Our first attempts at producing polymers from styrene and DVB (divinylbenzene) inside Chromosorb particles resulted in extraction- and heat-resistant materials but little else. Early plate numbers ranged below 2000/m; some significantly worse, in fact, than Fuller's data. By a series of modifications to the synthetic technique, the plate numbers could be raised above 4000/m on a 100/120 mesh support, and a wide variety of different compounds could be satisfactorily chromatographed. At that point, mindful of diminishing returns and the theoretical limits on column efficiencies, we considered that the study had essentially reached its goal.

Experimental

Materials

Chromosorbs W and G (in commercial AW and AW-DMCS forms) and Chromosorb 101 were all Johns-Manville products received as 100/120 mesh cuts. Poropak Q was obtained from Waters. The conventional divinylbenzene mixture (about 50 to 60% DVB in ethylvinylbenzene plus other materials) was supplied by BDH Chemicals. Neat (i.e. non-diluted but stabilized) divinylbenzene was purchased from Pfaltz and Bauer, 2,2-azobis(isobutyronitrile) from PolyScience, dimethyldichlorosilane from Aldrich, vinyldimethylchlorosilane from Petrarch, and 1,2,3,4-tetrahydronaphthalene (tetralin) from Fisher. Other chemicals were ACS grade or better.

Divinylbenzene (the "pure" material) was distilled in vacuum under nitrogen at 36 to 40°C and stored under nitrogen in the refrigerator before use. Other solvents and reagents were used as received.

Typical synthesis of a protected porous polymer

While the ingredients varied widely, most other synthesis conditions — in particular time and temperature of polymerization — remained the same. In the following paragraphs a fairly detailed procedure is given for the production of a high-efficiency, low-load support (PPP # 7 of Table 1, the best characterized of the protected porous polymers).

Five gram of Chromosorb W-AW-DMCS, 100/120 mesh (the commercial material), was placed into a Buchner flask fitted with a separatory funnel. The flask was evacuated to oil pump vacuum for about half an hour.

A reagent mixture was prepared by dissolving 0.28 g azobis(isobutyronitrile) in 12 mL acetone and adding 56 mL tetralin and 10 mL DVB (for similar types of synthesis, only the amount of tetralin was changed). This solution was poured into the separatory funnel, the vacuum line closed, and then the stopcock of the funnel opened. (On occasion, vacuum was again applied for a short time and released, in order to ensure, as far as possible, penetration of the monomer solution into the Chromosorb particles.)

The contents of the flask were shaken thoroughly and allowed to settle for 30 min. The excess of monomer solution was decanted and the rest removed by filtration, using a minimum of vacuum and time, on Whatman # 1 filter paper held by a frit. Larger sheets of this paper were then used to further blot the support, repeatedly, until it became free-flowing. (The latter operation was conveniently carried out in a flat pan or on a large, fine sieve in order to avoid losses of support. It prevented the particles from sticking together later on. While "drying" the support in this manner could be considered a haphazard undertaking, apt to result in uncontrollably varying polymer loads, the operation is actually quite reproducible.)

The coated support was transferred to a thick-walled glass bottle with septum and crimped cap, the air in the bottle replaced by nitrogen under slight overpressure, and the bottle placed into a GC oven. The oven was then programmed to heat up from 30 to 80°C at 0.5°/min and remain at the upper temperature for 40 h.

After cool-down the contents of the bottle were subjected to soxhlet extraction by benzene for 6 h, followed by acetone for another 5 h. The PPP material was then transferred, filtered, and washed by using two portions of fresh acetone, and dried in a heated desiccator at 100°C

under oil-pump vacuum over night. The dried product was resieved to ensure a 100/120 mesh fraction.

Gas chromatographic testing

The PPP phases were filled into 100 × 0.20 cm i.d. borosilicate glass U-tubes and tested with nitrogen as carrier gas, using flame ionization detection in a Bendix 2500 floor model gas chromatograph. Other conditions are given in the legends or in the text.

Other tests

Initial trends in polymer load were assessed — very roughly — through measuring the apparent ("free fall") density by filling 5 mL of a 10 mL graduate cylinder with slight tapping, and by weighing the phase; as well as by oxidative pyrolysis (to weight constancy) in a muffle furnace at 650°C. Occasionally, load was also determined by C, H analysis (Guelph Chemical Laboratories or Wuhan University).

Infrared spectra were run on HF-treated phases in KBr discs on a PE 2838 spectrometer, courtesy of the Atlantic Regional Laboratory of the National Research Council. Carbon-13 NMR spectra were obtained on a Bruker MSL-200 spectrometer, courtesy of Professor R. Wasylishen. Scanning electron micrographs were taken on a Bausch and Lomb Nanolab 2000 instrument after coating the phases with 60:40% Au:Pd.

Results and discussion

The primary interest of this study was to find out whether a change in macrostructure (thickness, shape), and the protection of that macrostructure against deformation by pressure, would lead to an improved chromatographic performance of relatively soft separation media. Although gel chromatography would have provided a more challenging model system and, with experiments successful, might have elicited greater general interest, this study focussed on porous polymers in packed-column gas chromatography as the easiest modified and fastest tested model system. Theoretical plate numbers were to be used as the primary criterion of improvement; temperature limitations as the secondary one. That is, chromatographic efficiency alone was to guide variations in synthetic procedure: only if the phases reached satisfactory plate numbers would their behaviour at a high temperature — where pressure deformation is most likely to occur — be further investigated.

A significantly greater number of syntheses were carried out than can be reported here in detail: however, their results all appeared to follow the general trends discussed below. The variation of synthesis conditions was stopped when the best PPP phases exceeded 4000 plates/m, even though limited improvement might still have been possible. There does exist some uncertainty about the precise theoretical HETP limit for a given particle size; however, considering the fact that, say, 5000 plates/m would have been equivalent to an HETP of less than one-and-a-half particle diameters (the average diameter of a 100/120 mesh particles is ca. 140 micron), protracted further effort would have meant staying in a game of rapidly decreasing odds.

Within this reasonable constraint, then, the following variations of synthesis proved to be the most significant.

Monomer selection

The only monomers used were styrene, divinylbenzene (DVB), and the materials contained in the conventional "DVB" material as used by industry (typically about 56% divinylbenzene, 38% ethylstyrene, and 6% of diethylbenzene and other saturated compounds, all as isomer mixtures). This is not to say that other vinyl monomers — or, for that matter, other types of monomers — would not have worked just as well or better, but simply that we wanted to restrict the initial study to the most basic and most frequently used of the porous polymer systems.

In our hands, styrene/DVB(mixture) systems gave rather low chromatographic efficiencies (measured in earlier experiments with benzene, in later experiments with the somewhat more efficient *n*-butanol). Matters improved when the DVB(mixture) was used without additional styrene, and again when DVB(neat) replaced DVB(mixture) as the only monomer source. It is not common procedure, of course, to use a cross-linker by itself, but here that came about simply as a matter of optimization guided by plate numbers. It may also be mentioned that Pollock *et al.* employed 95% DVB for stronger retention and separation of N_2, O_2, Ar, and CO at ambient temperature conditions (8).

Porogen (diluent) selection

Two types of porogens are commonly used: solvating aromatics like toluene and non-solvating aliphatics like heptane or decane. As is well known, the latter produce higher porosities. Under our initial conditions, toluene worked better than octane. Following a hunch that had to do with aromatic/aliphatic character, solubility, volatility, and molecular size (but was never validated by experiment), tetralin (1,2,3,4-tetrahydronaphthalene) was used and worked better than toluene. No further porogens were tried.

The amount of toluene and tetralin were varied within relatively wide limits as shown in Table 1, which presents selected but typical data of the best characterized and/or most important phases. The top performance was obtained with 75% tetralin; however, only one higher percentage was tested.

Figure 1 shows the number of theoretical plates — measured with *n*-butanol at or close to optimum flow — as it relates to polymer load. The term "polymer load" is chosen here for its analogy to the stationary phase load of GLC; it is simply the percent weight loss incurred by heating the material in air at 650°C to weight constancy. Table 1 shows some of these numbers, augmented in strategic cases by conventional combustion analysis for carbon and hydrogen (the latter values do not quite add up to the "polymer load", likely due to the silicic structure losing some additional water in the muffle furnace).

The chromatographic efficiency, not surprisingly, increases fairly steadily with decreasing polymer load. Eventually, of course, there has to be a downturn: whether that indeed occurs at a polymer load of about 10% is open to question. Only a far more detailed and time-consuming series of experiments could establish that. The numbers, if taken at face value, are not unreasonable though. A 10% load on Chromosorb W is comparatively high for a conventional stationary liquid phase (the nominal layer thickness is about 1000 Å). However, one would expect a porous polymer, which relies on adsorption rather than, as the liquid phase, on partition, to need thicker layers for maximum efficiency. (The argument presumes, of course, an *evenly distributed* separation medium — which often might not be present. Note also that the strongest mass transfer resistance terms of this comparison likely concern different phases: diffusion in the stationary *liquid* for classical GLC, diffusion in the more or less stagnant *gas* that fills the pores for the bead-type porous polymer.) In the protected and spread-out porous polymer, though, the resistance to mass transfer in and out of the polymer pores should be very small, as one can appreciate from the fact that the nominal layer thickness of the PPP is about a thousand times smaller than the radius of the porous polymer bead.

Aside from its effect on porosity, the amount of porogen also regulates the polymer load in our particular type of preparation: the larger the volume of porogen, the larger the total volume of

monomer + porogen + catalyst, and the smaller the amount of DVB the support can hold on to for subsequent polymerization.

Figure 2 shows the correlation of the percentage of porogen in the initial monomer solution versus the resulting polymer load. The data appear to be perhaps more consistent than they really were — considering, for instance, the vagaries of blotting wet support with filter paper. However, the control over synthesis conditions is clearly adequate and the overall trend is unmistakable: the larger the amount of porogen, the smaller the polymer load.

Support pretreatment

Not surprisingly, an acid-washed support produced better performance than a support not so treated (although this was checked only in one case). What was surprising was the significantly better performance of DMCS-treated materials, as can be seen by comparing phases # 7 and # 8, as well as # 9 and # 10, from Table 1 (and, in addition, several other phases not listed therein).

The surprise came from the fact that, while treatment of the support surface with dimethyldichlorosilane, as most other

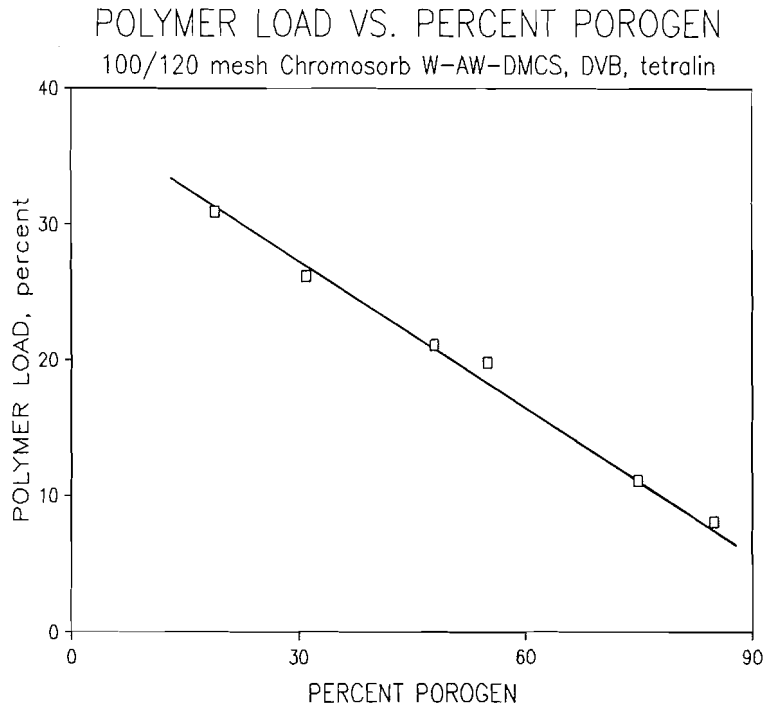

FIG. 2. Polymer load vs. percent porogen used in monomer formulation.

types of silanizations, often has a beneficial effect on plate numbers in GLC — by (presumably) reducing the interaction of surface silanol groups with, particularly, polar solutes — this effect was not expected to play a significant role in the case of porous polymers. The support surface, in the role of an adsorbent, can compete with a conventional liquid phase, but not with a porous polymer, in retentive strength (as one can easily demonstrate by chromatographing the same compounds on both a porous polymer and on a plain support, or easily deduce by considering the large differences in surface areas and elution temperatures between typical GLC and porous polymer GSC systems). In other words, the state of the diatomaceous support surface should be of little direct chromatographic consequence with all but the most polar and adsorptive solutes.

Why, then, do DMCS-treated supports lead to better chromatographic performance in the end? At this point, only speculation can be offered. As the monomer mixture initially coats the diatomaceous caverns of the Chromosorb particle, and as, later, polymerization starts and polymer and porogen separate, the physical form of the emerging polymer will strongly depend on its interaction with the surface. Does it initially "wet" the surface? And, if so, does the effect remain strong enough to make it accept the diatomaceous template throughout polymerization? Or does the polymer in statu nascendi coalesce into small droplets? Obviously, evenly distributed layers of diatom reciprocals would be far preferable to a few unextractable blobs of resin found here and there.

It may also be mentioned in this context that phases based on AW-DMCS type supports did produce peaks of less asymmetry than those based on AW type supports. In conventional GLC, peak asymmetry is usually attributed to the interaction of solute with the support surface, particularly when protic and/or polar substances tail while non-polar ones don't. The available evidence in the case of PPP's in this regard is not completely consistent and would have to be clarified by further experiments — but, on the whole, it appears that the tailing in the case of non-DMCS treated supports affects all types of compounds, not just protic and/or polar ones. Asymmetry, particularly of the sort that can be observed with both polar and non-polar types of analytes, could for instance arise from an uneven distribution of the retentive porous polymer inside its protective support.

For this study, the beneficial effect of DMCS was appreciated, exploited, and not explained. It may be added that the effect is also evident when the DMCS treatment of the support is carried out in the lab (as opposed to using the commercially treated support). However, a similar treatment with vinyldimethylchlorosilane did not provide the same benefit. As an aside in regard to the possibility of "bonding", the use of DMCS as a pretreatment for the easy *release* of bulk-polymerized styrene–DVB copolymers from glass tubes has been mentioned in the literature (5).

Polymer characteristics

A detailed characterization of the polymer part of the PPP phases is precluded for a simple, exploratory study such as this, not only by our dearth of suitable instrumentation but also by a dilemma inherent in the task: If the polymer is examined in situ, the presence of the diatomaceous support may influence the results; if the diatomaceous support is removed from the polymer prior to characterization, new surfaces are created and perhaps new internal regions become accessible that would not have made their presence felt in the chromatographic tests; and, finally, if the polymer is produced from the same monomer formulation but in the absence of the diatomaceous support, it is highly questionable whether a material with the same properties as the nominally corresponding PPP will emerge.

Consequently we shall make use only of data already available from the optimization studies, and do so mainly to establish a speculatory framework for later comparison with chromatographic behaviour.

One of the most important characteristics of the polymer is its surface area. A number of PPP phases were measured by BET nitrogen adsorption, and the results are shown in Table 1. It is well recognized that such data have to be interpreted with some

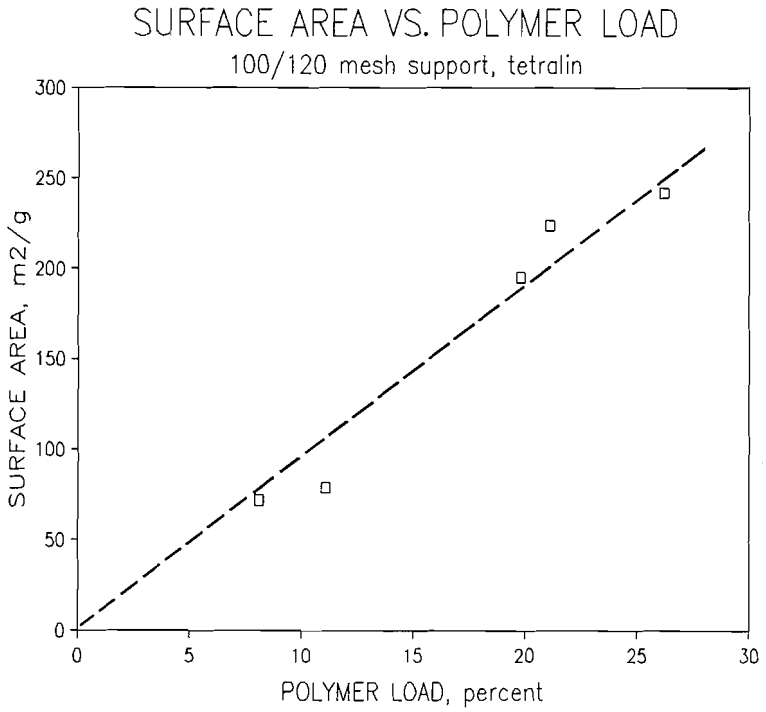

FIG. 3. Surface area of PPP's vs. polymer load. Pure DVB, tetralin. Surface area by BET (N_2).

caution (5). However, the trends shown by the numbers are very clear. Also, the commercial beads Porapak Q and Chromosorb 101 were run alongside and the results fell within the ranges given in the literature.

Figure 3 shows that (within the all-too-obvious error limit) the surface area turns out to be a linear function of polymer load. That is somewhat surprising since, as Fig. 2 has demonstrated, polymer load in our synthetic procedure was essentially determined by the amount of porogen added to an otherwise constant monomer mixture. And it is well known that the concentration of porogen can influence the surface area. Thus one might have expected to see a curve, not a straight line, appearing in Fig. 3. However, if it is truly a straight line, going through the origin — or, rather, through a negligible 1 m^2/g (the latter being the surface area of the clean support) — it would mean that the poly(divinylbenzene) fractions of *all* the samples have the *same* specific surface area (m^2/g of polymer) regardless of the amount of porogen and/or the polymer load used in their synthesis. Perhaps such behaviour is related to a very early phase separation during the polymerization process, promoted both by the alicyclic part of the tetralin porogen and the exclusive use of a cross-linking monomer (c.f. ref. 5).

If the specific surface area of the polymer itself (and, presumably, the chemical nature of its surface) remains constant, then retention must become a linear function of the amount of polymer present in the column. Or, since all GC test columns used in this study have similar lengths and volumes, retention should be a linear function of what one might call the "apparent polymer density", i.e. the grams of polymer present in one cubic centimeter of the PPP column packing. The latter number is easily estimated from the apparent or free-fall density of the packing and its polymer load (Table 1). It can be used to plot the retention times obtained from separating on various packings a standard test mixture (made up of four substances with boiling points all within 3°C of each other). The plot is shown in Fig. 4 and it is indeed linear and starts from the origin. Within (the fairly wide) error limits, then, the *specific* surface area of the polymer appears independent of the concentration of porogen used in its synthesis.

Which, in turn, raises the question what that specific surface area of the polymer itself is likely to be. It can be rather easily estimated by assuming that the support does not contribute to the surface area (its area is very small and, besides, most of it should be covered by the polymer), and that the polymer load (the weight loss on ignition) correctly describes the weight percent of polymer. Such estimates (using the few data available from Table 1) lead to very high numbers, with an average specific surface area close to 900 square meter per gram of polymer. While the spread in the numbers is very large (from 710 to 1060) and while that does not allow recognition of a possible (minor) extent of correlation with the porogen concentration, it is nevertheless clear that the specific surface areas of the porous polymer of this study are higher than those of the conventional bead types. This may be quite reasonable considering that the monomer is a pure crosslinking agent and the porogen a molecule with both solvating and non-solvating features. It is surprising only to the extent that one is accustomed to thinking of porous polymers in bead form — and, in a conventionally sized bead, such a high surface area (such narrow pores) would likely engender severe peak broadening and thus make the material unsuitable for most chromatographic uses.

Gas chromatographic performance

The perhaps most important chromatographic property of PPP's has already been mentioned: their significantly improved efficiency. The highest efficiency measured was 4200 plates/m, corresponding to a theoretical plate height of 0.24 mm. This was achieved with PPP # 7 (Table 1), whose polymer load is about 11% and (total phase) surface area 80 m^2/g; and whose synthesis is described in the Experimental part. A variety of different chromatographic tests were carried out with this and other columns, often in comparison with benchmark porous

polymers of the bead type such as Porapak Q or Chromosorb 101.

Van Deemter curve

In Fig. 5, Van Deemter curves for *n*-butanol at 130°C in nitrogen are plotted for PPP # 7, Porapak Q, and Chromosorb 101. Column # 7 is comparable in chromatographic efficiency with a very good, conventional GLC column filled with a packing of the same particle size (100/120 mesh). Its minimum HETP is about 0.24 mm (4200 plates/m). The low mass transfer resistance means that higher flow rates can be used with only a minor loss in efficiency, an advantage particularly welcome when working with porous polymers.

For purpose of comparison, PPP # 7 is a pure DVB polymer,

Solutes: *1*, methanol; *2*, ethanol: *3*, *i*-propranol; *4*, *n*-propanol; *5*, *t*-butanol; *6*, *s*-butanol; *7*, *i*-butanol; *8*, *n*-butanol; *9*, *t*-pentanol; *10*, *i*-pentanol; *11*, *n*-pentanol.

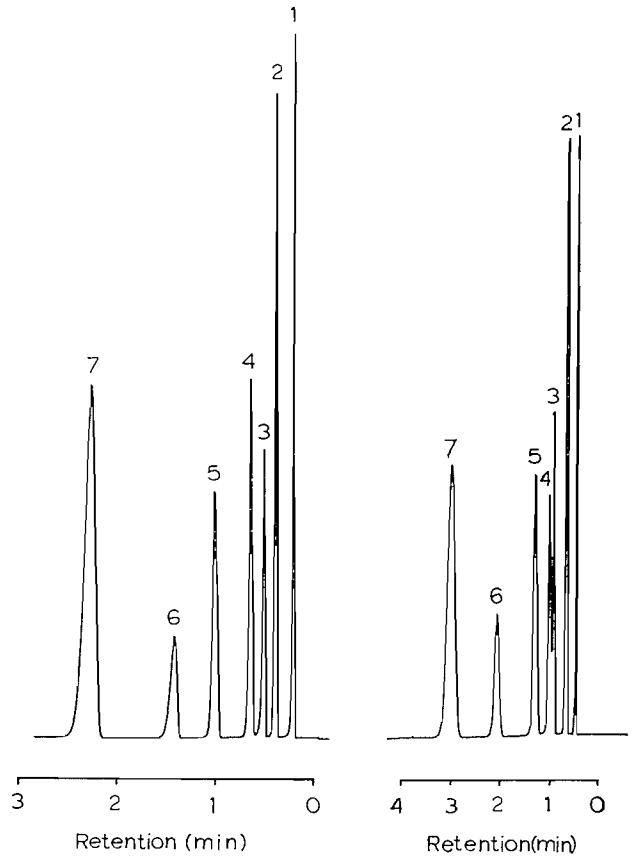

FIG. 7. Separation of various organic compounds. Left: PPP # 4 (Table 1); right: Chromosorb 101. Solutes: *1*, methanol; *2*, ethanol; *3*, acetonitrile; *4*, acetone; *5*, cyclopentane; *6*, chloroform; *7*, benzene.

Chromosorb 101 is a styrene-DVB co-polymer and Porapak Q is an ethylvinylbenzene–DVB copolymer (but *Q*-type materials are also listed as styrene–DVB as in the PoraPLOT *Q* column (6) or plain DVB as in the HayeSep *Q* material (9) and, furthermore, it should be realized that, as one of the referees of this manuscript poignantly put it, "there is no proof that they are, or should be, similar (like Coca Cola and Pepsi Cola)"). Surface areas do vary, but a recent book, with a cautionary note to that effect, lists 50 m^2/g for Chromosorb 101 and 500 to 700 m^2/g for Porapak Q (10). (Our own measurements on the materials we used for comparison yielded values of 46 and 510 m^2/g, respectively).

Some separations

A small number of separations are presented here for visual comparison and assessment. Figure 6 shows the chromatography of C-1 to C-5 alcohols, done on the three columns characterized by their Van Deemter profiles in Fig. 5. The alcohols display the shortest retention times on PPP # 7, closely followed by Chromosorb 101, but rather far from Porapak Q. Similar behaviour is also shown by other types of compounds. This is demonstrated in Fig. 7 by seven compounds hailing from six different chemical families, separating on PPP # 4 (a more retentive column with a polymer load of 21.1%) and Chromosorb 101. The peak sequences are similar though not identical on the various columns of Figs. 6 and 7 — not surprisingly so in light of the different chemical structure, polarity and porosity of the polymers that are being compared.

Free energy plots

The familiar log t_R' vs. #C plots, linear for homologous series, relate to the free energy of sorption and are helpful in comparing different types of chromatographic systems. For this reason we have tested PPP # 7 together with the two commercial porous polymers Chromosorb 101 and Porapak Q, by using the *n*-alkane, *n*-alkylbenzene, 2-alkanone, methyl-*n*-alkanoate, and *n*-alkanol(1) homologous series, i.e. paraffins, aromatics, ketones, esters, and alcohols. The results are quite interesting. (To avoid the proliferation of figures and, since Chromosorb 101 and Porapak Q have been well described in the literature, only the PPP # 7 plot is shown in Fig. 8. However, the following comparison is based on our own, not literature data; all obtained at 170°C and under identical chromatographic conditions).

What is striking about the comparison is that, despite the fact that the PPP and Chromosorb 101 have relatively similar retention capability, the PPP shows a considerably steeper slope (the difference in log t_R' per methylene group) — steeper, in fact, than even Porapak Q. The three slopes are 0.38, 0.34, and 0.28 for PPP # 7, Porapak Q and Chromosorb 101. This means that the later eluting one of two adjacent members of a homologous series will have isothermal retention times 2.4, 2.2, and 1.9 times longer than the earlier eluting one, respectively.

In chromatographic terms, this is important because it —

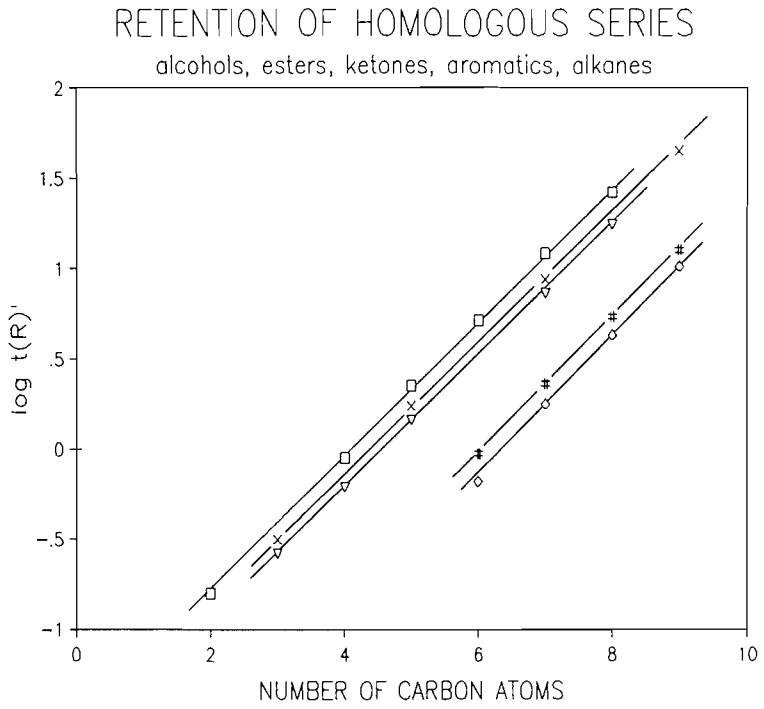

FIG. 8. Retention of homologous series. □, *n*-alcohols; ×, methyl esters; ▽, methyl ketones; #, *n*-alkyl benzenes; ◇, *n*-alkanes.

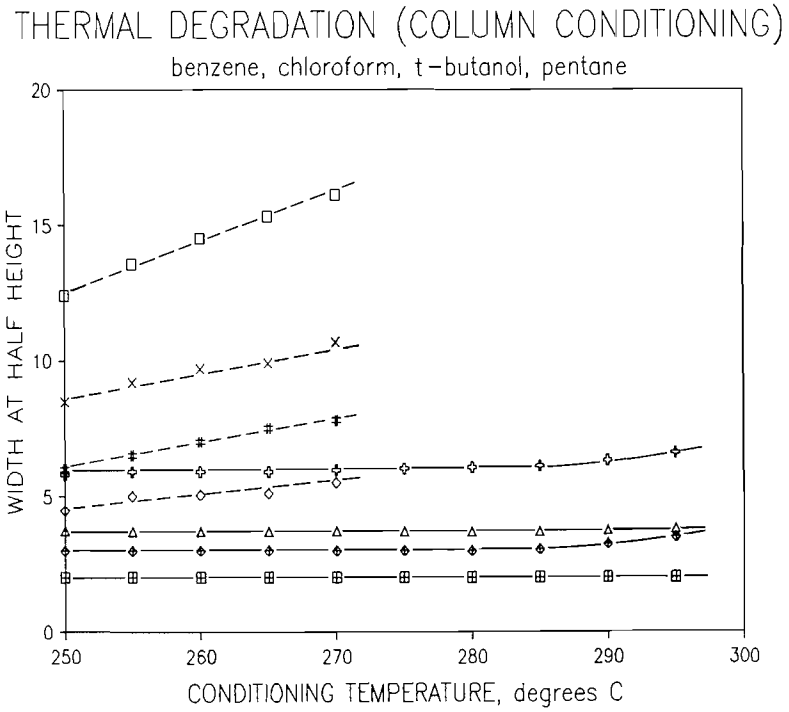

FIG. 9. Thermal degradation of protected and unprotected porous polymers. Dashed line: Porapak Q; full line: PPP # 6 (Table 1). Test compounds (from top to bottom): benzene, chloroform, *t*-butanol, pentane.

together with plate numbers, of course — determines the numbers of peaks that can be squeezed between two neighbouring alkanes (the Trennzahl or separation number). Thus, the PPP material offers both a high efficiency and a large retention interval per methylene group — or, differently put, it allows a narrower fraction of the boiling-point range to be separated within a given retention window.

It is interesting to speculate in polymer terms why this should be so. First, there could simply be a better *chemical* match, i.e. a larger interaction, between the methylene group and the polymer matrix. This would be analogous to non-polar liquid phases having steeper slopes than polar ones in log t_R'/#C GLC plots. However, neither the absolute retention nor the "polarity" of these phases suggests this to be the case (the "polarity", as can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12

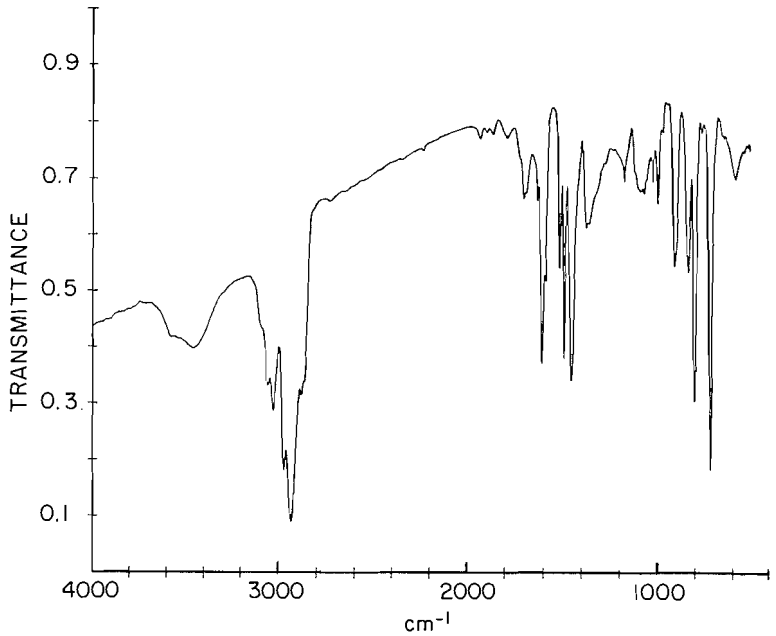

FIG. 10. Infrared absorption spectrum of pure DVB porous polymer. Diatomaceous support dissolved in HF, residual polymer pelletized with KBr.

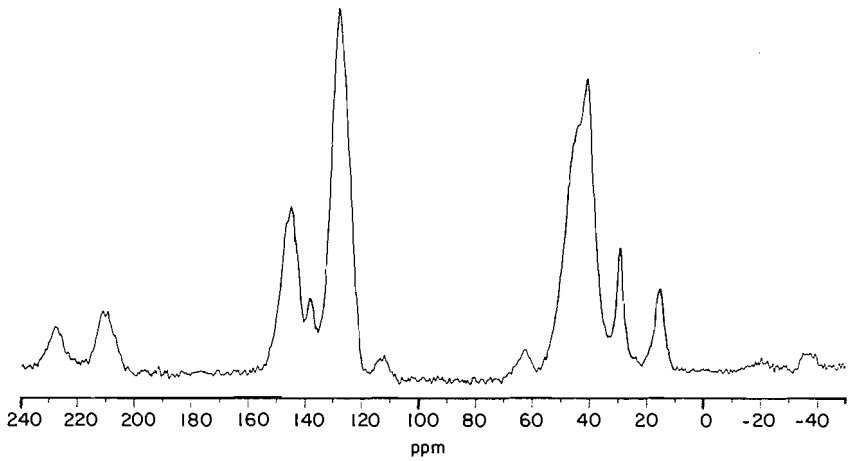

FIG. 11. ^{13}C NMR spectrum of intact PPP.

be roughly judged from the plots, shows PPP # 7 *between* the more polar Chromosorb 101 and the less polar Porapak Q — but all three are, as would be expected, fairly close to one another).

Second, there could simply be a better *physical* match between the test chromatographic solutes and the dimensions and distribution of polymer pores. Although this is not a separation on the basis of molecular size, the size of pores — particularly when they are relatively narrow — will affect sorption behaviour. One would expect that the most preferable situation, i.e. the steepest slope in the log $t_R'/\#C$ plot, will occur when the pore size distribution is narrow (and the pores themselves are narrow as well). It could be argued that a polymer made from *only* a cross-linker should be closest to fulfilling these conditions. This reasoning fits well to an experimental estimate, made earlier, that the porous polymer part of the PPP does, in fact, have a very high specific surface area. On the basis of that argument, then, one could indeed have predicted that the slopes should follow the sequence of the (polymers') specific surface areas, i.e. PPP > Poropak Q > Chromosorb 101. Still, in the absence of more — and perhaps different types of — data from a still larger number of systems, the argument must remain speculatory.

Sample capacity

In an adsorption mechanism, sample capacity should be related primarily to surface area (really: area active in retention) per column volume. One would therefore not expect large differences among PPP and conventional bead phases of comparable surface area. However, one always likes to be assured about the linearity of *ad*sorption isotherms. Besides, it is not clear what effect, if any, is produced by polymerizing within range of surface forces and whether the observed conditions lead to significant differences in pore size distributions. All of these factors could conceivably influence the sample capacity.

PPP # 7 was used as a test phase — in part because it showed

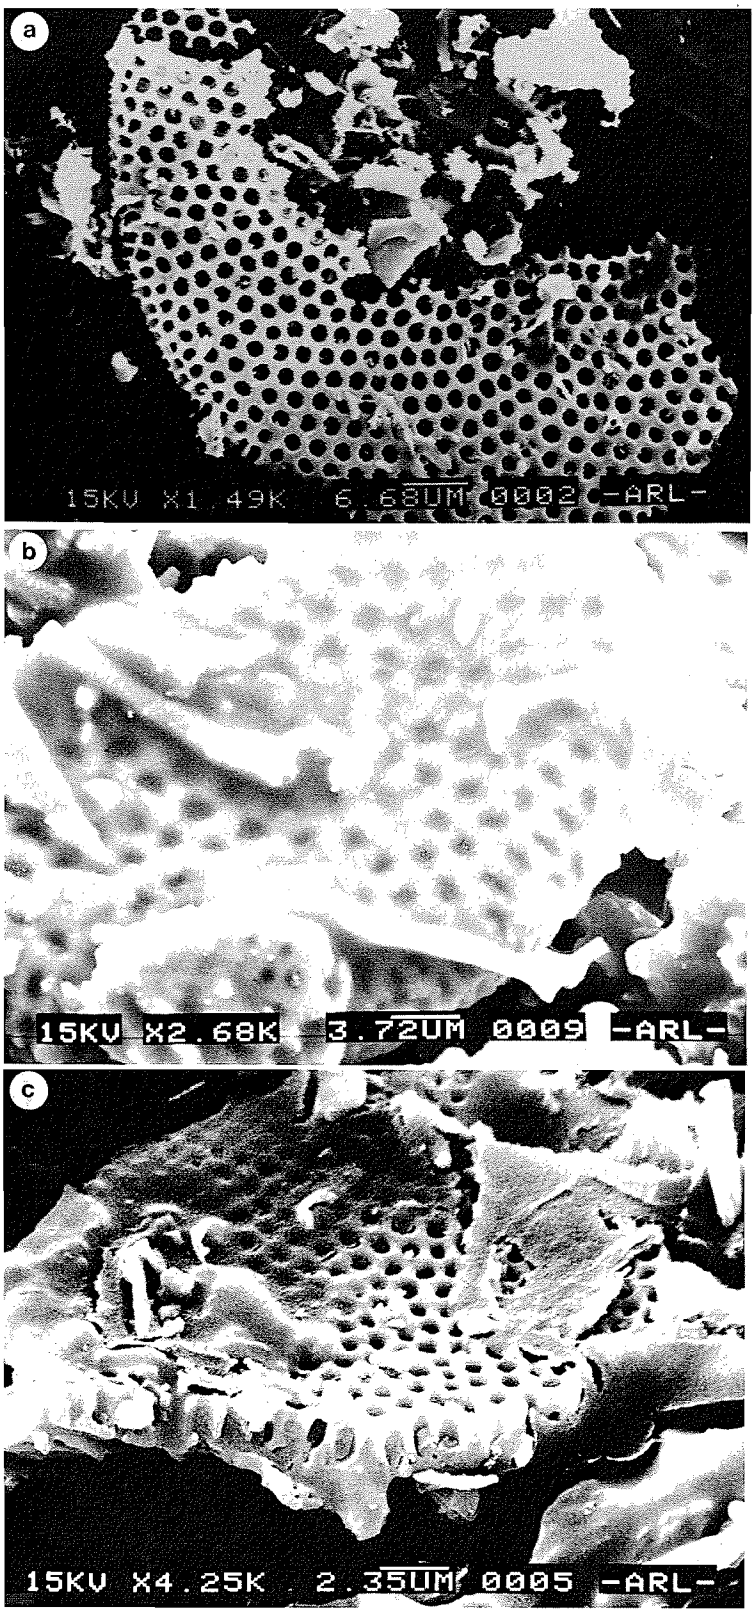

FIG. 12. Scanning electron micrographs of similar bare and porous-polymer-covered diatom structures. Corresponding polymer load: *a*, 0%; *b*, 37%; *c*, 11% (PPP # 7).

the highest plate number, in part because its polymer load was comparatively low (11.1%). In the tests PPP # 7 was compared to Chromosorb 101 (which is far closer in plate number and overall surface area than Porapak Q would have been). The tests did not show any great difference between the two phases. Under similar (and conventional) circumstances, both phases were capable of handling (single peak) samples of up to about 30 μg.

Temperature range

Similar to sample capacity, the useable temperature range of chromatographic separation media has no unambiguous definition, since it depends to some extent on what one wants to do with the phase — i.e. with what types of samples, in what concentration ranges, and with what detector it is going to be used. Furthermore, column performance at high temperatures can depend on the conditioning procedures, the purity of the carrier gas, the purity of the polymer (often: the purity of the monomer used to synthetize the phase), etc. In addition, porous polymers are subject to deformation at high temperatures — an effect that should be minimal for materials fitted with a diatomaceous exoskeleton.

We therefore chose to monitor the column bleed rate and probe peak width in a high-temperature range. Figure 9 shows selected but typical data from the more sensitive peak width study, with measurements on PPP # 6 (3660 plates, 19.8% polymer load) being carried out repeatedly at 130°C, *after* the various steps of the conditioning regime. The initial conditioning (after the routine conditioning carried out with *all* columns) lasted for 8 h at 250°C, then came 5 h at 255°C, then successive 1-h conditioning periods at 260, 265, etc., up to 295°C.

The peak width at half-height is a very sensitive indicator of any deterioration in performance, and it shows the first, slight change for the PPP phase at 290°C. Consequently we suggest that 280°C should be a safe upper limit. The bleed rates show only a slow rise and do not contradict this estimate. Yet it needs to be added that the question of thermal stability has been tested only in a perfunctory manner in this study, and may have to be re-evaluated in light of a particular intended usage.

It is safe to assert, however, that the highly cross-linked, relatively pure, and diatomaceously protected phases of this study show excellent thermal stability. This is particularly important in light of the typically strong retention ability of such porous polymers, i.e. of the limited volatility range of analytes that can be processed.

Mechanical stability

Almost by definition, there should be little if any pressure deformation of the polymer and/or settling of the column packing in the case of a diatomaceously encased porous polymer — unless the diatomaceous support should happen to break. And it is, indeed, well known that the fragility of various Chromosorbs can strongly contribute to poor performance of conventional GLC columns. In this regard, the protection afforded the porous polymer by the Chromosorb appears to have been reciprocated in kind: while a support like bare Chromosorb W is easily reduced to dust by rough treatment, it is far more resistant to abrasion when covered by the porous polymer. Polymer coatings have, of course, often been used to reduce or modify breakage of various inorganics (e.g. on car windshields, vacuum desiccators, and fused-quartz capillaries) Although we did not attempt to quantify the effect, it was clearly apparent and, for packing characteristics and lifetimes of columns, clearly beneficial.

Ancillary methods of characterization

Figure 10 shows the infrared spectrum of a pure-DVB protected polymer (for taking the IR spectra from a KBr disk, the diatomaceous protection had to be removed by a treatment with hydrofluoric acid). The spectrum is very similar to that of Porapak Q. The number of vinyl groups appears relatively low, as judged from the C—H stretch at 3085 and 3060 cm^{-1} and the C—H out-of-plane bending a 990 and 910 cm^{-1}.

Figure 11, for general interest, presents the ^{13}C NMR spectrum obtained on the intact phase with cross polarization and magic angle spinning. The spectrum shows only negligible differences from that of Porapak Q or that of DVB polymerized in bulk.

Figure 12 presents some scanning electron micrographs in order to illustrate — as opposed to define — (*a*) the mutual stabilization that support and porous polymer can offer one another, and (*b*) the easy chromatographic access that their interaction affords the solute molecules. The honeycomb-like structure of particular types of diatoms, which is commonly found in diatomaceous earths, was selected here to illustrate these two points. Figure 12*a* shows the diatom uncovered, Figs. 12*b* and 12*c* show it fully and partially covered. Figure 12*a* is a look at a speck of pure Chromosorb dust, while Figs. 12*b* and *c* are detail shots of the outside of particles with a 37% (not in Table 1) and 11% (#7 in Table 1) average polymer loads. It should be noted that coverages are not necessarily uniform throughout or among particles; nor need heavy loads of polymer appear everywhere as thick and smooth as they do in Fig. 12*b*. Cracks often appear in the polymer and it is not unusual, particularly at lower loads, to see the polymer half-filling the holes and cracking away from the walls (Fig. 12*c*, lower middle). It should be further realized that these scanning electron micrographs show only a small segment of the whole particle. Chromosorb particles are very loose conglomerates from diatoms of a wide variety of structures and sizes: that means essentially free access from/to the gas phase for the adsorbing/desorbing solutes, and only short diffusion paths (compared to a bead-type phase) through narrow polymer pores.

Conclusions

Protected porous polymers, at least as far as DVB-based materials are concerned, can be easily produced in the laboratory. They provide excellent column efficiency and pressure resistance. Beyond these practical advantages, they also offer evidence that porous polymers are not intrinsically less efficient than conventional GLC phases — provided their geometry permits facile access of carrier gas and solute molecules.

The optimization procedure used in this study was very crude and chromatographic performance could likely be further improved. Beyond DVB, other types of polymer systems could probably be deployed in similar fashion. It might also be worthwhile to attempt transferring some of the in-situ polymerization technique developed here, to other protective geometries commonly used in high performance and/or high pressure chromatographic systems.

A wide variety of mono-, di-, and tri-substituted tin compounds are transformed to, and transmitted as, chlorides, bromides, or iodides on injection into a gas chromatographic system doped with HCl, HBr, or HI, respectively. This transformation occurs directly from some thirty-odd analytes such as organotin oxides, hydroxides, organic esters, and other halides including fluorides. Three germanium compounds appear to behave similarly. A conventional, packed-column gas chromatographic set-up with flame photometric or flame ionization detector can tolerate the necessary acid doping. Compounds such as bis(tributyltin) oxide will elute, as halides, in subpicogram amounts. If the dopant flow is turned off, the packed column can act as a hydrogen halide reservoir for several days of operation. The transformations of tributyltin species into the halide form are generally fast on the timescale of chromatographic processes, i.e. sharp peaks result from the use of mixed hydrogen halides, and the retention time of mixed-halide peaks can be adjusted by varying the dopant composition.

Key words: organotins, gas chromatography, derivatization, acid doping, photometric detection.

WALTER A. AUE, BERNARD J. FLINN, CHRISTOPHER G. FLINN, VELUPPILLAI PARAMASIGAMANI et KATHLEEN A. RUSSELL. Can. J. Chem. **67**, 402 (1989).

Lorsqu'on injecte une grande variété de composés mono-, di- et tri-substitués de l'étain dans un système de chromatographie en phase gazeuse dopé par du HCl, du HBr ou du HI, ils sont respectivement transformés en, et transmis sous la forme de, chlorures, bromures ou iodures. Ces transformations se produisent directement à partir d'environ trente dérivés comme des oxydes, des hydroxydes, des esters organiques et d'autres halogénures (y compris les fluorures) organiques de l'étain. Il semble que trois composés du germanium se comportent de la même manière. Une colonne régulière de chromatographie en phase gazeuse remplie, munie d'une détecteur photométrique à flamme ou à ionisation à flamme, peut tolérer le dopage acide approprié. Des composés comme l'oxyde de bis(tributylétain) seront élués sous la forme d'halogénure, les quantités formées seront inférieures au picogramme. Lorsqu'on arrête l'écoulement de l'agent de dopage, la colonne remplie agit pendant plusieurs jours comme réservoir d'halogénure d'hydrogène. Les transformations des espèces tributylétain en dérivés halogénés sont généralement rapides si on les compare à l'échelle de temps des processus chromatographiques, c'est-à-dire que, lorsqu'on utilise des mélanges d'halogénures d'hydrogène, on observe des pics fins et le temps de rétention des pics provenant d'halogénures mixtes peut être ajusté en faisant varier la composition de l'agent de dopage.

Mots clés : composés organiques de l'étain, chromatographie en phase gazeuse, dérivatisation, dopage d'acide, détection photométrique.

Introduction

This study arose from a chance observation. We had attempted to use organotin hydrides (prepared by treating typical tin-containing biocides in methanol with silane gas) for gas chromatographic trace analysis with a flame photometric detector (1). In the picogram range, decomposition became apparent. Turning to a common remedy (c.f. ref. 2), we attempted to treat the column with dimethyldichlorosilane, a compound traditionally used to deactivate the silanol groups of the chromatographic support. The hydride peaks were not improved, but new peaks started to appear. The latter were traced to the action of the deactivation by-product HCl on tin-containing non-volatiles in the injection port. Since the presence of — chemisorbed or physisorbed — hydrogen chloride was apparently able to transform organotin compounds *in situ* to chlorides, and allow them to migrate in that state through the column at picogram levels, the conclusion appeared obvious that deliberate doping of the gas chromatographic system with HCl — or, perhaps, with HBr or HI — might prove interesting and useful.

Although it appeared surprising at first sight, the formation of organotin chlorides under these circumstances might have been predicted. Organotin halides are easily produced in solution — a fact that has often been used for analytical ends by extracting them from a complex sample matrix — and they elute at conveniently low temperatures from gas chromatographic columns. In fact, the earliest reports concerned with the gas chromatographic separation of organotin halides date back to 1965 (3, 4). The general literature on organotin compounds is extensive; we are mentioning here only a few, selected papers (refs. 5–17 and references cited therein), to set the stage and focus on aspects relevant to this study.

Despite the easy formation and adequate volatility of organotin halides, they have often taken second or third place to fully alkylated (Grignard) or hydride ($NaBH_4$) derivatives for various types of analysis, particularly those of the trace variety. This is not surprising since the fast, quasi-ionic reactions of organotin halides also imply interaction with various materials in the gas chromatographic system (presumedly metal oxides, silanol groups on glass tubes or phase supports, trace amounts of water, etc.). Obviously, the detrimental effects of these interactions

[2]To whom correspondence should be addressed.

are the more acutely felt the lower the amount of the organotin halide and the larger the number of hydroxide and other groups in the chromatographic system with which it can react.

In fact, it is useful to consider the chromatographic system as being governed by a network of equilibria such as

$$2but_3SnCl + H_2O \rightleftarrows (but_3Sn)_2O + 2HCl$$

with water being representative of a wide variety of similarly reactive, stationary or mobile chemical structures; and but_3Sn representative of the organotin moiety. (Note that bis(tri-*n*-butyltin) oxide, aka TBTO, is a much used and much researched marine antifouling agent.)

The equilibrium is useful for illustrating two points. First, to keep tributyltin in the chloride form and hence migrating through the column, a low level of water and a high level of hydrogen chloride (more general: a low level of ROH and a high level of HX) is advantageous. Second, at an appropriately high level of hydrogen chloride, analytes of low volatility such as TBTO can be directly injected into the chromatographic system for conversion to, and migration as, chlorides. Of course, the rate at which organotins approach the various *chemical* equilibria should be faster than the rate at which transport and diffusion establish the *physical* equilibria typical of chromatographic migration — in other words, the organotin kinetics should not unduly increase the peak dispersion beyond its purely chromatographic value.

The present study was designed to probe the feasibility, characteristics, range, and limitations of organotin transformations to, and gas chromatographic transmissions in, halide form. Analytical relevance was used as an important criterion in designing the experiments, but no attempt was made to focus on a particular compound or type of sample. Since organotins serve a wide variety of interests in industry and agriculture (5), they need to be determined at both high and low levels in vastly disparate matrices. In the context of doping a gas chromatographic system with a gas as reactive as hydrogen chloride, high levels of a (non-volatile) organotin analyte require more hydrochloric acid for conversion and may therefore represent a more severe test of the gas chromatograph's and particularly the column's ability to stomach large amounts of both analyte and dopant.

If the analyst is interested mainly in tin compounds, a selective detector is likely to be the correct choice; e.g. the flame photometric (7, 9, 10, 11, 13, 14), the hydrogen-rich flame ionization (8), or the electron capture detector (15, 16). Alternatively, one of the hyphenated-type instruments such as GC-MS (12), or machines capable of sample atomization and optical or mass spectral analysis (17) can be used. Here the flame photometric detector demonstrates detection at the sub-picogram level and, for higher analyte levels and the more general chemical objectives of most of this study, the non-selective flame ionization detector is used. Since the latter responds to the presence of CH in the analyte, essentially all volatile organic compounds will show up — whether they contain tin, another metal or metalloid, or no heteroatoms at all. This is important in the context of conversion rates, possible by-products, the behaviour of non-tin organometallics, and the correlation to hydrocarbon retention standards — all of which play a role in this study.

The questions that first spring to mind are these: Will a typical gas chromatograph — in particular, will typical stationary phases — stand up to hydrogen halide doping? Will the hydrogen halide really provide the expected benefits of *in situ* conversion and efficient chromatographic migration of the organotin moiety, both at high and low levels of analyte? What types of organotin compounds can be processed in this manner? Will the choice of hydrogen chloride vs. hydrogen bromide vs. hydrogen iodide make any difference? (Hydrogen fluoride was disregarded for a couple of fairly obvious reasons.) Will the exchange reactions be fast enough not to degrade peak shape? What levels of hydrogen halide are necessary for a well-functioning system? Will the gas chromatographic system retain larger amounts of hydrogen halides once their supply is turned off? Will retention times vary with the composition of dopant mixtures of different hydrogen halides? Will the presence of hydrogen halide in the hot gas chromatograph lead to undesirable degradation of the organotin structure, i.e. can the latter lose one or more alkyl or aryl groups? Can the developed methodology be extended to compounds of germanium and perhaps further elements?

Experimental

For experiments involving flame *photometric* detection, a Shimadzu GC-4BMPF gas chromatograph with a flame photometric detector was used. The quartz chimney of the detector was slightly modified to permit increased contact of the hot flame gases with the quartz surface — either on a radial quartz rod or on a wad of quartz wool (10) situated above the flame. The blue surface emission (together with the weaker, greenish SnOH and the red SnH gas-phase emissions) were monitored by the conventional Hamamatsu R-268 photomultiplier tube without additional spectral discrimination beyond that defined by its response profile.

Doping with hydrogen halides was carried out by adding HCl or HBr gas into the nitrogen line just before it entered the injection port, or by injecting into the chromatograph a few microliters of dilute solutions of HCl or HBr in methanol. In the former case, the flow of hydrogen halide gas was kept very low through a restrictor made by hammering a capillary steel tube until it was almost closed off, or by a stainless steel very fine metering valve (Nupro), or both.

In experiments involving flame *ionization* detection, a Tracor 550 gas chromatograph was used. The most common column packing was 10% Apiezon L on Chromosorb W, 45/60 mesh, in a 100 × 0.2 cm i.d. borosilicate tube. The doping gases hydrogen chloride and hydrogen bromide were usually diluted with nitrogen to 1 to 3% (for easier flow control) in a high pressure cylinder and slowly bled into the nitrogen carrier gas line before the injection port. Pressure controllers, valves, etc. were acid resistant (Matheson). The concentration of starting mixtures, as well as the amount of HX leaving the detector, were determined by titration. In some experiments involving HCl or HBr, and in all experiments using HI, the hydrogen halide was discontinuously introduced by injecting it in methanol solution. Depending on the analyte load, the flame ionization detector was cleaned of SnO_2 residues every two to four weeks.

Results and discussion

High-sensitivity experiments (flame photometric detection)

The experiments involving the modified Shimadzu photometric detector demonstrate that tri-organotins such as bis(tributyltin) oxide, triphenyltin hydroxide, and tricyclohexyltin hydroxide can be easily converted to the volatile halides by injecting them into the doped chromatograph. Either gas or solution doping work well.

Figure 1 shows the chromatography following injection of one *picogram* each of bis(tripropyltin) and bis(tributyltin) *oxides* into a chromatograph doped with HCl gas. The response indicates that most of the injected tin has reached the detector. (Note also that the small peak just prior to but_3SnCl implies

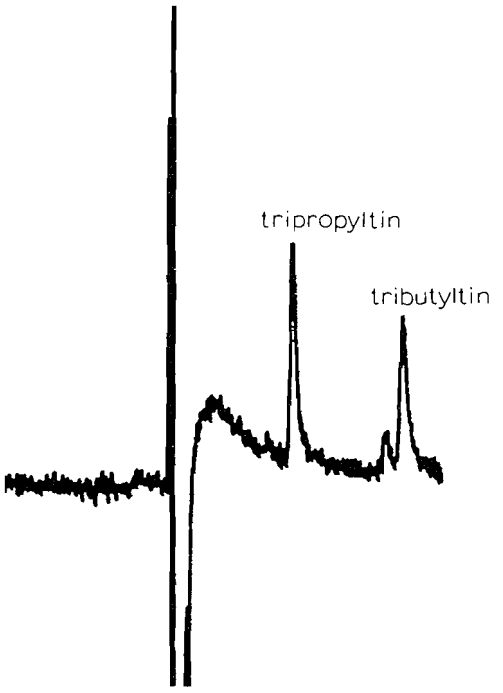

FIG. 1. Gas chromatogram of 1 picogram injected of each of bis(tripropyltin) and bis(tributyltin) oxides, detected as the respective chlorides in a flame photometric detector by quartz-surface luminescence. HCl (gas) rate of introduction ca. 4×10^{-7} mol/min.

some minor decomposition to but_2SnCl_2). Thus it appears that, even with the flame photometric detector close to its most sensitive state — it is no longer the *column* that restricts the limit of detection. That is highly significant: the 1 pg level is several orders of magnitude lower than what can be achieved in the gas chromatography of organotin halides *without* acid doping.

The column, incidentally, is a 50 × 0.3 cm i.d. borosilicate tube filled with Carbowax-20M modified (18) Chromosorb W, 80/100 mesh — a packing whose organic layer is only a nominal 15 Å thick and of which, since it is a polyether, one might not have expected satisfactory performance under acid doping conditions. It might be added that acid doping on the Shimadzu chromatograph was carried out (with a variety of columns) for about one year (1978/79). Aside from the bonded Carbowax column mentioned above, the liquid phases were usually of the dimethylpolysiloxane variety, e.g. OV-101. None of the columns suffered any obvious damage due to HCl or HBr, and the chromatograph and its photometric detector are still working well today.

In the experiments using the flame photometric detector (which preceded those using the flame ionization detector), di- and mono-substituted tin compounds were only superficially investigated and then only at levels above 100 pg injected. A variety of derivatives were obtained, but it was also obvious that, as is well known, the analytical difficulties decreased from mono- to di- to tri-organotin structures. The larger the number of halide atoms required for a particular analyte molecule, the heavier a dopant level was necessary for successful chromatography.

Depending on the dopant level and the temperature, it was also obvious that some degradation could occur (the term degradation is used here to describe the loss of alkyl or aryl substituents from tin). Under heavy doping conditions, for example, significant amounts of diphenyltindichloride and dicyclohexyltindichloride were obtained from the triphenyltin and tricyclohexyltin hydroxides, respectively. Even tetrabutyltin — but not the faster-eluting tetrapropyltin — would occasionally form minor amounts of tributyltinchloride. Judged merely by chromatogram, the degradation of organotins in injection port and early column can mimic the results of their degradation in the biosphere; and particular attention has to be paid to that fact in the analysis of environmental samples.

It can be assumed from basic principles that higher temperatures and stronger retention are generally helpful in terms of derivatization, harmful in terms of degradation. This actually happened to be the case. For instance, we had to use longer, more retentive columns for the very volatile methylated tin compounds, so the higher temperatures would speed up derivatization equilibria and maximize chromatographic efficiency. But we had to use shorter and less retentive columns for the much heavier analytes such as triphenyltinchloride and dioctyltindichloride, so the lower temperatures would minimize degradation.

(Note that, in case of derivatization *prior* to injection into the gas chromatograph — as in a CH_3OH/HX solution — one would not have to worry about *initial* derivatization. But one would have to worry about degradation, and about keeping the derivative in its halide form — i.e. about continuous and speedy *re*-derivatization, so to speak — because organotin species revert easily to non-volatile forms by reaction with components of the gas chromatographic system. Obviously, the overall analytical effort would be wasted if equilibrium conditions were to favor the derivative only in the injected sample, not in the chromatographic column.)

Notwithstanding such caveats, the important result of the experiments using the photometric detector is the demonstrated ability to derivatize, separate and detect, in *one* operation, extremely *small* amounts of a wide variety of organotin compounds.

Low-sensitivity experiments (flame ionization detection)

In contrast, the experiments using the Tracor gas chromatograph with the flame ionization detector were carried out with much larger amounts of organotins. This was done for a variety of purposes (besides being mandated by the general but much less sensitive response of the detector). First, a good deal of present-day organotin analysis is concerned with relatively large amounts of tin compounds, as they occur, for instance, in biocide or polymer stabilizer formulations. Second, the larger amounts of dopants necessary for larger amounts of analyte, as well as for *mono*- and *di*-organotins, present a greater challenge to the chromatographic system. Third, we needed to use a detector capable of monitoring hydrocarbons — e.g. for Kovats retention index measurements, for assessment of column degradation and chemical noise, etc. Yet it must be stressed in this context that our move to the flame ionization detector was solely for this fairly basic investigation — for most *analytical* tasks, a selective detector such as the flame photometric would do a far better job. The flame ionization detector is not only much less sensitive than the flame photometric detector, it also needs to be cleaned frequently when used for organotin halides — and its fits of electrical noise, caused by the dusty and corrosive environment, can reduce sensitivity further and lead to the occasional loss of data.

Bromide derivatives

In the first series of experiments with the flame ionization detector, HBr (gas) was used as the dopant. Its flow was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

measured before and after the experiments: it had remained fairly steady throughout the experiments at about 1.3×10^{-6} mol/min. This was considered a fairly heavy doping level and it served well to define the chemical challenge to the chromatographic system and to the analytes.

The first demonstration with the HBr (gas) system was concerned with one of those groups of organotin compounds that are expected to yield the *same* derivative, i.e. one peak of nonvariant retention time. The following tributyltin type structures were used: bis(tributyltin) oxide and sulfide, hexabutylditin, and tributyltin fluoride, chloride, bromide, acetate, and linoleate. They all gave a single, large peak of precisely the same retention time, i.e. that of tributyltin bromide. Other experiments agree with this result: none of the common tributyltin compounds at our disposal ever showed a different behaviour. We must therefore conclude that the transformation to halides occurs easily from many different types of structures. (Note again that this is not too surprising: organotin carboxylates, for instance, convert to the chlorides simply on being treated with a solution of sodium chloride in water (19). The only surprise is, perhaps, how well this works inside the arid gas chromatograph.)

However, how quantitative is the conversion inside the gas chromatograph? To answer this question, the response was calculated per weight of tributyltin moiety (not original compound) injected. It turned out to be (normalized to the fluoride) 0.98 (oxide), 1.00 (sulfide), 0.86 (ditin), 1.00 (fluoride), 1.14 (chloride), 0.86 (bromide), 1.02 (acetate), and 0.74 (linoleate). Given that these responses were similar in magnitude to those of non-derivatizable compounds such as tetrabutyltin; and given the questionable purity of most tin compounds, their slow degradation in storage, and the errors involved in sample preparation, injection, and response assessment; it seems reasonable to assume that the conversions were, in essence, quantitative.

This is relevant not only from a chemical but also from a biological point of view: the *biocidal* structure is the tributyltin moiety and it is the one that is being determined here — regardless of the remaining labile group used in the formulation. To demonstrate this behaviour, calibration curves were measured for three different tributyltin compounds. The composite result is shown in Fig. 2: all three calibration curves *coincide*.

Analogous experiments were conducted with dibutyl and monobutyl tin compounds; though we had only a smaller number of such compounds available for testing. Similar to the tributyltin compounds, the dibutyltin species in oxide, dichloride, dilaurate, and dibromide form produced peaks of precisely the same retention time (i.e. that of dibutyltindibromide). Three of the compounds were used for the "mixed" calibration curve shown in Fig. 3. Again, the conversions and determinations appear to be essentially quantitative.

Only two monobutyl compounds were available: monobutyltin hydroxide oxide (butylstannoic acid) and butyltintrichloride. Both gave the same peak (butyltintribromide). Figure 4 shows this peak (originating from the trichloride), together with the peaks of dibutyltindibromide (from the dilaurate) and tributyltinbromide (from the linoleate) in a temperature-programmed separation.

A number of further organotins were injected under HBr(gas)-doped conditions, simply to see whether sharp, essentially single peaks of about the correct size and retention could be obtained. The compounds that produced such peaks were:

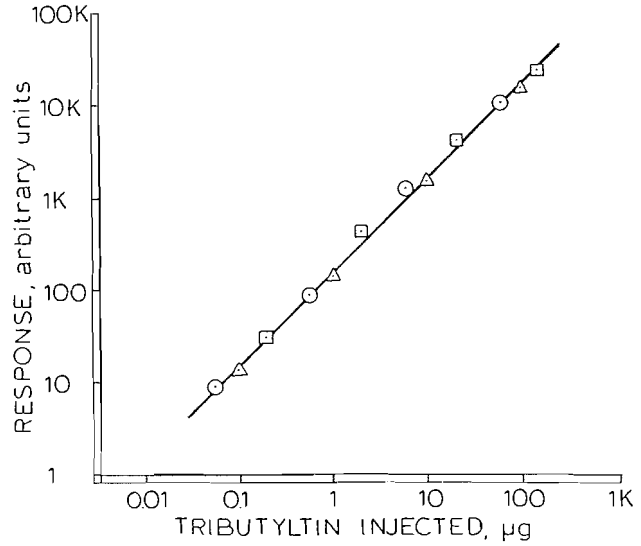

FIG. 2. Calibration curve of bis(tributyltin) oxide (○), tributyltin linoleate (△), and tributyltin fluoride (□), measured as tributyltin bromide in a flame ionization detector and plotted per μg of tributyltin injected. HBr (gas) rate of introduction 1.4×10^{-6} mol/min.

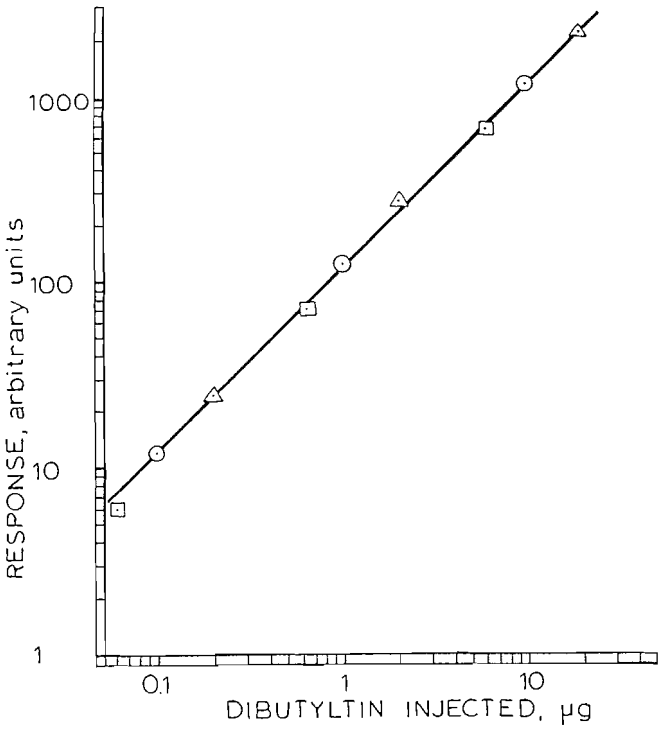

FIG. 3. Calibration curve of dibutyltindimethoxide (□), dibutyltindilaurate (○), and dibutyltindichloride (△), measured as dibutyltindibromide in a flame ionization detector and plotted per μg of dibutyltin injected. HBr (gas) introduction rate 1.4×10^{-6} mol/min.

phenyltintrichloride, diphenyltindichloride, triphenyltin chloride, triphenyltin hydroxide, bis(triphenyltin) oxide; dimethyltindichloride, dimethyltin oxide, trimethyltin chloride, trimethyltin hydroxide; bis(tripropyltin) oxide; dioctyltindichloride, diphenyltindichloride; cyclohexylstannoic acid, dicyclohexyltindibromide, dicyclohexyltin oxide, tricyclohexyltin bromide, and tricyclohexyltin hydroxide.

For exploratory interest only, a few organic derivatives of

For personal use only.

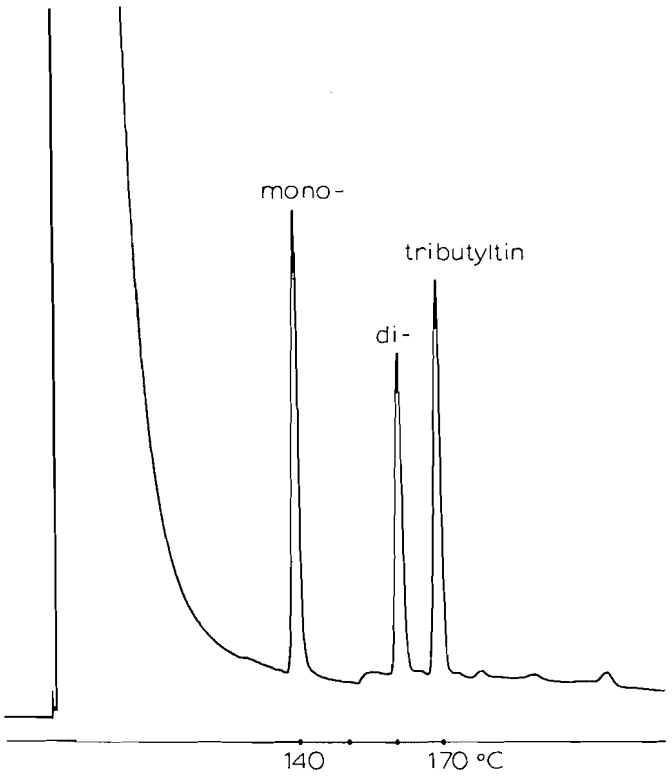

FIG. 4. Temperature-programmed chromatography of 0.5 μg injected of each of butyltintrichloride, dibutyltindilaurate, and tributyltin linoleate, separated and detected by flame ionization as butyltintribromide, dibutyltindibromide, and tributyltin bromide, respectively. HBr (gas) introduction rate 1.4×10^{-6} mol/min.

metals other than tin were also injected. Peaks were obtained — although not always sharp ones — from the three germanium compounds bis(trimethylgermanium) oxide, tributylgermanium chloride, and diphenylgermanium oxide, and from two arsenic species, phenylarsine oxide and phenylarsonic acid. We have no information on the identity of the peaks or the purity of the starting reagents, and we did not seek to explore the situation further. The only reason these seemingly positive results are mentioned here — and we should note that they were accompanied by seemingly negative results from further four compounds (another two arsenicals as well as an antimony and a lead compound) — is to demonstrate that there does exist a good possibility that organometallics other than those of tin may be amenable to acid-doped gas chromatography.

During the experimental series, i.e. during about three hot summer months of doping at a rate of 1.3×10^{-6} mol HBr/min, the color of the column packing (10% Apiezon L on Chromosorb W, 45/60 mesh) slowly changed from white to light yellowish-brown — but its ability to produce sharp, symmetrical peaks was not reduced.

Chloride derivatives

Further series of experiments were done with hydrogen chloride (gas) as the dopant. The first task was to establish that similar results could be obtained by doping with HCl as had been reported above for doping with HBr.

This was indeed the case. *All* thirty-odd organotin compounds that had given peaks with HBr, also gave peaks with HCl. The calibration curves of tributyltin chloride, tributyltin linoleate, and bis(tributyltin) oxide were identical within error margins (when plotted on a tributyltin basis) in the HCl gas system. Though the investigation of the quantitative aspects of organotin transformation and transmission was less extensive for HCl than for HBr doping, no serious differences were found.

Again as a sideline, the same non-tin organometallics earlier treated with HBr, were now exposed to HCl. The results were fairly similar. The three germanium compounds all gave peaks. Phenylarsine oxide again gave a peak, and a peak was also obtained from triphenylantimonydiacetate, which had not responded earlier in HBr. On the other hand, no peak was obtained for phenylarsonic with HCl. Based on these very sparse data we assume that organogermanium compounds behave fairly similar to tin compounds. Other peaks, such as those arising from certain arsenicals and antimonials, would need further work to identify. They might not even contain metal but might simply represent volatile decomposition products of the analyte (to which the flame ionization detector would respond equally well).

Halide exchange

Coming back to the primary targets of this study, namely the organotin compounds, we considered it interesting to investigate further the switch-over from HBr to HCl doping conditions and vice versa. The fact that sharp peaks are obtained from the injection of non-volatile analytes with either HCl or HBr suggests that the transformation (initial derivatization) to volatile chromatographic solutes must occur in the injection port or at the very front of the column, and that it occurs fast (fast, that is, on the timescale of separation kinetics). Furthermore, the peaks obviously stay sharp as they migrate through the rest of the column, and this suggests that the various equilibria (occasional hydrolysis, re-derivatization) are also fast compared to chromatographic peak dispersion. If the various equilibria are indeed reached fast enough in both HCl and HBr systems, then it is reasonable to assume that a mixture of HCl and HBr would lead to similarly fast derivatization and re-derivatization — and that the additional halide exchange equilibrium in the column, either directly

$$but_3SnCl + HBr \rightleftarrows but_3SnBr + HCl$$

or via oxygen-containing structures, would likewise be fast enough to satisfy chromatographic desiderata.

If so, then the equilibrium concept suggests that mixtures of dopants should not only produce sharp peaks, but that these peaks should migrate with speeds intermediate to those obtained by using pure dopants. In other words, chromatographic retention should become a function of the ratio of different dopant concentrations inside the chromatographic column. If a system is started, say, under HCl doping, and a peak is obtained at a particular retention time, that retention time should start to change smoothly upon the incessant introduction of HBr — until, when all reactive chloride in the column has been replaced by bromide, the peak again resumes constancy of retention (though now at a different value). Non-volatile organotin compounds that derivatize (fast) to the *same* chromatographic solute should behave identically in terms of retention time changes during such a switch-over.

An experiment along these lines was set up with three compounds: bis(tributyltin) oxide, hexabutylditin, and tetrabutyltin. The first two should derivatize to the same product. The third should not derivatize at all, hence its peak should remain at the same position in the chromatogram during dopant changes. The actual experiment involved a round trip from HCl to HBr and then back again to HCl (all injected in methanol).

The duration of this lengthy journey and the day-to-day changes in chromatographic conditions made it advisable to use not the raw retention times of the peaks but their Kovats retention indices.

The system performed precisely as expected. The Kovats indices of the first two compounds changed in unison from 1607 +/−4 to 1651 +/−2 and back again to 1607 +/−4. The index of tetrabutyltin stayed constant at 1601 +/−2. All peaks remained sharp and single throughout the experiment.

While the tributyltin peaks remained sharp through the switch-overs, this was not necessarily the case for other types of compounds. To gain some appreciation of possible effects, dibutyltindichloride was also injected from time to time. During both switch-overs, the peak became broad and tailed. Its position changed in the expected direction and it was situated in a retention range bordered by the pure chloride and bromide derivatives. As was mentioned earlier, the dibutyltins need more acid to yield sharp peaks, not surprisingly so since *two* halide atoms have to be introduced and the equilibrium constants are presumedly less favorable than those for the tributyltin analogues. Furthermore, in the switch-over, *three* volatile forms are possible (but_2SnCl_2, $but_2SnClBr$, and but_2SnBr_2), and additional equilibria are introduced, e.g.

$$but_2SnCl_2 + but_2SnBr_2 \rightleftarrows 2but_2ClBr$$

This makes it even more difficult for the migrating dibutyltin to approach the compound equilibrium fast enough to produce a sharp peak. In other words, the interchange among the three migrating halides themselves, as well as among them and the reactive halide and reactive hydroxyl populations in the column, must be so fast that each dibutyltin moiety travels with the same effective speed (which is the weighted average of the different speeds of the three pure dihalides) within distances that should presumedly not be much larger than the most important perturbation parameter, i.e. the particle diameter of the chromatographic support. It should be noted in this context that the occurrence of broad peaks for *di*-organotins has been mentioned several times in the literature, and that the kinetic explanation developed here for a special case is by no means the only one possible.

(For completeness' sake we should also mention that the concentration ratio [Cl]/[Br] is *not* constant along the length of the column in our experiment: the last injected hydrogen halide must dominate in the first segments of the column. In terms of chromatographic peak dispersion, however, a purely axial gradient is inconsequential.)

The change from chloride to bromide and back to chloride derivatives is interesting from both basic and applied viewpoints. We therefore tried to apply the idea to a second system, i.e. to the switchover from chloride to iodide and back to chloride. A new Apiezon L column was used for this purpose, mainly to check reproducibility in the chloride mode, and to ascertain thereby that the old column had not changed its characteristics during the long period of being subjected to chemical brainwashing. The dopants were HCl (gas) dissolved in methanol; and hydroiodic acid, dissolved in methanol and treated with $MgSO_4$.

Iodide derivatives

The results of the Cl → I → Cl exchange were similar to those observed for the Cl → Br → Cl switching sequence. Retention indices increased when HI was introduced — more so than with HBr, obviously — and the system could be returned to its initial state by re-injecting HCl. The retention of tetrabutyltin remained constant, of course. The tributyltin peaks were sharp throughout. Again, when dibutyltindichloride was injected, it required more of either acid than the tributyltin structures in order to produce a sharp peak. Also, organotin peaks sometimes appeared larger in the iodide than in the chloride system.

TABLE 1. Retention and response*

Compound	HCl		HBr		HI	
	KI	R	KI	R	KI	R
Bis(tributyltin) oxide	1608		1651	400		
	1596	336			1715	340
Hexabutylditin	1605		1651	310		
	1598	260			1715	256
Tetrabutyltin	1603		1600	315		
	1600	402			1595	400

*KI, Kovats index; R, response, in arbitrary units of peak area, per weight of original compound injected. Note: The two lines of values for each compound represent the Cl > Br > Cl and Cl > I > Cl dopant changes, respectively; with the latter being done on a new column.

Table 1 combines the retention indices of the two tributyltins and the standard tetrabutyltin, from the two experimental series mentioned above. Note that two columns were used, and that there exist therefore two sets of data for the chloride system. The retention ranges in the three dopant systems are clearly distinguished from each other, and the increased retention in the sequence Cl < Br < I is in accordance with expectation.

Table 1 also lists responses, in peak area per weight of (underivatized) substance injected. Responses from the hydrogen flame ionization detector, which monitors CH-containing species, should remain roughly the same for a particular (initial) analyte, regardless of whether the compound entering the detector had travelled and arrived in a chloride, bromide, or iodide system and form.

In this context it should be noted that the flame ionization detector is being severely challenged by experimental circumstances. Not only is it under the high-temperature assault of various strong acids, but the heavy amounts of tin compounds attempt to cover it with semiconducting debris (presumably SnO_2). Depending on injection load and other conditions, the detector had to be cleaned every two to four weeks — yet, it was still given to display interim fits of noise, and the time at which a particular value was measured may have had a bearing on the result. That this is so can be seen from the response of tetrabutyltin, which serves as a tin-containing standard not only for retention but also for response assessment.

With these caveats in mind, one can now examine the final data given in Table 1. They show that the response for each structure remains roughly comparable in the three dopant systems. Also, the response from the *reacting* tributyltin analytes is not significantly different from that of the *non-reacting* tetrabutyltin. That is a very strong indication indeed that the transformation and transmission of the tributyltin species is essentially quantitative in all three hydrogen halide-doped systems.

The experiments further suggest that iodide derivatives, just as chlorides and bromides, may be pressed into chromatographic service. To demonstrate that, a composite calibration curve of three of the (more difficult to chromatograph) *di*butyltins was measured and is shown in Fig. 5. Except for the different

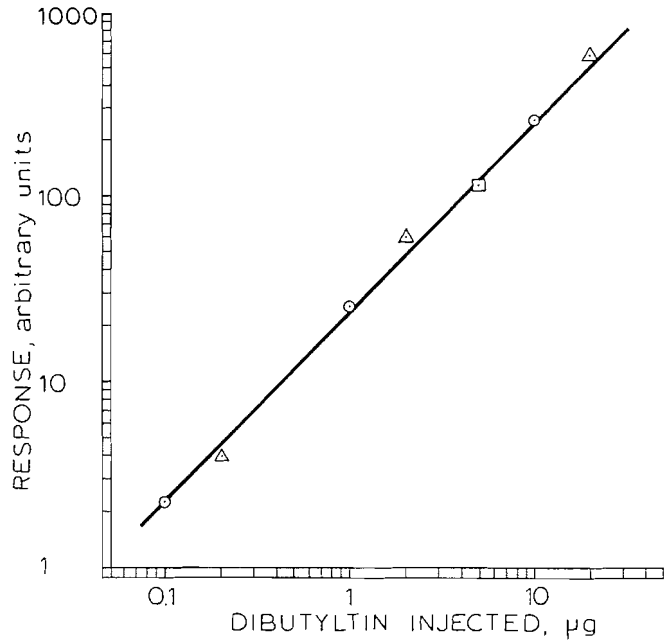

FIG. 5. Calibration curve of dibutyltindimethoxide (□), dibutyltindilaurate (○), and dibutyltindichloride (△), measured as dibutyltindiiodide in a flame ionization detector and plotted per μg of dibutyltin injected. Amount of HI injected (in methanol) ca. 8×10^{-5} mol.

dopant, it is comparable to Fig. 3. Still, the iodide experiment was only added as an afterthought, and no comparative studies were done on the wide variety of thirty-odd tin (and other) compounds as with chlorides and bromides.

During the doping experiments, a record was kept of the total amount of each acid injected. The value of this total amount was dependent on several criteria: in the beginning of the experimental series, acid was introduced until the tributyltins showed sharp peaks, then further acid was injected until dibutyltindichloride did the same. In the switch-overs, the new acid was added until the retention of the tributyltins became constant and dibutyltindichloride produced a sharp peak. Although these criteria are fairly subjective (and our protocol for complying with them was fairly lax), it is still interesting to note the approximate amount of each acid required for the task. On the five occasions that track was kept, this amount ranged between 3 and 10×10^{-5} moles of acid per initial doping or switch-over. We shall discuss the implications of this range later.

HCl retention and depletion

The final experiment of this study was designed to deal with the retention of HCl gas (really: reactive chloride) by the chromatographic system, and with the question of how much of it is necessary for adequate tributyltin transformation and transmission.

Obviously, the question can be answered only for a defined set of analyte and conditions — with the hope that the results will be fairly typical, hence applicable to other systems. The retention of the dopant will depend, *inter alia*, on the nature and amount of retentive materials in the gas chromatograph. For example, one would assume that a large-diameter packed column had a much larger capacity for halide retention than a capillary; or that a porous polymer packing might differ from one using a diatomaceous earth support; or that various tubing materials may act in a disparate manner. Furthermore, different organotin compounds and different dopants are wont to react with different degrees of effectiveness — as both kinetic and thermodynamic aspects are coming to the fore under suitable conditions — and the whole system is, furthermore, subject to the influence of temperature, flow rates, etc. Still, to have *some* idea of what is a useable/desirable dopant level may be quite helpful — as can be readily appreciated from the fact that at least part of this very study had been flying blind: The dopant levels of HCl or HBr in gaseous form were established in the beginning by guess and chance (we have not quite mastered yet the art of setting, and maintaining, a very low, precise flow of a highly reactive gas). Consequently, the steady-state hydrogen halide effluent from the column was occasionally measured by titration, but it was never optimized for a particular group of analytes or a particular gas chromatographic set-up.

By measuring the steady rate at which HCl emerges from the column, a particular dopant level can be correlated with chromatographic performance, i.e. peak area and shape. Furthermore, the amount of reactive chloride held by the column can be estimated.

An experiment of this sort was carried out by doping the one-meter, 10% Apiezon L on Chromosorb W column with a continuous flow of HCl that, measured as the (constant) column effluent rate, was 1.8×10^{-7} mol/min. The HCl tank was then shut off, allowing the gas that remained in the lines to bleed slowly through the restrictor valve and thereby provide an exponentially decreasing halide input. The column output of HCl was titrated again when the HCl input reached zero (as judged from a pressure gauge), and then titrated a few times more until it became too low to measure. From about the time of zero input (day 5) on, effluent HCl originated only from the column, which acted thus as a reservoir by equilibrating its HCl content with the nitrogen carrier gas stream flowing through it.

Throughout the experiment, tributyltin linoleate was injected a few times per day (weekends excepted) to check for chromatographic performance. The peak width started to broaden soon after the HCl tank was shut off; by the time no new HCl entered the column (day 5), it had reached about double the initial value. (The peak area, on the other hand, had remained essentially constant.) At that point in time, HCl emerged from the column at the rate of 6.4×10^{-9} mol/min.

The fact that the peaks started to broaden soon after the HCl tank was shut off indicates that the initial HCl input was just enough, or even a bit too low, for producing the sharpest peaks obtainable from tributyltin linoleate (really: tributyltin chloride). Note that the initial dopant concentration was almost an order of magnitude lower than that used earlier in some of the HBr (gas) experiments. The fact that the peak area stayed constant suggests that all of the analyte made it to the detector, but that the analyte derivatization rate (initial and/or in the column) became slow enough to broaden the peak.

It may be interesting to ask how much reactive chloride the column contained at this point. Figure 6 shows the drop in HCl output in a semilogarithmic plot. If, for the purpose of a rough estimate, one assumes that a strictly exponential function applies

$$r = r_0 \exp(-kt)$$

where r is the output rate at time t and r_0 is the initial output rate, then the integral to infinite time is r_0/k (the constant k is the slope in Fig. 6). If one assumes r_0 to have the value of day 5 (no further HCl input) and accepts the slope of the straight

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

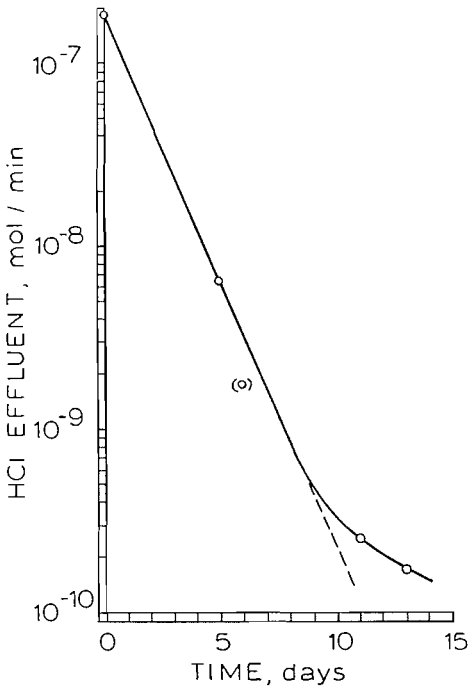

FIG. 6. Effluent rate of HCl (gas) over two weeks. See text for explanation. Titration at day 6 was prematurely terminated, resulting in only a minimum value.

line (as extrapolated in dashes), then the amount of elutable chloride from day 5 on is about $(6.4 \times 10^{-9}$ mol/min)/$(4.7 \times 10^{-4}$ min$^{-1}) = 1.4 \times 10^{-5}$ mol. (The actual amount is most likely higher, not only because the curve deviates from the pure exponential, but also because the column net loss started *before* the HCl input finally stopped on day 5, and because the injections of tributyltin linoleate consumed some additional HCl. However, this should not matter much in an order-of-magnitude calculation.)

It is interesting to compare this number (1.4×10^{-5} mol) with earlier measured amounts of acid necessary to condition the column or to switch halide (3 to 10×10^{-5} mol). Given that the first number is low (peak broadening of tributyltin linoleate is already apparent) and the second is high (not only tributyltin linoleate but also dibutyltindichloride produces a sharp peak), the amount of hydrogen halide typically necessary for this particular column and chromatographic system appears consistent in the two types of experiments.

One can further compare the overall range of 1 to 10×10^{-5} mol HX to the surface area, about 1.3 m^2, of the Chromosorb W support typically contained in the column. If one uses, for instance, an area of 12 Å^2 per halide, that area translates to about 1.8×10^{-5} mol of halide. In other words, this order-of-magnitude calculation would be consistent with the idea that the available (reactive) surfaces have to be more or less covered by chemically or physically sorbed hydrogen halide.

As the active chloride concentration further dropped in the column, the peak width continued to broaden. On the next day (day 6), peaks started to exhibit asymmetry. This is consistent with HCl being slowly swept from the column — the effect being most strongly felt at the start of the chromatographic path, i.e. in the injection port. The peak area, on the other hand, still remained about the same.

In fact, the peak area remained fairly constant — while peaks continued to broaden to about *four times* the original peak width — up to about day 13. Then it, too, started to deteriorate. By day 18 the peaks had become genuinely irreproducible and the experiment was terminated.

(It should be noted that this experiment, while quite rich in information content, was intrinsically unable to provide *precise* measurements of such parameters as peak broadening. The reason lies in the equilibria and the extent of interference that repeated testing brings to them. For instance, the injection of tributyltin linoleate consumes reactive chloride in the injection port and the beginning of the column. Some of the HCl is being replenished by diffusion of HCl from positions upstream (and, perhaps to a minor extent, downstream) in the flow path, i.e. the local equilibria slowly re-establish themselves. In agreement with this scenario, a rapid sequence of repeated injections will successively broaden peaks. If the chromatograph is then given some time to recuperate, its performance improves: the peak will be sharper now than the last peak of the rapid sequence run earlier — even though the effluent rate, and the total amount of reactive chloride in the column, keep continually decreasing.)

The rate of HCl effluence shown in Fig. 6 was governed not by a single but by a variety of processes. During the first days of the experiment, the rate simply reflected the exponentially decreasing HCl input. As the latter gradually ceased, the rate became dominated by condensed-phase/gas-phase equilibria. Overlaying these, and particularly important toward the end of the experiment, might have been the substitution of active surface chloride by hydroxyl from traces of water in the carrier gas (and/or the physical displacement of adsorbed HCl by H_2O). Although care was taken to dry the carrier nitrogen as far as possible (Linde molecular sieve 5A followed by a Supelco heated O_2/H_2O scavenger cartridge), it is likely that the residual moisture in the carrier gas could not be depressed much below the 1 ppm level — not to mention the possibility of moisture diffusing into the chromatograph from the atmosphere. A short calculation shows that a 1 ppm level of hydrogen chloride in the carrier gas (which corresponds, reactionwise, to 0.5 ppm water) amounts to about 10^{-9} mol HCl/min, i.e. a rate well within the range of the experiment. Therefore, the possible influence of even traces of moisture in the carrier gas cannot be lightly dismissed.

In any case, it is clear that the retention of HX by a packed-column chromatographic system can be extensive. This is, of course, the reason why the effect has been found in the first place. It enables the system to provide good chromatography under *dis*continuous doping, with the sharpness of the analyte peak (c.f. refs. 15, 16) serving as a quality control (halide concentration) indicator.

Beyond obvious analytical implications of the equilibria defining desirable doping levels in a gas chromatographic system, the halide transformation/transmission effects could also surface in other contexts. Imagine, for instance, a mass spectrometer's direct probe whose walls, courtesy of a prior sample, had acquired a chloride coating, and which was asked to procure a spectrum of TBTO: some of the sample might enter the source not as the oxide but as the chloride. Chromatographically, the migration of organotin structures as mixed halides is interesting in that it allows, within limits, a continual adjustment of retention relative to other compounds. Since analyte retention depends on the average composition of the migrating organotin halide, and since peak dispersion, given the right circumstances, includes *chemical* rate constants, certain kinetic data could also be derived from such a chromatographic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

system. Furthermore, it is unlikely that the effects should be restricted to organo*tin* compounds. Compounds of germanium will likely show similar behaviour. Halide exchanges occur easily among inorganic compounds of various elements, as documented by isotope exchange (e.g. 20). The benefit of doping a column with mercuric chloride for the efficient chromatography of organomercurials has been partly attributed to analogous processes (21). There must surely exist a variety of organic (as opposed to organometallic) compounds that are prone to exchange labile halide during gas chromatography. It is, furthermore, possible to envision the synthetic use of (preparative) gas chromatography for obtaining small amounts of particular (e.g. isotope-enriched) organometallic halides. Finally, it may be advantageous to use the volatilization of analyte in an HX stream for preconcentration of organotin and other organometallic compounds.

Soluble polymer supported synthesis of a monosubstituted tetraaryl porphyrin

Y. TAKAHASHI,[1] J. E. GUILLET, AND M. A. WINNIK
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 8, 1988

Y. TAKAHASHI, J. E. GUILLET, and M. A. WINNIK. Can. J. Chem. **67**, 411 (1989).

A new synthesis of monosubstituted tetraarylporphines is described based upon the soluble polymer supported synthesis strategy. Low molecular weight poly(ethylene glycol) is chloromethylated at both ends. These ends are then used to build up the polymer-bound ether of 5-(4′-hydroxymethyl)-10,15,20-tritolylporphine, which, after purification of the polymer, can be cleaved in high yield with $TiCl_4$. While the method offers useful conveniences, such as the ease of separation and purification of the desired material, the overall yield is low: 100 mg from 40 g of polymer. Oligomerization of the polymer during chloromethylation increases the polymer molecular weight and thereby decreases the number of end groups per gram of polymer.

Key words: porphyrin, tetraaryl, monosubstituted poly(ethylene glycol) oligomerization, polymer-supported synthesis.

Y. TAKAHASHI, J. E. GUILLET et M. A. WINNIK. Can. J. Chem. **67**, 411 (1989).

On a mis au point une nouvelle méthode de synthèse des tétraarylporphyrines monosubstituées qui est basée sur l'emploi d'un polymère soluble comme support. On a procédé à la chlorométhylation des deux extrémités d'un poly(éthylène glycol) de bas poids moléculaire. Ces extrémités sont alors utilisées pour construire l'(hydroxy-4′ méthyl)-5 tritolyl-10,15,20 porphine reliée au polymère par une liaison éther; après purification du polymère, on peut effectuer le clivage de cet éther avec de très bons rendements en utilisant du $TiCl_4$. Même si cette méthode offre plusieurs avantages, comme la facilité de séparation et de purification du produit désiré, le rendement global est faible : 100 mg à partir de 40 g de polymère. L'oligomérisation du polymère durant la chlorométhylation augmente le poids moléculaire du polymère et diminue ainsi le nombre de groupements terminaux par gramme de polymère.

Mots clés : porphyrine, tétraaryl, oligomérisation du poly(éthylène glycol) monosubstituée, synthèse basée sur l'emploi d'un polymère comme support.

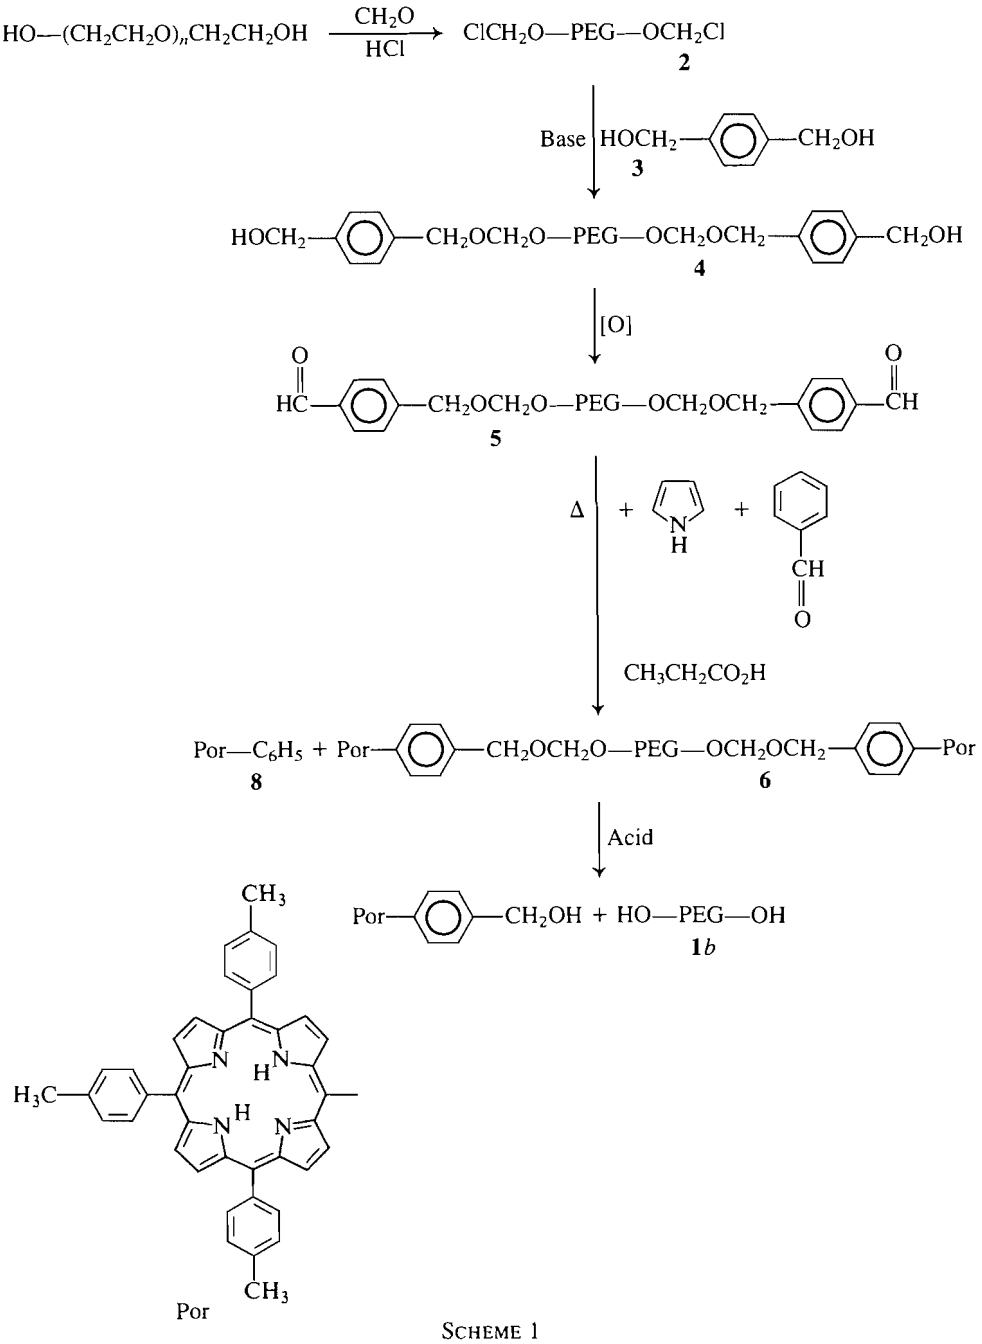
For many years we have been concerned with the problem of designing polymers that could serve as a mimic of the light-harvesting chlorophylls in a chloroplast (1). Porphyrins (Por) are ideal candidates for this function. Their spectroscopy is well understood (2). Certain derivatives are quite stable under many of the conditions under which a photosynthetic device might be operated and, most important, the R_0 value for self-energy transfer (Por* + Por → Por + Por*) by the dipole-coupling mechanism is suitably large (3).

To attach a porphyrin to a synthetic polymer, one needs a derivative with a single functional group. A monoacrylate or methacrylate derivative would allow porphyrins to be introduced as comonomers into a polymer chain by free radical copolymerization. Some such derivatives are not difficult to prepare, although in low yield, but they pose certain problems in their eventual application as antenna groups in the polymer. One could avoid these problems with other derivatives, but they are much more difficult to synthesize, isolate, and purify.

For example, one of the easiest monosubstituted tetraphenylporphyrin derivatives to obtain is the mono-4-hydroxy derivative **1***a*. It can be prepared by a mixed condensation of pyrrole, benzaldehyde, and *p*-hydroxybenzaldehyde. The yield is terrible (<5%) but the isolation and purification steps are not too difficult. Nevertheless, esters of **1***a* attached to water-soluble polymers experience two problems. The first is hydrolysis of the aromatic ester, which occurs much too quickly in water; and the second is the problem of photo-Fries reactions competing with the processes of interest. These particular problems could be overcome in a molecule such as **1***b* where the -OH is separated from the phenyl group by the $-CH_2-$ spacer.

There is a wide interest in the synthesis of porphyrins, often



1*a* X = OH
b X = CH_2OH
c X = $CH_2OC(=O)C(CH_3)=CH_2$

for the purpose of mimicking natural systems such as oxygen-binding proteins. These efforts have led to synthetic strategies that can be categorized into three groups. The mixed benzaldehyde condensation mentioned above (4) works well for symmetrical tetraaryl porphyrins. For monosubstituted derivatives the method has limited utility, since the separation of the desired product is successful only for tetraaryl porphyrins containing a strongly polar group such as HO, NO_2, and CO_2H.

Another approach involves substitution reactions on the porphyrin nucleus (5). This method usually results in a complex mixture of mono- and multi-substituted isomers. In exceptional cases, monosubstituted derivatives can be isolated from these reactions.

The most general route involves step-by-step synthesis (6).

[1]Permanent address: Oji Paper Co., Ltd., 1-10-6 Shinonome Koto-ku, Tokyo, Japan.

SCHEME 1

One starts with a single pyrrole and adds bridging methylene and successive pyrrole units to construct a linear tetrapyrrole. This species is then condensed with an appropriate aldehyde to give the porphyrin. The disadvantage of this method is one associated with all multistep syntheses: the skill required by the experimenter and the large number of isolation and purification steps involved in the transformation.

The other alternative is a synthetic scheme based upon polymer supported synthesis (7). This can be either of solid supported type employing crosslinked polymer beads (7, 8) or of the soluble polymer type (9). These methods simplify the steps of product isolation and purification, since the by-products and impurities are normally small molecules.

Leznoff and Svirskaya (8) used an insoluble support (crosslinked polystyrene) to prepare unsymmetrical tetrarylporphyrins. They attached an aromatic aldehyde to the polystyrene bead via a substituent in the *para* position. The polymer-bound derivative was condensed with an excess of pyrrole and benzaldehyde to provide a mixture of tetraphenylpyrrole and the desired product, bound to the particles. The separation and purification steps required for the product were somewhat more onerous than one might have anticipated. Later the authors applied this scheme to prepare unsymmetrical phthalocyanines (10).

An alternative approach involves synthesis on a soluble polymer support. For instance, poly(ethylene glycol) was used as a support for N-protected amino acids in peptide synthesis (9*a*). In the case of application of solvent-soluble supports, the low molecular weight reactants and by-products were separated by either ultrafiltration or selective precipitation.

We have chosen to examine a soluble polymer supported synthesis of 4-hydroxymethylphenyl-triphenyl porphyrin. While our approach did work, and is described in the sections that follow, success did not come as smoothly and simply as we had anticipated. Some of the problems we encountered are actually quite interesting from a polymer chemistry point of view. Those aspects are also examined in this paper.

Strategy

Polyethylene glycol (PEG) of sufficient molecular weight is insoluble in diethyl ether. If one uses the HO groups on the chain ends as points of attachment for chemical transformations, then the work-up of each step would involve filtration to remove unwanted solids, precipitation of the polymer into ether, followed by filtration to remove unwanted solvent and soluble by-products. This property suggested to us that if we could prepare a PEG sample containing an appropriate 4-substituted benzaldehyde at each end, this group could be incorporated into a porphyrin by cocondensation of the polymer with benzaldehyde and pyrrole. A vast excess of tetraphenylporphyrin would be produced as a by-product, but this could be removed by filtration from the soluble polymer-bound porphyrin. In Scheme 1, given below, the desired porphyrin could be cleaved from the polymer by treatment with acid.

We presumed that PEG could be chloromethylated using conditions similar to that used by Corey *et al.* (11) in their synthesis of the protecting group precursor $CH_3OCH_2CH_2OCH_2Cl$ (MEM-Cl). Reaction of the chloromethylated polymer **2** with an excess of the diol **3** in DMF containing sodium hydride should yield the difunctional polymer **4**, which could be oxidized in turn to the bisbenzaldehyde derivative **5**. Model studies indicated that the formaldehyde acetal linkage (as in **4** and **5**) was stable to the reaction conditions (refluxing propionic acid) necessary for the pyrrole–benzaldehyde condensation. As a consequence, we envisaged no problem with the condensation step **5** → **6**. Cleavage of the purified polymer **6** with $TiCl_4$ should lead to the desired porphyrin **1***b*.

Results and discussion

Experiments began with polyethylene glycol (PEG) of $M_w \approx 2000$ ($\bar{M}_n/\bar{M}_w = 1.1$). It was chloromethylated by treatment with s-trioxane and HCl gas in dry methylene chloride. The product, substituted at both chain ends ($ClCH_2O$—PEG—OCH_2Cl, **2**), was precipitated from diethyl ether. Analysis of the product by gel permeation chromatography (gpc), however, indicated a large increase in polymer molecular weight. This point is examined in more detail below.

The transformation of **2** to **4** introduces an aromatic ring whose uv absorption allows the extent of incorporation to be monitored. Thus treatment of **2** in THF with a large excess of *p*-di(hydroxymethyl)benzene in the presence of sodium hydride gave a polymer with uv-absorbing groups attached. This reaction could be monitored by gpc. Like PEG itself, the precursor polymer **2** gives a signal only in the differential refractive index detector (ri), whereas the product **4** shows a response in both the ri and uv (250 nm) detectors.

The most striking feature, which is apparent in comparing the traces in Fig. 1, is the shift of the elution volume and elution profile of the polymer. The sharp peak for PEG is broadened in **2** and appears at much shorter times. The gpc analysis confirms that molecular weight changes occur during chloromethylation. We presume that the oxacarbocation intermediate can be

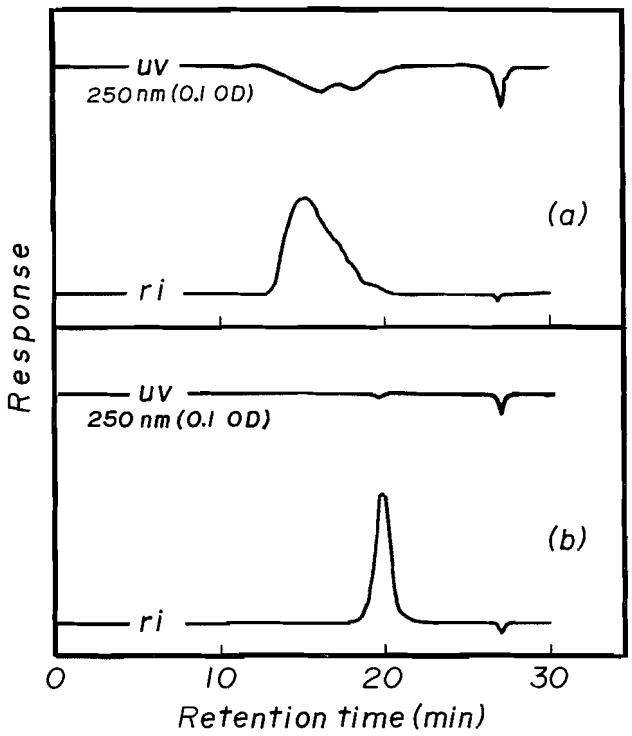

FIG. 1. Gel permeation chromatography traces (a) of $HOCH_2$—$C_4H_4OCH_2OPEGOCH_2OC_6H_4$—$CH_2OH$ (**4**) and (b) of the PEG sample used in its synthesis. Solvent: toluene. Detectors: ri, differential refractive index; uv, absorption at 250 nm.

trapped by reaction with a second PEG in competition with its reaction with chloride.

$$HO—PEG—OH \rightarrow [HO—PEG—O\overset{+}{C}H_2] \rightleftharpoons HO—PEG—OCH_2Cl$$

$$\downarrow \; HO—PEG—OH$$

$$HO—PEG—OCH_2O—PEG—OH$$

As a consequence of oligomerization, the number of functional groups available for synthetic use are reduced. The product distribution was remarkably insensitive to changes in the reaction conditions. If we estimate the polymer $\bar{M}_n$ from gpc to be 8000, uv analysis indicates that 85% of the chain ends contain benzyl alcohol groups.

The polymer **4** was treated with CrO_3/pyridine in dichloromethane to oxidize the $-CH_2OH$ groups to the aldehyde. The uv spectrum of the product is identical to that of benzaldehyde. Quantitative evaluation of the spectrum (using $\epsilon(250\text{ nm}) = 15\,700\text{ L mol}^{-1}\text{ cm}^{-1}$ for benzaldehyde) indicated essentially quantitative conversion.

The next step was to form the porphyrin nucleus by taking advantage of Adler's porphyrin synthesis (12). A 50-fold excess of pyrrole and tolualdehyde was mixed with the polymer **5** and refluxed in propionic acid for 30 min. The tetratolylporphine by-product, which precipitated from the solution, was filtered out of the mixture. The dark brown propionic acid solution was gradually added to diethyl ether to precipitate the polymer (**6**). Polymer **6** was repeatedly purified by dissolution and reprecipitation. Figure 2 displays the result of the gpc measurement. A strong response detected on the uv–vis detector monitored

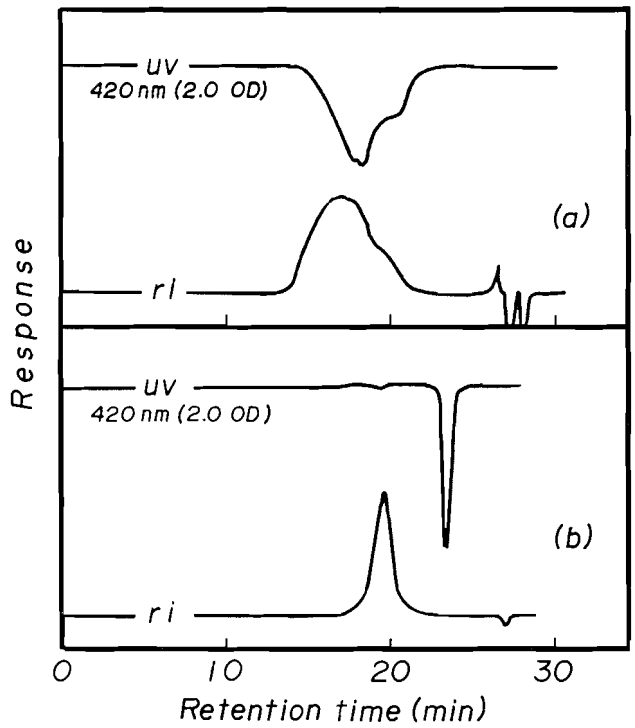

FIG. 2. Gel permeation chromatography traces (a) of PEG-bound porphyrin **6** and (b) of the polymer resulting from cleavage of the end groups with $TiCl_4$. Detectors: ri and uv–visible absorption at 420 nm.

in the visible region suggests the successful conversion of polymer-attached aldehydes (**5**) to visible light-absorbing chromophores, and the absence of small molecule contaminants. The absorption spectrum of polymer **6** displayed in Fig. 3 is characteristic of the porphyrin moiety. These data indicate that we have succeeded in the synthesis of porphyrin-attached PEG in this stage. By uv analysis only 10% of the polymer-bound aldehyde groups were converted to porphyrins. This result, though disappointing, is not surprising. The Alder synthesis normally gives low yields of symmetrical porphyrins, viz. the 15% yield of tetratolylporphine that precipitates from this reaction mixture. Thus, while product recovery here is not difficult, the yield of polymer-bound porphyrin is low.

To perform the cleavage (or deprotection) reaction to obtain the unsymmetric porphyrin **1***b*, the purified and dried polymer **6** was treated with $TiCl_4$ in dichloromethane at room temperature ($ZnBr_2$ did not work). This procedure not only successfully cleaved PEG-porphyrin to free unsymmetrical porphyrin but also cleaved chemical bonds that were responsible for the oligomerization of PEG. Figure 2 also illustrates the result of gpc measurements after the cleavage reaction, which shows (*i*) no uv/vis absorbing chromophore attached to the polymer, and (*ii*) regenerated, monodisperse distribution of the polymer molecular weight. Thus, we conclude that $TiCl_4$ selectively attacks the PEG—CH_2—O—CH_2—O—CH_2—R (R = porphyrin) function. This reaction presumably involves the special coordination configuration suggested by Corey (11).

The black solution produced by the cleavage reaction was concentrated and column chromatographed through silica. It was first eluted with chloroform, to get rid of the small amount of tetratolylporphine present, then with chloroform–THF mixed solvent (95:5 v/v). The desired compound (uv–vis spectrum, Fig. 3) was eluted as a major band, which was collected and dried to give purple crystals of **1***b*.

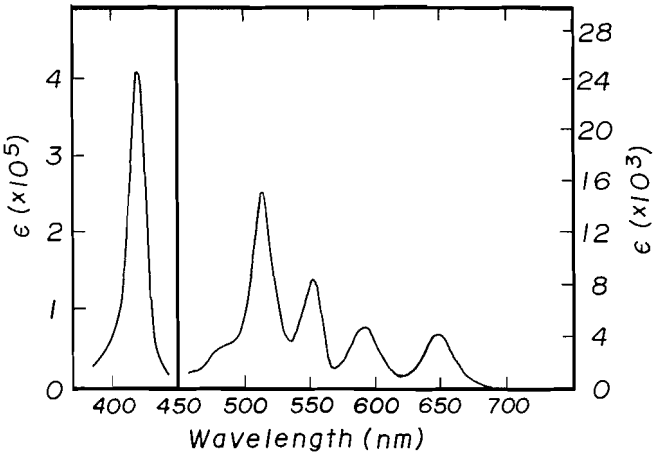

FIG. 3. Ultraviolet–visible spectrum of **1***b* in $CHCl_3$. The polymer-bound precursor **6** has an identical spectrum.

The methacrylate of **1***b* (**1***c*) could be prepared in a straightforward manner by its reaction with methacryloyl chloride, and incorporated into polymers by free radical copolymerization. The synthesis of these polymers and their fluorescence properties will be reported in due course.

Summary

A synthesis of 5-(4′-hydroxymethylphenyl)-10,15,20-tritolylporphine is reported, using a soluble polymer supported synthetic methodology. The key step involves the condensation of a PEG polymer containing appropriate aromatic aldehyde groups at both chain ends with an excess of pyrrole and tolualdehyde. The separation of the polymer-bound porphyrin from the excess tetratolylporphyrin by-product was simple, justifying the strategy of the method.

The yield of aldehyde-to-porphyrin conversion was low, only 10% for the polymer-bound aldehyde. As a consequence, one needs large amounts of polymer to produce small amounts of porphyrin. This problem is exacerbated by the first step in the polymer supported synthesis: chloromethylation of the chain ends led to coupling of the oligomers, producing material with fewer chain ends per gram of polymer. The synthetic scheme is less convenient than one might have hoped. Even though the reagents are not expensive, it still takes ca. 40 g of polymer to produce 0.1 g of purified porphyrin derivative. The major value of this approach to porphyrin synthesis is in the ease of purification of the unsymmetric porphyrin derivative.

Experimental

The ^1H nmr spectra were run on Varian T-60 and Varian XL 200 spectrometers and the ultraviolet–visible spectra on a Hewlett–Packard model 8451A diode-array spectrometer. The gpc measurements were made using a Waters model 6000 pump in conjunction with Waters 10^3 and 500 Å Ultrastyragel columns (THF as eluent), with a Waters model R401 differential refractive index detector and a Hitachi model 100-40 variable wavelength uv–vis detector.

Solvents and reagents

Poly(ethylene glycol) (Carbowax, Union Carbide, MW ~ 2000) was dried by azeotropic distillation of a toluene solution, precipitated into dry diethyl ether, and then dried under vacuum. Diethyl ether (Caledon) was refluxed over sodium metal using benzophenone as an indicator of dryness. Tetrahydrofuran (THF, Caledon) was dried in the same manner as diethyl ether. Dichloromethane (Caledon) was washed with concentrated H_2SO_4, then with water, and with saturated aqueous

solutions of NaCl. After being dried over 4 Å molecular sieves, dichloromethane was fractionally distilled and stored over 4 Å molecular sieves. Pyridine (Caledon) was refluxed and distilled over BaO. s-Trioxane (Aldrich) was used as received. Hydrogen chloride gas (Matheson practical grade) was dried by bubbling through concentrated H_2SO_4. Chromium trioxide (Fisher) was dried over P_2O_5 under vacuum. Dihydroxymethylbenzene (Aldrich) was used as received. Pyrrole (Aldrich) was distilled immediately before use. Tolualdehyde (Aldrich) was distilled under reduced pressure immediately before use. Propionic acid (Aldrich) and titanium tetrachloride (Fisher) were used as received.

Synthesis of chloromethylene-terminated PEG (2)

A mixture of 50 g of PEG (MW ~ 2000, 25 mmol) and 3.9 g of s-trioxane (47 mmol) was dissolved in 30 mL of dry dichloromethane. Dry hydrogen chloride was bubbled through this solution for 2 h. The exhaust gas was directed into a suction flask filled with aqueous ammonium hydroxide solution to quench any excess amount of HCl gas coming from the reactor. Subsequently, dry nitrogen gas was bubbled through the reaction mixture to get rid of dissolved HCl until little formation of ammonium chloride (white solid) was observed in the quenching flask (24–48 h). While bubbling with N_2, dichloromethane was continuously added to the mixture to avoid complete evaporation of the solvent. The methylene chloride solution of the polymer was then slowly added to the rapidly stirred dry diethyl ether (1.6 L) to precipitate the polymer (**2**). This process was repeated twice by using dry THF as a good solvent with dry diethyl ether as a poor solvent. The polymer was filtered and dried under vacuum. The gpc analysis showed oligomerization of the PEG at this stage. The amount of the polymer recovered was 48 g. Yield recovery of the polymer was 96%. This polymer was immediately used in the following reaction (within 24 h) because of suspected instability of the terminal chloromethyl groups.

Synthesis of benzylalcohol-terminated PEG (4)

(i) Preparation of sodium di(hydroxymethyl)benzene

To 27 g of *p*-di(hydroxymethyl)benzene (196 mmol) dissolved in 150 mL of dry THF under an inert atmosphere (nitrogen), 7 g of sodium hydride (292 mmol, 15 g of 50% suspension in mineral oil, washed twice with 15 mL each of dry pentane) was added at once. A white-grey solid precipitated, with formation of hydrogen gas, at the bottom of a 500-mL two-necked flask equipped with a magnetic stirrer and a refluxing condenser. The mixture was refluxed for 3 h.

(ii) Synthesis of benzylalcohol-terminated PEG (4)

To the cooled mixture of sodium di(hydroxymethyl)benzene in THF at 0–5°C, 48 g of chloromethylene-terminated PEG (**2**) dissolved in 250 mL of dry THF was gradually added with stirring, under an inert atmosphere. Upon addition of the PEG-CH_2Cl, the sodium salt started to dissolve. After addition was completed, the ice bath was removed and the mixture was gradually heated to reflux. It was refluxed for 24 h under an inert atmosphere. The cooled reaction mixture was then filtered through a sintered glass filter. The filtrate was gradually added to rapidly stirred dry diethyl ether (1.6 L) to precipitate the polymer (**4**). Precipitation was repeated twice, and after filtration the white polymer obtained was dried under vacuum. Yield (recovery of the polymer) was 45 g (94%). Chemical yield (based on uv analysis), 85%.

Synthesis of benzaldehyde-terminated PEG (5)

To a magnetically stirred solution of dry pyridine (19 g, 240 mmol) in 180 mL of dry dichloromethane, placed in a 500-mL round-bottom flask equipped with a magnetic stirrer and a drying tube, chromium trioxide (12 g, 120 mmol) was added in one portion. After 15 min of stirring, 45 g of the benzylalcohol-terminated PEG (**4**) dissolved in 60 mL of dry dichloromethane was added at once. Immediately after mixing, the color of the solution changed from burgundy to pale brown with formation of a black precipitate. After 30 min reaction at room temperature, dichloromethane was removed (rotary evaporator), leaving a dark-brown, viscous liquid. This was dissolved in 500 mL of toluene, then decanted, leaving a black precipitate. The liquid phase was centrifuged and then filtered through a 2 cm thick Celite bed to give a pale brown colored toluene solution, which was slowly added to rapidly stirred dry diethyl ether (1.6 L) to give 41 g of beige polymer (**5**). After two reprecipitations, the yield (recovery of polymer) was 91%. The chemical yield, based on uv analysis, was 96%.

Synthesis of porphyrin-terminated PEG (6)

To a magnetically stirred and refluxing mixture of 25 g of benzaldehyde-terminated PEG (3 mmol) and 20 g of tolualdehyde (160 mmol) dissolved in 500 mL of propionic acid, 10.6 g (160 mmol) of pyrrole was added dropwise over a period of 15 min. After an additional 30 min of refluxing, 250 mL of propionic acid was quickly distilled off under reduced pressure. Then, the rapidly cooled (with ice) mixture was filtered through a sintered glass funnel to collect tetratolylporphine (by-product, 4.0 g, yield 15%). The filtrate was repeatedly filtered to remove all solid components, then gradually added to rapidly stirred diethyl ether (2 L) to precipitate the polymer. The dark brown polymer (**6**) thus obtained was purified by repeated reprecipitation, then collected and air dried. It was then dried by azeotropic distillation of a toluene solution, followed by precipitation into dry diethyl ether. Yield (recovery of the polymer), 95%. Chemical yield (based on uv analysis), 10%.

Cleavage reaction of porphyrin-terminated PEG

To a magnetically stirred solution of porphyrin-terminated PEG (16 g) in 300 mL of dry dichloromethane, 10 mL of titanium tetrachloride was added over a period of 10 min. During this addition the viscosity of the solution increased and then decreased. A black precipitate appeared. The mixture was stirred overnight and then quenched by the addition of 100 mL of 10% aqueous ammonium hydroxide solution. The decanted liquid was combined with 50 mL of chloroform, and transferred to a separatory funnel. The organic phase was separated and washed repeatedly with distilled water and then dried over anhydrous magnesium sulfate. The black solid obtained was dissolved in 20 mL of chloroform and chromatographed on 400 g of silica gel. A small amount of tetratolylporphine (R_f = 1.0, $CHCl_3$) was eluted in chloroform. The desired product eluted in a mixture (95:5 v/v) of chloroform and THF. The major portion (R_f = 0.63 $CHCl_3$, R_f = 0.73 95:5 v/v $CHCl_3$–THF) was collected and evaporated to give 100 mg of purple crystals; ^{1}H nmr ($CDCl_3$): pyrrole CH (8H) δ 8.84, ArCH (hydroxymethyl phenyl-2,6) (2H) δ 8.20 (d, 8 Hz), ArCH (tolyl-2,6) (6H) δ 8.08 (d, 8 Hz), ArCH (hydroxymethyl phenyl-3,5) (2H) δ 7.73 (d, 8 Hz), ArCH (tolyl-3,5) (6H) δ 7.54 (d, 8 Hz), OCH_2 (2H) δ 5.05, CH_3 (tolyl) (9H) δ 2.69, NH (2H) δ −2.79. The peaks assigned to pyrrole CH, ArCH, and CH_3 (tolyl) are essentially identical to those reported for 5-(carbomethoxyphenyl)-10,15,20-tritolylporphine (*4b*). It proved impossible to obtain a reliable mass spectrum by electron impact ionization. It was, however, possible to obtain a low resolution spectrum by field desorption mass spectroscopy (Oji Paper Co., Tokyo, Japan), which gave exclusively the molecular ion at *m/e* 686.

Esterification of ***1*** b–***1*** c

To a magnetically stirred mixture of 50 mg of **1***b* and 2 mL of dry pyridine in 5 mL of dry THF, 0.5 mL of freshly distilled methacryloyl chloride was added over a period of 2 min at 0–5°C. The mixture was stirred at this temperature for 1 h, then heated to reflux for 5 h. The cooled mixture was combined with 50 mL of $CHCl_3$, then washed with 2 × 10 mL of dilute aqueous ammonium hydroxide. The separated organic layer was dried over anhydrous magnesium sulphate ($MgSO_4$), concentrated, and chromatographed on 40 g of silica gel with a 95:5 v/v mixture of $CHCl_3$ and THF. The desired compound (**6**) was eluted as the first band. Yield, 70%; ^{1}H nmr ($CDCl_3$): pyrrole CH (8H) δ 8.84, ArCH (methacryloxymethylphenyl-2,6) (2H) δ 8.20 (d, 8 Hz), ArCH (tolyl) (6H) δ 8.08 (d, 8 Hz), ArCH (methacryloxymethylphenyl-3,5) (2H) δ 7.73 (d, 8 Hz), ArCH (tolyl) (6H) δ 7.54 (d, 8 Hz), $=CH_2$ (1H) δ 6.34 (m), $=CH_2$ (1H) δ 5.70 (m), OCH_2 δ 5.55, CH_3 (tolyl) (9H) δ 2.70, CH_3—C= (3H), NH (2H) δ −2.80.

The structure of coprinolone (**1**), an oxygen-bridged protoilludane from the W2 isolate of the fungus *Coprinus psychromorbidus*, has been elucidated by chemical transformations and detailed ^1H and ^{13}C magnetic resonance studies, including homo- and heteronuclear correlation spectra. The $^1H-^1H$ coupling data and nuclear Overhauser difference spectra for **1** and derived isomers led to the establishment of its stereochemistry. A second metabolite was identified as Δ^6-coprinolone (**20**) by spectroscopic results. Confirmatory evidence in support of the structures was obtained from the labelling patterns of the compounds from cultures supplemented with sodium [1,2-$^{13}C_2$]acetate.

Key words: coprinolone, Δ^6-coprinolone, protoilludane, sesquiterpenes, NMR.

ALVIN N. STARRATT, EDMUND W. B. WARD et J. B. STOTHERS. Can. J. Chem. **67**, 417 (1989).

En se basant sur des transformations chimiques et des études détaillées de résonance magnétique nucléaire du ^1H et du ^{13}C, y compris des spectres de corrélation homo- et hétéronucléaires, on a élucidé la structure de la coprinolone (**1**), un protoilludane portant un pont oxygène qui a été isolé de l'extrait W2 du champignon *Coprinus psychromorbidus*. L'utilisation de données de couplage $^1H-^1H$ et de spectres Overhauser nucléaires de différence obtenus à partir du composé **1** et d'isomères qui en dérivent ont permis d'établir sa stéréochimie. Sur la base de données spectroscopiques, on a pu identifier un second métabolite, la Δ^6-coprinolone (**20**). En se basant sur les patrons de marquage des composés obtenus à partir de cultures auxquelles on avait ajouté de l'acétate-[$^{13}C_2$-1,2], on a obtenu des données qui ont permis de confirmer les structures.

Mots clés : coprinolone, Δ^6-coprinolone, protoilludane, sesquiterpènes, RMN.

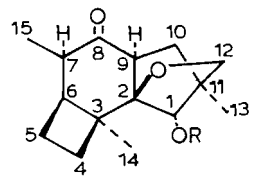
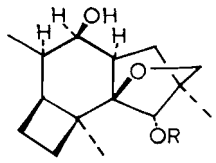
Introduction

The production of hydrogen cyanide by the W2 isolate of a low-temperature basidiomycete (1), now classified as *Coprinus psychromorbidus* (2, 3), which causes extensive snow mold damage to overwintering cereals, grasses, and legumes in western Canada, has been the subject of several studies (4–7). During our investigation, we observed the presence of a new metabolite that we have named coprinolone (8) in extracts of both the culture filtrate and the mycelium. This compound is a member of a small class of sesquiterpenes produced by various basidiomycetes that possess the protoilludane skeleton. It showed no evidence of phytotoxicity when tested on seedlings of winter wheat and soybeans at a concentration of 10^{-3} M and was also inactive when tested against fungi and bacteria. In this paper, we describe the isolation and the full experimental evidence leading to the structures of coprinolone (**1**) and a related metabolite Δ^6-coprinolone (**20**).



Results and discussion

Structure of coprinolone



Crystalline coprinolone, isolated by silicic acid – Celite chromatography of the extracts of the W2 isolate of *Coprinus psychromorbidus*, was the major metabolite, obtained in overall yields of ca. 100 mg/L from cultures grown for 21–24 days. Recrystallization from light petroleum afforded material melting at 105–107°C having an optical rotation of $[\alpha]_D^{23}$ −95°. Its empirical constitution of $C_{15}H_{22}O_3$, established by microanalysis and precise mass measurement, was indicative of a sesquiterpene. The ir spectrum included hydroxyl (3510 cm^{-1}) and ketonic carbonyl (1700 cm^{-1}) absorptions. The ^1Hmr spectrum in C_6D_6 solution exhibited signals for two tertiary methyl groups (δ 0.64 and 1.20), a secondary methyl group (δ 1.04, d, J = 6.7 Hz) coupled to a methine proton at δ 1.95 (ddq, J = 1.4, 9.0, 6.7 Hz), a $\diagdown\!\!\diagup$CHO— (δ 3.21, d, J = 0.9 Hz) and a —CH_2O— grouping, δ_A 3.56 (d, J = 6.7 Hz) and δ_B 3.27 (dd, J = 3.2, 6.7 Hz). In addition, a $\diagdown\!\!\diagup$CH—CH_2 unit was evident as an ABX pattern in which each proton exhibited an additional coupling. The methine proton, δ_X 2.91, J_{AX} = 10.6, J_{BX} = 3.9 Hz, was found to be coupled to the proton at δ 1.95 (J = 1.4 Hz) and the methylene protons, δ_A 1.52, δ_B 2.38, J_{AB} = 12.3 Hz, are coupled to the protons at δ 3.27 (J = 3.2 Hz) and 3.21 (J = 0.9 Hz), respectively. The ^{13}Cmr spectrum in C_6D_6 solution contained signals for a carbonyl carbon (δ_C 210.1), quaternary, methine, and methylene carbons bearing oxygen (93.3, 81.7, 75.5), as well as three methyl (10.1, 13.7, 24.8), three methylene (20.7, 27.7, 30.6), three methine (43.7, 51.1, 51.9), and two quaternary (41.8, 47.3) absorptions at higher field. Since there was no olefinic unsaturation, the compound is tetracyclic.

Acetylation of coprinolone (**1**) provided a monoacetyl derivative **2** exhibiting infrared absorption attributable to keto and acetyl groupings (1715, 1734 cm^{-1}). Treatment of **1** with sodium borohydride gave a more polar substance lacking carbonyl absorption in the ir spectrum. Acetylation of this new diol **3** furnished a monoacetyl derivative **4**, which is identical to that produced upon sodium borohydride reduction of **2**. As expected, coprinolone acetate (**2**) is formed by oxidation of **4**

with pyridinium chlorochromate (9). Clearly, the hydroxyl group formed upon reduction of the ketonic carbonyl in **1** is more hindered than the original hydroxyl function.

Both **1** and **2** yield monobromo derivatives, **5** and **6**, respectively, upon treatment with *N*-bromosuccinimide (NBS) in refluxing carbon tetrachloride. The appearance of a third methyl singlet replacing the methyl doublet in the ^{1}Hmr spectrum and the replacement of a methine signal with a new quaternary carbon peak in the ^{13}C spectrum indicated that the secondary methyl group in **1** is α to the carbonyl group. Acetylation of **5** affords bromocoprinolone acetate (**6**).

A crystalline compound precipitated from benzene solutions of **1** that had been at room temperature for extended periods. On chromatograms, this substance **7** gave color reactions typical of peroxides. Its ^{1}H spectrum contained three methyl singlets, δ 1.00, 1.10, and 1.39, and a new quaternary signal replaced one of the methine peaks in the ^{13}C spectrum. These changes and the shielding differences for the two other methine carbons indicated that peroxidation occurred at the same α carbon as that involved in the bromination with NBS. As expected, **7** was converted to a ketodiol **8** upon reduction in acetic acid with activated zinc dust.

Mild base treatment of **1** gave a more polar, crystalline compound **9** for which absorption at 1652 cm^{-1} in the infrared and at 252 nm in the ultraviolet spectrum indicated the presence of an α,β-unsaturated ketone. The ^{13}C spectrum contained signals for a carbonyl carbon (δ_C 200.1), two fully substituted olefinic carbons (135.5, 162.1), methine (80.8) and methylene (69.8) carbons bearing oxygen as well as for three methyl (10.5, 17.4, 25.2), three methylene (19.4, 30.8, 37.0), two methine (39.8, 47.8), and two quaternary carbons (40.5, 47.0). These features are accounted for by base-catalyzed opening of an oxide ring β to the carbonyl yielding an α,β-unsaturated ketone with a primary alcohol group. The relationship between the functional groups in **1** was further revealed upon isolation of a less polar compound with λ_{max} 266 nm after ketodiol **9** was oxidized with 4-(dimethylamino)pyridinium chlorochromate (10), a selective reagent for oxidation of allylic hydroxyl groups.

Oxidation of **1** in acetone with chromic acid yielded a carboxylic acid, which was converted to methyl ester **10** for characterization. The presence of a fully substituted enone unit bearing β oxygen was indicated by the uv absorption, λ_{max} 260 nm (ε 9080), and ^{13}C peaks at δ_C 109.3, 174.7, and 197.1. Thus, we could conclude that the generation of these two enones, **9** and **10**, involved β cleavage of a C—O bond with base and a C—C bond by oxidation, respectively.

The mass spectra of coprinolone and related compounds showed a strong peak at $M^+ - 28$, which was found by precise mass measurements to be due to the loss of ethylene and not carbon monoxide. Facile loss of ethylene from a cyclobutane ring has been found (11, 12) to be a characteristic feature for the sterpurane **11** and protoilludane **12** skeletons. Only the latter can accommodate a secondary methyl α to a carbonyl group, and the results of a series of nmr experiments showed that this is the carbon skeleton of coprinolone.

For each of the ^{13}C signals arising from protonated carbons, the absorptions for the directly bonded protons were identified through a ^{13}C–^{1}H heteronuclear correlation (COSY) spectrum. An important finding from this spectrum was the fact that the methine and methylene carbons at δ_C 51.1 and 30.6, respectively, are those bearing the protons giving rise to the ABX system noted above. Two- and three-bond proton–carbon couplings were revealed through long-range heteronuclear correlation experiments utilizing the XCORFE sequence (13). From the results for C_6D_6 solutions, it was found that the methyl protons at δ 1.04, bonded to the methyl carbon at δ_C 10.1, are coupled to the methine carbons at δ 51.9 and 43.7. The latter carbon bears the methine proton at δ 1.95. The methine carbon, δ_C 51.9, is vicinally coupled to the methyl protons at δ 1.20 (δ_C 24.8), which are also coupled to the quaternary carbon (δ_C 41.8) and the methylene carbon, δ_C 27.7. The protons for the third methyl group, δ 0.64 (δ_C 13.7), were found to be coupled to the quaternary carbon at δ_C 47.3, the carbinyl methine, δ_C 81.7, and methylene carbons at δ_C 30.6 and 75.5. It was also found that the proton bonded to the methine carbon at δ_C 51.1 is coupled to the quaternary carbons at δ_C 93.3 and 41.8. Additional information on the carbon–carbon connectivities was obtained from one- and two-dimensional double quantum coherence (INADEQUATE) spectra (14). A major observation from the 1D-INADEQUATE spectrum was the J_{CC} value of 10 Hz common to the methine carbons absorbing at δ_C 43.7 and 51.1; this is a typical geminal coupling between carbons flanking a carbonyl group and thus identified the α carbons in **1**. Further-

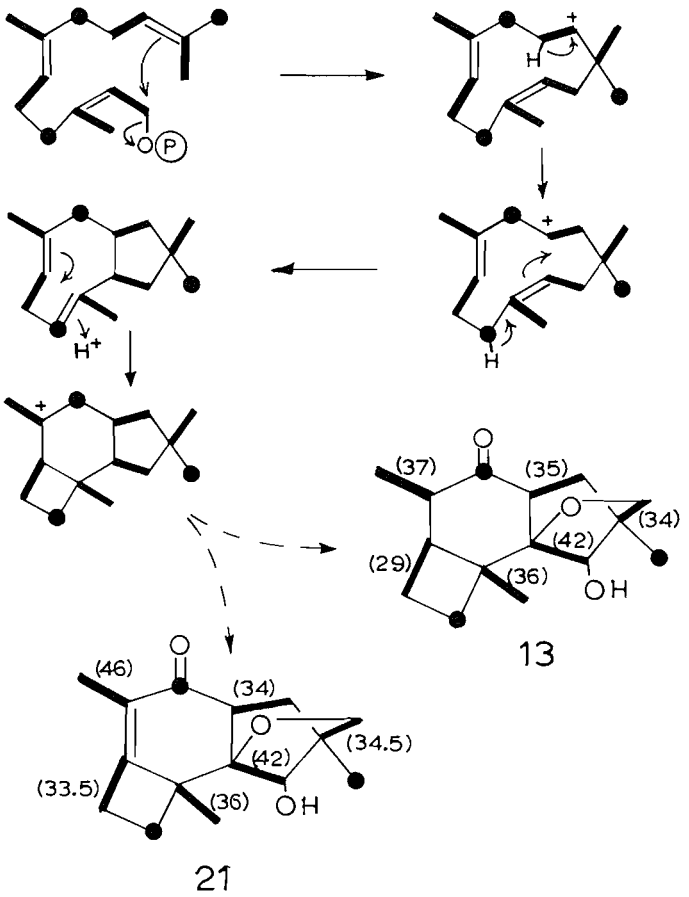

FIG. 1. Possible biosynthetic sequence leading to coprinolone and Δ^6-coprinolone from farnesyl pyrophosphate, illustrating the ^{13}C labelling patterns from [1,2-$^{13}C_2$]acetate incorporation.

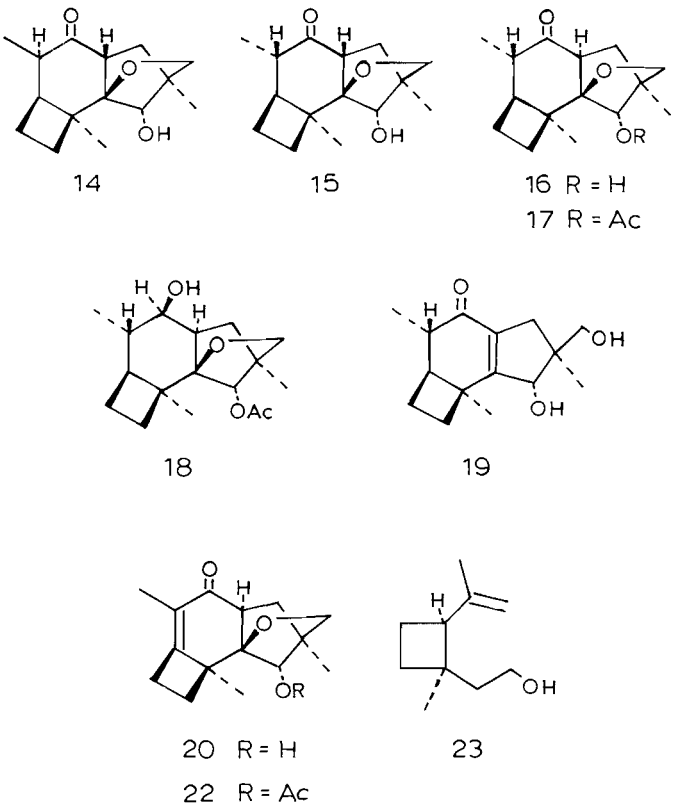
more the protons bonded to these carbons exhibited a long-range coupling of 1.4 Hz. In addition to confirming the linkages found from the XCORFE spectra, the 2D-INADEQUATE experiment showed that the methylene carbons at δ_C 20.7 and 27.7 are directly bonded, as are the quaternary (93.3) and carbinyl (81.7) carbons. All of these data are consistent with structure **1** for coprinolone in planar projection.



To confirm the proposed structure, coprinolone was isolated from cultures of *C. psychromorbidus* that had been amended with sodium [1,2-$^{13}C_2$]acetate at the time of maximum production of the metabolite. The ^{13}Cmr spectrum of **1**-$^{13}C_x$ isolated on day 13 showed that all carbons were labelled (4.0% specific incorporation) in the pattern **13**, possibly arising from the sequence outlined in Fig. 1, a pathway analogous to that proposed for illudins S and M (15). The heavy bonds in **13** represent intact acetate units for which the observed J_{CC} values are indicated in Hz, while the dark circles denote carbons arising from C-2 of the three mevalonate units. The relatively high enrichment level signals the formation of multilabelled species, the presence of which will increase the probability of ^{13}C incorporation at contiguous carbons in **1** that arise from different acetate units. Thus, additional information on the carbon connectivities was sought through a two-dimensional $^{13}C-^{13}C$ COSY spectrum. This experiment provided confirmation of direct bondings of C-4 with C-3 and C-5, C-7 with C-6 and C-8, C-9 with C-2 and C-8, and C-11 with C-1, C-10, and C-13.

The ^1H and ^{13}C shielding data are collected in Tables 1 and 2 for C_6D_6 and CD_2Cl_2 solutions while the observed coupling constants are listed in Table 3. Although solvent effects are minimal for the ^{13}C spectra, some distinctive shift differences, which aided the specific assignments by clarifying the multiplicities of certain absorption patterns, were observed for the ^1H spectra. A detailed discussion of the proton data is presented later.

Structures **2–10** for the compounds derived from **1**, as described above, follow directly and their nmr data are collected in Tables 1–3. The specific assignments followed from $^1H-^1H$ and $^{13}C-^1H$ correlation spectra analogous to those employed for the analysis of **1**.

Stereochemistry of 1

In the early stages of this study, attempts to isolate coprinolone from culture extracts by chromatography on alumina led to the isolation of two slightly more polar isomers of **1**, which could be partially separated by chromatography over silicic acid – Celite and were purified by crystallization. Neither of these isomers **14** and **15** was acetylated under the conditions leading to the formation of **2** from **1**, indicating that the hydroxyl group in each is more hindered than that in **1**. A small amount of a third isomer **16**, which could be readily acetylated, was obtained from the mother liquors from recrystallization of **1**. Reduction of this isomeric acetate **17** with sodium borohydride afforded **18**, an isomer of **4**. It may be noted that our initial nmr examination of **1** in $CDCl_3$ revealed the slow formation of small amounts of a second component upon standing for several hours. The subsequent isolation of **16** established that this slow process in $CDCl_3$ is an isomerization. Similarly the initial nmr sample of **14** in $CDCl_3$ solution was found to give a 50:50 mixture of **14** and **15** upon standing. Consequently, C_6D_6 was chosen for this study with several samples also run in CD_2Cl_2 solutions to alter the signal dispersion in the ^1Hmr spectra. Thus, four isomers having the same carbon skeletons were in hand and, on the basis of their behaviour under acetylation

conditions and in $CDCl_3$ solutions, these could be paired as **1** with **16** and **14** with **15**; the isomerizations presumably involve configuration differences at C-7 and -9. Examination of the ^{13}C spectra of these isomers did not reveal any clear trends that would indicate the relative stereochemistry at these centres, but the ^1H spectra allowed definitive assignments for each.

The protoilludane skeleton is characterized by the *cis–anti–cis* stereochemistry of the carbocyclic ring system as in **12** (16). Consideration of the long-range $^1H-^1H$ coupling interactions resolved in the spectra of **1** and **14–16**, together with the results from nOe difference spectra, revealed the relative stereochemistry at the two epimeric centres, C-7 and -9. The absorption patterns for H-9 were particularly informative. For **1**, this proton gave rise to a six-line multiplet through vicinal coupling to the 10-methylene protons, J = 3.9 and 10.6 Hz, and a long-range coupling of 1.4 Hz with H-7. The corresponding pattern for H-9 in **15** contained similar couplings with the 7 and 10 protons, J = 1.5, 5.1, and 8.9 Hz, as well as a long-range interaction of 0.7 Hz with H-1. A comparable coupling of 0.9 Hz was evident for H-9 with H-1 in **14**, for which $J_{9,10}$ = 5.1 and 10.2 Hz with no resolved coupling between H-9 and -7. For **16**, the H-9 pattern was a clean doublet of doublets $J_{9,10}$ = 4.0 and 11.5 Hz. From the nOe difference spectra, it was found that irradiation of the 3-methyl protons enhanced the H-9 absorptions in **1** and **16** but not in **14** and **15**, while the H-1 and -6 patterns were enhanced in all cases. Furthermore, irradiation of the H-9 patterns increased the intensity of the H-7 absorptions for **1** and **15** but not for **14** and **16**. Irradiation of the 7-methyl doublet revealed enhancement of the H-7 absorption in all cases, as expected, but only the H-6 patterns in **15** and **16**. From these results, we can conclude that H-9 is α in **1** and **16**, β in **14** and **15**, while H-7 is α in **1** and **14** but β in **15** and **16**.

Models show that H-1β and -9β in this skeleton are in the W arrangement conducive to four-bond coupling in saturated systems, nicely accounting for the long-range interaction observed for **14** and **15**. With a 1β-hydroxyl group, one would not expect to observe long-range coupling between the 1α and 9 protons. From models, this *cis* C-2,9 ring junction appears to increase the steric congestion around the α-hydroxyl group, in agreement with the fact that **14** and **15** are not readily acetylated. This orientation of the hydroxyl group is the same as that found for other members of the protoilludane family of sesquiterpenes, which are oxygenated at C-1 (17).

In the tetracyclic compounds **1–8** and **14–18**, the 12-methylene protons, denoted in Table 1 as *syn* and *anti* with respect to C-1, gave rise to an AB pattern, J_{AB} = 6.7 ± 0.2 Hz, with an additional coupling of 3.2 ± 0.4 Hz to one of the protons. The latter coupling interaction involves the 10α proton, which was identified by the magnitude of its vicinal coupling with H-9. For **1** and **16**, the dihedral angle relating the 9α and 10α protons is near zero and the J values are 10.6 and 11.5 Hz, respectively, while for **14** and **15** this angle between the 9β and 10α protons is near 120° with J = 5.1 Hz for each. With the heterocyclic ring bridged through a 2β oxygen, the 10α proton is in the zigzag, or W arrangement, with respect to *syn* H-12, accounting for the observed long-range coupling. The alternative 2α-oxygen bridge would place the 10β proton in a comparable orientation. It may be noted that a 1β-hydroxyl group would place H-1α in a W arrangement with respect to *anti* H-12 and lead to long-range coupling, contrary to the facts. Thus, the relative stereochemistry as shown for **1** and **14–16** was established. The $^1H-^1H$ coupling constants are collected in Table 3.

An attempt was made to determine if the isomers of **1** were present in the initial culture extracts. Coprinolone and its isomers, **14–16**, could be distinguished by capillary gas chromatography, having retention times of 4.0 (**15**), 4.6 (**16**), 4.8 (**1**), and 5.4 min (**14**). Two culture filtrate extracts showed, in addition to a major peak for **1**, many minor peaks of which one coincided with the retention time of **16**. In both cases, the area of this peak was ca. 8% of that for **1**. Although this provides evidence for **16** at an early stage of isolation, it does not exclude isomerization during the extraction steps. Isomer **14** was not detected but a composite peak was observed at the retention time of **15** with an area ca. 1% of that for **1**.

When coprinolone was chromatographed over alumina or exposed in refluxing benzene to alumina, ketodiol **9** also formed from opening of the oxide ring. Thin-layer chromatographic examination showed that this product was a mixture of two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

components, only one of which, **9**, crystallized. The same mixture was formed when **1**, **14**, or **15** was treated with methanolic potassium hydroxide. The ^{13}C spectrum of the noncrystalline component is remarkably similar to that of **9** and its ^1H spectrum contained a methyl doublet, δ 1.08, $J = 7.5$ Hz; two methyl singlets, 1.07 and 1.42; a 1-proton singlet, 4.72; an AB pattern, 3.43, 3.51, $J_{AB} = 10$ Hz; and a series of overlapping multiplets arising from eight protons, δ 1.5–2.4. These data (Tables 1 and 2) indicated that this material formed with **9** is ketodiol **19**.

Structure of Δ^6-coprinolone

A study to determine the period of most active synthesis of **1** by *C. psychromorbidus* revealed that a second major metabolite, slightly more polar than **1** on silica gel tlc plates, was present in relatively young cultures. The amount of this substance, however, declined in cultures after 15 days' growth and was not detected by tlc in extracts of 21- to 24-day-old cultures, the age at which cultures were normally used for the production of **1**. This compound, which could easily be separated from **1** by chromatography, melted at 186–187°C and had an optical rotation of $[\alpha]_D^{20}$ −105°. Its constitution as $C_{15}H_{20}O_3$ was established by microanalysis and precise mass measurement. The ketonic carbonyl absorption (1646 cm^{-1}) and uv maximum (λ_{max} 248, ε 11 760) are very similar to those found for ketodiol **9** and are indicative of an α,β-unsaturated ketone. The proton spectrum included three methyl singlets, δ 1.01, 1.56, 1.59, and absorption patterns closely resembling those exhibited by H-1, -9, -10, and -12 for **1** but with the absence of long-range coupling for H-9. These data point to structure **20** for this metabolite, Δ^6-coprinolone, and the ^{13}C spectrum was entirely consistent with this proposal; the nmr data are collected in Tables 1–3. In addition, a long-range $^{13}C-^1H$ COSY experiment confirmed the linkages of C-11 with C-1, C-10, C-12, and C-13, and of C-3 with C-2, C-4, and C-14. Further support for this structure was provided by the ^{13}C spectrum of the labelled material isolated from the [1,2-$^{13}C_2$]acetate incorporation experiment described earlier. All carbons were enriched (4.0% specific incorporation) in the labelling pattern **21** (Fig. 1) in which the J_{CC} values in Hz for the intact acetate units incorporated are indicated. As in the case of **1**-$^{13}C_x$, a $^{13}C-^{13}C$ COSY experiment with **20**-$^{13}C_x$ provided confirmation of the direct bondings of C-4 with C-3 and C-5, C-2 with C-3 and C-9, and C-11 with C-1, C-10, and C-13. Treatment with acetic anhydride – pyridine gave a monoacetyl derivative **22**, a structure fully supported by the nmr results (Tables 1–3).

Concluding remarks

It was proposed earlier (8) that the isolation of **1** from the W2 isolate may have taxonomic significance and might be of value because of the difficulty of identifying *C. psychromorbidus* owing to its failure to produce fruiting bodies in culture. However, only trace quantities, if any, of coprinolone were detected in cultures of three other isolates of *C. psychromorbidus* (W1, 1291, 1292) that can be distinguished from W2 on the basis of physiological and morphological characteristics (1, 2). The possibility remains, however, that **1** may be produced by other isolates of this fungus exhibiting properties more closely resembling those of W2.

The absolute configuration of **1** was not determined but very probably corresponds to that of other naturally occurring protoilludanes (17*d*, 18). If so, it may be possible to degrade **1**, perhaps by conversion to **8**, base-catalyzed opening of the oxide ring, and oxidation, to an intermediate containing the cyclobutyl ring, which could be transformed to (+)-grandisol (**23**), an aggregation pheromone of the cotton boll weevil (19). Grandisol, of undetermined absolute stereochemistry, has also been reported as a pheromone component of several other insects (20).

Experimental

Melting points were measured on a Kofler hot stage and are uncorrected. Microanalyses were performed by Dr. C. Daesslé, Montreal, and Guelph Chemical Laboratories, Guelph. Infrared spectra of compounds, in KBr unless otherwise indicated, were recorded on a Pye Unicam PU9516 spectrophotometer. Ultraviolet spectra were recorded on a Shimadzu UV-240 instrument and mass spectra were determined with either a Varian MAT 311A or a Finningan MAT 8230 system. Optical rotations were determined in chloroform on Schmidt–Haensch or Perkin–Elmer 241 polarimeters. Gas chromatography was done at 180°C using a Hewlett–Packard 5880A instrument equipped with a 10 m × 0.2 mm i.d. fused silica capillary column, coated with dimethyl silicone fluid (Hewlett–Packard), and a flame ionization detector. Thin-layer chromatography (tlc) was carried out on Macherey–Nagel silica gel precoated plastic sheets (Polygram Sil G/UV_{254}) and Whatman high performance silica gel plates (LHP-KF). Vanillin – phosphoric acid spray was used routinely for visualization. Light petroleum refers to the fraction with bp 35–60°C unless otherwise stated.

The nmr spectra were recorded with Varian XL-200 and -300 systems. Although initially some selective decoupling experiments were done to aid analysis of the proton spectra, all of the coupling interactions were identified by $^1H-^1H$ homonuclear correlation using the HOMCOR sequence of the XL software. The correlated spectra were obtained using a 1024 × 512 data matrix transforming 1024 points in both domains with a spectral width of 1000 Hz in both. A series of nOe difference spectra were recorded for **1** and **14**–**16** with a spectral width of 1000 Hz, 90° pulses, and acquisition time of 3 s with a delay of 10 s. A total of 15 16-transient blocks, each with four steady-state pulse cycles, was collected at various (6–10) irradiation frequencies, one of which was 5 kHz off-resonance. Subtraction of the latter FID from each of the others containing a saturated absorption before 16 K transformation gave the required difference spectra. Several examples were done with the irradiating frequency cycled through the lines of a multiplet for saturation. The ^{13}Cmr spectra were all obtained at 75.4 MHz and the protonated carbons distinguished with the APT technique (21). Heteronuclear $^{13}C-^1H$ correlation spectra were recorded to establish the one-bond correlations using the HETCOR sequence of the XL software, using a 2048 × 128 data matrix transforming 2048 and 512 points for ^{13}C and ^1H respectively, with sweep widths of 6700 (^{13}C) and 1000 Hz (^1H). The same parameters were employed for the XCORFE sequence (13) to obtain the two- and three-bond correlations using fixed delays of 0.064–0.128 s. The INADEQUATE spectra (14) for **1** were obtained with the XL software sequences using a 6700-Hz sweep width; for the 2D spectrum a 2048 × 128 data matrix transforming 2048 and 512 points was used. The ^{13}C COSY spectra for **1**-$^{13}C_x$ and **2**-$^{13}C_x$ were obtained with the HOMCOR sequence and a 1024 × 256 data matrix, transforming 1024 points in each domain with 6700- and 15 000-Hz sweep widths for each of two experiments.

Cultural conditions and extraction of metabolites

The W2 isolate of a low-temperature basidiomycete (1) was routinely grown at 15°C for 21–24 days in 1-L Roux bottles on a synthetic medium (150 mL /bottle) as described previously (4). After removal of the mycelium by filtration, the culture fluid from bottles was extracted with ethyl acetate. At this stage, the addition of ethyl alcohol and saturated NaCl solution (both 10% by volume) aided in the separation of the organic and aqueous layers. The extracts were combined, washed with saturated sodium chloride solution, and dried over anhydrous sodium sulfate. Removal of the solvent gave a thick brown oil (750 mg). Extraction of cultures with ether afforded a smaller quantity (430 mg) of a lighter coloured oil. Similar yields were

For personal use only.

obtained when this fungus was cultured on malt extract – yeast extract – glucose (5 g, 5 g, 15 g/L) medium.

Wet mycelium from 10 bottles was mixed with ethyl alcohol (50 mL) and ethyl acetate (100 mL) and homogenized in a Waring blender. The resulting paste was diluted with water and filtered through a pad of Celite. After washing the Celite thoroughly with ethyl acetate, the organic and aqueous phases of the filtrate were separated and the latter was further extracted with ethyl acetate. The combined extracts were washed with saturated sodium chloride solution and dried over sodium sulfate. After removal of solvent, a typical yield was 250 mg of a dark oil.

Three other isolates, W1 (1), 1291, and 1292 (2), were grown on synthetic media under the same conditions as W2. The culture filtrates were extracted with ether and, in each case, the yield of extracts was ca. 20 mg. To test for the presence of **1**, extracts were separated on silica gel sheets using chloroform–methanol (19:1), and the material in the zone corresponding to the sesquiterpenes was analyzed by gas chromatography. Trace amounts of a substance with a retention time corresponding to that of **1** were detected in extracts of W1 and 1291 but none was observed in the extract of 1292.

In a time course study, cultures from two bottles were extracted every second day between days 7 and 25 after inoculation, essentially as described above except that the mycelium was not separated. After the addition of ethyl alcohol (30 mL) and ethyl acetate (100 mL), the cultures were homogenized for 1.5 min and the resulting mixture was filtered through Celite. The Celite was washed well with ethyl acetate and the aqueous portion of the extracts was extracted twice with ethyl acetate (100-mL portions) after the addition of saturated sodium chloride solution (100 mL). Removal of the ethyl acetate after washing and drying yielded the metabolites. Inspection of a tlc of the extracts under short wavelength uv light revealed the presence of a second major metabolite, slightly more polar than coprinolone, which peaked in concentration around days 13–15 and declined thereafter. In contrast, the total amount of extract as well as the level of coprinolone, as judged by tlc, peaked at day 15 and remained relatively constant throughout the remaining period.

*Isolation of coprinolone (**1**)*

The crude extracts were chromatographed over silicic acid – Celite (4:1) using methylene chloride as eluent. In a typical separation, the culture filtrate extract (425 mg) was chromatographed over 30 g adsorbant (20 × 1.8 cm column). After examination by tlc (silica gel; chloroform–methanol, 19:1), fractions containing the major metabolite were pooled, yielding crystalline material (167 mg). Recrystallization from ether – light petroleum provided coprinolone, mp 105– 107°C; $[\alpha]_D^{23}$ −95° (*c* 1.03); ir: 3510, 1700 cm^{-1}. *Exact Mass* calcd. for $C_{15}H_{22}O_3$ (M^+): 250.1568; found: 250.1565. *Exact Mass* for $C_{13}H_{18}O_3$ (M^+ −28): 222.1255; found: 222.1253. *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 71.73, H 9.04.

Chromatography of a mycelial extract (252 mg) in the same way yielded fractions containing mainly coprinolone (38 mg), preceded by fractions containing another substance (85 mg) that had approximately the same R_f when analyzed by tlc. In contrast to coprinolone, this substance could be detected by viewing the tlc plates under uv light. Recrystallization from ether–methanol afforded plates, mp 149–152°C; $[\alpha]_D^{22}$ −116° (*c* 0.9); this substance was indistinguishable from ergosterol by tlc, uv, ir, and mixture mp.

*Coprinolone acetate (**2**)*

Coprinolone (56 mg) in pyridine (0.5 mL) was treated with acetic anhydride (0.25 mL) for 16 h at room temperature. Chromatography of the product over silicic acid – Celite (4:1) using methylene chloride yielded a substance that was recrystallized from light petroleum (60–80°C) to give acetate **2**, mp 102–103°C; $[\alpha]_D^{20}$ −50° (*c* 1.18); ir: 1734, 1715 cm^{-1}. *Anal.* calcd. for $C_{17}H_{24}O_4$: C 69.83, H 8.27; found: C 69.58, H 8.22.

*Diol **3***

Sodium borohydride (58 mg) was added to a stirred solution of coprinolone (250 mg) in methanol (5 mL). After 1.5 h, additional reagent (39 mg) was added as tlc showed the presence of starting material. Stirring was continued for a further 3.5 h, water was added, and the product was extracted into methylene chloride. Recrystallization from ether–hexane removed a small amount of coprinolone, which was further treated with sodium borohydride. Combination of the products and recrystallization from ether–hexane gave diol **3** (210 mg), mp 137–138°C; $[\alpha]_D^{24}$ −38° (*c* 0.84); ms 252 (M^+). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.56, H 9.53.

*Hydroxyacetate **4***

Diol **3** (179 mg) in pyridine (1 mL) was treated overnight at room temperature with acetic anhydride (0.5 mL). After purification by chromatography over silicic acid – Celite (4:1) with methylene chloride as eluent, the product was recrystallized from hexane to give hydroxyacetate **4**, mp 73–74°C; $[\alpha]_D^{22}$ +4° (*c* 1.04); ir: 3478, 1742 cm^{-1}. *Anal.* calcd. for $C_{17}H_{26}O_4$: C 69.36, H 8.90; found: C 69.25, H 8.89.

Hydroxyacetate **4** was also formed when coprinolone acetate (**2**) was treated with sodium borohydride. Oxidation of **4** in methylene chloride with pyridinium chlorochromate (9) yielded coprinolone acetate (**2**).

*Bromocoprinolone (**5**)*

Coprinolone (37 mg) was treated with *N*-bromosuccinimide (32 mg) in refluxing carbon tetrachloride (4 mL) for 30 min. Removal of the solvent after washing twice with water yielded material that was recrystallized from ether–hexane to give **5**, as needles, mp 145–148°C (dec.); $[\alpha]_D^{24}$ +127° (*c* 1.02); ir: 3562, 1713 cm^{-1}. *Anal.* calcd. for $C_{15}H_{21}O_3Br$: C 54.72, H 6.43; found: C 54.34, H 6.77.

*Bromocoprinolone acetate (**6**)*

Coprinolone acetate (**2**; 13 mg) was treated with *N*-bromosuccinimide (10 mg) in carbon tetrachloride (2 mL) as above. Isolation of the product and recrystallization from ether–hexane yielded bromoacetate **6**, mp 121–122°C; $[\alpha]_D^{22}$ +125° (*c* 0.51); ir: 1743, 1724 cm^{-1}. *Anal.* calcd. for $C_{17}H_{23}O_4Br$: C 54.99, H 6.24; found: C 54.82, H 5.97. The same substance was obtained when bromocoprinolone (**5**) was acetylated using acetic anhydride – pyridine.

*Hydroperoxide **7***

A solution of coprinolone (509 mg) in C_6D_6 deposited crystals during standing at room temperature for 4 weeks. Thin-layer chromatography of this material (25 mg) showed that it was more polar than coprinolone. Recrystallization from methanol yielded crystals, mp 181–183°C (vigorous gas evolution); ir: 3510, 3340, 1722 cm^{-1}; ms: 282 (M^+). Chromatograms of **7** showed a characteristic spot for a peroxide with potassium iodide – starch and ferrous thiocyanate sprays (22).

Treatment of **7** (10.1 mg) in acetic acid (2 mL) with freshly activated zinc dust (37 mg) by stirring for 16 h yielded a new compound, which was recrystallized from methylene chloride – hexane to give alcohol **8**, mp 170–173°C; ir: 3470, 1714 cm^{-1}. *Exact Mass* calcd. for $C_{15}H_{22}O_4$: 266.1517; found: 266.1517.

*Ketodiol **9***

Methanolic potassium hydroxide (1 N, 0.2 mL) was added to a solution of coprinolone (10 mg) in methanol (1 mL) under nitrogen. No starting material remained after 23 h at room temperature (tlc evidence). After addition of water, the product (7.8 mg) was extracted into methylene chloride. Recrystallization from ethyl acetate – hexane yielded ketodiol **9**, mp 144–146°C; $[\alpha]_D^{25}$ −27° (*c* 0.81); ir: 3410, 1652 cm^{-1}; uv(EtOH): 252 nm (ϵ 8490). *Exact Mass* calcd. for $C_{15}H_{22}O_3$: 250.1568; found: 250.1567.

Ketodiol **9** (6.8 mg) in 2 mL of methylene chloride was oxidized with 4-(dimethylamino)pyridinium chlorochromate (44 mg) in methylene chloride (1 mL) for 1 h at room temperature (10). Isolation of product and separation from starting material by tlc yielded a new substance (1.7 mg), uv(EtOH): 266 nm.

Oxidation of coprinolone

Coprinolone (44 mg) in acetone (10 mL) was treated at room temperature for 4 h with an excess of oxidant (23) prepared by dissolving chromium trioxide (3 g) in water (15 mL) and concentrated H_2SO_4 (2.7 mL). Reaction of the polar oxidation product with a solution of diazomethane in ether and recrystallization of the product

from ether–hexane yielded methyl ester **10**, mp 110–111°C; $[\alpha]_D^{22}$ +21° (*c* 1.00); ir: 1730, 1638, 1610 cm^{-1}; uv(EtOH): 260 nm (ε 9080); ms 278 (M^+) *Anal.* calcd. for $C_{16}H_{22}O_4$: C 69.04, H 7.97; found: C 68.82, H 7.50.

Isomerization of coprinolone on alumina

Chromatography of culture filtrate extracts on alumina (neutral, Grade III) yielded, in addition to coprinolone, several new compounds not initially present in the mixture (tlc evidence). To determine the source of these substances, coprinolone was applied in benzene to a similar column. Analysis (tlc) of material eluted after 27 h with ether showed that most of the coprinolone had disappeared and two slightly more polar compounds, which did not acetylate when treated with acetic anhydride – pyridine at room temperature, had formed. Rechromatography of fractions from alumina chromatography containing these two substances, over silicic acid – Celite (4:1) using methylene chloride, gave partial separation. Recrystallization of fractions rich in the less polar component, from aqueous methanol, yielded isomer **14**, mp 163–164°C; $[\alpha]_D^{18}$ −239° (*c* 1.06) ; ir: 3475, 1691 cm^{-1}. *Exact Mass* calcd. for $C_{15}H_{22}O_3$: 250.1568; found: 250.1567. Recrystallization of fractions rich in the other component, from hexane, yielded isomer **15**, mp 168–169°C; $[\alpha]_D^{17}$ −16° (*c* 0.32); ir: 3488, 1704 cm^{-1}. *Exact Mass* calcd. for $C_{15}H_{22}O_3$: 250.1568; found: 250.1562.

Isomer **14** in $CDCl_3$ at 4°C for 8 days isomerized to give approximately equal parts of isomers **14** and **15** (tlc evidence; high performance silica gel with ether – light petroleum – acetic acid, 40:60:1). No further change was noted when this mixture was treated with $CHCl_3$ at reflux for 1 h.

Longer contact with alumina resulted in the production of a polar material, which on plates containing fluorescent indicator was visible under uv light. Subsequent chromatography on a Whatman high performance silica gel plate using repeated development with ether – light petroleum – acetic acid (60:40:1) indicated that this material consisted of at least two components, one of which corresponded to keto diol **9**. This mixture was also obtained as the main product when coprinolone (20 mg) was exposed to alumina (1 g, Grade III neutral) in refluxing benzene for 1.3 h. The same mixture was obtained when isomers **14** and **15** were treated with methanolic potassium hydroxide as described above for **1**. Recrystallization yielded keto diol **9** (nmr evidence) corresponding chromatographically to the less polar component. A small quantity of the noncrystalline second component **19** was obtained from the mother liquors by preparative tlc on silica gel G using the ether – light petroleum – acetic acid system. Reinvestigation showed that coprinolone also afforded **19** in addition to **9** when treated with methanolic potassium hydroxide.

*Isomer **16***

Chromatography of material in mother liquors from recrystallization of coprinolone over 12 g silicic acid – Celite (4:1) with methylene chloride as eluent yielded fractions containing coprinolone followed by a mixture and then by a substance (6 mg) slightly more polar on tlc than coprinolone. Recrystallization from light petroleum gave isomer **16**, mp 80–105°C. *Exact Mass* calcd. for $C_{15}H_{22}O_3$: 250.1568; found: 250.1565.

*Acetate **17***

Material (93 mg) in mother liquors from recrystallization of coprinolone was acetylated (acetic anhydride – pyridine, room temperature) and the product chromatographed over 10 g silicic acid – Celite (4:1) with toluene to give coprinolone acetate (**2**), followed by fractions containing a second substance (18 mg) distinguishable from **2** by tlc (Whatman high performance silica gel plate developed three times with toluene). Recrystallization from hexane afforded acetate **17**, mp 64–66°C. *Exact Mass* calcd. for $C_{17}H_{24}O_4$: 292.1674; found: 292.1671.

Treatment of acetate **17** in methanol with sodium borohydride afforded a more polar substance **18**, ir($CHCl_3$): 3460, 1738 cm^{-1}, which could not be induced to crystallize.

*Δ^6-Coprinolone (**20**)*

Chromatography of the product (200 mg) obtained from 15-day cultures (see above description of time course experiment), over 30 g silicic acid – Celite (4:1) with methylene chloride, separated coprinolone (33 mg) from a new compound (31 mg), which was recrystallized from methylene chloride – ethyl acetate to give Δ^6-coprinolone, mp 186–187°C; $[\alpha]_D^{20}$ −105° (*c* 0.98); ir: 3400, 1646 cm^{-1}; uv(EtOH): 248 nm (ε 11 760). *Exact Mass* calcd. for $C_{15}H_{20}O_3$: 248.1412; found: 248.1416. *Anal.* calcd. for $C_{15}H_{20}O_3$: C 72.55, H 8.12; found: C 72.75, H 8.51.

Yields of coprinolone and Δ^6-coprinolone from the 13-day-old cultures were 10 and 15 mg respectively.

*Δ^6-Coprinolone acetate (**22**)*

Acetylation (acetic anhydride – pyridine, room temperature) of Δ^6-coprinolone (**20**) and recrystallization of the product from light petroleum yielded the acetate **22**, mp 82–87°C; ir($CHCl_3$): 1740, 1660 cm^{-1}. *Exact Mass* calcd. for $C_{17}H_{22}O_4$: 290.1517; found: 290.1518.

[1,2-$^{13}C_2$]Acetate incorporation study

A sterile solution (5 mL of sodium [1,2-$^{13}C_2$]acetate (0.06 M; 99.4 at.% ^{13}C) from MSD Isotopes, Point Claire – Dorval, was added to each of five Roux bottle cultures on days 8 and 10 after inoculation. The cultures were extracted, as described for the time course study, on day 13. Chromatography of the product (509 mg) over silicic acid – Celite (4:1) using methylene chloride gave coprinolone (155 mg) and Δ^6-coprinolone (50 mg). Recrystallization afforded ^{13}C-enriched coprinolone, mp 104–105°C, and Δ^6-coprinolone, mp 185–186°C.

Rate and equilibrium studies of the deprotonation of benzylic ketones bearing pyridinium cations

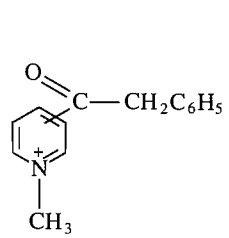
JOHN W. BUNTING AND DIMITRIOS STEFANIDIS
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 5, 1988

JOHN W. BUNTING and DIMITRIOS STEFANIDIS. Can. J. Chem. **67**, 428 (1989).

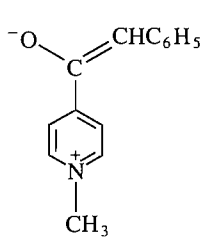
Rates and equilibria for the deprotonation of four benzylic ketones containing pyridinium substituents (**1**, **2**, **5**, and **6**) have been investigated in basic aqueous solution (ionic strength 0.1) over the range 15–45°C, and thermodynamic and activation parameters have been evaluated. Similar data are also reported for the deprotonation of nitroethane. The kinetic preference for hydroxide ion addition to the carbonyl group in competition with the thermodynamically preferred enolate ion formation, which was previously reported for the 1-methyl-4-phenylacetylpyridinium cation (**1**) and its 3-phenylacetyl isomer (**2**), is also found for the 1-(1-methyl-2-oxo-2-phenylethyl)pyridinium cation (**6**). Rates of equilibration of the 1-(2-oxo-2-phenylethyl)-pyridinium cation (**5**) with its enolate ion conjugate base are too rapid to allow investigation by stopped-flow spectrophotometry. For the hydroxide ion catalyzed deprotonation of each of **1**, **2**, **6**, and nitroethane, $\Delta S_d^{\ddagger}$ is more negative than ΔS^0. This difference, which represents the entropy of activation for protonation of the conjugate base of each of these carbon acids by water, is approximately constant at $\Delta S_p^{\ddagger} = -4.9 \pm 0.5$ cal deg^{-1} mol^{-1}.

Key words: carbon acids, kinetic studies, deprotonation, activation parameters, pK_a values.



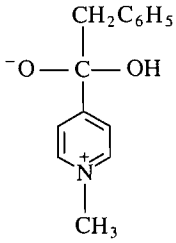
JOHN W. BUNTING et DIMITRIOS STEFANIDIS. Can. J. Chem. **67**, 428 (1989).

Opérant à des températures allant de 15 à 45°C, en solutions basiques aqueuses (force ionique de 0,1), on a déterminé les vitesses de déprotonation ainsi que les équilibres de quatre cétones benzyliques contenant des substituants pyridinium (**1**, **2**, **5** et **6**) et on a évalué les paramètres thermodynamiques et d'activation. On rapporte aussi des données semblables relatives à la déprotonation du nitroéthane. Il a été établi antérieurement, avec la cation méthyl-1 phénylacétyl-4 pyridinium (**1**) et avec son isomère phénylacétyle-3 (**2**), que d'un point de vue cinétique l'ion hydroxyde s'additionne sur le groupement carbonyle plutôt que de donner lieu à la formation de l'ion énolique qui est favorisée d'un point de vue thermodynamique; on a trouvé que cette conclusion vaut aussi pour le cation (méthyl-1 oxo-2 phényl-2 éthyl)-1 pyridinium (**6**). La vitesse d'équilibration du cation (oxo-2 phényl-2 éthyl)-1 pyridinium (**5**) avec sa base conjuguée, l'ion énolate, est trop rapide pour permettre une étude par spectrophotométrie à flux stoppé. Pour la déprotonation catalysée par l'ion hydroxyde des composés **1**, **2**, **5**, **6** et du nitro-éthane, les $\Delta S_d^{\ddagger}$ sont plus négatifs que les ΔS^0. On a observé que cette différence, qui représente l'entropie d'activation pour la protonation de la base conjuguée de chacun de ces acides carbonés par l'eau, est approximativement constante à $\Delta S_p^{\ddagger} = -4{,}9 \pm 0{,}5$ cal deg^{-1} mol^{-1}.



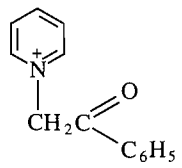
Mots clés : acides carbonés, études cinétiques, déprotonation, paramètres d'activation, valeurs de pK_a.

[Traduit par la revue]

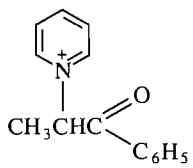


We recently reported (1) upon the kinetics of deprotonation of several series of benzylic ketones in aqueous solutions. While the *N*-methyl phenylacetylpyridinium cations **1** (pK_a = 9.02) and **2** (pK_a = 10.32) undergo deprotonation in a hydroxide ion catalyzed process, this deprotonation is not the kinetically controlled reaction when neutral aqueous solutions of these cations are adjusted to pH >11. In these basic solutions, the addition of hydroxide ion to the carbonyl group to give the *gem* diol anion (e.g., **4**) is faster than hydroxide ion catalyzed enolate ion formation (e.g., **3**), although the enolate ion is the thermodynamically favoured species in basic aqueous solutions of both **1** and **2**.

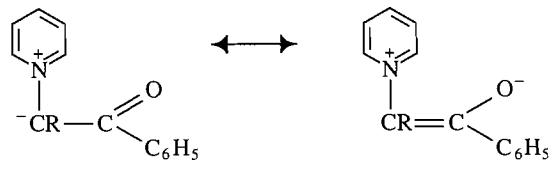
1: 4-pyridyl
2: 3-pyridyl



3



4



It seems likely that a similar competition between the products of kinetic and thermodynamic control may also exist for other carbonyl-activated carbon acids that contain similar pyridinium units. The methylene group of the *N*-phenacyl pyridinium cation (**5**) (1-(2-oxo-2-phenylethyl)pyridinium cation) is reported (2, 3) to be reasonably acidic in aqueous solution,

5

6

7

although we have been unable to locate any report of the kinetic acidity of either this species or any closely related species. We have now found that the thermodynamic acidity of **5** is readily measured in aqueous solution, but its equilibration with its enolate anion (**7**; R = H) is too rapid to allow investigation by stopped-flow spectrophotometry. However, both the kinetic and thermodynamic acidities of the methyl derivative **6** (1-(1-methyl-2-oxo-2-phenylethyl)pyridinium cation) are readily accessible in aqueous solution, and **6** does display the above noted competition between deprotonation and hydroxide ion addition in aqueous base.

We also report the temperature dependences of the rate and equilibrium constants for the deprotonation of **1**, **2**, **5** (equilibrium only), and **6**, and a reinvestigation of the deprotonation of

	35	8.37		
	45	8.31	+2.8 ± 0.2	−29.2 ± 0.5[b]

[a]All data at ionic strength 0.1. Standard errors in pK_a are always within ±0.03.
[b]Literature data (15) at ionic strength 0: pK_a (25°C) = 8.53; ΔH^0 = 2.40 kcal mol^{-1}; ΔS^0 = −31.0 cal deg^{-1} mol^{-1}.

nitroethane, which surprisingly is the only carbon acid for which we have been able to locate *both* thermodynamic *and* activation paramaters for hydroxide ion catalyzed deprotonation in aqueous solution (4).

Experimental

The bromide salts of **1** and **2** were available from a recent study (1). Nitroethane (99.5% from Aldrich Chemical Co.) was redistilled before use. The bromide salts of **5** and **6** were prepared by treatment of pyridine with 2-bromoacetophenone and 2-bromopropiophenone, respectively, in benzene solution (5). The bromide salts, which precipitated from the reaction mixtures, were recrystallized several times from ethanol and appeared pure by ^{1}H nmr spectroscopy.

The pK_a values for **1**, **2**, and **6** were obtained spectrophotometrically, while pK_a values for **5** and nitroethane were calculated from potentiometric titrations (6). All kinetic data were obtained in aqueous solutions of ionic strength 0.1 on the Durrum–Gibson stopped-flow spectrophotometer, with the temperature controlled to ±0.1°C. Stock solution syringes were thermostatted for 20 min to ensure thermal equilibration before the initiation of reactions. Kinetic studies employed the following wavelengths and concentrations of the carbon acids: **1**, 445 nm, 0.02 mM; **2**, 360 nm, 0.02 mM; **6**, 400 nm, 0.2 mM; nitroethane, 250 nm, 0.2 mM. Data collection and analysis closely followed the methods previously described (1).

Spectral data for stable species were obtained on a Cary 210 spectrophotometer. All pH measurements and potentiometric titrations utilized a Radiometer PHM82 pH meter, which was calibrated with standard buffer solutions thermostatted at the appropriate temperature. All pH measurements were made in a cell thermostatted at the temperature under investigation.

Results

Basic aqueous solutions (pH >11) of each of the cations **5** and **6** show long wavelength absorption maxima in the vicinity of 400 nm. However, these solutions are unstable, and this long wavelength absorption decays in a base-catalyzed process. We have not investigated this decomposition in any detail at the present time, but note that the alkaline cleavage of *N*-(β-ketoalkyl)pyridinium cations to a carboxylate anion and an alkylpyridinium cation has been reported previously (3, 7–9). From the data of Pearson and Dillon (3), we calculate a half-time of 97 min for the decomposition of **5** at pH 12 at 25°C. This decomposition occurs sufficiently slowly that we have been able to obtain a clean potentiometric titration of **5** with aqueous base and thus evaluate the pK_a value. Table 1 contains pK_a values evaluated for the acid–base equilibration of **5** with its conjugate base at a number of temperatures, and also the thermodynamic parameters for this process that have been calculated from the van't Hoff equation.

When a neutral aqueous solution of **5** is mixed with basic buffers in the stopped-flow spectrophotometer, the development of the absorbance in the vicinity of 400 nm is complete within the mixing time of this instrument. When a neutral aqueous solution of **6** is mixed with basic buffers in the stopped-flow spectrophotometer, the absorbance in the vicinity of 400 nm is observed to increase to a maximum value, prior to a much slower decay of this absorbing species. The pH dependence of this maximum absorbance describes a simple acid–base equilibration of **6** with its conjugate base, and pK_a values and thermodynamic parameters for this process are included in Table 1.

The increase in absorbance of a basic solution of **6** to its maximum value at that pH is consistent with a process that is kinetically first order in [**6**]. The pseudo-first-order rate constant (k_{obs}) for the equilibration of **6** with its conjugate base was evaluated as a function of pH over the range pH 11–13. The equilibration of a carbon acid (CH) with its conjugate base

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

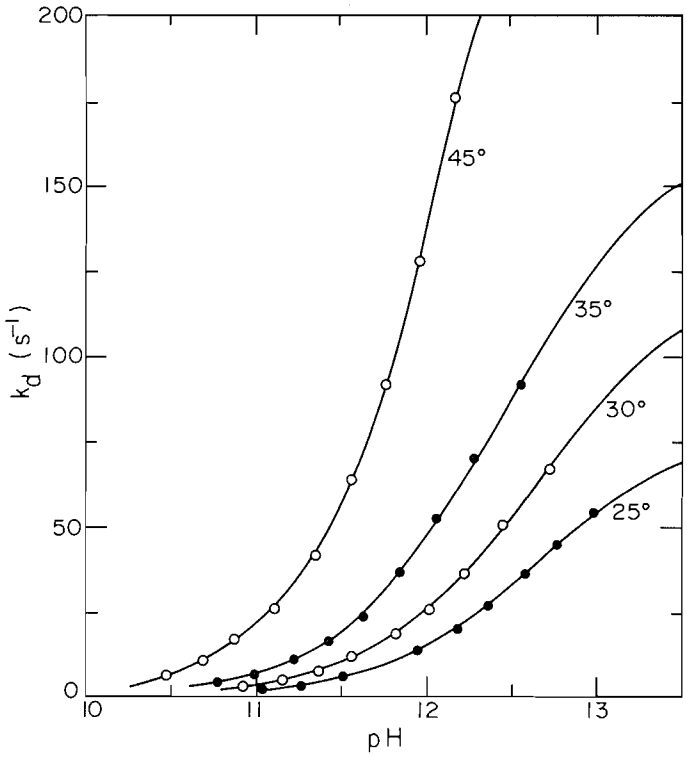

FIG. 1. The pH dependence of the pseudo-first-order rate constants for deprotonation of **6** at several temperatures. Curves are calculated from eq. [5] using the parameters in Table 2.

(C^-) is described by eq. [1], with k_{obs} being the sum of the individual rate constants for deprotonation (k_d) and protonation (k_p) at constant pH.

$$[1]\quad CH \underset{k_p}{\overset{k_d}{\rightleftharpoons}} C^-$$

$$[2]\quad k_{obs} = k_d + k_p$$

$$[3]\quad K_a = \frac{[H^+][C^-]}{[CH]} = k_d[H^+]/k_p$$

$$[4]\quad k_d = k_{obs}/(1 + [H^+]/K_a)$$

Individual values of k_d and k_p were calculated from each k_{obs}, and the pH dependences of these individual pseudo-first-order rate constants are shown in Fig. 1. The value of k_d increases with increasing pH, but appears to approach a limiting value in the most basic solutions. We have recently reported (1) similar observations for the hydroxide ion catalyzed deprotonation of both **1** and **2**, and have shown that this phenomenon is consistent with Scheme 1. In this scheme, the formation of the thermodynamically more stable conjugate base C^- of CH competes with the acid–base equilibration of CH with Z^- as the kinetically preferred process.

Analysis of Scheme 1, with the assumption that the K_z equilibrium is established much more rapidly than the formation of C^-, produces eq. [5].

$$[5]\quad k_d = k_{OH}[^-OH]/(1 + K_z[^-OH]/K_w)$$
$$= k_{OH}K_w/([H^+] + K_z)$$

Values of k_{OH} and K_z were evaluated from the pH dependence of k_d, and are collected in Table 2. Activation parameters for k_{OH} and thermodynamic parameters for the K_z process are given in Table 3.

$$H^+ + Z^- \overset{K_z}{\rightleftharpoons} CH \underset{k_{H_2O}}{\overset{k_{OH}[^-OH]}{\rightleftharpoons}} C^- + H_2O$$

	45	21.4		
	50	31.0		

[a]All data in aqueous solution at ionic strength 0.1.
[b]Calculated from $k_{H_2O} = k_{OH}K_w/K_a$.
[c]From the temperature dependence of pK_z for **1**: $\Delta H^0 = 8.3 \pm 0.8$ kcal mol^{-1}; $\Delta S^0 = -26 \pm 2$ cal deg^{-1} mol^{-1}.
[d]From the temperature dependence of pK_z for **2**: $\Delta H^0 = 6.2 \pm 0.2$ kcal mol^{-1}; $\Delta S^0 = -35.6 \pm 0.6$ cal deg^{-1} mol^{-1}.
[e]The estimation of k_{OH} for **5** is described in the text.
[f]From the temperature dependence of pK_z for **6**: $\Delta H^0 = 7.5 \pm 1.6$ kcal mol^{-1}; $\Delta S^0 = -33 \pm 5$ cal deg^{-1} mol^{-1}.

We have also investigated the temperature dependence of both the rate and equilibrium constants for enolate ion formation from **1** and **2**. The experimental kinetic data were analyzed in terms of Scheme 1 as previously described (1). The experimental rate and equilibrium constants, and the derived thermodynamic and activation parameters, are included in Tables 1–3. These tables also contain analogous data from our brief reinvestigation of the temperature dependence of the rates and equilibria for the deprotonation of nitroethane. The observed pseudo-first-order rate constants for the deprotonation of this latter carbon acid are cleanly proportional to hydroxide ion concentration over the range pH 11–13.

Discussion

Deprotonation of N-*(phenacyl)pyridinium cations*

N-(Phenacyl)pyridinium cations undergo deprotonation to their ylidic enolate ion conjugate bases (**7**) in basic solution (2, 3, 5). We have been unable to locate any previous potentiometric or spectrophotometric measurements of the pK_a values

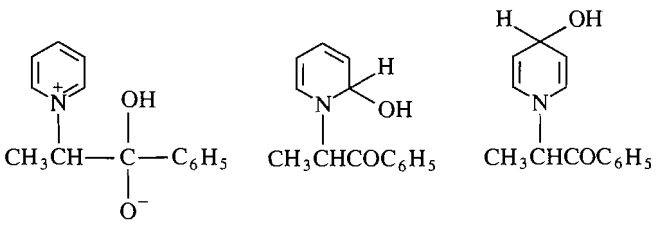
of either **5** or **6** in aqueous solution, although Pearson and Dillon (3) report $pK_a = 10.51$ (at 31.5°C) for **5** based upon a kinetic analysis of its decomposition in aqueous base. This value is reasonably consistent with our measurement of $pK_a = 10.79$ at 30°C (Table 1). The acidity of **5** in aqueous solution is somewhat less than that reported by Phillips and Ratts (5) in methanolic solution ($pK_a = 9.7$).

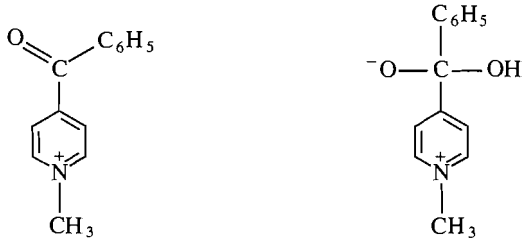
We have been unable to locate any previous measurements of the acidity of **6**, which we find to be 0.63 pK_a units less acidic than **5** at 25°C. This decrease in acidity upon methylation α to the carbonyl group is considerably smaller than the decreases in acidity by $\Delta pK_a = 1.6$ and 2.3 that have been reported upon α-methylation of ethyl acetoacetate (10) and acetylacetone (11), respectively. The cationic ketone **5** is only a slightly weaker acid than ethyl acetoacetate ($pK_a = 10.65$ at 25°C (10)) in aqueous solution.



The rates of deprotonation of **5** were found to be too rapid to be measured by stopped-flow spectrophotometry. This observation requires $t_{1/2} < 3$ ms at pH 12 where $k_{obs} \simeq k_d$, and allows an estimate of $k_{OH} > 2 \times 10^4$ M^{-1} s^{-1} for the hydroxide ion catalyzed deprotonation of **5**. The pH dependence of the pseudo-first-order rate constant (k_d) for the deprotonation of **6** (Fig. 1) is consistent with Scheme 1, and the derived eq. [5]. The second-order rate constant ($k_{OH} = 1680$ M^{-1} s^{-1} at 25°C) for the hydroxide ion catalyzed deprotonation of **6** is thus at least tenfold smaller than for deprotonation of **5**. α-Methylation of acetylacetone and ethyl acetoacetate results in decreases in k_{OH} by 200-fold and 60-fold, respectively (10, 11). For **6**, k_{OH} is considerably larger than $k_{OH} = 107$ M^{-1} s^{-1} (10) for the deprotonation of ethyl acetopropionate (**8**) ($pK_a = 12.25$), which is only a slightly weaker acid than **6**.

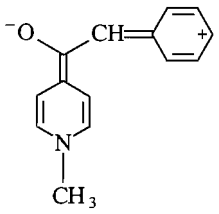
$CH_3COCH(CH_3)CO_2C_2H_5$

8

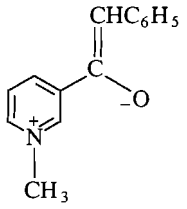


At present there is little direct experimental evidence relevant to the identity of the species Z^-, which is derived from **6** according to Scheme 1. However, in view of the structural simplicity of **6**, there are relatively few possibilities for Z^-. Since **6** has no significantly acidic protons other than the proton α to the carbonyl group, Z^- must be formed via hydroxide ion addition to **6**. The only reasonable sites for hydroxide ion addition to **6** are the carbonyl carbon atom, and the C-2 and C-4 carbon atoms of the pyridinium ring. Thus, **9**, **10**, and **11** would seem to be the only reasonable structures for Z^-.

The observed $pK_z = 12.68$ for the equilibration of Z^- with **6** is probably too low to be assigned as pK_{R^+} for formation of either of the pseudobases **10** or **11**. For the *N*-methyl pyridinium cation, pK_{R^+}, values of 18.2 and 20.5 have been estimated (12) for hydroxide ion addition to C-2 and C-4, respectively. For *N*-substituted heterocyclic cations, pK_{R^+} values are approximately correlated with σ^* for the *N*-substituent, with $\rho^* \simeq 4$ (13). Using $\sigma^* = 0.62$ for CH_3COCH_2 (14) as a reasonable approximation for $C_6H_5COCH(CH_3)$ allows the prediction of $pK_{R^+} \simeq 15.8$ and $\simeq 18.1$ for formation of **10** and **11**, respectively. These values are considerably larger than the experimental pK_z in Table 2, and seem to eliminate **10** and **11** as reasonable possibilities for the Z^- species.



9 **10** **11**



We are thus left with the geminal diol anion, **9**, as the most likely structure for Z^-. Analogous anions (e.g., **4**) were shown (1) to be consistent with the similar species Z^-, which was found necessary to describe the experimentally observed pH dependence of k_d for the deprotonation of both **1** and **2**. In an unpublished study, we have also observed the acid–base equilibration of the cationic ketone, **12**, with its geminal diol anion (**13**) ($pK_R = 12.25$). This further indicates the strong activating effect that an *N*-alkyl pyridinium cation has upon the susceptibility of such ketones to hydroxide ion addition. It appears that geminal diol anions are the kinetically controlled species that are formed upon basification of neutral aqueous solutions

12 **13**

14

15

of **1**, **2**, and **6** (and probably also **5**, although evidence for this is not currently available because of the very rapid deprotonation of this species).

For **6**, the $pK_a = 11.65$ (at 25°C) for deprotonation is sufficiently close to the kinetically determined $pK_z = 12.68$ (at 25°C) that equilibrated basic aqueous solutions of **6** will contain approximately a 10:1 ratio of enolate ion and Z^- (9).

Temperature dependence of deprotonation

The thermodynamic and activation parameters for the deprotonation of carbon acids by hydroxide ion are summarized in Table 3. Nitroethane is the only carbon acid for which we have been able to find literature data (4) for both the thermodynamic parameters and also the activation parameters for deprotonation by hydroxide ion. Since Pearson's study (4) for nitroethane was at only two temperatures (0°C and 5.2°C), we felt it appropriate to reinvestigate this species in the current study. In fact our data for $\Delta H_d^{\ddagger}$ and $\Delta S_d^{\ddagger}$ are quite close to the earlier results of Pearson (see Table 3), although Pearson's values of $\Delta H^0 = -12.2\,\text{kcal mol}^{-1}$ and $\Delta S^0 = -18.3\,\text{eu}$ for this reaction are quite different from more recent values (15).

The deprotonation of each of the carbon acids in Table 3 results in very extensive delocalization of negative charge. One would expect that there would be some rather dramatic solvent reorganizations upon the formation of the conjugate bases of these carbon acids. The magnitudes of ΔH^0 and ΔS^0, in particular, will be significantly influenced by such solvation changes, and it is difficult to comment upon the relative magnitudes of these parameters in any detail. However, of particular significance in this regard are the differences in ΔS^0 for **5** and **6**. Methylation of the acidic methylene group in **5** (to give **6**) would be expected to have a significant influence upon the solvation of the cationic charge of these carbon acids, and also upon solvation of the ylidic systems in the conjugate base species. The smaller ΔH^0 and more negative ΔS^0 for **6** than for **5** are in the same direction as the variation of these parameters upon successive α-methylation of nitromethane (15). Similar variations in ΔH^0 and ΔS^0 for deprotonation are also observed (16) upon successive *N*-methylations of ammonium ions.

It should also be noted that the similarity in the ΔS^0 parameters for the isomers **1** and **2** may be fortuitous, since two different factors have been proposed (1) to have an influence upon the stabilization of the conjugate bases of these two species. Resonance stabilization of the conjugate base of **1** via **14** is not expected to be significant for the conjugate base of **2**. On the other hand, the electrostatic interaction in **15** should be of little significance in the conjugate base of **1**.

For the deprotonation of each of **1**, **2**, **6**, and nitroethane by hydroxide ion, $\Delta S_d^{\ddagger}$ is more negative than ΔS^0. Interestingly, this difference, which represents $\Delta S_p^{\ddagger}$ for the protonation of the conjugate base by a water molecule, is approximately constant ($\Delta S_p^{\ddagger} = -4.9 \pm 0.5\,\text{cal deg}^{-1}\,\text{mol}^{-1}$), while $\Delta H_p^{\ddagger}$ is quite variable. While it is unreasonable to attempt to make any generalization on the basis of four cases, we note that these data do include acids and their conjugate bases having quite significant structural differences, and it will be interesting to see whether such a relationship persists as further data become available for other carbon acids. The much larger negative value for $\Delta S_d^{\ddagger}$ than for $\Delta S_p^{\ddagger}$ suggests that the solvation of the rate-determining transition state species is similar to the solvation of the conjugate base species from each of these carbon acids.

Synthesis and spectroscopic studies of some substituted 3-benzoylpyrroles and their tricarbonylchromium complexes

NIALL J. GOGAN,[1] ROBERT MCDONALD, HUGH J. ANDERSON, AND CHARLES E. LOADER
Department of Chemistry, Memorial University of Newfoundland, St. John's Nfld., Canada A1B 3X7

Received June 9, 1988

NIALL J. GOGAN, ROBERT MCDONALD, HUGH J. ANDERSON, and CHARLES E. LOADER. Can. J. Chem. **67**, 433 (1989).

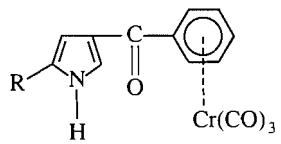
3-Benzoylpyrroles with a substituent on the pyrrole ring have been synthesized. Both the iodination and chlorination gave only the 2,4 derivatives while isopropylation gave mixtures of the 2,4 and 2,3 compounds. No 3,4 compounds were obtained. Both steric and electronic effects seem to determine the substitution pattern. The $Cr(CO)_3$ complexes (Cr on the benzene ring) were prepared and these complexes, together with the uncomplexed pyrroles, were studied by IR, ^{1}H-NMR, and ESR of the radical anions from the *N*-methylpyrrole derivatives. For the 2,4 compounds, the substituent on the pyrrole ring has relatively little effect on the spectral parameters of the benzene ring indicating relatively little electron delocalization between the two rings. 3-Benzoyl-2-isopropylpyrrole, however, gives an ESR spectrum very different from the other compounds.

Key words: benzoylpyrroles, tricarbonylchromium, ESR, chlorination, isopropylpyrroles.

NIALL J. GOGAN, ROBERT MCDONALD, HUGH J. ANDERSON et CHARLES E. LOADER. Can. J. Chem. **67**, 433 (1989).

On a synthétisé des benzoyl-3 pyrroles portant un substituant sur le noyau pyrrole. Leur iodation ainsi que leur chloration ne conduisent qu'aux dérivés 2,4 alors que la réaction d'isopropylation conduit à un mélange des dérivés 2,4 ainsi que 2,3. On n'a pas obtenu de composés substitués en 3,4. Il semble que des effets tant stériques qu'électroniques soient responsables des patrons de substitution. On a préparé des complexes du $Cr(CO)_3$ (le Cr étant porté par le noyau benzénique) et on a déterminé les spectres ir ainsi que les spectres rmn du ^{1}H de ces complexes ainsi que des pyrroles non-substitués; de plus, on a déterminé les spectres rpe des radicaux anions obtenus à partir des dérivés *N*-méthylpyrroles. Dans les cas des composés 2,4, le substituant présent sur le noyau pyrrole n'a pratiquement pas d'influence sur les paramètres spectraux du noyau benzénique; ces données suggèrent qu'il y a peu de délocalisation électronique entre les deux noyaux. Toutefois, le benzoyl-3 isopropyl-2 pyrrole présente un spectre rpe qui est très différent de celui des autres composés.

Mots clés : benzoyl pyrroles, chrome tricarbonylé, RPE, chloration, isopropyl pyrroles.



[Traduit par la revue]

Introduction

In a previous paper (1) we reported how the acylation of 1-(phenylsulfonyl)pyrrole led to the synthesis of a series of 3-aroylpyrroles. Subsequently these products were complexed on the benzenoid ring with a $Cr(CO)_3$ group and the resulting complexes and the parent pyrroles were studied by various spectroscopic techniques and molecular-orbital theory (2). These studies, together with ESR studies on the corresponding anions produced from the *N*-methyl derivatives (3), were very helpful in elucidating the electronic structures of these molecules. None of these compounds had a substituent on any of the pyrrole ring carbons.

Variation of substituents on the benzene ring or complexation by a $Cr(CO)_3$ group (on the benzene ring) resulted in no significant changes in the ^{1}H-NMR resonances of the pyrrole protons (2). In addition, the ESR spectra showed no hyperfine splittings (hfs) from the pyrrole ring. These results demonstrated that changes occurring on the benzene ring caused no measurable effects on the pyrrole ring. The opposite, however, could not be proven because the studies did not involve any changes on the pyrrole ring. A previously reported study of benzoylcyclopentadienyl manganese tricarbonyl complexes (4) showed that substituents on the cyclopentadienyl ring caused changes in the benzene ring proton hfs even though no hfs were observed for the cyclopentadienyl protons. The present study was carried out to see if changes on the pyrrole ring cause significant changes to various spectroscopic parameters of the benzene ring either in the complexes or in the parent pyrroles.

In general 2,4 substitution is preferred in each case so that effects can be directly compared. This structure is shown in

R = H, $CH(CH_3)_2$, Cl, I

FIG. 1. 2,4-Substitution of benzoylpyrroles.

Fig. 1. The isopropylation also yielded 3-benzoyl-2-isopropylpyrrole as a minor product which was useful in examining some steric effects. Friedel–Crafts isopropylation of 3-acetylpyrrole was explored in one of our laboratories (5). Hodge and Rickards (6) studied the chlorination of methylpyrrole-2-carboxylate and Farnier and Fournari (7) iodinated pyrrole-2-carboxaldehyde, These three studies were very helpful in enabling us to devise synthetic routes to the desired compounds.

This paper reports the synthesis of the 3-benzoylpyrroles and their $Cr(CO)_3$ complexes, IR and ^{1}H-NMR studies on these compounds, and ESR studies of the radical anions of the *N*-methyl derivatives.

Experimental

Melting points (°C) are uncorrected. Elemental analyses were performed by Canadian Microanalytical Service, Vancouver, B.C. The IR spectra were recorded in $CHCl_3$ solution on a Perkin-Elmer 283 spectrophotometer. ^{1}H-NMR spectra were determined using a Bruker WP-80 instrument and are expressed in ppm (δ values) relative to tetramethylsilane as internal reference in $CDCl_3$. Electron spin resonance spectra were recorded on a JEOLCO ME-3X spectrometer at room temperature (23°C).

The term "hexanes" refers to a mixture of isomers bp 65.8–69.0°C. 3-Benzoylpyrrole was prepared as described previously (8). Tricar-

bonylchromium complexes were prepared from the parent pyrrole and $Cr(CO)_6$ in refluxing di-*n*-butyl ether as previously described (9). The *N*-methyl derivatives of the ligands and complexes were prepared by reaction with dimethyl sulfate using phase transfer catalysis as outlined previously (10). The radical anions were prepared from the *N*-methyl derivatives using potassium in 1,2-dimethoxyethane (DME) as described in an earlier paper (4).

4-Benzoyl-2-iodopyrrole

A mixture consisting of 3-benzoylpyrrole (1.5 g, 8.8 mmol), iodic acid (0.31 g, 1.8 mmol), iodine (0.89 g, 3.5 mmol), water (1.9 mL), glacial acetic acid (4.4 mL), concentrated sulfuric acid (six drops), and carbon tetrachloride (63 mL) was stirred for 24 h. The crude 4-benzoyl-2-iodopyrrole which had precipitated was then redissolved using a minimum of dichloromethane, and the aqueous and organic layers separated. The organic layer was washed with saturated aqueous sodium thiosulfate (two 50 mL portions), aqueous sodium bicarbonate (50 mL of the 5% solution), and saturated aqueous sodium chloride (50 mL). After drying the organic solution over anhydrous magnesium sulfate and evaporating the solvent, the residue was purified by flash chromatography, using 1:5 ethyl acetate/petroleum (30–60°C) as the eluting solvent. The product thus obtained was recrystallized from dichloromethane/petroleum (30–60°C), yielding 0.75 g (29%) of fibrous, pale yellow crystals of 4-benzoyl-2-iodopyrrole; mp 150–151°C (dec.). *Exact mass* calcd. for $C_{11}H_8NOI$: 296.96524; found: 296.9667, deviation 1.5 mmu.

4-Benzoyl-2-chloropyrrole

A solution of 3-benzoylpyrrole (4.00 g, 23.4 mmol) in ethyl ether (150 mL) was chilled to 0°C in an ice bath, to which was added, with stirring, sulfuryl chloride (3.47 g, 25.7 mmol) in ethyl ether (75 mL) over a period of 30 min. The solution was then stirred at room temperature for 20 h, after which the solvent was evaporated. The residue was purified by flash chromatography using 1:5 ethyl acetate:hexanes as the eluting solvent. Recrystallization from ethyl acetate/hexanes gave 3.23 g (67.2%) of colourless crystals of 4-benzoyl-2-chloropyrrole; mp 169–170°C (dec.). *Exact mass* calcd. for $C_{11}H_8NOCl$: 205.02939; found: 205.0306, deviation 1.2 mmu.

4-Benzoyl-2-isopropylpyrrole and 3-benzoyl-2-isopropylpyrrole[2]

3-Benzoylpyrrole (1.56 g, 9.11 mmol) was dissolved in dichloromethane (30 mL), to which was added rapidly anhydrous aluminum chloride (Fluka) (2.55 g, 19.1 mmol) and, dropwise, isopropyl chloride (0.69 g, 8.8 mmol). This mixture was stirred with heating for 2½ h, then poured onto ice and water (30 g). The purple organic layer was drawn off and the aqueous solution extracted with ethyl ether (three 15 mL portions). The combined organic layers were dried over anhydrous magnesium sulphate and the solvent evaporated. The gummy light-violet residue was shown by thin-layer chromatography to contain two distinct products which were separated using flash chromatography with 1:7 acetone:hexanes as the eluting solvent. The fractions containing the second component were evaporated and the residue recrystallized from methanol to give 1.38 g (73.5%) of colourless crystals of 4-benzoyl-2-isopropylpyrrole; mp 125–127°C. *Anal.* calcd. for $C_{14}H_{15}NO$: C 78.84, H 7.09, N 6.57; found: C 78.56, H 7.06, N 6.53. Recovery of the first mixture component in the same manner gave 0.23 g (12.3%) of colourless crystals of 3-benzoyl-2-isopropylpyrrole; mp 172–173°C. *Anal.* calcd. for $C_{14}H_{15}NO$: C 78.84, H 7.09, N 6.57; found: C 78.87, H 7.08, N 6.57.

A subsequent isopropylation of 3-benzoylpyrrole was attempted to obtain a greater yield of the minor product. The reaction conditions described above were reproduced exactly except that the reaction time was reduced to 20 min. After extraction, purification and recrystallization, yield was 1.22 g (65.0%) 4-benzoyl-2-isopropylpyrrole and 0.60 g (32.0%) 3-benzoyl-2-isopropylpyrrole.

[2]This compound would be named 4-benzoyl-5-isopropylpyrrole relative to the other compounds described in this paper.

Results and discussion

Synthesis

The synthetic routes to the substituted aroylpyrrole ligands were based on earlier work on other substituted pyrroles. In the case of the 2-iodo- and 2-chloro-4-benzoylpyrroles, the previous halogenations (6, 7) had been done on 2-substituted compounds to produce the 4-halo- compounds, thus the applications here depended upon steric and electronic factors to yield the desired products. It was hoped that the size of the benzoyl group of 3-benzoylpyrrole would prevent substitution onto the 2- or 4-positions of the pyrrole ring. The fact that electrophilic substitution at the 2- or 5-positions of the pyrrole ring is favoured seems to additionally favour the conversion of 3-benzoylpyrrole into 4-benzoyl-2-halopyrrole by the appropriate reaction, and this seems to have been borne out by the recovery of the products of only this substitution pattern.

The isopropylation reaction was based on the Friedel–Crafts alkylation for 3-acetylpyrrole (5), which itself yielded 4-acetyl-2-isopropylpyrrole almost exclusively as the product. Substitution should be determined by both electronic and steric factors with the latter being especially important because the *i*-propyl group is bulky. Thus 4-benzoyl-2-isopropylpyrrole is the predominant product as expected. It is surprising, however, that 3-benzoyl-2-isopropylpyrrole is a substantial component of the isolated product; here it is thought that attack of the alkyl chloride – aluminum chloride complex occurs at both the electronically-favoured 2- and 5-positions of the pyrrole ring, and that the isopropyl groups tend to migrate to the sterically favoured 2-position (where the 4-position is benzoylated). This would account for the greater yield of the minor product after a shorter reaction time. Even though there is a mixture of products, the yield of the major isomer was better for both trials of this reaction than for the isopropylation of 3-acetylpyrrole, and in both trials over 80% of the initial 3-benzoylpyrrole was isopropylated.

Infrared and nuclear magnetic resonance studies

Substituents on the pyrrole ring have a very small effect on the ν_{CO} of the $Cr(CO)_3$ group (Table 1) in keeping with results obtained for benzophenone $Cr(CO)_3$ and benzoylcyclopentadienyl $Cr(CO)_3$ complexes (11). Even though the effect is small, the lowest value for the more precise *A* mode is observed for the 2-isopropyl derivatives (1982 cm^{-1}) while the highest value observed is for the 2-chloro derivative (1987 cm^{-1}). This follows the same trend as observed for substituents on the benzene ring, i.e. the value of ν_{CO} is higher the more electron-withdrawing is the substituent. This is consistent with some π-electron delocalization between the two rings because this effect is dependent on changes in π-donation to the CO groups

[a]Numbers in parentheses are the values for the $Cr(CO)_3$ complexes.
[b]SW = spectrum width.

of the $Cr(CO)_3$ moiety. Substituents change ν_{CO} (ketone) in the same direction for both ligand and complex suggesting that the orientation of the ketonic CO group with respect to the benzene ring is not significantly affected by complexation. Nuclear magnetic resonance resonances of the benzene protons (Table 2) show very little change with substituents on the pyrrole ring.

Complexation by a $Cr(CO)_3$ group has a small effect on ν_{CO} (ketone) but leaves ν_{N-H} unchanged with the exception of a 3 cm^{-1} increase for the 5-isopropyl compound. The benzene ^{1}H-NMR resonances show the usual upfield shift and the magnitude of this shift has little variation with substituent. The effect on the pyrrole resonances is small and does not follow a trend.

Electron spin resonance studies

The *N*-methyl derivatives were used in these studies because of the lability of the hydrogen attached to nitrogen as discussed in a previous paper (3). Solutions of the radical anions (5–8 × 10^{-3} *M* in DME) of the pyrroles are dark blue or purple whereas those of the complexes are yellow or orange. The ligands and complexes of the 2-substituted derivatives all show six lines consisting of a doublet split into triplets. This is the same pattern observed for the unsubstituted compounds (3) and the doublet is assigned to the *para* proton of the benzene ring and the triplet to the two equivalent *ortho* protons. No other splittings are observed leading to the conclusion that any unpaired electron (upe) density on the pyrrole ring is not great enough to be observed. The A_p in each case (Table 3) is 8.0 G for the uncomplexed substituted pyrroles compared to 8.3 G for the unsubstituted compound. The A_o values are greater for the I and Cl compounds than for the isopropyl which shows the same value as the unsubstituted compound. In the complexes, A_p is greater for the substituted compounds and A_o is the same for all three cases. The iodo complex did not give an ESR spectrum.

The ratio of spectrum width (ligand/complex) is given in Table 3. The greatest reduction of spectrum width on complexation occurs in the 2-chloro compound indicating that the electron-withdrawing effect of the chlorine is transmitted to the benzene ring.

It is concluded from these results that there is some electron delocalization between the two rings but it is not great enough to result in the observance of hfs from the pyrrole ring. This is in agreement with the SCCC-MO results obtained for 3-benzoylpyrrole and its $Cr(CO)_3$ complex (3) which indicated a small amount of upe on the pyrrole ring. It contrasts with the results obtained for substituted benzophenones and their complexes (13, 14) which showed significant and observable upe on both rings.

The ESR spectra of 3-benzoyl-2-isopropylpyrrole and its $Cr(CO)_3$ complexes were quite different from those of the 2-substituted compounds. For the uncomplexed compound, the spectral pattern is a quartet of quartets which would be expected from two sets of three equivalent protons. It is most likely that the hyperfine coupling constants of the *para* and *ortho* protons are equal, making up one equivalent set similar to what is observed for 2-methylbenzophenone (12). The other set may arise from three protons of one of the isopropyl methyl groups. Delocalization of upe density onto the methyl group could occur via direct interaction with the carbonyl oxygen. The values observed are $A_p = A_o = 4.5$ G and $A_{CH_3} = 1.1$ G. The spectrum of the complex is narrower and the lines are not sufficiently well resolved to give an unambiguous assignment.

J. D. PANDEY, R. D. RAI, and R. K. SHUKLA. Can. J. Chem. **67**, 437 (1989).

Various statistical and empirical theories of ultrasonic velocity have been applied to a binary liquid mixture (benzene + nitrobenzene) at elevated pressures and their validity have been tested. A pressure-dependent study of ultrasonic velocities has been made at three different temperatures (293.15, 303.15, and 313.15 K). The agreement between the theory and experiment is found to be satisfactory.

Key words: ultrasonic velocity, benzene + nitrobenzene, pressure dependent, theoretical evaluation, binary mixtures at elevated pressures.

J. D. PANDEY, R. D. RAI et R. K. SHUKLA. Can. J. Chem. **67**, 437 (1989).

On a appliqué diverses théories statistiques et empiriques de la vitesse ultrasonique à un mélange liquide binaire (benzène + nitrobenzène), à haute température, et on a évalué leur validité. Opérant à trois températures différentes (293,15, 303,15 et 313,15 K), on a réalisé une étude des vitesses ultrasoniques en fonction de la pression. On a trouvé que l'accord entre la théorie et l'expérience est satisfaisante.

Mots clés : vitesse ultrasonique, benzène + nitrobenzène, dépendant de la pression, évaluation, théorique, mélanges binaires à haute pression.

[Traduit par la revue]

Introduction

Successful attempts have been made in recent years (1–7) on the theoretical evaluation of ultrasonic velocity and its correlation with other thermodynamic properties in binary liquid mixtures using statistical and semi-empirical theories. Such studies have been limited to binary liquid systems at atmospheric pressure. Due to lack of experimental data on ultrasonic velocity at elevated pressure, such studies could not be extended at elevated pressures. For the first time, Takagi *et al.* (8–14) have carried out experimental measurements of ultrasonic velocity and related thermodynamic properties of a few binary liquid mixtures at elevated pressures over a wide range of temperatures (293.15, 303.15, and 313.15 K). In the present paper, we report results of theoretical calculations of ultrasonic velocity at elevated pressures using the above mentioned theories in mixture of benzene + nitrobenzene. Ultrasonic investigations of this system have been reported by Takagi and Teranishi (8). A comparative study has also been presented and correlated.

Theoretical

Flory–Patterson theory (15–17) in conjunction with the Auerbach relation (18) yields the following expressions for the ultrasonic velocity (C) in a binary liquid mixture.

$$[1]\quad C = \left(\frac{kP^{*2}T^{*}}{6.3 \times 10^{-4}\rho}\right)^{2/9} M\tilde{V}^{-5/3} - \left(\frac{\tilde{V}^{1/3}-1}{\tilde{V}^{2}}\right)\ln\left(\frac{V^{1/3}-0.5}{V^{1/3}-1.0}\right)^{2/3}$$

where k, P^*, T^*, ρ, $\tilde{V}$, and M are the Boltzman constant, characteristic pressure, characteristic temperature, mass density and reduced volume of the mixture, and fraction of nearest neighbours that a molecule loses moving from the bulk of the liquid to the surface. Here the value of M is 0.30 which is taken throughout the calculations. The characteristic and reduced parameters at elevated pressures have been evaluated by the usual procedure (15).

Van Dael (19), based on assumptions made by Richardson (20) and Blandamer and Waddington (21) obtained the expression for the ultrasonic velocity (C) in a binary liquid mixture which may be expressed as

$$[2]\quad \left(\frac{1}{X_1M_1 + X_2M_2}\right)\frac{1}{C^2} = \left[\frac{X_1}{M_1C_1^2} + \frac{X_2}{M_2C_2^2}\right]$$

where X_1, X_2, M_1, M_2, and C_1, C_2 are the mole fractions, molecular weight, and ultrasonic velocities of benzene and nitrobenzene, respectively.

Assuming the linearity of molecular sound velocity and additivity of molar volumes, Nomoto (22) suggested an empirical formula for the sound velocity in a binary liquid mixture.

$$[3]\quad C = \left(\frac{R}{V}\right)^3 = \left(\frac{X_1R_1 + X_2R_2}{X_1V_1 + X_2V_2}\right)^3$$

where R is the molar sound velocity and V is the molar volume of the mixture.

Schaaffs (23, 24) and Nutsch-Kuhnkies (25) developed an expression for evaluating sound velocity in binary liquid mixture

$$[4]\quad C = C_\infty(X_1S_1 + X_2S_2)\left(\frac{X_1B_1 + X_2B_2}{V}\right)$$

where $C_\infty = 1600\ \mathrm{ms}^{-1}$, S_1, S_2 and B_1, B_2 are the collision factors and actual volumes of the molecule per mole (benzene + nitrobenzene), respectively.

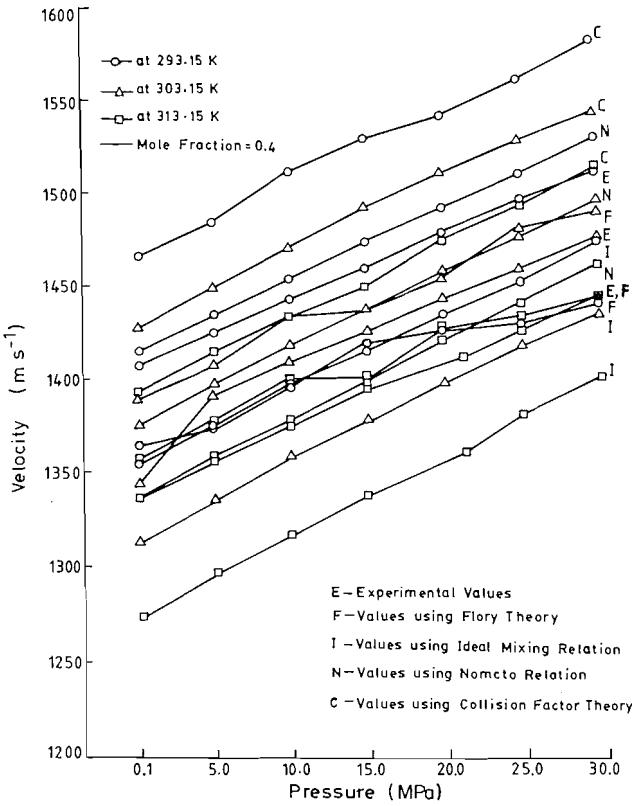

FIG. 1. Comparison between theoretical and experimental values of ultrasonic velocity of binary liquid mixture (benzene + nitrobenzene) at 293.15, 303.15, and 313.15 K at elevated pressure for mole fraction = 0.4 (benzene).

Results and discussion

Theoretical values of ultrasonic velocity computed from all the theories mentioned have been plotted against pressure at three different temperatures along with the experimental ultrasonic velocities at 0.4 mole fraction of benzene (Fig. 1). Figure 2 represents the variation of ultrasonic velocity with composition of benzene at three different temperatures (at 30 MPa). Both figures show linear or near linear behaviour for all the relations. Lack of smoothness in the figures are due to the interactions between the molecules at that instant. Interactions are the result of active collisions between the molecules. As temperature increases, collision between polar and non-polar molecules become more frequent hence increases the energy of activation. Further, high pressure adversely affects the temperature effect and figures seem to be more comprehensive. Non-linearity in Figs. 1 and 2 for the Flory approximation is also due to the computed values of thermal expansion coefficient (α) at elevated pressures using experimental data (8).

Table 1 contains the parameters for the pure component liquids at elevated pressures and temperatures where as Table 2 records the percentage deviations obtained from various theories. Percentage error of the measurement is not more than 0.3%. A close observation of Table 2 evinces that theoretical values of ultrasonic velocity agree satisfactorily with the experimental values. The average percentage deviations for Flory–Patterson theory, ideal mixing relation, Nomoto relation, and collision factor theory are 2.78, 2.60, 0.66, and 3.70 at 293.15 K, 1.75, 2.73, 0.72, and 3.83 at 303.15 K, and 1.66, 3.11, 0.48, and 3.74 at 313.15 K, respectively.

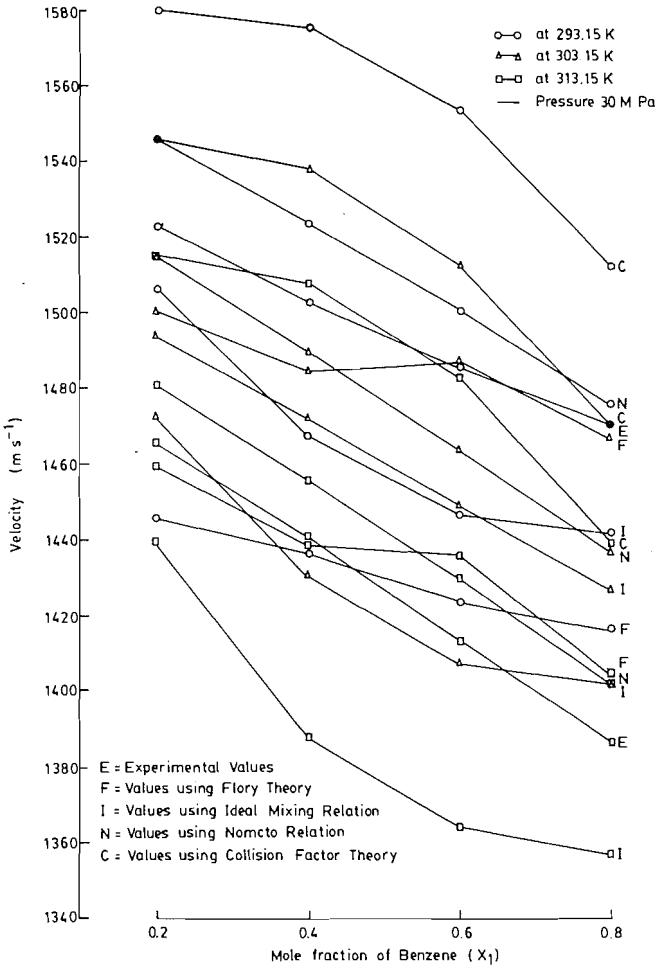

FIG. 2. Variation of ultrasonic velocities of binary liquid mixture (benzene + nitrobenzene) with the compositions of benzene at 293.15, 303.15, and 313.15 K at 30 MPa pressure.

In the collision factor theory, molecules are treated as real non-elastic substances which cause larger deviations. Benzene and nitrobenzene and organic volatile liquids which have weak intermolecular force of attraction. Hence, their collisions are likely to be elastic in nature.

It appears to be remarkable that it is the concentration of the nitrobenzene which causes interaction to an appreciable extent in binary liquid mixture. Nitrobenzene is supposed to be relatively complex molecule and its non-ideality in all probability may be due to the C—N as well as due to the polar nature of the group itself. As far as the contribution of the nitrogroup is concerned, it rotates freely along the C—N axis which is likely to activate the attached benzene ring. Larger deviations in the system may also result due to polar–nonpolar interactions, nonpolar–central forces and of structural origin. Consequently, in such system interactions are minimum. The intermolecular distance between the two parallel benzene rings may get reduced further due to the interaction with electron deficient rings of nitrobenzene which may be sandwiched between two aromatic benzene rings.

In conclusion, it appears from the preceding discussion that the Nomoto relation provides best result followed by the Flory theory, the theory of ideal mixing, and the collision factor theory for the benzene + nitrobenzene system at elevated pressures and temperatures.

Newton-variational solution of the Frank–Kamenetskii thermal explosion problem

AVYGDOR MOISE AND HUW O. PRITCHARD
Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received July 5, 1988

AVYGDOR MOISE and HUW O. PRITCHARD. Can. J. Chem. **67**, 442 (1989).

The Newton method was shown by Vatsya to be suitable for solving the generalised elliptic problem, and we show that this approach can be used to treat the Frank–Kamenetskii model of a thermal explosion, by using a variational solution of the sequence of linear equations that are encountered in the Newton method. Convergence to the desired solution is rapid in the case of spherical geometry. The method produces converging upper and lower bounds to the critical value of the dimensionless heat production rate, δ_c, and lower bounds to the dimensionless temperature excess distribution function θ and its critical form θ_c.

Key words: thermal explosions, Frank–Kamenetskii model.

AVYGDOR MOISE et HUW O. PRITCHARD. Can. J. Chem. **67**, 442 (1989).

Vatsya a démontré que la méthode de Newton permet de résoudre le problème elliptique généralisé et on montre que, si on fait appel à la solution variationnelle de la suite des équations linéaires rencontrées dans la méthode de Newton, cette approche peut être utilisée pour traiter le modèle de Franck–Kamenetskii d'une explosion thermique. Dans le cas d'une géométrie sphérique, la convergence de la solution désirée est rapide. La méthode fournit des limites supérieure et inférieure qui convergent vers la valeur critique de la vitesse de production de la chaleur (sans dimension), δ_c, ainsi que les limites inférieures de la fonction de distribution des températures en excès (sans dimension), θ, et sa forme critique θ_c.

Mots clés : explosions thermiques, modèle de Franck–Kamenetskii.

Introduction

The theory of thermal explosions, as developed by Frank–Kamenetskii (1), requires the solution of the equation

$$[1] \quad \nabla_\xi^2\theta + \delta e^\theta = 0$$

where θ is the (dimensionless) difference in temperature between a point inside the system and that at the outer boundary, and δ is a parameter (in fact, the dimensionless measure of the heat-release rate). This equation has the property that a minimal positive solution can be found below a certain critical value of δ, i.e. δ_c, but not above: thus, δ_c is identified with the critical condition for explosion.

Equation [1] has been the subject of many studies: these have included the conversion from a boundary-value to an initial-value problem (2, 3), asymptotic expansions (4, 5), and generalised polynomial expansions (6, 7). These methods suffer from two major defects, one that long expansion lengths are needed to obtain sufficient accuracy and two, that multiple solutions exist, and the unwanted ones have to be discarded by appeal to intuitive arguments. Recently, Vatsya proposed the solution of this problem by the use of Newton's method (8), and showed that the explosion condition could be defined uniquely, without the need for arbitrary exclusion of alternative "non-physical" solutions. In this paper, we show that the Newton method converges quickly to the required result, in contrast to all of the preceding approaches. The use of the Newton method linearises the equation and, in principle, could give rise to asymptotic *analytic* approximations. However, we have not been able to find a purely analytic representation in this case, beyond the first iteration, and have resorted to the Bubnov–Garlerkin generalisation of the variational method (9), which is known to be a convergent procedure, to obtain numerical solutions for the higher Newton approximants. The use of both the Newton method and the variational method in the solution of non-linear problems is a novel feature of this work.

We begin by defining the differential operator $\mathcal{L}$ and a function $\phi(x;\lambda)$ as follows:

(*i*) Let $\mathcal{L}^2(D,dx)$ be the real Hilbert space of square integrable functions with respect to the Lebesgue measure dx on $D = (0,1)$, and let $L = -d^2/dx^2$ be an operator from $\mathcal{D}(L) \to \mathcal{L}^2(D,dx)$.

(*ii*) Let $\phi(x;\lambda)$ be twice differentiable with respect to x for all $x \in D = (0,1)$, and let $\phi(x,\lambda) = 0$, $x \in \partial D = \{0,1\}$, where $\phi(x;\lambda)$ is the minimal positive solution of

$$[2] \quad L\phi = \lambda f(\phi) \qquad x \in D$$

λ is a positive parameter and $f(\eta) \equiv f(x;\lambda;\eta(x;\lambda))$ is a continuous, positive, increasing and convex function of $\eta(x;\lambda) > 0$; i.e. the derivative $f'(\eta)$ with respect to η of $f(x;\lambda;\eta(x;\lambda))$ is continuous, positive and increasing on D for $\eta > 0$.

Then, whenever eq. [2] makes sense, i.e. has a definite minimal positive solution, we may use Newton's approximating formula to produce successive lower bounds to $\phi(x;\lambda)$ and upper bounds to λ^*, where λ^* is the bifurcation point (8).

Application of Newton's method

If we choose an initial value for $\phi_0(x;\lambda) = 0$ (a guaranteed lower bound to $\phi(x;\lambda)$, since $\phi(x;\lambda)$ is strictly positive) then Newton's approximating formula takes the form,

$$[3] \quad [L - \lambda f'(x;\lambda;\phi_n(x;\lambda))]\phi_{n+1}(x;\lambda) = \lambda[f(x;\lambda;\phi_n(x;\lambda)) - \phi_n(x;\lambda)f'(x;\lambda;\phi_n(x;\lambda))]$$

$n = 0, 1, 2, \ldots$, and we are assured (8) that $\phi_n(x;\lambda) \uparrow \phi(x;\lambda)$ uniformly with respect to $x \in \bar{D} = D \cup \partial D$ for each fixed $\lambda < \lambda^*$. Let λ^* be the critical point, i.e. $\lambda > \lambda^*$ implies that eq. [2] does not have a minimal positive solution. For each fixed n, $\phi_n(x;\lambda)$ is known to exist up to some point $\bar{\lambda}_{n-1} > \lambda^*$. Furthermore, we know (8) that $\bar{\lambda}_n \uparrow \lambda^*$, where $\bar{\lambda}_n$ is the smallest eigenvalue of

$$[L - \bar{\lambda}_n f(\phi_n)]\phi_{n+1} = 0$$

By restricting ourselves to spherical geometry, eq. [1] can be rewritten as (7)

$$[4] \quad \frac{d^2u}{d\xi^2} + \delta\xi e^{u/\xi} = 0$$

where $0 \le \xi \le 1$ is the (scaled) distance from the centre, and

$u = \xi\theta$. With $\delta = \lambda$, it has the required form

$$[5] \quad Lu = \delta f(u)$$

and has been shown, elsewhere (7, 10), to satisfy the above conditions: it may, therefore, be solved by the Newton method.

Let $\{u_n\}$ be Newton's sequence for $u(\xi,\delta)$, and let $u_0 = 0$ be our initial input function in eq. [3]; u_0 is a lower bound to $u(\xi,\delta)$, since we already know that u is positive and $u_n \uparrow u$. Then, expressing eq. [5] in terms of [4] and [3] gives

$$[6] \quad \left[-\frac{d^2}{d\xi^2} - \delta e^{u_n/\xi}\right] u_{n+1} = \delta[\xi e^{u_n/\xi} - u_n e^{u_n/\xi}]$$

With $n = 0$, this reduces to

$$\left[-\frac{d^2}{d\xi^2} - \delta\right] u_1 = \delta\xi$$

or

$$\frac{d^2u_1}{d\xi^2} = -\delta(\xi + u_1)$$

to which the solution

$$[7] \quad u_1(\xi,\delta) = \frac{\sin \xi\sqrt{\delta}}{\sin \sqrt{\delta}} - \xi$$

is already known (7). In principle, we may now re-substitute this closed form approximation u_1 for u in eq. [6] and solve for u_2, but we were unable to find a tractable solution, and so proceeded to employ numerical methods by which to extract higher order approximations for u.

The variational approximation

When the function $\phi(x;\lambda)$ (or its Newton approximant $\phi_n(x;\lambda)$) cannot be expressed in closed form, it is possible to produce a variational expansion for $\phi_n(x;\lambda)$ and $\phi(x;\lambda)$ given by

$$\phi_{n,m}(x;\lambda) = \sum_{j=1}^{m} \beta_{j,n}\tilde{\phi}_j(x;\lambda)$$

$$\phi_m(x;\lambda) = \sum_{j=1}^{m} \beta_j\tilde{\phi}_j(x;\lambda)$$

where $\beta_{j,n}$ and β_j are defined by

$$[8] \quad \sum_{j=1}^{m} (\tilde{\phi}_i, [L - \lambda f'(\phi_{n,m})]\beta_{j,n+1}\tilde{\phi}_j) = \lambda(\tilde{\phi}_i, [f(\phi_{n,m}) - \phi_{n,m}f'(\phi_{n,m})])$$

and

$$[9] \quad \sum_{j=1}^{m} (\tilde{\phi}_i, [L - \lambda f'(\phi_m)]\beta_j\tilde{\phi}_j) = \lambda(\tilde{\phi}_i, [f(\phi_m) - \phi_m f'(\phi_m)])$$

respectively, (the notation (,) denoting the scalar product of two vectors) $\{\tilde{\phi}_j(x;\lambda)\} \subset \mathcal{D}(L)$ is some linearly independent basis set and m is the chosen expansion length (10). For each (Newton iteration) n we have that

$$\lim_{m\to\infty} \phi_{n,m}(x;\lambda) = \phi_n(x;\lambda)$$

and

$$\lim_{n\to\infty} \phi_n(x;\lambda) = \phi(x;\lambda)$$

Also (8), if $\phi_{n,m_k} \leq \phi_{n,\infty} = \phi_n(x;\lambda)$ for each n, where $m_k < m$ selects only that sub-set of the sequence that is monotonically increasing, then ϕ_{n,m_k} yields successive lower bounds to ϕ as $m \to \infty$ followed by $n \to \infty$.

Application to the Frank–Kamenetskii model

Rather than producing a variational approximation to u_n, we make use of the fact that (7) eq. [7] represents the θ function to within about 5% up to values of $\delta = 3.3$. Notice that the first Newton approximant can also be obtained independently by the use of an inverse Laplace transformation of a time-variant Frank–Kamenetskii equation, with the exponential term approximated in the usual manner (6), and the steady-state limit of that solution is naturally expressible in terms of a sum of sine functions (10). For this reason, we chose the set $\{\sin j\pi\xi\}_{j=1}^{\infty} \subset \mathcal{D}(L)$, (which obviously forms a basis in the appropriate space) to represent, in our variational procedure, the difference $\Delta u_n = u_n - u_1$, in a two-pronged attempt to reduce the number of terms required for an accurate representation of u; it is shown elsewhere (10) that Δu_n also satisfies all the requirements for convergence described above.

We re-write eq. [5] in terms of $\Delta u = u - u_1$

$$L(u_1 + \Delta u) = \delta\xi e^{(u_1+\Delta u)/\xi}$$

$$L(\Delta u) = \delta\xi e^{(u_1+\Delta u)/\xi} - Lu_1$$

$$= \delta[\xi e^{(u_1+\Delta u)/\xi} - (\xi + u_1)]$$

Thus

$$f(\Delta u) = \xi e^{(u_1+\Delta u)/\xi} - (\xi + u_1)$$

and

$$f'(\Delta u) = e^{(u_1+\Delta u)/\xi}$$

whence Newton's approximating sequence for $\{\Delta u_n\}$ becomes

$$\left[-\frac{d^2}{d\xi^2} - \delta f'(\Delta u_n)\right]\Delta u_{n+1} = \delta[f(\Delta u_n) - (\Delta u_n)f'(\Delta u_n)]$$

We now transform this operator equation into an $m \times m$ dimensional matrix equation that represents the variational equation [8]

$$A_n \cdot B_{n+1} = G_n$$

where the elements of A_n and G_n are $\alpha_{(i,j),n}$ and $\gamma_{j,n}$, defined by

$$\alpha_{(i,j),n} = \int_0^1 \sin(i\pi\xi)\left[-\frac{d^2}{d\xi^2} - \delta e^{(u_1+\Delta u_n)/\xi}\right]\sin(j\pi\xi)d\xi$$

$$\gamma_{j,n} = \int_0^1 \sin(j\pi\xi)\delta[(\xi - \Delta u_n)e^{(u_1+\Delta u_n)/\xi} - (\xi + u_1)]d\xi$$

A solution vector $B_{n+1} = (\beta_{j,n+1})$ will exist for all values of $\delta < \delta_{c,n}$ (where $n = 1, 2, 3\ldots$ represents the nth Newton's approximation); conversely, for each fixed n we can find a $\delta_{c,n}$ for which a solution ceases to exist. The non-existence of a solution to the above matrix equation will manifest itself when the determinant $\det(A_n(\delta))$ becomes singular. Since we know (8, 10) that u_n exists, and is continuous as long as $\delta < \delta_{c,n-1}$, therefore, the positive normalised determinant

$$\det(\bar{A}_n(\delta)) = \frac{\det(A_n(\delta))}{\det(A_n(0))}$$

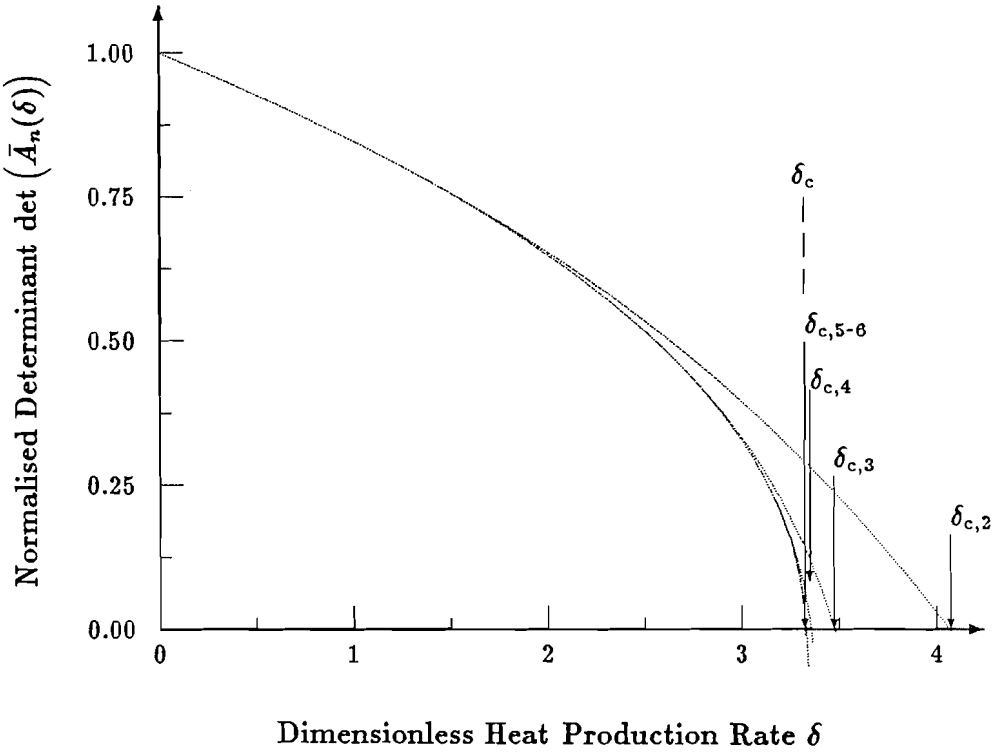

FIG. 1. Convergence characteristics of the normalised determinant det $(\bar{A}_n(\delta))$, using three basis functions and the initial value $\Delta u(\xi,\delta) = 0$.

will decrease towards zero as δ approaches $\delta_{c,n}$. Note that since $\lim_{\delta \to \delta_{c,n}} \det(\bar{A}_n(\delta)) = 0$, simply observing the sign and magnitude of the normalised determinant $\bar{A}_n(\delta)$ will enable us to compute successive upper and lower bounds to $\delta_{c,n}$.

Numerical implementation

The matrix and vector elements $\alpha_{(i,j),n}$ and $\gamma_{j,n}$ were computed by using a five-point Gauss–Legendre quadrature (11) applied to an integral number of sub-intervals in D. The number of intervals was chosen in such a manner as to ensure that there were at least four sub-intervals per integration segment for each zero crossing of any of the basis functions; this provides better accuracy than equal-interval formulae, without a significant increase in computational overhead.

The solution vector $B_{n+1}(\delta)$ was computed from the input matrix $A_n(\delta)$ and the vector $G_n(\delta)$ by using a standard Gauss–Jordan reduction method (11), which has the advantage of yielding simultaneously the required determinant det $(A_n(\delta))$. For each fixed value of δ, an initial guess for Δu_n, known to be less than Δu, was chosen and the Newton-variational method was applied repeatedly for $n = 1, 2, \ldots$ until either det $(\bar{A}_n(\delta))$ became negative, convergence was achieved to within some ϵ, defined by

$$\epsilon > \left|\frac{\det(\bar{A}_n(\delta)) - \det(\bar{A}_{n-1}(\delta))}{\det(\bar{A}_{n-1}(\delta))}\right| \text{ and } \left|\frac{\delta_{c,n+1} - \delta_{c,n}}{\delta_{c,n+1}}\right|$$

or else until a contradiction in the sense that det $(\bar{A}_n(\delta)) <$ det $(\bar{A}_{n-1}(\delta))$ was encountered.

In principle, for each new value of δ, one begins with $\Delta u_1(\xi,\delta) = 0$, but because $\Delta u_n < \Delta u$ for all n and Δu is a monotonically increasing function of δ, one can use the previous solution $\Delta u_n(\xi,\delta)$ as the initial guess for $\Delta u(\xi,\delta + d\delta)$, thereby reducing considerably the number of iterations required to achieve convergence.

TABLE 1. Comparison of Newton-variational approximations to the steady-state solution for a thermal explosion in a sphere, for expansion lengths of m = 4, 5, 8, and 10*

*Error criterion $\epsilon = 10^{-8}$.

Results

Figure 1 shows the behaviour of the normalised determinant det $(\bar{A}_n(\delta))$ when using only three basis functions, and an initial value of $\Delta u_1(\xi,\delta) = 0$. In the first numerical iteration, i.e. $n = 2$, the determinant remains positive up to a value of δ of about 4.1; the next iteration places the upper bound for δ_c at just below 3.5, and the Newton sequence converges between $n = 5$ and 6 to a value of δ_c just above 3.32, which is almost correct. Figure 2 shows the corresponding values for the dimensionless excess temperature at the centre of the vessel, for the highest value of δ that gave a valid solution, giving a maximum value, at

*$u = \xi\theta = \lim_{m,n\to\infty} u_n$,

$$u_n \equiv u_n(\xi,\delta) = \frac{\sin(\xi\sqrt{\delta})}{\sin\sqrt{\delta}} - \xi + \sum_{j=1}^{m} \beta_{j,n}(\delta)\sin(j\pi\xi).$$

convergence, which is also very nearly correct. A full summary of these results and details of the algorithm are available elsewhere (10).

The results of calculations for 4, 5, 8, and 10 basis functions are compared in Table 1, where the rapid convergence of the method can be seen; the numbers in this table are to be interpreted as follows: the δ values are upper bounds, with the lower bound for that value of the expansion length m being within 10^{-8} below it and for the θ and $d\theta/d\xi$ values, the uncertainty is in the last digit quoted. The final results are in excellent agreement with the accepted values (12), but are superior in the sense that the present method provides converging upper and lower bounds to $\delta_{c,n}$; also the θ function, at convergence, is known to be a lower bound. The lower part of this table shows the conditions for the first appearance of an inflection in the $\theta(\xi)$ function, also in excellent agreement with the result of Boddington and Gray (12). Table 2 gives a list of the 10th order expansion coefficients, from which the appropriate temperature profiles for these two unique conditions may be constructed.

Viscosities of mixtures of chloroform + triethylamine: analysis in terms of three components (A, B, and AB)

RICHARD P. SCHUTTE, TERRY C. LIU, AND LOREN H. HEPLER
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 22, 1988

RICHARD P. SCHUTTE, TERRY C. LIU, and LOREN H. HEPLER. Can. J. Chem. **67**, 446 (1989).

Viscosities and densities of highly non-ideal mixtures of chloroform (A) + triethylamine (B) have been measured at 25°C. It has been shown that the Grunberg equation (one adjustable parameter) can account for these viscosities over the whole range of compositions. It has also been shown that a new combination of the ideal associated solution model, based on consideration of an equilibrium of the type A + B = AB, with an ideal viscosity equation (also one adjustable parameter) accounts more accurately for all of the viscosities. This latter treatment also has the advantage of offering a clear pictorial model of the mixtures.

Key words: viscosity of solution, complex formation in solution, chloroform + triethylamine, triethylamine + chloroform.

RICHARD P. SCHUTTE, TERRY C. LIU et LOREN H. HEPLER. Can. J. Chem. **67**, 446 (1989).

Opérant à 25°C, on a mesuré les viscosités et les densités de mélanges de chloroforme (A) et de triéthylamine (B) qui s'écartent beaucoup de l'idéalité. On a montré que l'équation de Grunberg (avec un seul paramètre ajustable) peut expliquer les viscosités à toutes les compositions. On a aussi démontré qu'une nouvelle combinaison du modèle de la solution idéale associée, basé sur la considération d'un équilibre du type A + B = AB, avec une équation de viscosité idéale (qui est aussi adjustable avec un seul paramètre) permet de mieux expliquer toutes les viscosités. Ce traitement offre aussi l'avantage de présenter un modèle visuel clair des mélanges.

Mots clés : viscosité de la solution, complexé formation dans solution, chloroforme + triéthylamine, triéthylamine + chloroforme.

1. Introduction

Viscosities of many mixtures or solutions are of considerable direct importance in connection with a wide variety of flow processes and are also important in connection with processes that involve diffusion or thermal conductivities. In addition, viscosities have often been regarded as a probe to be used to gain understanding of molecular interactions in mixtures and solutions.

Our immediate interest has been to use the mole fraction dependence of the viscosity of a non-electrolyte mixture as a means of testing and possibly extending earlier treatments of the thermodynamic properties of such mixtures. A longer range interest is the development of improved methods for estimating the viscosities of multi-component mixtures, such as bitumen or heavy oil containing diluent or dissolved gas.

Many earlier investigators (1–12) of viscosities of mixtures have expressed these viscosities as weighted sums of viscosities of pure components. Long ago (1887) Arrhenius recognized that logarithms of viscosities of liquids were approximately proportional to $1/T$ and therefore suggested that the logarithm of the viscosity of a mixture might be expressed as a weighted sum of the logarithms of the viscosities of the pure components at the same temperature. Subsequent investigators have taken the weighting factors to be volume fractions or (more often) mole fractions. On this basis we begin by expressing the viscosity of an ideal mixture as

$$[1] \quad \ln \eta_{id} = \Sigma X_i \ln \eta_i$$

in which η_{id} is the viscosity of an ideal mixture, X_i is the stoichiometric mole fraction of component i, and η_i is the viscosity of pure liquid component i. Possibly the most often used extension of the ideal eq. [1] to non-ideal solutions was originated by Grunberg (1, 2), who wrote

$$[2] \quad \ln \eta = X_A \ln \eta_A + X_B \ln \eta_B + X_A X_B d$$

for a mixture of components A and B. In eq. [2] d is a parameter that is related to the molecular interactions that are responsible for the non-ideal properties of the mixture. It has been found that d is typically small and negative for mixtures that exhibit positive deviations from Raoult's law and is positive (sometimes relatively large) for mixtures that exhibit negative deviations from Raoult's law. Later in this paper we consider eq. [2] in relation to our viscosities of chloroform + triethylamine mixtures.

Because of uncertainties about the specific theoretical relationship of d in eq. [2] to molecular interactions, we have also applied another approach as follows. Several previous investigations (13) have shown that the "ideal associated solution model" (defined below) provides an accurate and convenient description of the thermodynamic properties of some mixtures for which there is good evidence for the reality of complex formation of the type represented by

$$[3] \quad A + B = AB$$

It has also been shown (14, 15) that this ideal associated solution model is applicable to the thermodynamic properties of the chloroform + triethylamine system of present interest.

In the present application of the ideal associated solution model it is specified that all apparent deviations from ideality of the two component systems (A + B) can be explained in terms of ideal properties of the three component system (A, B, and AB) and the equilibrium mole fractions of A, B, and AB. We have therefore considered the measured viscosities of the chloroform (A) + triethylamine (B) system in terms of a three component extension of eq. [1]

$$[4] \quad \ln \eta = Z_A \ln \eta_A + Z_B \ln \eta_B + Z_{AB} \ln \eta_{AB}$$

in which Z represents the equilibrium (as contrasted to the stoichiometric) mole fraction and η_{AB} represents the viscosity of the hypothetical pure liquid AB. As shown later in this paper, an equation of the form of [4] is consistent with our measured viscosities and the previously evaluated equilibrium constant for the equilibrium represented by eq. [3].

2. Experimental

Materials

Triethylamine from Jannsen Chemica was refluxed for 1.5 h over potassium hydroxide in a nitrogen atmosphere, then fractionally distilled. Chloroform from Anachemia was washed 3–5 times with distilled water and then dried for 48 h over anhydrous calcium chloride. Finally, the chloroform was distilled in a nitrogen atmosphere and stored (maximum of 4 days storage) in a dark bottle in a closed cabinet. Throughout the purification procedure, care was taken to protect the chloroform from exposure to light.

Mixtures of chloroform + triethylamine were prepared by mixing weighed amounts of pure components; stoichiometric mole fractions were calculated from the masses and molecular weights.

Apparatus and procedure

Densities of the liquids were determined with glass pycnometers of 25 cm^3 approximate volume, calibrated with distilled water and suspended in a water bath at 25°C. The temperature of the water bath was controlled by a Thermomix 1460 and was known to ±0.01°C and stable to ±0.005°C as monitored with a platinum resistance thermometer.

Kinematic viscosities (ν) were measured with Cannon–Fenske viscometers (Fisher Scientific sizes 25 and 50) suspended in the same water bath as the pycnometers. The viscometers were calibrated with distilled water and chloroform to determine k and K to be used in

$$[5] \quad \nu = \eta/\rho = kt - K/t^2$$

where η is dynamic viscosity, ρ is density, and t the flow time measured in seconds. Equation [5] is the Hagen–Poiseuille equation corrected for kinetic energy effects for capillaries with trumpet-shaped ends (16). Flow times as measured with a stopwatch ranged from approximately 90 to 230 s.

3. Results and calculations

Compositions of mixtures (expressed in terms of the stoichiometric mole fraction of chloroform, X_A), densities, and absolute viscosities (η) of chloroform (A) + triethylamine (B) are summarized in Table 1. Each density is the average of three determinations and each viscosity is the averge of six determinations. Standard deviations of the densities and viscosities were all close to 0.0002 g cm^{-3} and 0.003 CP. Our densities are in good agreement with the more accurate values previously reported (15) as part of a thermodynamic investigation.

After our measurements and calculations were completed, we became aware of viscosities and densities measured by Wei and Rowley (17). Densities from the two investigations agree to within 0.4% over the entire range of compositions, while differences in the viscosities range from about 1–4%. More important for our purposes than this reasonably good numerical agreement is the fact that the general shapes of the viscosity versus composition curves from the two investigations are very similar, which means that the same conclusions can be drawn from both sets of experimental results.

A graph of our viscosities against stoichiometric mole fractions is shown in Fig. 1, where it can be seen that the actual viscosities are greater than expected on the basis of an ideal mixture of two components, as in eq. [1]. This qualitative observation of positive excess viscosities was expected on the basis of the very accurate negative excess volumes previously reported (15) or the less accurate (also negative) excess volumes that can be calculated from our densities.

Now we turn to analysis of our viscosities in terms of the ideal associated solution model. The basis of this model is the assumption that observed non-ideal thermodynamic properties (vapor pressures, enthalpies of mixing, heat capacities, volumes) are entirely due to the kind of equilibrium represented by

TABLE 1. Stoichiometric mole fractions (X), densities (ρ), viscosities (η), and equilibrium mole fractions (Z) for chloroform + triethylamine mixtures

1.0000	1.4791	0.542	1.0000	0.0000	0.0000

eq. [3]. Because of this equilibrium, the actual mole fractions (of A, B, and AB) are not the same as the stoichiometric mole fractions (of A and B, no AB). It therefore follows that extension of this ideal associated solution model of thermodynamic properties to viscosities should be based on eq. [4], with the equilibrium mole fractions (Z) calculated from the known stoichiometric mole fractions (X) and the previously established (15) equilibrium constant ($K = 2.58$ at 25°C). For these calculations of Z values from X values and K, we set all activity coefficients equal to unity, as required by the model (13–15). The resulting equilibrium mole fractions (Z) are listed in Table 1.

If it were possible to measure the viscosity of the hypothetical pure liquid AB, it would then be possible to make a direct comparison of the calculated (by way of eq. [4]) viscosities of mixtures with the measured viscosities. But it is impossible to obtain pure liquid AB because mixtures of A + B all contain non-negligible amounts of all three species (A, B, and AB). We have therefore tested the applicability of eq. [4] as follows.

The effect of AB on the viscosities of mixtures of A + B is negligible near $X_A = 0$ and $X_A = 1$ where the equilibrium mole fractions of AB are very small, and is largest near $X_A \approx 0.5$ where the equilibrium mole fraction of AB is a maximum. (Later we consider in detail why the maximum in the graph of η against X_A is "off-centre".) The simplest procedure for evaluating the unknown viscosity of the hypothetical pure AB is to use the measured viscosity of one mixture (near the maximum in the curve in Fig. 1, $X_A = 0.5829$) with the corresponding values of Z_A, Z_B, and Z_{AB} and the known viscosities of the pure components to obtain a calculated viscosity of the hypothetical pure liquid AB to be $\eta_{AB} = 1.402$ cP. That is, we have forced a fit of eq. [4] at one stoichiometric composition. Then, with this value of η_{AB}, we have used eq. [4] in calculating the viscosities of mixtures having various compositions. The average difference between calculated and measured viscosities is 0.001_5 cP. It is therefore clear that our combination of the ideal associated solution model (13–15) with the ideal mixture viscosity equation [1] provides calculated viscosities that are in very good agreement (average deviation no larger than experimental uncertainties) with the experimental data.

Another, more elaborate, test of eq. [4] is based on choosing the value of the viscosity of the hypothetical pure liquid AB that will lead to the minimum average difference between all measured and calculated viscosities. In this way we have

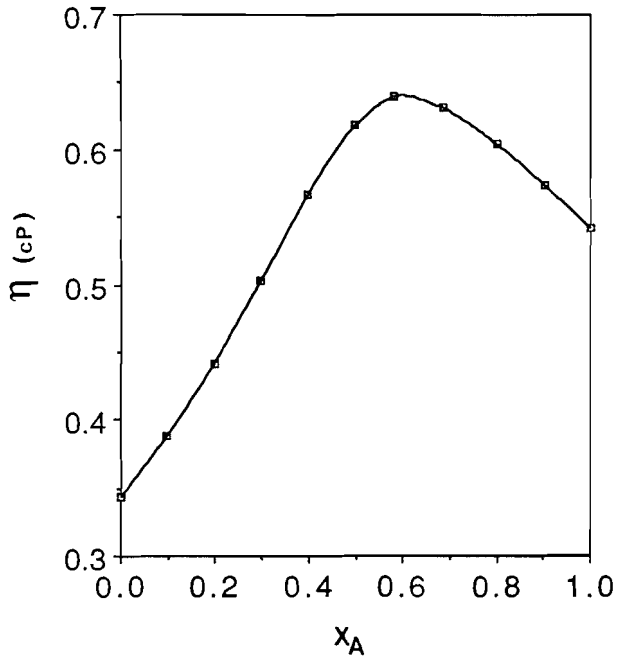

FIG. 1. Plot of absolute viscosity vs. stoichiometric mole fraction of chloroform.

obtained $\eta_{AB} = 1.386$ and thence obtain 0.001_1 cP as the average difference between measured and calculated viscosities. This procedure leads to an insignificant statistical improvement over the simpler treatment described in the preceding paragraph.

We now test eq. [2] from Grunberg (1, 2) in a way that is similar to our first test of eq. [4], as follows. We have used the measured viscosity of the mixture with $X_A = 0.5829$ to evaluate $d = 1.463$, and have then used this value of d in eq. [2] to calculate viscosities of the other mixtures. The average difference between these calculated viscosities and the measured viscosities is 0.019 cP, which is 13 times as large as the corresponding difference based on eq. [4], which also involves one adjustable parameter.

We have also tested the Grunberg eq. [2] by choosing the value of d that leads to the minimum average difference between all measured and calculated viscosities. In this way we have obtained $d = 1.333$ and 0.013 cP for the average difference between measured and calculated viscosities. This average difference between calculated and measured viscosities is 12 times as large as that found for the corresponding test of eq. [4].

Some of the thermodynamic properties (enthalpies of mixing and excess volumes) of chloroform + triethylamine mixtures are symmetrical about $X = 0.5$. Appropriate calculations (13–15) with the ideal associated solution model show that this observed symmetry is in accord with the model. In addition, it may be intuitively obvious that some effects caused by an equilibrium of the type [3] involving a 1:1 complex should be symmetrical about $X = 0.5$. On the other hand, it is clear from the compositions and viscosities listed in Table 1 and from the graph in Fig. 1 that the maximum in ln η (or in η) occurs at $X_A = 0.61$, rather than at the "expected" $X_A = 0.5$.

We first consider the shape (composition of the mixture with maximum viscosity) of ln η against X_A in terms of the Grunberg eq. [2]. To do so we substitute $X_B = 1 - X_A$ in eq. [2] and then differentiate with respect to X_A. The resulting d ln η/dX_A is set equal to zero and solved to obtain

$$[6] \quad X_A(\text{max. } \eta) = 0.5 + [\ln(\eta_A/\eta_B)]/2d$$

Using $d = 1.463$ and $d = 1.333$ and experimental values for η_A and η_B in eq. [6] leads to calculated $X_A(\text{max. } \eta) = 0.65_5$ and 0.67_1, in fair agreement with the observed $X_A(\text{max. } \eta) = 0.61$. Equation [6] shows that the maximum viscosity will occur at $X_A = 0.5$ only in the special case $\eta_A = \eta_B$.

We have also applied the same kind of procedure to eq. [4]. In this case the mathematics are much more complicated because eq. [4] is written in terms of the equilibrium mole fractions (Z), but we want to set d ln η/d$X_A = 0$. Details of this complicated derivation and subsequent calculation are available elsewhere;[1] results can be summarized by stating that eq. [4] leads to a maximum in ln η (or in η) at $X_A = 0.61_2$, in excellent agreement with the experimental results. Again we see that our combination of the ideal associated solution model with the ideal viscosity eq. [1] is more consistent with the experimental results than is the Grunberg equation.

4. Conclusions

It has been shown that the Grunberg equation (one adjustable parameter, d) can account for the composition dependence of the viscosities of highly non-ideal mixtures of chloroform+ triethylamine over the whole range of compositions. It has also been shown that a combination of the ideal associated solution model with the ideal viscosity equation (this combination also has one adjustable parameter, η_{AB}) provides a more accurate account of the viscosities of chloroform + triethylamine. In addition to providing an accurate quantitative representation of the viscosities over the entire range of compositions, this latter approach also has the appeal of offering a clear pictorial model of the mixtures.

Conformational analysis of configurationally isomeric dicyclohexano-12-crown-4 ethers and their lithium complexes in solution as studied via ^{13}C NMR spectroscopy

G. W. BUCHANAN,[1] R. A. KIRBY, AND K. BOURQUE

Ottawa–Carleton Chemistry Institute, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received August 2, 1988

G. W. BUCHANAN, R. A. KIRBY, and K. BOURQUE. Can. J. Chem. **67**, 449 (1989).

From ^{13}C NMR coalescence temperature measurements, the *cis-syn-cis* isomer of the title crown ether is shown to undergo a single degenerate ring inversion process with a barrier of 45.9 ± 0.3 kJ/mol. For the corresponding *cis-anti-cis* isomer, a second ring inversion process has been detected, giving rise to two conformations whose free energies differ by ca. 1.5 kJ/mol. The influence of lithium ion complexation on these barriers as well as on the ^{13}C spin-lattice relaxation times has been investigated.

Key words: crown ethers, dynamic stereochemistry.

G. W. BUCHANAN, R. A. KIRBY et K. BOURQUE. Can. J. Chem. **67**, 449 (1989).

En se basant sur des mesures de température de coalescence en RMN du ^{13}C, on a démontré que l'isomère *cis-syn-cis* de l'éther couronne mentionné dans le titre subit un seul processus dégénéré d'inversion de cycle, avec une barrière de 45,9 ± 0,3 kJ/mol. Pour l'isomère *cis-anti-cis* correspondant, on a détecté un deuxième processus d'inversion de cycle qui donne lieu à deux conformations dont les énergies libres diffèrent par environ 1,5 kJ/mol. On a étudié l'influence de la complexation par l'ion lithium sur ces barrières ainsi que sur les temps de relaxation spin réseau en RMN du ^{13}C.

Mots clés : éthers couronnes, stéréochimie dynamique.

Introduction

Recent publications from these laboratories have dealt with the detection, via ^{13}C nuclear magnetic resonance at low temperature, of multiple conformational equilibria in stereoisomeric dicyclohexano-18-crown-6 (1) and -14-crown-4 (2, 3) ethers and their alkali metal ion complexes. In view of the current interest in lithium ion complexation by 12-crown-4 ether systems (4), we wish to report results of our studies concerning the corresponding dicyclohexano-12-crown-4 cases.

Results and discussion

Catalytic hydrogenation of dibenzo-12-crown-4 ether (5) yields a mixture of *cis-syn-cis*-dicyclohexano-12-crown-4, **1**, and the corresponding *cis-anti-cis* isomer, **2**, in a ratio of ca. 20:1. The configurations of **1** and **2** have been determined by X-ray crystallography.[2] Figure 1 depicts the structures and numbering schemes for these materials, with the dispositions of the cyclohexane rings being consistent with the X-ray data.

Chemical shifts and coalescence data

These data are collected in Table 1. Chemical shift assignments at 298 K are made as a result of two considerations. Initially, distinction between resonances for CH vs. CH_2 carbons bearing oxygen is made on the basis of results of the APT experiment (7). Distinction between resonances for C-7,10,17,20 vs. C-8,9,18,19 is made subsequently on the basis of the known β-deshielding effect of oxygen on cyclohexyl ring carbon resonances (7).

For **1**, reduction of the temperature produces ^{13}C NMR spectral changes (Fig. 2) consistent with a single degenerate process becoming slow on the NMR time scale. The four-line spectrum at 298 K shows eight lines in the slow exchange limit.

From the coalescence temperatures (T_c) and limiting chemical shift differences in Table 1, one can use the Eyring equa-

tion to calculate $\Delta G^{\ddagger}$, the free energy of activation for the process. The value obtained, 45.9 ± 0.3 kJ/mol, is 3–4 kJ/mol *higher* than that obtained for ring inversion in simple 1,2-disubstituted cyclohexanes (8), or in related dicyclohexano-18-crown-6 (1) and -14-crown-4 systems (2, 3). Apparently the constraints of the smaller bridging units in the dicyclohexano-12-crown-4 ether **1** have introduced additional rigidity into the molecule and hence increased the inversion barrier. We attribute the present results to the degenerate double cyclohexane ring inversion process as depicted below. In the slow exchange limit there is an exceptionally large chemical shift difference of

11.26 ppm between methine carbons bearing oxygen, the more deshielded resonance being attributed to the carbon bearing equatorial oxygen, i.e., C-6,16, by analogy with earlier work (1–3). The most shielded resonance, at $\delta_C = 19.92$, is assigned to C-9,19, which bear a *gauche*-γ relationship to the axial oxygens at positions 2 and 12 respectively (8). The sites that are *trans*-γ to equatorial oxygen, i.e., C-8,18, resonate at δ_C = 25.08 ppm in the slow exchange limit.

For **1**·LiNCS, the data in Table 1 indicate only a minor increase (i.e., <1 kJ/mol) in $\Delta G^{\ddagger}$ for the ring reversal process relative to free **1**. This is in marked contrast to the case for the corresponding isomer in the dicyclohexano-14-crown-4 series (3), where complexation induced an increase of ca. 5 kJ/mol. The X-ray crystallographic data[2] indicate that the four oxygens of the LiNCS complex of **1** do not lie in a plane and hence a less than ideal coordination geometry results. Furthermore, the 12-crown-4 effective cavity diameter is substantially less than that regarded as optimal for Li complexation, so that stabilities of 12-crown-4 lithium complexes are substantially lower than those for the corresponding 14-crown-4 ether systems (5). The less effective complexation of Li^+ by **1** than in the case of the 14-crown-4 analog is further manifest in the spin-lattice relaxation time results (*vide infra*).

For the *cis-anti-cis* isomer **2**, the spectra (Fig. 2) clearly indicate the presence of a second conformation in the low temperature limit. From relative peak intensity measurements, the equilibrium constant K is 2.6 ± 0.3, giving rise, via the equation $-\Delta G^0 = RT \ln K$, to a free energy difference between these forms of 1.5 ± 0.3 kJ/mol at 183 K. It is also evident

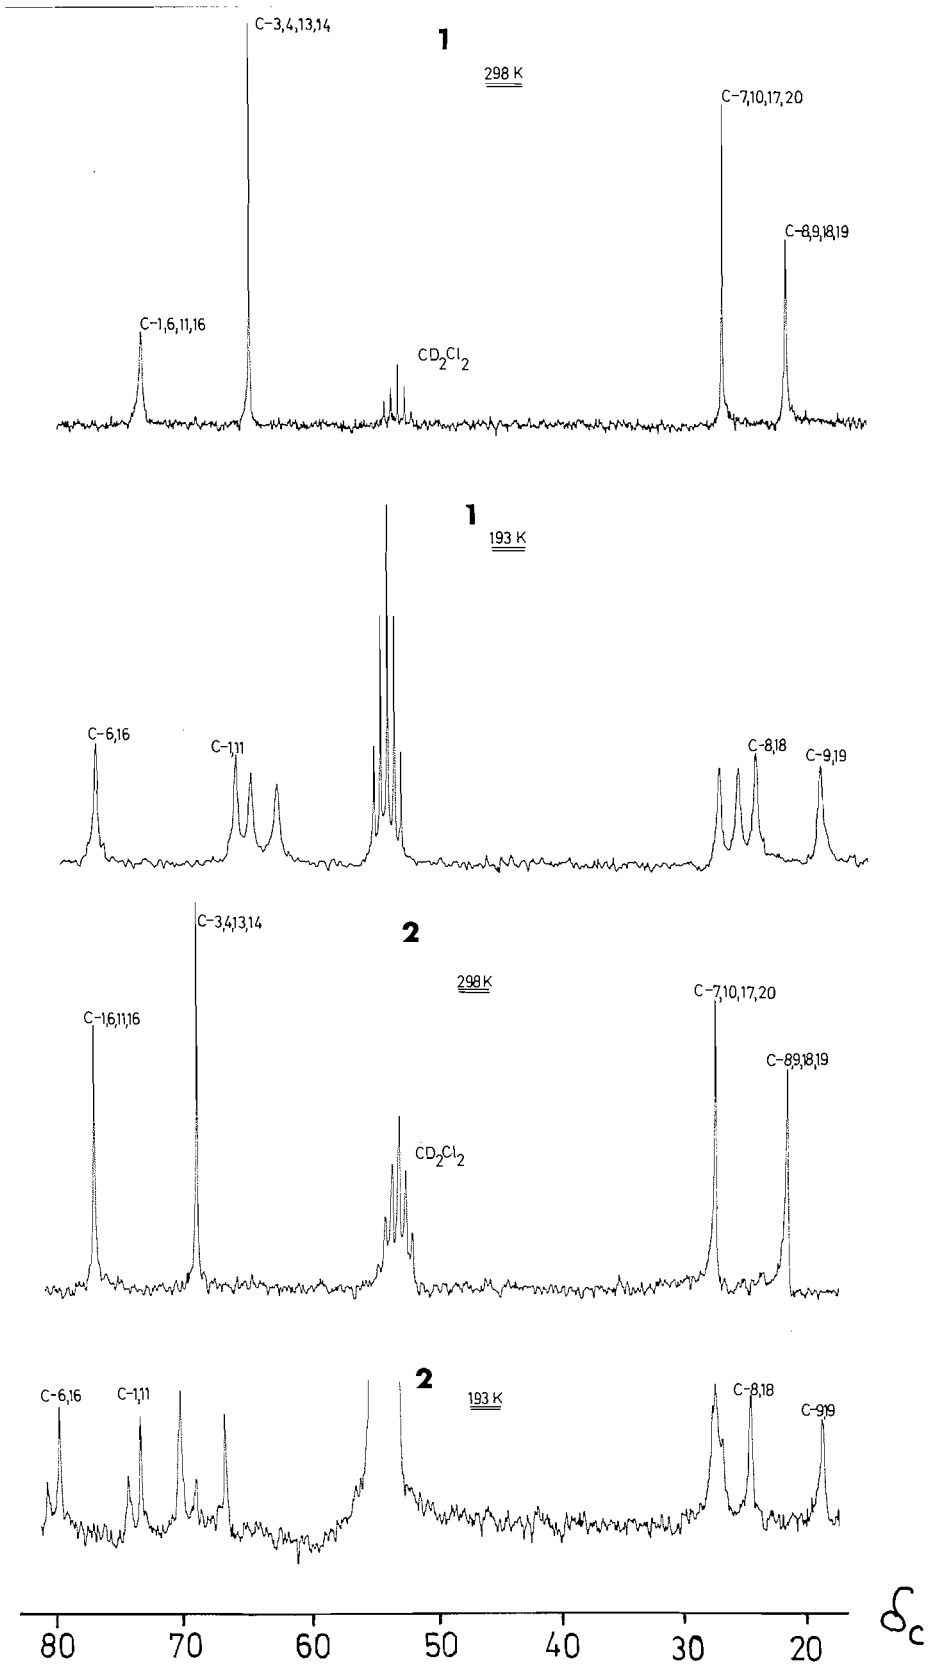
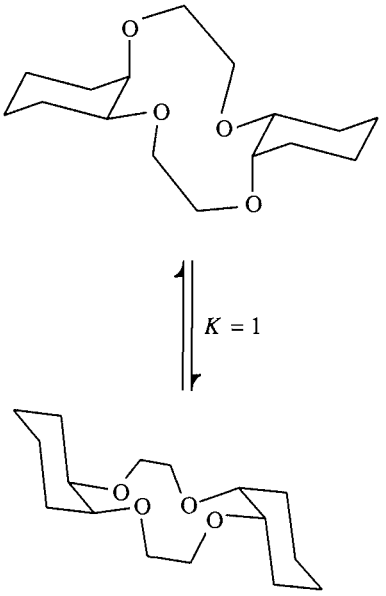
For personal use only.





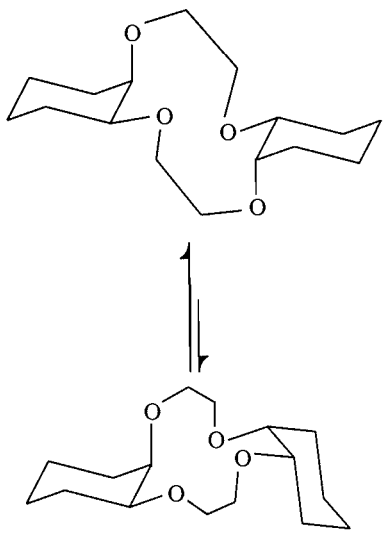


FIG. 2. The 50.3-MHz ^{13}C NMR spectra of **1** and **2** as a function of temperature.

from the spectra that peak overlap or accidental chemical shift equivalence renders the non-degenerate process invisible at the non-oxygenated carbons. For example, the C-8,9,18,19 resonance changes from a single line at 298 K appearing at δ_C = 22.47 to a pair of equal intensity lines at 19.23 and 24.91 ppm in the slow exchange limit. This observation indicates the presence of the degenerate double cyclohexane ring inversion process as depicted in the following scheme.

The free energy of activation for this process in **2** is significantly lower (ca. 4 kJ/mol) than that for **1**. This fact is reflected in the spectra of **1** and **2** at 298 K. There is already evidence of exchange broadening for the C-8,9,18,19 resonance of **1** despite the lower limiting chemical shift difference at this site than is found for **2**.

Although it is difficult to identify unambiguously the nature of the second dynamic process, we tentatively attribute it to the inversion of a single cyclohexane ring, accompanied by a reorganization of the macrocyclic geometry as shown below. The postulated structure of the minor conformation is such that the "chromophoric unit" is 1/2 a molecule, so that 8 carbons are anticipated for it in the limit of slow exchange. Unfortunately, accidental resonance overlap precludes observation of all the anticipated resonances for the conformers of **2**.

An alternative would be to suggest that 12-membered ring pseudorotation was the origin of the spectral changes, with no accompanying cyclohexane ring inversion. For 12-crown-4 itself, two dynamic conformational processes have been detected by low temperature ^1H and ^{13}C spectroscopy (9). The barriers for these processes, however, are ca. 26 and 23 kJ/mol respectively, which are substantially lower than observed in **2**. Accordingly, we suggest that it is the cyclohexane ring inversion that is rate limiting in the present case, with internal conformational changes in the 12-membered central ring remaining fast on the NMR time scale at 183 K. Notably, ΔG^0 of 1.5 kJ/mol between conformations of **2** is nearly identical to that found for the *cis-anti-cis* isomer of dicyclohexano-14-crown-4, a case where the nature of the second ring reversal process can be unambiguously identified (2, 3).

TABLE 2. ^{13}C Spin-lattice relaxation times (T_1)

Compound	Site	T_1 (s)
1	C-1, 6, 11, 16	1.76 ± 0.19
1·LiNCS	C-1, 6, 11, 16	1.29 ± 0.02
2	C-1, 6, 11, 16	2.84 ± 0.17
2 + 1 equiv. LiNCS	C-1, 6, 11, 16	2.06 ± 0.20
1	C-3, 4, 13, 14	0.79 ± 0.11
1·LiNCS	C-3, 4, 13, 14	0.78 ± 0.01
2	C-3, 4, 13, 14	1.72 ± 0.04
2 + 1 equiv. LiNCS	C-3, 4, 13, 14	1.23 ± 0.14
1	C-7, 10, 17, 20	0.82 ± 0.12
1·LiNCS	C-7, 10, 17, 20	0.82 ± 0.02
2	C-7, 10, 17, 20	1.68 ± 0.03
2 + 1 equiv. LiNCS	C-7, 10, 17, 20	1.49 ± 0.16
1	C-8, 9, 18, 19	0.82 ± 0.09
1·LiNCS	C-8, 9, 18, 19	0.76 ± 0.02
2	C-8, 9, 18, 19	1.52 ± 0.03
2 + 1 equiv. LiNCS	C-8, 9, 18, 19	1.42 ± 0.19

The lower ring inversion barriers in **2** relative to **1** and the presence of an additional conformation in **2** leads one to the conclusion that **2** is a more "mobile" species than **1** in solution at 298 K. Spin-lattice relaxation time data (*vide infra*) lend support to this thesis.

Although **2** does not form an isolable LiNCS complex, a solution of **2** containing 1 equivalent of LiNCS has been examined via low temperature ^{13}C NMR to detect any influence that solution interactions with the Li^+ species may have on the stereochemical equilibria. The results are included in Table 1. It is evident that there is only a minor influence on the barrier to degenerate double cyclohexane ring inversion, although the chemical shifts differ substantially between free **2** and the solution containing 1 molar equivalent of LiNCS. The spectra in the low field region do indicate the presence of a second conformation; however, peak overlap precludes determination of the ΔG^0 values between conformers.

^{13}C spin-lattice relaxation times (T_1)

These data were determined by the inversion–recovery method (10) and are presented in Table 2. Measurement of nuclear Overhauser enhancements indicated that spin-lattice relaxation in these molecules is dominated by the dipole–dipole mechanism to the extent of over 90% at all sites. In view of the molecular weights of **1** and **2** it is reasonable to assume that the motional narrowing conditions apply, hence the correlation time τ_c for the C—H vector is proportional to $1/T_1$.

Initially it is of interest to compare the T_1 data for uncomplexed **1** and **2**. At all carbons, the observed T_1's for **2** are substantially longer than for the corresponding carbons of **1**. This indicates a greater degree of mobility in the *cis-anti-cis* isomer **2** than in the *cis-syn-cis* counterpart **1**. Such behavioural differences between these isomers were suggested in the previous discussion, based on the lower ring inversion barriers found for **2** as well as the presence of a second conformational

isomer for **2**, which can be detected at temperatures below 200 K.

For the LiNCS complex of **1**, only the T_1 for the CH carbon bearing oxygen (i.e., C-1,6,11,16) is shortened relative to the data for free **1**. The relaxation times of the other sites are unchanged, indicating little alteration in the motional character of these C—H bonds as a result of lithium complexation. As a consequence of these apparently weak interactions of the lithium ion with **1**, the ring inversion barrier (Table 1) increases to only a minor extent. These findings are in marked contrast to the corresponding isomer in the 14-crown-4 series, where the T_1's were reduced to ca. 50% in the LiNCS complex relative to the free ligand, and lithium complexation increased the ring inversion barrier by ca. 5 kJ/mol (3).

The T_1 results for the solution of **2** and one equivalent of LiNCS indicate that the mobilities of both types of oxygenated carbon have been decreased upon addition of the Li^+ ion. By contrast, the T_1's for the non-oxygenated carbons are, within the limits of uncertainty, essentially identical. Hence there appears to be a weak specific solution binding interaction between **2** and the Li^+ ion despite the fact that no LiNCS or $LiClO_4$ complex is isolable. This weak binding interaction is manifest also in the minor increase in the ring inversion barrier noted for the solution of **2** and LiNCS.

For 12-crown-4 itself in methanol solution, the effects of complexation of Li^+, Ca^{2+}, and Mg^{2+} on the ^{13}C T_1's have been evaluated recently (11). The higher mobility of 12-crown-4 relative to the dicyclohexano analogs **1** and **2** is evident from the observed T_1 of ca. 6 s at 298 K. Upon complexation with LiCl this value is reduced to ca. 3 s, which reflects the expected reduction in the mobility of the crown ether carbons. Complexation effects on the T_1's of **1** and **2** are less pronounced than for 12-crown-4 itself. This is presumably due to the influence of the bulky cyclohexano groups, which prevent a facile reorganization of the 12-membered ring geometry to that most favorable for lithium ion complexation.

The 200-MHz ^1H spectra of **1**, **1**·LiNCS, and **2** are also temperature dependent; however, extensive resonance overlap in the spectra near $\delta = 3.6$ between the cyclohexyl methine protons and the methylene protons on C-3, 4, 13, and 14 precludes any detailed interpretation. It is clear for **2**, however, that the cyclohexyl methine protons decoalesce at a considerably higher temperature than do the methylene protons of the crown ether, and a degenerate process is observed. At 218 K, this is evident from the detection of distinct resonances of equal integrated intensity for the axial and equatorial methine protons with a chemical shift difference of ca. 1 ppm. Hence the ^{13}C NMR evidence for the degenerate double ring inversion in **2** at the higher temperatures is supported by the ^1H results.

At higher fields, i.e., 400 or 500 MHz, it may be possible to obtain useful information regarding the 12-membered ring conformations at lower temperatures in these materials, as has been carried out for 12-crown-4 itself (12) and a 2:1 12-crown-4:NaNCS complex (13). Such experiments are planned.

Experimental

Spectra

The ^{13}C NMR spectra were obtained using a Varian XL-200 spectrometer operating at 40.3 MHz. Sample concentrations were approximately 0.2 M in CD_2Cl_2 solutions contained in 5 mm o.d. tubes. Routinely spectra were recorded with complete ^1H noise decoupling. Normal operating conditions were as follows: sweep width = 5 kHz with 16K data points; pulse width = 6 μs (45°) and a repetition rate of 1.0 s. The number of accumulations for the low temperature spectra was typically 1000–2000. Temperatures were calibrated using a copper–constantan thermocouple in a dummy NMR tube.

For the T_1 measurements, the inversion–recovery sequence (10) was employed and data were processed using the standard XL-200 software.

Materials

Dibenzo-12-crown-4 ether was prepared via the published procedure (5) with the exception of the hydrolysis of 1,2-bis(*o*-methoxyphenoxy)ethane to 1,2-bis(*o*-hydroxyphenoxy)ethane. This was accomplished selectively using the trimethylsilyliodide reagent (14) as described previously (15).

Hydrogenation of dibenzo-12-crown-4 to a mixture of **1** and **2** was accomplished employing an American Instrument Co. 50 000 psi maximum pressure high pressure apparatus (1 psi = 6.9 kPa). A typical procedure follows. In 60 mL of dry 1-butanol was dissolved 2.0 g (0.0074 mol) of dibenzo-12-crown-4 and 0.40 g of 5% ruthenium on alumina catalyst. A pressure of H_2 gas of 1200 psi was used and the reaction was continued for 12 h at a temperature of 120°C. The catalyst was removed by filtration and the butanol by rotary evaporation at 70°C to yield 1.9 g (90%) of a dark oily mixture, which was estimated by ^{13}C NMR to contain two isomers in a ratio of ca. 20:1. Column chromatography was carried out on silica gel (70–230 mesh) with a 30:1 hexane:diethyl ether solvent mixture. Initial fractions contained a ca. 50:50 mixture of isomers while the latter ones contained an essentially pure isomer, mp 69–71°C. This was later shown by X-ray crystallography to be the *cis-syn-cis* compound **1**. The early fractions from several such columns were combined and subsequent column chromatography using the same solvent system yielded the minor (*cis-anti-cis*) isomer **2**, mp 101–103°C.

The LiNCS complex of **1** was prepared according to the following procedure. Equimolar amounts of **1** and LiNCS were dissolved in a minimum volume of dry methanol. Subsequently the solvent was removed via rotoevaporation to yield a thick oil. This oil was dissolved in dry methylene chloride and the solvent was allowed to evaporate slowly to yield white crystals of **1**·LiNCS, mp 202–204°C. The structure of this complex was verified by X-ray crystallography.[2]

Phosphorus-31 solid-state nuclear magnetic resonance study of monophosphazenes

WILLIAM P. POWER, RODERICK E. WASYLISHEN,[1] AND RONALD D. CURTIS
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 21, 1988

WILLIAM P. POWER, RODERICK E. WASYLISHEN, and RONALD D. CURTIS. Can. J. Chem. **67**, 454 (1989).

Simultaneous observation of anisotropic chemical shielding and dipolar coupling in polycrystalline monophosphazenes has been used to obtain information on the $^{31}P-^{14}N$ spin pair. Phosphorus-31 chemical shielding tensor components have been determined; the most shielded component was found to lie along the P=N bond. The $^{31}P-^{14}N$ dipolar coupling constants have provided P=N bond lengths from powder samples, equivalent for all compounds within experimental error; the value obtained for *N*-(triphenylphosphoranylidene)-aniline is in excellent agreement with that obtained in a recent X-ray diffraction study. Features of crystallographic significance have been determined from the solid-state nuclear magnetic resonance spectra for two of the compounds without resorting to diffraction techniques. Information on the magnitude and orientation of the ^{14}N electric field gradient tensor has been inferred from ^{31}P MAS spectra and *ab initio* calculations.

Key words: monophosphazenes, dipolar nmr, ^{31}P chemical shielding anisotropies, solid-state nmr.

WILLIAM P. POWER, RODERICK E. WASYLISHEN et RONALD D. CURTIS. Can. J. Chem. **67**, 454 (1989).

Dans le but d'obtenir de l'information sur la paire de spin $^{31}P-^{14}N$, on a observé simultanément le blindage chimique anisotropique et le couplage dipolaire de monophosphazènes polycristallins. On a déterminé les composantes du tenseur du blindage chimique du phosphore-31; la composante la plus blindée se trouve le long de la liaison P=N. Utilisant les constantes de couplages dipolaires $^{31}P-^{14}N$ déterminées à partir d'échantillons de poudres, on a pu évaluer les longueurs des liaisons P=N qui sont équivalentes pour tous les composés, aux erreurs expérimentales près; la valeur obtenue pour la *N*-(triphénylphospharanylidène)-aniline est en excellent accord avec celle qui a été obtenue dans une étude récente de diffraction des rayons-X. Sans recourir à des techniques de diffraction, mais en faisant appel à leurs spectres en résonance magnétique nucléaire, on a pu déterminer des caractéristiques cristallographiques importantes pour deux des composés. En se basant sur les spectres MAS du ^{31}P et des calculs *ab initio*, on a pu déduire des informations sur l'amplitude et l'orientation du tenseur du gradient du champ électrique du ^{14}N.

Mots clés : monophosphazènes, rmn dipolaire, anisotropies du blindage chimique de ^{31}P, rmn de l'état solide.

Introduction

Recent advances in the study of polycrystalline solids by nmr have led to an increase in the use of this technique to elucidate the structural and electronic characteristics of biological (1–5), organic (6–10), inorganic (11,12), and polymeric compounds (13, 14). In principle, the nmr spectrum of a solid contains much more information on the chemical nature of a compound than the corresponding solution spectrum. The solid-state spectrum defines the orientation dependence of various interactions, which in solution are either observed simply as their isotropic average, or not observed at all (15, 16).

In the simplest experiment, an isolated spin 1/2 nucleus is studied yielding its chemical shielding anisotropy, which arises from variations in the electronic screening of the nucleus with changes in the orientation of the molecule in the magnetic field (16). However, for powder samples, only the magnitudes of the principal components of the chemical shielding tensor are obtained and no information on the orientation of the tensor can be determined from an experiment of this type. Previously, the only methods by which the orientation could be derived were symmetry arguments, in favorable cases, or time-consuming single crystal analysis (17–20).

Recently, however, there have been several reports of determination of the orientation of the shielding tensor from a single experiment (1–14). This has been accomplished by studying an isolated spin pair where dipolar coupling exists between the two nuclei. The dipolar coupling is manifested in the overall lineshape, and provides a molecular frame of reference about which the chemical shielding tensor of one of the nuclei can be oriented.

Using this technique, we report both the magnitude of the principal components and the orientations of previously undetermined phosphorus-31 shielding tensors, as well as P=N bond lengths, in a series of monophosphazenes (**1**–**4**) by analysis of the solid-state ^{31}P spectra for a $^{31}P-^{14}N$ spin pair. With the exception of the diatomic molecule, PN (21), the anisotropy of ^{31}P shielding in compounds containing phosphorus–nitrogen bonds has not been previously investigated (22). The monophosphazene system is composed of a phosphorus(V) centre double-bonded to a nitrogen, and is of some importance with the recent development of inorganic polymers such as polyphosphazene (23).

Theory

For an isolated $^{31}P-^{14}N$ spin pair, the ^{31}P nmr frequencies depend on the strength of the applied static magnetic field, B_0, the ^{31}P chemical shielding tensor, σ, and the magnitude of the $^{31}P-^{14}N$ dipolar coupling (16, 24). Work in our laboratory has described a theoretical treatment for such a spin 1/2 – spin 1 system (in that study, $^{13}C-^{14}N$) in the case of axial symmetry in the spin 1/2 chemical shielding where the unique axis of the shielding tensor is constrained to lie along the internuclear vector (25). Following that notation, the phosphorus spin Hamiltonian is given by

$$[1] \quad h^{-1}H = -\nu_P[1 - \sigma_{iso} + \Delta\sigma(1/3 - \cos^2\theta)]\hat{I}_z + R[(1 - 3\cos^2\theta)\hat{I}_z\hat{S}_z - (3\sin\theta\cos\theta)\hat{I}_z\hat{S}_x]$$

where

$$[2] \quad \nu_P = (\gamma_P/2\pi)B_0$$

$$[3] \quad \sigma_{iso} = (\sigma_{||} + 2\sigma_{\perp})/3$$

$$[4] \quad \Delta\sigma = \sigma_{||} - \sigma_{\perp}$$

and

$$[5] \quad R = \frac{\gamma_P\gamma_N\hbar}{2\pi}\left\langle\frac{1}{r_{PN}^3}\right\rangle\frac{\mu_0}{4\pi}$$

θ is the angle between the applied magnetic field and the internuclear dipolar vector, and r_{PN} is the P=N bond length.

However, eq. [1] does not hold in the case of nonaxial symmetry in the chemical shielding of the ^{31}P nucleus, nor when the internuclear vector does not lie along the unique shielding axis. Analysis of such cases has been performed on spin 1/2–spin 1/2 systems (e.g., $^{13}C-^{15}N$ spin pairs) to yield a completely general treatment when both chemical shielding and dipolar coupling are present (1, 3, 6, 26). If this treatment is extended along the lines of the previous work but now including nonaxially symmetric chemical shielding and allowing the internuclear vector to assume any orientation relative to the shielding tensor, new expressions are obtained. Following the method of Valentine *et al.* (1), the chemical shielding and dipolar interactions are given respectively by

$$[6] \quad \nu_{CS} = (\gamma_P/2\pi)B_0\{1 - [\sigma_{11}\sin^2\theta\cos^2\phi + \sigma_{22}\sin^2\theta\sin^2\phi + \sigma_{33}\cos^2\theta]\}$$

$$[7] \quad \nu_D = R[1 - 3(\sin\beta\sin\theta\cos(\phi - \alpha) + \cos\beta\cos\theta)^2]$$

where θ and ϕ are the polar and aximuthal angles relating the applied magnetic field to the chemical shielding tensor (see Fig. 1). The angles α and β relate the orientation of the chemical shielding tensor to the internuclear vector, in this case the P=N bond, thus providing a molecular frame of reference. The principal components of the shielding tensor, σ_{11}, σ_{22}, and σ_{33}, can be expressed in terms of chemical shifts, δ_{ii}'s, from the isotropic resonance of a suitable reference compound with values increasing to higher frequency such that $\delta_{11} > \delta_{22} > \delta_{33}$. Note that δ_{11} corresponds to σ_{11} using this convention.

To simulate the experimental spectra, the chemical shielding and dipolar contributions to the spectrum are given by eqs. [6] and [7] and combine as

$$[8] \quad \nu_m = \nu_{CS} - m_N\nu_D$$

where $m_N = -1, 0, +1$, the three possible spin states of ^{14}N. Subspectra corresponding to each of these states were obtained by integration over the angles θ and ϕ in one-degree intervals and then summed to give the total lineshape. A Gaussian broadening function, $g(\nu)$, was also included to account for residual line broadening inherent in the experiment. This allows a better fit between the simulated and experimental spectra, giving as the final operative equation

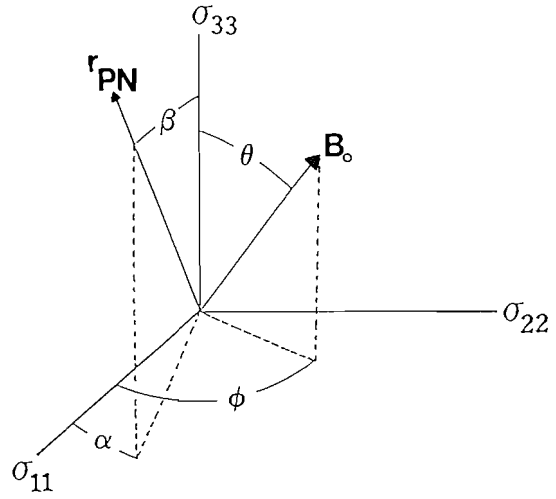

FIG. 1. The magnetic field vector, B_0, and the internuclear dipolar vector, r_{PN}, in the principal axis system of the chemical shielding tensor.

$$[9] \quad I(\nu) = \sum_{-I}^{+I}\int_0^{\pi/2}\int_0^{2\pi} g(\nu - \nu_m)\sin\theta\,d\theta\,d\phi$$

For the general case we have just treated, where the shielding is now no longer axially symmetric, the chemical shielding anisotropy is most conveniently expressed as the width of the entire lineshape, i.e.,

$$[10] \quad \Delta\sigma = \sigma_{33} - \sigma_{11} = \delta_{11} - \delta_{33}$$

and the asymmetry parameter, η, follows the usual convention as described by Spiess (27), Haeberlen (28), and others.

In this analysis, it has been assumed that the ^{14}N Zeeman spin functions are valid spin functions for this system. This may not be true, depending on the relative magnitude of the applied magnetic field and the ^{14}N nuclear quadrupole interaction. If the magnitude of the latter interaction is on the order of the ^{14}N Zeeman interaction, the high-field approximation breaks down and the Zeeman spin functions mix, introducing distortions in the nmr lineshape calculated from eq. [8]. Stoll *et al.* (29) have shown that provided the ratio of the ^{14}N Larmor frequency, $\nu_N = \gamma_N B_0/2\pi$, to the ^{14}N quadrupolar coupling constant, χ, is greater than 4, the high-field approximation results in relatively small errors when calculating the lineshape. If the electric field gradient (efg) is axially symmetric with the largest component oriented along the dipolar vector, the apparent dipolar splitting extracted from the spin 1/2 powder pattern corresponding to the $\theta = 0°$ and 90° orientations will have a negligible error provided $\nu_N/\chi \geq 3$ (25). Although nuclear quadrupolar coupling constants are unavailable for the ^{14}N of a P=N fragment, values are available for HN=SOF_2 (30), where the ^{14}N nuclear quadrupole coupling constant, χ, is 3.59 MHz. It is unlikely that χ in the monophosphazenes exceeds 4.0 MHz (*vide infra*), in which case $\nu_N/\chi \geq 3.6$.

TABLE 1. Principal components of the ^{31}P chemical shift tensor (ppm),[a] $^{31}P-^{14}N$ direct dipolar coupling constants (Hz), P=N bond lengths (Å), and the angles α and β (deg)

Compound	δ_{11}	δ_{22}	δ_{33}	δ_{iso}[b] Solid	δ_{iso}[b] Solution	Δσ	η	R[c]	r_{PN}	α[d]	β[d]
1	50	31	−85	−1 (−0.3)	−1.2	135	0.23	859	1.60	0	0
2	69	29	−72	9 (8.1)	−1.8	141	0.50	888	1.58	0	0
3	48	31	−91	−4 (−2.5, −4.8)	−2.1	139	0.20	875	1.59	0	0
4	49	35	−91	−2 (−1.7)	−1.7	140	0.16	889	1.58	0	0

[a]The shift tensor components can be converted to an absolute shielding scale as follows (22*b*): $\sigma_{ii}(^{31}P)$ = 356 ppm − $\delta_{ii}(^{31}P)$. The error in the reported ^{31}P chemical shift components is ±2 ppm. These values have not been corrected for bulk susceptibility effects.

[b]The values in parentheses were obtained from CP/MAS experiments. The error in the solid δ_{iso} is ±2 ppm, and ±0.2 ppm for the MAS and solution values.

[c]The error in the dipolar coupling constant is ±40 Hz, corresponding to ±0.02 Å for r_{PN}.

[d]The error in the angles α and β is estimated to be less than 10°.

Experimental

Compounds **1**–**4** were obtained from Aldrich Chemical Company and the Alfred Bader Library of Rare Chemicals. The compounds (approximately 0.3 g) were packed in aluminum oxide rotors under a nitrogen atmosphere. Solid-state spectra were recorded on a Bruker MSL-200 nmr spectrometer operating at 200.106 MHz for ^{1}H and 81.005 MHz for ^{31}P. All spectra were accumulated with high-power proton decoupling and cross-polarization. The $\pi/2$ pulses were 4.0 μs. The magic angle sample spinning (MAS) spectra were typically run with spinning rates of 3.0–3.5 kHz in a double-bearing axial spinner probe. All solid-state ^{31}P spectra were referenced to external $NH_4H_2PO_4$, which has a chemical shift of +1.0 ppm with respect to 85% H_3PO_4. Cross-polarization contact times were optimized for each compound in the MAS experiments, and were between 1.3 and 1.8 ms. Flipback of the ^{1}H magnetization was used to increase the sensitivity of the experiment (31). Recycle times were typically 50 s for both the static and MAS spectra. Normally, 32 scans were recorded for the MAS spectra, while up to 800 scans were recorded for some of the static spectra. Solution spectra were recorded on a Nicolet NB-360 spectrometer, operating at 146.15 MHz for ^{31}P. Solutions were 0.010 M in diethyl ether, with external 85% H_3PO_4 as the reference standard.

Simulations were performed using a computer program written in this laboratory based on the treatment outlined in the theory section. Computations were carried out an a VAX 8800 computer and a Perkin–Elmer 3230 computer, with plotting performed on Hewlett–Packard HP 7475A and Nicolet Zeta-12 plotters.

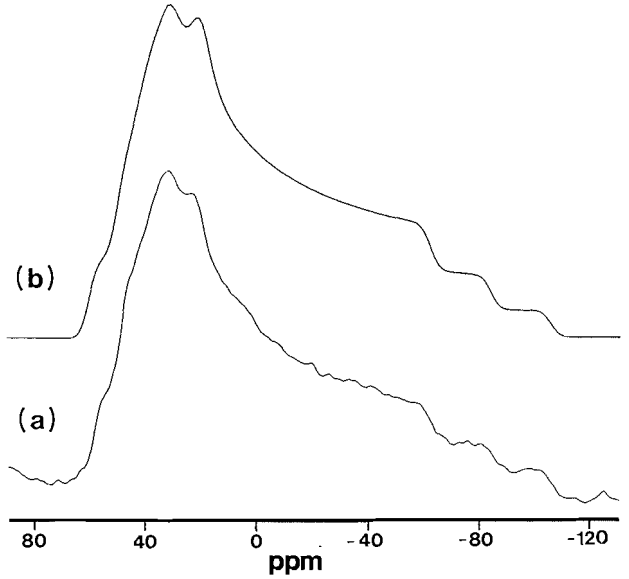

FIG. 2. Experimental (a) and simulated (b) ^{31}P powder spectra of the parent compound, **1**. The simulated spectrum included 200 Hz of Gaussian broadening to fit the experimental spectrum. This large line broadening results from $^{31}P-^{31}P$ intermolecular dipolar interactions.

Results and discussion

A ^{31}P nmr powder pattern typical of those obtained in these experiments is illustrated in Fig. 2(a) for **1**, the parent compound. This lineshape arises from the orientation dependence of both the chemical shift and the direct $^{31}P-^{14}N$ dipole–dipole interaction. Dipolar coupling with the ^{14}N splits the spectrum into three subspectra corresponding to each of the nitrogen spin states ($m_N = -1, 0, +1$). This splitting is clearly visible at the low frequency end of the spectrum. Shown in Fig. 2(b) is the simulation of the ^{31}P nmr spectrum for **1**. The simulation allows precise determination of the shift tensor components, the dipolar coupling constant (hence the P=N bond length), and the relative orientations of the principal components of these two interactions, a factor to which the lineshape is quite sensitive. The results from such analyses for compounds **1**–**4** are given in Table 1.

The parent compound, **1**, shows several characteristics that are consistent throughout this series of compounds. In all cases, the most shielded component of the chemical shift tensor, δ_{33}, was found to lie along the P=N bond. This indicates that the phosphorus nucleus is most shielded when the P=N bond axis is parallel to the applied magnetic field, B_0, a result in accord with other $R_3P{=}X$ systems, where X = O, S, and Se (32–34). However, the asymmetry in the shielding, η, is substantially greater for **1**–**4**, as would be expected for an asymmetric substituent like X = N—Ph. While the chemical shielding anisotropy varies little in this series, it is only 70% of that observed for $Ph_3P{=}O$ in the solid state (32–34) and is even less

than those for the corresponding sulfide and selenide compounds (33, 34).

The bond lengths we report for these compounds (**1–4**) were derived from the dipolar coupling constants and are equivalent for all four phosphazenes within experimental error. Note that these are determined from powder samples; there is no need for single crystals in this analysis. A recent X-ray diffraction study of **1** (35) has reported a P=N bond length of 1.602 Å, in excellent agreement with the value given here. Crystallographic data on other related compounds (36–38) establish a range of 1.55–1.61 Å for P=N bond lengths, indicating that those reported here are well within the expected limits. In determining bond lengths from dipolar coupling constants it is sometimes necessary to include contributions from anisotropy in the indirect (J) coupling (24). The small value for $J(^{31}P^{15}N)_{iso}$ in **1**, 32.9 Hz (39), leads one to expect negligible influence from such effects, so it could be safely ignored in this analysis.

Although there are general consistencies for these compounds, one obvious difference is present for the *ortho*-methyl substituted compound, **2**. The asymmetry in the ^{31}P shielding for this molecule is over twice as large as any of the other three. The two extreme components of the shielding, δ_{11} and δ_{33}, are substantially deshielded, leading to a 10-ppm shift to higher frequency for δ_{iso}. It should be noted that this is a solid-state effect; δ_{iso} for **2** in solution is similar to those for the other compounds. Presumably the *ortho*-methyl substitution has affected the crystal packing of this molecule, possibly by tilting the N-phenyl ring out of the PNC plane. However, as there are to our knowledge no available crystal structures of this compound, such conclusions are simply speculation at this point.

It has been possible to establish some crystallographic information for the *meta*-methyl substituted compound, **3**. Inspection of the ^{31}P MAS spectra for **2** and **3** (Figs. 3(a) and (b), respectively) indicates an apparent reversal in the intensity of the 2:1 "doublet" for **3**. Note that for compounds **1**, **2**, and **4** the asymmetric doublet had the same relative orientation. This asymmetric doublet has proven useful in elucidating structural characteristics for $^{13}C,^{14}N$ spin pairs (40–43), and results from a breakdown of the high-field approximation for the ^{14}N in the MAS technique. Under these conditions, magic angle sample spinning no longer completely suppresses the direct dipolar interaction involving ^{14}N and the splitting of the asymmetric doublet depends, among other things, on the orientation and magnitude of the ^{14}N efg tensor (40). It is unlikely that these parameters for the ^{14}N efg tensor in **3** would differ substantially from the corresponding values in **1**, **2**, and **4**; thus the apparent reversal of the asymmetric doublet for **3** must have a different origin. Notice, however, that a shoulder is present on the high frequency side of the doublet, indicating the possibility of nearly coincident resonances arising from magnetically nonequivalent molecules present in the unit cell. A subsequent ^{13}C MAS spectrum for **3** revealed a doubling of the methyl resonance, confirming this explanation. The utility of MAS experiments in identifying such crystal features has been pointed out recently by Harris *et al.* (44). To our knowledge, there have been no diffraction studies of this compound; however, it is unlikely that the nonequivalent molecules differ much in their overall shielding characteristics as the static ^{31}P powder pattern of **3** could be analyzed in terms of a single crystallographic site.

As previously mentioned, the asymmetric doublet observed in the ^{31}P MAS spectra contains information on the magnitude and orientation of the ^{14}N electric field gradient tensor, which should allow one to validate the high-field approximation. As there appear to be no values for this interaction in a ^{14}N=P(V) system available in the literature, estimates were derived from *ab initio* calculations and experimental values for a similar compound, HN=SOF_2 (30), where nitrogen is double bonded to a second row element, sulfur. Calculations were performed on this compound and on HN=PH_3 using the GAMESS *ab initio* calculation package (45) with 6-31G basis sets, to determine the characteristics of the ^{14}N efg tensor in both these compounds. It was found that while the orientation for the efg tensor was fairly accurately predicted by theory for HN=SOF_2 (within 10°), the magnitude of the principal component was overestimated by roughly 40%, common in such treatments when second row elements are involved (46). Subsequently the results for HN=PH_3 were used to establish the orientation of the ^{14}N efg tensor, and the magnitude was scaled according to the relationship between those for the experimental and calculated values for NH=SOF_2. This led to values for the HN=PH_3 system of χ = 3.17 MHz and η = 0.92. The calculated orientation placed the largest principal component of the efg tensor 17° from the P=N bond, with the smallest component lying roughly along the N—H bond. This is the same orientation that was determined experimentally for HN=SOF_2 (30). This information was then used to simulate the ^{31}P MAS

spectrum of **1** using reported routines (40), and a splitting of 154 Hz was calculated, compared to 140 ± 20 Hz observed. In this case, the ratio $\nu_N/\chi = 4.56$; thus for the analysis of the static spectrum, any error introduced by not accounting for the effect of the ^{14}N efg is negligible. While the number of parameters in these simulations does not allow a precise determination of the ^{14}N efg tensor for this system, it does provide a reliable estimate based on both theoretical and experimental methods.

There have been relatively few theoretical treatments of ^{31}P chemical shielding, most concentrating on P(III) species (47–51), while the majority of the experimental studies have been on phosphate and phospholipid systems that do not portray any similarities to the monophosphazenes. For P(III) species, the presence of the lone pair has a very substantial effect on the shielding of the phosphorus nucleus, an effect that is noticeably absent in the compounds studied here. In a recently investigated diphosphene (12), a chemical shielding anisotropy of 1239 ppm was reported, with the direction of greatest shielding not along the P═P bond, but perpendicular to the plane of the molecule, resembling the ^{13}C shielding for carbon nuclei involved in π-bonds (double bonding) of organic molecules (27). Theoretical (47) and experimental (21) work on the diatomic PN indicates an even larger anisotropy of 1376 ppm. Clearly the paramagnetic contribution to the ^{31}P shielding coming from the lone pair on the phosphorus is considerable, leading to the large observed anisotropies, though this is often overestimated by theory, as for ^{15}N in diazenes (52, 53).

In conclusion, the ^{31}P chemical shielding anisotropies observed for the monophosphazenes, approximately 140 ppm, are relatively small compared to those observed in P(III) compounds in which the phosphorus is involved in multiple bonding. As well, the orientation of the shift tensor is markedly different between the P(III) and P(V) oxidation states. The $\Delta\sigma$ values in **1**–**4** are comparable but slightly smaller than the values observed for analogous P(V) compounds where phosphorus forms a double bond to one of the chalcogens (O, S, and Se). It is hoped that the ^{31}P shielding constants reported here will stimulate the interest of theoretical chemists in understanding ^{31}P shielding in phosphorus(V) compounds. Also, the direct measurement of ^{14}N nuclear quadrupolar coupling constants and their orientation in monophosphazenes would clearly be of interest.

On the shape of spherically averaged Fermi-hole correlation functions in density functional theory. 1. Atomic systems

VINCENZO TSCHINKE AND TOM ZIEGLER[1]

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 27, 1988

VINCENZO TSCHINKE and TOM ZIEGLER. Can. J. Chem. **67**, 460 (1989).

We have compared, for atomic systems, the spherically averaged Fermi-hole correlation function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ in the Hartree–Fock theory with the corresponding function $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ employed in local density functional theory. It is shown that, in contrast to $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, the function $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ behaves qualitatively incorrectly at positions r_1 of the reference electron far from the nucleus. Furthermore, we have shown that the qualitatively incorrect behaviour of $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ can be remedied by an approximate expansion of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ in powers of s, where s is the inter-electronic distance. However, such an expansion must be conducted in two regions due to the discontinuity of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ as a function of s at the atomic nucleus. Based on the two-region expansion of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, we have developed an alternative approximate density functional expansion $\bar{\rho}_{PW}^{\alpha\alpha}(r_1, s)$ for the spherically averaged Fermi-hole correlation function. The corresponding exchange energy density functional yields values for the exchange energies of atoms in good agreement with Hartree–Fock results.

Key words: atomic exchange energy, density functional theory, Fermi hole.

VINCENZO TSCHINKE et TOM ZIEGLER. Can. J. Chem. **67**, 460 (1989).

Dans le cas de systèmes atomiques, on a comparé la moyenne sphérique de la fonction de corrélation de trou de Fermi $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ dans la théorie de Hartree–Fock avec la fonction correspondante $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ utilisée dans la théorie fonctionnelle de la densité locale. On démontre que, par rapport à la fonction $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, la fonction $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ se comporte qualitativement d'une façon incorrecte aux positions r_1 de l'électron de référence éloigné du noyau. De plus, on a démontré que l'on peut remédier au comportement qualitativement incorrect de la fonction $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ en utilisant une extension approximative de la fonction $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ en puissances de s, où s est la distance inter-électronique. Toutefois, à cause de la discontinuité de la fonction $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ comme fonction de s au niveau du noyau atomique, on doit procéder cette extension dans deux régions. En se basant sur une extension de la fonction $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ dans deux régions, on a développé une autre expression approximative de la densité fonctionnelle, $\bar{\rho}_{PW}^{\alpha\alpha}(r_1, s)$ qui peut s'appliquer comme moyenne sphérique de la fonction de corrélation de trou de Fermi. La densité fonctionnelle correspondante de l'énergie d'échange fournit des valeurs pour les énergies d'échange des atomes qui sont en bon accord avec les résultats de Hartree–Fock.

Mots clés : énergie d'échange des atomes, théorie fonctionnelle de la densité, trou de Fermi.

[Traduit par la revue]

I. Introduction

Hohenberg and Kohn (1) demonstrated in 1964 that the ground-state energy of an electronic system is an unique (albeit unknown) functional of the electron density. This remarkable theorem gave credence to previous work by Slater (2) and others (3), and initiated an extensive study (4, 5) into the relation between electronic energy and electron density, a field that now has become known as (energy) density functional theory.

In the last 15 years, due to a number of innovative implementations (6), it has become possible to carry out calculations based on approximate density functionals. Of the various approximate density functional methods, the Hartree–Fock–Slater (or Xα) scheme (7) is by far the most commonly used in chemistry. The accumulated experience with the HFS method seems to indicate that geometrical parameters (8), force constants (9), and spectroscopic energy differences (5*p*, 10) (ionization potentials and excitation energies) are in good to fair agreement with experiment. However, bond energies (8*a*–*b*, 11*a*) are not in general well represented by the HFS method as indicated in Table 1, where several of the theoretical values obtained from HFS calculations typically are too high in comparison with experiment.

The slightly more elaborate Local Spin Density method (LSD) (5*p*) provides geometrical parameters comparable to those obtained from HFS calculations (8*a*), whereas ionization potentials and excitation energies from LSD calculations (12) compare somewhat better with experiment than the corresponding HFS results. However, the LSD method does not uniformly improve (12) the quality of the calculated bond energies as indicated in Table 1.

The spherically averaged Fermi-hole correlation functions $\bar{\rho}_x^{\gamma\gamma}$ (to be defined in the next sections, with $\gamma\gamma = \alpha\alpha$ or $\beta\beta$) completely determine the exchange energies $E_x^{\gamma\gamma}$, one of the fundamental components of the total energy of an electronic system. Furthermore, the functions $\bar{\rho}_x^{\gamma\gamma}$ contain information on the correlated motion of like-spin electrons and several important properties of $\bar{\rho}_x^{\gamma\gamma}$ can be derived from general physical arguments. The functions $\bar{\rho}_x^{\gamma\gamma}$, and as a consequence, $E_x^{\gamma\gamma}$ are in the HFS and the LSD methods represented simply as local functions of the electron density, and most attempts to improve upon the two methods have involved the inclusion of correction terms depending on derivatives of the electron density in the representation of $E_x^{\gamma\gamma}$. However, in earlier investigations (13) the forms chosen for such correction terms were based on dimensional arguments rather than on an analysis of the functions $\bar{\rho}_x^{\gamma\gamma}$. Also, the expression for $E_x^{\gamma\gamma}$ in terms of electron-density derivatives, known as the gradient expansion of $E_x^{\gamma\gamma}$ or the non-local representation of $E_x^{\gamma\gamma}$, has met with considerable criticism (7), and it has been claimed that the gradient expansion of $E_x^{\gamma\gamma}$ in fact is divergent. It has been shown further (14) that potentials, $U_x^{\gamma\gamma}$, derived from the gradient expansion of $E_x^{\gamma\gamma}$ in certain cases are divergent.

In an important recent development, Becke (15*a*) has derived the lowest order gradient corrections to $\bar{\rho}_x^{\gamma\gamma}$, by expanding $\bar{\rho}_x^{\gamma\gamma}$ in powers of the inter-electronic distance s. This expansion affords in a transparent way a non-local expression for $E_x^{\gamma\gamma}$ in terms of electron density derivatives. Becke (15*c*) was in addition able to avoid divergencies of the related coulomb potentials $V_x^{\gamma\gamma}$,

due to $\bar{\rho}_x^{\gamma\gamma}$, by introducing an empirical cut-off factor, $f_x^{\gamma\gamma}$, in the exchange energy expansion. Bond energies (11, 12) based on Becke's functional are displayed in Table 1, and it follows from Table 1 that the result from Becke's functional constitute a significant improvement over the bond energies derived from HFS and LSD calculations. Other recently derived non-local density functionals (16) also seem to provide bond energies of high accuracy.

In view of the important role played by $\bar{\rho}_x^{\gamma\gamma}$ in density functional theory, we shall here initiate a detailed study of the spherically averaged Fermi-hole correlation functions $\bar{\rho}_x^{\gamma\gamma}$ (17). The present investigation (Section III) will be restricted to atomic systems for which $\bar{\rho}_x^{\gamma\gamma}$ is represented with high accuracy within the HF approximation. Section III provides further a similar analysis of the spherically averaged Fermi-hole correlation functions $\bar{\rho}_{x\alpha}^{\gamma\gamma}$ in the HFS (or Xα) theory, with special emphasis on the shortcomings of $\bar{\rho}_{x\alpha}^{\gamma\gamma}$ as a result of the simple local representation in terms of the electronic density. The expansion of $\bar{\rho}_x^{\gamma\gamma}$ in powers of s is discussed in Section IV and the origin of the divergent behaviour of $V_x^{\gamma\gamma}$ and the cut-off function $f_x^{\gamma\gamma}$ in Section VI. Finally, after an analysis of Becke's functional (Section V), we provide an alternative non-local representation of $\bar{\rho}_x^{\gamma\gamma}$ in Section VII.

II. The hole correlation functions

The total energy of a n-electron system can be expressed (18) in terms of the hole correlation functions $\rho_x^{\gamma\gamma'}(\boldsymbol{r}_1, \boldsymbol{r}_2)$ ($\gamma = \alpha, \beta$; $\gamma' = \alpha, \beta$), the one electron density matrix $\rho_1(\boldsymbol{r}_1, \boldsymbol{r}')$, and the one-electron density $\rho_1(\boldsymbol{r}_1)$, as

$$[1] \qquad E = \int_{r_1' \rightarrow r_1} h(\boldsymbol{r}_1)\rho_1(\boldsymbol{r}_1, \boldsymbol{r}_1')\delta\boldsymbol{r}_1 + \frac{1}{2}\int\frac{\rho_1(\boldsymbol{r}_1)\rho_1(\boldsymbol{r}_2)}{|\boldsymbol{r}_2 - \boldsymbol{r}_1|}\delta\boldsymbol{r}_1\delta\boldsymbol{r}_2 + \sum_{\gamma=\alpha}^{\beta}\sum_{\gamma'=\alpha}^{\beta} E_x^{\gamma\gamma'}$$

where

$$[2] \qquad E_x^{\gamma\gamma'} = -\frac{1}{2}\int\frac{\rho_1^{\gamma}(\boldsymbol{r}_1)\rho_x^{\gamma\gamma'}(\boldsymbol{r}_1, \boldsymbol{r}_2)}{|\boldsymbol{r}_2 - \boldsymbol{r}_1|}\delta\boldsymbol{r}_1\delta\boldsymbol{r}_2$$

and $h(\boldsymbol{r}_1)$ is the sum of the one-electron operators representing the kinetic energy of electron i and the attraction between electron i and the nuclei.

In the next sections we shall be dealing extensively with the spherically averaged hole correlation functions (19–21) $\bar{\rho}_x^{\alpha\alpha}$, $\bar{\rho}_x^{\alpha\beta}$, $\bar{\rho}_x^{\beta\alpha}$, $\bar{\rho}_x^{\beta\beta}$, in which all information about the relative orientation of two electrons at the fixed interelectronic distance $s \equiv |\boldsymbol{s}| = |\boldsymbol{r}_2 - \boldsymbol{r}_1|$ has been integrated out. The spherically averaged hole-correlation functions are defined (19–21) as

$$[3] \qquad \bar{\rho}_x^{\gamma\gamma'}(\boldsymbol{r}_1, s) = \frac{1}{4\pi}\int\rho_x^{\gamma\gamma'}(\boldsymbol{r}_1, \boldsymbol{r}_1 + \boldsymbol{s})\delta\Omega_s \qquad \text{with } \gamma = \alpha, \beta \text{ and } \gamma' = \alpha, \beta$$

where we have introduced the variable transformation $\boldsymbol{r}_2 = \boldsymbol{r}_1 + \boldsymbol{s}$, see Fig. 1*a*. The spherically averaged hole correlation functions $\bar{\rho}_x^{\gamma\gamma'}$ are useful since they, as discussed by Gunnarsson *et al.* (19–21), completely determine the expectation value of a scalar two-electron operator such as $1/|\boldsymbol{r}_2 - \boldsymbol{r}_1| = 1/s$. Thus, for $E_x^{\gamma\gamma'}$ of eq. [2] one has

$$[4] \qquad E_x^{\gamma\gamma'} = -2\pi\int\frac{\rho_1^{\gamma}(\boldsymbol{r}_1)\bar{\rho}_x^{\gamma\gamma'}(\boldsymbol{r}_1, s)}{s}(s^2\delta s)\delta\boldsymbol{r}_1$$

The spherically averaged hole correlation function $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$ is, Fig. 1*b*, centred around the reference electron at position $\boldsymbol{r}_1$. The function $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$ will to a larger or smaller extent exclude another electron of the same spin from approaching the reference electron at the distance $s = |\boldsymbol{r}_2 - \boldsymbol{r}_1|$, see Fig. 1*b*.

We shall on occasions write $E_x^{\gamma\gamma'}$ as

$$[5a] \qquad E_x^{\gamma\gamma'} = \frac{1}{2}\int\rho_1^{\gamma}(\boldsymbol{r}_1)V_x^{\gamma\gamma'}(\boldsymbol{r}_1)\delta\boldsymbol{r}_1$$

where

$$[5b] \qquad V_x^{\gamma\gamma'}(\boldsymbol{r}_1) = -4\pi\int\frac{\rho_x^{\gamma\gamma'}(\boldsymbol{r}_1, s)}{s}s^2\delta s$$

is the coulomb *potential* due to the spherically averaged hole correlation function $\rho_x^{\gamma\gamma'}(\boldsymbol{r}_1, s)$.

For the simple HF theory, where the many-electron wave function Ψ^0 is represented by a single normalized Slater

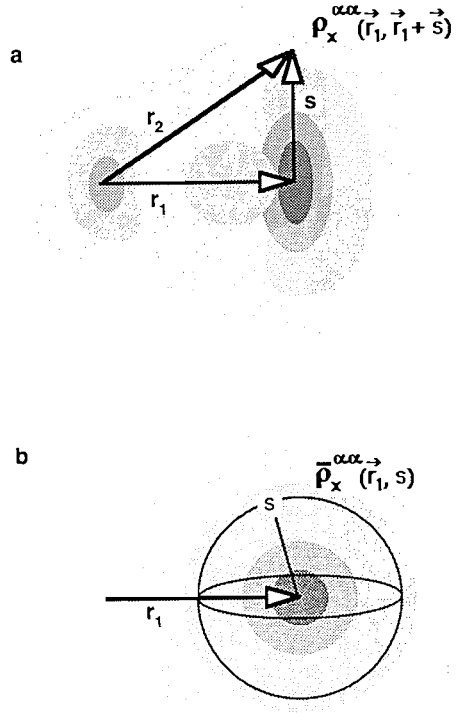

FIG. 1. Schematic representation of the hole correlation functions $\rho_x^{\alpha\alpha}(r_1, r_1 + s)$ and $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, for the reference electron at a fixed position r_1. Darker shaded areas correspond to larger values of the functions. (*a*) The hole correlation function $\rho_x^{\alpha\alpha}(r_1, r_1 + s)$; note the dependency on the distance $s \equiv |s|$ as well as on the orientation of the vector s. (*b*) The spherically averaged hole correlation function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, which depends only on the distance $s \equiv |s|$.

determinant, as

$$[6a] \quad \Psi^0 = |\phi_1^\alpha, \phi_2^\alpha, \ldots, \phi_{n_\alpha}^\alpha, \phi_{n_\alpha+1}^\beta, \phi_{n_\alpha+2}^\beta, \ldots, \phi_{n_\alpha+n_\beta}^\beta|$$

and $\{\phi_i(r_i)\}$ is a set of one-electron HF orbitals, one finds readily that

$$[6b] \quad \rho_x^{\alpha\beta}(r_1, r_2) = \rho_x^{\beta\alpha}(r_1, r_2) = 0$$

and

$$[7] \quad \rho_{xHF}^{\alpha\alpha}(r_1, r_1 + s) = \rho_{xHF}^{\alpha\alpha}(r_1, r_2) = \sum_i^{n_\alpha} \sum_j^{n_\alpha} \frac{\phi_i^\alpha(r_1)\phi_i^\alpha(r_2)\phi_j^\alpha(r_1)\phi_j^\alpha(r_2)}{\rho_1^\alpha(r_1)}$$

A similar expression for $\rho_{xHF}^{\beta\beta}(r_1, r_2)$ is obtained by substituting α by β in eq. [7]. The negative hole correlation functions $-\rho_{xHF}^{\alpha\alpha}$ and $-\rho_{xHF}^{\beta\beta}$ are often referred to as exchange densities.

The following relations can be derived from eq. [7] for $\rho_x^{\alpha\alpha}(r_1, r_2)$ and $\rho_x^{\beta\beta}(r_1, r_2)$ of like spins:

$$[8] \quad \int \rho_x^{\alpha\alpha}(r_1, r_2)\delta r_2 = 1$$

and

$$[9a] \quad \rho_x^{\alpha\alpha}(r_1, r_1) = \rho_1^\alpha(r_1)$$

The relation in eq. [9*a*] is a rigorous result. However, we would like to demonstrate that $\rho_{xHF}^{\alpha\alpha}(r_1, r_1 + s)$ and $\rho_1^\alpha(r_1 + s)$ are close for small values of s. To this end let us, without approximations, write $\rho_{xHF}^{\alpha\alpha}(r_1, r_1 + s)$ of eq. [7] in terms of a set of localized orbitals $\{\lambda_i\}$ obtained from a unitary transformation of the set $\{\phi_i\}$, as

$$[9b] \quad \rho_{xHF}^{\alpha\alpha}(r_1, r_1 + s) = \frac{\sum_{i=1}^{n_\alpha} \sum_{j=1}^{n_\alpha} \lambda_i(r_1)\lambda_i(r_1 + s)\lambda_j(r_1)\lambda_j(r_1 + s)}{\sum_{k=1}^{n_\alpha} \lambda_k(r_1)\lambda_k(r_1)}$$

There are various ways (22) in which $\{\phi_i\}$ can be transformed into a set of localized orbitals $\{\lambda_i\}$, and the set of orbitals $\{\lambda_i\}$ obtained from the different methods are in general quite similar (23). Let us now assume that the set $\{\lambda_i\}$ is well localized in such a way that each λ_k represents a region. That is, with r_1 in region k one finds that $\lambda_i(r_1) \neq 0$ for $i = k$, whereas $\lambda_i(r_1) \sim 0$ for $i \neq k$. With this set of assumptions, the function $\rho_{xHF}^{\alpha\alpha}$ will reduce to

$$[9c] \quad \rho_{xHF}^{\alpha\alpha}(r_1, r_1 + s) \sim \lambda_i(r_1 + s)\lambda_i(r_1 + s)$$

with the reference electron positioned at r_1 in region i.

The relation in eq. [9*c*] would indicate, since $\rho_1^\alpha(r) = \lambda_i(r)\lambda_i(r)$ for r in region i, that $\rho_{xHF}^{\alpha\alpha}(r_1, r_1 + s)$ not only is identical to $\rho_1^\alpha(r_1 + s)$ for $s = 0$, as it must according to eq. [9*a*], but also, at least approximately, in a domain around $s = 0$ where $r_1 = s$ is inside region i.

The following relations hold for the spherically averaged hole-correlation functions $\bar{\rho}_x^{\alpha\alpha}$ and $\bar{\rho}_x^{\beta\beta}$ (19–21),

$$[10] \quad \int \bar{\rho}_x^{\gamma\gamma}(r_1, s)\delta s = 1; \qquad \gamma = \alpha, \beta$$

$$[11] \quad \bar{\rho}_x^{\gamma\gamma}(r_1, 0) = \rho_1^\gamma(r_1); \qquad \gamma = \alpha, \beta$$

$$[12] \quad \lim_{s\to\infty} \bar{\rho}_x^{\gamma\gamma}(r_1, s) = 0; \qquad \gamma = \alpha, \beta$$

and

$$[13] \quad \bar{\rho}_x^{\gamma\gamma}(r_1, s) > 0; \qquad \text{all } r_1, s; \qquad \gamma = \alpha, \beta$$

The way in which (spherically averaged) hole correlation functions are represented in approximate density functional theory will be the subject of the next section.

III. The spherically averaged hole correlation functions in the Hartree–Fock and HFS theories

We shall here primarily be concerned with the spherically averaged hole-correlation functions $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ and $\bar{\rho}_x^{\beta\beta}(r_1, s)$ corresponding to electrons of the same spins. We shall further, for the moment, restrict the discussion to atomic systems. Hole correlation functions for electrons of like spins are also referred to as Fermi-hole correlation functions.

In order to illustrate the properties of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ and $\bar{\rho}_x^{\beta\beta}(r_1, s)$, we have plotted $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ for the simple He atom in Fig. 2. The plots in Fig. 2 are based on a single determinantal representation of the wave function Ψ^0 for He

$$[14a] \quad \Psi^0 = |\phi_{1s}(1)\alpha(1)\phi_{1s}(2)\beta(2)|$$

with

$$[14b] \quad \phi_{1s}(1) = \left[\frac{\sigma^3}{\pi}\right]^{1/2} \exp(-\sigma r_1)$$

and the hole correlation function $\rho_x^{\alpha\alpha}(r_1, r_2)$ has in this representation according to eq. [7] the following analytical form:

$$[15a] \quad \rho_x^{\alpha\alpha}(r_1, r_2) = \frac{\sigma^3}{\pi} \exp(-2\sigma r_2) = \frac{\sigma^3}{\pi} \exp(-2\sigma|r_1 + s|)$$

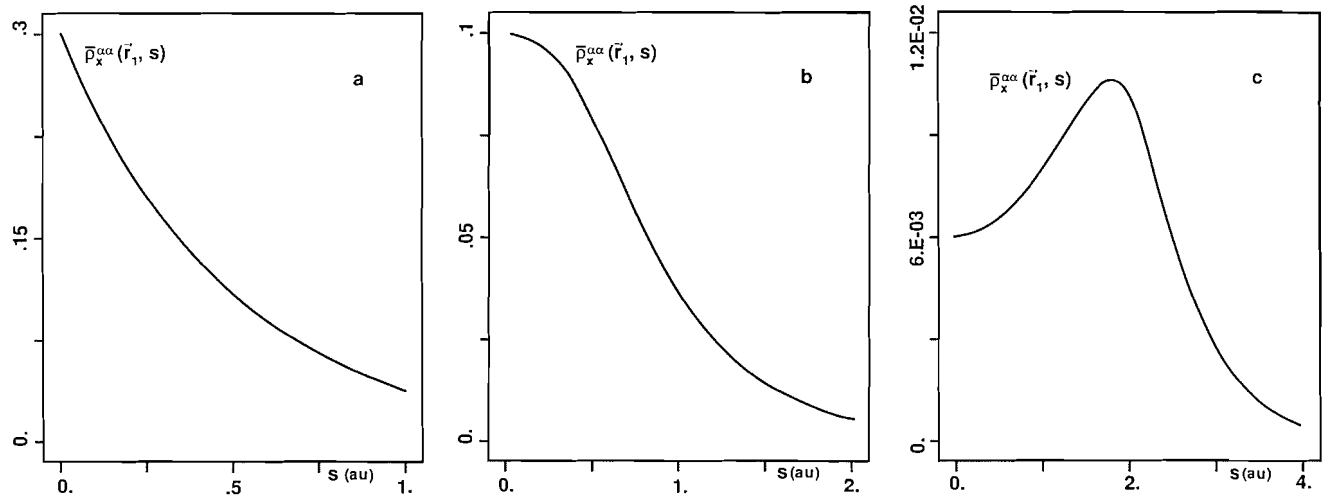

FIG. 2. The spherically averaged hole correlation function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ for the He atom. (*a*) $r_1 = 0$ au; (*b*) $r_1 = 0.5$ au; (*c*) $r_1 = 2$ au.

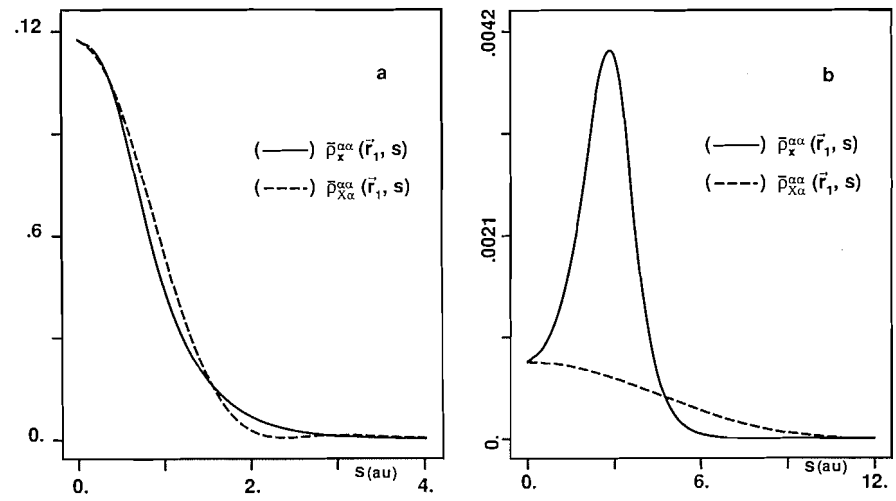

FIG. 3. The spherically averaged hole correlation functions $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ and $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ for the He atom. (*a*) $r_1 = 0.5$ au; (*b*) $r_1 = 3.0$ au.

whereas the spherically averaged hole correlation function $\bar{\rho}_x^{\alpha\alpha}$ is given by

$$[15b] \quad \bar{\rho}_x^{\alpha\alpha}(r_1, s) = \frac{\sigma}{4\pi r_1 s}\left\{\exp(-2\sigma|r_1 - s|)\left[\sigma|r_1 - s| + \frac{1}{2}\right] - \exp(-2\sigma|r_1 + s|)\left[\sigma|r_1 + s| + \frac{1}{2}\right]\right\}$$

where $|r_1 - s| = [(r_1 - s)^2]^{1/2}$. We shall on occasions refer to the simple He model in order to illustrate the salient concepts in our discussion.

The exponential function $\rho_x^{\alpha\alpha}(r_1, r_1 + s)$, defined in eq. [15*a*], has its maximum at $s = -r_1$. As a consequence, it is not surprising that the related function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ has its maximum at $s = r_1$ for large values of r_1 (Fig. 2*c*), and its maximum at $s = 0$ (Fig. 2*a*) for $r_1 = 0$. It is perhaps surprising that $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ not only has its maximum at $s = 0$ for $r_1 = 0$ but also for somewhat larger values of r_1, see Fig. 2*b*. The behaviour of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ in Fig. 2*b* can be readily understood from a numerical analysis. However, we shall postpone a detailed discussion to a later section.

The spherically averaged hole correlation function in the HFS method is modeled by writing $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ in the form

$$[16] \quad \bar{\rho}_x^{\alpha\alpha}(r_1, s) \sim \bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s) = \rho_1^{\alpha}(r_1) f(k_f s)$$

where $k_f = [6\pi^2 \rho_1^{\alpha}(r_1)]^{1/3}$. The unknown function $f(k_f s)$ is subsequently determined in such a way that $\bar{\rho}_{X\alpha}^{\alpha\alpha}$ of eq. [16] will satisfy all four constraints given in eqs. [10]–[13] for a spherically averaged hole correlation function.

Several functions (24–26) have the properties given in eqs. [10]–[13] and $f(k_f s)$ is as a consequence not uniquely determined. The most commonly used form (24) for $f(k_f s)$, derived from electron gas theory, is given by

$$[17] \quad f_g(k_f s) = 9\frac{[\sin(k_f s) - (k_f s)\cos(k_f s)]^2}{(k_f s)^6}$$

We compare in Fig. 3, for the He atom, $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ of eq. [16], derived from the density $\rho_1^{\alpha}(r_1) = \frac{\sigma^3}{\pi}\exp[-2\sigma r_1]$ and the expression for $f(k_f s)$ given in eq. [17], with $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ of eq. [15*b*]. For small values of r_1, both $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ and $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ have a maximum at $s = 0$ and exhibit closely the same dependency on s, see Fig. 3*a*. However, the two functions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

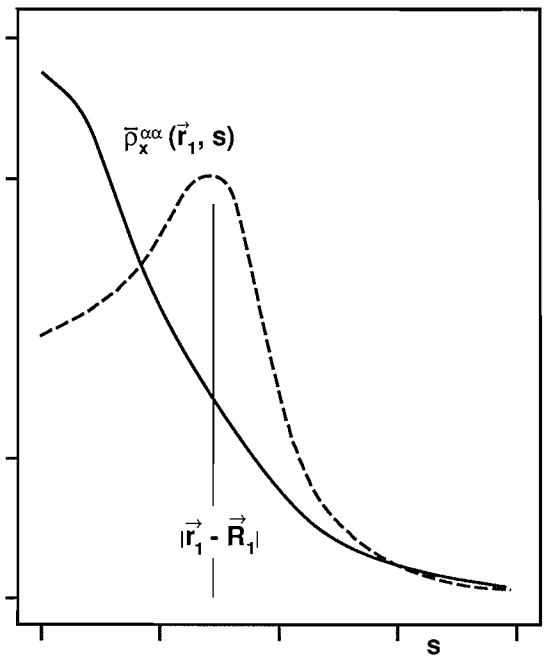

FIG. 4. Schematic representation of the spherically averaged hole correlation function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ for an atomic system, with r_1 inside a given shell. (—) $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ for r_1 near the principal maximum R_1 (see text) within the shell. (-----) $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ for r_1 at the edge of the shell, with distance $|r_1 - R_1|$ from R_1.

differ qualitatively for large values of r_1 (Fig. 3*b*), where $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, as already mentioned, has a maximum at $s = r_1$, whereas $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ in this region, as for any other value of r_1, has its maximum at $s = 0$. That $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ has a maximum at $s = 0$ for all values of r_1 is of course related to the fact that $f(k_f s)$ of eq. [17] has its maximum at $s = 0$.

Investigations (17, 20) of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, from HF calculations on atoms with more complicated shell structures than He, have revealed the following trends (see Fig. 4). When the reference electron is positioned (at r_1) near to a principal maximum R_i of the density in shell i, $\bar{\rho}_{xHF}^{\alpha\alpha}(r_1, s)$ is a decreasing function of s with a maximum at $s = 0$. On the other hand, the spherically averaged hole correlation function $\bar{\rho}_{xHF}^{\alpha\alpha}(r_1, s)$ has a principal maximum at $s = |r_1 - R_i|$ in the case where the reference electron is at the edge of shell i. By way of contrast, $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ exhibits for all r_1 a maximum at $s = 0$. Note that $R_1 = 0$ in the case of He.

It is readily shown (17*d*) that the qualitative incorrect behaviour of $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ at the edge of each shell results in exchange energies, $E_{X\alpha}^{\alpha\alpha} + E_{X\alpha}^{\beta\beta}$, that in absolute values are too low compared to exchange energies $E_{HFx}^{\alpha\alpha} + E_{HFx}^{\beta\beta}$ obtained by the HF method, see Table 2.

In the next section we shall discuss how the qualitatively incorrect behaviour of $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ at the edge of each shell can be alleviated. However, we would first like to point out that the so-called local density (LSD) method (5) has the same representation for $\bar{\rho}_{X\alpha}^{\alpha\alpha}$ and $\bar{\rho}_{X\alpha}^{\beta\beta}$ as the HFS scheme, and only differs from the latter method in the representation of the hole correlation functions of different spins. The shortcomings of the HFS scheme with respect to $\bar{\rho}_{X\alpha}^{\alpha\alpha}$ and $\bar{\rho}_{X\alpha}^{\beta\beta}$ applies thus as well to the LSD method.

IV. Expansion of the spherically averaged Fermi-hole correlation function in powers of s

The spherically averaged Fermi-hole correlation function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ can be expanded in powers of s. For atoms, however, such an expansion must be carried out in two parts, one for $0 < s < |r_1|$ and one for $s > |r_1|$, since the Fermi-hole correlation function $\rho_x^{\alpha\alpha}(r_1, r_1 + s)$ has a cusp (27) at $|r_1 + s| = 0$. As a consequence, the functions $\rho_x^{\alpha\alpha}$ and $\bar{\rho}_x^{\alpha\alpha}$ will have discontinuous derivatives of s at $s = -r_1$.

For $0 < s < |r_1|$, as already discussed by Becke (15*a*), the expansion of the spherically averaged Fermi-hole correlation function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ in powers of s has the form of a Taylor series

$$[18]\quad \bar{\rho}_x^{\alpha\alpha}(r_1, s) = \rho_1^{\alpha} + \sum_{i=1}^{\infty} \frac{s^{2i}}{(2i+1)!} \nabla_s^{2i} \rho_x^{\alpha\alpha}(r_1, r_1 + s)|_{s=0}, \quad 0 < s < |r_1|$$

The expansion of $\bar{\rho}_x^{\alpha\alpha}$ in the second region with $s > r_1$ is given by the Laurent series

$$[19]\quad \bar{\rho}_x^{\alpha\alpha}(r_1, s) = \sum_{j=-\infty}^{\infty} \frac{s^j}{2\pi i} \oint_C \frac{\bar{\rho}_x^{\alpha\alpha}(r_1, z)}{z^{j+1}} dz, \quad s > |r_1|$$

where i is the imaginary unit and z is a complex variable. Further, C is a circle of radius $R > |r_1|$.

For He, the spherically averaged hole correlation function is given by

$$[20a]\quad \bar{\rho}_x^{\alpha\alpha}(r_1, s) = \rho_1^{\alpha}(r_1) \sum_{i=0}^{\infty} \frac{1}{(2i+1)!} \left[1 - \frac{i}{\sigma r_1}\right] (2\sigma s)^{2i}, \quad 0 < s < r_1$$

and

$$[20b]\quad \bar{\rho}_x^{\alpha\alpha}(r_1, s) = \rho_1^{\alpha}(r_1) \sum_{i=-1}^{\infty} \frac{(-1)^i}{(i+1)!} \left[a_1 + \frac{a_2 i}{\sigma r_1}\right] (2\sigma s)^i, \quad s > r_1$$

where

$$a_1 = \frac{1}{2}\left(\frac{4\sigma^6}{\pi^2 \rho_1^{\alpha}} + 1\right)$$

and

$$a_2 = \frac{1}{4}\left(\frac{4\sigma^6}{\pi^2 \rho_1^{\alpha}} - 1\right)$$

The two series given in eq. [20] have been plotted in Fig. 5 for both small and large values of r_1.

For smaller values of r_1 ($r_1 < 1/\sigma$), Fig. 5*a*, we find that the Taylor series of eq. [20*a*] is, in its definition range ($0 < s < r_1$), a decreasing function of s, since all powers of s have negative coefficients. Outside its definition range at $s > r_1$, where the coefficients to all powers of s are negative ($r_1 < 1/\sigma$) and higher powers of s dominant, the Taylor series of eq. [20*a*] is a rapidly decreasing function of s, approaching $-\infty$. The function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ is in the range $s > r_1$ represented by the Laurent series of eq. [20*b*] and the Laurent series too is seen, Fig. 5*a*, in this range with $r_1 < 1/\sigma$ to be a decreasing function of s. However, the Laurent series is approaching zero for large s. This is according to eq. [12] the proper limit for $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$.

For large values of r_1 ($r_1 > 1/\sigma$), we find that the lowest powers of s in the Taylor expansion have positive coefficients whereas higher powers of s in eq. [20*a*] have negative coefficients. As a consequence, Fig. 5*b*, the Taylor expansion in eq. [20*a*] is at the onset (small values of s) an increasing function of s, since the lower powers of s are dominant. At the end of its definition range ($0 < s < r_1$), however, the series of

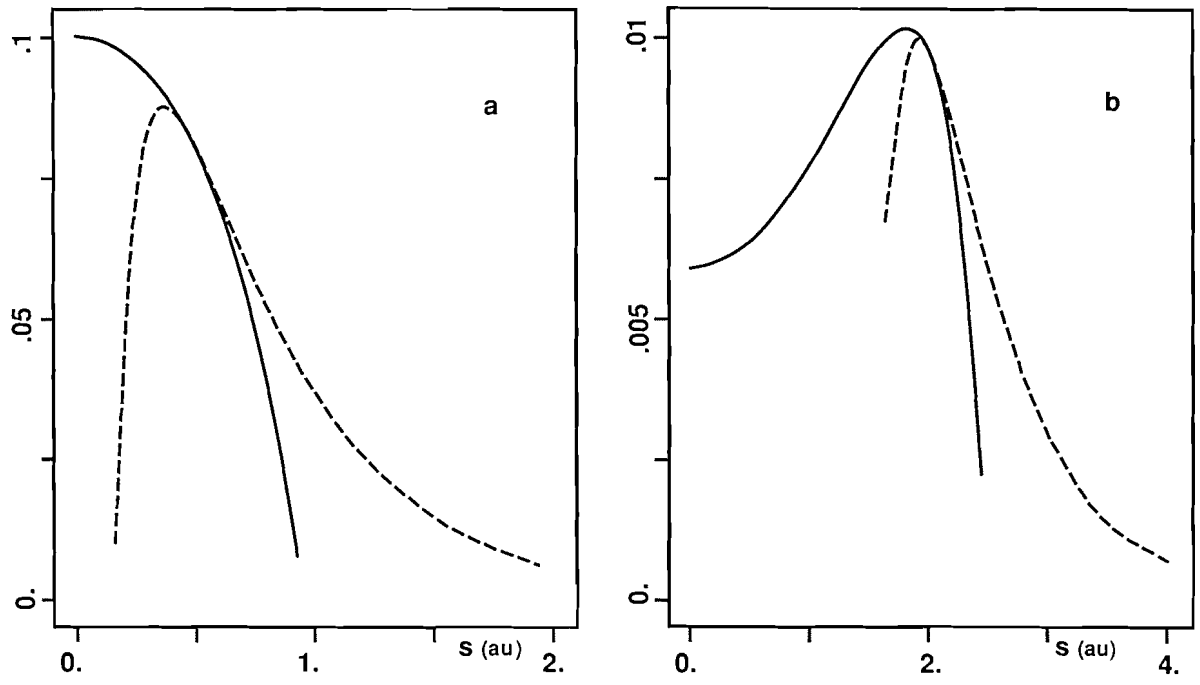

FIG. 5. He atom: Taylor expansion (—), defined for $0 < s < r_1$, and Laurent expansion (- - - - -), defined for $s > r_1$; of the spherically averaged hole correlation function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$. (*a*) $r_1 = 0.5$ au; (*b*) $r_1 = 2.0$ au.

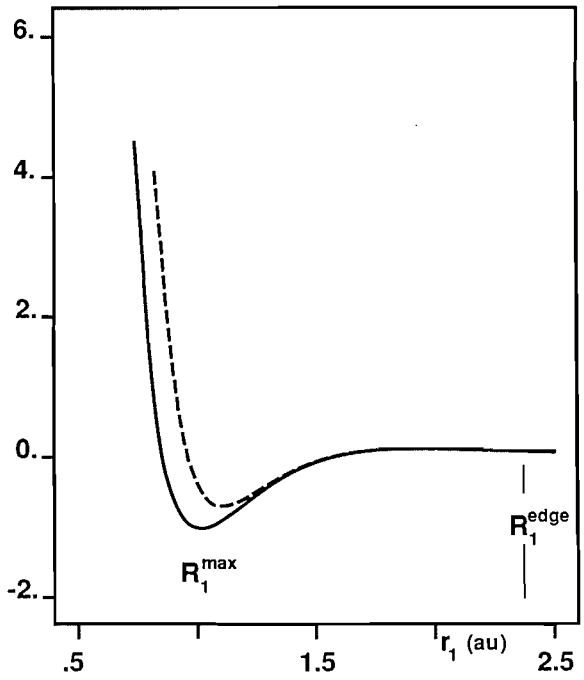

FIG. 6. Ar atom: plot of a_{HF} (—) and a_L (-----) as functions of r_1, for the M-shell ($n = 3$). The radius R_1^{max}, corresponding to the maximum of the density ρ_3 inside the shell, and the radius R_1^{edge}, at the edge of a shell, are indicated in the figure.

eq. [20a] will, after reaching a maximum, decrease due to the influence of higher powers of s. Outside its definition range ($s > r_1$), where higher powers of s are completely dominant, the Taylor expansion approaches $-\infty$. For $r_1 > 1/\sigma$, Fig. 5b, the Laurent expansion of eq. [20b] is, in its definition range ($s > r_1$), a decreasing function of s, with the correct asymptotic limit of zero for large values of s.

From the discussion up to this point, it follows that the shape of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ (the position of the maximum) for different values of r_1, at least for He, is determined by the Taylor expansion of eq. [18]. Our analysis would thus indicate that one would have to include, in any approximate representation of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ in which the shape of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ as a function of r_1 is reproduced qualitatively correctly, at least some of the terms in the Taylor expansion of eq. [18]. The Taylor expansion of eq. [18] is, with terms up to s^2 included, given by:

$$[21] \quad \bar{\rho}_x^{\alpha\alpha}(r_1, s) = \rho_1^\alpha(r_1) + as^2 + \ldots, \qquad 0 < s < |r_1|$$

where a, according to eq. [20a], has the form

$$[22] \quad a = \tfrac{1}{6}[\nabla_s^2 \rho_x^{\alpha\alpha}(r_1, r_1 + s)|_{s=0}]$$

Becke (15a) has shown that the coefficient a in the expansion of $\bar{\rho}_{xHF}^{\alpha\alpha}(r_1, s)$ can be expressed as

$$[23a] \quad a \sim a_{HF} = \frac{1}{6}\left[\nabla_1^2 \rho_1^\alpha(r_1) - 2\tau_1^\alpha + \frac{1}{2}\frac{|\nabla_1 \rho_1^\alpha(r_1)|^2}{\rho_1^\alpha(r_1)}\right]$$

where τ_1^α is the kinetic energy density

$$[23b] \quad \tau_1^\alpha = \sum_{i=1}^{n_\alpha} |\nabla_1 \phi_i(r_1)|^2$$

Furthermore, under the simplifying assumptions of perfect localization according to eq. [9c], we have that

$$[23c] \quad a \sim a_L = \tfrac{1}{6}[\nabla_s^2 \rho_1^\alpha(r_1 + s)|_{s=0}] = \tfrac{1}{6}[\nabla_1^2 \rho_1^\alpha(r_1)]$$

Thus, the coefficient a in eq. [21] is seen to be related to the curvature of $\rho_1^\alpha(r_1)$. In Fig. 6, we give a_{HF} and a_L as a function of r_1 for the Ar atom in the M-shell ($n = 3$). It is seen that a_{HF} and a_L follow each other closely. Also, note that a_{HF} and a_L are negative where $\rho_1^\alpha(r_1)$ has its maximum (and a negative curvature), and positive at the edge of the shell where $\rho_1^\alpha(r_1)$ has a positive curvature.

V. Becke's approximate spherically averaged Fermi-hole correlation function

Becke (15a) has recently introduced an approximate hole correlation function $\bar{\rho}_B^{\alpha\alpha}(r_1, s)$ in which some of the qualitatively incorrect features, see Section III, of $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ were remedied. Becke's approximate expression is given by

$$[25] \quad \bar{\rho}_B^{\alpha\alpha}(r_1, s) = \begin{cases} (1 + a_B s^2 + b_B s^4)\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s); & k_f s < z \\ \bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s); & k_f s > z \end{cases}$$

where $z = 4.4934$ represents the first zero (24) for $\bar{\rho}_{X\alpha}^{\alpha\alpha}$ as a function of $k_f s$. Becke (15a) obtained in addition, after some straightforward manipulations involving partial integration, the following approximate expression for the potential $V_x^{\alpha\alpha}$ of eq. [5b]

$$[26] \quad V_B^{\alpha\alpha}(r_1) = V_{X\alpha}^{\alpha\alpha}(r_1) - \frac{\beta}{2}\frac{|\nabla_1 \rho_1^\alpha(r_1)|^2}{(\rho_1^\alpha(r_1))^{7/3}}$$

whereas the energy expression $E_x^{\alpha\alpha}$ of eq. [4] takes on the form

$$[27] \quad E_B^{\alpha\alpha} = E_{X\alpha}^{\alpha\alpha} - \beta\int \frac{|\nabla_1 \rho_1^\alpha(r_1)|^2}{(\rho_1^\alpha(r_1))^{4/3}}\delta r_1$$

The constant β in eqs. [26]–[27] is given by $\beta = 0.00293$. The functional form of eq. [27] had already been derived by Herman *et al.* (13) from dimensional arguments, and by Sham (5r) on the basis of density functional theory. An interesting alternative nonlocal exchange functional was proposed by Gunnarsson *et al.* (21). These authors, rather than using a gradient expansion for $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, developed a general procedure to average the electron density around the reference electron. This average value was then inserted into the local Fermi-hole correlation function of eq. [17], thereby introducing a nonlocal dependency into the corresponding exchange energy functional.

The function $\bar{\rho}_B^{\alpha\alpha}(r_1, s)$ constitutes a considerable improvement over $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ in the tails of the atomic shells. However, it is, at variance with eq. [13], not positive for all s (17d), as shown in the Ar atom in Fig. 7.

Another shortcoming of the model proposed by Becke is the divergence as $(\rho_1^\alpha(r_1))^{-1/3}$ of the potential $V_B^{\alpha\alpha}(r_1)$ (13, 15a), in the tail of any exponentially decaying density $\rho_1^\alpha(r_1)$. Thus $V_B^{\alpha\alpha}(r_1)$ of eq. [26] will diverge for large r_1 in the atomic tail, as illustrated for He in Fig. 8. In order to overcome this problem, Becke (15c) multiplied the second term of $V_B^{\alpha\alpha}(r_1)$ and $E_B^{\alpha\alpha}$ by the cut-off function

$$[28a] \quad g_B(r_1) = (1 + \gamma y^2)^{-1}$$

where

$$[28b] \quad y = \frac{|\nabla_1 \rho_1^\alpha(r_1)|}{(\rho_1^\alpha(r_1))^{-4/3}}$$

and γ is an adjustable parameter ($\gamma = 0.0053$).

The modified potential is now well behaved as illustrated in Fig. 8, and the corresponding modified energy expression is

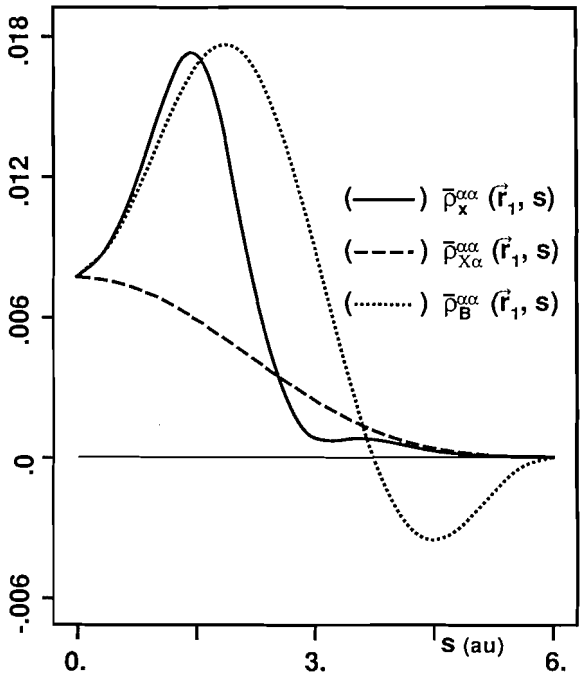

FIG. 7. Ar atom: the spherically averaged hole correlation functions $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ and $\bar{\rho}_B^{\alpha\alpha}(r_1, s)$, for r_1 in the third atomic shell with $r_1 = 2.5$ au. Note that $\bar{\rho}_B^{\alpha\alpha}(r_1, s)$ assumes negative values for large s.

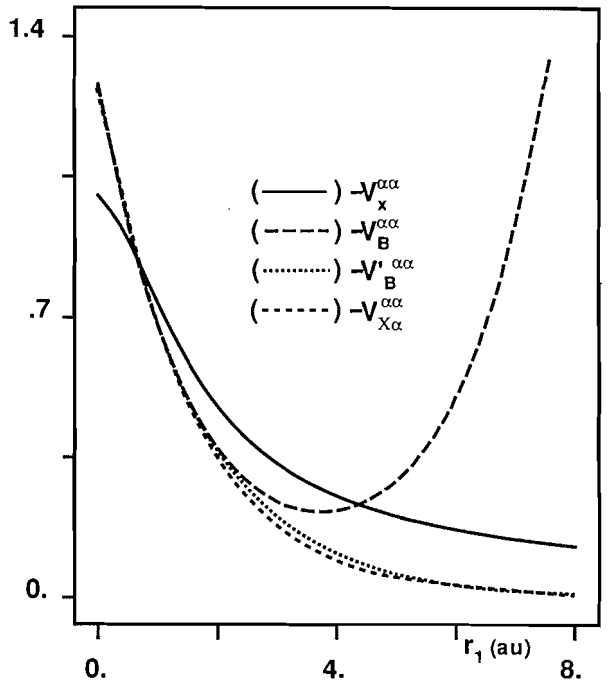

FIG. 8. He atom: the potentials $V_x^{\alpha\alpha}(r_1)$, $V_B^{\alpha\alpha}(r_1)$, and $V'^{\alpha\alpha}_B(r_1)$, as well as $V_{X\alpha}^{\alpha\alpha}(r_1)$. Note that the divergency of $V_B^{\alpha\alpha}(r_1)$ is eliminated by the cut-off factor (see text), present in $V'^{\alpha\alpha}_B(r_1)$.

given (15*c*) by

$$[28c] \quad E'^{\alpha\alpha}_B = E_{X\alpha}^{\alpha\alpha} - \beta \int (\rho_1^{\alpha}(r_1))^{4/3} y^2 (1 + \gamma y^2)^{-1} \delta r_1$$

DePristo and Kress (16*a*) have recently suggested an alternative cut-off function of the form

$$[29] \quad g_{DK}(r_1) = \beta_g (1 + a_{DK} y)(1 + b_{DK} y^2)^{-1}$$

in which a_{DK} and b_{DK} are adjustable parameters and $\beta_g = 0.001323$. The energy expression $E'^{\alpha\alpha}_B$ of eq. [28*c*] has been used with remarkable success to calculate bond energies and other properties in molecular systems (11, 12, 15*c*), and exploratory calculations indicate that the expression $E'^{\alpha\alpha}_{DK}$ based on eq. [29]) is equally appropriate. A gradient-type correction for the LSD exchange-correlation energy which leads to substantial improvements over the LSD results for atomic and solid-state systems was proposed earlier by Langreth and Mehl (5*e*). These authors also introduced an exponential cut-off factor (5*e*, 13) as a numerical tool in the evaluation of the integrals involved in their SCF calculations. Unlike the factors g_{DK} and g_B, this cut-off function does not influence the value of the calculated exchange energy (5*e*); also, dissociation energy values given by the Langreth and Mehl functional (15*c*) are in general less satisfactory than those given by Becke's functional.

The *ad hoc* introduction of a cut-off function is somewhat unsatisfactory and it is not quite clear what would be the form of the spherically-averaged hole correlation function corresponding to the expressions $E'^{\alpha\alpha}_B$ and $E'^{\alpha\alpha}_{DK}$. In the next sections, we shall illustrate the physical origin of the cut-off functions g_{DK} and g_B by proposing an approximate expression for the spherically averaged hole correlation functions, which automatically leads to potentials and energy expressions with a built-in cut-off function.

VI. The cut-off factor in the gradient correction to the HFS exchange energy

In Section IV, we have pointed out the necessity of expanding the Fermi-hole correlation functions of atoms in two regions, due to the presence of a cusp at $|s| = |-r_1|$. In this section we shall discuss the relation between the cusp at $|s| = |-r_1|$ and the origin of the cut-off factor introduced by Becke (15*c*) and DePristo *et al.* (16*a*). For an atom, we can expand the Fermi hole-correlation function as

$$[30] \quad \bar{\rho}_x^{\alpha\alpha}(r_1, s) = \begin{cases} \rho_1^{\alpha}(r_1) + as^2 + \ldots; & 0 < s < r_1 \\ [\rho_1^{\alpha}(r_1) + ar_1^2 + \ldots] f(r_1, s); & s > r_1 \end{cases}$$

with the coefficient a given by eq. [22]. Further, $f(r_1, s)$ can be immediately determined by recasting the expression for the spherically averaged Fermi-hole correlation function of eqs. [18], [19]). The function $f(r_1, s)$ is simply introduced here as a formal device that allows us to express $\bar{\rho}_x^{\alpha\alpha}$ in terms of its gradient expansion, for $s > r_1$.

Inserting eq. [30] into eq. [5*b*], and integrating over the s coordinate in the two different regions yields the coulomb potential expression

$$[31] \quad V_x^{\alpha\alpha}(r_1) = -\left[\frac{\pi}{2(6\pi^2)^{2/3}}(x_1)^2 + \frac{\pi}{6}F(r_1)\right](\rho_1^{\alpha}(r_1))^{1/3}$$
$$+ -\left[\frac{\pi}{4(6\pi^2)^{4/3}}(x_1)^4 + \frac{\pi}{2(6\pi^2)^{4/3}}(x_1)^2 F(r_1)\right]\frac{a}{(\rho_1^{\alpha}(r_1))^{4/3}} + \ldots$$

where $x_1 = k_f r_1 = (6\pi^2\rho_1^\alpha)^{1/3} r_1$. Further, the dimensionless factor F is defined as

$$F(\boldsymbol{r}_1) = (k_f)^2 \int_{r_1}^{\infty} s f(\boldsymbol{r}_1, s)\delta s$$

The first term on the r.h.s. of eq. [31] contains the potential given by the HFS approximation, multiplied by a dimensionless factor. Similarly, the second term contains the simple second order gradient correction $a/(\rho_1^\alpha)^{4/3}$, as obtained from the method by Becke (15*a*) (see Section V), also multiplied by a dimensionless factor. The contribution of the second order term to the potential is, according to eq. [31], given by

$$[33] \quad V_{NL}^{\alpha\alpha}(\boldsymbol{r}_1) = -\left[\frac{\pi}{4(6\pi^2)^{4/3}}(x_1)^4 + \frac{\pi}{2(6\pi^2)^{4/3}}(x_1)^2 F(\boldsymbol{r}_1)\right]\frac{a}{(\rho_1^\alpha(\boldsymbol{r}_1))^{4/3}}$$

Without the factor in brackets, the expression of eq. [33] would be divergent as $1/r_1$ (13) at the atomic nucleus, due to the singularity of the density laplacian contained in the coefficient a (see eq. [23*a*]). Furthermore, the expression of eq. [33] would be divergent as $(\rho_1^\alpha)^{-1/3}$ (13, 15*a*) in the atomic exponential tail, in the same way as the potential of eq. [26]. We shall now show that the bracketed factor in eq. [33] removes the two singularities. To this purpose, we point out that the term F of eq. [32] must be finite for any value of the Fermi-hole correlation function, in order to ensure that the exchange potential be finite.[2] Thus, both the first and the second term in brackets in eq. [33] are able to remove the singularity of $a/(\rho_1^\alpha)^{4/3}$ at the nucleus, through the factor r_1 in the x_1 term. Similarly, the factor $(\rho_1^\alpha)^{1/3}$ in x_1 removes the singularity in the atomic exponential tail.

The bracketed term in eq. [33] acts therefore as a cut-off function, much in the same way as the factor proposed by Becke (15*c*) and DePristo *et al.* (16*a*) to eliminate the divergence of the gradient corrected potential of eq. [26]. The cut-off factor of eq. [33] is zero at the atomic nucleus, larger than zero in intermediate atomic regions, and decays rapidly in the atomic exponential tail.

According to the above discussion, when the presence of the cusp in the Fermi-hole correlation function is taken into account, one can derive a gradient correction to the HFS potential, eq. [33], which is well-behaved and contains a cut-off factor. However, the value of eq. [33] is purely formal, since to evaluate the term F of eq. [32] it is necessary to know the exact Fermi-hole correlation function. In the next section we shall develop an approximate expression for the Fermi-hole correlation function, which leads to a gradient correction to the HFS exchange energy expression containing a cut-off factor.

[2]Since the spherically averaged Fermi-hole correlation function is always larger than or equal to zero (eq. [13]), the contributions to the potential $V_x^{\alpha\alpha}(\boldsymbol{r}_1)$ from the two regions of eq. [30], are of the same sign. Therefore, they both must be finite in order to ensure that $V_x^{\alpha\alpha}(\boldsymbol{r}_1)$ be finite. For $s > r_1$, the function $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$ is, according to eq. [30], given by

$$\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s) = [\rho_1^\alpha(\boldsymbol{r}_1) + a r_1^2 + \ldots] f(\boldsymbol{r}_1, s)$$

The factor in brackets is just the value of $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$ when s encompasses the nucleus. Such a value is always larger than zero for an atom, due to the presence of the cusp at the nucleus. Thus the contribution to $V_x^\alpha(\boldsymbol{r}_1)$ of eq. [31] from the second region ($s > r_1$), is given by the term F of eq. [32], multiplied by a nonzero factor. Hence, the term F must be finite in order to ensure a finite value for the coulomb potential due to $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$.

The physical origin of the cut-off function has also been examined recently by Perdew (16*b*–*c*). This author proposed an interesting model for the Fermi-hole correlation function, which generates exchange energy and potential expressions containing a cut-off factor, based on a second order expansion for the inhomogeneous electron gas Fermi-hole correlation function. Perdew was able to enforce the condition of non-negativity (eq. [13]) by introducing a step-function factor which eliminates the negative-valued regions, and to enforce the normalization condition by imposing a cut-off radius. Our alternative model given in the next section satisfies automatically the exact conditions of eqs. [10]–[13] by reproducing the change in analytical structure of the Fermi-hole correlation function in atomic systems expressed by eq. [30].

VII. An alternative approximation to the spherically averaged Fermi-hole correlation function

In this section we shall attempt to develop an approximate expression for $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$, based on the expansion of eq. [30]. Making the variable substitution $x = k_f s$, we have, from eq. [30]

$$[34a] \quad \bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s) = \begin{cases} \rho_1^\alpha(\boldsymbol{r}_1) + a'x^2 + \ldots; & 0 < x < x_1 \\ [\rho_1^\alpha(\boldsymbol{r}_1) + a'x_1^2 + \ldots] g(\boldsymbol{r}_1, x); & x > x_1 \end{cases}$$

where $g(\boldsymbol{r}_1, x) = f(\boldsymbol{r}_1, s)$ and $a' = a/(k_f)^2$, with a defined by eq. [24*a*]. Further, $x_1 = k_f r_1$ in the exact expression of eq. [34*a*]. As a first approximation, we shall truncate the expansion of eq. [34*a*] to the second order term. Furthermore, we shall treat the variable x_1 as a parameter, larger than zero, to be determined by the normalization condition on $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$, and we shall substitute the function $g(\boldsymbol{r}_1, x)$ by a suitable approximate expression $g'(\boldsymbol{r}_1, x)$. The resulting expression is given by

$$[34b] \quad \bar{\rho}_{PW}^{\alpha\alpha}(\boldsymbol{r}_1, s) = \begin{cases} \rho_1^\alpha(\boldsymbol{r}_1) + a'x^2; & 0 < x < x_1 \\ [\rho_1^\alpha(\boldsymbol{r}_1) + a'x_1^2] g'(\boldsymbol{r}_1, x); & x > x_1 \end{cases}$$

where $\bar{\rho}_{PW}^{\alpha\alpha}$ denotes the present approximation. Note that the parameter x_1 will vary with the value of $\boldsymbol{r}_1$. The simplest possible expression for g' is the exponential form

$$[34c] \quad g'(\boldsymbol{r}_1, x) = \exp[-\alpha(x - x_1)]$$

where α is a parameter which varies with the value of $\boldsymbol{r}_1$, with the imposed condition $\alpha > 0$. The normalization condition on $\bar{\rho}_{PW}^{\alpha\alpha}$ is expressed by

$$[34d] \quad 4\pi \int_0^\infty \bar{\rho}_{PW}^{\alpha\alpha} s^2 \delta s = \frac{2}{3\pi}\left[\frac{x_1^3}{3} + \frac{x_1^2}{\alpha} + \frac{2x_1}{\alpha^2} + \frac{2}{\alpha^3}\right] + \frac{4\pi}{3!(6\pi^2)^{5/3}} \frac{a}{(\rho_1^\alpha(\boldsymbol{r}_1))^{5/3}}\left[\frac{x_1^5}{5} + \frac{x_1^4}{\alpha} + \frac{2x_1^3}{\alpha^2} + \frac{2x_1^2}{\alpha^3}\right] = 1$$

The parameter x_1 should follow approximately the function $k_f r_1$ in order to reproduce the Fermi-hole correlation function for an atomic system. As depicted in Fig. 9 for the Ar atom, the function $k_f r_1$ is zero at the nucleus, increases with r_1 in intermediate atomic regions, and then reduces asymptotically to zero in the exponential tail. In the following discussion, we shall assume the same general behaviour for the parameter x_1 as a function of r_1. In particular, x_1 must tend to zero both for $r_1 = 0$ and for $r_1 \to \infty$ in order to remove the singularities of the term $a/(\pi_1^\alpha(\boldsymbol{r}_1))^{5/3}$ of eq. [34*d*], which diverges as $-1/r_1$ at the atomic nucleus and as $(\rho_1^\alpha(\boldsymbol{r}_1))^{-2/3}$ in the atomic exponential

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

tail, as discussed in Section VI. Also, if we want the approximate expression of eq. [34*b*] to reproduce the exact expression of eq. [34*a*] qualitatively correctly, we must assume that in the limit $r_1 \rightarrow \infty$ we have the condition $x_1/k_f \rightarrow \infty$. Given the above conditions on the behaviour of x_1, it is possible to outline the behaviour of the parameter α both at the nucleus and in the exponential tail of an atom. At the atomic nucleus, assuming that the second term on the RHS of eq. [34*d*] vanishes, the value of $\alpha = \alpha_0 = (4/3\pi)^{1/3}$ is readily determined from the normalization condition of eq. [34*d*]. Also, in the exponential tail of atoms, since as $r_1 \rightarrow \infty$ we assume that $x_1/k_f \rightarrow \infty$, we must have that $\alpha \rightarrow \infty$, in order to satisfy the normalization condition of eq. [34*d*] and to remove the singularity of the term $a/(\rho_1^\alpha(\boldsymbol{r}_1))^{5/3}$.

We shall now express x_1 in terms of α, so that only one unknown parameter is to be determined from the normalization condition of eq. [34*d*]. If we assume that the parameter α be a monotonically increasing function of r_1, then a general dependency of x_1 on α can be established. Thus, x_1 will be zero at $\alpha = \alpha_0$, will increase for intermediate values of α, and will eventually tend asymptotically to zero as $\alpha \rightarrow \infty$. One relation that satisfies all the conditions stated above is,

$$[34e] \quad x_1 = \frac{\alpha - \alpha_0}{c_0 + c_1\alpha + c_2\alpha^2}$$

We shall make use of the form of eq. [34*e*] in the following discussion. In eq. [34*e*] c_1 and c_2 are adjustable parameters to be determined from a least square fit of the exchange energy of atoms, as discussed at the end of the present chapter. Furthermore, c_0 is determined by imposing that the potential expression obtained by substituting eq. [34*b*] into eq. [5*b*] reduce to the HFS expression when $a = 0$, i.e. in the case of homogeneous density. The value of α can readily be determined by numerical methods from the normalization equation, as a function of the dimensionless variable

$$[35] \quad \lambda = \frac{a}{(\rho_1^\alpha(\boldsymbol{r}_1))^{5/3}}$$

once the relation of eq. [34*e*] has been established.

We should point out that the function $\bar{\rho}_{PW}^{\alpha\alpha}$ satisfies, by construction, the four conditions of eqs. [10]–[13] pertaining to the exact function $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$.

For atoms, the expression[3] of eq. [34*b*] follows the exact function $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$ reasonably well, as shown for the Ar atom in Fig. 10. At the atomic nucleus, we have that $x_1 = 0$ and $\alpha = \alpha_0$. Thus, eq. [34*b*] reduces to a simple exponential, in excellent accord with the exact expression $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$, which at the nucleus is close to the 1*s* orbital, see Fig. 10*a*. The behaviour of the exact function $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$ at the maximum of the density within a shell (Fig. 10*b*) and at the edge of a shell (Fig. 10*c*) is qualitatively well reproduced by our approximate expression $\bar{\rho}_{PW}^{\alpha\alpha}$.

We shall now show that the model presented here (eq. [34*b*–*e*]), is sufficient to generate a cut-off factor in the second order correction to the HFS potential expression. To this purpose, we shall consider the normalization condition on $\bar{\rho}_{PW}^{\alpha\alpha}$,

[3]Following the procedure developed by Becke (15*b*), we have adopted the approximate expression

$$\frac{1}{6}a \sim -\frac{1}{18}\nabla_1^2\rho_1^\alpha(\boldsymbol{r}_1) + \frac{2}{27}\frac{|\nabla_1\rho_1^\alpha(\boldsymbol{r}_1)|^2}{\rho_1^\alpha(\boldsymbol{r}_1)}$$

for the second order coefficient in the expansion of $\bar{\rho}_x^{\alpha\alpha}(\boldsymbol{r}_1, s)$.

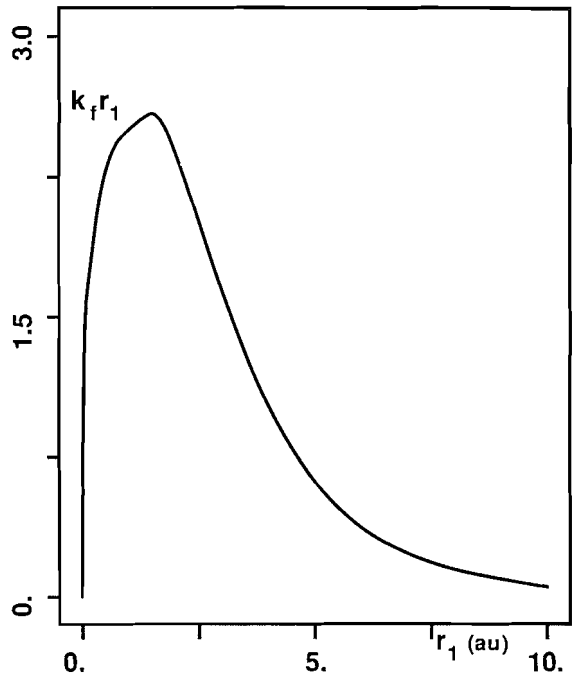

FIG. 9. Plot of $k_f r_1$ versus r_1 for the Ar atom.

given by eq. [34*d*], as well as the coulomb potential expression, obtained by inserting eq. [34*b*] into eq. [5*b*],

$$[36] \quad V_{PW}^{\alpha\alpha}(\boldsymbol{r}_1) = -\frac{4\pi}{(6\pi^2)^{2/3}}(\rho_1^\alpha(\boldsymbol{r}_1))^{1/3}\left[\frac{x_1^2}{2} + \frac{x_1}{\alpha} + \frac{1}{\alpha^2}\right] + -\frac{4\pi}{3!(6\pi^2)^{4/3}}\frac{a}{(\rho_1^\alpha(\boldsymbol{r}_1))^{4/3}}\left[\frac{x_1^4}{4} + \frac{x_1^3}{\alpha} + \frac{x_1^2}{\alpha^2}\right]$$

We shall now prove that the values of x_1 and α that satisfy the normalization condition of eq. [34*d*], and remove the two singularities of the term $a/(\rho_1^\alpha(\boldsymbol{r}_1))^{5/3}$, also lead to a well behaved expression for the potential of eq. [36], by removing the two singularities of the term $a/(\rho_1^\alpha(\boldsymbol{r}_1))^{4/3}$ in eq. [36], which diverges as $-1/r_1$ at the atomic nucleus and as $(\rho_1^\alpha)^{-1/3}$ in the atomic exponential tail, as discussed in Section V.

At the atomic nucleus, as the function α tends to the finite value α_0 and $x_1 \rightarrow 0$, we have the limit form

$$[37a] \quad x_1 = -\frac{\alpha_0^4 - 3\alpha_0^2(c_0 + c_1\alpha_0 + c_2\alpha_0^2)}{2b\lambda}; \qquad r_1 \sim 0$$

as it can be shown from eq. [34*d*–*e*], after some rather straightforward algebra. In eq. [37*a*] we have that $b = 4\pi/[3!(6\pi^2)^{5/3}]$ and λ is given by eq. [35]. The limit form of eq. [37*a*] is sufficient to remove the singularity of the term $a/(\rho_1^\alpha(\boldsymbol{r}_1))^{4/3}$ of eq. [36], leading to a well behaved potential expression at the atomic nucleus.

In the exponential tail of atoms, as $x_1 \rightarrow 0$ and $\alpha \rightarrow \infty$, we have from eq. [34*e*] the limit form

$$[37b] \quad x_1 = \frac{1}{c_2\alpha}; \qquad r_1 \gg 0$$

Thus the limit forms for the normalization equation and for the potential expression are given by

$$[37c] \quad 4\pi\int_0^\infty \bar{\rho}_{PW}^{\alpha\alpha}s^2\delta s = \text{const}_1 x_1^3 + \text{const}_2\frac{a}{(\rho_1^\alpha(\boldsymbol{r}_1))^{5/3}}x_1^5 = \text{const}_1 x_1^3 + \text{const}_2\lambda x_1^5 = 1; \qquad r_1 \gg 0$$

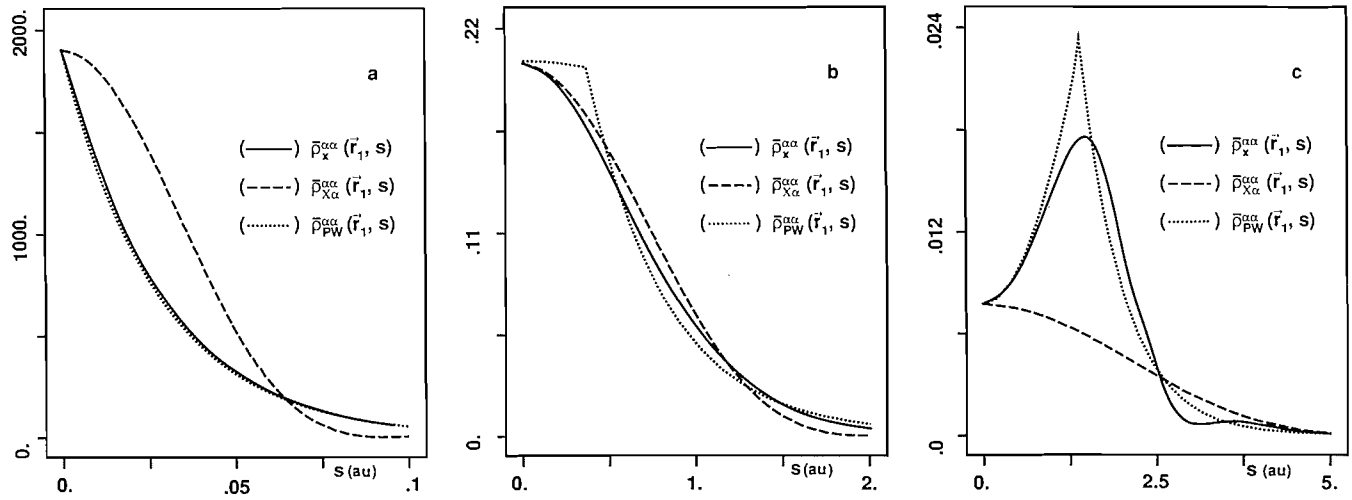

FIG. 10. Ar atom: the spherically averaged hole correlation functions $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$ and $\bar{\rho}_{PW}^{\alpha\alpha}(r_1, s)$. (*a*) for $r_1 = 0$ au; (*b*) for $r_1 = 1$ au; (*c*) for $r_1 = 2.5$ au.

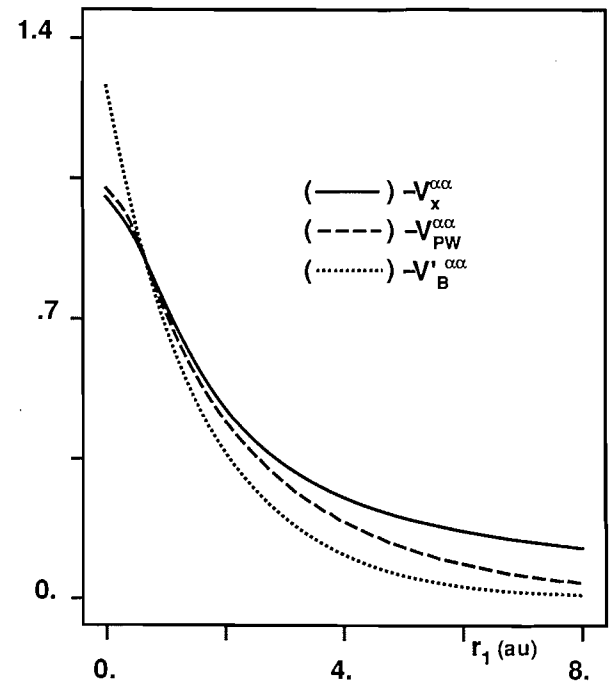

FIG. 11. He atom: the potentials $V_x^{\alpha\alpha}(r_1)$ and $V'^{\alpha\alpha}_B(r_1)$, as well as the present approximation $V_{PW}^{\alpha\alpha}(r_1)$.

and

$$[37d]\quad V_{PW}^{\alpha\alpha}(r_1) = -\text{const}_3(\rho_1^{\alpha}(r_1))^{1/3}x_1^2 - \text{const}_4\frac{a}{(\rho_1^{\alpha}(r_1))^{4/3}}x_1^4; \qquad r_1 \gg 0$$

Where the symbol const_n denotes a constant factor. From eq. [37*b*], it can immediately be shown that, as $x_1 \to 0$ and $\lambda \to \infty$, we have the limit form

$$[37e]\quad x_1 = \frac{1}{[\text{const}_2\lambda]^{1/5}} = \frac{1}{[(1/5 + c_2 + 2c_2^2 + 2c_2^3)b\lambda]^{1/5}}; \qquad r_1 \gg 0$$

where the value of const_2 is given explicitly. Also, the constant term b was defined in connection with eq. [37*a*]. The limit form given by eq. [37*e*] is sufficient to remove the singularity of the term $a/(\rho_1^{\alpha}(r_1))^{4/3}$ in the potential expression of eq. [37*d*], leading to a well behaved potential expression in the atomic exponential tail.

Thus, we have shown that our simple model $\bar{\rho}_{PW}^{\alpha\alpha}$ for the spherically averaged Fermi-hole correlation function, subject to the normalization condition of eq. [34*d*], leads to a well-behaved expression for the potential, eq. [36]. The expression of eq. [36] contains, as a factor of the term $a/(\rho_1^{\alpha}(r_1))^{4/3}$, a cut-off function analogous to the exact expression of eq. [33] and to the empirical expressions proposed by Becke (15*b*) and DePristo *et al.* (16*a*).

The behaviour of the potential expression of eq. [36] is depicted in Fig. 11, for the He atom. It appears that our model represents a qualitative improvement over the potential proposed by Becke (15*b*). It might be argued that such an improvement is due to the use of a realistic, albeit crude, model for the Fermi-hole correlation function which satisfies the exact conditions of eqs. [10]–[13], as already mentioned.

In the present approximation, the exchange energy is given by the expression

$$[38]\quad E_{PW}^{\alpha\alpha} = -\frac{2\pi}{(6\pi^2)^{2/3}}\int(\rho_1^{\alpha}(r_1))^{4/3}\left[\frac{x_1^2}{2} + \frac{x_1}{\alpha} + \frac{1}{\alpha^2}\right]\delta r_1 + -\frac{2\pi}{3!(6\pi^2)^{4/3}}\int\frac{a}{(\rho_1^{\alpha}(r_1))^{1/3}}\left[\frac{x_1^4}{4} + \frac{x_1^3}{\alpha} + \frac{x_1^2}{\alpha^2}\right]\delta r_1$$

obtained by substituting the potential of eq. [36] into eq. [5*a*].

Using the expression of eq. [38], we have calculated the exchange energies of the atomic systems from H to Ar, as well as Kr and Xe, for different values of the parameters c_0, c_1, and c_2. We have found that the lowest standard deviation relative to the Hartree–Fock exchange energies is given by the parameter values $c_0 = -0.195$, $c_1 = 0.290$, and $c_2 = 0.190$. The corresponding exchange energies are shown in Table 2. As indicated in Table 2, the values obtained from the present approximation compare favourably with the values obtained from the HFS exchange energy expression as well as the simple nonlocal expression of eq. [27] and the expressions containing

a cut-off factor due to respectively Becke (eq. [28*b*]) and DePristo *et al.* (eq. [29]).

VII. Concluding remarks

We have investigated various expressions based on the gradient expansion on the spherically averaged Fermi-hole correlation function $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ and the corresponding exchange energy expressions. In Section IV, we have shown that, for atomic systems, the expansion of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$ in powers of s must be carried out in two regions, for $0 < s < r_1$ where it is defined as a Taylor expansion, and for $s > r_1$ where it is defined as a Laurent expansion.

Becke (15*a*) has, as discussed in Section V, obtained an approximate expression, $\bar{\rho}_B^{\alpha\alpha}(r_1, s)$, for $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$, without taking into account the properties of the expansion in the second region. The function $\bar{\rho}_B^{\alpha\alpha}(r_1, s)$ represents a partial improvement over the local density approximation $\bar{\rho}_{X\alpha}^{\alpha\alpha}(r_1, s)$, since it goes to a maximum as a function of s for r_1 at the edge of an atomic shell, in agreement with the behaviour of the exact expression $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$. However, the coulomb potential $V_B^{\alpha\alpha}(r_1)$ corresponding to $\bar{\rho}_B^{\alpha\alpha}(r_1, s)$ is divergent in the exponential tail of atoms. A remedy for such a divergency was proposed by Becke (15*b*) in the form of an empirical cut-off factor for the second order gradient correction term in the potential expression. In Section VI, we have furnished a theoretical explanation for the origin of such a cut-off factor, based on the two-region expansion of $\bar{\rho}_x^{\alpha\alpha}(r_1, s)$. Finally, in Section VII, we have proposed an alternative approximate expression for the spherically averaged Fermi-hole correlation function $\bar{\rho}_{PW}^{\alpha\alpha}(r_1, s)$, derived from the two-region expansion of $\bar{\rho}_x^{\alpha\alpha}(r, s)$. The coulomb potential expression corresponding to $\bar{\rho}_{PW}^{\alpha\alpha}(r_1, s)$ contains a cut-off factor analogous to the function proposed by Becke and yields values for the exchange energies of atoms in good agreement with the Hartree–Fock results.

Laser flash photolysis studies of 2,4,6-trialkylphenyl ketones[1]

B. GUERIN[2] AND L. J. JOHNSTON

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received September 26, 1988

B. GUERIN and L. J. JOHNSTON. Can. J. Chem. **67**, 473 (1989).

2,4,6-Triisopropylbenzophenone (**3**), 2,4,6-trimethylbenzophenone (**4**), and 2,4,6-trimethylacetophenone (**5**) have been examined by laser flash photolysis. Relatively long-lived triplets compared to similar mono-alkyl substituted ketones have been observed for each (280 ns, >2 μs and 220 ns in acetronitrile for **3**, **4** and **5**, respectively). Photoenol intermediates with λ_{max} 360 nm and 380 nm were also observed from ketones **3** and **5**, respectively. Ketone **3** yielded a mixture of approximately equal amounts of *Z* and *E* enols in hexane. The *Z* enol had a lifetime of ~4 μs while the *E* enol did not decay appreciably during 100 μs. Biradical intermediates were not observed from any of the three ketones. Quenching rate constants for several energy transfer and hydrogen donor substrates are reported. For example, ketones **3** and **4** react with 1,4-cyclohexadiene with rate constants of 2.8×10^7 and 3.7×10^7 M^{-1} s^{-1}, respectively, to yield ketyl radicals with λ_{max} ~480 nm.

Key words: photoenolization, trialkyl phenyl ketone, flash photolysis, triplets.

B. GUERIN et L. J. JOHNSTON. Can. J. Chem. **67**, 473 (1989).

On a étudié les triisopropyl-2,4,6 (**3**) et triméthyl-2,4,6 (**4**) benzophénones ainsi que la triméthyl-2,4,6 acétophénone (**5**) à l'aide de la photolyse éclair au laser. Pour chacun de ces composés, on a observé des triplets dont la vie est relativement longue (280 ns, >2 μs et 220 ns respectivement pour les composés **3**, **4** et **5**, dans l'acétonitrile) si on la compare à celle de cétones semblables monosubstituées par des groupements alkyles. Dans les cas des cétones **3** et **5**, on a aussi observé des intermédiaires photoénoliques dont les λ_{max} sont respectivement à 360 et à 380 nm. Dans l'hexane, la cétone **3** fournit un mélange, en quantités pratiquement égales, des deux énols *Z* et *E*. Le temps de vie de l'énol *Z* est d'environ ~4 μs alors que l'énol *E* ne se décompose pratiquement pas durant 100 μs. On n'a observé d'intermédiaires biradicalaires avec aucune de ces trois cétones. On rapporte les constantes de vitesse de piégeage pour plusieurs transferts d'énergie et plusieurs substrats donneurs d'hydrogène. Par exemple, les cétones **3** et **4** réagissent avec le cyclohexadiène-1,4 avec des constantes de vitesse respectives de $2{,}8 \times 10^7$ et $3{,}7 \times 10^7$ M^{-1} s^{-1} et elles fournissent des radicaux cétyles dont le λ_{max} est d'environ ~480 nm.

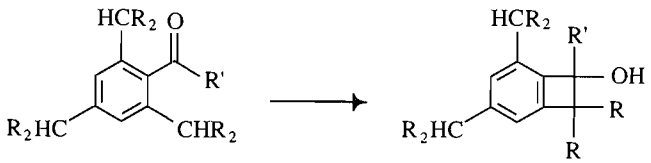
Mots clés : photoénolisation, phényl-cétone trialkylée, photolyse éclair, triplets.

[Traduit par la revue]

Introduction

The photoenolization of *o*-alkylphenyl ketones such as 2-methylacetophenone (**1**) and 2-methylbenzophenone (**2**) has been examined by conventional and laser flash photolysis by a number of groups (1–11). Despite some initial confusion, the mechanism for the reaction and the assignment of the various transients involved is now well-established. Briefly, intramolecular hydrogen abstraction from triplet **1** has been shown to give a rotationally equilibrated biradical (lifetime of 580 ns (3)) which then decays to a mixture of short- (*Z*) and long- (*E*) lived enols (2–5). In this case two kinetically distinct triplet states (0.5, 35 ns) have been observed with the shorter-lived *syn* conformer being the reactive species (3, 12). The long-lived *anti* conformer decays by bond rotation to the *syn* triplet followed by hydrogen abstraction. For ketone **2** the triplet is short-lived (~3.5 ns (11)) and yields a biradical with an approximately 30 ns lifetime in various solvents (2). The biradical again gives a mixture of two enols with lifetimes which vary with solvent. In both of these systems the net photochemistry (intra- or intermolecular) is inefficient since the primary decay pathway for the enol in the absence of trapping reagents is regeneration of the starting ketone (6, 13–15).

In contrast to ketones **1** and **2**, the intermediates involved in the photochemistry of 2,6-dialkylphenyl ketones have not been as well established. A variety of 2,4,6-trialkylacetophenones and benzophenones undergo photocyclization to benzocyclobutenols (reaction [1]) (16–19). For example, a quantum yield of 0.6 for photocyclization of 2,4,6-triisopropylbenzophenone (**3**) in benzene has been measured while a value of < 0.01 was determined for 2,4,6-trimethylbenzophenone, **4** (17, 18). Stern–Volmer quenching studies for these and related ketones have indicated that the triplet states are considerably longer-lived than those for ketones **1** or **2** (18), and the existence of two kinetically distinct triplets has been suggested for ketone **4** (18) and γ,2,4,6-tetramethylvalerophenone (15).



There are only several brief reports on transient measurements for trialkylphenyl ketones (3, 9, 20–22). For **3**, the transients observed by laser flash photolysis have been assigned to triplet **3** and the biradical formed by intramolecular hydrogen abstraction with lifetimes of 225 ns and 17 μs, respectively, in acetonitrile (20). Similar results were reported for 4′-substituted ketone **3** (21). Long-lived transients have been observed from several di- and trialkylbenzophenones but these have not been conclusively identified (8, 9, 22). The triplet state of 2,4,6-trimethylacetophenone (**4**) has been suggested to be relatively long-lived (ca. 300 ns) compared to **1** on the basis of Stern–Volmer analyses of methylnapthalene sensitization results and methyl viologen trapping (3). However, no definite conclusion as to the transients involved was reached.

We have examined ketones **3**, **4**, and **5** by laser flash photolysis in an attempt to identify the transients involved in the photoenolization. Our results confirm the presence of relatively long-lived triplet states for these ketones, as well as both short- and long-lived enols. However, no biradical intermediates were observed, which suggests that these intermediates have considerably shorter lifetimes than the triplet ketones and are, therefore, not detectable in our experiments. All three ketones have also been shown to undergo efficient hydrogen abstraction in the presence of good hydrogen donors.

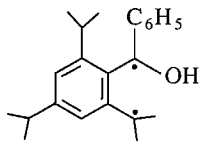
Results

Phosphorescence spectra

Phosphorescence spectra for ketones **3**, **4**, and **5** were measured in methylcyclohexane glasses at 77 K. Each gave a spectrum which showed the well-resolved vibrational structure typical of n,π* ketone triplets and which was not appreciably broader than the corresponding unsubstituted ketone. Triplet energies of 68.6, 68.4, and 72.1 kcal/mol were calculated from the 0,0 bands for **3**, **4**, and **5**, respectively. These may be compared to values of 68.6 and 73.7 kcal/mol for benzophenone and acetophenone in nonpolar solvents (23*a*). The phosphorescence spectrum of ketone **5** in a polar glass (9:1 ethanol/methanol) which would tend to favor a lowest π,π* triplet still showed the typical n,π* vibrational structure. Although these results are consistent with a n,π* lowest triplet, the measured lifetime of ~10 ms in methylcyclohexane at 77 K is somewhat longer than usual for n,π* states (23*b*). These results may indicate that the π,π* state is slightly lower in energy, with the emission arising from the nearby n,π* state.

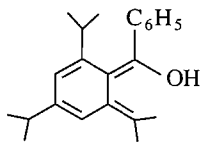
Phosphorescence spectra for all three ketones could also be readily measured in solution at room temperature using an optical multichannel analyzer. Phosphorescence from ketone **5** in methanol showed vibrational structure similar to that at 77 K.

Transient photochemistry of **3**



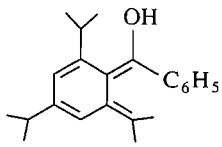
Excitation of ketone **3** at either 308 nm or 337 nm in methanol or acetonitrile (~3 m*M*) gave transient spectra similar to those previously reported (20). A short-lived transient with λ_{max} ~330 nm and a second broad band around 700 nm was observed on short timescales. This spectrum was replaced by a long-lived transient with λ_{max} = 360 nm (Fig. 1). Similar results were also obtained in hexane. In each solvent the decay of the short-lived transient could be monitored at 700 nm without any interference from other species. The decay kinetics at 700 nm corresponded very well to those of the growth of the long-lived signal at 360 nm (Fig. 1, insert) indicating that the first is the precursor of the second. The characterization of these two transients is discussed separately below.

(*a*) Triplet **3**. Lifetimes for the decay of the short-lived transient of 350, 280, 330, and 260 ns were measured at 700 nm in acetonitrile, methanol, benzene, and hexane, respectively. The decay kinetics at 325 nm agreed well with these results although there was a residual absorption due to the long-lived transient at this wavelength. The short-lived transient was confirmed to be triplet **3**, in agreement with the previous report (20), on the basis of the following observations.



In acetonitrile the ketone showed readily detectable phosphorescence which was similar to the spectrum recorded in a glass at 77 K and which decayed with the same lifetime as that of the triplet–triplet absorption at 700 nm. Furthermore, the 700 nm transient was efficiently quenched by typical triplet quenchers such as oxygen and 1,3-cyclohexadiene. Plots of the triplet decay rate at 700 nm against quencher concentration gave rate constants (k_q) of $3.3 \times 10^9\ M^{-1}\ s^{-1}$ and $1.9 \times 10^8\ M^{-1}\ s^{-1}$ for 1,3-cyclohexadiene and oxygen, respectively (see Table 1). It should be noted that similar results could be obtained at either 325 or 700 nm. The triplet was also quenched by 1-methylnapthalene with concomitant production of its triplet state (λ_{max} ~420 nm) with $k_q = 2.0 \times 10^9\ M^{-1}\ s^{-1}$. In this experiment the rate of decay of triplet **3** at 700 nm was measured as a function of added methylnapthalene. The growth kinetics of the methylnapthalene triplet were complicated by the presence of the additional long-lived species at 360 nm. Quenching rate constants for several other substrates are also tabulated in Table 1.

An Arrhenius plot for the decay of triplet **3** over the temperature range 240–312 K gave $E_a = 6.1 \pm 0.3$ kcal/mol^{-1} and log (A, s^{-1}) = 11.1 ± 0.2. These Arrhenius parameters are rather unusual for decay of the triplet by intramolecular hydrogen abstraction (24, 25).



(*b*) Enols **7** and **8**. The long-lived signal at 360 nm had previously been assigned to biradical **6** (20). However, the results outlined below indicate that this transient is a mixture of the *Z* and *E* enols, **7** and **8**. The decay kinetics at 360 nm (Fig. 2)

6

7

8

in hexane show one component with a lifetime of ~4 μs in addition to a much longer-lived residual which does not decay significantly over a 100 μs timescale. The latter accounts for approximately 50% of the total signal. Spectra obtained at 1.5 μs and 50 μs after laser excitation for the short and long components are similar except for slightly enhanced absorption at shorter wavelengths for the latter (Fig. 2). Qualitatively similar results are found in acetonitrile and methanol although the lifetimes for the short component are lengthened to 20 μs in acetonitrile and ~40 μs in methanol. These results suggest that the 360 nm transient is a mixture of the *Z* and *E* enols since both spectral and kinetic evidence agree well with that for enols in related systems (2, 4, 26). Furthermore, based on the data available for similar systems, biradical **6** would be expected to have an absorption similar to that of the ketyl radical from **3** and to be considerably shorter-lived than the transient at 360 nm (27, 28). For example, biradicals produced by intramolecular hydrogen abstraction in 2,4-dimethylbenzophenone and 2-*tert*-butylbenzophenone show absorption maxima at 535 nm (2) and 465 nm (29), respectively.

Quenching studies are also consistent with the enol assignment since oxygen, methyl viologen, and di-*tert*-butyl nitroxide all failed to affect the lifetime of the transient. However, each of these quenchers did decrease the triplet lifetime as well as decreasing the yield of the enol. These substrates are all known to react with biradicals with rate constants in excess of $10^9\ M^{-1}\ s^{-1}$ (27, 28) and would, therefore, react with a biradical

[a]At room temperature.
[b]Based on the triplet lifetime in oxygen-saturated solution.

of 17 μs lifetime at much lower quencher concentrations than those necessary to quench a 280 ns triplet. It is, thus, unreasonable to assign the observed species to biradical **6**.

Attempts to trap the proposed enols with typical dienophiles were unsuccessful since the triplet ketone was quenched by these substrates. For example, 0.01 *M* dimethylacetylene dicarboxylate was found to quench >50% of triplet **3**. The possibility of deuterium incorporation in recovered starting material was also investigated as a further test of the intermediacy of enols **7** and **8**. Accordingly, ketone **3** was photolysed to ~95% conversion in methanol and methanol-O-*d* with 350 nm light to prevent back reaction of the product cyclobutenol to starting material. The unreacted ketone was then examined by LC/MS to check for deuterium incorporation. The sample photolysed in deuterated solvent contained 30–40% monodeuterated ketone. Although this evidence suggests that deuterium incorporation may occur at the enol stage, the possibility of deuterium incorporation via the biradical cannot be ruled out.

(*c*) Attempted detection of biradical **6**. The above results suggest that although biradical **6** is probably formed from triplet **3**, it decays to enols **7** and **8** with a higher rate constant than that for triplet decay. No additional transients were observed on a short timescale in methanol, even at 65°C at which temperature the triplet lifetime has been shortened to ~70 ns. Similarly, no signals attributable to **6** were observed in the presence of sufficient 1,3-cyclohexadiene to substantially reduce the triplet lifetime.

Both direct and sensitized photolysis of benzocyclobutenol **9** have been reported to yield ketone **3**, presumably via biradical **6** (19). Accordingly **9** was investigated as an alternative source of

9

the biradical. Direct photolysis of **9** in acetonitrile gave very weak signals attributable to enols **7** and **8**. However, it was difficult to dissolve sufficient material to obtain a reasonable absorption of the starting material at the excitation wavelength (308 nm). Acetone sensitization at first appeared more promising since enols **7** and **8** were readily detectable upon 308 nm excitation of 0.15 *M* acetone in acetonitrile containing 0.05 *M* **9**. The growth of the enol signal was a function of the cyclobutenol concentration, as expected if it was produced from triplet **9** generated by energy transfer from acetone. Analysis of the enol growth as a function of [**9**] gave a rate constant for energy transfer of $\sim2\times10^7\ M^{-1}\ s^{-1}$, which agrees well with a previous estimate (19). This relatively slow rate constant made it impossible to add sufficient cyclobutenol to trap acetone

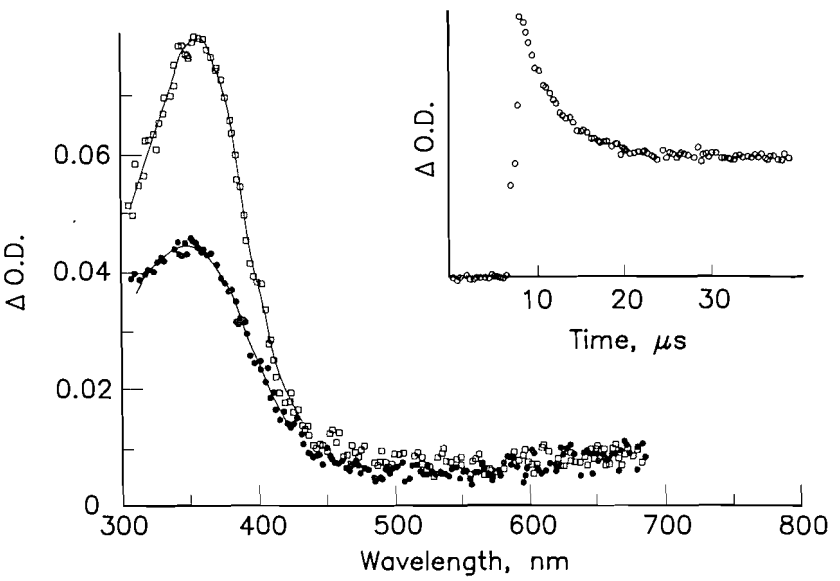

FIG. 2. Transient absorption spectra measured 1.5 μs (□) and 50 μs (●) after 308 nm excitation of **3** in hexane. *Insert*. Decay of the transient absorption at 360 nm.

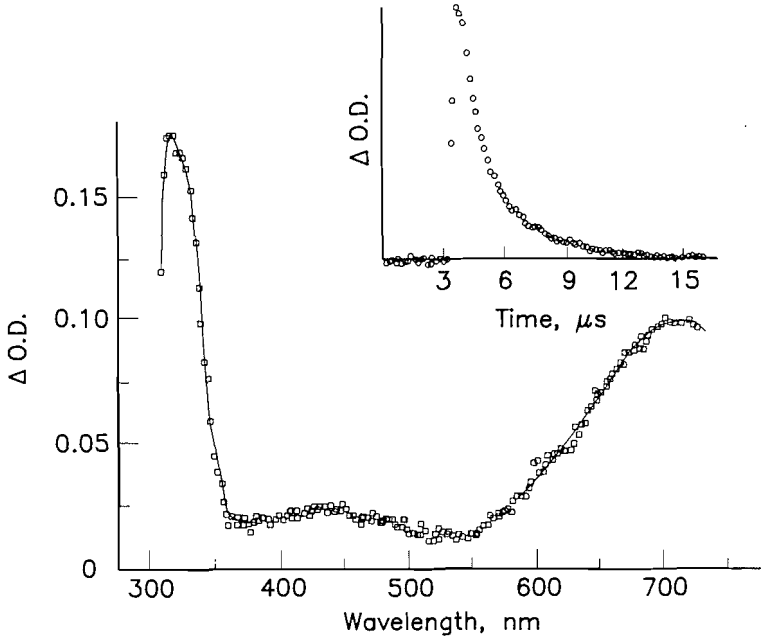

FIG. 3. Transient absorption spectrum produced by 308 nm excitation of ketone **4** in acetonitrile and measured 1 μs after the laser pulse. *Insert*. Decay of the transient absorption at 700 nm.

triplet sufficiently rapidly to detect signals from a short-lived biradical. Furthermore, the presence of relatively long-lived acetone triplets precluded the use of the commonly employed biradical trapping reagent, methyl viologen, as a means of determining the biradical lifetime.

2,4,6-Trimethylbenzophenone, **4**

Excitation of **4** at 308 nm in acetonitrile gave a spectrum which had λ_{max} at ~320 nm and a second broad band at 700 nm (Fig. 3) and which was very similar to that of triplet **3**. This transient was readily assigned to triplet **4** on the basis of its similarity to triplet **3**, its characteristic quenching by oxygen, 1,3-cyclohexadiene, and 1-methylnapthalene (Table 1) and the observation of phosphorescence at room temperature which decayed with the same lifetime as the transient absorption. Decay kinetics at either 320 or 700 nm gave lifetimes of ≥2 μs although the presence of a small second order component made it difficult to obtain a good first-order fit of the data. The second order component of the decay is attributable to triplet–triplet annihilation which is commonly observed for long-lived triplets at the transient concentrations produced by laser excitation.

In benzene, methanol, and hexane the triplet lifetimes were ≥4 μs, 850 ns, and 750 ns, respectively. Spectra in the latter two solvents showed a residual long-lived absorption in the 450–500 nm region which we attribute to ketyl radical formed by intermolecular hydrogen abstraction from solvent (see below; *vide infra*). The shorter triplet lifetimes in these solvents are, thus, readily explainable.

There was no evidence for the formation of any transients other than the triplet from ketone **4**. The long triplet lifetimes in

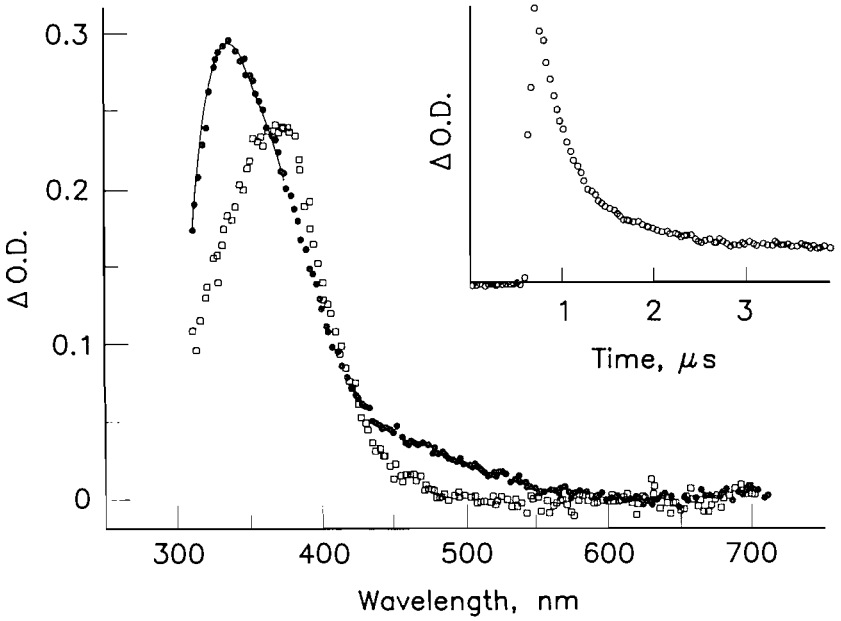

FIG. 4. Transient absorption spectra produced by 308 nm excitation of ketone **5** in methanol and measured 0.1 μs (●) and 2 μs (□) after the laser pulse. *Insert*. Decay of the transient absorption at 325 nm.

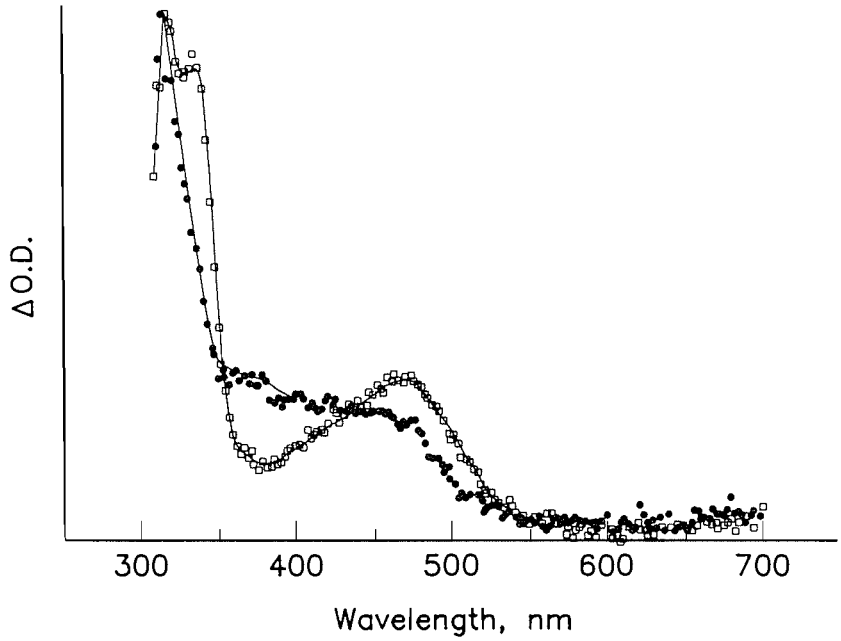

FIG. 5. Transient absorption spectra measured 1 μs after 308 nm excitation of ketone **3** in methanol + 1.1 *M* 1,4-cyclohexadiene (●) and of ketone **4** in acetonitrile + 0.21 *M* 1,4-cyclohexadiene (□).

inert solvents and the inefficient product formation (16) are consistent with the absence of biradical or enol signals in this system.

2,4,6-Trimethylacetophenone, **5**

Excitation at 308 nm of **5** in methanol produced a short-lived transient with $\lambda_{max} = 340$ nm and $\tau \sim 450$ ns. An additional weaker and longer-lived signal with $\lambda_{max} = 380$ nm was also observed (Fig. 4). Quenching experiments with oxygen and 1,3-cyclohexadiene (Table 1) confirmed that the short-lived signal was the triplet ketone. In these experiments, the triplet could be monitored conveniently at ~325 nm with only a small contribution (~15%) from the long-lived transient. Alternatively, the triplet absorbed weakly as 480 nm and could also be monitored at this wavelength. Triplet **5** was also quenched by 1-methylnapthalene although overlap of the signals due to triplet methylnapthalene, triplet **5**, and the 380 nm transient made it difficult to obtain an accurate rate constant in this case. Qualitatively similar results were obtained in benzene and acetonitrile where the triplet lifetimes were 100 and 220 ns, respectively.

The signal at 380 nm was assigned to the enol based on its similarity to the previous examples and on the following observations. There was sufficient overlap of the triplet and enol signals that, given the weak enol signals, it was not possible to observe the growth of the enol in methanol, acetonitrile, or benzene. However, quenching of the triplet with either oxygen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

or diene did result in a concomitant decrease in the enol yield, although the decay kinetics remained unchanged. For example, in oxygenated acetonitrile the triplet lifetime was shortened to ~35 ns (vs. 220 ns under nitrogen; 84% of the triplets quenched by oxygen) and ~80% of the enol signal was eliminated. These results demonstrate that all (or at least most of) the enol is formed from the observed triplet.

In all three solvents the enol was long-lived (>50 μs) and there was no evidence for a shorter-lived component that could be distinguished from the triplet ketone. This may be due to the relative extinction coefficients of the triplet and the short-lived enol as well as a low yield of the latter. Even in aerated solvents where the triplet lifetime was decreased to ~100 ns, a short-lived enol was not observed.

Intermolecular hydrogen abstraction by triplet **3**, **4**, and **5**

The triplet lifetimes of all three ketones are sufficiently long to permit intermolecular reactions with efficient hydrogen donors. Triplets **3** and **4** reacted with 1,4-cyclohexadiene with rate constants of $(2.8 \pm 0.2) \times 10^7\ M^{-1}\ s^{-1}$ and $(3.7 \pm 0.3) \times 10^7\ M^{-1}\ s^{-1}$, respectively (Table 1). In both cases the quenching of the triplet was accompanied by the appearance of a new long-lived absorption at approximately 480 nm (Fig. 5). These results are consistent with hydrogen abstraction by the triplet ketones to give substituted diphenylketyl radicals. Note that the spectrum for **3** in the presence of the diene still shows a small amount of enol in the 350–400 nm region. The growth of the radical could not be observed due to overlap with the triplet signals.

Ketone **5** was not readily quenched by 1,4-cyclohexadiene ($k_q < 1 \times 10^6\ M^{-1}\ s^{-1}$) but did react with tri-*n*-butyltin hydride with a rate constant of $(7.6 \pm 0.6) \times 10^7\ M^{-1}\ s^{-1}$.

Discussion

Triplet ketones

Ketones **3** and **4** both have triplet spectra which are considerably different from that of benzophenone itself (λ_{max} ~520 nm for the visible band (30)). However, the strong broad absorption at ~700 nm has been observed previously for another sterically hindered ketone, 2-*tert*-butylbenzophenone (29). Furthermore, the characteristic quenching behavior and the agreement between room-temperature phosphorescence lifetimes and those based on triplet–triplet absorption leave no doubt as to the assignment.

The relatively long lifetime for triplet **3** has been attributed to the fact that rotation is required for hydrogen abstraction to occur (18). This hypothesis was based on several factors. Firstly, the crystal structure (18) of **3** showed the most stable conformation to be one with the substituted phenyl nearly completely twisted from the plane of the benzoyl group and with the two *ortho*-isopropyl methine hydrogens 2.88 and 2.97 Å from the carbonyl oxygen. This distance was suggested to be too far for hydrogen abstraction to occur.[3] Secondly, the activation energy of 9.09 kcal/mol measured by Stern–Volmer quenching of product formation was thought to be too large for hydrogen abstraction (18). The Arrhenius parameters measured in the present study using direct detection are probably more reliable than the previous values. However, the activation energy of 6.1 kcal/mol, while lower than the previous number, is still somewhat higher than that normally measured for hydrogen abstraction by triplet ketones. For example, hydrogen abstraction by triplet benzophenone from cyclohexane shows an activation energy of 2 kcal/mol (25). Finally, Ito's hypothesis of bond rotation determining the triplet lifetime of **3** was also supported by the low isotope effect and by substituent effects on τ_T (18).

Ketone **4** has a considerably longer triplet lifetime than **3** in inert solvents and appears to undergo little, if any, intramolecular hydrogen abstraction. It is tempting to assume that the two *ortho* substituents are again forcing the ketone to adopt a conformation where the hydrogens are not within reach of the carbonyl. Since ketone **4** could not be obtained in crystalline form this hypothesis could not be tested by determining the crystal structure. Although the methyl groups would not be expected to exert as large an effect as the more bulky isopropyl groups, the abstraction of a primary hydrogen in **4** versus a secondary in **3** may be responsible for the longer lifetime of the former. For example, the intramolecular Type II hydrogen abstraction rate for valerophenone (secondary hydrogen) is over an order of magnitude larger than that for butyrophenone (primary hydrogen abstracted) (32). Certainly the difference in reactivity for the triplets of 2-methylbenzophenone and 2-*tert*-butylbenzophenone ($\tau_T < 1$ ns for both) compared to triplets **3** and **4** is remarkable.

Trimethylacetophenone also has a relatively long-lived triplet which may again be the result of steric hindrance from the two *ortho*-methyls preventing the necessary conformation for hydrogen abstraction. The longer lifetime for 5,8-dimethyltetralone compared to 2-methylacetophenone (4.5 ns versus 0.5 ns) has been attributed to a decrease in reactivity caused by increased π,π^* character resulting from trialkyl substitution (3). Similar effects may be operative for triplet **5**. A relatively long-lived triplet has also recently been reported for 2,4-*tert*-butylacetophenone (130 ns in methanol) (33).

A comparison of our results with previous studies of diene quenching of product formation indicates that, at least for **3** (18) and **5** (16*b*), similar diene concentrations quench both the observable triplet and cyclobutenol formation. This suggests that the triplet observed by flash photolysis is the precursor for the products. For ketone **4**, some cyclobutenol may arise from a shorter-lived triplet than the one observed here, based on the previously observed nonlinear Stern–Volmer plots (18). We also note that cyclobutenol formation from a short-lived triplet has also been suggested for a ketone similar to **5** (15). A triplet with a lifetime of ≤5 ns would not have been readily detectable in our experiments.

Biradicals

No transients attributable to biradicals produced by hydrogen abstraction could be observed. Given the long triplet lifetimes for the ketones and the variety of transients involved this result is not unexpected. The biradicals from **3** and **4** would reasonably be expected to have quite short lifetimes based on the measured lifetime for the 2-methylbenzophenone biradical (~30 ns) (2). In any case the earlier conclusion of long-lived (≥5 μs) biradicals from ketone **3** should be revised.

Enols

Previous product studies (17) had not shown any evidence for the formation of enols from ketone **3** but the present results indicate that a substantial yield of both *Z* and *E* enols is produced. This observation is fully consistent with previous studies of photoenolization of related ketones (2, 26). The *Z* enol is considerably longer-lived in both polar and nonpolar solvents than some earlier examples but this may result from steric effects on the enol decay. The observed solvent depen-

[3]It has been suggested that the upper limit for hydrogen abstraction is 2.72 Å (31).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

dence on enol decay agrees well with the literature data. The failure to observe products (17) derived from trapping of enols **7** and **8** is probably due to the fact that the typical dienophile concentrations required to trap other enols will also quench triplet **3** since it has a relatively long lifetime. We have in fact observed that 0.01 *M* dimethylacetylene dicarboxylate quenches >50% of triplet **3**. Although the reaction conditions for the attempted trapping of enols from **3** were not specified (17), we note that relatively high dienophile concentrations (>0.05 *M* (13)) are typically used in other examples. The reported rate constant for trapping of the enol from 2,4-dimethylbenzophenone is $10^2\ M^{-1}\ s^{-1}$ (9).

It is interesting to note that the yield of benzocyclobutenol product is quite high ($\Phi \leq 0.6$) for ketone **3** relative to **4** and **5** and other 2-alkyl aryl ketones. This raises the question of whether the product arises from the biradical or from one or the other of the enols. Although this question could be addressed by examining the benzocyclobutenol yield in the presence of a suitable enol trap, the complications resulting from the long-lived triplet prevent this approach. Furthermore, measurement of the quantum yields for enol formation in the transient experiments requires the enol extinction coefficient, a value which is not readily available.

The lack of enol signal from **4** is not surprising given its low reactivity towards intramolecular hydrogen abstraction. The previously observed and unidentified long-lived transient (8) from 2,6-dimethylbenzophenone in cyclohexane was most likely due to the ketyl radical not the enols. For ketone **5** only a long-lived enol was observed although it should be noted that a short-lived enol (<100 ns) would not have been readily detectable in this system. The observation of an enol transient in this system is consistent with the previous suggestion that deuterium incorporation in photolysed **5** occurs via the enol (16*a*). However, we again note that deuterium incorporation could occur at the biradical stage in both **3** and **5**.

Intermolecular reactivity

The measured rate constants for quenching of triplet **3** are all somewhat lower than for benzophenone itself (Table 1). For example, a rate constant of $7.4 \times 10^9\ M^{-1}\ s^{-1}$ has been reported for 1-methylnaphthalene quenching of benzophenone (26). For energy transfer quenchers such as 1,3-cyclohexadiene and 1-methylnapthalene these differences may be attributed to stereoelectronic effects which have been suggested in other systems where the π-systems of either the donor or acceptor are twisted such that the orbital overlap required for electron exchange is reduced (34). The results for the less hindered ketone **4** support this suggestion as the rate constants for quenching are consistently higher than those for **3**.

The rate of hydrogen abstraction from 1,4-cyclohexadiene for triplets **3** and **4** is approximately an order of magnitude lower than that for benzophenone ($k_q = 2.9 \times 10^8\ M^{-1}\ s^{-1}$) (25). This may also reflect steric effects of the *ortho* substituents although 4,4′-dialkyl substitution has also been found to decrease hydrogen abstraction rates for benzophenone (35). Twisting the rings away from planarity as in dibenzosuberone also produces the same effect as concluded from the fact that dibenzosuberone is less reactive than benzophenone in hydrogen abstraction reactions while dimethylanthrone is as reactive as benzophenone (36). The reactivity of triplets **3** and **4** towards hydrogen donors is in agreement with Ito's reports of shorter triplet lifetimes in hydrogen-donating solvents (e.g., mesitylene) based on Stern–Volmer studies (18). The low reactivity of triplet **5** towards 1,4-cyclohexadiene may reflect some π,π^* character for this triplet, since steric hindrance would not be expected to be as important here.

The spectra of ketyl radicals produced by intermolecular hydrogen abstraction for ketones **3** and **4** are considerably shifted from that of the diphenylketyl radical (λ_{max} ~540 nm) (37). This shift towards a more acetophenone ketyl-like spectrum probably reflects a decreased interaction between the two phenyl rings due to the presence of bulky *ortho* substituents. This is also consistent with the observation of λ_{max} ~465 nm for the 2-*tert*-butylbenzophenone biradical (29).

Conclusions

Ketones **3**, **4**, and **5** all have triplet states which are relatively long-lived (280 ns, >2 μs, and 220 ns, respectively) compared to similar 2-substituted ketones. For ketone **3** the long-lived transient previously assigned to biradical **6** (20) has been shown to be a mixture of *Z* and *E* enols, **7** and **8**. Biradical **6** was not detectable under our conditions indicating that its lifetime must be ≪100 ns rather than 17 μs as previously reported (20). For ketone **4** the long triplet lifetime is consistent with the absence of biradical or enol intermediates and with the inefficient photochemistry (17, 18). There was no evidence for more than one triplet state from any of the three ketones. All three ketones undergo relatively efficient quenching with energy transfer quenchers and hydrogen donors with, in some cases, decreases in rate constants which are consistent with steric or stereoelectronic effects resulting from the two *ortho* substituents. Ketyl radicals from **3** and **4** are readily detectable in the presence of 1,4-cyclohexadiene.

Experimental

Materials and general techniques

Ketones **3** (38) and **4** (39) were prepared by Friedel–Crafts acylation of 1,3,5-triisopropylbenzene and mesitylene, respectively, with benzoyl chloride and were purified by recrystallization from methanol and by chromatography, respectively. Ketone **5** was commercially available (Aldrich >99.5% by GC) and was used as received. Cyclobutenol **9** was synthesized by irradiation of **3** in benzene (350 nm) according to a literature procedure (16*a*). All solvents were spectrograde or Aldrich Gold Label and were used as received. 1,3-Cyclohexadiene and 1,4-cyclohexadiene were distilled before use and methyl viologen dichloride was recrystallized.

Phosphorescence spectra at 77 K were recorded on a Perkin–Elmer LS-5 spectrofluorimeter. Gas chromatographic analysis for purity of ketones **3**, **4**, and **5** and cyclobutenol **9** was done on a Perkin–Elmer 8320 gas chromatograph with a 12 m BPI on vitreous silica capillary column. LC/MS measurements were done on a Hewlett–Packard 5988A instrument with a reverse phase column with methanol/water mixtures as eluent.

Laser flash photolysis experiments

The laser flash photolysis facility has been described in detail elsewhere (40, 41). For these experiments either a Lumonics TE-860-2 excimer laser with a Xe–HCl gas mixture (308 nm, ~5 ns pulses, ≤20 mJ/pulse) or a Molectron UV-24 nitrogen laser (337 nm, ~8 ns pulses, ≤20 mJ/pulse) were used for excitation.

Samples were contained in $7 \times 7\ mm^2$ quartz cells and were deaerated by nitrogen purging. For oxygen quenching experiments samples were purged with oxygen/nitrogen mixtures of known composition prepared with a Matheson model 610 gas mixer.

Phosphorescence spectra at room temperature were recorded using an EG & G gated intensified optical multichannel analyzer (OMA) with either a 20 ns gate or a variable-time gate (>120 ns). Transient absorption spectra were also recorded using the OMA with the light from a 150 W xenon lamp as the monitoring beam.

The causative agent of toxicity in cultured mussels from a localized area of eastern Prince Edward Island has been identified as domoic acid, a neuroexcitatory amino acid. The toxin was isolated by a number of different bioassay-directed separation techniques including high-performance liquid chromatography, high-voltage paper electrophoresis, and ion-exchange chromatography, and characterized by a number of spectroscopic techniques including ultraviolet, infrared, mass spectrometry, and nuclear magnetic resonance. The isolation and purification methods are described in detail and some new analytical data for domoic acid are reported.

Key words: shellfish toxin, domoic acid, neurotoxin, bioassay-directed analysis.

On a identifié l'agent qui est la cause de la toxicité des moules d'élevage provenant d'une zone localisée de la portion est de l'île du prince Edouard; il s'agit de l'acide domoïque, un acide aminé neuro-excitant. On a isolé la toxine en faisant appel à un certain nombre de techniques de séparation basées sur des essais biologiques parmi lesquelles on peut citer la chromatographie liquide à haute performance, l'électrophorèse sur papier à voltage élevé ainsi que la chromatographie d'échange ionique; on l'a caractérisée par un certain nombre de techniques spectroscopiques dont l'ultraviolette, l'infrarouge, la spectrométrie de masse et la résonance magnétique nucléaire. On décrit en détail les méthodes d'isolement et de purification et on présente des données analytiques nouvelles concernant l'acide domoïque.

Mots clés : toxine des coquillages, acide domoïque, neurotoxine, analyse basée sur des essais biologiques.

[Traduit par la revue]

Introduction

Shellfish poisons have been known since antiquity (1) and a recent review (2) lists the different families of marine toxins. From a Canadian perspective, the paralytic shellfish poisons (PSPs) have been of most significance to the shellfish industry (3). PSPs are products of the cold-water dinoflagellates, *Gonyaulax* spp., which are ingested by filter-feeding shellfish. Another group of marine toxins of potential significance to the Canadian shellfish industry are the diarrhetic shellfish poisons (DSPs). These toxins are produced by other cold-water dinoflagellates belonging to the genus *Dinophysis*, and although there is no unambiguous evidence that a DSP outbreak has occurred in Canada, there have been serious outbreaks in Japan and Europe (4).

Towards the end of 1987, an outbreak of poisoning in Canada was traced to cultured blue mussels (*Mytilus edulis* L.) from a localized area of eastern Prince Edward Island (P.E.I.). During this period (November 11 to December 12) 153 cases of acute intoxication related to ingestion of toxic mussels were documented (5), corresponding to about three cases per thousand portions of mussels consumed.[3] Symptoms included vomiting and diarrhea, which in some cases were followed by confusion, memory loss, disorientation, and even coma. Three elderly patients died. In the other most severely affected cases neurological symptoms still persist (5). The term Amnesic Shellfish Poison (ASP) has been proposed for this new shellfish toxin.[4]

Chemical analysis at ARL and other laboratories soon established that the toxicity was not due to any of the marine toxins that are usually monitored,[5] nor to any of the known anthropogenic xenobiotics (e.g., heavy metals,[6] pesticides, PCBs, and PAHs[7]). Significantly, extracts of contaminated mussels, when injected intraperitoneally into laboratory mice, produced a very characteristic and reproducible scratching syndrome and even-

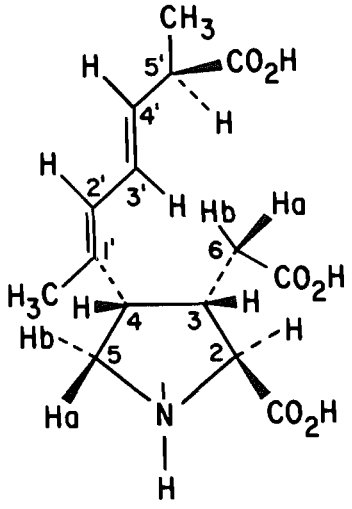
tual death. In the interest of public health the entire East Coast shellfish industry was closed down.



A task force was organized jointly by the Canadian Department of Fisheries and Oceans (DFO) and Health and Welfare Canada (HWC) to establish the extent of the contamination, the chemical nature of the toxin, and its origins. The Atlantic Research Laboratory (ARL) of the National Research Council of Canada, as part of the task force, was one of the laboratories that undertook the task of isolating and determining the chemical nature of the toxin. Within 5 days it was established at ARL that the mollusc toxin was domoic acid, a glutamate agonist (6) originally isolated some 30 years ago from the red alga *Chondria armata* Okamura (7, 8). This paper describes the methods used to isolate and identify domoic acid as the toxin in the contaminated mussels, and reports some new analytical and chemical data on this compound. The possible origin(s) of domoic acid in the 1987 outbreak are also discussed.

Results and discussion

Toxic mussels and control (nontoxic) mussels were supplied by DFO (Charlottetown, P.E.I.). In all cases extracts of both toxic and control mussels were taken through identical procedures. This was done to distinguish the effects of the unknown toxic factor in the bioassay from inherent salt toxicity in some fractions, and from possible interference of other factors such as chromatographic mobile phases. Furthermore, this parallel approach would highlight additional or unusual signals present only in chromatograms and spectra of toxic mussel fractions. Strict control over the dosage used in the mouse bioassay was an important element of the procedure. A preliminary dose–response curve indicated a narrow dynamic range, less than one order of magnitude, for the bioassay of the toxin(s). Extracts representing 0.3–2.5 g-equivalent of original wet tissue resulted in times of death (TOD) of 100–10 min after intraperitoneal injection respectively. Volumetric control was used to afford an intraperitoneal dose in the range of 1.2–2.5 g-equivalents original tissue, independent of the actual amount of nontoxic material extracted. In addition it was important to verify that the symptoms induced in the bioassay by toxic fractions were exactly the same as those observed with extracts of toxic mussels.

In initial experiments the digestive glands were separated from the remaining mussel tissue. Each tissue type was extracted with methanol:water (7:3 v/v), concentrated, and then partitioned against dichloromethane. In no case was organic-soluble toxicity found. Aqueous extracts of both tissue types from control mussels displayed no toxicity but the digestive-gland extracts of toxic mussels were found to be toxic. The remaining tissue of toxic mussels displayed some low-level toxicity but this was attributed to incomplete separation of the two tissue types. However, in the interest of time saving during very-large-scale extractions, the entire mussel was processed.

Later, when the toxin was firmly identified as domoic acid (**1**), other extraction procedures were studied. Quantitative extraction of **1** was achieved by boiling for 5 min, or by shaking for 24 h at room temperature, with either 50% aqueous methanol or water.[8] Interestingly, the standard Association of Official Analytical Chemists (AOAC) method (5 min boiling, 0.1 M HCl) for extracting PSPs for mouse bioassay (9) was less efficient (75–85% recovery). Moreover, the concentration of **1** in the extract was found to decrease upon storage at room temperature (up to 50% loss in 1 week), although this loss could be reduced by storage at −15°C. The feasibility of using the AOAC method for simultaneous monitoring for PSP and domoic acid has been examined.[9]

Domoic Acid

1

In the initial search for the toxin several methods of separation (high-performance liquid chromatography, hplc; high-voltage paper electrophoresis, hvpe; ion-exchange chromatography) were selected to avoid the possibility that in any one process the toxin might be obscured by other nontoxic compounds present in the extract. Furthermore, toxic fractions isolated by one scheme were cross-analyzed by another to verify that they were the same material, thus providing an internal check on the validity of the separation schemes.

Following cleanup of the toxic aqueous extract on an XAD-2 column, the resulting toxic fractions were subjected to hvpe. This approach has the advantage of separating the fraction into acidic, basic, or neutral components. By slicing the chromatogram into sections, followed by extraction with distilled water, it was found that *all* the toxicity moved towards the anode at pH 6.5, indicating that the toxin was acidic. By repeating this experiment and by taking narrower slices it was eventually apparent that the toxic activity was associated with a band that stained yellow with ninhydrin and migrated on the trailing edge of the red-staining band for glutamic acid.

Based on the premise that the toxic material was acidic and possibly a peptide, a reversed-phase hplc method was employed using a C_{18} stationary phase and gradient elution with water–acetonitrile mixtures containing 0.1% trifluoracetic acid (TFA) to suppress ionization of the carboxyl groups. Detection was provided by a diode-array detector (dad), which also allowed continuous acquisition of uv–visible spectra. The hplc profile of the toxic hvpe fraction obtained from the XAD-2 column, compared with the equivalent fraction from control mussels, is shown in Fig. 1. Initial runs were monitored by uv absorption at 210 nm since most peptides and organic acids absorb at this wavelength. The chromatogram for the toxic fraction showed a unique peak at retention time 12.1 min (peak D). The equivalent region in the control chromatogram showed no peak. Significantly, this same peak was consistently observed in other extracts of toxic mussels but could not be seen in any extracts

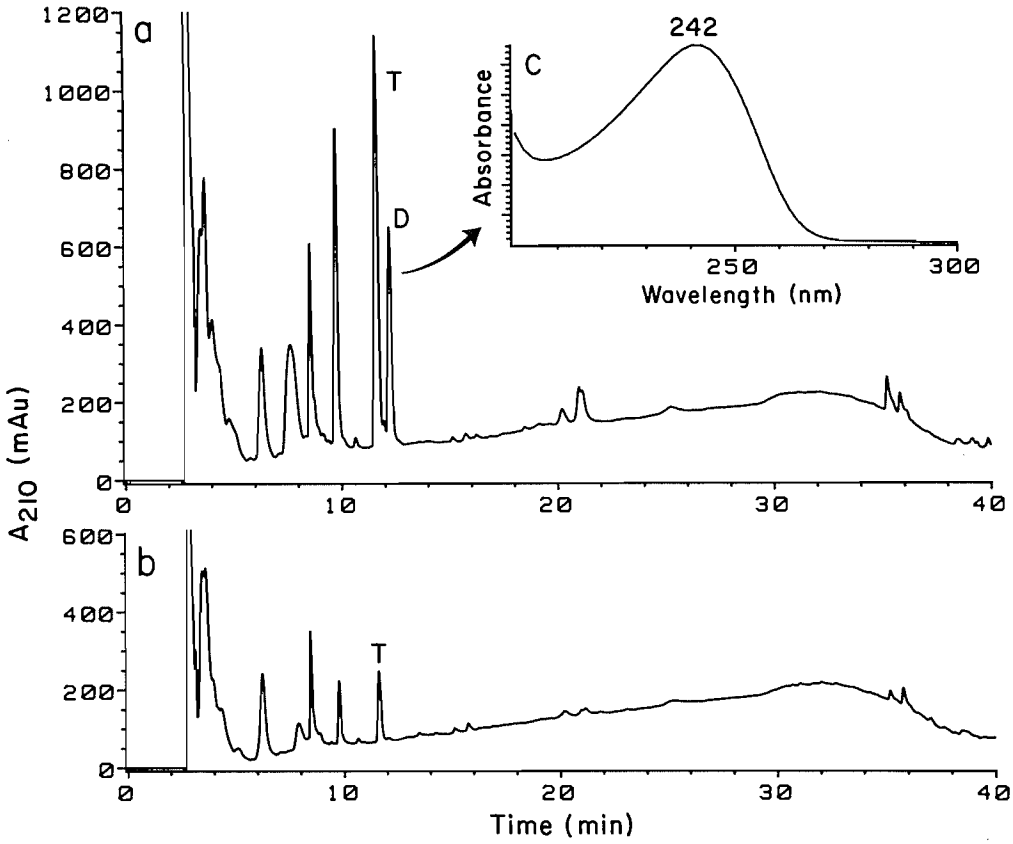

FIG. 1. Reversed-phase hplc chromatograms of XAD-2 cleaned extracts of (a) toxic and (b) control mussels. The inset (c) is the uv–visible spectrum acquired at the apex of peak D (domoic acid). Peak T is due to the amino acid tryptophan. Conditions: 25 cm × 2.1 mm i.d. 5-μm Vydac 201TP52 column at 40°C; 0.2 mL min^{-1} flow rate; gradient elution from TFA/H_2O (0.1:99.9) to CH_3CN/TFA/H_2O (50:0.1:49.9) in 25 min and then to CH_3CN/TFA (99.9:0.1) at 35 min and hold to 50 min; detection provided by absorption at 210 nm (20-nm bandwidth).

of control mussels. The uv–visible spectrum acquired at the apex of this peak revealed a single absorption maximum at 242 nm, suggesting the molecule contained two conjugated double bonds.

By employing the same chromatographic conditions on a preparative hplc scale it was possible to collect fractions corresponding to peak D as well as other regions of the chromatogram for bioassay and chemical analysis. However, all the fractions obtained in the first series of preparative runs displayed toxic effects both in the control and toxic samples, although the symptoms were different from those induced by toxic mussel extracts. This problem of general toxicity was resolved by replacing the rodenticide TFA used in the mobile phase with 1% acetic acid. The peak D fraction was then found to be toxic to mice, with the correct symptoms. All the other fractions from aqueous methanol extracts were nontoxic, even at a fivefold higher dose in terms of weight equivalents of original tissue. When the toxic hplc fraction was subjected to hvpe, a yellow band was observed at a position corresponding to where toxicity was previously observed. Bioassays of aqueous extracts of slices of this electrophoretogram revealed that only the yellow band was toxic. Conversely, this band obtained by preparative hvpe of crude extracts gave an hplc peak at the same retention time as peak D, and the same uv spectrum. The fact that such different fractionation schemes yielded the same toxic factor was very important to the certainty of the result.

Early on it was found the acidic toxin could also be eluted from a strongly basic ion-exchange resin (Dowex 1) using ammonia, and analysis of mussel extracts with a conventional amino acid analyser revealed an unusual peak present only in toxic samples. The compound eluted between methionine and isoleucine; the ninhydrin-reaction product absorbed strongly at 440 nm, consistent with a proline derivative. The acidic toxic factor could also be conveniently separated from a crude fraction using a weak anion-exchange resin. This proved to be a useful and facile method for purifying the toxin, and was also used to remove the toxin from the initial extract to assess the toxicity of the remaining residue. Concentrated residues from both toxic and control extracts obtained in this manner demonstrated some additional toxicity on mouse bioassay. However, the observed symptoms of general weakening and occasional cyanosis prior to death were quite different from those neurological symptoms induced by toxic mussel extracts. This additional toxic factor(s) was found to pass through a 500-Da ultrafilter membrane (Amicon YC-05) but once again the toxicity was the same for both control and toxic extracts. These symptoms of weakening, occasional cyanosis, and death have been observed with high salt concentrations; interestingly, similar symptoms have been observed in mice given intraperitoneal injections containing high (≥500 ppm) concentrations of zinc (10).

The ir spectra of the early toxic fractions from the preparative hplc runs were highly variable, due to dependence on the pH at which the films were deposited. Also, the spectrum of the toxin was partly masked by absorption bands due to acetate or trifluoracetate salts, contaminants originating from either acetic or trifluoroacetic acid used in the chromatographic separations. Both of these complications were removed by deposit-

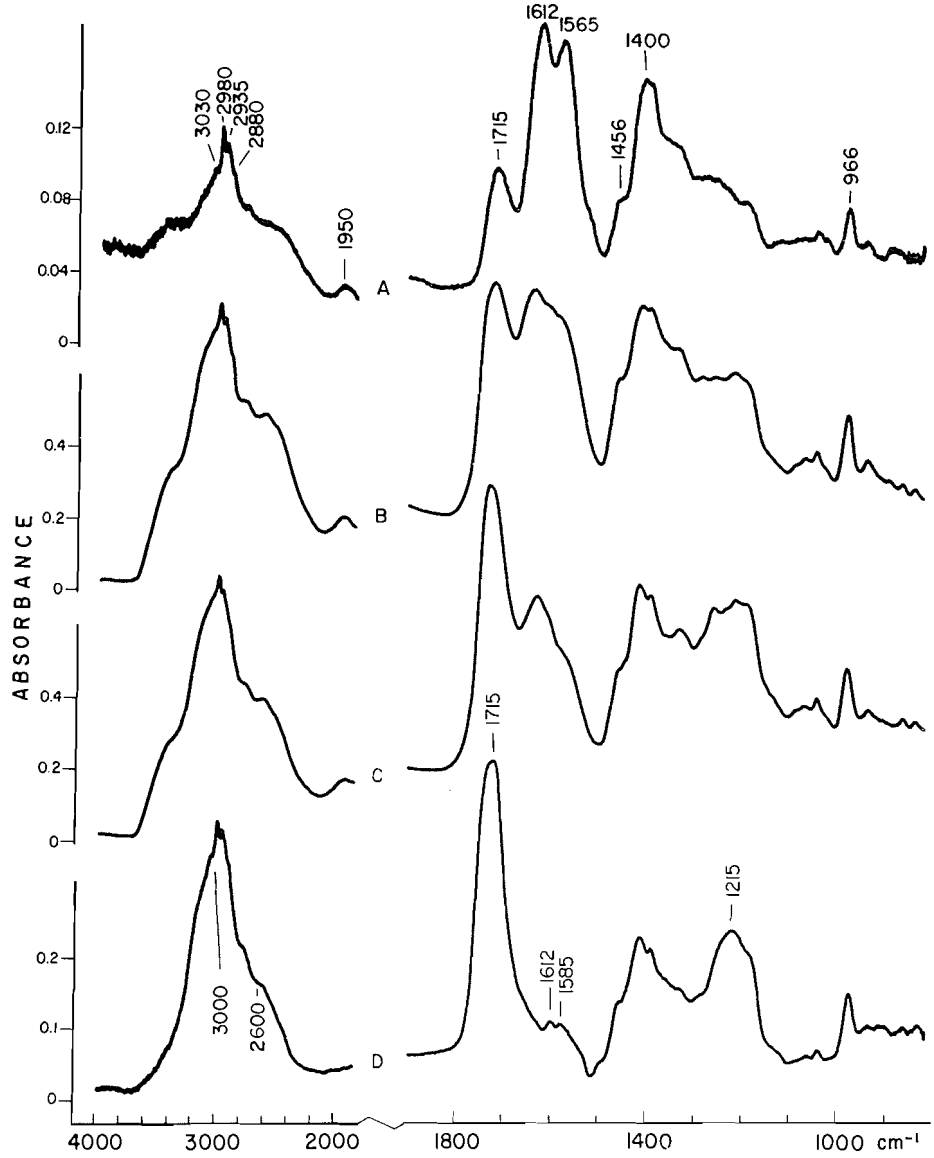

FIG. 2. Spectra of amorphous domoic acid films on a CaF_2 plate at increasing degrees of protonation from A to D.

ing the films from a solution of 0.1 M HCl. Acidification ensured a uniform and essentially complete protonation of the toxin molecules (shown by the absence of further spectral change upon evaporation from additional quantities of HCl). This procedure also replaced the acetate or trifluoracetate salts by the corresponding chlorides, which did not interfere with the spectrum, plus free acetic or trifluoroacetic acid, which rapidly evaporated during the preparation of the films. The spectrum of the toxin, when freed of such contaminants, contained absorption bands characteristic of non-ionized COOH (1215 and 1715 cm^{-1}, and a broad band with maxima at 3000, 2750, and 2600 cm^{-1}), ionized COO^- (1400 and 1612 cm^{-1}), NH_2^+ (1565–1585 and 1950 cm^{-1}), *trans* —CH=CH— (966 cm^{-1}), olefinic CH groups (3030 cm^{-1}), and aliphatic CH groups (2980, 2935, and 2880 cm^{-1}). Figure 2 shows a typical series of spectra obtained at pH varying from about 5.0 in Fig. 2A to about 1.0 in Fig. 2D, the molecule being fully protonated at the latter pH. Further details of the ir spectra and of vibrational assignments are discussed elsewhere (11).

Toxic and control fractions were continually screened by mass spectrometry (ms). In view of the water solubility of the toxin, ionization by fast atom bombardment (FAB) using a glycerol:water matrix (2:1 v/v) was selected. Since some early samples were heavily contaminated by chloride ions, the most useful spectra were initially obtained in the positive-ion mode where sodium adduct ions were the principal but less complicating problem. As the fractionation procedures succeeded in progressively concentrating the toxicity, the corresponding positive-ion mass spectra showed the increasing importance of an ion at *m/z* 312, which was absent from spectra of control samples. This observation, together with an ion at *m/z* 310 in the negative-ion spectra, suggested a molecular weight of 311 Da for the toxin.

Daughter-ion spectra of the positive FAB ions at *m/z* 312 displayed fragment ions at *m/z* 294, 266, 248, 220, and 74 (Fig. 3). An important feature of the daughter-ion spectra was the series of losses of 46 Da (presumably HCOOH) characteristic of protonated carboxylic acids including amino acids (12, 13). Because the even-electron ion at *m/z* 312 must contain an odd number of nitrogens, it appeared likely that this ion

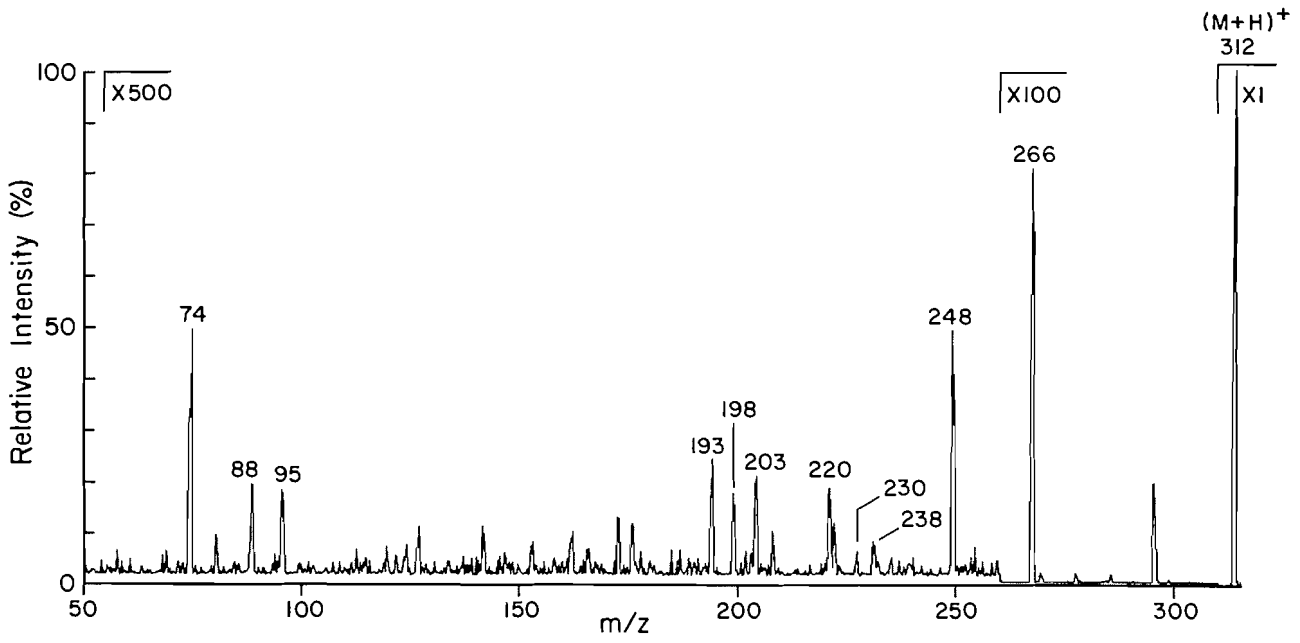

FIG. 3. Fragment-ion mass spectrum, for collision-induced dissociation in rf-only quadrupole, of MH^+ ions (m/z 312) formed by FAB ionization of the toxin in a glycerol/water matrix.

corresponded to a protonated molecule of a nitrogen-containing compound, perhaps an amino acid containing at least two carboxyl groups. This conclusion was substantiated by the successive losses of 44 Da (CO_2) from the $[M - H]^-$ anion.[10] Finally, in the positive-ion spectra, the intense signal at m/z 74 is characteristic of protonated α-amino acids and is ascribed (13) to the ion $H_2N{=}CH{-}COOH^+$. An alternative interpretation in terms of the odd-electron ion $C_3H_6O_2^{+\bullet}$ characteristic (14) of the substructure HOOC—$CH(CH_3)$— is unlikely to be valid for fragmentations of the even-electron species $[M + H]^+$ studied here.

Accurate mass measurement of the signal at m/z 312 gave a value of 312.146 ± 0.003 Da. Eleven molecular formulae are consistent with this value. However, by applying the additional restriction of an odd number of N atoms plus at least four oxygen atoms (at least two carboxyl groups, *vide infra*) the possibilities are reduced to just two, $C_{15}H_{22}NO_6$ and $C_{12}H_{26}NO_6S$, for the protonated molecule. In principle it should be possible to distinguish between these possibilities based on the relative intensities of the m/z 312, 313, and 314 signals. The intensity of the signal at m/z 313 invariably fell in the range 16–19% of that of the m/z 312 peak, favouring the $C_{15}H_{22}NO_6$ formula, but the intensity of the m/z 314 signal was highly variable due to beam-induced interaction of the analyte with the matrix.[10] Further support came from analysis by electron ionization (EI) of the *tert*-butyldimethylsilyl (TBDMS) derivative. Rapid (≤5 min) esterification of the three carboxyl groups gave a product whose spectrum displayed ions at m/z 653.395 ± 0.002 ($[M]^{+\bullet}$), 596.327 ± 0.002 ($[M - t\text{Bu}]^+$), and 494.314 ± 0.002 ($[M - t\text{BuMe}_2\text{SiO}_2\text{C}]^+$). After several hours reaction with the silylation reagent, intense signals were observed corresponding to a product in which the amine group was also derivatized: m/z 767.483 ± 0.002 ($[M]^{+\bullet}$), 710.414 ± 0.002 ($[M - t\text{Bu}]^+$), and 608.401 ± 0.002 ($[M - t\text{BuMe}_2\text{SiO}_2\text{C}]^+$).

[10]P. Thibault, M. A. Quilliam, W. D. Jamieson, and R. K. Boyd. Submitted for publication.

These data are consistent with a tricarboxylic amino acid of molecular formula $C_{15}H_{21}NO_6$.

The first useful ^1H nmr spectra of toxic fractions from preparative hplc were obtained with solutions in dry DMSO-d_6, this solvent having been chosen to avoid hydrogen exchange. Earlier ^1H nmr experiments using THF-d_8 had yielded broad spectra although, in retrospect, the domoic acid resonances are identifiable. The spectra in DMSO-d_6 showed the compound to be largely free of other organic impurities and enabled resonances characteristic of a vinylic methyl group (1.81 ppm, broad singlet) and an allylic methyl group (1.27 ppm, doublet) to be identified. The connectivity of the olefinic protons, H-5′, and the allylic methyl group was determined from their coupling patterns and a COSY experiment, establishing the partial structure CH_3—CH—CH=CH—CH=C—CH_3.

Throughout the structure analysis, the uv, ir, ms, and nmr data were continually updated and used to search the Chemical Abstracts and its accompanying Registry File on the STN International on-line database (16). The search, in which the partial structural data, toxicological data, and the marine origin of the toxin were used together, led at first to a long list of compounds. However, as the structural information became progressively more detailed this list shrank rapidly until the neuroexcitatory amino acid domoic acid (**1**) and its isomers emerged as likely candidates.

Meanwhile, ^1H nmr spectra of the toxin were found to sharpen when D_2O was added to the DMSO-d_6 solution, and in neat D_2O at pH 3.1 a ^1H spectrum was obtained that agreed in every respect (chemical shifts to 0.02 ppm, spin–spin couplings to 0.2 Hz) with detailed published data for domoic acid (15, 17), taking into account that the published data were obtained at an unspecified pH. It also became apparent that the ir and ms data for the toxin were consistent with the domoic acid structure, and further spectral data were collected that completed the final identification.

Further ^1H and ^{13}C nmr work (Table 1) was undertaken to confirm assignments and structural features of the toxin in D_2O

[a]Reference to TSP (sodium 3-trimethylsilylpropionate-2,2,3,3-D_4) solution in D_2O contained in a concentric tube. Domoic acid solution at pH 3.40 ± 0.05, temperature, 20.0°C.
[b]Error ca. ±0.02 ppm.
[c]s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, b = broad.
[d]Error ca. ±0.2 Hz. Spin–spin coupling connectivity confirmed by an ^{1}H COSY spectrum. Some couplings determined by simulation.
[e]Error ca. ±0.5% for single protons, ca. ±0.15% for methyl groups. Samples were not degassed or otherwise specially prepared for nOe measurements.
[f]^{13}C assignments determined from ^{13}C/^{1}H heterocorrelation experiment and ^{1}H-coupled ^{13}C spectrum.
[g]The nOe (if any) between H-4 and H-5β was not measurable in these experiments due to the closeness of the resonances.

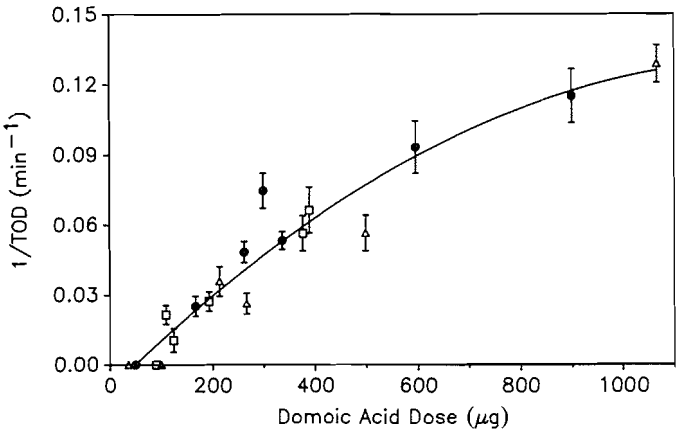

FIG. 4. Toxicity (expressed as reciprocal of time of death (TOD) of mouse) as a function of the amount of domoic acid injected into the mouse (as determined by hplc analysis). The toxicities of room temperature aqueous methanol (△) and boiling 0.1 M HCl (□) extracts of mussel tissue are similar to that of aqueous solutions of pure domoic acid (●). Each point is the mean of 2–4 replicate measurements of TOD for one solution, and the error bars represent an estimate of the standard deviation. The curve is a second-order polynomial least-squares regression on all data points.

solutions at pH 3.4. ^{1}H COSY spectra and spectral simulation showed that the published ^{1}H assignments (15, 17) were correct, as were ^{1}H–^{1}H spin–spin couplings apart from two minor differences probably resulting from our use of simulation to extract coupling constants. Homonuclear ^{1}H nuclear Overhauser enhancement (nOe) experiments with our sample of domoic acid (Table 1) confirmed the *Z,E* configuration of the conjugated double bond system in the side chain, as well as the *cis* relationship of H-3 and H-4 in the prolyl ring. The only nOe's between this side chain and the ring were those between the C-1′ methyl group and H-5α and H-6b, and between H-3′ and H-4. These are consistent with one orientation of the side chain, but rotation about the C-4—C-1′ bond is not necessarily precluded by the indetectability of nOe's that might be expected if rotation occurred. However, nOe between H-5′ and both H-3′ and H-4′ shows that rotation is possible about the C-4′—C-5′ bond.

Only sketchy details on the assignment of the ^{13}C nmr data of **1** have been published (7, 18) and a more complete account of the data and some reassignment is necessary. The ^{13}C nmr spectrum displayed 15 resonances composed of three carbonyl, four olefinic, and eight saturated carbons. All the carbons bearing hydrogen could be unequivocally assigned by a 2-D heterocorrelation experiment using the ^{1}H nmr shifts and coupling values previously assigned (15, 17) and reconfirmed in this work. Of the four remaining quaternary carbons the resonance at 133.8 ppm was assigned to C-1′. The high-resolution ^{13}C nmr data were used to distinguish the three remaining carboxyl resonances. The signal at 177.5 ppm ascribed to C-7 appeared as a doublet of triplets due to coupling with H-3 (J = 3.0 Hz) and with H-6a and H-6b (J = 7.2 Hz). The resonance for the C-2 carboxyl appeared as a doublet of doublets at 174.9 ppm (coupling to H-2 and H-3; J = 4.1 Hz) and the resonance for the C-5′ carboxyl appeared as a complex multiplet centred at 181.9 ppm (coupling to H-6′, H-5′, H-4′).

Finally, to determine if domoic acid accounted for all the observed toxicity, quantitative mouse and hplc assays were performed on a variety of extracts and on pure domoic acid solutions. The data, presented in Fig. 4 in the form of a dose–response curve, showed that no significant toxicity other than that due to domoic acid occurred in either the aqueous methanol or boiling acid (0.1 M HCl) extracts.

The intraperitoneal dose required for a 30-min death time in the mouse bioassay was about 10 mg kg^{-1} body weight (200 μg per average mouse). Pure domoic acid in aqueous solution produced the same symptoms in the mouse bioassay as did toxic-mussel extracts. The hplc assays have identified concentrations of domoic acid in toxic shellfish samples as great as 900 μg g^{-1} fresh tissue, although the levels varied greatly between batches and averaged about 300 μg g^{-1}.

This is the first report of domoic acid (**1**) in shellfish and the first known occurrence of human intoxication from ingesting the neurotoxin. Domoic acid was originally isolated from the warm-water red macro alga *Chondria armata* over 30 years ago (7, 8), and subsequently several isomers and derivatives of **1** have been isolated from the same algal source (17, 19). There are early reports (20) of the use of domoic acid as an anthelmintic for young children in Japan; however, the doses used were at the ~0.6 mg kg^{-1} level (20), an order of magnitude lower than those encountered by adult Canadians experiencing toxic effects from eating contaminated mussels.[4] Over the years there has been considerable interest in this group of metabolites because of their insecticidal properties (21) and because domoic acid (**1**) and the structurally related compound kainic acid (**2**) are potent members of a group of neurotoxic amino acids (22, 23). Biochemical, pharmacological, and physiological studies have shown that these excitatory amino acids act on three types of receptors in the brain, the hippocampus being the most sensitive structure in the central nervous system (CNS). These studies have been extensively reviewed (24–27). Very recently, the first electrophysiological evidence has been obtained that domoic acid activates kainate receptors and is more potent than kainic acid itself.[11] Furthermore, these electrophysiological results are in keeping with the clinical reports of patients hospitalized after ingesting the mussel toxin, and two post-mortem anatomopathological examinations are reported to reveal extensive damage of the hippocampus as well as spotty damage of thalamic and forebrain regions.[11]

Since domoic acid was not detected in mussels from elsewhere in P.E.I., it is unlikely that it is a metabolic product of the mussel itself. Moreover, toxic shellfish held in tanks of clean water for several weeks steadily purged themselves of domoic acid,[12] a phenomenon often associated with dietary products of shellfish (2). As efficient filter-feeding bivalves, mussels process huge volumes of water relative to their body size (28) and at least some of the toxin in their tissues could be derived from low (undetectable) levels of domoic acid in sea water. However, the food vector is probably much more important than the water vector to account for the substantial quantities of domoic acid found in contaminated mussels. It is estimated that the total amount of domoic acid in mussels from the affected area was probably in excess of 6 kg, with essentially all of the toxin body burden associated with digestive-gland tissue.

The major food items for cultured mussels are phytoplankton and other particulate detrital organic material such as fragmented seaweed tissue from benthic macrophytes and particulate organic material of terrestrial origin carried into the marine

environment by surface-water runoff. The available evidence on distribution and abundance of benthic macrophytes known to produce domoic acid, such as *Alsidium corallinum* C. Ag. (29), *Chondria armata* (6, 7), and its congener *C. baileyana* (Mont.) Harv. (unpublished result), effectively rule out these species as sources of the toxin in eastern P.E.I. Based on other shellfish toxin results, a more likely source of mussel contamination is the microalgal component of the plankton ingested by filter feeders.

Plankton tows made in early December 1987 by L. A. Hanic (University of Prince Edward Island) revealed an intense diatom bloom in the affected area. This diatom was subsequently identified as *Nitzschia pungens* Grun. f. *multiseries* Hasle.[13] When injected in mice, extracts of the plankton-tow samples produced symptoms identical to those produced by extracts from toxic mussels. As well, all toxic mussels harvested in December 1987 showed engorged digestive glands containing identifiable shell remnants of *N. pungens*; this was also true of toxic mussels harvested in late October and November, although no information is available on the plankton composition at that time. We observed domoic acid in plankton from the affected areas at levels sometimes in excess of 1% dry weight (30), sufficient to account for the levels observed in toxic mussels. This strong evidence that *N. pungens* was the major source of domoic acid in the toxic mussels is further supported by the demonstration of *de novo* production of domoic acid by laboratory cultures of *N. pungens* isolated from the affected area (34). Additional results from the St. Andrews Biological Station[14] and from the University of Rhode Island[15] document the very high probability that other phytoplankton such as *Amphora coffaeformis* (Ag.) Kütz. are also primary producers of domoic acid. In view of the importance of this new shellfish toxin to the Atlantic regional fisheries and the possibility that it may be more widespread, it is essential to determine what other marine organisms can synthesize domoic acid.

Experimental

All solvents were hplc grade from Anachemia. Distilled water was further purified by passage through a Millipore water-purification system (Milli-QR) equipped with ion-exchange and carbon filters. Trifluoroacetic acid (TFA) was purchased from BDH. Reference samples of domoic acid were obtained from Cambridge Research Biochemicals, England (Lot 12026), and Regis Chemical Company, Illinois, U.S.A. (Lot 2555). Melting points are corrected and were observed with a Kofler-type hot-stage apparatus. Optical rotations were measured using a Perkin Elmer model 141 polarimeter.

Infrared spectroscopy

Infrared spectra were recorded by microspectroscopic techniques using a BOMEM FT-IR spectrometer (model DA3.02) equipped with a "Spectroscope" microscope attachment made by Spectra-Tech Inc. The spectrometer was used with a KBr beamsplitter and a mercury – cadmium telluride detector. Spectra in the region 4000–700 cm^{-1} were recorded at a resolution of 2 cm^{-1} with 400 interferograms accumulated for each spectrum. A microgram quantity of domoic acid, dissolved in water and with the pH adjusted if necessary with dilute hydrochloric acid, was evaporated on a small AgCl or CaF_2 plate to yield a thin solid film approximately 3 mm in diameter and a few microns in thickness. Small circular areas of 0.1 mm diameter were visually selected, optically isolated by the microscope aperture, and their ir spectra recorded. The spectrum of an equivalent area of the empty plate was recorded as reference: the ratio of such spectral pairs yielded the transmittance spectrum, from which the absorbance spectrum was derived. Since the sample space was normally evacuated to a pressure of 0.2 Torr (26 Pa), the spectra obtained were those of anhydrous material.

Nuclear magnetic resonance spectroscopy

All nmr spectra were obtained with a Bruker MSL-300 spectrometer at room temperature (20°C), in 5-mm tubes, under the following conditions. ^1H spectra: 300.13 MHz, one-pulse sequence, spectral width (SW) 4505 Hz or 2403 Hz, acquisition time (AQ) 1.82 s or 3.41 s, 16 384 data points, delay between 45-deg rf pulses 8.6 s, data processed where necessary with exponential multiplication and zero-filling. Integrated intensities of signals were compared with those of a standard sucrose solution in D_2O using identical experimental conditions, allowing complete spin-lattice relaxation for quantitative estimation of concentrations. ^1H COSY spectra (31): SW 2401 Hz and 90-deg pulses. ^{13}C spectra: SW 16 667 Hz, AQ 0.983 s or 0.492 s, 30-deg pulses, and broadband ^1H-decoupling. ^{13}C coupled spectra used SW 13514 Hz and AQ 2.43 s. Nuclear Overhauser enhancements were obtained by irradiating selected resonances for 10 s between acquisitions at a power level just sufficient to cause saturation (ca. 180 mV peak–peak into a 50-ohm load via a directional coupler), and subtracting these spectra from one obtained under the same conditions but with irradiation well removed from any resonances. D_2O was used as a solvent and spectra were referred to TSP in a concentric tube. The concentration of domoic acid in the original preparation was estimated from the ^1H resonance areas to be 2.0(±0.1) mg in 0.7 mL D_2O, which was close to saturation at room temperature. A supersaturated solution of a later preparation of anhydrous domoic acid from mussels (9.4 mg in 0.6 mL D_2O) was used for ^{13}C–^1H correlation spectra. The ^1H and ^{13}C spectra reported in Table 1 were obtained from a saturated solution of the latter preparation at pH 3.4.

Mass spectrometry

All mass spectrometric measurements reported herein were conducted using a VG Analytical ZAB-EQ tandem hybrid mass spectrometer, or a VG Masslab 20-250 quadrupole mass spectrometer, each equipped with a VG11-250J datasystem. The FAB mass spectra were obtained using the ZAB-EQ instrument. Sample sizes in the range 10–100 nmol, in 1–10 μL of aqueous solution, were deposited on a gold probe tip, evaporated down to less than 1 μL, then mixed with about twice as much glycerol. Although this simple glycerol/water matrix kept the background to a minimum, the matrix was acidified with HCl when working in positive-ion mode. An 8-keV Xe^0 beam (Ion Tech FAB gun, 1-mA discharge current) was used. Conventional FAB mass spectra were obtained at a resolving power (10% valley) of 1500, scanning the range *m/z* 1300–50 Da with a cycle time of approximately 10 s. Mass assignments were reliable to within 0.1 Da. Masses of ions formed by FAB ionization were measured to better than 10 ppm by peak matching against either the matrix cluster ion at *m/z* 277 (3 glycerol molecules + H) or, in a separate determination for a sample doped with sodium iodide, the $Na_3I_2^+$ cluster at *m/z* 323; resolving power was 8000 (10% valley definition). Electron ionization (EI) spectra of the *tert*-butyldimethylsilyl derivatives formed by reaction of domoic acid in dimethylformamide with *N*-methyl-*N*-(*tert*-butyldimethylsilyl)trifluoracetamide (MTBSTFA, Regis Chemicals) were obtained using 70-eV nominal energy electrons. Accurate mass measurements of these EI ions were made by peak matching against perfluorokerosene at a resolving power of 8000. Tandem mass spectrometry experiments were done to obtain fragment-ion spectra of the ions at *m/z* 312 in the positive-ion FAB spectra. For these, the precursor ions were selected by the double-focusing BE stages of the instrument, decelerated, then focused into the rf-only quadrupole collision cell (q) containing argon at a pressure such that the intensity of the precursor ion signal was attenuated by 50–60% while the tandem quadrupole mass analyser (Q) was scanned. A collision energy (laboratory frame) of 30 eV was used. All tandem mass spectrometry data

were acquired in continuum mode, each spectrum representing the sum of at least 10 scans.

High voltage paper electrophoresis (hvpe)

Concentrated aqueous-methanol extract (approximately 1 mL) was streaked across the middle of a sheet of Whatman 3MM chromatography paper and air-dried. The paper on either side of the sample zone was wetted with pyridine–acetate buffer at pH 6.5 (pyridine:acetic acid:water, 25:1:225 by volume) and electrophoresis was carried out at 3 kV for 40 min in a Michl tank (32) with toluene as the heat exchanger. The paper was dried and vertical strips (1 cm wide) cut off and stained with cadmium acetate – ninhydrin (33). The remainder of the electrophoretogram was cut into horizontal zones, which were eluted with water and taken to dryness *in vacuo*.

Amino acid analysis

Dilute aqueous extracts (0.1 mL) were loaded on a Beckman 119CL automatic amino acid analyzer. The cation-exchange column (sulfonated polystyrene, 30 μm diameter) was equilibrated with 0.3 M sodium citrate buffer, pH 3.25, and eluted with 0.3 M sodium citrate buffers of pH 3.95 and pH 6.40. The dual-wavelength detector recorded absorbances of ninhydrin reaction products at 570 and 440 nm.

High performance liquid chromatography (hplc) and ultraviolet (uv) spectroscopy

Domoic acid determinations were performed on a Hewlett–Packard model 1090M hplc equipped with a ternary DR5 solvent delivery system, variable volume (1–25 μL) injector and autosampler, built-in HP1040 diode array detector (DAD), and HP79994 data system. A 25 cm × 2.1 mm i.d. 5-μm Vydac 201TP52 column (Separations Group, Hesperia, CA) was operated at 40°C with 0.5 mL min^{-1} 10% (v/v) acetonitrile in water with 0.1% (v/v) trifluoroacetic acid and 5-μL injection volumes. Detection was accomplished by monitoring absorption at both 210 and 242 nm with 10-nm bandwidths. Ultraviolet acquisition was either in the peak-triggered mode or in the continuous mode with a 640-ms scan interval. Prior to analysis, aqueous extracts (1–2 mL; pH 6–7) were applied to a prerinsed C_{18} solid-phase extraction cartridge (Supelco, Bellfonte, PA), eluted with 10% aqueous acetonitrile (3 mL) into a 5-mL volumetric, made up to volume, and filtered through a dry 0.22-μm filter. Calibration was accomplished using a solution of pure domoic acid isolated by heart-cutting the domoic acid peak from preparative hplc, and calculating domoic acid concentration from the literature molar absorptivity (7) at 242 nm (2.63×10^4) and the observed optical density at 242 nm. The molar absorptivity of purified domoic acid was later redetermined in our laboratory and found to be pH-dependent. The value is $(2.43 \pm 0.04) \times 10^4$ at pH 2.0 and $(2.61 \pm 0.04) \times 10^4$ at pH 7.0.

Isolation of domoic acid

(i) By ion-exchange chromatography

Digestive glands (572 g) were excised from frozen, cooked, mussel tissue (1826 g) (processed by North Ocean Enterprises Ltd., Souris, P.E.I.) and homogenized with a mixture of distilled water (450 mL) and methanol (650 mL). The homogenate was stirred and heated at 65°C for 10 min. The cooled mixture was centrifuged (3500 rpm for 10 min) and the supernatant decanted. The residue was washed twice with 50% aqueous methanol (1 × 600 mL; 1 × 300 mL). The combined supernatants were concentrated *in vacuo* to give a viscous golden-brown oily residue. This was taken up in water (200 mL); an aliquot (10 mL) was reevaporated to give a residue (1.62 g), shown by hplc to contain 35.8 mg of domoic acid.

The residue (30.8 g), obtained by evaporating the remaining solvent (190 mL), was triturated with methanol. This afforded an insoluble cream-coloured solid (11.13 g) and a methanol-soluble fraction (17.91 g).

The solid was dissolved in water (325 mL), the pH adjusted to 5.0, and the solution centrifuged. The supernatant was placed on a Bio-Rad AG 3-X4 column (2.5 × 25 cm; 107 mL resin; OH^- form). After washing with water (700 mL) and 2 M acetic acid (200 mL), fractions (400 mL) containing domoic acid were eluted from the column with 4 M acetic acid. Evaporation gave residue A (691 mg).

The methanol-soluble fraction above was dissolved in water (200 mL), extracted with dichloromethane (3 × 200 mL), placed on a Bio-Rad Ag 3-X4 column, and treated as described above. The domoic acid fraction (350 mL) was evaporated *in vacuo* to give residue B (889 mg).

Residues A and B were combined and crystallized from water to give domoic acid (208 mg), mp 200–205°C (subsequent crops gave an additional 273 mg of less pure material). Successive recrystallizations from water gave pure domoic acid dihydrate (180 mg), mp 215–216°C (lit. (8) mp 217°C). This melting point refers to loss of polarizing properties, and deformation, of the dihydrate crystal examined as soon as possible after preparation. Such crystals do not exhibit this well-defined behaviour on standing. $[\alpha]_D^{23}$ −120.5° for anhydrous material; reported value (29) for dihydrate, −108°, equivalent to −120.5° for the anhydrous compound. *Anal.* calcd. for $C_{15}H_{21}NO_6$: C 57.87, H 6.80, N 4.50%; found (after drying at 50°C for 18 h): C 57.54, H 6.98, N 4.16%.

(ii) By preparative hplc

Shucked frozen mussels (≈800 g wet wt) were homogenized with methanol:water (7:3 v/v; 3 L) and allowed to stand at room temperature for 24 h with occasional stirring. The slurry was filtered through glass-fibre paper and the filtrate concentrated *in vacuo*. The concentrate was partitioned twice against dichloromethane to yield an organic-soluble extract (12.4 g) and a water-soluble extract (≈65 g). Biological testing showed the toxicity to be present in the aqueous fraction. A portion of this aqueous extract (4 g) was applied to a column (40 × 3 cm) containing XAD-2 (Amberlite) resin. Fractions (200 mL) were collected during elution with a stepwise gradient from water through methanol. The toxicity was contained in the first two fractions. These were combined, concentrated *in vacuo*, and applied to a preparative reversed-phase column (Supelcosil LC-18 5 μm; 25 cm × 21.2 mm) and eluted with a linear gradient of 10% acetonitrile–water through 35% acetonitrile–water (1% acetic acid; flow rate 12 mL min^{-1}). The eluant was monitored at 242 nm and domoic acid (retention time 10.5 min) was collected following repeated injections. After concentration, the resulting yellowish oil was dissolved in the minimum volume of hot water and, upon cooling, straw-coloured crystals of domoic acid formed. Repeated crystallization yielded colourless needles, mp 212–214°C, identical (uv, ir, nmr) with authentic material.

Bioassays

The biological assays were performed using female mice (CD-1, Charles River Canada Inc.) weighing 16–23 g. Each was injected intraperitoneally with an extract (1 mL) and observed for up to 3 h. At least two mice were used for each test. The symptoms varied depending on the dose of domoic acid. Mice with death times of less than 13 min exhibited circling movements, occasional barrel rotation, and convulsions. Mice with longer death times exhibited loss of coordination, scratching of shoulder area with back legs alternating from one leg to the other at 3 to 20-s intervals, occasional aggressiveness, and gnawing or biting.

Acknowledgements

We acknowledge the efforts and cooperation of our DFO colleagues, particularly R. Bourque, J. Worms, and L. Lea (Gulf Region) and R. F. Addison and J. E. Stewart (Scotia-Fundy Region), and those of our HWC colleagues including H. B. S. Conacher, S. W. Gunner, J. F. Lawrence, and E. Todd. We thank L. A. Hanic, University of P.E.I., for phytoplankton samples, often collected under extreme weather conditions.

We would also like to thank our NRC colleagues, J. W. McLaren (Ottawa) for heavy metal analysis, C. J. Bird and J. L. McLachlan (Halifax) for biological examination of algal and mussel samples, A. M. Backman and A. R. Taylor, CISTI–ARL, for library services, and F. E. Isaacs, Public Relations and Information Services, for a magnificent job under enormous pressure. It is a particular pleasure to acknowledge the extraordinary efforts of the ARL staff throughout this work.

They include the following technical staff: C. A. Craft, E. W. Dyer, D. J. Embree, M. G. Flack, C. Gillis, M. Greenwell, W. R. Hardstaff, P. LeBlanc, N. I. Lewis, G. K. McCully, M. McInerney-Northcott, D. O'Neil, P. F. Seto, and D. F. Tappen, and the entire maintenance and administrative support staff, in particular K. V. Gray, W. J. Gray, H. O. Henderson, K. D. MacLeod, D. R. Robson, G. Saab, C. T. Vaughan, H. R. Watts, and B. Willis.

Finally, we thank Dr. Y. Ohfune, Suntory Institute for Bioorganic Research, Osaka, for the generous gift of a quantity of (−)-domoic acid obtained by total synthesis (ref. 15).

Synthetic antigenic determinants of the *Brucella* A polysaccharide: A disaccharide thioglycoside for block synthesis of pentasaccharide and lower homologues of α1,2-linked 4,6-dideoxy-4-formamido-α-D-mannose[1]

THOMAS PETERS[2] AND DAVID R. BUNDLE

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 4, 1988

THOMAS PETERS and DAVID R. BUNDLE. Can. J. Chem. **67**, 491 (1989).

Methyl glycosides **13**, **18**, and **22**, which represent potential antigenic determinants of the *Brucella* A polysaccharide, are the first synthetic analogues of this antigen. Their synthesis was necessitated by crystallographic studies of a Fab combining site obtained from a monoclonal antibody that binds the *Brucella* A antigen and synthetic pentasaccharide. Monosaccharide synthon **3** and disaccharide **7**, *S*-ethyl glycoside derivatives of 4-azido-4,6-dideoxy-D-mannose, have been used successfully as key intermediates in a convergent strategy to synthesize α1,2-linked homo-oligosaccharides of 4,6-dideoxy-4-formamido-D-mannose. The disaccharide thioglycoside **7** was activated by methyl triflate in the presence of selectively protected mono- or trisaccharide alcohols **1**, **6**, or **10** to give α1,2-linked tri- and pentasaccharides **8**, **9**, and **19**. Despite the non-participating glycosyl substituent at position two of the thioglycoside, 1,2-*trans* glycosidic products appeared to be formed exclusively. Conversion of **3** to the glycosyl bromide **5** by bromine under mild conditions provided routes to both the disaccharide building block **7** and a tetrasaccharide **15** using conventional silver triflate promoted glycosylation reactions. Deprotection was accomplished by transesterification, hydrogen sulphide reduction of azido groups, followed by *N*-formylation and finally hydrogenolysis of benzyl ethers.

Key words: *Brucella* A antigen, pentasaccharide synthesis, thioglycosides, oligosaccharide building units, 4,6-dideoxy-4-formamido-D-mannose, antibody combining sites.

THOMAS PETERS et DAVID R. BUNDLE. Can. J. Chem. **67**, 491 (1989).

Les glycosides de méthyle **13**, **18** et **22** qui représentent des déterminants antigéniques potentiels du polysaccharide de la *Brucella* A sont les premiers analogues de synthèse de cet antigène. On a dû réaliser leur synthèse pour effectuer des analyses de structure par diffraction des rayons-X sur un Fab cristallin combinant le site de liaison de l'antigène *Brucella* A et le pentasaccharide de synthèse. Le monosaccharide de synthèse **3** ainsi que le disaccharide **7**, des dérivés glycoside de *S*-éthyle de l'azido-4 didésoxy-4,6 D-mannose, ont été utilisés avec succès comme intermédiaires clés dans une stratégie convergente conduisant à la synthèse d'homo-oligosaccharides liés en α1,2 du didésoxy-4,6 formamido-4 D-mannose. On a activé le thioglycoside du disaccharide **7** par le triflate de méthyle en présence des mono- ou tri-saccharides alcools **1**, **6** ou **10**, protégés d'une façon sélective, et on a obtenu les tri- et penta-saccharides **8**, **9** ou **19** liés par les positions α1,2. Malgré la présence d'un substituant glycosyle non-participant en position deux du thioglycoside, il semble que les produits glycosidiques 1,2-*trans* se forment d'une façon exclusive. La transformation du composé **3** en bromure de glycosyle, par l'action du brome dans des conditions douces, fournit des voies pouvant conduire, par des réactions de glycosylation conventionnelles activées par le triflate d'argent, soit au disaccharide **7** ou au tétrasaccharide **15**. On a procédé à la déprotection par le biais d'une transestérification qui a été suivie d'une réduction des groupements azido par le sulfure d'hydrogène et d'une *N*-formylation et finalement d'une hydrogénolyse des éthers benzyliques.

Mots clés : antigène *Brucella* A, synthèse des pentasaccharides, thioglycosides, éléments d'édification des oligosaccharides, didésoxy-4,6 formamido-4 D-mannose, sites de liaison des anticorps.

[Traduit par la revue]

Introduction

Structural studies of the *Brucella* A and M antigens have shown these to be distinctive linear homopolymers of the rare monosaccharide 4,6-dideoxy-4-formamido-D-mannose (1, 2). The A antigen is an α1,2-linked polymer (1),

$$\rightarrow 2)\text{-}\alpha\text{-D-Rha4NFo}\,(1\rightarrow_n$$

while the M antigen possesses a repeating unit with four α1,2-linked and one α1,3-linked residues (2):

$$\rightarrow 2)\text{-}\alpha\text{-D-RhaNFo}(1\rightarrow 3)\text{-}\alpha\text{-D-Rha4NFo}(1\rightarrow 2)\alpha\text{-D-}$$
$$\text{Rha4NFo}(1\rightarrow 2)\text{-}\alpha\text{-D-Rha4NFo}(1\rightarrow 2)\text{-}\alpha\text{-Rha4NFo}(1\rightarrow$$

Despite their homology the A and M antigens may be distinguished by cross-absorbed antibody preparations and these are used to serologically differentiate *Brucella* strains (3–5). Monoclonal antibodies exhibiting similar specificity have been obtained (6)[3] and one crystalline Fab fragment has been successfully analyzed by X-ray diffraction.[4] To study the structural basis for the differentiation of the A and M antigen by antibodies and to map the antibody combining site by hapten binding studies, a series of oligomers containing from three to five saccharide residues was required.

The key intermediate **1** has been synthesized from D-mannose in 10 steps (7) and shown to be effective in the preparation of a disaccharide and trisaccharide using conventional silver salt promoted glycosylation reactions (7, 8). In this work we describe the utilization of **1** to prepare *S*-ethyl glycoside derivatives **3** and **7**, which undergo methyl triflate promoted glycosylation to provide 1,2-*trans*-linked oligomers of the *manno* series in both high yield and stereospecificity. A preliminary account of this work has appeared (9).

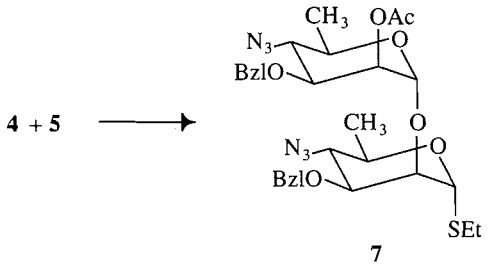
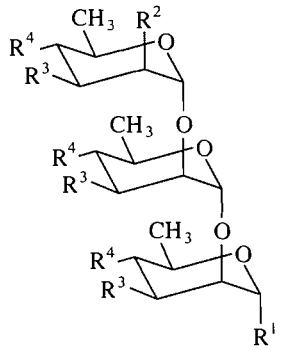
Results and discussion



The successful convergent approach adopted here for the synthesis of α1,2-linked homo-oligomers of the rare sugar 4,6-dideoxy-4-formamido-D-mannose was made possible by the use of thioglycosides. This is, to our knowledge, the first time synthetic analogues of the *Brucella* A antigen have been prepared by utilizing thioglycosides as key intermediates. The target oligosaccharides were essential components for studies of antibody combining sites directed against the *Brucella* A antigen. A crystalline Fab fragment from one antibody also crystallizes in the presence of the synthetic pentasaccharide.

A high yield synthesis from D-mannose (7, 8) of the key intermediate methyl 4-azido-3-*O*-benzyl-4,6-dideoxy-α-D-mannopyranoside (**1**) provided the foundation of our work. Acetylation and subsequent mild acetolysis of **1** gave the 1,2-

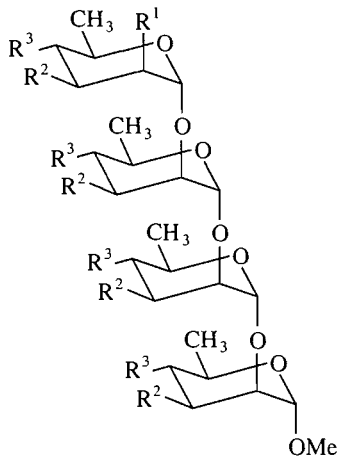


1 R^1 = OMe, R^2 = OH
2 R^1 = OAc, R^2 = OAc
3 R^1 = SEt, R^2 = OAc
4 R^1 = SEt, R^2 = OH
5 R^1 = Br, R^2 = OAc
6 R^1 = $O(CH_2)_8CO_2Me$, R^2 = OH

di-*O*-acetyl derivative **2** (8), which was converted to the corresponding *S*-ethyl glycoside **3** by reaction with Lewis acid and ethanethiol (10). Transesterification of **3** gave a selectively protected monosaccharide alcohol **4**, while reaction of **3** with bromine under mild conditions (11) provided a facile route to the glycosyl bromide **5**. Silver salt assisted glycosylation of **4** by **5** provided the crucial disaccharide **7**, which served as the building unit for oligosaccharide assembly. It was essential to utilize the glycosyl bromide **5**, because the more direct route to **7** from the two thioglycosides **3** and **4** utilizing methyl triflate activation causes concurrent activation of the glycosyl acceptor and the glycosyl donor.

7

The most attractive and direct route to synthesis of higher oligomers of 4,6-dideoxy-4-formamido-D-mannose involved block synthesis employing **7** as a glycosyl donor with mono- and trisaccharide acceptors such as **1** and **10**. The functionalized monosaccharide glycoside **6** provided access to an oligosaccharide that could be covalently attached to proteins (12). Trisaccharides **8** and **9** were prepared using disaccharide donor **7** and either of the selectively protected glycosides **1** or **6**. Methyl triflate activation (13, 14) of the *S*-ethyl disaccharide glycoside **7** in the presence of the monosaccharide alcohol in dichloromethane solution provided trisaccharides **8** and **9** in greater than 80% yield. A carbon-13 nmr spectrum indicated that the isolated product was exclusively α-linked by virtue of the one-bond heteronuclear coupling constant, $^1J_{C,H} \approx 170$ Hz



8 R^1 = OMe, R^2 = OAc, R^3 = OBzl, R^4 = N_3
9 R^1 = $O(CH_2)_8CO_2Me$, R^2 = OAc, R^3 = OBzl, R^4 = N_3
10 R^1 = OMe, R^2 = OH, R^3 = OBzl, R^4 = N_3
11 R^1 = OMe, R^2 = OH, R^3 = OBzl, R^4 = NH_2
12 R^1 = OMe, R^2 = OH, R^3 = OBzl, R^4 = NHCHO
13 R^1 = OMe, R^2 = R^3 = OH, R^4 = NHCHO

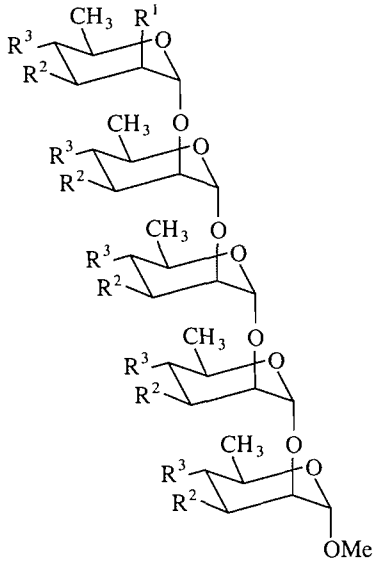
(15). In contrast to the experience of Srivastava and Hindsgaul (19), who obtained a β-linked oligosaccharide from a 2-*O*-(α-D-mannopyranosyl)-α-D-mannopyranosyl halide, no β-linkage was found in our reaction products. The acetate group at O-2 of the terminal glycosyl residue of **7** serves as a latent site for chain extension after glycosylation of the saccharide acceptor **1**.

The trisaccharide methyl glycoside **8** was transesterified to yield the selectively protected alcohol **10**, which then served as the precursor for synthesis of either a tetrasaccharide or pentasaccharide. Silver triflate promoted glycosylation of **10** by the glycosyl bromide **5** gave the tetrasaccharide methyl glycoside **15** in 80% yield. Synthesis of the pentasaccharide **19** was accomplished by electrophilic activation of the disaccharide thioglycoside **7** with methyl triflate. This led over a 2-day period to 1,2-*trans* glycosidic bond formation with the trisaccharide alcohol **10**. Heteronuclear coupling constants (15) again confirmed the stereoselective and exclusive formation of α-linked roduct. Preparation of the trisaccharide **9** by a block synthesis involving the *S*-ethyl disaccharide glycoside **7** and the monosaccharide glycoside (**6**) led to a trisaccharide hapten **14** that could be covalently attached to protein (12).

Deprotection of the oligosaccharides **8**, **9**, **15**, and **19** was



15 R^1 = OAc, R^2 = OBzl, R^3 = N_3
16 R^1 = OH, R^2 = OBzl, R^3 = N_3
17 R^1 = OH, R^2 = OBzl, R^3 = NHCHO
18 R^1 = R^2 = OH, R^3 = NHCHO

For personal use only.

performed in a four-step process. Transesterification afforded intermediates **10**, **16**, and **20** containing only azido and benzyl protecting groups. The former were converted to amines by mild H_2S reduction (16) and these were in turn *N*-formylated by methyl formate, used in solvent quantities (17, 18) to yield **12**, **17**, and **21**. Attempts to reduce the azido group by hydrogenation and to simultaneously remove benzyl ether residues were unsuccessful. Finally, palladium catalyzed hydrogenolysis in acetic acid gave the deprotected trisaccharides **13**, **14**, tetrasaccharide **18**, and pentasaccharide **22**. The overall yields for the combined deprotection steps ranged from 65 to 80%.

The rotational isomerism of the formamido group results in complicated nmr spectra, particularly for the higher oligomers. However, the ^1H and ^{13}C nmr spectra of oligosaccharides **13**, **18**, and **22** were amenable to analysis with the assistance of

19 $R^1 = OAc$, $R^2 = OBzl$, $R^3 = N_3$
20 $R^1 = OH$, $R^2 = OBzl$, $R^3 = N_3$
21 $R^1 = OH$, $R^2 = OBzl$, $R^3 = NHCHO$
22 $R^1 = R^2 = OH$, $R^3 = NHCHO$

homo- and heteronuclear two-dimensional nmr spectroscopy at 500 MHz. The spectra were consistent with the assigned structures.

The use of oligosaccharides **13**, **14**, **18**, and **22** to map the combining sites of crystalline monoclonal antibody fragments will be reported separately.[4]

Experimental

General

Unless otherwise indicated, methods used were similar to those reported in an earlier paper (8).

Hexane refers to a mixture supplied by Home Oil Company, Wichita, Kansas. Solvents were distilled before use and were dried where necessary by literature procedures (20). Reactions performed with dried solvents were conducted under dry nitrogen.

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer polarimeter.

The ^1H and ^{13}C nmr were recorded with Bruker AM 200 and AM 500 spectrometers. Solutions in organic solvents were referenced to internal tetramethylsilane and in D_2O solutions, relative to 1.0% v/v internal acetone (δ_H 2.225 ppm). Internal acetone (δ_C 30.50 ppm) was used as the internal ^{13}C reference for solutions in D_2O. Chemical shifts and coupling constants are first-order values. Assignments are based upon homo- and heteronuclear shift correlation spectroscopy (21–24).[5]

Ethyl 2-O-acetyl-4-azido-3-O-benzyl-4,6-dideoxy-1-thio-α-D-mannopyranoside **3**

Ethanethiol (6 mL, 81.02 mmol) and boron trifluoride etherate (6 mL, 48.78 mmol) were added to a stirred suspension of compound **2** (11.8 g, 32.56 mmol) (8) and powdered 4 Å molecular sieves (1.0 g) in dichloromethane (200 mL). After 2 h at room temperature (tlc, hexane – ethyl acetate 3:1 v/v) the reaction was stopped by dropwise addition of triethylamine (7 mL, 50.22 mmol). Filtration and removal of the solvents *in vacuo* afforded the crude reaction product, which was purified on a silica gel column (hexane – ethyl acetate 3:1 v/v) to give pure **3** (10.5 g, 88%) and a small amount of the β anomer (0.6 g, 5%). Pure **3**: syrup, $[\alpha]_D^{20}$ +179.22° (*c* 0.99, chloroform); ^1H nmr (200 MHz, $CDCl_3$) δ: 7.40–7.20 (m, 5H, Ph), 5.41 (dd, 1H, $J_{1,2}$ 1.6 Hz, $J_{2,3}$ 3.3 Hz, H-2), 5.19 (d, 1H, H-1), 4.67 (d, 1H, *J* 11.2 Hz, CH_AH_BPh), 4.51 (d, 1H, CH_AH_BPh), 3.89 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.4 Hz, H-5), 3.74 (dd, 1H, $J_{2,3}$ 3.3 Hz, $J_{3,4}$ 9.8 Hz, H-3), 3.43 (dd, 1H, H-4), 2.70–2.50 (m, 2H, SCH_2CH_3), 2.13 (s, 3H, OAc), 1.33 (d, 3H, H-6), 1.27 (dd, 3H, *J* 7.4 Hz, SCH_2CH_3); ^{13}C nmr (50 MHz, $CDCl_3$) δ: 82.30 (d, 1C, $J_{C1,H1}$ 166.0 Hz, C-1). *Anal.* calcd. for $C_{17}H_{23}N_3O_4S$: C 55.87, H 6.34, N 11.50; found: C 56.11, H 6.84, N 11.44. β anomer: syrup, $[\alpha]_D^{20}$ +107.66° (*c* 0.5, chloroform); ^1H nmr (500 MHz, $CDCl_3$) δ: 7.38–7.28 (m, 5H, Ph), 5.26 (d, 1H, $J_{1,2}$ 1.6 Hz, H-1), 5.02 (dd, 1H, $J_{2,3}$ 3.1 Hz, $J_{3,4}$ 10.1 Hz, H-3), 4.67 (d, 1H, *J* 12.2 Hz, CH_AH_BPh), 4.53 (d, 1H, CH_AH_BPh), 3.96 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.0 Hz, H-5), 3.94 (dd, 1H, H-2), 3.64 (dd, 1H, H-4), 2.61 (dq, 1H, $^2J_{gem}$ 13.0 Hz, $^3J_{vic}$ 7.8 Hz, $SCH_AH_BCH_3$), 2.55 (dq, 1H, $SCH_AH_BCH_3$), 2.07 (s, 3H, OAc), 1.35 (d, 3H, H-6), 1.25 (q, 3H, SCH_2CH_3); ^{13}C nmr (50 MHz, $CDCl_3$) δ: 81.60 (d, 1C, $J_{C1,H1}$ 155.0 Hz, C-1). *Anal.* calcd. for $C_{17}H_{23}N_3O_4S$: C 55.87, H 6.34, N 11.50; found: C 56.13, H 6.76, N 11.41.

Ethyl 4-azido-3-O-benzyl-4,6-dideoxy-1-thio-α-D-mannopyranoside **4**

Compound **3** (2 g, 6.18 mmol) in methanol (50 mL) was treated with 0.1 M sodium methoxide solution (1 mL). After 8 h, tlc (hexane – ethyl acetate 3:1, v/v) showed complete deacetylation of **3**. Neutralization was achieved with Amberlite IR-120 (H^+) ion exchange resin. Removal of the solvent under reduced pressure gave pure **4**; yield 1.9 g (95%), syrup, $[\alpha]_D^{20}$ +268.90° (*c* 4.1, chloroform); ^1H nmr (500 MHz, $CDCl_3$) δ: 7.41–7.20 (m, 5H, Ph), 5.28 (d, 1H, $J_{1,2}$ 1.2 Hz, H-1), 4.67 (d, 1H, *J* 11.4 Hz, CH_AH_BPh), 4.63 (d, 1H, CH_AH_BPh), 3.89 (d, 1H, $J_{4,5}$ 9.8 Hz, $J_{5,6}$ 6.0 Hz, H-5), 3.66 (dd, 1H, $J_{2,3}$ 3.0 Hz, $J_{3,4}$ 9.8 Hz, H-3), 4.02 (ddd, 1H, $J_{2,OH-2}$ 1.5 Hz, H-2), 3.45 (dd, 1H, H-4), 2.77 (d, 1H, OH-2), 2.58 (dq, 1H, $^2J_{gem}$ 12.6 Hz, $^3J_{vic}$ 7.2 Hz, $SCH_AH_BCH_3$), 2.54 (dq, 1H, $SCH_AH_BCH_3$), 1.31 (d, 3H, H-6), 1.26 (dd, 3H, SCH_2CH_3). *Anal.* calcd. for $C_{15}H_{21}N_3O_3S$: C 55.71, H 6.54, N 12.99; found: C 56.02, H 6.39, N 12.01.

2-O-Acetyl-4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl bromide **5**

Bromine (0.1 mL) was added to a solution of the thioglycoside **3** (1.1 g, 3.01 mmol) in dichloromethane (20 mL) at 0°C and the solution was stirred for 1.5 h while the temperature was allowed to rise to 20°C (tlc, hexane – ethyl acetate 3:1, v/v). The reaction mixture was concentrated and codistilled three times with toluene to give pure **5** as a syrup (1.1 g, 95%); ^1H nmr (200 MHz, $CDCl_3$) δ: 7.42–7.22 (m, 5H, Ph), 6.28 (d, 1H, $J_{1,2}$ 1.7 Hz, H-1), 5.49 (dd, 1H, $J_{2,3}$ 3.0 Hz, H-2), 4.69 (d, 1H, *J* 11.1 Hz, CH_AH_BPh), 4.56 (d, 1H, CH_AH_BPh), 4.21 (dd, 1H, $J_{3,4}$ 10.2 Hz, H-3), 3.74 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.4 Hz, H-5), 3.50 (dd, 1H, H-4), 2.13 (s, 3H, OAc), 1.37 (d, 3H, H-6).

*8-Methoxycarbonyloctyl-2-*O*-acetyl-4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranose* ***6***

8-Methoxycarbonyloctanol (300 mg, 1.59 mmol) was stirred with powdered 4 Å molecular sieves (300 mg) and silver triflate (500 mg, 2.0 mmol) for 1 h at 20°C in dichloromethane (10 mL). The freshly prepared bromide **5** (769 mg, 2.00 mmol) dissolved in dichloromethane (10 mL) was slowly dropped into this solution at −70°C. Stirring was continued overnight and the temperature allowed to rise slowly to 20°C (tlc, hexane – ethyl acetate 3:1, v/v). The reaction mixture was filtered through Celite, and the filtrate washed with saturated sodium hydrogen carbonate solution and concentrated. After column chromatography (hexane – ethyl acetate 4:1, v/v), pure **6** was obtained as a syrup (469 mg, 65%), $[\alpha]_D^{20}$ +57.81° (*c* 1.12, chloroform); ^{1}H nmr data was in accordance with the assigned structure. *Anal.* calcd. for $C_{25}H_{37}N_3O_7$: C 61.08, H 7.50, N 8.55; found: C 60.91, H 7.78, N 8.03.

*Ethyl 2-*O*-(2-*O*-acetyl-4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-4-azido-3-*O*-benzyl-4,6-dideoxy-1-thio-α-*D*-mannopyranoside* ***7***

The aglycon **4** (0.895 g, 2.77 mmol) was stirred with powdered 4 Å molecular sieves (0.9 g) and silver triflate (0.9 g, 3.6 mmol) in dichloromethane (10 mL) under a nitrogen atmosphere at Dry Ice temperature for 1 h. Then the bromide **5** (1.1 g, 2.86 mmol) dissolved in dichloromethane (20 mL) was slowly dropped into the cooled solution. After another 2 h of stirring at −70°C (tlc, hexane – ethyl acetate 3:1, v/v), the reaction mixture was filtered through Celite, washed with saturated sodium hydrogen carbonate solution, and concentrated to a syrup. Column chromatography gave pure **7** as a syrup (1.3 g, 75%), $[\alpha]_D^{20}$ +140.7° (*c* 1.3, chloroform); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 7.44–7.27 (m, 10H, Ph), 5.39 (dd, 1H, $J_{1',2'}$ 1.8 Hz, $J_{2',3'}$ 3.2 Hz, H-2′), 5.15 (d, 1H, H-1′), 4.81 (d, 1H, $J_{1,2}$ 2.0 Hz, H-1), 4.72 (d, 1H, *J* 11.0 Hz, CH_AH_BPh), 4.69 (d, 1H, *J* 11.6 Hz, $CH_{A'}H_{B'}$Ph), 4.58 (d, 1H, *J* 11.6 Hz, $CH_{A'}H_{B'}$Ph), 4.53 (d, 1H, *J* 11.0 Hz, CH_AH_BPh), 3.89 (dd, 1H, $J_{2,3}$ 3.0 Hz, H-2), 3.81 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.2 Hz, H-5), 3.80 (dd, 1H, $J_{3',4'}$ 9.8 Hz, H-3′), 3.65 (dd, 1H, $J_{3,4}$ 9.9 Hz, H-3), 3.62 (dq, 1H, $J_{4',5'}$ 10.0 Hz, $J_{5,6'}$ 6.2 Hz, H-5′), 3.34 (dd, 1H, H-4), 2.56 (m, 2H, SCH_2CH_3), 2.09 (s, 3H, OAc), 1.30 (d, 3H, H-6′), 1.28 (d, 3H, H-6), 1.25 (dd, 3H, *J* 7.4 Hz, SCH_2CH_3); ^{13}C nmr (125 MHz, $CDCl_3$) δ: 128.56, 128.52, 128.47, 128.09 (12C, Ph), 99.59 (1C, $J_{C1',H1'}$ 173.1 Hz, C-1′), 83.28 (1C, $J_{C1,H1}$ 165.8 Hz, C-1), 78.10 (C-5′), 76.29 (C-2), 75.33 (C-5), 72.17 (CH_2Ph), 71.57 (CH_2Ph), 67.72 (C-3), 67.59 (C-3′), 67.27 (C-2′), 64.41 (C-4), 63.87 (C-4′), 25.59 (SCH_2CH_3), 20.95 (OAc), 18.49 (C-6, C-6′). *Anal.* calcd. for $C_{40}H_{38}N_6O_7S$: C 57.49, H 6.11, N 13.41, S 5.12; found: C 57.60, H 6.14, N 13.26, S 5.23.

Methyl O*-(2-*O*-acetyl-4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-(1→2)-*O*-(4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-(1→2)-4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranoside* ***8***

Disaccharide **7** (1.0 g, 1.59 mmol), the alcohol **1** (0.47 g, 1.59 mmol), and powdered 4 Å molecular sieves (2 g) were stirred in dichloromethane (50 mL) for 1 h at 20°C. Methyl triflate (1.0 mL, 8.84 mmol) was added slowly to the stirred solution. After 48 h, tlc (hexane – ethyl acetate 3:1, v/v) showed complete conversion of the starting materials to the trisaccharide **8**. Triethylamine (5 mL, 35.87 mmol) was added dropwise at 0°C to the stirred solution, which was allowed to warm to room temperature with stirring over a 30-min period. The reaction mixture was filtered and washed with half-saturated sodium chloride solution. After concentration to a syrup and chromatography on silica gel (hexane – ethyl acetate 4:1, v/v), pure **8** (1.1 g, 80%) was obtained as a syrup; all physical data are identical with the literature data for the compound prepared by a silver triflate promoted reaction (8).

Methyl O*-(4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-(1→2)-*O*-(4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-(1→2)-4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranoside* ***10***

Trisaccharide **8** (200 mg, 0.233 mmol) in methanol (5 mL) containing 0.1 M sodium methoxide solution (0.1 mL) was deacetylated after 5 h at 20°C (tlc, hexane – ethyl acetate 3:1, v/v). Neutralization with Amberlite IR-120 (H^+) ion exchange resin and removal of the solvents under reduced pressure gave pure **10** as a syrup (188 mg, 99%), $[\alpha]_D^{20}$ +108.24° (*c* 0.56, chloroform); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 7.44–7.24 (m, 15H, Ph), 4.97 (d, 1H, $J_{1',2'}$ 2.0 Hz, H-1′), 4.96 (d, 1H, $J_{1'',2''}$ 1.8 Hz, H-1″), 4.73 (d, 1H, *J* 11.2 Hz, CH_AH_BPh), 4.69 (d, 1H, *J* 11.2 Hz, CH_AH_BPh), 4.68 (d, 1H, *J* 11.6 Hz, $CH_{A'}H_{B'}$Ph), 4.64 (d, 1H, *J* 11.6 Hz, $CH_{A'}H_{B'}$Ph), 4.62 (d, 1H, *J* 11.4 Hz, $CH_{A''}H_{B''}$Ph), 4.59 (d, 1H, *J* 11.4 Hz, $CH_{A''}H_{B''}$Ph), 4.56 (d, 1H, $J_{1,2}$ 1.9 Hz, H-1), 3.99 (ddd, 1H, $J_{2'',3''}$ 3.2 Hz, $J_{2'',OH}$ 1.8 Hz, H-2″), 3.94 (dd, 1H, $J_{2',3'}$ 3.2 Hz, H-2′), 3.85 (dd, 1H, $J_{2,3}$ 3.4 Hz, H-2), 3.73 (dd, 1H, $J_{3',4'}$ 10.0 Hz, H-3′), 3.70 (dd, 1H, $J_{3'',4''}$ 9.6 Hz, H-3″), 3.69 (dd, 1H, $J_{3,4}$ 10.0 Hz, H-3), 3.54 (dq, 1H, $J_{4',5'}$ 10.0 Hz, $J_{5',6'}$ 6.2 Hz, H-5′), 3.51 (dq, 1H, $J_{4'',5''}$ 10.0 Hz, $J_{5'',6''}$ 6.4 Hz, H-5″), 3.43 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.2 Hz, H-5), 3.41 (dd, 1H, H-4″), 3.32 (dd, 1H, H-4′), 3.31 (s, 3H, OMe), 3.24 (dd, 1H, H-4), 2.29 (d, 1H, OH-2″), 1.30 (d, 3H, H-6), 1.29 (d, 3H, H-6′), 1.19 (d, 3H, H-6″). *Anal.* calcd. for $C_{40}H_{49}O_{10}N_9$: C 58.89, H 6.05, N 15.45; found: C 59.06, H 6.19, N 15.35.

Tetrasaccharide **16** (100 mg, 0.093 mmol) was dissolved in pyridine (5 mL) and water (2.5 mL) and the solution was saturated with H_2S for 0.5 h at 40°C. Stirring for 12 h at this temperature afforded the amino derivative (tlc, chloroform–methanol–water 5:4:1, v/v/v). Nitrogen was passed through the reaction mixture to remove H_2S. The solution was filtered and the filtrate was concentrated *in vacuo* to a crude product, which was taken up in methyl formate (5 mL). Complete conversion into the *N*-formylated compound **17** was seen within 8 h at 20°C (tlc, chloroform–methanol 5:1). The concentrated crude syrup was purified on a silica gel column (chloroform–methanol 30:1, v/v) to give pure **17** (83 mg, 82%) as a syrup, $[\alpha]_D^{20}$ +36.1° (*c* 0.31, chloroform); ^{1}H nmr showed an approximate *Z/E* ratio of 2:1; ^{1}H nmr (500 MHz, $CDCl_3$) δ: 8.19 (bs, 4H, NHC*H*O-*Z*), 8.02 (bs, 4H, NHC*H*O-*E*), 7.42–7.12 (m, 20H, Ph), 5.20–4.80 (m, 3H, H-1‴, H-1″, H-1′), 4.76–4.37 (m, 9H, CH_2Ph, H-1), 4.21–3.92 (m, 4H, H-2‴, H-2″, H-2′, H-2), 3.87–3.44 (m, 8H, H-5‴, H-5″, H-5′, H-5, H-4‴-*Z*, H-4″-*Z*, H-4′-*Z*, H-4-*Z*), 3.36 (s, 3H, OMe), 3.35 (s, 3H, OMe), 3.40–3.30 (m, 4H, H-4‴-*E*, H-4″-*E*, H-4′-*E*, H-4-*E*), 1.38–1.10 (m, 12H, H-6‴, H-6″, H-6′, H-6). *Anal.* calcd. for $C_{57}H_{72}N_4O_{17}$: C 63.09, H 6.69, N 5.16; found: C 62.81, H 6.76, N 5.06.

Methyl O-*(4,6-dideoxy-4-formamido-α-*D*-mannopyranosyl)-(1→2)-*O*-(4,6-dideoxy-4-formamido-α-*D*-mannopyranosyl)-(1→2)-*O*-(4,6-dideoxy-4-formamido-α-*D*-mannopyranosyl)-(1→2)-4,6-dideoxy-4-formamido-α-*D*-mannopyranoside **18***

Tetrasaccharide **17** (20 mg, 0.018 mmol) was hydrogenated as described for preparation of trisaccharide **13**. Pure **18** (11 mg, 81%) was obtained as a syrup, $[\alpha]_D^{20}$ +47.3° (*c* 0.27, water); ^{1}H nmr revealed an approximate *Z/E* ratio of 3.5:1; ^{1}H nmr (500 MHz, D_2O) δ: 8.23–8.19 (4bs, 4H, NHC*H*O-*Z*), 8.06–8.02 (3bs, 4H, NHC*H*O-*E*), 5.21–5.14 (m, 2H, H-1″, H-1′), 5.05 (bs, 1H, H-1‴), 4.80, 4.78 (2bs, 1H, H-1), 4.18–4.03 (m, 4H, H-2‴, H-2″, H-2′, H-5‴), 4.01–3.74 (m, 12H, H-2, H-3‴, H-3″, H-3′, H-3, H-5″, H-5′, H-5, H-4‴-*Z*, H-4″-*Z*, H-4′-*Z*, H-4-*Z*), 3.46–3.34 (m, 4H, H-4‴-*E*, H-4″-*E*, H-4′-*E*, H-4-*E*), 3.40 (bs, 3H, OMe), 1.30–1.18 (m, 12H, H-6‴, H-6″, H-6′, H-6); ^{13}C nmr (125 MHz, D_2O) δ: 168.05 (1C, HN*C*HO-*E*), 165.12 (1C, HN*C*HO-*Z*), 102.14 (1C, C-1‴), 100.78 (2C, C-1″, C-1′), 99.76 (1C, C-1).

Methyl O-*(2-*O*-acetyl-4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-(1→2)-*O*-(4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-(1→2)-*O*-(4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-(1→2)-*O*-(4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranosyl)-(1→2)-4-azido-3-*O*-benzyl-4,6-dideoxy-α-*D*-mannopyranoside **19***

Disaccharide **7** (180 mg, 0.286 mmol), the trisaccharide alcohol **10** (234 mg, 0.287 mmol), and powdered 4 Å molecular sieves (300 mg) were stirred in dichloromethane (5 mL) for 1 h at 20°C. Then methyl triflate (0.3 mL, 2.7 mmol) was added to the stirred solution and, after 48 h, tlc (hexane – ethyl acetate 3:1, v/v) indicated complete conversion of the starting materials to the product **19**. Triethylamine (1 mL, 7.17 mmol) was added dropwise to the cooled, stirred reaction mixture at 0°C. After warming to 20°C, stirring was continued for another 0.5 h. The reaction mixture was filtered and washed with a 50% saturated sodium chloride solution. After concentration to a syrup and chromatography on silical gel (hexane – ethyl acetate 4:7, v/v), pure **19** (315 mg, 80%) was obtained as a syrup; $[\alpha]_D^{20}$ +95.9° (*c* 1.75, chloroform); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 7.45–7.24 (m, 25H, Ph), 5.43 (dd, 1H, $J_{1''',2'''}$ 1.8 Hz, $J_{2''',3'''}$ 3.2 Hz, H-2‴), 4.97 (d, 1H, $J_{1',2'}$ 1.9 Hz, H-1′), 4.89 (d, 1H, $J_{1'',2''}$ 1.9 Hz, H-1″), 4.88 (d, 1H, $J_{1''',2'''}$ 1.8 Hz, H-1‴), 4.87 (d, 1H, H-1‴), 4.76–4.55 (m, 10H, CH_2Ph), 4.54 (d, 1H, $J_{1,2}$ 1.7 Hz, H-1), 3.90 (dd, 1H, $J_{2',3'}$ 3.2 Hz, H-2′), 3.86 (dd, 1H, $J_{2''',3'''}$ 3.2 Hz, H-2‴), 3.82 (dd, 1H, $J_{2'',3''}$ 3.2 Hz, H-2″),

Block synthesis of two pentasaccharide determinants of the *Brucella* M antigen using thioglycoside methodologies[1]

THOMAS PETERS[2] AND DAVID R. BUNDLE
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 4, 1988

THOMAS PETERS and DAVID R. BUNDLE. Can. J. Chem. **67**, 497 (1989).

Two frame shifted pentasaccharides containing 4,6-dideoxy-4-formamido-D-mannose (4-deoxy-4-formamido-D-rhamnose) have been synthesized by application of a strategy utilizing *S*-ethyl disaccharide glycoside building blocks **16** and **25**. The target molecules contain a single α1,3 linkage as either the first or last inter-residue linkage in an otherwise α1,2-linked homo-pentameric structure:

α-D-Rha4NFo(1→3)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo-1→OCH_3

and

α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→3)-α-D-Rha4NFo-1→OCH_3

These structures represent possible biological repeating units of the *Brucella* M antigen and their synthesis is designed to facilitate the identification of the structural element that is polymerized to provide the intact polysaccharide antigen. The α1,2-linked tetrasaccharide component of each pentasaccharide was constructed by methyl triflate promoted activation of the α1,2-linked *S*-ethyl disaccharide glycoside **16**. Glycosylation of methyl 4-azido-2-*O*-benzyl-4,6-dideoxy-α-D-mannopyranoside **3** by **16**, followed by a second block extension, gave the pentasaccharide **22** with an α1,3 linkage at the reducing terminus. In analogous fashion the α1,3-linked *S*-ethyl derivative **25** was used in conjunction with methyl triflate to glycosylate the α1,2-linked trisaccharide **26**, and provided the pentasaccharide **27** that possesses a 1,3 linkage at its non-reducing end. The synthesis of an α1,3-linked disaccharide and a trisaccharide are also reported.

Key words: Brucella M antigen, synthesis of frame shifted pentasaccharides, thioglycoside building units, 4,6-dideoxy-4-formamido-D-mannose, biological repeating unit.

THOMAS PETERS et DAVID R. BUNDLE. Can. J. Chem. **67**, 497 (1989).

Faisant appel à une stratégie utilisant les disaccharides glycosides de *S*-éthyle **16** et **25** comme éléments d'édification, on a synthétisé deux pentasaccharides contenant du didésoxy-4,6 formamido-4 D-mannose (désoxy-4 formamido-4 D-rhamnose). Les molécules cibles contiennent une seule liaison α1,3 soit sur la première soit sur la dernière liaison inter-résidu d'une structure homo-pentamère autrement liée en α1,2 :

α-D-Rha4NFo(1→3)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo-1→OCH_3

et

α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→3)-α-D-Rha4NFo-1→OCH_3

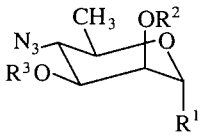
Ces structures représentent des unités biologiques qui pourraient se répéter dans l'antigène *Brucella* M et leur synthèse a été réalisée afin de faciliter l'identification de l'élément de structure qui est polymérisé pour fournir l'antigène polysaccharide intact. Afin de synthétiser les tétrasaccharides liés en α1,2 qui composent chacun des pentasaccharides, on a fait appel à une activation par le triflate de méthyle du disaccharide de glycoside de *S*-éthyle lié en α1,2 **16**. La glycosylation de l'azido-4 *O*-benzyl-2 didésoxy-4,6 α-D-mannopyranoside de méthyle (**3**) par le composé **16**, suivie par une deuxième extension, conduit au pentasaccharide **22** comportant une liaison α1,3 dans le terminus réducteur. D'une façon analogue, on a utilisé le dérivé *S*-éthyle lié en α1,3 (**25**) de concert avec le triflate pour effectuer la glycosylation du trisaccharide **26** lié en α1,2 et pour obtenir le pentasaccharide **27** qui possède une liaison 1,3 dans le terminus non-réducteur. On rapporte aussi la synthèse d'un disaccharide et d'un trisaccharide liés en α1,3.

Mots clés : antigène *Brucella* M, synthèse des pentasaccharides à structure décalée, éléments d'édification des thioglycosides, didésoxy-4,6 formamido-4 D-mannose, unité biologique répétitive.

[Traduit par la revue]

Introduction

The *Brucella* M antigen differs from the *Brucella* A antigen by the presence of several α1,3 linkages in an otherwise α1,2-linked homopolymer of 4,6-dideoxy-4-formamido-D-mannose (Rha4NFo) (1, 2). Evidence of detailed structural and immunochemical studies (3, 4) suggests that the biosynthetic assembly of these *O*-polysaccharides may occur by mechanisms that differ from those used by other Gram negative organisms such as the *Salmonella* (5). To assist immunochemical attempts to locate the position of the 1,3 linkages in the M polysaccharide antigen extracted from *Brucella* it was desirable to synthesize pentasaccharides in which the position of the 1,3 linkage was varied.



In this paper we report the synthesis of two pentasaccharides in which the 1,3 linkage is positioned at either the reducing or non-reducing end of the oligomer. In addition, the synthesis of a 1,3-linked disaccharide, α-D-Rha4NFo(1→3)-α-D-Rha4NFo, and a trisaccharide, α-D-Rha4NFo(1→2)-α-D-Rha4NFo(1→3)-α-D-Rha4NFo, are reported. The central chemistry of this approach involves the use of *S*-ethyl mono- and disaccharide glycosides, which also formed the basis of related work on synthetic analogues of the A antigen described in the preceding communication (6).

Results and discussion

To prepare an α1,3-linked disaccharide of 4-azido-4,6-dideoxy-D-mannopyranose, selective protection of glycoside **1** had to be accomplished. Two literature-based solutions to this problem were employed. Regioselective opening of a 2,3-ortho-acetate by aqueous acetic acid gave **2** (7, 8). Alternatively a phase transfer mediated benzylation of **1** gave **3**, as well as the minor 2,3-di-*O*-benzyl ether **4** (9).

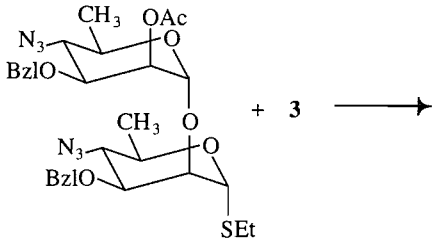
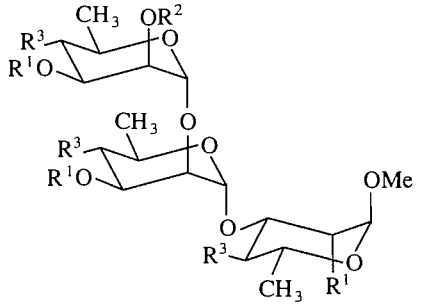
10 R^1 = Br, R^2 = Ac, R^3 = Bzl



Conversion of **1** to the corresponding *S*-ethyl glycoside **7** provided the glycosyl donor for synthesis of α1,3-linked disaccharide building blocks. This was accomplished by acetylation of **1** to the diacetate **5** followed by acetolysis to the triacetate **6**, which was obtained from **1** in 95% yield. Lewis acid catalyzed generation of the acetoxonium ion and *in situ* reaction with ethanethiol (10) gave the thioglycoside **7**, from which an additional glycosyl acceptor **9** may be generated via **8**. The glycosyl acceptor **9** permits the synthesis of disaccharide glycosides that are themselves suitable for use as a disaccharide building unit. For such purposes the glycosyl bromide **10** described in the preceding paper (6) is an essential partner, whilst **7** may also act as a glycosyl donor for partners devoid of thioglycoside functionality. Thus activation of **7** by methyl triflate (11, 12) and reaction of the intermediate sulphonium ion with the monosaccharide alcohol **2** gave the crystalline α1,3-linked disaccharide glycoside **11** in 80% yield.



11 $R^1 = R^2$ = OAc, $R^3 = N_3$
12 $R^1 = R^2$ = OH, $R^3 = N_3$
13 $R^1 = R^2$ = OH, $R^3 = NH_2$
14 $R^1 = R^2$ = OH, R^3 = NHAc
15 $R^1 = R^2$ = OH, R^3 = NHCHO

When the disaccharide thioglycoside **16**, described in the previous paper (6), was used in a similar reaction with the related monosaccharide alcohol **3** an 84% yield of a trisaccharide **17** was obtained. This was in turn selectively transformed to a trisaccharide alcohol **18**, which was further glycosylated by disaccharide **16** to give a pentasaccharide **22**.

The disaccharide **11**, trisaccharide **17**, and pentasaccharide **22** were each subjected to a similar deprotection scheme that first saw the removal of *O*-acetates by transesterification to

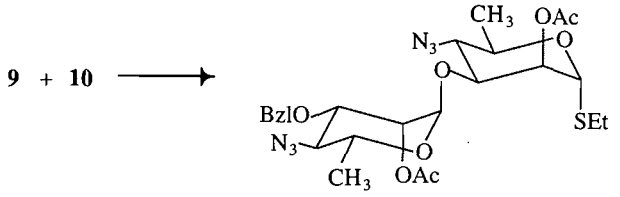
17 R^1 = Bzl, R^2 = Ac, $R^3 = N_3$
18 R^1 = Bzl, R^2 = H, $R^3 = N_3$
19 R^1 = Bzl, R^2 = H, $R^3 = NH_2$
20 R^1 = Bzl, R^2 = H, R^3 = NHCHO
21 $R^1 = R^2$ = H, R^3 = NHCHO

compounds **12**, **18**, and **23**. Reduction by H_2S provided the amino derivatives, which were not isolated but *N*-formylated by methyl formate (13), followed by catalytic hydrogenolysis to give respectively disaccharide **15**, trisaccharide **21**, and pentasaccharide **24**.

The second pentasaccharide was constructed from a trisaccharide alcohol **26**, the preparation of which was described in the preceding paper (6), and disaccharide **25**. The latter was synthesized from the glycosyl bromide **10** and the *S*-ethyl glycoside **9** in 83% yield. The disaccharide thioglycoside **25**, activated by methyl triflate in the presence of **26**, then gave the target pentasaccharide **27** in 64% yield. Compared to the disaccharide thioglycoside **16**, the disaccharide building block **25** is a much less reactive glycosyl donor, resulting in considerably longer reaction times and lower overall yields. Removal of blocking groups and conversion of the azido to formamido functionality to give deprotected pentasaccharide **28** (64% yield) used the strategy outlined for the other di-, tri-, and pentasaccharides **15**, **21**, and **24**.



The one-bond heteronuclear coupling constants (14) measured for each anomeric carbon atom confirmed the anticipated stereochemistry of the anomeric linkages.

24 R^1 = R^2 = H, R^3 = NHCHO

The series of di-, tri-, and pentasaccharides **15**, **21**, **24**, and **28** have been used in immunochemical mapping of the combining sites of *Brucella* A and M specific monoclonal antibodies.

25

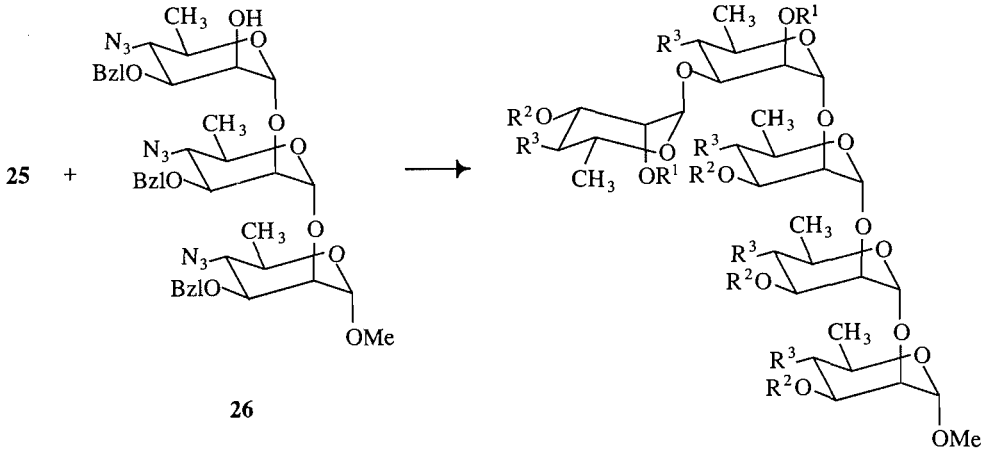
Experimental

The general experimental methods employed throughout this work are described in the preceding paper (6).

Methyl 4-azido-2-O-benzyl-4,6-dideoxy-α-D-mannopyranoside **3**

Benzyl bromide (0.63 mL, 5.00 mmol) and tetrabutylammonium bromide (50 mg) were added to a solution of the dialcohol **1** (1 g, 4.91 mmol) (6) in dichloromethane (20 mL) and this solution was stirred vigorously at room temperature for 30 h with aqueous NaOH solution (20% w/v). Two products (tlc, hexane – ethyl acetate 3:1, v/v) were obtained and these were purified by column chromatography (hexane – ethyl acetate 3:1, v/v) to give pure **3** (810 mg, 56%) and the minor product **4** (300 mg, 16%).

3; $[\alpha]_D^{20}$+8.54° (*c* 5.2, chloroform); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 7.43–7.29 (m, 5H, Ph), 4.73 (d, 1H, $J_{1,2}$ 1.4 Hz, H-1), 4.73 (d, 1H, ^2J 11.9 Hz, CH_AH$_B$Ph), 4.58 (d, 1H, CH$_A$$H_B$Ph), 3.85 (bd, 1H, H-3), 3.69 (dd, 1H, $J_{2,3}$ 3.7 Hz, H-2), 3.51 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.0 Hz, H-5), 3.33 (s, 3H, OMe), 3.28 (dd, 1H, $J_{3,4}$ 10.0 Hz, H-4), 2.65 (bs, 1H, OH-3), 1.34 (d, 3H, H-6). *Anal.* calcd. for $C_{14}H_{19}N_3O_4$: C 57.33, H 6.53, N 14.33; found: C 57.09, H 6.37, N 14.08.



4; $[\alpha]_D^{20}$+ 65.9° (*c* 2.51, chloroform); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 7.46–7.25 (m, 10H, 2Ph), 4.73 (d, 1H, ^2J 12.4 Hz, CH_AH$_B$Ph), 4.70 (d, 1H, $J_{1,2}$ 1.6 Hz, H-1), 4.70 (d, 1H, CH$_A$$H_B$Ph), 4.63 (d, 1H, ^2J 12.0 Hz, C$H_{A'}$H$_{B'}$Ph), 4.60 (d, 1H, CH$_{A'}$$H_{B'}$Ph), 3.77 (dd, 1H, $J_{2,3}$ 3.2 Hz, H-2), 3.75 (dd, 1H, $J_{3,4}$ 9.9 Hz, H-3), 3.63 (dd, 1H, $J_{4,5}$ 10.0 Hz, H-4), 3.50 (dq, 1H, $J_{5,6}$ 6.0 Hz, H-5), 3.32 (s, 3H, OMe), 1.37 (d, 3H, H-6). *Anal.* calcd. for $C_{21}H_{25}N_3O_4$: C 65.78, H 6.57, N 10.96; found: C 65.65, H 6.52, N 10.94.

Methyl 4-azido-2,3-di-O-acetyl-4,6-dideoxy-α-D-mannopyranoside **5**

The dialcohol **1** (5 g, 24.55 mmol) (6) was acetylated by standard procedures (acetic anhydride/pyridine) and crude **5** was subjected to column chromatography (hexane – ethyl acetate 3:1, v/v) to give pure crystalline **5** (6.7 g, 95%), mp 81–82°C; $[\alpha]_D^{20}$+111.68° (*c* 0.97, chloroform); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 5.25–5.16 (m, 2H, H-2, H-3), 4.61 (d, 1H, $J_{1,2}$ 1.8 Hz, H-1), 3.66 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.0 Hz, H-5), 3.47 (dd, 1H, $J_{3,4}$ 10.0 Hz, H-4), 3.38 (s, 3H, OMe), 2.16 (s, 3H, OAc), 2.06 (s, 3H, OAc), 1.38 (d, 3H, H-6). *Anal.* calcd. for $C_{11}H_{17}N_3O_6$: C 45.99, H 5.96, N 14.63; found: C 46.11, H 6.09, N 14.78.

4-Azido-4,6-dideoxy-1,2,3-tri-O-acetyl-α-D-mannopyranose **6**

A solution of **5** (1 g, 3.48 mmol) in acetic anhydride – acetic acid – sulfuric acid (50:20:0.5, 20 mL) was stirred at 20°C for 4 h, then poured into ice-cold aqueous potassium carbonate. The product was extracted with dichloromethane, the extract was dried (Na_2SO_4), concentrated, and toluene was distilled from the residue to give **6** (1.1 g, ~100%), mp 69–70°C; $[\alpha]_D^{20}$+128.4° (*c* 1.1, chloroform); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 6.01 (d, 1H, $J_{1,2}$ 1.8 Hz, H-1), 5.26–5.18 (m, 2H, H-2, H-3), 3.70 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.0 Hz, H-5), 3.55 (dd, 1H, $J_{3,4}$ 10.0 Hz, H-4), 2.08 (s, 3H, OAc), 1.38 (d, 3H, H-6). *Anal.* calcd. for $C_{12}H_{17}N_3O_7$: C 45.71, H 5.43, N 13.33; found: C 45.46, H 5.47, N 13.40.

Ethyl 4-azido-2,3-di-O-acetyl-4,6-dideoxy-1-thio-α-D-mannopyranoside **7**

Compound **6** (5 g, 15.86 mmol) was stirred with powdered 4 Å molecular sieves (0.5 g), dichloromethane (100 mL), ethanethiol (3 mL, 40.51 mmol), and boron trifluoride etherate (2.5 mL, 20.32 mmol) for 2 h at 20°C (tlc, hexane – ethyl acetate 3:1, v/v). Dropwise addition of triethylamine (3.0 mL, 21.52 mmol), filtration, and removal of the solvents *in vacuo* afforded the crude reaction product, which was purified by column chromatography (hexane – ethyl acetate 3:1, v/v) to give **7** as a syrup (4.5 g, 90%); $[\alpha]_D^{20}$+194.73° (*c* 1.3, chloroform): ^{1}H nmr (200 MHz, $CDCl_3$) δ: 5.31 (dd, 1H, $J_{1,2}$ 1.6 Hz, $J_{2,3}$ 3.4 Hz, H-2), 5.19 (d, 1H, H-1), 5.14 (dd, 1H, $J_{3,4}$ 10.0 Hz, H-3), 4.03 (dq, 1H, $J_{4,5}$ 9.8 Hz, $J_{5,6}$ 6.0 Hz, H-5), 3.53 (dd, 1H, H-4), 2.65 (dd, 1H, ^2J 3.4 Hz, ^3J 7.4 Hz, $SCH_AH_B CH_3$), 2.58 (dd, 1H, $SCH_AH_B CH_3$), 2.15 (s, 3H, OAc), 2.06 (s, 3H, OAc), 1.37 (d, 3H, H-6), 1.28 (dd, 3H, SCH_2CH_3); ^{13}C nmr (50 MHz, $CDCl_3$) δ: 81.73 (C1, J_{C_1,H_1} 168.0 Hz). *Anal.* calcd. for $C_{12}H_{19}N_3SO_5$: C 45.42, H 6.03, N 13.24, S 10.10; found: C 45.24, H 5.94, N 13.11, S 10.28.

Ethyl 4-azido-4,6-dideoxy-1-thio-α-D-mannopyranoside **8**

The di-*O*-acetylated compound **7** (3.2 g, 10.08 mmol) was subjected to a standard deacetylation with sodium methoxide as described before (6) to give pure **8** as a syrup (2.3 g, 99%), $[\alpha]_D^{20}$+281.7° (*c* 0.33, chloroform); ^{1}H nmr (500 MHz $CDCl_3$) δ: 5.28 (d, 1H, $J_{1,2}$ 1.2 Hz, H-1), 4.03 (dd, 1H, $J_{2,3}$ 3.5 Hz, H-2), 4.00 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.2 Hz, H-5), 3.82 (m, 1H, H-3), 3.33 (dd, 1H, $J_{3,4}$ 10.0 Hz, H-4), 2.65 (dq, 1H, ^2J 13.0 Hz, ^3J 7.2 Hz, $SCH_AH_BCH_3$), 2.58 (dq, 1H, $SCH_AH_BCH_3$), 1.36 (d, 3H, H-6), 1.30 (dd, 3H, SCH_2CH_3). *Anal.* calcd. for $C_8H_{15}N_3SO_3$: C 41.19, H 6.48, N 18.01, S 13.74; found: C 40.98, H 6.45, N 17.89, S 13.58.

Ethyl 2-O-acetyl-4-azido-4,6-dideoxy-1-thio-α-D-mannopyranoside **9**

A solution of **8** (1.5 g, 6.43 mmol) in dry *N,N*-dimethylformamide (25 mL) was stirred with triethylorthoacetate (1.5 mL, 8.2 mmol) and *p*-toluenesulphonic acid (25 mg) for 2 h at 50°C. Triethylamine (1.5 mL) was added and the mixture was concentrated to a syrup, which was then dissolved in aqueous acetic acid (15 mL, 80%). After 10 min the mixture was concentrated and toluene was distilled several times from the residue to give **9** as crystals (1.7 g, 98%), mp 57–58°C; $[\alpha]_D^{20}$+170.4° (*c* 1.6, chloroform); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 5.22 (d, 1H, $J_{1,2}$ 1.4 Hz, H-1), 5.16 (dd, 1H, $J_{2,3}$ 3.6 Hz, H-2), 3.97 (dd, 1H, $J_{3,4}$ 9.9 Hz, H-3), 3.95 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.2 Hz, H-5), 3.33 (dd, 1H, H-4), 2.61 (m, 1H, SCH_2CH_3), 2.17 (s, 3H, OAc), 1.36 (d, 3H, H-6), 1.28 (dd, 3H, *J* 7.6 Hz, SCH_2CH_3). *Anal.* calcd. for $C_{10}H_{17}N_3SO_4$: C 43.62, H 6.22, N 15.26, S 11.65; found: C 43.68, H 6.36, N 15.36, S 11.52.

Methyl 2-O-acetyl-4-azido-3-O-(4-azido-2,3-di-O-acetyl-4,6-dideoxy-α-D-mannopyranosyl)-4,6-dideoxy-α-D-mannopyranoside **11**

The alcohol **2** (100 mg, 0.408 mmol), the thioglycoside donor **7** (143 mg, 0.450 mmol), and powdered 4 Å molecular sieves (150 mg) were stirred in dichloromethane (10 mL) for 1 h at 20°C. Methyltriflate (0.1 mL, 0.884 mmol) was added to the stirred solution. After 50 h (tlc, hexane – ethyl acetate 3:1, v/v) the reaction was complete and triethylamine (0.5 mL, 0.359 mmol) was added carefully. The solution was stirred for another 0.5 h, then filtered and washed with a 50% saturated NaCl solution. The solution was concentrated to a syrup and purification was achieved by column chromatography (hexane – ethyl acetate 3:1, v/v). The product **11** was obtained as a crystalline solid (163 mg, 80%), mp 137–139°C; $[\alpha]_D^{20}$+114.95° (*c* 1.2, chloroform); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 5.27 (dd, 1H, $J_{1',2'}$ 1.8 Hz, $J_{2',3'}$ 3.4 Hz, H-2'), 5.17 (dd, 1H, $J_{3',4'}$ 10.2 Hz, H-3'), 5.09 (dd, 1H, $J_{1,2}$ 1.8 Hz, $J_{2,3}$ 3.4 Hz, H-2), 5.02 (d, 1H, H-1'), 4.60 (d, 1H, H-1), 3.93 (dd, 1H, $J_{3,4}$ 9.6 Hz, H-3), 3.70 (dq, 1H, $J_{4',5'}$ 10.0 Hz, $J_{5',6'}$ 6.1 Hz, H-5'), 3.62–3.40 (m, 2H, H-4, H-5), 3.45 (dd, 1H, H-4'), 3.34 (s, 3H, OMe), 2.18 (s, 3H, OAc), 2.15 (s, 3H, OAc), 2.06 (s, 3H, OAc), 1.35 (d, 3H, $J_{5,6}$ 6.0 Hz, H-6), 1.34 (d, 3H, H-6'); ^{13}C nmr (125 MHz, $CDCl_3$) δ: 170.33 (CO), 169.71 (CO), 169.53 (CO), 99.29 (C-1', $J_{C1',H1'}$ 172 Hz), 98.17 (C-1, $J_{C1,H1}$ 170 Hz), 76.29 (C-3), 70.52 (C-2), 69.76 (C-3'), 69.05 (C-2'), 67.87 (C-5'), 66.90 (C-5), 64.50 (C-4), 62.27 (C-4'), 55.05 (OMe), 20.84 (OAc), 20.78 (OAc), 20.67 (OAc), 18.34 (C-6), 18.17 (C-6'). *Anal.* calcd. for $C_{19}H_{28}N_6O_{10}$: C 45.60, H 5.64, N 16.79; found: C 45.40, H 5.55, N 16.66.

Methyl 4-amino-3-O-(4-amino-4,6-dideoxy-α-D-mannopyranosyl)-4,6-dideoxy-α-D-mannopyranoside **13**

Disaccharide **11** (100 mg, 0.200 mmol) in methanol (5 mL) was treated with 0.1 M sodium methoxide solution (0.1 mL) at 20°C until tlc (hexane – ethyl acetate 1:1, v/v) indicated complete deacetylation. Neutralization with Amberlite IR-120 (H^+) ion exchange resin and concentration afforded the intermediate **12**, which was dissolved in pyridine (10 mL) and water (5 mL). The solution was saturated with H_2S at 40°C for 0.5 h and then stirred at this temperature for another 24 h (tlc, chloroform—methanol—water 5:4:1, v/v/v). Filtration and concentration of the filtrate gave the crude product, which was purified on a silica gel column (chloroform–methanol–water 5:4:1, v/v/v). The disaccharide **13** was obtained as a syrup (53 mg, 83%); $[\alpha]_D^{20}$+73.0° (*c* 0.87, water); ^{1}H nmr was consistent with the proposed structure and is reported elsewhere.[3] *Anal.* calcd. for $C_{13}H_{26}N_2O_7$: C 48.44, H 8.13, N 8.69; found: C 48.24, H 8.04, N 8.56.

Methyl 3-O-(4-acetamido-4,6-dideoxy-α-D-mannopyranosyl)-4-acetamido-4,6-dideoxy-α-D-mannopyranoside **14**

Acetic anhydride (0.2 mL) was added to a solution of **13** (20 mg, 0.062 mmol) in methanol (2 mL). After 2 h at 20°C the solution was concentrated and, codistilled with toluene, gave pure **13** (18 mg, 72%); $[\alpha]_D^{20}$+10.5° (*c* 1.0, water); ^{1}H nmr was consistent with the proposed structure and is reported elsewhere.[3] *Anal.* calcd. for $C_{17}H_{30}N_2O_9$: C 50.24, H 7.44, N 6.89; found: C 50.02, H 7.37, N 6.66.

Methyl 3-O-(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-4,6-dideoxy-4-formamido-α-D-mannopyranoside **15**

Disacharride **13** (20 mg, 0.062 mmol) was dissolved in methyl formate (2 mL) and kept at 20°C overnight. After concentration, pure **15** was obtained as a syrup (23 mg, 99%); $[\alpha]_D^{20}$+90.6° (*c* 0.12, water); ^{1}H nmr was in agreement with expectation and details will be reported elsewhere.[3] *Anal.* calcd. for $C_{15}H_{26}N_2O_9$: C 47.61, H 6.93, N 7.40; found: C 46.59, H 6.73, N 7.39.

Methyl O-(2-O-acetyl-4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→2)-O-(4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→3)-4-azido-2-O-benzyl-4,6-dideoxy-α-D-mannopyranoside **17**

Disaccharide **16** (1.0 g, 1.59 mmol) (6) and the selectively protected alcohol **3** (466 mg, 1.59 mmol) were reacted under similar conditions to those described for the preparation of the 1,2-linked trisaccharide **26** (6).

Trisaccharide **17** was obtained as a syrup (1.15 g, 84%); $[\alpha]_D^{20}$+67.7° (*c* 4.3, chloroform); ^{1}H nmr (200 MHz, $CDCl_3$) δ): 7.46–7.25 (m, 15H, Ph), 5.44 (dd, 1H, $J_{1'',2''}$ 1.9 Hz, $J_{2'',3''}$ 3.2 Hz, H-2''), 5.02 (d, 1H, $J_{1',2'}$ 1.7 Hz, H-1'), 4.91 (d, 1H, H-1''), 4.72 (d, 1H, $J_{1,2}$ 1.7 Hz, H-1), 4.81–4.53 (m, 6H, CH_2Ph), 4.07 (dd, 1H, $J_{2',3'}$ 3.2 Hz, H-2'), 3.86 (dd, 1H, $J_{2,3}$ 3.2 Hz, $J_{3,4}$ 10.0 Hz, H-3), 3.81 (dd, 1H, $J_{3'',4''}$ 9.9 Hz, H-3''), 3.78 (dd, 1H, $J_{3',4'}$ 9.8 Hz, H-3'), 3.66 (dd, 1H, H-2), 3.65–3.30 (m, 6H, H-4, H-5, H-4', H-5', H-4'', H-5''), 3.34 (s, 3H, OMe), 2.11 (s, 3H, OAc), 1.37 (d, 3H, $J_{5',6'}$, 5.9 Hz, H-6'), 1.35 (d, 3H, $J_{5,6}$ 6.0 Hz, H-6), 1.26 (d, 3H, $J_{5'',6''}$ 6.0 Hz, H-6''); ^{13}C nmr (50 MHz, $CDCl_3$) δ: 100.85 (C-1'', $J_{C1'',H1''}$ 171 Hz), 99.38 (C-1', $J_{C1',H1'}$ 171 Hz), 98.10 (C-1, 168 Hz). *Anal.* calcd. for $C_{42}H_{51}N_9O_{11}$: C 58.80, H 5.99, N 14.69; found: C 58.89, H 6.12, N 14.80.

Methyl O-(3-O-benzyl-4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→2)-O-(3-O-benzyl-4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→3)-2-O-benzyl-4,6-dideoxy-4-formamido-α-D-mannopyranoside **20**

Trisaccharide **17** (200 mg, 0.233 mmol) was deacetylated in methanol (5 mL) with 0.1 M sodium methoxide (0.1 mL) and neutralization was achieved with Amberlite IR 120 (H^+) ion exchange resin. After

For personal use only.

filtration and concentration pure alcohol **18** was obtained in quantitative yield (190 mg, 99%); $[\alpha]_D^{20}$ +87.9° (*c* 1.1, chloroform). *Anal.* calcd. for $C_{49}N_9O_{10}$: C 58.89, H 6.05, N 15.45; found: C 58.76, H 6.16, N 15.51. The azido derivative **18** (190 mg, 0.232 mmol) was then dissolved in pyridine (5 mL) and water (2.5 mL), H_2S was bubbled through the solution for 0.5 h at 40°C, and stirring at this temperature was continued for 24 h (tlc chloroform–methanol–water 5:4:1, v/v/v).

After filtration and concentration the crude reaction product **19** was taken up in methyl formate (5 mL) and kept at 20°C for 12 h (tlc chloroform–methanol 5:1, v/v). Concentration and purification on a silica gel column (chloroform--methanol 30:1, v/v) afforded pure **20** as a syrup (164 mg, 86%); $[\alpha]_D^{20}$ +34.6° (*c* 1.1, chloroform); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 8.23–7.91 (m, 3H, NHC*H*O), 7.45–7.24 (m, 15H, Ph), 5.20–4.36 (m, 9H, H-1″, H-1′, H-1, CH_2Ph), 4.18–3.15 (m, 15H, H-2″, H-2′, H-2, H-3″, H-3′, H-3, H-4″, H-4′, H-4, H-5″, H-5′, H-5, OMe), 2.77 (bs, 1H, OH-2″), 1.36–1.00 (m, 9H, H-6″, H-6′, H-6). *Anal.* calcd. for $C_{43}H_{55}N_3O_{13}$: C 62.84, H 6.74, N 5.11; found: C 62.67, H 6.87, N 5.22.

Methyl O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→2)*-O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→3)-4,6-dideoxy-4-formamido-α-D-mannopyranoside* **21**

Trisaccharide **19** (21 mg, 0.025 mmol) was dissolved in glacial acetic acid (5 mL) and hydrogenated over 5% palladium on charcoal (50 mg) at 20°C and 5 kPa hydrogen pressure. Thin-layer chromatography (chloroform–methanol–water 5:4:1, v/v/v) indicated complete debenzylation after 5–6 h. After filtering the reaction mixture and concentration under reduced pressure, the crude product was purified on a Biogel P2 column to give **21** as a syrup (13 mg, 84%); $[\alpha]_D^{20}$ +80.5° (*c* 0.65, water); ^{1}H nmr showed an approximate *Z*/*E* ratio of 3.5:1.0; ^{1}H nmr (500 MHz, D_2O) δ: 8.24–8.20 (4s, 3H, NHC*H*O-*Z*), 8.06–8.02 (4s, 3H, NHC*H*O-*E*), 5.06–5.02 (m, 1H, H-1′), 5.02–4.99 (m, 1H, H-1″), 4.73 (d, 1H, $J_{1,2}$ 1.8 Hz, H-1), 4.13–3.80 (m, 12H, H-2″, H-2′, H-2, H-3″, H-3′, H-3, H-4″-*Z*, H-4′-*Z*, H-4-*Z*, H-5″, H-5′, H-5), 3.50–3.30 (m, 6H, H-4″-*E*, H-4′-*E*, H-4-E, OMe), 1.31–1.21 (m, 9H, H-6″, H-6′, H-6); ^{13}C nmr (125 MHz, D_2O) δ: 102.44 (C1′), 102.07 (C1″), 100.91 (C1). *Anal.* calcd. for $C_{22}H_{37}N_3O_{13}$: C 47.91, H 6.76, N 7.62; found: C 47.94, H 6.78, N 7.70.

Methyl O-*(2-O-acetyl-4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→2)*-O-*(4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→2)*-O-*(4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→2)*-O-*(4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→3)-4-azido-2-O-benzyl-4,6-dideoxy-α-D-mannopyranoside* **22**

Disaccharide thioglycoside **16** (185 mg, 0.294 mmol) and the trisaccharide alcohol **17** (232 mg, 0.284 mmol) were reacted by methyl triflate activation using the same procedure as described for the synthesis of the analogous pentasaccharide carrying only (1→2) linkages (6).

Pure **22** was obtained as a syrup (310 mg, 76%); $[\alpha]_D^{20}$ +80.0° (*c* 0.36, chloroform); ^{1}H nmr showed an approximate *Z*/*E* ratio of 3.5/1.0; ^{1}H nmr (500 MHz, $CDCl_3$) δ: 7.45–7.20 (m, 25H, Ph), 5.40 (dd, 1H, $J_{1''',2'''}$ 1.6 Hz, $J_{2''',3'''}$ 3.2 Hz, H-2′′′), 4.96 (d, 1H, $J_{1',2'}$ 1.6 Hz, H-1′), 4.92 (d, 1H, $J_{1'',2''}$, 1.6 Hz. H-1″), 4.91 (d, 1H, $J_{1'',2''}$ 1.7 Hz, H-1″), 4.84 (d, 1H, H-1′′′′) 4.73–4.51 (m, 10H, CH_2Ph), 4.68 (d, 1H, $J_{1,2}$ 1.5 Hz, H-1), 4.01 (dd, 1H, $J_{2',3'}$ 3.0 Hz, H-2′), 3.87 (dd, 1H, $J_{2'',3''}$ 3.1 Hz, H-2″), 3.82 (dd, 1H, $J_{2,3}$ 3.0 Hz, $J_{3,4}$ 10.0 Hz, H-3), 3.81 (dd, 1H, $J_{2''',3'''}$ 3.1 Hz, H-2′′′), 3.77 (dd, 1H, $J_{3''',4'''}$ 10.0 Hz, H3′′′′), 3.71 (dd, 1H, $J_{3',4'}$ 10.0 Hz, H-3′), 3.69 (dd, 1H, $J_{3'',4''}$ 10.0 Hz, H-3″), 3.66 (dd, 1H, $J_{3''',4'''}$ 10.0 Hz, H-3′′′), 3.60 (dd, 1H, H-2), 3.55–3.39 (m, 5H, H-5, H-5′, H-5″, H-5′′′, H-5′′′′), 3.54 (dd, 1H, $J_{4,5}$ 10.0 Hz, H-4), 3.36 (dd, 1H, $J_{4'''',5''''}$ 10.0 Hz, H-4′′′′), 3.32 (dd, 1H, $J_{4'',5''}$ 10.0 Hz, H-4″), 3.31 (s, 3H, OMe), 3.24 (dd, 1H, $J_{4''',5'''}$ 10.0 Hz, H-4′′′), 3.22 (dd, 1H, $J_{4',5'}$ 10.0 Hz, H-4′), 2.09 (s, 3H, OAc), 1.34 (d, 3H, $J_{5,6}$ 6.0 Hz, H-6), 1.28 (d, 3H, $J_{5''',6'''}$ 6.0 Hz, H-6′′′), 1.21 (d, 3H, $J_{5''',6''''}$ 6.0 Hz, H-6′′′′), 1.19 (d, 3H, $J_{5',6'}$ 6.0 Hz, H-6′), 1.14 (d, 3H, $J_{5'',6''}$ 6.0 Hz, H-6″); ^{13}C nmr (125 MHz, $CDCl_3$) δ: 100.97 (1C, $J_{C1''',H1'''}$ 170 Hz, C-1′′′′), 100.44 (1C, $J_{C1''',H1'''}$ 171 Hz, C-1′′′), 100.17 (1C, $J_{C1'',H1''}$ 172 Hz, C-1″), 99.13 (1C, $J_{C1',H1'}$ 171 Hz, C-1′), 98.24 (1C, $J_{C1,H1}$ 170 Hz, C-1). *Anal.* calcd. for $C_{68}H_{81}N_{15}O_{17}$: C 59.16, H 5.91, N 15.22; found: C 59.29, H 6.10, N 14.93.

Methyl O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→2)*-O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→2)*-O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→2)*-O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→3)-4,6-dideoxy-4-formamido-α-D-mannopyranoside* **24**

Pentasaccharide **22** (100 mg, 0.072 mmol) was subjected to a standard Zemplén deacetylation. The resulting syrup **23** was reduced by H_2S under identical conditions as described for the analogous 1,2-linked pentasaccharide (6) carrying only α1,2 linkages and also for the reduction of disaccharide **12** (this paper). *N*-Formylation was achieved using the standard procedure already described for preparation of disaccharide **15**. Hydrogenation under pressure was performed as described for the preparation of trisaccharide **21**.

The pentasaccharide **24** was a syrup (43 mg, 67%); $[\alpha]_D^{20}$ +74.2° (*c* 0.54, water); ^{1}H nmr shows an approximate *Z*/*E* ratio of 3.5:1; ^{1}H nmr (500 MHz, D_2O) δ: 8.22–8.19 (4s, 5H, NHC*H*O-*Z*), 8.05, 8.03 (2bs, 5H, NHC*H*O-*E*), 5.19, 5.12, 5.05, 5.01, 4.99 (5m, 4H, H-1′′′′, H-1′′′, H-1″, H-1′), 4.72 (m, 1H, H-1), 4.20–3.80 (m, 20H, H-2, H-2′, H-2″, H-2′′′, H-2′′′′, H-3, H-3′, H-3″, H-3′′′, H-3′′′′, H-4-*Z*, H-4′-*Z*, H-4″-*Z*, H-4′′′-*Z*, H-4′′′′-*Z*, H-5, H-5′, H-5″, H-5′′′, H-5′′′′), 3.50–3.34 (m, 8H, H-4-*E*, H-4′-*E*, H-4″-*E*, H-4′′′-*E*, H-4′′′′-*E*, OMe), 1.32–1.15 (m, 15H, H-6, H-6′, H-6″, H-6′′′, H-6′′′′); ^{13}C nmr (125 MHz, D_2O) δ: 168.07, 167.93 (5C, NCHO-*E*), 165.15, 164.63 (5C, NHCHO-*Z*), 102.28, 102.19, 101.07, 100.92, 100.71, (5C, C-1, C-1′, C-1″, C-1′′′, C-1′′′′). *Anal.* calcd. for $C_{36}H_{59}N_5O_{21}$: C 48.16, H 6.62, N 7.80; found: C 48.40, H 6.55, N 7.85.

Ethyl 3-O-*(2-O-acetyl-4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-2-O-acetyl-4-azido-4,6-dideoxy-1-thio-α-D-mannopyranoside* **25**

The monosaccharide alcohol **9** (122 mg, 0.44 mmol) dissolved in dichloromethane (5 mL) was stirred with powdered 4 Å molecular sieves (120 mg) for 1 h at 20°C. Freshly prepared bromide **10** (192 mg, 0.50 mmol) (6) dissolved in dichloromethane (5 mL) was added dropwise into the solution of **9** at 0°C. The reaction mixture was stirred overnight at 20° when tlc (hexane – ethyl acetate 3:1, v/v) indicated complete conversion into the disaccharide **25**. After filtration through Celite, washing with saturated hydrogen carbonate solution, and concentration to a syrup, the reaction product was subjected to column chromatography (hexane – ethyl acetate 5:1, v/v) to give pure **25** as a syrup (211 mg, 83%); $[\alpha]_D^{20}$ +149.7° (*c* 0.62, chloroform); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 7.40–7.28 (m, 5H, Ph), 5.44 (dd, 1H, $J_{1',2'}$ 1.8 Hz, $J_{2',3'}$ 3.2 Hz, H-2′), 5.21 (d, 1H, $J_{1,2}$ 1.6 Hz, H-1), 5.17 (dd, 1H, $J_{2,3}$ 3.5 Hz, H-2), 5.01 (d, 1H, H-1′), 4.68 (d, 1H, ^2J 11.2 Hz, CH_AH$_B$Ph), 4.51 (d, 1H, CH$_A$H$_B$Ph), 3.92 (dd, 1H, $J_{3,4}$ 10.0 Hz, H-3), 3.90 (dq, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 6.0 Hz, H-5), 3.75 (dd, 1H, $J_{3',4'}$ 9.8 Hz, H-3′), 3.53 (dq, 1H, $J_{4',5'}$ 10.0 Hz, $J_{5',6'}$ 6.0 Hz, H-5′), 3.52 (dd, 1H, H-4), 3.40 (dd, 1H, H-4′), 2.88–2.55 (m, 2H, SCH_2CH$_3$), 2.13 (s, 3H, OAc), 2.12 (s, 3H, OAc), 1.35 (d, 3H, H-6), 1.28 (d, 3H, H-6′), 1.28 (dd, 3H, SCH$_2$CH_3); ^{13}C nmr (125 MHz, $CDCl_3$) δ: 99.85 (C-1′, $J_{C1',H1'}$ 170.5 Hz), 81.88 (C-1, $J_{C1,H1}$ 168.0). *Anal.* calcd. for $C_{25}H_{34}N_6O_8S$: C 51.89, H 5.92, N 14.52, S 5.54; found: C 51.02, H 6.07, N 14.63, S 5.48.

Methyl O-*(2-O-acetyl-4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→3)*-O-*(4-azido-2-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→2)*-O-*(4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→2)*-O-*(4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranosyl)-(1→2)-4-azido-3-O-benzyl-4,6-dideoxy-α-D-mannopyranoside* **27**

Disaccharide **25** (91 mg, 0.16 mmol), the selectively protected trisaccharide alcohol **26** (117 mg, 0.14 mmol) (6), and powdered 4 Å molecular sieves (200 mg) were stirred in dichloromethane (5 mL) for 2 h at 20°C. Methyl triflate (0.3 mL, 2.65 mmol) was added and stirring was continued for another 4 days (tlc, hexane – ethyl acetate 3:1). The disaccharide donor **25** and the trisaccharide acceptor **26** were indistin-

guishable by tlc. Triethylamine (2 mL, 14.35 mmol) was added carefully and stirring was continued for another 0.5 h. The reaction mixture was filtered, and the filtrate was washed with a 50% saturated NaCl solution and then concentrated. Subsequently the crude reaction product was purified by column chromatography (hexane – ethyl acetate 6:1, v/v) and pure **27** was obtained as a syrup (143 mg, 64%); $[\alpha]_D^{20}$ +79.6° (*c* 2.19, chloroform); ^{1}H nmr ($CDCl_3$, 200 MHz) δ: 7.40–7.25 (m, 20H, Ph), 5.45 (dd, 1H, $J_{1'''',2''''}$ 1.8 Hz, $J_{2'''',3''''}$ 3.2 Hz, H-2''''), 5.17 (dd, 1H, $J_{1''',2'''}$ 1.7 Hz, $J_{2''',3'''}$ 3.2 Hz, H-2'''), 5.06 (d, 1H, H-1''''), 4.94 (d, 1H, $J_{1',2'}$ 1.6 Hz, H-1'), 4.88 (d, 1H, $J_{1'',2''}$ 1.8 Hz, H-1''), 4.84 (d, 1H, H-1'''), 4.74–4.46 (m, 9H, $4CH_2Ph$, H-1), 3.97 (dd, 1H, $J_{3''',4'''}$ 9.8 Hz, H-3'''), 3.87–3.12 (m, 20H, H-2, H-2', H-2'', H-3, H-3', H-3'', H-3''', H-4, H-4', H-4'', H-4''', H-4'''', H-5, H-5', H-5'', H-5''', H-5'''', OMe), 2.13 (s, 3H, OAc), 2.09 (s, 3H, OAc), 1.28 (d, 3H, $J_{5,6}$ 6.0 Hz, H-6), 1.27 (d, 3H, $J_{5''',6'''}$ 6.2 Hz, H-6'''), 1.26 (d, 3H, $J_{5'''',6''''}$ 6.0 Hz, H-6''''), 1.19 (d, 3H, $J_{5',6'}$ 6.0 Hz, H-6'), 1.17 (d, 3H, $J_{5'',6''}$ 6.0 Hz, H-6''); ^{13}C nmr (50 MHz, $CDCl_3$) δ: 100.37 (1C, $J_{C1'''',H1''''}$ 171 Hz, C-1''''), 99.99 (1C, $3J_{C1''',H1'''}$ 170 Hz, C-1'''), 99.79 (1C, $J_{C1'',H1''}$ 172 Hz, C-1''), 99.61 (1C, $J_{C1',H1'}$ 170 Hz, C-1'), 98.61 (1C, $J_{C1,H1}$ 171 Hz, C-1). *Anal.* calcd. for $C_{63}H_{77}N_{15}O_{18}$: C 56.79, H 5.82, N 15.77; found: C 56.77, H 5.88, N 15.57.

Methyl O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→3)*-O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→2)*-O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→2)*-O-*(4,6-dideoxy-4-formamido-α-D-mannopyranosyl)-(1→2)-4,6-dideoxy-4-formamido-α-D-mannopyranoside* **28**

Pentasaccharide **27** (20 mg, 0.014 mmol) was converted to the deblocked and *N*-formylated derivative **28** according to the procedure described for the conversion of pentasaccharide **22** to **24**. Pure **28** was obtained as a syrup (12 mg, 64%); $[\alpha]_D^{20}$ +35.8° (*c* 0.1, water); ^{1}H nmr shows an approximate *Z*/*E* ratio of 3.5:1; ^{1}H nmr (500 MHz, D_2O) δ: 8.22–8.19 (m, 5H, NHC*H*O-*Z*), 8.05–8.00 (m, 5H, NHC*H*O-*E*), 5.19, 5.17, 5.05, 5.00, 4.80 (5bs, 5H, H-1'''', H-1''', H-1'', H-1', H-1), 4.22–3.80 (m, 20H, H-2, H-2', H-2'', H-2''', H-2'''', H-3, H-3', H-3'', H-3''', H-3'''', H-4-*Z*, H-4'-*Z*, H-4''-*Z*, H-4'''-*Z*, H-4''''-*Z*, H-5, H-5', H-5'', H-5''', H-5''''), 3.48–3.34 (m, 8H, H-4-*E*, H-4'-*E*, H-4''-*E*, H-4'''-*E*, H-4''''-*E*, OMe), 1.36–1.15 (m, 15H, H-6, H-6', H-6'', H-6''', H-6''''). *Anal.* calcd. for $C_{36}H_{59}N_5O_{21}$: C 48.16, H 6.62, N 7.80; found: C 48.22, H 6.59, N 7.79.

Laboratoire de physicochimie des solutions, École nationale supérieure de chimie de Paris, Unité associée au Centre national de la recherche scientifique, n° 403, 11 Rue Pierre et Marie Curie, 75231 Paris CEDEX 05, France

Received August 12, 1988

F. TERRIER, J. C. HALLE, P. MACCORMACK, and M. J. POUET. Can. J. Chem. **67**, 503 (1989).

A detailed nuclear magnetic resonance study of 4,6-dinitro-2,1,3-benzoxadiazole N-oxide (DNBF), which includes a 2D INADEQUATE analysis and experiments with samples ^{15}N-labelled at the NO_2 groups, is described. The results lead to an unambiguous assignment of the carbon and proton chemical shifts in various solvents. Some ^1H and ^{13}C data pertaining to 4,6-dinitro-2,1,3-benzoxadiazole (DNBZ), the deoxygenated analog of DNBF, are also reported, allowing the influence of the N-oxide group on the proton and carbon chemical shifts to be discussed. It is shown that all of the ^1H nmr evidence so far reported for the characterization of DNBF σ adducts as arising from nucleophilic addition to the 7-position, i.e., as structure **2***a*, has no significance. That complexation actually occurs at this position is, however, convincingly demonstrated by ^{15}N data. These also allow us to establish that this process is both kinetically and thermodynamically favored.

Key words: nitrobenzofuroxans, Meisenheimer complexes, ^{13}C nmr of benzofuroxans, 2,1,3-benzoxadiazole N-oxides, nitrobenzofuroxan σ-adducts.

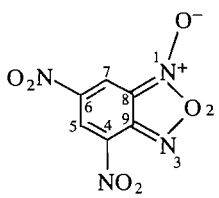
Une étude en résonance magnétique nucléaire très détaillée du dinitro-4,6 benzoxadiazole-2,1,3 N-oxyde, plus connu sous le nom de dinitro-4,6 benzofuroxanne (DNBF), a été réalisée dans divers solvants. Elle comporte notamment une analyse 2D INADEQUATE et des mesures faites avec des échantillons marqués à l'azote 15 sur l'un ou sur les deux groupes NO_2. Les résultats permettent d'attribuer sans ambiguïté les déplacements chimiques des protons et des carbones du DNBF. Une comparaison avec les résultats obtenus pour le dinitro-4,6 benzoxadiazole-2,1,3 (DNBZ) révèle l'influence considérable du groupe N-oxyde sur certains déplacements chimiques. Il est montré que les arguments rmn précèdemment développés pour affirmer que le DNBF réagit avec les nucléophiles en formant des complexes-σ en position 7 (complexes **2***a*) sont peu convaincants. Seule l'analyse des résultats obtenus avec les échantillons marqués en ^{15}N permet d'étayer valablement cette conclusion. Cette analyse montre en outre que la formation des complexes **2***a* est cinétiquement et thermodynamiquement contrôlée.



Mots clés : nitrobenzofuroxannes, complexes de Meisenheimer, rmn du ^{13}C des benzofuroxannes, benzoxadiazole-2,1,3 N-oxydes, σ-adduits des nitrobenzofuroxannes.

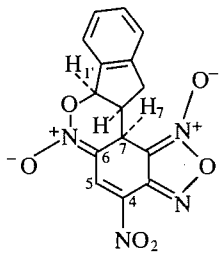
There is presently much interest in 4,6-dinitro-2,1,3-benzoxadiazole N-oxide, commonly known as 4,6-dinitrobenzofuroxan (DNBF). This compound exhibits an extremely high electrophilic character, which is useful in assessing the reactivity of very weak nucleophiles (1–7). So far, all reactions have been reported to involve covalent addition of the nucleophile to the carbocyclic ring, giving rise to stable σ adducts that have been formulated as having structure **2***a*, mainly on the basis of ^1H nmr.

As a continuation of our work in this field (3, 4, 6, 8), we have recently become interested in the reaction of DNBF with indene. In this instance, we have found a new product exhibiting none of the spectral and chemical characteristics of a σ complex that we could identify as being the dihydrooxazine N-oxide **3**. These results have recently been published (9) but our thorough nmr investigation has also led us to the surprising discovery that there are many contradictory assignments of the ^1H resonances of DNBF in the literature (2–5, 7, 10–12). Concomitantly, we realized that much of the ^1H nmr evidence reported for the characterization of the σ adducts **2***a* may be seriously questioned (2–5, 7, 10–12).



In this paper, we report a 2D INADEQUATE analysis of DNBF and we present the results of ^{15}N experiments carried out after ^{15}N labelling of the 6-NO_2 group or of both 4- and 6-NO_2 groups of this compound and its methoxide σ adduct. ^1H and ^{13}C results pertaining to 4,6-dinitro-2,1,3-benzoxadiazole (4,6-dinitrobenzofurazan or DNBZ), the deoxygenated analog of DNBF, are also included for purpose of comparison.

DNBZ

Results

4,6-Dinitrobenzofuroxan (DNBF)

The ^1H spectrum of DNBF shows the H_A and H_X doublets of the AX system at 9.27 and 8.95 ppm, respectively, in dimethyl sulfoxide (Me_2SO; J_{HA-HX} = 1.9 Hz). On ^{15}N labelling of the 6-NO_2 group, the H_A and H_X resonances show coupling with

[1]Post doctoral fellow of the Consejo Nacional de Investigaciones Cientificas y Tecnicas de la Republica Argentina.

Printed in Canada / Imprimé au Canada

the nitrogen atom but, due to an insufficient separation of the inner lines of the resulting double doublets, they both appear as a triplet. From the separation of the outer lines, the J_{N6HA} and J_{N6HB} coupling constants were readily calculated: $J_{N6HA} = 2.4$; $J_{N6HB} = 1.6$ Hz. On further ^{15}N labelling at the 4-NO_2 group, the resonance of H_A remains unaffected while that of H_X undergoes additional splitting: $J_{N4HX} = 2.9$ Hz. These observations show unambiguously that H_A is H-7 and H_X is H-5 in Me_2SO.

Similar experiments have been carried out in various solvents (Table 1). In THF and acetone, it is the high-field resonance of the observed AX and AB patterns, respectively, that is split on ^{15}N labelling of the 4-NO_2 group. This indicates a sequence of the H-7 and H-5 resonances in these solvents that is the same as that found in Me_2SO. In contrast, it is the H_A resonance that is affected by labelling the 4-NO_2 group in nitromethane, methylene chloride, chloroform, benzene, and acetonitrile. This shows that the low-field doublet of the AX (or AB) system is ascribable to H-5 in these solvents. A particular situation is found in methanol where the two protons have quite identical chemical shifts.

^{13}C chemical shifts were obtained from proton noise-decoupled ^{13}C spectra. From selective irradiations of H-7 and H-5, the resonances at 120.8 ppm and 126.5 ppm in Me_2SO were readily assigned as being due to C-7 and C-5, respectively. Then, the complete elucidation of the carbon skeleton, in Me_2SO, was obtained from a two-dimensional analysis: 2D INADEQUATE (13). Using the C-7 and C-5 carbons at 120.8 and 126.5 ppm as reference points, the assignment of the various quaternary carbons of DNBF was completed. The ^{13}C chemical shifts together with the various J_{CH} coupling constants in Me_2SO are summarized in Table 2.

In methylene chloride where no 2D INADEQUATE analysis was performed, the C-5 and C-7 carbons of DNBF have been firmly assigned from selective proton decoupling. Other carbons were assigned by analogy with the results (δ, J) obtained in Me_2SO. These assignments are also given in Table 2.

4,6-Dinitrobenzofurazan (DNBZ)

The ^1H spectrum of DNBZ shows an AX system comparable to that of DNBF in Me_2SO: $\delta_{HA} = 9.80$; $\delta_{HX} = 9.04$; $J_{HA-HX} = 1.8$ Hz (Table 1). From selective proton irradiation and comparison of the measured $^1J_{CH}$ coupling constants with those determined for DNBF, correlated ^{13}C and ^1H resonances at 122.59 and 9.80 were assigned to C-7 and H-7, respectively, while those at 125.17 and 9.04 were assigned to C-5 and H-5, respectively. Other carbons were also assigned by analogy with the results obtained for DNBF. The data are collected in Table 2.

The methoxide adduct of DNBF

The ^1H spectrum of this adduct consists of an AX system with the H_A and H_X doublets at 8.70 and 5.89 ppm, respectively ($J_{HAHX} = 0.6$ Hz), and a methoxyl singlet at 3.35 ppm in Me_2SO. ^{15}N labelling of the 6-NO_2 group leaves the H_X resonance essentially unchanged while it causes a splitting of the H_A resonance, which appears as a double doublet: $J_{N6HA} = 2.6$ Hz. Further splitting of H_A occurs on labelling the 4-NO_2 group, resulting in the appearance of a multiplet ($J_{N4HA} = 1.9$ Hz). In addition, ^{13}C spectra of the adduct formed from (4,6-^{15}N)-DNBF show a vicinal J_{C4-N4} coupling constant of 22.2 Hz. These results show unambiguously that the adduct has the structure **2***a* rather than the isomeric structure **2***b* (Nu = OCH_3; see Scheme 1).

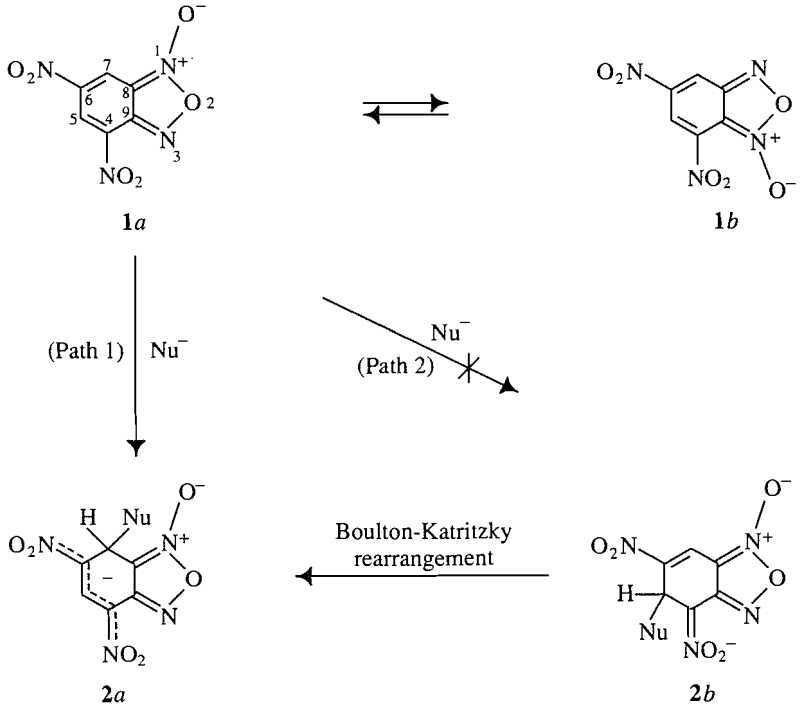
Discussion

^1H chemical shifts of DNBF and DNBZ

In an early study by Katritzky and co-workers (14), it was found that the ^1H spectrum of DNBF consists of a single AB or AX pattern, which persists over a large temperature range in dioxan, acetonitrile, and dimethyl sulfoxide. This showed that neither of the two possible types of tautomerism from **1***a* to **1***b* (Scheme 1) or **1***a* to **1***a*′ (Scheme 2 with **1***a*′ ≡ **1***a* for unlabelled DNBF) is important. DNBF was thus formulated as **1***a* on the basis that steric, electrostatic, and mesomeric effects are expected to cause the equilibrium **1***a* ⇔ **1***b* to lie very predominantly on the side of the isomer **1***a* (10, 11, 14). Interestingly, **1***a* was later found by an X-ray crystallography study to be the structure of DNBF in the solid state (15). Another interesting observation of Katritzky dealt with the solvent dependence of the AX or AB pattern, but no attempt to assign the H_A and H_B (H_X) resonances to the H-7 and H-5 protons of **1***a* was made (14).

In all solvents employed in this work, a unique AB or AX pattern has been observed. In accordance with Katritzky's observations, our results in Table 1 emphasize the large dependence of the proton resonances of DNBF on the solvent. They further reveal that the individual chemical shifts of H-7 and H-5 may be affected to such a different extent that the sequence of these chemical shifts may be reversed on going from one solvent to another. However, there is no apparent correlation of chemical shifts with common solvent parameters like polarity.



Because they can be related to previous work, some of our assignments are worthy of comment. From a comparison of the ^1H spectra of DNBF and its partially 5-deuterated analog, Brown and Keyes concluded in 1965 that the lower-field doublet of the AX pattern observed in methylene chloride corresponds to H-7 (10). As can be seen in Table 1, our ^{15}N experiments lead us to assign this doublet to H-5 and therefore to raise doubt about the validity of the structural characterization of the hydroxide adduct of DNBF reported by these authors (*vide infra*) (10). On the other hand, the majority of recent studies have been carried

out in dimethyl sulfoxide (2–5). However, no unambiguous assignment of the two proton resonances is found in these papers. Our determination that the H_A and H_X resonances correspond to the H-7 and H-5 protons, respectively, in this solvent agrees with some reports but disagrees with many others. This uncertainty in the exact chemical shift sequence in Me_2SO has been a major drawback in our efforts to characterize the dihydrooxazine N-oxide **3** and has led to the present study (9).

Consistent with a previous study is the observation of

SCHEME 2

close chemical shifts for H-7 and H-5 in acetone (14). Also remarkable is the coincidence of these chemical shifts in methanol.

Comparison of the ^1H spectra of unsubstituted benzofurazan and benzofuroxan has shown that the effect of adding an N-oxide oxygen atom is to cause a high-field shift of all the protons (16). This result has been attributed to a significant electron-donating influence of the N-oxide group, which is greater at the 4- and the 6- than at the 5-position, in agreement with theoretical expectation (Scheme 3). Due to an anisotropy effect of the N-oxide group, the 7-position suffers a much larger high-field shift. Interestingly, Table 3 shows that the shifts to high field are similar when the H-5, H-6, and H-7 resonances of 4-nitrobenzofurazan and 4-nitrobenzofuroxan are compared in acetone or Me_2SO (14). Table 3 also shows that a comparison of DNBF and DNBZ based on our assignments (from ^{15}N experiments) affords $\Delta\delta$ values for the H-7 and H-5 protons that are analogous to those found for unsubstituted or mononitro derivatives. This brings additional support for our assignments.

No assignment of the H-7 and H-5 resonances of DNBZ was previously made (17). Due to the absence of the influence of the N→O group mentioned above, the resonance of the H-7 proton of DNBZ appears at much lower field than that of DNBF. The result is that the sequence of the H-7 and H-5 chemical shifts of DNBZ is not solvent dependent despite notable variations in each of these chemical shifts on going from Me_2SO to CH_2Cl_2 (Table 1).

^{13}C chemical shifts and coupling constants of DNBF and DNBZ

Since it is based on a combination of the information accumulated from ^{15}N labelling, selective proton irradiation experiments, and a two-dimensional analysis, our assignment of the carbon resonances of DNBF in dimethyl sulfoxide given in Table 2 is unambiguous. In CD_2Cl_2, where no 2D-INADEQUATE analysis was performed, only the C-5 and C-7 carbons could be assigned with certainty but the validity of the assignments of the various quaternary carbons is indirectly confirmed by the observed consistency in the quoted carbon chemical shifts and J_{CH} coupling constants. It is also on grounds of analogy with DNBF that the quaternary carbons of DNBZ were assigned. Significantly, the results lead us to assign very similar chemical shifts to the C-9 carbons of these derivatives but very different chemical shifts to the C-8 carbons: in Me_2SO, C-8 is at ≈116 ppm for DNBF but at ≈150 ppm for DNBZ. This result agrees with a previous report by Anet and Yavari that addition of an oxygen to a nitrogen atom of benzofurazan causes a large upfield shift (≈40 ppm) of the resonance of the quaternary carbon (C-8) close to the N→O function, while that of the removed carbon (C-9) is only slightly affected (16). Here, the upfield shift observed on going from DNBZ to DNBF is ≈34 ppm and this supports our assignments of C-8 and C-9. This large substituent effect has been attributed to the presence of a partial negative charge on C-8 resulting from a significant

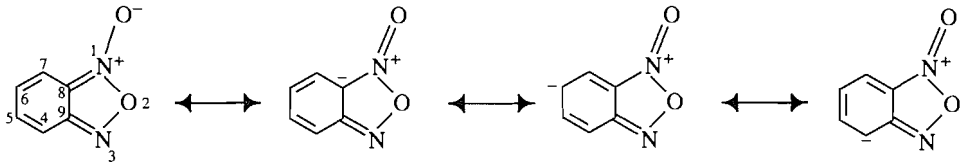
contribution of the second resonance canonical form of DNBF described in Scheme 3 (16). Evidence for the importance of this structure is provided by the finding by X-ray crystallography that the C8N1 bond (1.40 Å) is appreciably longer than the C9N3 bond (1.37 Å) (15).

Concerning the coupling constants, the close analogy between the $^1J_{C7H7}$ and $^1J_{C5H5}$ values of DNBF and DNBZ is noteworthy since it is reminiscent of that found between the same coupling in the unsubstituted parents (16).



^1H nuclear magnetic resonance characterization of DNBF σ adducts

Since it is the H_A resonance of the AX system corresponding to the DNBF–methoxide σ complex which is split by ^{15}N labelling of both the 4- and 6-NO_2 groups of the parent molecule, the present work leaves no doubt that this adduct has the structure **2***a* (Scheme 1) and therefore that DNBF undergoes preferentially covalent nucleophilic addition at the 7-position. While this conclusion agrees with all reported formulations of DNBF σ adducts (1–12), it is important to emphasize why our results provide the first convincing evidence for structure **2***a*.

Changes in the ^1H nmr spectra that take place on reaction of DNBF with a large variety of nucleophiles may only be understood in terms of σ complexation since they are closely reminiscent of those described in the reactions involving covalent addition of the same nucleophiles to nitroaromatics like 1,3,5-trinitrobenzene (TNB) (1, 10, 11). Thus, all reactions are accompanied by a considerable shift to high field of one of the resonances forming the AX or AB pattern of DNBF, as anticipated for a change from sp^2 to sp^3 hybridization at one of the hydrogen-bearing carbons of the carbocyclic ring. Concomitantly, the second resonance is also moved to high field but to a much smaller extent, consistent with loss of aromaticity and increased negative charge in the resulting hetarenide ring. However, both structures **2***a* and **2***b* are consistent with the observed nmr changes and it is not possible to discriminate between the two on this basis irrespective of whether the exact sequence of the H-7 and H-5 resonances in the original spectra of DNBF is known or not. Nevertheless, the observation of a single set of two weakly coupled resonances in all reported ^1H spectra indicates that only one of the two isomers is important in the solutions studied.

So far, only one study has been especially designed to decide on the structure of the resulting isomer. It is the early comparison by Brown and Keyes of the changes in the ^1H spectra brought about by the addition of hydroxide ion to DNBF and its partially 5-deuterated analog in *water* (10). Since it was the signal not affected by the deuteration, attributed to

SCHEME 3

H-7 in CH_2Cl_2 (*vide supra*), which moved to high field, it was concluded that the corresponding adduct had structure **2***a* (Nu = OH). This formulation has never been questioned since it agreed with consideration of resonance forms that favor **2***a* over **2***b*, and in all subsequent studies DNBF σ adducts were characterized as having structure **2***a* on the basis only of the observation of the anticipated AX patterns in ^1H nmr (2–5, 7, 12). Obviously, the finding that Brown and Keyes' assignments of the two proton resonances of DNBF in methylene chloride were erroneous has the effect of making their structural characterization of **2***a* (Nu = OH) totally inconclusive. Therefore, the definitive demonstration by nmr that structure **2***a* is valid is an important result in DNBF chemistry (1).

A most interesting point, which also merges from ^{15}N data, deals with the mechanism of the complexation of DNBF. The question is whether the formation of the adducts **2***a* arises from

2*a'*

direct nucleophilic addition at the 7-position (Scheme 1) or from initial addition at the 5-position to give **2***b*, followed by rapid Boulton–Katritzky rearrangement (Scheme 2). Should the latter pathway occur (18), it is clear that experiments carried out with a DNBF sample labelled at the 4- and 6-NO_2 groups would give adducts **2***a'* having only the 6-NO_2 group labelled. In this case, the H_A resonance of **2***a'* should appear as a double doublet and not as the multiplet found experimentally for the methoxide adduct. We therefore conclude that the formation of adducts **2** occurs via path 1 to give **2***a* (Scheme 1), which is both kinetically and thermodynamically favored.[2]

Experimental

Nuclear magnetic resonance

The ^1H and ^{13}C nmr spectra were recorded on a Bruker AM-250 spectrometer equipped with an ASPECT 3000 computer. Chemical shifts are reported in parts per million (δ, *J* in hertz) relative to internal Me_4Si. The 2D INADEQUATE spectrum of DNBF was obtained with the basic sequence proposed by Mareci and Freeman (13).

Materials

4,6-Dinitrobenzofuroxan (DNBF) and 4,6-dinitrobenzofurazan (DNBZ) were prepared according to previously reported methods. DNBF: mp 173°C (lit. (20, 21) mp 172–174.5°C); DNBZ: mp 133°C (lit. (8, 17) mp 129–132°C). [6-^{15}N]-4,6-Dinitrobenzofuroxan was obtained as recently described (9).

[4,6-^{15}N]-4,6-Dinitrobenzofuroxan

A solution of 1 mL of 40% H $^{15}NO_3$ (Aldrich, 98% ^{15}N) in 4 mL of sulfuric acid (*d* = 1.84) was added dropwise to a stirred solution of 0.5 g of benzofuroxan (3.7 mmol) in 8 mL of sulfuric acid (*d* = 1.84) maintained at ice-bath temperature. The resulting mixture was kept at this temperature for 30 min, then slowly heated and maintained at 60–70°C for 3 h. After the mixture returned to room temperature, it was poured onto cracked ice and the resulting orange crystals were filtered, washed with water, and vacuum dried over P_2O_5; mp 175°C; mass spectrum (obsd.), *m/e*: 228, 212, 198, 152, 121; for comparison, DNBF mass spectrum (obsd.), *m/e*: 226, 210, 196, 150, 120.

[2]Reversible formation of **2***a* from DNBF after initial and reversible formation of **2***b* in a fast preequilibrium step is an alternative mechanism that is ruled out by the kinetic results obtained for many interactions (1, 6, 8).

During our studies on metal–radiosensitizer complexes, a complex $RuCl_2(dmso)_2(4\text{-}NO_2Im)_2$ was found to show better radiosensitizing properties and lower toxicity than the free 4-nitroimidazole ligand; complexes with *N*-substituted-4-nitroimidazoles were less effective as radiosensitizers (Can. J. Chem. **66**, 117 (1988)). In the present study, the effects of replacement of the chloride ligand by bromide, and dimethylsulfoxide (dmso) ligand by tetramethylenesulfoxide (tmso), as well as the use of a wider variety of nitroimidazole ligands, are described. A series of ruthenium(II) complexes of formulation: $RuCl_2(dmso)_2L_2$ (L = a 2-nitroimidazole); $RuCl_2(tmso)_mL_n$ (L = a 2- or 4-nitroimidazole, m = 1–3 and n = 1 or 2); and $RuBr_2(dmso)_2L_n$ (L = a 4-nitroimidazole, n = 1 or 2), has been synthesized and characterized by spectroscopic methods, particularly ^1H nmr and X-ray photoelectron spectroscopy. The precursors used were $RuX_2(dmso)_4$, X = Cl, Br, and $RuCl_2(tmso)_4$. The *N*-methyl-4-nitroimidazole (NMe-4-NO_2Im) ligand of the complex $RuBr_2(dmso)_2$(NMe-4-NO_2Im) chelates through the imidazole-*N* and the oxygen of NO_2. Another substituted 4-nitroimidazole, RSU-3159,[3] in $RuCl_2(tmso)$ (RSU-3159), binds through the sulfur and is almost certainly chelated; the complex with a substituted 2-nitroimidazole, $RuCl_2(tmso)_2$(SR-2508), is five-coordinate and probably trigonal bipyramidal. The replacement of dmso by tmso does not markedly alter the redox properties and radiosensitizing ability of the 4-nitroimidazole complexes, but increases their lipophilicity. The tmso complexes (unlike the dmso analogues) do not bind to DNA, as evidenced by non-inhibition of restriction enzymes. The tmso/2-nitroimidazole complexes, in contrast to the dmso analogues, are stable in aqueous media. The substitution of Cl^- by Br^- reduces the radiosensitizing ability of the 4-NO_2Im complexes. At only 200 μM, the complexes $RuCl_2(tmso)_2(4\text{-}NO_2Im)_2$ and $RuCl_2(tmso)_2$(SR-2508) have promising sensitizing enhancement ratio values of 1.6 and 1.5, respectively, and require further biological assessment.

Key words: ruthenium, nitroimidazoles, sulfoxides, radiosensitizers.

Au cours de nos études sur les complexes métalliques radio-sensibilisateurs, on a trouvé un complexe – le $RuCl_2(dmso)_2(NO_2\text{-}4Im)_2$ – qui présente de meilleures propriétés radio-sensibilisatrices et une toxicité inférieure à celle du ligand nitro-4 imidazole libre; les complexes des nitro-4 imidazoles *N*-substitués présentent de moins bonnes propriétés comme radiosensibilisateurs (J. Can. Chim. **66**, 117 (1988)). Dans l'étude rapportée ici, on décrit les effets produits par la substitution du ligand chlorure par le bromure, la substitution du diméthylsulfoxyde (dmso) par le tétraméthylènesulfoxyde (tmso) ainsi que l'utilisation d'une plus grande variété de ligands nitroimidazoles. On a synthétisé une série de complexes du ruthénium(II) de formules $RuCl_2(dmso)_2L_2$ (L = un nitro-2 imidazole); $RuCl_2(tmso)_mL_n$ (L = un nitro-2 (ou -4) imidazole, m = 1 à 3 et n = 1 ou 2) et $RuBr_2(dmso)_2L_n$ (L = un nitro-4 imidazole, n = 1 ou 2) et on les a caractérisés par des méthodes spectroscopiques et, en particulier, par rmn du ^1H et par spectroscopie photoélectrique des rayons-X. On a utilisé le $RuX_2(dmso)_4$ (X = Cl et Br) et le $RuCl_2(tmso)_4$ comme précurseurs. Le ligand *N*-méthyl nitro-4 imidazole (NMe-4NO_2Im) du complexe $RuBr_2(dmso)_2$(NMe-4NO_2Im) se chélate par le N de l'imidazole et l'oxygène du NO_2. Un autre nitro-4 imidazole substitué, le RSU-3159[3] que l'on retrouve dans le complexe $RuCl_2(tmso)$ (RSU-3159), se complexe par le soufre et est vraisemblablement chélaté; le complexe issu d'un nitro-2 imidazole substitué, le $RuCl_2(tmso)_2$(SR-2508), est pentacoordonné et est probablement du type trigonal bipyramidal. Le remplacement du dmso par le tmso n'influence pratiquement pas les propriétés redox et radiosensibilisatrices des complexes nitro-4 imidazoles; toutefois, ces substitutions augmentent leurs propriétés lipophiles. Tel qu'on a pu le démontrer par le fait qu'ils n'inhibent pas les enzymes de restriction, les complexes du tmso (contrairement à leurs analogues dmso) ne se lient pas à l'ADN. Par opposition à leurs analogues du dmso, les complexes du tmso/nitro-2 imidazole sont stables en solutions aqueuses. La substitution d'un Cl^- par un Br^- réduit les propriétés radio-sensibilisatrices des complexes du 4-NO_2IM. A des niveaux de seulement 200 μM, les complexes du $RuCl_2(tmso)(4\text{-}NO_2Im)_2$ et du $RuCl_2(tmso)_2$(SR-2508) présentent des rapports d'augmentation de sensibilité de 1,6 et 1,5 respectivement et nécessitent d'autres examens biologiques.

Mots clés : ruthénium, nitroimidazoles, sulfoxydes, radio-sensibilisateurs.

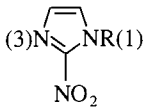
Introduction

Our interest in ruthenium complexes containing nitroimidazole ligands as radiosensitizers has been detailed elsewhere (1). In essence, by using the DNA-binding properties of Ru to take the nitroimidazole to DNA, we are attempting to improve the radiosensitizing properties of these nitroimidazoles in radioresistant hypoxic cells. The effectiveness of the complexes is measured in cultured mammalian cells by the sensitizing enhancement ratio (SER value), which is defined as the ratio of X-ray doses between hypoxic control and drug to give 1% cell survival.

The complex *cis,cis,cis*-$RuCl_2(dmso)_2(4\text{-}NO_2Im)_2$, **1**, was found to (*i*) have an SER value of 1.6 in hypoxic Chinese hamster ovary (CHO) cells, compared to 1.2 for the free 4-nitroimidazole ligand, (*ii*) bind to DNA, and (*iii*) have low genotoxicity (1–4). These encouraging findings prompted us to explore further this type of ruthenium complex, particularly with the variation of the ligand sets. The present paper reports on some complexes containing bromide, tetramethylenesulfoxide, and other nitroimidazoles; the synthesis, characterization, solution chemistry, and biological properties are discussed. Other reports have focussed on using metals to transport the classic, "electron affinic" nitro-compound radiosensitizers to the DNA target: as well as Ru, systems of Pt (5–9) and Rh (8) have been tested thus far; however, not all complexes sensitize better than the nitro-containing ligand itself (7, 8).

Experimental section



Chemicals and complexes

The sources and syntheses of $RuCl_3 \cdot 3H_2O$, *cis*-$RuCl_2(dmso)_4$, and some of the nitroimidazoles were given in an earlier paper (1). 2-Nitroimidazole (2-NO_2Im) and tetramethylenesulfoxide (tmso) were purchased from Sigma and Aldrich, respectively; 5-chloro-1-methyl-4-nitroimidazole (CMNI) was supplied by Dr. T. C. Jenkins (Medical Research Council, Harwell, Didcot, England); misonidazole (miso) and desmethylmisonidazole (De-miso) were donated by Roche Products Ltd; and etanidazole (SR-2508) was a gift from the US National Cancer Institute. All the imidazoles and tmso were used as received.

$RuCl_2(tmso)_4$, **2**. Some $RuCl_2 \cdot 3H_2O$ (3 g, 11 mmol) was added to previously dried methanol (50 mL), in a two-necked flask equipped with gas-inlet tube, reflux condenser, and magnetic stirrer. The solution was refluxed under H_2 (1 atm) overnight (approximately 16 h) to give a deep blue colour. To the Ru blue solution was added 3 mL of tmso. Refluxing under H_2 was continued for 6 h to yield an orange solution, which was cooled to room temperature (RT), when a yellow precipitate formed. No reaction was observed when the refluxing was carried out under N_2 or Ar. The solid was filtered off in air, washed with acetone, and dried *in vacuo* at RT (1.62 g, 70% yield). *Anal.* calcd. for $C_{16}H_{32}O_4S_4Cl_2Ru$: C 32.61, H 5.48, S 21.74; found: C 32.49, H 5.50, S 21.67. λ_{max} nm (log ϵ), H_2O: 343 (2.54), 303 (2.37). Infrared (Nujol): ν_{SO} 1133, 1094 cm^{-1}.

trans-$RuBr_2(dmso)_4$, **3**. Some $RuCl_2(dmso)_4$ (483 mg, 1 mmol) dissolved in CH_2Cl_2 (75 mL), and NaBr (205 mg, 2 mmol) dissolved in a minimum amount of water (approximately 3 mL), were mixed together, and sufficient methanol (approximately 40 mL) then added to

make the two layers miscible. This mixture was refluxed overnight (approximately 16 h) under N_2 to give an orange solution, which was roto-evaporated to dryness. The resulting pale orange solid was dissolved in dmso (3 mL) and the solution heated for 1 h. Acetone (approximately 25 mL) was added to precipitate a pale orange solid, which was filtered off in air, washed with acetone/water mixture (2:1) and acetone, and then dried *in vacuo* at RT (0.34 g, 60% yield). *Anal.* calcd. for $C_8H_{24}O_4S_4Br_2Ru$: C 16.76, H 4.22, S 22.36; found: C 17.01, H 4.24, S 22.46. λ_{max} nm (log ϵ), H_2O: 465 (2.32), 314 (2.17). Infrared (Nujol): ν_{SO} 1080 cm^{-1}. Complex **3** has been made previously by treating $RuBr_3$ with dmso (10, 11).

$RuCl_2(dmso)_2(2\text{-}NO_2Im)_2$, ***4***. The ligand 2-$NO_2$Im (282 mg, 2.5 mmol) was added to $RuCl_2(dmso)_4$ (483 mg, 1 mmol) in dry methanol (15 mL), and the solution refluxed for 6 h under N_2. The resulting blue solution was cooled to RT, when slow addition of diethylether (40 mL) gave a blue precipitate, which was filtered off in air, washed with hexanes and diethylether, and dried *in vacuo* at RT (0.36 g, 65% yield. *Anal.* calcd. fØ $Ç_{10}H_{18}O_6N_6S_2Cl_2Ru$: C 21.66, H 3.25, N 15.16; found: C 21.32, H 3.37, N 15.31. λ_{max} nm (log ϵ), EtOH: 332 (3.72), 420 (2.34). Infrared (Nujol): ν_{SO} 1112, 1084, ν_{NO_2} 1560, 1548 (1567, 1559 cm^{-1} for the free ligand).

$RuCl_2(dmso)_2(miso)_2$, ***5***. The complex $RuCl_2(dmso)_4$ (483 mg, 1 mmol) was added to miso (402 mg, 2 mmol) dissolved in toluene (10 mL), and the mixture refluxed for 6 h under N_2. The resulting blue solution was reduced in volume, and hexanes (30 mL) added slowly to give a blue, oily product. The oily product was cooled in liquid N_2 to yield a blue precipitate, which was filtered in air, washed with diethylether, and dried *in vacuo* at RT (0.36 g, 50% yield). *Anal.* calcd. for $C_{18}H_{34}O_{10}N_6S_2Cl_2Ru$: C 29.63, H 4.69, N 11.51; found: C 29.81, H 4.95, N 11.86. λ_{max} nm (log ϵ), EtOH: 325 (3.82), 638 (1.84). Infrared (Nujol): ν_{SO} 1100, 1089, ν_{NO_2} 1520, 1500 (1528, 1512 cm^{-1} for the free ligand).

$RuCl_2(dmso)_2(De\text{-}miso)_2$, ***6***. Dry methanol (15 mL) was added to $RuCl_2(dmso)_4$ (483 mg, 1 mmol) and De-miso (374 mg, 2 mmol), and the mixture refluxed for 4 h under N_2. The resulting blue solution was filtered hot, and the filtrate cooled to RT to give a blue precipitate. This was filtered off in air, washed with diethylether (20 mL), and dried *in vacuo* at RT (0.55 g, 78% yield). *Anal.* calcd. for $C_{16}H_{30}O_{10}N_6S_2Cl_2Ru$: C 27.35, H 4.30, N 11.96; found: C 27.15, H 4.27, N 12.07. λ_{max} nm (log ϵ), EtOH: 332 (3.57), 584 (2.01). Infrared (Nujol): ν_{SO} 1105, 1078, ν_{NO_2} 1532, 1515 (1538, 1527 cm^{-1} for the free ligand).

$RuCl_2(tmso)_2(4\text{-}NO_2Im)_2$, ***7***. Dry methanol (15 mL) was added to **2** (588 mg, 1 mmol) and 4-NO_2Im (282 mg, 2.5 mmol), and the solution refluxed for 4 h under N_2. The resulting brown solution was roto-evaporated to a reduced volume (3 mL) and diethylether/hexane (1:1) mixture (30 mL) added slowly to precipitate out a brown product, which was filtered off in air, washed with acetone and diethylether, and dried *in vacuo* at RT (0.33 g, 55% yield). *Anal.* calcd. for $C_{14}H_{22}O_6N_6S_2Cl_2Ru$: C 27.72, H 3.65, N 13.86; found: C 27.84, H 3.48, N 13.95. λ_{max} nm (log ϵ), EtOH: 330 (3.88). Infrared (Nujol): ν_{SO} 1102, 1075, ν_{NO_2} 1557, 1537 (1560, 1550 cm^{-1} for the free ligand).

$RuCl_2(tmso)_2(NMe\text{-}4\text{-}NO_2Im)_2$, ***8***. Complex **2** (588 mg, 1 mmol) was suspended in a methanol solution (20 mL) of NMe-4-NO_2Im (254 mg, 2 mmol), and the mixture refluxed for 6 h under N_2. The resulting blue solution was filtered hot and cooled to RT; slow addition of diethylether (30 mL) yielded a blue solid, which was filtered off in air, washed with acetone, and diethylether, and dried *in vacuo* at RT (0.44 g, 69% yield). *Anal.* calcd. for $C_{16}H_{26}O_6N_6S_2Cl_2Ru$: C 30.28, H 4.13, N 13.25; found: C 30.45, H 4.26, N 13.59. λ_{max} nm (log ϵ), H_2O: 309 (3.92), 413 (2.87). Infrared (Nujol): ν_{SO} 1115, 1088, ν_{NO_2} 1554, 1538 (1565, 1545 cm^{-1} for the free ligand), ν_{NCH_2-H} 2809 (2815 cm^{-1} for the free ligand).

$RuCl_2(tmso)_2(De\text{-}miso)_2$, ***9***. The De-miso ligand (374 mg, 2 mmol) was added to **2** (588 mg, 1 mmol) in dry methanol (10 mL), and the mixture refluxed for 6 h under N_2. The resulting blue solution was cooled to RT and filtered; slow addition of diethylether (30 mL) to the filtrate yielded a blue solid, which was filtered off in air, washed with acetone, and dried *in vacuo* at RT (0.54 g, 72% yield). *Anal.* calcd. for $C_{20}H_{34}O_{10}N_6S_2Cl_2Ru$: C 31.83, H 4.54, N 11.13; found: C 32.22, H 4.84, N 11.29. λ_{max} nm (log ϵ), H_2O: 330 (3.24), 532 (1.93). Infrared (Nujol): ν_{SO} 1114, 1078, ν_{NO_2} 1534, 1515 cm^{-1}.

$RuCl_2(tmso)_2(SR\text{-}2508)$, ***10***. The SR-2508 ligand (428 mg, 2 mmol) was added to **2** (588 mg, 1 mmol) in dry methanol (10 mL), and the solution refluxed for 4 h under N_2. The resulting blue solution was filtered hot and diethylether (30 mL) added slowly to the cooled filtrate to precipitate a blue solid; this was filtered off in air, washed with acetone and diethylether, and dried *in vacuo* at RT (0.44 g, 74% yield). *Anal.* calcd. for $C_{15}H_{26}O_6N_4S_2Cl_2Ru$: C 30.30, H 4.41, N 9.43; found: C 30.38, H 4.73, N 9.04. λ_{max} nm (log ϵ), H_2O: 341 (3.39), 495 (1.82). Infrared (Nujol): ν_{SO} 1093, 1050, ν_{NO_2} 1532, 1508 (1538, 1517 cm^{-1} for the free ligand).

$RuCl_2(tmso)_3(CMNI)$, ***11***. The compound CMNI)322 mg, 2 mmol) was mixed with **2** (588 mg, 1 mmol) in dry methanol (10 mL), and the solution refluxed for 6 h under N_2. The resulting green solution was cooled to RT, and diethylether (30 mL) was added slowly to precipitate out a green product. This was filtered off, washed with acetone, and dried *in vacuo* at RT (70% yield). *Anal.* calcd. for $C_{16}H_{28}O_5N_3S_3Cl_3Ru$: C 29.74, H 4.37, N 6.50; found: C 30.01, H 4.42, N 6.75. λ_{max} nm (log ϵ), H_2O: 320 (3.71), 381 (2.71). Infrared (Nujol): ν_{SO} 1094, 1057, ν_{NO_2} 1593, 1574 (1587, 1568 cm^{-1} for the free ligand).

$RuCl_2(tmso)(RSU\text{-}3159)$, ***12***. Complex **2** (588 mg, 1 mmol) was added to RSU-3159 (450 mg, 2 mmol) in methanol (15 mL), and the mixture refluxed for 6 h under N_2. The resulting dark green solution was filtered hot, and diethylether (40 mL) added slowly to the cooled filtrate to precipitate a green solid; this was filtered off in air, washed with acetone and diethylether, and dried *in vacuo* at RT (0.31 g, 62% yield). *Anal.* calcd. for $C_{11}H_{15}O_3N_5S_2Cl_2Ru$: C 26.34, H 3.01, N 13.97; found: C 26.33, H 2.93, N 13.74. λ_{max} nm (log ϵ), H_2O: 330 (3.89). Infrared (Nujol): ν_{SO} 1106, 1079, ν_{NO_2} 1681, 1652 (1673, 1641 cm^{-1} for the free ligand).

$RuBr_2(dmso)_2(4\text{-}NO_2Im)_2$, ***13***. Dry methanol (15 mL) was added to **3** (573 mg, 1 mmol) and 4-NO_2Im (282 mg, 2.5 mmol), and the solution refluxed for 4 h under N_2. The resulting brown solution was cooled to RT and diethylether (40 mL) added slowly to precipitate out a brown product, which was filtered off in air, washed with acetone and diethylether, and dried *in vacuo* at RT (0.45 g, 70% yield). *Anal.* calcd. for $C_{10}H_{18}O_6N_6S_2Br_2Ru$: C 18.67, H 2.82, N 13.06; found: C 18.43, H 2.71, N 12.78. λ_{max} nm (log ϵ), EtOH: 347 (4.17). Infrared (Nujol): ν_{SO} 1099, 1084, ν_{NO_2} 1552, 1539 cm^{-1}.

$RuBr_2(dmso)_2(NMe\text{-}4\text{-}NO_2Im)$, ***14***. Complex **3** (572 mg, 1 mmol) was dissolved in a methanol solution (15 mL) of NMe-4-NO_2Im (254 mg, 2 mmol) and the mixture refluxed for 4 h under N_2. The resulting blue solution was cooled to RT, when a blue precipitate formed. This was collected, washed with diethylether (20 mL), and dried *in vacuo* at RT (0.38 g, 70% yield). *Anal.* calcd. for $C_8H_{17}O_4N_3S_2Br_2Ru$: C 17.65, H 3.15, N 7.72; found: C 17.72, H 3.31, N 7.84. λ_{max} nm (log ϵ), H_2O: 306 (4.28), 440 (3.01). Infrared (Nujol): ν_{SO} 1092, 1073, ν_{NO_2} 1542, 1521 cm^{-1}.

Microanalyses were performed by Mr. P. Borda of the Department of Chemistry, U.B.C.

Physical techniques and methods

Equipment and procedures have been described in earlier papers (1–4, 12), except that a new X-ray source (Philips RT 250, 250 kV, 0.5 mm Cu) was used in the radiosensitization experiments. Briefly, assessment of radiosensitization and toxicity of compounds was carried out using Chinese hamster ovary cells in suspension, with hypoxia produced by nitrogen flow, and colony-forming ability at 7 days being the survival end-point. DNA-binding was indicated by inhibition of restriction endonuclease activity on plasmid pSV2-gpt DNA (12). Reduction potentials were determined by polarography. Partition coefficients (P) of the complexes and ligands were measured by equilibrating aqueous PBS solutions (0.01 *M* phosphate-buffered saline) of the appropriate compounds with *n*-octanol at 25°C, and determining the final concentrations of the species in the aqueous phase spectrophotometrically: P = (concentration in octanol)/(concentration in aqueous layer), where the concentration in octanol was obtained by difference (13). All solution studies were carried out under N_2.

TABLE 1. XPS data for Ru(II) compounds and free ligands[a]

Atom	Compound[b]	Group	BE[c]	FWHM[c]
N	**1** *Ru'*(4-NO_2Im)$_2$	—NO_2	405.5 (405.35)	2.5 (2.6)

[a]XPS binding energies and peak widths given in eV; estimated maximum error ±0.15 eV; FWHM is peak width at half-maximum.

[b]*Ru'* and *Ru''* represent $RuCl_2(tmso)_2$ and $RuBr_2(dmso)_2$, respectively.

[c]The number in parentheses is the BE/FWHM for the corresponding atom in the free ligand; BE values for atoms are given in ref. 15.

Results and discussion

The complexes made and their structural types will be first summarized, the spectroscopic data and assignments being considered in later sections.

Complexes **4–6**, $RuCl_2(dmso)_2L_2$ (L = 2-NO_2Im, miso, and De-miso), like the analogue **1** (L = 4-NO_2Im) reported on previously (1), are synthesized from *cis*-$RuCl_2(dmso)_4$[4] by a net substitution of *cis* disposed sulfoxide ligands (one O- and one S-bonded), and have a *cis,cis,cis*-geometry with two S-bonded dmso ligands, as evidenced by the XPS, ^{1}H nmr, and ir data. The $RuCl_2(tmso)_4$, **2**, is a new complex but, unlike *cis*-$RuCl_2(dmso)_4$ (14), contains no O-bonded sulfoxide and is probably of *trans* geometry. The complexes of formulation $RuCl_2(tmso)_2L_2$, **7–9** (L = 4-NO_2Im, NMe-4-NO_2Im, and De-miso), $RuCl_2(tmso)_2$(SR-2508) **10**, $RuCl_2(tmso)_3$(CMNI) **11**, and $RuCl_2$(tmso)(RSU-3159) **12**, are synthesized from **2** by substitution of one to three of the S-bonded tmso ligands. Complexes **7–12** contain only S-bonded sulfoxides but the geometric arrangements of the total ligand sets are in general uncertain. The *trans*-$RuBr_2(dmso)_4$ complex[4] containing only S-bonded sulfoxides (11) provides routes into $RuBr_2(dmso)_2$-(4-NO_2Im)$_2$ **13**, and $RuBr_2(dmso)_2$(NMe-4-NO_2Im) **14**, these containing S-bonded sulfoxides only; **13** is a purely *trans* structure, while **14** contains a chelated imidazole (via the imidazole nitrogen and oxygen of the NO_2 group), *cis* sulfoxides and *trans* bromide ligands.

X-ray photoelectron spectroscopic data

Application of XPS to these Ru/sulfoxide/imidazole type complexes was described earlier (1), and has proved to be invaluable in that we have been frustratingly unsuccessful in attempts to grow crystals of sufficient quality for X-ray analysis. The XPS data for the N, O, and S atoms within complexes **7**, **8**, **10–12**, **14**, and $RuCl_2(tmso)_4$, and for some of the free ligands, are summarized in Table 1. The N assignments have been discussed previously (1), and in **7** and **8**, as for the dmso analogue of **7** (1), the coordination shifts for N(3) (400.1 vs. 399.70, and 400.4 vs. 399.8 eV) appear smaller than expected, perhaps because of π-donation from the low-spin Ru(II) centre. Chelation via the oxygen of the nitrito group of NMe-4-NO_2Im in **14** is evidenced by the doublet seen for the O 1*s* of the NO_2 group (531.8 and 530.9 eV), as well as perhaps by the greater shift to higher BE of N(3) (0.8 eV) compared to the case for **7** (0.4 eV) and **8** (0.6 eV); corresponding chelation data were found for the chloro analogue $RuCl_2(dmso)_2$(NMe-4-NO_2Im) (1) but it is interesting to note that **8**, $RuCl_2(tmso)_2$-

[4]NOTE ADDED IN PROOF: A recent paper (28) has described the previously unknown isomers, *trans*-$RuCl_2(dmso)_4$ and *cis*-$RuBr_2(dmso)_4$.

$(NMe\text{-}4\text{-}NO_2Im)_2$, the tmso analogue, contains two monodentate nitroimidazole ligands, the single O 1*s* BE of the NO_2-group (531.9) being close to that of the free ligand (531.7 eV). Why the more sterically demanding tmso ligand (vs. dmso) allows for a higher coordination number is not immediately clear. The dmso complex is thought to contain *trans*-sulfoxides and *cis*-chlorides, while the arrangement of the ligands within **8** is unknown (see below): *cis*-sulfoxides, each *trans* to a nitroimidazole ligand, with *trans*-chlorides could perhaps accommodate sterically the six monodentate ligands. The N and O data for the NO_2 group within **10** rule out chelation for the SR-2508 ligand and, together with the ^1H nmr data (see below), show five-coordinate geometry for this complex.

The XPS data distinguish nicely between O- and S-bonded sulfoxides in these types of complexes (1), and the appropriate O 1*s* data for $RuCl_2(tmso)_4$, **2**, and $RuBr_2(dmso)_4$, **3**, reveal only one type of sulfoxide (shown by ^1H nmr, and crystallographic data for **3** (11) to be S-bonded). The corresponding O 1*s* and S $2p_{1/2,3/2}$ data for **7**, **8**, **10**–**12**, and **14** indicate only S-bonded sulfoxides in all these species. The S $2p_{1/2,3/2}$ BE for **10** is 0.4–0.5 eV less than the values for **2**, **7**, and **8**, indicating a weaker interaction between the Ru and the sulfur atoms in **10**, which is consistent with axial tmso ligands in a trigonal bipyramidal geometry.

The BE for the S $2p_{1/2,3/2}$ in the thioether sulfur of RSU-3159 (163.0 eV) is increased by 0.9 eV within $RuCl_2(tmso)$ (RSU-3159) **12**, strongly implying coordination via this sulfur. The less sterically demanding dmso ligand (vs. tmso) gives rise to a $RuCl_2(dmso)_2$ (RSU-3159) complex (1). The RSU-3159 ligand is considered to be chelated via the sulfur and the nitrogen of the NMe group (see below).

Infrared and nuclear magnetic resonance data

Bonding through the S of a sulfoxide increases the ν_{SO} with respect to the free ligand value, this being 1050 and 950 cm^{-1} for dmso and tmso, respectively (16–18). The ir data for all the new complexes **2** and **4**–**14** (see Experimental section) show bands consistent with S-bonded sulfoxides. Bands seen at 1075, 1035, 952, and 875 cm^{-1} for $RuCl_2(tmso)_4$ must be due to ν_{ring} (17, 18), because the XPS and ^1H nmr data show the presence of only S-bonded tmso. The 1080 cm^{-1} ν_{SO} band found for **3** agrees with that reported previously (11).

All the complexes have ir bands at about 1520–1560 and at 1500–1550 cm^{-1}, attributable to asymmetric and symmetric ν_{NO_2}, respectively (19), the values in general being up to 24 cm^{-1} lower than the free ligand values. The single exception is found in **11**, $RuCl_2(tmso)_3(CMNI)$, where the ν_{NO_2} values are 6 cm^{-1} *higher* than the values for CMNI itself; this is the only complex that contains three sulfoxide ligands, including the earlier series of 4-nitroimidazole derivatives (1), and implies some enhanced π-donation from the Ru(II) to the CMNI ligand. The coordination shifts for **14** are at the high end, entirely consistent with chelation of the $NMe\text{-}4\text{-}NO_2Im$ ligand, consistent with the XPS data.

The coordination shifts in ν_{NO_2} for **10** are small and are consistent with no coordination via NO_2, and thus five-coordinate geometry as indicated by the XPS (and nmr) data. The ν_{NO_2} values for the bromo complexes **13** and **14** are very similar to those of the chloro analogues synthesized earlier (1). As noted in the earlier work (1), we have been unable to assign metal–halide stretches in the far-ir region, because of the many bands seen in the 400–250 cm^{-1} region; also, the bromo derivatives **13** and **14** have different geometrical arrangements of ligands than the "corresponding" chloro analogues (see below), and this makes comparisons of the ir spectra difficult.

Coordination through the sulfur of an alkyl sulfoxide typically deshields the α-protons of the sulfoxide by ~1–2 ppm, while the deshielding is only ~0.1 ppm for coordination via the oxygen (16). Table 2 summarizes the relevant ^1H nmr data. The methyl resonances of dmso, and the methylene resonances of tmso, appear at values corresponding to S-bonded sulfoxide only for all the complexes, the data complementing well the XPS data. Complexes **4**–**6** and **13** and **14** show the dmso protons some 0.8–1.1 ppm downfield from the free dmso resonance at δ 2.60. In D_2O or non-dried $CDCl_3$, **5** and **6** dissociate nitroimidazole ligand(s) (see later) and more complex multiplets for the methyl resonances are evident, but no free dmso is observed. The data for **3**, known to be of *trans* geometry with four S-bonded dmso ligands in the solid state (11), agree with those reported in the literature (10, 11). The ^1H nmr spectrum of free tmso in $CDCl_3$ shows three sets of multiplets centred at δ 2.60 (S—C—CH_2CH_2), 2.19 (S—CH_2), and 1.75 (S—CH_2) ppm with an integration ratio of 2:1:1, respectively, in agreement with literature values (18). On coordination to Ru(II), the two S—CH_2 resonances are shifted downfield by ~1.7–2.0 ppm, while the S—C—CH_2CH_2 resonance(s) move the other way by up to 0.3 ppm. For **2**, the 1:1:2 multiplets centred at δ 4.00, 3,42, and 2.30 ppm imply equivalent tmso ligands, and thus a *trans* configuration for this complex.

The presence of four major, equal intensity, partly resolved Me multiplets for **4**–**6** reveals inequivalent Me groups for each of two inequivalent dmso ligands, and only the low symmetry, all *cis*-structure, of 6-coordinate complexes gives such an nmr pattern (20). The data correspond to those reported earlier for the $RuCl_2(dmso)_2L_2$ systems where L = a $4\text{-}NO_2Im$ derivative (1). The Me data for the dibromo complex **13** are markedly different, showing two quartets centred at δ 3.70 and 3.59 ppm which is interpreted as inequivalent methyls for each of two equivalent dmso ligands; this requires an all *trans* geometry and, of note, the precursor **3** has such geometry. By corresponding arguments, the chelated, 6-coordinate complex **14** must have *cis*, inequivalent sulfoxides and *trans* bromides, which contrasts with the chloro analogue which has *trans*-sulfoxides and *cis*-chlorides (1).

The ^1H nmr spectra for **7**–**12** show five sets of multiplets for the CH_2 resonances of tmso, centred at the δ values listed in Table 2, in each case with an integration ratio of 2:1:1:2:2 on going from lower to higher field. These relative intensities suggest that the two protons of one of the S—CH_2 groups of the coordinated tmso ligand are magnetically inequivalent. This perhaps results from the fixed orientation of the S=O when the tmso ligand is coordinated, so that one of the S—CH_2 protons will be in the same "plane" as the O—S—C atoms and the other one will be out of the "plane". If this explanation is correct, one would expect to observe a similar effect by the other S—CH_2 groups, giving rise to four sets of S—CH_2 and two sets of S—C—CH_2—CH_2 multiplets with an integration ratio of 1:1:1:1:2:2. However, this is not observed; perhaps the coupling between one set of S—CH_2 protons is smaller and the multiplet signal overlaps to give the observed 2:1:1:2:2 integration ratio. Complexes **7**–**12** all give similar —CH_2— nmr patterns, and yet **7**–**9** and **11** are 6-coordinate containing two or three tmso ligands, **12** is 5-coordinate containing one tmso ligand, and **10** is 5-coordinate containing two tmso ligands: we consider it unwise to speculate on the relative ligand arrangements. Complex **7**, based on some aqueous solution chemistry,

TABLE 2. Selected ^{1}H nmr spectral data for the Ru(II) compounds and the free imidazole ligands[a]

Compound[b]	^{1}H nmr spectra H-4[c]	H-5[c]	CH_3(dmso)	CH_2(tmso)
2 $RuCl_2(tmso)_4$				2.30, 3.42, 4.00

[a]δ in ppm with respect to TMS, in $CDCl_3$ at room temperature. In each case the integrations are consistent with the assignment. Resonances for the sulfoxide protons are multiplets, centred at the values shown; those for **13** are quartets; the imidazole protons appear as singlets.

[b]As in footnote *b* of Table 1, and *Ru* represents $RuCl_2$(dmso).

[c]Shifts in parentheses are for the free nitroimidazole ligand.

[d]Shifts for N—CH_2, CH_2—OCH_3, CH(OH), and —OCH_3 are at δ (ppm), 4.66 m, 4.42 m, 4.15 m, and 3.41 s, respectively, and are the same for the free miso ligand.

[e]Shifts for the N—CH_2, CH(OH), and CH_2OH are at δ (ppm) 4.39 m, 4.10 m, and 3.66 m ppm, respectively, and are the same for the free De-miso ligand.

[f]Shifts for the N—CH_2—C(O), —(O)CN(H)—CH_2 and CH_2OH are δ (ppm) 5.23 s, 3.66 t, and 3.39 t ppm, respectively, and are the same for the free SR-2508 ligand.

[g]Shifts for N—CH_3 δ (ppm): **8**, 3.91 (3.90)[c]; **11**, 3.56 (3.49)[c]; **12**, 3.62 (3.49)[c]; **14**, 3.95 (3.90).[c]

is, however, likely to be of the same all *cis* structure as the corresponding dmso analogue.

The relevant H-2, H-4, and H-5 resonances are, in every case except for **12**, slightly downfield compared with the free ligand values, similar to the situation in the 4-NO_2Im systems reported previously (1). With the chelated NMe-4-NO_2Im system, **14**, the effects are more marked, while the data for **10** (including footnote *f*) confirm no chelation by the SR-2508 ligand. In **12** there is an upfield shift for H-2, as well as a somewhat larger downfield shift (0.13 ppm) for the NMe protons; the data resemble those of the corresponding $RuCl_2$-$(dmso)_2$(RSU-3159) complex (1), and again are interpreted in terms of chelation via the S and nitrogen of NMe.

The $^{13}C(^1H)$ spectra for **13** and **14** are compatible with the corresponding ^{1}H nmr data: **13** has two ^{13}C shifts at δ 45.21 and 47.22 for the methyls of the two equivalent dmso ligands (as well as imidazole resonances at 112.35(C-2), 116.13(C-5), and 119.89(C-4)), while **14** has four peaks (δ 44.91, 45.16, 47.12, 47.58) for the inequivalent methyls (as well as imidazole resonances at 108.62(C-2), 112.39(C-5), 116.16(C-4), and 119.93(N-Me)). The small but significant differences in the imidazole carbon shifts for **13** and **14** compared to the chloro analogues (1) reflect (as do the ^{1}H nmr) differences in the geometrical isomers present (see above).

Aqueous solution chemistry

In water **4**, which contains the unsubstituted 2-NO_2Im ligand, does not dissociate a nitroimidazole, Cl^- or dmso, and the blue colour of the solution persists. When the substituted 2-nitroimidazole complexes **5** and **6** are dissolved in water, PBS, or water/PBS containing a 10-fold excess of Cl^- or dmso, the blue colour of the solutions disappears in about 5 min. The visible bands at 638 and 584 nm for complexes **5** and **6**, respectively, as observed in dry ethanol solution or in the solid state,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

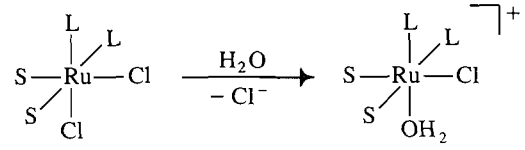
disappear. However, if the complexes are dissolved in water containing a 10-fold excess amount of the respective imidazole ligands, the colour of the solutions remains blue and the spectra are unchanged; the solutions are non-acidic and non-conducting and no Cl^- is liberated. These results together with the ^1H nmr data in D_2O indicate that the disappearance of the blue colour is due to the dissociation of the nitroimidazole ligand(s) and that the presence of the following aquation/anation equilibrium exists (L = miso, De-miso):

[1] $RuCl_2(dmso)_2L_2 + H_2O \rightarrow RuCl_2(dmso)_2(H_2O)_xL_y + xL$

Blue (**5**, **6**) Colourless ($x + y = 2$)

The different solution behaviour for **5** and **6** compared to **4** presumably reflects the hydrophilic nature of the hydroxy-containing substituents of the miso and De-miso systems which favours dissociation of the free ligands in the aqueous media. The aquation phenomenon (eq. [1]) is not observed for the tmso analogues **9** and **10**, and their aqueous solutions remain blue. Complexes **6** and **9** are analogous except for the sulfoxide ligands and the difference in aquation phenomenon may reflect the presence of different geometrical isomers (see above) or the more lipophilic tmso ligand in **9** (see below).

The aqueous solution behaviour of **7** follows closely that of the dmso analogue $RuCl_2(dmso)_2(4\text{-}NO_2Im)_2$ **1** (1): a molar conductivity of 108 $ohm^{-1}\,mol^{-1}\,cm^2$ results from loss of a chloride, and weak acidity results from a coordinated water ($pK_a = 4.40 \pm 0.10$, eq. [2]), while a second proton loss at higher pH ($pK_a = 9.01 \pm 0.10$) is attributed to loss of a pyrrolic-*N* hydrogen to form coordinated 4-nitroimidazolate.

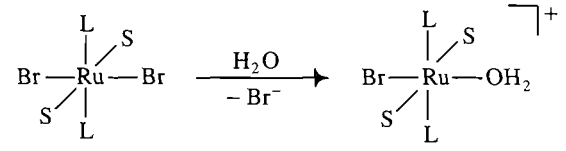


[2] $7 \xrightarrow[+H_2O]{-Cl^-} [RuCl(H_2O)(tmso)_2(4\text{-}NO_2Im)_2]^+$

$\xrightarrow{-H^+} RuCl(OH)(tmso)_2(4\text{-}NO_2Im)_2$

The pK_a values for the dmso analogue are 4.10 and 8.90 and the similarity in data suggests corresponding structures (all *cis*).

Aqueous solutions of **8**–**12** and **14** show no titratable protons are present at least up to pH 11 and, consistent with this, molar conductivity values measured within 10 min of dissolution are lower (18.0–30.0), showing little replacement of Cl^- by H_2O.



On dissolution in water **13**, $RuBr_2(dmso)_2(4\text{-}NO_2Im)_2$, instantly gives a molar conductivity of 118.7, corresponding to a 1:1 electrolyte formed by loss of a single Br^- (confirmed by $AgNO_3$ titration); however, the aquo derivative $[RuBr(H_2O)(dmso)_2(4\text{-}NO_2Im)_2]^+$, unlike the chloro analogues (e.g. [2] for both the tmso (**7**) and dmso (**1**) complexes) does not deprotonate at least up to pH 11. Thus this aquo(bromo) derivative has coordinated H_2O and imidazole ligands that are at least 10^7 and 10^2 times, respectively, less acidic than the corresponding ligands in $[RuCl(H_2O)(dmso)_2(4\text{-}NO_2Im)_2]^+$. The lower acidities are consistent with the presence of more basic bromide ligands, but a more important factor almost certainly arises because of the differences in the geometrical isomers present. The Cl^- loss from the all *cis* complex **1** (1) (and presumably **7**) is likely to be the one *trans* to the 4-NO_2Im (even though dmso has a strong *trans* effect (16)), because the other all *cis* $RuCl_2(dmso)_2L_2$ complexes with L = a substituted 4-NO_2Im (1) or a 2-NO_2Im (**4**–**6**) do not dissociate a Cl^-, i.e. the unsubstituted 4-NO_2Im is unique in labilizing the Cl^-:

[3] 

7, 15

(L = 4-NO_2Im, S = S-bonded tmso (**7**) or dmso (**1**))

For the all *trans* bromo complex **13**, bromide loss must occur according to eq. [4]:

[4] 

13

Now in terms of the pK_a values, for ligands *trans* to water, it has been argued that the higher the *trans* effect, the weaker the metal–oxygen bond and the stronger the oxygen–hydrogen bond, i.e. the weaker the acidity of the coordinated H_2O (21), this being based on data such as those for *cis*- and *trans*-$Pt(NH_3)_2(H_2O)_2^{2+}$ complexes (*cis*, $pK_a = 5.6$; *trans*, $pK_a = 4.3$). However, for the data: *trans*-$Pt(C_2H_4)(H_2O)Cl_2$ ($pK_a = 5$); *cis*-$Pt(NH_3)(H_2O)Cl_2$ ($pK_a \sim 7$), the correlation is clearly not valid because in terms of *trans* effects, $C_2H_4 \gg Cl^-$. Here, the strong π-acid properties of the C_2H_4 were invoked to account for stronger acidity of the water within the ethylene complex (21). The strong *trans* effect – weak acidity argument clearly does not hold for the aquo product of reaction [3] ($pK_a \sim 4$) vs. that of reaction [4] ($pK_a > 12$), because in the former the water is *trans* to 4-NO_2Im which is certain to have a stronger *trans* effect than Br^-. The stronger acidity could be rationalized in terms of the presence of the strong *trans* π-acceptor 4-NO_2Im.

Consistent with the aquation shown in eq. [4], the uv/vis spectrum of **13** in water is independent of pH (λ_{max} 342 nm, $\log \epsilon = 4.02$), this referring to the aquo species, while addition of Br^- regenerates **13** (λ_{max} 347 nm, $\log \epsilon = 4.13$). The uv/vis spectra of **7** and **15** (1) are both pH- and Cl^--dependent. All the new complexes show charge-transfer bands in the 310–500 nm region but they offer no insight into the coordination geometries.

Radiosensitization, toxicity, and related chemical properties

Table 3 lists reduction potentials, SER values, toxicity data, and partition coefficients (*P*) for the ligands, new complexes, and some of the $RuCl_2(dmso)_2L_n$ complexes (L = a 4-nitroimidazole, $n = 1$ or 2) described earlier (1). The techniques used have been given elsewhere (1–4, 12). Complexes **5** and **6** readily dissociate nitroimidazole ligand(s) (see above), but all the others listed are stable to nitroimidazole ligand loss within the 1 and 4 h periods used, respectively, for pre-incubation for the radiosensitizing experiments and for incubation during the toxicity experiments. The $E_{1/2}$, SER, and toxicity data refer to the aqueous solution species present, which is the same as the solid state formulations except for **5** and **6** (see eq. [1]), **7** and **1** (eqs. [2], [3]), and **13** (eq. [4]). The *P* values were measured at equilibrium conditions except for **5** and **6**, which were determined within 4 min of shaking the octanol/aqueous mixtures.

It is seen that the use of tmso, instead of dmso, increases the partition coefficient (lipophilicity) of the complexes. The neu-

13 *Ru"*(4-NO_2Im)$_2$	−645 (−685)	1.25 (1.2)	0.32 (0.058)	0.07 (0.24)
14 *Ru"*(NMe-4-NO_2Im)[f]	−515 (−535)	1.4 (1.2)	0.62 (0.49)	0.14 (0.16)

[a]Ligand and complex concentrations used for the SER values were 400 and 200 μ*M*, respectively, unless stated otherwise. First five entries include $E_{1/2}$ and SER data from refs. 1–3; numbers in parentheses in each column refer to the free nitroimidazole ligand.
[b]As in footnote *b* of Table 2.
[c]Reduction potential, mV vs. SCE.
[d]Toxicity measured by the plating efficiency (PE) after 4 h of incubation at 37°C under hypoxia; a higher PE means lower toxicity, and vice versa.
[e]P = partition coefficient (see text).
[f]The ligand concentrations used for comparative data were 200 μ*M* because the complex contains only one nitroimidazole ligand per Ru; 100 μ*M* was used for **12** and the RSU-3159 ligand.
[g]The concentration used for the complex and CMNI (one ligand per Ru) was 50 μ*M* because of their high toxicity.

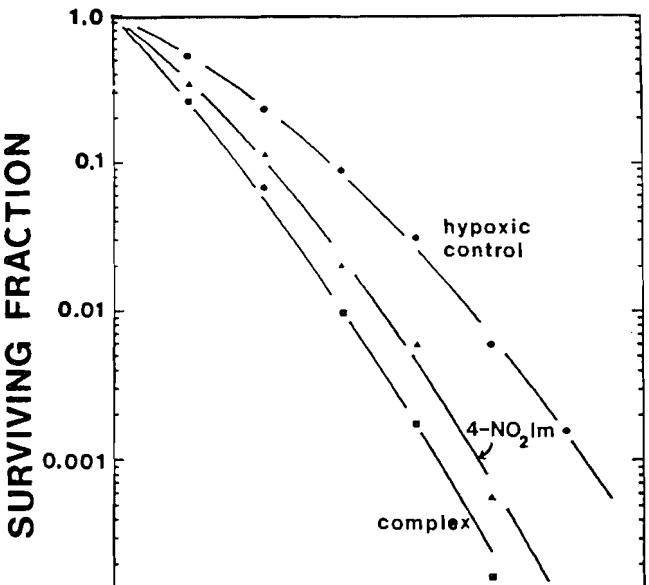

FIG. 2. Radiation response of hypoxic CHO cells treated with 200 μ*M* $RuCl_2(tmso)_2(4\text{-}NO_2Im)_2$, **7**, (■), and 400 μ*M* 4-NO_2Im (▲), compared with a control (●).

tral, aquation product $RuCl(OH)(tmso)_2(4\text{-}NO_2Im)_2$ from **7** has the highest P value (0.64) of all the complexes, while $RuCl(OH)(dmso)_2(4\text{-}NO_2Im)_2$ (from **1**) and **10** have P values (0.42 and 0.21, respectively) higher than the corresponding nitroimidazole ligands (P = 0.24 for 4-NO_2Im, and 0.05 for SR-2508). Moreover, it is noteworthy that **1**, **7**, and **10** have the highest SER values = 1.6, 1.6, and 1.5, respectively: these three complexes show the greatest improvement over the free ligand values (Table 3). The relevant data for **7** are shown in Fig. 2. No radiosensitizing enhancement was observed in hypoxic cells using dmso, tmso, $RuX_2(dmso)_4$ (X = Cl, Br), or $RuCl_2(tmso)_4$ at appropriate concentrations in control experiments, and there is no sensitization of oxic CHO cells to X-rays by any of the complexes or nitroimidazoles.

Coordinated nitroimidazole ligands have higher reduction potentials than the free ligands; that is, the ligand centres are more easily reduced when coordinated to metal, and this increase in reduction potential can be correlated with effectiveness of radiosensitizing ability within a given series of nitroimidazoles (1). The increased ligand reduction potential has been demonstrated for Pt(II) complexes (6, 22) and in our earlier Ru(II) work (1–3). This is again true for the new Ru(II) systems, and the change in potential on coordination of the unsubstituted 4-NO_2Im ligand (**1** and **7**) is significantly greater than for the other imidazole ligands. The absolute potential range does not appear critical in that **10**, an effective sensitizer, "operates" at a potential some 265 mV higher than **1** and **7**. The potential change for the bromide complex **13** (SER 1.25) is 30 mV less than for the chloride **1** (SER 1.6) and these data appear to fit the potential change: SER correlation, but there is certainly no such general correlation within the data of Table 3; indeed, it should be remembered that even within **13** and **7** the solution species present are in fact quite different (see eqs. [2]–[4]). Replacement of dmso by tmso increases the potential by 10–15 mV (**1** vs. **7**, **6** vs. **9**), while the comparable SER values are the same.

The hypoxic toxicity of the complexes toward CHO cells *in vitro*, measured as plating efficiency (PE) at a chosen time of drug treatment, is less than that of the corresponding free imidazole ligand (Table 3). The toxicity of some metal-free nitroheterocyclic compounds has been reported to increase with increasing electron affinity ($E_{1/2}$ value) (23, 24) but this is not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

seen for the nitroimidazoles or Ru(II) complexes that we have used. For 4-nitroimidazoles, the toxicity:electron affinity trend was attributed to depletion of thiols (24); certain radiosensitizers are thought to act by binding free, non-protein sulfhydryl groups (NPSH) which normally have a protective effect in irradiated cells (25). Of the complexes listed, only **5** and **6** under hypoxic conditions deplete non-protein thiol levels (26) but this is presumed to result from the presence of the dissociated miso and De-miso ligands; these ligands, 4-NO_2Im, and SR-2508 (out of all the 2-NO_2- and 4-NO_2Im derivatives used), were the only free ligands found to deplete thiols (26). The enhancement of radiosensitization properties of nitroimidazoles on coordination to Ru does not result from increased depletion of NPSH.

None of the new complexes binds to DNA, as evidenced by their inability to inhibit the activity of certain enzymes (26); complex **1** had been shown previously by such an assay to bind to DNA (2, 3), but clearly this is not an essential factor for effective radiosensitization properties as both **7** and **10** (the former showing aqueous solution behaviour essentially identical to that of **1**) are equally effective.

Factors that could affect radiosensitizing ability were summarized in an earlier paper (1), and many of these are alluded to in this section on biological activities. The new findings reinforce the view that much remains to be done and that, even when attachment of nitroimidazoles to Ru (and Pt(5)) has been documented to improve radiosensitizer properties of the nitroimidazole, the "fine-tuning" of the systems remains thus far a very empirical approach. The extremely diverse coordination chemistry exhibited by the Ru/halide/sulfoxide/nitroimidazole systems even within minor variations in ligand sets has surprised us.

Preliminary *in vivo* experiments suggest that complexes **7** and **10** may have radiosensitizing properties in mouse tumours (27); of note, **10** $RuCl_2(tmso)_2$(SR-2508), which contains only a single nitroimidazole ligand, has one of the highest SER values of 1.5 (see Table 3).

Vibrational spectral studies of solutions at elevated temperatures and pressures. 11. A Raman spectral study of aqueous iron(III) chloride solutions between 25 and 300°C

KATSUO MURATA,[1] DONALD E. IRISH,[2] AND GERALD E. TOOGOOD
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received August 31, 1988

KATSUO MURATA, DONALD E. IRISH, and GERALD E. TOOGOOD. Can. J. Chem. **67**, 517 (1989).

The Raman spectra of acidified aqueous iron(III) chloride solutions have been measured between 25 and 300°C. When Fe^{3+} concentrations are in the range 0.75 to 1.0 mol kg^{-1} and Cl^-/Fe^{3+} ratios, R, in the range 3 to 9.5, the dominant species at 25°C is *trans*-$[Fe(H_2O)_4Cl_2]^+$; at 300°C the sole iron-containing species is tetrahedral $FeCl_4^-$. Conversion of $[Fe(H_2O)_4Cl_2]^+$ into $FeCl_4^-$ appears not to involve intermediate iron species. In the presence of excess chloride the reaction $[Fe(H_2O)_4Cl_2]^+ + 2Cl^- \rightarrow FeCl_4^- + 4H_2O$ is presumed to occur; ΔH for this reaction has been estimated as $+65 \pm 8$ kJ mol^{-1}. In addition to increasing temperature, factors which favour $FeCl_4^-$ over other iron species include increasing acidity, increasing R, and decreasing dielectric constant.

Key words: high temperature aqueous solutions, iron(III) chloride, Raman spectroscopy.

KATSUO MURATA, DONALD E. IRISH et GERALD E. TOOGOOD. Can. J. Chem. **67**, 517 (1989).

Opérant à des températures allant de 25 à 300°C, on a mesuré les spectres Raman de solutions aqueuses acides de chlorure ferrique. A 25°C, à des concentrations de Fe^{3+} allant de 0,75 à 1,0 mol kg^{-1} et à des rapports de Cl^-/Fe^{3+} (R) allant de 3 à 9,5, l'espèce dominante est le $[Fe(H_2O)_4Cl_2]^+$-*trans*; à 300°C, la seule espèce contenant du fer est le $FeCl_4^-$ tétraédrique. La conversion du $[Fe(H_2O)_4Cl_2]^+$ en $FeCl_4^-$ ne semble pas impliquer d'espèces intermédiaires contenant du fer. En présence d'un excès d'ions chlorures, on suppose que le réaction $[Fe(H_2O)_4Cl_2]^+ + 2Cl^- \rightarrow FeCl_4^- + 4H_2O$; on a évalué que le ΔH de cette réaction est égal à $+65 \pm 8$ kJ mol^{-1}. En plus de l'augmentation de la température, les facteurs qui favorisent la formation du $FeCl_4^-$ par rapport aux autres espèces du fer sont les augmentations de l'acidité et de R et une diminution de la constante diélectrique.

Mots clés : solutions aqueuses à des températures élevées, chlorure ferrique, spectroscopie de Raman.

[Traduit par la revue]

Introduction

The nature and relative importance of species existing in aqueous solutions of ferric chloride have been studied by numerous investigators over many years using a variety of experimental techniques. Most of the work has involved studies at or close to room temperature, with the notable exception of some recent glassy state (−196°C) Raman work (1). Higher temperature investigations have been limited to the hydrated melt of $FeCl_3 \cdot 6H_2O$ (2, 3), at approximately 35–40°C, and to some aqueous solutions at 50°C (4). Because of the general interest in high temperature aqueous systems involving geochemically important elements, hydrometallurgy, corrosion of high temperature reactors, etc. (5), we have utilized Raman spectroscopic methods to study several such systems up to 300°C, with applied pressures up to 9 MPa to maintain the liquid phase (6, 7). We report here the results of a variable temperature investigation of several aqueous ferric chloride systems, between 25 and 300°C.

Although earlier workers have used Raman spectroscopy to study similar systems at room temperature (4, 8, 9) there is still disagreement concerning the interpretation of their results. Indeed such disagreements are not confined to Raman investigations. For example, various X-ray studies arrive at conflicting conclusions as to the major species present. A succinct summary of the major work through 1984 has appeared recently (10), and readers are referred to this paper for a discussion of the earlier work and possible reasons for the disagreements cited. It is clear that the nature of the species present, and their relative populations, stability constants, etc., are influenced to some degree by such variables as the concentration of $FeCl_3$, the Cl^-/Fe^{3+} ratio R, the pH, and the presence of other ions.

One particularly insidious problem is that of Fe(III) hydrolysis, a subject recently reviewed by Flynn (11). The slow formation, aging and agglomeration of hydrolytic polymers is one reason for some of the conflicting reports in the literature (12, 13). Signals due to hydrolysis products of general formula $[Fe(H_2O)_{6-n}(OH)_n]^{(3-n)+}$ occur in the Raman spectrum, as shown in Fig. 1, in the region 300–450 cm^{-1}. They clearly decrease in intensity with decreasing pH and are effectively absent in the most acidic solutions. For this reason, our variable temperature studies have been conducted in acid solutions which are sufficiently concentrated (5 *m* HCl or 5 *m* $HClO_4$) that hydrolysis is not observed.

Each of the systems we have studied over the 25–300°C temperature range had a fixed molality of iron (from $FeCl_3 \cdot 6H_2O$), acid (HCl or $HClO_4$), and of the internal Raman standard ($NaClO_4$ or $HClO_4$). Details are given in Table 1. We have used molalities because they are temperature-independent concentration units.

In separate studies, not reported in detail here, we have obtained the Raman spectra of numerous aqueous ferric solutions, at 25°C only, to provide background information for our high temperature work and to see whether advances in equipment (increased sensitivity) and data handling (more secure baseline subtractions and band fitting), coupled with the availability of recent XAFS and XANES results on species populations, enable a more definitive interpretation of such spectra than was possible in earlier studies (4, 8, 9). It is fair to say that, despite these advantages, we are not able to significantly improve on the quality of the spectra of Marsten and Bush (8), nor to offer major new definitive interpretations of the weaker signals in what are often very complicated spectra. As alluded

to in the preamble to the Results and discussion section, the problems of severe band overlapping and absence of standard spectra for many of the ferric species likely to be present are not easily overcome.

We will refer, where necessary, to these separate room temperature studies and comment upon those aspects of earlier Raman room temperature solution studies which can be corrected in the light of the recent X-ray and glassy state Raman work.

Experimental

Raman spectra were obtained using a digitally driven Jarrell-Ash 25-100 Spectrometer (1 m double Czerny-Turner monochromator), with an RCA 31034 photomultiplier and SSR model 1105/1120 photon counting system. Spectra were excited with the 647.1 nm line of a Coherent model 52 laser with a CR-500K krypton tube operating at 400 mW. Depolarization ratios were measured with a polaroid analyzer followed by an optical scrambler. Instrument control and data collection were performed with a Commodore Computer 2001 interfaced to the Spectrometer and to an HP 7470A plotter.

Resolution of overlapping lines was achieved with a BNDFT (Bandfit) program operating on an IBM 4341 computer (14). Raman spectra were recorded with a 3 cm^{-1} spectral slit width. The high temperature results were obtained using a furnace assembly described previously (15). Briefly, the apparatus provides controlled electrical heating of an insulated silver metal block within which the capillary Pyrex cell containing the sample is located. An applied pressure of 9 MPa was used to maintain the liquid phase. For room temperature runs samples were sealed in thin-walled capillary tubes held in a thermostatted copper block.

All solutions were prepared with Analar-Grade reagents. Iron(III) solutions were prepared from $FeCl_3 \cdot 6H_2O$ (BDH Chemicals) and $Fe(ClO_4)_3 \cdot xH_2O$ (Alfa Products) and standardized using gravimetric analysis (16). The water content of the Alfa compound was found to correspond to a formula $Fe(ClO_4)_3 \cdot 8H_2O$ — based on iron (16) and perchlorate (17) analyses. Acidity was controlled with HCl and $HClO_4$ (both Baker Analyzed Reagents) and measured by titration.

Results and discussion

Preamble

Notwithstanding the disagreements mentioned in the Introduction it seems clear that ferric chloride aqueous systems in which hydrolysis is prevented (i.e., low pH solutions) may contain one or more of the following species: $[Fe(H_2O)_6]^{3+}$ **[0]**,[3] $[Fe(H_2O)_5Cl]^{2+}$ **[I]**, $[Fe(H_2O)_4Cl_2]^+$ **[II]**, $[Fe(H_2O)_3Cl_3]$ **[III]**, and $[FeCl_4]^-$ **[IV]** — and it is probable that **III** and **I** are always minor contributors (1, 10, 18). Species with more than four chlorides per iron are not present in solution (though $[Fe(H_2O)Cl_5]^{2-}$ ions are known in some solids and their Raman spectra have been obtained (19, 20)), nor are polymeric species, despite earlier claims (4). It is possible for both **II** and **III** to have geometrical isomers and indeed both *cis* and *trans* forms of **II** have been identified by Mössbauer spectroscopy of *solids* (21). However, recent XANES work suggests only centrosymmetric species, apart from $FeCl_4^-$, as major iron-containing ingredients of aqueous ferric chloride solutions (10) so *cis* **II** and both *fac* and *mer* **III** are apparently unimportant, as are trigonal bipyramidal species such as $[Fe(H_2O)_2Cl_3]$ which have also been postulated earlier (8). However, stability constants have been calculated for each of the complexes (**I**–**IV**) (22, 23).

The Raman spectra of the limiting species **0** and **IV** have been unambiguously assigned, and the presence of either may be inferred by the appearance of bands at 510 cm^{-1} ($\nu_1(a_{1g})$ $[Fe(H_2O)_6]^{3+}$ polarized, broad, diffuse, Fig. 2) or 332 cm^{-1} ($\nu_1(a_1)$ $FeCl_4^-$ polarized, sharp, strong, Fig. 3). However, when these species occur in low concentrations relative to other iron-containing complexes such as **II**, their signals may be obscured by Fe—OH_2 or Fe—Cl stretches of the other species. Because the intermediate species, **I**, **II**, **III**, do not occur *alone* in solution, their spectra are not easily characterized. For example, in

[3]The symbols **0**, **I**, **II**, **III** and **IV** refer to the number of chloride ligands attached to the iron of the species listed.

Fig. 9*a*, which shows the effect of changing *R* (*vide infra*), for low *R* values the spectra clearly show the conversion of the hexaaquairon species (loss of 510 cm^{-1} shoulder) into a species characterized (for $R = 0.75$) by the ~316 cm^{-1} signal, via some intermediate(s) responsible for the asymmetry in the band envelope between 250–350 cm^{-1}, for $R = 0.16$ and 0.33. BNDFT analysis of these two spectra does not enable us to clearly identify the number and nature of the intermediate(s), although logically a sequence **0** → **I** → **II** is indicated (*vide infra*). It is true that *trans* **II** is a fairly common cation in $FeCl_3 \cdot nH_2O$ *solids* — and has been identified as such both by X-ray (24), and Mössbauer (21) investigations — and its Raman spectrum has been obtained (19). But the solution situation is different, even in the glassy state (−196°C), in respect of band positions (1) so it may not be possible to unambiguously assign all the signals due to **II** in any solution at room temperature.

We believe — on the basis of our study of the melted form of $FeCl_3 \cdot 6H_2O$, and by correlation with the recent XAFS and XANES work (2, 10) and glassy state Raman studies (1) — that we can assign the *strongest* signal of **II** in aqueous solution. It occurs at ~316 cm^{-1}. This is due to Fe—Cl stretches (ν_1, a_{1g}) of *trans*-$[Fe(H_2O)_4Cl_2]^+$. The position of other modes — stretches and deformations — may be speculated on (1, 4, 25) but such speculation is not useful here. Considering the apparent unimportance of **I** and **III** in most aqueous solutions, relative to some or all of the others, it is not surprising that spectroscopic evidence for them is uncertain. Due to band overlap, and weakness of signals from species present in small relative amounts, if it is not possible to unambiguously discern all possible Fe—OH_2 and Fe—Cl modes of **II**, this is doubly true for **I** and **III**. Bearing these facts in mind, we can discuss our results as follows.

Variable temperature results

It is clear from the spectra of each of the solutions A to E that at room temperature the dominant species is in all cases *trans*-$[Fe(H_2O)_4Cl_2]^+$, **II**, with its ~316 cm^{-1} band of much greater intensity than other signals. A typical baseline-corrected and resolved spectrum is shown in Fig. 4 in which the other major signal is that of the internal standard, ClO_4^-, at 462 cm^{-1} (ν_2).

The additional bands in the example, at approximately 420 cm^{-1} and in the 100–250 cm^{-1} region, are due to Fe—OH_2 stretches of **II** and to deformations of **II**, respectively. The exact band envelope and resolution of the low frequency region is uncertain to some extent because this is a very weak signal on the edge of the exciting line. It is not possible to draw firm

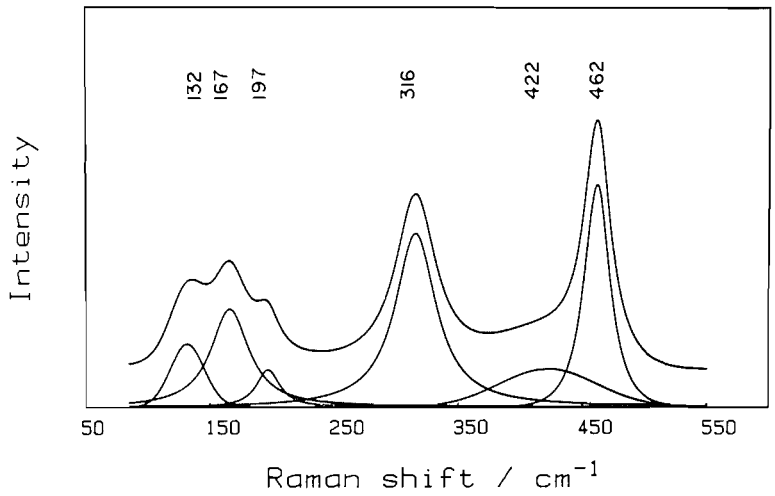

FIG. 4. Raman spectrum of 1.0 *m* $FeCl_3$ in 5 *m* $HClO_4$, solution A, at 25°C.

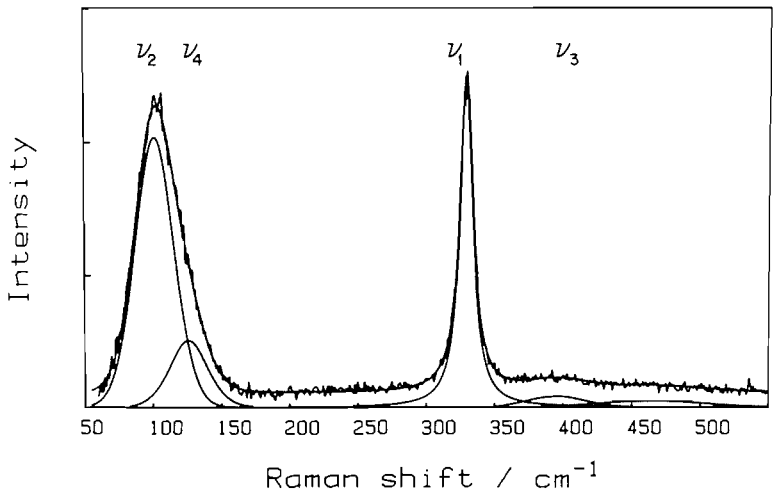

FIG. 5. The baseline-corrected and BNDFT-analyzed Raman spectrum of 1.0 *m* $FeCl_3$, 5 *m* HCl, 1 *m* $NaClO_4$, solution E, at 300°C and 9 MPa.

conclusions about all the components of the envelope. The ~167 cm^{-1} peak is a common feature whenever the ~316 cm^{-1} band is dominant.

For each of the systems studied the 300°C spectrum shows the characteristic four-line pattern $\nu_1(a_1)$ 332 cm^{-1}; $\nu_2(e)$ 107 cm^{-1}; $\nu_3(f_2)$ 395 cm^{-1}; $\nu_4(f_2)$ 132 cm^{-1} of tetrahedral $FeCl_4^-$ (26), which appears as the sole iron-containing species at that temperature. Figure 5 is a typical spectrum of this kind.

Spectra at intermediate temperatures in all cases contain either or both of **II** or **IV**, with no evidence for intervening species (Fig. 6). The threshold temperature at which the 332 cm^{-1} signal of **IV** becomes apparent varies depending on the composition of the solution.

From the variable temperature study of solutions A–E, and from the other room temperature studies, it is apparent that at least the following, in addition to higher temperatures, can affect the proportions of **IV** relative to other species. (*1*) Acidity: increasing acidity favours $FeCl_4^-$. In concentrated $HClO_4$, for example, essentially only **IV** exists, and a study at different molalities of $HClO_4$ (Fig. 7) shows the conversion from **II** to **IV** with increasing acid, at constant iron concentration, constant Cl^-/Fe^{3+}, *R*, and constant temperature. (*2*) *R* values: increasing *R* favours $FeCl_4^-$. Thus comparing the solution A and E results at, say, 100°C (Fig. 8) we see a larger contribution from **IV** in E ($R = 8$) than in A ($R = 3$), other things being equal. The combined affects of higher acidity and higher *R* are shown in Figs. 9*a* and 9*b* which include the spectra of solutions containing a constant iron concentration (0.67 *m* $Fe(ClO_4)_3$) and variable molalities of hydrochloric acid which provide *R* values ranging from 0.16 to 24. (*3*) Dielectric constant: it appears that lower solvent dielectric constants favour $FeCl_4^-$. As seen in Fig. 10, which shows spectra of $FeCl_3$ in various CH_3OH/H_2O ratio solutions, the proportion of **IV** is greater in the solution with the largest amount of alcohol. It should be noted that, even in this solution, water is present in large excess, relative to iron, so that it is not only the poor coordinating properties of methanol which contribute to this affect. The lower dielectric constant of water at elevated temperatures — at 200°C it is about the same as that of methanol at 25°C — may contribute to the increased proportion of **IV** with increasing temperature.

The increase in the proportion of $FeCl_4^-$ with temperature is analogous to that observed for $CoCl_4^{2-}$ (27) but is the reverse of the situation for $ZnBr_4^{2-}$ and $CdBr_4^{2-}$, where these species

are favored at low temperatures and their water-substituted complexes increase in importance with rising temperature (6, 7). Neither charge nor ligand field (LF) effects can be held solely responsible for these trends since Fe(III) (d^5 high spin), Zn(II), and Cd(II) (d^{10}) have zero LF stabilization energies in the geometries concerned, and the charge factors are the same for Co(II), Zn(II), and Cd(II).

The conversion of $[Fe(H_2O)_4Cl_2]^+$ into $FeCl_4^-$ in the solutions containing HCl (B–E) presumably occurs according to the equation:

[1] $[Fe(H_2O)_4Cl_2]^+ + 2Cl^- \rightarrow FeCl_4^- + 4H_2O$

since no evidence for other iron species (**0**, **I**, or **III**) is found. Solution A, on the other hand, has no extra chloride so such an equation cannot apply and a reaction such as:

[2] $2[Fe(H_2O)_4Cl_2]^+ \rightarrow FeCl_4^- + [Fe(H_2O)_6]^{3+} + 2H_2O$

must be occurring. However, there is no evidence for the hexaaquairon(III) cation (no 510 cm^{-1}, ν_1 signal). If it is present it should be 0.5 *m* in concentration according to [2] and ought to be weakly observable.

A feature of the $FeCl_4^-$ spectrum at elevated temperatures is the unexpectedly large intensity of the low frequency 102 cm^{-1} band, Fig. 5. The intensity of a deformation mode is normally much less than that of a stretching mode and is not expected to grow with a temperature increase. Possibly this phenomenon can be ascribed to a preferential hot band.

Another feature of considerable interest is the absence of intensity from the $\nu_2(e)$, 462 cm^{-1}, and $\nu_4(f_2)$, 625 cm^{-1} lines of ClO_4^-. In previous studies we have found that $HClO_4$ is stable to well above 150°C even for a composition as high as

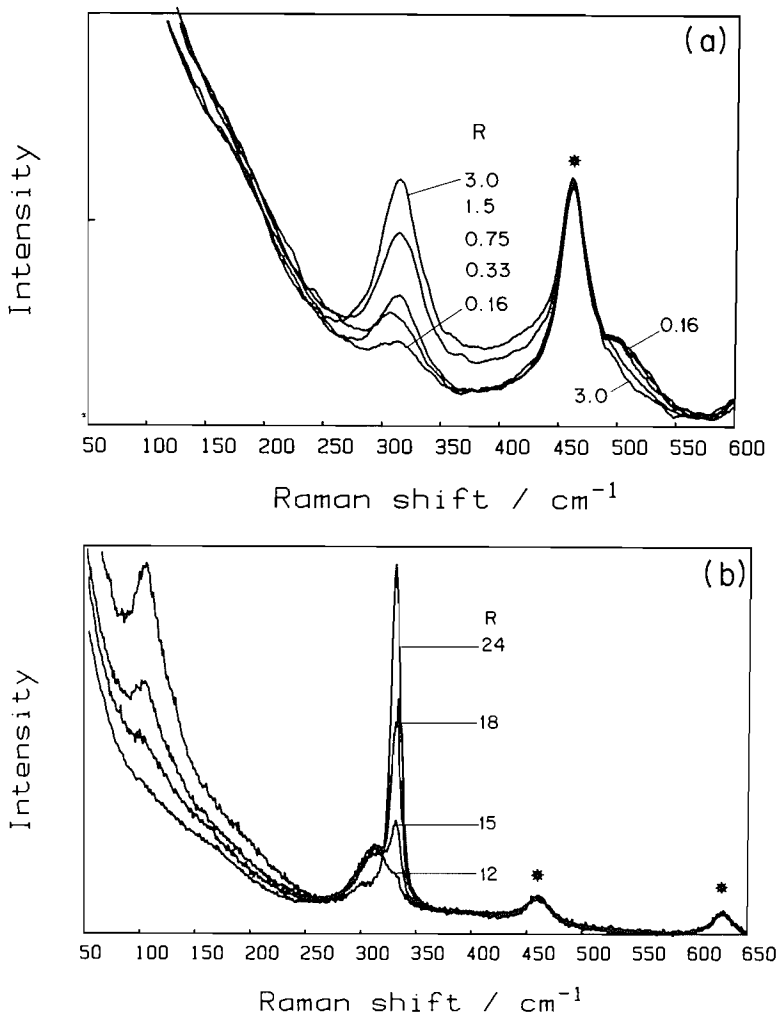

FIG. 9. (*a*) Raman spectra of 0.67 *m* $Fe(ClO_4)_3$ at 25°C with increasing *R*. At 315 cm^{-1} from bottom to top the *R* values are 0.16, 0.33, 0.75, 1.5, and 3.0. At 510 cm^{-1} the *R* values are reversed. Bands of ClO_4^- are indicated with a star. (*b*) Raman spectra of 0.67 *m* $Fe(ClO_4)_3$ at 25°C with increasing *R*. At 315 cm^{-1} from bottom to top the *R* values are 12, 15, 18, and 24. Bands of ClO_4^- are indicated with a star.

71 wt.% acid (28). In the presence of NH_4HSO_4 or Na_2SO_4 no decomposition was detected (29). However, the autocatalytic reaction

[3] $4H^+ + 4ClO_4^- \rightarrow 2H_2O + 2Cl_2 + 7O_2$

proceeds at measurable rates for 1.1–6.6 *m* $HClO_4$ in the range 295–332°C (30). Thus we did not anticipate that at the low concentrations used as an intensity standard ClO_4^- would be unstable. The evidence suggests otherwise.

In a separate experiment a sample with the composition 1.5 *m* $FeCl_3$, 5 *m* HCl, and 2 *m* $HClO_4$ was raised to 200°C and spectra were recorded at 200, 250, 300, 150, 100, and 75°C. At 300°C the 542 cm^{-1} band of aquated Cl_2 was detected; at 75°C it was much more intense and bubbles of gas were detected (cf. ref. 28). The 935 cm^{-1} band of ClO_4^- could still be seen. In another experiment with a sample of composition 1.5 *m* $FeCl_3$, 10 *m* HCl, and 5.0 *m* $HClO_4$ the temperature was raised and spectra were recorded at 100, 200, 250, and 100°C and the 935 cm^{-1} band of ClO_4^- was measured as a standard (twice at each temperature). The values for the integrated intensities were 1:0.73:0.64:1.02. Thus, although there was an apparent loss of intensity with increasing temperature, the intensity was reversibly recovered. The loss might be attributable to a change in refractive index (i.e., an optical effect) and not to a chemical decomposition in this case. However, we conclude from these and other experiments that the decomposition of ClO_4^-, as given by reaction [3], is apparently catalyzed in solutions containing iron(III).[4] Because of this decomposition, we have restricted a quantitative analysis based on relative integrated intensities to the temperature range 50 to 150°C.

We have obtained an approximate value for the apparent enthalpy change, ΔH, for reaction [1] from the observed population change with temperature. The strategy was to obtain a value for the molal scattering coefficient, J_{332}, of the 332 cm^{-1} band of $FeCl_4^-$ at 150°C, at which the conversion to $FeCl_4^-$ is essentially complete. This value was used to convert the intensities of the 332 cm^{-1} band to concentrations at temperatures of 50, 75, and 100°C:

[4] $m_{FeCl_4^-} = I^R_{332}/J_{332}$

The concentrations of other species were then obtained from the material balance expressions:

[4]It has been brought to our attention by a referee that Fe(III)-catalyzed decomposition of $HClO_4$ at 200°C has been reported previously (31).

ΔH based on Q_m eq. [9]	63 ± 6 kJ mol^{-1}, $r = 0.9827$					

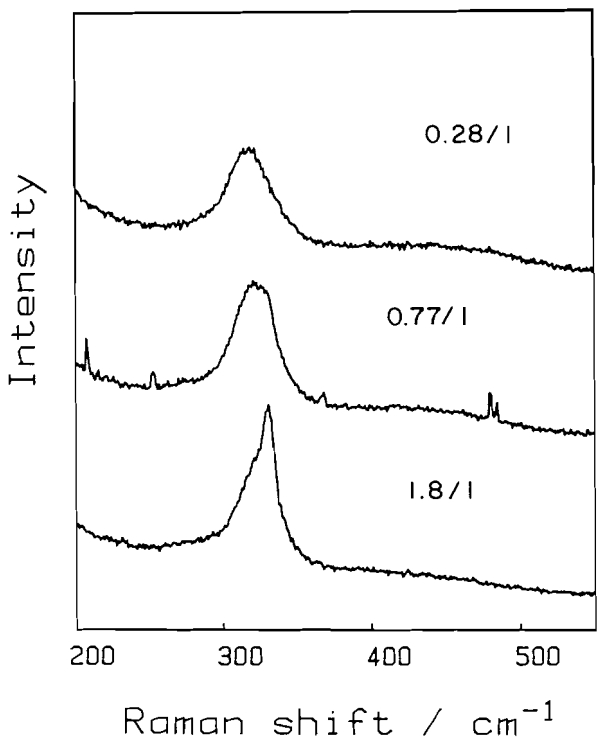

FIG. 10. Raman spectra in methanol/water mixtures with increasing CH_3OH/H_2O ratio. From top to bottom 0.28:1, 0.77:1, 1.8:1 mole ratios.

[5] $m_{[Fe(H_2O)_4Cl_2]^+} = m_{Fe(total)} - m_{FeCl_4^-}$

[6] $m_{Cl^-} = m_{Cl^-(total)} - 4m_{FeCl_4^-} - 2m_{[Fe(H_2O)_4Cl_2]^+}$

[7] $m_{H_2O} = 55.55 - 4m_{[Fe(H_2O)_4Cl_2]^+}$

The latter neglects hydration of chloride ion. From these equations it is possible to calculate the concentration quotient for process [1]:

[8] $$Q_m = \frac{m_{FeCl_4^-}(m_{H_2O})^4}{m_{[Fe(H_2O)_4Cl_2]^+}(m_{Cl^-})^2}$$

or, if one incorporates the water into the equilibrium quotient,

[9] $$Q_m = \frac{m_{FeCl_4^-}}{m_{[Fe(H_2O)_4Cl_2]^+}(m_{Cl^-})^2}$$

For the two solutions B, C (Table 1), at 150°C, the relative integrated intensities of the 332 cm^{-1} band were measured:

$$I^R_{332} = \frac{\text{Area of } 332 \text{ cm}^{-1} \text{ band}}{\text{Area of } 935 \text{ cm}^{-1} \text{ band}} m_{ClO_4^-}$$

The mean value of J_{332} was found to be 4.84 ± 0.13. Based on the insensitivity of J values of SO_4^{2-} and HSO_4^- to temperature over a greater range (29) this value was applied in eq. [4] for temperatures of 50, 75, and 100°C. The data are collected in Table 2.

ΔH was estimated from a fit to the van't Hoff equation

$$\left(\frac{\partial \ln K}{\partial T}\right)_p = \frac{\Delta H^0}{RT^2}$$

Activity coefficients are unknown and hence a rigorous treatment to obtain ΔH^0 from the temperature dependence of K is not possible. However, it has previously been shown that the slope obtained from a plot of $\ln Q_m$ versus T is almost parallel to the slope of $\ln K$ versus T for the HSO_4^-/SO_4^{2-} case (29). Thus we anticipate that an "apparent ΔH" value, within 30% of ΔH^0, is obtainable. The values of ΔH for the two compositions are collected in Table 2. A mean value of $+65 \pm 8$ kJ mol^{-1} is consistent with the data. For comparison ΔH for the analogous reaction of Co(II) has been reported as $+62$ kJ mol^{-1} by Fabes and Swaddle (27); and that for the reaction $[Fe(H_2O)_6]^{3+} + Cl^- \rightarrow [Fe(H_2O)_5Cl]^{2+} + H_2O$ as $+36$ kJ mol^{-1} (23).

Conclusions

When Fe^{3+} concentrations are in the range 0.75 to 1.0 mol kg^{-1}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

and R values in the range 3 to 9.5, tetrahedral $FeCl_4^-$ is the dominant iron-containing complex in acidified aqueous solutions of "ferric chloride" above ≈200°C; at 300°C it is the sole chloroiron species. Octahedral *trans*-$[Fe(H_2O)_4Cl_2]^+$ is the major and only unambiguously identifiable complex in such solutions at room temperature. As the temperature is raised the octahedral complex is converted into the tetrahedral tetrachloroferrate(III) ion, apparently without the production of any other iron complexes. In the presence of excess chloride this conversion presumably occurs via the reaction [1] for which an approximate ΔH is calculated to be $+65 \pm 8$ kJ mol^{-1}.

The decomposition of the internal intensity standard, perchlorate, at elevated temperatures, especially in the presence of ions such as Fe(III) which apparently catalyze the reduction to Cl_2, presents a problem for Raman spectroscopists. This has been overcome to some extent by the use of trifluoromethanesulfonic acid (HTFMS), which has the additional advantage of being non-complexing (6, 7). Although ClO_4^- has usually been considered as not complexing with metal cations, especially in the presence of much stronger ligands such as Cl^-, several authors have reported that equilibrium constants change dramatically with changing perchlorate concentration in some cases (8, 32). However, HTFMS is also susceptible to metal ion catalyzed decomposition (31) at elevated temperatures so its suitability in a particular experiment must be considered carefully.

A carbon-13 CP/MAS nuclear magnetic resonance study of several 1,4-disubstituted benzenes in the solid state

GLENN H. PENNER AND RODERICK E. WASYLISHEN[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 10, 1988

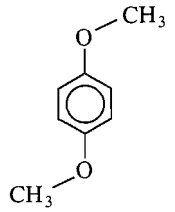
GLENN H. PENNER and RODERICK E. WASYLISHEN. Can. J. Chem. **67**, 525 (1989).

The carbon-13 chemical shifts of several 1,4-disubstituted benzenes in the solid state are reported. At least one of the substituents is unsymmetrical and in most cases this leads to different ^{13}C chemical shifts of C-2 and C-6 and in some cases to different shifts for C-3 and C-5. The ^{13}C chemical shifts observed in the solid state are compared with those measured in solution and, where possible, with those obtained in low temperature solution studies where internal rotation of the unsymmetrical substituent is slow on the ^{13}C chemical shift time scale. Agreement between the chemical shifts observed in the solid state and solution is excellent. The potential application of CP/MAS nuclear magnetic resonance in deducing the conformation of benzene derivatives with two unsymmetrical substituents is discussed.

Key words: carbon-13 CP/MAS NMR, ^{13}C NMR chemical shifts, substituent effects.

GLENN H. PENNER et RODERICK E. WASYLISHEN. Can. J. Chem. **67**, 525 (1989).

On a déterminé les déplacements chimiques du ^{13}C, à l'état solide, de plusieurs benzènes disubstitués en positions 1,4. Au moins un des substituants n'est pas symétrique et, dans la plupart des cas, ceci conduit à des déplacements chimiques du ^{13}C qui sont différents pour les carbones 2 et 6 et, dans quelques cas, à des déplacements chimiques différents pour les carbones 3 et 5. On a comparé les déplacements chimiques du ^{13}C qui ont été obtenus à l'état solide avec ceux qui ont été mesurés en solution et, lorsque cela s'est avéré possible, avec ceux obtenus au cours d'études en solution, à basse température, alors que la rotation interne du substituant qui n'est pas symétrique est lent par rapport à l'échelle de temps des déplacements chimiques du ^{13}C. L'accord entre les déplacements chimiques observés à l'état solide et en solution est excellent. On discute des possibilités d'utilisation de la résonance magnétique nucléaire CP/MAS pour déduire la conformation de dérivés du benzène portant deux substituants qui ne sont pas symétriques.



Mots clés : RMN CP/MAS du ^{13}C, déplacements chimiques du ^{13}C, effets des substituants.

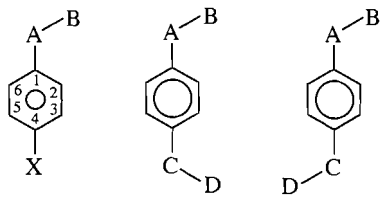
Introduction

It has been a decade since the first combined use of high-power proton decoupling, magic angle spinning (MAS), and cross-polarization (CP) in obtaining high resolution solid state nmr spectra (1). The application of these techniques has since become routine. Although these methods are said to produce "liquid-like" spectra, an important difference between liquid and CP/MAS solid state nmr spectra is that dynamic averaging due to internal rotation or inversion is often absent in the solid. There have been several examples of such "freezing" of internal rotation (2–14). A frequently cited example is 1,4-dimethoxybenzene (2, 3, 6, 15). In solution the four hydrogen-bearing ring carbon nuclei yield a single ^{13}C resonance due to rapid internal rotation of the methoxy substituents. The two possible "planar" structures in the solid state are **1***a* and **1***b*; X-ray crystallographic studies indicate that solid 1,4-dimethoxybenzene exists as **1***a* (16). The protonated ring carbons will experience two types of chemical environments and this is reflected in the ^{13}C CP/MAS spectrum, which indicates a shift difference between C-2 and C-6 (or C-5 and C-3) of 5.5 ppm.

1*a*



1*b*

Hays has warned that care should be taken in attributing observed shifts and splitting for a given carbon to changes in conformation, particularly if the X-ray structure is not available (14). Molecular packing may affect isotropic chemical shifts and splittings may also be due to the existence of non-congruent molecules in the unit cell. In recent years considerable experience has been gained in the analysis of high resolution solid state ^{13}C nmr spectra and, if appropriate caution is exercised, information about the molecular and crystal structure of moderately complex crystalline organic solids may be gleaned from the spectra.

Internal rotation in benzene derivatives has been extensively studied in solution. The dependence of both long-range spin–spin coupling (17) and chemical shifts (18) on the rotation of the side chain with respect to the ring is fairly well understood. The internal rotation of several unsymmetrical substituents attached to the benzene ring has been studied in solution by variable temperature dynamic nmr techniques (19). In the present study we examine the ^{13}C CP/MAS solid state spectra of several 1,4-disubstituted benzenes where one or both of the substituents are unsymmetrical (Fig. 1). The chemical shifts measured in the solid state are compared with those measured in solution at room temperature and, in some cases, at temperatures well below the coalescence temperature where internal rotation of an unsymmetrical substituent is slow. Diffraction data are available for some of the derivatives investigated and in such cases the chemical shifts are discussed in light of the known solid state structures. For molecules where the solid state structure is unavailable some effort is made to deduce the conformation of the side chain(s) from the ^{13}C chemical shifts observed in the solid state. The overall objective of this study is to report effects of unsymmetrical substituents on benzene ring carbon-13 chemical shifts and evaluate the utility of high resolution solid state nmr in deducing the conformation of 1,4-substituted benzenes in the solid state.

a *b* *c*

FIG. 1. The general structures of 1,4-disubstituted benzenes studied. C-2 is taken to be *cis* to the A—B bond. The A, B, C, and D moieties may represent more than one atom; for example, in acetophenones B is the carbonyl oxygen and A is the C-CH_3 group. The X moiety represents a symmetric substituent e.g., NO_2, C≡N. The C—D bond may lie *cis* or *trans* to the A—B bond as shown by (*b*) and (*c*), respectively.

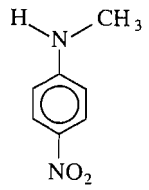
Experimental

Carbon-13 spectra of solid samples were obtained at 50.323 MHz on a Bruker MSL-200 using cross-polarization (CP), magic angle spinning (MAS), and high power decoupling. Contact and recycle times ranged from 1 to 5 ms and from 5 to 60 s respectively. MAS rates were 3.0–4.5 kHz. Aluminium oxide rotors of volume 0.35 cm^3 were used. Non-quaternary suppression (20) was occasionally used to aid in spectral assignment. Several samples required the use of the flipback (21) or TOSS (22) pulse sequences. Chemical shifts were referenced to external solid adamantane, which has shifts of 38.56 ppm (CH_2) and 29.50 ppm (*C*H) with respect to TMS (23). All spectra were recorded at ambient temperatures (20 ± 2°C). Errors in the chemical shifts relative to TMS are about ±0.3 ppm; however, errors in peak separations in any given spectrum are about ±0.1 ppm.

Solution carbon-13 spectra were obtained in acetone-d_6 solutions (0.2 g in 2.0 mL) at 90.81 MHz on a Nicolet 360 NB spectrometer with proton decoupling; chemical shifts were referenced to internal TMS.

All samples were commercially available with the exceptions of 4-methylformanilide (24), 4-(methylamino)acetophenone (25), and 1,4-di(methylthio)benzene (26).

Results and discussion



The ^{13}C chemical shifts of several solid 1,4-disubstituted benzenes measured using the CP/MAS nmr technique are presented in Table 1. All compounds studied contained at least one unsymmetrical substituent that is, in principle, capable of rendering C-2 and C-6 (as well as C-3 and C-5) nonequivalent (see Fig. 1). In solution, internal rotation of the unsymmetrical substituent is sufficiently rapid on the chemical shift time scale to cause chemical equivalence of C-2 and C-6 and of C-3 and C-5. Some of the compounds listed in Table 1 have also been studied in solution at low temperatures where internal rotation of one or both of the substituents is slow enough to render C-2 and C-6 (and possibly C-3 and C-5) nonequivalent.

With the exception of 4-nitrophenylformate, **12**, the heavy atoms of each compound are expected to reside in the plane (or nearly in the plane) of the benzene ring. This is based on crystal structures of these or related compounds.

(a) Molecules with one unsymmetrical substituent

(i) N-*Methylanilines*

The assignments of the ^{13}C resonances in the solid state were made largely on the basis of those in solution. As an example we briefly discuss the CP/MAS ^{13}C nmr spectrum of 4-nitro-*N*-methylaniline, **2**, shown in Fig. 2. First note that C-2 and C-6 are nonequivalent while separate resonances for C-3 and C-5 are not resolvable in the solid state. The magnitude of the chemical shift difference between C-2 and C-6, denoted $\Delta_{2,6} = \delta(C\text{-}2) - \delta(C\text{-}6)$, is −6.4 ppm in the solid state and is −6.5 ppm in solution at 210 K (27). On the basis of electron densities calculated using molecular orbital theory at the STO-3G level, earlier workers assigned $\delta(C\text{-}6) > \delta(C\text{-}2)$; thus $\Delta_{2,6}$ is negative (28). Based on the deviations from chemical shift additivity in 2-fluoro-*N*-methylaniline, where the *N*-methyl group is *trans* to the fluorine substituent (29), we also assign a negative value to $\Delta_{2,6}$ and a positive value to $\Delta_{3,5}$. These assignments are consistent with those expected for the "γ-substituent effect" as discussed by Olah and Donovan (30). Also, see ref. 18.

2

The second point to note is that all resonances that arise from carbon nuclei directly bonded to ^{14}N are broad or split into unsymmetrical doublets due to incomplete averaging of the $^{13}C-^{14}N$ dipolar interactions and the breakdown of the high field approximation (31).

The shift values for **2** in the solid state compare well with those observed in Freon solution at 210 K (27). Four $\Delta_{2,6}$ values for 4-X-*N*-methylanilines (X = F, H, Cl, NO_2) yield an average value of −6.2 ppm with a standard deviation of 0.2 ppm. The six available values of $\Delta_{3,5}$ (from low temperature solution work) range from 0.5 to 2.4 ppm (27).

(ii) Anisoles and thioanisoles

Internal rotation about the C_1—O and C_1—S bonds in anisoles and thioanisoles, respectively, has not been stopped by dynamic nmr techniques (32). X-ray diffraction studies of anisoles and thioanisoles unsubstituted in the 2 and 6 positions yield structures in which the O—CH_3 and S—CH_3 bonds are nearly in the plane of the benzene ring (33–37).

A negative value has previously been assigned to $\Delta_{2,6}$ in anisole derivatives on the basis of calculated electron densities (38). Examination of several *ortho*-substituted anisole derivatives confirms the negative value for $\Delta_{2,6}$ and indicates $\Delta_{3,5}$ is positive. Recent results (ref. 16, added in proof) also confirm our assignment. Together with the value reported here for 4-nitroanisole, **3**, a total of 17 $\Delta_{2,6}$ values, ranging from −2.9 to −9.2 ppm (ave. −6.5, std. dev. 2.0 ppm), are available for solid anisole derivatives (2, 8–10, 14, 38, 39). The large range in $\Delta_{2,6}$ may be due to varying compression of the methoxy group in different crystal environments. By comparison, the six $\Delta_{2,6}$ values available for *para*-substituted phenols only range from −1.6 to −2.7 ppm (12, 38) (ave. −2.1, std. dev. 0.4 ppm). The reduction in both magnitude and variation of $\Delta_{2,6}$ in the phenols is likely a result of the lack of a methyl group steric effect (18, 41, 42).

The largest reported value of $\Delta_{3,5}$ for a solid anisole derivative is +3.8 ppm (14). Several values of 0 ppm have been reported (10, 14, 38, 39). It is quite likely that most values are non-zero but simply unobservable due to large linewidths in the solid. As an example, a $\Delta_{3,5}$ value of 0 ppm was reported for the *para*-substituted carboxylic acid derivative of anisole (14) but a later investigation gave +0.8 ppm (38). No splitting of the *meta* ^{13}C resonance in solid phenols, with symmetric *para* substituents, has been reported.

The separation between the methyl and C-2 carbons is larger

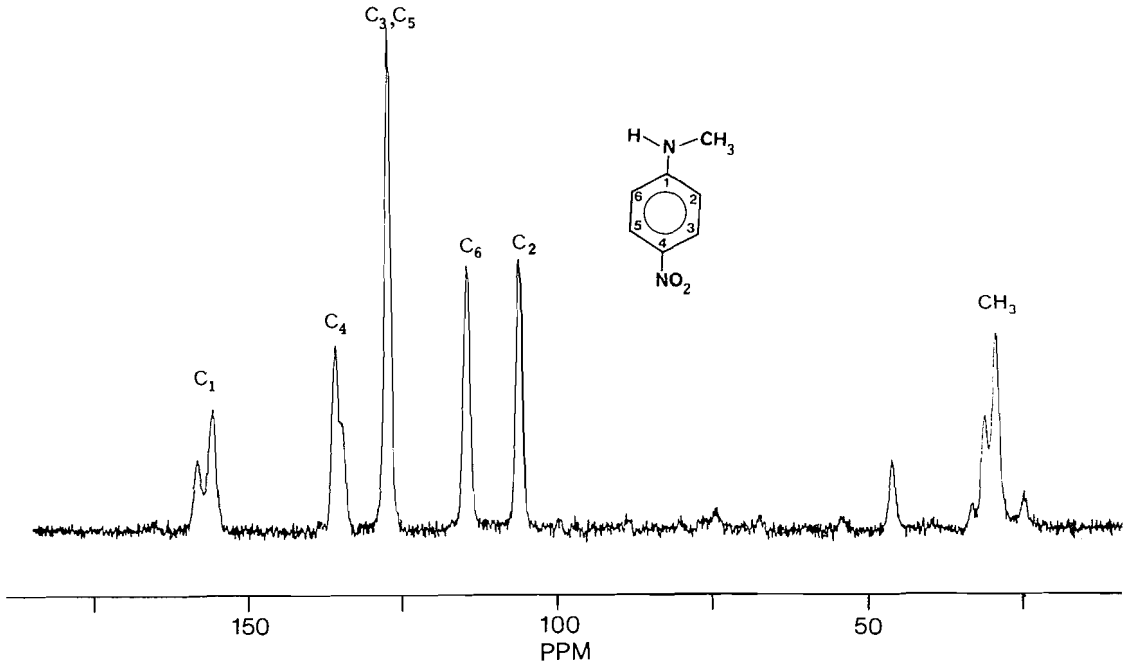

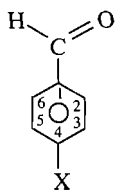

FIG. 2. The ^{13}C CP/MAS spectrum of solid 4-nitro-*N*-methylaniline **2**.

in thioanisoles than in anisoles, hence the steric contribution to $\Delta_{2,6}$ and the variation in $\Delta_{2,6}$ values are expected to be smaller. Values of $\Delta_{2,6}$ in solid thioanisoles are -3.9, -4.2, and -4.2 ppm for **4**, **5**, and **6**, respectively. The corresponding value in 4-methylmercaptobenzoic acid is -3.8 ppm.[2] Thus the average $\Delta_{2,6}$ value is -4.0 ppm with a range of only 0.2 ppm. We have assigned a negative value to $\Delta_{2,6}$ based on the sign deduced for the corresponding anisoles. Splitting of the *meta* ^{13}C resonances, $\Delta_{3,5}$, was not observed for **4** or **5**, where the *para* substituent is symmetric.

(iii) Benzaldehydes

In the solid state, benzaldehydes (43–48) and acetophenones (47–49) unhindered at the *ortho* positions are essentially planar, having angles, θ, between the carbonyl and phenyl ring planes less than 5°.

Based on low temperature solution ^{13}C spectra of 2-fluorobenzaldehyde, Drakenberg *et al.* have assigned δ(C-2) < δ(C-6) and δ(C-3) > δ(C-5) in *para*-substituted benzaldehydes (50, 51). These assignments are consistent with a negative value for $\Delta_{2,6}$ and a positive value for $\Delta_{3,5}$. The 12 values of $\Delta_{2,6}$ for *para*-substituted benzaldehydes, at low temperature in Freon solution, range from -7.6 to -9.0 ppm (ave. -8.4, std. dev. 0.5 ppm) (51). The value for 4-nitrobenzaldehyde, **7**, is -7.6 ppm (51); in the solid state a splitting of -6.7 ppm is observed. The CP/MAS spectrum of 4-dimethylaminobenzaldehyde, **8**, shows additional splittings (see Fig. 3) due to the

7 X = NO_2
8 X = $N(CH_3)_2$

[2]G. Penner and R. E. Wasylishen, unpublished results.

presence of two nonequivalent molecules within the crystallographic unit cell. Values of $\Delta_{2,6}$ and $\Delta_{3,5}$ may be partitioned between the nonequivalent molecules in two reasonable ways: first with values of -7.5 and $+5.3$ ppm and, alternatively, with -8.6 and $+4.2$ ppm, respectively.

Measured values of $\Delta_{3,5}$, in solution at low temperature, are generally about 0.5 ppm (0.4 ± 0.2 for 10 derivatives) with the exception of 2.7 ppm for 4-methoxybenzaldehyde (where the internal rotation of the methoxy substituent has not stopped) and 1.8 ppm for **8** (51). In the solid state, $\Delta_{3,5}$ is unobservable for **7** and has values ranging from 0.0 to 3.0 ppm for **8**, depending on assignment of the ^{13}C resonances of C-3 and C-5 in the nonequivalent molecules.

A recent ^{13}C CP/MAS study of an α-cyclodextrin complex of benzaldehyde at 193 K gave a $\Delta_{2,6}$ value of -7.8 ppm (52). The solution value at 150 K is -8.7 ppm (52).

(iv) Acetophenones

Low temperature nmr studies of six *para*-substituted acetophenones give $\Delta_{2,6}$ values ranging from -2.5 to -3.9 ppm and $\Delta_{3,5}$ values of 0 ppm (the exception, 4-OCH_3, has $\Delta_{3,5}$ = 2.1 ppm) (53). Following Drakenberg *et al.* (53) we assign negative and positive values to $\Delta_{2,6}$ and $\Delta_{3,5}$, respectively. With this assignment it can be seen that at low temperature in Freon solution the shift values of C-2 in the acetophenones are consistently about 1–2 ppm to low frequency of those in the corresponding benzaldehydes, whereas C-6 resonates about 3–5 ppm to low frequency. The substantial low frequency shift of C-6, with respect to the corresponding benzaldehyde, is consistent with the steric effect expected from a proximate methyl group (18, 41, 42).

The observed $\Delta_{2,6}$ values for **9** and **10** are -2.5 ppm and -4.8 ppm, respectively. The latter value is slightly higher than expected. The rotation of the acetyl group has not been stopped for either molecule by low temperature solution nmr. It is interesting to note that both molecules exhibit unexpectedly large $\Delta_{3,5}$ values. These are not due to non-congruence of molecules in the crystal (48, 49).

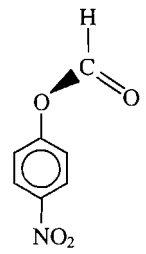
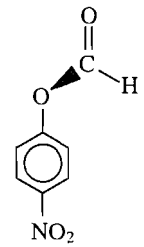
10 X = NH_2

(v) Nitrosobenzenes

Nitrosobenzenes are unique in that they display the largest $\Delta_{2,6}$ value of any benzene derivative. In low temperature solutions $\Delta_{2,6}$ values for nitrosobenzene and *N*,*N*-dimethylaminonitrosobenzene, **11**, are −34.5 ppm (54) and −31.6 ppm (55), respectively. The CP/MAS spectrum of **11** yields −30.8 ppm.



11



The negative sign of $\Delta_{2,6}$ is based on arguments by Lunazzi *et al.* (54), which are supported by electron density calculations.[2] The low temperature solution value for $\Delta_{3,5}$, 0.2 ppm, is not resolved in the CP/MAS spectrum of **11**.

(vi) Phenyl esters

As has already been mentioned, solid alkoxybenzenes unsubstituted in the *ortho* positions strongly prefer planar or nearly planar conformations. Replacement of the alkyl by an electron-withdrawing carbonyl moiety strongly reduces the conjugation between the ether oxygen and phenyl ring system. As a result, the preferred conformations of phenyl esters have θ values near 90°. This is in accord with the equivalence of the *ortho* ^{13}C resonances observed in solid 4-nitrophenylformate **12**. In the solid state **12** may exist in either the *Z* or *E* forms.

12*a* (*Z*)

12*b* (*E*)

Long-range couplings between the formate proton and ring protons (56) suggest that both forms exist in solution with the *Z* form predominating. Unfortunately, the $E \rightleftharpoons Z$ exchange has not been stopped in solution at low temperatures, hence the ^{13}C shifts of the two forms are not known and it is difficult to deduce the conformation of the formate group in **12** from the solid state CP/MAS spectrum. No crystal structures of phenyl formates unsubstituted in the *ortho* positions are available.

A recent ^{13}C CP/MAS spectrum of a phenylbenzoate derivative also reported identical shifts for C-2 and C-6 (8). An X-ray structure of this compound indicates that the phenyl and carbonyl planes are orthogonal (57).

(vii) Anilides

Internal rotation in amides has been studied extensively

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

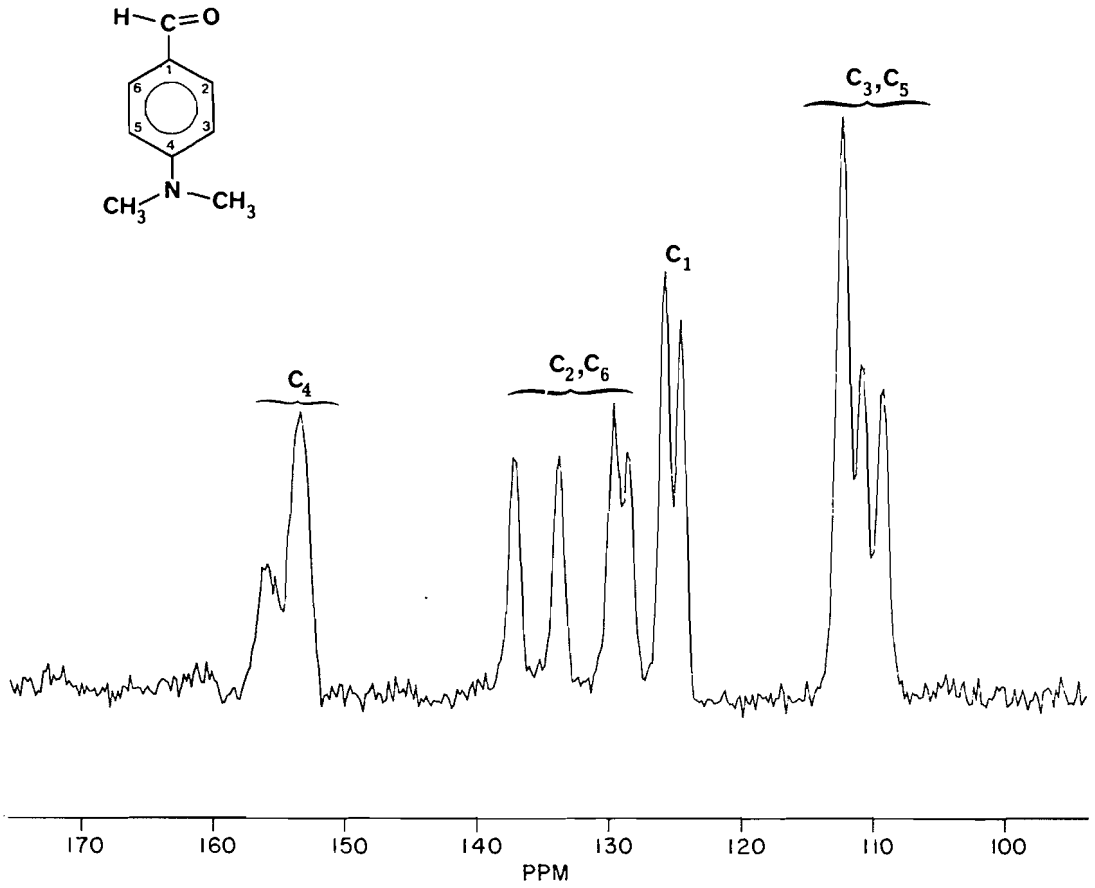


FIG. 4. The ^{13}C CP/MAS spectrum of the ring carbon-13 nuclei in 4-*N*,*N*-dimethylaminobenzaldehyde **8**.

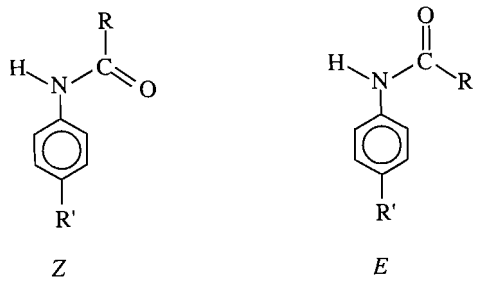
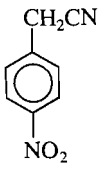
by dynamic nmr techniques (58). In principle, two forms of internal rotation may occur in anilides: rotation about the N—C bond, which interconverts between *Z* and *E* isomers, and rotation about the C_1—N bond, which renders C-2 and C-6 (and C-3 and C-5) nonequivalent. The first form of internal rotation is slow, even at ambient temperatures (59). Low temperature nmr techniques have, as yet, failed to slow the second form of rotation to render C-2 and C-6 nonequivalent.



The ^{13}C CP/MAS spectrum of **13** shows a splitting of the *ortho* carbons, $\Delta_{2,6}$, of +2.8 ppm, implying that rotation about the C1—N bond is slow and that the molecule is effectively planar. In solution **13** exists in an approximate 1:2 ratio of *E*:*Z*. The differences in carbon-13 chemical shifts between *E* and *Z* isomers in solution are too small to make a definite assignment of structure in the solid state; however, on the basis of additivity effects (see discussion to follow) the *Z* form is favored. No crystal structures of formanilides are available.

Solid acetanilide, **14**, is in the planar *Z* form (60). The CP/MAS spectrum indicates that $\Delta_{2,6}$ is +1.5 ppm, consistent with a planar molecule in the solid.

In solution *o*-fluoroformanilide is expected to be in a conformation with the formyl group *trans* to the fluorine. The rotation of the formyl group is slow on the ^{13}C chemical shift time scale at room temperature and the *Z* and *E* forms exist in an approximately 2:1 ratio. The deviation of the *ortho* ^{13}C chemical shifts from additivity implies $\Delta_{2,6}$ values of +2.9 ppm and −0.3 ppm, respectively, for the *Z* and *E* forms in the absence of the fluorine substituent. The observed magnitude of 2.8 ppm for **13** is rather close to that predicted, considering that the additivity method probably has an uncertainty of as much as 0.5 ppm. It is on this agreement that we base the positive sign of $\Delta_{2,6}$ for **13** and **14**. The fact that the predicted and observed values of $\Delta_{2,6}$ are so much closer for the *Z* form than for the *E* form implies the former as the solid state conformation of 4-methylformanilide, **13**.



(viii) Benzylcyanides

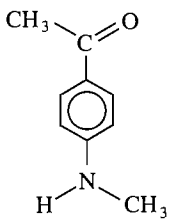
In solution benzylcyanides unsubstituted in the *ortho* positions experience nearly free internal rotation (40). The ^{13}C CP/MAS spectrum of **15** yields a splitting, $\Delta_{2,6}$, of ±2.5 ppm. This suggests that solid **15** may be planar or nearly planar. As

Z *E*

13 R = H, R' = CH_3
14 R = CH_3, R' = H

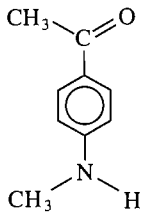
15

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.



the splitting is not very large, the possibility of nonequivalence of C-2 and C-6 due to crystal packing forces certainly cannot be ruled out. The *ortho* ring carbon resonance in pentamethylbenzylcyanide ($\theta = 90°$) shows no such splittings (40).

(b) Derivatives with two different unsymmetrical substituents in the 1 and 4 positions

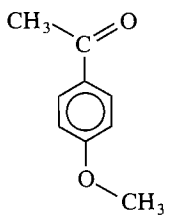


When two unsymmetrical substituents are *para* to each other, the observed splittings $\Delta_{2,6}$ and $\Delta_{3,5}$ depend on the $\Delta_{2,6}$ and $\Delta_{3,5}$ values associated with each individual substituent and on the relative orientation of the substituents. If the molecule has all heavy atoms in one plane, the two substituents may have a *cis* or *trans* configuration as shown in Figs. 1*b* and 1*c*, respectively.

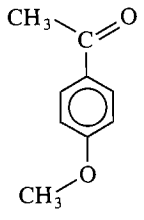
(i) 4-N-Methylaminoacetophenone, ***16***

The influence of two unsymmetrical substituents, *para* to one another, on the ring carbon chemical shifts is nicely demonstrated by the low temperature solution spectrum of 4-methylaminoacetophenone **16** (27). In conformation **16***a* the contributions of the acetyl and *N*-methyl groups to $\Delta_{2,6}$ and $\Delta_{3,5}$ are of opposite sign and will tend to cancel. On the other hand, in **16***b* they will add, yielding larger $\Delta_{2,6}$ and $\Delta_{3,5}$ values. At

16*a*



16*b*

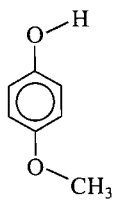


153 K in dimethyl ether solution internal rotation of both the *N*-methyl and acetyl groups is slow and two species **16***a* and **16***b*, of different stability, are present. We assign $\Delta_{2,6}$ and $\Delta_{3,5}$ magnitudes of 1.7 ppm and 6.2 ppm for **16***a* and 4.7 ppm and 7.6 ppm for **16***b*, respectively. The CP/MAS spectrum yields 0.6 ppm and 5.1 ppm, implying **16***a* as the solid state conformation.

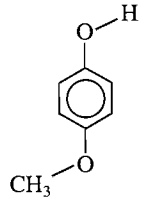
(ii) 4-Methoxyacetophenone, ***17***

In Freon solution at 123 K, internal rotation of the acetyl group in **17** is slow, yielding $\Delta_{2,6}$ and $\Delta_{3,5}$ values of (−)3.4 ppm and (+)2.1 ppm, respectively (53). In solid **17** the

17*a*



17*b*

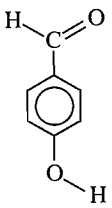


rotation of the methoxy group has also stopped and $\Delta_{2,6}$ and $\Delta_{3,5}$ are (−)4.7 and (−)7.8 ppm, respectively. That the rotation of the methoxy group has stopped is evident by the large increase in $\Delta_{3,5}$. The change in $\Delta_{2,6}$ may also be due to a contribution of the methoxy group. If this is so, the contributions of the acetyl and methoxy groups to $\Delta_{2,6}$ can only be additive if **17***b* is the conformation of 4-methoxyacetophenone in the solid state.

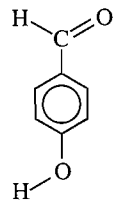
(iii) 4-Methoxyphenyl, ***18***

The magnitude of $\Delta_{2,6}$ in **18** is 0.9 ppm; this is smaller than the expected value (see Sect. *a.ii*). A possible explanation is that the OH and OCH_3 moieties are *cis* (**18***a*). In such a situation

18*a*



18*b*



the contribution of the methoxy group to $\Delta_{2,6}$ is expected to be small and positive and that of the hydroxy group small and negative, thus diminishing the magnitude of $\Delta_{2,6}$. The value of $\Delta_{3,5}$ is (−)6.3 ppm, in the range expected for carbons *ortho* to a methoxy group. The hydroxy group is not expected to contribute to $\Delta_{3,5}$.

(iv) 4-Hydroxybenzaldehyde, ***19***

The values of $\Delta_{2,6}$ and $\Delta_{3,5}$ in solid 4-hydroxybenzaldehyde are (−)9.1 and (−)2.1 ppm (12). These values are consistent with those expected if there were no contribution of the formyl group towards $\Delta_{3,5}$ or of the hydroxyl group towards $\Delta_{2,6}$. Under such circumstances an assignment of conformation **19***a* or **19***b* to solid 4-hydroxybenzaldehyde cannot be made on the basis of $\Delta_{2,6}$ or $\Delta_{3,5}$. X-ray diffraction studies indicate that **19***a* is the conformation of 4-hydroxybenzaldehyde in the solid state (43).

19*a*

19*b*

Another possible interpretation of the ^{13}C CP/MAS spectrum of **19** is that $\Delta_{3,5}$ = (+)2.1 ppm. Such a value would be expected for conformation **19***a* if the contribution of the O=C—H group to $\Delta_{3,5}$ were in the range of +3.0–+4.0 ppm. This is larger than the expected contribution of about +0.5–+1.5 ppm, therefore it appears that neither the formyl nor hydroxyl group contributes significantly to $\Delta_{3,5}$ or $\Delta_{2,6}$, respectively.

Conclusions

The results presented in this paper show that, for a variety of benzene derivatives, ^{13}C chemical shifts in the solid state are usually within about 1 ppm of those in solution. In addition, splittings of the *ortho* and *meta* ring ^{13}C resonances are observed due to the rigid conformation of unsymmetric substituents. These splittings are in good agreement with those observed in solution at low temperatures where internal rotation of the unsymmetric substituents is slow. In some cases the splittings are large and provide a useful tool for determining the conformations of benzene derivatives in the solid state. This is particularly useful if structures from diffraction studies are unavailable.

In the present study we have presented a few examples where it is possible to suggest the solid state conformation of 1,4-disubstituted benzene derivatives with two unsymmetrical substituents. Unfortunately, in many cases, $\Delta_{2,6}$ and $\Delta_{3,5}$ for any given substituent vary too much to make the deductions with certainty. It is important to point out that it is only on the basis of $\Delta_{3,5}$ values that one can distinguish between the relative orientations (Fig. 1, *b* and *c*) of two unsymmetrical substituents in 1,4-disubstituted benzenes. Both *ortho*- and *meta*-disubstituted benzene derivatives with unsymmetrical substituents show more promise, in particular those where the two substituents are identical. Work on these is presently underway.

Acknowledgements

We wish to thank Dr. Michael S. McKinnon for obtaining a few preliminary CP/MAS spectra, Mr. Brian Millier and Mr. Ron Curtis for their assistance in maintaining the nmr spectrometers, and the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support. G.H.P. is grateful to Dalhousie University for the award of a Killam Postdoctoral Fellowship. Finally we wish to thank Professor Ted Schaefer for several of the compounds.

The vibrational spectra (100–1600 cm^{-1}) and scaled 3-21G *ab initio* harmonic force fields for 7-oxanorbornane and 7-thianorbornane

R. A. SHAW, N. IBRAHIM, AND H. WIESER[1]

The University of Calgary, Department of Chemistry, Calgary, Alta., Canada T2N 1N4

Received September 26, 1988

R. A. SHAW, N. IBRAHIM, and H. WIESER. Can. J. Chem. **67**, 535 (1989).

The vibrational spectra in the region of 1600–100 cm^{-1} are reported for 7-oxa- and 7-thianorbornane. *Ab initio* 3-21G harmonic force fields based on optimized structures determined previously at the same level of theory were calculated for both molecules. The vibrational spectra were assigned unambiguously and almost completely with the aid of the 3-21G force fields, scaled using ten factors previously optimized in an overlay refinement to fit assigned frequencies of norbornane, norbornene, and norbornadiene, and including two others, where appropriate, from dimethyl ether and thietane. Reoptimization of 12 scaling factors reproduced 60 assigned frequencies out of a total of 70 in the specified region with average errors of 7.4 and 4.9 cm^{-1}, respectively, for the two molecules. The final refinement changed the scaling factors transferred from norbornane generally by less than 1%.

Key words: 7-oxanorborane, 7-thianorborane, vibrational spectra, *ab initio* harmonic force field.

R. A. SHAW, N. IBRAHIM et H. WIESER. Can. J. Chem. **67**, 535 (1989).

On a déterminé les spectres vibrationnels de l'oxa-7 et du thia-7 norbornane dans la région de 1600 à 100 cm^{-1}. Pour chacune de ces molécules, on a effectué des calculs *ab initio* 3-21G de champs de force qui sont basés sur les structures optimisées déterminées antérieurement au même niveau de la théorie. On a fait une attribution non-ambiguë et pratiquement complète des spectres vibrationnels en se basant sur les champs de force 3-21G dont l'échelle a été déterminée à l'aide de dix facteurs optimisés antérieurement par un affinement des fréquences attribuées au norbornane, au norbornène et au norbornadiène et, lorsque c'était approprié, au méthoxyméthane et au thiéthane. Une réoptimisation de l'échelle de 12 facteurs a permis de reproduire 60 des 70 fréquences attribuées dans la région spécifiée; pour chacune des molécules, les erreurs moyennes sont respectivement de 7,4 et 4,9 cm^{-1}. L'affinement final n'a généralement modifié les facteurs de l'échelle du norbornane que par moins de 1%.

Mots clés : oxa-7 norborane, thia-7 norborane, spectres vibrationnels, *ab initio* de champs de force.

Introduction

We have recently reported scaled *ab initio* force fields for norbornane, norbornene, and norbornadiene (1). These were derived by optimizing a set of 12 scaling factors to fit simultaneously the observed frequencies for all three molecules, with the assumption that analogous *ab initio* force constants were overestimated to the same extent for each compound. The validity of this assumption was verified by the excellent fit of calculated to observed frequencies (average error of 5.3 cm^{-1}), which further suggested that the derived factors might be appropriate for scaling the force fields of other related compounds.

In this report, we present the vibrational spectra of 7-oxabicyclo[2.2.1]heptane (7-oxanorbornane, 7-OXA) and 7-thiabicyclo[2.2.1]heptane (7-thianorbornane, 7-THIA; see Fig. 1). The 3-21G calculated force constants for each are scaled using the factors optimized for the norbornane–norbornene–norbornadiene set, and the spectra assigned on the basis of frequencies thus predicted.

The only previous work concerning the vibrational spectra of either molecule is that of Carlile *et al.* (2), who measured the far-infrared absorption spectrum of 7-OXA in the vapor phase. The transition energies for certain low frequency modes were also inferred from a microwave study (3), which in addition yielded certain structural data. Further structure information is available for both compounds from electron diffraction measurements (4, 5) and optimized STO-3G and 3-21G geometries (6).

Experimental and computational details

7-Oxabicyclo[2.2.1]heptane was purchased from Aldrich with a quoted purity of 98%, and used without further purification. 7-Thiabicyclo[3.2.1]heptane was prepared from the oxygen analog following a published procedure (7), and purified by sublimation to at least 99%.

The infrared absorption spectra were obtained with a Nicolet 8000 FT-IR spectrometer and the Raman on a Jarrell-Ash model 25-100 double grating monochromator interfaced to an IBM PC. The vapor phase infrared spectra (Figs. 2 and 3) were run using a Wilkes multipass cell, at a pathlength of about 18 m, and the spectra in solution (CCl_4 and CS_2) and of the neat liquid of 7-oxa in KBr cells of pathlength 0.1 and 0.015 mm, respectively (Figs. 4 and 5). Typically 400 scans were accumulated for the vapors and 1000 for the condensed phases. For the latter, closely spaced absorptions were resolved using the Fourier self-deconvolution (FSD) technique (8) with software supplied by Nicolet. The Raman spectra are presented in Figs. 6 and 7. Measured peak positions are summarized in Tables 1 and 2.

Cartesian force constants were evaluated for both molecules as numerical derivatives of the analytically calculated gradients at the optimized structures (6), using the 3-21G basis set with Gaussin 82 as implemented on the Cyber 205 supercomputer at the University of Calgary (9, 10). The force constants were then transformed to local symmetry coordinates (Table 3), chosen in accordance with those suggested by Pulay *et al.* (11) and defined analogously to those for the norbornane series (1). The local symmetry force constants were scaled according to $F_{ij} = (C_iC_j)^{1/2}K_{ij}$, were C_i and C_j denote the scaling factors for modes i and j, and F_{ij} and K_{ij} the scaled and unscaled *ab initio* force constants, respectively. For the least-squares refinement of the scaling factors, the observed frequency parameters λ_i were weighted by $(1/\lambda_i^{obs})^2$. Each refinement was allowed to continue until the calculated shifts were less than 0.0005 for all scaling factors.

Vibrational assignments and determination of force fields

The force fields for 7-OXA and 7-THIA were scaled initially using factors optimized to fit the observed frequencies for norbornane, norbornene, and norbornadiene (1), with additional factors for the C—O and C—S stretching coordinates

transferred from previous studies of dimethylether (12) and thietane (13). The frequencies predicted on this basis are listed in Tables 4 and 5 under columns "(1)".

We have not attempted to assign the C—H stretches. The frequencies calculated for this region are therefore only approximate. The assignments proposed for the remaining transitions fall into three categories. First, there are those for which experimental evidence unambiguously confirms the correct symmetry species, i.e., polarized Raman lines for 7-OXA and 7-THIA, and three apparent B-contours in the vapor phase spectrum of the former. For all of these cases the assignment is confirmed by closely lying calculated frequencies of the correct symmetry. Second, there are a number of observed features whose assignment is completely unambiguous in light of the calculated positions. For example, for 7-OXA, the vapor phase band at 799.2 cm^{-1} is readily designated as ν_{44} (calcd. 795.6 cm^{-1}), and ν_{34} (calcd. 806.5 cm^{-1}) and ν_{11} (calcd. 816.3 cm^{-1}) as assigned previously at 793.6 cm^{-1} and 826.1 cm^{-1} (2). Similarly, all of the transitions predicted below about 650 cm^{-1} were readily located, as were the CH_2 scissoring modes.

Finally, in certain instances the vibrational assignments were not straightforward even in light of the calculated positions. These cases are discussed separately below.

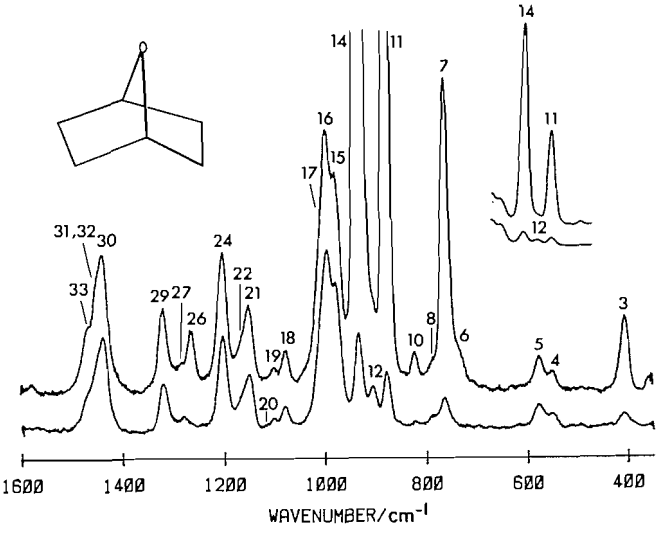

FIG. 6. Parallel (upper) and perpendicular (lower) polarized Raman spectra of liquid 7-oxanorbornane. Numbers identifying peaks correspond to "Peak no." in Tables 1 and 4.

7-Oxanorbornane

In the A_1 species ν_5 (calcd. 1334 cm^{-1}) is assigned to an infrared absorption observed at 1321.9 cm^{-1}, which we suspect to contain also the B_2 transition predicted at 1320 cm^{-1} (ν_{39}). Although they are not resolved in the condensed phase spectra, the unusual band contour suggests two overlapping absorptions (band no. 29 in Fig. 2). Both ν_7 (calcd. 1163 cm^{-1}) and ν_8 (calcd. 1025 cm^{-1}) are apparently weak or absent in the infrared absorption spectra, and are assigned to the Raman lines at 1164 and 997 cm^{-1} (peaks no. 22 and 16, respectively, in Fig. 6). Even in the absence of corroborative experimental evidence, such as infrared bandshapes or Raman polarization data, we believe that the calculated positions are sufficiently accurate and reliable to make these assignments with confidence. Two fundamentals namely ν_{30} (B_1) at 1193.8 cm^{-1} and ν_{40} (B_2) at 1199.6 cm^{-1} are predicted near the bands labelled 23 and 24 (Figs. 2 and 4). The dominant vapor phase absorption at lower

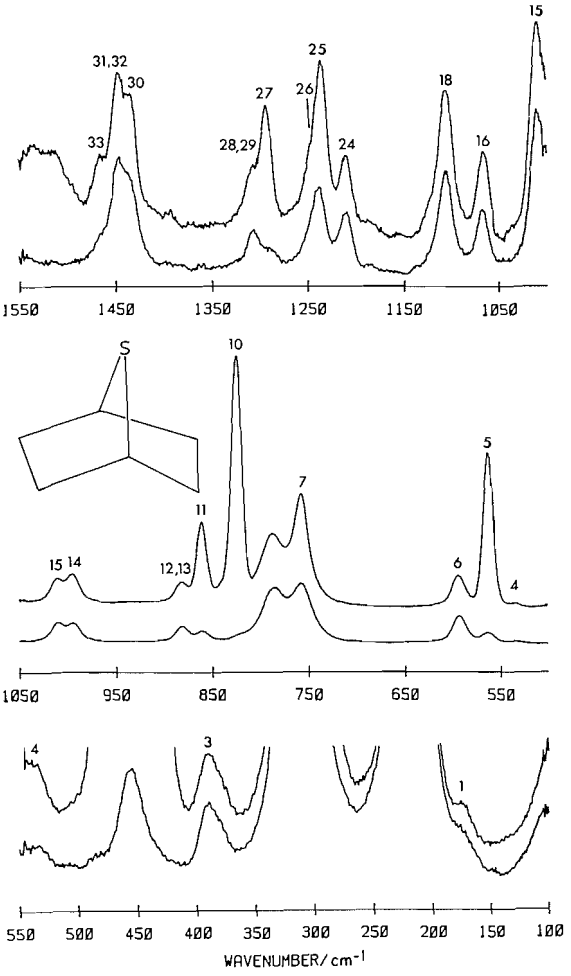

FIG. 7. Parallel (upper) and perpendicular (lower) polarized Raman spectra of 7-thianorbornane in CCl_4 solution. Peaks which are off scale in the 550–100 cm^{-1} region are CCl_4 lines. Numbers identifying peaks correspond to "Peak no." in Tables 2 and 5.

frequency (peak 23 at 1199.3 cm^{-1}) is assigned as the latter on the basis of its band contour which is very similar to that observed for the B_2 mode at 548.5 cm^{-1} (peak no. 4). The weaker feature on the high frequency side (1204.0 cm^{-1}) must then be the B_1 mode. The assignment of ν_{29} is based solely upon the predicted position at 1246 cm^{-1}, ascribing the status of a fundamental to the very weak infrared feature at 1240.8 cm^{-1} (peak 25 in Figs. 4 and 6). Such a low intensity is not entirely unexpected given that nature of the mode, which is primarily a CH_2 twist. Four of the eight A_2 modes below 1500 cm^{-1} were identified in the Raman spectrum. The others may be assumed to be a very low intensity and either absent or obscured by more prominent bands in all spectra.

7-Thianorbornane

Only six fundamentals fall into this category for 7-THIA. Two of these are predicted to lie very close to one another, namely ν_6 (A_1) at 1242.3 cm^{-1} and ν_{29} (B_1) at 1241.5 cm^{-1}. Two bands are clearly resolved upon Fourier self-deconvolution of the solution phase infrared spectrum at 1233.8 cm^{-1} and 1238.1 cm^{-1} (peaks nos. 25 and 26, Fig. 5). While the calculated frequencies suggest these should be assigned as B_1 and A_1, respectively, close inspection of the Raman spectrum over this region reveals that the lower frequency component of

the feature at 1235 cm^{-1} (peak no. 25 in Fig. 7) is polarized. Since the residual feature in the perpendicular spectrum (peak no. 26) is shifted to higher frequency, we assign this band as B_1 and the polarized band as A_1. Similarly, two bands are predicted near 1320 cm^{-1}, namely ν_{28} (B_1) at 1322.8 cm^{-1} and ν_{39} (B_2) at 1317.4 cm^{-1}. The solution phase infrared band at 1313 cm^{-1} does resolve upon Fourier self-deconvolution to show a strong absorption at 1310.2 cm^{-1} and a weaker feature at 1307 cm^{-1} (peaks nos. 29 and 28 in Table 2 and Fig. 5). These are assigned to the B_1 and B_2 symmetry species so as to match the ordering calculated for these modes. Finally, ν_7 (A_1) and ν_{43} (B_2) are assigned to absorptions in the infrared spectra solely on the basis of their predicted positions (peaks 17 and 12, respectively, in Figs. 3 and 5).

Based upon these assignments, we had several options for further refining the scaling factors. One possibility was to reoptimize all scaling factors to fit the new assignments. There exists ample evidence, however, to suggest that the factors for coordinates in common with the norbornane series, i.e. those involving the six-membered ring, should be clearly transferable to the 7-OXA and 7-THIA derivatives. We deemed it preferable to identify and reoptimize only those factors which might be expected to deviate from the transferred values, holding all others fixed. Accordingly we refined initially only the scaling factors for the C—O and C—S stretches and the deformation of the C—O—C bridge of the oxygen compound. The latter obviously requires adjustment in view of the poor fit to ν_{45} of 7-OXA. The reoptimized factors for the C—O and C—S stretches and C—O—C bridge deformation are listed under "Rfnmt.1" in Table 6, and the corresponding calculated frequencies in Tables 4 and 5. In the final refinement, all scaling factors were floated to fit the assigned transitions ("Rfnmt.2" in Table 6, and "Calcd. positions (3)" in Tables 6 and 5). While we suspected that the data might not be sufficient to determine

reliable values for all 12 scaling factors, those for the six-membered ring coordinates adopted final values which differ generally by less than 1% of those transferred (Table 6).

The final scaled diagonal force constants for 7-OXA and 7-THIA are summarized and compared with those of norbornane in Table 7. Complete listings of all symmetry allowed force constants are available from the authors upon request.

Discussion

In the final analysis some apparent ambiguities remained, in particular for 7-OXA. For example, the optimized C—O stretching factor (0.839) is substantially lower than the value transferred from dimethyl ether (0.903). Because this relatively large change was unexpected, we carefully reexamined the assignments for those modes containing substantial contributions from the C—O stretching. In the A_1 species the transitions assigned as ν_9 and ν_{11} are both polarized in the Raman spectra, leaving little doubt that those assignments are correct. For the B_1 species ν_{32} is assigned to a very intense band in the infrared spectra, which exhibits an apparent B-contour in the vapor phase. Although we have not calculated theoretical infrared absorption intensities, and did not consider the experimental band intensities in deriving the proposed assignments, it emerged that the three strongest bands in the absorption spectra (nos. 10, 14, and 17) were assigned as C—O stretches (ν_9, ν_{11}, and ν_{32} respectively). These observations provide strong experimental evidence that all three assignments are correct. The discrepancy between the optimized scaling factors for the C—O stretches of 7-oxanorbornane and dimethyl ether thus reflects a non-uniform overestimation of the C—O stretching force constant, as calculated for different molecules using the 3-21G basis set. We have made a similar observation when deriving a scaled 3-21G force field for 2-methyloxetane, for which the optimized C—O stretching scaling factor is 0.851

(14). In view of the present results it is tempting to suggest some correlation between the optimized C—O stretching scaling factors and the C—O—C angles for the three molecules. Such an analogous correlation is not found for C—C stretching coordinates for which optimized factors were determined previously as 0.96, 0.95, and 1.013, respectively, for propane, cyclobutane, and 2-methyloxetane (12, 14).

For the C—S stretch, the optimized scaling factor for 7-thianorbornane is lower by 0.04 (1.005) than the value transferred from thietane (1.048) (13). The C—S stretching fundamentals ν_{12} and ν_{34}, both very pure modes, are well reproduced by the force field. The calculated splitting between these modes is governed in the usual fashion by the geometry through the **G** matrix, and the CS/CS interaction force constant in the **F** matrix. It might be suspected that neither the geometry nor the interaction constant are calculated particularly accurately with the small split-valence basis set, since it is generally understood that the 3-21G basis overestimates the C—S bond length, and no accurately known or accepted value for the CS/CS interaction constant is available for comparison. The fact that the C—S fundamentals for 7-thianorbornane and thietane are accurately reproduced with the present procedure demonstrates that despite the stated uncertainties the 3-21G calculated structures and scaled force fields are completely adequate for molecules which contain the C—S—C group, both as a guide to the vibrational assignments and as a means of reproducing the observed fundamental frequencies. While we had some concern initially whether *d* functions might be required on sulfur, we decided not to tailor the basis set to suit one specific molecule in the series, viz. 7-THIA, since in that case the transferability of the scaling factors from norbornane to 7-thianorbornane and from the latter to related molecules not necessarily containing sulfur atoms might be compromised, and a marginally better value for the C—S bond length would not affect the vibrational assignment.

The C—S—C bridge deformation, ν_{45} (B_2), cannot be identified with certainty for 7-thianorbornane. The predicted position is calculated by scaling the force field under the assumption, employed also for the norbornane series, that the bridge deformation force constant may be scaled by the same factor as the in-plane ring deformation modes. On this basis, ν_{45} is predicted to lie between ν_{13} and ν_{35}. Accordingly, the

apparent shoulder to lower wavenumber on the Raman band, assigned as ν_{13} (peak no. 3, Fig. 7) is the only reasonable although uncertain choice.

The relatively high force constants for A_1 out-of-plane ring modes were initially quite unexpected (Table 7). For both 7-OXA and 7-THIA, as well as for norbornane, norbornene, and norbornadiene (1), the lowest A_1 transition corresponds primarily to the in-plane ring deformation (coordinate no. 40 in Table 3), whereas the out-of-plane mode is found to contribute to absorptions at higher frequencies, e.g. ν_8 (997 cm^{-1}) for

[b]Scaling factors previously optimized to fit the observed frequencies of norbornane, norbornene, and norbornadiene (Calc. A, Table IX of Ref. 1), except those for the C—O and C—S stretches which were optimized for dimethyl ether (ref. 12) and thietane (ref. 13), respectively. Positions calculated with these factors are listed as calcd. 1 in Tables 4 and 5.

[c,d]Scaling factors after optimization to fit observed frequencies. Factors in square brackets were fixed in the refinements. Calculated positions are listed as calcd. 2 and calcd. 3, respectively, in Tables 4 and 5. Uncertainties in the best fitting scaling factors are given in parentheses.

7-OXA and ν_9 (863 cm^{-1}) for 7-THIA. The large force constants and high transition frequencies for the out-of-plane ring deformation may be rationalized by observing that although the coordinate (no. 43 in Table 3) is defined as a combination of ring torsions, the actual deformation involves considerable bending of the C—C—X angles. This motion, often termed the "butterfly" mode, is thus a hybrid of ring torsions and ring angle bends, and in fact appears in the vibrational spectra at frequencies characteristic of C—C—X bends.

Conclusions

The vibrational spectra for 7-oxa- and 7-thianorbornane are reported here for the first time. *Ab initio* 3-21G harmonic force fields were calculated for both molecules, based upon optimized geometries determined previously at the same level of theory (6). A total of 12 scaling factors, 10 of which were transferred from a previous study of the vibrational spectra of norbornane, norbornene, and norbornadiene (1), and one each from dimethyl ether (12) and thietane (13), proved sufficiently accurate to assign reliably 60 of the 70 vibrational modes in the region of 1600–100 cm^{-1}. Refinement of only three of the scaling factors, i.e. those from sources other than the norbornane set, reduced the average error of the calculated positions from 9.0 and 6.1 to 7.9 and 5.7 cm^{-1}, respectively, for 7-oxa- and 7-thianorbornane. Further refinement of the entire set of scaling factors to fit simultaneously the assigned transitions of both molecules further lowered the average error to 7.4 and 4.9

[a]Force constants in units of mdyn/A (stretch) or mdyn A/rad^2 (bends and torsions). Complete lists of all symmetry allowed force constants are available upon request from the authors.

[b]Refer to Fig. 1 for atom numbering, and Table 3 for coordinate definitions.

[c]Reference 1. The force constants listed here for norbornane are slightly different to those of Table X of ref. 1. This is because the scaling factors used here, and for the prediction of frequencies for 7-OXA and 7-THIA, are from Calc. A, Table IX of ref. 1, where separate ring torsional factors were refined for each of norbornane, norbornene, and norbornadiene. The force constants listed in Table X of ref. 1 were derived using the scaling factors optimized with the same scaling factor applied to all ring torsion modes ("Final refinement" of Table IX, Ref. 1). See also Table 6.

[d]Force constants listed under 1 and 2 are scaled using factors listed under "Rfnmt. 1" and "Rfnmt. 2", respectively, in Table 6.

cm^{-1}, respectively, the factors transferred from norbornane changing very little (generally by less than 1%). This further demonstrates the excellent transferability of scaling factors, optimized for closely related molecules, and suggests that the factors derived here to scale 3-21G force fields should be useful for accurately predicting the vibrational spectra of other derivatives of norbornane, norbornene, and norbornadiene.

The use of perchlorato(tetraphenylporphinato)manganese(III) as a reagent for the spectrophotometric determination of anions in nonaqueous solvents

A. Scott Hinman,[1] Karen McGarty, Clement Tang, and Brad J. Pavelich
Department of Chemistry, The University of Calgary, Calgary, Alta, Canada T2N 1N4
Received August 17, 1988

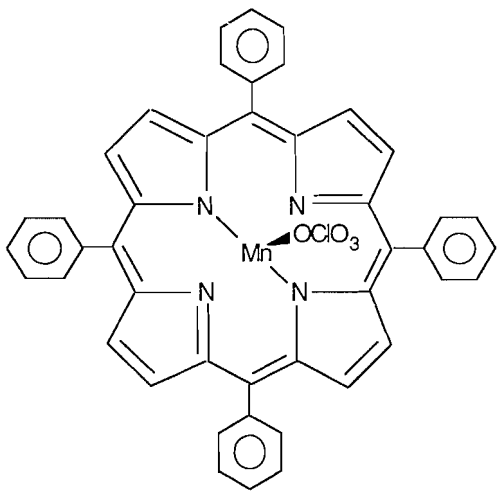
A. Scott Hinman, Karen McGarty, Clement Tang, and Brad J. Pavelich. Can. J. Chem. **67**, 545 (1989).

Perchlorato(tetraphenylporphinato)manganese(III) ($TPPMnClO_4$) is shown to be a useful reagent for the determination of a variety of anions in nonaqueous media. The analysis is based on the displacement of coordinated perchlorate by more strongly coordinating anions as monitored spectrophotometrically. The procedure is demonstrated for the determination of tetraalkylammonium salts of nitrate, nitrite, chloride, bromide, iodide, acetate, trifluoroacetate, cyanate, and thiocyanate in acetonitrile. Relative precisions and accuracies of the order of five parts per thousand are indicated.

Key words: perchlorato(tetraphenylporphinato)manganese(III), specrophotometric determination of anions, anions in nonaqueous media.

A. Scott Hinman, Karen McGarty, Clement Tang et Brad J. Pavelich. Can. J. Chem. **67**, 545 (1989).

On démontre que le perchlorato(tétraphénylporphinato)manganèse(III) ($TPPMnClO_4$) est un réactif utile pour déterminer divers anions dans des milieux non-aqueux. L'analyse est basée sur une détermination spectrophotométrique du déplacement du perchlorate par des anions qui se coordonnent plus fortement. On démontre l'utilité de la méthode par la détermination du nitrate, du nitrite, du chlorure, du bromure, de l'iodure, de l'acétate, du trifluoroacétate, du cyanate et du thiocyanate de tétraalkylammonium dans l'acétonitrile. On a évalué que les précisions et les exactitudes relatives sont de l'ordre de cinq parties par mille.



Mots clés : perchlorato(tétraphénylporphinato)manganèse(III), détermination spectrophotométrique des anions, anions dans des milieux non-aqueux.

Introduction

In nonaqueous solvents, a great number of common anions can be solubilized through the use of large organic countercations. Tetraalkylammonium ions are probably the most frequently employed in this regard, and a great number of tetraalkylammonium salts are commercially available. Many such salts are either deliquescent, or extremely hygroscopic, and it can thus be difficult to prepare solutions with accurately known concentrations. In this paper, we report on the use of perchlorato(tetraphenylporphinato)manganese(III) ($TPPMnClO_4$, **I**) as a reagent for spectrophotometric assay of a number of anions in nonaqueous solvents.

I

[1]Author to whom correspondence should be addressed.

It has long been known that $TPPMn^+$ forms 5-coordinate complexes of the type TPPMnX with a great number of anions, and that the electronic spectrum of the complexes in noncoordinating solvents is sensitive to the identity of the anion X^- (1, 2). Six-coordinate complexes with two axially bound ligands are also known (2–5), but these are few in comparison to the number of 5-coordinate complexes identified. Perchlorate ion in $TPPMnClO_4$ has been shown by conductometric studies to remain coordinated to the central metal atom of the complex in noncoordinating solvents (2). Our studies indicate that it can be quantitatively replaced even by anions as normally poorly coordinating as nitrate, according to reaction [1].

[1] $TPPMnClO_4 + X^- \leftrightarrow TPPMnX + ClO_4^-$

We have exploited the large changes in the visible spectrum of the complex resulting from the metathesis to assay tetrabutylammonium salts (TBAX) of nitrate, nitrite, acetate, trifluoroacetate, thiocyanate, cyanate, bromide, and iodide, as well as tetraethylammonium chloride (TEACl), by spectrophotometric titration in toluene/acetonitrile solvent mixtures.

Experimental

Tetraalkylammonium salts

Tetra-*n*-butylammonium (TBA) salts of nitrate, nitrite, and cyanate were obtained from Fluka. TBABr was from Aldrich, and TBAI and TEACl (TEA = tetraethylammonium) were MCB reagents. These salts had all been utilized in previous unrelated experiments, and exposed to the atmosphere for varying periods of time (overnight in the case of TEACl). With the exception of TBABr, which was dried under vacuum at 70°C for a minimum of 4 h, no attempt was made to dry the salts, so the assays reported here should not be taken as an indication of the purity as obtained from the manufacturer.

$TBA(CF_3CO_2)$ was prepared by combining 5.36 g of CF_3CO_2H (Aldrich) with 32.3 g of TBAOH (40 wt% aq., Aldrich). The solution was extracted with five 40 mL portions of CH_2Cl_2 which had

[a]Concentration used for determination of molar absorptivities was determined by titration with standard TBABr.

[b]Wavelengths and molar absorptivities determined from solutions prepared from the solid complex assuming 100% purity.

[c]Wavelengths and molar absorptivities determined following addition of solid TBAX to a standard solution of $TPPMnClO_4$.

previously been shaken with basic alumina and filtered. The CH_2Cl_2 extracts were dried over anhydrous $MgSO_4$ (15 g). Removal of the CH_2Cl_2 under vacuum left an oily residue. This was dried in a vacuum oven at 95°C overnight. The salt was molten at this temperature but solidified on cooling. The resulting solid (13.9 g) had a slightly yellowish colour and an acrid odour, suggesting that some decomposition occurred during the drying process. The presence of $CF_3CO_2^-$ was indicated by a strong band at 1688 cm^{-1} in the ir spectrum in CH_2Cl_2. The salt is deliquescent.

TBA(CH_3CO_2) was prepared in a similar fashion to the $CF_3CO_2^-$ salt by combining 4.27 g of glacial acetic acid with 25.8 g of 40% aq. TBAOH. This was extracted with eight 50 to 60 mL portions of ethylacetate. The extracts were combined and dried over anhydrous $MgSO_4$ (30 g). White crystals were obtained on concentrating the solution. These were collected, washed with diethylether, and dried under vacuum at 60°C. The yield was 6.59 g. The presence of $CH_3CO_2^-$ was verified by a strong band at 1581 cm^{-1} in the infrared spectrum observed in CH_2Cl_2.

TBA(SCN) was prepared by combining equimolar quantities of $TBAClO_4$ (Fluka, 11.38 g dissolved in 40 mL absolute ethanol) and KSCN (3.23 g dissolved in 60 mL absolute ethanol). The resulting white precipitate ($KClO_4$) was removed by filtration. The ethanol was removed from the filtrate by vacuum distillation, leaving an oily residue which solidified on cooling to room temperature. This was dried in a vacuum oven at 85°C, leaving 9.5 g of product. The ir spectrum displays a strong band at 2056 cm^{-1} in CH_2Cl_2, confirming the presenence of the SCN^- anion.

TPPMnX complexes

All of the TPPMnX complexes listed in Table 1 were isolated in the solid state, with the exception of the nitrite complex for which no attempt was made. TPPMn(CH_3CO_2) served as the starting material for all of the complexes. This was prepared by refluxing 3.0 g of tetraphenylporphine ($TPPH_2$, Aldrich) with 2.1 g of Mn(CH_3CO_2)-2·4H_2O in glacial acetic acid (350 mL) for 3 to 4 h. The solution was concentrated to 150 mL by distillation. The crude product was precipitated by slow (overnight) dropwise addition of 500 mL of water. (Rapid addition of water should be avoided as this results in a colloidal suspension from which it is difficult to recover the product.) The solid product was collected by filtration and washed with water. Separation from unreacted $TPPH_2$ was accomplished by washing with methanol. $TPPH_2$ has no significant solubility in methanol, as evidenced by the lack of any observable absorbance of saturated solutions, and is left behind on the filter paper. After concentration of the methanol washings to 100 mL by distillation, 300 mL of water were added dropwise overnight to precipitate the product. This was recrystallized from glacial acetic acid containing 10 vol.% acetic anhydride, and dried in a vacuum oven overnight at 100°C. The ir spectrum observed in a cast prepared by evaporating a concentrated CH_2Cl_2 solution on a KCl window displays a strong broad absorbance at 1542 cm^{-1}, confirming the presence of acetate in the product.

TPPMnX, where $X^- = ClO_4^-$, I^-, Br^-, Cl^-, NO_3^-, or $CF_3CO_2^-$, were prepared by dissolving 100 to 200 mg of TPPMn(CH_3CO_2) in 150 ml of methanol. Two to three mL of a 1 *M* aq. solution of the appropriate acid HX were added, and the products were precipitated by slow overnight addition of 300 to 400 mL of water from a dropping funnel. These were collected by filtration and dried in a vacuum oven at 100°C. That the exchange reactions were successful was indicated by the absence of any band ascribable to acetate in ir spectra of the complexes observed as casts from CH_2Cl_2. Appropriate bands for the coordinated anions were present in ir spectra of the ClO_4^- (1131 cm^{-1}), $CF_3CO_2^-$ (1699 cm^{-1}), and NO_3^- (1285 cm^{-1}) complexes. We have not observed any shock sensitivity associated with $TPPMnClO_4$, consistent with previous workers (2) observations, but **since perchlorate salts pose potential explosion hazards, appropriate precautions should be observed in preparing or handling large quantities of this material**.

TPPMnX, where $X^- = OCN^-$ or SCN^-, were prepared from TPPMn(CH_3CO_2) similarly to the procedure described above, except that the solid potassium salts, KX, were employed rather than the acids, HX. These were dissolved in the methanol/porphyrin solution in 20-fold excess prior to precipitation of the porphyrin complex via addition of water, as above. Again, the ir spectra of the products showed no indication of acetate, but displayed appropriate bands for coordinated SCN^- (2028 cm^{-1}) or OCN^- (2168 cm^{-1}). All of the TPPMnX complexes isolated in the solid state gave visible spectra identical to those observed on titration of $TPPMnClO_4$ with the appropriate tetraalkylammonium salt, giving further confirmation of the identity of the coordinated anion.

Analyses

Stock $TPPMnClO_4$ solutions for the spectrophotometric titrations were prepared in toluene and filtered prior to standardization. Concentrations were 2.5 to 3.0 × 10^{-7} mole per g of solution, and were accurately determined by titration with standard TBABr solutions. Stock solutions of the tetraalkylammonium salts were prepared in CH_3CN. Concentrations of these solutions were 0.8 to 3.0 × 10^{-5} mole per g of solution. These solutions were used directly for the alternate analyses, but were diluted approximately 10-fold for spectrophotometric titrations.

Spectrophotometric titrations utilized a Cary model 16 uv-vis spectrophotometer. In all cases a 1 mm pathlength cylindrical quartz cell was utilized for absorbance measurements. This was fitted by means of a ground glass joint to the bottom of a 50 mL round bottom flask, which served as the titration vessel. After addition of a quantity of titrant, the cell/flask assembly was inverted several times to ensure complete mixing of the solutions before recording an absorbance measurement. In a typical experiment, *ca.* 10 g of the stock $TPPMnClO_4$ were delivered to the titration vessel from a polyethylene squeeze bottle. The exact quantity delivered was determined by weight loss of the squeeze bottle. Thirty mL of toluene and 2 mL of CH_3CN were then added to the titration vessel. This solution was then titrated with the tetraalkylammonium salt solution, monitoring the absorbance of the solution after each addition of titrant. The titrant was delivered from a polyethylene squeeze bottle fitted with a piece of fine bore HPLC tubing for delivery, and the quantities delivered were determined by weight loss.

Gravimetric determination of TBA as the tetraphenylboron (TPB) salt was employed for comparative assays of the $CH_3CO_2^-$, $CF_3CO_2^-$, NO_3^-, NO_2^-, and OCN^- salts. Typically, 10 g of the stock TBAX/CH_3CN solutions were combined with 30 mL of a 0.1 *M* aqueous acetate buffer solution. A 0.05 *M* aqueous solution of NaTPB (Fisher) was then added slowly from a buret to provide a 2-fold excess. The resulting solutions were warmed to *ca.* 50°C to promote coagulation of the precipitate. In some cases it was necessary to add an additional 1 to

For personal use only.

2 g of $NaCH_3CO_2$ to bring about coagulation. The precipitates were collected on previously dried and tared Gooch crucibles, washed with aq. 0.1 *M* CH_3CO_2H, and dried overnight at 105°C. A similar procedure was employed for the gravimetric determination of Cl^- as AgCl in the TEACl solutions, except that aqueous $AgNO_3$ was employed as the precipitating agent.

Stock solutions of TBABr and TBAI were analyzed by potentiometric titration with standard $AgNO_3$. Aliquots (20 g) of the TBAX/CH_3CN solutions were titrated with standard 0.02 *M* $AgNO_3$ in $H_2O/CH_3CN/MeOH$ (10/20/70 vol%) delivered from a 50 mL buret. The potential difference of a Ag wire with respect to a commercial aq. SCE was monitored with a pH meter. The titrations gave the normal sigmoidal curves, and endpoints were determined by conventional means. It is well known that titrations of aq. I^- solutions with aq. Ag^+ frequently give rise to a hump on the rising portion of the sigmoidal titration curve due to the adsorption of I^- onto the colloidal AgI particles (6). This was not observed under our conditions.

The TBASCN/CH_3CN stock solution was analyzed by using it to titrate weighed quantities of $AgNO_3$ (*ca.* 100 mg) dissolved in *ca.* 20 mL of 0.1 *M* acetate buffer. The titrant was delivered from a squeeze bottle, and quantities determined by weight loss. The titrations were followed by measuring the potential difference of a Ag wire as measured with respect to a glass pH electrode.

Recovery of $TPPMnClO_4$

Because $TPPMnClO_4$ is not, to our knowledge, commercially available, it is desirable to be able to recover the reagent. This was conveniently accomplished by collecting all solutions from the spectrophotometric titrations, regardless of the anion, in an evaporating dish and allowing the solvent to evaporate in a fume hood. The $TPPMn^+$ was recovered in the perchlorate form by precipitation from a methanolic solution containing excess 1 *M* aq. $HClO_4$, as described above for the original preparation of the compound from TPPMn-(CH_3CO_2). A single precipitation appears to be adequate, although the procedure can be employed twice to ensure complete replacement of all other anions. The procedure provides 100% yield, as indicated by the absence of colour in the filtrate. In some instances, the methanol porphyrin solutions were first treated with $AgClO_4$ to remove halides, but this appeared to result in some decomposition of the porphyrin, resulting in lower yields.

Results and discussion

Spectra of the complexes

Table 1 indicates the major visible absorption bands and apparent molar absorptivities in reagent grade toluene of $TPPMn^+$ complexes of all the anions employed in this study. The Roman numeral designation of the bands is that originally employed by Boucher (1). The spectra are not significantly affected on addition of up to 10% acetonitrile. The spectrum of the perchlorate complex differs significantly from that of all other complexes investigated. Band V, in particular, differs significantly in wavelength and/or molar absorptivity for the TPPMnX complexes as compared to $TPPMnClO_4$, and can be used to monitor the conversion of $TPPMnClO_4$ to TPPMnX.

Figure 1 illustrates the spectral changes observed during the titration of $TPPMnClO_4$ with $TBANO_3$. The spectrum of the nitrate complex resembles that of the perchlorate complex more closely than any of the other anions involved in this study. Even so, it is evident from the figure that the visible spectrum provides a sensitive probe for following the formation of the nitrate complex.

Figure 2 illustrates the absorbance monitored at the wavelength of band V of the nitrate complex during a titration of $TPPMnClO_4$ with $TBANO_3$. Two linear regions are observed, intersecting at a nitrate to porphyrin molar ratio of unity. The first of these corresponds to increased absorbance due to the formation of the nitrate complex. The slightly negative slope in the second region results from dilution of the porphyrin complex on addition of titrant. Because the volume of the titrant added is small in comparison to the volume of the porphyrin solution, the dilution factor is small and can be considered constant throughout the titration.

The titration curve of Fig. 2 shows little, if any, curvature in the region of the equivalence point. The equilibrium constant associated with the titration reaction under the conditions employed is thus clearly large enough to be of analytical utility. Similar titration curves are obtained on monitoring the appropri-

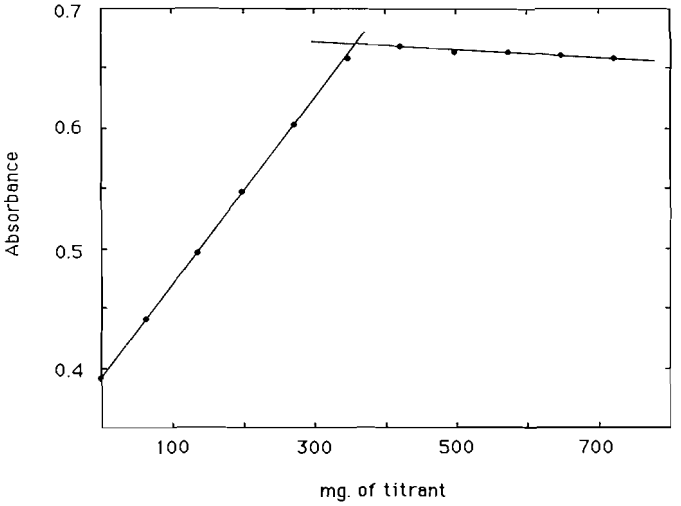

FIG. 2. Absorbance monitored at 476 nm during the titration of 2.3 mg of $TPPMnClO_4$ in 40 mL. of toluene/5% CH_3CN with $TBANO_3$ in CH_3CN (8.6×10^{-6} mol per g of solution). The pathlength was 1 mm.

ate band V absorbance when $TPPMnClO_4$ solutions are titrated with each of the anions listed in Table 1. It should be noted that during the early stages of most of the titrations employing band V, the wavelength will lie on the shoulder of the peak V absorbance for the perchlorate complex, rather than on a maximum. The absorbance will thus be quite sensitive to small variations in the wavelength. Measurements with the spectrometer set to a fixed wavelength throughout the titration are therefore preferable to those associated with spectral scans.

Most of the anions investigated show spectra more drastically different from that of the perchlorate complex than is apparent in Fig. 1 for titration of $TPPMnClO_4$ with nitrate. Figure 3 illustrates the spectral changes observed on titration of $TPPMnClO_4$ in toluene containing 5% acetonitrile with an acetonitrile solution of TBAI. It is apparent that, in this case, several wavelengths could be monitored to follow the complexation of I^- to the porphyrin. In particular, the $TPPMn^+$ complexes of I^-, Br^-, Cl^-, SCN^-, OCN^-, and NO_2^- all display band III absorbance at significantly higher wavelength than is observed for the perchlorate complex. These anions could thus readily be determined by monitoring the appropriate band III wavelength of the complex. Inspection of Table 1 reveals that, in general, the molar absorptivity associated with band III is lower by nearly an order of magnitude compared to that of band V. The availability of different wavelengths with different associated molar absorptivities is important in terms of providing versatility in choosing concentrations and/or optical pathlengths to be employed in the analytical procedure.

Analytical results

Table 2 illustrates replicate assays of some solid tetraalkylammonium salts as determined by the titration of $TPPMnClO_4$ in toluene/ 5% acetonitrile with acetonitrile solutions of the salt. The average values, $\bar{x}$, and standard deviations, σ_{n-1}, associated with these analyses are also included. TBABr is not included in the table as this salt served as a standard for determination of the porphyrin concentrations. In all cases the absorbance of band V of the complex was monitored and the endpoint was taken as the intersection of the two least squares lines obtained prior to and following the equivalence point. Although it is probable that a wide variety of solvents could be employed (see below), acetonitrile was specifically chosen as solvent for the salts since its miscibility with water allowed comparative assays to be obtained utilizing more conventional aqueous based methods. Results of these alternate assays are also included in Table 2.

In our hands, and following the procedures outlined in the Experimental section, titration of $TPPMnClO_4$ affords a relative precision generally better than 0.5% in assays of the various salts investigated. The only instance where a standard deviation better than this was not obtained was in the analysis of $TBANO_3$ solutions. While it is not clear that the somewhat greater standard deviation obtained in this case is significant, the spectrum of the nitrate complex does more closely resemble that of the perchlorate than most of the other anions. Also, nitrate is probably the most weakly coordinating anion investigated. It is possible that these factors are reflected in the precision.

It is evident in inspecting Table 2 that the results obtained by the spectrophotometric titrations, in general, agree within a few parts per thousand of those obtained by the alternate method of analysis, attesting to the general accuracy of the procedure. The exception is the trifluoroacetate case, where the spectrophotometric analysis afforded an average assay 1.4% higher than that indicated by gravimetric precipitation of the tetrabutylammonium counterion with tetraphenylboron. This difference does appear to be significant. Four different solutions of the trifluoroacetate were analyzed by both methods, and the spectrophotometric results were always higher by approximately 1.5% than the gravimetric results. There do not appear to be any problems inherent with the spectrophotometric procedure as applied to trifluoroacetate, however, as the spectra show several clearly defined isosbestic points during the titration, and plots of absorbance versus quantity of titrant show no departures from linearity or curvature in the endpoint region. As noted in the experimental section, some decomposition of this salt was indicated at the high temperatures employed to remove water, and this could be responsible for the apparent discrepancy in the analytical results. The presence of some trifluoroacetic acid formed via a Hoffman elimination reaction, for instance, would be anticipated to result in higher values for the spectrophotometric procedure since the cation, H^+, would not precipitate tetraphenylboron.

The list of anions determinable by this procedure probably goes beyond those included in the present study. Both azide (2) and cyanide (5) are known to form complexes with $TPPMn^+$ with spectra significantly different from that of the perchlorate complex, and these anions might well be determinable by this procedure.

Standardization of $TPPMnClO_4$

KBr disk infrared spectra of $TPPMnClO_4$ frequently display a broad absorbance near 3400 cm^{-1}, suggesting the presence of occluded water. This is lost only slowly with extended periods of drying in a vacuum oven at 105°C. For this reason it is necessary to standardize solutions of the porphyrin to be employed in analysis. Commercially available tetrabutylammonium bromide from Aldrich was found to be satisfactory for this purpose. After drying in vacuum at 70°C for 4 h, this salt afforded assays of 99.9, 100.1, and 100.2% by potentiometric titration with standard silver nitrate, and 99.8% by gravimetric precipitation of tetrabutylammonium ion with tetraphenylboron.

Titration with TBABr has indicated purities of greater than 99% for $TPPMnClO_4$ samples where these have been left in a vacuum oven at 105°C for 2 days or longer. Assays of 90 to 95%

are more common for samples which have been stored on the shelf for some time or have been subjected to shorter drying periods. This variability in the purity of the solid reagent does not affect its utility as an analytical reagent other than imposing the requirement of standardization. Once standardized, solutions of $TPPMnClO_4$ in toluene appear to be indefinitely stable when tightly sealed and stored in the dark. Identical standardizations by TBABr titration were obtained for the same solution 3 months apart.

Where lower precision is acceptable, it may be possible to use the initial absorbance of the $TPPMnClO_4$ solutions to determine their concentrations. We would caution, however, that the molar absorptivities of Table 1 were calculated from single absorbance measurements rather than Beer's law plots. The possibility of aggregration at higher concentrations, or dissociation of perchlorate at lower concentrations, should be ruled out before attempting to apply the simpler analytical procedure. Also, Kelly and Kadish have reported that the spectrum of $TPPMnClO_4$ is sensitive to solvent (2).

Solvents

It is clear that the choice of solvent, or solvents, is an important factor in the success of the analytical procedure. While titration of $TPPMnClO_4$ in toluene/5% acetonitrile with $TBANO_3$ in acetonitrile gives sharply defined endpoints, significant curvature in the endpoint region becomes apparent when similarly titrating porphyrin solutions in toluene containing 10% acetonitrile, and no endpoint is apparent at all for titrations of the porphyrin in acetonitrile alone. Titration of acetonitrile solutions of the porphyrin with chloride, on the other hand, gives rise to sharply defined endpoints with no apparent curvature near the equivalence point. Thus, while acetonitrile may effectively inhibit coordination of weakly coordinating anions such as nitrate, more strongly coordinating anions can still be analyzed in this more polar solvent. None of the anions could be determined by titration of methanol solutions of the porphyrin, but nitrate, trifluoroacetate, and chloride all gave well defined endpoints on titrating the porphyrin in 1,2-dichloroethane or dichloromethane.

While we have not conducted a complete investigation of the relative coordinating ability of the various anions employed in our work, or of the influence of various solvents, Kelly and Kadish (2) have reported on the coordination chemistry of a variety of TPPMnX compounds in twelve nonaqueous solvents, and their work should be consulted when considering analysis of anions in various solvents or solvent mixtures. In brief, they report that strongly bonding solvents coordinate to the porphyrin forming complexes of the type TPPMn(L)(X) and $TPPMnL_2^+$ (L = solvent). The extent to which these reactions occur depends on the particular anion involved, the donor number and dielectric constant of the solvent, and ionic strength. (The spectra of TPPMn(L)(X) complexes do not significantly differ from those of the TPPMnX complexes, so that coordination of a single solvent molecule should not preclude the observation of a sharply defined endpoint.)

Conclusions

$TPPMnClO_4$ serves as a convenient reagent for the spectrophotometric determination of a wide variety of anions under nonaqueous conditions. The anions can be determined in solution following dissolution of the solid salt, avoiding uncertainties in the solution concentrations associated with the weighing of very hygroscopic materials, or from the use of salts of uncertain composition. The reagent is readily prepared from commercially available materials, very little is required per analysis, and it can be conveniently recovered.

μ_4-Oxo-hexa-μ-chloro-tetrakis{(dimethyl sulfoxide)copper(II)}·dimethyl sulfide, from the reaction of copper metal, dimethyl sulfoxide, and carbon tetrachloride crystallizes as orange crystals in the orthorhombic noncentrosymmetric space group $P2_12_12_1$ with a = 10.5820(20), b = 10.5710(20), and c = 28.255(5) Å and Z = 4. The chirality of the individual molecules is attributed to twists of the planes of the sulfur and carbon atoms of the dimethyl sulfoxide ligands relative to the oxygen–copper–oxygen axes.

Key words: crystal structure, copper cluster complex.

Introduction

It has recently been reported that copper metal is dissolved at room temperature by a solution of dimethyl sulfoxide (DMSO) containing CCl_4 to yield dimethyl sulfide and $CuCl_2(DMSO)_2$ (1). No other copper-containing species were identified in this reaction. Similar results had been previously reported as part of a more extensive article (2). A considerably earlier publication (3) discussed the mechanism of the oxidation of Cu(I) chloride in DMSO–CCl_4 to yield Cu(II) along with carbon monoxide and carbon dioxide. These early workers made the point that all the Cu(I) is not oxidized to Cu(II) even with an excess of DMSO–CCl_4 but they were unable to identify the nature of the copper species. The crystal structure of $CuCl_2(DMSO)_2$ has been determined (4). We have been able to isolate in addition appreciable yields of μ_4-oxo-hexa-μ-chloro-tetrakis{(dimethyl sulfoxide)copper(II)}·dimethyl sulfide, **I**, from the reaction of copper metal, DMSO, and CCl_4.

I, without the solvated dimethyl sulfide, was first prepared from a refluxing mixture of $CuCl_2$ and CuO in methanol (5), and subsequently by decomposition of a phenoxo complex of Cu(II) (6). The crystal structure of $Cu_4Cl_6OL_4$, where L = diethyl sulfoxide, an analog of **I**, has been determined (7). The structures of many other $Cu_4Cl_6OL_4$ clusters have been solved but none of these has an inherent chirality (8–15). In the present article we will describe certain structural features of **I**.

Experimental

Chemicals

Copper powder (New Jersey Zinc Co.), cuprous chloride (Anachemia Chemicals), dimethyl sulfoxide (Baker Chemicals), carbon tetrachloride (Anachemia Chemicals), hexanes (BDH Chemicals), and absolute ethanol (des Alcohol de Commerce, Ltee.) were used as received.

Preparation of $Cu_4Cl_6O(DMSO)_4\cdot(CH_3)_2S$: Copper powder (0.635 g, 10 mmol) was stirred at room temperature in 20 mL of a 10:1 v/v solution of DMSO and CCl_4 until a homogeneous green solution was obtained. To this solution 20 mL absolute ethanol and 10 mL hexanes were added to give a green precipitate of $CuCl_2(DMSO)_2$ which was separated by filtration (mp 150–153°C, lit. 153–155 (16); ν_{S-O} 986 cm^{-1}, lit. 987 (16)). Orange crystals of **I** were obtained from the yellow–green filtrate by adding a further 20 mL of hexanes (or a 5:1 ratio of hexanes and CCl_4) and leaving the solution for a few hours at room temperature. In several preparative runs 0.2 to 0.7% CuCl was added to initiate dissolution of the copper powder (1). Isolated yields of 0.46 to 0.68 g of **I** were obtained. *Anal.* Calcd. for $Cu_4Cl_6O_5S_5C_{10}H_{30}$: C 14.00, H 3.52; found: C 14.48, H 3.51.

Microanalyses were performed by Mr. H. Seguin of the National Research Council of Canada. Infrared spectra were obtained on KBr pellets with a Perkin-Elmer 683 spectrometer.

X-ray diffraction intensities of a 0.25 × 0.10 × 0.03 mm crystal were collected at room temperature to $2\theta_{max}$ = 120° using a Picker diffractometer with graphite monochromatized CuK_α, radiation using the $\theta/2\theta$ scan technique with profile analysis (17). A total of 4675 unique reflections was collected in the octants $\pm h$, $\pm k$, and $\pm l$, of which 3883 reflections were considered significant with $I_{net} > 2.5\sigma(I_{net})$. In addition, 220 equivalent reflections were measured which yielded an agreement index of 0.031. Absorption corrections were made since μ = 104.6 cm^{-1}. The minimum and maximum transmission factors are 0.0497 and 0.4184. Cell parameters were obtained by least-squares refinement of the setting angles of 35 reflections with 2θ in the range 60–75° (CuK_α λ = 1.54056 Å). The structure was solved by direct methods and refined by full-matrix least-squares techniques. All calculations were performed using the NRCVAX program system (18). The final residuals are R_F 0.048 and R_W 0.057 for the significant data using unit weights, and R_F 0.063, R_W 0.070 for all reflections. An unbonded molecule of dimethyl sulfide was found for each copper cluster in the unit cell. All atoms were refined anisotropically except for the sulfur of the dimethyl sulfide molecule. This atom has a two-fold disorder with equal occupancy and therefore was refined isotropically.

The final atomic positional parameters and the mean of the principal axes of the thermal ellipsoids are listed in Table 1. The anisotropic temperature factors and the final structure factors are deposited as supplementary material.[2] The chirality parameter eta (19) refined to a

value of 1.19(14), confirming that the chirality of the structure is as reported in Table 1.

Results and discussion

It is not possible to derive **I** directly from $CuCl_2(DMSO)_2$ by a re-arrangement since the stoichiometry is different. It can therefore be concluded that the mechanism suggested for the dissolution of copper metal by CCl_4–DMSO (1) is not sufficient to explain all the observed products. The overall net equation [1] is

$$[1]\quad 2Cu + 2CuCl + 2{:}CCl_2 + 3(CH_3)_2SO \rightarrow Cu_4Cl_6O + 2CO + 3(CH_3)_2S$$

required for the formation of Cu_4Cl_6O, the kernel of **I**. The implication is that there must be a transfer of oxygen from DMSO directly to copper in some step of the reaction sequence, as well as oxygen transfer to dichlorocarbene which has been proposed as a reaction intermediate (1, 3).

The kernel of **I** is an oxygen surrounded tetrahedrally by four copper atoms. Each copper atom has a trigonal bipyramidal configuration with three equatorial chlorine atoms and two axial oxygen atoms. Therefore, the second nearest neighbours of the central oxygen atom are an octahedron of chlorines and the third nearest neighbours a tetrahedron of oxygens. This kernel structure is shown in Fig. 1 with the addition of the sulfur atoms of the co-ordinated DMSO molecules. A list of the bond distances and bond angles is presented in Table 2.

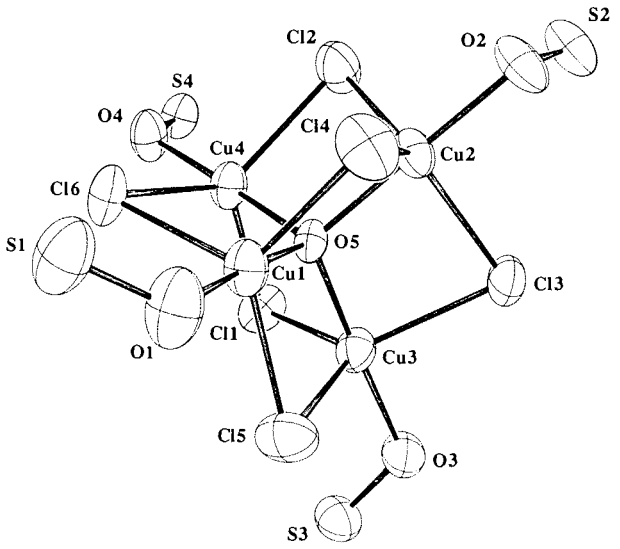

FIG. 1. The kernel structure of **I** with added sulfur atoms of the dimethyl sulfoxide ligands.

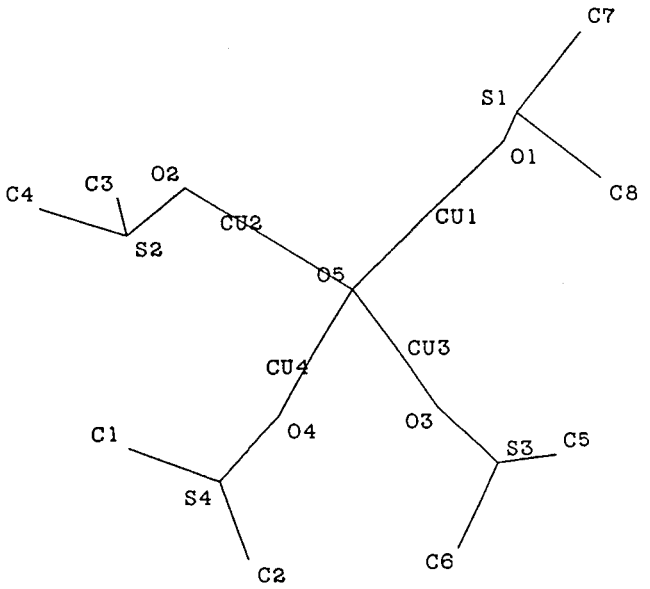

FIG. 2. A structure of **I** with the chlorine and dimethyl sulfide atoms deleted.

There is a slight, but significant distortion of the copper atoms from a perfect tetrahedral arrangement about the central oxygen with bond lengths varying from 1.868(10) to 1.917(9) Å and angles from 107.4(5) to 110.2(4)°. These results are very similar to those reported for the closely related molecule with diethyl sulfoxide as ligand (7). However, the DMSO oxygens of the third nearest neighbours have a smaller variation in the lengths of their bonds to copper (1.920(10) to 1.943(11) Å) and the bonds are significantly longer than for the diethyl sulfoxide analog (7). The copper–chlorine bond lengths range from 2.374(4) to 2.464(4) Å with a mean of 2.412 and an average deviation of 0.021 Å. These are similar to, but marginally longer than the bonds of the diethyl sulfoxide analog (7). A slight distortion from trigonal–bipyramidal geometry is observed in the equatorial plane of the copper atoms where the Cl—Cu—Cl bond angles vary between 113.5(2) and 125.2(2)° with a mean

value of 119.3° and an average deviation of 2.8°. This is considerably less distortion than that found for the diethyl sulfoxide analog (7). The sulfur–oxygen bond lengths vary from 1.516(11) to 1.538(11) Å. There does not appear to be any correlation among the varying values for all the preceding bond lengths and angles.

A significant feature in the structure of **I** is the location of the sulfur–oxygen bonds with respect to the copper–chlorine bonds. Three of the bonds from oxygen to sulfur roughly bisect the angle between two of the chlorines attached to the appropriate copper and are trans to the third chlorine. Figure 1 clearly shows that the bond O2—S2 is between Cl 2 and Cl 3 and *trans* to Cl 4. The same spatial relationships hold for the bond O3—S3 with C15, C11, and C13 and for the bond O4—S4 with C11, C12, and C16. The fourth oxygen sulfur bond O1—S1 is parallel to the Cu4—C16 bond and directed away from C14 and C15. C7 and C8, which are attached to S1, have much larger thermal parameters than the carbon atoms of the other dimethyl sulfoxide ligands suggesting some disorder. The length of the S1—C7 bond at 1.707(23) Å is much shorter than the average value for the other S—C bonds at 1.80(2) Å. For the diethyl sulfoxide analog a methyl group on each of two ligands showed similar thermal disorders (7). The sulfur atom of the dimethyl sulfide of solvation may occupy either of two sites, S5 or SS5. There are no non-bonded atoms within 3.5 Å of this sulfur so the disorder is not readily explicable. A stick diagram of **I** is presented in Fig. 2 to identify the complete atom numbering scheme. In every case, the plane generated by the sulfur atom and two methyl carbon atoms of a dimethyl sulfoxide ligand is twisted from a perpendicular intersection with the corresponding oxygen–copper–O5 axis. It is this twist which gives the molecule its chirality in the solid state as required in $P2_12_12_1$.

Étude de l'annélation à partir de dérivés dibromomés-1,4 et -1,5 en présence de carbanions

P. CANONNE[1] ET J. PLAMONDON
Département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Reçu le 5 mai 1988

P. CANONNE et J. PLAMONDON. Can. J. Chem. **67**, 555 (1989).

Les dibromures primaires–secondaires ont été préparés à partir des diols correspondants et employés, avec des acides du carbone, pour la préparation de composés cycliques disubstitués-1,2. L'utilisation d'un acide du carbone non-symmétrique en présence de NaH dans le DME favorise une importante diastéréosélection conduisant à la formation de l'isomère *trans*. Les facteurs qui influencent la stéréosélectivité sont également proposés.

Mots clés: S_N2 intramoléculaire, décarboxylation, acides alkyl-2 cycloalcanecarboxyliques-1, acides alkyl-1 indanecarboxyliques-2.

P. CANONNE and J. PLAMONDON. Can. J. Chem. **67**, 555 (1989).

Primary–secondary dibromides have been prepared from the corresponding diols and used with carbon acids to prepare 1,2-disubstituted cyclic compounds. With unsymmetrical carbon acid in presence of NaH in DME, a high diastereoselection of the *trans* isomer is observed. Factors that affect the stereoselectivity are proposed.

Key words: intramolecular S_N2, decarboxylation, 2-alkylcycloalkanecarboxylic acids, 1-alkylindan-2-carboxylic acids.

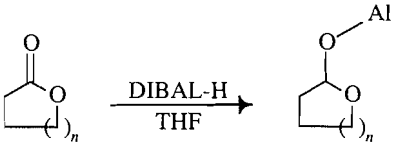
Les travaux de recherche de notre laboratoire ont été principalement axés sur l'élaboration de systèmes cycliques. Nous avons utilisé les réactifs de Grignard bisfonctionnels pour la synthèse des divers composés polycycliques et spiranniques fonctionnalisés (1). Récemment nous avons étudié la stéréochimie de la réaction de Grignard intramoléculaire (2), en utilisant les organodimagnésiens primaires–secondaires, et nous avons préparé stéréosélectivement des composés hydroxylés cycliques alkylés en position 2. En outre, l'introduction d'une fonction carboxylique nous a semblé d'un grand intérêt (3), surtout pour son aspect stéréochimique. Plus particulièrement, la synthèse des composés 1,2-disubstitués en séries cycloalcane et indane a attiré notre attention.

Dans cette perspective de développement de méthodologies intéressantes et rentables, nous nous sommes ainsi intéressés à la recherche des conditions opératoires permettant d'obtenir des acides alkylés en position 2. En effet, la littérature nous révèle que la formation la plus simple des acides méthyl-2 cyclohexanecarboxyliques-1 est basée sur la synthèse diénique (4), alors que celle des acides méthyl-2 cyclopentanecarboxyliques-1 (5) offre plusieurs possibilités mais paraît moins efficace. Par ailleurs, la synthèse des acides alkyl-2 cycloalcanecarboxyliques homologues ne semble pas être rapportée dans la littérature. Les méthodes de synthèse proposées pour la préparation des acides alkyl-1 indanecarboxyliques-2 sont encore moins satisfaisantes (6).



Pour ces raisons, il nous a semblé important de trouver une méthodologie générale et efficace pour la préparation de ces acides cycliques substitués en position 2 et de leurs dérivés. Nous avons alors entrepris d'examiner la réaction des dibromo-1,4 et -1,5 alcanes avec des acides du carbone, en fonction de la chaîne hydrocarbonée et de la grandeur du cycle.

Pour réaliser une telle étude, nous avons synthétisé (7) des dibromures primaires–secondaires (**21–34**) en se basant sur la transformation des diols correspondants (**3–11** à **16–19**) par le tribromure de phosphore (8) (éq. [1]).

Les α-alkyl benzènediméthanols-1,2 (**16–19**) sont préparés selon une méthode que nous avons mis au point mettant en jeu soit les phtalides substitués correspondants par une simple réduction (éq. [3]), soit dans le cas de α-(méthyl-1 éthyl)-1 benzènedimethanol-1,2 (**20**), par l'action du bromure à isopropylmagnésium sur le phtalide (9). Ces résultats démontrent que notre méthode est de loin la plus générale pour la synthèse des dibromures non-symétriques aussi bien en série à chaîne ouverte que cyclique.

Les dibromures, facilement accessibles par cette méthode, permettent de compléter une série homogène afin de cerner l'influence de la longueur de la chaîne sur la substitution nucléophile intramoléculaire, mettant en jeu un halogénure secondaire comme site réactionnel sensible à la réaction concurrente d'élimination.

Plusieurs nouvelles améliorations ont été proposées pour la réaction de substitution nucléophile, basées sur l'utilisation d'éthers en couronne (10) ou encore de sels d'ammonium quaternaires (11). Quelques essais préliminaires réalisés avec les dibromoalcanes primaires–secondaires n'ont montré aucun avantage appréciable au point de vue des rendements réactionnels mais, au contraire, augmenteraient le coût de revient opérationnel. Ainsi, nous avons retenu la méthode basée sur l'utilisation de l'hydrure de sodium dans le diméthoxy-1,2 éthane à la température ambiante, qui conduit avec des rendements satisfaisants aux composés désirés (**35–46**) et permet de minimiser les réactions secondaires lors de la cyclisation.

Les résultats obtenus sont présentés au tableau 1. De l'ensemble de ce travail, il ressort que la réaction d'élimination se manifeste seulement dans le cas des dihalogénures **26** et **29** qui ont fourni les composés d'annélation **40** et **41** avec des rendements plus faibles. Effectivement, la substitution nucléophile semble être légèrement empêchée en série cyclohexanique. Ainsi, les produits éthyléniques provenant de la réaction d'élimination intramoléculaire sont observés en faibles quantités. Il faut noter, cependant, que cette dernière est moins importante que lors de l'addition nucléophile intramoléculaire réalisée à l'aide des organomagnésiens (12).

On peut supposer que l'addition nucléophile sur le carbone du carbonyle est plus sensible à l'encombrement stérique, ou encore, que le transfert de l'hydrure par un mécanisme à six centres, dans le cas du cyclohexane, est particulièrement favorisé dans les réactions des organodimagnésiens.

Une deuxième analogie découle de cette recherche. Effectivement, quelques soient l'anion et le substrat secondaires, la formation des composés alkyl-2 cyclopentanedicarboxylate-1,1 de diéthyle (**35–39**) est très favorisée comme dans le cas des amines cycliques et autres composés hétérocycliques. Cette constatation rejoint notre première hypothèse concernant la formation des cyclopentanes. Les rendements moins élevés dans cette série ne sont attribuables qu'à une non-réaction, car le dibromure n'ayant las réagi a été récupéré.

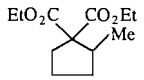
La vitesse des réactions du dihalogénure benzylique **25** et des dihalogénures dibenzyliques (**30–34**) est loin supérieure à celle des alkyles, comme il fallait s'y attendre. Ceci s'explique facilement en tenant compte de la stabilisation électronique de l'état de transition conjugué et de la limitation des degrés de liberté de la chaîne. Ainsi, en présence de malonate de diéthyle dans NaH et DME, les dihalogénures dibenzyliques (**30–34**) ont conduit aisément à la formation des alkyl-1 indanedicarboxylate-2,2 de diéthyle correspondants (**42–46**).

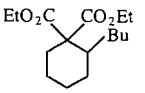
En conclusion, le présent travail démontre que par double substitution nucléophile (attaque sur l'halogénure primaire suivie de l'attaque sur l'halogénure secondaire), la cyclisation s'effectue en une seule étape avec des bons rendements et semble être peu influencée par la nature du groupe alkyle situé sur le carbone secondaire, à l'exception du groupe phényle.

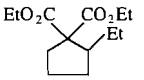
Les diesters ainsi obtenus (**35–39** et **42–46**) sont convertis en acides cyclopentanedicarboxyliques-1,1 (**47–51**) et en acides indanedicarboxyliques-2,2 (**52–56**) par hydrolyse en présence de KOH. La décarboxylation effectuée sous un léger vide, en absence de pyridine, fournit les acides (**57–63**) dont la spectroscopie de résonance magnétique nucléaire du proton révèle que l'isomère *trans* est légèrement favorisé. Ces acides diastéréoisomères sont dosés en se basant sur les signaux du proton en position 1 qui se présentent sous forme de deux multiplets bien séparés. En effet, lorsque le proton est *trans* par rapport au groupe alkyle, il résonne à ~2,80 ppm, et lorsqu'il est *cis*, il subit l'effet de blindage du groupe alkyle et, par conséquent, ce signal se situe à ~2,36 ppm. Ce même phénomène de blindage est constaté dans le cas d'esters méthyliques. Pour confirmer la précision du dosage nous avons également utilisé les signaux de groupe méthyle des esters méthyliques (**64–69**) obtenus par traitement des acides correspondants au diazométhane (tableau 2). La formation préférentielle de l'isomère *trans* observée peut facilement s'expliquer par le fait que le groupe alkyle dans la forme énolique prend la position équatoriale (13) et, par conséquent, la protonation s'effectue sélectivement du côté pseudoaxial.

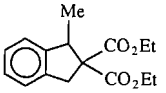
Les résultats de la première partie du présent travail démontrent clairement que la méthode envisagée est générale, à ce qui a trait la réaction du malonate d'éthyle avec un grand nombre de dibromures-1,4 et -1,5 de structures fort variées. En outre, ils suggèrent de reprendre les travaux sur la phénylacetonitrile, précédemment décrits dans la littérature (14, 15), pour les raisons qui motivent notre recherche à savoir :

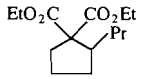
1. Améliorer l'efficacité de la réaction, en choisissant les conditions opératoires favorisant la réaction de substitution intramoléculaire et minimisant les réactions intermoléculaires en général et celles d'élimination intra- ou intermoléculaire en particulier. En effet, les rendements obtenus précédemment (14) étaient inférieurs à 60% lorsque le dihalogénure fut le dibromo-1,4 pentane, incluant le composé d'élimination difficilement séparable du composé cyclique, et de 30% dans le cas du dibromo-1,5 hexane (15).

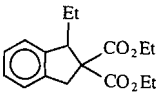


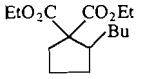


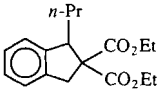


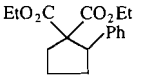


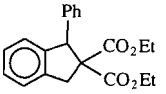


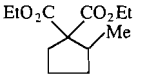


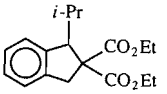












2. Améliorer la diastéréosélection, notamment lorsque les solvants utilisés sont peu dissociants.

3. Enfin, vérifier l'hypothèse précédemment émise à ce qui concerne la stéréosélectivité de la réaction de substitution nucléophile intramoléculaire en fonction de l'encombrement stérique de l'halogénure secondaire (15).

En premier lieu, nous avons vérifié si la nature du solvant ou de la base pouvait influencer la diastéréosélectivité. Pour ce faire, nous avons effectué la réaction de substitution nucléophile intramoléculaire du dibromo-1,4 pentane et du dibromo-

1,5 hexane avec le phénylacétonitrile dans différents milieux en utilisant, d'une part, les solvants et les bases mentionnés en littérature (13) et, d'autre part, en employant l'éther en couronne 18-C-6 afin de cerner si les facteurs précédemment mentionnés sont responsables de la diastéréosélection observée. L'addition de l'éther en couronne dans le milieu réactionnel à faible constante diélectrique, tel que le diméthoxy-1,2 éthane en présence de l'hydrure de potassium, devrait alors conduire à des résultats similaires à ceux obtenus dans le cas des solvants dissociants tels que le diméthylsulfoxyde, puisque l'éther en couronne permet de dissocier la paire d'ions en solution.

En effet, l'examen du tableau 3 ne montre aucune influence significative concernant la nature de la base dans divers solvants à faible constante diélectrique sur le déroulement stéréochimique de la réaction et vérifie les résultats précédemment décrits. Nous n'observons aucune variation importante de la distribution des diastéréoisomères concernant l'utilisation de l'éther en couronne 18-C-6. (La variation est de l'ordre de 5%.)

Dans un deuxième temps, nous avons entrepris une deuxième série de réaction sur le but d'étudier l'influence de la nature du groupe alkyle sur le contrôle stéréochimique de la réaction,

nous avons fait réagir le phénylacétonitrile avec divers dibromo-1,4 et -1,5 alcanes. Les résultats rassemblés au tableau 4 nous indiquent que la stéréochimie de la réaction de substitution nucléophile intramoléculaire est indépendante de la nature du substituant alkyle, contrairement à ce qui a été mentionné dans la littérature (15). Effectivement, quelque soit le dihalogénure utilisé, l'isomère *trans*-CN est majeur, sauf dans le cas du groupe phényle où l'isomère *cis*-CN est nettement favorisé. Nous pouvons également observer que les alkyl-2 phényl-1 cycloalcanecarbonitriles-1 (**62–70**) sont obtenus avec des rendements grandement améliorés (78–95%) aussi bien en série cyclopentanique que cyclohexanique.

En effet, les rendements moins élevés (30–60% selon le solvant) ainsi que la divergence de stéréosélectivité observée en fonction du dibromure chez les auteurs précédents (15) pourraient être attribuables, d'une part, à la faible dilution du milieu dans le DME et, d'autre part, à la température réactionnelle plus élevée. L'examen de leurs résultats montrent un écart beaucoup plus grand aussi bien dans les expériences avec le dibromo-1,4 pentane qu'avec le dibromo-1,4 hexane. Dans ce dernier cas les rendements n'étaient que de 30%.

Nos meilleurs résultats s'expliqueraient par le fait que nous avons opté pour un mode opératoire mettant en jeu des conditions plus douces qui optimisent le rendement global de la réaction (température ambiante, NaH et DME). Il est important de mentionner que nous avons réalisé ces réactions dans un milieu fortement dilué. Ainsi, le dibromure et l'anion ont été préalablement dissous dans les solvants réactionnels car la stéréochimie est influencée par l'homogénéité du milieu réactionnel.

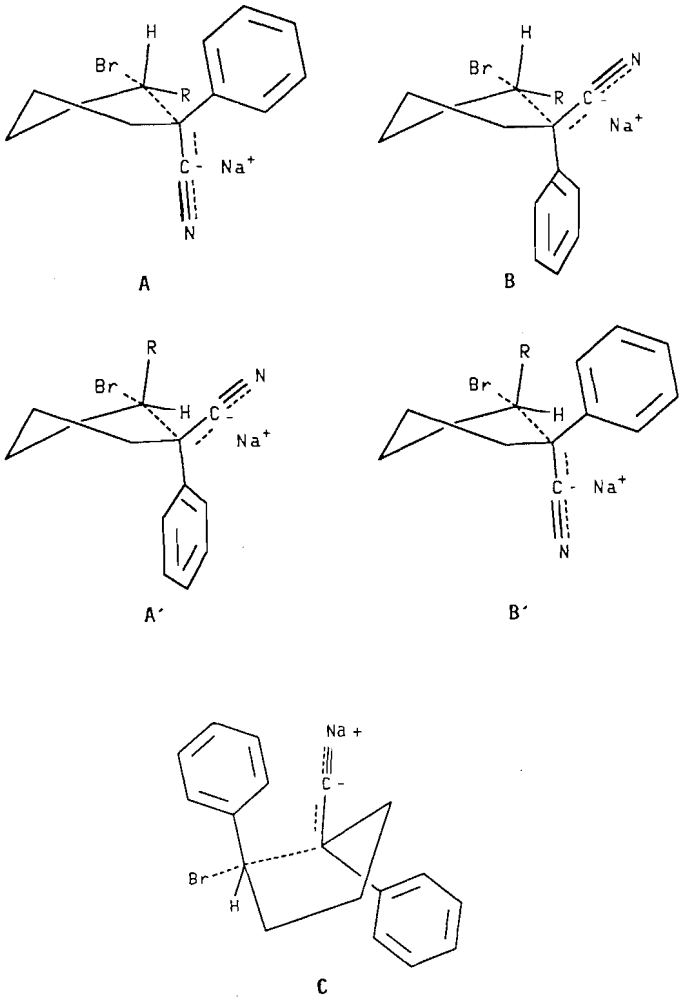

FIG. 1

De l'ensemble de ce travail il ressort que les réactions des dibromo-1,4 et -1,5 alcanes avec le malonate d'éthyle et le phénylacétonitrile conduisent aux composés cycliques correspondants avec des bons rendements quelle que soit la structure du groupe alkyle secondaire.

Il démontre, en outre, que la réaction du phénylacétonitrile est stéréosélective, en favorisant l'isomère *trans*, aussi quelle que soit la structure du groupe alkyle secondaire. L'examen des divers conformères présentés à la figure 1 indique que les A, A′ conduisent après cyclisation aux isomères *cis* alors que les conformères B, B′ conduisent aux isomères *trans* — composés majeurs.

Comme précédemment (14), nous retenons la délocalisation de la charge et la solvatation de l'anion nitrile. Par conséquent nous considérons que, dans tous les cas, le phényle, par son orientation, est moins volumineux que le groupe nitrile. L'état de transition B de la réaction de substitution nucléophile intramoléculaire est incontestablement plus favorisé aussi bien lorsque le groupe R est méthyle que lorsque le groupe R est éthyle, contrairement aux hypothèses précédemment émises (15). De même, en se basant sur les interactions entre atomes non liés, l'état de transition C est privilégié lors de la formation du composé **74***a*. En effet l'état de transition conduisant à l'isomère **74***b* présente un importante encombrement stérique.

La présente étude est surtout importante du point de vue synthétique, car les résultats obtenus nous ont permis d'envisager la synthèse de composés spiranniques intéressants du point de vue biologique.

Partie expérimentale

Les spectres de résonance magnétique nucléaire du proton ont été enregistrés sur les spectromètres 60 MHz Varian EM360A, 90 MHz Bruker HX-90 et 200 MHz Varian XL-200. Les spectres de résonance magnétique nucléaire du ^{13}C ont été déterminés à l'aide d'un appareil Bruker WP-80 (20,1 MHz) et Varian XL-200 multinoyaux (50,3 MHz). La plupart des spectres ont été enregistrés à partir de solutions de chloroforme deutérié et le tétraméthylsilane a été choisi comme standard interne. Les spectres dans le domaine de l'infrarouge ont été tracés à l'aide d'un spectromètre Beckmann (IR-4250). Quant aux spectres de masse, ils ont été effectués à l'aide d'un spectromètre Hewlett Packard 5992 GC/MS.

Les points de fusion, pris en tubes capillaires ouverts à l'aide d'un appareil Thomas–Hoover, ne sont pas corrigés. Les analyses chromatographiques sur couche-mince ont été réalisées sur des plaques de gel de silica 0,25 mm. Les séparations chromatographiques sur colonne ont été effectuées sur gel de silice Woelm (32–63 μm) pour colonne chromatographique « flash ».

Les analyses chromatographiques en phase gazeuse ont été réalisées à l'aide d'un chromatographe Varian 3700 muni d'une colonne de huit pieds 10% Dexsil 300 sur Chromosorb B et d'un détecteur à ionisation de flamme. Les spectres de masse précise ont été enregistrés au Centre régional de spectrométrie de masse à l'Université de Montréal.

Mode opératoire général de synthèse des cycloalcanedicarboxylates-1,1 et indanedicarboxylates-2,2 de diéthyle substitués en β (35–46)

À 0,033 mol d'hydrure de sodium en suspension dans 50 mL de diméthoxy-1,2 éthane (DME), est additionné 0,011 mol de malonate de diéthyle dilué dans 30 mL de DME, sous atmosphère d'azote. On laisse agiter 30 min à la température ambiante, ensuite on additionne goutte à goutte 0,01 mol du dibromure correspondant en solution dans 30 mL de DME. Une fois l'addition terminée, on maintient l'agitation durant 16 h à la même température, et si la réaction est incomplète, alors on porte à 60°C le mélange réactionnel, le temps nécessaire pour que la réaction soit complété. Dans le cas des dérivés d'indane, la réaction est complète après 8 h d'agitation à la température de la pièce. Après avoir refroidi le système à 0°C, on hydrolyse avec de l'acide chlorhydrique à 10%, jusqu'à un pH d'environ 4. On sépare les deux phases et on extrait la phase aqueuse à l'éther. Les extraits organiques sont séchés sur sulfate de magnésium, puis évaporés. On obtient une huile jaunâtre qu'on purifie par chromatographie flash sur gel de silice en utilisant un mélange acétate d'éthyle – éther de pétrole (35–60) comme éluant.

*Mode opératoire général de synthèse des acides cyclopentanedicarboxyliques-1,1 et indanedicarboxyliques-2,2 substitués en β (**47–56**)*

On introduit 16,8 mmol de KOH dans 3 mL d'eau, puis 2,8 mmol de diester dissous dans 3 mL d'éthanol à 95%. On porte à reflux durant une nuit, puis on distille le solvant (distillation azéotropique), on refroidit le résidu, extrait à l'éther afin d'éliminer les produits neutres, puis on acidifie la phase aqueuse à pH 1. On sature la phase aqueuse en chlorure de sodium et extrait de nouveau à l'éther. Les extraits organiques sont lavés à l'eau salée, séchés sur sulfate de magnésium anhydre, filtrés et évaporés. Les diacides obtenus sont purifiés par recristallisation.

*Acide méthyl-2 cyclopentanedicarboxylique-1,1 (**47**)* : Rdt, 78% (4,263 g). Cristaux blancs; F = 171–173°C (litt. *Mode opératoire général de préparation des diastéréoisomères des acides alkyl-2 cyclopentanecarboxyliques-1 et alkyl-1 indanecarboxyliques-2 (**57**–**63**)*

Les acides alkyl-2 cycloalcanecarboxyliques-1 et alkyl-1 indanecarboxyliques-2 sont obtenus par simple décarboxylation thermique à partir des diacides correspondants. Ainsi, dans un montage de microdistillation, on porte 2–5 mmol de diacides à 170–180°C jusqu'à cessation du dégagement de dioxyde de carbone. Afin de s'assurer d'un meilleur rendement, on fait un léger vide pour compléter la réaction. L'acide est estérifié sans purification préalable.

*Acide méthyl-2 cyclopentanecarboxylique-1 (**57**a,b)*

La spectroscopie de rmn ^1H nous révèle que l'isomère *trans* (**57***b*) est majeur (55%); Rdt, 86% (0,158 g). Liquide; Eb (**57***b*) : (litt. (7*a*) Eb (8 Torr) 111°C); Eb (**57***a*) : (litt. (7*a*) Eb (23 Torr) 122–123°C); ir ν_{max} (film, mélange) : 3500–2500, 2960, 2930, 2875, 1705, 1460, 1450, 1420, 1250, 1240 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,99 et 1,10 (3H, 2d, J = 6,96 Hz, CH_3 *cis* et *trans* COOH), 1,20–1,32 (7H, m), 2,40 et 2,80 (1H, 2m, H-1 *trans* et *cis* COOH), 11,78 (1H, COOH) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**57***b*) : 183,12, 51,81, 39,47, 34,91, 30,01, 24,56, 19,59 ppm; δ (**57***a*) : 181,96, 48,37, 37,42, 33,71, 27,34, 23,72, 16,12 ppm.

*Acide éthyl-2 cyclopentanecarboxylique-1 (**58**a,b)*

La spectroscopie de rmn ^1H révèle que l'isomère *trans* (**58***b*) est majeur (59%); Rdt, 89% (0,225 g). Liquide; Eb (mélange) : (litt. (7*a*) Eb (11 Torr) 125°C); ir ν_{max} (film, mélange) : 3500–2500, 2960, 2930, 2875, 1705, 1460, 1450, 1420, 1380, 1290, 1250, 1230 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,90 et 0,96 (3H, 2t, J = 7,33 Hz, CH_3 *trans* et *cis* COOH), 1,21–2,12 (9H, m), 2,36 et 2,84 (1H, 2m, H-1 *cis* et *trans* COOH), 12,08 (1H, s, COOH) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**58***b*) : 183,65, 50,00, 46,20, 32,22, 30,36, 28,05, 24,94, 12,52 ppm; δ (**58***a*) : 182,45, 47,64, 45,73, 30,58, 28,30, 23,94, 23,76, 13,08 ppm.

*Acide propyl-2 cyclopentanecarboxylique-1 (**59**a,b)*

L'analyse de rmn ^1H révèle que l'isomère *trans* (**59***b*) est majeur (51%); Rdt, 99% (0,209 g). Huile; ir ν_{max} (film, mélange) : 3500–2500, 2960, 2940, 2875, 1705, 1470, 1450, 1420, 1290, 1240, 1220 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,90 (3H, t), 1,16–2,11 (11H, m), 2,35 et 2,86 (1H, 2q, H-1, *trans* et *cis* COOH), 12,15 (1H, s, COOH) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**59***b*) : 183,65, 50,37, 44,33, 37,69, 32,65, 30,32, 24,92, 21,44, 14,24 ppm; δ (**59***a*) : 182,49, 47,75, 43,58, 33,18, 30,89, 28,32, 23,79, 21,77, 14,24 ppm. Masse précise pour $C_9H_{16}O_2$: 156,1151; tr. : 156,1162.

*Acide butyl-2 cyclopentanecarboxylique-1 (**60**a,b)*

L'examen des spectres de rmn ^1H révèle que l'isomère *trans* (**60***b*) est majeur (55%); Rdt, 62% (0,142 g). Liquide; ir ν_{max} (film, mélange) : 3500–2500, 2960, 2930, 2875, 1705, 1460, 1450, 1420, 1250, 1230 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,89 (3H, t), 1,12–2,12 (13H, m), 2,36 et 2,86 (1H, 2q, H-1, *trans* et *cis* COOH), 12,11 (1H, s, COOH) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**60***b*) : 183,58, 50,37, 44,49, 35,09, 30,96, 30,88, 30,22, 24,92, 22,86, 14,06 ppm; δ (**60***a*) : 182,43, 47,75, 43,82, 32,67, 30,63, 30,43, 28,32, 23,79, 22,86, 14,06 ppm. Masse précise pour $C_{10}H_{18}O_2$: 170,1307; tr. : 170,1322.

*Acide méthyl-1 indanecarboxylique-2 (**61**a,b)*

En calculant le pourcentage des diastéréoisomères selon l'intégration des signaux du méthyle, on constate que l'isomère *trans* (**61***b*) est majeur (68%); Rdt, 83% (0,244 g). Huile; ir ν_{max} (film, mélange) : 3500–2500, 2935, 1700, 1450, 1250, 1230, 750 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 1,22 et 1,40 (3H, 2d, J = 6,59 Hz, CH_3 *cis* et *trans* COOH), 2,78–3,09 (1H, m, H-2), 3,17–3,40 (2H, m, H-3), 3,44–3,49 (1H, m, H-1), 7,16 (4H, s), 9,12 (1H, COOH) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**61***b*) : 178,57, 145,96, 140,70, 126,40 (2C), 123,91, 122,80, 52,46, 43,00, 35,05, 18,96 ppm; δ (**61***a*) : 177,26, 145,90, 140,48, 126,51 (2C), 124,20, 123,24, 48,35, 41,48, 32,87, 16,83 ppm. Masse précise pour $C_{11}H_{12}O_2$: 176,0838; tr. : 176,0857.

*Acide propyl-1 indanecarboxylique-2 (**62**a,b)*

La spectroscopie de rmn ^{13}C révèle que l'isomère *trans* (**62***b*) est majeur (68%); Rdt, 77% (0,052 g). Huile; ir ν_{max} (mélange) : 3400–2800, 3020, 2960, 2930, 1700, 1250, 750 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,87 (3H, t), 1,20–2,65 (3H, m), 2,75 (1H, m), 2,92 (1H, m, H-2), 3,12–3,24 (2H, m, H-3), 3,25–3,58 (1H, m, H-1), 7,07 (4H, s), 12,13 (1H, COOH) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**62***b*) : 182,45, 145,05, 140,76, 126,70 (2C), 124,48, 123,59, 49,50, 48,41, 35,51, 37,05, 20,08, 14,32 ppm; δ (**62***a*) : 180,32, 144,98, 141,03, 126,75 (2C), 126,02, 124,15, 49,10, 46,70, 33,25, 32,62, 20,28, 14,17 ppm. Masse précise pour $C_{13}H_{16}O_2$: 204,1151; tr. : 204,1158.

*Acide phényl-1 indanecarboxylique-2 (**63**a,b)*

La spectroscopie de rmn ^{13}C révèle que l'isomère *trans* (**63***b*) est majeur (63%); Rdt, 77% (0,0085 g). Huile; ir ν_{max} (mélange) : 3400–2400, 1700, 1475, 1250, 750 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 3,05–3,38 (2H, m, H-3), 3,39–3,48 (1H, m, H-2), 4,74 (1H, m, H-1), 6,88–7,37 (9H, m) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**63***b*) : 180,05, 144,65, 142,98, 140,96, 128,52, 127,37 (2C), 127,10 (2C), 126,90 (2C), 124,93, 124,09, 54,48, 53,83 ppm; δ (**63***a*) : 177,92, 144,60, 142,00, 140,05, 128,46, 128,33 (2C), 128,08 (2C), 126,95 (2C), 125,10, 124,48, 53,83, 50,19 ppm. Masse précise pour $C_{15}H_{15}O_2$: 238,0994; tr. : 238,1002.

*Mode opératiore général de préparation des diastéréoisomères des alkyl-2 cyclopentanecarboxylates-1 de méthyle et alkyl-1 indanecarboxylates-2 de méthyle (**64**–**69**)*

À une solution de 3 mmol d'acide alkyl-2 cyclopentanecarboxylique-1 ou alkyl-1 indanecarboxylique-2 dans 3 mL d'éther, à 0°C, est additionnée une solution éthérée de diazométhane à 70%. Après 1 h d'agitation à 0°C, le solvant est évaporé, et le produit est purifié par une filtration sur gel de silice.

*Méthyl-2 cyclopentanecarboxylate-1 de méthyle (**64**a,b)*

La spectroscopie de rmn ^1H nous révèle que l'isomère *trans* (**64***b*) est majeur (56%); Rdt, 85% (0,589 g). Huile; ir ν_{max} (film, mélange) : 2960, 1730, 1450, 1370, 1265, 1160, 1095 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,89 et 1,05 (3H, 2d, J = 6,99 Hz et 6,35 Hz, CH_3 *cis* et *trans* CO_2CH_3); rmn ^{13}C ($CDCl_3$, mélange) δ (**64***b*) : 175,81, 51,35, 50,79, 38,96, 34,40, 29,61, 24,07, 19,10 ppm; δ (**64***a*) : 174,70, 50,39, 47,77, 37,05, 33,33, 27,12, 23,43, 15,75 ppm. *Anal.* calc. pour $C_8H_{14}O_2$: C 67,57, H 9,92; tr. : C 67,43, H 9,85.

*Ethyl-2 cyclopentanecarboxylate-1 de méthyle (**65**a,b)*

L'intégration des signaux des deux singulets du groupement ester méthylique en rmn ^1H nous indique que l'isomère *trans* (**65***b*) est majeur (57%); Rdt, 84% (0,165 g). Huile; ir ν_{max} (film, mélange) : 2955, 2920, 2860, 1730, 1460, 1430, 1375, 1255, 1165, 1150 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,90 (3H, d de t), 1,09–2,14 (9H, m), 2,33 et 2,84 (1H, 2q, H-1, *trans* et *cis* CO_2Me), 3,65 et 3,67 (3H, 2s, CO_2CH_3, *cis* et *trans*) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**65***b*) : 177,10, 51,46, 49,99, 46,17, 32,11, 30,41, 27,98, 24,74, 13,04 ppm; δ (**65***a*) : 175,83, 50,97, 47,46, 45,60, 30,67, 28,34, 24,07, 23,83, 12,52 ppm. *Anal.* calc. pour $C_9H_{16}O_2$: C 69,19, H 10,32; tr. : C 69,29, H 10,54.

*Propyl-2 cyclopentanecarboxylate-1 de méthyle (**66**a,b)*

La spectroscopie de rmn ^1H nous révèle, d'après l'intégration des signaux des esters méthyliques, que l'isomère *trans* (**66***b*) est majeur (53%); Rdt, 75% (0,146 g). Huile; ir ν_{max} (film, mélange) : 2955, 2920, 2855, 1730, 1460, 1430, 1375, 1255, 1170 cm^{-1}; rmn ^1H

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12

($CDCl_3$, mélange) δ : 0,89 (3H, t), 1,07–2,17 (11H, m), 2,32 et 2,84 (1H, 2m, H-1, *trans* et *cis* CO_2Me), 3,65 et 3,67 (3H, 2s, CO_2CH_3, *cis* et *trans*) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**66***b*) : 177,03, 51,89, 50,30, 44,24, 37,60, 32,51, 30,34, 24,74, 21,34, 14,23 ppm; δ (**66***a*) : 175,80, 50,93, 47,51, 43,48, 33,34, 30,96, 28,32, 23,85, 21,67, 14,23 ppm. *Anal.* calc. pour $C_{10}H_{18}O_2$: C 70,55, H 10,66; tr. : C 70,47, H 10,62.

*Butyl-2 cyclopentanecarboxylate-1 de méthyle (**67**a,b)*

La spectroscopie de rmn ^1H nous révèle que l'isomère *trans* (**67***b*) est majeur (56%); Rdt, 83% (0,131 g). Huile; ir ν_{max} (film, mélange) : 2940, 2920, 2855, 1730, 1465, 1450, 1375, 1255, 1185, 1150 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,88 (3H, t), 1,27 (6H, massif), 1,40–2,18 (7H, m), 2,32 et 2,85 (1H, 2m, H-1, *trans* et *cis* CO_2Me), 3,65 et 3,67 (3H, 2s, CO_2CH_3, *cis* et *trans*) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**67***b*) : 176,57, 51,35, 50,30, 44,40, 34,98, 31,02, 30,78, 30,38, 24,72, 22,79, 13,99 ppm; δ (**67***a*) : 175,76, 50,86, 47,50, 43,73, 32,53, 30,78, 30,31, 28,34, 23,81, 22,79, 13,99 ppm; sm *m/e* : 185 (M^+ + 1, 1%), 184 (M^+, 8%), 153 (M^+ − OCH_3, 19%), 152 (M^+ − OCH_3, 27%), 143 ($C_8H_{15}O_2$, 26%), 127 (M^+ − C_4H_9, 100%), 95 (C_7H_{11}, 15%), 87 ($C_4H_7O_2$, 56%), 67 (C_5H_7, 22%), 59 (CO_2CH_3, 14%), 55 (C_4H_7, 24%). *Anal.* calc. pour $C_{11}H_{20}O_2$: C 71,69, H 10,94; tr. : C 71,53, H 10,90.

*Méthyl-1 indanecarboxylate-2 de méthyle (**68**a,b)*

L'intégration des signaux des deux singulets du groupement ester méthylique nous indique que l'isomère *trans* (**68***b*) est majeur (69%); Rdt, 93% (0,247 g). Huile; ir ν_{max} (film, mélange) : 3075, 3030, 2960, 2930, 2870, 1735, 1470, 1450, 1375, 1250, 1225, 1215, 1190, 1165, 1020, 1000, 750 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 1,10 et 1,39 (3H, 2d, J = 6,98 Hz, CH_3, *cis* et *trans* CO_2CH_3), 2,76–3,09 (1H, m, H-2), 3,14–3,44 (2H, m, H-3), 3,46–3,61 (1H, m, H-1), 3,69 et 3,72 (3H, 2s, CO_2CH_3, *cis* et *trans*), 7,07 (4H, s) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**68***b*) : 175,02, 145,70, 140,50, 126,33 (2C), 123,82, 122,71, 52,33, 48,10, 42,93, 35,02, 18,77 ppm; δ (**68***a*) : 173,61, 145,21, 140,50, 126,42 (2C), 124,08, 123,11, 51,48, 48,10, 41,57, 32,83, 16,81 ppm; sm *m/e* : 190 (M^+, 3%), 175 (M^+ − CH_3, 11%), 131 (M^+ − CO_2CH_3, 26%), 129 (M^+ − CO_2CH_3, 29%), 116 (M^+ − CO_2CH_3 − CH_3, 12%), 115 (M^+ − CO_2CH_3 − CH_3, 23%), 91 (C_7H_7, 24%), 77 (C_6H_5, 11%), 66 (C_5H_6, 100%), 65 (C_5H_5, 21%). *Anal.* calc. pour $C_{12}H_{14}O_2$: C 75,76, H 7,42; tr. : C 75,47, H 7,75.

*Propyl-1 indanecarboxylate-2 de méthyle (**69**a,b)*

L'intégration des signaux des deux singulets du groupe méthoxycarbonyle nous indique que l'isomère *trans* (**69***b*) est majeur (61%); Rdt, 91% (0,053 g). Huile; ir ν_{max} (film, mélange) : 3080, 3030, 2960, 2880, 1735, 1480, 1460, 1435, 1365, 1225, 1190, 1165, 750 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,86 (3H, t), 1,09–1,58 (3H, m), 1,75 (1H, m), 2,81–2,93 (1H, m, H-2), 3,08–3,34 (2H, m, H-3), 3,37–3,50 (1H, m, H-1), 3,61 et 3,63 (3H, 2s, CO_2CH_3, *trans* et *cis*), 7,70 (4H, s) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**69***b*) : 175,86, 145,14, 140,90, 126,51 (2C), 124,42, 123,42, 51,72, 49,66, 48,31, 36,89, 35,71, 19,99, 14,28 ppm; δ (**69***a*) : 273,74, 145,09, 141,19, 126,61 (2C), 125,90, 124,02, 51,39, 48,93, 46,75, 33,62, 32,89, 20,23, 14,15 ppm; sm *m/e* : 219 (M^+ + 1, 2%), 218 (M^+, 9%), 159 (M^+ − CO_2CH_3, 16%), 158 (M^+ − CO_2CH_3, 32%), 157 (M^+ − CO_2CH_3, 12%), 131 (M^+ − CO_2CH_3 − C_2H_4, 36%), 130 (M^+ − CO_2CH_3 − C_2H_5, 28%), 129 (M^+ − CO_2CH_3 − C_2H_5, 47%), 117 (M^+ − CO_2CH_3 − C_3H_6, 30%), 116 (M^+ − CO_2CH_3, C_3H_7, 41%), 115 (M^+ − CO_2CH_3 − C_3H_7, 100%), 91 (C_7H_7, 37%), 89 (C_7H_5, 19%), 77 (C_6H_5, 47%), 65 (C_5H_5, 25%). *Anal.* calc. pour $C_{14}H_{18}O_2$: C 77,03, H 8,31; tr. : C 77,38, H 8,32.

*Mode opératoire général de préparation des diastéréoisomères des alkyl-2 phényl-1 cycloalcanecarbonitriles-1 (**70–78**)*

En suivant le même mode opératoire que celui des composés **35–46**, la réaction est complète après une agitation de 8 h à la température ambiante. Le produit est purifié par filtration sur gel de silice en utilisant un mélange acétate d'éthyle et éther de pétrole. Le pourcentage des diastéréoisomères est déterminé par chromatographie en phase gazeuse à l'aide d'une colonne Dexsil 300 et par spectroscopie de résonance magnétique nucléaire du proton.

*Méthyl-2 phényl-1 cyclopentanecarbonitrile-1 (**70**a,b)*

L'isomère *trans* (**70***b*) est majeur (82%); Rdt, 97% (1,792 g). Liquide incolore; Eb (0,05 Torr, mélange) = 82–83°C (litt. (14) Eb (2 Torr) 125–127°C); ir ν_{max} (film, mélange) : 3050, 3020, 2960, 2920, 2865, 2220, 1595, 1490, 1455, 1375, 750, 725, 690 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,62 et 1,03 (3H, 2d, J = 6,35 Hz et 6,98 Hz, CH_3 *cis* et *trans* nitrile), 1,42 (1H, m), 2,01 (3H, m), 2,40 (2H, t), 2,59 (1H, q), 7,33 (5H, s) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**70***b*) : 136,42, 128,07, 127,34 (2C), 126,96 (2C), 50,04, 45,35, 35,18, 31,37, 22,03, 15,26 ppm; δ (**70***a*) : 138,05, 128,44, 127,25 (2C), 125,53 (2C), 50,04, 46,28, 40,08, 31,90, 21,64, 14,43 ppm; sm *m/e*: 186 (M^+ + 1, 4%), 185 (M^+, 27%), 130 (C_9H_8N, 27%), 129 (C_9H_7N, 100%), 115 (C_8H_5N, 13%), 103 (C_7H_5N, 12%).

*Ethyl-2 phényl-1 cyclopentanecarbonitrile-1 (**71**a,b)*

L'isomère *trans* (**71***b*) est majeur (85%); Rdt, 78% (0,471 g). Liquide incolore; Eb (0,04 Torr, mélange) = 93°C; ir ν_{max} (film, mélange) : 3050, 3020, 2950, 2920, 2865, 2220, 1595, 1445, 1375, 1020, 750, 690 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,65 (1H, m), 0,82 et 1,04 (3H, 2t, J = 7,30 Hz, CH_2CH_3, *cis* et *trans* CN), 1,25 (1H, m), 1,43 (1H, m), 1,60–2,28 (4H, m), 2,43 (2H, m), 7,34 (4H, s) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**71***b*) : 137,08, 128,20, 127,44 (2C), 127,11 (2C), 53,28, 50,04, 37,18, 29,16, 23,32, 22,77, 12,57 ppm; δ (**71***a*) : 138,81, 128,60, 127,44 (2C), 125,77 (2C), 53,59, 50,04, 41,84, 29,85, 23,85, 22,08, 12,81 ppm. Masse précise pour $C_{14}H_{17}N$: 199,1362; tr. : 199,1360.

*Propyl-2 phényl-1 cyclopentanecarbonitrile-1 (**72**a,b)*

L'isomère *trans* (**72***b*) est majeur (93%); Rdt, 86% (0,898 g).

Propyl-2 phényl-1 cyclopentanecarbonitrile-1 r trans *(**72**b)*

Ce produit fut isolé par chromatographie sur gel de silice en utilisant AE:EP (5:95) comme éluant. Liquide incolore; Eb (0,032 Torr) = 101°C; ir ν_{max} (film) : 3050, 3020, 2950, 2920, 2870, 2220, 1595, 1460, 1375, 750, 690 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 0,65 (1H, m), 0,76 (3H, t), 1,00–1,60 (3H, m), 2,00 (4H, m), 2,43 (3H, m), 7,33 (4H, s) ppm; rmn ^{13}C ($CDCl_3$) δ : 137,12, 128,19 (2C), 127,42, 127,13 (2C), 51,21, 50,00, 37,20, 32,32, 29,50, 22,79, 21,16, 14,02 ppm. Masse précise pour $C_{15}H_{19}N$: 213,1518; tr. : 213,1512.

*Butyl-2 phényl-1 cyclopentanecarbonitrile-1 (**73**a,b)*

L'isomère *trans* (**73***b*) est majeur (89%); Rdt, 83% (0,375 g). Liquide incolore; Eb (0,04 Torr, mélange) = 113°C; ir ν_{max} (film, mélange) : 3070, 3040, 2960, 2940, 2880, 2220, 1660, 1500, 1470, 1450, 1380, 1265, 760, 740, 700 cm^{-1}; rmn ^1H ($CDCl_3$, mélange) δ : 0,62 (1H, m), 0,71 (3H, t), 0,98–1,48 (6H, m), 1,85–2,05 (4H, m), 2,35 (2H, m), 7,27 (4H, s) ppm; rmn ^{13}C ($CDCl_3$, mélange) δ (**73***b*) : 137,20, 128,26 (2C), 127,51, 127,21 (2C), 51,39, 49,98, 37,17, 30,11, 29,78, 29,53, 22,74, 22,56, 13,81 ppm; δ (**73***a*) : 137,22, 128,67 (2C), 127,51, 125,54 (2C), 51,68, 49,98, 41,74, 32,87, 30,50, 30,40, 22,05, 21,99, 13,81 ppm; sm *m/e*: 228 (M^+ + 1, 1%), 227 (M^+, 2%), 129 (C_9H_7N, 13%), 121 ($C_8H_{11}N$, 27%), 119 (C_8H_9N, 88%), 117 (C_8H_7N, 100%), 84 (C_6H_{12}, 26%), 82 (C_6H_{10}, 38%). Protium–deuterium exchange of 17-oxosparteine: Homoenolization of a lactam

NICK HENRY WERSTIUK, THOMAS HEMSCHEIDT, AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 29, 1988

NICK HENRY WERSTIUK, THOMAS HEMSCHEIDT, and GEORGE TIMMINS. Can. J. Chem. **67**, 565 (1989).

The H–D exchange of 17-oxosparteine (**1***b*) has been studied under homoenolization conditions. We find that **1***b* undergoes H–D exchange at the bridgehead carbon C7 at 130°C, but forcing conditions (240°C) using the medium $(CD_3)_3COK/(CD_3)_3COD$ are required to induce exchange at C11, C15, and other sites. C15-H_a exchanges only marginally faster than C15-H_e, indicating that the β-lactam carbanion is stabilized primarily by the dipolar effect of the amide group.

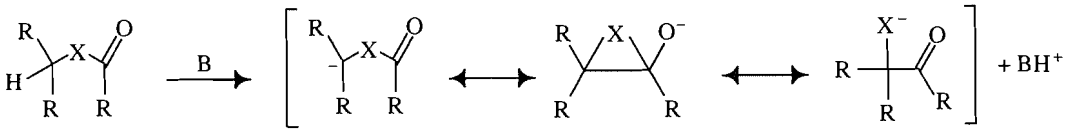
Key words: protium–deuterium exchange, 17-oxosparteine, homoenolization.

NICK HENRY WERSTIUK, THOMAS HEMSCHEIDT et GEORGE TIMMINS. Can. J. Chem. **67**, 565 (1989).

Opérant dans des conditions d'homoénolisation, on a étudié l'échange H–D de l'oxo-17 spartéine (**1***b*). On a trouvé que, à 130°C, le composé **1***b* subit un échange H–D au niveau du carbone C7 de l'atome de pont; toutefois, on doit forcer les conditions et opérer à 240°C dans un milieu $(CD_3)_3COK/(CD_3)_3COD$, pour pouvoir induire des échanges dans les positions C11, C15 ainsi que sur d'autres sites. Les échanges du C15-H_a ne sont que marginalement plus rapides que ceux du C15-H_e; ces résultats indiquent que la stabilisation du carbanion de la β-lactame reflète principalement l'effet dipolaire du groupement amide.

Mots clés : échange protium–deutérium, oxo-17 spartéine, homoénolisation.

[Traduit par la revue]



A wide variety of acyclic, monocyclic, and polycyclic ketones have been studied to detail the structural and stereoelectronic requirements for homoenolization (Scheme 1, X = C) of this class of compounds in $(CH_3)_3COK/(CH_3)_3COH(D)$ (1). However, there have been no reports of the homoenolization of amides (lactams), esters (lactones), or thioesters (thiolactones) in this medium even though carbanions can be generated α to nitrogen of amides or to sulfur of thioesters with LDA (2).

We set out to prepare sparteine (**1***a*) deuteriated at C8 in order to unambiguously assign the resonances for the axial and equatorial protons at this site, which was expected to be labelled by incorporation of cadaverine-3,3-d_2 (3). To this end, we undertook a study of the homoenolization of 17-oxosparteine (**1***b*) to establish whether deuterium could be incorporated at C8, β to the lactam carbonyl group. This 17-oxosparteine-8-d_n would be converted into **1***a*-8-d_n by LAH reduction (4). Furthermore, **1***b* also provides a unique opportunity to determine the relative rates of exchange at the other β sites (C6, C11, and C15) as well as at C7, the bridgehead carbon. This communication documents the first study of a lactam (amide) under homoenolization conditions.

At 130°C, **1***b* incorporates 0.73 of a deuterium atom (entry 1, Table 1). Analysis of the 125-MHz ^{13}C nmr spectra of **1***b*-$d_{0.73}$ and **1***a*-$d_{0.73}$ obtained by LAH reduction established that the deuterium is located at C7 (4). That exchange α to the carbonyl group is only 73% complete at 130°C is due to the unfavorable alignment of C7-H with the π-system of the carbonyl group (the dihedral angle is 23.6°) and to the fact that the enolate is generated at the bridgehead of a [3.3.1] system.

At 175°C, **1***b* incorporates 0.86 of the deuterium atom in 24 h (entry 2, Table 1). Its ^2H nmr spectrum showed that little deuterium is incorporated at sites other than C7. Consequently, **1***b* was reacted under more vigorous conditions. Since we showed previously that the medium $(CH_3)_3COK/(CH_3)_3COD$ is unstable (even at 185°C it decomposes slowly to isobutene and HOD), exchange reactions were carried out at 240°C in $(CD_3)_3COK/(CD_3)_3COD$ to avoid dilution of the deuterium pool and to increase the stability of the medium (5). Under these conditions (entries 3 and 4, Table 1), more deuterium is incorporated into **1***b*. Analysis of the high-field ^1H nmr and ^{13}C nmr spectra of **1***b*-d_n and **1***a*-d_n established that exchange at C7 was virtually complete; the signal for C7-H disappeared and the C7 resonance was replaced by ^2H-coupled ^{13}C satellites shifted upfield. That there was substantial H–D exchange at C15 was established by a marked decrease in the intensity of the C15 resonance of **1***a*-d_n. The ^2H spectra of **1***b*-$d_{1.73}$ and **1***b*-$d_{2.51}$ showed two additional strong signals at the chemical shifts of the axial (2.30 ppm) and equatorial (4.55 ppm) protons at C15 of **1***b* (6).

The ^2H nmr data show that the axial hydrogen at C15 undergoes H–D exchange marginally faster than the equatorial hydrogen (1.6:1) and that exchange at other sites occurs much

b, X = O

more slowly than at C7 and C15. The structure of **1***b*, optimized using the MM2 force field of MACROMODEL (7), is shown in Fig. 1. Ring D is a chair in keeping with an X-ray crystallographic structure determination (8). If homoconjugative stabilization of the incipient anion at C15 by the carbonyl group is important, a greater axial selectivity would be expected; while the dihedral angle between C15-H_a and the carbonyl group is 127.4°, C15-H_e is nearly in the plane (dihedral angle 9.5°) of the carbonyl group (Fig. 1). Axial selectivity would also be expected if the carbanion is resonance-stabilized as shown by the canonical forms **I**, **II**, and **III**. This resonance effect has

I **II** **III**

been invoked to account for the enhanced acidity of *N*-nitroso amines (9). That the diastereotopic hydrogens exchange at similar rates suggests that dipolar stabilization, through space and through bond, is the main mode of stabilization of this anion. This is in keeping with the results of computational studies carried out by Bach *et al.* on the anion derived from *N*-methyl formamide (10).

Although C11-H is adjacent to the lactam nitrogen as well, and its alignment (dihedral angle 132.9°) with the planar amide linkage (Fig. 1) is similar to C15-H_a, exchange at this site occurs

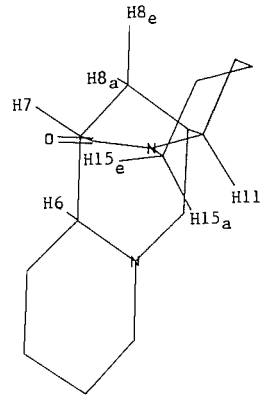

FIG. 1. MM2 optimized molecular structure of 17-oxosparteine (**1***b*).

much more slowly than exchange at C15, presumably because deprotonation yields a tertiary anion. This is also the case for C6. Four additional overlapping resonances ranging from 1.2 to 1.6 ppm and totaling 0.25 D (entry 4, Table 1) were present, but could not be assigned with certainty even though they fall in the region where the C8-H and C6-H resonances are expected (6). That exchange at C8 and C6 is slow relative to exchange at C15 is unexpected and is undoubtedly due to the fact that the electrophilicity of the carbonyl group is reduced by amide resonance. Studies on other sparteine derivatives are planned.

Even though **1***a*-8-d_n was not prepared, the C8 resonance of **1***a* was unambiguously assigned on the basis of the β-deuterium isotope shifts observed for the carbons β to C7 of **1***a*-7-$d_{0.73}$. Having assigned the C8 resonance, the C8-H resonances of **1***a* were then unambiguously assigned by carrying out a heteronuclear COSY experiment.

On the regioselectivity of the condensation of stabilized phosphoylids with 3-substituted phthalic anhydrides

LIVAIN BREAU AND MARGARET M. KAYSER[1]

Department of Chemistry, University of New Brunswick, P.O. Box 5050, Saint John, N.B., Canada E2L 4L5

Received September 9, 1988

LIVAIN BREAU and MARGARET M. KAYSER. Can. J. Chem. **67**, 569 (1989).

Condensations of stabilized phosphorane **1** with 3-substituted phthalic anhydrides were investigated. The importance of various effects influencing regio- and stereoselectivity of these reactions is discussed. It is proposed that the oxygen atom on the substituents in position 3 can act as a Lewis base toward the electron-deficient phosphorus of the ylid. The resulting complexation stabilizes the transition state for the reaction at the *ortho* carbonyl group, thus offsetting the usual steric and "push" effects, which favour attack at the *meta* carbonyl function.

Key words: Wittig condensations, phthalic anhydrides, regioselectivity, stereoselectivity.

LIVAIN BREAU et MARGARET M. KAYSER. Can. J. Chem. **67**, 569 (1989).

On a examiné les condensations du phosphorane stabilisé **1** avec les anhydrides phtaliques substitués en position 3. On discute de l'importance de divers effets qui influencent la régio- et la stéréo-sélectivité de ces réactions. On suggère que l'atome d'oxygène présent sur les substituants en position 3 peut agir comme base de Lewis par rapport au phosphore électro-déficient de l'ylure. La complexation qui en découle stabilise l'état de transition conduisant à une réaction avec le groupement carbonyl en *ortho* et contre-balance les effets stériques et ceux qui proviennent d'une « poussée » qui favorisent généralement une attaque de la fonction carbonyle en *méta*.

Mots clés : condensations de Wittig, anhydrides phtaliques, régiosélectivité, stéréosélectivité.

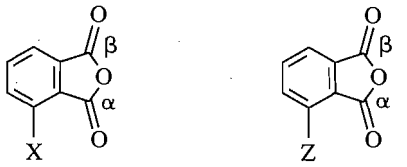
Introduction

Stabilized phosphoranes **1** react readily with phthalic anhydride (1). The condensation occurs under mild conditions, providing an excellent synthetic route to enol-lactones. The 4-substituted phthalic anhydrides show regioselectivity patterns that can be correlated with the electronic effects of the substituent. Thus, the electron-releasing groups such as $-NR_2$ or $-OCH_3$ promote reaction at the carbonyl-2, **2**, while the electron-withdrawing groups ($-NO_2$, -COOR) favour condensation at the carbonyl-7, **2** (2).

$Ph_3P{=}CHCOOCH_3$

1

2



The fact that the reactions of certain phthalic anhydrides have been shown to be reversible (3) does not appear to interfere with a simple interpretation based on electronic effects. On the other hand, the 3-substituted phthalic anhydrides give results that cannot be simply explained (2). Particularly in the case of oxygen-containing substituents ($-OCH_3$, $-NO_2$, and -COOR), projections based on electronic and (or) steric effects appear to be of little value.

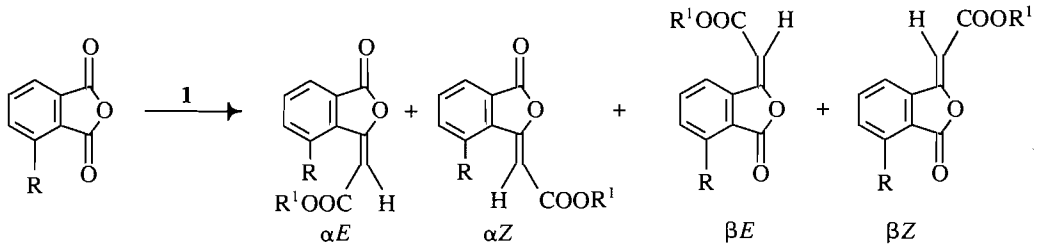
Our interest in regioselectivity control prompted us to investigate further the condensations of stabilized Wittig reagents with a number of 3-substituted phthalic anhydrides. The condensations of anhydrides with methyl- or ethyl-(triphenylphosphoranylidene) acetate **1** were carried out in refluxing dry THF under nitrogen. The appearance of the product(s) was monitored by gas chromatography. Proton nmr spectroscopy was found to be more suitable than gas chromatography for the determination of the product composition, since the retention times for the two *Z* or two *E* isomers were frequently very similar.

The isomers were separated on a centrifugally accelerated radial thin-layer chromatograph; their structures were established by proton nmr and isomerisation experiments. The results for a series of 3-substituted phthalides are shown in Table 1.

Results and discussion

According to FMO theory, nucleophilic addition to a carbonyl function is favoured at the carbon atom bearing the highest LUMO coefficient. The calculations for several 3-substituted phthalic anhydrides have shown that in alkyl-, hydroxyl-, methoxyl-, and halogen-substituted anhydrides the highest LUMO coefficient is located on the carbon atom of the *meta* carbonyl group, **3** (4). Hence, for these compounds the steric and electronic effects favour the reaction at the *meta* carbonyl function. When the substituent is electron withdrawing (-CN, $-NO_2$) the highest LUMO coefficient is located on the carbon atom of the *ortho* carbonyl group, **3** (4).

3



X = R, OH, halogens Z = CN, NO_2

From the steric viewpoint, the *meta* carbonyl group more remote from the substituent should be an easier target for the nucleophile in all cases.

Furthermore, the *ortho* carbonyl function is also deactivated vis-a-vis nucleophilic addition due to the repulsive van der Waals interaction with a substituent in position 3. Such an interaction causes a displacement of electrons from the oxygen to the carbon atom of the carbonyl function. The increased electronic density at the carbon atom lowers its electrophilicity, and consequently its reactivity towards nucleophiles. The above "push effect", related to the size of the substituent and not its electronic character, has been observed during ^{13}C and ^{17}O nmr studies of 3-substituted phthalic anhydrides (5).

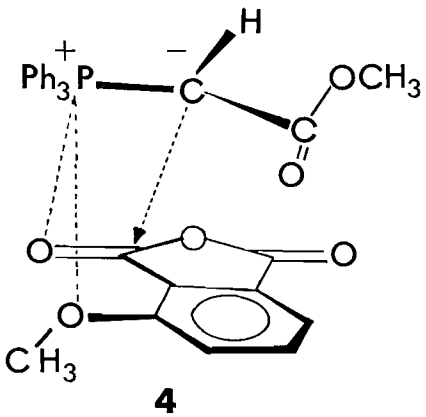
NO_2	**3***k*	15	42	34	9	82	57:43[a]	



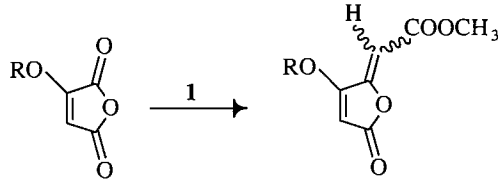
[a]The product ratio of the enol-lactones formed was established by proton nmr analysis of the crude reaction mixture, prior to the separation of individual enol-lactones.

The push-effect is, predictably, more important for bulkier groups such as I, Br, $N(CH_3)_3$, or NO_2 and is negligible for fluorine atoms.

In view of the above discussion, the results listed in Table 1 show an unexpectedly high proportion of the products resulting from the condensation at the *ortho* carbonyl group in phthalic anhydrides with the oxygen-bearing substituents in position 3.

Particularly intriguing are the results of the reactions with 3-methoxy, 3-ethoxy, and 3-nitrophthalic anhydrides. The methoxy and ethoxy substituents, by virtue of their electron-donating capacity as well as their steric influence, should exhibit regioselectivity similar to that observed in Cl- or Br-substituted phthalic anhydrides (6). The relatively important proportion of the reaction at the *ortho* carbonyl group suggests that effects other than those mentioned above are at work.

A possible explanation for the results obtained in the condensations with alkoxy-substituted phthalic anhydrides is that the reaction pathway for the ylid addition to the *ortho* carbonyl group is of lower energy than that leading to the condensation at the *meta* carbonyl group. We propose that the stabilization of the transition state lying along the preferred route is a result of a complexation between an oxygen atom of the substituent and a phosphorus atom of the ylid, **4**.



4

In view of the fact that interactions between bases such as -OR, -SR, -NR, and an electron-deficient phosphorus are well known (7–10), and lead to the formation of stable, sometimes isolable, hexacoordinated phosphorus complexes (11, 12), the transition state for an ylid addition should be stabilized when overlap between an accessible electron donor and the phosphorus atom can occur.

The highly regioselective condensations of alkoxy-substituted maleic anhydrides with stabilized phosphoranes, in which ylids add only to the carbonyl group adjacent to the alkoxy substituent (13), support the above hypothesis, **5**.

The amino substituents in position 3 (compounds **3***f* and **3***g*) do not manifest a similar stabilizing effect on the transition state. In aromatic amines the electrons of the lone pair on nitrogen are preferentially delocalized throughout the ring system, simultaneously deactivating the α-carbonyl function toward nucleophilic addition and diminishing the basicity of the amino group vis-a-vis an electron-deficient phosphorus of the ylid. As a result, the anticipated β-attack is in fact observed (Table 1).

In keeping with the above rationalization, the reactions of stabilized phosphoranes with 3-aminophthalic anhydrides are considerably slower than the condensations with alkoxy-

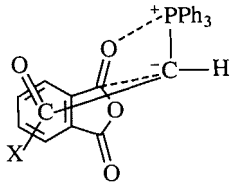
phthalic anhydrides. While the 3-aminophthalic anhydrides require prolonged reflux for the reaction to occur, the alkoxy analogues react rapidly at room temperature, and can be monitored by nmr.

In the course of several nmr experiments (^1H and ^{13}C) carried out for 3-methoxyphthalic anhydride at room temperature, as well as at low temperatures (−50 and −40°C), we were unable to detect any intermediates, even of a transient nature. The reaction proceeded smoothly to the products observed at termination. It may therefore be concluded that the rate-controlling step is irreversible and the reaction kinetically controlled.

A more exhaustive discussion of the studies of the mechanism of ylid reactions with cyclic anhydrides will be presented in a separate paper.

In the case of 3-NO_2 phthalic anhydrides, the selectivity for the *ortho* function could be associated with the electron-withdrawing effect of the substituent (4).

However, we should point out that the electron-withdrawing capacity of the NO_2 group is strongly reduced when it is rotated from coplanarity with the aromatic ring and, thus, the resonance effects suffer from "steric inhibition" (14). Recent experimental results suggest that the 3-nitro substituent in **6** assumes a



6

nonplanar conformation. From the study of the ^{17}O chemical shift–torsional angle relationship, it is estimated that the 3-nitro group is rotated 35° from the plane of the aromatic ring (15, 16). The MINDO/3 calculations (17) carried out on the model with nonplanar NO_2 show that the LUMO coefficient on the carbon of the *ortho* carbonyl group is only marginally larger than the LUMO coefficient on the carbon of the *meta* group **6**. The diminished electronic effects, coupled with the increased steric demand of the twisted NO_2 group and a strong push-effect, should promote the reaction at the more remote *meta* carbonyl function. Nevertheless almost 60% of the condensation takes place at the *ortho* carbonyl group (Table 1).

As in alkoxyphthalic anhydrides, a surprisingly high proportion of the sterically unfavourable enol-lactone may be due to the lower energy pathway leading to the condensation at the *ortho* carbonyl function. Here, partially negatively charged oxygen atoms of the NO_2 group are in an appropriate position for *p–d* overlap with the electron-deficient phosphorus atom of the ylid. This overlap should stabilize the transition state, and consequently facilitate the reaction at the *ortho* carbonyl group.

Finally, we should comment briefly on the stereochemistry of these reactions. The first Wittig reaction between phthalic anhydride and stabilized phosphorane **1** was described by Chopard *et al.* (1); the only product, an *E* isomer, was obtained in excellent yield. To account for the stereochemistry the authors proposed that the reaction proceeds through a transition state in which the -COOR group of the phosphorane is stacked in a plane parallel to the benzene ring, as shown in **7**. The π electrons of the carbonyl function interact with the relatively electron-deficient benzene ring of the phthalic anhydride. This explanation agrees reasonably well with our results, which

7

show that in the presence of an electron-withdrawing substituent on the aromatic ring the proportion of *E* isomer tends to be significant even in sterically unfavourable situations (see **3***d* and **3***k*, Table 1).

Conclusion

The results of the investigations discussed in this paper shed some light on the factors that control regioselectivity of phosphorane addition to 3-substituted phthalic anhydrides.

The combined steric, resonance, and push effects explain adequately the regioselectivity observed in the condensation of phosphorane with anhydrides **3***a*–**3***g*. The higher LUMO coefficient argument does not appear to be generally applicable in these reactions, judging by the relative lack of selectivity in the reaction with 3-fluorophthalic anhydride. This is probably due to the fact that certain condensations are under thermodynamic, while others are under kinetic, control.

The increased selectivity for the *ortho* carbonyl function in the reactions with anhydrides **3***h*–**3***k*, all bearing an oxygen-containing substituent, is best interpreted in terms of kinetic preference for the *ortho* function in these compounds. The complexation between the oxygen atom (from the 3-substituent) and an electron-deficient phosphorus stabilizes the "*ortho*" transition state **4** compared to that for the reaction at the *meta* carbonyl group, thus compensating somewhat for the unfavourable steric environment.

Recent studies of the mechanism of stabilized ylid reactions with aldehydes indicate that a transition state earlier than is generally believed may be involved in these condensations (18). The above conclusion agrees with our results suggesting that kinetic preference determines the regioselectivity of phosphorane addition to 3-alkoxy substituted phthalic anhydrides.

Experimental

Melting points were determined on a Fisher Scientific Co. hot-stage melting point apparatus and are uncorrected. Infrared spectra were obtained on a Perkin–Elmer 1420 ratio recording infrared spectrophotometer, either neat or with chloroform as solvent. Ultraviolet spectra were measured in methanol using a Varian Cary 219 spectrophotometer. The ^1H nmr and ^{13}C nmr spectra were recorded on a Varian EM 300L nmr spectrometer or on a Nicolet 360 spectrometer with $CDCl_3$ as solvent and $(CH_3)_4Si$ as internal standard. Mass spectra were recorded on a VG mass spectrometer with a DANI 7070 gas chromatograph. Gas chromatographic analyses were carried out with a Varian 3700 gas chromatograph, using a 50 cm × 1/8 in., 5% OV-101 on Chromosorb, G-HP 100/120 mesh column. Chromatographic separations were performed on a preparative, centrifugally accelerated, radial, thin-layer chromatograph (a Chromatotron model 7924T). tetrahydrofuran (THF) was dried over sodium metal and was distilled under nitrogen.

*General procedure for the reactions of $Ph_3P—CHCO_2CH_3$ **1** with phthalic anhydrides*

Molar equivalent amounts of an anhydride and methyl(triphenylphosphoranylidene) acetate **1** were dissolved in dry THF and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

solution was refluxed. The progress of the reaction was followed by gas chromatography and proton nmr. The crude products were separated on the Chromatotron. The isomeric lactones were identified by proton nmr, hydrogenation, and isomerization experiments.

Photochemical isomerization of enol-lactones

A pure sample of an enol-lactone was dissolved in cyclohexane and was placed in a petri dish surrounded by aluminum foil. The solution was immediately irradiated with an ultraviolet short wavelength lamp (254 nm), placed directly above the solution for a period of 15 min – 2 h. After evaporation of the solvent the residue was analyzed by proton nmr and gas chromatography.

The reaction of Ph_3P $CHCOOCH_3$ **1** *with 3-idiophthalic anhydrides* **3***a*

The reaction between 3-ideophthalic anhydride **3***a* (6) (0.50 g, 1.8 mmol) and the phosphorane **1** (0.60 g, 1.8 mmol) was completed in 5 h of reflux in THF. Proton nmr of the crude reaction mixture showed **3***aβE* and **3***aβZ* in the ratio 78:22. Chromatography, with petroleum ether/ether as elutant, gave (*E*)-3-methoxycarbonylmethylidene-7-iodophthalde **3***aβE*, 0.22 g (36%) (eluted first), crystallized from methanol as white crystals, mp 167–168°C: ir ($CHCl_3$) ν_{max}: 3120, 3010, 2960, 1790, 1715, 1655 cm^{-1}: proton nmr ($CDCl_3$) δ: 3.84 (s, 3H, $COOCH_3$), 6.16 (s, 1H, :CHCOOMe), 7.54 (t, J = 8.0 Hz, 1H), 8.12 (d, J = 8 Hz, 1H), 9.09 (d, J = 8 Hz, 1H); ms, *m/e*: 331 (M^+ + H, 100%), 330 (M^+, 58%), 299 (93%), 289 (17%), 203 (33%), 84 (41%), 83 (97%), and 75 (27%); and (*Z*)-3-methoxycarbonylmethylidene-7-iodophthalic **3***aβZ*, 60 mg (10%), which crystallized from methanol as white crystals, mp 213–215°C (dec.); ir ($CHCl_3$) ν_{max}: 2960, 1810, 1710, 1670 cm^{-1}; proton nmr ($CDCl_3$) δ: 3.82 (s, 3H, $COOCH_3$), 5.90 (s, 1H, :CHOOMe), 7.43 (t, J = 8 Hz, 1H), 7.74 (dd, J = 7.7 and 0.8 Hz, 1H, H4), 8.12 (dd, J = 7.7 and 0.8 Hz, 1H); ms, *m/e*: 331 (M^+ + H, 100%), 330 (53%), 299 (68%), 203 (96%), and 75 (13%). A solution of pure **3***aβZ* (25 mg) in cyclohexane was irradiated for 2 h to give a mixture of **3***aβE* and **3***aβZ* in the ratio of 22:78. Some polymeric material was also formed (proton nmr analysis).

The Wittig reaction with 3-fluorophthalic anhydride **3***d*

The 3-fluorophthalic anhydride **3***d* was synthesized as described in ref. 6. The reaction between 3-fluorophthalic anhydride **3***d* (1.00 g, 6.02 mmol) and the phosphorane **1** (2.02 g, 6.04 mmol) carried out according to the general procedure yields, after 15 min of stirring at room temperature, a white crystalline product, presumably the acyclic intermediates. These intermediates were converted into the corresponding enol-lactones upon 2 h reflux. Proton nmr analysis of the crude mixture showed that **3***dαE*, **3***dαZ*, **3***dβE*, and **3***dβZ* were present in the ratio of 21:23:38:18. Chromatography with petroleum ether/ether gave (*E*)-3-methoxycarbonylmethylidene-7-fluorophthalic **3***dβE* (eluted first) as white needles, mp 148.5–149°C; ir ($CHCl_3$) ν_{max}: 3040, 3020, 1800, 1720, 1655 cm^{-1}: proton nmr ($CDCl_3$) δ: 3.84 (s, 3H, OCH_3), 6.19 (s, 1H, :CHCOOMe), 7.35 (td, J = 8.2 and 0.3 Hz, 1H), 7.81 (td, J = 8.2 and 5 Hz, 1H), 8.93 (dd, J = 8.2 and 0.3 Hz, 1H); ms, *m/e*: 222 (M^+, 23%), 192 (12%), 191 (100%), 164 (9%), 107 (25%), 94 (14%), 69 (11%), and 28 (33%); (*E*)-3-methoxycarbonylmethylidene-4-fluorophthalic **3***dαE* (eluted second) as white crystals, mp 102–103°C; ir ($CHCl_3$) ν_{max}: 2960, 1730, 1670 cm^{-1}; proton nmr ($CDCl_3$) δ: 3.87 (s, 3H, OCH_3), 6.27 (s, 1H, :CHCOOMe), 7.44–7.84 (m, 3H); ms, *m/e*: 222 (M^+, 19%), 195 (11%), 192 (12%), and 191 (100%); (*Z*)-3-methoxycarbonylmethylidene-7-fluorophthalide **3***dβZ* (eluted third) as white crystals, mp 156–157°C; ir ($CHCl_3$) ν_{max}: 2960, 1810, 1715, 1675 cm^{-1}; proton nmr ($CDCl_3$) δ: 3.83 (s, 3H, OCH_3), 6.08 (d, J_{HF} = 0.77 Hz, 1H, :CHCOOMe), 7.36–7.82 (m, 3H); ms, *m/e*: 222 (M^+, 26%), 192 (15%), 191 (100%), 164 (11%), and 107 (33%); and (*Z*)-3-methoxycarbonylmethylidene-4-fluorophthalide **3***dαZ* (eluted last) as white crystals, mp 164–165°C; ir ($CHCl_3$) ν_{max}: 2960, 1805, 1710, 1675 cm^{-1}; proton nmr ($CDCl_3$) δ: 3.86 (s, 3H, OCH_3), 5.92 (s, 1H, :CHCOOMe), 7.25–7.89 (m, 3H); ms, *m/e*: 222 (M^+, 18%), 192 (11%), 191 (100%), 107 (26%), and 28 (78%). The fluorophthalide enol-lactones were obtained in an overall yield of 1.05 g (78%). The pure **3***dβE* (30 mg) in cyclohexane was isomerized to give **3***dβE*:**3***dβZ* 52:48 after 30 min and 36:64 after 1 h of irradiation. The pure **3***dαE* was isomerized to give **3***dαE*:**3***dαZ* 20:80 after 2 h of irradiation. In both cases a very small quantity of polymeric material was also formed.

The Wittig reaction with 3-aminophthalic anhydride **3**f

The reaction between 3-aminophthalic anhydride **3***f* (19) (0.5 g, 0.003 mmol) and the phosphorane **1** (1.0 g, 0.003 mmol) gave a mixture of two enol-lactones (0.4 g, 71%): **3***fβE* and **3***fβZ* in the ratio 72:28. Chromatography with petroleum ether/ether gave (*E*)-3-methoxycarbonylmethylidene-7-aminophthalide **3***fβE* (eluted first) as yellow-orange crystals, mp 145–150°C; ir ($CHCl_3$) ν_{max}: 3450, 3350, 2950, 1760, 1725 cm^{-1}; proton nmr ($CDCl_3$) δ: 3.78 (s, 3H, OCH_3), 5.32 (s, br, NH_2), 6.03 (s, 1H), 6.80 (d, 1H), 7.47 (t, 1H), 8.24 (d, 1H); and (*Z*)-3-methoxycarbonylmethylidene-7-aminophthalide **3***fβZ* (eluted second) as yellow crystals, mp 159–164°C; ir ($CHCl_3$) ν_{max}: 3450, 3350, 2950, 1775, 1725 cm^{-1}; proton nmr ($CDCl_3$) δ: 3.81 (s, 3H, OCH_3), 5.32 (s, br, NH_2), 5.78 (s, 1H), 6.77 (d, 1H), 6.95 (d, 1H), 7.42 (t, 1H). A solution of the mixture **3***fβE* and **3***fβZ* (72:28) in cyclohexane was irradiated for 1 h to give a mixture of **3***fβE* and **3***fβZ* in the ratio 30:0 (proton nmr analysis).

The Wittig reaction with 3-methoxyphthalic anhydride **3**i

The reaction between 3-methoxyphthalic anhydride **3***i* (20) (1.00 g, 5.62 mmol) and the phosphorane **1** (1.88 g, 5.62 mmol) was completed after 4 h of reflux in THF. Proton nmr analysis of the crude reaction mixture showed the **3***iαE*, **3***iαZ*, **3***iβE*, and **3***iβZ* in the ratio of 7:50:29:14. The observed regioselectivity, but not stereoselectivity, was consistent with the data reported in the literature (2). A characteristic resonance at δ 6.12 (s, 1H, :CHCOOMe), corresponding to the **3***iαE* isomer, has not been reported previously. This isomer was not isolated, as it isomerizes to α*Z* on chromatography.

The Wittig reaction with 3-ethoxphthalic anhydride **3**j

The reaction between 3-ethoxyphthalic anhydride **3***j* (20, 21) and phosphorane **1** was carried out as described for 3-methoxyphthalic anhydride **3***i*. Proton nmr of the crude mixture gave the distribution of the four enol lactones **3***jαE*, **3***jαZ*, **3***jβE*, and **3***jβZ* as 11:36:7:46. The irradiation experiment carried out on the mixture showed decrease of the vinylic proton signal of **3***jαE* and **3***jβE* and enrichment of the signals for **3***jαZ* and **3***jβZ*.

The Wittig reaction with 3-nitrophthalic anhydride **3**k

Using the general procedure, the reaction between 3-nitrophthalic anhydride **3***k* (3.00 g, 15.5 mmol) and the phosphorane **1** (5.19 g, 15.5 mmol) was completed in 8 h of reflux in THF. Proton nmr analysis of the crude reaction mixture showed that the **3***kαE*, **3***kαZ*, **3***kβE*, and **3***kβZ* were present in the ratio 15:42:34:9. Again the regioselectivity, but not the stereoselectivity, of the reaction was in agreement with the reaction carried out in $CHCl_3$ (2). The resonance at δ 6.30 (s, 1H, :CHCOOMe) for **3***kαE* has not been reported previously.

Diels–Alder addition of the fumarate and acrylate of *S*-methyl lactate to α-hydroxy orthoquinodimethanes

JAMES L. CHARLTON,[1] GUY L. PLOURDE, KEVIN KOH, AND ANTHONY S. SECCO
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 16, 1988

JAMES L. CHARLTON, GUY L. PLOURDE, KEVIN KOH, and ANTHONY S. SECCO. Can. J. Chem. **67**, 574 (1989).

The cycloaddition of α-hydroxy orthoquinodimethane, generated photochemically from 2-methylbenzaldehyde, to the fumarate and acrylate of *S*-methyl lactate has been found to give a single diastereomer with high asymmetric induction (>95% de). This reaction provides a new and versatile synthetic route to substituted tetralins of high optical purity. A *trans* stereochemistry between the vicinal hydroxyl and carboxylactyl groups has been established for these cycloadducts. This is in contrast to previous work where *cis* stereochemistry has always been found for major cycloadducts of α-hydroxy *o*-QDMs. The high asymmetric induction, unusual diastereoselectivity, and the potential use of these reactions in asymmetric synthesis are discussed.

Key words: *o*-quinodimethanes, Diels–Alder, asymmetric, cycloaddition, induction, diastereoselective.

JAMES L. CHARLTON, GUY L. PLOURDE, KEVIN KOH et ANTHONY S. SECCO. Can. J. Chem. **67**, 574 (1989).

On a observé que la cycloaddition de l'α-hydroxy orthoquinodiméthane, obtenu d'une façon photochimique à partir du méthyl-2 benzaldéhyde, sur le fumarate et sur l'acrylate du lactate de *S*-méthyle conduit à un seul diastéréomère avec une induction asymétrique élevée (>95% de). Cette réaction s'avère être une route de synthèse nouvelle et versatile vers les tétralines substituées de pureté optique élevée. On a établi que les groupements hydroxyle et carboxylactyle vicinaux de ces cycloadduits sont de stéréochimie *trans*. Ce résultat est en opposition avec ceux obtenus au cours de travaux antérieurs alors qu'on a toujours obtenu une stéréochimie *cis* pour les cycloadduits principaux des α-hydroxy *o*-QDM. On discute de l'induction asymétrique élevée, de la diastéréosélectivité inhabituelle et des usages possibles de ces réactions en synthèses asymétriques.

Mots clés : *o*-quinodiméthanes, Diels–Alder, asymétrique, cycloaddition, induction, diastéréosélective.

[Traduit par la revue]

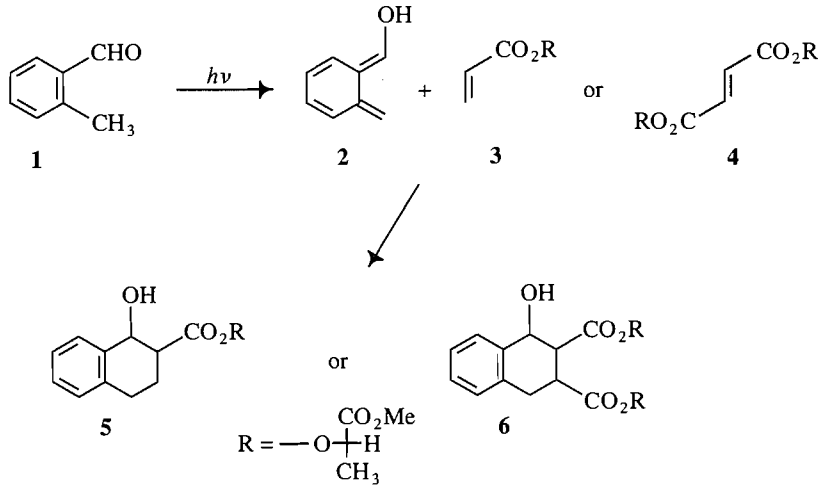
Introduction

Developing strategies towards the synthesis of enantiomerically pure compounds is one of the goals of modern organic chemistry and the study of asymmetric Diels–Alder reactions exemplifies the pursuit of this goal (1–5). The corresponding study of asymmetric Diels–Alder reactions of orthoquinodimethanes (*o*-QDMs) has received much less attention although *o*-QDMs have been extensively utilized as intermediates in non-asymmetric syntheses of chiral molecules (6). The addition of asymmetric control to the cycloaddition reactions of *o*-QDMs would provide a route to a large number of optically active compounds of interest. While a few examples of the intermolecular addition of chiral *o*-QDMs to achiral dienophiles have been published (6–9), only one example of a chiral dienophile reacting with an achiral *o*-QDM has been published (10). A possible reason for the lack of reports of asymmetric Diels–Alder reactions of *o*-QDMs is that high diastereoselectivity in such reactions is often achieved only in the presence of Lewis acid catalysts. Such catalysts are frequently incompatible with the conditions required to generate the transitory and very reactive *o*-QDMs.

Because of our interest in the use of *o*-QDMs in synthesis we have searched the literature to find chiral dienophiles that give high diastereoselectivity in Diels–Alder reactions in the absence of Lewis acid catalysts. Two of the more interesting candidates found were the acrylate and the fumarate of *S*-ethyl lactate (2, 11). At 0°C these dienophiles react with cyclopentadiene with diastereoselectivities of 80:20 and 95.5:4.5 respectively (*endo* adduct for addition of acrylate) (11). Because they have slightly less complex nmr spectra, we have chosen to study the reactions of the acrylate and fumarate of *S*-methyl lactate with *o*-QDMs. For ease of generation of the *o*-QDM we have chosen the photolysis of 2-methylbenzaldehyde (see Scheme 1).

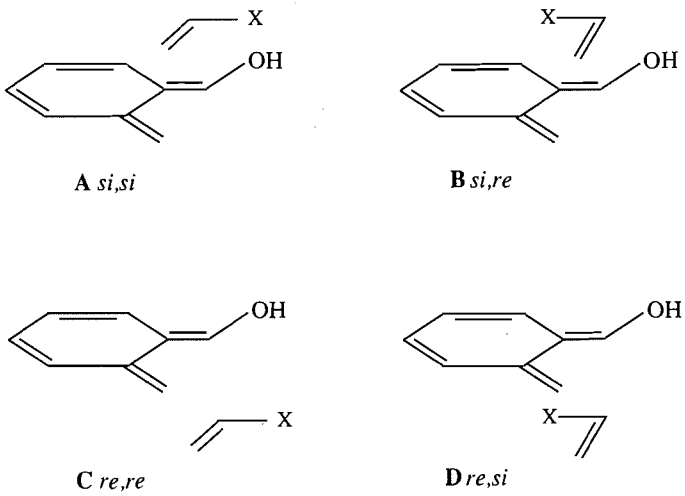
[1]Author to whom correspondence may be addressed.

Although the α-hydroxy group on the *o*-QDM increases the number of potential diastereomeric products, it also allows one to determine the facial selectivity of the reaction with respect to the *o*-QDM as well as the dienophile.



The photolysis of 2-methylbenzaldehyde is assumed to give the *E*-dienol (**2** in Scheme 1) (13–15) and, assuming that the cycloaddition is concerted, which appears to be true from previous studies (14), there are four possible approaches of the dienophile and the diene that can be classified as to their prochiral reacting faces as shown in Scheme 2 by modes **A–D**. (For an unsymmetrically substituted dienophile, there are four additional possible approaches and corresponding products with "*meta*" orientation. However, products with *meta* regiochemistry have not been observed previously (6, 12, 15), nor were they observed in this work.) In Scheme 2, the classification of the α-hydroxy carbon of the *o*-QDM is given first, followed by the classification of the face of the dienophile that will bond to that center.

The configurations of the respective cycloadducts resulting from the modes shown in Scheme 2 are shown in Scheme 3.



Previous work on *E*-α-hydroxy *o*-QDMs with achiral dienophiles such as dimethyl fumarate or methyl acrylate has shown that the major cycloadducts formed are **BB** or **DD**, having been formed via the *endo* transition states **B** or **D** shown in Scheme 2 (6, 15–18). The tendency towards *endo* transition states in Diels–Alder reactions (known as the Alder *endo* rule) has been explained on the basis of secondary orbital interactions between the electron-withdrawing group on the dienophile and carbon 2 of the diene (19). Solvent effects have shown that polar interactions between the diene and dienophile favor the *exo* transition states such as **A** and **C** (20). Transition states **A** and **C** and the resulting cycloadducts **AA** and **CC** are also thermodynamically more stable for steric reasons.

According to the most recent publication of Helmchen and co-workers, the most stable conformation of the fumarate of

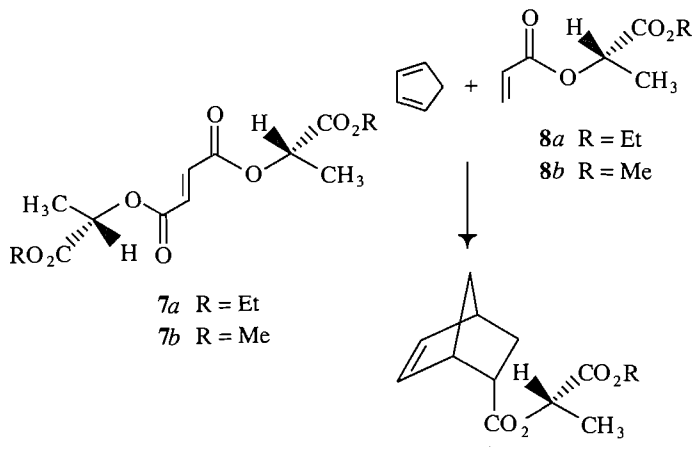
SCHEME 1

SCHEME 2. Reaction modes of *o*-QDM and dienophile classified according to their respective prochiral faces.

SCHEME 3

S-ethyl lactate is that shown in structure **7***a*, and addition of dienes to this dienophile occurs to the less hindered *re* (upper) face (11). Decreasing the polarity if the reaction medium increases the stereoselectivity for addition to the *re* face (11, 21). The reaction of the acrylate of *S*-ethyl lactate, **8***a*, with cyclopentadiene has been shown to yield primarily the *endo-re* cycloadduct as shown in **9** but the percentage of *exo* adduct increases with decreasing solvent polarity of the reaction medium as expected (20, 21).



Based on the preceding work, we expected that the Diels–Alder cycloaddition between an α-hydroxy *o*-QDM and **8***b* would give a cycloadduct of configuration **BB** via transition state **B** and that the fumarate **7***b* would react analogously.

Results and discussion

2-Methylbenzaldehyde was prepared by reduction of *o*-toluic acid ($LiAlH_4$) and reoxidation to the aldehyde with chromic acid.

The fumarate and acrylate of *S*-methyl lactate (**7***a* and **8***b*) were prepared by heating the corresponding acid chlorides with the *S*-methyl lactate. Irradiations of benzene solutions of mixtures of the fumarate or acrylate and 2-methylbenzaldehyde were carried out under nitrogen using a 450-watt Hanovia medium pressure mercury lamp and a Pyrex filter (see Experimental for details).

Irradiation of 2-methylbenzaldehyde with an excess of the fumarate **7***b* gave a single crystalline cycloadduct, which was isolated by column chromatography in 55% yield. The nmr (300 MHz) of the crude irradiation product exhibited no signals consistent with the presence of other diastereomeric cycloadducts, indicating a de of >95%. The only other significant product was the maleate of *S*-methyl lactate, presumably formed via a photoisomerization of the starting fumarate. The

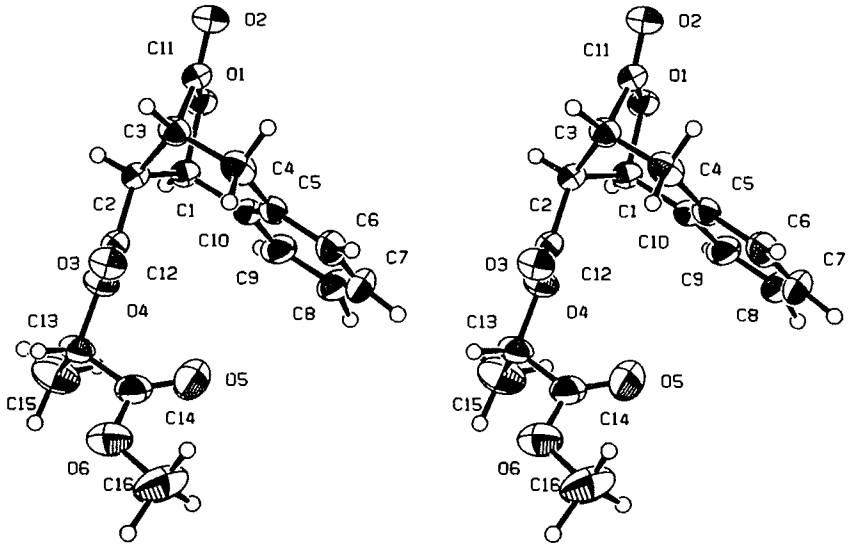

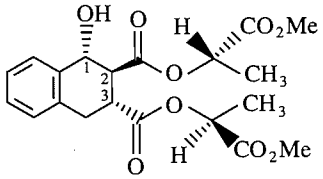

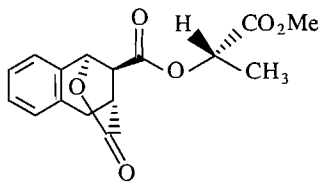

FIG. 1. Stereodiagram of the lactone, **11**; thermal ellipsoids at 50% probability level.

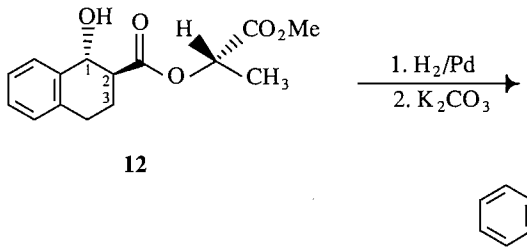
photoisomerization is probably sensitized by energy transfer from the excited 2-methylbenzaldehyde since irradiation of the fumarate in benzene alone gave only traces of the maleate isomer. The actual yield of the cycloadduct is much higher than the 55% isolated chromatographically, but we found it very difficult to separate the product from the maleate. The H-1 proton in the cycloadduct was clearly visible in the nmr, and a coupling constant ($J_{1,2}$) of 9.8 Hz suggested a *trans* disposition of the substituents on carbons 1 and 2. Similar compounds having a *cis* disposition of the 1 and 2 substituents have been found to exhibit a $J_{1,2}$ less than 5 Hz (17, 22). Although a *trans* 1,2 stereochemistry would mean that the cycloadduct would have formed via an unusual (see above) *exo* transition state (**A** or **C**), we tentatively assigned the cycloadduct structure **10**. The absolute stereochemistry shown in **10** is that which would arise from addition to the *re* face of the fumarate as expected.

10



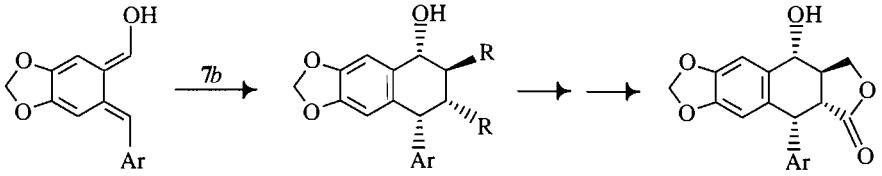
Treatment of the cycloadduct with toluenesulfonic acid in methylene chloride at room temperature for 3 days caused the elimination of one molecule of methyl lactate (determined by nmr), giving a product that appeared from ir to be a lactone (1788 cm^{-1}). The formation of a lactone between the 1-hydroxyl and the 3-carboxy group is not unreasonable and has been observed previously in a similar molecule (23). Thus the elimination product was assigned structure **11** shown below.

11

The lactone **11** fortunately produced crystals suitable for X-ray crystallography and we were therefore able to determine the relative stereochemistry of the chiral centers in **11** as shown in the ORTEP (24) drawing of **11** (Fig. 1). Since the absolute configuration of the lactate centers in **11** is known (*S*), the absolute configurations of the other centers could be assigned. In this way the absolute configuration of centers 2 and 3 in the cycloadduct was confirmed to be that shown in structure **10**. The relative stereochemistry of center 1 in **10** is based primarily on the nmr of **10** (see above) since inversion of this center could have occurred during the conversion of **10** to **11**.

Irradiation of 2-methylbenzaldehyde with an excess of acrylate **8***b* in a manner similar to that described above yielded only a single cycloadduct, which was purified by column chromatography (55% after chromatography). This adduct also exhibited a $J_{1,2}$ of 9.3 Hz, again indicative of a *trans* 1,2 stereochemistry. Based on our experience with the fumarate above, this acrylate adduct was assigned structure **12**. Nuclear

12



13

magnetic resonances of the crude cycloaddition product mixture did exhibit small signals, other that those due to **12**, which may be due to traces of other diastereomeric adducts. From integration we estimate that, as with the fumarate adduct, **12** is formed with a de of at least 95%. Hydrogenolysis and hydrolysis of **12** converted it to the known *S*-2-carboxy-1,2,3,4-tetrahydronaphthalene **13** ($[\alpha]_D$ −53° (lit. (25) $[\alpha_D]$ +55.5° for *R*)), confirming the assignment of the *S* configuration for center 2 and the absolute configuration of **12**.

Conclusions

From the results and discussion above we can conclude that

14

Ar = 3,4,5-trimethoxyphenyl; R = *S*-methyl lactylcarboxy

the cycloaddition of α-hydroxy *o*-QDM to the acrylate and fumarate of *S*-methyl lactate occurred between the *re* face of the dienophile and the *re* face of the *o*-QDM (mode **C** to give adduct type **CC**) (*exo* addition) with a diastereoselectivity of at least 95%. This is the first example of an intermolecular asymmetric cycloaddition to an *o*-QDM (giving a single enantiomer) that has high enough stereoselectivity to be truly synthetically useful (6). Based on earlier observations (see Introduction) we had expected addition by mode **B** to give adduct type **BB** (*re* face of the dienophile and *si* face of the *o*-QDM). The addition to the *re* face of the dienophile is as expected from earlier work of Helmchen and co-workers (2, 11, 21) and may be due to steric effects of the chiral auxiliary. The exclusive addition to the *re* face of the α-oxy center of the *o*-QDM (*exo* addition) is highly unusual and has not been observed previously for intermolecular cycloadditions of α-oxy *o*-QDMs except for those bearing an α′-phenyl group as well (17, 26). *Exo* addition to *o*-QDMs is common for intramolecular cycloadditions due to conformational preferences in the transition state (27). Perhaps hydrogen bonding between the α-hydroxy group of the *o*-QDM and the dienophiles used in this study make the subsequent addition more analogous to an intramolecular addition. Further studies of the mechanism underlying the diastereoselectivity and of the use of these highly selective reactions in asymmetric synthesis are in progress. We are particularly interested in whether addition of the fumarate **7** to an α-hydroxy-α′-aryl *o*-QDM will add with the same selectivity. If so, a very short asymmetric synthesis of podophyllotoxin **14** might be possible (28).

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AM-300 instrument using tetramethylsylane as internal standard. The ir spectra were recorded on a Perkin Elmer 881 spectrometer. Merck Kieselgel 60 was used for all chromatography. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada. Exact mass/mass spectra were obtained on an Analytical VG 7070E-HF instrument. Melting points were measured on a hot stage instrument and are uncorrected. Optical rotations were recorded on a Rudolf Research Corporation Autopol III instrument.

Acrylate of S*-methyl lactate,* **8**b

A mixture of *S*-methyl lactate (4.42 g, 42.2 mmol), acryloyl chloride (11.53 g, 10.4 mL, 127 mmol, 3 equiv.), and 3 Å molecular sieves (9 g) in CCl_4 was heated to reflux under nitrogen for 4 days. The mixture was filtered, evaporated, and chromatographed (20% ethyl acetate/hexane) to give a colourless oil (5.83 g, 87%) that was >97% pure by nmr (300 MHz); $[\alpha]_D^{20}$–43.5° (*c* 0.433, $CHCl_3$); ir (CH_2Cl_2): 1768, 1740 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.55 (d, 3H, $J_{1',2'}$ = 7.1), 3.76 (s, 3H), 5.16 (q, 1H, $J_{1,2}$ = 7.1), 5.88 (dd, 1H, $J_{2,2'}$ = 1.3, $J_{1,2}$ = 10.4), 6.20 (dd, 1H, $J_{1,2}$ = 10.4, $J_{1,2'}$ = 17.2), 6.46 (dd, 1H, $J_{2,2'}$ = 1.3, $J_{1,2'}$ = 17.2); mass spectrum *m/e* (rel. %) neohexane chemical ionization: 159 (12, *M* + 1), 127 (20), 71 (55), 55 (100); ammonia chemical ionization: 176 (10, *M* + 14), 159 (25, *M* + 1), 127 (20), 72 (17), 55 (100); electron impact: 114 (18), 99 (25), 55 (100).

Fumarate of S*-methyl lactate,* **7**b

A mixture of *S*-methyl lactate (5.44 g, 52.3 mmol) and fumaryl chloride (4.00 g, 26.1 mmol) was heated at 100°C for 20 h, dissolved in ethyl acetate, washed with aqueous $NaHCO_3$ (5%), dried ($MgSO_4$), and evaporated to give a yellow oil (7.58 g). The oil (1 g) was chromatographed (15% ethyl acetate/hexane) to give a colourless oil (0.62 g, 62% overall, >95% pure by 300 MHz nmr); $[\alpha]_D^{20}$–15.5° (*c* 0.32, $CHCl_3$); ir (CH_2Cl_2): 1733 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.56 (d, 3H, *J* = 7.1, CH_3), 3.77 (s, 3H, OCH_3), 5.22 (q, 1H, *J* = 7.1), 6.97 (s, 2H); mass spectrum *m/e* (rel. %): 288 (10), 185 (65), 140 (20), 113 (23), 99 (20), 87 (100), 59 (31). *Exact Mass* calcd. for $C_{12}H_{16}O_8$: 288.0848; found 288.0845.

Cycloadduct of acrylate **8**b *and 2-methylbenzaldehyde,* **12**

A solution of 2-methylbenzaldehyde (133 mg, 1.1 mmol), acrylate **8***b* (0.228 g, 1.44 mmol, 1.3 equiv.), and hydroquinone (1 mg) in benzene (30 mL) was purged with nitrogen and irradiated with a Hanovia 450-watt medium pressure mercury lamp through a Pyrex filter from a distance of 10 cm for 17 h. The solvent was evaporated and the residue chromatographed (40% ethyl acetate/hexane) to give an oil (107 mg, 55%); $[\alpha]_D^{20}$=36.3° (*c*, 1.35, $CHCl_3$); ir (CH_2Cl_2): 3499, 1739 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.55 (d, 3H, $J_{1',2'}$ = 7.1), 2.00 (m, 1H), 2.20 (m, 1H), 2.84 (m, 3H), 3.79 (s, 3H), 5.00 (d, 1H, $J_{1,2}$ = 9.3), 5.23 (q, 1H, $J_{1',2'}$ = 7.1), 7.20 (m, aromatics); mass spectrum *m/e* (rel. %): 278 (3), 173 (21), 156 (28), 146 (86), 129 (100). *Exact Mass* calcd. for $C_{15}H_{18}O_5$: 278.11543; found: 278.11534.

1,2,3,4-Tetrahydronaphthalene-2-carboxylate of S*-methyl lactate*

Cycloadduct **12** (146 mg, 0.525 mmol) and 5% palladium on charcoal (30 mg) in acetic acid (10 mL) were stirred under hydrogen (1 atom (101.3 kPa)) at 70°C for 3 days. The mixture was filtered, diluted with CH_2Cl_2 (40 mL), washed with water and 5% aqueous $NaHCO_3$, dried ($MgSO_4$), and evaporated to give a colourless oil (118 mg, 87%); $[\alpha]_D^{20}$–38.4° (*c*, 0.55, $CHCl_3$); ir (CH_2Cl_2): 1740 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.50 (d, 3H, $J_{1',2'}$ = 7.1), 1.90 (m, 1H), 2.25 (m, 1H), 2.85 (m, 3H), 3.10 (m, 2H), 3.75 (s, 3H), 5.15 (q, 1H, $J_{1',2'}$ = 7.1), 7.10 (m, aromatics); mass spectrum *m/e* (rel. %): 262 (2), 137 (37), 130 (100), 129 (26), 115 (14). *Exact Mass* calcd. for $C_{13}H_{18}O_4$: 262.1205; found: 262.1201.

S*-(−)-1,2,3,4-tetrahydronaphthalene-2-carboxylic acid,* **13**

A solution of the methyl lactyl ester of **13** (118 mg, 0.45 mmol) and K_2CO_3 (200 mg) in methanol (15 mL) and water (2 mL) was refluxed for 4 h. Most of the methanol was evaporated, and the solution diluted with water and washed with CH_2Cl_2. The aqueous portion was then acidified with 10% HCl and extracted with CH_2Cl_2, dried ($MgSO_4$), and evaporated to give crystals (69 mg, 86%). Recrystallization from methylene chloride/hexane gave colourless needles; mp 98–100°C; $[\alpha]_D^{20}$–53° (*c*, 0.788, $CHCl_3$); ir (CH_2Cl_2): 1707 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.90 (m, 1H), 2.25 (m, 1H), 2.85 (m, 3H), 3.05 (m, 2H), 7.12 (m, aromatics); mass spectrum *m/e* (rel. %): 177 (4), 176 (35), 131 (32), 130 (100), 115 (17), 104 (20). *Exact Mass* calcd. for $C_{11}H_{12}O_2$: 176.0837; found: 176.0843.

Cycloadduct of fumarate **7**b *and 2-methylbenzaldehyde,* **10**

A solution of 2-methylbenzaldehyde (96.7 mg, 0.81 mmol) and fumarate **7***b* (331.1 mg, 1.15 mmol, 1.42 equiv.) in benzene (30 mL) was flushed with nitrogen and irradiated for 6 h using a 450-watt

Hanovia medium pressure mercury lamp through a Pyrex filter from a distance of 10 cm. The solvent was then evaporated *in vacuo* to give a colorless oil, which was chromatographed (10% ethyl acetate/hexane) to give a crystalline solid (180.6 mg, 55%) that was >95% pure (300 MHz nmr). Recrystallization from hexane gave colourless needles; mp 84.5–85.0°C; $[\alpha]_D^{20}$– 64° (*c* 0.74, $CHCl_3$); ir (CH_2Cl_2): 3471, 1743 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.52 (d, 3H, *J* = 7.1, CH_3), 1.58 (d, 3H, *J* = 7.1, CH_3), 3.05 (m, 2H, H-2, H-4a), 3.27 (m, 2H, H-3, H-4b), 3.75 and 3.82 (s, 3H, OCH_3), 4.53 (br s, 1H, OH), 4.95 (d, 1H, *J* = 9.8, H-1), 5.13 (q, 1H, *J* = 7.1, H-1′), 5.31 (q, 1H, *J* = 7.1, H-1″), 7.11–7.27 (m, aromatics), 7.70 (d, 1H, *J* = 7.2, aromatics); mass spectrum *m/e* (rel. %): 408(2), 304(12), 276(17), 258(37), 201(34), 200(24), 173(35), 172(44), 171(19), 156(28), 155(100), 145(87), 129(78), 128(93), 127(24). *Exact Mass* calcd. for $C_{20}H_{24}O_9$: 408.1420; found: 408.1430. *Anal.* calcd. for $C_{20}H_{24}O_9$: C 58.80, H 5.93; found: C 58.81, H 5.70.

Lactone **11**

A solution of cycloadduct **10** (340 mg, 0.83 mmol) and *p*-toluenesulfonic acid (150 mg) in methylene chloride (40 mL) was stirred at room temperature for 3 days and then evaporated to give a semicrystalline solid. The product was chromatographed (25% ethyl acetate/hexane) to give a white crystalline solid (131 mg, 0.43 mmol, 52%), which was recrystallized from hexane and methylene chloride (traces) to afford white needles; mp 130.0–130.5°C; $[\alpha]_D^{20}$–22.0° (*c*, 1.18, $CHCl_3$); ir (CH_2Cl_2): 1747, 1788 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.38 (d, 3H, *J* = 7.0, CH_3), 3.10 (d, 1H, *J* = 17.7, H-4a), 3.35 (m, 1H, H-3), 3.48 (dd, 1H, *J* = 5.2, 17.7, H-4b), 3.50 (s, 3H, OCH_3), 3.85 (t, 1H, *J* = 5.0, H-2), 4.95 (q, 1H, *J* = 7.0, H-1′), 5.48 (d, 1H, *J* = 5.0, H-1), 7.23 (m, aromatics); mass spectrum *m/e* (rel. %): 304 (16), 201 (19), 200 (34), 172 (10), 156 (18), 145 (17), 144 (25), 129 (68), 128 (100), 127 (16), 117 (11), 115 (12). *Exact Mass* calcd. for $C_{16}H_{16}O_6$: 304.0947; found: 304.0944. *Anal.* calcd. for $C_{16}H_{16}O_6$: C 63.14, H 5.30; found: C 62.96, H 5.51.

X-ray analysis

Crystals of the lactone **11** suitable for X-ray structure analysis were grown from a hexane/methylene chloride solution. The crystal chosen for data collection measured 0.20 mm × 0.15 mm × 0.06 mm and was mounted in a general orientation on a Rigaku AFC6S diffractometer. Unit cell parameters were obtained from the setting angles of 25 reflections in the range 36° < 2θ <51°; 1664 reflections were measured with graphite-monochromatized CuKα radiation ($2\theta_{max}$ = 150°); 1270 were considered observed with $I > 3\sigma(I)$. Standard reflections showed no change over the period of data collection. Lorentz and polarization corrections were applied, but correction for absorption was not warranted.

The structure was solved by direct methods and refined by full-matrix least-squares procedures using the TEXSAN system of computer programs (29). Final values for $R = \Sigma \| F_o | - | F_c \| / \Sigma | F_o |$ and $R_w = [\Sigma w(| F_o | - | F_c |)^2 / \Sigma w | F_o |^2]^{1/2}$ were 0.034 and 0.043, respectively, for 1270 observed data and 264 variables; for all 1664 data, $R = 0.063$ and $R_w = 0.045$. The goodness of fit was 1.43 with weights of $\sigma^{-2}(F_o)$, and the maximum shift in the final cycle of refinement was 0.18σ. The largest peak in the final difference map was 0.12 e Å^{-3}.

Non-hydrogen atom coordinates are given in Table 1 and selected bond lengths are given in Table 2. Hydrogen coordinates, complete lists of bond lengths and angles, temperature factors, and structure factors have been deposited as supplementary material.[2]

Crystal data:

$C_{16}H_{16}O_6$ *fw* = 304.30

Orthorhombic, $P2_12_12_1$, a = 10.387(2), b = 23.637(5), c = 6.195(1) Å, V = 1521.0(5) Å^3, Z = 4, ρ_c = 1.33 Mg m^{-3}, μ = 8.19 cm^{-1} (21°C; CuKα, λ = 1.54178 Å), $F(000)$ = 640.

Acknowledgments

We are grateful to the Natural Sciences and Engineering Research Council of Canada for financial support of this project. We are also indebted to Drs. James Trotter and Steven Rettig, Department of Chemistry, University of British Columbia, for allowing one of us (A.S.S.) to collect data and to solve and refine the structure on their X-ray diffraction and computing facilities.

The chemistry of thujone. XIII.[1] Synthetic studies in the digitoxigenin series

JAMES P. KUTNEY,[2] KRYSTYNA PIOTROWSKA, JOHN SOMERVILLE, SHYH-PYNG HUANG, AND STEVEN J. RETTIG
Department of Chemistry, 2036 Main Mall, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6
Received September 23, 1988

JAMES P. KUTNEY, KRYSTYNA PIOTROWSKA, JOHN SOMERVILLE, SHYH-PYNG HUANG, and STEVEN J. RETTIG. Can. J. Chem. **67**, 580 (1989).

The thujone-derived chiral synthon **1** is converted, via selenium chmistry, to the important cross-conjugated dienone **2** and the latter is then convertible to the unsaturated cardenolide analogue **3**, which through known methodology (**3** → **26** → **27** → **4**), completes a formal synthesis of digitoxigenin (**4**). Extensive studies to afford **2** from androstenedione (**5**) are also described and a new approach to elaborate the essential butenolide ring system, characteristic of the cardiac active steroids, is developed.

Key words: thujone, steroid synthesis, digitoxigenin.

JAMES P. KUTNEY, KRYSTYNA PIOTROWSKA, JOHN SOMERVILLE, SHYH-PYNG HUANG et STEVEN J. RETTIG. Can. J. Chem. **67**, 580 (1989).

En utilisant la chimie du sélénium, on a transformé le synthon chiral **1**, obtenu à partir de la thujone, en la diénone importante **2** à conjugaison croisée que l'on peut convertir en analogue cardénolide insaturé **3**; ce composé, par le biais d'une méthodologie connue (**3** → **26** → **27** → **4**), donne lieu à une synthèse formelle de la digitoxigénine (**4**). On décrit aussi les études poussées qui ont été effectuées pour obtenir le composé **2** à partir de l'androstènedione (**5**) et on a développé une nouvelle approche au système cyclique buténolide essentiel, caractéristique des stéroïdes actifs au niveau cardiaque.

Mots clés : thujone, synthèse des stéroïdes, digitoxigénine.

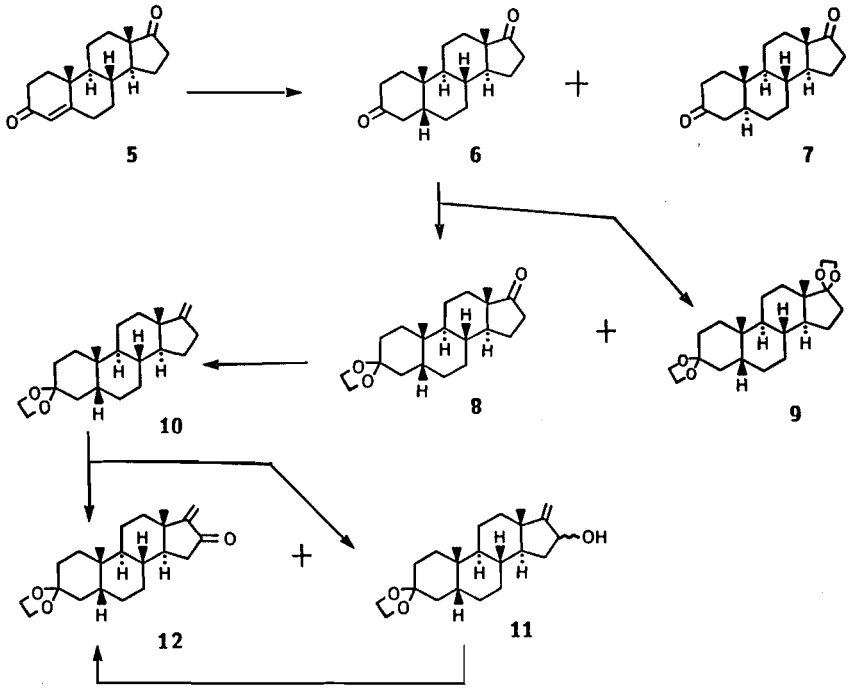
The cardiac active steroids are a well-known group of naturally occurring steroidal lactones of importance in the treatment of heart disease. One of the most commonly used cardiac active glycosides in medicine is digitoxin, isolated from *Digitalis purpurea* (Purple Foxglove) and the main constituent of the well-established heart drug, digitalis. This drug is responsible for one of the highest rates of drug-induced hospital admissions (2) since, to achieve the desired therapeutic effects, 60% of the lethal dose of the drug must be administered and, depending on the physical condition of the patient, the toxic dose can be much lower than anticipated (3). This latter effect is especially pronounced in the treatment of infants where the lethal dose can be much lower than the physician would estimate (4). As a result, there has been considerable incentive for medicinal chemists to synthesize analogues of the digitoxin system in the hope that an improved therapeutic index can be achieved.

Previous synthetic studies in various laboratories (5–17) have afforded synthetic routes to this series of compounds. In these studies, steroidal starting materials were employed and different routes to the butenolide ring system, characteristic of this family of natural products, were developed. We wish to present our studies involving thujone-derived chiral substrates as starting materials for the syntheses of compounds within this family.

Earlier studies in our laboratory (18, 19) revealed efficient routes to the chiral synthon **1** from thujone and we present herein the most recent results, in which **1** is converted into the appropriate building units for the digitoxigenin (**4**) series. The overall strategy of the synthetic program is summarized in Scheme 1.



It is well established that one of the important synthetic requirements in deriving the cardiac active steroid system involves the introduction of the C14-α hydroxyl group. With the exception of one study (11) involving remote functionalization, the utilization of conventional steroid substrates, normally lacking this functionality, requires a number of synthetic steps

SCHEME 1

to introduce this functional group. The majority of the studies reported thus far depend on C14—C15 unsaturated steroids, derived from C17 functionalized steroids, which, in turn, via established chemistry, allow introduction of the C14 hydroxyl group. We felt that our thujone-derived steroid analogues, obtained earlier (18, 19), may be advantageous in affording a more direct route to such unsaturated steroid systems. For

SCHEME 2

example, the thujone-derived intermediates possessing a cyclopropyl ring attached to ring D of the steroid system would, after cyclopropyl ring opening and oxidative cleavage of the resulting unsaturated side chain (18), allow facile entry into 16-keto-17-methyl steroids as exemplified by **1** (Scheme 1). The carbonyl group allows efficient introduction of the required C14—C15 double bond while the C17 methyl group provides for subsequent attachment of the butenolide ring. With **1** on hand, the conversion **1** → **2** (Scheme 1) was considered in our initial phases of this program.

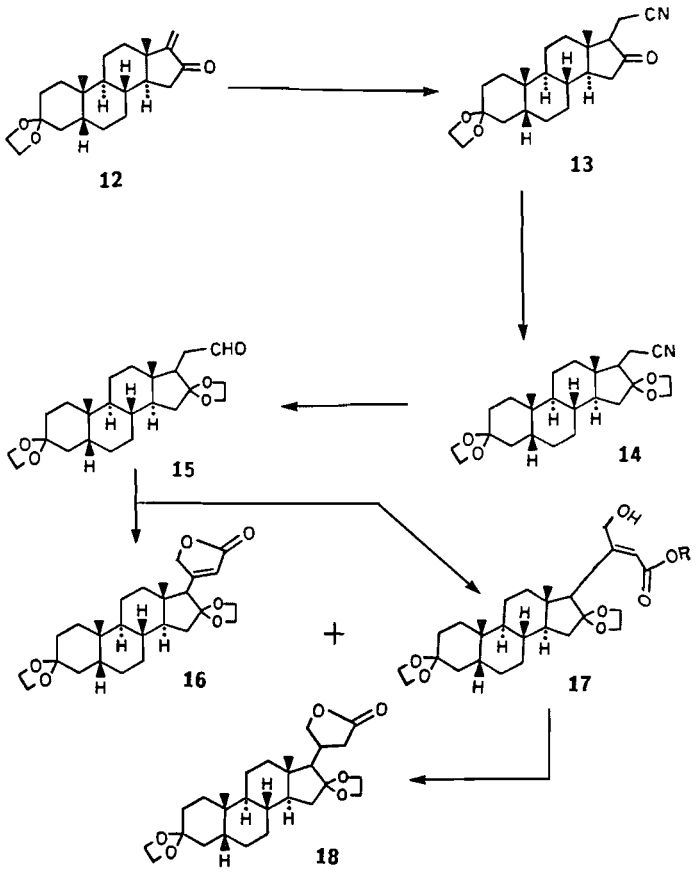
Selenium chemistry, as developed by Barton *et al.* (20), appeared well suited for the above conversion although private discussions with Barton revealed that five-membered ring carbonyl systems were not generally susceptible to dehydrogenation with benzeneseleninic anhydride. Neverthless, after considerable study with various reaction conditions, it was found that the desired dehydrogenation could be accomplished when a weak base (sodium bicarbonate) was employed. The dienone **2**, obtained in 42% overall yield, revealed the expected spectral characteristics (λ_{max} 249 nm; δ 5.23 (1H, s) and 5.97 (2H, s) for the olefinic protons).

It is noteworthy that the stereochemistry at C14 reflects the time and (or) yield in the above dehydrogenation reaction. The thujone-derived intermediate with the 14-β stereochemistry undergoes this reaction under milder conditions (42%, 20 h) while the corresponding 14-α isomer (**12**) (see later) converts to **2** only after 72 h (38%).

As the above thujone related chemistry was under study, a complementary route to **2** from the readily available steroid, androstenedione (**5**), was being developed. The latter study would allow comparisons of compounds prepared from these routes and thereby establish with certainty the total structure and absolute stereochemistry of **2**, as shown in Scheme 1. The overall sequence from **5** to **2** is summarized in Scheme 2.

Catalytic hydrogenation ($Pd/CaCO_3$) of **5** afforded a mixture of C5β (**6**) and C5α (**7**) isomers in an approximate ratio of 2:1 respectively and in excellent overall yield (95%). These isomers are conveniently separated by preparative hplc.

The desired A/B *cis* isomer (**6**) was treated with ethylene glycol and a catalytic amount of *p*-toluenesulfonic acid to provide the required C3 monoketal **8** as a major product (76%), and the latter, upon reaction under conventional Wittig olefination conditions, yielded the exocyclic olefin **10** (91%).



Allylic oxidation of **10** to a mixture of **11** and **12** followed essentially the procedure developed by Schmuff and Trost (21). The allylic alcohol **11** was the major product (75%) and facile separation from the ketone **12** could be achieved. However, for preparative purposes, the resulting mixture of **11** and **12** was subjected to treatment with oxalyl chloride and dimethyl sulfoxide to provide **12** in an overall yield of 82% from **10**. Dehydrogenation with benzeneseleninic anhydride afforded **2** (38%), identical in every respect with the product obtained earlier in the thujone sequence. As noted earlier, the conversion of **12** to **2** requires more drastic conditions (72 h vs. 20 h) than in the case of the corresponding C14-β isomer **1**. As we found later, an attractive alternative to the dehydrogenation reaction proved to be a method employed in the synthesis of the tricyclopentanoid (±)-coriolin (22). Thus, the enolate of the α,β-unsaturated ketone **12**, generated by treatment with lithium hexamethyldisilylamide in tetrahydrofuran at −40°C, was quenched with trimethylsilyl chloride to give the corresponding silyl-enol ether. Oxidation of this enol ether with 2,3-dichloro-5,6-dicyanoquinone resulted in the desired cross-conjugated dienone **2** in 84% yield.

The next phase of our synthetic program involved the development of appropriate chemistry for the elaboration of the required butenolide attached to ring D of the steroid skeleton. For this purpose, the conjugated ketone **12** was selected as starting material and the overall sequence is presented in Scheme 3.

Conjugate addition of cyanide proceeds smoothly to yield the cyano ketone **13** in 91% yield and the latter compound is

SCHEME 3

converted to the ketal **14** by conventional means. The proton and ^{13}C nmr spectra show that both compounds **13** and **14** are single isomers, rather than a mixture of C17 isomers as may be expected. To determine the configuration at C17, the nuclear Overhauser effect (nOe) was employed. Therefore, the nOe-difference experiment was performed for **13** and **14**. In the case of the cyano ketone **13**, irradiation at 0.75 ppm (C18 methyl group) resulted in the enhancement of a quartet at 2.17 ppm (assigned as one of the C20 proton signals). Similarly, in the case of the ketal derivative **14**, irradiation at 0.75 ppm (C18 methyl group) resulted in the enhancement of two quartets at 2.25 and 2.35 ppm (C20 hydrogens) but showed no effect on the C17 proton resonance. These results are consistent with the nitriles **13** and **14** having the desired C17-β configuration. DIBAL reduction of **14** afforded the important intermediate aldehyde **15** (79%). According to literature precedent, the conversion of the aldehyde function to the required butenolide ring system should be achieved. For example, Pettit *et al.*, in their extensive and elegant studies on syntheses of bufadienolides (23), established that steroidal ketones upon reaction with glyoxylic acid or its derivatives provide intermediates convertible to the desired lactones. Similarly Kreiser and Nazir (24) established that steroidal aldehydes undergo reaction with glyoxylic acid under acidic conditions (HCl or CH_3COOH, CH_3COONa) to afford the appropriate butenolide systems. Unfortunately, utilization of the latter conditions in the conversion **15** → **16** did not provide encouraging results and we turned our attention to the possibility of employing the stable methyl ester (25) in the condensation reaction with aldehyde **15**. Indeed reaction of **15** with potassium hydride and anhydrous menthyl

SCHEME 4

glyoxylate, followed by borohydride reduction, afforded a mixture of the desired butenolide **16** (17%) and the unsaturated hydroxyester **17** (24%, R = *l*-menthyl). The latter compound, on catalytic reduction to the saturated ester followed by alkaline hydrolysis and cyclization, affords the saturated lactone **18**, thereby potentially providing an additional source of the butenolide **16** via a dehydrogenation process.

Having established the above synthetic procedures with the more readily available ketone **12**, we turned our attention to studies with the cross-conjugated ketone **2**. Unfortunately the introduction of cyanide via conjugate addition employing the above-noted procedure afforded a complex mixture of products resulting from cyanide attack at both of the olefinic sites. However the Nagata procedure (26), in which diethylaluminum cyanide is involved, provided the desired cyano derivative **20** as a mixture of C17 isomers. This mixture was very difficult to separate, but after extensive chromatographic separations, it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

was possible to obtain a pure sample of the major C17-β isomer (ratio of C17-β to C17-α is 2:1) for detailed nmr studies. The nOe difference experiments established the stereochemistry of the major product. Thus irradiation at 1.24 ppm (C18 methyl) resulted in enhancement (8%) of a quartet at 2.26 ppm, which is assigned to one of the C20 protons. The corresponding enhancement of the C17 proton signals (doublet of doublets) was only 4%, thereby suggesting a *trans* relationship between the C17 proton and the C18 methyl group.

Since the chromatographic purification of the major isomer **20** was very inefficient, we decided to perform the next two reactions employing the mixture of isomers. Thus, the cyano ketones were reduced with sodium borohydride, in the presence of cesium chloride (27), to a mixture of allylic alcohols (**21**). This mixture was again difficult to separate so it was treated directly with acetic anhydride, in the presence of dimethylaminopyridine (DMAP) in CH_2Cl_2, to produce a mixture of four acetates. The major acetate produced from cyanoketone **20** in 68% yield was separated from the mixture by column chromatography on TLC grade silica gel. The results of the nOe experiment suggested that the structure of the major acetate **22** was as shown in Scheme 4, since irradiation at 1.06 ppm (C18 protons) resulted in enhancement of a quartet at 2.47 ppm, assigned to one of the C20 protons, and enhancement of a broad doublet corresponding to the proton at C16. However, to establish definitely the structure of **22**, the compound was submitted for X-ray crystallography. The details of the X-ray studies are provided as an appendix.

In accord with our synthetic strategy, the next consideration was removal of the C16 substituent in **22**. This was achieved via nucleophilic displacement of the acetate group with hydride anion and involving palladium intermediates (28). For this purpose, the palladium complex of the acetate **22** was initially formed in a reaction with tetrakis(triphenyl phosphine) palladium(0) followed by addition of sodium borohydride to yield the desired derivative **23** in 79% yield.

Utilizing methodology employed for the conversion **15** → **16** + **17** (Scheme 3), the cyano derivative **23** was reduced with DIBAL and the resultant aldehyde **24** (81% yield) was reacted with potassium hydride followed by menthyl glyoxylate and sodium borohydride to produce a mixture of butenolide **3** and unsaturated *trans* ester **25** in 24 and 20% yield respectively.

The butenolide system **3** produced in the course of our synthesis can be easily transformed into digitoxigenin with the employment of well-known methods previously established in the chemistry of cardenolides (29). Thus, after deketalization to the known ketone **26**, reduction (**26** → **27**, Scheme 1) with iridium reagents (30), and subsequent hydroxylation of the C14—C15 double bond (30, 31), the final product digitoxigenin (**4**) is obtained.

It should be noted that another approach for elaboration of the butenolide ring system was considered, and employed the thioketal derivative **19**. For this purpose, **2** was reacted with the anion of 1,3-dithiane in the presence of HMPA (32) to afford a mixture (86% yield) of the C17 isomers (ratio 2:1, as established by nmr). Unfortunately the separation of these isomers proved extremely difficult and subsequent studies to remove the sulfur protecting group led to extensive decomposition. This approach was therefore abandoned.

Finally, it should be indicated that the above studies allow a rather versatile synthetic entry into cardenolide analogues with functionality in ring D. The latter series is not presently available from natural sources or alternative synthetic routes. For example, intermediates **16**, **18**, and **22** afford convenient routes into such analogues. We believe that the latter compounds will afford the opportunity for further structure–activity studies in the hope that lower toxicity within this family of compounds can be obtained. Such studies are being presently considered.

Experimental

Melting points were determined on a Reichert hot stage apparatus and are uncorrected. Ultraviolet spectra were recorded on a Cary 15 spectrometer in methanol solution. Infrared spectra were measured on Perkin Elmer 710 and 1710 (Fourier transform) spectrometers using chloroform as a solvent. The ^{1}Hmr spectra were recorded on Bruker WH-400 or Nicolet–Oxford H-270 instruments and the chemical shifts are in δ values. Deuteriochloroform was used as the solvent with TMS as internal standard. Low resolution mass spectra were determined on an AEI-MS-902 spectrometer. High resolution mass measurements were made on an AEI-MS-50. Optical rotations were measured on a Perkin Elmer 141 automatic polarimeter. Circular dichroism curves were recorded on a Jasco J-20 spectropolarimeter. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel 60 G. Petroleum ether refers to the fraction with boiling range 30–60°C. The hplc chromatography was performed on a Waters LC-500 instrument.

17-Methylene-5β-androst-14-en-3,16-dione-3,3-ethylene ketal (2)

From 1[3]

A mixture of ketone **1** (80 mg, 0.23 mmol), sodium bicarbonate (50 mg), and benzeneselenic anhydride (208 mg, 0.58 mmol) in chlorobenzene (2 mL) was heated at 70°C with stirring for 20 h. The mixture was then evaporated and the oily residue dissolved in ethyl ether and filtered. Evaporation of the solvent and purification by preparative layer chromotography with ether – petroleum ether (1:1, v/v) yielded 34 mg (42.5%) of pure **2**; mp 146°C (hexane); $[\alpha]_D$ +221 ± 6° (*c* 0.2320, CH_2Cl_2); uv λ_{max} (EtOH): 249 nm (*c* = 2.32 × 10); ir ν_{max} (KBr): 1695 cm^{-1}; ^{1}Hmr δ: 1.07 (3H, s), 1.27 (3H, s), 1.3–2.05 (16H, m), 2.47 (1H, dt, *J* = 4, 10 Hz), 3.93 (4H, 2), 5.23 (1H, s), 5.97 (2H, s); ms *m/z*: 342 (M^+), 327, 125, 99. High resolution molecular weight determination calcd. for $C_{22}H_{30}O_3$: 342.2197; found: 342.2199. *Anal.* calcd. for $C_{22}H_{30}O_3$: C 77.21, H 8.83; found: C 77.16, H 8.59.

From 12, Method A

A mixture of enone **12** (344 mg, 1 mmol), sodium bicarbonate (250 mg), and benzeneselenic anhydride (360 mg, 1 mmol) in chlorobenzene (9 mL) was heated at 60°C with stirring for 72 h. The reaction mixture worked up and purified as above gave 131 mg (38%) of dienone **2**.

From 12, Method B

A solution of lithium hexamethyldisilylamide was prepared by adding 5.67 mL (9.07 mmol) of a solution of *n*-butyllithium (1.6 M, hexanes) to a solution of hexamethyldisilazane (3.34 mL, 15.1 mmol) in dry THF (15 mL) at −40°C (CH_3CN/CO_2 bath), and added to a solution of the α,β-unsaturated ketone **1** (2.60 g, 7.56 mmol) in dry THF (15 mL) under Ar atmosphere. After 15 min at −40°C, the reaction was quenched with an excess of TMSCl (4.8 mL, 38 mmol) and allowed to warm up to room temperature. The above solution was then added to a solution of 2,3-dicyano-4,5-dichlorobenzoquinone (2.06 g, 9.07 mmol) in CH_3CN (150 mL) at room temperature. After stirring for 1 h, the resulting black mixture was evaporated to dryness, redissolved in 200 mL ethyl acetate, and washed with NaOH (3×, 100 mL, 10% aqueous) and brine (2×, 100 mL). The organic layer was dried over $MgSO_4$, filtered, and concentrated *in vacuo* to yield a brown foam. This crude product was then purified on a short silica gel column using ethyl acetate – toluene (5:95, v/v) to yield 2.19 g (84%) of the cross-conjugate diene **2**.

5β-Androstane-3,17-dione (6)

A solution of androstenedione (**5**) (5.72 g, 20 mmol) in 2-propanol (500 mL) containing 10% $Pd/CaCO_3$ (500 mg) was stirred under H_2 for 5 h. The catalyst was removed by filtration through Celite and washed with hot 2-propanol (2 × 50 mL). The combined filtrate and washings were evaporated to leave a colourless oil. The reaction yielded a mixture of 5α and 5β isomers of androstanedione. The mixture was separated by hplc chromatography with ethyl acetate – petroleum ether (2:3, v/v) to yield 3.84 g (67%) of pure **6** and 1.60 g (28%) of pure **7**.

The physical properties of **6** are as follows: mp 131.0–132.5°C (ligroin); $[\alpha]_D$ 106.2 ± 2° (*c* 1.0165, $CHCl_3$); cd (MeCN, $c = 6.58 \times 10^{-3}$): 280 (+2.92); ir ν_{max}: 1725, 1705 cm^{-1}; ^{1}Hmr δ: 0.9 (3H, s), 1.06 (3H, s), 1.15–2.23 (16H, m), 2.32 (2H, dt, *J* = 6, 16 Hz), 2.47 (1H, dd, *J* = 8, 20 Hz), 2.68 (2H, t, *J* = 16 Hz); ms *m/z*: 288 (M^+), 273, 255. High resolution molecular weight determination calcd. for $C_{19}H_{28}O_2$: 288.2089; found: 288.2086. *Anal.* calcd. for $C_{19}H_{28}O_2$: C 79.12, H 9.79; found: C 78.86, H 9.80.

And for **7**: mp 133.5–134.0°C (ether/pentane); $[\alpha]_D$ 116 ± 2.5° (*c* 1.0266, $CHCl_3$); cd (MeCN, $c = 7.229 \times 10^{-3}$): 286 (+5.15); ir ν_{max} (KBr): 1725, 1705 cm^{-1}; ^{1}Hmr δ: 0.89 (3H, s), 1.05 (3H, s), 1.23–2.48 (22H, m); ms *m/z*: 288 (M^+), 270, 255. High resolution molecular weight determination calcd. for $C_{19}H_{28}O_2$: 288.2089; found: 288.2093. *Anal.* calcd. for $C_{19}H_{28}O_2$: C 79.12, H 9.79; found: C 78.96, H 9.69.

5β-Androstane-3,17-dione-3,3-ethylene ketal (8)

To a solution of **6** (4.3 g, 14.9 mmol) in benzene (200 mL) was added *p*-toluenesulfonic acid (50 mg) and ethylene glycol (0.923 g, 14.9 mmol). The mixture was heated under reflux with azeotropic removal of H_2O for 3 h. The mixture was cooled, diluted with petroleum ether, washed with $NaHCO_3$, dried ($MgSO_4$), and evaporated. The residue was chromatographed on silical gel with ether – petroleum ether (2:3, v/v) to give the desired product (**8**) (3.77 g, 76%) and diketal (**9**) (0.58 g, 10.3%) in addition to some unreacted starting diketone **6** (0.22 g, 5%).

The physical properties of **8** are as follows: mp 130.5–131.0°C; $[\alpha]_D$ +96 ± 4° (*c* 0.2035, EtOH); ir ν_{max}: 1725 cm^{-1}; ^{1}Hmr δ: 0.87 (3H, s), 0.99 (3H, s), 1.09–2.07 (20H, m), 2.1 (1H, t, *J* = 8 Hz), 2.45 (1H, dd, *J* = 8, 20 Hz), 3.94 (4H, s); ms *m/z*: 332 (M^+), 317, 276, 125, 99. High resolution molecular weight determination calcd. for $C_{21}H_{32}O_3$: 332.2350; found: 332.2350. *Anal.* calcd. for $C_{21}H_{32}O_3$: C 75.92, H 9.71; found: C 76.00, H 9.76.

The physical properties of **9** are as follows: mp 58.0–59.0°C (methanol); $[\alpha]_D$ −6.19 ± 0.7° (*c* 1.115, CH_2Cl_2); ^{1}Hmr δ: 0.85 (3H, s), 0.96 (3H, s), 1.00–2.10 (22H, m), 3.80–4.00 (8H, m); ms *m/z*: 376 (M^+), 125, 99. High resolution mass measurement calcd. for $C_{23}H_{36}O_3$: 376.2614; found: 376.2614. *Anal.* calcd. for $C_{23}H_{36}O_3$: C 73.47, H 9.65; found: C 73.75, H 9.16.

17-Methylene-5β-androstan-3-one-3,3-ethylene ketal (10)

To a bright yellow mixture of methyltriphenylphosphonium bromide (5.86 g, 16.4 mmol) and potassium *tert*-butoxide (1.76 g, 15.6 mmol) in THF (20 mL) was added ketone **8** (3.69 g, 11.1 mmol) in THF (100 mL). After refluxing for 5 h, the mixture was portioned between hexane (220 mL) and water (180 mL). The organic layer was washed with 50% MeOH (200 mL) and brine (200 mL), dried ($MgSO_4$), and evaporated *in vacuo*. Column chromatography of the crude product with 5% of ethyl ether in petroleum ether (v/v) yielded **10** (3.34 g, 91%) as a colorless oil; $[\alpha]_D$ +38.2° (*c* 0.2120, EtOH); ir ν_{max}: 1655 cm^{-1}; ^{1}Hmr δ: 0.77 (3H, s), 0.98 (3H, s), 1.0–2.53 (22H, m), 3.95 (4H, s), 4.61 (1H, br s), 4.63 (1H, br s); ms *m/z*: 330 (M^+), 315, 268, 125, 99. High resolution molecular weight determination calcd. for $C_{22}H_{34}O_2$: 330.2559; found: 330.259. *Anal.* calcd. for $C_{22}H_{32}O_2$: C 80.01, H 10.38; found: C 80.20, H 10.50.

16-Hydroxy-17-methylene-5β-androstane-3-one-3,3-ethylene acetal (11) and 17-methylene-5β-androstane-3,16-dione-3,3-ethylene ketal (12)

From 10

To a suspension of selenium dioxide (558 mg, 5 mmol) in methylene dichloride (25 mL) at room temperature was added a 70% solution of *tert*-butyl hyperoxide (1.93 mL, 1.82 g, 20 mmol). The mixture was stirred at room temperature for 1 h. The steroidal olefin **10** (3.30 g, 10 mmol) in methylene dichloride (55 mL) was then added and stirring was continued for 5 h. The reaction mixture was diluted with ethyl ether (500 mL) and washed with 10% sodium hydroxide (2 × 250 mL) and water, separated, dried ($MgSO_4$), and evaporated. Chromatographic separation of the reaction mixture with ether – petroleum ether (3.7 v/v) gave allylic alcohol **11** (2.59 g, 75%) and unsaturated ketone **12** (0.61 g, 18%).

The physical properties of **11** are as follows: mp 167–168°C (EtOH); $[\alpha]_D$ 2.4 ± 0.3° (*c* 2.852, CH_2Cl_2); ir ν_{max}: 3580 cm^{-1}; ^{1}Hmr δ: 0.77 (3H, s), 0.97 (3H, s), 1.06–1.91 (20H, m), 1.98 (1H, t, *J* = 12 Hz), 3.92 (4H, s), 4.63 (1H, br s), 4.83 (1H, d, *J* = 2 Hz), 5.03 (1H, d, *J* = 2 Hz); ms *m/z*: 346 (M^+), 328, 313, 125, 99. High resolution molecular weight determination calcd. for $C_{22}H_{34}O_3$: 346.2499; found: 346.2503. *Anal.* calcd. for $C_{22}H_{34}O_3$: C 76.37, H 9.91; found: C 76.31, H 9.88.

17-Methylene-5β-androstan-3,16-dione-3,3-ethylene ketal (12)

From 11

To a solution of oxalyl chloride (670 μL, 975 mg, 7.68 mmol) in methylene dichloride (15 mL) at −78°C was added a solution of dimethyl sulfoxide (1.7 mL, 1.2 g, 15.36 mmol) in methylene dichloride (5 mL) and the mixture stirred at −78°C for 5 min. A solution of allylic alcohol (**11**) (2.39 g, 6.9 mmol) in methylene chloride was then added to this mixture at −78°C. After stirring for 15 min, neat triethylamine (2.85 mL, 2.07 mmol) was added. The solution was allowed to warm to −20°C and held at this temperature for 3 h. The reaction mixture was diluted with chloroform (75 mL), washed with 10% hydrochloric acid, water, sodium bicarbonate, and again with water. After drying ($MgSO_4$), and removal of the solvent the product was purified by column chromatography to give pure **12** (2.04 g, 86%); mp 99.5–100°C (isopropanol); $[\alpha]_D$ −119 ± 0.3° (*c* 0.2771, EtOH); uv λ_{max}: 227 (3.66); ir ν_{max}: 1722 cm^{-1}; ^{1}Hmr δ: 0.95 (3H, s), 1.01 (3H, s), 1.09–2.07 (19H, m), 2.24 (1H, dd, *J* = 18, 8 Hz), 3.94 (4H, s), 5.0 (1H, d, *J* = 1 Hz), 5.79 (1H, d, *J* = 1 Hz); ms *m/z*: 344 (M^+), 329, 287, 195, 125, 99. High resolution molecular weight determination calcd. for $C_{22}H_{32}O_3$: 344.2351; found: 344.2351. *Anal.* calcd. for $C_{22}H_{32}O_3$: C 76.71, H 9.36; found: C 76.49, H 9.35.

17-Cyanomethyl-5β-androstan-3,16-dione-3,3-ethylene ketal (13)

A mixture of enone **12** (1.85 g, 5.4 mmol), dimethylformamide (85 mL), potassium cyanide (0.84 g, 12.5 mmol in 5.6 mL H_2O), and ammonium chloride (0.5 g, 9.4 mmol in 5.6 mL H_2O) was refluxed for 3 h, cooled, diluted with water, and extracted with ethyl acetate. The organic layer was washed with water, dried ($MgSO_4$), and evaporated. The crude product was purified on a short chromatography column with ether – petroleum ether (1:1, v/v), yielding pure cyano derivative **13** (1.82 g, 91.2%); mp 162–162.5°C (EtOH); $[\alpha]_D$ −126 ± 0.1° (*c* 1.3796, EtOH); ir ν_{max}: 2310, 1730 cm^{-1}, ^{1}Hmr δ: 0.77 (3H, s), 0.99 (3H, s), 1.12–1.95 (17H, m), 2.01 (1H, t, *J* = 12 Hz), 2.12–2.35 (4H, m), 2.72 (1H, dd, *J* = 18, 4 Hz), 3.94 (4H, s); ^{13}Cmr (75 MHz, $CDCl_3$) δ: 12.113 (C11), 13.158 (C18), 20.217 (C12), 22.879 (C19), 26.242 (C6), 29.886 (C1), 32.493 (C8), 33.678 (C2), 34.550 (C10), 35.477 (C4), 37.147 (C7), 37.404 (C20), 39.723 (C9), 40.4222 (C5), 41.776 (C13), 50.066 (C14), 58.773 (C17), 63.826 (C15), 63.885 and 64.016 (C3 ethyleneketal), 109.380 (C3), 118.434 (C21), 214.071 (C16); ms *m/z*: 371 (M^+), 356, 314, 125, 99. 5β-Card-20(22)-enolide-3,16-dione-3,3,16,16-diethylene ketal (16) and R(−)-menthyl-21-hydroxy-3,3,16,16-diethylene-dioxy-24-nor-chol-20(22)-en-23-ate (17)

From ***15***

To a suspension of potassium hydride (244 mg of 22%, 122 mmol) in THF (6 mL) was added over 5 min at room temperature a solution of aldehyde **15** (418 mg, 1 mmol) in THF (6 mL). After hydrogen evolution had ceased, the turbid yellowish solution was stirred for another 15 min. Then freshly distilled anhydrous (*R*)-menthyl glyoxylate (318 mg, 1.5 mmol) in THF (2 mL) was added and the mixture was stirred for 1 h at room temperature. The reaction was quenched with H_2O (0.5 mL), diluted with 5 mL of MeOH, sodium borohydride (190 mg, 5 mmol) was added, and the mixture was stirred for 30 min. Excess of borohydride was decomposed with acetone. Then the reaction mixture was evaporated and partitioned between ethyl acetate (200 mL) and 1 M hydrochloric acid (200 mL). The organic layer was washed with water and sodium bicarbonate, dried ($MgSO_4$), and evaporated to give 970 mg of crude reaction product. Subsequent, careful separation on a chromatography column with ether – petroleum ether (2:3, v/v) yielded butenolide **16** (78 mg, 17.0%) and unsaturated hydroxyester **17** (147 mg, 24.0%).

The physical properties of **17** are as follows: mp 197–198°C (heptane); $[\alpha]_D$ 11.3 ± 0.7° (*c* 2.2629, CH_2Cl_2); ir ν_{max}: 3612, 1704 cm^{-1}; ^{1}Hmr δ: 0.75 (3H, d, *J* = 8 Hz), 0.85–0.98 (12H, m), 1.03–2.07 (30H, m), 2.28 (1H, t, *J* = 6 Hz), 3.72–3.95 (8H, m), 4.21 (1H, dd, *J* = 14, 8 Hz), 4.48 (1H, dd, *J* = 14, 8 Hz), 4.74 (1H, dt, *J* = 10, 2 Hz), 6.19 (1H, s); ms *m/z*: 614 (M^+), 552, 476, 125, 99. High resolution molecular weight determination calcd. for $C_{27}H_{38}O_6$: 458.2970; found: 458.2969. *Anal.* calcd. for $C_{27}H_{38}O_6$: C 70.74, H 8.30; found: C 70.98, H 8.49.

5β-Cardanolide-3,3,16,16-diethylene ketal (18)

A solution of **17** (100 mg, 0.16 mmol) in 2-propanol (20 mL) containing 10% $Pd/CaCO_3$ (30 mg) was stirred under H_2 for 2 h. The catalyst was removed by filtration and washed with hot propanol (10 mL). The combined filtrate and washings were evaporated. The crude reduction product was hydrolyzed in a mixture of 10% NaOH (50 mL) and ethanol (50 mL) for 10 min at reflux. Then the solution was diluted with water (50 mL) and, after evaporation of ethanol, neutralized (10% HCl) and extracted with ethyl acetate. The organic layer was washed with sodium bicarbonate, dried ($MgSO_4$), and evaporated *in vacuo*. The column chromatography with ether – petroleum ether (1:1, v/v) yielded pure **18** (47 mg, 62.5%); ir ν_{max}: 1772 cm^{-1}; ^{1}Hmr δ: 0.84 (3H, s), 0.95 (3H, s), 1.04–1.92 (2H, m), 1.98 (1H, t, *J* = 12 Hz), 2.35–2.55 (2H, m), 2.78–2.89 (1H, m), 3.75–3.95 (9H, m), 4.45 (1H, t, *J* = 6 Hz); ms *m/z*: 460 (M^+), 375, 305, 125, 99. High resolution molecular weight determination calcd. for $C_{27}H_{40}O_6$: 460.2829; found: 460.2827. *Anal.* calcd. for $C_{27}H_{40}O_6$: C 70.43, H 8.69; found: C 70.40, H 8.59.

20,20-(1′, 3′-Propylene)-dithio-5β-pregn-14-ene-3-one-3, 3-ethylene ketal (19)

To a solution of 1,3-dithiane (77 mg, 0.64 mmol) and HMPA (222 μL, 1.28 mmol) in THF (6 mL), *n*-BuLi in hexane (1.6 M, 0.42 mL, 0.67 mmol) was added and the mixture was stirred at −25°C for 2 h to form anion. Then cross-conjugated ketone **2** (219 mg, 0.64 mmol) in THF (7 mL) was added and the mixture was allowed to warm up slowly to room temperature and stirred for another hour. Quenching with aqueous ammonium chloride followed by extraction (methylene dichloride), evaporation, and chromatographic separation yielded pure dithio derivative **18** (159 mg, 86.1%) as a mixture of two 17-isomers (2:1 ratio). The separation of the isomers proved to be very difficult and only a small sample of the pure major isomer was isolated for the purpose of characterization; mp 186°C; ir ν_{max} ($CHCl_3$): 1700 cm^{-1}; uv λ_{max} (EtOH): 232 nm; ^{1}Hmr δ: 1.04 (3H, s), 1.09 (3H, s), 1.26–2.27 (10H, m), 2.43–2.51 (2H, m), 2.87 (4H, m), 3.94 (4H, s), 3.8 (1H, dd), 5.75 (1H, s); ms *m/z*: 462 (M^+), 343, 330, 216, 133, 125, 99. *Anal.* calcd. for $C_{26}H_{38}O_3S_2$: C 67.53, H 8.23; found: C 67.52, H 8.36.

17-Cyanomethyl-5-β-androstene-3,16-dione-3,3-ethylene ketal (20)

A solution of the diene **2** (443 mg, 130 mmol) in dry benzene (12 mL) was prepared at room temperature and to this was quickly added 1.30 mL (1.30 mmol) of a solution of diethylaluminum cyanide (1 M, toluene). Upon addition of the diethylaluminum cyanide the solution turned deep orange and quickly faded (in about 30 s) to a light orange color. After stirring for 30 min at room temperature, the reaction was quenched with NaOH (2 mL, 10% aqueous), which caused the orange color to disappear. This mixture was then diluted with ethyl acetate (100 mL) and washed with NaOH (2 × 50 mL, 10% aqueous), brine (2 × 50 mL), dried over $MgSO_4$, filtered, and concentrated *in vacuo* to yield a white foam. This crude product was purified on a short silica gel column using ethyl acetate – hexanes (1:4, v/v) to yield 360 mg (75%) of the unsaturated nitrile **20** as a mixture of C17 epimers. Gas–liquid chromatographic analysis of this mixture showed that the ratio of isomers was about 2:1. Repeated attempts to separate these isomers by column chromatography (hplc) was only partially successful. It was possible to enrich the mixture in the major isomer enough that the minor isomer could not be detected by ^{1}Hmr (but could be detected by capillary gas chromatography). The data given here are for this mixture.

The physical properties of the nitrile **20** are as follows: mp 54.0–55.0°C (hexanes); ir ν_{max}: (KBr): 2342, 1703, 1605 cm^{-1}; uv λ_{max}: 233 nm (9.64 × 10^3, ethanol); ^{1}Hmr δ: 1.05 (3H, s), 1.24 (3H, s), 0.83–2.35 (17H, m), 2.26 (1H, q, *J* = 18, 16 Hz, C20-H), 2.45 (1H, dd, *J* = 16.4 Hz, C17-H), 2.49 (1H, m, C8-H), 2.92 (1H, dd, *J* = 18.4 Hz, C20-H′), 3.93 (4H, s, C3 ketal), 5.80 (1H, s, C15-H); ms *m/z*: 369 (M^+), 125 ($C_7H_9O_2$), 99 ($C_5H_7O_2$). High resolution mass measurement for $C_{23}H_{31}O_3N$: 369.2292; found: 369.2298. *Anal.* calcd. for $C_{23}H_{31}O_3N$: C 74.79, H 8.40, N 3.79; found: C 74.40, H 8.86, N 3.58.

16-Hydroxy-17-cyanomethyl-5β-androstene-3-one-3,3-ethylene ketal (21)

The unsaturated cyanoketone **20** (mixture of C17 epimer, 1 g, 2.71 mmol) was dissolved in a 0.4 M solution (36 mL) of cerium

chloride hydrate in methanol. Then sodium borohydride (266 mg, 7 mmol) was added and the reaction was stirred at room temperature for 30 min. After evaporation of the solvent the residue was redissolved in ethyl acetate, washed with water, dried over $MgSO_4$, and evaporated again. Crude product (1.05 g) consisting of four isomeric allylic alkaloids was used in the next transformation without further purification.

A small sample of the major alcohol **21** was obtained after hplc separation; ir (neat) ν: 3600 (br), 2290; ^{1}Hmr δ: 0.98 (3H, s), 1.00 (3H, s), 1.24–2.11 (19H, m), 2.44 (1H, dd), 2.65 (1H, dd), 3.92 (4H, s), 4.46 (1H, m), 5.20 (1H, s); ms *m/z*: 371 (M^+), 353, 125, 99. *Anal.* calcd. for $C_{23}H_{33}NO_3$. C 74.36, H 8.95, N 3.77; found: C 74.10, H 8.87, N 3.90.

16-Acetoxy-17β-cyanomethyl-5β-androstene-3-one-3,3-ethylene ketal (22)

The crude mixture of the allylic alkaloids (**21** and isomers, 440 mg, 1.19 mol) was dissolved in methylene chloride (20 mL) and treated with acetic anhydride (380 μl, 1 mmol) in the presence of dimethylaminopyridine (146 mg, 1.2 mmol) at room temperature for 15 min. The reaction mixture was subsequently washed with 10% hydrochloric acid, water, and sodium bicarbonae, dried ($MgSO_4$), and evaporated to dryness. The column chromatography with ether – petroleum ether (3:7, v/v) of the crude product consisting of four isomeric allylic acetates yielded a pure major isomer **22** (255 mg, 68.1% from **17** cyanoketone; 54.2% from the mixture of **17**α and **17**β isomers); mp 158°C; ir ν_{max}: 2252, 1730 cm^{-1}; ^{1}Hmr δ: 0.98 (3H, s, C19), 1.06 (3H, s, C18), 1.26–2.14 (17H, m), 2.10 (3H, s, acetate), 2.2 (1H, m, C17), 2.47 (1H, dd, C20), 2.61 (1H, dd, C20), 3.92 (4H, s, ketal), 5.2 (1H, s, C15), 5.46 (1H, bd, C16); ms *m/z*: 413 (M^+), 370, 353, 338, 125, 99. *Anal.* calcd. for $C_{25}H_{35}NO_3$: C 72.64, H 8.47, 3.39; found: C 72.60, H 8.40, N 3.19.

17β-Cyanomethyl-4β-androstene-3-one-3,3-ethylene ketal (23)

A yellow solution of the acetate **22** (100 mg, 0.240 mmol) and tetrakis(triphenylphosphine) palladium (0) (9275 mg, 0.240 mmol) in 4 mL of THF was stirred at room temperature under an argon atmosphere. After 10–15 min, the mixture turned black, sodium borohydride (100 mg, 2.63 mmol) was added, and the stirring was continued until the starting material disappeared (tlc, 1–2 h). After the excess of sodium borohydride was decomposed with acetone, the reaction mixture was evaporated to dryness and purified on a short silica gel column with ether – petroleum ether (1:4, v/v) to yield 68 mg (79.1%) of cyano derivative **23**.

The physical properties of **23** are as follows: ir ν_{max}: 2248 cm^{-1}; ^{1}Hmr δ: 0.90 (3H, s, C18), 0.98 (3H, s, C19), 1.20–2.05 (18H, m), 2.165 (1H, m), 2.395 (2H, dd), 2.5 (1H, m), 3.94 (4H, s), 5.14 (1H, s); ms *m/z*: 355 (M^+), 340, 315, 298, 125, 99. High resolution mass measurement calcd. for $C_{23}H_{33}NO_2$: 355.2511; found: 355.2520.

20-Oxo-5β-pregn-14-ene-3-one-3,3-ethylene ketal (24)

A solution of nitrile **23** (355 mg, 1 mmol) in benzene (10 mL) was treated with a 1 M solution of diisobutylaluminum hydride in hexane solution (1.2 mL, 1.2 mmol) at room temperature. The mixture was stirred for 30 min, then quenched with saturated ammonium chloride solution and diluted with petroleum ether. The organic layer was washed with water, dried ($MgSO_4$), and evaporated to dryness. The chromatographic separation with ether – petroleum ether (3:7, v/v) yielded pure aldehyde **24** (290 mg, 81.0%); ir ν_{max}: 1719 cm^{-1}; ^{1}Hmr δ: 0.82 (3H, s, C18), 0.98 (3H, s, C19), 1.17–2.11 (1H, m), 2.27 (1H, m), 2.45 (2H, m), 2.56 (1H, m), 3.94 (4H, s), 5.18 (1H, s, C15), 9.8 (1H, 5); ms *m/z*: 358 (M^+), 330, 314, 125, 99. High resolution mass measurement calcd. for $C_{23}H_{34}O_3$: 358.2508; found: 358.2516.

5β-Card-14,20(22)-dienolide-3-one-3,3-ethylene ketal (23) and R *(−)-methyl-21-hydroxy-3,3-ethylenedioxy-24-nor-chol-14,20(22)-dien-23-153 (25)*

To a suspension of potassium hydride (50 mg of 30%, 0.36 mmol) in THF (2 mL), at room temperature, was slowly added a solution of aldehyde **24** (107 mg, 0.3 mmol) in THF (2 mL). After hydrogen evolution had ceased, the turbid yellow suspension was stirred for 20 min and the solution of freshly distilled anhydrous (*R*)-methylglyoxylate (95.4 mg, 0.45 mmol) in THF (2 mL) was added. The reaction was stirred for another hour at room temperature, then quenched with water (0.15 mL), diluted with methanol (1.5 ml), and treated with sodium borohydride (60 mg, 1.58 mmol). After 30 min of stirring the excess of sodium borohydride was decomposed with acetone. Then the reaction mixture was evaporated and partitioned between ethyl acetate (60 mL) and 10% hydrochloric acid (60 mL). The organic layer was washed with water and sodium bicarbonate, dried ($MgSO_4$), and evaporated to dryness. Separation of the crude product on a chromatography column with ether – petroleum ether (2:3, v/v) yielded butenolide **3** (29 mg, 24.4%) and hydroxyester **26** (33 mg, 19.9%).

The physical properties of **3** are as follows: ir ν_{max}: 1782, 1747, 1632 cm^{-1}; ^{1}Hmr δ: 0.81 (3H, s, C18), 0.97 (3H, s, C19), 1.23–2.11 (17H, m), 2.47 (2H, m, C16), 2.8 (1H, t, C17), 3.94 (4H, s, ketal), 4.77 (2H, dd, C2), 5.25 (1H, s, C15), 5.90 (1H, s, C22); ms *m/z*: 398 (M^+), 354, 125, 99. High resolution mass measurement calcd. for $C_{25}H_{34}O_4$: C 75.38, H 8.54; found: C 75.91, H 8.54.

And for the ester **25**: ir ν_{max}: 1690 cm^{-1}; ^{1}Hmr δ: 0.73–0.99 (15H, m), 1.23–2.22 (27H, m), 2.33 (2H, m, C16), 3.94 (4H, s, ketal), 4.25 (2H, t, C21), 4.29 (1H, s, OH), 4.71 (1H, dt), 5.17 (1H, s, C15), 6.17 (1H, s, C22); ms *m/z*: 554 (M^+), 536, 416, 398, 380, 354, 284, 125, 99. High resolution mass measurement calcd. for $C_{35}H_{54}O_5$: 554.3971; found: 554.3977. *Anal.* calcd. for $C_{35}H_{54}O_5$: C 75.77, H 9.81; found: C 75.70, H 9.62.

Appendix

X-ray crystallographic analysis of the compound structure 22

A crystal bounded by the six faces (followed by the distances in mm between parallel faces): (0 0 1), 0.020, ±(0 1 −1), 0.30, (1 0 −1), 0.53 was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 20–33°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are as follows:

$C_{25}H_{35}NO_4$ f.w. = 413.56

Monoclinic, a = 6.526(1), b = 10.728(2), c = 17.011(2) Å, β = 94.867(8)°, V = 1137.5(3) Å^3, Z = 2, ρ_c = 1.207 Mg m^{-3}, $F(000)$ = 448, μ(Mo-$K\alpha$) = 0.75 cm^{-1}. Absent reflections: 0k0, k odd, space group $P2_1$.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf–Nonius CAD4-F diffractometer. An ω–2θ scan at 1.3–10.0° min^{-1} over a range of (0.85 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, showed only small (<4%) random variations. Of the 2351 independent reflections measured and processed,[3] 1033(43.9%) had intensities greater than or equal to 2σ(I) above background where σ^2(I) = S + 2B + (0.04(S–B))^2 with S = scan count and B = normalized background count.

Since the molecule is chiral the space group was assumed to be $P2_1$. The structure was solved by direct methods, all non-hydrogen atoms being positioned from an E-map. In the

final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters, and hydrogen atoms were fixed in idealized positions (methyl orientations based on observed positions, C(sp^2)–H = 0.97, C(cp^3)–H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$). The absolute configuration was based on the known configurations at atoms C(5), C(8), C(9), C(10), and C(13). Scattering factors for all atoms were taken from ref. 33. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of 270 variables. Reflections with $I < 2\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.047$ and $Rw = 0.041$ for 1033 reflections with $Ia \geqslant a2\theta(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $Rw = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.01 and 0.21σ respectively. The mean error in an observation of unit weight was 1.406. A final difference map showed maximum fluctuations of −0.16 to +0.18 e Å^{-3}. The final position parameters for the non-hydrogen atoms appear in Table 1. Bond lengths, bond angles, and intra-annular torsion angles are given in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, and measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4]

Basicity of substituted 2-phenyl-1,1,3,3-tetramethylguanidines and other bases in acetonitrile solvent

KENNETH T. LEFFEK,[1] PRZEMYSLAW PRUSZYNSKI, AND KOHILA THANAPAALASINGHAM
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4H6

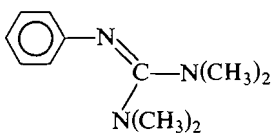
Received August 15, 1988

KENNETH T. LEFFEK, PRZEMYSLAW PRUSZYNSKI, and KOHILA THANAPAALASINGHAM. Can. J. Chem. **67**, 590 (1989).

A series of 30 phenyl substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine was synthesized and the pK_a value of each was measured in acetonitrile using a conventional, general purpose glass electrode. The slope of the Hammett relationship, for the *para* and *meta* substituted compounds, $\rho = 2.18 \pm 0.16$, is significantly lower than $\rho = 2.85 \pm 0.06$ found for anilines in water, even though the phenyl ring is attached directly to the basic centre in both cases. The influence of electronic and steric effects on the basicity of the compounds is discussed. The solvent effect on the basicity is also discussed, by comparison of the pK_a values in acetonitrile and water. The mean value of $\Delta pK_a^{AN-H_2O} = 8.1 \pm 0.5$ is slightly higher than the value previously observed for ammonia and aliphatic amines, $\Delta pK_a^{AN-H_2O} = 7.5 \pm 0.3$. Additionally, the p$K_a$ values were measured for seven other cyclic bases, including 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and 1,5-diazabicyclo[4.3.0]non-5-ene (DBN).

Key words: 2-phenyl-1,1,3,3-tetramethylguanidines, pK_a measurements.

KENNETH T. LEFFEK, PRZEMYSLAW PRUSZYNSKI et KOHILA THANAPAALASINGHAM. Can. J. Chem. **67**, 590 (1989).



On a synthétisé une série de 30 phényl-2 tétraméthyl-1,1,3,3 guanidines substituées sur le noyau phényle et, utilisant une électrode de verre conventionnelle d'usage général, on a mesuré les valeurs de leur pK_a dans l'acétonitrile. La pente de la relation de Hammett, pour les composés substitués en *méta* et en *para*, $\rho = 2{,}18 \pm 0{,}16$, est beaucoup plus faible que la valeur de $\rho = 2{,}85 \pm 0{,}06$ qui a été observée pour les anilines dans l'eau, même si le noyau phényle est attaché directement au centre basique dans chacun des cas. On discute de l'influence des effets stériques et électroniques sur la basicité des composés. En se basant sur une comparaison des valeurs des pK_a dans l'acétonitrile et dans l'eau, on discute aussi de l'effet du solvant sur la basicité. La valeur moyenne du $\Delta pK_a^{AN-H_2O} = 8{,}1 \pm 0{,}5$ est légèrement supérieure à la valeur observée antérieurement pour l'ammoniac et les amines aliphatiques, $\Delta pK_a^{AN-H_2O} = 7{,}5 \pm 0{,}3$. De plus, on a mesuré les valeurs de pK_a de sept autres bases cycliques, dont le diaza-1,8 bicyclo[5.4.0]undécène (DBU) et le diaza-1,5 bicyclo[4.3.0]nonène-5 (DBN).

Mots clés : phényl-2 tétraméthyl-1,1,3,3 guanidines, mesures de pK_a.

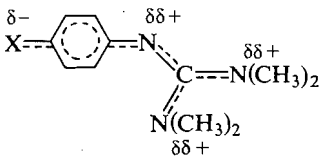
Introduction



Derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine (**1**) (PhTMG) represent a potentially useful group of strong bases within which smooth changes of basicity and (or) steric hindrance around the basic site may be achieved by substituting the phenyl ring with different groups.

1

Such series of bases are known in the case of weak bases, e.g., anilines or pyridines, and have been used in countless numbers of physicochemical studies. In the range of higher basicity the lack of such a family of closely related compounds has often forced the use of structurally different compounds, giving rise to difficulties in the interpretation of the experimental data. For studies concerned with proton transfer reactions from carbon acids such a series of strong bases is of special importance. Substitution at the *para* and *meta* positions allows the study of only electronic interactions with the reaction site. Thus the influence of base strength on the kinetics of the reaction under study can be isolated from steric factors. On the other hand, by changing the size of *ortho* substituents, the importance of steric factors can be evaluated.

PhTMG and its *para*-methyl substituted derivative (4-CH_3-PhTMG) were synthesized by Bredereck and Bredereck (1) by a condensation reaction of 1,1,3,3-tetramethylurea (TMU) with aniline and *p*-toluidine, respectively, in the presence of $POCl_3$. A number of other derivatives of PhTMG were later synthesized by Kessler and Leibfritz (2) and used for nmr studies of the mechanism of *syn–anti* isomerization. Interest in the basic properties of the derivatives of PhTMG in recent years resulted in the synthesis of further derivatives and pK_a measurements in ethanol–water (3) and water (4) solutions. Pruszynski (4) presented a fairly wide collection (17 compounds) of pK_a values in water and interpreted them in comparison with similarly substituted anilines. The unique ability of the $N{=}C[N(CH_3)_2]_2$ (TMG) group in a resonance interaction with electron-withdrawing substituents, like NO_2, was observed. This interaction was reflected in the need for a special σ value for NO_2. The slope of the Hammett plot for *meta* and *para* substituted derivatives of PhTMG, $\rho = 1.84 \pm 0.05$ (4), much lower than $\rho = 2.85 \pm 0.06$ found for anilines (5), was explained in terms of a resonance delocalization of the positive charge over all three nitrogens, resulting in an effective shift of the charge further from the phenyl ring and reducing the influence of substituents on the basicity. In other words, electron-withdrawing substituents reduce the density of the lone pair electrons of the nitrogen that is protonated, to a much lesser extent than in the case of the anilines. This is because the Π bond buffers this effect by shifting the partial positive charge towards the terminal 1 and 3 nitrogen atoms of the TMG group (**2**).

[a]Values reported earlier (4) except those marked with *.
[b]σ values from ref. 11.
[c]The special σ values reported for anilines.
[d]The apparent σ_{ortho} values for anilines.
[e]From ref. 12.

The high basicity of the derivatives of PhTMG is a result of a resonance stabilization of the positive charge after protonation, the property typical for all guanidines. Electron-donating substituents on the phenyl ring stabilize the protonated form of the derivatives of PhTMG, but the sensitivity of these compounds to such stabilization is low because only a part of the positive charge is located next to phenyl ring, the rest being delocalized onto two bonds further away. These factors were used to explain the lower ρ value for 2-PhTMG than for anilines (4).

^{35}Cl nuclear quadropole resonance measurements for a series of five chloro substituted 2-PhTMG (6) proved the unusually effective electron-releasing action of the TMG group, and the sensitivity of this action towards the presence of *ortho* substituents. The origin of this sensitivity is steric in character and reflects the difficulty in achieving a planar structure in the presence of an *ortho* substituent.

With all of the above in mind, we decided to synthesize a further series of derivatives of PhTMG and to measure the pK_a values in acetonitrile solvent. Acetonitrile is the solvent of choice for many physical organic studies and the availability of pK_a values of a large series of bases in this solvent and in water will be of value in many future investigations. The method of measurement, potentiometric titration against a glass electrode, was designed to follow the exact procedure of Coetzee and Padmanabhan (7, 8) and Kolthoff and Chantooni (9, 10), to form a consistent series of data for basicity in acetonitrile.

Seven additional cyclic nitrogen bases were measured to further increase the range of structures available for physical organic investigations in acetonitrile.

Some further pK_a values in water, in addition to those reported earlier (4), were also measured using ultraviolet spectrophotometry.

Results and discussion

Table 1 presents the pK_a values measured in acetonitrile and water. The differences in pK_a of the bases in acetonitrile and

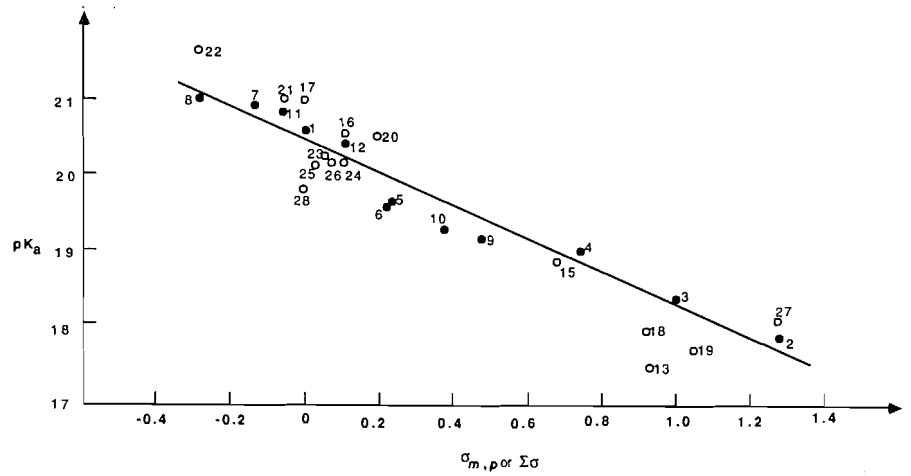

FIG. 1. Hammett relationship for the derivatives of PhTMG compounds. *meta* and *para* substituted compounds, filled circles; other derivatives, open circles. Compounds numbered as in Table 1.

water, $\Delta pK_a^{AN-H_2O}$, are also presented in this table together with the Hammett substituent constants, σ, where applicable.

The data in Table 1 show that all the compounds studied are stronger bases in acetonitrile than in water. Although the $\Delta pK_a^{AN-H_2O}$, value is fairly constant throughout the series of bases studied, the prediction of a pK_a in acetonitrile from the value in water cannot be done with an accuracy better than 0.5 pK_a units. For the PhTMG series the mean value of $\Delta pK_a^{AN-H_2O}$ is 8.1 ± 0.5 and for the five cyclic amines $\Delta pK_a^{AN-H_2O}$ is 7.9 ± 0.2. Both of these measurements are slightly higher than the value 7.5 ± 0.5 found by Coetzee and Padmanabhan (8) for the series of aliphatic amines, pyridine, some anilines, and diphenylguanidine.

Figure 1 shows the relationship of the measured pK_a^{AN} values against the Hammett substituent constant, σ, for all PhTMG bases.

The closed circles on the plot represent the *meta* and *para* monosubstituted compounds for which the slope ρ = 2.18 ± 0.16 was calculated. This value is significantly lower than ρ = 2.85 ± 0.06 (5) found for a series of anilines in water solvent, although both PhTMG and the anilines have nitrogen undergoing protonation bonded directly to phenyl ring. A lower than expected value of ρ = 1.84 ± 0.05 for the PhTMG series was also observed for the pK_a values in water (4). This means that there is a lower sensitivity of the density of the lone pair of electrons in the free base molecule, and (or) the stabilization of the protonated form, towards the presence of a substituent on the phenyl ring. This lower sensitivity is caused by the ability of the guanidinyl group to delocalize the positive charge over all three nitrogen atoms and thereby shift it further from the phenyl ring. As a result of such an action the electon-withdrawing substituents do not reduce the density of the lone pair electrons on the nitrogen at which protonation takes place to the extent that they do in the series of anilines. The pK_a values for *p*-di-(1,1,3,3-tetramethylguanidino)benzene and *m*-di-(1,1,3,3-tetramethylguanidino)benzene, 22.1 and 21.7 respectively, may be used to determine the substituent constants σ for the *meta* and *para* TMG substituent. If ρ and the intercept obtained from relationship for *meta* and *para* substituted compounds (Fig. 1) are used, these values are σ_m (TMG) = −0.6 and σ_p(TMG) = −0.80, in good agreement with values calculated from ^{35}Cl nqr measurements (6) (−0.62 and −0.88 respectively).

The open circles on Fig. 1 represent all disubstituted and *ortho* substituted derivatives of PhTMG. The σ values used in this relationship are given in Table 1. In the case of disubstituted compounds the sum of the substituent constants was used. Some of the points deviate from the general relation. The *ortho*-methoxy substituted bases, points 17, 22, and 27, show a pK_a higher than would be expected from the σ constant values (positive deviation). These compounds, 2-OMe, 2,4-diOMe, and 2-OMe-4NO_2 derivatives respectively, represent the case where intramolecular hydrogen bonding may occur in the protonated base. The positive deviations of about 0.5 pK_a unit correspond to stabilization due to such an effect of about 0.7 kcal mol^{-1}. Such an effect should also, according to other authors (8, 13), be reflected in an increased $\Delta pK_a^{AN-H_2O}$ value, which is the case of these bases (Table 1) and is discussed below.

Points 16(2-Me), 20(2,6-diMe), 21(2,4-diMe), which represent compounds with at least one methyl group in the position *ortho* to the TMG substituent, also show greater pK_a values than the general correlation predicts. This effect, observed previously for the 2-Me derivative in water (4), may be explained by a greater destabilization of the free base than its protonated form due to steric interactions, so that when the protonation takes place there is release of a steric strain. This effect is probably counterbalanced in the case of *ortho* substituents by the other effect, steric inhibition of solvation. This latter effect, according to Coetzee and Padmanabhan (8), operates in acetonitrile to a greater extent than in water and may be used to account for the pK_a values of the bases represented by points 23(2-iPr), 24(2,6-di-Et), 25(2-iPr), 26(2,6-di-iPr), 28(2-Ph). This negative contribution to the pK_a value is clearly dependent on the size of the *ortho* substituent, which gives additional support to the validity of such an explanation. Points 13, 18, 19 representing the 3,5-diCF_3, 2,4-diCl, and 2,5-diCl derivatives lie significantly lower than would be expected. This may be due to the inappropriateness of the standard σ values of these substituents in the reaction involving the very strong electron-releasing group, tetramethylguanidinyl. The values of σ_p and σ_m have been analyzed to consist of an inductive part (σ_I) and a resonance part (σ_R), as in eq. [1]:

$$[1] \quad \sigma = \sigma_I + \sigma_R$$

For σ_m the σ_R component is multiplied by a factor α less than unity (α = 0.33 has been used (14)). For the chloro substituents (σ_I = 0.47, σ_R = −0.23), because of the strongly electron-releasing nature of the TMG group, a reduction or elimination of

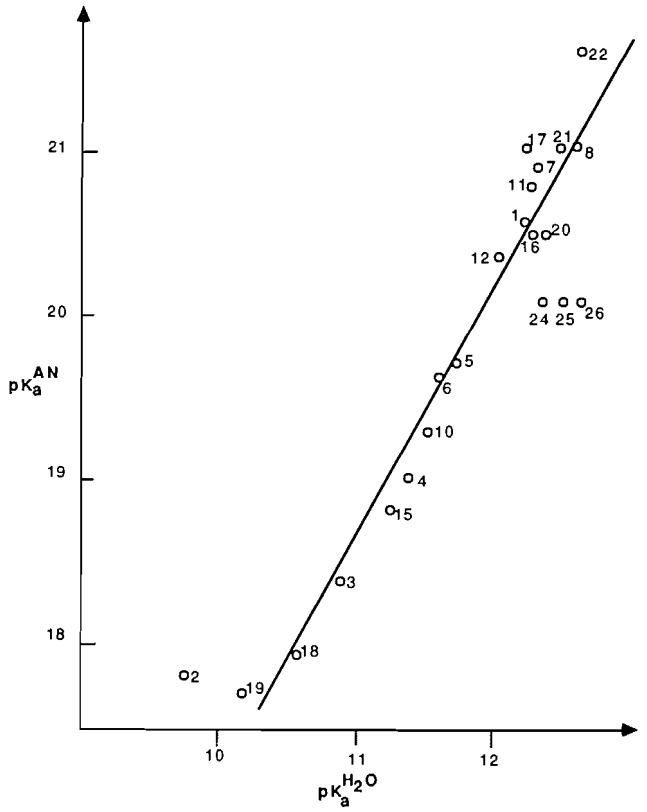

FIG. 2. The relation between pK_a in acetonitrile and in water for substituted derivatives of PhTMG.

the negative σ_R would enhance σ up to the limit 0.47 for σ_p and σ_m, which would move points 18 and 19 much closer to the correlation line. The 3,5-di-CF_3 compound (point 13) has a much smaller pK_a value than expected. This may be partially explained by assuming that the electron-withdrawing resonance effect ($\sigma_R = 0.11$) is increased by the electron-releasing TMG, which would again increase the value of σ_m by increasing α, possibly to a value 0.57 ($\sigma_I = 0.46$, $\sigma_R = 0.11$). The ^{19}F nmr measurements for the series of CF_3 substituted derivatives, listed in the experimental section, with the signals for *meta* derivatives presenting the largest upfield shift, seem to support this proposal.

Figure 2 presents the relationship between the pK_a values in water and in acetonitrile. If this relationship is assumed to be linear, the line drawn in Fig. 2 defines the regularity of the relationship. The slope of this line is not unity, therefore ΔpK_a is not constant throughout the series, reinforcing the conclusion that the pK_a of a base in a particular solvent can be only very roughly estimated from its pK_a in another solvent, within about half a pK_a unit at the best. Uncertainties of this magnitude are usually too large for meaningful discussion of kinetic or other data.

In addition to the fact that the slope of the line is greater than unity, certain points fall clearly off the line.

The position of points 17(2-OMe) and 22(2,4-diOMe) fall above the line, consistent with the postulated intramolecular hydrogen bonding in the protonated bases. This kind of interaction is more important in acetonitrile than in water (8, 13), giving additional stabilization of the protonated form in acetonitrile and as a consequence increasing the strength of the base. The points for sterically hindered bases, 24(2,6-di-Et), 25(2-iPr), 26(2,6-di-iPr), and to a lesser extent 20(2,6-di-Me) and 16(2-Me), show the pK_a^{AN} lower than would be expected from their values in water. This effect is a reflection of the steric inhibition of solvation, an effect more important in acetonitrile than in water (8, 13).

In the area of weaker bases, large positive deviations from the line are observed especially for the case of point 2 (4-NO_2). The strong resonance interaction of TMG and 4-NO_2 groups, which manifests itself for example in the λ_{max} of 398 nm in the free base compared to 380 for 4-nitroaniline, both measured in water, creates a substantial negative charge located on the oxygens of the NO_2 group. This gives rise to possible interactions by means of hydrogen bonding with water molecules, which stabilize the free base form reducing the strength of the base in water relative to that in acetonitrile. In the case of point 2 (4-NO_2) this effect corresponds to a difference of about 1–1.25 pK_a units or 1.3–1.6 kcal mol^{-1}.

The need for the empirical determination of pK_a values in each solvent for any meaningful discussions of kinetic data and the lack of extensive numerical values of pK_a in acetonitrile justify the presenting of results for some other bases in Table 1. The five unrelated cyclic bases show no systematic variation in $\Delta pK_a^{AN-H_2O}$ with structure, although the values range only from 7.6 to 8.3 pK_a units. Thus, despite the fact that $\Delta pK_a^{AN-H_2O}$ is fairly constant, it is not a reliable parameter for estimating undetermined pK_a values in any particular solvent, and should be used only when there is no alternative. One such case is found in the pK_a values for the strong amidine bases, DBU and DBN, which are of proven synthetic utility and are of interest also for synthetic organic chemists. These two bases are so strong that the direct measurements of their pK_a values in water are affected by the levelling effect of this solvent. This is true especially in the case of the stronger DBU base. Therefore, the pK_a of these bases in water may be estimated only from the measurements in other, less acidic solvents. Despite uncertainties of such estimates, the impossibility of direct measurements leaves no alternative. There is the pK_a value of 23.3 (10) in acetonitrile measured for 1,1,3,3-tetramethylguanidine (TMG), the base of almost the same strength as DBU. The corresponding values for this compound in water, $pK_a^{H_2O} = 13.6$ (15), and in 50% aqueous ethanol, pK_a = 13.3 (16), were reported. These data give the difference in pK_a values $\Delta pK_a^{AN-H_2O} = 9.7$. For DBN in 50% aqueous ethanol (16) pK_a = 13.5 was measured, which corresponds to the $pK_a^{H_2O} = 13.8$. If the measured value in acetonitrile $pK_a^{AN} = 23.4$ for DBN (Table 1) is used, a $\Delta pK_a^{AN-H_2O} = 9.6$ may be estimated. This value is in good agreement with the value previously calculated for TMG. The similar strength of the bases TMG, DBN, and DBU supports the use of $\Delta pK_a^{AN-H_2O} = 9.6$ for DBU, which together with the $pK_a^{AN} = 23.9$ (Table 1) give its $pK_a^{H_2O}$ as 14.3.

An alternative approach is to estimate the pK_a of DBU in water using phenyl substituted phenyltetramethylguanidines plotted in Fig. 2. A purely empirical approach to the plot in Fig. 2 requires points 2, 24, 25, 26 to be disregarded. The remaining points give a slope of 1.58 ± 0.08, different from what would be obtained by combining the ρ values for each solvent, because of different data values used. However, the slope 1.58, intercept 1.3 ± 1.0, represent the best empirical relationship for the calculation of the pK_a for DBU in water, which is (23.9 − 1.3)/1.58 = 14.3.

Experimental

2-Phenyl-1,1,3,3-tetramethylguanidines were synthesized by the method of Bredereck (1) with an additional extraction during the work-up that resulted in higher purity of the products (4). The solution of 0.1 mol of 1,1,3,3-tetramethylurea (Aldrich, dried over 4A

molecular sieve) in 100 mL of dry benzene was treated dropwise with 0.15 mol of $POCl_3$ in 20 mL of benzene. The reaction mixture was stirred overnight and a solution of 0.15 mol of the appropriate aniline was then added. The reaction mixture was refluxed for 7 h, after which the lower, oily phase was separated and water and 2 N NaOH solution were added to bring the pH to 8–9. An extraction with benzene performed at this pH removes the unreacted tetramethylurea and aniline. If performed carefully, the only component of the mixture present in the form of a salt in the water phase is the derivative of 2-phenyl-1,1,3,3-tetramethylguanidine. Thus by further raising the pH to about 14, followed by extraction with benzene, drying over anhydrous sodium sulphate, evaporation, and finally vacuum distillation, a pure sample of the base was obtained.

Thiomorpholine, 1,2,3,4-tetrahydroisoquinoline, *N*-methylpiperidine, *N*-methylpyrrolidine, *N*-methylmorpholine, DBN, and DBU were commercially available samples, which were dried over KOH.

The purity of all the bases was checked by means of gc–ms analysis using a Hewlett–Packard 5890 A/5970 MSD apparatus. All bases were dried and freshly distilled under vacuum on the day of measurements.

Commercial purity picric acid was recrystallized twice from acetone and dried at 80°C in a vacuum oven.

Picrates of the bases under study were prepared by dissolving 0.5–1 g of base in about 10 mL of absolute ethanol and titrating this solution with a saturated ethanol solution of picric acid using a glass electrode. The precipitate was dissolved by heating the suspension and the crystals were filtered after cooling. The second crystallization from ethanol was followed by drying in a vacuum desiccator. The spectra and other physical properties of many of the compounds were reported earlier (4). Several of the PhTMG derivatives used in these studies have not been reported in the literature before. The properties of these compounds are listed below. The melting points were measured using a Fisher–Johns melting point apparatus and are uncorrected. The ^1H, ^{13}C, and ^{19}F nmr spectra were obtained with TMS as the internal reference using a Nicolet 360 nmr spectrometer with Fourier transform, at the Atlantic Resonance Centre at Dalhousie University. The mass spectra were recorded on a modified Du Pont CEC model 21-104 mass spectometer at 70 eV. The ^{13}C nmr signals are reported in the sequence presented on the following structure, followed by signals for substituents on the phenyl ring:

2-(4′-Trifluoromethylphenyl)-1,1,3,3-tetramethylguanidine

Yield 55%; bp 142°C/5 Torr (1 Torr = 133.3 Pa); ^1H nmr δ: 6.72 (2H, d, 8.4 Hz), 7.42 (2H, d, 8.4 Hz), 2.71 (12H, s); ^{13}C nmr δ: 155.3, 121.7, 125.6, 123.3, 125.6, 121.7, 160.4, 39.3, CF_3 group 120.8 (q); ^{19}F nmr δ: −61.303; mass spectrum (rel. intensity, %): 259(42), 244(11), 215(100), 200(29). Picrate: mp 135–137°C.

2-(3′-Trifluoromethylphenyl)-1,1,3,3-tetramethylguanidine

Yield 70%, bp 120°C/3 Torr; ^1H nmr δ: 6.85 (1H, d, 8 Hz), 6.93 (1H, s), 703 (1H, d, 7.5 Hz), 726 (1H, t, 7.5 Hz), 2.68 (12H, s); ^{13}C nmr δ: 152.2, 117.6, 125.7, 115.5, 128.7, 124.4, 160.2, 39.1, CF_3 group 130(q); ^{19}F nmr δ: −62.848; mass spectrum (rel. intensity, %): 260.7(7), 259(43), 215(100), 201(25), 200(30). Picrate: mp 148–150°C.

2-(2′-Trifluoromethylphenyl)-1,1,3,3-tetramethylguanidine

Yield 40%; bp 135°C/4 Torr; mp 42–43°C; ^1H nmr δ: 6.54 (1H, d, 8 Hz), 6.83 (1H, t, 7.5 Hz), 7.28 (1H, t, 7.5 Hz), 7.48 (1H, d, 8 Hz), 2.68 (12H, s): ^{13}C nmr δ: 152.9, 123.4, 126.3, 118.7, 131.8, 123.0, 159.1, 39.5, CF_3 group 120.5(q); ^{19}F nmr δ: −61.303; mass spectrum (rel. intensity, %): 259(39), 216(18), 215(100), 200(22). Picrate: mp 135–137°C.

2-(3′,5′-Ditrifluoromethylphenyl)-1,1,3,3-tetramethylguanidine

Yield 75%; bp 199°C/5 Torr; mp 60.5–61°C, ^1H nmr δ: 7.08 (2H, s), 728 (1H, s), 2.74 (12H, s); ^{13}C nmr δ: 153.3, 121.0, 131.2, 112.4, 131.2, 121.0, 161.0, 39.6, CF_3 groups 131.7(q); ^{19}F nmr δ: −63.342; mass spectrum (rel. intensity, %): 327(25), 281(100), 267(24). Picrate: mp 187–189°C.

2-(2′-Ethylphenyl)-1,1,3,3-tetramethylguanidine

Yield 41%; bp 138.3°C; ^1H nmr δ: 7.11 (1H, d, 7.5 Hz), 7.02 (1H, t, 7.5 Hz), 6.81 (1H, t, 7.5 Hz), 6.48 (1H, d, 7.5 Hz), 2.65 (12H, s), 2.56 (2H, q, 7.5 Hz), 1.20 (3H, t, 7.5 Hz); ^{13}C nmr δ: 149.8, 134.7, 127.7, 120.0, 125.8, 121.1, 158.4, 39.4, ethyl group 13.5, 24.4; mass spectrum (rel. intensity, %): 219(20), 190(20), 175(21), 148(37). Picrate: mp 119–121°C.

2-(2′-Isopropylphenyl)-1,1,3,3-tetramethylguanidine

Yield 40%, bp 112°C/2 Torr; ^1H nmr δ: 6.43 (1H, d, 7 Hz), 6.82 (1H, t, 6.7 Hz), 6.95 (1H, t, 6.7 Hz), 7.15 (1H, d, 6.7 Hz), 3.23 (1H, septet, 7 Hz), 2.67 (12H, s), 120 (6H, d, 7 Hz); ^{13}C nmr δ: 148.8, 139.1, 125.4, 120.0, 125.0, 120.9, 157.9, 39.4, isopropyl group 23.0, 27.4; mass spectrum (rel. intensity, %): 232(22), 218(22), 190(67), 189(25), 162(38), 144(79). Picrate: mp 109–111°C.

2-(2′-Phenylphenyl)-1,1,3,3-tetramethylguanidine

Yield 60%, bp 199°C/5 Torr; ^1H nmr δ: 6.88–7.43 (9H, m), 2.36 (12H, s); ^{13}C nmr δ: 149.0, 132.4, 130.2, 120.3, 125.9, 124.1, 157.8, 38.5, phenyl substituent 127.4, 127.7, 128.5; mass spectrum (rel. intensity, %): 267(72), 266(20), 252(21), 223(100), 207(29), 196(48). Picrate: mp 131–132°C.

p-*Di-(1,1,3,3-tetramethylguanidyno)benzene*

Yield 60%; mp 153–154°C; ^1H nmr δ: 6.58 (4H, s), 2.66 (24H, broad signal at room temperature); ^{13}C nmr δ: 144.6, 121.8, 121.8, 144.6, 121.8, 121.8, 159.3, 39.3 (b); mass spectrum (rel. intensity, %): 305(22), 304(100), 289(31), 260(23), 233(32). Picrate: mp 276–280°C.

m-*Di-(1,1,3,3-tetramethylguanidyno)benzene*

Yield 70%; bp 198°C/4 Torr; mp 75–77°C; ^1H nmr δ: 6.12 (1H, s), 6.20 (2H, d, 7.8 Hz), 7.00 (1H, t, 7.8 Hz), 2.69 (24H, s); ^{13}C nmr δ: 152.3, 115.2, 152.3, 113.7, 128.3, 113.7, 159.4, 39.5; mass spectrum (rel. intensity, %): 305(20), 304(100), 303(20), 260(38), 233(21). Picrate: mp 253–255°C.

Tetramethylammonium perchlorate was prepared by titration of a 10% solution of tetraethylammonium hydroxide in water with perchloric acid using a glass electrode to just beyond the equivalence point. The salt was recrystallized twice from water and dried in a vacuum oven at 60°C.

Tetraethylammonium picrate was prepared by titration of a saturated aqueous solution of picric acid with a 10% solution of tetraethylammonium hydroxide in water using a glass electrode to just beyond the equivalence point. The solution was evaporated until crystallization occurred. This product was recrystallized once again from water, then from 90% ethanol, and finally it was dried in a vacuum over P_2O_5; mp 267–270°C (lit (17) mp 254–257°C).

Acetonitrile was prepared by the method of O'Donnell *et al.* (18), followed by fractional distillations from P_2O_5 and calcium hydride.

The potentiometric measurements were performed using the method described by Coetzee and Padmanabhan (7, 8). The H-type cell was constructed (Fig. 3) equipped with the thermostated water jacket (the temperature of the measurements was 25°C).

The side arm of an external reference electrode half-cell was dipped into the 0.1 M tetraethylammonium perchlorate solution. The reference electrode was a flowing junction silver – 0.01 M silver nitrate (in acetonitrile) half cell, as previously described by Kolthoff and Reddy (19). The middle compartment, closed on both sides with fine-porosity sintered glass disks, was filled with 0.1 M tetraethylammonium perchlorate solution in acetonitrile. The large, 20 mm i.d., compartment was filled with the buffer solution. The glass electrode (Corning, pH triple purpose Ag/AgCl, cat. no. 476022) was immersed in a way that allowed for tight closing and protection against moisture and

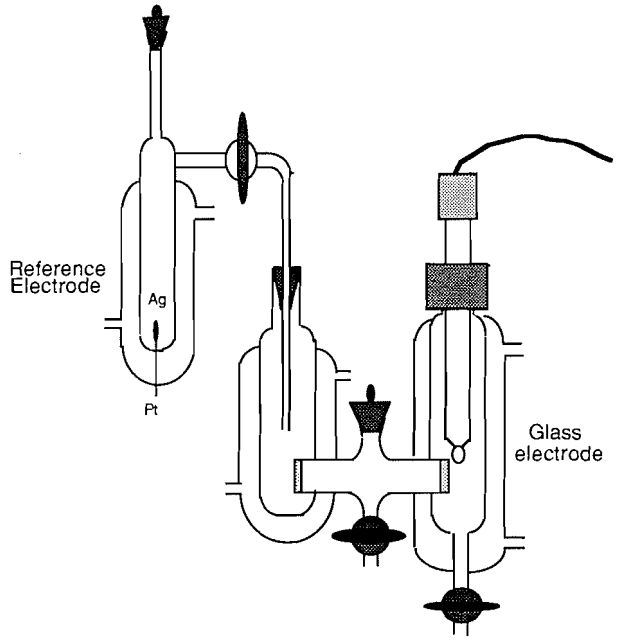

FIG. 3. The potentiometric cell for the pK_a measurements in acetonitrile.

carbon dioxide. The middle and glass electrode compartments were equipped with taps providing easy drainage after each set of measurements. When not in use the glass electrode was kept in water, and before each measurement it was washed with absolute ethanol, dried in a stream of dry nitrogen, and immersed for at least 2 h in acetonitrile. An Orion Research model 601A pH-meter was used. The glass electrode was calibrated in picric acid – tetraethylammonium picrate buffers. The theoretical justification for the use of above buffer system has been given previously (7). A $pK_a = 11.0$ for picric acid was used (9). The calibration was performed with five buffers of different ratios and was repeated several times during the course of the study. The agreement was such that the change in pK_a value was smaller than the calculated standards deviations when the results from different calibration curves were employed. The buffers of the bases for which the pK_a values were measured were prepared in such a way that the concentrations of tetraethylammonium perchlorate and picrate of the base under study were kept constant, both 5×10^{-4} M, and the concentration of the base was changed typically between 3×10^{-4} M and 4×10^{-3} M. Equilibrium was reached in about 5–10 min, and the readings of the emf were very stable (for at least half an hour). In the case of *p*-di-(1,1,3,3-tetramethylguanidino)benzene and *m*-di-(1,1,3,3-tetramethylguanidino)benzene, bases with two basic centres, both pK_a values (for di- and monovalent cations) were determined. The solution of monopicrate of both bases was prepared by dissolving an equimolar amount of dipicrate and free base. The dipicrate–monopicrate and monopicrate – free base buffers were used for the measurements of pK_{a1} and pK_{a2} respectively.

The pK_a value was calculated using eq. [2]:

$$[2] \quad pK_{a\ base} = pK_{a\ picric\ acid} + \log 0.89 + (C - E)/S$$

where $pK_{a\ picric\ acid} = 11.0$; C is the emf value for picric acid buffer of buffer ratio = 1; E is the emf value for base buffer of buffer ratio = 1; S is the slope of the relation, emf = $f(\log (c_{HPi}/c_{Pi^-}))$; 0.89 is the ratio of the activity coefficients for the monocharged and uncharged species at ionic strength 1×10^{-3} M as calculated by the "reduced" Debye–Hückel equation. The additional correction for the change of activity coefficients for mono and divalent cations was done in the case of both dipicrates. The mean value of slope from all measurements was $S = 59.1 \pm 1.8$ mV/pH unit.

The reproducibility of the results of Coetzee and Padmanabhan (8) was checked by repeating the pK_a measurements for piperidine. The value 18.92 ± 0.05 was reported by them and the value 19.06 ± 0.09 was found by us.

The pK_a values in water were measured spectrophotometrically using the procedure described previously (4). Fisher certified NaOH solutions were used. Measurements were done using a Cary 219 uv–vis spectrophotometer equipped with a thermostating device.

The binding of bilirubin by immobilized oligopeptides containing lysine

M. BOUVIER,[1] G. R. BROWN,[2] AND L. E. ST-PIERRE
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received February 9, 1988[3]

M. BOUVIER, G. R. BROWN, and L. E. ST-PIERRE. Can. J. Chem. **67**, 596 (1989).

Peptides consisting of portions of the sequence Arg-$(Lys)_2$-$(Ser)_2$-Lys-$(Ala)_3$ have been immobilized onto a polyacrylamide support by solid phase peptide synthesis. Isotherms at 0°C for the adsorption of bilirubin from phosphate buffer by these peptide resins are highly dependent on pH, in the range 7.80–11.00, demonstrating the importance of ionic interactions. The adsorption behaviour of bilirubin-related tetrapyrroles shows that structural factors also influence the process. Peptide resins containing two or more residues of lysine have two binding sites on each pendant and are characterized by positive cooperativity, to a degree that is highly dependent on the number of residues. It is proposed that bilirubin molecules bound by lysine-containing pendants are stacked, the dimer state being stabilized by $\pi-\pi$ electron interactions, hydrogen bonds, and hydrophobic interactions. Site binding constants show that arginine-containing pendants manifest a stronger affinity for bilirubin.

Key words: bilirubin, adsorption, lysine, oligopeptides, cooperativity.

M. BOUVIER, G. R. BROWN et L. E. ST-PIERRE. Can. J. Chem. **67**, 596 (1989).

Des peptides consistant en différentes portions de la séquence Arg-$(Lys)_2$-$(Ser)_2$-Lys-$(Ala)_3$ ont été greffés, via la technique de synthèse en phase solide des peptides, à un support de polyacrylamide réticulé. Des isothermes caractérisant l'adsorption de la bilirubine en milieu tampon, à 0°C, par ces adsorbants sont dépendants du pH, dans l'intervalle 7,80–11,00, démontrant ainsi l'importance des interactions ioniques. L'adsorption de tétrapyrroles similaires à la molécule de bilirubine a démontré que des facteurs reliés à la structure du ligand influencent le processus d'association. Les adsorbants qui contiennent deux résidus de lysine ou plus ont deux sites d'adsorption par pendant et sont caractérisés par un mode d'adsorption à coopérativité positive, le degré duquel est dépendant du nombre de résidus de lysine dans la séquence. Il est proposé que les pendants contenant des résidus de lysine favorisent la dimérisation des molécules de bilirubine liées, le dimère étant stabilisé par des interactions $\pi-\pi$, des ponts hydrogènes et des interactions hydrophobiques. Des constantes d'association ont démontrées que les pendants qui contiennent des résidus d'arginine manifestent une grande affinité pour la bilirubine.

Mots clés : bilirubine, adsorption, lysine, oligopeptides, coopérativité.

Introduction

Bilirubin (Fig. 1) is the bile pigment known to produce a yellow coloration in the skin of neonates who show delayed development of the excretory functions. Under such circumstances the increased concentration of plasma bilirubin can result in serious physiological disorders (1). Attempts have been made to remove the toxic bile pigment by hemoperfusion using adsorbents such as cholestyramine, immobilized human serum albumin (HSA), and similar materials (2–5).

Previous reports from this laboratory have demonstrated that certain peptides immobilized on a cross-linked polymer support form efficient adsorbents for bilirubin (6–8). This paper describes the adsorption behaviour of adsorbents with pendants synthesized from amino acids, such as lysine and arginine, that have been shown previously to be of key importance for the adsorption of bilirubin (6–8) and have been reported to be involved in the binding of bilirubin by HSA (9–11). Residues of serine are also incorporated into the sequence. The adsorbents are designed to obtain a better understanding of the interactions between bilirubin and the peptide pendants. To this end, adsorption isotherms and corresponding Scatchard plots are obtained from which site binding constants are derived.

Experimental

Syntheses of peptide resins

The support used for synthesis of peptide resins was a copolymer of dimethylacrylamide and *N*-acryl-1,6-diaminohexane hydrochloride reticulated with bisacrylyl-1,2-diaminoethane (Polyamide Peptide Resin 1 from Chemical Dynamics Corp.). Potentiometric titration for the chloride using silver nitrate gave a substitution of 0.22 mmol/g. The amino acids were purchased as the L form of the Boc-α amino acids (Vega Biotechnologies) with the side-chain groups protected as follows: Lys (ε-2-chloro-benzyloxycarbonyl), Ser (*O*-benzyl), Arg (nitro). (Three-letter symbols are used for designations of the amino acids as recommended by the Joint Commission on Biochemical Nomenclature of IUPAC-IUB.) Syntheses were done using a Vega 250 synthesizer based on a previously published program (6). Activated amino acids in the form of symmetrical anhydrides were used in the coupling reactions. Coupling and deprotection procedures were monitored by the ninhydrin test (12). A spacer consisting of three alanine residues was introduced at the beginning of the sequence to separate the remaining amino acids from the support. Samples of the peptide resins were removed after each coupling step following the addition of the last residue of alanine. The protecting groups on the side chains of the amino acids were removed by treating the dried peptide resins with anhydrous hydrogen fluoride in the presence of anisole for 1 h at 0°C. The deprotected peptide resins were then washed with ether, dried, and stored in a desiccator.

Amino acid analyses

Peptide resins were hydrolyzed at 110°C for 48 h according to previously published procedures (8). Amino acid analyses were performed using a Varian 5500 Analyzer.

Adsorption experiments

A stock solution of bilirubin (Sigma Chemicals) was prepared daily by dissolving the pigment in a minimal amount of 0.10 M NaOH and adjusting the volume with degassed 0.050 M KH_2PO_4/NaOH buffer to give a final concentration of 10 mg/dL and a final pH of 7.80. Bilirubin was shown to be of high purity by thin-layer chromatography and by nmr studies (13), and was used without further purification.

Adsorption studies were performed with bilirubin solutions of different initial concentrations, prepared from the stock solution, with approximately 10 mg of adsorbent. The adsorption studies were done at 0°C, under a constant flow of nitrogen, using a specially designed flask (14). Prior to the adsorption experiments, the flask was routinely

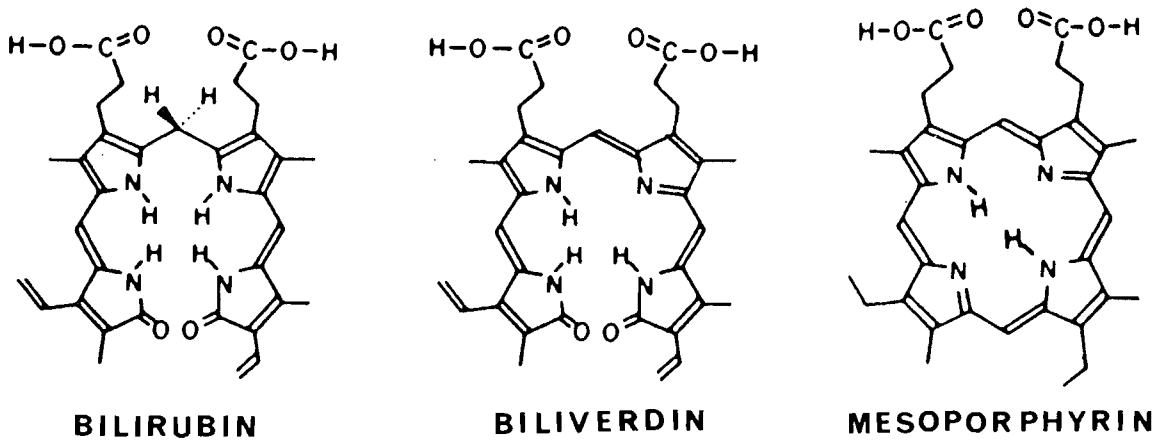

FIG. 1. Structures of bilirubin, biliverdin, and mesoporphyrin.

silanized and coated with bilirubin, by stirring in it a concentrated bilirubin solution, to minimize deposit of the pigment on the glass surface (14). The concentration change in the known volume was followed by measuring the absorbance of free bilirubin at the absorbance maximum, 438 nm, using a Beckman 25 spectrophotometer. Studies of the kinetics of adsorption were initially done to determine times required to achieve equilibrium for each adsorbent. All experiments were performed in the dark under a red light. Control experiments, without resin, showed minimal loss of bilirubin in the time allowed for these adsorption experiments.

Adsorption studies of biliverdin and mesoporphyrin (Porphyrin Products Inc.) by a selected adsorbent were done in a manner identical to that for the adsorption of bilirubin. In the concentration ranges used for adsorption, $(1.69–8.45) \times 10^{-5}$ M for biliverdin and $(1.51–5.82) \times 10^{-5}$ M for mesoporphyrin, the solutions obeyed Beer's law. Absorbance values for free biliverdin and mesoporphyrin were taken at 374 and 366 nm, respectively, corresponding to their absorbance maxima. The tetrapyrroles, as purchased, exhibited relatively high purity (85–90%), so that the compounds were used without further purification.

Results

Rationale

The completed peptide sequence designed to serve as an adsorbent for bilirubin is shown below:

Arg-Lys-Lys-Ser-Ser-Lys-$(Ala)_3$-support

Some of the characteristics of the selected amino acids are given in Table 1. Studies in this laboratory have demonstrated that the presence of the basic amino acids, arginine and lysine, results in materials with a high binding capacity and strong affinity for bilirubin (7, 8). Serine residues are incorporated into the sequence to provide the possibility of additional hydrogen bonding between the side-chain hydroxyl group and the hydrogen acceptor (two propionic acid groups and two lactam CO groups) or the hydrogen donor (four NH groups) on bilirubin. Although the acid form of bilirubin is known to have an intramolecularly hydrogen bonded structure (15, 16), it is not known to what extent these bonds are preserved in aqueous solution (17).

The order of attachment of the amino acids to the support is based on the following factors: A segment of the proposed sequence, -Lys-Ser-Ser-Lys-, forms a peptide with a symmetrical arrangement of amino acids. It is of interest to evaluate the ability of such a peptide to interact with bilirubin, which itself has high molecular symmetry (Fig. 1). It is noteworthy that a very similar peptide sequence is found in HSA between residues 189 and 194 (18).

TABLE 1. Characteristics of the amino acids immobilized onto the polyacrylamide support

Amino acids	Resin designation						Classification	Charge (pH 7.80)
	1	2	3	4	5	6		
$(Ala)_3$	↕	↕	↕	↕	↕	↕	Hydrophobic	
Lys	↕	↕	↕	↕	↕	↕	Basic	+
Ser		↕	↕	↕	↕	↕	Polar	
Ser			↕	↕	↕	↕	Polar	
Lys				↕	↕	↕	Basic	+
Lys					↕	↕	Basic	+
Arg						↕	Basic	+

Interestingly, both bovine and human serum albumins have a cluster of serine and lysine residues at the tips of loops no. 4 and no. 5. Residues located at the tips of loops represent, in accordance with Brown's model for the tertiary structure of albumin (19), sites with a high potential for binding bulky ligands like bilirubin. In particular, loop no. 4 has been mentioned as a potential location for the binding of bilirubin, as demonstrated from fragment studies (11, 20–23).

The single arginine residue at the end of the sequence forms, along with the adjacent lysines, a cluster of basic residues. Such a "nest" of basicity should be a very important factor for the adsorption of bilirubin, as suggested from previous results (7). Finally, the primary structure of the defined sequence is such that it carries a net overall positive charge of 4 + ; this represents an advantageous feature for the binding of a negatively charged molecule.

Based on the above rationale, the proposed sequence is expected to show many interesting features that justify the study of its properties for the adsorption of bilirubin.

Amino acid analyses

The results of the amino acid analyses are given in Table 2 as ratios based on the complete recovery of the three alanine residues of resin 1. They indicate coupling of the first lysine residue to 90% of the $(Ala)_3$ spacer units. Subsequently, no peptide chains fail to grow until resin 6, where there is an additional decrease of ratio to 0.7, indicating a further loss of 20%.

Adsorption isotherms and binding interactions

Studies of the kinetics of adsorption showed that 1–3 h are required for the adsorbents to reach adsorption equilibrium.

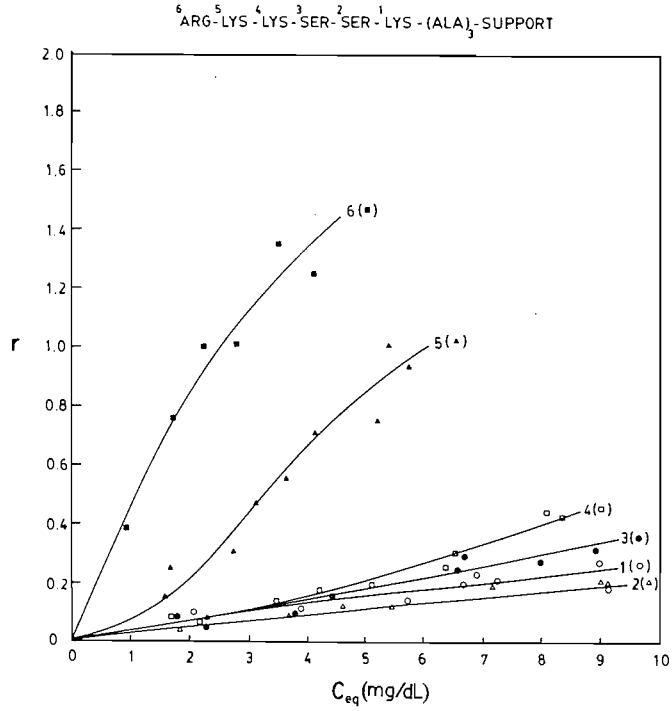

FIG. 2. Experimental adsorption isotherms, KH_2PO_4/NaOH (0.05 M), pH = 7.80, and 0°C.

Figure 2 presents the equilibrium isotherms, obtained at 0°C, for adsorbents with pendants composed of increasing portions of the proposed sequence. The parameters r and C_{eq} represent the equilibrium molar ratio of bound bilirubin per peptide pendant and the equilibrium concentration of free bilirubin (also $[A]_{eq}$, in M), respectively. The curves drawn through the experimental points are derived from a nonlinear iterative computer program from SAS (SAS Institute, 1982), using a method described previously (24). The adsorption data are estimated to have an associated uncertainty of ±5%.

A normalization process, based on the results of the amino acid analyses, was applied to the experimental adsorption isotherms in a manner described previously (8). The normalized isotherms (Fig. 3) describe the adsorption behaviour of adsorbents as though they were substituted at 100% by the indicated peptide sequence. Normalization causes some adjustments to the absolute values of r but the relative positions of the isotherms are unaffected. The adsorption isotherm corresponding to the polymer support is given in Fig. 3, for purposes of comparison, and shows minimal adsorption of bilirubin. Although the bilirubin solutions used for these studies are probably supersaturated, losses due to spurious nucleation by polymer therefore appear to be unimportant.

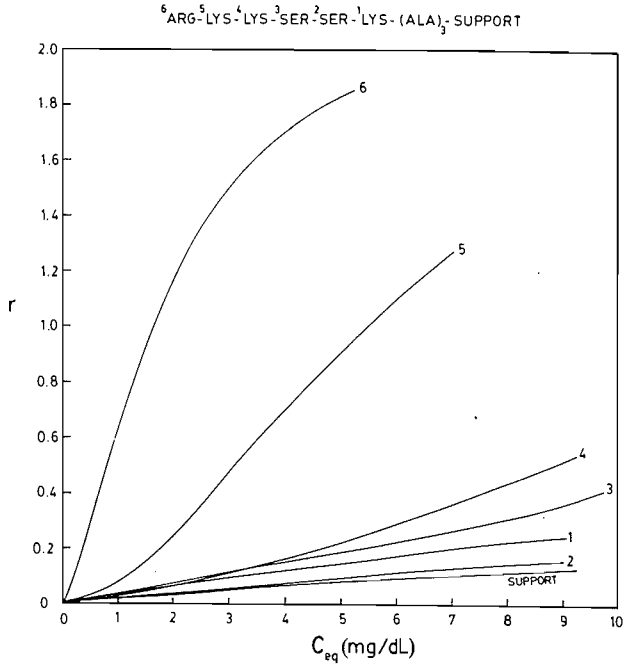

FIG. 3. Normalized adsorption isotherms.

As reported previously (7), the addition of the Lys-(Ala)$_3$-fragment to the polymer support, to form resin 1, results in an adsorbent with a binding capacity that is only slightly higher than that of the support (Fig. 3). This increment in capacity can be attributed to the presence of the lysine residue since the addition of three alanine residues has been shown previously to have minimal effect (7). A reverse trend, i.e., a decrease, occurs with the addition of a serine residue so that the binding capacity of the resulting adsorbent, resin 2, is similar, within experimental error, to that of the polymer support. The addition of this residue has slightly reduced the favorable contributions of the lysine residue to the adsorption process, possibly as a result of interactions, e.g., hydrogen bonds, between the lysine and serine residues.

An increase in binding capacity, above that of the isotherm corresponding to resin 1, results from the addition of a second serine residue to form resin 3. This suggests that the lysine residue, in particular, has become more available for interaction with bilirubin, possibly from a disruption of the interactions between the residues forming the sequence.

The trend towards moderate increase in binding capacity, especially at high adsorbate concentrations, is continued in the formation of resin 4 that includes a second residue of lysine. It is of interest to note that this isotherm is remarkably similar to that for the (Lys)$_2$-(Ala)$_3$-support resin (7). This points to a lack of involvement of the two serine residues in the binding process, a behaviour that was already manifested by resin 3. It should be noted that the isotherms corresponding to resins 3 and 4 demonstrate very low slopes at low adsorbate concentrations with continuously sharper increments in r, especially at high values of C_{eq}, and are quite different from those associated with regular "Langmuir" type adsorption. The shapes of the various adsorption isotherms will be considered in more detail later.

A considerable increase in binding capacity occurs as a result of the coupling of a third lysine residue to form resin 5. This large increase in capacity is thought to be related primarily to an increase in basicity although other factors, such as the length

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

of the resulting peptide sequence, should favorably influence binding of the adsorbate. The isotherm corresponding to resin 5 exhibits a sigmoidal shape, which resembles that for the binding of oxygen on hemoglobin (25).

Finally, the addition of an arginine residue completes the development of the sequence and results in a marked increase in binding capacity. This effect demonstrates the importance of arginine residues in the binding of bilirubin, as suggested by Jacobsen (9).

The adsorption results confirm some of the hypotheses presented initially in designing the sequence. Indeed, the addition of lysine and arginine residues affects the binding capacity in a manner that correlates with our previous results (6–8) and with evidence given in the literature regarding the participation of these amino acids in the binding of bilirubin by HSA (9–11). The clustering in the sequence of the basic residues produces a material with a high binding capacity for bilirubin. On the other hand, there is no indication that hydrogen bonds between the adsorbate and the OH groups on serine residues are of importance in the binding. The formation of resin 4, Lys-Ser-Ser-Lys-$(Ala)_3$-support, does not result in a large increase in binding capacity, relative to those of the previous sequences, indicating that the presence of the symmetrical unit has no special effect on the binding character of these pendants.

To verify the importance of ionic interactions in the binding process, adsorption studies were repeated at pH 10.85 using resin 5. At this pH the lysine residues should be mostly in a neutral form, based on the pK_a of the side chain of this residue being 10.58 (ref. 25, p. 90) and on the behaviour of polylysine at a similar pH (27). Changes in the ionic state of bilirubin in the pH range 7.80–10.85 are somewhat controversial. Some authors strongly hold that bilirubin exists as a monoanion in the pH range 6–9 and as a dianion above (28, 29), while others argue that bilirubin exists as a dianion even near neutrality (30). Assuming a change in the ionization state of bilirubin from monoanion to dianion, ionic interactions should be favored. However, Fig. 4 shows a considerable decrease in capacity at pH 10.85, in accordance with an adsorption mechanism involving ionic interactions. Changes in peptide conformations are expected to be a minor factor because of the limited development of secondary and tertiary structures for this relatively short sequence. Furthermore, the conformation of bilirubin can be assumed to play a minor role since X-ray analyses have shown that the bile pigment maintains a similar three-dimensional conformation regardless of its ionization state (31).

Based on the previous results, it is clear that ionic interactions are greatly influencing the binding between bilirubin and peptide pendants. However, it was of interest to determine if other factors were also contributing to the adsorption process. To this end, the binding behaviour of molecules that are chemically similar to bilirubin, but that bear some structural differences from it, were studied. The adsorbates selected for this purpose were biliverdin and mesoporphyrin. These compounds share many chemical features with bilirubin (Fig. 1), including the presence of two propionic carboxyl groups, but differ in that the inherent molecular flexibility is reduced. Indeed, biliverdin, in contrast to bilirubin, has a fully conjugated system since both pyrromethenone chromophores are connected by a methene bridge. This relatively small difference in the center of the molecule prevents free rotations within the molecule. Bilirubin and biliverdin, although shown in a cyclic conformation in Fig. 1 to emphasize basic chemical differences,

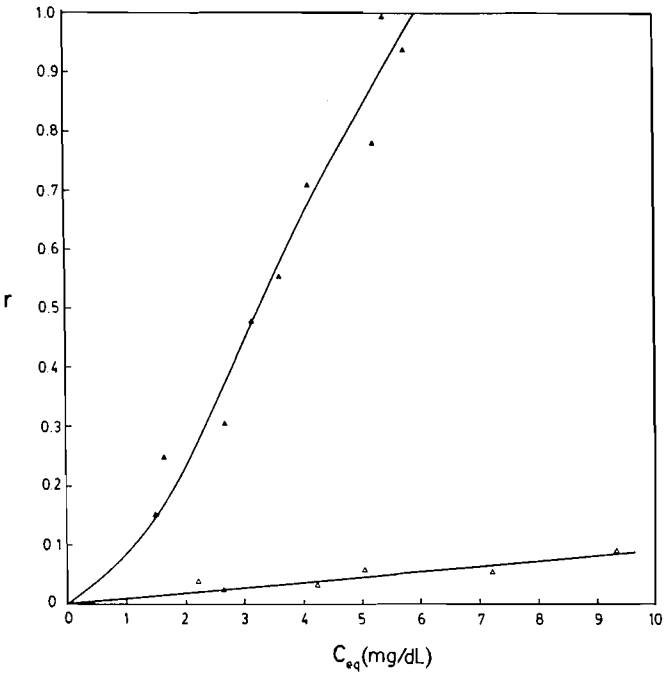

FIG. 4. Effect of pH on the adsorption of bilirubin by resin 5; ▲, pH = 7.80, KH_2PO_4/NaOH (0.05 M), 0°C; △, pH = 10.85, Na_2HPO_4/NaOH (0.05 M), 0°C.

are known to adopt "ridge-tile" and spiral configurations, respectively (16). On the other hand, mesoporphyrin is a conjugated, cyclic tetrapyrrole molecule with no possibility of internal rotation at the level of the ring system and hence is planar and rigid. Furthermore, whereas biliverdin and mesoporphyrin are dianions at pH 7.80, bilirubin is probably a monoanion (28, 29). This difference in the ionization state of the adsorbates should favor the adsorption of biliverdin and mesoporphyrin, assuming a binding process governed by ionic interactions.

The isotherms for the adsorption of these molecules by resin 6 (Fig. 5) show that it adsorbs considerably greater amounts of bilirubin than either biliverdin or mesoporphyrin, which suggests that binding cannot be rationalized solely on the basis of favorable ionic interactions. The observed differences are thought to reflect differences in the structural features of the adsorbates.

Therefore, although salt linkage interactions play a major role in the binding of bilirubin by the synthesized adsorbents, other factors are also involved. It is possible that the three-dimensional conformation of bilirubin is such that it confers a unique binding character to the molecule. Indeed, owing to an accentuated molecular flexibility compared to that of biliverdin and mesoporphyrin, bilirubin can adapt to the binding sites on the pendants in a manner such that well-fitted complexes can form. Since mesoporphyrin and biliverdin possess entirely different three-dimensional arrangements from that of bilirubin, the binding behaviour of these molecules reveals that the adsorption is also influenced by factors related to the structural features of the adsorbate.

Scatchard plots and binding constants

A quantitative assessment of the affinity of the peptide pendants for bilirubin is given by binding constants that can be derived from Scatchard plots. Resins 1 and 2 were found to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

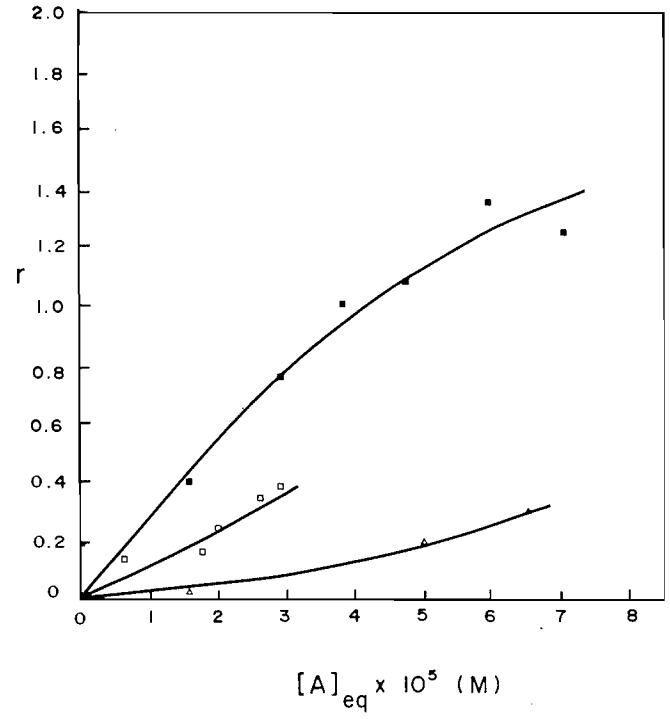

FIG. 5. Isotherms for the adsorption of tetrapyrroles by Arg-$(Lys)_2$-$(Ser)_2$-Lys-$(Ala)_3$-support, KH_2PO_4/NaOH (0.05 M), pH = 7.80, and 0°C. ■, bilirubin; △, biliverdin; □, mesoporphyrin.

have typical, linear Scatchard plots, as expected for adsorbents having only one binding site per pendant. The derived values of k (Table 3), as given by the Scatchard equation (32), are 2.1×10^3 and $1.2 \times 10^3\,M^{-1}$ for resins 1 and 2, respectively.

The Scatchard plots associated with the remaining peptide resins show concave downward curvature (Fig. 6), in a more or less developed manner, due to limitations that result from the low solubility of bilirubin. A maximum number of two moles of bound ligand per mole of pendant is assumed for these adsorbents, as demonstrated from a comparison of the size of the molecule of bilirubin relative to the length of the peptide pendants. Space filling molecular models indicate that steric factors would preclude the adsorption of additional ligands. The Scatchard plot associated with resin 6 strongly supports this assumption.

Downward curvature in a Scatchard plot reflects an adsorption process by which binding of the second molecule by the pendant occurs with a stronger affinity than that of the first, i.e., a second site binding constant larger than that of the first. This phenomenon is the manifestation of positive cooperativity between the binding sites, usually associated with an adsorption isotherm for which, as the adsorbate concentration increases, r rises slowly at low values, then increases sharply, and finally reaches saturation, i.e., a sigmoidal shape.

Site binding constants for these four peptide resins were derived graphically using a modified Scatchard equation described previously (24). It is based on a model that considers interactions between two initially *equivalent* binding sites on each pendant. The equations describing the binding model allow the derivation of site binding constants from Scatchard plots based on the following intercepts: $r/[A] = 2k_1$ (at $r = 0$) and $r/[A] = (k_1k_2)^{1/2}$ (at $r = 1$), where the parameters k_1 and k_2 represent first and second *site* binding constants. The ordinate intercepts of Figs. 6(A) and 6(B) are (1.8, 1.1, 1.8, and 30) $\times 10^3\,M^{-1}$ for resins 3, 4, 5, and 6, respectively. These values correspond to k_1 of (0.90, 0.55, 0.90, and 15) $\times 10^3\,M^{-1}$ (Table 3). The values of $r/[A]$ at half saturation are (2.2, 3.6, 11, and 37) $\times 10^3\,M^{-1}$ for resins 3, 4, 5, and 6, respectively, corresponding to k_2 values of (5.1, 23, 130, and 91) $\times 10^3\,M^{-1}$ (Table 3).

TABLE 3. Site equilibrium constants for the binding of bilirubin by peptide resins at 0°C

Bilirubin	Site binding constant $\times 10^{-3}$ (M^{-1}) k_1	k_2
1 -Lys-$(Ala)_3$-support	2.1	0
2 -Ser-	1.2	0
3 -Ser-	0.90	5.1
4 -Lys-	0.55	23
5 -Lys-	0.90	130
6 Arg-	15	91
Arg-$(Lys)_2$-$(Ser)_2$-Lys-$(Ala)_3$-support		
Biliverdin	0.065	630
Mesoporphyrin	5.1	27

Since k_2 is larger than k_1 for all four systems, the constants are consistent with positive cooperativity. If the binding sites are considered to be initially equivalent, the value of ξ, equal to k_2/k_1, can be thought of as a direct measure of the degree of cooperativity. The enhancement values for resins 3–6 are 6, 37, 141, and 6, respectively. There is a continuous increase in the value of ξ up to resin 5, but the addition of the arginine residue causes a marked decrease. Positive cooperativity for the binding of bilirubin by lysine-containing pendants has been observed in previously work (7, 33). Indeed, peptide resins such as $(Lys)_2$-$(Ala)_3$-support and $(Lys)_5$-$(Ala)_3$-support have enhancement values of 3 and 1500, respectively. Positive cooperativity has also been observed, but to a much lesser degree, for the binding of bilirubin by certain arginine-containing adsorbents (33). The $(Arg)_2$-$(Ala)_3$-support, $(Arg)_3$-$(Ala)_3$-support, and Arg-$(Ala)_3$-Arg-$(Ala)_3$-support adsorbents have enhancement values of 1.5, 1.1, and 1.7, respectively, whereas $(Arg)_5$-$(Ala)_3$-support has a value of ξ equal to 0.53. Such low values of ξ for arginine-containing pendants correlate well with the results of the present study and demonstrate that positive cooperativity is a characteristic of lysine-containing pendants and is considerably less evident for those with arginine.

Site binding constants for the adsorption of biliverdin and mesoporphyrin by resin 6 are also given in Table 3. It is of interest to note that values of k_2 larger than k_1 are also obtained for these systems.

Discussion

This study clearly demonstrates, by the effect of pH on the adsorption, the favorable interactions between oppositely charged species. The incorporation of the basic amino acids, arginine and lysine, into the pendants is generally accompanied by a considerable increase in the binding affinity (6–8) whereas the addition of the negatively charged glutamic acid markedly reduces it (8). These results are consistent with direct evidence for the interaction between the COO^- groups of bilirubin molecules and the NH_3^+ groups of L-lysyl-L-lysine from changes in nmr relaxation times (13). Thus, there is strong

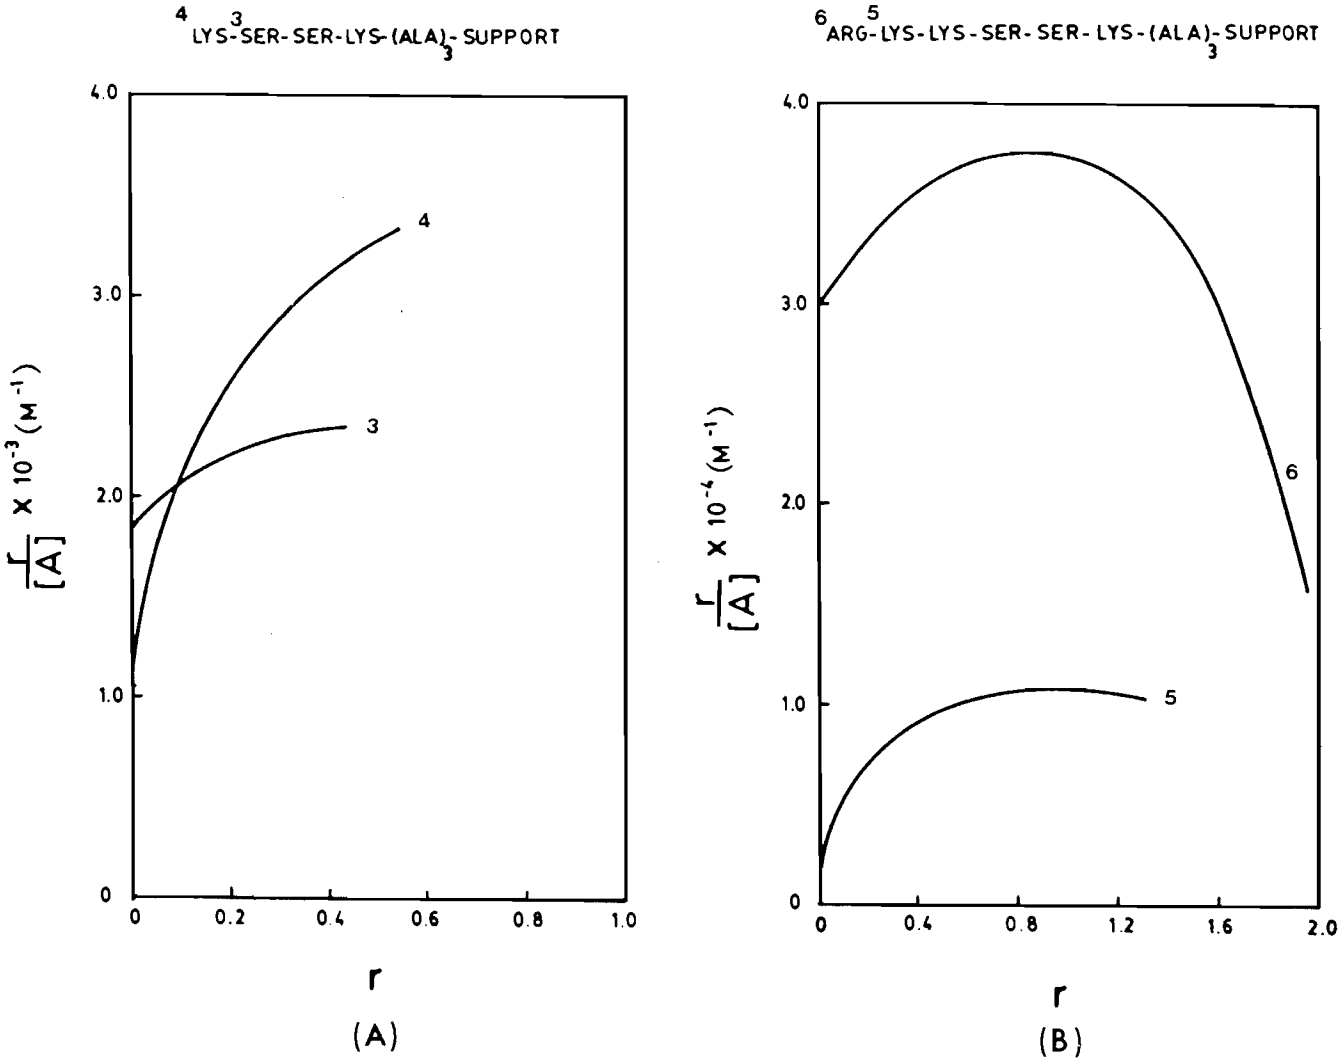

FIG. 6. Scatchard plots for resins 3–6.

experimental evidence to indicate that interactions based on salt linkages are the major driving force for the binding of bilirubin by immobilized peptides. However, the adsorption results for biliverdin and mesoporphyrin show that other factors, likely related to the structure of the adsorbate, also influence the process.

The positive cooperativity characterizing the adsorption behaviour of bilirubin by resins 3–6 suggests that specific interactions are involved between the bound ligands and the pendants. The binding of bilirubin molecules at or in the immediate neighborhood of lysine- and (or) arginine-containing pendants results in a partial neutralization of the negatively charged carboxylate groups. This should effectively decrease repulsions between the bound molecules and favor $\pi-\pi$ electron interactions between the conjugated systems, i.e., stacking of the bound ligands.

This model is based on the interactions of nucleotides or dyes with basic polypeptides at neutral pH. In aqueous solution, free nucleic acid bases and certain dye molecules manifest a pronounced tendency for stacking (34, 35). It is well documented (36–40) that the binding of these ligands by polylysine or polyarginine is characterized by positive cooperativity, i.e., the incoming ligands show a marked preference for binding to sites adjacent to those already occupied. This preference has been attributed to the effect of charge neutralization, upon addition of a positively charged polymer, on the tendency for negatively charged ligands to stack. Similarly, free bilirubin is also known to undergo dimerization and oligomerization in aqueous alkaline solutions (pH from about 8 to 12) (17, 41). The binding force responsible for the stability of the free dimer is thought to include $\pi-\pi$ electron interactions between the pyrromethenone chromophores (41), as well as hydrogen bonds (17).

Explanations for differences in the degree of positive cooperativity of the lysine- and arginine-containing pendants can be obtained from a consideration of the nature of the side-chain groups. Arginine has a bulky terminal guanidino group that provides some rigidity to the chain as well as delocalization of the charge. Consequently, $\pi-\pi$ electron interactions between the conjugated systems of bilirubin and the guanidino group are possible, as suggested by Wagner and Arav (38) for the binding of nucleotide bases by polyarginine. Thus, arginine-containing pendants should show a stronger binding affinity for bilirubin, i.e., the k_1 values are expected to be substantially larger than those for the lysine analogues. This is consistent with the data in Table 3 and with previous binding affinity results (8, 33) as well as with the more basic character of arginine. Thus, binding of the first bilirubin molecule by an arginine-containing pendant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

can include highly favorable interactions that are not present in the lysine-containing pendants and can, to some extent, mask the positive cooperativity of the binding process. On the other hand, the accentuated molecular flexibility, minimal steric hindrance, and point-charge character of the lysine side chain represent features that should enhance the tendency for the bilirubin molecules to stack. It should be noted that favorable conformational changes in the peptide pendants, as a consequence of the binding of the first ligand, should also be considered as contributing to the phenomenon of positive cooperativity.

This explanation, which accounts for the observed positive cooperativity, is entirely consistent with the behaviour of free biliverdin and mesoporphyrin in aqueous solutions. Indeed, these molecules manifest a tendency for dimerization (42, 43) and it is therefore expected that they would exhibit a binding mode identical to that of bilirubin when adsorbed by lysine-containing pendants, if it is accepted that positive cooperativity is a reflection of the stacking tendency of the bound ligands. Furthermore, circular dichroism studies of the bilirubin–polylysine complex, at pH 11.00 (26), strongly support the presence of the bound dimers of bilirubin on the polypeptide.

Conclusions

The adsorption isotherms of these adsorbents have confirmed that the basic amino acids arginine and lysine are of major importance in the binding of bilirubin. This supports Jacobsen's proposal on the participation of these residues in the in vivo binding of bilirubin by the high-affinity site on HSA. The positive cooperativity characterizing the binding of bilirubin by lysine-containing pendants suggests a tendency of the bound molecules to dimerize on the immobilized pendants. This molecular mechanism is based on a consideration of the interactions thought to dominate the binding process, i.e., salt linkage interactions. Although the presence of an arginine residue in the sequence of a pendant reduces the degree of positive cooperativity, it causes an increased binding affinity consistent with the strongly basic character of this residue.

Finally, the adsorption results for the binding of biliverdin and mesoporphyrin show that a consideration of the chemical groups on the adsorbate, particularly the presence of carboxyl groups, is not a sufficient criterion to explain the binding data.

Acknowledgments

Financial support in the form of operating grants from the Natural Sciences and Engineering Research Council of Canada and the Province of Quebec (FCAR) is gratefully acknowledged. We would also like to express our appreciation to Dr. S.-D. Clas and Professor W. C. Galley of McGill University, for helpful discussions and suggestions.

Electron affinities of substituted nitrobenzenes

S. CHOWDHURY, H. KISHI,[1] G. W. DILLOW, AND P. KEBARLE[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 17, 1988[3]

S. CHOWDHURY, H. KISHI, G. W. DILLOW, and P. KEBARLE. Can. J. Chem. **67**, 603 (1989).

The electron affinities of 14 substituted nitrobenzenes including nitrobiphenyls were determined by measurement of electron transfer equilibria [1] in the gas phase with a pulsed high pressure mass spectrometer: $A^- + B = A + B^-$ [1]. These data, when combined with previous determinations from this laboratory, lead to electron affinities for 35 substituted nitrobenzenes and provide a comprehensive data set for the examination of substituent effects. The data are used to derive Taft gas-phase substituent parameters. A qualitative discussion based on frontier orbital molecular theory examines the substituent effect on the benzene and nitrobenzene LUMOs. The lifetimes for electron autodetachment from excited nitrobenzene negative ions, $(A^-)^*$, studied earlier by Christophorou, are examined in light of the present electron affinity data.

Key words: electron affinities, substituent effects, frontier orbital treatment, electron autodetachment from nitrobenzene radical anions.

S. CHOWDHURY, H. KISHI, G. W. DILLOW et P. KEBARLE. Can. J. Chem. **67**, 603 (1989).

En se basant sur des mesures d'équilibre du transfert électronique [1] en phase gazeuse ($A^- + B = A + B^-$ [1]) effectuées à l'aide d'une spectromètre de masse pulsé à haute pression, on a déterminé les affinités électroniques de 14 nitrobenzènes substitués comprenant des nitrobiphényles. Lorsqu'on combine ces données avec des déterminations qui ont été faites antérieurement dans ce laboratoire, on obtient les affinités électroniques de 35 nitrobenzènes substitués qui forment un ensemble étendu de données qui permet d'évaluer les effets des substituants. On a utilisé ces données pour évaluer les paramètres de Taft des substituants, pour la phase gazeuse. Une discussion qualitative basée sur la théorie des orbitales moléculaires frontières permet d'examiner l'effet des substituants sur les OM basses vacantes du benzène et du nitrobenzène. Les temps de vie de l'auto-détachement électronique des ions négatifs de nitrobenzènes excités, $(A^-)^*$, étudiés antérieurement par Christophorou, ont été examinés à la lumière des nouvelles données sur l'affinité électronique.

Mots clés : affinités électroniques, effets des substituants, traitement des orbitales frontières, auto-détachement électronique des ions négatifs de nitrobenzène.

[Traduit par la revue]

Introduction

A large number of electron affinity (EA) determinations based on measurement of electron transfer equilibria [1] with a pulsed high pressure mass spectrometer (PHPMS) were reported recently from this laboratory (1) and have been summarized in a review article (2). The technique was shown to be highly suitable for the determination of EAs for many classes of compounds including nitro-, cyano-, and pentafluoro-substituted benzenes as well as quinones, dicarbonyl compounds, and polycyclic aromatics (1, 2).

[1] $A^- + B = A + B^-$

With the availability of extensive EA data on several series of substituted molecules, it has been possible to examine the effects of substituents on the stability of radical anions. Thermochemical data derived from the measurement of gas-phase equilibrium processes are best suited for the determination of intrinsic substituent effects in substituted series of ions since they are free of problems such as preferential solvation and ion-pairing, which may mask intrinsic substituent effects in solution. The determination of gas-phase acidities and basicities has been of central importance in recent studies of substituent effects (3). However, examination of substituent effects on gas-phase electron transfer equilibria is potentially equally as useful, but much less work has been done in this area.

In this paper we report new determinations of the EAs of 14 substituted nitrobenzenes that were measured by PHPMS. These data are combined with previous data from this laboratory (2) to give EAs for 35 substituted nitrobenzenes bearing the substituents H, NO_2, CHO, CH_3CO, CN, CF_3, C_6H_5, CH_3, F, Cl, Br, OCH_3, and NH_2. This extensive data set provides a good base for the examination of substituent effects on the stability of substituted nitrobenzene radical anions. Interest in this series of molecules was prompted in part by the availability of theoretical studies on substituent effects in substituted benzenes (4) and a few benzene radical anions (5).

In the earlier EA studies (1), a striking similarity between the substituent effects on the electron affinities of nitrobenzenes and the acidities of phenols was observed. This similarity was also reported earlier, by Fukuda and McIver (6). Since the electron affinities are generally related to the energy of the LUMO of the molecule, it seemed a challenge to uncover the factors responsible for the similarity with the acidity substituent effects.

Experimental

The measurements of electron transfer equilibria [1] were performed with a pulsed high pressure mass spectrometer (PHPMS), which has been described elsewhere (2, 7). The experimental procedures used were essentially the same as described previously (2, 7). Reaction mixtures in the ion source consisted of methane at 5 Torr pressure (1 Torr = 133.3 Pa) containing mTorr partial pressures of A and B, which were selected to ensure that electron transfer equilibrium was achieved within ~200 μs of initiation of the reactions by a 10-μs primary electron pulse. The ion intensities of A^- and B^-, $I(A^-)$ and $I(B^-)$, which were detected after equilibrium was reached, were inserted into equilibrium expression [2], enabling the equilibrium constant for reaction [1], K_1, to be calculated. The free energy change for reaction [1], ΔG_1^0, was calculated by inserting K_1 into eq. [3].

$$[2] \qquad K_1 = \frac{[B^-][A]}{[A^-][B]} = \frac{I(B^-)[A]}{I(A^-)[B]}$$

$$[3] \qquad \Delta G_1^0 = -RT \ln K_1$$

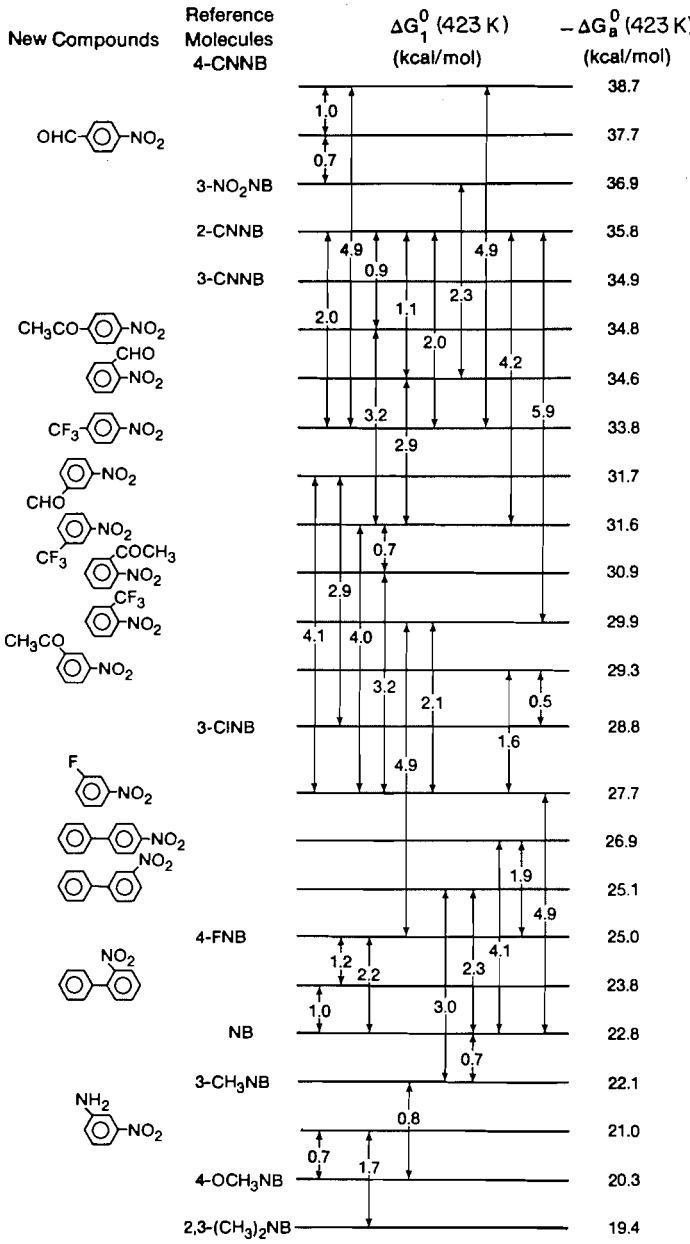

FIG. 1. Free energy changes, ΔG_1^0, for electron transfer reactions, $A^- + B = A + B^-$, measured at 423 K (NB = $C_6H_4NO_2$). The ΔG_a^0 values correspond to the free energy changes for the capture in the gas phase of a stationary electron: $e^- + A = A^-$. These were obtained from the ΔG_1^0 scale and the known ΔG_a^0 for the reference compounds (2).

A reaction temperature of 150°C (423 K) was used since intense adduct ions of the form AA^-, AB^-, and BB^- may be formed at lower temperatures while thermal electron detachment from the radical anions may occur at higher temperatures. In most of the measurements, A^- and B^- were by far the dominant ions. When side reactions were observed, measurements of K_1 were made only when the rates of the reactions removing A^- and B^- were much slower than the equilibration rate in equilibrium [1]. The [A]/[B] concentration ratio was varied by up to a factor of 10 to ensure that K_1 is independent of this ratio.

Results

The equilibrium constants for reaction [1], K_1, involving the 14 new nitrobenzenes and a series of reference compounds were measured as described in the experimental section. The ΔG_1^0 evaluated with eqs. [2] and [3] are shown in Fig. 1. Since the electron attachment free energy, $\Delta G_a^0(B)$, corresponding to the free energy for electron capture as shown in reaction [4], had been determined previously for the reference compounds (2), ΔG_a^0 could be evaluated for the new nitrobenzenes from the relative ΔG_1^0 values in Fig. 1. These ΔG_a^0 values are also shown in Fig. 1. The stationary electron convention (1*b*) was used in these evaluations.

TABLE 1. Thermochemical results for electron capture, reaction [4]

3-C_6H_5·NB	25.1	25.9	1.12
2-C_6H_5·NB	23.8	24.6	1.07
3-NH_2·NB	21.0	21.8	0.95

[a] ΔH_a^0 obtained from ΔG_a^0 by subtracting 0.8 kcal mol^{-1} for all substituents except CHO, CH_3CO, and NO_2, for which 1.3 kcal mol^{-1} was subtracted. These values correspond to estimated $T\Delta S$ terms; see text.
[b] NB = $C_6H_4NO_2$.

[4] $\quad e^-_{(g)} + B_{(g)} = B^-_{(g)} \qquad \Delta G_4^0 = \Delta G_a^0$

The temperature dependence of K_1 was not determined in the present investigation. However, in a previous study (1*b*) the temperature dependence of K_1 was evaluated for a number of substituted nitrobenzenes, enabling ΔH_1^0 and ΔS_1^0 to be obtained from van't Hoff plots. Nitrobenzene was found to have $\Delta S_a^0 = -0.5$ cal deg^{-1} mol^{-1}. Many substituted nitrobenzenes had $\Delta S_a^0 \approx -2$ cal deg^{-1} mol^{-1}, while 1,4-dinitrobenzene had $\Delta S_a^0 = -4.5$ cal deg^{-1} mol^{-1}. The other two strong π-acceptor substituents, CHO and CH_3CO, caused similar entropy decreases. It is assumed that the negative ΔS_a^0 in 1,4-dinitrobenzene is due to stiffening of the C—N internal rotation and bending motions in the anion due to an increase in the C—N bond order as a result of the extra electron in the π-system (1*b*). Since the overall ΔS_a^0 values are small and the error in the ΔS_1^0 determinations is large (±2 eu), enthalpy values for electron capture by the new substituted nitrobenzenes, ΔH_a^0, were estimated by assuming that $\Delta S_a^0 = -2$ cal deg^{-1} mol^{-1} for all the compounds except the CHO, CH_3CO, and NO_2 substituted nitrobenzenes, for which $\Delta S_a^0 = -3$ cal deg^{-1} mol^{-1} was assumed. These ΔH_a^0 values are listed in Table 1. Since the data relate to 423 K, the corresponding $T\Delta S$ terms result in a difference between ΔG_a^0 and ΔH_a^0 of approximately 0.8 and 1.3 kcal mol^{-1} respectively.

Fukuda and McIver (6) have reported a ΔG_1^0 ladder involving several substituted nitrobenzenes, which was obtained by electron transfer equilibria measurements at much lower pressures ($\approx 10^{-6}$ Torr) with an ion cyclotron resonance (ICR) spectrometer. To facilitate a comparison of the ICR and PHPMS results, we have anchored the results of Fukuda and McIver to our primary reference compound, SO_2, for which a value of $\Delta G_a^0 = -26.1$ kcal mol^{-1} has been determined independently by a number of methods (1*a*, 1*b*). The ΔG_a^0 (ICR) obtained in

TABLE 2. Substituent coefficients determined by multiple regression fits of the substituted nitrobenzene $-\Delta G_a^0$ values to eq. [8]

Substituent type	Ring position	Substituent coefficients ρ_R	ρ_F	ρ_α	Coefficient of correlation
σ-Acceptor/π-acceptor	C-4	45.7±4.5	19.2±1.4	[a]	0.997
	C-3	15.1±3.0	17.5±1.0	[a]	0.997
	C-2	32.8±9.3	13.7±2.9	[a]	0.974
σ-Acceptor/π-donor	C-4	17.0±3.5	16.3±2.7	−1.5±2.0	0.987
	C-3	8.0±0.5	16.0±1.0	−0.2±0.3	0.999
	C-2	22.6±1.0	15.8±1.0	0.8±0.5	0.999

[a]Multiple regression analyses that included polarizability effects were performed for these substituents, but the calculated ρ_α values were small and did not improve the correlations significantly.

this manner, when compared with the ΔG_a^0 (PHPMS) from Fig. 1, were found to be in very good agreement, the differences being generally smaller than ±0.2 kcal mol^{-1}.

Discussion

Effect of substituents on the electron affinities of nitrobenzenes. Taft's resonance and field parameters

Most of the substituents used may be classified into two categories (4):

(*i*) σ-acceptor/π-acceptor substituents: NO_2, CHO, $COCH_3$, CN

(*ii*) σ-acceptor/π-donor substituents: F, Cl, Br, OCH_3, NH_2

It was noted in the earlier work on electron affinities (1*a*, 2, 6) that the substituent effect on the electron affinities of nitrobenzenes, i.e., the free energy change, eq. [5], was close to identical to the substituent effect on the gas-phase acidities of phenols, $\delta\Delta G^0_{PhOH}$, see eq. [6]. The correlation, which includes the latest data for the nitrobenzenes, is shown in Fig. 2.

[5] $$NO_2C_6H_5^- + NO_2C_6H_4X = NO_2C_6H_5 + NO_2C_6H_4X^- \qquad \delta\Delta G^0_{NB}$$

[6] $$C_6H_5O^- + XC_6H_4OH = C_6H_5OH + XC_6H_4O^- \qquad \delta\Delta G^0_{PhOH}$$

Taft *et al.* (3) have developed methods for the separation of the substituent effects, $\delta\Delta G^0$, into contributions due to resonance (R) and field-inductive effects (F). In early work (3*c*), the resonance R and field inductive term F were obtained from the experimental $\delta\Delta G^0$ values from measurements in solution and eqs. [7]. The assumptions in [7*b*] allow the separation into R and F to be obtained from the $\delta\Delta G_p^0$ and $\delta\Delta G_m^0$ of a single substituted series of compounds.

[7*a*] $$-\delta\Delta G_p^0 = R_p + F_p = \rho\sigma_p$$
$$-\delta\Delta G_m^0 = R_m + F_m = \rho\sigma_m$$

[7*b*] $$F_m \cong F_p \quad R_m = 0.2\,R_p \quad (\pi\text{-withdrawing substituents})$$
$$R_m = 0.6\,R_p \quad (\pi\text{-donating substituents})$$

The analysis could be greatly extended after $\delta\Delta G^0$ values from measurements of gas-phase proton transfer equilibria became available for many acid–base series. The separation of the σ and ρ values for substituents in a given position to the functional group was obtained (3*a*, *b*) with eq. [8], which includes also substituent polarizability (α) effects.

[8] $$-\delta\Delta G^0 = \rho_R\sigma_R + \rho_F\sigma_F + \rho_\alpha\sigma_\alpha$$

In eq. [8], $-\delta\Delta G^0$ is the relative free energy change for some chemical transformaion such as removal of a proton ($-\delta\Delta G^0$ = 0 kcal mol^{-1} for substituent -X); σ_R, σ_F and σ_α are system-independent substituent parameters that rank the resonance, field, and polarizability capacities, respectively, of the various substituents; ρ_R, ρ_F, and ρ_α are system-dependent coefficients that indicate the magnitude of the respective substituent effects on $-\delta\Delta G^0$ within a given family of molecules.

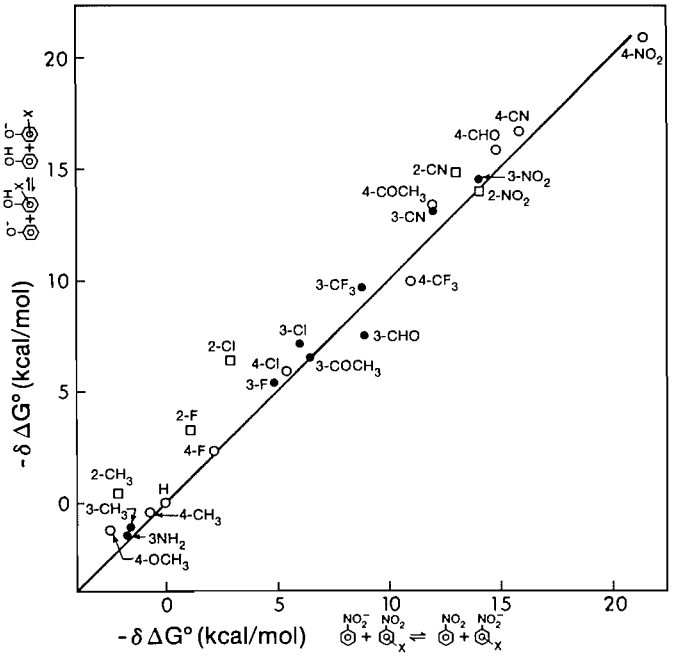

FIG. 2. Plot of $\delta\Delta G^0$ of gas phase acidities of substituted phenols, from refs. 12 and 13, versus $\delta\Delta G^0$ of electron attachment free energies for substituted nitrobenzenes.

In the present work, multiple regression analysis was used to correlate $-\delta\Delta G_a^0$ for electron capture by the substituted nitrobenzenes with the σ_R, σ_F, and σ_α values compiled by Taft *et al.* (3*b*). Table 2 lists the ρ_R, ρ_F, and ρ_α values determined by this procedure along with the coefficients of correlation for each fit. Generally, the high degree of correlation suggests that $-\delta\Delta G_a^0$ may be described very well by eq. [8]. This confirms that the influence of the substituents on the EA ($\approx -\delta\Delta G_a^0$) of the substituted nitrobenzenes may be accounted for well in terms of resonance and field effects, although the polarizability of the substituents also seems to play a small role with σ-acceptor/π-donor groups.

As expected from the closeness of the experimental $\delta\Delta G^0$ for the phenol acidities and the nitrobenzene electron attachment energies, the present ρ values (Table 2) are very similar to those obtained by Taft *et al.* (3) for the phenol acidities. Thus, for the

[a]$\delta\Delta G^0$ experimental results from Table 1 in kcal mol^{-1}; R and F values also in kcal mol^{-1}; σ_F and σ_R values from Taft (3*b*). Values for F and R that are shown without parentheses were obtained with Taft's σ values and ρ values shown in Table 2. Values for F and R shown in parentheses are for substituents for which σ are not available; these were obtained from σ_R and σ_F values calculated in this study.

[b]Values for substituents are shown in the order *para*, *meta*, *ortho*, i.e., positions 4, 3, 2.

[c]Calculated from eq. [8] using ρ_R and ρ_F values from Table 2.

For personal use only.

σ-acceptor/π-acceptor substituents, in position 4, the ρ_R = 45.7 for nitrobenzenes vs. 49 for phenols (3*b*), and ρ_F = 19.2 for nitrobenzenes vs. 18.9 for phenols (3*b*).

The approximate contributions of resonance and field effects to $\delta\Delta G^0_a$ may be assessed for each substituted nitrobenzene by calculating $R = \rho_R\sigma_R$ and $F = \rho_F\sigma_F$ using the σ values compiled by Taft (3) and the ρ values determined in this study. Table 3 lists the R and F values obtained from this procedure along with the respective σ values used in this calculation and $\delta\Delta G^0_a$ for each substituted nitrobenzene. For the substituents phenyl and bromine, no σ values were available; the σ values shown in Table 3 for these substituents were calculated by inserting appropriate values of $\delta\Delta G^0_a$ and ρ from Table 3 into eq. [8] and solving the resultant simultaneous equations. Cross checks showed that the R and F terms obtained by eqs. [7] and [8] were very similar.

The magnitude of the R and F values for most of the substituents shown in Table 3 have been discussed previously in connection with acidities of phenols and other systems (3). All of these have involved even-electron, complete valence shell reactants. In the next section we discuss how the substituent effects on the electron affinities of benzenes can be related to those for the systems above.

MO and frontier orbital PMO

Taft's early separation of substituent effects into R and F contributions (3*c*) was inspired by valence bond concepts; however, the procedure itself was based entirely on experimental results. Later, when MO calculations could be executed for substituted benzenes (8) at the minimal STO-3G basis set level, it was found that changes in σ and π electron populations, based on Mulliken population analysis, conformed to the σ and π electron shifts expected from the F and R effects. More recent work (9, 10) has led to even closer confirmations. Also of interest is the fact that the energy changes ΔE for isodesmic reactions like [6] obtained from the total energies E of the reactants calculated with minimal STO-3G basis set were found to be close to the experimentally obtained ΔH values for the same reactions based on ion–molecule equilibria measurements (11–13).

A very useful qualitative extension of MO concepts occurred with the application of perturbation molecular orbital (PMO) theory to substituent effects (4). In this approach, the highest occupied or the lowest unoccupied orbitals (HOMO or LUMO) of the substituent ψ_j and of benzene, ψ_k, considered first as separate entities, interact to produce two new orbitals, one of lower and the other of higher energy. The new orbitals are substituted benzene orbitals.

The stabilization energy, SE, corresponding to the energy lowering of the new lower orbital relative to the lower of the two initial orbitals is given by eq. [9]:

$$[9] \qquad SE = \frac{C^2_{rj}C^2_{sk}\beta^2_{rs}}{\Delta E}$$

where C_{rj} and C_{sk} represent the coefficients of the atoms r in the orbital ψ_j and s in orbital ψ_k where atoms r and s are the interacting ones in the new orbital. $\beta_{r,s}$ is the resonance integral associated with these atoms and ΔE represents the energy separation between ψ_j and ψ_k. For a detailed account, see Pross and Radom (4*b*).

MO concepts are particularly well suited for discussion of the electron affinities of molecules, and the description that the extra electron enters the LUMO of the molecule and that the EA increases as the energy of the LUMO decreases is widely used. For this reason, the PMO framework outlined above appears particularly useful for the qualitative discussion of substituent effects on electron affinities.

The approximate energy levels of the π-withdrawing substituents' LUMOs, the π-donating substituents' HOMOs, and the

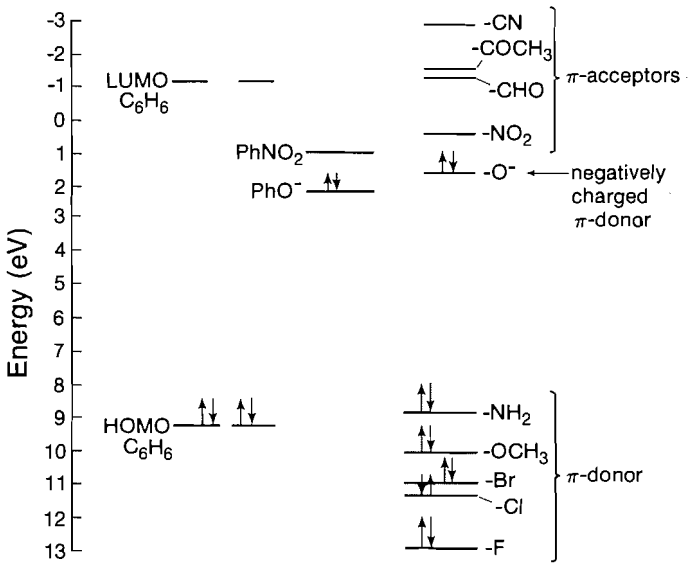

FIG. 3. Approximate orbital energies of HOMO and LUMO in benzene, the LUMO of π-acceptor groups, and the HOMO of π-donor groups. Also given are the LUMO of nitrobenzene ($PhNO_2$) and the HOMO of the phenoxide anion (PhO^-). For origin of data see text.

benzene LUMO and HOMO are given in Fig. 3. The energies of the LUMOs for the π-acceptor substituents were taken to be equal to the electron affinities of the corresponding substituted methanes determined by electron transmission spectroscopy (14) where the EA is negative or by PHPMS and other techniques for positive EA (2). The LUMOs of benzene are from ref. 14 while the energies of the HOMOs of benzene and the π-donating substituents were taken to be to the ionization potentials of benzene and the respective substituted methanes (15). Also shown in Fig. 3 are the energies of the HOMO of the phenoxide ion taken as the EA of phenoxide (17) and the HOMO of the π donor oxy substituent O^- taken as the EA of hydroxide (17). These orbitals will be of use in the subsequent discussion.

PMO. Single substitution of benzene with π acceptors

The qualitative frontier orbital scheme given in Fig. 4 shows the important interactions when the substituent is attached to benzene. The dominant interaction is the combination of the substituent LUMO (ψ_L) with one of the degenerate π* benzene LUMOS (ψ_3). These orbitals are close in energy (see Fig. 3) and the chosen benzene π* has high atomic orbital coefficients on the substitution site. The lower of the two resulting orbitals, ($\psi_{L'}$), interacts weakly with the energy distant HOMO of benzene (ψ_1); this slightly destabilizes $\psi_{L'}$ and stabilizes ψ_1 to produce ψ_{1a}. An additional factor that influences the orbital energies is the electrostatic effect of the substituent's electronegativity and dipole, which polarizes the electrons in benzene. Polarization of electrons towards the σ acceptor substituent "deshields" the nuclear charge and leads to stabilization of the orbitals of benzene and particularly those with high density near the substituent (4). Deshielding may be considered as the PMO counterpart of the σ-withdrawal field effect.

Taking nitro substitution as an example, the formation of the $\psi_{L'}$ LUMO for nitrobenzene leads to an increase of EA from -26.5 kcal mol^{-1} for benzene (14) to 23.0 kcal mol^{-1} in nitrobenzene (16). Hence, while electron capture into the π* LUMO produces only a temporary negative ion state in benzene, nitrobenzene forms a stable long-lived negative ion (16). Similarly strong interactions are expected for the other π-withdrawing substituents CHO, $COCH_3$, and CN, due to the closeness in energy between their LUMOs and that of benzene; see Fig. 3.

PMO single substitution of benzene with π donors

The interaction of π donor substituents like F and OH with benzene are also shown in Fig. 4. The main interaction is between the lone pair substituent HOMO (ψ_N) and the HOMO of benzene, since these two orbitals are close in energy, see Fig. 3. The resulting pair of occupied orbitals are designated as ψ_{1b} and $\psi_{N'}$. The higher of these ($\psi_{N'}$) engages in a weak secondary interaction with the distant in energy benzene LUMO (ψ_3), which slightly stabilizes $\psi_{N'}$ and destabilizes ψ_3 to produce ψ_{3b}. The benzene LUMO, ψ_4, which does not undergo any interaction, becomes the LUMO in these molecules. As discussed for π-acceptor substituents, the energy of that LUMO will be affected by deshielding due to the substituent's electronegativity. According to this scheme, the EA of benzenes substituted by π donors are not affected by π delocalization (resonance) and are thus close to the EA of benzene, but small EA increases are expected as a result of the deshielding (σ-withdrawing) effects of the substituents. These predictions are borne out by experimental results (14).

Of interest in connection with the similarity of the substituent effects on the electron affinities of nitrobenzenes and the acidities of phenols is the PMO scheme for substitution of benzene with the very strong π donor substituent, O^-. This substitution leads to formation of the phenoxy anion. The lone pair ψ_N orbital of the O^- lies very much higher than that of the neutral π donors, see Fig. 3. This results in a strong interaction with the close in energy ψ_3 LUMO of benzene, and is associated with extensive electron transfer from the substituent (O^-) to benzene. It will be seen in the next seciton that the similarities of the substituent effects on the phenol acidities and the nitrobenzene electron affinities can be traced to similarities of the LUMO of nitrobenzene and the HOMO of the phenoxide anion.

Double substitution, EA of substituted nitrobenzenes, and acidities of phenols

In much the same way as has been discussed for benzene, addition of a π-acceptor substituent to nitrobenzene leads to an interaction of the nitrobenzene LUMO, $\psi_{L'}$, with the LUMO of the substituent. Since the nitrobenzene LUMO is considerably lower than the benzene LUMO, the energy match with the substituent LUMO is not as good as was the case for benzene, see Fig. 3. Therefore the SE for nitrobenzene will be smaller relative to the SE for the same substituent on benzene. For example, CHO, a substituent that acts mostly by delocalization, increases the EA of benzene by ~36 kcal mol^{-1} (1*d*) but the EA of nitrobenzene by only 15 kcal mol^{-1}, see Table 3. The effect of a substituent like CN, which has a smaller delocalization term but a large deshielding (field) effect, is expected to decrease less from benzene to nitrobenzene and this is experimentally observed (1*d*). These changes cause a reversal of the substituent order: CHO > CN for benzene (1*d*), and CHO < CN for nitrobenzene, see Table 3.

In a previous experimental study (1*d*) of substituent effects by π-accepting substituents on the electron affinities of benzene, naphthalene, anthracene, and nitrobenzene, it was found that the above CHO, CN reversal proceeds gradually in the above order. It was also observed that the ρ values for a given strongly π-withdrawing substituent decreased in the same order, i.e.,

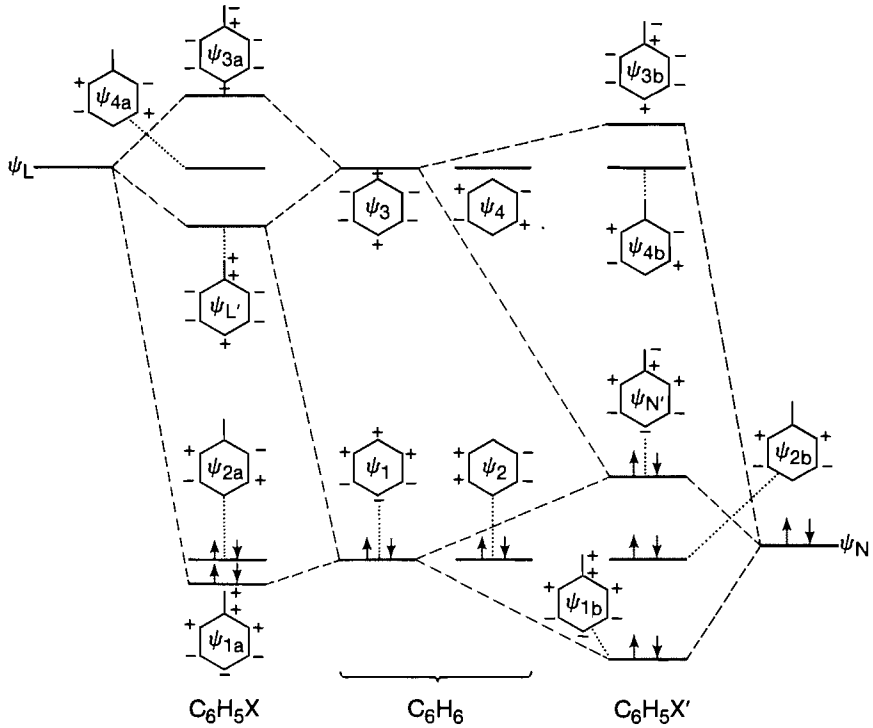

FIG. 4. Qualitative frontier orbital scheme showing interactions of benzene HOMO and LUMO with the LUMO of π-acceptor substituents and the lone pair HOMO of π-donor substituents.

benzene, naphthalene, anthracene, nitrobenzene. This order corresponds to increasing ΔE between the LUMO of the substituent and the LUMO of the above compounds (1*d*) and thus to a decrease of SE in the same order. The PMO scheme provides thus, in a very direct manner, a prediction of the concept: "The dependence of resonance effects of substituents on electron demand," investigated by Taft *et al.* (3*b*) in closed valence shell systems.

For the electron affinities of nitrobenzenes, the stabilizing effect of the substituent in different postions relative to the nitro group is experimentally observed to decrease in the order *para* > *ortho* > *meta*, see Tables 2 and 3. The orbital coefficients (C) for the nitrobenzene LUMO, obtained from *ab initio* calculations involving STO-3G basis sets (4*b*), are shown below.

According to eq. [9] the SE should follow the squares of these coefficients, C^2, and this predicts the experimentally observed order of decreasing ρ_R. On the basis of eq. [9] one would expect C^2 at each position to be proportional to ρ_R calculated for that position, see Table 2. An approximately linear relationship between C^2 and ρ_R for each position is evident, although ρ_a(*meta*) is larger than would be expected on the basis of C^2 at the *meta* position. The cause for this discrepancy is not clear. Possibly, π-electron changes in orbitals other than the frontier orbitals considered by eq. [9] could be responsible.

A comparison of the SE for the nitrobenzene LUMO and the phenoxide HOMO when interacting with the LUMO of a π-withdrawing substituent can be made on the basis of the orbital energies shown in Fig. 3 and the orbital coefficients shown above. The energies of the nitrobenzene and the phenoxide orbitals are seen to be relatively close. The carbon atom orbital coefficients are also fairly close. Therefore, similar substituent effects on the LUMOs of the substituted nitrobenzenes and HOMOs of the phenoxides are indicated by the PMO scheme. Since the electron affinities of the substituted nitrobenzenes follow the LUMOs and the acidities of the substituted phenols are largely determined by the stabilization of the substituted phenoxide ions, i.e., the energies of the phenoxide HOMOs, relatively similar substituent effects are predicted for these two systems by the PMO scheme.

The destabilizing effect of π-donor substituents on the electron affinity of nitrobenzene is due to the interaction of the HOMO of the substituent (ψ_N) with the LUMO of nitrobenzene ($\psi_{L'}$), see Figs. 3 and 4. The resulting lower energy orbital is fully occupied while the higher energy one becomes the LUMO of the substituted nitrobenzene. Since the interacting orbitals have fairly close energies, the interaction is expected to be significant and this is in accord with the substantial destabilization observed for the R terms of the π-donating substituents, see Table 3. The σ-withdrawing effect of the substituents leads to nuclear deshielding and stabilization of the substituted nitrobenzene LUMO, and therefore opposes the destabilizing π-donor effect.

The destabilizing effect due to π donation is expected to follow the squares of the nitrobenzene LUMO, i.e., *para* > *ortho* > *meta*. The order in Table 3 is *ortho* > *para* > *meta*. Generally Taft's scheme (3) is not used for the *ortho* position because of irregularities due to steric interference between the two groups and other factors. Possibly, in the present case, the *ortho* > *para* observation, Table 3, is due to an electrostatic repulsion, since both the NO_2 group and the substituent probably carry small partial negative charges in the negative ion. Since this repulsion is not accounted for in the ρ_F value, it appears in the destabilizing ρ_R.

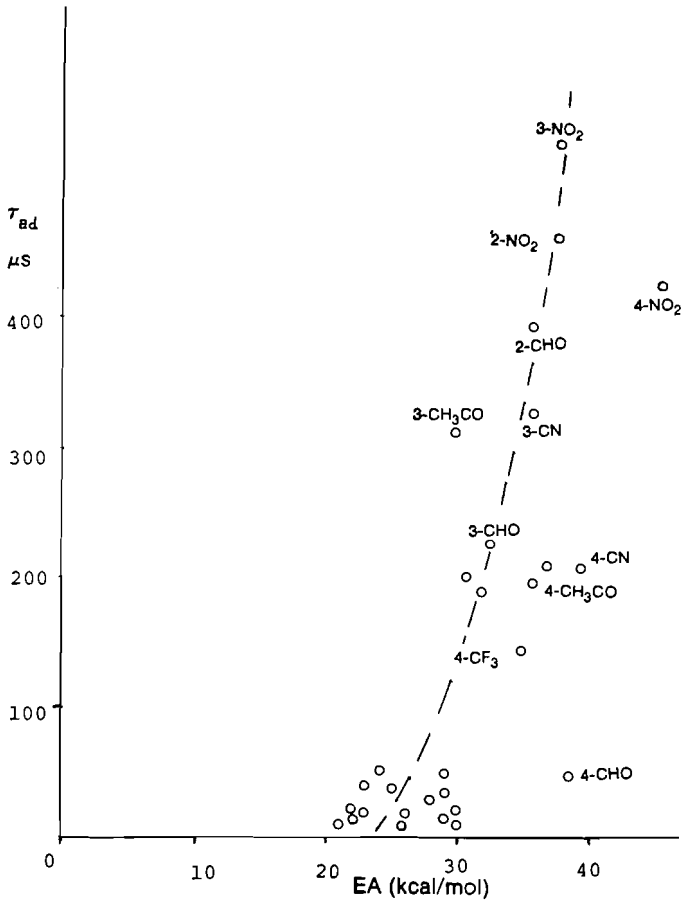

FIG. 5. Plot of autodetachment lifetimes τ_{ad} for $(A^-)^*$ formed by electron capture: $e + A = (A^-)^*$, Christophorou (16), versus electron affinities (actually $-\Delta G_a^0(NB)$) from present work. Due to high density of points only some points are identified. It will be noted that in general τ_{ad} increases with EA. For π-withdrawing substituents like CHO, CH_3CO, NO_2, the 4-substituted isomers have very much shorter lifetimes than the 3- and 2-substituted compounds.

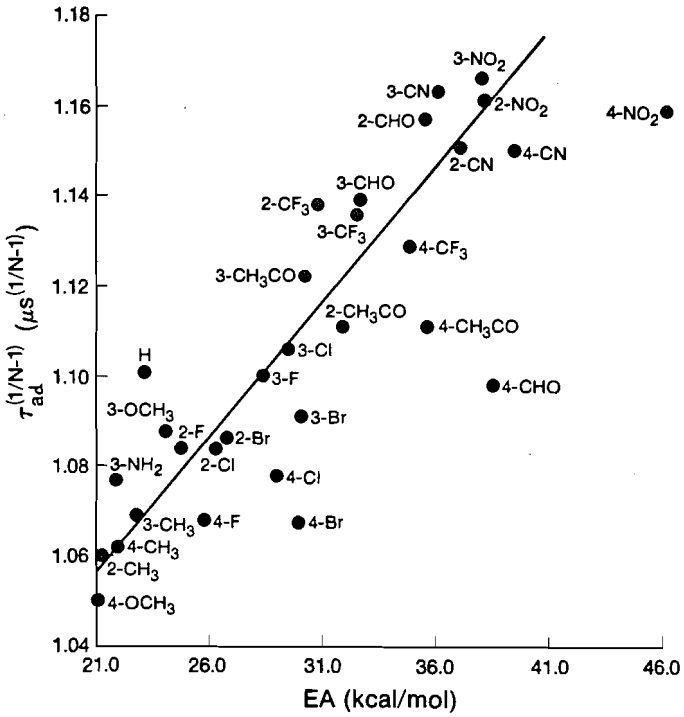

FIG. 6. Plot of $\tau^{1/(N-1)}$ versus electron affinities. Only rather poor correlation with straight line dependence predicted by eq. [13] is observed. The π-withdrawing substituents (CHO, CH_3CO, NO_2) in 4-position show largest deviations.

Stabilities and lifetimes of substituted nitrobenzenes after electron capture in the gas phase

Capture of (near) thermal electrons in the gas phase by molecules such as the nitrobenzenes is followed by eventual electron autodetachment in the absence of third body collisions. These processes are represented for molecule A in eq. [10]

$$[10] \quad e + A \underset{k_{ad}}{\overset{k_a}{\rightleftharpoons}} (A^-)^*$$

$$[11] \quad \tau_{ad} = 1/k_{ad}$$

$$[12] \quad \frac{k_a}{k_{ad}} = \frac{\rho(A^-)^*}{\rho(A)}$$

The autodetachment lifetime, τ_{ad}, is given by eq. [11], while eq. [12] gives the relationship between the rate constants for attachment and autodetachment and the density of the states for the ion $(A^-)^*$ and the neutral A (16). The τ_{ad} can be determined experimentally with time of flight or ICR mass spectrometers and a number of such values have been compiled by Christophorou (16). The τ_{ad} for substituted nitrobenzenes vary over a wide range, i.e., 10–530 μs. A plot of τ_{ad} from Christophorou versus the EA(NB) determined in this laboratory is shown in Fig. 5. The data show that τ_{ad} becomes of the order of a few μs around EA(NB) ≈ 20 kcal mol^{-1} and in geneal increases rapidly with increasing EA.

Christophorou (16) developed the very simple equation that gives a relationship between τ_{ad}, EA, and the number of normal vibrations N in the given NB. Details of the derivation can be found in Christophorou (16). Two important assumptions need to be mentioned: (*a*) the attachment rate constants, k_a, are assumed to be the same for all NB; (*b*) the internal energy in $(A^-)^*$ is assumed to be statistically distributed into all the vibrations *and* the vibrational frequencies, ν_i, of all vibrations are the same. Assumption (*a*) is probably correct if differences within a factor of 2 are neglected (16, 18), while (*b*) leads to the RRK form (19) of eq. [13].

$$[13] \quad \tau_{ad} \propto (EA(NB))^{N-1}$$

According to eq. [13], a plot of $\tau_{ad}^{1/(N-1)}$ vs. EA(NB) should lead to a straight line. At the time when Christophorou used the equation, the only source of EA(NB) where polarographic halfwave reduction potentials of the NB. These are expected to be linear with EA(NB) only if the solvation energies of the different NB^- are the same or if the solvation energies change but remain proportional to the EA(NB). Only a limited number of halfwave potentials obtained under identical conditions were available to Christophorou. The present EA(NB) plotted vs. $\tau_{ad}^{1/(N-1)}$ are shown in Fig. 6. Although a straight line can be drawn, the points are strongly scattered. The scatter is similar to that observed by Christophorou with the more limited polarographic data.

It is interesting to note that the largest deviations occur for the NB that are substituted in the *para* position by the strongly π-withdrawing substituents CHO, CH_3CO, and NO_2; see Fig. 6 and Table 3. These compounds have much shorter lifetimes relative to those expected on the basis of their electron affinities. As mentioned in the results section, the entropy changes for

electron capture by NB, i.e., ΔS_a^0(NB), were found to involve the largest loss of entropy for exactly these substituents.

The π-withdrawing substituents CHO, CH_3CO, and NO_2 increase their electron density and bond order in the radical anion due to π conjugation with the ring. This leads to stiffening of the C—CHO, C—$COCH_3$, and C—NO_2 internal rotations as well as stiffening of bending motions involving these substituents groups. It is exactly the soft modes, i.e., internal rotations and bending vibrations, that make the largest contributions to the density of states. The entropy losses indicate a large loss of density of states for the ions. Thus a treatment taking into account the actual contributions of the different vibrational modes to the density of the states of the molecule A and the ion A^-, particularly the loss of freedom in the above nitrobenzene anions, should provide a much better straight line correlation than that observed in Fig. 6.

Gas phase acidities of aliphatic carboxylic acids, based on measurements of proton transfer equilibria

GARY CALDWELL, RICHARD RENNEBOOG, AND PAUL KEBARLE[1]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 12, 1988

GARY CALDWELL, RICHARD RENNEBOOG, and PAUL KEBARLE. Can. J. Chem. **67**, 611 (1989).

Measurements of the gas phase proton transfer equilibrium [1]: AH + B^- = A^- + BH with a pulsed electron high pressure mass spectrometer (PHPMS) lead to ΔG^0_1 and ΔH^0_1 data. These relative acidities are converted to the absolute acidities [2]: AH = A^- + H^+ by calibration of the relative ΔG^0_1 and ΔH^0_1 scale to the known values for ΔG^0_1 and ΔH^0_1 of a reference compound (HCl). Earlier determinations that included 16 aliphatic AH are extended in the present work and provide data for 47 aliphatic carboxylic acids. These include halogen, OH, CH_3O, C_2H_5O, PhO, and NH_2 substituted acetic acids, and halogen substituted, unsaturated, and cyclic RCO_2H of higher carbon number. The effects of the various substituents on the gas phase acidity are briefly examined.

Key words: acidities in gas phase, proton transfer equilibria, ion–molecule equilibria, mass spectrometry.

GARY CALDWELL, RICHARD RENNEBOOG et PAUL KEBARLE. Can. J. Chem. **67**, 611 (1989).

En se basant sur des mesures de l'équilibre [1] de transfert de charge en phase gazeuse (AH + B^- = A^- + BH) réalisées à l'aide d'un spectromètre de masse à haute pression et à électrons pulsés (PHPMS), on a calculé les valeurs des ΔG^0_1 et ΔH^0_1. On a transformé ces acidités relatives en acidités absolues (AH = A^- + H^+ [2]) en calibrant l'échelle relative ΔG^0_1 et ΔH^0_1 par rapport aux valeurs de ΔG^0_1 et ΔH^0_1 connues pour un composé de référence (HCl). Dans le présent travail, on a étendu les déterminations antérieures qui incluaient 16 composés AH aliphatiques et l'on fournit des données pour 47 acides carboxyliques aliphatiques qui comprennent des acides acétiques portant des substituants halogène, OH, OCH_3, OC_2H_5 ou OPh ainsi que d'autres acides, contenant un plus grand nombre de carbones, qui sont substitués par des halogènes, insaturés ou cycliques. On discute brièvement des effets des divers substituants sur l'acidité en phase gazeuse.

Mots clés : acidités en phase gazeuse, mesures de l'équilibre de transfert de charge, équilibre ion–molécule, spectrométrie de masse.

[Traduit par la revue]

Introduction

Earlier determinations of the gas phase acidities of aliphatic and aromatic carboxylic acids (1–5) based on determination of the proton transfer equilibrium [1] with a pulsed electron high pressure mass spectrometer (PHPMS) (6) provided important first insights into the effects of substituents in the absence of solvent. Thus, for example, it was found (2) that for the halosubstituted acetic acids CH_2XCOOH, acidities increased in the gas phase in the order F, Cl, Br, which is the opposite of that found in aqueous solution. On the other hand, good linear correlations were obtained (4) between acidities in the gas phase and solution for benzoic acids substituted with a variety of substituents (linear free energy plots). Findings such as these, together with extensive measurements of equilibria (1) also with ion cyclotron resonance (ICR) mass spectrometers (7), have provided the required data for comprehensive investigations of substituent effects in the gas phase and solution (8).

[1] $AH + B^- = A^- + BH$

[2] $AH = A^- + H^+$

[3] $-RT \ln K = \Delta G^0$

The present work concentrates on aliphatic carboxylic acids RCO_2H. To obtain a fully consistent set of data, the 16 previously measured aliphatic acids RCO_2H were included in the present determinations. These acids, combined with the new compounds, lead to gas phase acidities for 47 RCO_2H. The resulting data provide information on alkyl group effects, halide substituent effects, and oxy (HO, MeO, EtO, PhO) substituent effects. The thermochemical data can be also used to obtain values for the electron affinities of the free radicals RCO_2, and bond dissociation energies RCOO—H.

In all gas phase acidity determinations (1–7, 9–11), one obtains the equilibrium constants K_1 from the experimental measurement of equilibrium [1] and evaluates $\Delta G^0_1 = -RT \ln K_1$. The ΔG^0_1 values are then combined into a scale of relative gas phase acidities. The relative values can be converted into an absolute scale for acid dissociation, ΔG^0_2, see eq. [2], by calibrating the scale of the ΔG^0_2 for one acid A_0H in the scale whose $\Delta G^0_2(A_0H^0)$ value is known from the literature, i.e., was determined by some other method. The number of determinations of acid dissociation energies of carboxylic acids, phenols, alcohols, nitrogen acids, and carbon acids obtained by this method cover more than 1000 compounds (11).

Experimental

Apparatus and method

The pulsed electron high pressure mass spectrometer (PHPMS) and method of measurements have been described in detail elsewhere (1–6). Only a brief outline and information specific to the present work will be given here.

Gas mixtures were prepared in a 5-L storage bulb that was part of the heated gas handling plant (6). The major (carrier) gas, methane, was at ~700 Torr (1 Torr = 133.3 Pa) while the reagents AH, BH, and NF_3 were in the Torr range. This gas mixture was allowed to flow in and out of the ion source – reaction chamber at a total pressure of ~4 Torr. Typical pressures in the ion source were: CH_4, 4 Torr, 30 mTorr of the weaker acid AH, a few mTorr BH, and 30 mTorr NF_3. A short 10–20 μs pulse of 2000-V electrons leads to ionization of the CH_4. The secondary electrons produced in this manner and slowed down by further collisions with CH_4 engage in dissociative electron capture, eq. [4*a*]. The strong base F^- deprotonates AH and BH, see eqs. [4*b*, *c*], and reactions of A^- and B^- with BH and AH lead to the proton transfer equilibrium [1].

[4a] $e + NF_3 = F^- + NF_2$

[4b] $F^- + AH = FH + A^-$

[4c] $F^- + BH = FH + B^-$

The ion concentration changes with time are monitored through measurement of the intensities of the ions escaping through a slit from the ion source into the vacuum of a mass spectrometer (6).

The temperature of the ion source was 600 K for most equilibria measurements. At this temperature, the formation of adducts AHA^-, BHA^-, and BHB^- was relatively minor. The adducts, when present, were in equilibrium, see eq. [5], with the negative bases so that the simultaneous equilibrium [1] could still be measured.

[5] $A^- + HA \leftrightarrows AHA^-$

Thermal decomposition

The 4-L storage bulb in which the gas mixture spends approximately 1 h, is at 120°C, and the ion source, where the gas spends a few seconds, is at 327°C. These exposures to heat can lead to thermal decomposition of some of the acids. An auxiliary quadrupole mass spectrometer mounted in the vacuum chamber outside the ion source was used to monitor the neutral gases escaping through the ion source slits into the vacuum. The reported equilibria determination involve only acids that did not give indication of thermal decomposition. Decomposition was observed for malonic and succinic acids. For these acids the quadrupole detected significant amounts of CO_2. Furthermore, a large abundance of HCO_2^- ions originating from the high pressure ion source was also observed. These ions probably result from deprotonation of formic acid by F^-, where the formic acid is presumably formed by thermal decompostion of malonic and succinic acid. When measurements with $HSCH_2CO_2H$ were tried, the anion corresponding to the deprotonated acid could not be detected. We attribute this to thermal decomposition of the acid. Thermal decomposition of mercaptoacetic acid has been observed (12) at temperatures as low as 120°C. Decomposition of 4-acetylbutyric acid was also indicated by the present experiments.

Adsorption of acids on the wall

For certain acids, i.e., cyclohexane carboxylic acid, lactic acid, 1-adamantane acetic acid, and 1-adamantane carboxylic acid, it was observed that one had to maintain the flow from the storage bulb through the ion source for about 1 h, before consistent equilibrium [1] measurements could be obtained. The observations were consistent with a strong adsorption of these acids on the walls of the flow system and with the need for the establishment of a given wall coverage, before the partial pressure ratio of the acid in the ion source became equal to that expected on the basis of the gas mixture used.

Failed acidity measurements

Equilibrium [1] measurements involving several acids were not successful. The equilibrium quotient was not constant as the concentration [BH]/[AH] was changed. This was the case for $CNCH_2CO_2H$, $C_6H_5(CH_2)_3CO_2H$, $ClCH_2(CH_3)_2CCO_2H$, and $C_6H_5SCH_2CO_2H$. Attempted measurements involving the acids $(C_6H_5)_2CHCO_2H$, $(C_6H_5)_3CHCO_2H$, $C_6H_5C{\equiv}CCO_2H$, CCl_3CO_2H, $Br(CH_2)_2CO_2H$, and $I(CH_2)_2CO_2H$ were unsuccessful because the anion of these acids was not observed. Some of these acids probably have vapor pressures below 1 Torr at the 120°C storage bulb temperature; however, no serious attempts were made to establish the cause for the absence of the anion.

Chemicals

All samples were commercially available except $CF_3CH_2CO_2H$, for which sample we are indebted to Professor R. W. Taft. The following were purified by fractional distillation: acetic, propionic, valeric, isobutyric, pivalic, *n*-butyric, iso-valeric, and caproic acid. Dibromoacetic acid was sublimed and all other samples were used as is.

Results and discussion

(a) Relative acidities from proton transfer equilibria [1]

A typical measurement of the proton transfer equilibrium [1] is shown in Fig. 1. The two acids used were CH_2FCO_2H and $MeOCH_2CO_2H$ at a concentration ratio of 6. The figure shows the observed intensities of the two anions as a function of time after the electron pulse. The two ions are seen to rapidly reach equilibrium, which for the logarithmic plot used corresponds to a constant vertical distance between the two curves. The slow linear decrease is due to diffusion of the ions to the wall followed by discharge. The ion ratio observed is 3.6, which leads to a $\Delta G_1^0 = -3.7$ kcal mol^{-1} at 600 K, see eqs. [1] and [3].

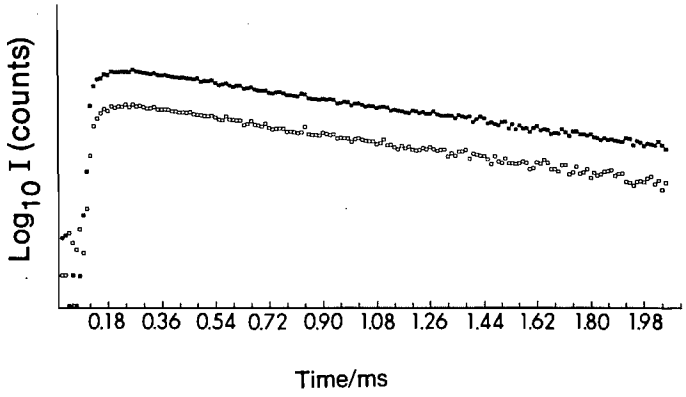

FIG. 1. Ion intensities observed after short (20 μs) electron pulse: $FCH_2CO_2^-$, $MeOCH_2CO_2^-$. Ions reach the proton transfer equilibrium [1] rapidly (200 μs). This is indicated by the constant ion ratio, which corresponds to constant vertical distance in the plot. The slow linear decrease of ion intensities is due to diffusion of ions to the wall. 5 Torr CH_4; pressure ratio, $CH_3OCH_2CO_2H/FCH_2CO_2H = 6$. Temperature 600 K.

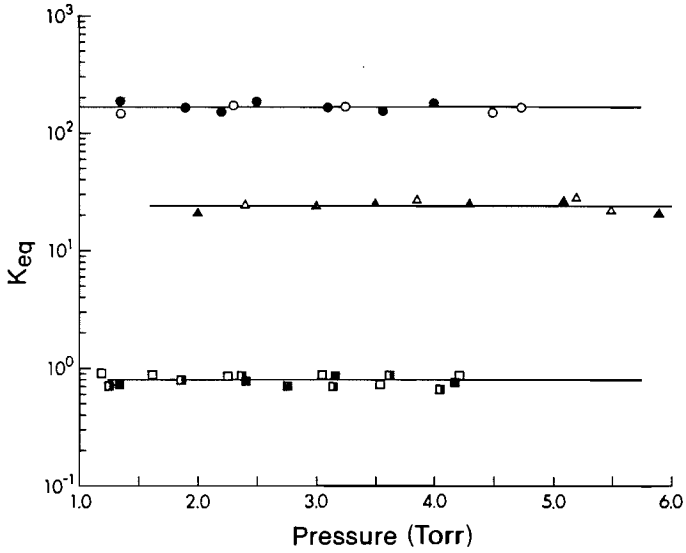

FIG. 2. Dependence of equilibrium constant K_1 for the proton transfer reaction [1]: $AH + B^- = A^- + BH$, on total ion source pressure (≈ bath gas CH_4 pressure) and on ratio of concentrations R = [BH]/[AH] in ion source. AH = $CH_3OCH_2CO_2H$, BH = CH_3CO_2H: R = 18 ●, R = 5 ○; AH = $CH_3OCH_2CO_2H$, BH = *t*-$BuCO_2H$: R = 2 ■, R = 5 □; AH = FCH_2CO_2H, BH = $CH_3OCH_2CO_2H$: R = 6 ▲, R = 2 △. Temperature 600 K.

Tests of the independence of the equilibrium constant K_1 on the reactant ratio and the total pressure are illustrated in Fig. 2.

The evaluated ΔG_1^0 at 600 K are shown in Fig. 3. The interconnecting data are combined in a scale that gives the

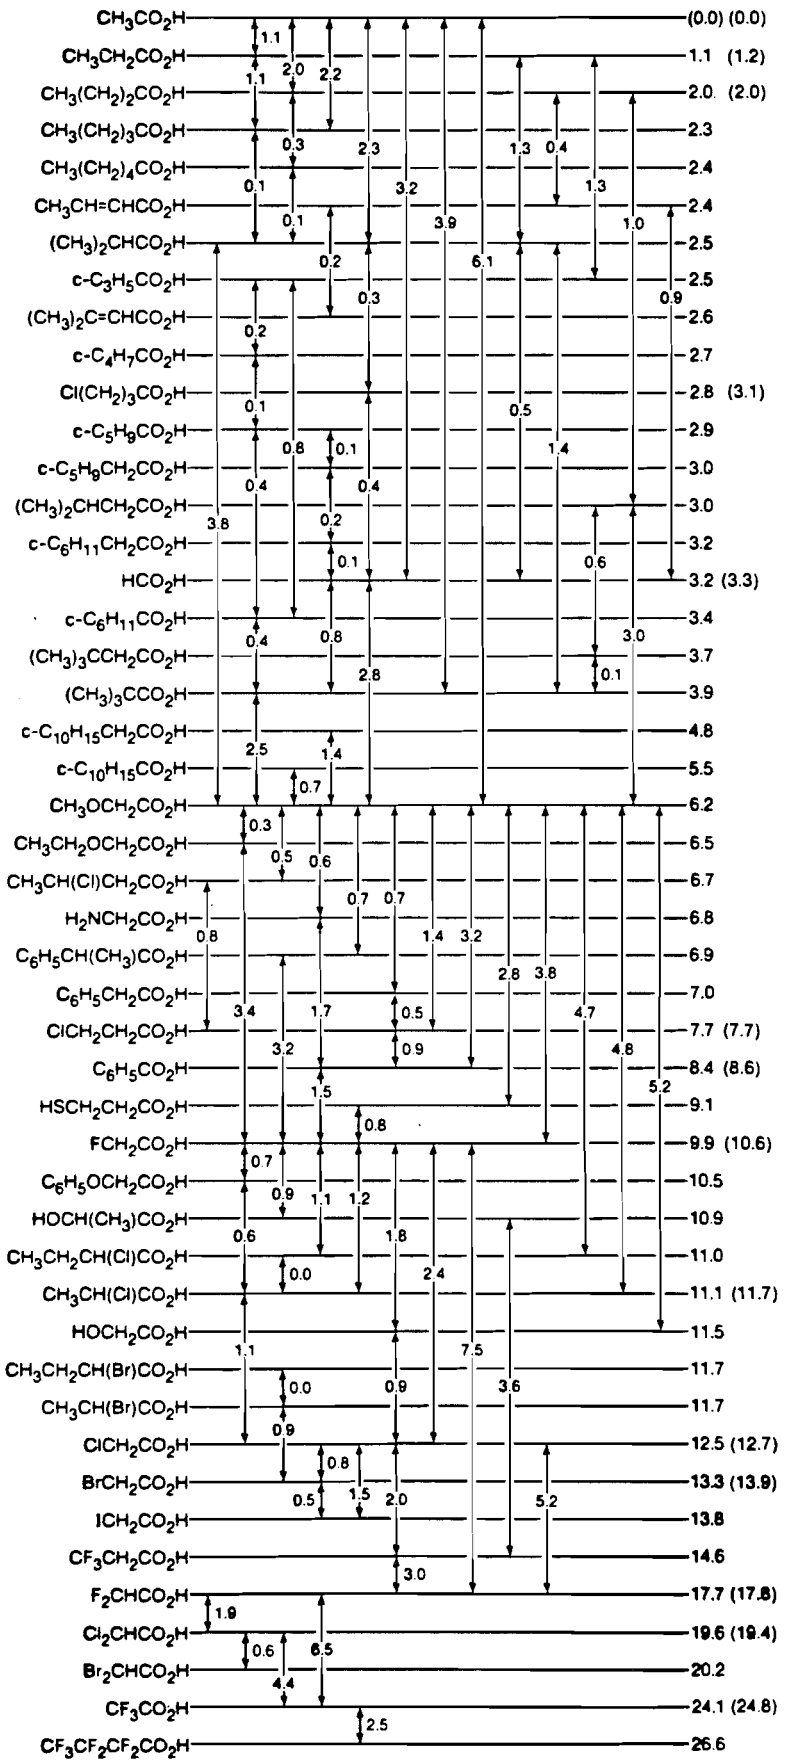

FIG. 3. Carboxylic acids acidity scale based on free energy changes ΔG_1^0 for proton transfer reaction [1]: AH + B^- = A^- + BH. Individual ΔG_1^0 values measured shown between double arrows. Acidities relative to acetic acid, i.e., ΔG_6^0 for reaction [6]: $CH_3CO_2H + B^- = CH_3CO_2^- +$ BH, shown in column to the right. Values given in parentheses are earlier data from Cumming and Kebarle (9). All values in kcal mol^{-1}, temperature 600 K; however, very similar values expected also for 300 K. *c*-$C_{10}H_{15}$ stands for 1-adamantyl. Acidity increases from top to bottom.

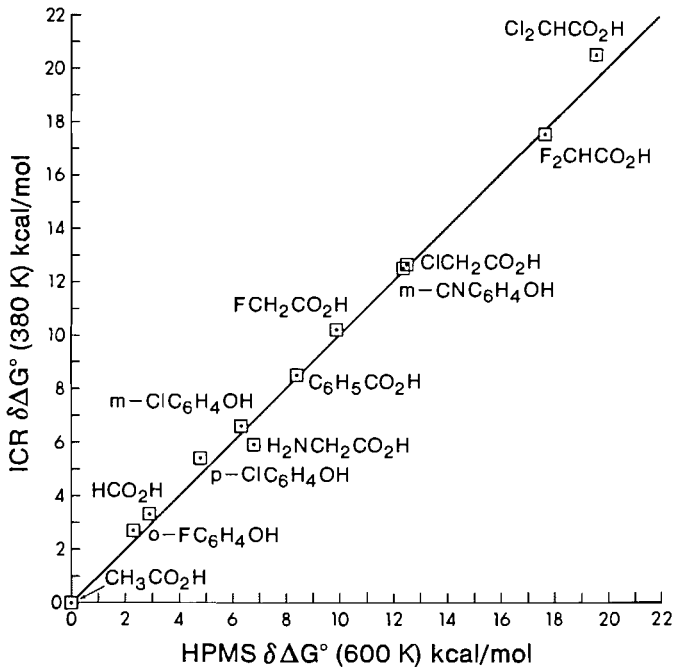

FIG. 4. Comparison of ΔG^0 values for proton transfer $CH_3CO_2H + B^- = CH_3CO_2^- + BH$, where BH are acids shown in figure. Solid line corresponds to slope = 1. The PHPMS data for 600 K, present work, and the ICR data for Bartmess and McIver (7) at ~380 K are very close, which means that the ΔS^0 changes are generally less than 2 cal deg^{-1} mol^{-1}. Largest deviation observed for $H_2NCH_2CO_2H$ is probably due to a larger ΔS due to intramolecular H bonding in anion, see Discussion, Sect. *j*.

acidities relative to that for the weakest acid CH_3CO_2H, i.e., the ΔG_6^0 value for reaction [6].

[6] $CH_3CO_2H + A^- = CH_3CO_2^- + AH$

There are many redundant thermodynamic cycles in Fig. 3, which illustrate that, in general, the data are consistent to ±0.2 kcal mol^{-1}. Data for those acids that were investigated previously in this laboratory and were included in the summary of Cumming and Kebarle (9) are also given in Fig. 3. For acids that are less acidic than FCH_2CO_2H, the agreement is within 0.3 kcal mol^{-1}. At FCH_2CO_2H and above, the present data become, on the average, lower by ~0.4 kcal mol^{-1}. Most of the acids in the earlier determinations (9) with acidity higher than FCH_2CO_2H were anchored to that acid. The present value for FCH_2CO_2H is 0.7 kcal mol^{-1} lower than the previous result. In the present determinations, see Fig. 3, there are five equilibria to acids with lower acidities that fix the value for FCH_2CO_2H while in the previous work there was only one. The present results for this acid and all higher acidity acids are more reliable.

(b) Entropy changes for proton transfer reactions [1]

As indicated in the experimental part, the available temperature range at which the proton transfer equilibria could be measured was restricted. A lower limit was set by excessive proton adduct formation (AHA^-, AHB^-, B_2H^-) and an upper limit by the thermal decomposition of the neutral acids. Therefore the temperature dependence of K_1 was determined only for one system of special interest, see Sect. *j* on cyclization of $HOCH_2CO_2^-$ due to intramolecular hydrogen bonding.

For the vast majority of acids only very small ΔS_1^0 changes are expected. Previous temperature determinations of proton transfer equilibria [1] led, via van't Hoff plots, to entropy changes ΔS_1^0 that were less than 2 cal deg^{-1} mol^{-1}. A summary of these measurements and procedures for estimating ΔS_1^0 on the basis of rotational symmetry number and estimated internal rotational changes is given in Cumming and Kebarle (9). For the present group of acids, see Fig. 3, little information on the internal motions of the acids and the anions is available and ΔS_1^0 estimates are in general difficult. The fact that the values are generally small can be illustrated by a comparison of ΔG_1^0 values determined by ICR (7, 10) at ~380 K and the present

TABLE 1. Absolute acid dissociation scale[a]

Acid	ΔG^0(300 K) (kcal mol^{-1})	ΔH^0 (kcal mol^{-1})

[d]Bond dissociation energies, Miller and Golden (16).
[e]Calculated from eq. [10] where $IP(H^0)$ = 313.6 kcal mol^{-1}.
[f]Estimated value.

determinations at 600 K. The data given in Fig. 4 show that only small deviations from the unity slope line are observed. Since the temperature difference is close to 220°, the less than 0.5 kcal mol^{-1} deviations from the unit slope line indicate ΔS_1 terms of less than 2 cal deg^{-1} mol^{-1}.

(c) Thermochemical data ΔG_2^0 and ΔH_2^0 for gas phase: $RCO_2H = RCO_2^- + H^+$

Evidence presented in Sect. *b* demonstrated that the ΔS_1^0 values are generally less than ±2 cal deg^{-1} mol^{-1}. Therefore the assumption in eq. [7] is justified. In the earlier work (9), the

[7] $\Delta G_1^0 = \Delta H_1^0$

acid dissociation energies for ΔH_2^0 and ΔG_2^0 at 300 K for acetic acid, see eq. [8], were obtained by calibrating the scale to the primary standard HCl.

[8] $\Delta H_2^0(CH_3CO_2H) = 348.5$ kcal mol^{-1}; $\Delta G_2^0(CH_3CO_2H) = 341.5$ kcal mol^{-1}

The same values, eq. [8], were adopted in the Ion–Thermochemistry compilation by Lias *et al.* (11).

Combining the values in Fig. 3 with the absolute acidity values in eq. [8] and using the assumption in eq. [7] we obtain the acidities $\Delta G_2^0(RCO_2H)$ and $\Delta H_2^0(RCO_2H)$ given in Table 1. These absolute values are believed accurate to ±2 kcal mol^{-1}.

(d) Heats of formation of RCO_2^- in the gas phase

When the heat of formation of the acid $HA_{(g)}$ is known, the $\Delta H_f(A^-_{(g)})$ can be evaluated by eq. [9], which follows from eq. [2]. The $\Delta H_f^0(RCO_2^-)$ evaluated with eq. [9] and $\Delta H_f(RCO_2H)$ from the literature (13) are given in Table 2 for nine acids. These data are only a sample of the $\Delta H_f(RCO_2^-)$ that can be obtained. Additional $\Delta H_f(RCO_2H)$ values can be found in compilations (14) and converted to $\Delta H_f(RCO_2^-)$ on the basis of ΔH_2 results in Table 1.

[9] $\Delta H_f(A^-) = \Delta H_2^0 - \Delta H_f(H^+) + \Delta H_f(HA)$

(e) Electron affinities of RCO_2 and bond energies RCOO—H

The acid dissociation enthalpy ΔH_2, the electron affinity EA(A), and the bond dissociation energy D(A—H) are related by eq. [10] where IE(H) is the ionization potential of the hydrogen atom. Thus, when D(RCOO—H) are available, $EA(RCO_2\cdot)$ can be evaluated (15), and vice versa, from the ΔH_2 data given in Table 1. Table 2 contains a sampling of $EA(RCO_2\cdot)$ evaluated from available D(RCOO—H) data, Miller and Golden (16). Unfortunately, the bond dissociation energies are not very reliable. Also no direct experimental determinations of $EA(RCO_2\cdot)$, which would have provided cross checks of the data, seem to be available.

TABLE 3. Comparison of alkyl group effect on acidity of RCO_2H and ROH[a]

R	$\delta\Delta G_{600K}$ (PHPMS)[b] RCO_2H	$\delta\Delta G_{380K}$ (ICR)[c] ROH

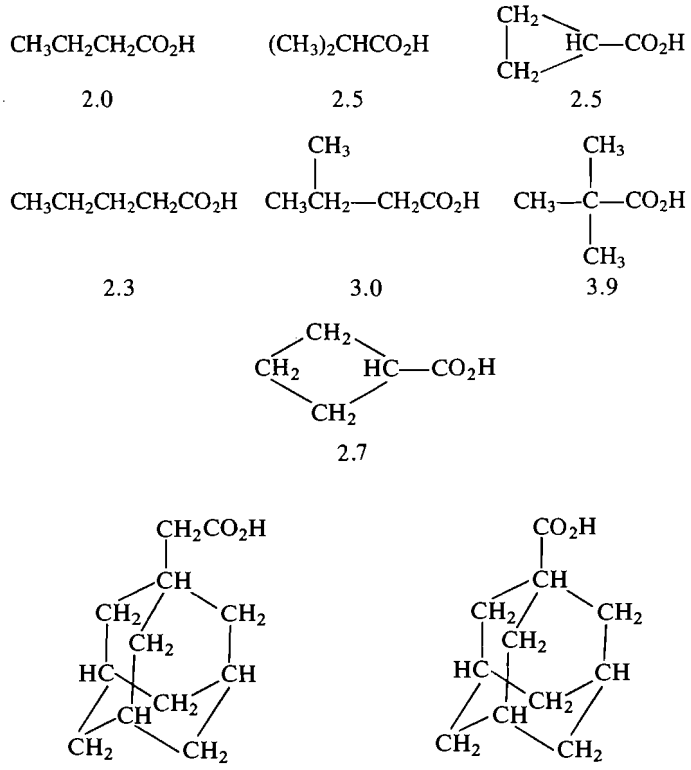
[a]All values in kcal mol^{-1}. Positive values for $\delta\Delta G^0$ correspond to an increase of acidity from Me to R.
[b]Data from Table 1.
[c]Data from Bartmess and Scott (18) as quoted in Lias *et al.* (11).

[10] $\Delta H_2 = D(A—H) + IE(H) - EA(A\cdot)$

(f) Alkyl group effect on the acidity of RCO_2H

Methyl substitution on sp^2 hybridized carbon decreases the acidity, thus HCO_2H is 3.4 kcal mol^{-1} more acidic than CH_3CO_2H, see Fig. 3 and ref. 1. The methyl effect was first observed by Brauman and Blair (17), who found that the gas phase acidity of methylacetylene is lower than that of acetylene. A similar effect is observed for the phenols, where Me substitution in *m* and *p* positions leads to a (small) decrease of acidity (5, 8). From Fig. 3 one obtains the ΔG_6^0 data shown below for *n*-alkyl substitution of the aliphatic acids:

$MeCO_2H$	$EtCO_2H$	n-$PrCO_2H$	n-$BuCO_2H$	n-$PeCO_2H$	
0	1.1	2.0	2.3	2.4	(kcal mol^{-1})



The acidity increase is relatively small and can be attributed to the stabilizing effect of the polarizability of the alkyl group on the negative ion. This stabilizing effect is somewhat larger than the destabilizing field-inductive effect and pseudo π donation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

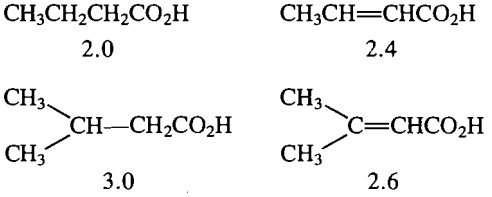
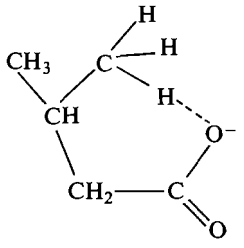
The above order for alkyl substitution was observed also for the acidity of alcohols (7, 17) although a less complete series of compounds was involved. A comparison between effects of alkyl groups R in the acidity of RCO_2H and ROH is given in Table 3. The ROH data are due to Bartmess *et al.* (18) and are based on proton transfer equilibria measurements. The trends observed for RCO_2H and ROH are similar; however, for ROH the effect of increasing size of R or branching is seen to be roughly twice as large as that for RCO_2H. This is an expected result. In RCO_2^- the charge is delocalized onto two oxygens and the stabilization due to the polarizability of the alkyl group is smaller than for RO^- where the charge is mostly on the one oxygen atom.

Branched alkyl groups lead to a higher acidity than straight chain substituents. This is illustrated by the ΔG_6^0 values from Fig. 3 shown below:



(ΔG_6^0 values in kcal mol^{-1})

It is interesting to note, in the C_4 series, that the t-C_4H_9 is of significantly higher acidity than the cyclic isomer. While the dominant conformations of the anions in the gas phase are not known, probably the tertiary compound leads to the closest distances of the alkyl carbons to the negative charge and thus maximizes the polarizability stabilization.



The strongest acid in the group shown above is 1-adamantyl carboxylic acid. Present in this case is the acidifying effect of the tertiary group and the additional polarizability due to the extensive carbon structure.

(g) Effect of π systems on the acidity of RCO_2H

Since π systems in R of RCO_2^- cannot directly conjugate with the CO_2^- group, relatively smaller stabilization is expected for this group in comparison to RO^- anions, where delocalization of the negative charge to the π system can occur. For example, the acidity difference between $MeCO_2H$ and $PhCO_2H$ is 8.4 kcal mol^{-1} (9), while that between MeOH and PhOH is 27.8 kcal mol^{-1} (5, 7). The dominant contributions to the acidifying effect of the phenyl group in $PhCO_2H$ should be the electron-withdrawing field-inductive effect and the polarizability. Of interest also is the comparison between acids that have one double bond and the corresponding alkanes RCO_2H:

The unsaturated crotonic acid is found to be 0.4 kcal mol^{-1} more acidic than butyric acid. This effect is expected due to the electron-withdrawing field-inductive effect of the vinyl group. Somewhat surprisingly, the β-methyl crotonic acid is found to be 0.4 kcal mol^- less acidic than the saturated 3-methyl butyric acid. It is conceivable that rotamers of the anion, see structure **I**, which correspond to intramolecular hydrogen bonded structures, contribute to the stabilization of the anion.

I

Convincing evidence for intramolecular hydrogen bonding stabilization is provided in Sect. *j* for the stronger hydrogen donor groups OH and NH_2, which lead to much stronger stabilization. The minor stabilization due to I, if real, is of course not restricted to that particular alkanoic anion but will occur with all acids RCO_2H where the alkane R contains a chain of at least 3 carbon atoms.

(h) Halide effects on acidity of RCO_2H

The effect of halide substituents on RCO_2H acids was examined in two earlier publications (2, 3). The new measurements are in good agreement with the older data. The availability of a larger number of compounds amplifies the previous findings. The introduction of a halide substituent is strongly acidifying. The effect decreases as the halide is removed farther away from the carboxy group, as illustrated by the ΔG_6^0 values for the chloride series below:

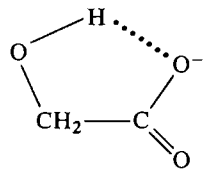
$CH_3CH_2CH_2CO_2H$	$CH_2ClCH_2CH_2CO_2H$	$CH_3CHClCH_2CO_2H$	$CH_3CH_2CHClCO_2H$	
2.0	2.8	6.7	11	kcal mol^{-1})

For single substituents the acidifying effect increases in the order F, Cl, Br, I. This is an order opposite to that observed in solution. The acidifying effect of the halide atom is due to the stabilization of the negative charge by the electron-withdrawing field-inductive effect and the polarizability of X. In the absence of solvent, the polarizability becomes very important and the increasing polarizability from F to I leads to the observed gas phase acidity increase. In the series X_2CHCO_2H, the introduction of the second X provides a somewhat smaller increase of acidity than the first. The effect of the second substituent decreases in the order F to Br. This result indicates that the effective decrease of negative charge on the CO_2^- oxygens due to the field effect of the X_2 substituents reduces the stabilizing effect of their polarizability. On this basis one might expect almost equal acidity in the CX_3CO_2H acids for X (F, Cl, Br). Unfortunately data for only CF_3CO_2H are available.

FCH_2CO_2H	$ClCH_2CO_2H$	$BrCH_2CO_2H$	ICH_2CO_2H	F_2CHCO_2H	Cl_2CHCO_2H	Br_2CHCO_2H	
9.9	12.5	13.3	13.8	17.7	19.6	20.2	(kcal mol^{-1})

Multiple fluorine substitution leads to large acidifying effects, thus CF_3CO_2H is 24 kcal mol^{-1} and $CF_3CF_2CF_2COOH$ 26.6 kcal mol^{-1} more acidic than CH_3CO_2H, see Fig. 3.

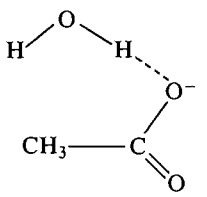
(i) Effect of oxy substituents on the acidity of RCO_2H



The oxy substituents HO, MeO, EtO, and PhO lead to relatively large increases of acidity, as shown by the data below, from Fig. 3.

$MeOCH_2CO_2H$	$EtOCH_2CO_2H$	$PhOCH_2CO_2H$	$HOCH_2CO_2H$	
6.2	6.5	10.5	11.5	(kcal mol^{-1})

The changes can be understood in terms of the field-inductive effect and polarizability for all groups except for OH. Evidently, for the OH substituent, additional stabilization of the anion must be present and this must be due to intramolecular hydrogen bonding.



(j) Intramolecular hydrogen bonding in $HOCH_2CO_2^-$

The high acidity of $HOCH_2CO_2H$ relative to the MeO and EtO substituted acetic acids, observed in the preceding section, must be due to intramolecular hydrogen bonding. The cyclization induced by such bonding, see structure **II**, is expected to

$\Delta H_{cyc} \approx -10$ kcal mol^{-1}

II

$\Delta H \approx -17$ kcal mol^{-1}

III

lead to an entropy loss, which can be measured. Shown in Fig. 5 is a van't Hoff plot of the equilibrium constant K_{13} for the proton transfer reaction [13].

[13] $FCH_2CO_2^- + HOCH_2CO_2H = FCH_2CO_2H + HOCH_2CO_2^-$

The slope and intercept of the plot lead to $\Delta H^0_{13} = -6.3$ kcal mol^{-1}, $\Delta S^0_{13} = -7.5$ cal deg^{-1} mol^{-1}, and $\Delta G^0_{13}(600\ K) = -1.8$ kcal mol^{-1}.

Assuming that the entropy change for the proton transfer in eq. [13] would be negligible in the absence of cyclization, see Sect. *b*, the entire $\Delta S^0_{13} = -7.5$ cal deg^{-1} mol^{-1} can be attributed to the cyclization, i.e., $\Delta S^0_{cyc} \approx -7.5$ cal deg^{-1} mol^{-1}. The hydrogen bond energy, ΔH^0_{cyc}, can also be estimated assuming negligible entropy changes for proton transfer without cyclization. On adding $-\Delta H^0_{13} = 6.3$ kcal

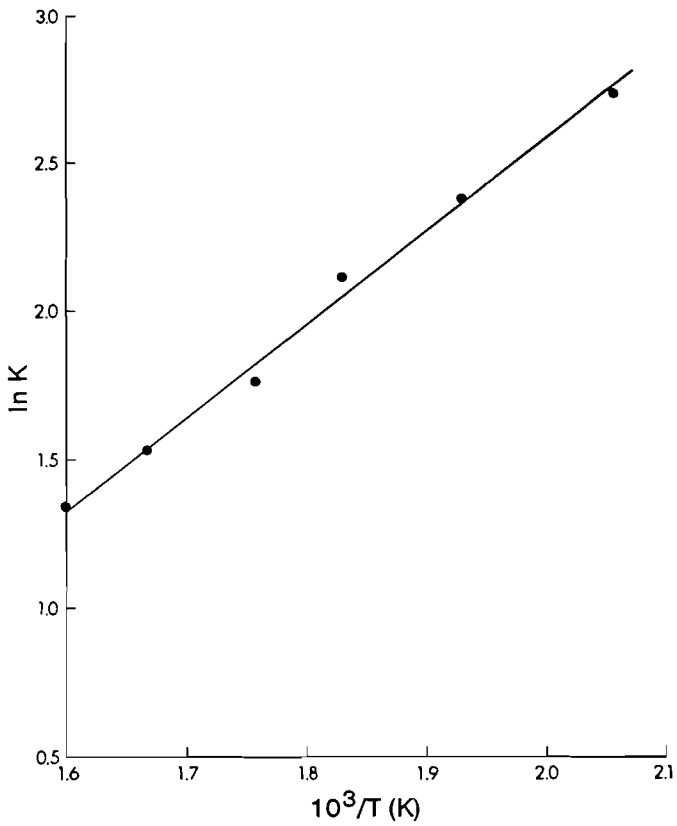


FIG. 5. van't Hoff plot of equilibrium constants K for proton transfer equilibrium: $FCH_2CO_2^- + HOCH_2CO_2H \rightleftharpoons FCH_2CO_2H + HOCH_2CO_2^-$.

mol^{-1} to $\Delta G^0_6(CH_2FCO_2H) = 9.9$ kcal mol^{-1}, from Fig. 3, one obtains $\Delta H^0_6(HOCH_2CO_2H) = 16.2$ kcal mol^{-1}, the estimated enthalpy change for proton transfer [6] involving the cyclized structure **II**. The enthalpy change ΔH^0_6 for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

uncyclized structure can be assumed to be the same as $\Delta G^0_6(CH_3OCH_2CO_2H) = 6.2$ kcal mol where it is assumed that in the absence of cyclization the acidifying effects of HO and CH_3O are the same. The cyclization enthalpy is, then, $-\Delta H_{cyc} = 16.2 - 6.2 = 10$ kcal mol^{-1}.

This is a reasonable value for the very strained hydrogen bond that is expected to occur in structure **II**. It can be compared with the H bond in structure **III**. This bond can be expected to be close to 17 kcal mol^{-1} on the basis of experimental measurements by Meot-Ner and Sieck (19) and a theoretical calculation by Jorgensen and co-workers (20), see structure 10c in Jorgensen. The bond in structure **II** is much weaker, mostly because it is very strained. Also, prior to the cyclization, the hydroxy group in $HOCH_2CO_2^-$ may be expected, due to the negative charge transfer from the carboxy group to the O atom, to be a slightly poorer hydrogen bond donor than the free HOH that leads to structure **III**.

The rather small $-\Delta S^0_{cyc} \approx 8$ cal deg^{-1} mol^{-1} indicates that structure **II** is quite loose at temperatures in the 300–600 K range.

Some cyclization may also be present in the anion of glycine, $NH_2CH_2CO_2^-$. Lock and McIver (21) have determined the gas phase acidity of glycine. If their free energy of proton transfer at 380 K, see Fig. 4, is combined with the present proton transfer value, see Figs. 3 and 4, at 600 K one obtains an estimate of $\Delta S^0_{cyc} \approx -4$ cal deg^{-1} mol^{-1}. This entropy loss is quite small and corresponds to the presence of hindered rotation rather than cyclization. It is known that NH is a much poorer hydrogen donor than OH. Therefore a much weaker H bond in the glycine anion is expected. The "cyclized" structure in this case is so loose that it allows hindered internal rotation around the C—C and the C—N bonds.

An even looser cyclized structure was suggested in Sect. *g*, involving CH groups as hydrogen donors and leading to a possible weak stabilization of unsubstituted alkane carboxyl anions.

Received October 5, 1988

ANDRÉ D. BANDRAUK, K. D. TRUONG, and C. CARLONE. Can. J. Chem. **67**, 619 (1989).

A new semiconducting ternary compound of stoichiometry TEDA·$I_{2.5}$·TCNQ is reported. The crystal is made up of linear chains of $TCNQ^{-1/2}$, nonlinear chains of I_3^-, and monodides of doubly charged triethylenediamines (TEDA). Half the TEDA's are hydrogen bonded to the TCNQ's and I_3^-. The conductivity measurements indicate semiconducting behaviour with two discontinuities in activation energy, one at high (330 K) and the other at low (160 K) temperatures. Resonance Raman spectra of the crystals manifest strong resonance enhancement of the iodide moieties. In particular, selective resonance excitation at 647 nm of nonsymmetric I_3^- is observed, thus indicating an increasing asymmetry of the I_3^- in the low temperature phase and suggesting coupling between the three species in this phase.

Key words: semiconductor, ternary compound, resonance Raman spectra, tetracyanoquinodimethane (TCNQ), tri-iodide (I_3).

ANDRÉ D. BANDRAUK, K. D. TRUONG et C. CARLONE. Can. J. Chem. **67**, 619 (1989).

On a préparé un nouveau composé ternaire semi-conducteur de stoechiométrie TEDA·$I_{2.5}$·TCNQ. Le cristal est formé de chaînes linéaires de $TCNQ^{-1/2}$, de chaînes non-linéaires de I_3^- et de monoiodures de triéthylènediamines, TEDA, doublement chargées. La moitié des TEDA sont liés par des ponts hydrogènes à des TCNQ et des I_3^-. Les mesures de conductivité indiquent que le comportement semi-conducteur est lié à deux discontinuités dans l'énergie d'activation, l'une à haute (330 K) et l'autre à basse température (160 K). Les spectres de résonance Raman présentent de forts renforcements de la résonance des portions iodures. En particulier, on observe une excitation sélective de la résonance non-symétrique du I_3^-, à 647 nm; cette propriété reflète une augmentation de l'asymétrie du I_3^- dans la phase à basse température et suggère que dans cette phase il existe un couplage entre les trois espèces.

Mots clés : semi-conducteur, composé ternaire, spectres de résonance Raman, TCNQ, I_3.

Introduction

Many organic donors are known to form conducting charge transfer compounds with halide ions. One of the early organic metals, a perylene–iodine complex, exhibited various stoichiometries and conductivities (1, 2). Further research on a variety of organic conductors has led to the importance of obtaining segregated stacks, partial charge transfer, extensive π-overlap between adjacent molecules in the cation or anion columns (2), leading finally to the discovery of the ambient pressure low temperature organic superconductors $(TMTSF)_2ClO_4$ (3) and $(BEDT–TTF)_2I_3$ (4–6), the latter containing the I_3^- anion as a counterion.

Most organic conductors are formed from a single doner (D) and a single acceptor (A), albeit in different stoichiometries. One class of conductors involving iodine, tertiary amines, and TCNQ leads to ternary salts in which the iodine forms linear chains of I_3^- parallel to the conducting linear chains of TCNQ (tetracyanoquinodimethane), and the amine is hydrogen bonded to the $TCNQ^-$ anions. We suggested in previous work that these compounds should be more readily considered as alloys of $M^+I_3^-$ and $(M^+)_2(TCNQ_3)^{-2}$, giving the experimental composition $(M^+)_3I_3^-(TCNQ_3)^{-2}$, where M is the donor amine (7). In the course of our work on hydrogen bonding in these systems, we described a TCNQ complex with the di-tertiary amine triethylenediamine, $TEDA_2TCNQ_3$, which had the novel feature that linear chains of hydrogen-bonded TEDA's were now parallel to the linear chains of the TCNQ's (7, 8). This linear arrangement of the TEDA's was also found in two of its iodide salts, TEDA·I_3 and TEDA·$I_{3.4}$ (9). We have therefore tried to synthesize a ternary compound of TEDA, I, and TCNQ, obtaining a *new* compound of stoichiometry TEDA·$I_{2.5}$·TCNQ, unlike the previously known ternary compounds. We present here the structure, resonance Raman spectra, and other physical properties of this new compound.

One of the interesting aspects of the ternary compounds has been the question of the involvement of the iodine chain in the metal–semiconductor phase transition known to occur in these compounds at low temperatures. We were able to show, in previous work, by selective resonance Raman scattering (RRS) of I_3^- in single crystals of TMA (trimethylammonium·I·TCNQ, that the I_3^- anions are excellent probes of the phase transition (10). Thus the frequency, intensity, and linewidth of the ν_1 symmetric mode (115 cm^{-1}) of I_3^- were shown to have discontinuities at the phase transition, indicating a direct involvement of the ion chains, probably as a disorder–order transition within the iodine chain, and thus applying a commensurate potential of wavevector $2k_F$ on the TCNQ chains. Such external commensurate potentials due to counterions introduce pseudo Peierls gaps, with the consequence that the system becomes semiconducting (11–13).

We recently examined (14) the behaviour of I_3^- by similar RRS techniques on single crystals of the β-form of $(BEDT–TTF)_2I_3$, which is known to become superconducting at 7 K (4–6). Again we have found the I_3^- to be sensitive to the onset of a superlattice structure known to occur below 180 K in this compound (15). One motivation for our examining the new ternary compound reported here is that in both β-$(BEDT–TTF)_2I_3$ and TEDA·$I_{2.5}$·TCNQ one finds similar *nonlinear* (zigzag) chains of I_3^-, contrary to previous organic conductors, such as TMA·I·TCNQ (10, 16) and $DIPS\Phi_4I_{2.86}$ (13), where the I_3^- form *linear* chains.

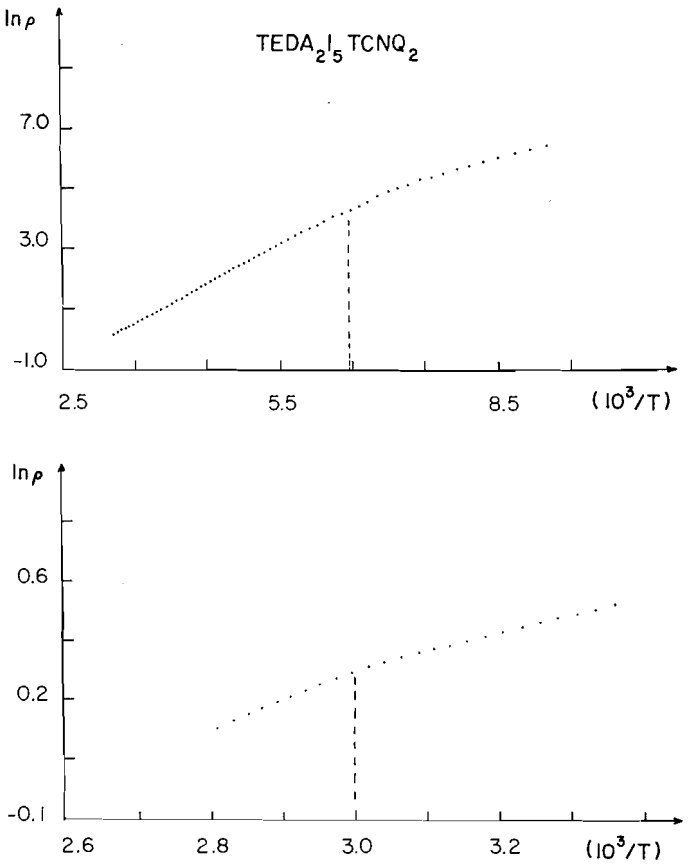

FIG. 1. Temperature variation of ln ρ vs. $10^3/T$ showing anomalies around 160 and 330 K.

Experimental

Preparation

TEDA·$I_{2.5}$·TCNQ was synthesized starting from $TEDA^{2+}(I^-)_2$ by oxidation with TCNQ in distilled methanol. The solvent factors formation of the triiodide ion. The final compound includes unoxidized I^- anions. Blue-black crystals are obtained from the solution. Chemical analysis confirms the reported stoichiometry (theoretical % in parentheses): C 34.47 (34.04), N 13.61 (13.20), H 2.95 (2.68), I 48.93 (50.0).

Conductivity

The electronic resistivity ρ (or conductivity $\sigma = \rho^{-1}$) is measured by a four-probe method along the long axis of the needlelike crystals. Room temperature conductivity is rather low, 0.651 $(\Omega\ m)^{-1}$. Anomalies are observed around 330 K and 160 K. A plot of ln ρ vs. $10^3/T$, Fig. 1, reveals that the anomalies are due to changes of activation energy E_c, if we apply the relation $\rho = \rho_0 \exp(E_c/RT)$. E_c is found to have a high temperature value (above 330 K) of 0.18 eV, a room temperature value of 0.1 eV, and a low temperature value (below 160 K) of 0.06 eV. Both transitions are gradual, unlike conductor–semiconductor transitions, which usually involve structural changes and accompanying discontinuities in $\rho(T)$ (11–13).

Electronic spectra

These were measured with a standard Cary 14 spectrometer. The spectra essentially resemble those of TEDA·CH_2Cl·$TCNQ_2$, a 1:2 complex (8). Thus maxima are found at 28 500, 17 000, 11 300, and 4000 cm^{-1}. The first two correspond to localized $TCNQ^-$ excitations, whereas the last two correspond to delocalized excitations, $A^-A^- \rightarrow A^{2-}A$, and $A^-A \rightarrow AA^-$, referred to usually as charge transfer bands (17). An I_3^- band, attributed to a $\sigma_g \rightarrow \sigma_u$ electronic transition (18) also is found to extend below 17 000 cm^{-1}. This I_3^- band will serve to selectively excite the ion in RRS.

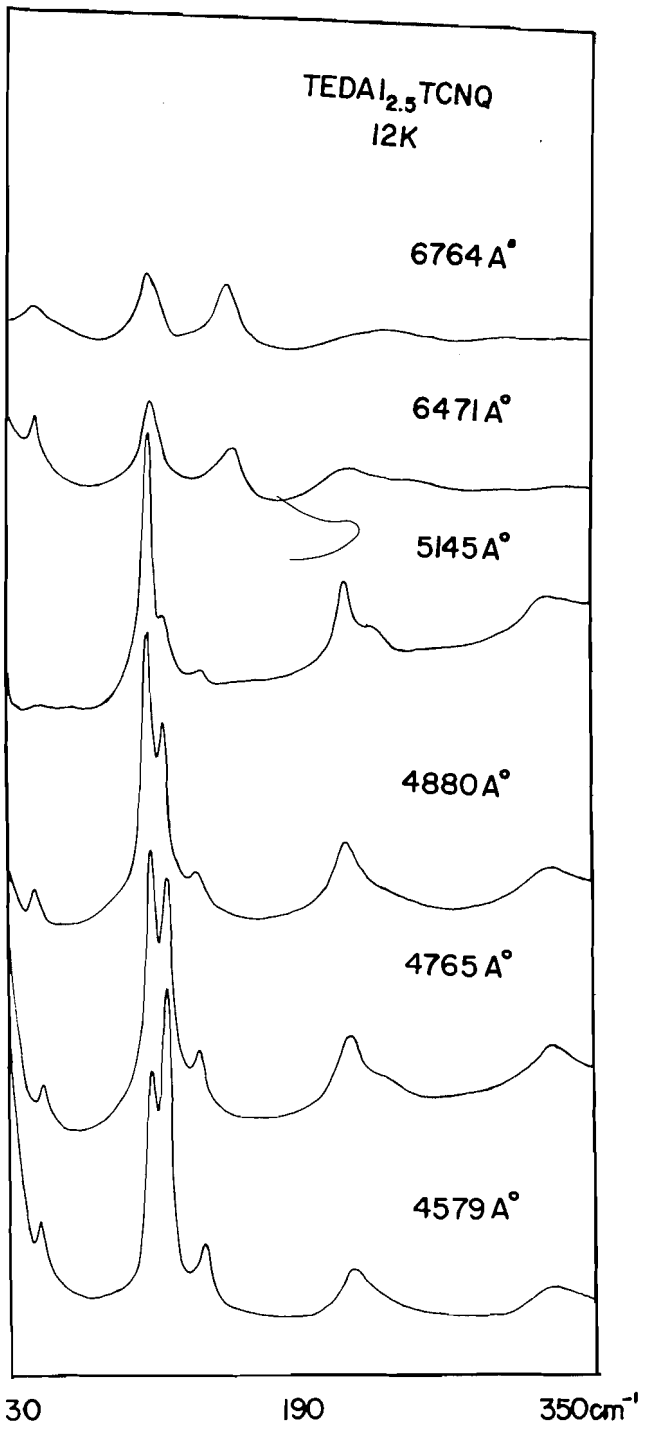

FIG. 2. Raman spectrum of a single crystal of TEDA·$I_{2.5}$·TCNQ at 12 K as a function of laser wavelength.

ESR spectrum

A rather large signal without hyperfine structure is observed ($g \sim 2.002$). The integrated intensity, I_n, increases with decreasing temperature, and follows a Curie-like law as in the $DEPD_2TCNQ_3$ complex (19). Plotting ln ($I_n \times T$) vs. $1/T$ gives a straight line, with a slope $-E_s/k$, from which one obtains the activation energy $E_T = 0.02$ eV. This small triplet activation energy was relatively constant as compared to the conduction activation energy E_c, Fig. 1, which manifests two sharp changes.

Raman spectra

The spectra were measured with argon ion and krypton lasers at low

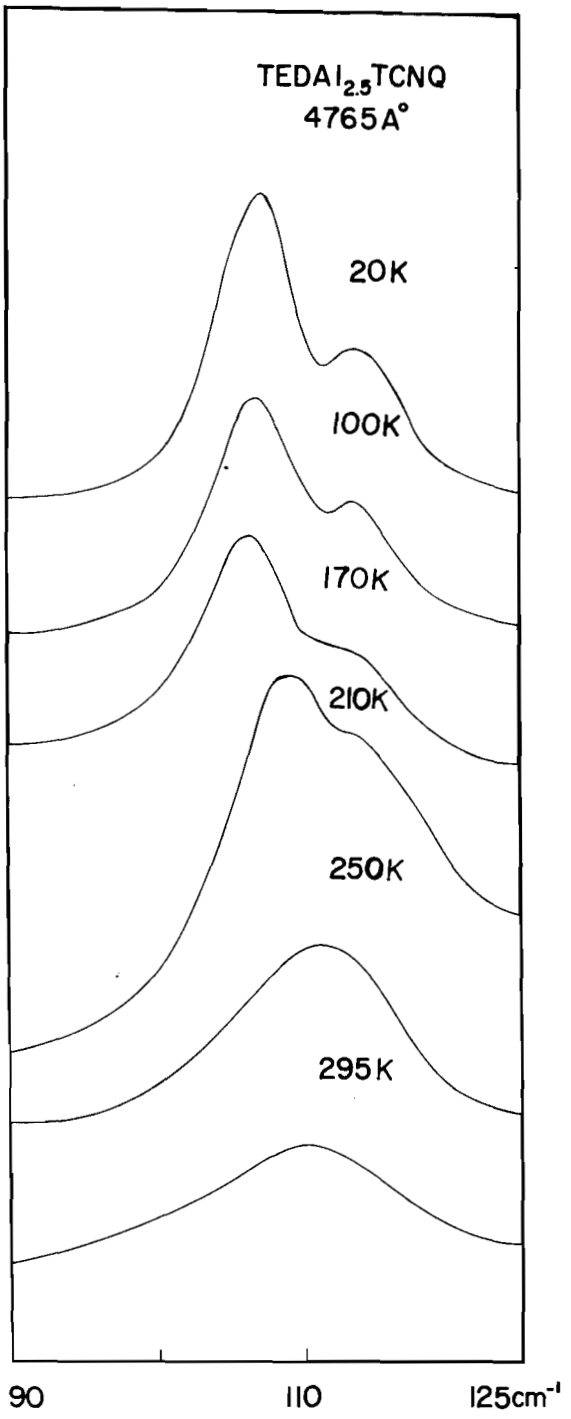

FIG. 3. Raman spectrum of a single crystal of TEDA·$I_{2.5}$·TCNQ as a function of temperature at 4765 Å laser wavelength excitation (power ≤ 5 mW).

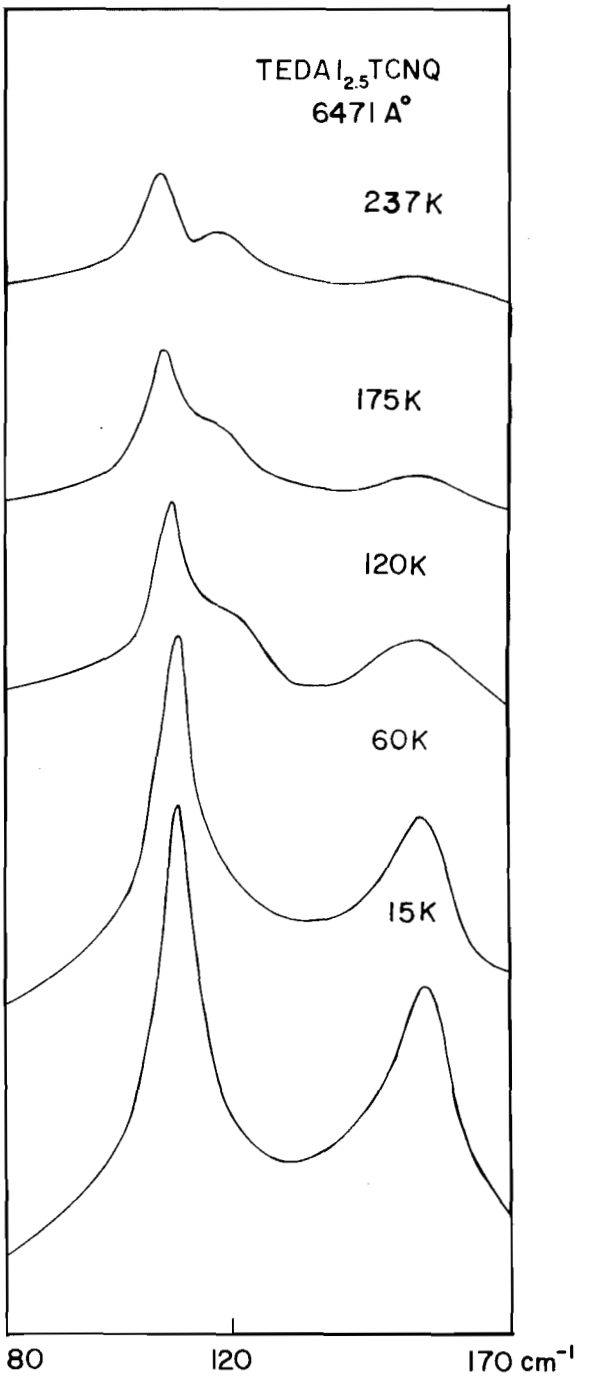

FIG. 4. Raman spectrum of a single crystal of TEDA·$I_{2.5}$·TCNQ as a function of temperature at 6471 Å laser wavelength excitation (power ≤ 5 mW).

powers, below 5 mwatts, to eliminate any surface heating and oxidation. Spectra were recorded with a perpendicular geometry, as in our previous work on single crystals of KTCNQ (20) and TMA·I·TCNQ (10). With high energy excitation (457.9, 488 nm), a large progression of overtones of the ν_1 symmetric mode of I_3^- as in TMA·I·TCNQ was observed. Lower energy excitation (647 nm) enhances nonsymmetric modes (see Fig. 2). The temperature dependence of these modes is illustrated in Figs. 3 and 4 and is discussed in the next sections with reference to the crystal structure.

Discussion

(a) Crystal structure

Preliminary X-ray results (21) show that there are two independent TCNQ molecules of similar geometry. The average bond distribution in each (Table 1) is consistent with the acquisition of a charge of 0.5 e (22). Average bond lengths in the TEDA ions are consistent with the assumed doubly protonated state (Table 1). Iodine is present as two isolated I^- ions and one I_3^- ion (Figs. 6 and 7). The latter is slightly nonlinear with different I—I distances (Table 1). The terminal I atom of the longer bond appears to be a proton acceptor. The

TABLE 1. Selected bond lengths and angles (see Fig. 5 for atom numbering) (ref. 21)

I(2)—I(1)—I(3)	178.82°	

asymmetry and nonlinearity of the I_3^- ion have been discussed previously elsewhere (23).

The TCNQ molecules lie essentially normal to [101], and are arranged in staggered face-to-face stacks extended in this direction. The sequence is 1-2-2′-1′-1 etc. (Fig. 6). There are thus *three* types of nearest-neighbour interaction, with slightly different interplanar spacings (1–1′, 3.37 Å; 2–2′, 3.42 Å; 1–2, 3.29 Å). The modes of overlap are found to be all very similar, and are of the type commonly occurring in TCNQ complexes, with the double bond c (Fig. 5) lying over the centre of the ring of the adjacent molecule.

The I_3^- ions are arranged in zigzag chains parallel to, and lying between, adjacent TCNQ stacks (Fig. 6). The TCNQ–I_3^- complex thus fills a layer parallel to the x–z plane. Adjacent layers are separated by parallel layers of $TEDA^{2+}$ ions and I^- ions. The other TEDA ion donates a proton to one I^- ion, while its second proton appears to be *shared* by a terminal atom of the I_3^- ion and the CN groups of one TCNQ molecule. It appears that the latter interaction, by reducing charge mobility in the TCNQ stack, is one cause of the low conductivity of this compound (see next section). The TCNQ molecules that accept protons occur in *pairs* along the stack (i.e., TCNQ(1) and TCNQ(2), Fig. 6). The relation of this structural feature to the conductivity is discussed in the following section.

(b) Structure and semiconducting properties

The structure, as illustrated in Figs. 6 and 7 (the first gives a side view of the TCNQ columns whereas the second figure illustrates tentative N—H bonds), indicates a tetramerization of the TCNQ stacks with a weak dimerization within the stacks. The repetitive unit can be presented as 211′2′ with long 2–2′ distance (3.42 Å), short 1–2 distance (3.29 Å), and intermediate 1–1′ distances (3.37 Å). Such structure is typical of *spin-Peierls* systems (24, 25). The charge on each TCNQ is estimated to be close to 0.5 e. The total charge distribution per unit cell is $2TCNQ^{-1/2}$, $2TEDA^{2+}$, I_3^-, and $2I^-$, giving a net zero charge. From the X-ray structure and the stoichiometry it is clear that half of the TEDA's are oriented towards, and are therefore hydrogen bonded to, apparent TCNQ ions thus creating the short TCNQ(1)—TCNQ(2) distance of 3.29 Å. As a result of this distribution of the donors that have a repeat periodicity $4a$ (a = average distance between TCNQ's) (see Fig. 6), the anions create a donor modulating positive potential with wave vector $k_D = 2\pi/4a$ on the TCNQ's. The modulating potential due to the iodides is described to a first approximation by wave vector $k_I = 2\pi/2a$. Since for a half-charged uniform chain of TCNQ ions one has a Fermi level at $k_F = \pi/4a$, then a $2k_F$ Peierls instability should occur at $2k_F = 2\pi/4a$. Clearly the main influence of the counterions comes from the TEDA's that have periodicity $4a$; these are hydrogen bonded to the TCNQ's. These introduce a perturbation of wave vector $k_D = 2\pi/4a$, which will induce a gap, a Peierls "pseudo gap", at the Fermi surface. It is to be noticed that the cations on the left of the chain are displaced by the distance a with respect to the cations on the right, i.e., a phase difference $k_D a = \pi/2$. This phase shift does not cancel out the electrostatic potential on the next TCNQ molecule so that the counterion potential remains effective. We emphasize that in the TMTTF highly conducting complexes, the counterion potentials on each side of the organic chain are out of phase by π, thus reducing the counterion potential on the conducting chain (26, 27). In the present case the counterion potentials persist and can be expected to play a critical role in the conduction mechanism of the system. These are probably also responsible for the tetramerization observed, which results in a semiconductor with a gap of 0.1 eV at room temperature. We emphasize that, as a first approximation, the I_3^- should have no influence on the conducting properties since their periodicity is $2a$, i.e., a wavevector four times the Fermi vector $k_F = \pi/4a$.

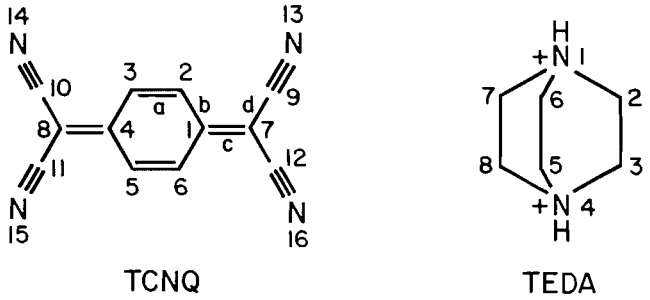

FIG. 5. Labelling of atoms reported in Table 1.

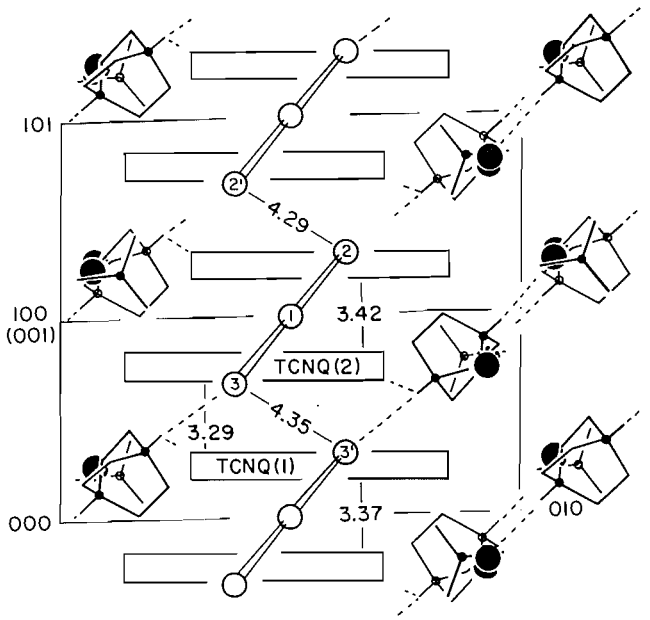

FIG. 6. Part of the structure viewed along [101]. Large circles are I atoms (shaded for I^-, open for I_3^-), small circles are N atoms. H atoms are omitted, except for the amino protons.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

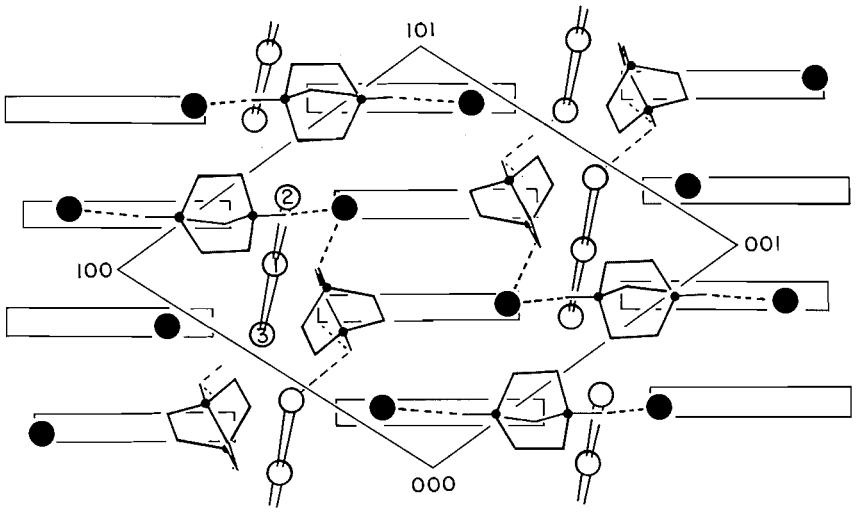

FIG. 7. The structure viewed along [101]. The TCNQ molecules are represented by rectangles.

This is similar to the case of the conductors $TTT_2 \cdot I_{3+\delta}$ as opposed to $DIPS\phi_4 \cdot I_{3(0.76)}$, where in the former the iodide periodicity is $4k_F$ and in the latter it is $2k_F$ with respect to the conducting bands (12). It is thus found that in the $TTT_2 \cdot I_{3+\delta}$ compound the conductivity is not altered by ordering of the iodides at low temperatures, whereas the iodide ordering induces the conductivity loss in $DIPS\phi_4 \cdot I_{3(0.76)}$ as in TMA·I·TCNQ due to $2k_F$ pseudo Peierls effects (13, 16).

Since in most of the known ternary TCNQ semiconducting compounds, $TCNQ^{-2/3}$ chains are parallel to linear chains of I_3^-, we have here a *novel* system with nonlinear chains of I_3^- parallel to chains of $TCNQ^{-1/2}$. Furthermore, in the previous ternary compounds such as TMA·I·TCNQ (16), it was the iodide chain that was shown to be involved in the metal–semiconductor transition known to occur at 160 K (10). This transition occurs in the latter because the iodine potential periodicity is equal to $2k_F$, k_F being the Fermi wavevector of the conduction electrons in the $TCNQ^{-2/3}$ chain. In the present case, the I_3^- seem to be spectators, whereas the hydrogen bonding of the TEDA donors regulates the semiconducting properties of the system by imposing a $2k_F$ modulating electrostatic potential on the conducting TCNQ chain and thus opening a gap at the Fermi level of the chain. The tetramerization evident in Fig. 6 is normally attributed to Peierls distortions as a result of charge or spin density wave formations (24). Intermolecular hydrogen bonding in the phenothiazine–TCNQ complex has recently been identified as the driving force for an observed structural modulation in that compound (28). In the present ternary compound we would seem to have both mechanisms operating, since it is clear that Peierls distortions and electrostatic (crystal) effects cannot be separated. In fact conductivity measurements were extended to high temperatures (400 K) to see if the reverse spin-Peierls transition (dimerization ↔ tetramerization) could be observed, as in $MEM \cdot TCNQ_2$ (24, 25). No change in conductivity or ESR spectrum was observed. A change in activation energy was observed at 330 K, with a quasidoubling of the activation energy occurring above that temperature (Fig. 1). This anomaly remains unexplainable as it did not show up in the RRS spectrum, as discussed in the following section. The doubling of the activation energy above 330 K with respect to its room temperature value is reminiscent of Q (quinolinium)·$TCNQ_2$, which essentially has the same activation energies as our compound but with the energy discontinuity occurring at about 400 K (17). This was considered to be an early example of an order–disorder semiconductor (29). The second discontinuity in activation occurs at ~160 K in $TEDA \cdot I_{2.5} \cdot TCNQ$. We will show in the next section that the iodide ions seem to be involved in this "pseudo" phase transition at this low temperature. We note that the terminal I atoms in the I_3^- anions are on the average at normal van der Waals contact distances, 4.3 Å, and are directed at a diagonal to the conducting chain. Similar conditions occur in the crystals of the superconductor β-$(BEDT\text{–}TTF)_2I_3$. For the latter compound, the angle between the I_3^- ion axis and the organic chain direction is 20° (15), while on our compound this angle is 39° (Fig. 6).

(c) Resonance Raman spectra

Figure 2 illustrates the resonance behaviour of different I_3^- vibrations at very low temperatures (12 K). At 676.4 nm excitation, three bands, 47, 100 and 152 cm^{-1}, are observed. These are usually attributed to bending, symmetric, and antisymmetric modes of I_3^- (30). At 457.9 nm excitation, the bending mode remains, whereas the $\nu_1 = 110\ cm^{-1}$ band is split in two vibrations at 107 and 115 cm^{-1}, thus reflecting the slight asymmetry in the bond lengths (Table 1). A new mode at 132 cm^{-1}, which could be an overtone (~ 47 + 107) cm^{-1}, and harmonics of the symmetric band (222, 327 cm^{-1}) also appear at this high energy excitation. The main resonant effect is the disappearance of the $\nu_1 = 115\ cm^{-1}$ mode and increasing intensity of the $\nu_2 = 152\ cm^{-1}$ mode as one goes from 457.9 to 676.4 nm excitation. Such a resonant effect confirms the antisymmetric character of the $\nu_2 = 152\ cm^{-1}$ mode, which is strongly coupled to the $\sigma_g \rightarrow \sigma_u$ electronic transition at ~600 nm of I_3^- (18). The 115 cm^{-1} mode, contrary to its 107 cm^{-1} partner, would seem to couple to high energy excitations, which is typical of symmetric modes of the iodide ion (19, 30).

Figures 3 and 4 illustrate in finer detail the structure of the I_3^- low frequency bands as a function of temperature for the two extreme excitations 476.5 and 647.1 nm, respectively. Thus in Fig. 3, at room temperature, one observes only a single ν_1 band at 476.5 nm excitation with a maximum at 110 cm^{-1}, typical of the I_3^- ν_1 symmetric mode. Around 200 K a splitting of the band into two components at 107 and 115 cm^{-1} begins to occur. The splitting of this band is accentuated as one lowers the temperature. A similar gradual splitting of the symmetric I_3^- mode has been observed upon lowering the temperature in β-(BEDT–

$TF)_2I_3$ and is attributed to a rearrangement of the donor molecule and the onset of a superstructure (14, 15) that is essential for superconductivity in that compound. In Fig. 4, the mode at 152 cm^{-1} attributed to the antisymmetric ν_2 vibration of I_3^- broadens and decreases considerably in intensity around the phase transition temperatures, 160 K, when it is resonant with the excitation wavelength 647.1 nm. The same resonant excitation of the ν_1 mode manifests an intensity nehaviour contrary to the 476.5 nm excitation (Fig. 3). At the lower energy excitation, the ν_1 mode is a single band below the phase transition, 160 K, and splits above that temperature. Contrary to the conductivity results, Fig. 1, the Raman spectra do not indicate a sharp transition but a rather gradual perturbation of the I_3^- ions beginning already above the transition temperature.

In our previous work on the ternary compound $TMA^+ \cdot I^{-1/3} \cdot TCNQ^{-2/3}$, we used the I_3^- symmetric vibration $\nu_1 = 115\ cm^{-1}$ as a probe to measure the involvement of the iodine chain in the conductor–insulator transition, which occurs at 160 K in that compound (10). No evidence was found of the antisymmetric $\nu_2 = 150\ cm^{-1}$ vibration in that compound and the ν_1 vibration underwent discontinuous intensity changes, but no splitting. In the present case, the ν_2 vibration is enhanced in intensity as one crosses the phase transition and the ν_1 mode splits in a continuous fashion around the transition temperature. Although the room temperature X-ray data suggest already a slight asymmetry in bond lengths of the I_3^- due to some weak hydrogen bonding to the TEDA's, Fig. 6 and Table 1, it is not clear why the ν_1 band splits above the phase transition for $\lambda = 647.1$ nm (Fig. 4) and below it for $\lambda = 476.5$ nm (Fig. 3). A possible explanation would be the presence of inequivalent TCNQ's, 2–2′ and 1–1′, resulting in different crystal effects for I_3 and I_3', Fig. 6.

Conclusion

As discussed in Sect. b, the periodicity of the iodides precludes any strong interaction of I_3^- with the TCNQ electronic bands. This would explain the gradual onset of perturbations in the I_3^- Raman spectra.

The TEDA periodicity, on the other hand, is expected to influence strongly the electronic properties of the compound via a $2k_F$ pseudo Peierls effect. These donors are, however, hydrogen bonded to both the I_3^-'s and to the TCNQ's (N(1)—I(3) = 3.76 Å; N(1)—N(16) = 2.98 Å, Figs. 5 and 6). Any rearrangement of the TEDA's should effect the activation energy as seen in the conductivity via the pseudo Peierls effect, Fig. 1. Simultaneously, such rearrangements would influence the I_3^- spectra via the H-bonding. The increase in the Raman intensity of the antisymmetric ν_2 I_3^- vibration below the phase transition is suggestive of increasing coupling between the three species around the phase temperature of 160 K. The anomalous intensity behaviour of the symmetric ν_1 doublet (Figs. 3 and 4) as one crosses the phase transition is complex and we offer no immediate explanation for this observation. Further temperature dependent X-ray work would be of help to elucidate the dynamics of this system and the coupling between the three species TCNQ, TEDA, and I_3^- at the phase temperature of 160 K indicated by the conductivity measurements.

Ab initio calculations (Hartree–Fock) at the level of 3-21G and 6-31G* as well as MP2/6-31G* have been performed on the carcinogen dimethylnitrosamine and its products of oxidative metabolism *E*- (and *Z*-) hydroxymethylmethylnitrosamines and certain ester conjugates. The *E*- and *Z*-hydroxymethylmethylnitrosamines are found to be close in energy and to be configurationally stable as is found experimentally. Alternative pathways are examined for the spontaneous decomposition of the primary metabolite in aqueous solution. Direct cleavage of *E*-hydroxymethylmethylnitrosamine to *Z*-methanediazohydroxide and formaldehyde is highly endothermic. Protonation of the NO group of the hydroxylated metabolite strongly stabilizes this species in contrast to nitrosoureas but in accord with experiment. Incorporation of water together with consideration of entropy effects satisfactorily accounts for the spontaneous exothermic decomposition of *E*-hydroxymethylmethylnitrosamine in aqueous media, as well as its relative stability in aprotic media. *Ab initio* calculations were also performed on selected nitrosoiminium ions which participate in the enzymatic activation and metabolism of certain dialkylnitrosamine carcinogens.

Key words: carcinogenesis, dimethylnitrosamine, *ab initio* calculations, nitrosoiminium ions.

MARTINE DEMEUNYNCK, J. WILLIAM LOWN et ANNE-MARIE SAPSE. Can. J. Chem. **67**, 625 (1989).

On a effectué des calculs *ab initio* (Hartree–Fock) aux niveaux 3-21G et 6-31G* ainsi que MP2/6-31G* sur la diméthylnitrosamine cancérigène et sur ses produits de métabolisme oxydant, les hydroxyméthylméthylnitrosamines-(*E*) et (*Z*), et sur certains de ses esters conjugués. On a trouvé que les hydroxyméthylméthylnitrosamines-(*E*) et (*Z*) sont proches d'un point de vue énergétique et que d'un point de vue de la configuration elles sont stables, comme on l'a trouvé expérimentalement. On a examiné d'autres voies qui permettraient une décomposition spontanée du métabolite primaire en solution aqueuse. Le clivage direct de l'hydroxyméthylméthylnitrosamine-(*E*) en hydroxydiazométhane-(*Z*) et en formaldéhyde est fortement endothermique. La protonation du groupement NO du métabolite hydroxylé stabilise beaucoup cette espèce par rapport aux nitrosourées; cette conclusion est en accord avec les données expérimentales. L'incorporation d'eau et de considérations d'effets d'entropie explique d'un façon satisfaisante la décomposition exothermique spontanée de l'hydroxyméthylméthylnitrosomine-(*E*) en solutions aqueuses ainsi que sa stabilité relative en milieux aprotiques. On a aussi effectué des calculs *ab initio* sur des ions nitrosoiminium choisis qui participent à l'activation enzymatique et au métabolisme de certaines dialkylnitrosamines cancérigènes.

Mots clés : carcinogenèse, diméthylnitrosamine, calculs *ab initio*, ions nitrosoiminium.

[Traduit par la revue]

Introduction

The current widespread interest in nitrosamines was spurred by the report of Magee and Barnes of their carcinogenicity (1–3). However, it has been established that, in most cases, nitrosamines are not carcinogenic in themselves but require enzymatic oxidative metabolism to convert them into a precursor of the ultimate carcinogen (3, 4). A considerable body of evidence indicates that damage to cellular DNA and proteins by electrophiles generated from these metabolites may be responsible for their characteristic biological effects (5–10). Certain DNA base lesions, particularly guanine O^6 alkylation (8), are apparently more critical in giving rise to cell transformation than others, e.g. N_7-alkylation (9). In order to provide a better understanding of structure – carcinogenic activity relationships, particularly as regards the site-selectivity of electrophile attack, the steps leading to the carcinogenic species must be considered. It has been demonstrated that, of the possible sites of enzymatic oxidation, hydroxylation at the positions α to the *N*-nitroso group ultimately produces the carcinogen (11). The resulting α-hydroxymethylnitrosamines have been suggested to lose formaldehyde readily to generate the primary alkylnitrosamine which tautomerizes to the alkanediazohydroxide (4*b–e*, 11). The latter being a powerful electrophile alkylates sensitive cellular nucleophiles, including DNA base sites (6–9).

The α-hydroxynitrosamines have until recently eluded direct isolation owing to their instability, and therefore information on the properties of these critical species is limited. Conjugates of these species, including esters, are more stable and may represent transportable forms of the latter which are subsequently subjected to esterase action close to the eventual site of alkylation (12, 13). The α-acetoxymethylalkylnitrosamines are especially pertinent since they have been shown to be potent carcinogens (14).

Accordingly, theoretical quantum chemical methods were used to investigate the parent dimethylnitrosamine **1** (Fig. 1), the isomeric *E*- and *Z*-hydroxymethylmethylnitrosamines **2** and **3** and their respective ester conjugates *E*- and *Z*-acetoxymethylmethylnitrosamines **5** and **6** and the results compared with experimental observations. The calculations were performed in order to obtain optimized geometries, energies, net atomic charges, and LUMO atomic contributions. A related object of study is the energetics of decomposition of the en-

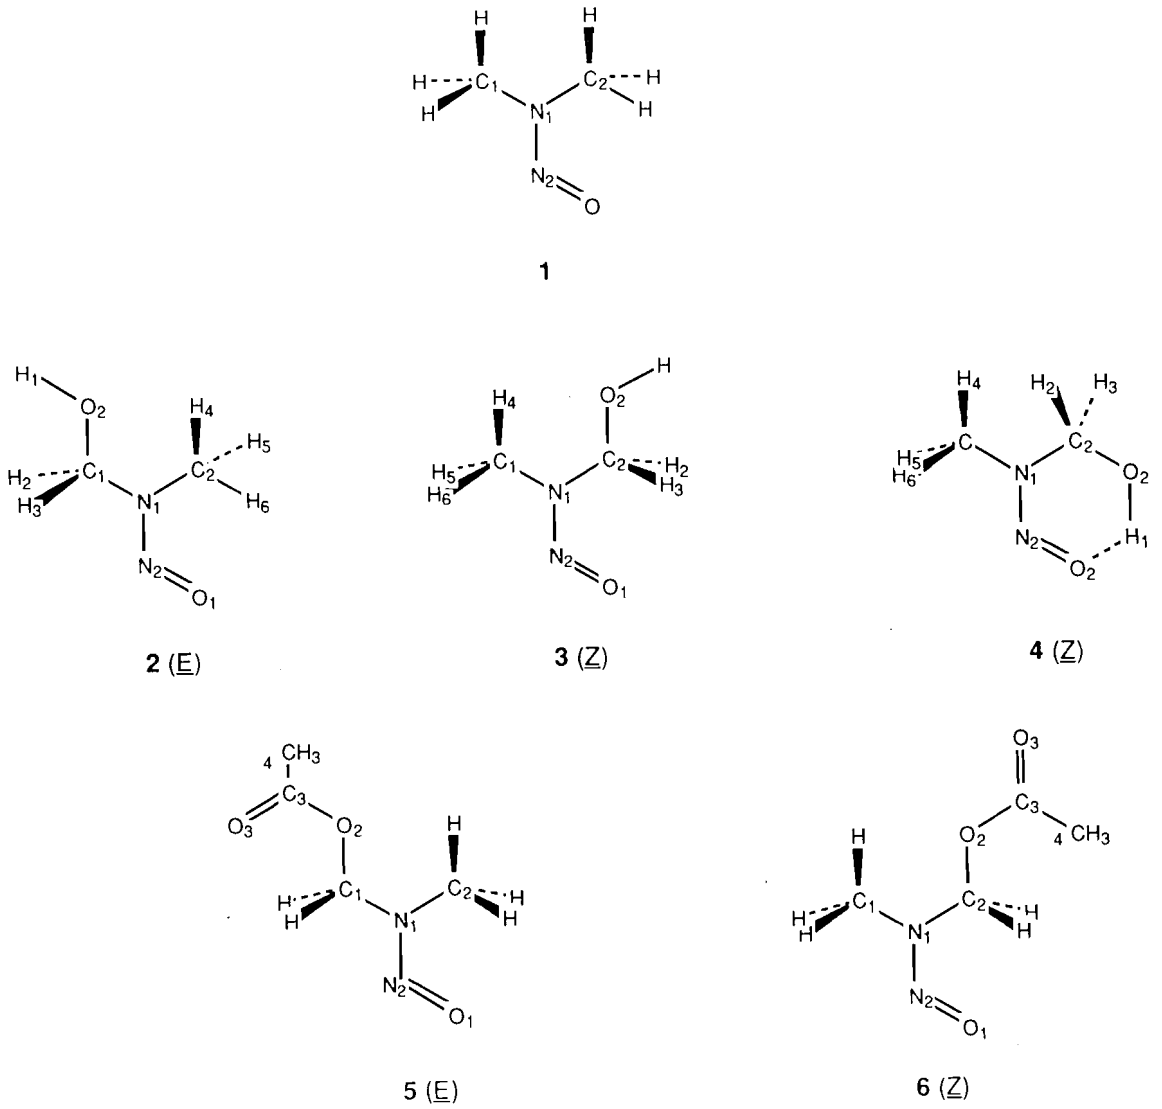

FIG. 1. Structures and numbering of dimethylnitrosamine, its metabolites and their conjugates.

zymatically selectively generated *E*-hydroxymethylmethylnitrosamine under physiological conditions into methylnitrosamine, methyldiazohydroxide, and formaldehyde, together with the pH dependence of the process.

Experimental evidence implicates nitrosoiminium ions in the enzymatic activation and metabolism of certain dialkylnitrosamine carcinogens (ref. 15*a*, *b*; for a review, see ref. 15*c*)[3]. Therefore, an additional objective was to elucidate the structure of such species together with their stabilities and other properties relevant to reactivity such as atomic charges and LUMO participation.

Methods

Self-consistent field (SCF) *ab initio* calculations were made, with full geometry optimization of the principal conformers, obtaining energies, net atomic charges, and LUMO atom contributions of dimethylnitrosamine, its metabolites and their conjugates. The *ab initio* calculations at the Hartree–Fock level were performed using the 3-21G and 6-31G* Gaussian basis set, as implemented in the Gaussian-80 program (16). The geometry optimization procedure is the Berny (gradient method) (17) and the Hessian matrices were examined in order to ensure that all the eigenvalues are positive and, as such, the stationary point is a true minimum. SCF calculations with split valence or larger basis sets are known usually to predict accurate geometries (16–19). The net atomic charges are calculated via the Mulliken Population Analysis. In certain cases the optimized geometries have been used to perform single point MP2/6-31G* calculations in order to estimate the correlation energies of the structures and to assess their influence on stabilities.

Results

Dimethylnitrosamine, E- and Z-hydroxymethylmethylnitrosamine

Dimethylnitrosamine **1** was investigated at Hartree-Fock level using the 3-21G basis set, and the *E*- and *Z*-hydroxymethylmethylnitrosamines **2** and **3** were examined with both 3-21G and 6-31G* basis sets (20). Examination of **3**

[3]The widespread significance of potentially reactive and toxic iminium species generated from the oxidative metabolism of xenobiotic N-alkylamino compounds has been recognized only relatively recently.

included consideration of the intramolecularly hydrogen bonded structure **4**. The reason for employing both basis sets for **2**, **3**, and **4** is that while geometries and net atomic charges are reliable with both basis sets, the energetics of chemical reactions (i.e. the decomposition of **2**, **3**, or **4**) are better described by the 6-31G* basis set (20).

The results of the optimization for **1–4** together with the energies are shown in Table 1 while Table 2 shows the net atomic charges and the LUMO atomic participation values. In dimethylnitrosamine, N_1 is, as expected, quite negative. N_2 is positive owing to the influence of the oxygen and there is no significant difference in the charges between C_1 and C_2, however C_2 participates more to the LUMO. It may be seen from Table 2 that the 6-31G* calculations predict shorter N_1N_2 bond lengths and shorter OH, CO, and N_2O_1 bond lengths than the 3-21G calculations. The N_1C_1 bonds are predicted to be longer by the 6-31G* basis set. Typical experimental lengths of such bonds fall between these values. The values of the interbond angles predicted by both basis sets are closely comparable. Both basis sets predict **3** to be somewhat more stable than **2**. However, the difference is small amounting to less than 1 kcal/mol.

The structure **4** is computationally a minimum in energy, but only a local minimum, higher by 6 kcal/mol than structure **3**. Loew *et al.* employing MNDO calculations also find structure **4** to be higher in energy (21). It therefore appears that **4** does not benefit significantly by intramolecular hydrogen bond formation. Indeed **4** is higher in energy than **3** by 4.7 kcal/mol at 3-21G level and by 6 kcal/mol at 6-31G* level. The charges and LUMO contributions are better predicted by the 6-31G* basis set (20) and are reported in Table 2. It is evident that, in structures **2–4**, the hydroxyl oxygen is much more negative than the nitroso oxygen (*vide infra*). The hydroxyl oxygen does not contribute to the LUMO in either case.

Ester conjugates of E- *and* Z-*hydroxymethylmethylnitrosamine*

The *E*- and *Z*-acetoxymethylmethylnitrosamines **5** and **6** were investigated at the Hartree–Fock level using the 3-21G basis set. The results of the geometry optimization for **5** and **6**, together with their energies are shown in Table 1. It is seen from Table 1 that **5** is somewhat more stable than **6**. This result is in agreement with experimental observations of Mochizuki *et al.* that the *E* structures are more stable than the *Z* isomers (22). Moreover, NMR evidence confirms that *E* and *Z* forms are configurationally stable and do not readily interconvert (22). The N_1N_2 bond length does not show any significant change from **1** to **5** or **6** and neither do the other bond lengths.

Stability of hydroxymethylmethylnitrosamine in aprotic media and decomposition in aqueous solution

Experimentally it is known that whereas *E*- and *Z*-hydroxymethylmethylnitrosamines have moderate stability in aprotic media, they decompose spontaneously to formaldehyde and methylnitrosamine or methanediazohydroxide, or its kinetic equivalent the methane diazonium ion (22). Possible alternative pathways were considered for this process and examined by quantum chemical methods. In the process for the protonated *E* isomer, which is formed preferentially in the enzymatic oxidation, the energies of different structures corresponding to a progressive stretching of the N_1C_1 bond were computed (Fig. 3). When the energy of the reactant is compared to that of the products the reaction appears to be endothermic. In fact, the differences in the energies of the protonated hydroxymethylmethylnitrosamine and its decomposition products (Fig. 2*a*, *b*) which exhibit much higher energies predict a highly endother-

mic reaction with ΔE = 42 kcal/mol. In addition, a transition state for this direct decomposition appears to be located at $N_1C_1 \simeq 3.0$ Å, corresponding to an energy of activation of 47 kcal/mol. These calculations, performed at Hartree–Fock level, do not include correlation energy. However, this reaction proceeds via the transfer of an electron pair and not via homolytic bond cleavage. Therefore neglect of the correlation energy should not affect the results significantly. Since, as we will show later this is *not* the proposed mechanism, MP2 calculations were not deemed necessary. Predictions of an endothermic reaction result whether one considers initial decomposition to formaldehyde and *Z*-methylnitrosamine **8** (Table 3, Fig. 2*b*) or to the more stable tautomer *Z*-methanediazohydroxide **7** (Fig. 2*a*).

The rationale for investigating the decomposition of the protonated species is the following.

We have previously demonstrated that the decomposition of other *N*-nitroso compounds (nitrosoureas) is greatly facilitated by the acquisition of a positive charge on the nitroso group, i.e.

by metal ion complexation or protonation (23). Accordingly, protonation of the NO group was considered as an alternative pathway in the case of nitrosamines (Fig. 2*c*). However, it may be seen from Table 4, which summarizes energies calculated at 6-31G* level, that protonation of the NO groups in **2** and **3** significantly stabilizes these species and as shown above this process is predicted to be highly unfavourable energetically. This result is in complete agreement with those of Mochizuki *et al.* who find that the rate of decomposition is much reduced in acidic media (22). Thus it appears that protonation stabilizes **2** and **3** in contrast to the nitrosoureas where, as we have shown, protonation or metal ion complexation of the nitroso group facilitates decomposition (23). This is illustrated in Fig. 3.

Therefore other mechanisms have to be examined. The difference in energy (endothermic process) between **2** and its decomposition products is ca. 7 kcal/mol. This energy difference is reduced if one takes into account the fact that formaldehyde is hydrated in aqueous solution. When the comparison is made between **2** plus a water molecule and the sum of energies of *Z*-methanediazohydroxide and hydrated formaldehyde as shown in Fig. 4, the energy difference reduces to 1.2 kcal/mol. Similar trends are observed if one considers *Z*-methylnitrosamine as a product. Thus at the 6-31G* level with *Z*-methylnitrosamine and formaldehyde as decomposition products an endothermic reaction is predicted with $\Delta H = 4.1$ kcal/mol. Incorporation of a water molecule in the transition state then predicts a slightly exothermic reaction with $\Delta H = -2.7$ kcal/mol.

Another factor to take into consideration is entropy as suggested by Loew *et al.* Indeed the $T\Delta S$ term in the free energy of the decomposition reaction as shown by Loew *et al.* (24) is about 12 kcal/mol. Thus the reaction becomes exothermic with $\Delta H \simeq -11$ kcal/mol. When correlation energy is taken into account, by performing MP2/6-31G* calculations on **2**, *Z*-methanediazohydroxide and formaldehyde, the results do not change substantially. Indeed, the energy of **2** is −338.6749 au while *Z*-methanediazohydroxide features an MP/G-31G* energy of −224.4879 au. Formaldehyde has an MP2/6-31G* energy of −114.1648 au. Therefore **2** is more stable by 14 kcal/mol. If the entropy term of 12 kcal/mol is taken into account, again the energy of the products becomes almost equal to that of the reactants. The MP2/6-31G* are single point calculations.

decomposition of hydroxymethylmethylnitrosamine **2** is in accord with the observations of Mochizaki *et al.* (22) who reported that, while **2** and **3** are relatively stable in aprotic solvents such as chloroform, decomposition is immediately initiated in aqueous media. Therefore, in order to investigate the possible incorporation of water, an appropriate transition state or intermediate **10** has been examined as shown in Fig. 4. The energy of this state, obtained with the 3-21G basis set, proved to be quite low. At a distance of 2.93 Å of the water oxygen to carbon C_1 and with one of the water hydrogens within hydrogen-bonding distance to O_2, this structure features an energy lower by 6 kcal/mol than the sum of the energies of **2** and a water molecule. This value is an approximation, due to superposition error and neglect of correlation energy. We estimated the magnitude of the superposition error as follows. Assuming that the 6-31G* basis set would provide less of a superposition error, we calculated the energy of hydroxymethylnitrosamine (replacing the CH_3 by H in structure **2**) and an approaching water molecule as in structure **10**. At 3-21G this structure is lower by 4 kcal/mol than the sum of hydroxymethylnitrosamine and water. At 6-31G* level, it is higher by ca. 8 kcal/mol. Therefore the superposition approximation can be estimated at about 12 kcal/mol. If structure **10** is then higher by only 6 kcal/mol than the reactants the reaction could still proceed readily when initiated by the incorporation of a water molcecule to C_1. Indeed, C_1 bears a net positive charge (as determined by Mulliken Population Analysis using the 6-31G* basis set, which is known to predict accurate atomic charges) so the oxygen of a water molecule would be attracted to it. When structure **4** is considered, a low energy hydration complex is also obtained.

Nitrosoiminium ions

Nitrosoiminium species have been proposed as intermediates in the nucleophilic displacement of ester conjugates of α-hydroxyalkylalkylnitrosamines (15). Additional experimental support for the existence of these species was obtained by the isolation of stable antimony hexachloride salts of the *Z*-nitrosoiminium ions (15*b*). No quantum chemical studies of these species have been reported hitherto. The nitrosoiminium ions **11**, **12**, and **13** (Fig. 5) were investigated using the 3-21G basis set to obtain optimized geometries, energies, net atomic charges, and LUMO participation of atoms. Table 5 summarizes the results on nitrosoiminium, 1,2-dimethylnitrosoiminium, and 1,2-diethylnitrosoiminium ions. In principle, these species could exist in *Z* or *E* forms. While the difference in energies between *E* and *Z* isomers is small (see Table 5), the geometry optimization calculations clearly show that the *Z*-configuration is preferred for these reactive ions with a coplanar geometry for the four atoms in the grouping $C{=}\overset{+}{N}{-}N{=}O$. Therefore, all the results on energies, atomic charges, and LUMO values presented pertain to the *Z* configurations. The rotational barrier around the NN bond is expected to be higher

than that for a single bond, owing to delocalization of the π electrons from the NO bond and NC bond into the NN bond. Indeed, this is the case in nitrosamines where the rotational barrier between **2** and **3**, calculated by setting the NO bond at 90° dihedral angle with the plane of $C_1N_1C_2$ and optimizing the other parameters of the molecule, with the 3-21G or 6-31G* basis sets, is ca. 32 kcal/mol. The value of 90° was chosen as the one which would completely break the overlap between the *p* orbitals of N_1, N_2, and O_1, by setting the N_2 and O_1 *p* orbitals perpendicular to those of N_1. In contrast, in nitrosoiminium ions a similar procedure (employing the 3-21G basis set) leads to values of 6.7 kcal/mol for **11**, 7.9 kcal/mol for **12**, and 8.3 kcal/mol for **13**. These much lower values are in agreement with the inordinate lengths of the NN bond in these species which are 1.658 Å, 1.582 Å, and 1.586 Å, respectively. These results suggest substantial contribution of the resonance form $H_2C{=}NH\ldots N{\equiv}\ddot{O}$. In support of this suggestion is the relatively low negative charge on the oxygen (−0.2 eu as compared to −0.44 eu in nitrosamines with both values calculated with the 3-21G basis set). The decreasing length of the NN bond in **12** and **13** is ascribed to stabilization of the nitrosoiminium ion by alkyl substitution.

Since these species are highly electrophilic it is conceivable that they may attack nucleophilic sites in DNA directly (6, 7, 25, 26). In this regard, the LUMO shows an antibonding character for the N_1C_1 bond and, therefore, breakage of this bond will be facilitated upon nucleophilic attack. This also implies that the attack will have a soft–soft character and, as such, attack might be expected at softer sites in the bases such as the O^6 of guanine (6, 7). The latter has been implicated as a carcinogenic lesion. In addition, the positive charge concentrated at C_1 will contribute to its chemoselectivity as an electrophile.

The 3-21G calculations are indicative of the properties of nitrosoiminium ions. However, calculations at higher level (6-31G* and MP2) are being performed in our group and will be reported in due course.

Discussion

Oxidative metabolism of nitrosamines can occur at the α, β or other positions relative to the *N*-nitroso function (4, 11). Several paths have been suggested for the oxidation process such as proton abstraction and subsequent oxidation of the carbanion (27). The data available do not distinguish between this possibility and that of homolytic cleavage. Other studies led to the suggestion of action by a complex of nitrosamine demethylase enzymes, several of which appear to be membrane bound (28). There is general agreement that, of the possible sites of oxidative metabolism, it is hydroxylation at the α positions that ultimately produces the carcinogenic electrophile from nitrosamine (4, 11). Michejda *et al.* (12) have presented evidence that enzymatic hydroxylation of dimethylnitrosamine occurs *anti* to the nitroso group and suggested that this reaction affords the more stable isomer. The present results indicating the configurational stability of the (*E*) and (*Z*) α-hydroxymethylmethylnitrosamine metabolites and the slightly greater stability of the latter suggests that the hydroxylation process may be kinetically controlled. However, the difference in stability between *E* and *Z* isomers is quite small. Our calculations refer to the gas phase. It is reasonable to suppose that in water the *E* isomer will be preferentially stabilized versus the *Z* isomer since its dipole moment is higher (4.4 vs. 3.6 D) as predicted from the 6-31G* basis set calculations.

The experimental ^{1}H-NMR studies confirm that the (*E*) and

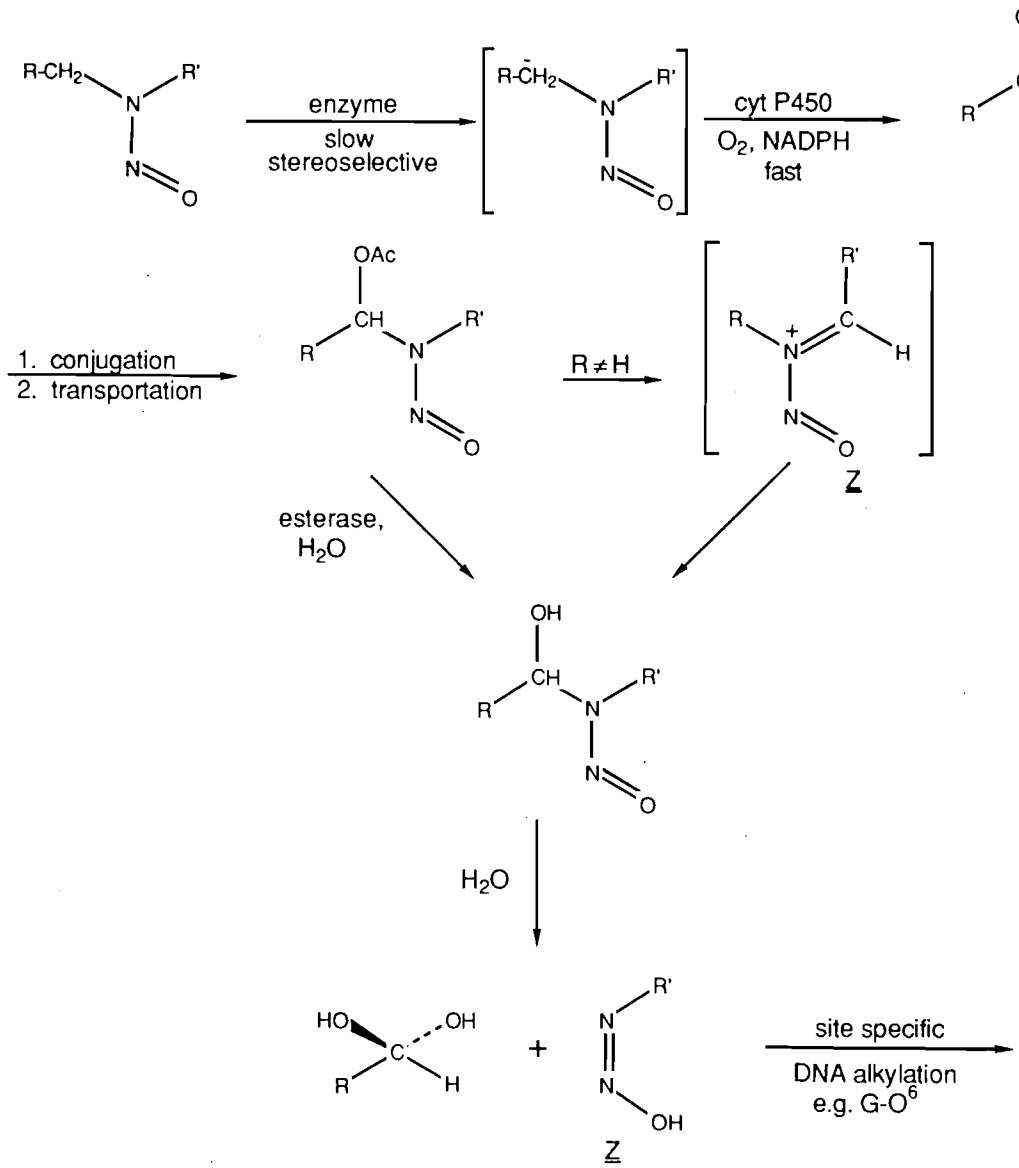

FIG. 6. Representation of metabolic fate of alkylnitrosamines with initial stereoselective and kinetically controlled enzymatic hydroxylation followed by conjugation of the resulting *E*-hydroxymethylalkylnitrosamine, transport, and esterase hydrolysis of the latter via competing pathways with water promoted stereospecific decomposition to afford *Z*-alkanediazohydroxide which, via HOMO–LUMO interaction, preferentially alkylates DNA bases including guanine-O^6.

(*Z*) ester conjugates are configurationally stable (22). As such the theoretical calculations are in agreement with the experimental observations which indicate *E* to be more stable than *Z* (15*a*, 22).

The instability of the hydroxymethylmethylnitrosamine towards decomposition to formaldehyde and *E*-methanediazohydroxide may be rationalized in terms of a combination of entropic factors and the contribution of hydration energies which predict a slightly exothermic process. This result is in contrast to the endothermic process predicted for either *E* or *Z* isomer when hydration is not taken into account. The theoretical treatment provides a rationale for the observed relative stability of *E*- and *Z*-hydroxymethylmethylnitrosamines in aprotic solvents contrasted with the spontaneous decomposition initiated by addition of water (22).

Results from solvolyses of substituted ester conjugates of hydroxyalkylnitrosamines are, by contrast, in accord with the intermediacy of nitrosoiminium species (15). The *ab initio* calculations on the latter indicate a preferred *Z* geometry but that the barrier to rotation about the NN bond is much lower than in the *N*-nitrosamine precursors.

A tentative overall scheme emerges for the fate of dialkylnitrosamines *in vivo*. This involves kinetically controlled *anti* enzymatic oxidation, conjugation to form the more stable ester derivatives, transportation of the latter to a sensitive cellular target, and esterase action to reform the reactive α-hydroxylated metabolite. The latter can be formed by two distinct pathways in the case of substituted ester conjugates as shown in Fig. 6.

The LUMO atom orbital coefficients summarized in Table 2 reveal that contributions of the methyl carbon in both *E*- and *Z*-hydroxymethylmethylnitrosamine isomers is small. This effect is carried over into the *Z*- and *E*-methanediazohydroxides where it assumes greater significance since these species are viewed as the ultimate electrophiles leading to carcinogenesis.

Calculations at the level of 6-31G* on methanediazohydroxides (25) showed that the LUMO contribution of the methyl carbon in the *E* isomer disappears almost entirely suggesting that attack of this species on guanine would occur, as is found experimentally, preferentially at the harder HOMO N_7 site. The *Z* isomer having a methyl carbon LUMO coefficient of the p_z orbital of 0.233 and therefore soft may permit attack at the softer HOMO O^6 site of guanine. Several lines of evidence suggest that the latter DNA lesion is carcinogenic (6–9).

The kinetics of oxidation of proline by periodate has been studied at pH 1.40–8.83 and 30.0°C. The reaction rate is first order in both periodate and amino acid, and the overall reaction follows second-order kinetics. There was no evidence for the formation of an appreciable amount of intermediate. The reaction rate is highest at pH 4–7 and the oxidation is catalysed by HPO_4^{2-} ions. The pH dependence of the reaction rate can be explained in terms of reaction of periodate monoanion and the protonated and dipolar forms of the amino acid. The mechanism proposed and the derived rate law are consistent with the observed kinetics. The rate constants obtained from the derived rate law are in agreement with the observed rate constants, thus justifying the rate law and the proposed mechanistic scheme.

Key words: oxidation of proline, oxidation by periodate.

ROSA PASCUAL, MIGUEL A. HERRAEZ et EMILIO CALLE. Can. J. Chem. **67**, 634 (1989).

Opérant à 30,0°C et à des pH allant de 1,40 à 8,83, on a étudié la cinétique de l'oxydation de la proline par le periodate. La vitesse de la réaction est du premier ordre tant en periodate qu'en acide aminé et la réaction globale est du deuxième ordre. On n'a trouvé aucune indication suggérant la formation de quantités appréciables d'intermédiaire. La vitesse réactionnelle est à son maximum à des pH allant de 4 à 7 et l'oxydation est catalysée par les ions HPO_4^{2-}. Pour expliquer la relation qui existe entre la vitesse de la réaction et le pH, on suggère que la réaction implique le monoanion du periodate et les formes protonées et dipolaires de l'acide aminé. Le méchanisme proposé et la loi de vitesse sont en accord avec les cinétiques observées. Les constantes de vitesse que l'on peut calculer à partir de la loi de vitesse sont en accord avec les constantes de vitesses qui ont été observées; cet accord justifie cette loi de vitesse et donc le schéma réactionnel proposé:

Mots clés : oxydation de la proline, oxydation par le periodate.

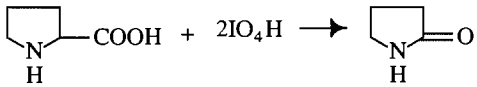
[Traduit par la revue]

Introduction

Periodate is a clean and relatively selective reagent for the oxidative cleavage of organic compounds containing α-hydroxy, -oxo, -amino, or -carboxyl groups. There is extensive literature on the kinetics of the periodic acid oxidation of glycols (1, 2) but the kinetics of the periodate oxidation of amino alcohols (3), dicarbonyl compounds (4), and amino acids (5), has received much less attention. Oxidation with periodate has been shown to cause denaturation of proteins and inactivation of enzymes and these findings have been interpreted on the basis of attack of periodate on essential amino acids. The importance of these reactions attracted our attention and mechanistic studies on periodic oxidations of amino acids were undertaken in our laboratory (6). In this paper, we report on the results obtained for the oxidation of proline by periodate. This amino acid is an essential constituent of some proteins, such as collagen.

Experimental

Materials



Proline was obtained from Sigma. All other reagents were Merck analytical grade. Doubly distilled water from alkaline permanganate was used to prepare all solutions. Chloroacetate, acetate, phosphate and borate buffers have been used to maintain constant pH. The ionic strength of the system was kept constant (0.20 *M*) by the addition of sodium perchlorate. Standard stock solutions of amino acid were freshly prepared by dissolving accurately weighed amino acid in buffer solution. Aqueous solution of periodate was standardized by iodometry (7) and preserved in brown bottles to prevent photochemical deterioration. Control experiments demonstrated that the short exposure of ultraviolet light at 310 nm used to take the readings did not cause significant decomposition of periodate.

Kinetic method

Reaction rates were measured by following the decrease of periodate concentration with time. A spectrophotometric procedure was used and the reactions were followed by measuring the absorbance at 310 nm of the unreacted periodate during the course of reaction at different time intervals as described in our previous paper (6). The runs were carried out in either a Pye-Unicam SP600 UV or a Shimazdu UV-240 spectrophotometer, with water-jacketted cell holders. Although the absorption maximum of periodate (8) is at 222 nm, this wavelength was not of practical use because of interfering absorption by other compounds in the reaction mixture. The molar absorptivities at 310 nm were obtained at all pH values used in the experiments. Reaction was followed in acid medium to ca. 80–90% conversion of the initial periodate concentration. Since the reaction becomes slow in basic medium, initial rates were determined in this pH range and the rates of duplicate runs were reproducible to ±10%.

Stoichiometry

Varying ratios of periodate to amino acid, keeping (periodate) > (amino acid) in all buffers, were allowed to stand until completion of the reaction. Estimation of residual oxidant (9) showed that 2 moles of periodate are consumed per mole of amino acid. Carbon dioxide and pyrrolid-2-one as the products of the reaction were detected (10). The reaction can be represented as:

$$+ CO_2 + H_2O + 2IO_3H$$

Results

The kinetics of oxidation of proline by periodate was investigated at several initial concentrations of the reactants in the pH range 1.40–8.83.

In acid medium at constant pH with the amino acid in excess, plots of log $(\text{periodate})_0/(\text{periodate})$ vs. time were linear,

*I = 0.200 M; t_C = 30.0°C.

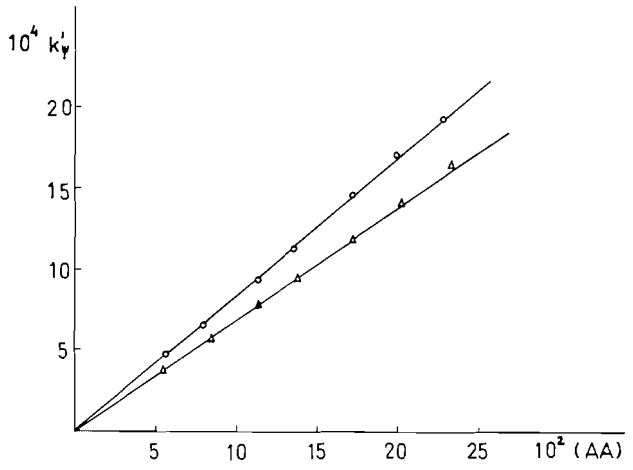

FIG. 1. Plot of k'_ψ vs. (AA); (Per) = 11.5 × 10^{-3} M; I = 0.200 M; t_C = 30.0°C; (○) pH = 4.94; (△) pH = 4.10.

indicating that the reaction is first-order in periodate concentration (Per). The pseudo first-order rate constants, k'_ψ, are given in Table 1. This was further confirmed by varying the periodate concentration, which did not show any change in the pseudo first-order rate constant (Table 1). The values of k'_ψ increase with amino acid concentration. Plots of log k'_ψ vs. log (amino acid)$_0$ are linear with a slope of unity, thus indicating a first-order dependence on the amino acid concentration (AA). Under these conditions the constancy of the second-order rate constants, k''_ψ was checked. Plots of k'_ψ against the amino acid concentration were linear (Fig. 1) with intercepts close to zero, and their slopes gave the second-order rate constants for the oxidation of amino acid.

In basic medium periodate was varied in the concentration range (10.0–5.00) × 10^{-3} M at fixed amino acid concentration (8.00 × 10^{-2} M). A plot of initial rates vs. (Per)$_0$ gave a straight line passing through the origin, indicating a first-order dependence on (Per). The pseudo first-order rate constant was obtained from the slope of the line (Table 2). The concentration of proline was varied in the range (23.0–5.00) × 10^{-2} M at constant initial periodate concentration (10.3 × 10^{-3} M). A plot of the initial rates vs. (AA)$_0$ gave a straight line passing through the origin, indicating a first-order dependence on (AA). The values of k''_ψ were obtained from the slopes of the lines (Table 2).

It was observed that pH changes have a marked effect on the rates of oxidation of the amino acid. The variation of the observed rate constants with pH is shown in Table 3. In this pH range the rate of oxidation in chloride, chloroacetate, acetate, and borate buffers at constant pH, is independent of the buffer concentration, but increased with increase in phosphate buffer concentration (Table 4). This acceleration is greater at pH 7.5 than at pH 6.5, suggesting that the reaction is subject to general base catalysis by HPO_4^{2-} ion. From the linear plots of the observed second-order constants against (HPO_4^{2-}) the value of k_B, the catalytic constant of HPO_4^{2-} was evaluated (Table 6).

In a separate set of experiments carried out in 1 M H_2SO_4, reaction mixtures with reactant concentrations as used in the kinetics were prepared. It was observed that no reaction occurred under these conditions.

Discussion

Amino acids exist as zwitterions in aqueous solution. The equilibria involved in acid and basic media are (11):

[1] $$^{+}H_2N\underset{AA^+}{\text{—R—}}COOH \overset{K_a}{\rightleftharpoons} H^+ + {}^{+}H_2N\underset{AA^{\pm}}{\text{—R—}}COO^- \overset{K_b}{\rightleftharpoons} HN\underset{AA^-}{\text{—R—}}COO^- + H^+$$

In aqueous periodate solutions, equilibria:

[2] $$H_5IO_6 \overset{K_1}{\rightleftharpoons} H_4IO_6^- + H^+$$

[3] $$H_4IO_6^- \overset{K_D}{\rightleftharpoons} IO_4^- + 2H_2O$$

[4] $$H_4IO_6^- \overset{K_2}{\rightleftharpoons} H_3IO_6^{2-} + H^+$$

[5] $$H_3IO_6^- \overset{K_3}{\rightleftharpoons} H_2IO_6^{3-} + H^+$$

have been detected (8) and several equilibrium constants determined.

The results suggest that the oxidation of proline by periodic acid involves multisteps. Since Δ^1-pyrroline has been reported to be formed during the course of reaction (10), for the purpose of the kinetic treatment, the following scheme can be proposed:

$$[6] \quad AA + Per \underset{k_-}{\overset{k}{\rightleftharpoons}} C_1$$

$$[7] \quad C_1 \xrightarrow{k_1} \Delta^1\text{-pyrroline} + CO_2 + HIO_3$$

$$[8] \quad \Delta^1\text{-pyrroline} + Per \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C_2$$

$$[9] \quad C_2 \xrightarrow{k_3} \text{pyrrolid-2-one} + HIO_3$$

We assume that the amino acid and periodate can reversibly form a complex (C_1) which decomposes to give the intermediates Δ^1-pyrroline, carbon dioxide, and iodate. Δ^1-pyrroline reacts with a second mole of periodate to give pyrrolid-2-one.

The observation of overall second-order kinetics under all conditions tested can be interpreted as an indication that there is no accumulation of a periodate – amino acid complex. We accept that the concentrations of C_1, Δ^1-pyrroline, and C_2 are low and that we can apply the steady-state approximation to them. In addition, if C_1 decomposes to products so rapidly that the rate of reaction is governed by the formation of C_1, i.e., $k_1 \gg k_-$, the kinetics expression for the reaction is:

$$[10] \quad -\frac{d(Per)}{dt} = k(AA)(Per)$$

This is in conformity with the orders in (AA) and (Per) as found experimentally.

To understand the process by which periodate oxidizes proline, it is necessary to know what species of periodate are active in this reaction. The pH dependence of the oxidation rate shown in Fig. 2, together with the pK values of Table 4, suggest that in the lower pH range (pH < 4) the oxidation of substrate must be brought about by the periodate monoanion (Per^-). Since in 1 *M* H_2SO_4 the reaction does not take place, we exclude the reaction of undissociated periodic acid (Per^0) with the protonated amino acid. It may be supposed that undissociated periodic acid does not react with the dipolar form of the amino acid either, or the probability of this reaction is low. Thus at pH < 4 we only consider reaction of periodate monoanion with the dipolar and protonated forms of amino acid, and the decline in rate constant around pH 4 as we get to higher acidities must be due to the decline in significance of the periodate monoanion in that region. Moreover, the reactivity of the protonated form of amino acid must not be high compared with that of the dipolar form. Then, moving to higher pH, where all amino acid is in the dipolar form, the decline in rate constant around pH 8 can only be due to the decline in the concentration of the reactive periodate species. This led us to consider that the reaction between the periodate dianion (Per^{2-}) and the dipolar amino acid is negligible and that the oxidation of substrate must be brought about by the periodate monoanion. In the pH range 4–8, where we must consider only reaction between dipolar amino acid and periodate monoanion, changes of rate constant are not expected and the increase in the rate in the pH range 6–8 can be attributed to the catalysis of the phosphate buffer.

In analyzing the variation of reaction rate with pH, we assume the effective reactants to be the monoanion ($H_4IO_6^- + IO_4^-$) of periodate and the protonated and dipolar ionic form of the amino acid. Thus, for the overall rate equation, we can write:

$$[11] \quad k'_\psi(Per)(AA) = k^0(Per^-)(AA^\pm) + k^+(Per^-)(AA^+)$$

where k^0 and k^+ represent the rate constants for reaction between periodate monoanion and zwitterion and protonated amino acid, respectively. Our kinetic treatment does not distinguish between the hydrated ($H_4IO_6^-$) and dehydrated (IO_4^-) forms of the periodate monoanion.

The total concentration of periodate (Per) and amino acid (AA) over the pH range studied are as follows:

$$[12] \quad (Per) = (Per^0) + (Per^-) + (Per^{2-})$$

$$[13] \quad (AA) = (AA^\pm) + (AA^+)$$

From dissociation equilibria [1]–[5] and eqs. [12] and [13], eq. [10] becomes:

$$[14] \quad -\frac{d(Per)}{dt} = k''_\psi(AA)(Per)$$

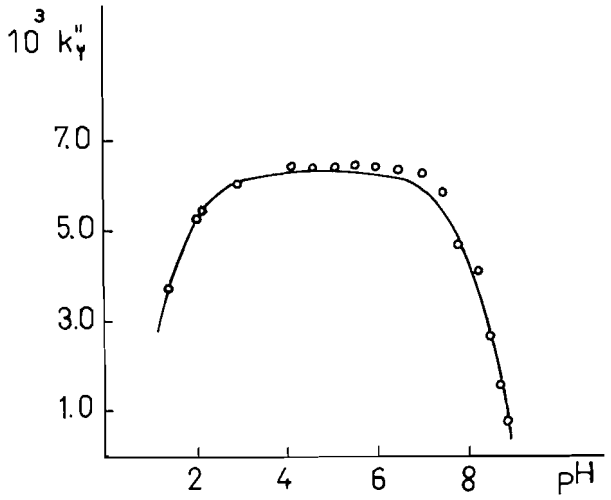

FIG. 2. Variation of the second-order rate constant with pH. The curve represents the dependence on pH calculated from eq. [15] and the points represent the observed rate constants (extrapolated to zero phosphate buffer concentration at pH 5.92–7.80). Experimental conditions in Table 3.

where

$$[15] \quad k''_\psi = \frac{k^0 K_1(H^+)}{(H^+)^2 + K_1(H^+) + K_1K_2}\frac{K_a}{(H^+) + K_a} + \frac{k^+ K_1(H^+)}{(H^+)^2 + K_1(H^+) + K_1K_2}\frac{(H^+)}{(H^+) + K_a}$$

To calculate the values of k^0 and k^+ in eq. [15], we will consider the various pH regions separately (Fig. 2). In treating the results we use values of K_1 and K_2, the apparent first and second dissociation constants of periodic acid (Table 5) expressed in terms of concentrations. They were determined for the ionic strength 0.200 M and 30.0°C from existing results (8).

At pH < 4 the term K_1K_2 is negligible if we compare it with $(H^+)^2$ and $K_1(H^+)$ and eq. [15] reduces to:

$$[16] \quad k''_\psi = \frac{k^0 K_1 K_a + k^+ K_1(H^+)}{(H^+)^2 + (H^+)(K_1 + K_a) + K_1K_a}$$

Using the values k''_ψ from Table 3 for pH < 4 and eq. [16] in the form:

$$[17] \quad k''_\psi f(H^+) = k^0 K_1 K_a + k^+ K_1(H^+)$$

where

$$[18] \quad f(H^+) = (H^+)^2 + (H^+)(K_1 + K_a) + K_1K_a$$

we obtain the values of k^0 and k^+ for the reaction. A plot of $k''_\psi f(H^+)$ vs. (H^+) gives a straight line. For the intercept and the slope of the line the values of 10^3k^0 = 5.85 L mol^{-1} s^{-1} and 10^3k^+ = 7.00 L mol^{-1} s^{-1} are obtained.

At pH 4.0–5.5 we consider all amino acid to be zwitterion. Under these conditions K_1K_2 and $(H^+)^2$ are insignificant compared to $K_1(H^+)$ and eq. [15] can be reduced to

$$[19] \quad k''_\psi = k^0$$

In this pH range k^0 equals k''_ψ and a constant value of k''_ψ would be expected, as found experimentally.

At pH > 5.5 where the amino acid is entirely zwitterion and $(H^+)^2$ is much lower than $K_1(H^+)$ and K_1K_2, eq. [15] reduces to:

$$[20] \quad k''_\psi = \frac{k^0(H^+)}{K_2 + (H^+)}$$

A plot of $k''_\psi(K_2 + (H^+))$ vs. (H^+) gives a straight line passing through the origin. From the slope of the line a value of 10^3k^0 = 6.40 L mol^{-1} s^{-1} was found. Since in the pH range 5.92–7.80, where phosphate buffer was used, a catalytic effect was observed, the values of k''_ψ used in the above plot were extrapolated to zero buffer concentration.

To verify rate law [15], we use it to calculate the rate constants as (H^+) varies with the constants in Table 6. The agreement between the k^0 value evaluated in neutral and basic media and those obtained from the acid region is reasonable, so

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

the mean values are used. The calculated values of k''_{ψ} are shown in Fig. 2 along with the experimental values.

In this treatment, it has been assumed that the reaction could be represented by a summation of bimolecular reactions, each involving one molecule of periodate monoanion and one molecule of amino acid either protonated or in the form of a zwitterion. The data agree with this assumption to within the experimental error.

To explain the general base catalysis we suggest that the intermediate C_1, in our reaction scheme, is cyclic, similar to that assumed to be formed between 1,2-diol, 1,2-diamines, or 1,2-aminoalcohols and periodate (2, 3) although their existence has not been demonstrated in many cases. It can be proposed, according to the treatment used by Buist *et al.* for pinacol oxidation (2*d*), that periodate monoanion and proline react reversibly to form an open-chain intermediate, C_1^*, which undergoes ring closure to a cyclic intermediate, C_1, which in turn decomposes rapidly to Δ^1-pyrroline. The general base catalysis can be attributed to the catalysis of the cyclization of the open-chain amino acid – periodate intermediate:

$$Per^- + AA^{\pm} \rightleftharpoons C_1^*$$

$$C_1^* + HPO_4^{2-} \rightleftharpoons C_1 + H_2PO_4^-$$

$$C_1 \rightarrow \Delta^1\text{-pyrroline}$$

It has been assumed that the formation of an open-chain intermediate is not general base catalysed, because this would require simultaneous reactions of amino acid, periodate, and catalyst, and such probability would be low. Since the breakdown of C_1 to products is intramolecular, the rate constant of this step is not dependent on base catalysis. The observation of general catalysis by phosphate at pH 6–8 indicates that the formation of cyclic intermediate C_1 is rate determining in this pH range. We have assumed that the formation of C_1 is rate determining over the entire pH range studied, but below pH 6 and above pH 8 where the rate is not affected by general catalysis an alternative explanation is that there is an equilibrium between C_1 and reactants and the decomposition of C_1 is rate determining. If the equilibrium constant is low, then second order kinetics will result. In both situations the rate constant is proportional to the concentration of the periodate monoanions and hence we can not discern between them.

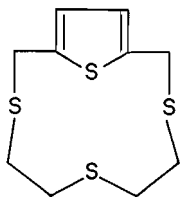
Received July 15, 1988

C. Robert Lucas, Shuang Liu, Michael J. Newlands, Jean-Pierre Charland, and Eric J. Gabe. Can. J. Chem. **67**, 639 (1989).

Preparations of the thiophenophane $C_{13}H_{20}S_5$, (L2), its binuclear copper(II) complex, $(CuCl_2 \cdot L2)_2$ and the related thiophenophane complex $(CuCl_2 \cdot L1)_2$ (L1 = $C_{10}H_{14}S_4$) are described. The ^{13}C and ^1H nmr spectra of L2 and the ir and electronic spectra of the complexes are reported. The molecular structures of L2, $(CuCl_2 \cdot L1)_2$, and $(CuCl_2 \cdot L2)_2$ have been determined. For L2: space group $P2_1/a$, a = 14.658(1), b = 5.9800(3), c = 19.772(2) Å, β = 111.00(1)°, Z = 4, R_f = 0.050, R_w = 0.046. For $(CuCl_2 \cdot L1)_2$: space group $Pbca$, a = 15.383(6), b = 11.409(3), c = 17.423(4) Å, Z = 4, R_f = 0.057, R_w = 0.036. For $(CuCl_2 \cdot L2)_2$: space group A_2/a, a = 12.616(1), b = 10.0542(6), c = 29.180(2) Å, β = 95.81(1)°, Z = 4, R_f = 0.055, R_w = 0.038. The complex $(CuCl_2 \cdot L1)_2$ has distorted octahedral coordination geometry about each copper. The copper atoms are linked by two bridging chlorines and each copper also bears one terminal chlorine, two thioether-sulfurs and a thiophene-sulfur. In contrast, $(CuCl_2 \cdot L2)_2$ does not involve coordination by thiophene-sulfur and the remaining coordination sphere has undergone distortion from square pyramidal towards trigonal bipyramidal. Differences in the electronic spectra are interpreted in terms of the structures of the complexes.

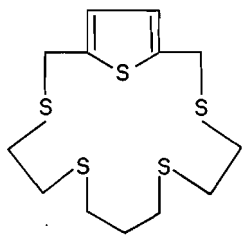
Key words: binuclear copper(II) thiophenophane complex.

C. Robert Lucas, Shuang Liu, Michael J. Newlands, Jean-Pierre Charland et Eric J. Gabe. Can. J. Chem. **67**, 639 (1989).



On décrit la préparation du thiophénophane $C_{13}H_{20}S_5$(L2), de son complexe binucléaire du cuivre(II), $(CuCl_2 \cdot L2)_2$, et du complexe apparenté [$(CuCl_2 \cdot L1)_2$ (L1 = $C_{10}H_{14}S_4$)] du thiophénophane. On a déterminé les spectres rmn du ^1H et du ^{13}C du L2 ainsi que les spectres ir et électroniques des complexes. On a déterminé les structures moléculaires du L2, du $(CuCl_2 \cdot L1)_2$ et $(CuCl_2 \cdot L2)_2$. Pour L2: groupe d'espace $P2_1a$, a = 14,658(1), b = 5,9800(3) et c = 19,772(2) Å, β = 111,00(1)°, Z = 4, R_f = 0,050 et R_w = 0,046. Pour $(CuCl_2 \cdot L1)_2$: groupe d'espace $Pbca$, a = 15,383(6), b = 11,409(3) et c = 17,423(4) Å, Z = 4, R_f = 0,057 et R_w = 0,036. Pour $(CuCl_2 \cdot L2)_2$: groupe d'espace A_2/a, a = 12,616(1), b = 10,0542(6) et c = 29,180(2) Å, β = 95,81(1)°, Z = 4, R_f = 0,055 et R_w = 0,038. Le complexe $(CuCl_2 \cdot L1)_2$ possède une géométrie de coordination octaédrique déformée autour de chaque cuivre. Les atomes de cuivre sont liés par deux chlores agissant comme ponts et chaque atome de cuivre porte aussi un chlore terminal, deux soufres de thioéthers et un soufre de thiophène. Par ailleurs, le $(CuCl_2 \cdot L2)_2$ n'implique par de coordination avec un soufre de thiophène et le reste de la sphère de coordination a subi une déformation de la pyramide carrée vers une bipyramide trigonale. On explique des différences dans les spectres électroniques en fonction des structures des complexes.

Mots clés : complexe binucléaire du cuivre(II) du thiophénophane.



[Traduit par la revue]

Introduction

We have recently reported the preparation and some properties of the ligand, L1, and its copper(I) complex $[Cu(L1)_2]^+$ (1). As a continuation of that study, we now describe the synthesis of the thiophenophane, L2, which has a larger cavity and greater flexibility than L1, and of copper(II) complexes with L1 and L2. One of these, $(CuCl_2 \cdot L1)_2$ shows evidence of interaction between sulfur in the thiophene ring and the copper atom. Sulfur-bound thiophene complexes are rather rare although examples with iron (2), ruthenium (3), silver(I) (4), and copper(I) (5) are known. To our knowledge the present example is the first involving copper(II). Complexes of thiophene are of interest in the study of catalytic hydrodesulfurization of fossil fuels and in particular of coal (6).

L1

L2

Experimental

Commercially available reagents were obtained from the Aldrich Chemical Co. Inc. or from Morton Thiokol, Alfa Products Inc., and were used without further purification. We have previously described the preparation of L1 (1). Spectroscopic data were obtained using the following instruments: ir, Perkin Elmer Model 283; nmr, General Electric 300-NB; mass spectra, V.G. micromass 7070 HS. X-ray diffraction data were collected using an Enraf Nonius CAD-4 or a Picker ($(CuCl_2 \cdot L1)_2$) diffractometer. Analyses were performed by Canadian Microanalytical Service Ltd.

Preparative

(a) $C_{13}H_{20}S_5$ (ligand L2)

The 2,5-bis(chloromethyl)thiophene (8) used in this preparation

must be purified or the overall yield of L2 will be low. Purification can be achieved by washing the crude brown liquid with saturated sodium carbonate solution and then water until the washings are neutral, drying over anhydrous $MgSO_4$, and recrystallizing from petroleum ether. Sodium (0.92 g, 40 mmol) was dissolved in commercial absolute ethanol (500 mL) under an atmosphere of dry nitrogen and 1,4,8,11-tetrathiaundecane (7) (4.57 g, 20 mmol) was added slowly. The mixture was refluxed for a further 10 min. To the refluxing mixture, a solution of purified 2,5-bis(chloromethyl)thiophene (3.62 g, 20 mmol) (8) was added dropwise with stirring over 8 h and the refluxing and stirring were continued for a further 4 h. Volatiles were removed on a rotary evaporator, the residue extracted with CH_2Cl_2, washed with water several times, dried over anhydrous $CaCl_2$, and taken to dryness. The yellow solid was recrystallized twice from benzene to give white needles. Melting point 128–129°C. Yield 3.2 g (47%). Mass spectrum: parent ion 336 $[C_{13}H_{20}S_5]^+$. Nuclear magnetic resonance ($CDCl_3$, ppm from TMS int. std., assignments from ^{13}C—^1H heteronuclear correlation and attached proton test, position identification from Fig. 1), ^{13}C: 142.6 Cl—C4, 125.7 C2—C3, 32.0 C7—C11, 31.6 C6—C12, 31.5 C9, 31.34 C8—C10, 31.27 C5—C13; ^1H: 6.78 (s, 2H) C2—C3, 3.90 (s, 4H) C5—C13, 2.67 (m, 4H) C6—C12, 2.57 (m, 4H), 2.46 (t, J = 7.52 Hz, 4H), C8—C10, 1.69 (m, 2H) C9.

(b) $(CuCl_2 \cdot L1)_2$

To a solution of $CuCl_2 \cdot 2H_2O$ (42.6 mg, 0.250 mmol) in acetonitrile (15 mL) was added a solution of ligand L1 (100 mg, 0.381 mmol) in CH_2Cl_2 (5 mL). The deep green solution was filtered and then allowed to evaporate gradually until dark green crystals formed. Yield 70 mg (71%), mp 132–135°C (dec). Infrared: (Nujol mull) 1430(m), 1412(m), 1349(w), 1292(m), 1252(sh), 1250(m), 1232(m), 1209(m), 1180(m), 1133(w), 1114(w), 1095(w), 1035(m), 1019(w), 1000(m), 940(vw), 928(w), 918(w), 872(m), 860(m), 845(m), 832(vs), 776(m), 740(vw), 719(w), 700(m), 690(s), 681(s), 674(m), 652(w), 635(w), 574(m), 482(m), 453(vw), 400(vw), 305(vs), 270(sh), 252(m), 244(s), 232(sh) cm^{-1}. *Anal.* calcd. for $C_{20}H_{28}Cl_4Cu_2S_8$: C 30.26, H 3.56; found: C 30.38, H 3.56.

(c) $(CuCl_2 \cdot L2)_2$

A procedure similar to that above was followed with $CuCl_2 \cdot 2H_2O$ (42.6 mg, 0.250 mmol) in tetrahydrofuran (10 mL) and ligand L2 (84.0 mg, 0.250 mmol) in the same solvent (5 mL). Yield of green crystals 95 mg (81%). Melting point 123–125°C (dec). Infrared: (Nujol mull) 1438(sh), 1410(s), 1390(s), 1345(m), 1300(m), 1255(sh), 1245(s), 1230(m), 1190(m), 1180(m), 1132(w), 1128(m), 1108(m), 1098(m), 1025(s), 960(w), 938(m), 860(m), 849(w), 830(w), 810(vs), 775(s),

X-ray studies

A summary of crystal data for L2, $(CuCl_2 \cdot L1)_2$, and $(CuCl_2 \cdot L2)_2$ is in Table 1. The diffraction intensities were collected at 295 K using the $\theta/2\theta$ scan technique (ω scan mode for L2) with profile analysis (9) at a scan speed of 4°/min. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Space groups were determined by systematic absences. Unit cell parameters in Table 1 were obtained by a least-squares refinement of the setting angles for 26 reflections ($88° \leq 2\theta \leq 117°$) for L2; 50 reflections ($40° \leq 2\theta \leq 50°$) for $(CuCl_2 \cdot L1)_2$ and 21 reflections ($7° \leq 2\theta \leq 23°$) for $(CuCl_2 \cdot L2)_2$. Lorentz and polarization factors were applied but no corrections were made for absorption.

The structures were solved with MULTAN (10) plus a difference Fourier map and refined by full matrix least-squares with counting statistics weights. H-atom positions were calculated but their parameters were not refined. All heavier atoms were refined anisotropically. All calculations were performed with the NRCVAX Crystal Structure programs (11). Scattering factors were taken from the International tables for X-ray crystallography (12). The final atomic positional parameters, the equivalent isotropic temperature factors and important bond lengths and angles are listed in Tables 2–7. Anisotropic thermal parameters, a full listing of bond lengths and bond angles and final structure factors are available as supplementary data.[3] Figures 1–4 show various views of the molecules and their atomic numbering schemes.

Results and discussion

Synthesis of L2 was carried out in 47% yield by a traditional high dilution S_N2 cyclization (equation [1]) similar to that which we reported earlier (1) for L1.

[1] 

As noted during preparation of L1, decreased yields of L2 also occur when impurities are present in the reagents (see Experimental).

The macrocyclic ligands L1 and L2 have constraints imposed upon the size and shape of their cavities and upon the orientations of non-bonding electron pairs of their thioether sulfur atoms. These constraints are a result of the rigidity of the thiophene sub-unit and its two adjacent methylene groups which limits the overall flexibility of the macrocyclic ring. For L1, the consequence is a ring cavity which although large enough to accommodate a first row transition metal such as copper, does not do so because the orientation of non-bonding electron pairs on the thioether-sulfurs is exocyclic and because approach to the cavity is hindered on both sides by hydrogen atoms. As a result, L1 acts as a bidentate ligand to Cu(I), forming $[Cu(L1)_2]ClO_4$ (1). In this report we examine the behaviour of L1 with Cu(II), in order to ascertain whether the chelating mode of bonding and other structural features of coordinated L1 are retained as the oxidation state of the central metal is changed. We then examine the effect on structural and spectroscopic properties of increased aliphatic chain length and flexibility and increased cavity size. As noted previously (1), the Cu(I) state is sufficiently stabilized by L1 that preparation of a Cu(II) complex can only be accomplished in solvents free from alcoholic or other easily oxidized components. Thus the Cu(II) complex of L1, $(CuCl_2 \cdot L1)_2$ was prepared in mixed acetonitrile–dichloromethane while that of L2, $(CuCl_2 \cdot L2)_2$, was obtained from tetrahydrofuran. The conformation of L1 in $(CuCl_2 \cdot L1)_2$ is essentially the same as that found in $[Cu(L1)_2]^+$ (1) and compared to uncomplexed L1, the main differences occur at S3 and C8 where inversions have taken place to orient the non-bonding electron pairs on S2 and S3 so that a chelate ring may form using these donor sites (Fig. 3).

Two views of L2 are shown in Figs. 1 and 2. The macrocycle's cavity is large (~4.8 × ~8.0 Å) but like L1, its cavity is inaccessible and unsuitable for complex formation, at least in the conformation of the free ligand. All electron pairs on thioether-sulfurs are exocyclic and the cavity is shielded on one side by hydrogens on C6, C9, and C12 and on the other by many hydrogens. As a result, complex formation (Fig. 4) occurs by conformational change within the flexible thioether chain so that the adjacent sulfurs, S2 and S3, may engage in chelation. The behaviour of L1 and L2 as ligands is therefore similar in spite of their differences in structure.

The complex, $(CuCl_2 \cdot L1)_2$ has two Cu(II) centres, the coordination geometry being the same at both. Each copper is surrounded by two chlorine-bridges to the other copper atom. One of these bridge-chlorines occupies a position on the tetragonal axis of a copper atom while the other bridge-chlorine occupies an equatorial site. The remaining three equatorial sites are occupied by a terminal chlorine and two adjacent sulfur atoms from L1. The molecule is centrosymmetric and thus the two terminal Cu—Cl bonds project on opposite sides of the

[a]Symmetry related atoms in the other half of the molecule have the parameters $-x, -y, 2 - z$.

[b]B_{iso} is the mean of the principal axes of the thermal ellipsoid.

Cu_2Cl_2 plane and the same is true for the macrocyclic ligands. All but one of the bond angles at Cu deviate less than 10° from ideal values with the largest deviation being 10.89° at Cl(1)—Cu—Cl(2′). Each copper atom lies 0.09 Å above the least-squares plane of its four nearest neighbours. The bridging Cu—Cl distances are 2.702(3) Å (axial) and 2.321(3) Å (equatorial) while the terminal Cu—Cl length is 2.234(3) Å. Angles at the chlorine bridgeheads are 86.87(10)° and the Cu—Cu distance is 3.464(7) Å. Corresponding distances and angles in the open chain chelate $(CuCl_2 \cdot BBTE)_2$ (13) (BBTE = $BuSCH_2CH_2SBu$) are 2.825(2) (axial), 2.266(2) (equatorial), 2.242(2) Å (terminal) while the chlorine bridgehead angle is 94.22(5)° and the Cu—Cu distance is 3.749(2) Å. The two complexes, $(CuCl_2 \cdot L1)_2$ and $(CuCl_2 \cdot BBTE)_2$, are superficially similar in the number and type of atoms bonded to copper but there are structural differences associated mainly with the Cu—Cu and Cu—Cl distances and associated angles. In fact, the structure of $(CuCl_2 \cdot L1)_2$ corresponds well to that of a fragment of cupric chloride consisting of two coppers and four chlorines from two adjacent bands in the band structure of anhydrous cupric chloride (14). In that structure, each copper is surrounded by four chlorines at 2.30 Å in a two-dimensional $(CuCl_2)_n$ band and by two more chlorines from adjacent bands at a distance of 2.95 Å to give a tetragonally distorted octahedral array. In $(CuCl_2 \cdot L1)_2$, the bridge angles at Cl are close to 90° as at the interband bridgehead in cupric chloride and the bridging equatorial Cu—Cl length is within 0.02 Å of the corresponding length in cupric chloride. The terminal Cu—Cl length of 2.23 Å is shorter than the 2.30 Å found in cupric chloride because the bond is terminal in $(CuCl_2 \cdot L1)_2$, not bridging as in cupric chloride. The axial Cu—Cl length of 2.70 Å in $(CuCl_2 \cdot L1)_2$ is significantly shorter than the 2.95 Å found in cupric chloride due to the absence of the *trans* influence of a second Cl on the tetragonal axis of $(CuCl_2 \cdot L1)_2$.

The Cu—S distances in $(CuCl_2 \cdot L1)_2$ are 2.349(3) and 2.358(3) Å compared to 2.308(2) and 2.369(2) in $(CuCl_2 \cdot BBTE)_2$ or 2.289–2.398 Å in $Cu^{II}([15]aneS_5)$ (15). Interestingly, the tetrahedral copper(I) complex ion $[Cu(L1)_2]^+$ also has Cu—S bond lengths in the range 2.301 to 2.392 Å which suggests that the Cu—S bond length is not very sensitive to oxidation state or coordination geometry unless, fortuitously, the two are having equal but opposite effects in this instance.

The thiophene-sulfur of L1 lies on the tetragonal axis of $(CuCl_2 \cdot L1)_2$ at a distance of 3.013(7) Å from copper. The covalent radius of divalent sulfur is 0.03 Å larger than that of chlorine (16) and following the analogy between the structures of anhydrous cupric chloride and $(CuCl_2 \cdot L1)_2$, the expected distance from copper to a coordinated thiophene-sulfur would be 2.98 Å. The observed distance is reasonably close to that predicted and significantly less than 3.20 Å which is the sum of the van der Waals radii (16). Shortening of the Cu—Cl(2)′ bond

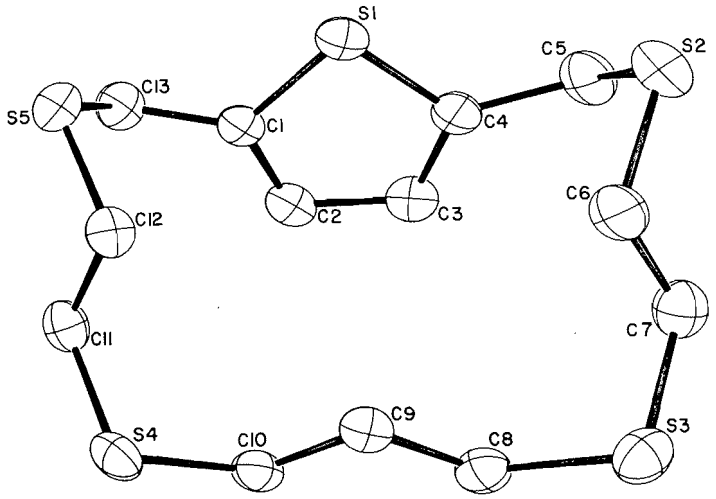

FIG. 1. ORTEP drawing of L2.

(2.702(3) Å) in $(CuCl_2 \cdot L1)_2$ compared to the corresponding bond (2.95 Å) in cupric chloride suggests a weaker *trans* influence by thiophene-sulfur than by a chlorine atom. Furthermore, in $(CuCl_2 \cdot L2)_2$ where the corresponding Cu—S distance is 3.307(9) Å, thiophene-sulfur is clearly too far away to be considered bonded to copper and the Cu—Cl distance *trans* to it is even shorter (2.661(4) Å). On these grounds, it seems reasonable to assume a bonding interaction between copper and thiophene-sulfur in $(CuCl_2 \cdot L1)_2$ and thus the coordination geometry of copper in $(CuCl_2 \cdot L1)_2$ is best regarded as distorted octahedral.

Thiophene does not usually form strong bonds through its

[a]Symmetry related atoms in the other half of the molecule have the parameters x, $0.5 - y$, $0.5 - z$.

[b]B_{iso} is the mean of the principal axes of the thermal ellipsoid.

sulfur atom to transition metals and there are very few structural reports with which $(CuCl_2 \cdot L1)_2$ may be compared. Recent studies of iron (2), silver (5), and copper(I) (4) thiophene complexes, however, suggest that a Cu—S (thiophene) bond length between 2.96 and 3.16 Å might be expected which compares favourably with the Cu—S distance we have observed. It should be noted, however, that the angles Cu—S(1)—C(1) and Cu—S(1)—C(4) are 136.8(4)° and 90.87(8)°, respectively, which reveal that the bonding between copper and thiophene is asymmetric and strained. Spectroscopic evidence (*vide infra*) supports our conclusion that the thiophene sulfur in $(CuCl_2 \cdot L1)_2$ is coordinated to copper.

For $(CuCl_2 \cdot L2)_2$, the coordination geometry is somewhat different. Additional atoms in the macrocycle make it possible for the thiophene-sulfur to lie further from copper in $(CuCl_2 \cdot L2)_2$ (3.307(9) Å) than in $(CuCl_2 \cdot L1)_2$ (3.013(7) Å) so that the geometry about each copper atom in $(CuCl_2 \cdot L2)_2$ is approximately square pyramidal. The reduced crowding near copper that results from the retreat of the thiophene-sulfur makes it possible for both S3 and Cl1 to swing down ~12° below the basal plane of an idealized square pyramid. The dimeric molecule is centrosymmetric and each copper atom lies 0.42 Å out of the least-squares plane defined by Cl1, Cl2′, and S3. If viewed as a trigonal bipyramid, the angles at copper between axial and equatorial positions deviate less than 10° from the ideal of 90° but the angles within the equatorial plane are the sites of great molecular distortion. They have values of 101.69(15)°, 102.01(15)°, and 153.12(17)° and it is readily apparent that the first two arise from ~12° distortion from the ideal value for a square pyramid. Thus, this structure is probably better regarded as a slightly distorted square pyramid than as a grossly distorted trigonal bipyramid. Apparently, the preferred geometry about copper(II) of this S_2Cl_3 ligand donor-set is trigonal bipyramidal but in the presence of coordination by thiophene-sulfur and the resulting steric crowding in $(CuCl_2 \cdot L1)_2$, a square pyramidal configuration is adopted. As crowding decreases upon changing to $(CuCl_2 \cdot L2)_2$, the square pyramidal structure begins to distort towards trigonal bipyramidal.

The Cu—S (thioether) distances in $(CuCl_2 \cdot L2)_2$ are 2.355(5) and 2.358(4) Å and Cu—Cl distances of 2.661(4) (bridging), 2.277(4) (bridging), and 2.265(4) Å (terminal) are similar to the corresponding distances in $(CuCl_2 \cdot L1)_2$. Angles at the chlorine bridgeheads are 90.94(14)° compared to 86.87(10)° in $(CuCl_2 \cdot L1)_2$ and the Cu—Cu distance is 3.530(4) Å compared to 3.464(7) Å in $(CuCl_2 \cdot L1)_2$.

Thus, the structures of $(CuCl_2 \cdot L1)_2$ and $(CuCl_2 \cdot L2)_2$ are superficially similar. Both resemble a fragment from the band structure of anhydrous cupric chloride to which S-donor ligands have been appended. In $(CuCl_2 \cdot L1)_2$ the coordination is distorted octahedral with one of the donor atoms being a thiophene-sulfur. The remaining S_2Cl_3 donor-set achieves a square pyramidal geometry with only slight distortion. In

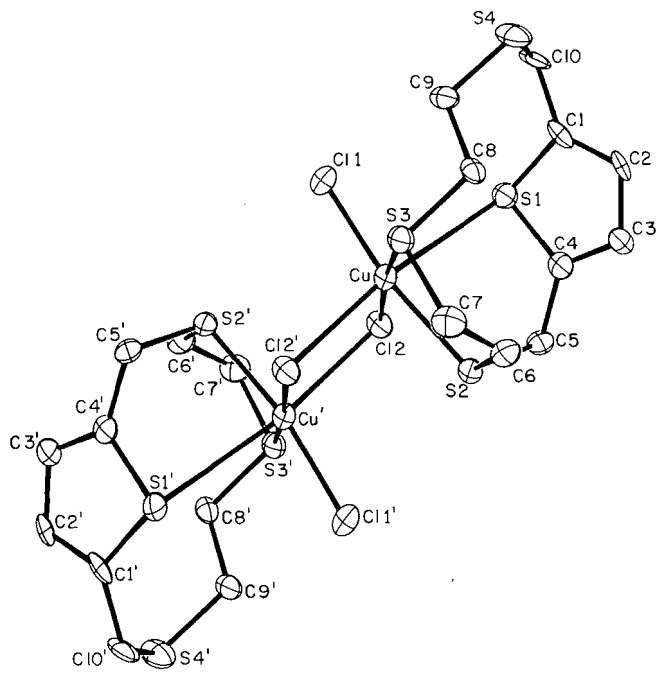

FIG. 3. ORTEP drawing of $(CuCl_2 \cdot L1)_2$.

$(CuCl_2 \cdot L2)_2$ the thiophene is not bonded and the S_2Cl_3 donor set has distorted ~12° from square pyramidal towards trigonal bipyramidal at the two basal sites S3 and Cl1.

The ir spectra of both complexes exhibit strong bands at ~300 and ~250 cm^{-1} that are absent from spectra of the free ligand and analogous copper(I) complexes (1). These bands are assigned to Cu—Cl vibrations. The double chlorine bridge in $[CuCl_3]_2^{2-}$ has ir-active Cu—Cl stretching modes at 236 and 193 cm^{-1} that are weaker and lower in energy than its terminal Cu—Cl stretches at 301 and 278 cm^{-1} (17). By comparison, the higher energy, more intense bands near 300 cm^{-1} in spectra of $(CuCl_2 \cdot L1)_2$ and $(CuCl_2 \cdot L2)_2$ are assigned to terminal Cu—Cl stretches and those near 250 cm^{-1} are also assigned to a Cu—Cl stretch but specific assignment to a terminal or bridge vibration is more problematical and has not been attempted.

Details of the electronic spectra are in Table 8 and are similar to those of the distorted square pyramidal CuS_2Cl_3 unit in $(CuCl_2 \cdot BBTE)_2$ (18). The lowest energy band in spectra of both $(CuCl_2 \cdot L1)_2$ and $(CuCl_2 \cdot L2)_2$ is an envelope of unresolved *d—d* transitions, no further absorptions being detected up to 2000 nm. Changes from a distorted CuS_3Cl_3 chromophore in $(CuCl_2 \cdot L1)_2$ towards distorted square pyramidal CuS_2Cl_3 in $(CuCl_2 \cdot BBTE)_2$ and $(CuCl_2 \cdot L2)_2$ have little effect on the energy of the charge transfer bands. They do, however, shift the maximum of the ligand field band envelope to longer wavelength. This shift is

probably due to changes in the relative intensities of the unresolved *d*—*d* transitions. That transition having the highest intensity has the longest wavelength in trigonal bipyramidal geometry but the opposite is true in square pyramidal or octahedral geometry (19). Spectra of $(CuCl_2 \cdot L1)_2$ are almost unaffected by changes in solvent in contrast to the noticeable effect of solvent on the ligand field band of $(CuCl_2 \cdot L2)_2$. Furthermore, the ligand field band of $(CuCl_2 \cdot L1)_2$ in all solvents used in this study is close to the energy of the corresponding band in the spectrum of $(CuCl_2 \cdot BBTE)_2$ recorded in the solid state or in the non-coordinating solvent CH_2Cl_2. These observations imply that solvent has little effect on the ligand field experienced by copper in $(CuCl_2 \cdot L1)_2$ but a significant effect upon that experienced by copper in $(CuCl_2 \cdot L2)_2$. Therefore, these spectral results support the conclusions concerning coordination of thiophene-sulfur obtained from our structural studies. Thus, in $(CuCl_2 \cdot L1)_2$, thiophene-sulfur occupies a coordination site on the copper atom in both the solid and in solution. In $(CuCl_2 \cdot L2)_2$, however, thiophene-sulfur is not coordinated to the metal in either the solid or in solution and solvent influence on the ligand field experienced by the metal is occurring presumably via the vacant octahedral site. In this regard, it may be noted that the shift in wavelength of the ligand field band of $(CuCl_2 \cdot L2)_2$ parallels the change in ligand field strength of the solvent. A strong absorption at 260 nm due to the thiophene portion of the organic ligand (thioether bands are expected at 194 and 215 nm) (20) obscures the highest energy Cl $\rightarrow d_{x^2-y^2}$ LMCT band which should appear in the same region (18).

Relationships between structure and redox properties of these compounds is a subject of our continuing studies.

Excess molar volumes, speeds of sound, and isentropic compressibilities of binary mixtures of furfural with some aliphatic alcohols

HOMENDRA NAOREM, NAND KISHORE, AND S. K. SURI[1]

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi-110016, India

Received August 17, 1988

HOMENDRA NAOREM, NAND KISHORE, and S. K. SURI. Can. J. Chem. **67**, 648 (1989).

Excess molar volumes and isentropic compressibilities for the binary mixtures of furfural with methanol, ethanol, 1-propanol, 2-propanol, 1-butanol, and 2-butanol have been computed from the experimentally measured densities and sound speeds at 308.15 K over the entire composition range. All the systems studied exhibit contraction on mixing. The results have been discussed in terms of the specific interactions between the component molecules of the binary mixtures.

Key words: excess molar volumes, isentropic compressibilities, furfural, aliphatic alcohols, unlike reactions.

HOMENDRA NAOREM, NAND KISHORE et S. K. SURI. Can. J. Chem. **67**, 648 (1989).

Utilisant les densités et les vitesses du son mesurées expérimentalement, à 308,15 K, sur l'ensemble des compositions des mélanges, on a calculé les volumes molaires en excès ainsi que les compressibilités isentropiques des mélanges binaires du furfural avec le méthanol, l'éthanol, les propanols-1 et -2 et les butanols-1 et -2. Dans tous les systèmes étudiés, les mélanges provoquent une contraction. On discute des résultats en fonction d'interactions spécifiques entre les molécules qui composent les mélanges binaires.

Mots clés : volumes molaires en excès, compressibilités isentropiques, furfural, alcools aliphatiques, réactions dissemblables.

1. Introduction

The thermodynamic properties of binary mixtures containing a self-associated component exhibit a significant deviation from ideality, arising not only from differences in molecular size but also from the changes in the hydrogen bonding between like and unlike molecules. As an extension to our studies on the thermodynamic properties of binary mixtures containing a self-associated component (1–3), the excess molar volumes, V^E, and the isentropic compressibilities, k_s, of binary mixtures of furfural with six aliphatic alcohols, namely, methanol, ethanol, 1-propanol, 2-propanol, 1-butanol, and 2-butanol have been determined at 308.15 K over the entire composition range and reported in this paper. These studies are aimed to provide information on the binary mixtures with a view to understanding the nature of interactions present in these mixtures.

2. Experimental

Analytical reagent grade samples of methanol, ethanol, 1-butanol and 2-butanol supplied by E. Merck and Laboratory reagent grade samples of 1-propanol and 2-propanol supplied by BDH were purified by following the standard established procedures (4). The sample of furfural was essentially the one used for our earlier studies (5). The liquids were stored in brown bottles and fractionally distilled immediately before use. The densities (ρ) and refractive indexes of the purified liquids agreed closely with the accepted literature values (4, 6).

The excess molar volumes of mixing have been calculated from the experimental density data. The solutions for the measurement of densities were prepared by weight and correction for buoyancy were applied. The details of experimental techniques for the preparation of solutions have been described elsewhere (7). The densities were measured using a vibrating tube flow densimeter (Model DMA 60/602 Anton Paar, Austria). Water from a thermostat was circulated through the densimeter module at a flow rate of 2–3 L min^{-1}. The temperature of the thermostat was maintained at ±0.01 K by using a precision temperature controller. The densimeter was calibrated with nitrogen gas and degassed ion exchanged water by using the densities of Kell (8). Duplicate densities of liquids and the liquid mixtures were reproducible to within 5×10^{-5} g cm^{-3}. An analysis of experimental uncertainties lead to the conclusion that the reported excess volumes of mixing are within ±0.008 cm^3 mol^{-1}.

TABLE 1. Values of the parameters in eq. [1] and standard deviation $\sigma(V^E)$

Furfural +	A_0	A_1	A_2	A_3	$\sigma(V^E)$
Methanol	−0.8247	−0.2498	0.1868	−0.0776	0.003
Ethanol	−0.7455	−0.2663	−0.0079	0.0329	0.002
1-Propanol	−0.6693	−0.3768	0.0369	0.1233	0.002
2-Propanol	−0.3100	−0.0408	0.1089	0.0489	0.002
1-Butanol	−0.5972	−0.2274	0.2008	0.1636	0.005
2-Butanol	−0.1351	−0.1193	0.0676	0.1650	0.004

The isentropic compressibilities were computed from the ultrasonic speeds of sound, u, using the relation:

$$k_s = (u^2\rho)^{-1}$$

The speeds of sound were measured using a single crystal interferometer (Model F-81, Mittal Enterprises, New Delhi, India) operating at a frequency of 2 MHz. The maximum error in the measurement of u was estimated to be around 0.15%. This renders the k_s values uncertain by ±2 T Pa^{-1}.

Results and discussion

The experimental data[2] on excess molar volumes were fitted to smoothing equation:

$$[1] \quad V^E/(cm^3\,mol^{-1}) = x(1-x)\sum_{i=0}^{n} A_i(2x-1)^i$$

Where x is the mole fraction of furfural in the mixture. The parameters A_i evaluated by the method of least squares (unweighted) are recorded in Table 1 along with the standard deviation $\sigma(V^E)$. Since the $\sigma(V^E)$ values in all the systems studied are less than the experimental uncertainty, the constants

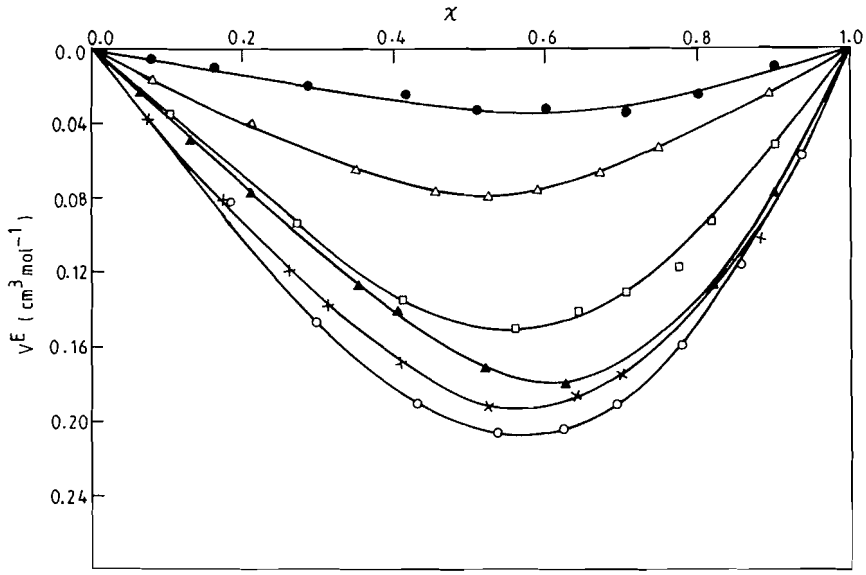

FIG. 1. Molar excess volumes, V^E, at 308.15 K for the binary mixtures of furfural with (○) methanol, (×) ethanol, (▲) 1-propanol, (△) 2-propanol, (□) 1-butanol, and (●) 2-butanol.

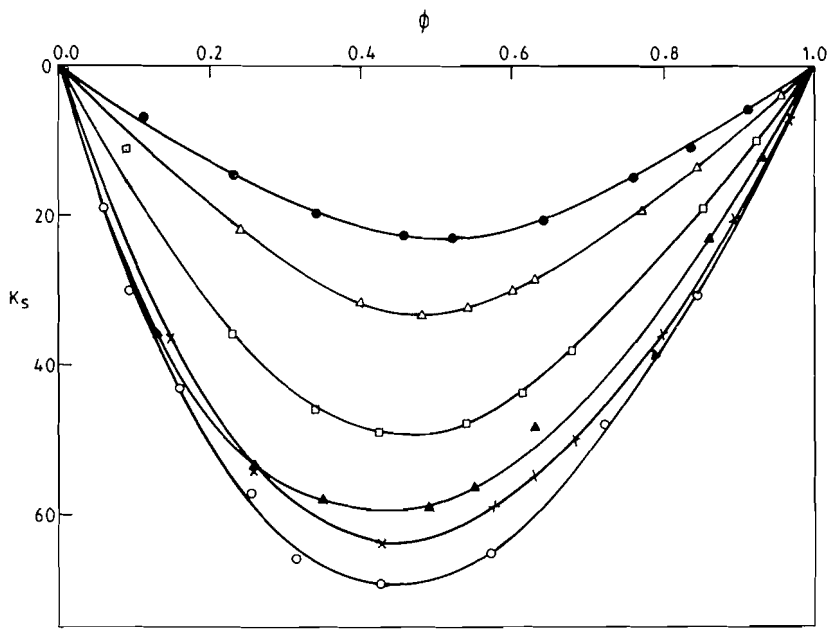

FIG. 2. Values of K_s against volume fraction of furfural for the binary mixtures of furfural with (○) methanol, (×) ethanol, (▲) 1-propanol, (△) 2-propanol, (□) 1-butanol, and (●) 2-butanol at 308.15 K.

of eq. [1] can be taken to represent experimental results. The graphical representation of the results are shown in Fig. 1.

The deviation in the isentropic compressibilities K_s of binary mixtures were computed from the experimentally determined isentropic compressibilities using the expression:

$$[2] \quad K_s = k_s - \phi k_{s,1} - (1 - \phi)k_{s,2}$$

where ϕ is the volume fraction of furfural in the binary mixtures, k_s, $k_{s,1}$ and $k_{s,2}$ are the isentropic compressibilities of the liquid mixture, furfural, and alcohols, respectively. The variation of K_s with the volume fraction of furfural in the binary mixtures are shown in Fig. 2. The K_s values thus obtained have been fitted to the polynomial:

$$[3] \quad K_s = \phi(1 - \phi)[B_0 + B_1(2\phi - 1) + B_2(2\phi - 1)^2 + B_3(2\phi - 1)^3]$$

The parameters B_0, B_1, B_2, and B_3 determined by the method of least squares (unweighted) are given in Table 2, along with the standard deviation $\sigma(K_s)$.

To the best of our knowledge there is no data available in the reported literature for the V^E and K_s of any of the binary mixtures under investigation to compare with our results.

It is observed from Fig. 1 that all the binary mixtures studied exhibit contraction on mixing over the entire composition range. The excess molar volumes at equimolar concentration, $V^E_{0.5}$ increases in the order: methanol < ethanol < 1-propanol

TABLE 2. Values of parameters of eq. [3] and standard deviation $\sigma(K_s)$

Furfural +	B_0	B_1	B_2	B_3	$\sigma(K_s)$
Methanol	−270	64	−24	13	2
Ethanol	−253	80	4	−87	2
1-Propanol	−231	54	41	53	3
2-Propanol	−134	85	89	−283	3
1-Butanol	−201	62	89	−103	1
2-Butanol	−93	3	30	−8	1

< 1-butanol < 2-propanol < 2-butanol. The large negative excess volume for the binary mixtures containing methanol (Fig. 1) indicate that the volumetric effects arising from the unlike interactions between furfural and methanol supercedes the positive contribution to V^E due to the structure breaking of the polymer aggregates of methanol. The self-associated polymer aggregates of higher alcohols are relatively easier to break and are associated with the relatively smaller volumetric effects. Also, the hydrogen bond energy between the hydroxyl group of the alcohol and the hydrogen acceptor oxygen of furfural and consequently the volumetric effects arising therefrom decrease with the increasing alkyl chain length of the alcohol. Experimentally determined V^E values (Fig. 1) reveal that the unlike interactions between the aliphatic alcohols and furfural are fairly strong and predominant to determine the solution behaviour of these binary mixtures. A comparison of V^E values for the binary mixtures of furfural + *n*-alkanols with data reported in literature for the binary mixtures of tetrahydrofuran + *n*-alkanols (3) reveals that the unlike interactions are very strong in the former case resulting in the formation of intermolecular "complexes" through hydrogen bonding. A relatively higher V^E for mixtures containing 2-propanol and 2-butanol as compared to those containing 1-propanol and 1-butanol, respectively, reflects on their weaker hydrogen-bonding interactions with furfural due to steric factors (3, 9). For these systems, the positive contribution to V^E arising from the easiness of breaking the intermolecular structure of branched chain alcohols is expected to be small and hence less significant.

It is observed from Fig. 2 that K_s values for all the mixtures studied are negative over the entire composition range and follow the order: methanol < ethanol < 1-propanol < 1-butanol < 2-propanol < 2-butanol. It is established that the presence of specific interactions between the component molecules in binary mixtures leads to a decrease in the free space whereby contributing to a positive deviation in speeds of sound and negative deviation in isentropic compressibilities (10). The K_s is expected to become increasingly negative as the strength of interactions between the unlike molecules increases. The observed K_s values corroborates the conclusions drawn from V^E studies.

Carbohydrate metal ion complexes. Interaction of D-glucono-1,5-lactone with Zn(II), Cd(II), and Hg(II) ions in the solid and aqueous solution, studied by ^{13}C-NMR, FT-IR, and X-ray powder diffraction measurements

H. A. TAJMIR-RIAHI

Department of Chemistry, University of Laval, Quebec, P.Q., Canada G1K 7P4

Received August 12, 1988

H. A. TAJMIR-RIAHI. Can. J. Chem. **67**, 651 (1989).

D-Glucono-1,5-lactone interaction with zinc group metal ions has been studied in aqueous solution and solid salts of the type Zn(D-gluconate)$_2$.2H$_2$O, Cd(D-gluconate)$_2$ and Hg(D-gluconate)$_2$ have been isolated. These metal sugar salts were characterized by elemental analysis, ^{13}C-NMR, FT-IR spectroscopy, and X-ray powder diffraction measurements.

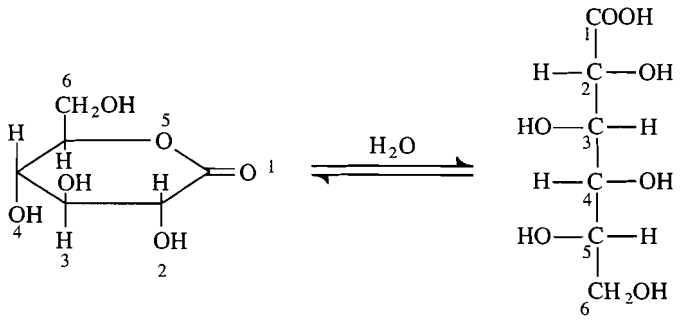
X-ray powder diffraction diagrams and other spectroscopic evidence showed that Zn(D-gluconate)$_2$.2H$_2$O is isomorphous with the structurally identified Mn(D-gluconate)$_2$.2H$_2$O, suggesting a similar metal–sugar binding mode, through a carboxylate oxygen atom (O-1) and an OH group of the two sugars anions as well as to two H$_2$O molecules, resulting in a six-coordinate Zn(II) ion. The Cd(II)- and Hg-D-gluconate salts are not similar and show dissimilarities to the Zn(II) compound. The Cd(II) ion binds to two D-gluconate anions possibly through the carboxylate O-1 and sugar O(2)—H, and O(3)—H groups of each anion, giving a six-coordinate Cd(II) ion. The Hg(II) ion is possibly four-coordinate, binding to two sugar anions via a carboxylate O-1 and O(2)—H groups of each D-gluconate anion. The zinc group metal–D-gluconate salts are aggregated through bridging sugar OCO$^-$ groups with sugar anion possibly having bent-chain conformation.

Key words: carbohydrate, metal ions, ^{13}C-NMR, FT-IR, X-ray powder diffraction.

H. A. TAJMIR-RIAHI. Can. J. Chem. **67**, 651 (1989).

Opérant en solutions aqueuses, on a étudié les interactions de la D-gluconolactone-1,5 avec les ions métalliques du groupe du zinc et on a isolé des sels solides du type Zn(D-gluconate)$_2$.2H$_2$O, Cd(D-gluconate)$_2$ et Hg(D-gluconate)$_2$. On a caractérisé ces sels métalliques des sucres en faisant appel à des analyses élémentaires, à la rmn du ^{13}C, à la spectroscopie ir par transformation de Fourier et par des mesures de diffraction des rayons-X sur des poudres.

Les diagrammes de diffraction des rayons-X sur des poudres et d'autres données spectroscopiques démontrent que le Zn(D-gluconate)$_2$.H$_2$O est isomorphe du Mn(D-gluconate)$_2$.H$_2$O dont la structure a été identifiée; ces résultats suggèrent que le mode de liaison métal–sucre est semblable, qu'il se produit par le biais d'un atome d'oxygène (O-1) du carboxylate et des groupements OH de deux anions de sucre ainsi que deux molécules de H$_2$O et qu'il conduit à la formaion d'un ion Zn(II) qui est hexa-coordonné. Les sels de Cd(II)– et Hg–D-gluconates ne sont pas semblables et ils présentent des dissymétries par rapport au composé Zn(II). L'ion de Cd(II) se lie à des anions de D-gluconate, possiblement par le biais de l'oxygène O-1 du carboxylate et des groupements O(2)—H et O(3)—H du sucre de chacun des anions, et il donne naissance à un ion Cd(II) qui est hexa-coordonné. Il est possible que l'ion Hg(II) soit tétra-coordonné par la liaison à deux anions de sucres par le biais des groupements O-1 d'un carboxylate et O(2)—H de chacun des anions de D-gluconate. Les sels métalliques du D-gluconate avec des métaux du groupe du zinc forment des agrégats à l'aide de groupements OCO$^-$ agissant comme ponts avec des anions de sucre qui existent peut-être dans des conformations de chaînes repliées.



Mots clés : hydrate de carbone, ions métalliques, RMN du ^{13}C, FT-IR, diffraction des rayons-X.

[Traduit par la revue]

Introduction

On the basis of lanthanide-induced ^{1}H-NMR studies, Taga *et al.* (1) have demonstrated how the polyhydroxyl carboxylic acids containing α-carboxy, α-hydroxy, and β-hydroxy oxygen atoms such as glyceric acid, gluconic acid, and lactobionic acid can chelate the lanthanide(III) ions through O-1, O-2, and O-3 oxygen atoms. Similarly, the binding modes of lanthanide ions with D-galacturonic and D-glucuronic acids have been reported (2, 3). The chelating ability of several sugar moieties such as D-glucuronic acid, L-arabinose, D-fructose, and D-glucose with zinc group and alkaline earth metal ions has been reported (4–10). Recently, on the basis of ^{13}C-NMR, FT-IR spectroscopy, and X-ray powder diffraction measurements, we have shown (11) how the alkaline earth metal ions bind to D-gluconic acid (Scheme 1) through O-1, O-2, and O-3 oxygen atoms. Therefore, it is of interest to study the zinc group metal ion interaction with D-gluconic acid, both in the solid and in aqueous solution.

In the present work, we describe the synthesis and characterization of several complexes formed between D-gluconate anion and zinc group metal ions (zinc, cadmium, and mercury), both in the solid and in aqueous solution, using ^{13}C-NMR, FT-IR spectroscopy and X-ray powder diffraction measurements, that have not been reported elsewhere. Furthermore, comparisons were made between the spectroscopic properties of these metal–D-gluconate salts and those of the structurally known Mn(D-gluconate)$_2$.2H$_2$O (12), Pb(D-gluconate)$_2$ (13), and Mg(D-gluconate)$_2$.2H$_2$O (11), in order to detect the characteristic features of each structural type of compound synthesized for the zinc group metal cations and to establish a correlation be-

TABLE 1. ^{13}C-NMR chemical shifts (ppm) for D-glucono-1,5-lactone, D-gluconic acid, and their metal ion complexes in D_2O solution*

Compounds	Chemical shift					
	C-1	C-2	C-3	C-4	C-5	C-6
D-Glucono-1,5-lactone	175.20	82.24	73.50	72.00	67.95	60.80
D-Gluconic acid	176.40	73.25	72.30	71.95	71.50	63.50
Zn(D-gluconate)$_2$, $2H_2O$	178.80	73.67	72.93	71.87	71.47	63.37
Cd(D-gluconate)$_2$	179.10	73.95	72.95	71.83	71.65	63.47
Hg(D-gluconate)$_2$	177.90	74.45	72.50	71.89	71.50	63.49
Pb(D-gluconate)$_2$	180.50	75.40	72.99	71.99	71.77	63.40

*Using dioxane as the reference (67.40 ppm).

tween the spectral modifications and the binding sites used by D-gluconate anion.

Experimental

Materials and methods

D-Glucono-1,5-lactone was purchased from Aldrich Chemical Company and used as supplied. All other chemicals were reagent grade and were used without further purification.

Synthesis of the zinc group metal–D-gluconate complexes

A solution of zinc group metal carbonate (1 mmol) in H_2O (20 mL) was added to a hot solution of D-glucono-1,5-lactone (2 mmol) in H_2O (50 mL) and the mixture was heated up to 80°C till at the insoluble metal carbonate was dissolved. The solution was cooled down to room temperature and ethanol (75 mL) was added to precipitate the white compound. This was filtered off and washed with ethanol several times. *Anal.* calcd. for $Zn(C_6H_{11}O_7).2H_2O$: C 29.30, H 5.29, Zn 13.30; found: C 28.70, H 5.15, Zn 12.95. *Anal.* calcd. for $Cd(C_6H_{11}O_7)_2$: C 28.05, H 4.38, Cd 22.36; found: C 27.80, H 4.20, Cd 21.90. *Anal.* calcd. for $Hg(C_6H_{11}O_7)_2$: C 24.04, H 3.72, Hg 33.96; found: C 23.75, H 3.55, Hg 33.60. The zinc group metal–D-gluconate salts are soluble in hot water and not soluble in common organic solvents.

Physical measurements

The ^{13}C-NMR spectra were recorded on a Bruker WH-80 instrument in D_2O solution containing dioxane as reference. X-ray powder diffraction diagrams were recorded on a diffractometer Philips Pw 1011 with copper K_α radiation. The FT-IR spectra were recorded on a DIGILAB FTS-15C/D Fourier Transform infrared interferometer equipped with HgCdTe detector and KBr beam splitter. The spectra were taken as KBr pellets with resolution of 2 to 4 cm^{-1}.

Results and discussion

^{13}C-NMR spectra

The assignments of the ^{13}C-NMR chemical shifts of the free D-gluconic acid and D-glucono-1,5-lactone have been reported (14) and our results given in Table 1 are in good agreement with those reported in literature (14). Upon acid complexation, the free acid C-1 (carboxyl) chemical shift at 176.40 ppm showed major downfield shift at 178–179 ppm, the C-2 at 73.25 ppm was shifted to 73.7–74.5 ppm, and C-3 at 72.30 ppm also showed a small downfield shift at about 72.5–72.95 ppm, whereas the C-4, C-5, C-6 were almost unaffected by sugar complex formation (Table 1). The downfield shifts of the C-1 and C-2 chemical shifts are due to the participation of the sugar carboxylate oxygen atom and O(2)—H group in metal–D-gluconate bindings. Similar shifts were observed for the structurally known Pb(D-gluconate)$_2$ salt (Table 1), where metal–sugar bindings were found to be through carboxylate oxygen atom and O(2)—H hydroxyl group (13). Similar trends were also observed in the ^{13}C-NMR spectra of the alkaline earth metal–D-gluconate complexes, where metal–sugar binding via

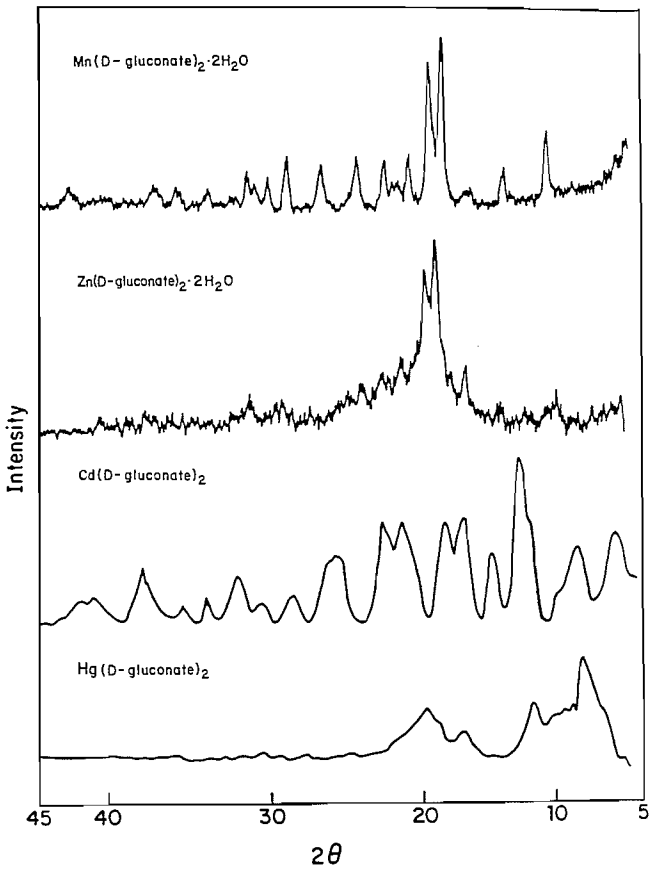

FIG. 1. X-ray powder diffraction patterns of the zinc group metal–D-gluconate complexes and the structurally known Mn(II)–D-gluconate salt.

O-1 and O-2 were suggested (11). It should be noted that although the structures of the zinc group metal–D-gluconate salts are different in the solid state (due to different coordination numbers and binding modes), their ^{13}C-NMR spectra are almost identical and this is indicative of similar structural behaviours of these metal–sugar complexes in aqueous solution.

X-Ray powder diffraction diagrams

The X-ray powder diffraction patterns of the zinc group metal–D-gluconate salts are compared with those of the structurally known Mn(D-gluconate)$_2$.$2H_2O$ in Fig. 1. It is evident that the X-ray powder pattern of the Zn(D-gluconate)$_2$.$2H_2O$ is almost similar to that of the known Mn(D-gluconate)$_2$.$2H_2O$ (particularly, the strongest features of both spectra) (Fig. 1). These suggest a similar coordination number and sugar binding mode, for the Zn(D-gluconate)$_2$.$2H_2O$ salt. On the other hand, the X-ray powder patterns of the Cd(II)– and Hg(II)–D-gluconate salts are dissimilar and they are different from those of the zinc and manganese complexes (Fig. 1). The observed dissimilarities are related to different sugar binding modes, in the Cd(II)– and Hg(II)–sugar salts. It might be possible that the binding of the D-gluconate anions in the Cd(D-gluconate)$_2$ occur through O-1, O-2, and O-3 of each sugar anion, resulting in a six-coordination around the cadmium ion, while in the Hg(D-gluconate)$_2$ salt, each sugar binding is via O-1 and O-2 oxygen atoms, with Hg(II) ion being four-coordinate. It should be noted that the poor quality of X-ray powder patterns of the Cd(II)– and Hg(II)–D-gluconate salts are related to the less crystallinity of these metal–sugar salts. However, several important features of each spectrum are comparable with those of the zinc– and manganese–D-gluconate complexes (Fig. 1).

FT-IR spectra

The FT-IR spectra of the zinc group metal–D-gluconate and D-glucono-1,5-lactone have been studied in the 3700–500 cm^{-1} region and comparisons were made with those of the corresponding structurally identified compounds Mn(D-gluconate)$_2$.2H$_2$O, Pb(D-gluconate), and Mg(D-gluconate)$_2$.2H$_2$O. The spectral analysis results are discussed below:

Sugar OH stretching vibrations and zinc group metal ion bindings

In the crystal structure of D-glucono-1,5-lactone, there are four distinct H-bonding systems (15) and based on the intermolecular O...O distances, the four strong and broad bands observed in the 3500–3200 cm^{-1} region in the IR spectrum of the free lactone are assigned as follows: A broad and strong band at 3462 cm^{-1} is assigned to the O(6)—H...O(2) with O...O = 2.882 Å, a broad and strong band at 3387 cm^{-1} is due to the O(4)—H...O(1) with O...O = 2.849 Å, a broad absorption band at 3277 cm^{-1} is attributed to the O(2)—H...O(3) with O...O = 2.720 Å and finally, a strong and broad band at 3225 cm^{-1} is assigned to the strongly hydrogen bonded O(3)—H...O(6) with O...O = 2.680 Å (Fig. 2).

Upon zinc group metal ions complex formation, the lactone OH stretching vibrations in the 3500–3200 cm^{-1} region showed shifting and broadening in the spectra of the Zn(II)–, Cd(II)–, and Hg(II)–D-gluconate salts (Fig. 2). The shifting and broadening of the sugar OH stretching vibrations, on complexation, are related to the participation of the sugar OH groups in metal–ligand bondings. Similar spectral changes were observed in the IR spectra of the structurally known Mn(D-gluconate)$_2$.2H$_2$O (Fig. 2), where metal–sugar bindings were found to be via sugar OH groups as well as carboxylate anions (12). It is interesting to note that the IR spectrum of the Mn(D-gluconate)$_2$.2H$_2$O, Mg(D-gluconate)$_2$.2H$_2$O, and Zn(D-gluconate)$_2$.2H$_2$O salts are almost identical (Fig. 2 and ref. 11). This is indicative of the similar coordination numbers (C.N. = 6) and sugar binding modes for the Zn(D-gluconate)$_2$.2H$_2$O salt. This is also consistent with X-ray powder diffraction patterns, which showed isomorphic features for the Zn(II)– and Mn(D-gluconate)$_2$.2H$_2$O compounds (Fig. 1). It should be noted that the major broadenings of sugar OH stretching vibrations, in the spectra of the zinc group metal–D-gluconate salts, are due to the presence of a strong H-bonding network between the sugar OH groups and H$_2$O molecules in the crystal structures of these metal–sugar salts, which is responsible for the stabilization of the solid structure and for holding the aggregate units together. Such a H-bonding system found in the crystal structure of the Mn(D-gluconate)$_2$.2H$_2$O salt in aggregated form (12).

A broad band with medium intensity at about 3150 cm^{-1}, in the spectra of the Zn(II)– and Mn(D-gluconate)$_2$.2H$_2$O, which is absent in the lactone spectrum and Cd(II)– or Hg(II)–D-gluconate salt, is attributed to the OH stretching vibration of the bonded H$_2$O molecules (Fig. 2). Similarly, a shoulder band at about 1640 cm^{-1} in the spectra of the Mn(II)– and Zn(D-gluconate)$_2$.2H$_2$O salts, which is not present in the uncomplexed sugar and other zinc group metal–D-gluconate compounds, is also assigned to the bending mode of the coordinated water molecule (Fig. 3).

Sugar carbonyl stretching vibration and zinc group metal ion bindings

The carbonyl stretching vibration of the D-glucono-1,5-lactone was observed as a strong band at 1728 cm^{-1} and exhibited splitting and shifting towards lower frequencies, in the spectra of the zinc group metal-D-gluconate complexes (Fig. 3). The

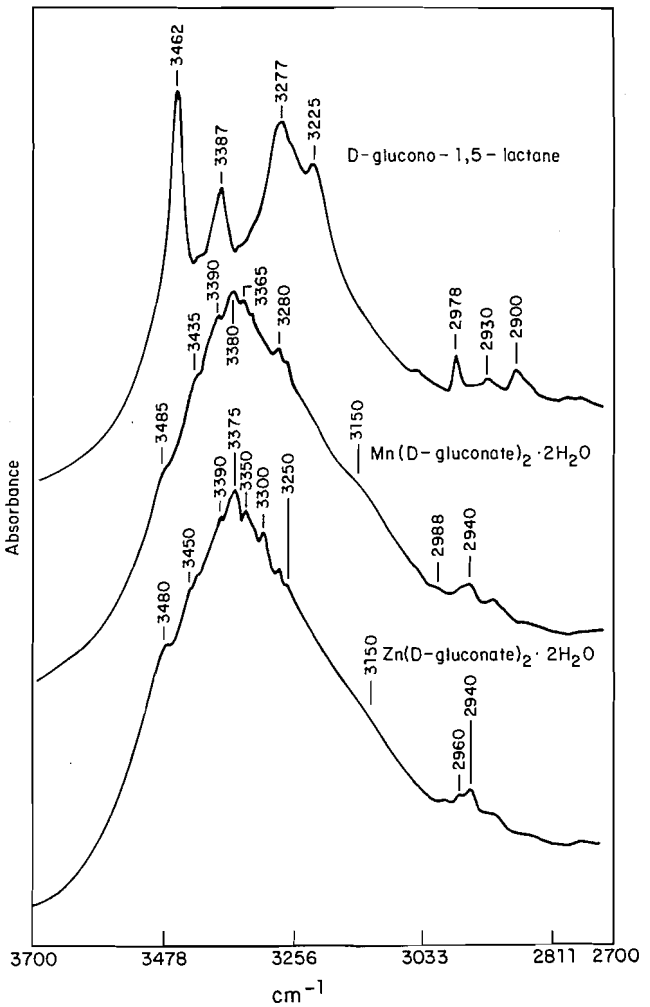

FIG. 2. FT-IR spectra of the free D-glucono-1,5-lactone and its metal ion salts in the region of 3700–2700 cm^{-1}.

two broad and strong bands at about 1600 and 1400 cm^{-1} observed in the spectra of these metal–sugar salts are assigned to the antisymmetric and symmetric carboxylate OCO^- stretching vibrations, respectively (16). The shifting and splitting of the carbonyl stretching vibration, upon lactone complexation, are due to the sugar ionization and participation of the OCO^- group in metal–sugar bindings. Similar shifting and splitting of the carbonyl group stretching frequency was observed in the spectra of the structurally known Mn(D-gluconate)$_2$.2H$_2$O (Fig. 3) and Pb(D-gluconate)$_2$ compounds (17), where direct metal–carboxylate coordination was observed (12, 13). It has been suggested that separation between the antisymmetric and symmetric OCO^- stretching vibrations is a measure of the unidentate, bidentate or bridging coordination of the carboxylate group, in a series of metal–carboxylate complexes (18). The separation of about 180–185 cm^{-1} of the two OCO^- components, observed in the IR spectra of the zinc group metal–D-gluconate compounds is indicative of the unidentate and bridging modes of OCO^- binding, in these metal–sugar complexes (Fig. 3). This is in agreement with the structural analysis of the Mn(D-gluconate)$_2$.2H$_2$O and Pb(D-gluconate)$_2$ salts, which contained unidentate and bridging metal–carboxylate bindings (12, 13). It should be noted that aggregation of these metal–sugar complexes occurs through carboxylate oxygen atoms.

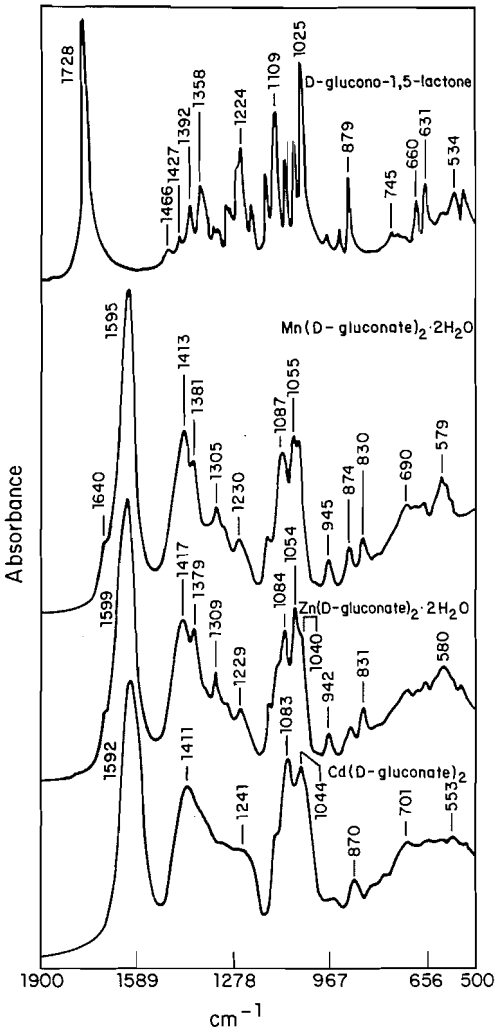

FIG. 3. FT-IR spectra of the free D-glucono-1,5-lactone and its metal ion salts in the region of 1900–500 cm^{-1}.

Sugar ring vibrational frequencies and zinc group metal ion interaction

The lactone ring CH_2, COH, and CCH bending modes (19, 20) at about 1460–1100 cm^{-1}, exhibited shifting and broadening, upon zinc group metal ion complex formation (Fig. 3). The observed spectral changes for the OH bending modes and sugar OH stretching vibrations in the region of 3500–3200 cm^{-1} together are the results of the metal–sugar binding via D-gluconate OH groups. Similar spectral modifications are observed in the sugar OH bending modes in the spectra of the known Mn–D-gluconate salt (Fig. 3), which contains Mn–sugar OH bindings as well as Mn—OCO^- interaction (12). The lactone ring C—O stretching vibrations (19, 20) appeared as several strong bands in the region of 1100–900 cm^{-1} and exhibited broadening and shifting, on sugar salt formation (Fig. 3). These observed spectral changes are the consequences of the metal–sugar OH bindings and the rearrangements of the sugar H-bonding system, upon acid ionization and metallation.

In conclusion, Zn((D-gluconate)$_2$.$2H_2O$ is similar in structure to that of the known Mn(D-gluconate)$_2$.$2H_2O$ (12) and Mg(D-gluconate)$_2$.$2H_2O$ (11) salts (having almost identical ^{13}C-NMR, FT-IR, and X-ray powder spectra), suggesting a similar six-coordination and binding mode (through each sugar anion carboxylate oxygen atom and an OH group as well as to two H_2O molecules) for the Zn(II) ion. The Cd(II) ion six-coordination could be completed by binding to two D-gluconate anions via O-1, O-2, and O-3 of each sugar anion. Similar binding modes through α-carboxy, α-hydroxy, and β-hydroxy oxygen atoms were found in the lanthanide(III)–D-gluconate complexes (1) and for the Ca(II), Sr(II), and Ba(II)–D-gluconate salts (11). The Hg(II) ion could be four-coordinate, binding to two sugar anions through O-1 and O-2 oxygen atoms of each acid anion, forming a five-membered ring chelation. The IR spectra and X-ray powder patterns of the Cd(II)– and Hg(II)–D-gluconate salts were different from those of the Zn(II)– and Mn(II)–sugar salts.

The marked spectral similarities of the zinc group metal–D-gluconate salts with those of the Mn(II)–, Pb(II)–, or alkaline earth metal–D-gluconate compounds suggest a similar aggregation for these metal–sugar complexes. Such aggregation can occur through a bridging carboxylate oxygen atoms or other sugar donor groups, which is consistent with the polymeric nature of the Mn(II)– or Pb(II)–D-gluconate salt, in the solid state, found through X-ray diffraction measurements (12, 13). In the structurally identified Mn(D-gluconate)$_2$.$2H_2O$ compound, the sugar anion has a bent-chain conformation (12) and on the basis of the similarities in their spectroscopic properties, one can suggest a similar bent-chain conformation, for the zinc group metal–D-gluconate salts.

Reaction of ^{197}Au atoms with CO has been studied in inert hydrocarbon matrices in a rotating cryostat at 77 K by EPR, FTIR, and UV/visible spectroscopy. $Au(CO)_2$ has been positively identified by FTIR spectroscopy and there is evidence for the formation of AuCO, a gold microcrystallite – CO complex and, upon annealing, $Au_2(CO)_4$. Electron paramagnetic resonance spectra are consistent with the formation of Au(CO) (OC) with the magnetic parameters: a_{13} = 325 MHz, a_{17} = 44 MHz, and g = 2.0014 and a gold microcrystallite – CO complex with g = 2.014. An intense broad absorption in the optical spectrum at 525 nm is assigned to $Au(CO)_2$ and a less intense narrow band at 320 nm is assigned to Au_nCO. There is no spectroscopic evidence for the formation of $Au(CO)_3$ in hydrocarbon matrices.

Key words: gold carbonyls, EPR, FTIR, UV/visible, matrix isolation.

J. H. B. CHENIER, J. A. HOWARD, H. A. JOLY, B. MILE et M. TOMIETTO. Can. J. Chem. **67**, 655 (1989).

Faisant appel aux spectroscopies rpe, UV/visible ainsi que IR par transformation de Fourier et opérant à 77 K, on a étudié la réaction des atomes du ^{197}Au avec le CO dans des matrices d'hydrocarbures inertes, dans un cryostat en rotation. Grâce à la spectroscopie IR par transformation de Fourier, on a pu identifier le $Au(CO)_2$ d'une façon positive et on a obtenu des indications relatives à la formation de AuCO, un complexe micro-cristallin d'or et de CO qui se transforme en $Au_2(CO)_4$ par recuisson. Les spectres rpe sont en accord avec la formation de Au(CO)(OC) dont les paramètres sont les suivants: a_{13} = 325 MHz, a_{17} = 44 MHz et q = 2,0014 et d'un complexe micro-cristallin d'or et de CO avec q = 2,014. On a attribué au $Au(CO)_2$ une bande d'absorption large et intense qui est observée à 525 nm du spectre optique alors qu'une bande fine et moins intense observée à 320 nm est attribuée au Au_nCO. On n'a décelé aucune indication spectroscopique suggérant la formation de $Au(CO)_3$ dans les matrices d'hydrocarbures.

Mots clés : carbonyles d'or, RPE, FTIR, UV/visible, isolement de la matrice.

[Traduit par la revue]

Introduction

Electron paramagnetic resonance (EPR) spectroscopic studies of the reaction of Cu and Ag atoms with CO in solid argon have confirmed the formation and structures of the unstable mononuclear mono- and tricarbonyls, CuCO, AgCO, $Cu(CO)_3$, and $Ag(CO)_3$ (1–4). The dicarbonyls $Cu(CO)_2$ and $Ag(CO)_2$ are also formed but they are EPR "silent" because they are linear molecules with a $^2\Pi$ electronic ground state (1, 3).

These reactions have also been performed in inert hydrocarbon matrices (5–10) and while CuCO and $Cu(CO)_3$ have the same structure in the two distinct types of matrix the silver di- and tricarbonyls can have two conformations in adamantane. Thus bent $Ag(CO)_2$ with the unpaired electron located essentially in the metal 5s orbital is EPR "visible" and $Ag(CO)_3$ can adopt a planar ($^2A_2''$) and a pyramidal ($^2A_1'$) conformation in the same adamantane matrix (9).

Reaction of Au atoms with CO has also been studied in rare gas matrices (11) by infrared spectroscopy and this coinage metal atom is different from Cu and Ag in that $Au(CO)_3$ is not formed but two isomers of the dicarbonyl are produced, one with two metal–carbon bonds, $Au(CO)_2$, and one with metal–carbon bond and one metal–oxygen bond, isocarbonyl(carbonyl)gold, Au(CO)(OC). EPR studies of the reaction of Au atoms with CO in argon (12) have confirmed the formation of AuCO but there was no evidence for isocarbonyl(carbonyl)gold.

Because of the interesting differences between reactions of CO with Cu and Ag and with Au in solid argon and CO with Ag in solid rare gas and inert hydrocarbon matrices we thought it worthwhile to study the reaction of CO with Au atoms in hydrocarbon matrices to determine whether the tricarbonyl can be formed under our experimental conditions and to confirm by EPR spectroscopy the formation of Au(CO)(OC). The results of this study are reported here.

Experimental

The rotating cryostat and furnace used to study the reactions of Au atoms with CO in inert hydrocarbon matrices have been described previously (13). Au was evaporated from a molybdenum pouch clamped between the electrodes of the furnace. EPR spectra were obtained on Varian E-4 and E-12 and Bruker ESP 300 instruments equipped with a Systron-Donner Model 6054 microwave frequency counter and a Bruker Model ER 035 proton magnetometer. Temperature control was achieved with an Oxford Instruments ESR 9 liquid helium cryostat and a cold nitrogen gas controller. The computing methods used to derive the magnetic parameters from the experimental spectra and to produce simulated spectra have already been discussed in previous papers (13, 14).

In situ IR spectra of deposits on the drum of the cryostat were obtained on a Mattson Sirius 100 FTIR spectrometer as described previously (14). They were recorded initially at 77 K and then at higher temperatures by warming up the deposits on the drum of the cryostat. If major changes in the spectrum occurred at high temperatures the cryostat was recooled to 77 K and the spectrum rerecorded at this temperature. Spectra were the average of 256 scans at 4 cm^{-1} resolution from 4000–400 cm^{-1}.

In situ UV/visible spectra were recorded with the aid of an Oriel pulsed light photometer. Light from the pulsed xenon lamp (10 Hz) monochrometer combination was directed with a silica fibre optic on to the deposit on the drum at an angle of 10° to the normal and the diffuse reflected beam was collected by another fibre optic along the normal and transmitted to a phase-locked photomultiplier detector. A reference spectrum was obtained by masking the lower half of the deposit so that only the top portion contained gold—CO species. A minicomputer with associated software was used to increment the wavelength output from the monochrometer, store the detector output at each wavelength

from the two halves of the deposit, and process the data so as to give an absorbance–wavelength curve. The cyrostat plug, mask, and fibre opticals are shown in Fig. 1.

Pure gold metal was kindly provided by Dr. C. M. Hurd (NRCC). Carbon monoxide (99.99%), ^{13}CO-enriched to 99.9 atom% in ^{13}C and $C^{17}O$-enriched to 36.8 atom% in ^{17}O were obtained from Matheson, Merck, Sharp, and Dohme Ltd., Montreal, and Prochem Isotopes, Summit, NJ, respectively. Adamantane was obtained from Aldrich.

Results

EPR

Au and CO (0.05 Torr) in adamantane at 77 K gave a red-colored deposit the EPR spectrum of which had three quartets from Au atoms isolated in three trapping sites (13) and the central feature shown in Fig. 2*a*. This part of the spectrum consists of two major resonances, a broad feature (A) centered at $g = 2.014$ and a line (B) at higher field with $g = 2.0014$. There was no evidence for a quartet with a Au hyperfine interaction (hfi) of *ca.* 1700 MHz similar to the quartet that has been assigned by Kasai and Jones (12) to monocarbonylgold, AuCO. When this reaction was performed with ^{13}CO the line at $g = 2.0140$ remained unchanged except for minor changes in lineshape, whereas the line centered at $g = 2.0014$ was replaced by two lines centered at the same g factor with a spacing of 325 MHz, indicating coupling with one carbon nucleus but no resolved Au hfi. The spectrum given by $Au/^{13}CO$ in adamantane is shown in Fig 2*b*.

Annealing experiments revealed that species A disappeared faster than species B until at 255 K the much sharper spectrum shown in Fig. 3 was obtained from Au and ^{13}CO.

Au and CO enriched in ^{17}O gave a spectrum similar to Fig. 2*a* at 100 K while annealing to 250 K revealed the presence of six satellite lines indicated by the stick diagram in Fig. 4. This sextet from one oxygen nucleus ($I = 5/2$) was centered at $g = 2.0014$ and is therefore associated with species B. Analysis of the ^{17}O-enriched spectrum gave $a_{17} = 44$ MHz.

FTIR

IR spectra given by Au atoms and ^{12}CO, ^{13}CO, and a 1:1 mixture of ^{12}CO and ^{13}CO in adamantane at 77 K in the CO stretching region are shown in Fig. 5. ^{12}CO gave two bands C and D at 2107 and 1943 cm^{-1} with relative intensities of 1:5.7, a weak band (E) at 2052 cm^{-1}, and a shoulder (F) to band D at 1930 cm^{-1}. Almost the same pattern of bands was obtained from $Au/^{13}CO$ with C at 2059 cm^{-1}, D at 1897.2 cm^{-1}, E at 2027 cm^{-1}, and F at 1885.6 cm^{-1}. Thus all the bands in the CO stretching region were shifted by ~45 cm^{-1} to lower frequency

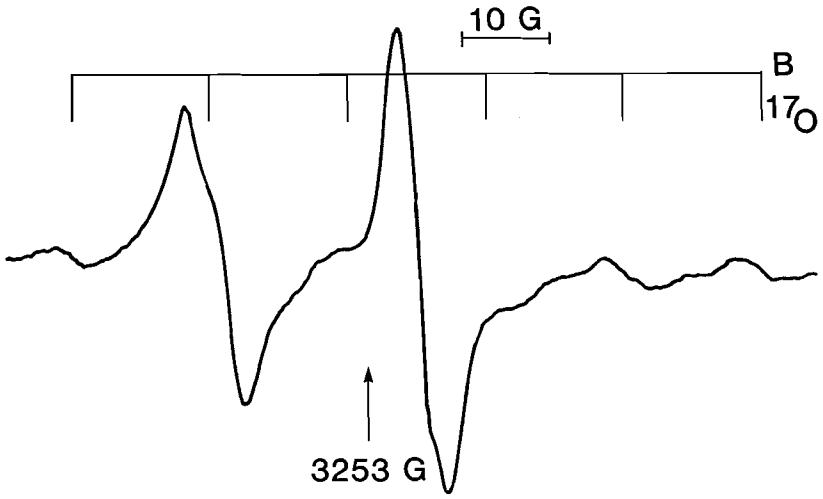

FIG. 4. EPR spectrum of Au atoms and CO enriched to 36.8 atom% in ^{17}O at 250 K.

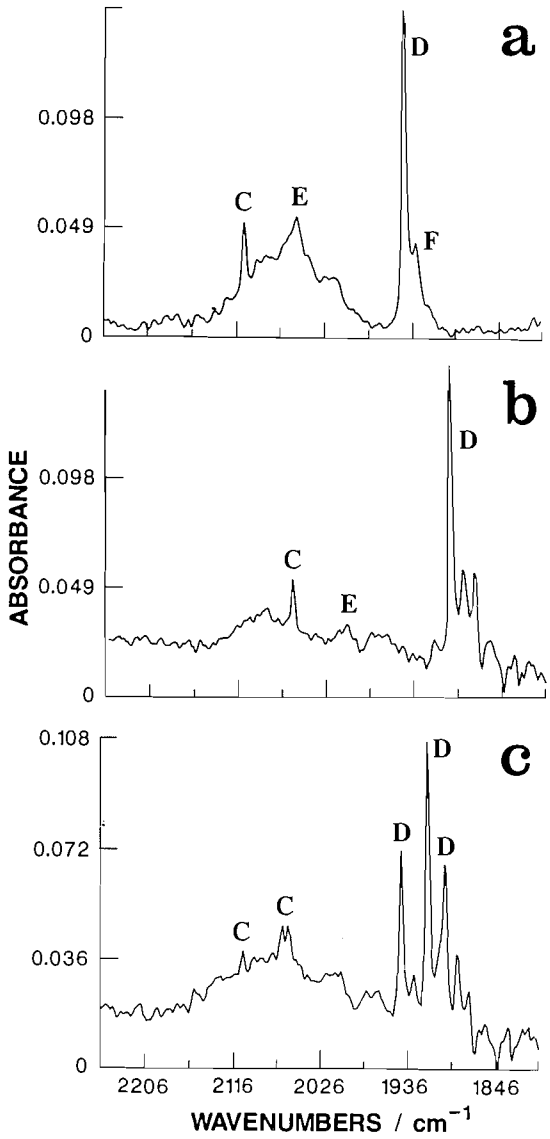

FIG. 5. FTIR spectra of Au and ^{12}CO (*a*), Au and ^{13}CO (*b*), and Au and 1:1 mixture of ^{12}CV and ^{13}CO (*c*).

in the Au/^{13}CO system and can be assigned to gold carbonyls. The spectrum from Au/^{12}CO/^{13}CO gave two bands C at 2106 and 2059 cm^{-1} and three bands D at 1943.5, 1916.5, and 1897.2 cm^{-1} with relative intensities of 1:2:1. Bands C and D are therefore assigned to gold carbonyls with one and two CO ligands, respectively. Bands E were too weak to detect in this mixed isotopes experiment.

Upon annealing Au/^{12}CO/adamantane to 104 K band E had disappeared and the intensity of band C had decreased by ~10% while band D remained unchanged. At 141 K band C had disappeared and band D had decreased by ~10% and a broad band (G) at 2072 cm^{-1} developed. At 200 K band G was the dominant band although band C was still evident. In the Au/^{13}CO system band G occurred at 2027 cm^{-1}. Infrared spectra of this system at 77, 141, 200 K are shown in Fig. 6.

UV/visible

Au atoms in adamantane gave a salmon pink deposit which exhibited a broad band centered at about 300 nm with a width-at-half-height of about 100 nm. There were, however, distinct broad adsorptions at 380, 345, and 320 nm and narrower adsorptions at 300, 290, 275, 265, and 250 nm (Fig. 7). This spectrum was similar to that of Au in rare gases and hydrocarbons (15) but was not as well resolved. The broad lower energy bands have been assigned to Au_2 and Au_3 while the higher energy bands are from Au atoms. The EPR spectrum of this deposit was dominated by the three quartets from Au atoms in three magnetically distinct trapping sites and a feature at $g = 2.008$ probably from a Au microcrystallite. There was no evidence for the spectrum of Au_3 (16), indicating that none of the bands in the optical spectrum were from this species. Au_2, on the other hand, is expected to be diamagnetic and would not influence the EPR spectrum.

Au atoms and CO in adamantane gave a deep red deposit at 77 K that exhibited the optical spectrum shown in Fig. 8*a*. Most of the features of the spectrum of Au/adamantane had disappeared except for a feature J at 250 nm. The broad intense band (H) and a narrow, less intense band I were new bands that appeared at 525 and 325 nm, respectively. Upon annealing to 132 K and 525 nm band decreased by ~20% and the 325 nm band by ~50% (Fig. 8*b*). At 200 K bands I and J were absent from the spectrum while band H was still evident, although down in intensity by a factor of about 3 (Fig. 8*c*) from the 77 K spectrum.

Discussion

EPR spectral analysis

EPR spectra given by Au atoms and CO in adamantane reveal the presence of Au atoms and two paramagnetic species A and B with markedly different g factors but no features that can be unambiguously assigned to the mononuclear carbonyl AuCO and dicarbonyl $Au(CO)_2$; $Au(CO)_3$ is certainly not formed.

Species A. The only magnetic parameter that can be deduced for A is the g-value of 2.014, ^{197}Au, ^{13}C, and ^{17}O hyperfine interactions are all less than the linewidth of 10 MHz. The line shape is, however indicative of a conduction EPR spectrum and perhaps can be assigned to a gold microcrystallite with adsorbed CO molecules. The spin density at each Au nucleus and CO molecule is too low to give rise to a resolvable hyperfine interaction. The small g shift ($\Delta g = g - 2.0023 = 0.0117$) and the overall line shape with an asymmetry parameter (positive peak height/negative peak height) of ~1.5 indicates particles of 10^2–10^3 nm in size (17). We think that we are justified in suggesting adsorbed CO because this line is absent in Au/adamantane deposits in the absence of CO (13). Furthermore, CESR spectra of Au in pure gold slabs have $g = 2.11$ and broaden rapidly above 10 K (18).

Species B. The ^{13}C hfi of B (325 MHz) is similar to that of linear AuCO (12) but the absence of a Au hfi precludes this assignment. The ^{13}C and ^{17}O (44 MHz) hfi are remarkably similar to those of formyl, HCO, which is a bent σ radical with an HCO angle of ~110° (19) but we can again discount bent AuCO because it would have a Au hfi at least as large as the H hfi of HCO (a_H = 384 MHz). In the absence of a resolved Au hfi positive assignment of B is difficult. Two possible structures that warrant consideration are isocarbonylgold **1** and isocarbonyl (carbonyl) gold **2**.

1 **2**

Preliminary MO calculations indicate that linear isocarbonyl metal species with most of the unpaired spin on carbon have a significant unpaired spin population on oxygen but little unpaired spin population at the metal center which is consistent with structures **1** and **2**. In the absence of other evidence we favor **2** because under our experimental conditions higher carbonyls such as $Rh(CO)_4$ (20), $Al(CO)_2$ (21), and $Ga(CO)_2$ (14) are formed from metal atom – CO reactions in the rotating cryostat. We, therefore, very tentatively assign species B structure **2**. Why the Au atom and the Au atom alone among group 11 and 13 metals forms an isocarbonylcarbonyl is puzzling.

However, it should be noted that the ^{13}C hfi of B is also consistent with a second Au microcrystallite–CO complex with the spin density located mainly on one CO that is bent with respect to the Au—C bond. Examples are known where CO is angled with respect to the carbon–metal bond both in organometallic compounds (22) and on metal surfaces (23).

The magnetic parameters of the gold carbonyls formed from Au atoms and CO at cryogenic temperatures (<77 K) in rare gas and inert hydrocarbon matrices are summarized in Table 1.

FTIR spectral analysis

There is IR evidence for the production of at least five gold carbonyls from reaction of Au atoms with CO under our experimental conditions. Band D (1943 cm^{-1}) is assigned to the asymmetric stretching mode of linear ($D_{\infty h}$) dicarbonylgold, $Au(CO)_2$, because it is shifted by 45.8 cm^{-1} to lower frequency when ^{13}CO is used instead of ^{12}CO and only one triplet with relative band intensities of 1:2:1 is given by a 1:1 mixture of ^{12}CO and ^{13}CO with the centre band at 1917 cm^{-1} assigned to $Au(^{12}CO)$ (^{13}CO). Furthermore the frequency of the 1943 cm^{-1} band is similar to ν_{CO} = 1935.8 cm^{-1} of $Au(CO)_2$ produced by reaction of Au atoms with ^{12}CO in neon (11). The frequency of the CO stretching mode is significantly larger than ν_{CO} = 1842 cm^{-1} of $Cu(CO)_2$ (1) and ν_{CO} = 1842 cm^{-1} of $Ag(CO)_2$ (3) suggesting less p and/or d electron back donation from the metal-to-ligand antibonding orbitals. This is understandable since the 6p level is 1 eV further removed from the 2π^* orbital of CO.

Band E, which disappears quickly upon warm-up, has a frequency (2052 cm^{-1}) similar to ν_{CO} of AuCO in N_2, Ar, and Kr (11). Its instability is probably the reason why the EPR spectrum of linear AuCO is not observed in adamantane while it is readily detected at lower temperature in Ar (12). Again ν_{CO} of AuCO is higher than ν_{CO} of CuCO (2010 cm^{-1}) (1) and AgCO (1951 cm^{-1}) (3). The elusive $Au(CO)_3$ should have ν_{CO} ~ 2052 cm^{-1} if like $Cu(CO)_3$ and $Ag(CO)_3$ ν_{CO} is *ca.* 100 cm^{-1} higher than ν_{CO} of the dicarbonyl, but this assignment is unlikely because of our failure to detect the tricarbonyl by EPR, a more sensitive technique than FTIR.

Band G at 2072 cm^{-1} only appears upon annealing and is assigned to tetracarbonyldigold, $Au_2(CO)_4$, produced by dimerization of $Au(CO)_2$. This is because band G only appears as band D disappears and none of the other bands that disappear upon annealing are intense enough to contribute significantly to

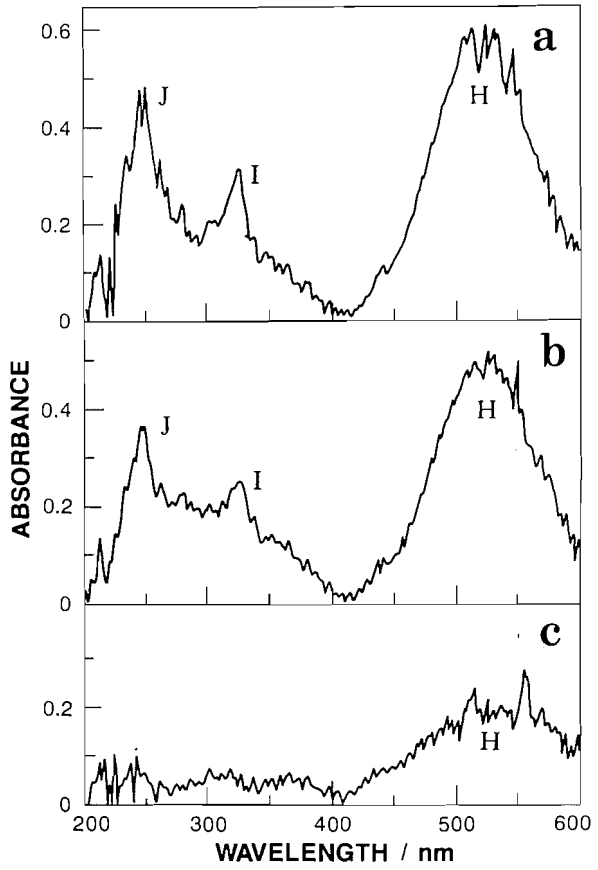

FIG. 8. Optical spectra of Au and ^{12}CO at 77 K (*a*), 132 K (*b*), and 200 K (*c*).

the intensity of band G. The frequency of this band is ~37 cm^{-1} higher than ν_{CO} of $Cu_2(CO)_6$ in adamantane (10).

ν_{CO} of band C (2107 cm^{-1}) is closer to ν_{CO} of trapped CO (2135 cm^{-1}) than ν_{CO} of $Cu_2(CO)_6$, Cu(CO), and $Cu(CO)_2$ (1) and is clearly not associated with a mono- or di-nuclear gold carbonyl. There does appear to be sound EPR evidence for a gold microcrystallite – CO complex and band C is therefore tentatively assigned to such a complex. This assignment is not unreasonable because Cu cluster monocarbonyls (Cu_2CO, Cu_3CO, and Cu_5CO) have ν_{CO} in the range 2116–2095 cm^{-1} (24) and CO adsorbed on polycrystalline gold has ν_{CO} = 2115 cm^{-1} (25). EPR and IR spectra assigned to this species decrease in intensity upon annealing perhaps because the CO is only weakly bound and is readily desorbed.

The high frequency shoulder F, ν_{CO} = 1930 cm^{-1}, to band D is difficult to assign. It could be from $Au(CO)_2$ in a second trapping site but it appears to be more intense from $Au/^{13}CO$ than from $Au/^{12}CO$. Unfortunately, the more intense band from $Au(^{12}CO)(^{13}CO)$ was not resolved so there is some doubt about this assignment. Alternatively, it could be from Au(CO) (OC) which in CO has ν_{CO} = 1927 cm^{-1} (11).

The infrared data of binary gold carbonyls formed from Au atoms and CO at cryogenic temperatures (< 77 K) in rare gas and inert hydrocarbon matrices are presented in Table 2.

UV/visible spectral analysis

Optical spectra are similar to those obtained by McIntosh and Ozin (11) for Au/CO in argon and CO which exhibit a main absorption at ~520 and ~538 nm, respectively, compared with a band maximum at 525 nm in adamantane. These bands have been assigned to the $^2\Pi_u \rightarrow {}^2\Pi_g$ electronic transition of $Au(CO)_2$ and Au(CO) (OC), respectively. Although we do not know the relative extinction coefficients of the various gold carbonyls IR spectra indicate that $Au(CO)_2$ is formed in the highest yields at 77 K. The 525 nm band is consequently assigned to the $^2\Pi_u \rightarrow {}^2\Pi_g$ electronic transition of $Au(CO)_2$, in agreement with the results in argon (11). There is some evidence for fine structure on this band and also on the corresponding band in McIntosh and Ozin's spectrum (11). It is probably associated with vibration of the Au—C bond at about 500 cm^{-1} but the poor resolution did not justify further analysis. The weak bands at 407 and 350 nm in Ar and CO that have been assigned to $^2\Pi_u \rightarrow 2\Sigma_g^+$ transitions of $Au(CO)_2$ and Au(CO) (OC) are not apparent in our spectra. The energy gap of ~6 eV between these levels in the quantitative molecular orbital energy level diagram

of $Au(CO)_2$ (Fig. 9) and Au(CO) (OC) (11) is, however, not entirely consistent with transitions at 407 and 350 nm.

The band I at 325 nm in our spectra is not associated with $Au(CO)_2$ because it disappears at a faster rate than the 525 nm band upon warm-up and is tentatively assigned to a monocrystallite gold – CO complex. Band J at 250 nm is readily assigned to Au atoms because of the similarity with the bands at 246 and 253 nm from Au atoms in cyclohexane (15) and from the fact that the ESR spectrum of Au/CO/adamantane shows the presence of unreacted Au atoms. Interestingly a band at 285 nm observed in cyclohexane is absent in our spectrum.

Absence of $Au(CO)_3$

We have confirmed the conclusion drawn from lower temperature studies of the reaction of Au atoms with CO, that $Au(CO)_2$ is the highest carbonyl given by Au atoms and CO, unlike Cu and Ag which give 17 electron tricarbonyls. The non-formation of $Au(CO)_3$ compared with the facile production of the Cu and Ag congeners is at first sight puzzling but is probably associated with the higher ($6s$–$6p$) promotional energy in Au(4.63 eV) compared to Cu(3.8 eV) and Ag(3.86 eV), disfavoring sp^2 hybridization. The $6p$ level is also ~1 eV further removed from the antiboding $2\pi_z$* orbital of CO thus mitigating against stabilization by p–π back donation. The absence of $Au(CO)_3$ because of rapid dimerization to $Au_2(CO)_6$ can be discounted because of the absence of IR bands assignable to the dinuclear carbonyl in low temperature spectra.

Conclusions

Under our experimental conditions Au atoms react with CO to give principally dicarbonylgold and a gold microcrystallite – CO complex. The dinuclear carbonyl, $Au_2(CO)_4$, is only produced upon annealing and the 17 electron binary gold carbonyl $Au(CO)_3$ is absent. There is tentative IR evidence for the formation of AuCO but it is not confirmed by EPR spectroscopy. A major paramagnetic product with an unresolved Au hyperfine interaction but a large ^{13}C hfi of 325 MHz has magnetic parameters consistent with isocarbonyl(carbonyl)gold but we cannot completely discount a gold cluster – CO complex with a large spin density on a carbonyl with a C=O bond at an angle to the cluster surface. Neither structure has been confirmed by IR or UV/visible spectroscopy.

Binuclear, antiferromagnetically coupled, macrocyclic copper(II) complexes, $[Cu_2(C_{28}H_{32}N_4O_4)]\cdot H_2O$ (**II**) and $[Cu_2(C_{36}H_{32}N_4O_4)]\cdot CH_3CN\cdot H_2O$ (**III**), involving asymmetric ligands with two deprotonated amide, two azomethine nitrogen, and two phenoxide donors at the binuclear centre, have been synthesized and characterized by single-crystal X-ray diffraction and variable temperature magnetic studies. Complex **II** crystallizes in the monoclinic system, space group $P2_1/n$, with $a = 16.4854(9)$ Å, $b = 7.6005(13)$ Å, $c = 21.1617(11)$ Å, $\beta = 104.090(5)°$, $Z = 4$, $R_f = 0.068$ for 2062 significant reflections. The two copper(II) centres have square planar N_2O_2 donor sets with two phenoxide oxygen atoms bridging the copper centres with a copper–copper separation of 2.898(2) Å. A long copper–oxygen (amide) contact (2.808(10) Å) forms a weak dimer association. Complex **III** crystallizes in the triclinic system, space group $P\bar{1}$, with $a = 8.7771(9)$ Å, $b = 12.3983(16)$ Å, $c = 15.7299(16)$ Å, $\alpha = 85.003(11)°$, $\beta = 84.574(8)°$, $\gamma = 76.838(10)°$, $Z = 2$, $R_f = 0.041$ for 2966 significant reflections. The two copper(II) centres have distorted square-pyramidal geometry involving an N_2O_2 in plane donor set and two phenoxide oxygen bridges with a copper–copper separation of 3.018(1) Å. The fifth coordination site at each copper centre involves an amide oxygen from a neighbouring molecule (Cu(1)—O 2.371(4), Cu(2)—O 2.413(3) Å) in a staggered intermolecular array. Very strong antiferromagnetic exchange is observed in both cases ($-2J = 689 \pm 7$ cm^{-1} (**II**), $-2J = 816 \pm 8$ cm^{-1} (**III**)).

Key words: macrocycles, binuclear copper(II) complexes.

SANAT K. MANDAL, LAURENCE K. THOMPSON, MICHAEL J. NEWLANDS, AMAL K. BISWAS, BIBHUTOSH ADHIKARY, KAMALAKSHA NAG, ERIC J. GABE et FLORENCE L. LEE. Can. J. Chem. **67**, 662 (1989).

On a synthétisé les complexes macrocycliques, binucléaires et couplés d'une façon antiferromagnétique du cuivre(II), $[Cu_2(C_{28}H_{32}N_4O_4)]\cdot H_2O$ (**II**) et $[Cu_2(C_{36}H_{32}N_4O_4)]\cdot CH_3CN\cdot H_2O$ (**III**), impliquant des ligands asymétriques avec deux déprotonés, deux azotes d'azométhine et deux donneurs phénolates au centre binucléaires; on les a caractérisé par diffraction des rayons-X sur un cristal unique et par des études magnétiques à temperatures variables. Le complexe **II** cristallise dans le système monoclinique, groupe d'espace $P2_1/n$, avec $a = 16{,}4854(9)$, $b = 7{,}6005(13)$ et $c = 21{,}1617(11)$ Å, $\beta = 104{,}090(5)°$, $Z = 4$ et $R_f = 0{,}068$ pour 2062 réflexions significatives. Les deux centres de cuivre(II) comportent des ensembles de donneurs N_2O_2 plans carrés avec deux atomes d'oxygène du phénolate formant un pont entre les centres de cuivre séparés par une distance cuivre–cuivre de 2,898(2) Å. Un contact à longue distance entre le cuivre et l'oxygène (amide) (2,808(10) Å) forme une association dimère qui est faible. Le complexe **III** cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec $a = 8{,}7771(9)$, $b = 12{,}3983(16)$ et $c = 15{,}7299(16)$ Å, $\alpha = 85{,}003(11)$, $\beta = 84{,}574(8)$, $\gamma = 76{,}838(10)^0$, $Z = 2$ et $R_f = 0{,}041$ pour 2966 réflexions significatives. Les deux centres de cuivre(II) possèdent une géométrie pyramide-carrée déformée impliquant un N_2O_2 dans l'ensemble de donneur plan et deux ponts formés par les oxygènes de phénolates avec une distance cuivre–cuivre de 3,018(1) Å. Le cinquième site de coordination de chaque centre de cuivre implique un oxygène d'amide d'une molécule adjacente (Cu(1)—O 2,371(4), Cu(2)—O 2,413(3) Å) dans un arrangement intermoléculaire décalé. Dans chacun des cas, on observe un échange antiferromagnétique très important ($-2J = 689 \pm 7$ cm^{-1} (**II**), $-2J = 816 \pm 8$ cm^{-1} (**III**)).

Mots clés : macrocycles, complexes binucléaires du cuivre(II).

[Traduit par la revue]

Introduction

In recent years metal complexes derived from macrocyclic ligands that possess dual ligand functions of saturated polyamine macrocycles and carboxamide moieties of oligopeptides have received considerable attention (1–14). The incorporation of a divalent 3*d* cation into the cavity of such diamidopolyamino macrocycles causes loss of two amido protons and the resulting neutral complexes attain considerable thermodynamic and kinetic stability that can be modulated by variation of ring size. Of particular interest are the copper(II) and nickel(II) complexes which undergo reversible one-electron oxidation at a moderately positive potential to produce corresponding stable complex species in the 3+ oxidation state. The implication that copper(III) might be involved in certain enzymatic processes (15–17), more especially in galactose oxidase, a two-electron oxidant that converts an alcohol to an aldehyde, has made these copper(III) macrocyclic systems attractive biomimetic models.

In contrast to the mononuclear macrocyclic systems considered above, Kida and co-workers (18) reported a neutral, binuclear copper(II) complex ((**I**), Fig. 1) containing two copper(II) centres bridged by two phenoxides and each bound to an azomethine and an amido nitrogen donor. The low room temperature magnetic moment observed for this compound (0.78 BM) indicates strong spin coupling between the copper centres. We have synthesized the neutral complexes **II** and **III** (Fig. 1),

which contain the same basic donor group arrangement as that found in **I**. Crystal structures are reported for **II** and **III** and a variable temperature magnetic study shows strong antiferromagnetic exchange in these complexes ($-2J = 689 \pm 7\ cm^{-1}$ (**II**), $-2J = 816 \pm 8\ cm^{-1}$ (**III**)).

Experimental

Synthesis of ligands and complexes

The following syntheses are outlined in the scheme given in Fig. 2.

$[Cu_2(L_2)]\cdot H_2O$ (II)

The intermediate complex B1 was synthesized as described previously (18). *Anal.* calcd. for $C_{13}H_{18}N_4O_4Cu_2\cdot 2H_2O$: C 34.14, H 4.85, N 12.25, Cu 13.89; found: C 34.05, H 4.75, N 12.30, Cu 13.75.

Complex B1 (0.45 g, 0.50 mmol) was suspended in *N,N*-dimethylformamide (dmf) (40 mL) and a solution (10 mL) of 1,3-dibutyryl-2-hydroxy-5-methylbenzene (19) (0.12 g, 0.50 mmol) in dmf was added. The reaction mixture was heated under reflux for 6 h in a nitrogen atmosphere. During this period complex B1 gradually dissolved and the resulting deep brown solution was filtered hot to remove any undissolved material. The solution was kept covered on a hot plate and on slow cooling brown crystals (**II**) deposited. These were collected by filtration, washed with methanol, and air dried. Yield 0.15 g. *Anal.* calcd. for $C_{28}H_{34}N_4O_5Cu_2$: C 53.03, H 5.37, N 8.84, Cu 20.06; found: C 53.00, H 5.44, N 8.91, Cu 20.45. Infrared (cm^{-1}): 3450(br), 1605(s), 1585(m), 1530(s), 1550(s). Ultraviolet (nm) (ε ($dm^3\ mol^{-1}\ cm^{-1}$)): 320(9675), 370(6825), 580(225) (spectrum run in dmso).

$[Cu_2(L_3)]$ (III)

This complex was prepared in a similar manner to **II** by reaction of the intermediate complex B2 (Fig. 2) with 1,3-dibenzoyl-2-hydroxy-5-methylbenzene (19) in methanol and obtained as green crystals. The

complex was recrystallized from $MeCN/CHCl_3$. The intermediate diamine (H_3A2) was prepared in a similar manner to H_3A1, using 1,3-propanediamine and dimethyl-4-methyl-phenol-2,6-dicarboxylate (18) and was isolated as a pale yellow viscous oil on removal of excess diamine under vacuum. It was used, as before, without further purification. *Anal.* calcd. for $C_{36}H_{32}N_4O_4Cu_2$ (**III**): C 60.70, H 4.50, N 7.85, Cu 17.85; found: C 60.55, H 4.55, N 7.75, Cu 17.70. Infrared (cm^{-1}): 1610(s), 1575(s), 1540(s), 1535(s). Ultraviolet (nm) (ε (dm^3 mol^{-1} cm^{-1})): 325(14000), 370(8200), 580(190) (spectrum run in dmso).

The intermediate complex (B2) was obtained as blue–violet crystals and contained two additional ligand molecules, which are assumed either to be trapped in the crystal lattice or very weakly associated with the two copper centres. *Anal.* calcd. for $C_{45}H_{70}N_{12}O_{10}Cu_2$([$Cu_2$(A2)-(OH)]·2$H_3$A2): C 50.70, H 6.55, N 15.75, Cu 11.90; found: C 50.45, H 6.50, N 15.65, Cu 11.75. Details on this species will be published elsewhere.

C, H, N, Cu analyses were performed by the Australian Mineral Development Laboratories, Melbourne, and by Canadian Microanalytical Service, Vancouver. Infrared spectra were carried out as KBr pellets using a Beckman IR-20 and electronic spectra were recorded using a Pye-Unicam SP8-150 spectrometer. The sample of compound **III**, which was submitted for X-ray structural analysis, was prepared according to the procedures outlined above, but was shown to contain solvent of crystallization, [$Cu_2(L_3)$]·CH_3CN·H_2O(III)). X-ray diffraction data were collected using an Enraf Nonius CAD-4 diffractometer with graphite-monochromatised MoK_α radiation.

Magnetic measurements

Room temperature magnetic moments were measured with a PAR 150 vibrating sample magnetometer and variable temperature magnetic susceptibility data were obtained in the range 5–300 K (compounds **II** and **III**) using an Oxford Instruments superconducting Faraday magnetic susceptibility system with a Sartorius 4432 microbalance. A main solenoid field of 1.5 T and a gradient field of 10 T m^{-1} were employed.

X-ray crystallographic analysis of complexes II and III

Diffraction intensities were measured at 295 K using the ω scan technique at a scan speed of 4°/min. Three standards were measured after every 100 reflections and no significant crystal decay was detected. The space group of **II** was uniquely determined by systematic absences. Compound **III** was triclinic and its structure was solved and refined

successfully in the space group $P\bar{1}$. The unit cell parameters in Table 1 were obtained by a least-squares refinement for 38 reflections ($40° \leq 2\theta \leq 45°$) for $[Cu_2(L_2)]\cdot H_2O$ (**II**) and for 60 reflections ($40° \leq 2\theta \leq 45°$ for $[Cu_2(L_3)]\cdot CH_3CN\cdot H_2O$ (**III**). Lorentz and polarization factors were applied but no corrections were made for absorption.

The structures were solved by MULTAN (20) plus difference Fourier maps and refined by full-matrix least-squares with counting statistics weights. H-atom positions for **II** were calculated but their parameters were not refined. H-atoms for **III** were placed in calculated positions and allowed to refine. All heavier atoms (except for C14 and C25 in **II**) were refined anisotropically. All calculations were performed with the NRCVAX crystal structure programs (21). Scattering factors were taken from the International tables for X-ray crystallography (22). The final atomic positional parameters and equivalent isotropic temperature factors for **II** are listed in Table 2 and those for **III** in Table 3. Anisotropic thermal parameters (supplementary Tables 1 (**II**), 4 (**III**)), calculated hydrogen parameters (supplementary Table 3) and observed and calculated structure factors (supplementary Tables 2 (**II**), 6 (**III**)) are available as supplementary data.[3] Hydrogen atoms in **II** are given the U_{iso} value of the carbon atom to which they are attached, plus 0.01.

Results and discussion

Description of the structures of $[Cu_2(L_2)]\cdot H_2O$ (II) and $[Cu_2(L_3)]\cdot CH_3CN\cdot H_2O$ (III)

The molecular structure of complex **II** is illustrated in Fig. 3. Selected bond lengths and angles relevant to the copper coordination spheres and the ligand are given in Table 4 (a detailed listing of bond distances and angles for **II** is given in supplementary Table 6[3]). The structure consists of two essentially square-planar copper(II) centres bridged by two phenoxide oxygen atoms with one imino and one carboxamido nitrogen donor completing the CuN_2O_2 plane. The copper–copper separation is 2.898(2) Å and the oxygen bridge angles from the azomethine unit (Cu(1)—O(1)—Cu(2) 99.0(4)°) and from the carboxamido unit (Cu(1)—O(2)—Cu(2) 100.6(4)°) are slightly different. Azomethine linkages N(2)—C(11) and N(3)—C(22), (mean 1.246 Å), are essentially double bond in character, whereas the carboxamide C—N bond lengths (N(1)— C(8) 1.335(17), N(4)—C(28) 1.322(17) Å) have much more single bond character and do not differ significantly from the free peptide value (1.32 Å) (23). These values, however, contrast sharply with C—N bond lengths in a related macrocyclic dicopper(II) complex involving saturated azomethine groups (C—N 1.499(8) Å) (24). Cu—N bond lengths to the carboxamido nitrogen atoms (Cu(1)— N(4) 1.861(10) Å, Cu(2)—N(1) 1.865(10) Å) are marginally shorter than Cu—N bond lengths involving the azomethine nitrogen centres, but significantly shorter than in the related macrocyclic derivative with saturated azomethine centres (Cu—N 1.986(5) Å) (24).

Each copper square plane is somewhat distorted with fairly acute angles within the Cu_2O_2 ring (O(2)—Cu(1)—O(1) 79.8(3)°; O(2)—Cu(2)—O(1) 80.4(4)°). Copper atom Cu(2) coincides with the mean plane described by the donor set N(1)–N(2)—O(1)— O(2), while Cu(1) is displaced from the mean plane of the donor set O(1)—O(2)—N(3)—N(4) by 0.137 Å towards a carboxamide oxygen (O(3)) of a neighbouring molecule. In fact the molecules are arranged in pairs in the crystal lattice, related by a centre of symmetry, in such a way that the Cu(1)—O(3)′ interaction (2.808(10) Å) can be considered to be a very weak bonding contact. The coordination geometry around Cu(1) is therefore best described as a square pyramid with the weak axial interaction involving O(3)′. The basic binuclear centre itself is almost flat with displacements of individual donors from the mean N_2O_2 planes of <0.02 Å and an angle of 0.6° between the N_2O_2 mean planes themselves (least-squares plane data are given in supplementary Table 7[3]). The bridging oxygen atoms (O(2), O(3)) have virtually no pyramidal character with solid angles at O(1) and O(2) of 359.5 and 360.1°, respectively.

The molecular structure of complex **III** is shown in Fig. 4 and selected interatomic distances and angles relevant to the copper coordination spheres are given in Table 5 (a detailed listing of bond distances and angles for **III** is given in supplementary Table 8[3]). The two copper(II) centres are bound by four short equatorial contacts (CuN_2O_2) and somewhat longer contacts (Cu(1)—O(3)″ 2.371(4); Cu(2)—O(4)′ 2.413(9) Å) to carboxamide oxygen atoms from neighbouring molecular units in an arrangement that stacks the molecules in the ***b*** direction in the crystal lattice. Each copper(II) centre is thus best described as

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

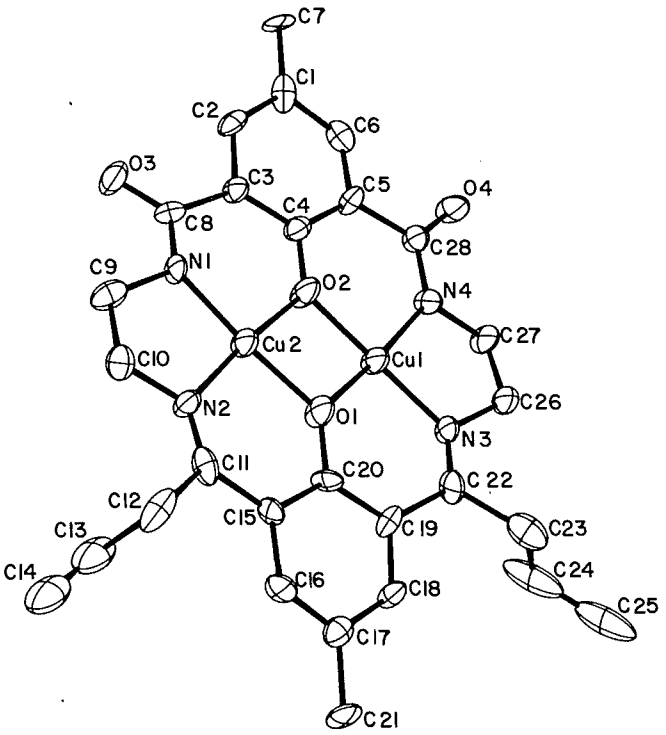

FIG. 3. Structural representation of $[Cu_2(L_2)]$ (**II**) with hydrogen atoms omitted (40% probability thermal ellipsoids).

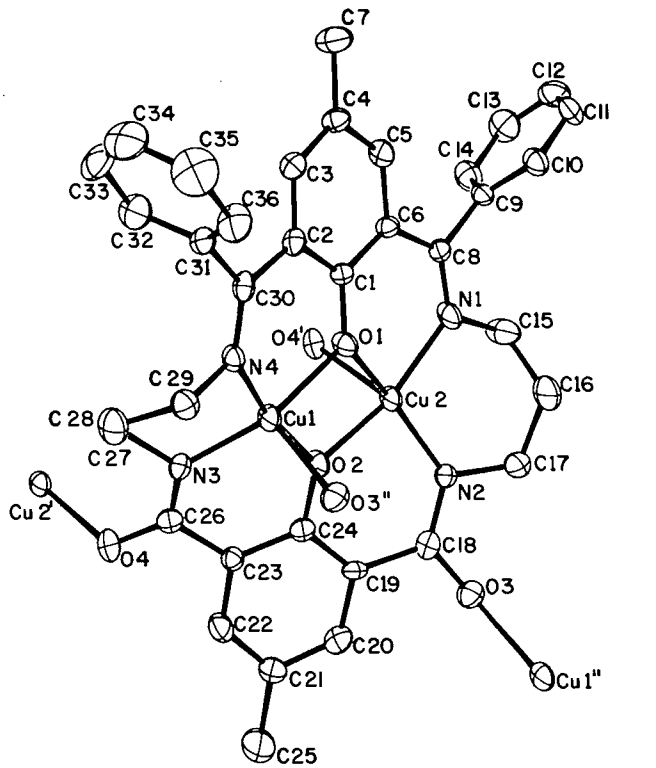

FIG. 4. Structural representation of $[Cu_2(L_3)]$ (**III**) with hydrogen atoms omitted (40% probability thermal ellipsoids).

having a five-coordinate, square-pyramidal structure. Copper–nitrogen distances in **III** are, in general, longer than those in **II**, which may be attributed, in part, to the presence of the $-(CH_2)_3-$ bridge, which creates a six-membered chelate ring. Once again Cu—N distances to the carboxamido nitrogen atoms are comparable with those associated with the azomethine centres, although Cu(2)—N(2) (1.937(4) Å) is significantly shorter than Cu(2)—N(1) (1.961(4) Å).

Some distortion occurs in the basal plane of the copper square-pyramids, with a marked compression of the O—Cu—O angles (O(1)—Cu(1)—O(2) 79.00(14); O(1)—Cu(2)—O(2) 77.90(13) Å), which are somewhat smaller than those found in **II**. Also both copper centres experience much more of a tetrahedral distortion of the equatorial donor set than is found in **II** (O(1)—Cu(1)— N(3) 153.63(16), O(2)—Cu(1)—N(4) 170.34(16)°; O(2)—Cu(2)—N(1) 165.41(16), O(1)—Cu(2)—

N(2) 154.46(15)°) which can be attributed in part to the flexibility imparted to the macrocyclic ligand by the six-membered chelate ring involving the N—$(CH_2)_3$—N moiety. Least-squares plane calculations show that for Cu(1) donors O(1) and N(3) are displaced by 0.190(4) and 0.236(5) Å, respectively, on one side of the N_2O_2 mean plane, whereas donors O(2) and N(4) are displaced by 0.189(4) and 0.262(5) Å, respectively, on the other side. A similar situation exists around Cu(2) (O(1) 0.209(4), N(2) 0.243(5), O(2) −0.206(4), N(1) −0.272(6) Å). Least-squares plane data are given in supplementary Table 9.[3]

The binuclear centre itself is somewhat bigger than that in **II** with a Cu(1)—Cu(2) separation of 3.0179(9) Å, longer average Cu—O bond lengths, and larger average Cu—O—Cu angles. The phenoxide bridge angles are quite different in this compound (Cu(1)—O(1)—Cu(2) 98.18(15)°, Cu(1)—O(2)—Cu(2) 104.91 (16)°), in contrast to **II**. The carboxamide C—O bond lengths are very slightly longer in this compound than in **II**,

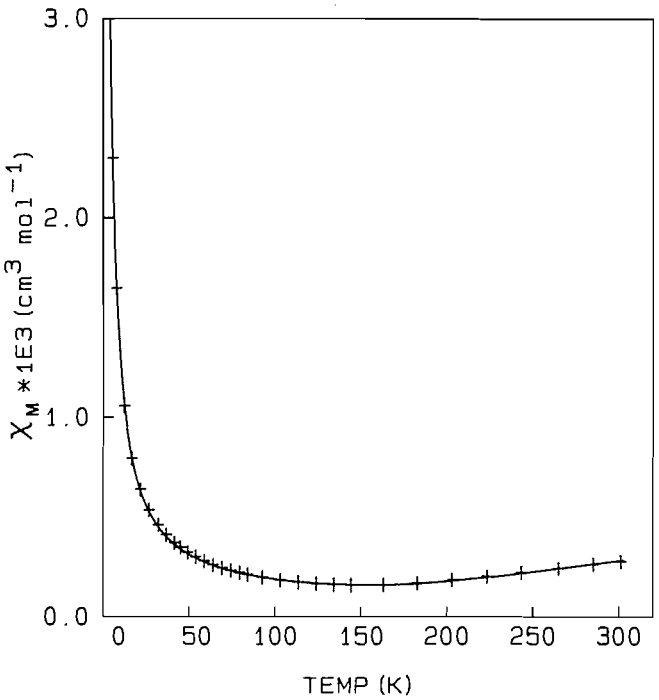

FIG. 5. Variable temperature magnetic susceptibility data for $[Cu_2(L_2)]\cdot H_2O$ (**II**). The solid line was calculated from eq. [1] with $g = 2.110 \pm 0.004$, $-2J = 689 \pm 7\,cm^{-1}$, $N\alpha = 120 \times 10^{-6}\,cm^3\,mol^{-1}$ complex, and $\rho = 0.030$ (3.0% paramagnetic impurity).

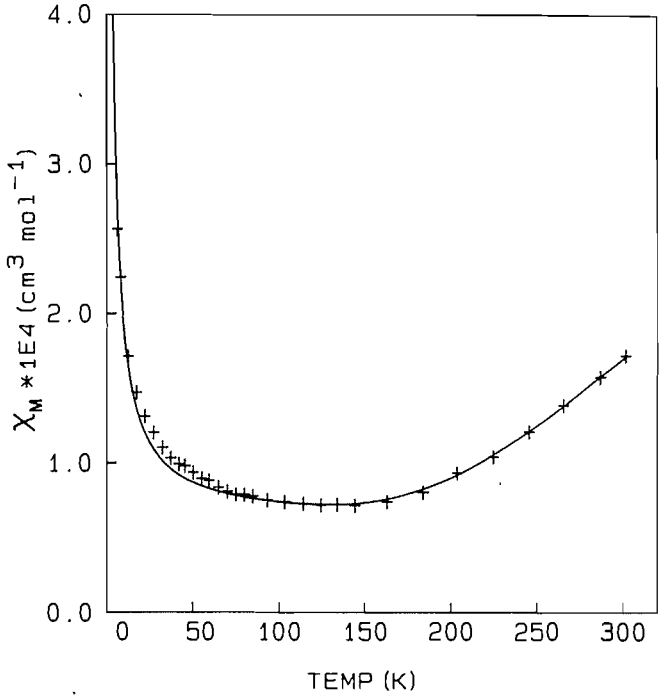

FIG. 6. Variable temperature magnetic susceptibility data for $[Cu_2(L_3)]\cdot CH_3CN\cdot H_2O$ (**III**). The solid line was calculated from eq. [1] with $g = 2.11 \pm 0.02$, $-2J = 816 \pm 8\,cm^{-1}$, $N\alpha = 120 \times 10^{-6}\,cm^3\,mol^{-1}$ complex, and $\rho = 0.00325$ (0.325% paramagnetic impurity).

indicating little change in the bonding character of this group as a result of the much more significant interaction of the carboxamide oxygens with the copper centres in adjacent molecules. Also, in contrast to the situation found in **II**, a significant pyramidal distortion exists at O(1) (solid angle 354.3°).

Magnetic properties

Room temperature magnetic moments for **II** and **III** are very low (0.52 (302 K), 0.72 (301 K) BM, respectively), indicative of strong antiferromagnetic coupling between the copper(II) centres. Variable temperature magnetic susceptibility measurements were performed on powdered samples of **II** and **III** in the temperature range 5–300 K. The results are summarized in Figs. 5 and 6, respectively. The shapes of the susceptibility plots reveal behaviour typical of strongly antiferromagnetically coupled binuclear compounds with the maximum of the susceptibility occurring at a temperature higher than 300 K. The susceptibility increase at low temperature is indicative of the presence of a small amount of monomeric paramagnetic impurity. The best-fit lines were calculated from the modified Van Vleck equation (25) for exchange-coupled pairs of copper(II) ions (eq. [1]):

$$[1]\quad \chi_M = \frac{N\beta^2 g^2}{3kT}\left[1 + \frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-\rho) + \left[\frac{N\beta^2 g^2}{4kT}\right]\rho + N\alpha$$

In this expression $2J$ (in the spin Hamiltonian $H = 2Js_1 \cdot s_2$) is the singlet–triplet splitting or exchange integral and other symbols have their usual meaning and ρ represents the fraction of a possible magnetically dilute copper(II) impurity. The temperature-independent paramagnetism for a binuclear copper(II) complex, $N\alpha$, was taken as $120 \times 10^{-6}\,cm^3\,mol^{-1}$. The parameters giving the best fit were obtained by using a nonlinear regression analysis with ρ as a floating parameter. The exchange integral ($-2J$) for complex **II** was found to be $689 \pm 7\,cm^{-1}$ ($g = 2.110 \pm 0.004$, $\rho = 0.030$) and for complex **III** was found to be $816 \pm 8\,cm^{-1}$ ($g = 2.11 \pm 0.02$, $\rho = 0.00325$) indicating strong to very strong exchange between the copper(II) centres.

It is of interest to compare the magnetism of complexes **II** and **III** in the light of their structural data. The dominant structural feature, which is likely to influence the antiferromagnetic exchange between the copper centres the most, is the planar arrangement of oxygen bridges and the phenoxide bridge angle. It is well established that magnetic exchange in a series of dihydroxo-bridged binuclear copper(II) complexes, $[Cu_2B_2(OH)_2]^{2+}$ (B = bidentate nitrogen donor) varies as a function of hydroxide bridge angle (26). For a hydroxide bridge angle of, for example, 104°, $-2J$ was found to be $481\,cm^{-1}$. It may be noted than in complex **II**, for which $-2J = 689\,cm^{-1}$, the two phenoxo bridge angles are 99.0° and 100.6°, and for **III**, whose singlet–triplet energy separation is $816\,cm^{-1}$, the phenoxo bridge angles are 98.18° and 104.91°. These exchange integral values are significantly greater than those of dihydroxo-bridged copper(II) complexes having comparable bridge angles. Unfortunately magneto-structural data are not available for a related series of diphenoxo-bridged copper(II) complexes and so no comparable relationship has been established. However, in a number of dicopper(II) complexes with mixed phenoxo-hydroxo bridges, which are structurally and magnetically characterized (27–32), no obvious correlation emerged between $-2J$ and bridge angle values.

The average Cu—O—Cu bridge angle for **III** (101.55°) is slightly larger than that for **II** (99.80°), but one phenoxide oxygen in **III** (O1) has significant pyramidal character (solid

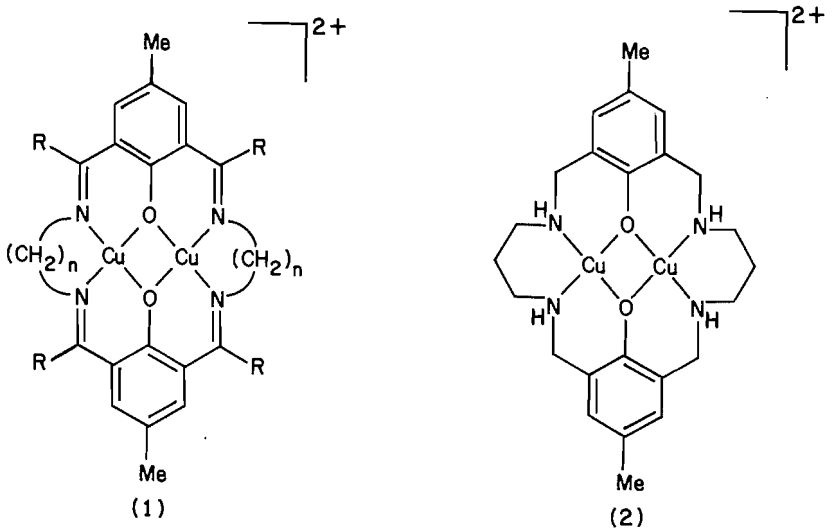

FIG. 7. (*1*) R = H, $n = 3$, $-2J = 850\ cm^{-1}$; R = H, $n = 4$, $-2J = 857\ cm^{-1}$; R = Me, $n = 3$, $-2J = 835\ cm^{-1}$; R = Pr, $n = 3$, $-2J = 806\ cm^{-1}$ (ref. 36). (*2*) $-2J = 824\ cm^{-1}$ (ref. 37).

angle 354.3°) and there are significant tetrahedral distortions in the CuN_2O_2 basal planes in this compound. Both of these effects might be expected to contribute to a reduced exchange in this system (33, 34). Pyramidal distortions in related phenoxo-bridged complexes (34) have been shown to lead to reduced antiferromagnetic exchange, but small distortions from planarity do not appear to influence exchange significantly (35). The large phenoxide bridge angle, Cu(1)—O(2)—Cu(2), of 104.9° in **III** might be considered to dominate the exchange situation for this compound, but considering the magnitude of the exchange ($-2J = 816\ cm^{-1}$) it seems reasonable to assume that both oxygen bridge groups contribute significantly to spin exchange. In comparing a variety of bisphenoxo-bridged macrocyclic dicopper(II) complexes of this sort (Fig. 7) it is evident that even major changes in the ligand itself, e.g. unsaturated versus saturated nitrogen donors and variable chelate ring sizes, do not have major effects on spin exchange (36, 37). Also for the butylene bridged complex $[Cu_2L(ClO_4)_2]$ (Fig. 7, 1, R = H, $n = 4$), which involves two pyramidally distorted oxygen bridges (solid angle 353.2°) and an oxygen bridge angle of 101.8°, very strong exchange is observed ($-2J = 857\ cm^{-1}$) (36) indicating the apparent insensitivity of the exchange towards pyramidal oxygen bridge distortions of this magnitude. Although distances within the amide framework are not really significantly different between the two compounds, quite major differences are observed in the bond distances within the $N_4O_2Cu_2$ framework (average Cu—N 1.875 Å, Cu—O 1.895 Å (**II**); average Cu—N 1.937 Å, Cu—O 1.950 Å (**III**)). This can be attributed, in part, to the "tight" binding arrangement generated by the ethylene bridge in **II** compared with the propylene bridge in **III**. On the basis of the shorter bond lengths within the magnetic framework ($d_{x^2-y^2}$) in **II**, a much larger exchange would have been expected.

In-plane Cu—O (bridge) distances, the degree of planarity of the copper magnetic orbitals and the slight pyramidal distortions at the oxygen bridge groups clearly do not account for the major differences in exchange between **II** and **III**. The only remaining structural feature of importance which could lead to a difference in exchange is the average phenoxide bridge angle, which differs by 1.75°. It is questionable whether such a small difference could be responsible for a difference in $-2J$ of $127\ cm^{-1}$. However, if the average oxygen bridge angles in **II** and **III** are substituted into the straight-line relationship observed for the dihydroxo-bridged species ($-2J = 74.53\phi - 7270\ cm^{-1}$; ϕ = hydroxide bridge angle) (26) a difference of $130\ cm^{-1}$ is obtained. It is perhaps unwise to attach much significance to the magnitude of the differences but to say that a 1.75° difference in phenoxide bridge angle could lead to a substantial difference in the exchange integral. It is clear that the situation concerning these macrocyclic complexes is much more complicated that that associated with the dihydroxo-bridged series and, until a larger selection of the macrocyclic systems is examined from a structural and magnetic standpoint, little can be said about magnetostructural trends.

Excess partial molar enthalpies of 2-butoxyethanol and water in 2-butoxyethanol–water mixtures

WILLIAM SIU[1] AND YOSHIKATA KOGA[2]

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received October 31, 1988

WILLIAM SIU and YOSHIKATA KOGA. Can. J. Chem. **67**, 671 (1989).

Excess partial molar enthalpies of 2-butoxyethanol (BE) and water, $H_m^E(i)$ (i = BE or H_2O), were measured from 25 to 35°C in the entire concentration range. The results indicated that there are three concentration regions bounded at about $x_B = 0.02$ and $x_B = 0.5$, x_B being the mole fraction of BE. In each region, the concentration and temperature dependence of $H_m^E(i)$ (i = BE or H_2O), is distinctively different from those in the other regions, and appears to support the following views: In the water-rich region, $x_B < 0.02$, BE molecules cause an enhancement in the structure of water, and this effect spans a long range via a structurally enhanced network of water. The solute–solute (BE–BE) interaction is repulsive and of a long range character in terms of enthalpy. As x_B increases, the repulsive solute–solute interaction becomes stronger sharply to the threshold value, $x_B \approx 0.017$, whereupon the mode of such mixing no longer becomes possible. In the intermediate range, $0.02 < x_B < 0.5$, a new scheme whereby BE molecules tend to associate is predominant. Two clathrate-like aggregates of the types $h[BE(H_2O)_k]$ with $k = 55$ and 4 may exist together with BE clusters $(BE)_n$. In the third region, $0.5 < x_B$, BE molecules are exactly in the same environment as in pure liquid, while water molecules are almost in the same environment as in pure water. The solution consists of BE and water clusters.

Key words: excess partial molar enthalpy, 2-butoxyethanol–water.

WILLIAM SIU et YOSHIKATA KOGA. Can. J. Chem. **67**, 671 (1989).

Opérant à des températures allant de 25 à 35°C et sur l'ensemble des concentrations, on a mesuré les enthalpies molaires partielles en excès du butoxy-2 éthanol (BE) et de l'eau, $H_m^E(i)$ (i = BE ou H_2O). Les résultats indiquent qu'il existe trois régions de concentrations dont les limites sont $x_B = 0{,}02$ et $x_B = 0{,}5$ (x_B correspond à la fraction molaire de BE). La relation qu'on peut observer dans une région entre $H_m^E(i)$ (i = BE ou H_2O) et la concentration ainsi que la température diffère beaucoup de celle que l'on peut dans les autres régions; cette observation supporte les hypothèses suivantes: dans la région riche en eau, $x_B < 0{,}02$, les molécules de BE provoquent une meilleure organisation de la structure de l'eau et cet effet s'étend à de grandes distances par le biais d'un réseau d'eau mieux organisé d'un point de vue structural. En termes d'enthalpie, l'interaction soluté–soluté (BE–BE) provoque des répulsions à longue distance. Avec une augmentation de x_B, les interactions de répulsions soluté–soluté deviennent beaucoup plus importantes, jusqu'à une valeur limite x_B d'environ 0,017 alors que ce mode de mélange n'est plus possible. Aux concentrations intermédiaires, $0{,}02 < x_B < 0{,}5$, un nouveau schéma dans lequel les molécules de BE tendent à s'associer devient prédominant. Deux agrégats ressemblant à des clathrates, du type $h[BE(H_2O)_k]$ avec $k = 55$ et 4, peuvent coexister avec des amas de $(BE)_n$. Dans la troisième région, $x_B > 0{,}5$, molécules de BE sont exactement dans le même environnement que dans le liquide pur alors que les molécules d'eau sont presque dans le même environnement que dans l'eau pure. La solution comporte des agrégats de BE et d'eau.

Mots clés : enthalpie molaire partielle en excès, butoxy-2 éthanol/eau.

[Traduit par la revue]

Introduction

In the previous papers from this laboratory (1–3), the measured values of excess *partial* molar enthalpies, $H_m^E(i)$ (i = TBA or H_2O), of tert-butanol (TBA) and water in the TBA–water mixtures were reported. The results have provided more direct information than hitherto available on the nature of the solute–solvent and solute–solute interactions, and hence provided more insight into the mode of molecular aggregation.

The present paper reports the directly measured values of excess *partial* molar enthalpies of BE and water, $H_m^E(BE)$ and $H_m^E(H_2O)$, in the BE–water mixtures from 25 to 35°C in the entire concentration range. This system has been studied extensively together with the TBA–water system, since anomalies in various physical properties are equally pronounced in the water-rich region (4–14). While the results of the recent light scattering (7, 9, 10) and ultrasonic relaxation measurements (8, 11, 13) have appeared to be consistent with the existence of molecular aggregates of the type $h[BE(H_2O)_k]$, with $k = 55$ and 4, there also exist some puzzling results. For example, the hydrodynamic radii calculated from the self-diffusion coefficient and viscosity were found to be about the same or even smaller than each molecular radius (12) in the concentration range where such molecular aggregates are believed to exist. On the other hand, there is an indication of the existence of a large cluster with hydrodynamic radius of about 1000 Å for $x_B < 0.02$ at room temperature (13, 14), although such existence may be sample-dependent (14), x_B being the mole fraction of BE.

The original purpose of this work was to obtain some information on the solute–solvent and the solute–solute interactions similar to that for the TBA–water system (1–3). It turned out that the concentration dependence of $H_m^E(BE)$ changes very drastically at $x_B \approx 0.017$. The plots of the derivative, $(\partial H_m^E(BE)/\partial x_B)_{N.T.P}$ (which is proportional to solute–solute interaction), exhibits a surprisingly similar shape of a heat capacity anomaly against temperature at a second order phase transition pertaining to a change in a bulk structure. This is relevant to the idea that there is a new type of phase transition in analogy to a surfactant solution (15).

Experimental

The specimen of 2-butoxyethanol used in this work was purchased from Aldrich, the same supplier as the samples used by Kato *et al.* (13) and Bender *et al.* (14). As will be discussed below, the existence of a species with a very large hydrodynamic radius of the order of 1000 Å

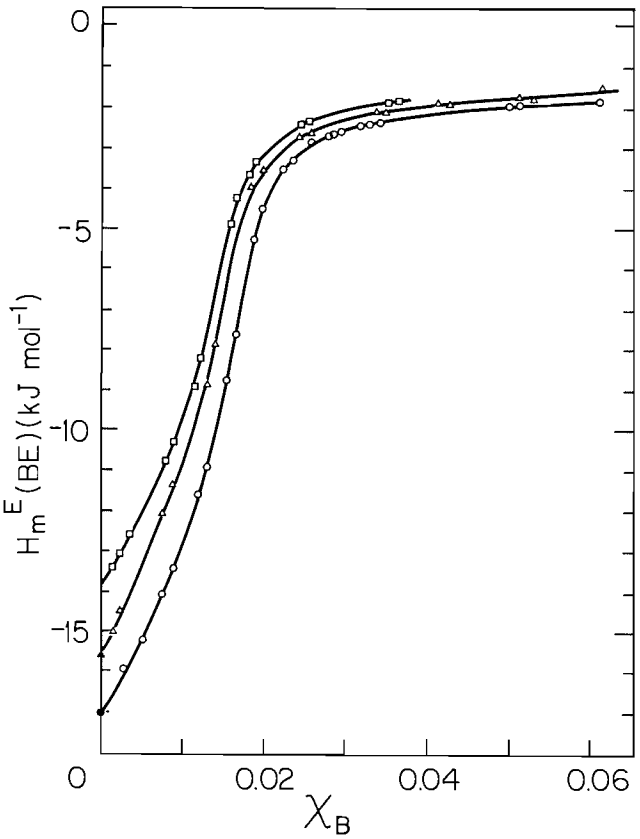

FIG. 1. The excess partial molar enthalpies of BE, H_m^E(BE), against mole fraction of BE, x_B. ○, 25°C; △, 30°C; □, 35°C; ●, ▲, refs. 17 and 18.

was observed in these two studies. An analytical gas chromatography indicated the purity to be better than 99.9%. This specimen was used without further purification.

The excess partial molar enthalpies were measured by means of an LKB Bromma precision calorimetry system. The buret method as described in a previous paper (2) was employed. The values of H_m^E(i) (i = BE or H_2O) were calculated as described previously (1–3, 16). The errors were estimated to be 1% with an upperbound error of ± 0.1 kJ mol^{-1} and a lower bound error of ± 0.03 kJ mol^{-1}. As pointed out previously, the buret method is not as accurate as the ampoule method (2).

Results and discussion

The measured values of H_m^E(i) (i = BE or H_2O) are listed in Table 1 and plotted in Figs. 1 and 2. In terms of their composition and temperature dependence, there are clearly three regions bounded at about $x_B = 0.02$ and $x_B = 0.5$. As shown in Fig. 1, the extrapolated values of H_m^E(BE) to $x_B = 0$ compare well with those available in literature (17, 18). For the entire concentration range, however, no data of H_m^E(i) (i = BE or H_2O) are available for direct comparison with the values from this work. Thus, the excess (integral) molar enthalpies, H_m^E, were calculated from the values of H_m^E(i), (i = BE and H_2O) read off the smooth curves drawn in Figs. 1 and 2. Such values are plotted in Fig. 3 together with the available literature values (19, 28). The comparison appears satisfactory.

If the values of the excess partial molar free energy, G_m^E(i), are available, those of the excess partial molar entropy, S_m^E(i), can be calculated. The values of S_m^E(i) and their concentration and temperature dependence together with those of H_m^E(i) would provide a deeper insight into the nature of the solution. The vapour pressures of eight mixtures of the BE–H_2O system were measured (20). The data were analysed by forcing a single analytic function for G_m^E for the entire concentration range, from which analytic expressions for G_m^E(i) (i = BE or H_2O) were given (20). However, the excess (integral) heats of dilution obtained from the temperature dependence of G_m^E did not fit well with the observed values (19) for $x_B > 0.2$. Moreover, the immiscibility gap calculated from the inflection points in G_m^E was wider in temperature and concentration than that observed. Therefore, such calculations for S_m^E(i) will have to be postponed until the vapour pressures are measured at very close intervals in concentration.

The solute–solvent interaction is given as the value of H_m^E(BE) at $x_B \approx 0.0$. As seen in Fig. 1, it is strongly exothermic. This result together with a large positive value of C_p^E(BE) at $x_B \approx 0.0$ (4) is consistent with the suggestion that the solute enhances the structure of the solvent water, as in the case of TBA–water solutions (1–3, 21–24).

Intuitively, the derivative of the partial molar enthalpy of BE with respect to the number of moles of BE is a measure of the solute–solute interaction. The formal connection between the two without invoking any model system, however, is not immediately obvious. To begin with, a formal separation of the internal energy of the system into solute–solvent and solute–solute interactions is a difficult task without relying on a model. If we have a model system, on the other hand, a relationship can be derived between the derivative, $(\partial H_m^E(\mathrm{BE})/\partial n_{\mathrm{BE}})_{n\mathrm{H_2O},T,P}$, and the solute–solute interaction defined within the scope of the model system. In the mean-field approximation, for example, it is elementary to show that the derivative is indeed proportional to the solute–solute interaction parameter defined in the mean-field approximation. Obviously, the mean-field approximation is far from the reality for the present system. In the absence of an appropriate model, we calculate the derivative graphically using the present data. Since H_m^E(BE) is an intensive variable, it follows that

$$[1]\quad N(\partial H_m^E(\mathrm{BE})/\partial n_{\mathrm{BE}})_{n_{\mathrm{H_2O}},T,P} = (1 - x_B)(\partial H_m^E(\mathrm{BE})/\partial x_B)_{N,T,P}$$

where $N = n_{\mathrm{BE}} + n_{\mathrm{H_2O}}$. The values of $(\partial H_m^E(\mathrm{BE})/\partial x_B)_{N,T,P}$ were evaluated as the tangents of the smooth curve drawn in Fig. 1, and the values of the right hand of eq. [1] are plotted in Fig. 4 for the range, $x_B < 0.04$. As is apparent from Fig. 4, the values of the solute–solute interaction are finite and positive in this concentration range, and do not appear to extrapolate smoothly to zero at $x_B = 0.0$. This indicates that the solute–solute interaction is repulsive and is of a very long (almost infinite) range. The ratio of the hydrogen bonds intact in water has been argued to be well above the percolation threshold (25). Namely, the hydrogen bond network spans over the entire bulk of water. If a BE molecule enhances the structure of such hydrogen bond network, the second BE molecule should feel the effect of structure enhancement even at an infinite distance via the hydrogen bond network. As the concentration of BE increases, the repulsive interaction becomes stronger sharply, as is apparent from Fig. 4, to a threshold, $x_B \approx 0.017$ at 25°C, beyond which such interaction diminishes sharply. In terms of the concentration dependence of $(1 - x_B)(\partial H_m^E(\mathrm{BE})/\partial x_B)$, the crossover from the water-rich region to the intermediate region is very drastic suggesting a kind of phase transition pertaining obviously not to a bulk structure but an intermediate scale structure. It is striking that the shape of the anomalies in Fig. 4 resembles that of the heat capacity vs. temperature for a second

order (bulk) phase transition. A general relationship between the order of the transition and the shape of heat capacity anomalies has been explored (26, 27). It is worth noting that the same plots for the TBA–water system shows a smaller and much smoother hump (2) than the present case, resembling a heat capacity anomaly of a higher than the second order (bulk) phase transition (26, 27). Roux *et al.* (4, 15) have suggested a kind of phase transition in analogy to the formation of micellar aggregates of the surfactant solutions and drawn a phase boundary (4) from the peak position of the excess partial molar heat capacity, C_p^E(BE). Such a phase boundary is reproduced in Fig. 5, together with the positions of anomalies in the plots of Fig. 4. The recent ultrasonic relaxation (13) and light scattering measurements (14) showed that there is a boundary below which the hydrodynamic radii of diffusing species are very large, of the order of 1000 Å. These thresholds are also plotted in Fig. 5. While the sample-dependent feature in the light scattering measurements (14) needs to be clarified further, various techniques point to the existence of the "phase boundary" shown in Fig. 5, suggesting that there is a genuine change in the intermediate scale structure, or the mode of molecular aggregation across the boundary. It is important to note that the thermodynamic quantities which show anomalies at this phase boundary are related to the *third* derivative of the free energy; the partial molar heat capacity of the work by Roux *et al.* (4) is the derivative of the free energy with respect to temperature twice and concentration once, while the quantity expressed by eq. [1] of this work is that with respect to temperature once and concentration twice.

The mode of molecular aggregation that can be deduced from the present results is summarized as follows: In the water-rich region, below the boundary shown in Fig. 5, BE molecules

modify the hydrogen bond network of water. By so doing, they interact each other repulsively via the structurally enhanced network of the solvent. Thus the implication is that they avoid each other in this concentration range. Obviously, data of the excess partial molar entropy, or the excess partial molar free energy are required for a more definite conclusion in this regard. However, it is worthwhile to note that the Kirkwood–Buff parameter for the BE–BE pair is negative (10), and that the joint diffusion coefficient for the BE–BE pair is also negative (12) in this concentration range, suggesting mutual repulsion among BE molecules.

As the concentration of BE increases, the BE–BE repulsion becomes stronger until the concentration reaches that of the "phase boundary", at which this mode of mixing no longer becomes possible, and a new scheme becomes operative. The threshold concentration corresponds to the stoichiometric ratio, the number of water molecules over that of BE molecules, of about 55. Thus it appears that below this threshold a clathrate-like aggregate of the type $BE(H_2O)_k$ with a fixed value of 55 does not exist, but rather it is forced to form at and perhaps beyond the phase boundary.

In the intermediate region, beyond the phase boundary and up to about $x_B = 0.5$, a precursory situation of the phase separation that occurs above the critical solution temperature, 49.4°C (9), may be expected. Indeed, a Rayleigh and Raman scattering work suggested the existence of two kinds of clathrate-like species; $g[BE(H_2O)_{50}]$ and $h[BE(H_2O)_4]$, their compositions being the same as those of two phases into which the solution separates above 49.4°C. As apparent from Fig. 2, however, there is no singular behaviour in H_m^E(BE) at $x = 0.200$, where all the water molecules would be exhausted to form $h[BE(H_2O)_4]$.

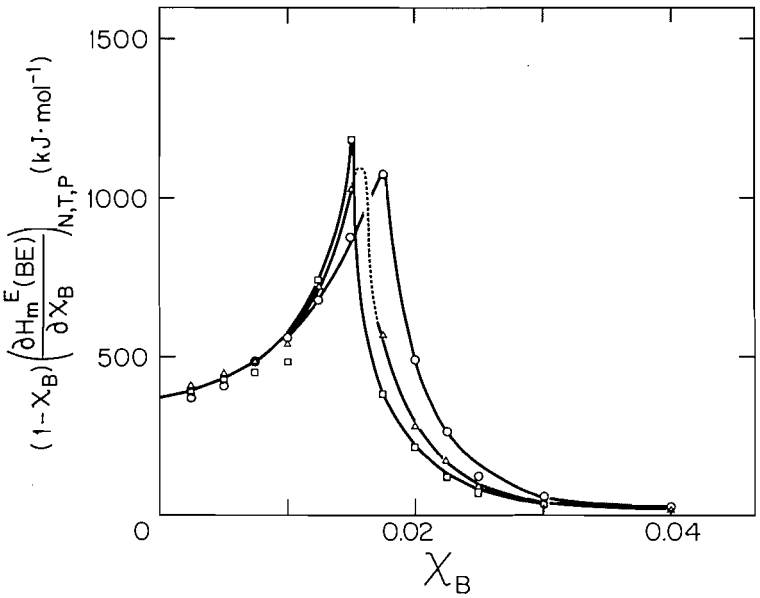

FIG. 4. The solute–solute interaction, $(1 - x_B)(\partial H_m^E(BE)/\partial x_B)_{N,T,P}$, against mole fraction x_B. ○, 25°C; △, 30°C; □, 35°C.

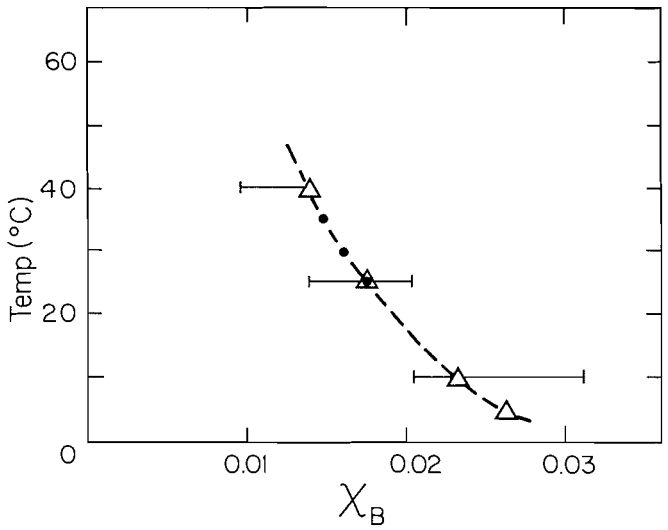

FIG. 5. The "phase diagram". ●, this work; △, ref. 4; ⊢⊣, ref. 14.

This may suggest that in this range the aggregates of BE have already started to mix in. The interpretation for the second mechanism of ultrasonic relaxation also pointed to the existence of BE clusters (13). The observations that the Kirkwood–Buff parameters (10) and the joint diffusion coefficients (12) for the BE–BE as well as the H_2O–H_2O pairs are highly positive support the notion of the formation of BE and H_2O aggregates already in this concentration range.

In the third concentration region, $x_B > 0.5$, it is striking that H_m^E(BE) is zero and $H_m^E(H_2O)$ is small, negative, and constant. These facts suggest that an additional BE molecule always settles in the environment which is exactly the same as that in pure liquid in terms of enthalpy. An additional H_2O molecule, on the other hand, finds itself in an environment very slightly more favourable than that in pure water. Such an environment stays the same all through this region. The following picture, though speculative, appears consistent with these findings: In this concentration range, the solution consists of clusters of BE and clusters of water. The enthalpy of the interfacial region between two kinds of clusters is slightly more exothermic for H_2O than in the inside of H_2O clusters, while for a BE molecule the inside of BE clusters is more exothermic than the interfacial region. Thus an additional BE molecule settles into the inside of BE clusters and an additional H_2O in the interfacial region of the two kinds of clusters. This presents an interesting question as to the size of such clusters, small enough not to be recognized as a bulk phase but large enough for the inside of the BE clusters to be the same as that of the bulk BE.

Nitrogenous metabolites from the deep water sponge *Hexadella* sp.

SANDRA A. MORRIS AND RAYMOND J. ANDERSEN[1]

Departments of Chemistry and Oceanography, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 23, 1988

SANDRA A. MORRIS and RAYMOND J. ANDERSEN. Can. J. Chem. **67**, 677 (1989).

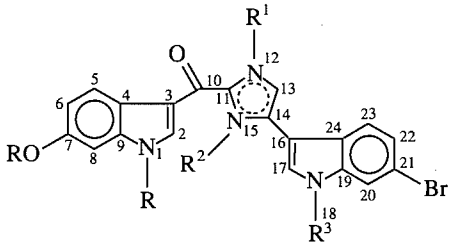
The secondary metabolites of the sponge *Hexadella* sp., collected by SCUBA (−40 m) and manned submersible (−100 to −200 m) in Jervis Inlet, British Columbia, have been examined. The submersible-collected material contained only the previously reported compound topsentin B2 (**1**). Sponge material collected in shallower water via SCUBA contained hexadellins A (**2**) and B (**3**), two new dibromotyrosine derived metabolites. The structures of **2** and **3** were determined by spectroscopic analysis of the diacetyl derivatives **6** and **7**.

Key words: sponge, metabolite, *Hexadella*, nitrogenous.

SANDRA A. MORRIS et RAYMOND J. ANDERSEN. Can. J. Chem. **67**, 677 (1989).

On a étudié les métabolites secondaires d'éponges *Hexadella* sp., récoltées par plongée (−40 m) et par des submersibles habités (de −100 à −200 m) dans l'anse de Jervis, en Colombie britannique. Les éponges recueillies à l'aide des submersibles ne contiennent que de la topsentine B2 (**1**), un produit observé antérieurement. Les éponges recueillies dans des eaux moins profondes contiennent des hexadellines A (**2**) et B (**3**), deux nouveaux métabolites dérivés de la dibromotyrosine. On a déterminé les structures des composés **2** et **3** en se basant sur les données spectroscopiques de leurs dérivés acétyles, **6** et **7**.

Mots clés : éponge, métabolite, *Hexadella*, azoté.



[Traduit par la revue]

Sponges are widely distributed in the world's oceans, occurring at all depths and latitudes. A large amount of work on SCUBA accessible species has shown that sponge secondary metabolism is spectacularly diverse, complex, and novel (1). Only a limited number of deep water species have been examined to date (2). It is already clear, however, that interesting chemistry is not restricted to species of sponges collected in shallow waters. What remains to be determined is the extent to which very deep water sponges will yield metabolites that are substantially different from those found in their shallow water relatives.

A recent opportunity to collect marine invertebrates with the manned submersible PICES IV has permitted us to investigate the secondary metabolites of the deep water sponge *Hexadella* sp. (3)[2] collected at Dark Cove and Agamemnon Channel in Jervis Inlet, B.C. We now wish to report that specimens of the sponge collected with PICES IV at −100 to −200 m contained only the previously reported metabolite topsentin B2 (**1**) (4),[2] while specimens of the same sponge collected with SCUBA at −40 m contained hexadellins A (**2**) and B (**3**), two new dibromotyrosine derived metabolites.

Hexadella sp. (Order Verongida, Family Aplysinidae (3)) is always found growing on the skeletons of dead hexactinellid glass sponges *Aphrocallistes vastus* and *Chonelasma calyx* at depths greater than −40 m. Freshly collected specimens of *Hexadella* sp. from both depths were immediately immersed in methanol. Contact with the methanol caused the *Hexadella* sp. tissue to undergo a rapid color change from bright sulfur yellow to dark purple that is characteristic of Verongiid sponges (5). Routine bioassays indicated significant cytotoxic (L1210) and antimicrobial activities (against *Staphylococcus aureus* and *Bacillus subtilus*) in the crude methanol extracts of *Hexadella* sp. from both depths.

Bioassay guided fractionation of the methanol extract of the PICES IV collected *Hexadella* sp., employing sequential application of Sephadex LH 20 (7:3 $MeOH/CH_2Cl_2$) and reverse phase high performance liquid (3:1 $MeOH/H_2O$) chromatographies, gave a pure biologically active molecule designated HEX I as the only detectable secondary metabolite. A parent ion doublet in the electron impact high resolution mass spectrum (EIHRMS) of **1**, having equal intensity peaks at m/z 420.0224 (ΔM, +0.2 mmu) and 422.0202 (ΔM, −0.1 mmu) daltons, was consistent with a molecular formula of $C_{20}H_{13}N_4O_2Br$. Both the ^1H and ^{13}C nmr spectra of **1** showed too many resonances for a molecule containing 20 carbon and 13 hydrogen atoms (see Experimental). We attributed the complexity in the nmr spectra of **1** to the existence of two tautomers. Treatment of HEX I (**1**) with dimethyl sulfate and potassium carbonate in refluxing acetone trapped the tautomers as a mixture of the trimethylated and tetramethylated derivatives **4** and **5**.

1 R = R^1 = R^3 = H
4 R = Me R^1 = Me R^3 = H
5 R = Me R^2 = Me R^3 = Me

TrimethylHEX I (**4**) showed parent ions (1:1) in the EIHRMS at m/z 462.0672 (ΔM, −1.8 mmu) and 464.0663 (ΔM, −0.7 mmu) daltons, appropriate for a molecular formula of $C_{23}H_{19}N_4O_2Br$, which contains three carbon and six hydrogen atoms more than the molecular formula of the parent compound. Resonances at δ 3.91 (s, 3H), 3.99 (s, 3H), and 4.16 (s, 3H) in the ^1H nmr spectrum of **4** confirmed that the new atoms had been added as three methyl groups. Proton nmr double resonance and nOe (Fig. 1) experiments suggested the presence of a 1-methyl-3-alkyl-6-methoxyindole fragment in **4**. A series of mass spectral fragments at m/z 188 ($C_{11}H_{10}O_2$), 174 ($C_{10}H_8O_2$), and 145 (C_9H_8O) daltons confirmed the existence of the indole

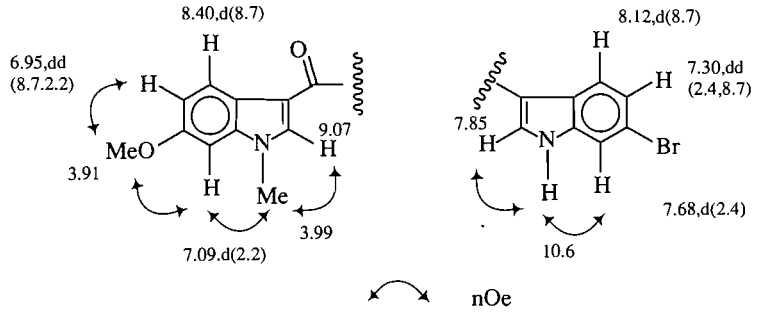

FIG. 1.

fragment and also revealed that the C3 substituent was a carbonyl. Further nOe (Fig. 1) and decoupling experiments identified a second set of proton resonances that could be assigned to a 3-alkyl-6-bromoindole fragment by comparison with published ^{1}H nmr chemical shifts for molecules containing this substructure (2*c*, 6). The remaining atoms ($C_4H_4N_2$) and unaccounted for spectral features (^{1}H nmr δ 7.65 (s, 1H), 4.16 (s, 3H); ^{13}C nmr δ 121.8 (CH), 136.7 (C), 138.8 (C), 36.5 (CH_3)) of **4** could readily be assigned to a 2,4-disubstituted-*N*-methylimidazole moiety. A series of nOe experiments (Fig. 2) unambiguously located the 1-methyl-3-keto-6-methoxyindole, 6-bromoindole, and methyl substituents on the imidazole ring as shown in **4**. HETCOR, COSY, and a series of SINEPT experiments were in complete agreement with the proposed structure **4** for trimethylHEX I. With the structure of trimethylHEX I (**4**) in hand, it was a routine exercise to assign structures to tetramethylHEX I (**5**) and the parent metabolite HEX I (**1**).

Shortly after we had determined the structure of **1**, Bartik *et al.* (4*a*) reported the isolation of the same compound, which they named topsentin B2, from the shallow water Mediterranean sponge *Topsentia genetrix* collected off the coast of France. We subsequently learned that topsentin B2 had also been isolated from a deep water Caribbean sponge (4*b*).

The crude methanol extract of the SCUBA collected *Hexadella* sp. (−40 m) was evaporated *in vacuo* to give an oily residue that was suspended in water and sequentially extracted with hexane and chloroform. Separation of the chloroform soluble materials by Sephadex LH 20 chromatography (3:1 MeOH/CH_2Cl_2) gave an antimicrobial green/yellow fraction containing mainly hexadellins A (**2**) and B (**3**) as indicated by ^{1}H nmr analysis. Acetylation of the material in this fraction with acetic anhydride and pyridine gave a crude acetylated mixture that was fractionated via silica gel flash (gradient: 4:1 hexane/EtOAc to 4:1 EtOAc/MeOH) and normal phase high performance liquid (95:5 EtOAc/MeOH) chromatographies to give pure samples of diacetylhexadellin A (**6**) and diacetylhexadellin B (**7**). There was no detectable topsentin B2 (**1**) in the methanol extracts of the SCUBA collected samples (−40 m) of *Hexadella* sp.

Diacetylhexadellin A (**6**) failed to show a molecular ion in either the electron impact or chemical ionization mass spectra. The molecular formula of $C_{25}H_{27}Br_4N_3O_7$ for **6** was therefore obtained by summing the atoms present in a number of fragments that were readily identified from the ^{1}H and ^{13}C nmr spectra (Tables 1 and 2).

The ^{1}H nmr resonances observed at δ 3.76 (s, 3H, OMe), 5.85 (s, H1), 6.32 (s, H5), 3.09 (d, J = 18 Hz, H7), 3.46 (d, J = 18 Hz, H7′), and 2.15 (s, OAc) in the spectrum of **6** could be assigned to a spirocyclohexadienyldihydroisoxazole

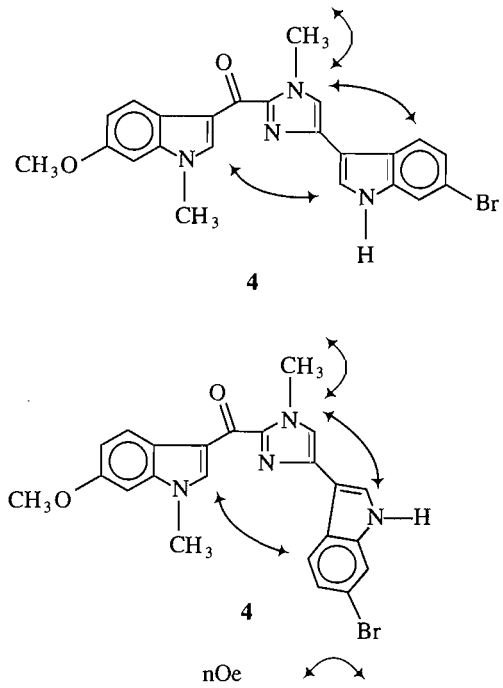

FIG. 2.

fragment **A** by comparison with published chemical shifts for diacetylaerothionin (**8**) (7) and tetraacetylfistularin-3 (**9**) (8) (Table 1). A second set of resonances at δ 7.17 (bt, J = 6 Hz, H10), 3.71 (dt, J = 5.2, 6.0 Hz, H11,11′), 2.11 (tt, J = 5.6, 6.2 Hz, H12,12′), 4.09 (t, J = 5.6 Hz, H13,13′), 7.35 (s, H16,16′), 2.75 (t, J = 7.2 Hz, H18,18′), 3.47 (dt, J = 5.2, 7.2 Hz, H19,19′), and 5.58 (bt, J = 6 Hz, H20) in the ^{1}H nmr spectrum of **6** could be assigned to fragment **B** by comparing their chemical shifts (Table 1) with published values for the identical fragment found in diacetylpsammaplysin-A (**10**) (7). Double resonance, COSY, and nOe ^{1}H nmr experiments verified the structure of fragment **B**. A final methyl singlet at δ 1.98 was assigned to an acetamide. Having identified all the substructures of diacetylhexadellin A (**6**), it only remained to determine which of the terminal nitrogen atoms (N10 or N20) in fragment **B** was attached to the acetyl residue and which was attached to the carbonyl functionality in fragment **A**.

Examination of the NH chemical shifts in a series of model compounds such as diacetylpsammaplysin A (**10**) (7) and diacetylfistularin-3 (**9**) (8) (Table 1) revealed that a proton on a nitrogen attached to fragment **A** would have a chemical shift in the range of δ 6.60–7.30, while a proton on a nitrogen that was acetylated would have a chemical shift in the range of

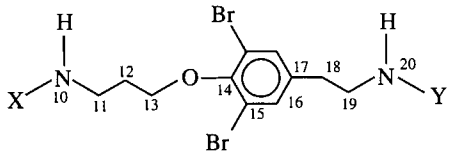
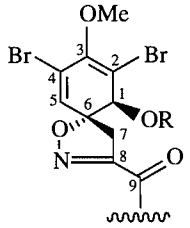
[a]Proton attachments determined via APT.

δ 5.5–6.1. Since H10 in **6** had a chemical shift of δ 7.17 and H20 had a chemical shift of δ 5.58 it was possible to conclude that fragment **A** was attached to N10 and the acetyl group was attached to N20 of fragment **B** as shown. The nonacetylated parent molecule hexadellin A therefore had structure **2**.



Diacetylhexadellin B (**7**), like diacetylhexadellin A (**6**), failed to show molecular ions in either the EI or CI mass spectra so its molecular formula of $C_{25}H_{27}Br_4N_3O_7$ was also obtained by summing the atoms present in fragments that could be clearly identified from nmr experiments. The nmr data for **7** were nearly identical to those of **6** (Tables 1 and 2), allowing the almost immediate recognition of fragments **A** and **B** as well as an N-acetyl in **7**. Once again, double resonance and COSY experiments confirmed the structures of the proposed fragments. A difference in the chemical shifts of NH10 (δ 6.10 in **7**: δ 7.17 in **6**) and NH20 (δ 6.65 in **7**: δ 5.58 in **6**) in **6** and **7** indicated that fragment **A** was attached to N20 and the acetyl group to N10 in **7** as shown. The structure of the parent metabolite hexadellin B therefore must be **3**.

Our studies of the chemistry of *Hexadella* sp. have shown that the sponge apparently has different secondary metabolite contents at the extremes of its depth distribution. The new dibromotyrosine derived compounds hexadellin A (**2**) and B (**3**) isolated from the SCUBA collected material are typical metabolites of Verongiid sponges. The absence of dibromotyrosine derived metabolites and the presence of topsentin B2 (**1**) in the PICES IV collected material is unexpected and difficult to reconcile within the framework of our current knowledge about chemical taxonomy of the porifera (5). There is no precedent for a sponge having different chemistry at different depths, and tryptophan derived metabolites such as topsentin B2 (**1**) are unknown from Verongiid sponges.



One obvious explanation would be that the PICES IV collected material was simply incorrectly identified. However, the deep sponges were found growing on the dead remains of glass sponges, they underwent the color change characteristic of the Verongidae, and to an experienced sponge taxonomist[2] they appeared identical to the shallower sponges by both visual inspection and microscopic examination. Therefore, we feel confident that both collections were *Hexadella* sp.

Perhaps the most likely explanation for our observations

is that *Hexadella* sp. contains dibromotyrosine derived metabolites (i.e., **2** and **3**) at −40 m and that it contains neither these metabolites nor topsentin B2 (**1**) at −100 to −200 m. The discovery of topsentin B2 (**1**) in the deep water collection could be explained by the presence of a small undetected amount of a second sponge, probably a *Topsentia* species (4), buried in the glass sponge skeleton. Unfortunately, due to suspension of the submersible program, we have not been able to re-collect deep water specimens of *Hexadella* sp. and consequently we have been unable to adequately resolve this issue.

Experimental

The nmr spectra were recorded on Varian XL 300 and Bruker WH 400 spectrometers. Tetramethylsilane was used as an internal standard. Low resolution mass spectra were recorded on an AEI MS 902 spectrometer and high resolution mass spectra were recorded on an AEI MS 50 spectrometer. Infrared spectra were recorded on a Perkin–Elmer 1600 Fourier Transform spectrometer. Merck silica gel 230–400 mesh was used for flash chromatography and a Whatman Magnum-9 Partisil-10 column was used for preparative hplc. Sephadex LH 20 was used for molecular exclusion chromatography.

Collection

Hexadella sp. was collected at Dark Cove, Jervis Inlet, in November, 1986, using the manned submersible PICES IV (−110 to −200 m) and at Agamemnon Channel in October, 1987, using SCUBA (−40 m).

*Isolation of HEX I (Topsentin B2) **1***

The PICES IV collected sponge (500 g, wet wt.) was immersed in methanol immediately after collection. Concentration of the methanol extract *in vacuo* yielded 6 g of crude residue. A 400-mg portion of the crude residue was chromatographed on a Sephadex LH 20 column prepared and eluted with methanol/dichloromethane (7:3). Fractions containing **1** were further purified via reverse phase hplc (methanol/water; 3:1) to give 71 mg (1.8% of crude residue) of **1**.

*HEX I (Topsentin B2) **1***: yellow/green oil (2:1 mixture of tautomers); uv (MeOH): 286 nm (ε 17 000), 382 nm (ε 15 500); ir (film): 3300 (br), 1702, 1524, 1158, 868 cm^{-1}; ^1H nmr (acetone-d_6), major tautomer, δ: 6.87 (dd, J = 8.7, 2.2 Hz, H6), 7.02 (d, J = 2.2 Hz, H8), 7.27 (dd, J = 8.6, 1.5 Hz, H22), 7.68 (d, J = 1.5 Hz, H20), 7.72 (d, J = 2.1 Hz, H13), 7.86 (d, J = 2.5 Hz, H17), 8.09 (s, OH), 8.22 (d, J = 8.6 Hz, H23), 8.32 (d, J = 8.7 Hz, H5), 9.43 (s, H2), 10.59 (bs, H18), 10.90 (bs, H15), and 12.20 (bs, H1); minor tautomer, δ: 6.84 (dd, J = 8.7, 2.2 Hz, H6), 6.99 (d, J = 2.2 Hz, H8), 7.33 (dd, J = 8.6, 1.5 Hz, H22), 7.61 (d, J = 1.5 Hz, H20), 7.73 (d, J = 1.5 Hz, H13), 7.87 (d, J = 2.6 Hz, H17), 7.92 (d, J = 8.6 Hz, H23), 8.09 (s, OH), 8.29 (d, J = 8.7 Hz, H5), 9.22 (s, H2), 10.80 (bs, H18), 10.90 (bs, H12), 12.20 (bs, H1); EIMS (formula, rel. intensity): 422/420 (M^+, 23), 289/287 ($C_{12}H_7N_3OBr$, 5), 263/261 ($C_{11}H_8N_3Br$, 4), 160 ($C_9H_6NO_2$, 44), 133 (C_8H_8NO, 100); HREIMS, $C_{20}H_{13}BrN_4O_2$, M^+: 422.0203/420.0222 (ΔM, −0.6 mmu/+0.2 mmu).

*Methylation of **1***: 40 mg of **1** (0.09 mmol) was refluxed overnight under N_2 together with 35 μL (0.4 mmol) of dimethyl sulfate and 66 mg (0.5 mmol) of potassium carbonate in 15 mL of freshly distilled acetone. Removal of excess reagents and solvent *in vacuo* gave an oily residue that was purified via reverse phase preparatory tlc (eluent: MeOH/CH_3CN/H_2O (82:10:8) to give 11 mg of pure **4** (R_f 0.52) and 3 mg of pure **5** (R_f 0.44).

*TrimethylHEX I (**4**)*: yellow/green oil; ir (film): 3134, 1706, 1593, 1520, 1250, 1072, 926, 836 cm^{-1}; ^1H nmr (acetone-d_6) δ: 3.91 (s, H25), 3.99 (s, H26), 4.16 (s, H27), 6.95 (dd, J = 8.7, 2.2 Hz, H6), 7.09 (d, J = 2.4 Hz, H8), 7.30 (dd, J = 8.7, 2.4 Hz, H22), 7.65 (s, H13), 7.68 (d, J = 2.4 Hz, H20), 7.85 (s, H17), 8.12 (d, J = 8.7 Hz, H23), 8.40 (d, J = 8.7 Hz, H5), 9.07 (s, H2), 10.60 (bs, H18); ^{13}C nmr (acetone-d_6) δ: 33.9(q), 36.5(q), 55.9(q), 94.2(d), 111.7(s), 112.3(d), 115.1(s), 115.2(d), 115.3(s), 121.8(d), 122.4(s), 122.6(d), 123.2(d), 123.6(d), 123.8(d), 125.1(s), 136.7(s), 138.4(s), 138.8(s), 140.5(d), 143.8(s), 157.9(s), 178.4(s); EIMS (formula, rel. intensity): 464/462 (M^+, 96), 275/273 ($C_{12}H_{10}BrN_3$, 1), 188 ($C_{11}H_{10}NO_2$, 100), 174 ($C_{10}H_8NO_2$, 7), 145 (C_9H_7NO, 20); HREIMS, $C_{23}H_{19}BrN_4O_2$: 464.0670/462.0690 (ΔM, +0.7/−1.8 mmu).

*TetramethylHEX I (**5**)*: yellow-green oil; ir (film): 1709, 1595, 1522, 1076, 843 cm^{-1}; ^1H nmr (acetone-d_6) δ: 3.90 (s, H25), 3.96 (s, H28), 3.99 (s, H26), 4.04 (s, H27), 6.93 (dd, J = 8.6, 2.4 Hz, H6), 7.08 (d, J = 2.4 Hz, H8), 7.26 (s, H17), 7.31 (dd, J = 8.7, 2.5 Hz, H22), 7.59 (d, J = 8.7 Hz, H23), 7.63 (s, H13), 7.77 (d, J = 2.5 Hz, H20), 8.39 (d, J = 8.6 Hz, H5), 8.90 (s, H2); HREIMS, $C_{24}H_{21}BrN_4O_2$: 478.0813/476.0828 (ΔM, −1.3/+0.2 mmu).

Isolation of hexadellins A and B

The SCUBA collected *Hexadella* sp. (800 g, wet wt.) (Agamemnon Channel −40 m) was immediately immersed in methanol. Evaporation of the methanol *in vacuo* gave a residue that was suspended in water and sequentially extracted with hexane (2 × 1L) and chloroform (2 × 1L). The combined chloroform extracts were concentrated and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

chromatographed on Sephadex LH 20 ($MeOH/CH_2Cl_2$ 3:1) to give a number of antibacterial fractions containing a mixture of **2** and **3** (74 mg). The material in these fractions was acetylated with acetic anhydride/pyridine (room temperature, 24 h) to give a crude mixture of **6** and **7**. The acetylated derivatives were purified via gradient silica gel column chromatography (EtOAc/hexane 4:1 to EtOAc/MeOH 4:1) and normal phase hplc (EtOAc/MeOH 95:5) to give pure diacetylhexadellin A (**6**) (30 mg) and pure diacetylhexadellin B (**7**) (19 mg).

Diacetylhexadellin A (6): pale yellow oil; ir (film): 3338, 2928, 1752, 1656, 1544, 1215, 737 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; HREIMS, $C_{23}H_{25}{}^{79}Br_3{}^{81}BrN_3O_5$ ($M^+ - C_2H_2O_2$): 740.8505 (ΔM, −0.1 mmu); EIMS (rel. intensity): 739/741/743/745/747 (0.5), 418/420/422 (0.5:1.0:0.5), 407/405/409 (1:2:1), 359/361/363 (12:24:12), 303/305/307 (18:36:18), 276/278/280 (50:100:50).

Diacetylhexadellin B (7): pale yellow oil; ir (film): 3305, 2936, 1758, 1657, 1543, 1216, 772, 737 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; EIHRMS, $C_{23}H_{25}O_5N_3{}^{79}Br_2{}^{81}Br_2$ ($M^+ - C_2H_2O_2$): 742.8490 (ΔM, +0.4 mmu); EIMS (rel. intensity): 755/757/759/761/763 ($M^+ - C_2H_2O$, <0.5), 739/741/743/745/747 ($M^+ - C_2H_2O_2$, <0.5), 638/640/642/644/646 (<0.5), 303/305/307 (50:100:50), 276/278/280 (7:14:7).

Kadsulignan A and B, two novel lignans from *Kadsura coccinea*

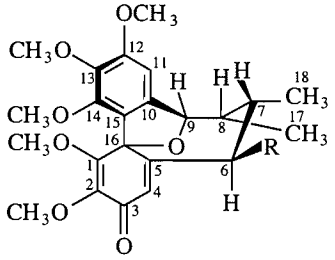
JIA-SEN LIU,[1] LIANG LI, AND HAN-GANG YU
Shanghai Institute of Materia Medica, Academia Sinica, 319 Yueyang Rd., Shanghai 200031, China

Received September 20, 1988

JIA-SEN LIU, LIANG LI, and HAN-GANG YU. Can. J. Chem. **67**, 682 (1989).

Two novel lignans, kadsulignan A (**1**) and B (**2**), were isolated from the seeds of *Kadsura coccinea*. Their structures were elucidated by 2D ^1H–^{13}C COSY, 2D ^1H–^{13}C long-range COSY experiments, and chemical transformation to a known compound (**5**) using $AlCl_2H$.

Key words: isolation and structures, kadsulignan A, kadsulignan B, *Kadsura coccinea*.



JIA-SEN LIU, LIANG LI et HAN-GANG YU. Can. J. Chem. **67**, 682 (1989).

On a isolé deux nouveaux lignanes, les kadsulignanes A (**1**) et B (**2**), à partir des graines de la *Kadsura coccinea*. On a déterminé leurs structures en soumettant le composé connu **5** à un transformation chimique à l'aide de $AlCl_2H$ et en faisant appel à des expériences de COSY en 2D de ^1H–^{13}C et de ^1H–^{13}C à longue distance.

Mots clés : isolation et structures, kadsulignane A, kadsulignane B, *Kadsura coccinea*.

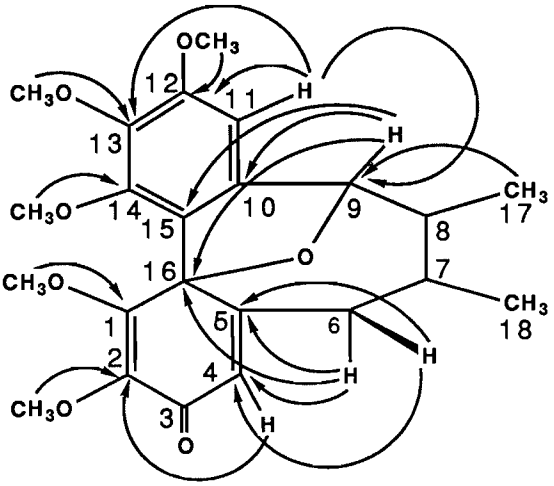
[Traduit par la revue]

In our continuing studies on the chemistry of *Schisandraceae* plants (1), 13 new lignan compounds were isolated from the seeds of *Kadsura coccinea* (Lem.) A.C.Sm., collected in Rongshui county of Guangxi, China. Two of the new lignans, named kadsulignan A (**1**) and B (**2**), possess a novel spiro-dienone structure. In the present paper we report the isolation and structural elucidation of these two novel lignans.

1 R = H **2** R = $OCOCH_3$

Kadsulignan A (**1**) is a yellow gum, $C_{23}H_{28}O_7$, the spectra of which display different features in comparison with those of dibenzocyclooctadiene lignans commonly found in this family of plants. Its ultraviolet (uv) spectrum shows maxima at 212, 240, 283, and 301 nm. The infrared (ir) spectrum (1662, 1650 cm^{-1}) and ^{13}C nmr spectrum (δ 183.7) reveal the presence of a α,β,α′,β′-dienone moiety and two oxygenated carbons, a tertiary sp^3 carbon (δ 89.6), and a quaternary sp^3 carbon (δ 87.1). Analysis of 2D ^1H–^{13}C COSY and 2D ^1H–^{13}C long-range COSY spectra (Fig. 1) allowed us to establish the connectivity between carbon-13 nuclei and hydrogens via $^2J_{CH}$ and $^3J_{CH}$, and showed that the same oxygen connects both of the tertiary (C-9) and quaternary (C-16) sp^3 carbons forming a spiro ring. Thus, structure **1** is proposed for kadsulignan A.

A further confirmation of the structure assignment of **1** and determination of its absolute stereochemistry were provided by chemical transformation. Treatment of **1** with dichloroaluminum hydride (2) cleaved the spiro-oxy bridge and gave the common dibenzocyclooctadiene lignans, compounds **3** and **4**. Then, methylation of the latter (**4**) afforded a known compound, deangeloyl schisantherin F dimethyl ether (**5**) (3). Since the absolute configurations of **5** are known, the absolute configurations of **1** are unambiguously assigned as 7*R*, 8*R*, 9*R*, and 16*S*.



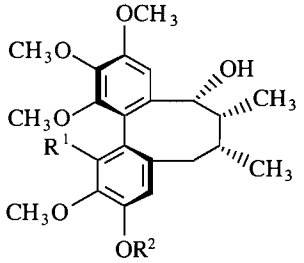


FIG. 1. ^1H–^{13}C long range shift correlation via $^2J_{CH}$ and $^3J_{CH}$ in kadsulignan A (**1**).

Kadsulignan B (**2**) is also a yellow gum, $C_{25}H_{30}O_9$, and shows a similar uv spectrum to that of **1**. Its ir spectrum (1740 cm^{-1}), ^1H nmr (δ 2.04, 3H, s and δ 5.79, 1H, d) and ^{13}C nmr (δ 169.6, 15.9, and 73.4) spectra display the presence of an acetoxyl in the molecule. Comparison of ^1H and ^{13}C nmr data (Tables 1, 2) of **1** and **2** indicates that compounds **1** and **2** differ by an acetoxyl substituent at C-6 of **2**. The coupling

3 $R^1 = R^2 = H$

TABLE 2. The ^{13}C nmr data* of kadsulignan A (**1**) and B (**2**)

Carbon (multiplicity)	Compound **1**	Compound **2**
1(s)	157.1	155.9
2(s)	137.8	138.0
3(s)	183.7	184.0
4(d)	122.1	122.7
5(s)	158.8	157.8
6	37.2(t)	73.4(d)
7(d)	28.8	34.7
8(d)	45.2	44.8
9(d)	89.6	89.4
10(s)	138.4	139.6
11(d)	99.3	99.3
12(s)	155.3	155.8
13(s)	141.5	141.9
14(s)	147.6	148.2
15(s)	122.6	122.7
16(s)	87.1	86.0
17(q)	11.0	12.8
18(q)	20.0	20.4
OMe-12(q)	55.8	56.3
OMe(q)	59.7	60.4(2)
	59.9(2)	60.7
	60.1	60.8
Ac		15.9(q, Me) 169.6(s, CO)

*δ, ppm in $CDCl_3$ (25.2 MHz); the assignments are based on DEPT spectra, 2D ^{1}H–^{13}C COSY and 2D ^{1}H–^{13}C long-range COSY experiments.

constants between H-6 and H-7 ($J = 9.9$ Hz) and between H-6 and H-4 ($J = 2.2$ Hz) indicate that H-6 should have an α configuration. Examination of a molecular model of **2** shows a dihedral angle close to 90° between the C_6—H and C_4—H bonds, and a dihedral angle close to 180° between the C_6—H and C_7—H bonds, consistent with the assignment. Therefore, we propose that kadsulignan B (**2**) is 6β-acetoxyl kadsulignan A.

Further support for the structure of **2** was obtained by nOe measurement of **2**. On irradiation of Me-8 (δ 1.22), H-6 (δ 5.79) and H-9 (δ 5.34) show 10.2 and 9.0% nOe enhancements respectively, indicating a *cis* relationship between H-6, H-9, and Me-8 of **2**. These results also indicate a boat conformation of the cyclooctene ring and a chair conformation of the cycloheptoxide ring, since a chair conformation of the cyclooctene ring with a boat conformation of the cycloheptoxide ring cannot accommodate the nOe result between H-6 and Me-8. Furthermore, the consistent ^{1}H nmr data between **1** and **2** (Table 1) show a similar conformation in **1** and **2**. The absolute configurations of **2** are assigned as 6*R*, 7*S*, 8*R*, 9*R*, and 16*S* based on the similarity of the circular dichroism (cd) curves of **2** to that of **1**.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. The following instruments were used for the spectra described here: uv, Pye Unicam SP1800; ir, Perkin–Elmer 599B; ^{1}H nmr and nOe experiments, Bruker AM-400 (400 MHz); ^{13}C nmr, 2D ^{1}H–^{13}C COSY, and 2D ^{1}H–^{13}C long-range COSY experiments, Bruker AC-100 (25.18 MHz for ^{13}C nmr, 100 MHz for ^{1}H nmr); hrms, Varian MAT-711; cd, Jasco J-500A; optional rotations, Jasco DIP-181. Silica gel for column chromatography was manufactured in the Qingdao Haiyang Chemical Factory.

Extraction and preliminary separation

The crude alcoholic extract of the seeds of *Kadsura coccinea* (Lem.) A.C.Sm. was suspended in water and extracted with ether. The ether extract was chromatographed on a silica gel column (100–200 mesh) eluting, in turn, with petroleum ether – benzene (1:1), benzene, benzene – ethyl acetate (10:1, 4:1, and 2:1). The fractions eluted with petroleum ether – benzene (1:1) and the early fractions of benzene were combined and designated Part A. Similarly, the late fractions of benzene and fractions eluted by benzene – ethyl acetate (10:1) were combined as Part B; fractions eluted by benzene – ethyl acetate (4:1) were combined as Part C; and fractions eluted with benzene – ethyl acetate (2:1) were combined as Part D.

Kadsulignan A (1)

Part B was chromatographed on a silica gel column (200–300 mesh) eluting with petroleum ether – acetone (10:1). The middle fractions were subjected to chromatography again on a silica gel column (200–300 mesh) using petroleum ether – diethyl ether (6:1) as an eluent. Crude kadsulignan A was found in the early fractions. It was purified by preparative tlc (petroleum ether – diethyl ether (6:1)) to give 350 mg (0.0049%) of **1** as a yellow gum; $[\alpha]_D$ +100.89° (*c* 0.0451, acetone); uv (MeOH) λ_{max} (log ε): 212(4.68), 240(4.28), 283(3.71), 301(3.59) nm; ir (KBr) ν_{max}: 1662, 1650, 1610, 1470 cm^{-1}; ^{1}H nmr and ^{13}C nmr, see Tables 1 and 2; hrms *m/z*: 416.1849 (M^+, 100%, calcd. for $C_{23}H_{28}O_7$: 416.1835), 401.1563 ($M - CH_3$, 12.1%), 385.1676 ($M - OCH_3$, 9.6%), 331.1148 ($C_{18}H_{19}O_6$, 32.7%), 301.1043 ($C_{17}H_{17}O_5$, 28.3%); cd (MeOH) Δε (nm): +5.60(239), −1.30(258), +2.60(281), +4.60(304), −0.45(356).

Kadsulignan B (2)

Part C was chromatographed on a silica gel column (200–300 mesh) eluting with petroleum ether – diethyl ether (5:1 and 2:1). The late fractions eluted by petroleum ether – diethyl ether (5:1) and the early fractions of petroleum ether – diethyl ether (2:1) were combined and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

chromatographed again on the silica gel column using the same eluent. The late fractions of petroleum ether – diethyl ether (5:1) gave **2**, 59 mg (0.00082%) as a yellow gum, $[\alpha]_D$ +97.03° (*c* 0.0133, acetone); uv (MeOH) λ_{max} (log ε): 213(4.75), 240(4.32), 284(3.72), 305(3.63) nm; ir (KBr) ν_{max}: 1740, 1735, 1655, 1610 cm^{-1}; ^1H and ^{13}C nmr, see Tables 1 and 2; ms *m/z*: 474 (M^+), 414 (M − CH_3COOH), 389, 347; cd (MeOH) Δε (nm): +8.50(235), −1.50(259), +1.80(279), +3.20(303), −1.10(349).

*Reduction products (**3** and **4**) of **1***

Kadsulignan A (**1**, 40 mg) dissolved in diethyl ether and cooled to 0°C was reacted for 5 min at 0°C with an ethereal solution of dichloroaluminum hydride (freshly prepared from aluminum chloride (100 mg) and lithium aluminum hydride (10 mg) (2)). The reaction mixture was treated with water (10 mL) and extracted with diethyl ether. The concentrated ether extract was separated by preparative tlc (solvent: petroleum ether – acetone (3:1)), affording a major product **3**, 20 mg, and a minor product **4**, 4 mg.

The structure of compound **3**, mp 203–205°C, is based on the following spectral data: ir (KBr) ν_{max}: 3550–3385, 1585, 1510 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 0.95(3H, d, *J* = 7.6, Me-7), 1.18(3H, d, *J* = 7.1, Me-8), 1.95(1H, m, H-7), 2.08 (1H, m, H-8), 2.60(2H, m, H-6), 3.45, 3.86, 3.87, 3.88(3H each, s, OCH_3 × 4), 4.62(1H, s, H-9), 5.64(1H, s, OH), 6.38, 6.84, 6.86(1H each, s, Ar-H × 3); cd (MeOH) Δε (nm): +43.00(218), −28.40(236), −23.50(252), −4.25(292).

For compound **4** the spectral data are as follows: ^1H nmr (400 MHz, $CDCl_3$) δ: 0.92(3H, d, *J* = 7.4, Me-7), 1.18(3H, d, *J* = 7.3, Me-8), 1.92(1H, m, H-7), 2.07(1H, m, H-8), 2.59(2H, m, H-6), 3.57, 3.64, 3.86, 3.87, 3.93(3H each, s, OCH_3 × 5), 4.71(1H, s, H-9), 5.77(1H, s, OH), 6.38(1H, s, H-11), 6.67(1H, s, H-4); ms *m/z*: 418 (M^+), 400 (M − H_2O), 388, 223.

*Deangeloyl schisantherin F dimethyl ether (**5**)*

Compound **4** (4 mg) was methylated with an ethereal solution of diazomethane. Work-up in the usual way gave compound **5**, 3 mg, mp 162–163°C (from MeOH); ir (KBr) ν_{max}: 3520, 1590, 1580 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 0.92(3H, d, *J* = 7.5, Me-7), 1.18(3H, d, *J* = 7.2, Me-8), 1.92(1H, m, H-7), 2.08(1H, m, H-8), 2.61(2H, m, H-6), 3.60, 3.67, 3.85(3H each, s, OCH_3 × 3), 3.87(9H, s, OCH_3 × 3), 4.64(1H, s, H-9), 6.37(1H, s, H-11), 6.56(1H, s, H-4); ms *m/z*: 432 (M^+), 414 M − H_2O), 376, 225, 209, 182. Comparison of the ir spectra and mixture melting points shows that it is identical with authentic compound **5** derived from schisantherin F (3).

Gas phase ligand substitution reactions in fast atom bombardment mass spectrometry: effects of ligand base strength and choice of matrix liquid in substitution reactions of difluoroborn cations

K. BALASANMUGAM, J. S. HARTMAN,[1] J. M. MILLER,[1] AND Z. YUAN
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received October 14, 1988

K. BALASANMUGAM, J. S. HARTMAN, J. M. MILLER, and Z. YUAN. Can. J. Chem. **67**, 685 (1989).

Strongly basic amidine and guanidine ligands displace weaker-base ligands such as pyridine from $D_2BF_2^+$ complexes in the gas phase in Fast Atom Bombardment mass spectrometry. The choice of protic vs. aprotic matrix liquid inhibits or promotes gas phase ligand substitution reactions.

Key words: ligand substitution, difluoroboron cations, FABMS.

Introduction

Fast atom bombardment mass spectrometry (FAB) has become an important technique for the characterization of cationic compounds (1–4). However, recent work by several research groups has demonstrated that significant ion–molecule reactions can take place in the gas phase (5–8). We have shown, using a dual target FAB probe tip made by dividing a wider FAB probe target, that ligands such as crown ethers react with gas phase species containing alkali metal ions, giving alkali metal ion – crown ether complexes (8); in this system most of the complex ions detected by FAB are apparently produced by gas phase reaction. Reinterpretation of FAB results, and re-thinking of how closely FAB spectra correspond to composition of the samples being analysed, is therefore a high priority.

We now report dual target FAB studies of gas phase ligand substitution in fluoroboron cations $[D_2BF_2]^+$, which have previously been characterized by FAB and other methods (9). Especially stable fluoroboron cations have been shown to form when the donors D are the strongly basic amidine ligands 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (10).

DBN DBU

Experimental

FAB mass spectra were obtained on a Kratos (AEI) MS 30 mass spectrometer, retrofitted (11) with a Kratos FAB source in beam 1 and interfaced to a Kratos DS 55 data system. Argon was used as the bombarding gas with atom gun (Ion Tech) energies of 8 kV and a gun current of approximately 1 mA. Ions were accelerated to 4 kV, with a repeller potential on the FAB tip on the order of 20 V. The source pressure was typically 10^{-5} Torr for normal FAB operation and the pressure rose to (1–5) $\times$ 10^{-4} Torr when the volatile bases were introduced. (This measurement was made in the pumping line just outside the source housing, but unlike an EI source, the FAB source is of an open design, and the measured pressure may be within a half order of that in the source proper, though much lower than the high pressure region jsut above the sample surface.) The system was operated at room temperature at a resolving power of 1000. The divided FAB probes (Fig. 1) are 4.3 mm in diameter and are cut in half by a 3 mm deep and 0.6 mm wide slot so that different samples can be placed on either half without being mixed (8). To obtain FAB spectra, fluoroboron cations (9, 10) were dissolved in a matrix (15 mg/mL), either 3-nitrobenzyl alcohol (NBA) and tetramethylene sulfone (SUL), and placed on the "A" half of the probe tip which is closer to the ion optics (8). These probe tips are similar to those used by Munster *et al.* (7). Different ligands without any matrix liquid were deposited on the "B" half of the divided FAB probe. Each spectrum is an average of eight to ten scans.

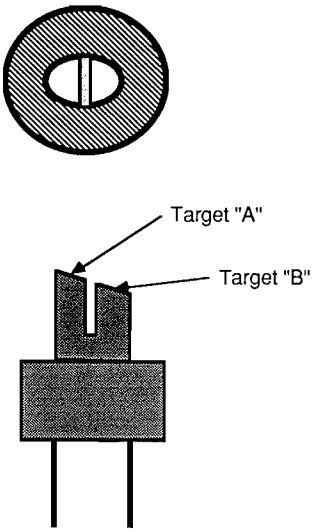

FIG. 1. MS30 divided FAB probe tip.

Use of NBA as matrix liquid allowed many scans to be collected before degradation of the sample, while normally only four to seven scans could be obtained using SUL. Considerable adjustment of experimental conditions was necessary in order to match vaporization rates from the "A" and "B" halves of the probe tip and optimize the formation of ions containing components from both halves.

The possibility of spattering of material from one half of the probe tip to the other during a run was excluded by collecting the samples from each half of the probe tip after a run, and obtaining their FAB

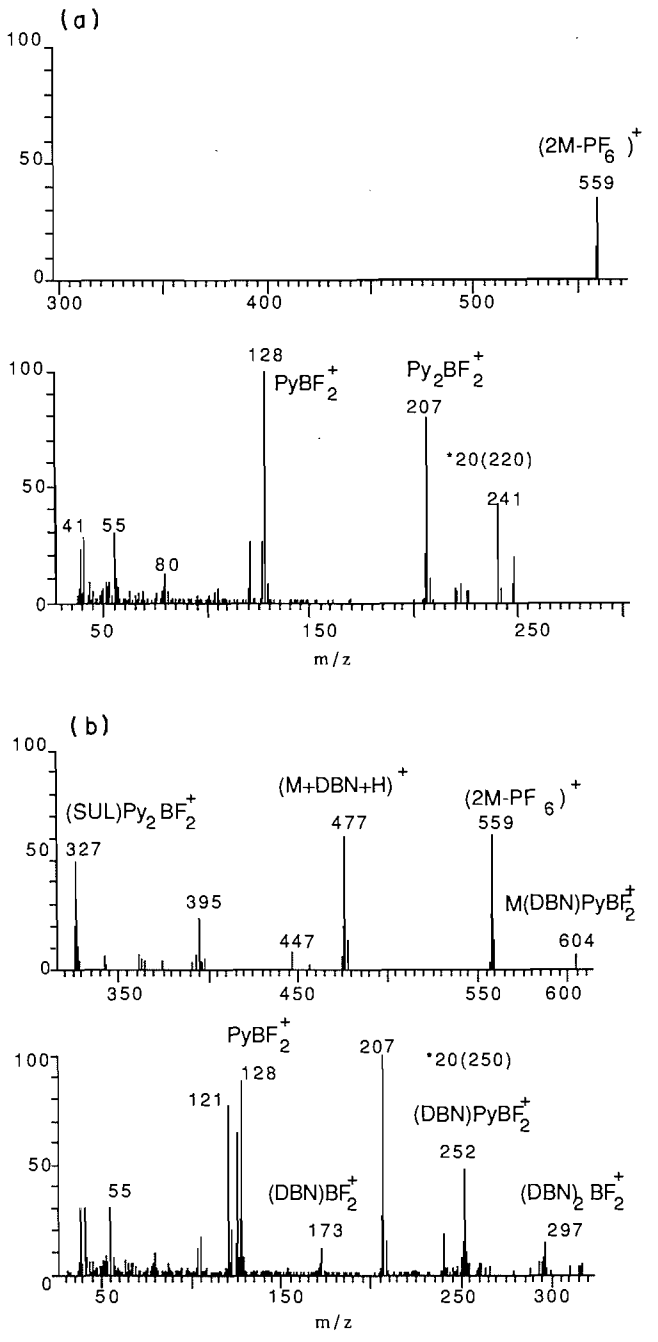

FIG. 2. (*a*) Positive ion FAB spectrum of $[py_2BF_2][PF_6]$ in SUL matrix, (*b*) positive ion FAB spectrum of $[py_2BF_2][PF_6]$ in SUL matrix on target "A" in the presence of neat DBN on target "B".

spectra separately, or simple cleaning off one side and examining the spectrum obtained from the other side. These spectra were clean, with no evidence of cross-contamination, when samples were relatively non-volatile. However, the possibility of adsorption of a volatile material from the gas phase into the liquid matrix, followed by sputtering back into vacuum cannot be ruled out for very volatile samples.

The ligands pyridine (py), quinuclidine (Q), 1,5-diazabicyclo-[4.3.0]non-5-ene (DBN), 1,1,3,3-tetramethylguanidine (TMG), and 15-crown-5 (15C5) were purchased from the Aldrich Chemical Company and used without further purification. 1,8-Diazabicyclo-[5.4.0]undec-7-ene (DBU) was a gift from Air Products and Chemicals Incorporated, and was distilled at a pressure of 20 Torr, the fraction distilling at 130–134°C being used.

Since gas phase basicities are available only for some of the ligands, and for those available the trends are in the same order as the aqueous solution values, we use the latter in our discussion.

Results and discussion

The positive ion FAB spectrum of $[py_2BF_2]^+.[PF_6]^-$ in SUL matrix liquid is shown in Fig. 2*a*. Similar spectra were obtained using either NBA or SUL as matrix liquid, except for differences in minor solvated-cation peaks. This spectrum is typical of FAB spectra of fluoroboron cations (9, 10): the parent cation peak at $m/z = 207$ is prominent, as are peaks corresponding to $pyBF_2^+$ and $(py + H)^+$. In addition, a cluster ion is present at $m/z = 559$, corresponding to $[(py_2BF_2)_2PF_6]^+$, i.e., $[2M - PF_6]^+$. Note that peaks of m/z greater than 220 in Fig. 2*a*, and 250 in Fig. 2*b*, have been amplified by a factor of twenty. Figure 2*b* was obtained using the dual target FAB probe tip, with SUL as the matrix liquid for $py_2BF_2^+$ on "A" and neat DBN on "B". All of the ions of Fig. 2*a* are still detected, and in addition there is a major peak corresponding to $(DBN + H)^+$, and lower-intensity peaks corresponding to $py(DBN)BF_2^+$, $(DBN)_2BF_2^+$, and $(DBN)BF_2^+$, as well as new cluster ion peaks (Table 1). Since DBN and $py_2BF_2^+$ can mix only in the gas phase (see Experimental), the DBN-containing fluoroboron cations must be produced by gas phase substitution reactions.

Except for $(DBN + H)^+$, the intensities of the additional peaks of Fig. 2*b* are very low when the matrix liquid for $py_2BF_2^+$ is NBA rather than SUL. We attribute this to gas phase protonation of the basic ligand by $(NBA + H)^+$ ions produced by the primary ionization process, so that the ligand is no longer able to react with the $py_2BF_2^+$ cation.

Tables 1–3 summarize the results obtained with the series of difluoroboron cation salts $[(py)_n(Q)_{2-n}BF_2]^+.[PF_6]^-$ (n = 2–0) on the "A" side of the dual probe tip, and a number of free ligands on the "B" side. The matrix-liquid peaks $(SUL + H)^+$ and $(2SUL + H)^+$ are omitted from the tables. In each case the difluoroboron salt side "A" of the dual target FAB probe tip was preferentially irradiated with the fast atom beam as a result of the geometry of the FAB retrofit and the source ion optics. In the reverse experiment in which the free ligand was placed on "A" and fluoroboron cation salt dissolved in a matrix on "B", no boron-containing species were detected, the spectrum consisting of peaks from the ligand itself.

Quinuclidine and pyridine were also used as free ligands on the "B" side, but no peaks attributable to boron-containing ions with these ligands could be detected. Pyridine is the least basic of the ligands studied (pK_b = 8.77), and may well be insufficiently basic to displace quinuclidine from $Q_2BF_2^+$ and $pyQBF_2^+$. However, pyridine is also very volatile and probably volatilized too quickly from the probe tip. Quinuclidine (pK_b = 2.9) is far more basic than pyridine, but its low volatility may have prevented our detecting mixed products.

A number of trends are evident from the data in the tables. The peak arising from the parent difluoroboron cation is always a major peak, except for the anomaly of $py_2BF_2^+$ with DBU (Table 1). The protonated-incoming-ligand peak (e.g., $(DBN + H)^+$) is always a major peak, the proton-donor source when SUL rather than NBA is the matrix liquid presumably being radiation-damaged matrix. The quinuclidine radical cation peak is major when starting from $Q_2BF_2^+$ but is not detected at all when starting from $pyQBF_2^+$, consistent with preferential loss of py from this complex ion. Displacements to give other four-coordinate cations occur most readily from $py_2BF_2^+$ (compare Table 1 with Tables 2 and 3). The greater ease of

[a]$M = [Q_2BF_2]^+PF_6^-$.

displacement is consistent with pyridine's weaker basicity. In most cases starting from $pyQBF_2^+$ and $Q_2BF_2^+$, the substituted four-coordinate cations have not been detected. In all cases except $pyQBF_2^+$ with 15C5, the peak of the substituted three-coordinate cation ($DBN.BF_2^+$, etc.) is by far the largest peak arising from a species which incorporates both boron and the substituting ligand. In the $pyQBF_2^+$ systems (Table 2), the QBF_2^+ peak is always much more intense than the $pyBF_2^+$ peak, again consistent with pyridine's weaker basicity and greater ease of displacement.

The extent of the gas phase reactions summarized in Tables 1–3 can be rationalized by the volatilities and basicities of the ligand used. DBN, DBU, and TMG are all strong bases, with pK_b's in the 0.4 to 1.1 range (12), and all three are of intermediate volatility: sufficient to provide adequate vapour pressure, but low enough to be long-lasting. The volatility of 15C5 is intermediate between quinuclidine and the DBN, DBU, and TMG group, so gas phase concentrations are lower. Basicities would also be lower; hence the low relative intensities of 15C5-containing ions.

Cluster ion peaks have fairly low relative intensities which vary considerably from system to system, and the causes of the variations are not obvious. However, it is clear from the intensities of the $(M + \text{ligand} + H)^+$ peaks, which can approach the intensity of the $(2M - PF_6)^+$ peaks, that the clusters need not originate in the matrix liquid, but frequently form in the gas phase. The greatest intensities are consistently seen with DBN as ligand and with $py_2BF_2^+$ and $pyQBF_2^+$, and it is difficult to rationalize the absence of cluster peaks with the same ligand and $Q_2BF_2^+$. We have previously observed weak cluster peaks $(2M - Br)^+$ from $Q_2BF_2^+.Br^-$ (9).

Conclusion

Gas phase displacement reactions are a complication in FAB that can make interpretation more difficult, especially if complex mixtures are being analysed. Displacement reactions by basic ligands that may be present in such mixtures can be minimized by choice of a slightly acidic matrix liquid such as NBA.

Radical ions in photochemistry. 21. The photosensitized (electron transfer) tautomerization of alkenes; the phenyl alkene system[1]

DONALD R. ARNOLD[2] AND SHELLEY A. MINES
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 28, 1988

DONALD R. ARNOLD and SHELLEY A. MINES. Can. J. Chem. **67**, 689 (1989).

Alkenes, conjugated with a phenyl group, can be converted to nonconjugated tautomers by sensitized (electron transfer) irradiation. For example, irradiation of an acetonitrile solution of the conjugated alkene 1-phenylpropene, the electron accepting photosensitizer 1,4-dicyanobenzene, the cosensitizer biphenyl, and the base 2,4,6-trimethylpyridine gave the nonconjugated tautomer 3-phenylpropene in good yield. Similarly, 2-methyl-1-phenylpropene gave 2-methyl-3-phenylpropene, and 1-phenyl-1-butene gave *E*- and *Z*-1-phenyl-2-butene. The reaction also works well with cyclic alkenes. For example, 1-phenylcyclohexene gave 3-phenylcyclohexene, and 1-(phenylmethylene)cyclohexane gave 1-(phenylmethyl)cyclohexene. The proposed mechanism involves the initial formation of the alkene radical cation and the sensitizer radical anion, induced by irradiation of the sensitizer and mediated by the cosensitizer. Deprotonation of the radical cation assisted by the base gives the ambident radical, which is then reduced to the anion by the sensitizer radical anion. Protonation of the ambident anion at the benzylic position completes the sequence. Reprotonation at the original position is an energy wasting step. Tautomerization is driven toward the isomer with the higher oxidation potential, which is, in the cases studied, the *less* thermodynamically stable isomer. The regioselectivity of the deprotonation step is dependent upon the conformation of the allylic carbon–hydrogen bond. The tautomerization of 2-methyl-1-phenylbutene gave both 2-phenylmethyl-1-butene and 2-methyl-1-phenyl-2-butene (*E* and *Z* isomers), while 2,3-dimethyl-1-phenylbutene gave only 3-methyl-2-phenylmethyl-1-butene. In the latter case, steric interaction of the methyls on the isopropyl group prevents effective overlap of the tertiary carbon–hydrogen bond with the singly occupied molecular orbital, thus inhibiting deprotonation from this site.

Key words: photosensitized, electron transfer, alkene, tautomerization, radical cation.

DONALD R. ARNOLD et SHELLEY A. MINES. Can. J. Chem. **67**, 689 (1989).

Sous l'influence d'une irradiation sensibilisée (transfert d'électron), on peut transformer des alcènes conjugués avec un groupement phényle en tautomères qui ne le sont pas. Par exemple, l'irradiation du phényl-1 propène, un alcène conjugué, en solution dans l'acétonitrile, en présence de dicyano-1,4 benzène agissant comme photo-sensibilisateur acceptant des électrons, de biphényle agissant comme cosensibilisateur et de triméthyl-2,4,6 pyridine agissant comme base, fournit de phényl-3 propène, le tautomère qui n'est pas conjuguée, avec un bon rendement. De la même manière, le méthyl-2 phényl-1 propène fournit du méthyl-2 phényl-3 propène alors que le phényl-1 butène-1 conduit à un mélange des phényl-1 butènes-2-(*E*) et -(*Z*). La réaction donne aussi de bons résultats avec les alcènes cycliques. Par exemple, le phényl-1 cyclohexène fournit du phényl-3 cyclohexène alors que le (phénylméthylène)-1 cyclohexane conduit au (phénylméthyl)-1 cyclohexene. Le mécanisme proposé implique la formation initiale du cation radical de l'alcène et l'anion radical du sensibilisateur qui est induite par l'irradiation du sensibilisateur avec la médiation du cosensibilisateur. La déprotonation du cation radical sous l'influence de la base fournit le radical ambivalent qui est alors réduit en anion par l'anion radical du sensibilisateur. La protonation de la position benzylique de l'anion ambivalent complète la séquence. La reprotonation dans la position originale est une étape qui fait perdre de l'énergie. La tautomérisation est orientée vers l'isomère possédant le potentiel d'oxydation le plus élevé; dans les cas étudiés, il s'agit de l'isomère qui est le *moins* stable d'un point de vue thermodynamique. La régiosélectivité de l'étape de déprotonation dépend de la conformation de la liaison allylique carbone–hydrogène. Le méthyl-2 phényl-1 butène fournit les deux tautomères, phénylméthyl-2 butène-1 ainsi que méthyl-2 phényl-1 butène-2 (isomères *E* ainsi que *Z*) alors que le diméthyl-2,3 phényl-1 butène ne fournit que le méthyl-3 phénylméthyl-2 butène-2. Dans ce dernier cas, l'interaction stérique des groupements méthyles de l'isopropyle empêche le recouvrement efficace de la liaison tertiaire carbone – hydrogène avec l'orbitale moléculaire occupée par un seul électron; la déprotonation de ce site est ainsi inhibée.

Mots clés : photo-sensibilisé, transfert d'électron, alcène, tautomérisation, cation radical.

[Traduit par la revue]

Introduction

Tautomerization of alkenes, by either acid or base catalysis, is an old and relatively well-understood process (3). The composition of the equilibrium mixture is a direct reflection of the relative thermodynamic stability of the isomers. Alkenes substituted with electron-donating groups (e.g., alkyl) or with groups that interact by conjugation (e.g., aryl) are generally more stable than the alternative tautomer(s). Archetypical of the conjugated aryl substituted alkenes is 1-phenylpropene (**1**). Equilibration favors **1** over the nonconjugated tautomer, 3-phenylpropene (**2**), by several orders of magnitude (4).

The conjugated tautomers are frequently more readily available than the nonconjugated isomers. Many synthetic procedures for the preparation of alkenes, including those which involve an elimination by the E1 mechanism, are limited to the preparation of the most stable of the possible isomers. While there are procedures for the specific preparation of the less stable tautomers, a general method for the tautomerization of conjugated alkenes to nonconjugated isomers would be synthetically useful.

We have reported a general photochemical method for the tautomerization of 1,1-diphenyl substituted alkenes to nonconjugated isomers (2). The mechanism proposed for this process involves the initial formation of the alkene radical cation and the sensitizer radical anion, induced by irradiation of the sensitizer and mediated by the cosensitizer. Deprotonation of the radical cation, assisted by the base, gives the ambident

radical, which is then reduced to the anion by the sensitizer radical anion. Protonation of the ambident anion at the bis-benzylic position completes the sequence.

Only minor modification of the reported procedure was required to extend this method to the tautomerization of the monophenyl analogues. The results provide further insight into the mechanism of the reaction, which knowledge helps to define the scope and limitations of the process.

Results

The starting materials, conjugated phenyl alkenes, were known compounds prepared by classical methods (dehydration of the alcohol prepared by the Grignard reaction, or by the Wittig reaction). Spectral analysis, in particular ^{1}H nmr spectroscopy, confirmed the structural assignments.

The photosensitized (electron transfer) tautomerization reaction involves a simple, convenient procedure. A solution of the conjugated alkene in acetonitrile, with 1,4-dicyanobenzene as electron-accepting sensitizer, biphenyl as a cosensitizer, and collidine (2,4,6-trimethylpyridine) as base, was irradiated through Pyrex with a medium-pressure mercury vapor lamp. Progress of the reaction was followed by gas chromatography (gc/fid). Irradiation was continued until the reaction was complete, when column chromatography of the crude photolysate gave the tautomer, usually in excellent yield. The electron-accepting sensitizer, the cosensitizer, and the base were largely recovered. The results are summarized in Table 1.

The tautomerization does not require the cosensitizer. However, the yield of tautomer and the efficiency of the reaction were improved when biphenyl was added to the irradiation mixture. The yields reported in Table 1 are from cosensitized reactions.

In the previous study involving tautomerization of 1,1-diphenyl alkenes, lutidine (2,6-dimethylpyridine) was used as the base (2). Collidine was found to be more effective than lutidine for these reactions involving monophenyl alkenes.

The yields reported in Table 1 were determined by quantitative gas chromatography using a flame ionization detector (gc/fid). The isolated yield of some of the more volatile tautomers was lower than that reported in the table due to evaporation of the product along with the solvent following the chromatographic separation.

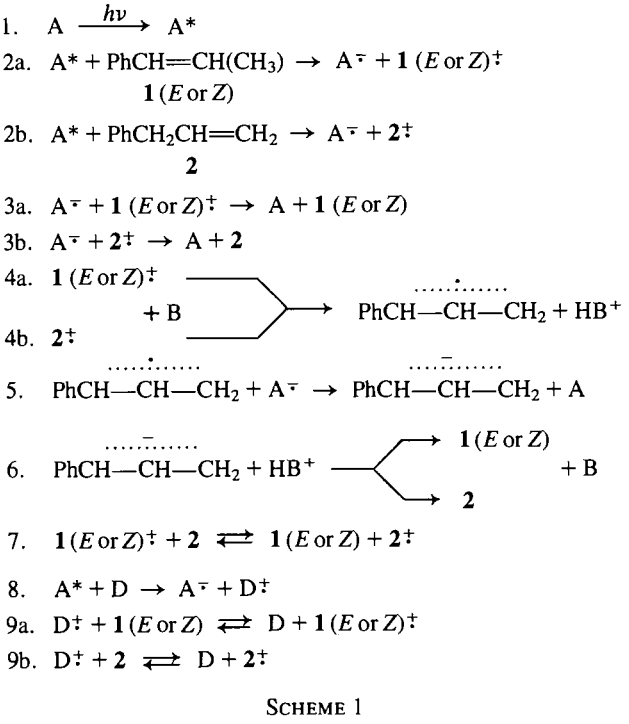

TABLE 2. Oxidation potentials of the phenyl alkenes studied[a]

Phenyl alkene	$E^{ox}_{1/2}$ (V)[b]
(*E*)-1-Phenylpropene (**1**)	1.73
3-Phenylpropene (**2**)	2.26
2-Methyl-1-phenylpropene (**3**)	1.60
2-Methyl-3-phenylpropene (**4**)	2.24
(*E*)-1-Phenyl-1-butene (**5**)	1.67
3-Methyl-2-phenylmethyl-1-butene (**11**)	2.25
1-Phenylcyclohexene (**13**)	1.61
3-Phenylcyclohexene (**14**)	2.13
1-(Phenylmethylene)cyclohexane (**15**)	1.62
1-(Phenylmethyl)cyclohexene (**16**)	1.95

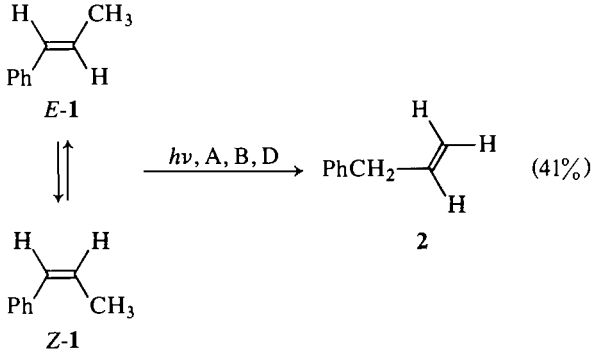
[a]Oxidation potentials measured at a platinum electrode relative to a saturated calomel electrode (SCE) using tetraethylammonium perchlorate (0.1 M TEAP) as electrolyte in acetonitrile.
[b]The anodic wave was not reversible; the half-wave potential was taken as 0.03 V before the peak potential (6).

Structural assignments for the products were unambiguously established on the basis of spectral analysis (^{1}H and ^{13}C nmr) and comparison with literature data when it was available. The nonconjugated alkene **11** was a new compound. The gross structures were easily assigned. The configuration of the isomeric 1-phenyl-2-butenes (**6**, *E* and *Z*) and 2-methyl-1-phenyl-2-butenes (**9**, *E* and *Z*) was assigned on the basis of the magnitude of the coupling between the carbon of the allylic methyl group and the vicinal vinyl proton in the ^{13}C nmr spectrum. This carbon–proton coupling follows the same trend as the analogous *cis–trans* proton–proton coupling; that is, the allylic carbon – vinyl proton coupling constant is greater for the *trans* than for the *cis* orientation (5).

The oxidation potentials of the alkenes were determined by cyclic voltammetry. Pure samples of the alkenes were obtained

SCHEME 1

by preparative gas chromatography prior to analysis. The shape of the voltammogram was indicative of an irreversible oxidation. The oxidation potential was estimated as 0.03 V before the peak potential (6). These data are summarized in Table 2.



Discussion

Several very different types of reaction can result from the irradiation of a solution of a given cyanoaromatic compound and an alkene. These include, in addition to tautomerization of the alkene (2): configurational isomerization (*E*–*Z*) of the alkene (7); cyclodimerization of the alkene, forming either cyclobutane or, in the case of conjugated alkenes, cyclohexene dimers (8, 9); cycloaddition of the alkene to the aromatic ring at the 1,2-, 1,4-, or 2,4-position (10), or at the cyano group (11); addition of nucleophile to the alkene radical cation followed either by addition of the resulting radical to the cyanoaromatic radical anion to give the substituted dihydroaromatic (12), or by substitution of the resulting radical for the cyano substituent on the ring (the photo-NOCAS reaction) (1*a*, 13); substitution of the allylic radical for the cyano substituent on the aromatic ring (14); and, *anti*-Markovnikov addition of hydroxylic solvent to the alkene with the cyanoaromatic acting as a photosensitizer (15). The problem of understanding this complex behaviour is exacerbated by the fact that some of these products may be formed by more than one mechanism. Nevertheless, it is frequently possible to obtain a good yield of a single product and to explain (if not predict) why a particular reaction dominates.

The ultimate result of the irradiation of a given pair of reactants depends upon the relative rates of several competing processes. The ability to predict this reactivity will require an understanding of how reactant structure and irradiation conditions influence these rates.

The proposed mechanism for the tautomerization reaction is shown in abbreviated form in Scheme 1, using Reaction 1 as an example. Consideration of the factors that influence the rate of each step provides a basis for predicting when to expect this reaction.

Reaction 1

A = 1,4-dicyanobenzene
B = collidine
D = biphenyl

Steps 1–7 are involved when the reaction is brought about by irradiation of the electron-accepting sensitizer (A = 1,4-dicyanobenzene) in the absence of an added donor that serves as a cosensitizer (D = biphenyl). Steps 8 and 9 occur in preference to step 2 when a cosensitizer has been added to the irradiation mixture.

The long wavelength ultraviolet absorption spectrum of 1,4-dicyanobenzene extends beyond 280 nm. This is about the short wavelength limit of the transmission of Pyrex glass. The alkenes are transparent in this region, so the first step in the reaction scheme is excitation of the electron acceptor.

The second step involves electron transfer from the alkene to the singlet excited state of 1,4-dicyanobenzene. The likelihood of this process is accurately predicted by the Weller equation (eq. [1]) (16), using the singlet energy and reduction potential of 1,4-dicyanobenzene and the oxidation potential of the alkene.

[1] ΔG (kcal mol^{-1}) =
$$23.06[E_{ox}(D)\text{-}E_{red}(A)\text{-}e/\varepsilon\alpha]\text{-}E_{o,o}(\text{kcal mol}^{-1})$$

The excited singlet state of 1,4-dicyanobenzene will accept an electron, at the diffusion controlled rate, from any donor with an oxidation potential less than ca. 2.4 V.[3] All of the phenyl conjugated alkenes have an oxidation potential significantly less than this. In fact, the oxidation potentials of the nonconjugated tautomers are also below this limit. Clearly, the exclusive formation of the nonconjugated tautomer cannot be explained on the basis of the relative rates of the alternative electron transfer processes. Steps 2a and 2b should both be diffusion controlled.

There are several distinct stages involved during the electron transfer process (step 2): sequential formation of an encounter complex, an exciplex, a radical cation – radical anion pair, and finally, there may be degrees of solvent separated radical ions. The rates of progression through these stages of increasing charge separation are dependent upon the polarity of the solvent. Since the degree of charge separation has an influence on the ultimate product, product formation is also a function of solvent.

[3]The reduction potential of 1,4-dicyanobenzene is −1.66 V, the singlet energy is 97.6 kcal mol^{-1} (17), and the oxidation potential of the aryl conjugated alkenes is ca. 1.7 V (Table 2). The Coulombic attraction within the radical ion pair, the last term in the brackets, is relatively small (1.29 kcal mol^{-1}) in acetonitrile solution. The rate of the electron transfer process becomes diffusion limited when $\Delta G < -3$ kcal mol^{-1} (16). All of the potentials cited here are in reference to the saturated calomel electrode (SCE).

In nonpolar solvents, deactivation of the exciplex is relatively slow; as a result, the lifetime of the exciplex may be sufficient for reaction to compete with deactivation. Reaction at the exciplex stage generally leads to the formation of cycloaddition products (10, 11). Exciplex deactivation is more rapid in polar solvent, therefore the cycloaddition reaction can be inhibited by carrying out the irradiation in polar solvent (e.g., acetonitrile).

The tautomerization reaction requires formation of the alkene radical cation and is therefore favored in polar solvent. The rate constant for the solvent separation of some radical ion pairs, similar to those involved here (step 2), and in acetonitrile solution, is ca. 5×10^8 s^{-1} (18).

Alkene radical cations are susceptible to attack by nucleophiles. If methanol were used as solvent, the product could be the methyl ether having the *anti*-Markovnikov regiochemistry (15). Irradiation of 1-phenylcyclohexene (**13**) in acetonitrile–methanol (3:1) gives a good yield of the *anti*-Markovnikov adducts, *E*- and *Z*-1-methoxy-2-phenylcyclohexane (Reaction 8) (15*c*). There was no evidence for formation of the tautomer under these conditions. When this reaction was carried out using methanol -OD, only one deuterium atom was incorporated in the ether product, at the benzylic 2-position. There was no evidence for exchange of proton(s) at the allylic position in unreacted alkene. In acetonitrile–methanol, nucleophilic addition of methanol to the alkene radical cation competes favorably with deprotonation. Acetonitrile is a polar, relatively non-nucleophilic solvent suitable for the tautomerization reaction. The added base must also be non-nucleophilic.

Step 3, the back electron transfer process from the radical anion of the electron acceptor to the alkene radical cation, is one of the most important energy wasting steps. The rate of this process in closely related systems has been determined and the main factor affecting the rate has been identified (19). Back electron transfer becomes slower with increasing exothermicity, as indicated by the sum of the reduction potential of the acceptor (E_{red}(A)) and the oxidation potential of the donor (E_{ox}(D)), eq. [2].

$$[2] \quad \Delta G_{-3} = E_{red}(A) - E_{ox}(D)$$

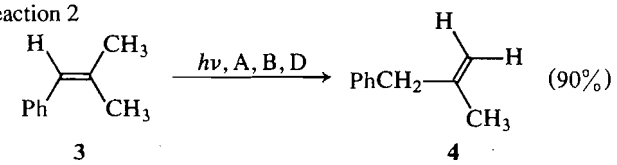
That is, the rate falls in the Marcus "inverted region" (20). For example, back electron transfer from the radical anion of 9,10-dicyanoanthracene to the radical cation of biphenyl is exothermic by 2.9 eV ($\Delta G = -67$ kcal mol^{-1}) and the rate constant is ca. 1.0×10^8 s^{-1}, competitive with diffusive separation (19). Step 3a is even more exothermic ($\Delta G = -75$ kcal mol^{-1}), so the lifetime of the radical ion pair is long enough to allow solvent separation.

The relative rates of steps 3a and 3b could conceivably play a role in determining the final ratio of tautomers. However, the oxidation potential of the nonconjugated tautomer is significantly greater than that of the conjugated alkene, hence step 3b must be even slower than step 3a. The product ratio cannot be explained on this basis.

The detailed mechanism of step 3 has been studied by the technique of photochemically induced dynamic nuclear polarization (photo-CIDNP) (7*a*). When the energy of the radical ion pair is greater than the triplet energy of one of the components of the pair, back electron transfer within the triplet radical ion pair will give the triplet of that component with the lower triplet energy. The energy (eq. [2]) stored within the radical ion pair in step 3a (75 kcal mol^{-1}) is greater than the triplet energy of both the electron acceptor (1,4-dicyanobenzene, 70.1 kcal mol^{-1} (17)) and of the donor (phenyl conjugated alkenes, ca. 50 kcal mol^{-1} (7*a*)). Hence the triplet donor, which has the lower triplet energy, is preferentially produced.

The intersystem crossing process from the π,π^* triplet of the alkene will yield both configurations (*E* and *Z*) of the ground state. This process may account for the relatively efficient configurational isomerization of the starting conjugated alkene. There was no evidence in these photo-CIDNP studies for tautomerization of the conjugated alkene (7*a*).

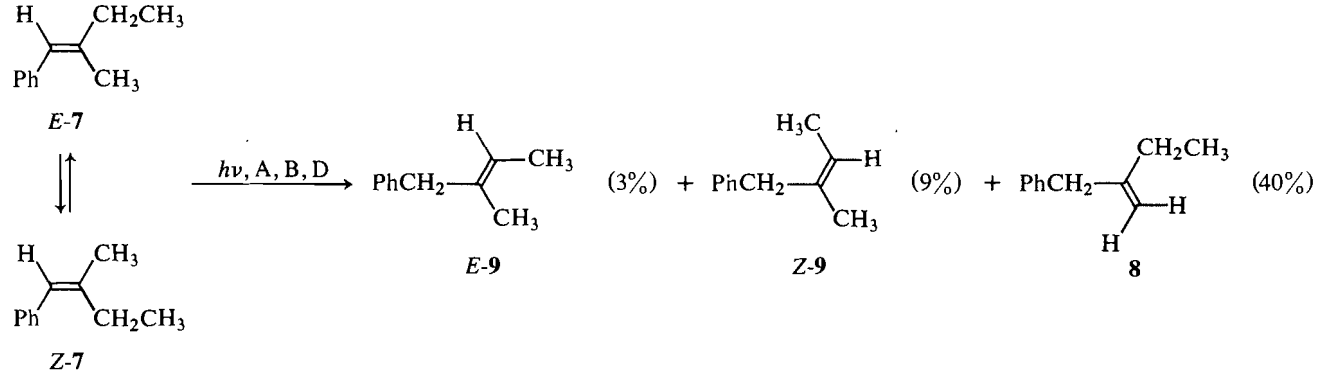
Another mechanism for the configurational isomerization, involving a radical-ion chain process, has been identified. In fact, the photosensitized (electron transfer) isomerization of **1** to an *E*:*Z* mixture (1:1), under conditions very similar to those used here, was studied by Pac and co-workers (7*d*). The reaction conditions were identical to those used here *except that no base was added to the irradiation mixture*. The proposed mechanism involves formation of a π-complex between the radical cation of the cosensitizer and the alkene. The development of partial positive charge and (or) spin density on the alkene component of the π-complex may decrease the bond order of the double bond, thus lowering the barrier for isomerization. If π-complex formation were reversible, the isomerization would occur by a chain mechanism with the cosensitizer radical cation serving as a catalyst. There was no mention of tautomerization of **1** in this report (7*d*). The significant difference between this reported configurational isomerization reaction and the tautomerization reaction reported here can be attributed to the presence of base.



We have confirmed Pac's observation (7*d*): irradiation of an acetonitrile solution of **1**, 1,4-dicyanobenzene, and biphenyl leads to *cis–trans* isomerization; however, no tautomerization is observed in the absence of added base. We take this to mean that step 4, the deprotonation of the alkene radical cation, requires base. In fact, the strength of the base is important. This effect was observed previously in the case of the 1,1-diphenyl alkene tautomerization (2). While tautomerization of the diphenyl alkenes was catalyzed by pyridine ($pK_a = 12.3$ (21)), the reaction was significantly more efficient when the stronger base lutidine ($pK_a = 15.4$) was used. Now we find that for the tautomerization of these monophenyl alkenes, the even stronger base collidine ($pK_a = 16.8$) is significantly more effective than lutidine, and pyridine is almost ineffective.

An estimate of the acidity of the alkene radical cation, toward deprotonation at the allylic position, can be obtained from analysis of the thermochemical cycle based upon the oxidation potential of the alkene and the allylic carbon–hydrogen bond dissociation energy (22). For compounds with very similar standard oxidation potentials, a difference in their respective bond dissociation free energies of 2.5 kcal mol^{-1} corresponds to a difference of ca. 2 pK_a units in the acidity of the respective radical cations. Conversely, for compounds with very similar bond dissociation free energies, a difference in the standard oxidation potentials of 0.1 V corresponds to a difference of ca. 2 pK_a units in the acidity of the radical cations.

As an example we may compare the radical cation of **1** with that of toluene. The resonance stabilization energy of the 1-phenylpropenyl radical is 5.4 kcal mol^{-1} greater than that of the benzyl radical (23). However, the resulting increase in acidity of the radical cation of **1** is more than compensated for by the lower oxidation potential of **1**, 0.25 V less than that of toluene. The estimated pK_a of the radical cation of **1** is ca. −12 compared to −13 for the radical cation of toluene.

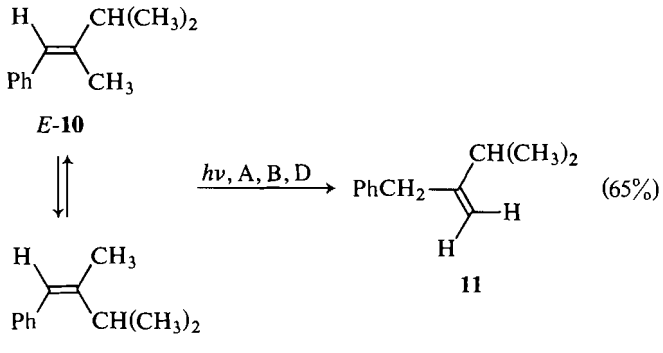


The bond dissociation free energy of the allylic, benzylic carbon–hydrogen bond in **2** is even less than the allylic carbon–

Reaction 2

3 4

Reaction 4



A = 1,4-dicyanobenzene
B = collidine
D = biphenyl

hydrogen bond in **1**, and the oxidation potential of **2** is greater than that of **1**; hence the thermodynamic acidity of the radical cation of **2** must be significantly greater than that of **1**. Step 4b is more exothermic than step 4a; preferential formation of **2** obviously cannot result from thermodynamic inhibition of the deprotonation process. In fact, from these thermodynamic considerations, it is not clear that deprotonation should require an added base. Acetonitrile (pK_a ca. −11) could conceivably serve as a base for such strong acids.

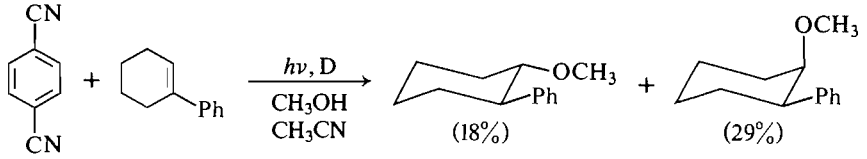
There is, however, no reason to expect that the rate of deprotonation will be rapid (i.e., diffusion limited), even for such an exothermic process. Other factors influence the kinetics of the deprotonation. Analysis of the product(s) resulting from the tautomerization of the series 2-methyl-1-phenylpropene (**3**), 2-methyl-1-phenylbutene (**7**), and 2,3-dimethyl-1-phenylbutene (**10**) provides evidence that the conformation of the allylic carbon–hydrogen bond, relative to the singly occupied molecular orbital (SOMO), has an influence on the kinetics of the deprotonation process.

Tautomerization of **3** gives an excellent yield of 2-methyl-3-phenylpropene (**4**) (Reaction 2), which indicates there is no impediment to deprotonation from a primary allylic position. Deprotonation from the radical cation of **7** can occur from either a primary or a secondary allylic position. Formation of the secondary allylic radical is favored on the basis of thermodynamics since the carbon–hydrogen bond strength is less. In fact, the nature of the observed products indicates that both radicals are formed (Reaction 4). The difference in bond strength is even greater for the carbon–hydrogen bonds in the two allylic positions of **10**, primary vs. tertiary; yet in this case only the terminal alkene is formed (Reaction 5). Deprotonation from the primary position is apparently favored. The rate of deprotonation from alternative allylic positions of the alkene radical cation does not follow the order of thermodynamic acidity.

Reaction 5

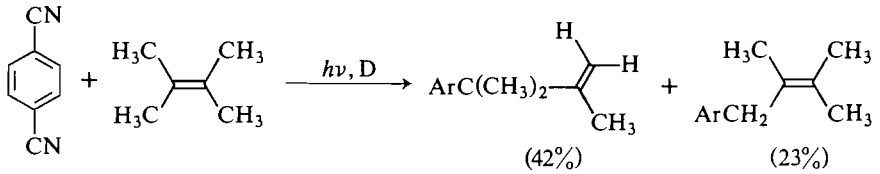
11

A = 1,4-dicyanobenzene
B = collidine
D = biphenyl



The profound increase in acidity of the allylic proton of the alkene radical cation requires overlap of the allylic carbon–hydrogen bond with the SOMO. In the likely event that the preferred conformation of the radical cation of **10** places the methyl groups of the isopropyl group in the staggered orientation, the tertiary allylic carbon–hydrogen bond is held orthogonal to the SOMO, and deprotonation will be slow. Alternatively, an allylic carbon–hydrogen bond of the freely rotating methyl group can overlap with the SOMO and deprotonation is uninhibited. This type of stereoelectronic effect, controlling the reactivity of radical cations, has been observed before (2, 24).

The relative rates of steps 4a and 4b could influence the ratio of tautomers. Before discussing the conformational overlap of the allylic carbon–hydrogen bond with the SOMO of the radical cation of **2**, it is necessary to define the "site" of the SOMO. Consideration of the oxidation potentials of the separated, noninteracting, moieties would suggest that the SOMO is largely associated with the phenyl ring. The oxidation potential of toluene, $E^{ox}_{1/2} = 2.0$ V (25*a*), is significantly lower than that of propene, $E^{ox}_{1/2} = 3.1$ V (25*b*). The measured oxidation potential of **2**, $E^{ox}_{1/2} = 2.26$ V (Table 2), is close to that of toluene. It therefore seems likely that the SOMO of **2** is largely associated with the benzyl moiety.



The preferred conformation of the radical cation should allow overlap of the benzylic carbon–hydrogen bond with the SOMO. However, significant reorganization is required at the transition

Reaction 8 (ref. *c*)

Reaction 9 (ref. 13)

D = biphenyl
Ar = 4-cyanophenyl

state for deprotonation, to bring both the phenyl and the vinyl groups into conjugation with the incipient radical. This may be a factor controlling the ratio of tautomers in some cases.[4]

Step 5 represents the reduction of the allylic radical by the sensitizer radical anion. This step will impose a limitation on the tautomerization reaction in general. The reduction potential of the electron-accepting sensitizer must be negative enough to reduce the allylic radical; otherwise, competing reactions will occur. The reduction potentials of the allylic radicals involved here are not known, but for the related diphenylmethyl radical $E^{red}_{1/2}$ is -1.14 V and that of the benzyl radical is -1.45 V (26). The reduction potential of 1,4-dicyanobenzene is -1.66 V; hence it is reasonable to suggest that step 5 is exothermic for these diphenyl and phenyl substituted allylic radicals.

Such is not the case for alkyl substituted allylic radicals; the reactivity of 2,3-dimethyl-2-butene is illustrative. Irradiation of an acetonitrile solution of 1,4-dicyanobenzene and 2,3-dimethyl-2-butene initially follows the same course, steps 1–4. However, the reduction potential available in the anion radical of 1,4-dicyanobenzene is insufficient to reduce the allylic radical (step 5) in this case. Instead, the allylic radical adds to the *ipso* position of the anion radical. Loss of cyanide ion then completes the sequence, forming the substitution product (Reaction 9) (13). Cyclohexene and 1-methylcyclohexene gave similar allylic radical substitution products. Here, again, the reduction potential of the allylic radical is not known, but alkyl groups increase (make more negative) the reduction potential of radicals. For example, the reduction potential of the *tert*-butyl radical is less than -2 V and $E^{red}_{1/2}$ of the cumyl radical is -1.73 V (26). It seems likely that the radical anion of 1,4-dicyanobenzene cannot reduce a *tert*-allylic radical.

Step 5, as shown, represents a bimolecular process involving two relatively reactive species that would normally be present in very low concentration. It seems likely that, during the course of the irradiation, processes such as coupling and disproportion initially consume the more reactive radical. Eventually the concentration of the radical anion increases to the point where step 5 can compete with the other reactions of the radical. This is an example of a reaction controlled by "internal suppression of fast modes" (27).

Step 6 in Scheme 1, protonation of the ambident anion, completes the sequence. The competition for reprotonation at the two ends of the ambident anion will affect the efficiency of the tautomerization reaction, but not the position of the equilibrium. A thorough study probing the effects that influence the position of protonation and the configurational stability of allylic anions have been reported (*4b*). The allylic anion from *E*-1-phenylpropene, when protonated, gives *E*-1-phenylpropene two to four times faster than 3-phenylpropene. Configurational isomerization of the allylic anion is slow.

Step 7 involves the equilibration of the radical cation of the conjugated and nonconjugated alkenes. Much of the control over the ratio of tautomers, in the cases reported here, can be attributed to this step. Equilibration will favor formation of that radical cation with the lower oxidation potential. In the first approximation, if the equilibrium follows the Nernst equation (eq. [3]) the radical cation of the conjugated alkene **1** will be favored over that of the nonconjugated alkene **2**, by ca. 10^9.

$$[3] \quad \ln[(\mathbf{1})(\mathbf{2}^{\cdot+})/(\mathbf{1}^{\cdot+})(\mathbf{2})] = F[E^{ox}_{1/2}(\mathbf{2}) - E^{ox}_{1/2}(\mathbf{1})]/RT$$

Although the tautomerization reaction occurs upon irradiation in the absence of an additional donor (D), the efficiency of the reaction is improved upon cosensitization. That is, the irradiation time required to complete the reaction is reduced and the yield of product is increased when biphenyl is added to the irradiation mixture.

The long wavelength ultraviolet adsorption of biphenyl does not extend much beyond 290 nm; 1,4-dicyanobenzene is still absorbing most of the light. In fact, the singlet energy of 1,4-dicyanobenzene (97.6 kcal mol^{-1}) and biphenyl (95.9 kcal mol^{-1} (28)) are similar. Substituting the oxidation potential ($E^{ox}_{1/2} = 1.80$ V) and singlet energy of biphenyl, and the reduction potential of 1,4-dicyanobenzene, in the Weller equation (eq. [1]) gives $\Delta G = -17.43$ kcal mol^{-1}. The electron transfer process (Scheme 1, step 8) should be diffusion controlled. The back electron transfer energy wasting process is exothermic by 3.5 V (eq. [2]) in this case, so diffusive separation of the radical ion pair should be competitive.

The secondary electron transfer process (Scheme 1, step 9) involves oxidation of the alkene by the radical cation of the cosensitizer. In the most simple terms, this process would give

[4]Stereoelectronic effects are known to affect the rate of ionization of the neutral alkene to form the allylic carbanion. However, the second-order rate constant for the ionization of **1** (1×10^{-7} L mol^{-1} s^{-1}) is significantly slower than for **2** (4×10^{-5} L mol^{-1} s^{-1}) in potassium *tert*-butoxide – *tert*-butyl alcohol at 25°C (*4b*).

an equilibrium mixture of the radical cations controlled by the relative oxidation potentials of biphenyl and the alkenes. Since the oxidation potential of biphenyl falls between the oxidation potential of the conjugated and nonconjugated alkenes, formation of the radical cation of the conjugated alkene should be favored. This may be an important factor influencing the ratio of products. In fact, while biphenyl should serve as a cosensitizer for the formation of the radical cation of **1**, the sensitized formation of the radical cation of **2** should be quenched by biphenyl. However, there is evidence for complex formation involving the biphenyl and alkene radical cation, so factors other than oxidation potential may be important in influencing the relative rates of these processes (Scheme 1, steps 9a and 9b) (*1a*, *7d*, 29).

Conclusions

Several of the conditions necessary for the photosensitized (electron transfer) tautomerization reaction have now been identified.

1. The photosensitizer must be chosen so that the electron transfer process from the conjugated alkene, or from the cosensitizer if one is used, to the photosensitizer is exothermic. This choice can be guided by the use of the Weller equation (eq. [1]). Electron transfer can be expected to be diffusion controlled if ΔG is negative by 3 or more kcal mol^{-1}.
2. The oxidation potential of the cosensitizer must be greater than that of the conjugated alkene.
3. Reaction requires a polar, non-nucleophilic solvent.
4. Reaction requires a non-nucleophilic base. The strength of the base depends upon the structure of the alkene. Collidine is a strong enough base for the tautomerization of monophenyl alkenes.
5. The reduction potential of the photosensitizer must be great enough to reduce the allylic radical formed upon deprotonation of the radical cation of the alkene. The reduction potential of 1,4-dicyanobenzene (−1.66 V) is sufficient to reduce the phenyl substituted allylic radical.
6. Tautomerization is driven toward the tautomer with the higher oxidation potential.
7. Competitive deprotonation from alternative allylic positions is influenced be a stereoelectronic effect. The preferred conformation of the radical cation must allow favorable overlap of the allylic carbon–hydrogen bond with the SOMO, for deprotonation to occur.

These conditions, which must be considered necessary but not sufficient for tautomerization, will be helpful in ultimately determining the scope and limitations of the reaction. It is already clear that the reaction will have some synthetic utility. The reaction works well for diphenyl and monophenyl conjugated alkenes. How general and how useful the reaction will be remains to be established.

Experimental

General Information

The ^1H and ^{13}C nmr spectra were recorded on a Nicolet 360 NB nmr spectrometer coupled to an Oxford Instruments superconducting magnet and a Nicolet 192 kword data acquisition system, and are reported in parts per million to high frequency from TMS. Coupling constants are reported as absolute values; the signs of the couplings were not determined. Infrared spectra (ir) were recorded on an air-purged Perkin–Elmer 180 grating infrared spectrometer and are reported in wavenumbers relative to the 1601.4 cm^{-1} absorption of polystyrene. Mass spectra (ms) were recorded on a Hewlett–Packard 5970 series mass selective detector and are reported as m/z (relative intensity). The melting points were determined using a Cybron Corporation Thermolyne melting point apparatus and are uncorrected.

Product analyses were determined by gas chromatography (gc) using either a Hewlett–Packard (HP) 5890 gc, fitted with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33-μm film thickness), coupled to a HP 5970 mass selective detector (ms), or a Hewlett–Packard 5890 gc, fitted with a DB-1701 or DB-225 fused silica WCOT column (30 m × 0.25 mm, 0.25-μm film thickness), with a flame ionization detector (fid). The digital signal from the fid was transmitted to a HP 3392A integrator and the data were acquired by software developed at the Department of Chemistry, Dalhousie University, using a Commodore PC-II.

Compounds that were obtained as liquids were purified prior to analysis by preparative gas chromatography using a Varian Aerograph 90-P and a 3/8 in. × 6 ft aluminum column packed with 10% SE-30 on Chromosorb W 60/80 NAW, or a 3/8 in. × 10 ft aluminum column packed with 10% DEGS on Chromosorb W 60/80 NAW. Preparative medium-pressure liquid chromatography (mplc) was carried out using a 2.5 cm × 1 m column packed with TLC grades silica gel (without binder) (Merck) at 15 psi (helium) (1 psi = 6.9 kPa). The chromatograms were developed with hexanes and the eluant was monitored–collected by a uv spectrometer-fraction collector.

Materials

Solvents were fractionally distilled. Acetonitrile (Fisher ACS grade) was distilled successively from sodium hydride and phosphorus pentoxide, and was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), and fractionally distilled. The 1,4-dicyanobenzene (Aldrich) was purified by treatment with Norite in methylene chloride, followed by sublimation and recrystallization from 95% ethanol. Biphenyl (Aldrich) was recrystallized from methanol. Collidine (BDH) was purified by distillation. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized (three times) from 95% ethanol and dried in a vacuum oven (12 h, 80°C, 10 Torr; 1 Torr = 133.3 Pa) before use.

Irradiations

An acetonitrile solution of the alkene (0.2 M), the electron accepting photosensitizer (1,4-dicyanobenzene) (0.15 M), the cosensitizer (biphenyl) (0.12 M), and the base (2,4,6-trimethylpyridine) (0.4 M) was flushed with dry nitrogen and sealed in a Pyrex tube (2 cm i.d.). The irradiation vessel was placed ca. 2.5 cm from a CGE 1-kW medium-pressure mercury vapor lamp contained in a water cooled quartz immersion well. The temperature was maintained at 10°C. The photolysate was separated by medium-pressure liquid chromatography (mplc) on a silica gel column, taking ca. 10-mL fractions. For quantitative studies, the progress of the reaction and the ratio of products were followed by gc/fid. Peak areas were calibrated relative to an inert internal standard (cyclododecane).

Cyclic voltammetric measurements

Oxidation potentials were obtained by cyclic voltammetry using an apparatus similar to that previously described (30). The working electrode was a platinum sphere (1 mm diameter), while the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (SCE), which was connected to the solution by a Luggin capillary. The electrolyte was TEAP (0.1 M) and the solvent was acetonitrile. Substrate concentrations were typically 0.005 M. The anodic wave was not reversible; the half-wave potential was taken as 0.03 V before the anodic peak potential (6).

Preparation and characterization of starting materials

E-*1-Phenylpropene* (*1*)

This alkene (*E*/*Z*, 95:5) was purchased from Aldrich Chemical Co. The ^1H nmr of the *E* isomer (361.1 MHz, $CDCl_3$) δ: 7.31–7.11 (m, 5H, aromatic), 6.35 (dd, 1H, H1, ^4J(H1, H3)= 1.4 Hz, ^3J(H1, H2)= 14.5 Hz), 6.18 (dq, 1H, H2, ^3J(H2, H1)= 14.5 Hz, ^3J(H2, H3)= 5.1 Hz), 1.83 (dd, 3H, H3, ^3J(H3, H1) = 1.4 Hz, ^3J(H3, H2) = 5.1 Hz); ^{13}C nmr of the *E* isomer (90.1 MHz, $CDCl_3$) δ: 137.8, 130.9, 128.3, 126.6, 125.7, 125.4, 18.3; ms (HP) m/z: M^+ 118 (80), 117 (100), 115 (49), 91 (52); $E^{ox}_{1/2}$ 1.73 V (SCE).

*2-Methyl-1-phenylpropene (**3**)*

The Grignard reaction, starting with isobutyraldehyde and phenylmagnesium bromide, gave the crude alcohol in excellent yield (97%). Dehydration of the alcohol, by the copper(II) triflate catalyzed procedure (31), gave the alkene **3**, which was purified by column chromatography with silica gel and hexanes as the eluent. Pure alkene 3 was isolated in 73% yield; ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.32–7.14 (m, 5H, aromatic), 6.27 (brs, 1H, H1), 1.90 (d, 3H, H3, ^4J(H3, H1)= 0.8 Hz), 1.86 (d, 3H, H2, ^4J(H2, H1)= 1.0 Hz) (these experimental values are in agreement with literature values (32)); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 138.5, 135.3, 128.6, 127.9, 125.6, 125.0, 26.8, 19.3; ms (HP) *m/s*: M^+ 132 (77), 131 (20), 117 (100), 115 (51), 91 (45); $E^{ox}_{1/2}$ 1.60 V (SCE).

*1-Phenylbutene (**5**) (E- and Z-)*

A solution of butyraldehyde (10.9 g, 0.15 mol) in diethyl ether was added dropwise to phenylmagnesium bromide (0.18 mol, prepared by adding 28.4 g of bromobenzene to 4.4 g of magnesium turnings) in ether at 0°C. After 24 h the reaction was quenched by addition to an iced solution of saturated NH_4Cl (200 mL). The aqueous layer was extracted with ether and the combined ether layers were washed with saturated NaCl and distilled water to remove inorganic impurities. The ethereal layer was then dried over magnesium sulphate, filtered, and evaporated. The crude alcohol (21.9 g, 0.145 mol), obtained in 96% yield, was purified by column chromatography over silica gel using hexanes as the eluent. The pure alcohol (18.2 g, 0.12 mol) was obtained in good yield (83%).

The pure alcohol (4.14 g, 27.6 mmol) was added to $Cu(Otf)_2$ (copper(II) triflate) (0.82 g, 2.76 mmol) and heated to reflux (ca. 100°C) for 27 h (31). The mixture was cooled, water was added, and the alkene was extracted with ether. The combined ether layers were washed with saturated NaCl and distilled water to remove the inorganic impurities. The solution was then dried over magnesium sulphate and the solvent was evaporated. The resulting alkene was purified by column chromatography over silica gel, eluting with hexanes. The pure alkene, a mixture of *E*- and *Z*-**5** (99:1) (2.41 g, 0.018 mol), was obtained in 67% yield based upon reacted alcohol.

For the *E* isomer: ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.35–7.15 (m, 5H, aromatic), 6.37 (d, 1H, H1, ^3J(H1, H2)= 15.9 Hz), 6.25 (dt, 1H, H2, ^3J(H2, H1)= 15.9 Hz, ^3J(H2, H3)= 6.3 Hz), 2.23 (dq, 2H, H3, ^3J(H3, H2)= 6.3 Hz, ^3J(H3, H4)= 7.4 Hz), 1.08 (t, 3H, H4, ^3J(H4, H3)= 7.4 Hz) (these values compare well with literature values (33)); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 138.4, 132.6, 128.8, 128.4, 126.7, 125.9, 26.1, 13.7; ms (HP) *m/s*: M^+ 132 (39), 117 (100), 116 (13), 115 (48), 91 (39); $E^{ox}_{1/2}$ = 1.67 V (SCE).

*2-Methyl-1-phenylbutene (**7**) (E- and Z-)*

Starting with triphenylbenzylphosphonium bromide and 2-butanone, the Wittig procedure gave the alkene, which was purified by distillation under vacuum (5×10^{-2} Torr (1 Torr = 133.3 Pa); ca. 40°C). Pure alkene **7** (*E*- and *Z*-) (3:2) was obtained in 80% yield.

For the *E* isomer: ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.33–7.15 (m, 5H, aromatic), 6.27 (brs, 1H, H1), 2.18 (q, 2H, H3-*E*, ^3J(H3, H4)= 7.5 Hz), 1.86 (d, 3H, H2-*E*, ^4J(H2, H1)= 1.2 Hz), 1.12 (t, 3H, H4-*E*, ^3J(H4, H3)= 7.5 Hz) (these values are in good agreement with those reported (34)); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 123.5, 33.4, 17.7, 12.7; ms (HP) *m/z*: M^+ 146 (100), 131 (82), 115 (64), 91 (52).

For the *Z* isomer: ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.33–7.15 (m, 5H, aromatic), 6.27 (brs, 1H, H1), 2.23 (q, 2H, H3-*Z*, ^3J(H3, H4)= 7.5 Hz), 1.88 (d, 3H, H2-*Z*, ^4J(H2, H1)= 1.4 Hz), 1.01 (t, 3H, H4-*Z*, ^3J(H4, H3)= 7.5 Hz; ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 124.8, 25.5, 23.6, 12.9; ms (HP) *m/z*: M^+ 146 (100), 131 (75), 115 (52), 91 (40).

*2,3-Dimethyl-1-phenylbutene (**10**) (E- and Z-)*

This alkene was prepared by the Wittig reaction, starting with triphenylbenzylphosphonium bromide and 3-methyl-2-butanone, using a procedure similar to that described above. The pure alkene was obtained by vacuum distillation in 57% yield (35).

For the *E* isomer: ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.30–7.12 (m, 5H, aromatic), 6.26 (brs, 1H, H1-*E*), 2.40 (qn, 1H, H3-*E*, ^3J(H3, H4)= 6.8 Hz), 1.80 (d, 3H, H2-*E*, ^4J(H2, H1)= 1.3 Hz), 1.08 (d, 6H, H4-*E*, ^3J(H4, H3) = 6.9 Hz; ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 122.7, 37.7, 21.4, 15.1; ms (HP) *m/z*: M^+ 160 (74), 145 (100), 117 (81), 115 (5), 105 (29), 91 (78).

For the *Z* isomer: ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.33–7.15 (m, 5H, aromatic), 6.18 (brs, 1H, H1-*Z*), 3.03 (qn, 1H, H3-*Z*, ^3J(H3, H4)= 6.8 Hz), 1.77 (d, 3H, H2-*Z*, ^4J(H2, H1)= 1.5 Hz), 1.01 (d, 6H, H4-*Z*, ^3J(H4, H3) = 6.8 Hz); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 124.3, 28.8, 21.0, 18.2; ms (HP) *m/z*: M^+ 160 (48), 145 (100), 117 (48), 115 (38), 91 (51).

*1-Phenylcyclohexene (**13**)*

This alkene was purchased from Aldrich Chemical Co.; ir (neat) ν, cm^{-1}: 3040 (m), 2942 (s), 1610 (m), 1585 (w), 1503 (s), 1455 (s), 762 (s), 743 (s), 697 (s); uv (hexanes) λ_{max}: 246 nm (ε 9000); ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.36–7.16 (m, 5H, aromatic), 6.10–6.08 (m, 1H, H2), 2.40–2.35 (m, 2H), 2.20–2.15 (m, 2H), 1.77–1.72 (m, 2H), 1.66–1.60 (m, 2H); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 142.6, 136.6, 128.7, 128.1, 126.5, 124.9, 124.7, 27.4, 25.9, 23.1, 22.2; ms (HP) *m/z*: M^+ 158 (39), 143 (50), 130 (77), 129 (100), 115 (77), 91 (39); $E^{ox}_{1/2}$ 1.16 V (SCE).

*1-(Phenylmethylene)cyclohexane (**15**)*

To a round-bottom flask (500 mL, N_2 atmosphere), fitted with a reflux condenser, was added sodium hydride (2.30 g, 0.050 mol) (50% suspension in oil). Pentane (20 mL) was added to dissolve the oil and then the supernatant was carefully decanted. Dimethylsulfoxide (20 mL) was added to the flask and the mixture was stirred until the evolution of hydrogen was complete (ca. 1/2 h). Triphenylbenzylphosphonium bromide (20.0 g, 0.050 mol) was slowly added to the reaction mixture in portions, with stiring between each addition. The mixture turned a bright orange colour and was left to stir for 1/2 h. Cyclohexanone (9.50 g, 0.110 mol) was added in excess to the reaction mixture and then refluxed at ca. 75°C for 3 h. The reaction was quenched by addition to water (250 mL) and the mixture was extracted with pentanes. The organic layer was washed with water, dried over $MgSO_4$, filtered, and the solvent was evaporated. The crude product (9.74 g, 0.057 mol) was distilled under vacuum (5×10^{-2} Torr) at ca. 56°C and pure alkene **15** was obtained (6.75 g, 0.059 mol) in 80% overall yield; ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.31–7.14 (m, 5H, aromatic), 6.22 (s, 1H), 2.36 (t, 2H, ^3J=5.6 Hz), 2.25 (t, 2H, ^3J=5.6 Hz), 1.66–1.52 (m, 6H) (in good agreement with reported values (32)); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 143.4, 138.3, 128.9, 128.1, 127.9, 125.7, 121.9, 37.7, 29.4, 28.6, 27.9, 26.7; ms (HP) *m/z*: M^+ 172 (65), 143 (13), 129 (60), 115 (50), 104 (77), 91 (81), 81 (100); $E^{ox}_{1/2}$ 1.62 V (SCE).

Isolation and characterization of product alkenes

*3-Phenylpropene (**2**)*

Irradiation of a solution of *E*-1-phenylpropene (**1**), under the conditions described above, gave 3-phenylpropene (**2**) in 41% yield at 94% conversion. The unreacted 1-phenylpropene was a 1:1 mixture of the *E* and *Z* isomers. When a solution of **2** was irradiated under these conditions, no **1** was detected.

The structure of this alkene (**2**) was firmly established by direct comparison with an authentic sample obtained from Aldrich Chemical Co.; ir (neat) ν, cm^{-1}: 3045 (s), 2920 (m), 1650 (m), 1613 (m), 1505 (s), 1463 (s), 1441 (m), 1000 (s), 926 (s), 742 (s), 701 (s); uv (hexanes) λ_{max}: 253, 260 nm (ε 9000); ^{1}H nmr (361.1 MHz, $CDCl_3$) δ: 7.28–7.11 (m, 5H, aromatic), 5.99–5.90 (m, 1H, H2, ^3J(H2, H3)= 6.6 Hz), 5.09–5.03 (m, 2H, H1A, H1B), 3.36 (d, 2H, H3, ^3J(H3, H2)= 6.6 Hz); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 140.0, 137.3, 128.4, 128.3, 125.9, 115.6, 40.1; ms (HP) *m/z*: M^+ 118 (62), 117 (100), 115 (41), 91 (46); $E^{ox}_{1/2}$ 2.26 V (SCE).

*2-Methyl-3-phenylpropene (**4**)*

Irradiation of 2-methyl-1-phenylpropene (**3**) under these conditions gave 2-methyl-3-phenylpropene (**4**) in 90% yield. The spectral data, obtained on a pure sample isolated from the irradiation mixture, are in good agreement with those reported (36); ir (neat) ν, cm^{-1}: 3048 (m), 2990 (s), 2939 (s), 1660 (w), 1508 (s), 1465 (s), 1386 (m), 1088 (w), 895 (s), 741 (s), 702 (s); uv (cyclohexane) λ_{max}: 259 nm (ε 500); ^{1}H

nmr (361.1 MHz, $CDCl_3$) δ: 7.32–7.14 (m, 5H, aromatic), 4.80 (d, 2H, H1, ^2J= 0.7 Hz), 3.31 (s, 2H, H3), 1.67 (s, 3H, H2); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 145.1, 139.7, 128.9, 128.2, 126.0, 111.9, 44.7, 22.1; ms (HP) *m/z*: M^+ 132 (65), 117 (100), 115 (41), 91 (65), 65 (28); $E^{ox}_{1/2}$ 2.24 V (SCE).

*1-Phenyl-2-butene (**6**) (E- and Z-)*

These alkenes were formed upon irradiation of *E*-1-phenyl-1-butene (**5**). When the reaction was 98% complete, the combined yield of *E*- and *Z*-1-phenyl-2-butene was 65% and the *E*:*Z* ratio was 4:1. The ratio of the *E*:*Z* isomers of unreacted starting material (**5**) was also 4:1.

These alkenes have been described (37) and the ^1H nmr spectrum of the products isolated from the irradiation mixture is in good agreement with the reported spectra.

For the *E* isomer: ^1H nmr (361.1 MHz, $CDCl_3$) δ: 7.30–7.16 (m, 5H, aromatic), 5.60–5.52 (m, 2H, H2-*E*, H3-*E*), 3.30 (d, 2H, H1-*E*, ^3J(H1-*E*, H2-*E*)= 6.3 Hz), 1.68 (d, 3H, H4-*E*, ^3J(H4-*E*, H3-*E*)= 6.0 Hz); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 124.8, 39.1, 17.9; ms (HP) *m/z*: M^+ 132 (50), 117 (100), 115 (92), 91 (48), 65 (39).

For the *Z*-isomer: ^1H nmr (361.1 MHz, $CDCl_3$) δ: 7.30–7.16 (m, 5H, aromatic), 5.60–5.52 (m, 2H, H2-*Z*, H3-*Z*), 3.40 (d, 2H, H1-*Z*, ^3J(H1-*Z*, H2-*Z*)= 5.1 Hz), 1.72 (d, 3H, H4-*Z*, ^3J(H4-*Z*, H3-*Z*)= 4.9 Hz); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 125.8, 33.1, 12.9; ms (HP) *m/z*: M^+ 132 (32), 117 (100), 115 (75), 91 (36), 65 (25).

*Irradiation of 2-methyl-1-phenylbutene (**7**)*

Irradiation of a solution of a mixture of the *E*- and *Z*-2-methyl-1-phenylbutene (**7**) (*E*:*Z*, 6:4) isomers led to formation of all three tautomers, *E*- and *Z*-2-methyl-1-phenyl-2-butene (**9**), and 2-phenylmethyl-1-butene (**8**), in a combined yield of 50%. The ratio of products, *E*-**9**:*Z*-**9**:**8**, was 1:2:11. At the beginning of the irradiation the ratio of the isomeric starting alkenes (2-methyl-1-phenylbutene), *E*-**7** to *Z*-**7**, was 2:1; after 90% conversion, the ratio was 1:1.

The structural assignments were made on the basis of the good agreement between the spectral data obtained on pure samples of the products isolated from the irradiation mixture and those reported (38).

*2-Phenylmethyl-1-butene (**8**)*: ^1H nmr (361.1 MHz, $CDCl_3$) δ: 7.27–7.15 (m, 5H, aromatic), 4.82 (brs, 1H, H1), 4.73 (brs, 1H, H1), 3.35 (s, 2H, H2), 1.97 (q, 2H, H3, ^3J(H3, H4)= 7.4 Hz), 1.54 (t, 3H, H4, ^3J(H4, H3)= 7.4 Hz); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 109.8, 43.2, 28.2, 23.3; ms (HP) *m/z*: M^+ 146 (27), 131 (27), 117 (100), 115 (32), 91 (66).

E-*2-Methyl-1-phenyl-2-butene* (E-**9**): ^1H nmr (361.1 MHz, $CDCl_3$) δ: 7.27–7.15 (m, 5H, aromatic), 5.39 (qt, 1H, H3-*E*), 3.37 (brs, 2H, H1-*E*), 1.72 (dd, 3H, H4-*E*), 1.62–1.60 (m, 3H, H2-*E*); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 120.4, 37.5, 15.5, 13.7; ms (HP) *m/z*: M^+ 146 (51), 131 (100), 117 (18), 115 (18), 91 (70).

Z-*2-Methyl-1-phenyl-2-butene* (Z-**9**): ^1H nmr (361.1 MHz, $CDCl_3$) δ: 7.27–7.15 (m, 5H, aromatic), 5.31 (qt, 1H, H3-*Z*), 3.27 (brs, 2H, H1-*Z*), 1.62–1.60 (m, 3H, H4-*Z*), 1.52 (t, 3H, H2-*Z*); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 125.8, 46.2, 13.5, 12.2; ms (HP) *m/z*: M^+ 146 (34), 131 (100), 117 (17), 115 (17), 91 (68).

*3-Methyl-2-phenylmethyl-1-butene (**11**)*

Irradiation of a solution of 2,3-dimethyl-1-phenylbutene (a mixture of the isomers *E*-**10** and *Z*-**10** in the ratio of 4:5), under the above conditions, resulted in the formation of 2-phenylmethyl-3-methylbutene (**11**) in 65% yield; the other possible tautomer, 2,3-dimethyl-1-phenyl-2-butene (**12**) was not detected. At 98% conversion the ratio of *E*-**10** to *Z*-**10** was 1:8. The structural assignment for **11** rests on an analysis of the spectral data observed for the pure product isolated from the irradiation mixture; ir (neat) ν, cm^{-1}: 3042 (w), 2980 (s), 2890 (w), 1654 (w), 1613 (w), 1508 (m), 1465 (m), 1389 (w), 1373 (w), 1085 (w), 896 (s), 701 (s); ^1H nmr (361.1 MHz, $CDCl_3$) δ: 7.30–7.14 (m, 5H, aromatic), 4.85 (s, 1H, H1), 4.62 (s, 1H, H1), 3.37 (s, 2H, H2), 2.20 (qn, 1H, H3, ^3J(H3, H4)= 6.8 Hz), 1.03 (d, 6H, H4, ^3J(H4, H3)= 6.8 Hz); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 155.2, 140.1, 129.1, 128.2, 125.9, 109.0, 41.6, 33.0, 21.9; ms (HP) *m/z*: M^+ 160 (49), 145 (100), 117 (62), 115 (52), 104 (22), 91 (36); $E^{ox}_{1/2}$ 2.25 V (SCE).

*3-Phenylcyclohexene (**14**)*

Irradiation of 1-phenylcyclohexene (**13**), under the conditions described above, gave 3-phenylcyclohexene (**14**) in 86% yield. Spectral data, obtained on a sample isolated from the irradiation mixture, were in good agreement with those reported (39); ir ν, cm^{-1} (neat): 3038 (m), 2942 (s), 1611 (m), 1502 (s), 1461 (s), 1085 (w), 758 (s), 701 (s); uv (hexanes) λ_{max}: 247 nm (ε 9000); ^1H nmr (361.1 MHz, $CDCl_3$) δ: 7.36–7.15 (m, 5H, aromatic), 5.91–5.85 (m, 1H), 5.74–5.69 (m, 1H), 3.41–3.37 (m, 1H), 2.11–1.50 (m, 6H); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 146.2, 130.1, 128.3, 128.2, 127.7, 125.9, 125.5, 41.9, 32.6, 25.0, 21.2; ms (HP) *m/z*: M^+ 158 (96), 130 (85), 129 (100), 128 (50), 115 (82), 91 (47); $E^{ox}_{1/2}$ 2.13 V (SCE).

*1-(Phenylmethyl)cyclohexene (**16**)*

This alkene was obtained, in 41% yield, from the irradiation of 1-(phenylmethylene)cyclohexane (**15**). Comparison of spectral data obtained on a sample isolated from the irradiation mixture with those reported (40) established the structure; uv (hexane) λ_{max}: 248 nm (ε 500); ^1H nmr (361.1 MHz, $CDCl_3$) δ: 7.29–7.16 (m, 5H, aromatic), 5.46 (brs, 1H), 3.24 (brs, 2H), 2.02–2.00 (m, 2H), 1.85 (brs, 2H), 1.61–1.51 (m, 4H); ^{13}C nmr (90.1 MHz, $CDCl_3$) δ: 140.4, 137.2, 128.9, 128.1, 125.8, 122.9, 44.7, 28.0, 25.3, 22.9, 22.4; ms (HP) *m/z*: M^+ 172 (53), 129 (35), 104 (18), 91 (55), 81 (100); $E^{ox}_{1/2}$ 1.95 V (SCE).

Acknowledgments

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada and from the Petroleum Research Fund administered by the American Chemical Society. We thank Dr. D. L. Hooper at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University for the high-field nmr spectra and for help in the preparation of the manuscript.

Oxidation of allyl and benzyl ethers by 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ)

E. LEE-RUFF AND F. J. ABLENAS
Department of Chemistry, York University, North York, Ont., Canada M3J 1P3

Received April 4, 1988[1]

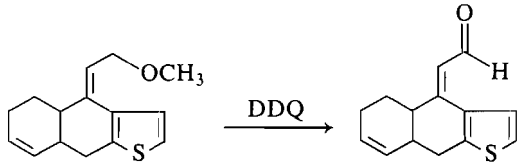
E. LEE-RUFF and F. J. ABLENAS. Can. J. Chem. **67**, 699 (1989).

Benzylic and allylic ethers are oxidized by 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) to give the corresponding carbonyl containing compounds (aldehydes and ketones) and alcohols. The reaction proceeds readily with ethers bearing activating groups. Primary ethers are further oxidized with excess DDQ giving the corresponding esters. Mechanisms for these processes are proposed, based on nuclear magnetic resonance and stoichiometric analyses.

Key words: dehydrogenation, allylic and benzylic ethers.

E. LEE-RUFF et F. J. ABLENAS. Can. J. Chem. **67**, 699 (1989).

L'oxydation d'éthers benzyliques et allyliques par la dichloro-2,3 dicyano-5,6 benzoquinone (DDQ) fournit les composés carbonylés correspondants (aldéhydes et cétones) ainsi que les alcools. La réaction se produit facilement avec les éthers portant des groupements activants. Sous l'influence d'un excès de DDQ, les éthers primaires subissent une oxydation plus poussée conduisant aux esters correspondants. En se basant sur les spectres en résonance magnétique nucléaire et sur des analyses stoechiométriques, on propose des mécanismes pour ces processus.



Mots clés : déhydrogenation, éthers benzyliques et allyliques.

Introduction

The use of 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) (1, 2) in the dehydrogenation of annelated cyclohexanes to give polycyclic benzenoid derivatives is the method of choice principally because of the relatively mild conditions compared to other dehydrogenation agents. The oxidation proceeds by a mechanism thought to involve initial hydride abstraction (1*b*, *c*) to generate a stabilized benzylic or allylic cation, followed by loss of a proton and concomitant formation of reduced 2,3-dichloro-5,6-dicyanohydroquinone, which usually precipitates out of solution in nonpolar solvents. Evidence for such an ionic mechanism has been obtained from trapping of the intermediate carbocations with nucleophilic solvents such as water (3) and methanol (4). In our investigations on the preparation of polynuclear aromatic hydrocarbons incorporating thiophene rings (5) we observed that, upon attempted dehydrogenation of the tetrahydro naphthothiophene **1** with DDQ, the only product formed was the unsaturated aldehyde **2**. Although oxidations of allylic alcohols with DDQ have been observed (6, 7), the conversion of **1** and **2** by DDQ represents formally a demethanation reaction that to our knowledge is unprecedented in quinone chemistry. Recently Yonemitsu and co-workers (8, 9) have shown that the 4-methoxybenzyl group can be used as a protecting group for hydroxy functions with selective deprotection taking place in the presence of DDQ and water. However, no mechanistic details were provided in these studies. To investigate the scope and limitation of this unusual oxidation we carried out a systematic study of the DDQ reaction with representative benzylic and allylic ethers.

1 **2**

[1]Revision received December 14, 1988.

Results and discussion

In addition to the allyl methyl ether **1** used in the study, the following allylic and benzylic ethers were investigated: benzyl methyl ether (**3**), benzyl ethyl ether (**4**), *trans*-cinnamyl methyl ether (**5***a*), *trans*-cinnamyl benzoate (**5***b*), *trans*-cinnamyl benzyl ether (**5***c*), *trans*-cinnamyl trityl ether (**5***d*), 1,1-phenylmethoxyethane (**6**), methyl 4-methoxy-2-butenoate (**7**), thiophenoxymethyl methyl ether (**8**), 1,2-phenylmethoxyethane (**9**), *p*-nitrobenzyl methyl ether (**10**), and 3-methoxycyclohexene (**11**). The reactions were carried out in toluene solution heated to reflux or in carbon tetrachloride at room temperature. The details of individual reactions are tabulated in Table 1. All of the products were compared with known compounds. Although these reactions formally represent oxidative dealkylations, the alkyl group is transformed to its alcohol in the products as seen from the reactions of **5***b–d*. Although the presence of methanol could be confirmed by nmr spectroscopy from the reactions of the methyl ethers, its isolation was difficult due to losses in the work-up procedures. It is noteworthy that the oxidations proceed with allyl and benzyl ethers that do not possess electron-withdrawing groups, as can be seen from the absence of oxidation products in the cases of **7** and **10**.

Furthermore, the inertness of **7**, **9**, and **10** to oxidation suggests that the initial hydride abstraction and formation of a carbocation is rate determining. To shed some light on the mechanism and establish the fate of the methyl group during the oxidation of the methyl allyl/benzyl ethers with DDQ we carried out a systematic nmr investigation of ether **5***a*, which was found to be most reactive in this series and gave smooth conversion at room temperature.

The ^{1}H nmr spectrum of a $CCl_4/CDCl_3$ solution containing *trans*-cinnamyl methyl ether (20 mM) and DDQ (20 mM) was observed at room temperature. The spectrum after 1 h showed a small amount of cinnamaldehyde (17%) in addition to signals corresponding to an acetal **13**. The presence of cinnamaldehyde was significantly diminished upon the addition of ground and freshly activated 4 Å molecular sieves.

The assignment of the mixed acetal was based on the splitting pattern of the acetal and vinylic protons at 5.8 (J=5.8 Hz)

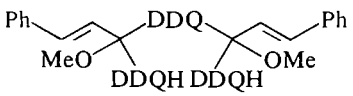

SCHEME 1

(H—C—O), 6.1, and 6.7 ppm respectively, and comparison of these with acetal **14** prepared independently. The methoxy protons of **13** appeared as a pair of singlets at 3.35 and 3.40 ppm. The relative integration of the methoxyl to acetal proton signals was approximately 3:1. Comparison of the spectral data of the reaction mixture with authentic **14** rules out the presence of the dimethyl acetal **14**. Furthermore, only one half of the expected reduced $DDQH_2$ precipitated from solution at this point in time, although the reduction product $DDQH_2$ is insoluble in carbon tetrachloride. This observation, along with the formation of a major product containing an acetal proton as seen by ^{1}H nmr, suggests that one half equivalent of DDQ is covalently bound to the oxidized substrate. Attempted isolation and purification of acetal **13** by chromatography led to its hydrolysis to *trans*-cinnamaldehyde and $DDQH_2$ (~½ equiv.). Increasing the initial concentration of DDQ to 1.8 equivalents (36 mM) resulted in the formation of methyl *trans*-cinnamate in addition to cinnamaldehyde. (This ester was also obtained in 12% yield as a by-product from the oxidation of the ether **5***a* with 1.1 equivalents of DDQ.) Following this reaction mixture by ^{1}H nmr spectroscopy, we observed another transient with peaks at 3.24 ppm (OCH_3) and an AB pattern at 5.9 and 6.9 ppm. This

15

16

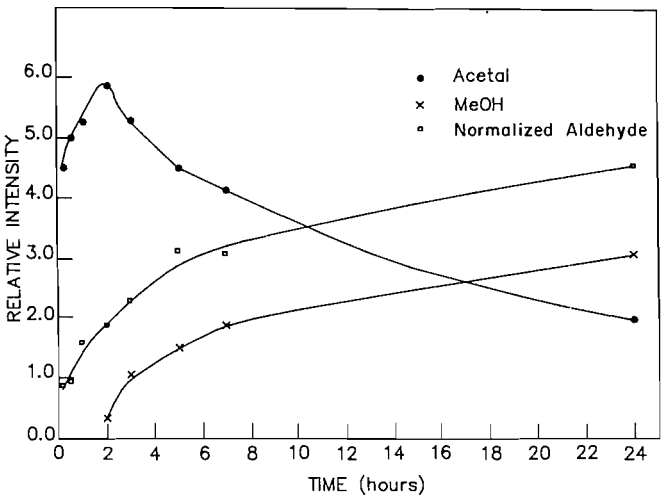

FIG. 1. Reaction profile for DDQ/ether **5***a* = 1:1 equiv.

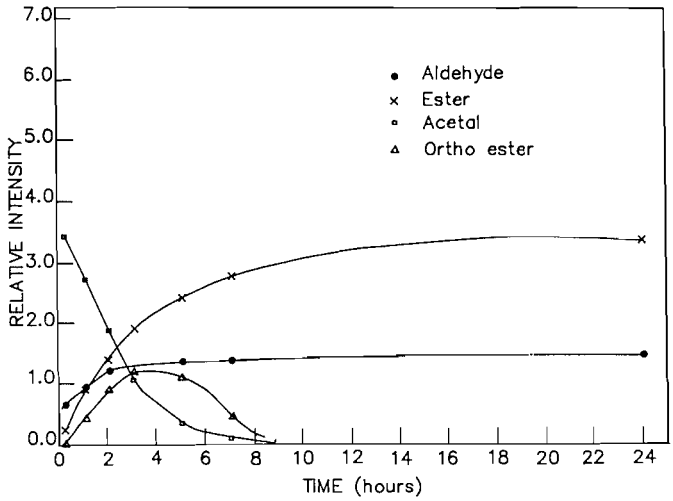

FIG. 2. Reaction profile for DDQ/ether **5***a* = 1.8:1 equiv.

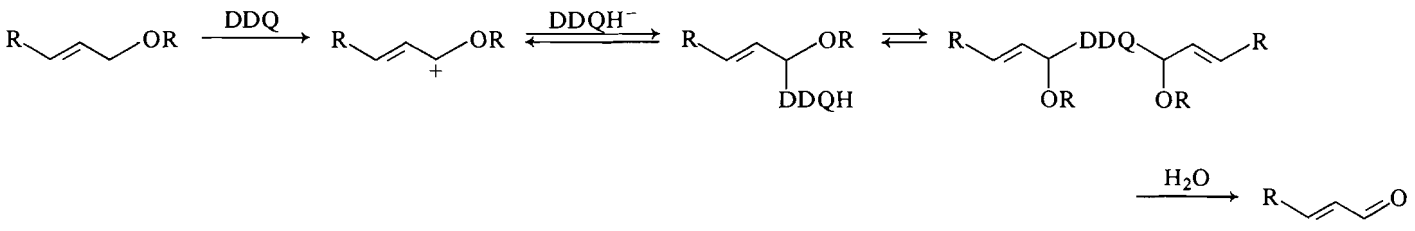

transient has been tentatively assigned the structure of the ortho ester **15**. No signal associated with an acetal proton was observed in this case. The relative integration of the methoxy signal (3.43) to the vinyl signal (AB 5.9 ppm or 6.9 ppm) was approximately 3;1. These data do not preclude structures such as **16** as the transient species although the OH signals associated with **16** were not discernible in the ^{1}H nmr spectrum.

This transient upon prolonged reaction (and, ostensibly, hydrolysis) gave methyl cinnamate. Kinetic profiles based on nmr time-resolved spectra of the reaction mixtures containing 1:1 and 1.8:1 molar ratios of DDQ and ether **5** are shown in Figs. 1 and 2 respectively. It can be seen in Fig. 1 that the concentration of the acetal **13** peaks at about 2 h and then decreases with accompanying increase in formation of both methanol and cinnamaldehyde. In Fig. 2 the concentration of acetal **13** peaks earlier and decreases more rapidly than in Fig. 1. At the same time the transient associated with the ortho ester **15** gradually increases and peaks at 3.5 h before diminishing while the aldehyde and ester concentrations level off. These observations point to two intermediates from which the aldehyde and ester are formed. The nmr spectroscopic evidence suggests that the acetal **13** and the ortho esters **15** or **16** may be precursors to cinnamaldehyde and methyl cinnamate respectively. It is clear from the spectral data that cinnamaldehyde is not oxidized by DDQ to methyl cinnamate, but DDQ is oxidizing the acetal **13** to an ortho ester. The minor amount of cinnamaldehyde formed initially is attributed to the presence of adventitious water, which could be minimized by the addition of activated molecular sieves. This is demonstrated when the addition of D_2O to the reaction mixture results in hydrolysis of the acetal **13** to cinnamaldehyde in a separate nmr experiment. The data suggest that the oxidation of allylic/benzylic ethers by DDQ proceeds by initial and rate-determining hydride abstraction of the α-carbon (Scheme 2). This is seen from the relative reactivities of ethers possessing electron-donating and -withdrawing R substituents. Electron-deficient electrophilic R groups will deactivate this process as is seen in the inertness of ethers **7** and **10**, although the lack of reactivity of **8** is somewhat surprising. Given the failure of the reaction to occur in dioxan, it may be that the formation of a π-complex between DDQ and the Lewis base renders DDQ inactive as a dehydrogenating reagent. Furthermore, the stabilization of the resultant cation is crucial, as is observed in the unreactive nature of ether **9**. Thus oxidation of allylic or benzylic ethers by DDQ is possible, provided that no electrophilic substituent is prpesent in the conjugated chromophore and no available β-hydrogen is present. In the latter case dehydrogenation results as the dominant process, as is observed for ether **11**.

These results suggest that DDQ can be used as an alternative method for the deprotection of benzyl ethers under neutral conditions as was also shown by Yonemitsu (8, 9). Furthermore, the benzyl methyl ether function can be used as a "masked" aryl carboxaldehyde in which the methoxymethyl substituent would activate the aryl ring system and direct electrophilic substitution with a regiochemistry different from the formyl group.

These results also indicate that electron-rich allyl alcohols or

SCHEME 2

unsaturated aldehydes (via acetals) can be oxidized to aldehydes and esters with DDQ, without the competing degradative oxidation that is frequently a complication with the use of chromium-(VI) reagents.

Experimental

The ^{1}H nmr spectra were recorded in $CDCl_3$ or CCl_4 solution with TMS as an internal reference on a Bruker AM-300 nmr spectrometer. Infrared spectra were recorded neat on NaCl discs on a Unicam SP1000 instrument, low resolution mass spectra were obtained on a VG Micromass 16F instrument, and high resolution mass spectra were obtained on a VG ZAB-E instrument.

Anhydrous $CDCl_3$ and CCl_4 were obtained by storing these over molecular sieves for 48 h. Toluene was dried over sodium metal. Cinnamyl methyl ether (**5**) was prepared from cinnamyl alcohol (10).

General procedure for DDQ oxidations

In a typical run cinnamyl methyl ether **5***a* (157.4 mg; 1.06 mmol) and DDQ (244.5 mg, 1.08 equiv.) were dissolved in dry toluene (20 mL) and refluxed for 1.5 h. The resulting slurry was cooled, $DDQH_2$ filtered out, and the solvent removed to afford an oil, which was flash chromatographed (silica gel, dichloromethane) to afford methyl cinnamate (20.0 mg, 12%) followed by cinnamaldehyde (112.0 mg, 80%).

(8a-H-4,4a,7,8-Tetrahydronaphtho[2,3-b]thien-9-ylidene)-acetaldehyde (2)

The methyl ether **1** (62.7 mg; 0.255 mmol) was dissolved in dry toluene (50 mL) with DDQ (127.8 mg, 2.2 equiv.) and the solution refluxed 2 h. The solution was cooled, concentrated, and flash chromatographed (silica gel, dichloromethane) to afford the aldehyde as the only product, **2** (30.6 mg, 52%); ir ν_{NaCl}:1680 (C=O) cm^{-1}; ^{1}H nmr δ:10.20, d(J = 6.0 Hz), CHO; 7.24, d(J = 5.2 Hz), H2; 7.13, d(J = 5.2 Hz), H1; 6.32, d(J = 6.0 Hz), Hα; 5.75–5.95, m, H5,6; 3.65, d(J = 7.5 Hz), 1H; 3.13, dd(J = 7.5,1.0 Hz), 1H; 2.60–2.80, m, 2H; 2.15–2.80, m, 2H; 1.65–2.00, m, 2H; ppm; ms m/z : 230(100), 201(84).

Nuclear magnetic resonance analysis of DDQ: ether 5a mixtures

The ether **5***a* and DDQ were mixed together in dry carbon tetrachloride to afford a 40 mM solution, which was diluted to 20 mM with deuteriochloroform. The ^{1}H nmr spectra were recorded at 23°C. The relative concentrations of the aldehyde, ester, methanol, acetal **13**, and ortho ester **15** were based on the height of the peaks (relative to $CHCl_3$) at δ 9.72, 3.81, 3.48, 3.36, and 3.24 ppm, respectively.

Cinnamaldehyde dimethyl acetal

This compound was prepared by the general procedure involving 2,2-dimethoxypropane (11) and had a bp identical to the known dimethyl acetal (12); ^{1}H nmr δ: 7.26–7.43, m, 5H; 6.73, d(J = 16.1 Hz), Hα; 6.15, dd(J = 16.1, 4.9 Hz), Hβ; 4.96, d(J = 4.9 Hz), Hγ; 3.38, s, OCH_3.

Preparation of cinnamyl trityl ether 5d (Z-3-phenyl-1-triphenylmethoxy-2-propene)

Cinnamyl alcohol (0.69 mL, 5.36 mmol) was dissolved in dry dichloromethane (10 mL) with trityl chloride (1.50 g, 1.0 equiv.) and lutidine (0.62 mL, 1.0 equiv.). The solution was stirred for 4 days, the solvent removed, and the residue recrystallized from petroleum ether-:toluene (5:1, 10 mL) to afford the trityl ether (1.04 g, 52%); mp (pet. ether) 126.5–127°C; ir ν_{CHCl_3}: 2985, 1587, 1480, 1439 cm^{-1}; ^{1}H nmr δ: 7.2–7.6 m, 20H; 6.70, d(J = 15.9 Hz), Hα; 6.20, dt (J = 15.9, 5.0 Hz), Hβ; 3.79, d(J = 5.0 Hz), CH_2; ppm; ms m/z: 244(35), 243(100, Ph_3C^+), 183(17), 149(18). *Anal.* calcd. for $C_{28}H_{24}O$: C 89.31, H 6.44; found: C 89.49, H 6.78.

Received October 11, 1988

ELEONORA ALTMAN, JEAN-ROBERT BRISSON, and MALCOLM B. PERRY. Can. J. Chem. **67**, 703 (1989).

One- and two-dimensional high resolution ^1H and ^{13}C nuclear magnetic resonance spectroscopy at 500 MHz and 125 MHz together with methylation and partial hydrolytic degradation methods were used to determine the structure of the antigenic O-polysaccharide produced by *Actinobacillus (Haemophilus) pleuropneumoniae* serotype 6 (ATCC 33590). The O-polysaccharide was shown to be a high molecular weight unbranched linear polymer of repeating pentasaccharide units having the structure: →3)-α-D-Glc*p*-(1→2)-β-D-Gal*f*-(1→6)-α-D-Glc*p*-(1→6)-β-D-Glc*p*-(1→3)-β-D-Gal*f*-(1→.

Key words: *Actinobacillus pleuropneumoniae*, lipopolysaccharide, O-antigen, nuclear magnetic resonance.

ELEONORA ALTMAN, JEAN-ROBERT BRISSON et MALCOLM B. PERRY. Can. J. Chem. **67**, 703 (1989).

On a fait appel à la résonance magnétique nucléaire mono- et bi-dimensionnelle du ^1H et du ^{13}C, à 125 et à 500 MHz, ainsi qu'à des méthodes de méthylation et de dégradation par hydrolyse partielle pour déterminer la structure du polysaccharide antigénique qui est produit par l'*Actinobacillus (Haemophilus) pleuropneumoniae* du sérotype 6 (ATCC 33590). On a démontré que le O-polysaccharide est un polymère linéaire, de haut poids moléculaire et sans ramifications, formé d'unités d'un pentasaccharide possédant la structure suivante : →3)-α-D-Glc*p*-(1→2)-β-D-Gal*f*-(1→6)-α-D-Glc*p*-(1→6)-β-D-Glc*p*-(1→3)-β-D-Gal*f*-(1→.

Mots clés : *Actinobacillus pleuropneumoniae*, lipopolysaccharide, O-antigène, résonance magnétique nucléaire.

Introduction

Actinobacillus (Haemophilus) pleuropneumoniae is an important primary bacterial pathogen causing contagious pleuropneumonia in pigs. The organism is encapsulated and 10 serotypes based on the structurally different polysaccharide capsular antigens have been identified (1–3). Two further serotypes of as yet undetermined antigenic structure have recently been added (4).

The lipopolysaccharides (endotoxin) associated with *A. pleuropneumoniae* strains have been implicated in the pathogenesis of porcine pleuropneumonia (5). Our structural studies of the antigens of the different serotypes of *A. pleuropneumoniae* have revealed the association of a unique lipopolysaccharide with each serotype, the differences residing in the structure of their respective O-polysaccharide components (6–9).

This paper records the structural analysis of the O-polysaccharide component of the lipopolysaccharide produced by *A. pleuropneumoniae* serotype 6 and relates its structure and observed serological cross reactivity (10) with that of the lipopolysaccharide produced by *A. pleuropneumoniae* serotype 3.

Experimental

Production of O-polysaccharide

Actinobacillus pleuropneumoniae serotype 6 (ATCC 33590) was grown in Bacto PPLO broth (yield 3 g wet weight/L) and the lipopolysaccharide isolated by the phenol extraction procedure as previously described (8). A solution of LPS (0.2 g) in aqueous 2% acetic acid (100 mL) was kept at 100°C for 2 h, the precipitated lipid A was removed by low speed centrifugation, and the O-polysaccharide was recovered by Sephadex G-50 gel filtration as previously described (8).

Analytical methods

Quantitative methods for glycose analysis and glc and glc–ms methods used were the same as previously described (8). Samples (0.5 mg) of oligo- and polysaccharides were hydrolyzed in sealed glass tubes with 10 M hydrochloric acid (1 mL) for 15 min at 90°C, or with 2 M hydrochloric acid (1 mL) for 17 h at 100°C, followed by concentration to dryness. Glycoses were determined by glc of their alditol acetate derivatives (11) using *myo*-inositol as an internal standard. The configuration of glycoses was established by capillary glc of their acetylated (−)-2-butyl glycosides (12). Lipids were identified by glc–ms of their methyl esters derived by sealed-tube methanolysis of samples (1 mg) with 3% methanolic HCl for 4 h at 100°C. Thin-layer chromatography was performed on silica gel (Merck) with 1-propanol – concentrated ammonia – water (6:3:1). Gel filtration was performed on columns on Sephadex G-50 (2 × 100 cm) or Bio-Gel P-2 (1.6 × 100 cm) (200–400 mesh) (Bio-Rad Labs). SDS-PAGE and methylation analyses were made under the same previously reported conditions (8).

Partial hydrolysis

A solution of the O-polysaccharide (18.6 mg) in cold aqueous 48% hydrofluoric acid (1 mL) was kept for 96 h at 4°C, then concentrated to dryness in high vacuum over NaOH. The residue was neutralized with aqueous 5% ammonium hydroxide and lyophilized. The products were fractionated by gel filtration on a column of Bio-Gel P-2.

Nuclear magnetic resonance spectroscopy

Proton-decoupled ^{13}C nmr spectra (125 MHz) were recorded at 24°C for a 25-kHz spectral width, using a $\pi/2$ pulse and a 32K data set on a Bruker AM 500 spectrometer. Chemical shifts are expressed relative to internal acetone (1%, 31.07 ppm). The ^1H nmr spectra (500 MHz) were recorded at 24°C using a spectral width of 2.5 kHz, a $\pi/2$ pulse, and a 16K data set for a digital resolution of 0.3 Hz/point. Chemical shifts are expressed relative to internal acetone (0.1%, 2.225 ppm) and coupling constants are reported in Hz. A sample of purified O-polysaccharide was passed through Chelex-100 (Bio-Rad) resin (3 mL) and then exchanged twice with D_2O (99.8%). Spectra were recorded on solutions (25 mg/mL, pD 9.0) in 99.8% D_2O (5-mm-diameter tubes).

Proton homonuclear-correlated 2D-nmr experiments COSY (13) and relay COSY (14) were performed at 24°C, using the standard software provided by Bruker (DISNMR). Quadrature detection in both dimensions was employed in the COSY experiments. The initial (t_1, t_2) matrices of 512 × 2048 data points were zero-filled to 1024 × 2048 data points to provide digital resolution of 1 Hz/point in both domains. Resolution enhancement in both domains was done by non-shifted sine bell function prior to Fourier transformation. Magnitude spectra, symmetrized about the diagonal, were used to represent the data. The number of transients per FID was 8 for the COSY experiment. The nOe experiments were performed in the difference mode with sequential

irradiation of each line in a multiplet (15, 16). The total irradiation time was 400 ms. A heteronuclear ^{13}C–^{1}H shift correlation experiment was done on a Bruker AM 500 spectrometer using the CHORTLE (carbon–hydrogen correlations from one-dimensional polarization transfer spectra by least-squares analysis) techniques (17). The experiment was done at 24°C on a solution (15 mg/mL) of the O-polysaccharide in D_2O. Four proton evolution times of 0.24, 1.0, 2.4, and 3.2 ms were used with 4000 transients/FID.

Results and discussion

Extraction of *Actinobacillus pleuropneumoniae* serotype 6 cells (185 g, wet weight) by a modified lysozyme phenol–water procedure (18), followed by purification of the LPS by repeated ultracentrifugation, afforded an aqueous-phase LPS (924 mg) and a phenol-phase soluble LPS (328 mg). Both LPS preparations gave identical separation patterns on SDS-PAGE analysis (19), indicative of S-type LPS (20). However, the phenol-phase soluble LPS contained less O-chain polysaccharide (8.6%) than the aqueous phase LPS and was not examined further. Fission of the aqueous-phase soluble LPS (233 mg) with hot dilute acetic acid gave an insoluble lipid A (21 mg). Gel filtration of the water-soluble products on Sephadex G-50 afforded an O-chain polysaccharide (K_{av} 0.03, 46 mg), a core oligosaccharide (K_{av} 0.63, 24 mg), and a low-molecular-weight fraction (K_{av} 0.83, 26 mg), containing 3-deoxy-2-octulosonate.

The O-polysaccharide was contaminated by a minor quantity of previously characterized capsular polysaccharide, which was a contaminant of the LPS preparation due to its coprecipitation in the preparative ultracentrifugation. Purification of the O-chain was achieved by ion-exchange chromatography on DEAE-Sephacel; the O-polysaccharide was eluted at the void volume, whereas the capsular polysaccharide (21) was eluted with ≈0.1 M sodium chloride.

The purified O-polysaccharide was readily soluble in water and had $[\alpha]_D$ +30° (*c* 0.75, water) (*Anal.* found: C 41.38, H 5.99, N 0.90, ash 2.5%). On the basis of pc and glc of the derived alditol acetates and the acetylated derivatives of their (−)-2-butyl glycosides, the O-polysaccharide was found to be composed of D-glucose and D-galactose in the molar ratio ≈ 3:2. The ^{1}H nmr spectrum (500 MHz, 24°C) of the O-chain polysaccharide contained five signals for anomeric protons at δ 5.26 (d, 1H, $J_{1,2}$ 0.8 Hz), 5.16 (d, 1H, $J_{1,2}$ 1.6 Hz), 5.05 (d, 1H, $J_{1,2}$ 3.7 Hz), 4.95 (d, 1H, $J_{1,2}$ 3.7 Hz), and 4.67 ppm (d, 1H, $J_{1,2}$ 7.9 Hz). Consistent with these results, the ^{13}C nmr spectrum (125 MHz, 24°C) contained signals for anomeric carbons at δ 109.6, 107.0, 103.1, 98.9, and 98.8 ppm. The methylated and hydrolyzed O-chain afforded a product that, after reduction ($NaBD_4$) and acetylation, gave glc–ms results (Table 1) that indicated that the O-chain of *A. pleuropneumoniae* serotype 6 is composed of linear pentasaccharide repeating units containing →3)-D-Gal*f*-(1→,→3)-D-Glc*p*-(1→,2→)-D-Gal*f*-(1→, and →6)-D-Glc*p*-(1→ (1:1:1:2) residues. The methylation data showed that two D-galactose residues were furanoid, a conclusion substantiated by the observed characteristic signals for anomeric carbons at δ 109.6 and 107.0 ppm in the ^{13}C nmr spectrum, and two signals at δ 5.26 and 5.16 ppm in the anomeric region of the ^{1}H nmr spectrum of the O-polysaccharide. Both ^{1}H nmr and ^{13}C nmr spectra of the O-chain showed a close similarity to the spectra of the O-chain of the LPS *A. pleuropneumoniae* serotype 3, which is composed of a repeating pentasaccharide unit containing two galactofuranosyl residues (8). However, as expected from the composition and methylation analyses, the O-chain of *A. pleuropneumoniae* serotype 6 contains a second 1,6-linked glucopyranosyl residue instead of a 1,6-linked galactopyranosyl residue, present in the O-chain of *A. pleuropneumoniae* serotype 3 (8).

Assignments of the proton resonances were made from COSY (13) (Fig. 1) and relayed COSY (14) experiments. The residues in the O-chain polysaccharide were arbitrarily labelled a–e according to the decreased order of the chemical shifts of the H-1 resonances. Following the cross-peaks, the majority of the proton resonances were readily assigned (Table 2). The heteronuclear shift-correlated experiment (CHORTLE (17)) enabled unambiguous assignments of all the carbon resonances in the repeating unit of the O-polysaccharide (Table 3). Comparison of the ^{1}H and ^{13}C nmr spectra of the *A. pleuropneumoniae* serotype 3 (8) and serotype 6 O-chains (Tables 2 and 3) shows a striking similarity in the chemical shifts with the exception of the resonances of unit **d** (6-linked α-D-glucopyranosyl). These spectral features suggest that the linear sequence found for the *A. pleuropneumoniae* serotype 3 O-polysaccharide was maintained in the O-chain of the *A. pleuropneumoniae* serotype 6.

Since all proton resonances were assigned it was possible to determine the monosaccharide sequence by one-dimensional nOe difference experiments (15, 16). Irradiation of each anomeric resonance gave an intraresidue nOe, which provided linkage information (Fig. 2) and established the linkage sequence **a**→**c**→**b**→**d**→**e**→. In the case of unit **e**, saturation of

SCHEME 1. Degradation of the O-chain of *A. pleuropneumoniae* serotype 6 by partial hydrolysis.

the H-1**e** resonance (Fig. 2E) produced intraresidue nOe's to both H-2**a** and H-3**a**; however, the methylation and ^{13}C nmr data required that the unit **e** was linked 1,3 to a β-D-galactofuranosyl residue, unit **a**.

Further proof of the proposed structure was obtained from partial hydrolysis of the O-chain with aqueous 48% hydrofluoric acid, followed by gel filtration on Bio-Gel P-2, which afforded oligosaccharides *A*, *B*, and *C* (Scheme 1). Oligosaccharide *C* (K_{av} 0.80) had $[\alpha]_D$ +108.5° (*c* 0.19, water) and gave a single spot in tlc (R_f 0.31). Reduction of *C* with $NaBD_4$ afforded oligosaccharide *C1*, which, on hydrolysis and glc–ms of the derived alditol acetates, was shown to contain D-glucose and galactitol-1-*d* in the molar ratio 1:1; nmr data: ^1H (500 MHz, 24°C), δ: 5.47 (d, 0.3H, $J_{1,2}$ 3.6 Hz, H-1α), 5.38 (d, 0.7H, $J_{1,2}$ 3.9 Hz, H-1′), 5.10 (d, 0.3H, $J_{1,2}$ 3.8 Hz, H-1′), 4.74 (d, 0.7H, $J_{1,2}$ 8.4 Hz, H-1β) ppm; ^{13}C (125 MHz, 27°C), δ: 98.8 (0.6C), 97.5 (0.4C), 97.1 (0.6C), and 90.5 (0.4C) ppm. The glc–ms of methylated *C1* (Table 1, column IV) in conjunction with the ^1H and ^{13}C nmr data indicated *C* to be α-D-Glc*p*-(1→2)-D-Gal.

Oligosaccharide *B* (K_{av} 0.67) had $[\alpha]_D$ +52.3° (*c* 0.24, water) and gave a single spot on tlc (R_f 0.15). Reduction of *B* with $NaBD_4$ gave oligosaccharide *B1*, which, by glc–ms of the derived alditol acetates, was shown to be a trisaccharide composed of D-glucose and galactitol-1-*d* in the molar ratio 2:1; nmr data: ^1H (500 MHz, 24°C), δ: 5.28 (d, 0.3H, $J_{1,2}$ 3.5 Hz, H-1α), 4.96 (d, 1H, $J_{1,2}$ 3.9 Hz), 4.71 (d, 1H, $J_{1,2}$ 7.7 Hz), 4.63 (d, 0.7H, $J_{1,2}$ 7.9 Hz, H-1β) ppm; ^{13}C (125 MHz, 27°C), δ: 104.7 (1C), 98.8 (1C), 97.1 (0.6C), 93.0 (0.4C) ppm. The glc–ms analysis of methylated *B1* (Table 1) together with the ^1H and ^{13}C nmr data indicated *B* to be α-D-Glc*p*-(1→6)-β-D-Glc*p*-(1→3)-D-Gal.

Oligosaccharide *A* (K_{av} 0.43) had $[\alpha]_D$ +37.9° (*c* 0.33, water) and gave a single spot of tlc (R_f 0.07). Reduction of *A* with $NaBD_4$ gave oligosaccharide *A1*, which, by glc–ms of the derived alditol acetates, was shown to be a pentasaccharide composed of D-glucose, D-galactose, and galactitol-1-*d* in the molar ratio 3:1:1; nmr data: ^1H (500 MHz, 24°C), δ: 5.28 (d, 0.3H, $J_{1,2}$ 3.3 Hz, H-1α), 5.15 (d, 1H, $J_{1,2}$ <2 Hz), 5.06 (d, 1H, $J_{1,2}$ 3.8 Hz), 4.95 (d, 1H, $J_{1,2}$ 3.8 Hz), 4.71 (d, 1H, $J_{1,2}$ 8.1 Hz), 4.63 (d, 0.7H, $J_{1,2}$ 7.9 Hz, H-1β) ppm; ^{13}C (50 MHz, 24°C), δ: 107.0 (1C), 104.7 (1C), 98.9 (1C), 98.7 (1C), 97.0 (0.7 C), 93.0 (0.3C) ppm. The glc–ms analysis of methylated *A1* (Table 1) indicated that the D-glucopyranosyl unit formed the nonreducing end of the pentasaccharide and that the D-galactose residue formed the reducing end. The prior structural identification of *B* and *C* now permits the sequence of the pentasaccharide *A* to be established as

α-D-Glc*p*-(1→2)-β-D-Gal*f*-(1→6)-α-D-Glc*p*-(1→6)-β-D-Glc*p*-(1→3)-D-Gal

The combined chemical and nmr evidence permits the structure of the O-antigen chain to be established as the linear repeating pentasaccharide unit:

→3)-α-D-Glc*p*-(1→2)-β-D-Gal*f*(1→6)-α-D-Glc*p*-(1→6)-β-D-Glc*p*-(1→3)-β-D-Gal*f*-(1→$_n$

Structural similarity between O-antigenic chains of *A. pleuropneumoniae* serotype 3 (8) and serotype 6 could account for a serological cross-reactivity between serotypes 3 and 6 (10).

Core oligosaccharide

The core oligosaccharide obtained from the aqueous-phase LPS had $[\alpha]_D$ +66° (*c* 0.55, water) and was composed of D-glucose, D-galactose, D-*glycero*-D-*manno*-heptose, and L-*glycero*-D-*manno*-heptose in the molar ratio 1.1:1.0:0.6:1.0.

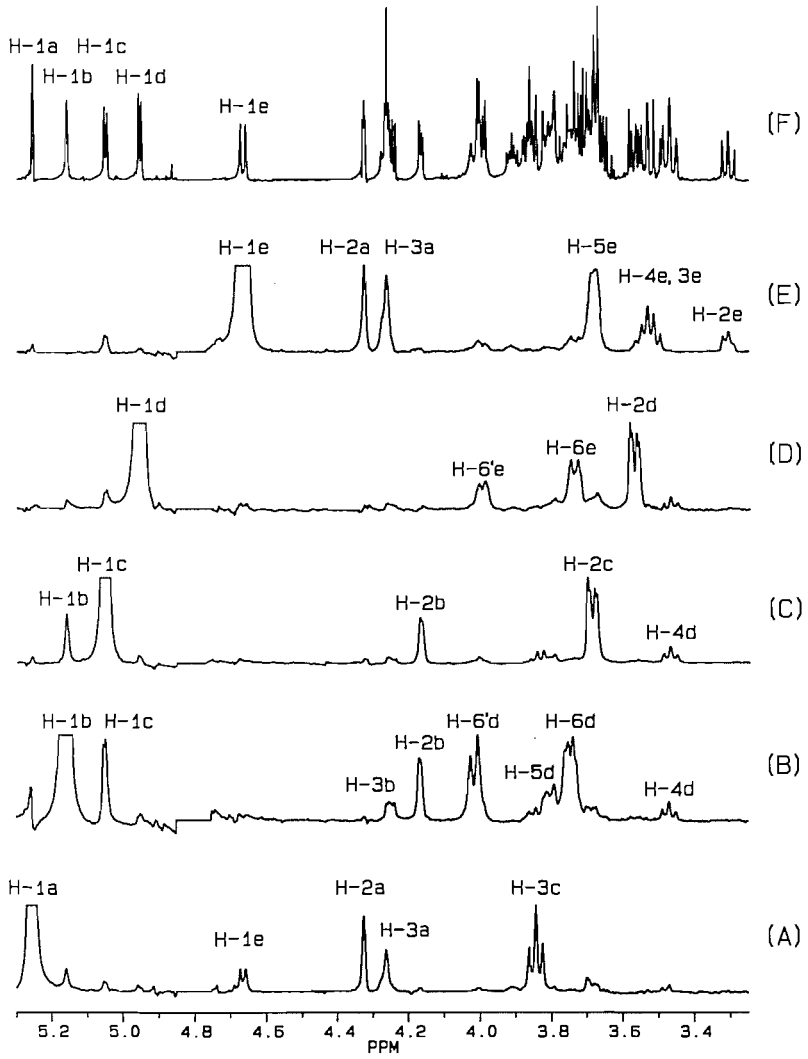

FIG. 2. The nOe difference ^{1}H nmr spectra for the *A. pleuropneumoniae* serotype 6 O-polysaccharide on saturation of the resonances: (A) H-1**a**, (B) H-1**b**, (C) H-1**c**, (D) H-1**d**, (E) H-1**e**, and (F) an off-resonance control spectrum, measured at 24°C.

Lipid A

Methanolysis of lipid A followed by glc–ms (programme C) showed the lipid A of the aqueous-phase LPS to be composed of the following fatty acids: 3-hydroxydodecanoic acid (1.2%), *n*-tetradecanoic acid (39.7%), *cis*-9-tetradecenoic acid (2.4%), 3-hydroxytetradecanoic acid (55.6%), and *n*-hexadecanoic acid (1.1%).

Acknowledgements

We thank Mr. F. P. Cooper for the glc–ms and Mr. D. W. Griffith for the large-scale production of cells.

Behaviour of 2′-*O*-*p*-toluenesulfonyl uridine towards excess of a Grignard reagent

ANNIE GROUILLER AND HASSAN ESSADIQ

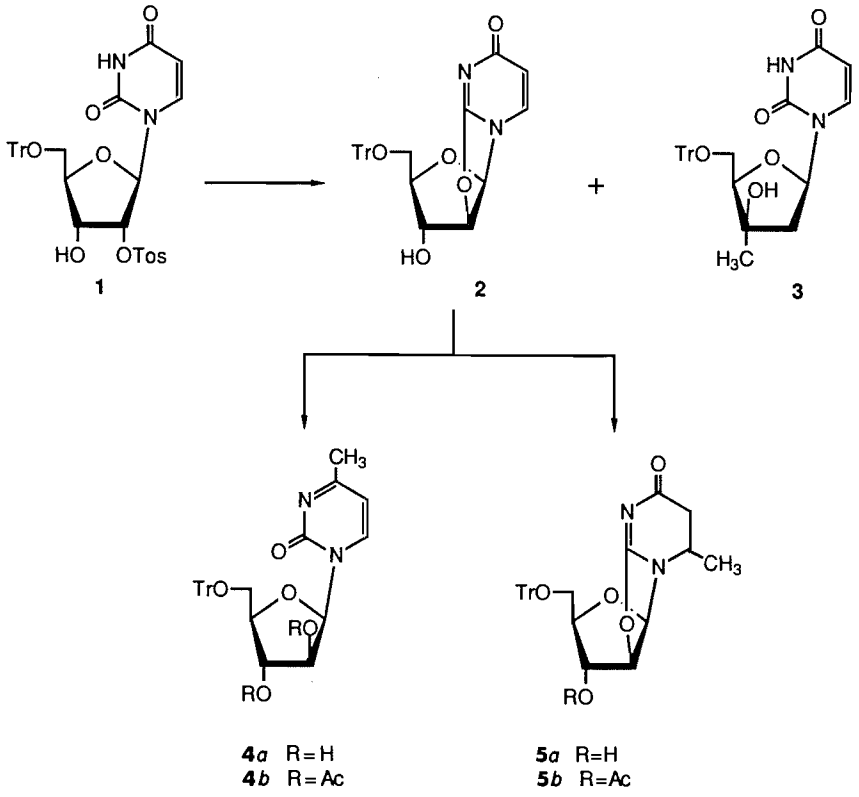
Université Lyon 1. École supérieure de chimie industrielle de Lyon, Laboratoire de chimie organique II, 43 Boulevard du 11 Novembre 1918, 69622 Villeurbanne, France

Received July 18, 1988

ANNIE GROUILLER and HASSAN ESSADIQ. Can. J. Chem. **67**, 708 (1989).

Two C-methylated base nucleosides were obtained when 2′-*O*-tosyl-5′-*O*-trityluridine was reacted with 30 equivalents of methylmagnesium iodide.

Key words: nucleoside, Grignard reaction, *C*-methyl pyrimidinone, anhydro derivative, arabinofuranosyl.



ANNIE GROUILLER et HASSAN ESSADIQ. Can. J. Chem. **67**, 708 (1989).

La réaction d'un excès d'iodure de méthylmagnésium avec la *O*-tosyl-2′ *O*-trityl-5′ uridine conduit à la formation de deux nucléosides C-méthylés sur la base.

Mots clés : nucléoside, réaction de Grignard, pyrimidinone *C*-methylée, dérivé anhydro, arabinofuranosyl.

Previous studies (1, 2) have shown that the Grignard reactions of 2′-*O*-tosyl-5′-*O*-trityluridine (**1**) with 7 and 15 equivalents of methylmagnesium iodide afford, respectively, either the anhydro nucleoside **2** or the branched-chain deoxy-sugar nucleoside **3**. This paper[1] now reports the results obtained when **1** was reacted with 30 equivalents of the same Grignard reagent under the conditions previously described (1) for the preparation of **3**.

Besides the deoxy nucleoside **3** formed in 17% yield, a mixture of two products **4***a* and **5***a* in 1:1 ratio was obtained in 42% yield. The latter two compounds were characterized after their separation, which was made possible only at the level of their peracetylated derivatives **4***b* and **5***b*. Their structures were deduced using various spectrometric techniques (UV, ^{1}H and ^{13}C NMR, mass). The mechanism proposed for the formation of these C-methylated base arabinofuranosyl nucleosides involves, respectively, a 1,2 or 1,4 nucleophilic addition to the C=C—C=O system of the presumed intermediate, anhydronucleoside **2**. To verify this suggestion, the same reaction was applied to 5′-*O*-trityl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (**2**) prepared from 5′-*O*-trityluridine via its 2′,3′-carbonate according to Ogilvie and Iwacha (4). The same mixture was obtained, consisting of a similar ratio of **4***a*:**5***a*, in 77% yield.

This result provides a direct synthesis of the methylpyrimidinone nucleosides studied for their biological interest, some years ago, by two teams (5, 6).

Experimental

General methods

Melting points were determined on an Electrothermal apparatus. ^1H and ^{13}C NMR spectra were recorded on a Cameca spectrometer at 350 MHz and a Bruker spectrometer at 50.32 MHz. The proton chemical shifts (δ) are given relative to Me_4Si (δ=0). IR spectra were recorded on a Beckman Acculab 4 spectrophotometer and UV spectra on a Beckman DU 8 spectrophotometer. Mass spectra were obtained on a ZAB HF mass spectrometer (FAB^+ source). TLC was performed using silica gel 60 F_{254} aluminum sheets and short column chromatography (7) on silica gel 60 G.

Procedure for Grignard reaction

To a stirred solution at 0°C, containing 2′-*O*-tosyl-5′-*O*-trityluridine (**1**) (1.20 g, 1.85 mmol) in anhydrous tetrahydrofuran (60 mL) a solution of methylmagnesium iodide (30 equiv.) in diethylether (40 mL) was added under a nitrogen atmosphere over a period of 0.5 h. The reaction mixture was then stirred at room temperature over a period of 1.5 h, subsequently heated at 65°C for 0.5 h, cooled to ice-bath temperature, and finally treated with 10% aqueous ammonium chloride (13 mL). The organic layer was separated, dried, and concentrated under high vacuum at a temperature less than 35°C. The residue was chromatographed on a silica gel column using 2% ethanol/chloroform mixture. Elution of the more polar compound afforded the Grignard reaction product **3** (152 mg, 17%). Continued elution with the same solvent afforded the mixture of **4***a* and **5***a* (370 mg, 42%).

Peracetylation of the compounds **4**a *and* **5**a

Acetic anhydride (0.20 mL) was added to a stirred solution of the foregoing mixture in pyridine (10 mL) at room temperature. After 4 h, the reaction mixture was diluted with ice-water, poured into aqueous sodium hydrogen carbonate (5% w/v), and extracted with chloroform. The organic layer was dried and concentrated. The crude crystalline product was chromatographed on a silica gel column, eluting first with dichloromethane and then with 1% ethanol–chloroform mixture to give a clean separation of **4***b* (90 mg, 42%) and **5***b* (83 mg, 42%).

*1-(2,3-DiO-acetyl-5-O-triphenylmethyl-β-D-arabinofuranosyl)-4-methyl-2-pyrimidinone (***4***b)*

Melting point 170–172°C; R_f 0.80 (15% methanol–chloroform): UV λ_{max}: 305 nm (at pH 4.7 and 12): IR ν_{KBr}: 3060, 1750, 1680, and 1650 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.77 and 2.10 (2s, 6H, MeCO), 2.35 (s, 3H, MeCN), 3.55–3.45 (m, 2H, H-5′ and H-5′′), 4.22 (t, 1H, H-4′), 5.35–5.20 (m, 1H, H-3′), 5.60–5.50 (m, 1H, H-2′), 6.05 (d, 1H, $J_{5,6}$ = 7.0 Hz, H-5), 6.30 (d, 1H, $J_{1',2'}$ = 4.0 Hz, H-1′), 7.60–7.20 (m, 15H, trityl), 7.80 (d, 1H, H-6); ms (FAB^+), *Exact Mass* calcd. for $C_{33}H_{33}N_2O_7$ $(M + H)^+$: 569, 2288; found: 569, 2316.

*3′-O-Acetyl-5,6-dihydro-6-methyl-5′-O-triphenylmethyl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (***5***b)*

Melting point 164–165°C; R_f 0.70 (15% methanol–chloroform): UV λ_{max}: 302 (pH 7), 301 (pH 4), and 303 nm (pH 12): IR ν_{KBr}: 3060, 1750, and 1580 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.31 (d, 3H, $J_{Me,6}$ = 5.5 Hz, Me), 2.13 (s, 3H, MeCO), 2.22 (dd, 1H, $J_{5a,6}$ = 9.9 Hz, $J_{5a,5b}$ = 19.0, H-5a), 2.27 (dd, 1H, $J_{5b,6}$ = 7.4 Hz, H-5b), 3.05 (dd, 1H, $J_{5',5''}$ = 11.5 Hz, H-5′); 3.12 (dd, 1H, H-5″), 3.65–3.54 (m, 1H,H-6), 4.41 (t, 1H, $J_{4',5'}$ = 6.6 Hz, H-4′), 5.13 (d, 1H, H-2′), 5.35 (s, 1H, H-3′), 5.89 (d, 1H, $J_{1',2'}$ = 6.6 Hz, H-1′), 7.45–7.20 (m, 15H, trityl); ^{13}C nmr δ: 17.9 (Me-6), 20.7 (Me-acetyl), 37.2 (C-5), 45.3 (C-6), 63.3 (C-59), 77.2 (C-4′), 84.5 (C-2′), 84.9 (C-1′), 87.0 (quaternary C-trityl), 88.9 (C-3′), 127.2, 128.4, and 129.2 (C-Ar), 143.0 (quaternary C-Ar), 164.9 (C-2), 169.1 (C-4), 177.1 (CO-acetyl); ms (FAB^+), *Exact Mass* calcd. for $C_{31}H_{31}N_2O_6$ $(M + H)^+$: 527, 2182; found: 527, 2211.

An acidity scale, $[H^+]^{h\nu}$, for proton quenching of excited states in aqueous perchloric acid

J. A. PINCOCK[1] AND P. R. REDDEN
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 12, 1988

J. A. PINCOCK and P. R. REDDEN. Can. J. Chem. **67**, 710 (1989).

An acidity scale for excited state protonation kinetics in aqueous perchloric acid has been developed using 1-cyanonaphthalene as a fluorescent indicator. A comparison of the quenching rate constants obtained using this scale is made with both the more general excess acidity function, X, and the transition state activity coefficient approach. A variety of chromophores were studied including 1- and 2-cyanonaphthalenes, 1- and 2-methoxynaphthalenes, benzyl alcohols, toluenes, benzonitriles, and 2-vinylnaphthalene.

Key words: acidity scale, proton fluorescence quenching.

J. A. PINCOCK et P. R. REDDEN. Can. J. Chem. **67**, 710 (1989).

Utilisant le cyano-1 naphtalène comme indicateur fluorescent, on a mis au point une échelle d'acidité pour la cinétique de protonation des états excités dans l'acide perchlorique aqueux. On a établi une comparaison entre les constantes de vitesse de piégeage obtenues avec cette échelle et celles obtenues avec la fonction plus générale d'acidité en excès, X, ainsi qu'avec l'approache basée sur le coefficient d'activité de l'état de transition. On a examiné une variété de chromophores, y compris les cyano-1 et -2 naphtalènes, les méthoxy-1 et -2 naphtalènes, des alcools benzyliques, des toluènes, des benzonitriles et le vinyl-2 naphtalène.

Mots clés : échelle d'acidité, piégeage de la fluorescence par le proton.

[Traduit par la revue]

Introduction

Recently, we described a procedure for establishing an acidity scale, $[H^+]^{h\nu}$, that proved to be a useful way of analyzing data for proton quenching of the fluorescence of excited states of aromatic substrates (1, 2). Thus, the modified Stern–Volmer expression, eq. [1], can be used to obtain linear plots even in quite concentrated acidic solutions where the concentration of the quenching protons is no longer a measure of their activity. Only a single indicator, 1-cyanonaphthalene, was required to obtain $[H^+]^{h\nu}$.

$$[1] \quad I^0/I = 1 + K_{SV}[H^+]^{h\nu}$$

$$[2] \quad [H^+]^{h\nu} = k_q^I\tau^{0I}/K_{SV}^I(a_{H^+}f_{S1}^I/f_{\neq}^I)$$

An analysis of this equation by current acidity function – activity coefficient approaches revealed that $[H^+]^{h\nu}$ can be expressed as in eq. [2], where a_{H^+} is the activity of the proton relative to a standard state of infinite dilution,[2] $f_{S_1}^I$ and $f_{\neq}^I$ are the activity coefficients for the excited singlet state of the indicator and for the transition state for protonation of that excited state respectively, k_q^I, τ^{0I}, and K_{SV}^I are the quenching rate constant, the lifetime of the excited state, and the empirical Stern–Volmer slope for the indicator 1-cyanonaphthalene, respectively. If a substrate gives a linear Stern–Volmer plot versus this function with a slope K_{SV}, then eq. [3] applies, where f_{S_1} and $f_{\neq}$ are similar activity coefficients but now for the substrate of interest. It is obvious that the Stern–Volmer slope can only be used to obtain $k_q\tau^0$ if the activity coefficient term in parentheses equals unity.

$$[3] \quad K_{SV} = k_q\tau^0\cdot(K_{SV}^I/k_q^I\tau^{0I})\cdot(f_{S1}/f_{\neq}\cdot f_{\neq}^I/f_{S_1}^I)$$

In our previous paper (2) we made the assumption that this might be true and, therefore, discussed the k_q values as if they were correct. The reactions involved are rapid, exothermic protonations with very low activation barriers (ref. 3, *vide infra*) so that the transition state for protonation may be early and have a structure and solvation very similar to that of the excited state itself. We suggested that the necessary cancellation occurs because $f_S/f_{\neq} \sim 1$ for the substrates examined. These results were obtained in a medium consisting of 20% ethanol: 80% aqueous sulfuric acid, which made it impossible to test this assumption because the required activity coefficient data cannot be obtained.

In this paper, we report results for the fluorescence quenching of the substrates **1–19** in aqueous perchloric acid. The results allow a comparison between the $[H^+]^{h\nu}$ method and the established ground-state methods: excess acidity (4) and transition-state activity coefficients (5).

Results

Fluorescence quenching data at 25.0°C as a function of acidity in aqueous perchloric acid are reported in Table 1 (**1–4**), Table 2 (**5–10**), Table 3 (**11–14**), and Table 4 (**15–19**). In addition, fluorescence quenching data for **1** as a function of temperature at 35, 45, and 55°C were obtained. Compounds **1–15** have previously been described (2). Compounds **16–19** are available from the Aldrich Chemical Company.

Discussion

As stated in the Introduction, the objective of this study was to examine the proton quenching of excited state fluorescence in an aqueous acidic medium where current ground-state acidity function approaches have been extensively examined. Aqueous sulfuric acid was not chosen because of the possibility of sulfonation of some of the reactive aromatic substrates. Moreover, sulfuric acid is dibasic and not completely ionized at high acidities (6). Since excited state protonation reactions have recently been shown (7, 8) to display general acid behaviour, the complication of having several sources of protons present seemed undesirable. Several preliminary experiments with aqueous hydrochloric acid revealed that excited-state quenching by the halide ion was occurring for substrates like 1-cyanonaph-

thalene with electron-withdrawing groups. This type of quenching has been well documented and is known to occur by electron transfer from the halide ion to the neutral aromatic (9). Aqueous perchloric acid therefore proved to be the best choice since it is monobasic, completely ionized at all concentrations, and is unreactive.

Evaluation of $[H^+]^{h\nu}$ in aqueous perchloric acid

The fluorescence quenching data for **1** are plotted versus titratable proton concentration in Fig. 1. The inset shows the expanded region up to 0.6 M in acidity as determined by titration. The least-squares slope of this line is 1.53 M^{-1} and obviously the normal Stern–Volmer relationship, $I^0/I = 1 + k_q\tau^0[H^+]$ is valid up to this point. As outlined previously (1, 2) extrapolation of this line into the high acidity region followed by a horizontal projection from the quenching curve gives values of $[H^+]^{h\nu}$. This is shown pictorially in Fig. 1. These values are listed in Table 5 along with values for h_0 (10), h_c (11), log a_{H^+} (12), and X (6) obtained by interpolation of plots of literature data for each of these functions versus perchloric acid concentration.

Plots of I^0/I values for 1-cyanonaphthalene and 3-methoxy-1-methylnaphthalene versus h_0 and h_c are shown in Fig. 2. Clearly, these plots are unsuitable for obtaining slopes and the related k_q values. The "correct" slopes from the X method (*vide infra*) are shown as solid lines on the figure and the curves tend to converge to that slope at low acidities. Both acidity functions overcorrect at high acidities and h_c is worse than h_0 in that respect. However, h_c undercorrects at low acidities. Interestingly, although h_0 is derived from protonation of amines and h_c for aromatic hydrocarbons, neither function correlates the excited state protonations; 1-cyanonaphthalene probably protonates on nitrogen and 3-methoxy-1-methylnaphthalene probably on the ring (1, 2).

Evaluation of k_q values using $[H^+]^{h\nu}$

Plots of I^0/I versus $[H^+]^{h\nu}$ gave good straight lines for **1**, **4**, **8–12**, and **15–19**. Two assumptions are now required to obtain k_q values. The first is that the activity coefficient term in parentheses of eq. [3] is unity. The second is that, for aqueous perchloric acid, $[H^+]$, for the titratable protons, equals C_{H^+}, the concentration of free protons in the solution so that $K^I_{SV}/k^I_q\tau^{0I}$ equals unity. Values of $k_q\tau^0 = k_{SV}$ along with correlation coefficients of the Stern–Volmer plots are given in Table 6. For substrates that are quenched at low enough acidities so that the acidity function treatment is unnecessary, plots of I^0/I versus $[H^+]$ were also nicely linear; $k_q\tau^0$ values and

correlation coefficients for **5**, **6**, **7**, **13**, and **14** are listed in Table 6. For all compounds, measurement of τ^0 in water by nanosecond single-photon counting allows for the determination of k_q values (Table 6).

As was discussed previously (2), complications due to static quenching should become apparent when k_q values exceed $10^9\,M^{-1}\,s^{-1}$ and when proton concentrations exceed 1 M. Normally, static quenching will lead to upward curvature of Stern–Volmer fluorescence intensity plots because the observed fluoresence intensity is lower than one would expect based on a rate resulting from a process requiring diffusion through the medium. However, when data for substrates like **5**, **6**, **7**, **13**, and **14** are obtained in the higher acidity region, plots versus $[H^+]^{h\nu}$) show downward curvature. The probable reason for this is that

[e]The values are those obtained in 20% ethanol: 80% aqueous sulfuric acid of ref. 2.

an acidity function is proportional to a_{H^+}, which is increasing rapidly as an acid becomes more concentrated. Static quenching is determined by the concentration, and not by the activity of the protons. Thus, as the quenching becomes more and more dominated by the value of C_{H^+} the points will begin to fall below the line defined by $[H^+]^{h\nu}$.

Evaluation of k_q *values using excess acidity,* X

As has been demonstrated by Cox (4), the excess acidity method is a reliable technique for the investigation of reaction mechanisms in concentrated acidic media. Its application to various ground-state kinetic schemes has been discussed in detail (13). The closest analogy to the reactions discussed here would be rate-determining proton transfer to the substrate with subsequent reactions of SH^+ being fast, i.e., the A-S_E2 mechanism, eq. [4], where log k_ψ is the observed pseudo first-order rate constant, C_{H^+} the concentration of protons, which is equal to the titratable concentration for perchloric acid, $m^{\neq}$ is a slope parameter for the kinetics of protonation, m^* is a slope parameter for equilibrium protonation relative to the excess acidity, X, and k_0 is the desired medium-independent rate constant. Application of these ideas to Stern–Volmer fluorescence quenching gives eq. [5]. Plots of the left-hand side of eq. [4] versus X (Table 5) should give a straight line of slope $m^{\neq}m^*$ and intercept of log k_q. Examples for compounds **1**, **8**, and **11** are shown in Fig. 3. Values of $m^{\neq}m^*$, k_q, and correlation coefficients are listed in Table 6. Although the excess acidity method was used to determine the correct k_q values they should be used with caution since at very low X values the plots deviate markedly from linearity. A similar effect was previously

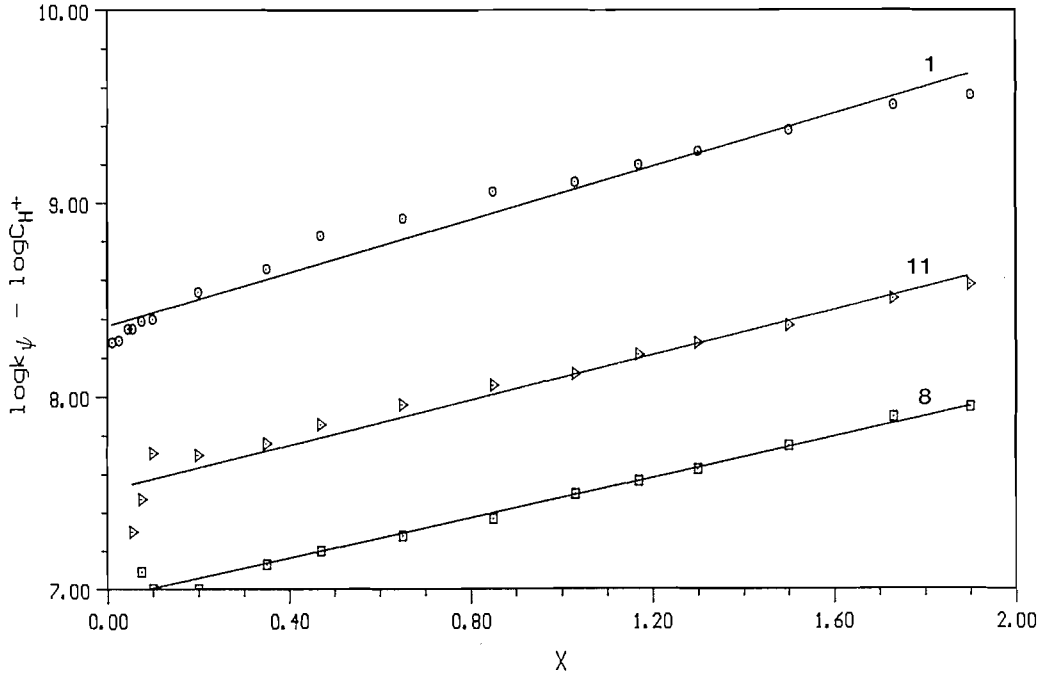

FIG. 3. Plots of eq. [4], the X method, for 1-cyanonaphthalene, **1**, 4-methoxytoluene, **11**, and 1-methylnaphthalene, **8**.

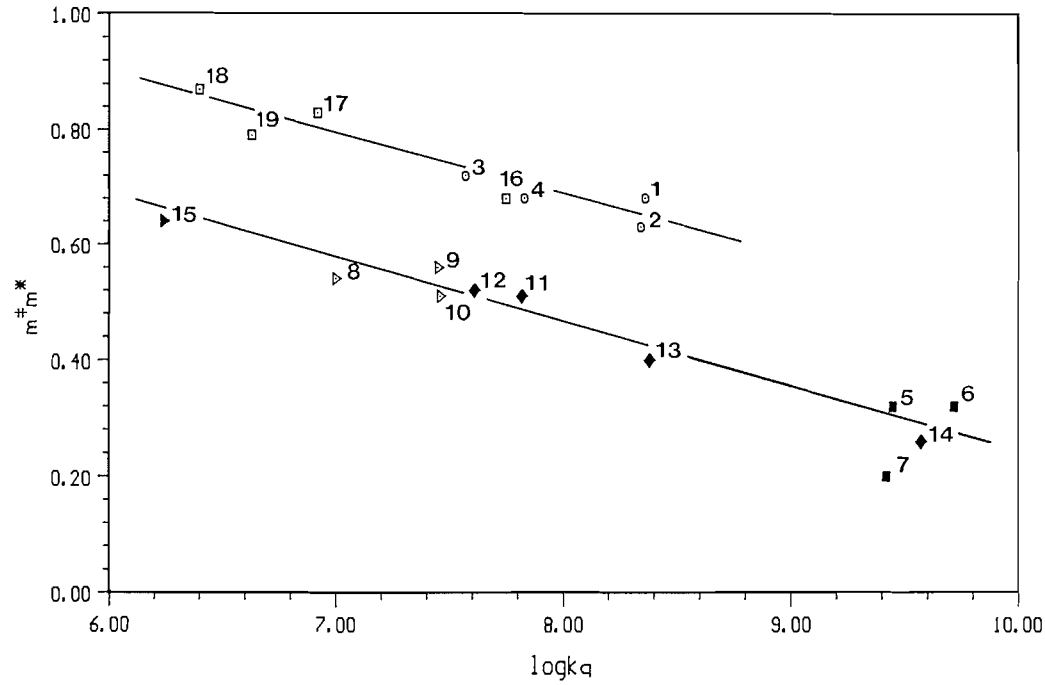

FIG. 4. Plots of $m^{\neq}m^*$ versus log k_q. (⊙) are for cyanonaphthalenes, (⊡) for cyanobenzenes, (■) for 1-methylnaphthalenes, (▷) for 2-methoxynaphthalenes, ◆ for methoxybenzenes, and ▶ for 2-vinylnaphthalene.

observed (2) where log $C_{H^+} + H_0$ (14) was used to approximate X in 20% ethanol: 80% aqueous sulfuric acid. Since in both treatments the intercept gives k_q, the scatter will affect the intercept and hence k_q.

[4] $$\log k_\psi - \log C_{H^+} = m^{\neq}m^*X + \log k_0$$

[5] $$\log\{(I^0/I - 1)/\tau^0\} - \log C_{H^+} = m^{\neq}m^*X + \log k_q$$

As has been discussed, the slopes of the excess acidity plots are a composite of $m^{\neq}m^*$ where m^* is a slope parameter for the equilibrium protonation and $m^{\neq}$ is a slope parameter for the kinetics of protonations. For ground-state reactions, this composite can be separated into the individual components since independent estimates of m^* are often available. Interpretation of $m^{\neq}$ then gives useful mechanistic information (6). This slope parameter is identical to the term, α, which has been defined by Kresge *et al.* (15) and is interpretable as the degree of proton transfer at the transition state. For excited-state protonations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

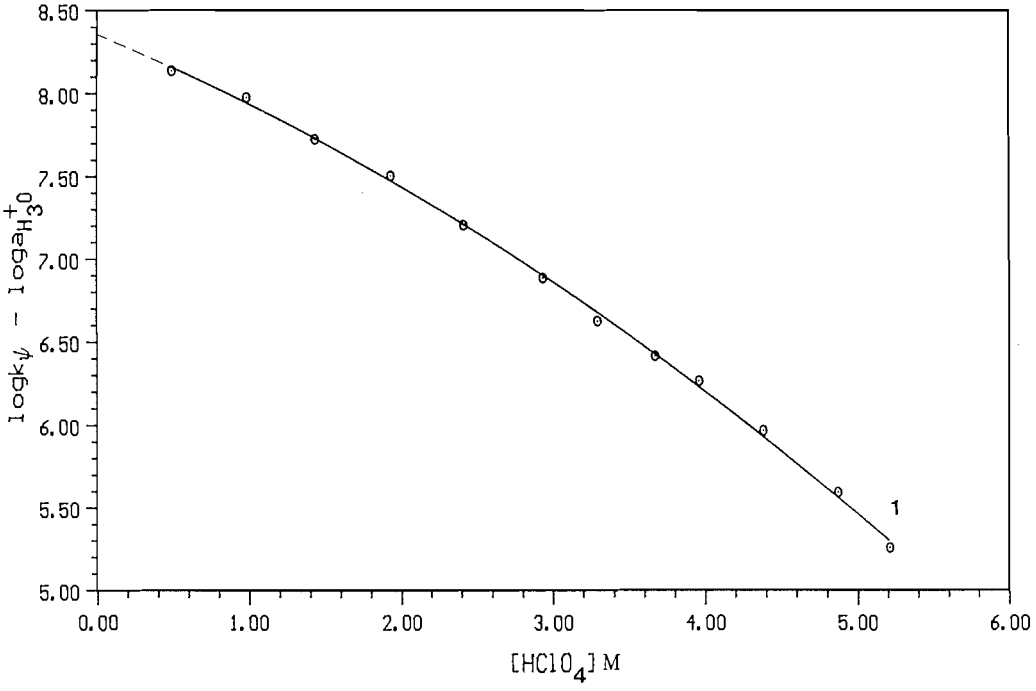

FIG. 5. Plot of eq. [7], the TSAC method, for 1-cyanonaphthalene, **1**.

separation is impossible since values of m^* for equilibrium protonation are not available. However, there are trends in the composites themselves. This is shown in Fig. 4 where $m^{\neq}m^*$ is plotted versus log k_q. The results seem to define two lines of the same slope, one line for the methoxy derivatives and one for the cyano derivatives. The negative slope indicates that the more reactive compounds have lower $m^{\neq}m^*$ values. Until more results are available, any interpretation of this trend would be quite speculative.

Evaluation of k_q *values using the transition-state activity coefficient method (TSAC)*

This approach for studying the mechanisms of reactions in concentrated acidic media avoids the difficulties inherent in acidity function methods (5). Activities and activity coefficients are used directly since values are now available for both aqueous perchloric and sulfuric acid. For a mechanism involving rate-determining protonation the desired expression for ground-state reactions is eq. [6] where $a^*_{H_3O^+}$, Table 5, is the activity of the hydronium ion (the asterisk refers to the fact that these are experimentally inaccessible single-ion activities and are therefore expressed relative to a standard reference ion, tetraethylammonium (16), and f_S and $f^*_{S_{\neq}}$ are the activity coefficients for the substrate and its transition state for rate-determining protonation, respectively. Application of these ideas to Stern–Volmer fluorescence quenching gives eq. [7] where now f_{S_1} and $f^*_{\neq}$ are activity coefficients for the excited singlet state and its transition state for protonation, respectively. Plots of the left-hand side of eq. [7] versus any function of the acidity are smooth and monotonic. An example for compound **1** is given in Fig. 5. Extrapolation of these plots to zero acidity gives log k_q since $f_{S_1}/f^*_{\neq}$ should approach unity at this standard state. Values of log k_q obtained by this method are included in Table 6 as well.

[6] $\log a^*_{H_3O^+} - \log k_\psi = \log(f^*_{S_{\neq}}/f_S) - \log k_0$

[7] $\log\{(I^0/I - 1)/\tau^0\} - \log a^*_{H_3O^+} = \log k_q + \log(f_{S_1}/f^*_{\neq})$

For ground-state reactions, once k_0 is known log $f_{S_{\neq}}$ can be determined since log f_S values can be measured experimentally. These TSAC values, as a function of acidity, have been shown (5) to give useful information about the structure of the transition state and hence details about the reaction mechanism that would not have been available otherwise. For the excited-state Stern–Volmer approach, f_{S_1} values are not experimentally available. However, values of $\log(f_{S_1}/f^*_{\neq})$ can be calculated. Plots for compounds **1**, **8**, and **11** are shown in Fig. 6. All other plots are very similar to those shown with the range of $\log(f_{S_1}/f^*_{\neq})$ at 5.2 M $HClO_4$ being only from 3.06 to 3.64. It is satisfying to notice that these plots extrapolate to zero at zero acidity as required. In the Introduction of this paper, the assumption that the values of $f_{S_1}/f^*_{\neq}$ might approximate unity (or log $f_{S_1}/f^*_{\neq}$ approach zero) independent of the acidity was discussed. Clearly, this is not true since $f_{S_1}/f^*_{\neq}$ values vary from unity at zero acid concentration to almost 10^4 at 5.2 M perchloride acid.

Therefore, although qualitative information about activity coefficients can be obtained from the TSAC approach, the k_q values obtained should again be used with caution since they are obtained by extrapolation to the intercept of a nonlinear function. Of greater consequence is the problem outlined in eq. [3]. The Stern–Volmer slopes obtained by the $[H^+]^{h\nu}$ method do not give $k_q\tau^0$ directly but are altered by the product between this ratio of activity coefficients for the substrate of interest and the reciprocal of this ratio for the indicator, 1-cyanonaphthalene, as shown in eq. [3]. Not surprisingly, since the plots of Fig. 6 are nearly superimposable for all substrates, the cancellation works reasonably well. More quantitatively, calculation of these products of ratios can be made and plots for compounds **2**, **3**, **4**, **5**, **8**, **10**, **13**, and **14** are shown in Fig. 7. Despite the rather large experimental error in calculating these values it is apparent that above 1.0 M perchloric acid, where the acidity function approach is required, these plots are relatively flat. Thus, the $[H^+]^{h\nu}$ method will give straight lines in general.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

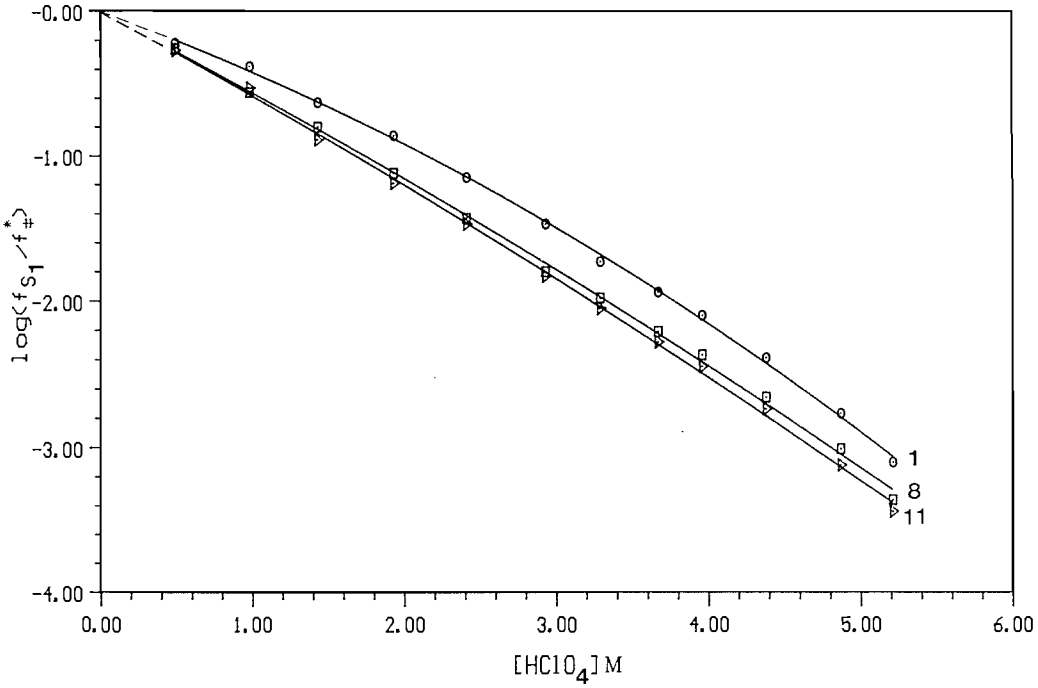

FIG. 6. Plots of $\log(f_{S_1}/f_{\neq}^{*})$ versus $[HClO_4]$ for 1-cyanonaphthalene, **1**, 4-methoxytoluene, **11**, and 2-methoxynaphthalene, **8**.

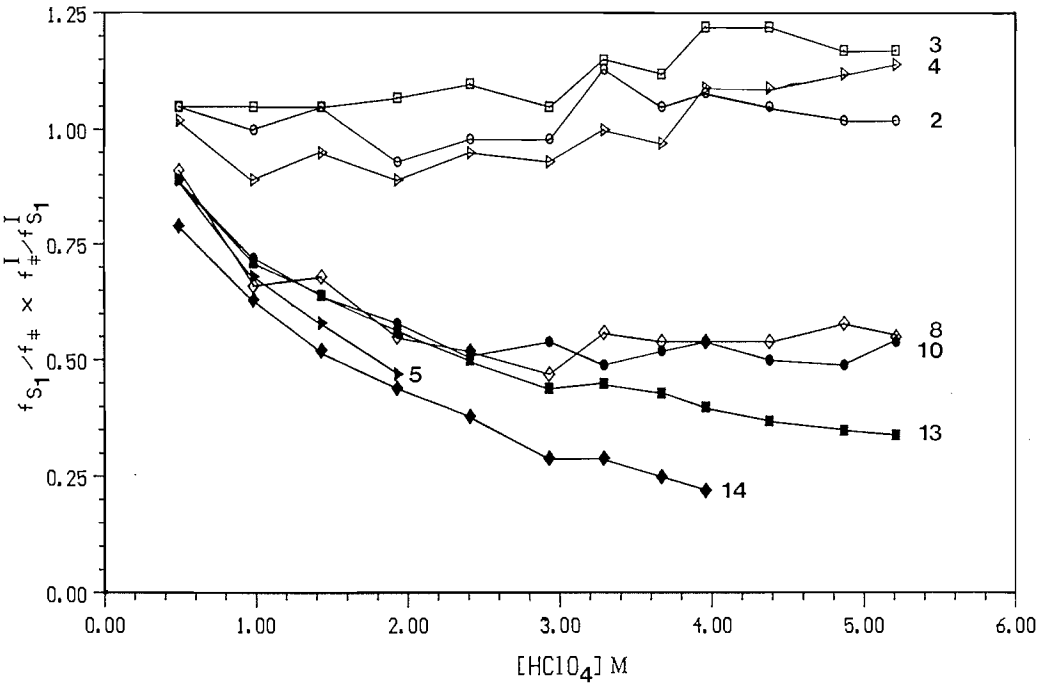

FIG. 7. Plots of $f_{S_1}/f_{\neq} \times f_{\neq}^{I}/f_{S_1}^{I}$ versus $[HClO_4]$.

For the cyanonaphthalene derivatives, the $(f_{S_1}/f_{\neq}^{*})(f_{\neq}^{*I}/f_{S_1}^{I})$ values are close to unity, as expected for compounds that are structurally related to the indicator. For a compound such as 2-methoxynaphthalene, the values average around 0.6 so that the $[H^+]^{h\nu}$ method will give a rate constant that is too small by that factor (see Table 6). Since these ratios are around unity or less for all compounds studied, the k_q values obtained by the $[H^+]^{h\nu}$ method are usually somewhat lower than the correct values. Although this seems like a criticism of the method, examination of the values in Table 6 reveals that the $[H^+]^{h\nu}$ method does remarkedly well at determining photochemical quenching constants since these deviations are relatively small.

The Arrhenius plot of the quenching rate constant, k_q, for **1** versus $1/T$ is shown in Fig. 8. The activation energy obtained is only 1.6 kcal/mol, which is similar to but larger than the value of 0.5 kcal/mol reported for **5** (3). As mentioned in the Introduction, this is consistent with the idea that these reactions are rapid, exothermic protonations indicating that the transition

For personal use only.

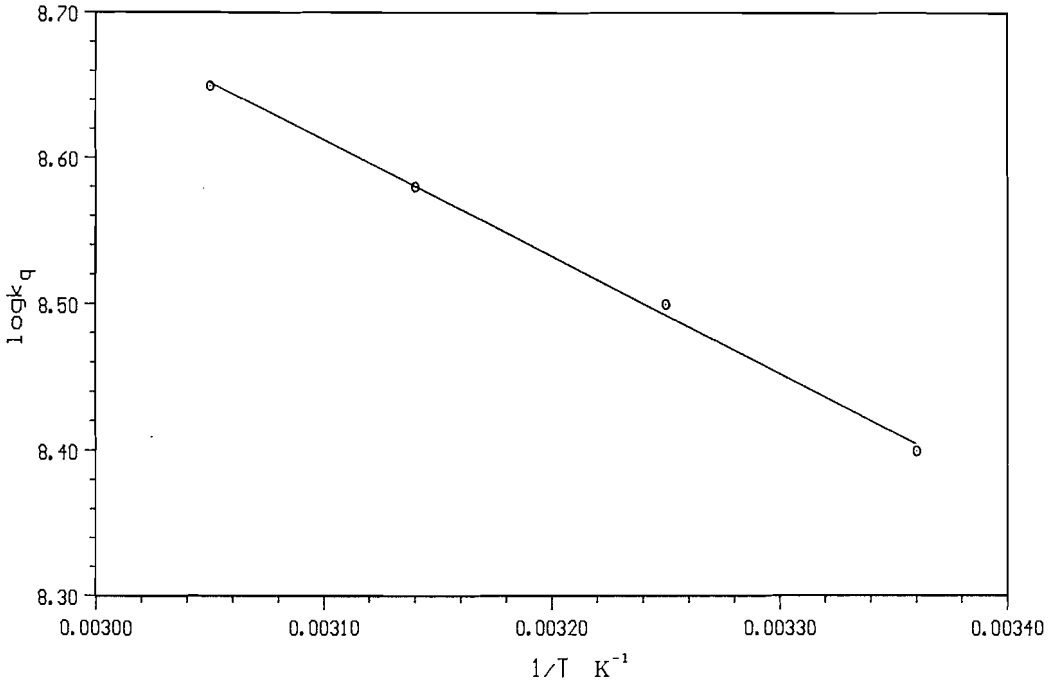

FIG. 8. Arrhenius plot for 1-cyanonaphthalene.

state is early. In fact, the rate constant for quenching of **5** is approaching diffusion so that the measured activation energy might be largely a reflection of decreased viscosity with increased temperature. For 1-cyanonaphthalene, however, the rate constant for quenching is almost two orders of magnitude below the diffusional rate so that the measured activation energy reflects a real kinetic barrier. Since no emission is seen from the conjugate acid of any of these excited-state bases, the question of whether these protonations are diabatic or adiabatic followed by rapid internal conversion cannot be answered. Of course, once in the ground state these conjugate acids will deprotonate rapidly.

Analysis of quenching rate constants

For the most part the k_q values obtained in perchloric acid are in good agreement with the values obtained for the same compounds in 20% ethanol: 80% aqueous sulfuric acid media (2). The relative order of quenching of the naphthalene compounds is the same as before so a discussion is not required here. The results for the cyanobenzenes are new and there does appear to be a small substituent effect. Both 2- and 3-methylcyanobanzene are quenched at a faster rate than unsubstituted cyanobenzene, which is in turn quenched slightly faster than 4-methylcyanobenzene. This is as predicted by excited-state electron density distribution as estimated by HMO calculations, i.e., the "*meta* effect" (17, 18). It was previously suggested by gas phase results that cyanobenzene in the excited state protonates in the nitrile functional group (19). Recent *ab initio* MO calculations on the excited states of simple nitriles suggest that protonation on either carbon or nitrogen would be favourable.[3] Our observation of a small *meta* effect is suggestive of nitrogen protonation since that puts the positive charge on the carbon and allows interaction of this charge with the substituents.

[3]K. Yates and M. K. Boyd. Unpublished results.

Summary

The results presented here along with the previous discussion (2) suggest that developing an acidity scale for protonation of excited states via quenching of fluorescence is a valid procedure. The quenching rate constants obtained are in good agreement with the values obtained from more traditional methods, i.e., excess acidity and the TSAC approaches. Although each of the three methods has pitfalls for determination of k_q, the fact that all three methods give approximately the same value suggests that each method is quite reliable. The great advantage of the $[H^+]^{h\nu}$ method is that the scale can be generated very quickly and very easily in any solvent system and at any temperature. In contrast, a great many years and much labour have gone into devising and developing the excess acidity function. As long as there is recognition of the activity coefficient problem, the $[H^+]^{h\nu}$ method should prove very useful in giving k_q values that were previously unobtainable. Moreover, in the past solvent systems have been chosen on the basis of whether there was an associated excess acidity function or at least a ground-state acidity function. This is no longer necessary.

Experimental

Perchloric acid, 70%, was used directly as supplied by Fisher Scientific, without further purification. The molarities of the aqueous perchloric acid solutions were determined by titration with NaOH and are given in Tables 1–5.

All fluorescence values were measured using a Perkin–Elmer MPF-66 spectrofluorimeter whose sample holder was maintained at 25.0 ± 0.1°C. Solutions of substrates were prepared to have an approximate concentration of 10^{-4} M by pipetting 3 mL of the aqueous perchloric acid into a fluorescent cuvette designed to be attached to a vacuum line, and then adding 5 μL of a stock solution of the substrate. A blank solution containing water and 5 μL of the substrate was also prepared. The intensity ratio, I^0/I, was obtained by measuring the emission of the blank over the emission in the acidic solutions. Five readings of each sample were taken and the values reported are averages.

The homogeneous sulfonations of β-carboline derivatives norharmane **2**, harmane **3**, harmine **4**, harmol **5**, *N*,*N'*-dimethylharmane **6**, and harmaline **7** have been studied in 80–90% w/w sulfuric acid solutions at 25°C. Ultraviolet–visible and ^{13}C nuclear magnetic resonance spectra and chemical analysis of the reaction mixtures show that for all the substrates studied only C-6 sulfonated products are obtained. The sulfonation reactions of the benzene unsubstituted substrates **2**, **3**, and **6** and the partially aromatic substrate **7** proceed by direct electrophilic attack of the $H_3SO_4^+$ cation on the benzene ring of the β-carboline skeleton. Sulfonation of **4** and **5** at the lower sulfuric acid concentrations is effected by the $H_3SO_4^+$ entity. With increasing sulfuric acid concentration there is a gradual changeover of the sulfonating entity from $H_3SO_4^+$ to $H_2S_2O_7$. The different mechanisms of sulfonation are discussed.

Key words: β-carbolines, sulfonation, kinetics.

M. C. CARMONA GUZMÁN, M. BALÓN ALMEIDA, J. HIDALGO TOLEDO, M. A. MUÑOZ PEREZ et M. LOPEZ POVEDA. Can. J. Chem. **67**, 720 (1989).

Opérant à 25°C, dans des solutions à 80–90% P/P d'acide sulfurique, on a étudié les sulfonations homogènes des dérivés de la β-carboline que sont le norharmane (**2**), l'harmane (**3**), l'harmine (**4**), l'harmol (**5**), le *N*,*N'*-diméthylharmane (**6**) et l'harmaline (**7**). Les spectres ultraviolet–visible et résonance magnétique nucléaire du ^{13}C et les analyses chimiques des mélanges réactionnels montrent que tous les substrats étudiés ne fournissent que les produits substitués en C-6. Les réactions de sulfonation des substrats qui ne sont pas substitués sur le noyau benzénique (**2**, **3** et **6**) ou qui ne sont que partiellement aromatiques (**7**) se produisent par une attaque électrophile directe du cation $H_3SO_4^+$ sur le noyau benzénique du squelette de la β-carboline. La sulfonation des composés **4** et **5** aux concentrations les plus faibles d'acide sulfurique se produisent sous l'effet de l'entité $H_3SO_4^+$. Avec une augmentation de la concentration d'acide sulfurique, il se produit un changement graduel de l'entité responsable de la sulfonation, de $H_3SO_4^+$ à $H_2S_2O_7$. On discute des divers mécanismes de sulfonation.

Mots clés : β-carbolines, sulfonation, cinétique.

[Traduit par la revue]

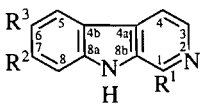
Introduction

During a recent study of the prototropic equilibria of some β-carboline alkaloids (1–3) it was observed that, unlike other β-carboline derivatives, solutions of fully and partially aromatic compounds were very unstable in highly concentrated sulfuric acid solutions. Apparently these compounds are easily sulfonated in these media (4). This behaviour is noteworthy because related compounds such as pyridine, indole, and carbazole are insensitive towards sulfonation in concentrated sulfuric acid solutions. Sulfonation of the latter compounds requires more powerful sulfonating agents and more vigorous conditions of reaction (5). However, in spite of the synthetic and theoretical interest of this kind of process, relatively little is known concerning this and other electrophilic substitution reactions of β-carboline derivatives (6).

In fact, nitration and sulfonation reactions of some β-carbolines have been only qualitatively studied to establish the position of substitution, and there is still no clear evidence about the structure of the reaction products. While nitration of β-carboline **2** with concentrated nitric acid yields 6-nitronorharmane (7), nitration of **3** gave two mononitro derivatives (8). The higher melting isomer was shown to be 6-nitroharmane and the lower melting isomer was presumed to be the 8-nitro derivative, although this was not established. More recently (9, 10), it was reported that nitration of **4** gives the 6-nitro derivative, but in the nitration of **7** the nitro group was present at C-8.

The sulfonation of **4** gave a compound that was initially formulated as an N_{ind}-sulfonic acid (4). However, Kermack *et al.* (11) found that *N*,*N'*-dimethylharminium chloride, in which N-substitution was no longer possible, was also sulfonated to give a compound that they formulated as the 6-sulfonated derivative. They rejected their earlier tentative suggestion (4) that N-sulfonation of **4** had occurred and postulated that sulfonation of the benzene ring had taken place.

On the other hand, in a recent study on the prototropic equilibria of some Harmala alkaloids (12) in highly concentrated sulfuric acid solutions, the authors established that after the protonation of the pyridinic nitrogen of the β-carboline ring, a second protonation on carbon took place. According to the authors, the blue shift of the fluorescence maxima in solutions of H_0 close to -7 was the result of C-6 protonation with the formation of a positive charge on the pyrrolic nitrogen atom. The possibility of a sulfonation process was not even mentioned.



Recently, evidence of sulfonation instead of protonation of **3** in highly concentrated sulfuric acid solutions has been presented

[1]The β-carboline ring is named systematically as 9*H*-pyrido[3,4-*b*]-indole; trivial names of β-carboline derivatives will be used throughout.

(13). We have now extended this work to other β-carboline derivatives to obtain quantitative data on these kinetically controlled sulfonation processes and to definitively establish the structure of the sulfonated products.

Experimental

Norharman-6-sulfonic acid **1**, norharmane **2**, harmane **3**, harmine **4**, harmol **5**, harmaline **7**, diphenylamine **8**, and diphenylaminesulfonic acid **9** were purchased from Aldrich Chemie. All these materials were of the best available commercial quality and were used without further purification. R.A. sulfuric acid was purchased from Merck. *N,N'*-Dimethylharmane **6** sulfate was synthesized by known procedures (14).

The ^{13}C nmr spectra were run at 50.2 MHz on a Varian XL-200 spectrometer. The spectra of the free bases were recorded in DMSO-d_6 as the solvent, the internal lock, and the internal standard. In sulfuric acid solutions, benzene was used as an external standard (coaxial tube). The assignments were made with the aid of the Frequency Off-resonance Decoupling Spectra (SFORD) and the ^{13}C nmr data of the alkaloids were taken from the literature (15–18). Also, to confirm the structural assignments of the sulfonated products the spectra of three model compounds **1**, **8**, and **9** were recorded in sulfuric acid solutions and DMSO.

Kinetic runs were made in the thermostated cell compartment of a Perkin Elmer Lambda-5 spectrophotometer. The temperature in the cell was fixed at 25.0 ± 0.1°C. The sulfonation reactions were carried out in a very large excess of sulfuric acid, so that the concentration of this reagent remained essentially constant during the reaction. The pseudo-first-order rate constants, k_{obs}, were obtained by a non-linear least-squares fitting of the absorbance–time data to eq. [1]:

$$[1] \quad A_t = A_\infty + (A_0 - A_\infty)\cdot\exp(-k_{obs}\cdot t)$$

where A_0, A_∞, and k_{obs} were taken as floating parameters. Excellent agreement between experimental and calculated A_t values was always obtained for more than 3–4 half-lives. Rate constants in duplicate runs were reproducible to within better than 5%.

Results and discussion

Isolation and identification of sulfonated products

The stability of alkaloid solutions in sulfuric acid was monitored by uv–visible spectrometry. Spectra did not show much change from 0.1 M to 14–16 M (70–80% w/w) sulfuric acid solutions. In media of higher sulfuric acid concentrations, time dependent changes of the spectra were evident. These changes were irreversible and their rates depended upon sulfuric acid concentration. The spectral characteristics of these solutions after complete substrate conversion are collected in Table 1. It is noteworthy that these spectra are completely similar to those reported by M. Krishnamurthy and S. K. Droga (12) for the C-6 protonated dications of the respective β-carbolines.

Precipitation by dilution from concentrated sulfuric acid solutions of **2** and **3** yielded products whose elemental analysis and mass spectrometry were in agreement with the formulae $C_{11}H_8N_2SO_3\cdot H_2O$ and $C_{12}H_{10}N_2SO_3\cdot 2H_2O$ (13), respectively. Furthermore, the uv–visible spectrum of **2s** was fully superimposable with that of **1** obtained in a weakly acidic solution of methanol.

The structure of the sulfonated products was determined by ^{13}C nmr spectral analysis of the concentrated sulfuric acid solutions of the alkaloids after complete substrate conversion (Tables 2 and 3). Sulfonation occurs on the benzene ring of the β-carboline skeleton for all the compounds and only one sulfonated derivative was obtained. The main evidence for sulfonation on carbon is supported by the replacement of a strong doublet in the nondecoupled ^{13}C nmr spectra of the substrates by a small singlet upon acidification in 90% w/w H_2SO_4.

The sulfonation site was established by comparison with the ^{13}C nmr spectra of the substrates in DMSO and in concentrated sulfuric acid solutions. The assignments of the ^{13}C resonances of the alkaloids in DMSO were aided by the literature data (15–18). As there are no data on the ^{13}C chemical shifts of these alkaloids in concentrated sulfuric acid solutions, the following procedure was used to assign the ^{13}C signals in these media; as is known (19, 20), the β-carboline alkaloids are very easily protonated on their pyridinic nitrogen atom (pK_a values ranged between 7 and 10). The effect of this protonation was studied by recording the ^{13}C nmr spectra of four selected compounds **2**, **3**, **4**, and **7** in weak sulfuric acid solutions (~0.1 M). The influence of sulfonation on ^{13}C chemical shifts was analyzed by comparison with the spectra of the model compounds **1**, **8**, and **9** obtained in concentrated sulfuric acid solutions.

This comparative analysis of the ^{13}C nmr spectra allowed us to establish C-6 as the only position of sulfonation for all the substrates studied in 80–90% w/w sulfuric acid solutions and at room temperature. This carbon atom, as previously stated, is the most reactive center for other electrophilic substitution reactions of β-carbolines (6, 9, 10).

Kinetics and mechanisms of sulfonation reactions

It is well known that electrophilic aromatic sulfonations usually proceed by an S_E2 mechanism involving a σ-complex as an intermediate state (21, 22). The electrophilic attacking species and, therefore, the detailed reaction mechanism varies with the nature of the sulfonating reagent and the experimental conditions (23, 24). To obtain this information in the reactions under study, we have tried a correlation between the observed rate constants (Table 4) and the activities of the sulfonating entities previously established to be more reactive in aqueous sulfuric acid solutions of characteristics similar to those used in this work, viz. $H_3SO_4^+$ and $H_2S_2O_7$ (24).

As can be seen, the plots of log k_{obs} vs. log $a_{H_2S_2O_7}$ (Fig. 1) or log $a_{H_3SO_4^+}$ (Fig. 2) for the unsubstituted benzene substrates **2**, **3**, and **6** are straight lines over the whole range of sulfuric acid activities studied (85–90% w/w). The slopes of these plots are 0.72 and 1.07 for **2**, 0.75 and 1.10 for **3**, and 0.72 and 1.07 for **6**

respectively. These slopes are very similar to those observed for the sulfonation of other aromatic hydrocarbons, such as mono and dialkylbenzenes, for which the rates of sulfonation are also more nearly proportional to the activity of $H_3SO_4^+$ than to the activity of $H_2S_2O_7$ (25). Considering these slopes and the interpretation of the results for the alkylbenzenes (25, 26), we proposed on the basis of the unit slope criterion that sulfonation of compounds **2**, **3**, and **6** in 85–90% w/w sulfuric acid is effected by the species $H_3SO_4^+$.

On the other hand, it is interesting to consider that, as in the case of aniline (27), the sulfonations of these compounds could proceed via the formation of an N-sulfonated derivative intermediate, which rearranges further to give the final product. The fact that **6**, for which N-substitution is no longer possible, is also sulfonated in a similar way to **3**, rules out this possibility. Therefore, it can be concluded that sulfonation of **2**, **3**, and **6** in 85–90% w/w sulfuric acid at 25°C must occur by direct electrophilic attack of the $H_3SO_4^+$ species on the C-6 position of the benzene ring of the β-carboline, according to the following mechanism:

with reaction [2] as the rate-limiting step.

The correlations of log k_{obs} with log $a_{H_3SO_4^+}$ and log $a_{H_2S_2O_7}$ for **4** and **5** are shown in Figs. 3 and 4, respectively. Each of the graphs has two linear parts below and above 85% w/w sulfuric acid. The slopes of the graphs log k_{obs} vs. log $a_{H_3SO_4^+}$ are 0.73 and 1.39 for **4** and 0.77 and 1.19 for **5**. The corresponding slopes of the similar graphs for $a_{H_2S_2O_7}$ are 0.50 and 0.93 for **4** and 0.48 and 0.80 for **5**. Similar behaviour and differences in slopes between the two types of graphs have already been observed for such other aromatic substrates as anisole and phenol (28).

The main difference between this group of alkaloids and the one discussed before is the presence of an OR substituent (R = H or CH_3) on their benzene rings. In the case of the similarly substituted aromatic substrates anisole and phenol, it has been claimed that protonation of the OR group gave rise to smaller values of the slopes than those observed for the nonsubstituted substrates (28). In our case, the only cationic species present in solution are those protonated on the pyridinic nitrogen and they are the majority species in the sulfuric acid range studied. The protonation of the OR group does not apparently occur. Thus, O-protonation should induce a downfield shift of the OCH_3 lines (29). As can be seen in Table 2, the ^{13}C chemical shifts of the OCH_3 groups of **4** and **5** essentially do not change on passing from DMSO to highly concentrated sulfuric acid solutions.

The protonation of the OR group of these β-carbolines seems to occur at higher acid concentrations than those used in the present study. Recently it has been observed that the fluorescence maxima of **4**, **5**, and **7** suffered a blue shift in solutions of H_0 close to −10, although no changes were observed in their absorption spectra (12). The authors have argued that these shifts were presumably due to the protonation

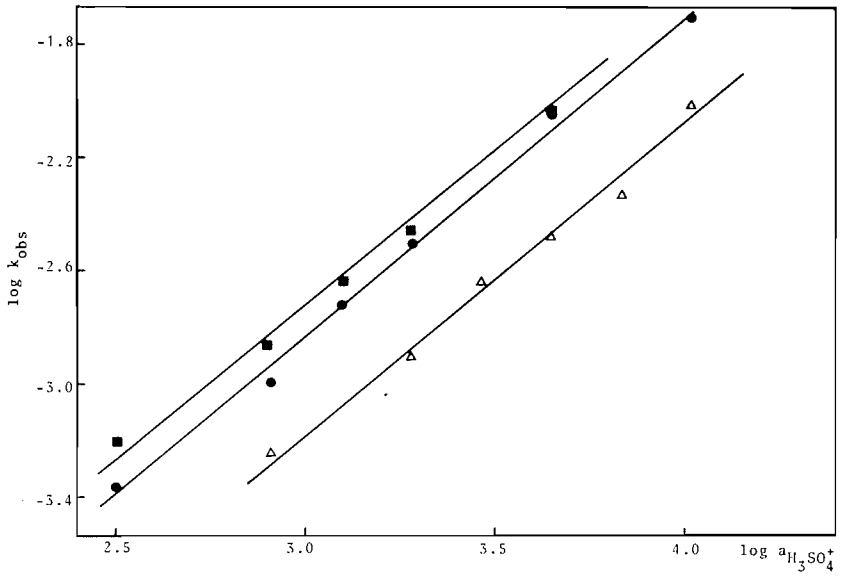

FIG. 2. Correlation of log k_{obs} of the sulfonation of **2** (△), **3** (●), and **6** (■) with log $a_{H_3SO_4^+}$.

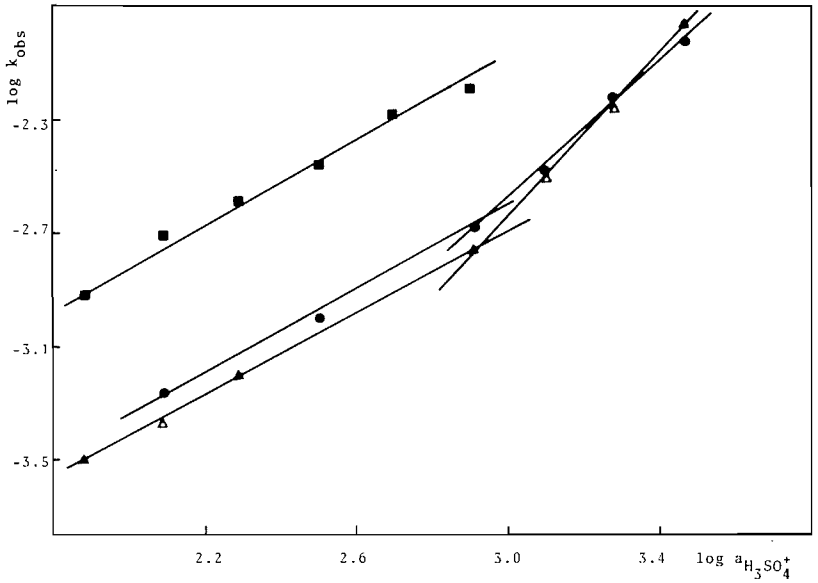

FIG. 3. Correlation of log k_{obs} of the sulfonation of **4** (△), **5** (●), and **7** (■) with log $a_{H_3SO_4^+}$.

of the OR group, since in the case of **3**, where no phenolic oxygen is present, this shift was not observed.

Then, in the sulfuric acid range used in the present work, the sulfonation of **4** and **5** will proceed predominantly via the monoprotonated substrates. Considering the slopes of the log k_{obs} vs. log $a_{H_3SO_4^+}$ and log $a_{H_2S_2O_7}$ and the interpretation of the results of other similar aromatic substrates (28), we propose that sulfonation at the lower sulfuric acid concentrations is effected by the species $H_3SO_4^+$ according to the sequence [2]–[3]. With increasing sulfuric acid concentration there is a changeover in the sulfonating entity from $H_3SO_4^+$ to $H_2S_2O_7$, with the latter species effecting the sulfonation according to the sequence [4]–[3].

$$[4]\quad ArH + H_2S_2O_7 \rightleftarrows Ar^+\begin{matrix}H\\ \diagup\\ \diagdown\\ SO_3H\end{matrix} + HSO_4^-$$

The constancy of the product obtained indicates that the substitution position is the same for both sulfonation mechanisms. This fact has already been observed in the sulfonation reactions of anisole and phenol (28).

The graphs of log k_{obs} vs. log $a_{H_3SO_4^+}$ and log $a_{H_2S_2O_7}$ for the partially aromatic compound **7** (Figs. 3 and 4) are linear with slopes of 0.69 and 0.46 respectively. Therefore, under these conditions sulfonation of **7** will be effected by the species $H_3SO_4^+$ according to the sequence [2]–[3]. It is to be noted

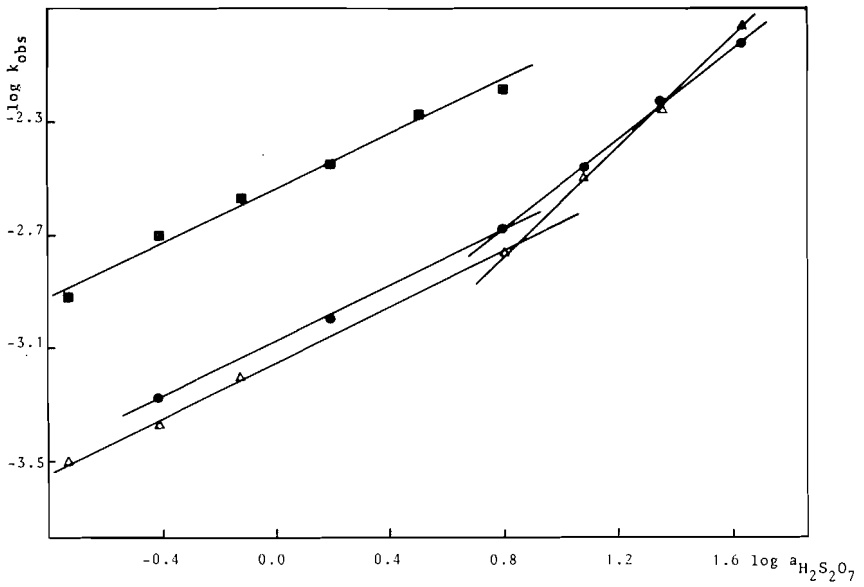

FIG. 4. Correlation of log k_{obs} of the sulfonation of **4** (△), **5** (●), and **7** (■) with log $a_{H_2S_2O_7}$.

that, while **4** and **5** show a similar behaviour, **7** appears to be far more reactive than the fully aromatic substrates. This can be explained by taking into account the different delocalization of the positive charge of the monocations on the benzene ring of the β-carbolines. The greater the aromaticity, the greater the delocalization by resonance of the positive charge will be. Thus the partially aromatic substrate **7** will be more reactive towards electrophilic substitutions than the fully aromatic ones.

The differences, previously mentioned in the Introduction, among sulfonation reactions of β-carbolines and other related compounds can be rationalized in a similar way. Thus, in the range of sulfuric acid concentration used in the present work, indole and carbazole are fully protonated on carbon (30) and nitrogen (31) respectively. This process disrupts the aromaticity of these compounds and the positive charge of the resulting indoleninium and anilinium cations strongly deactivates their benzene ring upon electrophilic substitution reactions. This is also the case of tetrahydro-β-carboline derivatives, which, as typical indoles, protonate on carbon (1) and, therefore, are not easily sulfonated. On the contrary, the pyridinic protonation of β-carbolines does not disrupt the aromaticity and their benzene rings are deactivated in less extension towards electrophilic substitution. Moreover, as our experimental results indicate, the concentration of sulfonating electrophiles, in the sulfuric acid range used, is sufficient to favour the kinetically controlled process over the thermodynamically controlled second protonation previously suggested (12).

Finally, the different reactivity of the unsubstituted benzene and substituted benzene β-carbolines can be qualitatively explained on the basis of substituent effects. The OR-substituted substrates are activated with respect to the non-OR-substituted owing to the electron-releasing effects of the OR substituents.

Apparent molar volume and adiabatic compressibility studies of aqueous solutions of some drug compounds at 25°C

MOHAMMAD IQBAL and R. E. VERRALL[1]

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received August 5, 1988

MOHAMMAD IQBAL and R. E. VERRALL. Can. J. Chem. **67**, 727 (1989).

Apparent molar adiabatic compressibilities and volumes of aqueous solutions of the following drugs (sodium salicylate, methyl orange, L-tryptophan, phenol, and the hydrochloride salts of propranalol, procaine, pilocarpene, and ephedrine) have been calculated from high precision density and sound velocity measurements at 25°C. These drugs are considered important in several biochemical phenomena such as anomalous protein binding, anesthesia, or unique structure–activity relationship and this study is part of a comprehensive investigation of drug–protein interactions in biological systems. The data are qualitatively interpreted in terms of solute–solvent and solute–solute interactions. Some plausible modes of drug hydration are discussed with particular reference to the structure of the drug molecules. The adiabatic compressibility shows a strong correlation with the hydrational behaviour of the solute molecule and appears to be sensitive to the structural features of the solute, such as shape, size, branching, and presence of aromatic rings. It is argued that these aspects are important in terms of considering the geometrical fit of the solute into the ordered form of the aqueous solvent surrounding these solutes.

Key words: apparent molar adiabatic compressibilities, apparent molar volumes, hydration of drugs.

MOHAMMAD IQBAL et R. E. VERRALL. Can. J. Chem. **67**, 727 (1989).

Utilisant des mesures de haute précision de la densité ainsi que de la vitesse du son, à 25°C, on a calculé les volumes et les compressibilités molaires apparentes de solutions aqueuses des drogues suivantes: salicylate de méthyle, orange de méthyle, L-tryptophane, phénol ainsi que les chlorhydrates de la propanolamine, de la procaïne, du pilocarpène et de l'éphédrine. Ces drogues sont souvent considérées comme importantes dans plusieurs phénomènes biochimiques tels que la liaison anormale des protéines, l'anesthésie ou une relation structure–activité particulière; cette étude a été réalisée dans le cadre d'un examen général des interactions drogues–protéines dans des systèmes biologiques. Qualitativement, on interprète ces données en fonction d'interactions soluté–solvant et soluté–soluté. On discute de quelques modes plausibles pour l'hydratation des drogues et en particulier la structure des drogues. Il existe une importante corrélation entre les compressibilités adiabatiques et les possibilités d'hydratation des molécules en solution vis-à-vis de l'hydratation; de plus, elles semblent être sensibles aux caractéristiques structurales du soluté, comme la forme, la grosseur, les ramifications et la présence de noyaux aromatiques. On suggère que ces aspects sont importants lorsqu'on veut insérer ces solutés dans la forme ordonnée du solvant aqueux qui entoure ces solutés.

Mots clés : compressibilités adiabatiques molaires apparentes, volumes molaires apparentes, hydratation des drogues.

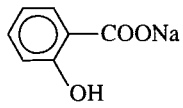
[Traduit par la revue]

Introduction

Drug–macromolecular interactions are an important phenomenon in physiological media, such as blood, membranes, intra- and extracellular fluids. The processes of drug transport, protein-binding, anesthesia are but a few examples where drug and biomacromolecules appear to interact in an important and vitally significant manner. The mechanisms of these molecular processes, however, are not clearly understood. Because of the complexities associated with the structure of biomacromolecules, or with the interpretation of their data, it is generally difficult to carry out direct studies of the physiological media. Consequently, it is imperative that one first investigate the properties of each component in an aqueous medium before beginning studies of the more complex systems.

One of the well recognized approaches to the study of molecular interactions in fluids is the use of thermodynamic methods. Thermodynamic properties are generally convenient parameters for interpreting solute–solvent and solute–solute interactions in the solution phase. Fundamental properties such as enthalpy, entropy, and Gibbs energy represent the macroscopic state of the system as an average of numerous microscopic states at a given temperature and pressure. An interpretation of these macroscopic properties in terms of molecular phenomena is generally difficult. Sometimes, higher derivatives of these properties can be interpreted more effectively in terms of molecular interactions. For example, the partial molar volume, the pressure derivative of partial molar Gibbs energy, is a useful parameter for interpreting solute–solvent interactions. Various concepts regarding molecular processes in solutions, electrostriction (1), hydrophobic hydration (2), micellization (3), and cosphere overlap during solute–solute interactions (4, 5), to a large extent have been derived and interpreted from the partial molar volume data of many compounds. The compressibility property, which is the second derivative of the Gibbs energy, also is a sensitive indicator of molecular interactions and can provide useful information about these phenomena, particularly in cases where partial molar volume data alone fail to provide an unequivocal interpretation of the interactions.

It has been shown that perceptible thermodynamic changes are associated with the processes of drug–protein binding (6–15), anesthesia (16–18), etc. In the case of protein binding, anomalous behavior has been noted with respect to certain drugs (19–24). For example, Scatchard plots with positive slopes are observed which signify a decrease in the amount of bound drug as the concentration of protein is increased. This type of binding appears to involve unusual and complex mechanisms. Despite various explanations of the phenomenon, viz., cooperativity or drug-induced protein aggregation (22–24), the role of these drugs remains uncertain and there is a need to further investigate the molecular interactions between proteins and certain specific drugs.



Volumetric changes in drug-containing membranes have been implicated in the phenomenon of anesthesia (16–18). According to the concept of critical volume (16, 17), the anesthetic drug causes an expansion in the bilayer system up to a critical volume level, resulting in a diminution of nerve conduc-

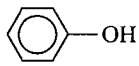
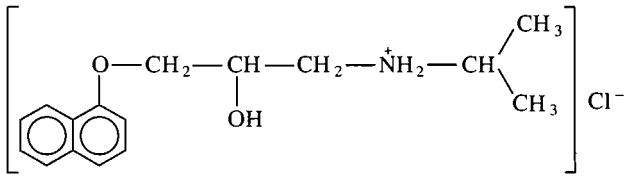
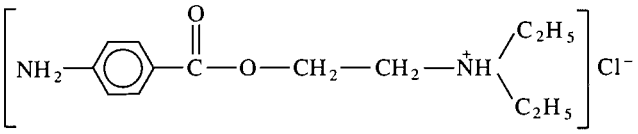
Sodium salicylate (NaSl)



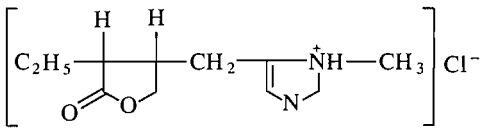
Methyl orange (MeOr)



L-Tryptophan (Trp)



Phenol (PhOH)



Propranalol HCl (PrHCl)

Procaine HCl (PcHCl)

Pilocarpene HCl (PlHCl)

Ephedrine HCl (EpHCl)

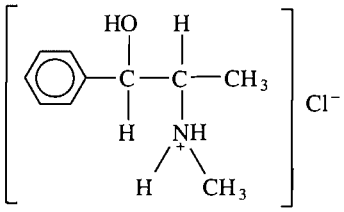


FIG 1. Drugs used in this study and their molecular structures.

tion. The importance of the volumetric behavior of the anesthetic agent is clearly identified in this concept and it appears certain that a definite mechanism will be difficult to establish without a better understanding of the volumetric behaviour of the drugs involved.

As part of the longer term objective to investigate thermodynamic aspects of biochemical processes involving such drug–macromolecular interactions, we report the results of determinations of apparent molar adiabatic compressibilities and volumes of eight drugs in aqueous solution at 25°C. The drugs studied are: (*i*) sodium salicylate (NaSl): an analgesic that binds with plasma proteins (19); (*ii*) methyl orange (MeOr): a dye that binds with proteins (19); (*iii*) L-tryptophan (L-Trp): an amino acid that binds with proteins (19); (*iv*) phenol (PhOH): a molecule that binds to serum proteins (7, 8, 25); (*v*) propranalol HCl (PrHCl): a β-adrenergic blocking agent that binds with proteins (19); (*vi*) procaine HCl (PcHCl): an anesthetic (26) agent; (*vii*) pilocarpene HCl (PlHCl): a muscle and gland stimulant of unique molecular structure that acts through membranes (26); (*viii*) ephedrine HCl (EpHCl): a drug that stimulates the central nervous system by acting through membranes (26). The molecular structures of these drugs are shown in Fig. 1.

The rationale for choosing these drugs for study is based primarily on their role in various pharmacological phenomena as discussed above.

Experimental

Materials

All drugs were recrystallised from commercial samples of reasonably high purity. Their source and the purification procedures followed are given below: (*i*) Sodium salicylate (Sigma, lot No. 32F-012B) was recrystallised twice from an ethanol–water mixture (15:1, v/v), and

dried under vacuum in a pistol dryer over boiling water. (*ii*) Methyl orange (BDH, lot No. 788569) was recrystallised twice from hot water, then washed with cold ethanol followed by diethyl ether. It was dried under vacuum in a pistol dryer over boiling water. (*iii*) L-tryptophan (Sigma, lot No. 63F-0321) was recrystallised twice from a water–ethanol mixture (ca. 1:1, v/v) washed with anhydrous diethyl ether, and dried at room temperature under vacuum over P_2O_5. (*iv*) Phenol (Analar BDH, lot No. 0605270) was recrystallised from 75% (w/w) solution in water by cooling to 11°C. The crystallised material was centrifuged, rinsed with cold water (0–2°C) saturated with phenol, and dried at room temperature. (*v*) Propranalol HCl (Sigma, lot No. 81F-0306) was recrystallised twice from absolute ethanol, dried under vacuum at room temperature over P_2O_5, and stored at 0–5°C. (*vi*) Procaine HCl (Sigma, lot No. 80F-0020) was recrystallised twice from absolute ethanol and dried under vacuum in a pistol dryer over a boiling mixture of ethylene glycol – water (3:7 v/v). (*vii*) Pilocarpene HCl (McArthur Chemical Co. lot No. K12433417) was recrystallised twice from absolute ethanol and dried as in the case of PcHCl over a boiling mixture of ethylene glycol – water (3:2 v/v). (*viii*) Ephedrine HCl (Sigma, lot No. 121F-0223) was recrystallised twice from absolute ethanol and dried as in the case of PcHCl over boiling ethylene glycol.

The purity of the drug compounds was checked by comparing the observed melting points with those reported in the literature. In all cases, excellent agreement was found between the observed and reported values.

Water used in these experiments was distilled and deionized by using a Millipore Super-Q system and was degassed before use. All solutions used for thermodynamic measurement were prepared on a weight basis.

Apparatus and procedure

Apparent molar volumes (ϕ_v) of the drugs were calculated using the following relation

$$[1] \qquad \phi_v = \frac{M}{d} + \frac{1000(d_0-d)}{mdd_0}$$

where M is the relative molar mass of the solute, m is the molality of the solution, and d and d_0 are the densities of solution and solvent, respectively. Densities of the aqueous drug solutions were measured at 25°C using a high precision digital densimeter (Model 02D Sodev Inc.) experimental details of which are described elsewhere (27). Thermostating of the densimeter was maintained by a closed-loop Sodev Temperature Controller which maintained the temperature constant to better than ±0.001°C. The absolute temperature of the solution in the cavity was obtained by using a tissue implantation thermistor calibrated against a Pt resistance thermometer (Leeds and Northrup). Temperatures were found to be accurate to within ±0.01°C. The instrument was calibrated with water (28), dry nitrogen (density calculated from the ideal gas equation), and NaCl solution (29) using density data from the literature. In order to minimize errors instrument calibration was performed prior to each series of measurements. The density of each solution was obtained relative to that of the solvent which was measured immediately before and after measuring the solution density. The precision in the density data are better than ±2.0 ppm.

Compressibility can be measured under either isothermal or adiabatic conditions. The former is difficult to obtain experimentally with high accuracy for dense fluids. On the other hand, the adiabatic compressibility is more complex to interpret but is relatively easy to measure with high accuracy. It is calculated from sound velocity and density data. The isothermal compressibility can be estimated from the adiabatic analogue if the coefficient of thermal expansion, α, heat capacity at constant pressure, C_p, and density of the solution are known (1).

Ultrasonic velocities were measured as previously described (30). The following equation was used to calculate the sound speed, u, in ms^{-1}.

$$[2] \qquad u = \ell f(1 + \alpha t)/(7 - t_d f)$$

where ℓ is the sonic path length in meters, f is the frequency in hertz, t is the temperature of the solution in degrees Celsius, α is the coefficient of thermal expansion of the probe metal, and t_d is the electrical delay time in seconds. Values of ℓ, α, and t_d are supplied by the manufacturer, but ℓ and t_d can be determined independently. The original glass vessel supplied with the instrument was replaced by a cell having a smaller volume (70 mL) fitted with a thermostating arrangement and a suitable lid for transferring material to and from the cell whenever required. The temperature was controlled by a closed-loop temperature controller (Sodev Inc. Canada), capable of maintaining the temperature constant to better than ±0.001°C. The velocimeter was calibrated by obtaining values of ℓ and t_d using previously reported sonic velocity data for water (31) and aqueous NaCl solutions (32). In the case of NaCl, the data were statistically analysed and regression constants were obtained as a function of concentration. In order to minimize errors, instrument calibration was performed prior to each series of measurements. The precision in the sound velocity was found to be better than ±0.02 ms^{-1}.

Adiabatic compressibility coefficients, β, in units of Pa^{-1} were derived from the relation

$$[3] \qquad \beta = 1/u^2 d$$

where d is the solution density in kg m^{-3}. The apparent molar adiabatic compressibility (ϕ_k) of liquid solutions was calculated from the relation

$$[4] \qquad \phi_k = \frac{1000}{md_0}(\beta - \beta_0) + \phi_v \beta$$

where m is the molality of the solution, M is the relative molar mass of the solute, d is the density of the solution, d_0 is the density of the solvent, and β_0 and β are the compressibility coefficients of the solvent and solution, respectively.

Results

Apparent molar volume

ϕ_v data for all compounds in aqueous solution were calculated using eq. [1]. Experimental ϕ_v data for all the systems studied are found in the supplementary material.[2] Apparent molar volume data for the hydrochloride salts and phenol were checked for possible changes arising from the proton ionisation reaction (33, 34).

$$[5] \qquad BH^+ + H_2O \rightleftarrows B + H_3O^+$$

where BH^+ and B represent the protonated and unprotonated form of the compound, respectively. The volume correction can be either calculated or can be eliminated by studying the solutions in sufficiently acidic medium (in order to suppress these reactions). In the former case, the corrected value, ϕ_v(corr) is related to the observed value, ϕv(obs), through the following relation

$$[6] \qquad \phi_v(corr) = \phi_v(obs) - \gamma \Delta \bar{V}^0$$

where $\Delta \bar{V}^0$ is the change in volume for eq. [5] and γ is the degree of dissociation. In the present cases it can be calculated from the following relation

$$[7] \qquad \gamma = -K + (K^2 + 4Km_0)^{1/2}/2m_0$$

where K is the ionisation constant for eq. [5] and can be obtained from pK data and m_0 is the initial concentration of the solute. $\Delta \bar{V}^0$ can be calculated from the corresponding volumes of the individual species involved in eq. [5], e.g.,

$$[8] \qquad \Delta \bar{V}^0 = \bar{V}^0(B) + \bar{V}^0(H_3O^+) - \bar{V}^0(BH^+) - \bar{V}^0(H_2O)$$

[2]A complete set of tables of apparent molar volume, apparent molar compressibility, sound velocity, and density data for these systems may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

where $\bar{V}^0(H_2O)$ is taken from the density of the pure solvent and $\bar{V}^0(B)$ is generally obtained from experimental data. In the absence of experimental data, however, it can be approximated through the use of simple additivity rules. $\bar{V}^0(BH^+)$ can also be estimated through such additivity methods, e.g.,

[9] $\bar{V}^0(B) = \bar{V}^0(BHCl) - \bar{V}^0(HCl)$

[10] $\bar{V}^0(BH^+) = \bar{V}^0(BHCl) - \bar{V}^0(Cl^-)$

The magnitude of the correction to the volume arising from the ionisation process, eventually, depends on the value of γ. In the case of the compounds studied in this work, it was found that, due to the high pK values of the bases (35, 36), values of γ were found to be sufficiently small so that the net correction to experimental ϕ_v values was negligible and within the experimental error. The observed volumetric data were thus taken as the true data for the hydrochloride salts. A similar assessment was obtained in the case of phenol, which is known to undergo slight proton ionisation in aqueous medium. Corrections due to other possible reactions (disproportionation, etc.) were not considered since the degree to which these reactions occur is believed to be much smaller than that of the proton ionisation.

ϕ_v data for hydrochlorides, sodium salicylate, and methyl orange were treated as a function of the square root of concentration, to take into account their electrolyte character. They were fitted to the following equation

[11] $\phi_v = \phi_v^0 + S_v m^{1/2}$

The use of empirical slopes rather than theoretical slopes for the electrolyte compounds may lead to different infinite dilution data but in the present cases the differences lie within the uncertainty of the extrapolated values obtained from the empirical relation, eq. [11].

Data for the remaining compounds, viz., phenol and L-tryptophan were fitted to the relation

[12] $\phi_v = \phi_v^0 + S_v m$

Table 1 contains the values of the coefficients obtained for these fits. The limiting values of the apparent molar volumes were taken as the partial molar volumes, $\bar{V}^0$, of the respective compounds at infinite dilution. Figure 2 shows graphs of the concentration dependence of ϕ_v for all the drugs studied.

With one exception, a linear relation between the apparent molar volumes and the independent variable, either molality or $m^{1/2}$, is seen to hold throughout the entire concentration range studied. Propranalol hydrochloride shows (Fig. 2) a linear dependence at low concentrations (below 0.0625 m), only. Above this concentration values of ϕ_v begin to rise rather sharply. The coefficients $\bar{V}^0$ and S_v for PrHCl were obtained by fitting the data in the linear region only.

Efforts were made to minimise personal error and possible experimental artifacts by carefully controlling experimental procedures. Systematic errors were analysed separately and were found to be significant at lower solute concentrations. However, errors in apparent molar volumes arising from uncertainty in concentration were, generally, not a limiting factor. Uncertainties associated with the density were found to be more important. The maximum estimated error in ϕ_v derived from the error analysis treatment was $\pm 1.00 \times 10^{-6}$ m^3 mol^{-1} at 0.002 m, the lowest limit of concentration used in this study.

Apparent molar adiabatic compressibility

ϕ_k values of drug compounds were calculated using eq. [4]. Density, sound velocity, and ϕ_k data for all systems are found in the supplementary material.[2] ϕ_k data for the hydrochloride salts and phenol were analyzed for possible changes arising from the proton ionisation reaction (33, 34). The correction to ϕ_k due to this reaction was found to be within the experimental error.

ϕ_k data for hydrochloride salts, sodium salicylate, and methyl

orange were treated as a function of the square root of concentration, to take into account their ionic nature. They were fitted to the following equation

[13] $\phi_k = \phi_k^0 + S_k m^{1/2}$

Data for phenol and L-tryptophan were treated as a direct function of concentration and were fitted to the following equation

[14] $\phi_k = \phi_k^0 + S_k m$

The infinite dilution value, ϕ_k^0, of the apparent molar adiabatic compressibility is equal to the partial molar adiabatic compressibility, $\bar{K}^0$. Figure 3 shows graphs of the concentration dependence of ϕ_k for the systems studied and values of ϕ_k and S_k are shown in Table 2.

A linear relation between the apparent molar adiabatic compressibilities and the independent variable, either molality or $m^{1/2}$, is seen to hold throughout the entire concentration range studied, with one exception. Propranalol hydrochloride shows a linear dependence at low concentrations (below 0.0625 m), only. Above this concentration ϕ_k appears to increase rather sharply, the change being more pronounced than in the case of ϕ_v. The coefficients $\bar{K}^0$ and S_k for PrHCl were obtained by fitting the data within the linear region only.

Errors in ϕ_k data were estimated and it was found that, due to the observed uncertainties in density (2 ppm) and in sound velocity (1 ppm), the overall magnitude of the uncertainty at 0.002 m, the lower limit of concentration studied, was $\pm 1.0 \times 10^{-15}$ m^3 mol^{-1} Pa^{-1}.

Discussion

The partial molar volumes and adiabatic compressibilities at infinite dilution of these compounds can be described in terms of two primary contributions, i.e., constitutive and hydrational.

[15] $\bar{M}^0 = \bar{M}_c^0 + \bar{M}_h^0$

where $\bar{M}^0$ is the partial molar property at infinite dilution, $\bar{M}_c^0$ is the constitutive component, composed of the sum of atomic and group contributions, and $\bar{M}_h^0$ is the hydrational component. The latter is believed to be more significant in terms of interpreting solute–solvent interactions.

In the case of volume studies, $\bar{V}_h^0$ can be obtained from $\bar{V}^0$ and $\bar{V}_c^0$ values. $\bar{V}_c^0$ data may be estimated either from the crystallographic volumes or by using an additivity scheme for atomic or group (van der Waals) volumes. No crystallographic data were available for these compounds. Furthermore, the use of additivity schemes generally was found to be too unrealistic, and, consequently, no further estimation of $\bar{V}_h^0$ was attempted. Assuming that the molecular skeleton of these solutes is practically incompressible, the $\bar{K}_c^0$ component of the partial molar compressibility can be considered to be negligible. Therefore, to a good approximation, the observed compressibility can be taken as the compressibility of hydration, $\bar{K}_h^0$.

Most of the drug compounds studied in this work are ionic in nature. Extrathermodynamic assumptions can be applied to obtain relative measures of partial molar ionic volumes and compressibilities at infinite dilution. This procedure provides for a qualitative comparison of ion–solvent interaction for different ions. For sodium and hydrochloride salts, literature values of $\bar{V}^0$ and $\bar{K}^0$ for Na^+ and Cl^- ions were employed in some cases to estimate the respective thermodynamic values for their counter ions.

The concentration dependence of the volume and compressibility properties in aqueous medium were interpreted in terms of the cosphere overlap model (4, 5), the characteristics of the

cospheres being dependent upon the drug structure, size, shape, and hydrophobicity. The results are discussed below in more detail for the volume and compressibility studies. A brief description of the behaviour and use of the drug compounds in physiological systems is included with the discussion of the volume results. The volume and compressibility results are discussed separately to focus better on variations in these properties within the series of compounds. In general, it has been found that the compressibility results provide better insight into the hydration phenomena of these compounds.

Apparent molar volume

Sodium salicylate

The use of NaSl as a drug is largely based on its analgesic and antipyretic properties, much like aspirin (26, 36–39). Salicylates are found to exhibit protein-binding properties (19, 22, 24) and Scatchard plots having positive slopes have been reported (22, 24) for salicylate – serum albumin systems. Salicylates are also found to impair the binding of the drug diflunisal to plasma protein by displacing it from the primary binding sites (40).

While the Na^+ ion is believed to cause electrostriction in water, the hydration of the salicylate ion is not clearly understood. Various studies of benzene and its derivatives in water have led to conflicting interpretations with respect to their hydration behaviour. Shahidi (41) has described benzene solvation in terms of extensive hydrophobic hydration in aqueous medium. Contrary to this explanation, Masterton (42) and Hepler (43) have indicated that the aromatic ring causes little influence on water structure, presumably due to the counterbalancing effects arising from its hydrophobic and structure breaking character. The structure-breaking effect is due to a poor fit of the planar ring into the tetrahedral structure of water. The data reported here support the view presented by Masterton and Hepler. However, the effect of substituents and the negative charge on the salicylate ion may disturb this apparent balance such that a weaker hydration of the anion can be expected as a result of the diffuse charge and the potential for hydrogen bond formation between water and phenolic OH. An overall constriction in the solution volume possibly may occur.

A value of $\bar{V}^0$ for NaSl was calculated from group volume data obtained from the literature and compared to the experimental value obtained in this study. Values of 85.92×10^{-6} m^3 mol^{-1} for PhCOONa (41) (Ph = phenyl group) and 3.63×10^{-6} m^3 mol^{-1} for phenolic OH (41) give a calculated $\bar{V}^0$ of 89.55×10^{-6} m^3 mol^{-1} for NaSl, 3.85×10^{-6} m^3 mol^{-1} smaller than the experimental value. The difference may be due to interactions between the adjacent substituents on the ring that, otherwise, are not taken into account in the additivity scheme.

The concentration dependence of the apparent molar volume is given by the S_v value which is 1.20×10^{-6} m^3 $mol^{-3/2}$ $kg^{1/2}$. This is smaller than the Debye–Hückel limiting law slope value (1.868×10^{-6} m^3 $mol^{-3/2}$ $kg^{1/2}$), for 1:1 electrolytes in water at 25°C (1). However, a direct comparison of the S_v data of this work with the Debye–Hückel coefficient is not appropriate since the lower range of concentration used in this study is well above the range of the limiting law region.

Methyl orange

This dye is known to bind to proteins. Its medicinal value is due to its germicidal action and selective staining capability on certain tissues and skin (26, 36–38). It is one of the drugs that exhibit positive Scatchard plots (22, 23). ϕ_v data for this compound were obtained at very low concentrations in water because its poor solubility precluded determination of apparent molar volumes at concentrations above 0.016 *m*. The data, consequently, have substantial scatter and larger standard deviations in calculated parameters than for the other compounds. $\bar{V}^0$ of the anion was estimated from the measured value of $\bar{V}^0$(MeOR) (227.58×10^{-6} m^3 mol^{-1}) and the literature value of $\bar{V}^0(Na^+)$ (-6.61×10^{-6} m^3 mol^{-1}) (44) to give a value of 234.19×10^{-6} m^3 mol^{-1}.

The negative value of S_v (cf. Table 1) is presumably due to the hydrophobicity of this molecule. The solute–solute interactions in such cases are believed to occur by means of constructive overlap of cospheres (5).

L-*Tryptophan*

This essential amino acid has been widely investigated in protein-binding studies (19–24, 45). Scatchard plots having positive slopes have been reported for L-tryptophan binding with serum albumins (22, 23). L-tryptophan in its zwitterionic form is believed to be extensively hydrated in aqueous medium. Some previous studies have reported volumetric data for D- and DL-tryptophan. Millero *et al.* (46) reported a value of $\bar{V}^0$ for D-tryptophan of $(143.91 \pm 0.14) \times 10^{-6}$ m^3 mol^{-1} while Cohn and Edsall (47), and Mishra and Ahluwalia (48) have reported $\bar{V}^0$ values for DL-tryptophan of 144.1 and $(143.8 \pm 0.2) \times 10^{-6}$ m^3 mol^{-1}, respectively. The value of $\bar{V}^0$ for L-tryptophan reported here compares well with these data. Differences due to subtle stereo-specific interactions, however, cannot be discerned.

The values of S_v for tryptophan reported in the literature differ markedly from one study to another. The value reported by Millero *et al.* (46) for D-tryptophan is $(0.233 \pm 0.14) \times 10^{-6}$ m^3 mol^{-2} kg while that reported by Mishra and Ahluwalia (48), for the DL-isomer is $(5 \pm 19) \times 10^{-6}$ m^3 mol^{-2} kg. The value of $(0.59 \pm 0.45) \times 10^{-6}$ m^3 mol^{-2} kg reported here for L-tryptophan differs from both, although it lies within the range of the two.

Phenol

Phenol and its derivatives are well known for their antibacterial action. There are many reports of phenol binding with proteins. Breuer (7, 8) has measured volume changes associated with the binding of phenol with keratin. Normal binding of phenol with serum albumin is indicated from Scatchard plots (25). Shahidi (41) has reported partial molar volume studies of phenol and has given a value of $\bar{V}^0$ of $(84.90 \pm 0.03) \times 10^{-6}$ m^3 mol^{-1}. The value of $(85.20 \pm 0.01) \times 10^{-6}$ m^3 mol^{-1} reported here compares well with it.

The molecular solvation of phenol in water is expected not to be too dissimilar from that of benzene. The effect of OH substitution on the benzene ring, in terms of hydrational changes, is difficult to predict from the partial molar volume data.

Propranalol HCl

Propranalol hydrochloride is used as a β-adrenergic blocking agent (35–38). It is well known as a suppressor of heart rate and contractility and can be used in cardiac failures resulting from arrhythmia. The D-isomer is a better antiarrhythmic but is found to be nearly devoid of β-adrenergic blocking activity. The compound studied in this work was the DL-isomer.

Values of $\bar{V}^0$ of PrHCl in this work are derived from extrapolation of ϕ_v data below 0.0625 *m*. Above this concentration, apparent molar volumes tend to rise quite sharply. This rise can be interpreted as due to the onset of molecular aggregation (49). The overall hydrational picture of this molecule is difficult to

predict. Its molecular structure (Fig. 1) shows a naphthalene ring attached to a hydrocarbon chain with an intervening amino group and two hydrogen bonding sites. The effect of charge on the amino nitrogen appears to be dissipated because of its delocalisation over the extended structure, leaving the cation with little electrostatic character. The aggregation above 0.0625 *m*, in effect, implies an overall hydrophobic nature of the molecule. The presumed aggregation may be described as due either to the stacking of aromatic rings (50) or micellization promoted by the hydrophobic chain of the molecule.

Procaine HCl

It is the least toxic and most widely used anesthetic drug in a variety of conditions where nerve blockage is desired (35–38). No data, however, are available to test the critical volume hypothesis.

The hydrational picture of the PcHCl molecule is difficult to establish with certainty because of its complex structure. Figure 1 shows the structure of the molecule as having several polar sites dispersed among hydrophobic regions. The polarity of these sites, however, appears to be diminished by the hydrophobicity of the remaining structure. An aromatic ring, two intervening methylenes and a branched hydrocarbon portion of the molecule seem to impart an overall hydrophobic character to the molecule. A negative value of S_v, presumably, is indicative of this hydrophobicity and thus suggestive of a molecular hydration similar to that associated with typical hydrophobic solutes. The presence of the aromatic ring is expected to perturb the hydration layer stretching around the extended structure of the molecule. It may be argued that solute–solute interactions, in this case, can occur via overlap of hydration spheres engulfing the branched chain terminus of the molecule.

Pilocarpene HCl

This drug is known for its direct action on cells and is used as a stimulant for muscles and gland cells (35–38). It shares many of the properties of acetylcholine.

Like PrHCl and PcHCl, its structure is complex so that its hydration behavior is difficult to predict from partial molar volume data alone. A small negative value of S_v (Table 1) may be interpreted as showing the compound to be slightly hydrophobic in character. It appears that there is a near balance between hydration of the polar and hydrophobic parts of the molecules leading to the observed small net hydrophobicity.

Ephedrine HCl

This drug is a strong stimulant of the central nervous system that penetrates membranes and the brain better than other drugs of similar function (35–38). It is used to prevent a variety of allergic syndromes, to act as a respiratory stimulant and as an antidote to morphine and other barbiturates.

The present volumetric data indicate solution behaviour similar to that seen in the case of pilocarpene HCl. However, the net result of the opposing ionic and hydrophobic effects in the structure of ephedrine HCl appears to indicate marginal dependence of the volume on the ionic effect, as shown by the slightly positive value of S_v (Table 1).

Apparent molar compressibility

It is well established that solutes causing electrostriction lead to a decrease in the compressibility of the solution (51, 52). This is reflected by the negative values of $\bar{K}^0$ of electrolyte solutions. Hydrophobic solutes often show negative compressibilities, as well, due to the ordering that is induced by them in the water structure (3, 51). The compressibility of hydrogen bonded structures, however, varies depending on the nature of the H-bonds involved (51).

TABLE 3. Ionic compressibilities of the drug compounds

Ion	$\bar{K}^0 \times 10^{15}$ ($m^3\ mol^{-1}\ Pa^{-1}$)
Salicylate	−12.09
$MeOr^-$	+7.83
PrH^+	−1.85
PcH^+	+3.93
PlH^+	−0.41
EpH^+	−2.73

Data reported here indicate that all the compounds studied in this work, except phenol, have negative compressibilities, which range from $(-13$ to $-46) \times 10^{-15}$ $m^3\ mol^{-1}\ Pa^{-1}$. $\bar{K}^0$ of phenol is $+9.53 \times 10^{-15}$ $m^3\ mol^{-1}\ Pa^{-1}$ which may be a result of combined effects of the aromatic ring and of the hydrogen bonding between phenolic OH and water molecules. The poor fit of the aromatic ring (42, 43) as well as the possibility of flexible H-bond formation appear to be responsible for causing a more compressible environment in the aqueous medium. The negative values of compressibilities for the remaining compounds indicate an overall constriction in the solution volumes, caused by varying degrees of electrostriction or hydrophobic hydration.

Individual ionic compressibilities were calculated for the ionic drugs, using values of $\bar{K}^0(Na^+)$ (46) $= -33.5 \times 10^{-15}$ $m^3\ mol^{-1}\ Pa^{-1}$ and $\bar{K}^0(Cl^-)$ (46) $= -17 \times 10^{-15}$ $m^3\ mol^{-1}\ Pa^{-1}$. Values of the counterion compressibilities were obtained by subtracting these values from the experimental data and are shown in Table 3. The results show that the counterions have a relatively larger compressibility than the smaller Na^+ and Cl^- ions. Also, they appear to show the existence of a correlation between compressibility and the size of the counterion or the structural complexity (e.g., branching or ring structure). It can be argued that as the size of the ion increases or its structure becomes more complex, it becomes increasingly difficult for the solute to be accommodated in the ordered aqueous medium. Consequently, it appears to cause a greater degree of disorder in the solvent. The compressibility of such disordered structures is expected to be higher than the ordered structures, such as those accompanying electrostriction or hydrophobic hydration. For example, the salicylate ion, being the smallest in size among these ions, has the lowest value of $\bar{K}^0$(ion). The anion of methyl orange appears to be the largest in size due to the presence of two aromatic rings joined in an extended structure. This is likely to create greater structural disorder in the aqueous environment. As well, a similar effect appears to be present in the hydrochloride salts. For example, EpH^+ is the smallest ion and has the lowest compressibility whereas PcH^+, a larger ion, has the greatest ionic compressibility.

The concentration dependence of the apparent adiabatic compressibility, S_k (Table 2), is seen to vary considerably among these solutes. While the values of S_v (Table 1) are generally positive for ionic solutes and tend to decrease as the hydrophobic character of the solute increases, there does not appear to be a strong correlation between values of S_k and such qualitative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

features of the solutes. In the case of simple model compounds S_k and S_v data follow the same trend, however, in the case of these somewhat amphiphilic solutes the solute–solute interactions, as monitored by the compressibility property, appear to depend on the net hydration effect in an unpredictable manner.

Millero *et al.* (46) have reported a value of $\bar{K}^0$ for D-tryptophan of -30.24×10^{-15} m^3 mol^{-1} Pa^{-1} and an S_k value of -41.10×10^{-15} m^3 mol^{-2} kg Pa^{-1}. The values of these parameters for L-tryptophan in this work are -30.64×10^{-15} m^3 mol^{-1} Pa^{-1} and -29.49×10^{-15} m^3 mol^{-2} kg Pa^{-1}, respectively. The reasons for the large difference in S_k values are difficult to ascertain. It is to be noted that the low solubility of this compound is a factor which restricts the determination of thermodynamic properties to very low concentrations, below 0.01 *m*. Consequently, a larger scatter in ϕ_k values is obtained. The process of deriving the infinite dilution value ($\bar{K}^0$) and the interaction parameter (S_k) is strongly dependent on the type of data treatment used. It is likely that different methods of statistical analysis may produce different values of $\bar{K}^0$ and S_k parameters. Values of $\bar{K}^0$ reported herein were obtained using a weighted least squares fit, whereas Millero *et al.* (46) have reported an unweighted least-squares treatment of their data. Stereoisomerism may give rise to some of this difference but it is difficult to ascertain from these results.

In the case of PrHCl, the change in ϕ_k with increasing concentration, above 0.0625 *m*, is much more pronounced than was observed in the case of ϕ_v. This change is believed to be due to the onset of aggregation similar to micellization, an observation supported by the ϕ_v results and ultrasonic relaxation studies (49).

Conclusion

Apparent molar volume data of the drugs studied in this work show solution behaviour consistent with the general rules governing the behaviour of electrolytic, non-polar, and amphiphilic solutes in water. The S_v data appear to depend upon the net polar or hydrophobic character of the solute. Propranalol hydrochloride shows a marked increase in ϕ_v values above 0.06 *m* and this suggests possible aggregation of the drug in aqueous medium. The calculated values of individual ionic compressibilities show that a rough correlation exists between the observed compressibility and factors such as size of the ion, structural complexity (e.g., branching or ring structures), etc. The larger size or the greater structural intricacy of the ion appears to perturb an otherwise compact and homogeneous hydration shell around the solute species. The results also can be viewed in terms of the geometrical fit of the solute species in an ordered solvent. It can be argued that as the size of the ion increases or its structure becomes more complex, it is increasingly difficult to accommodate the solute in an ordered solvent environment.

Kinetics of oxidation of Cu(I) complexes of cysteine and penicillamine: nature of intermediates and reactants at pH 10.0

STEPHEN P. MEZYK AND DAVID A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 15, 1988

STEPHEN P. MEZYK and DAVID A. ARMSTRONG. Can. J. Chem. **67**, 736 (1989).

The Cu(I).L_2 complex with cysteine ligands at total Cu(I) concentrations of 10–30 μM was shown to be oxidised by cysteinyl radicals ($RS^{\cdot}$) with a diffusion-controlled rate constant $k_{11a} = 1.8 \times 10^9\ M^{-1}\ s^{-1}$. The corresponding reaction with the cysteine disulphide anion ($RS^{\cdot}$—SR^-) proceeded at a slower rate, $k_{11b} = 2.7 \times 10^8\ M^{-1}\ s^{-1}$. At higher Cu(I) concentrations, a slow and a fast component of absorption growth was observed. The slow component rate was independent of Cu(I) concentration, but it became more intense as the Cu(I) concentration rose. The yields and kinetic data were shown to be consistent with the presence of an equilibrium between the Cu(I).L_2 species and a second Cu(I) complex, $Cu(I)_2.L_3$, with an equilibrium constant of $K_1 = 162$.

[1] $$2Cu(I).L_2 \underset{}{\overset{K_1}{\rightleftharpoons}} Cu(I)_2.L_3 + L$$

This finding is consistent with the earlier work of Bagiyan *et al.* The rate constant of the oxidation of $Cu(I)_2.L_3$ by the cysteinyl radical was $k_{12} = 1.0 \times 10^9\ M^{-1}\ s^{-1}$. Similar results were obtained with penicillamine, except the rate constants and equilibrium constant were smaller, ($k_{11a} = 4.5 \times 10^8\ M^{-1}\ s^{-1}$, $k_{11b} < 2 \times 10^8\ M^{-1}\ s^{-1}$, $k_{12} = 5.5 \times 10^8\ M^{-1}\ s^{-1}$ and $K_1 = 113$). This was attributed to the presence of the β-methyl groups in penicillamine, which exert a large steric effect.

The ultraviolet spectra of the long-lived products, which are stable on a millisecond timescale, was consistent with a Cu(II).L_2 structure with a square planar geometry. The oxidation of the $Cu(I)_2.L_3$ species proceeded via intermediates, which relaxed to the final product spectra with rate constants of $k_{13b} = 2.6$ and $1.1 \times 10^4\ s^{-1}$ for cysteine and penicillamine, respectively. Comparison of the spectra of the intermediates with published data showed that they were consistent with the presence of a bridging thiolate ligand between Cu(I) and Cu(II).

Key words: oxidation, copper, mixed valence, cysteine, penicillamine, complexation.

STEPHEN P. MEZYK et DAVID A. ARMSTRONG. Can. J. Chem. **67**, 736 (1989).

On a montré que, à des concentrations totales de Cu(I) allant de 10 à 30 μM, les complexes Cu(I).L_2 portant des ligands cystéines sont oxydés par les radicaux cystéinyles ($RS^{\cdot}$) avec une constante de vitesse $k_{11a} = 1{,}8 \times 10^9\ M^{-1}\ s^{-1}$ qui est contrôlée par la diffusion. La réaction correspondante avec l'anion disulfure de la cystéine ($RS^{\cdot}$—SR^-) se produit à une vitesse plus lente, $k_{11b} = 2{,}7 \times 10^8\ M^{-1}\ s^{-1}$. A des concentrations de Cu(I) plus élevées, on a observé une composante lente et une autre qui est rapide pour la croissante de l'absorption. La composante lente est indépendante de la concentration du Cu(I) et elle devient plus intense avec une augmentation de la concentration du Cu(I). On a démontré que les rendements et les données cinétiques sont en accord avec la présence d'un équilibre entre le Cu(I).L_2 et un second complexe de Cu(I), $Cu(I)_2.L_3$, avec une constante d'équilibre de 162.

[1] $$2Cu(I).L_2 \underset{}{\overset{K_1}{\rightleftharpoons}} Cu(I)_2.L_3 + L$$

Cette observation est en accord avec le travail antérieur de Bagiyan et de ses collaborateurs. La constante de vitesse pour l'oxydation du $Cu(I)_2.L_3$ par le radical cystéinyle est $k_{12} = 1{,}0 \times 10^9\ M^{-1}\ s^{-1}$. On a obtenu des résultats semblables avec la pénicillamine, excepté que les constantes de vitesse et d'équilibre sont plus faibles ($k_{11a} = 4{,}5 \times 10^8\ M^{-1}\ s^{-1}$, $k_{11b} < 2 \times 10^8\ M^{-1}\ s^{-1}$, $k_{12} = 5{,}5 \times 10^8\ M^{-1}\ s^{-1}$ et $K_1 = 113$). On attribue cet abaissement à la présence, dans la pénicillamine, de groupements méthyles en β qui exercent un effet stérique important.

Les spectres uv des produits de longue vie, qui sont stables à l'échelle de la milliseconde, sont en accord avec une structure Cu(II).L_2 avec une géométrie plan carré. L'oxydation des espèces $Cu(I)_2.L_3$ procède par le biais d'intermédiaires qui se relaxent en spectres du produit final avec des constantes de vitesse respectives de $K_{13b} = 2{,}6$ et $1{,}1 \times 10^4\ s^{-1}$ pour la cystéine et la pénicillamine. Une comparaison des spectres des intermédiaires avec les données rapportées dans la littérature a permis de montrer qu'ils sont en accord avec la présence d'un ligand thiolate agissant comme pont entre le Cu(II) et le Cu(II).

Mots clés : oxydation, cuivre, valences mixtes, cystéine, pénicillamine, complexation.

Introduction

The strong binding between mercaptide and copper ions has been a subject of interest for many years (1). During the past two decades, several studies of the stoichiometry and dissociation constants of both the copper(I) (2, 3) and copper(II) (4–6) complexes have been made, and some spectroscopic (6, 7) and crystallographic (8, 9) evidence relating to their structural features has been reported. The diversity of structures and redox states of the complexes is very intriguing, and interest has been further stimulated by the resemblance between some of the simple mercaptide complexes and the copper–sulphur centres, which occur in important redox-active proteins (3, 7, 9). Particular attention has been paid to 1,2-amino thiol compounds, since these can become bidentate ligands when the nitrogen atoms are deprotonated (2–6).

This paper describes an investigation of the redox reactions of copper(I) complexed with cysteine and penicillamine in aqueous solution. At strongly alkaline pH these two amino acids have the structures $^-SCH_2C(NH_2)HCO_2^-$ and $^-SC(CH_3)_2C(NH_2)HCO_2^-$, respectively.

The extensive studies of aqueous Cu(I) systems by Bagiyan and co-workers (2) have shown that there is a strong tendency

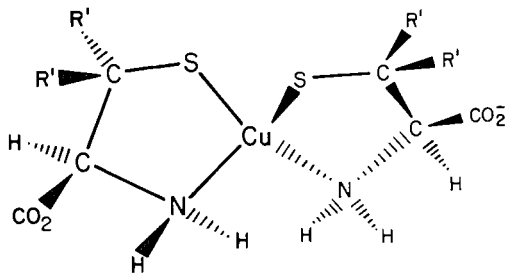
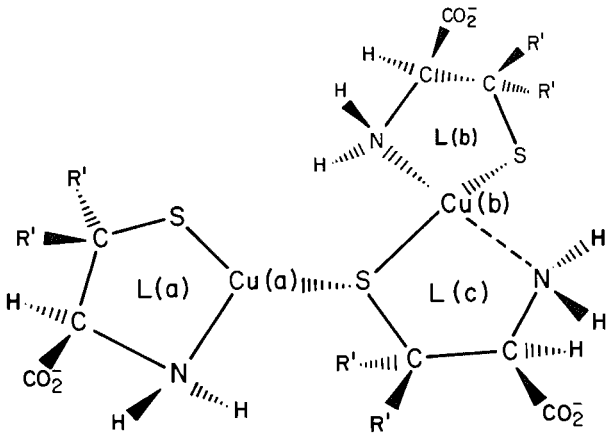
For personal use only.

to form polynuclear complexes of stoichiometry $(Cu.L)_n$ and $(Cu_2.L_3)_m$ at Cu(I) concentrations above 10^{-4} *M*. The proportions of the two forms and the degree of polymerisation depend on the [Cu(I)]:[L] ratio, the absolute Cu(I) concentration and the structure of L. Mononuclear species dominate, however, as [L] is raised and [Cu(I)] reduced. Thus for 0.01 *M* cysteamine ($^-SCH_2CH_2NH_2$) with 10^{-4} *M* total Cu(I) at pH 8.5, 30% of the copper was found to be in the polynuclear form. The remainder was identified as $Cu(I).L_2$ and $Cu(I)_2.L_3$ with the magnitude of the equilibrium constant K_1



[1] $2Cu(I).L_2 \rightleftharpoons Cu(I)_2.L_3 + L$

estimated to be 2.2×10^3. When the Cu(I) concentration was confined to less than 10^{-5} *M*, their spectroscopic studies of the mononuclear complex gave $K_2 = 2 \times 10^{-3}$ and $K_3 = 1.6 \times 10^{-11}$.



[2] $Cu(I).L_2 \rightleftharpoons Cu(I).L + L$

[3] $Cu(I).L \rightleftharpoons Cu(I) + L$

For cysteine and penicillamine, K_1 and K_2 were not reported, but K_3 was found to be 4.2×10^{-12} and 3.0×10^{-12} for the two thiols, respectively. Acid–base titrimetry showed that the NH_2 lone pairs were involved in complexation at alkaline pH with the thiolate group being the more strongly bound site of these bidentate ligands. Since the normal geometry of Cu(I) complexes is tetrahedral (10, 11), one would anticipate the following structures for the $Cu(I).L_2$ and $Cu(I)_2.L_3$ species:

I

II

(R' = H for Cysteine, CH_3 for penicillamine)

with the accommodation of the S to N distance of the 1,2-amino thiol possibly requiring some degree of distortion of the tetrahedron.

As in the case of Cu(I) complexes, the first thiolate ligand is bonded very strongly to Cu(II). However, spectrophotometric titrations have shown that the preferred stoichiometry of Cu(II) complexes with cysteine and penicillamine in alkaline solution is $Cu(II).L_2$ (4–6) and the tendency to form polynuclear complexes is less strong. The structures for these complexes are square planar, with the possibility of *cis* and *trans* forms (6).

An earlier investigation (12) demonstrated that one or more intermediates, with lifetimes in the region of 10^{-4} s, occurred in the one-electron oxidation of $Cu(I).(Cl^-)_x.L_y$ complexes, with L = cysteine and penicillamine, to $Cu(II).L_2$. The primary purpose of this work was to determine whether similar species occurred when there was no chloride ion in the system, and only species I and II were present. As in the previous study, the thiyl radicals ($RS^{\cdot}$) of cysteine and penicillamine, which have $E_{RS^{\cdot}/RS^-} = 0.80$ V (13), were used as the one-electron oxidants. The choice of these species was dictated by the fact that the free RS^- ligand concentration must be kept in the region of 10^{-2} *M* to establish the desired equilibria [1] and [2]. Other one-electron oxidants, such as $^{\cdot}N_3$ and $^{\cdot}ClO_2$, would therefore interact with it and not react directly with the Cu(I) complexes.

The thiyl radicals were produced through the following well-established radiation initiated reactions (14):

[4] $4.2H_2O \longrightarrow 2.7e^-_{(aq)} + 0.5H^{\cdot} + 2.8^{\cdot}OH + 2.7H^+_{(aq)} + 0.5H_2 + 0.7H_2O_2$

[5] $e^-_{(aq)} + N_2O + H_2O \rightarrow OH^- + {}^{\cdot}OH + N_2$

[6] $^{\cdot}OH$ (or $^{\cdot}H$) + $RSH \rightarrow H_2O$ (or H_2) + $RS^{\cdot}$

Solute concentrations were adjusted so that [5] and [6] were the only significant reactions of $e^-_{(aq)}$, $^{\cdot}OH$, and $^{\cdot}H$, and reaction of the thiyl radicals with copper species was then observed on a ~1 μs or longer time scale by using the technique of pulse radiolysis (14).

Quantitative information relating to the uv spectrum of $Cu(II).L_2$ was also obtained in this study for the case of L = penicillamine. Here the steric hindrance caused by the two methyl groups of the β-carbon atom substantially reduces the rate of reaction [7]

[7] $2Cu(II).L_2 + 2RSH \rightleftharpoons 2Cu(I).L_x + RSSR + 2H^+ + (4 - 2x)L$

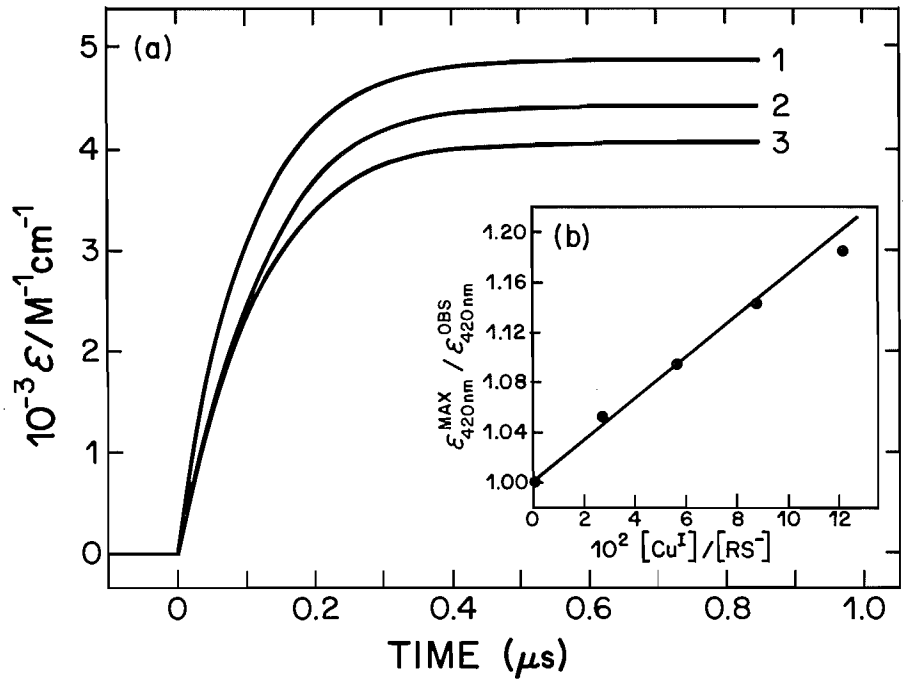

FIG. 1. (*a*) The change in the absorption intensity observed at 420 nm in 10^{-2} *M* CysSH solutions with (*1*) [Cu(I)] = 0, (*2*) [Cu(I)] = 4.0×10^{-4} *M*, (*3*) [Cu(I)] = 8.0×10^{-4} *M*. (*b*) The competition plot analysis for Cu(I)/10^{-2} *M* CysSH showing the fitted slope, k_{10} = $1.5 \times 10^9\ M^{-1}\ s^{-1}$ in comparison with the experimental data.

a process which is thermodynamically favoured and occurs quite rapidly for unhindered thiols (6, 15, 16).

Experimental

Pulse radiolysis experiments were performed using the 1.5 MeV Van de Graaff accelerator at the University of Calgary, and the 8 MeV linear accelerator at the Notre Dame Radiation Laboratory. Details for the facilities, the pulse radiolytic methods, and the dosimetry measurements for both systems have been previously described (17, 18). The dose used throughout these experiments was in the range of 4–6 Gray per pulse.

The D-penicillamine free base (99.5%) and L-cysteine (99.5%) were purchased from Sigma Chemical Company. Cuprous and cupric chloride (99.9%) were obtained from Fisher Scientific Company. Other chemicals were the purest available from standard suppliers. All were used as received.

Solutions were prepared from triply distilled, or Millipore Milli-Q water and were buffered using 20 m*M* borax. The pH was adjusted to 10.0 using NaOH and measured with an Orion 811 pH meter, calibrated against Orion reference buffers. All solutions were made by adding the N_2O degassed RSH/buffer solutions to the directly weighed copper chlorides. Unless otherwise stated, the total thiol concentrations used in these experiments were 1.0×10^{-2} *M* cysteine and 1.5×10^{-2} *M* penicillamine. All experiments were performed at 23 ± 2°C and an ionic strength of 0.05.

Radical yields, which are needed for each system where extinction coefficients are to be calculated were determined by using the formula (19):

$$[8] \qquad g_{R^\cdot} = 5.2 + 3.0\left\{\frac{(k[RSH]/\lambda)^{1/2}}{1 + (k[RSH]/\lambda)^{1/2}}\right\}$$

Here $g_{R^\cdot}$ is the yield of radical production (molecules per 100 eV), k is the rate constant for the reaction of $^\cdot$OH with RSH, [RSH] is the concentration of the protonated thiol in the system, and λ is the track recombination coefficient which is equal to $4.7 \times 10^8\ s^{-1}$.

For solutes where the $^\cdot$H atom also reacted to produce a radical, an additional term of +0.55 is added to account for the $^\cdot$H atom contribution (14). Rate constants for the reaction of various solutes with $^\cdot$OH were as follows: penicillamine $k = 5.9 \times 10^9\ M^{-1}\ s^{-1}$ cysteine, $k = 1.8 \pm 0.1 \times 10^{10}\ M^{-1}\ s^{-1}$ (20). The yields obtained for $g_{PenS^\cdot}$ and $g_{CysS^\cdot}$ at pH = 10 were 6.2 ([PenSH] = 2.4×10^{-3} *M*) and 6.5 ([CysSH] = 3.0×10^{-3} *M*), respectively.

Results

1. Oxidation of Cu(I)/CysSH complexes

Overall spectral changes

In the presence of thiolate ions the thiol radical forms disulphide anions ($RS^\cdot$—SR^-), as shown in equilibrium [9]

$$[9] \qquad RS^\cdot + RS^- \underset{k_{-9}}{\overset{k_9}{\rightleftharpoons}} RS^\cdot\text{—}SR^-$$

The magnitude of K_9 for cysteine was determined under our conditions of ionic strength at pH 10 to be 366 ± 27 (21). The absorption of $RS^\cdot$—SR^- is much stronger than that of $RS^\cdot$, and the absorption maximum is shifted: $\epsilon_{RS^\cdot} = 140\ M^{-1}\ cm^{-1}$ at $\lambda_{max} = 340$ nm, and $\epsilon_{RS^\cdot\text{—}SR^-} = 7600\ M^{-1}\ cm^{-1}$ at $\lambda_{max} = 420$ nm (22). Hence in the absence of Cu(I), the absorbance at 420 nm grows very rapidly after the pulse, until equilibrium [9] is established. In the presence of Cu(I) complexes, this growth is still observable (see Fig. 1*a*), but the maximum absorbance at 420 nm is smaller, due to the competition for $RS^\cdot$ between RS^- and the Cu(I) complex in reactions [9] and [10].

$$[10] \qquad RS^\cdot + (\text{Cu(I) complex}) \xrightarrow{k_{10}} \text{products}$$

This competition was not analytically solvable, due to the presence of the back reaction [−9] and the fact that $RS^\cdot$—SR^- also reacts with Cu(I) complexes (see below). However, an approximate analysis by means of the competition kinetics plot shown in Fig. 1*b* indicated that k_{10} was in the range $1–2 \times 10^9\ M^{-1}\ s^{-1}$. The ratio of ϵ^{max}_{420}, the maximum absorbance of $RS^\cdot$—SR^- per initial $RS^\cdot$, calculated from K_9 and [RS^-] and assuming no other reactants, to ϵ^{obs}_{420} has been plotted against

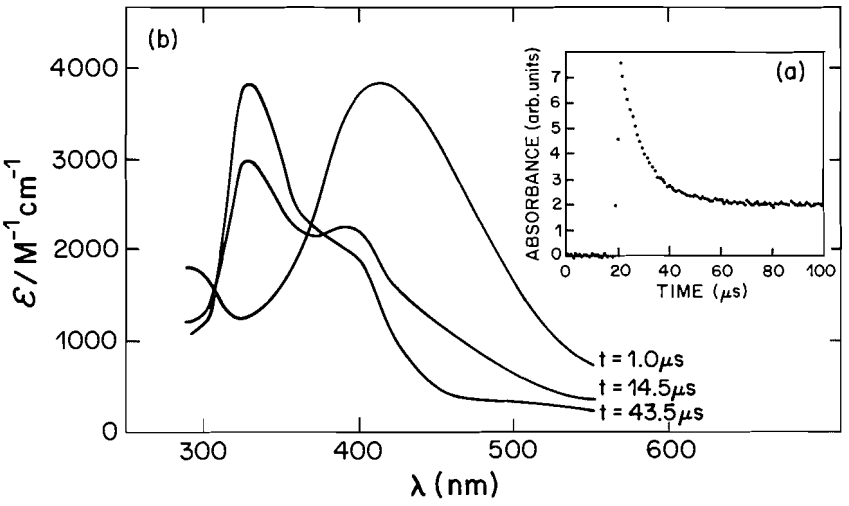

FIG. 2. (*a*) The absorbance growth and decay of a 10^{-3} *M* Cu(I) and 10^{-2} *M* CysSH solution, observed at 420 nm on a 100 μs timescale. (*b*) The time evolution of the spectrum of the same solution on the same timescale.

[Cu(I)]/[RS$^-$] and the slope is an approximate measure of k_{10}/k_9. The value of k_9 used, (9.6×10^8 M^{-1} s^{-1}), was measured under the actual pH and ionic strength conditions, and corrections were made for the proportion of RS$^-$ bound in the copper complexes.

Figure 2*a* shows a trace of the dependence of the absorbance at 420 nm for a 10^{-3} *M* Cu(I) solution over a much longer timescale. It is evident that the absorbance due to the RS$^{\cdot}$—SR$^-$ radical decays beyond the maximum, and this is attributed to the continuing oxidation of Cu(I) complexes via reactions [−9], [10], and other processes (see below). The analysis which follows is based on the assumption that reactions [9] and [−9] are sufficiently rapid that equilibrium [9] was maintained during the decay, and all data were consistent with this.

The time evolution of the spectrum in Fig. 2*b* shows that the initial broad absorbance, centered at 420 nm, disappears to give a more structured absorbance with a peak at 335 nm. This product absorbance extends out to 600 nm, but has a very small extinction coefficient at wavelengths above 470 nm. At 470 nm, there is a large RS$^{\cdot}$—SR$^-$ absorbance ($\epsilon = 6600$ M^{-1} cm^{-1}), no absorbance due to the RS$^{\cdot}$ radical and only a small contribution due to the product. Thus all kinetic measurements of RS$^{\cdot}$—SR$^-$ decay were done at this wavelength.

Kinetics of the 340 nm growth

To follow the kinetics of the growth, observed at 340 nm, it was necessary to subtract the absorbance of the sulphur radical species at this wavelength from the total absorbance. This contribution can be calculated from the absorbance at 470 nm and the ratio of the absorbance of the sulphur species at 470 nm and 340 nm, obtained from an identical experiment with no Cu(I). It was in fact demonstrated, from the intensities at 1.0 μs, that more than 95% of the initial absorbance at 340 nm was due to sulphur radical species.

An example of the corrected growth at 340 nm as a function of time is shown in Fig. 3. This cannot be fitted with a single first order growth plot. There are two distinct processes, one being fast and the other much slower. When the Cu(I) concentration was varied over the range (2.0–10.0) $\times 10^{-4}$ *M*, the total absorbance per unit dose and the spectrum at long times remained constant. However, the proportion of absorbance due to the fast and the slow processes changed, the amount of the slower component becoming more important at higher Cu(I) concentrations. The rate of the fast component also became faster, while there was no visible effect on the rate of the slow component. The latter was fitted by a first order rate constant, k_s, with a value of $(2.6 \pm 0.1) \times 10^4$ s^{-1}.

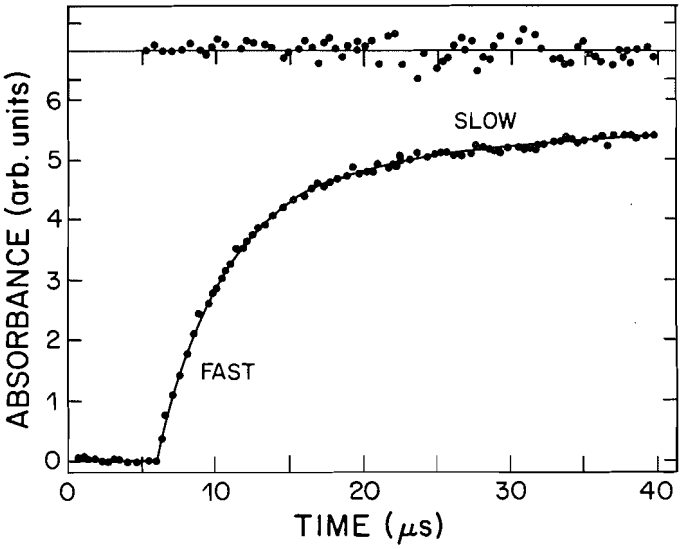

FIG. 3. Example of the growth kinetics seen at 340 nm for 10^{-3} *M* Cu(I) solution in 10^{-2} *M* CysSH. The solid line and residuals plotted on an arbitrary scale at the top of the diagram show the agreement obtained on fitting the sum of two first order growths to this data.

The 340 nm absorption growth was found to be fitted excellently by the sum of two exponentials (see fitted line and residuals in Fig. 3):

$$F = A[1 - \exp(-k_f t)] + B[1 - \exp(-k_s t)]$$

The two parameters, *A* and *B*, were related to the proportions of the fast and slow components. These two variables, and the fast growth rate constant, k_f, were obtained iteratively by a non-linear χ^2 minimisation routine (23) on an IBM PC, with the k_s rate constant being fixed at its measured value. This was done for all Cu(I) concentrations. The subtraction of the sulphur radical absorbance at 340 nm before the fitting of the 340 nm peak growth was found to be very important. When this was not

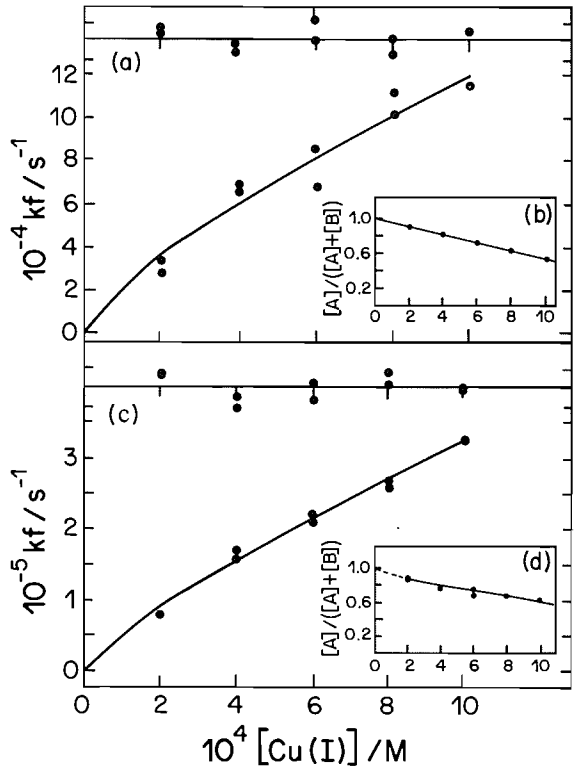

FIG. 4. (*a*) The Cu(I) concentration dependence of the fitted k_f rate constants for Cu(I)/10^{-2} *M* CysSH solutions. The solid line and residuals plot show the agreement of the experimental data and the values predicted using the appropriate equilibrium and rate constants from Table 1. (*b*) The Cu(I) concentration dependence of the ratio of the fast growth component intensity to the total intensity under the same conditions. (*c*) and (*d*) As for (*a*) and (*b*), respectively, but for Cu(I)/1.5 × 10^{-2} *M* PenSH solutions.

done, good fits could not be obtained, and the fast component rate constants were in error by up to 75%. The k_f rate constants obtained by this technique for a fixed total cysteine concentration of 10^{-2} *M* are shown in Fig. 4*a*, as a function of the total Cu(I) concentration. The ratio of the intensity of the fast process to the total intensity, over the same Cu(I) range, is shown in Fig. 4*b*.

The proportion of the fast component of the growth in Fig. 4*b* is seen to increase towards unity as the Cu(I) concentration falls. This feature suggests that the slow component is due to the presence of different Cu(I) species at higher concentrations. As stated in the Introduction, species **I** should dominate at low Cu concentrations, while species **II** should become important as the Cu concentration and the ratio of Cu to sulphydryl is raised. Thus it appears that the slow growth component has to be attributed to reactions with species **II**.

In the previous work of Bagiyan *et al.* (2) it was found that only a single Cu(I) species was formed when a Cu(I):sulphydryl ratio of less than 5 × 10^{-3} was used. In the data of Fig. 4, that ratio was (1.3–6.7) × 10^{-2}. Thus two or more Cu(I) species could have been present, which would explain the effects observed when the Cu(I) concentration was increased. Experiments to determine whether a slow growth component could be seen from species **I** were therefore performed, using Cu(I):cysteine ratios of (6–13) × 10^{-4}. Under these conditions Cu(I).L_2 would be the only initial species, and the oxidation processes should be

TABLE 1. Summary of equilibrium and rate constants*

Parameter	Value	
	Cu(I)/CysSH	Cu(I)/PenSH
K_1	162 ± 23	113 ± 14
K_9/M^{-1}	366 ± 27	16 ± 1
$k_{11a}/M^{-1}\,s^{-1}$	1.8 ± 0.1 × 10^9	4.5 ± 0.5 × 10^8
$k_{11b}/M^{-1}\,s^{-1}$	2.7 ± 0.1 × 10^8	< 2 × 10^8
$k_{12}/M^{-1}\,s^{-1}$	1.0 ± 0.3 × 10^9	5.5 ± 0.3 × 10^8
k_{13b}/s^{-1}	2.6 ± 0.1 × 10^4	1.1 ± 0.1 × 10^4

*Standard deviations were derived from the fitting procedures described in the text. Temperature, 296 ± 2 K: ionic strength, 0.05; and pH, 10.0.

[11*a*] $RS^{\cdot} + Cu(I).L_2 \xrightarrow{k_{11a}} RS^- + Cu(II).L_2$

and/or

[11*b*] $RS^{\cdot}—SR^- + Cu(I).L_2 \xrightarrow{k_{11b}} 2RS^- + Cu(II).L_2$

Writing $\theta = K_9[RS^-]$, a kinetic analysis shows

$$k_f = \{k_{11a} + k_{11b}\theta\}[Cu(I).L_2](1 + \theta)^{-1}$$

Thus a plot of $(1 + \theta)k_f$ versus θ, which can be varied by changing the total RSH concentration, should give a straight line of intercept k_{11a}[Cu(I).L_2] and slope k_{11b}[Cu(I).L_2]. This is shown for 20 μM Cu(I).L_2 in Fig. 5*a*, from which one finds $k_{11a} = 1.8 \times 10^9\,M^{-1}\,s^{-1}$ and $k_{11b} = 2.7 \times 10^8\,M^{-1}\,s^{-1}$.

Further experiments over the [Cu(I).L_2] range 10–30 μ*M* with a CysSH concentration of 10^{-2} *M* established that the growth at 340 nm could be fitted excellently by using single first order kinetics. Another important point was that the pseudo first order rate constants for the 340 nm growths and the 470 nm decays were identical. The overall second order rate constant for the combined oxidation by $RS^{\cdot}$ and $RS^{\cdot}—SR^-$ was found from the slope of a plot of the pseudo first order constants versus [Cu(I).L_2] to be 4.6 × $10^8\,M^{-1}\,s^{-1}$. This corresponds to $\{k_{11a} + k_{11b}\theta\}(1 + \theta)^{-1}$ and is in good agreement with k_{11a} and k_{11b} above.

Returning to the higher Cu(I) concentrations, where species **II** is present, one must also consider the oxidation reactions:

[12*a*] $RS^{\cdot} + Cu(I)_2.L_3 \rightarrow RS^- + Cu(I).Cu(II).L_3$

[12*b*] $RS^{\cdot}—SR^- + Cu(I)_2.L_3 \rightarrow 2RS^- + Cu(I).Cu(II).L_3$

However, due to the greater steric hindrance expected in species **II** and the small value of k_{11b} relative to k_{11a}, it was assumed that k_{12b} would be negligibly small.

Because of the higher affinity of Cu(II) for the bidentate ligands (24), the mixed product of reaction [12*a*] would not be expected to be stable under our conditions. Thus the slow process could be explained by reactions [13*a*] and [13*b*], which involve the addition of a fourth ligand, followed by a dissociative rearrangement.

[13*a*] $Cu(I).Cu(II).L_3 + L \rightarrow Cu(I).Cu(II).L_4$

[13*b*] $Cu(I).Cu(II).L_4 \rightarrow Cu(I).L_2 + Cu(II).L_2$

There is an alternative reaction pathway, in which the oxidising $RS^{\cdot}$ radical would add to the complex upon Cu(I) oxidation to form the species Cu(I).Cu(II).L_4 directly:

[12*c*] $RS^{\cdot} + Cu(I)_2.L_3 \rightarrow Cu(I).Cu(II).L_4$

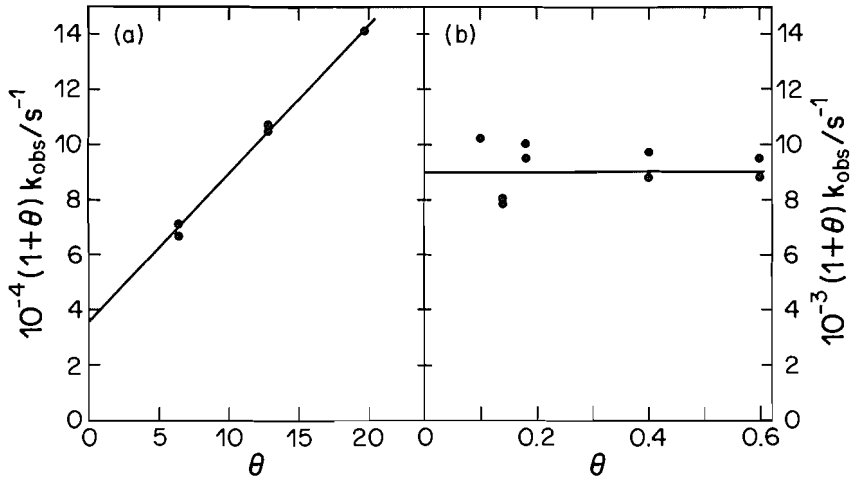

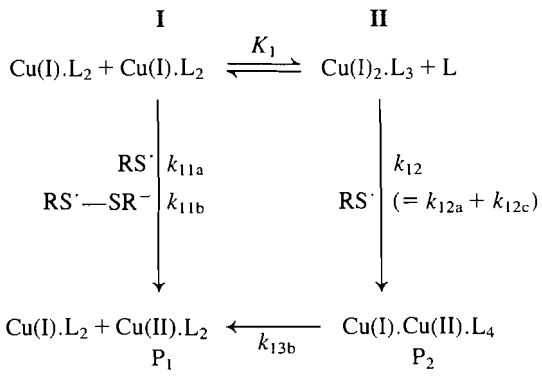

FIG. 5. (*a*) The determination of the rate constants k_{11a} and k_{11b} for 20 μ*M* Cu(I)/CysSH solutions. (*b*) As for (*a*) but for 20 μ*M* Cu(I)/PenSH solutions.

However, as the RS^- concentration is high, reaction [13*a*] would be rapid, and the slow process, k_s, would mainly reflect the ligand rearrangement (reaction [13*b*]). This was confirmed in experiments where the RS^- concentration was varied over the range 4.6×10^{-3} *M* to 3.0×10^{-2} *M* with no change in the slow step reaction rate constant being observed. Since it was not possible to distinguish between these two formation pathways, only a single Cu(I).Cu(II) intermediate, with four co-ordinating ligands, was used in the reaction mechanism. In schematic form, this is given by:

SCHEME 1

From this mechanism, the first order rate constant for the fast growth seen at 340 nm, which is assumed to result from the direct oxidation, is given by

$$[14] \quad (1 + \theta)k_f = (k_{11a} + k_{11b}\theta)[\mathbf{I}] + k_{12}[\mathbf{II}] = k_{11}^*[\mathbf{I}] + k_{12}[\mathbf{II}]$$

From equilibrium [1], (with constant K_1) and the mass balance equation [15],

$$[15] \quad [\mathbf{I}] + 2[\mathbf{II}] = [Cu]$$

we can write the values of [**I**] and [**II**] in terms of K_1:

$$[16] \quad k_f = k_{11}^*\left\{\frac{([RS^-]^2 + 8K_1[Cu][RS^-])^{1/2} - [RS^-]}{4K_1}\right\} + k_{12}\left\{\frac{(4K_1[Cu] + [RS^-]) - ([RS^-]^2 - 8K_1[Cu][RS^-])^{1/2}}{8K_1}\right\}$$

This expression was fitted to the total Cu(I) concentration dependence of the measured k_f values for a total CysSH concentration of 10^{-2} *M*. The RS^- concentration available for reaction [9] was corrected for the amount of thiol bound in the Cu(I) complexes by subtracting a value of $1.7 \times$ [Cu(I)] from the initial RS^- concentration. This was an "averaged" value, because the amount of complexed thiol depended on the relative concentrations of the species present. If all the Cu(I) were in the species **I** form, then the correction would be $2 \times$ [Cu(I)], and, if there were only species **II** present, it would be $1.5 \times$ [Cu(II)]. Knowing this and the value of k_{11}^*, a non-linear fitting routine (algorithms and programs taken from ref. 23) was used to determine the best values for K_1 and k_{12}. The values, which have been included in Table 1, were $K_1 = 162$ and $k_{12} = 1.0 \times 10^9\ M^{-1}\ s^{-1}$. Varying the RS^- concentration correction ratio from 1.5 to 2.0 had no effect on k_{12a} and gave only a 3% change in the equilibrium constant. This uncertainty was small in comparison to the standard deviations in K_1 and k_{12a}, which were derived from the fitting procedure and are shown in Table 1. The solid line in Fig. 4*a* shows the values of k_f predicted from the determined k_{11}^*, k_{12}, and K_1 values. The agreement with the experimental points is good.

At the higher Cu(I) concentrations, changing the RS^- (or L) concentrations affects the ratio of species **I** and **II**, as well as the values of θ. Values of k_f predicted from the parameters in Table 1 and eq. [14] for total [RSH] of 6, 10, 20, and 40 m*M* were 19, 14, 11, and $10 \times 10^4\ s^{-1}$, respectively. The good agreement with the observed values of 19, 13, 11, and $9 \times 10^4\ s^{-1}$ substantiates the stoichiometry of equilibrium [1].

The spectrum of the intermediate

The spectrum of the intermediate complex Cu(I).Cu(II).L_4 can now be determined. This was done most accurately from the 1.0×10^{-3} *M* Cu(I)/1.0×10^{-2} *M* Cys solution as it gave the highest concentration of species **II**. The unresolved spectrum at 43.5 μs is shown in Fig. 2*b*. At this time the absorbance observed at 470 nm had reached a limiting value, and thus the $RS^{\cdot}$—SR^- radical decay was judged to be complete. It was assumed that the Cu(I).L_2 and Cu(I)$_2$.L_3 concentrations did not change significantly from their initial equilibrium values on the radical reaction timescale. As the total change in the concentrations of the two Cu(I) species is very small, at worst 3.8 and 1.0% (assuming total reaction of the initial $RS^{\cdot}$

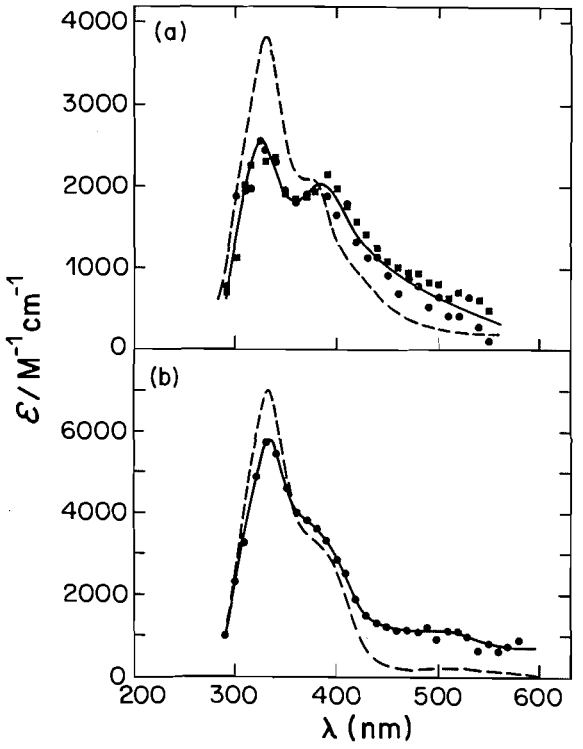

FIG. 6. (*a*) Comparison of the cysteine P_2 intermediate spectrum with the 500 μs final product spectrum (---) in a 10^{-3} *M* Cu(I)/10^{-2} *M* CysSH solution. (●) Determination of intermediate spectrum from data at t = 29.0 μs. (■) Determination from t = 43.5 μs. (*b*) Comparison of the penicillamine P_2 intermediate spectrum (●) determined from data at 43 μs in a 10^{-3} *M* Cu(I)/1.5×10^{-2} *M* PenSH solution with the spectrum of Cu(II).L_2 of penicillamine taken on a Cary 219 spectrophotometer (---).

radical concentration, 4.8 μ*M*, with species **I** (1.26×10^{-4} *M*) or species **II** (4.37×10^{-4} *M*) respectively), this appears reasonable.

A Runge–Kutta differential equation-solving program (23) was then used to calculate the time dependence of the concentration of all the species in these reactions until the time, 43.5 μs, had been reached. At this time, the concentrations of the final (P_1) and intermediate (P_2) products, relative to the initial RS· concentration, were 0.786 and 0.208, respectively. The unreacted sulphur radicals accounted for the small remaining fraction.

The spectrum of the P_2 intermediate is given by

$$\epsilon_{P_2} = \frac{\epsilon_{43.5\,\mu s} - 0.786\epsilon_{P_1}}{0.208}$$

and is shown in Fig. 6*a*, in comparison to the 500 μs spectrum where the spectrum was essentially stable. The intermediate spectrum is structured, and shows two distinct peaks at low wavelengths (326 nm, ϵ = 2480 M^{-1} cm^{-1} and 390 nm, ϵ = 1980 M^{-1} cm^{-1}) and an absorbance tailing into the visible.

The reliability of this method for determining intermediate spectra was checked by repeating the calculation at 29.0 μs. Under the same initial conditions, the P_1 and P_2 fractions were 0.680 and 0.298, respectively, with 0.02 remaining in the RS·/RS·—SR$^-$ form. In this instance, the remaining radical fraction had a significant absorbance, which also had to be subtracted from the intermediate spectrum. This calculated spectrum is also shown in Fig. 6*a*. Although there was some scatter at the higher wavelengths, the agreement between the two determinations confirms the validity of the results obtained.

Kinetics of the 470 nm decay

Further evidence supporting the proposed reaction mechanism can be obtained from the RS·—SR$^-$ absorbance decay observed at 470 nm. The absorbance at any time t, $A_{470,t}$, is given by:

$$A_{470,t} = \epsilon_{RS\cdot\text{—}SR^-}[RS\cdot\text{—}SR^-] + \epsilon_{P_2}[P_2]$$

This expression can now be solved explicitly, in terms of known parameters. Since we are observing the decay of the RS·—SR$^-$ radical,

$$[RS\cdot\text{—}SR^-] = K_9[SR^-][RS\cdot] \quad \text{from [9]}$$
$$= \theta[RS\cdot]$$

Therefore

$$\frac{d[RS\cdot\text{—}SR^-]}{dt} = \frac{d\theta[RS\cdot]}{dt} = \theta\frac{d[RS\cdot]}{dt}$$

and

$$(1 + \theta)\frac{d[RS\cdot]}{dt} = \{k_1^*[\mathbf{I}] + k_{12}[\mathbf{II}]\}[RS\cdot]$$

giving

[17] $$[RS\cdot] = [RS\cdot]_0[\exp(-k_f t)]$$
and $$[RS\cdot\text{—}SR^-] = \theta[RS\cdot]_0[\exp(-k_f t)]$$

The rate expression for the P_2 species is:

$$\frac{d[P_2]}{dt} = k_{12}[\mathbf{II}][RS\cdot] - k_{13b}[P_2]$$

i.e.

$$\frac{d[P_2]}{dt} + k_{13b}[P_2] = k_{12}[\mathbf{II}][RS\cdot]_0[\exp(-k_f t)]$$

and on integration this yields:

[18] $$[P_2] = \frac{k_{12}[\mathbf{II}][RS\cdot]_0}{(k_f - k_{13b})}\{[\exp - k_{13b}t] - [\exp(-k_f t)]\}$$

Thus the absorbance at 470 nm is given by:

[19] $$A_{470,t} = \left\{\epsilon_{RS\cdot\text{—}SR^-}\theta[RS]_0 - \frac{\epsilon_{P_2}k_{12}[\mathbf{II}][RS\cdot]_0}{(k_f - k_{13b})}\right\}\{\exp(-k_f t)\} + \left\{\frac{\epsilon_{P_2}k_{12}[\mathbf{II}][RS\cdot]_0}{(k_f - k_{13b})}\right\}\{\exp(-k_{13b}t)\}$$

This analysis shows that the decay seen at 470 nm is composed of two exponential decays, with rate constants the same as those calculated from the 340 nm growth data, i.e.

[20] $$A_{470,t} = A'[\exp(-k_f t)] + B'[\exp(-k_s t)]$$

When these rate constants were substituted into eq. [20], it was found that the 470 nm decays fitted well over the entire range of Cu(I) concentrations used.

When allowance is made for the small absorbance due to the Cu(II) product, and the decay rate constants are fixed at the values determined from the 340 nm data, the parameters A' and B' can be calculated. In terms of extinction coefficients one has:

$$B' = \frac{\epsilon_{P_2}k_{12}[\mathbf{II}]}{(k_f - k_{13b})}[RS\cdot]_0$$

This enables ϵ_{P_2} at 470 nm to be determined. The value obtained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

by this method for the 10^{-3} *M* Cu(I) solution was $\epsilon_{P_2} = 780 \pm 100\ M^{-1}\,cm^{-1}$, which agrees very well with the value of $\epsilon_{P_2} = 850\ M^{-1}\,cm^{-1}$ from the calculated spectrum.

The rate constants, and the other values for this system, have been summarized in Table 1.

II. Cu(I)/PenSH oxidation

Similar oxidation experiments were also performed for the aminothiol 2,2-dimethyl cysteine (penicillamine). The major difference between these two thiols was in the magnitude of their K_9 values, the measured value for PenSH being only 16 ± 1 (21). The large value for cysteine ($K_9 = 366 \pm 27$) meant that most of the radicals in the irradiated solution existed in the dimer form $RS^{\cdot}—SR^{-}$ (74% at 1.0×10^{-2} *M* thiol). Because of this and the small value of k_{11b}, reaction [−9] would have been an important process in the Cu(I) oxidation. In contrast the lower K_9 for penicillamine meant that almost all the radicals were in the $RS^{\cdot}$ form (84% at 1.5×10^{-2} *M* thiol), and hence reaction [−9] would have little role in the oxidation.

The Cu(II).L_2 spectrum of PenSH taken on a Cary 219 spectrophotometer was found to be structured, with a peak at 330 nm, and very little absorbance above 470 nm (see Fig. 6*b*). For consistency, the wavelengths 340 nm and 470 nm were again used for kinetic measurements. The decay at 470 nm again showed a limiting baseline and its intensity was larger than for cysteine.

The subtraction of the 470 nm time profile from the kinetic data at 340 nm was also important for this system. After subtraction the 340 nm absorbance was again shown to consist of a fast and a slow growth process. Over the Cu(I) range studied, $(2–10) \times 10^{-4}$ *M*), the slow growth rate constant was $= 1.1 \pm 0.1 \times 10^4\ s^{-1}$, and independent of Cu(I) concentration.

Using the determined k_s value, the fast growths at 340 nm and the proportions of the fast and slow processes were determined as for cysteine, and are shown in Figs. 4*c* and 4*d*. Due to the smaller values of θ the k_f rate constants obtained are much faster than those for cysteine (cf. Fig. 4*a*). Also the dependence of the k_f values on Cu(I) concentration was more linear for penicillamine than for cysteine.

As the 340 nm data in penicillamine exhibited the same kinetic characteristics as seen for cysteine, the same reaction mechanism was assumed to apply in this system. In experiments conducted at very low Cu(I) concentrations (10–30 μ*M*) the 340 nm absorbance was excellently fitted by single first order growth kinetics, confirming that the slow component reaction was again due to radical reaction with the dimer Cu(I) complex, species **II**. The pseudo first order growth rate constants at 340 nm were also identical to the decay rate constants at 470 nm.

The rate of oxidation of Cu(I).L_2 was determined from the dependence of $(1 + \theta)k_f$ on θ shown in Fig. 5*b* for 20 μ*M* Cu(I).L_2 and varying the [PenSH]. Because of the smaller value of K_9, the accessible range of θ was limited to 0.1 to 0.6. Over that range the experimental data exhibited no dependence on θ, within the scatter of data points, from which one can show that $k_{11b} < 2 \times 10^8\ M^{-1}\ s^{-1}$. The intercept leads to $k_{11a} = (4.5 \pm 0.5) \times 10^8\ M^{-1}\ s^{-1}$, which is significantly smaller than for cysteine (cf. $(1.8 \pm 0.1) \times 10^9\ M^{-1}\ s^{-1}$). The same value was obtained from a plot of the pseudo first order rate constants for 340 nm growth and 470 nm decay vs. [Cu(I)] for values below 30 μM.

The K_1 and k_{12} values were determined by applying eq. [16] to the k_f data of Fig. 4*c*. In this instance, the thiolate ion concentration correction was given by $(1.50 \times 10^{-2} - 1.7 \times$ [Cu(I)]) *M*, and the best fit values were $K_1 = 113$ and $k_{12} = (5.5 \pm 0.3) \times 10^8\ M^{-1}\ s^{-1}$.

The spectrum of the intermediate was determined from the 1.0×10^{-3} *M* Cu(I)/1.5×10^{-2} *M* penicillamine solution, as before, and is seen in Fig. 6*b*. Once again, we can confirm the extinction coefficient at 470 nm obtained from the Runge Kutta simulation, $1200\ M^{-1}\,cm^{-1}$, by looking at the kinetic 470 nm decays. Fitting the two known rate constants, and determining the *B'* parameter, gives ϵ_{P_2} as $1100 \pm 200\ M^{-1}\,cm^{-1}$, which is in very good agreement with the other value.

The kinetic parameters are shown in comparison to the Cu(I)/CysSH data in Table 1.

Discussion

1. Characterisation of Cu(I) species

The fact that the 340 nm growth and 470 nm $RS^{\cdot}—SR^{-}$ decays for both amino thiols were fitted by a single kinetic process for total Cu(I) concentrations of 10–30 μ*M* is consistent with the presence of one type of Cu(I) complex. The observation of a long-lived intermediate, which became increasingly important at higher Cu(I) concentrations (see Figs. 4*b* and 4*d*), and the fact that the fast growth became non-linear in total [Cu(I)] represents unequivocal evidence for the presence of additional Cu(I) species with different kinetics of oxidation by $RS^{\cdot}$ and $RS^{\cdot}—SR^{-}$ radicals.

In the preceeding section the data for cysteine and penicillamine have been shown to be consistent with parameters in Table 1 for species **I** and **II**, which exist in an equilibrium as proposed by Bagiyan *et al.* (2). The characterisation of Cu(I)–thiolate complexes by titrimetry and ultraviolet spectroscopy, which have previously been used (2, 3), is a difficult and involved process. Thus independent evidence from the present kinetic observations for two of the copper species proposed by Bagiyan *et al.* is a very significant contribution. The larger polynuclear complexes proposed by them are not required to explain the present data for pH 10 up to 10^{-3} *M* [Cu(I)]. However, they may be present in small concentrations.

Bagiyan *et al.* did not report K_1 for penicillamine or cysteine. Their value for cysteamine is somewhat larger (2000) than those in Table 1. However, that may be caused by a reduction in the stability of Cu(I)$_2$.L_3, as this complex bears a −4 charge for penicillamine and cysteine, as opposed to −1 for cysteamine.

2. The long-lived products of reaction

As shown by the dashed line in Fig. 6*b*, the spectrum of Cu(II).L_2 for L = PenSH, taken on a Cary 219 spectrophotometer, consisted of two unresolved peaks centered at 370 nm, and an absorbance tail extending from 440 to 600 nm. These features are typical of a thermally equilibrated square planar Cu(II) with thiolate ligands (4, 5). The strong peaks are attributed to $RS^{-}(\sigma) \rightarrow$ Cu(II)(*d*) charge transfer transitions, while the tail probably contains bands due to $RS^{-}(\pi) \rightarrow$ Cu(II)(*d*) and Cu(II)($d \rightarrow d$) transitions (7). The Cu(I) species used here do not absorb significantly above 300 nm (2).

The systematic studies of Bosnich and co-workers (7) have shown that distortion from the square planar geometry causes significant changes in the absorption spectrum. For example, for a tetrahedral geometry, which is expected for the initial Cu(I) thiolate environment, the $RS^{-}(\sigma) \rightarrow$ Cu(II)(*d*) bands are red-shifted to the 400 to 500 nm range. In the present systems, the dominant feature of the spectra of all long-lived products at 500 μs was the strong unresolved double peak at 370 nm, confirming that on that time scale the main product was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

$Cu(II).L_2$ with the thiolate ligands close to their equilibrium square planar configurations. This has been illustrated in Fig. 6*a* for cysteine, the 500 μs product spectrum of which is shown by the dashed line.

Similar conclusions relating to the nature of the long-lived products were reached in ref. 12. The present study has concentrated on establishing the mechanism of reaction and the origin of the slow growth component of the 340–380 nm absorbance in the absence of chloride ion, which nucleates the formation of Cu(I)–Cu(II) mixed valence clusters (8, 9). Further work will be required to determine whether Cl^- affects the mechanism of oxidation.

3. Oxidation of $Cu(I).L_2$

The kinetic analysis for the 10–30 μM Cu(I) solutions showed the 340 nm growths and the 470 nm radical decays to be identical. This means that the initial product of oxidation of species **I** by $RS^\cdot$ and $RS^\cdot$—SR^- must rearrange from the Cu(I) geometry (see structure **I**) to the square planar configuration of Cu(II) on a time scale of $\sim 10^{-5}$ s or less. Also any Cu(I).L.$RS^\cdot$—SR^- complex, formed by the addition of $RS^\cdot$ to an RS^- ligand, must be similarly short lived. When allowance is made for ionic strength and the charges of the $RS^\cdot$ and $Cu(I).L_2$ reactants (−1 and −3, respectively), it is evident that reaction [11*a*] for cysteine is a diffusion controlled process with an interaction distance of about 0.6 nm.[1] The negative free energy of reaction is significant ($E^0_{RS^\cdot/RS^-} = 0.8$ V (13), $E^0_{Cu(II)/(Cu)(I)} \sim 0.2$ V (footnote 2)) and the process may occur via an outer sphere mechanism. With penicillamine the free energy change will be similar, but the β-methyl groups in both the $RS^\cdot$ and the copper bound ligand will create steric effects, which would restrict the approach of $RS^\cdot$ to the S—Cu—S centres. This appears to reduce the value of k_{11a} by a factor of about 4 (see Table 1).

The present experiments appear to be the first in which rates of oxidation of a metal centre by $RS^\cdot$ and $RS^\cdot$—SR^- have been separately delineated. The driving force for reaction [11*b*] is about 0.2 V lower than that of [11*a*], since $E^0_{RS^\cdot—SR^-/2RS^-}$ (0.6 V (13)) is smaller than $E^0_{RS^\cdot/RS^-}$. However, due to the presence of the second R group, $RS^\cdot$—SR^- is much larger than $RS^\cdot$ and this should exert a steric effect, which could also reduce the rate of reaction [11*b*]. For cysteine the value of k_{11b} is about six fold less than k_{11a}, but still significant.

4. Oxidation of $Cu(I)_2.L_3$

As in the case of $Cu(I).L_2$, the rate constant for oxidation of $Cu(I)_2.L_3$ by $RS^\cdot$ in the cysteine system was effectively diffusion controlled. The rate for the penicillamine system was a factor of two slower, which again can be attributed to steric effects caused by the presence of β-methyl groups. The smaller value of k_{13b} for penicillamine (see Table 1) shows that they also hinder the dissociation/rearrangement of the $Cu(I).Cu(II).L_4$ intermediate.

A consideration of molecular models of $Cu(I)_2.L_3$ showed that structures which yielded optimal ligand interactions did not provide identical geometries of the two Cu(I) atoms. Furthermore, the Cu site with the greatest number of ligand interactions was (obviously) the least accessible to $RS^\cdot$ or $RS^\cdot$—SR^-, and at the same time, the one able to afford the greatest stabilisation of the excess positive charge, following oxidation of the S—Cu—S—Cu—S system. The Cu(b) site in structure **II** (see Introduction) illustrates these points. This structure was drawn to maximise the Cu(I)–L interactions and minimise steric and coulombic repulsions.

Formation of the intermediate in reaction [12*a*] should lead immediately to localisation of excess positive charge at the Cu(b) site.[3] A Cu(II) geometry close to square planar could subsequently be achieved by a simple rotation of L(b). The result is a Cu(I)–Cu(II) mixed valence compound with a bridging thiolate ligand, and it is of interest to compare the spectra of the present intermediates with those of two systems of this type, which have been reported in the literature.

The mercaptosuccinic acid complexes are of stoichiometry [Cu(I)—RS^-]$_4$Cu(II) (26). Those of the bidentate 1,2-amino-thiols-2,2 dimethyl-β-mercaptoethylamine and penicillamine, which are also stable in solution, have been shown by crystallographic examinations to form $(Cu(I))_8(Cu(II)_6(^-SC(Me)_2CH(R)NH_2)_{12}$ networks around a Cl^- core (8, 9, 27). Every thiolate is coordinated to two of the eight Cu(I) ions, and also to a Cu(II). The Cu(II) ions are in square planar configuration with overall S_2N_2 coordination by two amino thiols. Both systems have absorption maxima at 520 nm. These are attributed to charge transfer transitions from the Cu(I)-complexed RS^- electrons to Cu(II)(d), and have absorbance coefficients per RS^- of $\sim 1000\ M^{-1}\ cm^{-1}$ (9, 15, 27). Neither system has any non-Cu(I)-coordinated RS^- and there are therefore no strong absorbances of the kind seem here at 340–380 nm.

The main characteristics of the P_2 spectra in Fig. 6 can now be explained. The spectrum for penicillamine in Fig. 6(*b*) shows clear evidence of a shoulder at 520 nm, which is more intense than the d → d bands of the $Cu(II)L_2$ product (dashed line) and is of the intensity expected for a [Cu(I)RS^-] → Cu(II)(d) transition. The data for cysteine are more scattered, but also exhibit significant absorbance at 520 nm. At the same time, for both ligands, the absorbances in the 340–380 nm region are diminished from those of $Cu(II).L_2$, as would be expected since only one non-Cu(I)-coordinated thiolate is now present per Cu(II).

More specific characteristics, such as the quantitative features and differences between the spectra for the cysteine and penicillamine ligands, cannot be accounted for until more precise structural information is obtained. However, the steric hindrance of the methyl groups in penicillamine may cause a preference for different orientations of the complexes. Also, it is conceivable that with cysteine there is significant addition of $RS^\cdot$ radicals at Cu(a) (see structure **II**) in reaction [12*c*], which could lead to a Cu(II) coordination that is not S_2N_2 square planar. This would account for the greater distortion of the 340–380 nm bands seen in P_2 of Fig. 6*a*.

Coordination compounds of indium. Part 45. Indium(I) derivatives of aromatic diols

HASSAN E. MABROUK AND DENNIS G. TUCK
Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received August 18, 1988

HASSAN E. MABROUK and DENNIS G. TUCK. Can. J. Chem. **67**, 746 (1989).

The electrochemical oxidation of anodic indium in acetonitrile solutions of the aromatic diols $R(OH)_2$ (= 1,2-dihydroxybenzene; 2,3-dihydroxynaphthalene; 2,2′-dihydroxybiphenyl; 1,2-dihydroxytetrabromobenzene) yields the new compounds In[OR(OH)]. These unusual indium(I) species can be oxidized by iodine to $In^{III}I_2[OR(OH)]$, and by the *ortho*-quinone $Br_4C_6O_2$ to $In^{III}[OR(OH)](O_2C_6Br_4)$. The hydroxy–oxo ligand can be deprotonated by Et_3N to give the salts $Et_3NH[In(O_2R)]$. The nature of these reactions, and the structure of the initial products, are confirmed by infrared and ^1H nmr spectroscopy.

Key words: indium, electrochemistry, oxidation, aromatic diols.

HASSAN E. MABROUK et DENNIS G. TUCK. Can. J. Chem. **67**, 746 (1989).

L'oxydation electrochimique de l'indium anodique, dans des solutions d'acétonitrile des diols aromatiques $R(OH)_2$, (= dihydroxy-1,2 benzène; dihydroxy-2,3 naphtalène; dihydroxy-2,2′ biphényl; dihydroxy-1,2 tétrabromobenzène), fournit de nouveaux composés In[OR(OH)]. Sous l'influence de l'iode, ces espèces inusitées de l'indium(I) peuvent être oxydées en $In^{III}I_2[OR(OH)]$ alors que sous l'influence de l'*ortho*-quinone $Br_4C_6O_2$ il y a formation de $In^{III}[OR(OH)](O_2C_6Br_4)$. Le ligand hydroxy-oxo peut être déprotoné par la base Et_3N pour donner les sols $Et_3NH[In(O_2R)]$. En se basant sur les specroscopies infrarouge et rmn du ^1H, on a confirmé la nature de ces réactions ainsi que la structure des produits initiaux.

Mots clés : indium, électrochimie, oxydation, diols aromatiques.

The coordination chemistry of indium(I) received little or no attention for many years, largely no doubt because of the lack of suitable synthetic materials. Relatively few simple salts have been described, and the four monohalides, together with the oxide In_2O and sulphide In_2S, are the only known binary compounds. These substances are not very satisfactory as the starting point of synthetic work, but the situation was improved significantly by the discovery that the chloride, bromide, and iodide form solutions, stable at low temperatures, in mixtures of aromatic solvents and neutral donors (1). The oxidative addition reactions of indium(I) halides in such media have been investigated (2–6). Cyclopentadienylindium(I), InCp, is also a useful compound synthetically, since it is soluble in a number of organic solvents, and it is relevant to the present work to note that the reaction of InCp with β-ketoenolates such as 4,4,4-trifluoro-1-(thiene-2′-yl)butane-1, 3-dionate (ttaH) in ether/benzene mixtures gave the extremely hygroscopic indium(I) derivatives (e.g., In(tta)), and analogous derivatives of other bidentate chelating monoanionic ligands were also obtained by the metathetical reaction $InCp + HL \rightarrow InL + C_5H_6$ (7).

We have now found that the electrochemical oxidation of anodic indium in non-aqueous solutions of aromatic diols $R(OH)_2$ (= 1,2-dihydroxybenzene; 2,3-dihydroxynaphthalene; 2,2′-dihydroxybiphenyl; 1,2-dihydroxytetrabromobenzene) gives rise to the unusual indium(I) compounds In[OR(OH)], which are derivatives of the corresponding oxophenolate anions. These compounds undergo oxidative addition reactions with I_2 to give $In^{(III)}I_2[OR(OH)]$, and with the substituted *ortho*-quinone $Br_4C_6O_2$ in the presence of 2,2′-bipyridine (bpy) to form the corresponding $In[OR(OH)](O_2C_6Br_4)bpy$.

Experimental section

General

Indium metal (Alfa, m4N) was beaten into a thin sheet 1 × 1 cm^2 to form the anode of the cell. Acetonitrile, diethyl ether, and benzene were dried and distilled before use, and stored over drying agents. All other substances including the aromatic diols listed above, tetrabromo-*o*-quinone, and 2,2′-bipyridine (Aldrich), were used as supplied.

Infrared spectra were run as KBr discs on a Nicolet 5DX spectrometer, and ^1H nmr spectra were recorded on a Bruker W-80 instrument. Conductivity measurements were performed with a YSI Model 31 conductivity bridge and a conventional cell calibrated with 0.1 mol L^{-1} aqueous KNO_3 solution.

Indium analysis was by atomic absorption spectrophotometry, using an IL-250 instrument, and halogen analysis by Volhard titration. Carbon, hydrogen, and nitrogen microanalyses were by the Guelph Chemical Laboratories Ltd.

Electrochemical techniques

The preparative electrochemistry followed the techniques described elsewhere (8–10). The cell consisted of a 100 mL tall-form beaker containing an acetonitrile solution of the parent dihydroxy compound, with a platinum wire cathode and the sacrificial indium anode immersed in the liquid via a platinum wire lead. The high applied voltage required to drive the ions through the low conductivity solution phase was supplied by a Coutant LQ 50/50 power supply. All preparative work was carried out under dry nitrogen. The solution composition, electrochemical conditions, and yields are given in Table 1.

A typical experiment involved the electrochemical oxidation of indium metal in a solution of CH_3CN (50 mL) containing Et_4NClO_4 (ca. 20 mg) and 1,2-$C_6H_4(OH)_2$ (0.19 g). As the electrolysis proceeded, hydrogen gas evolved at the cathode, and a white product formed at the anode. This material gradually deposited in the cell, and at the end of the experiment was collected by filtration, washed with acetonitrile (5 mL) and then diethyl ether (5 mL), and dried *in vacuo*. The colourless solid was identified as In[OC_6H_4(OH)-1,2], 2-hydroxyphenolato indium(I). Essentially identical procedures were used to prepare and isolate the corresponding In^I[OR(OH)] compounds (R = $C_{10}H_6$, $C_{12}H_8$, C_6Br_4), which were characterized by elemental analysis (Table 2), and by infrared and ^1H nmr spectroscopy.

Preparation of $[In(O_2R)]^-$ anionic complexes

(*i*) Et_3N (0.2 mL, 0.15 g, 1.43 mmol) was added to In[OC_6(OH)-1,2] (0.30 g, 1.33 mmol) suspended in acetonitrile (20 mL), and the reaction mixture stirred for 4 h at room temperature. At the end of this period, the white product was collected, washed with 5 mL acetonitrile, and dried *in vacuo*. The product (0.37 g, 86% yield) was identified as $Et_3NH[In(O_2C_6H_4$-1,2)]. The molar conductivity of a millimolar solution in dimethylsulphoxide (dmso) was 46 ohm^{-1} mol^{-1} cm^2.

(*ii*) To In[$OC_{10}H_6$(OH)-2,3] (0.40 g, 1.46 mmol) was added Et_3N

TABLE 1. Experimental conditions for the direct electrochemical synthesis of $In^{I}[OR(OH)]$ compounds

Diol[a]	Solution composition[b] $R(OH)_2$ (g)	Initial voltage[c] (V)	Time of electrolysis (h)	Metal dissolved (mg)	% Yield[d]	E_F[e]	Product
$C_6H_4(OH)_2$	0.19	40	2	190	92	1.01	$In[OC_6H_4(OH)$-1,2]
$C_{10}H_6(OH)_2$	0.26	10	2	190	100	1.00	$In[OC_{10}H_6(OH)$-2,3]
$C_{12}H_8(OH)_2$	0.34	10	2	190	77	1.00	$In[OC_{12}H_8(OH)$-2,2′]
$C_6Br_4(OH)_2$	0.74	10	2	195	88	1.03	$In[OC_6Br_4(OH)]$

[a]$C_6H_4(OH)_2$ = 1,2-dihydroxybenzene; $C_{10}H_6(OH)_2$ = 2,3-dihydroxynaphthalene; $C_{12}H_8(OH)_2$ = 2,2′-dihydroxybiphenyl; $C_6Br_4(OH)_2$ = 1,2-dihydroxytetrabromobenzene.
[b]In 50 mL acetonitrile containing 20 mg Et_4NClO_4.

(0.25 mL, 1.81 mmol) in tetrahydrofuran (thf) (20 mL). After 4 h stirring, the white solid was collected, washed with thf, and dried *in vacuo*. The product (0.49 g, 80% yield) was identified as $Et_3NH[In(O_2C_{10}H_6$-2,3)]. The molar conductivity of a millimolar solution in dmso was 51 ohm^{-1} mol^{-1} cm^2.

Reaction of In[OR(OH)] with I_2

(*i*) $In[OC_6H_4(OH)$-1,2] (0.25 g, 1.0 mmol) was added to a solution of I_2 (0.25 g, 1.0 mmol as I_2) in petroleum ether (20 mL) with stirring under nitrogen, and the mixture stirred for 4 h. During this time, the purple colour of iodine discharged and a gray–blue solid formed; this was collected, washed with petroleum ether (5 mL), and dried *in vacuo*. The deep blue product (0.45 g, 94% yield) was identified as $I_2In[OC_6H_4(OH)$-1,2].

(*ii*) Solid $In[OC_{10}H_6(OH)$-2,3] (0.28 g, 1.02 mmol) was added gradually to a solution of I_2 (0.26 g, 1.02 mmol) in thf (10 mL). The suspension of $In[OC_{10}H_6(OH)$-2,3] dissolved immediately and a pale yellow–brown solution formed. This was stirred for 4 h, after which the solution was filtered to remove impurities, and the filtrate evaporated *in vacuo* to give a deep brown solid (0.52 g, 97% yield), identified as $InI_2[OC_{10}H_6(OH)]$. Similar reactions involving other In[OR(OH)] compounds gave the corresponding products in yields of 87% or better.

Reaction of In[OR(OH)] with o-$Br_4C_6O_2$

(*i*) $In[OC_6H_4(OH)]$ (0.16 g, 0.73 mol) was added to CH_3CN (20 mL) containing bpy (0.12 g, 0.73 mmol). After a period of stirring (1 h), *o*-$Br_4C_6O_2$ (0.31 g, 0.73 mmol) in the same solvent was added, causing an immediate change in the colour of the solution to green. After 4 h stirring, the solid, which by then had become deep green in colour, was collected, washed, and dried *in vacuo*. The product is the bpy complex of the oxidative adduct, $In[OC_6H_4(OH)$-1,2]$(O_2C_6Br_4$-1,2).bpy; yield 0.53 g, 91%.

(*ii*) A solution of *o*-$Br_4C_6O_2$ (0.59 g, 1.38 mmol) in diethyl ether (20 mL) was added to $In[OC_{10}H_6(OH)$-2,3] (0.38 g, 1.38 mmol) in the same solvent. The red solution changed colour to green. The mixture was stirred for 4 h, by which time a brown solid had formed; bpy (0.22 g, 1.41 mmol) was then added, at which point a yellow product immediately formed. After a further 2 h period of stirring, the yellow product was collected, washed with diethyl ether, and dried *in vacuo*. The product is $In[OC_{10}H_4(OH)$-2,3]$(O_2Br_4C_6$-1,2).bpy; yield 1.02 g 86%. Analogous oxidative addition processes were also identified when the derivatives of other 1,2-diols were treated with *o*-$Br_4C_6O_2$ in the presence of bpy.

Unsuccessful reactions

(*i*) Methyl iodide (0.09 mL, 1.45 mmol) was added to a suspension of $In[OC_6H_4(OH)]$ (0.30 g, 1.34 mmol) in acetonitrile (20 mL) at room temperature. The mixture was stirred for 24 h, after which time the solid was collected, washed with acetonitrile, and dried *in vacuo*. The material recovered at the end of this period was identified as the unchanged In[OR(OH)] (0.30 g).

TABLE 2. Analytical results for In[OR(OH)] compounds and related products

Compound	Colour	In % found (calcd)
$In[OC_6H_4(OH)$-1,2][a]	Colourless	50.9 (51.3)
$In[OC_{10}H_6(OH)$-2,3][b]	Pale yellow	42.1 (42.0)
$In[OC_{12}H_8(OH)$-2,2′]	Pale yellow	38.6 (38.3)
$In[OC_6Br_4(OH)]$	Colourless	21.2 (21.4)
$Et_3NH[InO_2C_6H_4$-1,2]	Colourless	35.7 (35.4)
$Et_3NH[InO_2C_{10}H_6$-2,3]	Colourless	30.9 (30.7)
$In[OC_6H_4(OH)](O_2C_6Br_4)$.bpy[c]	Green	14.1 (14.3)

[d]Found C 37.1, H 1.19, N 2.91; calcd. C 36.6, H 1.64, N 3.27.

(*ii*) Ethyl bromide (0.1 mL, 1.34 mmol) in acetonitrile (20 mL) was added to a suspension of 0.30 g (1.34 mmol) of $In[OC_6H_4(OH)]$ in the same solvent. The mixture was stirred with refluxing for about 4 h; after this time, the solid was collected, washed with acetonitrile, and dried *in vacuo*, and identified as the original In[OR(OH)] (0.30 g).

Results and discussion

Preparation of $In^{I}[OR(OH)]$ compounds

The anodic oxidation of indium in the presence of aromatic 1,2-diols is a simple and efficient route to a series of novel indium(I) compounds which have not been previously reported, although the use of electrochemical synthesis to produce metal derivatives of catecholates and similar aromatic diolates has been described elsewhere. In the case of zinc and cadmium (11), the products were the homopolymeric $M(O_2R)$ compounds, while with tin, the analogous tin(II) derivatives were obtained (10). This latter group of compounds was shown to undergo oxidation by iodine or tetrahalogeno-*o*-quinones to give the appropriate tin(IV) species, reactions which obviously parallel

to those described above for In[OR(OH)]. In the present work, as in the previous studies, the electrochemical synthesis is simple and efficient, and although the experiments were conducted on a relatively small scale, there is little difficulty in producing larger quantities of product either by using larger cells or by running several cells in series.

The electrochemical efficiency, defined as moles of metal dissolved per Faraday of charge, is 1.01 ± 0.01 mol F^{-1} for the synthesis of all the In[OR(OH)] compounds reported here (see Table 1). This E_F value, together with the evolution of hydrogen gas at the cathode, at its simplest implies the formation of a singly charged anion $[(HO)RO]^-$ at the cathode. This would migrate to the anode to form the product, according to the reaction sequence:

Cathode

[1] $R(OH)_2 + e \rightarrow [(HO)RO]^- + (1/2)H_2\,(g)$

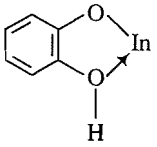
Anode

[2] $[(HO)RO]^- + In \rightarrow In[OR(OH)] + e$

We should note that in previous papers (10, 11) a possible alternative mechanism was also proposed, based on the formation of RO_2^{2-} anions at the cathode, and in this case the anode reaction would be

[3] $RO_2^{2-} + 2In \rightarrow In_2(O_2R) + 2e$

followed by the electronless process



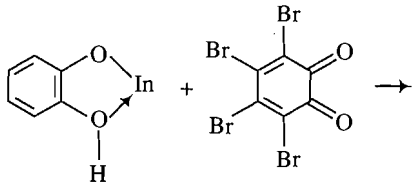
[4] $In_2(O_2R) + R(OH)_2 \rightarrow 2In[OR(OH)]$

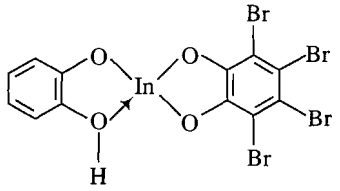
This problem will be the subject of a future study.

As noted in the Introduction, there is little previous work against which this electrochemical preparative route can be compared. An analogous thallium compound $Tl[OC_{12}H_8(OH)]$, derived from 2,2′-dihydroxybiphenyl, was prepared some years ago by Brady and Hughes (12) by reacting thallium(I) acetate with the parent diol in basic aqueous ethanol; treatment with KOH yielded $Tl_2(O_2C_{12}H_8)$. With Et_2TlOH, reaction with this same diol gave $Et_2Tl[OC_{12}H_8(OH)]$, and in this compound, as in $Tl[OC_{12}H_8(OH)]$, the hydroxy group was assumed to be acting as part of a chelating ligand, although no spectroscopic evidence was of course available at the time. Compounds with such oxo-hydroxy ligands are unusual, and present a number of interesting structural problems for future investigation.

Reactions of In[OR(OH)] compounds

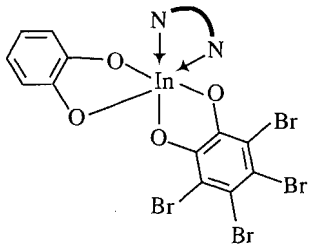
The oxo-hydroxy derivatives of aromatic diols are novel and interesting substances, partly because they represent the first known 2-dihydroxyphenolatoindium(I) compounds (and analogues), and equally because they show typical indium(I) chemistry. The compounds are unstable in air, changing colour to green–gray or gray with a few hours. They do not melt below ~300°C, and are insoluble in acetonitrile, tetrhydrofuran, pyridine, but soluble in dimethylsulphoxide at room temperature, and in these properties they closely resemble the tin(II) derivatives of the same aromatic diols. The solubilities suggest crosslinking to give a homopolymer in the solid state, with solvation then being responsible for the solubility in dimethylsulphoxide. The exact mode of this cross-linking cannot be identified at this point. Given that the simplest representation of In[OR(OH)] is





the homopolymer may simply involve O → In donation to give chains similar to those recently identified in the solid state of $In(SeC_6H_5)_3$ (13). Additionally, or alternatively, the hydrogen atom of the hydroxy group may hydrogen-bond to the oxo-oxygen of the ligand of a neighbouring molecule, and the lone pair of the indium atom may also be involved in lattice stabilization.

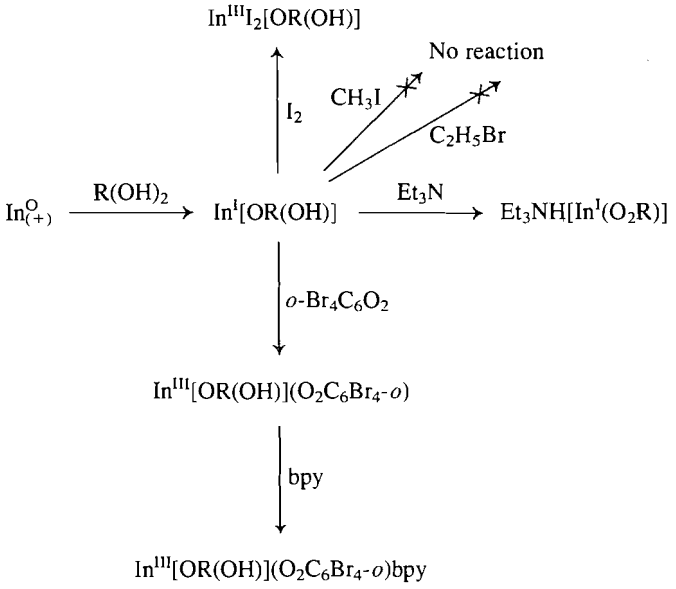
The presence of the hydroxy group in the various $RO(OH)^-$ ligands has been confirmed spectroscopically (see below) but direct chemical evidence was also obtained by deprotonation with Et_3N to give the corresponding salt $Et_3NH[InO_2R]$, shown to be a 1:1 electrolyte in dimethylsulphoxide (c.f. conductivities of 46–51 ohm^{-1} cm^2, compared with standard range of 50–70 ohm^{-1} mol^{-1} cm^2 established for such salts in this solvent (14)). The anions of these salts are isoelectronic with the tin(II) derivatives of aromatic diols discussed elsewhere (10).



We have shown previously that indium(I) compounds are readily oxidized, and the present compounds confirm this generality. The reaction of $In^I[OR(OH)]$ with iodine gives $In^{III}I_2[OR(OH)]$, which formally results from the oxidative insertion of indium(I) into the I—I bond; analogous reactions are known for CpIn (15), InX (16), and InX_2^- (17). Similarly, when In[OR(OH)] reacts with the *ortho*-quinone *o*-$Br_4C_6O_2$ in the presence of the bidentate ligand 2,2′-bipyridine, the final product is a six-coordinate indium(III) complex. The first process is clearly that of oxidative addition

[5]

and this reaction is exactly analogous to those of InX (6), SnX_2 (18), and tin(II) catecholates (10). The details of such oxidations are discussed elsewhere, and it is sufficient to note here that the product is an indium(III) derivative with two dioxoligands, one being the tetrabromocatecholato ligand, and the other the oxo-hydroxy ligand formed in the original electrochemical synthesis. This oxidation process is followed by coordination by the neutral bidentate ligand to give the six-coordinate complex



typical of indium(III) chemistry. The oxidative addition reaction of InX (X = Cl,Br) with *o*-$X_4C_6O_2$ (Y = Cl,Br) in the presence of neutral bidentate ligands such as bpy, phen, or tmen (= L) has been shown to yield diolato-indium(III) derivatives of the type $InX(O_2C_6Y_4).L$ (6).

The reactions identified at this point for these In[OR(OH)]

TABLE 3. ^{1}H nmr spectra for In[OR(OH)] compounds and derivatives

SCHEME 1

species are summarized in Scheme 1. No reaction was observed with either CH_3I or C_2H_5Br, although oxidative addition reactions between alkyl halides and indium(I) compounds have been observed (19–21), and this may be because the polymeric nature of the solid In[OR(OH)] resists attack under the mild conditions used in the present work.

Spectroscopic results

The infrared spectra of all the In[OR(OH)] compounds studied showed the presence of ν(O—H) of the anion, observed as broad absorptions in the 3200–3400 cm^{-1} region. The ν(C—O) mode, observed between 1280 and 1230 cm^{-1} in the parent diols, occurs at 1254 (R = $O_2C_6H_4$-1,2), 1257 (R = $O_2C_{10}H_6$-2,3), 1222 (R = $O_2C_6Br_4$-1,2), and 1249 and 1212 cm^{-1} (R = $O_2C_{12}H_8$), respectively. The adducts with bpy showed the characteristic infrared spectrum of the complexed ligand.

For the products of the reaction of In[OR(OH)] with *o*-$Br_4C_6O_2$, the most important observation is that ν(C=O) of the *ortho*-quinone at ~1700 cm^{-1} is absent in every case in the product, being replaced by bands at 1430 and 1240 cm^{-1}, assigned as ν(C—O). Similar results were observed in the $Sn(O_2R)$/*o*-$Br_4C_6O_2$ (10), SnX_2/*o*-$Br_4C_6O_2$ (18), and InX/*o*-$Br_4C_6O_2$ (6) systems. In the infrared spectrum of $Et_3NH[In(O_2C_6H_4)]$, multiplet absorptions between 2490 and 2780 cm^{-1} are identified as ν(N—H^+), and ν(C—H) occurs at 2842 and 2931 cm^{-1}, in agreement with the earlier work of Chenon and Sandorfy (22).

The ^{1}H nmr spectra of a number of In[OR(OH)] compounds and their derivatives are presented in Table 3. The important feature of the nmr spectra of In[OR(OH)] in d_6-dmso is the presence of broad signals at 6.1, 9.5, and 6.3 ppm (R = C_6H_4, $C_{10}H_6$, and $C_{12}H_8$) which are assigned to the hydrogen of the hydroxy group of the ligand. This hydrogen is removed in the reaction of In[OR(OH)] with Et_3N to form $Et_3NH[InO_2R]$ (R = C_6H_4, $C_{10}H_6$), and the spectrum changes accordingly; the broad signals at 4.95 and 3.73 ppm were assigned to the hydrogen of the Et_3NH^+ cation in CD_3CN and d_6-dmso, respectively. The remaining features are also consistent with the presence of the Et_3NH^+ cation.

In general, the spectroscopic results confirm the proposed reaction Scheme.

The synthesis, characterization, and some reactions of phosphonium thiolates and selenolates: the X-ray crystal structure of tetraphenylphosphonium 2,4,6-trimethylbenzenethiolate

JOANNE M. BALL, P. MICHAEL BOORMAN,[1] JAMES F. FAIT, A. SCOTT HINMAN, AND PENELOPE J. LUNDMARK
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 19, 1988

JOANNE M. BALL, P. MICHAEL BOORMAN, JAMES F. FAIT, A. SCOTT HINMAN, and PENELOPE J. LUNDMARK. Can. J. Chem. **67**, 751 (1989).

Synthetic methods for the preparation of $PPh_4[SAr]$, PPN[SAr], and $PPh_4[SeAr]$ (Ar = aryl; PPN = bis(triphenylphosphine)iminium) salts are described, and ^1H NMR, infrared, and ^{77}Se NMR spectroscopic characterization is given. The X-ray crystal structure of $[PPh_4][Smes]$ (mes = 2,4,6-trimethylbenzene) was carried out: space group $P\bar{1}$, a = 9.946(3) Å, b = 10.100(2) Å, c = 14.874(3) Å, α = 70.19(2)°, β = 69.13(2)°, γ = 82.54(2)°, Z = 2, R = 0.100, R_w = 0.074. The structure establishes the ionic nature of this compound in the solid state, and conductance measurements in acetonitrile are consistent with 1:1 electrolyte behaviour. It is shown, however, that solutions of the thiolates are quite sensitive to hydrolysis to the thiol, and also the strong nucleophilicity of the thiolate and selenolate anions enables them to react with halocarbon solvents. The selenolate solutions are extremely sensitive to oxidation to the diselenide, which limited their study. Cyclic voltammetry on selected thiolate salts shows that impurities quickly develop even in acetonitrile solvent, but comparisons with the voltammograms of thiols and disulphides confirm the assignment of an irreversible oxidation wave at ca. −0.3 V (vs. $Ag/AgNO_3$, 0.01 *M*) to the process: $2SR^- \rightarrow R_2S_2 + 2e^-$. The potential at which this reaction occurs is related to the degree of substitution of the phenyl ring of the SAr^- ion.

Key words: phosphonium thiolates, phosphonium selenolates, tetraphenylphosphonium 2,4,6-trimethylbenzene thiolate.

JOANNE M. BALL, P. MICHAEL BOORMAN, JAMES F. FAIT, A. SCOTT HINMAN et PENELOPE J. LUNDMARK. Can. J. Chem. **67**, 751 (1989).

On décrit des méthodes de synthèse pour la préparation des sels $PPh_4[SAr]$, PPN[SAr] et $PPh_4[SeAr]$ (Ar = aryl; PPN = bis(triphénylphosphine)iminium) et on présente les données des spectroscopies infrarouge ainsi que RMN du ^1H et du ^{77}Se. On a déterminé la structure cristalline du sel $[PPh_4][Smes]$ à l'aide de la diffraction des rayons-X : groupe d'espace $P\bar{1}$, a = 9,946(3), b = 10,100(2) et c = 14,874(3) Å, α = 70,19(2), β = 69,13(2), γ = 82,54(2)°, Z = 2, R = 0,100 et R_w = 0,074. La structure a permis d'établir la nature ionique de ce composés à l'état solide et des mesure de conductance dans l'acétonitrile sont en accord avec le comportement d'un électrolyte 1:1. Toutefois, on démontre que les solutions des thiolates sont très sensibles à une hydrolyse en thiol et que le caractère nucléophile marqué des anions thiolate et sélénolate leur permet de réagir avec les halogénures de carbone qui agissent comme solvant. Les solutions de sélénolates sont extrêmement sensibles aux oxydations en disélénures et cette particularité a limité leur étude. La voltamétric cyclique sur des sels choisis de thiolate a permis de montrer que des impuretés se forment rapidement, même dans l'acétonitrile; toutefois, des comparaisons avec les voltamogrammes de thiols et de disulfures ont permis de confirmer l'attribution d'une vague d'oxydation irréversible, à environ −0.3 V (vs. $Ag/AgNO_3$, 0,01 *M*), au processus: $2SR \rightarrow R_2S_2 + 2e^-$. Le potentiel caractéristique de cette réaction est relié au degré de substitution du noyau phényle de l'ion SAr^-.

Mots clés : thiolates de phosphonium, sélénolates de phosphonium, thiolate triméthyl-2,4,6 benzène de tétraphénylphosphonium.

[Traduit par la revue]

Introduction

The recent publication of three reviews (1–3) on metal thiolate complexes is an indication of the high current interest in this area of chemistry. The subject has been of ongoing interest in our laboratory with particular emphasis on the preparation of tungsten and molybdenum thiolate complexes (4). During this work, we had occasion to examine the use of simple quaternary thiolate salts as synthetic reagents, following reports by several workers on their ability to displace both neutral and anionic ligands (5–10). Such compounds would complement the more commonly used reagents such as the alkali metal thiolates, thiol/Et_3N, and the trialkylsilyl- and trialkyltin-thiolates, as a means of forming metal–thiolate bonds.

The very recent publication (11) of an application of quaternary ammonium thiolates as initiators for the polymerization of *n*-butyl acrylate suggests that the possible uses of simple thiolate salts may be much wider than merely in the synthesis of metal complexes. We therefore undertook a literature search on the synthesis and characterization of both thiolates and selenolates, to establish what evidence there is for the existence of pure compounds which can be truly formulated as $[R_4X]^+[ER]^-$, (where X = N, P; E = S, Se, Te).

The first report of the preparation of a phosphonium thiolate which we could find was by Liesk, Schulz, and Klar in 1975 (12). These workers found that alkali metal benzenechalcogenolates could be prepared by reduction of the dichalcogenides in liquid ammonia. By adding PPh_4Cl to solutions of the alkali salts in liquid ammonia and recrystallizing the products from ethanol/THF compounds were prepared which analysed as $PPh_4[EPh]$. No further characterization was reported, and in the light of other literature which demonstrates the feasibility of P(V) compounds of this type existing as 5-coordinate phosphoranes rather than simple salts (13) some ambiguity was left by this report.

More recent work on the synthesis of thiolato metal complexes has involved tetraalkylammonium thiolates, but in many instances these salts have been generated *in situ*, and not been isolated. A notable exception to this can be found in a paper by McDonald and co-workers who, after utilizing the *in situ* method in much of their work reported the successful isolation of $[NEt_4][SPh]$ and $[NEt_4][S(benzyl)]$ in 1987 (6). Characterization was again restricted to elemental analysis, but cyclic

voltammetry was performed on a series of tetraethylammonium thiolate salts by Wedd and co-workers (14). In total there appeared to be no spectroscopic data on these compounds and certainly no X-ray crystallographic structural evidence to justify formulation of these compounds as ionic species.

We report here the synthesis of several aryl thiolate and aryl selenolate salts,[2] their spectroscopic and solution properties, and the X-ray crystal structure of one of these salts, tetraphenylphosphonium 2,4,6-trimethylbenzene thiolate, **1**. This compound, with its proven structure, is then used as the reference point for characterization of the other salts. Since the alkylthiolates are too unstable to handle, we restricted this study to arylthiolates and selenolates but with ring substituents chosen to give convenient ^{1}H NMR labels and a range of chemical behaviour.

Finally we report the cyclic voltammetry of several of the compounds and compare these data with those reported by Wedd and co-workers (14).

Experimental

General procedures

Because of the extreme sensitivity of the chalcogenolate salts to moisture and/or oxygen all solvents were rigorously dried and deoxygenated prior to use, by standard literature methods. The chloride salts used as starting materials for all syntheses, PPh_4Cl and PPNCl(PPN = bis(triphenylphosphineiminium)), were obtained from Aldrich, and were dried by heating to 80°C under vacuum for 24 h. All materials were handled using glovebox and double manifold techniques.

Spectra and physical measurements

Nuclear magnetic resonance spectra were recorded using a Bruker ACE 200 spectrometer (^{1}H and ^{13}C) and a Bruker ACE 400 spectrometer (^{77}Se). Infrared spectra were recorded as Nujol mulls on a Nicolet 5DX FTIR or a Perkin Elmer 467 spectrometer. Conductance measurements were made in acetonitrile solution at varying concentrations using a closed glass cell and a YSI Model 35 conductance bridge.

Synthesis

All the salts were synthesised by essentially the same method, namely, by reacting the sodium thiolate (or selenolate) with $PPh_4^+Cl^-$ (or PPN^+Cl^-) in acetonitrile. The synthesis of the sodium salts was specific to each case, however. In a typical synthesis, tetraphenylphosphonium *para*-tolylthiolate was prepared as follows. *p*-Tolythiol was reacted, in a slight excess, with sodium in methanol. After removal of the methanol the sodium salt was washed with ether, and dried in vacuum at 80°C for 24 h. Approximately 2 g of this salt was then reacted in a 1.2:1.0 molar excess with PPh_4Cl (4 g) in a Schlenk tube with dry MeCN (ca. 50 mL) as the solvent. The resulting slurry was stirred for ca. 72 h, after which the solids were removed by filtration, leaving a solution of (mainly) the desired product. This solution was evaporated to dryness under vacuum leaving the crude product which was then redissolved in acetonitrile, and ether was added until a fine, crystalline solid began to form. The solution was then cooled to 5°C and left for 24 h, after which the product was filtered off, rinsed with ether, and dried in vacuum. (Yield, 85%, based on the limiting reagent, PPh_4Cl.) This procedure had to be modified to prepare 2,4,6-triisopropylbenzenethiolate (Stip) in that the reaction of the thiol with sodium was carried out in 1,2-dimethoxyethane, rather than in methanol. This solvent was also more satisfactory for the preparation of the sodium mesitylthiolate salt.

The selenolate salts can be prepared from the analogous reaction of sodium selenolate with the phosphonium chloride, using acetonitrile as the solvent. However, the sodium salts are most conveniently prepared by reduction of the appropriate diselenide with sodium in THF. In many instances it is necessary to prepare the diselenides from an aryl halide, since few are available commercially. This can be achieved by making the aryl Grignard reagent in THF, reacting it with elemental selenium and hydrolysing the ArSeMgBr so formed to yield the selenol. This product is immediately oxidized in alkaline solution to give the desired product. The synthesis follows a procedure published by Sharpless and Young (15).

The ease of handling the phosphonium and PPN thiolates and selenolates varies considerably from case to case. These salts are in some instances low melting (e.g. Ph_4P[Stip]), and hence difficult to purify and work with. On the other hand, Ph_4P(Smes), **1**, can be obtained as well-formed crystals, and this enabled us to obtain an X-ray crystal structure of this compound (see below). Some were found to crystallize with solvent in the lattice, and the lability of this solvent led to difficulty in obtaining reproducible analytical data. An added problem is the ease of oxidation of the salts to produce the disulfide (or diselenide), and also the hydrolysis of the thiolate to yield free thiol in solution. Hence we found that, having verified the existence and nature of these salts it was most convenient to use ^{1}H NMR spectroscopy to monitor the purity of new members of the series, and new batches of the salts.

Anal calcd. for $[P(C_6H_5)_4][SC_7H_7]$: C 80.49, H 5.88; found (M.H.W.): C 76.02, H 5.36.

Anal calcd. for $[P(C_6H_5)_4][SC_9H_{11}]$: C 81.60, H 6.11; found (M.H.W.): C 78.15, H, 6.24.

Anal. calcd. for $[(C_6H_5)_3P]_2NSC_7H_7$: C 78.03, H 5.63, N 2.13, S 4.84; found (Canadian Microanalytical Services): C 72.53, H 5.32, N 2.12, S 5.11.

Previously, Liesk and co-workers have reported very good analyses for the compounds $[PPh_4][EPh]$ (E = S, Se, Te), and McDonald and co-workers also reported C and H analyses on a sample of Et_4NSPh, but in no case were we able to obtain such good agreement on samples sent by mail to commercial analysts. We ascribe these poor analyses to the instability of the salts as noted above, and were unable to obtain microanalytical services "in house".

Infrared spectra

In general the IR spectra of these salts were uninformative since the presence of phenyl rings in both the anion and the cation (in most instances) dominates the spectra. However, we report them as part of the complete characterization, making comments only on unique bands associated with the anion. Spectra of closely related species (e.g. PPh_4Cl, PhEEPh) are given for comparative purposes. Spectra (2000–250 cm^{-1}) were recorded as Nujol mulls unless otherwise stated, and peaks in the Nujol regions (1380, 1460 cm^{-1}) have been included in the listings in cases where they cannot be distinguished from absorptions due to the compounds under study.

The most useful aspect of these spectra, as far as the identification of the products is concerned, is the presence of bands characteristic of multiply substituted aromatic rings in the spectra of the *p*-tolyl and 2,4,6-trialkylbenzenethiolate salts. These can be used as an indication of the completion of the metathesis reaction of PPh_4Cl with the sodium thiolates. Since this is a heterogeneous reaction such an indicator of its progress can be of assistance. Most characteristic of the multiply substituted rings are bands in the region 800–880 cm^{-1}, which are associated with aromatic C—H bending modes. In the spectra of PPh_4S(*p*-tol) and the parent thiol there are bands at 813 and 815 cm^{-1}, respectively. In the more highly substituted rings these vibrations occur at higher wavenumbers, namely at 860 cm^{-1} in both the Smes and Semes salts of the tetraphenylphosphonium cation, and at 880 cm^{-1} for PPh_4[Stip]. Unfortunately these vibrations also occur, with very little change in frequency, in the spectra of the thiols and the disulfides (or diselenides). Since these are the major possible contaminants of the salts this limits the usefulness of the IR spectra as indicators of product purity.

X-ray structural determination of Ph_4P(Smes), 1

Data collection

A suitable transparent, block-shaped crystal was wedged into a Lindemann glass capillary, and mounted on an Enraf-Nonius CAD4 diffractometer. The triclinic unit cell parameters and their standard deviations were derived from the setting angles of 24 reflections in the range $6.32° < \theta < 12.11°$. Reduced cell calculations did not indicate any higher metric symmetry. The space group was determined to be $P\bar{1}$ on the basis of the strongly centric distribution of E values, and the choice was supported by the successful solution of the structure in this space group. Crystal and instrumental instability were monitored through the measurement of three standard reflections every 0.5 h of X-ray exposure time; there were no indications of crystal decomposition. The net intensities of the data were corrected for Lorentz and polarization effects. Variance, $\sigma^2(I)$, was calculated based on counting statistics and instrumental instability as estimated from the standard reflections. Crystal data and experimental details of the structure determination are given in Table 1.

Structure solution

The mesityl ring of the anion and much of the tetraphenylphosphonium cation were located in an E map with phases derived from symbolic addition using the program SIMPEL(16). The remaining non-hydrogen atoms were located in difference Fourier maps. All non-hydrogen atoms were refined anisotropically, with hydrogens refined with independent isotropic temperature factors. Convergence was reached at $R = 0.100$. The final values of the refined positional parameters are presented in Table 2.[3] Neutral atom scattering factors were used with anomalous dispersion corrections applied (17). All calculations were carried out on a VAX 11/780 computer at the University of Calgary using the program package XTAL2.2 (16).

Electrochemistry

Electrochemical experiments were carried out in a dry box, under an argon atmosphere. The solvent was acetonitrile containing 0.1 *M* tetra-*n*-butylammonium perchlorate (TBAP) as supporting electrolyte. Acetonitrile was purified as noted above. TBAP (Fluka) was recrystallised from isopropanol/water (70:30, vol:vol) and dried for 24 h in a vacuum oven at 100°C before use. The electrochemical cell and the instrumentation are described in detail in ref. 18. The working electrode was a platinum wire, positioned concentrically within the coils of a Pt wire helix, which served as the counter electrode. The reference electrode was a silver wire immersed in CH_3CN/0.01 *M* $AgNO_3$/0.1 *M* TBAP. Two fine glass frits and a Luggin capillary positioned within 2 mm of the working electrode surface separated the working and reference electrode compartments. Solutions were prepared in the dry box utilizing previously degassed CH_3CN. Argon was bubbled through the solutions immediately after preparation to ensure complete removal of any traces of residual oxygen.

Results and discussion

Structure of tetraphenylphosphonium 2,4,6-trimethylbenzenethiolate 1

The conclusive identification of the series of compounds as salts of general formula $[Cation]^+[ER]^-$, (E = S, Se) is based on the successful determination of the X-ray crystal structure of [PPh_4][Smes], **1**. The anion of **1** is shown in Fig. 1, with a stereo

[3]Tables of observed and calculated structure factor amplitudes, of hydrogen positions, thermal parameters, and a comprehensive list of bond lengths and bond angles may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

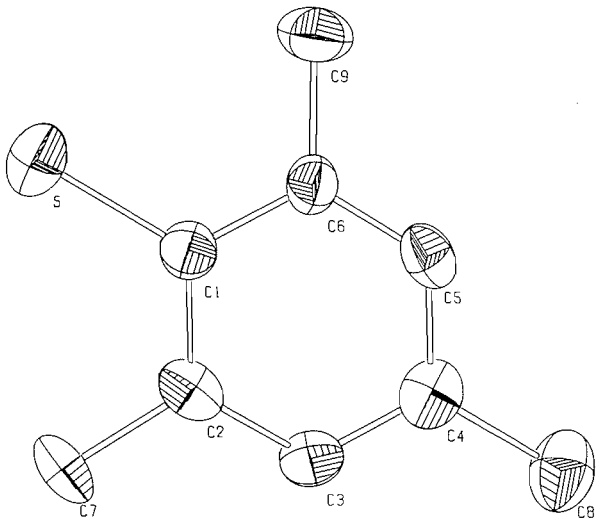

FIG. 1. ORTEP drawing of the 2,4,6-trimethylbenzenethiolate anion showing the numbering scheme; 50% thermal ellipsoids are drawn, hydrogens are omitted for clarity.

packing diagram in Fig. 2. The key feature of the structure can be seen from the packing diagram, namely that there are no close contacts between the thiolate sulfur, S, and any other atoms, and especially that it is not coordinated to the phosphorus to give a phosphorane, in this crystal at least. The calculated separation of S and P is 6.149(3) Å. Hence further experiments were designed to show that the solution and spectroscopic properties of **1** were consistent with this formulation, and that the other members of the series had similar properties, and hence analogous structures.

The bond lengths and bond angles within the anion (Table 3) are within the ranges expected; the S—C(1) distance is 1.767(6) Å, and the S—C(1)—C(2) and S—C(1)—C(6) angles are 121.7(4) and 121.2(5), respectively. The sum of the angles subtended at C(1) is 360°, confirming its planarity. At the centre of the phosphonium cation the C—P—C bond angles are all close to 109°, and again verify that no coordination of the sulfur of the anion to the P atom is occurring. The packing of the cations is such that layers of phenyl groups occur in the *ab* plane, and at $z = 0.5$ a layer of alternating phenyl rings from the anion and the cation is observed. It appears that the anions help to bind the layers of cations together.

Solution properties and NMR spectra

As mentioned in the Experimental section, the instability of the thiolate and selenolate salts presented a significant problem in handling them, particularly in solution. However, those members of the series which crystallized from solution to give solids with reasonably high melting points could be kept under a dry nitrogen atmosphere for periods of weeks without decomposition. The most useful method of characterization was the ^1H NMR spectrum. Pertinent data are given in Table 4.

The ^{77}Se spectra of selected samples were obtained, and compared with literature values of related compounds. For PhSeSePh a δ of 481 ppm (in $CDCl_3$ solution, D_2O lock; ref. Me_2Se, 0 ppm, KSeCN, −330 ppm) which is consistent with the literature value (19) while in mesSeSemes the chemical shift is 391 ppm. The sample of PPh_4[SePh], whose ^1H spectrum is uninformative at 200 MHz, showed a peak at relatively high field in CH_3CN solution, viz. −601 ppm, thus making it very useful as a diagnostic technique to identify the anion. The spectrum showed no resonance at 481 ppm, indicating no measurable oxidation of the sample to Ph_2Se_2.

Conductance measurements

To demonstrate that the salts are indeed dissociated in the preferred solvent, acetonitrile, conductance measurements were made over a concentration range of 10^{-2}–10^{-4} *M* (25°C). Interpolated values at 10^{-3} *M*, commonly cited to establish 1:1 electrolyte behaviour, were as follows:

PPh_4[Smes], 112; PPh_4[tipt], 80; PPN[S(ptol)], 100; PPh_4[SePh], 186; PPh_4Br, 148; PPh_4Cl, 170; PhSeSePh, 2.2; $ohm^{-1}\ cm^2\ mol^{-1}$. (Literature values for 1:1 electrolytes, 10^{-3} *M*, 25°C: 120–160 $ohm^{-1}\ cm^2\ mol^{-1}$ (20).)

These data clearly establish that the thiolate and selenolate salts exist as 1:1 electrolytes in acetonitrile. As expected they show increasing association at higher molarities, reflected in lower conductance values. The predicted dependence of the Λ_M values on the anion size, and consequently on the mobility, is consistent with these data. The conductance measurements were also found to be very sensitive to sample oxidation in the dilute solutions, and for this reason data were recorded on freshly prepared solutions, in a stoppered conductance cell. Even under these circumstances the conductance values diminished over a period of 1 h. Some specific salts (e.g. PPh_4[Sptol]) were so sensitive that even the data obtained as described here showed

that the solution had already undergone partial oxidation and/or hydrolysis.

Electrochemical behaviour

The solution properties of the thiolate salts were next examined by cyclic voltammetry in acetonitrile solution. Previous work by Wedd and co-workers on tetraethylammonium thiolates (14) had established that an oxidation peak occurs in the region −0.5 to −0.2 V relative to the $Ag|AgNO_3$ (0.1 *M*) electrode Figure 3 shows the cyclic voltammogram for a 0.001 *M* solution of [PPN][Sptol] in acetonitrile. There are three peaks, labelled A, B, and C. In accordance with the results of Wedd, and the observations discussed below, the anodic peak A is assigned as the oxidation of thiolate to disulphide, as per the equation:

$$2SR^- \rightarrow 2RSSR + 2e^- \qquad E_p = -0.34 \text{ V}$$

The cathodic peak C is observed only following anodic sweeps into the region of peak A, indicating it is due to reduction of a product of the thiolate oxidation. That this product is the disulphide was confirmed in cyclic voltammetric studies of a solution of *p*-tolyldisulfide, which underwent reduction at potentials identical to that of peak C in Fig. 3. This reduction process was irreversible, but led to the appearance, on subsequent anodic scans, of a peak occurring at identical potentials to A for oxidation of the thiolate. Thus, peak C is assigned as reduction of the disulfide to the thiolate according to:

$$RSSR + 2e^- \rightarrow 2RS^- \qquad E_p = -2.24 \text{ V}$$

Also apparent in Fig. 3 is a second anodic peak, labelled B, at +0.17 V. This only occurs in solutions which have been standing for some time and is not related to any species generated by electrochemical processes. This peak was not reported by other workers (14), but we observed it in all solutions of thiolate after a period of time. We ascribe this peak to an oxidation process involving an unidentified decomposition product of thiolate. The intensity of peak B grows over a period of time under open circuit conditions, while peak A, due to oxidation of the thiolate, decreases. Peak A is completely absent in solutions left standing under argon for more than an hour. Peak B is not evident in the voltammetry of the disulfide, and thus does not appear to be related to any process involving this species.

Cyclic voltammetry of a solution of *p*-tolylthiol was undertaken in order to investigate the possibility that the unassigned peak B might involve this species. No process at potentials comparable to peak B was evident. Consistent with the results of Wedd (14), reduction of the thiol gave rise to an irreversible cathodic peak at −2.05 V, 190 mV positive of that observed for reduction of the disulfide. Subsequent anodic scans following this reduction displayed an anodic peak at −0.34 V, coincident with peak A observed for thiolate oxidation. These observations are again consistent with Wedd's interpretation of the thiol reduction occurring according to:

$$RSH + 1e^- \rightarrow RS^- + \tfrac{1}{2} H_2 \qquad E_p = -2.05 \text{ V}$$

Anodic scans of the *p*-tolylthiol solution revealed an irreversible anodic peak at +0.74 V. This was followed on subsequent cathodic scans by the appearance of a new cathodic peak coincident with that observed for reduction of the disulfide. The

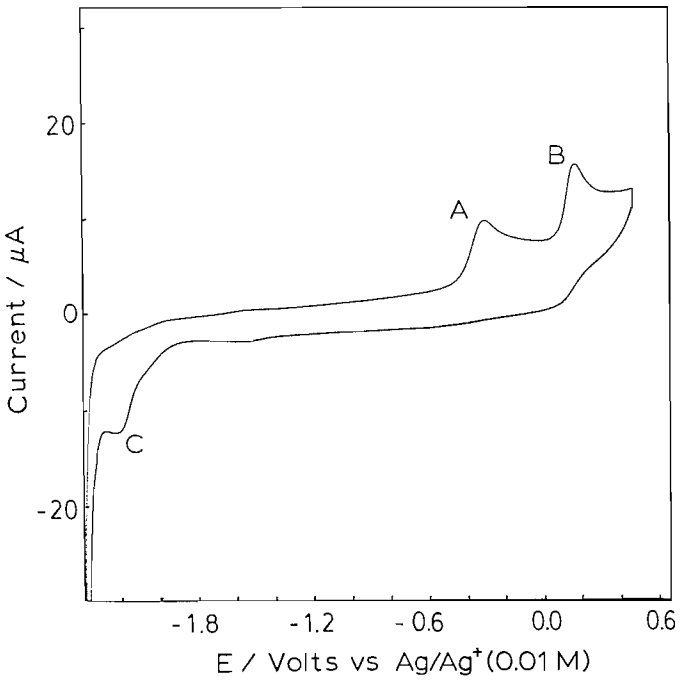

FIG. 3. Continuous sweep cyclic voltammetry of [PPN][Sptol] (0.001 *M*) in CH_3CN using $[N(n\text{-}Bu)_4][ClO_4]$ as supporting electrolyte. The solution had been allowed to stand ca. 20 min prior to initiating the cycling.

thiol oxidation thus appears to follow:

$$2\,RSH^- \rightarrow RSSR + 2H^+ + 2e^- \qquad E_p = +0.74\ V$$

Since none of the processes discussed is reversible, changes in sweep rate result in changes to the peak potentials. All the results described here were obtained using a sweep rate of 100 mV s^{-1}.

The results obtained for a series of thiolate salts are collected in Table 5, and compared with those of Wedd and co-workers (14). For the *p*-tolyl compounds common to both studies there is close agreement in the results and their interpretation, with the exception of the oxidation wave for the thiol. We did not experience the same problem that Wedd and co-workers reported, namely, a very low current density for this wave lending uncertainty to its identification. On the contrary we observed a readily identified peak at +0.74 V, very similar to the other two thiols in our study. The data for PPh_4[Smes] and PPh_4[Stip] are very similar to those reported (14) for the $[SPh]^-$ and $[Sptol]^-$ salts, except that once again we were unable to leave the solutions for any period of time without the appearance

of the wave B. This was present at −0.04 and −0.02 V, respectively, even in freshly prepared solutions, and this peak grew to be predominant after extended periods of time spent under open circuit conditions.

The positions of the peaks for thiolate oxidation show a trend, indicating that oxidation becomes easier as the degree of substitution of the phenyl ring of the thiolate anion increases. The electron donating effect of the alkyl substituents may thus be more important in determining the ease of oxidation of the thiolates to the disulfides than steric crowding around the sulfur atom. On the basis of steric arguments alone, it might be anticipated that $Smes^-$ and $Stip^-$ would be the most resistant to oxidation, which is the opposite of what is actually observed in the electrochemical studies.

Reactions of thiolate salts

The potential uses of the phosphonium chalcogenolates in synthetic coordination chemistry are limited by the highly nucleophilic nature of the naked anions. Although at first sight

this may seem attractive in terms of ligand replacement reactions it imposes a severe constraint on the selection of solvent. Chlorocarbon solvents, a popular choice for many syntheses, are likely to react with ER^-, with the displacement of chloride. The ^1H NMR spectra of PPh_4[Sptol] in CD_3CN (*A*) and in $C_2D_2Cl_4$ (*B*) are shown in Fig. 3. The resonance for the CH_3 protons of the tolyl group is a clean singlet in acetonitrile whereas it appears as a complex multiplet in the chlorocarbon. Further experiments showed that the salts are rapidly degraded in dichloromethane and hence this useful solvent is inappropriate for preparing and handling thiolate or selenolate salts. This compares with the report of Shaver and co-workers (21) who reacted NaSH with a metal complex in CH_2Cl_2 and unexpectedly prepared a complex of the chelating ligand $CH_2S_2^{2-}$.

The other major difficulty we encountered in handling the salts, even in an apparently inert solvent, was that the solutions are extremely sensitive to oxidation and in the case of the thiolate, to hydrolysis. Fortunately the ^1H NMR spectra of the alkyl-substituted aryl thiolates or selenolates provide a convenient method of checking for the degree of decomposition of the salts. Hence any problems with reagent decomposition can be identified.

Given these constraints it is still possible to use the salts for many synthetic purposes and some of these will be described later.

Étude chimique et cinétique de l'oxydation homogène en phase gazeuse d'alcanes légers. I. Isobutane

BERNARD VOGIN,[1] FRANÇOIS BARONNET[2] ET GÉRARD SCACCHI

Département de chimie physique des réactions, Unité associée n° 328 du Centre national de la recherche scientifique, Institut national polytechnique de Lorraine – École nationale supérieure des industries chimiques, 1, rue Grandville, B.P. 451, 54001 Nancy CEDEX, France

Reçu le 9 juin 1988

BERNARD VOGIN, FRANÇOIS BARONNET et GÉRARD SCACCHI. Can. J. Chem. **67**, 759 (1989).

Une mise au point bibliographique sur l'oxydation en phase gazeuse homogène des alcanes légers montre que, malgré un nombre substantiel de travaux, il subsiste, y compris dans le cas de l'isobutane, une liste importante de problèmes non résolus, rendant aléatoire l'écriture d'un schéma réactionnel. Afin de disposer de données expérimentales plus sûres, nous avons entrepris une étude de l'oxydation homogène de l'isobutane en appareillage statique classique à 310 et 340°C, à pression subatmosphérique. Le but principal de cette étude était de mettre en évidence les produits primaires principaux de la réaction. Pour interpréter ces observations, un mécanisme radicalaire en chaînes s'appuyant sur les produits primaires et sur l'évaluation des constantes de vitesse de réactions élémentaires par les méthodes de la Cinétique Thermochimique est proposé. Les différents processus élémentaires sont discutés et comparés aux observations expérimentales. Il est possible de mettre en évidence deux chemins réactionnels prépondérants, l'un conduisant à la formation d'isobutène et l'autre à la formation d'oxyde d'isobutène. Les conclusions du présent travail et les perspectives en découlant sont également précisées.

Mots clés : oxydation, cinétique chimique, méchanisme de réaction, isobutane.

BERNARD VOGIN, FRANÇOIS BARONNET, and GÉRARD SCACCHI. Can. J. Chem. **67**, 759 (1989).

A literature survey on the homogeneous gas-phase oxidation of light alkanes shows that despite a rather high number of papers there are still, even in the case of isobutane, an important number of unresolved questions, which makes the writing of a reaction scheme rather difficult. To obtain more reliable experimental data, we have studied the homogeneous gas-phase oxidation of isobutane in a conventional static system, at 310 and 340°C and subatmospheric pressure. This investigation is chiefly aimed at identifying and measuring the major primary products of the reaction. A chain radical scheme based on the primary products and on estimation of the rate constants of the elementary steps by the methods of Thermochemical Kinetics is put forward to interpret our experimental results. Two major reaction routes appear, one corresponding to the formation of isobutene and the other to the formation of isobutene oxide. The conclusions of the present investigation and suggestions for further developments are also mentioned.

Key words: oxidation, chemical kinetics, reaction mechanism, isobutane.

I. Introduction. Généralités sur l'oxydation des alcanes légers : cas de l'isobutane

I.1. Mise au point bibliographique

Malgré de nombreux travaux et la publication d'un certain nombre de mises au point dont celles de Baker et Yorke (1), Pollard (2) et Benson (3, 4), le mécanisme de l'oxydation homogène de substances organiques, y compris des alcanes, est loin d'être totalement élucidé et des aspects que l'on peut considérer comme fondamentaux ne sont pas encore résolus. Sans aller jusqu'à tenter d'interpréter des phénomènes tels que les flammes froides ou les inflammations de 2ème stade, la simple oxydation lente des hydrocarbures pose encore des problèmes même au niveau des processus élémentaires constituant le mécanisme.

D'après les auteurs qui se sont intéressés à ces réactions, deux types de mécanismes ont été proposés pour rendre compte des résultats observés :

(*i*) Certains travaux soulignent la prépondérance de l'isomérisation des radicaux alcoylperoxy qui avait été plus spécialement développée par Fish (5). Cette interprétation peut être représentée par le mécanisme symbolique ci-dessous où RH représente l'alcane de départ, R· le radical alcoyle qui en dérive par arrachement d'hydrogène, RO_2· le radical alcoylperoxy formé à partir de R· par addition de O_2 et ·QOOH le radical isomérisé issu de RO_2· par transfert interne d'hydrogène :

[1] $RH + O_2 \rightarrow R\cdot + HO_2\cdot$

[2] et [−2] $R\cdot + O_2 \rightleftarrows RO_2\cdot$

[3] et [−3] $RO_2\cdot \rightleftarrows \cdot QOOH$

[4] $\cdot QOOH \rightarrow$ produit + $OH\cdot$ ou $HO_2\cdot$

La facilité d'isomérisation de RO_2· en ·QOOH dépend de la taille du cycle constituant l'état de transition; le cycle à six centres est favorisé en raison de la très faible énergie de tension. Il convient également de noter que la réversibilité du processus [2] semble limiter ce mécanisme à des températures relativement basses, inférieures à des valeurs de l'ordre de 300–350°C selon la littérature.

(*ii*) À plus haute température, entre 300 et 500°C, les résultats expérimentaux publiés paraissent suggérer que l'alcane se transforme essentiellement en l'alcène conjugué. Pour expliquer ces observations, Knox (6) a proposé une théorie dite théorie oléfinique. L'alcène apparaîtrait essentiellement lors du processus suivant :

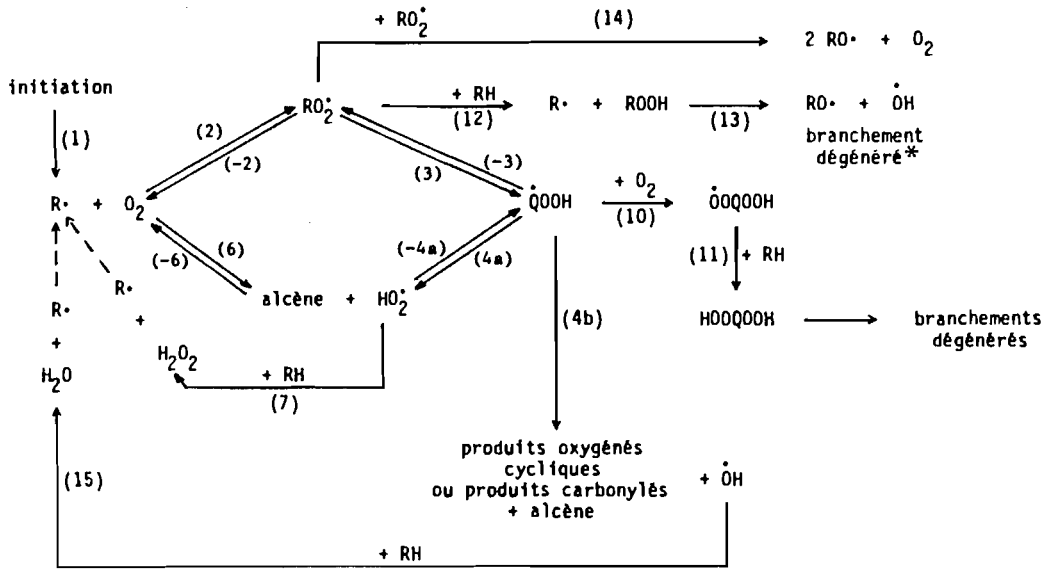
[5] $R\cdot + O_2 \rightarrow$ alcène + $HO_2\cdot$

et l'oxydation de l'alcène contribuerait pour une part appréciable à la formation de produits oxygénés. Toujours d'après Knox, les produits mineurs seraient formés de façon hétérogène à partir des radicaux alcoylperoxy. Les processus suivants peuvent donc être écrits :

[5] $R\cdot + O_2 \rightarrow$ alcène + $HO_2\cdot$

[6] $RH + HO_2\cdot \rightarrow R\cdot + H_2O_2$

[2] $R\cdot + O_2 \rightleftarrows RO_2\cdot$



[7] $RO_2\cdot \xrightarrow{\text{paroi}}$ produits mineurs

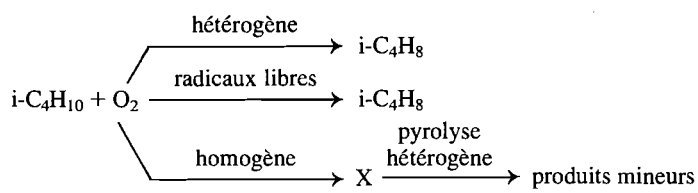
* Un branchement dégénéré correspond à la formation de radicaux libres à partir d'une espèce intermédiaire élaborée elle-même par les étapes de propagation, engendrant ainsi de nouvelles chaînes réactionnelles.

FIG. 1. Schéma mécanistique généralisé de l'oxydation des alcanes d'après la mise au point de Fish (5).

Knox (7) suggère qu'en début de réaction, c'est $HO_2\cdot$, radical sélectif et relativement peu réactif, qui arrache l'atome d'hydrogène à l'alcane et que, par la suite, il est remplacé par $OH\cdot$, radical réactif et peu sélectif. Ceci pose donc le problème du mécanisme pouvant convertir $HO_2\cdot$ en $OH\cdot$. Sans anticiper sur la suite de cette présentation, ce mécanisme pose aussi la question de la réactivité de $HO_2\cdot$ qui est en fait très limitée; il paraît difficile d'imaginer que ce radical puisse arracher un atome H à une molécule d'alcane avec une vitesse suffisante pour conduire à des phénomènes tels que les flammes froides ou les inflammations spontanées qui sont des phénomènes à la fois cinétiques et thermiques.

En accord avec le point de vue de Knox, confirmé par des travaux sur l'oxydation d'alcanes en C_6, hexane (8) et méthyl-2 pentane (9), la théorie oléfinique est censée s'appliquer surtout aux alcanes légers (C_2–C_4); dans le cas d'hexanes, on observe relativement peu d'alcène conjugué et une gamme assez large de produits oxygénés. Fish (5) a tenté de concilier les deux types de mécanismes en un schéma unique puisque le radical $RO_2\cdot$ est présent dans la théorie oléfinique de Knox comme dans les mécanismes faisant intervenir son isomérisation.

Le mécanisme généralisé que l'on peut proposer compte-tenu de la mise au point de Fish est présenté figure 1.



Si un tel schéma généralisé constitue une approche intéressante, il n'est cependant pas applicable directement à un alcane particulier car il n'est qu'un mécanisme formel.

Ceci nous conduit donc, avant de développer une étude expérimentale, à faire le point sur les travaux déjà publiés sur l'oxydation de l'isobutane. Il est à noter qu'il y a relativement peu de publications fondamentales susceptibles d'apporter des précisions sur les points soulevés précédemment.

En effet, la majeure partie des articles sur la réaction d'oxydation des alcanes légers concerne les réactions *catalytiques* qui ont des applications industrielles plus directes que la réaction non-catalytique alcane + oxygène. De plus, il faut mettre de côté, sans les rejeter, les articles concernant cette fois l'oxydation non-catalytique mais qui commentent les résultats de manipulations effectuées à un trop fort avancement de la réaction. Dans ce cas il devient très difficile de distinguer les produits primaires des produits secondaires et l'écriture des mécanismes réactionnels s'en ressent, en ce sens que l'auteur bénéficie alors d'une liberté plus grande, mais qui ne lui est pas toujours permise. Les articles concernant les flammes froides sont également à tenir à l'écart car les manipulations auxquelles ils font référence ne correspondent pas non plus aux conditions expérimentales que nous nous sommes fixées.

Semenov (10) et Sawerysyn et Lucquin (11) suggèrent que la réaction est entièrement hétérogène dans les tout premiers instants, puis devient homogène une fois la réaction autocatalytique stabilisée. Nous rappellerons pour mémoire que Zeelenberg et Bickel (12) ont proposé une réaction totalement homogène, dans laquelle tous les produits sont formés par des réactions d'isomérisation et de décomposition des radicaux alcoylperoxy au cours desquelles les chaînes sont propagées par les radicaux $\cdot OH$, $HO_2\cdot$ et $RO_2\cdot$.

Un mécanisme global de réaction est schématisé par Irvine et Knox dans le cadre d'une étude du rôle de la surface dans l'oxydation d'alcanes de C_2 à C_4 entre 300 et 480°C (13) :

Irvine et Knox ont étudié l'oxydation compétitive de mélanges binaires et ternaires d'éthane, propane et isobutane dans des réacteurs traités et non traités. Leurs résultats les conduisent à faire apparaître trois chemins réactionnels symbolisés ci-dessus dans le cas de mélanges contenant de l'isobutane : (*i*) une voie purement hétérogène, négligeable, pour l'éthane et le propane mais plus importante dans le cas de l'isobutane et susceptible de

For personal use only.

provenir, d'après ces auteurs, de l'adsorption de cet alcane à la surface; (*ii*) une voie homogène, avec propagation radicalaire conduisant à la formation de l'alcène conjugué; (*iii*) une voie «mixte» conduisant à la formation homogène d'un produit intermédiaire X de nature non précisée, dont la pyrolyse hétérogène rendrait compte de produits mineurs.

Il ne semble pas que cette interprétation et cette spécificité de l'isobutane aient été confirmées par d'autres auteurs.

Parmi les travaux que nous avons relevés sur l'isobutane, une première publication en 1973 de Barnard et Handscombe (14) semblait assez prometteuse, compte-tenu, en particulier, des objectifs fixés par les auteurs : réaction isotherme et à très faible avancement. Ils annonçaient également un article plus détaillé sur l'oxydation de l'isobutane, qui est paru en 1977. Leurs auteurs, Barnard et Brench (15), se sont en fait rapidement écartés de l'étude de la réaction isotherme à faible avancement pour s'intéresser aux phénomènes non-isothermes (flammes froides, ...). Ils ont cependant présenté un mécanisme interprétant la formation d'un bon nombre de produits identifiés et dosés, mais certains processus qui y conduisent sont peu réalistes en termes de mécanismes ou de cinétique.

Cette étude bibliographique nous conduit à penser qu'il n'existe pas d'étude expérimentale publiée répondant de façon satisfaisante aux objectifs. Son élargissement aux cas du propane et du *n*-butane conduit à la même conclusion (16).

Le choix de l'isobutane pour cette première étude expérimentale reposait sur les considérations suivantes :

(*i*) Les études de Barnard (14, 15) constituent une première approche qui pouvait servir de base à une étude plus détaillée.

(*ii*) La molécule d'isobutane possède un hydrogène tertiaire, donc plus mobile, sur lequel pourraient s'effectuer préférentiellement les arrachements d'atomes d'hydrogène. On peut donc espérer, par cette orientation de la réactivité, une certaine simplification (dans le cas du propane, les atomes d'hydrogène portés par le carbone central sont secondaires; la différence de mobilité de ces atomes par rapport aux atomes primaires des groupements terminaux est moins marquée).

(*iii*) Des recherches sur l'oxydation de l'isobutane paraissaient bien intégrées à des travaux déjà en cours au laboratoire, une osmose entre différents sujets assurant une meilleure progression des résultats. Cette étude ne constituait qu'un moyen d'approche des réactions d'oxydation homogène et, dans la seconde phase de ce travail, nous nous intéresserons à des hydrocarbures tels que le propane ou le *n*-butane étant donné qu'ils sont produits en larges quantités par l'industrie pétrochimique et que, de ce fait, leur valorisation présente un important intérêt économique.

I.2. Homogénéité de la réaction

Dans le cas de l'isobutane comme dans celui des autres alcanes légers se pose le problème de l'homogénéité de la réaction et de l'influence des parois. De ce point de vue, les résultats publiés sont plutôt contradictoires et nous avons déjà mentionné dans ce qui précède des travaux faisant appel à certains processus hétérogènes. Il apparaît, compte tenu des travaux publiés dans ce domaine, que les hautes températures ont tendance à favoriser le mécanisme homogène, ce qui paraît logique si l'on considère des résultats antérieurs obtenus au laboratoire sur des réactions de pyrolyse et que l'hétérogénéité du mécanisme diminue également lorsque la masse moléculaire de l'alcane augmente, ce qui paraît plus difficile à interpréter. Selon certains auteurs, c'est la formation de l'alcène conjugué qui contribue pour une large part à l'hétérogénéité de la réaction (17) alors que d'autres ont constaté que la formation des produits oxygénés intermédiaires était sensible aux effets de parois du réacteur (18, 19). Le comportement homogène ou hétérogène dépendrait alors de la compétition entre différents processus concurrents.

Il est à noter cependant que certains auteurs (dont Knox *et al.*) présentent la part hétérogène comme indépendante de la part homogène (13). D'autres auteurs ont recherché des corrélations entre hétérogénéité et structure. C'est ainsi que pour Atherton *et al.* (17), la part hétérogène serait d'autant plus importante que l'isomérisation du radical alcoylperoxy par un cycle à six centres et arrachement d'un atome d'hydrogène secondaire ou tertiaire est empêchée. Ceci expliquerait alors pourquoi les alcanes légers s'oxyderaient selon un mécanisme dont la part hétérogène est importante.

Les différents points mentionnés dans ce qui précède montrent la quasi-impossibilité d'aboutir à des conclusions sûres. Pour y arriver, il paraît nécessaire d'entreprendre des essais systématiques de différents réacteurs variant tant par leur rapport surface sur volume que par la nature des parois.

Faute d'une telle étude, d'ailleurs de mise en oeuvre longue et délicate, il est difficile d'estimer l'importance des effets hétérogènes. Ceux-ci se manifestent d'abord au niveau des problèmes de reproductibilité des expériences, point dont nous reparlerons plus loin.

Du point de vue mécanisme réactionnel et contrairement à l'opinion d'un certain nombre d'auteurs, il semble que les effets de parois soient à attribuer aux radicaux OH· plutôt qu'aux radicaux HO_2· (20), ce qui paraît qualitativement en accord avec les résultats expérimentaux obtenus dans notre laboratoire, en particulier dans le cas du méthyl *tert*-butyl éther (MTBE), relativement peu sensible aux effets de parois dans le cas de la réaction d'oxydation (21).

Ces quelques rappels soulignent non seulement l'imprécision des données expérimentales mais aussi leur insuffisance. Ils corroborent l'opinion de Benson et Nangia (4) qui soulignent qu'un nombre appréciable de problèmes ne sont pas encore résolus. Parmi ces problèmes figurent la nature des porteurs de chaînes, HO_2· ne paraissant pas suffisamment réactif, l'origine du coefficient négatif de température, les réactions des radicaux HO_2· et RO_2· entre eux (par exemple, la dismutation $2RO_2\cdot \rightarrow 2RO\cdot + O_2$), les processus d'amorçage (la réaction $RH + O_2 \rightarrow R\cdot + HO_2\cdot$ paraissant trop lente, même à 300°C) et les processus d'isomérisation.

Toutes ces incertitudes nous ont donc paru justifier une nouvelle étude expérimentale dans le cas de l'isobutane, sans pour autant prétendre résoudre toutes les questions soulevées précédemment en une étude de durée limitée.

II. Étude expérimentale de l'oxydation de l'isobutane

II.1. Appareillage et analyses

L'oxydation de l'isobutane est étudiée à pression sub-atmosphérique, généralement avec des mélanges équimoléculaires isobutane/O_2, vers des pressions totales de 125 Torr (1 Torr = 133.3 Pa), dans le domaine de température 300–350°C. Les réacteurs statiques de verre Pyrex ont un volume intérieur voisin de 250 cm^3. Le réacteur est chauffé par un dispositif à faible inertie, constitué de deux coquilles formées de spires jointives de fil chauffant «Thermocoax» isolé électriquement, l'ensemble étant équipé d'une régulation appropriée reliée à un thermocouple placé sous les spires.

L'isobutane et l'oxygène prémélangés sont introduits dans le réacteur à l'instant $t = 0$ et, pour déterminer la composition au temps t, les gaz sont détendus et trempés à l'ambiante et prélevés dans des ampoules en U permettant une insertion facile dans les circuits de gaz vecteur de chromatographes.

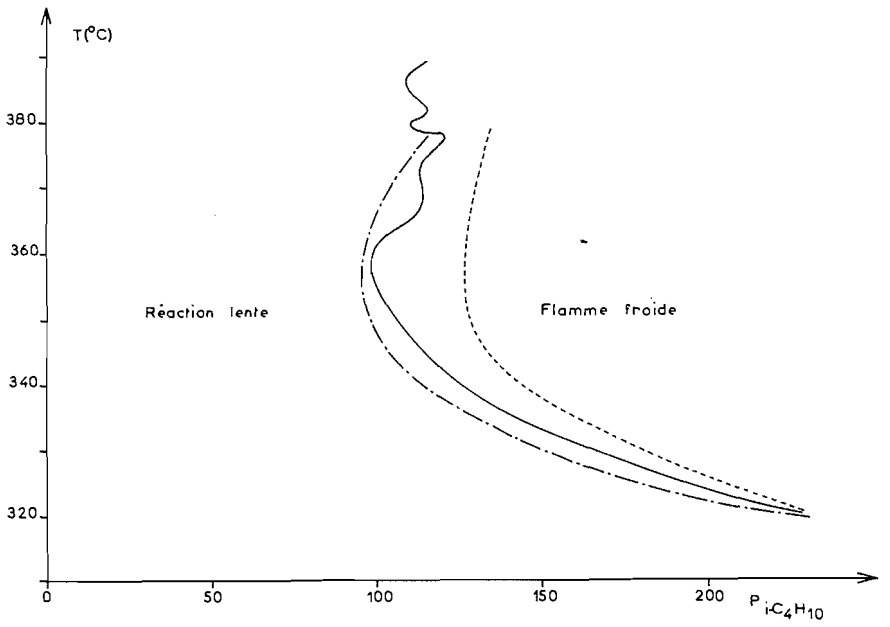

FIG. 2. Diagramme pression – température de l'oxydation de l'isobutane. Mélange équimolaire isobutane–oxygène. Réacteur sphérique en verre Pyrex d'un volume de 250 cm^3. (—) mélange binaire isobutane–oxygène; (- - -) mélange ternaire isobutane–oxygène–azote, P_{totale} = 600 Torr; (- - - -) mélange ternaire isobutane–oxygène–hélium, P_{totale} = 600 Torr.

Les hydrocarbures sont dosés sur une colonne de Durapak (phényl isocyanate greffé sur Porasil), les produits oxygénés sur une colonne de Carbowax 20 M, O_2 et CO sur une colonne de tamis moléculaire, CO_2 et l'eau sur une colonne de Porapak Q. Le formaldéhyde est dosé par colorimétrie, l'eau oxygénée et les peroxydes par une méthode utilisant la chimiluminescence que nous avons adaptée aux conditions de cette étude (22).

II.2. Diagramme pression–température

Ce diagramme a été étudié en utilisant un réacteur muni d'un thermocouple fin (0,08 mm de diamètre) situé en son centre afin de déterminer les conditions expérimentales correspondant à la réaction lente. La limite réaction lente – flammes froides a été déterminée point par point, par encadrement; elle est représentée sur la figure 2.

Bien que légèrement déplacée par rapport à des limites analogues publiées dans la littérature, la limite obtenue expérimentalement paraît compatible avec d'autres travaux publiés (cf. par ex., réf. 17). Les écarts peuvent être attribués à des conditions expérimentales quelque peu différentes (forme et volume du réacteur, rapport i-C_4H_{10}/O_2...).

Afin d'observer qualitativement l'effet que provoque la dilution par des gaz inertes, nous avons ajouté de l'azote puis de l'hélium pour travailler à une pression totale de 600 Torr en conservant le rapport i-C_4H_{10}/O_2 voisin de 1. L'azote a peu d'influence; il déplace simplement la limite réaction lente – flammes froides vers des pressions un peu plus basses.

L'hélium présente au contraire la particularité de déplacer la limite réaction lente – flammes froides vers des pressions plus élevées; toutes choses égales par ailleurs, une addition d'hélium transforme une flamme froide en réaction lente. Une telle observation avait déjà été faite par J. Wilson (23) dans le cas du méthyl-2 pentane. Ce phénomène est dû aux propriétés thermiques de l'hélium, plus spécifiquement à sa conductivité thermique, et ceci confirme, si besoin en était, la nature cinétique *et* thermique des flammes froides.

À la suite de ces premiers essais, nous avons choisi pour notre étude les conditions expérimentales suivantes : rapport i-C_4H_{10}/O_2 = 1; pression initiale de mélange, 125 Torr; température de réaction variant de 310 à 340°C.

II.3. Reproductibilité des expériences. Effets de parois

Compte-tenu des résultats mentionnés par d'autres auteurs, nous nous attendions à des difficultés expérimentales liées aux effets de parois, se traduisant en particulier par une certaine irreproductibilité des expériences.

Nous avons d'abord utilisé un réacteur sphérique de Pyrex, vide, de volume intérieur 250 cm^3 et de rapport surface sur volume (s/v) voisin de 0,8 cm^{-1}, sans traitement préalable. Une seconde série d'essais a été effectuée dans ce même réacteur, mais après traitement des parois selon la méthode que nous mentionnerons plus loin.

Les conditions expérimentales de la réaction ont été fixées de manière à obtenir environ 2% de l'isobutane transformé en isobutène pour un temps de réaction de 6 min, la pression initiale de mélange équimoléculaire isobutane–oxygène étant 125 Torr et la température du réacteur 330°C.

La réaction a été suivie en dosant l'isobutène formé et ces essais ont confirmé nos craintes concernant la reproductibilité, la variation étant de l'ordre de 10% autour d'une valeur moyenne.

Nous avons alors tenté de «conditionner» le réacteur en faisant précéder l'expérience proprement dite d'une première manipulation non retenue, de façon à ce que le réacteur ait toujours subi les mêmes opérations avant d'être utilisé pour l'expérience de référence. Cette technique de «conditionnement» conduit à une atténuation relative des variations mais la reproductibilité paraît encore insuffisante pour des études cinétiques. Le vieillissement du réacteur («seasoning») par des expériences répétées ne semble pas conduire à une limitation de ces irreproductibilités. C'est pourquoi nous avons essayé un traitement des parois de ce même réacteur.

Nous avons préféré ne pas utiliser de traitements ou de recouvrements ayant a priori des effets cinétiques importants comme KCl. Par ailleurs, les traitements ou recouvrements envisagés doivent être stables en présence d'oxygène et à des températures pouvant atteindre 400°C. Ceci excluait donc des recouvrements par des résines ou des dérivés halogénés (24) ou par des matériaux riches en carbone provenant de pyrolyses de composés halogénés (25); ce dernier type de traitement s'était révélé efficace dans l'étude de la pyrolyse du MTBE, réaction qui s'était révélée très sensible aux effets de parois (26).

Compte-tenu de ces remarques, nous avons choisi la méthode proposée par Marshall et coll. (27) consistant en un traitement à la soude 10 M puis à l'acide nitrique 10 N et rinçage à l'eau distillée. On constate d'abord que la réaction est accélérée par rapport à la cinétique avant traitement par un rapport voisin de 2, toutes autres conditions égales par ailleurs. Ceci souligne l'importance des effets hétérogènes évoqués précédemment, même en réacteur vide.

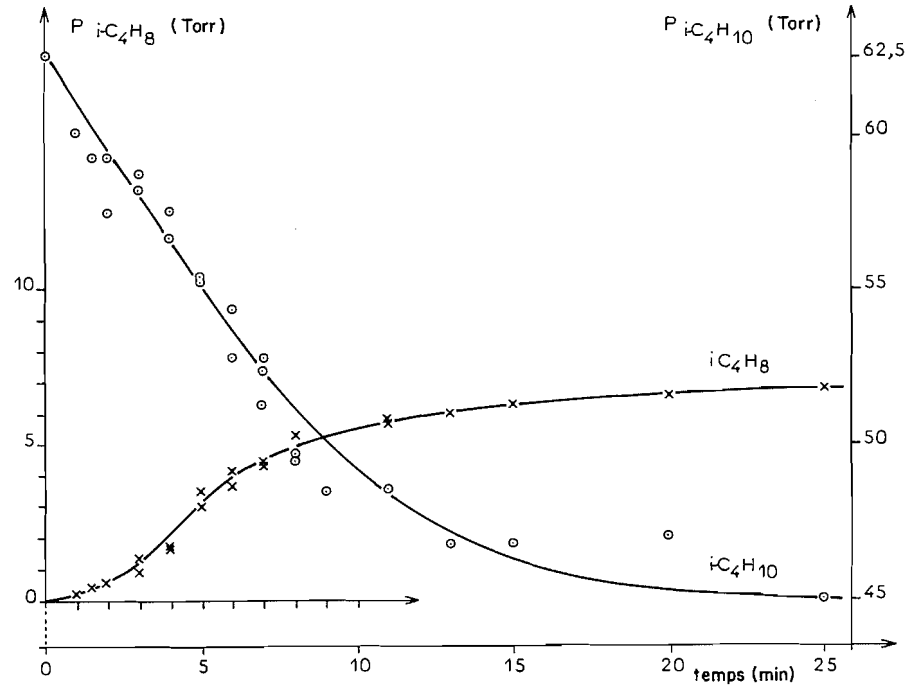

FIG. 3. Courbes de consommation de l'isobutane et de formation de l'isobutène. Pression initiale du mélange équimoléculaire isobutane–oxygène : 125 Torr. Température de réaction : 340°C.

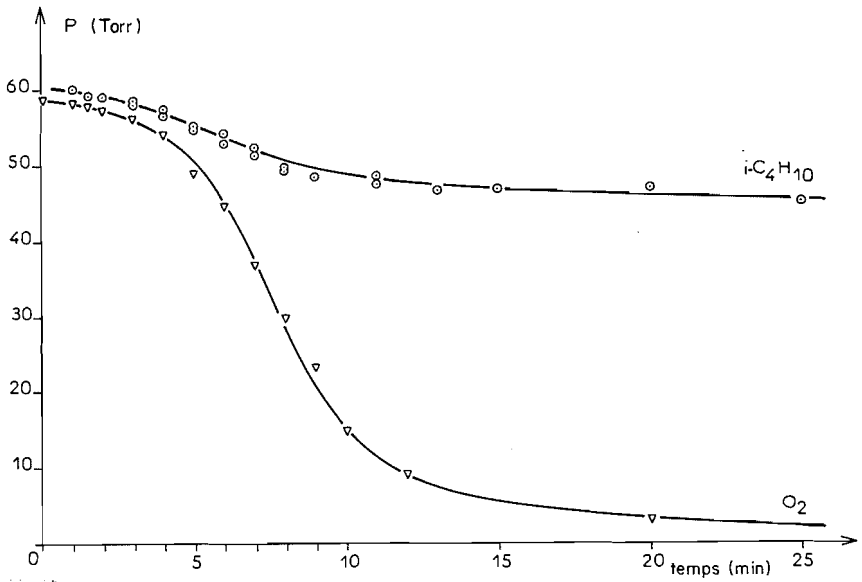

FIG. 4. Oxydation de l'isobutane à fort avancement : courbes de consommation des réactifs. Pression initiale du mélange équimoléculaire isobutane–oxygène : 125 Torr. Température de réaction : 340°C.

La dispersion des résultats est encore sensible mais nous l'avons jugée tolérable, en particulier pour une étude préliminaire visant d'abord à établir les bilans-matière de la réaction.

II.4 Étude préliminaire de la réaction. Bilans matière

Cette étude préliminaire a été effectuée à 340°C, à une pression de 125 Torr de mélange équimoléculaire isobutane–oxygène. Nous avons d'abord dosé l'isobutane consommé et l'isobutène formé; les résultats obtenus sont représentés figure 3. Il apparaît que le rapport isobutène formé sur isobutane consommé est sensiblement inférieur à 80%, en désaccord avec un certain nombre de travaux sur l'oxydation d'alcanes légers; les valeurs calculées à partir des points expérimentaux non lissés varient entre 20 et 45%.

Nos premiers résultats suggèrent qu'une quantité importante d'isobutane se transforme en produits autres que l'isobutène, directement ou via l'isobutène qui serait alors consommé en partie par des réactions secondaires.

Sur la figure 4 nous avons comparé la consommation d'isobutane et la consommation d'oxygène. Cette dernière présente la forme en S classique obtenue dans les réactions d'oxydation.

Il apparaît donc très rapidement une consommation beaucoup plus importante de l'oxygène qui tend à devenir pratiquement totale alors que seulement 30% de l'isobutane initial est consommé. Ceci explique qu'après être passé par un maximum, la vitesse de la réaction diminue à la suite du manque d'oxygène, ce qui est en accord avec l'allure sigmoïdale des courbes de production d'isobutène et de consommation d'isobutane. Il convient également de noter que les proportions d'isobutane et d'oxygène correspondent à un mélange riche par

TABLEAU 1. Bilan sur les éléments carbone, oxygène et hydrogène lors de l'oxydation de l'isobutane à 340°C (125 Torr de mélange équimoléculaire)

Temps de réaction (min)	2	3	4	5	6	7	8	10	11	15
Taux de conversion (%)	3,44	6,64	9,15	15,7	21,9	25,0	26,1	27,8	28,8	30,5
Bilan en carbone (%)	100,2	99,4	102,1	100,0	97,9	98,5	100,4	104,4	104,8	105,1
Bilan en oxygène (%)	101,6	100,0	97,1	97,2	91,8	85,0	83,9	80,4	80,0	79,6
Bilan en hydrogène (%)	99,7	99,8	102,4	101,9	101,4	99,5	102,5	105,2	103,8	103,1

rapport à l'équation stoechiométrique de combustion totale. L'équation stoechiométrique : i-C_4H_{10} + O_2 = i-C_4H_8 + H_2O_2 ne permettrait donc pas de représenter l'essentiel de la réaction.

Ces premiers résultats paraissent suggérer également qu'il se forme de substantielles quantités de produits oxygénés, ce qui nous a conduits à identifier les produits formés et à déterminer leur nature primaire ou secondaire.

Les produits suivants ont été identifiés et dosés : hydrocarbures : à côté de l'isobutène, méthane, éthylène et propène; produits oxygénés : formaldéhyde, acétaldéhyde, propionaldéhyde, isobutyraldéhyde et acétone, oxydes d'isobutène et de propylène, CO, CO_2, H_2O.

Ces résultats ont permis d'établir des bilans de matière sur les trois éléments carbone, oxygène et hydrogène. Les premières déterminations ont fait apparaître des anomalies, en particulier un écart entre la pression mesurée en fin de réaction et la somme des pressions partielles des produits dosés. Ces anomalies ont été rapidement attribuées à un dosage erroné (par défaut) de l'eau, en raison de sa condensation dans différentes parties de l'appareillage, y compris les tubulures et l'ampoule de prélèvement. Les différentes parties concernées ont été chauffées par un cordon chauffant vers 70°C, ce qui a nettement amélioré les bilans (tableau 1).

Ces bilans comportent des incertitudes et des irreproductibilités qui se traduisent par certaines valeurs supérieures à 100% mais, globalement, l'examen de ces bilans conduit à penser que nous n'avons pas manqué de produits importants lors de cette étude expérimentale. La fiabilité de notre étude paraissant ainsi établie, il nous a été possible d'aborder l'étude de l'oxydation à faible avancement, de manière à déterminer les produits primaires de la réaction, donnée importante pour l'établissement d'un mécanisme réactionnel.

II.5. Étude de l'oxydation à faible avancement

Pour réaliser cette étude, nous avons réduit la température de réaction de 30°C, l'avancement à 5 min passant de 15,7% à 340°C à 0,65% à 310°C, toujours pour une pression initiale de 125 Torr de mélange équimoléculaire. Cet abaissement de température devrait également limiter ou éviter certaines réactions secondaires car l'isobutène, alcène conjugué, paraît être plus réactif que l'isobutane.

La gamme de produits obtenus est la même que celle reportée précédemment; les courbes de formation de produits sont regroupées sur la figure 5 mais, pour en faciliter la lecture, nous n'avons pas reporté les points expérimentaux.

Cependant les courbes représentées ne permettent pas de distinguer facilement entre les produits primaires et les produits non primaires, en raison de l'allure auto-accélérée des courbes de formation.

Pour tenter de faire la différence entre produits primaires et produits non primaires, nous avons calculé le rapport de la quantité de chacun des produits dosés (sauf l'eau et les peroxydes) à leur somme pour les différents temps de séjour explorés. Ces rapports, extrapolés à l'instant initial (avancement nul), permettent de déterminer le pourcentage du produit considéré à l'instant initial par rapport à la somme des produits dosés. Si l'extrapolation donne une valeur nulle le produit est secondaire.

Les résultats de cette étude figurent dans le tableau 2 où nous avons reporté les valeurs déterminées à l'instant initial et observées à un temps de séjour de 5 min. L'isobutène est effectivement le produit principal. Ces résultats nous permettent de penser que l'oxyde de propylène et le monoxyde de carbone ne sont pas primaires ainsi vraisemblablement que l'éthylène et le méthane; la détermination se révèle plus délicate pour le formaldéhyde et l'acétaldéhyde. Les autres produits peuvent être considérés comme primaires.

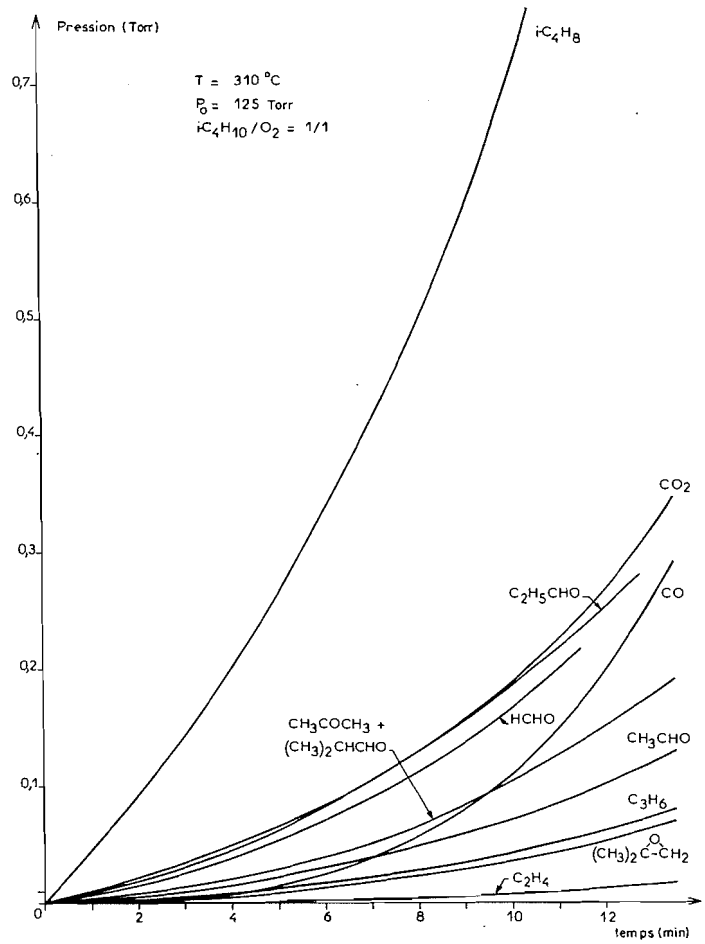

FIG. 5. Oxydation de l'isobutane à faible avancement : courbes de formation des produits. Pression initiale du mélange équimoléculaire isobutane–oxygène : 125 Torr. Température de réaction : 310°C.

Notons que les valeurs du tableau sont surestimées puisque l'eau, produit formé en relativement grandes quantités, n'est pas comptabilisée dans ces calculs en raison de l'imprécision du dosage. Pour fixer les idées, à 5 min il y a des quantités presque doubles (1,85 fois) d'eau par rapport à celles d'isobutène.

La principale difficulté qui apparaît à la lecture de ce tableau est la valeur obtenue pour le dioxyde de carbone qu'on attendrait comme produit non primaire. Malgré des investigations complémentaires, nous n'avons pas pu lever cette ambiguïté. Il convient de noter cependant que CO_2 doit être dosé sur un chromatographe muni d'un détecteur à conductibilité thermique (thermistances), méthode nettement moins sensible que l'ionisation de flamme (F.I.D.). L'appareil utilisé dans cette série, de conception relativement ancienne (F6.3 Perkin–Elmer) et donc de sensibilité limitée, peut être pour une part à l'origine d'erreurs appréciables.

TABLEAU 2. Répartition des produits dosés à 5 min et extrapolation à l'instant initial (T = 310°C, 125 Torr de mélange équimoléculaire)

Produit	% Molaire à $t = 0$	% Molaire à $t = 5$ min
CH_4	0	0
C_2H_4	0,1 ≃ 0	0,2
C_3H_6	2,35	2,4
i-C_4H_8	56,7	49,2
HCHO	?	10,1
CH_3CHO	≃0	4,2
C_2H_5CHO	10,4	11,8
i-C_3H_7CHO + CH_3COCH_3	4,9	5,5
Oxyde de propène	0	<0,1
Oxyde d'isobutène	2,0	1,7
CO	0	2,7
CO_2	[13,2]	12,2
Total		100

Malgré ces quelques difficultés, nous pensons ainsi avoir obtenu suffisamment de données expérimentales pour aborder l'aspect mécanistique.

III. Détermination du mécanisme de la réaction et commentaires

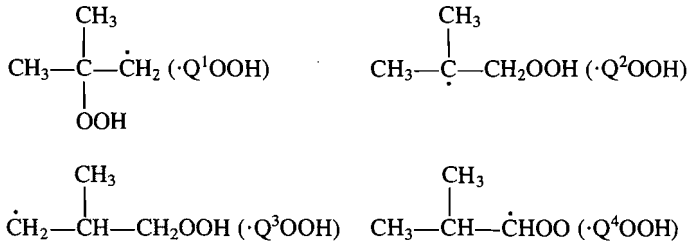
III.1. Détermination du mécanisme

Le mécanisme réactionnel est déterminé en s'appuyant sur les résultats expérimentaux précédents, en particulier les produits primaires, pour écrire les processus élémentaires auxquels peuvent donner lieu les différentes espèces radicalaires présentes dans le système. Ce que nous cherchons à écrire, ce sont des processus élémentaires vrais et non des réactions globales, compatibles avec les principes de la cinétique (réversibilité microscopique, moindre changement de structure, etc...) et avec les connaissances actuelles en chimie radicalaire et en thermochimie. Les processus écrits tiennent compte également des schémas proposés antérieurement par d'autres auteurs (Fish et Knox en particulier) pour rendre compte des oxydations d'alcanes.

L'écriture de ce mécanisme réactionnel peut être obtenue de manière systématique en analysant les diverses catégories de processus élémentaires pouvant intervenir, compte-tenu de la nature des radicaux dérivés de la molécule d'isobutane.

Compte-tenu de la plus faible énergie de dissociation de liaison entre un carbone et un H tertiaire (qu'entre un carbone et un H primaire), il est logique d'admettre que le radical *tert*-butyle t-$C_4H_9\cdot$ sera prépondérant devant le radical isobutyle i-$C_4H_9\cdot$ lors de l'amorçage primaire de la réaction.

On considère ensuite l'addition réversible de l'oxygène sur les radicaux alcoyles R· dérivés de la molécule d'isobutane RH par arrachement d'un atome d'hydrogène ($R^1\cdot$, t-$C_4H_9\cdot$ et $R^2\cdot$, i-$C_4H_9\cdot$)



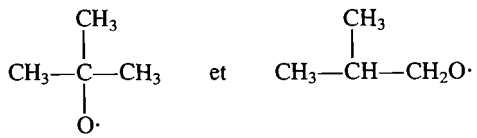
$$R\cdot + O_2 \rightleftarrows RO_2\cdot$$

Cette réaction conduit à la formation de radicaux alcoylperoxy $RO_2\cdot$, *tert*-butylperoxy $R^1O_2\cdot$ et isobutylperoxy $R^2O_2\cdot$.

En accord avec les schémas retenus par Fish, ces radicaux alcoylperoxy, ici sous deux formes isomères $R^1O_2\cdot$ et $R^2O_2\cdot$, peuvent s'isomériser par transfert d'hydrogène interne en radicaux hydroperoxyalcoyle ·QOOH

$$RO_2\cdot \rightleftarrows \cdot QOOH$$

Compte-tenu de la structure des radicaux alcoylperoxy et des isomérisations internes possibles, il est possible théoriquement d'obtenir ainsi quatre formes de radicaux hydroperoxy alcoyle :

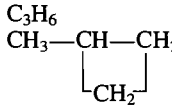


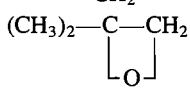
Cependant la formation de $\cdot Q^4OOH$ suppose le passage par un état de transition constitué par un cycle à quatre centres, donc nécessitant une énergie d'activation élevée, en raison de la tension du cycle. Les calculs montrent, en accord avec cette observation, que la concentration des radicaux $\cdot Q^4OOH$ peut être considérée comme négligeable par rapport à celle des autres radicaux isomérisés provenant de $R^2O_2\cdot$.

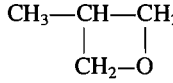
Nous postulons, en accord avec le mécanisme de Fish, que certains produits primaires proviennent également de la décomposition des radicaux alkoxy, que l'on peut supposer être dérivés des radicaux $RO_2\cdot$ par des réactions de dismutation.

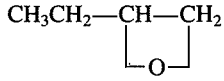
Il est certain que l'écriture de *tous* les processus élémentaires possibles conduirait à un mécanisme global particulièrement complexe qui ne serait que d'une aide très limitée à l'interprétation de nos résultats expérimentaux. Pour simplifier ce schéma réactionnel et surtout déterminer les réactions élémentaires *essentielles* susceptibles de rendre compte des caractéristiques observées, il faudrait disposer des constantes de vitesse de tous les processus élémentaires pouvant être écrits. Les données expérimentales étant généralement limitées dans le cas des réactions d'oxydation, très peu de ces constantes sont disponibles.

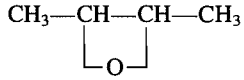
Compte-tenu de ce manque de données, nous avons jugé préférable d'utiliser une méthode semi-empirique d'estimation des constantes de vitesse des processus élémentaires figurant











dans les schémas réactionnels, méthode qui a également l'avantage de fournir des données homogènes, même si leur précision est limitée. Il serait fastidieux de développer ici les calculs correspondants ou même d'exposer les principes de la méthode utilisée. Rappelons que ces méthodes ont été développées par Benson et co-auteurs sous le nom de «Cinétique Thermochimique». Elles ont été détaillées par S. W. Benson dans l'ouvrage intitulé «Thermochemical kinetics—Methods for the estimation of thermochemical data and rate parameters», dont la seconde édition est parue en 1976 (28). L'application plus spécifique de ces méthodes aux réactions d'oxydation et de combustion a fait l'objet d'une mise au point par Golden (29). Rappelons seulement que ces méthodes nécessitent d'abord l'estimation des données thermochimiques (ΔH_f^0, S^0, C_p^0) par des méthodes d'additivité de groupes ou en tenant compte des paramètres structuraux de l'espèce considérée, molécule ou radical.

Dans le cas présent, tous les calculs de ΔH_f^0 et S^0 sont faits

à 300 K; ils seront utilisés à 583 K sans correction en raison du nombre important de valeurs de C_p^0 non tabulées. Les variations en fonction de la température sont relativement faibles et il faut noter que les corrections sur ΔH^0 et S^0 se compensent lors du calcul de ΔG^0. Les résultats de ces calculs sont donnés tableau 3.

Compte-tenu de la relation entre les grandeurs thermodynamiques ΔH^0, ΔS^0 et la constante d'équilibre K:

$$-RT \log K = \Delta H^0 - T\Delta S^0$$

la connaissance de ΔH^0, de ΔS^0 et de la constante de vitesse de la réaction directe k_d ou inverse k_i conduit à la valeur de l'autre ce qui suppose, en l'absence de données expérimentales, des approximations raisonnables obtenues par des analogies avec des réactions voisines.

Les résultats de l'estimation des grandeurs cinétiques sont donnés dans le tableau 4.

Dans ce tableau, nous donnons les valeurs du facteur préexponentiel A, de l'énergie d'activation E et de la constante k calculée à 583 K (unités : L, mol, s).

TABLEAU 4. Paramètres cinétiques calculés pour les différents processus élémentaires proposés dans le mécanisme d'oxydation de l'isobutane (A, E et constante calculée à 583 K)

Réactions	A	E (kcal·mol^{-1})	k (s^{-1}) (à 583 K)

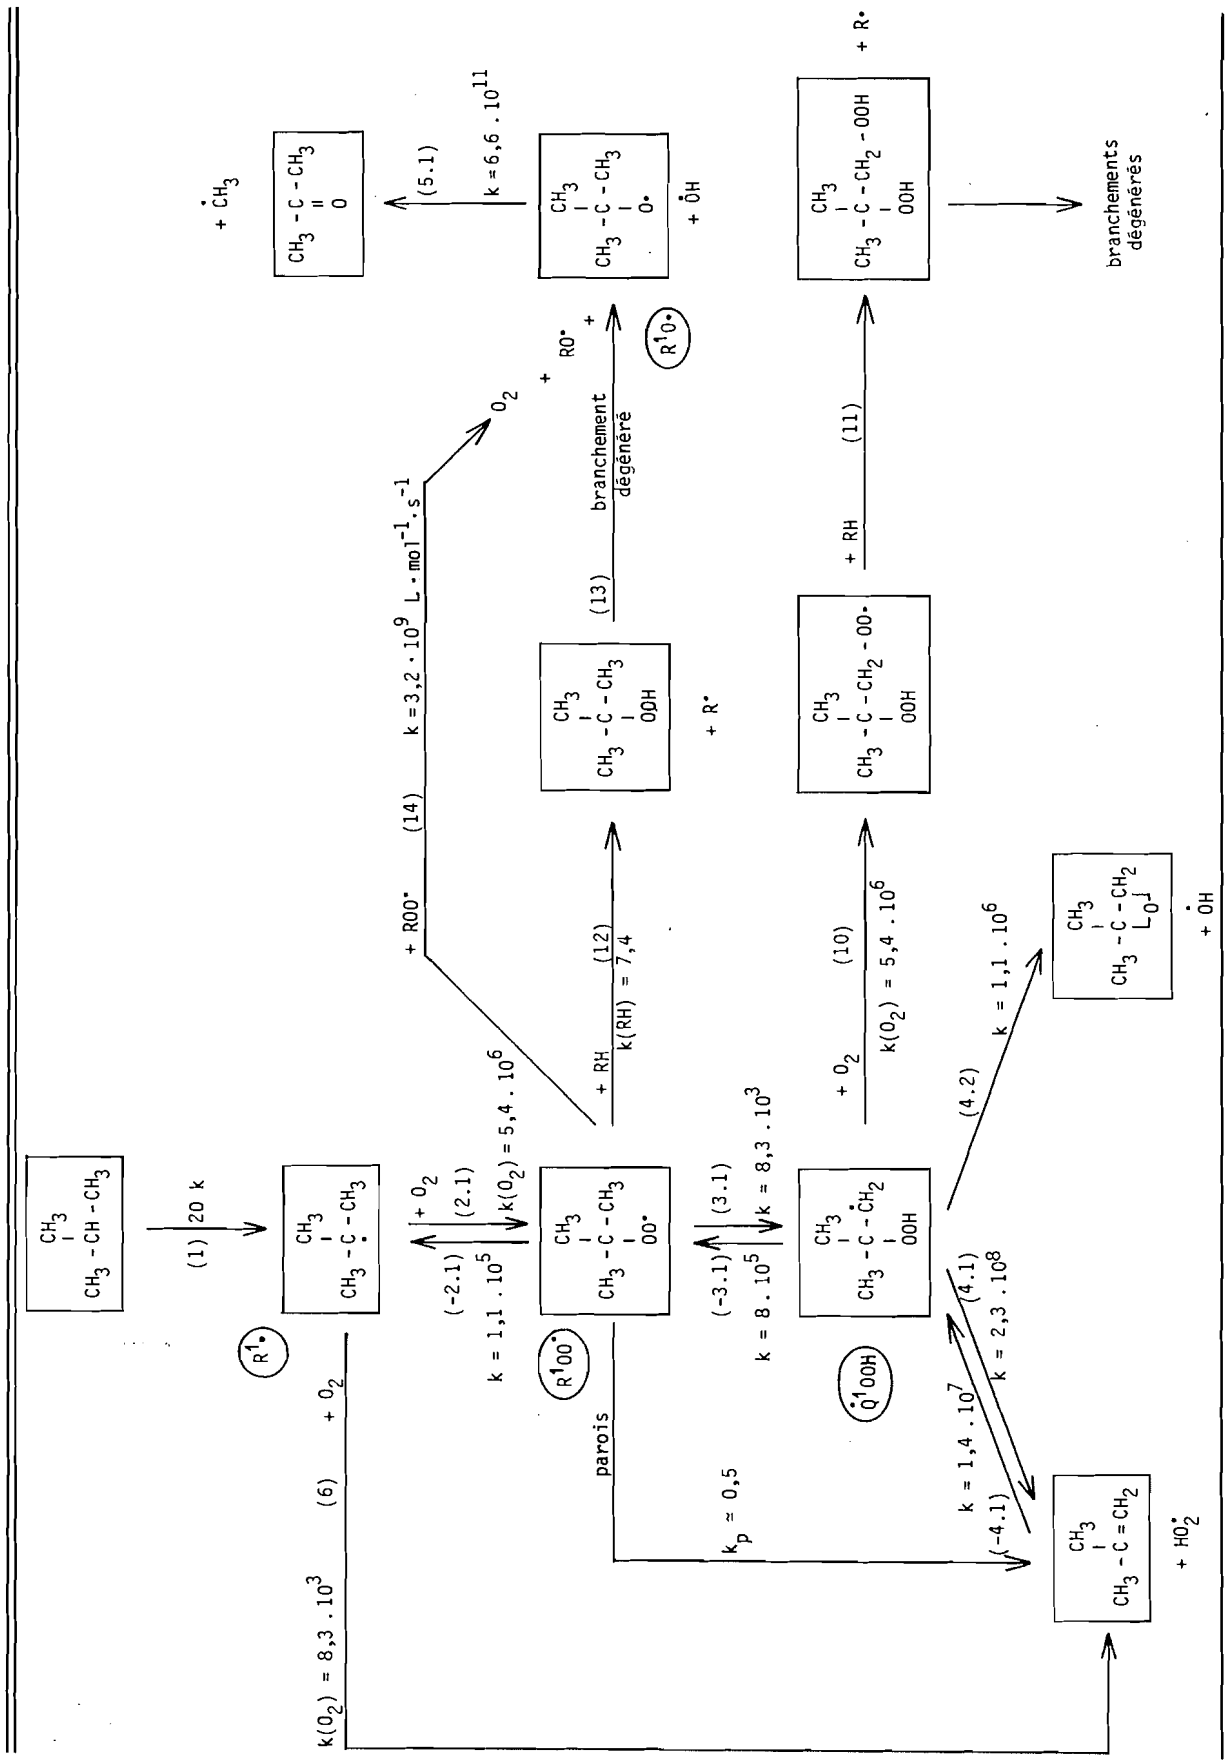
[a]Pour l'arrachement d'un atome H primaire.
[b]Pour l'arrachement d'un atome H secondaire.
[c]Pour l'arrachement d'un atome H tertiaire.

L'ensemble des processus élémentaires retenus, compte-tenu des commentaires précédents, ainsi que les constantes de vitesse calculées à 583 K sont donnés dans les tableaux 5 et 6, le premier à partir du radical *tert*-butyle, le second à partir du radical isobutyle.

Des calculs ont pu ainsi être développés à partir des schémas mécanistiques proposés dans ces deux tableaux et en tenant compte des valeurs numériques des constantes de vitesse. Il a été possible par exemple d'estimer les rapports des concentrations des différents radicaux ·QOOH. À partir de ces calculs, nous avons pu établir que ·Q^1OOH, ·Q^2OOH et ·Q^3OOH sont présents en des concentrations d'ordres de grandeur voisins alors que celle de ·Q^4OOH peut être considérée comme négligeable. Compte-tenu de ces calculs, des comparaisons ont pu être établies avec les résultats expérimentaux. En effet, disposant d'une estimation des constantes de vitesse des processus de décomposition des radicaux ·QOOH, il devient possible de déterminer les rapports théoriques des vitesses initiales de formation des produits primaires et de les confronter aux résultats expérimentaux tout au moins en ce qui concerne les produits primaires ne provenant pas de la dismutation éventuelle des radicaux RO_2·.



III.2. Commentaires sur le mécanisme proposé

Il serait fastidieux de discuter ici chaque chemin réactionnel en le comparant avec les formations de produits observées expérimentalement. Une comparaison détaillée de cette nature a été faite dans un mémoire de thèse (16). Il est à noter qu'à ce stade de notre travail nous n'avons pas ajusté les paramètres cinétiques obtenus par les méthodes de Benson à nos résultats expérimentaux. Comme nous l'avons déjà mentionné, ces méthodes ne visent qu'à donner une valeur approximative des

TABLEAU 5. Mécanisme d'oxydation de l'isobutane (processus élémentaires issus du radical $t\text{-}C_4H_9^{\cdot}$)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

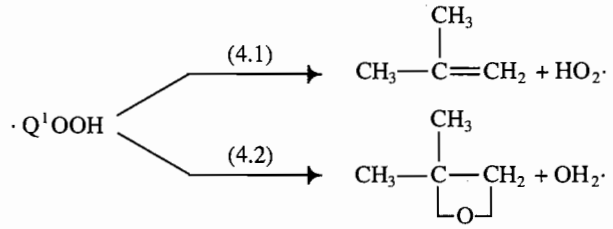

TABLEAU 6. Mécanisme d'oxydation de l'isobutane (processus élémentaires issus du radical i-$C_4H_9^{\cdot}$).

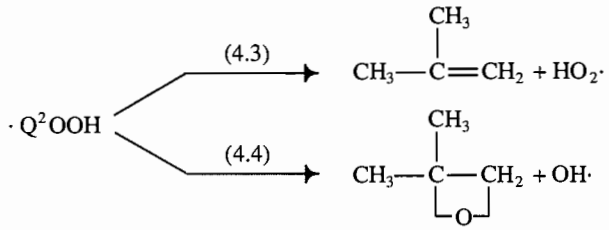


constantes de vitesse et un écart d'une puissance de 10 demeure tout à fait acceptable.

Pour fixer les idées, traitons d'abord le cas du couple isobutène – oxyde d'isobutène (désigné dans certains calculs par i-Butox). Ces deux produits sont issus parallèlement de deux voies (se reporter aux tableaux 5 et 6 pour la nomenclature) :

(*i*) à partir du radical $\cdot Q^1OOH$:

(*ii*) à partir du radical $\cdot Q^2OOH$:

Le calcul du rapport des vitesses de formation des deux espèces s'écrit alors :

$$\frac{v_{\text{i-C}_4\text{H}_8}}{v_{\text{i-Butox}}} = \frac{k_{4.1}(\cdot Q^1OOH) + k_{4.3}(\cdot Q^2OOH)}{k_{4.2}(\cdot Q^1OOH) + k_{4.4}(\cdot Q^2OOH)}$$

Compte-tenu de l'évaluation des concentrations relatives des radicaux et de l'estimation des constantes de vitesse, ce rapport peut être estimé à 220 dans nos conditions expérimentales.

Expérimentalement, le rapport des pourcentages initiaux des deux produits conduit à :

$$\frac{\%\ \text{i-C}_4\text{H}_8}{\%\ \text{i-Butox}} = \frac{56.7}{2} \simeq 28$$

Si l'on se reporte aux remarques précédentes sur l'estimation des constantes de vitesse, la concordance peut être considérée comme correcte.

D'autres remarques peuvent être faites à partir du mécanisme proposé. Dans nos conditions expérimentales, le processus oléfinique direct :

$$R\cdot + O_2 \rightarrow \text{i-C}_4\text{H}_8 + HO_2\cdot$$

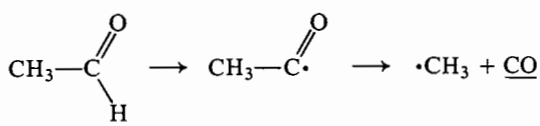
apparaît relativement peu important, de l'ordre de 1,5% par rapport à la formation issue de l'isomérisation de $RO_2\cdot$ (via $\cdot QOOH$). La formation directe d'oléfines aux parois apparaît négligeable (de l'ordre de 10^{-2}%), en accord avec le point de vue de Walker (32).

La comparaison entre la formation théorique de propène et nos observations expérimentales montre des difficultés au niveau du processus (4.6); il paraît nécessaire d'envisager un autre processus de formation via (5.2) selon une suggestion de Barnard et Brench (15).

La formation de certains produits carbonylés, dont le propionaldéhyde suscite également quelques difficultés au niveau de la comparaison entre formations estimées à partir du schéma réactionnel et résultats expérimentaux. En effet, il paraît logique d'attribuer la formation de ces produits à la décomposition de radicaux alcoxy, eux-mêmes pouvant être attribués à la dismutation de deux radicaux alcoylperoxy :

$$2RO_2\cdot \rightarrow 2RO\cdot + O_2$$

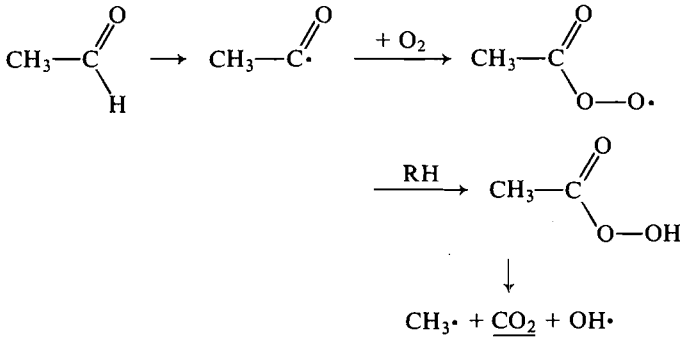
si l'on veut être en accord avec la nature primaire de ces produits. En réalité, ces produits carbonylés pourraient être pour une part de nature secondaire mais avoir une allure pseudo-primaire, s'ils sont formés à partir de produits primaires suffisamment réactifs et en quantités relativement importantes (oléfines par exemple).



En ce qui concerne les hydroperoxydes, une comparaison entre résultats expérimentaux et prévisions déduites du mécanisme est assez difficile à réaliser. Elle nécessiterait d'abord davantage de précision au niveau expérimental par la réalisation d'un dosage permettant de différencier les peracides, l'eau oxygénée et les peroxydes organiques. Savaya (33) et Hoare et coll. (34) utilisent une méthode par iodométrie proposée par Cullis et Newitt (35) permettant cette distinction mais, en raison des relativement faibles avancements de nos réactions, les méthodes de dosage par iodométrie classique avaient déjà échoué. Néanmoins le rapport calculé de la formation globale d'hydroperoxyde à celle de l'oxyde d'isobutène paraît acceptable par rapport aux observations expérimentales.

Il serait intéressant de disposer de davantage de données quantitatives concernant l'eau. Il convient de remarquer que son dosage, dans nos conditions opératoires, est généralement difficile pour deux raisons :

(*i*) il est relativement difficile de prélever quantitativement l'eau formée d'un appareillage statique en Pyrex, en raison des phénomènes d'absorption sur les parois des lignes de transfert et des ampoules d'échantillonnage. Les quantités dosées sont très sensibles à la température de ces éléments et comme nous l'avons mentionné précédemment, nous avons dû utiliser des cordons chauffants pour obtenir des mesures paraissant satisfaisantes.



(*ii*) Les analyses chromatographiques sont elles-mêmes délicates, surtout pour de faibles quantités. Rappelons que l'eau a été dosée sur colonne de Porapak Q, longueur 1 m, température 39°C, gaz porteur H_2 et détection par thermistances.

Si la nature non primaire du monoxyde de carbone ne pose pas de problème, il paraît difficile de préciser un mécanisme sûr rendant compte de sa formation. Un des schémas les plus raisonnables, mais non vérifié expérimentalement, expliquerait sa formation par l'intermédiaire d'aldéhydes :

En revanche, la nature apparemment primaire de CO_2 semble très paradoxale, surtout si l'on tient compte du fait que le monoxyde de carbone est non primaire. À ce stade de nos recherches, nous ne pouvons pas donner de solution par un mécanisme réactionnel. Comme nous l'avons signalé, la sensibilité limitée de nos méthodes chromatographiques peut être, en partie au moins, à l'origine de cette apparente anomalie. Ici encore, la source de dioxyde de carbone pourrait être pseudo-primaire, c'est-à-dire passer par l'intermédiaire de produits réactifs formés primairement. L'oxydation d'un aldéhyde conduisant à un peracide correspond à ce type de schéma mais, ici encore, il ne s'agit que d'hypothèses :

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

Cette hypothèse, ainsi que la précédente sur la formation de CO, souligne le rôle très important des aldéhydes dans les schémas d'oxydation.

L'examen des différents produits fait donc apparaître encore un certain nombre de difficultés ou de schémas détaillés non encore résolus. Cependant, le but poursuivi dans le cadre du présent travail n'était pas de donner une interprétation précise et sûre de tous les produits formés, y compris en faibles quantités, mais plutôt de proposer un schéma général de l'oxydation d'alcanes légers.

IV. Discussion et conclusion

Un nombre substantiel de processus élémentaires figurant dans le mécanisme a fait l'objet de discussions et commentaires dans ce qui précède. Nous nous bornerons ici à reprendre certains problèmes plus généraux.

Le problème essentiel qui se pose dans l'interprétation mécanistique est la nature des porteurs de chaînes. Si le radical hydroperoxyle paraît être formé de manière prépondérante dans les premiers instants de la réaction, les caractéristiques de celles-ci, dont en particulier la nature des produits formés, paraissent suggérer que le radical hydroxyle OH·, réactif et non sélectif, joue un rôle essentiel dans le schéma réactionnel. C'est par la réactivité de OH· que l'on interprète un certain nombre de phénomènes dans les réactions non isothermes, dont les flammes froides et les inflammations de 2ème stade (cf. par ex., les références 36, 37).

À partir du schéma réactionnel précédent, nous pouvons estimer le rapport des concentrations initiales de $HO_2\cdot$ et de OH· en calculant le rapport des vitesses initiales de formation. Dans nos conditions expérimentales :

$$\frac{V_{HO_2\cdot}}{V_{OH\cdot}} \simeq 60$$

Initialement, ce qui paraît d'ailleurs logique compte-tenu du schéma réactionnel, il y aurait un large excès de radicaux hydroperoxyle par rapport aux radicaux hydroxyle, mais ceci n'est pas incompatible avec un rôle prédominant des radicaux OH·, ceux-ci étant beaucoup plus réactifs que $HO_2\cdot$. Si nous comparons l'arrachement d'un hydrogène tertiaire par ces deux radicaux :

$$HO_2\cdot + RH \rightarrow H_2O_2 + R\cdot \qquad k = 4{,}3 \times 10^3\ L\cdot mol^{-1}\cdot s^{-1}$$

$$OH\cdot + RH \rightarrow H_2O + R\cdot \qquad k = 1{,}3 \times 10^9\ L\cdot mol^{-1}\cdot s^{-1}$$

d'après les données de Walker (32), les valeurs numériques étant calculées dans nos conditions expérimentales (310°C).

Le seuil de concentration élevé des radicaux $HO_2\cdot$ compense en partie leur faible réactivité mais les réactions auxquelles ils peuvent donner lieu ne sont pas encore complètement élucidées (4). En dehors de l'arrachement d'hydrogène relativement difficile (cf. valeur précédente de la constante) et d'une éventuelle destruction hétérogène à la paroi, deux radicaux hydroperoxyle peuvent donner lieu à une dismutation :

$$HO_2\cdot + HO_2\cdot \rightarrow H_2O_2 + O_2 \qquad k = 10^{9,3}\ L\cdot mol^{-1}\cdot s^{-1}$$

l'eau oxygénée donnant lieu à des réactions de branchement, surtout à relativement haute température (400–500°C).

Il faut remarquer que les réactions impliquant l'alcane de départ RH (réactions de métathèse ou de transfert d'hydrogène) sont très vraisemblablement rapidement remplacées par des processus analogues impliquant un (ou des) produit(s) possédant un atome d'hydrogène mobile comme l'ont déjà remarqué plusieurs auteurs (4) (36). Ces produits à hydrogène mobile peuvent en particulier être des aldéhydes.

Compte-tenu des schémas écrits précédemment et du rôle du radical OH·, il paraît logique d'observer l'accumulation de quantités substantielles d'eau. On s'attendrait aussi à d'appréciables quantités d'eau oxygénée, compte-tenu du seuil élevé de concentration des radicaux $HO_2\cdot$ et de la relativement basse température de réaction (310–340°C) pour laquelle l'eau oxygénée est encore stable. Or les dosages globaux de peroxydes, incluant l'eau oxygénée, conduisent à des valeurs basses.

Il faut cependant remarquer que les difficultés soulignées pour le dosage de l'eau se retrouvent pour l'eau oxygénée et que les méthodes de dosage de H_2O_2 sont vraisemblablement moins sensibles que l'analyse de l'eau par chromatographie en phase gazeuse. Le rôle des différents processus écrits pour le radical hydroperoxyle paraît assez difficile à quantifier; la faible réactivité de $HO_2\cdot$, la décomposition des peroxydes organiques et la destruction de $HO_2\cdot$ aux parois peuvent rendre compte, pour une part au moins, des faibles concentrations observées.

En conclusion, l'étude précédente montre qu'aux environs de 300°C, le mécanisme global d'oxydation de l'isobutane rendant compte des caractéristiques essentielles de la réaction peut être représenté par un schéma très simple faisant intervenir deux chaînes réactionnelles prépondérantes, l'une conduisant à l'alcène conjugué et l'autre à l'oxyde de l'alcène, en accord avec l'étude expérimentale et avec les constantes de vitesse des processus élémentaires déterminées par les méthodes de la Cinétique Thermochimique.

Si la présente étude n'a pas permis de répondre à tous les problèmes posés par le mécanisme d'oxydation des alcanes, tels que ceux mis en évidence par des auteurs comme Benson (4), elle a permis de proposer un schéma de principe cohérent, en accord satisfaisant avec les constantes de vitesse estimées et avec les résultats expérimentaux.

Il est certain qu'une preuve plus complète de la validité d'un mécanisme réactionnel, apportant de plus des éléments de réponse à des questions restant posées, serait la modélisation de la réaction, permettant en particulier de reproduire les courbes de formation des divers produits en fonction du temps, à partir du mécanisme réactionnel et en utilisant des valeurs ajustées des constantes de vitesse des processus élémentaires. Par addition d'une équation thermique, une telle modélisation pourrait même conduire à reproduire les phénomènes non-isothermes.

Il nous paraît cependant, en tenant compte des connaissances actuellement acquises, que nous ne disposons pas encore de tous les éléments nécessaires pour mener à bien une telle modélisation; il serait utile de disposer d'éléments plus complets,

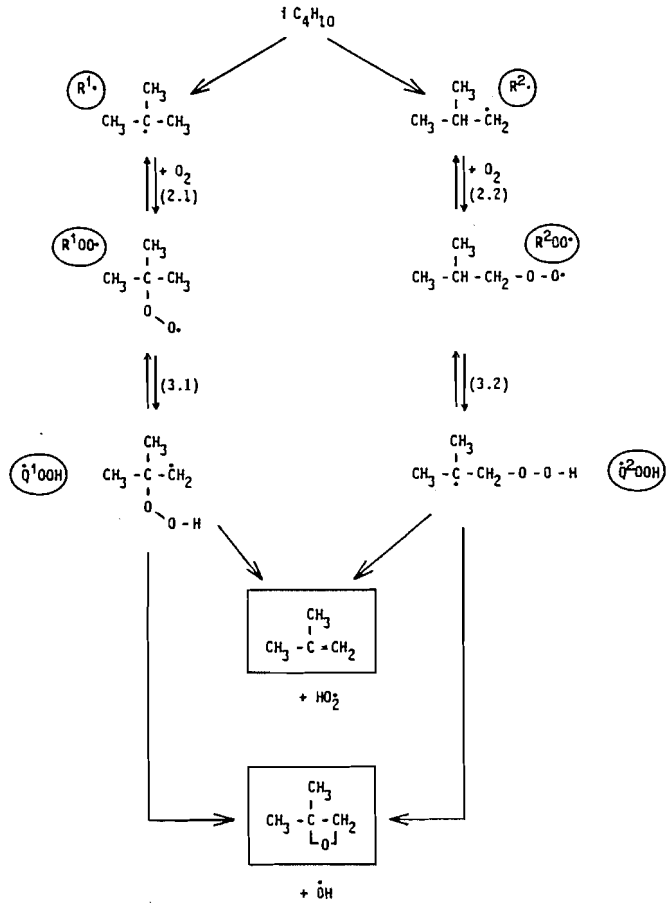

FIG. 6. Représentation schématique du mécanisme d'oxydation de l'isobutane.

par exemple sur l'amorçage de la réaction (nature des agents de branchement dégénéré), sur la terminaison de la réaction, sur certaines constantes de vitesse de processus élémentaires et vraisemblablement de méthodes numériques plus performantes. Les premiers essais que nous avons tentés dans cette voie sur l'exemple du propane[3] ont montré la complexité de cette tâche, qui cependant est susceptible d'apporter d'utiles précisions sur le mécanisme. Le travail que nous avons présenté dans ce mémoire nous paraît constituer une étape intermédiaire très importante, voire essentielle, dans la réalisation d'une modélisation complète.

Nous pensons vérifier les premières conclusions de la présente étude et le degré envisageable de généralisation du schéma proposé sur un second exemple qui sera le propane (38).

Remerciements

Received December 5, 1988

WILLIAM A. AYER, PETER A. CRAW, THOMAS J. STOUT, and JON CLARDY. Can. J. Chem. **67**, 773 (1989).

The structures of four new drimane-type sesquiterpenes **1–4** produced in liquid cultures of the fairy ring fungus, *Marasmius oreades*, have been determined by a combination of chemical and spectroscopic methods. The structure assigned to one of these sesquiterpenes (**1**) has been confirmed by an X-ray crystallographic study. An unprecedented feature of all four sesquiterpenes is the biosynthetic elaboration of C8–C12 and C15 of the drimane skeleton to a dioxabicyclooctane moiety. In addition, two of the sesquiterpenes possess an uncommon α orientation of the hydroxyl groups at C3.

Key words: sesquiterpenes, fungal metabolites, drimanes, fairy ring mushroom, crystal structure.

WILLIAM A. AYER, PETER A. CRAW, THOMAS J. STOUT et JON CLARDY. Can. J. Chem. **67**, 773 (1989).

Faisant appel à une combinaison de méthodes chimiques et spectroscopiques, on a déterminé les structures de quatre nouveaux sesquiterpènes (**1–4**) du type drimane qui sont produits dans des cultures liquides de champignons mousserons, *Marasmius oreades*. La structure attribuée au sesquiterpène **1** a été confirmée par une étude effectuée à l'aide de la diffraction des rayons-X. Ces quatre sesquiterpènes possèdent une caractéristique nouvelle, l'élaboration biosynthétique des carbones C8–C12 et C15 du squelette du drimane en une portion dioxabicyclooctane. De plus, les groupements hydroxyles présents en position C3 de deux des sesquiterpènes se trouvent dans la configuration α qui est inhabituelle.

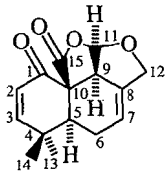
Mots clés : sesquiterpènes, métabolites des champignons, drimanes, champignons mousserons, structure du cristal.

[Traduit par la revue]

Introduction

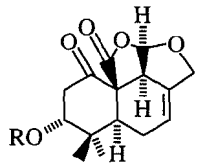
Fairy rings (witches' rings) in turf grasses are found throughout the world and can be caused by a variety of Basidiomycete fungi (1, 2). In Western Canada the fungus most commonly associated with fairy rings is *Marasmius oreades* (Bolt.:Fr.)Fr. (3). The fairy rings result from the apical growth habit of fungal hyphae and increase in diameter by about 15–30 cm per year. On the prairies there are some rings, with diameters over one kilometer, that are several centuries old (2).

The mature rings of *Marasmius oreades* are conspicuous because they often occur in lawns, golf courses, playing fields, and parks, disfiguring the turf. These rings have an inner and outer zone of stimulated grass growth and a zone of dead grass in the middle attributed to the dense mycelium interfering with the penetration of water. There are also reports that the fungus produces hydrogen cyanide and other cyanogenic compounds (4), with the suggestion that these kill the grass and at the same time restrict the growth of other soil microorganisms that are notably scarce in the soil of fairy rings of *Marasmius oreades*. Very little is known about the chemistry of *Marasmius oreades*, which we felt was surprising in view of the resistance of this fungus to currently available fungicides. We therefore decided to undertake an investigation of the metabolites produced by *Marasmius oreades* in the hope of better understanding the factors that may be responsible for the distinctive and disfiguring zones associated with fairy rings of this fungus.



Results and discussion

Marasmius oreades was grown in still culture on a medium of potato dextrose broth containing yeast extract. After 8 weeks the broth was separated from the mycelium and extracted with ethyl acetate. Flash chromatography of this extract then led to the isolation of the four new sesquiterpenes anhydromarasmone (**1**), marasmone (**2**), isomarasmone (**3**), and dihydromarasmone (**4**). It was apparent from a comparison of ^1H and ^{13}C nuclear magnetic resonance (nmr) spectra that each of the four new sesquiterpenes possesses the same dioxabicyclooctane moiety fused with ring B in a drimane-type skeleton. Thus, the ^1H nmr spectrum of each compound displays an acetal doublet (J 4.3–4.5 Hz) in the range δ 5.98–6.44 (H11), which is coupled to a broad singlet between δ 3.30 and 3.68 (H9). The varying positions of these signals reflect changes in the position and oxidation state of substituents in ring A of each compound. The signal of H9 is in each case coupled to a vinyl hydrogen signal in the region δ 5.94–6.00 (H7), which in turn is coupled to two allylic dihydrofuran hydrogen multiplets from δ 4.48 to 4.61 (H12), and a multiplet due to two allylic hydrogens within the range δ 2.18–2.50 (H6). Coupling between the H6 multiplet and a doublet of doublets due to H5 (δ 2.36–2.49) can be demonstrated in all but the spectrum of isomarasmone (**3**) where the signal of H5 is obscured within the multiplet due to H6. In the ^{13}C nmr spectra of the four new sesquiterpenes the positions of the signals due to C6 (δ 24.0–25.4), C7 (δ 124.0–126.3), C8 (δ 131.3–133.5), C9 (δ 47.9–49.5), C11 (δ 103.9–106.0), and C12 (δ 72.2–73.6) show little variation within the quoted ranges of chemical shifts, whereas the difference in the ring A substituents is reflected more clearly in the positions of the signals due to C5 (δ 34.0–42.0), C10 (δ 55.7–64.8), and C15 (δ 169.5–176.3). The location of the substituents in ring A of the four different compounds was determined as described below for the individual compounds.



Anhydromarasmone (**1**) was obtained as prisms, mp 194–196°C, and is the least polar sesquiterpene eluted by flash chromatography of the ethyl acetate extract of the culture broth. High resolution mass spectrometry (hrms) and chemical ionization mass spectrometry (cims) indicate a molecular formula of $C_{15}H_{16}O_4$. The Fourier transform infrared (Ftir) spectrum displays characteristic lactone (1760 cm^{-1}) and α,β-unsaturated

ketone (1663 cm^{-1}) absorptions (5). The presence of an α,β-unsaturated ketone is also apparent from a maximum in the ultraviolet (uv) spectrum at 235 nm, doublets in the ^1H nmr spectrum at δ 6.01 (*J* 10.2 Hz) and δ 6.87 (*J* 10.2 Hz), and methine carbons in the ^{13}C nmr spectrum at δ 125.6 (C2) and δ 162.7 (C3). The remaining signals in the ^1H and ^{13}C nmr spectra are in accord with the structure assigned to anhydromarasmone (**1**), but equally well may be accounted for by the isomeric structure **5**. However, two features of the nmr spectra strongly favor structure **1**. First, the signals of the lactone (δ 169.7) and the α,β-unsaturated ketone (δ 193.6) carbonyl carbons occur significantly upfield (ca. 8–10 ppm) of the positions normally associated with either of these classes of carbon signals. Upfield shifts of similar magnitude have, however, been reported for the lactone and saturated ketone carbonyl signals of momilactone A (**6**) (δ 174.3 and δ 205.0 respectively) (6) and the ballotinone derivative **7** (δ 174.8 and δ 207.1 respectively) (7). These upfield shifts are possibly due to an interaction between the dipoles of the lactone and ketone carbonyl groups causing a mutual shielding of the carbonyl carbons. Such a dipole–dipole interaction may be responsible for the uncharacteristic upfield positions of the lactone and conjugated carbonyl signals in the spectrum of anhydromarasmone (**1**), but is not consistent with the isomeric structure **5**. The second and perhaps more conclusive feature that is inconsistent with **5** is the presence of large nuclear Overhauser enhancements (nOe) of the β-hydrogen doublet (δ 6.87) of the α,β-unsaturated ketone (10.2% and 11.2%) when either of the C4 methyl singlets (δ 1.23 and δ 1.48 respectively) are irradiated. These nOe enhancements can only be accounted for if the β-hydrogen of the α,β-unsaturated ketone is located adjacent to the two methyl groups at C4 as in the structure assigned to anhydromarasmone (**1**). A large nOe (8.3%) from only the methyl singlet at δ 1.48 (H13) to a doublet of doublets at δ 2.37 (H5) is consistent with the assignment of the methyl singlets in the ^1H nmr spectrum of **1**. Significant negative nOe effects are observed from H3 to H2 (−3.5% and −2.8%) when either of the methyl singlets (δ 1.23 and δ 1.48 respectively) is irradiated. As the structures of the other three sesquiterpenes from *Marasmius oreades* reported in this paper can be correlated with anhydromarasmone (**1**) (Scheme 1), the structure of **1** was confirmed by an X-ray crystallographic study. A computer generated perspective drawing of the final X-ray model of anhydromarasmone is given in Fig. 1. The enantiomer illustrated was not determined by the X-ray experiment but was selected arbitrarily. The structure contains few surprises. The two six-membered rings are roughly planar, that is, C1–C4 and C6–C9 are planar while C5 is above and C10 is below this plane. Both of the six-membered rings are in the half-chair conformation. The two five-membered rings are both in the *C*2 or skew conformation with the approximate twofold axes running from O3 through the C9—C10 bond and from O2 through the C9—C8 bond.

Marasmone (**2**) is the corresponding β-ketol of anhydromarasmone (**1**). Compound **2** was obtained as an oil that resisted all attempts to induce crystallization. The molecular ion was not detected in the hrms of this compound, but cims confirmed a molecular weight of 278 corresponding to a formula of $C_{15}H_{18}O_5$. As in the mass spectrum of anhydromarasmone (**1**), an abundant ion arising from loss of CO_2 (*m/z* 234) is observed in the spectrum of **2**. The Ftir spectrum displays the expected hydroxyl (3490 cm^{-1}) and ketone (1716 cm^{-1}) carbonyl absorptions. The ^1H nmr spectrum differs most notably from that of anhydromarasmone (**1**) by the replacement of the signals of the α,β-unsaturated ketone by two geminally coupled doublets of doublets at δ 2.50 (*J* 14.0, 4.4 Hz, H2α) and δ 3.17 (*J* 14.5, 2.3 Hz, H2β), which are both vicinally coupled to a doublet of doublets at δ 3.95 (*J* 3.8, 2.4 Hz, H3). The two small coupling constants for the H3 signal support an α orientation of the C3-hydroxyl (assuming a chair conformation of ring A), but equally well might correspond to a β-hydroxyl at C3 if ring A

SCHEME 1. (a) $(CH_3CO)_2O$, pyridine, rt, 8 h; (b) $NaBH_4$, CH_3OH, rt, 10 min; (c) PDC, CH_2Cl_2, rt, 8 h.

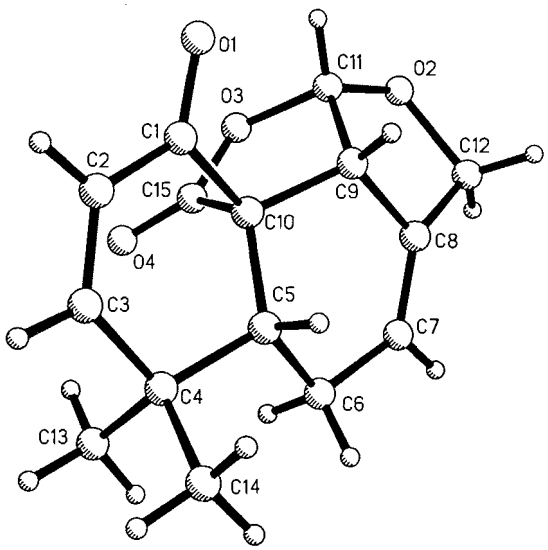

FIG. 1. A computer generated perspective drawing of the final X-ray model of anhydromarasmone.

adopts a boat conformation. Unfortunately, extensive nOe experiments (Table 1) failed to provide any information that would allow the stereochemistry of the C3-hydroxyl to be assigned, although the presence of large nOe effects from both of the methyl groups at C4 to H3 (8% and 13%) did at least support the regiochemistry of the β-ketol in ring A of marasmone (**2**). The regiochemistry of **2** was also confirmed when attempted acetylation gave a good yield of anhydromarasmone (**1**) instead of the corresponding acetate **8**. The stereochemistry at C3 of **2** was determined by chemical correlation with another of the sesquiterpenes isolated from *Marasmius oreades* (see below). Somewhat surprisingly, attempted dehydration of marasmone (**2**) to anhydromarasmone (**1**) failed with either catalytic or larger amounts of *p*-toluenesulfonic acid in benzene. Even after refluxing for several hours very little of the β-ketol appeared (tlc) to have been consumed in the reaction. The regiochemistry of the β-ketol in **2** is further supported by the positions of the lactone (δ 169.5) and ketone (δ 203.9) carbonyl signals in the

TABLE 1. Nuclear Overhauser enhancements in the ^1H nmr spectrum of marasmone (**2**)

Saturated signal (δ)	Observed enhancements (δ)
1.07 (13-CH_3)	2.28–2.36 (H6, 5%), 2.50 (H2α, 13%), 3.95 (H3, 8%)
1.40 (14-CH_3)	2.28–2.36 (H6, 10%), 3.17 (H2β, 6%), 3.95 (H3, 10%)
3.38 (H9)	6.16 (H11, 16%)
3.95 (H3)	2.50 (H2α, 5%), 3.17 (H2β, 5%)

^{13}C nmr spectrum. These signals are significantly upfield (ca. 8–10 ppm) of the more usual positions of isolated lactone and ketone carbonyl signals and, as in the case of anhydromarasmone (**1**), support a 1,3-disposition of these carbons in marasmone (**2**). It appears that the positions of lactone and ketone carbonyl signals in the ^{13}C nmr are useful for predicting the location of a ketone in ring A of related decalin type terpenes that contain a lactone carbonyl at either C13, C14, or C15.

Isomarasmone (**3**) was obtained as prisms, mp 247–250°C, which, unlike marasmone (**2**), did display a molecular ion in the hrms corresponding to a molecular formula of $C_{15}H_{18}O_5$. The mass spectra of **2** and **3** also differ in that the abundant ion at m/z 234 in the spectrum of **3** ($C_{13}H_{14}O_4$) arises from loss of elements of vinyl alcohol (presumably from C1, C2) rather than CO_2. In the Ftir spectrum of **3** strong absorptions are seen for the lactone (1755 cm^{-1}) and ketone (1699 cm^{-1}) carbonyl groups. The signals of the β-ketol moiety in the ^1H nmr spectrum of **3** occur as two geminally coupled doublets of doublets at δ 2.49 (*J* 14.2, 4.3 Hz, H2α) and δ 3.31 (*J* 14.3, 2.1 Hz, H2β), which are vicinally coupled to a doublet of doublets at δ 4.35 (*J* 4.0, 2.1 Hz, H1). The small coupling constants of the latter signal, like those of H3 in the spectrum of **2**, support either an α or β orientation for the β-ketol hydroxyl depending on the conformation adopted by ring A. The positions of the lactone (δ 176.3) and ketone (δ 215.6) carbonyl signals in the ^{13}C nmr spectrum of **3** indicate the lack of a dipole–dipole interaction between the carbonyl groups and support the regiochemistry assigned to the β-ketol functionality of isomarasmone (**3**).

The stereochemistries of the C3-hydroxyl in marasmone (**2**) and the C1-hydroxyl in isomarasmone (**3**) were secured by chemical correlation with dihydromarasmone (**4**), which is the fourth sesquiterpene we obtained from chromatography of the broth extract of *Marasmius oreades*. Dihydromarasmone (**4**) crystallizes as irregular prisms, mp 164–165°C, which displayed an abundant ion (*m/z* 280) in the hrms corresponding to a molecular formula of $C_{15}H_{20}O_5$. The base peak in the hrms at *m/z* 200 arises from loss of CO_2 and two molecules of water (fragment ions at *m/z* 262, 236, 218). The presence of two hydroxyl groups was also indicated by a strong absorption at 3394 cm^{-1} in the Ftir spectrum and methine signals at δ 68.8 (C1) and δ 78.5 (C3) in the ^{13}C nmr spectrum, while the presence of a lactone group was confirmed by a carbonyl absorption at 1768 cm^{-1} in the Ftir spectrum and a signal at δ 174.4 in the ^{13}C nmr spectrum. The signals due to H1, H3, and H9 (δ 3.88, 3.81, 3.68) were assigned in the following manner. Irradiation of the broad singlet at δ 3.68 collapsed the acetal doublet at δ 5.97 (H11) to a singlet, confirming the assignment of the signal due to H9. Of the two remaining signals, that at δ 3.88 must be due to H1 since saturation of this signal results in a large nOe enhancement of the acetal doublet (H11) and a small nOe enhancement of the H9 signal (Table 2). Finally, the signal at δ 3.81 must be that of H3 since large nOe enhancements of this signal are observed when either of the C4-methyl singlets at δ 1.11 and δ 1.26 are irradiated. The signals of H1 (br ddd, *J* 8.0, 3.0, 3.0 Hz) and H3 (dd, *J* 3.0, 3.0 Hz) are equally coupled to an apparent two-proton triplet at δ 2.17 (*J* 3.0 Hz), which is in fact two coincident doublets of doublets (*J* 3.0, 3.0 Hz, H2α, H2β). Irradiation of the signal of either H1 or H3 simplifies the signal for the C2 hydrogens to a doublet (*J* 3.0 Hz). The additional coupling observed in the signal of H1 (*J* 8.0 Hz) is to a doublet at δ 4.93 (*J* 8.8 Hz), which we have assigned to the C1-hydroxyl hydrogen. The second hydroxyl hydrogen (C3-OH) occurs as a broad singlet at δ 2.40.

The equivalent small coupling between the hydrogens at C2 and those at C1 and C3 indicated that the two hydroxyl groups in dihydromarasmone (**4**) have the same orientation and are either both α-axial if ring A exists in a chair conformation, or β if ring A exists in a twist conformation. To distinguish between the two possible orientations of the hydroxyl groups, the ^{1}H nmr spectrum was recorded in solutions of 1% and 5% v/v deuteropyridine in deuterochloroform containing tetramethylsilane. The most significant changes observed for the spectrum in 1% C_5D_5N–$CDCl_3$ were the broad singlet at δ 2.40 (C3-OH) shifted to δ 4.11, the doublet at δ 4.93 (C1-OH) shifted to δ 5.50, and the doublet of doublets at δ 2.36 (*J* 11.5, 7.0 Hz, H5) shifted to δ 2.41. In the spectrum recorded in 5% C_5D_5N–$CDCl_3$ the C3-OH signal now occurred at δ 5.80, the C1-OH signal at δ 6.18, and the H5 signal had shifted to δ 2.46. There were also small shifts (<0.05 ppm) of the signals of H1, H3, and H9 in both spectra. The large shifts of the hydroxyl signals indicate hydrogen bonding between the hydroxyls and the deuteropyridine, which also results in the observed deshielding of H5 (8). Accordingly, the two hydroxyls in dihydromarasmone (**4**) must have an α orientation. Dihydromarasmone (**4**) was also characterized as the corresponding diacetate **9** for which the signals of H1, H2, and H3 in the ^{1}H nmr spectrum occur as an identical doublet of doublets (*J* 3.0, 3.0 Hz) at δ 5.25 and δ 4.80, while the signal of H2 occurs as a similar doublet of doublets at δ 2.20.

Having established the stereochemistry of dihydromarasmone (**4**) at C1 and C3, the stereochemistry of the hydroxyl groups in marasmone (**2**) and isomarasmone (**3**) could now be confirmed. Thus, oxidation of dihydromarasmone (**4**) with one equivalent of pyridinium dichromate in dichloromethane gave a low yield of a mixture of marasmone (**2**) and isomarasmone (**3**) and establishes that the hydroxyl groups in both β-ketols are α oriented. None of the diketone **10** was isolated from the oxidation of dihydromarasmone (**4**). Furthermore, sodium borohydride reduction of marasmone (**2**) to dihydromarasmone (**4**) also supports the stereochemistry assigned to **2**.[2] The reduction of marasmone (**2**) also gave the 1β,3α-diol **11**, which crystallized as fine needles, mp 235–237°C. The differences between the spectra of **4** and **11** are consistent with these two compounds being epimeric at C1. Thus, hydrogen bonding to the C1-hydroxyl shifts the lactone carbonyl absorption in the Ftir spectrum of **11** to 1750 cm^{-1} (cf. 1768 cm^{-1} in the spectrum of **4**). In addition, the difference in C1 stereochemistry results in upfield shifts of the signals of H2α, H5, and H9 in the ^{1}H nmr spectrum of the 1β,3α-diol **11**, and downfield shifts of the signals of H1 and H11. The coupling constant of 12.5 Hz between the signals of H1 and H2β is consistent with an *anti* relationship of these hydrogens. The 1β,3α-diol **11** was not isolated from the extracts of the cultures of *Marasmius oreades*.

Investigations are currently in progress to determine the possible relationship between the physiology of fairy rings of *Marasmius oreades* and the metabolites produced in our liquid cultures of this fungus. One possibility is that the sesquiterpenes reported in this paper or related sesquiterpenes produced by the fungus may function as plant growth regulators. Preliminary tests also indicate that the sesquiterpenes from *Marasmius oreades* may possess some antibiotic activity. We are currently reexamining the extracts of liquid cultures of *Marasmius oreades* in the search for further novel sesquiterpenes.

Experimental

General

High resolution electron impact mass spectra (hreims) were recorded on an AEI MS-50 mass spectrometer. Unless diagnostically significant, only those peaks with an intensity of <20% of the base peak are recorded. Chemical ionization mass spectra (cims) were obtained using an AEI-MS-12 mass spectrometer with ammonia as the reagent gas. The data were processed using DS-55 software and a Nova-4 computer. Fourier transform infrared (Ftir) spectra were recorded on a Nicolet 7199 FTIR interferometer. Nuclear magnetic resonance (nmr) spectra (^{1}H and ^{13}C) were obtained on Bruker WH-300, WM-360, or WH-400 spectrometers with either Aspect 2000 or Aspect 3000 computer systems. ^{1}H chemical shifts and coupling con-

[2]The reduction of isomarasmone (**3**) was not examined as only small amounts of this compound were isolated from the broth extract.

stants are reported as if they are first order. Tetramethylsilane was used as an internal standard. Ultraviolet (uv) spectra were obtained on a Hewlett Packard 8450A Diode Array spectrophotometer and optical rotations in a Perkin Elmer 241 polarimeter. Circular dichroism (cd) spectra were recorded on a Jasco Optical Rotatory Dispersion SS-20-2 recorder. Melting points are uncorrected and were determined on a Thomas model 40 melting point apparatus. E. Merck silica gel 60 (230–400 mesh) was used for flash chromatography. Preparative thin-layer chromatography (ptlc) was performed on E. Merck precoated 20 × 20 glass plates of silica gel 60 F-254. Analytical thin-layer chromatography (tlc) was carried out on cut sections of E. Merck precoated aluminium sheets of silica gel 60 F-254. Ultraviolet active materials were detected by visualization under a uv lamp (254 nm). The tlc plates were then dipped in a solution of phosphomolybdic acid for several seconds, and the spots were visualized by gentle heating over a hot plate. All solvents were distilled prior to use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

Growth of Marasmius oreades *on potato dextrose yeast broth and isolation of metabolites*

Slant tubes of *Marasmius oreades* (strain Mo 17) were obtained from Dr. K. Mallett, Northern Forest Research Institute, Edmonton, and a specimen sample of the fungus was deposited with the University of Alberta Microherbarium, Edmonton (register number UAMH 5750). Slant cultures of the fungus were maintained on potato dextrose agar (PDA) at 4°C. A PDA plate was inoculated with the fungus and incubated at 25°C for approximately 4 weeks and then the contents of the plate were aseptically transferred to a sterile blender and blended with 200 mL of distilled water to give a mycelial suspension. Ten 2.8-L Fernbach flasks each containing 1 L of potato dextrose broth (PBD) plus yeast medium (20 g PDB (Difco), 0.4 g yeast extract (Difco), 1 L water) were inoculated with ca. 20 mL of a mycelial suspension of the fungus (see above) and the still cultures were kept at room temperature (20–25°C) for 8 weeks.

The mycelium was separated by filtration through cheesecloth, then air-dried for 72 h and ground to a coarse powder (70.2 g). The filtered broth was concentrated to 0.5 L at reduced pressure (waterbath 40–45°C) and then filtered through Celite. The Celite was washed with 100 mL water, and methanol (20 mL) and sodium chloride (20 g) were added to the combined filtrates, which were then continuously extracted with 1.5 L refluxing ethyl acetate for 18 h. Evaporation at reduced pressure gave a brown foam (3.96 g), which was adsorbed onto silica gel (20 g) and then loaded onto a column of silica gel (150 g) that had been packed using dichloromethane. Fractions of 25 mL were collected eluting successively with 1% (fractions 1–20), 2% (fractions 21–40), and 4% (fractions 41–84) methanol–dichloromethane. Each fraction was examined by analytical tlc (5% methanol–dichloromethane) and fractions with similar mixtures of components were combined and subjected to further chromatography.

Fractions 33–45 (9.4 mg) were combined and chromatographed on a column of silica gel (20% ethyl acetate – Skellysolve B) to give anhydromarasmone (**1**, 4.9 mg). Fractions 46–49 (148 mg) were combined and chromatographed on a column of silica gel (33% ethyl acetate – Skellysolve B) to give, successively, further anhydromarasmone (**1**, 2.3 mg), marasmone (**2**, 19.7 mg), isomarasmone (**3**, 1.5 mg), and dihydromarasmone (**4**, 13.6 mg).

Single crystal X-ray diffraction analysis of anhydromarasmone (1)

Compound **1** crystallized as rough cubes suitable for X-ray diffraction analysis. A crystal approximately 0.5 mm on an edge was attached to a glass fiber with epoxy cement. Preliminary X-ray photographs

showed orthohombic symmetry and lattice constants of $a = 8.542$ (1), $b = 14.132$ (3), $c = 10.436$ (2) Å. Systematic absences, a calculated density (1.37 g/cm^3), and the optical activity were uniquely accommodated in space group $P2_12_12_1$ with one molecule of composition $C_{15}H_{16}O_4$ forming the asymmetric unit. All unique diffraction maxima with $2\theta \leq 112°$ were collected on a computer controlled four-circle diffractometer with Cu Kα radiation (1.54178 Å) and 1° ω-scans. Of the 1251 reflections surveyed, 1224 (98%) were judged observed ($|F| \geq 4\sigma(F)$) and used in subsequent calculations. No corrections were made for absorption or decomposition. The structure was solved relatively easily using the direct methods procedure in SHELXTL-PLUS. Full-matrix least-squares refinements with anisotropic heavy atoms and fixed isotropic hydrogens riding on the heavy atoms have converged to a conventional crystallographic residual of 0.0535 for the observed data. Crystallographic parameters have been deposited as archival data.[3]

Reduction of marasmone (2)

Sodium borohydride (1.0 mg) was added to a solution of compound **2** (5.4 mg) in methanol (0.5 mL) and the mixture was stirred at room temperature for 10 min, then 1 M hydrochloric acid (0.1 mL) was added. Evaporation gave an oil, which was chromatographed on silica gel. Elution with 50% ethyl acetate – Skellysolve B gave dihydromarasmone (**4**, 1.7 mg), which crystallized from dichloromethane – ethyl acetate – Skellysolve B as prisms, mp 163–165°C (correct ^{1}H nmr spectrum). Further elution with 66% ethyl acetate – Skellysolve B gave [4a*S*-(4aα,6α,8β,8a*S**,10aα,10bα)]-4,4a,5,6,7,8,10a,10b-octahydro-6,8-dihydroxy-5,5-dimethylbenzo[*e*]furo[2,3,4-*cd*]isobenzofuran-9(2*H*)-one, **11** (2.0 mg), which crystallized from dichloromethane – ethyl acetate – Skellysolve B as thin needles, mp 235–237°C; $[\alpha]_D^{24}$ −21.4° (*c* 0.22, CH_3OH); tlc: R_f 0.40 (66% ethyl acetate – Skellysolve B); Ftir ($CHCl_3$ cast): 3450 (br, OH), 1750 (s, lactone C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.04 (3H, s, H13), 1.25 (3H, s, H14), 1.72 (2H, br s, OH), 1.92 (1H, ddd, J = 13.1, 4.1, 4.1 Hz, H2α), 2.16–2.25 (1H, m, H6β), 2.19 (1H, dd, J = 12.0, 5.2 Hz, H5), 2.20 (1H, ddd, J = 13.0, 12.5, 2.0 Hz, H2β), 2.22–2.27 (1H, m, H6α), 3.04 (1H, m, H9), 3.72 (1H, dd, J = 3.9, 2.0 Hz, H3), 4.29 (1H, br ddd, J = 12.2, 4.8, 4.8 Hz, H1), 4.42 (1H, ddd, J = 10.5, 1, 1 Hz, H12β), 4.50 (1H, dddd, J = 10.5, 1, 1, 1 Hz, H12α), 5.98 (1H, m, H7), 6.17 (1H, d, J = 4.5 Hz, H11); ^{13}C nmr ($CDCl_3$) δ: 22.1 (C14), 24.1 (C6), 27.3 (C13), 35.2 (C2), 36.9 (C4), 38.7 (C5), 52.6 (C9), 55.7 (C10), 71.4 (C1), 72.0 (C12), 77.2 (C3), 105.1 (C11), 126.2 (C7), 131.7 (C8), 173.9 (C15); hreims (probe 150°C), m/z calcd. for $C_{14}H_{20}O_3$ ($M^+ - CO_2$): 236.1413; found: 236.1406 (2), 218 ($M^+ - CO_2 - H_2O$, 9), 190 (70), 175 (48), 172 (28), 157 (53), 147 (22), 143 (21), 135 (25), 132 (22), 131 (24), 129 (30), 121 (22), 119 (41), 118 (30), 117 (57), 116 (51), 105 (53), 104 (23), 96 (24), 95 (24), 93 (41), 92 (30), 91 (100), 83 (24), 81 (33), 79 (41), 77 (48), 74 (76), 73 (20), 71 (31), 70 (24), 69 (60), 67 (37), 65 (22), 60 (23), 57 (61), 56 (64), 55 (70), 53 (28); cims, m/z: 298 ($M^+ + 18$, 100).

Oxidation of dihydromarasmone (4)

Pyridinium dichromate (15 mg, 0.04 mmol) was added to a solution of compound **4** (10.3 mg, 0.037 mmol) in dichloromethane (2 mL) and the resulting suspension was stirred at room temperature for 2 h. Ether (5 mL) was added and the precipitated chromium complexes were removed by filtration through a short column of silica gel. The column was washed with ether and the combined filtrates were evaporated to give an oil (5.3 mg), which was chromatographed on silica gel. Elution with 33% ethyl acetate – Skellysolve B gave successively marasmone (**2**, 1.4 mg, correct ^{1}H nmr spectrum), and isomarasmone (**3**, 0.7 mg, correct ^{1}H nmr spectrum).

Acetylation of dihydromarasmone (4)

A solution of **4** (3.8 mg) and acetic anhydride (0.01 mL) in pyridine (0.025 mL) was allowed to stand at room temperature for 18 h, then benzene (2 mL) was added and the solution evaporated to dryness. Column chromatography of the resulting solid, eluting with 25% ethyl acetate – Skellysolve B, gave [4a*S*-(4aα,6α,8α,8a*S**,10aα,10bα)]-4,4a,5,6,7,8,10a,10b-octahydro-6,8-diacetyloxy-5,5-dimethylbenzo[*e*]furo[2,3,4-*cd*]isobenzofuran-9(2*H*)-one, **9** (4.6 mg), which crystallized from dichloromethane – Skellysolve B as fine needles, subl. 265–266°C; tlc: R_f 0.24 (33% ethyl acetate – Skellysolve B); ^{1}H nmr ($CDCl_3$) δ: 1.03 (3H, s, H13), 1.33 (3H, s, H14), 2.07 (3H, s, OAc), 2.14 (3H, s, OAc), 2.20 (2H, dd, J = 3.0, 3.0 Hz, H2), 2.30–2.38 (2H, m, H6), 2.44 (1H, dd, J = 11.2, 6.2 Hz, H5), 3.10 (1H, m, H9), 4.51 (1H, ddd, J = 11.5, 1.5, 1.5 Hz, H12), 4.56 (1H, dddd, J = 11.2, 1.5, 1.5, 1.5 Hz, H12), 4.80 (1H, dd, J = 3.0, 3.0 Hz, H3), 5.25 (1H, dd, J = 3.0, 3.0 Hz, H1), 5.95 (1H, d, J = 4.2 Hz, H11), 5.98 (1H, m, H7); ^{13}C nmr ($CDCl_3$) δ: 21.1, 21.2, 22.1, 24.0, 26.8, 27.3, 35.6, 35.9, 48.4, 53.1, 67.5, 72.5, 76.2, 104.0, 125.6, 131.1, 169.6, 170.2, 172.5.

Attempted acetylation of marasmone (2)

A solution of compound **2** (5.0 mg) in acetic anhydride (0.05 mL) and pyridine (0.05 mL) was allowed to stand at room temperature for 8 h, then benzene (4 mL) was added and the mixture evaporated to dryness. Column chromatography of the resulting pale brown solid, eluting with 20% ethyl acetate – Skellysolve B, gave anhydromarasmone (**1**, 4.0 mg, correct ^{1}H nmr spectrum), which crystallized from dichloromethane – Skellysolve B as prisms, mp 193–194°C.

The synthesis, separation, and crystal and molecular structures of the three bisphenols, an ethanol solvate of one of them, and of a minor by-product, 6,6′,7,7′-tetrachloro-8,8′-methylenebis(4*H*-benzo-1,3-dioxin), prepared by condensation of formaldehyde with 3,4-dichlorophenol

GEORGE FERGUSON,[1] ROBERT MCCRINDLE,[1] AND ALAN JAMES MCALEES

Received September 6, 1988

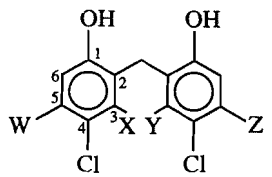
GEORGE FERGUSON, ROBERT MCCRINDLE, and ALAN JAMES MCALEES. Can. J. Chem. **67**, 779 (1989).

Samples of all three of the expected bisphenols, 4,4′,5,5′-tetrachloro-2,2′-methylenebisphenol (**1**) and the 3,4,4′,5′- (**2**) and 3,3′,4,4′-tetrachloro (**3**) isomers, and of a minor by-product, 5,5′,6,6′-tetrachloro-8,8′-methylenebis(4*H*-benzo-1,3-dioxin) (**4**), have been isolated from the mixture formed by acid-catalyzed condensation of 3,4-dichlorophenol with one half of a molar equivalent of formaldehyde. In addition, the structures and solid state conformations of all four compounds, and of an ethanol solvate of **1**, have been revealed by X-ray crystallographic studies. The three bisphenols (**1**, **2**, **3**) all crystallize in space group $P\bar{1}$, as centrosymmetric hydrogen-bonded dimers, while the solvate, **1·EtOH**, although it also belongs to space group $P\bar{1}$, forms relatively open infinite bands of hydrogen-bonded molecules. Crystals of **4** belong to space group *Fdd*2 and the molecules have twofold crystallographic symmetry.

Key words: X-ray crystallography, bisphenols, tetrachloro-2,2′-methylenebisphenols, tetachloro-8,8′-methylenebis(4*H*-benzo-1,3-dioxin).

GEORGE FERGUSON, ROBERT MCCRINDLE et ALAN JAMES MCALEES. Can. J. Chem. **67**, 779 (1989).

La condensation acido-catalysée du dichloro-3,4 phénol avec un demi équivalent molaire de formaldéhyde conduit à un mélange à partir duquel on a pu isoler les trois bisphénols attendus, les tétrachloro-4,4′,5,5′ (**1**), -3,4,4′,5′ (**2**) et -3,3′,4,4′ (**3**) méthylène-2,2′ bisphénols, ainsi qu'un sous-produit mineur, la tétrachloro-5,5,6,6′ méthylène-8,8′ bis(4*H*-benzodioxinne-1,3) (**4**). De plus, faisant appel à la diffraction des rayons-X, on a déterminé les structures ainsi que les conformations à l'état solide de chacun de ces quatre composés. Les trois bisphénols (**1**, **2** et **3**) cristallisent dans le groupe d'espace $P\bar{1}$, sous la forme de dimères centrosymétriques reliés par des liaisons hydrogènes; par ailleurs, le composé **1** sous une forme solvatée, **1·EtOH**, appartient au même groupe d'espace mais il forme des bandes infinies relativement ouvertes de molécules liées par des ponts hydrogènes. Les cristaux de composé **4** appartiennent au groupe d'espace *Fdd*2 et les molécules possèdent une symétrie cristallographique binaire.



Mots clés : diffraction des rayons-X, bisphénols, tétrachloro méthylène-2,2 bisphénols, tétrachloro méthylène-8,8′ bis(4*H*-benzodioxinne-1,3).

In the course of a synthetic project, we required a sample of 2,2′-methylene-4,4′,5,5′-tetrachlorobisphenol **1**. This was reported (1) as the major product isolated from the mixture formed by acid-catalyzed condensation of 3,4-dichlorophenol with one half of a molar equivalent of formaldehyde. Formation of the isomers **2** and **3** was also claimed. A more recent paper (2) assigned structure **2** to the major product by chemical interconversions. We have repeated this reaction under similar conditions and have confirmed the latter assignment. In addition, we have been able to isolate and characterize the other two isomers and an additional, minor, product.

The solid product obtained by work-up of the phenol–formaldehyde reaction mixture gave an ^{1}H nmr spectrum that clearly indicates the presence of all three expected bisphenols, **1**–**3**. In particular, the resonances arising from the methylene bridges are well resolved (even at 60 MHz) and were assignable using the spectra of the pure components, thus allowing an estimation of the relative proportions of the isomers (ca. 9:4:2 for **2**:**1**:**3**). Other non-aromatic resonances of relatively minor intensity are present, the most prominent of these being a pair of singlets arising from the by-product **4**. The subsequent separation of these products by fractional crystallization was readily monitored by ^{1}H nmr spectroscopy. Thus, crystallization of the reaction mixture from toluene gave a relatively pure sample of **2**. Crystallization of the residue from toluene, or cyclohexane, *containing a small amount of ethanol, or*

1 W = Z = Cl, X = Y = H
2 W = Y = Cl, X = Z = H
3 W = Z = H, X = Y = Cl

4

methanol, gave a fraction containing mainly the originally desired isomer **1** as its mono-alcohol solvate. Although **1** did not crystallize readily from the mixture in the absence of alcohol, the crystalline solvate could be recrystallized from toluene alone to give unsolvated material. After separation of bisphenol **1** from the reaction mixture, a further crop of crystals was recovered by crystallization from toluene. This fraction contained comparable quantities of the major product **2** and of the minor isomer **3**. Crystallization of this mixture from a small

volume of methanol yielded a substantially pure sample of **3**. Yet a further crop of crystals was obtained from the residues of the original mixture by crystallization from methanol. This proved to consist largely of the non-phenolic by-product **4**, which was purified by recrystallization from chloroform.

The structures of the three bisphenols, **1–3**, were assigned on the basis of the ^{1}H nmr spectra and were confirmed by X-ray cyrstallography. The ^{1}H nmr spectrum of the by-product **4** at 60 MHz contains only four singlets. Assuming that the singlet at highest field arises from a bridging methylene and therefore represents two protons, a structure such as **4** (or the other possible symmetrical isomer) appeared to be a likely candidate. A mass spectrum of this compound showed *inter alia* the appropriate molecular ion pattern in addition to prominent $M - 60$ peaks corresponding to the loss of two mols of formaldehyde. A proton 2D COSY nmr plot for this product revealed that each aromatic proton has small couplings of similar magnitude both to the bridging methylene and to a benzylic methylene of a dioxin ring. Thus, unfortunately, the relative sizes of these couplings could not be used as a basis for the assignment of structure to the compound. Earlier reports (3) indicate that *ortho* and *para* benzylic coupling constants are frequently similar in magnitude. That this product has structure **4** was revealed by an X-ray crystallographic study of a single crystal. Perhaps surprisingly, in view of the extensive literature on phenol–formaldehyde condensation, there is apparently only a single report (4) of a product with an analogous structure, 6,6′-dinitro-8,8′-methylenebis(4*H*-benzo-1,3-dioxin). In the present reaction, **4** may be produced in preference to the other isomers because of steric factors (see following section). However, ^{1}H nmr spectra of residues from crystallization of the bisphenols show small peaks that can possibly be attributed to other benzo-1,3-dioxin-containing species.

As noted above, the key to recovering the required bisphenol **1** from the product mixture was the presence of a *small* proportion of methanol or ethanol in the crystallizing medium. Interestingly, when pure samples of each of the three isomers, **1–3**, were recrystallized in the presence of alcohol, only **1** gave an alcohol solvate. Since this solvent was readily lost from the crystals on standing at room temperature and solvent-free crystals could be obtained by crystallizing **1** from toluene alone, it was initially surmised that the alcohol molecules were loosely trapped in voids in the crystal lattice; our X-ray analysis of **1·EtOH**, however, shows that the compound has a quite different crystal structure and solid state conformation from those found for **1**, **2**, and **3**.

Crystal structures of 1, 2, 3, and 1·EtOH

Crystal data and refinement details for these four compounds are given in Table 1, fractional coordinates are in Table 2, and

†The *z*-coordinate of Cl14 was fixed to define the origin

*Starred atoms were refined isotropically. Anisotropically refined atoms are given in the form of the isotropic equivalent thermal parameters defined as: $4/3(a^2B_{11} + b^2B_{22} + c^2B_{33} + ab\cos\gamma B_{12} + ac\cos\beta B_{13} + bc\cos\alpha B_{23})$.

principal dimensions are summarized in Table 3. Compounds **1**, **2**, and **3** crystallize as centrosymmetric hydrogen-bonded dimers as shown in Fig. 1; in each molecule there is also an O—H···O intramolecular hydrogen bond. The crystal packing in **1**, **2**, and **3** results in centrosymmetric eight-membered [(O-H)$_4$] rings formed by pairs of intra- and inter-molecular O—H···O hydrogen bonds, with O—H···O 2.705(2)–2.796(2) Å; geometrical details are summarized in Table 2. The intramolecular hydrogen bonds are achieved by appropriate rotation of the phenyl rings about the central C—CH$_2$—C moiety to bring the O—H groups into suitable juxtaposition. The conformational angles, which precisely describe the conformation of each molecule, are given in Table 4 and illustrate that achieving an intramolecular O···O separation of 2.7–2.8 Å can be realized with a considerable range of phenyl ring orientations, the different orientations presumably serving to minimize intramolecular repulsions between adjacent phenyl rings, as well as intermolecular packing effects. The role of these intermolecular packing forces can be seen in compound **1** (Table 3) where there are two independent molecules in the asymmetric unit with similar overall geometry but whose conformational angles ϕ_1 and ϕ_2 differ by 4° and 10° respectively.

The crystal structure of **1·EtOH** (Figs. 2 and 3) proved to be entirely different from those of **1**, **2**, and **3**. The ethanol molecules link pairs of molecules of **1** to form centrosymmetric 12-membered [(O-H)$_6$] rings in which the ethanol acts as both an acceptor and a donor in O—H···O hydrogen bond formation. This involvement with ethanol totally changes the orientation of the phenyl rings about the central C—CH$_2$—C moiety from those found in the unsolvated species and results in the formation of centrosymmetric dimers with 16-membered rings, an intermolecular O—H···O distance of 2.743(2) Å, and no intramolecular hydrogen bond. This leads to the development of relatively open infinite bands of hydrogen-bonded molecules as shown in Fig. 3.

As mentioned above, crystals of **1·EtOH** lose solvent on standing in air, becoming opaque and powdery on the surface. This can be easily envisaged upon examination of the structure of **1·EtOH** (Fig. 3); loss of ethanol will totally disrupt the crystal lattice. However, despite the marked structural differences between **1** and **1·EtOH**, they have identical melting

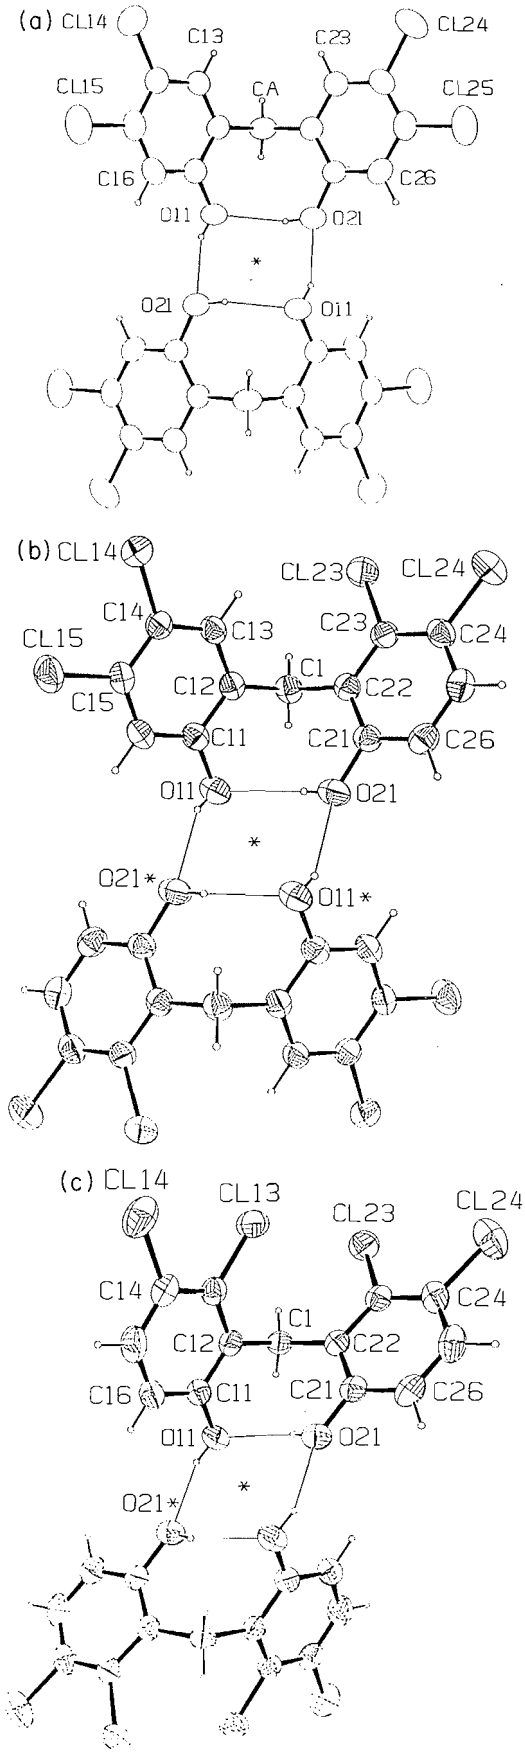

FIG. 1. Views of the centrosymmetric dimer structures, showing the atom numbering schemes. (a) One of the two independent dimers of molecule **1**; (b) molecule **2**; (c) molecule **3**. Ellipsoids are at the 50% level (except for hydrogen atoms, which are shown as spheres of an arbitrary size).

O—H···O (inter)	150(3)	159(3)	152(2)	148(3)	171(2)	

*There are no intramolecular O—H...O bonds in **1·EtOH**. The hydrogen bond dimensions involving ethanol are O(EtOH)···O(11) (at $-1+x, y, z$), 2.615(3) Å; O(EtOH)···O(21), 2.818(2) Å; O(EtOH)—H, 0.72(2) Å; O(11)—H···O(EtOH) (at $1+x, y, z$), 175(2)°; O(EtOH)—H···O(21), 163(3)° (see Fig. 3).

TABLE 4. Conformational details

Compound	1		2	3	1·EtOH	4
ϕ_1*	−2.3	−6.7	−15.8	−13.4	+12.9	+1.8†
ϕ_2	+3.8	+14.1	+14.8	+29.0	−69.9	+1.8†

*ϕ_1 and ϕ_2 are the rotation angles (as shown above) by which the molecules differ from a theoretical model in which the plane of each phenyl ring is normal to the C_{sp^2}—C_{sp^3}—C_{sp^2} plane with the O—H groups proximal. Positive ϕ values rotate the phenolic oxygen towards the centre of the diagram, negative values rotate the oxygen away from the centre. The standard deviation in torsion angles is between 0.3° and 0.4°.

†Because **4** has twofold crystallographic symmetry the rotation angles ϕ_1 and ϕ_2 have the same magnitude and sign. The oxygens at C11 are distal.

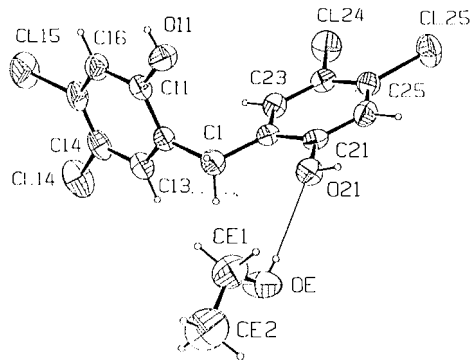

FIG. 2. A view of the asymmetric unit of **1·EtOH**, with our numbering scheme. Ellipsoids are at the 50% level (except for hydrogen atoms, which are shown as spheres of an arbitrary size).

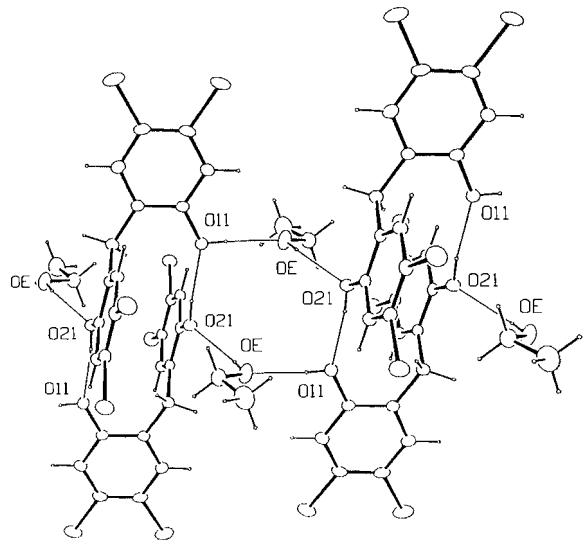

FIG. 3. The hydrogen bonding arrangement in **1·EtOH**. Non-hydrogen atoms are shown as open ellipsoids at the 20% probability level. Hydrogen atoms are shown as spheres of an arbitrary size.

points. Upon loss of ethanol, the intermolecular hydrogen bonds linking molecules of **1** may very well be retained, and reorganization, with loss of overall crystallinity to yield the intramolecular hydrogen bonded structure found for pure **1**, may proceed only as the temperature approaches the melting point.

The failure of compounds **2** and **3** to form ethanol or methanol solvates is probably associated with their inability to adopt a conformation similar to that found in **1·EtOH** because the bulky 3-chloro substituent would cause severe intramolecular overcrowding with the adjacent phenyl ring.

The molecular dimensions summarized for these four structures in Table 2 are unexceptional and are in accord with accepted values. No obvious effect of intramolecular overcrowding was anticipated in **1** and none was found. In **2**, with the 3,4,4′,5′-tetrachloro substitution, there are no untoward bond angles, and conformational angles ϕ (Table 3) are not much larger than were found for **1**. In the 4,4′,5,5′-tetrachloro isomer, the adoption of conformational angles similar to those found in **1** and **2** would have led to impossibly short intra-ring Cl···Cl contacts, which are overcome by one of the rings rotating further about the exocyclic C—C bond while still retaining the intramolecular O—H···O hydrogen bond.

The structures of five additional 2,2′-methylenebisphenols have been reported (5*a–e*). None of these displays the association into centrosymmetric dimers found for **1**, **2**, and **3**, presumably because all five have bulky substituents in the 6 and 6′ positions. In four of these compounds (5*a–d*) the two hydroxyl groups are proximal and form an intramolecular hydrogen bond, although in one case (5*d*) it is relatively weak. The fifth compound (5*e*) has its two hydroxyl groups distal.

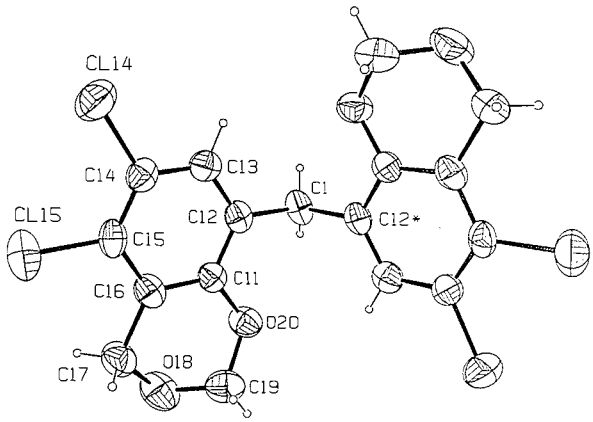

FIG. 4. A view of the molecule **4**, with our numbering scheme. Ellipsoids are at the 50% level (except for hydrogen atoms, which are shown as spheres of an arbitrary size). The twofold crystallographic axis passes through C1.

Crystal structure of 4

Crystal data and refinement details for **4** are given in Table 1, fractional coordinates in Table 2, and principal dimensions are summarized in Table 3. In the crystal, **4** has twofold crystallographic symmetry as illustrated in Fig. 4, the conformation of the molecules being close to the idealized structure depicted in Table 4 but with the phenol-derived oxygens distal. Conformations with these oxygens proximal would be subject to severe steric interactions. The preferred formation of **4** rather than the analogous methylenebis(benzodioxin) isomers derivable from bisphenols **2** and **3** may result because these isomers would have one or two severe chlorine...oxygen interactions if they were to adopt a conformation similar to that found for **4**.

The molecular dimensions for the dioxin ring of **4** (Table 3) are in good agreement with those reported for other benzodioxins (for leading references see ref. 6). This ring has a puckered conformation, with the deviations of C17, O18, C19, O20 from the aromatic ring plane being −0.10, −0.33, +0.47, +0.07 Å respectively. Interestingly, the C—O bond lengths C17—O18 and C19—O20 are identical (1.426(4) Å), while C19—O18 is significantly shorter (1.373(4) Å).

Experimental

Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. The ^{1}H nmr spectra were run on a Varian EM360 spectrometer using $CDCl_3$–CD_3OD (5:1; v,v) as solvent (internal TMS standard) for the bisphenols and $CDCl_3$ for **4**. We thank Wellington Environmental Consultants, Guelph, for the electron impact mass spectrum of **4**.

Reaction of 3,4-dichlorophenol with formaldehyde

The procedure used was similar to that reported (2). A mixture of 3,4-dichlorophenol (20 g), paraformaldehyde (1.9 g), water (5 mL), concentrated sulfuric acid (20 mL), and dichloromethane (50 mL) was stirred at ambient temperature for 18 h. The resulting mixture was partitioned between water (100 mL) and dichloromethane (75 mL additional) and the aqueous layer was washed with dichloromethane (2 × 25 mL). The combined organic layers were evaporated *in vacuo* and the residue subjected to steam distillation to remove traces of unreacted dichlorophenol. A ^{1}H nmr spectrum (in CD_3CN) of the residue remaining after drying *in vacuo* revealed the presence of mainly **1**, **2**, and **3** in a ratio of ca. 4:9:2. This material was crystallized from toluene (100 mL) to give fraction A (7.5 g), which was largely (^{1}H nmr) **2**. Recrystallization from toluene gave pure **2**, mp 200–202°C; δ: 4.04 (s, 2H, CH_2), 6.72 (d, 1H, J = 10 Hz), 6.92 (s, 1H), 7.03 (d, 1H, J = 10 Hz), and 7.25 (s, 1H). The mother liquors from fraction A were evaporated *in vacuo* and the residue allowed to crystallize from toluene–ethanol (40 mL:2 mL) to give fraction B (4.5 g), which consisted largely of **1**, mp 175–177°C (ex toluene), mp 176–177°C (ex methanol – carbon tetrachloride), and mp 170–176°C (ex ethanol–cyclohexane); δ: 3.75 (s, 2H, CH_2), 6.88 (s, 2H), and 7.15 (s, 2H). The last two samples contained (^{1}H nmr) 1 mol of alcohol. The residue, after separation of fraction B, was dissolved in toluene (25 mL) to give crystalline fraction C (1.3 g), the major component of which was **3** along with a substantial amount of **2**. Recrystallization of this material from methanol (2 mL) gave substantially pure **3** (0.34 g), mp 220–226°C (after recrystallization from ethanol–hexane); δ: 4.25 (s, 2H, CH_2), 6.56 (d, 2H, J = 10 Hz), and 7.09 (d, 2H, J = 10 Hz). The residues remaining after recovery of crop C were dissolved in hot methanol and yielded, upon cooling, fraction D (0.43 g), which was essentially pure **4**, mp 198–202°C (upon recrystallization from chloroform); δ: 3.80 (s, 2H, bridging CH_2), 4.86 (s, 4H, OCH_2C), 5.23 (s, 4H, OCH_2O), and 7.07 (s, 2H).

X-ray crystallography
