pour permettre d'appliquer le modèle VSEPR aux cas où les arguments usuels ne permettent pas d'expliquer le nombre ou le type de concentrations de charge qui existent dans la couche extérieure d'un atome.

Mots clés : distribution de Laplace de la densité de la charge, modèle VSEPR, élément de transition.

[Traduit par la revue]

Introduction

The valence-shell electron pair repulsion or VSEPR model (1) is a natural extension of the localized electron pair model of Lewis (2). It has become the most successful and widely used model for the prediction of the geometries of closed-shell molecules AX_n. The VSEPR model has two basic assumptions: (1) the valence charge density of the central atom A is spatially localized into pairs of electrons, and (2) the geometrical arrangement of the ligands X about atom A is that which maximizes the separations between the pairs, assuming the pairs to be on the surface of a sphere centred on the A nucleus. In general, not all the pairs are equivalent and three subsidiary postulates are required to determine the relative sizes of the electron pair domains: (a) nonbonding pairs have larger domains than bonding pairs; (b) bonding pair domains decrease in size with increasing electronegativity of the ligand, and increase in size with increasing electronegativity of the central atom; (c) double and triple bond domains are larger than single bond electron pair domains.

The Laplacian distribution of the electronic charge density, the quantity $\nabla^2\rho$, has been shown to provide the physical basis for the Lewis and VSEPR models (3). It does this by demonstrating the presence of local concentrations of charge in the valence shell of an atom in a molecule. These local charge concentrations, local maxima in $-\nabla^2\rho$, faithfully duplicate in number, location, and size the spatially localized electron pairs of the VSEPR model (3, 4), recovering all of the properties ascribed to them as put forth in the postulates of the model. The existence and the arrangement of the local charge concentrations within the valence shell of an atom are a consequence of the partial condensation of the valence electrons into pairs (3*b*, 4). The condensation is caused by a corresponding spatial localization of the Fermi hole, a localization that arises from the ligand field acting in concert with the Pauli exclusion principle. Because of this linking of the concepts of the VSEPR model to a physical property of a system, the model is reduced to but a

single postulate. This postulate is that the most stable molecular geometry of a molecule AX_n corresponds to maximally separating, according to size and magnitude, the local maxima in the valence shell of charge concentration (VSCC) of the atom A as defined by the Laplacian of the charge density.

An advantage of finding a physical basis for a model is that one can then investigate those cases that are perhaps of greatest interest in providing a deeper understanding of the phenomena covered by the model, namely, the exceptions to the model. The VSEPR model does not fail for closed-shell systems composed of main group elements. Exceptions to the model can be found, however, for systems containing transition group elements. This brief note is an initial study of one such exception, as provided by the molecule $VOCl_3$.

The basic tetrahedral geometries of main group compounds such as POF_3 and $POCl_3$ are explained on the basis of the presence of four electron domains in the valence shell of phosphorus, three containing singly bonded pairs and one containing the two bonded pairs of the double bond. The subsidiary postulate regarding the relative sizes of single and double bond domains then correctly predicts the XPO angle to be greater than the XPX angle and for this latter angle to be less than tetrahedral in these molecules. In agreement with these predictions, the XPX angle is 101.3° in the fluoride and 103.3° in the chloride. Table 1 gives the geometrical parameters for these and other related molecules. In the compounds SO_2X_2, the XSX angle is smaller than the OSO angle. Also given in this table are data for transition metal compounds that exhibit contrasting behaviour. In the CrO_2X_2 systems, the XCrX angle is greater than the OCrO angle. In the molecule $VOCl_3$, the OVCl angle is actually slightly less than tetrahedral, being equal to 108°, thereby yielding a value of 111° for the ClVCl angle. This opening of the ClVCl angle to a value greater than the tetrahedral value cannot be explained by the VSEPR model if one assumes, as is correct for the corresponding main group compounds, that the valence shell of the central atom has but four electron domains. The model is saved if one could argue that five electron domains exist in the outermost electron shell of a transition element, with the fifth domain being located in the nonbonded position along the threefold axis, that is, opposite the oxygen atom. It is shown here that the Laplacian of the charge density for the vanadium atom in $VOCl_3$ does indeed exhibit five local maxima or local charge concentrations in its outermost shell of charge concentration, with the largest of these concentrations being found in the nonbonded position along the threefold axis. The positions of the three "bonded maxima" associated with the chlorine atoms are, however, not as anticipated on the basis of analogous behaviour with the main group compounds. A corresponding polarization of the outermost shell of charge concentration is shown to be present in the molecule VCl_3. The properties of the Laplacian distribution, which link the tenets of the model to observed properties of the charge distribution, do more than simply extend the domain of application of the model. In addition, the Laplacian of ρ delineates the differences in the properties of the electronic charge distributions that exist between main group and transition metal atoms, differences that are responsible for their differing chemical behaviour. Gillespie *et al.* (5) have stated that "the 3*d* electrons cannot be clearly identified as either valence shell electrons or as core electrons. This special nature of the 3*d* electrons is responsible for most of the unusual properties of the transition metals."

Calculations

The RHF SCF calculations for VCl_3 and $VOCl_3$ were caried out using the Huzinaga basis sets (6): V(532121*s*/5211*p*/221*d*), O(5211*s*/321*p*/1*d*), Cl(53211*s*/5211*p*/1*d*).[2] The calculations included an optimization of the geometries. The calculated geometrical parameters for $VOCl_3$ are R(V—O) = 1.501 Å, R(V—Cl) = 2.147 Å, ∠ClVCl = 110.5°, ∠OVCl = 108.4°. The agreement with the experimental values is good (see Table

[2]A single polarization function was added to each atom's basis (*d* for O, Cl and *p* for V). The V basis was that optimized for the $(3d)^4(4s)^1$ atomic state. To satisfactorily describe the diffuse charge on the ligands, diffuse *s* and *p* functions were added to their bases (exp. = 0.08 for O, 0.05 for Cl).

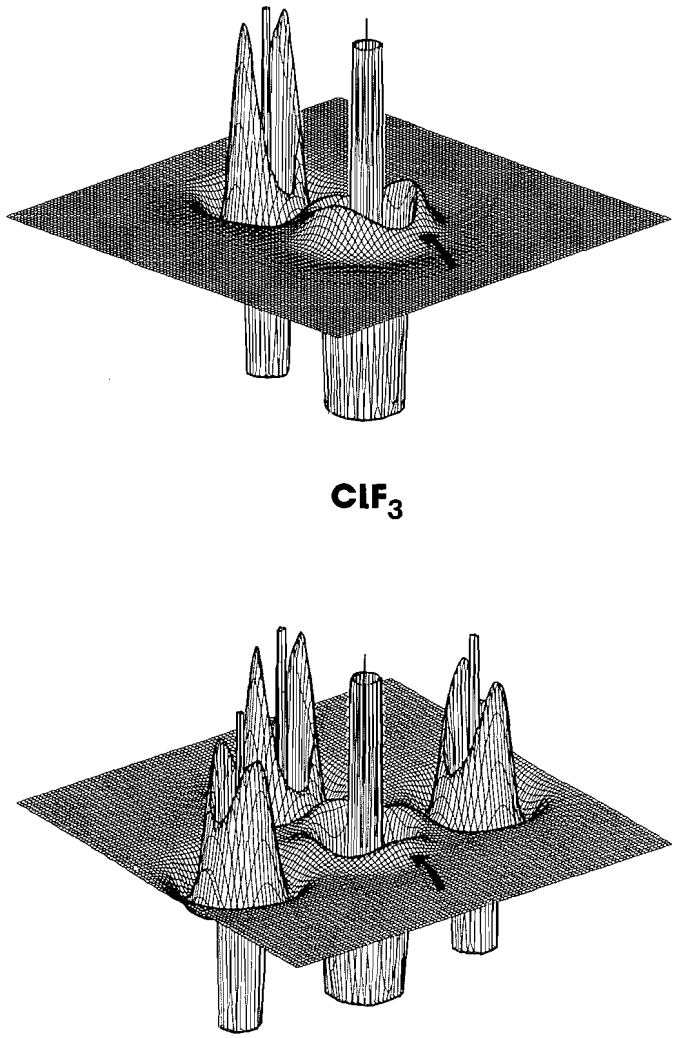

FIG. 1. Relief maps of $-\nabla^2\rho$ for the equatorial (upper) and the axial (lower) planes of ClF_3. The chlorine atom exhibits three shells of charge concentration. The equatorial plane shows the presence of two nonbonded and one smaller bonded charge concentration. In the axial plane there are three bonded charge concentrations and a fourth apparent maximum indicated by an arrow. This peak is actually another view of the (3, −1) critical point between the two nonbonded maxima, which is also denoted by an arrow. The VSCC of Cl possesses five local charge concentrations, three bonded and two larger nonbonded maxima in $-\nabla^2\rho$.

1), particularly the bond angles. The theoretical model certainly recovers the angular behaviour that is the topic of discussion. The calculated parameters for VCl_3 are R(V—Cl) = 2.184 Å, ∠ClVCl = 120.0°. The calculated energies are $E(VOCl_3)$ = −2395.66771 au, $E(VCl_3)$ = −2320.89293 au.

The VSEPR model and the local charge concentrations of the Laplacian of ρ

The spherical surface on which the electron pairs are assumed to be localized in the VSEPR model is identified with the sphere of maximum charge concentration found in the valence shell charge concentration, the VSCC, of the central atom (3), and the localized pairs of electrons are identified with the local concentrations of charge present on the surface of this sphere. This is illustrated for the chlorine atom in the molecule ClF_3 in Fig. 1. Since a local charge concentration corresponds to a maximum in $-\nabla^2\rho$, this and other relief diagrams illustrate the negative of the Laplacian of ρ, a maximum in this function being a maximum in charge concentration. There are pairs of regions, one negative, one positive, for each quantum shell, with the innermost region being a spike-like maximum in charge concentration. This shell structure is evident in the figure, with three shells being present on chlorine and two on fluorine.

The extrema in ρ or $-\nabla^2\rho$ are points where the first derivative of the scalar field vanishes. Whether such a point is a maximum, minimum, or a saddle is determined by the signs of the associated curvatures of the function at the critical point, i.e., by the eigenvalues of the Hessian of the function. If all three eigenvalues or curvatures are negative, the function exhibits a local maximum at that point, a (3,−3) critical point. If all three curvatures are positive, the function exhibits a local minimum, a (3,+3) critical point. The other two possible critical points with three nonzero curvatures are correspondingly labelled as (3,−1) and (3,+1). The outer or valence shell of charge concentration of Cl exhibits five maxima in $-\nabla^2\rho$, or local charge concentrations. There are two nonbonded and three bonded concentrations, with the size and magnitude of these maxima decreasing in the following order: nonbonded > equatorial bonded > axial bonded. The angle between the two nonbonded maxima is relatively large and equal to 148°, while the axial bonded–nonbonded angle is opened to 97°. In higher energy geometries of this molecule, the angles between the bonded and nonbonded maxima are all smaller than those found for this favoured geometry. Similar results are obtained for other molecules containing third-row elements such as ClF_3O, SF_4, SF_4O, and ClF_5 (3*a*, 4).

The Laplacian distribution of the vanadium atom is first investigated in the simpler, more symmetrical compound VCl_3. This molecule is known experimentally only in its polymeric form. The Laplacian distribution of this molecule is shown in Fig. 2. Also shown in this figure are the intersections of the interatomic surfaces as defined by the zero flux boundary condition that defines a quantum subsystem, the basis of the theory of atoms in molecules (7). All properties of such a subsystem, which is identified with an atom in a molecule, are defined by quantum mechanics. In this brief account we shall refer to only the average electron population. This is obtained by an integration of ρ over the basin of the atom. The charge on the Cl atom in ClF_3 for example is +1.56*e*. In VCl_3, the charge on the vanadium atom is +1.992*e*, 0.664*e* having been transferred to each Cl atom. The vanadium atom has the electron configuration $[Ar]4s^23d^3$ and two of the five valence electrons of V have been transferred to the ligands in VCl_3. Because of this charge transfer, the vanadium nuclear-electron attractive force increases in dominance within the atomic basin and the orbital ordering approaches more closely the true one-electron case. Thus the 3*d* orbitals are closer in spatial extent and *energy* to the *s* and *p* orbitals of the third quantum shell in the bound than they are in the free vanadium atom. This ordering of the orbital levels and the transfer of valence density are in agreement with the presence of three quantum shells on the vanadium atom (Fig. 2). As is discussed below, still stronger evidence for the mixing of the 3*d* orbitals with the 3*s* and 3*p* orbitals of the bound vanadium atom is provided by the polarizations of this shell.

Each Cl atom exhibits the anticipated three complete quantum shells, Fig. 2. The polarization of the VSCC of each of these atoms towards the positively charged vanadium atom is evident from the contour diagram of the Laplacian and there is a bonded charge concentration in the VSCC of each Cl atom of magnitude

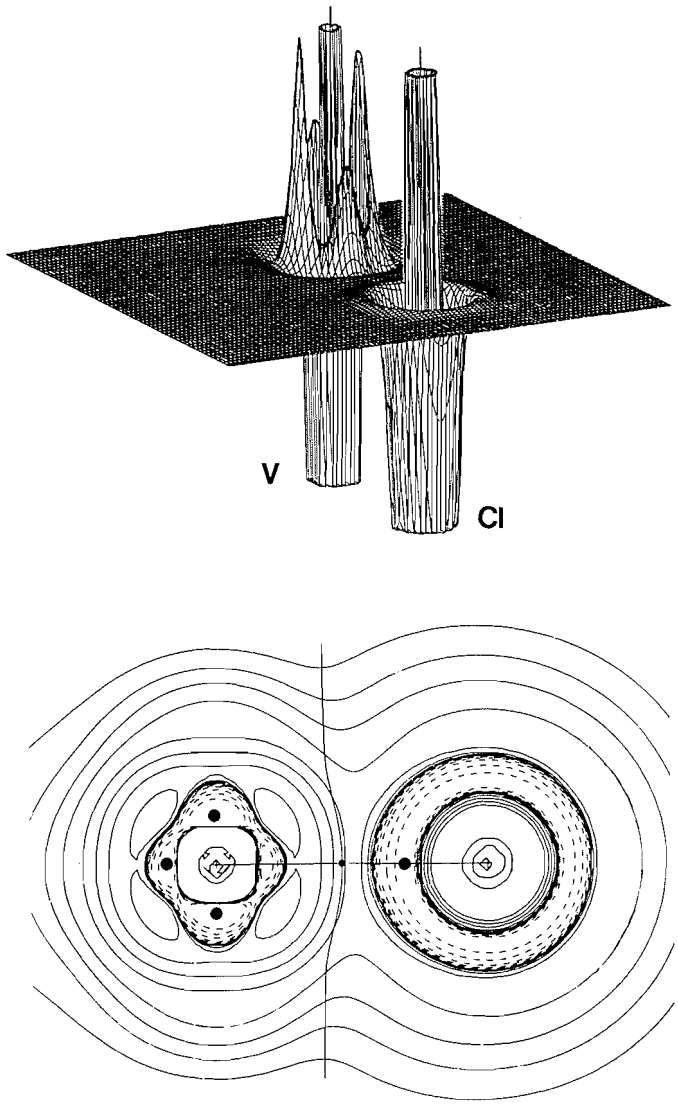

FIG. 2. Contour and relief maps of the Laplacian of ρ for VCl_3. The plane shown contains the vanadium nucleus and one of the chlorine nuclei. The dashed contours denote negative, the solid contours positive values of $\nabla^2\rho$. The interatomic surfaces and the bond paths are also shown, the bond critical points being indicated by the small dots. The large dots indicate the positions of maxima in the i-VSCC of vanadium and in the VSCC's of the ligands. Note the extreme polarization of the i-VSCC of the vanadium atom. The relief map shows that the vanadium atom does not possess a fourth or valence shell of charge concentration. The peak in the i-VSCC of vanadium nearest the Cl is a (3, −1) critical point. Directly behind it is the nonbonded maximum induced in the i-VSCC by the negatively charged Cl ligand. The two remaining and largest of the peaks in the i-VSCC are the axial nonbonded charge concentrations.

0.63 au; 1 au = 1 atomic unit = e/a_0^5. Because of its small relative magnitude, its presence is not evident in the relief map. Since vanadium does not possess a fourth shell of charge concentration, there are no bonded charge concentrations on vanadium. However, the shell of charge concentration associated with the third quantum shell of vanadium exhibits very marked polarizations. It is the thrusting of this inner shell of charge concentration of a transition metal atom into the forefront of chemical interaction with the ligands that accounts for the differing behaviour of a transition metal atom from main group elements.

The third shell of charge concentration on V shall be referred to as the inner-valence shell charge concentration, or i-VSCC. There are cases where a first-row transition metal atom still possesses a fourth shell of charge concentration, an example being $Mn_2(CO)_{10}$ (3*b*). In such a case, where the bonding to the transition metal atom involves two quantum shells, the second shell is distinguished by referring to it as the outer or o-VSCC. The i-VSCC of vanadium exhibits a (3,−1) critical point on each of the V—Cl bond paths (with a magnitude of 17 au), with its unique positive curvature lying in the plane of the nuclei. Thus this critical point appears as a two-dimensional maximum in the display shown in Fig. 2, since its two negative curvatures lie in the plane of the diagram. On the side of the i-VSCC opposite each such (3,−1) critical point is a (3,−3) critical point, or local charge concentration of magnitude 22 au. The i-VSCC is clearly very susceptible to polarization by the negatively charged ligands, and a local charge concentration is induced in this shell opposite each of the chlorine atoms. Two more maxima are present in the i-VSCC on the threefold axis on each side of the molecular plane. They are by far the largest of the local charge concentrations found in this shell, with a magnitude of 39 au. The existence of concentrations of electronic charge along distinct spatial axes indicates that the electrons in the third shell of vanadium possess significant angular momentum, and they cannot be described as occupying a closed, albeit slightly polarized, inner shell. Thus the charge concentrations in the i-VSCC of vanadium form a trigonal bipyramid, reminiscent of the set of sp^3d hybrid orbitals of the valence bond model. In agreement with the observation that the o-VSCC of vanadium is absent and that the 3*d* orbitals have reverted to the third quantum shell, the i-VSCC of vanadium can be described as possessing the configuration $3s^23p^63d^2$. There are five pairs of electrons in the third quantum shell of the vandium atom and, correspondingly, its i-VSCC exhibits five local concentrations of charge.

Figure 3 shows corresponding diagrams of the Laplacian distribution for $VOCl_3$. The vanadium atom in this molecule possess a charge of $+2.405e$, with each chlorine bearing a charge of $-0.554e$ and the oxygen one of $-0.743e$. The VSCC of oxygen exhibits a bonded charge concentration with a magnitude of 2.64 au and a single, slightly larger, nonbonded maximum of magnitude 3.09 au. The bonded charge concentration present in the VSCC of each Cl is slightly reduced from its value in VCl_3, to 0.60 au. The i-VSCC of vanadium is topologically equivalent to that found in VCl_3 — the same number and type of critical points are present in each case — but their relative magnitudes have changed in significant ways. The extent of charge concentration in the i-VSCC of vanadium is decreased relative to that found in VCl_3 because of the further loss of charge to the oxygen atom. The magnitude of the (3, −1) critical point along the bond path to each of the chlorines is decreased to 10 au and the opposing maximum induced in the i-VSCC by the presence of the negatively charged ligand is reduced in magnitude to 19 au. It is the axial charge concentrations, however, that undergo the largest changes. The magnitude of the axial charge concentration lying on the bond path to the oxygen, now a bonded charge concentration in the i-VSCC of vanadium, is reduced from 39 au to 9.5 au while the magnitude of the remaining axial concentration, a nonbonded charge concentration, is reduced by a lesser amount, to 21 au. Thus the charge concentration along the threefold axis, while reduced in magnitude from that present in VCl_3, is strongly polarized away from the oxygen into the corresponding nonbonded region.

One anticipates that the addition of oxygen to the ligand

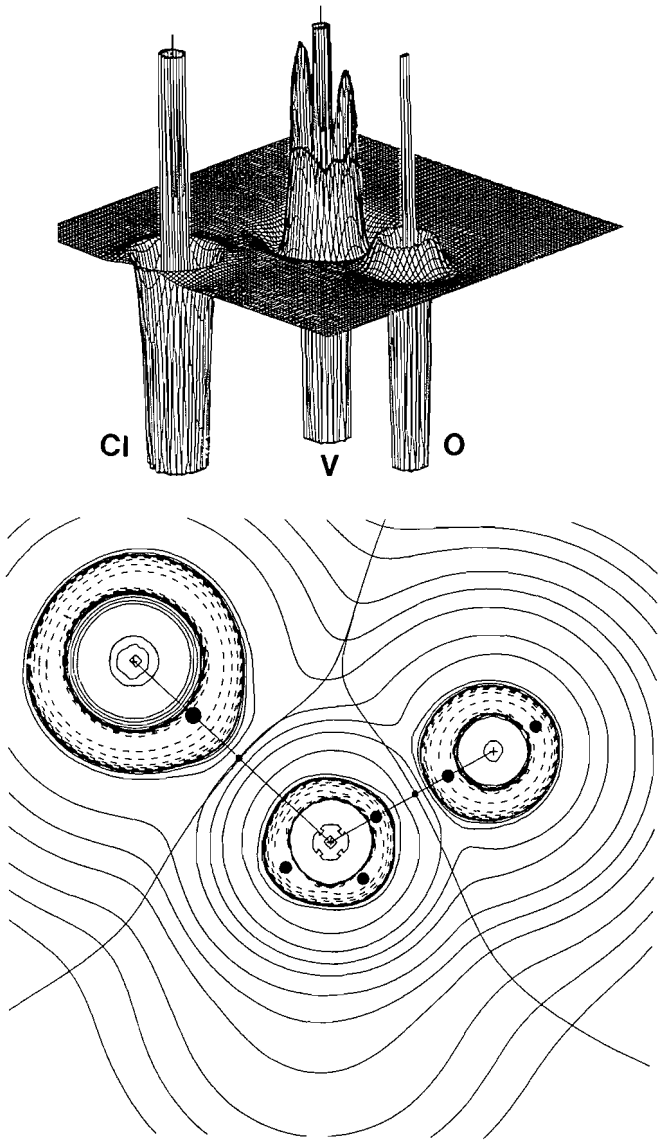

FIG. 3. Contour and relief maps of $VOCl_3$ for a plane containing the vanadium, the oxygen, and one of the chlorine nuclei. Details as for Fig. 2. Note the increase in the angle between the axial nonbonded and one of the nonbonded maxima opposite a Cl from the value of 90° found in VCl_3. The i-VSCC of vanadium in this plane exhibits three local charge concentrations — the bonded maximum nearest oxygen and the larger axial nonbonded maximum directly behind it with the nonbonded induced maximum lying between them. The peak nearest the Cl corresponds to a (3, −1) critical point.

sphere with its double-bonded domain will cause the ClVCl angle to decrease from its value of 120° in VCl_3. However, it is clear from the polarization of the i-VSCC of the vanadium that the ClVCl angle will not be reduced to less than the tetrahedral value, as would be found for a main group element, because of the presence of the axial nonbonded charge concentration, the largest of all the charge concentrations in the i-VSCC of vanadium. Because of the dominance of the nonbonded charge concentration in the i-VSCC of vanadium, the angle between it and the nonbonded charge concentration opposite each of the chlorine atoms is increased from the value of 90° in VCl_3 to 106.1°. This upward shift in these critical points away from the axial nonbonded concentration is coupled to the downward motion of the Cl ligands that are responsible for their presence. This downward motion is equilibrated for a ClVCl angle greater than tetrahedral by the approach of the bonded maxima on the chlorine ligands to the axial nonbonded maximum on the metal and by the approach of the nonbonded maxima associated with the chlorines towards the bonded maximum opposite oxygen within the i-VSCC of vanadium.

Conclusions

It has been suggested (*3b*, 4) that a modified VSEPR model be given in terms of the Laplacian of the charge density, one which is free of the assumptions regarding the existence of some number and arrangement of localized pairs of electrons with prescribed sets of properties. In the modified version of the model, this information is provided by the Laplacian of ρ, an observable and physical property of a system. The prediction of a molecular geometry then requires but a single postulate, that the minimum energy geometry is the one that maximizes the separations between the local concentrations of charge in the outer shell of charge concentration of the central atom. It is possible in some systems, particularly those involving transition metal atoms, that charge concentrations in both the o-VSCC and i-VSCC play a role in determining the geometry. The domain of applicability of the model is then extended to all systems, since the Laplacian distribution has a definable set of properties in every system. What remains to be done is to continue to categorize the properties of the Laplacian of the charge density and discover in what ways it can deviate from our models of localized electron pairs. The vanadium systems that have been discussed in this brief note illustrate how this can be done. With these examples, there can be no doubt as to the fundamental nature of the basic assumption underlying the VSEPR model, that the most stable molecular geometry is in some manner determined by maximizing the separations between local concentrations of electronic charge. The Laplacian of ρ extends the physical basis of the model and removes the constraints of its range of applicability, but Gillespie's basic assumption remains true.

Acknowledgement

The authors wish to thank Professor Gillespie for suggesting the problem addressed in this paper. They also wish to dedicate the paper to him and to his ideas. P.J.M. and M.B.H. thank the National Science Foundation (U.S.A.) for partial support of this work. P.J.M. thanks N.S.E.R.C. of Canada for the award of a postdoctoral fellowship.

"Through-space" spin–spin coupling between thallium and fluorine in fluorophenylthallium compounds

GERALD NORMAN PECKSEN AND RAYMOND FREDERICK MARTIN WHITE
Department of Chemistry, City of London Polytechnic, Jewry Street, London, England EC3N 2EY

Received January 24, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

GERALD NORMAN PECKSEN and RAYMOND FREDERICK MARTIN WHITE. Can. J. Chem. **67**, 1847 (1989).

Thallium to fluorine spin–spin coupling constants have been measured for a number of fluoro- and trifluoro-methyl-substituted mono- and di-arylthallium derivatives. The results provide evidence of "through-space" coupling in the diaryl derivatives when the fluoro- or trifluoro-methyl group is *ortho* to the thallium atom.

Key words: thallium, fluorine, NMR, through-space coupling.

GERALD NORMAN PECKSEN et RAYMOND FREDERICK MARTIN WHITE. Can. J. Chem. **67**, 1847 (1989).

On a mesuré les constantes de couplage spin–spin du thallium au fluor pour un certain nombre de dérivés mono- et di-arylthallium substitués par des groupements fluoro- et trifluoro-méthyles. Les résultats obtenus confirment que, dans les dérivés diaryles portant une groupement fluoro- ou trifluoro-méthyl en *ortho* de l'atome de thallium, il existe un couplage «à travers l'espace».

Mots clés : thallium, fluor, RMN, couplage à travers l'espace.

[Traduit par la revue]

Introduction

"Through-space" spin–spin coupling can occur when the internuclear distance between a pair of nuclei is abnormally small (1, 2). Observation of a coupling constant that is larger than might be otherwise expected is frequently taken to be indicative of a through-space mechanism (3–6). Examples of through-space coupling involving nuclei other than hydrogen or fluorine are few, but recent examples include $^{13}C-^{77}Se$ coupling in *cis*-selenoimidates (7) and $^{13}C-^{31}P$ coupling in phosphorus-substituted alkenes (8). McFarlane (9) has suggested that van der Waals penetration and concomitant through-space coupling are likely between fluorine and the magnetic nuclei of elements larger than helium, in their *o*-trifluoromethyl derivatives. Mercury and phosphorus(III) are favourable in this respect and evidence for through-space coupling in *o*-trifluoromethylphenyl derivatives of these nuclei have been reported (9, 10). A study of the thallium-to-hydrogen side-chain coupling constants for mono- and di-arylthallium derivatives in which a series of alkyl groups (CH_3-, C_2H_5-, *i*-C_3H_7-, *t*-C_4H_9-) are *ortho* and *para* to the thallium atom has provided evidence of through-space coupling between thallium and hydrogen in some of the *o*-alkylphenylthallium compounds (11).

Values of J_{Tl-H} for arylthallium compounds were first reported by Maher and Evans (12), who proposed Fermi contact as the dominant mechanism of spin–spin coupling in these compounds. The observed increase in the magnitude of J_{Tl-H} in the series R_3Tl, R_2Tl^+, and RTl^{2+} (where R is aryl) was qualitatively (12, 13) interpreted on the basis of the Fermi contact term increasing with both the effective nuclear charge (Z_{eff}) of the thallium atom and the *s*-character of the thallium valence electrons, an interpretation supported by other workers (14, 15). McKillop *et al.* (16) have measured J_{Tl-H} and J_{Tl-CH_3} for a range of arylthalliumtrifluoroacetates obtained by the direct thallation technique, and the results of their studies are in agreement with those of Maher and Evans (12, 13). The large differences in the coupling constants for Tl–*o*H, Tl–*m*H, and Tl–*p*H make possible the unambiguous determination of the orientation of any substituent with respect to the thallium atom and to distinguish among mono-, di-, and tri-arylthallium compounds.

From homonuclear double resonance (H–{H}) experiments Maher and Evans (12) were able to show that in any one of the compound types R_3Tl, R_2TlX, or $RTlX_2$ the couplings $^3J_{Tl-H}$, $^4J_{Tl-H}$, and $^5J_{Tl-H}$ all had the same *relative* sign. Hildenbrand and Dreeskamp (15) used heteronuclear double resonance to determine signs of coupling constants relative to $^1J_{C-H}$ and $^3J_{H-H}$ (experimental evidence (17) has shown that the absolute sign of $^3J_{H-H}$ in *p*-nitrotoluene is positive) for a number of organometallic compounds. Their measurements on a liquid ammonia solution of diphenylthallium chloride showed that all thallium-to-hydrogen coupling constants are positive for this compound.

Although the nmr spectra of arylthallium compounds have been extensively studied, little has been reported on the nmr spectra of fluorophenylthallium derivatives (ref. 18, and references therein). Deacon *et al.* have reported parameters, including signs of some coupling constants, for a number of polyfluorophenylthallium derivatives (18). They find that the general pattern of thallium-to-fluorine constants $^3J > {}^4J > {}^5J$ and $^nJ_{R_2TlX} > {}^nJ_{R_3Tl\cdot dioxane}$ parallels the behaviour of thallium-to-hydrogen coupling constants and they conclude that thallium-to-fluorine coupling is probably dominated by the Fermi contact term.

The aim of the present work was to investigate the possibility of through-space coupling between thallium and fluorine in suitable compounds and evidence is presented for the occurrence of this coupling mechanism in *o*-fluoro- and *o*-trifluoromethylphenylthallium derivatives. To detect the effects of through-space coupling it is necessary to compare coupling constants in structurally similar compounds that differ only in the proximities of possibly interacting groups. In this study mono- and di-aryl compounds in which the groups of interest are *ortho*, *meta*, and *para* to the thallium atom are compared, and where possible the signs as well as the magnitudes of the coupling constants have been determined. Through-space coupling might be possible for the *ortho*-substituted derivatives whereas *meta* and *para* substitution offers no opportunity of a through-space contribution to the coupling constant because of the greater distance separating the coupled nuclei. In addition it would be expected (11) that the through-space effect would be less

pronounced for monoarylthallium derivatives than for the corresponding diaryl compounds.

Results and discussion

Initial heteronuclear double irradiation experiments, interpreted on the basis that $^3J_{H-H}$ in aryl groups is positive, showed that, as expected, Tl–H coupling constants in monoarylthallium compounds are all positive.

Values of $^nJ_{Tl-F}$ (n = 3–5) for fluorophenylthallium compounds in which fluorine is directly bonded to the aromatic ring are given in Table 1; different couplings to the isotopes ^{203}Tl and ^{205}Tl were not resolved but showed up as broadening of lines. Double resonance experiments showed that all thallium-to-ring-fluorine coupling constants are positive, and these are discussed further below. The coupling constants show the same trend as $^nJ_{Tl-H}$, decreasing in the order $^3J_{Tl-F} > {}^4J_{Tl-F} > {}^5J_{Tl-F}$. The second trend followed by thallium–hydrogen couplings, $^nJ(RTlX_2) > {}^nJ(R_2TlX) > {}^nJ(R_3Tl)$, which was found to be followed by $^nJ_{Tl-F}$ in di- and tri-polyfluorophenylthallium compounds (18), is, in the present work, found to be followed by mono- and difluorophenylthallium compounds only when n = 4 or 5; when n = 3 the thallium-to-fluorine coupling constant in R_2TlX is *greater* than the corresponding coupling constant in $RTlX_2$. This anomalous result suggests that although J_{Tl-F} in these compounds is dominated by the Fermi contact term an additional mechanism can operate when thallium is *ortho* to a fluorine atom in the aromatic ring.

It is not possible to calculate accurate internuclear distances and thence the extent of penetration of van der Waals radii of nuclei in arylthallium compounds; however, reasonable approximations (11) indicate that there is steric overcrowding between *ortho* thallium and fluorine atoms, the overcrowding and associated through-space effect being more pronounced in diarylthallium derivatives than it is in monoarylthallium. The anomalously high values of $^3J_{Tl-F}$ are then interpreted as arising from a positive through-space contribution to the coupling that is greater in bis(*o*-fluorophenyl)thallium than in mono-(*o*-fluorophenyl)thallium derivatives.

Double resonance experiments have shown (12, 15) that in phenylthallium compounds all J_{Tl-H} have the same sign. Similar experiments in the present work show that for fluorine attached to the aromatic ring in mono- and di-fluorophenylthallium derivatives all J_{Tl-F} are positive. This is in contrast to the report by Deacon *et al.* (18) that $^3J_{Tl-F}$ and $^4J_{Tl-F}$ are positive while $^5J_{Tl-F}$ is negative. In their discussion of J_{Tl-H} in polyfluorophenylthallium compounds they make the point that while fluorine is strongly inductively electron withdrawing through σ bonds, it is electron donating by resonance effects through π bonds; hence multiple fluorine substitution could shift $^5J_{Tl-H}$ in the opposite direction from $^3J_{Tl-H}$ and $^4J_{Tl-H}$. If $^5J_{Tl-F}$ is transmitted via both σ and π bonds and these effects are opposed, the net result could be the small negative coupling that they observed for $^5J_{Tl-F}$. The present work provides some support for this suggestion in that $^5J_{Tl-F}$ in 4-fluorophenylthallium bis(trifluoroacetate) is +242 Hz while in 2,4-difluorophenylthallium bis(trifluoroacetate) it is only +68 Hz; in the corresponding diaryl compounds the values of $^5J_{Tl-F}$ are +121 and +18 Hz, showing a marked decrease in $^5J_{Tl-F}$ when an additional fluorine atom is attached to the aromatic ring.

In addition to the above investigation, compounds containing a trifluoromethyl substituent in the aromatic ring were studied and the thallium-to-fluorine coupling constants for these are given in Table 2; where experimental difficulties allowed (see experimental section), the signs of these coupling constants were also determined and are included in the table. In the mono-(trifluoromethylphenylthallium) halides $^nJ_{Tl-F}$ follows the same pattern of signs as $^nJ_{Tl-CH_3}$ in methylphenylthallium derivatives, with ^4J and ^6J negative and ^5J positive. Surprisingly, in bis(2-trifluoromethylphenyl)thallium bromide $^4J_{Tl-F}$ is positive. In addition, this compound shows an unusually large solvent dependence of $^4J_{Tl-F}$, which varies from 58 Hz for a solution of the compound in chloroform to being unresolvably small

	Br	P			38

*Solvent P = C_5D_5N, A = $(CD_3)_2CO$, C = $CDCl_3$.
†Signs of coupling constants were only obtained from solutions in acetone-d_6.

in a pyridine solution. Titration with pyridine of a chloroform solution containing a known amount of bis(2-trifluoromethylphenyl)thallium bromide gave an almost linear decrease of $^4J_{Tl-F}$ to 29 Hz at an approximately 1:1 ratio of pyridine to thallium; after this the decrease of $^4J_{Tl-F}$ with added pyridine was much slower and only in the presence of a large excess of pyridine did the coupling become undetectably small. Thallium-to-hydrogen coupling constants in this compound show no such unusual variation; $^3J_{Tl-H}$ varies only from 477 Hz (chloroform solution) to 470 Hz (pyridine solution).

Through-space coupling is to be expected for magnetic nuclei of elements larger than helium in their *o*-trifluoromethyl derivatives (9), and the through-space effect is expected to be more pronounced in diaryl- than in monoaryl-thallium compounds (11). The observed couplings observed for the trifluoromethylphenyl derivatives can then be interpreted in terms of a dominant positive through-space coupling in bis(2-trifluoromethylphenyl)thallium bromide, giving a resultant positive $^4J_{Tl-F}$, while in the mono-(2-trifluoromethylphenyl) derivative any smaller through-space contribution is dominated by a negative through-bond coupling.

The results of the titration experiment are consistent with an appreciable interaction between pyridine and thallium. If the through-space contribution to coupling depends on the extent to which fluorine lone-pair orbitals overlap empty thallium orbitals, the presence of a competing pyridine ligand coordinating to the thallium atom could reduce the availability of thallium orbitals and hence reduce the through-space contribution. If this were a major factor a similar effect would be expected for the coupling in bis(2-fluorophenyl)thallium derivatives. Table 1 contains two examples that show that a change from acetone to pyridine solvent leads to an *increase* in $^3J_{Tl-F}$, suggesting that in fact reduced availability of thallium orbitals on coordination of pyridine does not influence the through-space contribution to coupling. A second possible explanation of these results comes from McFarlane's discussion of through-space coupling between mercury and fluorine in 2-trifluoromethylphenylmercury compounds (9). Here it has been suggested that the shortest mercury–fluorine separation (on the assumption of free rotation of the trifluoromethyl group) is more significant than the mean mercury–fluorine distance, as through-space coupling will depend on $\langle r^{-n} \rangle$ rather than $\langle r \rangle^{-n}$ where r is the mercury–fluorine separation and n is fairly large. If similar considerations apply to the thallium compounds considered here, then coordination of pyridine molecules could introduce a steric hindrance to the free rotation of the trifluoromethyl group, resulting in an increase in $\langle r^{-n} \rangle$ (where r is now the thallium–fluorine separation) and consequently a decrease in the through-space contribution to the coupling. Such a steric effect might not eliminate the through-space contribution completely, for as one fluorine atom in the trifluoromethyl group is moved away from the vicinity of the thallium atom one of the other fluorine atoms of the group approaches the thallium atom, a case of "the further off from England the nearer is to France" (19). More experimental data, including information on degrees of ionization and dissociation and on possible dimer formation, are necessary for better understanding of the unusual solvent effects described above.

Experimental

Instrumentation

The nmr spectra were recorded using a JEOL C-60-H spectrometer operating at 60 MHz for ^1H and 56.45 MHz for ^{19}F. The second radiofrequency field for heteronuclear double resonance experiments was derived from a frequency synthesizer (Schlumberger FS 30 digital signal generator) and fed via a tuned amplifier to a tuned circuit with a coil within the spectrometer probe. An auxiliary stabilized 20-MHz output of the frequency synthesizer was used as the master oscillator of the spectrometer so that there were no relative frequency drifts. As the organothallium compounds studied gave rise to slightly broadened spectra, an external field/frequency lock was found to be adequate. The spectrometer could be operated in either field or frequency sweep mode, the latter being used for double resonance experiments.

Determination of the relative signs of coupling constants requires a minimum of three coupled nuclei, AMX, and an experiment in which the spectrum of A is observed while the sample is irradiated at the frequency of an M transition (A–{M} experiment) can then give the relative signs of J_{AX} and J_{MX} (ref. 20, and references therein). Magnitudes of J_{Tl-F} were determined from ^{19}F spectra, which could also be used to obtain the range of ^{19}F frequencies required for double resonance experiments. Signs of J_{Tl-F} were then obtained relative to J_{Tl-H} (shown to be positive with respect to $^3J_{H-H}$). Difficulties were encountered with the trifluoromethyl derivatives as $^4J_{H-F}$ in these compounds is small and only gives rise to a broadening of peaks in the ^1H spectrum. However, by the use of low power radiofrequency fields for double irradiation it was possible in favourable cases to detect sharpening of peaks in H–{F} experiments and hence to determine relative signs. Low solubility and peak broadening prevented sign determinations in the cases of bis(3-trifluoromethylphenyl)thallium bromide and bis(4-trifluoromethylphenyl)thallium bromide.

Preparation of compounds

As previously (11), organothallium compounds were prepared by standard methods. Direct thallation of substituted benzenes by thallic trifluoroacetate (McKillop *et al.* (21)) yields an arylthallium bis(trifluoroacetate) and addition of this to trimethyl phosphite yields the diarylthallium trifluoroacetate, McKillop *et al.* (13). Reaction of an arylboronic acid with aqueous thallic chloride gives either mono- or di-arylthallium chlorides depending on the relative quantities of the reactants (22). Substituted boronic acids are prepared by reaction of an aryl Grignard derivative with a borate ester followed by hydrolysis to produce the boronic acid (23, 24). Diarylthallium compounds were also obtained by reaction of thallic halide with the appropriate Grignard reagent at 0°C, followed by hydrolysis and extraction with pyridine (12).

A nuclear magnetic resonance spectroscopic study of some tri-sulfide bridged ferrocenes

IAN R. BUTLER[1] AND WILLIAM R. CULLEN
The Chemistry Department, The University of British Columbia, Vancouver, B.C., Canada V6Y 1Y6

Received November 29, 1988

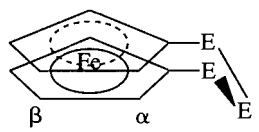
This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

IAN R. BUTLER and WILLIAM R. CULLEN. Can. J. Chem. **67**, 1851 (1989).

The synthesis of some new $[S_3]$-bridged aminoferrocenophanes is described. The ^1H nuclear magnetic resonance spectra of these compounds are completely assigned and are discussed in terms of the stereochemistry of the tri-sulfide bridge. In addition $^{13}C/^1H$ correlation spectra of one of the derivatives are presented to illustrate the complete assignment of the ^{13}C spectrum.

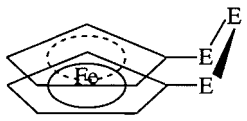
Key words: ferrocene derivatives, sulfur-bridged, synthesis, NMR, conformation.

IAN R. BUTLER et WILLIAM R. CULLEN. Can. J. Chem. **67**, 1851 (1989).



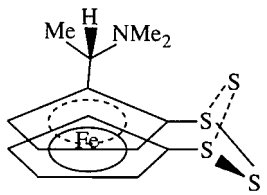
On décrit la synthèse de quelques nouveaux aminoferrocènophanes comportant des ponts de $[S]_3$. On a attribué toutes les bandes des spectres RMN du ^1H de ces composés et on les discute en fonction de la stéréochimie du pont trisulfure. Afin d'illustrer l'attribution complète des spectres du ^{13}C, présente aussi le spectre de corrélation $^{13}C/^1H$ d'un de ces dérivés.

Mots clés : dérivés du ferrocène, ponts de soufre, synthèse, RMN, conformation.



[Traduit par la revue]

Introduction



The stereochemistry of chalcogen bridged [3]-ferrocenophanes has been investigated by a number of workers (1–5) since the preparation of the first compound, **1** E = S (2), and an extensive series of such compounds now exists. Abel and coworkers (3, 5) have prepared and carried out nmr studies on a variety of these compounds. They established, by dynamic band shape fitting, that the barrier to the bridge reversal process (**1***a* ⇌ **1***b*) is relatively high, lying in the range 60–80 kJ mol^{-1}. The temperature of coalescence of the α-ferrocenyl ring protons, adjacent to the heteroatom substituent, is higher than that of the β protons. This reflects the large chemical shift differences observed between the individual α protons (compared to those of the β protons) caused by the anisotropic effect of the heteroatoms.

1*a*

1*b*

2*a,b*

Our initial interest in this class of compounds arose because the formation of [3]-ferrocenophanes, from the reaction of hetero-ring dilithiated ferrocenes, proved to be a useful method for establishing the sites of lithiation (6). We are now beginning to study the reaction chemistry of [3]-ferrocenophanes such as **2** in which a ring substituent in addition to the chalcogen atoms is available for coordination; the few reports on this topic to date (7–9) indicate that this will be a fruitful area to study in depth.

[1]Present address: Chemistry Department, University of Ottawa, Ottawa, Ont., Canada.

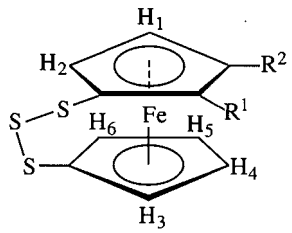
*Difficult to estimate because of the poorly resolved spectrum.
†The isomers may be **5***b* (major) and **5***a* (minor).

The present paper describes the synthesis of a number of new S_3-bridged ferrocenophanes that also have an amine function in the molecule. The nmr spectra of these products are described in relation to their assignment and the presence of diastereomers.

Experimental

The ^1H nmr spectra were recorded by using Bruker WH-400, WM-270, or Varian XL-300 spectrometers, SUPER-COSY experiments were conducted as previously described (1). Mass spectra were recorded by using a Kratos MS-50 instrument (probe temperature, 150°C). Elemental analyses were performed by Mr. Peter Borda of this department. Solvents were distilled prior to use after predrying by conventional methods. *N,N'*-dimethylaminomethylferrocene (10) was purchased from Strem Chemicals Inc. and was dried under vacuum prior to use, and *n*-butyllithium solutions were obtained from Aldrich Chemical Company. Selected spectroscopic data for new compounds are given in the tables.



Preparation of **4**

To a solution of *N,N'*-dimethylaminomethylferrocene (2.0 g, 8.23 mmol) in diethyl ether (25 mL), was added 5.1 mL of a 1.6 M solution of *n*-butyllithium. The reaction solution was stirred for 2 h and a further 5.5 mL of *n*-butyllithium solution and TMED (1.0 g, 8.62 mmol) were added. The reaction solution was stirred overnight. Elemental sulfur (1.0 g, 3.9 mmol, S_8) was then added carefully and the reaction mixture was stirred for a further 2 h before it was hydrolyzed with a saturated solution of sodium bicarbonate (ca. 25 mL). The ether fraction was separated and the aqueous phase (and solids) was extracted with ether (3 × 40 mL). The combined ether fractions were evaporated to dryness. The solid residue was washed with hot petroleum ether (bp

30–60°C), 30 mL. The residue was next extracted with CH_2Cl_2 (15 mL). The resultant solution was filtered through a small column containing alumina (2 cm thick). A top layer of hexane (20 mL) was added to the dichloromethane solution and the mixture was cooled to −20°C for 3 days during which time crystals of **4** grew as yellow nodules (yield 65–70% including a second crop from the concentrated solutions of the supernatant). *Anal.* calcd. for $C_{13}H_{15}FeNS_3$: C 46.29, H 4.41, N 4.15; found: C 45.78, H 4.52, N 4.26.

Preparation of 5

A solution of 1,1'-bis(α-*N*,*N*'-dimethylaminobenzyl)ferrocene (11) (1.0 g, 2.2 mmol) in diethyl ether (80 mL) was treated with a solution of *n*-butyllithium in hexane (3.0 mL, 1.6 M). The reaction mixture was stirred overnight before excess sulfur (1.0 g, 3.9 mmol) was added. After the reaction mixture was stirred for a further 2 h, it was hydrolyzed and worked up as described for the preparation of **4**. Crystallization of the dichloromethane solution gave **5** (15–25%) as yellow/orange nodules. These were characterized by mass spectroscopy (Table 3), and ^1H nmr spectroscopy: major isomer δ: 2.01 (s, 6, $2N(CH_3)$), 2.06 (m, 1), 3.33 (m, 1), 3.38 (m, 1), 3.53 (m, 1), 4.37 (m, 1), 4.55 (m, 1) (ferrocenyl protons), 3.51 (s, 1, *CH*), 7.20–7.34 (m's, 10, $2C_6H_5$)).

Preparation of 6

A solution of 2-(*N*,*N*'-dimethylaminomethylferrocenyl)diphenylphosphine (12) (1.0 g, 2.34 mmol) in diethyl ether (25 mL) was treated with a solution of *n*-butyllithium in hexane (3.0 mL, 1.6 M) and TMED (0.5 g, 4.3 mmol). The reaction mixture was stirred at 20°C for 12 h and then was carefully treated with excess sulfur (1.0 g, 3.9 mmol). The remaining work-up procedure was identical with that described for the preparation of **4**. The hexane washings yielded a small quantity of **6** in addition to the bulk portion obtained from dichloromethane/hexane as golden orange crystals (total yield 45%). *Anal.* calcd. for $C_{25}H_{24}FeNPS_4$: C 54.25, H 4.37, N 2.53; found: C 54.44, H 4.45, N 2.53.

Results and discussion

The reaction of the dilithio derivative of ferrocenyldiphenylphosphine with S_8 affords two isomers ***3a*** and ***3b*** in the ratio 3:1 (1); both isomers have eclipsed cyclopentadienyl rings in the solid state like **1**, E = S (13). Because both isomers contain a disubstituted cyclopentadienyl ring, resulting in planar chiral-

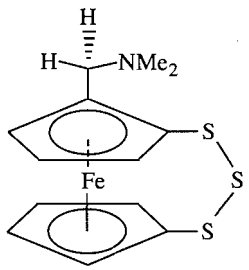
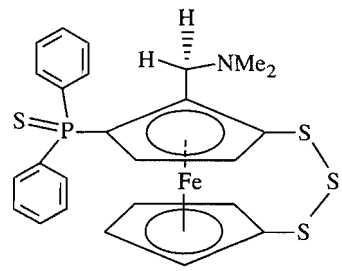
3a *3b*



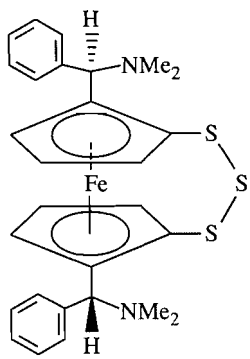
ity, and an S_3-bridge, they can exist as diastereomeric conformers defined by the conformation of the half chair. Nuclear magnetic resonance studies show that at room temperature in solution **3***a* exists as a 60:40 mixture of conformers while **3***b* exists predominantly as one diastereomer (>90%). The predominant conformers in solution are those indicated by the full lines of **3***a* and **3***b* (1).

We previously described the synthesis of **2** from the reaction of dilithiated α-*N*,*N*′-dimethylaminoethylferrocene with S_8 (6), and now report that **4**, **5**, and **6** can be prepared similarly from the appropriate starting material.



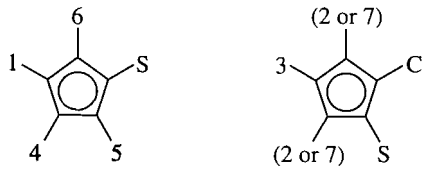
The reactions require little comment apart from noting that **5** is the product, obtained in low yield, from a crystalline precursor mixture of *rac* and *meso* 1,1′-disubstituted ferrocenes (11) and that lithiation of amino substituted ferrocenes is almost exclusively directed to the ring position adjacent to the substituent (14). Of course, lithiation of an unsubstituted cyclopentadienyl ring is random.

The ^{1}H nmr spectra of the products **2**, **4**–**6** reveal the presence of isomers in solution, as found for solutions of **3***a* and **3***b*. These new spectra can be completely assigned using a similar strategy to that used for the conformers of **3***a* and **3***b* (1). As an example, the assignment of the ^{1}H nmr spectrum of **2** is made as follows.



At ambient temperature the ^{1}H nmr spectrum of **2** shows two sets of resonances, Fig. 1, which are associated with the two

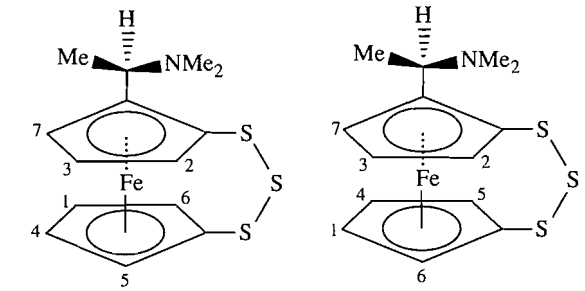
4



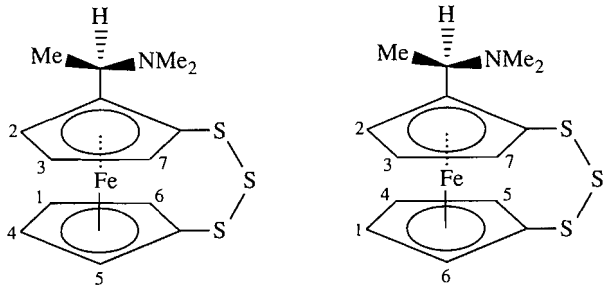
6

5

conformers **2α** and **2β**. All seven ferrocenyl protons in each conformer are magnetically inequivalent and the cyclopentadienyl region (δ 3.50–5.05) of the spectrum consists of 14 multiplets (7 major, 7 minor, Fig. 1b). Integration of the spectrum gives the ratio of **2α** to **2β** as 73:27. Considerable resonance overlap is apprent. It should also be noted that the spectra are solvent dependent and some subtle changes result on changing solvents, the most important of these being the possible transposition of resonances 3 and 4.



The initial proton resonance assignments for the major conformer **2α** were made following the application of homonuclear decoupling in conjunction with resonance line shape analysis. On this basis the monosubstituted ring of **2α** can be fully assigned as shown in **A**; however, there are two alternate formulations, **B**, of the disubstituted ring because protons 2 and 7, adjacent to the sulfur substituted carbon, cannot be unequivocally assigned using only this information. Previous nmr studies on



A **B**

S_3-bridged ferrocenophanes show that the chemical shift of the protons adjacent to the S_3-bridge is highly dependent on the stereochemistry of the bridge itself.

The information gained from decoupling experiments is verified on examination of the SUPER-COSY (15) spectrum of **2**, Fig. 2, which shows all the connectivities of the ferrocenyl protons; for example, the connectivities of resonances 1, 4, 5, and 6 are easily discerned in the figure. In addition, resonance 2 can be assigned tentatively to the proton adjacent to the C substituent since a cross peak is observed between resonance 2 and the α-C*H* resonance. Thus, by using the available information to this point, four possible resonance assignments of **2α** can be made, shown as **C**–**F**. There is a preference for **E** or **F**

C **D**

E **F**

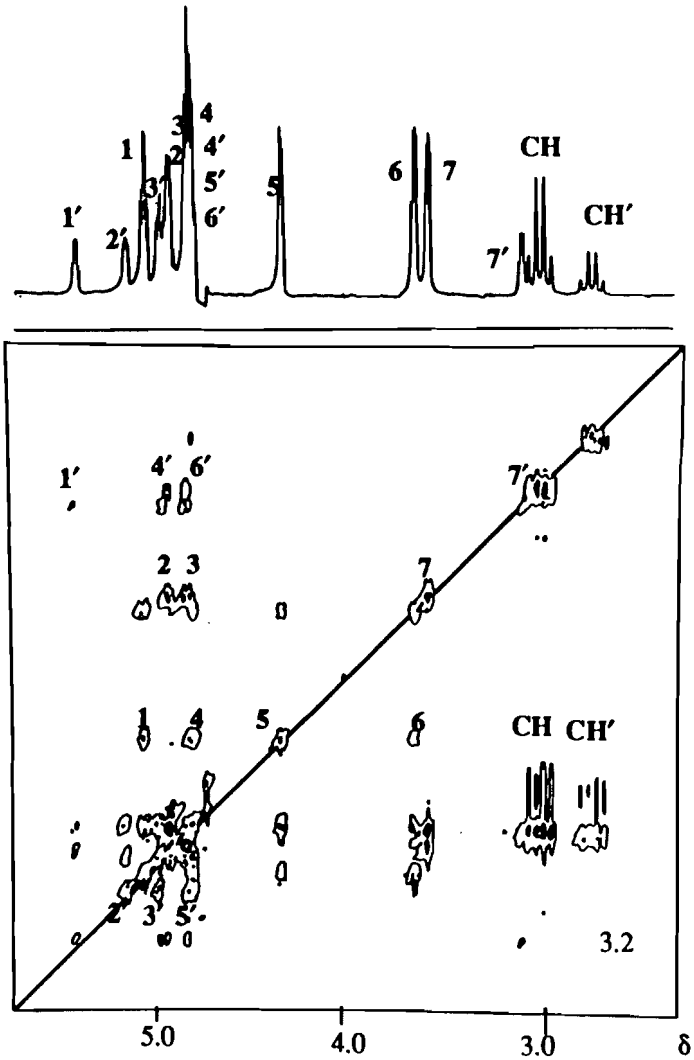


FIG. 2. The SUPER-COSY spectrum of **2** (ferrocenyl region).

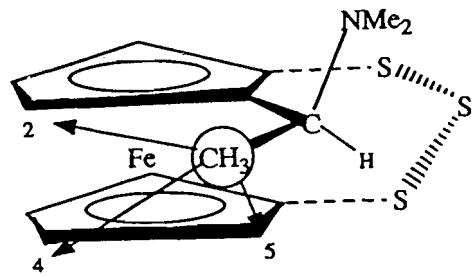

FIG. 3. Observed nOe enhancements on irradiating the C-methyl protons of **2**.

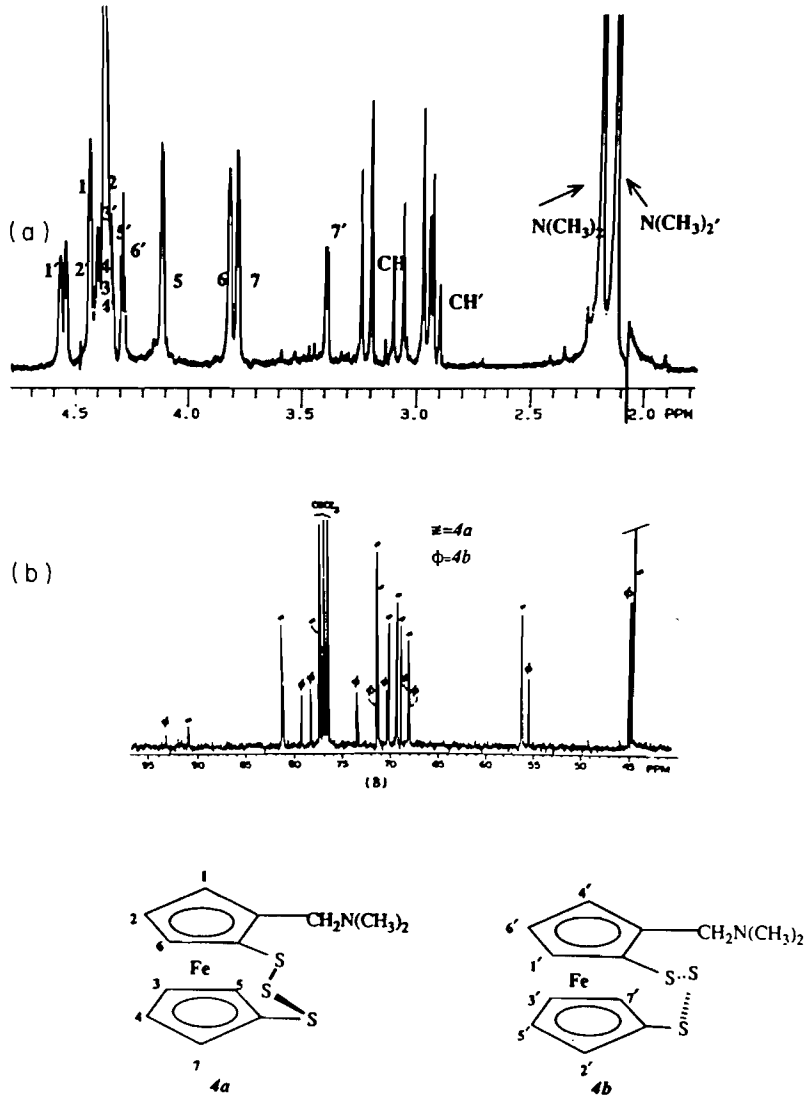
because of the assignment of resonance 2. It should be emphasized that the stereochemistry of the S-bridge is not indicated, although it is expected that the major isomer present in solution would be the one in which, for steric reasons, the middle S atom in the bridge is directed away from the ring substituent (1).

It should be noted that although many of the ferrocenyl proton resonances of the minor conformer **2β** are hidden in the normal 1-D spectrum because of overlap, the SUPER-COSY spectrum technique allows the complete positional characteriztion of all the resonances (1′–7′).

To complete the resonance assignments of **2** to specific proton

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.



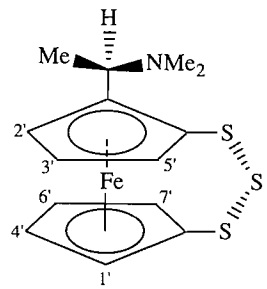


FIG. 4. (a) The ^{1}H nmr spectrum of **4**. (b) The ^{13}C nmr spectrum of **4**.

sites, the results of an nOe difference experiment were used. The C(CH_3) position was irradiated, resulting in strong positive enhancements of resonance 2 (major confomer) and 2′ (minor conformer). Simultaneously, information regarding the relative position of the lower cyclopentadienyl ring protons is garnered since positive enhancements are also observed in resonances 5 and 7′. Weak enhancements may be present for the 4 and 3′ protons but these are difficult to assign because of resonance overlap. This spatial correlation is more clearly seen in Fig. 3. Thus the correct assignment for the major conformer present in solution is given by **F**. The minor conformer is assigned as in **G**.

The ^{1}H nmr and ^{13}C nmr spectra of **4** and **6** are shown in Figs. 4 and 5 respectively. The chemical shift differences for the major and minor conformer resonances of the α-carbon atoms in **4** is 0.7 ppm (resonances near 56 ppm) and of the *N*-methyl carbons is 0.37 ppm (resonances near 45 ppm) in the opposite direction. However, the most pronounced difference (2.35 ppm) is observed for the S-substituted carbon of the lower ring (resonances near 92 ppm). A similar but less pronounced effect is found in the case of **6**. Correspondingly, in the proton nmr spectrum of **4** the α-C*H* protons are shifted downfield in the major conformer, relative to the minor conformer, by 0.14 ppm

G

and 0.05 ppm respectively. The more pronounced effect observed on one of the two CH_2 protons indicates that, for the major conformer present in solution, a strong deshielding effect is apparent on the C*H* nearest to the S_3 bridge. On bridge reversal the ferrocenyl protons experience the stronger deshielding influence. This observation is consistent with our previous findings indicating that the anisotropic effect of the exocyclic S-atom is as shown in Fig. 6. Interestingly, in the case of **2** and **4** the carbon and proton resonances of the N(CH_3)$_2$ groups in the major conformer are upfield of those of the minor.

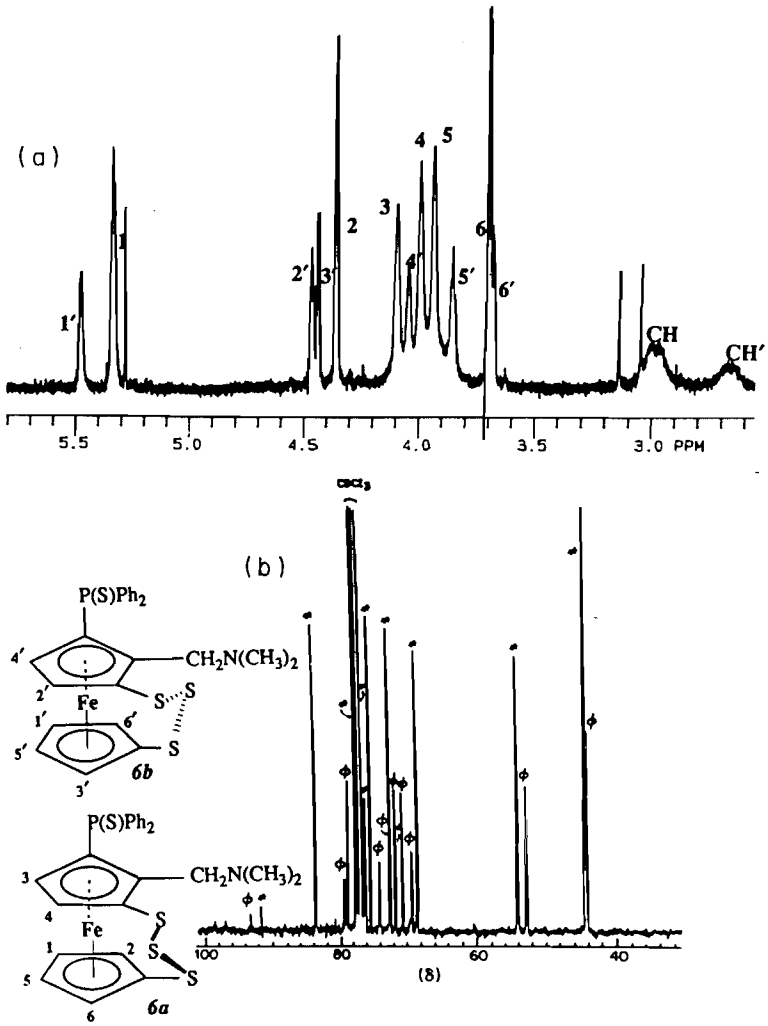

FIG. 5. (a) The ^1H nmr spectrum of **6**. (b) The ^{13}C nmr spectrum of **6**.

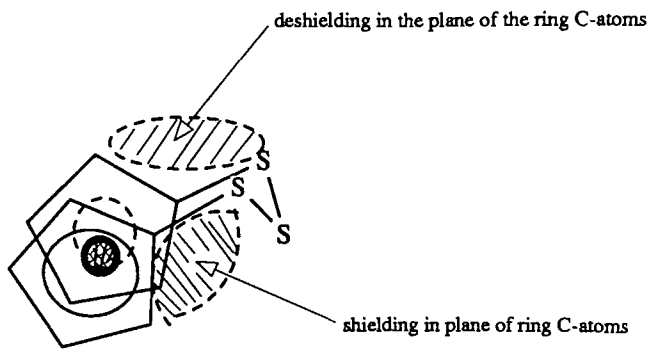

FIG. 6. The anisotropic effect of the S_3-bridge on ferrocenyl ring proton chemical shifts.

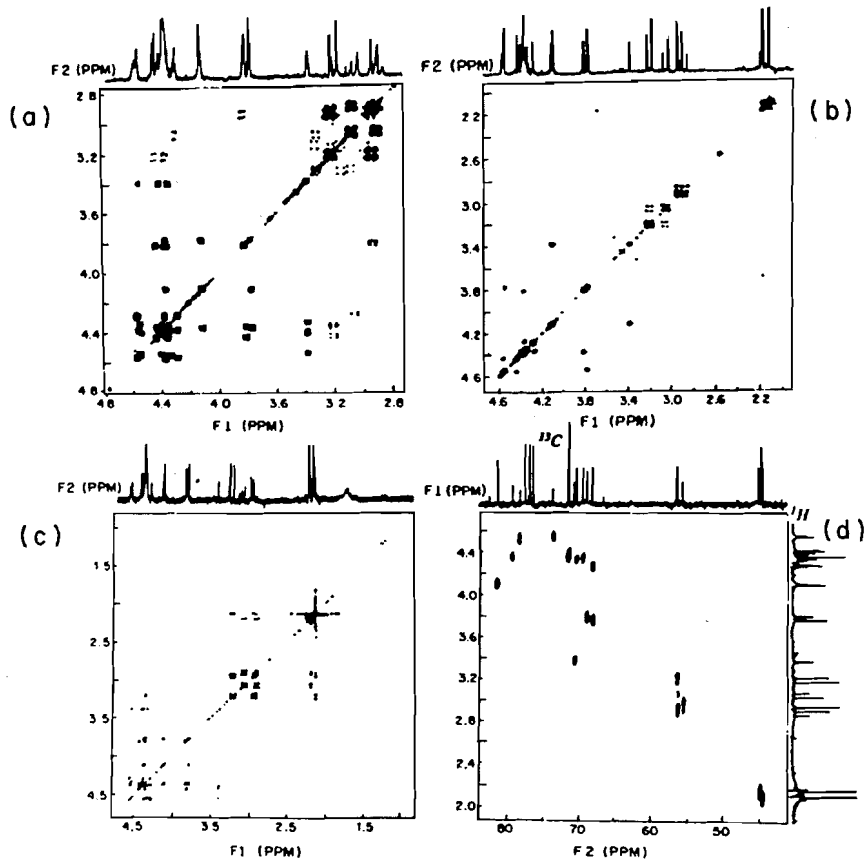
Further ^1H nmr studies on compound **4** have been made. These involve a variety of experiments including homo- and hetero-correlation, 2D-*J* and NOESY spectroscopic techniques. Some of these results are shown in Figs. 7a–7d. Of particular interest are the NOESY spectra, which enable the direct correlation of major and minor conformer resonances of **4**; they also contain the spatial information necessary for a complete structural assignment. This technique, which is complementary to the COSY experiment, leads to the unequivocal identification of all the ^{13}C resonances of **4**. On bridge reversal (major conformer–minor conformer, $4\alpha \rightleftharpoons 4\beta$, see Fig. 4), an extensive shift of the cyclopentadienyl carbon resonance lines is observed for atoms that are adjacent to the S-substituted carbons; the typical chemical shifts vary from 9.4 to 12.3 ppm. Cyclopentadienyl carbon atom resonances for carbons β to the S-bearing carbon show much smaller shifts on bridge reversal (0–2.5 ppm). This information serves as a cross-check of the original assignments for the disubstituted ring protons since the protonated carbon atoms adjacent to the sulfur should be extensively shifted in comparison to the protonated carbon adjacent to the methylene group. This is indeed found.

In addition, *inter-ring* coupling is observed between protons adjacent to the sulfur. Interestingly this phenomenon is *only* observed in the case of the major conformer **4**α and can perhaps be explained in terms of an interaction that includes the middle S atom in the bridge, which in this case lies between the coupled protons.

In compound **5**, where both the top and the bottom rings are disubstituted, two products, **5***a* and **5***b*, are possible depending on whether the starting material was the *meso* or *rac* compound (11). When the orientation of the S_3-bridge is considered, a preponderance of one conformer would be expected in the case of the *meso* compound; this conformer would have the central sulfur atom in the bridge pointing away from both ring substituents as shown in **5***a*. In the case of the ferrocenophane derived



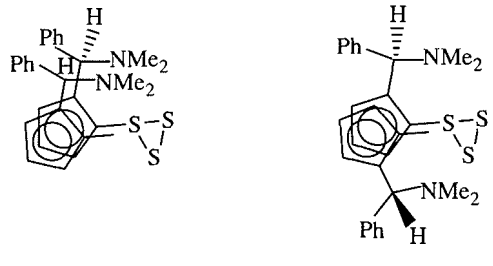


FIG. 7. (a) COSY spectrum of the ferrocenyl region of **4**. (b) NOESY spectrum of **4**. (c) Full COSY spectrum of **4**. (d) $^{13}C/^{1}H$ HETCOR spectrum of **4**.

5a *5b*

from the *rac*-derivative ***5b***, the bridge flipping process would be undetectable by ^{1}H nmr because the ferrocenophanes would be homomeric. The ^{1}H nmr spectrum of the isolated product is poorly resolved but shows a preponderance (>90%) of one isomer. The spectrum is best interpreted in terms of a mixture of ***5a*** and ***5b*** with ***5b*** predominant, because the ferrocenyl proton chemical shifts observed from the major product (δ 4.55–2.61) indicate that the central S atom points towards at least one ring substituent, as shown in ***5b***. This result essentially establishes that the starting material for the preparation was the *rac* isomer of $Fe(C_5H_4CH(Ph)NMe_2)_2$.

In the case of **6** the chemical shifts of the $N(CH_3)_2$ groups are almost identical. This shift can be attributed to an anisotropic effect of the central sulfur, which is pointing towards the $N(CH_3)_2$ groups, in the minor conformer. The ^{1}H nmr spectrum of **6** (Fig. 5a), recorded at ambient temperature, indicates a broadening of the resonances on the trisubstituted ring while the resonances on the monosubstituted ring are sharp. Although this broadening, in part, is caused by the additional phosphorus coupling, the extent seems to indicate a kinetic phenomenon, namely, a faster equilibration. This broadening is also observed in the side-chain resonances.

The conformer distribution found for compounds **2**–**6** is listed in Table 1. The conformer (α) is assigned the structure in which the central sulfur atom in the bridge is directed away from the other substituents (the solid line in the diagrams). The high ratio (α):(β) in **2** compared with **4** presumably reflects the steric effects of the extra CH_3 group in the former case. The isomer ratio found for **6** is slightly higher than **2** but much less than the diphenylphosphine sulfide ***3b*** (4). This observation affords indirect evidence that the S-substitution in **6** is α to carbon rather than to phosphorus. (This is expected as a consequence of the amine assisted lithiation of the starting materials (14).) The steric effect of the substitutent, therefore, greatly influences the ratio of the conformers (α):(β).

When a solution of **2** in DMSO is heated to 120°C, a gradual change is observed in the proton nmr spectrum, Fig. 8a. At 120°C the four proton resonances neighbouring sulfur are sharp; however, the remaining three proton resonances (i.e., 5, 6, and 7 of the major isomer) adjacent to the sulfur have completely collapsed. Further heating results in slow decomposition of **2**.

A similar experiment, conducted in nitrobenzene-d_5 to attain higher temperatures, indicates a resharpening of the broadened resonances at 3.85 ppm, Fig. 8b. After collapse, however, further heating again results in partial decomposition of the sample; unmetallated diene resonances appear in the spectrum. The ^{1}H nmr spectrum recorded after cooling these samples is identical to that of an unheated sample provided decomposition has been minimized by performing all operations as quickly as

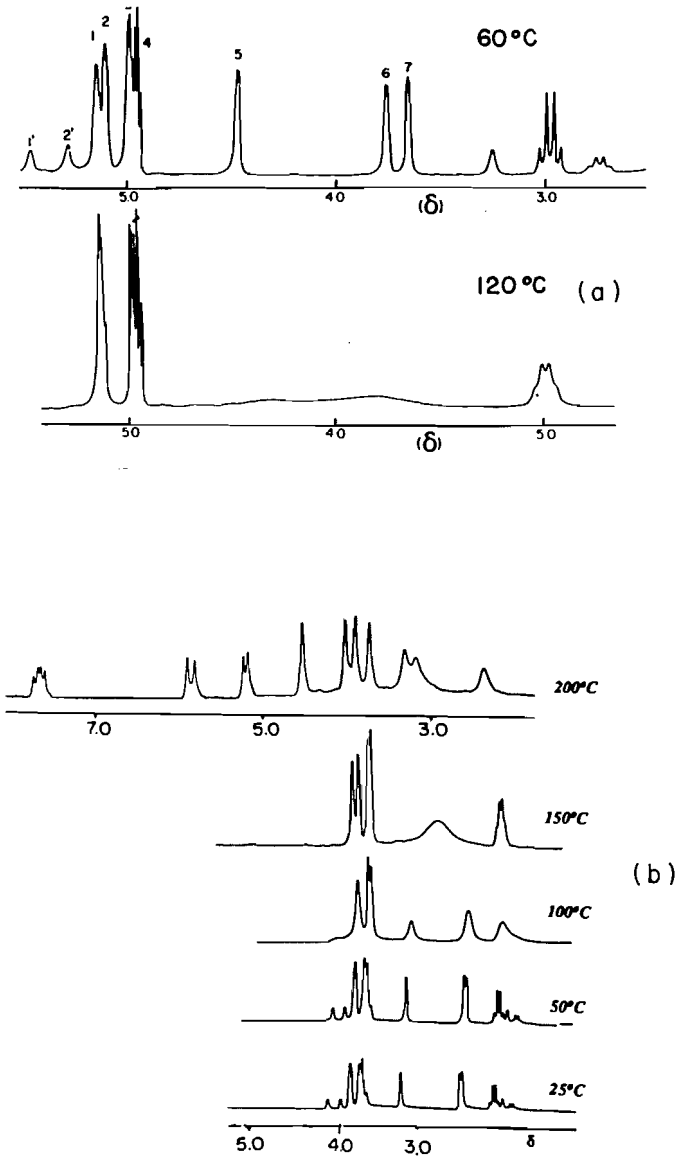

FIG. 8. The variable temperature ^1H nmr spectrum of **2**. (a) in DMSO-d_6; (b) in nitrobenzene-d_5.

possible. These results correlate with those previously described for the unsubstituted [3]-ferrocenophanes in which the coalescence temperature of the protons adjacent to the sulfur atom is higher than that of the other pair.

The far-ultraviolet photochemistry of alkylcyclopropenes in solution

BRIAN J. FAHIE AND WILLIAM J. LEIGH[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 4, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

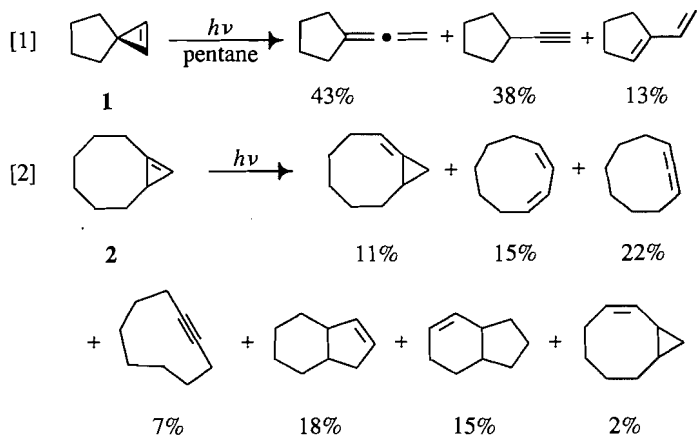
BRIAN J. FAHIE and WILLIAM J. LEIGH. Can. J. Chem. **67**, 1859 (1989).

The photochemistry of 1,3,3-trimethylcyclopropene and 1-*tert*-butyl-3,3-dimethylcyclopropene has been investigated in hydrocarbon, methanol, and 1-hexene solution with far-ultraviolet (185–228 nm) light. Direct photolysis of the two compounds affords allene, alkyne, and 1,3-diene derivatives, formally as a result of initial bond cleavage to yield vinylcarbene intermediates. Products derived from cleavage of the most substituted (C1—C3) cyclopropene bond account for 60–80% of the observed mixture in each case. Results from the photolysis of 1,3,3-trimethylcyclopropene-1-^{13}C suggest a second pathway for formation of alkyne products in cyclopropene photochemistry, which occurs in competition with (or by exclusion of) the vinylcarbene [1,2]-hydrogen migration pathway. The data are consistent with the intermediacy of a vinylidene species, formed by [1,2]-hydrogen migration/ring opening, although attempts to chemically trap this intermediate with methanol or alkene were unsuccessful.

Key words: cyclopropene, photolysis, vinylmethylene, propenylidene, far-UV.

BRIAN J. FAHIE et WILLIAM J. LEIGH. Can. J. Chem. **67**, 1859 (1989).

Opérant dans des solutions d'hydrocarbure, de méthanol et de hex-1-ène et utilisant de la lumière ultraviolette lointaine (185–228 nm), on a étudié la photochimie des 1,3,3-triméthylcyclopropène et 1-*tert*-butyl-3,3-diméthylcyclopropène. La photolyse directe de ces deux composés fournit des dérivés allènes, alcynes et 1,3-diènes qui proviennent d'une façon formelle du bris initial d'une liaison qui fournit des intermédiaires vinylcarbènes. Dans chacun des cas, les produits qui proviennent du bris de la liaison la plus substituée (C1—C3) du cyclopropène forment de 60 à 80% du mélange observé. Les résultats obtenus lors de la photolyse du 1,3,3-triméthylcyclopropène-1-^{13}C suggèrent que, lors de la photochimie des cyclopropènes, il existe une deuxième voie de formation des alcynes qui est en compétition avec (ou à l'exclusion de) la voie impliquant la migration-[1,2] d'hydrogène du vinylcarbène. Les données sont en accord avec la présence d'intermédiaires vinylidènes qui seraient formés par une migration-[1,2] d'hydrogène/ouverture de cycle; toutefois, des essais effectués en vue de piéger cet intermédiaire avec du méthanol ou un alcène se sont avérés infructueux.



Mots clés : cyclopropène, photolyse, vinylméthylène, propénylidène, UV lointaine.

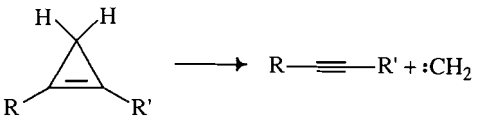
[Traduit par la revue]

Introduction

The photochemistry of cyclopropenes has received a considerable amount of attention over the past 20 years (1–3). Early studies of phenylated cyclopropenes demonstrated that the product distribution from direct photolysis is normally characteristic of reactivity associated with vinylcarbene intermediates, formed by cleavage of the C1—C3 and (or) C2—C3 cyclopropene bonds in the first excited singlet state (4–6), although other reaction pathways can intervene if the system bears appropriate substituents (1, 2, 7, 8). In addition, numerous theoretical studies have been carried out in an effort to assist in understanding the nature of the excited state(s) and intermediates involved (9–15). Considering that the majority of theoretical studies have been confined to the parent C_3H_4 system while experimental studies have mostly concentrated on phenylated systems, the agreement between the two approaches has been quite remarkable.

While the photochemistry of arylcyclopropenes has thus been extensively investigated (1–8), there have been few reported studies of simple alkyl-substituted derivatives in solution (16, 19), probably because the parent chromophore is devoid of absorption above 210 nm and hence requires the use of far-uv techniques for its investigation. Recent reports of the photochemistry of two bicyclic alkylcyclopropene derivatives (eqs. [1] (16) and [2] (19)) have demonstrated that the photochemical behaviour of alkylated systems differs in several respects from

that typical of arylcyclopropenes. These compounds afford substantial amounts of allene and alkyne products in addition to the 1,3-dienes and other products that are characteristic of vinylcarbene intermediates. The photochemistry of compounds **1** and **2** supplements the elegant studies of Steinmetz *et al.* (16–18) and Johnson and co-workers (19–21) on the photochemistry of allene derivatives. Allenes have been shown to afford cyclopropenes in both the ground and singlet excited state via vinylcarbene as well as concerted pathways (3, 16–22).



Recent *ab initio* theoretical investigations of the thermal and photochemical interconversions of the C_3H_4 hydrocarbons (14, 15) underline the need for further studies of the photochemistry of simple cyclopropene derivatives. On the basis of these calculations, at least two unknown thermal and (or)

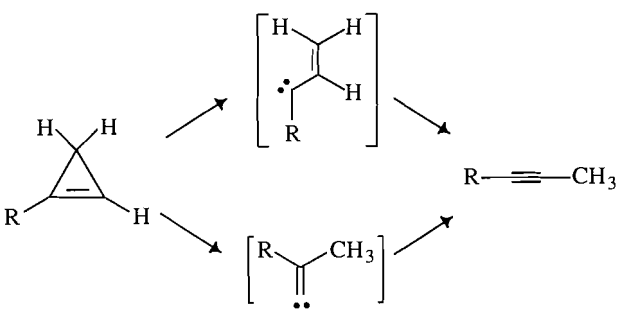
For personal use only.



photochemical reaction pathways (in addition to vinylmethylene formation), whose efficacy may depend dramatically on substitution and the excited state energy of the chromophore, have been proposed.

The *ab initio* SCF-CI calculations of Sevin and Arnaud-Danon suggest that two-bond fragmentation leading to a carbene and an alkyne (eq. [3]) may provide an important

[3] 

photochemical decomposition pathway in simple cyclopropenes with high singlet excitation energies (14). Carbene photoextrusions are rather common in cyclopro*pane* photochemistry (23, 24) (particularly in alkyl-substituted systems) (24), but have apparently not been observed in cyclopropene systems.

More recently, Yoshimine and co-workers have proposed that the well-documented, thermal rearrangement of cyclopropene to propyne (3, 25) may proceed by *two* competitive pathways (eq. [4]), one involving [1,2]-H migration in vinylmethyl-

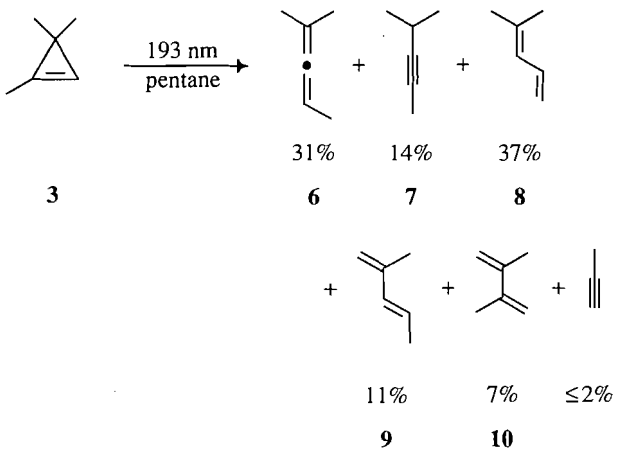
[4] 

ene and the other involving the intermediacy of propenylidene (15). The latter intermediate (formed by concerted[2] or stepwise [1,2]-hydrogen migration/ring opening) has been calculated to be ca. 16 kcal/mol lower in energy than either of the two lowest singlet states of vinylmethylene, and is thus a viable intermediate on both the ground and excited singlet state potential energy surfaces for the cyclopropene/propyne interconversion (26). While direct experimental evidence for this process (either thermal or photochemical) evidently does not yet exist, the reverse reaction, thermal rearrangement of vinylidene carbenes to cyclopropenes, has been documented (27).

We have undertaken a study of the photochemistry of two unsymmetrical, alkyl-substituted cyclopropenes (**3** and **4**) in hydrocarbon and methanol solution with far-uv light. These compounds afford the possibility of exploring the effects of substituent on the mode of cyclopropene bond cleavage in monocyclic, alkyl-substituted systems (i.e., the competition between ring opening to yield substituted vs. unsubstituted vinylmethylene intermediates), and could provide the basis for comparison with the analogous behaviour of phenylated cyclopropenes. Furthermore, the thermal chemistry of both compounds has been previously reported (28, 29) and is thus available for comparison with their photochemical behaviour. In addition, the possibility that the photochemical rearrangement to alkynes may proceed via propenylidene intermediates

[2]NOTE ADDED IN PROOF: More recent calculations favour a concerted mechanism for the cyclopropene to propenylidene conversion, and indicate that both *syn* and *anti* vinylmethylenes undergo ring closure to cyclopropene. See ref. 15*c*.

3 **4** **5**



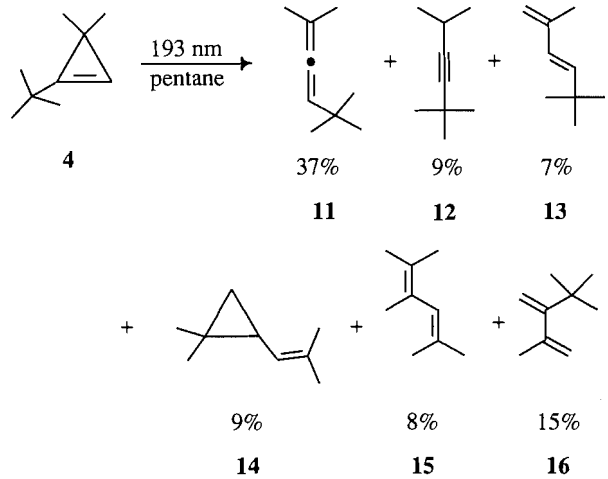
has been investigated using a ^{13}C-labelled derivative of **3** (**5**). The results of our study are reported below.

Results

1,3,3-Trimethylcyclopropene (**3**) and (1-^{13}C)-1,3,3-trimethylcyclopropene (**5**) were synthesized by base-catalysed decomposition of the tosylhydrazones of mesityl oxide and (2-^{13}C)-mesityl oxide, respectively, with only minor changes to the previously reported procedure for the preparation of **3** (30). (2-^{13}C)-Mesityl oxide was synthesized according to the reported procedure for the unlabelled compound (31), starting from (2-^{13}C)-sodium acetate. 1-*tert*-Butyl-3,3-dimethylcyclopropene (**4**) was synthesized in similar fashion from the tosylhydrazone of 2,2,5-trimethylhex-4-en-3-one.

The uv absorption spectra of **3** and **4** in deoxygenated pentane solution showed single peaks with λ_{max} = 194 ± 1 nm (ϵ = 4500) and 196 ± 1 nm (ϵ = 6800), respectively. Both spectra were devoid of absorption above ca. 235 nm.

Photolysis of a deoxygenated, 0.041 M pentane solution of **3** with the unfocussed pulses from an Ar/F_2 excimer laser (193 nm; ca. 8 ns; 20–80 mJ) produced the six primary products shown in eq. [5]. Each compound was identified by coinjection



[5] 

of the photolysate and an authentic sample on at least two vpc columns. Relative product yields for **6**–**10** were determined by triplicate vpc analyses of the photolysate at several light dosages between ca. 0.5 and 5% conversion (see experimental section). *cis*-**9** could not be detected in the photolysis mixture up to ca. 10% conversion. The yield of propyne could not be accurately determined, but is estimated to be in the 0.3–2% range. Propene could *not* be found in the photolysis mixture (limit of detection <0.3%), under vpc conditions adequate to separate it from propyne.

Similarly, 193-nm photolysis of a deoxygenated, 0.018 M pentane solution of **4** produced the eight primary products shown in eq. [6]. Products **14** and **15** were identified by coinjection of the photolysate with authentic samples on two different vpc columns. Products **11**–**13** and **16** were isolated by preparative vpc from larger scale runs carried to ca. 20% conversion, and identified by ir and $^1H/^{13}C$ nmr spectroscopy and gc/ms analysis, and comparisons to literature data in the cases of **11** and **12**. Relative product yields were determined by a similar method to that used for the photolysis of **3**. The

[6] 

photolysate also contained two additional, minor products (each in <8% yield) for which quantities sufficient for identification could not be obtained. 3,3-Dimethyl-1-butyne was not observed as a product of photolysis of **4** (i.e., yield ≤0.3%), as indicated by vpc analysis of the photolysate under conditions adequate for resolving this compound from the solvent or any other component of the mixture.

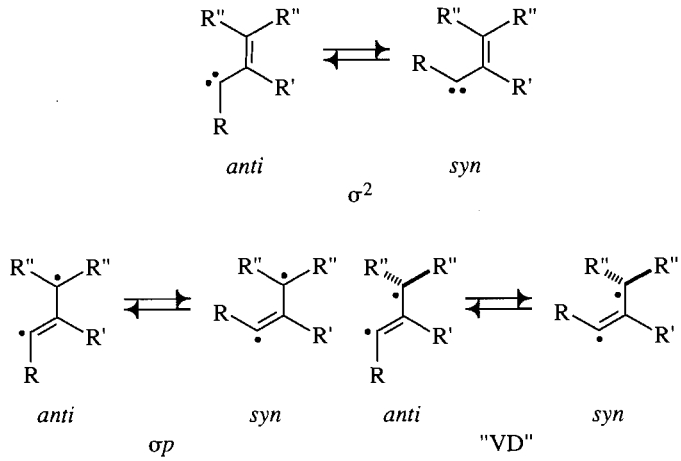
We have ruled out sequential two-photon excitation by the laser as contributing to the observed photochemistry for either **3** or **4** on the basis that photolysis of deoxygenated pentane solutions of the two compounds with a low pressure mercury lamp (185 + 254 nm) resulted in similar product distributions to those obtained in the 193-nm runs.

Reaction quantum yields were not determined quantitatively, but they appeared to be quite low on the basis of qualitative comparisons to other systems that we have studied under similar conditions (32). We thus estimate the upper limit for the quantum yields of disappearance of **3** and **4** to be in the range 0.01–0.1.

A deoxygenated, 0.25 M pentane solution of **5** was photolysed (193 nm) to approximately 25% conversion, and the products were isolated from the crude photolysate by semi-preparative vpc. As expected, the formal product distribution from photolysis of **5** was virtually identical to that obtained from **3**. The distribution of the ^{13}C label in each product was determined by integration of the ^{13}C nmr spectrum of a $CDCl_3$ solution containing $Cr(acac)_3$ (to shorten the ^{13}C spin-lattice relaxation time (33*a*)), and comparison to the spectrum of the corresponding unlabelled material recorded under identical conditions (see experimental section). These results are summarized in eq. [7]. For **8**–**10**, these experiments indicated that the label exists almost exclusively at a single carbon (see eq. [7]), but the error in the determinations for these

[7] 

compounds may be as high as ±30% due to the qualitative procedure that was employed for the ^{13}C integrations in these cases. More rigorous procedures were employed for **6** and **7**. In the case of **6**, the spectrum was recorded using inverse gate decoupling (in which nOe enhancement is suppressed by turning on the proton decoupler only during acquisition of the FID (33*b*)), and with a delay of $>5T_1$ between pulse sequences to ensure complete relaxation. The distribution of the label in **6** that is quoted in eq. [7] is the average of three independent determinations, and the error is quoted as a single standard deviation from the mean. In the case of **7**, the determination involved a much more rigorous approach, which has been described in detail elsewhere (34), and which affords significantly lower systematic errors compared to the more conventional method that was used for **6**.



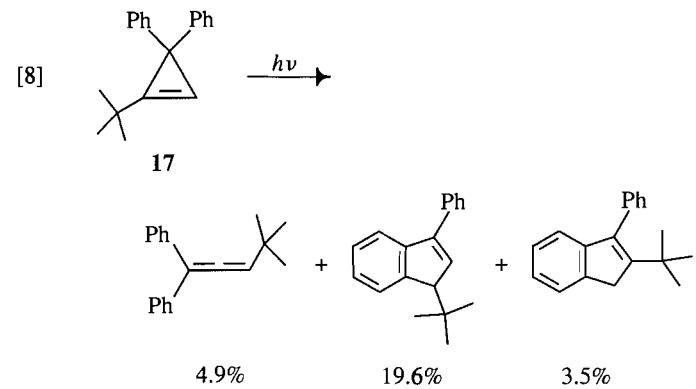
Photolysis of deoxygenated, 0.05 M pentane solutions of **3** was also carried out using Zn (214 nm) and Cd (228 nm) resonance lamps as the light sources. Product yields were determined by vpc from photolysates carried to ca. 5% conversion, and did not differ significantly from those obtained using the excimer laser (193 nm) as the light source. Photolyses of deoxygenated, 0.05 M solutions of **3** in methanol and in 1-hexene with the 214- and 228-nm light sources, respectively, afforded product distributions that were similar in all respects to those obtained in the pentane runs. In particular, no new products were formed in either case within the detection limits of our vpc method.

Discussion

It is well established that the photochemistry of cyclopropene derivatives is dominated by initial ring opening to yield vinylcarbene intermediates. In the parent (C_3H_4) system, the ground state of vinylmethylene is the planar vinyl-diradical (σp) triplet state (9–15, 35), but the two lowest excited singlet states, the carbenic σ^2 and higher energy σp (vinyl-diradical) states, are thought to be the ones normally obtained in thermal or photochemical ring opening of cyclopropenes (3). Calculations reveal that the ground state of cyclopropene correlates with the vinylmethylene σp state, while the first excited singlet state correlates with the lower energy σ^2 state (9–15). The avoided crossing of these surfaces is thought to result in σ^2 vinylcarbene being the result of thermal cyclopropene ring opening, while the excited singlet state process involves initial formation of σp vinylcarbene (14–21). Also pertinent to discussion of vinylcarbene reactivity is the bisected vinyl-diradical geometry ("VD"), which is related to singlet σp vinylcarbene by rotation (90°) about the C2—C3 bond.

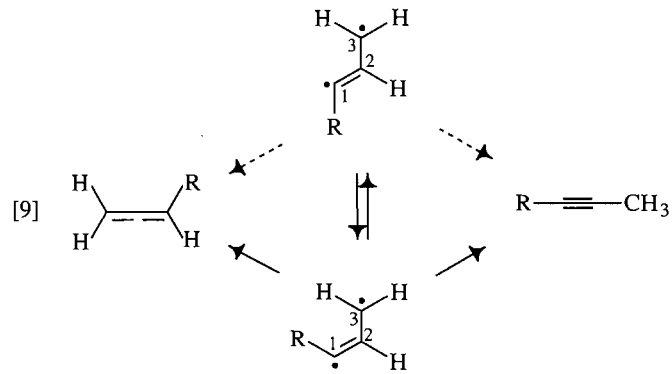
The most recent calculations for the parent (C_3H_4) system indicate that (for both planar and bisected geometries of σ^2 and σp vinylmethylene) the *anti* geometric isomers are <2 kcal/mol lower in energy than the *syn* isomers, with low (<8.3 kcal/mol) barriers for their interconversion (15). This situation should clearly be expected to change with substituents, however. The bisected (VD) conformers are calculated to be ca. 1.5 and 4.5 kcal/mol higher in energy than the planar *syn* and *anti* σp states, respectively, with no barrier to interconversion between the planar and bisected geometries. In fact, the bisected geometries may represent energy *maxima* on the σp vinylcarbene potential energy surfaces (15, 21).

The predominant reaction pathway for both thermally and photochemically generated vinylcarbenes is ring closure to cyclopropene (3). This leads to a rather large component of reversibility in both thermal (36) and photochemical (37) ring



opening of cyclopropenes, and presumably ensues from the *anti* vinylcarbene isomer(s) (15*c*). From the planar vinylcarbene isomers, ring closure requires C2—C3 bond rotation, either preceding or in concert with bond formation.

Substituted 1,3-butadienes are formed via [1,2]-hydrogen (or -alkyl) migration when R = alkyl, or by [1,4]-hydrogen migration when R″ = alkyl. Presumably, the former can proceed from either the *syn* or *anti* vinylcarbene isomers, while the latter proceeds only from the *anti* isomer.

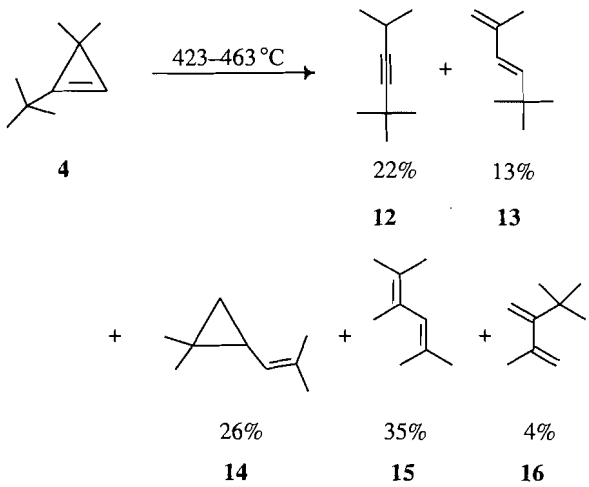


[1,4]-Hydrogen migration might thus be expected to lead to stereospecific diene formation, although numerous examples in arylcyclopropene photochemistry are nonstereospecific (1, 2). Indenes and furans are formed in systems where R″ = Ph and acyl, respectively (1, 2), presumably also from the *anti* vinylcarbene isomers. None of these reaction pathways require C2—C3 bond rotation.

Allenes and acetylenes are of particular current interest due to the fact that the generality of their formation from singlet excited cyclopropenes has only recently been established (see, for example, eqs. [1] (ref. 16), [2] (ref. 19), and [8] (ref. 18))

(3, 21). Depending on substitution, products of this type can clearly be the predominant ones from photolysis of cyclopropenes. These products can be most simply envisaged as deriving from the *syn* vinyl-diradical by [1,2]-H-migrations to either C3 or C1 (17) (eq. [9]). Both H-migrations must be accompanied (or preceded) by rotation about the C2—C3 bond. Evidently, the formation of these products is blocked (or largely so) in derivatives substituted with alkyl groups at the 2-position. Klett and Johnson have also reported the formation of allene products in low yield from photolysis of 1,3,3-triphenyl- and 1,2,3,3-tetraphenylcyclopropene, and attributed their formation to [1,2]-aryl migration in the corresponding vinylcarbenes (21). On the basis of the observation that allenes and acetylenes appear to be formed in much higher yield from photolysis of cyclopropenes than from either thermolysis of the same compound or from independently generated (presumably σ^2) vinylcarbene (18–21), the σp state is strongly implicated. Whether σp vinylcarbene affords these products directly (in state-specific fashion (17)) or indirectly, as a result of funnelling to the σ^2 state at an appropriate geometry for hydrogen migration (18, 19, 21), has been the subject of some discussion. The possibility that these products may alternatively be formed from excited cyclopropene by a concerted process has also been suggested (21).

In the present cases, ring opening of **3** and **4** can proceed in two ways: cleavage of the C1—C3 bond, to ultimately yield products formally derived from a (C1) alkyl-substituted vinylcarbene, or cleavage of the C2—C3 bond to yield products derived from an un- (i.e., H) substituted vinylcarbene. The



product distribution obtained from photolysis of **3** is such that 70–90% of the observed products can be formally attributed to the initial formation of the more highly substituted of the two possible vinylcarbene intermediates from ring opening of this compound. Only diene **10** is derivable from the less substituted of the two possible vinylcarbenes. This trend also holds for the behaviour of **4**, as well as that of **2** (eq. [2] (19)) and **17** (eq. [8] (18)). For example, of the seven products shown in eq. [7], only the first is attributable to the less substituted vinylcarbene formed by cleavage of the exocyclic (C8–C9) cyclopropenyl bond; the rest can be rationalized as arising from the vinylcarbene formed by cleavage of the endocyclic (C1—C8) bond. Similarly, the first two products shown in eq. [8] are both attributable to the vinylcarbene derived from cleavage of the more substituted cyclopropene σ-bond.

Similar selectivities have been observed in the thermolysis of **3** and **4**. Gas-phase thermolysis of **3** has been reported to afford **9** and **10** in yields of 71 and 21%, respectively; no other products were reported (28). Thermolysis of **4** has been reported to afford the products shown in eq. [10] (29). In both these cases, the observed product distributions are consistent with predominant (70–90%) ring opening to yield the more highly substituted vinylcarbene isomer. However, aside from this gross similarity between the ground and excited state behaviour of **3** and **4**, the more detailed aspects of these product distributions differ considerably (*vide infra*).

This general behaviour contrasts that frequently observed in phenylated cyclopropene derivatives (1–3). In 1-aryl (21) and 1-aryl-2-alkyl (6, 37, 38) systems, for example, it has been found that while thermolysis affords products associated with ring opening to yield the thermodynamically more stable vinylcarbene, photolysis yields products associated with formation of the less stable carbene. This has been explained in terms of

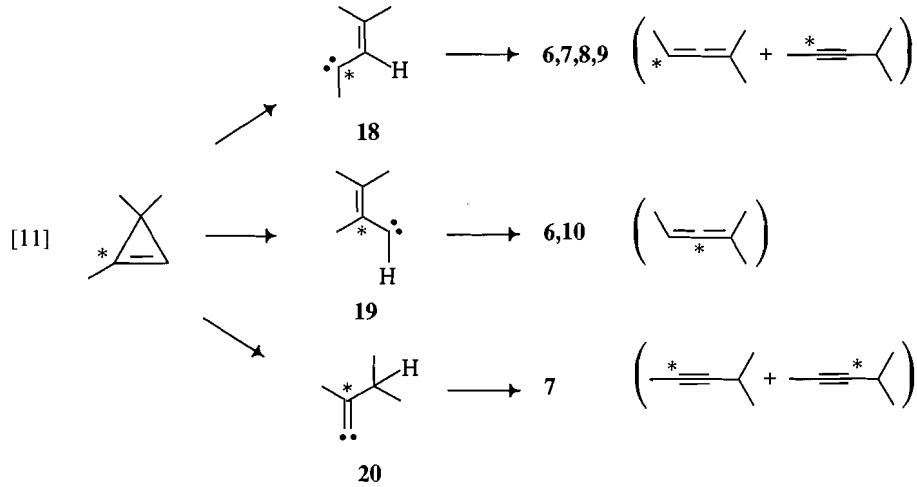
[10] 

the "funnel theory" of excited- to ground-state conversions (39); the thermodynamically less stable product is formed photochemically because its potential energy surface is the one that approaches the excited state potential surface for cyclopropene ring opening in closest proximity (1, 2). In the present alkyl systems, however, the differences in thermodynamic stability between the two possible carbenes are much smaller than is the case in aryl-H or aryl-alkyl systems. Since the two (sets of) vinylcarbene surfaces will approach the cyclopropene excited state surface to comparable extents, funneling to the lower energy of the two surfaces might be expected to be more facile. The result is that ring opening to the more stable carbene is favoured. Klett and Johnson have pointed out that reversal of the ground- and excited-state bond orders for the two cyclopropene σ-bonds could provide an alternative explanation for the differences observed in thermal and photochemical arylcyclopropene ring opening (21).

For both **3** and **4**, the formation of allenes and acetylenes is substantially enhanced (at the expense of dienes and intramolecular C—H insertion products) in the excited state compared to the ground state (thermal) reactions. Allenes are usually absent altogether in cyclopropene thermolysis (3), and calculations indicate that this is due to a higher activation barrier for the formation of this product from vinylmethylene compared to that for formation of alkyne (15). Photochemical activation provides a pathway to the higher energy potential energy surface, leading to allene that is essentially inaccessible from the ground state of cyclopropene, and in both cases the allene is the major product of direct photolysis.



The results of the carbon-labelling experiment (photolysis of **5**; eq. [6]) indicate that the origins of allene **6**, alkyne **7**, and 1,3-dienes **8**–**10** can all be rationalized as due *predominantly* to formal [1,2]- or [1,4]-H migrations in the two possible vinylcarbene intermediates (**18** and **19**; see eq. [11]), as expected (3, 15). However, careful nmr analysis of **6*** and **7*** reveals that these products are not exclusively formed by [1,2]-H migration pathways in **18**. The result that **6*** contains ca. 15% of the label at carbon-3 indicates that the allene may be formed to a minor extent from [1,2]-methyl migration, formally involving the less substituted vinylcarbene (**19**) that is also responsible for the formation of diene **10**. While [1,2]-aryl migrations leading to allenes are known to be facile in vinylcarbene chemistry (21, and references cited therein), there have been no reports of similar migrations involving alkyl groups. The present results verifies that the process is an exceedingly minor reaction pathway for 2-alkyl substituted vinylcarbenes, though it is finite. Steinmetz *et al.* have found that [1,2]-alkyl migrations in the reverse direction (i.e., excited allene ⇒ vinylcarbene) occur in cyclic systems when the migration can substantially relieve ring strain (17). We note that diene **15**, formed in both the thermolysis (29) and photolysis of **4**, is also derived from [1,2]-methyl migration in the corresponding vinylcarbene, although this involves migration of a *tert*-butyl-methyl group to the C1 carbon.

The scrambling of the label that occurs in product **7*** is more significant. [1,2]-H migration in **18** should lead to material containing label only at C4, and the preponderance of label that exists at this position in **7*** may be due to a substantial contribution from this pathway. An attractive mechanism that would account for scrambling of the label between C3 and C4 is the propenylidene route suggested by Yoshimine and co-workers (15). Cyclopropene excited state C2—C3 bond cleavage accompanied by hydrogen migration (from C2 to C3) in **3** (**5**) would yield the vinylidene species (**20**) shown in eq. [11]. It is well known that carbenes of this type afford alkynes by [1,2]-alkyl migration (26). Thus, methyl migration would afford C3-labelled **7***, and isopropyl migration would afford the C4-labelled isomer. While the relative migratory aptitudes of alkyl groups in vinylidene carbenes is evidently unknown, it seems reasonable to suggest that the migratory aptitude of isopropyl is *at least* as large as that of methyl, given the electrophilic nature of alkylidene carbenes (26). The relative proportion of ^{13}C-label at C3 and C4 in **7*** thus indicates that at least 40% of this product must arise via the alkylidene pathway, assuming equal migratory aptitudes for methyl and isopropyl.

Attempts to obtain further evidence for the formation of this intermediate in the photochemistry of **3**, by trapping with 1-hexene or methanol, are inconclusive since no new products were observed upon photolysis in either solvent. We were initially disturbed by our failure to observe *any* new products from photolysis in methanol, since we expected to at least observe allylic ethers corresponding to trapping of the vinylcarbene intermediates by the solvent. There are numerous reports of successful alcohol-trapping experiments with vinylcarbenes derived from arylcyclopropene derivatives (1, 2, 5). Indeed, in aryl systems, alcohol trapping of vinylcarbenes appears to proceed quantitatively (5). We note, however, that Stierman and Johnson have reported similar (negative) results from the photolysis of **2** (as well as 1,2-cyclononadiene) in methanol (19). Evidently, simpler (alkyl-substituted) vinylcarbenes are substantially less reactive towards bimolecular OH insertion than their phenylated counterparts. This can probably be explained in terms of unfavourable frontier molecular orbital interactions in the alkylated systems. One example of intramolecular OH insertion in an alkyl vinylcarbene has been reported (40). Intermolecular trapping of alkylidenes by alkenes is well documented (26*b*), although direct generation of these species has traditionally been carried out by thermal methods. It is possible that the photochemical generation from cyclopropenes yields the alkylidene in an excited state, from which alkyl migration is too fast to allow bimolecular trapping to compete. It should also be recognized that, in the present case, the alkylidene is formed in fairly low (≤7%) yield, and its trapping products could have easily avoided detection under our vpc conditions. Bimolecular vinylcarbene trapping by alkenes has also been reported for a cyclic vinylcarbene derivative in which ring closure to cyclopropene (the predominant fate of acyclic vinylcarbenes) is blocked by geometric constraints (41).

The formation of propyne in low yield from photolysis of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12

3 is difficult to explain, since the accompanying presence of propene in the photolysate could not be verified. By a two-bond cleavage pathway, these two products should be formed together, since the latter is the expected observable product of dimethylcarbene. Solvent trapping of the carbene (by C—H insertion) should be noncompetitive with intramolecular H migration to yield propene (42), so it is unlikely that the absence of this product is due to other reaction pathways of the carbene. Two-bond cleavage products are not observed from photolysis of **2** (19), spiro[4.2]hept-6-ene (**1**; eq. [1]) (16), or **4**. We conclude that, in solution, this decomposition pathway is unimportant even for cyclopropenes with high excited singlet state energies.

Summary and conclusions

The present study represents the first investigation of the photochemistry of monocyclic, alkyl-substituted cyclopropene derivatives in solution. Photolysis of these compounds yields a variety of products, most of which are formally derived from the vinylcarbene formed by cleavage of the more highly substituted cyclopropene σ-bond in the excited singlet state. Carbon-13 labelling experiments have demonstrated that alkynes may be formed by two competitive pathways, one involving H-migration in a vinylcarbene intermediate, and the other involving alkyl migration in an alkylidene species. The latter is presumably formed by (concerted (15*c*)) [1,2]-H-migration/ring opening in the cyclopropene excited state, as suggested by recent theoretical calculations of the C_3H_4 ground state surface. Our results indicate that the alkylidene pathway accounts for at least 40% (perhaps more, depending on the relative migrative aptitudes of isopropyl vs. methyl groups in alkylidene carbenes) of the alkyne formed in direct cyclopropene photolysis. Two-bond cleavage of excited cyclopropenes to yield carbenes and alkynes is unimportant in solution, even for cyclopropenes with high excitation energies.

Experimental

The ^{1}H nmr spectra were recorded on Varian EM390 (90 MHz) or Bruker AM500 (500 MHz) spectrometers in carbon tetrachloride (or deuteriochloroform where noted). The ^{13}C nmr spectra were recorded at 62.5 or 125.6 MHz on Bruker WM250 or AM500 spectrometers, respectively. All spectra are reported in parts per million downfield from tetramethylsilane. Mass spectra were recorded on a Finnigan 4000 mass spectrometer with a model 4500 ion source. The mass spectrometer was interfaced with a Finnigan gas chromatograph, equipped with a 60 m × 1.0 μm DB1-30W (Chromatographic Specialties, Inc.) fused silica capillary column. Ultraviolet absorption spectra were recorded in deoxygenated pentane solution using a Perkin–Elmer Lambda 9 spectrometer equipped with a model 3600 data station. Infrared spectra were recorded on a Perkin–Elmer 283 spectrometer as the neat liquids or in carbon tetrachloride or chloroform solution; spectra are reported in wavenumbers, calibrated using the 1601.9 cm^{-1} polystyrene absorption.

Analytical vpc separations were carried out using a Varian 3700 gas chromatograph (injector temperature = 80°C) equipped with a flame ionization detector, a Varian CDS101 or Hewlett–Packard HP-3393a integrator, and one of the following columns: (a) 1.0 μm SPB-1 wide-bore capillary (60 m × 0.75 mm i.d. borosilicate; Supelco, Inc.); or (b) 20% β,β-oxydipropionitrile (ODPN) on 80/100 Chromosorb PNAW (14 ft × 1/8 in. stainless steel; Supelco, Inc.); or (c) 23% SP-1700 on 80/100 Chromosorb PAW (15 ft × 1/4 in. stainless steel; Supelco, Inc.). Relative detector responses toward products and starting materials from photolysis of **3** and **4** (with the exception of propyne) were verified to be approximately unity by analysis of a few standard solutions of authentic samples.

Semipreparative vpc separations employed a Hewlett–Packard 5750B gas chromatograph equipped with a thermal conductivity detector (detector temperature 160°C) and one of the following stainless steel columns: (d) 3.8% UC W982 on 80/100 PNAW (24 ft × 1/4 in.; Supelco Inc.); (e) 20% ODPN on 80/100 Chromosorb PNAW (24 ft × 1/4 in. stainless steel; Supelco Inc.).

n-Pentane (Baker Photrex) and methanol (Caledon HPLC) were used as received from the supplier. Mesityl oxide (Aldrich Chemical Co.) was distilled once before use. 1-Hexene (Aldrich) was distilled four times prior to use and had final optical densities as follows (1.0 mm path length): <210 nm (>3); 220 nm (0.74); 230 nm (0.53). *p*-Toluenesulfonhydrazide, 3,3-dimethyl-2-butanone, *trans*-2-methyl-1,3-pentadiene (**9**), 2,3-dimethyl-1,3-butadiene (**10**), 3-methyl-2-butanone, 2,5-dimethyl-2,4-hexadiene, and sodium hydride were all used as received from Aldrich. 4-Methyl-2,3-pentadiene (**6**; ICN Pharmaceuticals Inc.), 4-methyl-2-pentyne (**7**; Farchan), and (2-^{13}C)-sodium acetate (MSD Isotopes) were also used as received from the suppliers.

1,3,3-Trimethylcyclopropene (3) was synthesized by a variation of the previously published method (30). A suspension of mesityl oxide tosylhydrazone (10 g, 0.038 mol; from mesityl oxide and *p*-toluenesulfonhydrazide (30)) in *o*-dichlorobenzene (40 mL) was added over a period of 1 h to a solution of sodium hydride (1.8 g, 0.076 mol) in refluxing *o*-dichlorobenzene (150 mL), in a two-neck, round-bottom flask fitted with a small Vigreux column. The column head was connected to three sequential cold-traps, which were immersed in Dry Ice/acetone baths. The addition rate of the tosylhydrazone solution and the reaction temperature were controlled in such a manner as to prevent the condensation of any solvent vapours in the cold traps. After the addition of the tosylhydrazone was complete, the reaction flask was heated for an additional 30 min. The contents of the cold traps were combined (3.1 g, ca. 50% **3** by vpc). After bulb-to-bulb distillation,

compound **3** was purified (>99.9% purity) by semipreparative vpc (column (d), column temperature 30°C). The material exhibited spectral characteristics (ir, ^{1}H nmr) similar to those previously reported (43).

*1-*tert*-Butyl-3,3-dimethylcyclopropene (**9**)* was prepared in similar fashion from the tosylhydrazone of 2,2,5-trimethylhex-4-en-3-one (44). A solution of glacial acetic acid (25 mL), water (100 mL), and 3,3-dimethylbutanone (40 g, 0.40 mol) was placed in a 500-mL three-neck, round-bottom flask equipped with a reflux condenser, a thermometer, and an addition funnel. The solution was heated to 85°C while bromine (22 mL, 0.38 mol) was added dropwise. After addition of the bromine was complete (ca. 45 min), the solution was stirred for an additional 2 h. The resulting pale yellow mixture was then cooled to 10°C and neutralized with solid sodium carbonate. The resulting oil was separated from the aqueous layer and distilled under vacuum to give a colourless liquid (bp 73°C (25 Torr; 1 Torr = 133.3 Pa); 44 g, 0.25 mol), which was identified as 1-bromo-3,3-dimethylpropan-2-one on the basis of its ^{1}H nmr spectrum (δ($CDCl_3$): 1.25 (s, 9H), 4.23 (s, 2H)).

The bromoketone (10 g, 0.056 mol) and acetone (5 g, 0.086 mol), both dried over 4A molecular sieves, were dissolved in dioxane (100 mL; distilled from sodium) and placed in a 250-mL two-neck, round-bottom flask fitted with a reflux condenser, powder funnel, and gas inlet. A dry nitrogen atmosphere was maintained over the reactants. Freshly activated zinc (45) (5.6 g, 0.086 mol) was added slowly with stirring. After the addition of the zinc was complete, the contents of the flask were stirred for an additional hour and then cooled to room temperature. The solution was dried over anhydrous sodium sulfate and the solvent was partially removed on the rotary evaporator to yield a pale yellow dioxane solution of 2,2,5-trimethylhexan-5-ol-3-one, identified on the basis of its ^{1}H nmr spectrum (δ($CDCl_3$): 1.15 (s, 9H), 1.25 (s, 6H), 2.65 (s, 2H)).

Dehydration of this compound by the previously published method (46) yielded 2,2,5-trimethylhex-4-en-3-one (3.5 g, 0.025 mol, 45% overall yield). Identification was made on the basis of its ^{1}H nmr spectrum (δ($CDCl_3$): 1.12 (s, 9H), 1.90 (s, 3H), 2.10 (s, 3H), 6.33 (br s, 1H).

A solution of the alkenone (5 g, 0.035 mol) and *p*-toluenesulfonhydrazide (6.5 g, 0.035 mol) in methanol (50 mL) was refluxed for 6 h in a 100-mL round-bottom flask. The reflux condenser was then removed and the methanol was allowed to distill until the solution became turbid. The heat source was then removed and enough methanol was added to the solution to remove the turbidity. The solution was allowed to cool slowly to room temperature, affording crystalline 2,2,5-trimethylhex-4-en-3-one tosylhydrazone (2.3 g, 0.0074 mol, 21%, mp 108–113°C), which was identified on the basis of its ^{1}H nmr spectrum (δ($CDCl_3$): 1.40 (s, 3H), 1.80 (s, 3H), 2.40 (s, 3H), 5.30 (s, 1H), 7.25 (s, 1H), 7.35 (s, 1H), 7.78 (s, 1H), 7.88 (s, 1H)).

Base-catalysed thermal decomposition of the tosylhydrazone (4 g, 0.013 mol) by the published method (44) afforded a colourless liquid that was identified as 1-*tert*-butyl-3,3-dimethylcyclopropene (**4**; 0.24 g, 0.0019 mol). The compound was obtained in greater than 99.9% purity after bulb-to-bulb distillation and vpc purification (column (e), column temperature 85°C); ir ($CDCl_3$, cm^{-1}): 3068, 2960, 2930–2875, 1755, 1700, 1588, 1519, 1396; ^{1}H nmr δ(CCl_4): 1.08 (s, 15H), 6.55 (s, 1H) (the singlet at 1.08 ppm can be resolved at high field (250 MHz) into a singlet and a doublet, which integrate 3:2, respectively); δ(C_6D_6): 1.18 (s, 9H), 1.37 (s, 6H), 6.65 (s, 1H); ^{13}C nmr δ(C_6D_6): 28.5, 29.0, 33.0, 109.2, 143.2; ms (*m/e* (I)), 124 (2), 109 (82), 91 (15), 81 (64), 79 (40), 77 (22), 69 (27), 68 (18), 67 (100), 65 (20).

*1-^{13}C-1,3,3-Trimethylcyclopropene (**5**)* was prepared in similar fashion to **3**, from the tosylhydrazone of (2-^{13}C)-mesityl oxide, as a 10% mixture with unlabelled material (**3**). To a suspension of anhydrous sodium acetate (2.25 g, 0.027 mol), (2-^{13}C)-sodium acetate (0.25 g, 0.003 mol, 99.6 at.% ^{13}C), lithium (1 g, 0.15 mol), and glass beads in anhydrous ether (500 mL) was added a solution of 1-bromo-2-methylpropene (12 g, 0.088 mol) in anhydrous ether, dropwise over 20 min (46). A dry argon atmosphere was maintained over the reactants during the entire reaction. After vigorous stirring for 24 h, the reaction mixture was cooled in an ice bath. Excess lithium was removed from the flask and the solution was treated with an excess of saturated aqueous ammonium chloride. The organic portion was separated, dried over anhydrous sodium sulfate, and the solvent was removed carefully on a rotary evaporator while maintaining a bath temperature of ca. 0°C. The product obtained was shown to be a mixture of (2-^{13}C)-4-methyl-3-penten-2-one and 2,5-dimethyl-2,4-hexadiene (2.6 g; ca. 75% mesityl oxide by ^{1}H nmr). The product was used without further purification for the preparation of **5**, using a procedure similar to that outlined above for **3**, and was purified to >99.9% purity by semipreparative vpc (see above). The ^{13}C spectrum of the mixture (δ($CDCl_3$): **131.00**, 112.56, 27.0, 9.97), compared to that of unlabelled **3**, showed it to be approximately 10% enriched at the 1-position (δ 131.0 ppm).

*4-Methyl-1,3-pentadiene (**8**) and* cis*-2-methyl-1,3-pentadiene (*cis*-**9**)* were prepared by dehydration of 2-methyl-2,4-pentanediol according to the published method (45). Purification by semipreparative vpc (columns (d) and (e)) afforded both compounds in greater than 99% purity. *cis*-**9** exhibited the following spectral data: ir (CCl_4): 3082, 2950, 1790, 1640, 1600, 1450, 1370, 885, 665, 515; ^{1}H nmr, δ(CCl_4): 1.64 (d, 3H), 1.70 (s, 3H), 4.67 (s, 1H), 4.78 (s, 1H), 5.35 (m, 1H), 5.67 (d, 1H); ^{13}C nmr, δ(CCl_4): 140.85, 131.83, 124.78, 115.05, 23.29, 14.43.

*1-(2,2-Dimethylcyclopropyl)-2-methylpropene (**14**)* was prepared in 87% yield from 2,5-dimethyl-2,4-hexadiene, diiodomethane, and Zn/Cu couple by a previously described method for the generation of cyclopropanes from alkenes (47), with only slight modification to the general procedure. After work-up, bulb-to-bulb distillation and purification by semipreparative vpc (column (d), column temperature 80°C) afforded **14** in greater than 99% purity. The ^{1}H and ^{13}C nmr spectra of the compound agreed satisfactorily with those previously reported (47).

*2,3,5-Trimethyl-2,4-hexadiene (**15**)*

Finely chopped lithium (0.23 g, 0.033 mol) and about 50 glass beads were added to anhydrous ether (100 mL) in a two-neck round-bottom flask fitted with a reflux condenser, magnetic stirrer, and dropping funnel. A slight positive pressure of dry argon was maintained inside the reaction flask. A solution of 1-bromo-2-methyl-propene (48) (4 g, 0.03 mol) in anhydrous ether (30 mL) was added dropwise to the reaction flask with vigorous stirring, controlling the addition rate to maintain a gentle reflux. After the addition of the bromide was complete, the reaction was stirred for an additional 15 min. A solution of 3-methyl-2-butanone (2.6 g, 0.03 mol) in anhydrous ether (30 mL) was then added dropwise to the mixture. Following addition of the ketone, the reaction mixture was stirred at room temperature for an additional hour. The reaction mixture was quenched with 5% aqueous HCl, the ether layer was separated, and the remaining aqueous fraction was extracted with ether (3 × 25 mL). The combined ether extracts were washed with water and dried over anhydrous sodium sulfate. Evaporation of the solvent on the rotary evaporator afforded a pale yellow oil (3.5 g, 0.025 mol, 82%), which was identified as 2,3,5-trimethylhex-4-en-3-ol on the basis of its ^{1}H nmr spectrum. The alkenol (3.5 g, 0.025 mol) and a crystal of *p*-toluenesulfonic acid were dissolved in benzene (150 mL), and the resulting solution was refluxed for 4 h in a 250-mL round-bottom flask fitted with a small Dean–Stark trap and reflux condenser. The solution was then cooled to room temperature and the solvent was removed on the rotary evaporator, affording a yellow oil (2.7 g, 0.022 mol, 87%). Bulb-to-bulb distillation followed by semipreparative vpc (column (e), column temperature 80°C) yielded a colourless liquid in greater than 99.5% purity, which was identified as 2,3,5-trimethyl-2,4-hexadiene (**15**) by comparison of its ir and ^{1}H nmr spectra with previously reported data (49).

Photochemical experiments employed the pulses (193 nm, ca. 10 ns, 20–100 mJ, 2.0 and 0.25 Hz repetition rate for quantitative and preparative photolyses, respectively) from a Lumonics TE-861M excimer laser filled with an argon/fluorine/helium mixture, a 10-W Osram HNS 10W/U OZ low pressure mercury lamp (185 + 254 nm),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

a 16-W zinc resonance lamp (Philips 93106E; 214 nm), or a 16-W cadmium spectral lamp (G. W. Gates & Co.; 228 nm). The lamps were given a 20-min warm-up period before each experiment and were cooled with a stream of dry nitrogen.

Preparative photolyses were carried out with the laser in rectangular cells constructed from 10 × 20 mm rectangular Suprasil tubing (Vitro Dynamics). The solutions were deoxygenated before irradiation with dry nitrogen, and agitated during irradiation with a small magnitude stirrer.

The products from photolysis of **3** were identified by coinjecting photolysates carried to ca. 5% conversion with authentic samples on at least two vpc columns, and by comparison of the ^{1}H nmr spectra of isolated (from preparative runs carried to 20–25% conversion; by vpc with column (e)) samples with those of the authentic samples.

Compounds **11–13** and **16** were isolated from a preparative photolysis of **4** in *n*-pentane by semipreparative vpc (column (e)). They were identified on the basis of their ir, nmr (^{1}H and ^{13}C), and gc/ms spectra, and comparisons of the ^{1}H nmr spectra with published data. Compounds **14** and **15** were identified by coinjection of authentic samples with a photolysate carried to ca. 5% conversion on two vpc columns and by gc/ms comparisons to the authentic materials.

*2,2,5-Trimethyl-2,3-hexadiene (**11**)*: ^{1}H nmr (ref. 50), δ: 1.10 (d, 6H), 1.51 (s, 9H), 2.50 (m, 1H); ms, *m/e* (I): 124 (38), 109 (42), 81 (22), 79 (17), 77 (18), 68 (35), 67 (100), 65 (15).

*2,2,5-Trimethyl-3-hexyne (**12**)*: ^{13}C nmr (ref. 51), δ: 87.64, 83.93, 31.17, 30.60, 23.27, 20.07; ms, *m/e* (I): 124 (7), 109 (39), 81 (33), 79 (19), 77 (39), 67 (100). The ^{1}H nmr spectrum of this compound agreed with that previously published (50).

trans-*2,5,5-Trimethyl-1,3-hexadiene (**13**)*: ir ($CDCl_3$): 2962, 2865, 1607, 1551, 1437, 1364, 1263, 1202, 1007; ^{1}H nmr, δ: 1.06 (s, 9H), 1.80 (s, 3H), 4.87 (s, 2H), 5.6 (d, 1H), 6.05 (d, 1H); ^{13}C nmr, δ: 18.5, 29.5, 32.7, 114.2, 127.4, 141.3, 142.0; ms, *m/e* (I): 124 (28), 109 (100), 81 (29), 79 (18), 67 (77).

*2-Methyl-(3-*tert*-butyl)-1,3-butadiene (**16**)*: ^{1}H nmr (500 MHz), δ: 1.09 (s, 9H), 1.87 (t, 3H), 4.64 (m, 1H), 4.71 (d, 1H), 4.84 (m, 1H), 4.86 (d, 1H); ^{13}C nmr, δ: 25.8, 29.8, 35.4, 108.7, 113.0, 147.4, 161.4; ms, *m/e* (I) = 124 (12), 109 (100), 81 (29), 79 (15), 68 (36), 67 (92).

Quantitative photolyses were carried out at ambient temperature (ca. 23°C) in 10 × 25 mm cylindrical Suprasil quartz cells (Hellma). In all cases, the sample was agitated during irradiation with a small magnetic stirrer or with a mechanical shaker. Solutions were deoxygenated before irradiation by bubbling dry nitrogen or argon through the cooled (to ca. 0°C) solutions for 5–15 min. Photolysis solutions were monitored between 0.25 and 5% conversion, with aliquots being withdrawn at suitable time intervals (every 50–100 laser pulses) for vpc analysis on column (b). Relative product yields were determined from triplicate vpc analysis. The yields listed in eqs. [5] and [6] for the photolyses (193 nm) of **3** and **4** in pentane represent the averages of the determinations at several conversions below 5%.

Carbene trapping experiments were attempted in deoxygenated methanol (0.1 M **3**, 214 nm) and 1-hexene (0.1 M **3**, 228 nm) solution. The pure methanol and methanol/**3** solutions had uv absorbances (1 mm pathlength) of 0.15 and >5 respectively at 214 nm. Similarly, the 1-hexene and 1-hexene/**3** solution had uv absorbances of 0.7 and >5 respectively at 228 nm. In both experiments, aliquots were taken at various irradiation times, up to 6–10% conversion, and analysed by vpc (column (a)). In both cases, the product distributions were indistinguishable from those obtained in control runs at each wavelength using deoxygenated *n*-pentane as solvent.

The ^{13}C-labelled products **6*–10*** were isolated by semipreparative vpc (column (e)) from the preparative photolysis of **5**. Their identities were verified on the basis of their ^{1}H and ^{13}C nmr spectra. Single-pulse ^{13}C nmr spectra of **8*–10*** were measured at 62.5 MHz in $CDCl_3$ in the presence of $Cr(acac)_3$, with a delay of 0.6 s between pulses. Prior to obtaining the Fourier transform, 10^4–10^5 acquisitions were signal-averaged in 16K of memory, and processed with 40-Hz line-broadening. The spectra were compared to those of the unlabelled compounds recorded under the same conditions. The positions of the ^{13}C-label in **6*–10*** are indicated below with boldface text.

*2-Methyl-2,3-pentadiene (**6***)*: ^{13}C nmr, δ: **203.43**, **93.86**, 83.57, 20.61, 14.90.

*4-Methyl-2-pentyne (**7***)*: ^{13}C nmr, δ: **84.97**, **74.37**, 23.19, 20.34, 3.29.

*4-Methyl-1,3-pentadiene (**8***)*: ^{13}C nmr, δ: 135.64, **133.35**, 125.84, 113.98, 25.74, 18.09.

trans-*2-Methyl-1,3-pentadiene (**9***)*: ^{13}C nmr, δ: 142.05, 134.07, **125.27**, 113.69, 18.56, 17.98.

*2,3-Dimethyl-1,3-butadiene (**10***)*: ^{13}C nmr, δ: **143.29**, 112.71, 20.36.

Quantitative ^{13}C nmr integrations were carried out with solutions of **6*** and **7*** (ca. 0.05 M) and $Cr(acac)_3$ (ca. 0.01 M) in $CDCl_3$ using an inverse gate decoupling pulse sequence (33*a*). Carbon T_1 measurements were carried out for **6** and **7** on the Bruker AM500, and employed a π–τ–$\pi/2$ nonselective inversion–recovery pulse sequence. In the presence of $Cr(acac)_3$, the carbon T_1 values were found to vary between 0.6 and 1.1 s for both compounds. A delay of 7 s was therefore used between acquisitions for quantitative integrations.

For **6***, 10^4 free induction decays were recorded and signal-averaged in 16K of memory, and were processed with baseline correction and 40-Hz line-broadening prior to obtaining the Fourier transform. Comparison to a spectrum of unlabelled **6** recorded under the same conditions revealed relative signal enhancements for only the peaks due to C3 (203.43 ppm) and C4 (93.86 ppm); the relative intensities of the peaks due to all other carbons in the molecule were indistinguishable from those in the unlabelled material. Enrichment factors at C3 and C4 were then calculated using the integrals for the other carbon signals as a standard. The enrichment factors for **6*** reported in eq. [7] are the average of three independent determinations, and the error is quoted as a single standard deviation of the mean.

The more rigorous procedure employed for **7*** has been described in detail elsewhere (34). Briefly, spectra were recorded for a solution of **7*** and $Cr(acac)_3$ in $CDCl_3$ in a 5-mm nmr tube in which was placed a coaxial insert containing a $CDCl_3$ solution of ethanol of accurately measured concentration. The latter functioned as an external integration standard. For **7***, 10^3 free induction decays was recorded and signal-averaged in 16K of memory, and were processed with baseline correction, 40-Hz line-broadening, and zero-filling to 64K, followed by the Fourier transform. The integrals for each carbon in the spectrum were measured as the peak heights. Ten such spectra were recorded, and the peak heights of the signals due to **7*** relative to those due to the standard were averaged. The procedure was repeated for six different concentrations of the ethanol external standard, and the results plotted against inverse ethanol concentration. The slopes of these plots are proportional to the number of ^{13}C nuclei in the sample for each carbon. Comparison to data obtained for a sample of unlabelled **7** by a similar procedure reveals that only the signals due to C3 (84.97 ppm) and C4 (74.37 ppm) are enhanced in the labelled material. Enrichment factors at C3 and C4 were then calculated using the integrals (slopes of the above plots) for the other carbon signals as a standard, and are listed in eq. [7]. The errors were calculated using the standard deviations from least-squares analysis of the intensity vs. $[\text{ethanol}]^{-1}$ plots.

Acknowledgments

We thank Professor A. D. Bain (McMaster University) for his help with the ^{13}C nmr analyses, Professor R. E. Hill (McMaster University) for the gc/ms analyses, and Mr. B. Sayer for technical assistance. The financial support of this work by the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

The reactions of nitrosoarenes with cationic cyclohexadienyl complexes of iron tricarbonyl: an ESR study

LIJUAN LI, RICHARD E. PERRIER, DONALD R. EATON,[1] AND MICHAEL J. MCGLINCHEY
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received March 31, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

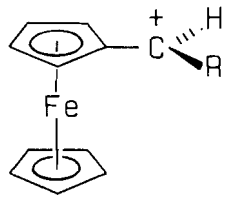
LIJUAN LI, RICHARD E. PERRIER, DONALD R. EATON, and MICHAEL J. MCGLINCHEY. Can. J. Chem. **67**, 1868 (1989).

The reactions of nitrosoarenes with the (cyclohexadienyl)$Fe(CO)_3$ cation have been investigated by using electron spin resonance spectroscopy. The radicals produced are nitroxides of the type $(OC)_3Fe(C_6H_7)(Ar)N—O•$ but, in some cases, disproportionation and loss of the metal carbonyl fragment leads to the corresponding $C_6H_5(Ar)N—O•$ radical. With bulky nitrosoarenes, such as C_6Me_5NO, isomers are observed in which the aryl ring rotation is slow on the ESR time scale. The analogous reactions with the cyclohexadienyl cation derived from the B ring of (ergosteryl acetate)$Fe(CO)_3$ lead to initial attack not at one of the termini of the delocalized system but rather at the central carbon, i.e., at C-7. Subsequent hydrogen migration leads to the (5,7-diene)$Fe(CO)_3$ complex bearing the arylnitroxide at the 7-position. The mechanisms of these reactions are discussed.

Key words: nitrosoarenes, iron cations, ESR.

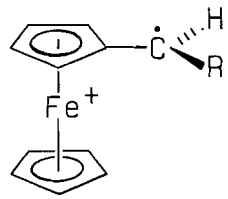
LIJUAN LI, RICHARD E. PERRIER, DONALD R. EATON et MICHAEL J. MCGLINCHEY. Can. J. Chem. **67**, 1868 (1989).

Utilisant la spectroscopie RPE, on a étudié les réactions des nitrosoarènes avec le cation (cyclohexadiényl)$Fe(CO)_3$. Les radicaux qui sont produits sont des nitroxydes du type $(OC)_3Fe(C_6H_7)(Ar)N—O•$; toutefois, dans quelques cas, il se produit une disproportionation et la perte du fragment métallocarbonyle conduit à la formation du radical $C_6H_5(Ar)N—O•$ correspondant. Avec des nitrosoarènes encombrés, comme le C_6Me_5NO, on observe la formation d'isomères dans lesquels la rotation du noyau aryle est lente pour l'échelle de temps de la RPE. Les réactions analogues effectuées sur le cation cyclohexadiényle dérivé du cycle B de l'(acétate d'ergostéryle)$Fe(CO)_3$ conduisent à une première attaque qui s'effectue sur le carbone central, C-7, et non sur les extrémités du système délocalisé. Une migration subséquente d'hydrogène conduit au complexe (5,7-diène-$Fe(CO)_3$ portant le nitroxyde d'aryle en position 7. On discute des mécanismes de ces réactions.



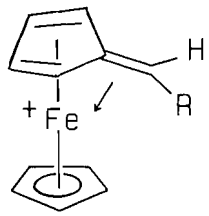
Mots clés : nitrosoarènes, cations du fer, RPE.

[Traduit par la revue]



Introduction

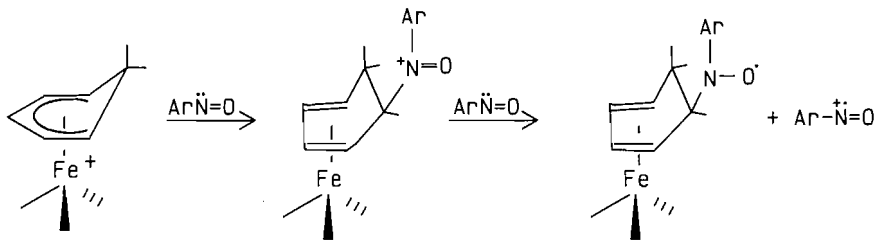
Nitroso compounds have been used extensively for spin trapping (1). Their use for this purpose has been particularly developed by Terabe *et al.* (2–4). The chemistry involved is rather straightforward. An unstable radical R• reacts rapidly with a nitroso compound R′NO to give a stable nitroxide radical RR′N—O•. The ESR spectrum of the nitroxide radical may be examined at leisure and the structure of the short-lived radical R• inferred from the analysis. The technique has been extensively applied to the identification of free radicals generated by the photolysis of organometallic compounds (5). A number of reactions are also known in which nitroxide radicals are generated by the reactions of nitroso compounds with diamagnetic materials. In these cases, the chemistry must be rather more complex since two diamagnetic spin-paired molecules react to give an odd electron radical. The reactions with certain olefins, for which an "ene" mechanism has been suggested (6–8), are perhaps the best characterized.



There are also several reports in which the reaction of nitroso compounds with diamagnetic organometallic complexes yields nitroxide radicals. Cais and co-workers (9, 10) studied the reactions of nitrosobenzene with cationic iron complexes with substituted cyclopentadienyl, cycloheptadienyl, and other dienyl ligands. In the first type of compound the ferrocene **1***a* had a CHR^+ substituent and it was suggested that reaction might occur via a structure **1***b* containing Fe^{3+} and CHR• moieties. Spin trapping of the latter fragment seemed a very reasonable experiment to try. Nitroxide radicals corresponding to addition at the CHR group were indeed detected but the observation that the precursor CH_2OH compounds gave the same products with

1*a*

1*b*



1*c*

equal ease cast doubts on the radical mechanism. An alternative mechanism involving nucleophilic attack by the nitrosobenzene was suggested. Subsequent X-ray crystallographic studies of both iron and osmium analogues of **1** reveal that the exocyclic methylene is bent towards the metal by ≈20°, and so the best representation of the ferrocenylmethyl cation may well be that shown in **1***c* (11, 12) Returning to the reactions of nitroso compounds with organometallic molecules, we note that Belousov and Kolosova have recently reported the reactions of 2-methyl-2-nitrosopropane with a number of iron carbonyls. A variety of radicals, including some nitroxides, were observed by ESR and the mechanisms of the reactions discussed in some detail (13).

3*a* Ar = C_6H_5
b Ar = C_6Me_4H
c Ar = C_6Me_5

In the present paper, we describe initially the reactions of several nitroso compounds with the [(η^5-cyclohexadienyl)tricarbonyliron(I)]$^+$ cation, **2**. This complex, which is particularly notable for the stabilization of the organic cation brought about by complexation, should provide a site for facile nucleophilic attack by the nitroso compound. This complex is also a model for cationic derivatives of steroids, and spin labelling of the steroidal system (14) has considerable potential for structural and stereochemical studies. Thus, having established the reactivity pattern for the model system **2**, we then describe the behavior of several nitrosoarenes with the novel cation **4** in which the metal-stabilized cyclohexadienyl system is located in the steroidal B ring (15).

Results

[(η^5-Cyclohexadienyl)tricarbonyliron(I)]$^+$ tetrafluoroborate, **2**, was allowed to react with nitrosobenzene, nitroso-2,3,5,6-tetramethylbenzene (nitrosodurene), and also with nitrosopentamethylbenzene. In each case nitroxide radicals were detected by ESR spectroscopy and we describe each separately since their reactions are not identical.

Reaction of 2 with C_6H_5NO

Upon mixing a well-degassed solution of **2** in acetonitrile with nitrosobenzene at ambient temperature, an ESR spectrum appears within about 20–30 min. This spectrum (see Fig. 1a) comprises a triplet of quintets. The triplet structure is ascribed to ^{14}N hyperfine splitting (a_N = 11.2 G) and the pseudo-quintet to ^1H coupling where four protons exhibit almost equivalent hyperfine coupling (a_H = 3.0 G). The radical has a g value of 2.0067 and the spectrum remains unchanged after several days in a sealed ESR tube. The spectrum disappears if the tube is irradiated with a high pressure mercury lamp and in this case no other ESR signal is observed. The spectrum illustrated in Fig. 1a is attributed to the nitroxide radical **3***a* formed by addition of C_6H_5NO to the cationic carbon atom of the iron complex **2**.

If the above reaction is carried out in dichloromethane rather than in acetonitrile, the same ESR spectrum is initially observed. However, this radical is not stable in CH_2Cl_2 and, after 1 day, a complex spectrum develops, which eventually simplifies to that shown in Fig. 1c. This latter radical is very stable and has been identified as diphenylnitroxide. A simulated spectrum using literature hyperfine coupling constants (16) is presented as Fig. 1d. Although $(C_6H_5)_2NO\bullet$ is clearly the major product of the reaction, there are also some additional lines from a second radical. During this reaction the colour of the solution changes from yellowish-green to dark yellow and the formation of some brown precipitate is observed. The ESR parameters obtained from the above spectra are collected in Table 1.

Reaction of 2 with C_6HMe_4NO

Nitrosodurene has some advantage over nitrosobenzene as a spin trap in that the resulting ESR spectra are generally simpler and hence easier to analyse. In the solid, and also in solution, nitrosodurene exists as a colourless dimer (17). When such a solution is warmed a light green colour appears and this has been attributed to dissociation of the dimer to reactive monomer. It was found that, even at room temperature when the concentration of monomer is very small, nitrosodurene reacts with **2** and the product gives an ESR spectrum. The mixture of the cationic iron complex, **2**, and C_6HMe_4NO is not soluble in either pure acetonitrile or pure chloroform; there is, however, sufficient solubility in a 1:1 mixture of these solvents to obtain ESR spectra. The initial spectrum (Fig. 2a) is a triplet of doublets (a_N = 13.75 G, a_H = 3.6 G, g = 2.0069) as anticipated. However, over a period of several days, new and more complex spectra appear as shown in Fig. 2b. The final spectrum (Fig. 2c) corresponds to a very stable radical and no subsequent changes were observed over a further period of 4 days. Very similar spectra were obtained in CH_3CN/CH_2Cl_2 (1:1) mixtures. However, if the reaction is run in a 1:1 mixture of dimethylsulfoxide and benzene there is evidence for a second less abundant radical and the spectrum (Fig. 3a) can be simulated (Fig. 3b) as a superposition of two six-line spectra with an intensity ratio of 4:1. The parameters extracted from this analysis were a_N = 13.4 G, a_H = 3.3 G, and g = 2.0068 for the more intense species and a_N = 13.95 G, a_H = 12.3 G, g = 2.0060 for the minor component. It may be noted that the parameters for the more intense species are very similar to those obtained in $CH_3CN/CHCl_3$ mixtures. These spectra also changed with time to give initially a complex spectrum (Fig. 3c) but finally reverted to a six-line spectrum (Fig. 3d) very similar to the initial more intense spectrum. Further spectra were obtained in other mixed solvent systems containing chloroform or methylene chloride in addition to benzene and DMSO. The radicals obtained were essentially the same as those of Fig. 3, suggesting that acetonitrile is necessary to obtain the spectrum shown in Fig. 2c. Hyperfine coupling constants and g values obtained from the nitrosodurene spectra are collected in Table 2.

Reaction of 2 with C_6Me_5NO

The reaction was examined in mixtures of DMSO and benzene (1:1) and in benzene alone. The results in the two solvent systems were very similar. In both cases, the initial spectra consisted principally of two six-line patterns, which in this case were of roughly equal intensity. There are two additional lines in the wings of the spectrum that we are unable to assign. The hyperfine parameters obtained from the two six-line spectra are very similar to those obtained from the corresponding nitroso-

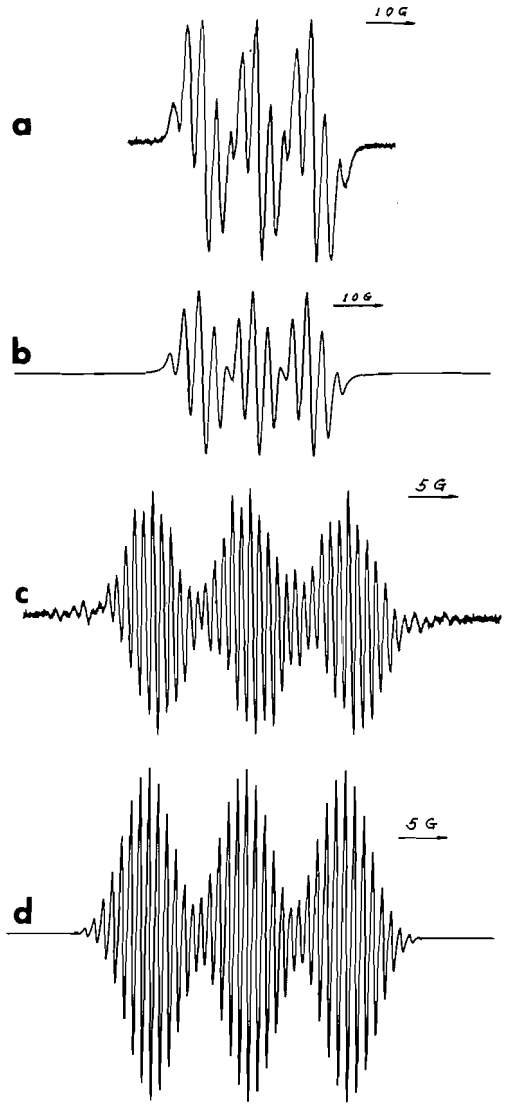

FIG. 1. ESR spectra from the reaction of **2** with C_6H_5NO (a) in CH_3CN; (b) simulation of (a) using the data in Table 1; (c) in CH_2Cl_2 after 6 days; (d) simulation of $(C_6H_5)_2N$—O• using data from ref. 20.

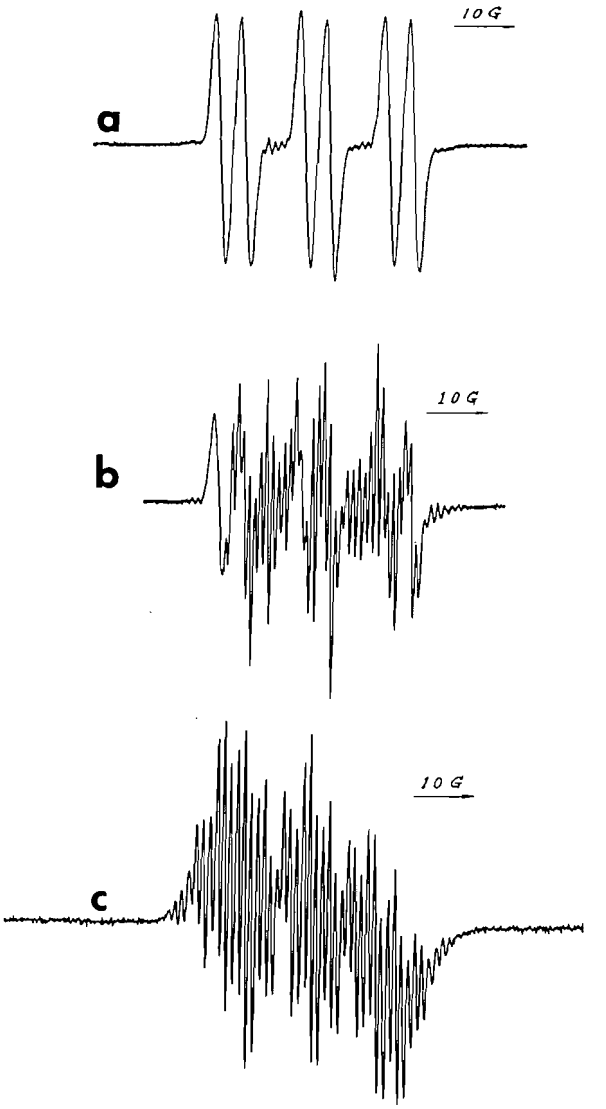

FIG. 2. ESR spectra from the reaction of **2** with C_6Me_4HNO in 1:1 $CH_3CN/CHCl_3$ (a) after 30 min; (b) after 20 h; (c) after 4 days.

durene reaction. On standing, more complex, but not analysable, spectra appear. Eventually most of the additional lines disappear and a six-line spectrum corresponding to one of the original spectra is left, as was the case for nitrosodurene in the DMSO/benzene solvent mixture. The data for this set of spectra are given in Table 2.

*Reaction of **4** with C_6H_5NO*

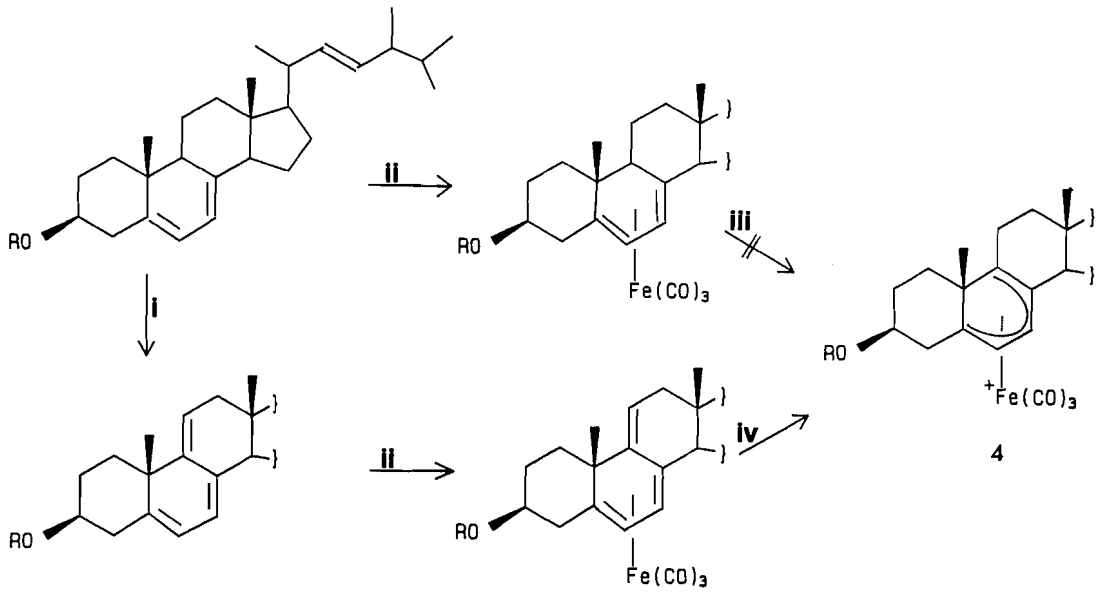
The steroidal cation **4** reacts with nitrosobenzene in acetonitrile solution almost immediately and causes a colour change from yellowish-green to yellow and, after a day, to red. The spectrum shown in Fig. 4a is that observed after ≈3 h and exhibits the expected triplet pattern for the nitrogen coupling as well as the hyperfine interactions with the phenyl protons. However, there is an extra and unanticipated relatively large doublet splitting (2.95 G) that, over the course of 24 h, gradually disappears. The final spectrum (Fig. 4b) still exhibits hyperfine coupling to the C_6H_5N moiety but the 2.95 G doublet splitting has disappeared. The data are collected in Table 1.

*Reaction of **4** with C_6Me_5NO*

The ESR spectrum initially produced when **4** reacts with nitrosopentamethylbenzene reveals a triplet of doublets overlapping a simple triplet (Fig. 5a); over a period of 10 h the latter feature (i.e., the triplet) gradually increases at the expense of the former. The final spectrum (after 21 h) is shown as Fig. 5d and exhibits a hyperfine interaction only with nitrogen.

*Reaction of **4** with C_6HMe_4NO*

Nitrosodurene and **4** give ESR spectra almost identical to those produced in the analogous nitrosopentamethylbenzene reaction.



Discussion

$[(Cyclohexadienyl)Fe(CO)_3]^+$ systems such as **2** are thermally stable, air-stable cations that react readily with nucleophiles (18) and so are valuable synthetic intermediates. Steroidal analogues of **2** are also known in which the delocalized system is sited in the A ring. It is only very recently that B ring cationic systems have become available. Attempts to remove the 9α hydrogen from the iron tricarbonyl complex of ergosteryl acetate are thwarted by the bulk of the organometallic fragment, which hinders the approach of the trityl cation that is normally used as the hydride abstracting agent. Instead, a multistep route

SCHEME 1. Synthetic route to the steroidal cation **4**. (i) Mercuric acetate/acetic acid. (ii) (Benzylideneacetone)$Fe(CO)_3$. (iii) $[(C_6H_5)_3C]^+ BF_4^-$. (iv) HPF_6.

has been developed that involves initial oxidation of ergosterol to 9,11-dehydroergosterol; complexation of the $Fe(CO)_3$ moiety to the 5,6,7,8-diene unit and subsequent protonation at C-11 yields the required cation **4**, as shown in Scheme 1.

Nucleophilic attack on metal-complexed polyenyls generally occurs at one of the termini of the delocalized system (19); indeed, nucleophilic attack by the nitrosoarene on the [pentadienyl)$Fe(CO)_3$]$^+$ cation **5** is an entirely reasonable mechanism to account for the observations of Cais *et al.* (9, 10). They reported that the initially formed radical **6** can be reduced to the corresponding amine **7**, and the latter molecule, which is diamagnetic, was readily characterized by NMR spectroscopy.

Assignments of the ESR spectra

The ESR data we have obtained are collected in Tables 1 and 2. These tables also contain some relevant literature data. The

initial task is to assign the various spectra. By analogy with the results of Cais *et al.*, the radical that would be expected is that shown as **3**, that is, the cyclohexadiene iron tricarbonyl system substituted at the formerly cationic carbon by the group NOAr, where Ar varies according to the identity of the nitrosoarene

used. In Table 1 the hyperfine coupling constants obtained from the spectra resulting from the reaction of **2** with nitrosobenzene are compared with those reported by Cais and with several organic nitroxide radicals with mixed phenyl and aliphatic substituents. The hyperfine coupling constants of the initial radical from the reactions of **2** in both CH_2Cl_2 and CH_3CN agree closely with those of molecules from the literature possessing analogous structural features and there seems little doubt that the structure of the radical is **3***a*, where Ar = phenyl. As noted above, the final spectrum of the reaction in dichloromethane has been identified as the diphenylnitroxide radical.

The six-line spectrum initially obtained from the reaction of **2** with nitrosodurene is entirely consistent with a radical of structure **3***b*, with Ar = C_6Me_4H. The single proton splitting arises from the hydrogen at the point of attachment to the cyclohexadiene ring. As described above, in DMSO/benzene two six-line spectra are observed. They differ substantially in the hydrogen coupling constant: 3.3 G compared with 12.3 G. It is suggested that these two spectra arise from different rotamers of the same radical depending on the orientation of the NOAr group. There is ample precedent for slowed rotation in nitroxides containing such bulky substituents as durene or pen-

[a]Ar = durenyl; S = steroidal group; Ar′ = pentamethylphenyl.

tamethylbenzene (20). Simulation of the spectra indicates that the two isomers are present in a ratio of approximately 4:1. The angular dependence of the β-hydrogen coupling constants of nitroxide radicals has been discussed by Chapelet-Letourneux *et al.* (20). These workers examined the spectra of a variety of radicals with both alkyl and saturated ring substituents and suggested a relationship of the form $a_H = B \cos^2 \theta$ between the hyperfine coupling constant and the angle made between the C—H_β bond and the axis of the p orbital containing the unpaired electron. By calculating an average value of B from the literature data (5) we can see that a hyperfine coupling constant of 12.3 G gives an angle θ of 46° while a coupling constant of 3.3 G yields a θ value of 69°. We are currently in the process of trying to grow crystals of a closely analogous molecule with a view to obtaining X-ray data that could clarify this point.

There are data in the literature that support this assignment of the isomers. Thus Suehiro *et al.* (17) have trapped substituted 1,4-cyclohexadienyl radicals (the present results refer to the 1,3 isomer) and report a_H values of 6–8 G for the proton on the adjacent carbon atom. Kanimori *et al.* (21) report additional radicals of this type and discuss the hydrogen coupling constants in terms of the angle between the C—H bond and the p orbital on the nitrogen. It may be noted that the reported hyperfine coupling constants in these cases are close to the average of the values we find for the two isomers (1/2(3.3 + 12.3) = 7.8 G). A further paper by Konaka *et al.* (22) reports the observation of

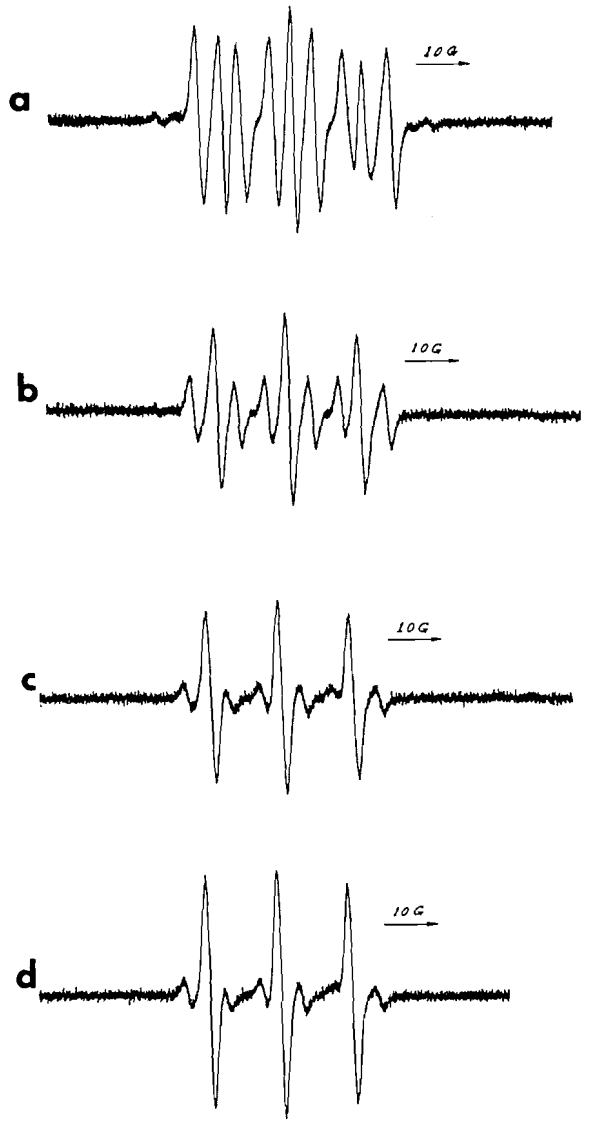

FIG. 5. ESR spectra from the reaction of **4** with C_6Me_5NO in CH_3CN (a) after 3 h; (b) after 6 h; (c) after 9 h; (d) after 21 h.

line width alternations for nitroxide spectra obtained with nitrosodurene. This observation is attributed to restricted rotation because of the bulkiness of the duryl group. The present observation is therefore consistent with more extreme steric restrictions. It may be taken as excellent proof that the iron tricarbonyl group remains attached to the nitroxide radical.

By analogy with the results with nitrosobenzene, it would have been expected that the more complex spectra that were obtained from the decomposition of the above radicals would correspond to the nitroxide radical with a phenyl group and a duryl group as substituents. However, the spectrum cannot be fitted to the hyperfine coupling constants expected for this radical. It appears more complex and we suspect that it may be a mixture of isomeric radicals differing in the relative orientations of the phenyl and duryl radicals. Again, this implies that the iron tricarbonyl group remains attached to the radical. The analysis of the spectra obtained from the reaction of **2** with nitrosopentamethylbenzene is identical to that for nitrosodurene. The angles derived from the proton coupling constants are also very similar. We have been unable to analyse the more complex spectra and similar reasons, based on mixtures of isomeric radicals, are suggested.

In a similar manner, the ESR spectra derived from the reactions of the steroidal cation **4** with the various nitrosoarenes can be assigned in a relatively straightforward manner. The initial spectrum in each case shows hyperfine couplings appropriate for the presence of the ArN fragment and also a single hydrogen on the steroidal carbon adjacent to the nitrogen. However, in each of the final spectra it is clear that the hydrogen atom is no longer bonded to the aforementioned carbon. In the nitrosopentamethylbenzene case, for example, ultimately we see merely the triplet splitting from the nitrogen.

Mechanistic considerations

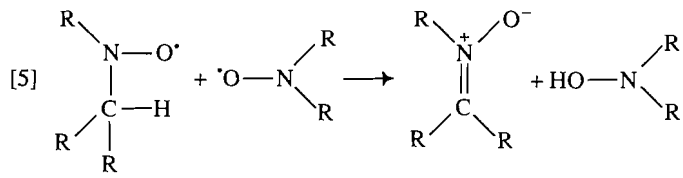
The initial stages of these reactions are directly analogous to those studied by Cais, which involved the attack of nitroso compounds on pentadienyl- or cycloheptadienyl-$Fe(CO)_3$ cations. One of the suggested mechanisms involved nucleophilic attack at the cationic carbon to give an oxo-ammonium ion that suffers one-electron reduction to give the nitroxide radical. There are some variations possible on this theme — reduction may occur before addition of the nitroso moiety or the reactive species may be a triplet ferricinium complex — but the end result is the same. It is assumed that a second molecule of nitroso compound acts as the one-electron reducing agent.

The subsequent reactions are rather more speculative but a reasonable scheme can be devised based on reactions that have literature precedents. We note first that the homolytic decomposition of nitroso compounds according to eq. [1] has been shown by Chatgilialoglu and Ingold (23) to be thermodynamically improbable as a thermal reaction, although it proceeds readily photochemically. However, Bilkis and Shein (24) have demonstrated that the analogous reaction involving the radical anion occurs readily, as in eq. [2].

[1] $R—N{=}O \rightarrow R\bullet + \bullet N{=}O$

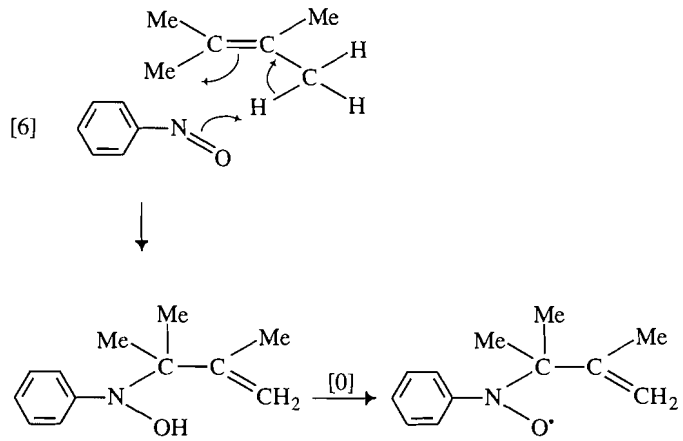
[2] $[R—N{=}O]^- \rightarrow R\bullet + [NO]^-$

More relevant, perhaps, is the report (25) that dialkylnitroxides react with $SbCl_5$ giving *N,N*-dialkyl-*N*-oxoammonium salts; these in turn yield NO^+, as in eqs. [3] and [4].



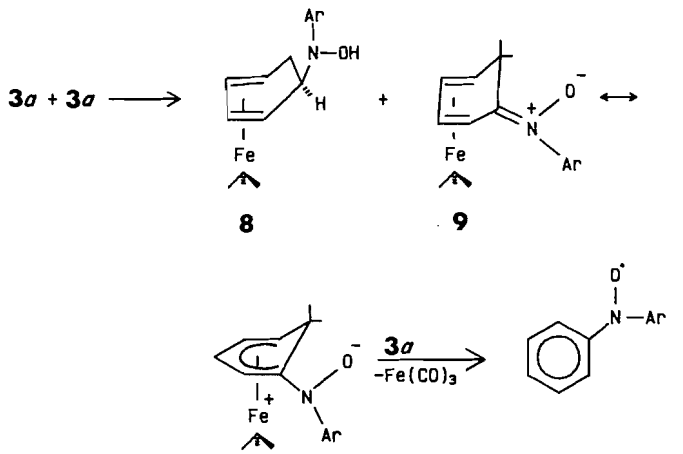
[3] $(t\text{-Bu})_2N—O\bullet + SbCl_5 \rightarrow [(t\text{-Bu})_2N{=}O]^+SbCl_6^-(+ SbCl_3)$

[4] $[(t\text{-Bu})_2N{=}O]^+SbCl_6^- \rightarrow N{\equiv}O^+SbCl_6^- + Me_2C{=}CH_2 + HCl$



Thus, a not unreasonable initial postulate is that fragmentation of the radical cation arising from the one-electron reduction of the initially formed adduct of nitrosobenzene and **2** yields NO^+ and the phenyl radical; this in turn can be trapped by nitrosobenzene to form diphenylnitroxide. One should note, however, that analogous reactions with C_6Me_5NO and C_6HMe_4NO would then be expected to give rise to the corresponding diarylnitroxides, i.e., $(C_6Me_5)_2NO\bullet$ and $(C_6HMe_4)_2NO\bullet$, but these are not observed in reactions with **2**. In fact, there is another possible route to $Ph_2NO\bullet$ that involves dehydrogenation of the cyclohexadienyl(phenyl)nitroxide ***3a***. (We mention parenthetically that the reaction of *t*-BuNO with cation **2** yields not only the expected nitroxide but also C_6H_5—(*t*-Bu)$NO\bullet$, which must arise via dehydrogenation of a cyclohexadienyl intermediate.) In this context, we next recall information on the self-reactions of nitroxides. These have been extensively studied by Ingold and co-workers (26–28) and also by Golubev *et al.* (29). Several different products can be formed depending on the nitroxide substituents but the typical reaction involves dimerization followed by hydrogen atom transfer to give a reduced product, often a hydroxylamine, and an oxidized product, frequently a nitrone, as in eq. [5].

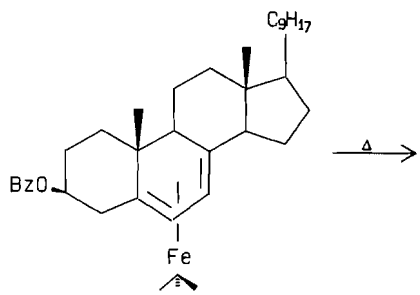
Furthermore, the mechanism of the ene reaction of nitroso



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

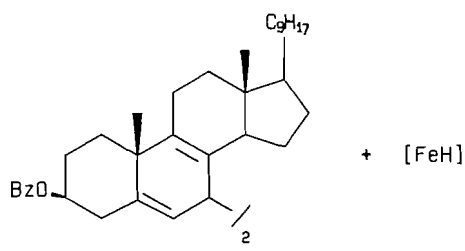
compounds with olefins involves initial formation of a C—N bond followed by hydrogen atom transfer to give a hydroxylamine; subsequently there occurs oxidation of the hydroxylamine to a nitroxide by a second molecule of nitroso compound, as in eq. [6] (7, 8, 30).

One could follow these literature precedents and postulate a disproportionation of radical **3***a* with a second nitroxide radical to give the hydroxylamine **8** and a neutral product **9**; subsequent



hydrogen abstraction by another molecule of **3***a* and loss of the $Fe(CO)_3$ fragment would then yield $Ph_2NO\bullet$. The formation of the aromatic ring would provide the thermodynamic driving force for such a reaction. Of course, the $Fe(CO)_3$ moiety binds strongly to diene units but is generally less firmly attached to arene rings; consequently, the radicals detected at the end of the reaction sequence are those of the noncomplexed diarylnitroxide and the metal is left as a residue at the bottom of the tube.

To summarize, therefore, the reaction of **2** with nitrosobenzene in acetonitrile yields the radical **3***a*, Ar = C_6H_5; in contrast, in dichloromethane the disproportionation reaction becomes significant. This leads to the corresponding hydroxylamine and nitrone; the latter can then suffer hydrogen atom abstraction by another molecule of **3***a* so that eventually there is complete conversion to diphenylnitroxide.



With nitrosodurene (and also with C_6Me_5NO) the initial reaction in CH_3CN/CH_2Cl_2 follows the pattern established for nitrosobenzene. Disproportionation occurs but the steric bulk of the polymethylated arene is sufficient to prevent free rotation and so a mixture of Ph(Ar)NO• isomers is detectable on the ESR time scale. In the DMSO/benzene mixtures two isomers are observed for the initial cyclohexadiene radical **3***b* (**3***c*). We speculate that these too can disproportionate but that in this solvent mixture the equilibrium favors the nitroxide radicals rather than the hydroxylamines. The existence of this equilibrium is, however, sufficient eventually to convert all of the cyclohexadienyl niroxide to the more favored isomer.

*Reactions of ArNO with the steroidal cation, **4***

By analogy with the reactivity pattern established for the unsubstituted $[(cyclohexadienyl)Fe(CO)_3]^+$ cation, **2**, one would anticipate initial nucleophilic attack by the nitrosoarene at a terminus of the delocalized system, that is at C-5 or C-9. Furthermore, in accord with the known chemistry of such iron complexes (18), the incoming nucleophile will approach from the distal side relative to the metal carbonyl unit. That is, attack will occur on the β face of the steroid. In principle, the two sites of attack are readily differentiable since binding to the C-5 position, as in **10**, should produce a radical showing weak coupling to the olefinic hydrogen at C-6 (and possibly even to the 4α and 4β protons). In contrast, if the ArNO were to attack at C-9, as in **11**, one should see essentially a simple triplet since there is no alkene hydrogen at C-8. The result of the experiment revealed that attack had occurred at neither C-5 nor C-9. The initial ESR spectrum from the reaction of C_6Me_5NO (Fig. 5a) shows the expected 1:1:1 triplet with a_N = 13.5 G and also a doublet splitting (7.7 G) clearly indicating the presence of a single hydrogen only two bonds away from the nitrogen. Apparently, the steric problems engendered by the placement of an aryl nitroso moiety at positions C-5 or C-9 render the C-7 site, as in **12**, a more attractive target (see Scheme 2). In seeking a precedent for bond formation at the 7-position, we note that the pyrolysis of ergosteryl benzoate iron tricarbonyl, **13**, is reported to yield the dimeric product **14** in which radical coupling has occurred at the 7-position (31).

SCHEME 2. Possible sites of reaction of nitrosoarenes with the steroidal cation **4**.

In Figs. 6a, 6b, and 6c we present energy-minimized conformers that were calculated by using the program MACROMODEL (32). It is readily apparent that incorporation of the attacking nucleophile can place a bulky aryl group in rather unfavorable positions with respect to the steroidal methyl substituents at C-10 and C-13. When the nitrosoarene attacks on the β face at C-5 the A/B rings are forced into a *cis*-fusion and the methyl must bend so as to avoid the new functional group. Similarly, attack at C-9 leads to steric problems but, as shown in Fig. 6b, attachment at C-7 is relatively unencumbered. It is interesting to note that for the energy-minimized structure of the initial adduct at C-7, i.e., **12**, there is a dihedral angle of 33° between the arene ring plane and the C—H bond; this translates as a 57° angle made by the *p* orbital on nitrogen and the C—H bond. Gratifyingly, the experimental hyperfine interaction to the H-7 nucleus is 7.9 G, which corresponds to an angle of 56°.

This initial product **12** leaves the $Fe(CO)_3$ fragment attached to a 1,4-cyclohexadiene system and, as is commonly the case with such nonconjugated diene complexes (33), a subsequent 1,3-hydrogen transfer occurs to generate the favored isomer **15** in which double bond conjugation is achieved. In this latter isomer the extra hyperfine coupling from the nearby hydrogen is lost. The net result of the whole process is to introduce a functional group at the 7-position of the steroid. Future work will focus on the reduction of the nitroxide radical to the more synthetically versatile amino function.

In contrast to the behaviour described above for nitrosoarenes, the corresponding reactions with *t*-BuNO exhibit a rather novel effect. The final product of the reaction with either **2** or **4** is $(t\text{-Bu})_2NO^{\bullet}$, but the ESR spectrum of this radical exhibits fascinating behaviour in that its intensity varies in an oscillatory manner with time. We prefer not to advance mechanistic speculations at this time until we have a better understanding of the kinetic parameters involved.

Experimental

Cyclohexa-1,3-diene, nitrosobenzene, and 2-methyl-2-nitropropane were purchased from Aldrich and were used without further purification. Nitrosodurene and nitrosopentamethylbenzene were synthesized following published procedures (36, 37). All syntheses were carried out under an atmosphere of nitrogen and all solvents were dried using standard procedures.

The (cyclohexadiene)$Fe(CO)_3$ complex was prepared by heating cyclohexa-1,3-diene with an $Fe(CO)_3$ precursor, namely, (benzylideneacetone)iron tricarbonyl (36) under reflux for 24 h in toluene. The reaction mixture was cooled, filtered through Celite, and the solvent removed by rotary evaporation. Subsequent chromatographic separation on a silica column and elution with a 1:1 mixture of hexane and toluene afforded the appropriate complex (≈60% yield) as previously reported by Birch *et al.* (39). The complex was then treated with Ph_3C^+ BF_4^- in CH_2Cl_2 and the cationic complex **2** was obtained as a yellow precipitate upon addition of ether. The steroidal cation **4** was synthesized as shown in Scheme 1. The experimental details and NMR spectroscopic data on **4** are the subject of a forthcoming paper (15).

ESR spectra were recorded on a Bruker ER-100D instrument operating at X-band frequency with 100-kHz modulation. Spectral simulations were carried out using the ESR program on the Bruker ASPECT 2000 computer. The *g* values were calculated from a knowledge of the microwave frequency and the magnetic field, the latter having been calibrated by use of DPPH. The ESR samples were prepared on a vacuum line with the cationic iron complex and the nitroso compounds degassed three times separately before mixing in an ESR tube. The concentrations of the reagents used were in the range 0.005–0.02 M.

Received April 5, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

MADHUMITA BARDAN, THOMAS BIRCHALL, CHRISTOPHER S. FRAMPTON, and PRATIBHA KAPOOR. Can. J. Chem. **67**, 1878 (1989).

The ^{127}I Mössbauer spectra of a series of mono- and diaryliodine(III) carboxylates have been recorded at 4.2 K. The observed parameters are shown to be strongly dependent on the primary bonding arrangement about iodine only and the secondary bonding interactions have little or no effect. The crystal and molecular structure of bis(trifluoroacetato)pentafluorophenyliodine(III), $(C_6F_5)I(O_2CCF_3)_2$, has been determined. Crystals are triclinic, of space group $P\bar{1}$, with a = 5.732(2) Å, b = 12.127(4) Å, c = 29.658(9) Å, α = 116.53(2)°, β = 98.02(2)°, γ = 117.09(2)°, V = 1482.0(8) Å^3, D_c = 2.33 g cm^{-3} for Z = 4, and R_1 = 0.0420 (R_2 = 0.0431) for 2722 reflections with $I > 3\sigma(I)$. The two independent molecules in the asymmetric unit have essentially the same primary geometry about the central iodine, a distorted T-shaped AX_3E_2 arrangement.

Key words: ^{127}I Mössbauer, aryliodine(III) carboxylates, crystal structure, $(C_6F_5)I(O_2CCF_3)_2$.

MADHUMITA BARDAN, THOMAS BIRCHALL, CHRISTOPHER S. FRAMPTON et PRATIBHA KAPOOR. Can. J. Chem. **67**, 1878 (1989).

Opérant à 4,2 K, on a enregistré les spectres de Mössbauer du ^{127}I d'une série de carboxyles de mono- et di-aryliode(III). On a démontré que les paramètres observés dépendent fortement et uniquement de l'arrangement de la liaison primaire autour de l'iode; les interactions secondaires de liaison n'ont que peu ou pas d'effet. On a déterminé les structures cristalline et moléculaire du bis(trifluoroacétato)pentafluorophényliode(III), $(C_6F_5)I(O_2CCF_3)_2$. Les cristaux sont triclinique et appartiennent au groupe d'espace $P\bar{1}$, avec a = 5,732(2), b = 12,127(4) et c = 29,658(9) Å et α = 116,53(2), β = 98,02(2) et γ = 117,09(2)°, V = 1482,0(8) Å^3, D_o = 2,33 g cm^{-3} et Z = 4; on a affiné la structure jusqu'à des valeurs respectives de R_1 et R_2 de 0,0420 et 0,0431 pour 2722 réflexions avec $I > 3\sigma(I)$. Les deux molécules indépendantes de l'unité asymétrique possèdent pratiquement la même géométrie primaire autour de l'iode central, un arrangement AX_3E_2 en forme de T déformé.

Mots clés : Mössbauer du ^{127}I, carboxyle d'aryliodide(III), structure cristalline, $(C_6H_5)I(O_2CCF_3)_2$.

[Traduit par la revue]

Introduction

We recently reported the ^{127}I Mössbauer parameters of some tris(carboxylato)iodine(III) complexes (1). In the course of this study the crystal and molecular structure of tris(acetato)iodine(III) was determined to gain further information regarding the nuclear environment of the iodine atom in compounds of this type and also to give an insight into any secondary bonding interactions that may be present. It was shown that the observed ^{127}I Mössbauer parameters were predominantly influenced by the strong primary bonds to the iodine nucleus, which are mainly of *p*-character, and that the secondary bonding interactions had little or no effect. This result was somewhat surprising since it has been shown by both Alcock *et al.* (2) and ourselves that there is an associated geometry change about the iodine nucleus from square-planar to pentagonal-planar coordination when going from a halogeno-iodine(III) compound to an equivalent oxo-iodine(III) compound. This change in geometry is based on the arrangement of both the primary and secondary bonds to the iodine nucleus and one would therefore expect slight changes in the observed quadrupole coupling constant and asymmetry parameter to occur.

Previous crystallographic studies on phenyliodine(III) carboxylates include compounds of the type $(C_6H_5)I(O_2CR)_2$, where R = $-CH_3$ (2, 3), $-CHCl_2$ (2), and $-CF_3$ (4) and also the μ-oxo derivative $[(C_6H_5)I(O_2CCF_3)]_2O$ (5). Inspection of the bonding in these materials reveals a variety of structural modifications, to what is nominally an AX_3E_2 trigonal-bipyramidal system. These structural modifications arise from differing secondary bonding arrangements about the central iodine nucleus.

Given the above information it was decided to extend the range of available data for these complexes and a systematic series of aryliodonium carboxylates were prepared and characterized by various techniques. In this paper, the second in a present series, we report the ^{127}I Mössbauer parameters, at 4.2 K, for a series of phenyl and diphenyliodine(III) carboxylates. The crystal and molecular structure of $(C_6F_5)I(O_2CCF_3)_2$ was determined and the ^{127}I Mössbauer data interpreted in relation to this and other available structural data.

Experimental

Materials and general procedures

Acetic acid (BDH, AnalaR) was refluxed with 2 mol% acetic anhydride (BDH) for 24 h and then distilled. The fraction distilling at 114–115°C was collected for use. Trifluoroacetic acid (Baker analyzed) was refluxed for 2 mol% of trifluoroacetic anhydride (BDH) for 8 h and then distilled. The fraction distilling at 72°C was collected for use. Mono- and dichloroacetic acids (Aldrich) were made anhydrous by the addition of their respective anhydrides. Iodine (BDH, AnalaR) was freshly sublimed before use. Iodobenzene (Aldrich, 98%), iodopentafluorobenzene (Aldrich, 99%), silver acetate (MCB, 99.5%), silver trifluoroacetate (Aldrich, 98%), and potassium iodide (reagent grade) were used without further purification.

Preparation of the compounds

The iodine absorbers used in this study were prepared using

TABLE 1. Crystal data for $(C_6F_5)I(O_2CCF_3)_2$

Parameter	Value
Formula	$C_{10}F_{11}O_4I$
FW	519.99
System	Triclinic
Space group	$P\bar{1}$ No-2
a, Å	5.732(2)
b, Å	12.127(4)
c, Å	29.658(9)
α, deg	116.53(2)
β, deg	98.02(2)
γ, deg	117.09(2)
V, Å^3	1482.0(8)
Z	4
D_c, g cm^{-3}	2.33
$F(000)$	973.95(976)
μ(MoKα), cm^{-1}	23.5 (21.2)
Final R_1, R_2[a,d]	0.0635, 0.0604
Weighting scheme	$w = (\sigma^2F + 0.000986F^2)^{-1}$
Error in observation of unit weight[b]	1.3116
Highest peak, e Å^{-3}; location	1.10; 0.41, 0.94, 0.54[c]
Lowest peak, e Å^{-3}	−0.97

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_2 = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2}$.
[b] $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. m = no. of reflections, n = no. of variables.
[c] 1.06 Å from $I(1)$.
[d] R_1, R_2 for 2722 reflections with $I > 3\sigma(I)$: 0.0420, 0.0431 respectively.

established literature methods (6, 7) and their authenticity verified by X-ray crystallography and (or) analysis for iodine and acid ligand using standard procedures (8).

Synthesis of bis(trifluoroacetato)pentafluorophenyliodine(III)

This compound was prepared according to the method of Schmeisser *et al.* (9), mp 118°C. *Anal.* calcd. for $C_{10}O_4F_{11}I$: I 24.40, acid ligand 43.47; found: I 24.89, acid ligand 42.87.

Synthesis of (trifluoroacetato)diphenyliodine(III)

Diphenyliodonium bromide (10) (2.0 g; 5.54 mmol) dissolved in 100 mL of hot water was added with stirring to a solution of 1.25 g (5.66 mmol) of silver trifluoroacetate in 100 mL of hot water. The resulting precipitate of silver bromide was quickly removed by filtration. The filtrate was concentrated and (trifluoroacetato)diphenyliodine(III) precipitated as white crystals on cooling, mp 198°C. *Anal.* calcd. for $C_{14}H_{10}O_2F_3I$: I 32.20, acid ligand 28.67; found: I 32.74, acid ligand 28.13.

X-ray crystallography

Clear needle-like crystals were examined under a polarizing microscope for homogeneity and well-formed specimens were sealed in Lindemann capillaries. Unit cell parameters were obtained from a least-squares fit of χ, φ, and 2θ for 15 reflections in the range $16.1° < 2\theta < 24.5°$ recorded on a Syntex $P2_1$ diffractometer with use of graphite monochromated MoKα radiation (λ = 0.71069 Å at 22°C). Intensity data were also recorded on a Syntex $P2_1$ diffractometer with a coupled θ(crystal)–2θ(counter) scan, for 4462 reflections in the quadrant $h, \pm k, \pm l$ with $2\theta \leq 45°$. The methods of selection of scan rates and initial data treatment have been described (11, 12). Two standard reflections (0,3,5; 4.4% and −2,4,−5; 5.6% monitored every 48 reflections) showed signs of some crystal decomposition and the data were adjusted accordingly (maximum rescale factor (on I), 1.580). Corrections for Lorentz and polarization effects were applied to all reflections but not for absorption (maximum error in I, 2.28%). Symmetry-equivalent data (1081 reflections) were averaged (R_{int} = 0.0297) to give 3831 unique reflections. A summary of crystal data is given in Table 1.

Solution of the structure

The structure was solved by routine heavy atom methods. Full-matrix least-squares refinement of the coordinates of the iodine atoms followed by a three-dimensional electron density synthesis revealed all the remaining atoms and confirmed the positional assignments for the heavy ones. After refinement the temperature factors of all the atoms, which were previously isotropic, were made anisotropic and further cycles of refinement using block-matrix least squares (alternately refining molecule 1 and molecule 2), minimizing $\Sigma w(|F_o| - |F_c|)^2$, were terminated when the maximum shift/error reached 0.014. Final R_1 = 0.0420, R_2 = 0.0431 for 2722 reflections with $I > 3\sigma(I)$. Correction for secondary extinction was made by the method in SHELX-76 (13). Throughout the refinement, scattering curves were taken from ref. 14 and corrections for anomalous dispersion (15) were applied to the curve for iodine. All calculations were performed on a VAX 8650 computer. Programs used: XTAL (16), data reduction; SHELX-76 (13), structure refinement; MOLGEOM (17), molecular geometry; and SNOOPI (18), diagrams. Final atomic positional parameters are given in Table 2 and selected intra- and intermolecular bond lengths and bond angles are given in Table 3.[4]

Mössbauer spectroscopy

The source of 57.6 keV radiation was $Mg_3{}^{127m}TeO_6$. Details of the source preparation, irradiation, and Mössbauer spectrometer have been described elsewhere (1). Powdered absorber samples containing approximately 0.05 g cm^{-2} of ^{127}I were placed neat or mixed with dry Teflon powder in 20 mm i.d. threaded Kel-F Mössbauer cells under an atmosphere of rigorously dried nitrogen. Both source and absorber were immersed in liquid helium (4.2 K) in a research cryostat manufactured by the Janis Research Corp. The velocity scale was calibrated using a standard iron foil and a $^{57}Co/Rh$ source mounted on the reverse end of the transducer; calibration spectra were thus recorded without interruption of the drive sequence. The calibration spectra were computer fitted to give a linear velocity scale and folding point.

Folded ^{127}I spectra were fitted using the program GMFP (19), which incorporates full transmission integral procedures. The source linewidth was arbitrarily set at the natural linewidth 1.27 mm/s, the effective recoilless fraction was set equal to that of a previous source of $Ca_3{}^{127m}TeO_6$, 0.75 at 4.2 K, and the dimensionless absorber thickness, T_a, was made a variable parameter of the iterative fitting process. All isomer shifts were referenced to $K^{127}I$ at 4.2 K (20).

Results and discussion

Structure

From an examination of the data contained in Table 3 it can be seen that both molecules in the asymmetric unit have essentially the same geometry. A view of molecule 1 with atom numbering scheme is depicted in Fig. 1.

The primary geometry about the trivalent iodine atom can be best described as a distorted T-shaped, AX_3E_2, trigonal-bipyramidal arrangement consisting of two covalent I—O bonds to the trifluoroacetate groups in the "axial" positions and the remaining I—C covalent bond to the pentafluorophenyl group and the two nonbonding lone pairs in the "equatorial" plane. Principal bond lengths and angles about iodine are as follows. Molecule 1: I(1)—C(16), 2.078(10) Å; I(1)—O(11), 2.147(6) Å; I(1)—O(13), 2.128(6) Å; O(11)—I(1)—C(16), 81.5(3)°; O(13)—I(1)—C(16), 81.1(3)°; O(11)—I(1)—O(13), 162.6(3)°. Molecule 2: I(2)—C(12), 2.063(6) Å, I(2)—O(21), 2.145(9) Å; I(1)—O(23), 2.136(8) Å; O(21)—I(2)—C(26),

$U_{eq} = \frac{1}{3}(U_{11} + U_{22} + U_{33} + 2\cos\alpha U_{23} + 2\cos\beta U_{13} + 2\cos\gamma U_{12})$.

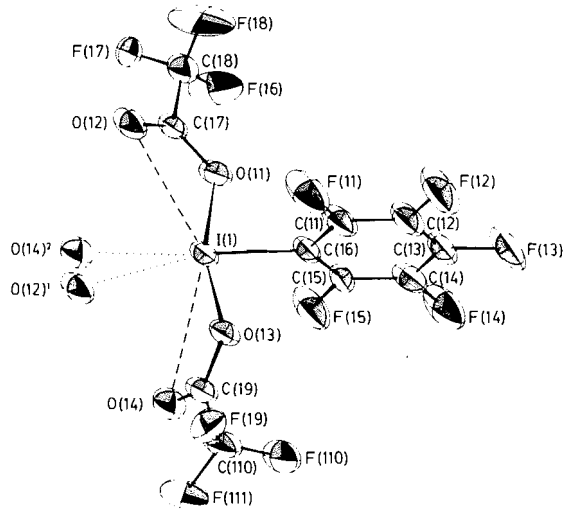

FIG. 1. View of $(C_6F_5)I(O_2CCF_3)_2$, molecule 1, showing atom numbering scheme. The intramolecular and intermolecular I···O secondary interactions are illustrated as dashed and dotted bonds respectively. The numbering scheme for molecule 2 may be inferred from the above.

80.8(3)°; O(23)—I(2)—C(26), 82.2(3)°; O(21)—I(2)—O(23), 163.0(2)°. The I—C and I—O distances found are not unusual for this type of compound although the asymmetry usually observed (2) in the I—O bonds is much less pronounced and is probably a consequence of the crystal packing (*vide infra*). This T-shaped geometry is predicted from VSEPR (21) theory and has been observed for a number of tellurium(II) (22), chlorine(III) (23), iodine(III) (1–5, 24), and xenon(IV) (25) complexes. The trifluoroacetate groups are oriented such that they are almost perpendicular to each other with a dihedral angle between the least-squares mean planes defined by the C—CO_2 atoms of 84.3(4)° and 82.5(4)° for molecules 1 and 2 respectively. As with most of these complexes the primary bonding arrangement does not describe the geometry about the central atom completely and there are further inter- or intramolecular contacts known as secondary bonds (26, 27) that complete the coordination sphere.

For $(C_6F_5)I(O_2CCF_3)_2$ there are two intramolecular contacts which bisect XE edges of the trigonal-bipyramid, I(1)···O(12), 3.075(8) Å, I(1)···O(14), 3.120(10) Å and I(2)···O(22), 3.080(7) Å, I(2)···O(24), 3.146(11) Å; these are illustrated as dashed bonds in Fig. 1. The coordination about the iodine is completed by two further intermolecular contacts. The first is an XEE face capping interaction of a centrosymmetrically related molecule forming a dimer via an I_2O_2 trapezoidal ring similar to that reported for $(C_6H_5)I(O_2CCHCl_2)_2$ (2) and $(C_6H_5)I(O_2CCF_3)_2$ (4) with I(1)···O(12),[1] 2.955(11) Å; I(2)···O(22),[3] 2.918(9) Å. These atoms lie 0.63 and 0.65 Å respectively above the plane defined by the "distorted T". The least-squares mean planes of the trifluoroacetate groups as defined above form dihedral angles with the plane of the distorted T of 40.1(4)°, 122.5(4)° for molecule 1 and 44.0(4)°, 124.8(4)° for molecule 2. These values differ from similar angles reported for $(C_6H_5)I(O_2CCHCl_2)_2$, (8.64° and 77.53°) (2), and are such that the remaining intermolecular contact caps the opposing XEE face of a centrosymmetrically related molecule, which is also translated 1 unit cell distance in *b* for molecule 1 or *a* for molecule 2, linking the dimers into chains,

I(1)···O(14),[2] 3.190(9) Å; I(2)···O(24),[4] 3.322(8) Å. O(14)[2] and O(24)[4] lie 1.35(1) and 1.31(1) Å below the plane of the distorted T and are illustrated as dotted bonds in Fig. 1. Thus it can be seen that O(12), O(14), O(22), and O(24) are inter- and intramolecularly bonded to iodine; Fig. 2 shows a stereoview of the chain formation of molecule 2. These intermolecular distances are less than the sum of the van der Waals radii (3.55 Å), and hence may still be classified as secondary bonds. The overall geometry about the iodine may be described as a distorted pentagonal $AX_3Y_2Y_2'E_2$, arrangement (for notation see ref. 27). It is worthwhile to compare the results from the present structure to those obtained for other iodine(III) complexes such as $I(O_2CCH_3)_3$ (1), and also for the related aryliodine(III) compounds $(C_6H_5)I(O_2CCH_3)_2$ (2, 3), $(C_6H_5)I(O_2CCHCl_2)_2$ (2), $(C_6H_5)I(O_2CCF_3)_2$ (4), and $[(C_6H_5)I(O_2CCF_3)]_2O$ (5). The above structures all have the same primary bonding geometry, i.e., a distorted T-shaped, AX_3E_2, arrangement based upon a trigonal-bipyramid as expected for trivalent iodine, but they differ in their arrangement of secondary bonding contacts.

$I(O_2CCH_3)_3$ (1) forms three intramolecular secondary bonding contacts. Two cap the XEE faces of the trigonal-bipyramid and are reasonably strong with lengths 2.46 and 2.52 Å, while the third is weaker (3.03 Å), and bisects an XE edge, hence the overall geometry may be described as $AX_3Y_2Y'E_2$. The case for $(C_6H_5)I(O_2CCH_3)_2$ (2, 3) is similar to that of $I(O_2CCH_3)_3$, whereby there are two intramolecular XEE face capping secondary bonds (2.817 and 2.850 Å) giving an $AX_3Y_2E_2$ geometry. Both structures are monomeric with a pentagonal planar arrangement of primary and secondary bonds. As mentioned earlier, $(C_6H_5)I(O_2CCHCl_2)_2$ (2) and the isostructural $(C_6H_5)I(O_2CCF_3)_2$ (4) dimerize in a similar manner to that of the present structure except that the dimers are stacked in columns along *b* rather than linked into chains. These complexes form one intermolecular interaction, bisecting an EE edge of an inversion equivalent molecule, and two intramolecular interactions, one bisecting an XE edge and one capping an XEE face giving an $AX_3YY'_2E_2$ arrangement. Their lengths are 2.94, 3.05, 2.94 Å and 3.00, 3.16, 3.06 Å, for the bis(dichloroacetate) and bis(trifluoroacetate) respectively.

The μ-oxo derivative, $[(C_6H_5)I(O_2CCF_3)]_2O$ (5), presents a further interesting feature in that the secondary geometry about the two unique iodine sites is different. The first site has just one intramolecular XEE face capping secondary interaction of 2.94 Å whilst the second site has an intermolecular EE edge bridging interaction of 3.08 Å from an inversion equivalent molecule, thus forming the molecules into dimers, and an intramolecular XEE face capping interaction of 3.27 Å from the same trifluoroacetate. The geometries of the two iodine sites may be described as AX_3YE_2 and $AX_3Y_2Y'E_2$ respectively.

With the variety of structural modifications displayed by the aryliodine(III)bis(carboxylate) complexes one might expect significant changes in the appearance of their ^{127}I Mössbauer spectra; this, however, does not appear to be the case.

Mössbauer spectroscopy

^{127}I Mössbauer data recorded at 4.2 K for the aryliodine(III)carboxylates are presented in Table 4 together with literature data for some related compounds for comparison purposes. The quadrupole coupling constant, $e^2q^{127}Q_g/h$, is positive for all of the complexes studied with the line from the transition, 5/2(ground)–7/2(excited), at high negative velocity (28). This is as expected for a central iodine(III) nucleus with bonds in the *xy* plane and the two nonbonding electron pairs above and below the coordination plane along the internuclear *z*-axis, the principal axis of the electric field gradient tensor. A representative spectrum of the monophenyliodine(III)bis(carboxylate) series, that of $(C_6H_5)I(O_2CCF_3)_2$, is shown in Fig. 3.

Examination of the data contained in Table 4 for the monophenyliodine(III)carboxylate series reveals, with one exception, that both the quadrupole coupling constants and the isomer shifts exhibit the expected trends with the electronegativity of the carboxylate group, i.e., an increase in carboxylate electronegativity leads to greater values of quadrupole coupling constant, $e^2q^{127}Q_g/h$, and more negative values of isomer shift; the electronegativities of the carboxylate ligands have been shown to follow the functional group order (29)

$$-CF_3 > -CCl_3 > -CHCl_2 > -CH_2Cl > -CH_3$$

This illustrates clearly the dependence of these parameters on the primary interactions at the iodine nucleus. The exception to the above is the isomer shift of the bis(trifluoroacetate) derivative. ^{127}I isomer shifts are relatively insensitive to changes in electron configuration because of the small value of $\delta R/R$ (30) and as such this result may be just an artifact. Since $\delta R/R$ is also negative for ^{127}I, the *s*-electron density at the iodine nucleus in these compounds must be greater than that of reference material, $K^{127}I$, indicating that the bonds are mainly

of *p*-character. Removal of *p*-electron density from the iodine nucleus greatly reduces the shielding effect on the 5*s* electrons, hence giving a more negative isomer shift.

The members of the above series also display large values of asymmetry parameter, η. This implies that although V_{zz} is through the nonbonded electron pairs perpendicular to the *xy* plane there exists a high degree of asymmetry within the electron density in the *x* and *y* directions. This has the effect of making the Mössbauer spectrum appear more symmetrical and as such the sign of the quadrupole coupling constant becomes harder to determine visually; the spectrum would be totally symmetrical when $\eta = 1$ (28). The high asymmetry parameter observed for these compounds is a direct consequence of the difference in the relative electronegativities of the carbon and oxygen atoms, the C—I bond contributing more electron density to the *xy* plane than the bonds to the more electronegative

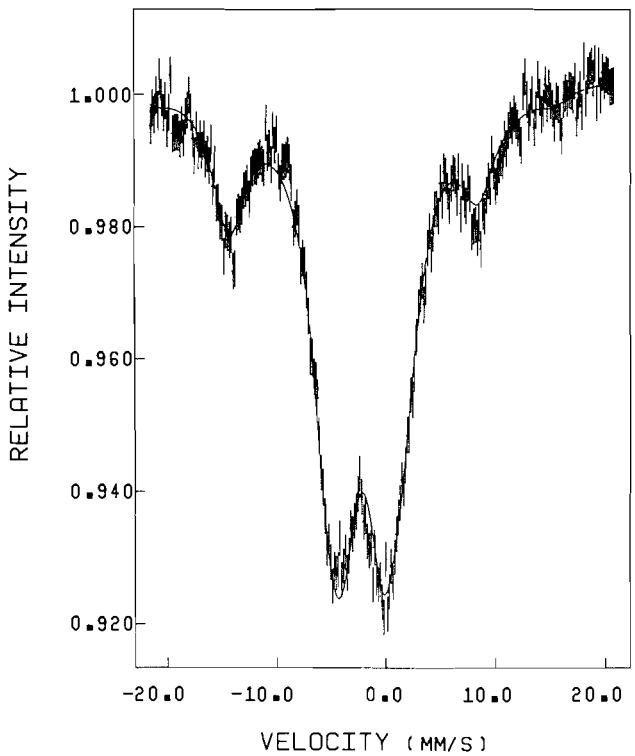

FIG. 3. ^{127}I Mössbauer spectrum of $(C_6H_5)I(O_2CCF_3)_2$ measured at 4.2 K. The solid line is the best fit to the data.

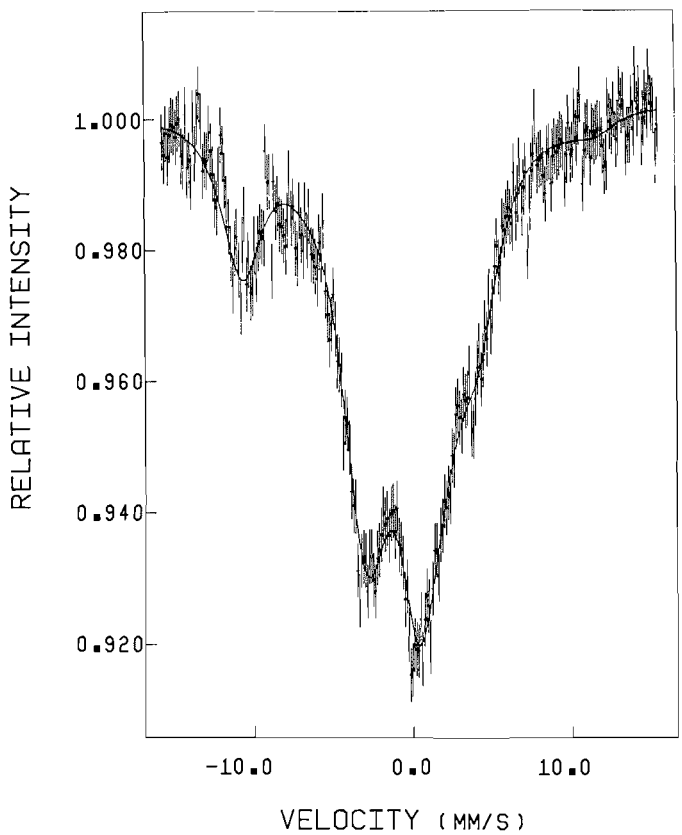

FIG. 4. ^{127}I Mössbauer spectrum of $(C_6H_5)_2I(O_2CCF_3)$ measured at 4.2 K. The solid line is the best fit to the data.

oxygens. The spectrum of $(C_6F_5)I(O_2CCF_3)_2$ bears this out in that replacement of the phenyl group with a more electronegative pentafluorophenyl group significantly reduces the asymmetry parameter from ~0.80 to 0.55. It has been shown that the asymmetry parameter is further reduced to ca. zero if the phenyl group is replaced by a trifluoroacetate (1).

The Mössbauer spectrum of the μ-oxo derivative, $[(C_6H_5)I(O_2CCF_3)]_2O$, is best fitted to just one single iodine site even though the results of the crystal structure determination show the two iodine sites to be nonequivalent through secondary bonding considerations (5). Attempts were made to fit this spectrum to two similar independent iodine sites commensurate with the findings of the crystal structure determination; however, this always yielded divergent fits. The somewhat broad linewidth (Γ = 2.43 mm/s) displayed by this material is probably a reflection of the presence of a second very similar site, although this value is still less than twice the natural linewidth ($2\Gamma_0$ = 2.54 mm/s). This result lends further weight to the conclusion that the ^{127}I Mössbauer parameters are dependent on the primary bonding arrangement about iodine only, and that the secondary bonds to the iodine nucleus have little or no effect on the Mössbauer spectrum.

The Mössbauer spectrum of $(C_6H_5)_2I(O_2CCF_3)$ is illustrated in Fig. 4. The fitted parameters for this compound are in good agreement with those observed for other diphenyliodine(III) species, e.g., $[(C_6H_5)_2IX]_2$ (31), where X = Cl, Br, I, and $C_6H_5(o\text{-}CO_2C_6H_4)I\cdot H_2O$ (24). The quadrupole coupling constant for this compound is reduced in comparison with that of the monoorganoiodine(III) species by the loss of the more electronegative carboxylate ligand. This change is also reflected in the increase in the value of the isomer shift. The decreased magnitude of η illustrates further that this parameter is dependent on both the electronegativity of the bound ligand and its position in relation to the geometry of the rest of the molecule. A full single crystal X-ray structure determination is currently in progress to determine the precise nuclear environment of the iodine in $(C_6H_5)_2I(O_2CCF_3)$.

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

ARVIND KUMAR JAIN, A. N. TRIPATHI, and VEDENE H. SMITH, JR. Can. J. Chem. **67**, 1886 (1989).

Momentum densities $\Pi(\boldsymbol{p})$, Compton profiles $J(\boldsymbol{q})$, and internally folded densities $B(\boldsymbol{r})$ have been calculated from self-consistent field wavefunctions for the alkaline earth oxides BeO, MgO, CaO, and SrO. The results are analyzed both by means of a partial wave decomposition and by comparison with separated ionic reference moieties. The Compton profile anisotropies for these systems are shown to be quite different than those predicted on the basis of a simple scaling relation from data for the alkali fluorides.

Key words: alkaline earth oxides, Compton profiles, momentum densities, internally folded densities, *B* functions.

ARVIND KUMAR JAIN, A. N. TRIPATHI et VEDENE H. SMITH, JR. Can. J. Chem. **67**, 1886 (1989).

Utilisant des fonctions d'onde en champ auto-cohérent, on a calculé les densités des moments $\Pi(\boldsymbol{p})$, les profils de Compton $J(\boldsymbol{q})$ ainsi que les densités refermées d'une façon interne $B(\boldsymbol{r})$ des oxydes des métaux alcalino-terreux BeO, MgO, CaO et SrO. On a analysé les résultats à l'aide de la décomposition partielle des ondes ainsi que par une comparaison avec les portions de référence ioniques séparées. On a démontré que les anisotropies du profil de Compton de ces systèmes sont très différentes de celles que l'on peut prédire en se basant sur une simple relation scalaire établie à partir de données pour les fluorures alcalins.

Mots clés : métaux alcalino-terreux, profils de Compton, densités des moments, densités refermées d'une façon interne, fonctions *B*.

[Traduit par la revue]

Introduction

Compton scattering studies of atomic and molecular systems provide valuable information about the electronic structure of atoms and molecules through the analysis of Compton line shapes (1–5). In recent years a considerable amount of work (6–19) has been done relating Compton profiles and momentum densities to chemical bonding.

There are four different approaches that have been used to analyse the effect of bonding on Compton profiles. Each approach has its own special features and we shall outline them very briefly here. The first approach is essentially based on population analysis (20), which is followed routinely in position space studies. In this approach, the Compton profile (CP) is partitioned into various components ("atomic" and "overlap") stemming from the partitioning of the density matrix $\gamma(\boldsymbol{r}|\boldsymbol{r}')$, which is a bilinear form in the orbitals. The second approach (11, 12) partitions the CP into core, lone pair, and bond contributions arising from the individual localized molecular orbitals obtained from the self-consistent field procedure by one of the usual localization methods. In the third procedure, the bond difference profile (9) is constructed by subtracting from the molecular profile the sum of the profiles of the isolated atoms (reference moieties) in a promolecule condition. In the last approach, a partial wave analysis is performed to partition the profile into its various angular momentum components, thereby obtaining related chemical information (18, 19).

Among these approaches, the population analysis and bond difference profile methods have been quite popular in analyzing profiles and related anisotropies. Sharma *et al.* (17) have used these schemes to analyze the bonding effects on the isotropic Compton profile and on the momentum densities of alkaline earth oxides. In the present study we calculate the directional properties of the momentum density, Compton profile, and $B(\boldsymbol{r})$ function (internally folded density) for the alkaline earth oxides. Further, we also investigate how a study of the partial wave components reveals the changes in chemical properties and different bonding situations in this homologous series of diatomic molecules. In the analysis comparison is made with results for the appropriate separated reference moieties. They are chosen to be the singly ionized atomic ions in their ground states ($E^+(^2S) + O^-(^2P)$) where E = Be, Mg, Ca, and Sr respectively. The various other plausible choices of reference moieties and their implications have been examined by Sharma *et al.* (17). It should be noted that it is not possible to use the chemically intuitive choice of the doubly charged free ions ($E^{2+}(^1S) + O^{2-}(^1S)$) because O^{2-} is not bound (21).

Theory

Within the framework of the impulse approximation (1, 4), the directional Compton profile $J(\boldsymbol{q})$ can be expressed (3) in terms of the one-electron momentum density $\Pi(\boldsymbol{p})$ as

$$[1] \quad J(\boldsymbol{q}) = \int \Pi(\boldsymbol{p}) \delta(\boldsymbol{p}\cdot\boldsymbol{q}/q - q) \mathrm{d}\boldsymbol{p}$$

where q is the projection of the initial electron momentum $\boldsymbol{p}$ on the scattering vector of the incident particle. $\Pi(\boldsymbol{p})$ can be obtained from the electronic wavefunction ψ of the N-electron system by the prescription

$$[2] \quad \Pi(\boldsymbol{p}) = (2\pi\hbar)^{-3} \int e^{i\boldsymbol{p}\cdot(\boldsymbol{r}-\boldsymbol{r}')} \Gamma^{(1)}(\boldsymbol{r}|\boldsymbol{r}') \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{r}'$$

where $\Gamma^{(1)}(\boldsymbol{r}|\boldsymbol{r}')$ is the spin-traced, position space one-electron reduced density matrix defined by

$$[3] \quad \Gamma^{(1)}(\boldsymbol{r}|\boldsymbol{r}') = N \int \psi^*(\boldsymbol{r}'\sigma_1, \boldsymbol{x}_2 \ldots \boldsymbol{x}_N) \psi(\boldsymbol{r}\sigma_1, \boldsymbol{x}_2 \ldots \boldsymbol{x}_N) \mathrm{d}\sigma_1 \mathrm{d}\boldsymbol{x}_2 \ldots \mathrm{d}\boldsymbol{x}_N$$

Here $x_i = (r_i, \sigma_i)$ is the combined spin-space coordinate of electron i.

In recent years a physically meaningful quantity, the autocorrelation function $B(r)$, also known as the reciprocal form factor (internally folded density), has been introduced (22–25) for the analysis of the Compton profile. It is defined by

$$[4] \quad B(r) = \int \Gamma^{(1)}(s|s + r)ds = \int \Pi(p)e^{ip\cdot r}dp = \int J(q)e^{iq\cdot r}dq$$

In the partial wave analysis (18, 19), the $\Pi(p)$, $J(q)$, and $B(r)$ can be expressed in terms of spherical harmonics, Y_{lm}, as

$$[5a] \quad \Pi(p) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \Pi_{lm}(p)Y_{lm}(\theta_p, \phi_p)$$

$$[5b] \quad J(q) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} J_{lm}(q)Y_{lm}(\theta_q, \phi_q)$$

and

$$[5c] \quad B(r) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} B_{lm}(r)Y_{lm}(\theta, \phi)$$

For linear molecules with the molecular axis aligned along the polar axis, which includes the alkaline earth oxide diatomics of this study, $\Pi(p)$ has $D_{\infty h}$ symmetry irrespective of whether the molecular skeleton has $C_{\infty h}$ or $D_{\infty h}$ symmetry (18, 26). Thus the expansions [5] simplify for a linear molecule as follows:

$$[6a] \quad \Pi(p) = \Pi_0(p) + \Pi_2(p)P_2(\cos\theta_p) + \Pi_4(p)P_4(\cos\theta_p) + \ldots$$

$$[6b] \quad J(q) = J_0(q) + J_2(q)P_2(\cos\theta_q) + J_4(q)P_4(\cos\theta_q) + \ldots$$

$$[6c] \quad B(r) = B_0(q) + B_2(r)P_2(\cos\theta_q) + B_4(q)P_4(\cos\theta_q) + \ldots$$

when the P_L are Legendre polynomials, $\Pi_0(p)$ is precisely equal to the spherically averaged momentum density $\overline{\Pi}(p)$, and the higher partial waves $\Pi_2(p)$, $\Pi_4(p)$, ... ($J_2(q)$, $J_4(q)$, ..., $B_2(r)$, $B_4(r)$ ...) represent the anisotropy.

The partial wave components $J_l(q)$ and $B_l(q)$ are related to the Π_l by

$$[7] \quad J_l(q) = 2\pi \int_{|q|}^{\infty} P_l(q/p)\Pi_l(p)p\,dp$$

and

$$[8] \quad B_l(r) = 4\pi(-i)^l \int_0^{\infty} \Pi_l(p)j_l(pr)p^2dp$$

In the evaluation of eqs. [7] and [8], the basic quantity of importance is $\Pi_l(p)$. Analytic formulae for these purposes are given explicitly in the paper by Kaijser and Smith (3), eqs. 129–133 and 143–147, for spherical harmonics and Cartesian Gaussian type basis functions respectively.

Equations [6] provide an alternative procedure to analyze the momentum density, Compton profile, and $B(r)$ functions into the various partial wave components, i.e., $l = 0, 2, 4, 6$, etc. This type of analysis is well suited to $\Pi(p)$, $J(q)$, and $B(r)$ because they are essentially monocentric functions (26).

In the present study self-consistent field (SCF) functions constructed (27) from basis sets of Slater type functions were employed to calculate $\Pi(p)$, $J(q)$, and $B(r)$ at the equilibrium internuclear separation (R_e) for the lowest $^1\Sigma$ state, which is the true ground state for these molecules (28). The highest occupied molecular orbitals are $(m\sigma)^2(n\pi)^4$ in BeO, CaO, and SrO with the inverted order $(n\pi)^4(m\sigma)^2$ in MgO.

These basis sets may be described as Be (6*s*, 2*p*, 1*d*, 1*f*), Mg (7*s*, 5*p*, 1*d*, 1*f*), and O (6*s*, 4*p*, 1*d*, 1*f*) in BeO and MgO, as Ca (8*s*, 5*p*, 1*d*, 1*f*) and O (4*s*, 2*p*, 1*d*, 1*f*) in CaO, and as Sr (10*s*, 7*p*, 3*d*) and O (4*s*, 2*p*, 1*d*) in SrO. The BeO and MgO wavefunctions are very close to the Hartree–Fock limit but the CaO and SrO wavefunctions are only of double zeta plus polarization quality. Of course wavefunctions including electron correlation and relativistic effects would be more appropriate, in particular for the heavier oxides (CaO, SrO). However, the qualitative trend displayed by the SCF momentum space properties should be correct to the same extent as in the case of the position space properties already calculated by Yoshimine (27).

Before we consider our results ($\Pi(p)$, $J(q)$, and $B(r)$)[2] for this homologous series, it is worthwhile to discuss the reliability and the accuracy of the partial wave expansion approach, which entirely depends upon how fast the various terms in the expansion (eqs. [5]) converge to the true value. Thakkar *et al.* (18) carried out for $\Pi(p)$ a detailed study of convergence tests on 21 linear molecules. They found that such an expansion converges very rapidly for small momentum values ($0 \leqq p \leqq 3\hbar a_0^{-1}$) and less rapidly for large momentum. Furthermore, from their study of partial wave decomposition of the momentum density, it is also evident that in the region of small momentum (the valence region) all the anisotropy of the momentum density can be understood from a chemical point of view by simply considering the first four partial waves: $l = 0$, 2, 4, and 6. Therefore, we shall pay attention to the first four partial waves in all our subsequent discussions of anisotropy for this homologous series of molecules, although the calculations have been done through $l = 10$ and for the parallel and perpendicular components directly. Fortunately, the alkaline earth oxides, which belong to the same class of linear molecules, have weakly anisotropic momentum densities ($\Pi_l(p)$) and therefore for this set of molecules a very rapidly convergent partial wave expansion is obtained. The same also holds for the case of the $J_l(q)$ and $B_l(r)$ expansions.[3] We have confirmed this by calculating $J_\perp(q)$ and $J_\parallel(q)$, $B_\perp(q)$ and $B_\parallel(q)$ directly.

Results and discussion

Momentum density: $\Pi(\mathbf{p})$

Figure 1 shows the spherically averaged momentum density $\overline{\Pi}(p) = \overline{\Pi}_0(p)$ per electron for the alkaline earth oxides EO (E = Be, Mg, Ca, Sr respectively). In view of the recent interest (29–31) in the monotonic (or otherwise?) behaviour of $\overline{\Pi}(p)$, it is seen that all the alkaline earth oxides in Fig. 1 have nonmonotonic isotropic momentum densities ordered in the sequence Mg, Be, Ca, Sr. Figures 2 and 3 show the different components of the partial waves ($l = 2$, 4, 6) for these molecules. Note that all quantities are per electron on the same scale to facilitate comparison among the molecules.

It is clearly seen from Fig. 2 that the behaviour of the $\Pi_2(p)$ and $\Pi_4(p)$ components for BeO is quite different from that

[2]Tables of the calculated values may be obtained on request from the authors.

[3]The convergence properties of the $J_l(q)$ and $B_l(r)$ expansions are discussed elsewhere (R. P. Sagar, A. M. Simas, V. H. Smith, Jr., and A. J. Thakkar. To be published).

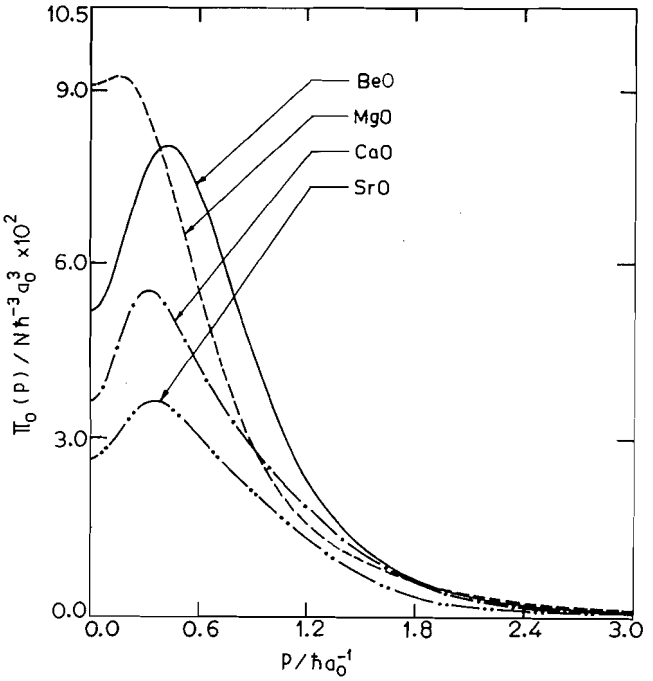

FIG. 1. Isotropic component of the momentum density (per electron) for BeO, MgO, CaO, and SrO.

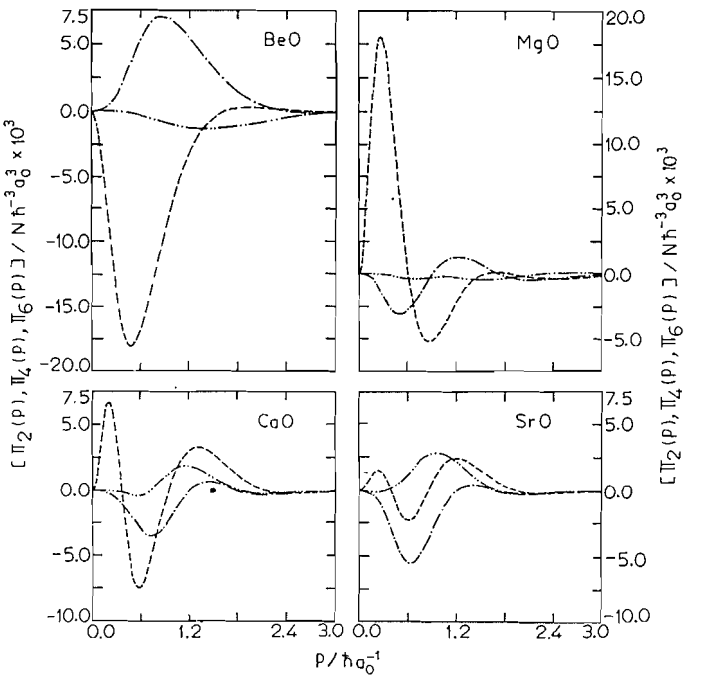

FIG. 2. Higher partial waves of the momentum density (per electron) for BeO, MgO, CaO, and SrO. (-----) $\Pi_2(p)$; (- · - · -) $\Pi_4(p)$; (- · · - · · -) $\Pi_6(p)$.

of the other oxides in the series (MgO, CaO, and SrO). On the whole, this can be rationalized by noting that $\Pi_2(p)$ is dominated by bonding contributions while $\Pi_4(p)$ and $\Pi_6(p)$ oscillate, as bonding and antibonding contributions dominate at different values of momentum p. This behaviour for $\Pi_l(p)$ is quite in agreement with the empirical rules outlined earlier (20, 21) for the prediction of the qualitative valence region behaviour of the contributions of canonical molecular orbitals (MO's) to the chemically dominant partial waves. The magnitude of the higher components, i.e., $\Pi_6(p)$, $\Pi_8(p)$, ..., is negligibly small for BeO and MgO but increases for the heavier oxides.

Our calculations of $\bar{\Pi}(p)$, $\Pi_{\parallel}(p)$, $\Pi_{\perp}(p)$, and $\Pi_{si}(p)$ at equilibrium bond length for BeO (2.4377 a_0), MgO (3.3052 a_0), CaO (3.4412 a_0), and SrO (6.283 a_0) respectively were used to construct Figs. 3(a–c). From Figs. 3 it is observed that the anisotropy ($\Pi(\boldsymbol{p}) - \Pi_{si}(p)$) of the momentum density decreases with increasing equilibrium bond length R_e in the sequence BeO, MgO, CaO, and SrO. The effects of bonding exhibited in Figs. 3(a, b) for the isotropic and parallel components of the momentum density are quite similar in nature and in both cases they follow the sequence Mg, Be, Ca, and Sr, in contrast to the sequence shown in Fig. 3(c) for the perpendicular component.

Compton profile: $J(\mathbf{q})$

Figures 4 and 5 display the isotropic Compton profile $\bar{J}(q) = J_0(q)$ and the partial wave components $J_{2l}(q)$ per electron on the same scale for all the oxides. The present calculations for $\bar{J}(q)$ are in perfect agreement with the earlier calculations of Sharma *et al.* (19) for the same wavefunctions. The $l = 0$ component ($J_0(q)$) provides the major contribution to the total profile, in particular at small q values. As q increases, there is a gradual decrease of $J_0(q)$, with the decrease more pronounced for BeO and slower for the heavier oxides in this homologous series. This reflects that the contribution from the tightly bound core electrons dominates the large q behaviour of the profile. The higher components, i.e., $l = 2$, 4, and 6, which provide the anisotropy in the various directions to the profile, are shown in Fig. 5. Note that the contributions are per electron and on the same scale.

For BeO, the $J_2(q)$ component peaks around $q = 0$ and then falls off rapidly showing a minimum around $q = 0.7$ whereas for MgO this component peaks around $q = 0.3$ and then passes through a minimum at $q = 0.7$. For CaO and SrO, the behaviour of the $J_2(q)$ component is different at smaller q (<0.5) but beyond $q > 0.5$ they exhibit a very similar pattern of variation, i.e., peaking around $q = 1.2$ and 1.1 respectively and falling rapidly thereafter.

Figures 6(a, b) show the difference between the parallel ($J_{\parallel}(q)$) and perpendicular $J_{\perp}(q)$) directional Compton profiles (DCP) and the same superposition of free moieties. From Figs. 6(a, b) it is seen that all the difference profiles are negative at small q and positive at intermediate q. This is similar to the bond difference profile ($\bar{J}(q) - \bar{J}_{si}(q)$) given in ref. 19. The lowering of $J_{\parallel}(0)$ ranges from 1 to 21% of $\bar{J}(0)$ whereas the corresponding lowering for $J_{\perp}(0)$ varies between 7 to 17% of $\bar{J}(0)$. The difference function ($J_{\perp}(0) - J_{si}(0)$) follows the sequence Mg, Be, Ca, Sr as compared to Be, Mg, Ca, and Sr for ($J_{\parallel}(0) - J_{si}(0)$) and ($\bar{J}(0) - \bar{J}_{si}(0)$). The value of $J_{\parallel}(0) - J_{si}(0)$ measures the amount of buildup of the bonding orbitals (σ, π) momentum density in a plane perpendicular to the bond and through the origin in p-space. As a consequence, the decreasing value of this difference in the sequence Be, Mg, Ca, and Sr reflects that there is an increasing concentration of the bonding orbitals in a plane orthogonal to the bond and passing through $p = 0$.

There exists in the literature an empirical relation (8, 19) used to make a crude prediction of the anisotropies of the DCP's at zero momentum, i.e., $J_{\parallel}(0) - J_{\perp}(0)$. It has been shown that this relation works moderately well for alkali halides. This empirical relation can be used to predict the anisotropies of the isoelectronic alkaline earth oxides (EO) with the help of data

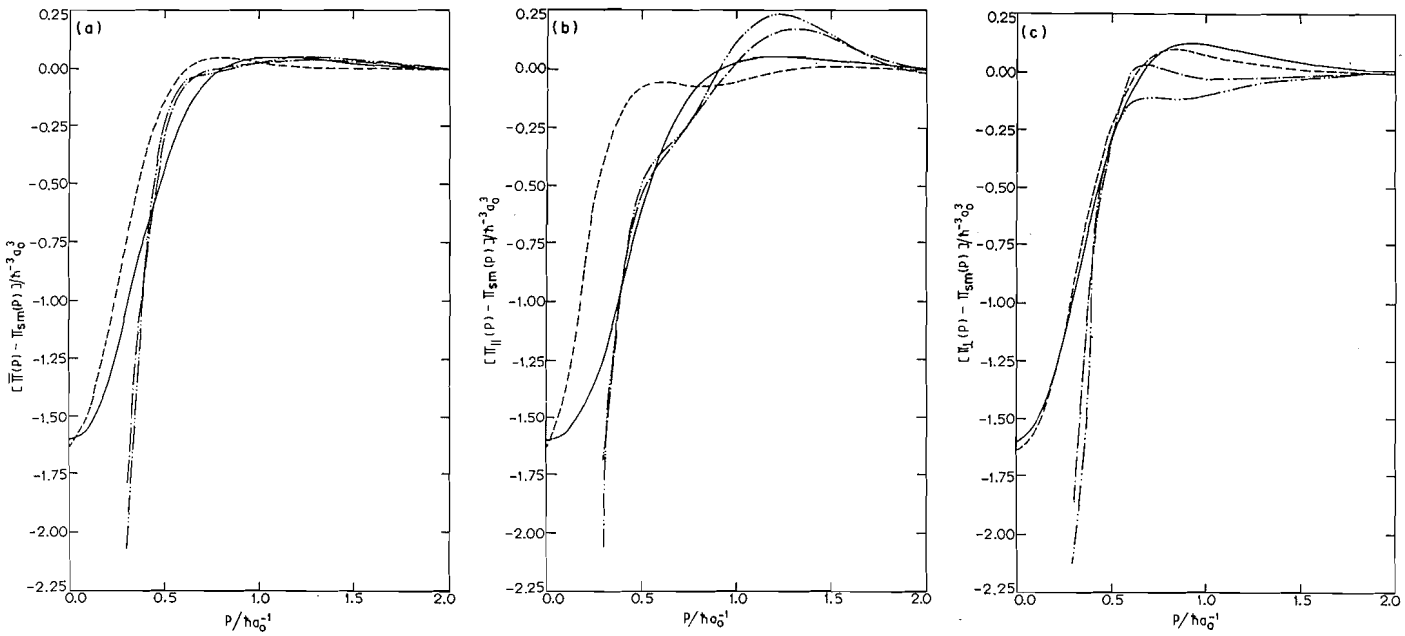

FIG. 3. (*a*) Difference curve between the molecule and superposition of free ions for the isotropic momentum density. (—) BeO; (- - -) MgO; (- · · · · ·) CaO; (- · · · · · · ·) SrO. (7) for the anisotropies of the alkali fluorides AF (A = Li, Na, K, Rb), thus assuming that

$$[9] \quad (J_\parallel(0) - J_\perp(0))_{EO} = \ln(Z_O/Z_E)[J_\parallel(0) - J_\perp(0)]_{AF}/\ln(Z_F/Z_A)$$

where Z's denote nuclear charges. Using the data for the alkaline fluorides, 3.3, −0.85, −2.0, and −2.0% of $\bar{J}(0)$ respectively in LiF, NaF, KF, and RbF, the anisotropies are predicted by eq. [9] to be −1.8, 1.5, 2.3, and 2.2% of $\bar{J}(0)$ in BeO, MgO, CaO, and SrO respectively, while the corresponding anisotropies from the present accurate molecular calculations (15.6, 1.5, −5.8, and −8.7%) are much larger and of opposite sign, except in the case of MgO where there is agreement. In addition it is seen that the DCP anisotropies of the alkaline earth oxides are larger than those of the isoelectronic alkali fluorides.

It is worth noticing that the dimensionless quantity $A = \langle p \rangle \bar{J}(0)/N^2 = 0.992, 1.143, 1.315$, and 1.566 respectively for

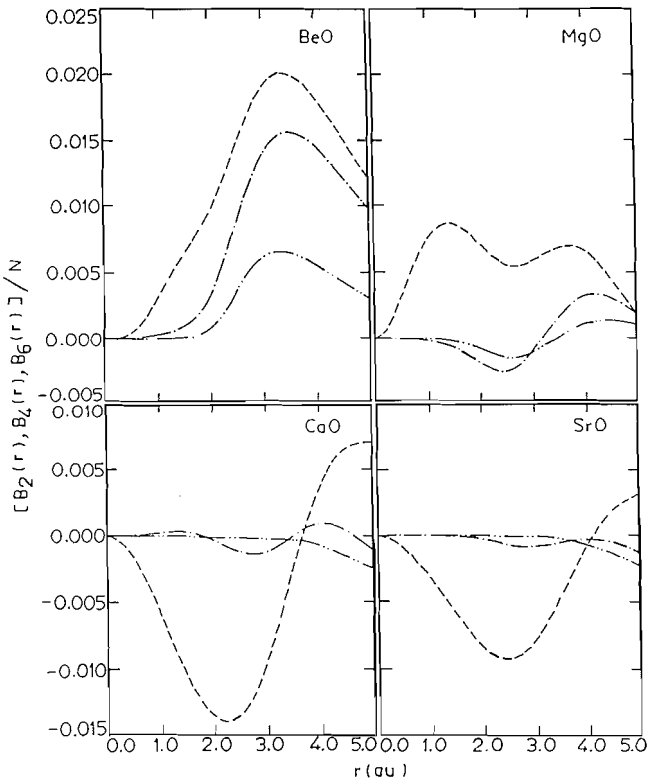

FIG. 8. Higher partial waves of $B(r)$ function (per electron) for BeO, MgO, CaO, and SrO.

BeO, MgO, CaO, and SrO. These values for the heavier oxides show that the approximation (32), $A \approx 1$, can be in error by as much as 50%.

The values of $\bar{J}(0)/a_0\hbar^{-1}$ for the alkali fluorides LiF, NaF, KF, and RbF respectively (7) are 3.99, 5.63, 7.71, and 9.80. Notice that these values are lower than those of the isoelectronic alkaline earth oxides (BeO, MgO, CaO, and SrO) calculated here, i.e., 4.47, 6.46, 8.01, 10.02, reflecting the fact (33) that the latter are less tightly bound than the alkali fluorides.

The characteristic momentum (24)

$$[10] \quad p^* = (\bar{J}(0)/2\pi\bar{\bar{\Pi}}(0))^{1/2} = (\langle p^{-1}\rangle/4\pi\bar{\bar{\Pi}}(0))^{1/2}$$

is known to increase with increasing electron sharing and number of valence electrons. Here we note that p^* for the reference moieties ($E^+ + O^-$) is fairly similar and decreases in the series, i.e., 0.6064 ($Be^+ + O^-$), 0.5544 ($Mg^+ + O^-$), 0.4797 ($Ca^+ + O^-$), and 0.4771 ($Sr^+ + O^-$); for the bound molecules (EO), p^* is large and very similar throughout the series except for MgO where it is about one-third smaller than

the others, i.e., 1.068 (BeO), 0.7510 (MgO), 1.118 (CaO), and 1.140 (SrO).

Internally folded density: B(**r**) *function*

The $B(r)$ functions have the advantage, when compared with the Compton profiles, that one is back in position space. As a result the valence electrons can be probed by studying $B(r)$ at larger values of r where the core electrons are of vanishing importance. Although a few calculations of $\bar{B}(r)$ functions have been reported, a limited amount of experience is available in interpreting the $\bar{B}(r)$ function for systems in the gaseous phase.

The isotropic internally folded density (reciprocal form factor) $\bar{B}(r) = B_0(r)$ per electron is displayed in Fig. 7 for all the alkaline earth oxides. It is seen that all the curves show an initial monotonic decrease with r and a crossing of the r-axis (zero passage) at different values of r for the various molecules. Figure 8 shows the various components $B_l(r)$. Notice that for BeO, the different components such as $B_2(r)$, $B_4(r)$, and $B_6(r)$ show a broad and positive peak in the intermediate range of r, while for the other oxides these components oscillate with both positive and negative amplitudes. $B_2(r)$ is more pronounced for the CaO and SrO molecules. The magnitude of the other components such as $B_4(r)$, $B_6(r)$ is, as usual, smaller than $B_2(r)$.

Summary and conclusions

From the foregoing analysis it is seen that partial wave analysis provides a good basis for understanding the anisotropy of these linear molecular systems. All the qualitative features of the various properties ($\Pi(p)$, $J(q)$, and $B(r)$) can be well understood in terms of the four chemically dominant partial waves (18, 19). The momentum density, Compton profiles, and the $B(r)$ functions in the parallel direction are distinctly different from the ones along the perpendicular direction.

A continuing role for sulfuric acid cryoscopy. The IO_2^+ ion

J. A. LEISTEN[1]

Chancellor College, University of Malawi, P.O. Box 280, Zomba, Malawi

Received February 14, 1989

This article is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

J. A. LEISTEN. Can. J. Chem. **67**, 1892 (1989).

The present state of sulphuric acid cryoscopy is discussed. A simplified technique with test results is presented for use in particular with cryoscopic solvent mixtures. Evidence is found for the existence of the iodyl ion, IO_2^+, in sulfuric acid solutions of enhanced acidity.

Key words: sulphuric acid, cryoscopy, iodyl ion.

J. A. LEISTEN. Can. J. Chem. **67**, 1892 (1989).

On discute de l'état actuel de la cryoscopie de l'acide sulfurique. On présente une technique simplifiée avec des résultats à l'appui en vue d'une utilisant dans des mélanges de solvants cryoscopiques. On prouve l'existence de l'ion iodyle IO_2^+ dans des solutions d'acide sulfurique dont l'acidité est augmentée.

Mots clés : l'acide sulfurique, la cryoscopie, l'ion iodyle.

[Traduit par la revue]

Introduction

In the first half of this century cryoscopy was a principal way of studying reactions with sulfuric acid in solvent proportions, and contributions to the dawning understanding of reaction mechanism were among its successes (1). The power of cryoscopy to solve problems of complex solute behaviour was greatly increased as a result of Gillespie's work on the sulfuric acid system (2), which led to more accuracy in the interpretation of freezing point depressions in 100% sulfuric acid (3), and to the introduction of four sulfuric acid solutions as cryoscopic solvents that enable the different types of particle produced by a solute on dissolution to be distinguished (4).

Perversely, these improvements occurred at a time when colligative methods were being overtaken by quicker and more convenient spectroscopic methods, and the use of cryoscopy therefore declined. The main purpose of the present work is to establish a simpler technique that makes sulfuric acid cryoscopy more accessible.

Four solutes of known behaviour were chosen to verify the technique. They react with sulphuric acid according to the following equations: benzoic acid (4*c*), [1]; ammonium sulfate, [2]; *o*-phenylene diamine (4*c*), [3]; and potassium nitrate (2), [4].

[1] $C_6H_5CO_2H + H_2SO_4 = C_6H_5CO_2H_2^+ + HSO_4^-$

[2] $(NH_4)_2SO_4 + H_2SO_4 = 2NH_4^+ + 2HSO_4^-$

[3] $C_6H_4(NH_2)_2 + 2H_2SO_4 = C_6H_4(NH_3)_2^{2+} + 2HSO_4^-$

[4] $KNO_3 + 3H_2SO_4 = K^+ + NO_2^+ + H_3O^+ + 3HSO_4^-$

Two other solutes were chosen for their interest.

Fernandez and Sutor found a van't Hoff *i* factor of 4.1 for bis(diethylamine)methane in aqueous sulfuric acid (5) and suggested the surprising reaction [5]; but several reactions, for example [6], could account for this result and further study seemed worthwhile.

[5] $Et_2NCH_2NEt_2 + 2H_2SO_4 = EtNH_3^+ + CH_2NEt_2^+ + 2HSO_4^-$

[6] $Et_2NCH_2NEt_2 + 3H_2SO_4 = Et_2NHCH_2NEtCH_2CH_2SO_3H^+ + H_3O^+ + 2HSO_4^-$

[1]Present address: 45 Ashleigh Drive, Loughborough LE11 3HN, England.

The final solute, potassium iodate, was first thought to react according to eq. [7] (6), but Gillespie and Senior obtained evidence instead for the formation of iodyl hydrogen sulfate (eq. [8]), and its subsequent polymerisation (7). They found no reason to believe that the iodyl ion is formed either in sulfuric acid (eq. [9]) or in oleum, although the existence of this ion in fluorosulfonic acid has been deduced from the conductivity of the solute IO_2SO_3F (8).

[7] $KIO_3 + 2H_2SO_4 = K^+ + H_2IO_3^+ + 2HSO_4^-$

[8] $KIO_3 + 3H_2SO_4 = K^+ + H_3O^+ + IO_2HSO_4 + 2HSO_4^-$

[9] $KIO_3 + 3H_2SO_4 = K^+ + H_3O^+ + IO_2^+ + 3HSO_4^-$

Results and discussion

Freezing point depressions for known molalities of the test solutes were measured in slightly aqueous sulphuric acid and four other sulphuric acid solutions, and *i* factors obtained from the results.

If water molecules or hydrogen sulfate ions are produced when a solute dissolves, the total number of foreign particles in the sulfuric acid may increase, decrease, or stay the same, depending on which of the five cryoscopic solvents is being used. Table 1 specifies this information (4*c*). Combining the information with that of eqs. [1] to [4] it is possible to calculate *i* factors that are consistent with the known behaviour of the test solutes. In Table 2 these calculated values (in italics) are compared with the experimental ones. Agreement between experimental and calculated *i* factors for the four model solutes in all five of the solvents is acceptable for the cryoscopic mixtures method, and the discrepancies can be taken into account when assessing the results for other solutes. The last set of *i* values in Table 2 shows a similar level of agreement to that in the four model sets, and this confirms eq. [5] as the reaction of bis(diethylamine)methane in sulfuric acid. (For the eq. [6] alternative the predicted *i* values in solvents A to E would be, respectively: *4*, *0*, *−1*, *0*, and *2*.)

The five solvents differ quite sharply in certain chemical properties, such as acidity and the ability to sulfate and sulfonate (4*b*), and there is always a danger when using results in the way just described for bis(diethylamine)methane that the behaviour of the solute may change from one solvent to another. In recompense, however, these differences in properties some-

times allow the solutions to be used for probing a solute's chemical reactivity, and this extra function is illustrated by the final set of results.

It seemed possible that in sulfuric acid solutions containing very little HSO_4^- (i.e., more strongly acid solutions) iodyl hydrogen sulfate, $IO_2.HSO_4$, might yield the IO_2^+ ion. Ionization of KIO_3 might occur according to eq. [9] rather than to eq. [8] as in 100% sulfuric acid. This solute was therefore examined in the more strongly acid solvents B and C.

For comparison potassium iodate was also examined in solvent E. In this case the polymer described by Gillespie and Senior began to deposit before the solute had all dissolved and the *i* factor changed gradually from 2.7 to 2.4, consistently with their findings and interpretation. The chemical behaviour in solvents B and C, however, was quite different. The solutions remained clear overnight, and the freezing point depressions were constant. The *i* factors shown in Table 3 and compared with the values calculated for eqs. [7], [8], and [9], point clearly to reaction [9].

The results are evidence that the iodyl ion can exist in sulfuric acid containing small concentrations of tetrahydrogensulfatoboric acid.

For a normal solute *i* factors in any three of the solvents will give all the information that the cryoscopic mixtures method can offer. Exactly the same information can be obtained (9) by a combination of conductimetric titration in oleum (10) with conductimetric (11) and cryoscopic measurements in 100% sulfuric acid. The difference in principle makes this method a valuable alternative, and it has the advantage of greater precision (12). The conductimetric titration, however, requires some 20 additions of solute, an inconvenience if the solute dissolves slowly. The method of cryoscopic mixtures is relatively quick and simple, and may still be useful in cases where slow reactions occurring after the solute has dissolved would make a conductimetric titration uncertain.

TABLE 3. Observed *i* factors for KIO_3 and (in italics) predicted *i* factors for different modes of ionization

	i			
	Experimental value	Predicted		
		eq. [7]	eq. [8]	eq. [9]
Solvent B	−0.3	*0*	*1*	*0*
Solvent C	−1.1	*0*	*0*	*−1*

For diagnosing behaviour in strong acids during recent years spectroscopic methods have been the most widely used: but spectroscopic precision is not always matched by interpretation (13), and sulfuric acid cryoscopy has a complementary function (still) that can be perilous to ignore.

Experimental

The cryoscopic technique was a much simplified modification of that previously used with the solvent mixtures (4*c*).

Re-examination of the five cryoscopic solvents showed that a significant improvement could be made by changing the composition of D to 0.13 *m* $H_2S_2O_7$, 0.15 *m* $HS_2O_7^-$. This solvent was prepared in a flask fitted with a thermometer and Teflon follower, starting with a weighed quantity of 98% sulfuric acid which was cooled in ice/water until it could be seeded. Additions of Merck 65% oleum were made, with periodic cooling to maintain the presence of sulfuric acid crystals, until the temperature, after first rising, had fallen to 8.5°C. Ammonium sulphate (0.99 g) was added for each 100 g of this oleum. Large quantities of the other solvents were similarly prepared, using the previous recipes (4*c*). A suitable composition for the slightly aqueous acid, solvent A, is 0.1 *m* H_3O^+, 0.1 *m* HSO_4^-: fp 9.4°C.

The cryoscope was a 150 mm long flat-bottomed tube of 27 mm bore, having at the top end a socket for the thermometer holder, and a cone (with socket stopper) for the addition of solutes. To allow room

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

for both joints the cone was at 30° to the vertical. A Teflon follower was used for stirring. Temperature was measured with a −20 to +30°C laboratory thermometer, graduated in 0.1°, and read to 0.01° by means of a cathetometer. It was fitted to the cryoscope by a standard holder with glass cone and O-ring seal.

The air jacket of controllable temperature consisted of a foam plastic box enclosing a copper cooling coil, through which water was pumped directly from and to a bath by means of a windscreen washer pump. The box was mounted on an auto-reverse magnetic stirrer plate. The bath had a stirrer, immersion heater, and constant level device, and during measurements it was adjusted by use of the heater and additions of ice to a temperature that was kept 4° (±0.1°) below the temperature in the cryoscope. (The optimal temperature difference would vary slightly with the design and ambient temperature.)

For each experiment about 70 g of the required solvent was transferred to the weighed cryoscope, which was then re-weighed and closed by the thermometer and other stopper, using chlorofluorocarbon grease. To determine the freezing point, the sulfuric acid was supercooled by dipping the cryoscope in an ice–water beaker on a stirrer plate, and then allowed to stand for a few minutes in the air jacket until a steady reading was obtained 1–2° below the freezing point. Freezing was induced and the steady temperature recorded after 6–10 min. (Longer times was sometimes needed with solvent B.) Freezing out of solid changes the concentration of dissolved species to an extent that depends on the supercooling, necessitating a small correction to the observed freezing point (14) that was read from a prepared chart.

Although platinum wire cooled in liquid nitrogen provides a more convenient way to induce freezing (1*a*) it was necessary in the present work to seed the solution with solid sulfuric acid in a loop of platinum wire. To prepare the seed the platinum loop was suspended in the surface of 100% sulfuric acid in a closed boiling tube which was stored in a freezer.

The solute, if solid, was added with a weighing bottle and funnel (both items being weighed): if liquid a weight pipette was used. The amount added must be small in relation to the solvent additives, typically 0.025 *m* but even less if the solute yields many particles per molecule. After re-determination of the freezing point the *i* factor was obtained as before (4*c*) from the equation $i = \theta/6\ m$, where *m* is the molality of the solute and θ is the associated freezing point depression. Reproducibility was checked by carrying out five separate experiments with bis(diethylamine)methane in solvent A. The mean *i* factor with standard deviation was 3.7 ± 0.1. Fernandez and Sutor quote the result 4.1 ± 0.5 for five determinations with the same solute and solvent but using a different technique (5).

The technique described is easy to set up. No way was found of reducing the 30 min or so required for each freezing point measurement, because the accuracy depends on a close approach to equilibrium, but much time and tedium is saved by recognising that the experimental error is small in relation to the general precision of the cryoscopic mixtures method and that it is not time-effective to duplicate measurements. Examination of a solute by the necessary three solvents thus requires a total of only three solute additions and six freezing point measurements.

Fluorosulfonic anhydride: a potential fluorosulfonating agent

DEBYANI G. NIYOGI, SUKHJINDER SINGH, AND R. D. VERMA
Department of Chemistry, Panjab University, Chandigarh-160014, India

Received April 12, 1989

This article is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

DEBYANI G. NIYOGI, SUKHJINDER SINGH, and R. D. VERMA. Can. J. Chem. **67**, 1895 (1989).

Reactions of pyrosulfuryl fluoride, $S_2O_5F_2$, with various inorganic substrates are carried out to explore its potential and usefulness as a fluorosulfonating agent. New fluorosulfonates, viz; $\phi_3\overset{+}{P}O\overset{+}{P}\phi_3.2SO_3F^-$, $\phi_3\overset{+}{As}O\overset{+}{As}\phi_3.2SO_3F^-$, $NaBiO(SO_3F)_2$, and $Ti(OCH_3)_2(SO_3F)_2$ have been prepared by reacting ϕ_3PO, ϕ_3AsO, $NaBi(CF_3COO)_4$, and $Ti(OCH_3)_4$, respectively, with $S_2O_5F_2$. These compounds have been characterized by elemental analyses and infrared and ^{19}F nmr spectra.

Key words: new fluorosulfonates, $(C_6H_5)_3\overset{+}{P}O\overset{+}{P}(C_6H_5)_3.2SO_3F^-$, $(C_6H_5)_3\overset{+}{As}O\overset{+}{As}(C_6H_5)_3.2SO_3F^-$, $NaBiO(SO_3F)_2$, $Ti(OCH_3)_2(SO_3F)_2$.

On a effectué un certain nombre de réactions du fluorure de pyrosulfuryle, $S_2O_3F_2$, avec divers substrats inorganiques afin d'évaluer son potentiel et son utilité comme agent de fluorosulfonation. En faisant réagir le $S_2O_5F_2$ successivement avec le ϕ_3PO, le ϕ_3AsO, le $NaBi(CF_3COO)_4$ et le $Ti(OCH_3)124$, on a obtenu les nouveaux fluorosulfonates suivants : $\phi_3\overset{+}{P}O\overset{+}{P}\phi_3.2SO_3F^-$, $\phi_3\overset{+}{As}O\overset{+}{As}\phi_3.2SO_3F^-$, $NaBiO(SO_3F)_2$ et $Ti(OCH_3)_2(SO_3F)_2$. On a caractérisé ces composés à l'aide d'analyses élémentaires et de spectres ir et rmn du ^{19}F.

Mots clés : nouveaux fluorosulfonates, $(C_6H_5)_3\overset{+}{P}O\overset{+}{P}(C_6H_5)_3.2SO_3F^-$, $(C_6H_5)_3\overset{+}{As}O\overset{+}{As}(C_6H_5)_3.2SO_3F^-$, $NaBiO(SO_3F)_2$, $Ti(OCH_3)_2(SO_3F)_2$.

[Traduit par la revue]

Introduction

Fluorosulfonic anhydride (pyrosulfuryl fluoride), $S_2O_5F_2$, has been known for nearly four decades (1). However, its chemistry has not been much explored. The inorganic aspects of the chemistry of $S_2O_5F_2$, its reactions with the oxides and oxide halides of nitrogen in anhydrous acetonitrile have been reported (2). Reactions of its analogue, trifluoromethanesulfonic anhydride, $(CF_3SO_2)_2O$, with various inorganic and organic substrates are known (3, 4).

In this article, we reacted $S_2O_5F_2$ with various substrates and explored its potential as a fluorosulfonating agent. We are successful in reacting $S_2O_5F_2$ with ϕ_3PO, ϕ_3AsO where ϕ = C_6H_5, $NaBi(CF_3COO)_4$, and $Ti(OCH_3)_4$ to obtain new fluorosulfonates, viz. $\phi_3\overset{+}{P}O\overset{+}{P}\phi_3.2SO_3F^-$, $\phi_3\overset{+}{As}O\overset{+}{As}\phi_3.2SO_3F^-$, $NaBiO(SO_3F)_2$, and $Ti(OCH_3)_2(SO_3F)_2$, respectively. The reaction between Bi_2O_3 and $S_2O_5F_2$ led to the formation of the previously known fluorosulfonate, $Bi(SO_3F)_3$ (5).

Experimental

Material and methods

Pyrosulfuryl fluoride (6), $NaBi(CF_3COO)_4$ (7), and $Ti(OCH_3)_4$ (8) were prepared as described in the literature. Bismuth(III) oxide (Riedel) was dried overnight in an oven at 110°C. Triphenylphosphine oxide (E. Merck) and triphenylarsine oxide (BDH) were recrystallized from benzene. Trifluoroacetic anhydride (Aldrich) and titanium(IV) chloride (Fluka) were distilled before use. Fluorosulfonic acid was prepared as reported earlier (9). The solvents were dried and distilled before use. Caution! Pyrosulfuryl fluoride is a toxic material and should be handled with care (10).

The infrared spectra of the compounds were recorded either as Nujol/hexachlorobutadiene mulls or as neat solid between AgCl or polythene plates on a Perkin Elmer 1430 infrared spectrophotometer. The ^{19}F nmr spectra were recorded on an EM 390 spectrophotometer using Freon-11 as external reference.

Sulfur and fluorine were determined as reported earlier (11, 12). Metals were analysed by standard methods (13). Carbon and hydrogen were determined microanalytically. All manipulations were carried out either in a vacuum line or in a dry box filled with nitrogen.

Preparation of $\phi_3\overset{+}{R}O\overset{+}{R}\phi_3.2SO_3F^-$, R = P or As

Triphenylphosphine oxide (1.39 g, 5 mmol) was loaded into a 50 mL Pyrex reactor fitted with a Rotaflo stopcock and evacuated for 2 h. Fluorosulfonic anhydride (1.456 g, 8 mmol) was condensed onto it via vacuum. The reaction mixture was allowed to warm slowly from −196 to +20°C and held at room temperature for 5 days. The pressure of volatiles in the reactor was checked from time to time and the reaction was terminated when no further consumption of $S_2O_5F_2$ was observed. The compound $\phi_3\overset{+}{P}O\overset{+}{P}\phi_3.2SO_3F^-$ (1.84 g, 2.5 mmol) was obtained as a white solid in quantitative yield after removal of all volatiles. *Anal.* calcd. for $C_{36}H_{30}F_2O_7P_2S_2$: C 58.54, H 4.07, F 5.15, P 8.40, S 8.67; found: C 57.9, H 3.88, F 5.20, P 8.24, S 8.81. Infrared: 1588w, 1490w, 1440m, 1340vw, 1310m, 1160w, 1125ms, 1075mw, 1040w, 998w, 940mw, 850sh, 750vw, 735bs, 690vw, 619w, 602w, 590m, 565sh, 530ms, 495w, 480w, 435vw, 415w cm^{-1} (s = strong, m = medium, w = weak, v = very, sh = shoulder, b = broad).

Similarly, $\phi_3\overset{+}{As}O\overset{+}{As}\phi_3.2SO_3F^-$ was obtained as a white solid in nearly quantitative yield by reacting ϕ_3AsO and $S_2O_5F_2$. *Anal.* calcd. for $C_{36}H_{30}As_2F_2O_7S_2$: C 52.30, H 3.63, As 18.16, F 4.60, S 7.75; found: C 51.86, H 3.55, As 18.30, F 4.52, S 8.11. Infrared: 3060w, 2925ms, 2870sh, 1580ms, 1485mw, 1475mw, 1443w, 1340ms, 1315ms, 1290m, 1265w, 1235w, 1185w, 1170sh, 1085m, 1060mb, 1025w, 1000m, 975w, 940w, 850vw, 775m, 740bs, 688w, 640m, 575mb, 520ssh, 470m, 360mb cm^{-1}.

Preparation of $Bi(SO_3F)_3$

The reaction between Bi_2O_3 (0.56 g, 1.2 mmol) and $S_2O_5F_2$ (1.456 g, 8 mmol) was carried out at ~65°C in an analogous manner as described above. However, the reaction was complete in 24 days. Removal of volatiles in vacuum gave $Bi(SO_3F)_3$ as a white solid in quantitative yield (1.218 g, 2.4 mmol). *Anal.* calcd. for $BiF_3O_9S_3$: Bi 41.30, F 11.26, S 18.97; found: Bi 40.75, F 11.08, S 19.24%. Infrared: 1300m, 1210w, 1080b, 860m, 770m, 640mw, 612w, 560m, 475w, 420sh cm^{-1}.

Preparation of $NaBiO(SO_3F)_2$

$NaBi(CF_3COO)_4$ (2.32 g, 3.4 mmol) was loaded into a 50 mL Pyrex reactor as earlier and evacuated for 6 h. An excess of $S_2O_5F_2$ (1.73 g, 9.5 mmol) was condensed onto it and the contents refluxed at ~60°C for 5 days. Final drying *in vacuo* gave a constant weight of $NaBiO(SO_3F)_2$ (1.47 g, 3.3 mmol) as a white shining powder. *Anal.*

For personal use only.

calcd. for $BiF_2NaO_7S_2$: Bi 46.86, F 8.52, S 14.35; found: Bi 46.40, F 8.39, S 14.24%. Infrared: 1280sh, 1265s, 1090bs, 815ms, 660bs, 590s, 520wb, 475m cm^{-1}.

Preparation of $Ti(OCH_3)_2(SO_3F)_2$

Freshly sublimed $Ti(OCH_3)_4$ (0.72 g, 4.2 mmol) was transferred to a 50 mL Pyrex reactor fitted with a standard B-14 joint and $S_2O_5F_2$ (4.46 g, 24.5 mmol) was condensed onto it via vacuum transfer. The reactor was detached from the vacuum line and fitted with a reflux condenser and drying tube. The reaction mixture was heated at reflux for 50 h. The volatiles were pumped off carefully. The white solid $Ti(OCH_3)_2(SO_3F)_2$ (1.294 g, ~4.2 mmol) obtained was further treated with 0.5 mL of fresh $S_2O_5F_2$ and heated at reflux. No change in weight of product was observed after removing all volatiles. *Anal.* calcd. for $C_2H_6F_2O_8S_2Ti$: C 7.79, H 1.95, F 12.34, S 20.78, Ti 15.58; found: C 7.67, H 1.90, F 12.41, S 20.48, Ti 15.29. Infrared: 2958w, 2930m, 2858mw, 1450mw, 1405m, 1385vw, 1202s, 1155mb, 1095m, 1018w, 978vs, 818vs, 645ms, 590m, 500w, 470ssh, 390w, 368sh, 345mw, 318mw, 295w, 272m, 245m, 222m cm^{-1}.

The completion of the reactions was determined as follows: The volatile materials were removed via vacuum and change in weight of the reactor recorded from time to time. Each time these materials were condensed back into the reactor and reaction allowed to proceed under said condition. The reaction was considered to be complete when no further change in weight of reactor was observed.

Results and discussion

The reaction of triphenylphosphine oxide and triphenylarsine oxide with a slight excess of $S_2O_5F_2$ produced $\phi_3\overset{+}{M}O\overset{+}{M}\phi_3.2SO_3F^-$; M = P or As at ambient temperature. The reaction may be represented by reaction [1] or [2]:

$$[1]\quad 2\phi_3MO + S_2O_5F_2 \xrightarrow[5\text{ days}]{\text{ambient temperature}} \phi_3\overset{+}{M}O\overset{+}{M}\phi_3.2SO_3F^-$$

$$[2]\quad \phi_3MO + S_2O_5F_2 \longrightarrow \phi_3\overset{+}{M}OSO_2.SO_3F^- \xrightarrow{\phi_3MO} \phi_3\overset{+}{M}O\overset{+}{M}\phi_3.2SO_3F^- \qquad M = P \text{ or } As$$

The evidence for the formation of the salt $\phi_3\overset{+}{M}O\overset{+}{M}\phi_3.2SO_3F^-$ is based primarily on the elemental analyses (Experimental section). No change in weight of the product was noted when the reactants were allowed to react even for longer periods.

The analogous reaction between triphenylphosphine oxide and trifluoromethanesulfonic anhydride is known and the formation of monophosphonium salt, $\phi_3\overset{+}{P}OSO_2CF_3.CF_3SO_3^-$, has been reported (14). However, it was shown by a different group of workers (15) that a diphosphonium salt is obtained either by reacting ϕ_3PO or $[(CH_3)_3N]_3PO$ with trifluoromethanesulfonic anhydride. Formation of diphosphonium salt had been confirmed by X-ray crystallography (15) and P—O—P angle was found to be 180°.

The ^{19}F nmr of $\phi_3\overset{+}{M}O\overset{+}{M}\phi_3.2SO_3F^-$ shows signals (relative to $CFCl_3$) at +37.7 and +38.3 ppm for the phosphorus and arsenic compounds, respectively. Appearance of a single peak corresponding to the S—F resonance reveals the presence of only one type of fluorosulfonate group. Whilst in the case of the salt $\phi_3\overset{+}{M}OSO_2F.SO_3F^-$, two signals may be anticipated for two chemically different types of SO_3F groups. Also the chemical shift in the present compounds at ca. +38.0 ppm is comparable to that in ionic KSO_3F (+37.4 ppm).

The infrared spectra of $\phi_3\overset{+}{M}O\overset{+}{M}\phi_3.2SO_3F^-$ are given in the Experimental section. The $\nu_{P=O}$ band appears sharp and strong at 1195 cm^{-1} in pure triphenylphosphine oxide (16). No band is observed at 1195 cm^{-1} in the diphosphonium salt, $\phi_3\overset{+}{P}O\overset{+}{P}\phi_3.2SO_3F^-$. This rules out the presence of any free or unreacted ϕ_3PO in the salt. Similarly, absence of the 880 cm^{-1} band (17) in $\phi_3\overset{+}{A}sO\overset{+}{A}s\phi_3.2SO_3F^-$ rules out the possibility of a ϕ_3AsO impurity in diarsonium salt. Generally, the distinction between covalent and ionic fluorosulfonate groups is made on the basis of ν_{S-F} (800–900 cm^{-1} for covalent and 700–800 cm^{-1} for ionic) (18). Strong to medium intensity broad bands at 735 and 740 cm^{-1} in diphosphonium and diarsonium salts, respectively, reveal the presence of ionic fluorosulfonate groups in these compounds. Assignments relating to other modes of SO_3F group and ϕ_3P group are not made unambiguously as both the groups produced overlapping regions.

Fluorosulfonic anhydride, $S_2O_5F_2$, reacts with Bi_2O_3 at ~65°C for 24 days to produce the already reported (5) bismuth(III) fluorosulfonate, $Bi(SO_3F)_3$ in a facile fashion, reaction [3]:

$$[3]\quad Bi_2O_3 + 3S_2O_5F_2 \xrightarrow[24\text{ days}]{\sim 65°C} 2Bi(SO_3F)_3$$

The infrared spectrum of $Bi(SO_3F)_3$ (1300m, 1210w, 1080b, 860m, 770m, 640mw, 612w, 560m, 475w, 420sh cm^{-1}) is in good agreement with its reported spectrum (5) (1295m, 1215w, 1095m, 1075m, 865m, 770m, 635w, 610w, 540mw, 470w, 420sh cm^{-1}), where two different types of fluorosulfonate groups have been anticipated.

The reaction between $S_2O_5F_2$ and $NaBi(CF_3COO)_4$ at ~60°C for 5 days yields $NaBiO(SO_3F)_2$ in nearly quantitative yields, reaction [4]:

$$[4]\quad NaBi(CF_3COO)_4 + S_2O_5F_2 \xrightarrow[5\text{ days}]{\sim 60°C} NaBiO(SO_3F)_2 + 2(CF_3CO)_2O$$

The formation of trifluoroacetic anhydride during the reaction was confirmed by infrared spectrum of the volatile material. No attempt was made to separate $(CF_3CO)_2O$ and $S_2O_5F_2$ and determine the amount of $(CF_3CO)_2O$ formed during the reaction. The completion of the reaction was monitored as described in the Experimental section.

The salient features of the ir spectrum of $NaBiO(SO_3F)_2$ are given in Experimental section. The bands at 1265, 1090, and 815 cm^{-1} corresponding to $\nu_4(E)$, $\nu_1(A_1)$, and $\nu_2(A_1)$ modes may be attributed to a tridentate fluorosulfonate group having C_{3v} symmetry (18, 19). A band observed at 815 cm^{-1} in the 700–900 cm^{-1} region relating to ν_{S-F} supports the presence of only one type of fluorosulfonate group. A comparison of the ir spectra of $NaSO_3F$ (2590w, 2390w, 1295sb, 1165w, 1095s, 940w, 850w, 785s, 740sh, 584sb, 565sh, 425w cm^{-1}) (20) with that of $NaBiO(SO_3F)_2$ (see Experimental section) indicates that $NaBiO(SO_3F)_2$ is a definite moiety and does not contain any free $NaSO_3F$. The $\nu_{Bi=O}$ band appears at 520 cm^{-1} in BiOCl (21). It was difficult to assign the bismuth–oxygen multiple bond in $NaBiO(SO_3F)_2$ because of fluorosulfonate group bending vibrations in the same region.

The reaction between titanium(IV) methoxide and excess $S_2O_5F_2$ at reflux (~56°C) yields bis(fluorosulfonato)titanium-(IV) dimethoxide, $Ti(OCH_3)_2(SO_3F_2)$, reaction [5]:

$$[5]\quad Ti(OCH_3)_4 + 2S_2O_5F_2 \xrightarrow[50\text{ h}]{\sim 56°C} Ti(OCH_3)_2(SO_3F)_2 + 2CH_3OSO_2F$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

The completion of the reaction was monitored as before. Formation of methyl fluorosulfonate, CH_3OSO_2F, was confirmed by comparison with its reported infrared spectrum.

Titanium(IV) methoxide sublimes (8) at 243°C in vacuum (52 Torr). No sublimed product could be detected even when the product, $Ti(OCH_3)_2(SO_3F)_2$, was heated at ~230°C in vacuum (5 Torr). This observation is indicative of the fact that the product does not contain unreacted $Ti(OCH_3)_4$.

Various bands in the infrared spectrum of $Ti(OCH_3)_2(SO_3F)_2$ are given in the Experimental section. A comparison of its ir spectrum with that of $Ti(OCH_3)_4$ (2912s, 2812ms, 1456mw, 1434mw, 1142mb, 1088ms, 1044ms, 574mb, 460m, 398w, 260vs cm^{-1}: only vibrations of significant intensity are given here) reveals that $Ti(OCH_3)_2(SO_3F)_2$ is a definite entity. A careful perusal of the ir frequencies of $Ti(OCH_3)_2(SO_3F)_2$ reveals splitting of *E* modes of SO_3F group. The bands at 1405, 1202, and 978 cm^{-1} may be attributed to the monodentate SO_3F group (22). Also a strong band at 818 cm^{-1} is assigned to the covalent SO_3F group in $Ti(OCH_3)_2(SO_3F)_2$. A number of bands in the region 200–300 cm^{-1} (295, 272, 245, and 222 cm^{-1}) may be due to the metal–oxygen lattice vibrations both due to OCH_3 and SO_3F groups.

In conclusion, a potential fluorosulfonating agent is possible in $S_2O_5F_2$ as is evident from various examples described above.

Received May 10, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

WILLIAM W. WILSON, KARL O. CHRISTE, JIN-AN FENG, and ROBERT BAU. Can. J. Chem. **67**, 1898 (1989).

Single crystals of $[N(CH_3)_4]HF_2$ were obtained as a by-product during the recrystallization of $[N(CH_3)_4]ClF_4$ from CH_3CN solution. X-ray diffraction data show that $[N(CH_3)_4]HF_2$ crystallizes in the orthorhombic space group $Pmn2_1$ with $Z = 2$ and unit cell dimensions $a = 6.611(5)$, $b = 8.753(5)$, and $c = 5.386(4)$ Å. The structure was solved by direct methods and refined by least squares to a final $R = 0.055$ by using 205 independent reflections. The HF_2^- anions are symmetric, exhibit an unusually short F···F distance of 2.213(4) Å, and vibrational frequencies close to those of the free HF_2^- anion.

Key words: tetramethylammonium bifluoride, crystal structure, Raman spectrum.

WILLIAM W. WILSON, KARL O. CHRISTE, JIN-AN FENG et ROBERT BAU. Can. J. Chem. **67**, 1898 (1989).

On a obtenu des cristaux uniques de $[N(CH_3)_4]HF_2$ comme sous-produit de la recristallisation du $[N(CH_3)_4]ClF_4$ dans des solutions de CH_3CN. Les données de diffraction des rayons-X indiquent que le $[N(CH_3)_4]HF_2$ cristallise dans le groupe d'espace $Pmn2_1$, avec $Z = 2$ et $a = 6{,}611(5)$, $b = 8{,}753(5)$ et $c = 5{,}386(4)$ Å. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à une valeur finale de $R = 0{,}055$ pour 205 réflexions indépendantes. Les anions HF_2^- sont symétriques; la distance F···F est relativement courte [2,213(4) Å] et les fréquences de vibration sont proches de celles de l'anion HF_2^- libre.

Mots clés : bifluorure de tétraméthylammonium, structure cristalline, spectre Raman.

[Traduit par la revue]

Introduction

During repeated recrystallization of $[N(CH_3)_4]ClF_4$ (1) from CH_3CN, some single crystals were obtained which were identified by X-ray diffraction as $[N(CH_3)_4]HF_2$. The crystals were formed by attack of some of the $[N(CH_3)_4]ClF_4$ on the solvent. Although $[N(CH_3)_4]HF_2$ is well known (2), and crystal structures have previously been reported for the higher polybifluorides containing the $H_2F_3^-$, $H_3F_4^-$, and $H_5F_6^-$ anions (3), no structural data were available for $[N(CH_3)_4]HF_2$ itself.

The HF_2^- anion is of significant structural and theoretical interest. It is a classic example for semi-ionic three centre-four electron bonding (4, 5) and exhibits the strongest known hydrogen bridge bond (6) which, depending on the symmetry of the surrounding crystal field (7), can be either symmetric or asymmetric (6, 8). Furthermore, strong oscillator coupling effects between the HF_2^- anions (9) occur in these salts which can result in very broad bands in the vibrational spectra and give rise to difficulties with their assignments. Thus, the assignment of the HF_2^- stretching modes has been in question until very recently (10–12). Since the tetramethylammonium cation is large, has a low positive charge over radius ratio, and is highly symmetrical, minimal ion–ion interactions are expected for $[N(CH_3)_4]^+HF_2^-$, and the HF_2^- anion should be relatively undisturbed. It was, therefore, interesting to compare the structure of the HF_2^- anion in $[N(CH_3)_4]HF_2$ with those of the free HF_2^- anion (12) and other HF_2^- salts.

Experimental

Single crystals of $[N(CH_3)_4]HF_2$ were obtained as a less soluble by-product during the recrystallization of $[N(CH_3)_4]ClF_4$ (1) from CH_3CN solution. They were separated from the $[N(CH_3)_4]ClF_4$ solution by decantation, followed by removal of last traces of solvent in a dynamic vacuum. Crystals were mounted in flamed out quartz capillaries in the dry nitrogen atmosphere of a glove box. A Nicolet/Syntex $P2_1$ automated four circle diffractometer, with Mo Kα radiation and a graphite crystal monochromator, was used for the intensity data collection. The unit cell parameters were determined by least-squares refinement of 15 centered reflections. Data were collected using the ω-scan technique for all reflections such that $4.0° < 2\theta < 45.0°$. Throughout the data collection, three reflections were monitored periodically, and no decay was observed. Of 206 reflections collected, 204 reflections with $I > 3\sigma(I)$ were retained for the ensuing structure analysis.

The structure was solved by direct methods using the SHELXS86 system (13) of crystallographic programs. There were two space groups that are consistent with the reflection pattern: $Pmn2_1$ (#31) and $Pmmn$ (#59). The positions of the nitrogen atom and two carbon atoms of the tetramethylammonium cation were revealed after direct method analysis of the data for both space groups. A subsequent difference-Fourier map distinctly revealed the bifluoride anion for both space groups. However, least-squares refinement of the atomic coordinates and thermal parameters in space group $Pmmn$ (#59) resulted in final agreement values of $R = 8.34\%$ and $R_w = 13.09\%$, while refinement in space group $Pmn2_1$ (#31) resulted in final agreement factors of $R = 5.52\%$ and $R_w = 7.47\%$. The ratio of agreement factors, $(8.34/5.52) = 1.51$, is sufficient (by Hamilton's R factor ratio test (14)) to state that space group $Pmn2_1$ (#31), with the lower R factor, is correct at the 99.5% confidence level. Details of the data collection parameters and other crystallographic information are given in Table 1, and the final atomic coordinates are summarized in Table 2.[2] The important bond lengths and angles are given in Tables 3 and 4, respectively, and Fig. 1 shows a packing diagram.

The Raman spectra were recorded on either a Cary Model 83 or a

Results and discussion

Crystal structure. The structure of $[N(CH_3)_4]HF_2$ can be derived from a primitive cubic CsCl lattice which is orthorhombically distorted by the nonspherical HF_2^- anions. The packing in $[N(CH_3)_4]HF_2$ (see Fig. 1) is identical to that recently found (15) for $[N(CH_3)_4]O_3$, except for HF_2^- being linear while O_3^- is bent. For $[N(CH_3)_4]O_3$ the alternate space group *Pmmn* has been suggested in which the twofold screw axis along the ***a*** axis has been eliminated, and the only symmetry element remaining along this axis is a perpendicular symmetry plane. It should be noted, however, that the bent nature of O_3^- does not necessarily require the elimination of the twofold screw axis, and that the possibility of $Pmn2_1$ should also be tested for the ozonide.

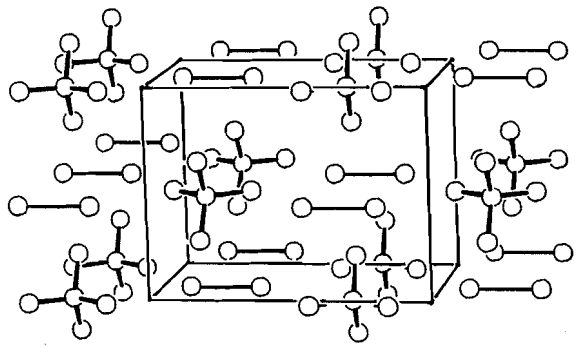

FIG. 1. Packing diagram of $[N(CH_3)_4]^+[HF_2]^-$ viewed along the ***c*** axis.

By analogy with the O_3^- salt, the large size of the $N(CH_3)_4^+$ cations minimizes the anion–anion interactions in $[N(CH_3)_4]HF_2$ and allows the HF_2^- anions to arrange in a manner (15), in which the fluorines of one HF_2^- are pointing at the fluorines of neighboring anions. In the structures of HF_2^- salts with smaller cations, such as K^+, Rb^+, or Cs^+, the negatively polarized terminal fluorine atoms of $\overset{\delta-}{F}—\overset{\delta+}{H}—\overset{\delta-}{F}$ always point at the positively polarized hydrogen atom of a neighbouring HF_2^- anion (16), as expected from Coulombic considerations. If one proceeds, however, within the family of bifluorides to salts with even smaller cations, such as Li^+ or Na^+, the HF_2^- anions are packed again in a parallel manner (16), similar to that found for the closely related linear N_3^- salts (17). It, thus, appears that for very small and very large cations, the most favorable packing conditions, i.e. a parallel arrangement of the HF_2^- anions, dominate over electrostatic dipole effects. The latter are dominant only when the cations and anions are of comparable size.

In $[N(CH_3)_4]HF_2$, all atoms, except for two methylcarbons, lie in mirror planes normal to the ***a*** axis, and the HF_2^- anions also possess a mirror plane normal to their bond line, as expected for a symmetric HF_2^- anion. Whereas the $N(CH_3)_4^+$ cation is for practical purposes an ideal tetrahedron with the expected (3, 15, 18, 19) bond lengths and angles, the F—F distance of 2.213(4) Å in HF_2^- is considerably shorter than those of 2.26–2.28 Å observed for other HF_2^- salts (16) and the free HF_2^- anion (12). This shortening is difficult to rationalize, particularly also in view of the vibrational spectrum (see below) which is very similar to that (12) of the free HF_2^- anion which has an F—F distance of 2.28 Å. It should be noted that in the alternate, but less likely (see above), *Pmmn* space group the HF_2^- anion exhibits a similarly short F—F distance of 2.22 Å. Therefore, a change in the space group of $[N(CH_3)_4]HF_2$ from $Pmn2_1$ to *Pmmn* would not result in a significant change of the F—F distance.

ground single crystals of $[N(CH_3)_4]HF_2$ were recorded. The Raman spectrum is shown in Fig. 2, and the observed frequencies together with their assignment are listed in Table 5. The bands due to the $N(CH_3)_4^+$ cation are in good agreement with previous literature data (1) and were assigned accordingly. The infrared spectrum agreed well with a previous report (2) from which the remaining frequencies for ν_3 and ν_2 of the HF_2^- anion were also taken. Table 6 gives a comparison of the frequencies of the fundamental vibrations, and the F—F and F—H distances of HF_2^- in the free ion and several salts containing either symmetric or asymmetric anions. The fundamental vibrations show the expected trends. With increasing size of the cation and better isolation of the anions, the frequencies of the symmetric HF_2^- anions approach those of the free HF_2^- anion. For the asymmetric HF_2^- anions, the frequency of ν_3 increases, and those of ν_1 and ν_2 decrease with increasing asymmetry. Therefore, the vibrational frequencies can be used for the detection of pronounced asymmetry in these anions.

The computation of standard valence force fields for HF_2^- in these salts is not rewarding in view of the uncertainties in the frequency values of ν_3, caused by their large band widths, and of the very large ionic contributions to the bonding (4, 5) which are not properly reflected by these force constants. In order to account for the strong ionic contributions to the bonding in HF_2^-, ionic force fields (20) should be used which have a stretching force constant and a force constant derived from the Coulombic force. The shortening of the F—F distance of HF_2^- in its $[N(CH_3)_4]^+$ salt is not reflected by the vibrational frequencies (see Table 6). It might, therefore, be attributed to increased Coulombic forces, but other explanations, such as possibly a slight bending of the anion caused by crystal field effects or strong librations due to loose packing of the anions, cannot be ruled out.

Conclusion

The crystal structure of $[N(CH_3)_4]HF_2$ has been determined, and the vibrational spectra have been recorded. The data show that the large $[N(CH_3)_4]^+$ cations minimize the anion–anion interactions, and that the vibrational frequencies of the HF_2^- anion approach those of the free HF_2^- anion. As expected, the $[N(CH_3)_4]^+$ cations are essentially tetrahedral, and the HF_2^- anions are symmetric. The only unexpected feature which, at the present time is not fully understood and requires further investigation, is the unusually short F—F distance of 2.213(4) Å.

Received January 13, 1989

This article is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

ALOIS HAAS and THOMAS MISCHO. Can. J. Chem. **67**, 1902 (1989).

$CF_3S(Cl)$=$NSi(CH_3)_3$ is found to undergo intermolecular decomposition to give oligomeric, possibly cyclic $(CF_3SN)_x$ rather than monomeric CF_3SN, formed by intramolecular decomposition. Monomeric thiazyltrifluoromethane, CF_3SN, is formed in the thermal decomposition of CF_3SN_3 and may be trapped before polymerizing by formation of a 1:1 adduct with hexachlorocyclopentadiene. The structure of this adduct is determined by single crystal X-ray diffraction. From the molecular structure it is evident that a (4 + 2) cycloaddition has not occurred but rather the formation of a thioketimine (**I**). The same material is formed when a suspension of CF_3SNH_2 and lead(IV) acetate in CH_2Cl_2 is refluxed and the intermediate CF_3SN is again trapped by C_5Cl_6.

By comparison ClSN and C_5Cl_6 interact in an analogous manner to give C_5Cl_6NSCl (**II**), whose structure was determined by single crystal X-ray diffraction. FSN, on the other hand, when reacted with C_5Cl_6 yields the corresponding fluoro derivative only as an intermediate. At 20°C using SO_2 as solvent C_5Cl_6NSCl (**II**) is formed. At 75°C in SO_2 the new compound C_5Cl_6N—S—NSO forms. The latter compound may also be formed from (**II**) and $Hg(NSO)_2$. In the reaction of FSN with C_5F_6 only decomposition products were observed.

Some of the reactions of C_5Cl_6NSCl (**II**) were investigated. With $Hg(SCF_3)_2$ C_5Cl_6N—$SSCF_3$ is obtained; with $SbCl_5$ in SO_2 C_5Cl_6N—S—NC_5Cl_6 forms as the main product.

Key words: synthesis of CF_3SN, preparation of C_5Cl_6NSX ($X = CF_3$, Cl, NSO, SCF_3, C_5Cl_6N), crystal structures of C_5Cl_6NSX ($X = CF_3$, Cl), chemical properties of C_5Cl_6NSCl, nmr-, ir-, ms-data.

ALOIS HAAS et THOMAS MISCHO. Can. J. Chem. **67**, 1902 (1989).

On a trouvé que le $CF_3S(Cl)$=$NSi(CH_3)_3$ subit une décomposition intermoléculaire conduisant à la formation de $(CF_3SN)_x$ oligomère et possiblement cyclique plutôt qu'une décomposition intramoléculaire conduisant au CF_3SN monomère. Le thiazyltrifluorométhane monomère, CF_3SN, se forme par la décomposition thermique du CF_3SN_3 et on peut le piéger avant sa polymérisation par la formation d'un adduit 1:1 avec l'hexachlorocyclopentadiène. On a déterminé la structure de cet adduit grâce à une étude par diffraction des rayons-X effectuée sur un cristal unique. A partir de la structure, on peut conclure qu'il ne s'est pas produit de cycloaddition (4 + 2) et qu'il y a eu formation de thiocétimine (**I**). Le même composé se forme lorsqu'on porte une suspension de CF_3SNH_2 et d'acétate de plomb(IV) dans le CH_2Cl_2 au reflux; on peut encore une fois piéger l'intermédiaire CF_3SN par le C_5Cl_6.

Par comparaison, le ClSN et le C_5Cl_6 interagissent d'une façon analogue pour donner le composé C_5Cl_6NSCl (**II**) dont la structure a été déterminée par diffraction des rayons-X sur un cristal unique. Par ailleurs, la réaction du FSN avec le C_5Cl_6 ne fournit que le dérivé fluoré correspondant comme intermédiaire. A 20°C, utilisant le SO_2 comme solvant, il se forme du C_5Cl_6NSCl (**II**). A 75°C, dans le SO_2, le nouveau composé C_5Cl_6N—S—NSO se forme. Ce dernier composé peut aussi se former à partir du produit **II** et du $Hg(NSO)_2$. Lors de la réaction du FSN avec le C_5F_6 on n'observe que la formation de produits de décomposition.

On a examiné quelques unes des réactions du C_5Cl_6NSCl. Avec le $Hg(SCF_3)_2$, on obtient du C_5Cl_6N—$SSCF_3$; avec le $SbCl_5$, dans le SO_2, le produit principal est le C_5Cl_6N—S—NC_5Cl_6.

[Traduit par la revue]

Introduction

A number of monosubstituted thiazyl compounds have been prepared. These are

FSN (1), ClSN (2), BrSN (3), HOSN (4), $(CF_3)_2NOSN$ (5),

(6), and F_5TeOSN (7).

Their thermal stability and reactivity appear to depend on the size and electronegativity of the substituents.

Thiazyltrifluoromethane, another member of this group, has been mentioned twice in the literature (8, 9) as an unstable intermediate. In the present investigation an attempt is made to provide evidence for its existence. Since coordinated FSN in the form of $[Re(CO)_5(NSF)]^+[AsF_6]^-$ (10) is well known and subsequent halogen exchange reactions with SiX_4 yield $[Re(CO)_5NSX]^+[AsF_6]^-$ (X = Cl, Br) (11), initial attempts were aimed at the synthesis of $[Re(CO)_5(NSCF_3)]^+[AsF_6]^-$. As an alternate approach the trapping of intermediate CF_3SN by suitable dienes was contemplated. Similar trapping reactions with FSN and ClSN should provide a good basis for comparing these three thiazyl compounds.

Results and discussion

Reactions of $[Re(CO)_5NSF]^+[AsF_6]^-$ with $Hg(CF_3)_2$ or $(CH_3)_3SiCF_3$ in SO_2 at 20°C failed to give the anticipated

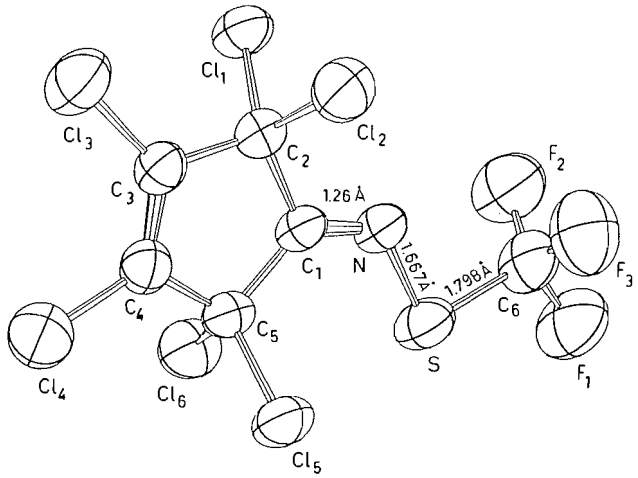

FIG. 1. Molecular structure of hexachloro-3-cyclopentenyliden-aminotrifluormethylsulfide (**I**).

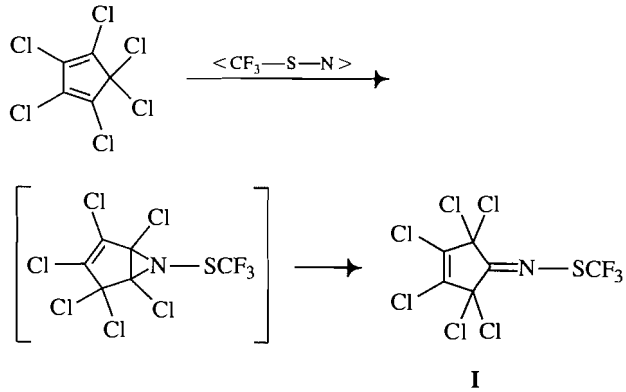


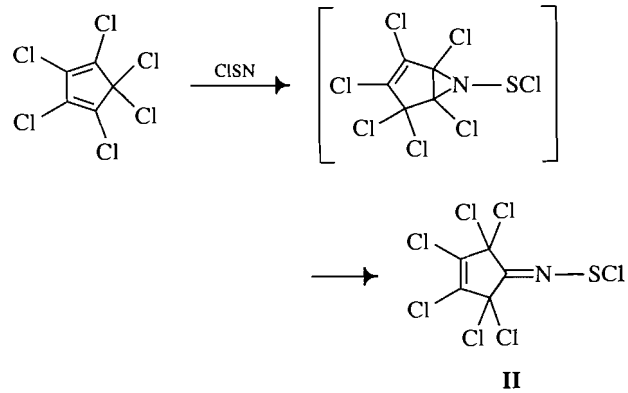
$[Re(CO)_5NSCF_3]^+[AsF_6]^-$. In both cases no F/CF_3 exchange takes place. Instead the reaction with $(CH_3)_3SiCF_3$ in CH_2Cl_2 at 20°C yields quantitatively $Re(CO)_5Cl$ and $(CH_3)_3SiF$ as well as small amounts of S_4N_4 and S_8.

The decomposition of $CF_3S(Cl)=NSi(CH_3)_3$ (8) in the presence of dienes provides a different way to detect CF_3SN. It is assumed that the final product will be oligomeric $(CF_3SN)_x$, formed via CF_3SN as a reactive intermediate.

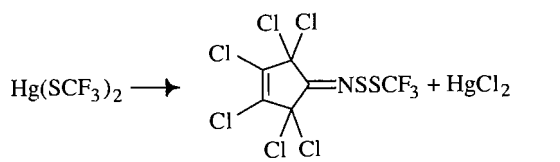
Decomposition of $CF_3S(Cl)=NSi(CH_3)_3$ in the presence of butadiene, cyclopentadiene, hexachlorocyclopentadiene, or tetraphenylcyclopentadienone afford no addition products of CF_3SN. The only materials isolated are polymeric $(CF_3SN)_x$ and $(CH_3)_3SiCl$. The dienes are recovered quantitatively. These observations are consistent with inter- instead of intramolecular condensation. A reaction scheme, illustrating this condensation process, has been proposed in a preliminary communication (12). Because neither Cl nor $(CH_3)_3Si$, both possible end groups in a chain polymer, could be detected by elemental analysis, it is concluded that $(CF_3SN)_x$ is cyclic in nature, possibly with rings of different size.

Another method to generate CF_3SN is an *in situ* decomposition of the azide CF_3SN_3, made from CF_3SCl and $(CH_3)_3SiN_3$ (9) with $(CF_3SN)_x$ as the final product. In the presence of hexachlorocyclopentadiene a white solid is obtained in low yields, which analyses as a 1:1 adduct of C_5Cl_6 and CF_3SN. Surprisingly, the chemical shift in the ^{19}F-nmr spectrum ($\delta(CF_3) = -51.6$) appears in a region where normally trifluoromethylthioamino ($CF_3S—N=$) groups resonate. This raises some doubt whether the product obtained is formed by a (4 + 2) cycloaddition reaction. The presence of a discrete CF_3SN group is confirmed by single crystal X-ray diffraction analysis. The compound $C_5Cl_6 \cdot CF_3SN$ is found to have a thioketimine structure, shown in Fig. 1 (see crystal structure). These results prove convincingly that the intermediate CF_3SN does not react with C_5Cl_6 as a "thiazyl" but as a "nitrene", presumably via an unstable (2 + 1) cycloaddition intermediate rearranging to the final hexachloro-3-cyclopentenylidenamino-trifluoromethylsulfanide (**I**) according to reaction [1]. The low yields are caused by polymerisation of the intermediate CF_3SN to $(CF_3SN)_n$ and decomposition of the latter to the detected products CF_3SSCF_3 and N_2 (19). Alternative reaction pathways can be excluded. It could be demonstrated that under these conditions C_5Cl_6 does not react with $(CH_3)_3SiN_3$.

[1]

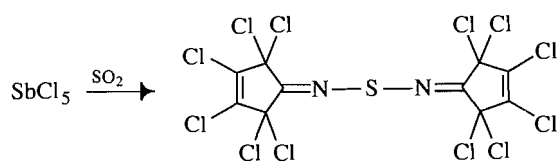


I



A second independent synthesis for **I** supports the proposed mechanism. Generally nitrenes are also produced by oxidation of primary amines (13). When a mixture of CF_3SNH_2, C_5Cl_6, and $Pb(CH_3COO)_4$ is refluxed in CH_2Cl_2, 5.4% **I** is formed in addition to $(CF_3S)_2NH$ and $CF_3SN{=}S{=}NSCF_3$, confirming the appearance of CF_3SN as a nitrene intermediate in the reaction.

These results raise the question of how ClSN interacts with C_5Cl_6. Generation of ClSN was accomplished by refluxing a solution of $Cl_3S_3N_3$ in toluene (14). In the presence of C_5Cl_6 the mixture turns red after 3 h and pale yellow crystals are isolated in 38% yield. They decompose slowly in moist air and are soluble in nonpolar solvents. Analytical results indicate the formation of a 1:1 adduct of the general formula $C_5Cl_6 \cdot NSCl$. A crystal structure analysis showed the compound to have an almost identical structure with **I**. Hexachloro-3-cyclopentenyl-idenaminosulfanyl chloride (**II**) is probably formed similarly to **I** according to reaction [2]. The reactivity of **II** is comparable to that of other sulfanyl chlorides. With $Hg(SCF_3)_2$ $C_5Cl_6NSSCF_3$ forms in good yields and with $SbCl_5$ in SO_2 the reaction takes place according to reaction [3]. Again it is evident that ClSN reacts as a nitrene with C_5Cl_6. The reactions of FSN with



[2]

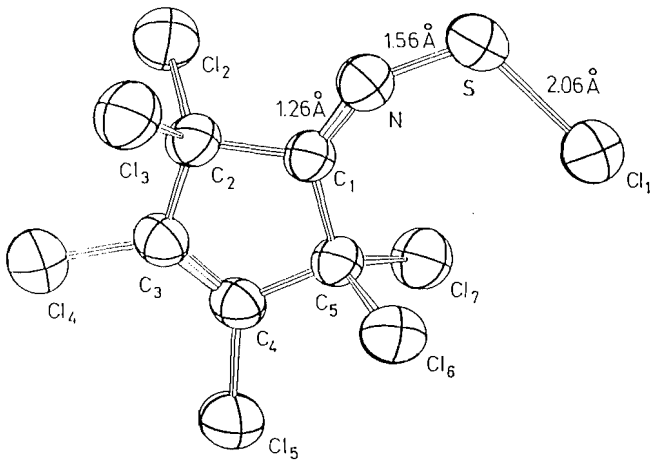

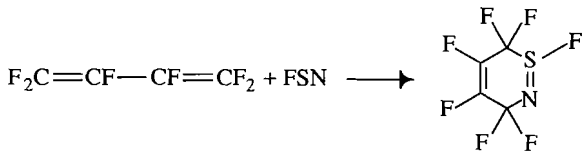

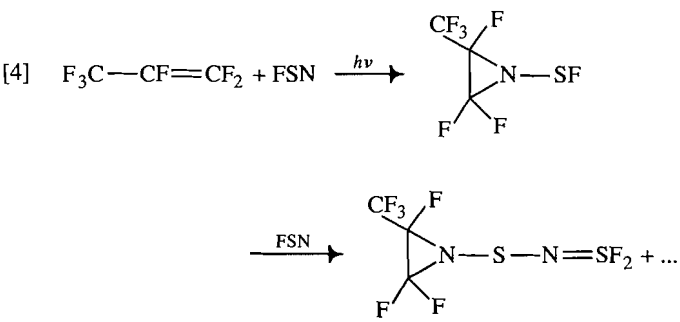

FIG. 2. Molecular structure of hexachloro-3-cyclopentenylidenaminosulfanyl chloride (**II**).

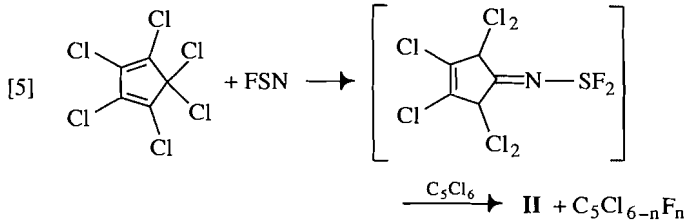
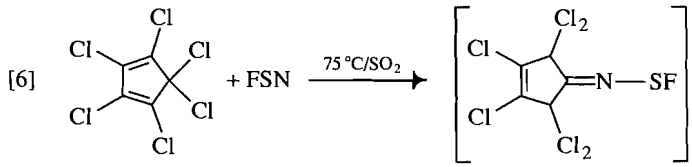
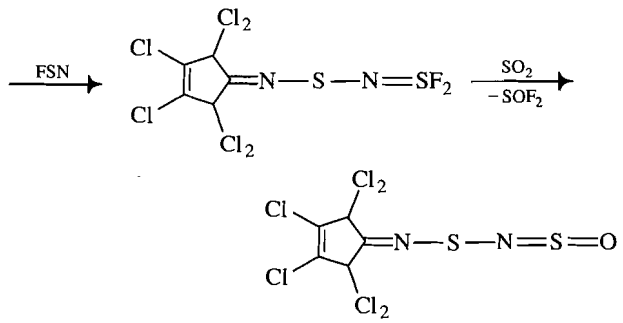


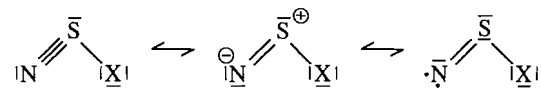
C_5Cl_6 are found to be somewhat more complicated. Analogous reactions of FSN with perfluoroolefines are reported in the literature. The products obtained are dependent on reaction conditions and the nature of the olefins. With perfluorobutadiene a (4 + 2) cycloaddition product (15) is formed and with perfluoropropene under the influence of uv-light an aziridine ring is postulated as an intermediate which adds additional FSN





to yield the corresponding iminosulfur difluoride derivative (16) according to reaction [4].

In analogy to the chemical behaviour of CF_3SN and ClSN discussed above, it is expected that FSN forms with C_5Cl_6 the corresponding sulfanyl fluoride Cl_6C_5NSF. However, the reactivity of the known dialkylaminosulfanyl fluorides of the type $R_2N—S—F$ (R = CH_3, C_2H_5) (17) suggests that such a compound may not be isolatable. Indeed the reaction of FSN with C_5Cl_6 (molar ratio 2:1) in SO_2 at 20°C gives C_5Cl_6NSCl (**II**) in 20% yield. In addition, partially fluorinated derivatives of C_5Cl_6 are formed according to the ^{19}F nmr spectra. The formation of **II** can be explained according to eq. [5]. If this procedure is carried out at 75°C in a stainless steel autoclave (other parameters not changed) hexachlorocyclopentenylidenamino-*N*-sulfinyliminosulfide, C_5Cl_6NSNSO (**III**) is obtained according to reaction [6]. The structure of **III** was confirmed by an alternate route. Although **II** does not react with $(CH_3)_3SiNSO$, with $Hg(NSO)_2$ it forms **III** in 82% yield. Since iminosulfanyl fluorides are stabilized by perfluorinated groups



III

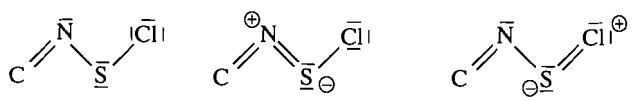
$((CF_3)_2C=N—S—F$ is stable at 55°C) (18), perfluorocyclopentadiene was treated with FSN. Instead of the expected reaction, decomposition occurred and S_4N_4, S_8, and SOF_2 were detected. Perfluorocyclopentadiene is not observed in the ^{19}F nmr spectrum any more and may have decomposed or polymerized.

The reactions studied so far at least with C_5Cl_6 as a reaction partner strongly suggest that XSN does not behave as a thiazyl compound but as a nitrene. Obviously the following mesomeric structures

explain the reactivity of X—SN (X = CF_3, F, Cl) best. Structural parameters are given in Table 2, X-ray structures are presented in Figs. 1 and 2. The observed differences for bond distances and angles in the groups C=N—S—CF_3 in **I** and C=N—S—Cl in **II** call for comments. The pertinent details of the two structures are shown below.

I **II**

In **I** d(N—S) = 1.66 Å is comparable to other normal N—S single bond distances, e.g., in $S_{11}N_2$ where d(S—N) = 1.67 Å (22). In contrast to this normal distance, hexachloro-3-cyclopentylidenaminosulfanyl chloride (**II**) d(N—S) is 1.56 Å, a considerable shorter distance, but such a value is not without precedents. In $[(CF_3SO_2)_2N]_2[SiF_6]$ the S—N bond length equals 1.586 (4) and 1.574 (4) Å and $\angle(S_1—N—S_2)$ = 125° (23). The shortening of d(N—S) in **II** may be explained by strong p_π–d_π interactions in the following manner.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12

Chlorine, on account of the difference in electronegativities will act both as σ and π acceptor towards sulfur, formally in 2+ oxidation state. This is clearly different for **I** where the CF_3— group is only capable to function as a σ acceptor. As a consequence the sulfur alone in **II** will become a stronger acceptor than its counterpart in compound **I**, resulting in extensive charge delocalisation via dative $p_\pi - d_\pi$ interaction between the sp^2 hybridized nitrogen as donor and sulfur as acceptor. The C—N bonds become, for both compounds, nearly identical and are typical for normal C=N double bonds.

The proposed charge delocalisation sequence from N → S and from S → Cl is reflected not only in the trends in bond distances, but also in the observed bond angles. In **II** ∠CNS is 147.3°, considerably widened from the "ideal" angle of 120° for sp^2 nitrogen. In **I** this angle is a normal 124.3°. The same tendency is reflected in bond angles on sulfur. For **I** ∠NSC is 94.9°, very typical for a normal angle which are generally around 90° (24) for divalent sulfur compounds. For **II** this angle is again widened to 114.9°, consistent both with higher electron density in the S—N bond and some delocalisation from lone pair electron density on sulfur to chlorine. The two sets of bond angles discussed are completely consistent with expectations based on Gillespie's valence shell electron-pair repulsion theory (VSEPR) (24).

Alternatively the following mesomeric structures may be considered,

a **b** **c**

with contributions from forms ***b*** and ***c*** reflected in the observed bond parameters. For the CF_3— compound, only the mesomeric forms ***a*** and ***b*** will contribute, with ***b*** only involved to a limited extent.

Experimental

All reactions were carried out in two- or three-necked flasks or thick-walled 50 mL tubes fitted with J. Young valves. To avoid hydrolysis all equipment was dried *in vacuo* or in a stream of hot argon. Volatile compounds were handled in a standard-vacuum-line equipped with J. Young (o-ringette PTFE stopcock) valves. Solids were manipulated in a dry argon atmosphere. Solvents were dried carefully.

Literature methods were used to prepare $(CH_3)_3SiN_3$ (25), CF_3SCl (26), CF_3SNH_2 (27), $S_3N_3Cl_3$ (28), FSN (29), $Hg(NSO)_2$ (30), $Hg(SCF_3)_2$ (31), C_5F_6 (32), $Hg(CF_3)_2$ (33), $[(CO)_5Re(NSF)]^+(AsF_6)^-$ (10), $CF_3Si(CH_3)_3$ (34), $CF_3S(Cl)$=$NSi(CH_3)_3$ (8).

Mass spectra were obtained with a MAT-CH 7 spectrometer using electron impact ionisation (70 eV). Infrared spectra were recorded with a Bruker IFS 85 spectrometer using KBr pellets.

Nuclear magnetic resonance spectra were measured at room temperature on a Bruker AM 400 spectrometer using a 5-mm probe tuned to 100.618 MHz to observe ^{13}C, and on a Bruker WM 250 spectrometer using a 15-mm probe (broad band over the frequency range 11–25 MHz) tuned to 18.070 and 25.357 MHz to observe ^{14}N and ^{15}N.

^{19}F nmr spectra were obtained on a Bruker WM 250 spectrometer (10-mm probe) by using the ^1H decoupler coil retuned to 235.36 MHz as observer coil.

For ^{13}C nmr spectra, the free induction decays were accumulated in 32 k words of memory over a spectral width of 25 KHz (0.7 Hz/data point, line broadening of 1 Hz) with pulse width of 1.5 μs in 45000 scans.

For $^{14,15}N$ and ^{19}F nmr spectra, the free induction decays were accumulated in 16 k words of memory over a spectral width of 12.195 kHz (1.5 Hz/data point, line broadening of 5 Hz) with pulse width of 50 μs in 7000 scans ($^{14,15}N$ nmr spectra) and over a spectral width of 50 kHz (6.1 Hz/data point, line broadening of 1 Hz) with pulse width of 5 μs in 16 scans (^{19}F nmr spectra).

Samples were run locked (d_6-acetone for ^{13}C nmr spectra, $CDCl_3$ for $^{14,15}N$ and ^{19}F nmr spectra) and are referenced internally to TMS and $CFCl_3$ and externally to CH_3NO_2. All melting points are uncorrected.

Data for C_5Cl_6NSCl are recorded in parentheses.

Single set of reflections 4671 (8710)

No absorption correction was applied, since $\mu = 15.04$ (17.82) cm^{-1}. The structure was solved by direct methods and refined using SHELXTL-81. The structures have been refined anisotropically to a final R-value of 0.083 (0.056), respectively. The final difference Fourier map shows maxima of 0.7 (0.5) e/Å^3. The shift of the atoms in the last "least-squares cycle" is <0.002 for the atomic and <0.005 for the thermal parameters. $R_w = 0.081$ (0.069); weighting scheme: $W = 1/\sigma^2(F) + 0.000183 \times F \times F)/K$ (K = scale factor). Atomic co-ordinates and selected bond lengths and bond angles are given in Tables 1 to 4. Thermal parameters and F_o/F_c lists are available on request from the Depository of Unpublished Data.[2] Computations are made with SHELXTL-81 (20) and Figs. 1 and 2 are prepared with ORTEP-II (21).

Reactions of $[Re(CO)_5(NSF)]^+(AsF_6)^-$

(i) With $Hg(CF_3)_2$ in SO_2

$[Re(CO)_5(NSF)]^+(AsF_6)^-$ (100 mg, 0.17 mmol) and $Hg(CF_3)_2$ (58 mg, 0.17 mmol) were dissolved in 1.5 g SO_2 in a 5-mm thick-walled nmr tube fitted with a Young valve. No reaction was observed after 5 days at 20°C by means of ^{19}F nmr spectroscopy.

(ii) With $CF_3Si(CH_3)_3$ in SO_2 or CH_2Cl_2

$[Re(CO)_5(NSF)]^+(AsF_6)^-$ (100 mg, 0.17 mmol) and $CF_3Si(CH_3)_3$ (25 mg, 0.17 mmol) were dissolved in 4 mL SO_2 in a 10-mm thick-walled nmr tube fitted with a Young valve. At 20°C no reaction took place.

When this procedure was carried out in CH_2Cl_2 at 20°C, complete decomposition of the Re-complex is observed after 1 h with formation of $Re(CO)_5Cl$, $(CH_3)_3SiF$, and minor amounts of S_4N_4 and S_8. The products were characterized by their known ir- and mass spectra.

[2]A complete set of supplementary material, comprising structure factors, final atomic positional parameters, final thermal parameters, and interatomic distances, and angles may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Pyrolysis of $CF_3S(Cl)$=$NSi(CH_3)_3$ in the presence of dienes

In a typical reaction a two-fold excess of butadiene (18 mmol) was dissolved in 150 mL toluene in a three-necked flask, equipped with a reflux condenser, cooled dropping-funnel, and gas-inlet tube. To this solution $CF_3S(Cl)$=$NSi(CH_3)_3$ (2.0 g, 9.0 mmol) dissolved in 20 mL toluene at −40°C were added dropwise. At a reaction temperature of 110°C the reaction was completed after 3 h. No addition product was detected by ^{19}F nmr and mass spectroscopy neither in solution nor in the residue, obtained after evaporation of toluene *in vacuo*. Insoluble, polymeric $(CF_3SN)_x$ (8), the principle product, decomposes under these conditions to yield CF_3SSCF_3 (characterized by ir, ^{19}F nmr and mass spectra) and nitrogen.

*Preparation of hexachloro-3-cyclopentenylidenaminotrifluoromethylsulfide (**I**)*

(i) By pyrolysis of CF_3SN_3

The reaction was carried out in a 100-mL three-necked flask equipped with condenser (−30°C), two gas inlet tubes, magnetic stirring bar, and connected via one inlet tube to a vacuum line. $(CH_3)_3SiN_3$ (8.66 g, 75 mmol), C_5Cl_6 (4.5 g, 16 mmol), and toluene (20 mL) were placed in the reaction flask and cooled to liquid nitrogen temperature. The apparatus was evacuated to 0.01 Torr. CF_3SCl (8.51 g, 62 mmol) was introduced via the gas inlet tube.

After vigorous stirring at 110°C (3 h) the formation of solid products was observed. After removing the solvent and the volatile reaction products, e.g. CF_3SSCF_3 (characterized by ^{19}F nmr and GC/MS) and N_2, formed by decomposition of $(CF_3SN)_x$, the product was sublimed at 40°C/10^{-3} Torr. Three-fold recrystallisation from CH_2Cl_2 affords analytically pure **I**. Yield: 0.40 g (6.2% based on C_5Cl_6). Subsequent sublimation at 22°C/10^{-3} Torr yields colorless single crystals suitable for X-ray diffraction studies.

(ii) By oxidation of CF_3SNH_2

In a two-necked 100-mL flask equipped with condenser a solution of CF_3SNH_2 (3.47 g, 29 mmol), dissolved in CH_2Cl_2 (10 mL) was added dropwise at 40°C (2 h) to a vigorously stirred suspension of $Pb(Ac)_4$ (7.78 g, 17 mmol) and C_5Cl_6 (3.9 g, 14 mmol) in CH_2Cl_2 (20 mL). Stirring was continued for 2 h at 40°C.

After evaporating solvent and volatile reaction products ($(CF_3S)_2NH$, CF_3SN=S=$NSCF_3$ identified by ^{19}F nmr and GS/MS) *in vacuo*, the

residue was sublimed and purified as mentioned above. Yield: 0.27 g (5.4% based on C_5Cl_6).

Characterisation of **I**

Due to the large quadrupole moment of chlorine, the ^{13}C nmr spectra of the ring carbon atoms showed only broad singlets for all compounds.

^{13}C (ppm): 158.9 (C=N), 142.4 and 140.4 (C—Cl), 85.0 and 82.2 (CCl_2), 132.3 (q) (CF_3), $^1J_{CF}$ = 310 ± 1.9 Hz. ^{19}F (ppm): −51.6 (s). Melting point: 79°C. Infrared (cm^{-1}): 1648 (w), 1606 (m), 1211 (s), 1190 (s), 1178 (s), 1167 (s), 1118 (s), 839 (s), 818 (sh), 767 (w), 740 (m), 669 (m), 640 (m), 604 (m), 586 (vw), 503 (vw), 442 (w). Mass spectroscopy (*m/e*): 387 (M^+, 7), 352 (100), 317 (49), 248 (80), 69 (23). (CAUTION: It should be mentioned that sometimes explosions occur during mass spectroscopic examinations!) *Anal.* calcd. for $C_6Cl_6F_3NS$: C 18.6, N 3.6, S 8.3, Cl 54.8; found: C 18.6, N 3.6, S 8.3, Cl 54.9.

Reaction of ClSN with C_5Cl_6 to form **II**

In a 100-mL flask, equipped with condenser, $S_3N_3Cl_3$ (1.65 g, 20 mmol) was allowed to react at 110°C (3 h) with C_5Cl_6 (3.82 g, 14 mmol) in toluene (20 mL). The color of the reaction mixture turned from deep red to brown, and a brownish precipitate formed. After removing the solvent *in vacuo*, the residue was sublimed at 70°C/10^{-3} Torr. Recrystallisation from CH_2Cl_2 (4 times) gave analytically pure **II**. Yield: 1.9 g (38% based on C_5Cl_6). Pale yellow single crystals, suitable for X-ray structure analysis, were obtained by subsequent sublimation at 30°C/10^{-3} Torr.

Characterisation of C_5Cl_6NSCl

The compound slowly decomposes in d_6-acetone within 12 h.

^{13}C (ppm): 143.2 (C=N), 136.0 (C—Cl), 82.0 and 80.0 (CCl_2). ^{15}N (ppm): −81.0 (s). Melting point: 68°C. Infrared (cm^{-1}): 1646 (s), 1608 (s), 1205 (s), 1175 (m), 1155 (m), 1038 (m), 800 (vs), 693 (s), 636 (s), 590 (m), 582 (m), 451 (s). Mass spectroscopy (*m/e*): 355 (M^+, 12), 318 (100), 211 (40), 46 (8). *Anal.* calcd. for C_6Cl_7NS: C 17.0, N 4.0, S 9.1, Cl 70.0; found: C 17.1, N 3.9, S 9.2, Cl 69.8.

Reaction of FSN with C_5Cl_6

(i) at 20°C

In a sealed (Young valve) 50-mL glass pressure tube a mixture of C_5Cl_6 (2.73 g, 10 mmol) and FSN (1.30 g, 20 mmol) in SO_2 (14 g) was stirred for 2 days at 20°C.

Solvent and volatile reaction products were removed *in vacuo*. Sublimation of the residue at 70°C/10^{-3} Torr gave analytically pure **II**. Yield: 0.72 (20.3%). Melting point: 68°C.

(ii) at 75°C

In a 50-mL stainless steel autoclave equipped with a magnetic stirring bar FSN (0.90 g, 13.8 mmol) and SO_2 (10 g) were condensed *in vacuo* onto C_5Cl_6 (1.87 g, 6.9 mmol). The reaction mixture was vigorously stirred at 75°C for 48 h. Solvent and volatile reaction products (SOF_2) were removed *in vacuo*, leaving a red viscous oil. Sublimation at 60°C/10^{-3} Torr produced yellow crystals of analytically pure C_5Cl_6NSNSO. Yield: 0.68 g (25.9%).

Characterisation of C_5Cl_6NSNSO

^{13}C (ppm): 151.7 (C=N), 141.5 (CCl), 83.8 (CCl_2). ^{14}N (ppm): −36 (NSO), −84 (C=N). Melting point: 96°C. Infrared (cm^{-1}): 1629 (s), 1598 (s), 1214 (s), 1186 (vs), 1161 (s), 1020 (m), 985 (m), 841 (sh), 815 (vs), 750 (s), 676 (m), 659 (m), 639 (s), 601 (s), 585 (sh), 539 (w), 485 (vw). Mass spectroscopy (*m/e*): 380 (M^+, 5), 345 (25), 262 (21), 46 (100). *Anal.* calcd. for $C_5Cl_6N_2OS$: C 15.8, N 7.4, S 16.8, Cl 55.8; found: C 15.7, N 7.3, S 16.9, Cl 55.5.

Reactions of C_5Cl_6NSCl

(i) with $Hg(NSO)_2$

To a mixture of $Hg(NSO)_2$ (0.90 g, 2.8 mmol) in acetonitrile (40 mL) C_5Cl_6NSCl (0.98 g, 2.8 mmol) was added and stirred at 20°C. Reaction ceased after 10 h. After removing solvent the residue obtained was treated with dry pentane to dissolve the product. The suspension was filtered and the filtrate was evaporated to dryness *in vacuo*. Yield: 0.87 g (82%). From the residue yellow crystals of C_5Cl_6NSNSO were obtained by vacuum sublimation at 60°C/10^{-3} Torr.

(ii) with $SbCl_5$ in SO_2

In a typical reaction C_5Cl_6NSCl (0.49 g, 1.4 mmol) dissolved in SO_2 (19 g) was loaded into a Pyrex two-bulb reaction vessel (60 mL) as described previously equipped with a medium-sintered glass fritt, magnetic stirring bar, and J. Young valves. Both components were frozen at liquid nitrogen temperature and $SbCl_5$ (0.47 g, 1.6 mmol) was condensed *in vacuo* onto the mixture, forming a deep blue colored ring at the surface of the two phases. When the mixture was warmed to 20°C, precipitation of a solid takes place and the solution turns red. The soluble products were separated by filtration through the frit into the second bulb, and the white insoluble solid was washed several times with the solvent. Recrystallisation in CH_2Cl_2 yielded white needles of analytically pure $C_5Cl_6NSNC_5Cl_6$. Yield: 0.26 g (62.2% based on **II**).

(iii) with $Hg(SCF_3)_2$

C_5Cl_6NSCl (150 mg, 0.42 mmol) was treated during 48 h at 20°C with $Hg(SCF_3)_2$ (170 mg, 0.42 mmol) in CH_2Cl_2 (20 mL) in a 50-mL Schlenk tube sealed with a Young valve. Fine colorless needles of solid $HgCl_2$ form, the solution was filtered and the filtrate evaporated to dryness. Sublimation of the residue at 22°C/10^{-3} Torr yielded colorless crystals of analytically pure $C_5Cl_6NSSCF_3$. Yield: 0.152 g (86%).

Characterisation of $C_5Cl_6NSNC_5Cl_6$

Since the material showed only poor solubility in organic solvents, no ^{13}C nmr spectra could be obtained. Melting point: 263°C. Infrared (cm^{-1}): 1627 (s), 1598 (s), 1212 (vs), 1178 (m), 1158 (m), 982 (m), 841 (s), 813 (vs), 775 (s), 764 (s), 751 (sh), 731 (m), 725 (sh), 671 (s),

640 (s), 600 (s), 584 (m), 456 (w), 444 (w). Mass spectroscopy (m/e): 604 (M^+, 0.2), 569 (3.2), 318 (5.8), 248 (5.7), S_2 (100). *Anal.* calcd. for $C_{10}Cl_{12}N_2S$: C 19.8, N 4.6, S 5.3, Cl 70.2; found: C 19.7, N 4.6, S 5.4, Cl 69.9.

Characterisation of $C_5Cl_6NSSCF_3$

^{13}C (ppm): 154.9 (C=N), 137.1 (CCl), 79.0 (CCl_2), 129.2 (q) (CF_3), $^1J_{CF} = 315 \pm 0.2$ Hz. ^{19}F (ppm): −45.7 (s). Melting point: 76°C. Infrared (cm^{-1}): 1635 (m), 1603 (s), 1314 (w), 1296 (w), 1212 (s), 1170 (s), 1155 (s), 1102 (s), 983 (m), 817 (s), 753 (m), 739 (m), 693 (m), 638 (s), 602 (s), 586 (m), 451 (m). Mass spectroscopy (m/e): 419 (M^+, 24), 384 (100), 318 (10), 251 (58), 69 (68). *Anal.* calcd. for $C_5Cl_6F_3NS_2$: C 17.2, N 3.3, S 15.3, Cl 50.7; found: C 17.2, N 3.5, S 15.2, Cl 51.0.

Reaction of FSN with C_5F_6

FSN (100 mg, 1.5 mmol) and C_5F_6 (261 mg, 1.5 mmol) were condensed into a thick-walled 10-mm nmr tube sealed with a Young valve and frozen at liquid N_2 temperature together with $CFCl_3$ (3 g) as solvent. The reaction was followed by ^{19}F nmr spectroscopy. Immediately after warming up to 20°C the yellow solution turned red, forming an insoluble black precipitate. SOF_2, S_4N_4 (20 mg), and S_8 (12 mg) were isolated and characterised by infrared-, mass-, and ^{19}F nmr spectroscopy.

Phosphorus-31 NMR studies of several phosphines in the solid state

GLENN H. PENNER[1] AND RODERICK E. WASYLISHEN[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received March 29, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

GLENN H. PENNER and RODERICK E. WASYLISHEN. Can. J. Chem. **67**, 1909 (1989).

Phosphorus-31 NMR powder spectra and high resolution MAS spectra have been obtained for a number of solid phosphines under conditions of high-power proton decoupling and cross-polarization. The principal components of the ^{31}P chemical shift tensor obtained from static powder spectra or slow MAS spectra are discussed in terms of the known structures of many of the phosphines. The CP/MAS ^{31}P NMR spectra are used to determine the number of crystallographically nonequivalent molecules in the unit cell. The NMR results are consistent with data available from X-ray diffraction. In one case there is evidence of polymorphism.

Key words: ^{31}P NMR of solid phosphines, principal components of ^{31}P chemical shift tensors, crystallographic nonequivalence from ^{31}P CP/MAS NMR.

GLENN H. PENNER et RODERICK E. WASYLISHEN. Can. J. Chem. **67**, 1909 (1989).

Opérant dans des conditions de découplage des protons et de polarisation croisée à haute puissance, on a examiné les spectres RMN de poudre du ^{31}P ainsi que les spectres MAS à haute résolution d'un certain nombre de phosphines solides. On discute de la nature des composantes principales du tenseur du déplacement chimique du ^{31}P et des spectres lents de MAS en fonction des structures bien connues de plusieurs de ces phosphines. On a utilisé les spectres RMN CP/MAS du ^{31}P pour déterminer le nombre de molécules non-équivalentes d'un point de vue cristallographique présentent dans la maille. Les résultats de la RMN sont en accord avec les données disponibles à partir de la diffraction des rayons-X. Dans un cas, on a des connées permettant de confirmer l'existence d'un polymorphisme.

Mots clés : RMN du ^{31}P de phosphines solides, composantes principales des tenseurs du déplacement chimique du ^{31}P, non-équivalence cristallographique à partir des spectres rmn CP/MAS du ^{31}P.

[Traduit par la revue]

Introduction

Phosphorus-31 NMR is one of the most important tools available for characterizing the structure and conformation of organophosphorus compounds (1, 2). Numerous studies have been carried out to examine the influence of electronic and molecular structure on ^{31}P chemical shifts (3–6). Although empirical rules are available for predicting isotropic chemical shifts in a series of closely related compounds such as phosphines (3, 5, 6), our understanding of the physical basis of these rules is lacking (7). The status of theoretical calculations of ^{31}P chemical shifts has recently been reviewed by Chesnut (7). There are few *ab initio* calculations of ^{31}P chemical shifts and most of the calculations have been restricted to phosphine, PH_3 (7). Recent calculations by Fleischer *et al.* (8) indicate that large basis sets including *d* functions are essential for accurate calculations of ^{31}P shift tensors. The implication is that it may be several years before reliable molecular orbital calculations of ^{31}P chemical shifts are available for organophosphines of the type investigated in this study.

A first step in improving our understanding of ^{31}P chemical shifts is to study the variation of the principal components of the chemical shift tensor, δ_{ii} ($i = 1-3$) with molecular structure. In principle, the diagonal components of the shift tensor should be more informative than the trace or isotropic shift, $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$. For example, there are cases where a change in molecular structure may lead to a small or negligible change in δ_{iso} while the individual principal components of the shift tensor may exhibit substantial variations in opposing directions (10).[3]

The principal components of the shift tensor, δ_{ii} ($i = 1-3$), can be obtained by studying the compound of interest in a liquid crystal system (11), from static (non-spinning) powder spectra (11–14), or from an analysis of the spectra obtained under conditions of slow MAS (15, 16). If large single crystals are available, both the principal components and their orientation in the molecular frame can be established from single crystal NMR studies (17). In this study we have measured the principal components of the ^{31}P shift tensor of a number of tertiary phosphines from static powder spectra and slow MAS spectra. As well, we have carried out MAS studies on these compounds to obtain information regarding the number of crystallographically nonequivalent molecules in the unit cell (18).

To our knowledge only a few, mostly unusual, phosphines have been studied previously by solid state ^{31}P NMR (19–22).

Experimental

All compounds were commercially available. Phosphorus-31 NMR spectra were obtained at 80.962 MHz using a Bruker MSL-200 (B_0 = 4.7 T). Powder samples (0.3 g) were packed into aluminum oxide rotors. Spectra were recorded at 21°C with high-power proton decoupling and cross-polarization using the Hartman–Hahn match. Contact and recycle times ranged from 2 to 5 ms and from 10 to 30 s, respectively.

Static spectra had acquisition times of 41–102 ms, and sensitivity enhancements corresponding to 50–100 Hz line broadening were applied before Fourier transformation.

Magic angle spinning spectra were obtained with acquisition times of 102–205 ms. Typically the MAS spinning rate was 3 kHz. The FID's were zero filled to twice their original size and the signal-to-noise was enhanced with 5–10 Hz line broadening before Fourier transformation.

Chemical shifts were referenced with respect to the ^{31}P NMR signal of external $NH_4H_2PO_4$, which has a shift of 1.00 ppm with respect to 85% H_3PO_4.

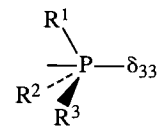
[a]Estimated errors in δ_{11}, δ_{22}, δ_{33}, and $\Delta\delta$ are ~1 ppm; errors in δ_{iso} are 0.1 ppm unless otherwise stated. The errors in δ_{ii} are determined by the magnitude of the intermolecular ^{31}P,^{31}P dipolar coupling,which causes the broadening of the shoulders and the discontinuities in the static powder spectra (9, 31).

[b]Following ref. 14 the asymmetry parameter is defined $\eta = (\delta_{yy} - \delta_{xx})/(\delta_{zz} - \delta_{iso})$ where the axes are labelled so that $|\delta_{zz} - \delta_{iso}| \geq |\delta_{xx} - \delta_{iso}| \geq |\delta_{yy} - \delta_{iso}|$. Note that δ_{xx}, δ_{yy}, and δ_{zz} are the principal components of the chemical shift tensor given above.



[c]Estimated errors in δ_{11}, δ_{22}, δ_{33}, and $\Delta\delta$ are ~5 ppm.

[d]Estimated errors in δ_{11}, δ_{22}, δ_{33}, and $\Delta\delta$ are ~2 ppm.

Results and discussion

The results of this study together with available crystallographic information are summarized in Table 1. The chemical shift anisotropy is simply defined as $\delta_{11} - \delta_{33}$; this provides a direct measure of the maximum width of the spectrum. More elegant definitions can be found elsewhere (13, 14). The asymmetry parameter, η, will be defined following the convention of Haeberlen (14); it is restricted to values between 0 (axial symmetry) and 1. A few general conclusions may be obtained upon examination of Table 1. First, the number of ^{31}P resonances observed in each CP/MAS spectrum agrees with the number of crystallographically nonequivalent phosphorus nuclei, N, predicted from X-ray diffraction results. Second, the chemical shift anisotropy, $\Delta\delta$, for the phosphines relative to other phosphanes (23) follows the order $\Delta\delta$ (phosphine oxides) > $\Delta\delta$ (phosphine sulphides) > $\Delta\delta$ (phosphine selenides) > $\Delta\delta$ (phosphines). Interesting exceptions to this trend are phosphirenes and phosphiranes (20, 21), three-membered cyclic systems consisting of one phosphorus and two carbon atoms. In these systems the $\Delta\delta$ values are about an order of magnitude greater than those reported here for unstrained phosphines. Third, the effects of conjugative interactions between the phosphorus lone pair and the π-systems of the phenyl rings do not seem to dominate the variation in chemical shift tensor components. Rather, overall molecular structure, in particular the conformation of the substituents, R, appears to have a greater effect. It should also be noted that the variation in δ_{33} for the phenyl and alkyl phosphines, **1–11**, is significantly smaller (by a factor of over 3) than for components δ_{11} and δ_{22}.

In this study δ_{33}, the most shielded component of the chemical shift tensor, is taken to lie along the C_3 (or pseudo C_3) axis (**14**). The orientation of δ_{11} and δ_{22}, which lie in planes perpendicular to δ_{33}, is ambiguous. When there is threefold symmetry at the phosphorus, δ_{11} and δ_{22} are degenerate, and "axially symmetric" ($\eta = 0$) powder spectra are expected.

14

Although the symmetry at the phosphorus in solid triphenylphosphine, **1**, is not C_3 (24), the ^{31}P NMR powder spectrum is consistent with an axially symmetric chemical shift tensor. There are a number of possible reasons for this: the degeneracy of δ_{11} and δ_{22} is accidental, the difference between δ_{11} and δ_{22} is below the resolution of the experiment, or δ_{11} and δ_{22} are averaged by large-amplitude motion of the phenyl rings (25).

The molecular structure of solid tris(*p*-methoxyphenyl)-phosphine, **2**, (26) has the ring planes at angles of 48°, 31°, and 46° from the pseudo C_3 axis. Therefore asymmetry in the ^{31}P shielding tensor is expected and, indeed, an η value of 0.18 is measured.

The crystal structure of tris(*p*-tolyl)-phosphine, **3** (27), shows threefold symmetry about the phosphorus and the expected axially symmetric powder spectrum is observed, as indicated in Fig. 1a.

A significant deviation from axial symmetry is observed in the powder spectrum of tris(*m*-tolyl)-phosphine, **4**. The molecular structure of crystalline **4** (28) has two of the methyl groups on the same side of the molecule as the phosphorus lone pair (*exo*) and one on the other side (*endo*). Such a conformation allows the chemical shift tensor to deviate from axial symmetry (see Fig. 1b).

The static and CP/MAS ^{31}P spectra of tris(*o*-tolyl)-phosphine, **5**, exhibit several interesting features. Two resonances are observed in the CP/MAS spectrum of solid **5**. This is consistent with the reported X-ray crystal structure (29), which indicates that there are two types of molecules in the unit cell. The separation between the two resonances is 5.5 ppm. A

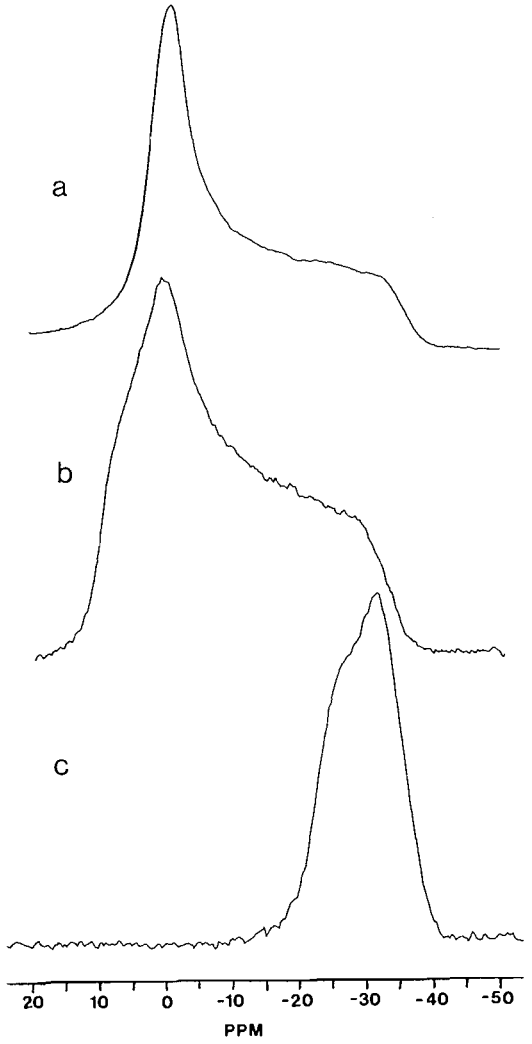

FIG. 1. Static ^{31}P NMR spectra of (a) *p*-tolyl, (b) *m*-tolyl, and (c) *o*-tolyl phosphine.

second interesting feature is the small chemical shift anisotropy, $\Delta\delta$, of the powder spectra (Fig. 1c). Although the static powder spectra for the two types of ^{31}P cannot be resolved, an upper limit of 15 ppm can be placed on their $\Delta\delta$ values. Some information on the individual shielding tensors can be obtained from slow MAS experiments. A spectrum obtained with magic angle sample spinning at 310 Hz allows the centre and spinning side bands of the two resonances to be separated while still maintaining some information on the shift tensor. Even at a MAS rate of only 310 Hz the spinning side bands are of such low intensity relative to the centre band that a reliable analysis using the Herzfeld–Berger (15) or related methods is not possible. What the experienced eye can discern from the slow MAS spectrum is that the higher frequency ^{31}P resonance has associated with it a shielding tensor of significantly higher asymmetry. An X-ray investigation of **5** shows that the major difference between the structures of the two independent molecules is in the torsion angles made by the phenyl rings with the pseudo C_3 axes. One molecule has angles of 46.8°, 40.7°, and 45.6°; the other has 36.7°, 49.0°, and 43.1°. In other words the latter molecule deviates most from C_3 symmetry and one may tentatively assign the high frequency resonance to this molecule. Obviously single crystal ^{31}P NMR measurements will be necessary to assign the ^{31}P resonances of **5**.

The CP/MAS spectrum of commercially available trimesitylphosphine, **6**, displays three resonances, which we assign as due to two closely spaced pairs (Fig. 2a). This is inconsistent with the X-ray crystal structure (30), which indicates that there are two nonequivalent molecules per unit cell. Recrystallization of **6** from chloroform/ethanol following the procedure used to prepare a single crystal for X-ray studies yielded a ^{31}P CP/MAS spectrum in which the intensity of the low frequency pair was greatly diminished (see Fig. 2b). The commercial sample was obtained by recrystallization from toluene/ethanol.[4] These results suggest that a recrystallization from toluene/ethanol yields two morphological forms of crystalline **6** in approximately equal proportions, whereas recrystallization from chloroform/ethanol yields mostly the polymorph responsible for the high frequency pair of resonances. The polymorph responsible for the high frequency resonances, and for which a crystal structure is available, will be referred to as **6*a***; the other modification, responsible for the low frequency peaks, will be referred to as **6*b***.

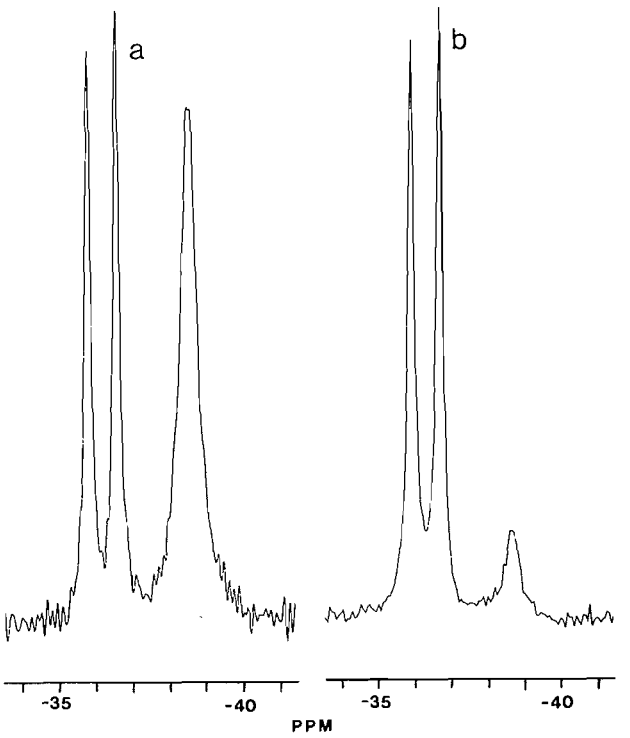

FIG. 2. MAS ^{31}P NMR spectra of trimesitylphosphine: (a) commercial sample; (b) after recrystallization from $CHCl_3$/EtOH. Only a single ^{31}P NMR resonance was observed for samples a and b in solution.

Crystalline **5** and **6*a*** are isomorphous (29, 30). The peak separations in **6*a*** and **6*b*** are 0.8 ppm and ca. 0.1 ppm (estimated from linewidth), respectively (see Fig. 2). The spectra of **6*a*** and **6*b*** share some common features with that of **5**. The rather low frequency chemical shifts of **6*a***, and **6*b***, and **5** as well as the unusually small chemical shift anisotropies are due to a large low frequency (high field) shift of the chemical shift tensor components δ_{11} and δ_{22}. The major differences in the molecular of **5** and **6** are the presence of methyl groups at the 4 and 6 positions of the phenyl rings in **6** and larger CPC bond angles for **6**. The similarities between the spectra of **5** and **6** suggest that it is the presence of the methyl groups in the *exo* position that is the major contributor towards the large low frequency shifts of δ_{11} and δ_{22}.

[4]Organometallics Inc., E. Hampstead, NH 08326, U.S.A. Private communication.

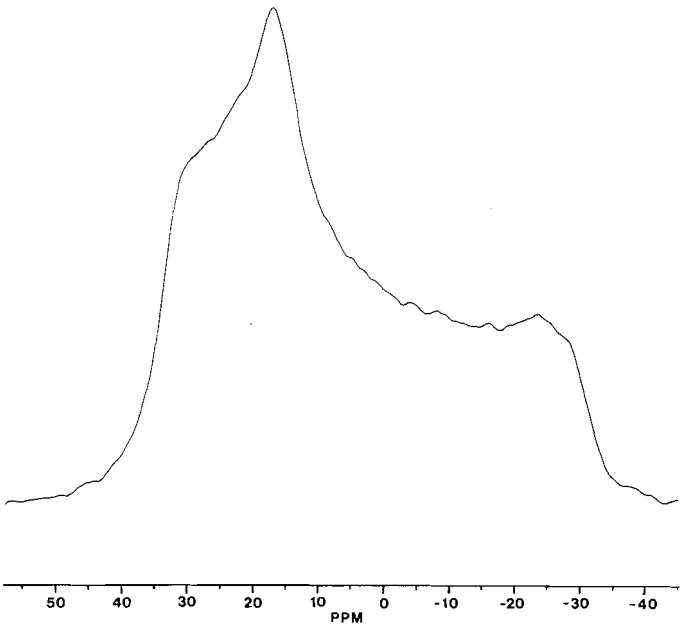

FIG. 3. Static ^{31}P NMR spectrum of tricyclohexylphosphine.

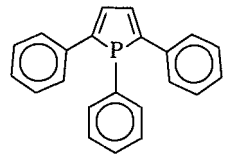

Having established the dominant contribution to the low frequency shift of δ_{11} and δ_{22} in *o*-tolylphosphine derivatives, it can be suggested that the larger low frequency shift of δ_{22} (or δ_{11}, assignment is arbitrary) in diphenyl-*o*-tolylphosphine, **7**, is due to the *o*-tolyl substituent being oriented in such a way that the *ortho* methyl group is on the same side of the molecule as the phosphorus lone pair. A crystal structure of **7** is not available in the literature.

The CP / MAS spectrum of diphenyl-2-methoxyphenylphosphine, **8**, consists of two resonances; both are broader than those for the other phosphines. The large linewidths may be a relaxation phenomenon or may be due to the presence of four, not two, nonequivalent molecules per crystal unit cell.

A common feature of the static powder spectra of compounds **9**, **10**, and **11** is the high frequency shift of δ_{11}. These three molecules have one or more alkyl substituents on the phosphorus. The asymmetries for **9** and **11** are rather large, as expected for unsymmetrically substituted phosphines. Tricyclohexylphosphine, **10**, is symmetrically substituted but, as shown in Fig. 3, the asymmetry of the chemical shift tensor is large, indicating a large deviation from C_3 symmetry in the molecule. Unfortunately an X-ray structure is not available for **10**.

X-ray studies of tri(2-cyanoethyl)phosphine, **12**, at 100 K (32) and 298 K (33) indicate a mirror plane through the molecule. The plane is defined by the heavy atoms of one of the CH_2CH_2CN substituents. The molecule is significantly distorted from C_3 symmetry; therefore a nonzero η is expected and indeed the ^{31}P powder spectrum indicates an η value of 0.64. All components of the chemical shift tensor are to lower frequency of those expected although the anisotropy, $\Delta\delta$, is typical of a phosphine. The symmetry of crystalline **12** suggests that one component of the chemcal shift tensor (δ_{33}) is along the phosphorus lone pair, another is in the mirror plane oriented at 90° to δ_{33}, and the third component is oriented perpendicular to the mirror plane. The exact assignment of the last two components to δ_{11} or δ_{22} cannot be made at present.

An X-ray diffraction investigation of the molecular structure of 1,2,5-triphenylphosphole, **13**, was undertaken by Ozbirn *et al.* (34) to assess the possibility of electron delocalization within

13

the phosphole ring. They concluded that "all the structural evidence indicates that the heterocyclic ring exhibits little if any electron delocalization." The chemical shift tensor components and the anisotropy for **13** are typical of a phosphine and provide no evidence for delocalization. Phosphine oxides, sulfides, and selenides, which exhibit resonance structure of the form $R_3P{=}X \rightleftharpoons R_3P^+{-}X^-$ (23), have ^{31}P chemical shift anisotropies in the ranges 150–200, 80–180, and 80–150 ppm, respectively. The ^{31}P NMR powder spectrum of 1,2-bis(2,4,6-tri-*tert*-butylphenyl)diphosphene (22), a system containing a formal P=P double bond, shows an exceptionally large shift anisotropy of 1239 ppm. Based on these observations, a larger value for $\Delta\delta$ would be expected if there were any significant delocalization in **13**.

Summary

The number of crystallographically nonequivalent phosphorus atoms in each solid phosphine is reflected by the number of resonances observed in the ^{31}P CP / MAS spectrum. The possibility of delocalization between the phosphorus lone pair and the ring π system is phenylphosphines does not have a significant effect on the principal components of the ^{31}P shielding tensor; rather, conformational effects dominate. One such conformational effect is the orientation of *o*-tolyl substituents with respect to the approximate C_3 axis at the phosphorus. The molecular symmetry about the phosphorus in the solid state is reflected by the symmetry of the ^{31}P powder spectrum. In general, the greater the deviation from C_3 symmetry, the larger the asymmetry, η, of the chemical shift tensor.

Finally, the principal components of the ^{31}P shielding tensor in solid 1,2,5-triphenylphosphole provide no evidence for electron delocalization in the heterocyclic five-membered ring.

Acknowledgements

We wish to thank Professor H. C. Clark and his group for supplying us with commercial samples of several phosphines and Professor E. Alyea for the commercial sample of trimesitylphosphine. We are grateful to Ron Curtis and Brian Millier for their assistance in maintaining the NMR spectrometer, and Bill Power and Professor O. Knop for several helpful suggestions. We thank Organometallics for information about compound **6**. The financial assistance of NSERC is gratefully acknowledged. Trigonal prismatic versus octahedral coordination geometry of transition metal dithiolates: Comparison between saturated and unsaturated early transition metal tris(1,2-dithiolate) complexes

JOEL L. MARTIN[1] AND JOSEF TAKATS[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 20, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

JOEL L. MARTIN and JOSEF TAKATS. Can. J. Chem. **67**, 1914 (1989).

Reaction of a stoichiometric amount of H_2edt/NaHedt (edt = ethane-1,2-dithiolate) with the appropriate metal amide, followed by cation exchange, gave the complexes $[NEt_4]_2[M(edt)_3]$ (M = Ti, **1**; Hf, **2**) and $[AsPh_4]$ $[Nb(edt)_3]\cdot CH_3CN$, **3**. The structure of **3** has been determined crystallographically (space group; cell dimensions; Z; unique data ($I \geq 3\sigma(I)$); R/R_w): $P\bar{1}$; a = 9.095(1), b = 14.609(3), c = 15.639(3) Å and α = 60.09(2), β = 80.07(3), γ = 89.89(2)°; z = 2; 1488; 4.3/4.5. The coordination geometry of **3** is severely distorted from the trigonal prismatic (TP) structure found in the analogous $Nb(1,2\text{-}S_2C_6H_4)_3^-$, which contains an unsaturated 1,2-dithiolate ligand system. The average twist angle between triangular faces is 33.3°. However, on the basis of VT ^{1}H NMR spectroscopy it is argued that the TP form is at most 9–10 kcal mol^{-1} less stable than the observed geometry. A comparison between the structures of tris-chelate complexes of the early transition metals containing saturated and unsaturated 1,2-dithiolates and related ligands is made, and the factors thought to be responsible for TP vs. octahedral geometry are reviewed and their relative importance assessed.

Key words: structure, trigonal prismatic, 1,2-dithiolate, early transition metals.

JOEL L. MARTIN et JOSEF TAKATS. Can. J. Chem. **67**, 1914 (1989).

La réaction d'une quantité stoechiométrique de H_2edt/NaHedt (edt = éthane-1,2-dithiolate) avec des amidures métalliques, suivie d'un échange de cation, fournit les complexes $[NEt_4]_2[Me(edt)_3]$ (M = Ti, **1**; Hf, **2**) et $[AsPh_4][Nb(edt)_3]\cdot CH_3CN$, **3**. On a déterminé la structure du composé **3** par diffraction des rayons-X. Les cristaux appartiennent au groupe d'espace $P\bar{1}$ avec a = 9,095(1), b = 14,609(3) et c = 15,639(3) Å et α = 60.09(2), β = 80,07(3) et γ = 89,89(2)° et Z = 2; on a affiné la structure jusqu'à des valeurs respectives de R et R_w de 0,043 et 0,045 pour 1488 réflexions avec $I \geq 3\sigma(I)$. La géométrie de coordination du composé **3** est fortement deformée par rapport à la structure prismatique trigonale (PT) qui a été observée antérieurement avec l'analogue $Nb(1,2\text{-}S_2C_6H_4)_3^-$ qui contient un ligand 1,2-dithiolate insaturé. L'angle moyen de déviation entre les faces triangulaires est de 33,3°. Toutefois, sur la base de la RMN du ^{1}H à température variable, on suggère que la différence de stabilité entre la forme PT et la géométrie observée ne favorise cette dernière que par 9–10 kcal mol^{-1}. On a comparé les structures des complexes tris chélates des métaux de transition du début contenant des ligands 1,2-dithiolates saturés et insaturés ainsi que d'autres ligands apparentés; on passe en revue les facteurs que l'on croit responsable des structures PT vs. les géométries octaédriques et on évalue leurs importances relatives.

Mots clés : structure, prismatique trigonal, 1,2-dithiolate, métaux de transition du début.

[Traduit par la revue]

Introduction

The possibility of trigonal prismatic (TP) geometry in highly covalent d^0 transition metal complexes was predicted as early as 1932 by Hultgren (1), based on the concept of metal orbital hybridization presenting a more favorable bonding picture for TP than for octahedral geometry. This result has been corroborated by Hoffman *et al.* (2) on the basis of extended Hückel MO calculations.

In 1965 the first observation of a discrete TP complex, $Re(1,2,\text{-}S_2C_2Ph_2)_3$ (3), rekindled interest in TP geometry and since then a host of factors, such as (a) ligand constraint (4, 5), (b) ligand field stabilization energy (2, 4, 6), (c) interdonor atom bonding (3, 7–9), (d) proper matching of ligand and metal orbital energies (1, 2, 10–12), (e) the symmetry of ligand π orbitals (2, 8, 13), and (f) the overall charge of the complex, have been suggested as important factors influencing the formation of TP, octahedral, or intermediate geometries. From experimental work of Holm and co-workers (4) and Eatough *et al.* (14) and theoretical work of Holm (4), Kepert (5), and Wentworth (6) it appears that the two most important factors involved are probably the ligand constraint (provided by cage type ligands and (or) the "bite" distance of chelating ligands) and the ligand field stabilization energy in that order. However, the ordering of factors (c) through (f) is certainly still a subject of debate. Indeed any attempts to assess the importance of subtle electronic factors in favoring TP geometry must carefully avoid the problems of ligand constraint and ligand field stabilization energy. The studies that will be considered here were directed at understanding the geometry of transition metal complexes containing unsaturated 1,2-dithiols and attempted to avoid the complications of the two overriding factors mentioned above.

The synthesis of early transition metal complexes of benzene 1,2-dithiol (15) provided the unique opportunity to study an isoelectronic series of complexes: $Mo(bdt)_3$, $Nb(bdt)_3^-$, and $Zr(bdt)_3^{2-}$ (btd = 1,2-benzenedithiolate). Although the decreasing stability of TP geometry in the order Mo > Nb > Zr suggested to Cowie and Bennett (11) that the proper matching of metal d-orbital and ligand orbital energies was an important condition for TP geometry, the study was not conclusive because the change in overall charge of the complexes should also favor the observed trend. To confirm the hypothesis of Cowie and Bennett, we undertook structural analysis of $Ta(bdt)_3^-$ and $Sb(bdt)_3^-$ complexes, which strongly resemble the Nb complex in metal size and also have the same charge (12, 16). The increasing distortion away from TP geometry in the order Nb < Ta < Sb provides substantial evidence that the stability of TP

M = Ti (**1**), Hf (**2**), Nb (**3**)

SCHEME 1

geometry hinges upon the availability of metal *d* orbitals of appropriate energy. Also, the study of the entire series of benzene-1,2-dithiolate complexes, in our mind, has cast serious doubt about the importance of interligand donor atom bonding in this regard.

However, an interesting question that remains is whether π bonding or σ bonding, as originally suggested by Hultgren (1) and later revived (10), is the factor that favors TP geometry. A possible approach to this question is to compare the behavior of analogous complexes containing unsaturated and saturated 1,2-dithiols, since the σ/π bonding capabilities of these ligand systems are expected to be different.

In this paper we present our synthesis of $M(edt)_3^{n-}$ (edta = ethane-1,2-dithiolate; M = Ti, Hf, $n = 2$; M = Nb, $n = 1$) complexes, describe the solid state structure of the niobium complex (tetraphenylarsonium salt), and comment on the relevance of these complexes to the question of TP vs. TAP coordination geometry in transition metal dithiolates. Since our initial disclosures (17), other groups have extensively investigated the chemistry and structure of transition metal complexes of ethane-1,2-dithiol (18–21). The synthesis and structure of $[NEt_4]_2[Ti(edt)_3]$ and $[NEt_4][Nb(edt)_3]$ have been reported by Holm and co-workers (20) and Tatsumi, Nakamura, *et al.* (21*a*), respectively.

Results

Synthesis and spectroscopic properties

As reported previously for the synthesis of the analogous benzene-1,2-dithiolate complexes (15), the reaction of the appropriate transition metal amide with $H_2edt/Hedt^-$, according to the stoichiometry shown in Scheme 1, gave the corresponding tris(ethane-1,2-dithiolate) complexes in moderate yield. The Ti and Nb (and Ta) complexes were also obtained from the reaction of the appropriate metal halide with Na_2edt and Li_2edt respectively, in the required 1:3 stoichiometric ratio (20, 21). It is not known whether the Hf complex also obtains from this simplified procedure.

The complexes reported are well-behaved, crystalline solids (**1** and **3** red, **2** almost colorless), but are somewhat more unstable toward hydrolysis than the corresponding benzene-1,2-dithiolate compounds. Solutions of both types of compounds are sensitive to moisture carried in the air. Under inert atmosphere, complexes **1–3** are stable in CH_3CN but, like the corresponding benzene-1,2-dithiolate complexes, the Ti and Hf derivatives decompose in CH_2Cl_2. Stability in the solid state ranges from the readily hydrolyzed Hf compound to the reasonably unreactive Ti and to the stable Nb complex. However, we note that Tatsumi, Nakamura, *et al.* (21*b*) report an interesting rearrangement of the latter compound via C—S bond cleavage, a feature not observed with the analogous unsaturated dithiol complexes.

The infrared spectra of compounds **1** and **2** show two strong bands in the metal–sulfur stretching region (**1**, 355 and 322 cm^{-1}; **2**, 297 and 268 cm^{-1}), and are tentatively thus assigned. The M–S stretching region for **3** is obscured by the tetraphenylarsonium ion bands, but Tatsumi, Nakamura, *et al.* (21*a*) report Nb–S and Ta–S stretching vibrations at 354(s), 338(s), 240(w) and 335(s), 318(s), 225(w) cm^{-1}, respectively. Once the difference in relative atomic masses between these metals is taken into account, the strength of the M–S stretch is Ti ≈ Hf < Ta ≈ Nb. The ^1H NMR spectra of the complexes at room temperature exhibit a sharp singlet for the methylene protons of the ligand. The position of the signal shifts to lower field in the order Hf, Ti, and Nb (δ: **2**, 3.23; **1**, 3.38; **3**, 3.76 ppm), which is the same order as the stability sequence of the compounds. The cause of the strong coloration of the Ti and Nb complexes is evident from Fig. 1. Charge transfer transitions, which dominate the spectra, shift to higher energy in the order Nb < Ti < Hf. Systematic blue shift of all uv–visible absorption bands on going from $Nb(edt)_3^-$ to $Ta(edt)_3^-$ was also reported by Tatsumi, Nakamura, *et al.* (21). The dependence of the lowest energy maximum upon the metal is suggestive of LMCT character of the bands. A detailed assignment of the spectra cannot be made at this time, but it must be pointed out that the same type of metal dependence was observed in the benzene-1,2-dithiolate complexes.

The chemical reactivity, infrared spectra in the ν_{M-S} region, ^1H NMR spectra, and uv–visible spectra of the ethane-1,2-

dithiolate complexes all show the trends expected for increased bond strength in the order Hf < Ti < Nb, just as in the benzene-1,2-dithiolate complexes. The rationale here, as before, is that the metal *d* orbitals are increasingly stabilized in the order Hf < Ti < Ta < Nb and as a result both σ and π donation from the ligand are enhanced. However, as yet no means other than X-ray crystallography has been developed that can answer questions regarding the exact geometry of the metal complexes. Accordingly, the single crystal X-ray structure of the Nb complex was determined.

Description of the structure of **3**

A summary of pertinent distances and angles is presented in Table 1. Numbering of the $Nb(edt)_3^-$ anion is evident from Fig. 2, which is a view down the approximate threefold axis of the complex anion. The contents of the unit cell are shown in Fig. 3 and establish that the crystal structure consists of well-separated ions and CH_3CN molecules, with no unusual interionic contacts. The disordered CH_3CN molecules are shown as five atoms, which was the model used to fit them. As may be expected for this type of disorder, the bond lengths and angles are slightly irregular and have large standard deviations. However, the C—C bond lengths, 1.35(5) and 1.40(4) Å, C≡N bond lengths, 1.17(5) and 1.18(5) Å, and C—C≡N bond angles, 174°(4) and 175°(4), are in agreement with accepted values. The geometry of the tetraphenylarsonium ion is in good agreement with previous determinations of this ion, with As—C bonds averaging 1.884(3) Å and C—As—C angles averaging 109.5(8)°.

Although there is no crystallographically imposed symmetry, it is clear from Fig. 2 that the complex anion is quite symmetrical. The six sulfur atoms are approximately equidistant from the

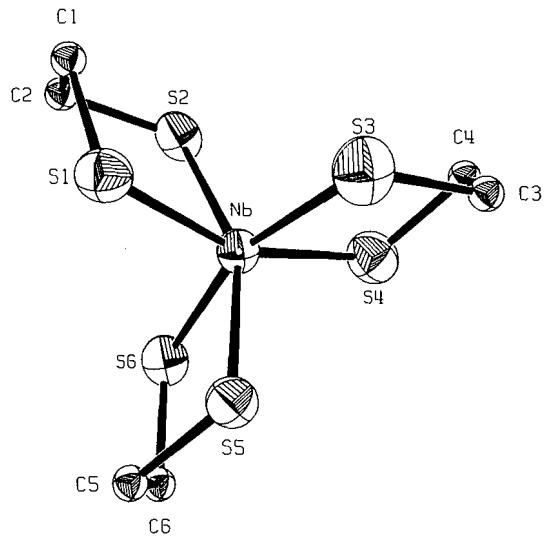

FIG. 2. A perspective view of the molecular structure of the complex anion, $Nb(edt)_3^-$, in **3**. The thermal vibrational ellipsoids for Nb and S atoms represent 50% probability, while the isotropic thermal parameters for C atoms have been reduced for clarity.

Nb center (Nb—S: 2.419(3)–2.438(3) Å, ave. 2.431(3) Å). The three five-membered chelate rings are disposed in a well-ordered propeller-like arrangement, each exhibiting the symmetric half-chain conformation. The angles also cover a fairly narrow range: S—Nb—S (bite), 81.7(1)–82.2(1)°; S—Nb—S (*trans*), 156.6(1)–161.5(1); ligand dihedral angles (SCCS), 59(1)° (S(1)—S(2)), 57(1)° (S(3)–S(4)), 55(1)° (S(5)–S(6)). The triangular faces at opposite ends of the complex anion

(S(1,3,5) and S(2,4,6)) are tilted from being parallel by only 1°. The projected twist angles of the individual ligands (22), are $\phi_{1,2} = 32.6°$, $\phi_{3,4} = 33.3°$, and $\phi_{5,6} = 33.7°$ ($\phi_{ave} = 33.3°$) and indicate a coordination polyhedron intermediate between a trigonal prism and an octahedron. Thus the complex anion approximates D_3 molecular symmetry, the configuration shown in Fig. 2 is Δ(λλλ), and the unit cell of course contains the enantiomeric pair.

It is gratifying to note that the geometry of the complex anion in $[NEt_4]$ $[Nb(edt)_3]$ (21), **3′**, which contains a different counterion and crystallizes in a different space group, is nearly identical with the one found in **3**. The pertinent values are: Nb—$S_{(ave)}$, 2.434(7) Å; S—Nb—S (bite), 81.58(4)–82.14(4)°; S—Nb—S (*trans*), 156.29(4)–157.55(4)°. The projected twist angles (φ) are: 31.4, 30.6, and 29.4° with the average value ($\phi_{ave} = 30.5°$) being only 2.8° different from that found in **3**. The absolute configuration of **3′** was determined as Λ(δδδ). Clearly the coordination geometry of the complex anion, $Nb(edt)_3^{2-}$, is determined mainly by electronic factors between the transition metal and the coordinated ethane-1,2-dithiolate; crystal packing forces can play but a minor role in this regard.

An immediate observation that can be made concerning the structure of **3** is that it has moved away from the TP geometry of the related $Nb(bdt)_3^-$ complex, which contains unsaturated 1,2-dithiolates, yet the stereochemistry of **3** is among the closest to the TP among complexes with non-dithiolene type ligands. To properly assess the importance and the degree of this distortion it is instructive to compare the structure of **3** with those of the closely related $Ti(edt)_3^{2-}$ and $M(bdt)_3^{n-}$ (M = Nb, $n = 1$; M = Zr, $n = 2$) complexes. The relevant distances and the projected twist angles are listed in Table 2.

The C—S bond distances in **3** are typical of carbon–sulfur single bonds involving sp^3 hybridized C and S atoms (predicted value 1.81, ref. 23). These distances are significantly longer than those in $Nb(bdt)_3^-$, even after corrected for the change from sp^3 to sp^2 carbon in the latter. It is then interesting that the change in ligand character is not accompanied by a change in Nb—S bond distances, which, if anything, are marginally shorter in **3** featuring the saturated ethane-1,2-dithiolate ligand system. Thus the *strength* of the Nb—S interaction in the two complexes must be very similar even though the *nature* of the Nb—S interaction is different. A final note of interest is the very slight change in M—S distances on going to the $Ti(edt)_3^{2-}$ complex. The decrease is certainly less than anticipated from the change in ionic radii between two metal ions (0.03 Å) (24), and the longer than "predicted" distance is not inconsistent with the greater chemical reactivity of $Ti(edt)_3^{2-}$ compared to the Nb complex, and hence with the somewhat reduced Ti—S bond strength.

Reference to Table 2 shows that all the complexes listed present an average projected twist angle, ϕ_{ave}, that is smaller than the "corrected octahedral limit" imposed by the constraint of the ligand bite distance, thus indicating a real tendency of these systems to distort toward the TP geometry. The degree of distortion (measured by $\phi_{calc} - \phi_{ave}$) is $Nb(bdt)_3^-$ (47°) ≫ $Nb(edt)_3^-$ (17°) > $Ti(edt)_3^{2-}$ (13°) > $Zr(bdt)_3^{2-}$ (9°). Although it has been established that the ligand in $Zr(bdt)_3^{2-}$ is at the reduced dithiolate extreme (11), it is nevertheless noteworthy that the $Ti(edt)_3^{2-}$ and $Nb(edt)_3^-$ complexes, with saturated 1,2-dithiolate ligands, show a more severe twisting toward the prism. Clearly, unsaturation is not enough to stabilize the TP. The order of distortion toward the prismatic geometry $Nb(edt)_3^-$ > $Ti(edt)_3^{2-}$ > $Zr(bdt)_3^{2-}$ follows the progressive increase in *d*-orbital energies and further corroborates our contention that proper match between ligand and metal orbital energies is an important factor for prism stability. Yet the almost perfect TP geometry of $Nb(bdt)_3^-$ in contrast to the distorted geometry of $Nb(edt)_3^-$ also shows that unsaturated 1,2-dithiolates, and possibly related chelating ligands, have some additional property that further enhances the possibility for TP coordination geometry.

Varible temperature ^1H NMR study of 3

At ambient temperature the ^1H NMR spectrum of complex **3** shows a sharp singlet for the CH_2 hydrogen atoms.

From Fig. 2 it is evident that the methylene hydrogens of the

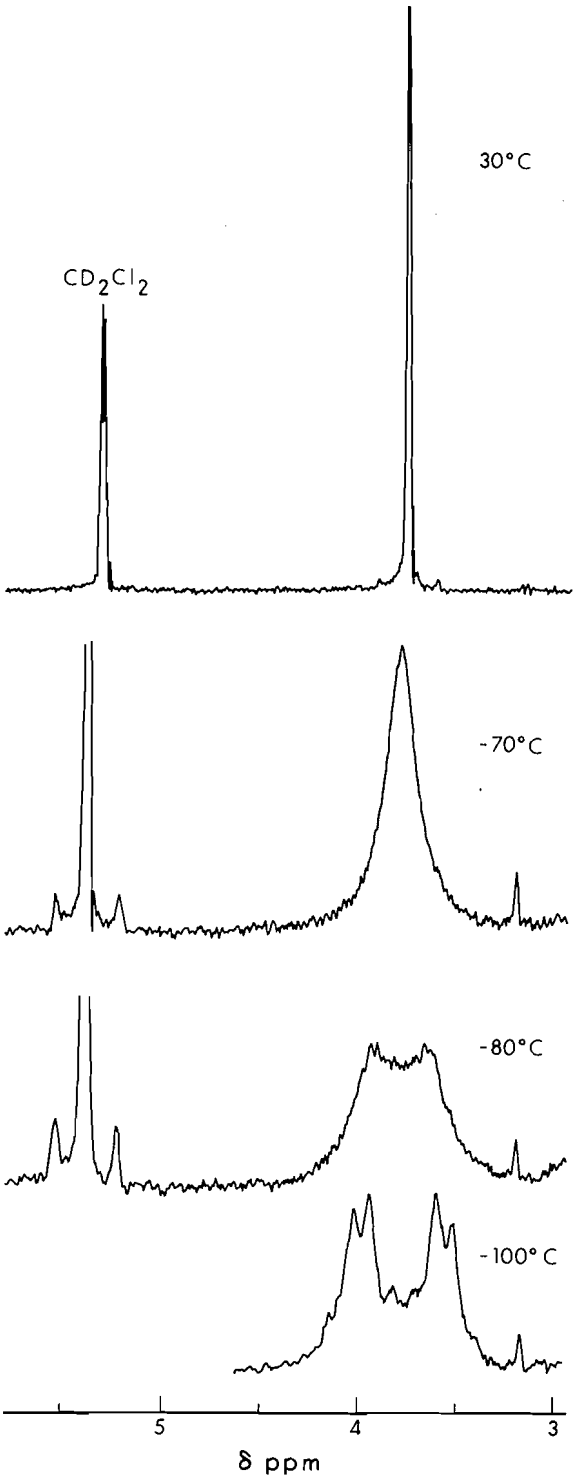

FIG. 4. Variable temperature ^1H NMR spectra of **3** in CD_2Cl_2.

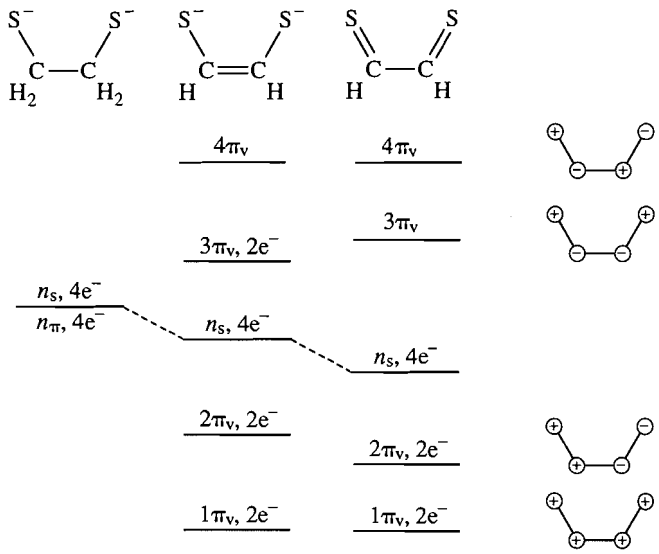
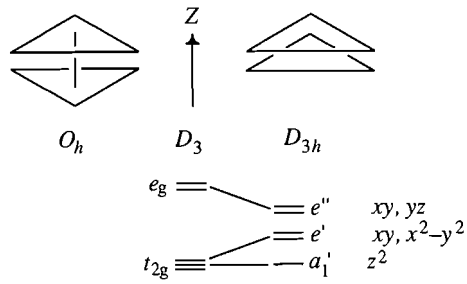
ligands form two nonequivalent sets, H_{axial} and $H_{equatorial}$. As it is lucidly explained elsewhere (25), in the absence of racemization of such tris-chelate complexes the hydrogen atoms are inherently nonequivalent, even with rapid inversion of the puckered five-membered ring, and should give rise to an AA'BB' pattern. Equilibration of the two types of hydrogen atoms and observation of a single resonance is only possible by operation of both processes.

Upon cooling a solution of **3** in CD_2Cl_2, the spectral changes shown in Fig. 4 are seen. By −103°C, a well-resolved AB quartet is obtained, indicating stoppage of one of the previously mentioned processes. The $\Delta G^{\ddagger}$ associated with the process at −78°C is estimated as 9.2 kcal mol^{-1} (26). We have no direct proof that the observed fluxional behavior is intramolecular, but a dissociative process seems highly unlikely due to the reactivity of the free ligand with the solvent. Indeed the Ti and Hf complexes decompose in CH_2Cl_2. A spectrum obtained in the presence of excess of the free dithiol showed no evidence of ligand exchange.



Although it is not possible to delineate which of the two previously described processes has stopped at low temperature, should the racemization go via the trigonal twist type process, the barrier observed represents an upper limit for the stabilization of the twisted form over the TP geometry in this complex.

Discussion

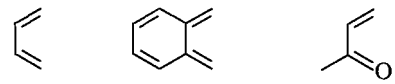


As indicated in the Introduction, the major focus of this study was to compare the structure of early transition metal tris-chelate complexes containing the saturated ethane-1,2-dithiolate ligand with those of the analogous complexes with unsaturated benzene-1,2-dithiolate moieties, with a view to establishing the electronic factors responsible for changes in coordination geometry in the complexes.

To assess the anticipated bonding changes on going from the saturated to the unsaturated 1,2-dithiolate ligand, reference to the qualitative energy level diagram is made, Scheme 2. Ethane-1,2-dithiolate can act as a σ donor donating two electrons from a lone pair on each sulfur atom for a total of four σ electrons. In principle, it can also donate additional electrons to the metal from the remaining lone pairs on the sulfur atoms through the formation of π bonds, although the orientation of these lone pairs may not contribute to this very effectively (see Fig. 2). This situation has been considerably altered in the case of unsaturated 1,2-dithiolates. These ligands can still donate the same number of electrons through σ-bonding, but two of the remaining sulfur atom lone pairs have been delocalized over the ligand π framework. Two of these electrons have gone into a bonding orbital ($2\pi_v$) and have been somewhat stabilized, and the remaining two electrons have been placed into an antibonding orbital ($3\pi_v$) and have been destabilized. This π delocalization then has two effects. First, it reduces the effective charge on the sulfur atoms and therefore stabilizes the lone pairs and, second, it causes the ligand system to become a strong π donor due to the presence of the two antibonding π electrons. The whole ligand system is then a six-electron donor. From the above reasoning an important conclusion can be drawn regarding the relative behavior of saturated and unsaturated 1,2-dithiols, namely, that the former ligand system should be a better σ but poorer π donor than the latter. Also shown in the scheme is the oxidized, dithioketone formulation of the unsaturated ligand. Under this formulation, which is the more traditional view with these "dithiolene" type ligands (7, 8, 13), the ligand presents a low-lying symmetric π-acceptor orbital ($3\pi_v$) to the metal. Although the π-donor picture is more appropriate with the anionic complexes of the early transition metals since, as detailed elsewhere (11, 12, 15), these complexes contain the more reduced form of the unsaturated 1,2-dithiolates, it is clear that to achieve a unified picture for the possible importance of π bonding in stabilizing the TP geometry with different 1,2-unsaturated ligands the π-acceptor extreme will also have to be invoked.

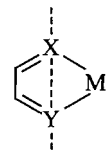
Returning then to the structure of $Nb(edt)_3^-$, the distortion away from the TP geometry of the analogous $Nb(bdt)_3^-$ complex

SCHEME 2



SCHEME 3

seems to imply that π bonding is responsible for, or at least contributes to, the stabilization of the TP geometry, since, according to the reasoning presented above, π bonding is expected to be less important with the saturated ethane-1,2-dithiolate than with the unsaturated benzene-1,2-dithiolate ligand system. Further support for this conclusion comes from a tris(1,2-dihydroxoethane) complex of tungsten, $W(OCH_2CH_2O)_3$ (27). This complex exhibits an average twist angle of 36.9°, once again intermediate between the TP and octahedral limits and in sharp contrast to the TP geometry observed for tris(9,10-phenanthrenequinone)molybdenum(0) (28).



To understand how π bonding can stabilize the TP geometry, let us consider the well-known level ordering of the predominantly metal *d* character orbitals in octahedral and TP ML_6 complexes, Scheme 3 (adapted from ref. 2), and the interaction of these orbitals with the unsaturated ligands in both π-acceptor and π-donor extremes. We recall that under D_{3h} symmetry (TP geometry) the $3\pi_v$ MOs of the ligands will give rise to two group molecular orbitals of a_2' and e' symmetries.

Let us first consider the ligands in their oxidized form. This situation implies metals in low oxidation states with their full complement of valence electrons in *d*-type orbitals. It is clear from the scheme that occupation of the high-lying e' orbitals, which will happen for any d^n electronic configuration with $n > 2$, will destablize the TP in favor of the octahedral geometry. However, the 1,2-dithioketone ligands have low-lying empty orbitals of e' symmetry (see above), which can effectively stabilize the e' metal orbitals and hence lead to TP geometry. This is not a new result and had been considered by previous workers in the field (2, 8, 13). Nevertheless, it provides a natural link to other "even" type unsaturated ligands that present a symmetrical empty π-acceptor orbital to the central metal atom and properly account for the TP geometry observed in tris(buta-1,3-diene)molybdenum (29), tris(*ortho*-xylyl)tungsten (30), and tris(methylvinylketone)tungsten (31) (for the respective ligands see **a**, **b**, and **c**). Indeed recently Green, Mingos, *et al.*

a **b** **c**

(32) have used molecular orbital calculations to support the importance of π back-bonding for the observed TP rather than octahedral geometry about the metal atom in tris(buta-1,3-diene)Mo/W. It is also worthy of note that the π-bonding model provides a rationale for the often observed folding of the ligand in TP complexes about the donor–donor axis, **d**, and, in a

d

qualitative sense, for its extent. Clearly the all-carbon ligands (**a** and **b**) with no lone pair on the terminal atom(s) are the most oxidized of these unsaturated ligands and consequently elicit the largest amount of back-bonding from the metal to stabilize the e' orbital and achieve the TP geometry. This is accomplished by severe folding, to bring the $3\pi_v$ MO into maximal overlap with the metal e' orbital. Indeed all Mo—C bond distances in Mo(buta-1,3-diene)$_3$ were found equal (2.29(1) Å) (29). Replacing one CH_2 end group by an oxygen atom gives the methylvinylketone complex. Both σ donation from the oxygen lone pair and the more reduced nature of the ligand are expected to result in decreased π back-bonding and consequently to cause a smaller ligand folding. Reflecting these predictions, the terminal W—C and W—O distances (2.12(2) and 2.11(2) Å) are significantly shorter than the remaining W—C bonds (2.29(2) and 2.42(2) Å) (31). Continuing the trend toward more reduced ligands and less oxidized metal center, the situation with the unsaturated 1,2-dithiol type ligand with σ donation from two sulfur atoms, might have been expected to result in planar MS_2C_2 chelate rings. However, in most cases there is folding (11, 13). The folding of the planes within the same complex is sometimes irregular, and this is probably a consequence of crystal packing forces. Nevertheless we believe, as do Cowie and Bennett (11), that the major driving force for the ligand folding is to maximize the π bonding between $3\pi_v$ ligand molecular orbital and the metal e' (d_{xy}, $d_{x^2-y^2}$) orbitals. Ligand folding, but of an unusual type, has also been seen in the prismatic tris(9,10-phenanthrenequinone)molybdenum (28). Only one ligand is folded, the other two remain planar. However, the ligand exhibiting folding has longer C—C and Mo—O bond distances and shorter C=O bond lengths than the other two, closer to the oxidized form and hence in line with the folding arguments. We should like to close this section by mentioning that contrary to the TP geometry of the phenanthrenequinone complex, the structure of the related tetrachloro-1,2-benzoquinone derivative of chromium, Cr(1,2-

$O_2C_6Cl_4)_3$, is of the octahedral type (33). On the basis of structural parameters, Pierpont suggested that the metal center is best described as Cr(O), d^6, with only very slight contribution from the ligand empty π-acceptor orbital in the bonding. Clearly the distortion away from TP finds explanation in the orbital picture shown in Scheme 3 and the d^6 electronic configuration of the metal.

The stability of TP geometry seems not to have been discussed as fully in terms of the π-donor model as the π-acceptor property of these ligands. Yet the two points of view must ultimately lead to the same conclusion since they represent two extremes of the electronic structure of the same ligand system. The physical reality, which depends on the nature of the metal and the ligand, must lie somewhere in between. Indeed it is easily appreciated that as the metal *d* orbitals and ligand π-acceptor levels approach one another in energy, the metal is gradually oxidized and the electrons are transferred into primarily ligand-based molecular orbitals. The acceptor oribitals are full and the π acceptor has been transformed into a π donor. Even though there is this transparent link between the two extremes, we wish to present a discussion of the π-donor model because, as stated before, the ligands in the early transition metal complexes are closer to the dithiolate limit. The analysis will attempt to clarily the behavior of the saturated 1,2-dithiolates and, as we shall see, it emphasizes different aspects of the M—S interaction.

Our analysis begins by considering the unsaturated ligand at the 1,2-ditholate extreme. Since the ligand is fully reduced, the accompanying metal ion is in the high, 6+, oxidation state. In this limit of highly ionic bonding, repulsion between ligand donor atoms dominates and the octahedral geometry is favored. This again is a well-known result (1, 2). As the ligand becomes a better π donor, the energy of the $3\pi_v$ donor molecular orbital approaches that of the metal *d* levels. Under D_{3h} symmetry (TP geometry) there can be effective overlap of the full ligand *e'* MOs and empty metal *e'* orbitals; electron density now flows from ligand to metal and results in strong, delocalized bonding with concomitant decrease in ligand donor atom repulsion and stabilization, or at least movement toward the TP geometry. We recognize that it is very difficult to dissociate the contribution from, and variation in, the M—S σ bonding from the overall molecular geometry, especially in view of the results of Hultgren (1) and Hoffman (2), which show that for d^0–d^2 electronic configurations M—S σ bonding alone could result in TP geometry. Nevertheless on the basis of the structural change between $Nb(bdt)_3^-$ (TP) and $Nb(edt)_3^-$ (distorted toward octahedral), we believe that the π component is a contributor to the overall stability of the TP. This energy contribution may be quite substantial, as seen with the strongly π-acceptor ligands (butadiene, methylvinylketone), or quite small, as evidenced by the small rearrangement barrier of the $Nb(edt)_3^-$ complex (*vide supra*).

It is especially evident from the above analysis that a major role of the highly delocalized π bonding and, of course, that of the primary σ component as well is to moderate interligand repulsion, otherwise the TP geometry would be unfavorable. Thus we would argue, along with Cowie and Bennett (11), against the still sometimes held belief that interligand S---S bonding is an important factor in stablizing the TP geometry. The postulate of interligand S---S bonding rests, to a large extent, upon the observation of constant prism dimensions in the series of compounds $Re(1,2,-S_2C_2Ph_2)_3$, $Mo(1,2\text{-}S_2C_2H_2)_3$, and $V(1,2\text{-}S_2C_2Ph_2)_3$, despite the varying metal size (13). However, it can just as easily be argued that the observed interligand S---S distances in TP dithiolene complexes arise as a natural consequence of the TP geometry in complexes with M—S bond lengths on the order of 2.3–2.4 Å. The near constancy of M—S bond lengths in the previously mentioned V, Mo, and Re compounds may be a consequence of interligand donor atom repulsions tending to lengthen the M—S bonds in the smaller members rather than interligand S---S bonding determining the M—S bond length. There is some experimental support for the view that reducing interligand repulsion is important for the stability of the TP. In contrast to the distorted geometry of $Mo(mnt)_3^{2-}$ (mnt = $S_2C_2(CN)_2^{2-}$, maleonitriledithiolate) (34), the structure of $Mo(mnt)_2(dtc)^-$ (dtc = $S_2CNEt_2^-$, diethyldithiocarbamate) is TP (35).

To the best of our knowledge $Mo(mnt)_2(dtc)^-$ is the only compound containing the mnt^{2-} ligand that displays TP geometry and this may be due to an increased stabiliztion of the $3\pi_v$ orbital in this ligand and its attendant poor π-donor ability. While $Mo(mnt)_3^{2-}$ has a geometry distorted from TP, $Mo(qdt)_3^{2-}$ (qdt = quinoxaline-2,3-dithiolate, **e**) (36) and

e

$Mo(S_2C_2(COOCH_3)_2)_3^{2-}$ (37) adopt TP geometry. The Mo—S distances in both compounds average 2.393 Å and are marginally longer than in the valence isoelectronic complex $Mo(mnt)_3^{2-}$ (2.324(8) Å). The corresponding interligand S---S distances of 3.141(7) and 3.18(6) Å are nearly the same as the 3.188 Å average for $Mo(mnt)_3^{2-}$, further calling into question the interligand sulfur bonding model.

In summary, trends in the uv–visible spectra, in the M–S stretching frequencies, in the reduction potentials, and in the structural parameters for early transition metal complexes with either benzene-1,2-dithiolate, ethane-1,2-dithiolate, or the recently reported propane-1,3-dithiolates (38) point to the fact that the metal *d* orbitals lie above the ligand π orbitals in energy. Moving to the right in the periodic table, the metal *d* orbitals are stabilized. This gives rise to π bonding first from the unsaturated dithiolates, which are stronger π donors. For high valence molybdenum and rhenium, the *d* orbitals appear to be sufficiently stable that TP geometry is even observed for the weaker π-donating, saturated ligands, as seen in $Mo(SCH_2CH_2SCH_2CH_2S)_2$ (39) and $Re[(SCH_2)_3CCH_3]_2^-$ (40), although constraint imposed by the tridentate ligand may also contribute to the observed geometry. Thus, while Gray's MO scheme provides a reasonable model for interpreting the uv–visible spectra, it appears to overestimate the stability of the metal *d* orbitals, for the earliest transition metals, with respect to the ligand $3\pi_v$ level. Consequently, it is necessary in that scheme to invoke bonding with the metal d_{z^2} orbital to arrive at the correct level ordering. We propose that the metal d_{z^2} orbital is largely nonbonding, therefore the occurrence of TP geometry for d^1 and d^2 complexes is not surprising and there are numerous examples (36, 37, 39–42). We are, therefore, drawn to the conclusion that overlap of the empty metal $d_{x^2-y^2}$ and d_{xy} orbitals with filled ligand π orbitals is more crucial to the appearance of TP geometry than interdonor atom bonding and is not limited to unsaturated 1,2-dithiolates. The charge of the complex ion, although of import, may also play a secondary role

as shown by the series of TP complexes $Mo(btd)_3$, $Mo(qdt)_3^{2-}$, and $Mo(S_2C_2(COOCH_3)_2)_3^{2-}$.

The final question to address is the importance of σ bonding relative to π bonding. The occurrence of TP geometry not only in dithiolates but also in tris(butadiene)molybdenum (29), tris-(*ortho*-xylyl)tungsten (30), tris(methylvinylketone)tungsten (31), $Tc(NHC_6H_4S)_3$ (42), $Mo(NHC_6H_4S)_3$, and tris(thiobenzoyldiazene)molybdenum (43) strongly implies that π bonding, if not an essential prerequisite, plays a significant role in stablizing this interesting coordintion geometry.

Experimental

All of the procedures and techniques used here have been described previously (15) except the modifications below. Reagent grade acetonitrile was dried by distillation first from P_2O_5 and then from CaH_2. Tetrahydrofuran was distilled from Na/K alloy. Commercially available ethane-1,2-dithiol was stirred at 0°C with a small amount of $LiAlH_4$ until the vigorous reaction subsided and then distilled and stored under nitrogen. Metal dialkylamides were prepared by published methods (44–47). Tetraethylammonium chloride was used as previously described (15).

Physical measurements

Visible and uv spectra were recorded at $\sim 10^{-3}$ M in CH_3CN on a Unicam SP 1700 spectrophotometer. ^1H NMR spectra were recorded on a Varian Associates A60 or HA-100 spectrometer. Infrared spectra were recorded as KBr pellets or mineral oil and Fluorolube mulls with CsI windows, for the low energy region, on a Perkin–Elmer 467 infrared spectrometer. All analyses were performed at the analytical facilities of the University of Alberta. The sample of the Hf complex used for analysis was weighed on a Cahn electrobalance in a dry box.

Preparation of $[(C_6H_5)_4As][Nb(1,2\text{-}S_2C_2H_4)_3]\cdot CH_3CN$, 3

Sodium cyclopentadienide (2.70 mmol) in ~5 mL of THF was added to 0.60 mL (8.20 mmol) of ethane-1,2-dithiol in 50 mL of THF, resulting in the formation of a white precipitate. To this mixture 0.846 g (2.70 mmol) of pentakis(dimethylamido)niobium(V) was added in 20 mL of THF and the reaction mixture rapidly turned dark red. The mixture was stirred for ~20 h after which time a dark red precipitate was observed. Solid tetraphenylarsonium chloride (1.13 g, 2.70 mmol) was added and, after stirring 1 h, the solvent was stripped off under vacuum and replaced by 100 mL of CH_3CN. After stirring for ~20 h, most of the solid still had not dissolved so the mixture was heated to boiling and filtered hot. By cooling the filtrate overnight at ~−10°C, dark red crystals were obtained. After filtration and vacuum drying, 0.60 g (30% yield) of product was obtained. Treating the residue above with an additional 100 mL of CH_3CN produced 0.28 g of product for a total of 41% yield. The two crude products were recrystallized from 100 mL of boiling CH_3CN and, after filtration and cooling, 0.60 g of product was obtained, mp 131–138°C (dec.) uncorrected; uv–visible λ_{max} (nm) (10^{-3} ε, M^{-1} cm^{-1}): 245(12.6), 251(12.2), 307(12.1), 369(10.7), 504(5.1); ^1H NMR (CD_2Cl_2) δ: 7.5–8.0 (complex multiplet, 20H, Ph), 3.75 (s, 6H, CH_2) 1.96 (singlet, 3H, CH_3CN). *Anal.* calcd. for $C_{32}H_{35}AsNS_6Nb$: C 48.41, H 4.44, N 1.76, S 24.24; found: C 48.45, 48.25; H 4.53, 4.48; N 1.80, 1.71; S 23.65, 23.56.

Preparation of $[(C_2H_5)_4N]_2[Ti(1,2\text{-}S_2C_2H_4)_3]$, 1

Sodium cyclopentadienide (0.68 g, 7.80 mmol) in 20 mL of THF was added to 0.98 mL (11.6 mmol) of ethane-1,2-dithiol in 30 mL of THF. Tetrakis(diethylamido)titanium(IV) (3.68 mmol) in 20 mL of THF was added next, resulting in a brown solution that gradually turned orange and finally red. The sodium salt of the Ti complex is soluble, in contrast to Nb. After stirring for ~18 h, 25.8 mL of a 0.272 M solution of tetraethylammonium chloride in CH_3CN was added, resulting in formation of an orange precipitate. The solvent was stripped off under vacuum and replaced by 50 mL of CH_3CN. After stirring ~½ h the mixture was filtered to give a red solution. By alternately cooling and concentrating the solution, the product was finally obtained as large dark-red crystals. However, on occasion a yellow decomposition product was observed in small quantities and was filtered off. The yield of dark-red crystals was 0.698 g, 34%; ir ν_{Ti-S}: 355 and 332 cm^{-1}; uv–visible λ_{max} (nm) (10^{-3} ε, M^{-1} cm^{-1}): 233(33.2), 357(9.0), 414(9.6); ^1H NMR (CD_3CN) δ: 3.38 (s, 6H, CH_2 anion), 3.30 (q, 16H, CH_2N), 1.24 (tt, 24H, CH_3N). *Anal.* calcd. for $C_{22}H_{52}NS_6Ti$: C 45.17, H 8.96, N 4.79, S 32.89; found: C 45.11, 45.28, H 8.91, 9,04; N 5.12; S 32.71, 31.97.

[a]See text for explanation for using two crystals.
[b]Δ2θ is a correction in the scan width for the dispersion of the $K_{\alpha 1}$–$K_{\alpha 2}$ doublet.

Preparation of $[(C_2H_5)_4N]_2[Hf(1,2\text{-}S_2C_2H_4)_3$, 2

This compound was prepared in the same way as the Ti compound above and was obtained as a single crystal ~1 cm long, yield 0.683 g, 23%. The product is almost colorless; ir ν_{Zr-S}: 297 and 268 cm^{-1}; uv–visible λ_{max} (nm) (10^{-3} ε, M^{-1} cm^{-1}): 249(20.4), 272 sh (15.1); ^1H NMR (CD_3CN) δ: 3.23 (s, 6H, CH_2 anion), 3.30 (q, 16H, CH_2N), 1.25 (tt, 24H, CH_3N). *Anal.* calcd. for $C_{22}H_{52}NS_6Hf$: C 36.93, H 7.32, N 3.91; found: C 36.64, 36.71; H 7.19, 7.25; N 3.88.

X-ray analysis of 3

Dark-red crystals of the compound were obtained by slow cooling of a saturated CH_3CN solution.

Details of the crystal data, intensity collection, and refinement are given in Table 3.

Weissenberg photographs using CuKα radiation and precession photographs using MoKα radiation revealed no systematic absences and 1 Laue symmetry. The intensity data were collected on a Picker FACS-1 four-circle automated diffractometer at ambient temperature using graphite monochromated MoKα radiation. Accurate cell dimensions were determined using 12 general reflections ($34° < 2\theta < 38°$). Intensity data were collected by the θ–2θ technique with background counts of 20 s at each end of the scan range. A set of three standard reflections was collected every 100 measurements, and an additional set of 10 reflections every 24 h, to test for crystal alignment and

[a]These are "equivalent" isotropic thermal parameters calculated from the anisotropic temperature factors by the program SFLS5.

stability. Approximately halfway through the collection, the intensity of the standards fell of sharply. Another crystal was mounted and collection resumed; this time no significant intensity changes were observed. The data were corrected for Lorentz and polarization effects and by an empirical absorption correction. The redundant data between the two crystals were merged.

The structure was solved by a combination of Patterson and difference Fourier maps and refined (using two scale factors) by full-matrix least-squares methods; the function minimized was $\Sigma w(|F_o| - |F_c|)^2$. Various models were attempted to describe the disordered CH_3CN molecule. Finally, use of a five-atom model, two acetonitriles with a common terminal carbon atom, seemed justified. Using occupancies of 0.45 and 0.55 for the two molecules, based upon the behavior of thermal parameters, reasonable bond distances were obtained by alternate refinement of the two molecules with all other parameters fixed. In the last two cycles of refinement the acetonitrile was not refined but the tetraphenylarsonium hydrogens were included as rigid bodies (C—H, 0.95°), also not refined. A final difference Fourier synthesis revealed peaks of 0.61, 0.56, and 0.47 e/Å^3 in the vicinity of the tetraphenylarsonium rigid bodies and a peak of 0.45 e/Å^3 near an acetonitrile carbon atom. All other features were less than 0.37 e/Å^3. The programs used in this study are those described previously (12).

Atomic coordinates and equivalent isotropic thermal parameters for the complex anion $Nb(edt)_3^{2-}$ are listed in Table 4. Anisotropic thermal parameters of the anion, atomic coordinates and thermal parameters for the rest of the complex, and structure factors are available as supplementary material in Tables S1–S3, respectively.[3]

Kinetics of reactions of undecacarbonyl(triethyl phosphite)triruthenium with some P- and As-donor ligands

LEZHAN CHEN AND ANTHONY J. POË[1]

Erindale College and the Department of Chemistry, University of Toronto, Mississauga, Ont., Canada L5L 1C6

Received February 28, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

LEZHAN CHEN and ANTHONY J. POË. Can. J. Chem. **67**, 1924 (1989).

The kinetics have been studied of reactions of the cluster $Ru_3(CO)_{11}(P(OEt)_3)$ with a variety of P- and As-donor nucleophiles, L, in alkane solution. Reactions proceed according to the rate equation: $k_{obsd} = k_1 + k_2[L]$ and activation parameters for the two paths have been obtained. When combined with activation parameters for $Ru_3(CO)_{12}$ and some other $Ru_3(CO)_{11}L'$ clusters the values of $\Delta H_1^{\ddagger}$ and $\Delta S_1^{\ddagger}$ are found to lie on a good isokinetic plot. The changes in the activation parameters are consistent with major and systematic changes in the nature of the $Ru_3(CO)_{10}L'$ moieties left after CO dissociation.

Analysis of the dependence of log k_2 on the electronic and steric nature of the various nucleophiles leads to the derivation of electronic and steric profiles that are characteristic of the cluster, together with values for the intrinsic or standard susceptibility of the cluster towards nucleophilic attack. These kinetic characteristics are compared with those similarly derived for $Ru_3(CO)_{12}$.

Key words: metal carbonyls, ruthenium, clusters, kinetics, mechanisms.

LEZHAN CHEN et ANTHONY J. POË. Can. J. Chem. **67**, 1924 (1989).

On a étudié la cinétique des réactions de l'agrégat $Ru_3(CO)_{11}(P(OEt)_3)$ avec une variété de nucléophiles donneurs de P et d'As, L, en solution dans les alcanes. Les réactions se produisent d'après l'équation de vitesse : $k_{obs} = k_1 + k_2[L]$ et on a obtenu les paramètres d'activation pour les deux voies. Lorsqu'on combine les paramètres d'activation des agrégats du $Ru_3(CO)_{12}$ et d'autres agrégats de formule $Ru_3(CO)_{11}L'$, on trouve que les valeurs des $\Delta H_1^{\ddagger}$ et des $\Delta S_1^{\ddagger}$ se trouvent sur une bonne droite isocinétique. Les changements dans les paramètres d'activation sont en bon accord avec les changements majeurs et systématiques dans la nature des portions $Ru_3(CO)_{10}L'$ qui restent après la dissociation d'un CO.

Une analyse de la relation entre le log k_2 et la nature électronique et stérique des divers nucléophiles permet de dériver des profils électroniques et stériques qui est caractéristique de l'agrégat effectuée en tenant compte des valeurs intrinsèques ou standard de la susceptibilité des agrégats aux attaques nucléophiles. On compare ces caractéristiques cinétiques à celles obtenues de la même manière à partir du $Ru_3(CO)_{12}$.

Mots clés : métal carbonyl, ruthénium, agrégats, cinétique, mécanismes.

[Traduit par la revue]

Introduction

Systematic studies of the reaction kinetics of metal carbonyl clusters (1) are capable of providing characteristic reactivity profiles (2). These define the nature of a particular cluster or group of clusters in a way that complements, and is of comparable importance to, the information provided by structural studies. A given cluster can be quantitatively characterized by its sensitivity to the electronic and steric nature of a series of P-donor nucleophiles (2), by its "intrinsic" reactivity towards nucleophilic attack (2), and by the distribution between substitution and fragmentation products formed as a consequence of nucleophilic attack (3). Alternatively, the S_N1 kinetics of a series of related clusters, differing only in the nature of their P-donor or similar substituents, can also lead to characteristic electronic and steric profiles (4). These studies provide an essentially new way of probing the nature of a large and significant group of organometallic compounds. They are also capable of providing some of the quantitative background necessary when assessing the environmental effects of immobilizing metal carbonyl clusters on surfaces or within zeolytic or other cavities (5), and they therefore form part of the general and continuingly hopeful search (5*b*, 5*c*, 6) for some practical use for these academically fascinating compounds. As part of an extensive study of the effects of substituents on cluster reactivity we have investigated the kinetics of some reactions of the cluster $Ru_3(CO)_{11}(P(OEt)_3)$, and our results are presented below.

Experimental

General methods

Dodecacarbonyltriruthenium (Strem Chemicals) was used as received. Decalin was washed successively with 4 *M* H_2SO_4 and water, dried over $MgSO_4$, and distilled several times under reduced pressure to ensure the absence of any unsaturated impurities. It was stored over molecular sieves (Linde type 4A). THF (Aldrich) was distilled over sodium benzophenone. Liquid phosphorus ligands (triphenyl phosphite, triethyl phosphite, tri-*n*-butylphosphine, triethylphosphine, diethylphenylphosphine, diphenylethylphosphine, and tri-*t*-butylphosphine) were obtained from commercial sources and were purified by distillation under low pressures of argon or nitrogen immediately before use. Etpb, $(P(OCH_2)_3CEt)$ (Strem Chemicals), was sublimed (50°C, 0.12 mm Hg) immediately before use. Other ligands were obtained and used as described previously (7). Infrared spectra were measured with a Nicolet 10DX FTIR spectrophotometer, and ^{31}P NMR spectra with a Varian XL-200 spectrometer. Ultraviolet–visible spectra of solutions were measured with a Cary 2300 spectrophotometer, the solutions being contained in 10-mm silica cells placed in a thermostated cell holder.

Preparation of $Ru_3(CO)_{11}(P(OEt)_3)$

The cluster $Ru_3(CO)_{11}(P(OEt)_3)$ was prepared by the general method of Bruce *et al.* (8). $Ru_3(CO)_{12}$ (100 mg, 0.156 mmol) in THF (6 cm^3) was reacted with $P(OEt)_3$ (0.029 cm^3, 0.17 mmol) in the presence of a few drops of sodium ketyl in THF at 40°C until the IR band at 2060 cm^{-1} due to $Ru_3(CO)_{12}$ was no longer detectable. Solvent was removed under vacuum, the reddish oily product was dissolved in hexane, and the solution was filtered. The IR spectrum of the clear red filtrate showed bands due (Table 1) to those expected for $Ru_3(CO)_{11}(P(OEt)_3)$ by comparison with the spectrum of $Ru_3(CO)_{11}(P(OMe)_3)$ (8*c*). The cluster was purified by chromatography on

[c]In heptane.

a foil-wrapped 60–100 mesh Florisil column. Traces of unreacted $Ru_3(CO)_{12}$ were eluted first with a mixture of hexane and dichloromethane (ca. 2:1 by volume), followed by $Ru_3(CO)_{11}(P(OEt)_3)$, some mononuclear products remaining on the column. The $Ru_3(CO)_{11}(P(OEt)_3)$ was isolated in ca. 40% yield as a dark red oil by removal of hexane under vacuum. Attempts to obtain the cluster in crystalline form were unsuccessful.[2] It was characterized by its IR spectrum (Table 1) which is virtually identical with that of the crystallographically characterized $Ru_3(CO)_{11}(P(OMe)_3)$ (9). Its purity was demonstrated by means of its ^{31}P NMR spectrum, a single sharp peak being observed at −138.3 ppm relative to $P(OMe)_3$ and decoupled from ^1H. No peaks due to free $P(OEt)_3$ or to $Ru_3(CO)_{10}(P(OEt)_3)_2$ (4) were observed. $Ru_3(CO)_{10}(P(OEt)_3)_2$ and $Ru_3(CO)_{10}(P(OMe)_3)_2$ were prepared and purified in a similar manner (8*c*) but using ≥2 equivalents of ligand. The clusters $Ru_3(CO)_{10}(P(OEt)_3)_2$ and $Ru_3(CO)_9(P(OEt)_3)_3$ could be separated by chromatography.

Kinetic procedures

Most kinetic runs were carried out on decalin solutions prepared in Schlenk tubes wrapped with aluminium foil and equipped with rubber-septum caps to allow convenient sample removal by using a syringe with a stainless steel needle. All solutions were purged with a stream of N_2 or Ar (Canox Ltd.) for ca. 10 min before immersing the Schlenk tube in a water bath and continuing the bubbling for another 5 min. Solutions were thermostated to ±0.1°C by a Lauda Constant Temperature Bath RCS-6. Samples were withdrawn periodically, transferred to small phials, and the reaction quenched by cooling the phials in dry ice or liquid N_2. Infrared spectra of the quenched liquid samples were recorded in the absorbance mode using 1.0-mm path-length solution cells with NaCl windows. Initial concentrations of reacting complex were generally ca. 4×10^{-4} *M*.

Infrared spectra taken during the reactions followed exactly the changes expected for successive substitutions and fragmentations. The reaction of $Ru_3(CO)_{11}(P(OEt)_3)$ with PPh_3 showed that the further reaction of the initial product, $Ru_3(CO)_{10}(P(OEt)_3)(PPh_3)$, with PPh_3 was too rapid to allow accurate values of A_∞ to be obtained when employing UV–vis methods. Thus all rate measurements for this and other similar reactions had to be obtained through IR monitoring.

[2]The cluster $Ru_3(CO)_{11}(P(OMe)_3)$ has been prepared in an exactly similar manner and crystals of this cluster suitable for crystallographic investigation (9) were obtained.

Rate constants were generally obtained by monitoring the decreasing absorbances of the IR band at 2045 cm^{-1} due to $Ru_3(CO)_{11}(P(OEt)_3)$. In all cases values of A_∞ were very small and plots of ln $(A_t - A_\infty)$ were linear for ca. 80–90% reaction. The rate constants calculated instead from the decreasing absorbances at 2100, 2032, and 2014 cm^{-1} and from the increasing absorbances due to the fragmentation products (see below) were virtually the same in most of the cases tested, the differences being ca. 5%.

Infrared spectra of reactions of $Ru_3(CO)_{11}(P(OEt)_3)$ with $AsPh_3$ showed that the initial product $Ru_3(CO)_{10}(P(OEt)_3)(AsPh_3)$ (Table 1) was quite stable under the conditions used. There were very clean isosbestic points in the IR spectra and no evidence for significant further reaction of $Ru_3(CO)_{10}(P(OEt)_3)(AsPh_3)$ with $AsPh_3$ was observed. Ultraviolet–visible monitoring of this reaction was thereby shown to be satisfactory in providing good values of A_∞ and the growing band at 460 nm was monitored to obtain the rate constants. Pre-thermostated solutions were contained in 10 mm cuvettes placed in the thermostated cell holder of a Cary 2300 spectrophotometer. Solutions were purged with a stream of Ar for ca. 10 min and the cells were then sealed with Teflon stoppers. Reactions were followed by repetitive scanning of groups of up to four reacting solutions. Cell temperatures were measured with an iron–constantan thermocouple connected to a digital multimeter. In two cases reactions were instead followed using IR monitoring techniques and employing standard Schlenk tube methods.

Results

Products of reactions

The changes in the IR spectra during reactions with all nucleophiles apart from $AsPh_3$ showed initial formation of $Ru_3(CO)_{10}(P(OEt)_3)L$ followed by further reactions to form $Ru_3(CO)_9(P(OEt)_3)L_2$. The rates of these latter reactions were much faster when L = PPh_3, P-*i*-Bu_3, and P-*n*-Bu_3 than when L = $P(OPh)_3$ and $P(OEt)_3$ but no quantitative kinetic studies were performed.

In addition it was clear from the IR spectra that mononuclear $Ru(CO)_4L$ and $Ru(CO)_3L_2$ complexes were formed (Table 1) as well as the trinuclear substitution products, and the relative yields of the mononuclear products, compared with the substitution products, increased with increasing [L]. Molar absorption

coefficients for the bands due to $Ru(CO)_4(P(OEt)_3)$ and $Ru(CO)_3(P(OEt)_3)_2$ were obtained (Table 1) from IR studies of these complexes prepared from solutions of $Ru(CO)_4(C_2H_4)$ of known concentration (11). Measurements of the growing intensities of these bands during the initial stages of the reaction of $P(OEt)_3$ with $Ru_3(CO)_{11}(P(OEt)_3)$ showed that the products $Ru(CO)_4(P(OEt)_3)$ and $Ru(CO)_3(P(OEt)_3)_2$ were formed in the constant molar ratio (2.02 ± 0.13):1, irrespective of the values of $[P(OEt)_3]$ and the temperatures. Mononuclear products, in easily detectable amounts, were also observed with L = etpb, P-n-Bu_3, and $P(OPh)_3$, but not with L = PPh_3 or P-i-Bu_3.

Kinetics of reactions of $Ru_3(CO)_{11}(P(OEt)_3)$ with L

Most reactions proceeded via a mixture of first and second order paths with the rate equation being given by $k_{obsd} = k_1 + k_2[L]$. In these cases a weighted linear least-squares analysis (10) was applied in order to obtain values for k_1 and k_2, and their probable errors. Precise values of k_1 when L = P-n-Bu_3 could not be obtained because of the high contribution from the $k_2[L]$ path. The value of k_2 at the highest temperature used for reactions with P-i-Bu_3 was very uncertain because of the high relative contribution from the k_1 path at this temperature. When L = $AsPh_3$ or PPh_3 the values of k_{obsd} showed no significant dependence on [L] and they were simply averaged to give k_1. For these, and for some other reactions when the $k_2[L]$ term was small, the values of k_{obsd} at the lower values of [L] tended to be slightly lower than expected from the rate equation. This was probably due to slight retardation of the [L]-independent path by the CO released and, when any such doubt arose, these low values were omitted from the least-squares analysis because of their tendency to lead to incorrectly high values of k_2. The values of k_1 and k_2 for all these reactions are given in Table 2.

that each value could be weighted in the least-squares analysis according to the inverse of its variance. Two procedures could be followed. In one only relative weightings were used and absolute values for the uncertainties in the activation parameters were obtained by making use of the residuals between the calculated and experimental values of ln (k/T). Occasionally the data fitted very closely to the linear Eyring plot in spite of having relatively high individual uncertainties. This led to accidentally small residuals, and uncertainties in the activation parameters that were unreasonably low in view of the individual uncertainties in ln (k/T). In these cases the uncertainties in the activation parameters were calculated according to an equation in which the absolute uncertainties in ln (k/T) lead directly to the uncertainties in the activation parameters. However, there were cases where the internal consistency of the data at each temperature was high and the uncertainties in each value of ln (k/T) were less than the scatter of the data around the linear Eyring plot. In these cases the uncertainties in the activation parameters were unreasonably small in view of the errors involved in the actual temperature dependence and so the first method of estimating the uncertainties was used instead, i.e. in all cases the method leading to the greater uncertainties in the activation parameters was the one used. In the case of reactions with PPh_3 and $AsPh_3$, where there were no k_2[L] terms, each individual value of ln (k_{obsd}/T) was used in the analysis with equal weighting.

Derivation of electronic and steric profiles

The characterization of electronic and steric effects in associative reactions of metal carbonyls with nucleophiles has been thoroughly described elsewhere (2, 12–15). A plot of log k_2 (40°C) for reactions of $Ru_3(CO)_{11}(P(OEt)_3)$ with L against values of pK_a do not show a clear linear relationship (Fig. 1). It is obvious that steric effects are important because reactions are much slower when L = P-*i*-Bu_3 than when L = P-*n*-Bu_3. Although these nucleophiles have similar basicities (16) P-*i*-Bu_3 is bigger than P-*n*-Bu_3 (17). However, the nucleophiles $P(OPh)_3$ and P-*n*-Bu_3 have very similar cone angles (17), and their relative values of log k_2 can be taken to be determined mainly by electronic effects, making allowances (15) for the small differences in cone angle. This provides a measure of the electronic effect, for hypothetical nucleophiles of cone angle 130°, that can be quantified by the gradient, β, of the line drawn in Fig. 1. Deviations from this line of the values of log k_2 can be ascribed to steric effects. We can calculate values (2, 15) of $\log k_2^0 = \log k_2 - \beta(pK_a + 4)$ and those for reactions at 40°C are plotted in Fig. 2 against cone angles of the nucleophiles (17).

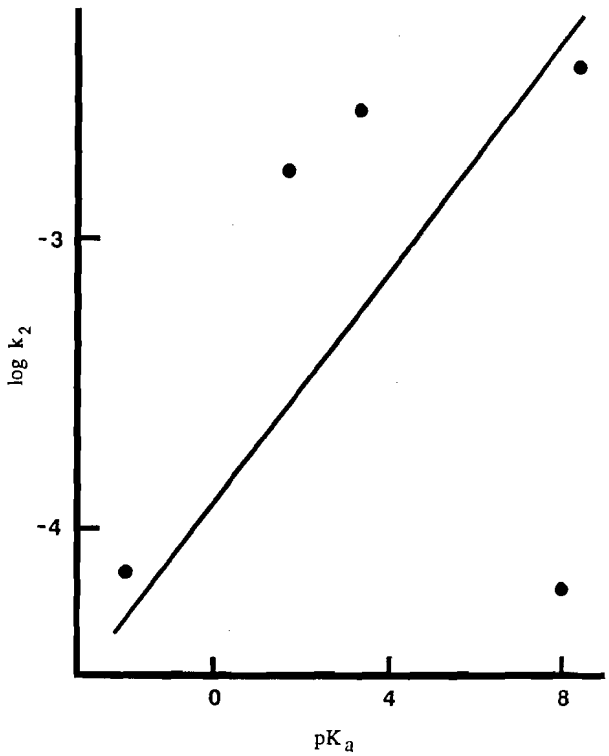

FIG. 1. Dependence of log k_2 (40°C) for reactions of $Ru_3(CO)_{11}(P(OEt)_3)$ on the σ-basicity (pK_a) of the nucleophiles. The nucleophiles are, from left to right, $P(OPh)_3$, etpb, $P(OEt)_3$, P-*i*-Bu_3, and P-*n*-Bu_3. The line is drawn for hypothetical P-donor nucleophiles of the same respective basicity as $P(OPh)_3$ and P-*n*-Bu_3 but with identical cone angles of 130°. It allows for the slightly different cone angles of $P(OPh)_3$ and P-*n*-Bu_3 (see text).

Discussion

The kinetic parameters, and their uncertainties, listed in Tables 2–4 show that the data for the reactions studied here are of very good precision. The values of k_1, $\Delta H_1^{\ddagger}$, and $\Delta S_1^{\ddagger}$ obtained by using several different entering ligands are in excellent agreement with each other (Table 3).

The [L]-independent path

The reaction governed by k_1 is normally assumed to proceed by a simple CO dissociative mechanism (18). Although other mechanisms are possible (19, 20) there is no positive evidence for them and it seems preferable therefore to continue to regard these reactions as being simply dissociative in nature. The kinetic parameters for $Ru_3(CO)_{11}(P(OEt)_3)$ can be compared (Table 5) with those reported elsewhere for $Ru_3(CO)_{11}L'$ (L′ = CO, PPh_3, or P-*n*-Bu_3). The values of k_1 fit quite well with eq. [1] (11) where $\beta_{L'}$ and $\gamma_{L'}$ represent the dependence of

$$[1] \quad \log k_1 = \alpha_{L'} + \beta_{L'}\delta + \gamma_{L'}\theta$$

the rates on the electronic parameters, δ (22)[3], and on the cone angles, θ, respectively, which are characteristic of the individual substituents, L′. Because there are only four different substituents, covering a relatively restricted range of δ and θ,

[3]The parameter δ measures the ^{13}C chemical shift of $Ni(^{13}CO)_3L$ relative to that in $Ni(^{13}CO)_4$ and is chosen (11) to represent the net electron donor capacity of L′ because, being a substituent and not a nucleophile, π-acidity of L′ will be important as well as σ-basicity (11, 22).

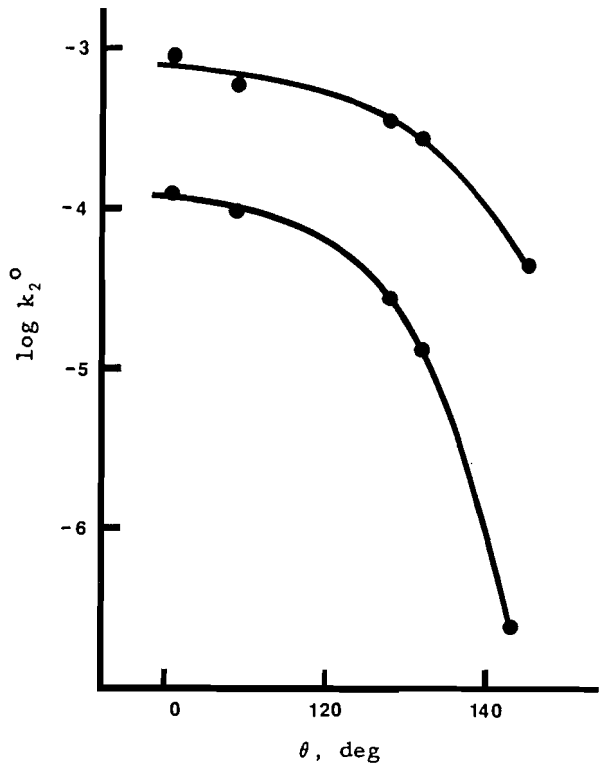

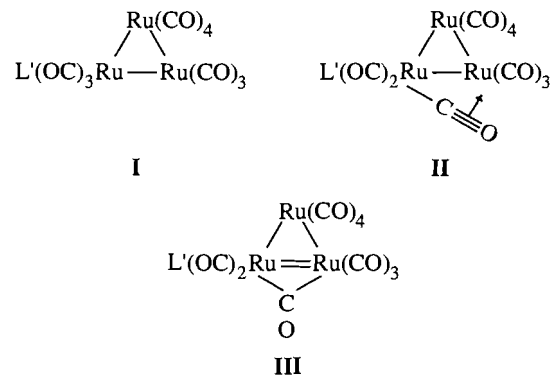

FIG. 2. Dependence of log k_2^0 at 40°C (see text) on the cone angles, θ, of the nucleophiles (upper curve for $Ru_3(CO)_{12}$; lower curve for $Ru_3(CO)_{11}(P(OEt)_3)$). The nucleophiles are, from left to right, etpb, $P(OEt)_3$, $P(OPh)_3$, P-*n*-Bu_3, and PPh_3 (upper curve) or P-*i*-Bu_3 (lower curve).

the precisions of the three parameters obtained are not very good but the values of $\beta_{L'}$ and $\gamma_{L'}$ are all positive and show a clear decrease with increasing temperature. These results will be discussed in detail elsewhere (4) together with trends in rate constants at 40°C involving a much wider range of substituents.

Apart from these trends in the rate constants we can also examine the trends in the activation parameters (Table 5). The decrease in $\Delta H_1^{\ddagger}$ is opposed, but not overcome, by a decreasingly favourable value of $\Delta S_1^{\ddagger}$ and the data fall on a good isokinetic plot[4] (Fig. 3) the gradient of which leads to an isokinetic temperature of ca. 180°C. This shows that the relative rates of the reactions are more dependent on the enthalpy of activation than on the entropy and that changes in $\Delta G_1^{\ddagger}$ are less pronounced than those of $\Delta H_1^{\ddagger}$. This also accounts for the decreasing values of $\beta_{L'}$ and $\gamma_{L'}$ with increasing temperatures because the rate constants will become completely independent of the nature of the substituent, L',at the isokinetic temperature.

The lower values of $\Delta S_1^{\ddagger}$ are not typical of those found for simple CO dissociative reactions, especially of mononuclear carbonyls (18). However, low values of this sort have been obtained several times for dissociative reactions of metal carbonyl clusters (23, 24). They can be ascribed (23) to rearrangements undergone by the residual clusters during the loss of the CO ligands. These rearrangements have the effect of maintaining the 18-electron nature of the cluster by recourse to formation of bridging carbonyls and metal–metal double bonds. The intermediates here can be envisaged (23*a*) as being of types varying from **I** (high $\Delta S_1^{\ddagger}$), **II** (intermediate $\Delta S_1^{\ddagger}$), and **III** (low $\Delta S_1^{\ddagger}$).

These correspond to increasingly tight bonding, decreasing values of $\Delta H_1^{\ddagger}$, and correspondingly decreased values of $\Delta S_1^{\ddagger}$ that result from increased strength of the bonding within the cluster (i.e. higher vibrational frequencies) and increasingly precise atomic movements to form the intermediate clusters. The values of $\Delta H_1^{\ddagger}$ decrease monotonically with increasing net electron donating capacity of L' and this correlates with the increasing tightness of bonding in the $Ru_3(CO)_{10}L'$ intermediate. The bridging nature of **II** would be expected to be encouraged by a more electron donating L', and **III** might be expected to be a logical extension of this process since this Ru_3 cluster involves four bonding electron pairs rather than the original three. Any steric effects are not sufficiently large to be rationalized at this time.

The [L]-dependent path

The procedure previously used (2, 13, 15) for separating the electronic and steric effects of different nucleophiles in associative reactions of metal carbonyl clusters is also entirely

[4]The value of $\Delta S_1^{\ddagger}$ for $Ru_3(CO)_{12}$ should probably be slightly lower than shown, compared with the values for the substituted clusters, for statistical reasons. A CO ligand can dissociate from any of the three $Ru(CO)_4$ moieties in $Ru_3(CO)_{12}$ but from only one or two of the Ru atoms in the substituted cluster. This will result in only a small adjustment to the value of $\Delta S_1^{\ddagger}$ for $Ru_3(CO)_{12}$ although it will be in the direction of making the data for $Ru_3(CO)_{12}$ fit a little less well to the isokinetic plot.

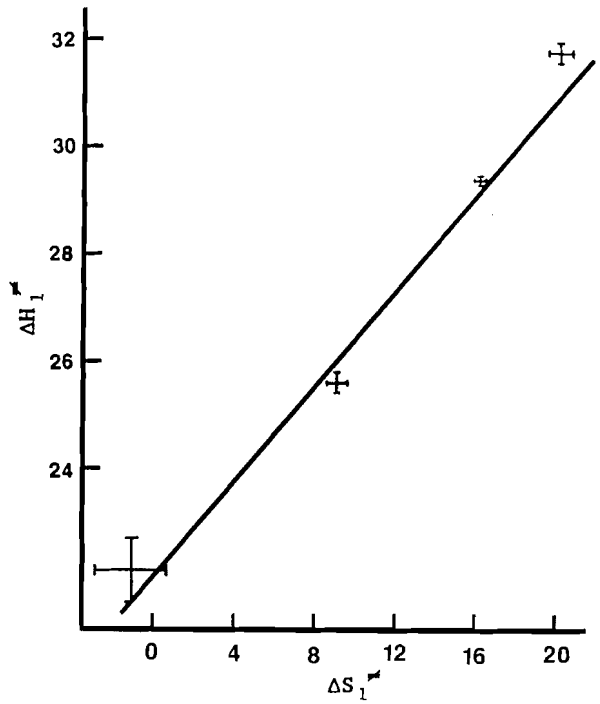

FIG. 3. Isokinetic plot of activation parameters for dissociative reactions of $Ru_3(CO)_{11}L'$ (L', from left to right, = P-*n*-Bu_3, PPh_3, $P(OEt)_3$, and CO).

successful for reactions of $Ru_3(CO)_{11}(P(OEt)_3)$ (Figs. 1 and 2). Although the gradient of the line in Fig. 1 is determined by only two points we do know that values of log k_2 depend linearly on pK_a in associative reactions of metal carbonyls for which steric effects are negligible (2, 12, 18(*b*), 25). The gradient corresponds to an electronic selectivity parameter, β, of 0.20 compared with a similarly derived value of 0.15 for $Ru_3(CO)_{12}$ (15). The slightly larger value for $Ru_3(CO)_{11}(P(OEt)_3)$ implies (2, 13) that the extent of bond making in the transition states is somewhat higher than for reactions of the unsubstituted $Ru_3(CO)_{12}$. This is counter to what might have been expected from the presumed increase of electron density on the cluster due to the presence of the electron donating P-donor substituents.

The steric profile for $Ru_3(CO)_{11}(P(OEt)_3)$ is clearly similar in form (Fig. 2) to that for $Ru_3(CO)_{12}$ but the downward curvature with increasing θ is more pronounced for the substituted cluster. This is very simply in accord both with the slightly higher degree of bond making deduced above for the reactions of $Ru_3(CO)_{11}(P(OEt)_3)$ and, more particularly, with the greater steric effect expected when a small CO is replaced by the larger $P(OEt)_3$ ligand. A similar steric effect is observed (15) for $Ru_3(CO)_{10}(\mu\text{-}Ph_2PCH_2PPh_2)$.

The steric profiles provide another kinetic parameter for the two clusters. Both steric profiles approach the horizontal as θ decreases. This means that the steric effects would decrease to zero if small enough nucleophiles were available. The value of log k_2^0 would then correspond to the value of log k_2 that would be observed for a hypothetical small and very weak nucleophile of p$K_a = -4$. This standard reactivity has been chosen so that it approaches the intrinsic reactivity of the cluster towards nucleophilic attack (2*b*, 2*c*, 15). The steric profiles coupled with the relative values of β, suggest that the substituted cluster is intrinsically less susceptible to nucleophilic attack than $Ru_3(CO)_{12}$ by ≥1 log unit or ≥1.4 kcal mol^{-1} in $\Delta G_2^{\ddagger}$ at 40°C.

The increasing yields of mononuclear products with increasing values of $[P(OEt)_3]$ show clearly that at least some of the second order reactions are proceeding by F_N2 processes (2*c*, 3). The fact that $Ru(CO)_4(P(OEt)_3)$ and $Ru(CO)_3(P(OEt)_3)_2$ are formed in the mole ratio 2:1 shows that it is mainly the $Ru_3(CO)_{11}(P(OEt)_3)$ that is undergoing direct fragmentation (3). The expansion in the Ru_3 cluster that is required during the formation of the transition state will be likely to facilitate the ultimate formation of mononuclear products, especially when this Ru_3 cluster is already expanded even in the ground state of the molecule (9, 26). The observation of substantial amounts of mononuclear products, resulting from F_N2 processes, in the reactions of $Ru_3(CO)_{11}(P(OEt)_3)$ with several other nucleophiles that show k_2 terms is therefore not unexpected but it is interesting that the proportion of F_N2 processes also depends on the nature of the nucleophiles.

Finally, it is important to note the trends in activation parameters for associative reactions of some Ru_3 clusters. The data in Table 4 show that the values of $\Delta H_2^{\ddagger}$ for attack on $Ru_3(CO)_{11}(P(OEt)_3)$ by L increase substantially in the order L = $P(OEt)_3$ < P-*n*-Bu_3 < $P(OPh)_3$ < P-*i*-Bu_3. These changes are offset by corresponding increases in $\Delta S_2^{\ddagger}$ and the data do, in fact, lie on a reasonable isokinetic plot with an isokinetic temperature of ca. 170°C. The trends in the rate constants that were discussed above are therefore clearly more dependent on $\Delta H_2^{\ddagger}$ than on $\Delta S_2^{\ddagger}$. The changes in the values of $\Delta S_2^{\ddagger}$ enable us to suggest that the expansion of the Ru_3 cluster that accompanies attack by the larger P-*i*-Bu_3 may be more pronounced than in attack by the smaller P-*n*-Bu_3. This allows for similar amounts of bond-making and must account for the higher value of $\Delta H_2^{\ddagger}$ for reaction with P-*i*-Bu_3. The greater expansion implies a more weakly bonded $Ru_3(CO)_{11}(P(OEt)_3)$ moiety in the transition state with a correspondingly less negative value of $\Delta S_2^{\ddagger}$. The low value of $\Delta H_2^{\ddagger}$ for attack by the smaller $P(OEt)_3$ can therefore be ascribed to the need for a lesser expansion of the cluster in order to have the same degree of bond making, and a corresponding more negative value of $\Delta S_2^{\ddagger}$.

The values of $\Delta H_2^{\ddagger}$ for attack by P-*n*-Bu_3 on the clusters $Ru_3(CO)_{11}L'$ increase by ca. 7 kcal mol^{-1} along the series L' = P-*n*-Bu_3 (21) < CO (13*a*) < $P(OEt)_3$ (this work). The values of $\Delta H_2^{\ddagger}$ and $\Delta S_2^{\ddagger}$ also lie on a fair isokinetic plot with an isokinetic temperature of roughly 125°C. This trend is not so easy to rationalise in view of the expected (2*b*, 2*c*) differences in extents of bond making in the transition states and the different dimensions (9, 26), and consequently different steric effects, of the clusters involved.

Received March 31, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

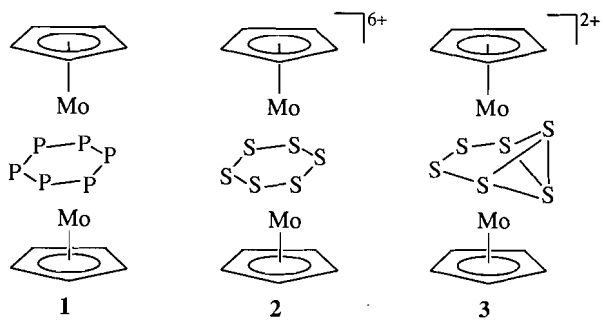
JANICE A. CRAMER, MICHAEL J. MCGLINCHEY, and JEAN-YVES SAILLARD. Can. J. Chem. **67**, 1931 (1989).

Extended Hückel molecular orbital calculations on S_6 in the planar D_{6h} configuration and in the bent C_{2v} geometry reveal that the former is favored for S_6^{2+} and the latter for S_6^{4-}. It is shown that the additional six electrons would populate one π^* and two σ^* orbitals in the planar structure. In contrast, when these hexasulfur fragments are incorporated in triple-decker sandwich compounds the pseudo-D_{6h} structure is favored for $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{6+}$ but the C_{2v} geometry is predicted for $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{2+}$ which possesses only four more electrons. The required extra two electrons are shown to originate from a metallic δ-type molecular orbital. These EHMO calculations are in complete accord with some very recent experimental results from Gillespie's laboratory.

Key words: Molybdenum–sulfur clusters, EHMO calculations.

JANICE A. CRAMER, MICHAEL J. MCGLINCHEY et JEAN-YVES SAILLARD. Can. J. Chem. **67**, 1931 (1989).

Des calculs d'orbitales moléculaires selon la méthode de Hückel étendue sur S_6 dans la configuration plane D_{6h} ainsi que dans la géométrie C_{2v} tendue démontrent que la première est favorisée pour le cation S_6^{2+} alors que la dernière est favorisée pour l'anion S_6^{4-}. On démontre que les six électrons additionnels occuperaient une orbitale π^* et deux orbitales σ^* de la structure plane. Au contraire, lorsque ces fragments de S_6 sont incorporés dans des composés sandwich à trois étages, la structure pseudo-D_{6h} est favorisée pour le composé $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{6+}$, mais les calculs prédisent que la géométrie C_{2v} serait favorisée pour $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{2+}$ qui possède 4 électrons de plus. Les deux électrons supplémentaires requis proviendraient d'une orbitale moléculaire métallique de type δ. Ces calculs sont en parfait accord avec quelques résultats expérimentaux obtenus très récemment dans les laboratoires du professeur Gillespie.



Mots clés : clusters de molybdène–soufre; calculs EHMO.

[Traduit par la revue]

Introduction

The interface of main group and transition metal cluster chemistry has attracted considerable interest in recent years and numerous synthetic and theoretical approaches have been described. Fortunately, a comprehensive overview has been provided by Whitmire (1). Among the more fascinating systems are those in which metal atoms are sandwiched between layers of organic or inorganic rings. The prototypical triple-decker, namely $[(C_5H_5)Ni(C_5H_5)Ni(C_5H_5)]^+$, which was synthesized by Werner and Salzer (2) and whose bonding patterns were rationalized by Hoffmann and co-workers (3), prompted much elegant experimental activity. One might focus particularly on the contributions of Scherer and co-workers who have prepared a series of clusters of the general type $(C_5H_5)M(P_n)M(C_5H_5)$ (4, 5). Recent extended Hückel molecular orbital calculations by Jemmis and Reddy (6) on $(C_5H_5)Mo(P_6)Mo(C_5H_5)$, **1**, and related molecules pointed out the possibility of correlating the molecular geometry, especially the metal–metal distances, with the valence electron count. Furthermore, the rich variety of structural types available for the $(C_5H_5)M(S_4)M(C_5H_5)$ system has been studied by Tremel, Hoffmann, and Kertesz (7).

Our interest in these findings was heightened as the result of a conversation with our colleague R. J. Gillespie who informed us of the synthesis and X-ray characterization of a rather novel product arising from the reaction of $(C_5H_5)_2Mo_2(CO)_6$ with S_8^{2+} (8). We have idealized the structure to the C_{2v} geometry shown in **3**. It is clear that one could construct the hypothetical molecule $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{6+}$, **2**, which would have a 28-electron count and presumably the same structure as **1**. (In these triple-decker systems, the convention is to include only the π-electrons of the ligands in the count.) We were intrigued that the addition of four electrons took **2**, which has local D_{6h} symmetry, into **3** in which an S_2 moiety has apparently been twisted out of the central plane. To this end, we report the results of an EHMO study on the effects of distorting a planar S_6 ring by rotating a sulfur–sulfur bond through 90°; subsequently, the effects are contrasted with those observed for the corresponding clusters in which the S_6 unit (in both the D_{6h} and C_{2v} conformations) is sandwiched between two $(C_5H_5)Mo$ fragments.

1 **2** **3**

Results and discussion

We note initially that the S_6 system has been the subject of several theoretical investigations using different approaches. In their extensive treatment of the structural changes on oxidation and reduction of the sulfur species S_3, S_4, S_6, and S_8, Salahub, Foti, and Smith (9) used the SCF-Xα-SW procedure. These

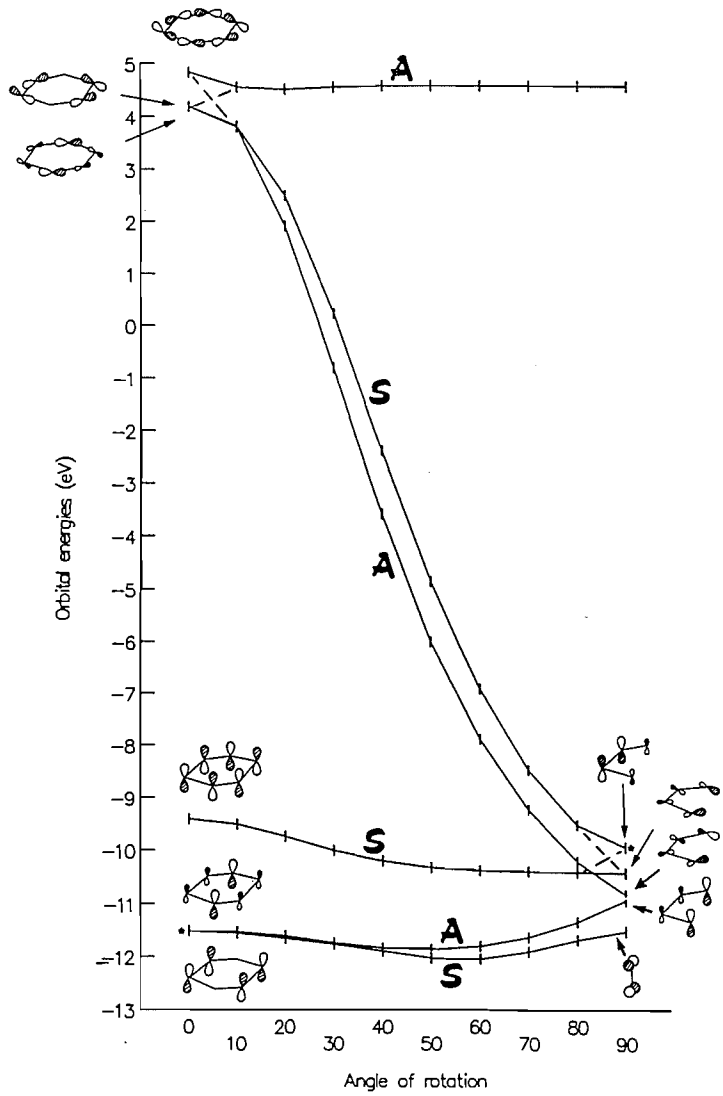

FIG. 1. Walsh diagram showing the effects of rotating a sulfur–sulfur moiety relative to the plane of the four remaining sulfur atoms. On the left hand side, $\theta = 0°$, the asterisk marks the HOMO for the D_{6h} S_6^{2+} system. On the right hand side, $\theta = 90°$, the asterisk marks the HOMO for the C_{2v} S_6^{4-} system.

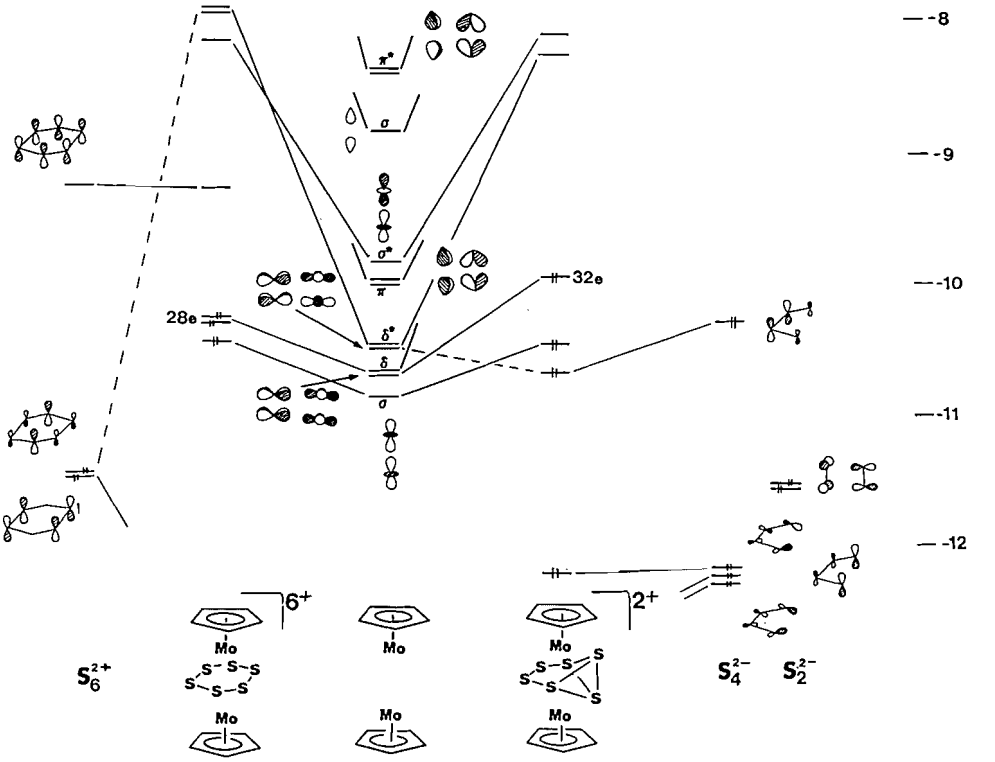
results were in general accord with the EHMO calculations from this laboratory on a variety of six-atom species (10). Among the geometries which have been examined for the six-atom clusters are the octahedron (O_h), the trigonal prism (D_{3h}), the boat (C_{2v}), the flattened boat (D_{2h}), and the planar hexagon (D_{6h}). Several of these calculated geometries correspond to structurally characterized molecules: thus Te_6^{4+} is D_{3h} (11) while P_6^{4-} adopts the D_{6h} configuration (12). We are unaware of any calculations on the benzvalene-type structure, **4**, whereby a sulfur–sulfur vector has been rotated about an axis bisecting two bonds. Figure 1 depicts a Walsh diagram showing the effects on the frontier orbitals of rotating an S—S bond from $\theta = 0°$ through $\theta = 90°$. On the left hand side we see the familiar pattern for a 10π Hückel system while on the right hand side there are no longer any orbital degeneracies since we are now in the C_{2v} point group. During the transit from one structure to the other we maintain only a C_2 axis and the S and A designations reflect this lowered symmetry.

The consequence of this D_{6h} to C_{2v} isomerization in terms of structure is a replacement of two S—S bonds by four S···S loose contacts (2.38 Å). The effect of this bond breaking process on the electronic structure of the S_6 system is the generation of non-bonding MO's from bonding and antibonding σ-type levels of the planar S_6 system: two high-lying levels which are antibonding with respect to the broken bonds are strongly stabilized while several bonding MO's are destabilized. Because the sulfur–sulfur distance of 2.00 Å in the planar system is too long to provide significant overlap, the π-type levels contribute little to the S—S bonding and become even more non-bonding in the bent S_6 system.

In Fig. 1, we note that for S_6^{2+} the HOMO is a degenerate σ^* e_{2u} set and the LUMO is a single π^* orbital of b_{2g} symmetry. Of course, it is well known that the addition of two electrons to S_6^{2+} would fill the LUMO and generate S_6 itself which is not planar but adopts the D_{3d} (cyclohexane-chair) structure; however, the planar molecule yields a large HOMO/LUMO gap for S_6 itself which renders this structure *a priori* possible, if not for the free molecule, at least for S_6 as a complexed ligand (see below). We can also see from Fig. 1 that the addition of six electrons to planar S_6^{2+} to produce planar S_6^{4-} by filling not only the π^* orbital but also the high-lying e_{1u} set is evidently greatly disfavored. The Walsh diagram reveals that



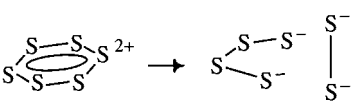


FIG. 2. Frontier orbital energy level diagram depicting the interaction of the Cp_2Mo_2 fragment with planar S_6^{2+} and with S_4^{2-} and S_2^{2-} units. The favored electron counts (28 electrons for **2**, 32 electrons for **3**) are indicated.

two high-lying orbitals of the planar molecule have undergone a precipitous drop in energy during the transformation from D_{6h} to C_{2v}; furthermore, the b_{2g} orbital (the LUMO in S_6^{2+}) correlates with a filled orbital on the right hand side of Fig. 1. It is now readily apparent that the favored count for the hexasulfur system in the C_{2v} geometry is 40 electrons, and that one has effectively generated two almost independent fragments, viz., S_4^{2-} and S_2^{2-}. A moment's thought leads to the realization that by adding six electrons to planar S_6^{2+} we have not only filled the π manifold but also populated two orbitals of strongly σ^* character. In fact, the *A* and *S* high-lying orbitals which descend so steeply are not simply the e_{1u} set; the symmetric component of this degenerate orbital does indeed fall in energy but the *A* orbital which crosses the HOMO-LUMO gap arises from a_{2g}; that is, there is an avoided level crossing at the very beginning of the transformation. Not only the electron count, but also the frontier orbital set of the S_6 system has changed during the D_{6h} to C_{2v} process. One now has two new in-phase and out-of-phase combinations of sulfur lone pairs on the termini of the S_4 fragment. On the other side, the S_2 fragment bears six frontier orbitals: the in-plane and out-of-plane π and π^* fragment orbitals, and the in-phase and out-of-phase combinations of the σ-type lone pairs on the two sulfur atoms.

To summarize, therefore, we see that rotation of a sulfur–sulfur fragment out of the S_6 plane increases the S—S distances to their former neighbours in the D_{6h} system from 2.00 to 2.38 Å. We have effectively cleaved two sulfur–sulfur σ-bonds leading ultimately to S_4^{2-} and S_2^{2-} moieties.

Turning now to the metal-complexed systems **1**, **2**, and **3**, we present in Fig. 2 the frontier molecular orbital (FMO) schemes for the well-known fragment $(C_5H_5)Mo\cdots Mo(C_5H_5)$ and for the $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{n+}$ cluster in both its pseudo-D_{6h} and C_{2v} geometries. The metal FMO's for the

4

$(C_5H_5)Mo\cdots Mo(C_5H_5)$ moiety are labelled with their conventional σ, σ^*, π, π^*, and δ, δ^* designations. The interactions of these Cp_2Mo_2 frontier orbitals with those of planar S_6 give rise to the hypothetical molecule $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{6+}$, **2**, possessing pseudo-D_{6h} symmetry. Analogously, the C_{2v} cluster $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{2+}$, **3**, is derived from its Cp_2Mo_2, S_4, and S_2 constituents. As anticipated from the work of Jemmis and Reddy (6), the orbital energy level diagram for the 28-electron system $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{6+}$ resembles qualitatively that for the isoelectronic $[(C_5H_5)Mo(P_6)Mo(C_5H_5)]$ cluster, **1**. It is further apparent that planar 30-electron triple-deckers would arise as a result of filling the vacant b_{2g} orbital, i.e., the LUMO in **1** and **2**. This possibility was raised by Hoffmann and co-workers (3) in their original paper in which they rationalized the 34-electron species $[Cp_3Ni_2]^+$. Since that time, examples of 30-electron clusters such as $(C_6H_6)Cr(C_6H_6)Cr(C_6H_6)$ or $CpFe(C_2B_2SR_4)FeCp$ have synthesized (13–15). However, it should be noted that these complexes have a somewhat different electronic structure from that of **2** or **3**.

The presence of the planar S_4 fragment situated between the two molybdenum atoms in both **2** and **3** accounts for the many similar features in the orbital energy level diagrams. The major change is the destabilization in **3** of one of the delta components (the $d_{x^2-y^2}$ combination) which now correlates with a vacant level. This situation arises because the in-phase $d_{x^2-y^2}$ orbital combination overlaps with the in-plane π orbital of S_4 and also with the in-phase combination of the S_2 lone pairs. The in-phase d_{xy} combination from Cp_2Mo_2 which yields the other

For personal use only.

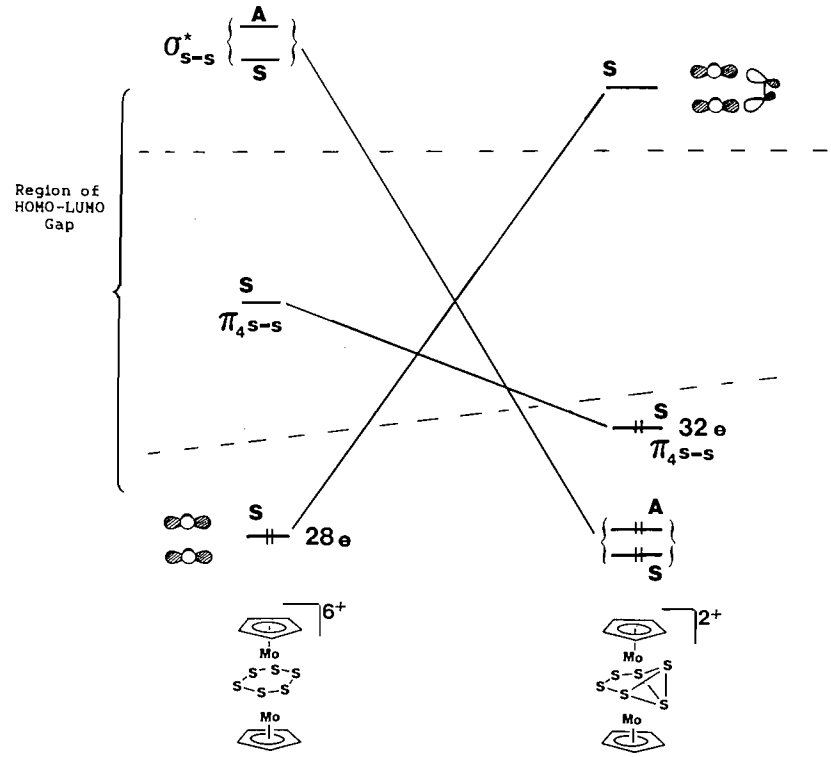

FIG. 3. Schematized correlation diagram showing how three vacant orbitals in planar $[Cp_2Mo_2S_6]^{6+}$ correlate with filled orbitals in $[Cp_2Mo_2S_6]^{2+}$; concomitantly, a δ orbital in **2** is greatly destabilized in **3**.

δ component is less affected than is its $d_{x^2-y^2}$ partner since the corresponding interaction is with the out-of-plane π orbital of S_2; the overlap integral in the d_{xy} case is smaller and consequently the δ orbital suffers only minor destabilization.

As a result of this orbital analysis, we can now explain an initially puzzling feature of the clusters **2** and **3**. It was apparent from the earlier discussion that the transformation of planar S_6^{2+} into S_4^{2-} and S_2^{2-} fragments requires a formal six-electron reduction and the population of one π* and two σ* orbitals; in contrast, this process apparently requires only a four-electron reduction to take D_{6h} $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{6+}$, **2**, into the C_{2v} cluster $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{2+}$, **3**. The schematized correlation diagram in Fig. 3 shows the two previously described high-lying antibonding orbitals which cross the HOMO-LUMO gap as one rotates an S_2 moiety through 90° relative to the original S_6 plane; moreover, the weakly antibonding b_{2g} orbital (the LUMO in D_{6h}) is occupied in the C_{2v} geometry. However, the destabilization of the $d_{x^2-y^2}$ component of δ symmetry results in a net increase of only two occupied orbitals and a consequent change from a 28-electron to a 32-electron cluster. If we regard the planar ring in **2** as S_6^{2+}, i.e., a 10π Hückel system, then the overall charge of 6+ tells us that the formal oxidation state of each molybdenum is 3+ (d^3); in contrast, the calculations reveal that in **3** the hexasulfur fragment has a charge of 4− which leaves each molybdenum in the 4+ (d^2) formal oxidation state. Thus the transformation from planar $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{6+}$ into the bent $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{2+}$ can be viewed as a six-electron superreduction of S_6^{2+} with a concomitant two-electron oxidation of $[Cp_2Mo_2]^{4+}$ to $[Cp_2Mo_2]^{6+}$. However, it should be noted that oxidation states are formal and rather different from the real atomic charges since the strong ligand-to-metal bonding implies large charge transfers: for example, the calculated charge on Mo was found to be 1.2+, a value significantly lower than 4+.

At Mo—Mo distances of about 2.6–2.8 Å, the δ-type overlap is negligible and the depopulation of one in-phase δ combination should not affect the Mo—Mo separation. In our calculations on **2** and **3**, the Mo—Mo overlap populations were found to be 0.139 and 0.159, respectively. The distances observed in $[(C_5H_5)Mo(P_6)Mo(C_5H_5)]$, **1** (2.648 Å) and $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{2+}$, **3** (2.752 Å) may simply be attributable to the different nature and structure of the central ligand system.

The results for these 28- and 32-electron systems allow one to make some comments about other potentially viable molecules. Clearly, one would expect $[(C_5H_5)Mo(S_6)Mo(C_5H_5)]^{6+}$, **2**, to possess a planar hexasulfur ring but the rather high charge on such a cluster probably precludes its synthesis. The same structure could perhaps be obtained by taking another 28-electron system such as $[(C_5H_5)Zr(S_6)Zr(C_5H_5)]^{2+}$. Future reports will focus on experimental and calculative approaches in this general area of organometallic multiple decker compounds.

Experimental

All calculations were performed via the extended Hückel method (16) using weighted H_{ij}'s (17). Atomic parameters were taken from previous studies (18, 19). The sulfur–sulfur bond lengths in the planar hexagon were taken as 2.00 Å; the molybdenum–molybdenum distance in **3** (2.752 Å) was taken from the X-ray crystallographic data (8).

The disproportionation of diselenium dichloride, Se_2Cl_2, and diselenium dibromide, Se_2Br_2

MARC LAMOUREUX and JOHN MILNE
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received March 6, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

MARC LAMOUREUX and JOHN MILNE. Can. J. Chem. **67**, 1936 (1989).

Diselenium dichloride and dibromide have been shown by Raman and ^{77}Se-nmr spectroscopy to be equilibrium mixtures of Se_2X_2 and small amounts of SeX_2 and Se_nX_2. Equilibrium constants have been estimated for the disproportionation reactions,

$$2Se_2X_2 = SeX_2 + Se_3X_2$$

$$3Se_2X_2 = SeX_2 + Se_4X_2$$

The origin of "spurious" peaks in the reported vibrational spectra of Se_2Br_2 and Se_2Cl_2, which have been variously assigned to overtone and combination bands and impurities has been clarified. Mixtures of Se_2Br_2 and Se_2Cl_2 are shown to contain Se_2BrCl in equilibrium according to

$$Se_2Br_2 + Se_2Cl_2 = 2Se_2BrCl$$

Key words: ^{77}Se nmr, Raman spectroscopy, selenium halides, diselenium dichloride, diselenium dibromide.

MARC LAMOUREUX et JOHN MILNE. Can. J. Chem. **67**, 1936 (1989).

Faisant appel aux spectroscopies Raman et rmn du ^{77}Se, on a démontré que les dichlorure et dibromure de disélénium sont des mélanges à l'équilibre de Se_2X_2 et de faibles quantités de SeX_2 et Se_2X_2. On a évalué les constantes d'équilibre pour les réactions de disproportionation suivantes:

$$2Se_2X_2 = SeX_2 + Se_3X_2$$

$$3Se_2X_2 = SeX_2 + Se_4X_2$$

On a clarifié l'origine de bandes "parasites" dont l'apparition dans les spectres de vibration avaient été rapportée antérieurement et qui avaient été attribuées à des impuretés ainsi qu'à des bandes harmoniques et de combinaison. On a démontré que les mélanges de Se_2Br_2 et de Se_2Cl_2 contiennent du Se_2BrCl formé par l'équilibre suivant:

$$Se_2Br_2 + Se_2Cl_2 = 2Se_2BrCl$$

Mots clés : rmn du ^{77}Se; spectroscopie Raman; halogénures de sélénium; dichlorure de disélénium; dibromure de disélénium.

[Traduit par la revue]

Introduction

Diselenium dichloride, Se_2Cl_2, and dibromide, Se_2Br_2, are among the oldest known compounds of selenium (1). Crystal structure determinations confirm them to be pure as solids (2). However, the vibrational spectrum of liquid Se_2Cl_2 (3–8) has weak bands, which cannot be assigned to fundamental modes and which have been variously assigned as overtones and combinations (4–8) or as due to impurities (3–6). Some vibrational bands in the spectra of the chloride and bromide have nearly identical frequencies to those exhibited by $SeCl_2$ and $SeBr_2$ (9). It appeared possible that Se_2Cl_2 and Se_2Br_2 might undergo some kind of disproportionation in the liquid phase. In order to test this hypothesis and to extend our knowledge of lower selenium halides, a study of the Raman and ^{77}Se-nmr spectra of diselenium dichloride, dibromide, and bromide chloride, as neat liquids and in solution was carried out. The work on the neat liquids is reported here.

Experimental section

Elemental selenium pellets (Aldrich, 99.99%) and chlorine (Air Products, 99.5%) were used without further purification. Bromine (Fisher Reagent) was distilled (bp 59°C) from phosphorus pentoxide. Selenium tetrachloride, diselenium dichloride and dibromide were prepared by standard methods (10, 11). Pure diselenium dichloride was also prepared from pure selenium and selenium tetrachloride in a closed container.

$$3\,Se + SeCl_4 = 2\,Se_2Cl_2$$

The reactants were weighed out with an analtyical balance and were accurate to ±1 mg. For the quantities used, the error in the 1:1 stoichiometry amounts to ±0.07%. This product will be called stoichiometric Se_2Cl_2 hereafter. Mixtures of Se and $SeCl_4$ in Se_2Cl_2 were also made up by weighing. In a typical experiment 0.443 g Se were added to 11.203 g of Se_2Cl_2. Although it has been claimed that Se is insoluble in Se_2Cl_2 (12), it was found that up to 4% by weight could be dissolved. The same method was used for Se_2Br_2 and its mixtures but in this case Se and Br_2 were used and the reaction was carried out with cooling. All manipulations were carried out in a dry box. Exclusion of oxygen was not necessary.

Raman spectra were measured with a Jobin-Yvon monochromator in conjunction with a Hamamatsu PM tube and a Princeton Applied Research photon counting system. The spectra were excited with the 647.1 nm line of a Spectra Physics Kr ion laser.

Selenium-77 nmr spectra were measured with a Varian XL-300 spectrometer operating at 57.28 MHz. The ^{77}Se reference was a saturated solution of selenous acid in distilled water made up using SeO_2 (Aldrich, 99.999%). The chemical shift for this reference is 1282 ppm to low field from selenium dimethyl (13). The probe temperature was 20°C.

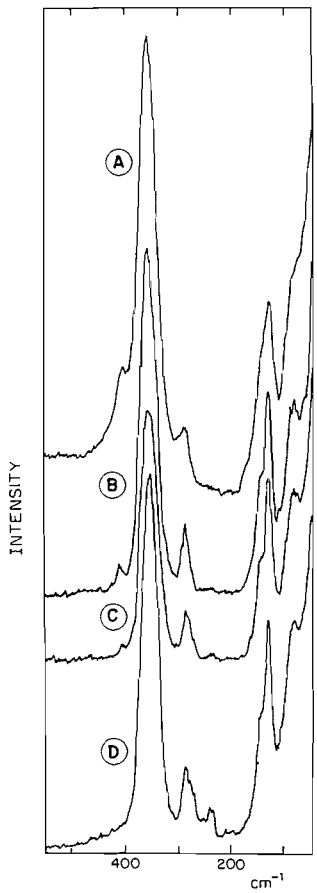

FIG. 1. The Raman spectra of Se_2Cl_2 solutions. Trace *A*: 9.5 wt.% (0.098 mole fraction) $SeCl_4$ in Se_2Cl_2; trace *B*: Se_2Cl_2, prepared by the method of Lenher and Kao (11); trace *C*: stoichiometric Se_2Cl_2; trace *D*: 3.5 wt.% (0.095 mole fraction) Se in Se_2Cl_2. Resolution: 10 cm^{-1}.

Results and discussion

Diselenium dichloride

Raman spectroscopy The Raman spectra of Se_2Cl_2, stoichiometric Se_2Cl_2 and solutions of 9.5 wt.% $SeCl_4$ (0.098 mole fraction) and 3.5 wt.% Se (0.095 mole fraction) in Se_2Cl_2 are given in Fig. 1. The spectra of Se_2Cl_2 and stoichiometric Se_2Cl_2 are in close agreement with the spectra reported earlier (3–6) and differ only in the relative intensity of the peak at 410 cm^{-1}. This peak, which has been attributed to an impurity by other workers (3, 6), corresponds to the symmetric stretching (ν_1) mode of $SeCl_2$ (9). The bending mode (ν_3) of $SeCl_2$ also appears in these spectra and those of Kiefer (6) as a weak shoulder at 166 cm^{-1}. Selenium dichloride is apparently present in Se_2Cl_2. The asymmetric stretching mode of $SeCl_2$ (ν_2) at 381 cm^{-1} is lost in the strong Se_2Cl_2 envelope (ν_1 and ν_5 of Se_2Cl_2) at 358 cm^{-1}. When $SeCl_4$ is added to Se_2Cl_2 up to 10 wt.%, homogeneous liquid mixtures are formed. The Raman spectrum of this mixture (trace *A* in Fig. 1) shows a stronger peak at 410 cm^{-1} consistent with the reaction

[1] $Se_2Cl_2 + SeCl_4 = 3\ SeCl_2$

The addition of elemental selenium to Se_2Cl_2 up to 3.5 wt.% yields a homogeneous mixture. The Raman spectrum (trace *D*) shows a barely observable peak at 410 cm^{-1} and a new peak at 240 cm^{-1} and a shoulder at 275 cm^{-1}. These new peaks have been attributed to Se_nCl_2 species present in Se/Se_2Cl_2 melts (100°C) by Volkov *et al.* (7). The additional peaks at 81 and 139 cm^{-1} reported by these authors are difficult to observe due to the presence of other strong Se_2Cl_2 bands. At the low Se concentrations studied here, these observations are consistent with the reaction

[2] $Se + Se_2Cl_2 = Se_3Cl_2$

The observations of a peak at 410 cm^{-1} in the spectrum of stoichiometric Se_2Cl_2 where the 1:1 Se / Cl mole ratio is precise to within ±0.07% indicates that Se_2Cl_2 undergoes a self-disproportionation.

[3] $2Se_2Cl_2 = SeCl_2 + Se_3Cl_2$

The very weak peak at 240 cm^{-1} in the spectrum supports the simultaneous occurrence of Se_3Cl_2 in the mixture. The simultaneous appearence of peaks due to $SeCl_2$, Se_2Cl_2, and Se_3Cl_2 species in the Se/Se_2Cl_2 solution confirms that the disproportionation [3] is taking place. The intensity of the peak at 410 cm^{-1} is stronger in the spectrum of Se_2Cl_2 prepared by the method of Lenher and Kao (11) than in the spectrum of stoichiometric Se_2Cl_2. This is attributed to the use of SeO_2 in excess of the stoichiometrically required amount in the procedure of Lenher and Kao (11).

The equilibrium constant governing [3],

$$[4]\quad K = \frac{[SeCl_2][Se_3Cl_2]}{[Se_2Cl_2]^2}$$

may be estimated from the relative intensities of the 410 cm^{-1} band in the spectra of stoichiometric Se_2Cl_2 and of the solution with 9.5 wt.% of selenium tetrachloride (0.098 mole fraction dissolved in Se_2Cl_2.

Normalized band intensities and concentrations are given in Table 1. The normalization assumption was that the 358 cm^{-1} band of Se_2Cl_2 has an area of 5 cm^2. The contribution of ν_3 of $SeCl_2$ to this band is assumed to be negligible and has been ignored. Concentrations are expressed as mol L^{-1} and the solution volume has been calculated assuming the density of Se_2Cl_2 and its mixtures to be 2.77 g mL^{-1}. Areas were determined from several spectra but as a result of the low relative intensity of the 410 cm^{-1} peak, the largest error is in the area for this peak. Two expressions for K, one for each solution, may be derived.

$$[5]\quad K = \frac{(0.038/I_{SeCl_2})^2}{(5/I_{Se_2Cl_2})^2}$$

and

$$[6]\quad K = \frac{[3c_{SeCl_4} + [Se_3Cl_2]][Se_3Cl_2]}{[c_{Se_2Cl_2} - c_{SeCl_4} - [Se_3Cl_2]]^2}$$

where

$$[7]\quad [Se_3Cl_2] = \frac{\left[\frac{0.442}{I_{SeCl_2}}\right](c_{Se_2Cl_2} - c_{SeCl_4}) - \left[\frac{15c_{SeCl_4}}{I_{Se_2Cl_2}}\right]}{5/I_{Se_2Cl_2} + 0.442/I_{SeCl_2}}$$

and I_{SeCl_2} and $I_{Se_2Cl_2}$ are the molar scattering intensities of $SeCl_2$ (410 cm^{-1}) and Se_2Cl_2 (358 cm^{-1}) in liquid Se_2Cl_2. The molar scattering intensity of Se_2Cl_2 at 358 cm^{-1} was calculated to a reasonable degree of accuracy from the stoichiometric Se_2Cl_2 spectrum and found to be 0.41 cm^2 L mol^{-1}. The contribution to this peak from Se_3Cl_2, which is expected to have SeCl stretching bands in this region but which is present at low concentration

and $SeCl_2$, which is also present in low concentration, is small and has been ignored. Equations [5] and [6] yield $K = 8(\pm5) \times 10^{-4}$ for $I_{SeCl_2} = 0.11$ cm^2 L mol^{-1}.

^{77}Se-nmr spectroscopy. A routine ^{77}Se nmr spectrum of stoichiometric Se_2Cl_2 consists of a single signal at −9.8 ppm, which is close to the reported value of −7.9 ppm (14). With an increase in the number of transients collected additional weak peaks are observed. The chemical shifts and peak intensities of stoichiometric Se_2Cl_2, Se_2Cl_2, and solutions of $SeCl_4$ and Se in Se_2Cl_2 are given in Table 2. The principal signal in the spectra of all of these mixtures is due to Se_2Cl_2. This signal shifts slightly to high field, −8.51 to −9.81 ppm, as the $SeCl_4$ content is decreased. The spectrum of a mixture of Se_2Cl_2 with 3.95wt.% $SeCl_4$ (0.042 mole fraction) consists of, in addition to the Se_2Cl_2 signal, a moderately strong signal at 428.1 ppm and a very weak signal at −11.3 ppm. This latter signal was discernible in this solution as a result of the large number of transients collected (2800). The nmr spectra of the Se_2Cl_2 samples showed only two signals, that of Se_2Cl_2 and the low field signal near 425 ppm which had reduced intensity compared to that in the $SeCl_4/Se_2Cl_2$ solution spectrum. The solution of 3.23wt.% (0.088 mole fraction) Se in Se_2Cl_2 gave an nmr spectrum with three signals in addition to that for Se_2Cl_2. The intensity of the signal at 425.4 ppm was further decreased while that at −10.3 ppm, just to high field of the main Se_2Cl_2 signal, increased in intensity relative to the intensity observed in the spectrum of the $SeCl_4/Se_2Cl_2$ mixture. In addition, a weak signal at −365.5 ppm was observed. The variation in relative intensity of the lowest field signal shows that it arises from $SeCl_2$ while that just to high field of the main Se_2Cl_2 signal is assigned to Se_3Cl_2. Finally in solutions to which sufficient Se had been added, Se_4Cl_2 is formed and the signal at −365.5 ppm is assigned to this species. The chemical shifts of $SeCl_2$, Se_3Cl_2, and Se_4Cl_2 are in agreement with those observed for these species in other solvents (16). The strongest nmr signals for Se_nCl_2 will arise from molecules carrying a single ^{77}Se atom in the chain and, for Se_3Cl_2 and Se_4Cl_2, these should consist of two signals for each with intensity ratios 2:1 and 1:1, respectively. These pairs of signals are observed for alkyl tri- and tetraselenides (15) and for tri- and tetraselenium chlorides and bromides dissolved in non-aqueous solvents (16). Some broadening of these signals in Se_2Cl_2 is expected due to the high viscosity of the mixtures and quadrupole relaxation of the Cl and Br nuclei (I = 3/2 for all natural isotopes) to which the ^{77}Se atoms are linked over one or two bonds. However, the appearance of a single broad peak for each species where each member of the doublet is separated by over 20 ppm (16), indicates that some intramolecular exchange is taking place.

The observation of an nmr signal for $SeCl_2$ in the stoichiometric Se_2Cl_2 spectrum confirms the conclusion of the Raman study that Se_2Cl_2 disproportionates. From the peak areas of the spectra of the mixtures studied, the disproportionation constant, K (eq. [4]), may be estimated and these are given in Table 2. In the case of the $SeCl_4/Se_2Cl_2$ mixture, peak intensities and stoichiometry were used, since the intensity of the Se_3Cl_2 peak was too weak to be measured accurately. The average values of K from the Raman spectra and the three nmr measurements is $4(\pm2) \times 10^{-4}$. Considering the relatively weak signals recorded, and the uncertainty for similar reasons, in the intensity of the Raman peak at 410 cm^{-1}, the agreement between the two methods of

	−111.3	157	Se_2Br_2	
	−143.7	7(0.045)	Se_3Br_2	$K' = 1.5(\pm0.7) \times 10^{-6}$
	−375.1	5.8(0.037)	Se_4Br_2	
Se in Se_2Br_2	164.2	14.5(0.011)	$SeBr_2$	$K = 1.2(\pm0.1) \times 10^{-3}$
(5.8 wt.%;	−111.0	1350	Se_2Br_2	
0.199 mole fraction)	−135.2			
		114(0.084)	Se_3Br_2	
	−144.8			$K' = 1.9(\pm0.2) \times 10^{-6}$
	−361.2			
	−373.8	109(0.081)	Se_4Br_2	
	−392.5			

[a]The uncertainty on the intensities is ±0.5.
[b]Normalized values in parentheses are referred to Se_2Br_2 intensity = 1.00.

determing K is satisfactory. The lower values of K from the nmr work may well be due to masking of part of the Se_3Cl_2 signal by the strong Se_2Cl_2 signal. The greater relative intensity of the $SeCl_2$ signal in Se_2Cl_2, compared to that for stoichiometric Se_2Cl_2, confirms the earlier conclusion that the preparation of this product uses an excess of Se(IV).

The observation of an nmr signal for Se_4Cl_2, appearing simultaneously with the signal for $SeCl_2$ in the spectrum of the Se/Se_2Cl_2 solution indicates that a second equilibrium is present.

[8] $3\,Se_2Cl_2 \overset{K'}{=} 2\,SeCl_2 + Se_4Cl_2$

From the intensities of the signals for Se_2Cl_2, $SeCl_2$, and Se_4Cl_2, K' is estimated to be $3(\pm0.6) \times 10^{-6}$.

Diselenium dibromide

Raman spectroscopy. The Raman spectra of Se_2Br_2, prepared by the method of Lenher and Kao (11) and a solution of 14.1wt.% Se (0.40 mol fraction) in Se_2Br_2 are shown in Fig. 3. The peak at 286 cm^{-1}, which has been assigned to the Se—Se stretching mode, $\nu_2(A_1)$, of Se_2Br_2 (3–6) is coincident with $\nu_3(B_1)$ of $SeBr_2$ (9). With addition of elemental Se, this peak falls in intensity, indicating that there is at least some contribution to this peak from $SeBr_2$. With the addition of Se two new peaks also appear at 182 and 81 cm^{-1}, which are assigned to Se_nBr_2 species. Apparently equilibria parallel to [3] and [8] occur in these liquids.

[9] $2\,Se_2Br_2 \overset{K}{=} SeBr_2 + Se_3Br_2$

[10] $3\,Se_2Br_2 \overset{K'}{=} 2\,SeBr_2 + Se_4Br_2$

^{77}Se nmr spectroscopy. The ^{77}Se nmr chemical shifts and intensities from spectra of stoichiometric Se_2Br_2, Se_2Br_2, and a solution containing 5.8wt.% of Se (0.199 mole fraction) dissolved in Se_2Br_2 are given in Table 3. The spectrum of stoichiometric Se_2Br_2 is shown in Fig. 2. The strongest shift near −111 ppm is due to Se_2Br_2 (14). By analogy with the Se_2Cl_2 spectra, the single peak to low field near 164 ppm is

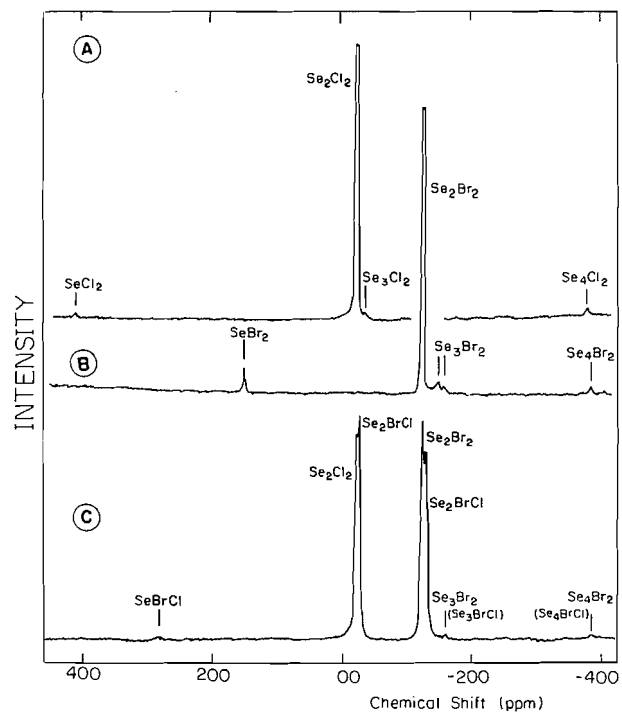

FIG. 2. The ^{77}Se-nmr spectra of Se_2X_2 solutions. Trace *A*: 3.23 wt.% (0.088 mole fraction) of Se in Se_2Cl_2: trace *B*: stoichiometric Se_2Br_2; trace *C*: 0.92:1.0:0.21 mole ratio solution of $Se_2Br_2/Se_2Cl_2/Se$.

assigned to $SeBr_2$, the two peaks just above the Se_2Br_2 shift arise from Se_3Br_2 and the set of peaks near −373 ppm are due to Se_4Br_2. This assignment is confirmed by the changes in intensities which occur when Se is added to Se_2Br_2. In the spectrum of the 5.8wt.% solution of Se in Se_2Br_2 the relative intensity of the low field peak due to $SeBr_2$, compared to that in the spectrum of pure Se_2Br_2, is lower and those of the high field peaks due to Se_3Br_2 and Se_4Br_2 are higher. Moreover, the relative intensities of the signals near −140 ppm and those near −373 ppm in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

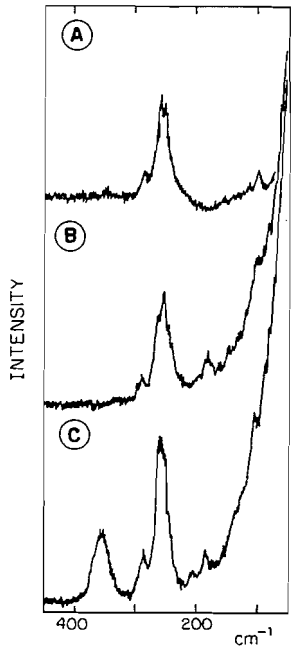

FIG. 3. The Raman spectra of Se_2Br_2 solutions. Trace *A*: Se_2Br_2, prepared by the method of Lenher and Kao (11); trace *B*: 5.8 wt.% Se (0.199 mole fraction) in Se_2Br_2; trace *C*: 0.92:1.0:0.21 mole ratio solution of $Se_2Br_2 / Se_2Cl_2 / Se$. Resolution: 10 cm^{-1}.

5.8wt.% Se solution, compared to those signals in the spectrum of stoichiometric Se_2Br_2, supports the assignment of the high field peak to Se_4Br_2. Apparently Se_2Br_2 produced by the method of Lenher and Kao contains some excess of Se and the normalized signal intensities lie between those of stoichiometric Se_2Br_2 and the 5.8wt.% solution of Se in Se_2Br_2. The nmr spectrum for Se_3Br_2 and Se_4Br_2 are expected, in the absence of exchange and considering only species with one ^{77}Se atom, to consist of doublets of 2:1 and 1:1 intensities, respectively. The envelope near −140 ppm has the appearance of a 2:1 doublet consistent with the assignment to Se_3Br_2, although the signal breadth causes the two peaks to overlap. The higher field signals appear to consist of a broad pair of peaks (−361.2 and −392.5; each intensity 1) bracketing a third peak (−373.8; intensity 4.5). Further work will be necessary to interpret the precise origin of these peaks. No evidence for Se_5Br_2 and higher homologues was found, although collection of a greater number of transients may reveal evidence for these.

All of the observations indicate that Se_2Br_2, like Se_2Cl_2, is not homomolecular but is disproportionated to a small extent according to equilibria [9] and [10]. From the intensities of the signals the disproportionation constants for these equilibria, K and K', may be estimated and these are listed in Table 3. The average values are $K = 1.1(\pm 0.2) \times 10^{-3}$ and $K' = 1.7(\pm 0.6) \times 10^{-6}$.

Diselenium bromide chloride

Raman spectroscopy. The Raman spectrum of a 0.92:1.0:0.21 mole ratio mixture of $Se_2Br_2 / Se_2Cl_2 / Se$ is shown in Fig. 3, trace *C*. The spectrum appears consistent with the sum of the individual spectra of Se_2Cl_2 and Se_2Br_2 except for the peak at 183 cm^{-1}, which corresponds to the peak assigned to the Se_nBr_2 species, and a weak band at 210 cm^{-1}. The formation of the mixed bromide chloride, according to

[11] $Se_2Cl_2 + Se_2Br_2 = 2\,Se_2BrCl$

−371.23	Se_4Br_2 (and Se_4BrCl ?)	2

[a]Peak heights are accurate to ±0.3.

is not excluded, however, since the bands expected for this product will lie very near those of Se_2Cl_2 and Se_2Br_2. No reasonable assignment of the new peak at 210 cm^{-1} to Se_2BrCl is, however, possible based upon assignments for Se_2X_2 (3–6) but this peak lies between the strong peaks of Se_nCl_2 and Se_nBr_2, 240 and 183 cm^{-1}, respectively, and probably arises from the same mode in Se_nBrCl. Similarly, the excess Se present will cause formation of Se_nBr_2, which is the origin of the peak at 183 cm^{-1}. The corresponding peak of Se_nCl_2 is masked by the strong band of Se_2Br_2 at 256 cm^{-1}.

^{77}Se nmr spectroscopy. The ^{77}Se nmr spectrum of the 0.92:1.0:0.21 mole ratio liquid mixture of $Se_2Br_2 / Se_2Cl_2 / Se$ is shown in Fig. 2 and the observed chemical shifts and peak heights are listed in Table 4. In earlier work (14) on a similar mixture, using field sweep methods, only two signals were observed and it was not possible to distinguish between a mixture of Se_2Cl_2 and Se_2Br_2 or formation of Se_2BrCl. In this work four signals were observed. The shifts at −9.11 and −110.93 ppm are readily assigned to Se_2Cl_2 and Se_2Br_2, respectively, from the shifts listed in Tables 2 and 3. The other two strong signals at −12.66 and 115.11 ppm must arise respectively from Se attached to Cl and to Br in Se_2BrCl and some halogen interchange reaction, according to

[12] $Se_2Br_2 + Se_2Cl_2 \overset{K''}{=} 2\,Se_2BrCl$

must take place. Using peak heights as a measure of concentration, K'' is estimated to be 3 but this estimate must be high, since the signal center at the base lies much loser to the Se_2Cl_2 and Se_2Br_2 peak positions than to those of Se_2BrCl, indicating that the Se_2BrCl peaks are weaker than those of the pure chloride and bromide. The apparent stronger signal for Se_2Cl_2 than for Se_2Br_2, which is the opposite of that expected from the stoichiometric ratio, is due to the differing degree of overlap with the Se_2BrCl signals. Three very weak peaks appear in the spectrum and these are assigned in Table 4 to small concentrations of disproportionation products.

Conclusion

The dihalides of selenium are regarded, for the most part, as molecules stable at high temperature in the gas phase but, more recently, $SeCl_2$ and $SeBr_2$ have been shown to be present in significant concentrations in aprotic solvents (9, 17), aqueous solution (18, 19) and now in equilibrium in diselenium dihalides. Selenium dihalide is present in higher molar concentration in Se_2Br_2 than in Se_2Cl_2, which parallels the relative stability of the dihalides in acetonitrile (9).

The presence of SeX_2 and Se_nX_2 species in pure Se_2X_2 results

in weak bands appearing in the reported spectra of these molecules (3–6), which have been assigned to vibrational modes of Se_2X_2 molecules. A reconsideration of the spectral assignment for these compounds will be necessary.

A low-temperature study of the magnetic properties of the molecular cations O_2^+, Br_2^+, and I_2^+

M. S. R. CADER, R. C. THOMPSON, AND F. AUBKE[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received May 4, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of this 65th birthday

M. S. R. CADER, R. C. THOMPSON, and F. AUBKE. Can. J. Chem. **67**, 1942 (1989).

Magnetic susceptibility measurements to 4.2 K are reported for $O_2^+[AsF_6]^-$, $Br_2^+[Sb_3F_{16}]^-$, and $I_2^+[Sb_2F_{11}]^-$. The data are interpreted utilizing previous results from photoelectron spectroscopy, known crystal structures, magnetic studies on the superoxide ion and the ozonide ion, and in the case of $O_2^+[AsF_6]^-$, previous ESR studies. The magnetic properties of the three materials are quite different. $Br_2^+[Sb_3F_{16}]^-$ obeys Curie–Weiss law between 80 and 4 K: $C_m = 0.49 \pm 0.01$ cm^3 mol^{-1} K and $\theta = -0.74 \pm 0.01$ K (with TIP = 120×10^{-6} cm^3 mol^{-1}). The magnetic moment decreases slightly from 2.04 μ_B at room temperature to 1.93 μ_B at 4 K. $I_2^+[Sb_2F_{11}]^-$ exhibits relatively strong antiferromagnetic coupling with a maximum in χ_M observed at −54 K. The magnetic moment (corrected for a TIP contribution of 68×10^{-6} cm^3 mol^{-1}) decreases from 1.92 μ_B at 124 K to 0.41 μ_B at 4 K. Experimental susceptibilities for this compound over the range 300–4 K have been compared to values calculated using three different theoretical models for extended chains of antiferromagnetically coupled paramagnetic species. $O_2^+[AsF_6]^-$ exhibits Curie–Weiss behaviour over the range 60–2 K ($C_m = 0.34 \pm 0.01$ cm^3 mol^{-1} K, $\theta = -1.90 \pm 0.01$ K). The magnetic moment, uncorrected for TIP, varies from 1.63 μ_B at 80 K to 1.17 μ_B at 2 K, and the presence of weak antiferromagnetic coupling in this material is suggested.

Key words: magnetic susceptibilities, dihalogen cations, dioxygenyl cation, low temperature behaviour.

M. S. R. CADER, R. C. THOMPSON et F. AUBKE. Can. J. Chem. **67**, 1942 (1989).

On rapporte les résultats de mesures de susceptibilité magnétique, effectuées à 4,2 K sur $O_2^+[AsF_6]^-$, sur $Br_2^+[Sb_3F_{16}]^-$ et sur $I_2^+[Sb_2F_{11}]^-$. On interprète les résultats en utilisant les resultats obtenus antérieurement à l'aide de la spectroscopie photoélectronique, de la diffraction des rayons-X, d'études magnétiques sur l'ion superoxyde et sur l'ion ozonide et, dans le cas de $O_2^+[AsF_6]^-$, à l'aide d'études rpe antérieures. Les propriétés magnétiques de ces trois composés sont très différentes. Entre 80 et 4 K, le produit $Br_2^+[Sb_3F_{16}]^-$ obéit à la loi de Curie–Weiss: $C_m = 0{,}49 \pm 0{,}01$ cm^3 mol^{-1} K et $\theta = -0{,}74 \pm 0{,}01$ K (avec TIP = 120×10^{-6} cm^3 mol^{-1}). Le moment magnétique diminue un peu, de 2,04 μ_B à la température ambiante à 1,93 μ_B à 4 K. Le $I_2^+[Sb_2F_{11}]^-$ présente un couplage antiferromagnétique relativement important; le maximum de χ_M est observé à ~54 K. Le moment magnétique (corrigé pour une contribution de TIP de 68×10^{-6} cm^3 mol^{-1}) diminue de 1,92 μ_B à 124 K à 0,41 μ_B à 4 K. On a comparé les susceptibilités expérimentales de ce composé, de 300 à 4 K, avec les valeurs calculées à l'aide de trois modèles théoriques différents pour des longues chaînes d'espèces paramagnétiques couplées d'une façon antiferromagnétique. Aux températures allant de 60 à 2 K, le $O_2^+[AsF_6]^-$ présente un comportement de Curie–Weiss ($C_m = 0{,}34 \pm 0{,}01$ cm^3 mol^{-1} K, $\theta = -1{,}90 \pm 0{,}01$ K). Le moment magnétique, non-corrigé pour une contribution de TIP, varie de 1,63 μ_B à 80 K à 1,17 μ_B à 2 K; ces données suggèrent la présence d'un faible couplage antiferromagnétique dans ce composé.

Mots clés : susceptibilités magnétiques, cations de dihalogène, cation de dioxygényle, comportement à basse température.

[Traduit par la revue]

Introduction

Only a limited number of compounds with paramagnetic homonuclear ions of non-metallic main group elements are known. Of these, compounds with diatomic cations stabilized by very weakly basic fluoroanions are the subject of this study. The cations in this group consist of the dioxygenyl cation O_2^+, first discovered in $O_2^+[PtF_6]^-$ by Bartlett and Lohmann (1), and the two dihalogen cations I_2^+ and Br_2^+, first identified in strong acid and superacid solutions by Gillespie *et al.* (2, 3).

Single crystal X-ray diffraction studies were subsequently reported for $Br_2^+[Sb_3F_{16}]^-$ (4) and $I_2^+[Sb_2F_{11}]^-$ (5), while powder diffraction studies have afforded a more limited structural insight into a number of dioxygenyl salts (6). For the dihalogen cations, electronic spectra of the solvated species (2, 3), resonance Raman spectra (7), and magnetic measurements at room temperature (2, 4*a*) have allowed some information on the electronic structure, suggesting a $^2\Pi_{3/2g}$ ground state (10). In addition, a study by Herring and McLean (8) has pointed to a strong similarity between the solvated cations $I_2^+{}_{(solv)}$ and $Br_2^+{}_{(solv)}$ and their gaseous counterparts as studied by photoelectron spectroscopy (9) or molecular spectroscopy (10). This connection should permit at least an approximation of the energy separation to the nearest excited states, not only for the dihalogen cations, but also for O_2^+, where a $^2\Pi_{1/2g}$ ground state is suggested (10).

The present study involving low-temperature magnetic susceptibility measurements on suitable compounds containing the three homonuclear diatomic cations has four objectives: (*i*) To compare the magnetic behaviour of what appear to be the only three suitable paramagnetic molecular cations formed by non-metals. Structural and spectroscopic information discussed above should help in the interpretation. (*ii*) To see whether, and to what extent, van Vleck's theory of molecular paramagnetism (11), developed almost 60 years ago, can be applied to solid-state cations. So far, nitric oxide, NO, has served as the best example; however, useful experimental data for this molecule do not extend into the condensed phase. (*iii*) To examine reasons why the magnetic moments reported so far for O_2^+ salts (discussed below) fall well below the spin-only value of 1.73 μ_B. Measurement down to very low temperatures should allow detection of antiferromagnetic coupling, which is a possible cause for reduced magnetic susceptibilities. (*iv*) To compare the magnetic susceptibilities of $I_2^+[Sb_2F_{11}]^-$ and $Br_2^+[Sb_3F_{16}]^-$ below 80 K, since earlier measurements above that temperature (12) had suggested antiferromagnetic coupling for $I_2^+[Sb_2F_{11}]^-$, but not for $Br_2^+[Sb_3F_{16}]^-$.

Experimental

Both $Br_2^+[Sb_3F_{16}]^-$ and $I_2^+[Sb_2F_{11}]^-$ were synthesized according to the method reported by Wilson *et al.* (12). This method involves the oxidation of previously purified Br_2 and resublimed I_2 by bis(fluorosulfuryl) peroxide, $S_2O_6F_2$, at a precise 2:1 mole ratio, and the subsequent solvolysis of the product mixture in an excess of freshly distilled antimony(V) fluoride. The reactions were followed by weight and the purity checked by melting points.

$Br_2^+[Sb_3F_{16}]^-$ (4.777 g or 5.762 mmol) was obtained from 0.924 g (5.782 mmol) of Br_2 and 0.5724 g (2.891 mmol) of $S_2O_6F_2$ after solvolysis in about 10 g of SbF_5 at room temperature and removal of all volatiles *in vacuo*. The bright red solid melted at 84 ± 1°C (lit. 85.5°C) (12).

$I_2^+[Sb_2F_{11}]^-$ (2.775 g or 3.928 mmol) was obtained from 0.9986 g (3.934 mmol) I_2 and 0.3895 g (1.967 mmol) of $S_2O_6F_2$ and subsequent solvolysis in ~12 g of SbF_5 at 50°C. The black–blue solid obtained after removal of all volatiles melted at 129 ± 1°C (lit. mp 127°C) (12).

A sample of $O_2^+[AsF_6]^-$ was obtained from Dr. Karl O. Christe of Rocketdyne. The compound was synthesized by UV photolysis of O_2, F_2, and AsF_5 in quartz. A Princeton Applied Research model 155 vibrating sample magnetometer was used to obtain magnetic susceptibilities in the 2.0–124 K range. Details on the instrument have been published previously (13). Magnetic field strengths of 7501, 9225, and 9625 G were used and temperatures lower than 4 K were achieved by pumping on the sample chamber. Samples of ~200–300 mg were loaded into Kel-F capsules. All hygroscopic solids were handled in a Vacuum Atmospheres Corp. "Dri-Lab" model No. H3-493, filled with purified dry N_2 and equipped with a Dri-Train circulating unit. Molar magnetic susceptibilities, χ_M, listed in Tables 1 and 2, are corrected for diamagnetism, with the corrections given in Table 3. For $Br_2^+[Sb_3F_{16}]^-$ and $I_2^+[Sb_2F_{11}]^-$, slightly larger χ_{dia} values are used than reported previously (12). The magnetic moments given in Tables 1 and 2 for the Br_2^+ and I_2^+ compounds are corrected for temperature-independent paramagnetism (TIP = 120 and 68 × 10^{-6} cm^3 mol^{-1}, respectively, calculated as described in the text). The Curie–Weiss law in the form $\chi_M = C_m/(T - \theta)$ is used throughout. Pertinent structural and spectroscopic features of the three compounds studied and of the three cations, O_2^+, Br_2^+, and I_2^+, either as solvated or gaseous species, are summarized in Table 3.

Results and discussion

The discussion will center around three aspects: (*i*) the selection of suitable compounds for this study in the light of previous magnetic susceptibility studies; (*ii*) the magnetic measurements on $O_2^+[AsF_6]^-$, $I_2^+[Sb_2F_{11}]^-$, and $Br_2^+[Sb_3F_{16}]^-$; and (*iii*) an attempted interpretation of these results.

Magnetic measurements in our laboratory on the compounds in the current study require ~300–500 mg of high-purity sample for duplicate measurements when the vibrating sample magnetometer is used, while the Gouy measurements require between 1–2 g. All cations are extremely reactive and only I_2^+ is sufficiently stable in HSO_3F–SbF_5 solution (2, 12), not undergoing disproportionation or further oxidation. This rules out purification by recrystallization as a general procedure for all three salts. The limited thermal stability of all materials reported so far precludes purification by sublimation. Hence, synthesis on the desired scale from highly pure starting materials, with little or no chance for side-reactions and facile product isolation, becomes the only route to materials for the intended study.

There appears to be no real choice among the Br_2^+ containing compounds, because necessary details on $Br_2^+[AsF_6]^-$ (14), the only other Br_2^+ salt, are not readily available. The original synthesis of $Br_2^+[Sb_3F_{16}]^-$ (4), from BrF_5, Br_2, and SbF_5, did produce a sample suitable for a single-crystal X-ray diffraction study, but judging by the reported physical data, in particular

the melting point and a magnetic moment of $\mu_{eff} \sim 1.6\mu_B$, the method appears to be unsuited for our purpose. Similarly, the method used for the preparation of single crystals of $I_2^+[Sb_2F_{11}]^-$ (5), the oxidation of I_2 by SbF_5 in SO_2, is not suited for preparation on a large scale, as is evident from the reported analytical data (5). The problem appears to be the quantitative separation of the by-products SbF_3 or $SbF_3 \cdot SbF_5$. Formation of anions of the type $Sb_3F_{14}^-$ becomes a possibility and, in addition, a diamagnetic compound of the composition $I_4^{2+}[(SbF_6)\text{-}(Sb_3F_{14})]^{2-}$ has recently been obtained by this synthetic route (15) with reaction conditions only slightly different. Substitution of SO_2 by AsF_3 as solvent, appears to lead to $I_2^+[Sb_2F_{11}]^-$ of higher purity, but $I_2^+[Sb_3F_{16}]^-$ may form as a by-product as well (16). Any uncertainty in the molar mass of the product will limit the usefulness of a magnetic study. Other materials not deemed suitable for our magnetic studies include the substances formulated as $(SbF_5)_2I$ (17) and the insufficiently characterized $I_2^+[TaF_6]^-$ (17).

An alternate synthetic route to both $I_2^+[Sb_2F_{11}]^-$ and $Br_2^+[Sb_3F_{16}]^-$, the oxidation of I_2 or Br_2 by stoichiometric amounts of bis(fluorosulfuryl) peroxide and subsequent solvolysis in an excess of SbF_5 according to:

$$[1]\quad 2I_2 + S_2O_6F_2 + 8SbF_5 \xrightarrow{50°C} 2I_2^+[Sb_2F_{11}]^- + 2Sb_2F_9SO_3F$$

$$[2]\quad 2Br_2 + S_2O_6F_2 + 10SbF_5 \xrightarrow{25°C} 2Br_2^+[Sb_3F_{16}]^- + 2Sb_2F_9SO_3F$$

has produced sufficiently large quantities of both compounds for a magnetic study between 298 and 80 K using the Gouy technique (12). With all starting materials readily purified and the volatile reaction product $Sb_2F_9SO_3F$ (18) easily separated from the product, this method, employed in the present study as well, is applicable to the synthesis of both $I_2^+[Sb_2F_{11}]^-$ and $Br_2^+[Sb_3F_{16}]^-$.

With well over a dozen different O_2^+ salts reported so far, this group of compounds appears to offer a wider choice, but here additional problems surface, which seem to have adversely affected earlier magnetic studies. Some of the reported compounds, $O_2^+[PtF_6]^-$ (1), $O_2^+[PdF_6]^-$ (19), $O_2^+[RuF_6]^-$ (20), or $O_2^+[RhF_6]^-$ (20) have two different paramagnetic centers in the same molecular unit. The initial approach by Bartlett and Beaton (21) involving the subtraction of the molar susceptibilities of $NO^+[PtF_6]^-$ from those obtained for $O_2^+[PtF_6]^-$ has clearly allowed identification of O_2^+ as a paramagnetic ion; however, magnetic exchange between O_2^+ and Pt(V)(d^5) is a plausible contributing cause for the observed decreasing trend of the magnetic moments attributed to O_2^+ with decreasing temperature. Magnetic ordering due to $O_2^+ \cdots Pt(V)$ exchange has subsequently been reported for this compound (23).

In addition, the high-pressure synthesis of dioxygenyl salts from O_2–F_2 mixtures and either metal fluorides or the metal itself (20, 22, 24) in metal reactors has often resulted in materials with ferromagnetic contamination (19, 23). While monel impurities can be recognized by the characteristic Curie temperature of 335 K and corrections have been attempted (23) in magnetic susceptibility studies, such materials remain suspect where the possibility of weak antiferromagnetic ordering exists.

Ultraviolet photolysis in quartz vessels (25) represents a more suitable synthetic method, but a number of the O_2^+ salts such as $O_2^+[BF_4]^-$ (26) and $O_2^+[GeF_5]^-$ (27) show rather limited thermal stability. Nevertheless, a magnetic study of $O_2^+[BF_4]^-$ between 293 and 85 K has been reported (28*a*), but only limited conclusions were reached. For the products obtained from the reaction of O_2 and F_2 with SbF_5 by either UV photolysis or high-pressure synthesis, some structural ambiguity exists. Both $O_2^+[SbF_6]^-$ and $O_2^+[Sb_2F_{11}]^-$ are well characterized (6, 24), and $O_2^+[Sb_3F_{16}]^-$ has been postulated as well (29). The problems caused by this structural ambiguity are apparent from magnetic susceptibility studies on "$O_2^+[SbF_6]^-$" reported in the Russian literature (28).

To avoid similar problems, $O_2^+[AsF_6]^-$ obtained by UV photolysis (25) was chosen for our study. An additional reason for this choice is the availability of structural information. A phase transition at 255 ± 3 K (30) results in a rhombohedral distortion of the cubic structure found at room temperature (6). This distortion is also evident from ESR studies down to 4 K (23, 31); in this work conclusions regarding the ground state of O_2^+ in this compound are useful in the interpretation of our results.

There have been two previous magnetic susceptibility studies of $O_2^+[AsF_6]^-$ down to 4 K, with rather contradictory results. In a study by Grill *et al.* (32), no ordering of the O_2^+ cations is observed down to 4 K, while weak $O_2^+ \ldots O_2^+$ exchange is suggested in another study (23) based on the small Weiss constant obtained. However, these conclusions are rendered somewhat tenuous because of ferromagnetic monel impurities in the sample, requiring correction of the susceptibility data (23).

In all previous magnetic susceptibility studies of O_2^+ salts, the magnetic moments obtained over the whole temperature range are well below the spin-only value of 1.73 μ_B, and explanations have varied from suggesting "van-Vleck behaviour" (22) in analogy to the behaviour of NO (11), to invoking the presence of 17% of an unidentified, magnetically inert impurity in $O_2^+[AsF_6]^-$ (32). Likewise in some studies down to 80 K (28), μ_{eff} values for $O_2^+[SbF_6]^-$ appear to decrease with decreasing temperature, while for the structurally related $O_2^+[AsF_6]^-$, μ_{eff} is said to be invariant with temperature to 4 K (32). It is unclear why there are so many discrepancies and contradictions in previous studies. It is felt, however, that sample identity and purity play a major role here.

The results of our magnetic susceptibility studies on $Br_2^+[Sb_3F_{16}]^-$ below 80 K, together with results obtained in our earlier study (12) at higher temperatures, are summarized in Table 1. Both sets of χ_M and μ_{eff} data have been calculated using the same diamagnetic correction and TIP values (279 and 120×10^{-6} cm^3 mol^{-1}, respectively). The agreement between the data sets in the overlap region is excellent for this compound. The data obtained here for $I_2^+[Sb_2F_{11}]^-$ and $O_2^+[AsF_6]^-$ are given in Table 2. Because of poor agreement in the 100-K region with the earlier Gouy data (12), we extended the current studies with the vibrating sample magnetometer up to 124 K for the I_2^+ compound. We also extended our studies on the O_2^+ compound down to 2 K in the hope (not realized, unfortunately) of observing a maximum in the susceptibility of this compound at very low temperatures. The contrast in the magnetic properties of the three paramagnetic cationic species studied in this work is clearly evident from the plots of magnetic moment versus temperature shown in Fig. 1. Two of the compounds, $O_2^+[AsF_6]^-$ and $Br_2^+[Sb_3F_{16}]^-$, exhibit Curie–Weiss behaviour over a wide temperature range, as is seen by the plots of χ_M^{-1} versus T given in Fig. 2.

The magnetic behaviour of $Br_2^+[Sb_3F_{16}]^-$ appears to be rather straightforward and will be discussed in detail first. The χ_M^{-1} versus T plot for this compound indicates Curie–Weiss law behaviour over the temperature range from 80–4 K ($C_m = 0.49 \pm 0.01$ cm^3 mol^{-1} K, $\theta = -0.74 \pm 0.01$ K). The magnetic moments (even when corrected for TIP) decrease slightly with temperature. A TIP correction had been arbitrarily assigned in the earlier work (12) in order to bring the magnetic moment in the high-temperature region into agreement with the value of 2.0 μ_B predicted by theory (11) for a species with a $^2\Pi_{3/2g}$ ground state and no thermally accessible excited state (see Table 3). The correction for TIP in the present study was taken as $4N\beta^2/3\Delta E$ (33), where ΔE is the energy separation between the ground $^2\Pi_{3/2g}$ and the excited $^2\Pi_{1/2g}$ state with which it is mixing. The ΔE value for Br_2^+ is the spin–orbit coupling constant, λ, for this species, estimated at 2890 cm^{-1} for the solvated ion (Table 3), and using this value a TIP of 120×10^{-6} cm^3 mol^{-1} is calculated. Magnetic moments calculated using this TIP correction are within ±2% of the theoretical value of 2.0 μ_B over the very wide temperature range of 297–55 K (Table 1). The cause of the very small drop in the moment,

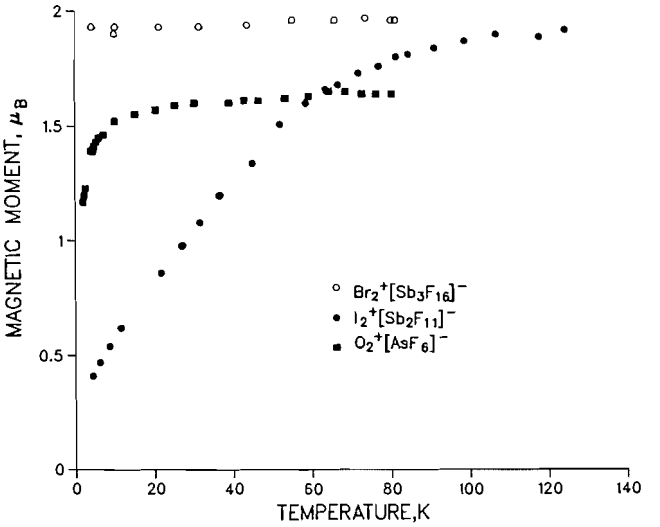

FIG. 1. Magnetic moment versus temperature plots.

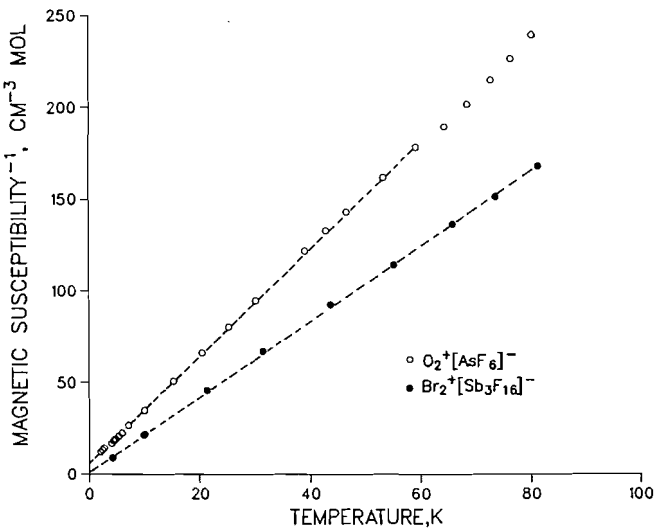

FIG. 2. Plots of inverse susceptibility versus temperature for $O_2^+[AsF]_6^-$ and $Br_2^+[Sb_3F_{16}]^-$.

particularly at the lowest temperatures (corresponding to the effect of a Curie–Weiss rather than Curie law behavior) is not certain. Although the shortest non-bonding Br···Br contact at 6.445 Å (46) is too long to invoke significant direct magnetic interaction, F···Br contacts ranging from 2.86–3.34 Å, comparable to or shorter than the sum of the van der Waals radii of 3.32 Å (34), suggest the possibility of very weak exchange via bridging anions. In any event, the effect is very minor and it is reasonable to conclude that in $Br_2^+[Sb_3F_{16}]^-$ the Br_2^+ cation is in a thermally isolated $^2\Pi_{3/2g}$ ground state and there is no conclusive evidence for any magnetic coupling between paramagnetic centers down to 4.2 K. In this regard $Br_2^+[Sb_3F_{16}]^-$ is somewhat unique, since for all other paramagnetic main group species, including O_2^- (35), the recently studied ozonides, KO_3, RbO_3, and CsO_3 (36), and solid O_2 (37), as well as I_2^+ and O_2^+ (discussed below), at least weak antiferromagnetic coupling has been suggested.

The magnetic properties of $O_2^+[AsF_6]^-$ are similar to those of the Br_2^+ compound in that Curie–Weiss law behavior is followed (Fig. 2), although over a more limited temperature range of 60–2 K. Here the Curie constant, C_m, is significantly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

smaller and the absolute value of the Weiss constant, $|\theta|$, greater ($C_m = 0.34 \pm 0.01$ cm^3 mol^{-1} K, $\theta = -1.90 \pm 0.01$ K). Consequently, the effective magnetic moments are significantly smaller for $O_2^+[AsF_6]^-$ and show a stronger temperature dependence, particularly in the low temperature region (Fig. 1). We note a slight departure from linear behaviour in the Curie–Weiss plot (Fig. 2) above 60 K. This may be significant, as it coincides with the observed broadening of the ESR line (23), possibly caused by tumbling motions of O_2^+ in the crystal lattice. These findings are at variance with a previous report by Grill *et al.* (32), who first found Curie–Weiss behaviour with a positive θ value (according to our formulation of the law) of 0.7 K. Our results are in reasonable agreement with those of DiSalvo *et al.* (23), who obtained $C_m = 0.309$ cm^3 mol^{-1} K and $\theta = -0.8$ K (sign changed from ref. 23 to conform to our formulation of the law), although it must be taken into consideration that a temperature-independent paramagnetism contribution was allowed for in the earlier work and corrections for ferromagnetic impurities had to be made. In our study we chose not to correct the susceptibilities for TIP. A crystal-field analysis of ESR data for $O_2^+[AsF_6]^-$ suggests the separation between the ground and first electronic excited state is 1480 cm^{-1}, caused by both spin–orbit coupling and crystal-field splitting due to O_2^+ being in a site of orthorhombic or lower symmetry (31). In this case one is clearly not dealing with pure $^2\Pi_{1/2g}$ and $^2\Pi_{3/2g}$ states and it is not clear what the TIP correction should be. In any event, the large separation between the states means such a correction will be small, and hence ignoring it should not significantly affect our conclusions.

Turning to the question of the magnitude of the magnetic moment we observe for $O_2^+[AsF_6]^-$ in the higher temperature region, moments in the range of 1.6 μ_B agree well with values predicted using the average g values, g_{ave} of 1.89 (23) and 1.905 (31) obtained by ESR. As described by Goldberg *et al.* (31), both crystal-field splitting and spin–orbit coupling contribute to the ground state in $O_2^+[AsF_6]^-$. In a pure $^2\Pi_{1/2g}$ ground state the spin and orbital contributions cancel, and there is no first-order paramagnetism associated with this state (33). If this were the case for O_2^+ with negligible thermal population of excited states, only temperature-independent paramagnetism would be present. This is clearly not the case here. The crystal-field interactions have the effect of quenching the orbital contribution, although not completely, resulting in a μ_{eff} value slightly below the spin-only value. Quite the opposite effect is observed for the alkali metal superoxides, MO_2 with M = Na, K, Rb, Cs (35). Here the ground state is $^2\Pi_{3/2g}$ and in all instances the μ_{eff} values are well above the spin-only value of 1.73 μ_B, as was found for $I_2^+[Sb_2F_{11}]^-$ and $Br_2^+[Sb_3F_{16}]^-$ (12).

Returning to $O_2^+[AsF_6]^-$, the decrease in μ_{eff} with decreasing temperature, particularly significant below ~20 K, requires futher consideration. With a splitting of 1480 cm^{-1} separating the ground state from the nearest excited state, the variation in the effective magnetic moment with temperature observed here cannot be accounted for by the sort of van Vleck behaviour observed for gaseous NO (33). The possibility of antiferromagnetic exchange between paramagnetic centers must be considered.

The limited structural information available on $O_2^+[AsF_6]^-$ (25, 31, 38) derived from powder diffraction data does not permit an accurate determination of the shortest O···O nonbonding contact distance. Estimates of 4.00 (30*b*) and 4.05 Å (32) respectively, used to argue against O···O interaction, are simply the unit cell length a_0 divided by 2 for the room-temperature phase (25, 31, 38). The distance $a_0/2$ describes the separation between the mass centers of the O_2^+ cations, assumed to be in the most probable sites. The low-temperature phase, which is directly relevant to our study, has a powder diffraction pattern that has not been successfully indexed (30); hence the conclusion (32) that there can be no antiferromagnetic exchange in $O_2^+[AsF_6]^-$ because the O_2^+ ions are too far apart is most likely invalid.

For $O_2[Mn_2F_9]$, where a single crystal X-ray diffraction study at room temperature and at −150°C is reported (39), non-bonding O···O contacts of 3.86 Å are detected at −150°C with values of 3.98 Å observed at room temperature. However, the anion is described as a double chain of *cis*-bridged MnF_6-octahedra with O_2^+ cations between the anion layers, and the resulting structure is not comparable with that of $O_2^+[AsF_6]^-$. Moreover, studies on this material would not be suitable for our purposes as the magnetism would be complicated by the presence of Mn^{4+}, a second paramagnetic center.

With the sum of the van der Waals radius 3.02 Å for oxygen, one would reasonably expect distances of 3.2–3.3 Å as the limit for significant direct antiferromagnetic exchange. This estimate is corroborated by recent reports on the structures of the alkali metal ozonides KO_3 (40–42), RbO_3 (40, 41), and CsO_3 (43), which all exhibit more significant antiferromagnetism (34) than found for $O_2^+[AsF_6]^-$, and where O···O nonbonding contacts range between 3.01–3.15 Å for KO_3 and 3.01–3.30 Å for RbO_3, respectively. For CsO_3, where antiferromagnetic exchange is rather weak (36), only powder data are reported (43) and indexed suggesting CsO_3 to be iso-structural with RbO_3. The unit-cell dimensions indicate slightly longer O···O contacts for this compound (42). Contact distances of the order of those observed in the ozonides could be present in $O_2^+[AsF_6]^-$ and this could account for its observed magnetic properties. In summary, there appears to be weak antiferromagnetic coupling in $O_2^+[AsF_6]^-$ that may involve either super-exchange through intervening AsF_6^- anions (the smallest anion of the three encountered in this study) or even direct weak O···O interaction.

In our previous report on $I_2^+[Sb_2F_{11}]^-$ we showed that a TIP correction in excess of that assumed for the Br_2^+ compound was required to bring the experimental room-temperature moment into agreement with the value of 2.00 μ_B required by theory (12). In addition, it was suggested in the earlier work that the observed decrease in the magnetic moment on decreasing temperature to 80 K may arise from antiferromagnetic exchange between contiguous I_2^+ cations in the solid lattice. Our studies to 4.2 K reported here confirm the presence of antiferromagnetic coupling. The susceptibility rises to a maximum at ~54 K, then decreases on further cooling (Fig. 3). The rise again in susceptibility on cooling below ~10 K is probably due to trace amounts of paramagnetic structural impurity, as is often observed in antiferromagnetically coupled systems (13). In view of the clear evidence that this system is exchange-coupled, there is no justification for arbitrarily reducing the room-temperature moment to 2.00 μ_B with an appropriate TIP correction, as was done previously (12). Indeed, in view of the fact that the $^2\Pi_{3/2g}$–$^2\Pi_{1/2g}$ separation is significantly greater in the I_2^+ compound compared to Br_2^+, any TIP would be expected to be smaller in the former. TIP for I_2^+ calculated as described above for Br_2^+ is 68×10^{-6} cm^3 mol^{-1}. Magnetic moments calculated employing this value of TIP are given in Table 2. The decrease in μ_{eff} with decreasing temperature is con-

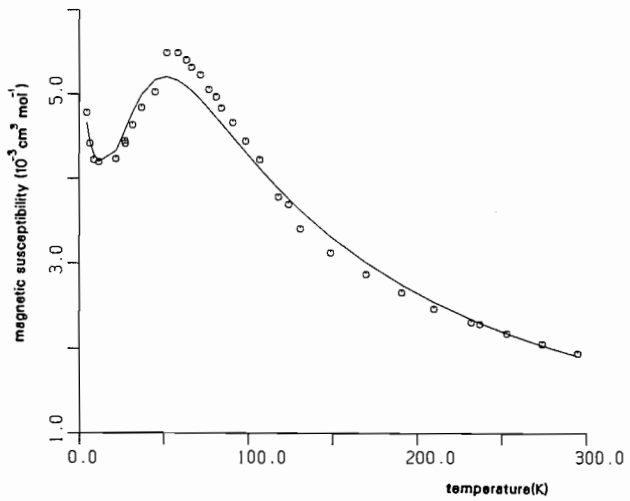

FIG. 3. Magnetic susceptibility versus temperature plot for $I_2^+[Sb_2F_{11}]^-$. Circles are experimental data. Solid line is the best fit to the Ising $S' = 1/2$ model.

sistent with antiferromagnetic coupling; interestingly though, the absolute values in the high-temperature region are in excess of the theoretically predicted value of 2.0 μ_B (11).

We have attempted to analyze our magnetic susceptibility data (including the data from 295–130 K from ref. 12) according to three theoretical models for antiferromagnetic exchange in one-dimensional systems. Considering the $^2\Pi_{3/2g}$ ground state of I_2^+ as having an effective spin, $S' = 3/2$ (44), we fitted the data to the model developed by Weng (45) employing the equations and appropriate coefficients given by Hiller *et al.* (46). The best fit of the data was with $J = -7.2$ cm^{-1}, the effective $g = 1.23$, and % paramagnetic impurity, $\%p$, = 0.35. The value of the fitting function, F (defined in ref. 47) was 0.0560. This model employs the isotropic Heisenberg Hamiltonian. In view of the molecular anisotropy of the magnetic species, the anisotropic Ising model should be examined. Unfortunately, while an exact solution exists for the parallel susceptibility of the Ising $S = 3/2$ case (48), there is no solution for the perpendicular case and hence we cannot analyze our powder data according to this model.

An alternative approach to the data analysis is to consider the possibility that the four-fold degeneracy of the ground $^2\Pi_{3/2g}$ state has been lifted by second- or higher-order interactions with excited states, leaving a thermally isolated Kramer's doublet as the only significantly thermally populated ground level. In this case one needs to consider an effective spin, $S' = 1/2$, and here both Heisenberg and Ising models are available. Employing the Weng model (45), again with appropriate coefficients taken from the paper of Hiller *et al.* (46), we obtained a best fit between theory and experiment with $J = -28$ cm^{-1}, effective $g = 2.72$ and $\%p = 0.61$ ($F = 0.0487$). Exact solutions for both the parallel and perpendicular susceptibilities for the Ising $S' = 1/2$ case are available, and we analyzed our data using the equation of Fisher (49) (assuming $\chi_{powder} = (1/3)\chi_\parallel + (2/3)\chi_\perp$), the best fit being obtained with $J = -38$ cm^{-1}, effective $g = 2.61$ and $\%p = 0.54$ ($F = 0.0368$). The agreement between experiment and theory for this Ising $S' = 1/2$ case is illustrated in Fig. 3, where the solid line is calculated from theory. The agreement between experiment and theory for the other two models is visually very similar to that shown in Fig. 3, although in both cases the agreement is slightly poorer, as is indicated by the higher F values. In all three cases, as the temperature is lowered the experimental susceptibilities rise more steeply to a higher maximum value and then decrease more steeply as compared to the calculated susceptibilities.

The analysis of the magnetic susceptibility data clearly indicates that contiguous I_2^+ ions in the lattice of $I_2^+[Sb_2F_{11}]^-$ are relatively strongly antiferromagnetically coupled, although it does not provide a clear answer to the question of whether or not the thermally occupied ground state at low temperatures is a pure $^2\Pi_{3/2g}$ state. Measurements of magnetic susceptibilities at low temperatures on suitably oriented single crystals to obtain $\chi_\parallel$ values (47) would be informative, but would require the synthesis of relatively large crystals of the materials.

The major difference in magnetic behaviour betweeen Br_2^+ and I_2^+ is due to structural differences between $Br_2^+[Sb_3F_{16}]^-$ and $I_2^+[Sb_2F_{11}]^-$. Magnetic exchange through contiguous I_2^+ ions is suggested by the crystal structure of $I_2^+[Sb_2F_{11}]^-$ (6). The shortest I...I nonbonding contact is with 4.29 Å comparable to the sum of the van der Waals radii of 3.96 Å. In $Br_2^+[Sb_3F_{16}]^-$ (4*b*) the shortest Br...Br contact is with 6.445 Å about 2.8 Å longer than the van der Waals distance, and direct magnetic exchange becomes improbable as discussed above.

Finally, it is important to note that the antiferromagnetic coupling observed here for $I_2^+[Sb_2F_{11}]^-$ is distinctly different from the dimerization process suggested for $I_2^+{}_{(solv)}$ in HSO_2F (2), just as the solid-state structure of $I_2^+[Sb_2F_{11}]^-$ differs from the structures of $I_4^{2+}[AsF_6^-]_2$ and $I_4^{2+}[(SbF_6)(Sb_3F_{14})]^{2-}$ (15) where square planar, diamagnetic I_4^{2+} cations are found.

On pentavalent perfluoroorgano bismuth compounds

W. TYRRA AND D. NAUMANN[1]

Fachbereich Chemie, Universität Dortmund, Postfach 500 500, 4600 Dortmund 50, Federal Republic of Germany

Received December 16, 1988

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

W. TYRRA and D. NAUMANN. Can. J. Chem. **67**, 1949 (1989).

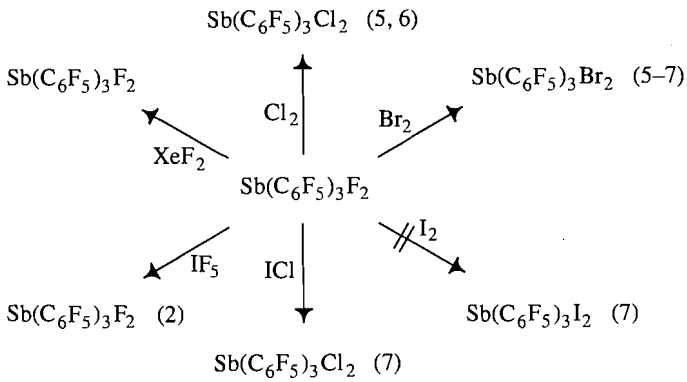
The reactions of $Bi(R_f)_3$ ($R_f = CF_3$, C_6F_5) with a series of oxidizing halogenation reagents have been investigated. From the reactions of $Bi(R_f)_3$ with Cl_2, Br_2, I_2, ICl, and IF_5 no oxidation to Bi(V) compounds can be detected; in all cases the Bi(III) halides and the corresponding R_fX compounds are formed. Only the reaction of $Bi(C_6F_5)_3$ with XeF_2 yields the perfluoroorgano bismuth(V) compound $Bi(C_6F_5)_3F_2$.

Key words: bismuth perfluoroorganic compounds, polar perfluoroorganylations, oxidation with xenon difluoride.

W. TYRRA et D. NAUMANN. Can. J. Chem. **67**, 1949 (1989).

On a étudié les réactions des composés $Bi(R_f)_3$ ($R_f = CF_3$, C_6F_5) avec une série de réactifs d'halogénation oxydants. Pour les réactions des produits $Bi(R_f)_3$ avec le Cl_2, le Br_2, le ICl et le IF_5, on n'a pas détecté la formation de composés du Bi(V); dans tous les cas, il y a formation d'halogénures de Bi(III) et des composés R_fX correspondants. Seule la réaction du $Bi(C_6F_5)_3$ avec le XeF_2 conduit à un composé perfluoroorganobismuth(V), le $Bi(C_6F_5)_3F_2$.

Mots clés : composés perfluoroorganobismuth, perfluoroorganylations polaire, oxydation avec XeF_2.



[Traduit par la revue]

Introduction

Tris(pentafluorophenyl)arsenic and -antimony difluoride can be prepared by reacting the tervalent compounds either with elemental fluorine (1) or xenon difluoride. Similar results were obtained by Frohn and Maurer (2) by reactions with iodine pentafluoride. Attempts to obtain tris(pentafluorophenyl)bismuth difluoride in a comparable way failed.

Until today only a few perfluoroorganobismuth(V) compounds could be synthesized (3). When we developed a new preparative method for the synthesis of tris(perfluoroorgano)-bismuth compounds (4) it was of interest to react tris(trifluoromethyl)bismuth and tris(pentafluorophenyl)bismuth with elemental chlorine, bromine, iodine, with iodine monochloride, iodine pentafluoride, and xenon difluoride to check their behaviour against oxidizers.

Comparable reactions with the corresponding antimony derivative have been carried out with the results given in the following scheme.

These results clearly show that tris(pentafluorophenyl)antimony can be oxidized by oxidizers stronger than iodine.

Though a great number of nonfluorinated aryl bismuth(V) compounds are known, no significant evidence has been found for alkyl or perfluoroorgano derivatives (8). The only hint for a pentavalent alkyl bismuth compound is given by Frohn and Maurer (2). Tri-*n*-butylbismuth difluoride can be detected by ^{19}F nmr spectroscopy from a reaction mixture of $(n\text{-}C_4H_9)_3Bi$ and IF_5 at −30°C in acetonitrile solution. Recently Schmuck and Seppelt reported some pentafluorophenyl bismuth(V) derivatives, e.g., $Bi(C_6F_5)_5$ (3).

Experimental

Materials

All commercially available compounds were purified by common methods. The preparations of $Bi(CF_3)_3$ and $Bi(C_6F_5)_3$ were carried out according to ref. 4, XeF_2 according to ref. 16, $[XeF][MF_6]$ according to ref. 17, and IF_5 according to ref. 18.

Nuclear magnetic resonance spectra

Bruker FT NMR spectrometer AM300; ^{19}F nmr, 282.41 MHz; ^1H nmr, 300.13 MHz; and ^{13}C nmr, 75.47 MHz.

General procedure

All reactions were carried out in a dry nitrogen atmosphere. The perfluoroorganobismuth compounds were dissolved in acetonitrile at room temperature. Before adding the corresponding reactant the solutions were cooled to −196°C and afterwards allowed to react at −30°C or room temperature, respectively; ^{19}F nmr spectroscopy was used for reaction control. The assignment of the signals was made in comparison with values given in the literature.

Tris(pentafluorophenyl)bismuth difluoride. Preparation and spectroscopic data

$Bi(C_6F_5)_3$ (1.42 g; 2 mmol) is dissolved in 10 mL CH_3CN in a Schlenk tube at room temperature and afterwards cooled to −196°C. A double excess of xenon difluoride (0.68 g; 4 mmol) is added to the frozen solution. The reaction mixture is allowed to warm to −30°C and stirred at this temperature until $Bi(C_6F_5)_3$ is no longer spectroscopically detected by ^{19}F nmr. The solvent, traces of pentafluorobenzene, and xenon difluoride are removed by vacuum condensation at 0°C. A white solid can be obtained, which contains no fluorine or hydrogen containing impurities. The yield is quantitative.

$Bi(C_6F_5)_3F_2$ is soluble in acetonitrile, chloroform, glyme, and dimethylformamide at room temperature without decomposition. It can be stored in glass flasks for several weeks at −10°C. Storage at room temperature or exposure to moisture or air leads to a decomposition of the compound.

Nuclear magnetic resonance data: ^{19}F nmr spectra, in Table 3; ^{13}C nmr (CH_3CN): δ(C1) 126.5 ppm, δ(C2,6) 139.8 ppm, δ(C3,5) 146.8 ppm, δ(C4) 146.2 ppm.

Mass spectrum (only mass fragments with $M > 160$ m/e): 748

(4.1%; $Bi(C_6F_5)_3F_2^+(M^+)$); 729 (2.3%; $Bi(C_6F_5)_3F^+$); 710 (6.5%; $Bi(C_6F_5)_3^+$); 581 (2.0%; $Bi(C_6F_5)_2F_2^+$); 562 (2.1%; $Bi(C_6F_5)_2F^+$); 543 (31.5%; $Bi(C_6F_5)_2^+$); 413 (31.5%; $Bi(C_6F_5)F_2^+$); 394 (19.1%; $Bi(C_6F_5)F^+$); 376 (52.9%; $Bi(C_6F_5)^+$); 334 (42.1%; $(C_6F_5)_2^+$); 303 (2.5%; BiF_5^+); 285 (2.1%; BiF_4^+); 266 (11.7%; BiF_3^+); 247 (14.2%; BiF_2^+); 228 (21.1%; BiF^+); 209 (53.6%; Bi^+); 187 (10.4%; $C_6F_6^+$); 168 (100%; $C_6F_5^+$).

Preparation of tris(pentafluorophenyl)antimony difluoride

To a solution of $Sb(C_6F_5)_3$ (1.93 g; 3.1 mmol) in 8 mL CH_3CN is added XeF_2 (0.56 g; 3.3 mmol) at −30°C. The reaction mixture is warmed to room temperature and allowed to react for about 2 days during which a white solid precipitates. Evaporation of the solvent and all volatile compounds left $Sb(C_6F_5)_3F_2$ as a colourless solid in quantitative yield (2.04 g; 99.6%). The spectroscopic data are identical to those in ref. 1.

Results and discussion

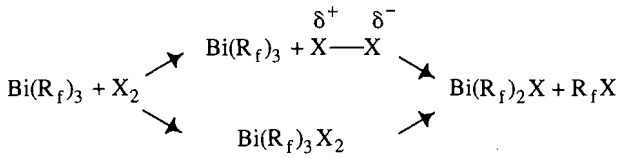
Reactions with elemental halogens

When we reacted $Bi(CF_3)_3$ and $Bi(C_6F_5)_3$ with elemental chlorine, bromine, or iodine, no oxidation occurred. In the case of the trifluoromethyl compound we could spectroscopically detect by ^{19}F nmr and assign the trifluorohalomethane and the intermediates $Bi(CF_3)_2X$ and $BiCF_3X_2$ (4). If tris(pentafluorophenyl)bismuth was used similar results were obtained but the intermediates could not be assigned clearly or were not observed.

$$Bi(R_f)_3 + X_2 \xrightarrow[CH_3CN]{} R_fX + Bi(R_f)_2X$$

$$Bi(R_f)_2X + X_2 \longrightarrow R_fX + BiR_fX_2$$

$$BiR_fX_2 + X_2 \longrightarrow R_fX + BiX_3$$



$$Bi(R_f)_3 + 3X_2 \longrightarrow 3R_fX + BiX_3$$

R_f: CF_3, C_6F_5; X: Cl, Br, I

No nmr spectroscopic evidence for bismuth(V) compounds was found. But these results do not prove unambiguously whether or not an intermediate pentavalent bismuth compound might have been formed.

The same product mixtures can be obtained either by a polar reaction of the perfluoroorgano bismuth with the halogen or a

decomposition of a bismuth(V) compound as shown below:

Reactions with interhalogens should give information about the possible reaction path.

Reactions with interhalogens

We previously described the reaction of tris(trifluoromethyl)-bismuth with iodine monochloride, forming quantitatively trifluoromethyliodide and bismuth trichloride (4). The reaction with the pentafluorophenyl derivative proceeds in the same manner, in contrast to the corresponding antimony compound (7).

$$Bi(R_f)_3 + 3ICl \rightarrow 3R_fI + BiCl_3$$

The fact that no R_fCl is formed provides evidence that these reactions proceed via a polar mechanism.

If we assume a bismuth(V) derivative, such as $Bi(C_6F_5)_3Cl_2$ or $Bi(C_6F_5)_3ClI$, subsequent decomposition will lead to the perfluoroorgano chlorine derivative.

To confirm this observation we carried out reactions of these compounds with iodine pentafluoride. Even with this strong oxidizing reagent no oxidation of the bismuth compounds was observed. The same results were obtained by Frohn und Maurer (8) using $Bi(C_6F_5)_3$ or $Bi(p\text{-}FC_6H_4)_3$. In no case was evidence found for bismuth(V) derivatives. Instead of oxidation a fluorine–aryl exchange takes place.

$$BiR_3 + 3IF_5 \rightarrow 3RIF_4 + BiF_3$$

R: CF_3; C_6F_5; $p\text{-}FC_6H_4$

These results clearly state that $Bi(R_f)_3$ is inert towards the oxidation of elemental halogens or interhalogens, but works as a powerful polar perfluoroorganylating reagent as found for perfluoroorgano cadmium complexes (4). This behaviour is proved by reactions with silver nitrate forming $[Ag(CF_3)_4]^-$, $[Ag(CF_3)_2]^-$, and CF_3NO (4, 9) as well as with $p\text{-}CH_3C_6H_4COCl$ forming the corresponding ketone.[2]

Reactions with xenon difluoride

Xenon difluoride and fluoro xenonium metallates are known to be excellent oxidizing fluorination reagents (11). It is also known that in acetonitrile solution XeF_2 dissociates into XeF^+ and F^- (12). The fluoroxenonium cation forms stable complexes with acetonitrile and other nitriles (13) as well as perfluorinated pyridine derivatives (14). These possibilities encouraged us to check the behaviour of $Bi(CF_3)_3$ and $Bi(C_6F_5)_3$ against XeF_2 and $[XeF][MF_6]$ (M: As; Sb; Ta).

If $Bi(CF_3)_3$ is used, CF_4, Xe, and BiF_3 are formed quantitatively even at −60°C according to

$$Bi(CF_3)_3 + 3XeF_2 \rightarrow BiF_3 + 3CF_4 + 3Xe$$

This reaction does not help us understand the reaction mechanism. There are two possibilities to explain these products: Firstly, polar trifluoromethylation of an intermediately formed XeF^+ cation may occur to give "CF_3XeF", which would decompose according to

$$Bi(CF_3)_3 + XeF^+F^- \rightarrow Bi(CF_3)_2F + \text{"}CF_3XeF\text{"} \rightarrow Xe + CF_4$$

[2]D. Naumann, W. Dukat, M. Finke, and W. Tyrra. Unpublished results.

Or, secondly, there may be oxidation of the bismuth compound to give "$Bi(CF_3)_3F_2$" followed by a decomposition of the bismuth derivative according to

$$Bi(CF_3)_3 + XeF_2 \rightarrow \text{"}Bi(CF_3)_3F_2\text{"} + Xe$$

$$\text{"}Bi(CF_3)_3F_2\text{"} \rightarrow Bi(CF_3)_2F + CF_4$$

and so on.

To observe one of the possible intermediates, "R_fXeF" or "$Bi(R_f)_3F_2$", we decided to carry out the reaction using the pentafluorophenyl compound.

To decide whether a polar reaction or a radical oxidation takes place, we reacted $Bi(C_6F_5)_3$ with XeF_2 and $[XeF][MF_6]$. Both reactions yield the same main product, tris(pentafluorophenyl)-bismuth difluoride, along with traces of pentafluorobenzene. Evidence for the formation of a pentafluorophenylxenon compound such as C_6F_5XeF or $[C_6F_5Xe][MF_6]$ (15) was not found.

These results show that tris(perfluoroorgano)bismuth compounds cannot easily be oxidized by common oxidizers such as elemental halogens or interhalogens. In these cases a polar reaction is favoured. Only strong fluorinating agents like xenon difluoride or fluoro xenonium metallates yield, with tris(pentafluorophenyl)bismuth, the corresponding difluoride under distinct conditions. But the oxidation of $Bi(CF_3)_3$ was never observed.

On the prediction of the structures of simple and hypervalent hydrides and fluorides containing unpaired electrons

N. Colin Baird, Markus Kuhn, and Toyanne M. Lauriston
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 9, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

N. Colin Baird, Markus Kuhn, and Toyanne M. Lauriston. Can. J. Chem. **67**, 1952 (1989).

Ab initio molecular orbital calculations are reported for the optimum structures of many free radicals, including several species in which the central atom is hypervalent, and for some triplet states. Most geometries are close to those predicted by the VSEPR method for molecules with one additional electron, with the unpaired electron occupying a "lone pair" position. Deviations from the ideal geometries of hypervalent radicals can be rationalized in terms of different strengths for repulsions between electrons of different types. Alternatively the geometries can be understood by using the three-centre, four-electron bond theory for the hypervalent species and the σ-conjugation concept for the non-hypervalent molecules. The distortions from ideality of the hypervalent structure occur to allow interaction of the electron pair of the nonbonding MO of the three-center unit to interact with a lobe of the unpaired electron's orbital.

Key words: geometry of free radicals, *ab initio* MO theory for radicals, VSEPR theory for radicals, sigma conjugation for radicals.

N. Colin Baird, Markus Kuhn et Toyanne M. Lauriston. Can. J. Chem. **67**, 1952 (1989).

On rapporte les résultats de calculs d'orbitales moléculaires *ab initio* effectués sur des structures optimisées de quelques états triplets ainsi que de plusieurs radicaux libres comportant plusieurs espèces dans lesquelles l'atome central est hypervalent. Dans la plupart des cas, les géométries ressemblent à celles qui sont prédites par la méthode VSEPR pour des molécules avec un électron additionnel comportant un électron non-pairé qui occupe une position de "paire isolée". On peut rationaliser les déviations par rapport aux géométries idéales des radicaux hypervalents en fonction des forces différentes pour les répulsions entres les divers types d'électrons. On peut aussi comprendre les géométries des espèces hypervalentes en faisant appel à la théorie des liaisons à quatre électrons et à trois centres alors que celles des molécules non-hypervalentes peuvent être expliquées par le concept de conjugaison σ. Les distorsions par rapport à la structure hypervalente idéale se produisent pour permettre à la paire d'électron de l'OM non liés de l'unité à trois centres d'interagir avec un lobe de l'orbitale de l'électron non-pairé.

Mots clés : géométrie des radicaux libres, théorie *ab initio* de l'OM pour des radicaux, théorie VSEPR pour des radicaux, conjugaison σ pour des radicaux.

For personal use only.

Introduction

The geometric structure of free radicals, particularly ones which contain hypervalent atoms, and of triplet states have been largely ignored in most simple qualitative valence theories. It is known that the geometry of systems with unpaired electrons can be rationalized and predicted using delocalized MO theory, for example in the form of Walsh diagrams (see, for example, ref. 1). In this report, we consider the structure and bonding in a number of prototype radicals and triplets using variants of VSEPR theory (2), three-centre bond theory (3), and Dewar's "σ-conjugation" concept (4). We also present a series of systematic *ab initio* MO calculations of the structures of a wide series of hydrogen- and fluorine-containing radicals — particularly hypervalent ones, since generally only the shapes of these are known from experimental studies and only scattered theoretical calculations have been published to date.

Calculations

The optimized structures and total energies calculated for the systems considered herein are listed in Tables 1 through 3. Except for ClF_2 and ClF_4, all these *ab initio* MO calculations were obtained using the Unrestricted Hartree Fock (UHF) method.

The basis sets used were the 3-21G, 3-21G$^{(*)}$, 6-31G, and 6-31G* expansions of Pople and co-workers (5*a*), where * denotes the presence of *d* orbitals on all non-hydrogen atoms and $^{(*)}$ denotes *d* orbitals only on second-row atoms. We also employed a 6-31G$^{(*)}$ basis, i.e. one which corresponds to the 6-31G basis for hydrogen and first-row atoms and the 6-31G* basis for second-row atoms. The GAUSSIAN86 program was used to perform all calculations (5*b*).

As discussed previously by Hehre *et al.* (5*a*), the bond lengths and angles in first-row hydrides containing unpaired electrons are not significantly dependent upon the basis set quality (once one is beyond the STO-3G level) nor upon the inclusion of corrections for the effects of electron correlation. Our results for the non-hypervalent second-row hydride systems (Table 1) display a similar lack of dependence upon basis set, and agree well with experiment where available (as do the results for the first-row hydrides).

Pople and co-workers discovered a substantial dependence of AF bond length upon basis set for both closed-shell and open-shell molecules for first-row atoms A (5*a*). The calculated AF distances are substantially shorter at the 6-31G* level than with the 3-21G basis, particularly if A carries p_π lone pairs; the origin of this difficulty presumably is similar to that encountered for the OO bond length in H_2O_2 (5*a*). In addition, inclusion of electron correlation corrections (reported for HNF, CF, NF, and F_2^+) had a further significant effect on bond lengths, as it also does in H_2O_2.

From the calculations shown in Table 1, it can be seen that basis set quality plays a role in determining AF bond length when A is a second-row atom. Thus the 6-31G* bond lengths in AlF_2, SiF_2, and PF_2 are 0.054, 0.087, and 0.102 Å shorter than those predicted by the 6-31G basis set. The bond angles are relatively unaffected by the size of the expansion (whether 3-21G or 6-31G) and by the presence or absence of *d* orbitals.

In order to find an efficient basis set for the hypervalent

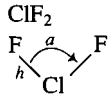
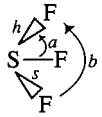
fluorides, we performed a number of test calculations on the smallest of them, namely ClF_2. The ClF distance drops by 0.10 Å when *d* orbitals are added to Cl, whether in the 3-21G or the 6-31G basis set. Addition of *d* orbitals to the 6-31G basis for the fluorines shortens the bonds by an additional but smaller amount, 0.036 Å, but has almost no effect on the angle. (This behaviour is similar to that for PF_2, for which comparative results also are listed in Table 1.) The predicted FClF angles all lie in the range suggested by experiment. Sannigrahi and Peyerimhoff have reported calculations for the ground state of ClF_2 which give a similar shape to the molecule (6). They found that the FClF angle decreased only slightly (by 2.5°), and the bond length increased only slightly (by 0.02 Å), when configuration interaction was included to allow for the effects of electron correlation. Further, Pople and co-workers have established that the geometries of closed-shell hypervalent fluorides (such as PF_5, SF_4, ClF_3, and ClF_5) are well described at the SCF level, and that the 3-21G(*) results are almost identical to those at the 6-31G* level (5*a*). Since the inclusion of *d* orbitals on fluorine appears to decrease the AF length somewhat but has only a small effect on bond angles and hence upon the shape of the molecule, and since their inclusion raises enormously the running time of the calculations, we have employed the 6-31G(*) and 3-21G(*) basis sets only for the rest of the hypervalent fluorides. No attempt has been made to account for the effects of electron correlation, which appear from the ClF_2 example above and the PH_4 discussion below to be small.

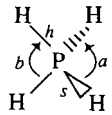
The calculated structures and energies for the hypervalent radicals are given in Table 2. In all cases, there is virtually no difference between the 3-21G(*) and the 6-31G(*) results. A number of reasonable starting geometries of differing symmetries were tried using the 3-21G(*) basis set (7), but in all cases that shown in Table 2 was clearly superior energetically and the other results will not be discussed further. With the UHF method, the ClF_2 free radical under C_{2v} symmetry dissociates to free atoms (as does F_2^+), and similarly for ClF_4. There is substantial spin-contamination in the UHF wavefunctions for these systems; for example the S^2 value is 0.871 for ClF_2 in a 3-21G(*) calculation (at R = 1.707 Å, ∠FClF = 148.5°), whereas the values for the non-chlorine radicals all are close to 0.75 (see Table 2). For both ClF_2 and ClF_4, therefore, we employed the Restricted Hartree-Fock (RHF) method.

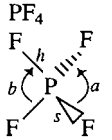
Unfortunately, there is very little structural data for hypervalent radicals with which to compare the theoretical predictions. Usually only the electron spin resonance (esr) spectrum and/or the vibrational spectrum is available, from which only the point group of the radical can be deduced.

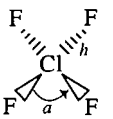
As mentioned above, the predicted shape of ClF_2, namely bent but only to about 150°C, agrees with experiment (8).

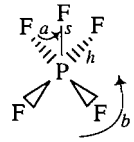












For SF_3, esr measurements (9), and *ab initio* calculations by So (10), favor a planar T shape with two types of fluorines. More elaborate *ab initio* calculations by Volatron *et al.* (11) and our own results both yield a somewhat non-planar T shape. Recently Volatron (11*b*) has shown that the pyramidal T-shape is obtained by RHF calculations even after configuration interaction is included (although the energy gain due to non-planarity becomes rather greater).

For SF_5, the infrared (12) and esr (13) spectra have been interpreted in terms of a C_{4v} structure, in agreement with our calculations. Semi-empirical INDO calculations for the C_{4v} radical by Gregory (14) also yielded a tetragonal pyramid, in contrast to the "umbrella" shape known for BrF_5.

The esr spectra of PF_4 (15), PH_4 (16), and a wide variety of phosphoranyl radicals (17) are all consistent with a "see-saw" shape, as indeed is obtained in our *ab initio* calculations for the tetrafluoro and tetrahydro systems. In contrast to the closed-shell sulfur systems, the "axial" atoms bend away from the central AX_2 unit rather than toward it. This prediction is maintained when the structure of PH_4 is re-optimized at the 6-31G* level with MP2 correction included for the effects of electron correlation; indeed none of the structural features of the

radical is affected significantly by correlation (see Table 2). The same type of structure for PH_4 previously was predicted by *ab initio* calculations using the 4-31G basis set (i.e. with no *d* orbitals included) by Howell and Olsen (18).

The RHF calculations for ClF_4 clearly favor a non-planar C_{4v} rather than a planar D_{4h} structure. This same result was obtained in *ab initio* calculations by So and Richards (19) in minimal basis set (STO-3G) calculations if *d* orbitals were included, but not if they were excluded. Earlier calculations by Ungemach and Schaefer (20) using minimal and double-ζ *s*, *p* basis sets also predicted a planar radical. However, we have found that a non-planar structure, with about half the out-of-plane distortion as is obtained with 6-31G(*), is predicted by 6-31G calculations. The esr spectrum clearly shows the equivalence of all four fluorines, which is consistent with both the C_{4v} and the D_{4h} structures. On the basis of the size of the ^{35}Cl hyperfine interaction, the D_{4h} structure has been favored. The MO for the unpaired electron in our 6-31G(*) calculation for the optimum (non-planar) geometry predicts the total spin density in the *s* orbitals on chlorine amounts to be 0.161e. All the calculations for ClF_4 (by ourselves and those reported previously) agree that in the square planar geometry the unpaired electron's MO is a_{1g} in character, and corresponds to the antibonding combination of the chlorine *s* orbital with fluorine-based nonbonding MO from $3c$—$4e$ bonds. In the non-planar geometry, this MO is of the same symmetry as the doubly-occupied p_π orbital on chlorine (a_{2u} in the square planar geometry); their interaction allows the chlorine *s* orbital population to increase and presumably is the driving force for pyramidalization.

Valence-shell electron pair repulsion (VESPR) theory

Although the VSEPR theory of Gillespie and Nyholm (2) applies formally only to closed-shell species, some researchers have assumed that the geometry of a free radical containing *n* electron pairs and an unpaired electron would lie somewhere between the optimum shape for *n* pairs and that for $n + 1$ pairs (see, for example, ref. 21). Indeed Morton and Preston state that "the unpaired electron behaves very much as would a lone pair" (22).

From the idea that the geometry should lie between that for

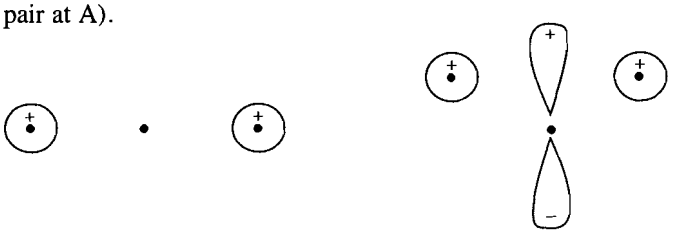
n and $n + 1$ pairs, we expect that the angles at boron and aluminum in their radical dihydrides and difluorides will lie between 180° (two electron pairs, as in BH_2^+) and 120° (three electron pairs, BH_2^-). The calculated 6-31G* values of 126.5° for BH_2, 120.2° for BF_2, 118.0° for AlH_2, and 117.1° for AlF_2 lie near or beneath the low end of this range. Apparently the effective VSEPR size of an unpaired electron here is about that of a shared electron pair.

The angles in the nitrogen and phosphorus dihydrides and difluorides (Table 1) are virtually identical to those in the corresponding trihydrides and trifluorides, so the structures are closer to those for four electron pairs than for three. Similarly the angles in pyramidal CF_3, SiH_3, and SiF_3 (see Table 1) are much closer to the tetrahedral value than to the 120° associated with the trigonal planar geometry; the latter shape is preferred only by CH_3, which must be considered an exception.

Unexpectedly (from the viewpoint of the VSEPR theory), the angles in the triplet states (two unpaired electrons) of CH_2, CF_2, SiH_2, and SiF_2 lie within a few degrees of those in the free radicals containing one less (unpaired) electron, i.e. BH_2, BF_2, AlH_2, and AlF_2 respectively (Table 1). It is not clear why a second unpaired electron should exert no influence over the bond angle. The lack of a significant change in angle from (singlet) CH_2 to NH_2 to H_2O (1*a*) also is problematic for VSEPR.

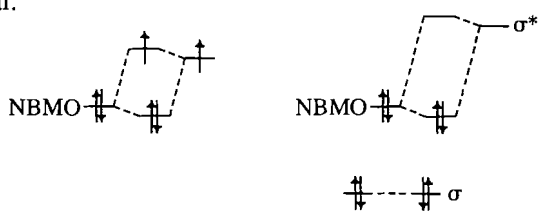
For ClF_2, we expect an FClF angle which lies somewhere between tetrahedral (109.5°) for four electron pairs and 180° for the axial positions in the five-pair structure. The calculated (and observed) weakly bent geometry with an angle of about 150° lies between these extremes. For SF_3, the non-planar (pyramidalized) T shape is intermediate between that for an AX_3E configuration (i.e. pyramidal, with all bond angles near 109.5°) and that for AX_3E_2 (planar T shape, with 90° and 180° angles) assuming that like a lone pair, the unpaired electron here occupies an equatorial position. However, the departure from planarity is relatively small. The free radicals PH_4 and PF_4 should also fall between structures expected for four pairs — i.e. a tetrahedron — and the "see-saw" shape expected for AX_4E molecules, again assuming the unpaired electron occupies an equatorial position. The calculated structures are closer to the latter than the former, although the axial bonds bend *away* from the equatorial PX_2 group — unlike the situation in SF_4, etc. but consistent with a transition toward a tetrahedral geometry.



Both ClF_4 and SF_5 have five electron pairs and one unpaired electron. The square pyramidal structure for ClF_4 would be expected if the lone pair and the unpaired electron occupied *trans* positions in an octahedron, and the four in-plane bonding pairs were repelled more by the lone pair than by the unpaired electron. Similarly, the optimum structure for SF_5 is a minor distortion from the square pyramid, with the four equivalent fluorines bent slightly away from the unique fluorine (indicating that repulsion by a bonding pair is slightly more effective than by an unpaired electron), rather than one based upon the trigonal bipyramid.

Three-centre bond theory

A linear geometry usually is considered optimal for a three-centre σ bond formed by a *p* orbital, since atomic orbital overlap is greatest for the *bonding* MO at 180° (3).

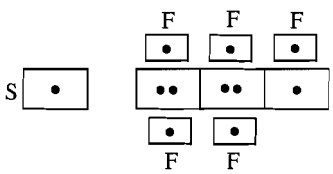


However a linear geometry precludes stabilization of the *nonbonding* MO, which to a first approximation is located only upon ligand atom orbitals, for systems in which the central atom's *s* orbital is doubly-filled (i.e. in which there is a lone pair at A).

NBMO — linear geometry NBMO — bent geometry

In such circumstances, some bending from 180° would result in stabilization of the nonbonding MO if the orbital with which it then overlaps is singly-occupied or is an empty antibonding orbital.

Analysis of the Mulliken population data indicates that the deviations from high symmetry of the geometries of the hypervalent radicals considered herein arise primarily from the stabilization of the electrons in the nonbonding MO of three-



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

centre bonds by interaction with the singly-occupied orbital. In ClF_2 the FClF angle decreases from linearity by 30° due to the stabilization of the nonbonding MO by its overlap with one lobe of the singly-occupied *p* orbital of the chlorine; according to 6-31G(*) calculations extrapolated to an angle of 180°, the energy gain from bending amounts to about 12 kcal mol^{-1}. Thus the bonding in ClF_2 consists of a three-centre, four-electron (3c–4e) bond shared between the fluorines and stabilized by bending to yield a molecular plane which also contains the unpaired electron.

Similarly, the 3c–4e $F_{ax}SF_{ax}$ unit in T-shaped SF_3 not only is bent slightly toward the 2c–2e unique S—F bond, but it is also bent down to overlap with one lobe of the singly-occupied *p* orbital of sulfur, thus yielding a pyramidalized T shape with an axial bond angle of 154.6°. The 6-31G(*) calculated energy gain due to pyramidalization and bending of the 3c–4e unit is 3.5 kcal mol^{-1}. (A similar distortion from planarity does not occur in ClF_3 since the corresponding *p* orbital on the central atom is doubly-occupied, and net destabilization would occur if it overlapped the nonbonding MO of the three-centre bond.)

In ClF_4, all the fluorines are involved in 3c–4e bonds; both units bend in the same direction, giving a pyramidal structure with *trans* FClF angles of 163°. The energetic stabilization of the distortion from D_{4h} symmetry is 8.6 kcal mol^{-1}, according to 6-31G(*) calculations, and arises from the interaction of the doubly-occupied p_π orbital on chlorine with the singly-occupied MO which in the square planar geometry is Cl—F antibonding and at chlorine is composed entirely of *s* orbital character.

Unlike many of the hypervalent radicals discussed above, the central atom in SF_5 does not possess an *s* lone pair since, formally, one *s* electron of sulfur has been promoted to a *p* orbital in order that the atom can form two 3c–4e bonds. The valence-shell electron configuration of sulfur is conveniently displayed in the box diagram below. (The *p* orbitals which form three-centre bonds are shown with fluorine atoms above and below their boxes.)

Indeed from the population analysis it is clear that the unpaired electron here occupies an orbital with a substantial degree of sulfur 3*s* character. No significant distortion of the 3c–4e units is required in order that their nonbonding MOs overlap with that of the unpaired electron. Thus the shape of SF_4 is very nearly that of a perfect square pyramid. Similarly ClF_6 does not depart from an octahedral geometry, at least according to the interpretation of its esr spectrum (23).

In PF_4, two of the fluorines are joined to phosphorus by 2c–2e bonds, and two by a 3c–4e unit. The most stable "ideal" geometry is the see-saw shape. The unpaired electron occupies an orbital which lies in the same plane as the two (equatorial) singly-bonded fluorines and which is high in phosphorus s character. Nevertheless the *p* character of the orbital is sufficient that the axial 3c–4e bond fluorines bend toward the sp^n hybrid and away from the equatorial fluorines, though the extent of bending is only 14° compared to 30° in ClF_2, and the energetic stabilization (6-31G(*)) amounts to 4.6 kcal mol^{-1}.

The optimum structure calculated for PH_4 is very similar to that for PF_4, although the 3c–4e units bend only by 10° and the gain in energy by this distortion is only 1.5 (1.1) kcal mol^{-1}, calculated by the 6-31G(*) basis (with MP2 correction). The electronegativities of phosphorus and hydrogen are sufficiently close that a 3c–4e HPH network is feasible, whereas comparable calculations for SH_3 reveal only a potential maximum (10). (A search for a stable SiH_5 radical gave a trigonal bypyramid structure with a 3c–3e bond, which upon frequency analysis turned out to be a transition state rather than a potential minimum. A similar result was obtained in RHF calculations for ClH_2.)

σ-Conjugation

Dewar has proposed that "σ-conjugation" plays a major and often a dominant role in determining the geometries of many systems containing unpaired electrons (4). According to this hypothesis, free radicals such as BH_2 and AlH_2, and the triplet states of CH_2 and SiH_2, will be bent with a bond angle of about 120° and with sp^2 hybridization at the central atom because this allows equal sharing of *s* orbital character between the bonding orbitals and that which houses the in-plane unpaired electron, and σ-conjugation is thereby maximized (4). For the same reason, CX_3 and SiX_3 free radicals normally should be pyramidal, with bond angles close to the tetrahedral value. Deviations from these "ideal" geometries occur in some cases due to steric and/or conjugative interactions.

Dewar's hypothesis is the simplest MO-based theory for the structure of non-hypervalent systems with unpaired electrons, and can be tested by considering the *ab initio* MO calculations for the small free radicals and for molecules with low-lying triplet states in Table 1. We also studied how the optimum XAX bond angle varies over a range of chosen AX distances, since corresponding calculations for closed-shell molecules have revealed the importance of steric effects in determining bond angles, and have determined "ideal", steric-free bond angles by extrapolating the angle-versus-distance curves to longer interatomic separations (24). A limit of about 90° was obtained for the ideal angle in molecules such as H_2O, NH_3, F_2O, $(CH_3)_2O$, etc., i.e. systems which are not forced to engage in hybridization at the central atom in order to increase their valence.

Plots of the optimum HAH bond angle (determined using the 6-31G* basis set and the UHF method) as a function of the chosen AH distance for a number of AH_2 and AH_3 systems containing unpaired electron(s) are shown in Fig. 1. The form of these angle-versus-length curves is similar to that obtained previously for closed-shell hydrides (24). In particular, the angle increases substantially as the AH distance becomes very short, and the increase in angle with decrease in distance is more pronounced for second-row than first-row central atoms.

The limiting angle for the ground state electron configurations of NH_2 and PH_2 is about 90°, which corresponds to the formation of a single AH bond by each of the two (initially) singly-occupied *p* orbitals on the central atom. (Beyond about 1.7 Å, other electron configurations start to play important roles in the ground state, and lead eventually to HAH angles very different from 90° at the dissociation limits. This is irrelevant, however, since our interest is to determine the "steric-free" optimum angle for that electron configuration which dominates the ground state at or near the equilibrium distance.) The unpaired electron is localized in the π system, and thus does not become engaged in the σ bond framework at any angle; therefore σ-conjugation cannot play a role here. The optimum angle in the equilibrium geometry of NH_2 (Table 1) is rather

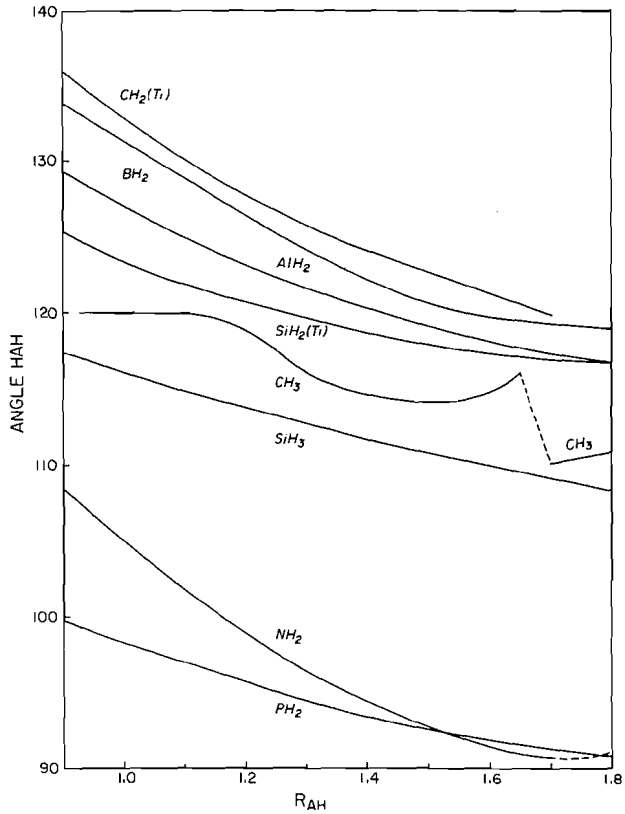


FIG. 1. Optimum angle (in deg) versus A—H bond distance (in Å) for hydrides AH_n containing unpaired electrons. Calculations use the 6-31G* basis set.

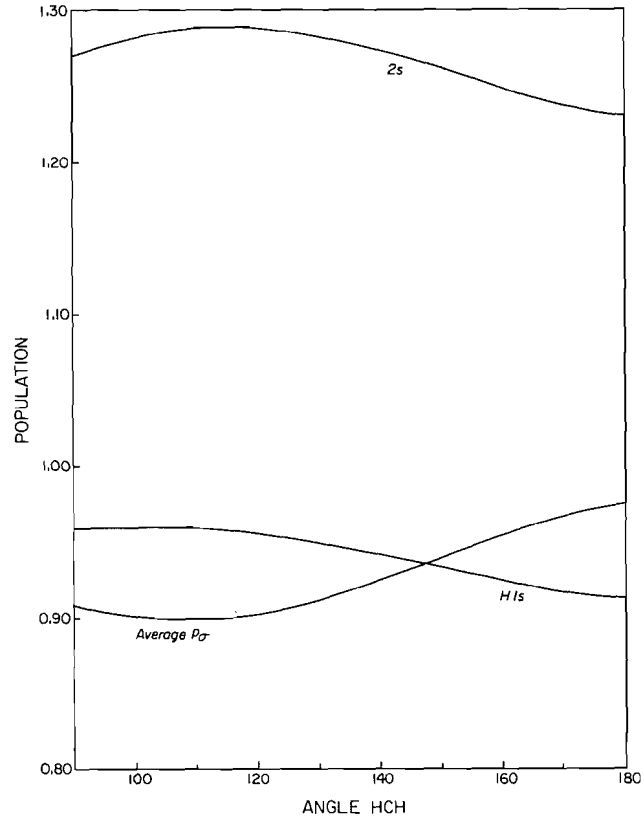

FIG. 2. Electron density in orbitals versus bond angle in triplet state of CH_2, calculated using the STO-3G basis set. The value for the p orbital is an average for the two in-plane $2p$ orbitals of carbon.

larger than that in PH_2 because the N—H bond is so short that the HNH angle opens up to relieve steric repulsion among the hydrogen atoms.

For BH_2 and AlH_2, and for the triplet state of CH_2 and SiH_2, an unpaired electron can exist in the σ framework if the molecule is bent; thus according to Dewar's theory, approximately sp^2 hybridization, with angles of 120°, should be optimum if steric and hyperconjugative factors are negligible. Although the angles at the first-row atoms exceed this value at the equilibrium geometries (Table 1), at long AH distances the optimum angle-versus-distance curves (Fig. 1) for all these cases appear to converge to just under 120°.

Dewar's theory predicts that CX_3 and SiX_3 free radicals should undergo sp^3 hybridization and have tetrahedral angles at the central atom, unless steric and/or hyperconjugative factors dominate. The angle-versus-distance curve for SiH_3 in Fig. 1 does indeed converge to a value in this region. In contrast to SiH_3, CH_3 is trigonal planar for CH distances less than 1.1 Å (which is just slightly greater than the distance in the equilibrium geometry (Table 1)) due to steric clashes among the hydrogens. The shape would be pyramidal if the optimum bond length was only a few hundredths of an angstrom larger.

The prediction that, in the absence of strong steric and/or hyperconjugative interactions, the in-plane singly-occupied orbital of a radical or triplet state should have equal hybrid character with the A—X bonding orbitals seems borne out semiquantitatively by the results for hydrides. We have also tested out Dewar's conclusion that when steric effects are absent, the superior σ-conjugation within CCC units, compared to HCH, will lead to smaller CCC and HCH angles by performing *ab initio* 6-31G* calculations on dimethylmethylene and on methylene. Indeed, the optimum CCC angle (at the optimum CC distance of 1.51 Å) of 127.2° is slightly smaller than that of 130.8° predicted for methylene.

Finally, we should like to note that the driving force behind the reduction in symmetry in molecules having unpaired electrons (i.e. from linear to bent in AX_2 systems, and from trigonal planar to pyramidal for AX_3) is the transfer of electron density from p orbitals of the central atom to its more stable s orbital. The involvement of the atomic orbital containing the unpaired electron with the MOs of the A—X bonds permits the latter to become less bonding in character since the singly-occupied orbital and its electron can take up the slack. Thus the s orbital population can increase since its density no longer needs to be shared as widely in covalent bond formation. This phenomenon is illustrated in Fig. 2, where the $2s$ electron density of the carbon atom in the triplet state of CH_2 is plotted against the chosen HAH bond angle (with the CH distance fixed at 1.10 Å in an STO-3G calculation). If the highest-occupied orbital contains two electrons rather than just one, all the bonding can be assumed by the p orbitals when the bond angles are close to 90°; the stablest valence-shell electrons then localize as a lone pair in the $2s$ orbital. This explanation of σ-conjugation seems more intuitively appealing than that derived from a localized MO basis by Dewar. The latter involves consideration of the interaction between a hybrid orbital on the central atom with the empty, antibonding MO formed by another hybrid of the same atom and an attached ligand (4). The net effect of this interaction is to introduce flexibility in the s/p ratio from that of the isolated sp^2 or sp^3 hybrids, and thus to allow an increase in the s orbital population at the expense of the p.

Conclusions

Overall, in agreement with the viewpoint expressed by Morton and Preston (22), we find that free radicals have geometries which usually are close to those predicted by VSEPR and found for closed-shell systems with one additional electron. Their generalization can be made more useful by noting that the unpaired electron in hypervalent systems occupies the same position as does a lone pair. Further, in hypervalent systems with both an unpaired electron and one or more lone pairs, the ligands distort their angles as if repulsion of a bonding pair by a lone pair exceeds its repulsion by an unpaired electron, and repulsion of a bonding pair by another bonding pair is intermediate (although this order seems inconsistent with the requirement that the unpaired electron occupies a position for a lone rather than a bonding pair):

$$\text{lone pair} - \text{bonding pair} > \text{bonding pair} - \text{bonding pair} > \text{unpaired electron} - \text{bonding pair}$$

Thus ClF_2 distorts from linearity, ClF_4 from square planarity (with all F atoms distorting in the same direction, away from the lone pair and toward the unpaired electron), PX_4 radicals distort from the see-saw shape toward the tetrahedral, and SF_5 distorts from the square planar shape toward the square pyramidal. The net distortion in SF_3 is the result of two opposing effects; the axial fluorines move in toward the equatorial fluorine due to lone pair – bond pair repulsions being greater than bond pair – bond pair, but then they leave the plane as their repulsion with the unpaired electron is less again.

The application of these modified "rules" to non-hypervalent systems containing unpaired electrons is less successful. It is not clear why the distortions from 120° angles in boron and aluminum systems should differ in sign, or why the second unpaired electron in triplet states should have no effect, or why the methyl radical should be planar.

The geometry of the hypervalent radical systems is explained equally well by the three-center bonding theory, as is the case with closed-shell hypervalent systems. The ligands of the 3c–4e units bend toward a lobe of the unpaired electron's orbital, or if the electron occurs in the 3c–4e network (e.g. ClF_4) the system bends toward one lobe of a lone pair orbital, in order to provide some net bonding energy gain (two electrons stabilized, one destabilized) to the system. When this hypothesis is combined with Dewar's σ-conjugation principle — that hybridization will include the orbital of an unpaired electron if this allows interaction with two-center bonds — and the concept that deviations of bond angles from the 120° or 109.5° or 90° values predicted by this principle occur mainly to reduce steric collisions, the geometries of almost all the systems discussed herein can be understood. The only exceptions are the bond angles of somewhat less than 120° encountered for the second-row difluorides.

Overall, it appears that the MO-based theory is marginally superior to VSEPR theory — as amended herein — in the prediction of geometries of molecules containing unpaired electrons, although as with closed-shell systems, both types of theory usually predict the same "ideal" structure.[1]

Received December 1, 1988

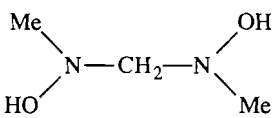
This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **67**, 1959 (1989).

The reaction of *N,N'*-dihydroxy-*N,N'*-dimethylmethanediamine with phenylboronic acid leads to the product 1,7-dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane rather than the expected product 1,5-dimethyl-3-phenyl-1,5-diaza-2,4-dioxa-3-boracyclohexane. The structure of *N,N'*-dihydroxy-*N,N'*-dimethylmethanediamine has been determined and is discussed in terms of its reaction with $PhB(OH)_2$. Crystals of *N,N'*-dihydroxy-*N,N'*-dimethylmethanediamine are tetragonal, $a = 8.5346(3)$, $c = 8.4178(7)$ Å, $Z = 4$, space group $P42_1c$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.036 and R_w of 0.038 for 333 reflections with $I \geq 3\sigma(I)$. The structure consists of hydrogen-bonded dimers having exact $\bar{4}$ (S_4) symmetry.

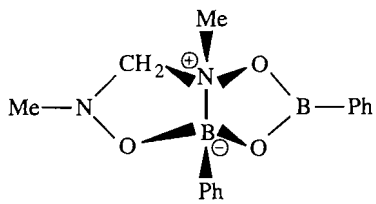
Key words: *N,N'*-dihydroxy-*N,N'*-dimethylmethanediamine, crystal structure.

WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **67**, 1959 (1989).



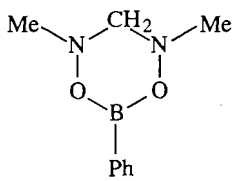
La réaction de la *N,N'*-dihydroxy *N,N'*-diméthylméthanediamine avec l'acide phénylboronique conduit à la formation du produit diméthyl-1,7 diphényl-3,5 trioxa-2,4,6 aza-7 azonia-1 bora-3 borata-5 bicyclo[3.3.0]octane plutôt que le produit attendu, le diméthyl-1,5 phényl-3 diaza-1,5 dioxa-2,4 bora-3 cyclohexane. On a déterminé la structure de la *N,N'*-dihydroxy *N,N'*-diméthylméthanediamine et on en discute en fonction de sa réaction avec le $PhB(OH)_2$. Les cristaux de la *N,N'*-dihydroxy *N,N'*-diméthylméthanediamine sont tétragonaux, avec $a = 8{,}5346(3)$ et $c = 8{,}4178(7)$ Å, $Z = 4$ et groupe d'espace $P42_1c$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs finales de R de 0,036 et R_w de 0,038 pour 333 réflexions avec $I \geq 3\sigma(I)$. La structure est composée de dimères liés par des ponts hydrogènes et possédant une symétrie $\bar{4}$ (S_4) exacte.

Mots clés : *N,N'*-dihydroxy *N,N'*-dimethylmethanediamine, structure cristalline.



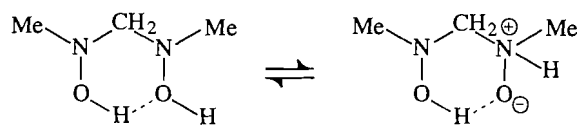
[Traduit par la revue]

Introduction



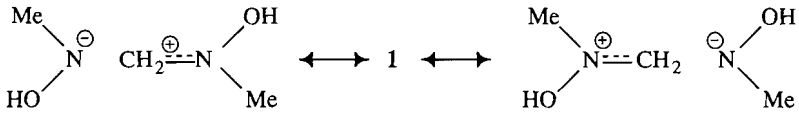
N,N'-Dihydroxy-*N,N'*-dimethylmethanediamine, **1** (1), has been employed in the synthesis of a stable pyroboronate ring system **2** (2). The crystal structure of **2** has been determined and establishes the presence of transannular N → B coordination (3). The formation of a six-membered monophenylboronate **3** should have been a favored reaction, analogous to facile

1



2

3



cycloboronate syntheses with 1,3-diols (4), assuming a *cis*-oriented hydrogen-bridged diol ligand **4** or its *N*-oxide tautomer **5** and also that phenylboronic acid is monomeric in solution as it is in the solid state (5). Infrared and ^1H nmr spectra of **1** (and other compounds of this type) indicate strong, and at least partial, intramolecular hydrogen bonding (2, 6, 7), but **3** could not be isolated or detected during the condensation experiments with phenylboronic acid (2). Reactions of **1** with other acylating agents (8, 9) or dipolarophiles (10), and mass spectrometric fragmentation patterns for **1**, show the tendency of **1** to dissociate at one of the central C—N bonds. This appears to be typical behavior for compounds of this type under the attack of electrophilic agents (11) and also under the conditions of the mass spectrum experiment (2).

Additional structural information about **1** is required in order to clarify the possibility of hydrogen bonding as shown in **4** and **5** and also for consideration of a possible anomeric (stereoelectronic) effect (12, 13) with respect to "double bond – no bond resonance" (13–15) or negative hyperconjugation (15). The "no bond resonance" formalism is symbolized by **6** and would require certain preferred conformations of **1** which would allow π-donation by one or both of the nitrogen lone pair electrons for $n\pi(N^1)/\sigma^*(N^2—C)$ orbital interaction. Parallelism of these orbitals would result in increased double bond character of one N—C bond and weakened single bond

6 6

character for the other, causing an inequality of the N—C bond distances. Ignoring the steric and electronic influences of the substituents R = OH or CH_3, four important conformations **7A–7D** may be considered for the N^1—C—N^2 system, only the conformations *A* and *B* being stabilized by the anomeric effect. The solid state structure of **1** has been determined in order to clarify this problem.

7A 7B 7C 7D

Experimental

N,N′-*Dihydroxy*-N,N′-*dimethylmethanediamine, 1*

The title compound was prepared according to the literature (1, 6) and was recrystallized from ethanol. Melting point 113–114°C. ^{1}H nmr and mass spectral data are detailed in ref. 2.

X-ray crystallographic analysis of 1

A crystal bounded by the fourteen faces (followed by the distances in mm between parallel faces): {1 1 0}, 0.36, 6 of {1 0 1}, 0.39, ±(0 −1 2), 0.35, ±(1 −2 1), 0.40 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 34–45°) measured on a diffractometer with Mo-Kα radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 21°C are:

$C_3H_{10}N_2O_2$ f.w. = 106.12

Tetragonal, a = 8.5346(3), c = 8.4178(7) Å, V = 613.14(6) Å^3, Z = 4, ρ_c = 1.150 Mg m^{-3}, $F(000)$ = 232, μ(Mo-$K\alpha$) = 0.88 cm^{-1}. Absent reflections: *hhl*, *l* odd, 00*l*, *l* odd, and 0*k*0, *k* odd, uniquely indicate the space group $P42_1c$ (D^4_{2d}, No. 114).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 0.9–10.0° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 65°. The intensities of three check reflections, measured every 4000 s throughout the data collection, showed only small random variations (<3%). Of the 653 independent reflections measured and processed,[1] 333 (51.0%) had intensities greater than or equal to 3σ(*I*) above background where

TABLE 1. Final positional (fractional × 10^4, H × 10^3) and isotropic thermal parameters (U × 10^3 Å^2) with estimated standard deviations in parentheses

Atom	x	y	z	U_{eq}/U_{iso}
O	5943(2)	2981(2)	1129(3)	55
N	6316(2)	4521(2)	1749(2)	48
C(1)	5000	5000	2728(4)	56
C(2)	7728(4)	4300(4)	2702(5)	77
H(O)	561(3)	319(4)	20(4)	71(9)
H(1)	474(3)	422(3)	343(3)	58(8)
H(2a)	764(4)	357(5)	348(5)	94(12)
H(2b)	807(5)	530(5)	320(5)	115(12)
H(2c)	859(6)	385(6)	204(5)	115(13)

$\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an *E*-map and those of the hydrogen atoms from a subsequent difference Fourier synthesis. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms with isotropic thermal parameters. Scattering factors for all atoms were taken from ref. 16. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 54 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (17–19). The final value of g was 5.1(6) × 10^4. Convergence was reached at R = 0.036 and R_w of 0.038 for 333 reflections with $I \geq 3\sigma(I)$. No attempt was made to determine the polarity of the structure, anomalous scattering terms not being included in the calculations. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.0004 and 0.003σ, respectively. The mean error in an observation of unit weight was 1.693. The final difference map was featureless, the largest peak being 0.16 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 4,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (20). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0014 Å^2. Analysis of the entire molecule gave rms ΔU_{ij} = 0.0015 Å^2 and physically reasonable results. The appropriate bond distances have been corrected for libration (20, 21), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; bond angles are given in Table 3. A complete listing of torsion angles (Table 5) is included as supplementary material.

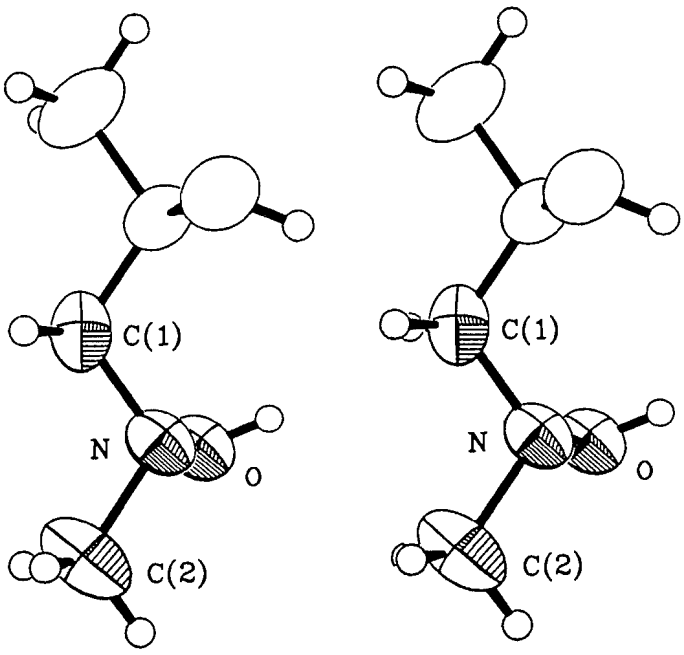

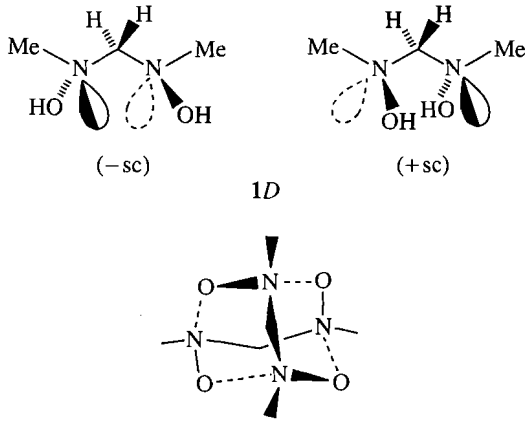

FIG. 1. Stereoscopic view of *N,N′*-dihydroxy-*N,N′*-dimethylmethanediamine; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Shaded non-hydrogen atoms comprise the asymmetric unit.

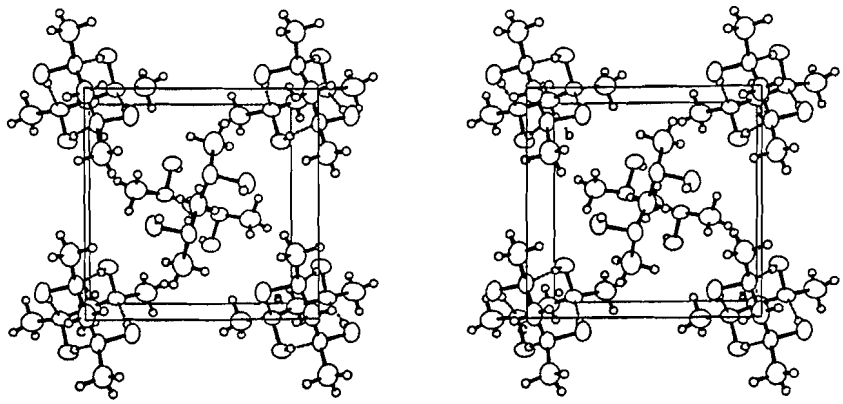
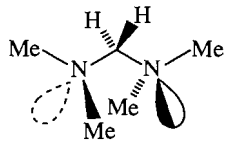
Results and discussion

In the solid state **1** adopts the conformation **7***D*, the methyl substituents being in a fully staggered antiperiplanar orientation with respect to the geminal nitrogen substituents and with the hydroxy groups exhibiting a *trans–gauche* orientation. As a result of the *trans* positioning of the *N*-hydroxy groups, two enantiomeric conformers are possible, with both OH substituents in (+sc) or both in (−sc) arrangements. Both of these, **1***D*(+sc) and **1***D*(−sc), are realized in the crystal (Fig. 2) as hydrogen-bonded dimeric pairs having crystallographically imposed $\bar{4}$ symmetry (O—H(O)···N (y, $1 - x$, $-z$), O···N = 2.775(3), H···N = 1.93(4) Å, O—H···N = 171(2)°).

1*D*(+sc)•**1***D*(−sc)
(- - - - = H-bridge

Individual molecules of **1** (Fig. 1) have exact C_2 symmetry (lying on a crystallographic two-fold axis at ($\frac{1}{2}$, $\frac{1}{2}$, z) and are similar to molecules of *N,N,N′,N′*-tetramethylmethanediamine **8** which has a similar molecular structure and the same symmetry in the gas phase (22). The central N—C bond lengths are identical (by symmetry), and as the model **7***D* points out, no anomeric interaction is involved in this molecular conformation. The model compound **7** with R = H has been geometrically refined by *ab initio* calculations (23) and has equal N—C bond distances of 1.4653 Å in the *D* conformation, consistent with the N—C distance of 1.461(3) Å in **1**. Since the orbital interaction (anomeric effect) is of little or no importance in crystalline **1**, the associative forces of the four intermolecular O—H···N hydrogen bonds in the dimer, along with the repul-





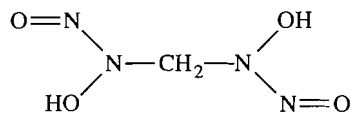


FIG. 2. Stereoscopic view of the packing arrangement of *N,N'*-dihydroxy-*N,N'*-dimethylmethanediamine.

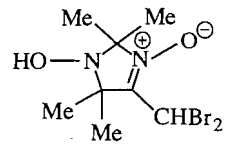
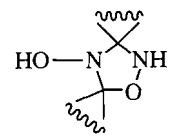
sive interaction between the *N*-methyl groups (demonstrated by the tetramethyl derivative **8** (22)), predominate in the stabilization of **1** in the solid state.

There is one other *N,N'*-dihydroxymethanediamine derivative that has been structurally characterized, the bis-*N*-nitroso derivative **9**. In this case crystal structures have been reported for the potassium (24) and sodium (25) salts of the dianion derived from **9**. The structure of the dianion shows marked differences in both bond lengths and in conformation from, and is not directly comparable with that of **1**. The C—N(O)—NO moiety in the dianion of **9** is nearly planar and the N—C bond length of 1.512(7) Å and N—C—N angle of 104.9° observed for the dipotassium salt (24) differ from corresponding values of 1.461(3) Å and 110.9° for **1** and 1.449(4) Å and 115.8° for the gas phase structure of **8** (22).



8



9

The geometry of the hydroxylamine moiety in **1** resembles that in MeNHOH.HCl (26) more than it does that in the free base MeNHOH as determined in the gas phase (27), since as in the H-bonded dimer of **1**, the nitrogen atom in *N*-methylhydroxylamine hydrochloride is quaternized. The N—Me and N—O bond lengths and the O—N—Me angle in **1** are 1.468(3) Å, 1.458(2) Å, and 105.2(2)°; corresponding values are 1.46 Å, 1.45 Å, and 105° for MeNHOH.HCl and 1.420 Å, 1.477 Å, and 107.7° for MeNHOH.

Infrared and ^{1}H nmr spectra indicate that the species **4** and/or **5** are present in solutions of *N,N'*-dihydroxy-*N,N'*-dimethylmethanediamine, **1**. The intramolecular hydrogen bond in **4** or **5** is not observed in the solid state which consists of stable hydrogen-bonded dimers of **1**. The intramolecular O···O distance in the *trans–gauche* conformation, 3.804(3) Å, is too large for intramolecular hydrogen bonding. *N*-oxide tautomers of **1** (such as **5**), if involved in the H-bonded dimer, would be expected to have shorter N—O bonds. The most comparable *N*-oxide, incorporated into an *N,N*-acetal structure, is that of hexamethylenetetramine *N*-oxide, hydrogen-bonded to formic acid (28) with an N—O distance of 1.388 Å and hydrogen-bonded to H_2O_2/H_2O (29) with N—O = 1.380 Å. Other related N—O distances have been reported for *N,N*-dimethyl-

10

11

2-aminoethanol *N*-oxide (30), 1.38 and 1.41 Å for intra- and intermolecular H-bonded moities, trimethylamine *N*-oxide, 1.42 Å H-bonded to HCl (31) and 1.388 Å for the free base (32). The structures of the cyclic *N,N*-acetals **10** (33) and **11** (34) (the *N,N*-acetal moiety being part of a tetracyclohexadecane system) with only one *N*-hydroxy group have been reported. The N—O(H) and (N)C—N(OH) distances in **1** of 1.458(2) and 1.468(2) Å may be compared with corresponding distances of 1.44 and 1.46 Å in **10** and 1.458(2) and 1.484(2) Å in **11**.

The *trans–gauche* orientation of the *N*-hydroxy groups of **1***D*(+sc), and also of **1***D*(−sc), is very similar to that in the phenylboronate **2** (2, 3). The torsion angles in the MeN(O)CH_2N(O)Me moiety of **2** differ by an average of 14.3° from those in **1**, the differences being greater about bonds involving the three-coordinate nitrogen atom (24.1°) than for those involving the four-coordinate nitrogen atom (4.4°). The N—C—N bond angle in **1** (110.9°) is compressed in **2** (mean 102.5°) by the formation of the fused system of five-membered rings via transannular N → B bonding. The C(1)—N—O angle of **1** (106.9°) is reduced to a mean of 101.0° at the trivalent nitrogen in **2** and remains nearly the same at the tetravalent nitrogen atom (mean 107.7°).

One significant change involves the *N,N*-acetal system: one of the N—C bonds is shortened from 1.461 Å in **1** to 1.452 Å in **2**, at the trivalent nitrogen atom, while the other is lengthened from 1.461 Å to a mean of 1.480 Å. The difference between the N—C bonds at the *N,N*-acetal function in **2** is nearly 0.03 Å, whereas in **1** both bond lengths are the same. Even though quaternization at one of the nitrogen atoms is a factor, this is interpretable in terms of a "double bond – no bond resonance" at the N—C—N segment of **2**, similar to that shown in formula **6**. Since the conformation of **2** (like that of **1**) is unfavorable for $n\pi/\sigma^*$-orbital interaction as defined by the anomeric effect (12, 13), other stabilizing forces must be active, like a more effective distribution of electrical charges (12*a*) resulting in the minimization of dipole–dipole interactions (12*c*, 13), i.e. the "reverse anomeric effect". A decrease of electron density at the trivalent nitrogen in **2** has recently been indicated by nuclear quadrupole double resonance experiments (35).

Thermodynamic factors are undoubtedly important in the reaction of **1** with phenylboronic acid. The expected product **3** would contain a sterically less favorable conformation of the ligand, but the energy difference is probably not large enough to prevent the reaction from occurring. The observed product **2**, however, is stabilized by both a transannular N → B interaction and the presence of the very stable B(sp^2)—O—B(sp^3) unit.

Synthesis, structure, and vibrational spectrum of poly-μ-pyrazine(pyrazine)(trifluoromethanesulfonato-O)copper(I)

T. OTIENO, S. J. RETTIG, R. C. THOMPSON,[1] AND J. TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received February 10, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

T. OTIENO, S. J. RETTIG, R. C. THOMPSON, and J. TROTTER. Can. J. Chem. **67**, 1964 (1989).

Orange–brown crystals of composition $Cu(pyz)_2(CF_3SO_3)$ (pyz = pyrazine, 1,4-diazine) were obtained from methanol solutions containing $Cu(CF_3SO_3)_2$ and pyrazine in approximate 1:2 mole ratio. Single crystal X-ray diffraction and infrared and Raman spectroscopy studies are reported. Crystals of the title compound are triclinic, a = 8.312(2), b = 10.903(3), c = 8.201(2) Å, α = 92.53(2), β = 113.77(2), γ = 91.40(2)°, Z = 2, space group $P\bar{1}$. The structure was solved by heavy atom methods and was refined by full-matrix least-squares to R = 0.035 and R_w = 0.044 for 2458 reflections with $I \geq 3\sigma(I)$. The compound contains chains of copper ions linked by bidentate bridging pyrazine ligands. The coordination around each copper is completed by monodentate pyrazine and trifluoromethanesulfonato groups to produce a distorted tetrahedral CuN_3O chromophore.

Key words: crystal structure, μ-pyrazine copper(I) triflate polymer, vibrational spectra.

T. OTIENO, S. J. RETTIG, R. C. THOMPSON et J. TROTTER. Can. J. Chem. **67**, 1964 (1989).

On a obtenu des cristaux bruns orangés, de composition $Cu(pyz)_2(CF_3SO_3)$ (pyz = pyrazine ou diazine-1,4), à partir de solutions méthanoliques contenant du $Cu(CF_3SO_3)_2$ et de la pyrazine dans un rapport molaire d'environ 1:2. On rapporte des études de diffraction des rayons-X sur des cristaux uniques ainsi que des études de spectroscopies infrarouge et Raman. Les cristaux mentionnés dans le titre sont tricliniques, avec a = 8,312(2), b = 10,903(3) et c = 8,201(2) Å, α = 92,53(2), β = 113,77(2) et γ = 91,40(2)°, Z = 2 et groupe d'espace $P\bar{1}$. On a résolu la structure par la méthode des atomes lourds et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 0,035 et R_w = 0,044 pour 2458 réflexions avec $I \geq 3\sigma(I)$. Le composé contient une chaîne d'ions cuivres liés par des ligands bidentates pyrazines agissant comme ponts. La coordination autour de chaque cuivre est complétée par des groupements pyrazine monodentate et trifluorométhanesulfonato qui produisent un chromophore CuN_3O tétraédrique déformé.

Mots clés : structure cristalline, polymère de μ-pyrazine cuivre(I) triflate, les spectres de vibration.

[Traduit par la revue]

Introduction

In an earlier study (1) we found that the reaction of copper(II) trifluoromethanesulfonate (copper(II) triflate) with an excess of 1,4-diazine (pyrazine, pyz) in methanol yields the molecular complex, $Cu(pyz)_4(CF_3SO_3)_2 \cdot H_2O$, and subsequent thermolysis of this compound produces the pyrazine-bridged polymeric material, $Cu(pyz)(CF_3SO_3)_2$. Subsequent attempts to prepare the bis(pyrazine) complex, the triflate analogue of $Cu(pyz)_2(CH_3SO_3)_2$ (2), by the reaction of $Cu(CF_3SO_3)_2$ with pyrazine in approximate 1:2 mole ratio in methanol failed to produce the anticipated product. Instead, on standing over a period ~3 weeks the solutions yielded orange crystals of a copper(I) complex of composition $Cu(pyz)_2(CF_3SO_3)$. We report here single crystal X-ray diffraction and vibrational spectroscopy studies on this compound.

While pyrazine-bridged complexes of copper(II) are not uncommon (1–4) examples of copper(I) compounds appear to be limited to those of composition Cu_2LX_2 (where L = pyz or a methylpyrazine and X is Cl, Br, I, or CN) reported by Lever, Lewis, and Nyholm (5, 6) in the early 1960's. The chloride and bromide pyrazine complexes were reportedly unstable and none of these materials were examined by X-ray diffraction. The compound reported in the present work is of special interest because it contains both bridging and terminal pyrazine ligands and this is the first X-ray structure determination to be reported on such a compound.

Experimental

Synthesis

Copper(II) triflate was prepared as described earlier (7). In a nitrogen atmosphere glove-box, pyrazine (2.96 mmol), dissolved in 3 mL of methanol (containing about 10% v/v of 2,2-dimethoxypropane), was added to copper(II) triflate (1.45 mmol) dissolved in 4 mL of the same solvent. A green solution resulted. The reaction flask was covered with parafilm and over a period of three weeks orange–brown crystals formed. The supernatant solution was decanted and the crystals washed several times with fresh solvent then left to dry in the glove-box. It was noted that an additional product in the form of fine black particles was also present and the crystals had to be physically separated from these. The crystals were subsequently handled in the atmosphere where they showed no visible signs of decomposition. Although the microanalytical data were consistently low for carbon the composition was determined unequivocally as $Cu(C_4H_4N_2)_2(CF_3SO_3)$ from the X-ray studies. *Anal.* calcd. for $CuC_9H_8N_4F_3SO_3$: C 29.00, H 2.15, N 15.03; found: C 28.24, H 2.25, N 14.84. The analytical data suggest the possibility of some hydration (~0.5 mol water per mole of complex) as observed previously for $Cu(pyz)_2(CH_3SO_3)_2$ (2); however, the presence of water was detected by neither the X-ray nor the infrared studies. Elemental analyses were performed by P. Borda of this Department.

Vibrational spectra

The infrared spectrum of a sample mulled in Nujol and pressed between KRS-5 plates (Harshaw Chemical Co.) was recorded on a Perkin Elmer 598 spectrophotometer. Calibration was achieved using polystyrene and frequencies are considered accurate to ±3 cm^{-1}. The Raman spectrum was recorded on a Spex Ramalog 5 spectrometer

equipped with a Spectra Physics 164 argon ion laser. The green line at 514.5 nm was used for excitation. The sample was finely ground and sealed in a melting point capillary.

X-ray crystallographic analysis

A crystal ca. 0.35 × 0.40 × 0.45 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 36–42°) measured on a diffractometer with Mo-$K\alpha$ radiation (λ = 0.71069 Å). Crystal data at 21°C are as follows:

$C_9H_8CuF_3N_4O_3S$ f.w. = 372.79

Triclinic, a = 8.312(2), b = 10.903(3), c = 8.201(2) Å, α = 92.53(2), β = 113.77(2), γ = 91.40(2)°, V = 678.8(3) Å^3, Z = 2, ρ_c = 1.82 Mg m^{-3}, $F(000)$ = 372, μ(Mo-$K\alpha$) = 18.07 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 16° min^{-1} over a range of (1.0 + 0.30 tan θ) degrees in ω (with up to 9 rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random fluctuations. After data reduction,[2] an absorption correction was applied using the analytical method (8, 9). Transmission factors ranged from 0.901 to 1.000. Of the 4428 reflections measured, 3969 were unique (R_{int} = 0.017) and 2458 (62.0%) of these had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = (S^2(C + 4B) + (0.025(F_o^2))^2)/Lp^2$ with S = scan rate, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by conventional heavy atom methods, the Cu and S atoms being positioned from the Patterson function and the remaining atoms (including hydrogen) from subsequent difference Fourier syntheses. The centrosymmetric space group $P\bar{1}$ was suggested by the Patterson function and was confirmed by successful refinement of the structure. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms with isotropic thermal parameters. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 10. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of 222 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.035 and R_w of 0.044 for 2458 reflections with $I \geq 3\sigma(I)$. For all 3969 reflections R = 0.087, for all 2395 reflections with $\theta \leq 25°$ R = 0.050. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.03σ. The mean error in an observation of unit weight was 1.92. The final difference map showed maximum fluctuations of −0.37 to 0.44 e Å^{-3}, the latter being 0.98 Å from the Cu atom. The final positional and equivalent isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are listed in Tables 2 and 3. Hydrogen parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[3]

Results and discussion

Synthesis

Although copper(I) triflate is known (11) there have been no reports, to our knowledge, of coordination complexes of this compound. $Cu(pyz)_2(CF_3SO_3)$ crystallized over a period of three weeks from a solution of $Cu(CF_3SO_3)_2$ and pyrazine in methanol. The isolation of a copper(I) complex of this type from a copper(II) salt in alcohol solution without added reducing agent is not without precedence. Dibromo(tetramethylpyrazine)dicopper(I) was prepared by refluxing copper(II) bromide and the ligand in ethanol (6); in this case the *o*-methyl groups on the ligand were considered to hinder sterically the formation of square planar copper(II) derivatives and thereby stabilize the linear copper(I) complex (12). In the case reported here the stabilization of the copper(I) derivative is achieved through the

formation of an insoluble polymer. In both cases the reducing agent is presumably the solvent.

Crystal structure analysis

The crystal structure analysis shows that the complex contains spiral chains of copper ions linked by bidentate bridging pyrazine ligands. The coordination around each copper is completed by monodentate pyrazine and triflate groups to produce a distorted tetrahedral CuN_3O chromophore. The geometry about copper together with the atom numbering scheme is shown in Fig. 1 and a stereoview of the unit cell is shown in Fig. 2. The terminal pyrazine groups and the triflate anions are both arranged syndiotactically along the polymer skeleton. The pyrazine rings are planar within experimental error, with the planes of the monodentate pyrazine rings approximately orthogonal to the planes of the bridging pyrazine ligands. This orientation minimizes repulsions between the terminal pyrazine and the triflate anion. Surprisingly, two slightly different bridging pyrazine groups alternate along the chain, one forming the shortest bonds to copper (1.971(2) Å) and the other the longest Cu—N bonds (2.027(2) Å). The Cu—N bond formed by the terminal pyrazine group is intermediate at 1.985(2) Å.

These bond lengths may be compared with published Cu(II)–pyrazine distances, keeping in mind the fact that the effective ionic radius of Cu^+ is estimated to be ~0.03 to 0.04 Å larger than that of Cu^{2+} (13). The Cu—N bond lengths in the title compound are all shorter than those found in the copper(II) pyrazine complexes, $Cu(pyz)_2(CH_3SO_3)_2$ (2.058(2) and 2.692(3) Å) (2) and $Cu(pyz)_2(ClO_4)_2$ (2.062(3) Å) (14), while only the longest of the three, at 2.027 Å, is longer than the relatively short Cu—N (pyrazine) bond found in $Cu(pyz)(NO_3)_2$ (1.984 Å) (15). This suggests relatively strong coordination by all of the pyz moieties in the compound studied here. For comparison, some representative Cu(I)—N bond lengths are: 2.05 Å in $[Cu(py)_4]ClO_4$ (16) and 2.045 Å in [Cu(phenanthroline)$_2$]ClO_4 (17). A listing of twelve copper(I) compounds containing CuN_4 chromophores in ref. 18 shows bond distances ranging from 1.985 to 2.117 Å.

The Cu—O bond length in the title compound (2.331(2) Å)

[b] Bridging.

is considerably greater than that seen in $Cu(pyz)_2(CH_3SO_3)_2$ (1.956(1) Å) (2) and, although shorter than that reported for $Cu(py)_4(CF_3SO_3)_2$ (2.425 Å) (1), is nonetheless indicative of weak coordination by the anion. In the tetranuclear cationic species $[Cu_4(OH)_4(SO_3CF_3)_2[N(C_5H_4N)_3]_4]^{2+}$ the triflates are bidentate bridging ligands (19) and here the Cu—O bonds are longer still (mean value of 2.57(4) Å). In ref. 18 thirteen Cu(I)—O bond lengths are listed for nine four-coordinate copper(I) species. They range from 2.077 to 2.278 Å, all shorter than the Cu(I)—triflate distance observed here.

Although two bridging pyrazine groups are distinguished by different Cu—N bond distances the internal bonding parameters are identical for the two species to within experimental error. Moreover, the C—C bonds (1.381(4) Å and 1.376(4) Å) and two of the C—N bonds in each (1.331(4) Å) are indistinguishable from the mean C—C and C—N bond lengths found in free pyrazine (20) (1.378 Å and 1.334 Å, respectively). The other C—N bonds at 1.324(4) Å and 1.325(4) Å are significantly shorter. The most distorted pyrazine moiety is the terminal one. It has two shortened C—C bonds at 1.361(5) Å and 1.368(5) Å and one short C—N bond at 1.322(5) Å. All three pyrazine rings in the compound studied here appear to be more distorted than those found, for example, in $Cu(pyz)_2(CH_3SO_3)_2$ (2), $Cu(pyz)(NO_3)_2$ (15), or $Cu(pyz)_2(ClO_4)_2$ (14) again consistent with relatively strong pyrazine–metal interactions in $Cu(pyz)_2(CF_3SO_3)$.

As in the previously studied $Cu(py)_4(CF_3SO_3)_2$ (1), the triflate anion in $Cu(pyz)_2(CF_3SO_3)$ adopts a staggered-ethane configuration about the C—S bond. Repulsions between adjacent oxygen atoms are apparently greater than those between the oxygen atoms and the trifluoromethyl group; consequently, the O—S—O angles are greater than, while the C—S—O angles are less than the tetrahedral angle. As expected, the S—O bond involving the oxygen coordinated to the copper is longer (1.440(2) Å) than the terminal S—O bonds (1.422(3) and 1.432(3) Å). Within experimental error these are identical to those found in $Cu(py)_4(CF_3SO_3)_2$ (1) and in the $[Cu(OH)_4(CF_3SO_3)_2[N(C_5H_4N)_3]_4]^{2+}$ cation (19). In general, the internal bonding parameters for the triflate anion in $Cu(pyz)_2(CF_3SO_3)$ are similar to those found in other triflate complexes. The mean bond distances and bond angles in $CF_3SO_3^-$ are compared with those found from some previous studies in Table 4. The relative insensitivity of these parameters to the mode of anion coordination is an indication of how "innocent" this anion is, forming only weak coordinative interactions with metals.

Vibrational spectroscopy

The use of vibrational spectroscopy to distinguish between terminal and bridging pyrazine ligands has been a matter of some interest since the first complexes of this type were characterized (6, 21, 22). $Cu(pyz)_2(CF_3SO_3)$ contains both types of pyrazine and it was of interest to see what effect this has on the vibrational spectrum of the compound. The triflate ion has also been the subject of studies directed at establishing correlations between vibrational frequencies and the mode of

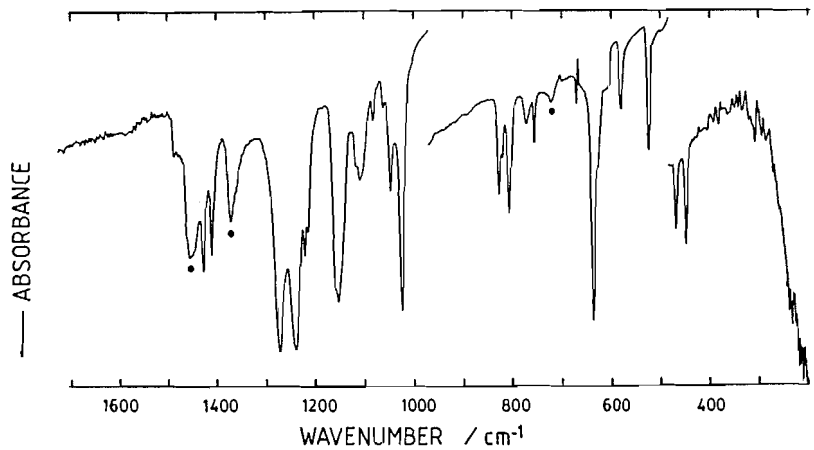

FIG. 3. Infrared spectrum of $Cu(pyz)_2(CF_3SO_3)$. Nujol peaks are identified.

coordination (1, 7, 19, 23–26). Infrared and Raman data, with assignments are given in Table 5 and the infrared spectrum is shown in Fig. 3.

The bands observed in the infrared spectrum of $Cu(pyz)_2(CF_3SO_3)$ may, for the most part, be readily separated into absorption arising either from the triflate anion vibrations or pyrazine vibrations. A pair of strong bands at 1279 and 1247 cm^{-1} is due to the antisymmetric SO_3 stretching vibration (E symmetry in C_{3v}), the splitting of the band arising from a lowering of the symmetry of the CSO_3 portion of the anion from C_{3v} to C_s due to the monodentate form of coordination. The magnitude of this splitting (32 cm^{-1}) is comparable to that observed for $Cu(py)_4(CF_3SO_3)_2$ (43 cm^{-1}) where X-ray data show a similar degree of anion distortion through coordination (1); whereas, the splitting is much smaller than that observed for $Fe(py)_4(CF_3SO_3)_2$ (~85 cm^{-1}) where X-ray studies show considerably greater anion distortion (25). We note also that the δ_{as} SO_3 (E) mode is split in the more distorted iron complex (25) but remains a single band in both of the weakly perturbed copper complexes.

It is difficult to make unambiguous assignments of the bands in the 1150 to 1230 cm^{-1} range since as indicated in Table 5 bands due to CF_3 stretching modes as well as pyrazine bands are expected in this region. Similarly, it is not possible to determine which of the two weak bands at 774 and 760 cm^{-1} is due to the C—S stretching mode and which is a neutral ligand band. The remaining bands in the infrared spectrum are readily assigned. Bands assigned to pyrazine vibrations are compared in Table 5 with those reported for $SnCl_4(pyz)_2$ (21), a compound containing non-bridging, monodentate pyrazine ligands. The doubling of these bands in $Cu(pyz)_2(CF_3SO_3)$ is clearly due to the presence of both bridging and monodentate pyrazine in this compound. In particular, we note the two medium intensity, sharp bands at 472 and 452 cm^{-1}. The lower frequency band may be assigned to the monodentate pyrazine molecules since bands at this frequency (but not at the higher frequency) and assigned to pyrazine have been observed for $SnCl_4(pyz)_2$, $SnBr_4(pyz)_2$, and $Cu(pyz)_4(CF_3SO_3)_2 \cdot H_2O$ (1, 21), all of which have monodentate pyrazine ligands only. The band at 472 cm^{-1} may be assigned to the bridging pyrazine ligand since both $SnCl_4(pyz)$ and $SnBr_4(pyz)$ (compounds containing only bridging pyz) exhibit a pyz vibration at this frequency. In $Cu(pyz)(CF_3SO_3)_2$ where, again, the pyz ligand is considered to be bridging the band appears at an even higher frequency, 504 cm^{-1} (1). This particular pyrazine band appears at 417 cm^{-1} in liquid pyrazine. Of all pyrazine vibrations observed this band is clearly the one most affected by coordination, invariably shifting to higher frequencies: to about 450 cm^{-1} in the case of monodentate coordination and to 470 cm^{-1} or higher for bidentate coordination. The position of this band would appear to be a reasonable indication of the mode of pyrazine coordina-

tion. Like most empirical criteria of this type, however, care must be taken in its application. $Cu(pyz)_2(CH_3SO_3)_2$ exhibits two bands, corresponding to the 417 band in liquid pyrazine, at 494 and 440 cm^{-1} (2). In this case there are two types of bridging pyrazine molecules. One is involved in relatively strong interactions with copper and no doubt gives rise to the higher frequency band. The other pyrazine ligand in this molecule is involved in very weak coordination to the metal and, although bridging, gives rise to a band at 440 cm^{-1}, lower even than that normally observed for monodentate pyrazine.

Raman frequencies which we observed for $Cu(pyz)_2(CF_3SO_3)$ are recorded in Table 5. The quality of the spectrum was not particularly good due perhaps to the fairly intense orange–brown color of the sample. Nonetheless, comparison of the spectrum with those reported for the pyrazine complexes of $SnCl_4$ and for liquid pyrazine (21) shows that we are able to observe bands corresponding to the strong to very strong absorptions reported in the earlier work. As indicated in Table 5, the very strong Raman band at 1031 cm^{-1} may be assigned as either the symmetric SO_3 stretching vibration or the pyrazine a_g (1015 cm^{-1} in liquid pyrazine) vibration, or both, while the medium intensity band at 1240 cm^{-1} is likely either the symmetric CF_3 vibration or the pyrazine a_g (1232 cm^{-1} in liquid pyrazine) vibration. The bands at 1608 and 669 cm^{-1} are assignable to pyrazine vibrations while the weak absorption at 1284 cm^{-1} is tentatively assigned to an SO_3 vibration. Unfortunately, the quality of the Raman spectrum did not permit one to distinguish between bridging and monodentate pyrazine.

Metal pyrazolate polymers. Part 1. Synthesis, structure, and magnetic properties of the $[Cu(pz)_2]_x$ polymer

M. K. EHLERT, S. J. RETTIG, A. STORR, R. C. THOMPSON, AND J. TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received February 10, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

M. K. EHLERT, S. J. RETTIG, A. STORR, R. C. THOMPSON, and J. TROTTER. Can. J. Chem. **67**, 1970 (1989).

A novel and reliable method for the synthesis of polybis(μ-pyrazolato-*N*,*N*′)copper(II), $[Cu(pz)_2]_x$ (where pz = $N_2C_3H_3$), is presented. Single crystals of the polymer suitable for X-ray study have been grown under carefully controlled conditions. Crystals of polybis(μ-pyrazolato-*N*,*N*′)copper(II) are orthorhombic, a = 7.917(1), b = 11.491(2), c = 7.778(1) Å, Z = 4, space group *Ibam*. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.029 and R_w = 0.038 for 507 reflections with $I \geq 3\sigma(I)$. The crystal structure consists of infinite double-bridged polymeric chains. The Cu atom has a D_2 distorted tetrahedral coordination geometry with Cu—N = 1.957(2) Å and N—Cu—N = 94.3(1)–139.5(1)°. Magnetic susceptibility studies (4.2 to 299 K) on this material reveal very strong antiferromagnetic exchange between copper(II) centres in the extended linear chains. The magnetic data have been successfully analyzed according to the isotropic Heisenberg model for linear chains with $-J = 78\ cm^{-1}$ and g = 2.12.

Key words: crystal structure, copper(II) pyrazolate chain polymer, antiferromagnetic exchange.

M. K. EHLERT, S. J. RETTIG, A. STORR, R. C. THOMPSON et J. TROTTER. Can. J. Chem. **67**, 1970 (1989).

On propose une nouvelle méthode de synthèse du polybis(μ-pyrazolato-*N*,*N*′)cuivre(II), $[Cu(pz)_2]_x$, dans lequel pz = $N_2C_3H_3$. Utilisant des conditions bien contrôlées, on a fait croître des cristaux uniques du polymère qui étaient appropriés pour une étude par diffraction des rayons-X. Les cristaux de polybis(μ-pyrazolato-*N*,*N*′)cuivre(II) sont orthorhombiques avec a = 7,917(1), b = 11,491(2) et c = 7,778(1) Å, Z = 4 et groupe d'espace *Ibam*. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 0,029 et R_w = 0,038 pour 507 réflexions avec $I \geq 3\sigma(I)$. La structure cristalline est composée de chaînes polymériques infinies à doubles ponts. L'atome de Cu possède une géométrie de coordination tétraédrique déformée D_2 avec Cu—N = 1,957(2) Å et N—Cu—N = 94,3(1)–139,5(1)°. Des études de susceptibilité magnétique effectuées sur ce matériel à des températures allant de 4,2 à 299 K révèlent l'existence d'un très puissant échange antiferromagnétique entre les centres de cuivre(II) des chaînes linéaires étendues. On a analysé avec succès les données magnétiques à l'aide du modèle isotrope d'Heisenberg pour des chaînes linéaires avec $-J = 78\ cm^{-1}$ et g = 2,12.

Mots clés : structure cristalline, chaîne polymérique de pyrazolato-cuivre(II), échange antiferromagnétique.

[Traduit par la revue]

Introduction

As part of our continuing interest in metal pyrazolate complexes and magnetic exchange effects in transition metal coordination polymers we have initiated a comprehensive study of binary transition metal pyrazolate compounds. Earlier studies in this area have been reviewed by Trofimenko (1) and the intractable nature of the polymeric species noted. Our primary interest in these materials stems from the expectation that they will provide examples of infinite-chain polymers with the bridging pyrazolate ligands acting as pathways for strong magnetic exchange between metal centres. By varying the substituents on the pz (pz = pyrazolyl) rings and studying different metal systems it should be possible to examine systematically how electronic and structural factors affect the magnetic and other properties of these materials. We present here a novel method for the synthesis of the $[Cu(pz)_2]_x$ polymer and provide evidence that the methods (2) employed in previous attempts to prepare this compound in fact yield a different product. In addition, the new route described provides excellent crystals of the binary copper(II) pyrazolate polymer enabling us to report the first X-ray crystal structure determination of this type of complex. We also describe electronic and vibrational spectroscopic, variable temperature magnetic susceptibility (4.2 to 299 K), and thermal studies on this novel material.

Experimental

Synthesis

Copper metal shot was cleaned by washing first in 12 *M* HCl, then water and finally acetone. A magnetic stir bar, 10.0 g (147 mmol) of pyrazole and 8.13 g (78.2 mmol) of cleansed copper shot were placed in a 100 mL round bottom flask fitted with a reflux condenser. The reaction mixture was heated, with stirring, to 110°C and air was bubbled into the molten pyrazole via a Pyrex tube lowered through the condenser. A green solid appeared almost immediately. The mixture was allowed to react for 18 h during which time sublimed pyrazole was periodically scraped back into the reaction mixture. The mixture, which had solidified on cooling, was then washed with 4 × 100 mL portions of CH_2Cl_2, 100 mL of high boiling petroleum ether and then suction filtered. $[Cu(pz)_2]_x$ was obtained as a bright green powder in 79% yield (based on copper shot reacted). The remaining reacted copper apparently formed a brown CH_2Cl_2 soluble material. Copper analysis was performed by gravimetry and C, H, and N analysis was performed by P. Borda of this department. *Anal.* calcd. for $C_6H_6CuN_4$: Cu 32.15, C 36.45, H 3.06, N 28.34; found: Cu 31.80, C 36.74, H 3.17, N 28.50.

Several attempts were made to prepare $[Cu(pz)_2]_x$ using the literature methods of Vos and Groeneveld (2). An insoluble black material was obtained in all cases, as described by the above authors, but the elemental composition indicated $Cu_2(pz)_3(OH)$ as the empirical formulation. *Anal.* calcd. for $C_9H_{10}Cu_2N_6O$: Cu 36.80, C 31.30, N 24.34, H 2.92, O 4.63; found: Cu 36.57, C 31.53, N 24.39, H 2.85, O 4.70.

Single crystals of $[Cu(pz)_2]_x$ suitable for X-ray analysis were synthesized in a manner similar to that described above except that only one piece of copper shot was used (~0.5 g), and the reaction mixture was not stirred. In addition, air was not bubbled through the mixture but allowed instead to slowly diffuse from the top of the reflux condenser. The reaction was allowed to proceed for 5 days after which the cooled mixture was washed with water and then acetone yielding dark green crystals.

Physical characterization

$[Cu(pz)_2]_x$ was found to be insoluble in both polar and non-polar solvents, but was solubilized with decomposition in acid. Differential scanning calorimetry measurements, obtained with a Mettler DSC 20 Standard Cell and TC10 TA Processor as described previously (3), showed the compound to decompose in air, without melting, at 270°C. $[Cu(pz)_2]_x$ exhibits thermochromism at low temperatures. The material is green at room temperature but at 77 K it is bright blue. Trofimenko, in an earlier review (4), made mention of this thermochromism in copper pyrazolate systems. At this low temperature single crystals of the polymer remain intact.

The electronic spectrum (12 200 – 31 200 cm^{-1}), obtained on a Nujol mull supported on filter paper, using a Perkin Elmer Coleman 124 spectrophotometer, showed two broad bands with maxima at 15 400 and 25 000 cm^{-1}. The infrared spectrum (4 000 – 250 cm^{-1}) was obtained on a Perkin Elmer Model 598 spectrophotometer. Samples were mulled in Nujol and pressed between KRS-5 plates (Harshaw Chemical Co.). Frequencies (cm^{-1}): 2895 s (N), 2840 s (N), 1495 m (sh), 1457 s (N), 1413 m, 1376 s (N), 1268 m, 1253 m (sh), 1181 s, 1170 s (sh), 1070 s, 974 w, 914 m, 882 m, 843 w, 770 s, 755 s, 722 m (sh) (N), 624 s, 377 m, 364 s (N = Nujol peak).

Magnetic susceptibilities over the temperature range of 4.2–100 K were measured using a P.A.R. Model 155 vibrating sample magnetometer (field = 9225 G) and over the temperature range of 80–300 K using a Gouy balance (field = 8000 G). The equipment used was as described in detail earlier (5) with the exception of the Gouy balance which has since been equipped with a Mettler AE 163 balance. Magnetic susceptibilities were corrected for diamagnetism: copper, −11; $C_3H_3N_2$, −40 (values in 10^{-6} cm^3 mol^{-1}). A correction of 60 × 10^{-6} cm^3 mol^{-1} was applied for temperature-independent paramagnetism. Values of molar magnetic susceptibilities and magnetic moments are given in Table 4.[1]

X-ray crystallographic analysis

A crystal ca. 0.10 × 0.15 × 0.20 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 26–35°) measured on a diffractometer with Mo-$K\alpha$ radiation (λ = 0.71069 Å). Crystal data at 21°C are:

$C_6H_6CuN_4$ f.w. = 197.69

Orthorhombic, a = 7.917(1), b = 11.491(2), c = 7.778(1) Å, V = 707.6(2) Å^3, Z = 4, ρ_c = 1.86 Mg m^{-3}, $F(000)$ = 396, μ(Mo-$K\alpha$) = 30.2 cm^{-1}. Absent reflections: hkl, $h + k + l$ odd, $0kl$, k and l odd, and $h0l$, h and l odd, space group *Ibam* (D_{2h}^{26}, No. 72) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 16° min^{-1} over a range of (1.47 + 0.35 tan θ) degrees in ω (with up to nine rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 70°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, remained constant to within 2%. After data reduction,[2] an empirical absorption correction, based on azimuthal scans for several reflections, was applied which resulted in transmission factors ranging from 0.907 to 1.000. Of the 832 independent reflections measured, 507 (60.9%) of these had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = (S^2(C + 4B) + (0.045(F_o^2))^2)/Lp^2$ with S = scan rate, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by direct methods in the centrosymmetric space group *Ibam* which was suggested by the E-statistics and confirmed by later calculations. The coordinates of the non-hydrogen atoms were determined from an E-map and those of the hydrogen atoms were determined from a subsequent difference Fourier synthesis. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 6. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 35 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.029 and R_w = 0.038 for 507 reflections with $I \geq 3\sigma(I)$. For all 832 reflections R = 0.081. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.03σ. The mean error in an observation of unit weight was 1.23. The final difference map showed maximum fluctuations of −0.34 to 0.43 e Å^{-3}. The final positional and (equivalent) isotropic thermal parameters appear in Table 1. Bond lengths and angles are listed in Tables 2 and 3. Hydrogen parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[1]

Results and discussion

In an earlier paper by Vos and Groeneveld (2), reactions of copper salts with pyrazole in aqueous base were reported to yield black polymeric material of composition $[Cu(pz)_2]_x$. Attempts to repeat these reactions in our laboratory invariably gave a black polymeric species as reported, but of composition $[Cu_2(pz)_3(OH)]_x$ rather than the $[Cu(pz)_2]_x$ formulation stated earlier. The alternate route described here, involving the reaction of metallic copper with molten pyrazole in the presence of air, has led to the desired polymer as a green colored solid. The polymer can be obtained as X-ray quality green crystals under carefully controlled conditions. The compound is both
