The conversion of 7-acetoxyroyleanone to 14-methoxytaxodione

ANNE-MARIE FAUCHER AND ROBERT H. BURNELL[1]
Département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received July 6, 1988

ANNE-MARIE FAUCHER and ROBERT H. BURNELL. Can. J. Chem. **67**, 1 (1989).

7-Acetoxyroyleanone (**1***a*) has been converted in five steps to the methoxy-*p*-quinone **9**. Since the latter was the penultimate intermediate in Eugster's partial synthesis of 14-methoxytaxodione (**2**), the transformation reported represents a formal synthesis of the latter.

Key words: 7-acetoxyroyleanone, 14-methoxytaxodione, synthesis.

ANNE-MARIE FAUCHER et ROBERT H. BURNELL. Can. J. Chem. **67**, 1 (1989).

L'acétoxy-7 royléanone (**1***a*) fut transformée en cinq étapes en méthoxy-*p*-quinone **9**. Ceci complèta la synthèse formelle de la méthoxy-14 taxodione (**2**) parce que cette *p*-quinone a déjà servi comme pénultième intermédiaire dans une synthèse partielle décrite par Eugster.

Mots clés : acétoxy-7 royléanone, méthoxy-14 taxodione, synthèse.

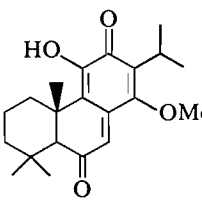
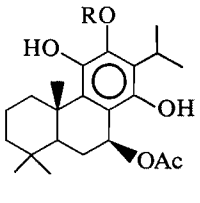
The similarity of the royleanones, such as the 7-acetoxy derivative **1***a*(1), to the often synthesized taxodione chromophore (2) as found for example in 14-methoxytaxodione **2**(3), suggests that the transformation of the former to the latter should be easy. In practice, however, we found it to be far from trivial. In essence it involves only the transposition of the oxygen function at C7 to C6 and suitable adjustment of the oxidation level. We were amazed at the fragile nature of the compounds when subjected to even the simplest of reactions and for this reason we chose to experiment first with the relatively stable 12-*O*-methyl derivative **1***b*.



Sodium dithionite in acetone reduced **1***b* to the hydroquinone **3***a* but, despite many variations of procedure, some elimination occurred, affording also **4***a*, and often the latter was the major product (typically 1:3). In practice we found it advantageous to subject the crude reaction mixture to methylation (using potassium carbonate and dimethyl sulfate) because, after this, only the methylated elimination product **4***c* was isolated (82% from **1***b*).

To introduce the necessary oxygen function at C6 we used the *N*-methylmorpholine *N*-oxide mediated *cis*-hydroxylation with osmium tetroxide (4), which allowed us to isolate, with difficulty, the 6α,7α-diol **5***a*. Acid catalysed dehydration of the latter (*p*-TsOH, benzene) gave the 6-ketone **6***a*. For both greater simplicity and higher yield, we found the best route to this ketone was by epoxidation of the double bond in **4***c* (*m*-CPBA in CH_2Cl_2) and subjecting the crude product to rearrangement, which raised the yield to a respectable 92% (from **4***c*). We considered that this relatively stable ketone **6***a* would be a key intermediate since we felt that any derivative with a phenolic hydroxyl at C12, such as **6***c*, which could conceivably arise by partial demethylation, should be readily oxidized, and the extended quinone chromophore of the taxodiones was a likely oxidative end product.



Of the many demethylation conditions to which the ketone **6***a* was subjected, none afforded a meaningful result. The reaction with boron trichloride (5) did afford recognisable products in the form of two coleon U derivatives **7***a* and **7***b* (13% and 7% respectively), confirming our suspicion that the methylene at C7, which is activated by the aromatic ring on one side and the C6 ketone on the other, is extremely susceptible to oxidation. Our *O*-methyl model had reached the end of its usefulness.

We prepared the 12-*O*-acetyl derivative **1***c* and subjected it to the dithionite reduction/methylation for a 71% yield of **4***d* and the latter was epoxidized and rearranged to afford the analogous C6 ketone **6***b* (in 68% yield from **4***d*). The *O*-acetyl residue was, of course, easily removed by hydrolysis but, again, the only products identified from the very colored mixture were two more coleon U ethers **7***c* and **7***d* (32% and 11% respectively). Since we did not detect these in the initial crude reaction mixture (tlc) we assumed that oxidation takes place on the silica gel used for purification (**6***a*,*b*). The C6 ketone was an obvious embar-

[a]In ppm from TMS.
[b]These values were abstracted from the spectrum of a 3:1 mixture of **4***a* and **3***a*.

rassment so we removed the C12 *O*-acetyl residue with lithium aluminium hydride, which also reduced the ketone, affording the hydroxy compound **8** (in 77% yield).

Our first cautious oxidation of **8** was with Jones reagent for 30 s and this gave mostly the phenolic ketone **6***c* (40%) accompanied by the methoxy *p*-quinone **9** (28%), but by extending the period of oxidation to 30 min we raised the yield of the latter to 70%. During the oxidation there is a methyl group migration from the methoxyl at C11 in the starting material to form that at C12 in the product. Due to its limited stability at room temperature we could not analyse **9** in the usual manner, but its nmr spectrum is identical with that described by Rüedi and Eugster (7). Thus, our preparation represents a formal synthesis of 14-methoxytaxodione (**2**) since Rüedi and Eugster also reported the transformation of **9** to the natural product.

Experimental

Unless otherwise stated, the conditions and instruments used to characterize the products were as follows: melting points, Electrothermal, uncorrected; ultraviolet spectra, ethanol solutions (ε in parentheses), Hewlett Packard 8450 A; infrared spectra, carbon tetrachloride solutions, Beckman 4250 and Perkin Elmer 457; 200-MHz proton and 50-MHz carbon-13 magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard (where relevant — multiplicity, integrated peak areas, coupling constants and assignments in parentheses), "dis. D_2O" signifies that the peaks in question disappeared on shaking the solution with a small volume of D_2O, Varian XL-200; mass spectra, Hewlett Packard 5992. Elemental analyses were by Galbraith Laboratories, Knoxville, TN. The high resolution mass spectra were recorded at the Centre régional de spectrométrie de masse, Université de Montréal. Unless otherwise stated, dry column chromatography implies the use of Merck Kieselgel 60F (70–230 mesh) and elution with hexane–ethyl acetate (proportions determined by prior thin-layer chromatography using Baker-flex Silica gel 1B2-F precoated plastic sheets).

*7-Acetoxy-12-*O*-methylroyleanone* **1***b*

Diazomethane generated from Diazald (4 g) was introduced to a suspension of 7-acetoxyroyleanone **1***a* (1.19 g) in ether (80 mL) and the mixture was stirred until the reaction was complete (tlc). The solvent was removed, affording a quantitative yield (1.234 g) of the *O*-methyl derivative **1***b*, mp 178–180°C (yellow needles from methanol); uv: 269(11 840) and 393(620) nm; ir: 1730, 1635, 1660, and 1600 cm^{-1}; ^1H nmr δ: 0.88 and 0.89 (2s, Me at C4), 1.16 and 1.21 (2d, J = 7 Hz, Me at C15), 1.29 (2, Me at C10), 2.02 (s, Me-CO), 2.62 (m, 1H, H-C1), 3.17 (sept, J = 7 Hz, H-C15), 3.88 (s, Me-O), 5.91 (dd, J = 4 and 2 Hz, H-C7); ^{13}C nmr, see Table 1. *Anal.* calcd. for $C_{23}H_{32}O_5$: C 71.10, H 8.30; found: C 70.94, H 8.20.

*7-Acetoxy-*O*-acetylroyleanone* **1***c*

Acetic anhydride (13 mL) was added to a solution of 7-acetoxyroyleanone **1***a* (355 mg) in pyridine (25 mL). The color changed almost immediately from orange brown to bright yellow. After stirring for 15 min the product was isolated by diluting with ether, washing with dilute aqueous HCl, and then with saturated aqueous $NaHCO_3$ solution. Removal of the solvent afforded a yellow oil (373 mg; quant), which crystallized slowly on standing, mp 99–100°C (from ethanol–water); uv: 222(2850) and 262(14 970) nm; ir: 1780, 1745, 1665, 1655(sh), and 1610 cm^{-1}; ^1H nmr δ: 0.88 (s, 6H, *gem*-diMe), 1.18 and 1.20 (2d, J = 7 Hz, Me at C15), 1.26 (s, Me at C10), 2.03 and 2.34 (Me in acetoxy at C7 and C12 resp), 3.10 (sept, J = 7 Hz, H-C15), 5.93 (dd, J = 4 and 1.7 Hz, H-C7); ^{13}C nmr, see Table 1; ms m/z: 416 (1.6, M^+), 374 (13), and 356 (20). *Exact Mass* calcd. for $C_{22}H_{28}O_4$ ($M - CH_3COOH$): 356.1988; found (hrms): 356.2057 (no molecular ion was detected).

*Dithionite reduction of 7-acetoxy-*O*-methylroyleanone* **1***b*

7-Acetoxy-*O*-methylroyleanone (2.50 g) was dissolved in acetone (100 mL) and sodium dithionite (3.0 g) was added. With vigorous

stirring, water (100 mL) was introduced in one portion and the solution became colorless in just a few minutes. Most of the acetone was evaporated and the aqueous solution then saturated with NaCl before extracting with ether. After washing and drying, the product (2.48 g) was unstable so the slightly orange oil was used without further purification for the next step.

From the ^{1}H nmr spectrum, the product was a 1:3 mixture of the two compounds **3***a* and **4***a*. After arduous and costly purification, they were identified as the following: *7-acetoxy-12-methoxy-11,14-dihydroxy-abieta-8,11,13-triene* **3***a*, ^{1}H nmr δ: 0.96 and 1.02 (2s, *gem*-diMe), 1.10, s, Me at C10, 1.35 (d, 6H, Me at C15), 2.16 (s, Me-CO), 3.33 (sept, J = 7 Hz, H-C15), 3.74 (s, Me-O-Ar), 6.09 (m, Ac-O-C*H*), and 7.27 (s, 2H, dis. D_2O, HO at C11 and C14). For ^{13}C nmr, see Table 1. *12-Methoxy-11,14-dihydroxy-abieta-6,8,11-13-tetraene* **4***a*, ^{1}H nmr δ: 0.96 and 1.03 (2s, Me at C4), 1.10 (s, Me at C10), 1.36 and 1.40 (2d, J = 7 Hz, Me at C15), 2.16 (t, 1H, H-C5), 3.34 (sept, J = 7 Hz, H-C15), 3.73 (s, Me-O-Ar), 6.01 (dd, J = 9.6 and 3 Hz, H-C6), 6.62 (dd, J = 9.6 and 3 Hz, H-C7) and 7.26 (s, 2H, dis. D_2O, HO at C11 and C14).

Methylation of mixture containing **3***a and* **4**a

The mixture from the preceding reaction (2.48 g, **3***a* and **4***a*) was dissolved in acetone (100 mL), solid potassium carbonate (15.6 g) was added, and the mixture was heated at reflux while dimethyl sulfate (15 mL) was slowly introduced. Refluxing was continued until the starting material was no longer detected by tlc (24–48 h). The mixture was then filtered and evaporated to give an oil, which was chromatographed over silica gel (petroleum ether/EtOAc 99:1). Only one product was isolated as a colorless oil (**4***c*, 1.924 g; 82% from **1***b*), which eventually crystallized, mp 92–93°C (from MeOH), *11,12-14-trimethoxy-abieta-6,8,11,13-tetraene*; uv: 220(20 325), 271(8980), 295(2920, sh), and 307(1960) nm; ir (film): 3040, 1735, 1625, and 1565 cm^{-1}; ^{1}H nmr δ: 0.97 and 1.04 (2s, Me at C4), 1.11 (s, Me at C10), 1.33 (d, 6H, J = 7 Hz, Me at C15), 2.15 (t, J = 3.2 Hz, H-C5), 3.39 (sept, J = 7 Hz, H-C15), 3.66, 3.75, and 3.80 (3s, Me-O-Ar at C14, C11, and C12 resp.), 5.95 (dd, J = 10 and 3.2 Hz, H-C6), and 6.70 (dd, J = 10 and 3.2 Hz, H-C7); ms m/z: 358(100, M$^+$), 359(29, M$^+$ + 1), 360(10, M$^+$ + 2), 343(13), 315(13), 301(21), and 276(85). *Exact Mass* calcd. for $C_{23}H_{34}O_3$: 358.2508; found (hrms): 358.2502. For ^{13}C nmr, see Table 1.

*Reduction and methylation of 7-acetoxy-*O*-acetylroyleanone* **1**c

Following exactly the same procedure as described for the reduction of **1***b* and the methylation of the product mixture (**3***a* and **4***a*), the *O*-acetyl derivative **1***c* afforded the analogous **4***d*, *12-acetoxy-11,14-dimethoxy-abieta-6,8,11,14-tetraene* in 71% yield, mp 134–135°C (from hexanes); uv: 220 (24 280), 269(11 570), and 305(1650, sh) nm; ir (CCl_4): 3040, 1765, 1650, 1620, 1570, and 1540 cm^{-1}; ^{1}H nmr δ: 0.96 and 1.02 (2s, Me at C4), 1.08 (s, Me at C10), 1.32 and 1.33 (2d, J = 7 Hz, Me at C15), 2.19 (t, J = 3.2 Hz, H-C5), 2.31 (s, Me-CO), 3.38 (sept, J = 7 Hz, H-C15), 3.70 and 3.71 (2s, Me-O-Ar), 6.00 (dd, J = 9.8 and 3.2 Hz, H-C6) and 6.71 (dd, J = 9.8 and 3.2 Hz, H-C7); ms m/z: 386(39, M$^+$), 344(68), and 262(100). *Exact Mass* calcd. for $C_{24}H_{34}O_4$: 386.2457; found (hrms): 386.2489. *Anal.* calcd. for $C_{24}H_{34}O_4$: C 74.56, H 8.87; found: C 74.06, H 8.71.

cis-*Dihydroxylation of* **4**c

To a solution of *N*-methylmorpholine-*N*-oxide (81 mg) in water (2 mL), acetone (1 mL), and *tert*-butanol (1 mL) was added a solution of osmium tetroxide (5 mg) in CCl_4 (2 mL). The olefin **4***c* (170 mg) in CCl_4 (2 mL) was then introduced and the mixture stirred at room temperature for 162 h. The crude product was obtained by diluting the reaction mixture with water and ether extraction, and chromatography over silica gel (CCl_4:EtOAc 98.2) afforded the *6α,7α-dihydroxy-11,12,14-trimethoxy-abieta-8,11,13-triene* **5** (62 mg; 35%), mp 200°C (sublimes, from hexanes); ir: 3460–3580, 1685, 1455, and 1240 cm^{-1}; ^{1}H nmr δ: 1.03 (s, Me at C4), 1.31 (s, Me at C10), 1.30 and 1.36 (2d, J = 7 Hz, Me at C15), 1.73 (s, Me at C4), 2.74 (s, 1H, dis. D_2O), 3.30 (sept, J = 7 Hz, H-C15), 3.77, 3.78, and 3.79 (3s, Me-O-Ar), 4.49 (d, 1H, J = 2.7 Hz, H-C6), 4.76 (d, J = 2.7 Hz, H-C7), 5.28 (s, 1H, dis. D_2O); ms m/z: 392 (M$^+$, 47), 289 (10), and 247 (15). For ^{13}C nmr, see Table 1. *Anal.* calcd. for $C_{23}H_{36}O_5$: C 73.81, H 9.81; found: C 73.81, 9.78.

Heating this diol in refluxing benzene containing a catalytic amount of *p*-toluenesulfonic acid gave the ketone **6***a* in quantitative yield. For the characterization of **6***a* see below.

Epoxidation of **4**c *and rearrangement to the ketone* **6**a

To the cooled (0–5°C) solution of olefin **4***c* (250 mg) in chloroform (15 mL) was added *m*-chloroperbenzoic acid (152 mg, 80%), also dissolved in chloroform (12 mL). The mixture was stirred at room temperature until no starting material was detected by tlc (20 h). The excess per-acid and benzoic acid were removed by extraction, but on evaporating the solvent it was clear that several products were present. Thin-layer chromatography, mass spectroscopy, and nmr pointed to the epoxide, the C6 ketone (**6***a*), C6, C7-diols, and the *m*-chlorobenzoate of the latter. All of these could afford the ketone **6***a* so the crude mixture was taken up in benzene and refluxed with *p*-TsOH (25 mg) until only one product was detectable (tlc). The cooled solution was diluted with ether, washed, and dried and evaporation gave an oil that crystallized on standing, *6-oxo-11,12,14-trimethoxy-abieta-8,11,13-triene* **6***a* (237 mg, from methanol), mp 99–101°C; ir (film): 1710 and 1615 cm^{-1}: ^{1}H nmr ($CDCl_3$) δ: 0.95 (s, Me at C4), 1.19 (s, Me at C4), 1.25 and 1.27 (2s, Me at C15), 1.29 (s, Me at C10), 2.53 (d, J = 1.5 Hz, H-C5), 3.22 (dd, J = 21 and 1.5 Hz, Hβ-C7), 3.27 (sept, J = 7 Hz, H-C15), 3.58 (s, Me-O-C11), 3.60 (d, J = 21 Hz, Hα-C7), 3.71 (s, Me-O-C14), and 3.74 (s, Me-O-C12); ^{1}H nmr (benzene-d_6) δ: 1.15 (Me at C4), 1.35 (Me at C10), and 1.45 and 1.49 (2d, J = 7 Hz, Me at C15), 1.60 (Me at C4), 2.38 (d, J = 1 Hz, H-C5), 3.25 (s, Me-O-C11), 3.47 (dd, J = 21 and 1 Hz, Hβ-C7), 3.55 (sept, H-C15), 3.56 (s, Me-O-C14), 3.68 (s, Me-O-C12), and 3.68 (d, J = 21 Hz, Hα-C7); ms m/z: 374 (M$^+$, 100), 359(9), and 331(18). *Anal.* calcd. for $C_{23}H_{34}O_4$: C 73.76, H 9.16; found: C 73.81, H 9.26. For ^{13}C nmr, see Table 1.

Epoxidation of **4**d *and rearrangement of the product to ketone* **6**b

Following exactly the same procedure as described above, the olefin **4***d* afforded the ketone **6***b* (68% yield) as a colorless oil that crystallized very slowly on standing, mp 146–147°C (from petroleum ether); ir (CCl_4): 1775, 1720, 1590, and 1560 cm^{-1}; ^{1}H nmr δ: 1.03 (s, Me at C4), 1.21 (s, Me at C10), 1.32 (d, J = 7 Hz, Me at C15), 1.34 (s, Me at C4), 2.34 (s, Me-CO), 2.59 (br s, H-C5), 3.35 (d, 1H, J = 20 Hz, Hβ-C7), 3.37 (sept, J = 7 Hz, H-C15), 3.70 and 3.75 (2s, Me-O at C14 and C11), and 3.71 (d, 1H, J = 20 Hz, Hα-C7); ms m/z: 402 (M$^+$, 8), 362 (8), 361 (50), 360 (100). *Exact Mass* calcd. for $C_{23}H_{34}O_5$: 402.2406; found (hrms): 402.2364. *Anal.* calcd. for $C_{23}H_{34}O_5$: C 71.60, H 8.87; found: C 71.84, H 8.40.

Attempted preparations of ketone **6**c

(a) By demethylation of **6**a *with boron trichloride–methyl sulfide*

The ketone (200 mg) was dissolved in dichloromethane (10 L) and, after cooling the mixture to 0°C, boron trichloride–methyl sulfide (10 mL of 0.1 M in CH_2Cl_2) was added, diluted with more CH_2Cl_2 (10 mL). All solvents were rigorously dried and the experiment was conducted under dried nitrogen. The mixture was refluxed for 24 h and, after the usual work-up, chromatography gave some starting material (71 mg; 27%) and two diosphenols **7***a* and **7***b*.

7-Oxo-12-methoxy-6,11,14-trihydroxy-abieta-5,8,11-13-tetraene (**7***a*, 33 mg; 13%): ir (CCl_4): 3500, 3380, 1720, 1610, and 1590 cm^{-1}; uv: 266(4130), 282(3050), 328(1960), and 402(2200) nm; ^{1}H nmr δ: 1.40 and 1.42 (2d, J = 7 Hz, Me at C15), 1.44 (s, 6H, Me at C4 and at C10), 1.65 (s, Me at C4), 3.36 (sept, J = 7 Hz, H-C15), 3.81 (s, 3H, Me-O-C12), 5.76 and 6.94 (2s, dis. D_2O, Ar-OH); ms m/z: 360(M$^+$, 47) and 345(100).

7-Oxo-11,12-dimethoxy-6,14-dihydroxy-abieta-5,8,11,13-tetraene (**7***b*, 19 mg; 7%): ^{1}H nmr δ: 1.34 and 1.35 (2d, J = 7 Hz, Me at C15), 1.44 (s, 6H, Me at C4 and C10), 1.45 (br s, dis. D_2O, HO-C6), 1.62 (s, Me at C4), 3.51 (sept, J = 7 Hz, H-C15), 3.82 and 3.83 (Me-O at C11 and C12), 6.93 (s, dis. D_2O, HO-C14).

(b) By hydrolysis of the acetyl derivative **6**b

To the acetyl compound **6***b* (85 mg) in methanol (15 mL) was added

aqueous sodium hydroxide (1 N, 5 mL) and the mixture was stirred at room temperature for 20 h. More water was then added, most of the methanol removed under vacuum, and the product obtained by ether extraction was chromatographed, affording two diosphenols (**7***c* and **7***d*) and a larger unidentified acid fraction (61 mg).

7-Oxo-11,14-dimethoxy-6,12-dihydroxy-abieta-5,8,11-13-tetraene(**7***c*, 25 mg; 32%), mp 207–209°C (pale yellow powder, from ether); ^{1}H nmr δ: 1.38 and 1.39 (2d, J = 7 Hz, Me at C15), 1.45 and 1.46 (2s, Me at C4 and C10), 1.67 (s, Me at C4), 3.41 (sept, J = 7 Hz, H-C15), 3.77 and 3.81 (Me-O at C14 and C11), 5.97 and 7.44 (2s, dis. D_2O, HO at C6 and C12); ms m/z: 374 (M^+, 58), 359(27), 331(39), 306(20), and 305(100). *Exact Mass* calcd. for $C_{22}H_{30}O_5$: 374.2093; found: 374.2064.

7-Oxo-11-methoxy-6,12-14-trihydroxy-abieta-5,8,11-13-tetraene (**7***d*, 8 mg; 11%), ^{1}H nmr δ: 1.40 and 1.42 (2d, J = 7 Hz, Me at C15), 1.44 (s, 6H, Me at C4 and C10), 1.65 (s, Me at C4), 3.35 (sept, J = 7 Hz, H-C15), 3.81 (s, Me-O-C11), and 5.75 and 6.93 (2s, dis. D_2O).

Hydride reduction of **6**b *(formation of alcohol 8)*

The acetyl derivative **6***b* (174 mg) in anhydrous ether was treated with lithium aluminium hydride (61 mg, added in small portions) and stirring continued at room temperature for 3 h. The excess hydride was decomposed by the cautious addition of water (20 mL) and the product recovered by ether extraction was crystallized from hexane affording the *11,14-dimethoxy-6*β*, 12-dihydroxy-abieta-8,11,13-triene* **8** (121 mg; 77%), mp 169–170°C (from hexane); ir ($CHCl_3$): 3600, 3520, 1600, and 2460 cm^{-1}; ^{1}H nmr δ: 1.05, 1.27 and 1.71 (3s, Me at C4 and C10 resp.), 1.35 (d, 6H, J = 7 Hz, Me at C15), 2.83 (dd, J = 17.6 and 4.3 Hz, Hα-C7), 3.08 (dt, J = 17.6 and 2 Hz, Hβ-C7), 3.35 (sept, J = 7 Hz, Hα-C15), 3.67 and 3.75 (2s, Me-O at C14 and C11), 4.69 (m, H-C6) and 5.76 (s, dis. D_2O, HO-C12); ms m/z: 362 (M^+, 100), 347(9), 330(17), and 329(79). *Exact Mass* calcd. for $C_{22}H_{34}O_4$: 362.2457; found(hrms): 362.2451. For ^{13}C nmr, see Table 1.

Jones oxidation of alcohol 8

(a) Formation of 6-oxoroyleanone methyl ether **9**

The alcohol **8** (33 mg) was dissolved in acetone (2 mL) and the solution cooled to 0°C. Freshly prepared Jones reagent (8 drops), also cooled to 0°C, was added and the mixture stirred for 30 min at 0°C and then diluted with saturated brine (20 mL). Ether extraction and chromatography afforded an orange oil, *6-oxoroyleanone methyl ether* **9** (22 mg; 70%); ir ($CHCl_3$): 1725, 1660, 1645, and 1600 cm^{-1}; ^{1}H nmr δ: 1.01 (s, Me at C4), 1.18 and 1.21 (2d, J = 7 Hz, Me at C15), 1.26 (s, Me at C4), 1.31 (s, Me at C10), 2.41 (br s, width at half height 3.4 Hz, H-C5), 3.07 (dd, J = 22 and 1.3 Hz, Hα-C7), 3.19 (sept, J = 7 Hz, H-C15), 3.36 (d, J = 22 Hz, Hβ-C7), and 3.92 (s, Me-O-C12). For ^{13}C nmr, see Table 1. This product was unstable at room temperature.

(b) Shorter oxidation time, formation of ketone **6**c

The alcohol (33 mg) was oxidized by exactly the same procedure (above) but the product was isolated after 30 s at 0°C. Chromatography gave some 6-oxoroyleanone methyl ether **9** (9 mg; 28%) and *6-oxo-11,14-dimethoxy-12-hydroxy-abieta-8,11,13-triene* **6***c* (13 mg; 40%), mp 175–178°C (from petroleum ether); uv: 287 (1390) nm; ir: 3500, 1590, and 1435 cm^{-1}; ^{1}H nmr δ: 1.03 and 1.27 (2s, Me at C4), 1.36 (s, Me at C10), 1.35 (d, 6H, J = 7 Hz, Me at C15). 2.64 (br. s, H-C5), 3.33 (dd, J = 20.5 and 1.46 Hz, Hα-C7), 3.34 (sept, J = 7 Hz, H-C15), 3.66 (d, J = 20.5 Hz, Hβ-C7), 3.68 and 3.77 (2s, Me-O and C14 and C11), and 5.73 (s, dis. D_2O, HO-C12); ms m/z: 360(M^+, 100), 345(11), and 317(22). *Exact Mass* calcd. for $C_{22}H_{32}O_4$: 360.2301; found (hrms): 360.2334.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada and the Ministère de l'éducation du Québec (F.C.A.R.) for operating and equipment grants. A graduate bursary from the Fonds J. A. Vincent (Université Laval) is also warmly acknowledged. The gift of the acetoxyroyleanone by Dr. O. E. Edwards was much appreciated.

Protium–deuterium exchange of substituted pyridines in neutral D_2O at elevated temperatures

NICK HENRY WERSTIUK[1] AND CHEN JU[2]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 14, 1988

NICK HENRY WERSTIUK and CHEN JU. Can. J. Chem. **67**, 5 (1989).

H–D exchange of a series of pyridines **1**–**15**, 10*H*-pyridino[3,2-*b*][1,4]benzothiazine (**16**), phenothiazine (**17**), and aniline has been carried out in neutral D_2O at elevated temperatures. The substrates undergo selective exchange and are generally isolated in good yield. Cyanopyridines **4**, **5**, and **6** hydrolyze readily in D_2O at elevated temperatures, and the resultant carboxylic acids decarboxylate. This reaction provides a convenient one-step route to selectively labelled pyridines. Possible mechanisms of exchange are presented.

Key words: protium–deuterium exchange, substituted pyridines, temperature effect

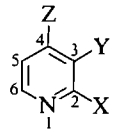
NICK HENRY WERSTIUK et CHEN JU. Can. J. Chem. **67**, 5 (1989).

Opérant dans du D_2O, à des températures élevées, on a réalisé l'échange H–D sur une série de pyridines (**1**–**15**), sur la 10*H*-pyridino[3,2-*b*][1,4]benzothiazine (**16**), sur la phénothiazine (**17**) ainsi que sur l'aniline. Les substrats subissent un échange sélectif et ils sont généralement isolés avec de bons rendements. Dans ces conditions, les cyanopyridines **4**, **5** et **6** s'hydrolysent facilement et les acides carboxyliques qui en résultent se décarboxylent. Cette réaction fournit une route en une étape conduisant à des pyridines marquées d'une façon sélective. On présente des mécanismes possibles pour ces échanges.

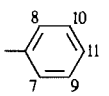
Mots clés : échange protium–deutérium, pyridines substituées, effet de température

[Traduit par la revue]

Introduction

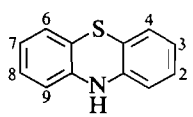


There have been many studies of acid- and base-catalyzed hydrogen isotope exchange of heteroaromatics in the past decade (1–3). However, it is apparent that no studies designed to detail the scope and limitations of exchange of aromatic compounds in neutral D_2O at elevated temperatures have been undertaken although some papers on this subject have been published (4–7).



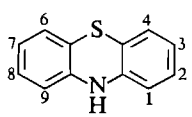
As an extension of our research on hydrogen-isotope exchange of heteroaromatic compounds in neutral D_2O at elevated temperatures (8), we undertook a study of the H–D exchange of an extensive series of pyridine derivatives **1**–**16**, phenothiazine (**17**), and aniline to begin to detail the scope and limitations of this potentially useful labelling method; the results are documented in this publication. While **1**–**3** and **8**–**17** undergo selective H–D exchange and generally can be isolated in good yield, cyanopyridines **4**, **5**, and **6** undergo hydrolysis in D_2O even at 170°C and the resultant carboxylic acids decarboxylate; this provides a useful one-step route to hydrogen-isotope-labelled pyridines. Pyridineacetonitrile (**7**) also undergoes hydrolysis and the acid decarboxylates, but can be labelled at the methylene group under mild conditions, as can 2-pyridinemethanol (**8**). Possible mechanisms of H–D exchange of the substrates are presented.

Results and discussion



H–D exchange of phenylpyridines

As shown in Table 1, phenylpyridines **1**, **2**, and **3** can be selectively labelled by heating the compounds in D_2O at elevated temperatures. While the pK_as of 2-, 3-, and 4-phenylpyridine are 4.55, 4.85, and 5.83, respectively (9), the basicities do not significantly affect the rate of H–D exchange,



1 X = Ph; Y = H; Z = H
2 X = H; Y = Ph; Z = H
3 X = H; Y = H; Z = Ph
4 X = CN; Y = H; Z = H
5 X = H; Y = CN; Z = H
6 X = H; Y = H; Z = CN
7 X = CH_2CN; Y = H; Z = H
8 X = CH_2OH; Y = H; Z = H
9 X = H; Y = Ch_2OH; Z = H
10 X = OH; Y = H; Z = H
11 X = SH; Y = H; Z = H
12 X = $NHCH_3$; Y = H; Z = H
13 X = SH; Y = OH; Z = H
14 X = NH_2; Y = OH; Z = H
15 X = H; Y = H; Z = pyrrodilinyl

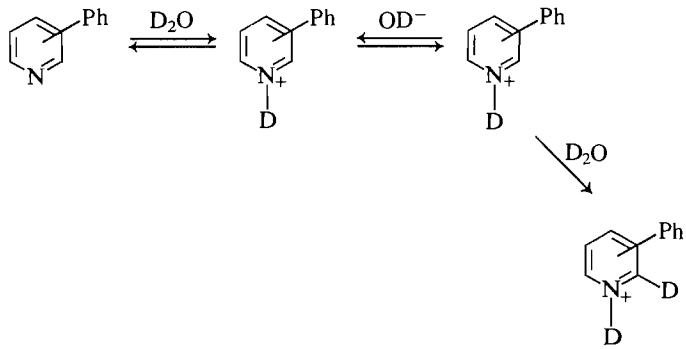
10	Pyridine	300°C, 62 h	D_2O	95	95	95	95	95		4.94



[a]The recovered yields of the deuterated substrates were over 80%.
[b]Exchange at C7, C8, C9, C10, and C11 is <1%.
[c]In excess of natural abundance.
[d]The signals due to the deuterons at C3, C5, C9, C10, and C11 overlap.

as shown by the data in Table 1 (entries 1–6). The mechanism of H–D exchange involves deprotonation of the pyridinium ion by deuteroxide ion to give an ylide, which is deuterated as shown in Scheme 1 (4, 5). The relative rates of exchange at C2(6), C3, and C4 are in accord with the relative stabilities of the 1,2-, 1,3-, and 1,4-ylides (6, 7). In 2% DCl–D_2O solution, the pyridinium ion is the predominant species but the OD^- concentration is low. Consequently, exchange of the pyridine ring is very slow (entry 9 of Table 1). Under these conditions H–D exchange of the phenyl rings occurs by electrophilic substitution with the expected *ortho* and *para* selectivity. In 1% acid at 250°C, only exchange α to nitrogen is observed although at 300°C exchange of the phenyl ring occurs as well (entries 7 and 8, Table 1). Back exchange in H_2O will provide a route to other specifically deuterium-labelled derivatives of **1**, **2**, and **3**. It is interesting to note also that pyridine can be prelabelled in D_2I at 300°C (entry 10).

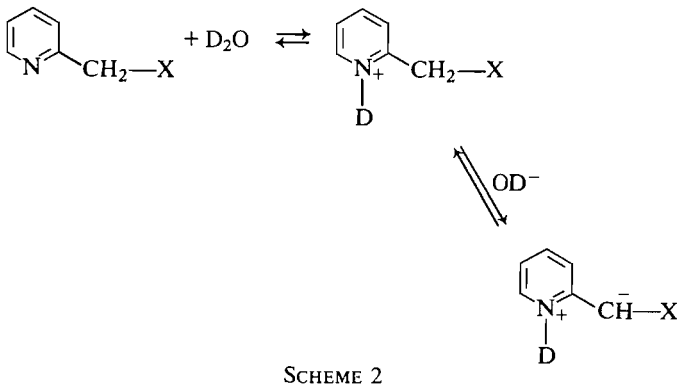
The H–D exchange studies in D_2O establish that it will be possible to tritiate phenylpyridines by using tritiated water of the appropriate activity; at low levels of incorporation, the location of the tritium can be inferred from the distribution of deuterium obtained in D_2O.

H–D exchange of cyanopyridines

H–D exchange of cyanopyridines **4**, **5**, and **6** in D_2O is more complicated due to hydrolysis of the cyano group, which occurs readily even at 170°C and which yields the corresponding pyridine carboxylic acid amides and acids; pyridine is produced by decarboxylation of the pyridine carboxylic acids (10). Since the basicities of the 2-, 3-, and 4-cyanopyridines are lower than the basicity of pyridine,[3] hydrolysis competes with exchange. Furthermore, picolinic acid obtained from 2-cyanopyridine decarboxylates before exchange of the pyridine ring occurs to a significant extent. Therefore, direct deuterium labelling of cyanopyridines and picolinic acid is not possible in neutral D_2O. However, hydrolysis of **4**, **5**, and **6** in D_2O followed by decarboxylation of the acid provides a useful one-step route to labelled pyridines (Table 2). When the corresponding acids are used as the substrates, several washings with D_2O are required to exchange the hydroxyl hydrogen (13). Figure 1 shows the 90-MHz ^1H nmr spectra of the deuterium-labelled pyridines obtained from **4** (entry 2, Table 2), **5** (entry 4), **6** (entry 7), and from exchange of pyridine at 260°C (entry 10, Table 2). The values in parentheses indicate the degree of exchange determined by a combination of the mass spectrometry and electronic integration of the nmr signals. We estimate the error to be ±5%. Since nicotinic acid undergoes decarboxylation more slowly than picolinic acid and isonicotinic acid, exchange of 3-cyanopyridine in D_2O (or THO) (entry 4, Table 2) is a useful route to nicotinic acid deuterated (tritiated) at C4 and C5 as well as at C2 and C6.

SCHEME 1

The facile hydrolysis of **4** and **6** — it is interesting to note that **5** is much less reactive than **4** and **6** — is most likely due to the fact that protonation of the pyridine at nitrogen activates the nitrile to nucleophilic attack by H_2O.



[3]The pK_as of pertinent pyridine derivatives are as follows: picolinic acid, 5.37; pyridine, 5.25; isonicotinic acid, 4.89; nicotinic acid, 4.73; 2-cyanopyridine, −0.26 (11). The order of basicity of other pyridine derivatives is 4Ph > H > 3Ph > 4CN > 3CN > 2Ph > 2CN (12).

					15[g]						4.62[d]
9	Pyridine	200°C, 24 h		75		15				15	0.30
10	Pyridine	260°C, 48 h		75		95	13	14	13	95	2.38

[a]The yield of pyridine was determined by analytical gc by using an internal standard.
[b]The yield was over 100% because the acid and amide contained water of hydration.
[c]The yield was estimated from the ^1H nmr.
[d]Determined for a mixture of acid and amide.
[e]The nmr spectra not obtained.
[f]In calculating the degree of deuteration at C3 from the ^1H nmr, we assumed that 2-, 3-, 6- and 2-, 3-, 4-, 6-sites were equilibrated with the deuterium pool (95% exchange).
[g]The product was intractable.

SCHEME 2

H–D exchange of 2-pyridineacetonitrile and pyridinemethanol

The methylene hydrogens of 2-pyridineacetonitrile (**7**) are easily exchanged in D_2O at 100°C (entry 1, Table 3). At 180°C, hydrolysis yields the amide and the acid, which decarboxylates to picoline. At 150°C after 24 h, **7** gives 28% picoline, 28% amide/acid, and 25% deuterated 2-pyridineacetonitrile; at 200°C after 24 h, the main product is picoline. While we find that **7** is decyanated readily in water even at 150°C, Van der Plas and Jongejan (14), in reporting on their studies on the decyanation of cyanomethyl derivatives of aza-aromatic compounds with hydrazine, stated that **7** yields only a trace of picoline at 210°C after 5 h in aqueous alkaline solution. The authors concluded that this demonstrated that decyanation of the nitriles studied did not proceed via hydrolysis to the acid followed by decarboxylation. Obviously, in their case hydrolysis occurs, but decarboxylation of the carboxylate anion is slow. This is so because at high pH the equilibrium concentration of the pyridinium ion required for ylide formation and facile decarboxylation is very low.

Like **7**, 2-pyridinemethanol (**8**) undergoes H–D exchange at the methylene group, albeit more slowly than **7** (entry 2, Table 3). Exchange at C6 occurs at a comparable rate to exchange of the methylene, in keeping with the results of our study on picolines (8). Exchange of **7** and **8** most likely proceeds via a 1,3-ylide as shown in Scheme 2. In the case of 3-pyridinemethanol (**9**), where neutralization of charge is not possible upon deprotonation, a higher temperature is required to exchange the hydrogens of the methylene group (entry 4, Table 3); at 200°C polymerization occurs. This provides support for the proposed mechanism of exchange of **7** and **8**.

H–D exchange of 2-hydroxy-, 2-mercapto-, 2-N-methylamino-pyridine, and 4-pyrrolidinopyridine

As shown in entries 5–7 and 8–10 of Table 3, 2-hydroxypyridine (**10**) and 2-mercaptopyridine (**11**) undergo exchange selectively at C3, C5, and C6. It has been reported that **10** exists predominantly in the lactam form in aqueous solution, and as the lactim in cyclohexane (Scheme 3). Analysis of the ^1H nmr spectrum of **10** in D_2O established that only the lactam form is present, in keeping with the results of the previous study (15). The sulfur analogue **11** also exists in one form in D_2O, according to its 500-MHz ^1H nmr spectrum. To account for the selectivity (C3, C5, and C6), we propose that exchange at C6 occurs via an ylide involving the lactim form as shown in Scheme 1, and exchange at C3 and C5 occurs via the pyridinolate and thiopyridinolate ions although the lactam[4] and lactim forms can undergo H–D exchange directly by electrophilic substitution. In the case of 2-*N*-methylaminopyridine

[4]A referee has suggested that **10** and **11** undergo exchange at C3 and C5 via the lactam forms by deuteration–deprotonation of the enamine subunits.

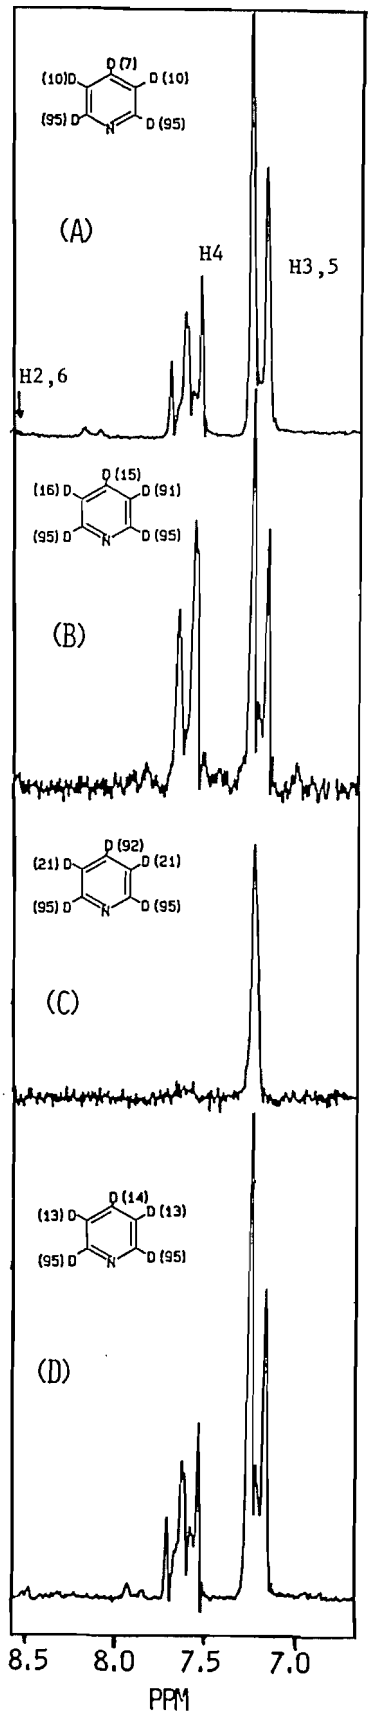

FIG. 1. The 90-MHz ^{1}H nmr spectra of (A) deuterated pyridine obtained from 2-cyanopyridine at 260°C (entry 2, Table 2); (B) pyridine obtained from 3-cyanopyridine at 260°C (entry 4, Table 2); (C) pyridine obtained from 4-cyanopyridine at 260°C (entry 7, Table 2); (D) deuterated pyridine obtained from exchange at 260°C (entry 10, Table 2).

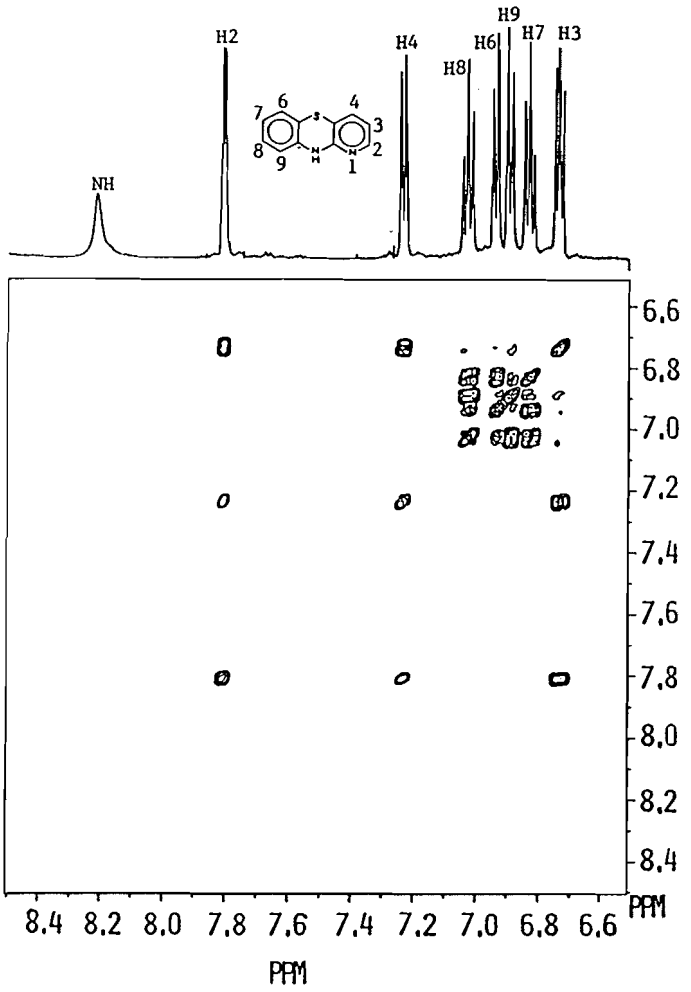

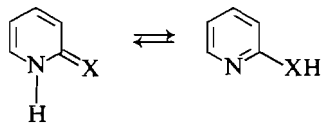

FIG. 2. 2D nuclear proton correlation (COSY) spectrum of **16**.

(**12**), exchange occurs much more slowly at C3 and C5 (entries 11–13, Table 3) than at C3 and C5 of **10** and **11**. This is due to the much lower acidity of the -$NHCH_3$ group and is in keeping with our proposal that **10** and **11** exchange at C3 and C5 via deuteration of the oxy and thio anions, respectively. It is interesting to note that H–D exchange of 2-mercapto- and 2-amino-3-hydroxypyridine (**13** and **14**) *ortho* and *para* to the hydroxy group occurs faster than exchange *para* to the mercapto (or amino) group.

It is noteworthy that hydrogens at C3 and C5 of the pyridine ring of 4-pyrrolidinopyridine (**15**) exchange faster (entries 17 and 18, Table 3) than the corresponding hydrogens of pyridine (entries 23 and 26, Table 3). When the data in entries 17 and 24 of Table 3 are compared, it also appears that exchange occurs more readily at C2 and C6 of **15** than in pyridine. When pyridine is heated with an equimolar amount of pyrrolidine, there is no enhancement of exchange (entry 24, Table 3). Consequently, the pyrrolidine group at C4 of **15** can accelerate exchange at C2, C3, C5, and C6 by increasing the basicity of the pyridine; this results in an increase of the concentration of the pyridinium ion. It is also possible that H3 and H5 are exchanged by electro-

philic substitution — the pyrrolidine ring is strongly electron donating. That exchange can occur by electrophilic substitution in D_2O at elevated temperatures is established by the fact that aniline (entry 27 of Table 3) undergoes facile exchange at 260°C *ortho* and *para* to the amino group.

*H–D exchange of 10*H*-pyridino[3,2-*b*][1,4]benzothiazine and phenothiazine*

It is remarkable that 10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**16**) undergoes selective H–D exchange in neutral D_2O (entries 19, 20, and 21, Table 3) at C2, C3, C4, C6, C7, C8, and C9. The degree of exchange at each site was determined by mass spectrometry and by ^1H and ^2H nmr spectroscopy. Assignment of the resonances of **16** (Table 4) is based on four parts: (*a*) the coupling constants $J(2,3)$ and $J(3,4)$ of the pyridine ring are different; (*b*) the proton α to the nitrogen of pyridine is downfield of the other resonances; (*c*) while a proton *ortho* to an amino nitrogen is shielded relative to the other protons, a mercapto group causes a downfield shift of this resonance; (*d*) a COSY experiment (Fig. 2) confirmed the coupling relation. The ^1H and ^2H nmr spectra of deuterated **16** (entry 21, Table 3), including the deuterium distribution, are given in Fig. 3. Exchange at C9 and C7, *ortho* and *para* to the amino group, occurs by electrophilic substitution. The ease of substitution at these sites in D_2O is remarkable. That **16** undergoes exchange at C3, which is *para* to N10, faster than pyridine undergoes exchange at C3 indicates that H3 is also exchanged by electrophilic substitution. This selectivity is enhanced in the case of benzothiazine (**17**), which also undergoes H–D exchange (entry 22, Table 3). That **16** undergoes exchange faster than **17** may be simply due to the fact that **16** is more soluble in D_2O than is **17**.

Conclusions

This study established that a variety of substituted pyridines can be selectively labelled simply by heating the compounds in neutral D_2O at elevated temperatures. While the pyridines exchange via formation of ylides, it is also clear that activated aromatics readily undergo H–D exchange by electrophilic substitution in neutral D_2O at temperatures between 200 and 300°C. It should be possible to prepare the analogous tritiated compounds simply by using tritiated water of the appropriate activity.

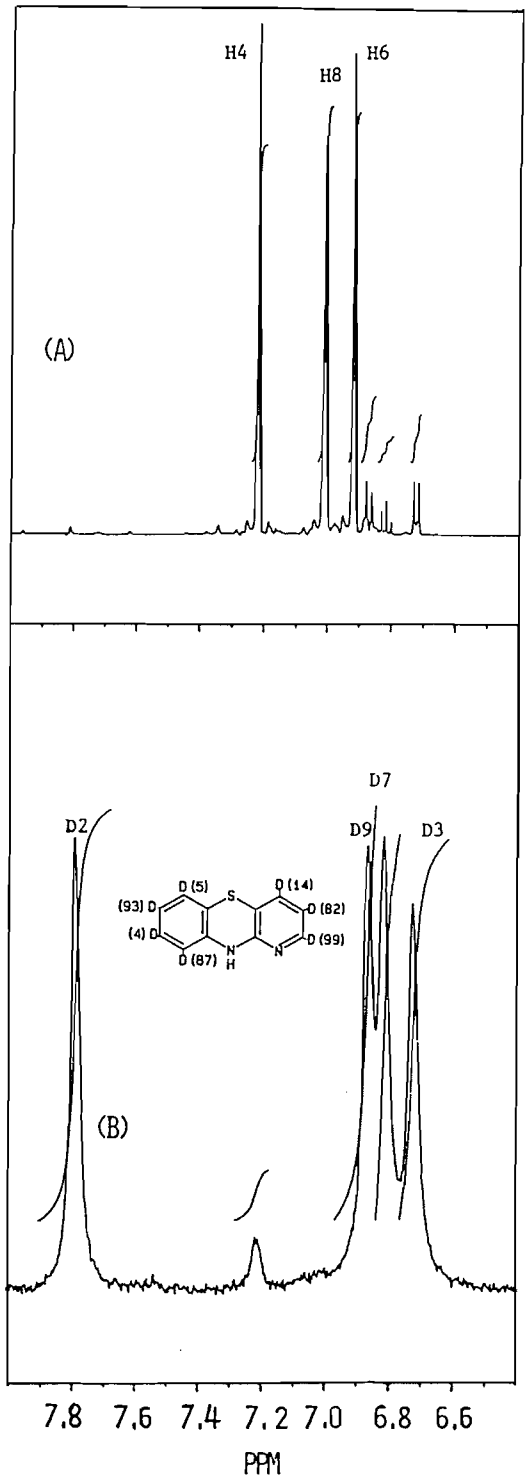

FIG. 3. (A) The 500-MHz ^1H nmr spectrum of deuterated **16** (entry 21, Table 3); (B) 76.8-MHz ^2H nmr spectrum of deuterated **16** (entry 21, Table 3).

Experimental

The reagents (95–98% purity) were obtained from Aldrich Chemical Co. and were used without further purification.

Proton and deuterium magnetic resonance spectra were recorded on Bruker AM 500 (^1H, 500 MHz; ^2H, 76.8 MHz), WM 250 (^1H, 250 MHz; ^2H, 38.4 MHz), and Varian EM 390 spectrometers. CCl_4 was used as nmr solvent for **1**, **2**, **4**, **5**, **6**, **7**, **11**, **12**, **13**, **14**, aniline, and pyridine; CCl_4 and trifluoroacetic acid were used for **3**; D_2O and H_2O were used for pyridinecarboxylic acid and **10**; acetone was used for **14**, **16**, and **17**. Deuterium assay analyses were performed on a VG Micromass 7070 mass spectrometer at low ionization voltage (12–15 eV) and expressed as atoms of deuterium per molecule in excess of natural abundance deuterium. All samples containing OH, SH, or NH were back-exchanged before mass determination.

Analytical gc analyses were performed on a Tracor 560 dual column analytical gas chromatograph equipped with flame ionization. Helium was the carrier gas with a 3% OV-17 column. Deuterated pyridine was isolated by preparative gc using a Varian Associates Aerograph model 700 chromatograph equipped with a 2 m × 6 mm o.d. 20% SE-30 on Chromasorb W column.

In a typical exchange reaction, substrate (0.20 g) was added to D_2O (5 mL) in a 15-mm o.d. medium-walled glass tube. The mixture was degassed via three freeze–pump–thaw cycles and sealed under vacuum. The tube was placed in a 600-mL Parr pressure vessel, which contained water to equalize pressure, and heated at the desired temperature for an appropriate period.

The data in Table 2 were obtained using the following procedure. After the reaction was complete, the substrate was extracted with ether. For reactions carried out at 260°C and 285°C (entries 2, 4, 5, 7, and 8, Table 2), the ether extract was concentrated by distillation and the percent of pyridine was determined by analytical gc using *tert*-butanol as a standard. Pyridine was separated by preparative gc and the deuterium content was determined by mass spectrometry. For reactions at 170°C (entries 1, 3, and 6, Table 2), the ether extract was evaporated to obtain a white solid, which was a mixture of cyanopyridine and pyridinecarboxylic acid and (or) amide. The cyanopyridines were isolated by preparative tlc (silica gel, 2 mm; developing solvent: ether). The D_2O layer that remained after ether extraction was evaporated in a stream of nitrogen with heating. The deuterium content of the acid/amide mixture was determined by mass spectrometry.

Investigation of stereoelectronic bond–antibond orbital interactions in 3-halogenated-1-benzoxepins

P. DIONNE AND M. ST-JACQUES[1]

Département de chimie, Université de Montréal, C.P. 6128, Succursale A, Montréal (Qué.), Canada H3C 3J7

Received May 31, 1988

P. DIONNE and M. ST-JACQUES. Can. J. Chem. **67**, 11 (1989).

The conformational properties of the 3-halogenated-1-benzoxepins (compounds **6–9**) have been studied by ^1H and ^{13}C dynamic nuclear magnetic resonance. The results show that for the heavier halogen derivatives (Cl, Br, and I), only two chair forms (C_a and C_e) are observed while for the F substituent, three forms (C_a, C_e, and *TB*) are detected. This is in contrast with the 3-halogenated-1,5-benzodioxepins (**2–5**), which were shown to exist as a mixture of three forms for the heavier halogens (Cl, Br, and I) and show only two forms (C_a and *TB*) for the F substituent. The results for these two systems characterize the conformational effects produced by one and two O—C—C—X vicinal interactions between polar bonds, which shed light on the nature of the intramolecular stereoelectronic σ–σ^* orbital interactions operative in both families of molecules.

Key words: 3-halogenated-1-benzoxepins, conformational properties, nuclear magnetic resonance, stereoelectronic orbital interactions

P. DIONNE et M. ST-JACQUES. Can. J. Chem. **67**, 11 (1989).

Faisant appel à la résonance magnétique nucléaire dynamique du ^1H et du ^{13}C, on a étudié les propriétés conformationnelles des halogéno-3 benzoxépines-1, **6–9**. Les résultats démontrent que, avec les dérivés halogénés de masse élevée (Cl, Br et I), on n'observe que deux formes chaises (C_a et C_e); par ailleurs, avec le fluor comme substituant, on peut détecter les trois formes (C_a, C_e et *BC*). Ce résultat est en opposition avec ceux obtenus avec les halogéno-3 benzodioxépines-1,5 (**2–5**) pour lesquels on a pu mettre en évidence l'existence d'un mélange des trois formes avec les halogènes de masse élevée (Cl, Br et I) et uniquement deux formes (C_a et *BC*) avec le fluor comme substituant. Les résultats obtenus avec ces deux systèmes caractérisent les effets conformationnels qui sont provoqués par une et deux interactions O—C—C—X vicinales entre des liaisons polaires et nous éclairent aussi sur la nature des interactions stéréoélectroniques intramoléculaires des orbitales σ–σ^* qui sont en opération dans ces deux familles de molécules.

Introduction

In previous publications (1–3), we have shown that conformational analysis of 3-substituted-2,3-dihydro-1,5-benzodioxepins (**1–5**) provides insight into the mechanism of the *gauche* conformational effect (4) between two polar bonds. Whereas studies of this phenomenon in 5-substituted-1,3-dioxanes (5–7) involved only the chair conformation, the twist-boat conformation (*TB*) of the 1,5-benzodioxepin system, being significantly stabilized, was observed for **1–5** together with the equatorial and axial chair forms (C_e and C_a). The variation in the amounts of the three conformers as a function of substituent electronegativity was used advantageously to define the contributing factors to the "*gauche* effect". Thus it has become apparent that the greater flexibility of the seven-membered ring provides a most convenient probe for the experimental investigation of certain aspects of stereoelectronic interactions.

The present work reports the conformational analysis of 3-halogenated-1-benzoxepins (**6–9**). It was designed to investigate the consequence of removing one oxygen atom from the seven-membered ring for which only a single O—C—C—X vicinal interaction between polar bonds remained.

The fact that the parent compound of series **6–10** exists as a single chair (8) form while that of the series **1–5** exists (3) as a mixture of *C* and *TB* suggested different behavior for the two series, so that predictions from one series to the other are not possible. But a comparison of both series should help define the extent to which stereoelectronic stabilization is a factor controlling conformational populations.

Results and spectral analysis

The high-field ^1H and ^{13}C nmr spectra for compounds **6–9** were recorded between 0 and −125°C. For ^1H and ^{13}C spectra, CHF_2Cl was used as polar solvent with some CD_2Cl_2 as locking agent. Less polar solvents used were CF_2Cl_2 with acetone-d_6 for ^1H and CH_3OCH_3 with CD_2Cl_2 for ^{13}C spectra.

The ^1H and ^{13}C nmr spectral analyses of compound **7** (X = Cl) at room temperature were carried out at 300 MHz using a 2D COSY experiment (9) together with a ^{13}C and ^1H nmr Heteronuclear Shift Correlation (HSC) experiment (10).

Figure 1 shows the 2D COSY contour spectrum of **7** in $CDCl_3$. The correlations between coupled protons appear off the diagonal line and the chemical shifts of these protons are obtained from the diagonal line. From recent work by Lachapelle and St-Jacques (8) on 1-benzoxepins, the two most shielded signals at 1.88 and 2.37 ppm can be unambiguously assigned to the H-4 protons. The diagonal peaks 1 and 6 (corresponding to the H-4 protons) each show four correlations. The 2 and 2′ correlation peaks arise from the coupling of the two H-4 protons. Knowing that these protons couple with H-5 and H-3 protons, it is reasonable to say that the most deshielded signal at ~4.32 ppm (correlations 5 and 5′) corresponds to H-3 because of the deshielding effect of the chlorine atom. Thus correlation peaks 3, 3′, 4, and 4′ suggest that the signals at 2.94 and 2.79 ppm correspond to the H-5 protons. Because the H-5 protons couple only with H-4 protons, additional evidence for this last assignment is given by the correlations 9, 9′, 10, and 10′ on the same horizontal line as the 7 and 8 diagonal peaks. Finally, the two last H-2 protons are situated at 3.75 and ~4.32 ppm.

To assign the aliphatic ^{13}C signals of compound **7**, an HSC experiment (10) was carried out at room temperature in $CDCl_3$. Figure 2 shows the ^{13}C and ^1H nmr HSC contour spectrum. For each proton signal there corresponds a correlation peak that ties it to a ^{13}C signal. Thus, the two H-4 signals each show one

[1]Author to whom correspondence may be addressed.

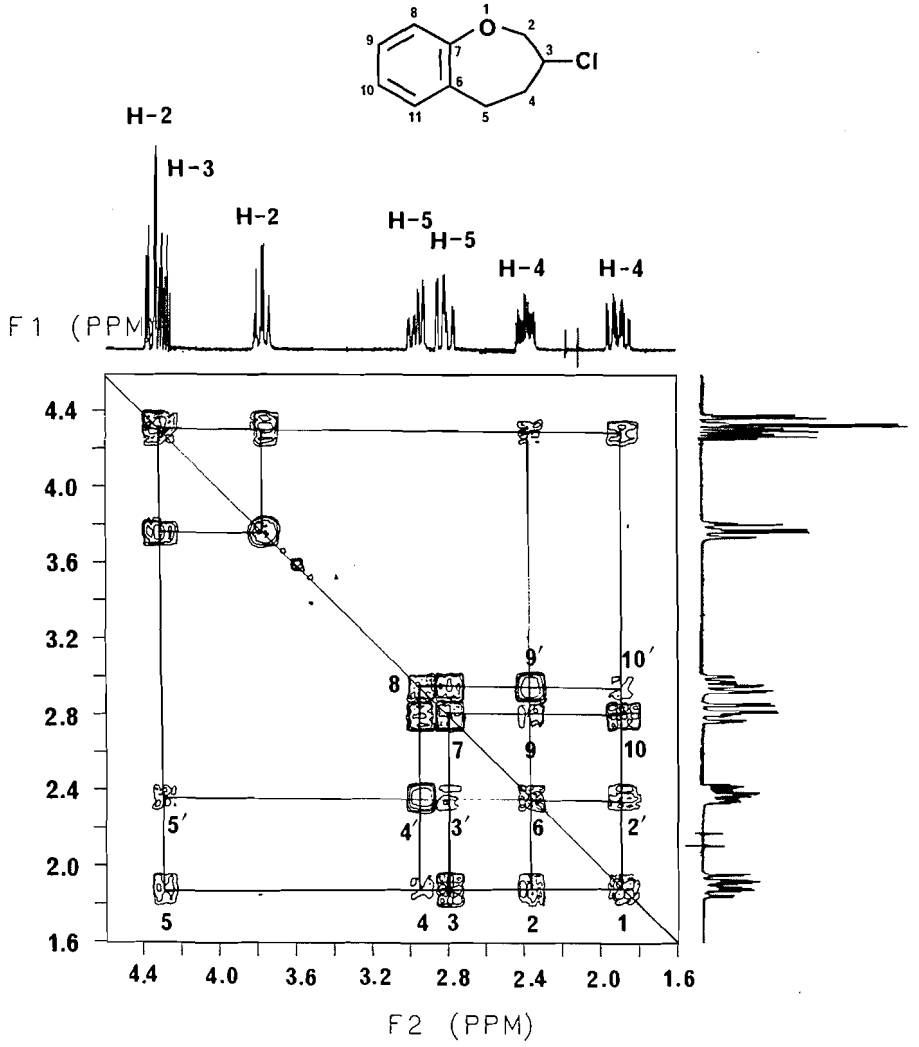

FIG. 1. The 300-MHz two-dimensional ^1H nmr (COSY) spectrum of **7** in $CDCl_3$ at room temperature.

correlation, namely 1 and 2, indicating that the C-4 signal is situated at 35.46 ppm. All carbon signals have been assigned by this procedure and their positions are indicated on Fig. 2.

Figure 3 illustrates the 100.62-MHz ^{13}C nmr spectral modifications observed for **7** (X = Cl) in CHF_2Cl on reducing the temperature. At 0°C, each carbon signal can readily be assigned using the results obtained from the HSC experiment and the aromatic chemical shifts of parent molecules (8). The results are summarized in Table 1.

At low temperature (−120°C), each carbon signal has split into two lines of unequal intensity. The identification of the ring conformation (*C* vs. *TB*) can be made, using the C-6 signals as a probe. For example, at −125°C in CHF_2Cl, the C-6 signals of compound **10** at lower field (137.93 and 137.04 ppm) are characteristic (8) of the C_a and C_e forms respectively, while the upfield signal at 130.54 ppm corresponds to the *TB* conformation. For compound **7** at −120°C, the two C-6 signals at 137.58 and 136.20 ppm are therefore associated with the C_a and C_e forms respectively. These assignments are supported by the analysis of the ^1H spectrum at −120°C described next and by the fact that there is no upfield *TB* signal detected for C-6. Because of the unequal intensity of the C_e and C_a signals, each peak can readily be assigned and the chemical shifts are reported in Table 1. Integration of the C-3 signals indicates that the ratio of the two chair forms is C_a:C_e = 42:58.

In the less polar CH_3OCH_3 solvent, the ^{13}C spectral analysis of compound **7** gave a C_a:C_e ratio of 25:75 at −120°C, as summarized in Table 1.

Figure 4 shows the 400.13-MHz ^1H nmr spectral changes observed for **7** (X = Cl) in CHF_2Cl. At 0°C, the assignment of all signals was readily made using the ^1H 2D COSY spectrum of **7** in $CDCl_3$ and the parameters are reported in Table 2.

Lowering the temperature to −120°C causes spectral modifications and it has been possible to assign the majority of the signals by homonuclear decoupling and integration. From studies on 1-benzoxepin derivatives (8) and 3-halotetrahydropyrans (11), the most shielded quartet at 1.69 ppm corresponds to the 4a-C_e proton (symbol 4a-C_e refers to the axial proton at the 4-position of the C_e conformation, etc...) and the triplet at 1.95 ppm should be due to the 4a-C_a signal. Selective irradiation of the 4a-C_e quartet transforms the triplet at 2.91 ppm to a doublet and changes the appearance of the signals at 4.28 and ~2.53 ppm, indicating that the multiplet at 4.28 ppm corresponds to the 3a-C_e proton. Furthermore, we can assign the signal at 2.91 ppm to the 5a-C_e proton because of its multiplicity (triplet) and the size of the coupling constants

For personal use only.

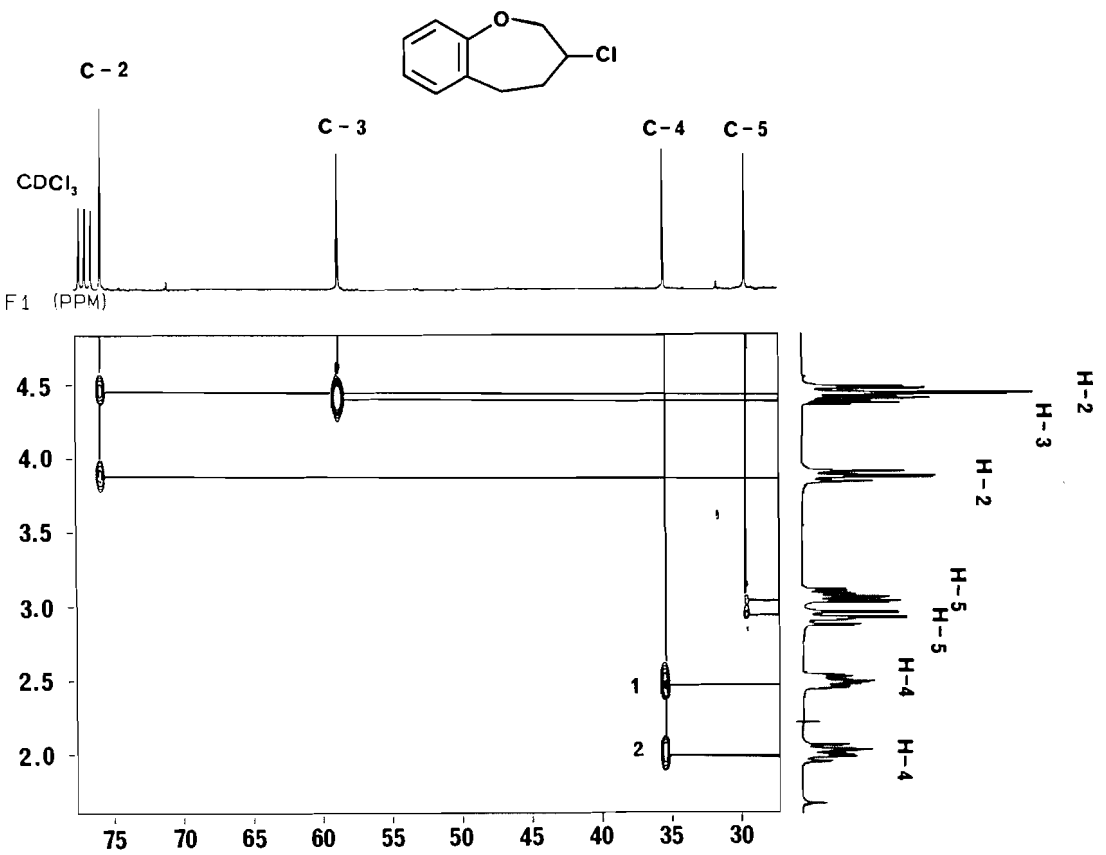

FIG. 2. 2D proton–carbon heteronuclear chemical shift correlation (HSC) spectrum of **7** in $CDCl_3$ at room temperature at 75.431 MHz for ^{13}C with F_1 = 300 MHz in the second dimension.

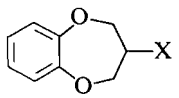
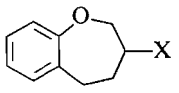
involved ($^2J_{HH}$ and $^3J_{HH} \approx 13.5$ Hz). Thus, the broadened signal at ~2.53 ppm represents the 4e-C_e proton. A second irradiation of the 5a-C_e proton changes the appearance of the split doublet at 2.77 ppm that corresponds to the 5e-C_e proton. Subsequent irradiations allowed assignment of all signals and the results are summarized in Table 2. Finally, integration of 4a-C_e and 4a-C_a signals indicates that the relative populations are 41:59 for C_a and C_e respectively.



The ^1H nmr spectral analysis of compound **7** (X = Cl) at low temperature in CF_2Cl_2 was carried out to give a C_a:C_e ratio of 23:77.

The ^1H and ^{13}C nmr spectral analyses of compounds **6** (X = F), **8** (X = Br), and **9** (X = I) were carried out similarly. On lowering the temperature two forms (C_a and C_e) were observed for compounds **8** and **9** while for compound **6**, three forms (C_a, C_e, and *TB*) were detected. Furthermore, the spectrum of compound **6** presents additional coupling with the fluorine atom. All pertinent data are reported in Tables 1 and 2.



Discussion

The geometry of the TB *form of* **6**

In the previous section, it was shown that two conformations (C_a and C_e) are observed for compounds **7**, **8**, and **9** while a third one (*TB*) is detected for compound **6** (X = F). Two *TB* conformations are possible depending on the orientation of the fluorine atom relative to oxygen, as illustrated by **11** (TB_g), in which the C—F and C—O bonds are *gauche*, and by **12** (TB_a), in which these bonds are *anti*. From the ^{13}C nmr spectrum of **6** at low temperature, only one set of *TB* resonances is detected,

1 X = OCH_3
2 X = F
3 X = Cl
4 X = Br
5 X = I

6 X = F
7 X = Cl
8 X = Br
9 X = I
10 X = OCH_3

indicating either a predominance of one *TB* form or a rapid equilibrium between these two forms. The multiplicity of the *TB* ^1H signals cannot be used to identify one of these forms because they are overlapping with the C_a signals or are too small to be resolved clearly. The ^{13}C chemical shifts of the *TB* carbon signals of compound **6** can be compared with those of compound **10** from which the predominance of the TB_g form has already been suggested (8). It is observed that the difference between the position of each aromatic carbon signal of compounds **6** and **10** is no more than 1 ppm. Furthermore, changing from the polar CHF_2Cl solvent to a less polar CH_3OCH_3 for compound **10** reduces the *TB* (10% to 6%) and C_a (70% to 44%) populations, indicating similar dipole moments for C_a and TB_g in accord with the predominance of the TB_g over the TB_a. For compound **6**, the same trend is observed, suggesting that TB_g also prevails.

Because the amount of this *TB* conformer is small for both **6** and **10**, it does not constitute as useful a probe for stereoelectronic interactions as do the C_a and C_e forms discussed next.

Stereoelectronic effects

Previous results (3) suggest that the factors expected to be prominent in the conformational analysis of 1-benzoxepins are electrostatic interactions, orbital interactions between vicinal polar bonds, and solvation. Whereas the solvation and electrostatic interactions have been amply described over the years and can easily be visualized (12), the bond–antibond orbital interactions are much more difficult to define. It is therefore useful to review briefly the rules that govern orbital interactions between two vicinal bonds.

From molecular orbital theory (13, 14) stabilization occurs when an occupied and an unoccupied orbital overlap. In fragments such as X—C—C—Y or H—C—C—X, bond–antibond interactions are important when C—H, C—X, and C—Y bonds are antiperiplanar. Furthermore, stabilization between a bonding orbital σ and an antibonding orbital σ^* is proportional to $S^2/\Delta E$ where S is the orbital overlap and ΔE represents the energy difference between the σ and σ^* orbitals (15). Thus the combination of a decreasing ΔE and an increasing S leads to better stabilization.

The dependence of the overlap contribution on electronegativity is specific to the nature of the orbital of the C—X bond, σ_{C-X} or σ^*_{C-X}. Indeed, increasing the electronegativity of X leads to an increase of electronic density (16) near C in a σ^*_{C-X} orbital while for σ_{C-X}, the charge density is displaced away from C toward X. This statement is valid for a series of X in the same row of the periodic table (13) as well as for the halogen substituents (17–19). Consequently, better overlap occurs in a σ_{C-Y}–σ^*_{C-X} interaction as the electronegativity of X increases for Y constant. The effect of substituent on ΔE is discussed later.

Figure 5 illustrates the effects of the substituent change on the populations of the C_e and C_a forms, which have been plotted against the electronegativity (20) of each substituent for the series of compounds **6–10**. Data for the OCH_3 substituent (8) are included in this figure and the points are joined to the others by a broken line. Thus, the lines drawn for C_e in both polar and nonpolar solvents show a gradual decrease from I to F, whereas

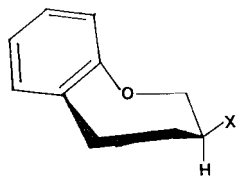
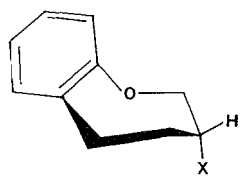
[a]The aromatic signals are not reported because of solvent (CHF_2Cl) overlapping peaks. All aromatic signals for compounds **6–9** appear between 6.8 and 7.1 ppm
[b]These signals were not identified, either because they are overlapping with the C_a and C_e signals or are too small to be resolved clearly.

the amount of C_a increases from I to F. Furthermore, inversion of the relative stabilities of the C_a and C_e forms occurs between Cl and O in each of the two solvents.



Because small amounts of the *TB* form are observed only for **6** and **10**, it is preferable to consider the conformational results in terms of two subgroups: the first part will bear on compounds **7**, **8**, and **9**, which show only two conformations (C_a and C_e), while the second part will consider compounds **6** and **10**.

From studies on 3-halogenated-1,5-benzodioxepins (3), it has been shown that for the I, Br, and Cl substituents, steric and electrostatic interactions are not dominant factors responsible for the population differences. Also, from studies on 3-halotetrahydropyrans (11), it has been suggested that some effect other than dipolar forces is responsible for the conformational behavior. Then, in this work, the same arguments lead to the conclusion that the trends noted for the three heavier halogen substituents in Fig. 5 cannot be due to steric and dipolar interactions.



Furthermore, changing solvent from CH_3OCH_3 to CHF_2Cl increases the C_a populations for all derivatives, as seen in Fig. 5, thus indicating that solvation is not a determining factor. Therefore, as for compounds **3**, **4**, and **5**, these observations point to the stereoelectronic bond–antibond orbital interactions (21, 22).

The relative energy levels of the σ^*_{C-X} orbitals given by CNDO/2 calculations (21) follow the order $\sigma^*_{C-H} > \sigma^*_{C-O} > \sigma^*_{C-F} > \sigma^*_{C-Cl} > \sigma^*_{C-Br} > \sigma^*_{C-I}$, while the order of the σ orbitals is $\sigma_{C-I} > \sigma_{C-Br} > \sigma_{C-Cl} > \sigma_{C-H} > \sigma_{C-O} > \sigma_{C-F}$, as revealed by CNDO/2 and *ab initio* calculations (21) and an analysis of ionization potentials of CH_3X molecules (19, 23). Figure 6 shows a qualitative assessment of the relative energy differences (ΔE) for σ–σ^* interactions from these trends (3). Normally donor σ and acceptor σ^* orbitals are assigned so as to minimize ΔE (21).

Important orbital interactions for the C_a and C_e forms are shown below structures **13** and **14**, where it is seen that the

in the CF_2Cl_2 solvent.

C_a (**14**) form could have two orbital interactions, namely $\sigma_{C—H}$–$\sigma^*_{C—X}$ and $\sigma_{C—H}$–$\sigma^*_{C—O}$. The $\sigma_{C—H}$–$\sigma^*_{C—O}$ interaction cannot explain the population changes because it is independent of X. Thus, $\sigma_{C—H}$–$\sigma^*_{C—X}$ must be the dominant interaction. In this case, ΔE stabilizes this interaction increasingly from Cl to I whereas the S term increases stabilization in the opposite sense. This divergence is useful to estimate the relative importance of the two terms using the experimental trends observed in Fig. 5. Thus, if ΔE were more important, stabilization of C_a would increase in the order Cl to I, whereas if S were predominant, then stabilization would increase from I to Cl. Figure 5 shows that the latter prediction corresponds to the observed C_a population change, thus indicating that the S term is the more important one.

For the C_e form (**13**), the dominant interaction is most difficult to determine in the absence of quantitative ΔE values. We must choose between $\sigma_{C—O}$–$\sigma^*_{C—X}$ and $\sigma_{C—X}$–$\sigma^*_{C—O}$. From a qualitative point of view, these interactions appear to have similar ΔE values and both may be operative with one being more stabilizing than the other. If the S term were more important than ΔE, because the oxygen atom is more electronegative than the halogen atoms, then the $\sigma_{C—X}$–$\sigma^*_{C—O}$ orbital interaction should be dominant and it would increase in the order Cl to I for both ΔE and S terms. Otherwise, if the $\sigma_{C—O}$–$\sigma^*_{C—X}$ orbital interaction were the dominant one, stabilization from ΔE would increase from Cl to I, whereas the S contribution would increase in the opposite sense. Figure 5 shows that the dominant interaction must be in line with an increasing stabilization from Cl to I, indicating that the $\sigma_{C—X}$–$\sigma^*_{C—O}$ orbital interaction ought to be more important because it is stabilized by both ΔE and S terms, in agreement with the earlier analysis for C_a, which suggested that the S term is more important than ΔE.

The results noted for the second subgroup with more electronegative substituents, compounds **6** (X = F) and **10** (X = OCH_3), show that a third conformation (*TB*) is present. Furthermore, contrary to the group of compounds **7–9** for which the C_e form is favored, the C_a form predominates for compounds **6** and **10**. Because the oxygen atom is not in the same family (i.e., in the same column of the periodic table) as the halogens, the OCH_3 points in Fig. 5 are joined to the others by broken lines. As well, it is likely that the electrostatic interactions are modified for OCH_3 because the dipole orientation of the methoxy group bisects the C—O—C angle of the most stable rotamer (8), whereas that of the halogen substituents is located along the C—X bond. Because dipolar interactions are expected to be repulsive for C_a and weakly attractive for C_e, the *TB* form provides an alternative to the C_a form for which the same orbital interactions can be maximized. Consequently, lowering the solvent polarity from CHF_2Cl to CH_3OCH_3 reduces significantly the populations of the most polar C_a form, as seen in Fig. 5.

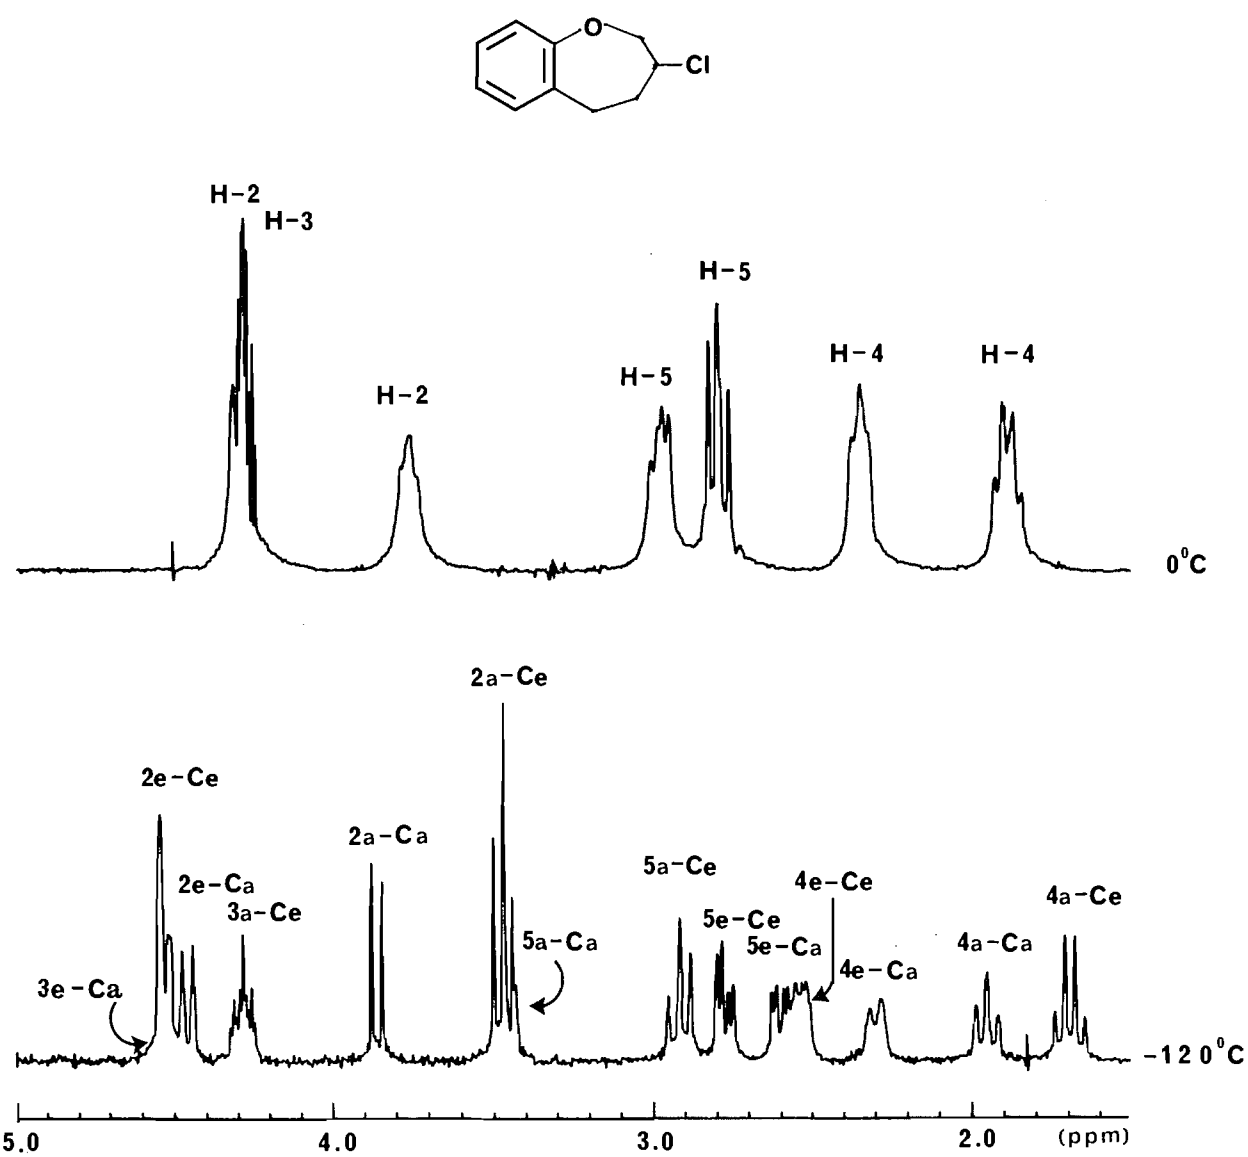

FIG. 4. The 400.13-MHz ^{1}H nmr spectra of the aliphatic protons of **7** in CHF_2Cl at 0°C and −120°C. The abbreviations refer to proton environments described in the text.

The dominant interaction for compounds **6** and **10** (X = F, O) in the C_e (**13**) form, is $\sigma_{C—O}$–$\sigma^*_{C—X}$. From a consideration of the ΔE and S contributions for X = F and OCH_3, this interaction should be more stabilizing for X = F because ΔE is larger and overlap is poorer for OCH_3. Similarly, in the C_a (**14**) form, the $\sigma_{C—H}$–$\sigma^*_{C—X}$ orbital interaction should be more stabilizing for X = F. The trends observed in Fig. 5 for both F and OCH_3 are in agreement with the fact that the $\sigma_{C—H}$–$\sigma^*_{C—X}$ interaction is more stabilizing than $\sigma_{C—O}$–$\sigma^*_{C—X}$, thus favoring the C_a form for both substituents. Finally, the population differences for X = F and OCH_3 indicate that the $\sigma_{C—H}$–$\sigma^*_{C—X}$ interaction is also more stable for X = F, in accord with predictions from the above theoretical framework.

In conclusion, conformational analysis of the 3-halogenated 1,5-benzodioxepins (**1**–**5**) and 1-benzoxepins (**6**–**10**) has revealed that intramolecular orbital interactions constitute an important force complementing electrostatic interactions and solvation. For the heavier halogens (I, Br, and Cl), the bond–antibond orbital interactions alone can explain the observed conformational trends, whereas for the most electronegative substituents, F and OCH_3, these interactions are in competition with dipolar interactions. In addition, the same orbital interactions lead to different overall conformational observations for each series of compounds, due to the fact that the *TB* form is more stabilized and accessible in the benzodioxepin system. Finally, the two systems, having two and one O—C—C—X vicinal interactions between polar bonds respectively, show that the effect of orbital interactions on conformations is not predictable using straightforward additivity schemes.

Experimental

Routine ^{1}H nmr spectra were recorded on a Bruker WH-90 spectrometer as solutions in $CDCl_3$ (10% w/v) containing Me_4Si as reference.

The two-dimensional spectra were recorded on a Varian VXR-300 instrument. The 2D COSY experiment was made using the following pulse sequence: RD–90°–t_1–90°–t_2 (FID) (9). A spectral width of 1080 Hz and quadrature detection were used to collect a 128 × 512 data matrix. Digital resolution was 2.1 Hz/point.

The 2D proton–carbon heteronuclear chemical shift correlation (HSC) was obtained using the standard pulse sequence (10). The experiment was performed on a VXR-300 spectrometer operating at 75.431 MHz for ^{13}C with F_2 = 299.949 MHz in the second dimension. The spectrum was acquired with 256 × 1K data points.

The low temperature ^1H nmr spectra at 400.13 MHz and ^{13}C nmr spectra at 100.62 MHz were obtained by using a Bruker WH-400 spectrometer equipped with a B-VT-1000 variable temperature unit. Calibration using a thermocouple inside a solvent-containing nmr tube indicates that the low temperatures reported are accurate within 3°C. For all ^{13}C nmr spectra, the following parameters are typical: flip angle = 20°–60°; SW (scan width) = 20 000 Hz; data size = 8–16K; AQ (acquisition time) = 0.43 s; RD (relaxation delay) = 0.6 s. For proton spectra, the typical instrumental parameters used are as follows: flip angle = 10°–70°; SW = 5000 Hz; data size = 8 and 16K; AQ = 0.8–1.0 s; RD = 0.01 s.

The ^{13}C samples were studied as solutions in CHF_2Cl or CH_3OCH_3 (100–150 mg in 2.2 mL of solution) containing Me_4Si and about 15–20% of CD_2Cl_2 as locking agent in standard 10-mm tubes that had been degassed and sealed. Integrations were carried out by using Bruker software and are precise within 2%.

Proton samples in standard 5-mm tubes (degassed and sealed) were recorded as solutions in CHF_2Cl or CF_2Cl_2 (10–20 mg in 0.55 mL of solution) containing Me_4Si and about 15–20% of CD_2Cl_2 or CD_3COCD_3 for locking purpose.

The high resolution mass spectra were taken using a modified MS-9 spectrometer at 70 eV.

2,3,4,5-Tetrahydro-3-fluoro-1-benzoxepin (6)

A solution of 1.0 g (0.006 mol) of 2,3,4,5-tetrahydro-1-benzoxepin-3-ol (8) in 100 mL of dry dichloromethane was cooled to 0°C and 2.3 mL (0.018 mol) of diethylaminosulfur trifluoride was added dropwise. The mixture was stirred at room temperature for 48 h, then cooled to −25°C, and 40 mL of methanol was added very slowly. Extraction was carried out with 2 × 100 mL of saturated $NaHCO_3$ solution, 2 × 100 mL of HCl 5%, and 2 × 50 mL of brine. The organic fraction was dried with $MgSO_4$, filtered, and the solvent was evaporated. The product was purified by flash chromatography with 10% dichloromethane and 90% hexane as eluant, giving 352 mg (51%) of a yellow liquid; ^1H nmr δ ($CDCl_3$): 4.82 (1H, m, H-3), 4.20 (1H, m, H-2), 4.07 (1H, dd, H-2), 3.12 (1H, t, H-5), 2.62 (1H, dd, H-5), 1.9–2.3 (2H, br, H-4), 7.0–7.2 (4H, m, Ar). *Exact Mass* calcd. for $C_{10}H_{11}OF$: 166.0794; found (70 eV): 166.0094.

2,3,4,5-Tetrahydro-3-mesylate-1-benzoxepin

A solution of 1.0 g (0.006 mol) of 2,3,4,5-tetrahydro-1-benzoxepin-3-ol in 100 mL of dry dichloromethane was cooled to 0°C and 1.3 mL of triethylamine was added dropwise followed by 0.72 mL (0.007 mol) of methanesulfonyl chloride. The mixture was stirred at room temperature for 16 h. The solution was then washed with 2 × 50 mL of cold water, 2 × 50 mL of cold HCl 10%, 2 × 50 mL of cold saturated $NaHCO_3$ solution, and 2 × 50 mL of cold brine. The organic phase was dried over $MgSO_4$, filtered, the solvent was evaporated, and 1.45 g (98%) of a yellow solid was obtained; ^1H nmr δ ($CDCl_3$): 2.14 (2H, m, H-4), 2.2–3.0 (2H, m, H-5), 3.10 (3H, s, CH_3), 4.15 (2H, br, H-2), 5.03 (1H, m, H-3), 7.0–7.2 (4H, m, Ar).

2,3,4,5-Tetrahydro-3-chloro-1-benzoxepin (7)

A solution of 1.5 g (0.006 mol) of the above mesylate, 6.93 g (0.025 mol) of benzyltriethylammonium chloride, and 15 mL of dry dimethyl sulfoxide was heated at 80°C for 16 h. The solution was cooled to room temperature and 150 mL of ether was added. The

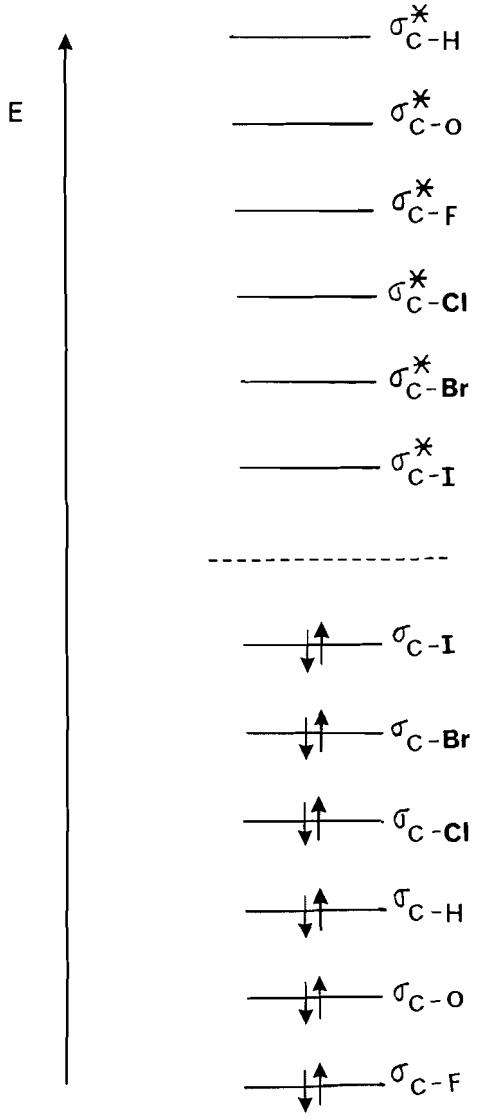

FIG. 6. Order of bond and antibond orbital energies of the C—X bond in various X—CH_2—CH_2—Y and CH_3X molecules.

mixture was washed with 3 × 100 mL of brine. The organic fraction was dried over $MgSO_4$, filtered, and evaporated to give 0.921 g of yellow liquid. Purification by flash chromatography with CCl_4 as eluant gave 0.706 g (62%) of a colorless liquid. Further purification was made by gas chromatography using an SE-30, 30% column; ^{1}H nmr δ ($CDCl_3$): 4.2–4.3 (2H, m, H-3 + H-2), 3.75 (1H, dd, H-2), 2.7–3.0 (2H, m, H-5), 2.37 (1H, m, H-4), 1.88 (1H, m, H-4), 7.0–7.2 (4H, m, Ar). *Exact Mass* calcd. for $C_{10}H_{11}OCl$: 182.0498; found (70 eV): 182.0508.

2,3,4,5-Tetrahydro-3-bromo-1-benzoxepin (8)

A mixture of 0.807 g (0.003 mol) of 2,3,4,5-tetrahydro-3-mesylate-1-benzoxepin, 4.33 g (0.013 mol) of tetrabutylammonium bromide, and 15 mL of dimethyl sulfoxide was stirred at 80°C for 16 h. After cooling the solution to room temperature, 150 mL of ether was added and this mixture was washed with 3 × 100 mL of brine. The organic fraction was dried over $MgSO_4$, filtered, and evaporated to give 0.738 g (97%) of a yellow liquid. Purification was made by distillation under reduced pressure; ^{1}H nmr δ ($CDCl_3$): 1.9–2.1 (1H, m, H-4), 2.4–2.6 (1H, m, H-4), 2.7–2.9 (2H, m, H-5), 3.80 (1H, dd, H-2), 4.41 (2H, m, H-2 and H-3), 7.0–7.2 (4H, m, Ar). *Exact Mass* calcd. for $C_{10}H_{11}OBr$: 225.9993 (50.54%), 227.9973 (49.46%); found (70 eV): 227.9971 and 225.9998.

2,3,4,5-Tetrahydro-3-iodo-1-benzoxepin (9)

A solution of 0.900 g (0.004 mol) of 2,3,4,5-tetrahydro-3-mesylate-1-benzoxepin, 2.80 g (0.019 mol) of NaI, and 50 mL methyl isobutyl ketone was refluxed for 16 h. After cooling the mixture to room temperature, the mixture was filtered and the solvent was evaporated under reduced pressure. The product was purified by flash chromatography on silica gel to give 0.706 g (69%) of brown liquid. Further purification by distillation under reduced pressure gave a pink liquid; ^{1}H nmr δ ($CDCl_3$): 2.0–2.2 (1H, m, H-4), 2.55 (1H, br, H-4), 2.7–2.9 (2H, m, H-5), 3.83 (1H, dd, H-2), 4.5–4.6 (2H, m, H-2 + H-3), 7.0–7.2 (4H, m, Ar). *Exact Mass* calcd. for $C_{10}H_{11}OI$: 273.9814; found (70 eV): 273.9838.

Isotope effects in nucleophilic substitution reactions. VII. The effect of ion pairing on the substituent effects on S_N2 transition state structure

ZHU-GEN LAI AND KENNETH CHARLES WESTAWAY[1]
Chemistry Department, Laurentian University, Sudbury, Ont., Canada P3E 2C6
Received October 6, 1987[2]

ZHU-GEN LAI and KENNETH CHARLES WESTAWAY. Can. J. Chem. **67**, 21 (1989).

The secondary α-deuterium kinetic isotope effects and substituent effect found in the S_N2 reactions between a series of *para*-substituted sodium thiophenoxides and benzyldimethylphenylammonium ion are significantly larger when the reacting nucleophile is a free ion than when it is a solvent-separated ion pair complex. Tighter transition states are found when a poorer nucleophile is used in both the free ion and ion pair reactions. Also, the transition states for all but one substituent are tighter for the reactions with the solvent-separated ion pair complex than with the free ion. Hammett ρ values found by changing the substituent on the nucleophile do not appear to be useful for determining the length of the sulfur–α-carbon bond in the ion pair and free ion transition states.

Key words: Isotope effects, ion pairing, nucleophilic substitution, S_N2 reactions, transition states.

ZHU-GEN LAI et KENNETH CHARLES WESTAWAY. Can. J. Chem. **67**, 21 (1989).

On a trouvé que, lorsque le nucléophile est un ion libre, les effets isotopiques cinétiques secondaires des atomes deutérium en α ainsi que l'effet de substituant qui ont été observés lors de réactions S_N2 d'une série de thiophénolates de sodium substitués en *para* avec l'ion benzyldiméthylphénylammonium sont beaucoup plus importants que lorsque ce nucléophile est une paire d'ions complexe séparée par le solvant. On a trouvé que les états de transition sont beaucoup plus compacts lorsqu'on utilise un mauvais nucléophile tant dans des réactions d'ions libres que dans des réactions de paires d'ions. Par comparaison avec les réactions se produisant avec l'ion libre, les états de transition de tous les substituants, à l'exception d'un, sont plus compacts pour les réactions avec la paire d'ions complexe séparée par le solvant. Il ne semble pas que les valeurs ρ de Hammett que l'on trouve en faisant varier la nature du substituant attaché au nucléophile soient utiles pour déterminer la longueur de la liaison entre le soufre et le carbone en α, tant dans la paire d'ions que dans les états de transition de l'ion libre.

Mots clés : Effets isotopiques, couplage ionique, substitution nucléophile, réactions S_N2, états de transition.

[Traduit par la revue]

Introduction

Recent work by Westaway and Lai (1) has shown that the form of the reacting anion has a significant effect on the magnitude of the secondary α-deuterium kinetic isotope effect and transition state structure of an S_N2 reaction. For example, changing the form of the reacting anion from a solvent-separated ion pair complex (ref. 1, *vide infra*) to a free ion in the S_N2 reaction between *n*-butyl chloride and sodium thiophenoxide in DMSO at 20°C, eq. [1], changes the secondary α-deuterium kinetic isotope effect from 1.034 ± 0.003 to 1.118 ± 0.009 (1). In fact, this change in the form of the reacting nucleophile seems to be a general phenomenon because the secondary α-deuterium kinetic isotope effect changes in at least three other S_N2 reactions when the form of the nucleophile is altered (1).[3] These results clearly demonstrate that the magnitude of the secondary α-deuterium kinetic isotope effect and transition state structure can be strongly dependent on the form of the reacting anion in an S_N2 reaction. Our interest in the substituent effects on the structure of S_N2 transitions states (3–5) and the many cases where the substituent effects found experimentally do not show a consistent pattern (6) made it important to determine how the form of the reacting anion in an S_N2 reaction affects the substituent effects on transition state structure.

$CH_3CH_2CH_2CL_2SC_6H_5 + Cl^-$ L = H, D

Results and discussion

The effect of ion pairing (the form of the reacting anion) on the substituent effect on transition state structure has been assessed by measuring the secondary α-deuterium kinetic isotope effects for the S_N2 reactions of a series of *para*-substituted sodium thiophenoxides and benzyldimethylphenylammonium ion in methanol at 20°C, eq. [2].

[2] $(Na^+)\ ^-S$–C$_6$H$_4$–$Z + C_6H_5CL_2\overset{+}{N}(CH_3)_2C_6H_5\ NO_3^- \rightarrow$

L = H, D Z = CH_3O, CH_3, H, and Cl

Obviously, the first requirement for this study of the effect of ion pairing on substituent effects was to demonstrate that the form of the reacting thiophenoxide ion could be changed from a free ion to a solvent-separated ion pair complex under the reaction conditions. Several results indicate that sodium thiophenoxide exists as ion pairs in methanol at high concentrations (1). First, the slope of the conductance versus concentration plot decreases sharply at a sodium thiophenoxide concentration of approximately 2×10^{-4} M. In addition, there is a rapid change in the uv spectrum when the sodium thiophenoxide concentration is 1×10^{-4} M. Finally, the addition of 15-crown-5 ether causes the same changes as dilution in the uv spectrum of sodium thiophenoxide solutions.

The cation independent λ_{max} of the uv spectra of lithium, sodium, and cesium thiophenoxide solutions, at concentrations where the salts exist as ion pairs in methanol, indicates that the nucleophilic reactant is a solvent-separated ion pair (7). Finally, the extremely sharp change in the uv spectrum and in the

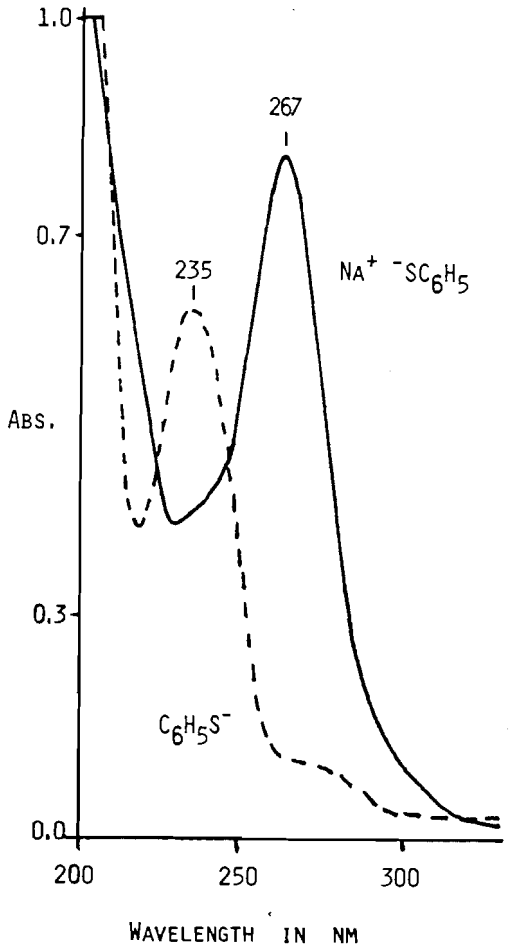

FIG. 1. The ultraviolet spectrum of a 1.54×10^{-3} M solution of the solvent-separated sodium thiophenoxide ion pair complex (—) and the free thiophenoxide ion (---) in methanol at 20°C. The free thiophenoxide ion was generated by adding 15-crown-5 ether.

secondary α-deuterium kinetic isotope effects with concentration (1) indicate that the solvent-separated ion pair must exist as a complex consisting of several solvent-separated sodium thiophenoxide ion pairs, eq. [3].

[3] $m\,Na^+ + m\,SC_6H_5^- \rightleftarrows (Na^+(solvent)_n(SC_6H_5^-))_m$

All of the experimental findings are consistent with such an equilibrium. First, the form of the reacting anion would only change rapidly with concentration if this equilibrium existed. As a result, this equilibrium will produce the rapid changes in the uv spectra and in the secondary α-deuterium kinetic isotope effects with concentration that are observed. The conductivity data are also consistent with the formation of the ion pair complex because the conductance of the ion pair complex is lower than that of the free ions (8). Finally, when 15-crown-5 ether is present, the secondary α-deuterium kinetic isotope effect for the S_N2 reaction between *n*-butyl chloride and sodium thiophenoxide at concentrations where the salt exists as a solvent-separated ion pair complex is identical to those found in the free ion reactions. This occurs because the 15-crown-5 ether complexes the sodium ions (9), preventing the formation of the ion pair complex.

The above experiments indicate that the sodium thiophenoxide exists as a solvent-separated ion pair complex at concentrations greater than 1×10^{-4} M in methanol at 20°C. However,

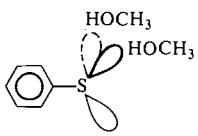
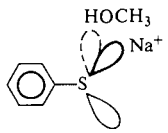
Cl	3.692 ± 0.026	3.209 ± 0.012	1.150 ± 0.009

[a]The errors are the standard deviation from at least three different kinetic runs.
[b]The error is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively (4).





the uv spectra in Fig. 1 show that the addition of 15-crown-5 ether clearly changes the form of the thiophenoxide ion. When the sodium thiophenoxide concentration is 3×10^{-3} M, the concentration used throughout this study, the uv spectrum shows a strong maximum at 267 nm, where the solvent-separated sodium thiophenoxide ion pair complex absorbs (1). When 15-crown-5 ether is added, the absorption at 267 nm almost completely disappears and a new absorption at 235 nm, where the free thiophenoxide anion absorbs, is found (1). Thus, the form of the reacting thiophenoxide ion can be changed from the solvent-separated ion pair complex to the free anion by adding 15-crown-5 ether, and a study of the effect of ion pairing on the substituent effects in S_N2 reactions is feasible.[4]

The secondary α-deuterium kinetic isotope effects found for the S_N2 reactions between benzyldimethylphenylammonium ion and a series of *para*-substituted free thiophenoxide ions and solvent-separated sodium thiophenoxide ion pair complexes, Tables 1 and 2, differ in several ways. First, the substituent effects on the secondary α-deuterium kinetic isotope effects cover a much larger range in the free ion reactions, i.e., the isotope effects range from 1.271 to 1.121 when the nucleophile is a free ion but only from 1.216 to 1.150 when the solvent-separated sodium thiophenoxide ion-pair complex is the reacting species. This observation is important because it illustrates

[4]Neither adding benzyldimethylphenylammonium nitrate nor changing the *para* substituent on the thiophenoxide ion affects the concentration at which the solvent-separated ion pair complexes begin to form in methanol.

that the substituent effect on S_N2 transition state structure is strongly dependent on the form of the ionic nucleophile.

One possible explanation for the different secondary α-deuterium kinetic isotope effects in the free ion and ion pair complex reactions is that the sodium ion alters the reduced mass of the nucleophile sufficiently to affect the isotope effect. This explanation seems unlikely for several reasons. First, the ion pair is a solvent-separated ion pair so the change in mass does not occur near the nucleophilic atom, i.e., the sodium is replacing a methanol molecule in the second or perhaps third solvent shell around the free ion and should have little or no effect on the reduced mass of the nucleophile. In any case, the mass of the methanol molecule and a sodium ion are similar. Also, theoretical calculations (10) indicate that the secondary α-deuterium kinetic isotope effect in the S_N2 reaction between benzyl chloride and an alkoxide ion only changes by 0.0002 when the developing chloride ion is solvated with three hydrogen-bonding solvent molecules. Since this change in the reduced mass of the chloride ion is much larger than that associated with changing a solvent molecule (methanol) to a sodium ion, it is unlikely that the mass of the sodium ion is responsible for the difference in the isotope effect.

A more plausible explanation for the change in the secondary α-deuterium kinetic isotope effect is that the sodium ion of the solvent-separated ion pair complex reduces the charge on the sulfur atom of the thiophenoxide ion. If the charge on the sulfur of the solvent-separated ion pair complex were indeed smaller than that on the sulfur of the free ion, one would expect that the nucleophile would have to approach closer to the α carbon to distort the α-carbon–chlorine bond and cause reaction. This would result in a tighter transition state and the smaller secondary α-deuterium kinetic isotope effect that is observed for all but one of the ion pair complex reactions (*vide infra*).

The sodium ion could also reduce the magnitude of the substituent effect resulting from a change in the *para* substituent on the nucleophile, by reducing the charge on the sulfur atom of the thiophenoxide ion. If the charge on the sulfur of the solvent-separated ion pair complex were smaller than that on the sulfur of the free ion, a change in the *para* substituent might have a smaller effect on the charge on the sulfur atom of the sodium thiophenoxide ion pair. If this occurred, the nucleophilicity of the thiophenoxide ion would not be altered as much by a change in substituent, and the change in transition state structure with *para* substituent (secondary α-deuterium kinetic isotope effect (substituent effect)) should also be smaller in the ion pair complex reactions.

This rationalization is supported by the results from CNDO/2 calculations of the charge on the sulfur atom of the partially solvated free thiophenoxide ion and the contact sodium thiophenoxide ion pair, Table 3. The CNDO/2 calculations were carried out on the thiophenoxide ion solvated by two methanol molecules and on the contact ion pair[5] solvated by only one methanol molecule because one of the lone pairs of electrons on the sulfur is involved in bond formation in the S_N2 transition state and cannot be solvated. As expected, the calculations indicate that the negative charge on the sulfur atom of the nucleophile is much smaller when the positive sodium ion is present. Although the substituent changes the amount of negative charge on the sulfur atom by the same relative amount, i.e., changing a hydrogen to a *para*-chloro substituent reduces the charge on the sulfur atom by the same percentage in both the free ion and the ion pair, it is important to note that the absolute change in charge on the sulfur ion with substituent is greater for the free ion. Since the substituent effect on the charge on the nucleophile is greater for the free ion than for the ion pair complex, the change in the nucleophilicity should be greater in the free ion reactions. As a result, one would expect the substituent effect on the secondary α-deuterium kinetic isotope effect (transition state structure) to be greater for the free ion than for the ion pair complex reactions. This is, in fact, what is observed.

Although CNDO/2 calculations predict charges in molecules very well (11), the calculated charges on the sulfur atom of the free ion and ion pair complex transition states are only representative of the changes in charge that occur in the actual reactions. However, the same trends in the charge on the sulfur ion with substituent were found for both the unsolvated and fully solvated ion pairs and free ions in methanol.[3] Moreover, the same trends were also found when the position of the sodium ion in the ion pair was varied. Since the same trends in the charge

[5]The calculations were not done on the solvent-separated ion pair complex because neither the structure nor the number of solvent molecules between the sodium and sulfur ions is known.

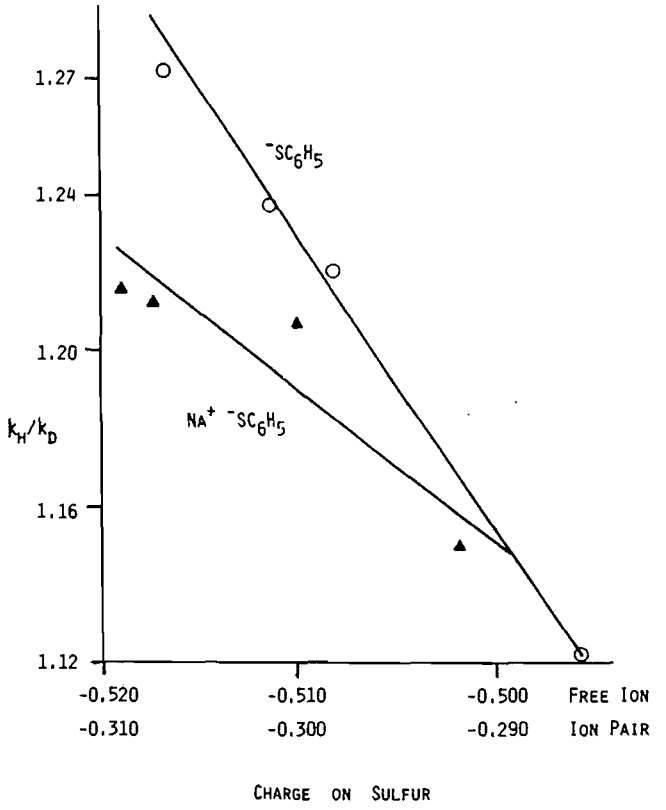

FIG. 2. The secondary α-deuterium kinetic isotope effect versus the charge on the sulfur atom of the free thiophenoxide ion (open circles) and the solvent-separated sodium thiophenoxide ion pair complex (solid triangles).

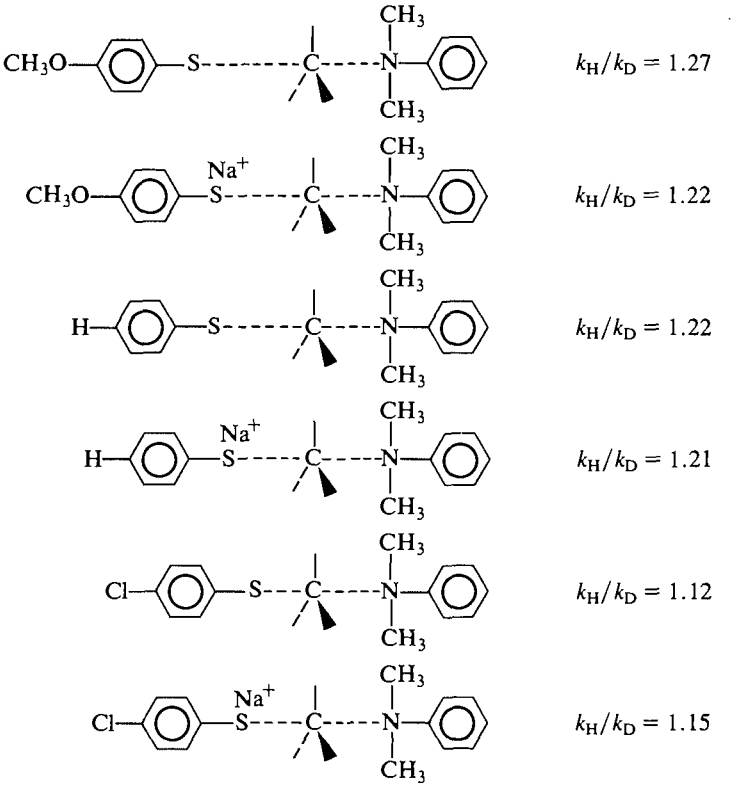

FIG. 3. The relative transition state structures for the S_N2 reactions between benzyldimethylphenylammonium ion and the free ion and solvent-separated ion pair complex forms of a series of *para*-substituted sodium thiophenoxides.

on the sulfur of the free ion and ion pair were observed regardless of the position of the sodium ion and the solvation of the contact ion pair and free ion, it is reasonable to assume that the sodium ion would also reduce the substituent effect on the charge on the sulfur anion of the solvent-separated ion pair complex. Thus, it is not surprising that the substituent effect on the nucleophilicity and, therefore, on transition state structure (the secondary α-deuterium kinetic isotope effect) is smaller for the solvent-separated ion pair complex than for the free ion S_N2 reactions.

The secondary α-deuterium kinetic isotope effects for the S_N2 reactions with the free ion and with the solvent-separated ion pair complex, Tables 1 and 2, both decrease when a poorer nucleophile is used. Since the C_α–H(D) bending vibrations are the same in the initial state of all of the free ion and ion pair reactions, the differences in the isotope effects must reflect differences in transition state structure. This suggests that the transition states are tighter, with shorter α-carbon–nucleophile and (or) α-carbon – leaving group bonds, when a poorer nucleophile is used in both the free ion and ion pair reactions. In fact, a plot of the secondary α-deuterium kinetic isotope effect (the tightness of the transition state) versus the negative charge on the sulfur atom for the free thiophenoxide ion reactions has a correlation coefficient of 0.996, Fig. 2. Thus, the structure of the free ion transition state depends directly on the charge on the sulfur atom (the nucleophilicity) of the reacting nucleophile. The smaller secondary α-deuterium kinetic isotope effect and tighter transition state found when a more electron-withdrawing substituent is in the free ion is expected. A poorer nucleophile should have to come closer to the α carbon to distort the α-carbon – leaving group bond and cause reaction (14).

Both the slope and correlation coefficient for the plot of the secondary α-deuterium kinetic isotope effect versus the charge on the sulfur ion in the solvent-separated ion pair complex reactions, Fig. 2, are smaller than the corresponding values found in the free ion reactions, i.e., the slope is only 3.86 rather than the 7.21 found for the free ion reactions and the correlation coefficient of 0.92 is significantly smaller than the 0.996 found for the free ion reactions. Thus, although the transition state structures for the ion pair reactions seem to depend on the nucleophilicity of the nucleophile, the relationship is not as strong as for the free ion reactions and it appears that some factor(s) other than the charge on the sulfur ion must be important in determining the transition state structures of the solvent-separated ion pair complex reactions.

The magnitude of these secondary α-deuterium kinetic isotope effects can also be used to compare the transition state structures for the solvent-separated ion pair complex and free ion reactions. When the *para* substituent on the nucleophile is methoxy, methyl, and hydrogen, the secondary α-deuterium kinetic isotope effects for the free ion reaction are larger than those found for the corresponding ion pair reactions. This suggests that the free ion transition states are looser (have longer nucleophile–α-carbon and (or) α-carbon – leaving group bonds) than the ion pair transition states, Fig. 3.[6] This is reasonable because the higher charge on the free ion nucleophile

[6]The length of the α-carbon – leaving group bonds has not been changed in these transition states when the substituent on the nucleophile is changed because other work in our laboratory has suggested that the length of the stronger transition state bond does not change significantly when a substituent is changed in the substrate, the nucleophile, or the leaving group of an S_N2 reaction (3, 4).[3]

TABLE 4. The rate constants and Hammett ρ values for the free ion and the solvent-separated ion pair complex S_N2 reactions between benzyldimethylphenylammonium ion and a series of *para*-substituted sodium thiophenoxides in methanol at 20°C

para-Substituent on the nucleophile	$k_{free\ ion} \times 10^3$ (L mol^{-1} s^{-1})	$k_{ion\ pair} \times 10^3$ (L mol^{-1} s^{-1})
CH_3O	10.33 ± 0.11	10.09 ± 0.10
CH_3	6.87 ± 0.02	7.06 ± 0.05
H	5.14 ± 0.03	5.18 ± 0.03
Cl	3.66 ± 0.03	3.69 ± 0.03
ρ	−0.85 ± 0.14	−0.84 ± 0.11
Correlation coefficient	0.98	0.98

would distort the α-carbon – leaving group bond and cause reaction at a greater distance from the α carbon (14).

Unfortunately, not all of the free ion transition states are looser than the ion pair transition states. The secondary α-deuterium kinetic isotope effect for the reaction with the *para*-chlorothiophenoxide ion pair complex is greater[7] (1.150 ± 0.009 versus 1.121 ± 0.014) than the isotope effect for the corresponding free ion reaction. Although other factors, such as a change in the amount of conjugation to the phenyl ring on the α carbon (10, 15), changes in the reaction coordinate motion (16, 17), tunneling (16, 17), and changes in the product composition (18), can affect the magnitude of secondary α-deuterium kinetic isotope effects, the simplest explanation is that the free ion transition state is tighter than the ion pair transition state when the nucleophile is *para*-chlorothiophenoxide ion, Fig. 3, and that some factor(s) other than the charge on the sulfur of the nucleophile is important in determining transition state structure.

The unexpected changes in the secondary α-deuterium kinetic isotope effect found when the *para*-chlorothiophenoxide ion is the nucleophile are not caused by changes in product composition (18) for two reasons. First, quantitative yields of the S_N2 products, benzyl phenyl sulfide and *N,N*-dimethylaniline, are found in these reactions. Secondly, the isotope effects in the side reaction would be very similar to that in the major reaction. Thus, even if a small amount of the side reaction occurred, the effect on the observed secondary α-deuterium kinetic isotope effect would be very small. Thus product composition cannot be responsible for the unexpected changes in the isotope effect.

Conjugation between the α carbon and the phenyl ring, which reduces the magnitude of secondary α-deuterium kinetic isotope effects, only appears to be important when strongly electron-donating groups are on the benzene ring on the α carbon (15). Thus, changes in conjugation would not seem to be the cause of the unexpected isotope effects.

Finally, the secondary α-deuterium kinetic isotope effects found in this study are less than or equal to those found in the S_N2 reactions of other quaternary ammonium salts (5, 19, 20). Since large secondary α-deuterium kinetic isotope effects, significantly greater than the equilibrium isotope effect, are found when changes in the reaction coordinate motion and (or) tunneling are important in determining the magnitude of secondary α-deuterium isotope effects (16, 17), it seems unlikely that this factor is important in affecting the magnitude of these isotope effects. As a result, it would appear that the more likely explanation is the simple one, i.e., that the magnitude of the isotope effects is related to the structure of the transition state. In any case, it would seem unlikely that changing a *para*-hydrogen to a *para*-chloro substituent, which only changes the rate constant by 40%, would change the reaction coordinate motion and (or) tunneling enough to cause the different behaviour of the isotope effect.

The Hammett ρ values, obtained by changing the *para* substituent on the nucleophile, were determined for both the solvent-separated ion pair complex and the free ion reactions, Table 4, in an effort to learn more about the relative S_N2 transition state structures for these reactions. The identical Hammett ρ values for the two types of reactions show that this technique is not useful in distinguishing between the lengths of the α-carbon–sulfur bonds in the free ion and solvent-separated ion pair complex transition states (1).

Finally, the difference between the secondary α-deuterium kinetic isotope effects for the free ion and the ion pair complex reactions is large when the nucleophile is *para*-methoxythiophenoxide ion but becomes smaller when a more electron-withdrawing substituent is on the thiophenoxide ion. In fact, the difference in the isotope effects is almost zero when the nucleophile is thiophenoxide ion and is inverse when the reactant is the *para*-chlorothiophenoxide ion. Although we do not understand these observations, these results are interesting because they suggest that the effect of ion pairing is largest when strongly electron-donating and electron-withdrawing substituents are present.

It is interesting that the difference between the rate constants for the free ion and solvent-separated ion pair complex reactions is very small. Although we do not understand why this is so, similar differences in rate have been found in several other S_N2 reactions we have studied (1).[3]

Conclusion

This work has shown that the secondary α-deuterium kinetic isotope effect (transition state structure) is altered significantly when the form of the reacting ionic nucleophile is altered from a free ion to a solvent-separated ion pair complex in the S_N2 reactions between benzyldimethylphenylammonium ion and a series of *para*-substituted sodium thiophenoxides in methanol. Also, the magnitude of the substituent effect found by changing a *para* substituent on the ionic nucleophile is significantly larger when the nucleophile is a free ion rather than a solvent-separated ion pair complex. The transition states are tighter when a poorer nucleophile is used in both the free ion and ion pair reactions. Also, with one exception, the S_N2 reaction between *para*-chlorothiophenoxide ion and benzyldimethylphenylammonium ion, the ion pair transition states are tighter than the free ion transition states. Finally, the Hammett ρ values found by changing the substituent on the nucleophile do not appear to be useful in determining the relative lengths of the α-carbon–sulfur bonds in the ion pair complex and free ion transition states.

Experimental

Preparation of reagents

The preparation of the benzyldimethylphenylammonium nitrate and the *para*-substituted sodium thiophenoxides is described elsewhere (2, 19). The purification of the solvent is described in ref. 1. The 15-crown-5 ether was purchased from Parrish Chemical Co.

Product analysis

Approximately 0.12 g of benzyldimethylphenylammonium nitrate was reacted with 0.12 g sodium thiophenoxide in 85 mL of purified

[7]Two different statistical tests, the Wilcoxin test and the Student's T test (12, 13) indicate that the secondary α-deuterium kinetic isotope effects for the ion pair and free ion reactions with *para*-chlorothiophenoxide ion are significantly different at the 99% confidence level.

methanol for 5500 min (approximately 14 half-lives) at 20°C. Then, the reaction mixture was poured into 1400 mL of pH 12 water and the products were extracted once with 200 mL, twice with 150 mL, and twice with 100 mL of ether. The combined ether layers wre extracted twice with 40 mL, and once with 30 mL of a 10% sulfuric acid solution. Evaporation of the ether layer under reduced pressure left a solid whose nmr spectrum was consistent with that of the expected S_N2 product, benzyl phenyl sulfide. No peaks associated with the other possible product, methyl phenyl sulfide, were apparent even at a high spectrum amplitude.

Most of the water was removed from the combined 10% sulfuric acid solutions on a rotary evaporator. A Kjeldahl analysis (2) of the concentrate was consistent with a 98% yield of *N,N*-dimethylaniline (the expected S_N2 product). If even a small amount of the other possible product, *N*-benzyl-*N*-methylaniline, had been present, a much lower yield of *N,N*-dimethylaniline would have been obtained.

An identical experiment, except that 2 mL of 15-crown-5 ether was present in the reaction mixture, gave the same results. The only substitution product visible in the nmr spectrum was benzyl phenyl sulfide, and the Kjeldahl analysis indicated the yield of *N,N*-dimethylaniline was 99%.

Kinetic method

After all of the apparatus had been cleaned and dried at 140°C, it was sealed while hot or cooled in a desiccator. Six 125-mL Erlenmeyer flasks with ground glass stoppers were filled with extra dry nitrogen and weighed accurately. Then, these flasks, samples of the appropriate *para*-substituted sodium thiophenoxide and benzyldimethylphenylammonium nitrate, a crude balance, and some spatulas were placed in an IR^2 glove bag that was sealed, filled, evacuated, and refilled with extra-dry nitrogen. About 520 mg (3.9×10^{-3} mol) of the *para*-substituted sodium thiophenoxide was placed in three of the Erlenmeyer flasks and approximately 59 mg (2.2×10^{-4} mol) of benzyldimethylphenylammonium nitrate was placed in the other Erlenmeyer flasks. These flasks were removed from the glove bag and the amount of each salt determined by weighing them accurately.

The Erlenmeyers containing the *para*-substituted sodium thiophenoxide, the Erlenmeyers containing the quaternary ammonium salt, adaptors fitted with a serum cap, a bottle of purified methanol (*vide supra*), a graduated cylinder, three glass-stoppered 50-mL Erlenmeyer flasks for each *para*-substituted sodium thiophenoxide sample, three 1-mL and one 75-mL pipettes, and a rubber pipetting bulb, were placed in the glove bag under a nitrogen atmosphere (*vide supra*). Approximately 40 mL of methanol was added to each Erlenmeyer containing the *para*-substituted sodium thiophenoxide and 75 mL of methanol was pipetted into the Erlenmeyers containing the quaternary ammonium salt. Finally, three 1-mL samples of each sodium thiophenoxide solution were transferred to the three 50-mL Erlenmeyers.

The reaction flasks containing the quaternary ammonium salt and the sodium thiophenoxide solutions were temperature equilibrated at 20.00 ± 0.02°C for at least 45 min. The purity of the thiophenoxide salt was determined by titrating the samples in the 50-mL Erlenmeyers with standard mercury II nitrate (2). Finally, the kinetic run was begun by injecting 5 mL of the *para*-substituted sodium thiophenoxide solution into the reaction vessel with a 5-mL Hamilton air-tight syringe.

The kinetic data were obtained by withdrawing 5-mL aliquots of the reaction mixture with a 5-mL Hamilton gas-tight syringe fitted with a 6-in. needle. Each sample was quenched by adding it to 15 mL of a solution prepared by diluting 2.3 mL of a 25% solution of nitric acid to 1 L with methanol. The unreacted thiophenoxide ion was determined in a titration using a standard mercury II nitrate (2). The rate constants were calculated using standard methods (3).

Mobility of thermal cations in liquids of *n*-alkanes, *n*-pentane to *n*-tetradecane: effect of viscosity and comparison to neutral molecule diffusion

NORMAN GEE AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 5, 1988

NORMAN GEE and GORDON R. FREEMAN. Can. J. Chem. **67**, 27 (1989).

The cation mobility μ_+ was measured in *n*-pentane at 295 K and in *n*-C_6 to C_{11} and *n*-C_{14} alkanes from ~295 K to their normal boiling points. The dependence on viscosity $\mu_+ \propto \eta^{-p}$ was reexamined and the best fit occurred with $p = 1.0$. The ratio of diffusion coefficients of neutral molecules to analogous cations was ~3 because of the stronger interaction of ions with the fluid molecules (electrostriction). The dependence of μ_+ on free volume is illustrated.

Key words: thermal cation mobility, *n*-alkane solvents, viscosity effects

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **67**, 27 (1989).

Opérant dans le pentane à 295 K de même que dans les alcanes *n*-C_6 à C_{11} et *n*-C_{14} de 295 K jusqu'à leurs points d'ébullition normaux, on a mesuré les mobilité cationiques μ_+. On a réévalué la relation qui existe entre μ_+ et η^{-p} et on a déterminé que la meilleure corrélation se produit lorsque $p = 1{,}0$. Le rapport des coefficients de diffusion des molécules neutres et ceux des cations analogues est d'environ 3; ce fait est le résultat de l'interaction plus forte des ions avec les molécules de fluide (électrostriction). On donne une illustration de la relation qui existe entre μ_+ est le volume libre.

Mots clés : mobilité cationique thermique, solvants des alcanes-*n*, effets de viscosité

Introduction

On the basis of Stokes' Law (1) and Walden's Rule (2) the mobility of cations μ_+ in liquids is often compared to the fluid viscosity η using

[1] $\mu_+ \propto \eta^{-p}$

While the rules suggest $p = 1$, experimentally a range of p from 0 to 1.5 has been reported (3–9). Indeed if a liquid is heated from below its normal boiling point T_b towards its critical fluid region the value of p varies in a complicated fashion with changing η/η_c (subscript c denotes critical fluid property) (9, 10).

In the *n*-alkane liquids *n*-pentane to *n*-hexadecane $p = 1.5$ has been reported (3–5), although examination of each liquid separately ($281 \leq T/K \leq 324$) showed that p varied from 1.0 to 1.7 (Table 1 of ref. 4). This contrasted with our findings in small *n*-alkanes methane to *n*-hexane (10, 11) where in the dense liquids $p \approx 1.0$. Recently we obtained sufficiently purified samples of *n*-pentane to *n*-tetradecane that electrons generated in them decayed with half lifes of 5 to 240 μs (12, 13). In this study μ_+ was measured in the purified liquids at temperatures from (295 ± 1) K to near T_b. The application of eq. [1] to the large *n*-alkanes is re-examined and the transport of the cations is compared to that of the neutral molecules in the liquids.

Experimental

A. Materials and sample preparation

The *n*-alkanes were (supplier, mol% purity): *n*-pentane (Aldrich HPLC, 99.5), *n*-hexane (Phillips Research Grade, >99.99), *n*-heptane (Aldrich HPLC, 99.9), *n*-octane (Phillips Research Grade, >99.88), *n*-nonane (Aldrich, 99), *n*-decane (Phillips Research Grade, >99.85), *n*-undecane (Aldrich, 99), *n*-tetradecane (Terochem Labs., >99). Each hydrocarbon was further purified by the procedure of ref. 12: 125 mL of liquid was (*a*) stirred with concentrated H_2SO_4 to remove unsaturated impurities and water; (*b*) decanted onto and held on Molecular Sieves 4A to remove trace acid; (*c*) vigorously bubbled with argon (Liquid Carbonic UHP, >99.999 mol%) and isolated under argon to exclude air; (*d*) transferred without further contact with atmosphere into a grease-free glass vacuum line and degassed to remove argon; (*e*) transferred into a glass bulb connected by a Hoke Inc. (model 4251N6Y) valve to the vacuum line. The bulb contained a 50/50 sodium/potassium alloy. After transfer, the valve was closed and the liquid gently stirred for >3 weeks on the alloy.

To get high purity samples, in which electron half lives of 10–100 μs could be obtained, two steps were needed: (*a*) the transfer distance from the bulb containing sample and alloy to the conductance cell was <30 cm; (*b*) the transfer time to the cell was <10 min.

After the sample was transferred onto alloy and stirred >3 weeks the sideline was isolated and the glass cut above the Hoke valve of the alloy bulb. The bulb was then repositioned and attached to the sideline above a second valve leading to the conductance cell such that when both valves were opened, the liquid would flow under the pull of gravity from the storage bulb into the reservoir bulb of the cell. The sideline was then repaired and evacuated. Before the cell was filled, it was evacuated to $<10^{-4}$ Pa and heated at >530 K while pumping for >1 week, then cooled back to room temperature (295 ± 1 K). After ~50 mL of liquid was flowed into the cell the material was frozen to liquid N_2 temperature, and the cell was sealed using a flame.

B. Apparatus and other techniques

The conductance cell was like that shown in ref. 14 with the electrode geometry shown in ref. 15*a* (plate separation $l = 4.76$ mm, collector area = 7.92 cm^2). The heating apparatus (15*a*), temperature control (15*a*) and measurement (11), voltage sources (15*b*), and data collection system (15*b*) have been described.

The cations were produced by ionizing the liquid in the cell with 0.3 or 1.0 μs pulses of X-rays, 1.3 or 4.0 (10^{11} eV/g), from a Van de Graaf accelerator. The free ion yield was less than 0.7 ion-pairs/(100 eV absorbed dose) at all (E,T) of this work (13), so that [ions]/[molecules] $< 10^{-12}$. The mobility was obtained from

[2] $\mu_+ = l^2/t_d V$

where V is the applied voltage. The time of flight t_d was taken to equal the time required for the radiation-induced ion current to return to the baseline (15*b*) or for the integrated charge to reach its maximum value (10*b*). The first method was used for *n*-heptane, *n*-octane, *n*-nonane, and *n*-undecane, and the second for the other liquids. These methods give the mobility of the slowest ion in the liquid, which is the cation rather than the anion (4, 8).

C. Physical properties

Values of the viscosity were from ref. 16 for *n*-decane and *n*-tetradecane, and from refs. 17 and 18 for the other liquids. Densities d were from ref. 18, but the tetradecane density at 293.2 K is 762.7 kg/m^3 not 772.7.

Results and discussion

The cation mobilities were independent of electric field strength at $2.1 \leq E\,(10^5\ V/m) \leq 21$. The value of μ_+ cited at

[a]No. of carbon atoms in alkane molecule.
[b]Dynamic fluid viscosity, refs. 16–18, 10^{-3} Pa s = 10^{-2} Poise.
[c]Reference 18.
[d]Neutral–neutral self diffusion coefficient, refs. 24–26.

each temperature of this work was obtained by averaging ~10 measurements, half using positive and half using negative applied voltage. The average deviation of the measurements from the mean was ~3%. The present results are summarized in Table 1.

A. Effect of viscosity

The cation mobilities are plotted against viscosity in Fig. 1. The η/η_c values are for n-pentane to n-octane in which $\eta_c = (2.68 \pm 0.04) \times 10^{-5}$ Pa s (18); this connects the present work to previous studies that related p (eq. [1]) to η/η_c (9, 10). At higher η the best fit of the present μ_+ was to

$$[3] \quad \mu_+ = A\eta^{-1.0}$$

with μ_+ (m^2/V s), η (Pa s), and $A = 1.6 \times 10^{-11}$ C/m. The mean deviation between the present experimental values and eq. [3] is 6%.

To show the lack of fit if $p = 1.5$, the dot–dashed line in Fig. 1 has the equation

$$[4] \quad \mu_+ = B\eta^{-1.5}$$

where $B = 4.0 \times 10^{-13}$ (C/m) (Pa s)$^{1/2}$.

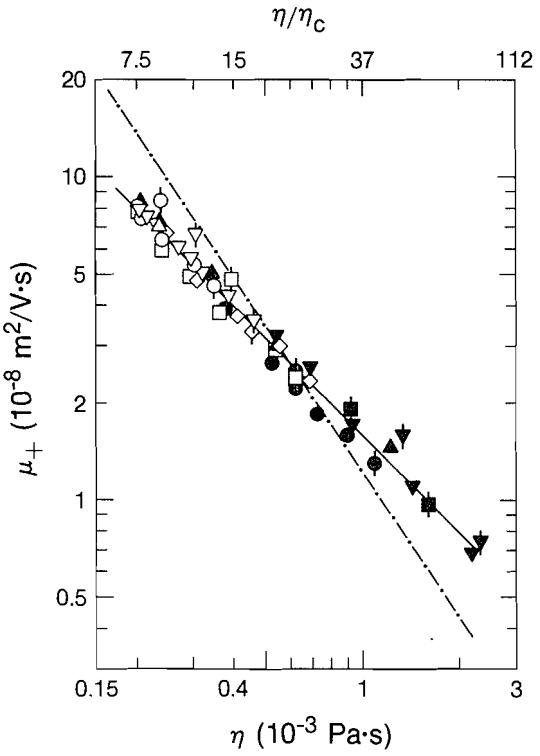

FIG. 1. Plot of cation mobility against fluid viscosity. The η/η_c scale is for *n*-pentane to *n*-octane ($\eta_c = (2.68 \pm 0.04) \times 10^{-5}$ Pa s (18)). Symbols are as follows: *n*-pentane (△,△), *n*-hexane (○,○), *n*-heptane (▽,▽), *n*-octane (□,□), *n*-nonane (◇,◇), *n*-decane (●,●), *n*-undecane (▲), *n*-dodecane (■), and *n*-tetradecane (▼,▼). The symbols with vertical bars are refs. 4 and 5; others are present work. —, eq. [3] with $A = 1.6 \times 10^{-11}$ C/m, ···, eq. [4] with $B = 4.0 \times 10^{-13}$ (C/m) (Pa s)$^{1/2}$.

Cation mobilities from Table 1 of ref. 4 are included in Fig. 1. The pioneering measurements of Adamczewski (3*a*, 4), which introduced the use of eq. [4], were excluded. Those measurements gave two cation mobilities, the values of which bracket the single values reported in later work (4, 5). For example in *n*-hexane at 294 ± 2 K Adamczewski reported 2.8×10^{-8} and 8.4×10^{-8} m^2/V s compared with 5.8×10^{-8} m^2/V s (5). The more recent values given in ref. 4 are in general agreement with the present work (Fig. 1) and are fitted by eq. [3] within the experimental uncertainty.

B. Comparison to molecular diffusion

Although positive hole (electron hopping) mobilities have been observed in two cyclic hydrocarbons (cyclohexane and transdecalin) (19, 20), the motion of cations in *n*-hydrocarbons is like that of the neutral molecules. Each diffusive displacement is small compared to a molecular diameter. The diffusion coefficient for the cations D_+ is related to the mobility μ_+ by the Nernst–Einstein or Nernst–Townsend equation

$$[5] \quad D_+ = \mu_+ k_B T/\xi$$

where k_B is Boltzmann's constant and ξ the protonic charge (21). Diffusion coefficients in turn are related to fluid properties by the Stokes–Einstein relation

$$[6] \quad D = k_B T/S\pi r\eta$$

where r is the radius of the diffusing particle and $S = 4$ in the slipping boundary limit or 6 in the sticking boundary limit

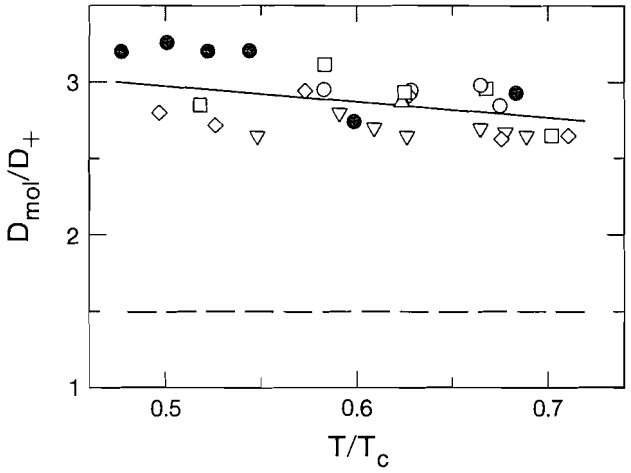

FIG. 2. Ratio of neutral molecule diffusion coefficient to cation diffusion coefficient (eq. [5]) against reduced temperature. T_c are from ref. 18. The dashed line indicates the value expected from the difference in eq. [6] between slip and stick boundary conditions. Symbols as Fig. 1.

(22, 23). For hydrocarbon liquids the neutral molecule self diffusion coefficient D_{mol} correlated with eq. [6] with $S \approx 4$. Available D_{mol} values for the present liquids are given in Table 1 (24–26). Using eq. [6] with $S = 4$ gave a radius r_{mol} that was constant in each liquid within a typical average deviation of ~2%. These radii were intermediate in value to radii estimated from polarizability α (27) using

$$[7] \quad r_\alpha = (\alpha/4\pi\epsilon_0)^{1/3}$$

where ϵ_0 is the permittivity of vacuum and α is in C m^2 V^{-1} (28), and radii estimated from neutral–neutral molecule Lennard–Jones collision diameters σ_{LJ} (29) using $r_{LJ} = \sigma_{LJ}/2$ (Table 2).

Because of their charge, ions interact more strongly with fluid molecules than do neutral molecules, so $S = 6$ in eq. [6] might apply (stick condition). Then if the cation radius r_+ is similar to r_{mol}, $D_{mol}/D_+ \sim 6/4 = 1.5$ would result (dashed line in Fig. 2). Experimentally $D_{mol}/D_+ \approx 3$. This larger ratio is largely due to electrostriction about the cations (30). In dense liquids of the less polarizable molecules xenon and argon, values of D_{mol}/D_+ were ~2.5 and ~1.7 respectively (30). Electrostriction (relative compaction of molecules about the ion) increased as the critical fluid was approached, so the values in Fig. 2 are shown against reduced temperature (critical point temperatures T_c are from ref. 18). By analogy with the Ar and Xe results (30), D_{mol}/D_+ in the present hydrocarbon liquids should increase as $T/T_c \rightarrow 1$.

Liquid phase diffusion coefficients (2, 25*a*, 26) and ion mobilities (5, 8, 9) are often presented as Arrhenius plots and discussed in terms of the associated activation energies. An alternate view describes transport in terms of temperature and density (or molar volume $v = M/d$ where M = molecular weight) without reference to energy barriers (31–34). Instead of plotting ln D against T^{-1}, straight or slightly curved lines are obtained by plotting D against molar volume v at constant T (35, 36), or for the saturated liquid (37), by plotting D against $T^{1/2}$ $(v - v_0)/v_0$ in which v_0 is the molar volume at which the liquid molecules are too crowded for diffusion to occur (32, 33). From eq. [5] it might be expected that

$$[8] \quad \mu_+ \propto (v - v_0)/v_0 T^{1/2}$$

This relation is examined for the present mobilities in Fig. 3

using v_0 values from Table 2. A slightly curved dependence results, with most deviation occurring at smaller free volumes $(v - v_0)$. All the present values seem to fall near the same curve. This illustrates the dominant effect of free volume on μ_+. The viscosity effect (Section III-A) is then indirect and reflects the fact that η is also determined by free volume (32).

ROBERT CHÊNEVERT, DANIEL CHAMBERLAND, MICHEL SIMARD and FRANÇOIS BRISSE. Can. J. Chem. **67**, 32 (1989).

The macrocyclic polyether 18-crown-6 forms complexes with hydrates of strong acids derived from transition metal chlorides and hydrochloric acid. The following charged-component complexes have been isolated and characterized: 18-crown-6.H_3O^+.$FeCl_4^-$, 18-crown-6.H_3O^+.$InCl_4^-$, and (18-crown-6.H_3O^+)$_2$.$Pd_2Cl_6^{2-}$. X-ray diffraction study of the palladium complex is reported. The oxonium ion is located at the center of the macrocyclic ether cavity and the symmetry of the ring is close to D_{3d}.

Key words: 18-crown-6 complexes, oxonium ions, X-ray diffraction, crystal structure

ROBERT CHÊNEVERT, DANIEL CHAMBERLAND, MICHEL SIMARD et FRANÇOIS BRISSE. Can. J. Chem. **67**, 32 (1989).

L'éther macrocyclique 18-couronne-6 forme des complexes avec les hydrates des acides forts dérivés des chlorures des métaux de transition et de l'acide chlorhydrique. Nous avons isolé et caractérisé les complexes suivants : 18-couronne-6.H_3O^+.$FeCl_4^-$; 18-couronne-6.H_3O^+.$InCl_4^-$; (18-couronne-6.H_3O^+)$_2$.$Pd_2Cl_6^{2-}$. La structure du complexe de palladium a été déterminée par diffraction des rayons X. L'ion oxonium se trouve au centre de la couronne dont la conformation est voisine de la symétrie D_{3d}.

Mots clés : complexes 18-couronne-6, ions d'oxonium, diffraction des rayons-X, structure cristalline

Introduction

The macrocyclic polyether 18-crown-6 readily forms complexes with hydrates of strong acids (pK_a of the acid < pK_a of H_3O^+ at −1.7) which exist as hydronium salts. This type of complexation was first observed for the *cis-syn-cis*-dicyclohexano-18-crown-6 with $H_3O^+ClO_4^-$ or $H_3O^+PF_6^-$ (1). In recent years, it has been shown that 18-crown-6 is a good complexing agent for the hydronium ion, and complexes have been obtained with several strong acids (2–7). In these studies, it was generally assumed that the H_3O^+ ion in the adduct is located at the center of the macrocyclic ether cavity, as this would maximize the electrostatic interactions between the two units. This was also expected on the basis of the strong hydrogen bonds revealed by infrared spectroscopy (4), as these bonds presumably involve the H_3O^+ ion and the oxygen atoms lining the interior of the ether cavity. This hypothesis has been confirmed by X-ray diffraction studies (5–7).

With weak acids (pK_a of the acid > pK_a of H_3O^+ at −1.7) such as carboxylic acids and weak inorganic acids, neutral component complexes have been obtained (8, 9). These usually have a 1:1:1 or 2:2:1 (acid:water:crown) stoichiometry, although some anhydrous complexes have been reported (8, 10). The adduct formed with cyanoacetic acid (11) and later characterized by X-ray diffraction (12), provides a good structural model for these aqua complexes, in which the water molecule presumably serves as a linker between the acid and the ether.

In the present study, we report the preparation and characterization of complexes of 18-crown-6 with the hydronium ions derived from transition metal chlorides and hydrochloric acid.

Experimental

Preparation of the complexes (general procedure)

The transition metal chloride (2 mmol) is dissolved in tetrahydrofuran (25 mL) and concentrated hydrochloric acid (2 mL). This solution is added to a solution of 18-crown-6 (2 mmol) in tetrahydrofuran (15 mL). The complex crystallizes immediately at room temperature. The solid complex is filtered and dried under vacuum. The complex is recrystallized in tetrahydrofuran and dried under vacuum until constant melting points are obtained.

Physical data pertaining to the individual complexes are given below:

H_3O^+.18-crown-6.$FeCl_4^-$, **1**. Yield: 89%; mp 155–156°C (yellow). *Anal.* calcd. for $C_{12}H_{27}O_7FeCl_4$: C 29.96, H 5.66, Fe 11.61, Cl 29.48; found: C 30.34, H 5.79, Fe 11.51, Cl 29.69.

H_3O^+.18-crown-6.$InCl_4^-$, **2**. Yield: 83%; mp 129–130°C (colorless). *Anal.* calcd. for $C_{12}H_{27}O_7InCl_4$: C 26.69, H 5.04, Cl 26.26; found: C 26.46, H 5.49, Cl 26.63.

(H_3O^+.18-crown-6)$_2$.$Pd_2Cl_6^{2-}$, **3**. Yield: 80%; mp 159–160°C (reddish-brown). *Anal.* calcd. for $C_{24}H_{54}O_{14}Pd_2Cl_6$: C 29.05, H 5.49, Cl 21.44; found: C 29.47, H 5.52, Cl 21.40.

The NMR spectra were taken on a Varian XL-200 multinuclear spectrometer. The infrared spectra, obtained from Nujol mulls contained between Irtran-2 (ZnS) windows, were recorded on a Beckman-4250 spectrometer. The Raman spectra were recorded on a microcomputer controlled Spex Model 1400 spectrometer using the 514.5 nm exciting line from a Spectra Physics Model 165 argon ion laser. The spectra were obtained from the solids contained in sealed glass capillary cells. Ultraviolet–visible spectra were taken on a Hewlett-Packard-8450 spectrometer. The microanalyses were peformed by Dr. C. Daessle, Organic Microanalysis, Montreal, or by ourselves on a Carlo Erba Strumentazione-1106 elemental analyses instrument.

Crystallographic work for the (18-C-6.H_3O^+)$_2$.($Pd_2Cl_6^{2-}$) complex

The compound was very stable at room temperature which permitted an initial precession camera work to be done before mounting the crystal on a Nonius CAD-4 diffractometer. From the camera work, the symmetry of the unit cell is found to be monoclinic.

The automatic centering procedure of 25 reflections initially yielded a triclinic reduced cell. However, the Niggli matrix revealed that this cell could be transformed to a monoclinic C-centered cell, this symmetry being consistent with the earlier camera work. No systematic absences beside those due to the C-centering were found upon verification by a rapid precollection technique. Thus the three possible

space groups $C2$, Cm, and $C2/m$ should be examined. The final unit cell was obtained after accurately centering higher angle reflections ($20° \leq \theta \leq 25°$). The final parameters are presented in Table 1.

As the absorption coefficient is relatively high, the intensity diffraction data were collected over the complete Laue diffraction sphere at higher scan speed (4°/s). This technique gives better intensity data after averaging of the symmetry related reflections once the absorption correction has been applied. The transmission factor has values between 0.11 and 0.36. Seven reference reflections were monitorized for the orientation and stability of the crystal. They showed less than ±1.6% variation of their intensities. Also, no reorientation of the crystal was necessary during the collection, the direction of the scattering vectors of the standard reflections being always less than 0.18° from the direction computed from the orientation matrix. Of the 7437 measured reflections, 6893 of them were declared observed based on the $I \geq 3\sigma(I)$ criteria. From this, 1975 unique reflections remained after averaging ($R_{av} = 0.039$) and were used in the structure resolution and refinement.

The structure was solved in the $C2/m$ space group by direct method and refined by full-matrix least-squares using the SHELX programs.[2] The palladium and two chlorine atoms were located first and were used as an initial phasing model. All the non-hydrogen emerged from the first difference Fourier synthesis, and upon isotropic refinement, the R ratio $\Sigma\Delta F/\Sigma F_o$, reached 0.116. Anisotropic refinement of the non-H atoms and the refinement of the H-atom coordinates and their isotropic temperature factors lowered the R-factor to 0.028. The introduction of a weighting scheme based on the counting statistics, $w = 1/(\sigma^2(F) + 0.00005(F)^2$, gave the following values at convergence: $R = 0.025$, $R_w = (\Sigma w\Delta F^2/\Sigma wF_o^2)^{1/2} = 0.034$ and the goodness-of-fit $S = [\Sigma w\Delta F^2/(m - n)]^{1/2} = 2.08$. The final difference Fourier synthesis showed only a background of less than 0.25 e/Å^3 with two residual peaks of 0.46 and 0.36 e/Å^3 at about 0.88 Å from the chlorine atoms. In all the above calculations the anomalous dispersion of Pd and Cl were included.

Results and discussion

Oxonium ion – crown ether complexes are prepared in 80–90% yield by mixing the transition metal chloride, aqueous hydrochloric acid, and 18-crown-6 in tetrahydrofuran. The complexes are stable solids with sharp melting points. The stoichiometry of the compounds were determined by elemental analysis (hydrogen, carbon, chlorine) and by atomic absorption analyses in the case of the iron complex. The analyses are in agreement with the stoichiometries defined by reactions [1] and [2] and with that observed in the X-ray determination for the palladium complex.

[2]The programs used here are modified versions of NRC-2, data reduction, NRC-10, bond distances and angles and NRC-22, mean planes; SHELX, program for structure determination and refinement and ORTEP, stereodrawings (13–15).

Spectroscopy

The infrared spectra are clearly indicative of the presence of the H_3O^+ ion in each complex. The bands are readily assigned by comparison to literature (16, 17) values for hydronium salts: 2780–3250 cm^{-1} (ν_1, symmetric stretching), 2500–3100 cm^{-1} (ν_3, asymmetric stretching), 1480–1705 cm^{-1} (ν_4, asymmetric bending), and 1050–1180 cm^{-1} (ν_2, symmetric bending). The stretching modes of H_3O^+ (ν_1, ν_3) are responsible for the strong and broad band at ~2950 cm^{-1} which overlaps with the sharper maximum arising from the C—H stretching of the crown in the 2925 cm^{-1} region (Table 2). The exact position of the ν_2 mode is difficult to determine as it occurs in a region of strong absorption by the C—O stretching of the crown ether. However, the first harmonic of ν_2 is always present at ~2190 cm^{-1}. The asymmetric bending mode (ν_4) gives a characteristic band at ~1650 cm^{-1}. Infrared spectra also indicate some departure from the D_{3d} symmetry for the crown. Infrared spectra of symmetric complexes such as M^+.18-C-6.Br^- contain two singlets in the 800–1000 cm^{-1} region: CH_2 rocking at 960 cm^{-1} and C—C stretching at 835 cm^{-1} (18, 19). The crown is distorted to a lower symmetry and two doublets are observed at ~805, 830 and ~930, 960 cm^{-1} in the spectra of oxonium complexes **1**–**3**. This distortion of the ring is confirmed by the X-ray diffraction study of the palladium adduct.

Compared with those of 18-crown-6, the ^{1}H NMR signals of the crown ether protons in the complexes are shifted downfield and new signals characteristic of the oxonium ion protons appear in the region 7–11 ppm (Table 2). The chemical shift for the oxonium ion protons is concentration-dependent. A significant paramagnetic shift of the crown proton resonance is observed in the iron compound whereas the shifts in other two complexes are small. The integrations further confirm the 1:1 stoichiometry of the complexes. In ^{13}C NMR, the chemical shift of the crown carbons in the indium and palladium adducts are close to the shift of the free crown carbons in the same solvent. Again, a larger shift (to higher field) can be observed with the iron adduct. Nuclear magnetic resonance signals of the indium and palladium adducts are relatively sharp whereas line broadening occurs for the iron compound as expected from the paramagnetic properties of iron.

[b]Irtran-2 cells are opaque below 700 cm^{-1} and the KBr pressed-pellet method was used for these bands.

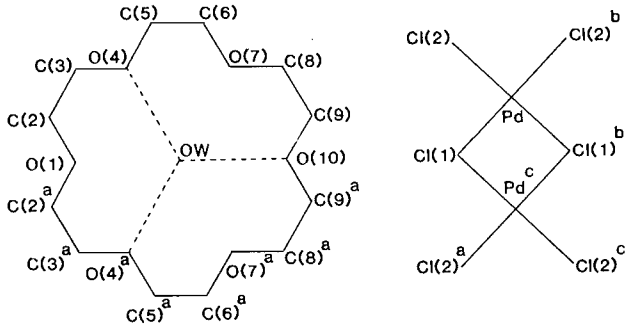

FIG. 1. Numbering scheme adopted for the $(18\text{-C-6}.H_3O)_2.(Pd_2Cl_6)$ complex, (*a*: $x, -y, z$; *b*: $-x, y, 1-z$; *c*: $-x, -y, 1-z$).

The tetrachloroferrate ion in compound **1** and the tetrachloroindate ion in compound **2** are characterized by very strong infrared absorptions at 370 and 320 cm^{-1}, respectively. These bands are attributable to the asymmetric stretching (ν_3) mode of the tetrahedral anions (20, 21). The Raman spectra of compounds **1** and **2** in the crystalline state show strong peaks at 332 and 322 cm^{-1} attributed to the symmetric stretching (ν_1) of regular tetrahedral $FeCl_4^-$ and $InCl_4^-$ ions (21). The electronic spectrum (Table 2) of the iron compound (**1**) is closely similar to those found for genuine organic salts of the tetrahedral $FeCl_4^-$ ion (20, 22). The palladium complex (**3**) shows an absorption at 251 nm while the indium complex has no significant absorption in the region studied.

Structural results

To gain further insight in the structures, X-ray analyses were undertaken; we report here the structure of $(18\text{-crown-6}.H_3O^+)_2.Pd_2Cl_6^{2-}$. It has been so far impossible to grow crystals of other compounds suitable for X-ray analysis. The X-ray structures of three complexes of H_3O^+ coordinated to macrocycles have been reported. The structure $[H_3O^+.18\text{-crown-6(COOH)}_4]Cl^-$ has been reported by Behr *et al.* (5). More recently the X-ray diffraction studies of $(18\text{-crown-6}.H_3O^+)_2.Mo_6O_{19}^{2-}$ and $(18\text{-crown-6}.H_3O^+).HCl_2^-$ have also been published (6, 7).

The unit-cell dimensions and other crystal data of interest determined from X-ray diffraction study of compound **3** are given in Table 1. The atomic numbering is given in Fig. 1. The bond distances and angles, calculated from the final atomic coordinates (see Table 3) are given in Tables 4 and 5.[3]

The crown ether

Since there are only two formulas, $(18\text{-C-6}.H_3O^+)_2.Pd_2Cl_6^{2-}$, per unit cell and the space group is $C2/m$ the 18-crown-6 ether has a mirror plane of symmetry passing through O(1) and O(10). The average C—O distance is 1.419 Å. The average C—C distance is 1.473 Å showing the characteristic shortening observed in all crystal structure analysis of the crown ethers so far published (accepted distance for a C—C bond is 1.535 Å). O—C—C angles (average value 108.6°) are smaller than tetrahedral (109.5°) while the average C—O—C angle is 113.1°. The detailed conformation of 18-crown-6 is best

[3]Tables of H-atom coordinates, anisotropic temperature factors, and the list of observed and calculated structure amplitudes have been deposited. Copies may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

described in terms of the torsion angles about the ring bonds (Table 6). All torsion angles about C—C bonds are close to *gauche* (average value is 64.2°) and those about C—O bonds are close *trans* (average value is 171.6°). The oxonium ion appears to be too small to fill the annular space within the ligand cavity and there is some departure from the crown conformation with D_{3d} symmetry. This distorsion is not as severe as in the $[H_3O^+.18\text{-crown-6(COOH)}_4]Cl^-$ complex reported by Behr *et al.* (5) where there is a highly disordered and pseudo-eclipsed O—C—C—O fragment.

The oxonium ion

The oxonium ion is also in the mirror plane of symmetry near the center of the crown (Fig. 2). It is 0.161(5) Å above the plane defined by O(4), O(10), O(4)[a] to which it is H-bonded and at −0.124(5) Å from the plane of the remaining ether oxygens, O(1), O(7), and O(7)[a]. Three strong hydrogen bonds hold the oxonium to the crown. The O(oxonium)...O(crown) separations are 2.641(3) and 2.644(6) Å. These distances are smaller than O(oxonium)...O(crown) distances found in other complexes (2.672–2.737 Å) so far reported (5–7). There has been some controversy about the geometry (pyramidal versus planar) of the oxonium cation (23). The X-ray study reported by Behr *et al.* (5) lends support for a pyramidal ion while in other studies (6, 7) the hydrogen atoms of the oxonium group could not be unequivocally located. In the present work, the H_3O^+

TABLE 6. Torsion angles (deg) in the 18-crown-6 moiety of the $(18\text{-C-6}.H_3O)_2.(Pd_2Cl_6)$ complex

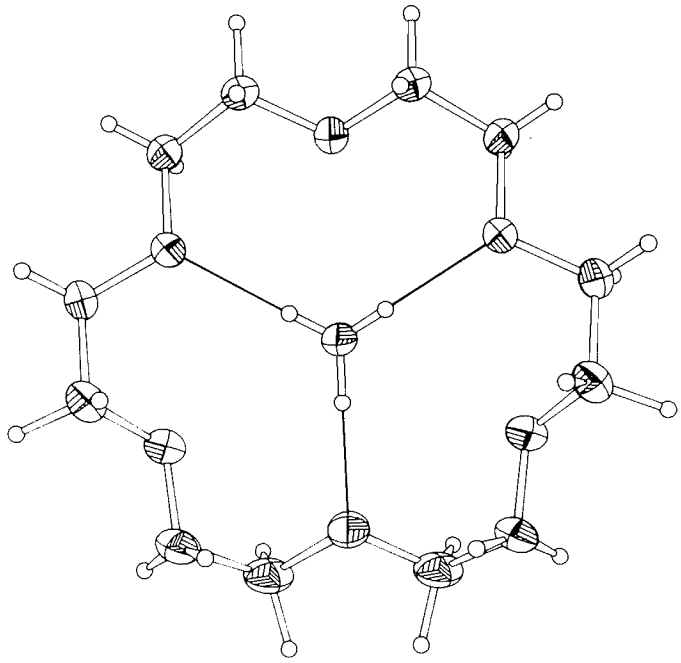

FIG. 2. View of the [18-6-C.H_3O^+] cation with the mirror plane of symmetry placed horizontally. The hydrogen atoms are represented by spheres of arbitrary size while the thermal ellipsoids of C and O atoms are drawn at the 50% probability level.

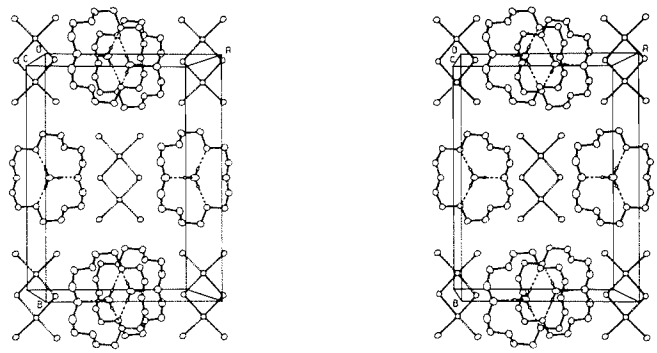

FIG. 3. Stereoview of the unit cell. The crown hydrogen atoms are omitted for clarity. Hydrogen bonds are represented as broken lines.

cation is *pyramidal*, the H—O—H angles are smaller (117° and 119°) than 120° and the oxygen atom is 0.091(5) Å above the plane of the H atoms.

The hexachlorodipalladate(II) anion

The anion is derived from the association of two square planar $PdCl_4^{2-}$ moieties by sharing two bridging chlorine atoms. The distances of 2.3260(7) and 2.6677(9) Å for the Pd—Cl bridge and Pd—Cl term are normal (24, 25). The bond angles around the metal centers, 85.89(3)–92.47(3)°, reflect the fact that the geometry is distorted from the planar shape due to the close arrangement of the Pd atoms. The Pd—Pd distance is 3.4053(3) Å. The two bridging chlorine atoms deviate the most, by ±0.116(1) Å, from the $Pd_2Cl_6^{2-}$ least-squares plane.

Some 6,6-disubstituted 2,4-cyclohexadien-1-ones and the facial selectivity in their Diels–Alder reactions with dimethyl acetylenedicarboxylate

PETER YATES, ANABELA GOMES, D. JEAN BURNELL,[1] DONG DAO CONG,[2] AND JEFFERY F. SAWYER
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 30, 1988

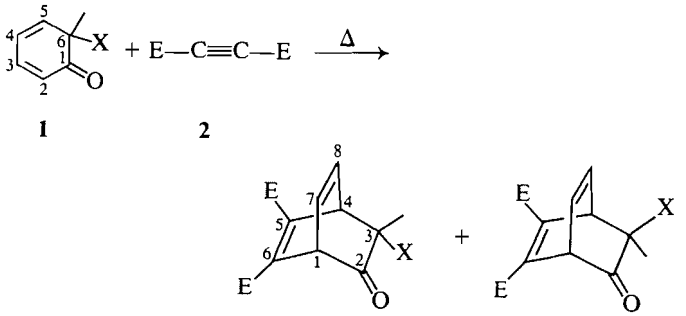
PETER YATES, ANABELA GOMES, D. JEAN BURNELL, DONG DAO CONG, and JEFFERY F. SAWYER. Can. J. Chem. **67**, 37 (1989).

6,6-Disubstituted 2,4-cyclohexadien-1-ones can be prepared by dibromination–bisdehydrobromination of the corresponding 6,6-disubstituted 2,2-dibromocyclohexanones. Such dienes undergo Diels–Alder reactions with dimethyl acetylenedicarboxylate to give 3,3-disubstituted 5,6-di(methoxycarbonyl)bicyclo[2.2.2]octa-5,7-dien-2-ones; when the substituents at C-6 in the dienones are different, two diastereomers of the adducts are formed in a ratio dependent on the "facial selectivity" in the Diels–Alder reactions. For the cases where one of the 6-substituents is methyl and the other is methoxycarbonyl, acetoxymethyl, dibromomethyl, or dichloromethyl it has been established via X-ray crystallography and chemical correlation that the *endo*-3-methyl/*exo*-3-methyl product ratio is 3.0, 0.9, 8, and 6, respectively. The origin of these differences is discussed briefly and a spectroscopic method for the assignment of structures to the individual diastereomers is proposed.

Key words: Diels–Alder reactions, substituted 2,4-cyclohexadien-1-ones, facial selectivity, dimethyl acetylenedicarboxylate.

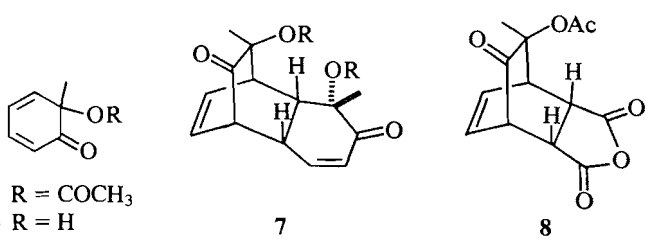
PETER YATES, ANABELA GOMES, D. JEAN BURNELL, DONG DAO CONG et JEFFERY F. SAWYER. Can. J. Chem. **67**, 37 (1989).

On peut préparer les cyclohexadiène-2,4 ones-1 disubstituées en 6,6 en procédant à la dibromation, suivie d'une bisdéhydrobromation, des dibromo-2,2 cyclohexanones disubstitués en 6,6. De tels dièmes peuvent être soumis à des réactions de Diels–Alder avec l'acétylènedicarboxylate de diméthyle et ces réactions conduisent à des di(méthoxycarbonyl)-5,6 bicyclo[2.2.2]octadiène-5,7 ones-2 disubstituées en 3,3; lorsque les deux substituants en position 6 sont différents, il y a formation des deux diastéréoisomères des adduits et leur rapport dépend de la «sélectivité faciale» des réactions de Diels–Alder. Dans les cas où l'un des substituants est un méthyle alors que l'autre est un méthoxycarbonyle, un acétoxyméthyle, un dibrométhyle ou un dichlorométhyle, on a déterminé, par diffraction des rayons-X ainsi que par corrélation chimique, que les rapports des méthyl-3-*endo*/méthyl-3-*exo* sont respectivement 3,0, 0,9, 8 et 6. On discute brièvement de l'origine de ces différences et on propose une méthode spectroscopique permettant d'attribuer les structures des diastéréoisomères individuels.



Mots clés : réactions de Diels–Alder, cyclohexadiène-2,4 ones-1 substituées, sélectivité faciale, acétylènedicarboxylate de diméthyle.

[Traduit par la revue]



Introduction

In work in these Laboratories on the synthesis of cedranoid sesquiterpenes (1), the "facial selectivity" in the Diels–Alder reaction between 2,4-cyclohexadien-1-ones of type **1** and dimethyl acetylenedicarboxylate (DMAD; **2**) (Scheme 1) is of importance in the exercise of stereochemical control. Two diastereomeric bicyclo[2.2.2]octadiene derivatives, **3** and **4**, can be formed in such reactions by attack of the dienophile on one or the other face of the diene. Although the *endo–exo* terminology is strictly applicable only to bicyclo[2.2.1]heptane derivatives and other bridged bicyclic systems with at least one bridge of different length than the others, we have found it convenient to extend it in the present cases in the sense shown in Scheme 1, where the *unsubstituted* bridge corresponds to the one-carbon bridge of the bicyclo[2.2.1]heptane system. Thus **3** is designated as the *exo*-3-methyl-*endo*-3-X isomer and **4** as the *endo*-3-methyl-*exo*-3-X isomer.[3]

Surprisingly, until relatively recently there has been little systematic work on facial selectivity in Diels–Alder reactions in general.[4] Many of the investigations pertaining to 2,4-cyclohexadien-1-ones have concerned compounds of types **5** and **6** formed via Wessely oxidation of phenols. These give Diels–Alder dimers that, when formed under kinetic control, have the stereochemistry shown in **7**, i.e., attack in both the diene and dienophile partner occurs selectively on the face bearing the OR group. They show this same selectivity when they react with dienophiles other than themselves, e.g., in **8** (2).

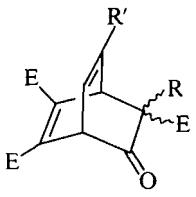
[2]Present address: Uniroyal Research Laboratories, Guelph, Ont., Canada N1H 6N3.



[3]It should be noted that the ring numbering for **3** and **4** and other bicyclo[2.2.2]octane derivatives in the Discussion is based on that for bicyclo[2.2.2]octan-2-one, to facilitate comparison among these compounds. For similar reasons the ring numbering for the dienones is based on 2,4-cyclohexadien-1-one. The IUPAC names for the compounds are used in the experimental section.

[4]Some early observations are summarized in ref. 2.

SCHEME 2

During the course of the present work Schultz *et al.* (3) reported the synthesis of the three 2,4-cyclohexadien-1-ones **9–11** and the Diels–Alder reaction of these with DMAD in boiling benzene to give diastereomeric mixtures of adducts **12***a,b*–**14***a,b*, respectively, in the ratios shown in Scheme 2. Because of the mild conditions of the reactions, it is probable that these product ratios are kinetically determined. However, configurational assignments were not made for the individual diastereomers.

There has been a great deal of recent work, both experimental and theoretical, on the facial selectivity of other dienes. Important contributions (4–8) have been made by Gleiter, Paquette, Vogel, Houk, Hehre, Valenta, and Fallis *inter al.*[5] This work has shown that the facial selectivity can be affected by a number of factors, although not all are necessarily important in a particular case. These include (*i*) steric effects, (*ii*) secondary orbital overlap, (*iii*) orbital tilting, (*iv*) torsional effects, (*v*) electrostatic interactions, (*vi*) polarizability, and (*vii*) coordination of the diene and dienophile. Although much has been learned about the dependence of facial selectivity on some of these factors, their number often makes it difficult to predict the facial selectivity in specific terms. Thus these results must be supplemented with additional empirical data. In the case of the reactions of 2,4-cyclohexadien-1-ones (**1**) with DMAD (**2**) we have sought to do this by determining the product ratios and the individual diastereomeric structures of the adducts of DMAD with compounds **9** and **15–17**. The syntheses of the dienones are first described, since some aspects of these are of intrinsic interest.

Results

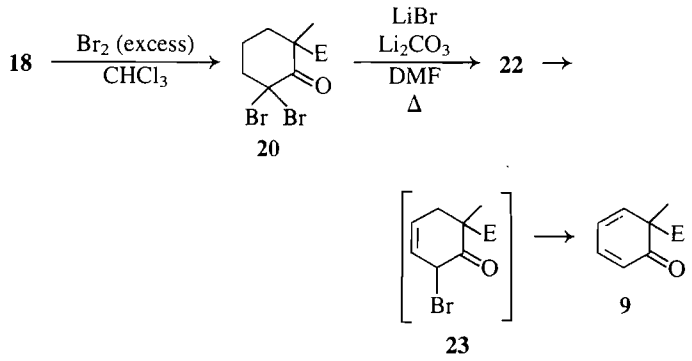
Preparation of 2,4-cyclohexadien-1-ones

The method we used for the preparation of 6-methoxycarbonyl-6-methyl-2,4-cyclohexadiene-1-one (**9**) involved introduction of two ethylenic bonds into the saturated keto ester **18**, and was initially based on an earlier synthesis of the analogous

[5]For summaries of some of these contributions, see ref. 9.

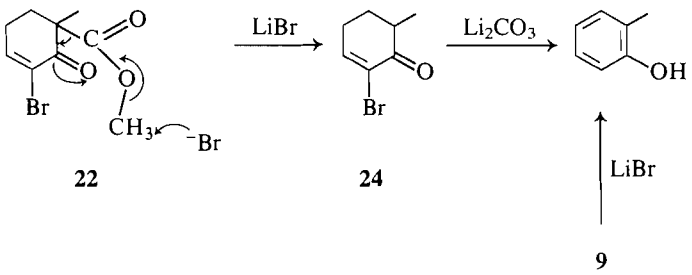
SCHEME 3

ethyl ester (10). Bromination of **18** with slightly more than one molar equivalent of bromine gave the monobromo product **19** contaminated with 30% of the dibromo compound **20** (Scheme 3). The ^{1}H nmr spectrum of the crude reaction product suggested that a single diastereomer of **19** was formed, but its configuration was not determined. Dehydrobromination of the crude bromination product in boiling quinoline gave methyl 1-methyl-2-oxo-3-cyclohexenecarboxylate (**21**) accompanied by a small amount of its 3-bromo derivative **22**. The latter must arise by dehydrobromination of the dibromo compound **20**. The yields obtained in the dehydrobromination were low (~25%).



We had originally planned to synthesize **9** by allylic bromination of **21** followed by dehydrobromination (10). However, it was observed that dehydrobromination of the dibromo compound **20** with boiling quinoline also gave **9**, albeit in poor yield. We therefore decided to prepare the dibromo compound **20** deliberately and to carry out its bisdehydrobromination. We also took the opportunity to use different dehydrobromination conditions, viz., treatment with lithium bromide and lithium carbonate in hot *N*,*N*-dimethylformamide (DMF) (11). Under these conditions the diene **9** was obtained, but still in low yield. Monitoring of the progress of the reaction by ^{1}H nmr spectroscopy showed that, as expected, the monodehydrobromination product **22** was first formed and then underwent slower conversion to **9**. The intermediacy of **22** under these conditions was also demonstrated by its dehydrobromination to **9** under the same conditions. This conversion is considered to proceed via base-catalyzed isomerization of **22** to the 3-cyclohexen-1-one **23** followed by 1,4-dehydrobromination (Scheme 4).

Because of the occurrence of competing reactions (*vide infra*) it was necessary to terminate the dehydrobromination before the reaction was complete, resulting in the isolation of a mixture of **9** and **22**. These could not be separated by chromatography, but the mixture could be used for the Diels–Alder reaction of **9**.



Although the yield via this route is very low (~15%), the method is preferable to that via **19** in that, in the latter, two separate dehydrobromination steps are required, while the former involves only a "one-pot" procedure for the dehydrobromination steps.

To obtain some insight into the cause of the low yields in the dehydrobromination reactions we treated compound **22** with lithium carbonate and lithium bromide in DMF for 3 h. Chromatography of the crude reaction product gave two major fractions; one was shown by ^{1}H nmr spectroscopy to be a

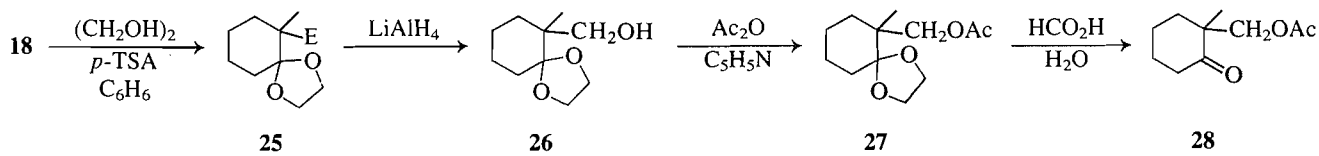
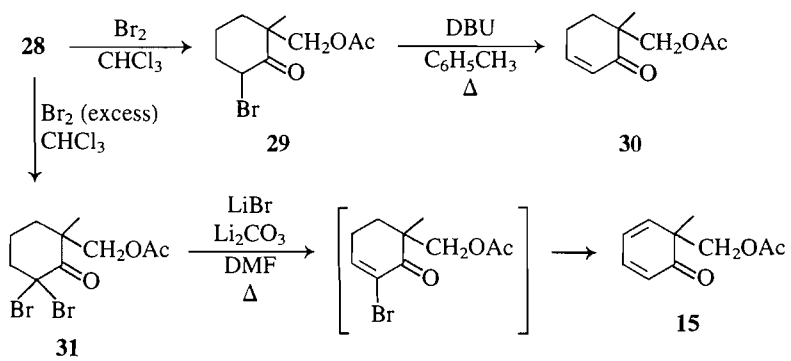
SCHEME 4

SCHEME 5



mixture of **22** and **9**, while the spectrum of the other showed that it was a mixture of two components, neither of which contained a methoxycarbonyl group. The ir and ^1H and ^{13}C nmr spectra of the latter mixture indicated strongly that the two components were 2-bromo-6-methyl-2-cyclohexen-1-one (**24**) and *o*-cresol. The formation of these products is readily accounted for as shown in Scheme 5. It has previously been shown (12) that esters undergo dealkoxycarbonylation on being heated with lithium bromide. Dehydrobromination of **24** would give *o*-cresol. Thus the low yield in the preparation of **9** by this route is attributable, at least in part, to the loss of the methoxycarbonyl group under the reaction conditions. In the case of 6-alkyl-6-alkoxycarbonyl-2,4-cyclohexadien-1-ones of type **9**, the route designed by Schultz *et al.*, involving Birch reduction — alkylation of *o*-hydroxybenzoic acid derivatives (3), is certainly preferable to the route that we have used. However, in the case of other 6,6-disubstituted 2,4-cyclohexadien-1-ones the dibromination–bisdehydrobromination route is practicable (*vide infra*) and the Birch reduction route may not be applicable.

Compound **15**, 6-(acetoxymethyl)-6-methyl-2,4-cyclohexadien-1-one, was synthesized from **25**, the ethylene ketal of **18**, by a route similar to that used in the case of **9**. Compound **28** was obtained by the route shown in Scheme 6. As in the case of **9**, conversion of **28** to **15** was first attempted via monobromination to **29** followed in this instance by dehydrobromination with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (cf. ref. 3) to **30**; however, allylic bromination of this with *N*-bromosuccinimide proved to be unsuccessful. Compound **28** was therefore dibrominated to give **31**, the analogue of **20**. Bisdehydrobromination of this with DBU was unsuccessful, but treatment with lithium bromide and lithium carbonate in DMF for 16.5 h gave an excellent yield of the diene **15** (Scheme 7).



The remaining 2,4-cyclohexadienones, **16** and **17**, were prepared as described previously via "abnormal Reimer–Tiemann" reactions of *o*-cresol (13) (Scheme 8). Because complex mixtures of products are formed, the yields of **16** and **17** are low; however, the starting materials are in abundant supply.

Diels–Alder reactions of 2,4-cyclohexadien-1-ones

Reaction of **9** with DMAD in boiling benzene for 2 days gave a 3:1 mixture of the diastereomeric Diels–Alder adducts, **12***a* and **12***b* (Scheme 9), as determined by ^1H nmr spectroscopy. The isomers were separated chromatographically. The most egregious differences in their spectra are the chemical shift difference ($\Delta\delta$ 0.05) between the highest field methoxyl proton signals and the difference in splitting patterns of the C-5 and C-8 vinyl proton signals. These differences must involve the 3-methoxycarbonyl group, which is situated at the seat of the difference in the relative configurations of the isomers. In the ^{13}C nmr spectra the signals of the corresponding C-7 and C-8 ($\Delta\delta$ 1.2, 1.6) carbon atoms and the signals of the C-2 ketonic carbonyl carbons ($\Delta\delta$ 3.5) adjacent to C-3 show the significant

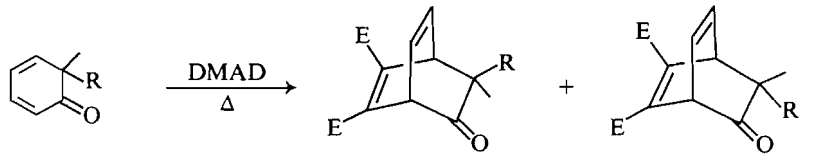
17 X = Cl

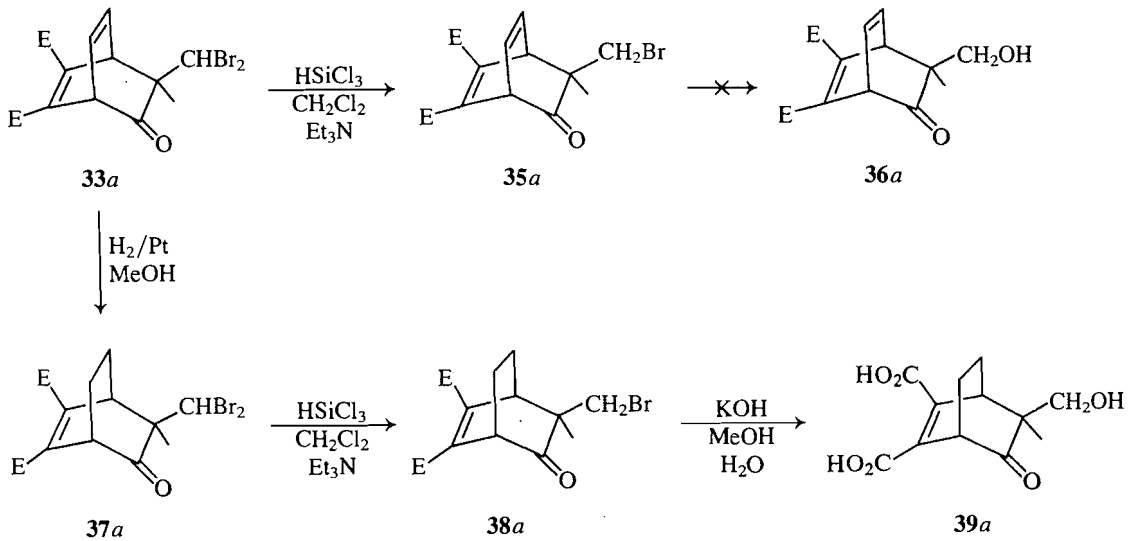
SCHEME 8



differences. Although these differences are small they are sufficient to distinguish the isomers; however, they provide no conclusive basis for the assignment of individual structures to these isomers. For this we had resort to an X-ray crystallographic determination of the structure of the major isomer, which was thus found to have structure **12***a* (14).

Reaction of **15** with DMAD in boiling benzene for 2 days gave a 0.9:1 mixture of the adducts **32***a* and **32***b* (Scheme 9). These stereoisomers were separated by repeated chromatography; their R_f values were very similar and the recovery of the pure compounds was low. Their gross structures and ratio in the reaction mixture were determined spectroscopically. In the ^{1}H nmr spectrum of the major isomer the vinyl proton assignments (H-7 and H-8) were established by double irradiation experiments with irradiations at the frequencies of the bridgehead proton signals, H-1 and H-4. In its ^{13}C nmr spectrum the assignments were verified by the use of ^{1}H–^{13}C 2-D chemical shift correlation via long-range coupling.

The minor isomer has similar spectra, which are distinct enough to allow the isomers to be differentiated, but not sufficiently so to permit unambiguous individual stereochemical assignments. An indication that the major isomer has structure **32***b* was obtained from an nOe experiment: irradiation at the frequency of the C-methyl signal at δ 1.11 resulted in an 8% enhancement of the C-4 bridgehead signal at δ 4.10 and a 5% enhancement of the C-8 vinyl proton signal at δ 6.60. However, the relatively low values of these enhancements were insufficient to establish the stereochemistry firmly, and the individual structural assignments in Scheme 9 were later confirmed by correlation with other Diels–Alder adducts (*vide infra*).



Reaction of the dienone **16** with DMAD was very much slower than that of **9** or **15**, and was carried out neat at 105–160°C for 2 days. It gave an 8:1 mixture of the adducts **33***a* and **33***b*, of which the first was isolated by crystallization and the other was obtained as an oil by chromatography of the mother liquor. As in the previous cases the spectra of the diastereomeric products could be distinguished but could not be used for individual stereochemical assignments. This was carried out by an X-ray crystallographic determination of the structure of the major isomer, which showed it to be the *endo*-methyl *exo*-(dibromomethyl) isomer **33***a* (Scheme 9) (15).

It was hoped originally that the structure of **33***a* could be established by correlation with that of **12***a* (Scheme 10). To this end **33***a* was reduced with trichlorosilane and triethylamine (16) to the monobromomethyl compound **35***a*, but this could not be converted to the corresponding hydroxymethyl compound **36***a* by basic treatment under a variety of conditions. Since this failure could result from cleavage reactions facilitated by the

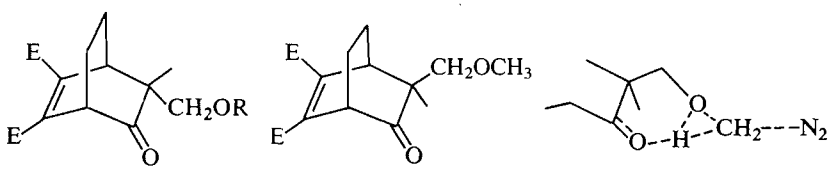
SCHEME 11

C-7—C-8 double bond, the dibromomethyl compound was converted to its dihydro derivative **37***a* by hydrogenation and this was reduced with trichlorosilane to give **38***a*, which on treatment with aqueous base gave the hydroxymethyl dicarboxylic acid **39***a*. This could not be converted to the triester **40***a*, which would have been correlatable with the dihydro derivative of **12***a*.

However, **39***a* served the purpose of correlation of the major dibromomethyl isomer **33***a* with the minor acetoxymethyl isomer **32***a* (Scheme 11). Esterification of **39***a* with diazomethane gave the hydroxymethyl diester **41***a*, which was shown to be spectroscopically identical with the hydroxymethyl diester formed by hydrolysis of the dihydro derivative **42***a* of the isomer **32***a*. The major isomer **32***b* was converted by the same route to **41***b* via the dihydro compound **42***b*. The spectra of this were found to be readily distinguishable from those of its isomer **41***a*. These observations confirmed the tentative assignments for **32***a* and **32***b* based on the nOe experiment discussed earlier.

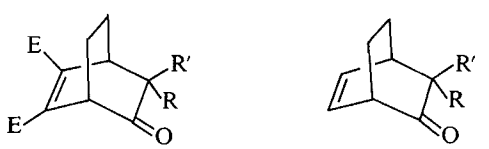


Methylation of **39***a* with diazomethane gave a minor product in addition to **41***a*; this is assigned structure **43***a* on the basis of the similarity of its ir spectrum to that of **41***a*, except for the absence of a hydroxyl-stretching band, and its molecular formula as determined by high resolution mass spectrometry. The methylation of an alcoholic hydroxyl group under these conditions is unusual, and may be ascribable to the formation of a transition state of type **44**.

The dichloromethyl analogue **17** of the dibromomethyl dienone **16** gives, with DMAD, a mixture of adducts, **34***a* and **34***b*, which in this case are formed in a 6:1 ratio. Only the major isomer was isolated in pure form and fully characterized spectroscopically. However, comparison of the ^{13}C nmr spectra of this isomer and a mixture of isomers enriched in the minor isomer **34***b* permitted the identification and assignment of the signals of the latter. The individual structures assigned to the major and minor isomers are based on analogy with the case of the dibromomethyl compounds.

Discussion

Facial selectivity



Valenta and co-workers have noted (7) that the major product in the Diels–Alder reaction of a planar non-symmetric diene results in most cases from addition to the less hindered face, although in some cases facial selectivity is determined by "what might loosely be called 'electronic' effects." We propose that for the 6-(dihalomethyl)-6-methyl-2,4-cyclohexadien-1-ones **16** and **17** the steric effect predominates, and that the bulky

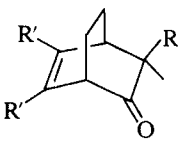
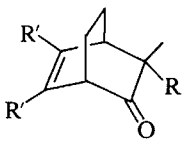
dihalomethyl groups hinder attack by DMAD, resulting in a strong preference for attack on the methyl face of the dienones and the formation of the *endo*-3-methyl *exo*-3-(dihalomethyl) isomers **33***a* and **34***a* as the major products.

It seems unlikely that for the 6-(acetoxymethyl)-6-methyl and 6-(methoxycarbonyl)-6-methyl dienones **15** and **9**, steric effects will be predominant with the *acetylenic* dienophile DMAD, whose steric demand is small. In conformity with this view **15** gives closely similar amounts of the adducts **32***a* and **32***b*, with a slight preference for the latter. Steric control, if operative, would be expected to favor formation of the former, since it is expected that the van der Waals radius of an acetoxymethyl group would be slightly greater than that of a methyl group. It is possible that the slight preference for attack on the acetoxymethyl face results from favorable secondary orbital interactions analogous to those postulated by Anh to occur in the Diels–Alder reaction of 5-acetoxycyclopentadiene with ethylene (17), where preferential attack also occurs on the more hindered, acetoxy face of the diene.

In the case of the 6-(methoxycarbonyl)-6-methyl dienone **9**, it is more difficult to assess which is the sterically more favorable pathway. The methyl face is expected to be more hindered than the methoxycarbonyl face, based on the conformational free energy differences of the appropriately substituted cyclohexanes (18). However, this criterion must be used with caution (19), and all that can be concluded is that there is a small steric factor favoring attack on the methoxycarbonyl face. The observed 3:1 preference for attack on the methyl face indicates that there is an unfavorable electronic interaction between the methoxycarbonyl group and DMAD. This could involve destabilizing interaction of the filled π-orbital of the acetylenic system that is perpendicular to the π-orbital directly involved in the cycloaddition. An unfavorable dipole–dipole interaction between the ester groups in the diene and dienophile could also contribute to disfavoring of attack on the methoxycarbonyl face of the former.



A further point of interest concerns our qualitative observation that reaction of DMAD with the dihalomethyl cyclohexadienones is significantly slower than with **9** and **15**. This indicates that additional unfavorable interactions occur in the transition states involving bulky substituents at C-6 arising either from increased steric interaction between these substituents and the methyl group at C-6 or from steric interaction between the bulky substituents and the diene on the face opposite to that on which addition occurs. The reference to transition states here draws attention to the fact that all the interpretations above are based on kinetic rather than thermodynamic control. This is considered to be a reasonable assumption based on general experience with non-aromatic-type dienes (7) and on the relatively mild conditions under which the present reactions occurred. Thus it has been found that in the Diels–Alder dimerization of 2,4-cyclohexadien-1-ones of type **5** the reaction is under kinetic control at 120°C and only comes under thermodynamic control at 160–190°C (20).



Configurational assignments

In discussing the assignments of configurations to individual adducts we have emphasized that the ^{1}H and ^{13}C nmr spectra of pairs of epimers are sufficiently different to permit their distinction, but insufficiently so to allow unambiguous individual structural assignments. The latter were made by X-ray crystallographic studies and by chemical correlation. It would be, of course, more convenient and expeditious if these assignments could be made spectroscopically. We propose that this is possible by comparison of the ^{13}C nmr spectra of the *dihydro derivatives* of the adducts. As shown in Table 1 the chemical shifts of the 3-methyl protons in pairs of C-3 epimers are consistently greater for the *endo*-3-methyl *exo*-3-X diastereomers than for the *exo*-3-methyl *endo*-3-X diastereomers ($\Delta\delta$ 2.2–3.2). In the cases of geminal methyl substitution at C-3, analogous chemical shift differences are observed.

Our suggestion that stereochemical assignments can be made on this basis is fortified by the fact that a rationale for their chemical shift differences can be discerned. The upfield shift of the *exo*-3-methyl signal relative to the *endo*-3-methyl signal is attributable to the γ-effect of C-8. Although a γ-effect of C-5 could be operative on the *endo*-3-methyl signal, it is expected that such an effect would be greater in the case of the sp^3 carbon atom at C-8. This interpretation provides an explanation for the difficulties encountered in making assignments for the adducts themselves, where both C-5 and C-8 are sp^2 carbon atoms.

Experimental[6]

Melting points were taken on a Fisher–Johns melting point apparatus and are uncorrected. Infrared (ir) spectra were taken neat or in chloroform with a Perkin Elmer 137 or 337 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were taken in deuteriochloroform at 60 MHz with a Varian T-60 spectrometer, unless otherwise specified. The ^{1}H nmr spectra were recorded at 200 and 400 MHz on Varian XL-200 and XL-400 spectrometers, respectively. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were taken in deuteriochloroform on a Varian CFT-20, XL-200, or XL-400 spectrometer. Mass spectra were recorded at 70 eV with a Dupont 21-490 single focussing mass spectrometer. Accurate mass measurements were made with an AEI MS 3074 double focussing mass spectrometer with a DS 50 data system.

Solutions were concentrated on a Buchi "Rotavapor ⟨*R*⟩" rotary evaporator under water aspirator pressure and the concentrates were then placed under the vacuum provided by a Welch "Duo Seal" two-stage vacuum pump.

Column chromatography was carried out on silica (Merck, grade 60, 230–400 mesh, 60 Å mean pore diameter). A slurry of silica gel in the solvent to be used for elution was prepared and added to the column.

[6]For further details of general experimental conditions, see ref. 9.

Thin-layer chromatography was carried out on aluminum-backed plates precoated with a 0.20 mm thickness of silica gel (Merck).

*Methyl 1-methyl-2-oxocyclohexanecarboxylate (**18**)*

Methyl iodide (80.0 mL, 182.4 g, 1.29 mol), methyl 2-oxocyclohexanecarboxylate (22) (93.48 g, 0.60 mol), and dry methanol (250 mL) were added to a 1-L 3-necked round-bottomed flask under nitrogen atmosphere. A solution of sodium methoxide (16.0 g) in methanol (375 mL) was added dropwise over 2.5 h, at room temperature, and stirring was continued for an additional 19 h (cf. ref. 23). The mixture was treated with water (400 mL) and extracted with ethyl acetate (3 × 100 mL) and the combined organic layers were washed with brine (3 × 100 mL) and water (2 × 100 mL). The organic layer was dried over anhydrous $MgSO_4$ and concentrated to yield a yellow oil. This was distilled to give **18** as a colorless oil (175.1 g, 1.03 mol; 80%); ir λ_{max}: 5.73 (sh), 5.82 (s) μm; ^{1}H nmr δ: 1.30 (s, 3H), 1.5–2.7 (m, 8H), 3.42 (s, 3H) ppm; ^{13}C nmr (100 MHz) δ: 20.5 (q), 21.95 (t), 26.8 (t), 37.5 (t), 39.85 (t), 51.6 (q), 56.35 (s), 172.7 (s), 206.9 (s) ppm.

*Methyl 3-bromo-1-methyl-2-oxocyclohexanecarboxylate (**19**)*

Chloroform (100 mL) and compound **18** (5.0 g, 29 mmol) were added to a 200-mL round-bottomed flask and cooled in an ice–salt bath. A solution of bromine (1 mL, 3.10 g, 398 mmol) in chloroform (30 mL) was added dropwise from a pressure-equalized dropping funnel over a 3-h period. The reaction mixture was allowed to warm up to room temperature, and saturated aqueous sodium metabisulfite was added until the solution became colorless. Extraction with chloroform (2 × 70 mL) followed and the organic layer was washed with saturated aqueous sodium metabisulfite (1 × 25 mL), saturated aqueous sodium bicarbonate (3 × 25 mL), and brine (2 × 25 mL). The organic layer was dried over anhydrous $MgSO_4$, concentrated, and chromatographed on silica gel with hexanes/ethyl acetate (3:1 v/v) as the eluent to yield **19** as a yellow oil (R_f 0.36; 2.83 g, 11.4 mmol; 39%); ^{1}H nmr δ: 1.40 (s, 3H), 1.55–2.7 (m, 7H), 3.78 (s, 3H), 4.50–5.05 (m, 1H) ppm.

Other chromatographic fractions, on treatment with hexanes, gave the dibromination product **20** (*vide infra*) as crystals (1.86 g, 19%).

*Methyl 1-methyl-2-oxo-3-cyclohexenecarboxylate (**21**)*

Freshly distilled quinoline (20 mL) and compound **19** (2.03 g, 8.16 mmol) containing some **20** were added to a 50-mL round-bottomed flask. The air was displaced with nitrogen, and the flask was heated in an oil bath at 113–123°C for 7 h. The reaction mixture was allowed to cool to room temperature and washed with 20% hydrochloric acid (~10 mL) until the aqueous layer was slightly acidic. Extraction with ethyl acetate (4 × 25 mL) followed and the combined organic layers were washed with 10% hydrochloric acid (4 × 10 mL) and water (3 × 10 mL), dried over anhydrous Na_2SO_4, and concentrated. The residual oil was chromatographed on silica gel with hexanes/ethyl acetate (3:1 v/v) as the eluent to yield a mixture of **21** (R_f 0.23; 0.35 g, 2.1 mmol; 25%) and **22** (*vide infra*), which was not separated. For **21**, ^{1}H nmr δ: 1.30 (s, 3H), 1.6–2.7 (m, 4H), 3.67 (s, 3H), 5.8–6.4 (m, 1H), 6.75–7.1 (m, 1H) ppm.

*Methyl 3,3-dibromo-1-methyl-2-oxocyclohexanecarboxylate (**20**)*

Chloroform (250 mL) and compound **18** (9.0 g, 53 mmol) were added to a 500-mL round-bottomed flask and cooled in an ice–salt bath. A solution of bromine (16.0 mL, 49.90 g, 0.312 mol) in chloroform (70 mL) was added dropwise from a pressure-equalized dropping funnel, over a 2.25-h period. The reaction mixture was allowed to warm to room temperature and saturated aqueous sodium metabisulfite was added until the solution became colorless. The mixture was extracted with chloroform (2 × 70 mL) and the combined organic layers were washed with saturated aqueous sodium metabisulfite (1 × 50 mL), saturated aqueous sodium bicarbonate (3 × 50 mL), and brine (2 × 50 mL). The organic layer was dried over anhydrous $MgSO_4$ and concentrated. The crude material was recrystallized from hexanes to yield **20** (14.45 g, 44 mmol; 83%) as white needles, mp 103–104°C; ir λ_{max}: 5.76 (sh), 5.71 (s) μm; ^{1}H nmr δ: 1.48 (s, 3H), 1.6–2.6 (m, 4H), 2.6–3.05 (m, 2H), 3.2 (s, 3H) ppm; ^{13}C nmr (50 MHz) δ: 21.2 (t), 24.7 (q), 35.6 (t), 50.2 (t), 52.7 (q), 54.6 (s), 67.95 (s), 171.6 (s), 192.6 (s) ppm; ms *m/z*: 330 (2.5), 328 (5), 326 (2.5). *Exact Mass* calcd. for $C_9H_{12}O_3Br_2$: 329.9111, 327.9130, 325.9149; found: 329.9113, 327.9143, 325.9174. *Anal.* calcd. for $C_9H_{12}O_3Br_2$: C 32.94, H 3.96, Br 48.74; found: C 32.76, H 3.65, Br 49.11.

*Methyl 1-methyl-6-oxo-2,4-cyclohexadienecarboxylate (**9**) and methyl 3-bromo-1-methyl-2-oxo-3-cyclohexenecarboxylate (**22**)*

Compound **20** (5.18 g, 16 mmol), lithium bromide (2.52 g, 29 mmol), lithium carbonate (3.47 g, 47 mmol), and dry, freshly distilled *N*,*N*-dimethylformamide (65 mL) were added to a 250-mL round-bottomed flask and the mixture was heated under a nitrogen atmosphere. The temperature of the oil bath ranged from 104 to 126°C in the 6.75-h period. The reaction mixture was allowed to cool and the excess lithium carbonate was destroyed by the careful addition of dilute sulfuric acid (100 mL). Extraction with dichloromethane (4 × 75 mL) followed and the organic layer was washed with water (5 × 50 mL) and dried over anhydrous $MgSO_4$. Concentration yielded a mixture of **9** and **22** as an oil. This was chromatographed on silica gel with hexanes/ethyl acetate (3:1 v/v) as the eluent to yield a mixture of **9** (R_f 0.27; 0.416 g, 2.5 mmol; 16%) and **22** (R_f 0.27; 0.674 g, 2.8 mmol; 18%), which could not be separated. This mixture was used for the preparation of the adduct of **9** with dimethyl acetylenedicarboxylate (*vide infra*). Compound **22** was not consumed and could be isolated free of **9** from the reaction mixture.

For **22**, ir λ_{max}: 3.55 (s), 5.76 (s), 5.95 (s), 6.21 (s) μm; ^{1}H nmr δ: 1.47 (s, 3H), 2.2–2.8 (m, 4H), 3.73 (s, 3H), 7.23–7.43 (distorted t, 1H) ppm; ^{13}C nmr (100 MHz) δ: 20.5 (s), 25.6 (t), 32.8 (t), 52.4 (q), 53.9 (s), 122.1 (s), 150.0 (d), 171.9 (s), 189.0 (s) ppm; ms *m/z*: 248 (18%), 246 (18%). *Exact Mass* calcd. for $C_9H_{11}O_3Br$: 247.9871, 245.9892; found: 247.9864, 245.9908.

For **9**, ^{1}H nmr δ: 1.50 (s, 3H), 3.67 (s, 3H), 6.0–6.35 (m, 3H), 6.8–7.4 (m, 1H) ppm.

*2-Bromo-6-methyl-2-cyclohexen-1-one (**24**)*

Compound **20** (3.34 g, 10.3 mmol), lithium bromide (1.78 g, 20.4 mmol), lithium carbonate (2.49 g, 34.3 mmol), and dry, freshly distilled *N*,*N*-dimethylformamide (45 mL) were heated at 120–125°C for 3.0 h. The reaction mixture was worked up as above and chromatographed to yield a mixture of **9** and **22** and a mixture of *o*-cresol and **24** (R_f 0.33; 0.40 g), whose spectra showed the following features in addition to those of *o*-cresol: λ_{max}: 5.95 (sh), 6.10 (s) μm; ^{1}H nmr δ: 1.10 (d, J = 6 Hz, 3H), 1.9–2.8 (m, 5H), 7.2–7.4 (m, 1H) ppm; ^{13}C nmr δ: 194.0 (s), 150.4 (s), 123.25 (s), 42.2 (d), 30.3 (t), 27.45 (t), 15.3 (q) ppm.

*Methyl 2,2-(ethylenedioxy)-1-methylcyclohexanecarboxylate (**25**)*

Compound **18** (2.48 g, 14.6 mmol), dry benzene (80 mL), ethylene glycol (2 mL, 2.224 g, 35.8 mmol), and a spatula-tip of *p*-toluenesulfonic acid were added to a 250-mL round-bottomed flask equipped with a Dean–Stark apparatus and a condenser. The system was placed under nitrogen and allowed to reflux for 23 h. After the mixture cooled, the benzene was evaporated and the residue was dissolved in ethyl acetate (200 mL). The solution was washed with brine (3 × 50 mL), dried over anhydrous Na_2SO_4, concentrated, and distilled (bp 180–181°C at 760 Torr; 1 Torr = 133.3 Pa) to yield **25** (2.44 g, 11.4 mmol; 78%) as a colorless oil; ir λ_{max}: 5.78 (s) μm; ^{1}H nmr δ: 1.23 (s, 3H), 1.4–2.1 (m, 8H), 3.67 (s, 3H), 3.93 (s, 4H) ppm; ^{13}C nmr (50 MHz) δ: 18.95 (q), 21.4 (t), 23.3 (t), 31.7 (t), 34.55 (t), 51.05 (s), 51.6 (q), 64.5 (t), 65.2 (t), 110.45 (s), 175.2 (s) ppm; ms *m/z*: 214 (47%). *Exact Mass* calcd. for $C_{11}H_{18}O_4$: 214.1205; found: 214.1202.

*2,2-(Ethylenedioxy)-1-(hydroxymethyl)-1-methylcyclohexane (**26**)*

Compound **25** (0.209 g, 0.168 mmol), lithium aluminum hydride (0.221 g, 5.83 mmol), and freshly distilled, dry tetrahydrofuran (15 mL) were added to a 50-mL round-bottomed flask, equipped with a condenser (cf. ref. 24). The reaction mixture was allowed to reflux under nitrogen for 24 h. After the mixture cooled, the excess lithium aluminum hydride was destroyed with ethyl acetate followed by ethanol and water. A gel was obtained; it was filtered from the solution

For personal use only.

and the aqueous layer was extracted with ethyl acetate (3 × 50 mL). The combined organic layers were washed with brine (2 × 25 mL), dried over anhydrous Na_2SO_4, and evaporated. The residual product was chromatographed on silica gel with hexanes/ethyl acetate (3:1 v/v) as the eluent to yield **26** as a colorless oil (R_f 0.09; 0.125 g, 0.674 mmol; 69%); ir λ_{max}: 3.13 (br), 3.68 (s) μm; ^{1}H nmr δ: 1.00 (s, 3H), 1.3–2.4 (m, 8H), 3.03 (br s, 1H), 3.53 (br s, 2H), 3.97 (s, 4H) ppm; ^{13}C nmr (50 MHz) δ: 18.7 (q), 20.4 (t), 23.5 (t), 30.4 (t), 33.2 (t), 41.8 (s), 64.3 (t), 64.5 (t), 68.8 (t), 113.8 (s) ppm; ms *m/z*: 186 (9%). *Exact Mass* calcd. for $C_{10}H_{18}O_3$: 186.1256; found: 186.1250.

1-(Acetoxymethyl)-2,2-(ethylenedioxy)-1-methylcyclohexane (27)

Compound **26** (1.39 g, 7.47 mmol), acetic anhydride (20 mL, 21.64 g, 0.212 mol), and pyridine (15 mL) were added to a 100-mL round-bottomed flask equipped with a drying tube. The mixture was stirred at room temperature for 20 h; water (100 mL) was added to destroy the excess acetic anhydride and this mixture was extracted with ether (3 × 50 mL). The ethereal layers were combined and washed with water (3 × 25 mL), brine (3 × 25 mL), 3% aqueous hydrochloric acid (3 × 20 mL), and dried over anhydrous $MgSO_4$. The ethereal layer was concentrated and distilled (bp 93.0–93.5°C at ~0.5 Torr) to yield **27** (1.26 g, 5.52 mmol; 74%) as a colorless oil; ir λ_{max}: 5.74 (s) μm; ^{1}H nmr δ: 0.96 (s, 3H), 1.3–1.7 (br s, 8H), 2.07 (s, 3H), 3.92 (s, 4H), 4.03 (d, J = 10 Hz, 1H), 4.14 (d, J = 10 Hz, 1H) ppm; ^{13}C nmr (50 MHz) δ: 17.6 (q), 20.3 (t), 20.8 (q), 23.2 (t), 30.55 (t), 32.45 (t), 41.9 (s), 64.4 (t), 64.7 (t), 67.9 (t), 111.2 (s), 171.1 (s) ppm; ms *m/z*: 228 (14%). *Exact Mass* calcd. for $C_{12}H_{20}O_4$: 228.1362; found: 228.1353.

2-(Acetoxymethyl)-2-methylcyclohexanone (28)

Compound **27** (39.41 g, 0.173 mol), 95% formic acid (350 mL), and water (13 mL) were added to a 500-mL round-bottomed flask and the mixture was stirred, at room temperature, for 4 h. Water (300 mL) was added slowly and the aqueous layer was extracted with dichloromethane (3 × 100 mL). The organic layer was washed with brine (5 × 75 mL) and saturated aqueous sodium bicarbonate (3 × 50 mL) and dried over anhydrous Na_2SO_4, concentrated, and distilled (bp 80.5–82.0°C at 0.5 Torr) to yield **28** (28.55 g, 0.155 mol; 90%); ir λ_{max}: 5.75 (s), 5.84 (s) μm; ^{1}H nmr δ: 1.17 (s, 3H), 1.6–1.9 (m, 6H), 2.07 (s, 3H), 2.3–2.6 (m, 2H), 4.15 (s, 2H) ppm; ^{13}C nmr (50 MHz) δ: 20.4 (q), 20.6 (q), 20.7 (t), 26.85 (t), 35.9 (t), 38.5 (t), 48.3 (t), 68.4 (t), 170.7 (s), 212.7 (s) ppm; ms *m/z*: 184 (7%). *Exact Mass* calcd. for $C_{10}H_{16}O_3$: 184.1100; found: 184.1105.

6-(Acetoxymethyl)-2-bromo-6-methylcyclohexanone (29)

Compound **29** was prepared from **28** in 82% yield as described previously for **19**; the crude reaction mixture was passed through a silica gel plug with hexanes/ethyl acetate (1:1 v/v) as the eluent to yield the product as a mixture of diastereomers; ^{1}H nmr δ: 1.27 (d, 3H), 1.7–2.2 (m, 6H), 2.07 (s, 3H), 3.93 (d, J = 10 Hz, 1H), 4.41 (d, J = 10 Hz, 1H), 4.8–5.2 (m, 1H) ppm.

6-(Acetoxymethyl)-6-methylcyclohex-2-enone (30)

Compound **29** (0.20 g, 0.76 mmol), toluene (30 mL), and 1,8-diazabicyclo[5.4.0]undec-7-ene (0.2 mL, 0.20 g, 1.34 mmol) were added to an 100-mL round-bottomed flask, set under nitrogen, and allowed to reflux for 11.25 h. Once cooled, dilute aqueous hydrochloric acid was added until the solution was neutral, and the mixture was extracted with ethyl acetate (4 × 30 mL) and dried over anhydrous Na_2SO_4. The residue obtained by concentrating the organic layer was chromatographed on silica gel with hexanes/ethyl acetate (1:1 v/v) as the eluent to yield **30** (0.069 g, 3.79 mmol; 50%) as an oil; ^{1}H nmr δ: 1.13 (s, 3H), 1.7–1.9 (m, 2H), 2.05 (s, 3H), 2.3–2.6 (m, 2H), 4.02 (d, J = 10 Hz, 1H), 4.32 (d, J = 10 Hz, 1H), 5.8–6.1 (dt, J = 10, 2 Hz, 1H), 6.7–7.1 (m, 1H) ppm.

2-(Acetoxymethyl)-6,6-dibromo-2-methylcyclohexanone (31)

Compound **28** (5.01 g, 27.2 mmol) and chloroform (125 mL) were added to a 250-mL round-bottomed flask and cooled in an ice–salt bath. A solution of bromine (4.0 mL, 12.48 g, 78.1 mmol) in chloroform (66 mL) was added dropwise over a 1.3-h period after which the solution was stirred in an ice–water bath for an additional 2.25 h. The excess bromine was destroyed with saturated aqueous sodium metabisulfite and the mixture was extracted with chloroform (3 × 50 mL). The organic layer was washed with saturated aqueous sodium bicarbonate (3 × 75 mL) and dried over anhydrous $MgSO_4$. Concentration of the organic layer yielded **31** (6.90 g, 20.3 mmol; 74.5%) as a pale yellow oil; ir λ_{max}: 5.75 (s), 5.80 (sh) μm; ^{1}H nmr δ: 1.47 (s, 3H), 1.8–2.2 (m, 4H), 2.10 (s, 3H), 2.8–3.3 (m, 2H), 4.02 (d, J = 10 Hz, 1H), 4.28 (d, J = 10 Hz, 1H) ppm; ^{13}C nmr (50 MHz) δ: 19.75 (t), 20.7 (q), 25.2 (q), 33.5 (t), 48.55 (s), 49.6 (t), 66.8 (s), 69.75 (t), 170.4 (s), 197.5 (s) ppm; ms *m/z*: 346 (6%), 342 (9%), 340 (6%).

6-(Acetoxymethyl)-6-methyl-2,4-cyclohexadien-1-one (15)

Compound **31** (4.53 g, 13.2 mmol), lithium bromide (7.53 g, 87.0 mmol), lithium carbonate (14.52 g, 0.197 mol), and freshly distilled and dried *N*,*N*-dimethylformamide (60 mL) were added to a 500-mL round-bottomed flask, equipped with a condenser on a nitrogen gas inlet. The reaction mixture was heated on an oil bath, at 102–110°C, and stirred for 15.5 h. After cooling, the excess lithium carbonate was destroyed by the careful addition of 10% aqueous hydrochloric acid (300 mL); extraction with chloroform (3 × 100 mL) followed and the organic layer was washed with water (3 × 50 mL) and dried over anhydrous Na_2SO_4. Concentration of the organic layer followed by chromatography on silica gel with chloroform/ethyl acetate (90:10 v/v) as the eluent yielded the dienone **15** (R_f 0.40; 2.136 g, 11.8 mmol; 90%) as a yellow oil; ir λ_{max}: 5.73 (sh), 5.78 (s), 6.03 (s), 6.14 (s), 6.90 (s) μm; ^{1}H nmr δ: 1.20 (s, 3H), 1.95 (s, 3H), 4.25 (s, 2H), 5.9–6.1 (d, J = 10 Hz, 1H), 6.2–6.3 (distorted d, J = 4 Hz, 2H), 6.8–7.2 (m, 1H) ppm; ^{13}C nmr (100 MHz) δ: 20.65 (q), 21.3 (q), 68.0 (s), 69.3 (t), 121.7 (d), 125.8 (d), 141.6 (d), 144.7 (d), 170.6 (s), 203.0 (s) ppm; ms *m/z*: 180 (3%). *Exact Mass* calcd. for $C_{10}H_{12}O_3$: 180.07865; found: 180.0787.

Trimethyl 5-methyl-6-oxobicyclo[2.2.2]octa-2,7-diene-2,3,5-tricarboxylates (12)

A mixture of compound **9** (1.26 g, 7.60 mmol) and compound **22**, dimethyl acetylenedicarboxylate (9 mL, 10.40 g, 73.2 mmol), two spatula-tips of hydroquinone, and dry benzene (200 mL) were added to a 500-mL round-bottomed flask. The mixture was refluxed under nitrogen for 46 h. The mixture was cooled, the hydroquinone filtered off, and the benzene was evaporated; the residue was chromatographed on silica gel with hexanes/ethyl acetate (55:45 v/v) as the eluent, yielding a 3:1 mixture of isomers (2.11 g, 6.85 mmol; 90%). Repeated chromatography with the same eluent yielded the major isomer **12***a* (R_f 0.33), which was recrystallized from water, mp 97–98°C, and the minor isomer **12***b*, also recrystallized from water, mp 103–104°C. Major isomer **12***a*, ir λ_{max}: 5.73 (br), 6.07 (sh) μm; ^{1}H nmr δ: 1.46 (s, 3H), 3.70 (s, 3H), 3.83 (s, 3H), 3.86 (s, 3H), 4.3–4.6 (dt, J = 6, 2 Hz, 2H), 6.4–6.9 (m, 2H) ppm; ^{13}C nmr δ: 23.9 (q), 48.4 (d), 49.4 (s), 52.5 (q), 56.8 (d), 128.7 (d), 135.7 (d), 137.4 (s), 141.8 (s), 163.9 (s), 165.4 (s), 170.8 (s), 197.9 (s) ppm. *Anal.* calcd. for $C_{15}H_{16}O_7$: C 58.44, H 5.23; found: C 58.35, H 5.31.

Minor isomer **12***b*, ir λ_{max}: 5.70 (sh), 5.80 (s) μm; ^{1}H nmr δ: 1.43 (s, 3H), 3.65 (s, 3H), 3.85 (s, 6H), 4.28–4.65 (m, 2H), 6.53–6.75 (m, 2H) ppm; ^{13}C nmr δ: 24.1 (q), 48.5 (d), 48.7 (s), 51.9 (q), 52.2 (q), 52.4 (q), 57.0 (d), 130.3 (d), 134.5 (d), 136.5 (s), 141.5 (s), 164.3 (s), 164.9 (s), 170.3 (s), 194.4 (s) ppm.

Dimethyl 6-(acetoxymethyl)-6-methyl-5-oxobicyclo[2.2.2]octa-2,7-diene-2,3-dicarboxylates (32)

2-(Acetoxymethyl)-2-methylcyclohexa-2,4-dien-1-one (2.00 g, 11.0 mmol), dimethyl acetylenedicarboxylate (11 mL, 12.716 g, 89.5 mmol), two spatula-tips of hydroquinone, and benzene (200 mL) were added to a 250-mL round-bottomed flask and placed under nitrogen. The reaction mixture was refluxed for 45.5 h. After cooling, the benzene was evaporated and the residue was chromatographed on silica gel with hexanes/ethyl acetate (55:45 v/v) as the eluent. Two isomers were obtained in a ratio of 1.1:1 in nearly quantitative yield; repeated chromatography of the crude oil on silica gel with the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

eluent yielded the major isomer **15***b* (R_f 0.28; 1.475 g, 4.58 mmol) and the minor isomer **15***a* (R_f 0.32; 0.9203 g, 28.6 mmol) as pale, yellow oils. Major isomer **15***b*, ir λ_{max}: 5.78 (sh), 5.82 (s), 5.87 (s), 6.15 (s), 6.30 (s) μm; ^{1}H nmr (400 MHz) δ: 1.11 (s, 3H), 1.96 (s, 3H), 3.71 (s, 3H), 3.72 (s, 3H), 3.86 (s, 2H), 4.11–4.13 (dd, J = 6, 2 Hz, 1H), 4.42–4.44 (dd, J = 6, 1.5 Hz, 1H), 6.49–6.52 (ddd, J = 7, 6, 2 Hz, 1H), 6.57–6.61 (ddd, J = 7, 6, 1.5 Hz, 1H) ppm; ^{13}C nmr (100 MHz) δ: 20.4 (q), 23.8 (q), 42.6 (s), 47.8 (d), 52.35 (q), 52.4 (q), 57.6 (d), 68.9 (t), 129.2 (d), 135.9 (d), 136.1 (s), 142.25 (s), 164.3 (s), 165.3 (s), 170.2 (s), 202.6 (s) ppm; ms m/z $(M + 1)^+$: 323 (8%). *Exact Mass* calcd. for $C_{16}H_{19}O_7$ (M + 1): 323.1125; found: 323.1123. *Anal.* calcd. for $C_{16}H_{18}O_7$: C 59.61, H 5.61; found: C 59.42, H 5.76.

*Dimethyl 6-(dibromomethyl)-6-methyl-5-oxobicyclo[2.2.2]octa-2,7-diene-2,3-dicarboxylates (**33**)*

6-(Dibromomethyl)-6-methyl-2,4-cyclohexadien-1-one (**16**) was prepared according to the procedure of Wenkert *et al.* (13*a*).

Compound **16** (3.43 g, 12.6 mmol) and dimethyl acetylenedicarboxylate (1.60 mL, 1.85 g, 13.0 mmol) were heated in a steel pressure bottle at 120°C for 24 h. An orange oil was obtained, containing an 8:1 mixture of two isomeric adducts (4.82 g, 0.115 mol; 93%). The major isomer **33***a* was recrystallized from diethyl ether as colorless crystals, mp 152–153°C; the minor isomer **33***b* was chromatographed on silica gel with hexanes/ether (3:1 v/v) as the eluent, yielding a yellow, dense oil. Major isomer **33***a*, ir (KBr) λ_{max}: 5.81 (s), 6.09 (s), 6.27 (m) μm; ^{1}H nmr δ: 1.47 (s, 3H), 3.77 (s, 3H), 3.80 (s, 3H), 4.3–4.6 (m, 2H), 5.53 (s, 1H), 6.5–6.8 (m, 2H) ppm; ^{13}C nmr δ: 21.6 (q), 46.8 (s), 50.5 (d), 51.9 (d), 52.7 (q), 58.3 (d), 130.2 (d), 133.6 (d), 137.8 (s), 142.5 (s), 163.8 (s), 165.2 (s), 197.6 (s) ppm; ms m/z: 343 (0.4%), 341 (0.4%). *Anal.* calcd. for $C_{14}H_{14}Br_2O_5$: C 39.84, H 3.34, Br 37.86; found: C 40.01, H 3.44, Br 38.50.

Minor isomer **33***b*, ir λ_{max}: 5.80 (s), 6.06 (s), 6.21 (s) μm; ^{1}H nmr δ: 1.46 (s, 3H), 3.82 (s, 3H), 3.86 (s, 3H), 4.42 (dd, J = 5, 3 Hz, 1H), 4.60 (dd, J = 5, 3 Hz, 1H), 5.67 (s, 1H), 6.5–6.7 (m, 2H) ppm; ^{13}C nmr δ: 23.4 (q), 47.0 (s), 50.7 (d), 50.8 (d), 52.7 (q), 57.9 (d), 131.2 (d), 135.6 (s), 142.4 (s), 163.9 (s), 165.4 (s), 197.1 (s) ppm; ms m/z: 343 (0.4%), 341 (0.4%).

Dimethyl exo-*6-bromomethyl*-endo-*6-methyl-5-oxobicyclo[2.2.2]octa-2,7-diene-2,3-dicarboxylate (**35**a)*

Compound **33***a* (0.247 g, 0.589 mmol), dichloromethane (2 mL), and trichlorosilane (0.2 mL, 0.269 g, 1.99 mmol) were added to a 50-mL round-bottomed flask placed in an ice bath. A solution of triethylamine (0.2 mL, 0.152 g, 1.51 mmol) and dichloromethane (1 mL) was added. The ice bath was removed and the reaction mixture was stirred at room temperature for 4 h. Diethyl ether (20 mL) was added and the reaction mixture was filtered to remove the solid formed. The ethereal solution was concentrated and the oil was chromatographed on silica gel with hexanes/ethyl acetate (3:1 v/v) as the eluent to yield **35***a* (R_f 0.25; 0.146 g, 0.427 mmol; 72.5%); ir λ_{max}: 5.78 (s), 6.09 (m), 6.25 (w) μm; ^{1}H nmr (200 MHz) δ: 1.26 (s, 3H), 3.21 (d, J = 10.5 Hz, 1H), 3.39 (d, J = 10.5 Hz, 1H), 3.81 (s, 3H), 3.85 (s, 3H), 4.40 (dd, J = 6, 2 Hz, 1H), 4.71 (dd, J = 6, 2 Hz, 1H), 6.55–6.6 (ddd, J = 7, 6, 2 Hz, 1H), 6.7–6.8 (ddd, J = 7, 6, 1.5 Hz, 1H) ppm; ms m/z: 344 (2%), 342 (2%).

Dimethyl exo-*6-(dibromomethyl)*-endo-*6-methyl-5-oxobicyclo[2.2.2]-oct-2-ene-2,3-dicarboxylate (**37**a)*

Compound **33***a* (0.1977 g, 0.471 mmol), dry methanol (10 mL), and a spatula-tip of platinum dioxide were placed in a 50-mL round-bottomed flask and stirred under hydrogen for 10 min. The platinum was filtered through a Celite plug and the solution was concentrated. Crystallization from diethyl ether gave **37***a* (0.172 g, 0.408 mmol; 87%) as colorless crystals, mp 148–149°C; ir λ_{max}(KBr): 5.83 (s), 6.12 (m) μm; ^{1}H nmr δ: 1.36 (s, 3H), 1.5–2.5 (m, 4H), 3.53 (m, 1H), 3.70 (m, 1H), 3.77 (s, 3H), 3.83 (s, 3H), 5.75 (s, 1H) ppm; ^{13}C nmr δ: 19.6 (t), 20.6 (t), 22.9 (q), 45.0 (d), 48.8 (d), 49.7 (d), 51.0 (s), 52.6 (q), 133.6 (s), 144.7 (s), 164.0 (s), 165.8 (s), 204.7 (s) ppm; ms m/z: 426 (2%), 424 (5%), 422 (2%), 165 (100%). *Anal.* calcd. for $C_{14}H_{16}Br_2O_5$: C 39.65, H 3.80, Br 37.68; found; C 39.85, H 3.89, Br 38.01.

Dimethyl endo-*6-(dibromomethyl)*-exo-*6-methyl-5-oxobicyclo[2.2.2]-oct-2-ene-2,3-dicarboxylate (**37**b)*

Compound **37***b* was prepared by hydrogenation of **33***b* under the same conditions as those used for the preparation of **37***a* from **33***a* (*vide supra*). It was obtained in 70% yield as colorless crystals, mp 89–90.5°C; ir λ_{max}(KBr): 5.80 (s), 6.10 (m) μm; ^{1}H nmr δ: 1.44 (s, 3H), 1.7–2.3 (m, 4H), 3.56 (m, 1H), 3.66 (m, 1H), 3.80 (s, 3H), 3.85 (s, 3H), 5.73 (s, 1H) ppm; ^{13}C nmr δ: 20.1 (q), 20.8 (t), 24.2 (t), 44.6 (d), 50.0 (d), 50.2 (d), 52.1 (s), 52.6 (q), 132.5 (s), 142.9 (s), 164.3 (s), 165.6 (s), 205.2 (s) ppm; ms m/z: 426 (2%), 424 (4%), 422 (2%), 165 (100%). *Anal.* calcd. for $C_{14}H_{16}Br_2O_5$: C 39.65, H 3.80, Br 37.68; found: C 39.85, H 3.85, Br 37.73.

Dimethyl exo-*6-(bromomethyl)*-endo-*6-methyl-5-oxobicyclo[2.2.2]-oct-2-ene-2,3-dicarboxylate (**38**a)*

Compound **37***a* (0.171 g, 0.408 mmol), dichloromethane (2 mL), and trichlorosilane (0.2 mL, 0.269 g, 1.99 mmol) were added to a 50-mL round-bottomed flask placed in an ice bath. The mixture was cooled and a solution of triethylamine (0.2 mL, 0.152 g, 1.51 mmol) and dichloromethane (1 mL) was added. The ice bath was removed and the reaction mixture was stirred at room temperature for 3.5 h. Diethyl ether (20 mL) was added and the reaction mixture was filtered to remove the solid formed. The ethereal solution was concentrated and the oil was put through a short column of silica gel with dichloromethane as the eluent to yield **38***a* (0.133 g, 0.378 mmol; 95%) as a colorless oil; ir λ_{max}: 5.81 (s), 6.12 (s) μm; ^{1}H nmr δ: 1.22 (s, 3H), 1.6–2.3 (m, 4H), 3.3–3.6 (m, 2H), 3.6–3.8 (m, 2H), 3.82 (s, 3H), 3.87 (s, 3H) ppm; ^{13}C nmr δ: 19.8 (t), 22.1 (t), 22.6 (q), 39.3 (t), 43.4 (d), 46.9 (s), 49.3 (d), 52.5 (q), 132.4 (s), 145.1 (s), 164.2 (s), 166.3 (s), 209.8 (s) ppm; ms m/z: 346 (2.5%), 344 (2.5%). *Exact Mass* calcd. for $C_{14}H_{17}O_5Br$: 346.0238, 344.0259; found: 346.0259, 344.0252.

exo-*6-(Hydroxymethyl)*-endo-*6-methyl-5-oxobicyclo[2.2.2]oct-2-ene-2,3-dicarboxylic acid (**39**a)*

Compound **38***a* (1.30 g, 3.78 mmol), potassium hydroxide (2.0 g, 35.6 mmol), methanol (10 mL), and water (10 mL) were placed in a 50-mL round-bottomed flask and the mixture was stirred at room temperature for 24 h. The mixture was neutralized with 10% hydrochloric acid and extracted with ethyl acetate (3 × 50 mL) and dried over anhydrous Na_2SO_4. The crude solid was recrystallized from diethyl ether/pentanes to give **39***a* (0.60 g, 2.36 mmol; 62.5%) as a colorless solid, mp 189–191°C; ir λ_{max}(KBr): 3.92 (br), 5.81 (s), 5.84 (s), 6.29 (s) μm; ms m/z $(M - 17)^+$: 237 (8%). *Anal.* calcd. for $C_{12}H_{14}O_6$: C 56.69, H 5.55; found: C 56.47, H 5.70.

Trimethyl endo-*5-methyl-6-oxobicyclo[2.2.2]oct-2-ene-2,3,* exo-*5-tricarboxylate (**40**a)*

Compound **12***a* (0.085 g, 0.262 mmol), dry methanol (10 mL), and a spatula-tip of 10% palladium on carbon were placed in a 50-mL round-bottomed flask and stirred under hydrogen for 10 min. The mixture was filtered through a Celite plug and the solution was concentrated. The residue was chromatographed on silica with hexanes/ethyl acetate (1:1 v/v) as the eluent to yield **40***a* (R_f 0.06; 0.081 g, 0.249 mmol; 95%) as a colorless oil (lit. (3) mp 46–47°C); ir λ_{max}: 5.76 (s), 6.13 (m) μm; ^{1}H nmr δ: 1.40 (s, 3H), 1.5–2.1 (m, 4H), 3.3–3.6 (m, 2H), 3.80 (s, 3H), 3.85 (s, 3H), 3.90 (s, 3H) ppm; ^{13}C nmr δ: 20.5 (t), 22.0 (q + t), 44.4 (d), 49.1 (d), 52.5 (q), 53.7 (s), 133.6 (s), 143.0 (s), 164.3 (s), 171.7 (s), 205.1 (s) ppm.

Trimethyl exo-*5-methyl-6-oxobicyclo[2.2.2]oct-2-ene-2,3,* endo-*5-tricarboxylate (**40** b)*

Compound **40***b* was prepared by hydrogenation of **12***b* under the same conditions as those used for the preparation of **40***a* from **12***a* (*vide supra*). It was obtained as a colorless oil; ir λ_{max}: 5.82 (s), 6.08 (w) μm; ^{1}H nmr δ: 1.47 (s, 3H), 1.6–2.1 (m, 4H), 3.3–3.6 (m, 2H), 3.67 (s, 3H), 3.82 (s, 3H), 3.85 (s, 3H) ppm; ^{13}C nmr δ: 19.0 (t), 19.8 (q), 23.7 (t), 43.8 (d), 49.0 (d), 52.3 (q), 53.8 (s), 133.4 (s), 142.9 (s), 164.3 (s), 165.6 (s), 170.7 (s) ppm (ketonic C=O signal not detectable above noise level).

Dimethyl exo-*6-(acetoxymethyl)*-endo-*6-methyl-5-oxobicyclo[2.2.2]-oct-2-ene-2,3-dicarboxylate (**42** a)*

Compound **32***a* (0.109 g, 0.338 mmol), dry methanol (15 mL), and platinum dioxide (2 spatula-tips) were added to a 50-mL round-bottomed flask. The mixture was stirred under hydrogen for 10 min; the mixture was filtered through a Celite plug and the solution was concentrated. The crude product was chromatographed on silica gel with hexanes/ethyl acetate (55:45 v/v) as the eluent to yield **42***a* (R_f 0.11) in quantitative yield as a colorless oil; ir λ_{max}: 5.70 (sh), 5.75 (s), 5.81 (sh), 6.10 (s) μm; ^{1}H nmr (400 MHz) δ: 1.15 (s, 3H), 1.5–1.6 (m, 2H), 1.7–1.85 (m, 1H), 1.85–2.0 (m, 1H), 2.08 (s, 3H), 3.19–3.20 (t, J = 3 Hz, 1H), 3.63–3.65 (dd, J = 4, 2 Hz, 1H), 3.77 (s, 3H), 3.82 (s, 3H), 4.01–4.04 (d, J = 11 Hz, 1H), 4.05–4.08 (d, J = 11 Hz, 1H) ppm; ^{13}C nmr (100 MHz) δ: 20.5 (t), 20.8 (q), 21.9 (q), 22.2 (t), 43.0 (d), 46.5 (s), 49.1 (d), 52.5 (q), 52.55 (q), 66.85 (t), 132.3 (s), 145.05 (s), 164.4 (s), 166.5 (s), 170.5 (s), 210.25 (s) ppm; ms m/z: 324 (4%).

Dimethyl endo-*6-(acetoxymethyl)*-exo-*6-methyl-5-oxobicyclo[2.2.2]-oct-2-ene-2,3-dicarboxylate (**42** b)*

Compound **42***b* was prepared from **32***b* in 80% yield as described for the minor isomer. Purification by chromatography on silica gel with hexanes/ethyl acetate (55:45 v/v) as the eluent gave the product (R_f 0.26) as a colorless oil; ir λ_{max}: 5.76 (sh), 5.80 (s), 5.85 (s), 5.90 (sh), 6.18 (s) μm; ^{1}H nmr (400 MHz) δ: 1.13 (s, 3H), 1.46–1.54 (m, 1H), 1.70–1.78 (m, 1H), 1.85–2.08 (m, 2H), 1.94 (s, 3H), 3.17–3.19 (t, J = 3 Hz, 1H), 3.56–3.58 (q, J = 4, 2 Hz, 1H), 3.72 (s, 3H), 3.73 (s, 3H), 3.83–3.86 (d, J = 11 Hz, 1H), 3.90–3.93 (d, J = 11 Hz, 1H) ppm; ^{13}C (100 MHz) nmr δ: 19.6 (q), 20.3 (t), 20.4 (q), 21.9 (t), 42.1 (d), 45.9 (s), 49.5 (d), 52.25 (q), 52.3 (q), 68.4 (t), 132.2 (s), 143.7 (s), 164.7 (s), 165.6 (s), 170.2 (s), 209.4 (s) ppm; ms m/z: 324 (4.5%).

Dimethyl exo-*6-(hydroxymethyl)*-endo-*6-methyl-5-oxobicyclo[2.2.2]-oct-2-ene-2,3-dicarboxylate (**41** a)*

*(i) From compound **42** a*

Compound **42***a* (0.109 g, 0.338 mmol), potassium carbonate (0.0637 g, 0.461 mmol), and dry methanol (15 mL) were added to a 50-mL round-bottomed flask, placed under argon, and stirred at room temperature for 3.3 h. The alcoholic solution was filtered, the methanol was evaporated and the concentrate was extracted with ethyl acetate. The extract was dried over anhydrous Na_2SO_4 and concentrated and the residue was chromatographed on silica gel with hexanes/ethyl acetate (1:3 v/v) as the eluent to yield **41***a* (R_f 0.40; 0.0568 g, 0.201 mmol; 60%) as a colorless oil; ir λ_{max}: 3.06 (br), 5.80 (s), 5.85 (s), 5.90 (sh), 6.10 (s) μm; ^{1}H nmr δ: 1.17 (s, 3H), 1.7–2.1 (m, 4H), 2.3–2.5 (br m, 1H, D_2O exchangeable), 3.1–3.3 (m, 1H), 3.3–3.5 (m, 1H), 3.5–3.8 (br s, 2H), 3.82 (s, 3H), 3.87 (s, 3H) (s, 3H) ppm; ^{13}C nmr (100 MHz) δ: 20.4 (t), 21.4 (q), 22.7 (t), 43.7 (d), 45.25 (s), 49.5 (d), 52.5 (q), 66.9 (t), 132.1 (s), 145.7 (s), 164.6 (s), 166.7 (s), 213.1 (s), ppm; ms m/z: 282 (5%). *Exact Mass* calcd. for $C_{14}H_{18}O_6$: 282.1103; found: 282.1105. *Anal.* calcd. for $C_{14}H_{18}O_6$: C 59.57, H 6.42; found: C 59.41, H 6.64.

*(ii) From compound **39** a*

Compound **39***a* (0.60 g, 2.36 mmol) was added to an ethereal solution of diazomethane (2.44 g, 5.78 mmol) and allowed to stand overnight. The concentrate was chromatographed on a preparative plate of silica gel with diethyl ether as the solvent, which yielded **41***a* (R_f 0.28; 0.61 g, 2.16 mmol; 91%) as a colorless oil, whose spectra were identical with those of the sample of **41***a* prepared from **42***a*.

Compound **43** a (R_f 0.46; 0.025 g; 3%) was also isolated from the preparative plate as a colorless oil; ir λ_{max}: 5.80 (s), 6.10 (s) μm; ms m/z: 296 (7), 165 (100). *Exact Mass* calcd. for $C_{15}H_{20}O_6$: 296.1260; found: 296.1272.

Dimethyl endo-*6-(hydroxymethyl)*-exo-*6-methyl-5-oxobicyclo[2.2.2]-oct-2-ene-2,3-dicarboxylate (**41** b)*

Compound **41***b* was prepared in 27% yield by adding compound **42***b* (0.094 g, 0.29 mmol), anhydrous potassium carbonate (0.099 g, 0.71 mmol), and methanol (15 mL) to a 50-mL round-bottomed flask and repeating the procedure described for the minor isomer; ^{1}H nmr: 1.23 (s, 3H), 1.3–2.2 (br s, 4H), 2.2–2.5 (br s, 1H), 2.5–2.9 (br s, 1H), 3.3–3.5 (br s, 1H), 3.67 (s, 6H), 3.90 (s, 2H) ppm.

*Dimethyl 6-(dichloromethyl)-6-methyl-5-oxobicyclo[2.2.2]octa-2,7-diene-2,3-dicarboxylates (**34**)*

6-(Dichloromethyl)-6-methyl-2,4-cyclohexadien-1-one (**17**) was prepared according to the procedure of Auwers and Keil (13*b*).

Compound **17** was treated with dimethyl acetylenedicarboxylate under the conditions used in the case of compound **16** (*vide supra*). The crude product consisted of a 6:1 mixture of the adducts **34***a* and **34***b*. The major isomer **34***a* crystallized from diethyl ether, as cubic crystals, mp 129–130°C; ir λ_{max}(KBr): 5.81 (s), 6.08 (s), 6.27 (s) μm; ^{1}H nmr δ: 1.40 (s, 3H), 3.81 (s, 3H), 4.3–4.7 (m, 2H), 5.60 (s, 1H), 6.5–6.8 (m, 2H) ppm; ^{13}C nmr δ: 19.5 (q), 47.8 (s), 49.3 (d), 52.7 (q), 58.0 (d), 78.0 (d), 130.2 (d), 133.8 (d), 137.9 (s), 142.3 (s), 163.9 (s), 165.3 (d), 197.9 (s); ms m/z: 297 (0.6; M − Cl), 221 (1.4), 195 (11), 163 (100). *Anal.* calcd. for $C_{14}H_{14}Cl_2O_5$: C 50.47, H 4.24, Cl 21.28; found: C 50.20, H 4.27, Cl 21.25.

The minor isomer **34***b* was not isolated; its presence was evident from the ^{13}C nmr spectrum of the crude product, δ: 21.2 (q), 47.9 (s), 49.4 (s), 52.8 (q), 57.9 (d), 77.2 (d), 131.1 (d), 135.2 (d), 138.2 (s), 142.1 (s), 164.0 (s), 165.3 (s), 197.7 (s).

Dimethyl exo-*6-(dichloromethyl-*endo-*6-methyl-5-oxobicyclo[2.2.2]-oct-2-ene-2,3-dicarboxylate (**45** a)*

Compound **34***a* was hydrogenated under the conditions used in the case of compound **33***a* (*vide supra*). Crystallization from diethyl ether gave **45***a* as colorless crystals, mp 112–114°C; ir λ_{max}(KBr): 5.78 (s), 6.10 (s) μm; ^{1}H nmr δ: 1.34 (s, 3H), 1.5–1.8 (m, 4H), 3.53 (m, 1H), 3.66 (m, 1H), 3.80 (s, 3H), 3.83 (s, 3H), 5.80 (s, 1H); ms m/z: 338 (1), 336 (77), 334 (11), 299 (7), 269 (3), 239 (7), 201 (8), 196 (7), 165 (100). *Anal.* calcd. for $C_{14}H_{16}Cl_2O_5$: C 50.16, H 4.81, Cl 21.15; found: C 50.17, H 4.84, Cl 21.21.

Reactions of "cyclen-" and "cyclam-phosphorane" with $[Pt_2Cl_4(PEt_3)_2]$. Monodentate and bidentate complexes and the crystal and molecular structure of $[PtCl(PEt_3)(cyclamPH)]Cl.CH_2Cl_2$

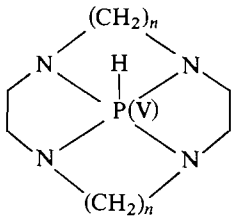
Reaction of "cyclamphosphorane" (cyclamPH) with $[Pt_2Cl_4(PEt_3)_2]$ yields $[PtCl(PEt_3)(cyclamPH)]Cl$. The complex crystallizes as a dichloromethane solvate in the monoclinic space group $P2_1/n$, with a = 13.877(3), b = 23.231(7), c = 8.295(2) Å, β = 91.86(4)°, and an X-ray diffraction study shows square planar platinum coordination in which the labile proton of cyclamPH has transferred from phosphorus to nitrogen and the ligand is attached via simple P(III)---N(III) chelation. The phosphorus is *trans* to chlorine in the platinum coordination plane.

The corresponding product, *trans*-$[PtCl_2(PEt_3)(cyclenPH_2)]Cl$, derived from reaction of "cyclenphosphorane" (cyclenPH) with $[Pt_2Cl_4(PEt_3)_2]$, is shown by NMR studies to have a quite different structure in which the ligand is protonated at two nitrogen sites but not at phosphorus. The phosphorus is pentacoordinate with four attachments to nitrogen atoms and one to platinum. The two chlorine atoms are mutually *trans* in the platinum coordination plane.

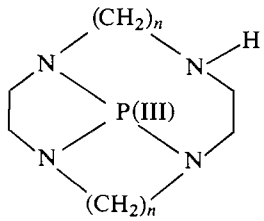
Key words: crystal structure, cyclenphosphorane reaction, cyclamphosphorane reaction, X-ray diffraction.

DAVID ERIC BERRY, JANE BROWNING, GORDON WILLIAM BUSHNELL, KEITH ROGER DIXON et ALAN PIDCOCK. Can. J. Chem. **67**, 48 (1989).



La réaction du «cyclamphosphorane» (cyclamPH) avec le $[Pt_2Cl_4(PEt_3)_2]$ conduit au $[PtCl(PEt_3)(cyclamPH)]Cl$. Les cristaux du complexe, qui cristallise avec une molécule de dichlorométhane, sont monocliniques, groupe d'espace $P2_1/n$, avec a = 13,877(3), b = 23,231(7) et c = 8,295(2) Å et β = 91,86(4)°; une étude par diffraction des rayons-X montre que la coordination du platine est plan carré, que le proton labile du cyclamPH a été transféré du phosphore à l'azote et que le ligand est attaché par le biais d'une simple chélation P(III)---N(III). Le phosphore est *trans* par rapport au chlore dans le plan de coordination du platine.

En se basant sur des études de rmn, on a démontré que la structure du produit correspondant, $[PtCl_2(PEt_3)(cyclenPH_2)]Cl$-*trans*, qui provient de la réaction du «cycloenphosphorane» (cyclenPH) avec le $[Pt_2Cl_4(PEt_3)_2]$, est très différente; le ligand est protoné à deux sites azotés, mais pas au phosphore. Le phosphore est pentacoordonné avec quatre azotes et un platine. Les deux atomes de chlore sont mutuellement *trans* dans le plan de coordination du platine.



Mots clés : structure cristalline, réaction du «cycloenphosphorane», réaction du «cyclamphosphorane», diffraction des rayons-X.

Introduction

Ia

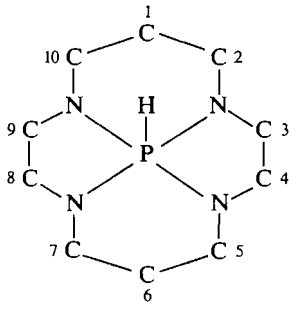
Ib

The coordination chemistry of "cyclenphosphorane", **I** (n = 2, and "cyclamphosphorane", **I** (n = 3), has attracted recent attention for several reasons (1, 2). Most novel are complexes in which a P—N bond of the deprotonated P^V form is η^2-coordinated to a metal to form a three-membered ring (1–3). However, the relatively subtle effects of ring size on the distribution of *a* and *b* forms are also interesting. In the free ligands cyclenPH[2] exists entirely as the *a* form whereas cyclamPH is about 18% in the *b* form (4). These differences seem to be exaggerated in metal complexes. Thus reactions of cyclenPH with $[Co_2(CO)_8]$ and $[Mo(CO)_3(\eta^5\text{-}C_5H_5)]_2$ yield respectively $[Co(CO)_3(cyclenP)]$ and $[Mo(CO)_2(\eta^5\text{-}C_5H_5)$-(cyclenP)] as the initial products, both complexes having η^2-coordinated P—N bonds (1). In contrast, in the reaction of cyclamPH with $[MoCl(CO)_3(\eta^5\text{-}C_5H_5)]$ the first product is $[Mo(CO)_2(\eta^5\text{-}C_5H_5)(cyclamPH)]Cl$, a simple P(III)---N(III) chelate compound derived from form *b* of the ligand (2, 3). A strong base, methyl lithium, is required to convert this initial product to $[Mo(CO)_2(\eta^5\text{-}C_5H_5)(cyclamP)]$, with an η^2-coordinated P—N bond (2, 3). The rhodium complex, [RhCl(CO)(cyclamPH)], also contains a P(III)---N(III) chelated ligand (2).

A recent report (5) of the reaction of cyclenPH with *cis*-$[PtCl_2(PPh_3)_2]$, leading to an η^2-(P—N) bond in $[PtCl(PPh_3)$-(cyclenP)], prompts us to report our own results on platinum complexes. These results confirm the differences between cyclenPH and cyclamPH and also provide the first structural characterisation of one of these ligands coordinated in the simple chelate, P(III)---N(III) form, **I***b* (n = 3).

Results

(a) [PtCl(PEt$_3$)(cyclamPH)]Cl



The chlorobridged platinum dimer, $[Pt_2Cl_4(PEt_3)_2]$, reacts with cyclamPH under mild conditions to give a white, crystalline product in high yield. After recrystallization of the product from a dichloromethane/diethyl ether solvent mixture, microanalysis is consistent with the formulation, $[PtCl(PEt_3)$-(cyclamPH)]$Cl.CH_2Cl_2$. ^1H NMR confirms the presence of CH_2Cl_2 and a proton decoupled ^{31}P spectrum shows two

TABLE 1. Carbon-13 NMR assignments for cyclamPH and $[PtCl(PEt_3)(cyclamPH)]^+$

Carbon number	cyclamPH (ppm)	J(P—C) (Hz)	Pt complex (ppm)	J(P—C) (Hz)	J(Pt—C) (Hz)
1	26.67		25.9		ca. 14
2	44.84		45.76		ca. 22
3	47.52	9.7	53.84	11.7	41.9
4, 8, 9	47.52	9.7	48.27	9.7	
			48.66	3.8	
			49.73	8.8	
5, 7	44.84		41.92		
			44.75		
6	26.67		21.91	4.3	
10	44.84		54.81		

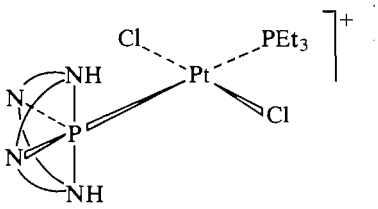
resonances, each with ^{195}Pt sidebands, δ(PN) +69.16 ppm, J(Pt—P) 4649 Hz, δ(PEt_3) +12.65 ppm, J(Pt—P) 3294 Hz. The small phosphorus–phosphorus coupling of 19.3 Hz indicates *cis* geometry at the metal centre (6). As expected the ^{195}Pt spectrum at Ξ 21.400375 MHz (δ +17.52 ppm) is a doublet of doublets confirming the Pt—P couplings. The very normality of the phosphorus data suggests that the complex is a simple P(III)---N(III) chelate rather than any more exotic structure. For example, the parameters for *cis*-$[PtCl(PEt_3)_2(pyridine)]^+$, δ +3.6 and +7.9 ppm, J(Pt—P) 3057 and 3454 Hz, J(P—P) 20 Hz, are closely comparable (7) except that electron withdrawal by nitrogen increases the magnitude of the Pt—PN_4 coupling in the present complex.

A proton NMR resonance at 5.66 ppm has ^{195}Pt sidebands with J(Pt—H) 68 Hz, and may be assigned to a proton on nitrogen, whereas a proton coupled ^{31}P spectrum shows no evidence for a direct P—H bond. The ^{13}C spectrum is discussed in detail below and shows a complete loss of symmetry for the cyclamPH ligand, with all ten carbon sites separately identifiable. All of these data indicate a complex cation, $[PtCl(PEt_3)(cyclamPH)]^+$ in which the cyclamPH proton has been transferred from phosphorus to nitrogen and the ligand coordinated in form **I***b* (n = 3) with the cyclam phosphorus *trans* to chlorine and the cyclam nitrogen *trans* to PEt_3, a structure which was ultimately confirmed by the X-ray diffraction study discussed below.

(b) Carbon-13 nuclear magnetic resonance

The fully symmetrical ligand, cyclenPH, shows a doublet ^{13}C resonance at 44.96 ppm, J(P—C) 9.0 Hz. By comparison, the three resonances of cyclamPH, which occur at 26.67, 44.84, and 47.52 ppm, in a 1:2:2 intensity ratio, are easily assigned to carbons 1, 2, and 3, respectively, as shown in Table 1. Only the 47.52 ppm resonance is doubled by coupling to phosphorus (9.7 Hz). The absence of coupling from phosphorus to C(2) is somewhat puzzling but may be explained by the multiple coupling paths available. Thus C(3), which shows significant coupling, is coupled to phosphorus via two bond and three bond paths whereas C(2) is coupled via two bond and four bond paths.

In the ^{13}C NMR of $[PtCl(PEt_3)(cyclamPH)]^+$, the expected resonances for triethylphosphine, δ(CH_3) 8.15, J(P—C) 2.5 Hz, J(Pt—C) 28.2 Hz, and δ(CH_2) 15.43, J(P—C) 39.2 Hz, J(Pt—C) 36.9 Hz, are accompanied by ten clearly resolved resonances of closely equal intensity for the cyclam ring. The assignment of these resonances cannot be unambiguous but the observed couplings to phosphorus and platinum, combined with the comparison with free ligand parameters, suggest the assignments shown in Table 1 as the most likely.



(c) $[PtCl_2(PEt_3)(cyclenPH_2)]Cl$

The reaction of cyclenPH with $[Pt_2Cl_4(PEt_3)_2]$ is superficially similar to that of cyclamPH. After recrystallization of the product from a dichloromethane/diethyl ether solvent mixture, microanalysis is consistent with the formulations, $[PtCl_2(PEt_3)(cyclenPH_2)]Cl.\frac{1}{2}CH_2Cl_2$ or $[PtCl_2(PEt_3)(cyclenPH)].CH_2Cl_2$. The presence of dichloromethane solvent is confirmed by ^1H NMR and it proved difficult to remove completely. The correctness of the diprotonated ionic formulation rather than the monoprotonated covalent structure is shown by conductance measurement and by a further reaction with potassium hexafluorophosphate which yields a PF_6^- salt with essentially the same NMR parameters as the chloride. In the ^1H spectra, broad resonances at 6.41 ppm (integral 1.6) for the chloride and 6.25 ppm (integral 1.9) for the hexafluorophosphate are assigned to protons on nitrogen. These protons exchange with D_2O and the precise extent of protonation in solution may vary with the conditions.

A proton decoupled ^{31}P NMR spectrum of $[PtCl_2(PEt_3)(cyclenPH_2)]Cl$ shows an AB pattern with ^{195}Pt sidebands, δ(PN) −6.33 ppm, J(Pt—P) 3659 Hz, δ(PEt_3) +9.51 ppm, J(Pt—P) 2234 Hz. A large P—P coupling of 793 Hz indicates mutually *trans* positions at the metal centre (6). The ^{195}Pt resonance at Ξ 21.416884 MHz (δ + 788.96 ppm) appears superficially simple as the expected doublet of doublets due

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

to coupling to phosphorus but interestingly requires analysis as the X region of an ABX pattern in order to match the J(Pt—P) values obtained from the phosphorus spectrum. In the ^{13}C NMR, the expected resonances for triethylphosphine, $\delta(CH_3)$ 7.78 ppm, J(P—C) < 3 Hz, J(Pt—C) ca. 30 Hz, and $\delta(CH_2)$ 13.13 ppm, J(P—C) 5.3 and 29.5 Hz, J(Pt—P) ca. 30 Hz, are accompanied by only two resonances, 42.11 (d 5.3 Hz) and 44.00 (s) ppm, for the cyclen ring, indicating a very symmetrical structure. This symmetrical ^{13}C spectrum is unchanged at −60°C. An X-ray diffraction study of the complex was attempted but ultimately failed to refine fully due to uncertainties in locating solvent of crystallization. However, as detailed in the experimental section, the space group symmetry requires that the molecule possess either a mirror plane or a two-fold axis of symmetry. There appears to be no reasonable structure which would have a two-fold axis, and the platinum coordination plane must therefore be a mirror plane with two nitrogens of the cyclenP ligand in this plane, and the other pair of nitrogens symmetrically above and below the plane, as illustrated in structure **II**. The protonated nitrogens could lie in the coordination plane or perpendicular to it. Coordination of the cyclenP ligand is via form **I***a* (n = 2) with the metal replacing the proton on phosphorus, in contrast to the chelate **I***b* (n = 3) form described above for the cyclamPH complex.

II

A similar structure has been proposed recently by Lattman and co-workers (5) for one of the products from reaction of cyclenPH with *cis*-[$PtCl_2(PPh_3)_2$], except that in that case the product had *cis* stereochemistry at the metal centre.

(d) Structure of [PtCl(PEt$_3$)(cyclamPH)]Cl.CH$_2$Cl$_2$

The atomic labelling scheme and the structure of a single cation of [$PtCl(PEt_3)$(cyclamPH)]Cl.CH_2Cl_2 are shown in Fig. 1. Fractional atomic coordinates and isotropic temperature parameters, bond lengths, and bond angles are collected in Tables 2–4, and further Tables of structure factors, anisotropic temperature factors, selected intermolecular distances, and fractional atomic coordinates, isotropic temperature parameters, and bond angles for the hydrogen atoms have been deposited as supplementary material.[3]

The structure of [$PtCl(PEt_3)$(cyclamPH)]$^+$ shows a platinum atom coordinated by chlorine, triethylphosphine, and by one nitrogen and the phosphorus of the cyclamPH ligand. The platinum and all four coordinating atoms lie within 0.05 Å of the least squares coordination plane, and the angles around Pt sum to exactly 360°. As predicted from the ^{31}P NMR data, the two phosphorus atoms are in mutually *cis* positions.

The bond lengths and angles in the coordination plane are summarized in Table 5. The Pt—Cl, Pt—N, and Pt—PEt_3 lengths fall within the normal ranges for these bonds when due allowance is made for the *trans* ligands. Thus previous results suggest 2.33–2.37 Å for Pt—Cl *trans* to phosphorus (8), 2.08–2.15 Å for Pt—N *trans* to phosphorus (8), and 2.24–2.31 Å for Pt—P *trans* to nitrogen (8). The Pt—PN_4 length, 2.136(11) Å, is relatively short for a bond *trans* to chlorine (more normal is 2.24–2.27 Å (8)), but not sufficiently so to suggest any unusual bonding. The most interesting comparison is to the coordination geometry of [$PtCl(PPh_3)$(cyclenP)] as summarized in Table 5. This complex was obtained by Lattman and co-workers from

[3]Copies of these tables may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]Estimated standard deviations are given in parentheses.

the reaction of cyclenPH with *cis*-[PtCl$_2$(PPh$_3$)$_2$] (5). During the reaction, cyclenPH loses its proton and becomes attached to platinum by η^2-coordination of a P—N bond. This is reflected in the structure by the very short N(1)—P(1) distance, 1.872(11) Å and the narrow N(1)—Pt—P(1) angle, 51.0(3)°. As is illustrated by Table 5, the present complex is quite different with a normal square planar angle (86.4(3)°) at N(1)—Pt—P(1) and a long N(1)—P(1) distance, 2.96(1) Å. The other P—N lengths are similar in the two complexes, ranging from 1.64–1.70 Å. In the present structure the final difference map gave evidence of additional electron density adjacent to N(1), indicating the presence of a proton on this atom. It is therefore clear that cyclamPH coordinates to platinum as a simple P(III)---N(III) chelate in which the proton has been transferred from phosphorus to nitrogen, rather than the deprotonation and η^2-(P—N) attachment adopted by cyclenPH.

Experimental

(a) Synthesis and spectroscopic studies

Data relating to the characterization of the complexes are given in the tables, the Results section, and in the preparative descriptions below. Microanalysis was by the Canadian Microanalytical Service, Vancouver, B.C., Canada.

^{1}H, ^{31}P, ^{13}C, and ^{195}Pt NMR spectra were recorded in $CDCl_3$ solution at 250.1, 101.3, 62.9, and 53.5 MHz, respectively, using a Bruker WM250 Fourier transform spectrometer locked to the solvent deuterium resonance. For ^{31}P, ^{13}C, and ^{195}Pt spectra, protons were decoupled by broad band ("noise") irradiation at appropriate frequencies. ^{1}H and ^{13}C chemical shifts were measured relative to external $Si(CH_3)_4$. ^{31}P chemical shifts were measured relative to external $P(OMe)_3$ and are reported in parts per million relative to 85% H_3PO_4 using a conversion factor of +141 ppm. ^{195}Pt chemical shifts are reported in ppm relative to $\Xi(^{195}Pt) = 21.4$ MHz (9). For all nuclei, positive chemical shifts are downfield of the appropriate reference. Simulated NMR spectra were calculated on an IBM 3083 computer and plotted on a Tektronix 4013 graphics screen for preliminary work or a Calcomp 1039 plotter for final data. The programs used were a locally constructed package based on UEAITR (10) and NMRPLOT (11).

All operations were carried out under an atmosphere of dry nitrogen using standard Schlenk tube techniques. Solvents were dried by appropriate methods and distilled under nitrogen prior to use. [$Pt_2Cl_4(PEt_3)_2$] (12) and cyclamPH (4) were prepared as previously described, the latter using the reaction of $P(NMe_2)_3$ (13) with 1,4,8,11-tetraazacyclotetradecane (cyclam) purchased from Strem Chemicals Inc.

(1) Reaction of [$Pt_2Cl_4(PEt_3)_2$] with cyclamPH

A solution of cyclamPH (0.37 g, 1.6 mmol) in tetrahydrofuran (4 mL) was added dropwise to a stirred solution of [$Pt_2Cl_4(PEt_3)_2$] (0.57 g, 0.74 mmol) in tetrahydrofuran (20 mL). The mixture was stirred for 90 min, during which time a white precipitate formed. The precipitate was collected by filtration, dissolved in dichloromethane

TABLE 5. Comparison of coordination geometries in $[PtCl(PEt_3)(cyclamPH)]^+$ and $[PtCl_2(PPh_3)$-(cyclenP)] (data for the latter compound are from ref. 5)

Compound	a	b	c	d	e
$[PtCl(PEt_3)(cyclamPH)]^+$	2.96(1)	2.136(11)	2.192(4)	2.254(4)	2.352(4)
$[PtCl(PPh_3)(cyclenP)]$	1.872(11)	2.120(10)	2.223(3)	2.214(3)	2.440(3)

Compound	f	g	f	i
$[PtCl(PEt_3)(cyclamPH)]^+$	86.4(3)	95.5(1)	94.0(2)	84.1(3)
$[PtCl(PPh_3)(cyclenP)]$	51.0(3)	110.3(1)	100.7(1)	97.6(3)

and crystallized by careful addition of diethyl ether followed by cooling to −18°C to yield $[PtCl(PEt_3)(cyclamPH)]Cl.CH_2Cl_2$ as colourless crystals (0.53 g, 0.76 mmol). *Anal.* calcd. for $C_{17}H_{38}Cl_4N_4P_2Pt$: C 29.3, H 5.49, Cl 20.3, N 8.03; found: C 29.1, H 5.55, Cl 18.1, N 8.06. ^{1}H NMR: PEt_3, δ(CH_3) 1.00 ppm (d, 17.9 Hz, of t, 7.7 Hz), δ(CH_2) 1.86 ppm (multiplet); cyclam, series of multiplets, 2.8–3.8 ppm; NH 5.66 ppm (1:4:1 t, J(Pt—H) 68 Hz). Other spectroscopic data are given in the Results section.

(2) Reaction of $[Pt_2Cl_4(PEt_3)_2]$ with cyclenPH

(i) Preparation of cyclenPH

Cyclen.4HCl was purchased from Geneva Chemical Co. but we were not successful in synthesising the required cyclenPH by direct reaction of cyclen.4HCl with $P(NMe_2)_3$. Previous workers used reaction of the free base with $P(NMe_2)_3$ (14). Accordingly, a Rexyn 201 OH^- column was prewashed with water until the washings were pH 7 and an aqueous solution of cyclen.4HCl was then passed through the column. The initial solution was acidic but the eluant was basic. After removal of the solvent water under reduced pressure the eluted material analyzed approximately as cyclen.$2H_2O$ and showed no appreciable chloride content by either addition of $AgNO_3$ or by potentiometric titration. *Anal.* calcd. for $C_8H_{24}N_4O_2$: C 46.1, H 11.61; found: C 46.2, H 10.19. This product was then reacted with $P(NMe_3)_3$ to prepare cyclenPH as previously described (14). ^{13}C and ^{31}P NMR spectra of the product were consistent with those reported previously. *Anal.* calcd. for $C_8H_{17}N_4P$: C 48.0, H 8.56; found: C 47.6, H 8.61.

(ii) Reaction with $[Pt_2Cl_4(PEt_3)_2]$

A solution of cyclenPH (0.11 g, 0.53 mmol) in dichloromethane (15 mL) was added dropwise to a stirred solution of $[Pt_2Cl_4(PEt_3)_2]$ (0.20 g, 0.26 mmol) in dichloromethane (15 mL). The mixture was stirred for 1 h before removal of the solvent *in vacuo*. The residue was washed with hexane (20 mL), dissolved in dichloromethane and crystallized by careful addition of diethyl ether followed by cooling to −18°C to yield $[PtCl_2(PEt_3)(cyclenPH_2)]Cl.\frac{1}{2}CH_2Cl_2$ as colourless crystals (0.16 g, 0.24 mmol). *Anal.* calcd. for $C_{14.5}H_{34}Cl_4N_4P_2Pt$: C 26.3, H 5.17, Cl 21.4, N 8.45; found: C 26.3, H 5.27, Cl 22.0, N 8.54. ^{1}H NMR: PEt_3, δ(CH_3) 1.14 ppm (d, 15.8 Hz, of t, 7.4 Hz), δ(CH_2) 1.78 ppm (multiplet); cyclen, complex multiplets, 3.40 and 3.59 ppm; NH 6.41 ppm. Other spectroscopic data are given in the Results section. Conductance in CH_3CN: 141 S cm^2 mol^{-1}.

A crystal of the complex was orthorhombic with a = 9.166(2), b = 20.063(3), and c = 14.283(3) Å, and the systematic absences in its X-ray diffraction pattern were consistent with space groups $Cmc2_1$ (No. 36), $Ama2$ (No. 40), or $Cmcm$ (No. 63). The density (1.66 g cm^{-3}) indicates four molecules per unit cell (calculated for $[PtCl_2(PEt_3)(cyclenPH_2)]Cl.\frac{1}{2}CH_2Cl_2$ is 1.68) which in space group No. 63 would lead to an impossibly high symmetry for the molecule. With four molecules per unit cell, space group No. 40 requires either that the molecule possess a plane of symmetry or a two-fold axis, and No. 36 requires a plane of symmetry.

(iii) Conversion to PF_6^- salt

A solution of $[PtCl_2(PEt_3)(cyclenPH_2)]Cl.\frac{1}{2}CH_2Cl_2$ (0.1 mmol) in dichloromethane (5 mL) was stirred with finely powdered KPF_6 (1 mmol) for 2 h. The supernatant was separated, diethyl ether added, and the solution cooled to −18°C to yield $[PtCl_2(PEt_3)(cyclenPH_2)]PF_6$ as pale yellow crystals. *Anal.* calcd. for $C_{14}H_{33}Cl_2F_6N_4P_3Pt$: C 23.0, H 4.55, N 7.67; found: C 23.0, H 4.48, N 7.65. ^{31}P NMR: δ(PN_4) −6.77 ppm (^1J(Pt—P) 3648 Hz); δ(PEt_3) 10.39 ppm (^1J(Pt—P) 2216 Hz); ^2J(P—P) 787 Hz; δ(PF_6) −143.87 ppm, ^1J(P—F) 713 Hz.

(b) X-Ray data collection

Crystals of $[PtCl(PEt_3)\{cyclamPH\}]Cl.CH_2Cl_2$ suitable for study by X-ray diffraction were grown by cooling (to −18°C) a solution of the complex in a mixture of diethyl ether and dichloromethane. Preliminary photographic work was carried out with Weissenberg and precession cameras using Cu K_α radiation. After establishment of the symmetry and an approximate unit cell the crystal was transferred to a Picker 4-circle diffractometer automated with a PDP11/10 computer and utilising Zr filtered Mo K_α radiation (λ = 0.71069 Å). The unit cell was refined by least-squares methods employing 22 pairs of centering measurements at ±2θ in the range $|2\theta|$ = 11–34°. The crystal was mounted approximately along the c axis. The crystal data at approximately 24°C were as follows:

$C_{17}H_{38}Cl_4N_4P_2Pt$ M_r = 697.37

Monoclinic, space group $P2_1/n$; a = 13.877(3), b = 23.231(7), c = 8.295(2) Å; β = 91.86(4)°; V(cell) = 2673(1) Å^3; Z = 4.

The asymmetric unit consisted of one molecule of the complex together with one molecule of dichloromethane. Intensity measurements were collected for two reciprocal space octants (h unrestricted, $k \geq 0$, $l \geq 0$) up to 2θ = 45°. A θ/2θ step scan was used with 160 steps of 0.01° in 2θ, counting for 0.25 s per step. Background measurements were for 20 s at each end of the scan. Each batch of 50 reflections was preceded by the measurement of three standard reflections (0,0,2; 0,8,0; and 2,0,0). The Lorentz and polarization factors were applied and each batch was scaled to maintain the sum of the standards constant. There was evidence of about 37% sample decomposition, possibly due to loss of CH_2Cl_2 during the data collection. Absorption corrections were applied with a numerical integration procedure utilizing a Gaussian grid (6 × 6 × 24). The crystal shape was defined by perpendicular distances to crystal faces from a central origin as follows: ±{100}, 0.1144 mm; ±{010}, 0.1234 mm; ±{001}, 0.4049 mm. The absorption coefficient was 60.50 cm^{-1}, and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

range of transmission factors was 0.22–0.30. Symmetry equivalent data were averaged and the final file contained 3481 independent reflections.

(c) Structure solution and refinement

The structure was found and refined using the SHELX-76 program package (15) and illustrations were drawn using ORTEP (16). The atomic scattering factors used were for neutral atoms, with corrections for anomalous dispersion (17). The structure was solved by direct methods, completed by standard Fourier synthesis procedures using difference maps, and refined by the method of least squares minimising $\Sigma w\Delta^2$ where $\Delta = ||F_o| - |F_c||$. The weights were obtained from counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$. Hydrogen atoms were not located but, except for that on the coordinated nitrogen atom and those in the CH_2Cl_2 solvent, their positions were calculated and included in the refinement. They were allowed to ride at 1.080 Å from their respective carbon atoms and temperature factors were calculated for the CH_n groups. All non-hydrogen atoms were treated anisotropically. There were 256 variable parameters to be determined from 3481 independent observations. Convergence was obtained with a maximum shift/esd ratio of 0.11. The residuals were $R = 0.0872$ and $R_w = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2} = 0.0795$. The final difference map had a maximum of +3.5 e Å^{-3} close to the platinum atom and a minimum of −3.1 e Å^{-3}, but gave no indication that any material had been overlooked. A peak of 0.68 e Å^{-3} at 1.16 Å from the coordinated nitrogen atom was evidence for a hydrogen at this location.

Received July 6, 1988

C. T. YIM and D. F. R. GILSON. Can. J. Chem. **67**, 54 (1989).

The orientational order parameters of *ortho*-, *meta*-, and *para*-dichlorobenzene, dissolved in the nematic solvents EBBA and 1132, have been measured as functions of temperature and concentration, and used to determine the values of the potential energy parameters for each solute–solvent pair. These potentials have been interpreted in terms of a short-range contribution, which depends upon the shape and size of the solute molecule, plus a long-range term due to the interaction between the average electric field gradient from the solvent and the molecular quadrupole moment of the solute.

Key words: dichlorobenzenes, nematic solvents, liquid crystals, orientation, potential energy parameters.

C. T. YIM et D. F. R. GILSON. Can. J. Chem. **67**, 54 (1989).

Les paramètres d'ordre d'orientation des *ortho*-, *meta*- et *para*-dichlorobenzènes dissous dans les solvants nématiques EBBA et 1132 ont été mesurés en fonction de la température et de la concentration et ils ont été utilisés pour déterminer les paramètres d'énergie potentielle de chacune des paires de soluté–solvant. On a interprété ces potentiels en fonction d'une contribution à courte distance, qui dépend de la forme et de la grosseur de la molécule soluté, et d'une contribution à longue distance qui dépend de l'interaction entre le gradient du champ électrique moyen provenant du solvant et la moment quadripolaire moléculaire du soluté.

Mots clés : dichlorobenzènes, solvants nématiques, cristaux liquides, orientation, paramètres d'énergie potentielle.

Introduction

The factors that determine the orientation of a solute molecule dissolved in a liquid crystal solvent are of interest in view of the technological applications of guest–host liquid crystal display devices, and also as probes of intermolecular forces in anisotropic media. The aim of the present studies is to derive parameters that link the terms in an orientational potential function with molecular properties of the solute. Early attempts by Saupe and Nehring (1, 2) to derive such expressions used a bond additive model for various fluoro- and chloro-benzene derivatives, which gave approximate agreement with the experimental results, but, due to the lack of experimental data at that time, this approach did not examine the effects of temperature, concentration, and solvent. Subsequent studies (3–18) have shown that the behaviour is more complicated, and the mean field approach, with a dependence on dispersion forces alone, is probably an oversimplification.

Burnell and co-workers (19–23) have proposed that the interaction between the solute molecular quadrupole moment and the solvent electric field gradient makes an important contribution to the ordering potential, particularly for small molecules. In recent studies of the orientation behaviour of monochlorobenzene (17), dissolved in two nematic liquid crystal solvents of different properties, EBBA and 1132, it was shown that the ring moiety played an important role in determining the difference in the solute orientational order in these two solvents. Since the field gradients in these two solvents are of opposite sign, it now seems probable that the observed differences in the orientation of chlorobenzene arise from the interaction with the quadrupole moment. The present study extends this to examine the effect of additional chlorine substitution.

The order parameters can be conveniently determined from an analysis of the proton magnetic resonance of the partially aligned solute molecules (24). Since all three solute molecules possess two perpendicular planes of symmetry, the orientation can be described by the elements of the Saupe order matrix S_{33} and $(S_{11} - S_{22})$. For the dichlorobenzenes, the 3-axis is taken to be the long molecular axis, and the 2-axis to be perpendicular to the benzene ring (Fig. 1). Thus S_{33} describes the tendency of the long molecular axis to align parallel to the director, and $(S_{11} - S_{22})$ describes the difference in alignment of the two perpendicular axes.

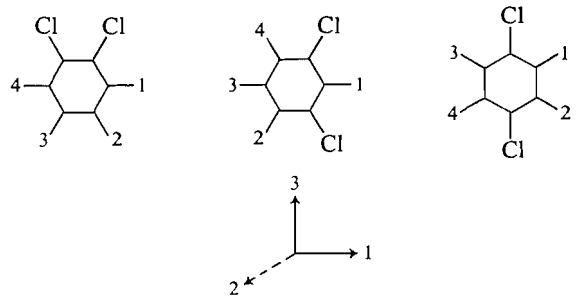

FIG. 1. Coordinate system and atomic labelling for dichlorobenzenes.

The calculated order parameters are obtained via the integrations of eqs. [1] and [2]:

$$[1] \quad S_{33} = (3/2Z)\int\int(\cos^2\theta \exp\{-U(\theta,\phi)/kT\}\sin\theta d\theta d\phi) - (1/2)$$

$$[2] \quad S_{11} - S_{22} = (3/2Z) \times \int\int(\sin^2\theta \cos 2\phi \exp\{-U(\theta,\phi)/kT\}\sin\theta d\theta d\phi)$$

where

$$Z = \int\int \exp\{-U(\theta,\phi)/kT\}\sin\theta d\theta d\phi$$

The intermolecular interaction potential $U(\theta,\phi)$, in this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

study, is written as

$$[3] \quad U(\theta,\phi) = -AS_1(\cos^2\theta + B\sin^2\theta\cos 2\phi)$$

where S_1 is the solvent order parameter, and

$$[4] \quad A = a[3] - (1/2)(a[1] + a[2])$$

and

$$[5] \quad B = (a[1] - a[2])/(2a[3] - a[1] - a[2])$$

The constants $a[i]$ characterize the interaction energy along the corresponding axis. The parameter A corresponds to a potential energy difference between two solute orientations with axis 3 parallel and perpendicular to the liquid crystal director, and AB is the difference between orientations with axis 1 and axis 2 parallel to the director. The parameter A will include both solute and solvent terms, but B should depend only upon the solute properties.

Experimental

The two liquid crystal solvents used were 1132, a mixture of cyanophenylcyclohexanes and cyanobiphenylcyclohexanes, which was supplied by BDH Chemicals Ltd., and EBBA (*N*-(*p*-ethoxybenzylidine)-*p'*-*n*-butylaniline), which was synthesized and purified by literature methods (25). The dichlorobenzenes were purchased from commercial sources and used without further purification. Samples of various concentrations were prepared by weighing appropriate amounts of solute and solvent into NMR tubes and then sealing under vacuum. The concentrations and nematic to isotropic transition temperatures of the samples studied are listed in Table 1.

The proton NMR spectra were recorded on either a Varian XL-200 or a Varian XL-300 spectrometer. Since spectra obtained with or without the use of the deuterium lock did not show any difference, most spectra were recorded without the lock. The temperatures were calibrated against the proton chemical shift difference in an ethylene glycol sample.

The spectral analyses were performed with a modified LAOCN 3 program using either an Olivetti M-24 or IBM PC microcomputer. For *p*-dichlorobenzene, the geometry published by Burnell *et al.* (26) was used to determine the order parameters. For the other dichlorobenzenes the geometry was varied until reasonable fits (rms error less than 1.0 Hz) to the experimental room temperature spectra were achieved, and the same geometry was used for analyzing the spectra recorded at other temperatures.

Results and discussion

The relative interproton distances of *ortho*- and *meta*-dichlorobenzene, Table 2 (for atomic labelling see Fig. 1), are in reasonable agreement with those reported by Diehl *et al.* (27–30) but, since the early results were obtained in azoxy-type liquid crystal solvents, exact agreement is not expected. Vibrational averaging effects have been ignored in the present work as the effect upon the calculated order parameters is small, and can be neglected in studying the orientation behaviour and its variation with temperature (12).

The A and B terms in the potential function were calculated by computing fits to eqs. [1] and [2] for each experimental value of the orientation parameter. The solvent order parameter values were obtained from the literature (32, 33).[1] The order parameter values cited for 1132 were derived from refractive index measurements (33), which depend upon the method used in their interpretation; those derived according to Neugebauer's approach (34) have been used. The order parameter of the solvent is a function of reduced temperature and is, therefore, independent of the solute and its concentration (35). The parameter A is expected to be dependent on temperature since it includes the distance dependence of the intermolecular forces. However, including this dependence by using the molar volume did not lead to significant improvement in the fit (17) and, in view of the uncertainty in the values of solvent order, the volume dependence of A was neglected in our analyses.

The variation of $S_{11} - S_{22}$ with S_{33} is a convenient way of

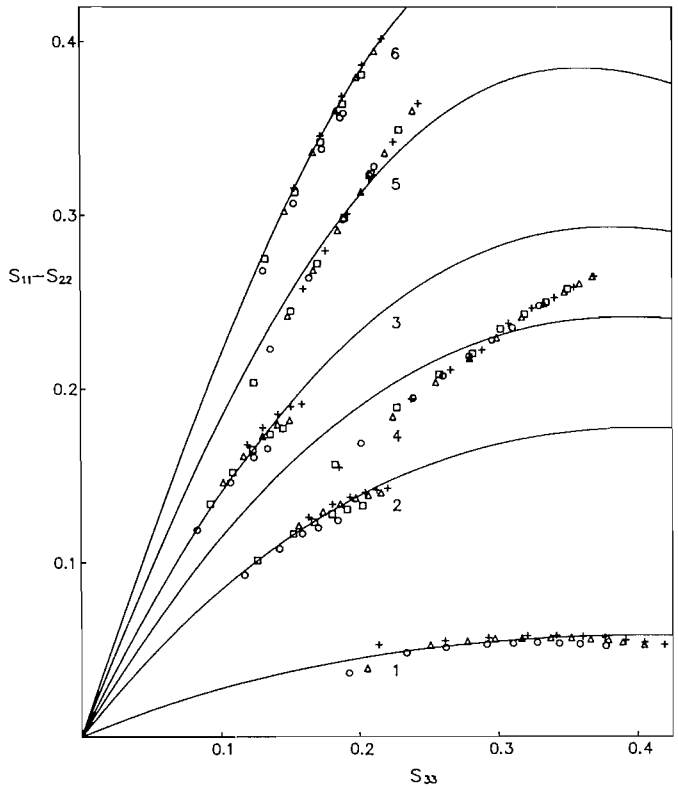

FIG. 2. Variation of $(S_{11} - S_{22})$ with S_{33} of dichlorobenzenes. 1, *p*-dichlorobenzene in EBBA, concentrations (in mol%) are: ○, 9.6; △, 3.9; +, 1.9; 2, *m*-dichlorobenzene in EBBA, concentrations are ○, 9.7; □, 6.9; △, 3.5; +, 2.2; 3, *o*-dichlorobenzene in EBBA, concentrations are ○, 10.1; □, 6.3; △, 4.1; +, 1.9; 4, *p*-dichlorobenzene in 1132, concentrations are ○, 9.5; □, 6.0; △, 3.1; +, 1.4; 5, *m*-dichlorobenzene in 1132, concentrations are ○, 10.6; □, 5.5; △, 2.8; +, 1.2; 6, *o*-dichlorobenzene in 1132, concentrations are ○, 10.5; □, 5.5; △, 2.7; +, 1.0. The solid lines are the calculated dependences of $(S_{11} - S_{22})$ on S_{33}, based on the average value of B for the most dilute solution (see Table 1).

illustrating the solute orientation parameter dependence upon the value of the parameter B. Plots of $S_{11} - S_{22}$ vs. S_{33} are shown in Fig. 2, together with calculated curves for different B values. The derivation of eq. [3] requires that B should be independent of solvent and of temperature, but, as was observed in the case of chlorobenzene (17) and for a number of other aromatic solutes (12, 15, 18), there is a strong solvent dependence of the parameter B (or its equivalent). Figure 2 also shows that there is a smaller variation with temperature and concentration, where the experimental value of B increases with increasing temperature in EBBA, but decreases in 1132. Emsley *et al.* (15, 16) have suggested that, for rigid molecules, the temperature dependence of B can be attributed to the neglect of higher rank terms in the assumed orientation potential, or to the biaxiality of the solvent molecules. Except for the case of *p*-dichlorobenzene in 1132, a reasonable fit of the order parameters can be obtained for a given value of B, and, rather than introduce additional terms in the potential, we choose to consider the averaged values of the energy parameters for each concentration, and to compare these with those derived for various molecular properties. The average values of A and B are listed in Table 1 for each of the systems studied. Both parameters A and AB were found to decrease with increasing solute concentration and have been fitted as linear functions of concentration to give A_0 or A_0B_0, the infinite dilution values, as the intercepts. For each solute, both A and AB are less dependent on concentration for 1132 than for EBBA. Similarly, the nematic to isotropic transition temperatures show a smaller depression in 1132, indicating a greater compatibility between solute and solvent (36). This indicates that these aromatic solutes are more capable of correlating their molecular orientations with the solvent 1132 than with EBBA, and hence are less effective in disordering 1132. Gas–liquid chromatographic studies (37) have shown that aromatic solutes prefer nematic solvents of the cyanobiphenyl type to Schiff-base type solvents (in this case MBBA). These conclusions are consistent with the present results and confirm that aromatic solutes are more highly oriented in 1132 than in EBBA.

If the $a[i]$ terms in eqs. [4] and [5] are replaced by the components of the polarizability tensor (38), or by molecular dimensions (based on van der Waals radii (39) and length model (18)), then the parameters B[pol] and B[vdW], given also in Table 3, can be derived and compared with the experimental values. There is no agreement for either solvent, but if the experimental values of B_0 are plotted against the calculated values, as in Fig. 3, there is a nearly linear dependence of B_0 on these parameters for the mono, *meta*, and *para* derivatives. Furthermore, the lines for each solvent are nearly parallel, with slopes close to unity. The point for *ortho*-dichlorobenzene lies above the line in the case of polarizability, but below in the case of molecular shape. This difference arises because the polarizability tensor for *ortho* and *meta* derivatives should be the same, but there is a difference in the dimensional or shape parameter.

The experimental values of A_0 are plotted in Fig. 4 against the values of A_0[vdW] calculated using eq. [4] with the appropriate molecular dimensions and van der Waals radii. The earlier results on benzene, trichlorobenzene, and tribromobenzene (18) are included. A reasonable correlation exists and the behaviour resembles that shown in Fig. 3 in that parallel lines are obtained. This result for both potential terms A_0 and B_0 for the two solvents suggests that there is a contribution to the ordering potential that leads to an enhancement of the solute orientation in 1132 and a diminution in EBBA. In their recent study of the orientation of small molecules with C_3 or higher symmetry, Burnell and co-workers (19, 23, 40) have demonstrated the importance of an interaction between the electric field gradient of the solvent and the molecular quadrupole moment of the solute. To include this contribution to the potential, each $a[i]$ is assumed to consist of a long-range interaction due to the field gradient – molecular quadrupole moment interaction, plus a size–shape dependent short-range interaction. Then $A_0 = A_{0LR} + A_{0SR}$, and $A_0B_0 = (A_0B_0)_{LR} + (A_0B_0)_{SR}$.

The short-range interactions are given by eqs. [4] and [5] with the $a[i]$ terms replaced by the van der Waals dimensions, and the long-range terms, A_{0LR} and $(A_0B_0)_{LR}$, by

$$[6] \quad A_{0LR} = (1/2)(Q_{33} - (Q_{11} + Q_{22})/2)F_{zz}/S_1$$

$$[7] \quad (A_0B_0)_{LR} = (1/4)(Q_{11} - Q_{22})F_{zz}/S_1$$

where Q_{ii} are the components of the molecular quadrupole moment tensor, and F_{zz} is the average electric field gradient along the liquid crystal director, the z-axis. The electric field gradient is temperature dependent, and it seems reasonable to assume that it is proportional to the solvent order parameter,

S_1, so that $F_{zz} = F_{zz}^0 \cdot S_1$ and where F_{zz}^0 should be a constant for a given solvent.[2]

Using the average of the data reported (21) for the two solvents at 298 and 320 K, the F_{zz}^0 values were found to be 2.41×10^{18} and -2.62×10^{18} V m^{-2} for 1132 and EBBA, respectively. Thus, if the molecular quadrupole moments are known, the long-range contributions can be calculated, but, unfortunately, the available data on the quadrupole moments of chloro-substituted benzenes are extremely sparse and do not permit any direct calculation of A_{0LR} and $(A_0B_0)_{LR}$, using eqs. [6] and [7]. The required data have been reported, however, for benzene and the trichloro and tribromo derivatives (41–44) and the two terms $(Q_{33} - (Q_{11} + Q_{22})/2)$ and $(Q_{11} - Q_{22})$ are both positive quantities in all cases. The results shown in Figs. 3 and 4 are thus explained by the opposite signs of the electric field gradients since the long-range interactions make a positive contribution to the total orientational potential in 1132 but a negative contribution in EBBA.

[2]The assumption that the electric field gradients are proportional to the solvent order parameter can be avoided if the data are compared at the same reduced temperatures used by Burnell and co-workers (21) since the order parameter is a universal function of reduced temperature. This limits the fit to only two temperatures in each case. The results are unchanged.

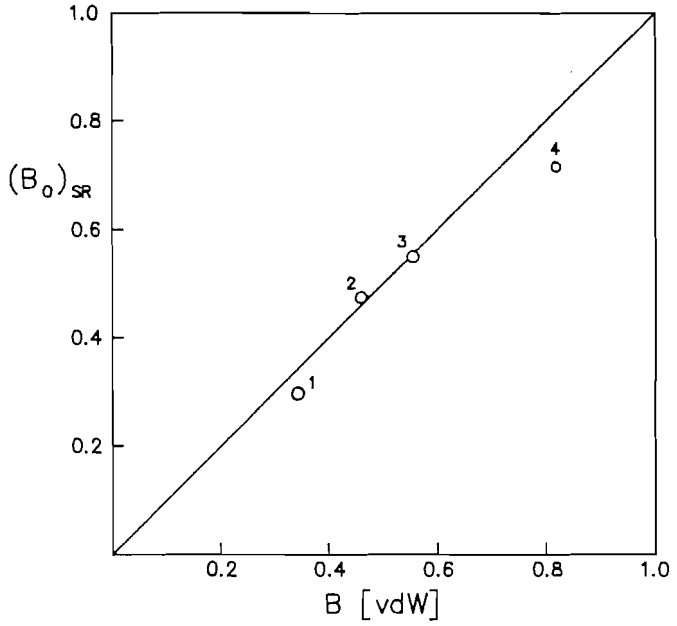

FIG. 5. Short-range interaction parameters B_{0SR} vs. B[vdW]. 1, *p*-dichloro; 2, monochloro; 3, *m*-dichloro; and 4, *o*-dichloro.

In the absence of molecular quadrupole moment data on chlorobenzene and the dichloro derivatives, it is necessary to eliminate some of the unknown parameters and to assume that, for a given solute, the ratios of the functions ${A_{0SR}}^{1132}/{A_{0SR}}^{EBBA}$ and $(A_0B_0)_{SR}{}^{1132}/(A_0B_0)_{SR}{}^{EBBA}$ should be equal. The short-range interaction can be written, eq. [8],

$$[8] \quad {A_{0SR}}^{1132} = w({A_0}^{EBBA} - x.{A_0}^{1132})/(1 - w.x)$$

where $w = {A_{0SR}}^{1132}/{A_{0SR}}^{EBBA}$, and x is the ratio of the two electric field gradients, $(F_{zz}^0)^{EBBA}/(F_{zz}^0)^{1132}$. Similar equations can be derived for ${A_{0SR}}^{EBBA}$ and for the $(A_0B_0)_{SR}$ terms. B_{0SR} is solvent independent and can be expressed as, eq. [9],

$$[9] \quad B_{0SR} = ((A_0B_0)^{EBBA} - x.(A_0B_0)^{1132})/({A_0}^{EBBA} - x.{A_0}^{1132})$$

so that it is independent of the ratio w. Using the F_{zz}^0 values given previously, the B_{0SR} values have been calculated and are given in Table 3 and plotted versus B_0[vdW] in Fig. 5. It can be seen that there is now good agreement for both solvents. This confirms the hypothesis that the short-range forces are proportional to a molecular shape or dimension function.

The values of $(F_{zz}^0)^{1132}$ and $(F_{zz}^0)^{EBBA}$ were calculated from the field gradient data of Burnell and co-workers (21) from their studies on the orientation of HD and D_2, and the extension to the molecules studied in the present work assumes that benzene and the chlorobenzenes experience the same average electric field gradient as the much smaller molecules. However, since the *ratio* of the field gradients is used, the calculated values of B_{0SR} are not likely to be strongly affected by this assumption.

Equation [8] can be used to derive individual values of the short- and long-range contributions, if a value for w is known. For example, if w is assumed to be independent of the solute, then w can be obtained in those cases where the molecular quadrupole moments are known. From the results obtained in earlier studies (18) on benzene, trichloro-, and tribromobenzene, the values of w are 0.90, 1.24, and 1.24, respectively. However, these ratios are subject to the rather large uncertainties involved in the experimental molecular quadrupole moments; for benzene the values reported for the principal component of the quadrupole tensor range from -10 to -42×10^{-40} C m^2 (31, 41–43). Using the average of the values given above for w, the calculated short- and long-range A_0 and A_0B_0 quantities are given in Table 3, and Table 4 lists the molecular quadrupole moments calculated from the long-range interactions. These values are reasonable but, in view of the errors involved, it is not suggested that they have any claim to accuracy.

TABLE 4. Molecular quadrupole moments, $\times 10^{-40}$ C m^2

	Q_{11}	Q_{22}	Q_{33}	Q_{22}(exp)

[b]Reference 44.
[c]Reference 44.

Both the short- and the long-range interactions are assumed to have the same dependence on the solvent order parameter. We also assume that the local environment in the host solvent seen by different solute molecules is unchanged, in particular that the solvent order parameter and the electric field gradient are invariant over all the local environments that a solute molecule might prefer.

Since there are two different mechanisms responsible for the solute orientation, and since molecular quadrupole moments are not additive properties, bond additive models are not suitable for describing the orientation of solute molecules in liquid crystal solvents.

Introduction

1-Acenaphthenol has been shown, by Schocken and Gibson (1), to form as an early metabolite in the bacterial oxidation of acenaphthene and acenaphthylene. The metabolism of acenaphthylene and acenaphthalene in mammalian systems was first examined by Young and co-workers, who established that these were metabolized to mixtures of *cis*- and *trans*-1,2-diols, acenaphthenequinone, and 1,8-naphthalic acid (2). Later studies by Simmons *et al.* (3) showed that a possible metabolite 1-acenaphthen-1-ol was oxidized to the ketone, which was further oxidized to 1,8-naphthalic acid. In an effort to learn more about the stereochemical preferences of some of the enzymes involved in these oxidations, we first established the configuration of *trans*-1,2-dihydroxyacenaphthene (4) and now turn our attention to the configuration of 1-acenaphthenol. Although this alcohol has been shown to be a substrate for several dehydrogenases (5–7), we were unable to find any reports describing the preparation of chiral material. We describe here a procedure for resolving the alcohol via its camphanate ester and the results of an X-ray structure determination of the (+)-camphanate ester of the (−)-alcohol, which establishes its configuration.

Discussion

The crystal conformation is depicted in Fig. 1 as an ORTEP (8) drawing and a packing diagram is given as Fig. 2. Molecular dimensions are given in Table 1 and a short table of C and O parameters as Table 2. Full refinement parameters, including anisotropic thermal parameters and hydrogen parameters, are available as supplemental material.[1] Since the observed absolute configurations at C1′ and C4′, *S* and *R* as depicted in Fig. 1, agree with the known configuration of (−)-camphanic acid as unambiguously determined by its synthesis from (+)-camphor following Gerlach (9), the absolute configuration at C1 is *R* as depicted. The chiral angles, which Ito, Kasai, and Silverton (10) have designated χ, are −69.9(1), +56.1(2), and +64(2)° for C1′, C4′, and C1, respectively. The molecular packing, as shown in Fig. 2, is reasonably efficient and contacts are of the order of van der Waals distances.

As mentioned in the introduction, 1-acenaphthenol has been employed as a substrate in assaying an indanol dehydrogenase found in rabbit liver (6) and in a dehydrogenase found in a *Beijerinckia sp.* strain B8/36 (1). While the optical purities of 1-acenaphthenol obtained by fractional crystallization of the camphanate were adequate for the crystallographic study, higher purities are required for studies of the relative rates of oxidation of the different enantiomers. We have found that the diastereomeric camphanates can be completely separated by preparative hplc on a silica column employing either methylene chloride (α = 1.13) or a 4:1 mixture of cyclohexane:ether (α = 1.23).

There have been previous crystallographic investigations of the racemates of acenaphthenol (11), acenaphthendiol (12), and acenaphthenquinone (13). These are early studies involving photographic, visually estimated intensity data but in all cases the molecular skeleton is reported to be flat and to possess symmetry consonant with the chemical formula. In the alcohols, but not in the quinone, the C1—C2 bond is longer than the usual value for a single bond and this observation also applies to the present structure where the length of the C1—C2 bond is 1.561(6) Å. The acenaphthenol skeleton in this structure exhibits small but significant deviations from planarity, with the greatest deviations at C2, which is 0.024 and 0.043 Å from the planes of the five-membered ring and the acenaphthene skeletons, respectively (Table 3). The fused naphthalene and cyclopentane rings are close to coplanarity and the individual ring dihedral angles do not exceed 1.5°. There are small differences in bond lengths that would not be predicted from the chemical formula, C7—C8:C3—C4, C2a—C3:C8a—C8, and C2a—C8b:C8a—C8b having differences of 0.044, 0.014, and 0.023 Å, respectively, but only the first difference is significant.

Experimental

Preparation of (+) 1-acenaphthenyl camphanate

To a cold (0°C) solution of 1.70 g of racemic 1-acenaphthenol and 1.34 g of 4-dimethylaminopyridine in 50 mL of methylene chloride

[1]These data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*Positional parameters are multiplied by 10 000 and equivalent *U* values by 1000. The equivalent *U* values are the geometric means of the diagonal terms of the vibration tensors.

was added 2.38 g of (−)-camphanic acid chloride. The reaction mixture was stirred overnight and allowed to warm to room temperature. The methylene chloride solution was first washed with water, then with saturated $NaHCO_3$, and dried over Na_2SO_4. The organic solution was concentrated and the residue crystallized 4 times from hexane. The resolution was monitored by gc on a HP 5890A gas chromatograph at 230°C using a 25-m SE-30 capillary column.[2] The ee of the crystalline material was 91%, mp 139–140°C; $[\alpha]_D$ +75.0° (*c* 2.25, $CHCl_3$).

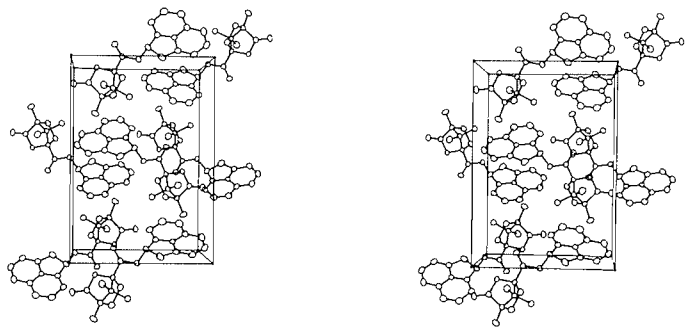

FIG. 2. Packing diagram. The direction of projection is *a*.

A sample strongly enriched in the (−)-camphanate was prepared by removing the higher melting, more crystalline (+)-enantiomer.

Preparation of (−)-1-acenaphthenol

To a solution of 100 mg (0.28 mmol) of (+)-1(*R*)-acenaphthenyl camphanate, $[\alpha]_D$ +75.0° (*c* 2.25, $CHCl_3$), was added 1.7 mL of 0.2 N NaOH and the solution refluxed for 3 h. The solution was concentrated and the residue extracted with ethyl acetate. The extract was washed with saturated $NaHCO_3$, water, dried, and concentrated. The crude alcohol was purified by flash chromatography on silica gel to yield (−)-1(*R*)-acenaphthenol (41 mg; 83%), $[\alpha]_D$ −1.46° (*c* 1.23, $CHCl_3$); mp 127–127.5°C.

Preparation of (+)-1-acenaphthenol

Hydrolysis of the (−)-camphanate, ee 88% as determined by gc,[2] yielded a sample of the (+)-alcohol, mp 125°C; $[\alpha]_D$ +1.34° (*c* 1.16, $CHCl_3$).

Pentacoordination and ionic character: crystal structure of Ph_4SbBr

OSVALD KNOP,[1] BEVERLY R. VINCENT, AND T. STANLEY CAMERON
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received March 29, 1988

OSVALD KNOP, BEVERLY R. VINCENT, and T. STANLEY CAMERON. Can. J. Chem. **67**, 63 (1989).

Ph_4SbBr ($P2_1/n$, a = 12.282(2) Å, b = 10.656(1) Å, c = 16.156(1) Å, β = 104.92(7)°, Z = 4) crystallizes with the same space group as Ph_4SbCl, but the two compounds are not isostructural. The structure of Ph_4SbBr consists of layers of Ph_4SbBr molecules with the Br atoms almost exactly in the 10$\bar{1}$ planes. The coordination figure of the Sb atom is a trigonal bipyramid (TBP) with Br in an axial position. The Sb—Br distance, 2.950(1) Å, is the longest reported for Sb(V) to date. The Sb(V)—Hal bond lengths and the Ph_4SbBr and Ph_4SbCl structures are compared in detail. Analysis of a large sample of Ph_4EX (E = P, As) structures and of all the available R_4EX (E = Sb, Bi; R = Ph, Me) structures shows that the former are always ionic, $R_4E^+X^-$, whereas in the latter the observed coordination figures represent R_4EX trigonal bipyramids with various degrees of axial distortion. The inverse variation of the axial bond lengths (the *trans* effect) in the TBP Sb compounds can be quantified as $Sb—C_{ax} \sim 2.4(Sb—X)^{-1/9}$ to a very high degree of correlation. This and other geometric relationships show that there exists a limiting E—X bond length (~3.3 Å for E = Sb and ~3.5 Å for E = Bi when X is oxygen) at which the TBP coordination becomes unstable and changes over to a tetrahedral R_4E. This change is accompanied by a rearrangement of the structure to an ionic $R_4E^+X^-$ solid (of high symmetry where permitted by the size and shape of the anion) with E···X separations no smaller than ~4 Å when E = Sb or Bi and X = O. The distribution of the CEC angles in the Ph_4EX (E = P, As) sample is analyzed; the mean (uncorrected) P—C and As—C bond lengths in Ph_4E^+ are found to be 1.789(11) and 1.902(12) Å, respectively.

Key words: crystal structure, organoantimony compounds, Ph_4SbBr, pentacoordination, tetraphenylantimony bromide.

OSVALD KNOP, BEVERLY R. VINCENT et T. STANLEY CAMERON. Can. J. Chem. **67**, 63 (1989).

Le Ph_4SbBr ($P2_1/n$, a = 12,282(2), b = 10,656(1) et c = 16,156(1) Å, β = 104,92(7)° et Z = 4) cristallise dans le même groupe d'espace que le Ph_4SbCl; toutefois, les deux composés ne sont pas isostructuraux. La structure du Ph_4SbBr est formée de couches de molécules Ph_4SbBr comportant des atomes de Br qui sont pratiquement dans les plans 10$\bar{1}$. La coordinence autour de l'atome de Sb est du type trigonal bipyramidal (TBP) avec un Br dans la position axiale. La distance Sb—Br, 2,950(1) Å, est la plus longue rapportée à date pour un Sb(V). On a effectué une comparaison détaillée des longueurs des liaisons Sb—Hal ainsi que des structures des Ph_4SbBr et Ph_4SbCl. Un examen d'un grand échantillon de structures de Ph_4EX (E = P, As) ainsi que de toutes les structures disponibles de R_4EX (E = Sb, Bi; R = Ph, Me) montre que les premières sont toujours ioniques, $R_4E^+X^-$, alors que dans les dernières les coordinences observées pour les composés R_4EX sont du type trigonal bipyramidal avec divers degrés de déformation. L'équation $Sb—C_{ax} \approx 2{,}4(Sb—X)^{-1/9}$ permet de quantifier avec un très haut degré de corrélation la variation inverse des longueurs des liaisons axiales (l'effet *trans*) des composés TBP du Sb. Cette relation ainsi que d'autres relations géométriques montrent qu'il existe une longueur limite de la liaison E—X (≈3, 3 Å pour E = Sb et ≈3,5 Å pour E = Bi lorsque X est un oxygène) au-delà de laquelle la coordinence TBP devient instable et se transforme en un tétraèdre R_4E. Ce changement est accompagné par une transposition de la structure en un solide ionique $R_4E^+X^-$ (de haute symétrie lorsque la grosseur ainsi que la forme de l'anion le permettent) dans lequel les séparations E···X ne sont pas plus faibles que ≈4 Å lorsque E = Sb ou Bi et X = O. On a analysé la distribution des angles CEC dans l'échantillon de composés Ph_4EX (E = P, As); on a trouvé que les longueurs moyennes des liaisons (non corrigées) P—C et As—C des composés Ph_4E^+ sont respectivement de 1,789(11) et 1,902(12) Å.

Mots clés : structure cristalline, composés organo-antimoniés, Ph_4SbBr, pentacoordination, bromure de tetraphenylantimoine.

[Traduit par la revue]

Crystalline compounds of the compositions $(Ph_4E)_mX_n$ (E = P, As, Sb, Bi) may be salts of the cations Ph_4E^+ or they may contain E with covalent bonds additional to the four C—C bonds. With E = P and As the E atom is, to the authors' knowledge, always four-coordinated, forming tetrahedral Ph_4E^+ cations.[2] The large size of these ions makes them very suitable as counter ions in the stabilization and characterization of large anions. Since this in fact is the main reason for the appearance of the very numerous tetraphenylphosphonium and -arsonium salts in the literature, it is not surprising that the interest in the properties of these cations *per se* has been secondary and that in only a fraction of the known salts has the cation received attention for its own sake.

Table 1 lists Ph_4P^+ and Ph_4As^+ salts of monatomic and other small anions the structures of which may be regarded as being dominated essentially by the Ph_4E^+ geometry.[3] The features of the cations in these compounds may be summarized as follows. The CEC angles range from ~103° to ~116° and have a distribution shown in Fig. 1, with statistics as in Table 2. The weakly bimodal character of the total CEC distribution appears to arise from the fairly large proportion of Ph_4E^+ ions of symmetry S_4 or $C_2 \sim S_4$ in the sample: the CEC angle 2α bisected by the C_2 axis is in these cases smaller than the CEC angle 2α′ between C atoms not related by C_2.[4] For ions of S_4 symmetry, $\tan\alpha' = [1 + 2(\tan^2\alpha)^{-1}]^{1/2}$; the distribution of these angles is also shown in Fig. 1. A more comprehensive sample would be needed to determine whether the separate distributions for E = P and E = As are significantly different. The mean of the (uncorrected) E—C bond lengths in these compounds is 1.789(11) Å for P and 1.902(12) Å for As (Table 2), the total ranges being 1.768–1.812 Å for P and 1.878–1.918 Å for As. The deviations of the internal CCC angles in the phenyl rings from 120° are not statistically significant even for the CCC angle adjacent to the E atom.

[1]To whom correspondence may be addressed.

[2]For a classification of structure types and packing arrangements see ref. 1.

[3]Although *geometrically* Ph_4E^+ could attain the D_{2d} symmetry, the highest observed symmetry in these ions is S_4.

[4]The exception appears to be $Ph_4As[HCl_2]$ (9), in which the C_2 symmetry of the cation does not approximate S_4 closely. In ref. 16 the angles 2α and 2α′ in $Ph_4As[FeCl_4]$ should be reversed.

[a]TC, tetrahedral Ph_4E^+ cation; TBP, trigonal bipyramid; SP, square pyramid; DO, distorted octahedron. Boldface indicates that crystal structure has been determined; ordinary type refers to evidence from vibrational spectra, Mössbauer spectra, conductometry etc. For method and particulars see refs. 2 and 3.
[b]In Ph_3MeSbF ($P2_1/c$) the axial positions of the TBP are occupied by Ph and F (4).
[c]In $Ph_4PBr \cdot H_2O$ and $Ph_4PBr \cdot 2H_2O$ (54).
[d]Fe (16), Ga (8), In (8, 16), Tl (17).
[e]$Ph_4AsNO_3 \cdot HNO_3$ ($C2/c$) (21).
[f]Monohydrate.
[g]TBP in $Ph_5Sb \cdot \frac{1}{2}C_6H_{12}$ ($P\bar{1}$) (32).
[h]$(Ph_4P)_2CuCl_4 \cdot H_2O$ ($P2_1/n$) (34).
[i]Distorted *anti*-CdI_2-type structure.

For E = Sb and Bi the situation is less simple. Here the only Ph_4EX crystal to date shown to be ionic on crystallographic evidence is Ph_4BiClO_4, although other evidence (vibrational and Mössbauer spectra, conductometry etc.; cf. refs. 2 and 3) points to the salt-like character of Ph_4SbClO_4, Ph_4EBF_4, and a number of other crystals containing composite anions (Table 1).[5] In all the other known structures Sb and Bi are five-coordinated, with trigonal-bipyramidal (TBP) coordination geometry (for Ph_5Sb see below) and with X in an axial position.

[5]The differences in the character of solid Ph_4EX compounds are reflected in their melting points. The trends observed in the Ph_4EHal, Ph_4EBF_4, and Ph_4EBPh_4 series are shown in Fig. 2.

The criteria of existence of the onion salts *vis-à-vis* the TBP species do not seem to have been formulated, and since pentacoordination presents interesting problems of its own, we have attempted, in the following, to analyze the existing structural evidence with this in mind. To increase the size of the small Ph_4EX (E = Sb, Bi) sample, we have determined the crystal structure of Ph_4SbBr and included in our considerations Me_4EX (41, 42, 53) and Ph_3MeSbF (4). Particulars of the main geometric features are assembled in Table 3.

Coordination geometry of Ph_4EX (E = Sb, Bi) species

The existence of the deviations of the $C_{ax}EX$ (E = Sb, Bi) angles from 180° (Table 3) might be thought to be indicative of

an incipient tendency of the TBP coordination geometry at the pentacoordinate E atom to undergo a distortion toward a square-pyramidal (SP) geometry, i.e. of a frustrated intramolecular ligand-exchange process via a pseudorotation mechanism. In that case the $C_{ax}EX$ angle and one of the geometric indices of the extent of the TBP → SP transition, the dihedral angle δ_{24} (= the $C_{ax}C_{eq}C_{eq}'/C_{eq}C_{eq}'X$ angle at the $C_{eq}C_{eq}'$ edge enclosed in the $C_{ax}EX < 180°$ angle), would be expected to follow a Berry coordinate, i.e. show a linear association (cf. for example ref. 43). However, the scatter in a plot of $C_{ax}EX$ vs. δ_{24} for the

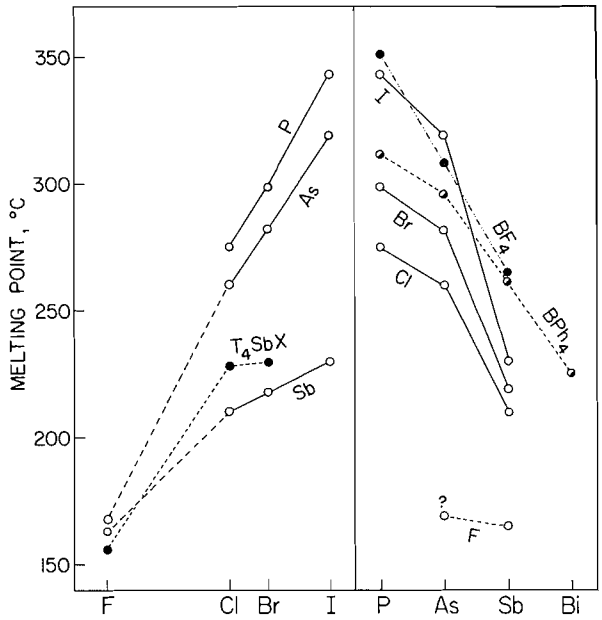

FIG. 2. Variation of the melting points of Ph_4EX with the effective radius of Hal^- (*left*) and with E (*right*; reliable effective radii of E(V) not available). The melting points shown are the highest found in the literature. The differences in trends between the ionic $Ph_4E^+X^-$ and the molecular Ph_4EX are consistent and clearly visible. T_4SbX = $(4\text{-}C_6H_4Me)_4SbX$ (cf. ref. 2).

compounds of Table 3 was such ($r^2 = 0.10$) that the notion of such a relationship could not be entertained, especially in view of the small range of $C_{ax}EX$ (less than 10°) and the sensitivity of this angle to uncertainties in the underlying interatomic distances when the angle is close to 180°. Since the only SP Ph_4EX species on record is Ph_5Sb (33), and that only in the pure Ph_5Sb crystal,[6] the tendency of the Ph_4EX species to assume SP configurations must be very weak. It is thus unlikely that the non-collinearity of the C_{ax}—E—X groupings finds its explanation in incipient pseudorotation, and other reasons must be looked for.

Examination of Table 3 reveals that the (uncorrected) Sb—C_{ax} bond length decreases with increasing Sb—X (the *trans* effect) both in the tetraphenyl and the tetramethyl species. A power-function regression of the ratio (Sb—C_{ax})/(Sb—X) on Sb—X for **1**–**14** results in a very high degree of correlation:

$$[1] \quad (Sb—C_{ax})/(Sb—X) = 2.3798(Sb—X)^{-1.1112}$$

$r^2 = 0.998$, $\sigma = 0.007 \sim 1.6\%$ of the ratio range (Fig. 3). For Bi the corresponding bond lengths are available for only two compounds, **16** and **17**, and then only with low accuracy, but the positions of the two points in Fig. 3 suggest that a similar correlation is to be expected also for the Ph_4BiX species.

Equation [1] shows that Sb—C_{ax} varies only slowly and within narrow limits with the strength of the Sb—X bond (as measured by its length), $Sb—C_{ax} \sim 2.4(Sb—X)^{-1/9}$. Equally importantly, the existence of the correlation over a wide Sb—X range and the relative smallness of the deviations of the $C_{ax}SbX$ angles from 180° demonstrate that the coordination at the Sb atom is properly described as TBP even at long Sb—X distances.

[6]In $Ph_5Sb \cdot \frac{1}{2}C_6H_{12}$ (32) the Sb coordination is TBP, as it also is in $(4\text{-}MeC_6H_4)_5Sb$ (43), and there are reasons to believe that the SP geometry in the Ph_5Sb crystal has its origin in packing factors (32, 44–46).

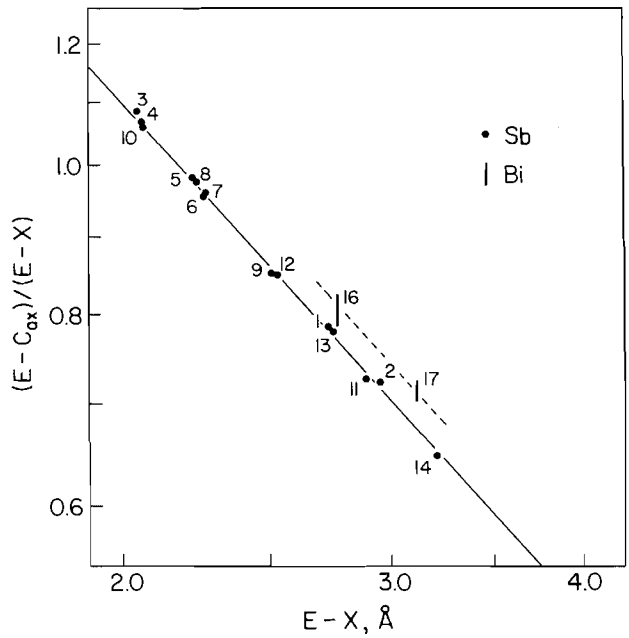

FIG. 3. Variation of log [(Sb—C_{ax})/(Sb—X)] with log (Sb—X) in R_4SbX species. The line through the Ph_4BiX points **16** and **17** is the best line parallel to the fitted Sb—X line (see text).

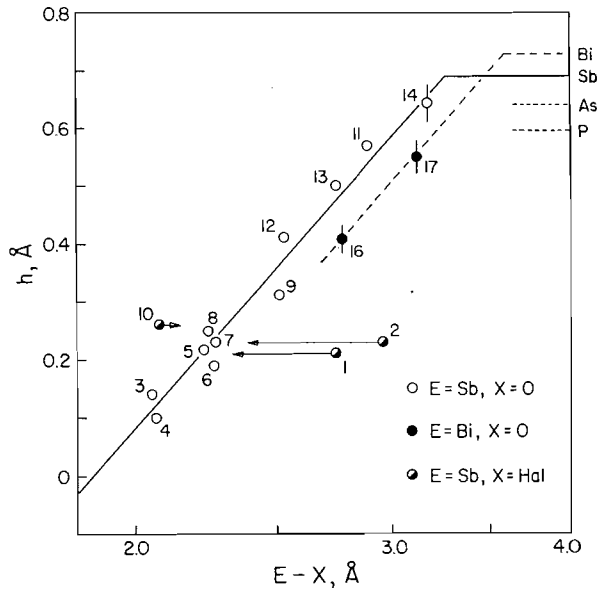

FIG. 4. Height h of atom E above the $C_{eq}C_{eq}'C_{eq}''$ plane toward C_{ax} vs. log (E—X). Estimated limiting h values for C_4E (E = P, As, Sb, Bi) tetrahedra (T_d) are indicated. The positions of the arrows indicate the E—Hal distances in **1**, **2**, and **10** on adjustment to the E—O scale.

The limits to the progressive axial distortion of the coordination TBP may be established from Fig. 4, where the height h of the E atom above the $C_{eq}C_{eq}'C_{eq}''$ triangle (toward C_{ax}) is plotted against E—X. At $h = 0$ the E atom is coplanar with the C_{eq} atoms, but with increasing h the coordination eventually becomes tetrahedral. The value of h at which this happens will depend on the (E—C_{ax})/⟨E—C_{eq}⟩ ratio, but as this ratio appears to converge toward unity as E—X increases, the tetrahedral limit may be estimated as $h \sim 0.69$ for Sb and ~0.73 for Bi. Since for the E—oxygen species of Table 3 h can be very satisfactorily represented by $h = -0.777 + 1.24$ ln (E—O) ($r^2 = 0.97$, $\sigma = 0.03$ Å), one can estimate the E···O distance beyond which C_4E coordination tetrahedra will be encountered

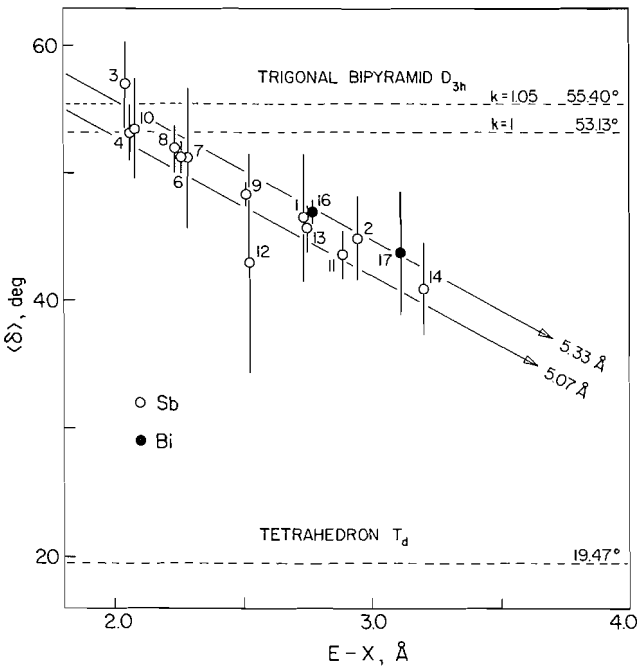

FIG. 5. Variation of the mean dihedral angle ⟨δ⟩ in trigonal-bipyramidal R_4EX (E = Sb, Bi) with the length of the E—X bond. Width of band, 2σ; $k = a/e = (E—C_{ax})/(E—C_{eq})$.

as ~3.3 Å for Sb and ~3.5 Å for Bi. In the Sb—oxygen species this distance would correspond to a limiting Sb—C bond length of 2.05(15) Å.

The extent of the departure from TBP(C_{3v}) coordination geometry can also be described by the mean dihedral angle $\langle\delta\rangle = \langle C_{ax}C_{eq}C_{eq}'\rangle/\langle C_{eq}C_{eq}'X\rangle$. This index is more general than h, since it is purely geometric and thus independent of the chemical nature of X, and is calculated directly from the positional coordinates, i.e. without any assumptions or simplifications. For a TBP of symmetry C_{3v},

$$[2]\quad \delta(C_{3v}) = \arctan\{2(x+a)(e^2-h^2)^{1/2}/[4(a+h)(x-h) - (e^2-h^2)]\}$$

where x = E—X, a = E—C_{ax}, e = E—C_{eq}. For the limiting situations this simplifies to

$$\delta[C_{3v}, x \rightarrow \infty, a = e] = \arctan[(e-h)/4(e+h)]^{1/2}$$

$$\delta(T_d) = \arctan 8^{-1/2} = 19.47°$$

and

$$\delta(D_{3h}) = \arctan[(a/e) - (e/4a)]^{-1}$$

$$\delta[D_{3h}, a = e] = \arctan \tfrac{4}{3} = 53.13°.$$

The general expression [2] for $\delta(C_{3v})$ cannot be represented graphically as a model function in a plot of δ against E—X because of the involvement of a, e, and h. However, when the actual ⟨δ⟩ values are plotted against E—X (Fig. 5), a linear regression turns out to be sufficient to yield a high degree of correlation: $\langle\delta\rangle = 76.22 - 10.92(E—X)$, $r^2 = 0.91$, $\sigma = 1.4° \sim 9\%$ of the ⟨δ⟩ range. Furthermore, when extrapolated the regression line intersects the $\delta(T_d) = 19.47°$ line at E—X = 5.20(13) Å, i.e. at a distance which matches the E···O distances observed in $Ph_4As^+ClO_4^-$ and $Ph_4Bi^+ClO_4^-$.

Transition from TBP R_4EX to $R_4E^+X^-$

As shown above, the increasing axial distortion of the coordination TBP corresponds to a continuous, progressive dissociative process which ultimately leads to tetrahedral R_4E^+ cations. The only genuinely ionic $R_4Sb^+X^-$ structure that appears to have been determined so far, $Me_4Sb^+[Al(OSiMe_3)_4]^-$ (*Pmmn*) (53), is untypical because of the size and geometry of the anion[7] and therefore perhaps not quite suitable as an example of the end result of the TBP → ionic transition. However, in $Ph_4As^+ClO_4^-$ (22) and $Ph_4Bi^+ClO_4^-$ (23) the shortest E···O separations cannot be smaller than ~5.1 Å, the orientational disorder of the ClO_4^- ion notwithstanding, and since it is highly probable that Ph_4SbClO_4 is ionic (cf. ref. 2 and the Ph_4EBF_4 series in Fig. 2) and isostructural with the As and Bi salts, we shall take these E···O distances as typical of the process discussed below.

The mean $C_{ax}SbX$ angle in **1–4** and **6–14** is 176(3)°.[8] In the oxy-ligand subset (**3–9**, **11–14**), $\langle C_{ax}SbC_{eq}\rangle$ increases with Sb—O from 93(1)° to 108(3)°, and from the increase in h with increasing Sb—O we have estimated that the C_4Sb portion of the TBP R_4SbO— will become a regular tetrahedron at Sb—O ~ 3.3 Å (~3.5 Å for Bi; for X ≠ O the E—X distance can be adjusted to the E—O scale, cf. Fig. 4). At this tetrahedral limit the R_4EX unit will be effectively an $R_4E^+ + X^-$ pair, with the C_4E tetrahedron still correctly oriented with respect to X, i.e. with C_{ax}—Sb—X more or less collinear, and that in spite of the effects of crystal packing. The dihedral angle ⟨δ⟩ becomes $\delta(T_d)$ at E···X ~ 5.2 Å (Fig. 5), but at this distance X is no longer in any particular geometric relationship to the C—Sb bonds and the C—Sb—X collinearity is lost. As a consequence the ions initially in the TBP oriented $R_4E^+ + X^-$ pairs will now redistribute themselves and the R_4E^+ cations will assume orientations in the structure such as to minimize the Coulombic energy of the crystal consistent with maximizing the packing density. With small regular anions this requirement is likely to result in arrangements of highly symmetry, as here the reorganization of the structure can proceed with a minimum of steric hindrance. This is indeed observed in $Ph_4As^+ClO_4^-$ and $Ph_4Bi^+ClO_4^-$, both of $I\bar{4}$ symmetry and in which E···O > 5.1 Å.

In these circumstances it is probable that the energy difference corresponding to Coulombic interactions at 3.5 Å and at 5.2 Å in individual $R_4Sb^+ + X^-$ pairs will not be a dominant factor compared to the collective Coulombic interactions in the crystal as a whole. Consequently the tetrahedral C_4Sb geometry will be indifferent to the length of the Sb···O distance between these limits. Thus while in the perchorates E···O > 5.1 Å, in $[Me_4Sb]^+[Al(OSiMe_3)_4]^-$ (in which the anion shares two mirror planes with the neighbouring cations[7]) the shortest Sb···O separations are ~3.9 and ~4.5 Å.

Of the Sb compounds in Table 3, **14** is the closest to the tetrahedral limit and has indeed been described (41) as purely ionic. However, Table 3 shows that the Sb coordination geometry in this crystal still qualifies as TBP. The reason why the TBP → $Me_4Sb^+X^-$ transition in **14** has not proceeded to completion is to be looked for in the particulars of its

[7]In the structure determination the Me_4Sb group was assumed to be a regular tetrahedron, Sb—C = 2.20 Å. The site symmetry at Sb is C_{2v}; the nearest oxygen atoms are two O(1) at ~3.9 Å and two O(2) at ~4.5 Å. If these oxygens are considered as completing the coordination figure of the Sb atom to form four individual distorted TBPs, the $C_{ax}SbO$ angles will be in the vicinity of 145°. Using $(Sb—O)_{eff} = (Sb—O)\cos(180 - 145)$ in eq. [1] yields Sb—C ~ 2.09 and 2.06 Å from O(1) and O(2), respectively, in agreement with the expected limiting Sb—C value of 2.05(15) Å.

[8]At $C_{ax}EX = 135.27°$ the E···X line will bisect an edge of a regular C_4E tetrahedron and there will be *two* symmetry-equivalent C_{ax} atoms. The TBP coordination geometry may be regarded as reaching its limit at this angle.

chemistry,[9] which prevent a more uniform redistribution of the pro-ion positions in space given the size and shape of the acid phthalate ion and the magnitude and distribution of its charge. The observed structure is a compromise between a tendency to complete ionization and the impossibility of attaining an ion packing arrangement of high symmetry (like that in $Ph_4As^+ClO_4^-$) owing to the one-sided concentration of charge in the anion. Similar considerations appear to apply to **17**, where the pro-anion is very asymmetric both because of the ligand geometries and the presence of a stereochemically active lone pair on the Bi atom.

The foregoing analysis of the available evidence provides a useful phenomenological rationale and norm for an understanding of the variability of the TBP coordination geometry in crystalline R_4EX (E = Sb, Bi) species. It also leads to the conclusion that the observed deviations of the $C_{ax}EX$ angles from 180° are due to accidents of crystal packing. The question of why covalency in these crystals takes precedence over ionization even in cases where on chemical grounds the latter might be expected to prevail is much more difficult to answer in general terms, considering the extensive dissociation into R_4E^+ and X^- which occurs in solution. For example, ionic (cf. Fig. 2) $Ph_4Sb^+BPh_4^-$ readily precipitates from aqueous or alcoholic solutions of Ph_4SbBr with $NaBPh_4$, and similar behaviour is well documented from solution studies of numerous R_4SbX and R_4BiX compounds containing pentacoordinated E in the solid state (cf. refs. 2 and 3).

[9]In **14** both the pro-cation and the pro-anion are on (020) mirror planes. The mirror bisecting the pro-anion 1,2-C_6H_4[CO(1)O(2)][C′O(1′)O(2′)]H contains the H atom which bridges O(1) and O(1′). An Me_4Sb tetrahedron is flanked symmetrically on the left by an O(2) and on the right by an O(2′) atom, each from a different pro-anion. The O(2) atom completes the coordination figure of Sb to a TBP on the left, while O(2′) completes it to a TBP on the right. The result is thus a superposition of two reflection-related TBPs, but the Sb atom is six-coordinated only in a formal sense, the two Sb—O distances being so long, and may as well be regarded as a limiting case of TBP coordination on one side at a time. The structure of **14** may thus be viewed as consisting of zig-zag···C_4Sb···O(2)—[ ]—O(2′)···C_4Sb··· chains ∥*b*.

TABLE 7. Ph_4SbBr: interatomic distances and bond angles

Bond	Distance (Å)	Bonds	Angle (deg)
Sb—C(11)	2.131(8)	C(11)—Sb—Br	175.7(2)
Sb—C(21)	2.106(6)	C(21)—Sb—Br	84.1(2)
Sb—C(31)	2.105(6)	C(31)—Sb—Br	81.1(2)
Sb—C(41)	2.131(6)	C(41)—Sb—Br	87.2(2)

		Sb—C(41)—C(46)	122.2(5)

Crystal structure of Ph_4SbBr

The positional parameters and anisotropic temperature factors of the non-hydrogen atoms are listed in Tables 4 and 5; the hydrogen atoms are detailed in Table 6, and bond lengths and angles in Tables 7 and 8.[10]

A conspicuous feature of the structure is the arrangement of the Br atoms (Fig. 6). They are situated almost exactly in the $10\bar{1}$ planes, the perpendicular distance of a Br atom from the nearest $10\bar{1}$ plane being only 0.09 Å. The Ph_4Sb units are thus completely contained within the parallel slabs into which the structure is divided by the $10\bar{1}$ planes. The structure may therefore be regarded as a layer structure and as such it would be more suitably described on a unit cell which reflects the layer character, e.g. $P'(-\mathbf{a}, \mathbf{b}, \mathbf{a}+\mathbf{c})$ or $B(\mathbf{a}+\mathbf{c}, \mathbf{b}, \mathbf{a}-\mathbf{c})$, except that P' is more oblique than $P(\mathbf{a}, \mathbf{b}, \mathbf{c})$, $\beta(P') = 117.5°$. Cell B is only marginally more oblique than P, $\beta(B) = 106.0°$, but it is twice the size of P.

The Sb—Br bonds are practically parallel (~3°) to the 010 plane. The Sb atom is coplanar with the phenyl rings 1 and 4, and about 0.25 Å out of the best planes of rings 2 and 3. The rings are planar to $\sigma = 0.011$ Å or better (Table 9).[10] The planes of rings 2 and 3 are only 14° from parallel; the axial ring 1 is approximately perpendicular to the mean plane of rings 2 and 3, and ring 4 is roughly at 90° to ring 1. The internal CCC angles in the rings are all 120° within 2 esd's. The Sb—C(11) and Sb—C(41) bonds are coplanar with their respective phenyl rings, while Sb—C(21) and Sb—C(31) are tilted by ~7°.

The means of the uncorrected bond lengths and angles are listed in Table 3. Additionally, $\langle C_{eq}SbBr\rangle = 84.1(27)°$ and $\langle SbCC\rangle = 120.0(26)°$, the latter with a range of 5.7(8)°.

[10]Copies of Tables 5, 6, and 8–10 can be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

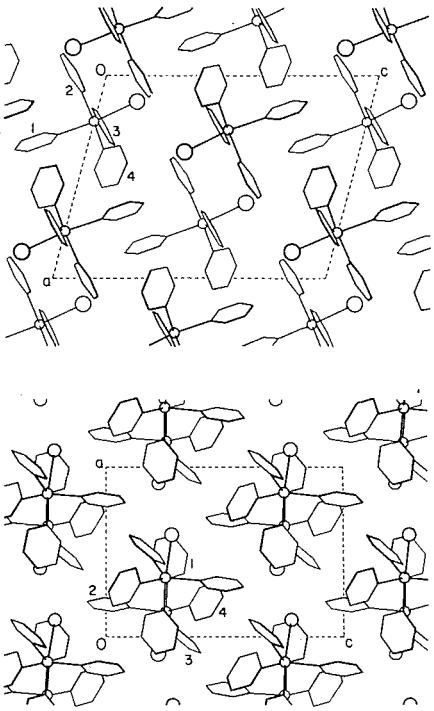

FIG. 6. (*Top*) Ph_4SbBr: projection on (010) (H atoms omitted for clarity). (*Bottom*) Ph_4SbCl (after ref. 5): projection on (010). The coordinates of ref. 5 have been transformed and the rings renumbered ($I \rightarrow 2$, $II \rightarrow 4$, $III \rightarrow 3$, $IV \rightarrow 1$) to match our description of the Ph_4SbBr structure. The two projections are on the same scale.

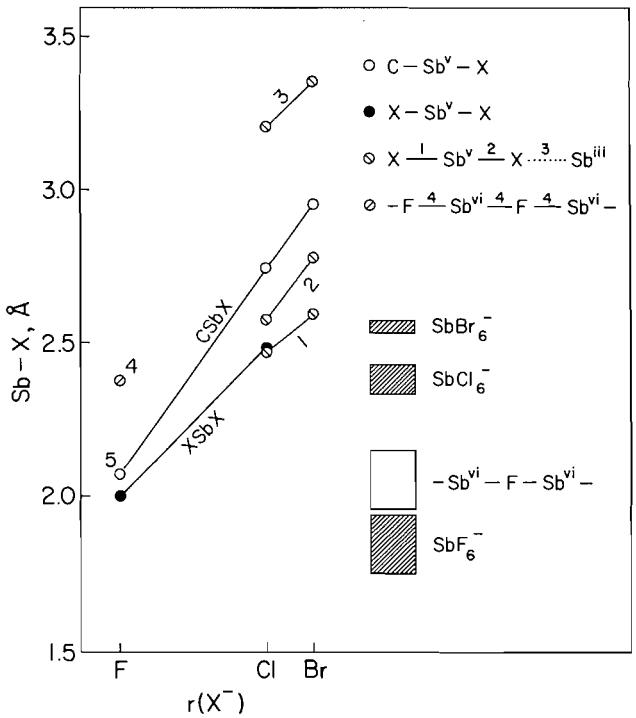

FIG. 7. Sb—X distances involving pentavalent Sb: CSbX (axial) in Ph_4SbX; XSbX (axial) in R_3SbX_2 (R = Ph, Me); XSbX···Sb(III) (axial) in $Me_3SbX_2 \cdot SbX_3$; —FSbFSb— in Me_4SbF (cf. ref. 2). (*Right*) Ranges of Sb(V)—X bond lengths reported in $Sb_mF_n^{k-}$ (terminal and bridging), $SbCl_6^-$ and $SbBr_6^-$ ions and some other compounds (48); the bond lengths in $SbBr_6^-$ have been corrected for thermal motion (49). *4*, Me_4SbF; *5*, Ph_3MeSbF. Sb^{iv}, Sb^v, and Sb^{vi} indicate four-, five-, and six-coordinated Sb atoms, respectively.

The Sb—Br bond of 2.95 Å appears to be the longest Sb(V)—Br bond reported to date (Fig. 7). Comparison of the Sb(V)—Hal bond lengths observed in Ph_4SbHal with those in R_3SbHal_2 (R = Ph, Me), $Me_3SbHal_2 \cdot SbHal_3$ and a variety of $Sb_mHal_n^{k-}$ ions as well as in a few other compounds shows that the bonds in Ph_4SbCl and Ph_4SbBr are considerably (about 15%) longer than the rest of the corresponding bonds. The Sb—F bond in Ph_3MeSbF also is about 15% longer than the terminal bonds in $Sb_mF_n^{k-}$ but in the range of the *bridging* Sb—F—Sb bonds in such ions; in Me_4SbF, however, the Sb—F bonds are longer than even the latter.

Compared with the purely inorganic Sb(V) halogen species, the Sb—Hal bonds in R_4SbHal are thus always longer, and that even in spite of the anionic, size-expanding charge on $SbHal_6^-$ and the higher coordination number of the Sb atom in these ions. That these bonds are abnormally long is seen from a comparison with Sb—Hal in the TBP R_3SbHal_2, in which the two *trans* Sb—Hal bonds are balanced, and with Sb(V)—Hal in the adducts $Me_3SbHal_2 \cdot SbHal_3$, where one of the two *trans* bonds is weakened by a Hal···Sb(III) interaction (Fig. 7). These bond lengths thus furnish evidence that even in *absolute* terms (as distinct from the correlation of Fig. 3) Ph_4SbCl and Ph_4SbBr represent Ph_4SbX species well *en route* from molecular to ionic, onium solids.

Comparison with Ph_4SbCl

The two compoudns crystallize with the same space group, $P2_1/n$, but they are not isostructural.[11] However, there are similarities as well as differences in their structural features. The two structures are compared in Fig. 6.

The Cl atoms again are close to the 101 planes but less so than the Br atoms in Ph_4SbBr; the shortest perpendicular distance is 0.97 Å. The Ph_4Sb skeletons here, too, are contained within the parallel slabs bounded by the 101 planes. However, the dominant feature of the chloride structure is the columns of Ph_4SbCl molecules parallel to *b*. In each column the molecules are related by a 2_1 axis, and the columns are arranged in a pseudohexagonal array.[12] The Sb—Cl bonds form an angle of ~19° with (010) as against ~3° in the bromide, which accounts for the increase in the $2b/(a + c)$ ratio relative to Ph_4SbBr, 1.21 compared to 0.75; $b(Cl)/b(Br) = 1.37$.

The differences between the structures of Ph_4SbCl and Ph_4SbBr are difficult to account for from the size disparity (~8% on radius) of the halogen atoms alone. Hydrogen–hydrogen repulsions clearly are involved, but as the actual structures are the result of a fine balance of a number of factors, assigning any *one* of them as the main or sole cause of the differences would seem mere speculation. The *similarities* of the gross features of the two structures are discussed in a larger context in ref. 54.

Experimental

Commercial Ph_4SbBr (Alfa) was recrystallized from $MeNO_2$, MeCN, and EtOH. The compound is very soluble in $MeNO_2$ and MeCN, and recrystallization therefore occurred from very concentrated solutions. Crystals from $MeNO_2$ were quite large, clear, and colourless; they melted at 203–212°C (dec.) to a golden-yellow melt (ref. 50, 210–218°C). Crystals from MeCN were similar but much smaller. In both cases ir spectra showed that the crystals were

[11]For Ph_4SbCl, $a = 10.141(4)$ Å, $b = 14.590(6)$ Å, $c = 14.027(6)$ Å, $\beta = 90.03(4)°$ (5).

[12]The c/a axial ratio, 1.38, differs by ~25% from $\sqrt{3}$ required for an orthohexagonal cell; $\beta \sim 90°$.

anhydrous Ph_4SbBr. Evaporation of EtOH solutions always resulted in gradual precipitation of a white powder (not characterized). For structure analysis a crystal was selected from the $MeNO_2$ crop.

Crystal data

$BrC_{24}H_{20}Sb$ fw = 510.08

Monoclinic, $P2_1/n$ (no. 14) (systematic absences: $0k0$, k odd; $h0l$, $h + l$ odd); $a = 12.282(2)$ Å, $b = 10.656(1)$ Å, $c = 16.156(1)$ Å, $\beta = 104.92(7)°$, $V = 2060(1)$ Å^3, $Z = 4$, $\rho_c = 1.645(1)$ g/cm^3; $\mu_{Mo} = 34.2$ cm^{-1}, $F000) = 1000$ e. Crystal, $0.28 \times 0.48 \times 0.75$ mm^3; CAD-4 four circle diffractometer; Mo $K\alpha_1$, $\lambda = 0.70926$ Å (graphite monochromator); θ range, 2–23°. Reflections: 3280 measured, 2877 unique, 2349 ($I > 2\sigma(I)$) unique used. Lorentz, polarization, and absorption corrections applied; $R_{merg} = 8.8\%$ before, 4.8% after absorption corrections. Scattering factors for neutral atoms and corrections for anomalous scattering from ref. 51.

Structure determination

The structure was solved using the SHELX 76 system (52). After the nonhydrogen atoms had been located, full-matrix least-squares ($w\Delta F^2$ = minimum) refinement was carried out with isotropic temperature factors until R was reduced to a reasonably low value. Although the hydrogen atoms were observable, at this stage they were placed, and the refinement was continued with anisotropic factors on the nonhydrogen atoms and isotropic factors on the hydrogens. The anisotropic temperature factor is defined as $T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. The least-squares weights were $w = 1.204(\sigma^2|F| + 0.001F^2)^{-1}$. The 002, 751, and 961 reflections suffered from extinction and were omitted from the final refinement. The highest peak in the final difference map was 1.3 e/Å^3 followed by six smaller peaks, all seven located within 1.2 Å of the Sb or Br positions; after these the next highest peak was 0.66 e/Å^3. Final $R = 5.46\%$, $R_w = 5.66\%$. The structure factors are listed in Table 10.[10]

Isomerization, fluorine exchange, and stereoselective synthesis of *cis*- and *trans*-F_2TePh_3Cl: application of the coordination model of reaction mechanisms

ALEXANDER F. JANZEN AND MEEHAE JANG

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 16, 1988

ALEXANDER F. JANZEN and MEEHAE JANG. Can. J. Chem. **67**, 71 (1989).

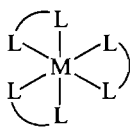
The stereoselective synthesis of *cis*- and *trans*-F_2TePh_3Cl (phenyl substituents adopt a *mer* arrangement) via 5-coordinate cations Ph_3TeFCl^+ and $Ph_3TeF_2^+$ is described. *trans*-F_2TePh_3Cl isomerizes to the thermodynamically more stable *cis* isomer, and *cis*-F_2TePh_3Cl has non-equivalent fluorines which undergo stereoselective fluorine exchange, as confirmed by ^{19}F and ^{125}Te nmr spectroscopy. These results are consistent with an intermolecular mechanism of isomerization and fluorine exchange involving Te—F bond cleavage.

The coordination model of reaction mechanisms provides a unified description of stereochemical rearrangements, ligand exchange processes, and chemical reactions in these, and related, octahedral and trigonal bipyramidal compounds.

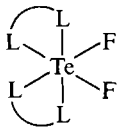
Key words: synthesis of *cis*- and *trans*-F_2TePh_3Cl, isomerization of octahedral Te compounds, fluorine exchange in *cis*-F_2TePh_3Cl, synthesis of Ph_3TeF, coordination model of reaction mechanisms.

ALEXANDER F. JANZEN et MEEHAE JANG. Can. J. Chem. **67**, 71 (1989).

On décrit la synthèse stéréosélective des F_2TePh_3Cl-*cis* et -*trans* (les substituants adoptent une arrangement *mer*) réalisée par le biais des cations penta-coordonnés Ph_3TeFCl^+ et $Ph_3TeF_2^+$. Le F_2TePh_3Cl-*trans* se transforme en isomère *cis* qui est thermodynamiquement plus stable; le F_2TePh_3Cl-*cis* possède deux atomes de fluor qui ne sont pas équivalents et qui subissent un échange stéréosélectif de fluor qui est confirmé par la spectroscopie rmn du ^{19}F et du ^{125}Te. Ces résultats sont en accord avec un mécanisme d'isomérisation intermoléculaire et un échange de fluor impliquant un clivage de la liaison Te—F.



Le modèle de coordination des mécanismes de réaction fournit une description unifiée des transpositions stéréochimiques, des processus d'échange de ligand et des réactions chimiques dans ces composés ainsi que dans les composés apparentés octaédriques ainsi que trigonaux bipyramidaux.

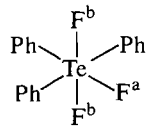


Mots clés : synthèse des F_2TePh_3Cl-*cis* et -*trans*, isomérisation de composés Te octaédriques, échange de fluor dans F_2TePh_3Cl-*cis*, synthèse de Ph_3TeF, modèle de coordination des mécanismes de réaction.

[Traduit par la revue]

Introduction

The mechanisms of stereochemical rearrangements of octahedral metal complexes may be placed into two categories: those which involve changes in coordination number of the metal, and those which do not. Isomerizations and racemizations of tris(bidentate) complexes are generally placed into the former category (1), as originally suggested by Werner (2), while isomerization of other octahedral complexes (3, 4), including tellurium fluorides (5), have been placed into the latter category.



Our nmr studies of ligand exchange in 4-, 5, and 6-coordinate silicon (6), phosphorus (7), sulfur (8), and tellurium (9, 10) fluorides are all consistent with the view that rapid coordination changes of metal and ligand are responsible for the lowest energy pathway of ligand exchange and chemical reaction. Stereochemical changes, including axial-equatorial scrambling of ligands in trigonal bipyramidal molecules, may accompany the formation of octahedral intermediates such as $SiF_5(base)^-$ (6), $PF_5(base)$ (7), $Me_2PF_3(solvent)$ (11), or $AsF_5(FCH_3)$ (12), while racemization and base-catalyzed hydrolysis of silanes may involve octahedral intermediates such as $R_3SiCl(solvent)_2$ (13) and $Me_3SiF(NHEt_2)(H_2O)$ (14), furthermore, many chemical reactions of pentacoordinated compounds probably require the formation of octahedral intermediates (15) as the first step along a reaction pathway. Since these mechanistic views are at variance with the postulate of low energy polytopal rearrangements, we decided to investigate the isomerization of some octahedral phenyltellurium(VI) fluorides which have been prepared by the oxidative-fluorination with XeF_2 (16). The problem of stereoselective fluorine exchange in Ph_3TeF_3 and Ph_3TeF_2OH has recently been studied by ^{19}F and ^{125}Te nmr and the structures of these molecules have been determined by X-ray crystallography (9, 10).

Results and discussion

Ph_3TeF was prepared from Ph_3TeCl and carbonyl fluoride (17) and converted to *mer*-Ph_3TeF_3, **1**, by addition of XeF_2 (9, 16).

[1] $Ph_3TeCl \xrightarrow{COF_2} Ph_3TeF \xrightarrow{XeF_2}$ 

mer-**1**

mer-**1** was then used in the synthesis of *cis*- and *trans*-F_2TePh_3Cl (phenyl substituents retain their *mer* arrangement) and our evidence for intermolecular mechanisms of isomerization and exchange involving Te—F bond cleavage is based on the following experiments: (*A*) stereoselective synthesis of *cis*- and *trans*-F_2TePh_3Cl, (*B*) stereoselective Te—F bond cleavage in *cis*-F_2TePh_3Cl, and (*C*) catalysis of isomerization and fluorine exchange by Lewis acids but inhibition by fluoride or chloride ions.

Preliminary experiments showed that *trans*-F_2TePh_3Cl, **3**, was the kinetically favoured isomer while *cis*-F_2TePh_3Cl, **5**, was the thermodynamically favoured isomer. *trans*-**3** was prepared in two-stages: treatment of *mer*-**1** with PF_5 removed either F^a or F^b and gave the cation $Ph_3TeF_2^+$, **2**, and addition of chloride then gave *trans*-**3**. The stereochemical outcome of each step in reaction [2] is presumably determined by the preference of three phenyl substituents for a planar arrangement in *mer*-**1**, cation **2**, and *trans*-**3**.

^{19}F and ^{125}Te nmr data for cation **2** and *trans*-**3** are given in

*Chemical shifts in ppm and coupling constants in Hz. Solvent is CD_2Cl_2. The ^{19}F and ^{125}Te chemical shifts were measured relative to internal C_6F_6 (−162.9 ppm with respect to $CFCl_3$) and external Ph_2Te (692 ppm with respect to Me_2Te).
†This work.

[2] *mer*-**1** $\xrightarrow{PF_5}$ **2** $\xrightarrow{Et_4NCl}$ *trans*-**3**

Table 1 and the chemical shifts and coupling constants of F^b in *trans*-**3** are very similar to those of the corresponding *trans* fluorines in *mer*-**1**.

Treatment of *trans*-**3** with PF_5 removed F^b and gave the cation Ph_3TeFCl^+, **4**, and addition of fluoride then gave *cis*-F_2TePh_3Cl, **5**, as confirmed by ^{19}F and ^{125}Te nmr (Table 1). *cis*-**5** was characterized previously by nmr, elemental analysis, and mass spectrometry (16).

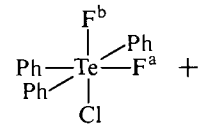
[3] *trans*-**3** $\xrightarrow{PF_5}$ **4** $\underset{PF_5}{\overset{NaF}{\rightleftharpoons}}$ *cis*-**5**

A trigonal bipyramidal geometry for cations **2** and **4** is consistent with the equivalence of fluorines in **2** and the equivalence of phenyl rings in **2** and **4**, as judged by carbon-13 nmr.[1] As seen in Table 1, the formation of cations **2** and **4** from octahedral *mer*-**1**, *trans*-**3** or *cis*-**5** results in an upfield shift of 100 to 120 ppm in the ^{125}Te nmr, and a decrease of 200–656 Hz in the Te—F^b coupling. Cation **4** was also prepared by the addition of PF_5 to *cis*-**5** and the loss, presumably, of either F^a or F^b.

In view of the report that octahedral *trans*-$F_2Te(C_6H_4CMe_2O)_2$ is converted to the *cis*-isomer after 3 days at 60°C by a *nondissociative* mechanism (5), we decided to estimate how quickly the step-by-step isomerization of *trans*-**3** to *cis*-**5** could be carried out according to eq. [3], with verification by nmr at each stage. It required a total of 1 h to add PF_5 to *trans*-**3**, remove excess PF_5, record the nmr of cation **4**, add NaF, filter off solid NaF, and record the nmr of *cis*-**5**. As far as we could tell, the chemical reactions during this time occurred more or less instantaneously and we conclude that the lowest energy pathway of *trans*-to-*cis* isomerization in octahedral Te(VI) fluorides occurs by an intermolecular route involving Te—F bond cleavage. This conclusion is supported by the report that *trans*-to-*cis* isomerization in $F_2Te(C_6H_4CMe_2O)_2$ and $F_2S(C_6H_4C(CF_3)_2O)_2$ is catalyzed by Lewis acids such as SbF_5 and SO_3 (5, 18).

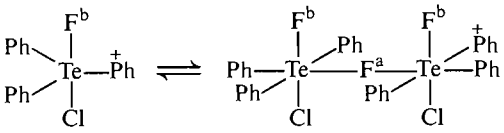
The previous finding that intermolecular fluorine exchange in *mer*-Ph_3TeF_3 is initiated by impurities but stopped by NaF or R_4NCl (9), suggests that impurities might also initiate exchange and isomerization in *cis*- and *trans*-F_2TePh_3Cl. This was found to be the case, as confirmed by monitoring a sample containing 100% *trans*-F_2TePh_3Cl, **3**, prepared according to eq. [2]. After 24 h in dichloromethane solution, only 64% *trans*-**3** remained, and the rest was mainly *cis*-F_2TePh_3Cl, **5**, along with smaller amounts of *mer*-Ph_3TeF_3, **1**. The formation of *mer*-**1** implies the presence of fluoride impurities, and nmr examination at this stage confirmed the presence of small amounts of $P(O)F_2OH$, $P(O)F(OH)_2$, and BF_4^- which may originate from the reaction of PF_5 and HF with moisture and glass nmr tubes. We therefore assume that Lewis acid impurities can generate cations **2** or **4** which in turn catalyze fluorine exchange and isomerization in octahedral Te(VI) fluorides. After one month in solution, all *trans*-**3** had disappeared and only *cis*-**5** and *mer*-**1** remained.

The fact that reactions of XeF_2 with Ph_3TeCl give the thermodynamically stable *cis*-**5** product (16) can probably be attributed to the slowness of the XeF_2 reactions, which take 8 h or more for completion. During this time XeF_2 is known to react with organic solvents (19), and an impurity-catalyzed isomerization, eq. [4], is then likely.



[4] *trans*-**3** $\xrightarrow[\text{e.g. HF, } BF_3]{\text{Lewis acid}}$ *cis*-**5**

cis-F_2TePh_3Cl, **5**, has non-equivalent fluorines, F^a and F^b, and it was possible to carry out stereoselective Te—F^a bond cleavage by adding small amounts of cation **4** to *cis*-**5**. The ^{19}F and ^{125}Te nmr spectra were very similar to those observed in the Ph_3TeF_3—$Ph_3TeF_2^+$ (9) and Ph_3TeF_2OH—Ph_3TeFOH^+ (10) systems and showed that F^a—F^b and Te—F^a couplings are lost, but Te—F^b coupling is retained in the *cis*-F_2TePh_3Cl–Ph_3TeFCl^+ system, consistent with a mechanism involving a fluorine-bridged intermediate in which F^a occupies the bridging position, eq. [5].



Occasionally, during reactions of PF_5 with *cis*-**5**, some *mer*-**1** was present and consequently both cations **2** and **4** were formed in solution, but the nmr spectra showed that there was no intermolecular fluorine exchange between cations **2** and **4**.

The coordination model of reaction mechanisms and the stereodynamics and reactivity of 4-, 5-, and 6-coordinate compounds

The coordination model of reaction mechanisms (20)[2] describes the connectivity of atoms and the discrete changes in coordination number that occur during a chemical process. A summary of this model is given below:

Changes in coordination numbers are described by coordination number operators, $\mathscr{C}$: $+\mathscr{C}_{M(m)N(n)}$, abbreviated as $+\mathscr{C}$, increases the coordination number of elements M and N by 1, from m to $m + 1$ and n to $n + 1$; $-\mathscr{C}_{M(m)N(n)}$ decreases the coordination numbers by 1, from $m + 1$ to m and $n + 1$ to n; operators $+\mathscr{C}^{n\text{-center}}_{M(m)N(n)}$, abbreviated as $+\mathscr{C}^c$, and $-\mathscr{C}^{n\text{-center}}_{M(m)N(n)}$ define coordination changes which occur via cyclic n-center steps and these are particularly favoured for 3- to 6-center steps.

Each operation $\mathscr{C}$ generates a single step along a pathway P, and these multistep pathways are represented by a directed graph P(X,$\mathscr{C}$), in which the vertex set X consists of reactants, intermediates, and products, and the edge set $\mathscr{C}$ consists of the coordination number operators $+\mathscr{C}$, $-\mathscr{C}$, $+\mathscr{C}^c$, and $-\mathscr{C}^c$. Operators $+\mathscr{C}$ and $-\mathscr{C}$, representing intermolecular steps, are drawn above dashed lines, while $+\mathscr{C}^c$ and $-\mathscr{C}^c$, representing intramolecular steps, are drawn above solid lines; $\mathscr{C}$ is drawn below the lines for the reverse reaction. These pathways P(X,$\mathscr{C}$) may be labelled according to the number of vertices and steps ("edges") in the graph e.g. P(3,1) or P(4,2) or by the sequence of steps P{$\mathscr{C}_n$} in an n-step pathway. Such a graph (topological) description can serve as the basis of a unified analysis of stereochemical rearrangements, ligand exchange processes, and reaction mechanisms.

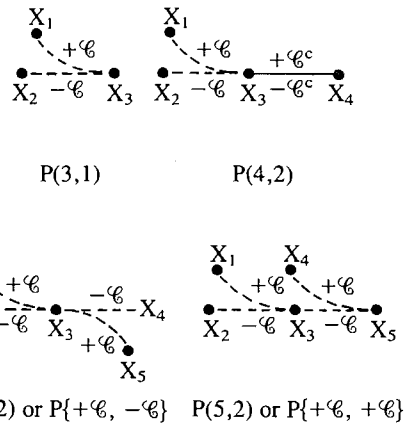

Table 2 illustrates the application of this model to phenyltellurium(VI) fluorides and a variety of other 4-, 5-, and 6-coordinate compounds. For the Ph_3TeF_2Cl–PF_5–Ph_3TeFCl^+–PF_6^- system we choose the minimum set of coordination numbers,

Te(5) Te(6)

P(5) P(6)

F(1) F(2)

and the coordination numbers of the other elements are specified in Table 2. Using only these coordination numbers it is possible to construct four pathways which can account for the exchange and chemical behaviour of all the examples listed in Table 2.

A rapid equilibrium between trigonal bipyramidal molecules X_1, donor solvents or bases X_2, and octahedral intermediates X_3, may be described by pathway P(3,1) which must, necessarily, be accompanied by axial–equatorial and apical–basal scrambling of ligands. If solvent interactions are indeed mechanistically significant, as suggested previously (7, 11) and confirmed by low temperature nmr identification of $SiF_5(base)^-$, $PF_5(base)$, $AsF_5(FCH_3)$, and numerous other donor adducts $MX_5(base)$, then pathway P(3,1) represents a lower energy pathway than alternative polytopal processes such as Berry pseudorotation or turnstile rotation (21).

All four pathways have P(3,1) as the first step. Adding a 5-center step gives pathway P(4,2) which is illustrated in Table 2 by the reaction of SiF_4 with 2,2′-bipyridine. Such a 5-center step is very common in inorganic systems ("chelate effect") or in phosphate hydrolysis ("five-membered ring effect") (22).

Fluorine transfer reactions of Si, Ge, P, As, or Te fluorides can be accommodated by pathway P(5,2) or P{+𝒞, −𝒞}, while racemization and base-catalyzed hydrolysis of R_3SiX appears to follow pathway P(5,2) or P{+𝒞, +𝒞}, as illustrated in Table 2.

In summary, the above analysis provides a unified description of the stereodynamics and chemical reactivity of tellurium(VI) fluorides, as well as numerous other 4-, 5-, and 6-coordinate compounds, all of which participate in rapid equilibria involving coordination changes of the metal and ligand.

[2]An earlier paper entitled "The coordination model and its application to reaction mechanisms, particularly hydrolysis of some P, Si, and C compounds" was presented at a departmental seminar, University of Manitoba, October 1, 1974.

Experimental

^{19}F nmr spectra were recorded on a Bruker WH90 spectrometer at 84.66 MHz. The chemical shifts were measured relative to internal C_6F_6 (−162.9 ppm with respect to $CFCl_3$). ^{125}Te nmr spectra were recorded on a Bruker AM300 spectrometer at 94.76 MHz. The chemical shifts were measured relative to external Ph_2Te (692 ppm with respect to Me_2Te). XeF_2, PF_5, COF_2 (PCR/SCM Specialty Chemicals), and Ph_3TeCl (K & K Laboratories) were used as supplied. Tetraethylammonium chloride was dried over P_2O_5 in a vacuum desiccator. All gases were handled in a standard vacuum line and reactions were carried out in Teflon inserts in glass reaction vessels. All Teflon apparatus was dried at 110°C for several days.

Triphenyltellurium(IV) fluoride, Ph_3TeF, and mer-*Ph_3TeF_3 (1)*

Excess carbonyl fluoride was condensed into a Teflon tube containing triphenyltellurium chloride (0.073 g, 0.19 mmol) in CH_2Cl_2 (4 mL) at −196°C, in a method similar to that reported by Shreeve and Gupta (17). After 8 h at 22°C all volatile materials were removed under vacuum to give a white solid which was identified as Ph_3TeF (90%) by ^{19}F nmr.

Addition of XeF_2 to Ph_3TeF in a 1:1 molar ratio (9) gave *mer*-Ph_3TeF_3, **1** (95%), which was recrystallized from a mixture (2:7) of dichloromethane and hexane, washed twice with acetonitrile, and identified by ^{19}F and ^{125}Te nmr (Table 1).

Preparation of trans-*F_2TePh_3Cl, 3*

Addition of excess PF_5 into a Teflon tube at −196°C containing a purified sample of *mer*-Ph_3TeF_3, **1** (0.48 mmol), in CH_2Cl_2 (4 mL), and keeping the sample at 22°C for 30 min gave $Ph_3TeF_2^+PF_6^-$, **2**, in quantitative yield (9). Solid Et_4NCl (0.087 g, 0.52 mmol) was then added to a solution of **2** in CH_2Cl_2 with continuous shaking until a clear solution containing *trans*-F_2TePh_3Cl, **3**, was formed, as confirmed by ^{19}F and ^{125}Te nmr (Table 1). After 24 h in dichloromethane solution, 36% of *trans*-F_2TePh_3Cl, **3**, had rearranged to *cis*-F_2TePh_3Cl, **5**, as well as small amounts of *mer*-Ph_3TeF_3, **1**. After 6 days, 77% of *trans*-**3** had isomerized, and after one month all *trans*-**3** had disappeared and only *cis*-**5** and *mer*-**1** remained.

Preparation of cis-*F_2TePh_3Cl, 5*

Solid XeF_2 (0.029 g, 0.17 mmol) was added to triphenyltellurium(IV) chloride (0.067 g, 0.17 mmol) in CH_3CN (3 mL) in a Teflon bottle. The reaction mixture was stirred at 0°C for 8 h until a slightly yellow solution formed. The crude product contained *cis*-F_2TePh_3Cl, **5**, as well as *mer*-Ph_3TeF_3, **1**, in a 4:6 molar ratio. *mer*-**1** was removed by recrystallization from a mixture (2:7) of CH_2Cl_2 and hexane and washed with acetonitrile. *cis*-F_2TePh_3Cl, **5**, is soluble in CH_2Cl_2 and CH_3CN.

Preparation of $Ph_3TeFCl^+PF_6^-$, 4

Condensation of PF_5 into a solution of either *cis*- or *trans*-F_2TePh_3Cl (0.073 g, 0.17 mmol) in CH_2Cl_2 (4 mL) gave $Ph_3TeFCl^+PF_6^-$ **4** (95%), as confirmed by ^{19}F and ^{125}Te nmr (Table 1). A small amount of $Ph_3TeF_2^+PF_6^-$, **2**, was also formed due to the presence of *mer*-Ph_3TeF_3. The two cations **2** and **4** were stable in CH_2Cl_2 for at least 1 day and no intermolecular fluorine exchange was observed between cations **2** and **4**.

$Ph_3TeFCl^+PF_6^-$, 4, and cis-*F_2TePh_3Cl, 5*

The cation Ph_3TeFCl^+, **4**, was also characterized by its chemical reaction with NaF. An excess of NaF was added to a solution of cation Ph_3TeFCl^+, **4**, in CH_2Cl_2. After 1 day, excess NaF was filtered off and ^{19}F nmr of the solution showed the formation of *cis*-F_2TePh_3Cl, **5**.

Stability relationships between solid cesium aluminosilicates in aqueous solutions at 200°C[1]

PETER TAYLOR,[2] SHEILA D. DEVAAL, and DERREK G. OWEN
Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0
Received April 20, 1988

PETER TAYLOR, SHEILA D. DEVAAL, and DERREK G. OWEN. Can. J. Chem. **67**, 76 (1989).

Interconversion reactions among the solids SiO_2 (quartz and fused), γ-AlOOH (boehmite), $CsAlSiO_4$, $CsAlSi_2O_6$ (pollucite), and $CsAlSi_5O_{12}$, in contact with aqueous solutions at 200°C, have been investigated. Results support earlier suggestions that $CsAlSi_5O_{12}$ is not stable with respect to $CsAlSi_2O_6 + SiO_2$. $CsAlSiO_4$ is only stable, if at all, when the activity product of dissolved Cs^+ and OH^-, with respect to unit molality standard states, exceeds about 10^{-2}. $CsAlSi_2O_6$ is stable with respect to boehmite and quartz when the cesium hydroxide activity product exceeds $10^{-7.8\pm1.5}$. The significance of these results to the possible immobilization of radioactive cesium as a solid aluminosilicate is discussed. Based on a comparison with published estimates of enthalpies of formation, the following revised values are suggested:

$$\Delta_f H^0(CsAlSi_2O_6, s, 298\ K) = -3070 \pm 20\ kJ\ mol^{-1}$$

$$\Delta_f H^0(CsAlSiO_4, s, 298\ K) = -2133 \pm 20\ kJ\ mol^{-1}$$

Key words: cesium aluminosilicates, enthalpy of formation, hydrothermal reactions, pollucite, thermodynamic stability.

PETER TAYLOR, SHEILA D. DEVAAL et DERREK G. OWEN. Can. J. Chem. **67**, 76 (1989).

On a étudié les réactions d'interconversion entre les SiO_2 (quartz et quartz fondu), γ-AlOOH (boehmite), $CsAlSiO_4$, $CsAlSi_2O_6$ (pollucite) et $CsAlSi_5O_{12}$ solides, en contact avec des solutions aqueuses, à 200°C. Les résultats obtenus supportent les suggestions faites antérieurement à l'effet que le $CsAlSi_5O_{12}$ n'est pas stable par rapport au système $CsAlSi_2O_6 + SiO_2$. Le $CsAlSiO_4$ n'est stable, s'il l'est, que lorsque, par rapport à des états standard d'unité molaire, le produit d'activité des ions Cs^+ et OH^- dissous est supérieur à 10^{-2}. Lorsque le produit d'activité de l'hydroxyde de césium est supérieur à $10^{-7.8\pm1.5}$, le $CsAlSi_2O_6$ est stable par rapport à la boehmite et au quartz. On discute de l'importance de ces résultats sur la possibilité d'immobiliser du césium radioactif sous la forme d'aluminosilicate solide. En se bazant sur une comparaison d'évaluations publiées pour les enthalpies de formation, on suggère les valeurs révisées suivantes:

$$\Delta_f H^0(CsAlSi_2O_6, s, 298\ K) = -3070 \pm 20\ kJ\ mol^{-1}$$

$$\Delta_f H^0(CsAlSiO_4, s, 298\ K) = -2133 \pm 20\ kJ\ mol^{-1}$$

Mots clés : aluminosilicates de cesium, enthalpie de formation, réactions hydrothermales, pollucite, stabilité thermodynamique.

[Traduit par la revue]

1. Introduction

Solid cesium aluminosilicates, especially pollucite, have attracted attention as possible host phases for the immobilization of radioactive cesium (1–19), and as possible alteration products arising from the interaction of cesium-containing waste, groundwater, and aluminosilicate minerals (20–29). Synthetic pollucite has a composition close to the stoichiometric formula $CsAlSi_2O_6$, but in nature, it invariably occurs in solid solution with analcime, $NaAlSi_2O_6 \cdot H_2O$ (9–11). It is the only mineral containing cesium as a principal component. According to Cerny (10, 11), typical natural pollucites contain between 68 and 82 mol% $CsAlSi_2O_6$. There is some systematic deviation from the ideal solid-solution stoichiometry (10), so that the compositions of natural pollucites are close to the general formula, $(Cs_xNa_y)(Al_{x+y}Si_{3-x-y})O_6 \cdot (1-x)H_2O$, where $x + y \simeq 0.90$, and $y \simeq 0.15$. As well as $CsAlSi_2O_6$, two other synthetic cesium aluminosilicates, $CsAlSiO_4$ and $CsAlSi_5O_{12}$, have been investigated as possible waste forms for radioactive cesium (6, 7, 12–15).

The preparation of these three cesium aluminosilicates, by high-temperature dry syntheses from a variety of cesium salts and aluminosilicate precursors, has been investigated by several groups (1, 6, 7, 9, 14–17). Leaching and hydrothermal alteration of these materials have also been reported in some detail (7, 8, 11, 12, 14, 15, 18, 19). In addition, pollucite has been observed as a product of hydrothermal reactions between cesium-containing solutions and a variety of natural and synthetic aluminosilicate materials (12, 20–29). In contrast, there are few reports of $CsAlSiO_4$, and none of $CsAlSi_5O_{12}$, being produced hydrothermally (6, 22, 23). Some cesium-containing zeolites have also been prepared by hydrothermal reactions (21, 24, 30, 31).

Leaching and alteration studies indicate that $CsAlSiO_4$ is the least stable of the three cesium aluminosilicates in aqueous solutions at 100–300°C (12). Komarneni and Roy (14) concluded that $CsAlSi_2O_6$ is the best of these three candidates for Cs-137 immobilization. They presented indirect evidence that $CsAlSi_5O_{12}$ is not stable with respect to pollucite and quartz:

[1] $$CsAlSi_5O_{12}(s) \rightarrow CsAlSi_2O_6(s) + 3SiO_2(s)$$

Nonetheless, $CsAlSi_5O_{12}$ is more resistant than $CsAlSi_2O_6$ to acid leaching because of its higher Si/Al ratio (7, 14, 15).

Although the preparation and hydrothermal reactions of the cesium aluminosilicates have thus been studied quite extensively, there is little information on equilibrium phase relationships involving these solids. The only thermodynamic data for their formation appear to be some estimates by Lindemer *et al.* (32) and Grossman (33), the latter work being restricted to high temperatures (800–2000 K). Therefore, we have tried to obtain some experimental information on phase equilibria in the aqueous cesium aluminosilicate system.

2. Experimental procedure

The following reagent-grade starting materials were used: CsOH, Cs_2CO_3, Cs_2SO_4, $Al(NO_3)_3 \cdot 9H_2O$, SiO_2 (crystalline quartz and fused

silica powders, and 30 wt% colloidal aqueous suspension), and H_3PO_4. Solutions were prepared with freshly deionized, distilled water. Solids were identified by X-ray powder diffraction (XRD), sometimes supplemented by Fourier-transform infrared spectroscopy (FTIR).

Boehmite, γ-AlOOH, was chosen as a source of aluminum in these experiments because it was easily prepared as a pure phase, and it was sufficiently reactive to form pollucite under our experimental conditions, but was not converted to other aluminum oxyhydroxides or aluminosilicates other than pollucite. To prepare boehmite, we first converted aluminum nitrate to Al_2O_3, using a Bunsen burner until visible evolution of NO_2 ceased, then heating to 600°C in an electric furnace to complete decomposition. The resulting alumina powder was converted to boehmite by heating in stirred water in a Teflon-lined stainless steel autoclave at 200°C for 2 days. Its identity was confirmed by XRD and FTIR (34–36).

To prepare cesium aluminosilicates in 5–10 g quantities, we first made precursor powders, $Al_2O_3 \cdot zSiO_2$, with the appropriate value of z, by dehydration and thermal decomposition of solutions containing aluminum nitrate and colloidal silica. In this way, the Al and Si were sufficiently well mixed that phase-pure cesium aluminosilicates could be obtained, with the exception of $CsAlSi_5O_{12}$ (see below). $CsAlSiO_4$ was made by firing an $Al_2O_3 \cdot 2SiO_2$ powder with a 50% excess of Cs_2CO_3 over that required for reaction [2], for 0.5 h at 1000°C, then for 1 h at 1200°C:

[2] $Cs_2CO_3(s) + Al_2O_3(s) + 2SiO_2(s) \rightarrow 2CsAlSiO_4(s) + CO_2(g)$

The excess Cs_2CO_3 was necessary to sustain a high Cs_2O activity during crystallization, and thus prevent the formation of $CsAlSi_2O_6$ as a by-product from the competing reaction [3]; this excess sublimed from the sample during firing.

[3] $Cs_2CO_3(s) + Al_2O_3(s) + 4SiO_2(s) \rightarrow 2CsAlSi_2O_6(s) + CO_2(g)$

The XRD pattern of the product was in good agreement with data reported by Gallagher *et al.* (6).

Gallagher and McCarthy (9) reported difficulty in preparing phase-pure $CsAlSi_2O_6$ by high-temperature dry synthesis. We found that it was more conveniently prepared by hydrothermal reaction of an $Al_2O_3 \cdot 4SiO_2$ powder with a small excess of CsOH or Cs_2CO_3 over that required for reaction [4]:

[4] $2Cs^+(aq) + 2OH^-(aq) + Al_2O_3(s) + 4SiO_2(s) \rightarrow 2CsAlSi_2O_6(s) + H_2O(1)$

The XRD pattern of the product, formed during 2 days in an autoclave at 200°C, agreed well with published data (9).

$CsAlSi_5O_{12}$ is the most difficult of these three compounds to prepare in a pure state (7, 14, 15), and we never obtained it completely free of $CsAlSi_2O_6$ or other aluminosilicate impurities. It was obtained as the major product, with $CsAlSi_2O_6$ impurity, when an $Al_2O_3 \cdot 10SiO_2$ powder was fired at 1200°C for 16 h with the appropriate quantity of Cs_2CO_3 for reaction [5]:

[5] $Cs_2CO_3(s) + Al_2O_3(s) + 10SiO_2(s) \rightarrow 2CsAlSi_5O_{12}(s) + CO_2(g)$

The major features in the XRD pattern were in good agreement with ref. 34.

Two types of autoclave were used in experiments to determine stability limits of these cesium aluminosilicates. All of the experiments with $CsAlSiO_4$ and $CsAlSi_5O_{12}$, and some with $CsAlSi_2O_6$, were run with individually heated, 0.5-L capacity, stirred, Teflon-lined stainless-steel vessels, containing 175 mL of solution when loaded at room temperature. The remaining experiments with $CsAlSi_2O_6$ were run with 10 mL of solution in 20-mL capacity unstirred vessels, also constructed of stainless steel with Teflon liners, heated in an oven. All autoclave experiments were carried out at 200°C; this temperature was chosen because it was the lowest at which formation or depletion of the solids could be detected on a convenient time scale. Usually 2 to 4 days were sufficient to determine the direction of reaction. Longer runs (up to 26 days) were required for some more sluggish reactions and a few equilibration experiments. In selected experiments, dissolved cesium analyses were performed on both starting and final solutions, by atomic absorption spectrophotometry. Measurements of pH in cooled solutions were calibrated against standard buffer solutions at ambient temperatures.

3. Experimental strategy

We have tried to avoid some of the complexities of this multicomponent system by attempting to measure equilibria involving two or three solids, chosen to reduce the number of degrees of freedom of the equilibrium solution composition. The conceptual equilibria we have considered are shown in eqs. [6] to [11]; {X} represents the product of the activity coefficient and the molal concentration of species X in aqueous solution.

[6] $2CsAlSiO_4(s) + H_2O(l) \rightleftharpoons Cs^+(aq) + OH^-(aq) + CsAlSi_2O_6(s) + AlOOH(s)$
$k_6 = \{Cs^+\}\{OH^-\}$

[7] $CsAlSiO_4(s) + H_2O(l) \rightleftharpoons Cs^+(aq) + OH^-(aq) + AlOOH(s) + SiO_2(s)$
$k_7 = \{Cs^+\}\{OH^-\}$

[8] $CsAlSi_2O_6(s) + 2H_2O(l) \rightleftharpoons CsAlSiO_4(s) + H_4SiO_4(aq)$
$k_8 = \{H_4SiO_4\}$

[9] $CsAlSi_2O_6(s) + H_2O(l) \rightleftharpoons Cs^+(aq) + OH^-(aq) + AlOOH(s) + 2SiO_2(s)$
$k_9 = \{Cs^+\}\{OH^-\}$

[10] $(1/3)CsAlSi_5O_{12}(s) + 2H_2O(l) \rightleftharpoons (1/3)CsAlSi_2O_6(s) + H_4SiO_4(aq)$
$k_{10} = \{H_4SiO_4\}$

[11] $CsAlSi_5O_{12}(s) + H_2O(l) \rightleftharpoons Cs^+(aq) + OH^-(aq) + AlOOH(s) + 5SiO_2(s)$
$k_{11} = \{Cs^+\}\{OH^-\}$

According to the phase rule, not all of these equations can represent stable equilibria. For example, only one of the three cesium aluminosilicates can coexist with a solution saturated with quartz and boehmite, so two out of equilibria [7], [9], and [11] must be metastable with respect to the third, whichever has the lowest equilibrium ionic product, $\{Cs^+\}\{OH^-\}$. Furthermore, available Gibbs energy data for aluminosilicates (37) indicate that even this would be a metastable equilibrium with respect to kaolinite $(Al_2Si_2O_5)OH)_4)$, or some other clay mineral, although no such products were detected with XRD in these experiments. We therefore believe that the following is a valid account of stability relationships at 200°C between the three cesium aluminosilicates, boehmite, and silica.

4. Results and discussion

4.1 Experiments involving $CsAlSiO_4$

There are few reports of the formation of $CsAlSiO_4$ is hydrothermal reactions, all of them involving concentrated CsOH solutions (6, 22, 23). In dilute solutions, $CsAlSiO_4$ is rather easily altered to $CsAlSi_2O_6$ (12). Therefore, it appeared likely that K_6 and K_7 would be relatively high and K_8 low. The constants K_6 and K_8 both define the relative stability of $CsAlSiO_4$ and $CsAlSi_2O_6$. Given the difficulty of controlling and measuring low dissolved silica activities, we attempted to measure K_6 rather than K_8. Using experimental values for K_6 and K_9, we could then calculate K_7 and K_8 (see Section 5, below).

In preliminary experiments with $CsAlSiO_4$ alone, 1.0 g samples were extensively converted to $CsAlSi_2O_6$ when contacted with water, 0.01 mol kg^{-1} Cs_2CO_3, or 0.01 mol kg^{-1}

CsOH, for 2 days at 200°C. Boehmite was also formed in the reaction with water, but was not detected in the products from the more alkaline solutions, in which Al is more soluble.

When a mixture of $CsAlSiO_4$, $CsAlSi_2O_6$, and γ-AlOOH (0.5 g each) was contacted with 0.01 mol kg^{-1} CsOH for 2 days at 200°C, the $CsAlSiO_4$ was almost entirely consumed. The final pH, measured at rom temperature, was still close to 12, and the analysed cesium concentration was 0.013 mol kg^{-1}. We can thus set a lower limit for K_6 of 10^{-4} mol^2 kg^{-2}. In similar experiments with higher CsOH concentrations (0.1 or 0.3 mol kg^{-1}), both the $CsAlSiO_4$ and $CsAlSi_2O_6$ persisted, in approximately equal amounts, but the AlOOH was dissolved completely. Since the solution was thus undersaturated with respect to AlOOH, equilibrium [6] no longer holds for interpreting these runs.

When either $CsAlSiO_4$ or $CsAlSi_2O_6$ was contacted with 0.1 or 0.3 mol kg^{-1} CsOH, together with AlOOH, each cesium aluminosilicate persisted unchanged, even after 7 days at 200°C, suggesting that the solutions in each case were not far from equilibrium, i.e., $K_6 \simeq 10^{-2}$ mol^2 kg^{-2}. We were unable, however, to determine equilibrium [6] reversibly, i.e., we never observed the hydrothermal formation of $CsAlSiO_4$, even at high CsOH concentrations, so this conclusion is tentative. We did not go to CsOH concentrations above 0.3 mol kg^{-1}, because the extremely high solubility of boehmite under such conditions make K_6 inaccessible. We therefore estimate that $\log_{10} K_6 = -2 \pm 2$.

4.2. Experiments involving $CsAlSi_5O_{12}$

If, as Komarneni and Roy have suggested, $CsAlSi_5O_{12}$ is not stable with respect to pollucite and quartz (reaction [1]), then K_{10} must exceed the solubility of quartz (14). We have attempted to verify this, by examining conditions under which $CsAlSi_5O_{12}$ is converted to $CsAlSi_2O_6$, and by trying to prepare $CsAlSi_5O_{12}$ hydrothermally.

When 0.5 g each of $CsAlSi_2O_6$ and silica (either crystalline quartz or fused SiO_2) were contacted with 175 g of water at 200°C for 2 days, or with 10^{-3} mol kg^{-1} CsOH for 7 days, no $CsAlSi_5O_{12}$ could be detected in the products. Reaction of an $Al_2O_3 \cdot 10SiO_2$ powder with either CsOH or Cs_2CO_3 solutions also failed to produce $CsAlSi_5O_{12}$; $CsAlSi_2O_6$ and γ-AlOOH were the only detectable crystalline products.

When $CsAlSi_5O_{12}$ (1.0 g), containing $CsAlSi_2O_6$ impurity, was contacted with 175 g of water at 200°C for 3 days, XRD revealed an increase in the relative intensities of $CsAlSi_2O_6$ diffraction peaks. This occurred even when quartz saturation was assured by adding 4×10^{-3} mol kg^{-1} of colloidal silica; the result was reproduced in a duplicate experiment. These results support the conclusion in ref. 14 that $CsAlSi_5O_{12}$ is unstable with respect to reaction [1] at 200°C, although the reaction is slow, with only about 10% conversion of powdered starting material in 3 days. In another experiment, the $CsAlSi_5O_{12}$ was completely consumed, and $CsAlSi_2O_6$ was the sole crystalline product, after contacting with 0.1 mol kg^{-1} CsOH for 2 days at 200°C, but in this case, the solution was not presaturated with silica.

Given that $CsAlSi_5O_{12}$ is unstable with respect to reaction [1], it follows that K_{11} must be greater than K_9, even though $CsAlSi_2O_6$ is the more cesium-rich phase.

4.3. Experiments on the stability limits of $CsAlSi_2O_6$

The preceding sections describe stability relationships of $CsAlSi_2O_6$ with $CsAlSiO_4$ and $CsAlSi_5O_{12}$. To complete this survey of the stability of $CsAlSi_2O_6$ in the system Cs_2O–Al_2O_3–SiO_2–H_2O–[pH] at 200°C, we have investigated equilibrium [9]. This sets a lower limit to the range of cesium hydroxide activity products over which pollucite can occur.

TABLE 1. Cesium analyses and room-temperature pH of solutions after contact with quartz + boehmite + pollucite powders at 200°C

Starting solution	Time (days)	Final pH (room temperature)	Final [Cs] (mmol kg^{-1})
H_2O	2	7.5	0.29[a]
H_2O	7	6.8	0.33[a]
H_2O	26	6.5	0.28[b]
3×10^{-4} mol kg^{-1} CsOH	7	7.2	0.36[a]
10^{-3} mol kg^{-1} CsOH	7	7.9	0.46[a]
10^{-3} mol kg^{-1} CsOH	10	8.0	0.26[a]
5×10^{-4} mol kg^{-1} $Cs_2B_4O_7$ (CsOH + H_3BO_3)	10	7.5	0.25[a]
5×10^{-4} mol kg^{-1} Cs_2CO_3	26	6.6	0.28[b]
5×10^{-4} mol kg^{-1} Cs_2SO_4	15	5.9	1.05[a]
5×10^{-4} mol kg^{-1} Cs_2SO_4	26	6.1	0.99[b]
5×10^{-4} mol kg^{-1} Cs_2SO_4 + 10^{-3} mol kg^{-1} H_2SO_4	15	6.6	1.66[a]

[a] ±10%
[b] ±5%

We first determined conditions under which $CsAlSi_2O_6$ can be formed hydrothermally from γ-AlOOH and SiO_2 powders and Cs-containing solutions. It was produced when these powders were contacted with solutions of CsOH down to 10^{-3} mol kg^{-1}, and Cs_2CO_3 down to 5×10^{-4} mol kg^{-1}, for 2 days at 200°C. At cesium concentrations of 10^{-4} mol kg^{-1} or less, insufficient cesium would be present to form enough $CsAlSi_2O_6$ to detect by XRD. We can thus estimate an upper limit of 5×10^{-7} mol^2 kg^{-2} for K_9 at 200°C (dilute solutions of CO_3^{2-} are almost completely hydrolyzed to $HCO_3^- + OH^-$ at this temperature (38)), i.e., $\log_{10} K_9 \leq -6.3$. For reasons given below, we cannot use the final pH of these runs to define an upper limit of K_9.

To define K_9 more narrowly, we investigated the equilibration of mixtures of SiO_2, γ-AlOOH, and $CsAlSi_2O_6$ with aqueous solutions having different initial cesium activities and pH. Resulting pH (measured at ambient temperature, ~22°C) and cesium concentrations from eleven such experiments are presented in Table 1.

For experiments starting with alkaline cesium solutions or pure water, results are clustered around pH 6.5–8.0, with cesium concentrations in the range 0.25–0.46 mmol kg^{-1}. Since initial conditions in these runs were above and below the equilibrium activity product, K_9 (cesium solutions and pure water, respectively), the convergence of composition to these narrow ranges of pH and [Cs] suggests approach to equilibrium. We cannot rule out overshooting or undershooting, however, which could arise from slow dissolution of one or more of the solids. The increase in both pH and [Cs] in the run with acidified Cs_2SO_4 is also consistent with the equilibrium pH being close to neutral at cesium concentrations near 10^{-3} mol kg^{-1}.

If the mass balance, as well as the equilibrium solution compositions, was determined by eq. [9], then changes in $[Cs^+]$ and $[OH^-]$ in the course of reaction should be equal. This was not the case; final $[Cs^+]$ values always exceeded $[OH^-]$, even when initial values were equal. Consumption of OH^- to form hydrolyzed species such as $Al(OH)_4^-$ and $OSi(OH)_3^-$ could not completely account for this discrepancy (39, 40); rather,

reaction of dilute hydroxide solutions with the Teflon liners of the autoclave appears to be at least partly responsible.

In our experience, it is difficult to control pH in the slightly alkaline region (10^{-4} mol kg^{-1} OH^- or less) in Teflon-lined vessels at or above 200°C, apparently because of reaction with the Teflon itself. Such control of pH is necessary for an accurate determination of K_9. In blank experiments with 10^{-4} or 10^{-3} mol dm^{-3} NaOH, and no solid reagents, pH fell towards neutral, and solution analyses revealed fluoride concentrations up to 10^{-5} mol dm^{-3} after 6–10 days at 200°C. This confirms the occurrence of some reaction with the Teflon, although mass balance considerations show that simple hydrolysis does not account entirely for the pH change. Other, more complex possibilities include the presence of perfluorocarboxylic acid groups in the Teflon, or the solution, or both. Since the Teflon liner was an integral part of the seal in the small pressure vessels, we did not have a convenient method to duplicate experiments in the absence of Teflon. These vessels also had a rather high ratio of Teflon surface area to solution volume ($\sim 2\ cm^{-1}$), which likely compounded the problem.

Experiments to control the pH with phosphate-buffered solutions were inconclusive, probably because of reaction between the boehmite and phosphate. Borax (41) and bicarbonate/carbonate (38) buffers are too alkaline for our purposes at 200°C. We can only conclude, therefore, that the combination of neutral pH and a cesium concentration of 3×10^{-4} mol kg^{-1} represents a lower limit for K_9 at 200°C. The value of pK_w at 200°C is 11.30 (42), whence neutral pOH = pH = 5.65, and $\log_{10} K_9 \leq 9.2$. Combining this with the upper limit of −6.3, determined above, we estimate that $\log_{10} K_9 = -7.8 \pm 1.5$ at 200°C. This uncertainty represents the span of the upper and lower limits; for calculation purposes, it is treated below as a 95% confidence limit.

Since the assemblage quartz + boehmite + water is not thermodynamically stable with respect to kaolinite formation, the limiting ionic products for coexisting pollucite + quartz + kaolinite, or pollucite + boehmite + kaolinite (eqs. [12] and [13]) will be somewhat higher than K_9.

[12] $CsAlSi_2O_6(s) + (3/2)H_2O(l) \rightleftharpoons (1/2)Al_2Si_2O_5(OH)_4(s) + SiO_2(s) + Cs^+(aq) + OH^-(aq)$ Kaolinite

$k_{12} = \{Cs^+\}\{OH^-\}$

[13] $CsAlSi_2O_6(s) + AlOOH(s) + 2H_2O(l) \rightleftharpoons Al_2Si_2O_5(OH)_4(s) + Cs^+(aq) + OH^-(aq)$

$k_{13} = \{Cs^+\}\{OH^-\}$

Also, K_9 for well-crystallized quartz and boehmite is likely to be somewhat higher than our experimental value. Our boehmite showed some XRD line-broadening typical of material prepared at 200°C (35), and we made no attempt to remove the amorphous-silica-like layer that is believed to exist on powdered quartz (43, 44).

In more complex solutions, such as groundwaters, which contain other silicate-forming cations (especially Ca^{2+} and Mg^{2+}), the stability field of pollucite will be encroached upon, or even obliterated, by those of other solids (12, 14).

5. Calculated equilibria

Having obtained values for the equilibrium constants K_6 and K_9, we can derive K_7 and K_8. Simple algebraic operations on equilibria [6] and [9] yield relationships [14] to [16].

[14] $[7] = \{[6] + [9]\}/2$

whence

$$\log_{10} K_7 = 0.5\,(\log_{10} K_6 + \log_{10} K_9) = -4.9 \pm 1.8 \text{ at } 200°C$$

[15] $[16] = \{[6] + [9]\}/2$

[16] $CsAlSiO_4(s) + SiO_2(s) \rightleftharpoons CsAlSi_2O_6(s)$

The equilibrium constant K_{16} can be expressed as a silica activity ($a(SiO_2)$) with reference to a quartz standard state:

$$\log_{10} K_{16} = 0.5\,(\log_{10} K_6 - \log_{10} K_9) = -2.9 \pm 1.8 \text{ at } 200°C$$

Rimstidt and Barnes (44) reported relationships between the silica-water equilibrium constant, K_{17}, and absolute temperature.

[17] $SiO_2(s) + 2H_2O(l) \rightleftharpoons H_4SiO_4(aq)$

$$K_{17} = \log \{H_4SiO_4\} = \text{(for quartz) } 1.881 - 2.028 \times 10^{-3}T - 1560/T = -2.38 \text{ at } 200°C$$

whence

$$\log_{10} K_8 = \log_{10} K_{16} + \log_{10} K_{17} = -5.3 \pm 1.8$$

6. Comparisons with estimated thermodynamic values

It is desirable to compare our results with the thermodynamic quantities estimated by Lindemer *et al.* (32) for the solid cesium aluminosilicates. These quantities are shown in Table 2, together with ancillary data from other sources. The estimated uncertainties in the enthalpies of formation of $CsAlSiO_4$ and $CsAlSi_2O_6$ in ref. 32 are 10–20 kJ mol^{-1}.

Similar uncertainties in Gibbs energies of reaction arise from the 200°C equilibrium constants. These uncertainties dominate in the following calculations, and limit the extent to which comparison is possible.

Comparisons are most straightforward with the all-solid reactions, [16] and [18].

[16] $CsAlSiO_4(s) + SiO_2(s) \rightleftharpoons CsAlSi_2O_6(s)$

[18] $(1/3)CsAlSi_2O_6(s) + SiO_2(s) \rightleftharpoons (1/3)CsAlSi_5O_{12}(s)$

Although literature values vary considerably, reactions of this general type [19] most commonly have small positive entropies (based on data in refs. 37, 45, and 46).

[19] $A(s) + SiO_2(s) \rightleftharpoons B(s)$

where A and B are both aluminosilicates.

The literature data in Table 2 give $\Delta_r G^0 = -11$ kJ mol^{-1} for reaction [16] at 25°C. From $\log K_{16} = -2.9 \pm 1.8$ (see above) we obtain $\Delta_r G^0 = -26 \pm 16$ kJ mol^{-1} at 200°C. Since $\Delta_r S^0$ and, presumably, $\Delta_r C_p^0$ for reaction [16] are small, $\Delta_r G^0$ varies only slightly with temperature (~0.6 kJ mol^{-1} difference between 25 and 200°C, according to entropy values in Table 2; up to about 3 kJ mol^{-1} can be reasonably expected based on the preceding paragraph). There is thus a strong indication that the data from ref. 32 underestimate the stability of $CsAlSi_2O_6$ relative to $CsAlSiO_4$ in reaction [16]. In other words, if the data in ref. 32 were exactly correct, then K_6 and K_9 would lie near the upper and lower limits, respectively, of our experimental estimates. Such a narrow stability range seems unlikely, given the widespread occurrence of $CsAlSi_2O_6$, and the rarity of $CsAlSiO_4$, as hydrothermal reaction products.

The published Gibbs energy data in Table 2 give $\Delta_r G^0 = -30$ kJ mol^{-1} for reaction [18] at 25°C, whereas our results set a lower limit of zero at 200°C. As with reaction [16], the Gibbs

[a]Calculated from enthalpy and entropy data within this table.
[b]T. B. Lindemer (personal communication). There is a typographical error in the value given in ref. 32.
[c]Data for H_4SiO_4 in ref. 45 are inconsistent with quartz solubility, as discussed by Sadiq and Lindsay (47).

energy of this reaction is not expected to be so temperature-sensitive. Therefore, we would not expect $\Delta_r G^0$ to be less than about −5 kJ mol^{-1} at 25°C. The thermodynamic data for SiO_2 are well established, and the entropy of reaction [18] is small; therefore, it appears that the enthalpy difference between $CsAlSi_2O_6$ and $CsAlSi_5O_{12}$ is overestimated in ref. 32.

Finally, we compare our experimental values of K_6 and K_9 at 200°C with calculated 25°C values. For this purpose, it is useful to express reactions [16] and [9] in the alternative forms [20] and [21], respectively, since the heat capacities of reactants and products should then be more closely matched.

[20] $2CsAlSiO_4(s) + H^+(aq) \rightleftharpoons Cs^+(aq) + CsAlSi_2O_6(s) + AlOOH(s)$

$K_{20} = \{Cs^+\}/\{H^+\}$

$\log_{10} K_{20} = \log_{10} K_6 + pK_w = 9.3 \pm 2$ at 200°C

whence

$\Delta_r G^0 = -84 \pm 18$ kJ mol^{-1} at 200°C

$\Delta_r S^0 = +60.6$ J mol^{-1} K^{-1} at 25°C (from Table 2)

whence

$\Delta_r G^0 = -73 \pm 20$ kJ mol^{-1} at 25°C

[21] $CsAlSi_2O_6(s) + H^+(aq) \rightleftharpoons Cs^+(aq) + 2SiO_2(s) + AlOOH(s)$

$K_{21} = \{Cs^+\}/\{H^+\}$

$\log_{10} K_{21} = \log_{10} K_9 + pK_w = 3.5 \pm 1.5$ at 200°C

whence

$\Delta_r G^0 = -32 \pm 14$ kJ mol^{-1} at 200°C

$\Delta_r S^0 = +67.3$ J mol^{-1} K^{-1} at 25°C (from Table 2)

whence

$\Delta_r G^0 = -20 \pm 16$ kJ mol^{-1} at 25°C

Corresponding values of $\Delta_r G^0$ at 25°C, again calculated from Table 2, are −69 kJ mol^{-1} for reaction [20] and −46 kJ mol^{-1} for reaction [21]. The large difference in values for reaction [21] indicates that the chief discrepancy lies in the data for $CsAlSi_2O_6$.

At first sight, there appears to be an inconsistency between the good agreement on $\Delta_r G^0$ for reaction [20] and the poor agreement for reaction [16], since both concern the relative stability of $CsAlSi_2O_6$ and $CsAlSiO_4$. The molar ratios of the two solids in the two reactions are different, however, and the good agreement for reaction [20] can be attributed to a fortuitous balancing of errors.

All of the discrepancies discussed above are greatly reduced if $\Delta_f G^0$ for $CsAlSi_2O_6$ is 20–30 kJ mol^{-1} lower than the value derived from ref. 32, and that for $CsAlSiO_4$ is lowered by half that amount. We can not separate enthalpic and entropic contributions to these changes, but the former likely predominate. We therefore suggest the following enthalpy values:

$\Delta_f H^0(CsAlSi_2O_6, 298\ K) = -3070 \pm 20$ kJ mol^{-1}

$\Delta_f H^0(CsAlSiO_4, 298\ K) = -2133 \pm 20$ kJ mol^{-1}

The enthalpy of formation of $CsAlSi_5O_{12}$ given in ref. 32, −5805 kJ mol^{-1}, represents a reasonable lower limit on the basis of our results and the discussion of reaction [18], above. It is unlikely that $CsAlSi_5O_{12}$ is more than marginally unstable at 200°C, so we suggest no change in this enthalpy value.

Given the roughness of these thermochemical estimates, caution is required in any discussion of ambient-temperature phase relationships. The following equilibrium constants outline the stability limits of pollucite at 25°C, with uncertainties of at least three log units: $\log_{10} K_6 = -1.8$; $\log_{10} K_8 = -8.3$; $\log_{10} K_9 = -10.3$; $\log_{10} K_{10} = -4.3$. The low value of $\log_{10} K_9$ (cf. -7.8 ± 1.5 at 200°C) points to a somewhat larger stability field for pollucite at the lower temperature, in alkaline solutions. In acidic solutions, however, this difference is offset by the change in K_w with temperature.

7. Conclusions

Experiments with $CsAlSiO_4$, $CsAlSi_2O_6$, and $CsAlSi_5O_{12}$ have confirmed that $CsAlSi_2O_6$ is the most stable of these solids in aqueous solutions at 200°C. It is stable with respect to quartz + boehmite at $\{Cs^+\}\{OH^-\}$ ionic activity products above about 10^{-8} mol^2 kg^{-2}. It is stable with respect to $CsAlSiO_4$ at $\{Cs^+\}\{OH^-\}$ products up to at least 10^{-4}, and probably 10^{-2} mol^2 kg^{-2}. It is stable with respect to $CsAlSi_5O_{12}$ in quartz-saturated solutions.

The relatively high equilibrium cesium concentrations (i.e., 10^{-3} to 10^{-4} mol dm^{-3} in neutral solution) associated with pollucite equilibria, even in simple systems, indicate that it would be difficult to justify pollucite as a waste-form material on thermodynamic grounds. Its stability range is likely to be even narrower in groundwaters containing high concentrations of other cations, especially Ca^{2+} and Mg^{2+}. Pollucite or $CsAlSi_5O_{12}$ may still be justifiable waste-form choices, however, on kinetic grounds, i.e., slow dissolution and alteration at moderate temperatures. It also appears unlikely that pollucite crystallization could retard migration of cesium from a waste vault, except with extremely high cesium release rates from the waste form, or if the pH is high. We note that analcime–pollucite solid solutions are likely to be somewhat more stable than pure $CsAlSi_2O_6$ in alkali-rich groundwaters. Partitioning of cesium into silicate phases (either pre-existing minerals or alteration products), such as zeolites or micas, also remains a plausible mechanism for retardation. Some aspects of the special affinity

For personal use only.

of cesium for the mica structure have been discussed recently by Komarneni and Roy (48).

These results help to determine appropriate conditions for the hydrothermal synthesis of pollucite, or conversely, for the extraction of cesium from natural pollucite. They are consistent with most of the reports of pollucite formation and stability in hydrothermal experiments, cited in the Introduction, and may also throw some light on the conditions under which pollucite occurs in nature. They have led to experimental values, admittedly rough, for the enthalpies of formation of $CsAlSiO_4$ and $CsAlSi_2O_6$, and a lower limit for $CsAlSi_5O_{12}$.

The photochemistry of 5-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene

CHRISTOPHER OWEN BENDER[1] AND DOUGLAS DOLMAN
Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4
Received June 13, 1988

CHRISTOPHER OWEN BENDER and DOUGLAS DOLMAN. Can. J. Chem. **67**, 82 (1989).

The direct irradiation of 5-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**18**) led to 6-cyanobenzocyclooctatetraene (**17**; $\Phi = 0.00075$), 6-cyanobenzosemibullvalene (**14**; $\Phi = 0.0003$), and 2-cyanonaphthalene ($\Phi = 0.00015$). The triplet excited state of **18**, generated by sensitization with a variety of ketone sensitizers (e.g., Michler's ketone and acetophenone), showed no unimolecular reactivity. Compound **18** does not participate in Zimmerman di-π-methane rearrangement; the potential product from such a transformation, 8-cyanobenzosemibullvalene (**19**), was, however, isolated from direct (Corex filter; $\Phi = 0{,}0010$) irradiation of the semibullvalene **14**. Deuterium labelling experiments suggest that **14** derives from a mechanism involving initial C4—C8 bonding of **18**, and that cyclooctatetraene **17** is probably formed by simple electrocyclic opening of the cyclobutene ring of **18**.

Key words: photochemistry, rearrangement mechanism, di-π-methane, semibullvalenes.

CHRISTOPHER OWEN BENDER et DOUGLAS DOLMAN. Can. J. Chem. **67**, 82 (1989).

La photolyse directe du cyano-5 benzo-2,3 bicyclo[4.2.0]octatriène-2,4,7 (**18**) conduit au cyano-6 benzocyclooctatetraène (**17**; $\Phi = 0{,}00075$), au cyano-6 benzo semi-bullvalène (**14**; $\Phi = 0{,}0003$), et au cyano-2 naphtalène ($\Phi = 0{,}00015$). L'état excité triplet de **18**, qui se produit par des irradiations sensibilisées par l'acétophénone ou par le cétone de Michler, ne manifeste pas d'activité unimoleculaire. Le composé **18** ne subissait pas de transposition di-π-méthane de Zimmerman; le cyano-8 benzo semi-bullvalène (**19**), le produit potentiel d'une telle transposition, a été obtenu par irradiation directe (filtre de Corex; $\Phi = 0{,}0010$) du semi-bullvalène **14**. Des études de marquages au deuterium suggèrent que le semi-bullvalène **14** dérive d'un mécanisme qui comporte la formation d'une liaison initiale entre C4 et C8 de **18**, et que le cyclooctatetraène **17** se produit probablement par un mécanisme qui comporte la simple ouverture électrocyclique de l'anneau du cyclobutène de **18**.

Mots clés : photochimie, mécanisme de transposition, di-π-méthane, semi-bullvalènes.

Introduction

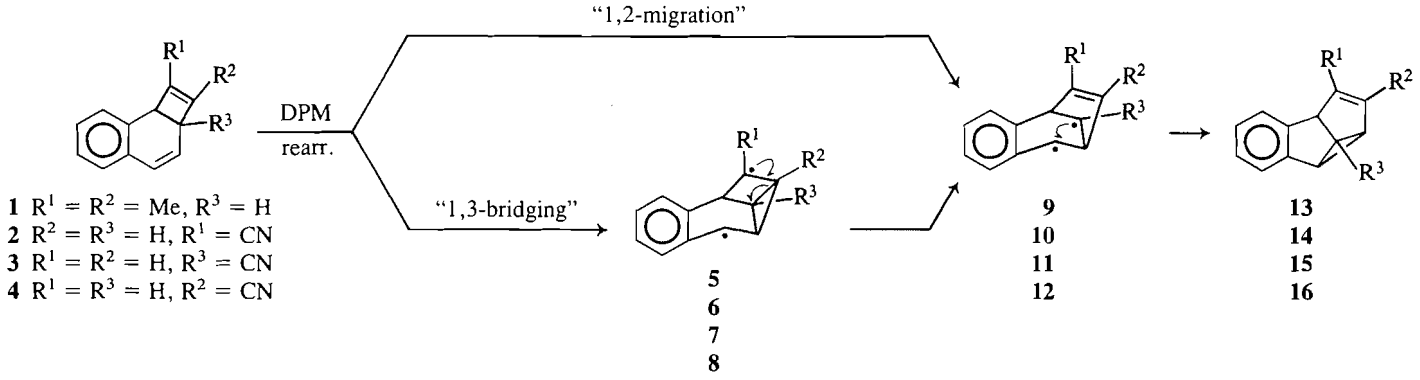
In recent publications we reported that upon irradiation with ultraviolet light 2,3-benzobicyclo[4.2.0]octa-2,4,7-trienes (e.g., **1** (1), **2** (2), **3** and **4** (3)) furnish, *inter alia*, semibullvalenes (SB's). Details of the reaction mechanisms were elaborated by the use of deuterium labelling and in all cases the SB formation could be accounted for in terms of a Zimmerman di-π-methane (DPM) rearrangement (4) of the starting diene (see Scheme 1); contending "1,3-vinyl,vinyl-bridging" and "1,2-vinyl-migration" versions of the rearrangements[2,3] are shown in Scheme 1. We now report on the photochemistry of 5-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**18**) and provide evidence for the first diene-to-SB conversion that does not involve a DPM rearrangement.

Results

Diene **18** was isolated, as previously described (2), as the minor product from the photolysis of 6-cyanobenzocyclooctatetraene (6-CN-BCOT, **17**; Scheme 2). The diene is thermally labile (as are the dienes **2** (2), **3**, and **4** (3)) and ring-opens to COT **17**. The isomerization is detectable on the gc at column temperatures > 125°C, and is essentially quantitative on heating at ca. 150°C for 4 h. On direct irradiation with 313-nm light, **18** undergoes rearrangement to SB **14** and COT **17**, and fragmentation to 2-cyanonaphthalene; the chemical (analytical) yields and quantum yields (Φ's) are given in Scheme 2. The photoproducts were identified by comparison (nmr, gc, and tlc) with authentic samples. Gas chromatographic monitoring during the progress of the photolyses established that 8-CN-SB (**19**), the potential DPM rearrangement product from diene **18**, was absent; **19** was independently prepared from SB **14** (*vide infra*) and used for gc comparisons.

In contrast to the direct irradiation of diene **18**, sensitized runs did not lead to observable unimolecular processes. Thus with Michler's ketone, *p*-dimethylaminobenzophenone, thioxanthone, or acetophenone as sensitizers, only polymeric or other high molecular weight materials were formed, and products isomeric with the starting diene were not detected by gc analysis.

Control experiments with the diene photoproducts SB **14** and COT **17**, and the potential DPM rearrangement product SB **19**, were carried out to examine for possible interconversions. Under the conditions used for the direct photolysis of diene **18**, i.e., irradiation with 313-nm light, solutions of SB's **14** and **19** were stable since neither absorbs light appreciably at this wavelength. However, with Corex-filtered light ($\lambda > 280$ nm) SB **14** yielded SB **19** ($\Phi = 0.001$), whereas the latter compound gave only polymeric material. Attempts to sensitize the photolysis of **14** and **19** with acetone as sensitizer led to the slow disappearance of the SB's without isomer formation.



The physical characterization of **19** proved troublesome since, like SB's **14** (2) and **16** (3), it undergoes facile polymerization upon solvent removal. The structural proof is therefore limited, and relies on spectroscopic data and reduction results.

The mass spectrum (via gc/ms) established the molecular weight as 179, and the ^{1}H nmr spectrum displayed chemical shifts and coupling constants diagnostic of the rigid SB system. The nmr data for **19** are compared with those of **15** (6) and parent benzosemibullvalene (**21**) (7) in Table 1. Further support for

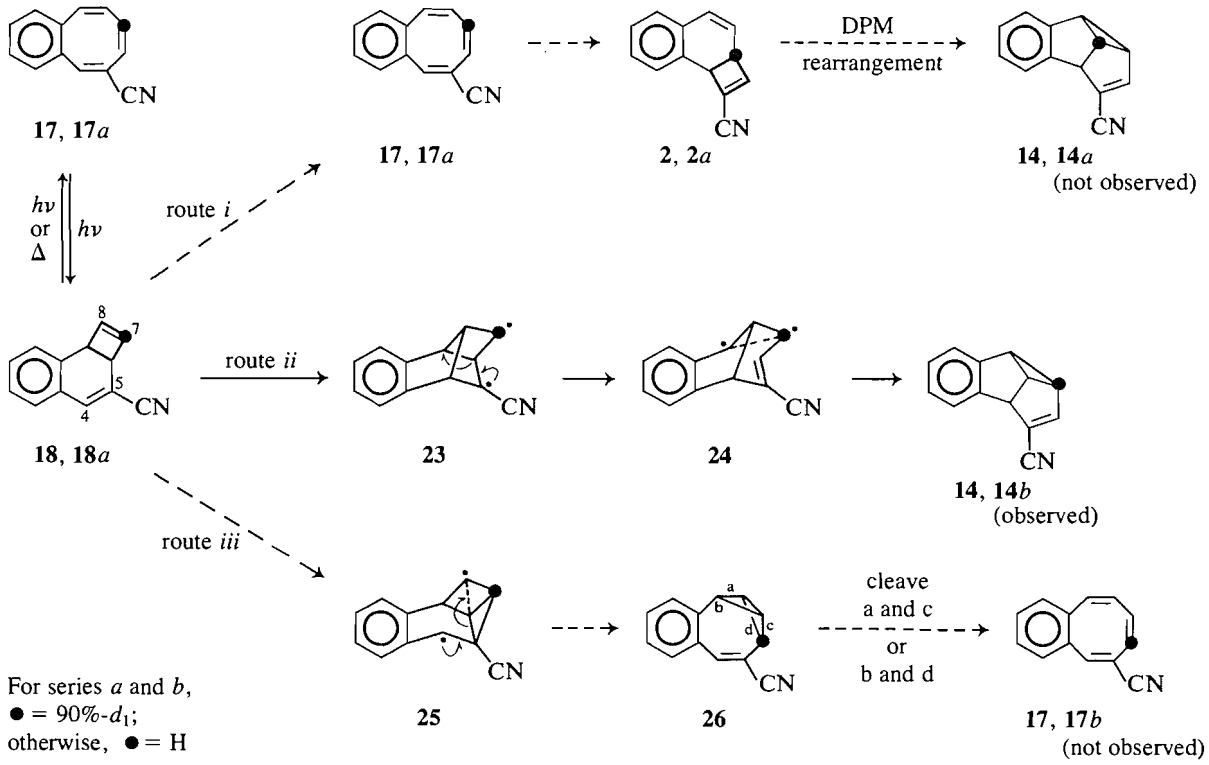
H-8	—	3.33 dd	2.60 dt

[a]Run in $CDCl_3$ (**15** and **19**) or CCl_4 (**21**) solvent with TMS as internal standard.
[b]Coupling constants for **19** are $J_{1,2} = J_{1,5} = 6$, $J_{5,6} = 2.5$, and $J_{6,7} = 5$ Hz; corresponding coupling constants for **15** and **21** are within 0.5 Hz.



SCHEME 3

structure **19** derives from its treatment with diimide whereupon 8-cyano-3,4-benzotricyclo[3.3.0.0.^{2,8}]oct-3-ene (**20**), a stable crystalline dihydro derivative of **19**, was obtained as the unique product (Scheme 3). The identification of **20** is based on comparison of its ^{1}H nmr spectrum with that of the closely related dihydro semibullvalene **22** (8). Details of the spectra are given in Table 2. Here we note that in common with other 6,7-dihydro SB's, **20** shows the characteristic "*W*" coupling constant of 1.5 Hz between H-5 and H-7 (2).

In the case of interconversions of **17**, the sensitized photolysis with *p*-dimethylaminobenzophenone as sensitizer proved the COT to be remarkably stable, and product formation was not observed even on extended irradiations. For the direct photolysis, the dienes **2** and **18** were initially formed, as shown in Scheme 2, and further irradiation eventually produced SB **14**. Since **14** is known to be the major product from the photolysis of diene **2** (2), it is tempting to speculate that the SB **14** found in the direct irradiation of diene **18** derives from the subsequent photochemistry of COT **17**, i.e., via the three-photon sequence: diene **18** → COT **17** → diene **2** → SB **14** (route *i*, Scheme 4). However, the failure to detect diene **2** in photolysates of **18** mitigates against this proposal, as do results from experiments with the deuterium labelled diene **18***a*.

Compound **18***a*, with deuterium attached to C-7, was

SCHEME 4

TABLE 2. The ^{1}H nmr data of the ring-attached protons of the dihydrosemibullvalenes **20** and **22**

Assignment	Description and signal positions, δ[a,b]	
	20	**22**[c]
Aromatics	7.00–7.33 m	7.02–7.20 m
H-1	3.36 dd	—
H-2	3.09 dd	3.15 dd
H-5	3.76 br t	3.87 br t
H-6	2.45 m	2.45 m
H-6′	1.68 br dd	1.76 br dd
H-7	2.10 ddd	2.01 m
H-7′	1.38 ddd	1.20 m
H-8	—	2.60 ddd

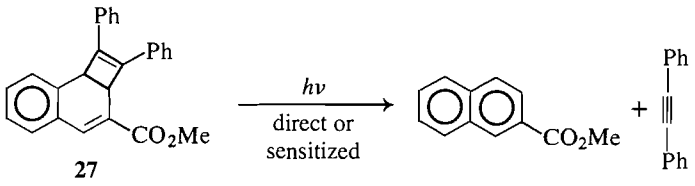
[a]Run in $CDCl_3$ solvent with TMS as internal standard.

[b]Coupling constants for **20** are $J_{1,2} = J_{6',7'} = 6.5$, $J_{1,5} = J_{5,6} = 5.0$, $J_{2,6'} = 1$, $J_{5,7} = 1.5$, $J_{5,6'} = J_{6',7} = 0$, $J_{6,7} = 8.5$, $J_{6,7'} = 11.5$, $J_{7,7'} = 13.5$; corresponding coupling constants for **22** are within 1.0 Hz.

[c]The original assignments reported for H-7 and H-7′ were in error and have been reversed here (8).

obtained from the photolysis of the known (6) deuterated COT **17***a* (ca. 90%-d_1 at C-8). The direct irradiation of **18***a* led to SB product **14***b*, with the deuterium located exclusively at C-8, as determined by ^{1}H nmr analysis (the integration results for **14***b* and all other labelled compounds are given in the Experimental). Thus the mechanism depicted as route *i* (Scheme 4), which requires the formation of SB **14***a* with deuterium located at C-1, is clearly ruled out by the labelling results. A plausible rationale that does account for the label distribution of **14***b* is shown as route *ii* in Scheme 4. It is a one-photon process that commences with initial C4—C8 bridging of the diene.[4]

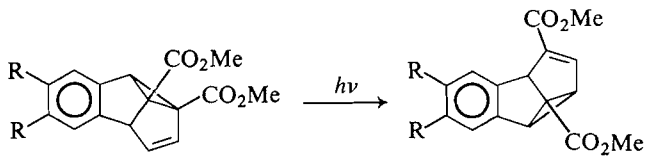
[4]Structures **23–25** should be interpreted as in footnote 3.



Also of mechanistic significance are the observations that the COT material obtained from the thermolysis and photolysis of **18***a* possessed the same label distribution as the original COT (**17***a*). Here we note that whereas the ground-state reaction cannot provide **17** by a single allowed electrocyclic process, the excited-state reaction can, by disrotatory opening of the cyclobutene ring. Interestingly, a previous study of the related diene **2** revealed that the deuterium distribution in the COT product resulting from thermolysis differed from that generated by direct irradiation, and involvement of an octavalene intermediate was proposed for the photochemical pathway (2). In the present case with diene **18**, an analogous mechanism (route *iii*, Scheme 4) cannot operate since this would engender the symmetric octavalene **26** and hence the formation of COT **17***b* rather than the observed COT **17***a*.[4]

Discussion

The singlet and triplet excited states of diene **18** show strikingly divergent behaviour. Thus whereas S_1 gives rise to both isomerization (to SB **14** and COT **17**) and fragmentation (to 2-cyanonaphthalene) processes, T_1 displays no unimolecular photochemistry. A pertinent point here is that regardless of the excited state multiplicity, the diene does not undergo DPM rearrangement (i.e., **18** does not give SB **19**). This observation is attributed to the known reluctance of DPM systems to rearrange via initial 1,3-bridging or 1,2-migration to the α-carbon of an acrylonitrile moiety. Note, for example, the avoidance of such a liaison in the sensitized rearrangements of 2-cyanobenzobarrelene (6), 5,6-dihydro-2-cyanobenzobarrelene (8), and 2-cyanobenzonorbornadiene (9). A similar rationale was used to account for the meager production (ca. 2% yield) of the DPM product SB **16** from diene **4** (3).



The most surprising finding in the present work is the formation of a semibullvalene product (SB **14**) from diene **18**, via a non-DPM pathway (route *ii*, Scheme 4). This result is unprecedented for a 2,3-benzobicyclo[4.2.0]octa-2,4,7-triene

SCHEME 6

and contrasts sharply with the photochemistry of diene **27** (10), the closest literature analogue to **18**, since it too is substituted with a strong electron-withdrawing group at C-5. Sasse and co-workers (10) found that on direct or sensitized irradiation **27** undergoes only cleavage to methyl 2-naphthoate and diphenylacetylene (Scheme 5).

A final unexpected result was the photoisomerization of SB **14** to SB **19**. The transformation is formally equivalent to a vinylcyclopropane rearrangement and can be viewed as an allowed Hückel 4-electron excited-state process (11), i.e., a $2\pi s + 2\sigma s$ sigmatropic [1,3] shift (12). Although the most common photoreaction of aro-fused SB's is isomerization to COT product (6, 13), there are at lest two literature examples of their participation in vinylcyclopropane interconversions. Both involve derivatives substituted at C-1 and C-8 with carbomethoxy groups, viz. **28** (→**30** (13); Scheme 6) and **29** (→**31** (14)), and the driving force for the conversions was suggested to be relief of the diester steric strain energy. Operation of the rearrangement in the case of SB **14**, which is devoid of such substituent strain, underscores the need for photochemical studies of other SB derivatives before further speculations on the product-controlling features of the reaction are warranted.

Experimental

The nmr spectra were recorded on a Bruker 400-MHz or a Varian 60-MHz instrument, with TMS as internal standard. The chemical shifts are in δ units and the coupling constants (*J*) in Hz. The abbreviations br, s, d, t, q, and m refer to broad, singlet, doublet, triplet, quartet, and multiplet, respectively. Melting points are uncorrected. Elemental analyses were performed by the Analytical Services Lab, Department of Chemistry, the University of Alberta. Column chromatography was carried out on Silica Gel 60 (Merck; 230–400 mesh) mixed with Sylvania 2282 phosphor and slurry packed into quartz columns permitting monitoring by a hand uv lamp. The gc analyses were made on a Varian 3700 instrument (FID), coupled to a Varian CDS 111 computing integrator, and fitted with an SE-30 fused silica capillary column 30 m × 0.32 mm; column temperatures of 125°C, or less, were used to minimize the thermal conversion of diene **18** to COT **17**. The gc/ms was recorded on an HP 5985 B instrument fitted with an SPB-1 fused silica capillary column, 30 m × 0.32 mm. Cyclohexane solvent for photolyses was prepared by scrubbing with 20% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Sensitizers were distilled or recrystallized (after sublimation) prior to use.

General procedures for preparative photolyses

The apparatus consisted of a 450-W Hanovia medium pressure mercury arc surrounded by a water-cooled quartz immersion well. The light was filtered through either cylindrical Corex or Pyrex sleeves, or an aqueous potassium chromate solution (300 mg K_2CrO_4 and 2.0 g of sodium carbonate in 1.6 L water; transmittance at 313 nm was 55%), or an aqueous lead nitrate solution (8 g $Pb(NO_3)_2$ and 750 g NaBr per 1 L of water; transmittance was 0% below 340 nm), or an aqueous copper sulfate solution (250 g $CuSO_4$ in 1 L of water; transmittance was 0% below 310 nm) contained in a concentric filter jacket (10-mm path length). Three types of sample cell were used. Cell A (250-mL sample volume) consisted of a cylindrical vessel (Pyrex), which surrounded the immersion well. Cell B (200-mL sample volume) consisted of a cylindrical collar (Pyrex), which surrounded the aqueous filter jacket. Both Cell A and Cell B were fitted with gas inlet and exit ports, and sample solutions were purged with argon prior to, and during, irradiations. Cell C (35-mL sample volume) was a test-tube-like vessel (quartz), and sample solutions contained therein were deoxygenated by flushing with argon and sealed under a positive pressure; the solutions were magnetically stirred throughout the course of the irradiations.

*Direct irradiation of diene **18***

A solution of 67.9 mg (0.38 mmol) of **18** (2) and 10.3 mg of tetradecane (gc standard) in 200 mL of cyclohexane was photolyzed at 313 nm for 4 h in Cell B (26% conversion by gc). The photolysate composition analysed (gc) for 0.6 mg (<1%) 2-cyanonaphthalene, 5.2 mg (8%) COT **17**, 50.0 mg (74%) diene **18**, and 1.8 mg (3%) SB **14**. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (2 cm × 45 cm; 2% ether–cyclohexane). The first band eluted was 4.6 mg (7%) of COT **17**, mp 72–74°C (from hexane; lit. (6) mp 73–74°C), identified by gc and nmr comparison with an authentic sample (6). The second band gave 48.4 mg (71%) of recovered diene **18**, and the third band contained a trace of 2-cyanonaphthalene (identified by gc, tlc, and nmr). The last band contained SB **14** of gc purity >98% (note: SB **14** polymerizes when solvent free), identified by gc and nmr comparison with an authentic sample (2).

*Sensitized irradiation of diene **18***

A solution of 33.0 mg (0.18 mmol) of diene **18**, 5.9 mg (0.026 mmol) of thioxanthone, and 13.8 mg of nonadecane (gc standard) in 35 mL of cyclohexane was irradiated at >340 nm (lead nitrate filter) for 2 h in Cell C. The photolysate composition analysed (gc) for 18.4 mg (56%) of diene **18** and 5.6 mg (95% recovery) of thioxanthone; no other products were detected. The photolysate was concentrated and the residue chromatographed on silica Gel 60 (2 cm × 45 cm; 2% ether–cyclohexane). The first band gave 17.3 mg (52%) of recovered diene **18**; the second band gave 5.1 mg (86%) of recovered sensitizer.

Under the same set-up, similar results were observed when Michler's ketone (at 0.57×10^{-3} M), *p*-dimethylaminobenzophenone (at 3.1×10^{-3} M), or acetophenone (at 1.4×10^{-1} M) were used as sensitizers.

*Thermolysis of diene **18***

A solution of 6.2 mg (0.035 mmol) of diene **18** and 2.3 mg of tetradecane (gc standard) in 2 mL of *n*-nonane was refluxed (ca. 150°C) during 5 h, under an argon atmosphere. The thermolysis product analysed (gc) for 6.0 mg (97%) COT **17**. Chromatography on Silica Gel 60 (1 cm × 10 cm; 2% ether–cyclohexane) gave 5.3 mg (85%) of COT **17**, mp 72–74°C (from hexane).

*Direct irradiation of SB **14***

A solution of ca. 28.5 mg (0.16 mmol) of SB **14** and 5.2 mg of tetradecane (gc standard) in 250 mL of cyclohexane was photolyzed for 50 min with Corex filtered light (66% conversion by gc) in Cell A. The photolysate composition analysed (gc) for 10.4 mg (36%) SB **19** and 9.8 mg (34%) SB **14**. The photolysate was concentrated to a small volume (ca. 5 mL; both SB's **14** and **19** polymerize when solvent free) and chromatographed on Silica Gel 60 (2.5 cm × 45 cm; 3% ether–cyclohexane). The first band contained SB **19** of gc purity >98%; details of the nmr data are given in Table 1; spin decoupling experiments: irradiation of H-6 collapsed H-7 to an s and H-5 to a d ($J_{1,5}$ = 6.0); irradiation of H-7 collapsed H-6 to a d ($J_{5,6}$ = 2.5); irradiation of H-5 collapsed H-6 to a d ($J_{6,7}$ = 5.0) and H-1 to a d ($J_{1,2}$ = 6.0); gc/ms showed molecular ion at m/e = 179 (65%), 178 (base peak). The second band contained recovered SB **14**.

*Diimide reduction of SB **19***

To a stirred mixture of ca. 25 mg (0.14 mmol) of **19** and 1.0 g (5.2 mmol) of potassium azodicarboxylate in 25 mL of dioxane at room temperature a 0.5-mL quantity of acetic acid was added in one portion. The mixture was stirred during 2.5 h, then added to 100 mL of toluene and washed with 10% sodium carbonate solution (100 mL), followed by water (2 × 75 mL). The toluene extract was dried ($MgSO_4$), concentrated, and the residue chromatographed on Silica Gel 60 (0.9 cm × 10 cm; 5% ether–cyclohexane). Sublimation (70°C/0.1 Torr; 1 Torr = 133.3 Pa) followed by crystallization of the main band from hexane gave 20.4 mg (81%) of colourless **20**, mp 58–60°C; ir (KBr): 2250 cm^{-1}, C≡N; uv (hexane): 258 sh (ε 370), 264 (600), 269 sh (820), 270 (910), and 278 nm (1 050); nmr (400 MHz; $CDCl_3$), see Table 2; spin decoupling experiments: irradiation of H-5 collapsed H-1 to a d ($J_{1,2}$ = 6.5), H-6 to a dt ($J_{6,6'} = J_{6,7'}$ = 11.5 and $J_{6,7}$ = 8.5), and H-7 to a dd ($J_{7,6}$ = 8.5 and $J_{7,7'}$ = 13.5); irradiation of H-1 collapsed H-5 to a br d ($J_{5,6}$ = 5) and H-2 to a br s; irradiation of H-2 collapsed H-1 to a d ($J_{1,5}$ = 5); irradiation of H-6 collapsed H-5 to a dd ($J_{5,1}$ = 5, $J_{5,7}$ = 1.5) and modified H-7, H-6′, and H-7′; irradiation of H-7 collapsed H-5 to a sharp t ($J_{5,1} = J_{5,6}$ = 5) and modified H-6 and H-7′; irradiation of H-6′ collapsed H-2 to a d ($J_{2,1}$ = 6.5) and modified H-6 and H-7′; irradiation of H-7′ collapsed H-6′ to a br d ($J_{6',6}$ = 11) and modified H-6 and H-7. Mass spectrum showed molecular ion at m/e = 181.0891 (68%), 128 (base peak); $C_{13}H_{11}N$ requires 181.0892. *Anal.* calcd. for $C_{13}H_{11}N$: C 86.15, H 6.12, N 7.73; found: C 86.26, H 6.04, N 7.71.

*Sensitized irradiation of SB **14***

A solution of ca. 32 mg (0.18 mmol) of SB **14** and 14.5 mg of tetradecane (gc standard) in 35 mL of acetone was irradiated for 7.5 h in Cell C with Pyrex-filtered light. The photolysate composition analysed (gc) for 15.8 mg (49%) of SB **14**; no other products were detected. The photolysate was concentrated and chromatographed on Silica Gel 60 (1 cm × 15 cm; 2% ether–cyclohexane). The nmr spectrum of the main band confirmed it to be recovered SB **14**.

*Labelled COT **17**a*

Deuterated COT **17***a* (90%-d_1 at C-8) was prepared as previously described (6); nmr (400 MHz; $CDCl_3$): 7.22–7.28 (m, 3.51H, H-5 + 2 aromatics + residual $CHCl_3$), 6.95–7.00 (m, 2.00H, 2 aromatics), 6.55 (d, 1.02H, H-10, $J_{10,9}$ = 11.5), 6.08 (dd, 0.07H, H-8, $J_{8,7}$ = 11, $J_{8,9}$ = 4), 6.04 (d, 1.00H, H-9, $J_{9,10}$ = 11.5), and 5.76 (br s, 0.97H, H-7). Integrations for **17***a* and all subsequent deuterium labelled compounds were normalized by assigning integer values to one or more aromatic proton signals, unless otherwise indicated; integration errors due to baseline undulations are estimated to be within ca. ±0.05H.

*Labelled diene **18**a from COT **17**a*

A solution of 238.9 mg (1.33 mmol) of COT **17***a* in 200 mL of cyclohexane was photolysed directly at >310 nm for 21 h in Cell B. The photolysate was concentrated and the residue crystallized from 5 mL of hexane to give 160.2 mg (67%) of recovered COT **17***a*. The mother liquors were column chromatographed on Silica Gel 60 (2 cm × 45 cm; 2.5% ethyl acetate – cyclohexane) into two bands. The second band gave 33.3 mg (14%) of diene **2***a* (2). The first band, containing diene **18***a* and COT **17***a*, was rechromatographed three times on Silica Gel 60 (2 cm × 45 cm; 2% ether–cyclohexane); COT **17***a* was eluted first, followed by diene **18***a*. This procedure led to the isolation of a further 26.4 mg (11%) of recovered COT **17***a*, and 12.6 mg (5%) of diene **18***a*; nmr (400 MHz; $CDCl_3$): 7.28–7.35 (m, 1.00H, 1 aromatic), 7.15–7.23 (m, 3.01H, 3 aromatics), 6.97 (br s, 1.00H, H-4), 6.22 (d, 0.09H, H-7, $J_{7,8}$ = 2.8), 6.10 (d, 0.97H, H-8, $J_{8,1}$ = 1), 4.27 (d, 1.00H, H-1, $J_{1,6}$ = 4.5), and 3.82 (d, 0.97H, H-6, $J_{6,1}$ = 4.5).

*Thermolysis of diene **18**a*

A solution of 5.3 mg (0.030 mmol) of diene **18***a* in 2 mL of *n*-nonane was refluxed (ca. 150°C) during 5 h, under an argon atmosphere. The thermolysis product was worked up as in the case of the nondeuterated diene to give 4.3 mg (81%) COT **17***a*; nmr (400 MHz; $CDCl_3$): 7.22–7.28 (m, 3.82H, H-5 + 2 aromatics + residual $CHCl_3$), 6.95–7.00 (m, 2.00H, 2 aromatics), 6.55 (d, 1.03H, H-10, $J_{10,9}$ = 11.5), 6.08 (dd, 0.10H, H-8, $J_{8,7}$ = 11, $J_{8,9}$ = 4), 6.04 (d, 0.98H, H-9, $J_{9,10}$ = 11.5), and 5.76 (br s, 0.97H, H-7).

*Direct irradiation of diene **18**a*

A solution of 29.5 mg (0.16 mmol) of **18***a* in 200 mL of cyclohexane was photolyzed at 313 nm for 4 h in Cell B. The photolysate, when worked up as in the case of the direct irradiation of unlabelled **18**, gave 2.8 mg (9%) COT **17***a*; nmr (400 MHz; $CDCl_3$): 7.22–7.28 (m, 3.35H, H-5 + aromatics + residual $CHCl_3$), 6.95–7.00 (m, 2.00H, 2 aromatics), 6.55 (d, 0.97H, H-10, $J_{10,9}$ = 11.5), 6.08 (dd, 0.10H, H-8, $J_{8,7}$ = 11, $J_{8,9}$ = 4), 6.04 (d, 1.00H, H-9, $J_{9,10}$ = 11.5), and 5.76 (br s, 0.96H, H-7); 18.2 mg (62%) of recovered diene **18***a*; nmr (400 MHz; $CDCl_3$): 7.28–7.35 (m, 1.00H, 1 aromatic), 7.15–7.23 (m, 2.90H, 3 aromatics), 6.97 (br s, 0.99H, H-4), 6.22 (d, 0.10H, H-7, $J_{7,8}$ = 2.8), 6.10 (d, 0.97H, H-8, $J_{8,1}$ = 1), 4.27 (d, 0.98H, H-1, $J_{1,6}$ = 4.5), and 3.82 (d, 0.98H, H-6, $J_{6,1}$ = 4.5); and ca. 1.0 mg (3%, estimated by gc) of SB **14***b*; nmr (400 MHz; $CDCl_3$): 7.33 (m, 1.00H, 1 aromatic) 7.18–7.28 (m, 3 aromatics + residual $CHCl_3$), 6.01 (s, 0.95H, H-7), 4.06 (d, 1.00H, H-5, $J_{5,1}$ = 6), 3.49 (t, 1.04H, H-1, $J_{1,2} = J_{1,5}$ = 6), 3.29 (d, 1.00H, H-2, $J_{2,1}$ = 6), and 2.79 (m, 0.08H, H-8).

Quantum yield determinations

Quantum yields were performed on an apparatus previously described (13), which includes an optical bench arranged for beam splitting into a ferrioxalate actinometer (15). Cyclohexane solutions (3 mL) of reactants (ca. (5–6.5) × 10^{-3} M) were deoxygenated prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations. The quantum yields (Φ's) were obtained from several runs extrapolated to zero conversion. Product analyses were determined by gc (internal tetradecane standard). For the direct irradiation of diene **18**, light of wavelength 313 nm was used; appearance Φ's were 0.00075 for COT **17**, 0.0003 for SB **14**, and 0.00015 for 2-cyanonaphthalene. For the direct irradiation of SB **14**, light of wavelength 280 nm was used; the appearance Φ for SB **19** was 0.0010.

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

MINGDA SHE, XIANRONG CHEN, and XIN-SHENG YU. Can. J. Chem. **67**, 88 (1989).

A least-square fitting method is given for exact evaluation of spin-Hamiltonian and line shape parameters from EPR powder spectra. The method is applicable to cases where the resonance fields can be analytically expressed or can only be obtained by diagonalization of Hamiltonian. It is also suitable for different line shapes and spin-Hamiltonians. The fitted spectra and corresponding refined parameters were obtained on FACOM-M340S computer with a Fortran 77 program.

Key words: spin-Hamiltonian, line shape parameters, electron paramagnetic resonance, calculated spectra, least squares fitting.

MINGDA SHE, XIANRONG CHEN et XIN-SHENG YU. Can. J. Chem. **67**, 88 (1989).

On présente une méthode d'ajustement par la méthode des moindres carrés pour évaluer d'une façon exacte l'Hamiltonien de spin et les paramètres de la forme des raies de spectres rpe de poudres. On peut appliquer la méthode à des cas où les champs de résonance peuvent soit être exprimés d'une façon analytique ou ne peuvent être obtenus que par une diagonalisation de l'Hamiltonien. Elle est aussi appropriée pour des formes de raies ou des Hamiltoniens de spin qui sont différents. On a obtenu les spectres ajustés ainsi que les paramètres affinés correspondants à l'aide d'un ordinateur FACOM-M340S opérant avec un programme Fortran 77.

Mots clés : Hamiltonien de spin, paramètres de la forme, résonance paramagnétique électronique, spectres calculés, ajustement par la méthode de moindres carrés.

1. Introduction

To obtain information on interactions between unpaired electrons and ligands, one needs to know the Hamiltonian and line shape parameters of EPR spectra, such as the **g** factor, the fine or hyperfine tensors **D** and **A**, line widths, and so on. It is difficult to determine these parameters from powder spectra when the paramagnetic centers are strongly anisotropic or when the line is broad. The spectrum from powder samples is a superposition of a large number of lines from randomly oriented microcrystallites, resulting in parts of fine or hyperfine splittings being smeared out by the overlapping of spectra.

The analyses of powder spectra are usually carried out by computer. When the spin-Hamiltonian is known and a reasonable simulated spectrum is obtained, it is desirable to refine the EPR parameters as much as possible. Most such refinements are done by manual or brute-force fitting. Such fittings lack mathematical criteria and are time consuming. But because of their simplicity in programming, these methods are widely used. Hauser and Renaud (1) and McGavin and Tennant (2) fitted the powder spectra by these methods and obtained the fitted values of the Hamiltonian parameters. Other authors (3–5), who analyzed EPR powder spectra by simulation or fitting, seldom reported how to get the final values but just gave the simulated spectra.

It seems possible to minimize computer time and get refined spectroscopic parameters more quickly by using the optimization theory. A difficulty here is that the expression of a powder spectrum in most cases only can be written as an integral function instead of an analytical one. When the off-diagonal elements of the Hamiltonian are large compared with the diagonal ones, the resonance fields can only be calculated numerically. Even if the resonance fields can be expressed analytically, the integrations of powder spectra can be worked out only in a few cases. This hampers the direct application of optimization theory to EPR powder spectrum parameter refinement. In some cases, where certain approximations are made, analytical expressions are available. Ibers and Swalen (6), Lardon and Günthard (7), and Siderer and Luz (8) derived several expressions, which were only applicable to certain line shapes under some assumptions. For example, the expressions in refs. 6 and 7 were based on Lorentzian shape. Formulae in ref. 8 omitted the influence of the anisotropic transition probability factors. A general procedure for powder spectrum fitting is desirable.

In this paper we present a method for extracting parameters from an EPR powder spectrum by least-square fitting. It is applicable to cases where the resonance fields can be analytically expressed or can only be obtained by the diagonalization of Hamiltonian. It is also applicable to different spin-Hamiltonians and different line shapes. The method was used to fit the powder spectra of blue copper protein and $CuSO_4 \cdot 7H_2O$. The refined parameters as well as the fitted spectra were obtained and the line shapes were determined.

2. Calculation of powder spectrum

Since the EPR powder spectrum is a superposition of the spectra from a large number of randomly oriented paramagnetic centers, the expression for the powder spectrum is an integral

[1]Present address: Department of Scientific Instrumentation, Xiamen University, Xiamen, Fujian, China.

[2]Revision received September 26, 1988.

function (9)

$$[2.1]\quad I(H) = \int_0^{2\pi}\int_0^{\pi} \sin\theta\, d\theta\, d\varphi \sum_m P_m(\theta,\varphi)\left|\frac{\partial H_m(\theta,\varphi)}{\partial h\nu}\right| f_m\left(\frac{H - H_m(\theta,\varphi)}{\Delta H_m(\theta,\varphi)}\right)$$

where $I(H)$ is the microwave absorption, θ and φ are the orientation of applied field H with respect to principal axes of the **g** tensor, H_m, ΔH_m, $f_m((H - H_m)/\Delta H_m)$ and $P_m(\theta,\varphi)$ are the resonance field, line width, line shape function, and transition probability of the mth transition, respectively, and ν is the microwave frequency. In EPR spectra f_m is usually taken to be Gaussian or Lorentzian. Assuming the spin-Hamiltonian of the observed system to be $\mathcal{H}(H)$, H being the external applied field, we have

$$[2.2]\quad h\nu = E_j(H_m) - E_i(H_m)$$

where E_i is the eigenvalue of $\mathcal{H}$,

$$[2.3]\quad \mathcal{H}|i\rangle = E_i|i\rangle$$

The transition probability $P_m(\theta,\varphi)$ can be written as (9)

$$[2.4]\quad P_m(\theta,\varphi) = \left(\frac{\pi}{2}\right)\beta^2 H_1^2[|\langle i|g_x\cos\theta\cos\varphi\,\hat{S}_x + g_y\cos\theta\sin\varphi\,\hat{S}_y - g_z\sin\theta\,\hat{S}_z|j\rangle|^2 + |\langle i|g_x\sin\varphi\,\hat{S}_x - g_y\cos\varphi\,\hat{S}_y|j\rangle|^2]$$

where the $\hat{S}_i$ $(i = x, y, z)$ stand for electron spin operators, β is the Bhor's magneton, and H_1 is the magnetic field amplitude of the microwave radiation. $|\partial H_m/\partial h\nu|$ can be calculated from (13)

$$[2.5]\quad \left|\frac{\partial H_m}{\partial h\nu}\right| = \left|\frac{\partial \Delta E}{\partial H}\right|^{-1} = \left|\frac{\partial E_j}{\partial H} - \frac{\partial E_i}{\partial H}\right|^{-1}$$

Usually the complete powder spectrum [2.1] is calculated numerically. The major work involved is the evaluation of resonance fields. When perturbation theory can not be used, the brute-force (or consecutive) method is usually used so the computation time is long.

We find that the computation time can be greatly reduced by using the least-square fitting procedure given by Misra and Vasilopoulos (10) to find the angular variations of fields. In this method, first we calculate $H_m(\theta,\varphi)$ $(m = 1, 2, \ldots)$, at a certain orientation of the magnetic field by either the perturbation approach or by the brute-force method (9). Then using $H(\theta,\varphi)$ as the initial value of $H(\theta + \Delta\theta, \varphi + \Delta\varphi)$, we minimize the deviation

$$[2.6]\quad S = (|E_j - E_i| - h\nu)^2 = (|\Delta E| - h\nu)^2$$

until convergence is achieved by iteration

$$[2.7]\quad H_{k+1} = H_k + \lambda_k p_k$$

where

$$[2.8]\quad p_k = -\left(\frac{\partial S}{\partial H}\right)_{H_k}\left(\frac{\partial^2 S}{\partial H^2}\right)_{H_k}$$

Computing $\partial S/\partial H$ and $\partial^2 S/\partial H^2$ follows the method of Misra and Vasilopoulos (10):

$$[2.9]\quad \partial S/\partial H = 2(E_j - E_i)(|\Delta E| - h\nu)\left(\frac{\partial E_j}{\partial H} - \frac{\partial E_i}{\partial H}\right)\Big/ |\Delta E|$$

$$[2.10]\quad \partial^2 S/\partial H^2 = 2\left(\frac{\partial E_j}{\partial H} - \frac{\partial E_i}{\partial H}\right)^2 + (|\Delta E| - h\nu)(E_j - E_i)\left(\frac{\partial^2 E_j}{\partial H^2} - \frac{\partial^2 E_i}{\partial H^2}\right)\Big/ |\Delta E|$$

where

$$[2.11]\quad \partial E_i/\partial H = \mathrm{Tr}\left[\frac{\partial \mathcal{H}}{\partial H}|i\rangle\otimes\langle i|\right]$$

$$[2.12]\quad \partial^2 E_i/\partial H^2 = \sum_n{}' \mathrm{Tr}\left[\frac{\partial \mathcal{H}}{\partial H}(|i\rangle\otimes\langle i|)\frac{\partial \mathcal{H}}{\partial H}(|n\rangle\otimes\langle n|)\right]\Big/(E_i - E_n) + \text{c.c.}$$

In [2.12], c.c. stands for the complex conjugate of the first term, Tr stands for the trace, and

$$[2.13]\quad (|i\rangle\otimes\langle i|)_{pq} = |i\rangle_p|i\rangle_q^*$$

To find the angular variations of resonance fields we suggest that the number of fitting points of resonance fields be small. The values between two adjacent points can be found by interpolation.

3. The procedure for least-square fitting of powder spectrum

The general form of expression for a powder spectrum can be written

$$[3.1]\quad Q(H,\boldsymbol{a}) = \int_0^{2\pi}\int_0^{\pi} F(H,\boldsymbol{a},\theta,\varphi)\,d\theta\,d\varphi$$

from eqs. [2.1] and [3.1] we know

$$[3.2]\quad F(H,\boldsymbol{a},\theta,\varphi) = \sum_m \left|\frac{\partial H_m}{\partial h\nu}\right| P_m(\theta,\varphi) f_m\left(\frac{H - H_m}{\Delta H_m}\right)\sin\theta$$

F is an analytical function only when the resonance fields can be analytically expressed. When the line shape functions f_m are Gaussian or Lorentzian, Q represents the intensity of microwave absorption. When f_m are taken as the first derivatives of the functions, Q represents the derivative of the absorption spectrum; $\boldsymbol{a}$ is a vector the components of which are the parameters of both Hamiltonian and line shape. It can be written as

$$\boldsymbol{a} = (a_1, a_2, \ldots, a_N)$$

where N is the number of parameters.

From discrete sampling of the recorded spectrum (usually in the form of derivatives of absorption intensities), we can get a set of discrete data $e(H_i)$ $(i = 1, 2, \ldots, n_d)$, n_d being the number of sampling points. Using the DFP method (11) to fit the spectrum, we have to calculate the first derivatives of χ^2 with respect to $\boldsymbol{a}$. χ^2, the deviation of simulated and recorded spectrum, is given by

$$[3.3]\quad \chi^2 = \sum_{i=1}^{n_d}[Q(H_i,\boldsymbol{a}) - e(H_i)]^2$$

In [3.3], when $e(H_i)$ is the first derivative of the absorption, the shape functions f_m should also take the form of derivatives

so that Q represents the derivative of absorption. For calculation we can assume a theoretical model for the powder spectrum by giving the form of the spin-Hamiltonian and the line-shape function. After initial values of the parameters are guessed, the calculated spectrum $Q(H,\boldsymbol{a})$ can be obtained numerically.

In the DFP method, $\boldsymbol{a}_{k+1}$, the parameters in the $(k+1)$th iteration which leads to a smaller χ^2, can be obtained from $\boldsymbol{a}_k$:

$$[3.4] \quad \boldsymbol{a}_{k+1} = \boldsymbol{a}_k + \lambda_k \boldsymbol{p}_k$$

where λ_k is the search step length, $\boldsymbol{p}_k$ is the product of the DFP update matrix h and the gradient of χ^2 with respect to $\boldsymbol{a}$,

$$\boldsymbol{p}_k = -h_k . \boldsymbol{g}_k$$

$$\boldsymbol{g}_k = \left(\frac{\partial\chi^2}{\partial a_1}, \frac{\partial\chi^2}{\partial a_2}, \ldots, \frac{\partial\chi^2}{\partial a_N}\right)_k$$

$$[3.5] \quad h_k = h_{k-1} + \frac{s.s^{\mathrm{T}}}{s^{\mathrm{T}}.y} - \frac{h_{k-1}.y.y^{\mathrm{T}}.h_{k-1}}{y^{\mathrm{T}}.h_{k-1}.y}$$

$$s = \boldsymbol{a}_k - \boldsymbol{a}_{k-1}$$

$$y = \boldsymbol{g}_k - \boldsymbol{g}_{k-1}$$

where s^{T}, y^{T} are the column matrices of vectors s and y. Before iteration, the update matrix is set to unity. In constructing h, the derivatives of χ^2 in the kth iteration are only needed up to first order. When the integrand F in [3.1] is analytical, these derivatives can be obtained readily. Otherwise, F and its derivatives only can be found numerically.

For the calculation of

$$[3.6] \quad \frac{\partial\chi^2}{\partial a_l} = 2\sum_{i=1}^{n_d}[Q(H_i,\boldsymbol{a}_k) - e(H_i)]\frac{\partial Q(H_i,\boldsymbol{a}_k)}{\partial a_l} \qquad (l = 1, 2, \ldots, N)$$

we have to know $\partial F/\partial a_l$, which can be expressed as

$$[3.7] \quad \frac{\partial F}{\partial a_l} = \sum_m \left[D_h P_m f_m + \left|\frac{\partial H_m}{\partial h\nu}\right| D_p f_m + \left|\frac{\partial H_m}{\partial h\nu}\right| P_m D_f \right]$$

where

$$[3.8] \quad D_h = \frac{\partial}{\partial a_l}\left|\frac{\partial H_m}{\partial h\nu}\right|$$

$$[3.9] \quad D_p = \partial P_m/\partial a_l$$

$$[3.10] \quad D_f = \partial f_m/\partial a_l$$

From eq. [2.5] and [2.4] we get

$$[3.11] \quad D_h = -\left|\frac{\partial H_m}{\partial h\nu}\right| \left(\frac{\partial^2 E_j}{\partial H \partial a_l} - \frac{\partial^2 E_i}{\partial H \partial a_l}\right) \Big/ \left(\frac{\partial E_j}{\partial H} - \frac{\partial E_i}{\partial H}\right)$$

$$[3.12] \quad D_p = (\pi/2)\beta^2 H_1^2\{(\langle i|g_x \cos\theta \cos\varphi\, \hat{S}_x + g_y \cos\theta \sin\varphi\, \hat{S}_y - g_z \sin\theta\, \hat{S}_z|j\rangle)^*(\cos\theta\cos\varphi\langle g_x\hat{S}_x\rangle_{ij,l} + \cos\theta\sin\varphi\langle g_y\hat{S}_y\rangle_{ij,l} - \sin\theta\langle g_z\hat{S}_z\rangle_{ij,l}) + (\langle i|g_x \sin\varphi\, \hat{S}_x - g_y \cos\varphi\, \hat{S}_y|j\rangle)^*(\sin\varphi\langle g_x\hat{S}_x\rangle_{ij,l} - \cos\varphi\langle g_y\hat{S}_y\rangle_{ij,l})\} + \text{c.c.}$$

$$[3.13] \quad D_f = \frac{\partial f_m}{\partial a_l}\bigg|_{H_m} + \frac{\partial f_m}{\partial H_m}\cdot\frac{\partial H_m}{\partial a_l}$$

In eq. [3.12]

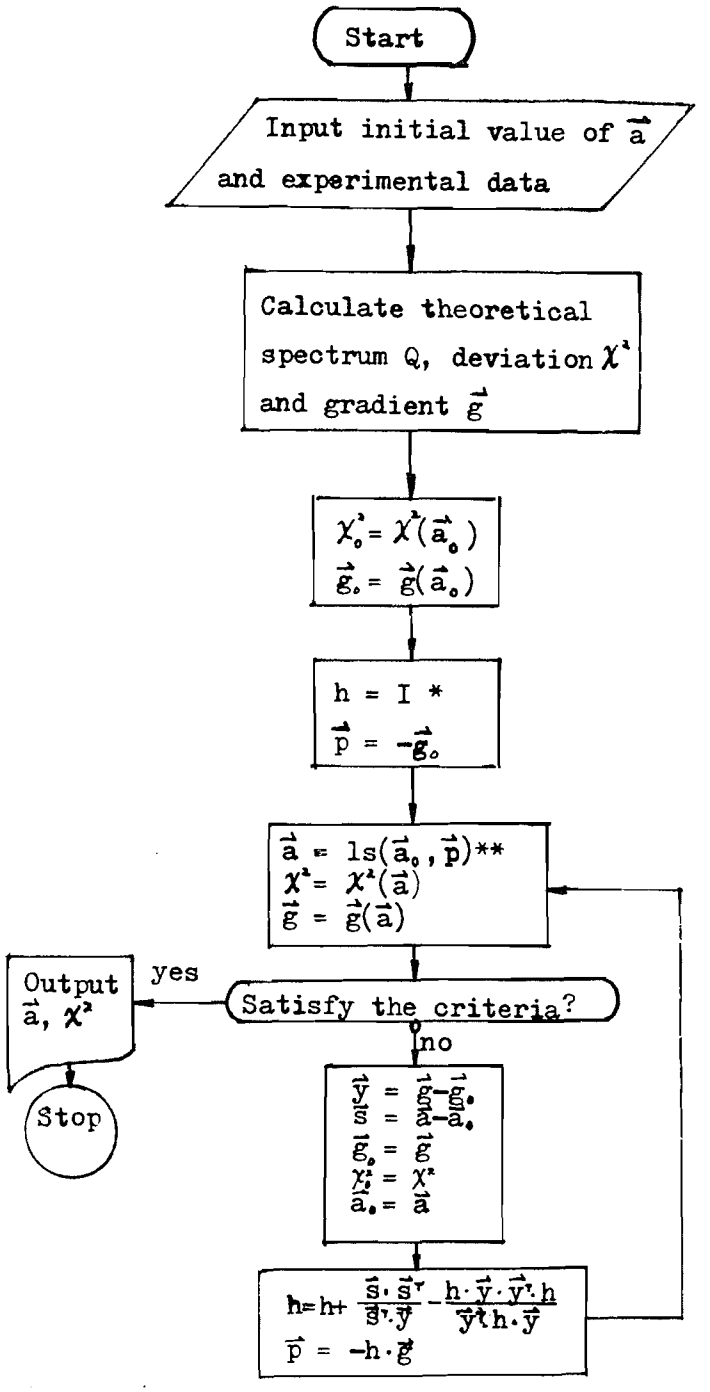

FIG. 1. The flow diagram of DFP subroutine (* I is a unit matrix. ** ls($\boldsymbol{a}_0$,$\boldsymbol{p}$) means the linear search of $\boldsymbol{a}$ which minimizes χ^2 following the search direction $\boldsymbol{p}$ and starting from $\boldsymbol{a}_0$ according to eq. [3.4]).

$$[3.14] \quad \langle g_k\hat{S}_k\rangle_{ij,l} = \frac{\partial g_k}{\partial a_l}\langle i|\hat{S}_k|j\rangle + g_k\Sigma_n{}'\,\mathrm{Tr}\left(\frac{\partial\mathcal{H}}{\partial a_l}|n\rangle\otimes\langle n|\hat{S}_k|j\rangle\otimes\langle i|\right)\Big/(E_i - E_n) + (\text{c.c. of second term with } i,j \text{ exchanged}) \qquad (k = x, y, z)$$

In eq. [3.13] the derivative of H_m is given by Van Veen (9)

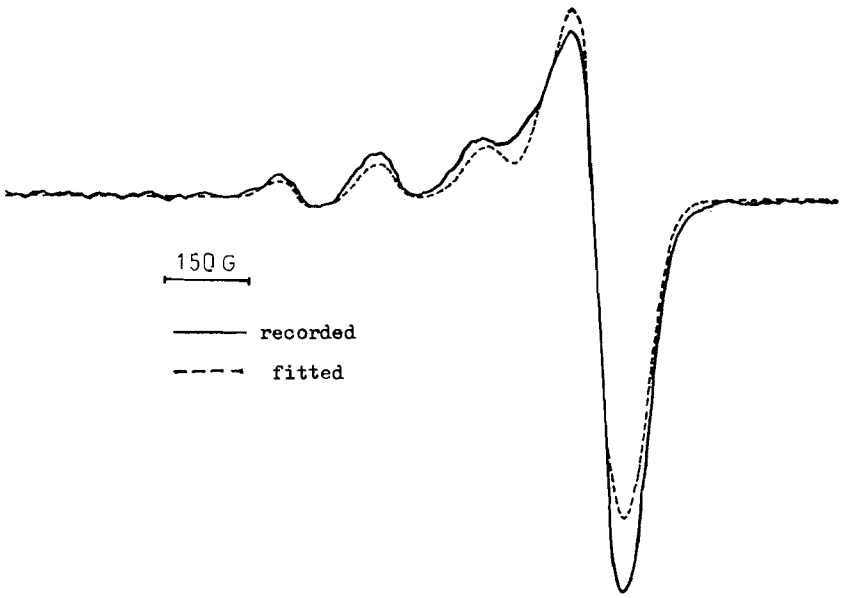

FIG. 2. Comparison of experimental and fitted spectrum of blue copper protein under Gaussian shape.

$$[3.15]\quad \frac{\partial H_m}{\partial a_l} = -\left(\frac{\partial E_j}{\partial a_l} - \frac{\partial E_i}{\partial a_l}\right) \Big/ \left(\frac{\partial E_j}{\partial H} - \frac{\partial E_i}{\partial H}\right)$$

In eqs. [3.11]–[3.15] only the first and second derivatives of energy E_i with respect to the parameters $\boldsymbol{a}$ and magnetic field H are needed. The way to calculate these derivatives numerically was given by Misra (10, 12).

4. Computer program for refining parameters by least-square fitting and illustrative examples

Using the method described above, we wrote a Fortran 77 program for powder spectrum fittings. The user must define the matrix elements of the Hamiltonian by writing a subroutine DEFHM. The initial parameters and experimental data are read first and then the DFP subroutine is called to fit the parameters. The flow diagram of DFP is shown in Fig. 1. The calculation of the gradients of χ^2 in DFP subroutine is performed by another subroutine GRD. In calculating the theoretical spectrum, the integration of [3.1] is performed and the values of resonance fields are obtained by least-square fitting as described in section 2. The values of $\Delta\theta$ and $\Delta\varphi$ are taken as 1 or 2 deg. As examples, we describe the fittings of room-temperature X-band EPR spectra of blue copper protein and $CuSO_4 \cdot 7H_2O$.

The number of fitting points N_d in both cases is taken as 45. Because the recorded spectra are the first derivatives of absorptions, the shape functions of individual lines which make up the powder spectra must take the form of first derivatives of Gaussian or Lorentzian functions,

$$[4.1]\quad f_G = y'_G\left(\frac{H - H_0}{\frac{1}{2}\Delta H_{pp}}\right) \exp\left[-\frac{1}{2}\left(\frac{H - H_0}{\frac{1}{2}\Delta H_{pp}}\right)^2\right]$$

$$[4.2]\quad f_L = y'_L\left(\frac{H - H_0}{\frac{1}{2}\Delta H_{pp}}\right)\left[1 + \frac{4}{3}\left(\frac{H - H_0}{\frac{1}{2}\Delta H_{pp}}\right)^2\right]^{-2}$$

where H_0 is the resonance field and ΔH_{pp} is the peak-to-peak line width of first derivative line shape and y'_G, y'_L are the normalization factors.

The spin Hamiltonian of blue copper protein can be written as

TABLE 1. Initial and fitted parameters of blue copper protein X-band EPR powder spectrum at room temperature

Parameter	Value	
	Initial	Final
$g_\parallel$	2.254	2.255
$g_\perp$	2.058	2.053
$A_\parallel$ (G)	167.8	162.8
$A_\perp$ (G)	7.8	7.1
ΔH_{pp} (G)	60.0	67.6

$$[4.3]\quad \mathcal{H} = \beta \boldsymbol{H}.\mathbf{g}.\boldsymbol{S} + \boldsymbol{I}.\mathbf{A}.\boldsymbol{S}$$

where $\mathbf{g}$ and $\mathbf{A}$ are axial symmetric. The initial values of the parameters listed in Table 1 are estimated from the experimental spectrum. In fitting, both Lorentzian and Gaussian line shapes are taken into consideration. The latter yields better result. When the fitting is completed, the reduction of χ^2 is 57% after 5 iterations and the CPU time taken in FACOM-M340S computer is 23 min. The fitted spectrum is given in Fig. 2.

In the spectrum fitting of $CuSO_4 \cdot 7H_2O$, the spin-Hamiltonian is taken as

$$[4.4]\quad \mathcal{H} = \beta \boldsymbol{H}.\mathbf{g}.\boldsymbol{S}$$

where $\mathbf{g}$ is asymmetric and the hyperfine splittings of Cu are neglected. The single crystal line width is assumed to be anisotropic due to the contribution of the unresolved hyperfine splittings (3),

$$[4.5]\quad \Delta H_{pp}^2 = \Delta H_1^2 \sin^2\theta\cos^2\varphi + \Delta H_2^2 \sin^2\theta \sin^2\varphi + \Delta H_3^2 \cos^2\theta$$

Like the case in ref. 1, the simulated spectrum using the initial guessed values, as extracted from the record spectrum, does not fit the experimental spectrum well and χ^2 is large. After 6 iterations χ^2 is reduced to 20% of the initial value. The

ΔH_2 (G)	160.0	187.0
ΔH_3 (G)	160.0	162.0

computation time is 33 min. The initial and final parameters are listed in Table 2. Figure 3 shows the fitted spectrum.

5. Concluding remarks

The method presented in this paper is suitable for the quick refinement of EPR parameters after a reasonable simulated spectrum is obtained. It can be used to get the best fit of experimental data with certain theoretical models. In our program, the method of Misra is used to fit the angular variations of resonance fields. This method is much faster compared with the brute-force (or consecutive) method in finding the angular variations of resonance fields. It may happen that two or more resonance fields converge to the same value of the field at a particular orientation of θ or φ (10). In this case the calculation of the resonance fields needs manual intervention. But after that, the relationship between the resonance fields and corresponding levels is determined completely and further fitting of the fields can be performed automatically.

Synthesis, characterization, and exchange of complexes of (*R*)-*N*,*N*-dimethylaminoethylferrocene with SO_2 and BF_3[1]

SYDNEY BROWNSTEIN, NAM FONG HAN, ERIC GABE, and FLORENCE LEE
Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received May 11, 1988

SYDNEY BROWNSTEIN, NAM FONG HAN, ERIC GABE, and FLORENCE LEE. Can. J. Chem. **67**, 93 (1989).

Sulfur dioxide and (*R*)-*N*,*N*-dimethylaminoethylferrocene (**I**) react with an enthalpy of formation of 21.5 ± 1 kcal mol^{-1} to give a complex with sulfur bonded to nitrogen. The SO_2 exchanges between adduct molecules by a dissociation mechanism. BF_3 reacts with the above amine to give an adduct and its partly hydrolyzed product, $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4\text{—}CH(CH_3)N(CH_3)_2\cdot BF(OH)_2]$ (**II**). **II** crystallizes in the orthorhombic space group $P2_12_12_1$ with a = 9.882(3), b = 10.625(5), and c = 13.988(13) Å and z = 4. R_f = 0.102 and R_w = 0.104.

Keywords: *N*,*N*-dimethylaminoethylferrocene complexes, X-ray structure, NMR exchange.

SYDNEY BROWNSTEIN, NAM FONG HAN, ERIC GABE et FLORENCE LEE. Can. J. Chem. **67**, 93 (1989).

Le dioxyde de soufre et le (*R*)-*N*,*N*-diméthylaminoéthylferrocène (**I**) réagissent avec une enthalpie de formation de 21.5 ± 1 kcal mol^{-1} pour donner un complexe dans lequel le soufre est lié à l'azote. Le SO_2 s'échange entre les molécules d'adduit par un mécanisme de dissociation. Le BF_3 réagit avec l'amine mentionnée plus haut; on obtient un adduit ainsi qu'un produit partiellement hydrolysé, $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4\text{—}CH(CH_3)N(CH_3)_2\cdot BF(OH)_2]$ (**II**). Le produit **II** cristallise dans le groupe d'espace orthorhombique $P2_12_12_1$, avec a = 9,882(3), b = 10,625(5) et c = 13,988(13) Å et z = 4. R_f = 0.102 et R_w = 0,104.

Mots clés : complexes de *N*,*N*-diméthylaminoéthylferrocène, structure par rayons-X, échange RMN.

Introduction

Reactions of aminoferrocenes with metal halides have been reported in the literature (1–3). Under certain reaction conditions 1:2 adducts of aminoferrocene – metal halides can be synthesized (3); but in most cases 1:1 adducts are the only products. *N*,*N*-Dimethylaminoethylferrocene, **I**, which can be easily resolved via its tartrate salt (4), is an important precursor for the synthesis of chiral ferrocenylphosphine ligands (5–10), but the donor ability of the amine itself seems to have not been studied with any common Lewis acid.

Complexes of sulfur dioxide and tertiary amines are well known, and the structure (11), and enthalpy of formation (12) of the simplest member $(CH_3)_3N\text{—}SO_2$, have been established. Boron trifluoride–amine complexes have been studied and the enthalpy of formation (13) and mechanism of exchange (14) determined for the triethylamine adduct.

As part of our continuing studies on the reactions of Lewis acids with tertiary aromatic amines (15), the reactions of **I** with SO_2 and BF_3 are presented here. The crystal structure of **II**, a partially hydrolyzed BF_3 adduct of **I**, is also described. There has been considerable study of the non-equivalence of groups in hindered tertiary amines arising either because of hindered rotation about the carbon–nitrogen bond (16), or because of slow inversion about pyramidal nitrogen (17). As far as we know, the present study is the first where the rate-determining step for averaging of magnetic non-equivalence of groups on a tertiary amine arises because of reversible quatenary complex formation.

Experimental

Chemicals

Boron trifluoride, from the suppliers cylinder, was stored over phosphorus pentoxide in a bulb on the vacuum line. Sulfur dioxide and methylene chloride were purified and stored as previously described (18). Chloroform was purified by a literature procedure (19). The amine **I** was prepared (20), and resolved (4) according to published procedures.

[1]NRCC No. 29696.

General procedures

*Reaction of **I** with SO_2*

The amine **I** was accurately weighed into an nmr tube equipped with a "Teflon" colinear "J. Young" valve so that the sequential addition of reactants could be done by vacuum transfer and each step of the reaction could be studied by nmr spectroscopy. A known quantity of $CHCl_3$ was condensed into the nmr tube and the nmr spectra of **I** were recorded. An appropriate amount of SO_2 (Table 1) was then transferred into the same tube and the nmr spectra at different temperatures were studied (Tables 1 and 2).

*Reaction of **I** with BF_3*

The reaction was carried out in essentially the same manner as for SO_2, using CH_2Cl_2 or $CHCl_3$ as solvent, and equimolar amounts of ***I*** (0.164 g) and BF_3 (0.043 g). After about 3 days at room temperature, the tube was opened and the solution was diluted with 5 mL of solvent followed by addition of 15 mL of hexane with stirring. A dark brown–green oily solid (*vide infra*) precipitated from the solution. The clear yellow–orange filtrate was kept at 4°C and orange crystals of **II** were obtained (ca. 40% isolated yield) and characterized by an X-ray crystal structure.

Magnetic resonance spectra were obtained on a "Bruker AM400" spectrometer at a magnetic field strength corresponding to 400 MHz for protons. Carbon and proton chemical shifts are reported with respect to tetramethylsilane, although the solvent was used as an internal reference and the appropriate correction applied. Fluorine resonance shifts are reported with respect to external $CFCl_3$.

X-ray diffraction intensities of an approximately 0.15 × 0.2 × 0.2 mm crystal of **II**, sealed in a glass capillary, were collected on a "Picker" diffractometer in the octants $+h$, $+k$, $+l$ to $2\theta_{max}$ = 45° with graphite monochromatized MoK_α radiation using the 2θ scan technique with profile analysis (21). A total of 1134 unique reflections were collected, of which 487 reflections were considered significant with $I_{net} \geq 2.5\sigma(I_{net})$. The absorption corrections were not made (μ = 1.0 mm^{-1}). The crystal decayed gradually and the intensities of the standard reflections at the end of the data collection were approximately 2/3 of the intensities at the start. The cell parameters were obtained by least-squares refinement of the setting angles of six reflections with two in the range of 28–32° (MoK_{α_1} = 0.70932 Å).

The structure was solved by direct methods and refined by full matrix least-squares techniques using the NRCVAX (22) program system. The final residuals are R_f = 0.103 and R_w = 0.104 for the significant

[a]The separate lines are not adequately separated so the peak/trough intensity ratio is listed.

data with unit weights. All atoms were refined isotropically except the Fe atom. H-atoms were placed at calculated positions on the ferrocene rings. The final atomic positional parameters and the equivalent isotropic temperature factors are listed in Table 3. The final structure factors are included as supplementary material as are the bond lengths and angles.[2]

The high R value is a consequence of the low crystal quality. Data were also collected for a second crystal and although the same structure was found, the final R values were even higher than reported here.

Results and discussion

Proton resonance spectra of chloroform solutions of **I** and SO_2 show, at room temperature, a single line for the hydrogens of the *N,N*-dimethyl group. As the temperature is lowered this line broadens, splits, and, at sufficiently low temperature, gives two sharp lines. These results are listed in Table 1. Since **I** contains a chiral carbon atom there will be magnetic non-equivalence for the two CH_2 groups bonded to nitrogen provided that it is co-ordinated to another ligand and therefore has a tetrahedral arrangement (23). The exchange which averages the two CH_3 signals in this system could arise either by dissociation of the SO_2 complex and recombination or by displacement of the complexed SO_2 by another SO_2 molecule in the solution, followed in each case by rapid inversion of pyramidal nitrogen. In the former case, the extent of dissociation, and therefore the rate of exchange, would be reduced by an excess of SO_2. In the latter case, the rate of displacement, and therefore the rate of exchange, would be increased by an excess of SO_2. The lifetimes towards exchange were determined by comparison of the experimental spectra with theoretical ones calculated for exchange via a stochastic procedure (24). These results, along with the concentrations, are listed in Table 1. It is obvious that the lifetime towards exchange increases with increasing SO_2 concentration, indicating that the exchange occurs by a dissociation mechanism.

The enthalpy of activation for exchange by a dissociation mechanism necessarily equals the enthalpy of formation of the SO_2 complex. From the temperature dependance of the lifetime for two of the samples of Table 1 activation enthalpies of 20.7 and 22.4 kcal mol^{-1} were calculated from the slope of the line fitted by a least-squares procedure. Therefore the heat of formation of the complex between **I** and SO_2 is 21.5 ± 1 kcal mol^{-1}. This is probably the first example of exchange averaging of two magnetically non-equivalent groups on a tertiary amine via dissociation of the quatenary adduct as the rate-determining step.

Additional weak peaks attributed to the H_2SO_3 adduct of **I** were observed at low temperature. At the temperatures used for the exchange studies there was no evidence for exchange on the nmr time scale between the SO_2 and H_2SO_3 adducts, although it did occur at room temperature. Although the SO_2 employed in these studies was dried over P_2O_5 traces of H_2SO_3 adducts, arising from H_2O in SO_2, or adsorbed on the glass of the vacuum system, were characterized in other amine systems (15). Chemical shifts of the assignable signals for these adducts are listed in Table 2.

The proton resonance spectra of $CHCl_3$ or CH_2Cl_2 solutions of **I** and BF_3 clearly indicate the presence of two different adducts which do not exchange at room temperature on the nmr time scale. As described in the experimental section, it is possible to isolate one of these species as orange crystals, **II** which are in the orthorhombic space group $P2_12_12_1$ with $a = 9.882(3)$, $b = 10.625(5)$, $c = 13.988(13)$ Å, $z = 4$, and $D_{calc} = 1.397$ Mg m^{-3}. A diagram of the structure is shown in Fig. 1 and bond distances and angles are listed in a supplementary table.[2] The iron atom is sandwiched between two cyclopentadienyl rings which are very close to planar and nearly parallel. The deviation from parallelism is 4.4°, and the rings are separated by an average of 3.30 Å. The atoms of one of the cyclopentadienyl rings are rotated by an angle of approximately 14° from the eclipsed position with the atoms of the other ring.

The crystal structure for **II** was solved in an effort to understand the magnetic resonance spectra of $CHCl_3$ or CH_2Cl_2 solutions of **I** and BF_3. Although the final refinement of the crystal structure of **II** is of poor quality, it is possible to unambiguously report that it is a partly hydrolyzed adduct of **I** and BF_3. Two equivalent atoms X, bonded to boron, have bond lengths of 1.48(7) and 1.59(9) Å. The third atom, Y, bonded to boron has a bond length of 1.18(9) Å. We assign the atoms X as oxygen, which will have a hydrogen bonded to it, and the atom Y as fluorine on the basis of the relative bond lengths and the ease of dissociation of the adduct (*vide supra*). A refinement of the crystal reflections with the X atoms as fluorine and Y as the OH fits the data equally well ($R_f = 0.102$ and $R_w = 0.104$). Unfortunately boron, oxygen, and fluorine are mutally interfering elements in the methods of elemental microanalysis. Boron–fluorine spin-coupling constants are frequently small and were not observable for this compound. Therefore, it is not possible to state with any confidence its exact identity. The primary purpose of showing that it is a partly hydrolyzed BF_3 adduct of **I** has been satisfied. The arrangement of the groups about the chiral carbon atom in **II** shows that it has retained its R configuration. The overall handedness of the crystal could not be determined with certainty.

Unlike the other amine adducts in this study, the proton resonance spectrum of the 1:1 adduct whose crystal structure was determined, **II** has only a single proton resonance signal for both methyl groups attached to nitrogen down to −60°C. The chemical shifts for **II** are listed in Table 2. Since $BF(OH)_2$ would be a weaker Lewis acid than BF_3, it is quite possible that exchange averaging of the two potential methyl resonances may be occurring by dissociation and recombination of the nitrogen–boron bond.

The proton, carbon, and fluorine magnetic resonance spectra of the other adduct, **III**, are listed in Table 2. These correspond in every way with what one would expect for a normal BF_3

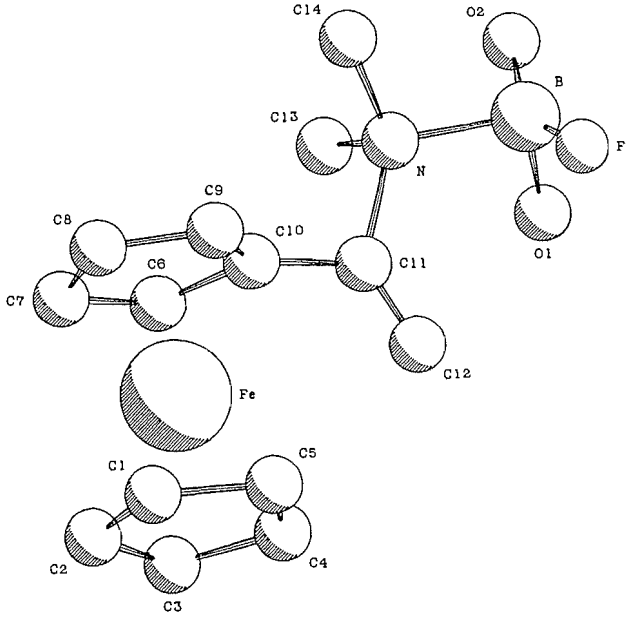

FIG. 1. The structure of $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4—CH(CH_3)N(CH_3)_2 \cdot BF(OH)_2$ (**II**), a partially hydrolyzed 1:1 adduct of **I** and BF_3.

adduct. The quadruplet of doublets assigned to the C—CH_3 group are assigned to a long range coupling ($J = 1.2$ Hz) with the three equivalent fluorines of the complexed BF_3. When the reaction mixture is diluted with *n*-hexane, a dark brown–green oily solid is precipitated. Its magnetic resonance spectral parameters, also listed in Table 2, are consistent with its assignment as the fluoborate salt of **I**. The most compelling evidence is the doubling of the signals for each N—CH_3 grouping by spin coupling with the H^+ bonded to nitrogen ($J = 4.9$ Hz). There is no magnetic resonance spectral evidence for a ring substituted species therefore the salt is thought to be produced from acid generated by hydrolysis of BF_3 by traces of water introduced in a similar fashion to that with SO_2, or in the workup of **II**.

We may conclude that addition of Lewis acids and the proton to **I** is solely on nitrogen in preference to iron. From the evidence for magnetic averaging of the two *N*-methyl groups we may conclude that the stability of the complexes to dissociation is $BF_3 \approx H^+ > SO_2 \approx H_2SO_3 > BF(OH)_2$.

Réactions ion/molécule de l'ion $C_2H_3Cl^+$ dans le mélange gazeux : chlorure de vinyle – chlorure d'éthyle

JAN A. HERMAN,[1] RODICA NEAGU-PLESU ET LESZEK WÓJCIK[2]

Département de chimie et Centre de recherches en atomes et molécules, Université Laval, Québec (Qué.), Canada G1K 7P4

Reçu le 13 juin 1988

JAN A. HERMAN, RODICA NEAGU-PLESU et LESZEK WÓJCIK. Can. J. Chem. **67**, 97 (1989).

Les réactions ion/molécule de $C_2H_3Cl^+$ ont été étudiées dans le mélange de chlorure de vinyle avec du chlorure d'éthyle. Les processus ioniques ont été suivis sur deux spectromètres de masse : le premier à résonance cyclotronique ionique (RCI), le deuxième à photoionisation et à haute pression. Les résultats obtenus sur ces deux instruments sont partiellement complémentaires. Il ressort que l'ion $C_2H_3Cl^+$ ne réagit pas directement avec le chlorure d'éthyle. Cependant, les ions $C_4H_3Cl^+$ et $C_4H_6Cl^+$, formés à la suite de la décomposition de l'ion-dimère excité du chlorure de vinyle, réagissent avec le chlorure d'éthyle dans une séquence de réactions de condensation avec élimination dans chaque étape du HCl ou Cl. Dans le mélange des deux chlorures les ions les plus abondants sont $C_8H_{13}^+$ et $C_8H_{14}^+$ dont l'intensité totale à 1 Torr de pression compte pour environ 50%.

Mots clés : réactions ion/molécule de $C_2H_3Cl^+$, mélange de chlorure de vinyle avec du chlorure d'éthyle, spectrométrie de masse.

JAN A. HERMAN, RODICA NEAGU-PLESU, and LESZEK WÓJCIK. Can. J. Chem. **67**, 97 (1989).

Ion/molecule reactions of $C_2H_3Cl^+$ have been studied in a mixture of vinyl and ethyl chlorides. The ionic processes have been followed using two mass spectrometers; one is based on the ionic cyclotronic resonance (ICR) while the other is based on photo-ionization at high pressure. The results obtained on these two instruments are complementary and they indicate that the ion $C_2H_3Cl^+$ does not react directly with ethyl chloride. However, the ions $C_4H_3Cl^+$ and $C_4H_6Cl^+$, which are formed following the decomposition of the excited ion-dimer of vinyl chloride, do react with ethyl chloride in a series of condensation reactions involving in each step an elimination of HCl or of Cl. In a mixture of the two chlorides, the most important ions are the $C_8H_{13}^+$ and $C_8H_{14}^+$; at a pressure of 1 Torr, their total intensity is equal to 50%.

Key words: ion/molecule reactions of $C_2H_3Cl^+$, vinyl and ethyl chloride mixtures, mass spectrometry.

Introduction

Les réactions ion/molécule de l'ion $C_2H_3Cl^+$ dans le chlorure de vinyle gazeux d'une part, et de l'ion $C_2H_5Cl^+$ avec le chlorure d'éthyle sont bien documentées (1–9).

Dans une étude des réactions ion/molécule par spectrométrie de masse RCI (Résonance Cyclotronique Ionique) du chlorure d'éthyle Beauchamp *et al.* ont remarqué que l'ion $C_2H_3Cl^+$, formé par décomposition de l'ion parent $C_2H_5Cl^+$, ne semble pas réagir avec le chlorure d'éthyle neutre (7). Il était intéressant de vérifier cette observation dans des conditions similaires à celles des expériences de Beauchamp *et al.* (ionisation par impact électronique à 15 eV) d'une part, et d'autre part dans les conditions d'un spectromètre de masse à haute pression où l'ion $C_2H_3Cl^+$ est formé à partir du chlorure de vinyle par photoionisation à 10,64 eV, ce qui est en dessous du seuil du potentiel d'ionisation du chlorure d'éthyle (PI = 10,97 eV) (10). Nous espérions que l'ion $C_2H_3Cl^+$, formé à partir de précurseurs C_2H_3Cl et C_2H_5Cl dans des conditions différentes, pourrait éventuellement réagir dans des processus ioniques distincts révélant leurs origines.

Partie expérimentale

Les mesures ont été exécutées sur deux spectromètres de masse : (*a*) à haute pression et à photoionisation, déjà décrit (11, 12), et (*b*) à résonance cyclotronique ionique dont voici une description succincte.

Ce spectromètre de masse, construit au laboratoire, est inspiré de celui décrit par McIver (13). L'électro-aimant avec son alimentation provient d'un spectromètre de masse cycloïdale M-66 de Varian Inc. Dans l'entrefer de 40 mm est logée la cellule cubique de 25 mm de côté qui sert à la détection des ions caractérisés par leur fréquence cyclotronique naturelle (14). Cette cellule est constituée de six plaques en molybdène isolées les unes des autres. Les deux plaques perpendiculaires aux lignes de force du champ magnétique, appelées plaques de piégeage, sont à un potentiel de +1 V. Les quatre autres plaques parallèles aux lignes de force du champ magnétique sont groupées par paire et servent à l'excitation et à la détection des ions. Les deux paires sont à un potentiel de −0,5 V. À une des paires de ces électrodes, dites d'excitation, est superposé un signal radiofréquence de 50–500 kHz de 0,5 V d'amplitude maximum. L'autre paire, appelée électrodes de détection, capte les signaux RF induits par le mouvement circulaire des ions en résonance cyclotronique avec le champ électrique alternatif de radiofréquence.

Le circuit électronique de détection est un pont capacitif décrit par McIver *et al.* (15), mais ayant le préamplificateur dans l'enceinte à vide le plus près possible de la cellule de mesure.[3] Un circuit d'impulsion dont la séquence est montrée à la figure 1 permet de varier le temps de réaction entre 2 et 1000 ms. Les périodes d'excitation et de détection sont respectivement de 2 et 4 ms.

L'enceinte principale contenant la cellule cubique de détection est évacuée au moyen d'une pompe de diffusion fonctionnant sur l'huile Santovac 5 et munie d'un piège à azote liquide. Le degré du vide est mesuré par une jauge à ionisation, modèle 844, de Varian Inc. et en absence d'échantillon gazeux il se situe à 10^{-7} Torr ($1,3 \times 10^{-4}$ N m^{-2}). Un système de robinets de haut vide à débit contrôlé, permet lors des mesures, de maintenir la pression de l'échantillon gazeux à une valeur fixe prédéterminée au voisinage de 10^{-5} Torr ($1,3 \times 10^{-2}$ N m^{-2}).

Les ions sont formés par impact d'électrons de 70 V dans une impulsion dont la durée est de 1,5 ms.

Le chlorure de vinyle et le chlorure d'éthyle de Matheson sont tous deux de pureté supérieure à 99,7% et sont utilisés tels quels. Leurs mélanges en proportions contrôlées sont préparés dans un système à vide conventionnel. Le chlorure de vinyle perdeutéré, 99,5%, provient de Merck, Sharp & Dohme.

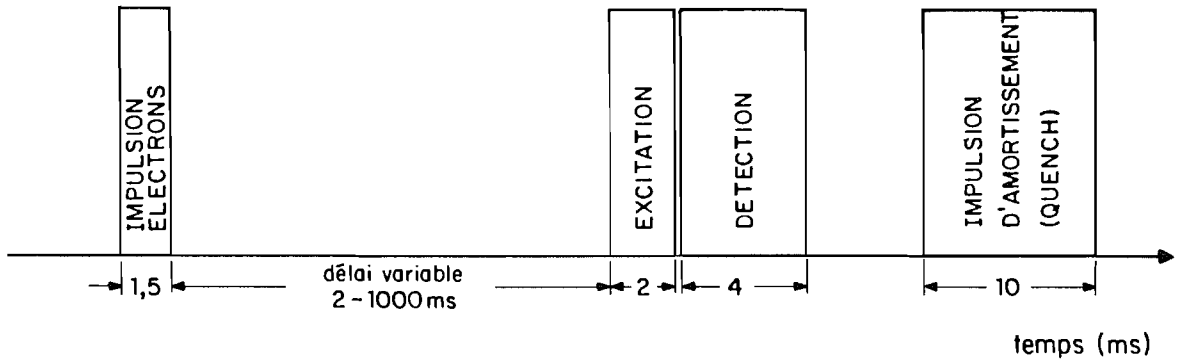

FIG. 1. Séquence d'impulsion du spectromètre de masse RCI.

Résultats et discussion

(a) Étude par spectrométrie de masse RCI

L'évolution des intensités fractionnaires des principaux ions des composés purs et de leurs mélanges est présentée à la figure 2. Le tableau 1 complète cette information en indiquant les intensités fractionnaires des autres ions présents dans la cellule de réaction après 20, 50 et 100 ms.

Les valeurs des intensités fractionnaires (figure 2 et tableau 1) pour le chlorure de vinyle pur peuvent être comparées à celles publiées par Baldeschwieler et coll. (1) et par Anicich et Bowers (4) obtenues par spectrométrie de masse RCI. Dans leurs cas la distribution des principaux ions formés dans les processus bimoléculaires est $C_3H_4Cl^+ : C_4H_5Cl^+ : C_4H_6Cl^+ = 0{,}29 : 0{,}57 : 0{,}14$, où les valeurs numériques sont les moyennes de leurs résultats. Dans le cas présent pour le temps le plus court de détection (2 ms), ce rapport devient : $C_3H_4Cl^+ : C_4H_5Cl^+ : C_4H_6Cl^+ = 0{,}19 : 0{,}57 : 0{,}24$. La différence entre les valeurs de ces rapports est probablement due aux différentes conditions expérimentales. L'utilisation d'une cellule à entraînement (anglais : drift cell), où le temps de séjour des ions est de l'ordre de 500 μs (1, 4), n'est pas comparable à nos conditions d'une cellule cubique où la présence des ions est beaucoup plus longue avant leur détection. D'autre part, il est reconnu que les constantes de vitesse absolues et relatives des réactions de condensation de l'ion $C_2H_3Cl^+$ sont très sensibles à des différences en énergie cinétique et interne, surtout entre 0 et 2 eV (4). Il n'est donc pas exclus que les résultats présents comparés à ceux d'Anicich et de Baldeschwieler ne soient le reflet que d'une différence en énergie interne des ions $C_2H_3Cl^+$.

Ces résultats confirment nos connaissances des processus ion/molécule dans le chlorure de vinyle et le chlorure d'éthyle purs (1, 4, 7–9). En effet, dans le chlorure de vinyle pur les réactions ion/molécule sont les suivantes :

[1] $C_2H_3Cl^+ + C_2H_3Cl \rightarrow (C_2H_3Cl)_2{}^+* \rightarrow C_4H_5Cl^+ + HCl$

[2] $\rightarrow C_4H_6Cl^+ + Cl^\cdot$

[3] $\rightarrow C_3H_4Cl^+ + CHCl^\cdot$

[4] $C_2H_3{}^+ + C_2H_3Cl \rightarrow C_2H_4Cl^+ + C_2H_2$

La réaction [4] apparaît dans le chlorure de vinyle ionisé par impact électronique, où l'énergie est suffisante pour dissocier l'ion parent en $C_2H_3{}^+$ (2). L'ion $C_4H_5{}^+$ (m/z = 53), qui apparaît dans le chlorure de vinyle pur, provient selon toute vraisemblance de la décomposition des ions $C_4H_5Cl^+$ et $C_4H_6Cl^+$ avec perte de chlore atomique ou de chlorure d'hydrogène. Remarquons que l'ion $C_4H_5{}^+$ ne semble plus

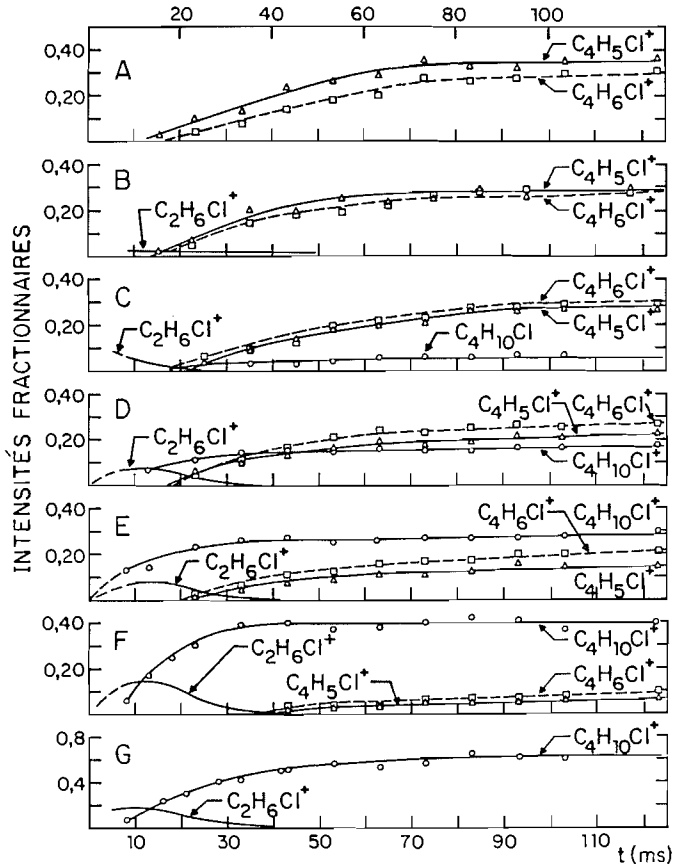

FIG. 2. Intensités fractionnaires des principaux ions dans les chlorure de vinyle et le chlorure d'éthyle purs et en mélange en spectrométrie RCI. (A) C_2H_3Cl (100%); (B) C_2H_3Cl (80%) + C_2H_5Cl (20%); (C) C_2H_3Cl (60%) + C_2H_5Cl (40%); (D) C_2H_3Cl (40%) + C_2H_5Cl (60%); (E) C_2H_3Cl (20%) + C_2H_5Cl (80%); (F) C_2H_3Cl (10%) + C_2H_5Cl (90%); (G) C_2H_5Cl (100%).

réagir avec les neutres, puisque son intensité fractionnaire augmente avec son temps de séjour dans la cellule de réaction (tableau 1).

L'ion moléculaire du chlorure d'éthyle pur réagit principalement dans un processus de formation de l'ion diéthylchloronium (7, 9) :

[5] $C_2H_5Cl^+ + C_2H_5Cl \rightarrow C_2H_6Cl^+ + C_2H_4Cl^\cdot$

[6] $C_2H_6Cl^+ + C_2H_5Cl \rightarrow (C_2H_5)_2Cl^+ + HCl$

et de plus il peut provenir de

[7] $C_2H_5^+ + C_2H_5Cl \rightarrow (C_2H_5)_2Cl^+$

L'ion $C_4H_{10}Cl^+$ ne réagit plus avec le chlorure d'éthyle neutre. Pareillement, les ions $C_2H_3Cl^+$ et $C_2H_4Cl^+$, formés par dissociation de l'ion parent $C_2H_5Cl^+$, semblent ne pas réagir avec le chlorure d'éthyle neutre puisque leurs intensités fractionnaires ne changent plus avec le temps (tableau 1). Les deux ions $C_4H_8^+$ et $C_4H_9^+$ proviennent probablement de la dissociation du $(C_2H_5)_2Cl^+$ excité, car ces ions apparaissent uniquement quand la proportion de l'ion diéthylchloronium est relativement importante dans le système.

En ce qui concerne les mélanges de C_2H_3Cl avec C_2H_5Cl, on note une absence totale des ions $C_4H_7Cl^+$ et $C_4H_8Cl^+$ qui pourraient être formés dans des réactions similaires aux processus [1] et [2]. On doit donc conclure que ni le $C_2H_3Cl^+$, ni l'ion $C_2H_5Cl^+$ ne réagissent respectivement avec le chlorure d'éthyle

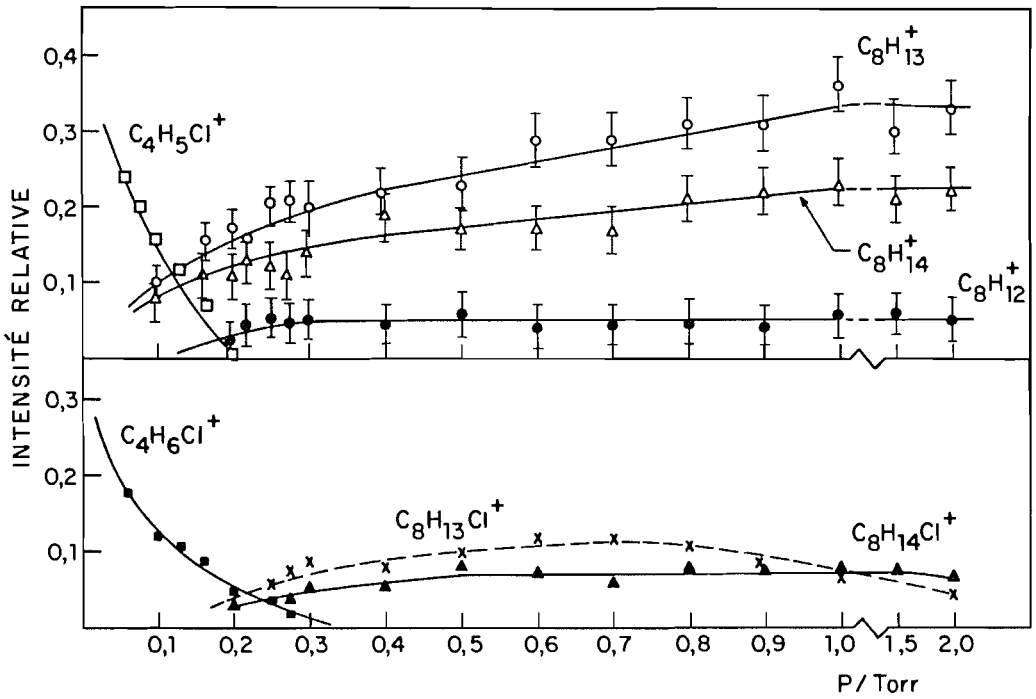

FIG. 3. Intensités fractionnaires en fonction de la pression totale des principaux ions dans le mélange C_2H_3Cl (10%) + C_2H_5Cl (90%) photoionisé.

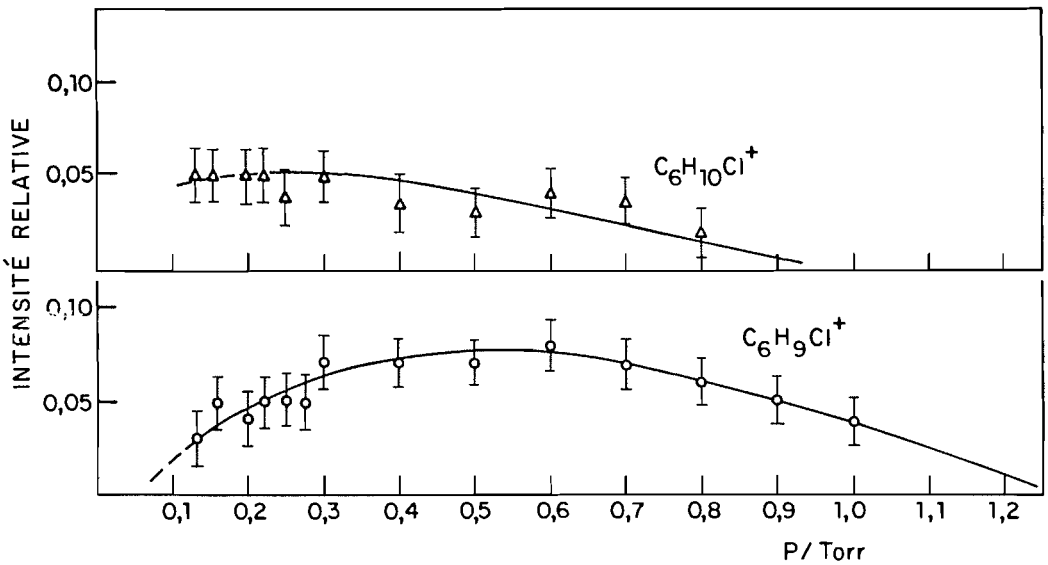

FIG. 4. Intensités fractionnaires en fonction de la pression totale des ions en C_6 dans le mélange C_2H_3Cl (10%) + C_2H_5Cl (90%) photoionisé.

neutre et le chlorure de vinyle neutre. Ceci est une indication que le complexe collisionnel excité $(C_2H_3Cl \cdot C_2H_5Cl)^+*$, formé dans le processus [8], a une vie trop courte pour un réarrangement de liaisons avant de se dissocier en réactifs initiaux.

$$[8] \quad C_2H_3Cl^+ + C_2H_5Cl \rightleftarrows (C_2H_3Cl^+ \cdot C_2H_5Cl)^* \longrightarrow\!\!\!\!\!\!\times\; C_4H_7{}^*Cl^+ + HCl \longrightarrow\!\!\!\!\!\!\times\; C_4H_8Cl^+ + Cl^\cdot$$

Cela confirme l'information de Beauchamp *et al.* (7), Łuczynski et Wincel (8) et Lampe (9), et en même temps, suggère que l'ion $C_2H_3Cl^+$ formé par dissociation du $C_2H_5Cl^+*$ garde (ou s'isomérise très rapidement en) la structure de l'ion moléculaire du chlorure de vinyle. Le seul ion qui semble provenir d'une interaction entre les ions issus des deux systèmes est le $C_4H_7{}^+$. Cet ion n'apparaît que dans les mélanges (tableau 1) et est absent pour les composés purs. Il est probable que cet ion soit formé dans les processus suivants où interviennent les ions fragmentaires des ions moléculaires :

$$[9] \quad C_2H_3{}^+ + C_2H_5Cl \rightarrow C_4H_7{}^+ + HCl$$

$$[10] \quad C_2H_5{}^+ + C_2H_3Cl \rightarrow C_4H_7{}^+ + HCl$$

Étude dans le spectromètre de masse à photoionisation

Les expériences faites avec le spectromètre de masse à photoionisation sont exécutées sur un mélange chlorure de

$C_4H_8Cl^+$	2	1	—

vinyle – chlorure d'éthyle à une seule concentration, soit 10% de C_2H_3Cl dans 90% de C_2H_5Cl. Le choix de cette valeur de la concentration est motivé par le désir de favoriser le nombre de rencontres entre l'ion $C_2H_3Cl^+$ et le chlorure d'éthyle neutre avant qu'il ne réagisse avec le chlorure de vinyle.

Comme source de photoionisation nous avons utilisé les raies de résonance du krypton, λ = 123,6 nm (10,03 eV) et λ = 116,5 nm (10,64 eV). À ces énergies le chlorure de vinyle est ionisé (PI = 9,995 eV), tandis que le chlorure d'éthyle ne l'est pas (PI = 10,97 eV) (10). Des expériences de ce laboratoire indiquent qu'environ 80% des ions $C_2H_3Cl^+$ sont formés par absorption de l'énergie provenant de la raie de résonance plus énergétique du krypton (10,64 eV) (16). En ce qui concerne le chlorure d'éthyle, l'absorption de ce rayonnement est très intense et conduit à une fragmentation en de nombreux radicaux et molécules neutres insaturées (17, 18). Il en résulte alors un spectre de masse très riche en de nombreux pics de faible intensité (<1%) parmi lesquels on peut identifier quelques groupes d'ions d'intensité fractionnaire nettement supérieure à 2%. L'intensité relative de l'ensemble de ces petits pics que nous négligeons est estimée de 15–25%. Remarquons aussi, qu'en raison de la forte absorption du rayonnement par le chlorure d'éthyle les ions ne commencent à paraître avec une intensité raisonnable dans le spectre qu'à partir d'une pression relativement élevée du mélange, soit environ 60 mTorr.

Les intensités fractionnaires des ions les plus proéminents en fonction de la pression totale du système sont présentées dans les figures 3 et 4. Dans le tableau 2 sont décrits celles d'autres ions aperçus surtout à basse pression et qui, pour alléger les figures, ne sont pas présentées sur les graphiques.

Le point saillant de ces résultats est la formation de deux espèces ioniques non-halogénées (m/z = 109 et 110) dont l'abondance est nettement supérieure aux intensités des autres ions. À pression élevée (>1 Torr) l'intensité fractionnaire de ces deux espèces contribue pour environ 50% du spectre entier. Il faut aussi remarquer que ces deux espèces ioniques auxquelles nous attribuons les formules $C_8H_{13}^+$ et $C_8H_{14}^+$ apparaissent très tôt dans le spectre, puisqu'on les voit même aux basses pressions (>60 mTorr). Ces espèces ioniques ne sont pas observées dans les spectres de masse ni du chlorure de vinyle pur, ni de celui du chlorure d'éthyle pur. Parmi les autres ions notons la présence d'éventuels précurseurs aux ions m/z = 109 et 110 : $C_6H_9Cl^+$, $C_6H_{10}Cl^+$ (figure 4) accompagnés de $C_6H_{11}Cl^+$ en faible quantité et de $C_8H_{13}Cl^+$, $C_8H_{14}Cl^+$ (figure 3) avec un pic peu intense de $C_8H_{15}Cl^+$. On distingue aussi l'ion m/z = 108 de faible intensité (figure 3) qui est partiellement caché dans le pied du pic intense m/z = 109.

Contrairement au spectre de masse RCI du mélange chlorure

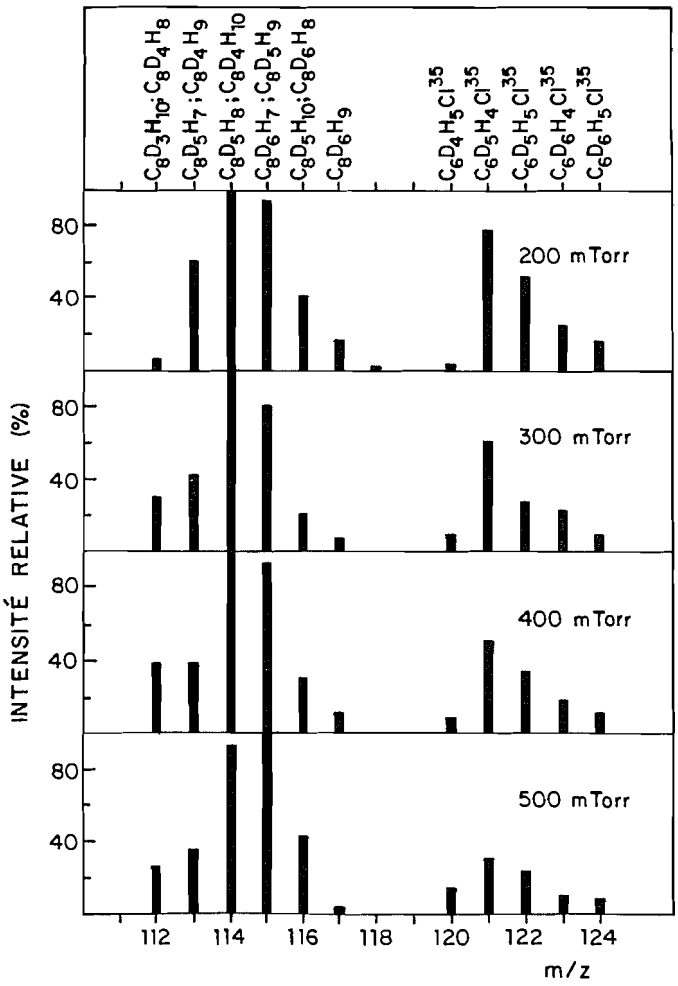

FIG. 5. Intensités relatives du groupe d'ions déshalogénés en C_8 et des ions chlorés en C_6 pour le mélange C_2D_3Cl (10%) + C_2H_5Cl (90%).

de vinyle – chlorure d'éthyle, où l'absence des espèces $C_4H_7Cl^+$ et $C_4H_8Cl^+$ était significative (voir la section précédente), on retrouve ces ions en faible intensité dans le spectre de masse du mélange photoionisé. Ces ions sont formés, selon toute vraisemblance, dans une séquence de réactions ayant pour origine le transfert du proton ou de l'atome d'hydrogène, puisqu'on les retrouve systématiquement dans les mélanges du chlorure de vinyle avec les alcanes :[4]

[11] $C_2H_3Cl^+ + C_2H_5Cl \rightarrow C_2H_4Cl^+ + C_2H_4Cl^{\cdot}$

[12] $C_2H_4Cl^+ + C_2H_5Cl \rightarrow [C_2H_4Cl\ C_2H_5Cl]^* \rightarrow C_4H_7Cl^+ + HCl$
$\rightarrow C_4H_8Cl^+ + Cl^{\cdot}$

Dans le cas présent ce processus reste marginale (tableau 2). Cependant, les ions ainsi formés participent aussi à des réactions de condensation, ce qui ne facilite pas le dépouillement du spectre de masse.

Le bilan en hydrogène des ions $C_8H_{13}^+$ et $C_8H_{14}^+$ suggère que ces espèces ioniques sont formées à partir des ions $C_4H_5Cl^+$ et $C_4H_6Cl^+$ qui réagissent successivement avec deux molécules de chlorure d'éthyle en éliminant du HCl et (ou) Cl. L'incorporation de deux squelettes carbonés du chlorure d'éthyle dans le complexe collisionnel est le résultat de la concentration élevée en C_2H_5Cl dans le mélange. Il est probable qu'une

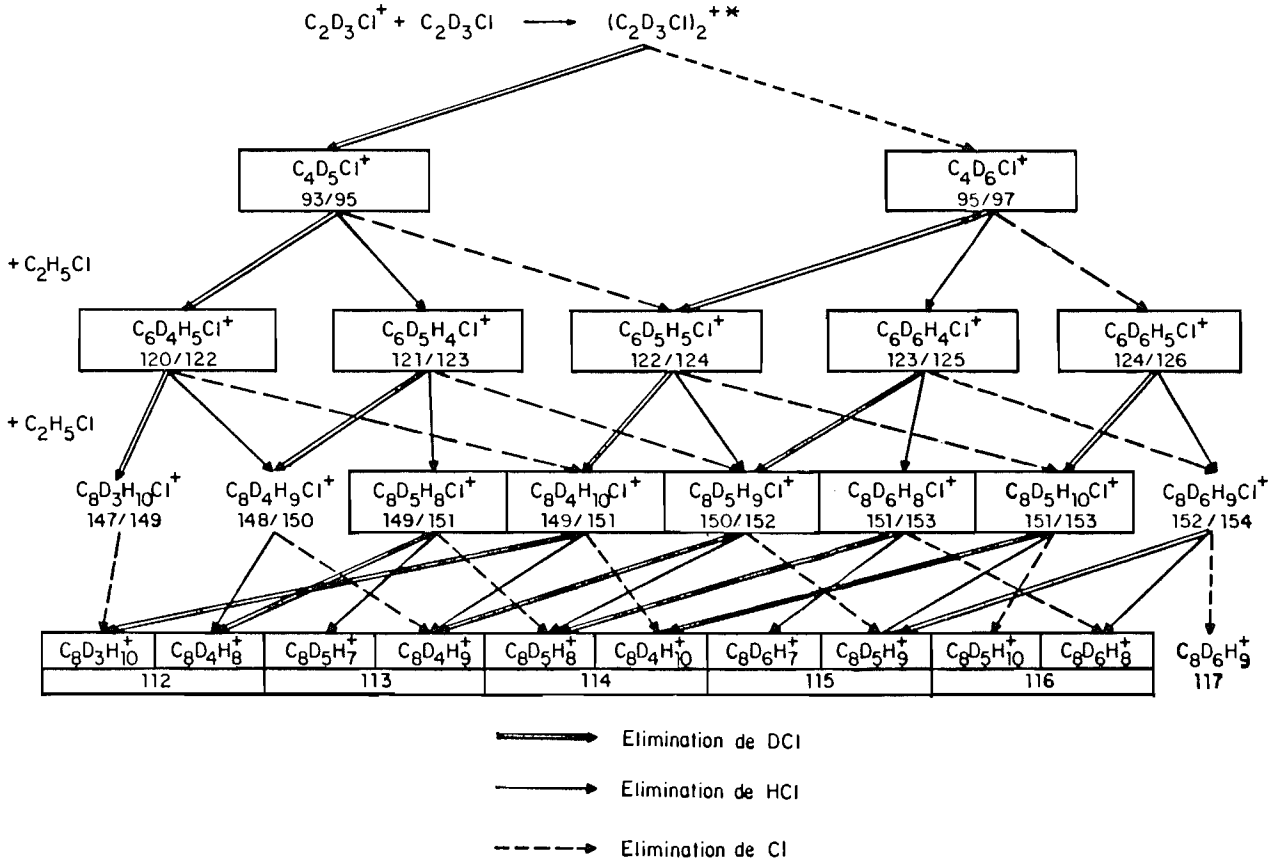

FIG. 6. Schéma des réactions ion–molécule conduisant à la formation des ions chlorés en C_6 dans le mélange C_2D_3Cl (10%) + C_2H_5Cl (90%). Les ions observés dans le spectre sont encadrés.

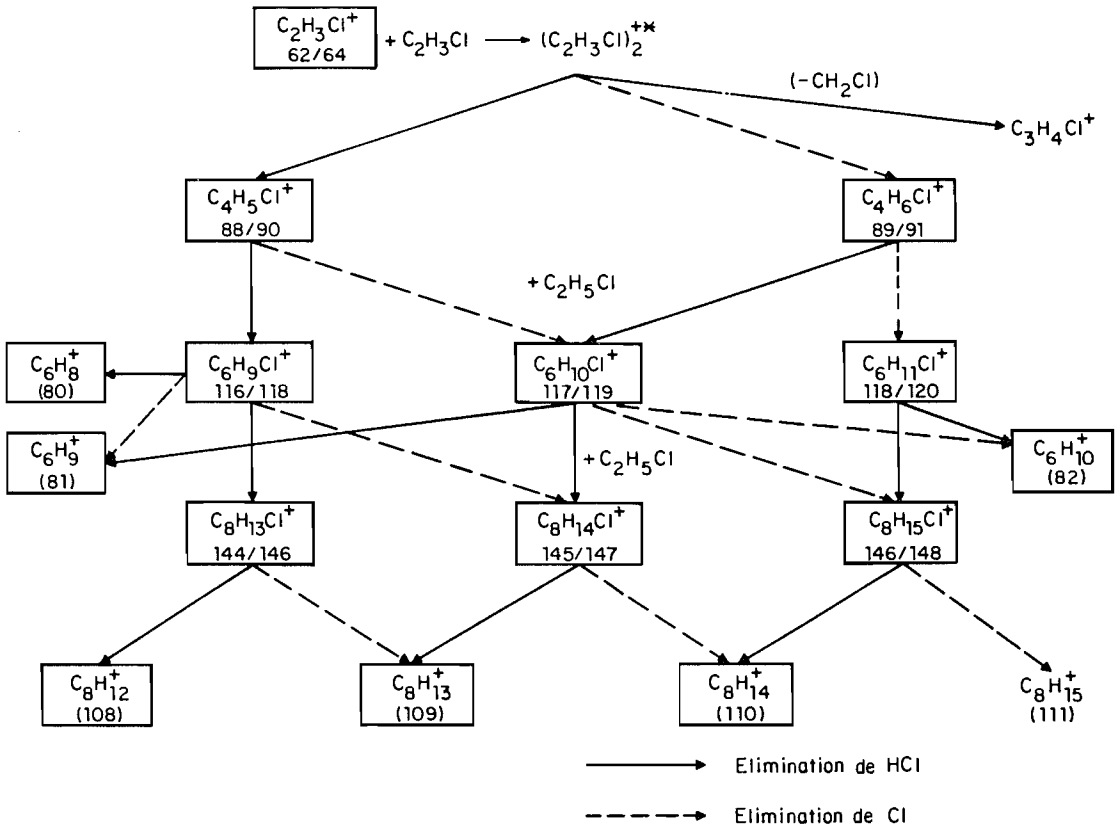

FIG. 7. Schéma des réactions ion–molécule pour la formation des principaux ions dans le mélange C_2H_3Cl + C_2H_5Cl. Les ions observés dans le spectre sont encadrés.

concentration plus forte en C_2H_3Cl dans le mélange aurait conduit à la formation d'espèces ioniques deshalogénées de formules brutes $C_8H_{11}^+$ et $C_8H_{12}^+$, impliquant des rencontres successives de trois chlorure de vinyle et d'un chlorure d'éthyle. En effet, on remarque qu'à pression élevée dans le chlorure de vinyle pur il y a formation de l'ion complètement déshalogéné, $C_8H_9^+$, qui proviendrait des processus suivants :[4]

$$[14]\quad C_2H_3Cl^+ \xrightarrow{V} C_4H_5Cl^+ \xrightarrow{V} C_6H_7Cl^+ \xrightarrow{V} C_8H_9$$
$$\xrightarrow{V} C_4H_6Cl^+ \xrightarrow{V} C_6H_8Cl^+ \longrightarrow ?$$

où le symbole V indique le chlorure de vinyle neutre.

Pour vérifier que les espèces $C_8H_{13}^+$ et $C_8H_{14}^+$ proviennent bien des processus impliquant deux molécules de chlorures d'éthyle neutres, nous avons refait le même genre d'expérience dans un mélange de C_2D_3Cl (10%) avec du C_2H_5Cl (90%). Si effectivement les ions m/z 109 et 110 ont comme précurseurs les espèces $C_4H_5Cl^+$ et $C_4H_6Cl^+$ formées dans les réactions [1] et [2], alors nous devrions trouver des ions ayant des formules $C_8D_5H_8$ et $C_8D_6H_8$ (m/z = 114 et 116) où nous négligeons les éventuels échanges entre les atomes d'hydrogène. La figure 5 montre les spectres de masse du groupe d'ions de m/z 112–124 à quatre pressions différentes.

En admettant que les complexes collisionnels dans lesquels survient l'élimination du chlorure d'hydrogène sont suffisamment fermes pour qu'il y ait mélange d'atomes d'hydrogène, alors il se peut que le fragment dissocié neutre soit du HCl ou du DCl. Puisqu'il y a deux étapes successives de rencontre avec le chlorure d'éthyle avec élimination chaque fois de chlorure d'hydrogène ou du chlore atomique, on assistera alors à l'apparition d'un groupe d'au moins six espèces ioniques : $C_8D_{3+n}H^+{}_{10-n}$ et $C_8D_{4+n}H^+{}_{10-n}$ où $n = 0$–2. Nous résumons l'ensemble des résultats à la figure 6, où les ions encadrés sont ceux observés expérimentalement.

En transposant ce mécanisme au mélange des espèces protonées : $C_2H_3Cl + C_2H_5Cl$, on aboutit à un schéma cinétique représenté à la figure 7. Cela semble bien correspondre aux observations.

Néanmoins, des questions restent sans réponses et méritent des études plus poussées. Entre autres, quelle est la configuration des espèces ioniques déshalogénées en C_8 plus stable que leur contre-partie contenant un atome de chlore? On peut aussi se demander si la formation des espèces $C_8H_{13}^+$ et $C_8H_{14}^+$ procède à partir des ions $C_6H_8^+$ et $C_6H_9^+$ qu'on observe en petite quantité dans le système, ou bien si la déshalogénation des ions $C_8H_{13}Cl^+$ et $C_8H_{14}Cl^+$ en est véritablement responsable, comme cela est indiqué à la figure 7.

Conclusions

Les ions $C_2H_3Cl^+$* excités ne réagissent pas par voie directe avec le chlorure d'éthyle. Cependant, cet ion à faible énergie interne peut former l'ion $C_2H_4Cl^+$ par transfert de proton ou d'atome d'hydrogène avec le chlorure d'éthyle. Néanmoins, ce processus semble être marginale.

Les principaux ions formés à pression élevée dans le mélange photoionisé à 10,64 eV sont les espèces $C_8H_{13}^+$ et $C_8H_{14}^+$. Ces ions sont probablement formés dans une séquence de processus de condensation à partir des espèces $C_4H_5Cl^+$ et $C_4H_6Cl^+$ avec le chlorure d'éthyle, et avec élimination concomitante de HCl ou Cl$^\bullet$.

Remerciements

Nous remercions MM. Bernard Boulé, André Bouffard, Réjean Drolet et Jocelyn Tremblay pour l'aide apportée à la construction du spectromètre de masse RCI. Nos remerciements vont aussi aux Dr. John E. Bartmess et Thomas Buckley pour les précieux conseils lors de la construction de cet instrument.

Finalement nous remercions le Conseil de recherche en sciences naturelles et en génie pour l'aide financière qui a permis la réalisation de cette étude.

Influence de la complexation sur la réactivité de nitrates d'halogènes

DIDIER GAUDE, GISÈLE GELLON, RAYMOND LE GOALLER ET JEAN-LOUIS PIERRE[1]

Laboratoire d'études dynamiques et structurales de la sélectivité, Université scientifique, technologique et médicale de Grenoble, B.P. 68, 38402, Saint Martin d'Heres CEDEX, France

Reçu le 18 janvier 1988[2]

DIDIER GAUDE, GISÈLE GELLON, RAYMOND LE GOALLER et JEAN-LOUIS PIERRE. Can. J. Chem. **67**, 104 (1989).

La réaction du nitrate d'iode ou du nitrate de brome dans l'acétonitrile ou le chloroforme avec divers phénols conduit à des mélanges de produits halogénés et nitrés. En présence de complexants forts des ions halonium, aucune réaction n'est observée. En présence de pyridine ou de triéthylamine, seuls sont obtenus des produits halogénés avec un effet *ortho*-directeur marqué de la fonction phénol.

Mots clés : phénols, nitrate d'iode, nitrate de brome, halogénation, nitration.

DIDIER GAUDE, GISÈLE GELLON, RAYMOND LE GOALLER, and JEAN-LOUIS PIERRE. Can. J. Chem. **67**, 104 (1989).

Iodine nitrate or bromine nitrate in acetonitrile or in chloroform react with a variety of phenolic substrates to form both halogenated and nitrated products. In the presence of strong complexing agents of halonium ions, no reaction occurs, while in the presence of pyridine or triethylamine, only halogenated phenols exhibiting a strong *ortho*-directing effect of the phenolic function are produced.

Key words: phenols, iodine nitrate, bromine nitrate, halogenation, nitration.

Introduction

À la suite de nos travaux sur la complexation des ions iodoniums et bromoniums (1), il nous a semblé intéressant d'étudier l'influence de cette complexation sur la réactivité des nitrates d'halogènes. Le nitrate d'iode, obtenu «*in situ*» par réaction de l'iode sur le nitrate d'argent en milieu organique, peut être complexé par deux molécules de pyridine et, ainsi isolé, conservé à l'abri de l'air. La réactivité de ce complexe sur les composés éthyléniques a été étudiée par Diner *et al.* (2–4). La réaction d'addition fournit les nitrates d'iodoalkyles attendus, accompagnés de nitrates d'iodoalcanes pyridinium. Les alcools primaires et secondaires sont oxydés en dérivés carbonylés (5). Les systèmes conjugués conduisent à la formation de sels de pyridinium (6). Les phénols conduisent à des dérivés polyiodés; s'ils sont substitués par une chaîne insaturée, ils donnent d'abord la réaction d'addition, suivie de la substitution électrophile sur le noyau (6).

À notre connaissance, la réactivité des nitrates d'iode et de brome, vis-à-vis des phénols, n'a jamais été étudiée en l'absence de pyridine. Les composés du type hypohalogénites semblent pourtant de bons candidats pour les réactions d'halogénation du noyau aromatique, comme en témoignent les travaux récents sur la fluoration par réaction de l'hypofluorite d'acétyle (7–9), du fluoroxytrifluorométhane ou du bis(fluoroxy) difluorométhane (10), sur la chloration par l'hypochlorite de tetrtiobutyle déposé sur argile (11) ou sur zéolithe (12) ou encore les travaux plus anciens sur l'iodation par le trifluorométhane sulfonate d'iode (13).

Dans ce travail, nous présentons les résultats obtenus par réaction du nitrate d'iode ou de brome sur divers phénols, en présence ou non de différents complexants. Ce travail s'inscrit également comme la suite d'une étude sur la nitration des phénols (14).

Résultats

Réactions en l'absence de complexant

En l'absence de complexant, l'obtention du nitrate d'iode par addition d'une quantité stoechiométrique d'iode à du nitrate d'argent dans l'acétonitrile ou le chloroforme n'est pas quantitative. L'addition d'une solution contenant 5 mmoles d'iode à 5 mmoles de $AgNO_3$ conduit à la formation de 2,5 mmoles de AgI que l'on élimine par filtration.

L'addition de 5 mmoles de phénol à cette solution se traduit par la formation de dérivés iodonitrés et nitrés du phénol, en même temps qu'apparaît un précipité correspondant à 2,5 mmoles de AgI, indiquant la formation *in situ* du nitrate d'iode.[3]

Le nitrate de brome donne lieu aux mêmes observations. De plus, et contrairement à INO_3, il réagit sur les hydrocarbures benzéniques (entrées 9 tableau 1).

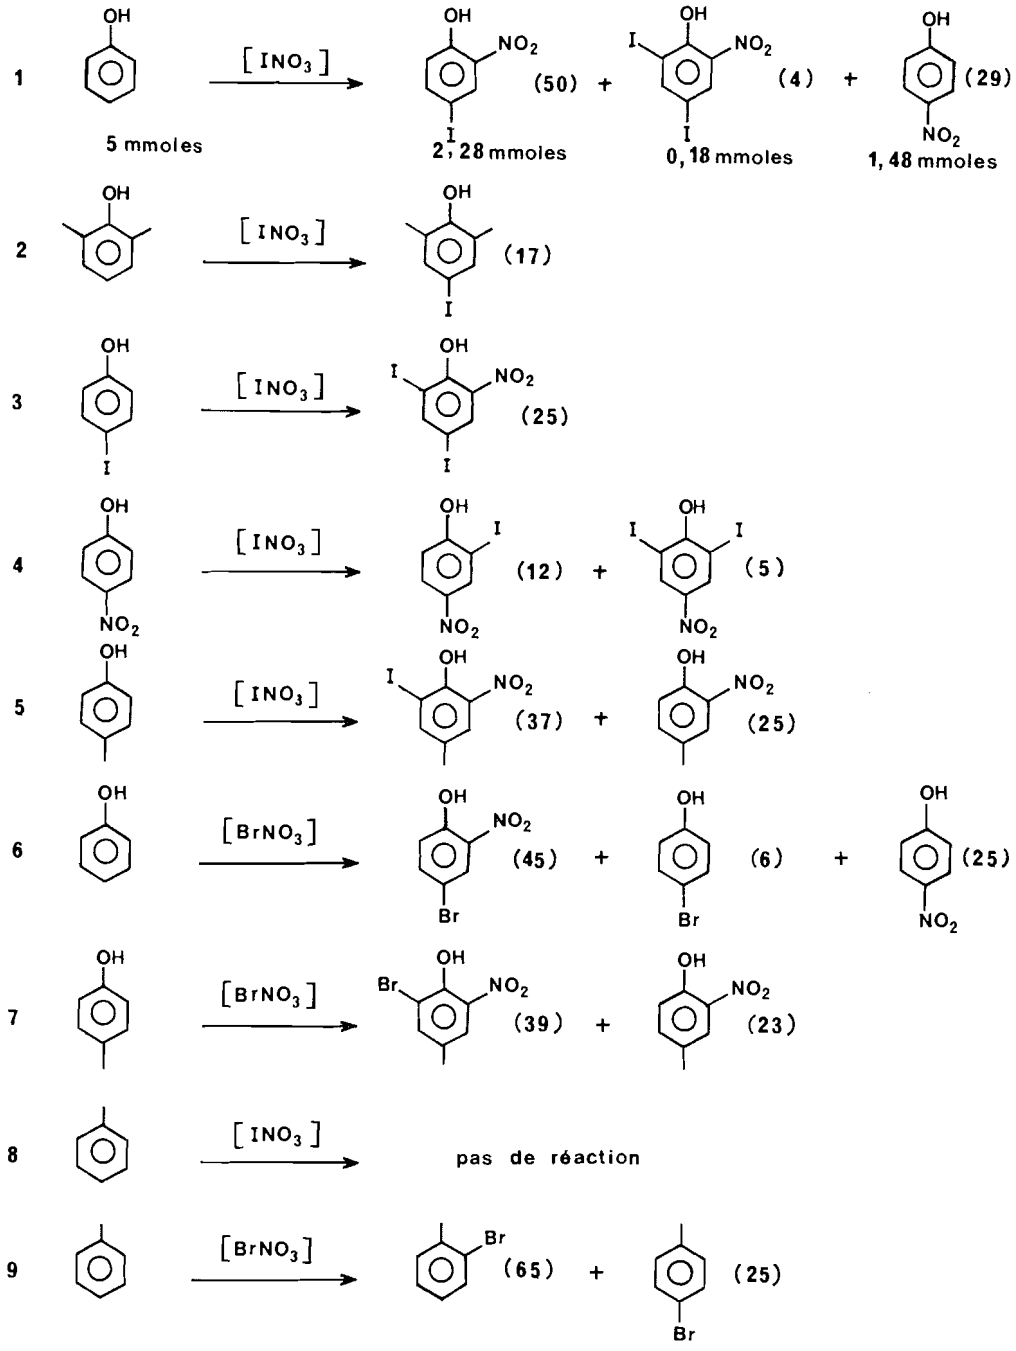
Le tableau 1 rassemble les résultats obtenus avec plusieurs dérivés du phénol et avec le toluène.

Réactions en présence de complexant

Dans les mêmes solvants, l'addition d'une solution d'iode (5 mmoles) à une solution de nitrate d'argent (5 mmoles) contenant 10 mmoles de pyridine (Π) donne lieu à la précipitation de 5 mmoles d'AgI, ce qui traduit la formation quantitative du complexe INO_3,2Π. Le tableau 2 montre que l'on obtient uniquement des produits iodés, ce qui confirme les travaux de Lown et Joshua (6).

Si on remplace la pyridine par de la triéthylamine, on observe une réactivité identique. Les résultats obtenus avec le nitrate de brome sont également rapportés dans le tableau 2.

En présence de cryptand [2.2.2], de Kryptofix 5 (1,13-bis(quinolyl-8) pentaoxa-1,4,7,10,13-tridécane), ou de diamines linéaires telles que le *N*,*N*,*N'*,*N'*-tétraméthyldiamino-1,6 hexane, utilisés à la place de la pyridine, la réaction est totalement inhibée et le phénol intégralement récupéré.



Discussion

En l'absence de complexant, INO_3 (ou $BrNO_3$) se comporte à la fois comme agent halogénant et nitrant. Les résultats quantitatifs (tableau 1, première ligne) montrent que 5 mmoles de INO_3 fournissent au minimum, compte-tenu des polymères, 6,6 mmoles d'électrophiles. Ils impliquent qu'une molécule de X—O—NO_2 soit donneur de deux électrophiles distincts

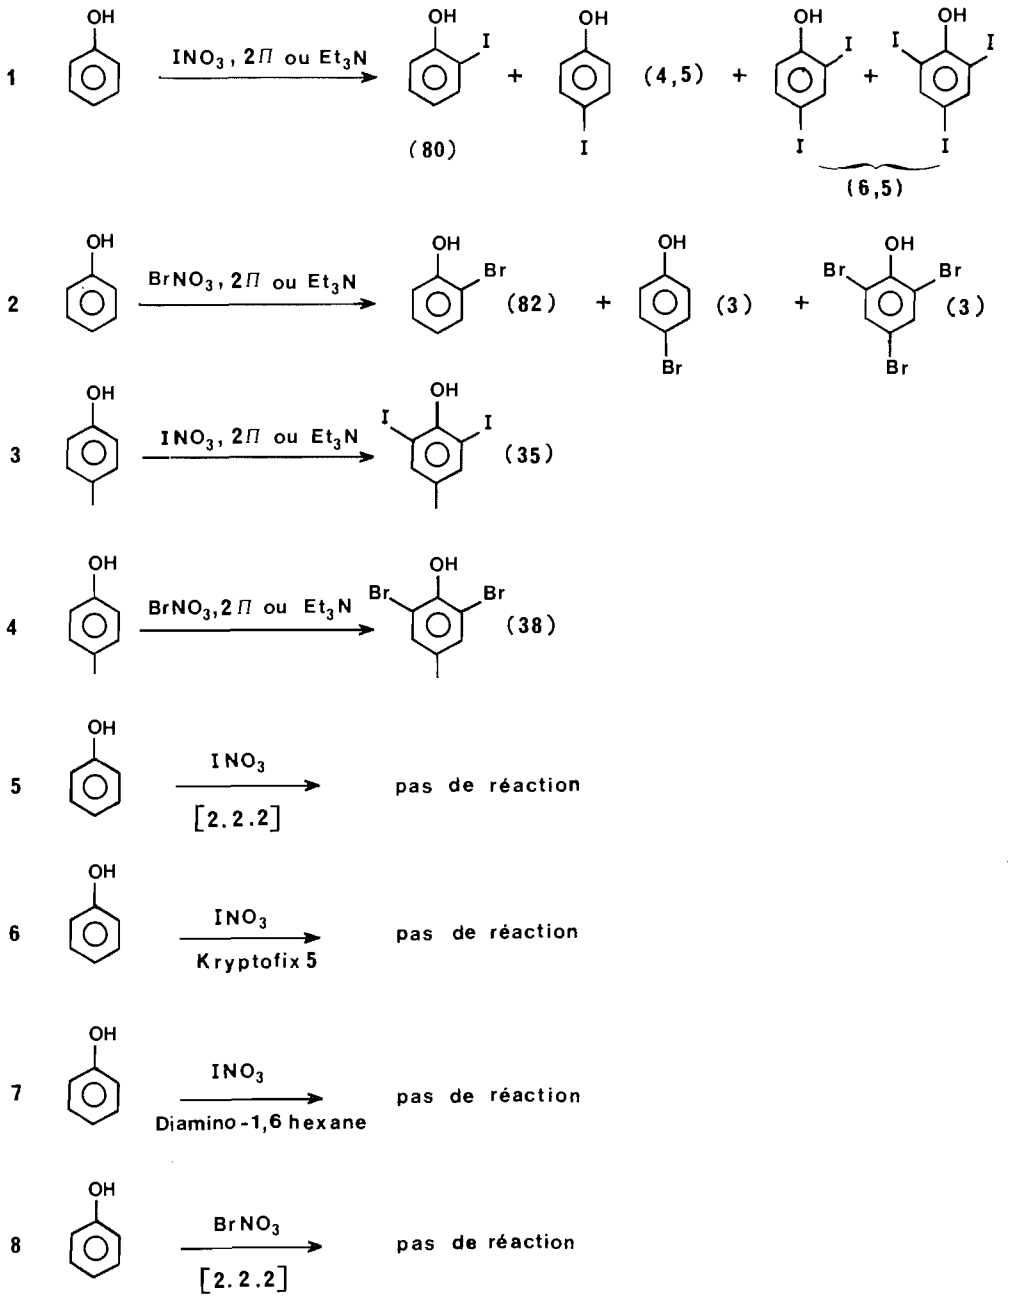
TABLEAU 1. Réactions de INO_3 et $BrNO_3$ sans complexants (% isolé par rapport au substrat)

et que le mécanisme soit autre qu'une substitution électrophile classique mettant en jeu X^+ et NO_2^+.

Nous avons montré antérieurement (1) que le cryptand [2.2.2] en présence de nitrate d'iode forme un cryptate d'halonium ($K = 3{,}2 \times 10^6$). Un complexe encore plus stable ($K = 3{,}5 \times 10^7$) est également formé avec Br^+. Au contraire, la triéthylamine et la pyridine forment des complexes beaucoup moins stables. Ainsi, le complexe iodé avec la triéthylamine implique un échange rapide devant l'échelle de temps RMN entre espèces libres et complexées, même à −90°C dans $CHFCl_2$ (15) alors que dans le cas des cryptands l'échange est lent à température ordinaire.



L'inhibition de réaction induite par le cryptand [2.2.2] que nous observons, implique sans nul doute la complexation de l'espèce X^+ : compte-tenu de la valeur de la constante d'équilibre on peut considérer qu'il n'y a pas de X^+ libre et que le X^+ complexé est soustrait au milieu par cryptation.

Bien qu'il n'ait pas été fait d'étude fondamentale correspondante, nos résultats montrent qu'il doit en être de même lorsque l'on utilise le Kryptofix 5 ou le diamino-1,6 hexane.

Lorsque X^+ est soustrait au milieu par un complexant fort, on n'observe pas non plus de nitration. Ce résultat suggère fortement que *l'halogénation précède la nitration et lui est nécessaire*.

TABLEAU 2. Réactions de INO_3 et $BrNO_3$ en présence de complexants (% isolé par rapport au substrat)

En présence de pyridine ou de triéthylamine, l'halogénation n'est pas inhibée, mais la nitration n'est pas observée. Le complexant doit donc interdire cette dernière réaction.

Il faut enfin noter la valeur du rapport de substitution *ortho/para*, supérieur à 1,8, dans le cas du phénol. Ce rapport reste constant lorsque les réactions sont effectuées dans une gamme de température allant de $-40°C$ à $+80°C$.

Ces observations nous amènent à proposer les mécanismes réactionnels suivants :

1. En l'absence de complexant, on peut envisager un schéma réactionnel en plusieurs étapes, dont la première est une substitution électrophile suivant :

[*a*] $ArH + XNO_3 \rightarrow [ArHX^+ \quad NO_3^-] \rightarrow ArX + HNO_3$

Pour ce qui concerne les étapes suivantes, il est possible d'envisager plusieurs processus expliquant la nitration et l'iodation ultérieure éventuelle :

[b_1] $HNO_3 + XNO_3 \rightarrow HOX + NO_2^+ + NO_3^-$

suivi d'une substitution électrophile mettant en jeu les espèces NO_2^+ ou X^+.

Ce processus peut être exclu car après la première étape il ne reste que 50% des molécules de XNO_3, or les exemples 1, 5, 6 et 7 du tableau 1 montrent qu'il s'est formé des produits nitrés qui nécessitent de 60 à 80% des molécules de XNO_3 mises en réaction.

De plus, les tentatives faites pour mettre en évidence

l'éventuelle formation de NO_2^+ se sont révélées négatives. Cette espèce est susceptible de réagir sur les amines (16). Des expériences menées en présence d'un excès de triéthylamine ou de pyridine n'ont pas permis de détecter les adduits attendus.

$$[b_2] \quad ArH + HNO_3 \xrightarrow{H^+} ArNO_2 + H_2O$$

$$H_2O + XNO_3 \rightarrow HOX + HNO_3$$

Ce processus autocatalytique nous semble très peu probable. En effet, dans nos conditions opératoires, les protons ne peuvent provenir que de la réaction de la première étape. De ce fait le milieu n'est probablement pas assez acide pour que l'équilibre d'autoprotolyse de l'acide nitrique soit déplacé dans le sens de la protonation.

Nous n'observons d'ailleurs pas de nitration du toluène ni du *para*-nitrophénol qui devraient réagir avec une telle espèce.

Les processus $[b_1]$ et $[b_2]$ ne nous semblant pas expliquer correctement nos résultats, nous avons été amenés à envisager un mécanisme faisant intervenir un transfert monoélectronique s'effectuant suivant l'une ou l'autre de ces équations :

$$[b_3] \quad ArH + H_2NO_3^+ \rightarrow [ArH^{\ddagger} \dot{N}O_2] + H_2O \rightarrow ArNO_2 + H_3O^+$$

$$[b_4] \quad ArH + HNO_3 \rightarrow [ArH^{\ddagger}, \dot{N}O_2] + OH^- \rightarrow ArNO_2 + H_2O$$

Dans les deux cas la nitration peut se faire sur ArH ou ArX présent dans le mélange réactionnel.

Bien que l'acide nitrique protoné devrait être un meilleur accepteur d'électron, nous pensons que le processus $[b_4]$ est plus vraisemblable pour les raisons invoquées précédemment (milieu trop faiblement acide).

Perrin (17) a été le premier à proposer, pour des réactions de nitration, un mécanisme faisant intervenir un transfert d'électron entre le noyau benzénique et NO_2^+ conduisant à la paire «radical cation du noyau aromatique – radical NO_2».

Laszlo et coll. (18) ont invoqué une interaction du même type entre phénol et ions métalliques pour expliquer la nitration de phénols par des nitrates métalliques déposés sur argile.

De la même façon, nous pensons qu'il est possible d'envisager que HNO_3 moléculaire, même à faible concentration, est assez oxydant pour accepter un électron du phénol et conduire à une paire de radicaux suivant le processus $[b_4]$. Ce mécanisme permet également d'expliquer que le toluène (tableau 1, lignes 8 et 9) et le *p*-nitrophénol (tableau 1, ligne 4), moins oxydables que les autres phénols, ne soient pas nitrés dans nos conditions réactionnelles. Nous avions déjà avancé une telle hypothèse pour expliquer la nitration de phénols en milieu biphasique (14).

En résumé, le mécanisme qui nous semble le plus probable comporte les deux étapes $[a]$ et $[b_4]$.

Cette interprétation justifie bien les faits observés : (*i*) une mole de XNO_3 peut fournir plus d'une mole d'électrophile; (*ii*) on observe toujours la formation d'au moins un produit halogéné, la nitration ultérieure pouvant se faire sur le phénol ou sur l'halogénophénol déjà formé (tableau 1, lignes 5 et 6).

2. En présence de complexants, les résultats dépendent de l'interaction XNO_3–complexant :

Une forte complexation de X^+ inhibe l'halogénation et la nitration ne peut avoir lieu (tableau 2, lignes 5–8).

Dans le cas d'une faible complexation par la triéthylamine ou la pyridine, l'ion X^+ n'est pas masqué et l'halogénation peut avoir lieu, mais le proton libéré est capté par l'amine et la nitration ne peut plus avoir lieu (tableau 2, lignes 1–4).

Conclusion

Nos résultats montrent qu'il est possible d'obtenir des nitrates d'halogènes *in situ* en l'absence de pyridine. Dans ce cas ils se comportent vis-à-vis des phénols comme des agents halogénonitrants. En présence d'amines telles que la pyridine ou la triéthylamine, on obtient uniquement des halogénophénols, et en présence de complexants plus forts tels que les cryptands, la réaction est totalement inhibée par cryptation de l'ion halonium. À notre connaissance, contrairement au nitrate d'iode, le nitrate de brome n'avait pas été utilisé à de telles fins. En l'absence de complexants, il s'est révélé plus réactif que le premier, et permet l'halogénation des hydrocarbures aromatiques.

Partie expérimentale

L'iode commercial bisublimé et le nitrate d'argent ont été utilisés tels quels. L'acétonitrile séché sur $CaSO_4$ est distillé deux fois et conservé sous azote. Les produits de réactions sont séparés sur colonne de silice (Merck Kieselgel 60, 230–400 mesh; éluant : hexane/acétate d'éthyle). Les rendements indiqués dans les tableaux 1 et 2 correspondent aux quantités de produits séparés. Ces produits ont été identifiés par comparaison de leurs spectres en infra-rouge (appareil Perkin–Elmer 397) et en résonance magnétique nucléaire du proton (appareil Bruker WP80 SY) avec ceux d'échantillons authentiques, commerciaux ou obtenus par synthèse. Leurs masses molaires ont été déterminées par spectrométrie de masse (70 eV) sur un appareil MS30 Kratos-AEI.

Réaction de INO_3 en l'absence de complexant

On dissout 5 mmol de $AgNO_3$ dans 15 mL d'acétonitrile auxquels on ajoute goutte à goutte une solution contenant 5 mmol d'iode dans de l'acétonitrile, en maintenant le ballon à 0°C. On filtre l'iodure d'argent obtenu (2,5 mmol) et on ajoute ensuite au filtrat 5 mmol de substrat dissout dans 10 mL d'acétonitrile. On poursuit l'agitation à température ambiante pendant 2 h. L'iodure d'argent qui précipite (2,5 mmol) est filtré. On évapore le solvant et on sépare les produits sur colonne.

Réaction de INO_3 en présence de complexant

On dissout 5 mmol de nitrate d'argent dans 15 mL d'acétonitrile contenant 2 mL du complexant (pyridine ou triéthylamine). On ajoute 5 mmol d'iode en solution dans l'acétonitrile, en maintenant le bain à 0°C. L'iodure d'argent (5 mmol) est ensuite filtré, et on ajoute au filtrat 5 mmol de substrat en solution dans l'acétonitrile. La réaction est terminée en 2 h à la température ambiante. Les produits sont isolés comme précédemment.

Dans les manipulations effectuées avec le cryptand [2.2.2], le Kryptofix 5 ou le diamino-1,6 hexane, le complexant est ajouté en quantité stoechiométrique.

Les réactions utilisant le nitrate de brome ont été effectuées suivant les mêmes modes opératoires.

Exemple type : réaction de INO_3 sur le phénol

(a) En présence de pyridine

La réaction, menée sur 5 mmol de phénol, conduit à un mélange dont les constituants sont élués sur colonne de silice par un mélange hexane – acétate d'éthyle (4:1). Les produits isolés sont

(*i*) *ortho*-Iodophénol (80%), identifié par comparaison de ses spectres avec ceux d'un échantillon authentique obtenu selon la référence 19. RMN ($CDCl_3$) δ (ppm) : 5,62 (1H, s) et 6,81–8,01 (4H, m).

(*ii*) *para*-Iodophénol (4,5%) dont les spectres sont identiques à ceux d'un échantillon commercial. RMN ($CDCl_3$) δ (ppm) : 6,62–7,50 (spectre AB, J = 8,8 Hz, 4H). Spectre de masse (intensité relative) : 220 (100), 93 (24, 4) 65 (29, 6).

On isole un mélange de deux produits (6,5%) qui ne peuvent être séparés. Ces produits sont le triiodo-2,4,6 phénol. RMN ($CDCl_3$) δ (ppm) : 7,91 (s); et le diiodo-2,4 phénol. RMN ($CDCl_3$) δ (ppm) : 6,75 (d, 1H), 7,55 (dd, 1H), 7,95 (d, 1H). Dans le spectre de masse

du mélange on trouve les masses molaires de ces deux produits : 346 (100%) et 472 (56%).

(b) En l'absence de pyridine

La réaction, effectuée sur 5 mmol de phénol, fournit, après les traitements décrits précédemment, les composés suivants :

Iodo-4 nitro-2 phénol (50%). RMN ($CDCl_3$) δ (ppm) : 6,95 (d, 1H), 7,75 (dd, 1H), 8,45 (d, 1H). Spectre de masse : 265 (100), 219 (8, 17), 92 (44, 92).

Diiodo-4,6 nitro-2 phénol (4%). RMN ($CDCl_3$) δ (ppm) : 8,34–8,39 (spectre AB). Spectre de masse : 391 (100), 345 (2, 6), 218 (15, 15), 189 (13, 34), 91 (16, 6).

para-Nitrophénol (29%) : spectres identiques à ceux d'un échantillon commercial.

An NMR study of dinucleoside monophosphates with an O4-ethylated thymine. d(e^{4}TpT) and d(Tpe^{4}T)[1]

GARRY W. BUCHKO, FRANK E. HRUSKA,[2] AND KRISHAN L. SADANA
Department of Chemistry, The University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 3, 1988

GARRY W. BUCHKO, FRANK E. HRUSKA, and KRISHAN L. SADANA. Can. J. Chem. **67**, 109 (1989).

Syntheses are described for d(e^{4}TpT) (**1**) and d(Tpe^{4}T) (**2**), the O4-ethylated analogues of d(TpT) (**3**), and mass spectrometric (FAB), ^{1}H nuclear magnetic resonance (300 MHz), and circular dichroic data are provided for the three molecules. The $[M - H]^-$ ions as well as the aggregates $[2M - H]^-$ and, in the case of **1**, $[3M - H]^-$, are easily detected by FAB mass spectrometry operating in the negative ion mode. In contrast with the modified nucleoside, e^{4}dT, the two methylene protons of the O4-ethyl groups of **1** and **2** are nonequivalent in the NMR spectra, and their chemical shift difference decreases with increasing temperature. This chemical shift difference can be related to intramolecular base stacking. The vicinal coupling constants of the sugar rings reveal an unusual shift at low temperature towards the 3′-*endo* conformation of the e^{4}Tp unit of **1**, but this shift is not noted for the pe^{4}T unit of **2**. O4-Alkylation of either unit of **3** effects a large reduction in the amplitude of the negative CD peak at 252 nm. The CD spectra of **1** and **2** are qualitatively similar to those of d(CpT) and d(TpC), respectively, and suggest that in some respects an O4-alkylated thymine base is "cytosine-like". The amplitudes of the positive CD peaks of **1** and **3** are reduced by 40% as the temperature is increased from 10 to 65°C, indicating the presence of some base stacking at low temperatures. However, the CD spectrum of **2** shows a much smaller reduction (<10%).

Key words: O-alkylation, oligonucleotides, stereochemistry, NMR, mass spectrometry.

GARRY W. BUCHKO, FRANK E. HRUSKA, et KRISHAN L. SADANA. Can. J. Chem. **67**, 109 (1989).

On décrit des synthèses des produits d(e^{4}TpT) (**1**) et d(Tpe^{4}T) (**2**), les analogues O4-éthylés du d(TpT) (**3**), et on rapporte les données relatives aux spectres de masse (FAB), aux spectres en résonance magnétique nucléaire du ^{1}H et au dichroïsme circulaire de ces trois molécules. Dans les spectres de masse FAB obtenus dans le mode des ions négatifs, on peut facilement détecter les ions $[M - H]^-$ et les agrégats $[2M - H]^-$ et, dans le cas du composé **1**, on peut aussi détecter l'agrégat $[3M - H]^-$. Par opposition avec ce qui est observé dans le spectre RMN du nucléoside modifié, e^{4}dT, les deux protons méthyléniques des groupements O4-éthyles des composés **1** et **2** ne sont pas équivalents et les différences dans leurs déplacements chimiques diminuent avec une augmentation de la température. On peut attribuer cette différence dans les déplacements chimiques à un empilement intramoléculaire des bases. Les constantes de couplage vicinal des cycles de sucre révèlent un déplacement inhabituel, à basse température, vers la conformation *endo-3′* de l'unité e^{4}Tp du composé **1**; toutefois, on n'observe pas ce déplacement pour l'unité pe^{4}T du composé **2**. La O4-alkylation de l'une ou l'autre des unités du composé **3** provoque une réduction importante de l'amplitude du pic négatif observé à 252 nm, dans le spectre de DC. Les spectres de DC des composés **1** et **2** sont respectivement similaires, d'un point de vue qualitatif, à ceux des composés d(CpT) et d(TpC) et ces résultats suggèrent que, sous certains aspects, une thymine alkylée en position 4 devient semblable à une cytosine. Lorsqu'on augmente la température de 10 à 65°C, les amplitudes des pics positifs de DC des composés **1** et **2** sont réduits de 40%; ces résultats indiquent que, à basse température, il se produit un empilement des bases. Toutefois, le spectre de DC du composé **2** montre que la réduction est beaucoup plus faible (<10%).

Mots clés : O-alkylation, oligonucléotides, stéréochimie, RMN, spectrométrie de masse.

[Traduit par la revue]

Introduction

The mutagenic and carcinogenic consequences of O-alkylation of nucleic acid bases have been the focus of many studies. Research was initially centered on O6-alkylated guanine (r^{6}G), but considerable interest shifted to the O2- and O4-alkylated thymines following their identification in DNA treated with the potent carcinogen ethylnitrosourea (1). O-Alkylation of guanine and thymine effects an alteration in their hydrogen bonding capacity that forms the basis for interpretation of the misincorporations observed during transcription and replication (2–4). Information about the electronic and geometrical changes resulting from O-alkylation has been provided by the X-ray crystallographic studies of O4-methyluridine (m^{4}U) (5), O4-methylthymidine (m^{4}dT) (6), O4-ethylthymidine (e4dT) (7), and O2-isopropylthymidine (i^{2}dT) (8), as well as for several O6-alkylated purine nucleosides and analogues (9–11). ^{1}H and ^{13}C NMR data have been reported for a large number of O-alkylated nucleosides (8, 12–14). More relevant data about the changes produced in DNA structure are now being provided by NMR investigations of oligodeoxynucleotides, but these are limited to a few recent studies (15, 16). In the present work we describe the synthesis of d(e^{4}TpT) (**1**) and d(Tpe^{4}T) (**2**), the O4-ethylated analogs of d(TpT) (**3**), in which the modified thymine is at the 5′ end and 3′ end of the molecule, respectively (Fig. 1). These syntheses require considerable care since the O-alkyl groups are labile in acid or basic media (4, 13). The molecular ions of the three dimers are readily observed by FAB (fast atom bombardment) mass spectrometry (negative ion mode). ^{1}H NMR data as well as circular dichroic (CD) data are provided for the three dimers and are discussed in conformational terms. Of particular interest is the chemical shift nonequivalence of the methylene protons of the O-ethyl groups, which can be rationalized in terms of intramolecular base stacking, and could be a means of monitoring structural changes in the vicinity of the O-alkyl lesion. A preliminary report of this work has appeared (17).

C7 and C8 refer respectively to the methylene and methyl carbons of the O4-ethyl group. H_R and H_S refer respectively to the *pro-R* and *pro-S* methylene protons of the O-ethyl group. Centre, sketch of **1** in a right-hand base-stacked conformation, which presents a view in the plane of the bases in the N3-to-C5 direction. The base are *anti* about the N-glycosyl bond and the O-ethyl group is oriented as in the crystal state (ref. 7). The sketch shows H_R projecting towards the thymine of the 3′-linked unit. Right, an analogous sketch of **2**, which shows H_S projecting towards the thymine of the 5′-linked unit.

Experimental

Materials and methods

Materials

All solvents used for synthesis, including absolute ethanol, were dried by standard procedures. Thymidine (Sigma Chemical Co.) was used without prior drying. 4-Chlorophenyl phosphodichloridate and 4-chlorophenyl phosphate were prepared as described earlier (18), as was tetra-*n*-butylammonium fluoride (0.6 M in tetrahydrofuran (THF)) (19). The oximate reagent for deprotection (0.3 M in 1:1 acetonitrile–dioxane) was prepared from *ortho*-nitrobenzaldoxime and 1,1,3,3-tetramethylguanidine (1.0 : 0.9 molar ratio). Chromatographic solvents were purchased from Fisher Scientific; all other reagents were purchased from Aldrich or Sigma Chemical Co. Kieselgel 60 (Merck) was used for dry-column flash chromatography (DCFC). Thin-layer chromatography (TLC) was carried out on Kieselgel 60 F_{254} plates from Merck. For paper chromatography, Whatman paper (No. 3001 917) was used.

Synthetic methods

The synthesized nucleoside derivatives were purified by DCFC, a modified flash chromatography (using suction instead of positive pressure (20)) that simplifies column loading and solvent elution. Deprotected nucleotides were purified initially by paper chromatography using solvent B′ (*n*-butanol:ethanol:water 4:1:5 v / v, organic phase). The dinucleoside monophosphates were purified by HPLC (Perkin Elmer Series 4 liquid chromatograph) using a semipreparative ODS-Hypersil column and a gradient of methanol and 0.1 M aqueous ammonium acetate (pH 6.0). The strategy used for the synthesis of **1** and **2** is shown in Scheme 1.

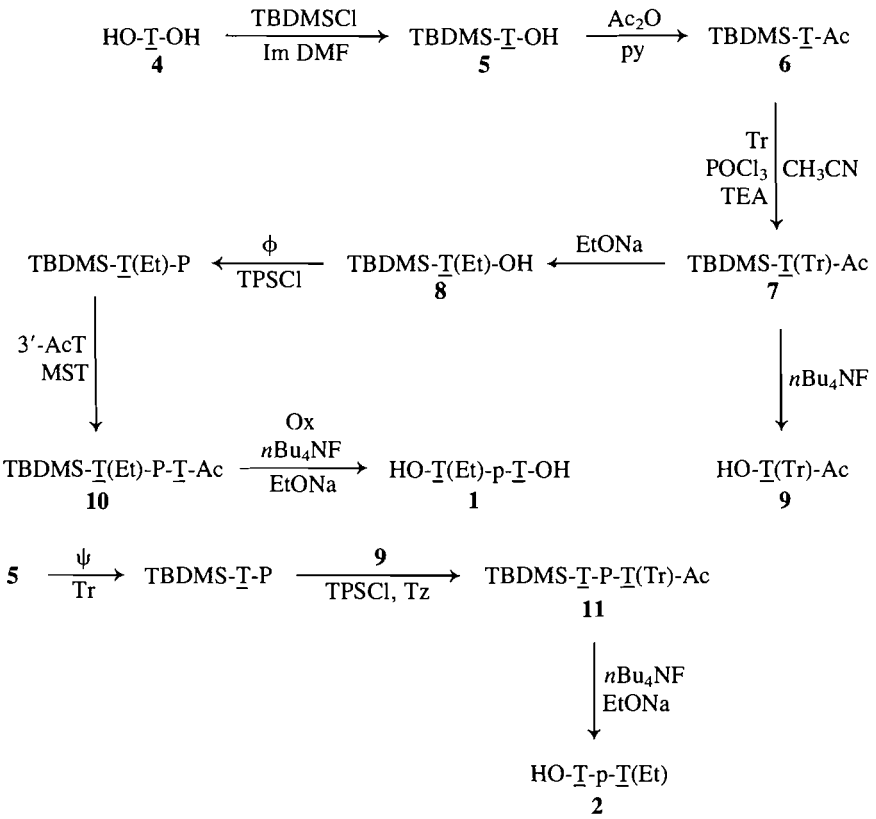
5′-O-tert-Butyldimethylsilylthymidine (**5**) was synthesized according to Ogilvie (19) with a slight modification to his purification procedure. Thymidine (**4**) (2.42 g, 10 mmol), *tert*-butyldimethylsilyl chloride (1.66 g, 11 mmol), imidazole (1.50 g, 22 mmol), and dimethylformamide (10 mL) were stirred (2.5 h) at room temperature and poured into water (1 L) to precipitate the crude product. (The product could also be isolated by extraction with chloroform or methylene chloride.) The product was separated from 3′, 5′-*tert*-butyldimethylsilylthymidine by DCFC using ethyl acetate as the eluting solvent (65% average yield) (λ_{max} = 267 nm in EtOH).

5′-O-tert-Butyldimethylsilyl-3′-acetylthymidine (**6**): Compound **5** (3.55 g, 10 mmol), pyridine (12.5 mL), and acetic anhydride (2.0 mL, 20 mmol) were stirred overnight. Methanol (10 mL) was added and the solvents were removed by codistillation with toluene, leaving a product that was sufficiently pure and dry for further synthesis.

5′-O-tert-Butyldimethylsilyl-3′-acetyl-4-(1,2,4-triazol-1-yl)-thymidine (**7**): The synthesis of **7** was based on the procedure of Divakar and Reese (21). The reaction was easily monitored by TLC (ethyl acetate) due to the appearance of a characteristic blue fluorescence, and was complete in an overnight reaction. The product was worked up as recommended (21) (λ_{max} = 251 nm in EtOH).

5′-O-tert-Butyldimethylsilyl-O4-ethylthymidine (**8**): Compound **7** (4.5 g, 10 mmol) was dried, and reacted with 60 mmol of sodium ethoxide (0.3 M in ethanol) for 30 min at room temperature. The mixture was neutralized with glacial acetic acid, the solvents were removed under vacuum, and the material was purified by DCFC with ethyl acetate (λ_{max} = 281 nm in EtOH).

3′-Acetyl-4-(1,2,4-triazol-1-yl)-thymidine (**9**): Compound **7** (4.5 g, 10 mmol) was dissolved in THF and stirred for 10 min with tetra-*n*-butylammonium fluoride (16.7 mL, 10 mmol). (*Cautionary note*: longer treatment leads to a gradual degradation of **9**.) Dowex-50 (Na^+-form) was added, stirred for 15 min, and then filtered out. The solvents were removed under vacuum and the product was purified by DCFC with ethyl acetate.



d(e^4TpT) (**1**): Pyridine-dried **8** (0.43 g, 1.1 mmol) was phosphorylated by stirring overnight with *p*-chlorophenyl phosphate (0.39 g, 1.3 mmol) and 2,4,6-triisopropylbenzenesulfonyl chloride (TPSCl) (0.83 g, cf. 2.8 mmol). 3′-Acetylthymidine (0.62 g, 2.2 mmol) and 1-(2-mesitylenesulfonyl)-tetrazole (0.83 g, 3.3 mmol) were added and the mixture was stirred overnight. The mixture was cooled in an ice bath and 1 mL H_2O was added. After 30 min most of the pyridine was removed by vacuum distillation and 40 mL H_2O was added. Extraction with methylene chloride followed and the organic solvent was dried over Na_2SO_4 and decanted. The fully-blocked dimer (**10**) was purified by DCFC (methylene chloride and methanol gradient). **10** (30 mg, 0.036 mmol) was treated overnight with oximate reagent (1 mL, 0.3 mmol). The mixture was poured over a silica gel column (40 mm length; 25 mm diameter) and the excess reagent was eluted with ether. The product was eluted with methanol, and the solvent was removed to obtain a dry material that was then treated overnight with tetra-*n*-butylammonium fluoride (0.23 mL, 0.14 mmol). Dowex-50 (Na^+-form) was added, followed by stirring for 15 min. The solid was filtered out; the filtrate was completely dried and then treated for 1 h with 0.3 M ethanolic sodium ethoxide (0.7 mL, 0.22 mmol). Excess reagent was neutralized with glacial acetic acid, and the solvents were removed. The material was redissolved in a few drops of water, streaked on Whatman No. 1 chromatographic papers, and developed in solvent B′. The material in the bands was eluted with H_2O and lyophilized. The appropriate band was selected on the basis of UV and 300-MHz ^{1}H NMR spectra and the desired product **1** was further purified by HPLC (λ_{max} = 273 nm; λ_{min} = 239 nm in H_2O).

d(Tpe^4T) (**2**): The phosphorylating agent was prepared from *p*-chlorophenyl phosphodichloridate (0.091 mL, 0.55 mmol) and triazole (0.14 g, 2.0 mmol) in 2–3 mL of pyridine, and was added to **5** (0.19 g, 0.5 mmol). After 15 min, the reaction was checked by TLC to ensure completion. **9** (0.26 g, 0.78 mmol), TPSCl (0.71 g, 2.34 mmol), and tetrazole (0.49 g, 7.02 mmol) were added; the condensation was complete in 1 h. The work-up and purification of the fully-blocked dimer (**11**) were carried out as for **10**. **11** (30 mg, 0.035 mmol) was treated for 1 min with 1 mL of the tetra-*n*-butylammonium fluoride solution. Dowex-50 (Na^+-form) was added and stirred for 10 min. The solids were filtered out and the solvents removed to dryness. The material was treated with 0.7 mL of sodium ethoxide (0.3 M in ethanol). After 1 h the solution was neutralized with glacial acetic acid and the product **2** was purified by chromatography and HPLC as described for **1** (λ_{max} = 272 nm; λ_{min} = 240 nm in H_2O).

Mass spectrometric experiments

Positive- and negative-ion FAB mass spectra (glycerol matrix, 8-keV xenon atoms) were obtained on a VG 7070E-HF spectrometer. The negative ion spectra proved more diagnostic and are reported here as follows: *m/z* (relative intensity, [ionic species]). *d(e^4TpT)*: 573(100, $[M - H]^-$); 1147(3.4, $[2M - H]^-$); 1721(0.05, [3M –

^{1}H nuclear magnetic resonance experiments

The ^{1}H NMR spectra were obtained at 300.13 MHz (Bruker AM300 spectrometer). All samples were examined in 5 mm (o.d.) tubes at the following concentrations in D_2O: **1**, 0.0070 M; **2**, 0.0017 M; **3**, 0.018 M. The concentrations were determined by UV absorbance measurements, assuming a molar extinction coefficient (ϵ) of 18 400 for **3** (22) and 16 300 for **1** and **2**. (The latter was calculated from the ϵ of the monomer units (22, 23) without correction for hypochromicity, which is not expected to be large for pyrimidine dimers (22)). At these concentrations intermolecular association should not be important. The solutions contained 0.01 M sodium phosphate buffer (pH = 6.9), EDTA (0.001 M) to chelate paramagnetic species, 0.1 M NaCl to maintain a constant ionic strength, and, for an NMR reference, a trace of *tert*-butanol, which is assigned a chemical shift of 1.231 ppm on the DSS scale. The samples were lyophilized twice from 99.8% D_2O and taken up in 99.9% D_2O. Spectra of the monomers (0.002 M) were obtained under the same conditions. Standard one-dimensional (1D) spectra were obtained at 10°C intervals from 10 to 70°C in 16K of computer memory (zero-filled to 32K). The HDO resonance was suppressed by presaturation (Bruker PRESAT. AU microprogram). Conventional homonuclear decoupling and two-dimensional (COSY-45°) (24) experiments were carried out for spectral assignments. The spectra were analyzed at 20 and 70°C (NUMARIT) (25) and computer-generated spectra confirmed the data. Using these data as guides, some chemical shift data were extracted from spectra at other temperatures (see Fig. 5) by assuming a first-order relationship between the protons, or an AB relationship in the case of H2′ and H2″.

Circular dichroism experiments

CD spectra were obtained on a Jasco J-500A spectropolarimeter using cells equipped for temperature control with a water bath. Each dimer at $(1.1–1.3) \times 10^{-4}$ M (calculated from UV absorption methods; see previous section) was dissolved in the phosphate buffer solution (pH 6.9) used for the NMR experiments.

Results and discussion

^{1}H nuclear magnetic resonance spectra, data, and assignments

The 1D NMR spectra of **1**, **2**, and **3** are shown in Figs. 2 and 3. Tables 1 and 2 provide chemical shift (δ) and coupling constant (*J*) data at 20 and 70°C obtained by computer analyses. Figures 4–6 show the temperature dependence of certain δ and *J* data in the 10–70°C range. The H6 and 5-CH_3 protons were assigned on the basis of the observed deshielding effect (0.22 ppm and 0.10 ppm, respectively) due to O4-alkylation at the monomer lever (7, 8, 12, 13). Also useful for assignments is the

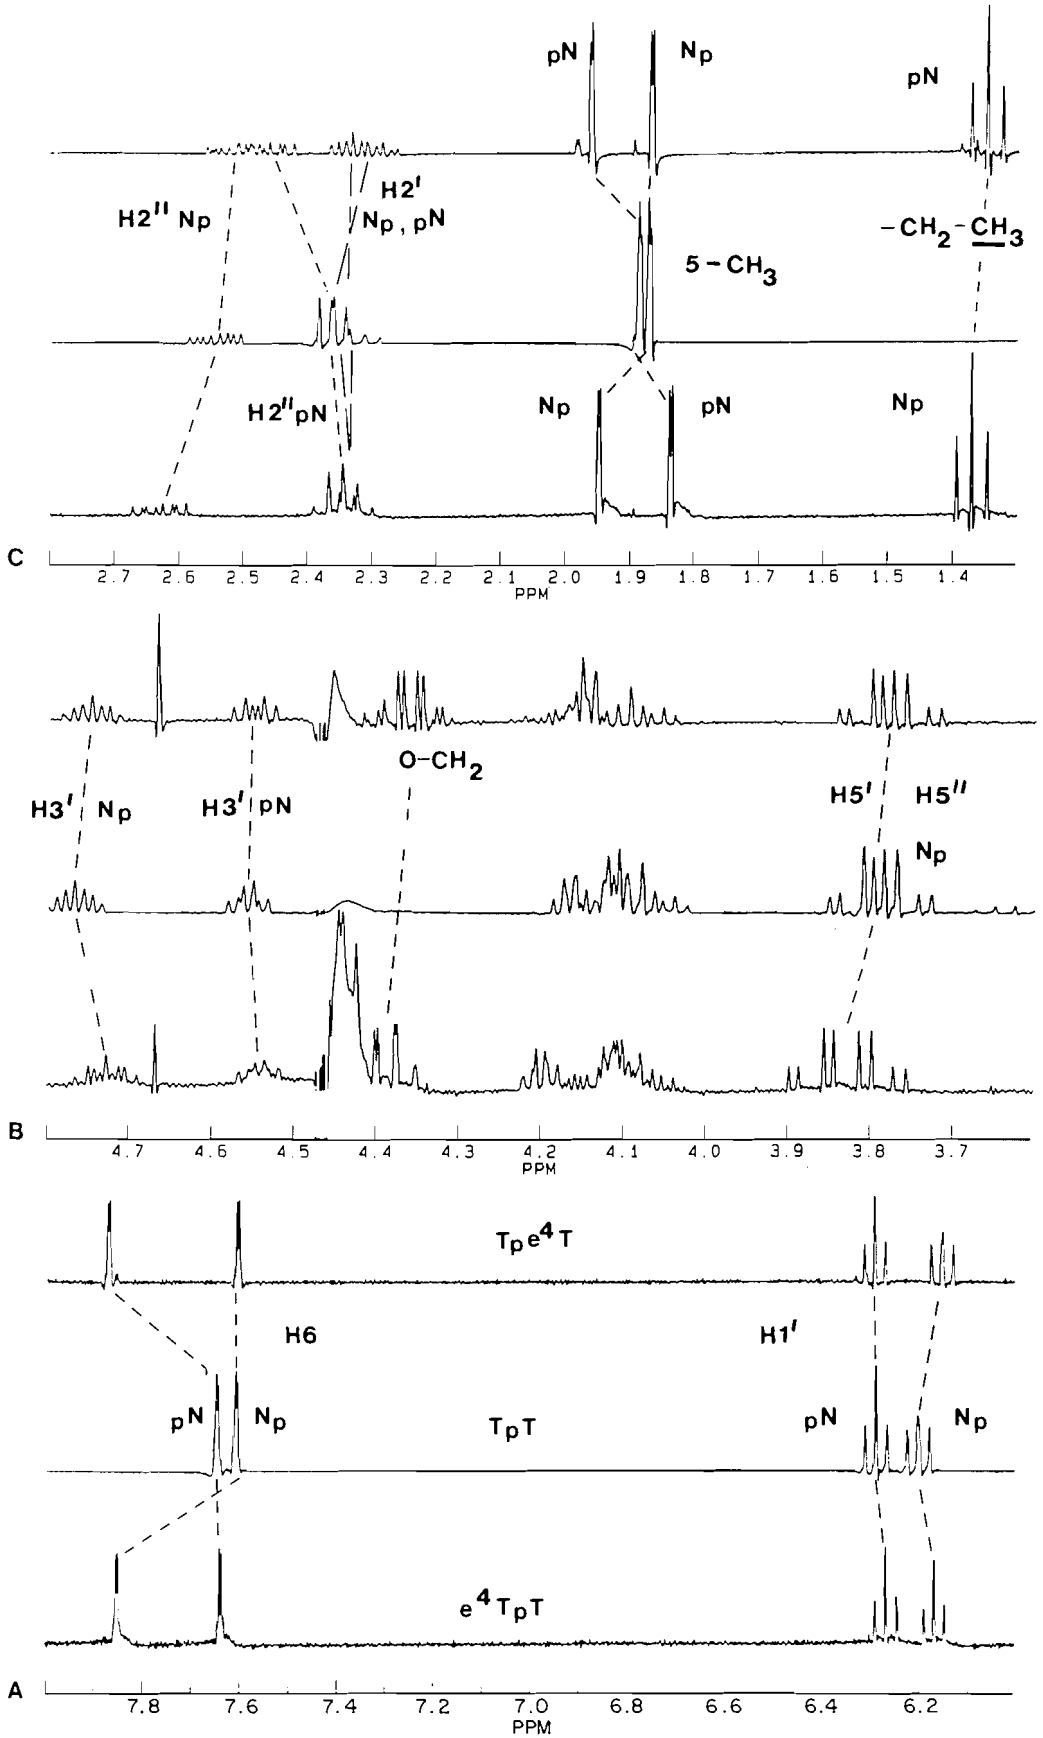

FIG. 2. Low-field (A), mid-field (B), and high-field (C) 300-MHz spectra (50°C) of d(Tpe^{4}T) (**2**) (upper panel of A, B, and C), d(TpT) (**3**) (middle panels), and d(e^{4}TpT) (**1**) (lowest panels). Np and pN represent the 3′- and 5′-linked nucleotidyl units, respectively. The 4.0 – 4.2 ppm bands in B comprise the H4′, H5′, H5″ of pN and H4′ of Np. The residual solvent-suppressed HDO signal appears at 4.45 ppm in B. An unidentified impurity is at 4.67 ppm in the spectra of **1** and **2**.

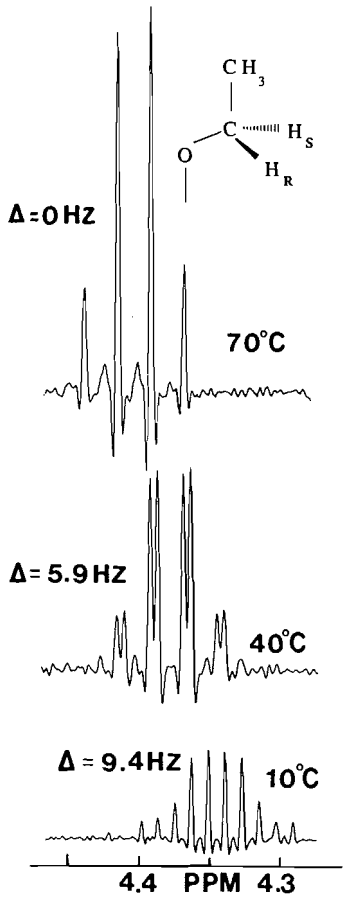

FIG. 3. Effect of temperature on the ^{1}H NMR band of the methylene H_R and H_S protons of the O4-ethyl group of d(e^{4}TpT). H_R and H_S refer to the *pro-R* and *pro-S* hydrogens (Fig. 1) and represent the AB part of an ABX_3 spin system (X_3 = 8-methyl protons). Δ is the chemical shift between H_R and H_S, with H_R assumed to be the more shielded. The decreasing value of Δ with increasing temperature is attributed to destacking of the bases. A similar phenomenon is noted for the methylene protons of d(Tpe^{4}T) (Δ = 10.7 Hz (10°C); 8.0 Hz (40°C); 4.7 Hz (80°C)), with H_S assumed to be the more shielded.

observation that the ^4J coupling between H6 and 5-CH_3 is consistently smaller by 0.1–0.2 Hz in the O4-alkylated thymine relative to the parent base (Table 2, Fig. 2).

Since the H3′ band of an Np fragment is easily distinguished from the corresponding band of the pN fragment, homonuclear decoupling can locate the connected H2′, H2″ bands and then the corresponding H1′ bands. The H2′ and H2″ protons of a particular residue are distinguished on the basis of (*a*) the larger deshielding effect of 3′-phosphorylation at H2″, (*b*) the deshielding effect of O4-alkylation at H2″ (0.09 ppm) and comparable shielding effect at H2′ (0.07 ppm) observed at the nucleoside level, and (*c*) coupling constant trends (26, 27). The H5′ and H5″ protons were assigned according to the literature (28). COSY-45° spectra were consistent with the assignments.

The O-alkyl group

Due to the presence of the chiral centres in the sugar, the C7 methylene protons of the O-ethyl groups of **1** and **2** are diastereotopic; the *pro-R* and *pro-S* protons are designated H_R and H_S in Fig. 1 and in Tables 1 and 2. At the nucleoside level (e^{4}dT), the ethyl group displays an A_2X_3 pattern in the ^{1}H NMR spectrum (methylene quartet, methyl triplet) (7), which indicates that the sugar is too distant to induce any observable differential shielding of H_R and H_S. However, in **1** and **2** these protons are not equally shielded, as is evident in the temperature-dependent ABX_3 patterns of their ethyl groups (Figs. 2, 3). At 20°C, for example, the relative H_R–H_S chemical shift (Δ) is 8.2 and 9.8 Hz in **1** and **2**, respectively (Table 1, Fig. 3). Δ decreases monotonically with increasing temperature (Table 1, Figs. 3, 5); at 70°C the quartet pattern for the methylene protons of **1** is restored (Fig. 3) but some residual splitting in the corresponding band of **2** remains even at 80°C.

Since Δ is not observed in e^{4}dT, it would seem to be a manifestation of intramolecular base stacking in **1** and **2**. Figure 1 provides a sketch of a right-handed base stack with the bases oriented in the *anti* conformation and the ethyl groups oriented as in crystalline e^{4}dT (7). In this conformation the shielding of H_R in **1** and of H_S in **2** should be more affected by the neighbouring thymine base. Disruption of the stack at elevated temperature would remove the differential shielding. Note (Fig. 4) that, in **1** and **2**, *both* methylene protons move downfield with increasing temperature, and tend toward the chemical shift of the methylene protons in e^{4}dT. This indicates that the neighbouring base shields each of the methylene protons, but it would seem that the proton inside the stack is more affected. With this reasoning we shall tentatively assign the high-field (more strongly temperature dependent) proton to H_R in **1** and to H_S in **2**. (We cannot discount some contribution from the conformation about the O4 — C7 bond that places H_S of **1** and H_R of **2** inside the stack; however, this conformation is deemed less likely since in it, unlike in the crystal conformation of e^{4}dT, the bulky 8-methyl group crowds the base.) No nuclear Overhauser enhancements between the bases were noted that could be used to distinguish the two protons. Temperature variation of the CD peaks confirms the presence of some structural ordering in **1** and **3** at low temperature (11°C), but little such variation is noted for **2** (see below).

In an ABX_3 system, the geminal (AB) as well as the vicinal (AX) coupling constants can be obtained. The geminal coupling between the *pro-R* and *pro-S* hydrogens ($J(RS)$ = −10.6 Hz) and the vicinal couplings between C7 and C8 hydrogens ($J(78)$ = 7.1 Hz) are identical in **1** and **2** (Table 2), and do not depend on temperature.

Sugar conformation

The sugar pucker can be evaluated from vicinal proton coupling constants (Table 2), or from certain sums of coupling constants (29). Figure 6 provides the temperature dependence of one such sum, $\Sigma 1' = J(1'2') + J(1'2'')$, which is easily obtained from the separation of the outer peaks of the H1′ region. The vertical axis also provides the *%S* (2′-*endo*) conformation as calculated in Rinkel and Altona (29). At the high temperature limit (70°C), the sugars of the unmodified units, including the monomer dT, have $\Sigma 1'$ in the narrow range 13.5 ± 0.2 Hz, which corresponds to *%S* ≅ 65%. The O-alkylated units, e^{4}Tp, pe^{4}T, and e^{4}dT, show $\Sigma 1'$ of 13.1 ± 0.2 Hz (55% *S*). Decreasing the temperature to 10°C effects a large decrease (1.4 Hz) in $\Sigma 1'$ of e^{4}Tp, and the 3′-*endo* (*N*) conformation now dominates (70% *N*); this proposed shift towards 3′-*endo* is consistent with the unusually large $J(3'4')$ (5.3 Hz) at 20°C (Table 2). Decreasing the temperature also reduces $\Sigma 1'$ in pT(**1**) and in each segment of **2**, but the changes here are much less (0.5 Hz). The two segments of **3** and the monomers are not influenced by temperature. Since no temperature effect is noted for the monomers, and since the pe^{4}T unit is much less affected, the shift towards 3′-*endo* in e^{4}Tp would seem to be a

sequence-dependent, base-stacking related phenomenon. As noted above, the effect of temperature on Δ suggests the presence of some base stacking at low temperature. This shift towards the *N* pucker in e⁴Tp is unusual since *S* is favored in small 2′-deoxyoligonucleotides in aqueous solution (26, 27, 29). Note, however, that e⁴dT is 3′-*endo* in the crystal state (7).

Table 3 provides populations for the *gauche*$^+$ (g^+), *trans* (t), and *gauche*$^-$ (g^-) conformers about the C4′ — C5′ bond, calculated from the J(4′5′) and J(4′5″) data (Table 2) via Haasnoot *et al.* (30). At 20°C the Np and pN fragments of the three dimers show preferences for g^+ in the narrow range 61 ± 5 and 79 ± 2%, respectively. A preference for g^+ is generally observed in oligomers (27, 29, 30). Increasing the temperature to 70°C reduces this preference in Np to 52 ± 2%, and in pN to 64 ± 2%. The g^- conformer is always the least populated with t of intermediate importance. Thus, O4-alkylation of **3** does not have a large effect on the C4′—C5′ bond of either nucleotidyl unit.

The population of the favored t conformer about the C5′—O5′ (β) bond of the pN units can be estimated from Σ′ (J(5′P) + J(5″P) (Table 2). Assuming the parameters of ref. 27, we find that %t varies only slightly for **1**, **2**, **3**, and lies in the narrow

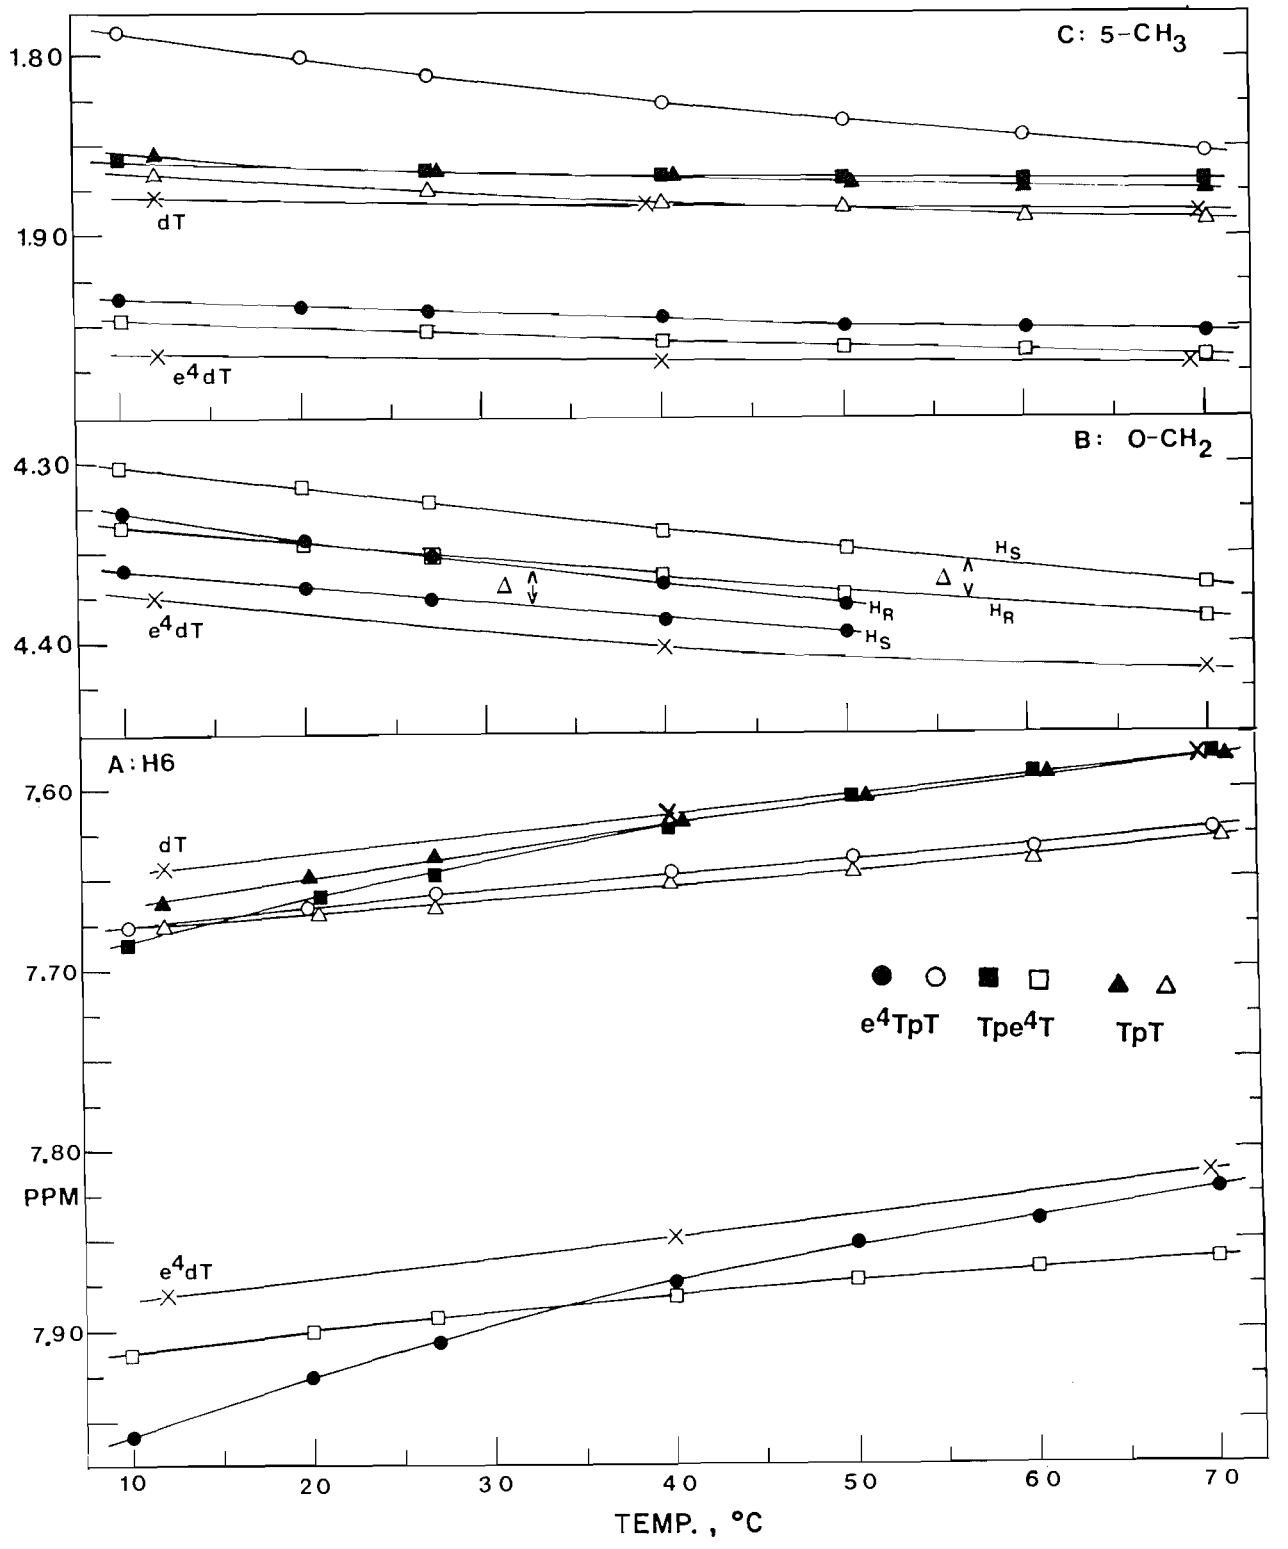

FIG. 4. Temperature profiles of the base proton chemical shifts of d(e^{4}TpT), d(Tpe^{4}T), d(TpT), and the nucleosides dT and e^{4}dT in ppm relative to internal DSS: H6 (panel A), methylene protons of the O—CH_2—CH_3 groups (panel B), and 5-CH_3 (panel C). The symbols are given in panel A; X refers to the nucleoside data. See captions of Figs. 1 and 3 for H_R, H_S, and Δ.

ranges 81 ± 3% at 20°C and 75 ± 1% at 70°C. The *J*(3′P) coupling constants that depend on the C3′—O3′ orientation of the Np units show little variation for **1**, **2**, and **3** (Table 2); preliminary unpublished $^{13}C - {}^{31}P$ coupling constant data indicate a preference for the *trans* conformation at the C5′—O5′ and C3′—O3′ bonds.

^1H chemical shifts

The effects of O4-alkylation and of temperature change on the proton shifts are shown in Figs. 4 and 5. Several trends are noteworthy.

1. *At high temperature* O4-alkylation of a thymine induces a downfield shift of about 0.25 and 0.10 ppm in its H6 and

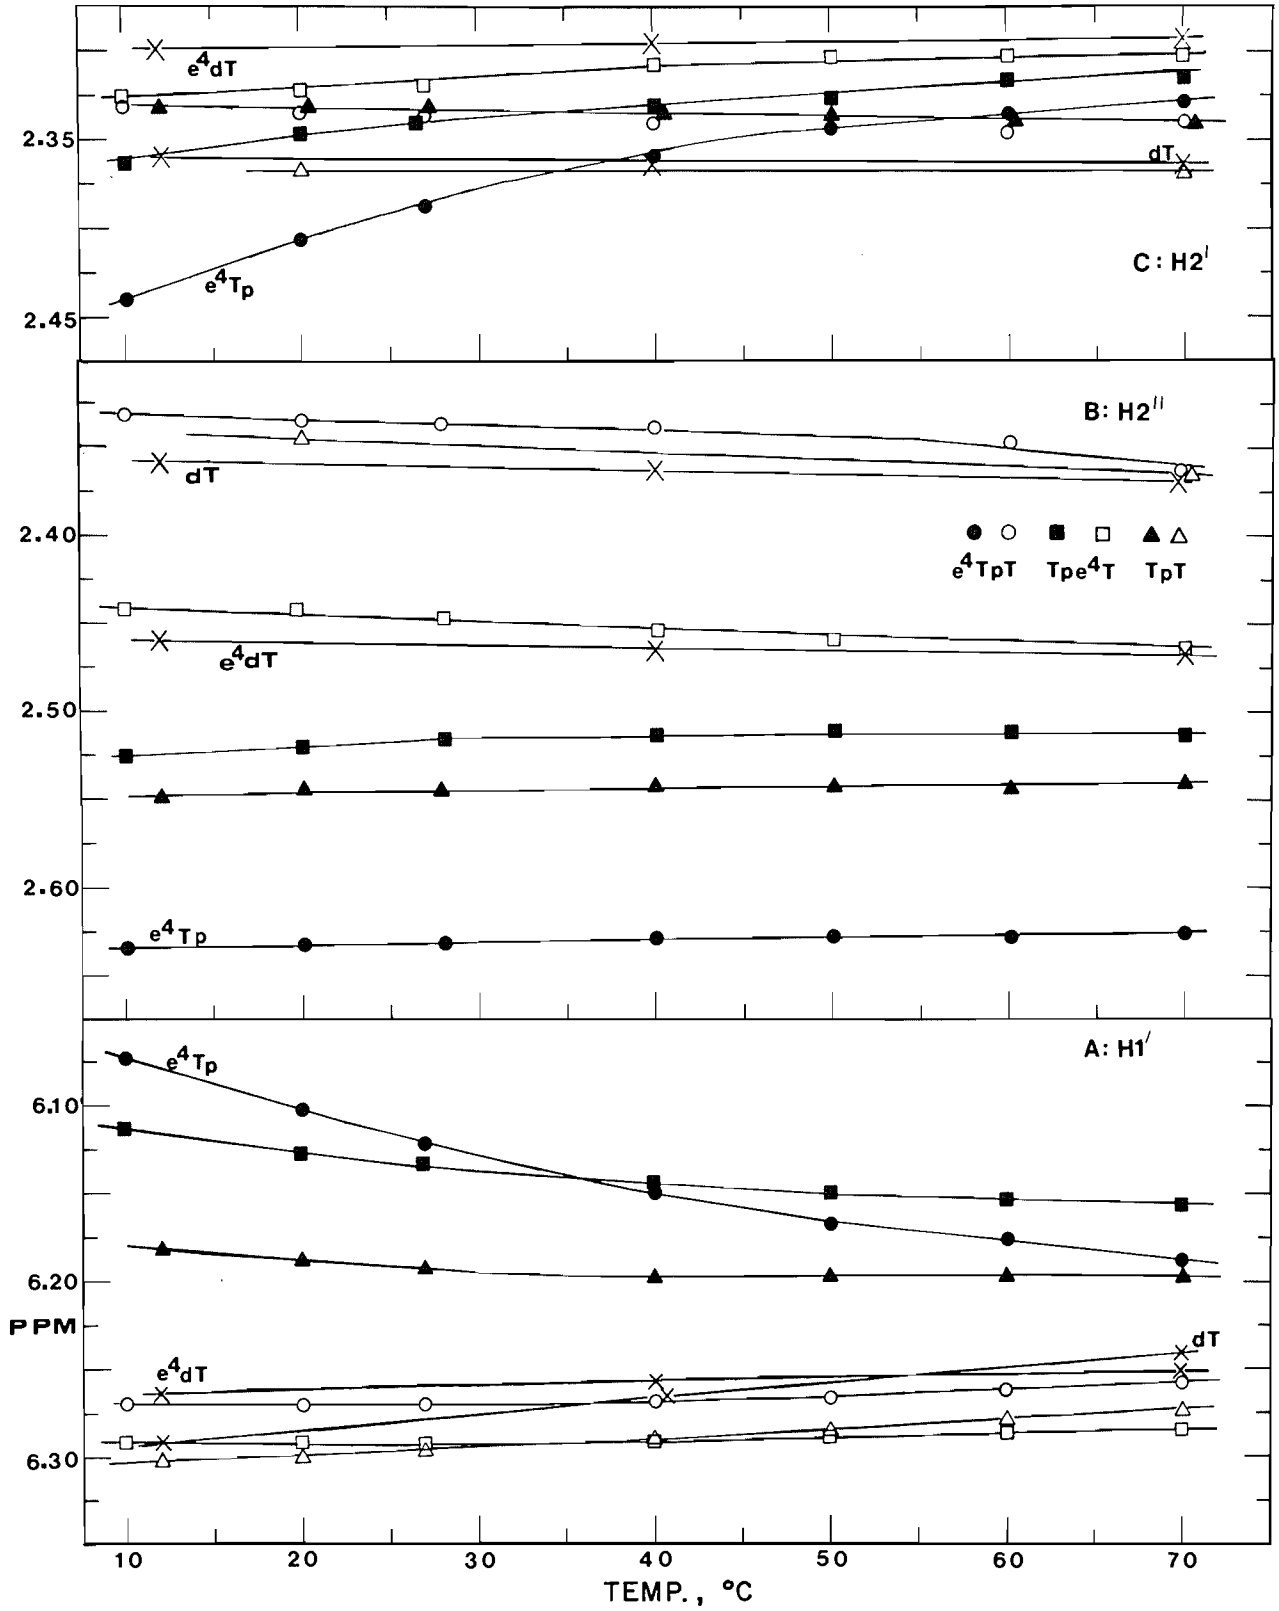

FIG. 5. Temperature profiles of the chemical shifts of the sugar protons of **1**, **2**, and **3**, and the nucleosides dT and e^4dT, in ppm relative to internal DSS: H1′(panel A), H2″(panel B), and H2′(panel C). The symbols are given in panel B; X refers to the nucleoside data. The data at 20 and 70°C are taken from Table 1; the other data were extracted from the spectra assuming a first-order relationship between the protons or an AB relationship in the case of H2′ and H2″.

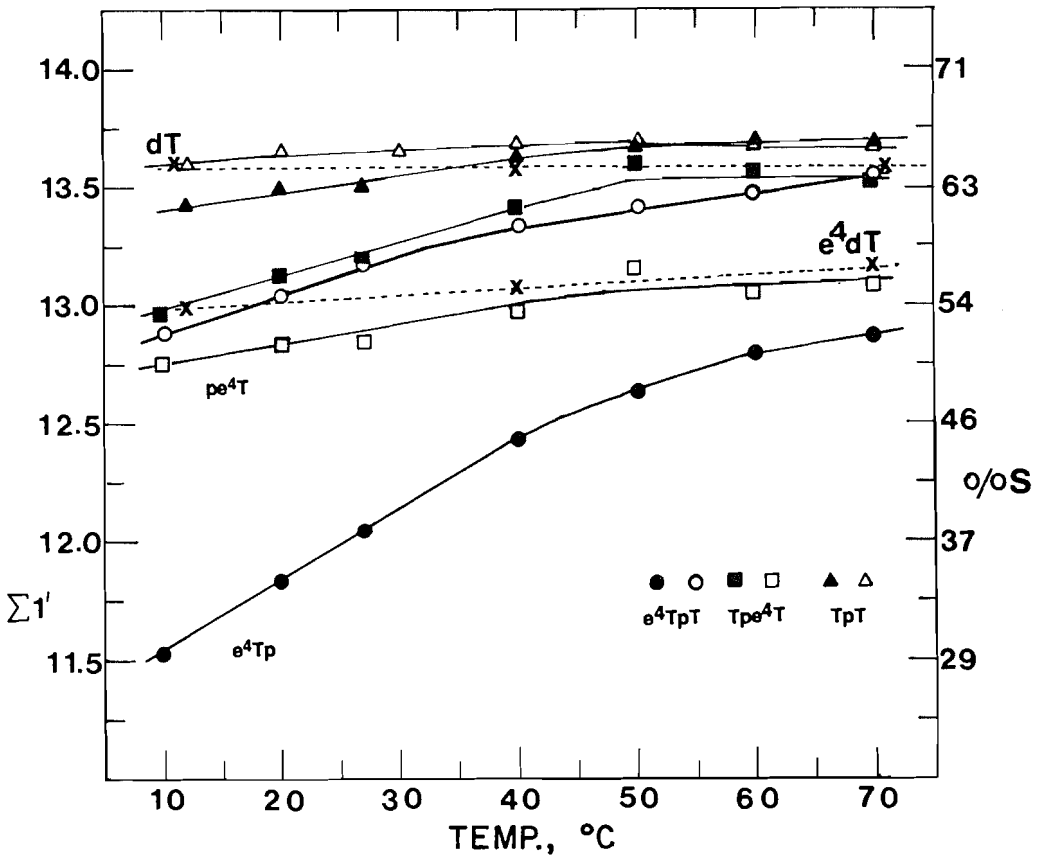

FIG. 6. Temperature profiles of $\Sigma 1' = J(1'2') + J(1'2'')$ in Hz for **1**, **2**, **3**, dT, and e⁴dT. The data at 20 and 70°C are from Table 2; the width of the H1′ band provides the values of $\Sigma 1'$ at the other temperatures. The vertical scale at the right provides the *%S* (2′-*endo*) conformation of the sugar ring calculated according to Rinkel and Altona (29). The symbols are defined in the diagram; X refers to the monomers.

TABLE 3. Calculated % populations[a] of the g^+, t, g^- rotamers about the C4′–C5′ bond for d(e⁴TpT) (**1**), d(Tpe⁴T) (**2**), and d(TpT) (**3**)

Dimer	Np	Temp (°C)	g^+	t	g^-	pN	Temp (°C)	g^+	t	g^-
1	e⁴Tp	20	66	29	5	pT	20	81	18	1
		70	54	35	11		70	65	30	5
2	Tp	20	58	32	10	pe⁴T	20	78	22	1
		70	51	37	13		70	62	34	4
3	Tp	20	56	33	11	pT	20	80	22	−2
		70	52	36	13		70	64	34	2

[a]Calculated according to ref. 30.

5-methyl protons, respectively (Fig. 4). The sugar protons are, in general, not much affected by the base modification except for H2″, which shifts downfield by 0.08–0.10 ppm (Fig. 5B); this reinforces the comparable deshielding of H2″ due to the 3′-phosphoryl group, and thus the H2″ (e⁴Tp) is the most deshielded of the six H2″ protons of the dimers. The relative chemical shifts of the H2″ protons can be understood in terms of this additivity of the deshielding influence of O-alkylation and 3′-phosphorylation.

2. For the most part, the various δ values show only slight variations as the temperature is increased from 10 to 70°C, with corresponding protons of the three dimers showing changes in the same direction. The largest changes are noted for **1**: the H6, H1′, and H2′ of the e⁴Tp unit and the 5-CH_3 of the pT unit. Since these protons are located on the base or near the N-glycosyl bond, we are inclined to suggest that the changes are, like the temperature variation of Δ, a reflection of some small degree of structural ordering of the dimers at low temperature. More precise structural details cannot be provided since the changes are small, presumably due to the low tendency for stacking at the dimer level and to the small ring currents associated with pyrimidine rings (31). Particularly interesting is the 0.10-ppm upfield shift of the H2′ proton of the e⁴Tp unit of **1**, which contrasts with the temperature independence of δ(H2″) of this unit. These trends can be rationalized on the basis of a right-hand base stack with a 3′-*endo* e⁴Tp unit since in this conformation the H2′ (but not H2″) of an Np unit is placed near to the base and O4′ atoms of the pN unit. Cheng and Sarma (32) have noted that the elevation of temperature (20 to 80°C) causes shielding of *both* the H2′ and H2″ protons of the Cp unit of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12

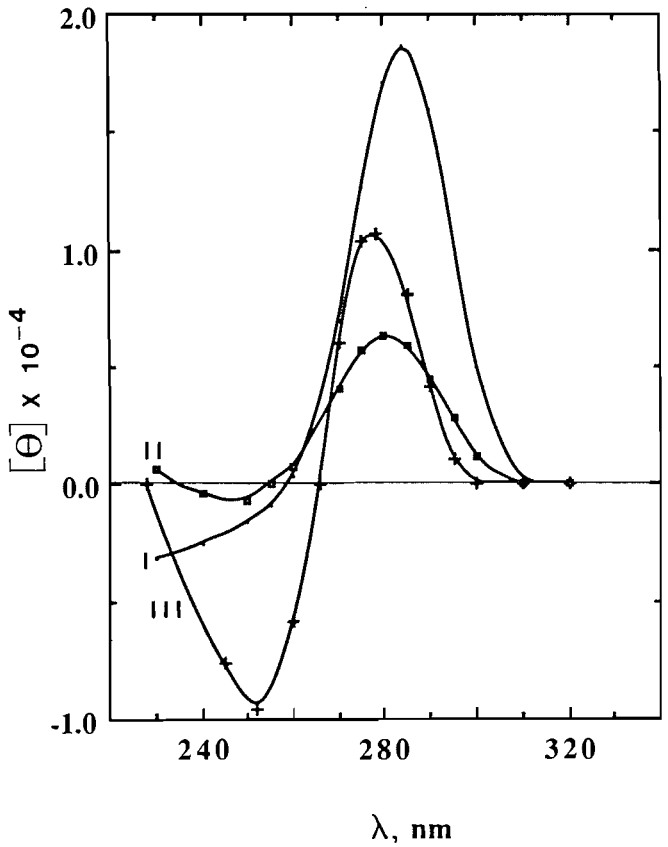

FIG. 7. Circular dichroism (CD) spectra (11–12°C) of **1**, **2**, and **3** at (1.1–1.3) × 10^{-4} M in aqueous solution. The vertical axis gives [θ] in deg M^{-1} cm^{-1}, the molar ellipticity per residue calculated following Cantor and Schimmel (35).

d(CpT). However, these authors observed that both sugars retain a preference for the 2′-*endo* pucker over the entire temperature range. Molecular models of a stacked dimer with a 2′-*endo* Np unit reveal that H2′ and H2″ of this unit make contacts with the pN unit, and hence the simultaneous variation of their δ values is not unexpected.

3. An interesting trend (Fig. 4A) is the downfield shift of all H6 resonances as the temperature is decreased from 70°C to 10°C. This shift is larger in the Np than in the pN and monomer units; the largest effect is seen in the e^4Tp unit (0.13 ppm relative to the DSS reference and 0.08 ppm relative to the H6 resonance of the corresponding monomer, e^4dT). The downfield shifts in the dimers indicate that some factor other than the ring current effect of the neighbouring base must be dominant. Comparable temperature effects have been noted earlier in dipyrimidine dimers, but were not easily explained (26, 33). The temperature dependence of the H6 resonances of the monomers indicates that simple solvent effects are relatively important. Indeed, evidence has been presented (34) that such effects can mask the upfield effects of ring currents even for stacked purine bases.

Circular dichroism

The CD spectra of **1**, **2**, and **3** at 11–12°C are shown in Fig. 7. The spectrum of **3** shows nearly equal positive and negative peaks at 278 and 252 nm, respectively, in good agreement with the observations at 26°C by Cantor *et al.* (36). The molar ellipticities per residue ([θ]) at the extrema of **3** are about 30% larger than those observed earlier (36), though their ratios are the same (278 nm : 252 nm = 1.2). The larger amplitudes observed in this work are due in part to the lower temperature of the experiment (see below). The two alkylated dimers are characterized by the dramatic reduction in the negative CD peak, and by the larger intensity of the positive peak in **1** relative to **2**. In view of the "cytosine-like" nature of the O4-ethyl base suggested by crystal structures (5–7), it is interesting to note that these features also characterize the CD spectra of d(CpT) and d(TpC) reported by Cantor *et al.* (36).

Increasing the temperature to 63–65°C leads to a 40% reduction in the amplitudes of the positive and negative peaks of **3**, and of the positive peak of **1**, which tend towards the values of [θ] measured for the constituent nucleosides (dT: λ_{max} = 276 nm, $[\theta]_{max}$ = 3800; e^4dT: λ_{max} = 279 nm; $[\theta]_{max}$ = 8560; measured here under the conditions used for the dimers and found to be independent of temperature in the 10–65°C range). The reduction in [θ] with increasing temperature is in line with the formation of some structural order in **1** and **3** at low temperature, and is consistent with the temperature variation of Δ noted above for **1**. However, **2** also shows a temperature-dependent Δ, yet we find that the amplitude of its positive band decreases by much less (10%) when the temperature is increased to 65°C. This could mean that variations in Δ and [θ] are reflecting different aspects of the ordered structure. Perhaps this interesting point would be better understood by the examination of longer oligonucleotides, which should be more extensively ordered, particularly if they contain purine bases.

Mass spectrometric experiments

Confirmation of the presence of the O-alkylated base in our dimers is provided by their FAB mass spectra, particularly when obtained in the negative ion mode. Prominent peaks in the spectra of **1** and **2** are observed at *m/z* 573 (and at *m/z* 545 in **3**), which can be assigned to the $[M - H]^-$ ion. Peaks at *m/z* 125 and *m/z* 153 are found in the spectra of **1** and **2**, and are assigned, respectively, to the base fragments $[thymine - H]^-$ and $[O4-ethylthymine - H]^-$ liberated by scission of the N-glycosyl bonds. The former (but not the latter) peak is observed in the spectrum of **3**. The peak at *m/z* 349 in **1** is assigned to $[3'e^4dTMP - H]^-$, the 3′-nucleotidyl fragment formed by scission of the O—C5′ bond to the nucleoside at the 3′ end. An *m/z* 349 peak is also observed in **2** and is assigned to the 5′-nucleotidyl unit $[5'e^4dTMP - H]^-$. Also of diagnostic value is the presence of the peaks at *m/z* 1147 in **1** and **2** (with intensities of 2–3% of the $[M - H]^-$ ion), which can be assigned to the molecular aggregates $[2M - H]^-$. In **1**, an assembly of three molecules, $[3M - H]^-$, is also apparent at *m/z* 1721, though at very low intensity (0.05% of $[M - H]^-$). Such aggregates were not detected in the spectrum of **3**. These observations demonstrate clearly the usefulness of the FAB technique for characterizing O-alkylated oligonucleotides.

Comparison of muonium and positronium with hydrogen atoms in their reactions towards solutes containing amide and peptide linkages in water and micelle solutions

MARY V. BARNABAS, KRISHNAN VENKATESWARAN, AND DAVID C. WALKER
Department of Chemistry of TRIUMF, University of British Columbia, Vancouver, B.C., Canada V6T IY6

Received May 25, 1988

MARY V. BARNABAS, KRISHNAN VENKATESWARAN, and DAVID C. WALKER. Can. J. Chem. **67**, 120 (1989).

Rate constants have been sought for the reaction of muonium (Mu) and *o*-positronium (Ps) with solutions of thirteen solutes containing the CO—N< (or —CS—N<) groups. Values of k range from $<10^5\ M^{-1}\ s^{-1}$ to $3 \times 10^{10}\ M^{-1}\ s^{-1}$ and show a variety of trends. For instance, Mu adds across the carbonyl group much faster than does H, but abstracts from an adjacent methyl group more slowly. Mu adds exceptionally efficiently to the thiocarbonyl group. Abstraction reactions are identified by large enhancements in reaction rates when localized in micelles. Ps behaves quite differently to the others in neither abstracting nor adding to these compounds, consistent with it not being a pseudo-isotope of hydrogen.

Key words: muonium, positronium, hydrogen, hydrated electrons, micelles.

MARY V. BARNABAS, KRISHNAN VENKATESWARAN, et DAVID C. WALKER. Can. J. Chem. **67**, 120 (1989).

On a cherché à évaluer les constantes de vitesse pour les réactions du muonium (Mu) ainsi que de l'ortho-positronium (Ps) avec des solutions de treize solutés contenant les groupements —CO—N< (ou —CS—N<). Les valeurs de k s'étalent de $<10^5\ M^{-1}\ s^{-1}$ à $3 \times 10^{10}\ M^{-1}\ s^{-1}$ et elles présentent les tendances les plus diverses. Par exemple, le Mu s'additionne beaucoup plus rapidement au groupement carbonyle que le H; toutefois, il procède beaucoup plus lentement à un enlèvement sur un méthyle adjacent. Le Mu s'additionne d'une façon exceptionnellement efficace sur le groupement thiocarbonyle. Lorsque les réactions d'abstraction sont localisées dans des micelles, elles sont identifiées par des augmentations importantes dans les vitesses de réactions. Le Ps se comporte d'une façon bien différente; il ne conduit pas à des réactions d'abstraction ou des additions sur ces composés et ces résultats sont en accord avec le fait qu'il n'est pas un pseudo-isotope de l'hydrogène.

Mots clés : muonium, positronium, hydrogène, électrons hydratés, micelles.

[Traduit par la revue]

Introduction

Muonium (μ^+e^-, chemical symbol Mu) is the neutral atom having a short-lived (2.2 μs) positive muon as nucleus and an electron in a 1*s* orbital almost identical to that of H. For this reason Mu is expected to behave as a light isotope of H, with just one ninth the mass of protium. The study of Mu atom reactions in solution with different solutes yields fresh information about kinetic isotope effects when compared with H (1). Studies with micelles have revealed enhancements for certain types of reactions (2) and shifts in the reaction channel when alternative paths are available, as in reaction with acetone (3). Ordinary hydrogen atoms cannot be so readily studied with micelles because they react too rapidly with the surfactant molecules themselves. A further advantage of Mu is the directness with which identity, yield, and reactivity can be observed, given a source of muons and the μSR techniques.

Positronium (e^+e^-, chemical symbol Ps) can also be envisaged as an exotic atom with some analogies to hydrogen. But Ps differs from H and Mu by having no "nucleus" (because of the equal masses of the electron and positron) and this leads to considerable differences in size, polarizability, and binding energy. Its rate of diffusion in water is comparable to that of Mu and H (4), however, and its chemical reactivity is worth contrasting with Mu. Some ionic solutes have recently been compared in this regard (5).

Comparisons with solvated electrons as the lightest of the quartet H/Mu/Ps/e^-_{aq} are also of interest, because the mass and mean thermal velocity of Ps are much closer to e^- than H. In studies of all four species the rate of disappearance is observed and only very rarely is a product of reaction identified. Contrasts and inter-comparisons therefore have to be used to infer the mechanism and type of reaction involved.

In the present paper organic molecules have been selected as solutes which contain amido-linkages and are of some biological interest. Mu and Ps might be expected to attack them through abstraction or addition reactions. Furthermore, some related compounds have recently been seen to produce muonated free radicals when studied by μSR (3, 6–8).

Experimental

1. μSR technique

Muonium atoms form at the end of some muon tracks when energetic positive muons (from pion decays) are injected into water. They are observed in transverse magnetic fields by the muon spin rotation technique (μSR) (9, 10). The muons were provided on the M20 and M13 beamlines of TRIUMF. Chemical reaction rate constants of Mu were evaluated from spin precession signals as the relaxation constant (λ) of the "triplet" muonium signal (parallel muon and electron spins) oscillating at its Larmor frequency (ω_M) of 1.39 MHz G^{-1}. A MINUIT χ^2-minimization fit of the muon lifetime histogram (as in Fig. 1*a*) to eq. [1],

$$[1]\quad N_t = N_0 \exp(-t/\tau)[1 + A_M \exp(-\lambda t)\cos(\omega_M t + \phi_M) + A_D \cos(\omega_D t + \phi_D)] + B$$

gives λ as one of the fitted parameters. (In eq. [1], N_t is the number of counts in the histogram corresponding to time t; N_0 a normalization factor; τ the mean muon lifetime; A_M and A_D, ω_M and ω_D, and ϕ_M and ϕ_D are the asymmetries, frequencies, and initial phases of the "muonium atoms" and "diamagnetic muon components", respectively; and B is the time-independent background signal). λ is related to a bimolecular chemical rate constant of Mu (k_M) through eq. [2],

$$[2]\quad k_M = (\lambda - \lambda_0)/[S] = \Delta\lambda/[S]$$

where λ is the observed value with solute present at concentration [S] and λ_0 the background value in the same medium, including micelle, but with [S] = 0. A narrow observational time-window of ~0.3 to ~4 μs is imposed by the μSR technique, because it is a nuclear physics technique based on the intrinsic decay of the muon (τ = 2.2 μs). Therefore, all solutions to be studied must have their muonium chemical-lifetimes carefully selected so that λ falls in the limited range of 3×10^6 to $2.5 \times 10^5\ s^{-1}$. This precludes the possibility of

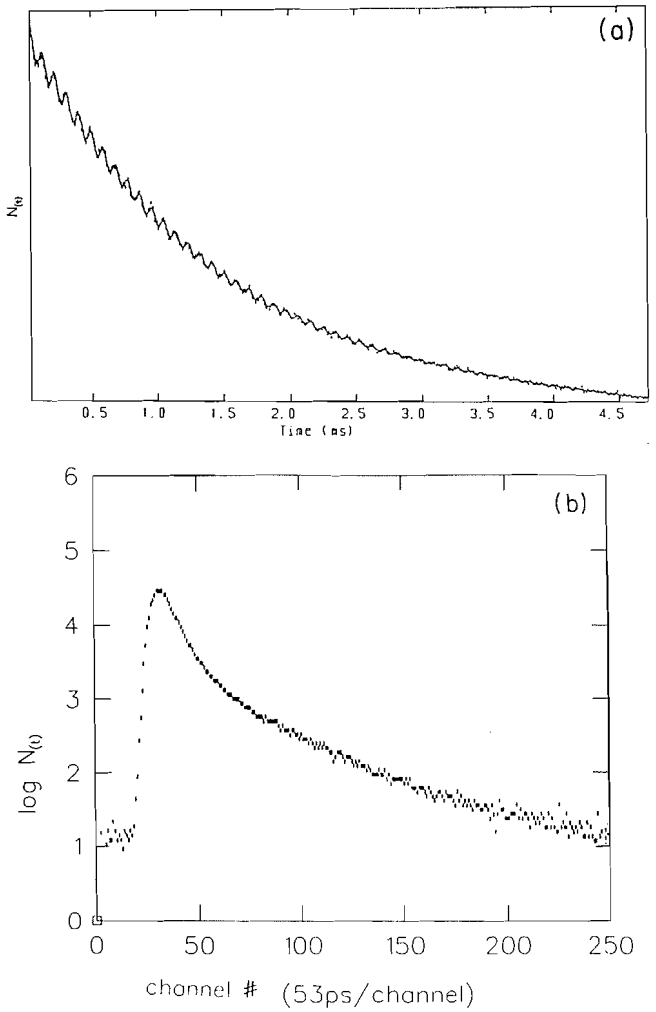

FIG. 1. Representative μSR and PAL "spectra" (counts vs. lifetime). (*a*) μSR lifetime histogram of water in a transverse field of 8 G. The line is the computer's fit to eq. [1]. (*b*) log(counts) vs. channel (lifetime) in pure water.

studying broad concentration-dependencies as one would normally like to undertake in a kinetic analysis. Furthermore, the micelle concentrations are restricted to $\leq 10^{-2}$ *M* because, with 50–80 surfactant molecules per micelles, the rate of reaction of muonium with surfactant, or its inseparable impurities, forces the "background" relaxation rate (λ_0) too close to λ for reasonable accuracy.

2. Positron annihilation lifetime (PAL) measurements

A positron source consisting of ~4 μCi of ^{22}Na sandwiched between two thin mylar sheets was used for positron lifetime measurements. About 2 mL of the appropriate solution under study was placed in a tube with the positron source centered in the liquid sample. The solution was deoxygenated by bubbling with N_2 gas using a hypodermic needle through a septum. All measurements were made at ~20°C. Positron lifetimes were measured by observing the time elapsed between the emission of a positron into the sample and its subsequent annihilation. A high energy (1.28 MeV) γ-photon is emitted simultaneously with the positron, and this is used as the trigger. The positron lifetime is determined as the time difference between the detection of the 1.28 MeV photon and detection of one of the 0.51 MeV annihilation photons, using the conventional delayed coincidence method (11). The resolution of this system was determined to be less than 350 ps by measuring the coincident photons from a ^{60}Co source.

Positrons emitted from the nuclear decay are thermalized in condensed matter (water in this case) within picoseconds, when some of them pick up electrons from the track to form Ps atoms. Annihilation occurs from all positron states. Some annihilate directly with electrons of the medium or after the formation of weak positron or positronium associations, others form *p*-Ps (too short-lived to study) and the relatively long-lived *ortho*-positronium atoms (parallel e^+ and e^- spins). Each of the annihilation processes contributes an exponential decay with a mean lifetime, τ_i, to the "spectrum". The lifetime spectrum is analysed (11) as a sum of exponentials, as in eq. [3],

$$[3] \quad N_t = \sum_{i=1}^{n} A_i \exp(-t/\tau_i)$$

where n corresponds to the number of components, $1/\tau_i$ is the annihilation rate constant of each component, and A_i is its amplitude.

The spectra obtained (as in Fig. 1*b*) were resolved into a multi-exponential function by a χ^2-minimization computer program POSITRONFIT EXTENDED (12). The results reported here are from three component fittings, with χ^2-values ~1. The resolved three different lifetimes $\tau_1 \sim 0.125$ ns, $\tau_2 \sim 0.50$ ns, and $\tau_3 \sim 1.5$ ns correspond to different positron and positronium states. The longest lived component τ_3 is due to the annihilation of free *o*-Ps atoms, which gives information about the chemical reactivity between Ps and molecules in the system. An intrinsic τ_3 decay in pure water of 1.8 ns restricts the time range that can be used to study Ps to about 10^{-9} s, and therefore to concentrations of solutes $> 10^{-2}$ *M*. The relationship between the concentration of solute molecules [S], the measured *o*-Ps lifetime τ_3, and the chemical reaction rate k_P is written as

$$[4] \quad k_P = \left(\frac{1}{\tau_3} - \frac{1}{\tau_3^0}\right) \Big/ [S]$$

where τ_3 and τ_3^0 are, respectively, the measured *o*-Ps lifetimes in aqueous (or aqueous micelle) solution with and without the solute present.

3. Solutions

The solutes used were reagent grade chemicals, their formulae and structures being given in Fig. 2. Aqueous solutions were prepared using triply distilled water. The surfactant used for μSR studies was CTAB (cetyltrimethylammonium bromide) and for *o*-Ps lifetime measurements was SHS (sodium hexylsulphate): the reason for this difference is that *o*-Ps studies require three orders of magnitude higher concentrations than those required for μSR studies. Figures 3*a* and *b* give the plots of λ_0 and $1/\tau_3$ versus concentration of $[CTAB]_{mic}$ and $[SHS]_{mic}$, respectively, from the μSR and PAL data. All the micellar solutions contained concentrations of the surfactant which are well above the critical micelle concentration (CMC), so the concentration is given by eq. [5]

$$[5] \quad [mic] = \frac{[surf] - CMC}{A}$$

where A is the mean aggregation number.

Results

Representative data from solute studied by μSR and PAL are given in Figs. 4 and 5. Figure 4*a* is the plot of λ against concentration of guanidine in water, and Fig. 4*b* is the plot of $\Delta\lambda$ against concentration of tetramethylthiourea in water and in dilute micelle solutions. The average number of solutes per micelle was fixed throughout these μSR studies at three to avoid a significant number of "empty" micelles (2). Figure 5 shows the plot of $1/\tau_3$ vs. concentration of benzoquinone in aqueous and in dilute micelle solutions.

Table 1 gives the thirteen solutes studied by μSR in aqueous solutions and in dilute CTAB micelle solutions, their maximum concentrations used, and the calculated rate constants of Mu using eq. [2]. Acetone is also listed for comparison with these solutes. Table 2 records the data from the PAL studies for the

same solutes, the rate constants of Ps being calculated using eq. [4]. Since the solutes of interest show only upper limits, benzoquinone is included in Table 2 for comparison purposes. In most cases only an upper limit to k_p and $k_{p(mic)}$ were obtained (invariably limited by the natural τ_3 in pure water for the various concentrations accessible).

Discussion

1. Muonium

Muonium has been shown previously to react with different solutes in a variety of ways, by addition across double or triple bonds, by abstraction of H, by reductive electron transfer, and by electron spin exchange (4). Rate constants ranging from $10^5\,M^{-1}\,s^{-1}$ to $2\times10^{10}\,M^{-1}\,s^{-1}$ have been observed where the latter seems to be the diffusion-controlled limit. Furthermore, kinetic isotope effects, relative to protium, have been found from 10^2 to 10^{-2}. Yet there was no indication hitherto how Mu would attack the amido-group, where it could add to the carbonyl, as with acetone, or abstract H from the —NH— group or from a methyl, or be unreactive.

Evidently, Mu reacts very slowly, if at all, with the simple amide linkage. The rate constant k_M for these solutes is less than $10^5\,M^{-1}\,s^{-1}$, except for tetramethylurea which shows k_M to be close to (4×10^5) this limit of measurement. Substituents on the

α-position and/or on the $—NH_2$ group do not change the rate very much. Use of higher concentrations could give a better limit for the rate constants, but impurities become too important at high concentrations since they can contribute to λ.

Addition of micelles to aqueous solutions of solutes containing just the simple amido-linkage increases the rate of reaction considerably. For tetramethylurea it is seen to increase by the factor 2×10^4 and for some of the others it is seen to increase by at least 10^4-fold. In two cases (*N*-methylacetamide and *N*,*N*-dimethylacetamide) the observed rate is very close to the limit of observation, and for guanidine and urea it was below that limit; but the indications are that $k_{M(mic)}$ is about 10^9 for these solutes. Again, higher concentrations can not be used, this time because of the background reactions (λ_0) of the surfactant molecules themselves. These 10^4-times enhancements are characteristic of abstraction reactions (2). Our conclusion therefore, is that Mu reacts very slowly but that there is an abstraction of H from methyl substituted amides.

[a]From ref. 16.

For thioamides the situation is completely different. Muonium reacts with thioacetamide and tetramethylthiourea with $k_M > 10^{10}\ M^{-1}\ s^{-1}$, which means they react on nearly every encounter. Addition of micelles has almost no effect on this observed rate. (In the case of tetramethylthiourea there is a two-fold decrease, but it must be recalled there are three solutes per micelle and $k_{M(mic)}$ is calculated on the mean bulk concentration.) The absence of a large effect on adding micelles has been found previously for reactions which have no activation barrier (2). The fact that the reaction is not seriously inhibited shows that muonium penetrates the micelle boundary and reacts in a highly efficient reaction regardless of whether the microenvironment is water or hydrocarbon.

Rhodes *et al.* (7) have recently reported the formation of a muonated thioacetamide radical in the μSR of pure thioacetamide. This suggests that the reaction with muonium atoms in dilute solution is also addition across the C=S bond, with Mu attached to the C, as in eq. [6]

[6] $Mu + CH_3C(=S)NH_2 \rightarrow CH_3C(-\dot{S})(Mu)NH_2$

Such an addition is discussed by Rhodes *et al.* in terms of hyperconjugation. It is also interesting to contrast it with acetone where k_M is only $8.7\times10^7\ M^{-1}\ s^{-1}$ and where the product is known by level-crossing resonance (2, 13) as well as transverse-field μSR (14) to have Mu bonded to O, as in eq. [7]

[7] $Mu + (CH_3)_2CO \rightarrow (CH_3)_2\dot{C}OMu$

Evidence for this assignment comes from both the hyperfine coupling constant when compared to other radicals seen by ESR, and the effect of solvents on the hydrogen-bonding (muonium-bonding here) (2, 14*e*).

Thiourea seems to be different from the other two thiocarbonyls. Its value of k_M resembles that of acetone. Perhaps addition still occurs, but at much lower rate with Mu bonded

to S. There is no evidence that the Mu reaction with thiourea is enhanced by addition of micelles, as with urea itself, probably because these solutes are very weakly localized, if at all, at micelles.

The compounds of biological interest studied here which have amide linkages are uracil, thymine, and cytosine. These compounds have a ring structure and Mu is fairly reactive ($\sim 10^9\ M^{-1}\ s^{-1}$) towards these solutes. Since there is no enhancement with micelles it is concluded that addition is more likely than abstraction. These additions, however, are slower than that with thiocarbonyl groups in thioacetamide or tetramethylthiourea but faster than acetone or thiourea. Mu probably adds across the C=C group in the rings.

2. Positronium

Positronium reacts rapidly with benzoquinone. The rate observed ($k_P = 3.5 \times 10^{10}$) is probably at the diffusion-controlled limit, signifying reaction on every encounter between Ps and benzoquinone. A similar upper limit of 2 to $3 \times 10^{10}\ M^{-1}\ s^{-1}$ has been found to the second-order rate constants for reactive solutes in water reacting with Mu, H, and hydrated electrons. The diffusion of these small reactive species is evidently controlled by the solvent (4).

Addition of micelles to a benzoquinone solution barely affects the rate at which Ps reacts. The 2.3-fold decrease actually observed (Table 2) probably combines two effects: first the solutes have been bunched into packets of three, on average, as far as the diffusion time of a wandering Ps atom is concerned; but second, an occupied-micelle presents a larger encounter radius than a benzoquinone molecule in water. The relative importance of these two opposite effects depends on the relative diffusion coefficients in water compared to micelle cores. Most importantly, however, localization of benzoquinone did not significantly impede the reactivity of Ps, so it clearly penetrates the lipid phase with a diffusion coefficient comparable to that in water.

Ps reactions are often described simply as "pick-off" or "spin-exchange" interactions which convert *o*-Ps to *p*-Ps following the formation of a reaction complex (5, 11). In the case of benzoquinone, Ps may attack the carbonyls or the ring C=C groups to form such complexes. Both types of group appear in the range of solutes studied here, so that some fast positronium reactions were anticipated. However, as Table 2 shows, no reactions were found in water with rate constants greater than $10^8\ M^{-1}\ s^{-1}$, and none with observable micelle-enhancements. Ps differs strikingly from Mu in two areas then: first it does not respond to the C=S group as Mu does; and second, it does not undergo the slow abstraction reactions which are now characterized in muonium chemistry by micelle enhancements close to the diffusion-controlled limit (2).

3. Comparison with H and e^-_{aq}

Table 3 lists the published values of rate constants of H and e^-_{aq} for these solutes, when available, to compare with our values of k_M and k_P (first and fourth columns, from Tables 1 and 2). In the case of k_H, most data were obtained from e^-_{aq} in acidified water and the "not-available" blanks in some cases may mean the rate was too small to determine (but, unfortunately, an upper limit was not given). For the H reaction with acetamide, Neta *et al.* (15) have concluded that this very slow reaction is one of abstraction to form H_2.

For three of the first seven solutes (all those that can be compared) H reacts faster than Mu, and this is normal for abstraction reactions. However, there is only a factor of four favouring the heavier isotope with guanidine (which is the only case without limits) whereas for several alcohols, or formate ions, abstraction usually favours H by a factor of 10^2 or so (4). Hydrated electrons react with these solutes at intermediate rates, 10^6–$10^8\ M^{-1}\ s^{-1}$, probably by electron attachment to the amido group. Urea seems to be particularly unreactive towards all four species.

Substituting O by the more polarizable S causes k_H and $k_{e^-_{aq}}$ to increase by several orders of magnitude, as it does for Mu. There are too few S compounds studied so far with all four species for general trends to emerge; but addition of Mu to C in some C=S compounds look as if it is not mimicked by H.

For the solutes of biological interest (last three listed) Mu falls directly between H and e^-_{aq} in its absolute reactivity. As suggested above, these are probably ring addition reactions for Mu. It is pertinent to note that the Mu data were obtained in solutions of these compounds at neutral pH, where they have biological significance. Data for H, on the other hand, refer to strongly acid solutions (pH ~ 1), because of the need to produce H by conversion of e^-_{aq} in radiolysis. Whereas that limitation on H atom data may not be serious for many simple solutes, it presents a real problem for studies of proteins, peptides and many other naturally occurring compounds. Consequently, once the full range of kinetic-isotope effects are understood, this means that muonium studies may generally be preferred as the means of elucidating hydrogen atom chemistry.

Acknowledgements

The assistance of Dr. J. M. Stadlbauer, Dr. B. W. Ng, Zhennan Wu, and the staff of the μSR group at TRIUMF is very much appreciated for the Mu studies. Dr. Yasuhiro Miyake's contributions in assembling and initiating the PAL apparatus is warmly acknowledged. Funds for these experiments came from NSERC of Canada.

The direct electrochemical synthesis of phenylselenolato complexes of some main group and late transition elements

RAJESH KUMAR AND DENNIS G. TUCK

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received August 18, 1988

RAJESH KUMAR and DENNIS G. TUCK. Can. J. Chem. **67**, 127 (1989).

The electrochemical oxidation of anodes of selected Main Group or late transition metals (M) in non-aqueous solutions of diphenyl diselenide gives the corresponding $M(SePh)_n$ compounds in high yields (M = Zn, Cd, $n = 2$; M = Cu, Ag, Tl, $n = 1$; M = Sn, $n = 4$). The addition of either 1,10-phenanthroline or triphenylphosphine to the electrochemical cell yields adducts in the case of cadmium and copper. The ^{77}Se nmr spectra have been recorded.

Key words: electrochemistry, synthesis, phenylselenates, ^{77}Se nmr spectra.

RAJESH KUMAR et DENNIS G. TUCK. Can. J. Chem. **67**, 127 (1989).

Lorsqu'on effectue l'oxydation électrochimique d'anodes formées de métaux du groupe principal ou de la fin des métaux de transition (M) dans des solutions non-aqueuses de disélénure de diphényle, il y a formation des composés $M(SePh)_n$ correspondants avec des rendements élevés (M = Zn, Cd et $n = 2$; M = Cu, Ag, Tl et $n = 1$; M = Sn et $n = 4$). Avec le cadmium et le cuivre, il y a formation d'adduits lorsqu'on ajoute de la phénanthroline-1,10 ou de la triphénylphosphine à la cellule électrochimique. On a déterminé les spectres rmn du ^{77}Se.

Mots clés : electrochimie, synthèse, phénylséléniates, ^{77}Se spectres en rmn.

Introduction

Compounds in which a metal atom is bonded to sulphur or selenium donor ligands are presently of considerable interest because of their importance in biological systems, such as metallo-proteins, and in a different sense because they are possible precursors for binary compounds for the microelectronics industry. A number of papers from this laboratory have described the synthesis of $M(SR)_n$ compounds by the electrochemical oxidation of a sacrificial anode in a non-aqueous solution of either a thiol or a disulphide (1–6). The present paper shows that these techniques can be extended to the one-step high yield synthesis of phenylselenolato complexes $M(SePh)_n$, and in some cases, their adducts with neutral donor ligands.

Experimental

Materials

The metals zinc, cadmium, copper, silver, indium, thallium, and tin were used as rods, 3–6 mm diameter; gold was as a foil, approximately 1 cm^2 in area. Metals were obtained from Alfa Products, and were of 99.9% purity or higher. The surface of these metals was cleaned by washing successively with concentrated nitric acid and then distilled water; after being dried, the surface was abraded with fine sandpaper and polished with tissue paper. Solvents (acetonitrile, toluene) were distilled from calcium hydride and stored over molecular sieves. Diphenyl diselenide, 1,10-phenanthroline (phen), and triphenylphosphine (Aldrich) were used as supplied.

Metal analysis of products was by atomic absorption spectrophotometry, using an IL-250 instrument. Microanalysis was by Guelph Chemical Laboratories Ltd.

Infrared spectra of KBr discs were obtained with a Nicolet 5DX instrument. Proton nmr spectra were recorded on a Varian EM-360 spectrometer, and ^{77}Se spectra on a Bruker 200.

Electrochemical procedures

The general method was derived from that described in papers on the synthesis of thiolates (1–6), using a cell of the general form $Pt_{(-)}/CH_3CN/toluene + Ph_2Se_2/M_{(+)}$. The details of solution composition and electrochemical conditions are given in Table 1. To prepare the solution phase, diphenyl diselenide was dissolved in toluene, with stirring, under nitrogen, and the appropriate volume of acetonitrile containing a small quantity of Et_4NClO_4 added; the stirring was continued for a few minutes to ensure homogeneity. This solution was then placed in a 100-mL tall-form beaker, and the platinum wire cathode, and the anode suspended on a second platinum lead, were introduced through a tightly fitting rubber bung. Dry nitrogen purged the cell throughout the electrolysis. Electrical energy was supplied by a Coutant LQ 50/50 D.C. power supply.

As the electrolysis proceeded, solid products precipitated in the case of M = Cd, Cu, Ag, and Tl. At the end of the experiment the solid was collected, washed with cold acetonitrile (10–15 mL) and then cold *n*-pentane (10–15 mL) and finally dried *in vacuo*. With anodes of zinc or tin, the initial product dissolved in the electrolyte phase; subsequent slow evaporation *in vacuo* gave a solid deposit, which was collected, washed, and dried as described above. In each of these experiments, the yield was essentially quantitative, based on the quantity of metal dissolved from the anode.

In a few experiments with Cd or Cu, the neutral ligands 1,10-phenanthroline or triphenylphosphine were introduced into the solution phase before electrolysis (see Table 1). No precipitation occurred during the electrolysis, but when the volume was reduced by slowly bubbling nitrogen through the solution for periods between 5 and 20 h, crystals were formed; these were collected, washed with acetonitrile and then diethyl ether, and dried *in vacuo*. The product yields were better than 80%.

When a gold anode was used in such a cell, only a small quantity of metal dissolved (see Table 1), and the solution phase became cloudy and dark coloured. No product could be isolated from this solution.

In the case of indium, the anode was rapidly covered with an adherent deposit which caused the current to drop to almost zero. Again, no product could be obtained under these circumstances. We note a possible hazard with this metal, in that any substantial increase in applied voltage may cause this anode deposit to break off from the anode with an accompanying spark discharge, which on one occasion was sufficient to break the reaction vessel. In order to include an indium-phenyl selenolate in our ^{77}Se nmr studies, a sample of $In(SePh)_3$ was prepared by refluxing indium metal with diphenyl diselenide in toluene (7).

The electrochemical synthesis of TlSePh by the anodic oxidation of thallium in a non-aqueous solution of diphenyl diselenide has also been described previously (7); the present system differs only slightly in the solution composition.

tion metals in non-aqueous solutions of diphenyl diselenide is clearly an efficient one-step route to the appropriate $M(SePh)_n$ compounds, and a slight modification serves to provide adducts in the few cases investigated. The method is no doubt applicable to other metals. The directness of this synthetic route offers several advantages over previously reported procedures to organoselenolato complexes, involving either metathesis between RSeH and a salt of the metal, or oxidative insertion into the Se—Se bond of R_2S_2.

The products, which involve the metals concerned in conventional oxidation states, were characterised by elemental analysis, and by infrared and ^1H nmr spectroscopy. The simple $M(SePh)_n$ compounds (or their alkyl analogues) are known compounds, but the adducts noted in Table 1 do not appear to have been reported previously. The spectroscopic results confirm the presence of the SePh ligand; Table 2 shows the standard broad multiple resonances of the phenyl ring, and the infrared spectra also demonstrated the typical absorption bands of the phenyl group. In addition, the characteristic modes of the —SePh ligand were observed at 665 and 1070 cm^{-1}.

Electrochemical

Following the standard procedure in this laboratory, we have measured the electrochemical efficiency, E_F, defined as moles of metal dissolved from the anode per Faraday of electricity, for each system. For copper, silver, and thallium, the value of 1.0 mol F^{-1} (see Table 1) corresponds to the sequence

[1] cathode: $(1/2)Ph_2Se_2 + e \rightarrow PhSe^-$

[2] anode: $PhSe^- + M \rightarrow MSePh + e$

and in keeping with this, the products are indeed the appropriate MSePh compounds. The value of 1.0 mol F^{-1} also holds for copper when neutral ligands are present, showing that complex formation is subsequent to the anode reaction [2] above. For

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

cadmium, $E_F = 0.5$ mol F^{-1}, corresponding to the overall anode reaction

[3] $2PhSe^- + Cd \rightarrow Cd(SePh)_2 + 2e$

One might have expected a similar value for the oxidation of zinc, but the reproducible value of 0.75 ± 0.05 mol F^{-1} implies a competing process occurring at the anode, causing dissolution of the metal by a non-electrochemical process, e.g.

[4] $Zn + Ph_2Se_2 \rightarrow Zn(SePh)_2$

For the oxidation of tin, we find $E_F = 0.5$ mol F^{-1}, although the final product is $Sn(SePh)_4$, as it is when tin metal reacts with Ph_2Se_2 in refluxing toluene (7). We conclude that the formation of $Sn(SePh)_2$ at the anode is followed by an oxidative addition reaction in solution

[5] $Sn(SePh)_2 + Ph_2Se_2 \rightarrow Sn(SePh)_4$

a process which is compatible with the known chemistry of tin(II) species. For indium, the E_F value of unity indicates the formation of In^ISePh as the primary product, in keeping with the behaviour of this metal in cells containing non-aqueous solutions of RSH, when the product is InSR (R = alkyl or aryl) (8). In this latter work, it was found that the aryl derivatives were readily oxidised or decomposed, and the present results suggest that InSePh is also very unstable.

Spectroscopic studies

As noted above, the infrared and ^1H nmr spectra confirmed the presence of the SePh ligand, and of the appropriate neutral donor ligands, in the compounds listed in Table 2. These results do not call for any detailed discussion. Table 2 also lists the ^{77}Se nmr chemical shifts for those products which are soluble in d_5-pyridine. Given that such resonance frequencies are influenced *inter alia* by coordination number, coordination geometry, and the properties of other ligands present (9, 10), it is not surprising that the results cover a range of values. The chemical shifts for $Zn(SePh)_2$ and $Cd(SePh)_2$ are very similar, implying the presence of isostructural species in solution, presumably $M(SePh)_2py_n$, resulting from the breakdown of the M ← Se cross-linked solid state homopolymer (c.f. ref. 1 for a discussion of analogous effects in $M(SPh)_n$ complexes). Replacement of pyridine in the coordination kernel by 1,10-phenanthroline causes a significant change in the resonance frequency.

The values for the copper(I) species are presumably also for pyridine solvates, but in view of the wide variety of structures which are known for the thiolato derivatives of copper(I), and their adducts, we cannot assign any structures from these results, although the closeness of the values implies similar copper-selenium environments. The value for $Sn(SePh)_4$ is close to that reported for this compound in CH_2Cl_2 (183.4 ppm) (11).

MAGDY GIRGIS and EDWARD GHALI. Can. J. Chem. **67**, 130 (1989).

The electrochemical behavior of lead deposition process in a temperature range between 25 and 75°C was studied in a medium of lead chloride and ammonium acetate by linear and cyclic sweep perturbation. The study was undertaken on four substrates: Pb, Cu, Ag, and C. An increase in temperature resulted in accelerating the deposition process and promoted dendrite formation. Moreover, different kinetic parameters such as adsorption isotherms, Tafel slopes, and diffusion coefficient were affected as a function of temperature elevation. Surface analytical study performed by Auger electron spectroscopy revealed an increase in peak intensities of Cl and Pb as the temperature increased.

Key words: electrodeposition, cyclic voltammetry, potentiostatic transients, underpotential deposition, temperature effect.

MAGDY GIRGIS et EDWARD GHALI. Can. J. Chem. **67**, 130 (1989).

Faisant appel à des perturbations de balayages linéaire et cyclique et opérant à des températures allant de 25 à 75°C, dans un milieu de chlorure de plomb et d'acétate d'ammonium, on a étudié le comportement électrochimique du processus de déposition du plomb. On a entrepris l'étude sur quatre substrats: Pb, Cu, Ag et C. Des augmentations de température provoquent des augmentations du processus de déposition et favorisent la formation de dendrite. De plus, une augmentation de la température affecte des paramètres cinétiques comme les isothermes d'adsorption, les pentes de Tafel ainsi que le coefficient de diffusion. L'étude analytique de la surface, réalisée à l'aide de la spectroscopie électronique d'Auger, a permis de mettre en évidence qu'une augmentation de la température provoque une augmentation des intensités des pics du Cl ainsi que du Pb.

Mots clés: électrodéposition, voltamétrie cyclique, «fugacités» potentiostatiques, déposition de sous-potentiel, effet de température.

[Traduit par la revue]

Introduction

The use of stationary electrode voltammetry in qualitative and quantitative investigations of electrolysis mechanisms has been extensive (1–3), particularly in the field of electrocrystallization (4, 5). Considerable difficulties arise in the electrochemical studies of metal deposition due to the complex structure of the underlying metal (6) which lead to poor reproducibility, particularly in the appearance and structure of the deposits (7). There have been several studies of electrodeposition of lead (8–11).

The choice of the acidified ammonium acetate bath was based on previous studies carried out in our laboratory (12–14) to investigate the dissolution of galena in different media. The results showed that the anodic passivation caused mainly by lead chloride formation is reduced in acetate medium due to the strong activity of ammonium acetate in dissolving $PbCl_2$.

In the frame work of this approach, other studies (15, 16) have been undertaken to study lead deposition process from these media in order to find the optimum conditions necessary to obtain the metal directly from the sulphide ore. The investigation of this system at ambient temperature was carried out using different electrochemical techniques (17). To obtain more information about the cathodic process we tried to study the effect of elevated temperature on the system. To our knowledge, the effect of temperature on the behaviour of lead ions during the deposition process has not been reported in literature.

This paper, therefore, has been intended to shed some light on the reaction mechanism during the deposition process in acetate medium as a function of temperature by employing the techniques of linear and cyclic sweep polarization. Surface analyses were performed by Auger electron spectroscopy (AES) and the morphology of the deposit was determined by scanning electron microscopy (SEM). Further studies are currently under investigation to obtain more insightful information about the deposition process. The study will include the effect of temperature on the process of electrocrystallization and the nature of nucleation and growth.

Experimental

Four polycrystalline substrates of high purity (99.99%) were used: Pb and Cu (Cominco Ltd), Ag (Fisher spectrographically pure), and C (Union Carbide spectrographic grade graphite) were used as working electrodes. Graphite and saturated calomel electrodes served as auxiliary and reference electrodes, respectively. The preparation of electrodes and the electrochemical set up are described in previous studies (15, 17).

The bath under study was made up of B.D.H. Analar reagents of 2.5 *M* CH_3COONH_4, 2.4 *M* CH_3COOH, and 0.11 *M* $PbCl_2$. Oxygen was purged from the solution by bubbling a highly pure nitrogen in the electrolyte for at least 45 min before conducting the experiment. Slight pressure of nitrogen gas was kept during the experiments.

The analysis by Auger Electron Spectroscopy (AES) was available in a multifunction apparatus, model ESCLAB-500, V. G. Scientific Ltd. The electrode was mounted in the UHV-chamber of the spectrometry, till the evacuation (the base pressure of the system was 10^{-8} Torr). The operating conditions were as follows: 10 keV electron gun voltage and current density was 40 $\mu A/cm^2$. The morphological structure of the deposit was determined by scanning electron microscopy (SEM) Model JEOL-2553.

The temperature of the bath was controlled to within 1°C with a thermoregulator, type Thermomix 1480, B. Braun Melsungen AG. The experiments were conducted at temperatures between 25 and 75°C.

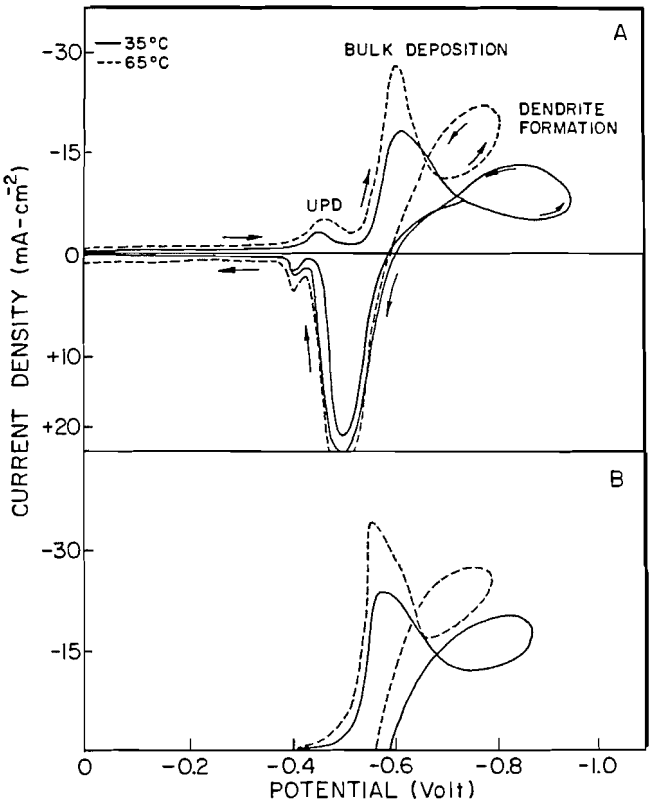

FIG. 1. General voltammogram for the deposition of lead from the acetate bath on (*A*) Ag electrode from the acetate bath, (*B*) Pb electrode at 35 and 65°C at scan rate 50 mV s^{-1}.

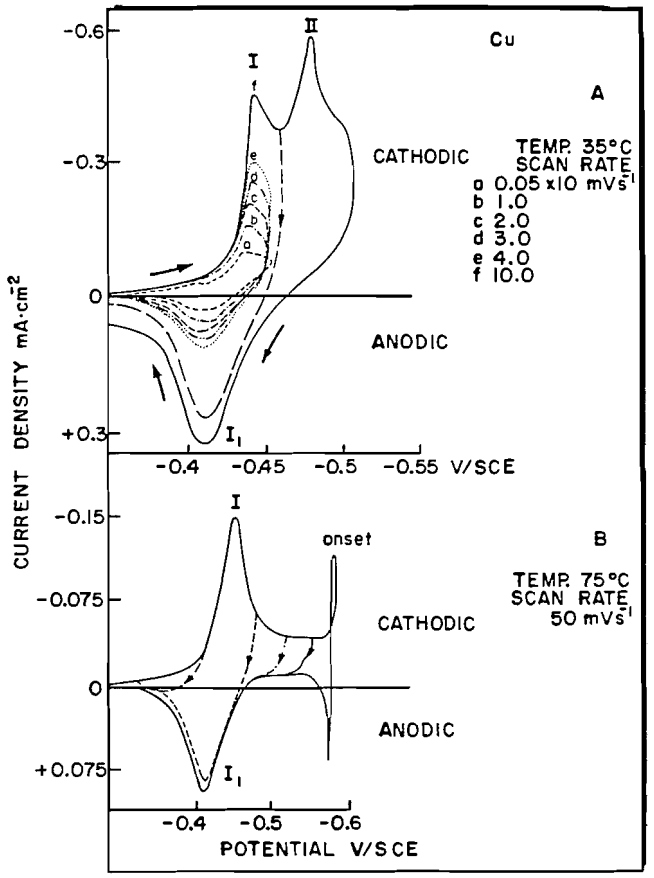

FIG. 2. Effect of temperature on the cyclic voltammograms in the UPD region for the deposition of Pb on the Ag electrode at (*A*) 35°C and (*B*) 75°C.

Results and discussion

As previously reported (17), various stages of lead deposition on different polycrystalline substrates were found to characterize the cyclic voltammograms, mainly and in the order: underpotential deposition (UPD), onset of the bulk deposition, bulk deposition, and dendrite formation. The lead UPD peaks appeared only on the Cu and Ag substrates. The voltammograms in the case of Pb electrode showed no anodic peak when the scan was driven in the anodic direction, indicating the irreversible nature of the deposition process. The general features of the voltammograms did not change as temperature increased from 25 to 75°C, i.e., the voltammograms were still characterized by the four regions as mentioned above. Figure 1 represents the general *C–P* profile of lead deposition on both Ag and Pb electrodes.

1. Effect of temperature on the voltammograms in the UPD Region

The voltammograms were characterized by a single UPD peak for both Cu electrode (at −0.47 V) and Ag electrode (at −0.44 V). Figures 2 and 3 depict a typical voltammograms for the underpotential peaks of lead on the Ag and Cu electrodes, respectively.

The increase in temperature from 35 to 75°C resulted in an anodic shift for the cathodic peak potentials for both electrodes; Cu (12 mV) and Ag (20 mV), while cathodic shift of 55 mV was observed for the anodic peak for the copper electrode and about 10 mV for the Ag electrode. To relate the anodic peaks with those appeared in the cathodic region, the negative limits to the potential range were changed. As shown in Fig. 2*B*, an anodic peak I was stripped when the cathodic scan was reversed at a potential beyond the region of peak I. Sweeping to further negative potential resulted in a further increase in the anodic current and was characterized by the formation of a cathodic current loop upon scan reversal (Fig. 2*B*). The current loop associated with the sudden increase in cathodic current is an indication of nucleation and multilayer growth of lead deposits.

The depolarization phenomenon observed at high temperature for both Cu and Ag electrodes may be discussed as follows.

In the presence of such large quantities of CH_3COONH_4 and CH_3COOH, one may expect that $PbCl_2$ will dissolve and the dominant species are likely to be $Pb(CH_3COO)_2$. In previous studies (15, 16), evidence for the formation of $Pb(CH_3COO)_2$ at room temperature was obtained from some surface analyses conducted by X-ray diffraction and Auger electron spectroscopy techniques.

The detection of such species formed on the electrode surface may imply that they exist in the solution. As temperature increases another kind of species, mainly lead chloride complexes $PbCl_1^+$, $PbCl_2^0$, $PbCl_3^-$, and $PbCl_4^{2-}$, start to form (18) and compete with lead acetate species. This interference of lead chloride complexes in the deposition process is probably the reason for the observed anodic shift of the cathodic peak potentials since lead chloride complexes are known to be reduced at potentials anodic to that of the lead acetate complexes (19). This hypothesis is strengthened by the fact that lead forms stable complexes with chloride ions at elevated temperatures. Also chloride ions have an effect on Ag and Au electrodes as competitive adsorbant (19) and form stable $CuCl^+$-type complexes with Cu (20).

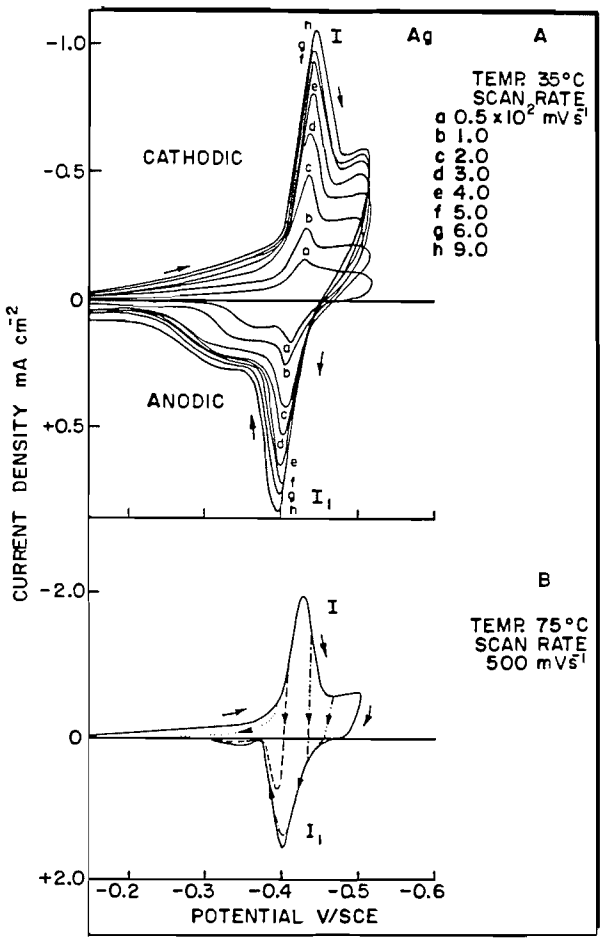

FIG. 3. Effect of temperature on the cyclic voltammograms in the UPD region for the deposition of Pb on the Cu electrode at (*A*) 35°C and (*B*) 75°C.

The analyses by Auger electron spectroscopy were performed after holding the substrate for about 20 min at potentials corresponding to the peak potentials in the UPD region. Figure 4 reveals the surface analysis for the lead deposit on Ag. The spectrum shows that the peak intensities of both Cl and Pb Auger signals increased as temperature was elevated from 25 to 50°C. This increase in peak intensity could be attributed to either strong adsorption of Cl^- ions (via the formation of lead chloride complexes) and/or to the entrapment of Cl^- ions in lead crystals which become porous at high temperatures. A change in the morphological structure was also observed from the scanning electron micrographs taken for lead deposits at −0.8 V (Fig. 5), where the deposit becomes more dendritic. Thus one may assume that the adsorption of chloride ions is favoured at high temperatures since the presence of chloride ion is known to promote the dendritic formation (15, 17).

The adsorption isotherm was determined by the integration of the cathodic peak corresponding to the adsorption of Pb after establishing adsorption equilibrium at defined underpotentials, $E_e - E_{Pb^{2+}}/Pb > 0$. The theoretical values calculated for a close packed lead monolayers (Q_s) with Pb^{2+} = 1.75 Å and for electrodes of surface areas of 1.1 (Cu) and 0.129 (Ag) cm^2 are 288 and 34 μC, respectively. Table 1 illustrates the experimental values (Q) and the degree of coverage θ. As shown in Table 1, the lead coverage on the Cu electrode is lower than that observed for Ag electrode under all conditions. This finding is in agreement with our previous observation (17) where SEM photomicrographs showed less formed nuclei on the surface of the copper electrode. This low coverage could be attributed to the specific anion adsorption, i.e., Cl^- and Ac^- ions on the surface of Cu electrode and this may hinder the formation of a complete monolayer of lead nuclei.

Lorenz (2) quoted from Staikov *et al.* (22) and Bewick *et al.* (23) that the 2D nucleation-like behavior in the systems $(Cu(111)/Pb^{2+}$ and $Ag(111)/Pb^{2+}$ in acetate media is probably caused by a pitting process within a pre-adsorbed anion layer consisting of specifically adsorbed acetate or oxygen, respectively. As also shown from the data in Table 1, more than one monolayer is formed on the Ag electrode. If the adsorption of Cl and/or acetate ions is the most influential factor on the surface of the substrate, it means that the effect of both ions on the Cu electrode is opposite to that on the Ag electrode. Further investigations using modern surface analyses are currently undertaken to clarify this point.

In the present study the effect of anions on the substrates manifested itself in a noticeable change in the underpotential shift ΔE_p, i.e. on the potential difference between the bulk and monolayer peaks as shown in Table 1. The data demonstrate lower values for the Cu electrode. The decrease in the underpotential shift is equivalent to a reduction in bond strength between the metal atom and the substrate surface (19). This confirms the above hypothesis that interaction of the anions with the Cu substrate is hindering the formation of lead monolayers, while promoting this process for the Ag electrode.

The behavior when the cathodic scan was reversed at the deposition potential was similar for all the foreign substrates used and at all temperatures. The voltammograms were characterized by a sharp increase in the cathodic current followed by an inductive current loop in the cathodic and anodic regions (Fig. 6). The current loop was inversely proportional to the scan rate, moreover the ratio of the cathodic/anodic peak currents approaches unity in all cases. The peak potentials in the cathodic and anodic regions were independent of the sweep rate. These observations, in addition to the symmetry of the *C–P* profiles, reflect that the reaction proceeds via a reversible mechanism and the process is related to nucleation in this particular region. The faster the sweep rate, the smaller the chance for the nuclei to form at a given degree of supersaturation. As a result, the current becomes smaller than in the same situation at a lower sweep rate.

It can also be assumed that the nuclei of the solid phase are separated by a distance greater than the diffusion layer, then a surface area greater than the geometric area is offered to the flux. This implies that the surface area is increasing with time (24). Pulsing the system to two cathodic limits (E_0, E_f) (see Fig. 6) which represent the beginning of the onset and the crossing potential upon scan reversal, respectively, resulted in a transient of the form shown in Fig. 8*B*. Pulsing to −0.55 (E_0) resulted in a transient which exhibits a falling current. This may represent the tailing current in the UPD region. The peak that is developed at −0.56 (E_f) is due probably to the formation of lead nuclei in the multilayer region followed by a subsequent overlap of the growing nuclei.

2. The behaviour in the bulk deposition region

The general profiles of the voltammograms showed no change from one substrate to another, characterized mainly by a cathodic peak that has the morphology of a diffusion-controlled process, followed by a large anodic peak (e.g. Fig. 1*A*) except for the Pb voltammograms where the absence of the anodic peak is evident (Fig. 1*B*).

TABLE 1. Calculated values of charge Q, degree of coverage θ, and the underpotential shift ΔE_p*

	Cu		Ag	
	25°C	75°C	25°C	75°C
$Q_{cathode}$	140	193	105	154
θ	0.44	0.67	3.08	4.53
Q_{anode}	56	86	58	77
θ	0.19	0.29	1.7	2.26
ΔE_p	79	97	87	130

Q, experimental charge (in μC); θ, coverage Q/Q_s, Q_s is the theoretical value for a close packed lead monolayer; ΔE_p, underpotential shift (in mV).

The deposition potential varied slightly from substrate to another (maximum difference is 10 mV), as temperature increased the deposition potential shifted to less negative potentials which is similar to the behaviour in the UPD region. The anodic shift was 18 mV for Ag, 20 mV for Cu, 30 mV for C, and 29 mV for Pb. The anodic peaks were shifted cathodically by 7, 30, and 30 mV for Ag, C, and Cu electrodes, respectively. The depolarization process observed at high temperature indicates that Cl ions exert a strong effect on the UPD and on the bulk deposition peaks due to the formation of chloride complexes at high temperatures. The calculated Tafel slopes were higher at the ambient temperatures than at elevated temperatures, e.g. for the Pb electrode, it was 185 mV at 25°C, while at 75°C, the value became 120 mV (Fig. 7). X-ray analyses revealed the presence of peaks related to acetate compounds at temperatures lower than 55°C most likely arise from lead acetate compound (15). From the behaviour of Tafel slopes as a function of of temperature and from the XRD analyses, one may infer that acetate anion adsorption on lead deposit decreases as temperature increases.

The kinetic studies for each system will now be discussed separately:

(a) Pb/Pb^{2+} system

The irreversible reaction of the Pb^{2+}/Pb system is evident as no current response was recorded when the scan was reversed in

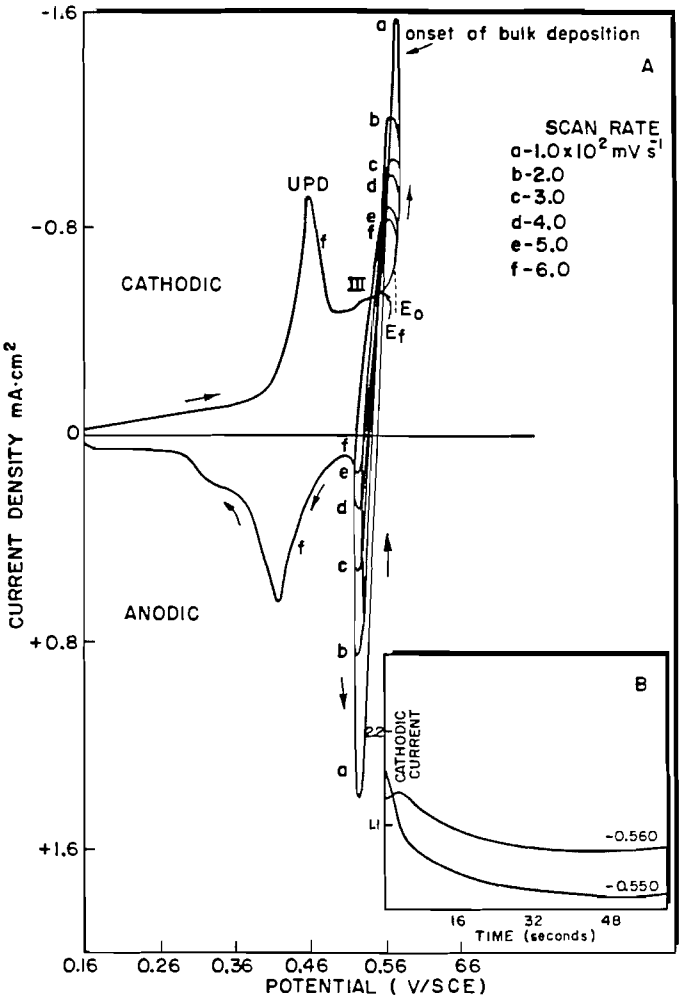

FIG. 6. (*A*) Cyclic voltammogram for lead deposition on Ag electrode in the region of onset at the bulk deposition at 35°C; (*B*) potentiostatic *i*–*t* curve for the Ag electrode at different imposed potentials at 35°C.

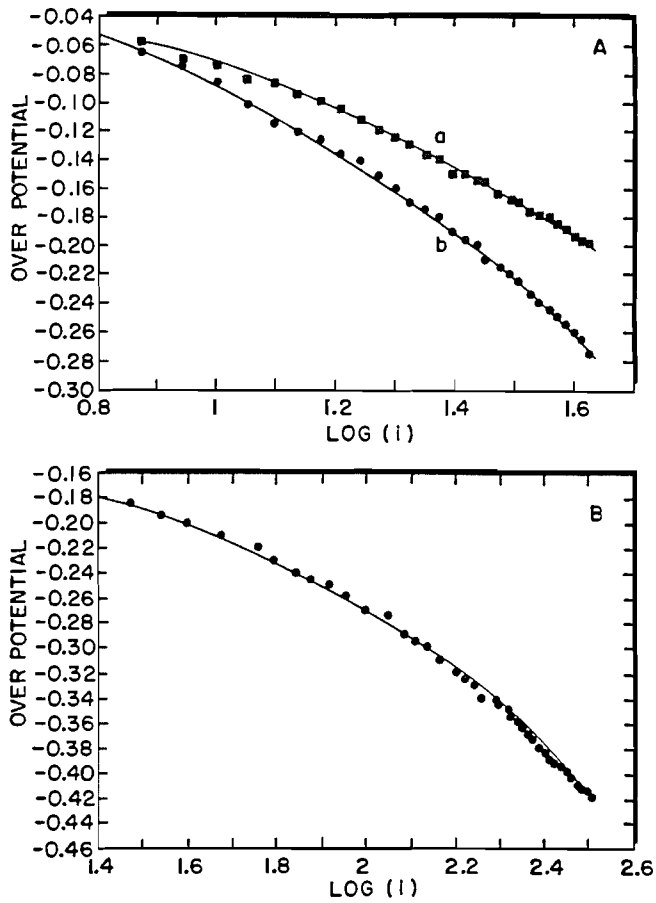

FIG. 7. (*A*) Calculated Tafel slops for the Pb electrode at (*a*) 35°C and (*b*) 55°C under unstirred conditions; (*B*) same as A except at 75°C.

the anodic direction. To evaluate the kinetic parameter αn_α, log i_p (peak current) was plotted against the potential E_p at different scan rates, according to eq. [1], which characterizes the irreversible system (25):

$$[1] \quad i_p = 0.227\, nFAC_0,K_s \exp\left[-\frac{\alpha nF}{RT}E_p - E^0)\right]$$

where C_0 is the concentration of lead ions (mol/cm^3) and α is the charge transfer constant. The slopes calculated at 25, 55, and 75°C gave the corresponding αn_α: 0.28, 0.3, and 0.32, respectively. The rate constant (K_s) calculated from the intercepts changed slightly as a function of temperature, e.g. it was about 1.1×10^{-4} cm/s at 25°C, while at 75°C it was 1.6×10^{-4} cm/s. This may strengthen the interpretation that the decrease of Tafel slopes as a function of temperature elevation is a result of the effect of anion adsorption.

Under diffusion-control process, the slope of $i_p - \nu^{1/2}$ plot at 25°C obeys the equation (26):

$$[2] \quad i_p/\nu^{1/2} = 2.69 \times 10^5\, n^{3/2}\, DC_0$$

where $i_p/\nu^{1/2}$ is the slope (A cm^{-2} $\nu^{-1/2}$ S$^{-1/2}$), n is the number of electrons, D is the diffusion coefficient (cm^2 s^{-1}), and C_0 is the concentration of the electroactive species (mol cm^{-3}).

The i_p was found to vary linearly with the square toot of scan rate ν as shown in Fig. 8. The extrapolation to the origin deviated only at temperatures higher than 45°C and the curves cut the current axis. This is probably due to the depolarization phenomenon exerted by the anions at higher temperature. In fact, if we substitute the following values in eq. [2], i.e. $C_{Pb^{2+}} = 0.11 \times 10^{-3}$ mol cm^{-3}, and the slopes obtained from Fig. 8 (e.g. 0.3 and 6.6 A cm^{-2}/$\nu^{1/2}$ s$^{-1/2}$) at 25 and 75°C, respectively, and $n = 2$, the diffusion coefficient of lead ions ($D_{Pb^{2+}}$) will have the value of 1.3×10^{-5} cm^2 s^{-1} (at 25°C) which is in perfect agreement with the D value reported in literature (27), while at 75°C the calculated D value was found to be 6.2×10^{-3} cm^2 s^{-1}.

b. Deposition on foreign substrates

The separation of the cathodic–anodic peak potentials was high for the C electrode (e.g. 120 and 183 mV at 25 and 75°C) and relatively low for the other electrodes (e.g. Ag 80 and 95 mV at 25 and 75°C, respectively). These data imply that the reaction may proceed via a quasi reversible mechanism and not through a complete reversible process, since E_p is dependent on scan rate and the potential shift increase with ν (28).

The plot of E_p vs. log ν gave two linear sections. The point of intersection gives the critical sweep rate, which may mark the transition from a quasi reversible to an irreversible behavior (it was $\geq$ 50 mV s^{-1} for the substrates used). The irreversible behaviour at high sweep rates ($>$ 50 mV s^{-1}) was evident from the increase in separation between the cathodic and anodic peak potentials, in addition, the decrease in magnitude of the anodic peak current is a function of the increase in sweep rate. Slopes

TABLE 2. Calculated values of ΔH‡ (in kcal/mol) for different substrates in temperature range 25–75°C

Scan rate ($mV\ s^{-1}$)	$\Delta H‡$				
	Pb	Cu	Ag	Au	C
10	8.6	4.8	5.5	5.7	2.5
50	7.8	4.0	3.8	4.8	3.0
100	6.5	4.4	4.1	4.1	3.3
150	6.1	4.7	3.9	4.0	3.4

with corresponding number of electrons equal to or approaching 1 (e.g. Cu Fig. 9) were obtained in the irreversible section. These values were confirmed for all substrates used.

The 10-fold increase in scan rate resulted in a cathodic shift of 85, 75, and 64 mV in peak potential at 25, 55, and 75°C, respectively, with corresponding αn equal to 0.35, 0.4, and 0.46, respectively. Assuming that $n = 2$, this will give values of α equal to 0.175, 0.2, and 0.23 at 25, 55, and 75°C, respectively. These data will give Tefel slopes $2.3RT/\alpha nF$ of values greater than 120 mV. These values compare favorably with those obtained by the linear sweep polarization method (130 mV at 25°C and 120 mV at 75°C).

When the cathodic scan was swept to more negative values, i.e., beyond the region of the bulk deposition another current loop was formed (Fig. 1). The second loop formation is due eventually to further growth of the Pb nuclei in the form of dendrites. The cathodic potential at which this loop starts to form was different from one substrate to another and was in the order Cu, C, Ag, respectively. The effect of temperature elevation resulted in faster loop formation than that observed at low temperature, indicating that high temperature favors the formation of dendrites. The investigation of the nucleation and growth mechanism by potentiostatic pulses will be discussed in another communication.

3. Heat of activation of the Pb/substrate system

The values of the heat of activation $\Delta H‡$ were calculated by plotting log i_p against T^{-1} (e.g. C, Fig. 10). The slopes of these curves ($d \log i/d T^{-1}$) give the corresponding $\Delta H‡$ values according to the equation (29).

$$[3] \quad i = K \exp[-\Delta H†/RT]$$

The plots give excellent linear relations over the wide range of temperatures. As shown from the values given in Table 2, higher $\Delta H‡$ were obtained for Ph electrode.

Summary

The study has shown that the formation of lead chloride complexes at high temperatures resulted in a noticeable depolarization effect on the cathodic process as the deposition potential shifted to more anodic values. The SEM studies showed a marked growth of lead deposit in the form of dendrities at high temperatures. Auger electron spectroscopy revealed the strong influence of the Cl ion on the Cu electrode which resulted in a lower coverage of lead monolayers, while the opposite effect was observed for the Ag electrode.

RONALD G. SUTHERLAND, CHUN-HAO ZHANG, ADAM PIÓRKO, and CHOI CHUCK LEE. Can. J. Chem. **67**, 137 (1989).

Reaction of cyclopentadienyliron (CpFe) complexes of chlorobenzenes with NaCN in DMF could give rise to products resulting from the addition of the cyanide ion or from substitution and addition reactions with the cyanide ion. Demetallation–oxidation of such products by treatment with DDQ would lead to the synthesis of benzonitriles and phthalonitriles. With the CpFe complex of chlorobenzene, reaction with NaCN in DMF for 3 min, 30 min, or 3 h gave rise to an approximately 90:10 mixture of (1–5-η^5-1-chloro-*exo*-6-cyanocyclohexadienyl)(η^5-cyclopentadienyl)iron (**9**) and (1–5-η^5-1,*exo*-6-dicyanocyclohexadienyl)(η^5-cyclopentadienyl)iron (**10**), a 40:60 mixture of **9** and **10** or pure **10**, respectively. When the 3-h reaction was worked up in the presence of an added aqueous solution of NH_4PF_6, only the substitution product, the (η^6-benzonitrile)(η^5-cyclopentadienyl)iron cation (**11**), was obtained as its hexafluorophosphate. Apparently, under the acidic conditions of the added aqueous NH_4PF_6, **10** could readily revert to **11** which then gave rise to its hexafluorophosphate. DDQ treatment of the 3-min or 3-h reaction product gave, respectively, *o*-chlorobenzonitrile or phthalonitrile. Similarly reaction of CpFe complexes of *o*-substituted chlorobenzenes could give rise to CpFe-complexed cyclohexadienyl systems with two cyano groups at the 1- and 6-positions and the original *o*-substituent at the 2-position. DDQ treatment of such products would lead to the formation of 3-substituted phthalonitriles, and in the present work, 3-methyl, 3-methoxy-, and 3-phenoxyphthalonitriles were prepared in this way. In another set of reactions, depending on the experimental conditions employed, the CpFe complex of 2,6-dichlorotoluene (**20**) could give products from cyanide addition only, the DDQ treatment of which led to the formation of 2,4-dichloro-3-methylbenzonitrile, or products from substitution and addition and subsequent DDQ treatment of which gave rise to 4-chloro-3-methylphthalonitrile.

Key words: η^6-chlorobenzene-η^5-cyclopentadienyliron cation, complexed chlorobenzenes, nucleophilic addition of cyanide ion, nucleophilic substitution with cyanide ion, synthesis of benzonitriles and phthalonitriles.

RONALD G. SUTHERLAND, CHUN-HAO ZHANG, ADAM PIÓRKO et CHOI CHUCK LEE. Can. J. Chem. **67**, 137 (1989).

La réaction des complexes des chlorobenzènes et du cyclopentadiénylfer (CpFe) avec la NaCN dans le DMF pourrait donner naissance à des produits provenant soit d'une addition de l'ion cyanure soit de réactions de substitution et d'addition avec l'ion cyanure. La réaction de tels produits avec de la DDQ provoque successivement une démétallation et une oxydation et devrait conduire à la synthèse de benzo- et de phtalo-nitriles. Avec le complexe du CpFe du chlorobenzène, des réactions de 3 min, 30 min ou 3 h avec du NaCN dans du DMF conduisent respectivement à un mélange environ 90:10 (η^5-chloro-1 cyano-6-*exo* cyclohexadiène-1–5 yl) (η^5-cyclopendiényl) (**9**) et de (η^5-dicyano-1,6-*exo* cyclohexadiène-1–5 yl) (η^5-cyclopentadiényl) (**10**), à un mélange environ 40:60 des composés **9** et **10** et au produit **10** pur. Lorsque les produits de la réaction de 3 h sont extraits en présence d'une solution aqueuse additionnée de NH_4PF_6, on n'obtient que le produit de substitution, le cation (η^6-benzonitrile) (η^5-cyclopentadiényl)fer (**11**) sous la forme d'hexafluorophosphate. Il semble que, dans les conditions acides obtenues par l'addition de NH_4PF_6 aqueux, le produit **10** se retransforme facilement en composé **11** qui conduit alors à son hexafluorophosphate. Lorsque les produits obtenus après des reactions de 3 min ou 3 h sont traités par de la DDQ, on obtient respectivement de l'*o*-chlorobenzonitrile et du phtalonitrile. De la même manière, la réaction des complexes des chlorobenzènes *o*-substitués et du CpFe pourrait donner lieu à la formation de CpFe complexés à des systèmes cyclohexadiényles portant des groupements cyano dans les positions 1 et 6 et le substituant ortho original dans la position 2. Le traitement de tels porudits par de la DDQ conduirait à la formation de phtalonitriles substitués en position 3; dans le présent travail, on a ainsi préparé les méthyl-3, méthoxy-3 et phénoxy-3 phtalonitriles. Dans un autre ensemble de réactions et suivant les conditions expérimentales, le complexe du CpFe et du dichloro-2,6 toluène (**20**) pourrait conduire soit au produit provenant exclusivement de l'addition du cyanure soit au produit provenant d'une substitution et d'une addition du cyanure; leur traitement subséquent par la DDQ conduirait DDQ conduirait respectivement soit à la formation de dichloro-2,4 méthyl-3 benzonitrile soit à la formation de chloro-4 méthyl-3 phtalonitrile.

Mots clés : cation η^6-chlorobenzène-η^5-cyclopentadiénylfer, chlorobenzènes complexés, addition nucléophile de l'ion cyanure, synthèse de benzonitriles et phtalonitriles.

[Traduit par la revue]

Introduction

Recently, we have reported (1) that reactions of the hexafluorophosphate salts of cyclopentadienyliron (CpFe) complexes of arenes containing an electron-withdrawing substituent with NaCN in dimethylformamide (DMF) resulted in a regiospecific *exo*-addition of the cyanide ion at a position *ortho* to the substituent, giving rise to CpFe complexes of cyclohexadienyl systems. It has also been found that DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone) is an effective reagent for the demetallation–oxidation of such complexed cyclohexadienyl systems, thereby providing a method for the synthesis of the liberated substituted arenes (2). Among the cyanide additions studied, for example, were the reactions with $C_6H_5(X)FeCp^+PF_6^-$, with X = NO_2 or COC_6H_5, and subsequent treatment of the adduct with DDQ gave *o*-$C_6H_4(NO_2)CN$ or *o*-$C_6H_4(COC_6H_5)CN$, in yields of 75% or 82%, respectively (2). As another illustration of such an introduction of a cyano group *ortho* to an electron-withdrawing substituent in a benzene ring, in the present work, the known CpFe complex of *p*-tolylsulfonylbenzene (**1**) (3) was treated with NaCN in DMF

to give adduct **2**, (1–5-η^5-*p*-tolysulfonyl-*exo*-6-cyanocyclohexadienyl)(η^5-cyclopentadienyl)iron. The spectral data in support of the assigned structure for **2** and for other cyclohexadienyl complexes are summarized in Tables 1 and 2. Upon treatment of **2** with DDQ, *o*-*p*-tolylsulfonylbenzonitrile (**3**), a compound that has not been prepared previously, was obtained.

1 **2** **3**

Nesmeyanov and co-workers (4) were the first investigators to report that a nucleophilic substitution reaction took place when the CpFe complex of chlorobenzene was treated with a number of nucleophiles, and such a reaction between the CpFe complex of *p*-chlorotoluene and the cyanide ion resulted in the replacement of the chloro group by the cyano group (5). In a recent study on possible steric hindrance effects in nucleophilic additions to CpFe complexed substituted benzenes (6), it was found, for example, that the reaction of the cyanide ion with the CpFe complex of *o*-chlorotoluene (**4**) or *o*-cyanotoluene (**5**) gave the same products, a 96:4 mixture of cyclohexadienyl complexes **6** and **7**. With **4** therefore, both cyanide addition and the substitution of the chloro group by the cyano group have taken place. The present work involved further studies on such addition–substitution reactions and their possible applications for the synthesis of benzonitriles and phthalonitriles.

5; X = CN
6 **7**

When the (η^6-chlorobenzene)(η^5-cyclopentadienyl)iron cation (**8**), as its hexafluorophosphate, was treated at room temperature with an excess of NaCN in DMF and the filtered reaction mixture was directly dissolved in ether and worked up to give the products, the nature of such products was found to be dependent on reaction time. With a short reaction time of 3 min, an approximately 90:10 mixture of cyclohexadienyl complexes **9** and **10** was obtained, **9** being derived from the cyanide addition to the chlorobenzene complex **8**, while **10** resulted from both substitution and addition. When the reaction time was extended to 30 min, the product ratio of **9**:**10** became 40:60, and for a reaction time of 3 h, pure **10** was obtained as the only product. Complex **10** was also prepared directly from the reac-

10; X = CN

tion of the (η^6-benzonitrile)(η^5-cyclopentadienyl)iron cation (**11**) with NaCN in DMF. Shown in Fig. 1 are the ^1H nmr spectra of these products obtained under the various reaction conditions.

When **8** was treated with NaCN in DMF for 3 h and then an aqueous solution of NH_4PF_6 was added and the mixture extracted with CH_2Cl_2–CH_3NO_2, the only product recovered was **11**, resulting from the substitution of the chloro group by the cyano group. Since cyanide adduct **10** was the sole product in the 3-h reaction when the reaction mixture was worked up without treatment with aqueous NH_4PF_6, **10** must have reverted back to **11** in the presence of aqueous NH_4PF_6. In our laboratory, we have found that CpFe complexes of cyclohexadienyl systems derived from nucleophilic additons could be readily reverted back to the complexed arenes under acidic conditions, and we have utilized the addition of the acetonyl anion to a complexed sulfone followed by acidification to regenerate the sulfone complex as a means for its purification (3). In the present reactions with chlorobenzene complex **8** to give substitution product **11**, the aqueous NH_4PF_6 solution added likely was sufficiently acidic to cause a ready reversal of adduct **10** to cationic complex **11**, which then gave rise to its hexaflurophosphate.

The present findings for the reactions of **8** with NaCN in DMF may, therefore, be summarized by Scheme 1. Initially, cationic complex **8** would undergo rapid and reversible cyanide addition to give **9**. Competing with the addition reaction would be a slower substitution reaction to give **11** and this substitution

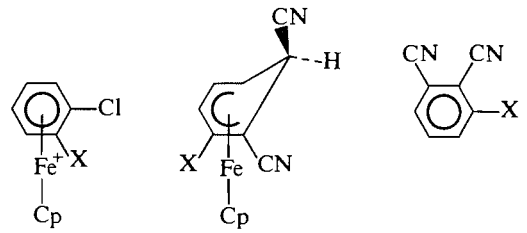
SCHEME 1

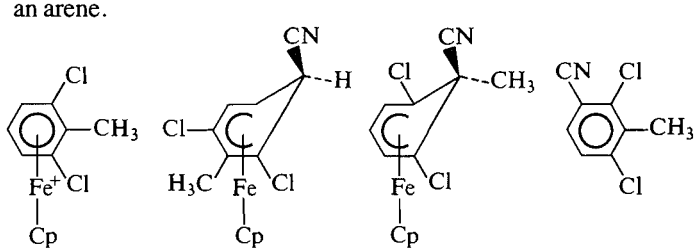


reaction would not be readily reversible. Complex **11**, once formed, would also undergo rapid and reversible cyanide addition to give **10**. Thus for a short reaction time of 3 min, the major product was **9**. As the reaction time was increased, more and more **10** would be formed. After a reaction time of 3 h, only **10** was obtained, except that if aqueous NH_4PF_6 was added, reversal of **10** and **11** would take place and **11** would then give rise to its hexafluorophosphate.

It is of interest to note from Scheme 1 that the reversal of cyanide adduct **9** to cationic complex **8**, which took place during the initial stages of these transformations, the reaction conditions were not acidic, while for the similar reversal of **10** to **11** the conditions were acidic. A factor that likely would enhance the ease of the conversion of **9** to **8** could be the competing irreversible reaction of **8** to give **11**, thus providing a driving force for the formation of **8** from **9**, while reversal of **10** to **11** did not result in a further reaction of **11** except for the formation of its hexafluorophosphate. Moreover, it is known that Meisenheimer-type of adducts of arenes are more stable and more readily formed for arenes containing more electron-withdrawing substituents (7). Possibly, adduct **10** derived from a complexed arene with a more electron-withdrawing cyano substituent would be more stable than adduct **9** derived from a complexed arene with a chloro substituent, and **10** would thus require more acidic conditions for its reversal to **11** than the reversal of **9** to **8**.

When the product mixture from the 3-min reaction, consisting of about 90% **9** and 10% **10**, was treated with DDQ, *o*-chlorobenzonitrile, derived from demetallation–oxidation of **9**, could be obtained. Similarly, DDQ treatment of pure **10** from the 3-h reaction between **8** and NaCN in DMF or from the direct cyanide addition to **11**, readily gave rise to phthalonitrile. Phthalonitrile is an important compound as it is utilized for the preparation of metal complexes known as phthalocyanines which have many commercial applications including their use as pigments and in dyestuffs (8). Phthalocyanines prepared from phthalonitriles with a substituent at the 3- or 4-position have been studied in order to ascertain the extent of changes in the properties of such substituted phthalocyanines, and it was concluded that a 3-substituted phthalonitrile would have a greater influence than a 4-substituted phthalonitrile on such properties as solubility, electronic absorption spectrum, and reactivity of the resulting phthalocyanine (9, 10). In the present work, a number of 3-substituted phthalonitriles have been prepared from the DDQ treatment of cyanide additon–substitution products.

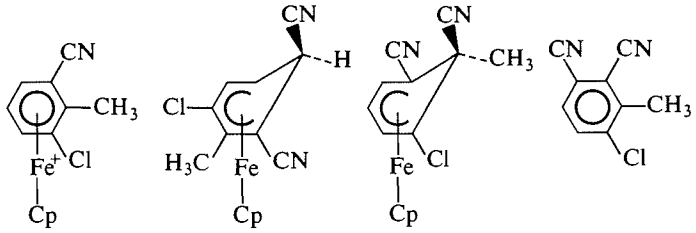
It has already been stated that *o*-chlorotoluene complex **4** or *o*-cyanotoluene complex **5**, on reaction with NaCN in DMF, gave the same products consisting of a 96:4 mixture of cyclohexadienyl complexes **6** and **7** (6). DDQ treatment of this mixture of products gave rise to 3-methylphthalonitrile (**12**), a compound that has previously been prepared by Siegl and coworkers (11). It may be pointed out that the DDQ treatment gave only the arene derived from complex **6**, and no arene could be liberated from the minor product **7**, a cyclohexadienyl complex with two substituents at the 6-position.



When the CpFe complex of *o*-methoxychlorobenzene (**13**) or *o*-phenoxychlorobenzene (**14**) (12) was treated with NaCN in DMF for 5 h and the reaction mixture worked up without any addition of aqueous NH_4PF_6, cyclohexadienyl complex **15** or **16**, respectively, was obtained, and these products were derived from both substitution and addition reactions with the cyanide ion. Upon treatment with DDQ, **15** or **16** readily gave rise to 3-methyoxyphthalonitrile (**17**) (10) or 3-phenoxyphthalonitrile (**18**) (9), respectively. Although **12**, **17**, and **18** have all been prepared previously (9–11), the present method provides an alternative approach to the synthesis of such 3-substituted phthalonitriles.

13; X = OCH_3 **15**; X = OCH_3 **12**; X = CH_3
14; X = OC_6H_5 **16**; X = OC_6H_5 **17**; X = OCH_3
19; X = Cl **18**; X = OC_6H_5

It is of interest to note that complexes of *o*-substituted chlorobenzenes, such as **13** and **14**, were prepared from the nucleophilic substitution of one of the two chloro groups of the CpFe complex of *o*-dichlorobenzene (**19**), and a variety of such mono-substitution products from **19** have been reported (12). Presumably, besides using **13** and **14**, if one were to start from the other *o*-substituted chlorobenzene complexes (12) and utilizing the substitution and addition reactions with the cyanide ion followed by demetallation–oxidation with DDQ, a general method for the synthesis of a variety of 3-substituted phthalonitriles may be feasible.



As another illustration of the addition and substitution reactions with the cyanide ion, when the (η^6-2,6-dichlorotoluene)(η^5-cyclopentadienyl)iron cation (**20**) was treated with NaCN in DMF for 15 min, a 66:33 mixture of adducts **21** and **22** were obtained. DDQ treatment of this product mixture gave a new compound, 2,4-dichloro-3-methylbenzonitrile (**23**), derived from demetallation–oxidation of **21**, while **22**, with two substituents at the 6-position, did not result in any liberation of an arene.

20 **21** **22** **23**

When **20** was treated with NaCN in DMF for 48 h and the reaction mixture worked up after the addition of an aqueous NH_4PF_6 solution, substitution product **24** was obtained and a subsequent reaction of **24** with NaCN in DMF gave a 55:45 mixture of adducts **25** and **26**. DDQ treatment of this mixture of products gave 4-chloro-3-methylphthalonitrile (**27**), a compound that has not been reported previously. Again it is seen that

For personal use only.

24 25 26 27

no arene was liberated from **26**, a cyclohexadienyl complex with two substituents at the 6-position.

The above results from the reaction with **20** are entirely consistent with expectation. A short reaction time resulted in the addition of a cyanide ion *ortho* to a chloro group, giving rise to **21** and **22**. A longer reaction time with work-up in the presence of added aqueous NH_4PF_6 gave substitution product **24**, which in turn could undergo cyanide addition to give adducts **25** and **26**. It is of interest to note that even with an excess of the cyanide ion and a reaction time of 48 h, only one of the two chloro groups of **20** was replaced by a cyano group to give **24**. A possible explanation for the occurrence of only mono-substitution may be suggested by analogy to the processes given in Scheme 1 for the reactions with chlorobenzene complex **8**. In the reaction of **20** with the cyanide ion, before aqueous NH_4PF_6 was added in the work-up of the reaction mixture, formation of substitution product **24** would be followed by a rapid and irreversible addition of the cyanide ion to give **25** and **26**, and these adducts would not give rise to a further nucleophilic substitution reaction since these complexed cyclohexadienyl systems would be richer in electron density than the complexed cation **24**. In the presence of added aqueous NH_4PF_6, adducts **25** and **26** would readily revert back to **24**, resulting in the recovery of the mono-substituted product **24** as its hexafluorophosphate.

Experimental

*(1-5-η^5-1-*p*-Tolylsulfonyl-*exo*-6-cyanocyclohexadienyl)(η^5-cyclopentadienyl)iron (2)*

A mixture of 498 mg (1.0 mmol) of (η^6-*p*-tolylsulfonylbenzene)(η^5-cyclopentadienyl)iron hexafluorophosphate (**1**) (3) and 500 mg (10.2 mmol) of powdered NaCN in 5.0 mL of DMF was stirred at room temperature for 30 min. The reaction mixture was then filtered through a sintered glass filter and the filtrate added to 200 mL of ether. The resulting ether solution was thoroughly washed with H_2O (5 × 100 mL) to remove the DMF. After drying over $MgSO_4$, the ether was removed by a rotary evaporator. The residue was redissolved in ether, filtered, and the ether removed to give 276 mg (75%) of **2** as a red solid. Its ^1H and ^{13}C nmr data are given in Tables 1 and 2; ir ν_{CN}, 2215 cm^{-1}. For this and other compounds described in subsequent sections, the nmr and ir data, respectively, were obtained using a Bruker AM300 nmr spectrometer and a Perkin Elmer model 781 IR spectrometer. *Anal.* calcd. for $C_{19}H_{17}O_2NSFe$: C 60.16, H 4.49, N 3.69; found: C 60.05, H 4.64, N 3.49.

o-*p*-*Tolylsulfonylbenzonitrile (3)*

To a solution of 379 mg (1.0 mmol) of **2** in 10 mL of CH_3CN, 227 mg (1.0 mmol) of DDQ was added and the mixture was stirred at room temperature for 30 min. The resulting material was filtered through a sintered glass filter and the filtrate evaporated to dryness. The residue was redissolved in 5.0 mL of CH_2Cl_2 and the solution passed through a short (about 20 cm) alumina column with elution by CH_2Cl_2. Removal of the solvent from the eluate gave 154 mg (60%) of **3** as a colorless solid, mp 107–108°C; ^1H nmr ($CDCl_3$) δ: 2.42(3H, s, CH_3), 7.35(2H, d, J=8.3 Hz), 7.96(2H, d, J=8.3 Hz)(*p*-substituted Ph), 7.68–8.33 (4H, m, *o*-substituted Ph); ^{13}C nmr ($CDCl_3$) δ: 21.6(CH_3), 115.6(CN), 111.0)(quat-CN), 128.5(2C), 129.5, 129.6(2C), 133.1, 133.2, 136.4, 136.5(quat), 143.8(quat), 145.3(quat) (Ar); ir ν_{CN}, 2235 cm^{-1}. *Anal.* calcd. for $C_{14}H_{11}O_2NS$: C 65.37, H 4.28, N 5.45; found: C 65.57, H 4.20, N 5.52.

Reactions with the (η^6-chlorobenzene)(η^5-cyclopentadienyl)iron cation (8)

A mixture of 378 mg (1.0 mmol) of **8**, as its hexafluorophosphate, and 500 mg of powdered NaCN in 5.0 mL of DMF was stirred at room temperature for 3 min, 30 min, or 3 h and then worked up as described in the preparation of **2**. From the 3-min reaction, the yield of products was 40%, and the ^1H nmr spectrum showed these products to be an approximately 90:10 mixture of (1–5-η^5-1-chloro-*exo*-6-cyanocyclohexadienyl)(η^5-cyclopentadienyl)iron (**9**) and (1–5-η^5-1,*exo*-6-dicyanocyclohexadienyl)(η^5-cyclopentadienyl)iron (**10**). From the 30-min reaction, the yield of products was 48% and these products were also **9** and **10** in a ratio of about 40:60, while from the 3-h reaction, a 54% yield of pure **10** was obtained. The ^1H and ^{13}C nmr data for these products are given in Tables 1 and 2; ir ν_{CN}, 2208 and 2205 cm^{-1}, respectively, for **9** and **10**. *Anal.* calcd. for $C_{13}H_{10}N_2Fe$ (**10**): C 62.40, H 4.00, N 11.20; found: C 62.75, H 4.20, N 11.08.

In another experiment, 756 mg (2.0 mmol) of **8**, as its hexafluorophosphate, and 1.0 g of powdered NaCN in 10 mL of DMF was stirred at room temperature for 3 h. A solution of 1.0 g of NH_4PF_6 in 20 mL of H_2O was then added and the resulting material extracted with a 1:1 mixture of CH_2Cl_2–CH_3NO_2 (4 × 100 mL). The combined extract was washed with H_2O and dried over $MgSO_4$. After removal of the solvent, the residue was crystallized from acetone–ether to give 479 mg (65%) of the hexafluorophosphate salt of the (η^6-benzonitrile)(η^5-cyclopentadienyl)iron cation (**11**). Cation **11** has been prepared previously by Nesmeyanov and co-workers (13) from a ligand exchange reaction.

o-*Chlorobenzonitrile*

Treatment of 260 mg of the 90:10 mixture of **9** and **10** from the above 3-min reaction with DDQ as described in the preparation of **3** gave 60 mg (43%) of demetallation product which, after crystallization from ethanol–water, gave *o*-chlorobenzonitrile melting at 44–45°C (lit. (14), mp 45–46°C); ^1H nmr ($CDCl_3$) δ: 7.39–7.68(4H, m, Ar); ^{13}C nmr ($CDCl_3$) δ: 115.9(CN), 113.2(quat-CN), 127.1, 130.0, 133.8, 133.9, 136.7(quat) (Ar); ir ν_{CN}, 2218 cm^{-1}.

Phthalonitrile

The treatment of 1.0 mmol of **10** with DDQ as described in the preparation of **3** gave a 61% yield of phthalonitrile, mp 140–141°C (lit. (15), mp 141°C); ^1H nmr ($CDCl_3$) δ: 775–7.86(4H, m, Ar); ^{13}C nmr ($CDCl_3$) δ: 115.6(2C, CN), 115.3(2C, quat-CN), 133.2(2C), 133.5(2C) (Ar); ir ν_{CN}, 2230 cm^{-1}.

3-Methylphthalonitrile (12)

The DDQ treatment of the product mixture from the reaction of *o*-chlorotoluene complex **4** (6), a 96:4 mixture of (1–5-η-1,*exo*-6-dicyano-2-methylcyclohexadienyl)(η^5-cyclopentadienyl)iron (**6**) and (1–5-η^5-1,*exo*-6-dicyano-*endo*-6-methylcyclohexadienyl)(η^5-cyclopentadienyl)iron (**7**), gave a 69% yield of **12**, mp 142–143°C (lit. (11), mp 143°C); ^1H nmr ($CDCl_3$) δ: 2.64(3H, s, CH_3), 7.60–7.66(3H, m, Ar); ^{13}C nmr ($CDCl_3$) δ: 20.7(CH_3), 115.7, 115.9(CN), 114.6(quat-CN), 115.7(quat-CN), 130.9, 132.7, 134.5, 144.1(quat) (Ar); ir ν_{CN}, 2225 cm^{-1} (broad).

3-Methoxyphthalonitrile (17) and 3-phenoxyphthalonitrile (18)

A mixture of 204 mg (0.5 mmol) of the hexafluorophosphate of the (η^6-*o*-methoxylchlorobenzene)(η^5-cyclopentadienyl)iron cation (**13**) (12), or 235 mg (0.5 mmol) of the hexaflurophosphate of the (η^6-*o*-phenoxychlorobenzene)(η^5-cyclopentadienyl)iron cation (**14**) (12) and 500 mg of powdered NaCN in 5.0 mL of DMF was stirred at room temperature for 5 h and then worked up as described in the preparation of **2** to give a 55% yield of (1–5-η^5-1,*exo*-6-dicyano-2-methoxycyclohexadienyl)(η^5-cyclopentadienyl)iron (**15**) from **13** or a 50% yield of (1–5-η^5-1,*exo*-6-dicyano-2-phenoxycyclohexadienyl)(η^5-cyclopentadienyl)iron (**16**) from **14**. The ^1H and ^{13}C nmr data for these adducts are given in Tables 1 and 2.

For personal use only.

Direct treatment of **15** from the above reaction with DDQ gave a 74% yield of 3-methoxyphthalonitrole (**17**), mp 182–183°C (lit. (10), mp 183–184°C; ^{1}H nmr ($CDCl_3$) δ: 4.00(3H, s, CH_3O), 7.25–7.66(3H, m, Ar); ^{13}C nmr ($CDCl_3$) δ: 56.7(CH_3O), 115.3, 117.0(CN), 106.0(quat-CN), 113.0(quat-CN), 115.9, 125.1, 134.6, 161.8(quat) (Ar); ir ν_{CN}, 2235 cm^{-1} (broad).

Similarly, a direct DDQ treatment of adduct **16** from the reaction with **14** gave a 68% yield of 3-phenoxyphthalonitrile (**18**), mp 110–111°C (lit. (9), mp 110–112°C); ^{1}H nmr ($CDCl_3$) δ: 7.05–7.60(8H, m, Ar); ^{13}C nmr ($CDCl_3$) δ: 115.1, 117.2(CN), 106.0(quat-CN), 112.7(quat-CN), 110.4, 120.4(2C), 126.2, 126.9, 130.5(2C), 134.4, 153.7(quat), 160.9(quat) (Ar); ir ν_{CN}, 2232 cm^{-1} (broad).

*(η^6-2,6-Dichlorotoluene)(η^5-cyclopentadienyl)iron cation (**20**)*

A ligand exchange reaction between ferrocene and 2,6-dichlorotoluene, carried out as described in a similar ligand exchange between ferrocene and *o*-chlorotoluene (16), gave a 35% yield of cation **20**, isolated as its hexafluorophosphate; ^{1}H nmr (acetone-d_6) δ: 2.89(3H, s, CH_3), 5.35(5H, s, Cp), 6.61(1H, t, J=6.2 Hz, H4), 6.84(2H, d, J=6.2 Hz, H3, 5); ^{13}C nmr (acetone-d_6) δ: 17.8(CH_3), 82.1(Cp), 87.2, 88.8(2C), 102.5(quat), 108.7(2C, quat) (Ar).

*(1-5-η^5-1,3-Dichloro-6-*exo*-cyano-2-methylcyclohexadienyl)(η^5-cyclopentadienyl)iron (**21**) and (1-5-η^5-1,5-dichloro-6-*exo*-cyano-6-*endo*-methylcyclohexadienyl)(η^5-cyclopentadienyl)iron (**22**)*

A mixture of 426 mg (1.0 mmol) of **20**, as its hexafluorophosphate, and 500 mg of powdered NaCN in 5.0 mL of DMF was stirred at room temperature for 15 min and then worked up as described in the preparation of **2** to give 217 mg (70%) of a 66:33 mixture of **21** and **22**. The ^{1}H and ^{13}C nmr data for these adducts are given in Tables 1 and 2. For this isomeric mixture, *anal.* calcd. for $C_{13}H_{11}NCl_2Fe$: C 50.81, H 3.58, N 4.56; found: C 50.51, H 3.78, N 4.62.

*2,4-Dichloro-3-methylbenzonitrile (**23**)*

DDQ treatment of the above mixture of **21** and **22** gave a 55% yield of **23**, mp 75–76°C; ^{1}H nmr ($CDCl_3$) δ: 2.53(3H, s, CH_3), 7.40(1H, d, J=8.4 Hz), 7.46(1H, d, J=8.4 Hz) (Ar); ^{13}C nmr, ($CDCl_3$) δ: 17.8(CH_3), 115.9(CN), 112.3(quat-CN), 128.2, 131.3, 136.6(quat), 137.8(quat), 140.5(quat) (Ar). *Anal.* calcd. for $C_8H_5NCl_2$: C 51.90, H 2.70, N 7.57; found: C 52.13, H 2.85, N 7.57.

*(η^6-3-Chloro-2-methylbenzonitrile)(η^5-cyclopentadienyl)iron cation (**24**)*

A solution of 856 mg (2.0 mmol) of **20**, as its hexafluorophosphate, in 10 mL of DMF was deaerated by bubbling N_2 through it for 20 min and then 1.0 g of powdered NaCN was added. The mixture was stirred at room temperature under N_2 for 48 h. A solution of 1.0 g of NH_4PF_6 in 20 mL of H_2O was then added and the resulting material was extracted with CH_3NO_2 (5 × 100 mL). The combined extract was washed with H_2O and dried over $MgSO_4$. After removal of the solvent by a rotary evaporator, the dark brown residue was treated again with 1.0 g of NH_4PF_6 in 20 mL of H_2O. The grayish yellow solid that resulted was collected by filtration, redissolved in CH_3NO_2, and dried over $MgSO_4$. After removal of the solvent, the product was recrystallized from acetone – methylene chloride – ether to give 460 mg (54%) of the hexafluorophosphate salt of **24** as a yellow powder; ^{1}H nmr (acetone-d_6) δ: 2.97(3H, s, CH_3), 5.56(5H, s, Cp), 6.88(1H, t, J=6.4 Hz), 7.02(1H, d, J=6.4 Hz), 7.16(1H, d, J=6.4 Hz) (Ar); ^{13}C nmr (acetone-d_6) δ: 18.8(CH_3), 82.8(Cp), 75.8(quat-CN), 88.5, 90.3, 91.3, 104.8(quat), 109.2(quat) (Ar), 115.9(CN). *Anal.* calcd. for $C_{13}H_{11}NClFePF_6$: C 37.41, H 2.64, N 3.46; found C 37.29, H 2.53, N 3.46.

*(1-5-η^5-3-Chloro-1,6-*exo*-dicyano-2-methylcyclohexadienyl)(η^5-cyclopentadienyl)iron (**25**) and (1-5-η^5-1-chloro-5,6-*exo*-dicyano-6-*endo*-methylcyclohexadienyl)(η^5-cyclopentadienyl)iron (**26**)*

A mixture of 417 mg (1.0 mmol) of the hexafluorophosphate of **24** and 500 mg of powdered NaCN in 5.0 mL of DMF was stirred at room temperature for 30 min and then worked up the usual way to give 238 mg (80%) of a 55:45 mixture of **25** and **26** as a red solid. The ^{1}H and ^{13}C nmr data for **25** and **26** are summarized in Tables 1 and 2. For this isomeric mixture, *anal.* calcd. for $C_{14}H_{11}N_2ClFe$: C 56.38, H 3.70, N 9.39; found: C 56.04, H 3.95, N 9.12.

*4-Chloro-3-methylphthalonitrile (**27**)*

DDQ treatment of the above mixture of **25** and **26** gave a 39% yield of **27**, mp 119–120°C; ^{1}H nmr ($CDCl_3$) δ: 2.68(3H, s, CH_3), 7.60(1H, d, J=8.3 Hz), 7.72(1H, d, J=8.3 Hz) (Ar); ^{13}C nmr ($CDCl_3$) δ: 19.1(CH_3), 115.1, 117.6(CN), 114.1(quat-CN), 114.5(quat-CN), 131.6, 133.7, 140.6(quat), 142.3(quat) (Ar); ir ν_{CN}, 2230 cm^{-1} (broad). *Anal.* calcd. for $C_9H_5N_2Cl$: C 61.36, H 2.84, N 15.90; found: C 61.53, H 2.84, N 15.97.

Received May 17, 1988

DARIN R. LATIMER, JOHN A. WEIL, J. WILSON QUAIL, and WARD T. ROBINSON. Can. J. Chem. **67**, 143 (1989).

The new compound tetrakis(phenylmethoxy)methane (also known as benzyl orthocarbonate) has been produced by the action of the sodium salt of benzyl alcohol on trichloronitromethane (chloropicrin), resulting in a white crystalline solid with a melting range of 68–70°C. The crystal structure has been determined at 153(5) K: triclinic, $P\bar{1}$, a = 10.161(4) Å, b = 12.664(4) Å, c = 20.472(5) Å, α = 71.78(2)°, β = 82.30(3)°, γ = 71.92(2)°. The results show the symmetry at each central carbon to be approximately S_4, with average C—O bond lengths of 1.397(4) Å, O—C—O angles ranging between 113–114° and 107–108°, and C—O—C angles of 115(1)°. Additional evidence for this structure is given by nuclear magnetic resonance, infrared and mass spectra.

Key words: benzyl orthocarbonate, orthocarbonate, tetrakis(phenylmethoxy)methane.

DARIN R. LATIMER, JOHN A. WEIL, J. WILSON QUAIL et WARD T. ROBINSON. Can. J. Chem. **67**, 143 (1989).

En faisant réagir le sel de sodium de l'alcool benzylique sur le trichloronitrométhane, on a obtenu le tétrakis(phénylméthoxy)méthane qui est aussi connu sous le nom d'orthocarbonate de benzyle); ce nouveau produit se présente sous la forme d'une poudre cristalline blanche, de point de fusion 68–70°C. On a déterminé sa structure cristalline à 153(5) K : les cristaux sont tricliniques, $P\bar{1}$, a = 10,161(4), b = 12,664(4) et c = 20,472 Å, α = 71,78(2), β = 82,30(3) et γ = 71,92(2)°. Les résultats montrent que la symétrie de chacun des atomes centraux est approximativement S_4, avec des longueurs de liaisons C—O de 1,397(4) Å, des angles O—C—O allant de 113–114° à 107–108° et des angles C—O—C de 115(1)°. On a obtenu des données additionnelles relatives à cette structure en faisant appel à la rmn et aux spectroscopies ir et de masse.

Mots clés : orthocarbonate de benzyle, orthocarbonate, tétrakis(phénylméthoxy)méthane.

Introduction

Several aliphatic orthocarbonates have been produced, via various methods (1–3), since the synthesis of the first such compound reported by Bassett in 1864 (4). The method employed here for the production of tetrakis(phenylmethoxy)methane, **I** (also known as benzyl orthocarbonate), is analogous to that used by Bassett, and later extended by Tieckelmann and Post (3), to produce several low-molar-mass aliphatic orthocarbonates.

The new compound was produced in the hope that the central carbon atom might be close to tetrahedrally bonded to four oxygen atoms (as indeed is the case) so that the molecule could be used to model the site in which (hypothetically) a carbon atom might occur substitutionally for silicon in minerals, such as the α-quartz structure.

Most of the known aliphatic orthocarbonates are not solid at room temperature and thus are not suitable for the determination of bond lengths and angles by X-ray diffraction. It was deemed necessary to synthesize an orthocarbonate with substituents sufficiently massive for the compound to be a solid at room temperature. In fact, several known aryl orthocarbonates are solids at room temperature (5–8), but are not desirable for our purposes. Compound **I** was selected because the benzyl substituent was deemed sufficiently large for the compound to be a solid at room temperature. A recent publication (9) has predicted, via Hartree–Fock SCF-MO calculations, that the local symmetry of the central carbon in orthocarbonate molecules should be S_4, which is now found by X-ray analysis to be approximately true for **I** in the condensed phase.

Experimental

Benzyl alkoxide was prepared by reacting freshly-cut sodium metal with benzyl alcohol (BDH reagent grade, distilled and dried over calcium hydride) until the yellow mixture of benzyl alcohol and benzyl alkoxide became so viscous that it could no longer be stirred by a magnetic stirrer. Compound **I** was then produced by heating the mixture to approximately 40°C and very carefully adding trichloronitromethane (chloropicrin), commercially available from Pfaltz and Bauer, while maintaining the temperature in the 40–60°C range. Tieckelmann and Post (3), for the aliphatic orthocarbonates which they were synthesizing, report that temperatures any lower than this allow the accumulation of chloropicrin with an explosive reaction following eventually, while higher temperatures cause the yield to be lowered. Indeed, in our work, rapid addition of the chloropicrin to the benzyl alkoxide reaction mixture caused the temperature to increase drastically.

Compound **I** was extracted into the carbon tetrachloride layer from water/carbon tetrachloride and allowed to crystallize. The crystals of **I** formed in an unknown viscous yellow oil. They were physically separated from the oil, and then recrystallized twice from 95% ethanol. The resulting white crystals were dried under vacuum over phosphorus pentoxide for a day and when removed had a melting range of 68–70°C.

In an attempt to prevent formation of the yellow oil in the reaction mixture, a different technique to isolate the orthocarbonate was tried. Here, after the reaction of the alkoxide with chloropicrin was complete, the reaction mixture was steam-distilled, with a white substance coming over. The orthocarbonate was again extracted from the contents of the reaction flask, however with decreased yield. Again the yellow oil was present, although in a lesser amount. Thus the value of the modified procedure is questionable.

Compound **I** is very soluble in carbon tetrachloride, less soluble in ethanol, diethyl ether, chloroform, and methanol, and insoluble in water.

Crystals of **I** for X-ray analysis were grown by slow evaporation of solvent from a solution in methanol and diethyl ether. The crystals were found to deteriorate within hours in an X-ray beam at room temperature. At 153 K, no measurable deterioration was observed.

The crystal data and X-ray diffraction conditions are as follows: $C_{29}H_{28}O_4$ molar mass = 440.57 g mol^{-1} Triclinic, $P\bar{1}$, a = 10.161(4) Å, b = 12.664(4) Å, c = 20.472(5) Å, α = 71.78(2)°, β = 82.30(3)°, γ = 71.92(2)°, V = 2376.7 Å^3, Z = 4, ρ_0 = 1.18 g cm^{-3} (298 K), ρ_c = 1.231 g cm^{-3} (153 K), $F(000)$ = 936 e, Mo K_α radiation (λ = 0.71069 Å), μ = 0.85 cm^{-1}, $(\sin\theta/\lambda)_{max}$ = 0.6278 Å^{-1}, crystal dimensions 0.34 × 0.50 × 0.52 (mm), no decay correction, temperature = 153(5) K.

Quantitative data collection was carried out with a single crystal on a Nicolet $R3m$ four-circle diffractometer using graphite-monochromated Mo K_α radiation; cell dimensions derived by least-squares calculations from angular settings of 25 reflections measured at $5 < 2\theta < 35°$; $\omega/2\theta$ scan mode. A total of 9911 reflections were collected to 2θ = 53°. A total of 7523 unique reflections (out of 9911) yielded values of the intensity $I > 2\sigma(I)$. Lorentz and polarization corrections were applied. Intensities of three standard reflections were monitored after every 97 reflections throughout the data collection. The average deviation of each standard reflection was less than 1%. Low temperature system: Nicolet LT-1 modified locally. No absorption correction was applied. Observed weights for the reflections were taken to be $[\sigma(F)]^{-2}$.

X-ray diffraction data collected on the orthocarbonate crystal were processed and the structure solved, in space group $P\bar{1}$, assuming two molecules per asymmetric unit, using a MSDOS version of SHELXS-86 (10). The structure was refined using the XTAL System (11) of Crystallographic Programs on a DEC Vax 8650 computer.

The positions of 65 of the 66 non-hydrogen atoms were determined from a calculated E map. The remaining non-hydrogen atom was found by use of a difference Fourier map. Least-squares isotropic refinement gave an R value of 0.078, using rigid C_6H_5 units with hydrogens at calculated positions. Anisotropic least-squares refinement of the non-hydrogens H atoms placed at fixed distance (1.00 Å) from C atoms; their isotropic temperature factors were assigned the final equivalent temperature factors of the attached carbons. Final R was 0.084, $R = (\Sigma||F_o| - |F_c||)/\Sigma|F_o|$. The R_w value was 0.053, $R_w = (\Sigma w\Delta F^2/\Sigma wF_o^2)^{1/2}$. The quantity minimized in refinement was $\Sigma w\Delta F^2$. The number of parameters refined was 596. The largest and average shift/error ratios were 0.336 and 0.012, respectively, in the final cycle. The value of the goodness-of-fit was 2.406. The largest residual peaks and holes on a difference Fourier synthesis were 0.51 and −0.62 e Å^{-3}, respectively. The peaks on the difference Fourier synthesis could be matched to most of the atoms of slightly disordered molecules of **I**. A stereo ORTEP (12) representation of an asymmetric unit of the orthocarbonate is shown in Fig. 1 and all final atomic coordinates[1] are given in Table 1.

Nuclear magnetic resonance (^{1}H and ^{13}C) spectra of **I** were run on a Bruker AM300 spectrometer at 25°C, with the orthocarbonate dissolved in deuterated chloroform containing approximately 1% TMS (Silanor C). All chemical shifts reported are with respect to TMS.

In the ^{1}H spectrum, the aromatic protons resonate in the region 7.33–7.35 ppm, and the aliphatic protons exhibit a single peak at

[1]Tables of observed and calculated structure factors and anisotropic thermal parameters are available as supplementary material. Complete sets of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

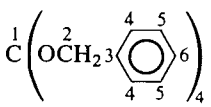

FIG. 2. Numbering scheme for ^{13}C NMR assignments.

4.80 ppm. A peak corresponding to the proton of chloroform is found at 7.25 ppm; this caused the ratio of the integral of aromatic protons to that of aliphatic protons to be 5.14:2 rather than the expected ratio of 5:2.

The peaks in the ^{13}C spectrum are assigned by comparison to an analogous compound, ethyl phenylacetate (13). Considering the numbering scheme in Fig. 2, the observed resonances in ppm, relative to TMS, of **I** carbon nuclei are: *1*, 120.29; *2*, 65.75; *3*, 137.85; *4*, 128.32; *5*, 127.59; *6*, 127.49.

Infrared spectra of **I** (in carbon tetrachloride) and of benzyl alcohol were run in the 4000–600 cm^{-1} region. No OH stretch peak of the alcohol was present in the orthocarbonate spectrum. The absorption in the 1150–1020 cm^{-1} region of the orthocarbonate spectrum, attributed to the C—O— stretches, becomes much more intense for the orthocarbonate than for the alcohol. This is consistent with the presence of C—O—C bonds (two unresolved C—O— stretches) replacing the C—O— stretch of the corresponding alcohol, resulting in a higher intensity due to the greater number of absorbers.

Mass spectra of **I** were obtained and both the 70 eV electron impact

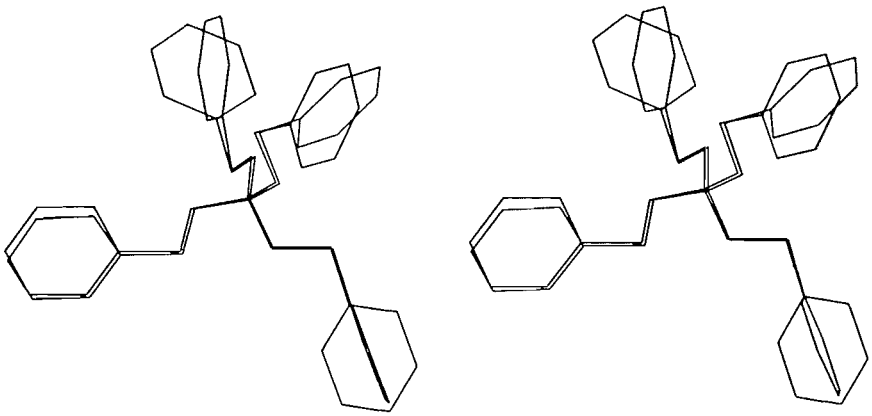

FIG. 3. Stereo view of the mapping of molecule A onto molecule B.

and the isobutane chemical ionization spectrum show the largest mass-to-charge ratio to be at $m/z = 333$. This ratio likely corresponds to the [tris(phenylmethoxy)methane]$^+$ cation; the parent ion could not be observed.

Chemical analysis for carbon and hydrogen found C 79.08%, H 6.37%, O 14.55% (by difference) which agreed very well with those expected: C 79.07%, H 6.40%, O 14.53%.

Results and discussion

Turning to the crystal structure, we note that the two molecules, A and B, of **I** in the asymmetric unit are not related by any element of symmetry. The bond angles around the central carbon atoms (Tables 2 and 3) show that there is appreciable distortion from tetrahedral symmetry at the central carbon atom in A and in B. Using an IRIS 3030 Graphics System and the program MMS (14), it was possible to superimpose molecule B onto molecule A (Fig. 3). To construct Fig. 3 the top molecule in Fig. 1 (molecule A) was held rigid. Atom C(B) was superimposed on C(A) and various orientations of molecule B were tested. In the superposition, O5 maps to O1, O2 to O6, O7 to O3, and O8 maps to O4. The configurations of the two molecules match remarkably closely. Only the rotations of the phenyl rings around their *para* axes are different. The symmetry at each central carbon is very close to S_4, with a compression along the S_4 axis, giving two O—C—O bond angles of 113–114° and the remaining four bond angles at 107–108°. This geometry is remarkably similar to the S_4 geometry predicted by *ab initio* calculations for tetramethoxymethane (9), including the actual values (112.4 and 108.0°, respectively) of the bond angles. The observed bond lengths, (1.40 Å) shown in Table 4, of the central carbon–oxygen bonds are very similar to the values (1.396 Å) found by electron diffraction reported by Mijlhoff *et al.* (15) in tetramethoxymethane, but the oxygen–carbon (peripheral) bonds are somewhat longer (0.02 Å).

We can compare the central skeleton of **I** with the silicon site

in crystalline quartz, which has four oxygen nearest neighbors in a quasi-tetrahedral configuration, with only C_2 symmetry. The central C—O bond length in the orthocarbonate is 1.40 Å, as compared to 1.61 Å for Si—O in α-quartz. (The C—O—CH_2 angles are 115°, as compared to 143° for Si—O—Si in α-quartz.) When considering a large number of silicates, relatively constant Si—O bond lengths (1.62 ± 0.04 Å) but various Si—O—Si angles (145 ± 35°) are found; it is likely that Si...Si interactions are of importance in the silicates (16). Our results suggest that the carbon atom is too small to fit substitutionally into the silicate structure. This is consistent with the absence in the literature of reports of occurrence of carbon at silicon sites in minerals (17).

Organic reactions in liquid crystalline solvents. 8. Deuterium NMR studies of the solubilization of some aromatic ketones in the liquid crystalline phases of 4′-butylbicyclohexyl-4-carbonitrile

BRIAN J. FAHIE, D. SCOTT MITCHELL, AND WILLIAM J. LEIGH[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 6, 1988

BRIAN J. FAHIE, D. SCOTT MITCHELL, and WILLIAM J. LEIGH. Can. J. Chem. **67**, 148 (1989).

The nature of the solubilization of β-phenyl-4-methoxypropiophenone (**1**) in the nematic and crystal-B liquid crystalline phases of *trans*,*trans*-4′-butyl-(1,1′-bicyclohexyl)-4-carbonitrile (CCH-4) has been investigated by deuterium nmr spectroscopy. This has been carried out using deuterium quadrupolar splitting ($\Delta\nu_Q$) and T_1 measurements on 1–15 mol% solutions of two selectively deuterated derivatives of the ketone in CCH-4 over the 25–110°C temperature range. The nmr studies have been supplemented with differential scanning calorimetry (DSC) and thermal microscopic investigations of variously proportioned mixtures of the parent ketone with CCH-4, over a similar temperature range. For comparison, ^{2}H nmr measurements have also been carried out for solutions of 4-methoxyacetophenone-α,α,α-d_3, benzene-d_6, and β-(4-cyclohexylphenyl)-4-methoxypropiophenone-α,α-d_2 in the same liquid crystal as a function of temperature. Our results indicate that the limit of solubility of **1** in the smectic phase of CCH-4 is less than 0.5 mol%. At temperatures above 35°C, excess ketone is solubilized in a ketone-rich nematic phase that coexists with the bulk smectic phase, and the composition of the ketone-rich phase varies continuously with temperature throughout this range. At around 35°C, the ketone-rich phase transforms into a metastable, non-birefringent phase which is characterized by isotropic nmr behaviour. Prolonged storage at room temperature causes crystallization of this phase, forming a stable binary mixture of ca. 9:1 CCH-4/**1** that undergoes a K–Sm transition at 27–28°C, a Sm–N transition at 43.5–44°C, and a broad N–I transition at 58–63°C. This stable modification can also be prepared by rapid cooling of a 10 mol% **1**/CCH-4 mixure from the nematic phase. The ^{2}H nmr studies of 4-methoxyacetophenone-α,α,α-d_3 and benzene-d_6 in CCH-4 indicate that these solutes have somewhat higher solubility in the crystal-B phase of this mesogen. The data necessitate a re-interpretation of our previously reported studies of the excited triplet state behaviour of **1** in the liquid crystalline phases of this material, and may be broadly applicable to numerous other studies of photochemical reactivity in this mesogen that have been reported.

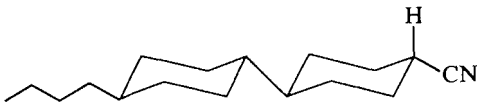
Key words: liquid crystal, smectic, ^{2}H nmr, photochemistry, aromatic ketone, bicyclohexyl-4-carbonitrile,4′-butyl.

BRIAN J. FAHIE, D. SCOTT MITCHELL et WILLIAM J. LEIGH. Can. J. Chem. **67**, 148 (1989).

Faisant appel à la rmn du deutérium, on a étudié la nature de la solubilisation de la β-phényl méthoxy-4 propiophénone (**1**) dans les phases nématique et cristalline du cristal liquide-B du butyl-4′ (bicyclohexyl-1,1′) carbonitrile-4-*trans*, *trans* (CCH-4). On a réalisé cette étude en effectuant des mesures de T_1 et de couplages quadripolaires du deutérium ($\Delta\nu_Q$) sur des solutions contenant de 1 à 15 mol% de deux dérivés sélectivement deutérés de la cétone **1** dissoutes dans le CCH-4, à des températures allant de 25 à 110°C. En plus des études rmn, on a aussi fait appel à la calorimétrie à balayage différentiel (CBD) et à la microscopie thermique qui ont été utilisés aux mêmes températures sur divers mélanges de la cétone **1** dans le CCH-4. Pour fins de comparaison, des études de rmn du ^{2}H ont aussi été effectuées sur des solutions de méthoxy-4 acétophénone-α,α,α-d_3 et de benzène-d_6, dans le même cristal liquide et dans les mêmes limites de température. Nos résultats indiquent que la limite de solubilité du composé **1** dans la phase smétique du CCH-4 est inférieure à 0,5 mol%. À des températures supérieures à 35°C, la phase riche en cétone se transforme en une phase métastable, qui n'est pas biréfringente et qui est caractérisée par une comportement rmn isotrope. Un entreposage prolongé de cette phase à la température ambiante provoque sa cristallisation et la formation d'un mélange binaire stable formé de CCH-4 et de **1** dans un rapport d'environ 9:1 et qui subit une transition K–Sm à 27–28°C, une transition Sm–N à 43,5–44°C et un large transition N–I entre 58 et 63°C. On peut aussi préparer cette modification stable en refroidissant rapidement un mélange contenant 10 mol% du composé **1** dans le CCH-4, à partir de la phase nématique. Les études par rmn du ^{2}H effectuées sur la méthoxy-4 acétophénone-α,α,α-d_3 et sur le benzène-d_6 dans le CCH-4 indiquent que ces solutés sont légèrement plus solubles dans la phase cristal-B de ce mésogène. Ces données nous obligent à réinterpréter nos études antérieures sur le comportement de l'état excité triplet du composé **1** dans les phases cristallines liquides de ce produit et elles peuvent s'appliquer d'une façon générale à de nombreuses autres études qui ont été effectuées antérieurement sur la réactivité photochimique de ce mésogène.

Mots clés : cristal liquide, smectique, rmn ^{2}H, photochimie, cétone aromatique, bicyclohexyl carbonitrile-4, butyl-4′.

[Traduit par la revue]



Introduction

There is considerable current interest in the potential effects of liquid crystalline order on the molecular mobility and associated chemical reactivity of dissolved solutes. A number of techniques have been used to study solute behaviour of this type in liquid crystals, including nanosecond laser flash photolysis (1–3), fluorescence (4, 5) and uv absorption (6) spectroscopy, electron spin (7) and nuclear magnetic (8) resonance, and product analysis methods (2, 3*b*, 9–14).

4′-Butylbicyclohexyl-4-carbonitrile (CCH-4; a.k.a. BCCN) has found particularly frequent use as a liquid crystalline solvent in the photochemical/photophysical investigations that have been reported to date (1–3, 4*c*, 14*d*). This mesogen has several advantages in studies of this type; it is commercially available in spectroscopic grade purity, is optically transparent at wavelengths above ca. 210 nm, and exhibits nematic and smectic liquid crystalline phases, as well as the isotropic phase, at convenient temperatures (K–Sm, 28°C; Sm–N, 54°C; N–I,

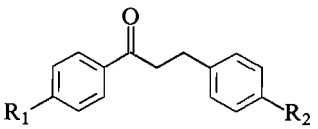
CCH-4

79°C (15)). The morphology of the smectic phase of this compound has recently been established by X-ray diffraction methods; it is classified as a bilayer crystal-B phase (16), similar to the high temperature smectic phase of the 4′-propyl homologue (CCH-3) that was characterized several years ago by Brownsey and Leadbetter (17). In this type of liquid crystal, the constituent molecules are arranged in correlated bilayers of thickness just slightly shorter than twice the molecular length. Within the bilayers, the molecules are hexagonally close-packed and oriented parallel to one another and perpendicular to the layer plane (refs. 16, 17; for comprehensive descriptions of the structure and properties of liquid crystals and leading references, see ref. 18). The feature of the morphology of the crystal-B phase that distinguishes it from the conventional smectic B phase is the presence of some degree of three-dimensional order (17). The 4′-butyl derivative forms an enantiotropic smectic phase, and is hence more useful as a reaction solvent than the 4′-propyl derivative, which forms monotropic smectic phases. However, a commercial material that contains CCH-3 as the ternary eutectic with the 4′-pentyl and -heptyl homologues is nematic at room temperature (15) and has found considerable use as a solvent for nmr studies (19) and uv absorption spectroscopy (6*c*, 20).



While the morphology of the liquid crystalline phases of pure CCH-4 is apparently well-established, the nature of its solubilization of guest molecules is unclear. Studies by us (1, 2) and others (3, 4*c*, 14*d*) have shown that solute conformational mobility can be substantially restricted in smectic CCH-4 compared to the corresponding behaviour in the nematic and isotropic phases, but the magnitude of the effect depends critically on the relationship between the structure of the solute and that of the liquid crystal, as well as the magnitude of the change in solute shape that accompanies the conformational motion. For example, the Arrhenius parameters for triplet decay of **1** (which depend directly on the energetics of C_α—C_β bond rotation in the ketone excited triplet state (21) are markedly phase-dependent in CCH-4; the Arrhenius plot shows a distinct change in slope at the bulk Sm–N phase transition temperature, corresponding to an increase in the activation energy and entropy for triplet decay (relative to their nematic phase values) of ca. 10 kcal/mol and 30 eu, respectively, at temperatures below 53°C (1*a*). On the other hand, when the length of the ketone is increased, for example as in **2**, phase-*independent* of phenylalkyl ketones (14*d*) in the smectic, nematic, and isotropic phases of CCH-4. All of these studies have more or less assumed homogeneous solubility of the probes in smectic CCH-4, although a recent report by Treanor and Weiss (22) has identified a solute-induced phase (previously assigned a plastic- or cubic-crystalline morphology on the basis of ^{13}C nmr results for solutions of benzene in CCH-4 (23)) that exists at temperatures less than *ca.* 35°C, and discussed the ramifications of the structure of this phase on the Norrish II reaction of alkylphenones. Recently, Sigaud and co-workers have reported that 1-aminopyrene and 1-aminofluorenone form stable, binary nematic and smectic A phases with CCH-4 (24).

Deuterium nmr spectroscopy is an extremely powerful technique for the investigation of the mobility and solubilization of solutes in liquid crystals, and several comprehensive reviews outline the theory and applications of the various techniques that have found widespread use (8*a*, 8*e*, 25). For a deuterated analog of a solute such as **1**, ^2H nmr spectroscopy can provide information on molecular motions that take place over considerably different time-scales than that probed in the laser flash photolysis technique. For example, the magnitude of the deuterium quadrupolar splitting ($\Delta\nu_Q$) that is observed of a deuterated molecule dissolved in an anisotropic solvent is dependent on the time-averaged motions of the molecule over a time scale of ca. 0.01–10 ms (25*b*), while the deuterium spin–lattice relaxation time (T_1) reflects molecular motions over the 0.01–10 ns time scale (25). Most importantly from our perspective, the pattern of response of these parameters to changes in temperature, solvent phase, and bulk solute concentration is capable of providing fairly detailed qualitative information on the variations in local solvation of the probe molecule with temperature and phase. Additional information on probe solubilization is available from differential scanning calorimetry (DSC) and thermal microscopy (TM) experiments, particularly when they are carried out with solute–liquid crystal mixtures over a wide range of concentrations.

We wish to report the results of ^2H nmr and deuterium T_1 measurements on two deuterated analogues of **1** (**3** and **4**) in the isotropic and liquid crystalline phases of CCH-4, as well as an investigation of the bulk phase behaviour of mixtures of **1** and CCH-4 by DSC and thermal microscopy. Our experiments have been carried out over a fairly wide range of sample composition, to permit more reliable identification of the type of solubilization experienced by **1** at the low (1 mol%) concentration employed in our previous (1) nanosecond laser flash photolysis experiments. For comparison, we also report ^2H nmr studies of CCH-4 mixtures with a few other representative solutes of substantially different structures compared to **1**; *viz.* 4-methoxyacetophenone-α,α,α-d_3 (**5**), β-(4-cyclohexylphenyl)-4-meth-

Arrhenius behaviour is observed for the triplet lifetime in CCH-4 (1*b*). Weiss and co-workers have reported similar dependencies of solute molecular mobility on molecular length in their studies of intramolecular excimer formation in bis-α,ω-pyrenylalkanes (4*c*), and the Norrish Type II reaction of a series

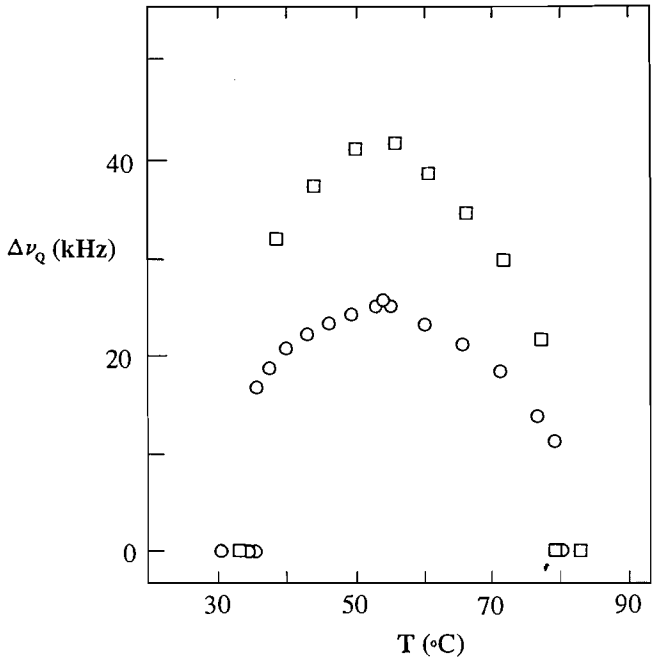

FIG. 1. Deuterium quadrupolar splitting ($\Delta\nu_Q$) versus temperature for 1 mol% mixtures of **3** (⊙) and **4** (□) in CCH-4.

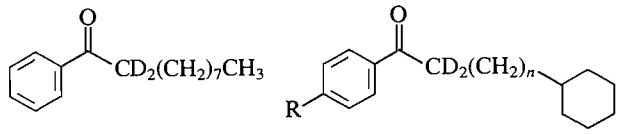

oxypropiophenone-α,α-d_2 (**6**), and deuteriobenzene (C_6D_6). These results allow a complete description of the solubilization of **1** in the liquid crystalline phases of CCH-4, and a detailed, more precise rationalization of the phase-dependent photochemical behaviour of **1** in this solvent than has been presented before (1). Furthermore, our results may be broadly applicable to the many other systems that have been investigated in this and related liquid crystalline solvents (2, 3, 4*c*, 14*d*, 22).

Results and discussion

β-Phenyl-4-methoxypropiophenone-α,α-d_2 (**3**) was synthesized from **1** by base-catalyzed deuterium exchange in NaOD/D_2O/dioxane. β-(4-Deuteriophenyl)-4-methoxypropiophenone (**4**) was synthesized from 4-deuteriobenzaldehyde by a similar procedure to that used previously for **1** (1*b*). 4-Methoxyacetophenone-α,α,α-d_3 (**5**) and β-(4-cyclohexylphenyl)-4-methoxypropiophenone-α,α-d_2 (**6**) were synthesized from their protio-analogues by a similar procedure to that used for **3**.

Deuterium nmr spectra of 1 mol% mixtures of **3** and **4** in CCH-4 were recorded at 76.8 MHz, at various temperatures between 20 and 80°C, using the quadrupolar echo pulse sequence (26). In the isotropic phase above 78°C, the spectra consist of single sharp singlets in both cases. As the sample temperature is lowered below this temperature, the singlet is replaced by a doublet of splitting $\Delta\nu_Q$, the appearance of which is characteristic of a uniformly-oriented sample (25*a*, *b*). The observed value of $\Delta\nu_Q$ for both samples varies with temperature, as is shown in Fig. 1. At *ca.* 35°C, the doublets in both spectra collapse to singlets. Careful control of the sample temperature within a 2° window of 35°C and a 1° window of 78°C allows the coincidental observation of both doublet and singlet patterns, whose relative intensities change monotonically as the phase transitions are traversed.

Treanor and Weiss have recently reported a (directly related) study correlating the ^2H nmr behaviour of a series of α-deuterated phenylalkyl ketones (**7**, **8**) in the various phases of CCH-4 (22)

7

8 *a*: $n = 0$; R = CH_2CH_3
b: $n = 2$; R = H
c: $n = 3$; R = H

with the Norrish II photoreactivity of their protio-analogues in the same liquid crystal (14*c*). These compounds exhibit ^2H nmr behaviour that is very similar to that described above for **3** and **4**. These workers emphasized the nature of the low temperature, solute-induced phase ("p-phase")[2] that exists below 20–35°C (the temperature depends on the solute), and the ramifications of the morphology of this phase on the nmr behaviour and photoreactivity of **7** and **8**. The isotropic solution-like mobility that characterizes ^2H nmr spectra of the "p-phase" (14*d*) is also manifested in the ^{13}C nmr spectra of the mixtures, which show well-resolved peaks for both solute and CCH-4 superimposed on a broad, structureless envelope corresponding to CCH-4 in the smectic phase. This behaviour was originally reported by Fung and Gangoda for solutions of benzene and dioxane in this liquid crystal (23), and we observe similar ^{13}C nmr behaviour for **3**/CCH-4 below 35°C. The p-phase has been assigned a cubic-or plastic-crystalline phase structure (23). In order to rationalize the substantial effects of the p-phase on the Norrish II reactivity of **7** and **8** with the ^2H nmr behaviour, Treanor and Weiss have proposed that the tumbling motions sampled in the nmr experiment correspond to coupled, isotropic tumbling of microscopic solute/solvent "clusters" which are individually ordered in such a way that the conformational mobility of the solute is still impeded to a similar extent as was the case in the higher temperature (smectic) phase (22). These authors reportedly did not observe p-phase formation by thermal microscopy, nor did they comment on the interesting behaviour of $\Delta\nu_Q$ above 35°C and below the "bulk" Sm→N transition temperature (22).

The variation in $\Delta\nu_Q$ with temperature between 30 and 80°C that is shown in Fig. 1 for the 1 mol% **3**/CCH-4 mixture is qualitatively very similar to those reported previously for **7** and **8** (22). The increase in $\Delta\nu_Q$ with decreasing temperature throughout the nematic phase is unexceptional, and indicates an increase in the order parameter of the solute as medium rigidity in the nematic phase increases (8, 25). The magnitude of $\Delta\nu_Q$ reaches a maximum at the *bulk* Sm–N transition temperature (53°C) and then decreases with temperature until at 35°C, the signal collapses to a narrow-line singlet due to "p-phase" formation. The main question that we wish to address in the following deals with the origin of the continuous decrease in $\Delta\nu_Q$ that accompanies decreasing temperature within the smectic phase of the bulk mixture.

The observation of a discontinuity in a plot of this type in the vicinity of a solvent phase transition is quite typical (8). The nature of the discontinuity depends on the difference between the microscopic structures of the two phases (i.e. the microscopic environment experienced by the C—D bond), rather than differences in macroscopic order that are reflected in the thermodynamics of the phase transition (8, 9, 25). Thus, a transition to a thermodynamically more-ordered phase may be

[2]The term "p-phase" is a short form for plastic (or cubic) phase (22). While we do not accept this morphological assignment (*vide infra*), we shall retain the terminology for the sake of convenience.

accompanied by an abrupt decrease in the magnitude of $\Delta\nu_Q$, an abrupt increase, or merely a change in the slope of the plot. The continuous decrease in the magnitude of $\Delta\nu_Q$ that accompanies reductions in temperature throughout the 35–53°C range in the present case indicates either that the order parameter of the solute decreases or that its favoured orientation (i.e. perpendicular or parallel to the applied field) changes with decreasing temperature in this region. Solute reorientation effects can be ruled out on the basis of our results for **4**. Since the orientation of the C—D bond in **4** with respect to the long molecular axis is roughly perpendicular to that in **3**, we would have expected $\Delta\nu_Q$ to respond differently to temperature in the two compounds, if an alteration in the favoured orientation of the solute were responsible for the decrease in $\Delta\nu_Q$ that accompanies decreasing temperature in the 35–53°C range. In fact, the similar behaviour exhibited by **3** and **4** probably indicates that the favoured orientation of the solute remains the same throughout the 53–78°C and 35–53°C temperature ranges. CCH-4 has negative diamagnetic anisotropy (19), and the sample will thus be aligned in a magnetic field such that the long molecular axes are oriented perpendicular to the field. Presumably, the difference in the magnitudes of $\Delta\nu_Q$ observed for **3** and **4** at a given temperature are predominantly the result of differences in the motionally-averaged orientations of the C—D bonds in the two molecules with respect to the applied field, and their relative magnitudes are consistent with the C—D bonds in **3** sampling a much larger range of angles than that in **4** (the difference between the quadrupolar coupling constants for aromatic and aliphatic deuterons is much too small to account for the factor of ca. 2 difference between $\Delta\nu_Q$ for **3** and **4**). This would be the case if rotation about the long molecular axis were the predominant motion that is sampled by the quadrupolar interaction.

It can thus be concluded that the observed behaviour of $\Delta\nu_Q$ below 53°C results from a decrease in the order parameter of the solute with decreasing temperature. Behaviour of this type is, in fact, not uncommon, and can be the result of any of a number of possible solvation phenomena. For example, if **1** is solubilized homogeneously in the smectic phase of CCH-4, then such behaviour could result if the probe's solubilization site within the smectic array *changes* from a relatively highly ordered region at the upper temperatures to a relatively disordered or more fluid one at the lower temperatures (27). A related possibility is that as the temperature is lowered within the smectic phase, the solvation shell about **1** adopts a cavity-like structure (28), and becomes less able to control solute orientation as the cavity becomes better defined with decreasing temperature. A third possibility is that the ketone resides in a continuously changing (composition-wise), *nematic* phase between 35 and 53°C, which could result if the limit of solubility of the ketone in the smectic phase is lower than the bulk solute concentration of the sample, and phase separation occurs at temperatures below 53°C. The Se possibilities have been investigated in detail by additional ^{2}H nmr experiments and DSC and TM techniques.

^{2}H nmr experiments were also carried out for 3, 5, and 10 mol% mixtures of **3** with CCH-4. The results for the 5 and 10 mol% mixtures are shown along with those for the 1 mol% mixture in Fig. 2. For the samples containing ≥5 mol% **3**, the solutions were allowed to equilibrate for 10–45 min at each temperature prior to obtaining the spectrum. In these cases, a change in temperature below that of the apex in the $\Delta\nu_Q$ vs. T plot is accompanied by a fairly slow transformation of the spectrum as

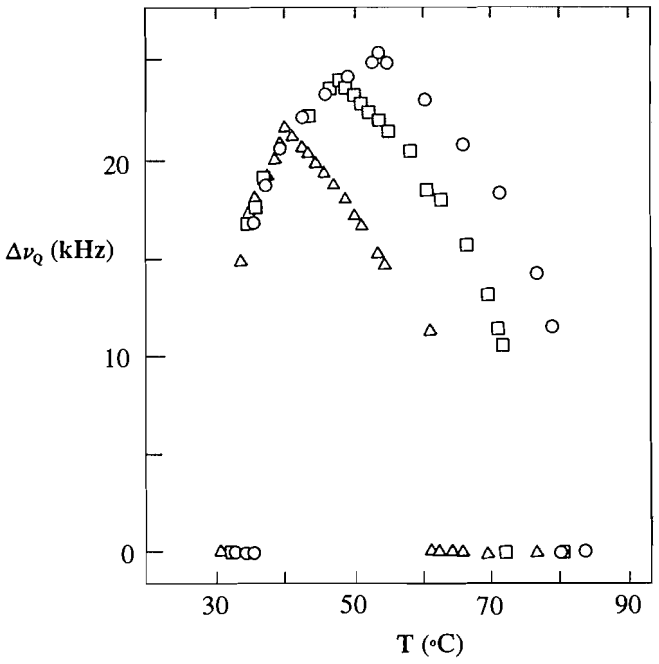

FIG. 2. Deuterium quadrupolar splitting ($\Delta\nu_Q$) versus temperature for 1.0 (⊙), 5.0 (□), and 10.0 (△) mol% mixtures of **3** in CCH-4.

the initial doublet gradually reduces in intensity and the final doublet grows in. For measurements at these temperatures, the samples were allowed to equilibrate for at least 2 h prior to recording the spectra. In the cases of the 5 and 10 mol% samples, we find that the apices in the $\Delta\nu_Q$ vs. T plots can be supercooled by up to *ca.* 5°C, if sufficient time is not permitted for sample equilibration. The phase transitions (N–I and the one at *ca.* 35°C) for the samples containing ≥5 mol% **1** are considerably broader than those for the samples of lower concentration, which results in the appearance of both the singlet and doublet patterns in the spectra of **3** over considerable temperature (approximately 3–7°) ranges.

The $\Delta\nu_Q$ vs. T plots in these nematic phases describe a series of approximately parallel curves that shift to lower temperature as the concentration of **1** in the solution is increased. This behaviour is exactly as expected for a series of homogeneous solutions of **1** in the bulk nematic phase, and a plot of the $\Delta\nu_Q$ values versus the reduced temperature ($T_{N-I} - T$) yields a single line that contains all the data for all concentrations. In each case, the data for temperatures below the apices fall on a single curve that is independent of the bulk sample composition. This is good evidence that at temperatures below the onset of the Sm–N transition, the ketone finds itself in a medium whose composition depends only on the temperature, and not on *bulk* solute concentration.

The ^{2}H nmr behaviour of the 3 mol% **3** sample described above is completely reversible, provided that the sample temperature is decreased slowly from above 50°C, and is not taken below 20°C for extended periods of time. Cooling the sample below 20°C, rapidly cooling it from above 50°C, or just allowing it to sit at room temperature for a few days causes apparent crystallization. The "crystallized" sample affords no deuterium signals under the same conditions as those used to record the above spectra until the sample temperature is raised above 43°C, at which point the characteristic doublet splitting of **3** in nematic CCH-4 is obtained.

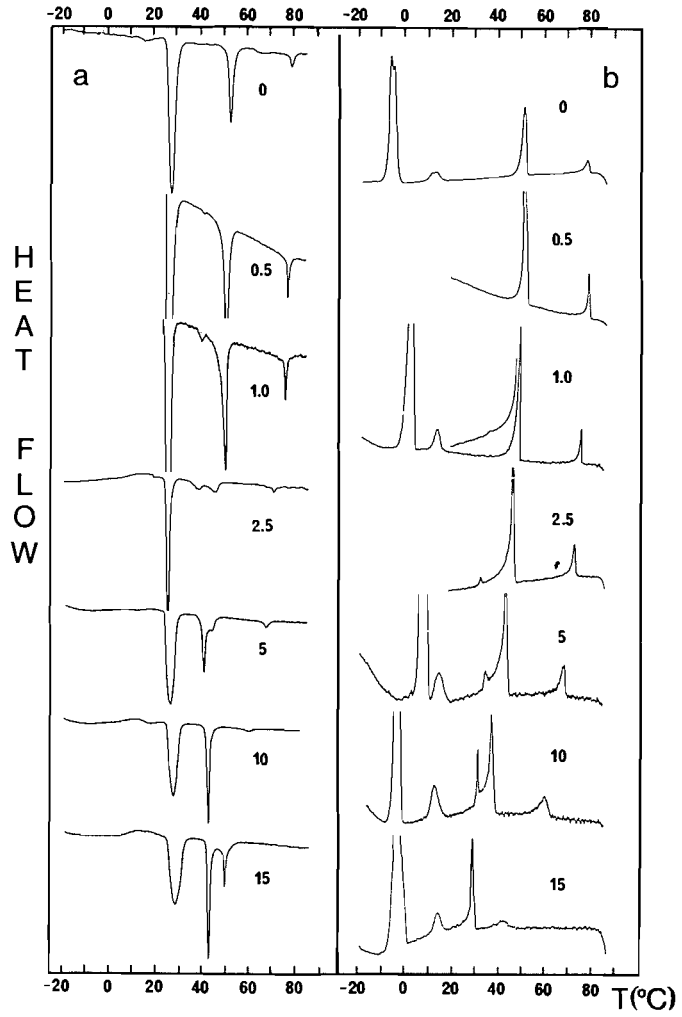

FIG. 3. Differential scanning calorimetry thermograms recorded for 0–15 mol% mixtures of **1** in CCH-4, measured with a 2°/min scanning rate. (*a*) Heating cycles; (*b*) cooling cycles. The mixtures of lower concentration in **1** were recorded at higher instrumental sensitivity.

DSC thermograms, recorded for several variously proportioned mixtures of **1** in CCH-4, are shown in Fig. 3. The addition of **1** to CCH-4 results in both a lowering and broadening of the N–I and Sm–N transitions, and the appearance of a new transition at 32–35°C. For the latter, the size of its corresponding peak in the DSC thermograms is proportional to the concentration of solute present, and it is reversible providing that the temperature of the sample is not taken below 5°C for extended periods of time. When the sample temperature is reduced to ca. −10°C (as was done routinely in the course of obtaining the DSC cooling cycles), the corresponding heating cycle does not mirror the cooling cycle; the transition at 32–35°C disappears and is replaced by a new one at 43–44°C. The DSC thermograms shown in Fig. 3 were recorded first as cooling cycles from 90°C to ca. −10°C (Fig. 3*a*), and then the corresponding heating cycles were obtained (Fig. 3*b*). Both sets of thermograms were obtained using a 2°/min temperature programme. For the mixtures containing <2.5 mol% **1**, the traces shown in Fig. 3 were recorded under conditions of higher instrumental sensitivity, to better resolve the weak transitions involving the solute-induced phases.

Thermal microscopic inspection of each of the above samples was carried out in order to ascertain the nature of the various phase transitions observed in the DSC experiments. These experiments are described in detail in the Experimental section, but can be summarized briefly as follows. In all samples of composition 0.5 ≤ **1** ≤ 15 mol%, slow cooling from the nematic phase results in phase separation (smectic + residual nematic) at temperatures below that at which the smectic phase initially appears, and at *ca.* 35°C the residual nematic phase transforms to an optically isotropic (non-birefringent) phase. This behaviour was missed in our earlier studies of the triplet state behaviour of **1** in CCH-4 (1); it is not readily obvious in the dilute mixtures without the benefit of the experience gained from examining mixtures of higher bulk concentration in **1**. We identify the optically isotropic phase as the "p-phase" that is responsible for the isotropic nmr behaviour of **3** and **4** below 35°C. In samples containing ≥5 mol% **1**, the p-phase can be discerned to have the character of a fairly viscous, isotropic *fluid*. The fluidity of this phase is more difficult to estimate in samples of lower bulk solute concentration, but in these cases, the relatively higher proportion of smectic phase is probably more effective at controlling the overall rigidity of the sample. Storage of the samples containing <10 mol% **3** for short periods of time at room temperature causes contraction of the p-phase fraction to form what appear to be crystallites dispersed throughout the mosaic monodomains of the bulk smectic phase. Upon heating, the "crystallites" undergo a distinct phase transition at 43–44°C to a nematic phase. Samples containing ≤0.25 mol% **1** showed no discernible evidence of phase separation, p-phase formation, or the 43–44°C transition by DSC or thermal microscopic inspection.

Rapid cooling of the 10 mol% sample to 23°C affords a homogeneous, solid binary mixture with a small number of microcrystals dispersed within it. The sample is stable indefinitely. The bulk of the sample undergoes a K–Sm transition at 27–28°C, a sharp Sm–N transition at 43.7–44°C, and a broad N–I transition at 58.5–63°C. The microcrystals (of presumably almost pure ketone) dissolve fairly rapidly between 44–48°C.

As Fung and Gangoda concluded, the solute-induced p-phase is indeed metastable, but in this case (at least) it is probably best described as an amorphous glass or (more likely) an isotropic liquid phase. With **1** as solute, the phase crystallizes to form a stable binary modification of composition 8–10 mol% **1**. While the microscopic texture of the binary phase that exists between 27 and 43.5°C is consistent with a smectic phase (18*c*), its precise morphology awaits identification.

The DSC and TM cooling and heating experiments are summarized in Fig. 4 as the complete binary phase diagrams for the **1**/CCH-4 binary system. These experiments clearly indicate that the presence of **1** in concentrations as low as 0.5 mol% causes phase separation below the bulk N–Sm transition temperature. The main features of the two diagrams differ considerably because of supercooling effects; in slowly-cooled mixtures containing <20 mol% **1**, the binary phase forms only after considerable storage times at room temperature. In mixtures containing ≥20 mol% **1**, the binary phase often (but not always) forms directly from the nematic phase; the cooling behaviour of these samples tends to be irreproducible because of erratic crystallization.

Several control experiments were carried out on the 1 and 3 mol% **3**/CCH-4 samples to verify that no additional doublet splittings (that might be attributed to ketone solubilized in the smectic phase component of the two-phase system) are present in the spectra at temperatures below 50°C. Using the 76.8 MHz spectrometer and the 1 mol% samples, the experiments con-

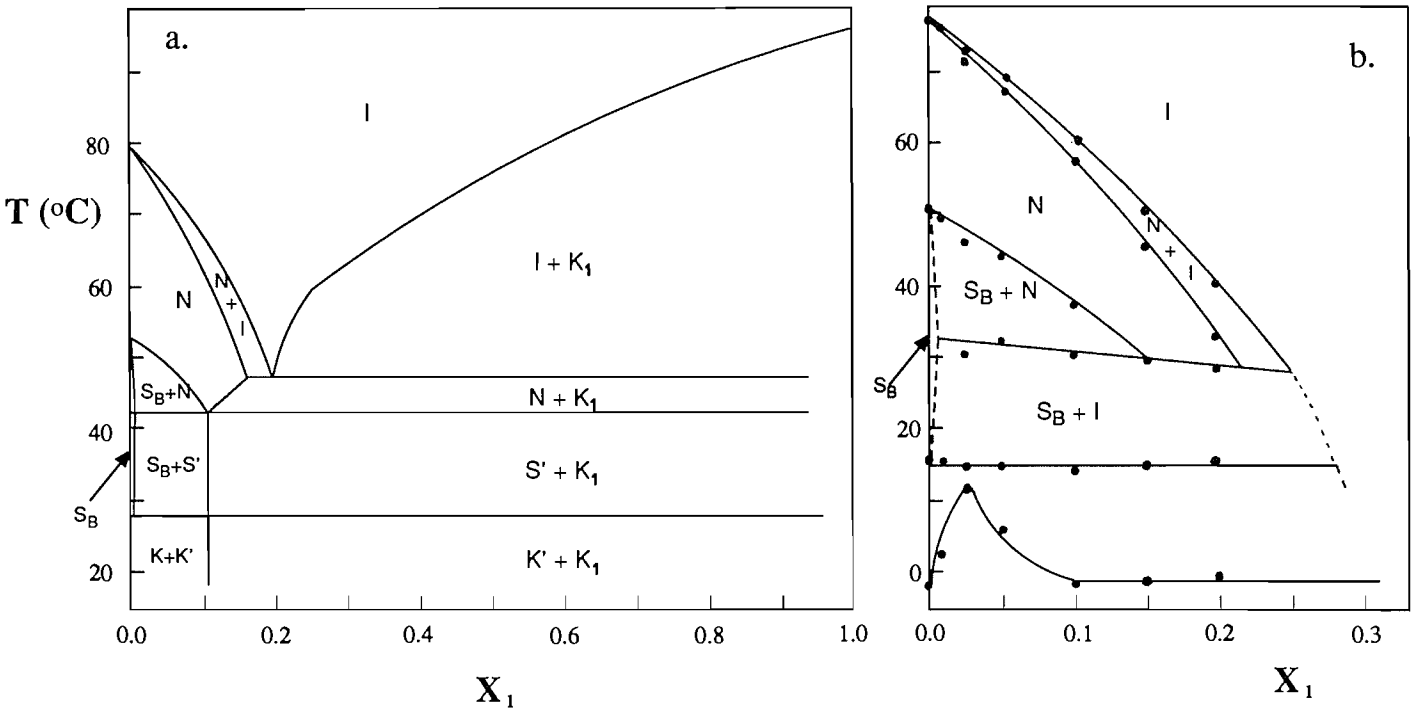

FIG. 4. Composition/temperature binary phase diagrams for **1**/CCH-4, constructed from DSC and thermal microscopy data. (*a*) Heating (idealized); (*b*) cooling (actual data), for 0–20 mol% **1**/CCH-4. (I, isotropic; N, nematic; S, smectic; K, solid. S′ and K′ represent the smectic and solid binary modification of composition *ca.* 10 mol% **1**).

sisted of varying the offset frequency in *ca.* 30 kHz steps up to 65 kHz from the carrier frequency, and scanning over a 165 kHz spectral window in each case; these failed to reveal any additional resonances within the limits of sensitivity of the instrument. With the largest variation in offset frequency, the spectrum suffered some distortion, but both components of the doublet were clearly observable. Spectra recorded with a 41.3 MHz spectrometer that is better equipped to carry out experiments on powder samples (see Experimental Section), similarly failed to reveal additional resonances within 100 kHz of centre-spectrum; in these cases, our limits of uncertainty can be taken to be much lower than those obtainable with the 76.8 MHz instrument.

Additional experiments were carried out with 0.2 and 0.5 mol% samples of **1** in CCH-4, in an attempt to define the limit of solubility of the ketone in the smectic phase. The 0.5 mol% sample exhibited behaviour similar to that of the 1.0 mol% sample, although the signal-to-noise ratio worsened dramatically as the temperature was lowered throughout the 52–35°C range. In the case of the 0.2 mol% sample, no deuterium signals could be observed at all between 10 and 50°C, but the isotropic singlet characteristic of p-phase formation could be clearly observed in spectra recorded below 8°C. We take the absence of spectral features below 50°C to indicate that the ketone is totally soluble in the crystal-B phase at these temperatures, and that the spectrum in this phase is either too broad or the components too widely separated to be observed with our spectrometer. These experiments afford upper and lower limits of 0.5 and 0.2 mol%, respectively, for the solubility limit of the ketone in the smectic phase of CCH-4. They also indicate that depending on bulk sample composition, p-phase formation can ensue from either smectic or nematic solutions of **1** in CCH-4.

The above results suggest that **1** is subject to rather more complicated solubilization in the smectic phase of CCH-4 under the conditions of our flash photolysis experiments than was previously thought (1*a*). Because sample (1 mol% in **1**) temperatures were routinely kept above 30°C (to keep them optically transparent (1)), the cooling phase diagram shown in Fig. 4*a* is the one that applies to the system under these conditions. Between ≈52–35°C, the sample consists of a biphasic system in which <50% of the ketone resides in a smectic phase of similar morphology to that of the pure mesogen and the remainder resides in a solute-enriched nematic phase. The relative proportions of the two phases present vary continuously with temperature, as do their compositions. Below 35°C, a second biphasic system is formed, that is comprised of a solute-depleted smectic phase (of a similar composition to that above 35°C) in equilibrium with a solute-enriched, isotropic liquid or glass phase.

For comparison purposes, ^{2}H nmr spectra of 3 mol% CCH-4 solutions of benzene-d_6, **5**, and **6** were recorded over the 20–85°C temperature range under similar conditions to those used above for **3** and **4**. The ^{2}H nmr behaviour of **6** is similar in all respects to that observed for **3**, except that $\Delta\nu_Q$ is somewhat larger in the former; the splitting varied between 12.9 and 27.7 kHz in the nematic phase and ultimately decreased to a value of 19.8 kHz as the temperature was lowered below 50°C, before collapsing to a singlet at *ca.* 30°C.

The ^{2}H nmr spectra of C_6D_6 and **5** show important differences at temperatures below 50°C compared to those of the other solutes investigated in this study, however. For these two compounds, cooling through the bulk N–Sm transition at ca. 50°C results in the appearance of a second doublet that coexists with that associated with the nematic phase.

Figure 5 summarizes the ^{2}H nmr behaviour of a 3 mol% sample of **5** in CCH-4 as a function of temperature, and representative spectra are included as inserts in the figure. Cooling the sample into the nematic phase affords a single

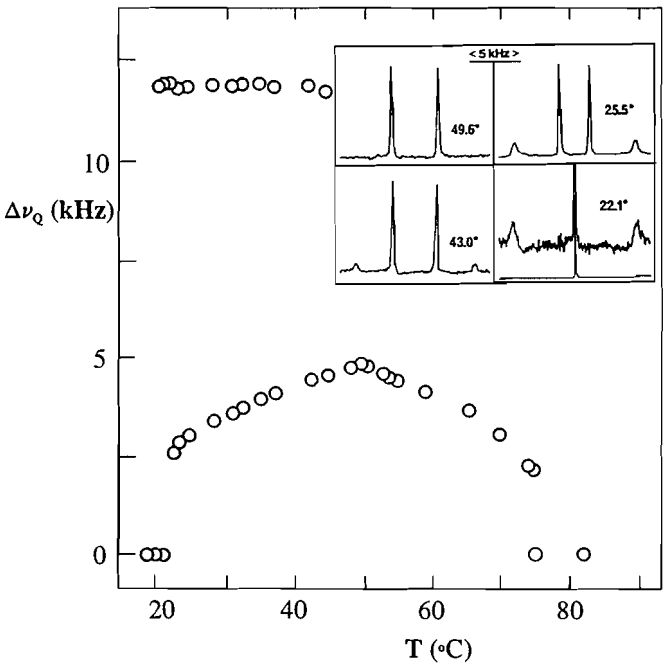

FIG. 5. Deuterium quadrupolar splitting ($\Delta\nu_Q$) versus temperature for a 3 mol% mixture of **5** in CCH-4. The insert shows some representative spectra measured at the various temperatures.

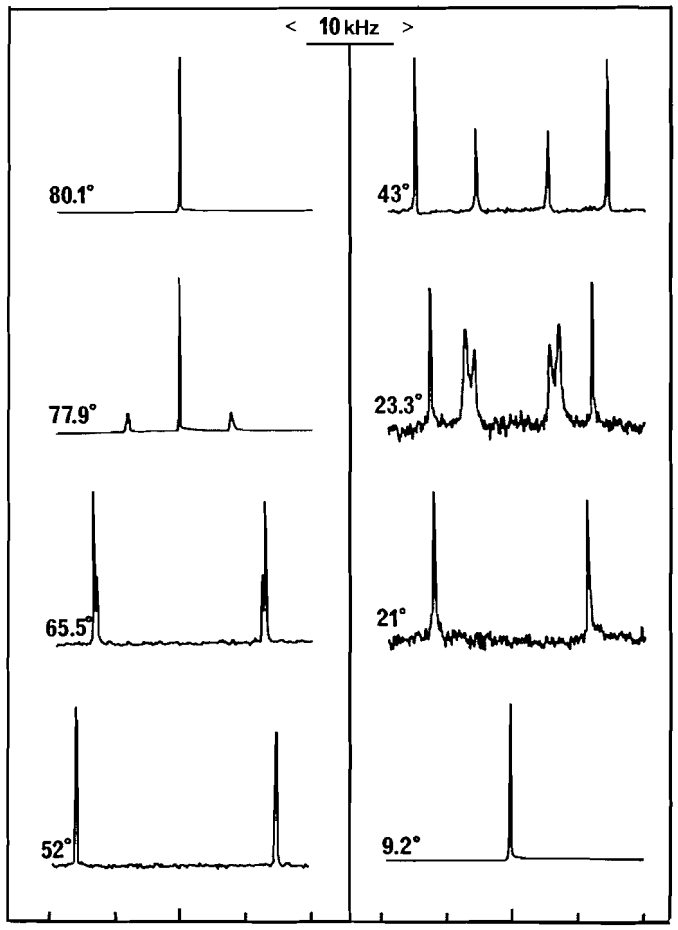

FIG. 6. Representative ^2H nmr spectra of a 3 mol% mixture of benzene-d_6 in CCH-4, at various temperatures between 9 and 80°C.

doublet of splitting 2.2 kHz at 75°C. Lowering the temperature below 50°C affords a second doublet signal, with splitting *ca.* three times that of the doublet associated with the nematic phase at this temperature, and which is assigned to **5** solubilized in the crystal-B phase of CCH-4. As expected for a biphasic system in which the solute is incorporated in *both* phases, further decreases in temperature results in an increase in the intensity of the outer (smectic) doublet compared to that of the inner doublet, presumably owing to progressive conversion of the nematic to smectic phase as the temperature is lowered. Interestingly, the magnitude of the outer doublet splitting remains constant at 11.8 ± 0.1 kHz with decreasing temperature in this range, indicating perhaps that the order parameter of the molecule does not vary significantly with temperature in the smectic phase. This may not be surprising, however, considering the very high degree of solvent order present in the crystal-B phase (18). As was found for the mixtures of **3** in the temperature region below 53°C, the doublet splitting associated with **5** in the nematic phase decreases in magnitude with decreasing temperature. At *ca.* 23–24°C, the spectrum collapses to a singlet (originating from the inner doublet) flanked by the outer doublet. This system thus also forms a p-phase at low temperatures, and it is clearly the binary nematic phase that is the precursor to the p-phase under these conditions. Further decreases in temperature result in the disappearance of the outer doublet at 19°C as the Sm phase crystallizes. Each of the above phase transitions appears to be completely reversible by ^2H nmr, although we have not cooled the sample to temperatures below 15°C to check the metastability of the p-phase.

A 1 mol% mixture of **5** in CCH-4 behaves similarly to the 3% sample, except that in the biphasic regions between 19 and 50°C, the intensity of the (outer) doublet assigned above to **5** in the crystal-B phase is considerably larger (compared to the residual nematic or p-phase signals) than is the case in the 3 mol% sample (32*b*).

The ^2H nmr behaviour of the C_6D_6/CCH-4 mixture is particularly interesting, and our results are summarized in Fig. 6. At temperatures between 52 and 71°C in the bulk nematic phase, each component of the original doublet is split into two signals, of intensity ratio *ca.* 1:2, within 250 Hz of each other. The origins of this splitting are not clear to us. By thermal microscopy, there is clearly only a single phase present at these temperatures, so the possibility of two solvation sites is unlikely. The size of the splitting and the relative intensities of the signals appear to be inconsistent with dipolar coupling (8*a–c*, 29), and previous ^2H nmr results for C_6D_6 in other nematic solvents (that revealed only a single quadrupolar doublet for the molecule (30)) render the possibility of restricted rotational motion about the short (D_{6h}) axis of the molecule unlikely.

As the temperature is lowered throughout the nematic phase, the doublet splittings increase in magnitude and the difference between the two decreases slightly. The two doublets finally coalesce to a singlet doublet ($\Delta\nu_Q$ = 15.5 Hz) at 51°C, and at 50°C a new doublet pattern ($\Delta\nu_Q$ = 5.4 Hz) appears in addition to that associated with the nematic phase. This inner doublet is attributed to C_6D_6 solubilized in the crystal-B phase of CCH-4. Continued cooling throughout the 50–33°C range causes the inner and outer doublet splittings to increase and decrease in magnitude, respectively. At 29°C, a third doublet splitting arises (of similar magnitude to the original inner doublet), and as the temperature is lowered to 23°C the relative intensity of the two inner doublets changes dramatically. At 21°C, the spectrum consists of a single doublet of splitting $\Delta\nu_Q$ = 11.9 kHz,

associated with C_6D_6 in the residual nematic phase. The appearance of the second inner doublet as the sample approaches 21°C may be associated with the formation of a second, monotropic smectic modification prior to crystallization to the solid phase; we have previously observed the formation of such a phase in pure CCH-4 in DSC cooling experiments (31). An alternate possibility that the spectral pattern is due to solubilization of the probe in two different environments within the crystal-B phase cannot be ruled out, however. The disappearance of the inner doublet splittings between 21–23°C is most reasonably due to the Sm–K transition, below which the polycrystalline nature of the sample precludes the observation of deuterium signals under the conditions used for these experiments. Continued cooling of the sample results in further decreases in the splitting of the remaining doublet until at *ca.* 10°C, it collapses to a singlet. This is close to the temperature reported by Fung and Gangoda for p-phase formation in 3.4 wt% solutions of benzene in CCH-4 (23). Again, it is clearly a solute-rich nematic phase that is the precursor to the p-phase.

The ^2H nmr results for the mixtures of **5** and C_6D_6 have considerable ramifications with respect to our interpretation of the various data presented above for solutions of **1**(**3**) in CCH-4. Most importantly, the relatively small solutes appear to be soluble in the crystal-B phase of CCH-4, but to a far more limited extent than might generally be appreciated. From our data for **3** and rough estimates of the relative intensities of the spectra associated with C_6D_6 and **5** in the nematic and smectic phases in the biphasic region (assuming the same proportionality between signal intensity and concentration in the two phases),[3] the solubility limits for C_6D_6, **5**, and **1** in smectic CCH-4 appear to be roughly 1–2, 0.5–0.8, and 0.2–0.4 mol%, respectively. There is an apparent trend to decreasing solubility with increasing solute size or substitution.

We have also carried out deuterium T_1 measurements on 3 mol% samples of **3** in CCH-4 and in 2:1 CCH-2/CCH-4 (EB: Sm–N, 25°C; N–I, 54°C (2, 31)) over temperature ranges of 23–110°C and 23–90°C, respectively, since it was hoped that this technique (which probes molecular motions occurring over much shorter time scales than $\Delta\nu_Q$ does — as short as 10 ps (25)) might provide information on the mobility of the ketone in CCH-4 that correlates more directly with our laser flash photolysis results for this compound. These experiments were carried out using a consecutive inversion-recovery/quadrupolar echo pulse sequence, and the results are plotted as $-\ln(T_1)$ vs. $1/T$ in Fig. 7. While there is a clear change in the slopes of both plots at the bulk N–I transition temperatures for the two liquid crystals, we are unable to identify any substantial changes in behaviour at either the bulk N–Sm or the "N–p" transition temperatures. T_1-values recorded for the **3**/CCH-4 sample at representative temperatures throughout the same range on a 33 MHz spectrometer were consistently slightly less than those measured at 76.8 MHz, but showed similar temperature dependence.

The deuterium spin–lattice relaxation time appears to be quite insensitive to changes in bulk solvent phase and composition, although our limits of uncertainty in the measurements below *ca.* 35°C are quite poor. While discontinuities at the temperatures corresponding to phase separation and p-phase formation may be revealed by more accurate T_1 determinations, it is clear that they will not be particularly pronounced. This

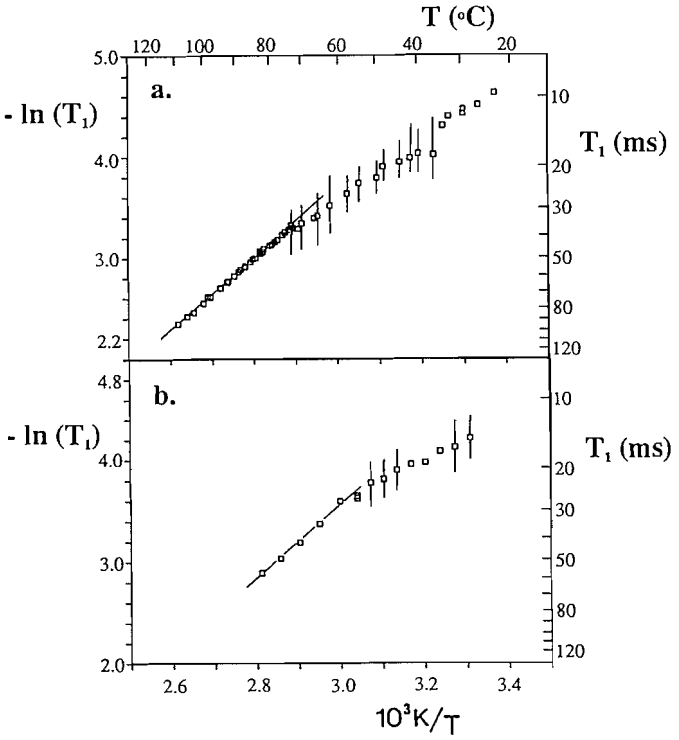

FIG. 7. Arrhenius plot showing the temperature dependence of T_1-values obtained for 3 mol% mixtures of **3** in (*a*) CCH-4 and (*b*) 2:1 CCH-2/CCH-4 (EB) between 25 and 120°C. Errors were calculated as twice the standard deviation for each point; error bars are shown only for those points with errors in excess of 10%.

behaviour is consistent with our assignment of the doublet splitting in the 35–53°C range as being due to solibilization in the nematic component of a two-phase system. Under these conditions, some difference in slope might be expected above and below 53°C, because the composition of the nematic phase is constant above this temperature and variant below it, but the difference should be small. Also, the very fast molecular reorientations that are reflected in T_1 are virtually unaffected by the transformation of the solute-rich nematic phase to the p-phase at 35°C.

The present study has very important ramifications to the interpretation of the triplet state behaviour of **1** in the liquid crystalline phases of CCH-4 (1*a*), and presumably, the behaviour of the considerable number of other solutes whose reactivity and/or normal behaviour has also been studied in this mesogen (1*b*, 2, 4*c*, 14*d*, 22, 27). It is interesting that **1** forms what appears to be a stable binary modification with CCH-4, and our experiments indicate that its composition is roughly 8–10 mol% in solute. Depending on conditions, the binary phase can be induced to form either with or without the intermediacy of the p-phase. While the morphology of the binary modification is unknown at present, it has a microscopic texture not unlike the classical mosaic texture of the Sm B phase (18*c*). We have been unable to observe ^2H nmr spectra of **3** in this phase on either the 76.8 or 41.3 MHz spectrometers, even with an 8 mol% sample. Interestingly, we have observed that the triplet lifetime of **1** in well-aged (at 20°C) samples in CCH-4 is considerably shorter than that observed when the sample is cooled slowly from the nematic phase (31). This would seem to indicate that the mobility of the probe with respect to C_α—C_β bond rotation is much higher in the binary modification than in the smectic or nematic phases. The propensity for aromatic

[3]This is not a good approximation, but it does serve to establish an upper limit for the solubility of the probe in the crystal-B phase.

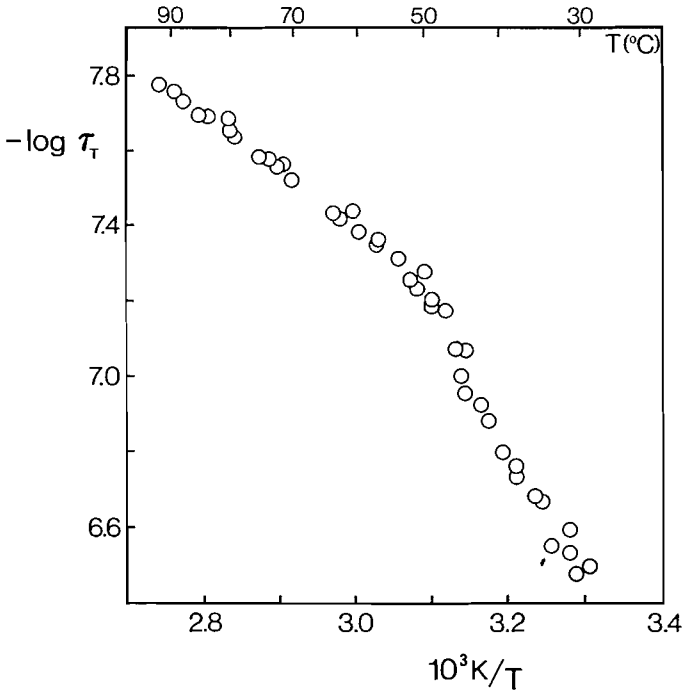

FIG. 8. Arrhenius plot showing the temperature dependence of the triplet lifetime of **1** as a 1 mol% mixture in CCH-4 (data from ref. 1*a*).

amines such as 1-aminopyrene and 1-aminofluorenone to form stable binary Sm A phases with CCH-4 (24) may provide an important clue to the identification of this binary phase.

The Arrhenius plot for the temperature dependence of the triplet lifetime of **1** as a 1 mol% mixture in CCH-4 is shown in Fig. 8 (1*a*). Clearly, the increase in the activation energy and entropy for triplet decay that is observed below the bulk N–Sm phase transition temperature *cannot* be attributed solely to the effects of solubilization of the ketone in the highly-ordered crystal-B phase of CCH-4, as was previously proposed (1). Rather, the lifetimes throughout the 53–30°C temperature range reflect a more complicated situation, since in a sample of this bulk composition, the nmr data indicate that *at least* 50% (perhaps as much as 80%) of the ketone *is excluded from the bulk crystal-B phase*. The excess solute is localized in a ketone-rich *nematic* phase whose composition varies with temperature between 35 and 53°C; below 35°C, the excess ketone is solubilized in a similarly enriched isotropic liquid or glass phase (the p-phase).

We have determined that the triplet lifetime of **1** in the nematic phase of CCH-4 is concentration-independent (between 1.0 and 10.0 mol% **1**) throughout the entire bulk nematic phase temperature range (32*a*). This rules out our initial suspicion that the increase in the Arrhenius parameters for triplet decay that occurs below the bulk Sm–N transition temperature might be due to a combination of temperature- and concentration effects on the lifetime of the ketone in the nematic phase component of the two-phase system. The ^2H nmr data shown in Fig. 2 illustrate that the continuously varying (composition-wise) nematic component of the two-phase system throughout the 53–35°C temperature range can be modelled fairly accurately by a series of bulk nematic solutions of the ketone in CCH-4. Thus, special effects on the mobility of the solute that might result in the 1 mol% sample from the intimate contact that would exist between the minor nematic component and the predominant, highly-ordered smectic component, can probably also be ruled out.

We suspect that the measured triplet lifetimes (between 30 and 53°C) in fact represent the averages of those due to ketone in the smectic phase and in the solute-rich nematic or p-phase at each temperature, in spite of the fact that at all temperatures, triplet decay appears to follow reasonably clean first-order kinetics.[4] The average would have to result from superposition of the first-order decay profiles due to ketone in the two phases in which it is solubilized; it is probably not a dynamic average caused by phase transfer equilibria, since this is expected to be much slower than the rate of triplet decay (given the very slow rate of diffusion that must characterize the highly ordered crystal-B phase (18)). Given the quality of the transient absorption data that is obtainable with such samples (1, 2), simple computer-modelling indicates that even an equally weighted sum of two independent first-order decay profiles would be difficult to distinguish from a single decay for differences of up to a factor of 3–4 in the decay rates of the two components. Extrapolation of the nematic phase portion of the plot to 35°C affords an estimate of *ca.* 90 ns for the triplet lifetime of **1** in the nematic phase at this temperature (in fact, a similar value has been measured at this temperature using EB as the nematic solvent (32*a*). Indeed, this is a factor of only *ca.* two shorter than the lifetime measured at the same temperature with the 1 mol% sample. To obtain a more accurate indication of the true effects of solubilization in the crystal-B phase on the conformational mobility of **1**, it will obviously be necessary to work with samples of much lower concentration (at or below the solubility limit) in the solute.

It is rather more difficult to estimate what is occurring below 35°C in the present case, where a *portion* of the ketone in the 1 mol% sample resides in the p-phase. Other workers have attributed solute behaviour in this temperature range to exclusive solubilization in this phase (22, 23, 27). This at least is probably not the case in the present instance, but it is impossible to distinguish whether the p-phase behaves as an isotropic or ordered phase with respect to its effects on the conformational motions that contribute to the triplet lifetime of **1**. If the p-phase is a viscous isotropic liquid, then because the Arrhenius behaviour of **1** in the nematic and isotropic phases are essentially indistinguishable (1), the Arrhenius plot below 35°C would be expected to simply continue without change from its character above this temperature. However, the same features will obtain if the p-phase affects the conformational mobility of the probe in a manner similar to the smectic phase, as Treanor and Weiss have proposed (22).

In a related study (23*b*), Gangoda and Fung ruled out the possibility that this phase could be an isotropic liquid, partly on the basis that there were no known examples of isotropic phases that exist at a *lower* temperature than the corresponding nematic phase. This is indeed a logical conclusion, provided that only two interconverting phases are involved in the transition. It is

[4]Correlation coefficients for data analysis by single-exponential, first-order decay were generally >0.99, and never less than 0.98. Nevertheless, reinspection of our data indicates that in the temperature range below 53°C, the first three or four points in the decays may deviate slightly from the least squares curve in some cases, although the deviation is not statistically significant. This may be indicative of the presence of a shorter-lived component. Occasionally, a small amount of longer-lived residual absorption occurred, but this was irreproducible and appeared to depend on sample quality (see ref. 1b).

possible though, that on cooling, a nematic phase could separate to give an isotropic liquid *and* a smectic or crystalline phase (i.e., N ⇄ Sm + I or N ⇄ K + I) (33). Our results are perfectly compatible with such behaviour, although it is difficult to obtain explicit experimental proof in the present case. Results with other systems offer a more clearcut indication that this is indeed the nature of the p-phase and the mechanism for its formation from either the nematic or smectic phases of solute/CCH-4 systems (32).

While some of the *details* or our interpretation of the temperature- and phase-dependent triplet state behaviour of **1** in the liquid crystalline phases of CCH-4 have now been defined more precisely, it is nevertheless clear that the major tenet of our original interpretation (1*a*) is correct. Solubilization in the crystal-B phase of CCH-4 *does indeed* impart dramatic inhibitory effects on the conformational mobility of **1**, compared to the situation in the more weakly ordered nematic phase or in the isotropic phase. However, the magnitude of the effect must be somewhat larger than is implied by the behaviour defined in Fig. 8 for a 1 mol% mixture. Furthermore, it seems likely that the phase-*independent* behaviour of other, differently substituted homologs of **1** in CCH-4 (and in CCH-2) (1) may result primarily from solubility factors.

Our experiments demonstrate that in mixtures of composition higher than the solubility limit of the solute in the smectic phase, the precursor to the p-phase is a solute-enriched nematic phase. In the case of **1**(**3**)/CCH-4 (and other solute/CCH-4 mixtures that we have studied (32*b*)), it is also formed in transitions involving the smectic phase, but at much lower temperatures. Furthermore, the **1**/CCH-4 p-phase is metastable, and transforms into a distinct binary smectic or solid modification. The latter can also be formed directly by rapid cooling from the nematic phase, without the intermediacy of the p-phase. This behaviour evidently does not extend to all solute/CCH-4 systems (*e.g.*, **5**/CCH-4 and benzene/CCH-4).

Given the close similarities between the ^{2}H nmr behaviour observed herein for **3** and that reported for **7** and **8** in the temperature range below 52–53°C, and the breadth of the N–Sm phase transition temperatures reported for mixtures of the latter compounds in CCH-4 (14*d*, 22), we speculate that the observed effects of this liquid crystal on the photochemistry of the latter compounds (as well as others that we have studied (2)) may in general be due to similar solubilization behaviour as that proposed above for **1**. In these cases, observed changes in ketone reactivity below 52–53°C is the result of some average between that of ketone in the smectic phase and that in a solute-enriched nematic or isotropic phase, with the relative weighting of the two contributions dependent on specific solubility limits.

Several questions remain to be answered with respect to the reactivity and conformational mobility of solutes in this liquid crystal and its homologs, and several new ones have arisen. The propensity of CCH-4 to form stable, solute-enriched binary smectic phases has now been demonstrated with three solutes (24) of very different structures, but the generality of these observations to other solute/CCH-4 systems remains to be determined. It is not clear how much information is available on the effects of these binary phases (or related ones) on the reactivity or conformational mobility of solutes relative to that in the nematic or smectic phase. Furthermore, we have yet to explain the reasons for the extraordinary substituent effects observed for the triplet state behaviour of **2** in this solvent (1); presumably, these effects are governed by similar solubilization phenomena to those observed with **1**. Experiments directed towards answering some of these questions are currently in progress.

Experimental

β-Phenyl-4-methoxypropriophenone (**1**) and β-(4-cyclohexylphenyl)-4-methoxypropriophenone were prepared in an earlier study (1) and had melting points of 96–97°C and 89–90°C, respectively. 4-Methoxyacetophenone (Aldrich Chemical Co.), benzene-d_6 (99.8% atom-*d*; MSD Isotopes), dichloromethane (Caledon HPLC), CCH-4, and CCH-2 (E. Merck) were all used as received from the suppliers.

β-Phenyl-4-methoxypropiophenone-α,α-d_2 (**3**), 4-methoxyacetophenone-α,α,α-d_3 (**5**), and β-(4-cyclohexylphenyl)-4-methoxypropiophenone-α,α-d_2 (**6**) were prepared from their protio-analogues by base-catalysed deuterium exchange. Typically, 1 g of the ketone was refluxed in a mixture of sodium hydroxide (1 g), dioxane (125 mL), and deuterium oxide (99.8% atom D; 5–10 mL) for 12–18 h. The resulting mixture was cooled to room temperature and extracted a few times with ether. After washing once with water, the combined ether extracts were dried over anhydrous sodium sulphate, filtered, and the solvent was evaporated on the rotary evaporator. The deuterated ketones were recrystallized two or three times from ethanol or ethanol/water and had melting points as follows: **3**, 95.5–97°C; **5**, 35.5–37.5°C; **6**, 89–90.5°C. Their ^{1}H nmr spectra (Varian EM390; chloroform-*d*) confirmed them to be >95% deuterated in the α-position in each case.

β-(4-Deuteriophenyl)-4-methoxypropiophenone (**4**) was prepared from 4-deuteriobenzaldehyde by the published route for **1** (21*e*). Benzaldehyde-4-*d* was prepared by D_2O/THF quenching of the aryllithium prepared from 4-bromo-(2-(1,3-dioxacyclopentyl)benzene and *n*-butyl lithium (in anhydrous tetrahydrofuran at −78°C), followed by hydrolysis of the acetal with 5% aqueous hydrochloric acid (30 mL) in THF (70 mL) under a nitrogen atmosphere. After isolation and three recrystallizations from ethanol/water, ketone **4** had a melting point of 96–97°C, and exhibited the following ^{1}H nmr spectrum (EM390; $CDCl_3$ *vs.* TMS): δ(ppm) = 3.14 (m, 4H), 3.83 (s, 3H), 6.90 (d, 2H), 7.30 (s, 4H), 7.93 (d, 2H). The high resolution ^{2}H nmr spectrum (76.8 MHz; in $CHCl_3$ with external $CDCl_3$ reference) for this compound showed a single resonance at 7.30 ppm.

Except where otherwise noted, ^{2}H nmr experiments were carried out at 76.78 MHz on a Bruker AM500 NMR spectrometer equipped with an Aspect 3000 computer, a Bruker BVT-100 Variable Temperature Unit, and a 10 mm VSP broadband probe. Temperatures were controllable to within ±1°, and were recorded with a copper–constantan thermocouple. Samples were prepared in 5 mm nmr tubes by adding the appropriate amounts of solute and liquid crystal and heating to the isotropic phase to ensure complete sample mixing. The sample and probe were allowed to equilibrate at each temperature for as long as was necessary to obtain reproducible spectra; this was generally 5–20 min for the samples containing ≤5 mol% solute, but extended to up to a few hours for those containing higher concentrations of **3**, particularly at temperatures below 45°C.

Deuterium nmr spectra were recorded on stationary samples using the quadrupolar echo pulse sequence (26), generally collecting 8–32K data points per scan over a 40–165 kHz sweep width. Typically, 96–512 such scans were collected and averaged (with a 0.2–0.8 s delay between scans, depending on sample temperature). The π/2 pulse width is *ca.* 27–30 μs on this instrument. The data were processed using 40–150 Hz line-broadening and exponential multiplication prior to obtaining the Fourier transform. At a given temperature, both the line-width and the observed splitting are approximately independent of the pulse sequence used (quadrupolar echo or single pulse) or whether the sample is spun or not.

A few experiments (mostly controls) were carried out at 41.3 MHz on a home-built spectrometer at the University of Guelph with assistance from Dr. K. H. Jeffrey. Samples were sealed under vacuum in 9 × 25 mm Pyrex tubes, and thereafter handled similarly to those

described above. The spectrometer has been described in detail elsewhere (34).

Deuterium T_1 measurements summarized in Fig. 7 for 3 mol% samples of **3** in CCH-4 and EB between 15–108°C were carried out on the Bruker AM500, and employed a $\pi-\tau-\pi/2$ or $\pi/2-\tau-\pi/2$ (for T_1 values less than 20 ms) non-selective inversion-recovery pulse sequence, followed by the quadrupolar echo. Typically, T_1 values were calculated from least squares analysis of data from 8–12 τ values. Errors were calculated as two standard deviations by a statistical method (35), and ranged from *ca.* 1–2% for values >50 ms to *ca.* 20% for those less than 15 ms. Error bars are included in the plot in Fig. 7 for those data with associated errors ≥ 10%.

T_1-values at a few representative temperatures in the 77–123°C range were measured on a Bruker AC200 NMR spectrometer equipped with a 10 mm broadband probe, with the assistance of Dr. C. Rodger (Bruker Canada). These values are not reported, but were consistently *ca.* 10% smaller than those measured on the AM500, and showed a similar variation with temperature.

DSC experiments employed a Setaram DSC-111 differential scanning calorimeter, interfaced to a Hewlett-Packard HP85 microcomputer. Samples (30–35 mg) of **1** in CCH-4 were prepared in aluminum crucibles after combining the appropriate amounts of CCH-4 and the ketone (as aliquots of a standard solution in dichloromethane), dissolving the mixture in *ca.* 5 mL dichloromethane, evaporating the solvent on the rotary evaporator, and finally pumping on the mixture under high vacuum (*ca.* 10^{-4} Torr) for 1–2 h. Heating and cooling scans (2°/min) were carried out at least twice for each sample between −10 and 90°C, in order to ensure reproducibility.

Thermal microscopy experiments were carried out with a Reichert Hot-Stage microscope fitted with polarizing filters and a glass thermometer. Transition temperatures are corrected. Samples were prepared in similar fashion to those for DSC experiments, and were contained on glass slides under a cover slip. Heating and cooling scans were carried out repetitively for each sample. Our observations are described in detail below.

Rapid cooling of samples containing 0.5 ≤ **1** ≤ 5 mol% to 23°C from the nematic phase yields a fairly uniform mosaic texture similar in appearance to that of the Sm phase of pure CCH-4 (18*c*). Heating the sample reveals a bulk K–Sm transition at 28–30°C, the development of fluid imperfections at 43–44°C, slow dissolution of the bulk smectic phase from 44–51°C, and finally a fairly abrupt transition of residual smectic phase to nematic at 51–53°C.

Compound **1** is uniformly soluble in the nematic phase of CCH-4 up to a concentration of ca. 20 mol%; in mixtures of higher concentration of **1**, the ketone crystallizes out of the nematic solution. For the mixtures containing ≤20 mol% **1**, the N–I transition is completely reversible (i.e. not "supercoolable"), but is lowered and broadened as [**1**] increases. The behaviour of the mixtures at lower temperatures (below the N–Sm transition of pure CCH-4), particularly the heating behaviour, depends strongly on the rate at which the sample is cooled to room temperature from the nematic phase, as well as the period of time for which the sample is allowed to equilibrate at room temperature. Slow (≤3°/min) cooling of *any* of the samples from the nematic phase results in the initial appearance of smectic monodomains interspersed in residual nematic phase. The appearance of the smectic phase is initially rapid (probably due to supercooling), but then slows down with further decreases in temperature. In the samples containing >2 mol% **1**, the smectic phase initially appears as serrated stars that gradually enlarge, leaving the nematic phase localized between the serrations. As sample cooling is continued, the proportion of smectic phase increases at the expense of the residual nematic phase. At 33–35°C, the latter transforms to an optically isotropic phase (the so-called "p-phase") which appears to be stable down to (at least) room temperature for short periods of time. Reheating these samples results in the reverse of their cooling behaviour. This initially rapid and then more gradual separation of smectic phase from nematic is readily discernible in the DSC traces shown in Fig. 2*a* as an incomplete return to baseline after the initial Sm–N endotherm. Complete formation of the smectic phase is, in all cases, arrested by transformation of residual nematic phase at 35°C to the "p-phase".

Allowing the samples to equilibrate at room temperature for extended periods of time (up to 2–3 days; the time is proportional to the bulk concentration of **1**) results in contraction of the isotropic fraction to yield (what appear to be) crystallites dispersed throughout the sample. This behaviour is observed for *all* compositions between 0.5 and 10 mol% **1**, but is especially pronounced in the samples containing >2 mol% **1**. Heating these samples results in a solid-smectic (K–Sm) transition involving the bulk monodomains at 28–30°C, a sharp transition at 43.5–44°C involving transformation of the "crystallites" to a nematic phase dispersed among the smectic monodomains, slow expansion of the nematic droplets as the temperature is increased further, and finally another relatively sharp transformation of the bulk residual smectic phase to nematic at 51–53.5°C.

Rapid cooling of the 10 mol% sample to 23°C affords a uniform, striated mosaic texture. The sample undergoes a K–K or K–Sm transition at 27–28°C, in which the striations disappear to leave a homogeneous, fine mosaic texture. Heating the sample further results in a single, sharp transition to an uniform nematic phase at 43.7–44°C, followed by a broad N–I transition at 58.5–63°C.

Samples containing 10 < [**1**] ≤ 15 mol% undergo phase separation and "p-phase" formation upon slow cooling as well, but the samples gradually reorganize to form a mixture of crystalline solid (presumably fairly pure **1**) and the binary mixture below 43°C. Samples containing > 15 mol% **1** undergo slow solidification without prior phase separation or p-phase formation, independent of cooling rate.

Acknowledgments

We are indebted to a number of people for lending their advice, expertise, and equipment for these studies, and making our introduction to nmr spectroscopy in ordered media a relatively painless one. We thank Dr. K. H. Jeffrey (University of Guelph) for graciously allowing us the use of his NMR spectrometer, giving generously of his time and expertise helping us operate it, and for enlightening discussions. We are especially grateful to Dr. A. D. Bain (McMaster University), who provided many helpful discussions and considerable assistance with the T_1 measurements. Dr. C. Rodger (Bruker Canada) is also gratefully acknowledged for making the Bruker AC200 spectrometer available to us and helping us with its operation. We also thank Dr. D. Hughes and Mr. B. Sayer (McMaster University) for technical assistance, and E. Merck (Darmstadt) for generous gifts of CCH-2 and CCH-4. Finally, the financial support of the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

Bifunctional reagents in organic synthesis. Total syntheses of the sesquiterpenoids (±)-pentalenene and (±)-9-*epi*-pentalenene

EDWARD PIERS AND VERANJA KARUNARATNE

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received July 28, 1988

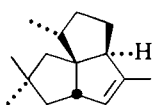
EDWARD PIERS and VERANJA KARUNARATNE. Can. J. Chem. **67**, 160 (1989).

Transformation of the readily available keto acetal **14** into the enone **23** was accomplished via a seven-step sequence of reactions. Reaction of **23** with the bifunctional Grignard reagent **5** in the presence of copper(I) bromide – dimethyl sulfide, followed by intramolecular alkylation of the resultant chloro ketone **24**, gave the tetracyclic ketone **25**. Treatment of **25** with hydrogen in the presence of platinum afforded a mixture of the ketones **27** and **28** (42:58, respectively), which was transformed into a separable mixture of (±)-pentalenene (**1**) (32%) and (±)-9-*epi*-pentalenene (**30**) (33%).

Key words: ±-pentalenene synthesis, ±-9-*epi*-pentalenene synthesis, sesquiterpenoid synthesis, methylenecyclopentane annulation, bifunctional reagents, triquinane synthesis.

EDWARD PIERS et VERANJA KARUNARATNE. Can. J. Chem. **67**, 160 (1989).

Faisant appel à une série de sept réactions, on a réalisé la transformation du céto-acétal **14**, qui est facilement accessible, en énone **23**. La réaction du composé **23** avec le réactif de Grignard bifonctionnel **5** en présence de bromure de cuivre(I) – sulfure de diméthyle, suivie d'une alkylation intramoleculaire de la chloro-cétone **24** qui en résulte, conduit à la cétone tétracyclique **25**. Le traitement du composé **25** par de l'hydrogène en présence de platine fournit un mélange des cétones **27** et **28** (dans une proportion de 42:58) qui a été transformé en un mélange de (±)-pentalènène (**1**) (32%) et de (±)-*épi*-9 pentalènène (**30**) (33%) que l'on peut séparer.



Mots clés: synthèse de ±-pentalènène, synthèse de ±-*epi*-9 pentalènène, synthèse sesquiterpénique, annelation de méthylènecyclopentane, réactifs bifonctionnels, synthèse de triquinane.

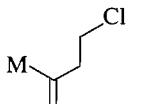
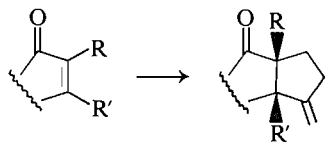
Introduction

The angularly fused triquinane (+)-pentalenene (**1**), isolated from *Streptomyces griseochromogenes* (1), is the parent hydrocarbon of the pentalenolactone family of sesquiterpenoid antibiotics. In fact, by carrying out appropriate feeding experiments with a culture of *Streptomyces* UC5319, Cane and Tillman (2) have shown that **1** is a biosynthetic precursor of (−)-pentalenolactone (**2**) and related substances. Since the absolute stereochemistry of (−)-**2** has been established (3), (+)-pentalenene is (1*S*,4*S*,8*R*,9*R*)-2,6,6,9-tetramethyltricyclo-[6.3.0.0^{4,8}]undec-2-ene (**1**).

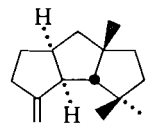


1



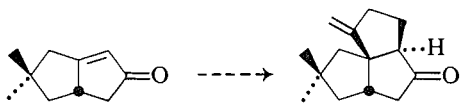
2

It is not particularly surprising that pentalenene (**1**) has attracted considerable attention within the community of synthetic organic chemists. Indeed, a considerable number of total syntheses of (±)-**1**, via notably diverse strategies, have been reported (4–11), while, recently, Hua described (12) an interesting enantioselective synthesis of (+)-**1**.



Recently, we reported that 4-chloro-2-trimethylstannyl-1-butene (**3**), upon transmetalation with methyllithium in tetrahydrofuran (THF) at −78°C, is transformed into the synthetically useful bifunctional reagent 4-chloro-2-lithio-1-butene (**4**) (13*a*,*d*). Furthermore, the latter species can readily be converted into the corresponding Grignard reagent **5** (13*c*,*d*) or the cuprates **6** and **7** (13*b*,*d*). Significantly, **5**–**7** serve as very useful conjunctive reagents for effecting methylenecyclopentane annulation sequences that can be represented in general terms by the conversion **8** → **9** (13*b*–*d*). Indeed, a total synthesis of the linearly fused triquinane sesquiterpenoid (±)-capnellene (**10**)

3 M = $SnMe_3$ **6** M = CuSPh(Li)
4 M = Li **7** M = CuCN(Li)
5 M = MgBr



8 **9**

10

was achieved via a route in which both of the "outside" five-membered rings were added to the central ring by means of this type of transformation (13*c*,*d*).

An examination of the structure of pentalenene (**1**) readily reveals that a total synthesis of this substance might be accomplished via a route in which the above-mentioned annulation method would play a key role. Explicitly, methylenecyclopentane annulation of the bicyclic enone **11** would proceed in the desired stereochemical sense (13*b*,*d*) and, if successful, would provide the tricyclic ketone **12**. Presumably, the latter substance would serve as a suitable synthetic precursor of (±)-pentalenene

11 **12**

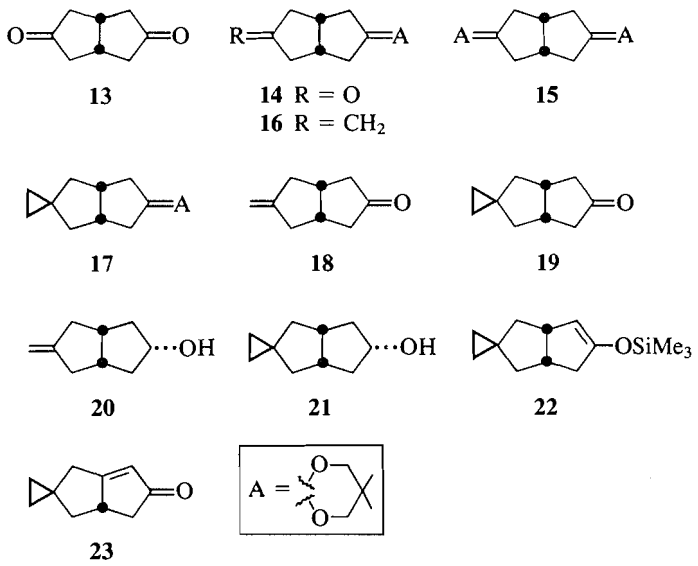


CHART 1

(**1**). We describe in this paper the details of a total synthesis of (±)-**1**, which is based on this synthetic plan.[1]

Results and discussion

(a) Preparation of the tricyclic enone 23

The starting material for our synthesis was the readily available *cis*-bicyclo[3.3.0]octane-3,7-dione (**13**) (15) (see Chart 1). Treatment of this substance with one equivalent of 2,2-dimethyl-1,3-propanediol in hot benzene containing *p*-toluenesulfonic acid provided an equilibrium mixture of the starting material **13**, the keto acetal **14**, and the bisacetal **15** (ratio 1:2:1, respectively). Fortunately, these compounds were readily separable by column chromatography. Furthermore, the dione **13** and the bisacetal **15** could be recycled and, after two such operations, the desired keto acetal **14** was obtained in 79% yield.

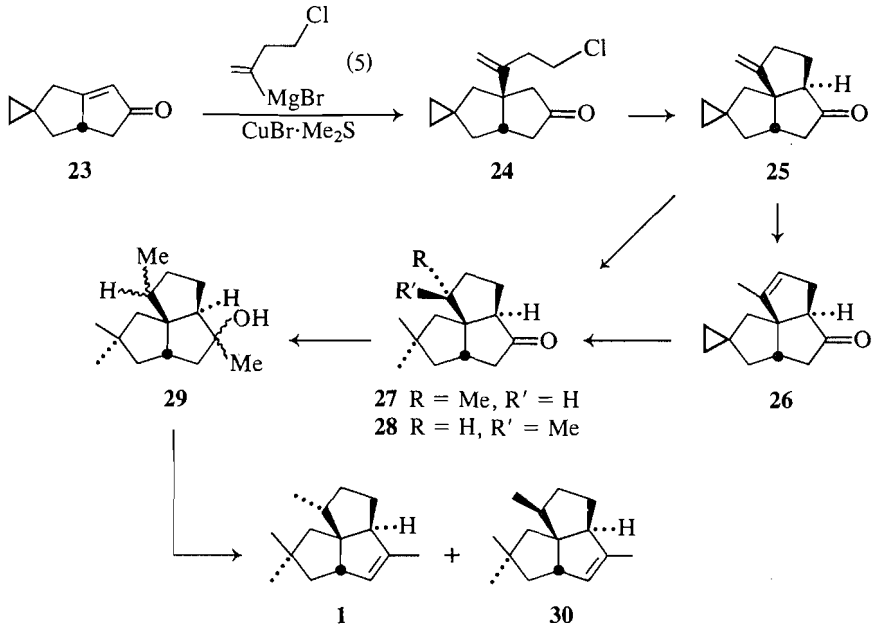
Treatment of **14** with methylenetriphenylphosphorane in THF provided the alkene **16** (84%). Attempted cyclopropanation of this material with diethylzinc–diiodomethane (16) gave a mixture of products from which the desired material **17** could be obtained in only poor yield (<25%). Although mild acid hydrolysis of **16** gave the keto alkene **18** in excellent yield, cyclopropanation (16) of the latter substance also proved to be problematic. At best, the tricyclic ketone **19** was produced in only 30% yield. Consequently, the ketone function in **18** was reduced ($LiAlH_4$) and the required cyclopropanation reaction (16) was carried out on the resultant alkene alcohol **20**. In this case, the carbenoid reaction proceeded smoothly and the tricyclic alcohol **21** was obtained in 76% yield from **18**. At this stage, it would undoubtedly have been possible to effect hydrogenolysis of the cyclopropyl ring. However, a future (envisaged) step of the synthetic sequence involved hydrogenation of a carbon–carbon double bond and, therefore, it was decided to retain the cyclopropane ring to that stage of the synthesis and then carry out the two reductive transformations in one operation.

Oxidation of the alcohol **21** with pyridinium chlorochromate (17) gave the ketone **19** in 87% yield. The method of Saegusa and co-workers (18) was employed to effect conversion of **19** into the corresponding enone **23**. Thus, reaction of **19** with freshly prepared iodotrimethylsilane (19) in cold (−78°C) dichloromethane containing triethylamine afforded the enol silyl ether **22**. The latter substance, upon treatment with palladium(II) acetate in acetonitrile (18), provided the required enone **23** (73% from **19**). The stage was thus set to carry out the key methylenecyclopentane annulation sequence.

(b) Conversion of the enone 23 into (±)-pentalenene (1) and (±)-9-epi-pentalenene (30)

Conjugate addition of the 2-(4-chloro-1-butenyl) group to the enone **23** was effected by reaction (THF, −78°C) of this material with the Grignard reagent **5** (13*c*,*d*) in the presence of copper(I) bromide – dimethyl sulfide complex (Scheme 1). The product **24**, upon treatment with potassium hydride in THF, cyclized smoothly to the tetracyclic annulation product **25** (66% from **23**).

Reaction of the intermediate **25** with hydrogen (3 atmospheres pressure; 1 atm = 101.3 kPa) in the presence of platinum in acetic acid resulted in hydrogenation of the alkene function and hydrogenolysis of the cyclopropane ring. Unfortunately, analysis (glc) of the product showed that it consisted of a mixture of the epimers **27** and **28**, in a ratio of 42:58, respectively. Attempts to increase the relative amount of the desired isomer **27** by use of other hydrogenation conditions proved to be fruitless. For example, hydrogenation of **25** in the presence of palladium-on-carbon in hexane effected only reduction of the alkene function. Subsequent hydrogenolysis (hydrogen, platinum) of the cyclopropane ring afforded **27** and **28** in a ratio of 22:78, respectively.



Upon treatment with *p*-toluenesulfonic acid in dichloromethane, compound **25** was converted cleanly into the endocyclic alkene **26**. Interestingly, however, hydrogenation–hydrogenolysis of the latter substance provided (80%) a 5:95 mixture of **27** and **28**, respectively.

In an earlier study (5) culminating in a synthesis of (±)-pentalenene (1), it was shown that conjugate addition of lithium dimethylcuprate to the enone **31** was completely stereoselective, providing the tricyclic ketone **33** in excellent yield. On the other hand, reaction of the enone **32** with triethylsilane – tris(triphenylphosphine)rhodium chloride afforded a mixture of the epimers **33** and **34** in a ratio of 2.24:1, respectively. Thus, interestingly, the cuprate delivers a methyl group exclusively to the concave (*endo*) face of the enone **31**, while, in the hydrosilylation reaction, the reagent transfers a proton primarily to the convex (*exo*) face of **32**. These findings, taken in conjunction with our hydrogenation results involving compounds **25** and **26**, demonstrate the difficulty associated with predicting the stereochemistry of (some) reactions of functionalized tricyclo[6.3.0.$0^{4,8}$]undecanes.

Since compounds **27** and **28** proved to be very difficult to separate by column chromatography, the 42:58 mixture of these substances was treated with methyllithium in THF. The product of this reaction consisted of a mixture of the starting materials (40%) and the desired alcohols **29** (60%). That the reaction had not proceeded to completion was undoubtedly due to the fact that proton transfer (enolate anion formation) was in competition with the desired nucleophilic addition reaction. Therefore, the product mixture was treated again with methyllithium and, after the recycling procedure had been carried out twice, the isolated material consisted of **27** and **28** (ratio 1:17, respectively) (18%) and the alcohols **29** (82%). Treatment of this mixture with *p*-toluenesulfonic acid in hot benzene, followed by chromatography of the resultant material on silver nitrate-

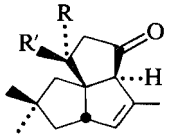

SCHEME 1

impregnated silica gel, afforded (±)-9-*epi*-pentalenene (**30**) (33%) and (±)-pentalenene (**1**) (32%). Our synthetic (±)-**1** exhibited spectra identical with those of the same material previously prepared by Paquette and Annis (5).[2]

When a 5:95 mixture of **27** and **28**, obtained by hydrogenation–hydrogenolysis of **26** (*vide supra*), was subjected to a sequence of operations identical with that described above, (±)-9-*epi*-pentalenene (**30**) was obtained in 68% yield.

Experimental

General information

Melting points and distillation temperatures, which refer to short-path (Kugelrohr) distillations, are uncorrected. Infrared (ir) spectra were recorded on a Perkin–Elmer model 710B spectrophotometer and were calibrated using the 1601 cm^{-1} band of a polystyrene film. Proton (^1H) and carbon (^{13}C) nuclear magnetic resonance (nmr) spectra were recorded on $CDCl_3$ solutions. Signal positions are given in ppm (δ) relative to Me_4Si. High resolution mass spectra were recorded with Kratos/AEI MS 50 or MS 902 spectrometers. Gas–liquid chromatography (glc) was accomplished with a Hewlett–Packard model 5880 gas chromatograph equipped with a 25 m × 0.21 m fused silica column coated with cross-linked SE-54. Thin-layer chromatography (tlc) was carried out on commercial silica gel plates (Eastman Chromatogram Sheet, Type 13181 or E. Merck, Type 5554). Conventional and flash (20) column chromatography were done on 70–230 and 230–400 mesh silica gel (E. Merck), respectively. Reagents and solvents were purified and dried using standard methods. NOTE: All compounds for which high resolution mass measurements are given exhibited one spot on tlc analysis and, except for the mixture of **27** and **28**, essentially one peak on glc analysis.

Preparation of the keto acetal ***14***[3]

A stirred mixture of *cis*-bicyclo[3.3.0]octane-3,7-dione (**13**) (70 g, 0.51 mol), 2,2-dimethyl-1,3-propanediol (53 g, 0.51 mmol), *p*-toluenesulfonic acid (0.5 g), and benzene (500 mL) was refluxed for 2 h under a Dean–Stark water trap. The solution was cooled, diluted with diethyl ether (500 mL), washed successively with 10% aqueous sodium hydroxide, water, and brine, dried ($MgSO_4$), and concentrated. Analysis (glc) of the resultant white semisolid showed that it consisted of a 1:2:1 mixture of the diketone **13**, the keto acetal **14**, and the bisacetal **15**. A solution of this material in 140 mL of 3:2:1 petroleum ether – ethyl acetate – dichloromethane was added to a column of silica gel (300 g). Elution of the column with 2:1 petroleum ether – ethyl acetate removed a mixture of **14** and **15**, while elution with ethyl acetate provided 16.4 g of the dione **13**. The mixture of **14** and **15**, dissolved in 100 mL of 3:2:1 petroleum ether – ethyl acetate – dichloromethane, was added to a column of silica gel (1500 g) and the column was eluted with 3:1 petroleum ether – diethyl ether. Concentration of the appropriate fractions provided 53.4 g of the keto acetal **14** and 36.9 g of the bisacetal **15**, both as crystalline white solids.

A stirred solution of the dione **13** (16.4 g) and the bisacetal **15** (36.9 g), obtained from the above reaction, in 250 mL of dry benzene containing 250 mg of *p*-toluenesulfonic acid was refluxed for 1 h. Work-up and purification of the crude product as described above gave 7.6 g of the dione **13**, 24.7 g of the keto acetal **14**, and 17.1 g of the bisacetal **15**. The recovered **13** and **15** were equilibrated again and chromatographic separation provided **13** (3.5 g), **14** (11.3 g), and **15** (7.8 g). Thus, the total of the desired keto acetal **14** was 89.4 g (79%).

The keto acetal **14** exhibited mp 48°C (from heptane); ir ($CHCl_3$): 1730, 1110 cm^{-1}; ^1H nmr (400 MHz) δ: 0.97 (s, 6H), 1.82 (dd, 2H, J = 14, 5 Hz), 2.17 (dd, 2H, J = 19, 4.5 Hz), 2.29 (dd, 2H, J = 14, 9 Hz), 2.46 (dd, 2H, J = 19, 10 Hz), 2.28 (m, 2H), 3.44, 3.47 (s, s, 2H each). *Anal.* calcd. for $C_{13}H_{20}O_3$: C 69.61, H 8.99; found: C 69.55, H 8.85. *Exact Mass* calcd.: 224.1413; found: 224.1416.

The bisacetal **15** exhibited mp 140–142°C (from ethanol or methanol); ir ($CHCl_3$): 1210 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95 (s, 12H), 1.72 (dd, 4H, J = 13, 6 Hz), 2.21 (dd, 4H, J = 13, 9 Hz), 2.55 (m, 2H), 3.45, 3.46 (s, s, 4H each). *Anal.* calcd. for $C_{18}H_{30}O_4$: C 69.64, H 9.74; found: C 69.94, H 9.70. *Exact Mass* calcd.: 310.2145; found: 310.2146.

[2]We are very grateful to Professor L. A. Paquette for his assistance in making this comparison possible.

[3]This experiment was carried out by Dr. Neil Moss. We are very grateful to Dr. Moss for providing us with a generous supply of the keto acetal **14**.

*Preparation of the alkene acetal **16***

To a cold (−78°C), stirred solution of methylenetriphenylphosphorane (11.6 mmol) in 10 mL of dry THF (argon atmosphere) was added a solution of the keto acetal **14** (2.0 g, 8.9 mmol) in 5 mL of dry THF. The solution was allowed to warm to room temperature and then was stirred for 3 h. Petroleum ether (40 mL) was added and the resultant suspension was filtered through a column of Florisil (20 g, elution with diethyl ether). Concentration of the eluate and distillation (105–110°C/10 Torr (1 Torr = 133.3 Pa)) of the residual oil afforded 1.66 g (84%) of the alkene **16** as a clear, colorless oil, which exhibited ir (neat): 3050, 1647, 1115, 895 cm^{-1}; ^1H nmr (400 MHz) δ: 0.96 (s, 6H), 1.50 (dd, 2H, J = 12, 6 Hz), 2.06 (br d, 2H, J = 14 Hz), 2.30 (dd, 2H, J = 12, 8 Hz), 2.42–2.60 (m, 4H), 3.44, 3.48 (s, s, 2H each), 4.81 (t, 2H, J = 2 Hz). *Exact Mass* calcd. for $C_{14}H_{22}O_2$: 222.1619; found: 222.1617.

*Preparation of the keto alkene **18***

A mixture of the alkene acetal **16** (1.8 g, 8.1 mmol), acetone (15 mL), and 0.1% aqueous sulfuric acid (15 mL) was stirred at room temperature under an argon atmosphere for 8 h. Saturated aqueous sodium bicarbonate (5 mL) and diethyl ether (25 mL) were added and the mixture was stirred vigorously for 5 min. The phases were separated and the aqueous layer was extracted twice with diethyl ether. The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Column chromatography of the residue on silica gel (75 g, elution with 2:1 petroleum ether – diethyl ether) and distillation (75–80°C/10 Torr) of the oil thus obtained provided 0.94 g (82%) of the keto alkene **18**, a colorless oil that exhibited ir (neat): 3045, 1710, 1640, 1415, 1400, 1160, 1140 cm^{-1}; ^1H nmr (400 mHz) δ: 2.05 (dd, 2H, J = 19, 4 Hz), 2.14 (br dd, 2H, J = 16, 2 Hz), 2.40 (dd, 2H, J = 19, 8 Hz), 2.58–2.71 (m, 2H), 2.71–2.85 (m, 2H), 4.89 (t, 2H, J = 2 Hz); ^{13}C nmr (20 MHz) δ: 39.37, 39.52, 43.49, 107.59, 151.53, 221.16. *Exact Mass* calcd. for $C_9H_{12}O$: 136.0888; found: 136.0883.

*Preparation of the alkene alcohol **20***

To a cold (−78°C), stirred solution–suspension of lithium aluminum hydride (118 mg, 3.1 mmol) in 12 mL of dry diethyl ether was added a solution of the keto alkene **18** (0.85 g, 6.25 mmol) in 3 mL of dry diethyl ether and the mixture was stirred for 1.5 h. Saturated aqueous ammonium chloride (2 mL) and diethyl ether (15 mL) were added and the mixture was allowed to warm to room temperature. The white slurry was filtered through a column of Florisil (20 g, elution with diethyl ether). The eluate was dried ($MgSO_4$) and concentrated. Distillation (78–82°C/10 Torr) of the residual oil afforded 0.82 g (94%) of the alcohol **20**, a colorless oil that showed one peak on glc analysis and exhibited ir (neat): 3300, 3050, 1645, 1100, 895 cm^{-1}; ^1H nmr (80 MHz) δ: 1.02–1.45 (m, 3H), 1.90–2.70 (m, 8H), 4.12 (quintet, 1H, J = 6 Hz), 4.83 (br s, 2H). *Exact Mass* calcd. for $C_9H_{14}O$: 138.1045; found: 138.1042.

*Preparation of the tricyclic alcohol **21***

To a well-stirred, warm (55°C) solution of the alkene alcohol **20** (0.6 g, 4.3 mmol) in 2 mL of dry toluene was added successively 4.79 mL (5.85 mmol) of a solution of diethylzinc in toluene (15% w/v) and 0.488 mL (5.85 mmol) of diiodomethane. Dry air was slowly passed through the mixture for 1.5 h while the temperature was maintained at 55°C. The mixture was cooled, 5% hydrochloric acid (4 mL) was added, and the layers were separated. The aqueous phase was washed twice with diethyl ether (10 mL). The combined organic phases were washed twice with 5% hydrochloric acid (3 mL) and once with brine and then were dried ($MgSO_4$) and concentrated. The remaining oil was chromatographed on silica gel (45 g, elution with 3:2 petroleum ether – diethyl ether) and the oil thus obtained was distilled (80–84°C/10 Torr) to provide 0.535 g (81%) of the tricyclic alcohol **21**, a colorless oil that exhibited ir (neat):' 3300, 3050, 1084, 1100 cm^{-1}; ^1H nmr (100 MHz) δ: 0.18–0.64 (m, 4H), 1.14–2.65 (series of m, 11H), 4.15 (m, 1H). *Exact Mass* calcd. for $C_{10}H_{16}O$: 152.1201; found: 152.1193.

*Preparation of the tricyclic ketone **19***

To a stirred slurry of pyridinium chlorochromate (1.03 g, 4.8 mmol) and sodium acetate (65 mg, 0.8 mmol) in 10 mL of dry dichloromethane was added a solution of the alcohol **21** (0.5 g, 3.3 mmol) in 2 mL of dry dichloromethane. The mixture was stirred at room temperature for 2 h. Diethyl ether (15 mL) was added and the mixture was filtered through a column of Florisil (10 g, elution with diethyl ether). Concentration of the eluate and distillation (80–85°C/10 Torr) of the remaining oil gave 0.429 g (87%) of the tricyclic ketone **19**, a colorless oil that exhibited ir (neat): 3047, 1725, 1400, 1165, 1010 cm^{-1}; ^1H nmr (400 MHz) δ: 0.38–0.47, 0.47–0.55 (m, m, 2H each), 2.31 (dd, 2H, J = 14, 4 Hz), 1.92 (dd, 2H, J = 14, 8 Hz), 2.16 (dd, 2H, J = 19, 4 Hz), 2.48 (dd, 2H, J = 19, 8 Hz), 2.87 (m, 2H). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1045; found: 150.1042.

*Preparation of the enone **23***

To a cold (−78°C), stirred solution of the ketone **19** (0.4 g, 2.6 mmol) and dry triethylamine (2.2 mL, 15.9 mmol) in 15 mL of dry dichloromethane (argon atmosphere) was added, dropwise, 2.92 mL (14.3 mmol) of freshly prepared iodotrimethylsilane. The resulting orange slurry was stirred at −78°C for 15 min. Saturated aqueous sodium bicarbonate (4 mL) was added and the mixture was allowed to warm to room temperature. The phases were separated and the aqueous layer was washed three times with diethyl ether (10 mL). The combined extracts were dried ($MgSO_4$) and concentrated to afford the enol silyl ether **22** as a yellow oil. This material was dissolved in 10 mL of dry acetonitrile (argon atmosphere), palladium(II) acetate (0.873 g, 3.9 mmol) was added, and the solution was stirred at room temperature for 3 h. The mixture was filtered through a short column of silica gel (10 g, thorough elution with diethyl ether). Concentration of the eluate provided a viscous brown oil, which was chromatographed on silica gel (45 g, elution with 3:2 diethyl ether – petroleum ether). Distillation (83–87°C/10 Torr) of the oil thus obtained gave 0.288 g (73%) of the tricyclic enone **23**, a colorless oil that exhibited ir (neat): 3025, 1690, 1620 cm^{-1}; ^1H nmr (400 MHz) δ: 0.55–0.69 (m, 4H), 1.55–1.68 (m, 2H), 2.19 (dd, 1H, J = 18, 4 Hz), 2.44, 2.74 (br d, br d, 1H each, J = 18 Hz in each case), 2.61 (dd, 1H, J = 18, 6 Hz), 3.29 (m, 1H), 6.17 (m, 1H). *Exact Mass* calcd. for $C_{10}H_{12}O$: 148.0888; found: 148.0893.

*Preparation of the chloro ketone **24***

To a cold (−78°C), stirred solution of 4-chloro-2-trimethylstannyl-1-butene (**3**) (0.48 g, 1.9 mmol) in 10 mL of dry THF (argon atmosphere) was added a solution of methyllithium (2.1 mmol) in diethyl ether and the solution was stirred at −78°C for 5 min. Anhydrous magnesium bromide (386 mg, 2.1 mmol) was added and the mixture was stirred at −78°C for 15 min. Copper(I) bromide – diethyl sulfide complex (110 mg, 0.54 mmol) and the tricyclic enone **23** (0.25 g, 1.6 mmol) were added successively and the deep yellow solution was stirred at −78°C for 1.5 h. Saturated aqueous ammonium chloride – ammonium hydroxide (pH 8) (5 mL) and diethyl ether (30 mL) were added and the vigorously stirred mixture was allowed to warm to room temperature. Stirring was maintained until the aqueous phase became deep blue. The organic layer was separated, washed with water and brine, dried ($MgSO_4$), and concentrated. Distillation (100–105°C/10 Torr) of the remaining oil gave 0.333 g (83%) of the chloro ketone **24**, a colorless oil that exhibited ir (neat); 3050, 1735, 1610, 1440, 1400, 1165, 900 cm^{-1}; ^1H nmr (80 MHz) δ: 0.52 (br signal, 4H), 1.31–3.12 (series of m, 11H), 3.67 (t, 2H, J = 7.5 Hz), 4.90 (t, 1H, J = 1.5 Hz), 5.02 (s, 1H). *Exact Mass* calcd. for $C_{14}H_{19}{}^{35}ClO$: 238.1124; found: 238.1129.

*Preparation of the tetracyclic keto alkene **25***

To a suspension of potassium hydride (116 mg, 2.9 mmol) in 6 mL of dry THF (argon atmosphere) was added a solution of the chloro ketone **24** (280 mg, 1.18 mmol) in 2 mL of dry THF and the mixture was stirred at room temperature for 3 h. Saturated aqueous ammonium chloride (5 mL) and diethyl ether (20 mL) were added and the mixture was stirred vigorously for 15 min. The phases were separated and the aqueous phase was extracted twice with diethyl ether (10 mL). The combined organic extracts were washed twice with brine (5 mL), dried ($MgSO_4$), and concentrated. Distillation (92–96°C/10 Torr) of the crude product afforded 190 mg (80%) of the ketone **25**, a colorless oil

For personal use only.

that exhibited ir (neat): 3035, 1720, 1623, 895 cm^{-1}; ^1H nmr (400 MHz) δ: 0.46–0.55 (m, 4H), 1.20–1.36 (m, 2H), 1.61. 2.12 (d, d, 1H each, J = 13 Hz in each case), 1.81–1.99 (m, 2H), 2.15–2.67 (series of m, 6H), 4.96, 5.02 (t, t, 1H each, J = 1.5 Hz in each case). *Exact Mass* calcd. for $C_{14}H_{18}O$: 202.1357; found: 202.1357.

Preparation of the tetracyclic keto alkene **26**

To a solution of the exocyclic alkene **25** (80 mg, 0.39 mmol) in 3 mL of dry dichloromethane (argon atmosphere) was added 6 mg of *p*-toluenesulfonic acid and the solution was stirred at room temperature for 24 h. Diethyl ether (10 mL) was added and the solution was washed twice with saturated aqueous sodium bicarbonate (2 mL). The organic phase was dried ($MgSO_4$) and concentrated. Distillation (90–95°C/10 Torr) of the residual oil gave 70 mg (88%) of the endocyclic alkene **26**, a colorless oil that exhibited ir (neat): 3046, 1715 cm^{-1}; ^1H nmr (80 MHz) δ: 0.47 (br s, 4H), 1.10–1.52 (m, 2H), 1.70 (br d, 3H, J = 2 Hz), 1.82–2.80 (series of m, 8H), 5.25 (br s, 1H), *Exact Mass* calcd. for $C_{14}H_{18}O$: 202.1358; found: 202.1358.

Preparation of mixtures of the tricyclic ketones **27** *and* **28**

To a solution of the tetracyclic ketone **25** (65 mg, 0.32 mmol) in 2 mL of glacial acetic acid was added 14 mg (0.064 mmol) of platinum oxide. The resultant suspension was shaken mechanically under hydrogen (3 atmospheres) at room temperature for 8 h. The reaction mixture was filtered and saturated aqueous sodium bicarbonate was added to the filtrate until it was basic. The resultant mixture was extracted three times with diethyl ether (5 mL). The combined extracts were washed with brine, dried ($MgSO_4$), and concentrated. Distillation (90–95°C/10 Torr) of the remaining oil gave 63 mg (96%) of a clear, colorless oil. Although this material showed one spot on tlc analysis (5:1 petroleum ether – diethyl ether), analysis by glc showed that it consisted of a 42:58 mixture of the epimeric ketones **27** and **28**, respectively. This mixture exhibited ir (neat): 1718, 1445 cm^{-1}; ^1H nmr (400 MHz) δ: 0.98, 1.01 (d, d, 3H total, J = 6, 4 Hz, respectively), 1.03, 1.035 (s, s, 6H total), 1.17–2.70 (series of m, 13H). *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1670; found: 206.1667.

Subjection of the tetracyclic ketone **26** (45 mg, 0.22 mmol) to hydrogenation under conditions identical with those described above gave 41 mg (91%) of a mixture of **27** and **28**, in a ratio (glc analysis) of 5:95, respectively.

*Preparation of (±)-pentalenene (***1***) and (±)-9-*epi*-pentalenene (***30***)*

To a cold (−78°C), stirred solution of the tricyclic ketones **27** and **28** (ratio 42:58, respectively) (50 mg, 0.24 mmol) in 1.5 mL of dry diethyl ether (argon atmosphere) was added a solution of methyllithium (0.28 mmol) in diethyl ether and the mixture was stirred at −78°C for 1.5 h. Saturated aqueous ammonium chloride (1 mL) and diethyl ether (5 mL) were added and the mixture was allowed to warm to room temperature. The phases were separated and the aqueous phase was washed twice with diethyl ether (3 mL). The combined organic extracts were washed with brine (2 mL), dried ($MgSO_4$), and concentrated. Analysis of the remaining oil by glc indicated that it consisted of a mixture of the ketones **27** and **28** (40% of the mixture) and the alcohols **29** (60% of the mixture). This material was treated with excess methyllithium as described above and the product mixture thus obtained was again allowed to react with excess methyllithium. Analysis of the crude product by glc showed that it consisted of a mixture of the ketones **27** and **28** (ratio 1:17, respectively, 18% of the mixture) and the alcohols **29** (82% of the mixture). This material was dissolved in 5 mL of dry benzene containing *p*-toluenesulfonic acid (14 mg) and the solution was refluxed under a Dean–Stark water trap for 1.5 h. The solution was cooled, washed with saturated aqueous sodium bicarbonate (1 mL), dried ($MgSO_4$), and concentrated. The remaining oil was chromatographed on silica gel (15 g) impregnated with silver nitrate (21). The column was eluted with petroleum ether.

Distillation (76–80°C/10 Torr) of the first-eluted hydrocarbon gave 16 mg (33%) of (±)-9-*epi*-pentalenene (**30**) as a colorless oil that exhibited ir (neat): 3020, 1440, 1375, 1360 cm^{-1}; ^1H nmr (400 MHz) δ: 0.94 (d, 3H, J = 7 Hz), 0.97 (s, 6H), 1.24–1.69 (m, 9H), 1.60 (br s, 3H), 2.62 (br d, 1H, J = 9 Hz), 2.88 (m, 1H), 5.16 (br s, 1H); ^{13}C nmr (100 MHz) δ: 13.41, 15.22, 28.52, 29.13, 31.45, 32.96, 39.75, 45.01, 46.23, 50.52, 54.81, 63.44, 131.30, 140.58. *Exact Mass* calcd. for $C_{15}H_{24}$: 204.1878; found: 204.1880.

Distillation (75–80°C/10 Torr) of the second-eluted hydrocarbon provided 15 mg (32%) of (±)-pentalenene (**1**), a colorless oil that exhibited ir (neat): 3040, 1445, 1362, 1350 cm^{-1}; ^1H nmr (400 MHz) δ: 0.91 (d, 3H, J = 7 Hz), 0.990, 0.995 (s, s, 3H each), 1.14–1.88 (series of m, 9H), 1.63 (br s, 3H), 2.56 (br d, 1H, J = 9 Hz), 2.66 (m, 1H), 5.16 (br s, 1H); ^{13}C nmr (100 MHz) δ: 15.41, 16.94, 27.64, 29.13, 29.98, 33.59, 40.51, 44.61, 46.90, 48.98, 59.39, 62.14, 64.77, 129.53, 140.63. *Exact Mass* calcd. for $C_{15}H_{24}$: 204.1878; found: 204.1892.

When a 5:95 mixture of the ketones **27** and **28**, obtained by hydrogenation–hydrogenolysis of compound **26** (*vide supra*), was subjected to a sequence of treatments with methyllithium as described above and the resultant mixture of alcohols was dehydrated, (±)-9-*epi*-pentalenene (**30**) was obtained in 68% yield.

High temperature–pressure aqueous oxidations. IV. A kinetic study of the oxidation and enolization of cyclohexanone in the presence of catalytic metal ions

JOHN W. THOMAS[1] AND JAY E. TAYLOR[2]

Department of Chemistry, Kent State University, Kent, OH 44242, U.S.A.

Received February 1, 1988

JOHN W. THOMAS and JAY E. TAYLOR. Can. J. Chem. **67**, 165 (1989).

The aqueous high pressure–temperature oxidation of cyclohexanone was found to be strongly catalyzed by silver, iron(III), and copper ions but not by aluminum, cobalt, manganese(II), or nickel ions. The reactivities of the catalytic ions were inhibited by the acidic oxidation products. Accordingly, initial reaction velocities were determined and used to correlate the kinetic data. A detailed kinetic study of copper ion catalysis has shown that in the presence of that ion the reaction was first order in cyclohexanone, one-half order in copper ion, and zero order in oxygen. The rate of enolization of cyclohexanone appeared to be unaffected by the presence of copper ion under conditions of constant acidity but was strongly catalyzed by both deuterium ion and acetate ion. Further, the rate of oxidation exceeded the rate of enolization at higher copper ion concentrations. These data contrast with the uncatalyzed oxidation, for which the kinetic reaction was first order in cyclohexanone, one-half order in oxygen, and the rate of oxidation was much less than the rate of enolization. The activation energies for the catalyzed and uncatalyzed oxidations were about the same, but the entropies of activation were quite different. From these data it is concluded that the enol is not a major intermediate for the catalyzed reaction. It is suggested that the copper ion may form an active peroxy complex with the oxygen molecule to serve as the reactive oxidant.

Key words: metal ion catalysis, kinetics, cyclohexanone, high temperature oxidation, high pressure oxidation.

JOHN W. THOMAS et JAY E. TAYLOR. Can. J. Chem. **67**, 165 (1989).

On a trouvé que l'oxydation de la cyclohexanone, en milieu aqueux et à des températures et des pressions élevées, est fortement catalysée par les ions de l'argent, du fer(III) et du cuivre, mais pas par les ions du aluminum, du cobalt, du manganèse(II) et du nickel. Le réactivité des ions catalytiques est inhibée par les produits acides de l'oxydation. On a donc déterminé les vitesses initiales des réactions et on les a utilisées pour établir une corrélation avec les données cinétiques. Une étude cinétique détaillée de la catalyse par l'ion du cuivre a montré que, en présence de cet ion, la réaction est du premier ordre en cyclohexanone, d'ordre un demi en ion du cuivre et d'ordre zéro en oxygène. Il semble que, à acidité constante, la vitesse d'énolisation de la cyclohexanone n'est pas affectée par la présence des ions du cuivre; toutefois, elle est fortement catalysée par l'ions deutérium et acétate. De plus, à des concentrations élevées d'ions du cuivre, la vitesse d'oxydation est plus élevée que la vitesse d'énolisation. Ces données sont en opposition avec ceux obtenus lors de l'oxydation non-catalysée de la cyclohexanone alors que la réaction cinétique était du premier ordre en cyclohexanone, d'ordre un demi en oxygène et que la vitesse d'oxydation était beaucoup plus faible que la vitesse d'énolisation. Les énergies d'activation pour les réactions catalysées et non-catalysées sont approximativement les mêmes, mais les entropies d'activation sont très différentes. Sur la base de ces données, on en conclut que l'énol n'est pas un intermédiaire important dans la réaction catalysée. On suggère que l'ion du cuivre et l'oxygène forment peut-être un complexe peroxy actif qui sert d'oxydant réactif.

Mots clés : catalyse par les ions du métal, cinétique, cyclohexanone, oxydation à pression élevée, oxydation à température élevée.

[Traduit par la revue]

Introduction

In previous studies of aqueous oxidations of low molecular weight ketones and alcohols (1–3) the reactions have been carried out under noncatalytic conditions. Catalysis of the oxidation of cyclohexanone was first indicated in preliminary work when difficulties in reproducing kinetic data were noted. Although glass or Teflon liners were used inside the stainless steel case, splashing or foaming over the liner occasionally permitted contact of the aqueous solution with the metal. The very corrosive combination of moisture, high pressure oxygen, and elevated temperatures effected formation of metal ions, which, upon reintroduction into the solution, caused seemingly irrational results. By avoiding overfilling and sudden pressure drops and using due care in stirring, this source of contamination was effectively eliminated, permitting the previously described studies.

The significance of metal ion catalysis was, however, indicated by these early results. This paper presents some quantitative studies that have been made on catalytic effects, particularly those of copper ion.

Very few studies of catalyzed aqueous oxidations of ketones have been made. Denisov *et al.* (4) studied the aqueous oxidation of 2-butanone in the presence of iron(III) ion and complexes of copper(II), iron(III), and manganese(II) ions at 50–60°C. Enolization followed by a series of complex radical reactions was proposed. There are, however, many references to metal ion catalyzed oxidations of aldehydes, ketones, hydrocarbons, etc. under nonaqueous conditions (5–7).

Experimental

The experimental procedures for the determination of the rates of oxidation and enolization and the purification of cyclohexanone have been previously described (1–3). Other chemicals were of reagent grade.

As will be further discussed, the rate constants for the catalyzed oxidations decreased with time, i.e., they were autoinhibited. To provide rate data that were interpretable, the initial rate constants were determined and evaluated. This was accomplished by dividing the initial reaction velocity (determined graphically as the initial slope) by the initial concentration of cyclohexanone. Some sacrifice in accuracy results from this procedure since variations in slope are more sensitive to experimental error at the outset of the reaction. An estimation of accuracy has been made from the data taken at 145°C. The average deviation was ±13%.

TABLE 1. Effects of various metal ions on the rates of oxidation of cyclohexanone by elemental oxygen in aqueous solutions

Metal compound	M × 10^4	Medium	Temperature (°C)	$k \times 10^4$ (s^{-1})
—	—	H_2O	145	0.105
$Ag_2C_2H_3O_2$	53	H_2O	145	0.66[d]
—	—	H_2O	172	0.77
$Al_2(SO_4)_3$	12[a]	H_2O	172	0.63
$Co(C_2H_3O_2)_2$	29.5	[b]	172	0.64
$Cu(C_2H_3O_2)_2$	1.09	[b]	172	14.1[d]
$Fe_2(SO_4)_3$	1.29[a]	[c]	172	14.3[d]
$Fe_2(SO_4)_3$	100.[a]	[c]	172	120.[d]
$Mn(C_2H_3O_2)_2$	8.3	[b]	172	0.71
$Ni(C_2H_3O_2)_2$	200.	[c]	172	0.66

[a]M indicates molarity of Al^{3+} or Fe^{3+}.
[b]0.50 M sodium acetate with 0.25 M acetic acid.
[c]5.0×10^{-3} M sulfuric acid.
[d]Determined from the initial reaction velocity.

Results

A brief survey of the possible catalytic activity of the following ions: Ag^+, Al^{3+}, Co^{2+}, Cu^{2+}, Mn^{2+}, and Ni^{2+}, was made. Dilute solutions were tested so that only significant activity would be noted. Only Ag^+, Fe^{3+}, and Cu^{2+} were appreciably reactive. See Table 1.

Catalysis by silver ion

As with each of the three active catalytic ions, silver ion catalysis was autoinhibited. The decrease in rate constant with time appeared to correlate with the formation of a gray, silver-containing precipitate that formed as the reaction proceeded. The precipitate was soluble in ammonium hydroxide and was assumed to be either silver oxide or insoluble silver salts of the product acids, presumably the latter. The initial rate constant for the silver ion catalyzed reaction is compared with that of the uncatalyzed reaction in Table 1, and the rate curve is plotted in Fig. 1. The plot of log concentration with time is not a straight line, and the concentration–time graph shows an unduly large initial decrease in rate with time, indicating autoinhibition. No further studies were made with this ion.

Catalysis by iron(III) ion

Iron(III) ion was a potent catalyst, as seen in Table 1. The rate of oxidation of cyclohexanone increased initially as much as 150-fold upon the addition of 0.01 M iron(III) ion. The plot of the autoinhibited catalysis by iron(III) ion is shown in Fig. 2.

No further studies were made with this ion since strongly acidic solutions were required to hold iron(III) ion in solution. The combination of acid, high pressure oxygen, and elevated temperature was quite corrosive to the sampling valve mechanism.

Catalysis by copper ion

Copper(II) ion was also an excellent catalyst, as indicated in Table 1. This ion has the merit of retaining solubility under near neutral conditions, thereby permitting a more exhaustive survey. The remainder of this paper deals with the effects of this ion.

Mechanism of autoinhibition of copper ion catalysis

As with the two previously discussed ions, copper ion catalysis was autoinhibited. Dicarboxylic acids have been shown to be products of the aqueous oxidation of cyclohexanone (3). If it is assumed that the simple hydrated copper ion was the catalytic species, the formation of an inactivating salt

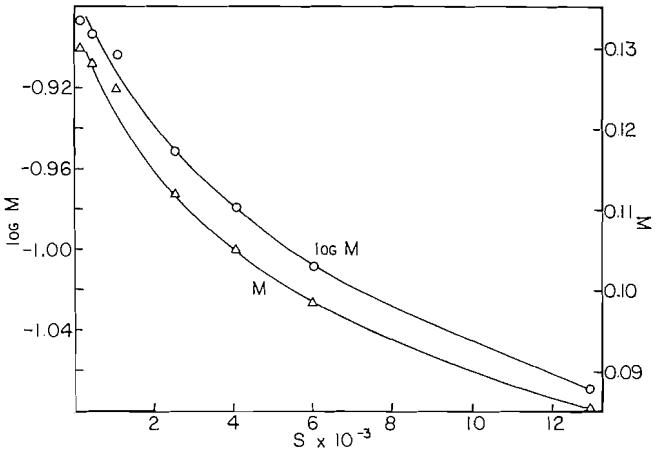

FIG. 1. The autoinhibited silver ion catalyzed oxidation of cyclohexanone. Dual plots show the variation of molarity and $\log_{10}$ molarity of cyclohexanone versus time in the presence of 0.0053 M silver acetate and 125 atm partial pressure of oxygen at 145°C.

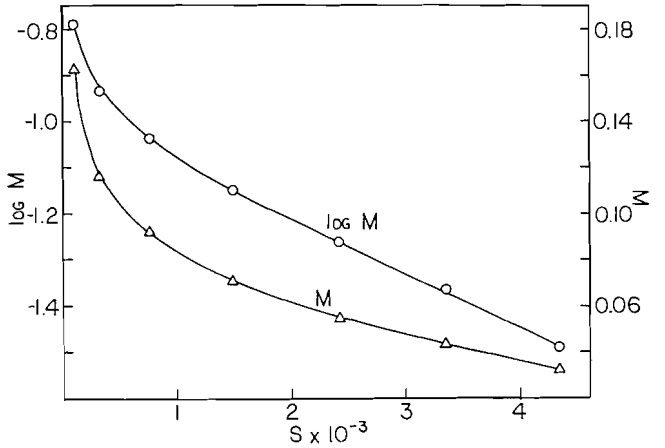

FIG. 2. The autoinhibited iron(III) catalyzed oxidation of cyclohexanone. Dual plots show the variation of molarity and $\log_{10}$ molarity of cyclohexanone versus time in the presence of 0.000129 M iron(III) sulfate, 0.005 M sulfuric acid, and 125 atm partial pressure of oxygen at 172°C.

(i.e., a salt with partial covalent bonding) between copper ion and the product acids should significantly decrease the catalytic activity of that ion. Further, the inhibitory effect should increase as the reaction proceeds and additional amounts of acids are formed.

To determine if such was the case, a copper ion catalyzed oxidation was carried out with 0.08 M butanedioic acid added, and was compared with a run not having this addition. The acid markedly inhibited the initial rate of oxidation (see Fig. 3). Another copper ion catalyzed mixture was allowed to oxidize to greater than 50% completion, and a fresh addition of cyclohexanone was made. Marked inhibition by the oxidation products was observed upon comparison with the initial rate of reaction (see Fig. 3).

It is therefore concluded that the decrease in rate was due to complexation of the catalytic copper ion by the product acids. The possibility of explaining the decreasing rates by assuming an involved mechanism seems unlikely since, as will be shown, the initial reaction rates may be readily correlated by well-defined kinetic relationships.

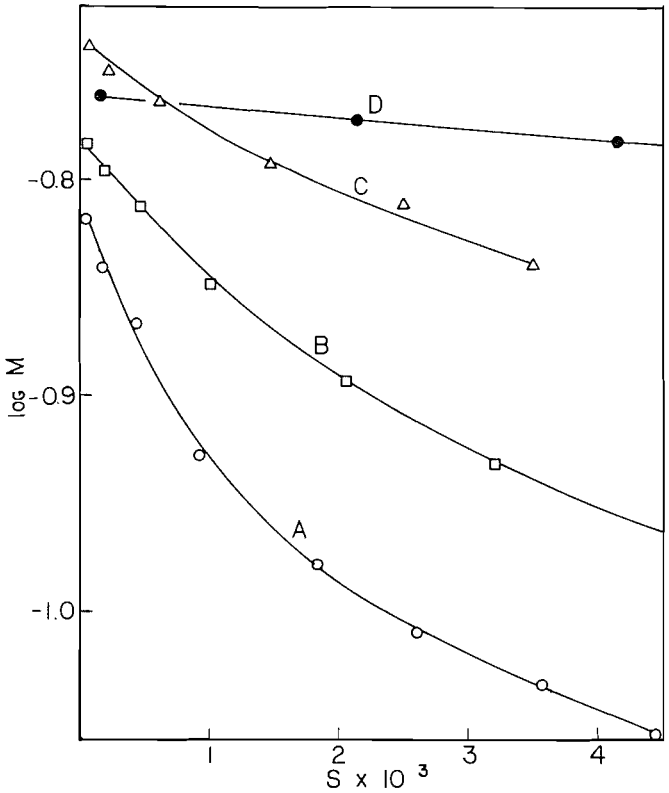

FIG. 3. The nature of autoinhibited copper(II) ion catalyzed oxidation of cyclohexanone. A, 0.00011 M copper(II) acetate, 0.50 M acetic acid, 0.25 M sodium acetate, and 125 atm partial pressure of oxygen at 145°C; B, same as A with the addition of 0.08 M butanedioic acid; C, after about 50% reaction with same conditions as A, fresh cyclohexanone was added to give these data; D, a corresponding uncatalyzed reaction at 145°C.

TABLE 2. Determination of the first-order rate constants for the 1.09×10^{-4} M copper ion catalyzed oxidation of cyclohexanone at 172°C in 0.50/0.25 M sodium acetate/acetic acid buffer at varying oxygen partial pressures

Partial pressure oxygen (atm)	$k \times 10^3$ (s^{-1})
125	1.4
128	1.5
59.9	1.3
27.6	1.3

The formation of these copper-carboxylic acid salts does not completely inhibit copper ion activity. Although the presence of reaction products greatly decreased the rate of the catalyzed oxidation, as seen in Fig. 3, the reaction was still appreciably more rapid (indicated by the greater slope) than under uncatalyzed conditions. The graph of the log rate constant versus time does, however, become a nearly straight line as compared to the initially catalyzed reaction. This suggests that a limiting inhibition of the catalysis may have been attained.

Kinetic order of oxygen

The partial pressure of oxygen was varied between 27.6 and 128 atm (1 atm = 101.3 kPa) with a constant copper ion concentration (see Table 2). The rate of oxidation was essentially

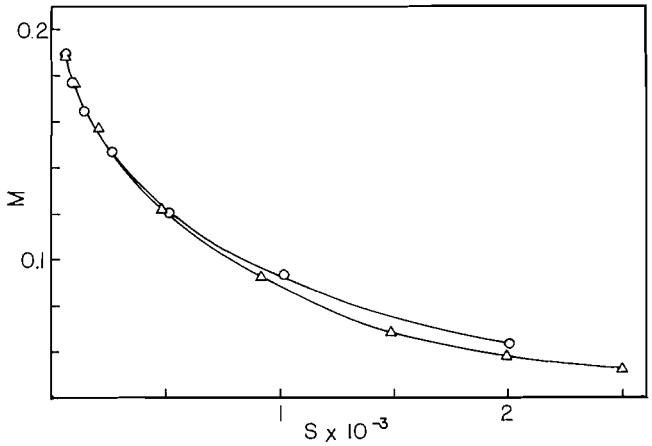

FIG. 4. Zero-order dependence on oxygen of the copper ion catalyzed oxidation of cyclohexanone. ○, 128 atm oxygen; △, 27.6 atm oxygen. Both reactions contained 0.000109 M copper acetate, 0.5 M acetic acid, 0.25 M sodium acetate, and were carried out at 172°C.

constant under widely varying oxygen pressures. The graphs of two extremes of oxygen partial pressures are shown in Fig. 4. Except for a small deviation the two graphs correlate quite closely over the range of the data. Since the lower pressure exhibits the slightly faster rate at the more advanced stages of oxidation, it is presumed that the difference is merely due to experimental error. The data conclusively demonstrate that the oxidation reaction was zero order with respect to elemental oxygen.

Kinetic order of cyclohexanone

A log–log plot of the initial rates of oxidation versus cyclohexanone concentrations is shown in Fig. 5. A slope of 1.04 indicates that, within experimental error, the order with respect to cyclohexanone was unity. The order of cyclohexanone under both catalytic and noncatalytic conditions was the same.

Kinetic order of copper ion

The plot of initial rate constants as they varied with copper ion concentrations at 145°C is seen in Fig. 6. The data are from Table 3. The slope and the indicated order with respect to copper ion are 0.5. As previously noted (3) the order with respect to oxygen in the absence of copper ion was 0.5. The addition of copper ion displaced oxygen in its kinetic order.

The integrity of the half-order relationship held over an extremely wide range of copper ion concentrations. This is particularly emphasized in both Fig. 6 and Table 3 where the copper ion concentration was varied from 1.5 to 1×10^{-4} M. Yet the three-halves-order rate constant held with excellent constancy.

Effect of copper ion on the rate of enolization

It has been shown that the rate of enolization of cyclohexanone was significantly faster than the rate of oxidation in the absence of catalytic ions (3). The concept that the enol served as an intermediate in the oxidation of ketones was definitely supported, but not proven.

The previously described technique for determining the rate of enolization (3) was applied in the presence of varying amounts of copper ion. That there was essentially no effect on the rate of enolization was demonstrated both in the presence of absence of buffers. Acetic acid-D_4 was added to give varying pD values at 116°C (see expts. 1–5, Table 4). Upon dividing the

k values for the enolizations by the deuterium ion concentrations a number was obtained that was constant over the range of pD and did not change with the presence or absence of copper ion.

Additional data were obtained at both 116 and 145°C in the presence of buffers. Upon altering the copper ion concentration by a factor of nearly 700 at 116°C and a constant pD, there was no significant impact upon the rate of enolization (see expts. 6 and 7, Table 4). Similarly, at 145°C the addition of copper ion had little effect upon the reaction rate at a constant pD (see expts. 8–11, Table 4). The rate was slightly faster in the absence of copper ion, but this appears to be merely an artifact. The lack of effect of copper ion is further emphasized in Fig. 7, where the similarity of the rate curves for the enolization of cyclohexanone with and without copper ion is clearly demonstrated. It may therefore be concluded that the addition of copper ion does not noticeably affect the rate of enolization.

Comparative rates of enolization and oxidation

Upon comparing the first-order oxidation rate constants of expts. 3–6, Table 3, with the first-order enolization rate constants of expts. 1–7, Table 4, it is seen that the oxidation rates equal or exceed the enolization rates at 116°C even under very favorable conditions for the latter, i.e., high buffer or acid conditions. Similarly, at 145°C the first-order copper catalyzed oxidation rate constants from expts. 13–21, Table 3, exceeded any of the first-order enolization rate constants from expts.

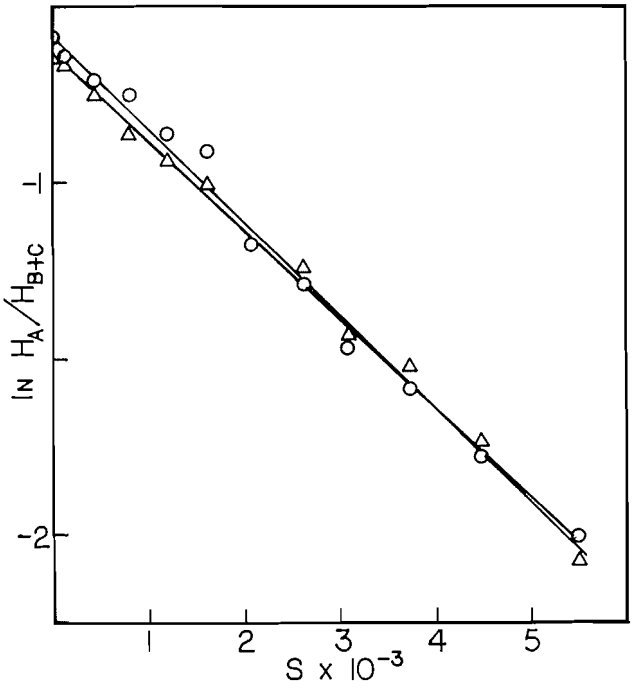

FIG. 7. The effect of copper ion on the rate of decay of the α-proton signal of cyclohexanone in D_2O with 0.50/0.25 M sodium acetate-D_3/acetic acid-D_4 buffer at 145°C. ○, no Cu^{2+}; △, with 1.13×10^{-4} M Cu^{2+}. H_A, H_B, and H_C represent the α, β, and γ protons of cyclohexanone, respectively.

8–11, Table 4. Again, at 172°C the first-order oxidation rate constants from expts. 23–26, Table 3, exceed any of the 172°C enolization rate constants of Table 1 from the preceding paper (3).

Accordingly, it may be concluded that the enol was not an intermediate for the copper ion catalyzed reaction. This obviously differs from the tentative conclusion made with the noncatalyzed oxidation suggesting that the enol is an intermediate. However, it may be necessary to reconsider the specific role of the enol for both the catalyzed and uncatalyzed reactions.

Buffer ion catalysis of the rate of enolization

The rates of enolization of cyclohexanone in D_2O were determined in the presence of acetic acid-D_4 or deuterated acetate buffers. With acetic acid-D_4 a constant number was obtained upon dividing the observed rate constant by the deuterium ion concentration, which was estimated at room temperature using a pH meter. See expts. 1–5, Table 4. The proportionality of the effect of deuterium ion on the rate of enolization is thereby indicated. Although the D^+ concentrations were undoubtedly higher at the elevated reaction temperatures than as measured, the actual high temperature D^+ concentrations were assumed to be proportional to the apparent values obtained from the room temperature pH measurements.

Upon introducing a deuterated acetate buffer, the D^+ proportionality no longer existed. Comparing expts. 5 and 7, Table 4, it is seen that at pD 3.68 (20°C) or $[D^+] = 2.1 \times 10^{-4}$, k was 0.30×10^{-4}, but at pD 5.40 (20°C) with 0.5 M sodium acetate-D_3 plus 0.25 M acetic acid-D_4, k was 2.52×10^{-4} or about eight times larger even though the $[D^+]$ had been reduced to 4.0×10^{-6}. Therefore, in addition to a deuterium ion promotion of the enolization reaction there is also a large buffer ion catalysis. The nature of this catalysis will not be further considered in this paper.

TABLE 5. Activation parameters for the oxidation of cyclohexanone

Reaction	E_a (kcal/mol)	$\Delta H^{\ddagger}$ (kcal/mol)	$\Delta S^{\ddagger}$ (eu)	log A
Uncatalyzed oxidation	23 ±2[a]	22	−27.	7.6
Catalyzed oxidation	26 ±3[a]	26	−5.	12.2
Enolization	12.7±0.2	11.9	−42.3	4.13

[a]Determined from the mean of the three-halves-order rate constants.

Activation parameters

The activation energies and entropies of log A values under both catalytic and noncatalytic conditions and for the enolization are tabulated in Table 5. The copper ion catalyzed oxidation has a slightly greater activation energy than the uncatalyzed oxidation, but this difference is within the range of experimental error. On the other hand the differences in the entropies of activation definitely reflect the large differences in reaction rates between the catalyzed and uncatalyzed oxidations.

Discussion

Although the specific acid content has not been determined for any of the metal ion catalyzed reactions as was done for the uncatalyzed oxidations, the products may be assumed to be a mixture of C_1 to C_6 acids of unspecified composition, carbon dioxide, and water. The difference between the heats of combustion of cyclohexanone and hexanedioic acid, for example, is 172 kcal/mol (8, 9). Yet even at 190°C the oxidation of cyclohexanone is relatively slow (3). A reaction with this large a potential for oxidation should be an ideal subject for catalysis, and this appears to be the case.

The characteristics of the catalyzed and uncatalyzed reactions differ markedly. The uncatalyzed reaction is first order in cyclohexanone, one-half order in oxygen, and appears to enolize before oxidation (though this is not conclusive). In contrast, the copper ion catalyzed oxidation is first order in cyclohexanone (the only similarity), zero order in oxygen, one-half order in copper ion, and the major reaction does not proceed via an enol intermediate.

Under conditions of copper ion catalysis the oxygen molecule serves as a secondary reactant; that is, it does not react directly with the cyclohexanone. On the other hand, the copper ion or a derivative of that ion is a direct reactant. The reservoir of oxygen, which is in constant supply (since it is kept at constant pressure), maintains the copper ion or its derivative in the reactive state.

The kinetic characteristics of the present work contrast sharply with those of earlier investigations. The study of the aqueous oxidation of 2-butanone (4) with iron(III) iron at 50–60°C showed that the rate of oxidation depended on pH, and the rate of oxygen dependence varied with ketone and iron(III) ion concentrations in a complex manner. Under nonaqueous conditions (5–7) cobalt, manganese(II), iron(III), and copper ions were indicated as catalysts for various substances, whereas only the latter two were shown to be highly reactive in this work.

Although numerous metal ion catalyses of lower temperature, nonaqueous, oxidations of aldehydes and ketones have been studied and characterized, there is neither reason nor evidence to conclude that higher temperature, aqueous, catalyzed reactions follow a similar mechanism. However, the data presented herein are insufficient to permit formulation of a detailed mechanism. Accordingly, two possibilities are presented.

1. Copper ion reacts directly with cyclohexanone to form a lower valence species, which is then reoxidized to the divalent ion by reaction with oxygen. This proposal implies a direct reaction of copper ion with the ketone, but, as such, does not explain the observed half order as noted for copper ion. Conceivably a radical chain process could be suggested, but again such a mechanism would be very difficult to correlate with the extremely wide range of concentrations over which the copper ion was seen to follow half-order kinetics.

2. An oxygen molecule forms a peroxy intermediate with copper ion, e.g., CuO_2^{2+}, and this in turn reacts with cyclohexanone. Since the oxygen was held at a specified pressure, an adequate supply of oxygen was present to maintain this intermediate during the course of the reaction.

This latter proposal appears to be the more reasonable since the peroxy copper ion could react in a manner similar to the mechanism suggested for the uncatalyzed reaction. The activation energy for the catalyzed reaction (Table 5) was about the same as for the uncatalyzed reaction; this indicates that the oxidation intermediate, whatever its nature, does not have a large heat of formation, either positive or negative. Therefore, the observed increase in rate correlates with the A or $\Delta S^{\ddagger}$ factor. With this mechanism an oxygen molecule becomes associated with the positive copper ion, and the resulting polarization creates a positive charge on an oxygen atom. Cyclohexanone is also a polar molecule. The presence of the keto group effects a negative polarity on the α carbons, presumably by partial enolization. The positive oxygen then is oriented to a negative carbon, effecting enhancement of the rate of reaction. This polar attraction should be manifested by an increase in the orientation factor, $\Delta S^{\ddagger}$ or $\log A$ with little effect on the activation energy, as observed in Table 5.

The possibility of enol intermediary was stressed in our previous paper (3), but with the clear reservation that it had not yet been proven. In keeping with the first mechanism from above, there is the possibility that the uncatalyzed oxidation proceeds by the previously suggested mechanism and the catalyzed reaction by a different mechanism.

There is then the possibility that the catalyzed and uncatalyzed oxidations may be quite similar in mechanism except for the initial interaction between the oxygen and ketone. With the uncatalyzed reaction the initial contact presumably is between the oxygen molecule and the enol or its equivalent, whereas with the catalyzed reaction the copper ion – oxygen adduct reacts as described in mechanism 2 above. Following these initial contacts, both reactions may be assumed to proceed in a similar manner, in keeping with the earlier proposed mechanism (3).

Further detailed research is planned to determine more accurately the mechanistic nature of this interesting reaction.

Electron affinities and Marcus reorganization energies. A correlation between gas phase electron affinities and solution phase redox potentials

DENNIS D. TANNER, NATASHA DEONARIAN,[1] AND ABDELMAJID KHARRAT[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 4, 1988

DENNIS D. TANNER, NATASHA DEONARIAN, and ABDELMAJID KHARRAT. Can. J. Chem. **67**, 171 (1989).

Redox potentials determined by cyclic voltammetry were used in conjunction with published electron affinities to determine the solvation energies for series of three classes of compounds: substituted benzoquinones, substituted nitrobenzenes, and polynuclear aromatic hydrocarbons. Excellent linear correlations were obtained between the measured electron affinities and the E^0 of the substrates. The calculated electron affinities, EA(E^0), were computed using the average solvation energies for the three classes of compounds, and were found to be in excellent agreement with the measured values. The nitrobenzenes and quinones had one solvation energy, while the aromatic hydrocarbons were correlated with a significantly different value. The solvation energy of a variety of compounds could also be related to their Marcus reorganization energies, $\lambda(0)$, by a linear plot with a high correlation coefficient. From simple electrochemical measurements of similar compounds, either electron affinities or Marcus $\lambda(0)$ values can be estimated.

Key words: electron affinities, Marcus reorganization energies, cyclic voltammetry.

DENNIS D. TANNER, NATASHA DEONARIAN et ABDELMAJID KHARRAT. Can. J. Chem. **67**, 171 (1989).

On a utilisé des potentiels redox, déterminés par voltamétrie cyclique, de concert avec des valeurs publiées d'affinités électroniques pour déterminer les énergies de solvatation de séries de trois classes de composés : des benzoquinones substituées, des nitrobenzènes substitués et des hydrocarbures aromatiques polynucléaires. On a obtenu d'excellentes corrélations linéaires entre les affinités électroniques mesurées et les valeurs E^0 des substrats. On a calculé les affinités électroniques, EA(E^0), en utilisant les énergies moyennes de solvatation des trois classes de composés et on a trouvé qu'elles sont en excellent accord avec les valeurs mesurées. On n'a utilisé qu'une seule énergie de solvatation pour les nitrobenzènes et les quinones alors que l'on doit utiliser une valeur assez différente pour établir une corrélation avec les hydrocarbures aromatiques. On peut aussi établir une corrélation entre l'énergie de solvatation d'un grand nombre de composés et leurs énergies de réorganisation de Marcus, $\lambda(0)$; cette corrélation est linéaire avec un coefficient de corrélation élevé. En effectuant des mesures électrochimiques simples sur des composés semblables, on peut donc évaluer soit les affinités électroniques ou les valeurs $\lambda(0)$ de Marcus.

Mots clés : affinités électroniques, énergies de reorganisation de Marcus, voltamétrie cyclique.

[Traduit par la revue]

Introduction

The electron affinities of both organic and inorganic molecules are of interest in fundamental studies of both vapor phase (3) and condensed phase (4) reactions. Until relatively recently compilations of electron affinity data were conspicuously scarce. In the last several years EA data have become more readily available due to the rapid development of physical methods for their determination in the gas phase. These developments have been the subject of reviews by Chen and Wentworth (5), Brauman and co-workers (3), Lineberger and co-workers (6), and Kebarle *et al.* (7). In 1984 Brauman and co-workers listed a comprehensive compendium of EA's that had been determined by a variety of physical methods. In this review, only 24 neutral organic molecules were listed. Most recently Kebarle *et al.* (7), using pulsed electron high pressure mass spectrometry (HPMS), have extended this compilation six-fold.

The polarographic half-wave potential for a reversible redox couple has been related to the electron affinity of the molecule by eq. [1] (5, 8).

$$[1] \quad -E^0 = \mathrm{EA} - \Delta G_{\mathrm{sol}} - \mathrm{constant}$$

In the empirical equation [1], ΔG_{sol} equals the difference in solvation energy between the neutral substrate and its radical ion, $(\Delta G^0(\mathrm{S})_{\mathrm{sol}} - \Delta G^0(\mathrm{S}^{\cdot-})_{\mathrm{sol}})$, while the constant equals the difference between the work function of the electrode and the potential difference for reduction between the working electrode and the reference electrode at the half-wave potential. EA is assumed to be $\simeq\Delta G^0(\mathrm{S})$, the energy for electron attachment in solution. The differences in solvation energies between the anion and the neutral, ΔG_{sol}, is often assumed to be constant, even though the correlation of reduction potentials with absolute EA's for aromatic hydrocarbons is reported not to be constant, at least with the solvents dioxane and dimethoxyethanol (9). Although very few absolute EA's were available for comparison with the existing electrochemical data, the relationship appears to be potentially useful. Briegleb (10) has used the assumed value of 1.37 eV for the EA of chloranil to establish a half-wave reduction potential scale, and calculated a value of −3.66 eV for ΔG_{sol}. Farragher and Page (11) assumed eq. [1] to be valid and calculated an average value of −2.37 eV for (ΔG_{sol} + constant) for tetracyanoethylene (TCNE), tetracyano-1,4-benzoquinone (TCBQ), chloranil, tetracyanobenzene, and tetracyanobutadiene using the magnetron results for the absolute EA's ($\mathrm{EA}_{\mathrm{Mag}}$) of these compounds. Since the publication of the extensive studies by Kebarle has made available a large data base to establish very accurately the solvation correction factor it seemed possible to test whether redox couples having very different structures would utilize the same solvation correction which might depend only on the solvent and electrode used.

A closely related, and equally important parameter, the Marcus reorganization energy, $\lambda(0)$, should be related to ΔG_{sol}, since the reorganization energy is comprised of energy changes that are necessary to reach the transition state for electron transfer (eq. [2]), by bond and solvent reorganization.

$$[3] \quad k_{obs} = 10^{11} \exp\left\{-\left[\frac{\lambda}{4}\left(1 + \frac{\Delta G^{0\prime}}{\lambda}\right)^2 \Big/ RT\right]\right\}$$

where

$$\lambda = (\lambda(0)_{ox} + \lambda(0)_{red})/2$$

When a change in charge occurs in an organic molecule, solvation stabilization is presumably the most important difference between its vapor and solution phase free energies. The λ(0) values for each reactant are usually determined from their self exchange reactions

$$A + A^{\cdot -} \rightleftharpoons [A A^{\cdot -} \leftrightarrow A^{\cdot -} A]^{\ddagger} \rightleftharpoons A^{\cdot -} + A$$

by such methods as isotopic exchange (12) and line broadening in NMR or ESR spectra (13). For this reason, it is profitable to determine whether a useful correlation between the thermodynamic ΔG_{sol} and the kinetic λ parameters exists. Although this relationship had been recognized prior to the present report, no correlation could be examined, since sufficient data were not previously available (14).

Results and discussion

The reduction potentials, E^0, for a series of ring-substituted nitrobenzenes (8), substituted 1,4-benzoquinones (14), and aromatic hydrocarbons (9) were determined using cyclic voltammetry (Au electrode vs. Ag/Ag^+, 0.001 *M* $AgClO_4$). All of the substrates were reduced in the same solvent, acetonitrile, with tetrabutylammonium perchlorate (0.1 *M*) as the supporting electrolyte, see Table 1. By using eq. [1] values of $\Delta G_{sol} + C$ were calculated with these electrochemical data and the data of

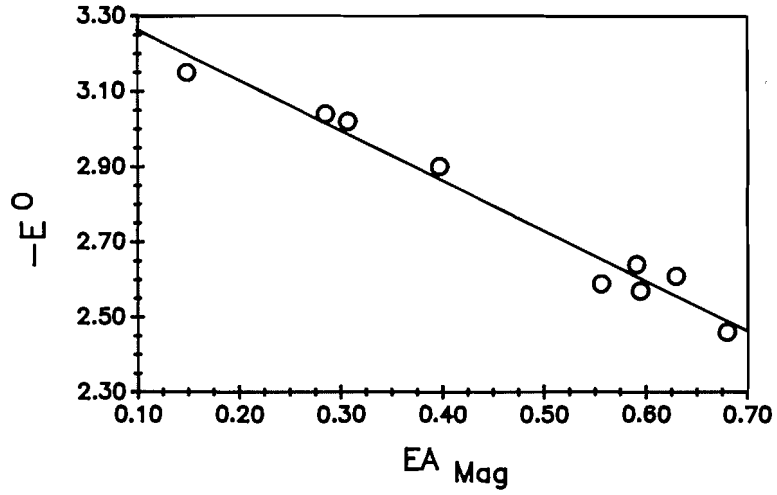

FIG. 2. Plot of $-E^0$ vs. EA_{Mag} (7) for a series of aromatic hydrocarbons.

Kebarle *et al.* (7) for the quinones and nitroaromatics, see Table 1. For the aromatic hydrocarbons the calculated values of $\Delta G_{sol} + C$ were based on our E^0 measurements and the EA's, EA_{Mag}, measurements by Chen and Wentworth (5) using the magnetron method (12). Average values of $EA + E^0$ were used to construct plots of the measured $(E^0 + \Delta G_{sol})$ vs. EA_{Mag}.

Excellent correlations were obtained for the plots of EA_{obs} vs. EA_{calc} for all three classes of compounds, see Table 2. The solvation energy, ΔG_{sol}, for all three classes of compounds measured, although somewhat different, seemed to be of two types: polar solvated substrates, quinones and nitrobenzenes, which are transformed into solvated delocalized radical anions, and nonpolar aromatic hydrocarbons which form ion-paired radical anions without resonance stabilization. A composite plot of E^0 vs. EA(HPMS) for the quinones and nitrobenzenes (Fig. 1), can be compared to one constructed for the hydrocarbons (Fig. 2). Since ΔG_{sol} (ave) for the quinones and for the nitrobenzenes are within experimental error (see Table 1), it was

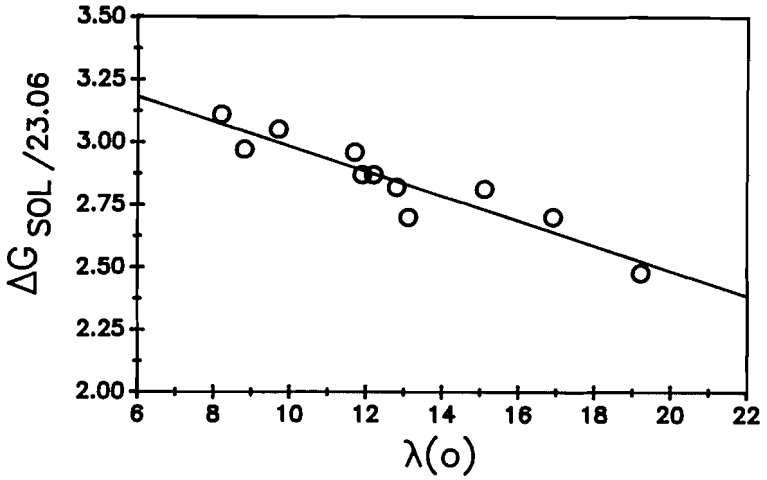

FIG. 3. Plot of ΔG_{sol} (kcal mol^{-1}) + *C* vs. Marcus reorganization energy $\lambda(0)$ (kcal mol^{-1}).

not surprising that a rather good correlation between $EA(E^0)_{calc}$ vs. EA(HPMS) exists for the composite plot using the average ΔG_{sol} for the two series of substrates, see Table 2. Although it is tempting to consider that changes in structure can cause an observable change in solvation energy (1, 7) in a series of substrates, in acetonitrile using our electrochemical data and Kebarles values for EA(HPMS) no dramatic changes in $EA(E^0)_{calc}$ from steric inhibition to solvation were apparent as a result of structural changes in the quinones studied.

The reorganization energies taken from the literature (Table 3) were used to construct a plot of $\Delta G_{sol} + C$ vs. $\lambda(0)$. The values of ΔG_{sol} determined for each substrate (i.e., E^0) were determined in the solvent (DMF) in which its $\lambda(0)$ value was determined. The results of this correlation are shown in Fig. 3. The plot, $\Delta G_{sol}/23.06 = -0.049\lambda(0) + 3.48$, showed a remarkably good straight line fit with $r = 0.930$, apart from its being of some theoretical interest (13), the correlation is of some practical use since the values of $\lambda(0)$ taken from the graph are in much better agreement with the experimentally determined values (i.e., ± 1.1 kcal mol^{-1}) than the theoretically calculated reorganization energies given in the literature (2), see Table 3.

Experimental

Materials

All the substrates were used as received. Tetrabutylammonium and silver perchlorate were dried over P_2O_5 under vacuum at 60°C before use. The solvents were purified by distillation over calcium hydride.

Cyclic voltammetry

Electrochemistry was performed using a Princeton Applied Research, EG and G Par Model 175 Universal Programmer wave form generator interfaced to an Amel model 551 potentiostat that provided feedback compensation for ohmic drop between the working and the reference electrodes. Cyclic voltammograms were recorded using a Princeton Applied Research Model RE0074 X-Y Recorder. Electrochemical measurements were carried out at room temperature in the appropriate solvent containing 0.001 *M* of the substrate and 0.1 *M* of tetrabutylammonium perchlorate as supporting electrolyte. The reference cell contains 0.001 *M* of the silver perchlorate and 0.1 *M* of tetrabutylammonium in the solvent.

Reversible waves were obtained at scan rates of between 20–500 mV/s.

Alkyl versus hydrogen substitution: an *ab initio* study of the addition of hydroxide to formaldehyde and to acetone

C. I. BAYLY AND F. GREIN[1]

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received April 22, 1988

C. I. BAYLY and F. GREIN. Can. J. Chem. **67**, 176 (1989).

The reaction profiles of the anionic nucleophilic addition of hydroxide to formaldehyde (system I) and to acetone (system II) were studied using theoretical *ab initio* methods. Calculations were carried out using the 4-31G basis set augmented with polarization and diffuse functions on some atoms. Electron correlation calculations were performed at the MP2 (frozen core), MP2, and MP4 levels for system I and at the MP2 (frozen core) level for system II. For both systems a local energy maximum was found at a C—OH distance of 2.5 Å. The barrier maximum was at lower energy than the separated reactants (−17.2 kcal/mol for system I and −5.6 kcal/mol for system II). This type of reaction profile is in accordance with a previous study on a prototype reaction. The energy difference between the barrier maximum and the secondary minimum (towards the reactants) was very small for system I (0.7 kcal/mol), but higher for system II (5.4 kcal/mol). The geometries of the two systems differed significantly in the region of the reaction coordinate containing the barrier and the secondary minimum.

Key words: quantum chemical study, addition of OH^- to H_2CO, addition of OH^- to $(CH_3)_2CO$, alkyl versus hydrogen substitution, potential energy curve.

C. I. BAYLY et F. GREIN. Can. J. Chem. **67**, 176 (1989).

Faisant appel à des méthodes théoriques *ab initio*, on a étudié les profils des réactions de l'addition nucléophile anionique de l'hydroxide sur le formaldéhyde (système I) et sur l'acétone (II). On a effectué les calculs à l'aide de l'ensemble 4-31G auquel on a ajouté des fonctions de polarisation et de diffusion sur quelques-uns des atomes. On a effectué des calculs de corrélation électronique aux niveaux MP2 (noyau solide). MP2 et MP4, pour le système I, et au niveaux MP2 (noyau solide),pour le système II. Dans chacun de ces systèmes, on a trouvé qu'il existe une énergie locale maximale à une distance C—OH de 2,5 Å. La barrière maximale se situe à une énergie plus faible que celle des réactifs séparés (−17,2 kcal/mol pour le système I et −15,6 kcal/mol pour le système II). Ce type de profil réactionnel est en accord avec une étude antérieure sur une réaction prototype. La différence d'énergie entre la barrière maximale et le minimum secondaire (par rapport aux réactifs) est très faible pour le système I (0,7 kcal/mol), mais plus élevée pour le systèmes II (5,4 kcal/mol). Les géométries des deux systèmes diffèrent beaucoup dans la région des coordonnées de la réaction contenant la barrière et le minimum secondaire.

Mots clés : étude de chimie quantique, addition de OH^- sur H_2CO, addition de OH^- sur $(CH_3)_2CO$, substitution alkyle versus hydrogène, courbe de l'énergie potentielle.

Introduction

Chemical reactions involving alkyl substituted carbons are frequently examined by *ab initio* theoretical methods. In many cases, where the alkyl substituents do not participate directly in bond making or bond breaking processes, they are routinely replaced in the model system by hydrogens (ref. 1–7 for example). This gives a considerable reduction in the length of the computation, since a fragment of at least the size of a methyl, bringing four centers and nine electrons into the calculation, is instead represented by the single center and single electron of hydrogen. In addition, many systems undergo an increase in symmetry if alkyl groups are replaced by hydrogens, again reducing the computer time required for the calculation.

The reasoning behind the replacement of alkyl groups with hydrogen lies in the view that the major difference between these two substituents is steric in nature, while the difference in their electronic influence is considered to be minimal. Thus, when the study of interest is focussing on the electronic interactions occurring along a reaction pathway, in principle the substitution of a hydrogen for an alkyl group should not make a big difference.

Is this reasoning sound? To what extent does this replacement give rise to a significant change in the reaction pathway? In the present study, these questions are addressed through the comparison of the anionic nucleophilic attack of hydroxide on formaldehyde (system I) with the attack of the same nucleophile on acetone, the dimethyl substituted analogue of formaldehyde (system II).

These systems were chosen for study because they were considered to be representative examples of organic nucleophilic additions and because the calculations would be computationally feasible (examples of previous theoretical studies on these and similar reactions can be found in refs. 2–7). A recent *ab initio* study of a prototype reaction, the nucleophilic attack of hydride on formaldehyde (2) (paper I), found the gas-phase reaction profile to exhibit a double well potential, with only a small energy barrier in going from the secondary minimum to the global minimum. It was felt that an energy profile with such features would give clear and marked responses to changes in the substitution.

Also, as a result of testing several basis sets, a relatively small and efficient basis set for probing the reaction profile of this type of organic reaction was proposed in paper 1. Using this basis set to examine system I and system II, as extensions of the prototype reaction in paper I, made possible a valid RHF description of the reaction profile while keeping the inclusion of electron correlation within range computationally.

Calculations

Calculations were carried out at the RHF (restricted Hartree–Fock) and MP (Moeller–Plesset) levels using the GAUSSIAN 82 (8) computer program. The MP electron correlation calculations were performed on the SCF optimized geometries at the

[a]All distances are in Å and all angles are in degrees.

following levels: MP2 (frozen core) (henceforth referred to as MP2(FC)), MP2, and MP4 for system I, and MP2 (frozen core) for system II. In paper I, the prototype hydride–formaldehyde reaction intermediates were optimized at the MP2 level in addition to the RHF optimizations, but the RHF energy profiles remained very similar and the geometries varied little aside from some bond lengthening; hence it was felt that in this work geometry optimization beyond the SCF level was unnecessary. The 4-31G basis set was used, augmented with polarization d functions on the oxygens and the carbonyl carbon only (exponent 0.80), and with diffuse *s* and *p* functions on the oxygens (exponent 0.0680). This basis set was chosen in the light of basis set comparisons made in paper I.

The geometry was specified as follows: the Y—C—Y plane (Y = H for formaldehyde; Y = C for acetone) was chosen as the frame of reference, and a dummy atom X placed bisecting the Y—C—Y angle. The C—Y bond lengths, and bond angles Y—C—X were allowed to vary during optimization. The carbonyl oxygen and hydroxide were allowed movement only in the C_s plane, i.e. the plane perpendicular to the Y—C—Y plane and containing the line C—X, in accordance with generally accepted views (9, 10) on the optimum approach of these reactants. The hydroxide oxygen – carbonyl carbon distance *R*(C—OH) was used as the reaction coordinate. For the methyl groups of system II, the C—H bonds were fixed at 1.085 Å, and the H—C—C angles were fixed at 110° (the 4-31G optimized values for the product geometry).

For each fixed value of the reaction coordinate *R*(C—OH), all other geometry parameters were optimized at the SCF level with enforced C_s symmetry, using the GAUSSIAN 82 gradient-searching algorithms. For system II, methyl group rotation (maintaining C_s symmetry) was included in the optimization. All structures corresponding to RHF energy maxima and minima included *R*(C—OH) in the geometry optimization. The geometry-optimized SCF transition structure had a single negative eigenvalue in the Hessian matrix, showing it to be a true saddle point on the potential energy (PE) hypersurface.

Results and discussion

For system I, the RHF optimized geometries are given in Table 1 and the corresponding RHF energies in Table 2; the structures of several intermediates indicated in Table 2 are shown in Fig. 1. While the minimum energy reaction pathway (MERP) of system I has been thoroughly studied previously by Madura and Jorgensen (MJ) (3) at the RHF level, this pathway was re-investigated in this work because of the inclusion of electron correlation in this study and because a different basis set was used in order to compare the results with those of system II. A comparison will be made between our RHF results for system I and those of the previous study; the results from the better basis set (6-31+G*) used by those authors permit an evaluation of the adequacy of our basis set.

TABLE 2. $H_2CO + OH^-$: RHF, MP2(FC), MP2, and MP4 energies relative to separated reactants

[a]The energy (in hartree) of the separated reactants is as follows: RHF, −189.07245; MP2(FC), −189.58936; MP2, −189.59949; MP4, −189.61423.

Both the geometries and the RHF relative energies obtained using our basis set were very close to those given by MJ; the RHF reaction profile of our results is compared with theirs in Fig. 2. The initial approach of the hydroxide is along the C_{2v} symmetry axis of formaldehyde towards the carbon. A shallow minimum (Fig. 1*a*) corresponding to a planar ion–dipole type complex then forms at a distance of 2.76 Å along the C_s reaction coordinate (still having C_{2v} symmetry). As in the MJ study this is not a real minimum but rather an extremely shallow maximum joining two identical planar species where the hydroxide is hydrogen bonding to a single formaldehyde hydrogen. The energy difference between this hydrogen bonding species and the C_s ion–dipole type complex was 0.01 kcal/mol (MJ: 0.1 kcal/mol), which is such a small energy difference that the C_s ion-dipole complex will henceforth be treated as a minimum in this work, as in the MJ study. The further approach of the hydroxide, now rising out of the plane H—C—H of formaldehyde, requires a very small energy barrier to be overcome (1.4

kcal/mol; MJ: 1.1 kcal/mol) whose energy maximum is lower than the energy of the separated reactants by −17.0 kcal/mol (MJ −18.0 kcal/mol). At the barrier maximum (Fig. 1*c*) the carbon–hydroxide distance is 2.35 Å (MJ 2.39 Å), the hydroxide is 63.6° above the H—C—H plane (MJ 59.3°), and the carbon is pyramidalizing, with the carbon-oxygen bond 8° below the H—C—H plane (MJ 6°) and lengthening. From here on the interaction is highly attractive, with the nuclei completing their trajectories to take up their equilibrium positions in the product (Fig. 1*d*) (energy relative to separated reactants E(rel) = −33.3 kcal/mol; MJ −35.1 kcal/mol). The similarities

between our RHF results and those of Madura and Jorgensen, especially considering that small energy changes are preserved, shows that for this system our choice of basis set gives results comparable to those from the 6-31+G* basis set.

To show the effects of electron correlation, the energies of the intermediates along the MERP were calculated at several MP levels. The results are given in Table 2; in Fig. 3 are shown the MP2(FC) and MP4 energy profiles, along with the RHF results for comparison. From these it may be seen that while the introduction of electron correlation into the calculations does not qualitatively alter the PE profile of system I, some of the changes are quantitatively significant. The location of the transition state along R(C—OH) changes by about 0.15 Å, increasing from the RHF value of 2.35 Å to about 2.50 Å (structure Fig. 1*b*), although the position of the secondary minimum (the ion–dipole complex) does not move appreciably. The small energy difference between the PE maximum and the ion-dipole minimum decreases even further to less than 1 kcal/mol, but does not disappear completely. On the other side of the local PE barrier, however, the RHF relative energies are significantly higher than the corresponding MP energies.

Due to computational limitations the greater size of system II permitted only MP2(FC) as the highest level of calculation, so the comparison of systems I and II could not go beyond that level. It is important therefore to compare within system I the MP2(FC) results with the higher orders of MP calculations, to be confident that the major features of the electron correlation are manifest at the lower MP level. From Table 2 it can be seen that the MP2(FC) relative energies are almost identical to those from the MP2 calculations, and differ only slightly from the MP4 values. The greatest variation with the latter occurs in a region of the reaction coordinate between the local maximum and the global minimum (see Fig. 3), but in the vicinity of the local maximum and the secondary minimum the agreement is very good, differing by less than 0.2 kcal/mol. In paper I, a similar comparison showed that for the prototype reaction of hydride adding to formaldehyde, the MP2 and MP4 results were also very similar.

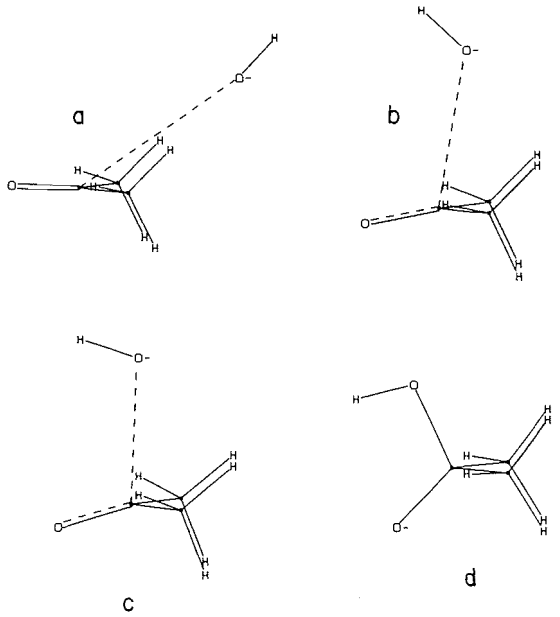

FIG. 4. The SCF optimized structures of several intermediates along the reaction pathway for system II ($(CH_3)_2CO + HO^-$).

For system II, the RHF optimized geometries are given in Table 3 and the corresponding RHF and MP2(FC) energies in Table 4; the structures of several intermediates indicated in Table 4 are shown in Fig. 4, and the reaction profile for both calculational levels is shown in Fig. 5. The same type of double-well reaction profile is present with this system as with system I: the PE decreases as the separated reactants are brought together, reaching a local minimum (Fig. 4*a*) analogous to the ion-dipole minimum of system I. As the reactants continue to approach, the PE increases to a local maximum (MP2(FC): Fig. 4*b*; RHF: Fig. 4*c*) which is lower than the energy of the separated reactants, and then it decreases quickly to form the tetrahedral adduct (Fig. 4*d*).

Some of the changes to the reaction profile upon the inclusion of electron correlation at the MP2(FC) level are qualitatively similar to the changes that took place in system I. The location of the PE local maximum moved farther out along *R*(C—OH) (by about 0.2 Å) while the location of the secondary minimum remained about the same, and the energy difference between the secondary minimum and the local maximum decreased. The energy difference between the local maximum and the global minimum remained about the same upon the addition of correlation. For system II, however, adding correlation caused the energy difference between the separated reactants and all the intermediates to increase, lowering the entire MP2(FC) curve in Fig. 5; this lowering was not found for system I (cf. Fig. 3).

Comparing the RHF reaction profiles of system I and system II at a more quantitative level, several major differences become apparent, as seen in Fig. 6 where the RHF profiles of both systems are shown together. The location of the secondary minimum is 0.75 Å further out along *R*(C—OH) in system II, which is easily explained in terms of an ordinary steric effect, as will be discussed later. The energy (relative to the separated reactants) at the secondary minimum is almost the same for both systems, suggesting that both systems achieve a similar amount of energetic stabilization up to this point in the reaction.

The energy change involved in proceeding from the secondary minimum to the local maximum, however, is significantly greater for system II than for system I. The 1.4 kcal/mol energy change for system I at the RHF level is very small, especially in the light of basis set inadequacy and the neglect of electron correlation, zero-point energy, and thermodynamic effects, even outside of considering possible solvent effects. The

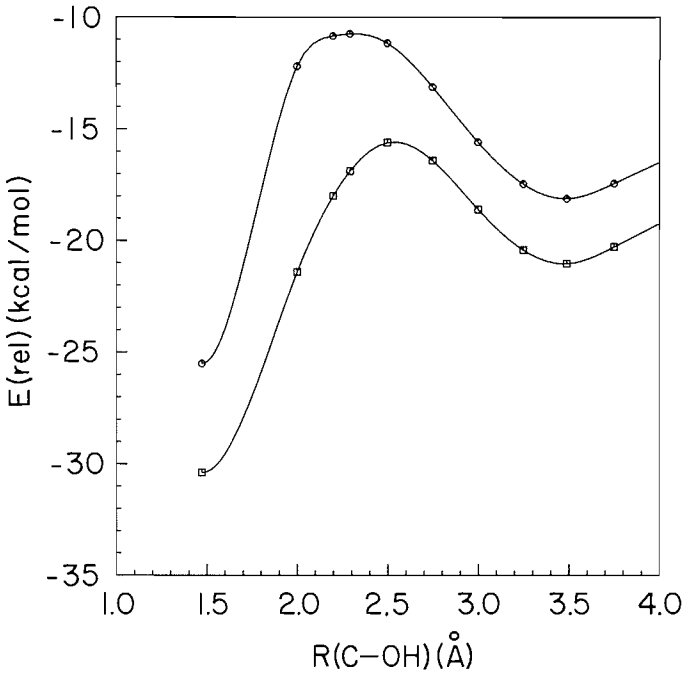

FIG. 5. Energy profiles for system II ($(CH_3)_2CO + HO^-$) including electron correlation; ○, RHF; □, MP2 (frozen core). Energies relative to separated reactants.

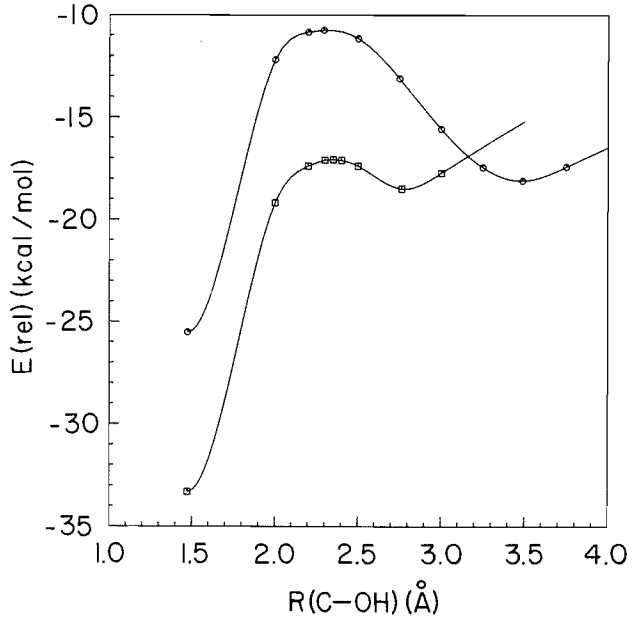

FIG. 6. RHF energy profiles for system I ($H_2CO + HO^-$) (□) and system II ($(CH_3)_2CO + HO^-$) (○). Energies relative to separated reactants.

increased size of the basis set used for system I in the MJ study (3), and the partial inclusion of electron correlation in our study (*vide infra*) both show a trend of decreasing this small energy difference. On the other hand, the energy difference of 7.4 kcal/mol for system II is large enough that correcting for the same factors mentioned above would probably still leave a barrier; after the inclusion of electron correlation at the MP2(FC) level, the barrier is still 5.4 kcal/mol (c.f. Table 4).

The comparison of the MP2(FC) results for systems I and II, shown together in Fig. 7, is similar to the RHF comparison, except for changes caused by the previously mentioned lowering of the system II MP profile. This now places the secondary minimum of system II several kcal/mol lower than that of system I, suggesting that a greater stabilization occurs for system II in going from reactants up to this stage. Otherwise, all the points mentioned above apply.

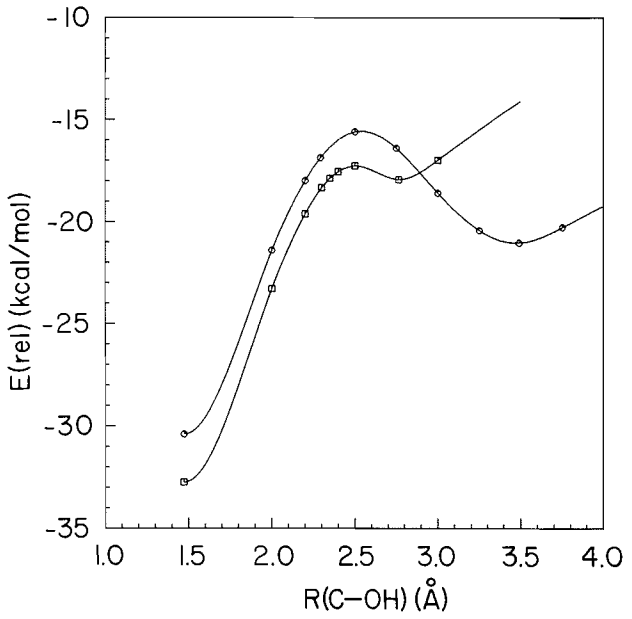

FIG. 7. MP2 (frozen core) energy profiles for system I ($H_2CO + HO^-$) (□) and system II ($(CH_3)_2CO + HO^-$) (○). Energies relative to separated reactants.

The geometry changes taking place over the course of the addition reaction are also an example of a qualitative similarity between these two systems having major differences at a quantitative level. Some of these dissimilarities can be attributed to the differences in steric effects between the two substituents, but others seem to be better explained in terms of an electronic effect.

During the initial stages of the reaction, before bonding interactions take place, the approach of the reactants is generally considered to be governed by charge dipole effects. That is, the negatively charged nucleophile (hydroxyl) will approach the substituted carbonyl dipole along the C_{2v} axis toward the carbonyl carbon, since this maximizes the electrostatic attractions. This leads to the formation of an ion–dipole type complex, giving rise to a PE minimum where the charge dipole attraction is countered by steric repulsion from the carbonyl substituents plus perhaps some other effects in addition. With system I, the ion–dipole complex (Fig. 1*a*) fits this description quite well, with the hydroxyl resting on the formaldehyde C_{2v} symmetry axis, 2.76 Å away from the carbonyl carbon and on the opposite side from the carbonyl oxygen. The analogous C_s species of system II (Fig. 4*a*), however, is quite different. The greater distance of the hydroxide from the carbonyl carbon in system II (3.49 Å) compared to system I is to be expected, reflecting the greater steric effects of the large methyl substituents compared to the small hydrogens of system I. What is interesting is that the nucleophile is significantly out of the molecular plane, with an angle HO—C—X of 34°, and the methyls rotated to direct one of their hydrogens towards the nucleophilic oxygen.

The out-of-plane position of the nucleophile can be explained in terms of a combination of hydrogen bonding to the methyl groups and steric interactions between the two methyls themselves. If the nucleophilic oxygen were to stay on the molecular

axis of acetone, maximizing the electrostatic attractions, then in principle the methyls could rotate, each bringing one of their hydrogens into the plane, directed towards the nucleophile to achieve the "best" hydrogen bonding situation. Under these circumstances, however, each methyl would have a hydrogen *syn* to the other methyl group, and these two hydrogens would be in close proximity to one another, giving bad steric interactions. In order to avoid these steric repulsions, the methyls in the structure of the secondary minimum have only partially rotated their hydrogen bonding hydrogens closer to the plane. The nucleophile, however, has maintained good hydrogen bonding in its position out of the plane, at the expense of some ion–dipole electrostatic interactions. This suggests that the secondary minimum for system II is significantly influenced by hydrogen bonding character, and hence is not strictly an ion dipole complex as the secondary minimum for system I appears to be.

The pattern of the methyl rotations of system II over the course of the reaction is interesting, reflecting the changes in hydrogen bonding to the nucleophile over the course of the reaction. The parameters HCCX and HCCNu in Table 3 can be used to follow methyl rotation and hydrogen bonding, respectively; the former expresses the torsion angle H—C—C—X between one of the methyl C—H bonds and the C—X reference line and the latter expresses the torsion angle H—C—C—OH between the hydrogen bonding methyl C—H bond and the developing C—OH bond. As the nucleophile moves out of the plane and over the methyl groups and carbonyl carbon, the methyls begin to rotate so as to keep a hydrogen directed towards the nucleophile for hydrogen bonding. This is the case over the region of the reaction coordinate from 3.75 Å up to about 2.75 Å, as indicated by HCCNu in this region showing an almost eclipsed H—C—C—OH torsion angle (~0°) while HCCX shows a continuous rotation to allow this near eclipsing. Between 2.75 Å and 2.50 Å there is a sudden change, with the HCCNu torsion angle now opening up again and the methyl rotation changing direction, as the methyls now begin to stagger their hydrogens between the two C—O bonds; this movement continues on to form the equilibrium structure of the tetrahedral adduct (Fig. 4*d*), with the HCCNu value of 54° showing that staggering is almost complete (60° would be "perfect" staggering). This shows that in terms of hydrogen bonding involving the methyl groups, the reaction of system II exhibits two stages, changing character around the position of the local energy barrier.

In proceeding along the reaction coordinate from the secondary minimum, the major difference between the geometries of system I and system II is seen in the angle HO—C—X, which expresses the amount the nucleophile has risen out of the reference plane Y—C—Y (*vide infra*). At a given point along *R*(C—OH) this angle is greater for system II than for system I (c.f. Tables 1 and 3). While the hydroxyl in system I remains in the plane until *R*(C—OH) has reached 2.76 Å (Fig. 1*a*), the hydroxyl at 2.75 Å in system II has risen 68.5° out of the plane, from its "head start" of 34° at the secondary minimum (Fig. 4*a*). From here the difference between the angle HO—C—X in system I and system II begins to decrease again, down to 2° at the tetrahedral adduct. Other geometrical parameters also reflect these differences, but to a lesser degree.

It is at the PE maximum that the dissimilarity between the geometry of system I and system II becomes most significant. Using the MP2(FC) results, which place the maximum at around 2.5 Å for both systems (structures Fig. 1*b* and Fig. 2*b*), the HO—C—X angles differ by 35°. For system I, the HO—C—X angle is 44°, an angle which, at that distance, would certainly create large steric interactions in system II. The larger angle of 80° in system II circumvents such large interactions, so in that sense this big geometry difference could be attributed to a steric effect. However, the two systems may also be at different stages electronically: the degree of pyramidalization of the carbonyl carbon is very small for system I (the CO bond has moved less than 3° below the H—C—H plane), whereas it is substantially larger for system II (the CO bond has moved almost 12° below the Me—C—Me plane). The Dunitz–Burgi attack angle (10), i.e. the HO—C—O angle, is 138.7° at the barrier maximum of system I, well outside the vicinity of 109° suggested by these authors. The corresponding angle for system II is 112.1°, in much better agreement. These comparisons suggest that system II has a better formed HO—C bond than system I at the barrier maximum. That different stages of bond formation between system I and system II are indicated does not necessarily mean that these electronic effects are a determining factor in the geometry differences. It could be other factors, such as the above-mentioned steric factor, which first dictates the larger HO—C—X angle for system II, with the bonding process adjusting *a posteriori* to accommodate the different approach.

These geometry differences for the maximum can become very important in terms of the alignment of reacting termini in an intramolecular reaction. For such reactions, extra energy is often required to distort the molecule into a geometry where the reacting termini can follow a trajectory leading to reaction. The amount of this "distortion energy" required is obviously strongly dependent on the actual geometries required by the reacting termini. Since the rate of reaction is determined by the height of the energy barrier, it is the geometry required by the reacting termini at the maximum that is of crucial importance. Given a reactant geometry having two available trajectories for the intramolecular reaction, each leading to a different product isomer, the preferred pathway will be the one with the lower energy maximum. In such a situation, the determining factor for which pathway is taken will be the difference in the distortion energy required for each pathway. For the reactions studied here, although the barrier maximum is of lower energy than the separated reactants, in an intramolecular situation the reactant geometry often falls within the range of the reaction coordinate containing the secondary minimum. In these circumstances, the local energy barrier would represent a real energy barrier to the reaction.

Conclusions

The comparison of the anionic nucleophilic addition of hydroxide to formaldehyde (system I) and to acetone (system II) is useful in examining the validity of replacing alkyl substituents with hydrogen in modeling organic reactions. For the reactions studied here, the replacement appears to be valid only at a qualitative level. The energy profiles of system I and system II exhibited the same number and relative ordering of maxima and minima, and the changes to the energy profile of a system in going from RHF to MP2(FC) levels of calculation were similar. Also, the general nature of the geometry changes taking place over the course of the reaction was the same for both systems. In particular, with the introduction of electron correlation, the position of the local energy maximum moved farther out along *R*(C—OH) by 0.15 to 0.2 Å.

There were several pronounced differences between the two systems at a quantitative level, however. At the RHF level, an insignificant-looking 1.4 kcal/mol energy difference in system I

between the secondary minimum and the local maximum becomes a definitely important 7.4 kcal/mol difference in system II. Upon the addition of electron correlation at the MP2(FC) level, this energy difference decreases to less than 1.0 kcal/mol in system I, and might disappear completely in the face of the neglect of other corrections. In system II, however, the barrier is still 5.4 kcal/mol. Also, the total energy change for the reaction (i.e. the energy difference between separated reactants and the tetrahedral adduct) increases significantly for system II in going from RHF to MP calculations, but for system I the change is again less than 1 kcal/mol.

The most important differences in geometry between system I and system II concern the angular movement of the nucleophilic oxygen out of the formaldehyde plane, described by the angle H—O—C—X. While the values for this angle differed very little between system I and system II for the product geometry (structures Fig. 1*d* and Fig. 4*d*), over most of the reaction pathway they differed substantially. Most significantly, at the MP2(FC) local energy maximum (structures Fig. 1*b* and Fig. 4*b*) they differed by 35°, with the nucleophile in system II positioned farther over the carbonyl group. Where this energy barrier could be rate-determining in an intramolecular reaction, the differing amounts of strain introduced into an intramolecular framework in requiring the reacting termini to adopt the geometry of system II versus system I could lead to quite different answers regarding the size of this barrier.

The results of this work suggest that the replacement of alkyl substituents by hydrogens in the modeling of organic reactions using theoretical *ab initio* methods does contain some pitfalls. Energy differences that appear to be small in the energy profile of the hydrogen substituted system may increase substantially with the introduction of alkyl groups. Also, while the reactants and products may exhibit very similar geometries, key intermediates along the pathway may have large and important differences in geometry. Such geometry differences may have particularly strong effects in intramolecular reactions.

Received July 12, 1988

CLEMENT W. KAZAKOFF, ROBIN T. B. RYE, and OSWALD S. TEE. Can. J. Chem. **67**, 183 (1989).

The enhancement of the $(C + 1)/C$ ratio in the fast atom bombardment mass spectra of seven pyridinium cations has been measured. No dependence of the enhancement on the cation reduction potential could be identified. The *N*-methyl pyridinium cation, which showed no enchancement under matrix-free conditions, exhibited an increase in the $(C + 1)/C$ ratio with decreasing concentration. This concentration dependence was eliminated when the bombardment energy was reduced from 9 to 5 keV. Possible mechanisms for the concentration dependence and the variation with bombardment energy are proposed.

Key words: fast atom bombardment, reduction, pyridinium salts.

CLEMENT W. KAZAKOFF, ROBIN T. B. RYE et OSWALD S. TEE. Can. J. Chem. **67**, 183 (1989).

On a déterminé l'augmentation du rapport $(C + 1)/C$ dans les spectres de masse, par bombardement avec des atomes rapides, de sept cations pyridinium. On n'a pas pu établir de corrélation entre l'augmentation de ce rapport et le potentiel de réduction du cation. La cation *N*-méthyl pyridinium ne présente pas d'augmentation dans des conditions où il n'y a pas de matrice; toutefois, on observe une augmentation du rapport $(C + 1)/C$ lorsqu'on diminue la concentration. On élimine cette relation avec la concentration lorsqu'on réduit l'énergie de bombardement de 9 à 5 keV. On propose des mécanismes qui pourraient expliquer la relation avec la concentration ainsi que la variation avec l'énergie de bombardement.

Mots clés : bombardement avec des atomes rapides, réduction, sels pyridinium.

Introduction

It is well established that extensive chemical reaction may occur during the fast- atom bombardment (FAB) experiment. Adduct ion formation and dehalogenation reactions may result from reaction of the "analyte" with atomic or free radical species generated from the matrix by particle bombardment (1–3). Reduction reactions have been reported for organic and inorganic salts (4, 5), organometallics (6), nucleosides (7), and organic dyestuffs (5, 8). Mechanisms involving combinations of one- and two-electron reduction, hydrogen atom abstraction, and protonation have been proposed (5, 7, 9), and a correlation with the reduction potential of the analyte has been suggested (5, 8). Many of these analyate – solvent reactions can be minimized by an appropriate choice of matrix material. Nevertheless, glycerol is still the most commonly used solvent for FAB, and study of effects related to its use continues to be of interest. We have recently observed (10) enhancement of the $(C + 1)/C$ abundance ratios (C stands for cation) in the FAB spectra of N(1)-substituted pyrimidinium salts in glycerol, and noted that this enhancement showed a significant concentration dependence. To explore this effect further we have now examined the FAB spectra of selected ring-substituted N-alkyl pyridinium salts in a glycerol matrix. These compounds were chosen because the electrochemical and chemical reduction of 1-alkyl pyridinium cations has been extensively studied (11), and because a series of closely related compounds with a range of reduction potentials could be obtained.

Experimental

Fast atom bombardment spectra were taken on a VG-7070E instrument, with 9 keV xenon atoms as bombarding particles at a beam current of 1.5 mA. The accelerating voltage was 6 kV. Data were acquired using the VG DEC PDP8A data system; peak intensities used for calculation of enhancement ratios are based on an average of five scans. Samples for quantitative measurements were prepared by weight. Samples for matrix-free experiments were dissolved in methanol/water, applied to the probe tip, and air dried before insertion into the source. Compounds **1**, **2**, **5**, **9**, **10**, and **11** were obtained from commercial sources and used as received. Other pyridinium salts were prepared from the appropriately substituted pyridine by quaternization with methyl iodide.

Results

Dependence on cation reduction potential

The seven pyridinium cations selected for study (see Table 1) have reduction potentials (vs. NHE, normal hydrogen electrode) ranging from −1.32 to −0.50 volts. Preliminary measurements showed that concentration effects (*vide infra*) were minor for the ca. 0.1 M solutions used. It is convenient to define an enhancement ratio, ER_n, as the ratio of the measured value of $(C + n)/C$ to the value expected on the basis of natural isotopic abundances. For compounds **1–4**, **6**, **8**, and **11** the values of ER_1 show little variation with cation reduction potential, with a mean value of 1.84 (Fig. 1). The ER_1 values for **5** and **7** are significantly higher (3.1 and 3.2, respectively), possibly reflecting the ease of protonation of the ring substituents, R^2, in these compounds. Substituted pyridinium cations with reduction potentials more positive than that of **8** were not available. The cationic dyes methyl violet, **9**, and methylene blue, **10**, with reduction potentials of −0.642 volts and −0.269 volts, respectively, gave results for ER_1 consistent with literature values (8). The results of Gale *et al.* (8) for **9**, **10**, and some other organic dyes (**12–16**) are also included in Fig. 1. A similar trend in the extent of reduction with E_{red} has been observed for inorganic cations. Thus, Fe(III) (E_{red} = 0.77 V) is strongly reduced, whereas Cr(III) (E_{red} = −0.41 V) is not (5). The facile reduction of Cu(II) to Cu(I) (E_{red} = 0.158 V) has also been

TABLE 1. Reduction potentials and $(C + 1)/C$ ratios

reported (6). It appears from these data that ER_1 is a function of reduction potential for cations with E_{red} more positive than −0.3 to −0.4 volts and, for the pyridinium cations, becomes essentially independent of E_{red} for values more negative than −0.4 volts.

The role of the solvent in the reduction processes observed in FAB has been the subject of a number of reports, and it is generally accepted that bombardment-induced matrix fragments can be involved in such reactions. Gale *et al.* noted that **10** did not undergo reduction using plasma desorption but such processes were significant in FAB (glycerol matrix). A recent study by Busch and co-workers (12) reports significant peaks due to reduction processes using a variety of solvent-free ionization methods, and it suggests several possible rationalizations of the earlier results. We have examined the solvent-free FAB spectra of **10** and three of the pyridinium salts available to us. For compounds **5** and **7** the measued ER_1 values (1.47 and 1.48, respectively) are lower than those measured for the 0.1 M solution, but are sufficiently large to confirm that reduction processes are occurring in the matrix-free system. For **3** and **10** the matrix-free FAB gave an ER_1 value of unity. The expected $(C + 2)/C$ ratios are very small for the pyridinium cations, typically in the 0.1–0.5 range, and in a glycerol matrix the signal-to-noise ratio was too low to permit reliable determinations of ER_2. For **1**, **3**, **5**, **7**, and **8** we estimate ER_2 values in the range 25–30, for 0.1 M solutions, with no obvious dependence on reduction potential. Values of ER_2 between 30 and 77 were reported (8) for the more easily reduced organic dyes.

Dependence on cation concentration

The effect of concentration as a variable in FAB has not received much attention. For the reduction processes considered here, where bombardment-generated fragments of both solvent and analyte may be involved, a complex variation of the extent of reduction with concentration would be expected. Such is clearly the case for **10**, with the relative abundances of the $(C + 1)$, $(C + 2)$, and $(C + 3)$ peaks showing a marked concentration dependence (Fig. 2). For **9** the effect of concentration is much less pronounced, and comparable to that observed for the pyridinium cations. Since reduction of **3** appears to be entirely solvent dependent, it was used to test for a concentration dependence of ER_1. Solutions of **3** in glycerol, at concentrations from 0.028 to 0.83 M, were run under experimental conditions such that the protonated glycerol peak at m/z 93 did not saturate the data system. The measured solute cation peak intensities at m/z 94 and m/z 95 were then corrected for isotope contributions from the solvent, before the ER_1 were calculated. The observed variation of ER_1 with concentration is shown in Fig. 3.

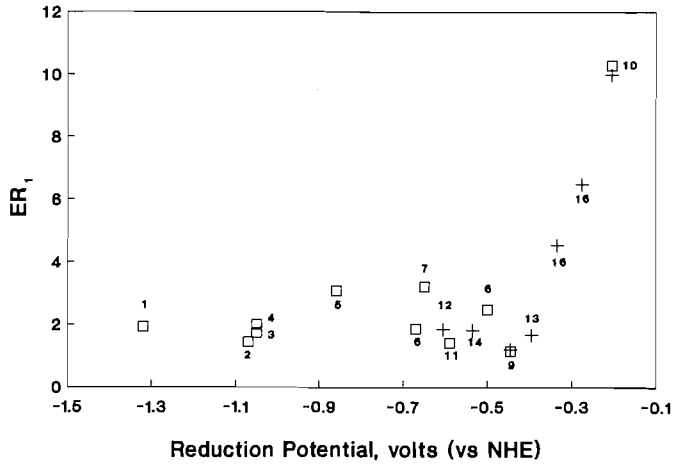

FIG. 1. Enhancement of the $(C + 1)/C$ ratio vs. cation reduction potential. Solute concentrations ca. 0.01 M. Squares, this work; crosses, data from ref. 8.

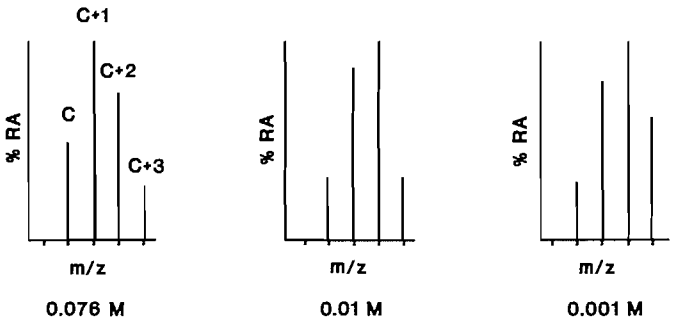

FIG. 2. Concentration dependence of the C^+ ion region of the FAB spectrum of methylene blue at 9 keV.

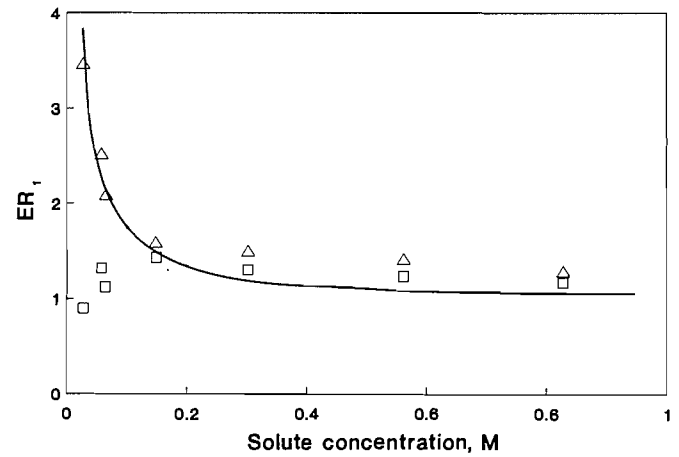

FIG. 3. Concentration dependence of the enhancement ratio ER_1 for *N*-methylpyridinium iodide (**3**): triangles, 9 keV; squares, 5 keV. The solid line was calculated from eq. [9] with $a = 0.005$ M.

The observed effect might possibly reflect changes in the solute concentration at the surface layer occurring when the bulk concentration is less than some critical value. However, if this were the case we would expect to see essentially the same effect in the experiments done at 5 keV (see below). From the absence of a significant concentration effect at the lower bombardment energy (Fig. 3) we conclude that an alternative explanation is required. It is well established (9) that particle bombardment produces electrons in the matrix via ionization, and that these electrons can then act as efficient reducing agents. Dissociation of the target molecule by loss of a hydrogen radical may also occur (13). At the concentrations employed in this work the most probable target molecule is the matrix, so that, as a first approximation, only ionization and dissociation of the glycerol needs to be considered:

[1] $G \rightarrow G^{+\cdot} + e$

[2] $G \rightarrow (G - H)^{\cdot} + H^{\cdot}$

Following these initial events, two pathways leading to $(C + H)^{+\cdot}$ are possible. Electron capture by the pyridinium cation, C^+, followed by protonation leads to the odd-electron ion:

[3] $C^+ + e \rightarrow C^{\cdot}$

[4] $C^{\cdot} + H^+ \rightarrow (C + H)^{+\cdot}$

Alternatively, hydrogen atom attack on C^+ generates the $(C + H)^{+\cdot}$ ion in one step:

[5] $C^+ + H^{\cdot} \rightarrow (C + H)^{+\cdot}$

Formation of the $(C + 2H)^+$ ion may then occur by competitive or consecutive reactions. The $(C + H)^{+\cdot}$ ion may abstract hydrogen from glycerol or it may be desorbed from the matrix. Hydrogen abstraction by $C^{\cdot}$ leads to the neutral species $(C + H)$ (eq. [7]), which may then be protonated.

[6] $(C + H)^{+\cdot} + G \rightarrow (C + 2H)^+ + (G - H)^{\cdot}$

[7] $C^{\cdot} + G \rightarrow (C + H) + (G - H)^{\cdot}$

Equations [2], [5], and [6], with application of the steady-state approximation to $[H^{\cdot}]$ and $[(C + H)^{+\cdot}]$, lead to the prediction that the concentration of $(C + H)^{+\cdot}$ is independent of $[C^+]$ and so

[8] $k'[(C + H)^{+\cdot}] = k_2[G]/((k_6/k')[G] + 1)$

where $k'[(C + H)^{+\cdot}]$ is the rate of loss of $(C + H)^{+\cdot}$ from the matrix. The alternative mechanism, using eqs. [1], [3], [4], and [7], also leads to a predicted independence of C^+ concentration. In the particular case where the rate of protonation of $C^{\cdot}$ (eq. [4]) is large compared to the rate of hydrogen abstraction (eq. [7]), an expression identical in form to [8] is obtained.

Although the individual rate constants are not known, the model can be tested in the following way. If x = concentration of solute in the prepared sample and a = steady-state concentration of $(C + H)^{+\cdot}$, then $(x - a)$ will be the concentration of solute cation sampled by the FAB experiment when the steady state has been established. The predicted $(C + 1)/C$ ratio is then $b + (a/x - a)$, and the calculated value of ER_1 is:

[9] $ER_1 = 1 + (a/(x - a))/b$

where b = the fraction of $C + 1$ from C^+ due to natural isotopic abundances. Equation [9] was fitted to the concentration vs. ER_1 data by trial and error. For a value of $a = 0.005$ M the agreement with experiment is reasonably good (Fig. 3). The question of whether ion formation in fast atom bombardment is a gas-phase or a solution-phase process has received considerable attention (14). Our proposed reaction scheme (eqs. [1]–[7]) would appear to be consistent with the gas collision model developed by Kebarle and co-workers (15), but we have not yet explored this possibility in detail.

A reduction of the bombardment energy from 9 to 5 keV reduced ER_1 values only slightly at the higher concentrations, but it essentially eliminated the concentration dependence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

below 0.1 M (Fig. 3). The proposed mechanisms predict that a reduction in the rates of ionization or dissociation would result in a lower value of ER_1. Fast atom bombardment of glycerol has been shown (3) to generate predominantly carbon-centred radicals. The energy requirements for C—H bond breaking are significantly lower than for ionization; thus the latter process might be expected to show the greater dependence on bombardment energy. On these grounds, the electron capture – protonation mechanism would seem to be favoured, but the limited data presently available do not justify a more detailed analysis.

^{13}C magnetic resonance studies. 138.[1] An examination of the [3.2.2.0] → [4.2.1.0] rearrangement via β-enolization and H/D exchange in tricyclic ketones

SRIYAWATHIE PEIRIS, J. B. STOTHERS, AND SHIRLEY E. THOMAS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

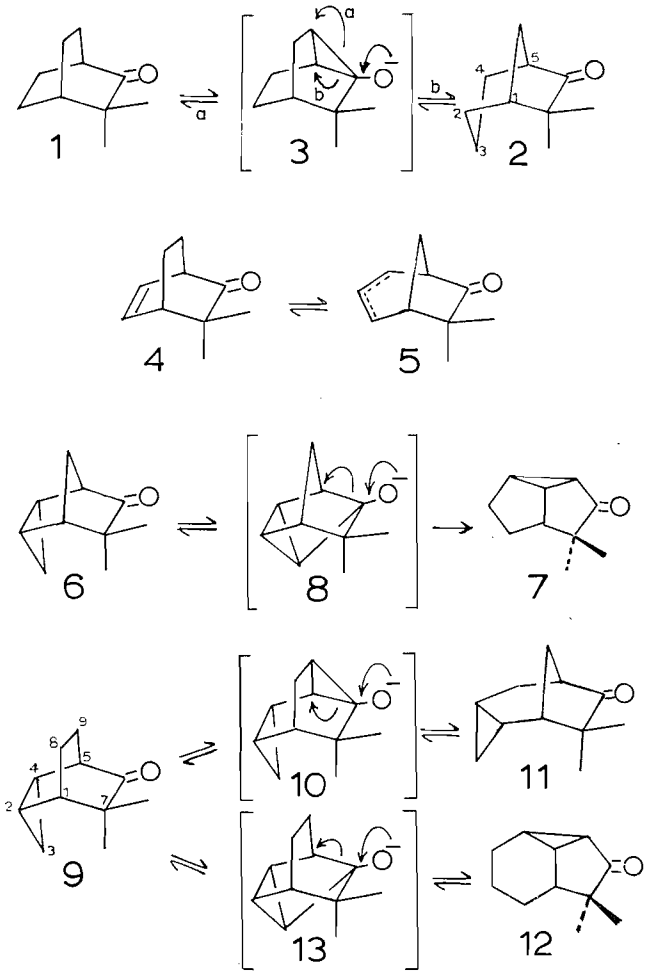
Received August 23, 1988

SRIYAWATHIE PEIRIS, J. B. STOTHERS, and SHIRLEY E. THOMAS. Can. J. Chem. **67**, 187 (1989).

The behavior of the *endo* and *exo* isomers of 7,7-dimethyltricyclo[3.2.2.$0^{2,4}$]nonan-6-one (**9**, **17**) under strongly basic conditions (*t*-BuO$^-$/*t*-BuOH/185°C) has been examined. In both cases rearrangement to the corresponding 8,8-dimethyltricyclo[4.2.1.$0^{2,4}$]nonan-7-one (**11**, **18**) was found, with the *exo* isomer reacting approximately 8 times faster. Experiments in *tert*-butyl alcohol-O-d_1 were carried out to determine the specific sites, the relative rates, and the stereochemistry of deuterium incorporation in the initial ketones. Although H/D exchange occurs most readily at the cyclopropyl methylene carbon in the *endo* isomer, none of the rearrangement product expected to arise via γ-enolate formation was observed. The results for these ketones are compared with our earlier observations in the related [2.2.2], [3.2.1.0], and [3.3.1.0] systems.

Key words: homoenolization, tricyclic ketones, H/D exchange.

SRIYAWATHIE PEIRIS, J. B. STOTHERS et SHIRLEY E. THOMAS. Can. J. Chem. **67**, 187 (1989).



On a examiné le comportement des isomères *endo* et *exo* de la diméthyl-7,7 tricyclo[3.2.2.$0^{2,4}$]nonanone-6 (**9** et **17**) dans des conditions fortement basiques (*tert*-BuO$^-$/*tert*-BuOH/185°C). Dans chacun de ces cas, on a observé une transposition vers la diméthyl-8,8 tricyclo[4.2.1.$0^{2,4}$]nonanone-7 (**11** et **18**) correspondante; l'isomère *exo* réagit environ 8 fois plus rapidement. Afin d'identifier les sites spécifiques, les vitesses relatives et la stéréochimie de l'incorporation du deutérium dans les cétones initiales, on a effectué des expériences à l'aide d'alcool *tert*-butylique-O-d_1. Même si l'échange H/D se produit principalement au niveau du carbone méthylénique du cyclopropane de l'isomère *endo*, on n'observe pas la formation du produit de transposition que l'on pourrait attendre à la suite de la formation d'un énolate-γ. On compare les résultats auxquels ces cétones donnent lieu avec ceux observés antérieurement dans les systèmes [2.2.2], [3.2.1.0] et [3.3.1.0] apparentés.

Mots clés : homoénolisation, cétones tricycliques, échange H/D.

[Traduit par la revue]

Introduction

The activation of remote proton abstraction by a ketonic carbonyl group at centres two and three bonds removed has been recognized for many years and has been demonstrated in a variety of acyclic and cyclic monoketones (1). These systems, upon treatment with *t*-BuO$^-$/*t*-BuOH/≥185°C, the classical (2) homoenolization conditions, generally exhibit abstraction from β-carbons, or β-enolization, but there are a few examples of γ-enolization (3). The process leads, most simply, to deuterium exchange if carried out in a deuterated medium and, in many cases, to skeletal rearrangement. A few examples of the use of β-enolization for the generation of some naturally occurring carbon skeletons from more readily available systems have been described (4) but a much fuller understanding of the factors governing the regioselectivity and the relative reactivity of these proton abstractions should enhance the scope of potential synthetic applications. Our earlier examinations of bicyclooctanones under the usual conditions revealed that the [2.2.2] and [3.2.1] skeletons are interconvertible (5), e.g., **1** ⇌ **2** via β-enolate **3** or its equivalent, and the rate of isomerization is increased markedly, ca. 250-fold, in the unsaturated analogs **4** ⇌ **5** (6). Subsequently, it was found that 6,6-dimethyl-*endo*-tricyclo[3.2.1.$0^{2,4}$]octan-5-one (**6**) rearranges to 4,4-dimethyltricyclo[3.3.0.$0^{2,8}$]octan-3-one (**7**) at a rate comparable to that of **4** under the same conditions, presumably through γ-enolate **8** or its equivalent. From these observations, it seemed reasonable to investigate the behavior of **9** since this ketone has a skeleton in which intramolecular competition between β- and γ-enolization may occur; β-enolization at C-9 can lead to **10**, which may ketonize to form **11**, while γ-enolization at C-3 can lead to **12** via γ-enolate **13**. It may be noted that **14**, an earlier candidate

for examination of competitive β- and γ-enolization, exhibited only H/D exchange while the *exo* isomer **15** rearranged smoothly, via β-enolization, to **16** (7). The failure of **14** to rearrange was attributed to the difference in orientation of the carbonyl group caused by the conformational change of the six-membered ring. Additional support for this conclusion was subsequently provided by the results for some closely related systems (8). For **9**, however, its relatively rigid skeleton would appear to render the orientation of the carbonyl group with respect to C-9, the expected β-enolization site, very similar to that in **1** and **4**, but the relationship of the carbonyl group and C-3, the potential γ-enolization site, will differ somewhat from that in **6**. In this report, we wish to describe the results of our examination of **9** and its *exo* isomer **17** upon treatment with *t*-BuO^-/*t*-BuOH/185°C for comparison with the earlier results for the related systems, including **1**, **4**, and **6**. The sites, rates, and stereoselectivity of proton abstraction from **9** and **17** were also established by the requisite H/D exchange experiments.

Results and discussion

Each of the parent ketones was prepared by the methods previously described in the literature (9, 10), and in each case methylation with MeI/$NaNH_2$/Et_2O gave the required dimethyl ketones in a single cycle.

Homoenolization experiments

The behavior of **9** under homoenolization conditions was examined initially following our usual procedures; **9** was dissolved in anhydrous *t*-BuO^-/*t*-BuOH and aliquots were transferred under nitrogen to predried glass tubes, which were then sealed and heated at 185°C for varying periods of time. The neutral product (>80% yields) was isolated by pentane extraction and analyzed by gas–liquid chromatography (glc) to reveal the smooth disappearance of the starting material **9** and the appearance of one new component (Table 1). Preparative glc provided samples of each and the ^{13}Cmr spectrum of recovered **9** showed the absence of any components with the same retention time. The new compound exhibited strong carbonyl absorption in the infrared (1736 cm^{-1}, liquid film), and a ^{13}C carbonyl signal at δ_C 225.8 indicated that the new ketone contained a cyclopentanone moiety; precise mass measurement confirmed that the new material is isomeric with **9**, having the molecular formula $C_{11}H_{16}O$. In addition to the carbonyl peak, the ^{13}C spectrum contained 10 signals (δ_C, $CDCl_3$): CH_3, 21.1, 26.7; CH_2, 13.7, 32.4_9, 32.5_3; CH, 5.3, 18.0, 40.8, 42.3, and a quaternary C, 48.4. The three signals at highest field (5.3, 13.7, 18.0) confirmed the presence of a 1,2-disubstituted cyclopropane ring, indicating that the product arose from β-enolization at C-9 to furnish **11** rather than through γ-enolization to yield **12**. This deduction was confirmed by the ^{1}Hmr spectrum having two methyl singlets (δ 0.955, 1.247), the cyclopropyl methylene multiplets centred at δ 0.04 and 0.66, with the corresponding methine absorptions at δ 0.70 and 1.26. In addition, the spectrum contained two bridgehead methine signals (2.22 and 2.38) and a doublet of doublets (δ 1.63, J = 1.3, 11.1 Hz, *anti*-H-9) coupled to a partially obscured one-proton multiplet at 2.10 (*syn*-H-9), which was flanked by the remaining methylene pattern at δ 2.00 and 2.15. The assignment of these methylene patterns was confirmed through a heteronuclear ^{13}C–^{1}H correlation spectrum and the specific ^{13}C signals for **11** are listed in Table 2.

The same treatment of **17** with *t*-BuO^-/*t*-BuOH/185°C also revealed the smooth conversion of the starting material to one new component and at a rate ca. 8-fold faster than that observed for **9** → **11** (Table 1). The new compound exhibited strong carbonyl absorption (1734 cm^{-1}, δ_C 226.7), again indicative of a cyclopentanone fragment, and precise mass measurement showed it to be isomeric with **17**, $C_{11}H_{16}O$. Its nmr data were consistent with structure **18**. The 10 sp^3 carbon signals (δ_C, $CDCl_3$) are as follows: CH_3, 20.0, 24.7; CH_2, 11.9, 25.0, 28.7; CH, 6.0, 15.6, 41.4, 43.7; and a quaternary C, 50.8. As in the case of **11**, the three signals at highest field (6.0, 11.9, 15.6) indicate the presence of a 1,2-disubstituted cyclopropane ring, as expected from β-enolization at C-9 in **17** followed by protonation at the original C-5 site to afford **18**. The proton spectrum contained two methyl singlets (δ 1.10 and 1.15), a cyclopropyl methylene pattern having δ_A 0.51 (ddd, J = 4.8, 4.8, 5.4 Hz) and δ_B 0.63 (ddd, J = 5.4, 8.6, 8.6 Hz), with two cyclopropyl methine multiplets δ 0.76 and 1.05. In addition, the spectrum contained two bridgehead patterns (2.06 and 2.27), a doublet of doublets (δ 1.46, J = 1.0, 12.8 Hz, *anti*-H-9), primarily coupled to a one-proton multiplet at 1.85 (*syn* H-9), with the remaining 5-methylene protons absorbing at δ 1.76

[a]In ppm from internal TMS for $CDCl_3$ solutions; values in parentheses may be interchanged.

(ddd, J = 1.3, 5.7, 14.0 Hz) and 2.02 (dddd, J = 2.0, 2.0, 8.6, 14.0 Hz). The ^{13}C–^{1}H heteronuclear correlation spectrum confirmed these assignments and the individual ^{13}C shieldings are listed in Table 2. Samples of **18**, isolated from the runs with **17**, were also heated with t-BuO^-/t-BuOH/185°C and found to give mixtures indicating the equilibrium concentrations to be 15% **17** and 85% **18**.

These and earlier experiments (5, 6) show that the reactivity toward proton abstraction at a β-methylene site in the ethano bridge of these [2.2.2] systems increases in the order **1** < **9** < **17** < **4** with rate constants for rearrangement of 1.0, 4.6, 37, and 240 × 10^{-7} s^{-1}, respectively. The significantly greater reactivity found for the unsaturated ketone **4** relative to its saturated analog **1** can be attributed to allylic stabilization of the incipient carbanion formed upon cleavage of the β-enolate leading to **5**. It could be anticipated that the cyclopropyl group in each of **9** and **17** may provide some stabilization of the developing carbanions on the route to the rearranged materials. Such an influence is clearly smaller for **9** than for **17**. Previously, the composition of the **1** ⇌ **2** equilibrium mixture was found to be 1:4, while for **4** ⇌ **5** the equilibrium composition is 8:92. To assess the equilibria for each of **9** and **17**, two tubes were heated at 200°C for >150 h after which it was found that the **17** ⇌ **18** ratio was 14:86, whereas **9** is favored by ca. 4:1 over **11**. Molecular mechanics (MM2) calculations (11) gave results that are in good agreement with the observations for the saturated systems. For the systems **1** ⇌ **2**, **9** ⇌ **11**, and **17** ⇌ **18**, the calculated equilibrium constants are 3.0, 0.24, and 6.4, respectively, compared with the observed values of 4.0, 0.25, and 6.1. Clearly, the *endo*-cyclopropyl ring in **11** destabilizes this ketone relative to **9** whereas, in the analogous *exo* system, **18** is more stable than **17**.

H/D exchange experiments

The rearrangements of **9** and **17** show that proton abstraction occurs at the β-methylene site of the ethano bridge in each; thus it was of interest to examine the stereoselectivity of this process and to find if other sites undergo exchange. For this purpose, samples of **9** were treated with t-BuO^-/t-BuOD at 185°C for 24, 72, 96, and 144 h.

After 144 h, the recovered **9**-d_x was found to contain 2.12 atoms ^{2}H/molecule by mass spectrometry and the ^{2}Hmr spectrum revealed eight sites of ^{2}H incorporation; the relative amounts at each site were determined by integration. These ^{2}Hmr signals and the ^{2}H content were found to be δ 0.14 (0.87), 0.52 (0.70), 0.98 (0.10), 1.04 (0.02), 1.18 (0.14), 1.70 (0.03), 1.84 (0.22), 2.61 (0.04). The ^{1}Hmr spectrum of **9** contained methyl singlets at δ 0.98 and 1.04, which correlate with the ^{13}C signals at δ_C 26.6 and 23.3, respectively, and can be assigned to the *exo*- and *endo*-methyl groups. Thus, **9** undergoes exchange at the methyl sites, with *exo*-methyl exchange favored, as expected by analogy with several related systems (1). The bridgehead protons H-1 and -5 gave rise to multiplets at δ 2.00 and 2.61, respectively, while the cyclopropyl methine protons H-2 and -4 exhibit multiplets at δ 1.06 and 1.18, as revealed by correlation with their corresponding ^{13}C signals at δ_C 14.5 and 12.5. The 3-methylene protons absorb at δ 0.14 and 0.52, J_{AB} = 7.2 Hz, with the higher field pattern containing additional couplings of 3.5 and 4.4 Hz and the lower field component having a coupling of 7.5 Hz to two other protons. The higher field absorption, δ 0.14, therefore was assigned to the *endo*-3 proton, since it is established that $J_{trans} < J_{cis}$ for vicinal coupling in cyclopropyl rings (12). The ^{13}C–^{1}H COSY spectrum gave the methylene correlations: δ_C 22.8 (δ_H 1.63, 1.80) and 22.2 (δ_H 1.70, 1.84), which were assigned to the 8- and 9-methylene groups, respectively, from the ^{2}H and ^{13}C spectra of the deuterated samples.

The ^{13}Cmr spectrum of the 144-h **9**-d_x sample revealed deuterium incorporation at the higher field 9-methylene site through the appearance of a characteristic triplet, J_{CD} = 20.4 Hz, centred 345 ppb upfield from the original δ_C 22.2 signal, while the absorption for the 8-methylene carbon contained an isotope-shifted component, $^{2}\Delta$ = 103 ppb, arising from ^{2}H at C-9. The ^{2}H spectra of the **9**-d_x samples showed that the less shielded of the two 9-protons, δ 1.84 and 1.70, exchanged more readily and is presumably the *exo*-9-H by analogy with the earlier results for **1**.

In the ^{13}C spectrum of the 24-h sample of **9**-d_x, two triplets centred upfield from the C-3 methylene signal were apparent, J_{CD} = 25.0 Hz for each, with one-bond ($^{1}\Delta$) isotope shifts of 296 and 323 ppb; the more intense triplet of this pair, $^{1}\Delta$ = 323 ppb, was readily attributed to *endo* exchange at C-3 since the intensity ratio of the δ 0.14 and 0.52 signals in the ^{2}H spectrum was found to be 5.0:3.5. The same intensity ratio was found for the two-bond, isotope-shifted components accompanying the signal for C-2 at δ_C 14.5 ($^{2}\Delta$ = 95, 124 ppb) and for C-4 at δ_C 12.5 ($^{2}\Delta$ = 98, 120 ppb); in each case, the more intense component exhibited the larger isotope shift. Each of these patterns also contained a third component indicative of dideuteration at C-3. A pair of isotope-shifted components, $^{3}\Delta$ = 40 and 65 ppb, in a 3.5:5.0 ratio, was also apparent for the C-5 absorption at δ_C 45.5, but the C-1 signal was only broadened without resolvable fine structure.

The ^{13}C spectrum of the 144-h sample revealed the appearance of deuterium at C-9 directly as noted above. Indirect evidence of ^{2}H was shown at C-5 through the presence of a $^{2}\Delta$ component of 105 ppb upfield from the δ_C 22.2 signal (C-9), and at C-4 by isotope-shifted components within the patterns for

C-2, $^2\Delta$ = 126 ppb, and C-3, $^2\Delta$ = 128 ppb. The incorporation level was too low at these and the methyl sites, however, to render the C—D triplets observable; also, the presence of additional isotope-shifted components in the absorptions for the bridgehead carbons was evident but the patterns were not resolved. Thus, deuterium incorporation occurred at C-3, -4, -5, and -9 as well as at both methyl groups. From the ^{2}Hmr spectra of the 24, 72, 96, and 144 h **9**-d_x samples the relative proportions of deuterium at the various sites of exchange were determined and these data permitted the extraction of approximate first-order rate constants, which are considered later.

To determine the regio- and stereochemistry of proton abstraction in **17**, a series of experiments in deuterated base was also carried out. Samples of **17**-d_x were isolated from the resulting mixtures with **18** by preparative glc after reaction times of 3, 12, and 20 h at 185°C in *t*-BuO$^-$/*t*-BuOD. The 20-h sample contained 1.04 atoms ^{2}H/molecule by mass spectrometry and its ^{2}Hmr spectrum revealed six sites of deuterium incorporation for which the relative amounts were measured by integration. These signals and the ^{2}H content were found at δ 0.63 (0.28), 1.05 (0.13), 1.08 (0.02), 1.50 (0.11), 1.65 (0.48), and 2.39 (0.02). The ^{1}Hmr spectrum of **17** exhibited methyl singlets at δ 1.08 and 1.23; thus, only one of the methyl groups exhibited slow exchange. The 3-methylene protons absorb at δ 0.63 and 1.03, J_{AB} = 6.0 Hz, and each is coupled to two vicinal protons with J = 7.8 and 3.7 Hz, respectively. Thus the higher field pattern arises from the *exo*-3 proton *cis* to H-2 and -4, since $J_{cis} > J_{trans}$ in cyclopropyl rings (12). The 2- and 4-protons absorb at δ 1.26 and 1.05, respectively, as shown by ^{13}C–^{1}H correlation, while H-1 and -5 appear at δ 1.93 and 2.39. The ^{13}C methylene signal at δ_C 19.4 correlated with proton multiplets near 1.4 and 1.6 ppm and that at δ_C 21.2 with multiplets near 1.5 and 1.65 ppm. Thus, the ^{2}H spectrum showed that deuterium exchange occurred at C-3, -4, -5, and -9 as well as at one of the methyls. Additional confirmation of the ^{1}H signal assignments was obtained by examination of the effect of added shift reagent, Eu(fod)$_3$, on the spectrum. In the presence of 0.2 equiv. of reagent, the bridgehead patterns initially at δ 1.93 and 2.39 shifted 0.36 and 1.03 ppm downfield, confirming the assignments for H-1 and -5, respectively, while the absorptions at δ 1.26 (H-2) and 1.05 (H-4) were shifted 0.35 and 0.50 ppm. The methylene multiplets near δ 1.5 and 1.65 moved 0.60 and 0.36 ppm, respectively, permitting their assignment to the *endo* and *exo* protons at C-9.

The ^{13}C spectrum of the 20-h sample gave direct evidence for deuterium at C-9 since the δ_C 21.2 signal was accompanied by a 1:1:1 triplet, J_{CD} = 20.3 Hz, $^1\Delta$ = 320 ppb, as was the C-3 signal (δ_C 7.0, J_{CD} = 24.2 Hz, $^1\Delta$ = 286 ppb). Deuterium at C-9 produced isotope-shifted components in the absorptions for C-8 ($^2\Delta$ = 112 ppb) and C-5 ($^2\Delta$ = 75 ppb) while that at C-3 was manifest in the patterns for C-2 ($^2\Delta$ = 90 ppb) and C-4 ($^2\Delta$ = 90 ppb). Indirect evidence for deuterium at C-4 was provided by the appearance of shifted components in the absorptions for C-2 ($^2\Delta$ = 120 ppb), C-3 ($^2\Delta$ = 120 ppb), and C-5 ($^2\Delta$ = 100 ppb). The incorporation levels at C-5 and the methyl site were too low to produce discernible signals in the absorptions for the neighbouring carbons but the ^{2}H spectrum clearly showed that slow exchange occurred at these positions and at both methylene protons on C-9, albeit at distinctly different rates with *exo* exchange favoured. The ^{2}H data for these samples permitted the extraction of approximate rate constants for the various exchange processes.

The samples of **18**-d_x resulting from the experiments with **17** in deuterated base were also examined by ^{2}Hmr to assess the stereoselectivity of deuterium incorporation at C-5 upon cleavage of β-enolate **19** leading to **18** from **17**. In the ^{2}H spectra of these **18**-d_x samples, two prominent signals, δ 1.75 and 2.05, together with three much weaker signals, δ 0.63, 0.76, and 1.10, were found. The individual assignments for these peaks followed readily from comparison with the ^{1}H spectrum of **18** in which the methyl singlets appeared at 1.10 and 1.15 and were correlated with the ^{13}C methyl signals at δ_C 24.7 and 20.0, respectively, arising from the *exo*- and *endo*-methyl carbons. The 3-methylene protons, δ 0.51 and 0.63, J_{AB} = 5.4 Hz, each of which is equally coupled to two other protons, J = 4.8 and 8.6 Hz, respectively, were readily assigned to the *endo*- and *exo*-3 protons, since the latter is expected to exhibit the larger vicinal couplings with the cyclopropyl methine protons. The multiplet arising from the 4-proton appeared at δ 0.76, correlating with the methine carbon signal at δ_C 6.0. The intense ^{2}H signal at δ 2.06 coincided with the bridgehead proton absorption in the ^{1}H spectrum and was, therefore, assigned to H-6, which was expected to undergo rapid exchange characteristic of bridgehead enolization in [3.2.1] bicyclic systems (13). The second prominent ^{2}H signal at δ 1.76 corresponds to an eight-line multiplet (ddd, J = 1.3, 5.7, 14.0 Hz) constituting the pattern for a methylene proton whose geminal partner absorbs at δ 2.02 (dddd, J = 2.0, 2.0, 8.6, 14.0 Hz), both of which correlate with a methylene carbon signal at δ_C 28.7. From the MM2 calculations noted earlier, the dihedral angles relating *exo* H-5 with H-4 and -6 are 98° and 50°, respectively, while the corresponding angles for *endo* H-5 are 17° and 65°. Thus, the absorption at δ 1.76 could be assigned to *exo* H-5 while *endo* H-5 gives rise to the δ 2.02 multiplet, which also contains a long-range coupling of 2.0 Hz to *syn* H-9. It was found that the δ 2.02 pattern is more than twice as sensitive to the addition of Eu(fod)$_3$ as its counterpart at δ 1.76, which is entirely consistent with the assignments.

Additional confirmation for the presence of deuterium at C-5 and -6 was provided by the ^{13}C spectra of the **18**-d_x samples. Characteristic 1:1:1 triplets were apparent in the patterns at δ_C 28.7 (J_{CD} = 20.1 Hz, $^1\Delta$ = 390 ppb, C-5) and 43.7 (J_{CD} = 20.5 Hz, $^1\Delta$ = 387 ppb, C-6). Deuterium at C-5 gave rise to isotope-shifted components in the absorptions for C-2 (δ_C 15.6, $^3\Delta$ = 50 ppb), C-3 (δ_C 11.9, $^3\Delta$ = 60 ppb), C-4 (δ_C 6.0, $^2\Delta$ = 110 ppb), and C-6 (δ_C 43.7, $^2\Delta$ = 82 ppb), while ^{2}H-6 produced such components in the patterns for C-4 (δ_C 6.0, $^3\Delta$ = 25 ppb), C-5 (δ_C 28.7, $^2\Delta$ = 112 ppb), and C-9 (δ_C 25.0, $^2\Delta$ = 107 ppb). From these results, deuterium exchange occurs primarily at the *exo*-5 and -6 positions with minor amounts at the *exo*-3, -4, and *exo*-methyl sites. It is particularly interesting that no deuterium signal at δ 2.02 was observed, showing that ketonization of β-enolate **19** proceeds to **18** exclusively by inversion of configuration at C-5.

The approximate first-order rate constants for exchange at the various sites in **9** and **17** extracted from the deuterium incorporation data are given in Fig. 1 together with earlier results for the parent [2.2.2] ketone **1** (5), the [3.2.1.0] analogs **6** and **20** (3), and the isomeric [3.3.1.0] ketones **14** and **15** (7). The stereoselectivity of deuteration at the β-methylene site in the ethano bridge of **9** and **17** is comparable to that found for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12

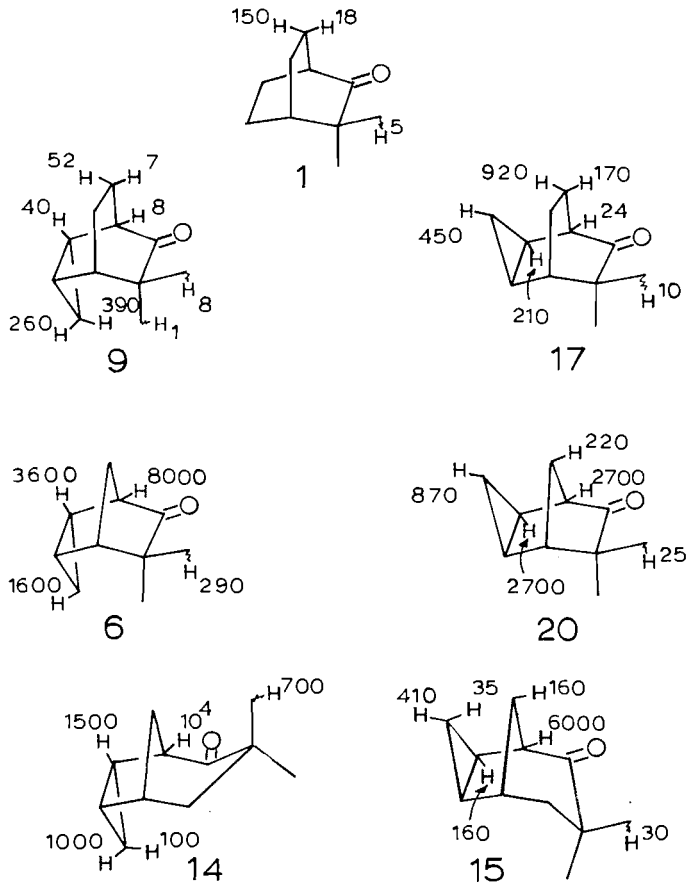

FIG. 1. Deuterium exchange rates ($k \times 10^8\ s^{-1}$) at the various sites in **1**, **6**, **9**, **14**, **15**, **17**, and **20** in *t*-BuO$^-$/*t*-BuOD at 185°C.

the parent ketone **1** with *exo* deuteration favored. Thus, one can conclude that the cleavage of the β-enolates formed by proton abstraction at this site, i.e., **3**, **10**, and **19**, proceeds preferentially with inversion of configuration to return to the initial ketone. This is consistent with the general tendency for β-enolate cleavage in many related systems (1). From these results for exchange at the β-methylene site, it could be anticipated that the alternative cleavage leading to the rearranged ketones, i.e., **3** → **2**, **10** → **11**, and **19** → **18**, would also favor inversion. In fact, it was found that, within the limits of detection, deuterium was only observed in the *exo* orientation at C-4 and C-5 in **2** and **18**, respectively. The enhanced rates at C-9 in **17** relative to the corresponding processes in **1** and **9** may implicate some interaction with the neighbouring cyclopropyl ring. There is also a significant increase in reactivity for exchange at the 5-bridgehead position in both **9** and **17** relative to **1**, for which it was not observed. This perhaps reflects an inductive effect of the cyclopropyl group, thereby increasing the acidity of the bridgehead proton in these tricyclic ketones. The bridgehead exchange rates in **9** and **17** are comparable to that found in the [2.2.1] system 3,3,6,6-tetramethylnorcamphor, $k = 30 \times 10^{-8}\ s^{-1}$ (14), which is markedly increased upon introduction of the cyclopropyl ring as in **6** and **20**.

By analogy with **6**, **14**, **15**, and **20**, exchange was expected to occur at C-3 and -4 in **9** and **17** but there are interesting quantitative differences between the three ring systems. Whereas the data for the *exo* ketones **15** and **17** are similar, although a higher stereoselectivity at C-3 in **17** is evident, the results for **9** differ strikingly from those for its *endo* analogs **6** and **14**. Exchange at these sites is distinctly slower in **9** and there is a marked difference in stereoselectivity at C-3, with *endo* exchange slightly favored in **9** contrasting sharply with the *exo* preference in **6** and **14**. It is conceivable that γ-enolate **13**, or its equivalent, is formed, which subsequently returns exclusively to **9** via cleavage with retention of configuration at C-3 with incorporation of *endo* deuterium. This has been found to be the favored mode of cleavage for other γ-enolates (1). As already noted, *exo*-methyl exchange occurred preferentially and at comparable rates in **9** and **17**. This contrasts sharply with the other tricyclic analogs, for which methyl exchange was found to be distinctly faster in the *endo*-cyclopropyl examples **6** and **14** relative to their *exo* counterparts **15** and **20**. Clearly, subtle factors must govern the reactivity of exchange in these systems and further data must be obtained before definitive interpretations can be put forward.

Experimental

Gas–liquid chromatography (glc) was carried out on Varian 920 and 3700 instruments using columns of 6% FFAP or 10% SE-30 on Chromosorb W as indicated. Flash chromatography columns were prepared as described in the literature (15). Diethyl ether was dried over Na/benzophenone and freshly distilled before use; methyl iodide was dried over 4 Å sieves.

Infrared spectra were recorded with a Bruker/IBM FTIR 32 instrument and mass spectra were obtained on a Finnigan MAT 8230 spectrometer at 70 eV (direct inlet). Routine ^1H spectra were recorded with a Varian EM-360 instrument while data for pure samples were collected with Varian XL-200 or -300 systems. The effect of Eu(fod)$_3$, as shift reagent, was utilized to increase the shift dispersion to permit unambiguous assignments, which were also confirmed by ^1H–^1H correlation (COSY) spectra; these gave definitive ^2H assignments since ^1H and ^2H shieldings are essentially identical. Integration of the ^2H spectra indicated the extent of ^2H incorporation at the sites undergoing exchange, while the total ^2H content was determined by mass spectrometry. The ^2H and ^{13}C nmr spectra were obtained at 46.1 and 75.4 MHz, respectively, on the Varian XL-300 system, and comparison of the fully decoupled ^{13}C spectra with those obtained with the APT sequence (16) identified the number of hydrogens directly bonded to each carbon. Correlation of the ^1H and ^{13}C spectra for **9**, **11**, **17**, and **18** was accomplished using the HETCOR sequence of the XL software with a 2048 × 128 data matrix, 3600-Hz spectral widths for ^{13}C, and 700–1000 Hz, as appropriate for ^1H, transforming 2048 and 512 points, respectively. ^1H–^1H COSY spectra were recorded for **11**, **17**, and **18** with the HOMCOR sequence of the XL software using a 1024 × 512 matrix, spectral widths of 600 (**11**), 700 (**17**), and 756 Hz (**18**), transforming 1024 points for both axes.

*7,7-Dimethyl-*endo*-tricyclo[3.2.2.0^{2,4}]nonan-6-one (**9**)*

A solution of *endo*-tricyclo[3.2.2.0^{2,4}]nonan-6-one (0.25 g, 1.8 mmol), prepared as described by Schueler and Rhodes (9), in anhydrous Et_2O (5 mL) was added to $NaNH_2$ (0.8 g) in Et_2O (5 mL) under a N_2 atmosphere and the mixture refluxed for 3 h. After cooling, methyl iodide (1.14 g, 8.0 mmol) was added and the mixture refluxed overnight. Methyl iodide (0.42 g, 3.0 mmol) was added and the mixture refluxed for 3 h before cooling to 0°C. Water (10 mL) was slowly added and the organic phase decanted. The aqueous phase was extracted with Et_2O (4 × 25 mL) and the combined extracts washed with water (3 × 30 mL) and twice with brine (20 mL) before drying over magnesium sulphate. After removal of solvent, the crude product was shown by glc (6% FFAP) to be essentially one component. This product was purified by flash chromatography (petroleum ether – Et_2O, 80:20) to provide **9** (0.23 g, 75%); ir (film): 1724 cm^{-1}; ^{13}Cmr: see Table 2; ^1Hmr ($CDCl_3$) δ: 2.61 (m, 1H), 2.00 (m, 1H), 1.50–1.95 (m, 4H), 1.00–1.25 (m, 2H), 1.04 (s, 3H), 0.98 (s, 3H), 0.52 (ddd,

J = 3.5, 4.4, 7.2 Hz, 1H), 0.14 (dt, J = 7.2, 7.5 Hz, 1H). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1203.

*7,7-Dimethyl-*exo*-tricyclo[3.2.2.0^{2,4}]nonan-6-one (17)*

Following the method described by Freeman, Balls, and Brown (17), *exo*-tricyclo[3.2.2.0^{2,4}]non-6-en-8-one was prepared from cycloheptatriene and acrylonitrile. Hydrogenation according to the procedure reported by Wenzinger and Ors (10) furnished the saturated analog, which was methylated as described above such that 350 mg of *exo*-tricyclo[3.2.2.0^{2,4}]nonan-6-one gave a yellowish liquid found to be >95% pure by glc analysis (SE-30). This was purified by flash chromatography (petroleum ether – Et_2O, 95:5) to furnish 270 mg (64% yield) of **17**: ir ($CHCl_3$): 1724 cm^{-1}; ^{13}Cmr: see Table 2; ^{1}Hmr ($CDCl_3$) δ: 2.39 (m, 1H), 1.93 (m, 1H), 1.55–1.70 (m, 2H), 1.48 (m, 1H), 1.40 (m, 1H), 1.26 (m, 1H), 1.23 (s, 3H), 1.08 (s, 3H), 1.05 (m, 1H), 1.03 (dt, J = 3.7, 6.0 Hz, 1H), 0.63 (dt, J = 6.0, 7.8 Hz, 1H). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1202.

Homoenolization experiments

Our standard procedures (18) for the rearrangement and exchange experiments were followed as illustrated for **9**. To a solution of t-BuO$^-$/t-BuOH (1.27 M, H_2O content <250 μg/mL) was added **9**, to give a solution that was 0.26 M in ketone. To a series of 5-mL predried, thick-walled glass tubes were transferred 0.35-mL aliquots of the reaction solution; the tubes were degassed and sealed before immersion in an oil bath at 185°C. Tubes were removed at intervals, cooled before opening, and the contents removed by washing with water (10 mL). The organic product was isolated by pentane extraction (3 × 15 mL). After drying the combined extracts over magnesium sulphate, removal of the solvent afforded a neutral organic product (>80% yields), which was analyzed by glc (FFAP) to reveal the presence of two barely resolved components, the major one of which was the initial ketone. The new component was ketonic (1736 cm^{-1}) and isomeric with the initial ketone. *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: C 164.1197. The new ketone was identified as **11** by ^{1}H and ^{13}Cmr as described in the text. In the same fashion, **17** was found to yield a mixture of two ketones upon heating at 185°C in t-BuO$^-$/t-BuOH for several hours. Separation by preparative glc (SE-30) furnished samples of the new ketone (1734 cm^{-1}), which was isomeric with **17**. *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1195. It was identified as **18** by ^{1}H and ^{13}Cmr as described in the text. A series of samples of **9** and **17** were also treated with t-BuO$^-$/t-BuOD (99% deuterated) to examine the exchange processes occurring under these reaction conditions; the results are described in the text.

Received July 12, 1988

BRIAN K. TAKASAKI and OSWALD S. TEE. Can. J. Chem. **67**, 193 (1989).

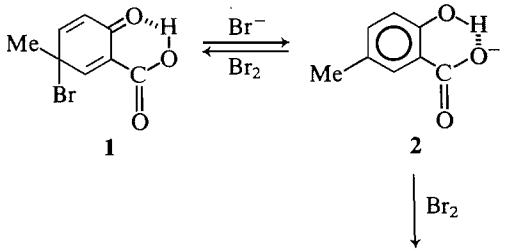
Debromination of the title dienone (**1**), formed during the bromination of 5-methylsalicylic acid (**2**), is strongly catalyzed by α-cyclodextrin (CD). The bromination of **2** is also catalyzed by CD. The extent of the catalysis of the debromination of **1** is independent of pH in the range pH 3–5 and it tends to saturate at high [Br^-] and high [CD]. Analysis of the [Br^-] dependence data in the presence of 1 mM CD yields a value of 0.68 M for the dissociation constant of the CD·Br^- complex. Also, from the dependence of the rate of debromination on [CD], the anion of the dienone **1** (i.e., $\mathbf{1}^-$) forms a complex with CD with a K_d of 15 mM, which appears to react with Br^- at a rate 170 times faster than does free $\mathbf{1}^-$. However, the catalysis is more likely due to the reaction of free dienone, reacting as **1**, with the CD·Br^- complex, which is 3400 times more reactive than uncomplexed Br^-. The combined effect of the internal catalysis by the carboxyl group of **1** and the external catalysis by CD is an overall rate enhancement of 12 million.

Key words: catalysis, cocatalysis, cyclodextrin, debromination, intramolecular.

BRIAN K. TAKASAKI et OSWALD S. TEE. Can. J. Chem. **67**, 193 (1989).

La débromation de la diénone mentionnée dans le titre (**1**), qui se forme lors de la bromation de l'acide méthyl-5 salicylique (**2**), est fortement catalysée par l'α-cyclodextrine (CD). La bromation du composé **2** est aussi catalysée par la CD. Le degré de la catalyse de la débromation du composé **1** ne varie pas avec le pH (de 3 à 5) et il a tendance à atteindre une valeur limite à des concentrations élevées de Br^- ou de CD. Une analyse des données relatives à l'influence des ions [Br^-], en présence de 1 mM de CD, permet d'évaluer à 0,68 M la constante de dissociation du complexe CD·Br^-. De plus, en se basant sur la relation qui existe entre la vitesse de débromation et la [CD], on peut déduire que l'anion de la diénone **1** (soit $\mathbf{1}^-$) forme un complexe avec la CD et que la K_d est 15 mM; ce complexe semble réagir avec le Br^- avec une vitesse qui est 170 fois plus grande que celle du $\mathbf{1}^-$. Toutefois, il est plus probable que la catalyse soit due à la réaction de la diénone libre, réagissant sous la forme de **1**, avec le complexe CD·Br^-; en effet, celui-ci est 3400 fois plus réactif que le Br^- qui n'est pas complexe. Les effets combinés de la catalyse interne par le groupement carboxyle du composé **1** et de la catalyse externe par la CD conduisent à une augmentation de la vitesse qui est de l'ordre de 12 millions.

Mots clés : catalyse, cocatalyse, cyclodextrine, débromation, intramoléculaire.



[Traduit par la revue]

Introduction

Cyclodextrins form inclusion complexes with many species, most notably with organic substrates (1, 2). As a consequence, they can have significant effects on the rates and products of organic reactions. Of particular note, they can function as catalysts in various kinds of reactions, although most attention has been paid to the cleavage of esters or amides and to various "model enzyme" reactions (1–4).

In this laboratory we have shown that α-cyclodextrin can function as a catalyst in the aqueous bromination of anisole (5), phenols and phenoxide ions (6), and in the debromination of "*ipso*-dienones" (7). These last derivatives are labile intermediates formed by *ipso* attack during the aqueous bromination of *p*-alkylphenols (8, 9). Under the reaction conditions they represent a "dead-end" and they decompose by a debromination that is bromide ion induced and general acid catalyzed (9). In the particular case of 4-bromo-4-methyl-2,5-cyclohexadienone-2-carboxylic acid (**1**), the debromination (**1** → **2**, eq. [1]) is catalyzed intramolecularly by the carboxyl group (9, 10).

The present paper reports a study of the catalysis of the debromination of the *ipso*-dienone **1** by α-cyclodextrin (CD). We hoped that the study would provide additional evidence for the mechanisms of CD-catalyzed bromination and debromination proposed earlier (6, 7), but the main object was to see how two very different forms of catalysis interact with one another. Independently, intramolecular catalysis by the carboxyl group

[1] 

ortho product

of **1** (9, 10) and the catalysis by CD of the debromination of other *ipso*-dienones (7) are both large; in combination they might afford very strong "cocatalysis", as long as they do not interfere with one another.

Enzymes achieve their remarkable efficiency by bringing together several catalytic effects in one process (4, 11). It is, therefore, of ongoing interest to find and understand chemical reactions in which more than one type of catalysis is operative.

Results

We have measured the rate of debromination of the dienone **I** as a function of [CD], pH, and bromide ion concentration. Also, we have measured the effect of added CD on the rate of bromination of 5-methylsalicylic acid (**2**).

At the high concentrations of bromide ion used in the present work, the formation of the weak CD·Br^- complex (12) results in an appreciable reduction in the amount of CD that is available for the complexation of other species, but this can be corrected for (5–7). Since [Br^-] >> [CD], the concentration of available

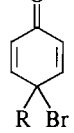
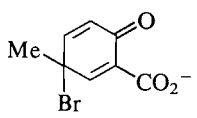
TABLE 1. Rate constants for the debromination of **1** as a function of the concentration of α-cyclodextrin[a]

$[CD]_T$ (mM)	k_{obs} (s^{-1})	k_{calc} (s^{-1})
0	0.111	0.111
1.0	1.01	1.02
2.0	1.86	1.84
3.0	2.62	2.60
4.0	3.23	3.29
6.0	4.54	4.51



[a]At 25°C, $I = 0.11$ M (0.1 M KBr + 0.01 M buffer salt), at pH 4.5 (acetate buffer). The dienone **1** was generated *in situ* from [**2**] = 0.5 mM and $[Br_2] = 0.05$ mM. The values of k_{calc} were calculated from the values of K_d and k_c (see text), obtained by an Eadie–Hofstee analysis, and using corrected values of [CD] from eq. [2].

CD is given by:



$$[2] \quad [CD] = [CD]_T K_I/(K_I + Br^-]); \qquad K_I = 0.286 \text{ M} \ (12)$$

where $[CD]_T$ is the total added CD and K_I is the dissociation constant of the CD·Br^- complex. The concentration of CD given by eq. [2] was used in all data analyses (5–7).

As with other *ipso*-dienones (**3**), generated by *ipso* bromine attack during the bromination of *p*-alkylphenols (7), we have found that the addition of CD leads to a considerable increase in the rate of debromination of the dienone **1** (see Table 1). The rate constants increase with [CD] in a curvilinear manner that conforms well to Michaelis–Menten behavior (1), and analysis by the Eadie–Hofstee approach yields a value of 14.7 mM for the dissociation constant (k_d) of the CD·dienone complex and 19.1 s^{-1} for the apparent rate constant (k_c) for the reaction of this complex, in 0.1 M KBr at pH 4.5. Thus, at saturation the rate increase is substantial: $k_c/k_u = 172$. Note also that the values of K_d and k_c must apply to the anion $\mathbf{1}^-$, since **1** ($pK_a = 3.06$ (10)) is largely ionized at the pH of 4.5.

3

$\mathbf{1}^-$

Figure 1 shows the pH dependence of rate constants for the debromination of **1** in the absence of CD and in the presence of 1 mM CD. The former results are in good agreement with those found earlier (10) and the dependence in the presence of 1 mM CD shows parallel behaviour,[3] the rate constants being about 7 times greater.

Figure 2 shows the dependence of the rate constant for debromination on [Br^-]: (a) without CD; (b) in the presence of 1 mM CD; (c) in the presence of 8 mM CD (Table 2). In the absence of CD the rate constant shows the expected first-order

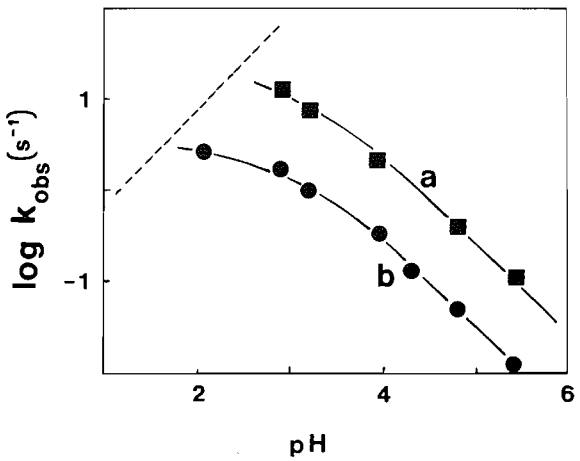


FIG. 1. The pH dependence of the rate of debromination of the dienone **1** in aqueous 0.1 M KBr + buffer ($I = 0.11$ M): (a) in the presence of 1 mM CD; (b) in the absence of CD. The latter results agree well with earlier work (10). The dashed line represents the pH dependence of the pseudo-first-order rate constant of the bromination of **2** under the same conditions (10).

dependence on [Br^-] (9), with a second-order rate constant of 0.950 M^{-1} s^{-1}, at pH 4.5. The larger rate enhancements due to increasing [Br^-] in the presence of CD (Fig. 2, b and c) confirm that both Br^- and CD are involved in the catalytic pathway. Moreover, the clear tendency to saturation-type behavior at high [Br^-] is further evidence of the formation of a weak CD·Br^- complex (12).

The dependence of the rate of bromination of **2** on [CD] has also been measured (Table 3). The apparent second-order rate constants (k_2^{app}) increase at low [CD] but then begin to decrease at high [CD], similar to the behaviour observed previously with simple phenols (6). The increase in k_2^{app} at low [CD] indicates that there is a significant contribution from a CD-catalyzed pathway for bromination while the decrease at high [CD] is due to the combined effects of the complexation of the substrate, Br_2, Br_3^-, and Br^- by CD (5, 6). If the bromination of **2** were not catalyzed by CD, the rate constants k_2^{app} would decrease substantially with increasing [CD] (see Fig. 1 of ref. 6).

Analysis of the variation with [CD] of k_2^{app} for the bromination of **2** is not as simple[4] as that for the phenols studied previously (6). This difference arises because the debromination of **1** is strongly catalyzed by the 2-carboxyl group such that this reaction is rapid enough to affect the overall rate of bromination of **2** (10). Thus, the value of k_2^{app} is dependent on the rate of debromination of **1**, as well as on the rate of bromine attack at the *ortho* and *para* positions of **2**. Furthermore, *all of these processes are catalyzed by CD*, which makes a rigorous analysis of the bromination data unmanageable.

Discussion

Bromide ion dependence

The curved dependence of the observed first-order rate constants for the debromination of **1** on the concentration of Br^- in the presence of CD, shown in Fig. 2b, can be analyzed using the following approach.

When a substrate reacts in the absence of CD (with rate con-

[3]Unfortunately, it was not possible to measure the rate of debromination of **1** in the presence of CD below pH 3 because there the rate of bromine attack on **2** is sufficiently slow as to interfere with the kinetics of debromination. However, in the pH region studied, the rate constant in the presence of CD shows the same pH dependence as in the absence of CD.

[4]In fact, the earlier analysis is not all that simple since several corrections must be made to account for the various equilibria involved (5, 6).

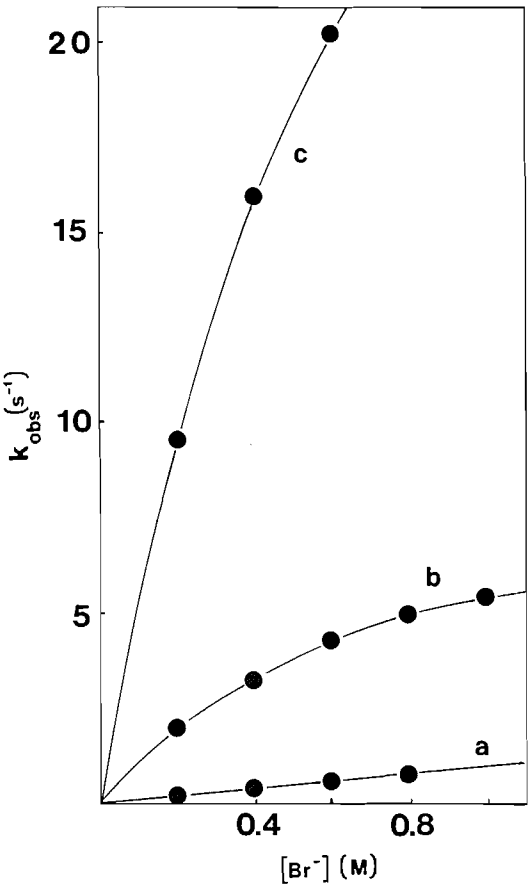

FIG. 2. The dependence of the rate of debromination of the dienone **1** on the concentration of bromide ion: (a) in the absence of CD; (b) in the presence of 1 mM CD; (c) in the presence of 8 mM CD. The ionic strength was maintained at 1.0 M (NaCl + KBr) and the pH at 4.5 with an acetate buffer (10 mM).

TABLE 2. Effect of $[Br^-]$ on the rate of debromination of **1** at different concentrations of α-cyclodextrin[a]

	k_{obs} (s^{-1})		
$[Br^-]$ (M)	$[CD]_T = 0$	1 mM	8 mM
0.2	0.216	1.97	9.54
0.4	0.408	3.27	15.97
0.6	0.601	4.28	20.34
0.8	0.785	4.99	[b]
1.0	—	5.51	[b]

[a]At 25°C, pH 4.5 (acetate buffer), I = 1.0 M (KBr + NaCl).
[b]Not measurable due to interference from the bromination step. At high $[Br^-]$ and [CD] the debromination is sufficiently fast as to be comparable in rate to the initial bromination (cf. Fig. 2).

stant k_u) and via a complex S·CD (with rate constant k_c) in the presence of CD, then:

[3*a*] $k_{obs} = (k_u K_d + k_c[CD])/(K_d + [CD])$

For the more complete set of data at [CD] = 1 mM (Fig. 2b) we can make use of the inequality K_d (= 15 mM) >> [CD], since [CD] < 1 mM due to the formation of the CD·Br^- complex. Then, eq. [3*a*] simplifies to

[3*b*] $k_{obs} = k_u + k_c[CD]/K_d$

TABLE 3. The effect of α-cyclodextrin on the rate of bromination of 5-methylsalicylic acid, **2**[a]

$[CD]_T$ (mM)	k_2^{app} ($M^{-1}\,s^{-1}$)
0	8 710
1.0	19 200
2.0	21 500
4.0	21 700
6.0	20 700
8.0	18 600

[a]At 25°C, pH 1.0 (0.1 M HCl), I = 0.2 M (KBr + HCl), [**2**] = 0.25 mM, $[Br_2]_0$ = 0.025 mM.

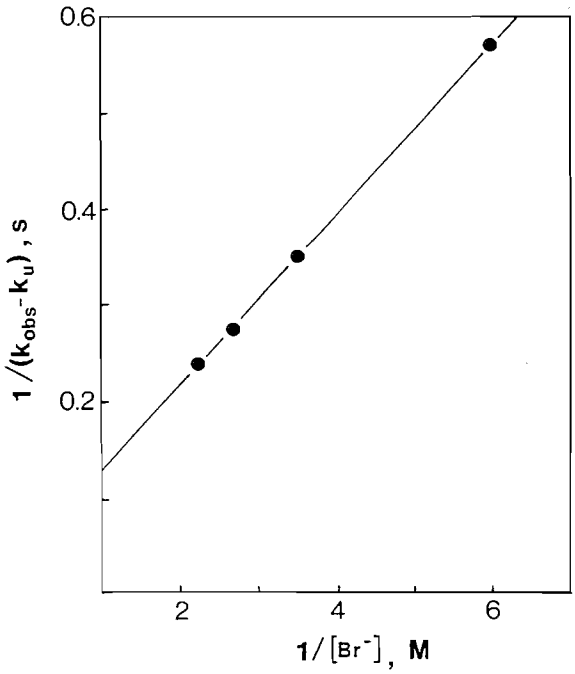

FIG. 3. Double-reciprocal plot of the $[Br^-]$ dependence data presented in Fig. 2b, based on eqs. [4] and [5] (see text).

To account for the overall dependence on $[Br^-]$ we must replace [CD] by the explicit expression given in eq. [2] and also include the dependence of k_c on $[Br^-]$ by expressing it as $k_2^c[Br^-]$. Hence:

$$[4] \quad (k_{obs} - k_u) = \frac{k_2^c[Br^-][CD]_T K_I}{(K_I + [Br^-])K_d}$$

Taking the reciprocal of both sides of this expression gives a Lineweaver–Burk type of equation,

[5] $1/(k_{obs} - k_u)$ = slope/$[Br^-]$ + intercept

where "slope" = $K_d/k_2^c[CD]_T$ and "intercept" = $K_d/k_2^c[CD]_T K_I$, and an estimate of K_I can be obtained from the slope/intercept.

For the data in Fig. 2b this treatment gives a good straight line, as shown in Fig. 3, and from the slope and intercept a value of K_I = 0.677 M is obtained. This value is only in fair agreement with the literature value of 0.286 M (12) and the reasons for the discrepancy between the two values are not immediately apparent. It may be due to the differences in ionic strength (I = 0.01–0.03 M (12) vs. I = 1.0 M, this work), the different assumptions involved in the two approachs, or it may

TABLE 4. Constants evaluated for the two models (eqs. [6*a*] and [6*b*]) for the CD-catalyzed debromination of 4-bromo-4-alkyl-2,5-cyclohexadienones, **3** and $\mathbf{1}^-$[a]

Dienone	K_d (mM)	k_c^a/k_u'	k_c^b/k_u'	k(1 mM CD)/k_u
3, R = Me	4.83	78	4600	5.7

$\mathbf{1}^-$ [b]	14.7	170	3400	7.1

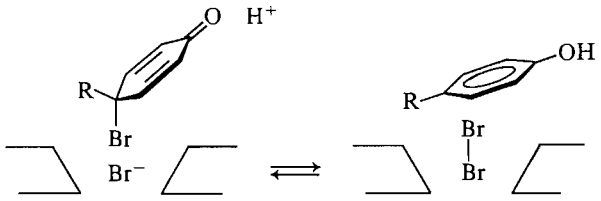
[a]At 25°C. The data for **3** are taken from ref. 7 and are normalized to 0.1 M HCl in 0.1 M KBr. The constant k_u' is for the reaction of the dienone with Br^-, k_c^a is for the reaction of the CD·dienone complex with free Br^- (eq. [6*a*]), k_c^b is for the reaction of the CD·Br^- complex with free dienone (eq. [6*b*]).
[b]At pH 4.5 (acetate buffer), in 0.1 M KBr.

be a reflection of the difficulty of determining the dissociation constants of weakly bound complexes.

More importantly, the formation of a weak CD·Br^- complex is confirmed. In the present paper we retain the use of K_I = 0.286 M, for consistency with the earlier work (5–7).[5]

Dependence on [CD]

It is clear that the debromination of the *ipso*-dienones **3** (7), and now **1**, are catalyzed by bromide ion *and* by α-cyclodextrin. These processes may be characterized by third-order rate constants (k_3) but it is most likely that they arise from either of two, kinetically indistinguishable, second-order processes (7): the attack of *free* Br^- on the dienone·CD complex (eq.[6*a*]); or attack of the CD·Br^- complex on the *free* dienone, **3** (eq. [6*b*]).[6]



$$[6a]\quad \mathrm{CD} + \mathbf{3} + \mathrm{Br}^- \underset{K_d}{\rightleftharpoons} \mathrm{CD}\cdot\mathbf{3} + \mathrm{Br}^- \xrightarrow{k_c^a} \text{products}$$

$$[6b]\quad \mathrm{CD} + \mathrm{Br}^- + \mathbf{3} \underset{K_I}{\rightleftharpoons} \mathrm{CD}\cdot\mathrm{Br}^- + \mathbf{3} \xrightarrow{k_c^b} \text{products}$$

In the first case $k_3 = k_c^a/K_d$, while in the second $k_3 = k_c^b/K_I$ (7).

Analysis of the data in Table 1 according to eq. [6*a*] is straightforward (7) and it gives values of K_d = 14.7 mM and k_c^a = 191 $M^{-1}s^{-1}$ (cf. Results) for the reaction of the anion $\mathbf{1}^-$ at pH 4.5. As shown above, the values of k_c^a and k_c^b are related, through k_3, by the factor K_I/K_d; multiplication of k_c^a by this factor gives a value of 3720 $M^{-1}s^{-1}$ for k_c^b, for debromination of the anion $\mathbf{1}^-$ by pathway [6*b*].[6]

For reasons given earlier (7), it was concluded that the catalysis of the debromination of 4-alkyl-4-bromo-2,5-cyclohexadienones **3** by CD occurs via the pathway shown in eq. [6*b*]. This pathway is more compatible with the effects of different alkyl substituents (7) and with conclusions regarding the catalysis of the bromination of phenols (6, 7). Both of our earlier studies (6, 7) point to a transition state in which the organic moiety is basically outside the CD cavity, while the bromine atoms are largely inside (Scheme 1). We believe that the dienone **1** reacts in a similar manner.

SCHEME 1

The catalytic rate constants for the debromination of **1** vary with pH (Fig. 1) in a manner that makes direct comparison with the earlier work on **3**, which was carried out at a much lower pH (7), inappropriate. However, the ratios "k_c/k_u" are pH-independent measures of the extent of the catalysis by the cyclodextrin. Such "catalytic ratios", calculated for both reaction models (eqs. [6*a*] and [6*b*]), for the dienones studied previously (7) and for the dienone anion $\mathbf{1}^-$ are collected in Table 4. As seen there, the dienone $\mathbf{1}^-$ behaves quite similarly to the other dienones, particularly when viewed in terms of the mechanism [6*b*], the favoured pathway (Scheme 1). For this model, the catalytic ratios vary only from 2400 to 4600, with that for the anion $\mathbf{1}^-$ falling in the middle of the range, at 3400.

A similar conclusion may be arrived at by looking at the data in a manner that is independent of any mechanistic model. As shown in Fig. 1, the addition of 1 mM CD increases the rate of debromination of the dienone **1** by a factor of about 7, which is independent of pH. This increase in the rate falls in the middle of the range of values (5.7–8.7) found for other dienones, as shown in Table 4. Thus, even though the dienone **1** is much more reactive than the other dienones **3** previously studied (7, 9), the catalytic effect of CD on its debromination is much the same. It seems safe, therefore, to conclude that the CD-catalyzed debromination of **1** proceeds via the same type of pathway as the dienones **3** (eq. [6*b*] and Scheme 1).

Cocatalysis

The debromination of the *ipso*-dienones **3** by bromide ion is catalyzed by the proton (and by general acids) (9). For the methyl derivative **3** (R = Me) the observed rate constant is 1.01 s^{-1} in 1.0 M HCl containing 0.1 M KBr (9) and so the apparent third-order rate constant (k_3) for the reaction shown in eq. [7] is 10 $M^{-2}s^{-1}$.

$$[7]\quad \mathbf{3}\ (\mathrm{R} = \mathrm{Me}) + \mathrm{H}^+ + \mathrm{Br}^- \rightarrow \text{products};\ k_3 = 10\ M^{-2}s^{-1}$$

$$[8]\quad \mathbf{1}^- + \mathrm{H}^+ + \mathrm{Br}^- \rightarrow \text{products};\ k_3 = 3.5 \times 10^4\ M^{-2}s^{-1}$$

$$[9]\quad \mathbf{1}^- + \mathrm{H}^+ + \mathrm{CD}\cdot\mathrm{Br}^- \rightarrow \text{products};\ k_3 = 1.2 \times 10^8\ M^{-2}s^{-1}$$

The observed rate constant for debromination of the anion $\mathbf{1}^-$ in 0.1 M KBr at pH 4.5 is 0.111 s^{-1} (Table 1) and so $k_3 = 3.5 \times 10^4\ M^{-2}s^{-1}$ (eq. [8]). Thus, the dienone anion $\mathbf{1}^-$ appears to be 3500 times[7] more reactive than the related dienone **3** (R = Me), which lacks the carboxylate group (eqs. [7] and [8]). This large rate enhancement arises because the debromination actually occurs on the nonionized dienone **1** and the reaction is

[5]If the value of K_I = 0.286 M is too small many of the derived constants obtained in earlier work (5–7) would be in error. Sample analyses of phenol bromination data (6), using the higher value of K_I, show that the effect on the catalytic rate constants is small (0–30%) and largely self-compensatory, whereas with the debrominations (7) the effect is larger. In neither case, however, would the *conclusions* of the earlier studies (and the present one) be changed significantly since the rate constants for different substrates would all be affected in much the same way.

[6]Note that the rate constants k_c^a and k_c^b include the dependence on [H^+].

[7]The earlier estimate of 2300 times (10) was based on different rate constants for **3** (R = Me) and for the anion $\mathbf{1}^-$ (10).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

catalyzed intramolecularly by the 2-carboxyl group (see eq. [1]) (9, 10).

For the reaction of the anion $\mathbf{1}^-$ with the CD complex of bromide ion, the rate constant $k_c^b = 3720\,M^{-1}s^{-1}$, at pH 4.5 (see previous section). Thus, for the reaction shown in eq. [9] the apparent value of k_3 is $1.2 \times 10^8\,M^{-2}s^{-1}$.

As argued above, the catalysis of the debromination of $\mathbf{1}^-$ by CD, actually reacting as **1**, is quantitively very similar to that of the dienones **3** (Table 4). This close similarity suggests that there is no significant cooperativity *or interference* between catalysis by the internal carboxyl group of **1** and that by α-cyclodextrin; the two catalytic effects are essentially independent of one another, and additive.

Nevertheless, as seen in eqs. [7]–[9], the combination of the two forms of catalysis is substantial: intramolecular catalysis increases the reactivity of the dienone anion $\mathbf{1}^-$, relative to **3** (R = Me), by a factor of 3500, and the apparent reactivity of the $CD \cdot Br^-$ complex towards $\mathbf{1}^-$ is 3400 times greater than that of free Br^-. Therefore, the combined result of internal catalysis by the carboxyl group of **1** and external catalysis by α-cyclodextrin is to enhance the reactivity by a factor of *12 million*!

Experimental

5-Methylsalicylic acid and α-cyclodextrin were obtained from Aldrich and they were used as received. All other reagents were of analytical grade.

Bromine solutions were made up by weight, as previously (5–7). Substrate solutions were prepared by diluting the appropriate amount of stock solution (0.25 M in hplc methanol) in the desired aqueous medium. The buffer solutions (I = 0.01 M) were prepared according to the recipes given by Perrin (13). The total ionic strength was generally maintained at 0.11 M (KBr + buffer), except for the experiments where $[Br^-]$ was varied, in which case the ionic strength was maintained at 1.01 M (KBr + NaCl + buffer). The effects of varying [CD] and $[Br^-]$ on the rate of debromination of **1** were measured at pH 4.5.

For the debromination experiments, the dienone **1** was generated *in situ* by the rapid mixing of equal volumes of 0.5 mM 5-methylsalicylic acid (**2**) and 0.2 mM bromine in the stopped-flow apparatus. The rate of bromination of **2** was measured using [**2**] = 0.25 mM and $[Br_2]$ = 0.025 mM. In both types of experiment one syringe contained **2** + CD in the desired medium, while the other contained bromine in the same medium. Thus, bromine was not brought into contact with CD until mixing in the stopped-flow apparatus (5–7).

The rate of debromination of the dienone **1** was measured as the decrease in absorbance at 250–255 nm (10). The rate of bromination of **2** was measured by monitoring the disappearance of bromine at 265 nm (Br_3^- band) (14). All rates were measurd at 25.0 ±0.1°C, using a stopped-flow apparatus interfaced to a microcomputer (15, 16). First-order rate constants were obtained by analysis of absorbance traces covering about 90% reaction, using an infinity reading taken after 10 half-lives (16).

J. L. ESCOBAR-VALDERRAMA, J. H. GARCÍA-TAPIA, J. RAMÍREZ-ORTÍZ, M. J. ROSALES, R. A. TOSCANO, and J. VALDÉS-MARTÍNEZ. Can. J. Chem. **67**, 198 (1989).

The crystal and molecular structure of the title compound has been determined from three-dimensional X-ray intensity data. The crystals are orthorhombic with space group *Pbcm*, $a = 8.877(4)$, $b = 9.813(2)$, $c = 6.545(2)$ Å, $Z = 4$. The structure has been refined to $R = 0.029$ and $R_w = 0.035$. The molecules are present in the thione form as planar molecules with only intermolecular interactions. Bond lengths and angles suggest that the electron density is more localized in the N—N—C—S ring fragment. Theoretical calculations (MNDO method) were also carried out on the compound both in the thione and its thiol tautomeric forms. Some comparisons are made between several properties (formation enthalpies, proton affinities, molecular electrostatic potentials, atomic charges) of both tautomers. The results indicate some important differences in reactivity between both forms.

Key words: crystal structure, molecular structure, electronic structure, 1-*H*-3-methyl-4-amine-5-thione-1,2,4-triazol.

J. L. ESCOBAR-VALDERRAMA, J. H. GARCÍA-TAPIA, J. RAMÍREZ-ORTÍZ, M. J. ROSALES, R. A. TOSCANO et J. VALDÉS-MARTÍNEZ. Can. J. Chem. **67**, 198 (1989).

On a déterminé les structures cristalline et moléculaire du composé mentionné dans le titre en faisant appel à la diffraction des rayons-X en trois dimensions. Les cristaux sont orthorhombiques, groupe d'espace *Pbcm*, avec $a = 8,877(4)$, $b = 9,813(2)$ et $c = 6,545(2)$ Å et $Z = 4$. On a affiné la structure jusqu'à des valeurs de $R = 0,029$ et $R_w = 0,035$. Les molécules sont présentes sous la forme thione de molécules planes ne présentant que des interactions intermoléculaires. Les longueures ainsi que les angles des liaisons suggèrent que la densité électronique est plus délocalisée dans la portions des cycles N—N—C—S. On a aussi effectué des calculs d'orbitales moléculaires (méthode CNDO) sur le composé tant dans sa forme thione que dans sur son tautomère thiolique. On a fait quelques comparaisons entre plusieurs propriétés (enthalpies de formation, affinités protoniques, potentiels électrostatiques moléculaires et charges atomiques) de chacun des tautomères. Les résultats indiquent qu'il existe d'importantes différences de réactivité entre les deux formes.

Mots clés : structure cristalline, structure moléculaire, structure électronique, 1*H*-méthyl-3 amine-4 thione-5 triazole-1,2,3.

[Traduit par la revue]

Introduction

Mercapto derivatives of substituted 4-amino-1,2,4-triazoles are particularly interesting as complexing agents due to the presence of four potential donor atoms (three nitrogen and one sulphur), consequently many metal derivatives of ligands of this type have been prepared (1–5), and they have also been used as analytical reagents.

Mercapto triazoles have been proposed to exist as thione–thiol tautomers (Fig. 1), both in solution and in solid state. In coordination compounds, several coordination modes have been suggested, mostly based on infrared data. One result that has been considered of great importance is the absence of an S—H vibrational band (ca. 2500 cm^{-1}) in the spectra of all complexes and which has been taken as an indication of the ligand, considered to be in the thiol from when free, suffering deprotonation and coordinating through the sulphur atom (1–5).

In the course of a study of metal complexes derived from 1-*H*-3-methyl-4-amine-5-thione-1,2,4-triazol, **1**, we noticed that no band was present around 2500 cm^{-1} in the infrared spectrum of the uncomplexed ligand. Since this observation could nullify the importance assigned by Gadag *et al.* (1–5) to the absence of this band in metal complexes, an X-ray study of a single crystal of the ligand was undertaken to determine the structure of **1** in the solid state. Theoretical calculations of the molecular and electronic structure were also carried out to gain insight into the coordination properties of this ligand, and into the relative stability of both tautomers. The results of these studies are reported in this paper.

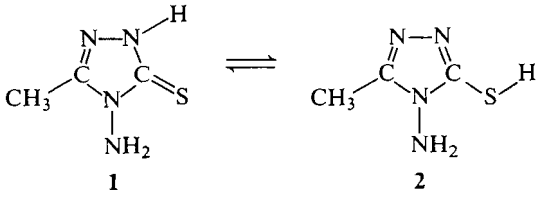

FIG. 1. Thione **1** and thiol **2** tautomers of 1-*H*-3-methyl-4-amine-5-thione-1,2,4-triazol.

Experimental

1 was prepared by the literature method (6), crystals were grown by slow evaporation of an ethanolic solution.

Crystals data are as follows:

$C_3H_6N_4S$ mw = 130.16

Cell dimension 0.1 × 0.4 × 0.36 mm, space group *Pbcm*, $a = 8.877(4)$, $b = 9.813(2)$, $c = 6.545(2)$ Å, orthorhombic, $V = 570.09$ Å^3, d(calc) 1.52 g cm^{-3}, $Z = 4$, μ(MoKα) 4.36 cm^{-1}, $F(000)$ 272.

Data collection, structure solution, and refinement

The data were collected on a Nicolet R3m four-circle diffractometer with monochromated MoK$\bar{\alpha}$ radiation (0.71069 Å) at 19.5°C. Of the 516 reflections measured up to $2\theta \leq 50°$, only 435 with $F > 3\sigma(F)$ were considered observed. No correction was made for absorption. The structure was solved by direct methods and Fourier difference techniques with SHELXTL (7). Full matrix least-squares refinement with anisotropic thermal parameters for all non-hydrogen atoms, reduced R to 0.0295 and R_w to 0.0348, $S = 1.119$, residual electron

± 0.25 e $Å^{-3}$. The hydrogen atoms bonded to the nitrogen atoms were located from a difference map and refined freely while the remaining hydrogen atoms were places in idealized positions. Atomic scattering factors are from ref. 8. All calculations were performed on a Nova 4S computer.

Final coordinates are given in Table 1, while bond distances and angles are listed in Table 2. Figure 2 shows a view of the molecule with the atomic numbering scheme.[3]

The semi-empirical method MNDO (9) was used to calculate the electronic structure of the ligand. Geometries of both tautomers was also optimized using MNDO.

Discussion

Structural results

The crystal consists of planar molecules in the thione form with intermolecular interactions involving the sulphur atoms and the hydrogen atoms bonded to N(1) and N(3) with N---S and H---S distances of 3.230(2) and 3.599(1) Å and 2.53(4) and 2.73(3) Å, respectively.

A characteristic of amine-1,2,4-triazoles that has been observed (10) is that the N—N distances in the triazol ring and in the side chain are similar. In this case the two bonds show a slight difference in bond length values with N(1)—N(2) and N(3)—N(4) distances of 1.382(3) and 1.397(3) Å, respectively. These values are larger than the corresponding one in 1,2,4-triazol (1.350 Å) (11), but smaller than the single bond value (1.470 Å).

The length for the C—S bond, 1.687(3) Å, is similar to that observed in 5-amino-2-thiol-1,3,4-thiadiazol (12) which was proposed to have substantial double bond character. Although it is shorter than a single S—C bond (1.801(5)–1.825(5) Å in some dithiacycloalkanes (13)), it is still longer than an S—C double bond distance (1.646(5) Å in (2-adipoyl)bis(1,3-thiazolidine-2-thione (14)).

The C—N bonds in **1** can be divided into two sets according to the bond distances observed. C(5)—N(1) and C(3)—N(2) have a mean value of 1.320 Å while C(5)—N(4) and C(3)—N(4) both show a distance of 1.374(3) Å. The C(5)—N(1) bond is 0.020 Å longer than C(3)—N(2); a difference that may be significant and which might suggest a larger double bond character in the second bond. The longer bonds observed in C(5)—N(4) and C(3)—N(4) suggest that the electron density is more localized among C(3)—N(2)—N(1)—C(5)—S(1). Taking into account all these observations, **1** can be assigned the thione tautomeric form, as shown in Fig. 1.

The crystal structure of the sodium salt of 4-amino-5-mercapto-1,2,4-triazol, **3**, has been described (15) and a comparison of bond lengths is given in Table 2. It can be observed that the distances between N(1) and N(2) and C(5) and S(1) are significantly longer in **3** than in **1**, indicating that the electron density in these bonds diminishes more than those in other bonds upon deprotonation of the ring.

Theoretical calculations

Structural data for tautomer **2** were calculated using MNDO and, to make the results of the theoretical calculations comparable, the geometries for both tautomers, the experimental and the calculated ones, were optimized with the same method. The geometry calculated for tautomer **1** agreed with the results experimentally obtained with a mean absolute error of 0.046 Å in bond length values. However, the MNDO method systematically assigns lower values to C=S distances (16) and this case was no exception, with a calculated bond length 0.113 Å shorter than the experimental value. If this distance is not considered, the mean absolute error is reduced to 0.037 Å.

In the calculated structure of tautomer **2**, as in the case of tautomer **1**, the ring is completely planar. Bond length values indicate an electronic delocalization, particularly along (C(3)---N(2)---N(1)---C(5). The C—S bond is longer in **2** than in **1** (1.668 Å against 1.574 Å). The hydrogen atom of the thiol group is coplanar to the triazol ring (ϕ: N(4)—C(5)—S(8)—H(9) = −179.6°).

The relative stability in the gas phase of tautomers **1** and **2** was evaluated by calculating their formation enthalpies by the MNDO method with the Dewar and McKee corrections (16). According to these results, the thione form, is more stable than the thiol form by 4.37 kcal/mol (50.91 and 55.28, respectively). Besides, it has been reported (17) than the MNDO method overestimates the stability of "hydroxy" tautomers by

TABLE 3. Atomic charges and atomic contributions to the HOMO of the thione **1** and thiol **2** tautomers

	Atomic charges		Contributions to the HOMO	
Atom	**1**	**2**	**1**	**2**
N(1)	−0.227	−0.124	0.4020	0.3792
N(2)	−0.107	−0.125	−0.3090	−0.3627
C(3)	0.089	0.041	−0.2756	−0.4885
N(4)	−0.262	−0.191	0.3005	0.0401
C(5)	0.256	−0.071	−0.0250	0.4697
C(6)	0.101	0.110	−0.2756	0.0791
N(7)	−0.066	−0.072	−0.0223	−0.0022
S(8)	−0.356	0.057	−0.7502	−0.4838
H(1)	0.264			
H(6a)	0.026	0.026		
H(6b)	0.023	0.014		
H(6c)	0.024	0.014		
H(7a)	0.117	0.112		
H(7b)	0.117	0.112		
H(8)		0.097		

about 8.6 kcal/mol over the "keto" form. It is therefore reasonable to assume that in the gas phase, under normal conditions, only tautomer **1** will be present.

To obtain some information on the chemical reactivity of both tautomers, some parameters that could reflect this were calculated. One of these was the proton affinity which was calculated as the change of enthalpy (at 298 K) associated with the separation of a proton from the chemical species HX. The enthalpies used for this calculation were those calculated in this work and the experimental value for $\Delta H_f^\circ(H^+)$, 367.2 kcal/mol (18). The value calculated for the proton affinity of **1** and **2** were 316.2 and 311.9 kcal/mol, respectively, which compared to the value of 345.2 kcal/mol measured for $HCOO^-$ and other reported values, indicates that both tautomers can be considered as acidic species.

The atomic charges calculated for tautomers **1** and **2** are listed in Table 3. Some important differences observed are that in tautomer **1**, the sulphur atom is the one with the largest electron density in the molecule while in **2** the same atom is even slightly electron deficient. Consequently, the chemical behaviour of the system towards an electrophile would depend on the tautomeric form present in the reaction, assuming, of course, that the sulphur atom is involved in the reactive site.

The most acidic hydrogen atom was the one bonded to N(1) in tautomer **1** or S(8) in tautomer **2**, but the electronic deficiency was much lower in the second case. It would therefore seem easier to pull a proton from tautomer **1** than from **2** and that the hydrogen atom involved in such a process would be that bonded to N(1).

The highest occupied molecular orbital in both tautomers was basically formed by a combination of the P_z orbitals of each heavy atom. Table 3 lists the contribution of these atomic orbitals to the HOMO of the tautomers. In this figure, each P_z orbital is perpendicular to the plane that contains the ring of the molecule. In tautomer **1** the contribution of the sulphur atom S(8) to the HOMO is considerably larger than that of any other atom while in **2**, contributions are more uniform, this suggesting that when reacting with an electrophile, the molecule will orientate more selectively in the thione form than in thiol form.

From the calculated energy of the HOMO (−9.26 and −9.64 eV for **1** and **2**, respectively), the order of reactivity with an electrophile would be:

Tautomer **1** > Tautomer **2**

The molecular electrostatic potentials (MEP) generated by the electronic and nuclear distribution have been widely used as an index of chemical reactivity of the type of electrostatic interactions between molecules and ions or solvents (19, 20). In this work the MEP's were calculated with the VSS program (21) which uses the electronic distribution obtained with the CNDO program (22, 23). This type of MEP calculations give results which are qualitatively correct, specially when calculations are carried out at distances above the van der Waals surface of the molecule where results are similar to those obtained with more precise calculations (24–27). For this reason, in this work MEP's were evaluated on the plane and 2 Å above the molecular plane. The MEP's calculated for tautomer **1** shows that the

For personal use only.

interaction of an electrophile with this molecule is directed towards the sulphur atom. However, in tautomer **2**, the attack is directed towards N(1) and N(2).

Differences between adsorption properties of two Rhodesian chrysotile samples. Relation with the DTA features introduced by leaching and grinding

HÉLÈNE SUQUET

Laboratoire de réactivité de surface et structure, Unité associée 1106 du Centre national de la recherche scientifique, Université Pierre et Marie Curie, 4 Place Jussieu, 75252 Paris CEDEX 05, France

Received May 9, 1988

HÉLÈNE SUQUET. Can. J. Chem. **67**, 202 (1989).

Substantial differences are founded between the absorption properties of two Rhodesian chrysotile samples (−1 and −2), which are, in most chemical and structural aspects, highly similar. The phenanthrene and CO_2 amounts adsorbed are much less important on chrysotile-2 than on chrysotile-1. This indicates that chrysotile-2 has fewer basic surface sites. DTA and XRD results show that dry grinding and leaching produce a breakdown of the chrysotile structure, yield amorphous silica, and lower the temperature of the dehydroxylation peak. The dehydroxylation peaks of chrysotile-1 and -2 are really doublets. As the low-temperature component of the dehydroxylation peak is greater in chrysotile-2 than in chrysotile-1, the chrysotile-2 contains more ground and (or) leached fibers than chrysotile-1 and consequently shows weaker absorption properties.

Key words: chrysotile, leaching, phenanthrene adsorption.

HÉLÈNE SUQUET. Can. J. Chem. **67**, 202 (1989).

On a observé des différences importantes dans les propriétés d'absorption de deux échantillons de chrysotile Rhodésiens (−1 et −2) qui sont, par leurs aspects chimiques et structuraux, très semblables. Les quantités de phénanthrène et de CO_2 qui sont adsorbées sur la chrysotile-2 sont beaucoup plus faibles que celles adsorbées sur la chrysotile-1. Ces données indiquent que la chrysotile-2 possède moins de sites basiques. Les résultats obtenus par ATD et par DRX montrent que le broyage à sec ainsi que la lixiviation provoquent un effondrement de la structure de la chrysotile qui conduit à de la silice amorphe et à un abaissement de la température du pic de déhydroxylation. Les pics de déhydroxylation des chrysotiles-1 et -2 sont en fait des doublets. Comme la composante basse température du pic de déhydroxylation est plus grande dans la chrysotile-2 que dans la chrysotile-1, on en conclut que la chrysotile-2 contient plus de fibres broyées et (ou) lixiviées que la chrysotile-1 et que, en conséquence, elle fait preuve de propriétés d'adsorption plus faibles.

Mots clés : chrysotile, lixiviation, adsorption de phénanthrène.

Introduction

Epidemiological studies have clearly shown that for smokers exposed to asbestos, the risk of bronchopulmonary cancer is strongly raised (1, 2). Carcinogenic compounds, in particular certain polycyclic aromatic hydrocarbons (PAH), are present in cigarette smoke. These observations have led several authors to study the adsorption properties of asbestos towards PAH (3–5). Recently, an in-depth study has been carried out on the adsorption of PAH on several solids having an electron-donor character, especially a sample of Rhodesian chrysotile (chrysotile-1), provided by the Union Internationale Contre le Cancer (UICC) in 1980 (6–8). In chrysotile (Fig. 1), electron-donor sites derive from (*i*) OH groups in low coordination located at crystal edges, and (*ii*) external OH groups bearing a negative charge due to the existence of isomorphic substitutions or cationic vacancies.

In an attempt to reproduce the adsorption isotherm of one PAH, namely phenanthrene, on another sample of Rhodesian chrysotile (chrysotile-2), also provided by the UICC, we obtained much lower values for the adsorbed quantities than had been observed with chrysotile-1. Hence we looked for reasons to justify this weaker surface reactivity of chrysotile-2 as compared to chrysotile-1. We studied the adsorption properties of chrysotile-2, not only with respect to phenanthrene, but also in relation to CO_2, another molecule capable of fixing itself on the basic sites present on the surface of chrysotile. In addition, using DTA curves, we investigated the adsorption properties of the chrysotile samples in relation to fiber characteristics and to the modification of these charcteristics with surface treatments (grinding and leaching).

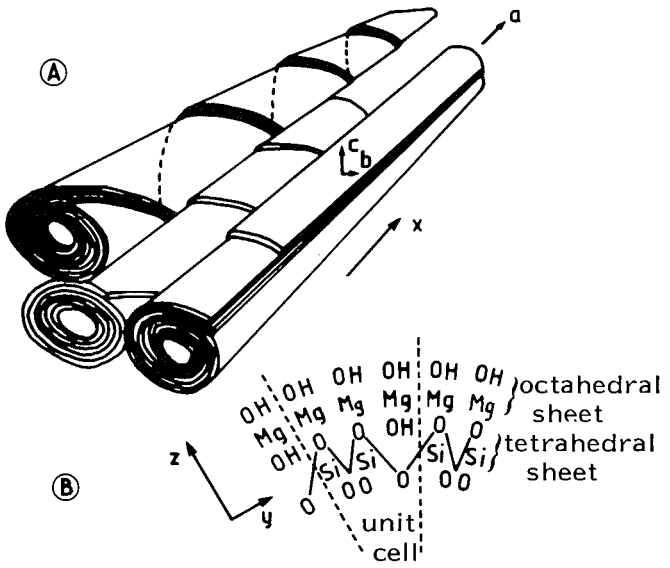

FIG. 1. Scheme of chrysotile structure.

Materials and methods

(a) Materials

The two samples of UICC chrysotile have a similar chemical composition, which is close to the theoretical composition (Table 1). Sample 1 contains about 30% more Al than sample 2 but its localization and its effect on the charge density are unknown. As there was not enough chrysotile-1 left, the charge was only determined in chrysotile-2: 1.7 electron/nm^2 (9). Moreover, Table 1 also indicates that there is a little more water in chrysotile-2 than in chrysotile-1. No

TABLE 1. Chemical composition of chrysotile samples

	SiO_2	Al_2O_3	FeO	Fe_2O_3	CaO	MgO	Na_2O	Weight loss (1030°C)
Chrysotile-1 (40% RH)	38.64	1.58	0.43	2.18	0.28	41.81	0.09	14.98
Chrysotile-2 (40% RH)	38.18	1.09	0.39	2.21	0.28	42.24	0.11	15.45
Theoretical values for $Mg_3Si_2O_5(OH)_4$	43.37					43.62		12.99

trace of nemalite, a fibrous brucite impurity of chrysotile, was found in the two chrysotile samples by IR, DTA, and X-ray diffraction (XRD). The two asbestos samples contain a black impurity, magnetite, which has been observed by XRD and by electron microscopy (SEM and TEM).

The chrysotile-1 and -2 have specific areas of 24 and 18 $m^2\ g^{-1}$ respectively.

Unlabeled phenanthrene, ^{14}C-marked phenanthrene, and xylene were supplied by Aldrich, Amersham, and Merck respectively.

(b) Methods

The adsorption properties were carried out on the bulk chrysotile-2.

Adsorption isotherm of phenanthrene

The chrysotile-2 was pre-washed twice with hot benzene to remove adsorbed organic impurities. Then it was dried under N_2 at 80°C and afterwards maintained under 40% relative humidity (RH).

The initial solution of PAH was obtained by mixing ordinary and radioactive phenanthrene in xylene to obtain a solute concentration varying between 2×10^{-3} and 30×10^{-3} mol L^{-1}. Twenty millilitres of the initial solution was brought into contact with 500 mg of chrysotile, the other 20 mL being kept as the standard solution. The slurry and the standard solution were shaken in a container maintained at 20°C for 18 h, to reach the adsorption equilibrium. The solutions were centrifuged for 10 min. Then, 1 mL of each solution (standard and supernatant) was mixed with 10 mL of scintillating liquid (Lumagel) and α-radioactivity was measured. Using the remainder method, the concentration at equilibrium (C_{eq}) and the absorbed quantity of phenanthrene (Q_a) were determined.

Three experiments were carried out for each initial concentration, and the precision is about 2% for C_{eq} and 5% for Q_a values in relation to the very weakly sorbed quantities.

Adsorption of CO_2

The adsorption of CO_2 was carried out using a Setaram microbalance model Mtb-10-8. For this test, the equilibrium states were always considered to have been achieved when the weight and the pressure were constant. The sample (100 mg) was desorbed under vacuum (10^{-4} Torr; 1 Torr = 133.3 Pa) to determine the anhydrous weight w_0. Then CO_2 (140 Torr) was introduced into the microbalance and the adsorption was achieved after 15 h. The sample was desorbed (10^{-4} Torr) until the equilibrium state (weight w) was reached. The amount of chemically sorbed CO_2 is given by $w - w_0$.

Grinding of chrysotile

Chrysotile-2 (200 mg) was severely hand ground for 15 min in an agate mortar. TEM examination indicated that chrysotile-2 had lost its silky appearance. The fibrils were very short (0.05–0.2 μm) and often agglomerated into an amorphous and shapeless material (10).

Leaching of chrysotile

The leaching was performed according to two operative methods. A partial leaching was obtained by treating the fibers at room temperature in non-stirred oxalic acid solution (0.05 mol L^{-1}) for 48 h (11). A total leaching was obtained by treating chrysotile at 50°C in 6 mol L^{-1} HCl–isopropanol solution, with stirring, for 56 h (12, 13). Thereafter the samples were thoroughly washed with hot water and dried at 80°C.

The amounts of magnesium and silicon remaining after leaching were determined by electron emission spectroscopy, and the rates of leaching (ratio of extracted Mg to initial Mg) were calculated as about 20% with oxalic acid and 100% with HCl.

Characterization of the two chrysotile samples

The X-ray diagrams (XRD) were obtained using a D500 Siemens diffractometer (Cu K_α radiation). The infrared spectra (IR) were recorded using a double beam Perkin–Elmer spectrometer 580B equipped with a data station. The KBr discs were prepared from a mixture of 150 mg KBr and 1 mg of chrysotile.

The surface areas of the fibers were determined from N_2 adsorption (BET method). The samples were initially heated at 40°C, under 10^{-4} Torr, for 16 h.

Thermogravimetric analyses (TGA) of chrysotile fibers (5 mg) were carried out under air and at a scanning rate of 5°C/min, using the Setaram Mtb-10-8 microbalance. Differential thermal analyses (DTA) were obtained with a micro-DTA M_4 Setaram at a scanning rate of 10°C/min in air, using 5 mg of fibers. The samples used for TGA and DTA were maintained under 40% RH.

Results and discussion

(A) Adsorption properties

Phenanthrene adsorption

The adsorption isotherm of phenanthrene on chrysotile-2 (Q_a vs. C_{eq}) is illustrated in Fig. 2a. This curve has an S shape, like the adsorption isotherm of phenanthrene on chrysotile-1 previously published (6), and reveals the presence of lateral interactions between adsorbed molecules (14). However, the quantities of phenanthrene adsorbed by chrysotile-2 are smaller, about 12 times less, than chrysotile-1 on the plateau (10 μmol g^{-1} vs. 118 μmol g^{-1}). As the phenanthrene molecules are adsorbed on the basic surface sites of the fibers, these curves show that there are fewer active surface sites in chrysotile-2 than in chrysotile-1.

The effect of water on the adsorption properties of chrysotile-2 is illustrated in Fig. 2: curves 2a and 2b correspond to fibers stored under 40% RH and 10% RH respectively and curve 2c relates to fibers dried in a stream of N_2 at 80°C and to xylene dried over zeolites. For this experiment the adsorption was carried out in a glove-box under an N_2 atmosphere. Comparison of the three curves of Fig. 2 shows that the amounts of adsorbed phenanthrene are greater when the samples contain less humidity. These results confirm the poisoning effect of water molecules for this PAH adsorption (6, 7). Besides, as the chrysotile-2 fixed only very small quantities of phenanthrene, it was necessary for precise analyses to increase the solid/liquid ratio from 5 (Fournier and Pezerat technique, refs. 6 and 7) to 25. In doing so, the precision is improved but water amounts introduced into the system are increased and, consequently, the competition of the adsorption between water and phenanthrene is enhanced.

CO_2 adsorption

The chrysotile-2 chemisorbs 0.52 mol CO_2 per nm^2 at a

For personal use only.

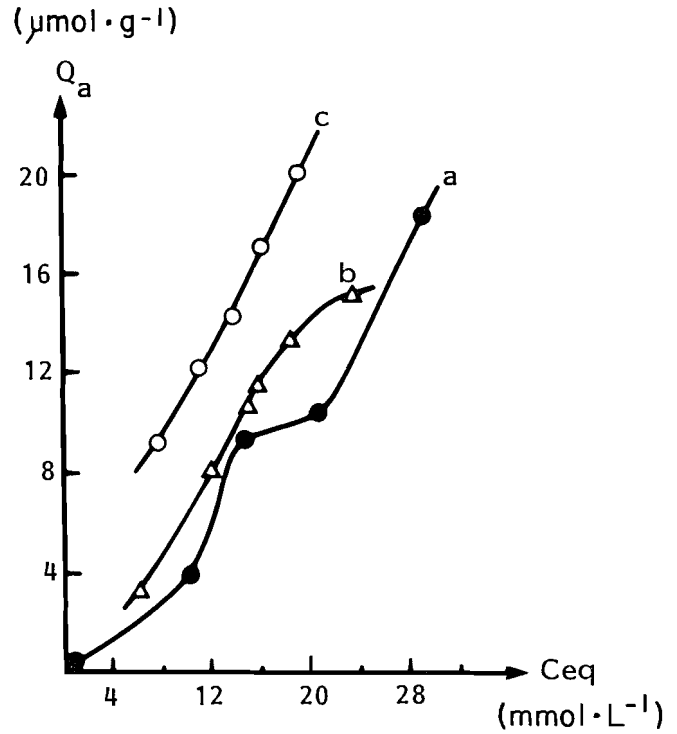

FIG. 2. Adsorption isotherm of phenanthrene on chrysotile-2: (a) chrysotile stored under 40% RH; (b) chrysotile stored under 10% RH; (c) chrysotile treated by a stream of N_2 at 80°C and xylene dried over zeolites.

pressure of 140 Torr. Under the same conditions, chrysotile-1 was observed to chemically adsorb 0.94 mol CO_2 per nm^2 (15). If a CO_2 molecule is supposed to be sorbed on a basic site (OH group acting as an electron-pair donor), the number of basic sites on the chrysotile-2 surface may be estimated to be about 45% lower than on the chrysotile-1. This result may partially explain the weaker affinity of chrysotile-2 for phenanthrene.

Water content

The fractional weight losses observed upon heating samples of chrysotile-1 and -2 in air are illustrated in Fig. 3, as a function of temperature (5°C/min). The TGA curves obtained are comparable to those reported by other authors (16–18). These curves exhibit three distinct portions corresponding to removal of residual water (up to about 370°C), dehydroxylation of fibers whose structure was modified by a surface treatment (up to about 600°C), and dehydroxylation of normal chrysotile fibers in the range 600–780°C. At 800–820°C well-crystallized forsterite, Mg_2SiO_4, and amorphous silica are produced. As the two initial samples do not contain nemalite or carbonate impurities, the second portion of the curves accounts for the loss due to water alone.

The TGA curves (Fig. 3) also show that, under 40% RH, chrysotile-2 contains more physisorbed water (about 36%) than chrysotile-1. As water is a poison for phenanthrene adsorption, chrysotile-2 adsorbs less phenanthrene than chrysotile-1, as previously observed.

(b) Characteristic properties of chrysotile-1 and -2

The preceding results show that two samples having the same origin (Rhodesia) but belonging to different lots exhibit adsorption properties that are *quantitatively* different. As the surface reactivity of minerals is strictly related to their surface state, further investigations were carried out to determine the characteristic properties of the two samples.

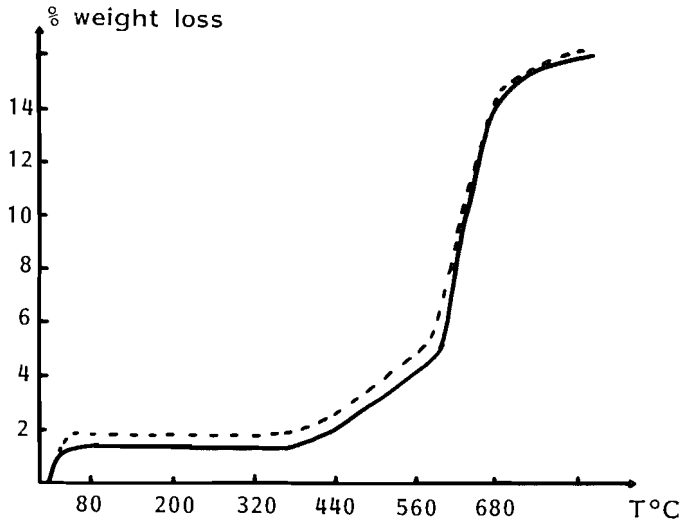

FIG. 3. Weight loss of the two samples of chrysotile fibers stored under 40% RH as a function of temperature in air heating (5°C/min): (—), chrysotile-1; (---), chrysotile-2.

IR absorption spectra

The IR absorption spectra of chrysotile-1 and -2 are similar and do not permit distinction between the surface states of the two lots. The frequencies of the vibrations agree with those reported previously (13, 16, 19–21). The intensities of some vibrations are similarly modified for the two samples, indicating that the fiber structure is slightly damaged (9).

Structure

The X-ray powder diagrams of chrysotile-1 and -2 are similar and indicate that the asbestos is mainly clinochrysotile. Furthermore, TEM examination shows that both chrysotiles have the same silky morphology and similar fiber lengths (10).

Differential thermal analysis

Typical DTA curves for chrysotile exhibit (*i*) a broad shallow endotherm below 150°C due to the removal of physisorbed water; (*ii*) a large endotherm peak at 650°C ± 20°C due to dehydroxylation; (*iii*) an exothermic reaction with a sharp peak at 810°C ± 10°C related to the crystallization of forsterite (17, 18, 22, 24).

The DTA curves of the Rhodesian chrysotiles show a significant difference: the 650°C dehydroxylation peak is really a doublet (Fig. 4). Chrysotile-1 shows a low-temperature component (660°C) that is less important than the high-temperature one (688°C) (Fig. 4A). In chrysotile-2, the two components (low and high temperature) are similar. This doublet phenomenon was first observed by Martinez (22) in a mixture of two samples of the same fiber that had been subjected to different degrees of intensive grinding in a ball mill.

We then tried to determine whether these observed doublet peaks correspond to two fiber morphologies (grinding) or to some other phenomenon such as leaching.

(i) Influence of dry grinding on DTA results. Chrysotile-2, strongly hand ground, becomes a dark grey powder because the size reduction results in a homogeneous distribution of the magnetite (the black impurity present in this sample). The XRD

does not exhibit any of the characteristic reflections of the chrysotile structure. The crystalline network of the fibers is broken down and amorphous silico-magnesia compounds are formed upon severe dry grinding (25). We verified that chrysotile-2, heated at 600°C for 4 h in air, yields an amorphous material with the same appearance when viewed by XRD and IR. This suggests that the energy produced by intensive dry grinding is similar to increasing the fiber temperature.

The DTA curve of dry ground chrysotile-2 (Fig. 4C) confirms the presence of (*i*) a large amount of surface water (broad endotherm at approximately 150°C), (*ii*) magnetite (exotherm peak at 346°C), and (*iii*) carbonate species (endotherm peaks at about 410 and 520°C).

The exotherm due to the magnetite oxidation is not observable on the DTA curve of the initial samples (Fig. 4A,B) because the thermal effect is weak and the magnetite particles have large dimensions (0.5–0.7 μm). The presence of the carbonate species in the dry ground sample has been confirmed by IR study (large band at about 1410 cm^{-1}) (10). These carbonate species probably result from a fixation of atmospheric carbon dioxide during the grinding. Thus grinding chrysotile leads to a decrease of the particle size of magnetite and fibers and to a fixation of water and CO_2 present in the ambient atmosphere.

The major part of the sample dehydrates at 643°C, i.e., 23°C below the low-temperature component of the untreated chrysotile-2. The high-temperature component stays at the same temperature (688°C), but it appears considerably reduced. Thus the dehydration of asbestos has been facilitated by a severe dry grinding. As well, decreasing the particle size yields an increase of the rate of dehydration as well as in the peak height of the exotherm at 810°C. The particle size has already been illustrated and discussed (22, 26, 27). With a small-size particle, the water is easily expelled and the dehydroxylation occurs rapidly. An X-ray amorphous phase is created, making the formation of forsterite difficult. At about 810°C, forsterite crystallizes extremely quickly, producing the large exotherm, as illustrated in Fig. 4C. With coarse particles, the water is expelled with difficulty and forsterite formation and dehydroxylation occur more or less at the same time. At about 810°C, little material remains to crystallize into forsterite, so that the height of the exotherm peak is reduced for the initial chrysotile (Fig. 4B).

(ii) Influence of leaching on DTA results. A great deal of work has been done on acid attack on chrysotile (7, 11–13, 21, 23, 28, 29). According to these authors, strong acid attack leaves the fibrous morphology of the mineral intact and produces an amorphous silica gel. The hydrated silica residue is fragmented and partially transformed into microparticles, which explains the increase in the specific area of the leached asbestos fibers.

Chrysotile-2 treated with oxalic acid or HCl yields either a partially leached chrysotile (20%) or a totally leached chrysotile (100%).

The lattice of the 20% leached chrysotile has been partially degraded. On its X-ray diagram the characteristic reflections of the chrysotile are still observable but they are broad and diffuse. The general shape of the DTA curve is retained (Fig. 4D). However, the presence of amorphous hydrated silica is indicated by an increase in surface water (endotherm below 150°C). The shift towards lower temperatures of the dehydroxylation peaks, 639 and 671°C instead of 666 and 688°C for the initial chrysotile-2, indicates that acid attack (like dry grinding) damages the structure of the asbestos fibers, which then dehydroxylate more easily.

The 100% leached chrysotile is transformed into amorphous hydrated silica. Its DTA trace (Fig. 4E) shows, apart from a broad shallow endotherm below 150°C due to the removal of water, virtually no thermal effects at the sensitivity used. There is no crystallization of the silica.

Conclusion

The samples of Rhodesian chrysotile-1 and -2 provided by UICC exhibit quantitatively different adsorption properties. The adsorption of phenanthrene and CO_2 molecules is reduced in sample 2 as compared to sample 1. This illustrates that the chrysotile-2 has fewer basic sites on its surface, thus a weaker electrostatic surface field. Therefore any action damaging the surface active sites, such as dry grinding or leaching, may explain the difference between the two samples of chrysotile.

Dry grinding gives amorphous silico-magnesia compounds, which rapidly fix water and carbonate species, while acid attack yields hydrated amorphous silica. The two treatments decrease the particle size and, therefore, the dehydroxylation temperature. As the low-temperature component of the dehydroxylation peak is greater in chrysotile-2 than in chrysotile-1, it can be concluded that chrysotile-2 contains more damaged surface fibers than chrysotile-1.

As dry grinding and acid leaching reduce the particle size and increase specific area, adsorbed quantities of polycyclic aromatic hydrocarbons should be greater for the modified fibers of chrysotile than for the initial ones. This study, showing that the adsorbed amounts are smaller for chrysotile-2, which contains more damaged fibers, concludes that most of the active sites created by the surface treatments are immediately poisoned by molecules present in the atmosphere (water, CO_2...). Consequently a chrysotile with damaged fibers should possess smaller biological activity.

Abietane diterpenes with antibiotic activity from the flowers of *Salvia canariensis*. Reaction of galdosol with diazomethane

ANTONIO G. GONZÁLEZ,[1] LUCIA S. ANDRÉS, JUAN R. HERRERA, JAVIER G. LUIS, AND ANGEL G. RAVELO

Centro de Productos Naturales Orgánicos Antonio González, C.S.I.C., Universidad de La Laguna, 38206 Tenerife, Canary Islands, Spain

Received July 13, 1988

ANTONIO G. GONZÁLEZ, LUCIA S. ANDRÉS, JUAN R. HERRERA, JAVIER G. LUIS, and ANGEL G. RAVELO. Can. J. Chem. **67**, 208 (1989).

The new diterpenes canariquinone (**9**), rosmaquinone (**10**), and 11-acetoxycarnosic acid (**6**), together with the already known 7-ethoxyrosmanol (**1**), 7-methoxyrosmanol (**2**), and rosmanol (**3**), were isolated from the flowers of *Salvia canariensis*. The structure of the new substances was established by a combination of chemical and spectroscopic means. Reaction of galdosol (**4**), isolated from the aerial part of the same plant, with diazomethane, unexpectedly gave the new homoditerpenes **15** and **16**, the structures of which were determined by spectroscopic methods. A mechanism accounting for the formation of these substances is suggested.

Key words: abietane diterpenes, *Salvia*, Labiatae, antibiotic activity, galdosol reactivity.

ANTONIO G. GONZÁLEZ, LUCIA S. ANDRÉS, JUAN R. HERRERA, JAVIER G. LUIS et ANGEL G. RAVELO. Can. J. Chem. **67**, 208 (1989).

Les nouveaux diterpénoïdes, la canariquinone (**9**), la rosmaquinone (**10**) et l'acide 11-acétoxycarnosique (**6**), avec le 7-éthoxyrosmanol (**1**), le 7-methoxyrosmanol **2** et le rosmanol (**3**), des composés connus antérieurement, ont été isolés des fleurs de la *Salvia canariensis*. On a établi les structures des nouvelles substances par des moyens chimiques et spectroscopiques. On a fait réagir le diazométhane avec le galdosol (**4**), isolé de la partie aérienne de la même plante, et on a obtenu les nouveaux homoditerpènes **15** et **16**, produits pas prévus, dont on a établi les structures par des méthodes spectroscopiques. On propose un mécanisme qui explique la formation de ces composés-ci.

Mots clés : diterpénoïdes abiétanes, *Salvia*, Labiatae, activité antibiotique, réactivité de galdosol.

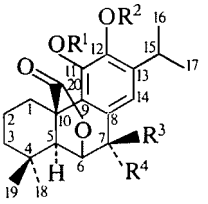
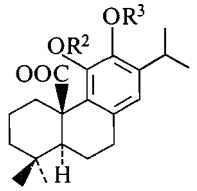
Introduction



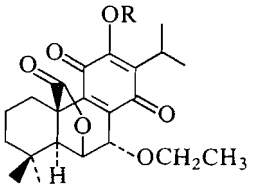
There are some 500 species of the genus *Salvia*, a member of the Labiatae family, extensively distributed throughout the world. Since ancient times, many species of this genus have aroused interest and have frequently been used for medicinal purposes. At present, they are used in the pharmaceuticals (1, 2), cosmetics, and preserving industries.

We have reported the isolation of the diterpenes galdosol (3) and arucatriol (4) from the aerial parts of *Salvia canariensis* L., a plant endemic to the Canary Islands; of deoxocarnosol-12-methyl ether, salvicanol, and 6α-hydroxydemethylcryptojaponol from the roots of the same plant; (5) and rosmanol, 11,12-dimethoxy-abieta-6,8,11,13-tetraen-20-oic acid methyl ester, rosmanoyl carnosate, 7-oxocarnosic acid, 6-oxo-7β-hydroxycarnosic acid, and 6-oxo-7α-hydroxycarnosic acid from its flowers (6, 7). All the latter compounds were isolated in acetate form from previously acetylated fractions of an acetone extract.



We here report the isolation of five diterpenes from less polar fractions of the untreated acetone extract of the flowers of *S. canariensis*, as well as the unexpected formation of two new homoditerpenes when galdosol was reacted with diazomethane.

Discussion



The least polar of the compounds was identified as 7-ethoxyrosmanol (**1**) from the following data. High resolution electron impact mass spectrometry (hreims) gives the molecular formula, $C_{22}H_{30}O_5$. The ir spectrum shows absorptions for lactone (1740, 1240 cm^{-1}), aromatic, ether, and phenol groups. In the ^1H nmr spectrum taken in $CDCl_3$ are signals typical of an aromatic isopropyl, two angular methyls, one aromatic proton, two broad singlets, interchangeable with D_2O, assigned to two phenolic protons, an AB system as two doublets of one proton

10

each, attributable to H-7 and H-6, respectively, and a proton singlet corresponding to H-5. This spectrum is very similar to that of rosmanol (**3**) (6, 8), the main difference being that **1** has an extra quartet of two protons at δ 3.84 and a three-proton triplet at δ 1.33 assignable to a $-OCH_2CH_3$ group. Double resonance experiments showed them to be coupled. All the spectral data of this product are completely superimposable upon those given in the literature (9) for 7-ethoxyrosmanol (**1**).

For the second product eluted, **2**, hreims gives the molecular formula, $C_{21}H_{28}O_5$. The ir spectrum has bands for lactone, phenol, and aromatic groups. The ^1H nmr spectrum is very similar to that of rosmanol, differing in that it shows a methoxy group as three singlet protons at δ 3.66. When **2** was treated

[1]Author to whom correspondence may be addressed.

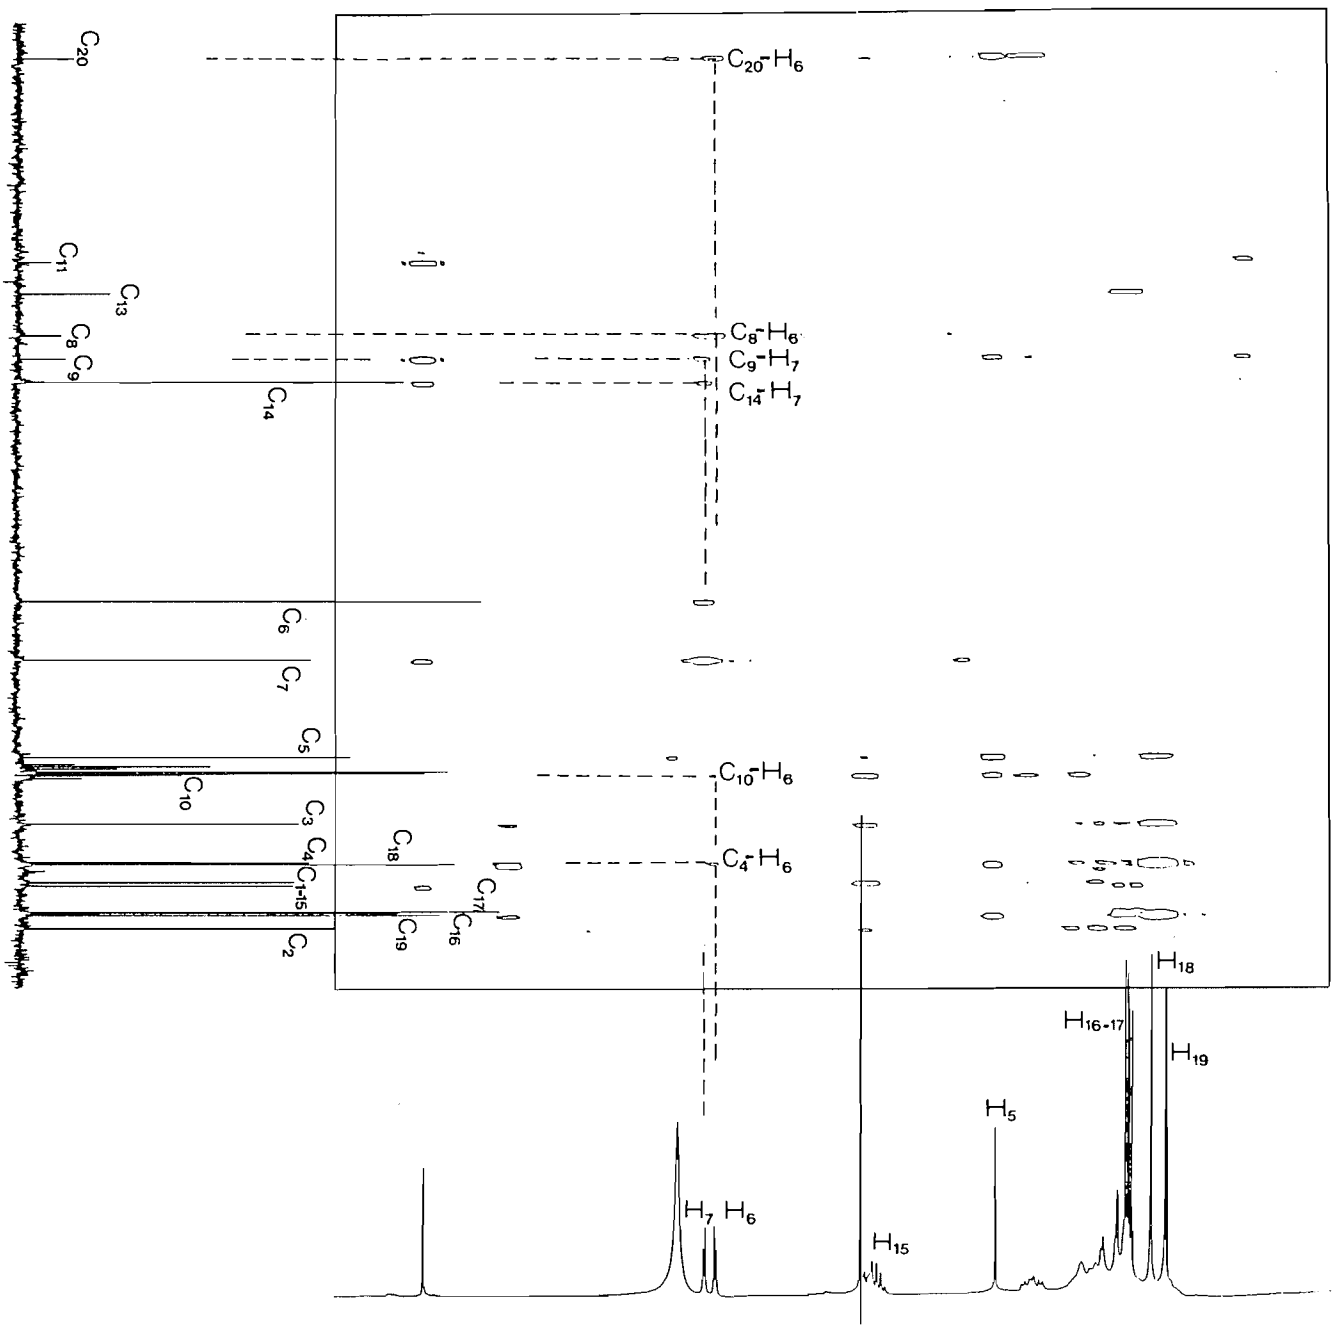

FIG. 1. Long-range $^{13}C-^{1}H$ correlation for rosmanol **3** in CD_3OD.

with methyl sulphate in acetone and potassium carbonate, a trimethoxy derivative was obtained, indicating that the free hydroxy groups in the original product are phenolic and that the methoxy group should, therefore, be situated on C-7. All the spectral data of this product are superimposable upon those given (9) for the 7-methoxy derivative of rosmanol.

The ^{1}H nmr spectrum of the trimethoxy derivative **5** is totally superimposable upon that given in the literature (10) for the 7β-methoxy isomer. The structure for this isomer should be corrected, since the absolute stereochemistry of rosmanol has been unequivocally determined by Nakatani and Inatani (11) and by ourselves (6) by means of X-ray diffraction studies, and the chemical shifts of H-6 and H-7 in **5** correspond to those of rosmanol and not to those of epirosmanol (11), in which H-6 and H-7 appear superimposed as a broad singlet at δ 4.72.

The benzylic H-7 should appear further downfield than the H-6 but, in the ^{1}H nmr of rosmanol (6, 8) and derivatives with different substituents on C-7, the proton that changes its chemical shift is at higher field and should thus be assigned to the H-7 while the chemical shift of the other proton is virtually unaltered (and should therefore be assigned to H-6). To clear up this apparent contradiction once and for all, $^{1}H-^{1}H$, ^{13}C and ^{1}H, and long-range $^{13}C-^{1}H$ COSY experiments were carried out. As seen in Fig. 1, long-range coupling is present between H-6 and C-4, C-8, C-10, and C-20, and also between H-7 and C-9 and C-14, determining the lower chemical shift as that of the H-7.

In an earlier paper (6), in order to correlate rosmanol (**3**) and galdosol (**4**), the latter was methylated with dimethyl sulphate to give the corresponding dimethyl derivative, **11**. In an attempt to obtain larger amounts of the same product, galdosol (**4**) was treated with excess diazomethane in ether but did not in fact

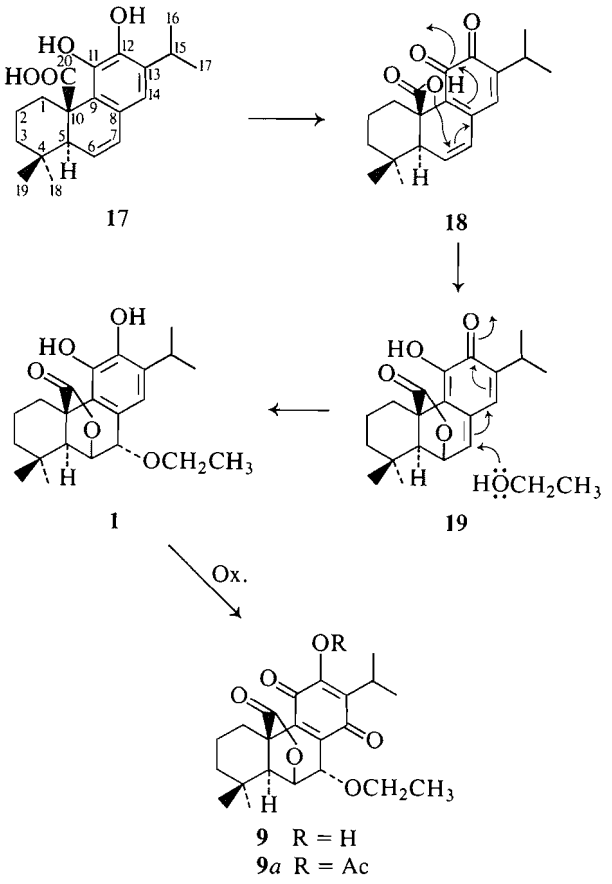
yield **11**, giving instead a mixture of products **15** and **16**, which was then subjected to column chromatography. Product **15** has the molecular formula $C_{24}H_{32}O_5$ under hrms. In its ir spectrum, absorptions for lactone and ether groups are seen. The most characteristic signals in the ^1H nmr spectrum are two one-proton singlets at δ 2.88 and 4.21 assigned to H-5 and H-6, respectively, indicating that the bridgehead proton and that of the lactone closure form a 90° angle (which is confirmed by a Dreiding stereo model); there is also an AB system assigned to the H-22 protons of the oxirane methylene, with the H-22a proton appearing as a doublet while the H-22b proton, also a doublet, shows long-range coupling. The H-8 protons appear as an AX system with H-8α as a doublet and H-8β as a doublet with long-range coupling. Irradiation of the H-8β proton makes its coupling with H-8α and its long-range coupling with H-22b disappear. All these data are completely in agreement with the structure proposed for **15** and with the α stereochemistry of the oxirane ring, where the low shift of the H-5 and H-8β protons is due to their being in front of the oxirane oxygen and lactone bridge, respectively. The ^{13}C nmr data are also in accordance with this structure.

Product **16** has the molecular formula $C_{25}H_{34}O_7$ (hrms). Its ir spectrum shows bands for hydroxy, lactone, ester, and ether groups. In its ^1H nmr spectrum, the most important signals are those corresponding to the H-5 and H-6 protons as two singlets, a proton interchangeable with D_2O for the hydroxy of a tertiary alcohol, and two protons of the methylene of an acetoxymethylene system as doublets with the methyl at δ 2.21. All these data are consistent with the structure proposed, **16**, and the stereochemistry assigned to C-7 accounts for H-14 being at δ 7.10 and for the H-5 being in front of the 7α OH at δ 2.25.

The formation of these products is accounted for by a well-documented process (12, 13) (Scheme 1). However, the diazomethane attack must take place on the less-hindered α face of the molecule (16). The attack on the β face could be due to anchimeric assistance of the lactone group ether bridge.



The following new products are described, in order of increasing polarity: **9** was isolated as an amorphous yellow solid. Its uv spectrum shows absorptions similar to those of royleanone (14), thus establishing the presence of an analogous chromophore. In ms, the greater mass fragment is observed at *m/z* 344, while hrms gives a formula of $C_{21}H_{28}O_4$ $[M - CO_2]^+$ with special importance being attached to the fragment at *m/z* 298, which corresponds to the loss of CH_3CH_2OH. In the ir spectrum, bands for the following are observed: hydroxy groups at 3380 cm^{-1}, lactone at 1770 cm^{-1}, quinone grouping at 1650 and 1635 cm^{-1}, and aromatic and ether groups. In the ^1H nmr spectrum, apart from signals corresponding to an isopropylic proton on an aromatic, only two angular methyls are observed, as singlets, with no methyl at C-10, which must, therefore, form part of the lactone ring. There are also signals corresponding to an ethoxy group. The H-5 proton appears as a singlet, indicating the existence of a single proton at C-6 forming a 90° angle with H-5, which puts the lactone closure at C-6. H-6 appears as a doublet coupled with another proton attributable to H-7, establishing the closure of the ethoxy group at C-7. The one-proton singlet at δ 7.06 is attributed to the phenolic hydrogen. **9** gives the aromatic monoacetate, **9***a*. All these data are in agreement with the quinone structure **9** for the product, which we have called canariquinone.

Since ethoxy compounds are very rare as natural products, it is just conceivable that diterpenoids **1** and **9** are artifacts arising from ethanol impurities in the organic solvent used in the extraction process (distilled cold acetone) and (or) in the chromatography (ethyl acetate). Other authors (15), however, have also isolated diterpene quinones with an ethoxy group on C-7 from *Salvia* species.

SCHEME 1

Diterpenoids **1** and **9** may be formed from 6,7-dehydrocarnosic acid (**17**) previously obtained in the form of its dimethyl ether from the same species (7) as shown in Scheme 2, whereby **17**, after oxidation, would give orthoquinone (**18**), which would later undergo an intramolecular nucleophile attack on C-6, on its β face, by the hydroxy group of the carboxyl acid to yield the methylene quinone **19**. This in turn, by nucleophile addition of ethanol at position 7α would give **1**, which would subsequently be oxidized to **9**. A similar sequence has been suggested by Wenkert *et al.* (16) for the formation of carnosol from carnosic acid. The stereochemistry of canariquinone at C-7 cannot be determined directly from the ^1H nmr since the dihedral angle between H-6 and H-7 is the same whether the ethoxy group is α or β, as can be seen from a Dreiding model. However, the chemical shifts of the H-6 and H-7 protons are similar to those of rosmanol, and the ethanol attack upon the methylene quinone diterpene lactone **19** should take place on the less-hindered α face of the molecule, as reported for this type of compound (16).

SCHEME 2

The structure of the next compound, **10**, was established from the following considerations: its ir spectrum shows the characteristic bands for alcohol, lactone (1770), and *o*-quinone (1660 cm^{-1}) groups, the *o*-quinone group being confirmed by the uv absorptions (270 and 402 nm). No phenol protons are visible in the ^1H nmr spectrum. This spectrum is very similar to that of rosmanol, with slight differences in the chemical shifts of the homologous signals. High resolution mass spectrometry gives the molecular formula $C_{20}H_{24}O_5$, with two hydrogen atoms less than rosmanol. All these data are in accordance with structure **10**, which was confirmed by chemical means, oxidation of rosmanol (**3**) with silver oxide (17) affording a substance with spectral constants totally superimposable upon those of **10**. We suggest the name rosmaquinone for this product.

The most polar product was established as 11-acetoxycarnosic acid (**6**) as follows: molecular formula, $C_{22}H_{30}O_5$ (hrms); ir with bands for acid (3720–2390 cm^{-1}), ester, and aromatic groups. The most characteristic signals in ^1H nmr are an isopropyl on an aromatic, an aromatic proton, an acetate methyl on an aromatic, and two angular methyls. The carboxyl group is situated on C-10 since there is no methyl on C-10 in this spectrum; in abietatriene diterpenes, the lowest-field methyl is always the C-10. All these data are consistent with structure **6** with the acetoxy group on C-11 or C-12. When **6** was treated with acetic anhydride in pyridine, the diacetate **7** was obtained with spectroscopic data superimposable on those of an authentic sample of carnosic acid diacetate. When **7** was treated with diazomethane, carnosic acid methyl ester diacetate (**8**) was obtained, also superimposable on an authentic sample.

The ^1H nmr spectra of **6** taken in py-d_5 and $CDCl_3$ show a difference of 0.20 ppm for the chemical shift of the isopropyl proton (18), H-15, and the acetoxy group was, therefore, placed at C-11.

11-Acetoxy-carnosic acid (**6**) and rosmaquinone (**10**) showed considerable antibiotic activity against the Gram (+) microorganisms, *Staphylococcus aureus* and *Bacillus subtilis* (19).

Experimental

General

High resolution elecronic impact mass spectra (hreims) were recorded on a V6-Micromass ZAB-2F spectrometer. Single scan infrared (ir) spectra were recorded on a Perkin–Elmer 681 spectrometer. Nuclear magnetic resonance (nmr) spectra were obtained on a Bruker WP-200 SY spectrometer. Tetramethylsilane was used as internal standard. Ultraviolet (uv) spectra were obtained on a Perkin–Elmer 550 SE. Melting points are uncorrected and were determined on a Kofler apparatus. Merck silica gel (0.063–0.2 mm) and Sephadex LH-20 were used for column chromatography. Analytical thin-layer chromatography (tlc) was carried out on precoated Schleicher and Schüll plates. Ultraviolet active materials were detected visually under uv lamp (254 or 350 nm). The plate was then sprayed with oleum and charred on a hot plate. *n*-Hexane, ethyl acetate, benzene, and mixtures of these were used as eluents for silica gel columns, as well as *n*-hexane/chloroform/methanol (2:1:1). Voucher plant specimens were lodged with the herbarium of the Department of Botany, Faculty of Biology, Universidad de La Laguna.

Plant extraction

The finely cut flowers of *S. canariensis* (4 kg) were extracted with distilled acetone (1 × 5 L) at room temperature. Filtering and evaporation of the solvent gave a reddish-brown extract (150 g). The extract was vacuum-chromatographed through dry column (24 × 10 cm) silica gel; 500-mL fractions were collected, using mixtures of *n*-hexane/ethyl acetate of increasing gradient. Only the fractions 2–4 were studied. The products were isolated by repetitive chromatography on silica gel and Sephadex columns.

Rosmanol (3): ^1H nmr (CD_3OD) δ: 0.87, 0.98 (each 3H, s, C-18 and C-19 Me), 1.15, 1.17 (each 3H, d, J = 7 Hz, $CH(CH_3)_2$ C-16 and C-17 Me), 2.22 (1H, s, H-5), 3.27 (1H, hept, J = 7 Hz, H-15), 3.28 (1H, bd, J = 10.48 Hz, H-1β), 4.48, 4.55 (each 1H, d, J = 3.24 Hz, H-6 and H-7), 6.80 (1H, s, H-14); ^{13}C nmr (CD_3OD) δ: 20.14 (C-2), 22.16 (C-17), 22.49 (C-19), 22.94 (C-16), 27.87 (C-15), 28.59 (C-1), 31.87 (C-18), 32.24 (C-4), 39.34 (C-3), 48.34 (C-10), 51.60 (C-5), 69.14 (C-7), 79.88 (C-6), 120.45 (C-14), 124.92 (C-9), 129.38 (C-8), 137.43 (C-13), 143.34 (C-12), 145.22 (C-11), 180.99 (C-20).

7-Ethoxyrosmanol (**1**) was isolated as a gum (8 mg) that did not crystallize: ir ($CHCl_3$): 3660, 3590, 3010, 2970, 2920, 1740, 1365, 1240, and 1040 cm^{-1}; uv (EtOH): 396, 327, and 286 nm; ^1H nmr ($CDCl_3$) δ: 0.92, 1.01 (each 3H, s, C-19 and C-18 Me), 1.22 (6H, d, J = 7 Hz, $CH(CH_3)_2$ C-16 and C-17 Me), 1.33 (3H, t, $-CH_2CH_3$), 1.99 (2H, ddd, H-2α,β), 2.28 (1H, s, H-5), 3.11 (1H, hept, J = 7 Hz, H-15), 3.84 (2H, q, CH_2CH_3), 4.36 (1H, d, J = 3.20 Hz, H-6), 4.66 (1H, d, J = 3.20 Hz, H-7), 5.59, 6.15 (each 1H, br s, 2 × Ar-O*H*), 6.79 (1H, s, H-14); hreims, m/z calcd. for $C_{22}H_{30}O_5$ (M^+): 374.2075; found: 374.2084 (100), 328 (87), 300 (29), 247 (17), 231 (24), 215 (68), 115 (24), 69 (40), 55 (51).

Methylation of 7-methoxyrosmanol (2)

Compound **2** (14.7 mg) dissolved in dry acetone was treated with anhydrous potassium carbonate (31.7 mg) and methyl sulphate (0.2 mL) and the reaction mixture stirred during 2 h, filtered, and evaporated *in vacuo*. Silica gel column chromatography gave **5** as a gum (12 mg); ir ($CHCl_3$): 3020, 2920, 2840, 1760, 1580, 1460, 1370, 1350, 1300, 1220, 1070, and 1040 cm^{-1}; hreims, m/z calcd. for $C_{23}H_{32}O_5$ (M^+): 388.2238; found: 388.2244 (100), 329 (74), 256 (32), 243 (39), 201 (31), 149 (63), 128 (20), 83 (37), 73 (31), 71 (31), 69 (70), 57 (71), 55 (90). The ^1H nmr was superimposable upon that given in the literature.

Methylation of galdosol (4) with diazomethane

Diazomethane in ether solution (15 mL) was added to 60 mg of galdosol (**4**) dissolved in ethyl ether (10 mL), and the mixture was left for 24 h at 0°C. Once the starting material had disappeared, the excess diazomethane was destroyed with acetic acid and the crude reaction product purified by chromatography, giving **15** (29.8 mg, 43.1%) and **16** (20.3 mg, 26.5%). **15** was a powder that could not be recrystallized; ir ($CHCl_3$): 3020, 2960, 1770, 1720, 1590, 1465, 1445, 1380, 1295, and 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.90 (3H, s), 1.07 (3H, s), 1.16 (3H, d, J = 7 Hz), 2.31, 4.11 (each 1H, d, J = 10 Hz, H-8α and H-8β), 2.82, 3.02 (each 1H, d, J = 4.5 Hz, H-22a and H-22b), 2.88 (1H, s), 3.24 (1H, m), 3.77 (3H, s), 3.78 (3H, s), 4.21 (1H, s), 6.54 (1H, s); ^{13}C nmr ($CDCl_3$) δ: 19.23 (t), 22.42 (q), 23.23 (q), 23.32 (q), 26.98 (d), 28.47 (t), 32.17 (q), 32.68 (s), 37.56 (t), 42.63 (t), 50.34 (d), 50.73 (s), 52.70 (t), 59.16 (s), 60.18 (q), 60.49 (q), 82.42 (d), 124.88 (d), 129.56 (s), 133.76 (s), 142.20 (s), 151.30 (s), 154.85 (s), 176.82 (s); hreims, m/z calcd. for $C_{24}H_{32}O_5$ (M^+): 400.2250; found: 400.2233 (100), 385 (2), 369 (3), 341 (5), 325 (5), 313 (6), 311 (4), 299 (3), 287 (6), 285 (4), 283 (5), 271 (6).

16 was isolated as a gum; ir ($CHCl_3$): 3020, 2960, 1770, 1740, 1600, 1465, 1450, 1390, 1380, 1325, 1285, 1215, 1170, 1110, and 1020 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.96 (3H, s), 1.05 (3H, s), 1.20 (3H, d, J = 7 Hz), 1.33 (1H, m), 2.21 (3H, s, H-23), 2.25 (1H, s, H-5), 2.96 (1H, s, O*H*), 3.26 (1H, m), 3.27 (1H, d, J = 5.3 Hz), 3.77 (3H, s), 3.81 (3H, s), 4.07, 4.58 (each 1H, d, J = 4.90 Hz, 2 × H-21), 4.49 (1H, s, H-6), 7.10 (1H, s, H-14); hreims, m/z calcd. for $C_{25}H_{34}O_7$: 446.2303; found: 446.2342 (M^+) (3), 387 (2), 373 (100), 345 (6), 329 (6), 327 (9), 299 (6), 287 (5), 285 (6) and 259 (18).

Canariquinone (**9**) was isolated as an amorphous yellow solid (98.3 mg); ir ($CHCl_3$): 3380, 3020, 2960, 2920, 2860, 1770, 1710, 1650, 1635, 1630, 1590, 1465, 1390, 1370, 1330, 1290, 1245, 1170, 1155, 1085, 1030, 1000, 960, and 910 cm^{-1}; uv: (EtOH), 280 nm; (EtOH + MeONa), 283 nm; (EtOH + $AlCl_3$), 270, 300, and 303 nm; (EtOH + $AlCl_3$ + HCl), 277, 310, and 363 nm; ^1H nmr ($CDCl_3$) δ: 0.87, 1.00 (each 3H, s, 2 × Me), 1.18, 1.20 (each 3H, d, J = 7.0 Hz, $CH(CH_3)_2$ C-16 and C-17 Me), 1.23 (3H, t, -OCH_2CH_3), 2.23 (1H, s, H-5), 3.14 (1H, hept, J = 7 Hz, H-15), 3.80, 4.00 (each 1H, q, -OCH_2CH_3), 4.39, 4.56 (each 1H, d, J = 2.5 Hz, H-6 and H-7), 7.06 (1H, s, ArO*H*); hreims, m/z calcd. for $C_{22}H_{28}O_6$ ($M^+ - CO_2$): 344.1985; found: 344.1989 (9), 300 (42), 298 ($M^+ - CO_2 - CH_3CH_2OH$) (58), 283 (10), 275 (13), 265 (4), 258 (11), 249 (2), 231 (40), 230 (27), 229 (13), 182 (12), 149 (45), 128 (17).

Treatment of **9** with acetic anhydride in pyridine gave **9*a***; ir ($CHCl_3$): 3020, 2960, 2930, 2865, 1770, 1670, 1650, 1595, 1450, 1390, 1370, 1330, 1275, 1185, 1165, 1150, 1130, 1085, 1025, 1000, 960, 940, 910, 870, and 815 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.89, 1.01 (each 3H, s, 2 × Me), 1.17, 1.21 (3H, d, J = 7.0 Hz, $CH(CH_3)_2$ C-16 and C-17 Me), 1.19 (3H, t, -OCH_2CH_3), 2.23 (1H, s, H-5), 2.32 (3H, s, ArOAc), 3.10 (1H, hept, J = 7 Hz, H-15), 3.20 (1H, bd, H-1β), 3.80, 4.01 (each 1H, q, -OCH_2CH_3), 4.36, 4.54 (each 1H, d, J = 2.5 Hz, H-6 and H-7); hreims, m/z calcd. for $C_{24}H_{30}O_7$: 388.1884; found: 388.1968 ($M^+ - C_2H_2O$) (3), 344 (388 − CO_2) (14), 342 (14), 340 (5), 300 (56), 298 (82), 296 (13), 283 (22), 242 (29), 231 (46), 229 (28).

Rosmaquinone (**10**) was isolated as a reddish-yellow amorphous solid (7 mg); ir ($CHCl_3$): 3590, 3440, 2960, 1770, 1660, 1460, 1390, 1170, and 1060 cm^{-1}; uv (EtOH): 402, 274, and 228 nm; ^1H nmr ($CDCl_3$) δ: 0.88, 1.02 (each 3H, s, C-19 and C-18 Me), 1.11, 1.12 (each 3H, d, J = 7 Hz, $CH(CH_3)_2$ C-16 and C-17 Me), 2.05 (1H, s, H-5), 2.93 (1H, hept, J = 7 Hz, H-15), 3.21 (1H, bd, J = 10.48 Hz, H-1β), 4.40, 4.52 (each 1H, d, J = 3.24 Hz, H-6 and H-7), 6.79 (1H, s, H-14); hreims, m/z calcd. for $C_{20}H_{24}O_5$: 344.1548; found: 344.1586 (M^+) (15), 316 (25), 285 (27), 257 (48), 238 (21), 231 (27), 230 (44), 229 (38), 215 (33), 211 (13), 203 (45), 201 (48), 187 (43), 173 (21), 161 (25), 159 (21), 141 (25), 131 (22), 128 (39), 115 (57), 105 (26), 91 (66), 55 (100).

Oxidation of rosmanol (3)

Rosmanol (46 mg) dissolved in dry ether was treated with freshly prepared excess Ag_2O and stirred at room temperature for 1 h. The solution was filtered and evaporated in a vacuum to give a product (45 mg) with ir and ^1H nmr superimposable upon that of **10**.

11-Acetoxy-carnosic acid (**6**) was obtained as a white crystalline solid; mp 123°C (*n*-hexane/ethyl acetate); ir ($CHCl_3$): 3720–2390, 1740, 1680, 1605, 1560, 1450, 1430, 1410, 1380, 1360, 1325, 1290, 1230, 1190, 1115, 1080, 1050, 1035, 1020, 985, 975, 955, 935, 915, 905, 890, 860, 815, and 640 cm^{-1}; uv (EtOH): 400, 330, and 284 nm; ^1H nmr ($CDCl_3$) δ: 0.89, 0.99 (each 3H, s, 19 and 18 Me), 1.15, 1.18 (each 3H, d, J = 7 Hz, $CH(CH_3)_2$ C-16 and C-17 Me), 2.28 (3H, s, ArOAc), 2.28 (1H, m, H-5), 2.86 (3H, m, H-15 and 2 × H-7), 3.33 (1H, d_b, J = 13.8 Hz, H-1β), 6.63 (1H, s, H-14); ^1H nmr (py-d_5) δ: 0.98, 1.21 (each 3H, s), 1.22 (6H, d, J = 7 Hz), 2.25 (3H, s), 3.06 (1H, hept, H-15), 6.73 (1H, s); hreims, m/z calcd. for $C_{22}H_{30}O_5$: 374.2101; found: 374.2097 (M^+) (2), 346 (1), 332 (2), 328 (9), 314 (1), 300 (2), 286 (100), 271 (11), 243 (19), 230 (48), 218 (20), 204 (21). Treatment of **6** with acetic anhydride gave a product with spectroscopic data superimposable on those of an authentic sample of carnosic acid diacetate (**7**). Treatment of **7** in its turn with ether solution of diazomethane gave **8**, identical to an authentic sample of carnosic acid diacetate methyl ester.

Photocyclization of aryl enaminones. An efficient route to indole alkaloid synthons

DANIEL GARDETTE, JEAN-CLAUDE GRAMAIN, MARIE-EVE LEPAGE, AND YVES TROIN
Chimie et biochimie des substances naturelles, Unité associée 485, Université de Clermont-II, B.P. 45, 63170 Aubière, France

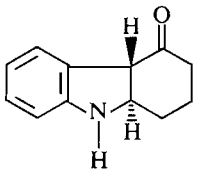
Received October 28, 1987[1]

DANIEL GARDETTE, JEAN-CLAUDE GRAMAIN, MARIE-EVE LEPAGE, and YVES TROIN. Can. J. Chem. **67**, 213 (1989).

The photocyclization of enaminones was extended to aryl enaminones bearing a substituent on the aromatic moiety. This reaction was studied in order to achieve the synthesis of indole alkaloid synthons. Trials of regioselectivity control were made by using groups with enhanced steric hindrance. The reactivity of secondary enaminones was tested, and the ratio of C-alkylation to N-alkylation was shown to be dependent on the nature of the aromatic substituent. During this work, new hexahydrocarbazolones were synthesized, with substituents on the A ring or the modified C ring.

Key words: photocyclization, aryl enaminones, indole alkaloids, hexahydrocarbazolones-4, cyclopenta[*b*]indoles.

DANIEL GARDETTE, JEAN-CLAUDE GRAMAIN, MARIE-EVE LEPAGE et YVES TROIN. Can. J. Chem. **67**, 213 (1989).



La photocyclisation d'énaminones a été généralisée aux aryl-énaminones substituées sur la partie aromatique. Cette réaction a été étudiée afin de synthétiser des précurseurs d'alcaloïdes indoliques. Des essais de contrôle de régiosélectivité ont été effectués en utilisant des groupements d'encombrement différent. La réactivité des énaminones secondaires a été testée et nous avons montré l'influence de la nature du substituant aromatique sur le rapport C-alkylation, N-alkylation. Au cours de ce travail, de nouvelles hexahydrocarbazolones ont été synthétisées avec des substituants sur le cycle A ou sur le cycle C-modifié.

Mots clés : photocyclisation, aryl-énaminones, alcaloidës indoliques, hexahydrocarbazolones-4, cyclopenta[*b*]indoles.

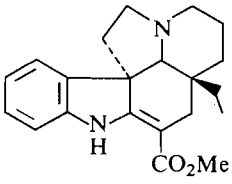
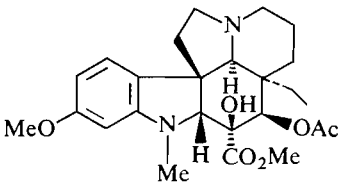
The hexahydrocarbazolone ring system **1** may be considered as a common structural element of a wide variety of indole alkaloids such as aspidospermidine **2**, vincadifformine **3**, and vindoline **4**. These alkaloids belong to a class of great interest due to their remarkable biological properties (1) and their importance in the preparation of active compounds like vincamine and vincaleucoblastine (2, 3).

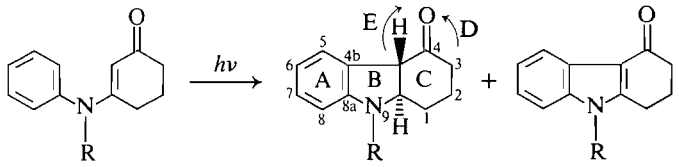


Hexahydro-4-carbazolones **5** (4) have been obtained in good yield by photocyclization of arylenaminones easily prepared from N-substituted anilines and 1,3-cyclohexanedione. This photocyclization reaction has recently received attention from



1

2



3

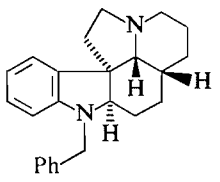
4

several laboratories (4–6) and leads to useful and original synthons for the building of such interesting heterocyclic compounds as the indole alkaloids. For instance, *N*(a)-benzyldeethyl aspidospermidine **6** (4, 5) can be obtained in a few steps with a 57% overall yield by a synthetic pathway based on this approach, and with a nearly perfect control of the crucial problem of the relative stereochemistry of rings C/D.

On the other hand, many natural alkaloids of *Aspidosperma* possess a substituent on ring A, usually methoxy groups on C-10, C-11, C-12 as in compound **7**, or sometimes hydroxy

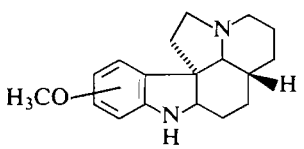
5 **9**

groups on C-10 and C-11 as in compound **8** (alkaloid numbering (7)).



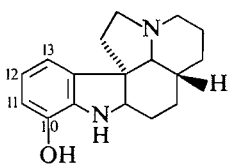
In the present paper we report, in Sect. 1, our investigations into the photocyclization of arylenaminones with a methoxy group on the aromatic moiety, a methoxy group which would be present on the final alkaloids. Because of the general synthetic interest of hexahydrocarbazole, we study and describe in Sect. 2 these tricyclic synthons with a modified C ring.

Results and discussion



1. Preparation of hexahydrocarbazolone-4 with a substituent on the aromatic ring

(a) Synthesis of enaminones **11**a–c



To test the regioselectivity of the photochemical process we studied the photocyclization of arylenaminones bearing a

TABLE 1. Alkylation of enaminones **11**

Starting products	Final products: N-alkylation	Final products: C-alkylation
11*a*	**12***a* 50%	**13***a* 27%
11*b*	**12***b* 39%	**13***b* 50%
11*c*	**12***c* 50%	**13***c* 10%

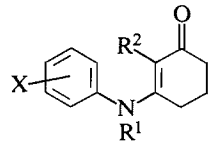
substituent on the aromatic ring, derived from *o*-, *p*-, and *m*-anilines.

Moreover, to simplify final product analysis, we started from 2-methyl-1,3-cyclohexanedione; indeed, using 1,3-cyclohexanedione may lead to oxidation product **9** (5) and would complicate the analysis of reaction mixtures.

Enaminones, useful for our study, must be prepared in two steps, according to standard procedures recently described (8, 9): condensation of 2-methyl-1,3-cyclohexanedione with substituted anilines followed by N-alkylation of the secondary enaminones thus obtained. Indeed, as we reported elsewhere (4), condensation between N-methylanilines and 2-methyl-1,3-cyclohexanedione failed, and secondary enaminones such as **10** are not photoreactive.

The enaminones **11***a–c* were prepared in good yields (74–87%) by condensation of *p*-, *o*-, or *m*-anisidine with 2-methyl-1,3-cyclohexanedione in toluene (10) (Dean–Stark apparatus).

The N-methylation of these secondary enaminones **11***a–c* was performed according to the procedure described by Greenhill *et al.* (9). But, beyond the expected N-methylation products **12***a–c*, C-alkylation compounds **13***a–c* were obtained as specified in Table 1. On the other hand the structure of products **13***a–c* was assigned on the basis of ir spectra, which exhibit absorptions at 1660 (C=N) and 1720 (C=O) cm^{-1}, and ^1H nmr spectra, which showed a *gem*-dimethyl group at 1.40 ppm. This structure was confirmed by chemical treatment: acidic hydrolysis of **13***a–c* leads to 2,2-dimethyl-1,3-cyclohexanedione in good yield (70%).



It will be noted that no C-alkylation product could be detected in the absence of a substituent on the aromatic ring (4). This C-alkylation is clearly linked to the donor effect of the methoxy group and is more important, as predicted, with *o*- and *p*-methoxy substituents (**11**). The *para*-methoxy group was changed to the *N,N*-dimethylamino group, a more powerful electron-donating group, to try to increase the yield of C-alkylation product. Thus we should obtain, after imine hydrolysis, an interesting method of preparation of 2-substituted 1,3-cyclohexanediones. Enaminone **14** was alkylated; the N-alkylation product **15** was obtained in 42% yield, and the C-alkylation product **16** in only 20% yield for unexplained reasons.

(b) Photocylization of enaminones **12**a–c

Enaminones **12***a–c* were irradiated under standard conditions (see experimental part).

Photocyclization of enaminone **12**a: Enaminone **12***a* was converted after 3 h of irradiation into *trans*-hexahydrocarbazolone **17***a* in 70% yield.

Photocyclization of enaminone **12**b: Photocyclization of enaminone **12***b* proceeded slowly to afford, after 22 h of irradiation, the expected *trans*-hexahydrocarbazolone **17***b* in moderate yield (30%). The low yield could be explained by the photocyclization of the alternate conformation, leading to an intermediate bearing the methoxy group on the C-4b position, followed by transformation, yielding products we were not able to isolate. Such complications have been described by Ninomiya *et al.* (12) in the case of photocylization of *o*-methoxy substituted enamides that lost one methoxy group.

Compound	R^1	R^2	X
10	H	H	H
11*a*	H	CH_3	*p*-OCH_3
11*b*	H	CH_3	*o*-OCH_3
11*c*	H	CH_3	*m*-OCH_3
12*a*	CH_3	CH_3	*p*-OCH_3
12*b*	CH_3	CH_3	*o*-OCH_3
12*c*	CH_3	CH_3	*m*-OCH_3
14	H	CH_3	*p*-NMe_2
15	CH_3	CH_3	*p*-NMe_2
18	H	CH_3	*m*-OH
19	H	CH_3	*m*-$OCPh_3$
20	CH_3	CH_3	*m*-$OCPh_3$
22	H	CH_3	*m*-OSitBu
23	CH_3	CH_3	*m*-OSitBu
26	CH_3	H	*m*-OTs

Photocyclization of enaminones **12**c: Of course, two regioisomers are expected in this case; treatment of enaminone **12***c* provided, in the same conditions as above, **17***c* and **17***d*, which were separated by fractional crystallization; they have the expected ir spectra (1720 cm^{-1}) and their structures were assigned on the basis of ^1H nmr spectra, by observing aromatic protons. For compound **17***c* the ^1H nmr spectrum indicated the presence of a methoxyl substituent on C-7 with H-5 at 7.55 ppm (d, J = 8.0 Hz), H-6 at 6.40 ppm (dd, J = 8.0 Hz and 2.2 Hz), and H-8 at 6.20 ppm (d, J = 2.2 Hz). For compound **17***d* H-7 appeared at 7.1 ppm (t, $J \simeq$ 8.0 Hz), H-6 at 6.40 ppm (d, J = 8 Hz), and H-8 at 6.15 ppm (d, J = 7.7 Hz). The two isomers are present in a 2:3 ratio, determined in ^{13}C nmr by time shared decoupling without nOe.

The results are summarized in Table 2 and, except in the case of enaminones **12***b*, support the great interest in this strategy for obtaining synthons that possess a methoxy group on the aromatic nucleus, the future ring A of *Aspidosperma* alkaloids.

Nevertheless, most of *Aspidosperma* alkaloids bear a methoxy group on the C-10 or C-11 position. Consideration of the molecular model showed that the regioselectivity of the photocyclization may be controlled by replacing the methoxy group by a bulky substituent whose interaction with CH_3 on C-4a would reduce the formation of C-5 substituted hexahydrocarbazolones. This bulky group has to be easy to introduce on a simple starting material such as aminophenol and easy to remove and replace by a methoxy group; it also must be photostable. Trityl and *tert*-butyldimethylsilyl groups for steric hindrance, and the tosyl group for steric hindrance and because of its electron-withdrawing effect, have been tried.

The enaminone **18**, prepared according to the usual proce-

TABLE 2. Photocyclization of tertiary enaminones

Enaminone	Irradiation time (h)	Product	Yield (%)
11*a*	3	**17***a*	70
11*b*	22	**17***b*	30
11*b*	1.5	**17***c* + **17***d*	70

dures from *m*-aminophenol and 2-methyl-1,3-cyclohexanedione, was treated with trityl chloride and triethylamine in the presence of 4-dimethylaminopyridine (13). The enaminone **19** thus obtained presented characteristic ir absorption (1640 cm^{-1}) and the assumed ^1H nmr data. The N-alkylation of **19** led to **20**.

The protected aminophenol **21** was prepared in 92% yield from aminophenol and *tert*-butyldimethylsilyl chloride (14) and was condensed with 2-methyl-1,3-cyclohexanedione to give enaminone **22**.

Alkylation of enaminone **22**, as described previously, gave enaminone **23** in 38% yield.

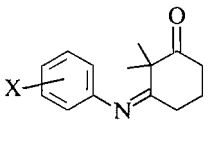
Enaminone **26** was prepared from the derivative **25** (obtained by reduction of the corresponding carbamate **24**) and 1,3-cyclohexanedione.

Irradiation of such enaminones, **20**, **23**, and **26**, led to complex mixtures: C-5, C-7 substituted *trans*-hexahydrocarbazolone deprotected products. The best results were obtained on irradiating enaminone **23**; **27***a* and **27***b* were prepared in 60% yield and in a 2:1 ratio, as determined by ^1H nmr. This result showed, in fact, the importance of steric hindrance: the major product **27***a* is the less hindered one. The structures of **27***a* and **27***b* were assigned, after chromatographic separation, on the basis of their ^1H nmr spectra. The multiplicity and the field of each aromatic proton (see experimental part) confirms the C-5 or C-7 position of the substituent.

In conclusion, these results proved the accuracy of the assumption that the regioselectivity of the photocyclization of substituted enaminones would be improved when bulky substituents were used. Nevertheless, this regioselectivity is not complete and the modest overall yield suffers from the number of the steps and the low yield of some of them. It will probably be better to separate the two isomers **17***c* and **17***d* bearing a methoxy group on the aromatic ring.

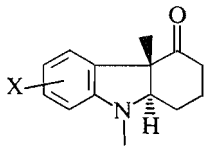
*2. Preparation of tricyclic compounds with modified C ring: dihydrocyclopenta[*b*]indole*

One of the first modifications tried was to replace 1,3-cyclohexanedione by 1,3-cyclopentanedione and 2-methyl-1,3-cyclopentanedione. Enaminones **28** and **29** were prepared.



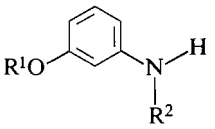
To our knowledge, photocyclization of such enaminones has not been studied. Kibayashi and co-workers (8) reported the cyclization of enaminone **30**, using palladium(II) acetate, leading to dihydrocyclopenta[*b*]indole **31** in modest yield (24%).

(a) Preparation of enaminones 28 and 29



Enaminone **28** was obtained in almost quantitative yield by condensation of 1,3-cyclopentanedione and the corresponding aniline (toluene, *para*-toluenesulfonic acid, Dean–Stark apparatus).

Under the same conditions, treatment of 2-methyl-1,3-cyclopentanedione with *N*-methylaniline afforded enaminone **29** in good yield (88%).



This result has to be compared with the same experiment between *N*-methylaniline and 2-methyl-1,3-cyclohexanedione, where the condensation was unsuccessful (4), and showed that the carbonyl group is less hindered in the case of 2-methyl-1,3-cyclopentanedione.

33

(b) Photocyclization of enaminones 28 and 29

Photocyclization of the enaminone **28** proceeded slowly to give the dihydrocyclopenta[*b*]indole **32**, after 4 days of irradiation, in 50% yield with only 25% conversion. Even when irradiation was accomplished in a perfectly deoxygenated solution, the nonoxidative photocyclization product was not isolated, in contrast with the results described in the 1,3-cyclohexanedione series (4). Consequently, the dihydro compound **32** acts as an internal filter with a large absorption at 313 nm and limits the conversion rate of **28**.

Photocyclization of enaminone **29** led to cyclopenta[*b*]indole **33** in almost quantitative yield based on consumed product **29**. The stereochemistry has not yet been assigned and would be difficult to predict, if we were to refer to analogous results reported in the literature (15, 16).

In conclusion, this work helps to illustrate the generality of photochemical ring closure of the 6π-electron system to afford tricyclic compounds. The good chemical yields and the availability of the starting materials make this an efficient method of great interest for obtaining useful synthons in new series and for the total synthesis of alkaloids.

Experimental

Melting points were determined on a Reichert micro hotstage apparatus and are uncorrected. Infrared spectra were obtained with a Perkin–Elmer 377 spectrophotometer and refer, unless otherwise stated, to carbon tetrachloride solutions. The ^1H nmr spectra were recorded on JEOL C60H and Bruker MSL 300H spectrometers and refer to deuteriochloroform solutions, tetramethylsilane serving as

internal standard. The ^{13}C nmr spectra were determined on a JEOL FX 60 (15.08 MHz) instrument. Mass spectra were run on a Varian CH5 spectrometer and uv spectra were recorded on a Beckman DU-8 spectrophotometer. Thin-layer chromatography was performed with Merck silica gel 60 F254 or with Merck aluminium oxide 60 F254.

Column chromatography was done with silica gel (Merck, 0.040–0.063 mm, 230–400 mesh ASTM) or with aluminium oxide (Merck, 0.063–0.200 mm, 70–230 mesh ASTM) in the specified solvent system. Microanalyses were performed in the Laboratoire central de microanalyses du CNRS in Lyon (France).

General procedure for condensation of aniline and 2-methyl-1,3-cyclohexanedione

To a solution of 2-methyl-1,3-cyclohexanedione (10 mmol) and aniline, freshly distilled (10 mmol), in toluene, was added *p*-toluenesulfonic acid monohydrate (50 mg). The solution was heated at reflux overnight in a Dean–Stark apparatus, then neutralised with K_2CO_3, filtered, and evaporated under reduced pressure to give, after chromatography (Al_2O_3, elution with AcOEt–hexane (5:5)), the desired enaminone.

2-Methyl-3-(4'-methoxyanilino)cyclohex-2-en-1-one **11***a*

The condensation of *p*-anisidine with 2-methyl-1,3-cyclohexanedione afforded the enaminone **11***a*, mp 155–157°C (AcOEt) in 87% yield; ν_{max} (CCl_4): 3430 (NH) and 1640 (C=O, enaminone) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.8–7.4 (5H, m, aromatic H and N-H), 3.85 (3H, s, OCH_3), 2.2–2.6 (4H, m, H-4, H-6), 1.9 (3H, s, CH_3), 1.8–2.1 (2H, m, H-5); ^{13}C nmr ($CDCl_3$) δ: 8.1 (CH_3), 21.8 (C-5), 27.0 (C-4), 36.5 (C-6), 55.4 (OCH_3), 106.3 (C-2), 114.2 (C-5', C-3'), 127.3 (C-6', C-2'), 131.8 (C-1'), 157.6 (C-4'), 160.2 (C-3), 195.6 (C-1). Anal. calcd. for $C_{14}H_{17}NO_2$: C 72.40, H 7.41, N 6.06; found: C 72.05, H 7.46, N 5.91.

2-Methyl-3-(2'-methoxyanilino) cyclohex-2-en-1-one **11***b*

The condensation of *o*-anisidine with 2-methyl-1,3-cyclohexanedione afforded the enaminone **11***b*, mp 112–113°C (AcOEt) in 74% yield; ν_{max} (CCl_4): 3420 (NH) and 1640 (C=O, enaminone) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.9–7.3 (4H, m, aromatic H), 6.4–6.5 (1H, NH), 3.9 (3H, s, OCH_3), 2.3–2.7 (4H, m, H-4, H-6), 1.9 (3H, s, CH_3), 1.8–2.1 (2H, m, H-5); ^{13}C nmr ($CDCl_3$), δ: 8.0 (CH_3), 21.9 (C-5), 26.9 (C-4), 36.6 (C-6), 55.6 (OCH_3), 107.8 (C-2), 111.0 (C-3'), 120.5 (C-5'), 124.2 (C-6'), 125.5 (C-4'), 128.2 (C-1'), 152.3 (C-2'), 158.8 (C-3), 195.6 (C-1). *Anal.* calcd. for $C_{14}H_{17}NO_2$: C 72.40, H 7.41, N 6.06; found: C 72.73, H 7.41, N 6.10.

2-Methyl-3-(3'-methoxyanilino)cyclohex-2-en-1-one **11***c*

The condensation of *m*-anisidine with 2-methyl-1,3-cyclohexanedione afforded the enaminone **11***c*, mp 136°C (AcOEt) in 78% yield; ν_{max} (CCl_4): 3425 (NH) and 1640 (C=O, enaminone) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.0–7.4 (1H, m, H-2'), 6.55–6.9 (3H, m, H-4', H-5', H-6'), 6.3–6.5 (1H, NH), 3.8 (3H, s, OCH_3), 2.2–2.7 (4H, m, H-4, H-6), 1.8 (3H, s, CH_3), 1.8–2.1 (2H, m, H-5); ^{13}C nmr ($CDCl_3$) δ: 8.4 (CH_3), 22.0 (C-5), 27.4 (C-4), 36.6 (C-6), 55.3 (OCH_3), 107.9 (C-2), 110.5 (C-4', C-2'), 117.1 (C-6'), 129.8 (C-5'), 140.3 (C-1'), 158.8 (C-3), 160.2 (C-3'), 196.1 (C-1). *Anal.* calcd. for $C_{14}H_{17}NO_2$: C 72.4, H 7.41, N 6.06; found: C 72.69, H 7.52, N 6.05.

General procedure for alkylation of enaminones

To a suspension of sodium hydride (60% dispersion in mineral oil) (1.1 equivalent) in dry toluene, under nitrogen, was added, drop by drop, a solution of 1.0 equivalent of the enaminone dissolved in toluene. The mixture was refluxed while stirring for 1 hour, then allowed to cool to room temperature. Then 2.2 equivalents of methyl iodide were added and the mixture was refluxed for 2 hours. After quenching by addition of ice-water, the layers were separated. The aqueous layer was extracted with CH_2Cl_2 and the combined organic layers dried. After removal of the solvent, the residue was chromatographed (Al_2O_3, elution AcOEt–hexane 2:8).

*2-Methyl-3-(*N*-methyl-4'-methoxyanilino)cyclohex-2-en-1-one* **12***a*

The alkylation of **11***a* (4.5 g; 19.48 mmol) afforded 2.4 g of **12***a*, mp 100–101°C (acetone–hexane) in 50% yield; uv (EtOH) λ_{max}: 327 nm (17 700); ν_{max} (CCl_4): 1660 (C=O, enaminone) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.85 (4H, s, aromatic H), 3.7 (3H, s, OCH_3), 3.2 (3H, s, NCH_3), 2.1–2.6 (4H, m, H-4, H-6), 1.4–2.0 (2H, m, H-5), 1.5 (3H, s, CH_3); ^{13}C nmr ($CDCl_3$) δ: 12.4 (CH_3), 21.1 (C-5), 29.4 (C-4), 37.2 (C-6), 41.1 (NCH_3), 55.4 (OCH_3), 114.4 (C-5', C-3'), 117.6 (C-2), 123.4 (C-6', C-2'), 140.9 (C-1'), 155.5 (C-3), 162.2 (C-4'), 198.6 (C-1). *Anal.* calcd. for $C_{15}H_{19}NO_2$: C 73.44, H 7.81, N 5.71, found: C 73.15, H 7.66, N 5.63.

Nucleophilic photosubstitutions of *o*-methoxynitrobenzenes

NIGEL J. BUNCE AND KAREN LABONTE STEPHENSON

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received June 13, 1988

NIGEL J. BUNCE and KAREN LABONTE STEPHENSON. Can. J. Chem. **67**, 220 (1989).

We report a new synthesis of 3-nitroveratrole, based on the directed lithiation of veratrole, and photochemical substitutions of both 3-nitroveratrole and *o*-nitroanisole with several nucleophiles. Both aromatic substrates undergo photocyanation *meta* to the nitro group. With hydroxide ion, 3-nitroveratrole reacts *meta* to the nitro group, but 2-nitroanisole undergoes replacement of either substituent, the proportion of reaction at each site depending upon the OH^- concentration. 3-Nitroveratrole undergoes an inefficient reaction with butylamine at each methoxy group; this reaction is apparently second order in amine. The reaction between *o*-nitroanisole and diethylamine results only in photohydrolysis.

Key words: photosubstitution, nucleophilic, 3-nitroveratrole, *o*-nitroanisole.

NIGEL J. BUNCE et KAREN LABONTE STEPHENSON. Can. J. Chem. **67**, 220 (1989).

On a réalisé une nouvelle synthèse du nitro-3 vératrole qui est basée sur la lithiation directe du vératrole et on a examiné des réactions de substitutions photochimiques tant du nitro-3 vératrole que de l'*o*-nitroanisole avec plusieurs nucléophiles. Les deux substrats aromatiques subissent des photocyanurations en position *méta* du groupement nitro. Avec l'ion hydroxyde, le nitro-3 vératrole réagit en position *méta* du groupement nitro; toutefois, dans les mêmes conditions, le nitro-2 anisole subit un remplacement de l'un ou l'autre des substituants et la proportion des produits provenant des substitutions à chacun des sites dépend de la concentration en OH^-. Avec la buylamine, le nitro-3 vératrole subit une réaction inefficace au niveau de chacun des groupements méthoxy; il semble que cette réaction est du deuxième ordre en amine. La réaction de l'*o*-nitroanisole avec la diéthylamine ne fournit que le produit de photohydrolyse.

Mots clés : photosubstitution, nucléophilique, nitro-3 vératrole, *o*-nitroanisole.

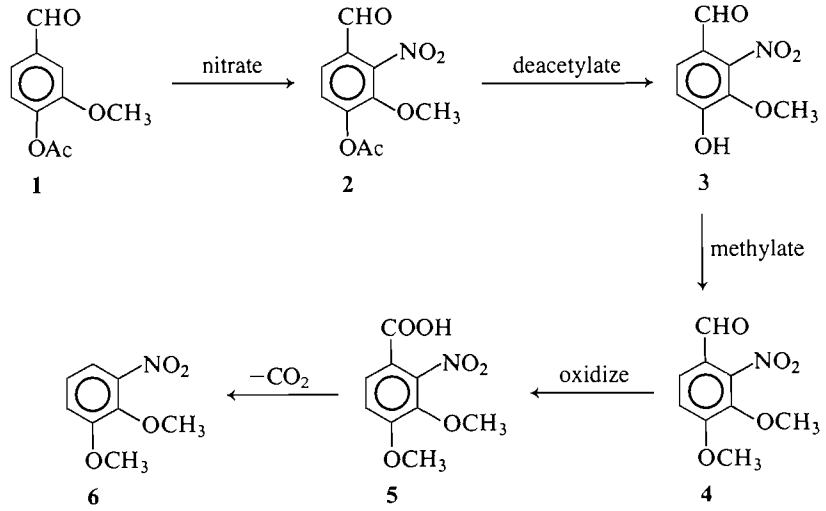
Introduction

Nucleophilic photochemical substitutions have been a subject of intense research activity since their first discovery in 1956. The scope of these reactions (1), empirical rules for product predictions (2), and possible mechanisms (3) have all been reviewed. Of considerable importance in developing our ideas about the scope and mechanisms of these photosubstitutions have been reactions carried out on methoxynitro compounds as substrates, notably with 3- and 4-nitroanisoles and 4-nitroveratrole. By contrast, the photochemical reactions of *o*-nitroanisole and of 3-nitroveratrole have been almost unexplored.

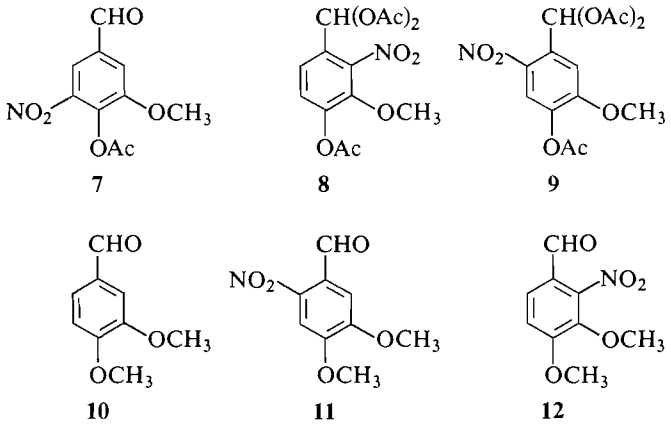
The whole area of methoxynitroaromatic compounds and their photochemistry has attracted new interest with the realization that nucleophilic photosubstitution reactions of these compounds can occur by two distinct pathways: a direct S_N2 Ar* photosubstitution and a route initiated by electron transfer from the "nucleophile" to the nitro compound (4, 5). Substitutions *meta* to the nitro group and those at the ipso position are S_N2 Ar* processes, and appear to be initiated by attraction of the incoming nucleophile to locations where the excited state HOMO electron density is low. Substitutions *para* to the nitro group are electron-transfer reactions in which the subsequent bond-forming step is a ground state process. For this type of substitution to occur, the nucleophile must be easily oxidizable (5).

Very little is known so far about the photochemistry of *o*-methoxynitrobenzenes. Letsinger and McCain (6) obtained the substitution products from the action of cyanide ion and de Vries[1] obtained those from the action of hydroxide ion with *o*-nitroanisole, but no mechanistic work was done. In the present work, we have devised a new route to the inaccessible 3-nitroveratrole, and have carried out preliminary investigations of the photosubstitution chemistry of both 3-nitroveratrole and *o*-nitroanisole.



[1]S. de Vries, quoted in ref. 1.

Results and Discussion



Synthesis of 3-nitroveratrole

We first attempted to reproduce an old synthesis (7, 8) of 3-nitroveratrole **6** from acetylvanillin **1** (Scheme 1). The critical step in this synthesis is the introduction of the nitro group at the 2-position of acetylvanillin to give the 1,2,3,4-tetrasubstituted benzene. According to the old literature (7) this is accomplished by dropping red fuming nitric acid onto dry, powdered acetylvanillin. In our hands, the major product of nitration by this route was **7**, with the two ring protons seen as narrow doublets ($J=2$ Hz), rather than the 8–10 Hz coupling that would be expected for protons *ortho* to each other, as in the desired compound **2**. Various nitrating conditions were tried, including HNO_3/H_2SO_4, HNO_3/Ac_2O, NO_2/Ac_2O, $HNO_3/NO_2/Ac_2O$, but in no case was the desired **2** more than a minor product. Concentrated, yellow fuming, and red fuming nitric acid were all tried. Under the milder conditions, the starting material was recovered; under forcing conditions the nitrotriacetates **8** (minor) and **9** were the major products. Nitration of vanillin methyl ether **10** was no more successful; the nitration product was **11** instead of the desired **12**.

We therefore abandoned a synthesis based on nitration in favour of a route based on the *ortho* lithiation of veratrole. Directed lithiations are particularly suited for the introduction of a new substituent *ortho* to one already present (9). The final synthesis is shown as Scheme 2. The lithiation of veratrole proceeded successfully as shown by the carbonation of the lithio derivative to the known 2,3-dimethoxybenzoic acid (10). The key to the synthesis of 3-nitroveratrole is the creation of the C—N bond. Unfortunately, few methods exist for this procedure. The direct introduction of an amino group occurs with methoxylamines (11) and reactions of aryllithiums with chloramine, nitrosyl chloride, and alkyl nitrates have all been reported, but the yields are poor. We attempted the direct introduction of the nitro group by the reaction of an aryllithium with

SCHEME 1. Planned synthesis of 3-nitroveratrole from acetylvanillin.

either N_2O_4 or $NO_2^+BF_4^-$, since NO_2^+ and CO_2 are isoelectronic. Unfortunately, electron transfer occurred, and the major organic product isolated was biphenyl (from phenyllithium as the lithio derivative).

We therefore employed the reaction between the aryllithium and *p*-toluenesulfonyl azide (12). The product was reduced to the amine by the use of sodium borohydride in a heterogeneous system with the aid of tetrabutylammonium hydrogen sulfate as a phase-transfer catalyst (13). Unfortunately, even under these conditions, the yield of the amine was relatively poor, and this meant that the overall synthesis of 3-nitroveratrole was not convenient for scaling up.

Oxidation of the amine to the nitro compound was achieved in two steps. The use of sodium tungstate/hydrogen peroxide (14) afforded comparable amounts of the nitroso compound and the corresponding azoxy compound, which was not wanted. This was circumvented by the modification of Agrawal and Bhattacharya (15) in which Mn(II) salts are used catalytically with sodium tungstate/H_2O_2, and the nitroso compound precipitates from the aqueous solution as it is formed. Finally, the nitroso to nitro conversion was effected by means of $Na_2Cr_2O_7/H_2SO_4$.

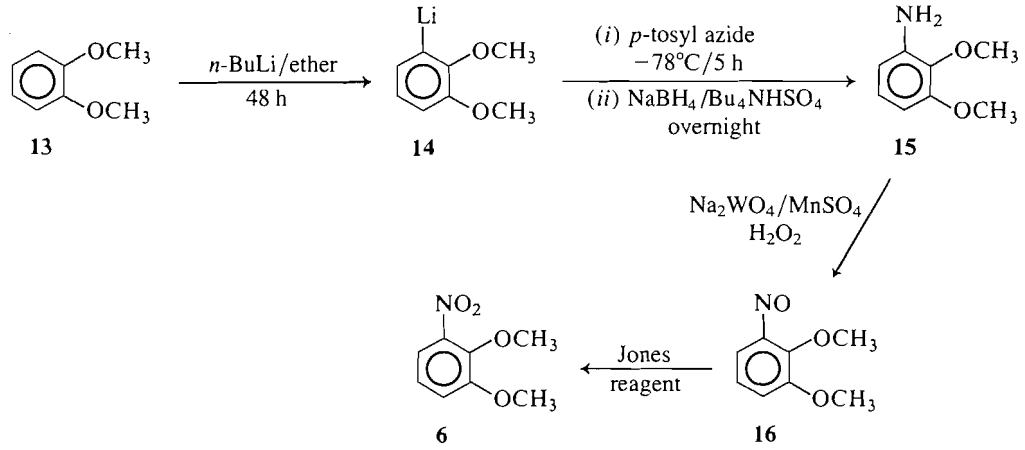
Photosubstitutions

In this preliminary survey, *o*-nitroanisole and 3-nitroveratrole were each reacted with three nucleophiles: OH^-, CN^-, and an amine. The solvent was 65:35 CH_3CN:H_2O by volume, and the reactions were carried out without deoxygenation. Control reactions showed that all of the reactions reported were true photochemical processes, and that no reaction occurred in the dark. Table 1 provides a summary of the study.

Photocyanation was the most straightforward reaction to interpret, with an exclusive *meta*-to-nitro orientation being observed. Thus 3-nitroveratrole afforded 2-methoxy-3-nitrobenzonitrile **13** in high yield, and with quantum yield (ϕ) close to 0.1, while *o*-nitroanisole yielded 4-methoxy-3-nitrobenzonitrile **14**, formal substitution of H^- having occurred. This behaviour is similar to that previously observed for the photoreaction of *p*-nitroanisole with this nucleophile (16). The selection of the position *meta* to the nitro group of *o*-nitroanisole is strongly influenced by solvent; in 65:35 CH_3CN:H_2O, **14** was the only product observed (HPLC), while in methanol we found that the alternative cyanation product **13** predominated. Previously, Letsinger and McCain (6) had found equal amounts of both products by the use of aqueous tertiary butyl alcohol as solvent.

Stern–Volmer plots of ϕ^{-1} vs. $[CN^-]^{-1}$ were linear for both substrates. For an S_N2 Ar* process, we would assume the mechanism of Scheme 3.

From Scheme 3, we obtain eq. [1] by the application of steady state kinetics.



$$[1] \quad \phi^{-1} = \left(1 + \frac{k_3}{k_4}\right)\left(1 + \frac{k_1}{k_2[Nu^-]}\right)$$

As a generalization, the intercept of the double reciprocal plot gives the proportion of intermediates that return to starting material rather than proceed to product, while the ratio intercept/slope is the Stern–Volmer quenching constant K_{SV}, which is the product of the rate constant for quenching (k_2) and the unquenched excited state lifetime ($1/k_1$).

In the case of photocyanations involving the formal replacement of (H^-), the mechanism frequently occurs by way of radical ions and, in addition, the final step of Scheme 3 is complicated by the need for oxidation of the radical intermediate (ArHCN) (17). With these provisos, the K_{SV} and intercept can still be interpreted in terms of the efficiency of the original interaction between ArX* and CN^-, and the inefficiency of the steps following.

We see that photocyanation of *o*-nitroanisole proceeds with lower quantum yield than that of 3-nitroveratrole, as a result of the inefficiency of the later steps of the reaction. This is consistent with the need for oxidation of the intermediate. Most

SCHEME 2. Reaction sequence for the synthesis of 3-nitroveratrole.

probably, this photoreaction could be made much more efficient if it were to be assisted by an electron-accepting agent such as persulfate ion[2] or a polycyanoarene (19), but this was outside the scope of the present study.

The reactions with OH^- bore some resemblance to those with CN^-. 3-Nitroveratrole again reacted cleanly, and fairly efficiently (upper limit of $\phi = 0.1$) with replacement of the *meta* methoxy group. *o*-Nitroanisole reacted with lower quantum efficiency. This time no reaction occurred *meta* to nitro; instead, at $[OH^-] = 0.1$ M, replacement of the methoxy group (*ortho* to nitro, which is unusual) predominated over replacement of the nitro group (ipso, and also *ortho* to methoxy, which is more conventional). The behaviour of *o*-nitroanisole resembles that of the *para* isomer, which also undergoes replacement of both substituents upon photohydrolysis in aqueous *tert*-butyl alcohol (20).

In our study, *o*-nitroanisole afforded *o*-nitrophenol and *o*-methoxyphenol in the ratio ca. 3.6:1. This contrasts with an earlier study[1] in which a 10:1 ratio was observed. From our study of the effect of $[OH^-]$ upon ϕ, we see that, at least in aqueous CH_3CN, the product ratio is quite sensitive to the OH^- concentration. High hydroxide concentrations favour *o*-nitrophenol formation, and we predict that at sufficiently low concentrations ($[OH^-] < 5 \times 10^{-3}$ M) *o*-methoxyphenol should predominate.

Photosubstitutions involving amines are frequently complicated by electron-transfer processes, and either photoreduction at the nitro group (21) or substitution *para* (or *ortho* ?) to nitro may be anticipated. This was indeed observed in the reaction of 3-nitroveratrole with butylamine, where at $[BuNH_2] = 0.1$ M, *N*-butyl-2-methoxy-6-nitroanailine **15** and *N*-butyl-2-methoxy-3-nitroaniline **16** were formed with similar efficiency. However, the chemical yield and the quantum yield were both low. At lower concentrations of butylamine the replacement of the *meta* methoxy group predominated but, as shown by the double reciprocal plots (Fig. 1a), even this is not a conventional S_N2

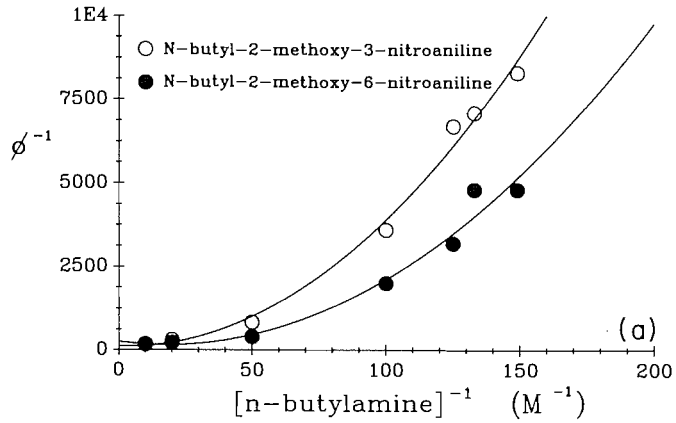
SCHEME 3

Ar* reaction. When ϕ for formation of these two products was studied as a function of the butylamine concentration, the double reciprocal plots were curved. Empirically, it was discovered that a linear relationship existed between ϕ^{-1} and $[BuNH_2]^{-2}$ (Fig. 1b).

The photoreaction between *o*-nitroanisole and diethylamine, again in aqueous CH_3CN, yielded *o*-methoxyphenol as the only isolable product (yield 61%). The reaction has two notable features: first, the diethylamine does not become incorporated into the product; second, the quantum yield for formation of *o*-methoxyphenol is independent of $[Et_2NH]$ over the wide concentration range $4 \times 10^{-3} < [Et_2NH] < 0.1$ M (Fig. 2).

We were led to consider the possibility that the role of diethylamine in this reaction is simply to form a low concentration of hydroxide ion, through equilibrium [2].

$$[2] \quad Et_2NH + H_2O \rightleftharpoons Et_2NH_2^+ + OH^-$$



Aliphatic amines have $pK_b \sim 4$ in water, and hence in the partly aqueous solvent we can expect $K_b = 10^{-4}$ mol L^{-1} to be an upper limit. Over the concentration range $4 \times 10^{-3} < [Et_2NH] < 0.1$ M, the calculated maximum concentration of OH^- is $6 \times 10^{-4} < [OH^-] < 3 \times 10^{-3}$ M for $K_b = 10^{-4}$ mol L^{-1}. This is the concentration range for OH^- in which *o*-methoxyphenol is the predominant photosubstitution product. Since the Stern–Volmer plot for methoxyphenol production is rather flat (slope = 6 M, intercept = 2600), it is easily possible for the production of methoxyphenol to show no apparent dependence on $[Et_2NH]$. Nevertheless, it is still very unexpected that the only participation of diethylamine in the reaction is to be a source of OH^-; most methoxynitro compounds undergo reactions characteristic of electron transfer upon photoexcitation in the presence of secondary amines. To our knowledge, the only exception to this

behaviour previously recorded is *m*-nitroanisole, which is unreactive towards diethylamine in aqueous CH_3CN solution (22).

Conclusions

o-Methoxynitro compounds display a range of behaviour upon photolysis in the presence of nucleophiles. Photocyanation is the most "conventional" process we have observed. Towards hydroxide ion, 3-nitroveratrole behaves similarly to 4-nitroveratrole,[3] with exclusive replacement of the *meta* methoxy group taking place. Likewise, *o*-nitroanisole undergoes photohydrolysis analogous to *p*-nitroanisole, with competing replacement of both substituents. Unexpected chemistry is seen with amines: 3-nitroveratrole reacts with butylamine in a reaction that appears to be second order in amine, while *o*-nitroanisole undergoes only photohydrolysis in the presence of diethylamine. Future work will be directed towards a more detailed study of the behaviour of these methoxynitro compounds with a range of amines, and towards time-resolved studies in order to elucidate reaction mechanisms in detail.

Experimental

Materials and methods

Yellow fuming nitric acid was obtained from Fisher. Nitrogen dioxide was supplied by Matheson Gas Products.

Thin-layer chromatography (TLC) was performed using Eastman 13181 silica gel and 13252 alumina with fluorescent indicators. Column chromatography was performed on Davison Chemical silica gel 28–200 mesh, BDH silica gel 60–120 mesh, or Fisher neutral alumina. Small samples (≤1 g) were separated on Waters SEP-PAK silica or neutral alumina cartridges. Solvent compositions are given as volume ratios. Petroleum ether was the fraction of bp 30–60°C. Melting points were determined on a Mel-Temp apparatus and are uncorrected.

Nuclear magnetic resonance (NMR) spectra were obtained at 60 MHz in $CDCl_3$, using a Varian EM 360L NMR spectrometer, or at 400 MHz on a Bruker WH-400 NMR spectrometer.

Mass spectra of pure compounds were obtained using a VG Analytical 7070F mass spectrometer. Combined gas chromatography/mass spectrometry (gc/ms) was carried out on a VG MM 12000 analytical mass spectrometer interfaced to a Hewlett–Packard 5790 gas chromatograph equipped with a 30-m or 60-m quartz capillary column containing J & W DB-5 fused silica. Fourier transform – IR were processed using a Nicolet 20SX/C FTIR. UV/visible spectra were obtained using a Perkin–Elmer Lambda 3 UV/visible spectrometer.

HPLC analyses were performed on a Waters system: Waters 501 HPLC pump, U6K injector, and model 440 absorbance detector operated at 254 nm and recorded using a Hewlett–Packard 3390A integrator. Analytical separations were performed using a Waters NOVAPAK C_{18} 5 μ 3.9 mm × 7.5 cm column. Semi-preparative separations (≤ 1 g) were performed on a Whatman Magnum 9 Partisil ODS-3 C_{18} 9.4 mm × 25 cm column. All solvents used were HPLC grade and were filtered and degassed before use. Solvent compositions are given as volume ratios.

Preparation of red fuming nitric acid (ref. 24)

A distillation apparatus was set up, substituting a dropping funnel in place of a thermometer. The receiving flask was placed in ice. To the boiling flask was added 100 g KNO_3 and 3.5 g starch. Concentrated sulfuric acid (100 mL) was added slowly dropwise from the dropping funnel. The reaction, which proceeds virtually without the application of heat, was heated gently with a heating mantle only when necessary.

*Synthesis of 3,4-dimethoxy-6-nitrobenzaldehyde, **11** (ref. 7)*

A sample of 3,4-dimethoxybenzaldehyde (1.00 g) was cooled in an ice bath. Yellow fuming nitric acid was added slowly with stirring so that the temperature of the reaction did not exceed 6°C. The acid was added until all the 3,4-dimethoxybenzaldehyde had dissolved. The reaction mixture was poured into ice water. The nitro compound separated as an oil that solidified on standing. The solid was filtered, washed with 5% $NaHCO_3$, and then with water. TLC showed only one component to be present. The yellow solid was recrystallized from methanol/water. The resulting fluffy yellow precipitate of **11** (0.70 g) was filtered and dried. Yield 55%; mp 129–131°C (lit. (25) mp 129–131°C); NMR (60 MHz) δ: 4.00 (s, 6H), 7.36 (s, 1H), 7.58 (s, 1H), 10.5 (s, 1H) ppm.

Nitration of acetylvanillin

Several different nitration procedures were attempted. They are shown in Table 2.

Lithiation of veratrole (ref. 10)

All glassware was rinsed with acetone, followed by drying overnight at a temperature of ~110°C. The glassware was then flushed with nitrogen while still hot, to maintain a dry inert atmosphere. A solution of veratrole (3.45 g) in ether (50 mL) was dried over 3Å molecular sieves and added under a nitrogen atmosphere. To this was added with stirring 2.5 M *n*-butyllithium in hexanes (20 mL). The solution was stirred at room temperature for 48 h. The identity of the lithio derivative was confirmed in one experiment by pouring the reaction mixture onto Dry Ice. After the Dry Ice had sublimed, the organic residue was acidified with HCl. The aqueous mixture was then extracted into ether, followed by extraction with base. The base extract was acidified to yield a brown residue, which was recrystallized from water to yield the acid as a pale yellow solid; mp 120–121.5°C (lit. (10) mp 120–122°C); NMR (60 MHz) δ: 4.06 (s, 3H), 4.20 (s, 3H), 7.27 (d, J=8 Hz, 2H), 7.78 (t, J=8 Hz, 1H), 10.02 (br, 1H) ppm.

The attempted nitration of phenyllithium by $NO_2(g)$

In a well-dried round-bottom flask under positive pressure of nitrogen was placed 2.0 M phenyllithium in 70:30 cyclohexane/ether (20 mL). Nitrogen dioxide gas was bubbled through the solution for several minutes. The gas was then turned off and the reaction quenched using wet ether and then water. The organic and aqueous layers were separated, the aqueous layer being extracted twice with ether. The organic extracts were combined and dried over $MgSO_4$. The solvent was removed under reduced pressure, yielding a dark brown liquid that then solidified on standing. The solid, biphenyl, was purified on a Waters alumina SEP-PAK cartridge, eluting with 10% toluene/petroleum ether. It was further purified by recrystallization from 95% ethanol; mp 69–71°C (lit. (26) mp 71°C); NMR (60 MHz) δ: ~7.5 ppm (complex multiplet); MS m/e: 154(M^+, 100), 155(M+1, 13), 39(25).

The attempted nitration of phenyllithium by NO_2BF_4

To a 100-mL 3-necked round-bottom flask equipped with a dropping funnel was added by syringe 2.0 M phenyllithium in 70:30 cyclohexane/ether (5 mL). The solution was stirred at 0°C under positive pressure of nitrogen while 0.5 M NO_2BF_4 in sulfolane (20 mL) was added slowly dropwise. After ~10 min the reaction was quenched by adding sulfolane/water, followed by water. The reaction mixture separated into a brown lower layer and a thin yellow upper layer (believed to consist of cyclohexane and ether). The layers were separated, the brown layer being saved for determination of nitrite. The yellow layer smelled strongly of nitrobenzene. TLC on silica gel, eluting with 40% toluene/petroleum ether, showed two spots whose R_f values corresponded to nitrobenzene and biphenyl respectively. The two components were separated on Waters silica SEP-PAK cartridges using petroleum ether, affording biphenyl (78%) and nitrobenzene (3%).

Synthesis of p-*-toluenesulfonyl azide (ref. 27)*

The azide was prepared by adding, with swirling, sodium azide (14 g) in water (20 mL) to *p*-toluenesulfonyl chloride (34 g) in 95% ethanol (200 mL). After 1 h, the mixture was poured into water (400 mL). The sulfonyl azide (17 g) separated as an oily layer, which was collected, quickly washed three times with water, and dried over sodium sulfate. Yield 48%; IR: 2115 (N_3) cm^{-1}. It was dissolved in anhydrous ether and dried over 3Å molecular sieves. The solution was then refrigerated.

Formation of the amine (ref. 12)

A lithiated sample of veratrole was cooled in a Dry Ice/acetone bath while still under nitrogen. A solution of *p*-toluenesulfonyl azide (6 g) in ether (40 mL) was added dropwise. When the addition was complete, the resulting mixture was stirred for 5 h, maintaining the temperature at −78°C. It was then warmed to room temperature and tetrabutylammonium hydrogen sulfate (8.5 g) was added. Over a 30-min interval, sodium borohydride (2.9 g) in water (9 mL) was added dropwise, keeping the temperature below 30°C. After allowing the mixture to stir overnight, the ether layer was decanted. The aqueous layer was extracted with ether. The combined organic layers were dried over magnesium sulfate and the solvent evaporated, yielding 2,3-dimethoxyaniline as an amber liquid (0.99 g). Yield 26%; IR: ~3400, ~3500 (NH_2) cm^{-1}.

Oxidation of the amine to the nitroso compound (refs. 14, 15)

A solution of $MnSO_4 \cdot 7H_2O$ (1.9 g), $Na_2WO_4 \cdot 2H_2O$ (2.2 g), and water (50 mL) was prepared in a 125-mL Erlenmeyer flask. To this was added the 2,3-dimethoxyaniline (0.5 g). The mixture was stirred, producing a suspension of the amine, while 30% hydrogen peroxide (3 g) was added slowly dropwise. After several minutes a brown precipitate formed and rose to the top of the aqueous layer. The mixture was filtered by suction and the precipitate of 3-nitrosoveratrole was collected (0.39 g). Yield 72%; IR: 1596 (NO) cm^{-1}.

Oxidation to 3-nitroveratrole (ref. 28)

Jones reagent was prepared by dissolving chromium trioxide (26.72 g) in concentrated sulfuric acid (23 mL), which had been diluted to a volume of 100 mL with water. The crude 3-nitrosoveratrole (0.20 g) was dissolved in acetone (20 mL). The solution was cooled in a water bath, while maintaining a temperature of 15–20°C. To the solution was added dropwise with stirring 10 mL of Jones reagent, while maintaining the temperature below 20°C. The solution was stirred for 48 h, after which it was filtered by suction. The filtrate was then evaporated under reduced pressure. The residue was dissolved in ether and washed with water. The organic layer was dried over $MgSO_4$. The solvent was evaporated, yielding a yellow residue. The compound was purified on a

[a]Lanthanide shift experiments showed the splitting of this peak into two separate doublets.

Waters SEP-PAK silica cartridge using 10% petroleum ether/toluene. This procedure yielded a pale yellow solid, 3-nitroveratrole (0.16 g). Yield 74%; mp 62–64°C (lit. (ref. 25, p. 4266) mp 64–65°C; IR: 1550, 1340 cm^{-1}; NMR (400 MHz) δ: 4.93 (s, 3H), 4.99 (s, 3H), 7.11 (d, J=8 Hz, 2H), 7.33 (dd, J=8 Hz, J=3 Hz, 1H) ppm; MS m/e: 183(M^+, 50), 136(32), 122(30), 107(58), 92(33), 77(100), 65(18).

Preparative irradiation procedures

Preparative scale irradiations were performed in a 350-mL quartz immersion well equipped with a Hanovia 450-W medium pressure mercury lamp. The solutions were stirred using a magnetic stirrer. Alternatively, irradiations were performed in ~20-mL quartz ampoules, in a Rayonet model RPR photoreactor equipped with 16 mercury lamps. Three types of lamps were available, having maximum transmission at wavelengths of 254, 300, or 350 nm.

Determination of chemical yields

Standards for quantitation were prepared from products isolated or authentic samples where available: Solutions of 8.03×10^{-3} M *o*-nitroanisole in acetonitrile and aqueous 0.3 M nucleophile (NaOH, KCN, diethylamine) were prepared. In an 8 mm o.d. quartz ampoule the *o*-nitroanisole (1.3 mL) and nucleophile (0.7 mL) were combined to a final composition of 5.22×10^{-3} M *o*-nitroanisole and 0.1 M nucleophile in 65:35 acetonitrile/water. The samples were then irradiated for a specified period of time, after which they were analyzed for substrate and product by HPLC using the external standard method. A constant volume of external standard was added to each sample after irradiation. The height ratios of the product/external standard were calibrated against a prepared calibration standard. All samples were analyzed in triplicate. The values obtained are precise to within 5%.

Chemical yields for 3-nitroveratrole were determined in the same way with a solution of 7.67×10^{-3} M 3-nitroveratrole in acetonitrile. Also, *n*-butylamine was used as the aliphatic amine, rather than diethylamine as in the case of *o*-nitroanisole.

o-*Nitroanisole/OH^-*

A solution of $\sim 5 \times 10^{-3}$ M *o*-nitroanisole (0.23 g) and 0.1 M NaOH (1.2 g) in 1:1 tetrahydrofuran/water (300 mL) was irradiated for 6 h. After irradiation, the nonaqueous solvent was evaporated under reduced pressure. The remaining aqueous solution was extracted with dichloromethane. The aqueous solution was then neutralized and reextracted with dichloromethane. The two separated organic extracts were dried over $MgSO_4$ and the solvent removed under reduced pressure. The former extract yielded *o*-nitroanisole. The latter extract showed two spots on TLC. The two were separated on alumina with 10% petroleum ether/toluene. The two components were identified as *o*-nitrophenol (0.13 g) and *o*-methoxyphenol (0.03 g) by comparison with authentic standards.

o-*Nitroanisole/CN^-*

A solution of $\sim 5 \times 10^{-3}$ M *o*-nitroanisole (0.27 g) and 0.1 M KCN (2.28 g) in 1:1 *tert*-butanol/water (350 mL) was irradiated for 16 h. After irradiation, the solution was extracted with ether. The organic layer was dried over $MgSO_4$ and the solvent evaporated *in vacuo* on a rotary evaporator. The residue was chromatographed on a Waters alumina SEP-PAK cartridge, eluting with toluene. This procedure yielded a white solid (0.09 g), 3-methoxy-4-nitrobenzonitrile **14**; mp 150–151°C (lit. (16) mp 151°C); IR: 2230 (CN) cm^{-1}; NMR δ: 4.06 (s, 3H), 7.23 (d, 1H), 7.87 (dd, J=10 Hz, J=2 Hz, 1H), 8.18 (d, J=2 Hz, 1H) ppm; MS m/e: 178(M^+, 35), 148(33), 131(100), 117(71), 102(77), 89(37), 76(33), 62(56).

o-*Nitroanisole/diethylamine*

A solution of $\sim 5 \times 10^{-3}$ M *o*-nitroanisole (2.4 mL) and 0.1 M diethylamine (44 mL) in 1:1 tetrahydrofuran/water (300 mL) was irradiated for 25 h. The organic solvent was evaporated under reduced pressure. The aqueous layer was extracted with dichloromethane, and yielded unconsumed *o*-nitroanisole and one other component. The two were separated on alumina, eluting with 20% petroleum ether/toluene. The base extract yielded a single component, which, when purified on alumina with 20% petroleum ether/toluene, turned out to be the same compound separated in the neutral fraction. The compound was identified as *o*-methoxyphenol (0.1 g) upon comparison with an authentic sample.

3-Nitroveratrole/OH^-

A solution of 0.01 M 3-nitroveratrole (0.037 g) and 0.1 M NaOH (0.08 g) in 65:35 acetonitrile/water (20 mL) was irradiated in the Rayonet photoreactor (λ = 254 nm) for 30 min. After irradiation, the organic solvent was removed under reduced pressure. The aqueous solution was extracted with ether. The organic layer was dried over $MgSO_4$ and the solvent evaporated under reduced pressure to yield 3-nitroveratrole. The aqueous layer was acidified and reextracted with ether. The organic layer was dried over $MgSO_4$ and the solvent removed as above. It yielded a yellow liquid. Purification on a Waters silica SEP-PAK cartridge eluting with toluene yielded a pale yellow solid, 2-methoxy-3-nitrophenol (0.02 g); mp 93–101°C (lit. (18) mp

102–103°C); IR: 1340, 1528 (NO_2), 3489 (br), 3620 (OH) cm^{-1}; NMR δ: 3.98 (s, 3H), 6.12 (br, 1H), 7.12 (t, 1H), 7.25 (dd, J=8 Hz, J=2 Hz, 1H), 7.47 (dd, J=8 Hz, J=2 Hz, 1H) ppm; MS m/e: 169 (M^+, 80), 152(3), 139(4), 126(9), 107(71), 94(55), 77(41), 65(100).

3-Nitroveratrole/CN^-

A solution of 0.01 M 3-nitroveratrole (0.037 g) and 0.1 M KCN (0.14 g) in 65:35 acetonitrile/water (20 mL) was irradiated for 30 min in the Rayonet photoreactor (λ = 254 nm). After irradiation, the organic solvent was removed *in vacuo* on a rotatory evaporator. The aqueous layer was extracted with ether. The organic extracts were dried over $MgSO_4$ and the solvent evaporated once more. Evaporation yielded a brownish solid, which was chromatographed on a Waters silica gel SEP-PAK cartridge eluting with toluene. Evaporation of the solvent yielded a white solid (0.03 g) identified as 2-methoxy-3-nitrobenzonitrile, **13**; mp 101.5–103°C (lit. (16) mp 104–105°C); IR: 1350, 1543 (NO_2), 2233 (CN) cm^{-1}; NMR δ: 4.23 (s, 3H), 7.35 (t, 1H), 7.87 (dd, J=12 Hz, J=4 Hz, 1H), 8.05 (dd, J=8 Hz, J=4 Hz, 1H) ppm; MS m/e: 178 (M^+, 30), 148(82), 131(74), 117(100), 102(76), 90(60), 77(73), 62(96).

*3-Nitroveratrole/*n*-butylamine*

A solution of 0.01 M 3-nitroveratrole (0.037 g) and 0.2 M *n*-butylamine (0.4 mL) in 65:35 acetonitrile/water (20 mL) was irradiated for 10 h in the Rayonet photoreactor (λ = 300 nm). After irradiation, the organic solvent was evaporated and the aqueous layer extracted with ether. The organic layer was dried over $MgSO_4$ and the solvent evaporated *in vacuo* on a rotary evaporator. The residue was dissolved in a minimum amount of 65:35 methanol/water. The components were separated by semi-preparative HPLC. The mobile phase, 65:35 methanol/water, was delivered at a flow rate of 3.0 mL/min. Three components were separated: 3-nitroveratrole, *N*-butyl-2-methoxy-6-nitroaniline (0.0024 g) **15**, and *N*-butyl-2-methoxy-3-nitroaniline (0.0019 g) **16**. For **15**, IR: 1340, 1525 (NO_2), 3357, 3450 (NH) cm^{-1}; NMR δ: 0.93 (t, 3H), 1.40 (sextet, 2H), 1.58 (quintet, 2H), 3.54 (t, 2H), 3.85 (s, 3H), 6.62 (t, 1H), 6.91 (dd, J=8 Hz, J=2 Hz, 1H), 7.71 (dd, J=8 Hz, J=2 Hz, 1H) ppm; MS m/e: 224(M^+, 11), 207(1), 190(18), 181(100), 173(4), 162(65), 147(27), 134(62), 120(26), 106(55), 92(34), 77(58), 65(70). For **16**, IR: 1340, 1525 (NO_2), 3419, 3510 (NH) cm^{-1}; NMR δ: 0.98 (t, 3H), 1.46 (sextet, 2H), 1.64 (quintet, 2H), 3.15 (q, 2H), 3.62 (s, 3H), 6.80 (dd, J=8 Hz, J=2 Hz, 1H); 7.05 (t, J=8 Hz, 1H), 7.10 (dd, J=8 Hz, J=2 Hz, 1H) ppm; MS m/e: 224 (M^+, 37), 208(2), 193(1), 181(100), 161(3), 151(18), 134(24), 120(49), 106(43), 91(18), 77(35), 65(36).

Determination of quantum yields

Quantum yields were determined in duplicate using the method of Bunce, LaMarre, and Vaish (23) in which azoxybenzene in 95% ethanol was used as the actinometer. The method involved simultaneous irradiation of three solutions placed in 8 mm o.d. quartz ampoules held vertically in quartz test tubes of 16 mm o.d. The ampoules were filled with 2.0 mL of solution A. The test tube was filled to the same level with solution B. The solutions concerned were 1. A = test solution, B = water; 2. A = azoxybenzene, B = water; 3. A = azoxybenzene, B = test solution. All samples were irradiated in the Rayonet photoreactor using 300-nm lamps. The photoreactor was equipped with a "merry-go-round" to ensure equal illumination of all samples. After irradiation, solutions 2A and 3A were appropriately diluted with 1 M alcoholic KOH. The absorbance of these solutions at 458 nm was recorded. The difference in the absorbances of solutions 2A and 3A were used to calculate the amount of light absorbed by test solution 1A.

Kinetic irradiations

The conditions of irradiation used for mechanistic investigations mimicked those for the determination of quantum yields. The solution of interest (2.0 mL) was contained in an 8 mm o.d. quartz ampoule. Substrate loss and product formation were monitored by HPLC using the external standard method. All analyses were performed in duplicate with values agreeing to within 5%.

An acidity scale, $[H^+]^{h\nu}$, for proton quenching of excited states

J. A. PINCOCK AND P. R. REDDEN
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3
Received April 28, 1988

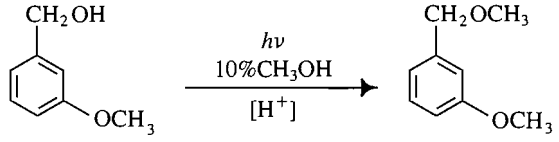
J. A. PINCOCK and P. R. REDDEN. Can. J. Chem. **67**, 227 (1989).

An acidity scale for excited state protonation kinetics in 20% ethanol:80% aqueous sulfuric has been developed using 1-cyanonaphthalene as a fluorescent indicator. The utility of this new scale is demonstrated using the proton quenching of fluorescence of a variety of chromophores. These include 1- and 2-cyanonaphthalenes, 1- and 2-methoxynaphthalenes, benzyl alcohols, toluenes, and 2-vinylnaphthalene.

Key words: acidity scale, fluorescence quenching, excited state basicity.

J. A. PINCOCK et P. R. REDDEN. Can. J. Chem. **67**, 227 (1989).

Utilisant le cyano-1 naphtalène comme indicateur fluorescent, on a développé une échelle d'acidité pour la cinétique de la protonation de l'état excité dans un mélange éthanol/acide sulfurique 20/80. On démontre l'utilité de cette nouvelle échelle en utilisant l'extinction par les protons de la fluorescence d'une grande variété de chromophores, dont les cyano-1 (et -2) et méthoxy-1 (et -2) naphtalènes, les alcools benzyliques, les toluènes et le vinyl-2 naphtalène.



Mots clés : échelle d'acidité, extinction de la fluorescence, basicité de l'état excité.

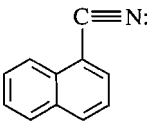
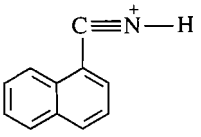
Introduction

We have recently outlined in a preliminary communication a procedure for establishing an acidity scale, $[H^+]^{h\nu}$, for proton quenching of excited states (1). It proved to be a useful method of linearizing otherwise non-linear Stern–Volmer fluorescence quenching plots and, along with lifetimes of the excited singlet states, obtaining quenching rate constants. Moreover, the results sugested that $[H^+]^{h\nu}$ may be a fundamental property of the medium independent of the functional group being protonated. The method relies on the fact that a functional group may have increased basicity in its excited singlet state (2). Recent studies have also demonstrated that, after excited state protonation, reaction may occur. Examples of this are the studies by Wan and Turro (3, 4) on the photosolvolysis of benzyl alcohols, eq. [1], and Yates *et al.* (5–7) on the photohydrations of alkenes and alkynes, eq. [2]. In these cases, rate-determining excited



[1] 

[2] 



singlet state protonation was easily monitored by either quenching of the substrate fluorescence or by product formation. Determination of the quenching rate constant, k_q, is simple if the quenching occurs in a region where the concentration of the protons gives a reasonable estimate of the proton activity. However, in many cases, appreciable quenching does not occur until higher proton concentrations are reached and Stern–Volmer plots of either fluorescence intensity I^0/I, or reaction quantum yield Φ^0/Φ, versus proton concentration are curved. An acidity scale approach would seem to be the next logical step to follow. Neither of these previous studies discuss this obvious possibility of using well established ground state scales (8, 9) and, therefore, we assumed that correlations attempted were unsuccessful (*vide infra*).

Ground state acidity scales and their application to acid-catalyzed reactions have been extensively studied (for a review, see refs. 10, 11). These ground state scales were initially determined by the Hammett assumption of the cancellation of indicator activity coefficient ratios in acid–base equilibria, i.e. the zero'th order approximation (for a review, see ref. 10). Later approaches such as the Bunnett–Olsen method (12, 13) or excess acidity (14) are based on the assumption that, for different bases, activity coefficient ratios of the form log $(f_B f_{H^+}/f_{BH^+})$ are linear functions of one another, i.e. the first order approximation. An excited state scale may be inherently different in that the measurable quantities such as Φ_F or Φ_R are always ratios relative to other processes of the same excited state. Moreover, excited state protonations for the example reactions, eq. [1] and eq. [2], seem to be irreversible. Although cases of reversible excited state acid–base equilibria are well known (2), evidence against reversibility is reported for the styrene substrates, eq. [2], since no hydrogen–deuterium substrate–solvent exchange was observed (15) at acidities where the excited state was efficiently quenched. Therefore, since these excited state protonations occur for reactions proceeding by the mechanism of kinetic rate-determining proton catalysis rather than pre-equilibrium proton catalysis, a different approach is necessary.

In this paper, we report full details of our previous communication (1) on a method to establish an acidity scale in 20% ethanol: 80% aqueous sulfuric acid for protonation of excited states, using 1-cyanonaphthalene, **1**, as a fluorescent indicator.

1

18

This particular acidic medium was chosen because it has a well defined ground-state H_0 scale (13, 16) and because the substrates we wished to examine had better solubility in it than in aqueous sulfuric acid alone. The choice of indicator was

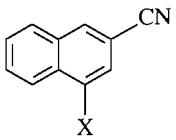
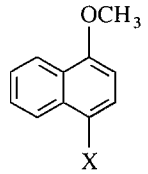
[a] I^0 refers to fluorescence intensity in 20% ethanol:80% water.
[b] Lifetime ratios as determined by single photon counting are given in parentheses.
[c] Determined by titration.
[d] C_{H^+} values were determined by interpolation of data in aqueous sulfuric acid from ref. 14.

based on the reported observation that 1-cyanonaphthalene has a high quantum yield of fluorescence (Φ_F = 0.37) and yet its fluorescence begins to be quenched in moderately acidic solutions (17). Moreover, estimates of the ground-state pK (~ −10) of its conjugate acid, **18**, indicate that ground-state protonation will not occur even in quite concentrated acidic solutions (18).



Results

The following compounds were studied. Compounds **1**, **6**, **9**, **12**, **13**, **14**, **15**, and **16** are commercially available (Aldrich). The preparation of **2**, **5**, **7**, **8**, and **11** have been described in previous work from this laboratory (19). Compounds **10** (20), **4** (21), and **3** (22) were prepared as reported in the literature.



Fluorescence quenching values and, in some cases, singlet lifetimes as a function of acidity in 20% ethanol:80% aqueous sulfuric acid are reported in Table 1 (**1–5**), Table 2 (**6–11**), and Table 3 (**12–16**). All results are at 25.0 ± 0.1°C. Since very small amounts of contaminating impurities in these compounds could have fluorescence that was unquenched by protons and therefore lead to erroneous results, no I^0/I values over 100 were used.

Discussion

Empirical evaluation of $[H^+]^{h\nu}$ and its application to Stern–Volmer plots

The fluorescence quenching data for **1** are plotted versus titratable proton concentration in Fig. 1. The lower line in the inset shows an expansion of the region up to 1.2 M in proton concentration as determined by titration. The least squares slope of this line is equal to 0.442 + 0.002 M^{-1}. Obviously, below 1.2 M the normal Stern–Volmer relationship, $I^0/I = 1 + K_{SV}[H^+]$ holds. (In this paper the symbol $[H^+]$ is used to define the concentration of protons as determined by titration, i.e., the normality of sulfuric acid. It is not the same as C_{H^+}, the concentration of free protons in the solution (*vide infra*). We have chosen to use $[H^+]$ as a measure of the acid concentration because it is a determinable experimental quantity.) As can be

[b]Lifetime ratios as determined by single photon counting are given in parentheses.
[c]Determined by titration.

seen from Fig. 1, above 1.2 *M* the plot becomes curved. This curvature begins as the activity of the protons becomes very different from the concentration.

In an attempt to obtain a straight line, I^0/I fluorescence values for **1** were plotted versus h_0, the ground state acidity function (16), as shown in Fig. 2. The plot, overall, is not linear, indicating that the ground state acidity function is not useful in this case. The more general excess acidity scale (14) is not available for 20% ethanol:80% aqueous sulfuric acid so a correlation could not be attempted.

However, as has been demonstrated (13), the general function (H_0 + log C_{H^+}) where C_{H^+} is the molarity of sulfuric acid, as determined by titration, is a useful way of correlating data for this mixed solvent.[1] In fact, in purely aqueous sulfuric acid $H_0 + \log C_{H^+} \simeq -X$ (23). The assumption used here is the original Bunnett/Olsen one (12), that sulfuric acid is monodissociated so that C_{H^+} is half the concentration of titratable protons. As shown in column 2 of Table 1 this is not quite true for purely aqueous sulfuric acid (14). Values are not known for most mixed organic solvent/aqueous media such as the 20% ethanol/80% aqueous sulfuric acid used here.

Although Stern–Volmer kinetic experiments are not usually treated using logarithmic scales of concentration, rearrangement is possible giving eq. [3]. Since $k_qC_{H^+}$ corresponds to k_ψ, the observable pseudo-first order rate constant in an $A\text{–}S_E2$ type mechanism, eq. [4] can be derived (24) where ϕ^*, the slope

$$[3] \quad (I^0/I - 1)/\tau^0 = k_qC_{H^+}$$

[1]We thank a referee for this suggestion.

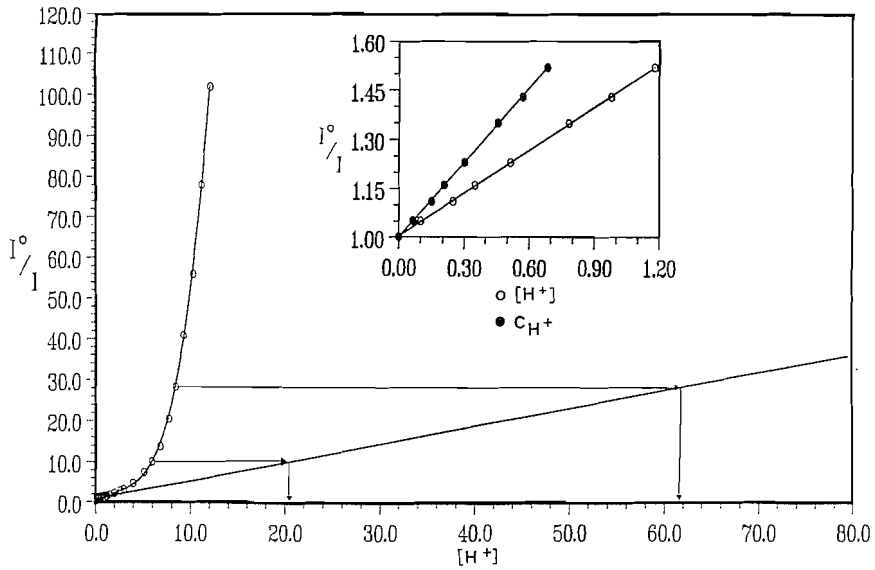

FIG. 1. Stern–Volmer quenching plot for 1-cyanonaphthalene of fluorescence intensity versus titratable $[H^+]$ in 20% ethanol:80% aqueous H_2SO_4 at 25°C. The lower line in the inset is for the region below $[H^+] = 1.20\ M$; the upper line is for the same data using C_{H^+}.

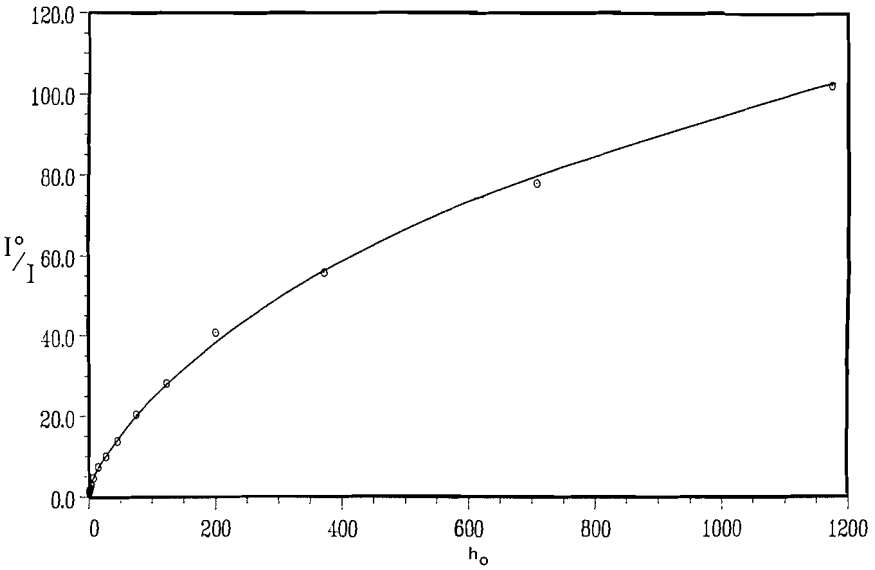

FIG. 2. Fluorescence intensity of 1-cyanonaphthalene versus h_0, the ground-state acidity function in 20% ethanol:80% aqueous H_2SO_4.

[4] $$\log\{(I^0/I - 1)/\tau^0\} + H_0 = \phi^*(H_0 + \log C_{H^+}) + \log k_q$$

parameter, is a measure of the solvation requirements of the transition state for protonation. The values required for this type of plot are in Table 4 for 1-cyanonaphthalene and the data is plotted in Fig. 3. A difficulty with this method becomes apparent. The experimentally most reliable values in Stern–Volmer plots are in the range of I^0/I from 1 to 10. Over this range the term ($\log k_\psi + H_0$) hardly changes and the points are all clustered in the top right of the plot with essentially zero slope. A least-squares correlation for all points gives an intercept of 8.11 ($r^2 = 0.983$) leading to $k_q = 13 \times 10^7\ M^{-1}\ s^{-1}$. Treatment of the results for all other compounds leads to very similar plots. The values of k_q that result are in Table 5.

Our method of evaluating an excited state acidity scale, $[H^+]^{h\nu}$, which is a linear rather than a logarithmic scale, was accomplished in the following manner. The linear portion of the Stern–Volmer fluorescence quenching plot for **1** (Fig. 1; lower line of inset) was extended well beyond the linear region. Evaluation of $[H^+]^{h\nu}$ at any $[H^+]$ involved only a projection from the quenching curve to the line obtained by extrapolating the slope of the linear region determined at low $[H^+]$ concentration. This is shown pictorially in Fig. 1. Mathematically, the values were determined from the Stern–Volmer slope. Values of $[H^+]^{h\nu}$, given in Table 4, represent the real quenching behavior of the acid media, at least for 1-cyanonaphthalene. Note that although most acidity scales are logarithmic, we have established the scale in concentration units in order for it to be compatible with photochemists' Stern–Volmer treatments.

The first obvious concern is that the projections required are long and the scale may, therefore, be unreliable. Table 4 shows that $[H^+]^{h\nu}$ values are between one and two orders of magnitude larger than the corresponding values of titratable protons. Moreover, the values are different from the corresponding

ground state acidity function, h_0. In fact, h_0 seems to undercorrect at low acidities but overcorrect at higher values. This shows that $[H^+]^{h\nu}$ is indeed a different type of scale and, therefore, tests of its applicability to other substrates are required.

In the previous communication (1), a variety of naphthalene substrates were studied including a series of 1-methoxy- (**6–8**) and 2-methoxy- (**9–11**) naphthalene derivatives. The plots of I^0/I versus $[H^+]^{h\nu}$ were all linear with very good correlation coefficients. These substrates were re-examined here at a constant temperature of 25.0 ± 0.1°C and over a larger range of acidic solutions. Normal Stern–Volmer plots versus titratable proton concentration were obtained for **6–8** (Fig. 4) in the low acid concentration region (<1.2 *M*). The Stern–Volmer slopes, K_{SV}, are given in Table 5. For compounds **9–11**, however, appreciable quenching occurred only at higher acidities (Fig. 5; inset). Normal Stern–Volmer plots in the low acid region are

[h]Values of 4.4 ns, 0.28 M^{-1} and $6.4 \times 10^7\ M^{-1}\ s^{-1}$ are reported in 20% CH_3CN:80% water (17).
[i]Values of 12 ns, 0.29 M^{-1} and $2.4 \times 10^7\ M^{-1}\ s^{-1}$ are reported in 20% CH_3CN:80% water (17).
[j]Values of 8.9 ns, 9.6 M^{-1} and $1.08 \times 10^9\ M^{-1}\ s^{-1}$ are reported in 20% CH_3CN:80% water (17).
[k]Values of 10 ns, <0.03 M^{-1} and $<3 \times 10^6\ M^{-1}\ s^{-1}$ are reported in 20% CH_3CN:80% water (17).
[l]Values of 4.4 ± 0.3 ns, 16.2 ± 0.1 M^{-1} and $3.7 \pm 0.2 \times 10^9\ M^{-1}\ s^{-1}$ are reported in aqueous acid (3).
[m]Values of 58.2 ns and $4.6 \times 10^6\ M^{-1}\ s^{-1}$ from fluorescence quenching and $4.5 \times 10^6\ M^{-1}\ s^{-1}$ from lifetime measurements are reported for aqueous H_2SO_4 (5).
[n]Based on τ^0/τ versus $[H^+]$.

unreliable because quenching occurs only to a very small extent. If the quenching data are plotted versus $[H^+]^{h\nu}$, very good linear results are obtained (Fig. 5). Now the Stern–Volmer slopes can be determined with much more precision and are given in Table 5 along with the correlation coefficients.

Another series of naphthalene compounds studied include 1-cyano- (**1**–**3**) and 2-cyano- (**4**, **5**) naphthalenes. The fluorescence quenching data for these compounds are shown in Fig. 6; inset. In all cases, plots using $[H^+]^{h\nu}$ are linear (Fig. 6). The Stern–Volmer slopes are given in Table 5.

Clearly the results to this point indicate that the scale is useful in linearizing non-linear Stern–Volmer plots. The question of whether chemically reasonable k_q values can be obtained will be addressed later. Since only naphthalene derivatives had been studied thus far the generality of the procedure was not yet clear. Substrates with different chromophores were required. Two of the methoxy-substituted compounds, 3- and 4-methoxy benzyl alcohol **13**, **15**, studied by Wan and Turro (3, 4) were re-examined here along with 3- and 4-methoxy toluene **12**, **14**. The fluorescence quenching data for these compounds is shown in Figs. 4 and 7. For compounds **12** and **13** extensive quenching occurred in the low acid region and Stern–Volmer slopes can be obtained by normal plots versus titratable proton concentration. These are given in Table 5.

For the *para*-substituted compounds **14** and **15** attempts to evaluate the Stern–Volmer slopes were very unreliable due to

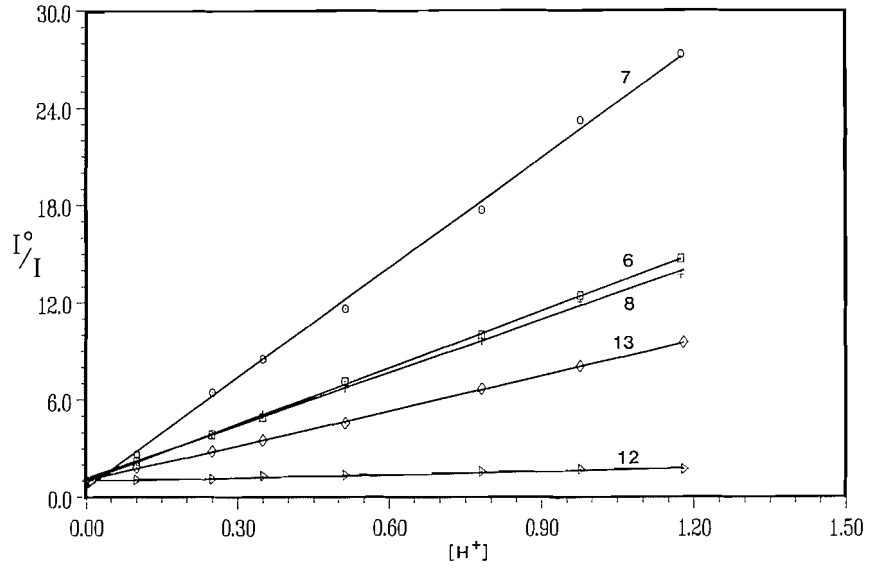

FIG. 4. Stern–Volmer quenching plots of fluorescence intensity versus titratable $[H^+]$ for **6**, **7**, **8**, **12**, and **13**.

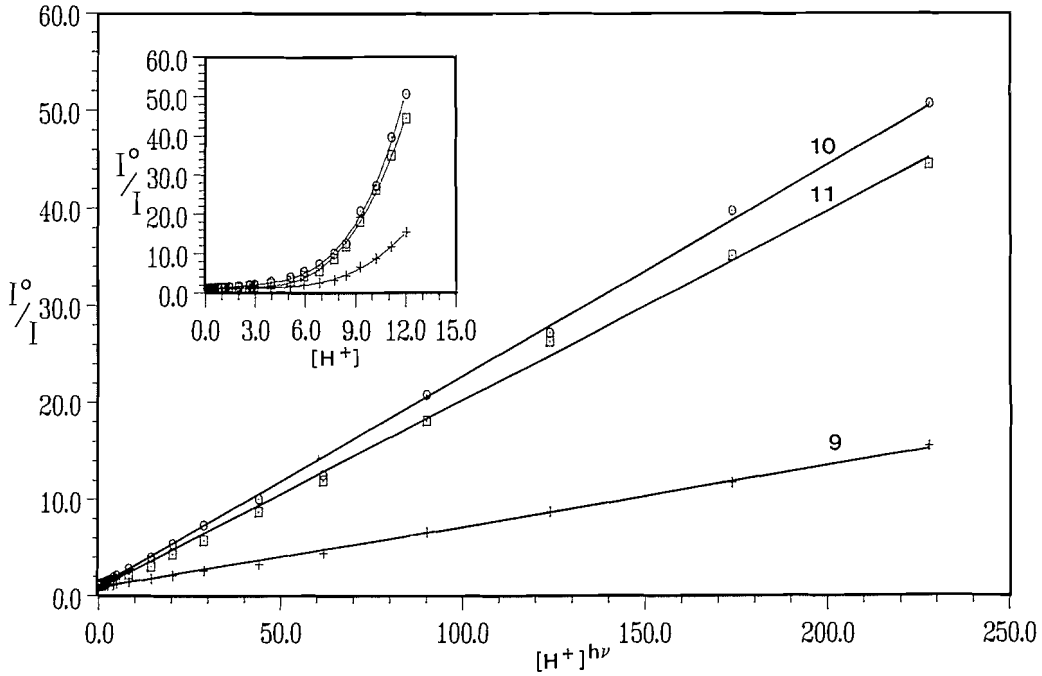

FIG. 5. Stern–Volmer quenching plots of fluorescence intensity versus $[H^+]^{h\nu}$ for **9**, **10**, and **11**. The inset shows the fluorescence intensity versus titratable $[H^+]$.

very little quenching. When I^0/I is plotted versus $[H^+]^{h\nu}$ as shown in Fig. 7 the correlation obtained is as good as it was for the naphthalene cases.

To test the usefulness and validity of the $[H^+]^{h\nu}$ scale further, the fluorescence quenching of 2-vinylnaphthalene, **16**, was studied. It is now well established that for many aromatic alkenes proton quenching of the excited state occurs at the double bond (5). For this particular compound the site of protonation is known to be at the beta carbon. As shown in Fig. 7 the results can again be correlated well using $[H^+]^{h\nu}$.

Derivation of the form of $[H^+]^{h\nu}$ using acidity scale concepts

In the previous section, we have demonstrated that a single indicator, 1-cyanonaphthalene, can be used to generate an empirical acidity scale. Surprisingly, this scale gave linear correlations for the proton quenching of a variety of functional groups. This is, in general, not true for ground state protonations and has resulted in different acidity scales for each functional group. Although some have called this "acidity function failure" (25), the development of the more general excess acidity scale (14) has shown that there is a relationship between the various scales. Our observation that there is an easily obtainable function, $f\{[H^+]\}$, which correlates data for excited state protonations, eq. [5], is therefore of interest.

$$[5] \quad I_F^0/F_F = 1 + K_{SV}f\{[H^+]\}$$

A derivation of the form of this function follows from the

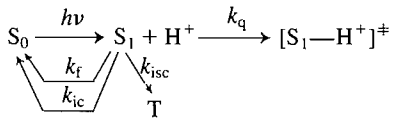
kinetic expression for excited state protonation using transition state theory in a way analogous to that for the kinetic expressions derived for ground state protonations (26).

In Scheme 1, S_0 is the ground state of the substrate, S_1 is the first excited singlet state, T is the triplet state, $[S_1—H^+]^{\ddagger}$ is the transition state for protonation of the excited singlet state, k_f is the rate constant for fluorescence, k_{ic} is the rate constant for internal conversion back to the ground state, k_{isc} is the rate constant for intersystem crossing to the triplet, and k_q is the bimolecular quenching rate constant.



At any given acidity the decay of S_1 is pseudo-unimolecular according to eq. [6] where τ, the lifetime of the excited state, is the reciprocal of the sum of all the rate constants that lead to loss of S_1, eq. [7].

$$[6] \quad -d[S_1]/dt = (1/\tau)[S_1]$$

$$[7] \quad 1/\tau = k_f + k_{ic} + k_{isc} + k_q f\{[H^+]\}$$

From transition state theory, eq. [6] can be rewritten as eq. [8], assuming that k_q is the only activated process (27) described

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

SCHEME 1

by transition state theory. In eq. [9], $K^{\ddagger}$ is the transition state equilibrium constant for the protonated singlet and f is the activity coefficient of the species indicated. Now eq. [8] can be rewritten as eq. [10].

$$[8] \quad -d[S_1]/dt = (k_{ic} + k_f + k_{isc})[S_1] + (kT/h)[S_1—H^+]^{\ddagger}$$

$$[9] \quad K^{\ddagger} = [S_1—H^+]^{\ddagger} f_{\ddagger}/[S_1] f_{S_1} a_{H^+}$$

$$[10] \quad -d[S_1]/dt = (k_{ic} + k_f + k_{isc})[S_1] + (kT/h)K^{\ddagger}[S_1] a_{H^+}(f_{S_1}/f_{\ddagger})$$

This then can be simplified to eq. [11]. In the absence of quencher the reaction rate is a function only of the lifetime of the singlet, eq. [12].

$$[11] \quad -d[S_1]/dt = [k_{ic} + k_f + k_{isc} + k_q a_{H^+}(f_{S_1}/f_{\ddagger})][S_1] = 1/\tau[S_1]$$

$$[12] \quad -d[S_1]/dt = (k^0_{ic} + k^0_f + k^0_{isc})[S_1] = 1/\tau^0[S_1]$$

Since the quantum yield of fluorescence is related to the intensity of fluorescence and to the lifetime of the singlet as shown in eq. [13], division of eq. [11] by eq. [12] yields the expression in eq. [14]. This is the normal expression obtained

$$[13] \quad I^0_F/I_F = \Phi^0_F/\Phi_F = \tau^0/\tau$$

$$[14] \quad \tau^0/\tau = I^0_F/I_F = 1 + k_q\tau^0(a_{H^+} f_{S_1}/f_{\ddagger})$$

for a Stern–Volmer analysis with the exception that the term in parentheses is the desired function of proton concentration. Our definition of the acidity scale is then given in eq. [15] where all the terms have their usual meaning except the superscript I refers to the indicator 1-cyanonaphthalene. By rearranging eq. [15] to eq. [16] and substituting for the activity of the protons in eq. [14], we obtain eq. [17] which shows the connection between the empirically derived $[H^+]^{h\nu}$ scale for the indicator and the quenching equation for other substrates. Our observation of linear Stern–Volmer plots for these substrates is defined by eq. [18]. Therefore, the connection between eq. [17] and eq. [18] gives eq. [19].

$$[15] \quad [H^+]^{h\nu} K^I_{SV} = k^I_q\tau^{0I}(a_{H^+} f^I_{S_1}/f^I_{\ddagger})$$

$$[16] \quad a_{H^+} = [H^+]^{h\nu}(K^I_{SV}/k^I_q\tau^{0I}) f^I_{\ddagger}/f^I_{S_1})$$

$$[17] \quad I^0_F/I_F = 1 + k_q\tau^0(K^I_{SV}/k^I_q\tau^{0I})(f_{S_1}/f_{\ddagger} \cdot f^I_{\ddagger}/f^I_{S_1})[H^+]^{h\nu}$$

$$[18] \quad I^0_F/I_F = 1 + K_{SV}[H^+]^{h\nu}$$

$$[19] \quad K_{SV} = k_q\tau^0(K^I_{SV}/k^I_q\tau^{0I})(f_{S_1}/f_{\ddagger} \cdot f^I_{\ddagger}/f^I_{S_1})$$

The activity coefficient term in the parentheses of eq. [19] is the only term that could vary with acid concentration. The fact that linear plots are obtained, i.e. K_{SV} is a constant, demands that this term also be a constant (at least within experimental error) over the range of acidities examined. Note that this is quite different from the usual first-order approximation in ground state systems where log $(f_B f_{H^+}/f_{BH^+})$ terms are linearly related for different bases. Of course, if this method is to be used to obtain k_q values, then it is not enough that this term be a constant. It must be unity as in the Hammett cancellation assumption. As is now well established, this is not, in general, true for ground state reactions (10).

Although there is considerable information available about individual activity coefficients for substrates and transition states in ground state reactions (28) in purely aqueous acidic media, such results are unavailable for mixed solvents such as the 20% ethanol medium used here. Moreover, there would be no obvious way of determining activity coefficient values for excited states which, because of changes in dipole moment upon excitation, would change from the ground state values. It is worth noting that if the quenching process is exothermic the transition state might be early and, as such, be reactant-like. In fact, activation energies have been measured for the protonation of excited 1-methoxynaphthalene (17) and the very low value of 0.5 kcal/mol in 4:1 H_2O:CH_3CN suggests that the transition state for protonation and the excited singlet may be very similar in structure and therefore in activity coefficient. Therefore the term in brackets in eq. [19], which must be a constant, could be close to unity for all substrates. Results in aqueous perchloric acid, a medium in which measurement of these ratios is possible, indicate that this suggestion is very nearly true for most substrates (29). Although only a working hypothesis, the simplification of eq. [19] to eq. [20] seems justified on this basis.

$$[20] \quad K_{SV} = k_q\tau^0 K^I_{SV}/k^I_q\tau^{0I}$$

Using eq. [20] to obtain k_q values is only possible if a value is known for the indicator i.e. k^I_q. In the dilute acid region (up to $[H^+]$ of 1.20 M) the Stern–Volmer plot for 1-cyanonaphthalene is linear. Therefore, the more general eq. [14] can be simplified to eq. [21]

$$[21] \quad I^{0I}_F/I^I_F = 1 + k^I_q\tau^{0I}C_{H^+}$$

where the activity coefficient terms have been removed and where C_{H^+} is now the concentration of free protons in the acidic medium. As discussed above, the assumption has been made in the 20% ethanol medium used here that C_{H^+} is equal to $(1/2)[H^+]$ (13). More recent estimates in purely aqueous sulfuric acid, Table 1, indicate that this is not quite true (14). We have chosen to use the more recent values.

At this point it is worth noting that $[H^+]^{h\nu}$ could have been defined relative to C_{H^+} from the start rather than $[H^+]$. However, this would require an assumption about the extent of ionization for any given acid in any given medium. If knowledge about the extent of ionization improved, changes in the scale would be required. Defining the scale with respect to the experimentally determinable $[H^+]$ means that the scale will remain the same and only derived k_q values would change. Of course, the relative magnitude of k_q values which is often of more interest than the absolute values themselves would still be correct.

At any rate, assuming the C_{H^+} values in Table 1, the quenching data for 1-cyanonaphthalene gives an excellent Stern–Volmer plot (upper line in inset of Fig. 1) with $k_q\tau^0 = 1.73 \pm 0.01\ M^{-1}$, correlation coefficient = 0.9998. Using this value in eq. [20] allows calculation of all k_q values. These are listed in Table 5.

As mentioned earlier in the discussion section of this paper, the fluorescence quenching data for all compounds was also correlated using eq. [4] and the k_q values are in Table 5. In general, the agreement between the two methods is very good. The $[H^+]^{h\nu}$ method would seem to be statistically more precise based on the standard deviations. Whether it is more accurate or not is difficult to know since systematic error is not easy to compare in the two methods. Systematic error in the $[H^+]^{h\nu}$

method is probably determined mainly by the cancellation of the activity coefficient term in eq. [19].

Some comment is also required about the possibility of static quenching. At high concentrations of a quencher, the excited state will be generated in "contact" with a quencher and diffusion is no longer required. Thus, the rate of quenching can exceed that of diffusion (30). For 1-cyanonaphthalene, the indicator used to establish $[H^+]^{h\nu}$, $k_q = 13 \times 10^7\ M^{-1}\ s^{-1}$ which is considerably slower than the diffusional rate of $3.3 \times 10^9\ M^{-1}\ s^{-1}$ calculated (31) using the viscosity, 18.1 mpoise at 25°C (32) for 20% ethanol:80% water. Although addition of sulfuric acid to water will raise the viscosity, even for the most acidic solution used here (52.5%), the diffusional rate constant can be estimated from the value in 50% aqueous sulfuric acid as $1.6 \times 10^9\ M^{-1}\ s^{-1}$ based on a viscosity of 38 mpoise (33). Therefore, the rate of quenching for 1-cyanonaphthalene is still considerably below diffusional and is determined by the activation barrier even for "contact" protons. For the most reactive substrate here, 1-methoxy-4-methylnaphthalene (**7**), $k_q = 4.0 \times 10^9\ M^{-1}\ s^{-1}$, which is now close to or even exceeding the rate of diffusion. Fortunately, the quenching process is now efficient enough to occur in dilute acid, so that static quenching may not affect the results. Note that even at 1 *M* quencher, the average diameter of the sphere containing a proton is 1.2–1.5 nm which is reasonably close to the estimated width across the long dimension of a naphthalene ring, ~0.7 nm. Interestingly, if a plot for **7** is made at higher acidities than those shown in Fig. 3 and a correlation is attempted versus $[H^+]^{h\nu}$, the plot begins to curve downward whereas an upward curvature would be expected if excess static quenching was occurring.

It is possible to check for complications of static quenching by comparing I^0/I plots versus τ^0/τ plots. Unfortunately, most of the substrates studied here have singlet lifetimes which are too short to measure over a wide range of acidities by nanosecond single photon counting. However, the lifetime ratios τ^0/τ obtained for 1-cyanonaphthalene were very similar to the fluorescence intensity ratio values (Table 1). This indicates that the quenching is dynamic at least in the low acid region. For 2-vinylnaphthalene, $\tau^0 = 71.2$ ns, a more complete τ^0/τ quenching plot is possible. As expected for a compound that has a slow rate of quenching, this plot gives $k_q = 2.18 \times 10^6\ M^{-1}\ s^{-1}$ (Table 5) which is very similar to that obtained from the I^0/I plot. This confirms that the quenching mechanism is dynamic for this substrate even in the most acidic solutions. Note as well, the reasonable agreement between the k_q value obtained by the $[H^+]^{h\nu}$ method and the literature value of $4.6 \times 10^6\ M^{-1}\ s^{-1}$ (5) considering that this value must have been very difficult to obtain since 2-vinylnaphthalene is quenched only to a very small extent in the region where the normal Stern–Volmer relationship applies.

Analysis of quenching rate Constants

Our interest in the work presented in this paper was initially stimulated by the observation of Turro and Wan (2, 3) that the proton-catalyzed photosolvolysis of benzyl alcohols showed large rate versus substituent effects. For instance, 3-methoxybenzyl alcohol, **13**, is quenched by protons 110 times faster than 4-methoxybenzyl alcohol, **15**, as determined by our acidity scale method (Table 5). This result was rationalized as a clear example of the photochemical "*meta*" effect as outlined by Zimmerman (34, 35) in his pioneering work on photosolvolysis. In contrast to this observation, we had not observed an enhanced rate of photosolvolysis for the 3-methoxy versus the 4-methoxy

17

X = H, 4-CH_3O, 3-CH_3O, 4-CN, 3-CN

substituent in a study of the photosolvolysis of (1-naphthylmethyl)trimethylammonium chlorides, **17** (19). In fact, the 4-methoxy compound reacted about 3.4 times as fast as the 3-methoxy one. Upon attempting to obtain proton quenching rate constants for a number of benzylic alcohols we immediately encountered the acidity function problem that prevented the determination of reliable rate constants for proton quenching. The $[H^+]^{h\nu}$ approach was developed to solve this problem. The last section of this paper will present an analysis of the rate constants thus obtained, including a discussion of the site of protonation for various excited state functional groups.

We initially examined the 1-naphthylmethyl alcohols **8** and **11** which are the naphthyl analogues of the benzylic alcohols **13** and **15** studied by Wan and Turro. In direct contrast to their results, the 4-methoxy isomer had a rate constant for proton quenching that was 66 times faster than the 3-methoxy isomer (Table 5). Moreover, it had been reported in the literature (17) that 1-methoxynaphthalene is quenched faster than 2-methoxynaphthalene by a factor greater than 300 in 20% CH_3CN/80% water and we have confirmed this relative rate for the same two compounds in 20% ethanol:80% water with a value of 160. It is well established by deuterium exchange experiments that the proton quenching of 1-methoxynaphthalene occurs by ring protonation, predominantly at C-5 (17). Probably the other 1-methoxy isomers, **7** and **8**, which are quenched at similar rates are also reacting by ring protonation. Since the 2-methoxy isomers, **9**, **10** and **11**, are also all quenched at similar rates but about a factor of 10^2 slower than the 1-isomers, the most likely process is again ring protonation. MO calculations (17) of excited state electron densities for 1- and 2-methoxynaphthalenes support this idea that the 1-methoxy isomers should be quenched more rapidly.

This observation prompted us to examine similar comparisons for the benzene cases. Surprisingly, in this case 3-methoxy toluene, **12**, was quenched more rapidly than the 4-methoxy isomer, **14**, by a factor of 5. Moreover, quenching of 3-methoxybenzyl alcohol was faster than 3-methoxy toluene by a factor of 13. This suggests that there really is a special excess reactivity for 3-methoxybenzyl alcohol which leads to photosolvolysis and that the "*meta*" effect is the explanation.

The reason for the difference in substituent effects between the benzene and naphthalene derivatives is not obvious. One suggested explanation is that the extra delocalization available for the naphthalene cases allows the changes in charge that occur on excitation to be distributed over a number of carbon atoms. Thus, although a 3-methoxy substituent is predicted to increase electon density at C-1 of naphthalene in the excited state, it also increases electron density at C-4, C-5, C-6, and C-7. The fastest rate may therefore be ring protonation and not enhanced photosolvolysis at the naphthylmethyl carbon. These questions can only be answered by a detailed study of the relative rates of hydrogen exchange versus photosolvolysis.

Considering, finally, the naphthylnitriles, **1–5**, the site of protonation seems very likely to be on the nitrile group. Electron density is well known to increase on the functional group upon excitation of aromatic rings having electron withdrawing substituents (2). Moreover, at least in the gas phase, the excited state of benzonitrile is reported to be protonated on nitrogen (36). Recent MO calculations on the excited states of simple nitrile functional groups suggest that C protonation is also possible (37). Yates and Haley (38) have searched without success for enhanced photohydrolysis of nitrile groups by excited state protonation. However, they point out that this type of catalysis is not likely for reactions that do not proceed by mechanisms involving rate-determining protonation. Again, only detailed hydrogen-deuterium exchange studies can give information (even if only negative evidence) on where aromatic nitriles in their excited states react with protons. The range of rate constant values for the nitrile protonations is quite small so that analysis of the small changes is more likely to be difficult. However, there are several interesting observations. First, the 2-cyanonaphthalenes, **4** and **5**, are quenched more slowly than the 1-cyanonaphthalenes, **1**, **2**, and **3**. Second, for 1-cyano-naphthalenes methyl substitution seems to slow down the rate of quenching whereas for the 2-cyano case methyl substitution increased the rate.

Summary

The important point of these findings is that an acidity scale to analyze excited state protonations can be obtained using a single fluorescent indicator. Since such a scale can be obtained easily and quickly in any solvent system at any temperature, this method should be very useful to researchers interested in this area. Secondly, a single scale seems to be sufficient to analyze protonation of a variety of chromophores. The ones studied here include aromatic ring carbons, nitriles, alkenes and alcohols. This suggests that $[H^+]^{h\nu}$ may be a fundamental property of the medium but analysis of results from an acidic medium simpler than sulfuric acid in 80% water:20% ethanol is required before this possibility can be confirmed. Such work is in progress.

Experimental

The 20% v/v ethanol:aqueous sulfuric acid solutions were prepared as follows. Commercial grade 95% ethanol and water were distilled twice before using. Sulfuric acid, 96–98%, was used directly as supplied by Mallinckrodt Inc. without further purification. To a series of 500 mL volumetric flasks 80.54 ± 0.05 g of 95% ethanol was added. Aqueous sulfuric acid was added to the flasks with the amount of acid added increasing to give a series of increasingly acidic solutions. Since a tremendous amount of heat was evolved upon addition of the acid the flasks were left to sit at room temperature overnight and then filled to the mark with water. They were tested by uv absorption and shown to have a flat baseline down to 230 nm. The normality of sulfuric acid equal to the molarity of titratable protons was determined by NaOH titration and the values are given in Tables 1–4.

All fluorescence values were measured using an Aminco–Bowman spectrofluorimeter whose sample holder was maintained at 25.0 ± 0.1°C. Solutions were prepared so as to have an approximate concentration of 10^{-4} *M* by pipetting 3 mL of the ethanolic acidic solutions into a fluorescent cuvette designed to be attached to a vacuum line and then adding 5 μL of a stock solution of the substrate. A blank solution containing 20% ethanol:80% water and 5 μL of the substrate was also prepared. All solutions were thoroughly degassed by three freeze–pump–thaw cycles. The fluorescence of all substrates was measured at their strongest emitting wavelength. The intensity ratio, I^0/I, was obtained by measuring the emission of the blank over the emission in the acidic solution. Five readings of each sample were taken and the values reported are averages.

All singlet lifetimes were determined by single photon counting using a PRA instrument.

Substrates **1**, **6**, **9**, and **12–15** are commercially available from Aldrich and were either recrystallized or vacuum distilled prior to use.

2-Methoxy-4-methylnaphthalene, **10**, was prepared as outlined by Baccolini *et al.* (20); mp 37–38°C, lit. 48–49°C; nmr ($CDCl_3$) δ2.60 (s, 3H) 3.86 (s, 3H) 7.00 (s, 1H) 7.3–8.0 (m, 6H).

2-Cyanonaphthalene, **4**. The procedure followed was that as outlined by Friedman and Schechter (39); mp 60–62°C lit. 66°C (40); nmr ($CDCl_3$) δ7.5–7.7 (m, 3H) 7.8–8.0 (m, 3H) 8.25 (s, 1H).

1-Cyano-3-methylnaphthalene, **3**, was prepared as outlined by Yoshida and Nagase (22); mp 51–52°C, lit. 52.5–53.5°C; nmr ($CDCl_3$) δ7.5–8.2 (m, 6H) 2.55 (s, 3H); uv (CH_3OH) λ_{max} = 297 nm; ms 167(100), 166(77), 141(77), 140(39), 139(48), 115(26), 75(25), 71(26), 69(35).

Some physicochemical studies on organic eutectics and 1:1 addition compound; *p*-phenylenediamine – benzoic acid system

U. S. RAI AND K. D. MANDAL

Chemistry Department, Banaras Hindu University, Varanasi – 221 005, U.P., India

Received June 8, 1988

U. S. RAI and K. D. MANDAL. Can. J. Chem. **67**, 239 (1989).

The phase diagram of *p*-phenylenediamine – benzoic acid system, determined by the thaw–melt method, shows the formation of two eutectics and a 1:1 addition compound. The linear velocity of crystallization of pure components, eutectics and addition compound, determined by measuring the movement of growth front in a capillary, suggests that crystallization data obey the Hillig–Turnbull equation. Using experimental values of heats of fusion, entropy of fusion and excess thermodynamic functions were calculated and the results are explained on the basis of cluster formation in the melts. X-ray diffraction data infer that these eutectics are not simply the mechanical mixture of the two components and there is preferential ordering of atomic planes during their formation. The infrared spectral studies suggest the formation of intermolecular hydrogen bonding between the components forming the molecular complex.

Key words: organic eutectics, growth kinetics, phase diagram, thermochemistry, X-ray diffraction studies.

U. S. RAI et K. D. MANDAL. Can. J. Chem. **67**, 239 (1989).

Le diagramme de phase du système *p*-phénylènediame/acide benzoïque, déterminé par la méthode de liquéfaction, montre qu'il y a formation de deux eutectiques et d'un composé d'addition 1:1. La vitesse linéaire de cristallisation des produits purs, des eutectiques ainsi que du produit d'addition, telle que déterminée par le mouvement du front de croissance dans un capillaire, suggère que les données de cristallisation obéissent à l'équation de Hillig–Turnbull. Utilisant les valeurs expérimentales pour les chaleurs de fusion, on a calculé l'entropie de fusion ainsi que les fonctions thermodynamiques en excès et on a expliqué les résultats expérimentaux en se basant sur la formation d'agrégats dans les produits de fusion. Les données de la diffraction des rayons-X suggèrent que les eutectiques ne sont pas simplement des mélanges mécaniques des deux produits et qu'il existe un ordre préférentiel des plans atomiques au cours de leur formation. Des études réalisées par spectroscopie infrarouge suggèrent qu'il y a formation de ponts hydrogènes intramoléculaires entre les produits formant le complexe moléculaire.

Mots clés: eutectiques organiques, cinétique de croissance, diagramme de phase, thermochimie, études par diffraction des rayons-X.

1. Introduction

Since the early sixties, the chemistry (1–5) of eutectics and addition compounds has been a field of potential interest due to their unusual physical properties not normally shown by the parent components. The metallic (6, 7) eutectics and intermetallic compounds constitute an active area of present investigation in metallurgy and materials science. However, the various studies carried out on these systems are inadequate and incomplete as high transformation temperature, opacity, and difficulties involved in purification present serious problems. Apart from these, wide difference in densities of the two components forming the metal eutectics causes density-driven convection effects, which in turn, affect their solidification. Due to low transformation temperature, ease in purification, transparency, low convection effects, and wider choice of materials, organic systems (8–12) are more suitable and are being used as model systems for detailed investigation of the parameters which control solidification. Further, the experimental techniques required for their investigation are simpler and more convenient as compared to those adopted in metallic systems.

Most of the organic systems studied in the past are simple eutectic type. There is only a limited number of cases in which two components form a molecular complex (13–15) with congruent melting point. Such systems are of potential technical interest since these are quite common in metallurgical systems. Organic systems, giving addition compounds which are organic analogues of intermetallic compounds, are important to material and metallurgical sciences since they permit visual observation of phase transformation and process during solidification. The formation of such molecular compounds can be established on the basis of phase diagrams which exhibit a characteristic maximum, surrounded by two eutectics, corresponding to the stoichiometry of the addition compounds formed. The growth morphology of eutectics and molecular compounds depend on the growth characteristics of individual constituent phases which can solidify either with faceted or with non-faceted interfaces. This behaviour is related to the nature of solid–liquid interface and can be predicted for pure materials from their entropy of fusion data. A unique crystallographic orientation relationship between the constituent phases and their mating planes was established by Hogan *et al.* (16). Gruzleski and Winegard (17) observed perfect lamellar grains in Sn—Cd eutectics but in a number of other systems, the eutectic grains did not exhibit a fixed crystal orientation with respect to external lines of forces. Bassi and Sharma (18) studied the infrared spectra of naphthalene – benzoic acid eutectic system and inferred that there exists a specific orientation between the constituents with respect to each other.

With a view to elucidate the chemistry of organic eutectics and the 1:1 addition compound, *p*-phenylenediamine (PPD) – benzoic acid (BA) system was undertaken and its phase diagram, linear velocity of crystallization and heat of fusion were studied. From the heats of fusion data the enthalpy of mixing, entropy of fusion, and excess thermodynamic functions were calculated to throw light on the nature of interactions among the components forming the melts. The structure of eutectics and molecular compound was also studied by infrared and X-ray methods.

2. Experimental

2.1. Materials and purification

p-Phenylenediamine (High Purity Chemicals, India) was purified by repeated distillation under vacuum and was stored in coloured bottles to avoid exposure to light. Benzoic acid (BDH) was recrystallised

from boiling water. The purity of the compounds was confirmed by determining their melting points which were in good agreement with literature values.

2.2 Phase diagram study

Phase diagram of *p*-phenylenediamine – benzoic acid system was determined (19, 20) by the thaw–melt method. Mixtures of various proportion covering the entire range of composition were taken in long-necked glass test tubes and were sealed. The mixtures were subjected to number of alternate melting in liquid paraffin followed by chilling in ice to make it homogeneous. The mixtures were taken out by breaking the test tubes and were further homogenized by grinding in a mortar with due care to avoid moisture or any other contamination. The melting and thaw temperatures were determined by Toshniwal Melting Point Apparatus.

2.3 Linear velocity of crystallization

The linear velocity of crystallization of pure components, eutectics and addition compound was determined (21, 22) by measuring the rate of movement of growth front in a capillary. The experimental details are reported earlier (22).

2.4. Heats of fusion

The heats of fusion of pure components, eutectics, and 1:1 addition compound were determined (23, 24) by their DTA patterns obtained from Stanton Redcroft STA-780 Series Unit. All the runs were carried out with heating rate 2°C/min, chart speed 10 mm/min, and chart sensitivity, 100 μV/10 mV. The sample weight range was 5–10 mg for each estimation. Using phenanthrene as a standard substance, the heats of fusion of unknown compounds were determined by the following equation:

$$[1] \qquad \Delta H = \Delta H_s \times \frac{W_s}{W} \times \frac{A}{A_s}$$

where ΔH is the heat of transition of unknown sample and ΔH_s is the heat of fusion of standard substance. W and A are weight and peak area, respectively.

2.5. Infrared studies

The infrared spectra of the pure components and adduct were recorded (25) in Nujol mull in the region 4000–600 cm^{-1}, on a Perkin–Elmer 783 Infrared Spectrophotometer.

2.6. X-ray diffraction studies

X-ray diffraction patterns of pure components, eutectics and 1:1 addition compound were recorded (24) on a computerized X-ray diffraction unit, PW 1710 model, using Cu-K_α radiation.

3. Results and discussion

3.1. Phase diagram

Phase diagram of *p*-phenylenediamine – benzoic acid system, given in Fig. 1, shows the formation of one 1:1 addition compound with congruent melting point surrounded by the two eutectics E_1 and E_2 having 0.228 and 0.807 mole fraction of benzoic acid, respectively. The melting temperatures of molecular compound and eutectics E_1 and E_2 are 145.0, 124.5, and 107.0°C, respectively. For each eutectic, the addition compound serves as one of the components. The flat maximum, observed in this system, suggests (13) that the addition compound dissociated in the molten state. From the phase diagram it can also be inferred that the addition compound is capable of existing as a solid compound in equilibrium with a liquid of the same composition. From the first eutectic point E_1 onwards, on addition of the second component, the melting point again rises, attains a maximum at C, where the composition of liquid and solid phases are identical. The existence of an eutectic point on either side of the maximum provides an information about the large stability of the molecular complex formed.

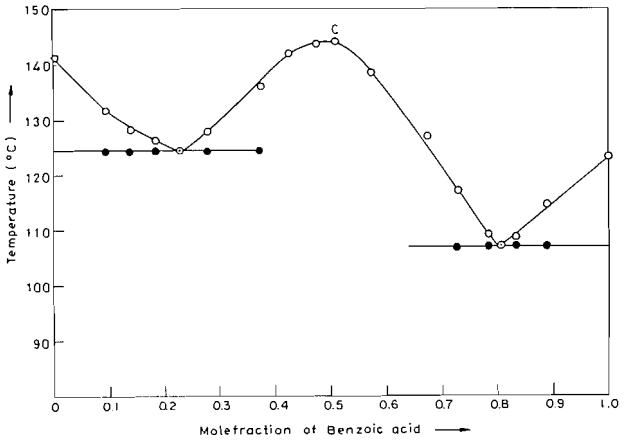

FIG. 1. Phase diagram of *p*-phenylendiamine – benzoic acid system. ○, Melting temperature; ●, thaw temperature.

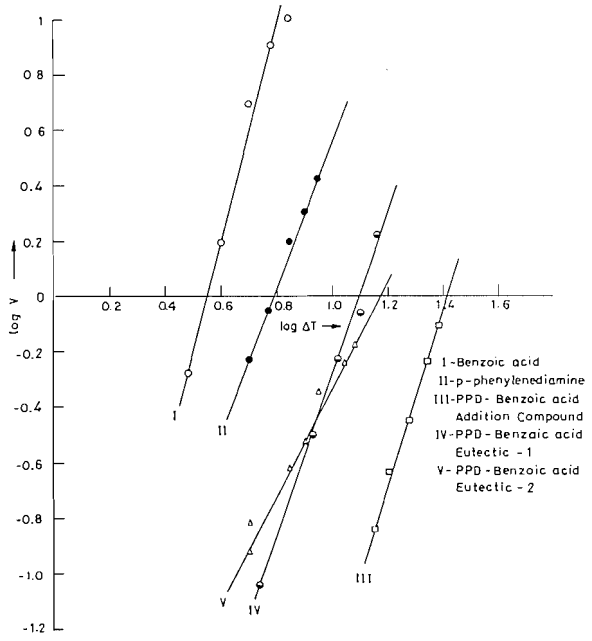

FIG. 2. Linear velocity of crystallization of pure components, eutectics and 1:1 addition compound at different undercoolings.

3.2. Growth kinetics

The linear velocity of crystallization, v, of pure components, eutectics and 1:1 addition compound, determined by measuring the rate of movement of growth front in a capillary at different undercoolings, ΔT, is given in Fig. 2 in the form of log v versus log ΔT. The linear dependence of growth velocity and undercooling suggests that the crystallization data obey Hillig–Turnbull (26) relation:

$$[2] \qquad v = u(\Delta T)^n$$

where u and n are constants depending on the nature of solidification of the sample under investigation. The experimental values of these constants are given in Table 1. The values of n being close to 2 suggest a square relationship between the linear growth velocity and undercooling. The slight deviations (20) in the values of n from 2, observed in some cases, may

TABLE 1. Values of u and n

Compound	u (mm/s deg)	n
p-Phenylenediamine	0.010230	2.60
Benzoic acid	0.007244	2.42
Eutectic-1	0.000794	2.71
Eutectic-2	0.005129	2.00
1:1 Addition compound	0.000071	2.87

be due to the difference between the bath temperature and the temperature of growing interface.

It is evident from the values of u, given in Table 1, that the crystallization velocity of eutectic-1 (E_1) and eutectic-2 (E_2) are lower than those of pure components and higher than the addition compound. The first eutectic (E_1), having a low molar concentration of benzoic acid, solidifies more slowly than the second eutectic (E_2) with a high molar concentration of benzoic acid. These results may be explained on the basis of the mechanism proposed by Winegard *et al.* (27). According to them, in binary system the eutectic solidification begins with the formation of the nucleus of one of the phases. This would grow until the surrounding liquid becomes rich in the other component and a stage is reached when the second component also starts nucleating. Now there are two possibilities. First, the two initial crystals may grow side by side. This explains the case in which the rates of solidification of eutectics are not lower than those of the parent components. The second possibility is that there may be alternate nucleation of the two components. This explains the solidification phenomena, in cases, where the crystallization velocity of the eutectics is lower than that of the parent components. Thus, the solidification of E_1 and E_2 takes place by side by side growth of the two components. For both eutectics, addition compound acts as one of the components and nucleates first. Thus, *p*-phenylenediamine and addition compound act as the parent components for E_1, while the molecular complex and benzoic acid do so for eutectic E_2. For E_1 and E_2 the nucleation of addition compound is followed by the nucleation of *p*-phenylenediamine and benzoic acid, respectively.

From the values of u, given in Table 1, it can be inferred that the 1:1 addition compound of *p*-phenylenediamine with benzoic acid crystallizes at a rate slower than that of pure components and both eutectics. Studies (14) on crystal morphology of the addition compounds indicate that they crystallize as a definite chemical entity. However, during crystallization, the two components from the melt have to enter the crystal lattice, simultaneously, in such a way that the composition of the melt corresponds to a 1:1 molar ratio of the two components. Due to this, the linear velocity of crystallization of the addition compounds may be expected to be of the order of the velocity of the species crystallizing at a slower rate.

3.3. Thermochemistry

The experimentally determined values of heats of fusion of parent components, eutectics, and addition compound are given in Table 2. If the eutectics were a simple mechanical mixture of the two components involving no heat of mixing or any type of association in the melt, the heats of fusion, $(\Delta_f h)_e$, would simply be given by the mixture law (28):

$$[3] \quad (\Delta_f h)_e = x_1 \Delta_f h_1 + x_2 \Delta_f h_2$$

where x_1 and x_2 are the mole fraction and $\Delta_f h_1$ and $\Delta_f h_2$ are the experimental values of heats of fusion of parent components 1 and 2, respectively. The heats of fusion, calculated from the mixture law, are also given in the same table. It is evident from the table that the values of heat of fusion calculated from eq. [3] are higher than the experimental values. This difference can be attributed to the formation of clusters in the eutectic melt. It can be imagined that during cluster formation, heat liberated may lower the actual value of heat of fusion. The cluster formation will be favoured if the molecules can associate themselves by certain weak intermolecular forces. In eutectic systems where one or both components contain hydroxyl groups, there would be a tendency to form hydrogen bonds and as a result, the cluster formation will be favoured. This is one of the reasons why the experimental values of heat of fusion are lower than those calculated from eq. [3]. The experimental value of heat of fusion of addition compound and its theoretical value, calculated by the mixture law, is also given in the Table 2. It is evident that the calculated value is higher than the experimental value. A similar type of cluster formation and explanation can also be suggested to justify this observation.

Heat of mixing (ΔH_m) which is the difference between the experimental and calculated values of heats of fusion is given by

$$[4] \quad \Delta H_m = (\Delta_f h)_{exp} - \Sigma x_i \Delta_f h_i$$

where $(\Delta_f h)_{exp}$ is the heat of fusion of the eutectic, determined experimentally, x_i and $\Delta_f h_i$ are the mole fraction and heat of fusion of the end components, respectively. It is evident from Table 2 that in all cases the heats of mixing are negative. Thermochemical studies suggest that the structure of eutectic melt depends on the sign and magnitude of the enthalpy of mixing. Three types of structures (29) are suggested; quasi-eutectic for $\Delta H_m > 0$, clustering of molecules for $\Delta H_m < 0$, and molecular solutions for $\Delta H_m = 0$. The negative values of ΔH_m of eutectics of system under investigation, suggest clustering of molecules in the eutectic melt and substantiate our earlier conclusion drawn on the basis of the mixture law. It is also very interesting to note that the molecular complex and one of the eutectics have low values of enthalpy of mixing, and one might argue for the possibility of simple molecular solutions instead of weak interactions. These results (30) are quite different from those of simple eutectic systems where merely ordering of the parent phases has been suggested in the melts. It seems that there is considerable enhancement in the interactions due to the presence of molecular complex in the eutectic melts.

In order to know the nature of interaction between the components forming the eutectics in the present systems, some thermodynamic functions, such as excess free energy, g^E, excess enthalpy of mixing, h^E, and excess entropy of mixing, S^E, were calculated using the following equations:

$$[5] \quad -\ln x_i^l \gamma_i^l = \frac{\Delta_f h_i^0}{R}\left(\frac{1}{T} - \frac{1}{T_i^0}\right)$$

$$[6] \quad g^E = RT(x_1 \ln \gamma_1^l + x_2 \ln \gamma_2^l)$$

$$[7] \quad h^E = -RT^2\left(x_1 \frac{\partial \ln \gamma_1^l}{\partial T} + x_2 \frac{\partial \ln \gamma_2^l}{\partial T}\right)$$

$$[8] \quad s^E = -R\left(x_1 \ln \gamma_1^l + x_2 \ln \gamma_2^l + x_1 T \frac{\partial \ln \gamma_1^l}{\partial T} + x_2 T \frac{\partial \ln \gamma_2^l}{\partial T}\right)$$

TABLE 3. Excess thermodynamic functions for eutectic-1 and eutectic-2

Material	g^E (J/mol)	h^E (J/mol)	s^E ($J\ mol^{-1}\ K^{-1}$)
Eutectic-1	927.53	21526.17	51.82
Eutectic-2	563.01	8484.05	20.84

where γ_i and T_i^0 are activity coefficient and melting temperature of the component indicated by the suffix and T and R are the eutectic temperature and gas constant, respectively. Equation [5] is obtained by considering the general condition of phase equilibrium for the two phases and assuming that heat of fusion is independent of temperature and the two components are miscible in the liquid phase only. This equation was used to calculate the activity coefficient of the end members at the eutectic point. The values of $\partial \ln \gamma_i^l / \partial T$ were calculated by differentiating eq. [5] and taking slope of the liquidus line near the eutectic point. The details of calculation of excess thermodynamic functions are reported earlier (28). Values of excess functions are given in Table 3. The positive values of excess free energy give measure of the departure of the system from ideal behaviour and suggest interaction among the components forming the eutectic melt. The values of h^E and s^E of Table 3 correspond to the excess free energy and are measures of excess enthalpy of mixing and excess entropy of mixing, respectively.

The entropies of fusion, ΔS, of pure components, eutectics and addition compounds were calculated using the following relation:

$$[9] \quad \Delta S = \frac{\Delta_f h}{T}$$

where $\Delta_f h$ is the heat of fusion and T is the fusion temperature, and are given in Table 2. In all the cases ΔS values are positive, indicating an increase of randomness during melting. According to Hunt and Jackson (1), the type of growth from a eutectic melt depends upon a factor α as defined by equation:

$$[10] \quad \alpha = \xi \frac{\Delta S}{R}$$

where ξ is a crystallographic factor depending upon the geometry of the molecules and has the values less than or equal to one. $\Delta S/R$, also known as Jackson's roughness parameter,

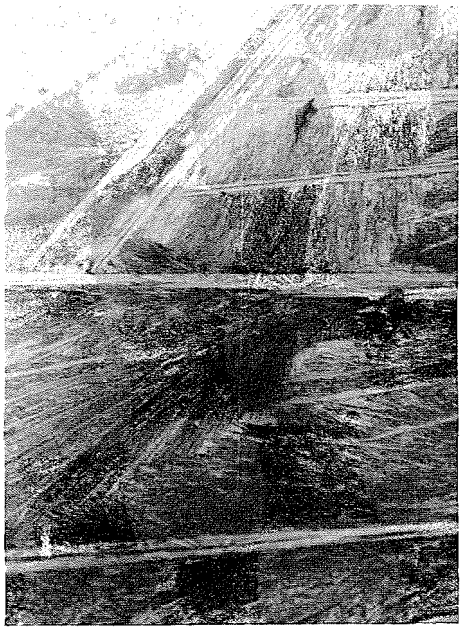

FIG. 3. Microstructure of eutectic E_1 (×200).

is the entropy of fusion in dimensionless unit and R is the gas constant. When $\alpha < 2$, non-faceted growth occurs whereas a faceted growth appears if $\alpha > 2$. In all cases, $\Delta S/R$ values are greater than 2, which indicate that they exhibit faceted growth. The microstructures of eutectic, recorded on a microscope (Leitz Laborlux D, West Germany) are given in Figs. 3 and 4, confirm this conclusion.

3.4. Infrared studies

The infrared spectrum of *p*-phenylenediamine shows a strong band at 3380 cm^{-1}. In the case of pure benzoic acid, there is no peak in the 3000–4000 cm^{-1} region. But the 1:1 addition compound of *p*-phenylenediamine with benzoic acid has three bands at 3230, 3340, and 3460 cm^{-1} in this range. The strongest band being at 3340 cm^{-1} shows a negative shift of 40 cm^{-1} as compared to the strong band observed in PPD at 3380 cm^{-1}. The other two bands in the 1:1 addition compound are attributed to free $—NH_2$ group present therein which is not involved in hydrogen bonding with benzoic acid. A band observed at 1690 cm^{-1} due to C=O stretching of benzoic acid was found to shift to 1640 cm^{-1} in the addition compound. These observations clearly indicate the formation of intermolecular

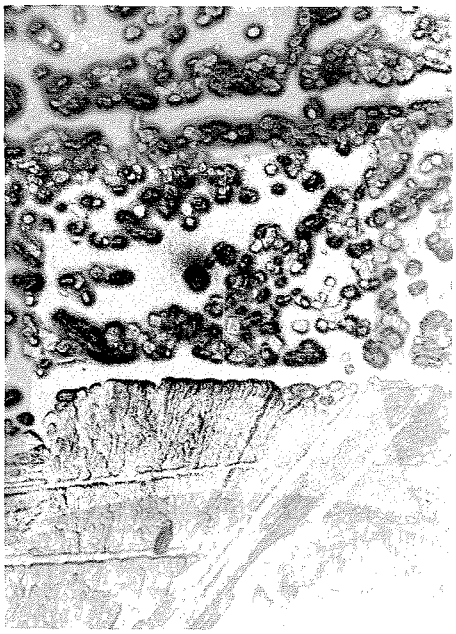

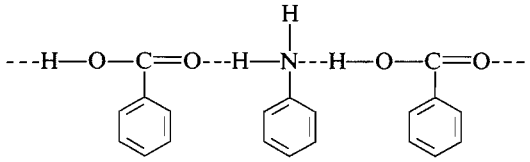

FIG. 4. Microstructure of eutectic E_2 (×200).

hydrogen bonding between the two components, which is represented below:

3.5. X-ray diffraction studies

Experimental results on some preliminary investigations of X-ray diffraction of pure components, eutectics, and addition compound are reported in Tables 4 and 5. It can be observed from the X-ray diffraction data that for a particular *d* value there is marked difference in the relative intensity of the components. This may be explained on the basis of the structure considerations of the compounds under investigation. It is evident from Tables 4 and 5 that the number of reflections of E_1, E_2, and addition compound are comparable. This suggests that they belong to the same crystal system and have similar lattices. In general, common reflections of benzoic acid and eutectic E_2 have smaller intensities in the case of eutectic. Common reflections of addition compound and eutectic E_2 also show decrease in intensities in the eutectic. Strong reflections of benzoic acid show a drastic decrease in intensity in the eutectic phase showing that the structure of the two differ very significantly. Whereas this is not true for the eutectic and addition compound. The structure of eutectic seems to be governed more by the addition compound as compared to benzoic acid because the high angle Bragg reflections are absent, both in addition compound and eutectic while they are present in benzoic acid. A drastic decrease of intensity of strong common reflections and the absence of high angle Bragg reflections are also observed in eutectic E_1 containing *p*-phenylenediamine as one of the components. There is no regular change of intensity of reflections of E_1 and addition compound but the tendency of decrease of intensity in the addition compound is dominant. Moreover the intensity of strong reflections of addition compound show drastic decrease in the eutectic E_1.

2.58	12	2.58	6	—	—

It is clear from Tables 4 and 5 that the intensities of the reflections diminish with decreasing *d* values. It is also noted from both the tables that some reflections of pure components and addition compound are absent in the corresponding eutectic. The first eutectic (E_1) formed between *p*-phenylenediamine and the addition compound has some strong reflections having *d* values 11.79, 6.58, 4.85, 4.41, 4.01, 3.93, and 3.85 Å whereas some reflections of PPD and molecular complex are missing in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

it. In the case of the second eutectic (E_2), formed between benzoic acid and the molecular complex, a similar trend is observed and strong reflections correspond to *d* values 11.79, 10.91, 5.15, and 4.00 Å. These experimental results infer that the eutectics are not simply the mechanical mixture of the two components. In them, there is orientation (30) of some atomic planes and preferential ordering also takes place during their formation. These findings are in accordance with our earlier conclusions drawn in the case of *p*-phenylenediamine–catechol system reported earlier (23).

Esterification of 1,4-dichlorobutane with sodium formate under solid–liquid phase transfer catalysis. A kinetic study

HAYDER A. ZAHALKA[1] AND YOEL SASSON
Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, 91904 Jerusalem, Israel

Received May 27, 1988

HAYDER A. ZAHALKA and YOEL SASSON. Can. J. Chem. **67**, 245 (1989).

Kinetic data are reported regarding the esterification of 1,4-dichlorobutane with sodium formate catalyzed by quaternary ammonium salts as a model for reactions in series, under solid–liquid phase transfer conditions. The process was found to follow a consecutive first-order mechanism of the general type A → R → S. The reactivity of the quaternary ammonium salts with regard to the counteranion was $Cl^- > Br^- > I^- > HSO_4^-$. The reaction rate was linearly dependent on catalyst concentration up to 12 mol% of catalyst relative to the substrate. Above this concentration the rate was constant and independent of the amount of the catalyst. The activation energy of the two consecutive steps was found to be similar (21 kcal/mol). Therefore, the product distribution (R/S) is not appreciably affected by temperature. A mechanism termed "Thin aqueous boundary layer" is suggested for nucleophilic displacement reactions under solid–liquid phase transfer conditions.

Key words: phase transfer catalysis, series reactions, kinetic study.

HAYDER A. ZAHALKA et YOEL SASSON. Can. J. Chem. **67**, 245 (1989).

Dans le but de développer un modèle pour des réactions en série effectuées dans des conditions de transfert de phase solide–liquide, on a déterminé les données cinétiques relatives à l'estérification, catalysée par des sels d'ammonium quaternaires, du dichloro-1,4 butane par le formate de sodium. On a trouvé que le processus est une réaction consécutive du premier ordre du type général A → R → S. La réactivité des sels d'ammonium quaternaires en fonction des contre-ions est $Cl^- > Br^- > I^- > HSO_4^-$. Jusqu'à 12 mol% de catalyseur par rapport au substrat, la vitesse de la réaction varie d'une façon linéaire avec la concentration du catalyseur. Au-dessus de cette concentration, la vitesse est constante et elle est indépendante de la quantité de catalyseur. On a trouvé que les énergies d'activation des deux étapes consécutives sont semblables (21 kcal/mol). La distribution des produits (R/S) n'est donc pas très affectée par la température. On suggère un mécanisme appelé «limité par une mince couche aqueuse» pour les réactions de substitutions nucléophiles effectuées dans des conditions de transfert de phase solide–liquide.

Mots clés : catalyse de transfert de phase, réactions en série, étude cinétique.

[Traduit par la revue]

Introduction

The traditional phase transfer catalyzed ester synthesis, where a carboxylate anion in aqueous solution reacts with an alkyl halide in the presence of a lipophilic onium salt (1, 2), cannot be applied in the case of the hydrophilic formate anion (3–5) due to the high susceptibility of the heterogeneous displacement process (eq. [1]) to catalyst poisoning (3) and to deactivation of the phase transfer catalyst by extraction of free acids via hydrogen bonding (4). We observed (6, 7) that quantitative conversions in chloride–formate exchanges were obtained only by the use of highly concentrated aqueous solutions of the formate salts, namely, under the conditions known as solid–liquid phase transfer catalysis (S–L PTC) in the presence of catalytic amounts of water, e.g., 0.20% water content of sodium formate (5), which were shown to be essential for the chloride–formate exchange (eq. [1]):

$$[1]\quad RCl_{org} + HCOONa_{aq.\ or\ S} \xrightarrow{PT_{catalyst}} HCOOR_{org} + NaCl_{aq.\ or\ S}$$

There have been no publications, to our knowledge, on the kinetics of complex substitution reactions (e.g., reactions in series) under S–L PTC conditions, although some reports on the kinetics of simple substitution reactions have appeared in the literature (7, 8). Therefore, we found it imperative to study systematically the various kinetic aspects of the esterification of 1,4-dichlorobutane with sodium formate (eq. [2]) in a solid–liquid system as a model for reactions in series under S–L PTC conditions, and to discuss the mechanistic implications of the results.

$$[2]\quad \underset{A}{Cl(CH_2)_4Cl} + HCOONa \xrightarrow[QX]{k_1} \underset{R}{Cl(CH_2)_4OOCH} + NaCl$$

$$\underset{R}{Cl(CH_2)_4OOCH} + HCOONa \xrightarrow[QX]{k_2} \underset{S}{HCOO(CH_2)_4OOCH} + NaCl$$

(QX ≡ quaternary ammonium salt)

Results

Reaction profile

The displacement reaction (eq. [2]) was studied under varying conditions of mechanical stirring speed, catalyst structure, catalyst concentration, catalyst counterion, and temperature. Standard reaction conditions consisted of 1.37 M 1,4-dichlorobutane in chlorobenzene, 80.6 mmol sodium formate containing 0.2% (w/w) water, 2.5 mmol tetrabutyl ammonium bromide ($Bu_4N^+Br^-$), 115°C, and a stirring speed of 1000 rpm.

The progress of the reaction was followed by gas-chromatographic analysis of samples that were taken from the organic phase at constant intervals. Figure 1 shows the composition–time curves for the three components (A, R, and S) in a typical run. It is apparent from Fig. 1 that A decreases exponentially, R rises to a maximum (R_{max}) and then falls, and that S rises continuously. These curves are consistent with the behaviour expected for consecutive first-order reactions (9). Figure 2 presents a kinetic profile of the first step (A → R) of reaction [2] plotted as a first-order reaction. It is clear that the behaviour is in excellent agreement with a first-order rate equation. The order of the second step (R → S) was determined by examination

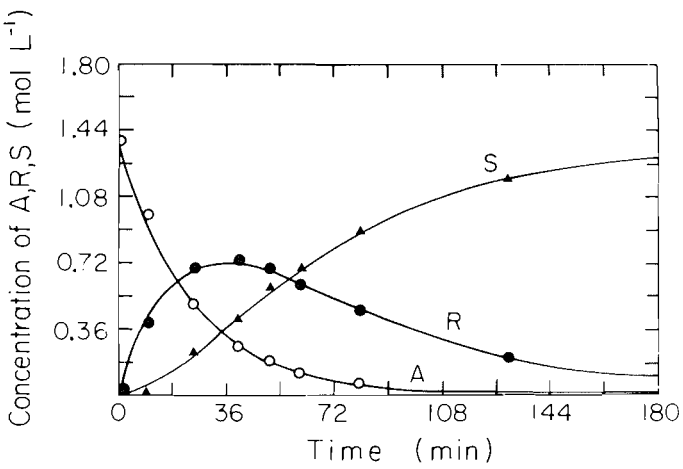

FIG. 1. Concentration–time curves for reaction [2]. Reaction conditions: 1,4-dichlorobutane (27.4 mmol), 99.8% sodium formate (80.6 mmol), tetra-*n*-butylammonium bromide (2.5 mmol), and chlorobenzene (17 mL) at 115°C with mechanical stirring at 1000 rpm. The concentration of S was calculated from the difference in the concentration of the reacting components by $C_S = C_{A_0} - (C_A + C_R)$.

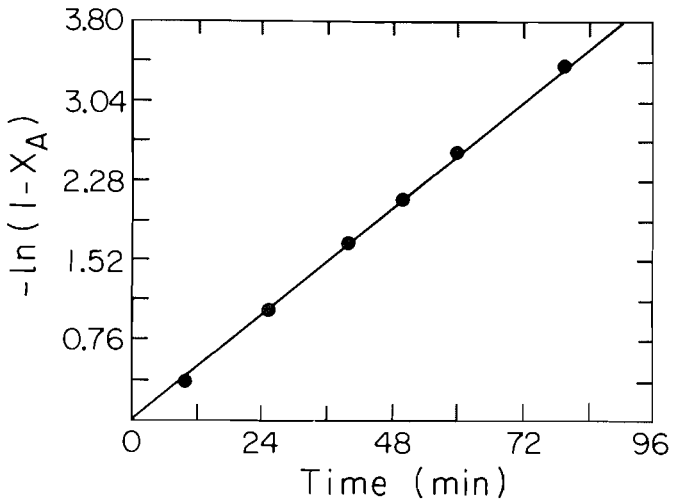

FIG. 2. Test for first order for the first step A → R in reaction [2]. Conditions, see Fig. 1.

of the variation in $C_{R,max}/C_{A_0}$ as a function of C_{A_0}: 1.37, 2.42, and 3.76 M. We obtained a constant ratio, viz. 0.5. Thus $C_{R,max}/C_{A_0}$ is independent of C_{A_0} and therefore the second step of the series (R → S) is first order as well (9).

Effect of stirring speed

Figures 3a and 3b show that the observed pseudo-first-order rate constants k_1 and k_2 are increased by increasing the stirring speed up to 400 rpm, and that they remain constant beyond this value. The curves exhibited in these figures are similar to those reported for liquid–liquid PTC systems (L–L PTC) (10, 11), in that the reaction rates are shown to increase upon increasing the stirring speed up to 300 rpm, and to remain constant beyond this value. It can safely be argued that the rate of mass transfer does not play a role in the substitution reaction if mixing above 400 rpm is applied.

Effect of catalyst structure

We studied the effect of catalyst structure on the observed rate constants of reaction [2]; the results are summarized in

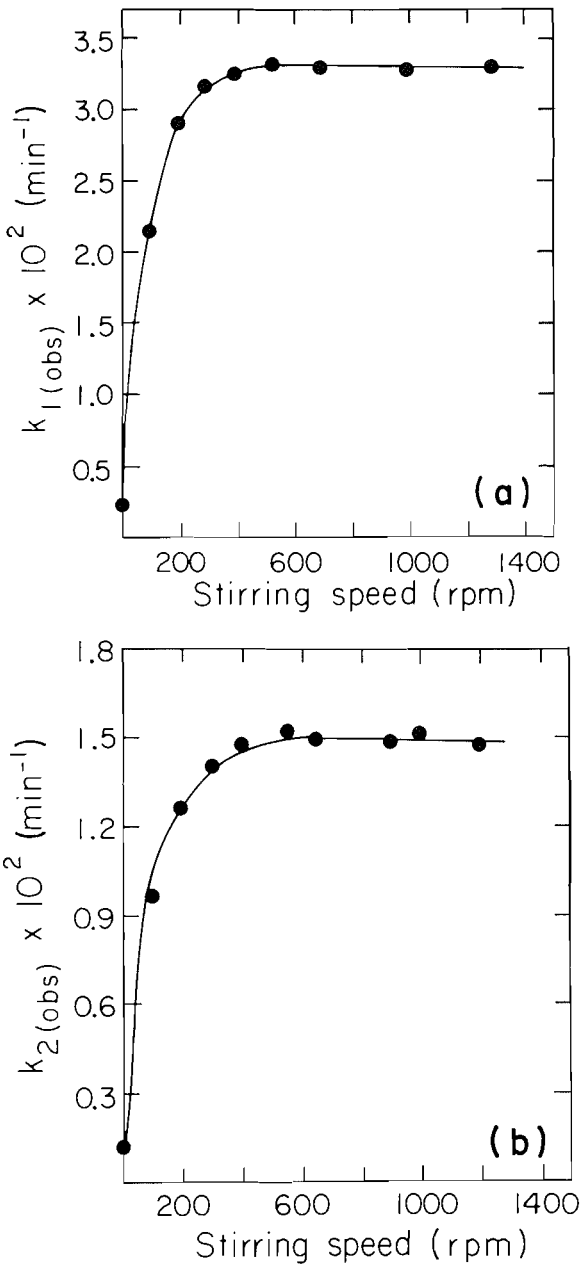

FIG. 3. Dependence of (a) $k_{1(obs)}$ and (b) $k_{2(obs)}$ on stirring speed. Reaction conditions: 1,4-dichlorobutane (27.4 mmol), 99.8% sodium formate (80.6 mmol), tetra-*n*-butylammonium bromide (1.6 mmol), chlorobenzene (17 mL) at 115°C.

Table 1. The data revealed similar catalytic activity for each of the various symmetrical tetra-*n*-alkylammonium bromides, $(C_nH_{2n+1})_4N^+Br^-$. The ammonium salts where the alkyl chain contained four or more carbons gave the maximum rate: $k_{1(obs)} = (3.2 \pm 0.1) \times 10^{-2}\,min^{-1}$, $k_{2(obs)} = (1.5 \pm 0.1) \times 10^{-2}\,min^{-1}$. This behaviour was expected due to the fact that the catalysts with $n \geq 4$ reside entirely in the organic phase (12). Thus, above the tetra-*n*-butyl cation the length of the alkyl chain has no marked effect on the reaction rate. In addition, it can be seen that symmetrical catalysts are much more efficient than unsymmetrical ones, e.g., Aliquat 336.

The catalysts TEBA-Cl and TEBA-Br were not found to be very effective as compared to other catalysts employed in this study (Table 1). This is mainly due to the poor solubility of the TEBA-Cl and -Br^- in the organic phase.

TABLE 1. Dependence of the observed rate constants of reaction [2] on catalyst structure

Catalyst*	$k_{1(obs)} \times 10^2$ (min^{-1})	$k_{2(obs)} \times 10^2$ (min^{-1})
—	0	0
$Bu_4N^+Br^-$	3.25	1.52
$Hep_4N^+Br^-$	3.31	1.60
$OCt_4N^+Br^-$	3.14	1.47
Aliquat 336	2.12	0.98
TEBA-Br	0.81	0.39
TEBA-Cl	0.99	0.47

Reaction conditions, see Fig. 3; stirring speed, 1000 rpm.
*$Bu_4N^+Br^-$ = tetra-*n*-butylammonium bromide; $Hep_4N^+Br^-$ = tetra-*n*-heptyl ammonium bromide; $OCt_4N^+Br^-$ = tetra-*n*-octylammonium bromide; Aliquat = tricaprylmethyl ammonium chloride; TEBA-Br = triethylbenzyl ammonium bromide; TEBA-Cl = triethylbenzyl ammonium chloride.

Effect of catalyst counteranion

The effect of the counteranion of the quaternary ammonium salts is presented in Table 2. It is clear that the halide anion (entries 2–4) behaved as would be expected, $Cl^- > Br^- > I^-$, but the hydrogen sulfate catalyst, which is usually considered as the catalyst of choice in L–L PTC systems (13), performed very poorly in the S–L PTC esterification. It is important to note that the reaction rate decreases on increasing the hydrogen sulfate concentration (entries 5, 6) while the total concentration of the catalyst was constant.

The poor performance of the bisulfate catalyst in the S–L PTC esterification with formate salts could be attributed to the *in situ* formation of formic acid, according to eq. [3]:

[3] $$HCOO^- + HSO_4^- \rightarrow HCOOH + SO_4^{2-}$$

The formic acid present in the system is extracted into the organic phase together with the ion pairs $HCOO^-Q^+$, via hydrogen bonding (eq. [4]), and inhibits the normal PTC substitution process (4).

[4] $$HCOOH_{aq.} + HCOO^-Q^+_{org} \rightarrow HCOOH\cdots HCOO^-Q^+_{org}$$

Effect of catalyst concentration

The catalyst $Bu_4N^+Br^-$ was used as reference compound for the kinetic study. This commercial and inexpensive catalyst was found to be very effective (Table 1) and less hygroscopic than the chloride counterpart.

The observed rate constants k_1 and k_2, Figs. 4a and 4b respectively, are linearly dependent on catalyst concentration up to 0.16 M, and remain constant beyond this value. We visualize that above 12 mol% of catalyst relative to the substrate (1,4-dichlorobutane) the interface is already saturated with the quaternary ammonium cations. Therefore, increasing the catalyst concentration swamps the interface. However, there is an optimal cation (Q^+) concentration that can participate in the phase transfer process. It is important to note that in the range of catalyst concentration examined (0.02–0.4 M), full solubility of the catalyst was observed in the organic phase.

Effect of temperature

The activation energies for the two consecutive steps (eq. [2]) were determined from the Arrhenius plots presented in Figs. 5a and 5b. The data yield 20.6 kcal/mol for the first step (A → R) and 21.5 kcal/mol for the second step (R → S). An activation energy of about 21 kcal/mol is typical for chemically controlled reactions (9).

The product distribution (R/S) is not appreciably affected by temperature. Therefore, the actual mode of operation for obtaining high selectivity towards the desired product in consecutive reactions, e.g., for the intermediate R, depends on the economics of the system under study.

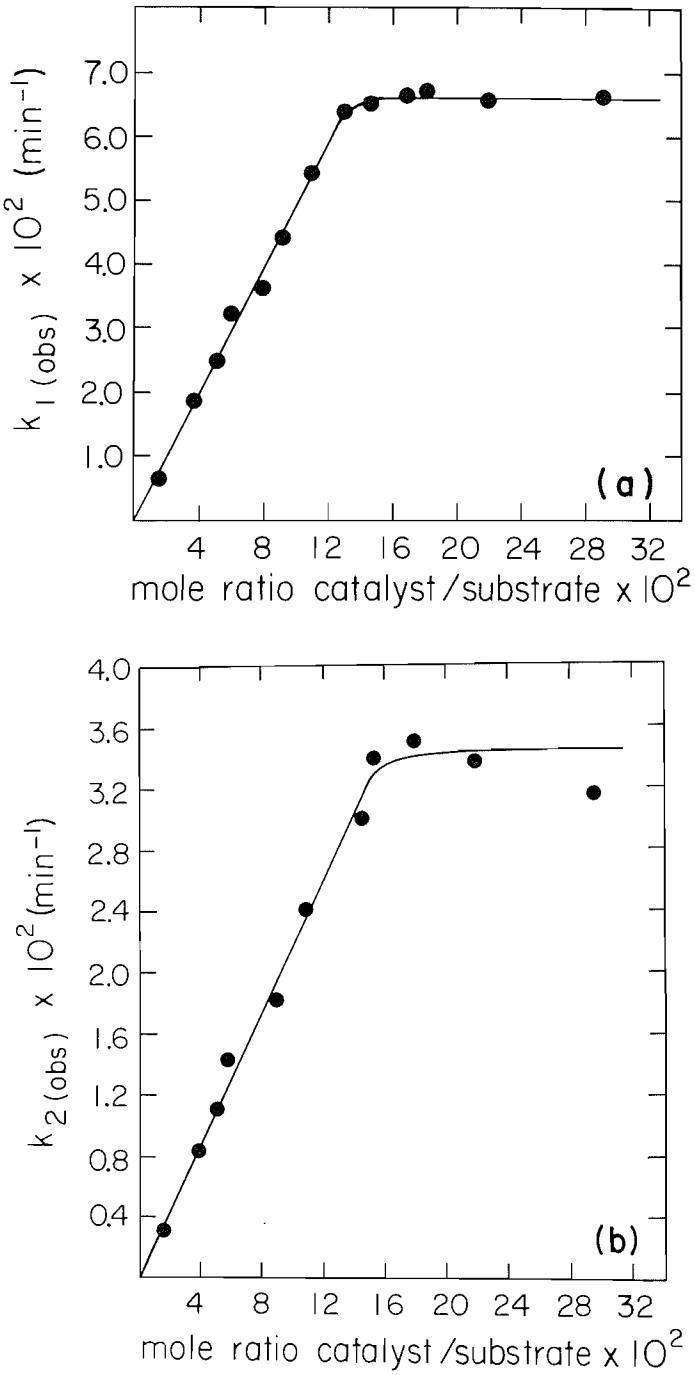

FIG. 4. Dependence of (a) $k_{1(obs)}$ and (b) $k_{2(obs)}$ on catalyst concentration.

Discussion

Analysis of the different variables examined in this study and in a previous report (5), regarding the critical importance of traces of water for chloride–formate exchange under S–L PTC conditions, suggests a detailed mechanism for substitution reactions catalyzed by quaternary onium salts under S–L conditions. We have termed the proposed mechanism "Thin aqueous boundary layer", as represented in Scheme 1.

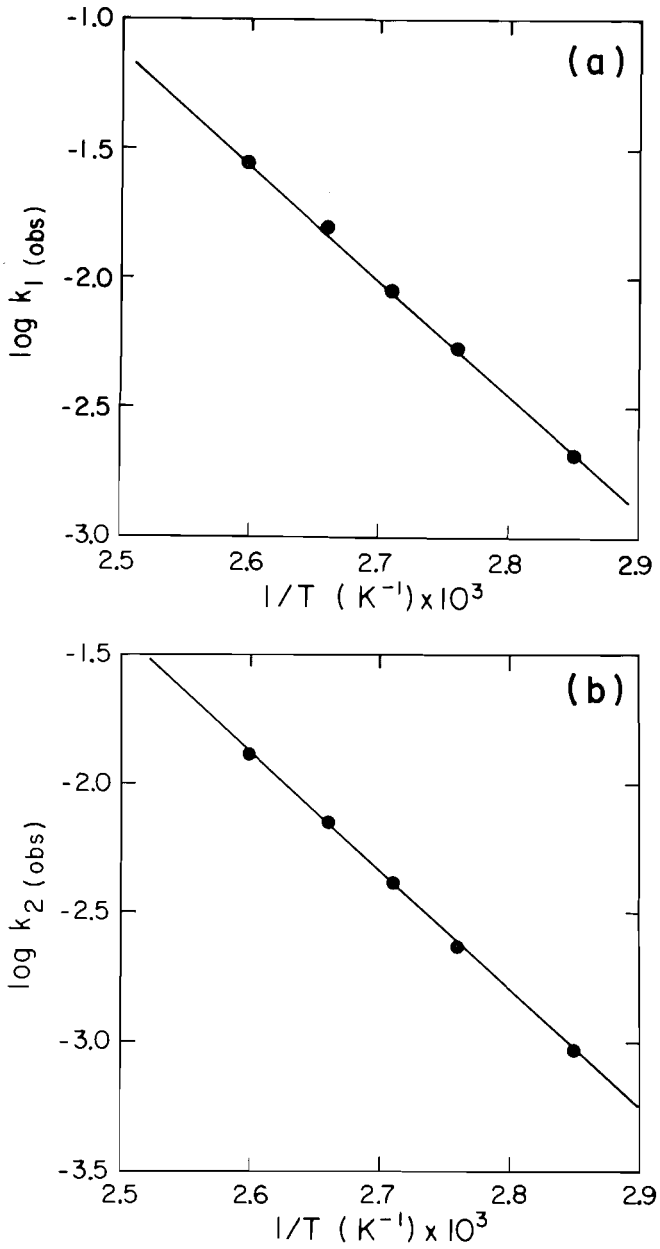

FIG. 5. Arrhenius plot: Dependence of (a) $k_{1(obs)}$ and (b) $k_{2(obs)}$ on temperature.

The first step involves activation of the formate ions by partial dissolution of the solid lattice molecules in the thin aqueous layer. In the second step the catalyst cation exchanges anions at the interface. The ion pair $HCOO^-Q^+$ reacts in the organic phase with the substrate and releases chloride (Cl^-), which combines with the cation (Q^+) and exchanges with formate anion at the interface. In a previous report (3) we demonstrated that highly concentrated aqueous solutions of sodium formate do not dissolve sodium chloride nor sodium bromide. Thus the chloride released during the course of reaction [2] precipitates as sodium chloride (Scheme 1) and does not participate in the phase transfer process. Therefore, the assumption that $[HCOO^-Q^+]_{org}$ is constant throughout the reaction is valid for the system under investigation.

According to the thin aqueous boundary layer mechanism and the experimental results, which are consistent with the suggested mechanism, we can write the rate equations of reaction [2] as:

$$[5] \quad \frac{-d[A]}{dt} = k_1[A]_{org}[HCOO^-Q^+]_{org}$$

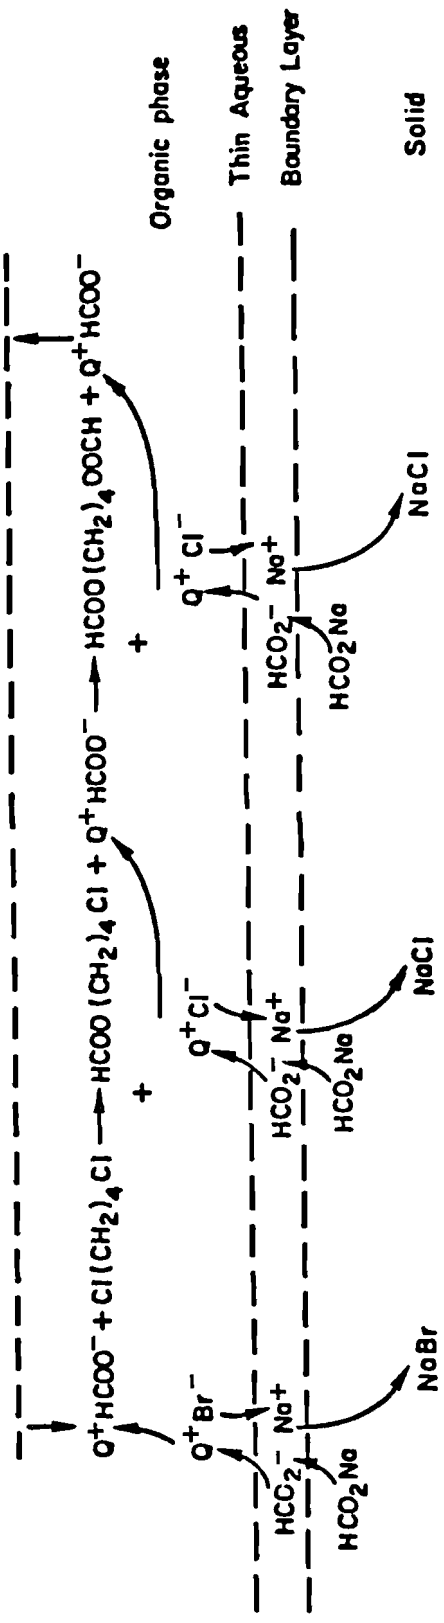
$$[6] \quad \frac{d[R]}{dt} = k_1[A]_{org}[HCOO^-Q^+]_{org} - k_2[R]_{org}[HCOO^-Q^+]_{org}$$

$$[7] \quad \frac{d[S]}{dt} = k_2[R]_{org}[HCOO^-Q^+]_{org}$$

Since $[HCOO^-Q^+]_{org}$ = constant, eqs. [5]–[7] can be rewritten as:

$$[8] \quad \frac{-d[A]}{dt} = k_{1(obs)}[A]$$

$$[9] \quad \frac{d[R]}{dt} = k_{1(obs)}[A] - k_{2(obs)}[R]$$



$$[10] \quad \frac{d[S]}{dt} = k_{2(obs)}[R]$$

where $k_{1(obs)} = k_1[HCOO^-Q^+]_{org}$ and $k_{2(obs)} = k_2[HCOO^-Q^+]_{org}$.

Experimental

All materials were commercially available at >99% purity. Analytical purity of chlorobenzene and 1,4-dichlorobutane were confirmed by

SCHEME 1. Mechanism of esterification of 1,4-dichlorobutane with sodium formate under S–L PTC conditions.

gc analysis. Anhydrous AR grade sodium formate was freeze-dried prior to the experiment. The precise amount of water in the formate salt was determined by thermogravimetric analysis. The particle size of sodium formate was below 5 μm.

Gas chromatographic determinations were performed on a Gow-Mac gas chromatograph (TC detector) equipped with a 2-m 15% OV-17 on Chromosorb W column operating at 110°C. From the appropriate calibration, concentrations of $Cl(CH_2)_4Cl$, $HCOO(CH_2)_4Cl$, and $HCOO(CH_2)_4OOCH$ in the reaction mixture were obtained. The reaction temperature was maintained ±0.5°C by a thermostatted bath. Stirring was provided by a Heidolph mechanical stirrer with appropriate gears attached to a flat-bladed Teflon paddle (36 mm length). The stirring speed was determined by a Jaquet tachometer to ±10 rpm.

In a typical reaction, a 50-mL round-bottomed flask with a side arm for sampling was charged with 5.481 g (80.6 mmol) sodium formate 99.8% w/w, 516 mg (1.6 mmol) $Bu_4N^+Br^-$, and with 27.4 mmol 1,4-dichlorobutane in 20 mL of chlorobenzene solution (1.37 M). The mixture was stirred with a mechanical stirrer at 115°C; at regular intervals, 20-μL samples of the organic phase were taken and immediately injected into the gas chromatograph. Phase separation was almost immediate after the stirring was stopped.

The rate constants were calculated by fitting the experimental data for A, R, and S to the appropriate kinetic equations (ref. 9, pp. 58, 59) by means of the least-squares method (14). The goodness of fit was estimated by calculation of χ^2, which was at least 0.98.

The identification of structural fragments of enolic monoterpenes, enolic pheromones, and related natural products, from OH stretching vibration frequencies and relative intensities

JOHN F. BACON AND JOHN H. VAN DER MAAS[1]

Laboratory for Analytical Chemistry, University of Utrecht, Croesestraat 77A, 3522 AD Utrecht, The Netherlands

Received September 6, 1988

JOHN F. BACON and JOHN H. VAN DER MAAS. Can. J. Chem. **67**, 250 (1989).

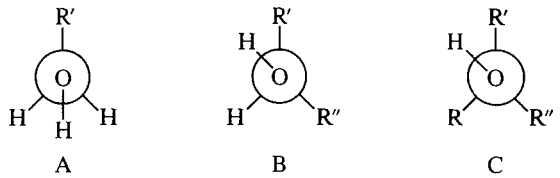
The OH stretching frequency has proved to be a powerful tool for structural investigations of enolic natural products containing diverse structural elements. The position of unsaturation can in many cases be determined directly from frequency measurements. Primary, secondary, and tertiary α–β and β–γ unsaturation can unambiguously be identified due to the possession of OH bands arising from an interaction of the OH proton with the π system. Frequently, unsaturation further removed than the γ position can be identified, particularly when a double bond is present, intermediate between the distal π system and the OH group. The identification of long-range OH–π system interactions relies on the observation that an intermediate double bond reduces the rotational freedom of the molecule. This reduction in entropy is assumed to be responsible for a significant population of the conformation in which the OH group is associated with the π system.

Key words: infrared, conformation, natural products, alcohols, molecular structure.

JOHN F. BACON et JOHN H. VAN DER MAAS. Can. J. Chem. **67**, 250 (1989).

La fréquence de la vibration d'élongation OH s'avère un outil puissant dans les études de structures des produits naturels énoliques comportant divers éléments de structure. Dans plusieurs cas, les mesures de fréquence permettent de déterminer directement la position de l'insaturation. En se basant sur la présence de bandes OH provenant d'une interaction entre le proton du OH et le système π, on peut identifier sans ambiguïtés les insaturations α–β ainsi que β–γ, tant primaire que secondaire ou tertiaire. On peut fréquemment identifier des insaturations dont la position est plus éloignée que la position γ; cette affirmation est particulièrement vraie lorsqu'il existe une double liaison entre le système π éloigné et le groupement OH. L'identification des interactions OH–π à distance est basée sur l'observation qu'une double liaison intermédiaire réduit la liberté de rotation de la molécule. On fait l'hypothèse que cette réduction de l'entropie est responsable de la présence d'une population importante de la conformation dans laquelle le groupement OH est associé avec le système π.

Mots clés : infrarouge, conformation, produits naturels, alcools, structure moléculaire.



[Traduit par la revue]

Introduction

The enols are diversely represented amongst physiologically active compounds (1–8). Many important pheromones of the sex attractant (2–4) and the insect feedant types (1) possess enolic functions. It has been shown that the position and configuration of the double bonds are responsible for the structure–reactivity relationship (2). In addition, a large number of retinols and monoterpenes possess the hydroxy-isoprene unit (5–8).

Modern methods of structural elucidation of the positions of enolic functions contained within these natural products have relied mainly upon the use of NMR (1–4, 7, 8), HPLC (3, 6), mass spectrometry (2), TLC (1), and UV–visible spectrometry (6). Classically, the infrared spectra of naturally occurring alcohols have been measured as concentrated solutions or mulls etc., conditions under which molecular association increases the number of conformational isomers and complicates the conformational analysis. Structural elucidation has therefore depended upon assignment of numerous vibrational bands with known structures, in conjunction with GLC and NMR analyses (9, 10).

Recent advances in the study of the OH stretching frequency in dilute solution, using FT–IR, have allowed structural correlation with band position to be made with great accuracy (12–14, 23), and structural elucidations of certain natural products have been made (11). The purpose of this paper is to show that measurement of the OH stretching frequency, alone, is capable of giving detailed information regarding the nature of the OH group and the positions and configurations of neighbouring double bonds.

Primary alcohols: A and B type rotamers
Secondary alcohols: B and C type rotamers
Tertiary alcohols: C type rotamer

FIG. 1. Projection along the C—O bonds of alcohols at an sp^3 carbinol carbon atom, showing the three possible rotamer types for primary, secondary, and tertiary alcohols.

We recently described the influence of structural changes on the OH stretching vibrations of allylic and β–γ enols in dilute solution in CCl_4 (12, 13). It was shown that equilibria exist between conformations in which the OH proton is associated with the π system and those in which it is free. The relative abundances of these conformations differ appreciably from those found in the vapour state (14–22). The OH stretching frequencies and relative intensities of the OH bands are dependent upon the conformations, which in turn are influenced by substitution in the vicinity of the carbinol and olefinic carbons.

For OH groups substituted at an sp^3 carbon atom, three rotamers are possible, due to rotation about the C—O bond (Fig. 1). For the allylic and β–γ enols, only the B or C rotamers are sterically capable of associating with the π system.

FIG. 2. Generalized conformation of allylic alcohols.

Primary alcohols, R = H; secondary alcohols, R = alkyl
Conformation **i**. R′ = H; conformation **ii**. R′ = alkyl

FIG. 3. Projections along C3—C2 bond of β–γ enols, showing the lowest energy rotamers of the alkene group of β–γ enols in which intramolecular hydrogen bonding occurs.

Figure 2 shows the typical intramolecularly hydrogen bonded conformation for allylic alcohols. Thus the allylic alcohols usually exhibit a composed OH stretching vibration band, which can be resolved into two bands by bandsplitting techniques (13). Typical OH stretching vibration frequencies are given in Table 1. The β–γ enols possess two types of intramolecularly hydrogen bonded conformations (**i** and **ii**, Fig. 3), which are mutually exclusive. Substitution at the β carbon atom determines which conformation is adopted (12).

In contrast with the allylic alcohols, the intensity ratios of free and bonded OH conformations are far more dependent upon the alkyl chain length and also upon the primary, secondary, or tertiary nature of the carbinol carbon. Unlike the allylic alcohols, it is possible for the A, B, and C type OH rotamers to exist in the free OH form. The OH stretching frequencies of these free OH rotamers are almost identical to the saturated analogues (Table 1). Therefore the OH stretching frequencies and relative intensities can be used to easily distinguish between α–β enols, β–γ enols, and saturated alcohols.

A large number of naturally occurring hydroxy monoterpenes possess unsaturation at the α–β or β–γ positions, frequently in conjunction with unsaturation further removed. Similarly, many pheromones of the sex attractant type are enolic, the position of saturation being somewhat variable. Such molecules may be primary, secondary, or tertiary alcohols. Based on results obtained so far, the use of the OH stretching frequency bands alone should be able to give detailed information regarding the configuration and conformation of certain structural elements that may be contained within the molecule. It is therefore useful to extend the study of the OH–π system interaction to a diverse variety of enolic natural compounds (Table 2), for the purpose of structural unit identification.

Experimental

The alcohols **1**–**12** were obtained commercially (**1**–**9** and **11**, Aldrich; **10**, Sigma); **13** was provided by Dr. L. Jirovetz, Institute for Organic Chemistry, University of Vienna. Trace water was removed with molecular sieves (3A). Infrared spectra were recorded for dilute (<0.004 M) solutions in CCl_4 (Merck) on a Perkin Elmer 1800 FT-IR spectrometer using 1-cm Infrasil quartz cells, resolution 1 cm^{-1}, number of scans 18. Accuracy is believed better than $+/-0.5$ cm^{-1}. Solvent subtraction was performed on a Perkin Elmer 7500 data station. Perkin Elmer interaction self-enhancement software was employed on the data station. The enhancement does the equivalent of a Fourier deconvolution by an operation that acts directly on the frequency spectrum. This convolution routine replaces each point in the spectrum with a weighted average of neighbouring points. The procedure is similar to smoothing, except that the coefficients for the weighted average are calculated to cause line narrowing. The

coefficients used depend upon the values selected for two parameters "WIDTH" and "FACTOR".

Results and discussion

The OH stretching frequencies of various unsaturated alcohols **1–13** are shown in Table 2. The structural relationships of the alcohols are shown in Fig. 4 and the observed spectra in the OH stretching region are shown in Fig. 5.

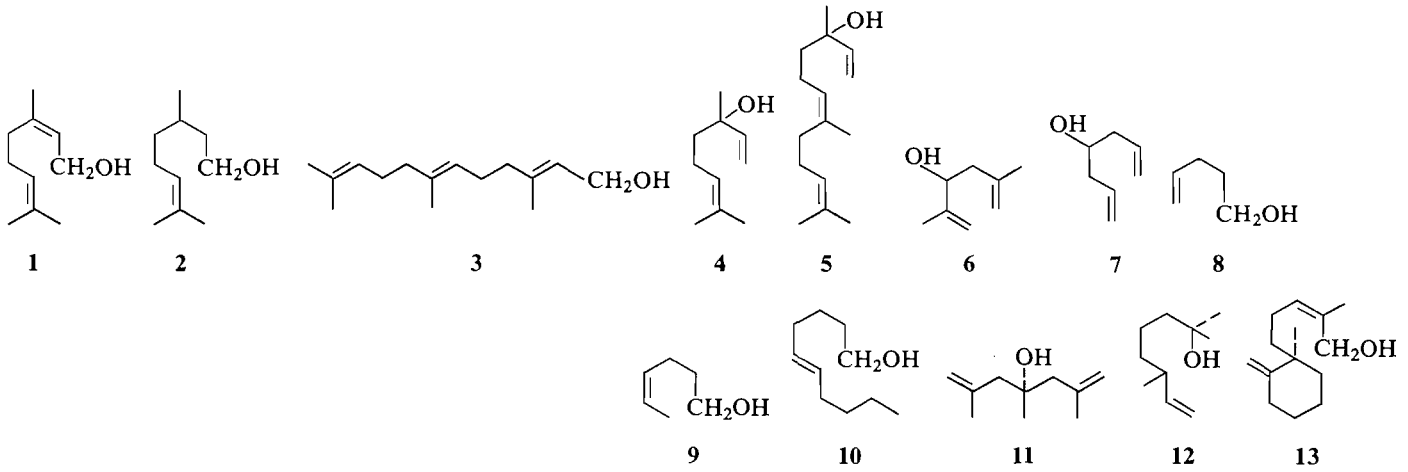
Correlations with α–β and (or) β–γ OH stretching frequencies

Compounds 1–3, 12, and 13

1 and **3** clearly possess a primary OH and a double bond at the α–β position, the A (free) and B (bonded) rotamer bands having typical frequencies and intensities. **2** does not possess α–β unsaturation and accordingly exhibits A (free) and B (free) OH rotamers. **1**, **2**, and **3** possess a double bond at the ε–ζ position. However, only alcohols **1** and **2** exhibit a band that could be correlated to an intramolecular association between the OH proton and the π system at an ε–ζ position. The frequency of this band is very similar in each alcohol (3552.0 cm^{-1} and 3550.5 cm^{-1}), although its intensity is greater in **1** than in **2**. In **3** (Fig. 4), the configuration of the α–β double bond is *trans*, while that of **2** is *cis*. Consequently it is impossible for the OH proton of **3** to interact with the π system at the ε–ζ position.

The difference in intensity of the band due to the ε–ζ double bond interaction with the OH proton is the result of the larger number of degrees of rotational freedom that **2** possesses compared with **1**. The presence of the double bond at the α–β position reduces the number of degrees of rotational freedom, making an interaction with the π system more probable. Thus the relative intensity of this band between the two alcohols is a function of the entropy of the systems. **13** possesses an α–β double bond; accordingly, the OH stretching frequencies are typical for the A (free) rotamers and B (bonded) rotamer. The π system present in the norbornyl skeleton is sterically hindered from an interaction with the OH proton.

The OH stretching frequency of **12** is typical of a saturated tertiary alcohol; the band cannot be resolved by self-enhancement, since the A/B (free) and C (free) OH rotamers are separated by too-small frequency differences. There is no band present that can be correlated with an association between the OH proton and the π system substituted at the ε–ζ position. The presence of five single bonds between the carbinol carbon and the double bond has a large entropy effect in favour of the free OH conformations. Consequently, no interaction between the OH proton and the π system can occur.



Compounds 4 and 5

The OH stretching frequencies of **4** and **5** correspond to those of a tertiary alcohol in which a C rotamer is intramolecularly hydrogen bonded with a double bond at the α–β position. In addition, another band is present for both alcohols, which can be attributed to the interaction of the OH proton with the double bond at the γ–δ position. The OH stretching frequencies are similar (3539.5 cm^{-1} and 3544.0 cm^{-1}). Inspection of the structures of **4** and **5** shows that the molecule **4** is a structural unit contained within the molecule **5**. In addition to this unit, **5** possesses another structural unit containing a double bond. Evidently, this double bond is too far away from the OH proton to be involved in a hydrogen bonding interaction.

Compounds 6 and 7

7 possesses OH stretching bands due to B (free) and B (bonded) rotamers, the latter being due to an interaction with the double bond at the β–γ position. The frequency of 3590.5 cm^{-1} indicates that there is no substitution at the β carbon. The presence of two β–γ double bonds cannot be proved, but can be inferred from the much lower than normal relative intensity of the free secondary OH rotamer. Thus an entropy effect is responsible for the increased relative intensity of the intramolecularly hydrogen bonded OH band.

6 has an OH stretching band at 3616.0 cm^{-1}, slightly lower than the normal frequency for a tertiary rotamer that is hydrogen

FIG. 4. The structural relationships of compounds **1**–**13**.

bonded to an α–β double bond. The OH band due to the interaction of the OH proton with the β–γ double bond occurs at a frequency of 3573.5 cm^{-1}. Taking into consideration the methyl substitution at the β carbon, we would anticipate an OH stretching frequency in the range 3581.0–3586.0 cm^{-1}. Evidently the usual rotamer positions are somewhat perturbed by repulsive forces between the two π systems. This lowering of the OH stretching frequencies is therefore of help in the identification of two π systems that, due to their proximity, apparently perturb the usual rotamer positions.

Compound 11

11 possesses an OH group placed symmetrically between two β–γ double bonds. No recent data for tertiary β–γ enols is available, therefore this data must be treated as empirical. Two OH bands have been resolved, as 3611.0 cm^{-1} and 3568.0 cm^{-1}. The proximity of the two π systems results in a considerable interaction between them, which would be expected to influence the conformation in two ways: (*i*) The double bonds will orientate themselves so that the *p* orbitals of each are, as far as possible, directed away from each other. (*ii*) Orientation of the OH group will be to minimize the lone pair – π system repulsion and to optimize the OH proton – π system attraction.

On the basis of our previous knowledge, we presume that the OH band at 3611.0 cm^{-1} is due to a free OH rotamer, while the band at 3568.0 cm^{-1} must be due to a bonded OH rotamer, although the rotamer positions are difficult to assign from the limited data.

Compounds 8–10

Structurally, **8** and **9** are very similar; both are primary alcohols with a double bond at the γ–δ position. The only difference between the two is the substitution of a methyl for a hydrogen at the δ carbon in **9**. Both alcohols show rotamer bands due to free primary and secondary OH rotamers. In addition, however, **7** possesses a band of very low relative intensity at 3592.0 cm^{-1}, which can only be attributed to an interaction of the OH proton with the π system. The absence of this band in **9** must be due to the presence of the methyl group at the δ carbon.

The very low relative intensity of the band at 3592.0 cm^{-1} suggests that this conformation is of very low relative population, i.e., it is highly unfavoured relative to the free OH conformations. The additional steric interactions that are created on substitution of a methyl group at the δ carbon are apparently sufficient to reduce the population of intramolecularly hydrogen bonded conformations to undetectable concentrations.

10 possesses a double bond at the δ–ε position and, like **9**, shows OH stretching bands that are typical of saturated alcohols. The π system is therefore too far removed to interact with the OH proton.

For primary alcohols, the double bond at the γ–δ position seems to be the limit of the distance between the OH group and the π system. The formation of the intramolecular hydrogen bond in this system represents the formation of a 6- or 7-membered ring depending upon the site of interaction of the OH proton with the π system. As explained above, the entropy of this system is reduced if double bonds are present intermediate between the OH group and the distal π system.

Conclusions

The OH stretching vibration frequencies of unsaturated alcohols can provide detailed information regarding the nature, position, and rotational conformation of the OH group and its steric relation to the double bonds.

Long-range interactions between the OH proton and the π system can in certain instances be used to determine exactly the

positions of unsaturation and, frequently, the proximity of two π systems. As a consequence of the "short"- and "long"-range hydrogen bonding interaction of the OH proton with the π system, the conformations of the molecules as shown in Fig. 3 are in many cases misleading. Conformations in which the OH is associated with the π system and those in which the OH is free are of course in an equilibrium, the predominant conformation being dependent upon the nature and position of substituted alkyl groups. For alcohols containing more than one π system, a number of distinct intramolecularly hydrogen bonded species are in equilibrium with the free OH forms. It is therefore necessary to undertake a detailed spectroscopic study, to establish the minimum energy conformations. It has been shown, however, that the "standard" data presented in Table 1, and extended in Table 2, can be used for the structural elucidation of unsaturated alcohols.

Limonoids from the Fijian medicinal plant *Dysoxylum richii*

MADHU K. JOGIA[1] AND RAYMOND J. ANDERSEN[2]

Departments of Chemistry and Oceanography, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received August 5, 1988

MADHU K. JOGIA and RAYMOND J. ANDERSEN. Can. J. Chem. **67**, 257 (1989).

Three new limonoids have been isolated from the Fijian medicinal plant *Dysoxylum richii*. Dried *D. richii* leaves collected at Suva yielded the known limonoid dysoxylin (**1**) as well as the previously unreported dysoxylone (**2**). A Taveuni collection of leaves contained the two new metabolites tigloyldysoxylin (**3**) and 6α-acetoxyobacunol acetate (**4**). The structures of all three new compounds were determined by spectroscopic analysis.

Key words: *Dysoxylum richii*, limonoid, dysoxylone, tigloyldysoxylin, 6α-acetoxyobacunol acetate.

MADHU K. JOGIA et RAYMOND J. ANDERSEN. Can. J. Chem. **67**, 257 (1989).

On a isolé trois nouveaux limonoïdes à partir de la plante médicinale Fidjienne *Dysoxylum richii*. On a récolté des feuilles séchées de *D. richii* à Suva et elles ont fourni le nouveau limonoïde dysoxyline (**1**) ainsi qu'un autre qui n'avait pas été rapporté antérieurement, la dysoxylone (**2**). Une collection de feuilles de Taveuni contenait deux nouveaux métabolites : la tygloyldysoxyline (**3**) et l'acétate de l'acétoxy-6α obacunol (**4**). On a déterminé les structures des trois nouveaux composés en faisant appel à des analyses spectroscopiques.

Mots clés : *Dysoxylum richii*, limonoïde, dysoxylone, tygloyldysoxyline, acetate de l'acétoxy-6α obacunol.

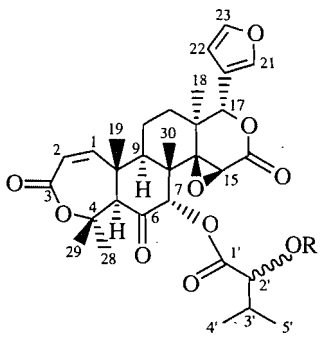
Introduction

The leaves of *Dysoxylum richii* (Gray) C.D.C. are used by natives of Fiji for medicinal purposes. A drink made by adding chopped *D. richii* leaves to a little boiling water is considered to be a cure for most aches and pains (1). We have investigated the extracts of *D. richii* as part of a survey of the chemical constituents of Fijian plants (2). From an initial collection of plant material, made at Suva in December 1985, we isolated dysoxylin (**1**), a new limonoid (3). A subsequent collection of *D. richii* leaves, made at Suva in December 1987, contained dysoxylin (**1**) and a second new limonoid dysoxylone (**2**), while a July 1987 collection of *D. richii* leaves from Taveuni contained the two new limonoids tigloyldysoxylin (**3**) and 6α-acetoxyobacunol acetate (**4**). The structures of the new metabolites **2**, **3**, and **4** are reported here.



Dysoxylone (**2**) was obtained as an amorphous white solid (mp 203–207°C) that gave a parent ion in the HREIMS at *m/z* 570.2450 daltons appropriate for a molecular formula of $C_{31}H_{38}O_{10}$ (ΔM −1.5 mmu). The ^1H (Table 1) and ^{13}C (Table 2) nmr spectra of dysoxylone (**2**) showed a number of similarities to the data reported for obacunol (**5**) (4) and obacunone (5), suggesting that all three molecules possess the same tetranortriterpenoid carbon skeleton as well as the same ring A, ring D, and furan functionalities. These readily identifiable fragments accounted for 26 of the 31 carbon atoms and six of the 10 oxygen atoms in the molecular formula of dysoxylone (**2**). An OH stretching band at 3400 cm^{-1} in the ir spectrum of **2** indicated that at least one of the remaining oxygen atoms was an alcohol. Dysoxylone (**2**) formed a monoacetate **6** upon treatment with acetic anhydride and pyridine. The ^1H nmr spectrum of the monoacetate revealed that one of the methine resonances had undergone an acetylation shift (δ 4.21 in **2**; δ 4.73 in **6**) consistent with the presence of a secondary alcohol in **2**. It was possible to identify the functionality containing the remaining three oxygen atoms from the ^{13}C nmr data (Table 2). Resonances at δ 165.7, 166.7, and 173.7 were assigned to ester carbonyl carbons and a resonance at δ 203.0 was assigned to a ketone carbonyl carbon. Two of the esters could be accounted for by the ring A and ring D lactones. Together, the remaining ester and the ketone accounted for the final three oxygen atoms in **2**.

part of a 2-hydroxy-3-methylbutanoate fragment. Irradiation of the carbinol methine resonance at δ 4.21 (H2′) simplified the complex multiplet at δ 2.1 (H3′) to a septet ($J = 7$ Hz) and irradiation of either of the methyl doublets at 0.98 and 1.08 (Me4′ and Me5′) simplified the multiplet at δ 2.1 (H3′) to a quintet ($J = 7$ Hz). A SINEPT experiment, optimized for polarization transfer through a $J_{C,H}$ of 7 Hz, demonstrated a two-bond coupling between the methine proton at δ 4.21 (H2′) and the ester carbonyl carbon at δ 173.7 (C1′).

A series of nOe experiments facilitated a complete assignment of the ^{1}H nmr spectrum of dysoxylone (**2**) and established the locations of the ketone functionality and the 2-hydroxy-3-methylbutanoate fragment. Irradiation of the methyl resonance at δ 1.22, assigned to Me19, induced nOe's into the olefinic resonance at δ 6.20 (H1), the methyl resonance at δ 1.12 (Me30), and the methyl resonance at δ 1.56 (Me29). Irradiation of the Me29 resonance at δ 1.56 induced nOe's into the C19 methyl resonance at δ 1.22 and into a methyl resonance at δ 1.37 assigned to Me28. Irradiation of the Me28 resonance (δ 1.37) induced a strong nOe into a methine singlet at δ 3.85 assigned to H5. The lack of coupling to the H5 resonance and its downfield chemical shift relative to the corresponding resonance in dysoxylin (**1**) (δ 3.85 in **2**; 3.01 in **1**) were consistent with the placement of the ketone functionality at C6 in dysoxylone (**2**). Irradiation of H5 (δ 3.85) in a SINEPT experiment showed polarization transfer to C4 (δ 81.5), C10 (δ 50.4), and C6 (δ 203.0) in agreement with the proposed arrangement of functionality. A strong nOe between the C30 methyl resonance at δ 1.12 and a methine singlet at δ 4.12 (H7β) suggested that the 2-hydroxy-3-methylbutanoate fragment was attached in the α orientation at C7. The nOe's between H7 (δ 4.12) and H15 (δ 3.51), between H2′ (δ 4.21) and H15 (δ 3.51), and between H2′ and H5 (δ 3.85) were consistent with the expected spatial proximities resulting from the attachment of the butanoate fragment at C7α. Finally, irradiation of the resonance at δ 2.92 (H9, dd, $J = 4$, 11 Hz) induced nOe's into H5 (δ 3.85) and into a methyl singlet at δ 1.32, which could then be assigned to Me18. The proposed structure **2** for dysoxylone effectively accommodates all the observed spectral data.

Tigloyldysoxylin (**3**) was obtained as a white solid that showed a parent ion in the HREIMS spectrum at m/z 552.2356 daltons appropriate for a molecular formula of $C_{31}H_{36}O_9$(ΔM −0.4 mmu). The similarity between the ^{1}H and ^{13}C nmr data recorded for tigloyldysoxylin (**2**) (Tables 1 and 2) and the nmr data previously found for dysoxylin (**1**) immediately suggested that **3** was simply a C7 acylated derivative of dysoxylin (**1**) (H7: δ 3.64 in **1**; δ 5.12 in **3**). Mass spectral fragments at m/z 453.1900 ($C_{26}H_{29}O_7$: ΔM −1.3 mmu) and 452.1866 ($C_{26}H_{28}O_7$: ΔM +3.1 mmu) daltons supported this assumption and, in conjunction with a companion fragment ion at m/z 83 daltons, revealed that acyl group had a formula of C_5H_7O. An olefinic methine resonance at δ 6.88 (qq, J = 1.5, 7 Hz, H3′) and two olefinic methyl resonances at δ 1.81 (dq, J = 7, 1 Hz, Me4′) and δ 1.88 (dq, J = 1.5, 1 Hz, Me5′) along with ^{13}C resonances at δ 127.8 (C2′), 139.1 (C3′), 14.7 (C4′), and 12.4 (C5′) demonstrated that **3** was a tiglate ester of dysoxylin (7). We used nOe, ^{1}H double resonance, and HETCOR experiments to assign the ^{1}H and ^{13}C nmr spectra (Tables 1 and 2) and to confirm the proposed structure of tigloyldysoxylin (**3**). All the data were consistent wih the proposed structure. In particular, irradiation of H7 (δ 5.12) induced nOe's into the H15 (δ 3.80) and Me30 (δ 1.18) resonances, as expected for an acylated derivative of dysoxylin.

6α-Acetoxyobacunol acetate (**4**), obtained as a very unstable

white amorphous solid, gave an unsatisfactory EI high resolution mass spectrum. The largest ion in the spectrum appeared at a mass of m/z 433.2209 daltons, corresponding to an elemental composition of $C_{24}H_{33}O_7$ (ΔM −1.7 mmu). It was apparent from the ^1H and ^{13}C nmr spectra of **4** (Table 1 and Experimental) that the molecule was a limonoid whose structure was closely related to obacunol (**5**) and dysoxylin (**1**). It was clear, therefore, that the ion at m/z 433 could not be a parent ion. A common mass spectral fragmentation pathway in all limonoids of this general structure leads to relatively intense $M^+ - 123$ ($C_6H_3O_3$) peaks (8). We assumed that the formation of the m/z 433 ion occurred via this pathway and therefore concluded that the molecular formula of **4** was $C_{30}H_{36}O_{10}$. The ^1H and ^{13}C nmr data recorded for **4** (Table 1 and Experimental) were in complete agreement with this conclusion.

Two deshielded methyl singlets at δ 2.01 and 2.15 in the ^1H nmr spectrum (Table 1) indicated that **4** was a diacetate. A series of three methine resonances at δ 2.64 (d, J = 12.4 Hz), 5.12 (dd, J = 12.4, 2.4 Hz), and 4.92 (d, J = 2.4 Hz) could be assigned to H5α, H6β, and H7β by comparison of their coupling constants to those observed for the same spin system in dysoxylin (**1**) (Table 1). The downfield shifts of H6 (δ 5.12 in **4**; 4.01 in **1**) and H7 (δ 4.92 in **4**; 3.64 in **1**) in **4** relative to their positions in **1** suggested that the oxygen atoms at C6 and C7 had been acetylated. The upfield shift of H15 in **4** (δ 3.63) relative to its position in obacunol (**5**) (δ 3.84) parallels the upfield shift of H15 in dysoxylin acetate (δ 3.69) (3) relative to its position in dysoxylin (**1**) (δ 3.95), offering further evidence of acetylation at C7. The remainder of the ^1H (Table 1) and ^{13}C (Experimental) nmr data was in complete agreement with the proposed structure **4**. 6α-Acetoxyobucanol (**4**) is closely related to surenin (**7**), which was isolated from leaves of *Toona sureni* (9).

The three new limonoids reported here were isolated from *D. richii* at two different locations in Fiji and at different times of the year. Further work is in progress to determine the extent of geographical and seasonal variation in the limonoid content of Fijian specimens of *D. richii*.

Experimental

The nmr spectra were recorded on Varian XL 300 and Bruker WH 400 spectrometers. Tetramethylsilane was used as an internal standard. Low resolution mass spectra were recorded on an AEI MS 902 spectrometer and high resolution mass spectra were recorded on an AEI MS 50 spectrometer. Infrared spectra were recorded on a Perkin–Elmer 1710 Fourier transform spectrometer. Merck silica gel 230–400 mesh was used for flash chromatography and Whatman Magnum-9 Partisil-10 and ODS-3 columns were used for preparative hplc. Sephadex LH 20 was used for molecular exclusion chromatography.

Isolation and extraction

Fresh leaves of *Dysoxylum richii* were collected at Suva and Taveuni, Fiji, in December and July 1987 respectively. A voucher specimen of this plant has been deposited at the South Pacific Regional Herbarium, Institute of Natural Resources, University of the South Pacific, Suva, Fiji.

Air-dried leaves (300 g) were soaked in methanol (1.5 L) for 3–5 days, the methanol extract was concentrated *in vacuo* to a gum, water was added, and the resulting suspension was extracted successively with hexane and chloroform. The chloroform layers were concentrated *in vacuo* and the residue was dissolved in ethyl acetate and stirred with alumina to decolorize it. Filtration of the suspension and evaporation of the ethyl acetate filtrate gave a gum (approximately 4 g). Fractionation of the gum by silica gel flash chromatography (step gradient: hexane to ethyl acetate) gave fractions containing crude dysoxylin (**1**) and dysoxylone (**2**) from the Suva collections, and fractions containing crude tigloyldysoxylin (**3**) and 6α-acetoxyobacunol acetate (**4**) from the Taveuni collections. Final purification of all four limonoids was accomplished by normal phase hplc (7:3 ethyl acetate/hexane).

Dysoxylone (**2**): white amorphous solid (yield, 0.003% dry wt.); mp 203–207°C; $[\alpha]_D^{25}$ −10° ($CHCl_3$, c 0.3); ir ($CHCl_3$): 1748, 1720, and 1685 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; HREIMS, M^+: 570.2450, $C_{31}H_{38}O_{10}$ (ΔM −1.5 mmu); LREIMS, m/z (rel. intensity): 570(1), 527(4), 358(20), 329(100), 143(76), 95(29), 55(57), 43(89).

Dysoxylone acetate (**6**): Dysoxylone (**2**) (3 mg) was stirred overnight at room temperature with pyridine (0.5 mL) and acetic anhydride (0.3 mL). Evaporation of the acetylation reagents *in vacuo* gave dysoxylone acetate (**6**) as a gum; ^1H nmr ($CDCl_3$) δ: 7.43 (m, 2H), 6.34 (d, J = 1 Hz), 6.19 (d, J = 12.9 Hz), 5.91 (d, J = 12.9 Hz), 5.58 (s), 4.73 (d, J = 6 Hz), 4.02 (s), 3.97 (s), 3.50 (s), 2.98 (dd, J = 11.4 Hz), 2.15 (s), 1.54 (s), 1.37 (s), 1.32 (s), 1.21 (s), 1.09 (s), 1.07 (d, J = 7 Hz), 1.05 (d, J = 7 Hz); HREIMS, M^+: 612.2569, $C_{33}H_{40}O_{11}$ (ΔM −0.3 mmu); LREIMS, m/z (rel. intensity): 612(0.5), 569(0.2), 469(2), 358(5), 329(36), 143(53), 115(52), 43(100).

Tigloyldysoxylin (**3**): amorphous white solid (yield, 0.1% dry wt.); mp 200–205°C; $[\alpha]_D^{25}$ +26° ($CHCl_3$, c 0.4); ir ($CHCl_3$): 1745, 1715, and 1695 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; HREIMS, M^+: 552.2356, $C_{31}H_{36}O_9$ (ΔM −0.4 mmu); LREIMS, m/z (rel. intensity): 552(1), 453(2), 429(2), 329(26), 95(27), 83(100), 55(86).

6α-Acetoxyobacunol acetate (**4**): amorphous white solid (yield 0.04% dry wt.); mp 236–238°C; ir ($CHCl_3$): 1745, 1700, and 1235 cm^{-1}; ^1H

A total synthesis of a protected form of the secoxyloganin aglucone[1]

PETER T. W. CHENG AND STEWART MCLEAN
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 5, 1988

PETER T. W. CHENG and STEWART MCLEAN. Can. J. Chem. **67**, 261 (1989).

A synthesis is described that leads from cyclopentadiene through 5-norbornen-2-one to the monosubstituted cyclopentenone **5**; a vinyl substituent is attached by the reaction of a cuprate, and the enolate intermediate is trapped as the silyl enol ether **4**, which is converted to **19**, a product with the 10-carbon framework and stereochemistry of the secoxyloganin aglucone, and with all functional groups differentially protected and in the correct oxidation state. Explorations of the cuprate reaction required to convert the cyclopentenone **5** to the siloxycyclopentene **4** and of the reactions required for the oxidative cleavage of **4** reveal problems with these reactions when they are applied to compounds that are cyclopentane derivatives. The resolution of these problems leads to reaction sequences that proceed with high yields and excellent diastereoselectivity.

Key words: synthesis, secoxyloganin, vinyl cuprate, oxidative cleavage.

PETER T. W. CHENG et STEWART MCLEAN. Can. J. Chem. **67**, 261 (1989).

On décrit une méthode de synthèse qui conduit du cyclopentadiène à la cyclopenténone **5** en passant par la norbornène-5 one-2. On attache un substituant vinyle par le biais de la réaction d'un cuprate et on procède au piégeage de l'intermédiaire énolique sous la forme de l'éther énolique silylé **4** qui est ensuite transformé en produit **19**, un produit comportant le squelette à 10 atomes de carbone et la stéréochimie de l'aglycone de la secoxyloganine ainsi que tous les groupements fonctionnels dans l'état d'oxydation approprié et protégés de façons différentes. Afin d'explorer la réaction avec le cuprate, il s'est avéré nécessaire de transformer la cyclopenténone **5** en siloxycyclopentène **4**; par ailleurs, un examen des réactions nécessaires pour réaliser le clivage oxydant du composé **4** révèle que ces réactions donnent lieu à des problèmes lorsqu'on les applique à des dérivés cyclopentaniques. La solution de ces problèmes a permis d'établir une séquence de réactions qui conduit à des rendements élevés et à une excellent diastéréosélectivité.

Mots clés : synthèse, secoxyloganine, cuprate vinyle, clivage oxydant.

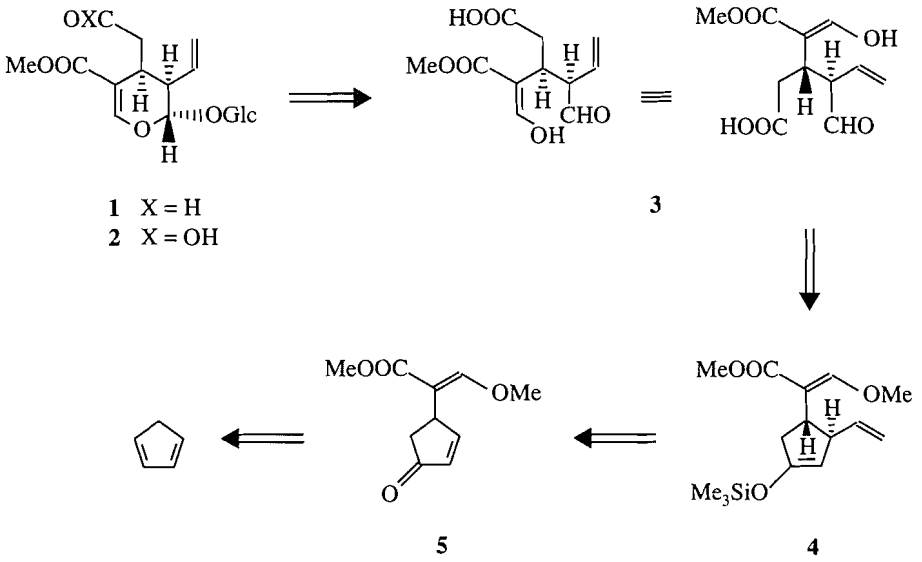
The central role of the secoiridoid secologanin (**1**) in the biosynthesis of several families of alkaloids was predicted and demonstrated about 20 years ago by Battersby *et al.* (1), who had prepared it from menthiafolin. Its direct isolation from a plant source soon followed (2). Many subsequent studies served to confirm the unique position of secologanin as the last non-nitrogenous precursor in the biosynthesis of a vast array of alkaloids (3). Although its importance has been recognized for a considerable length of time, no total synthesis of secologanin has yet been reported. The dense array of functional and stereochemical centres in a relatively small molecule presents obvious synthetic difficulties; there are, for example, four aldehyde or crypto-aldehyde centres, two of which are chiral. A less obvious difficulty is the instability of the aglucone, which undergoes a series of rearrangements under extremely mild conditions (3). Two syntheses of a protected form of the aglucone (4, 5) and a synthesis of a rearranged form of the aglucone (6) have been reported. Although much progress has been made in developing highly selective glucosidation reactions (7), no report of the glucosidation of the fragile secologanin aglucone has yet appeared.



The strategy we chose in our synthetic approach to secologanin set the aglucone of the iridoid secoxyloganin (**2**) as the first target. The aglucone, shown in its acyclic form (**3**), has all of the required functionality suitably differentiated and incorporates the stereochemical information that is crucial for further synthetic development. Besides being a precursor to the iridoids, **3** itself provides the proper ten-carbon unit corresponding to the secologanin-derived portion of a range of alkaloids, and its differentiated functionality could be used to couple it with tryptamine, for example, and open a synthetic route to the indole alkaloids of the Corynanthé–Strychnos biosynthetic group. Retrosynthetic logic (Scheme 1) shows that it should be possible to synthesize **3** in three stages from readily available starting materials derived from cyclopentadiene. In essence, in the synthesis two side chains, one equivalent to a formylacetate unit and the other a vinyl group, are to be attached to a cyclopentanoid framework and the five-membered ring is to be opened oxidatively.

Synthesis of the monosubstituted cyclopentenone 5

Ideally, the formylacetate unit should be incorporated intact. A slight modification of Trost's palladium-catalyzed reaction of dimethyl malonate with cyclopentadiene monoepoxide (8) provided the diester **6** in 90% yield. The corresponding reaction with the *N*,*N*-dimethylhydrazone of methyl formylacetate gave **7** with the side chain at the correct oxidation level, but the yield was only 47% and, in the next step, all attempts to oxidize the allylic alcohol selectively to the corresponding cyclopentenone failed. Attempts to achieve a selective partial reduction of diester **6** also failed, and it became apparent that the plan to introduce an intact formylacetate unit would have to be abandoned in favor of a stepwise process. It was possible to monodecarbomethoxylate the diester under the Krapcho conditions (9) after the hydroxyl group had been protected. The yield of monoester **8** was excellent, but an alternative route to **8** through 5-norbornen-2-one (**9**) was experimentally more convenient for scaling up. Moreover, since both enantiomers of **9** may be prepared from cyclopentadiene by the use of chiral dienophiles, this route can readily be adapted to the synthesis of compounds with either the natural or the unnatural configuration.

The Baeyer–Villiger oxidation of a norbornenone to provide intermediates corresponding to **8** has been a key reaction in several syntheses (10–12). The well-recognized difficulty with

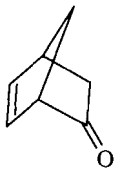
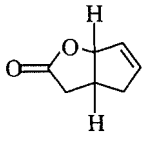


SCHEME 1

the reaction is that the oxidation product forms the rearranged lactone **10** (13) with extreme ease once the free hydroxy acid is liberated. The Baeyer–Villiger oxidation must, therefore, be carried out with alkaline peroxide; Le Drian and Greene (12) avoided forming the free acid by using an alkylating agent to trap the carboxylate ion. In our hands, however, the methyl ester was best prepared by very careful acidification of the intermediate followed by immediate treatment with diazomethane. Some of the lactone **10** inevitably formed, but the ester **8** could be obtained from the norbornenone in yields of about 45% on a preparative scale.



The hydroxyl group of **8** had to be protected before the C-formylation step, and the choice of protecting group proved to be critically important. One limiting factor was the extreme susceptibility of the cyclopentenol derivatives to rearrangement and elimination reactions under acidic conditions. The tetrahydropyranyl (THP) derivative was readily prepared, but it did not react with methyl formate when lithium diisopropylamide (LDA), even in excess, was used as the base. Suppression of the expected reaction in related cases has been attributed to a "complex-induced proximity effect" (14); the complex formed by LDA and the THP group sterically inhibits deprotonation of the ester by further LDA. The *tert*-butyldimethylsilyl ether was readily C-formylated by methyl formate and one equivalent of LDA, but attempts to desilylate in a later step led to decomposition of the molecule. The ethoxyethyl (EE) derivative did not react with methyl formate when one equivalent of LDA in the presence of hexamethylphosphoramide (HMPA) was used as base, but the simple expedient of using two equivalents of LDA led to a successful reaction. The complex with the first equivalent of LDA may have formed as in the THP case, but not have been bulky enough to inhibit the deprotonation step. The C-formylated compound was immediately treated with dimethyl sulfate and potassium carbonate, and the product was isolated in 80% yield for the two steps as a 10:1 mixture of *E* and *Z* isomers. These were separated, and only the *E* isomer (**11**) was carried forward. Treatment with pyridinium *p*-toluenesulfonate in acetone at room temperature removed the EE group, but even here extreme care was required to prevent degradation. Oxidation to the desired cyclopentenone **5** was carried out with pyridinium dichromate in the presence of 4-A molecular sieves in ethyl acetate.

11

Stereoselective attachment of the vinyl side chain

The first major stage of the projected synthesis, the construction of the cyclopentenone carrying a protected formylacetate side chain, was complete, and **5** was available in an overall yield of 13% from the norbornenone. The next stage of the synthesis required the introduction of the vinyl side chain by a cuprate reaction and trapping of the enolate formed with a silylating agent. Reactions of this type have recently received a considerable amount of attention in several laboratories. We undertook first to explore some of the variants of the reaction. Oxidation of the cyclopentenol **8** provided **12**, which served as a model cyclopentenone; furthermore, the anticipated product (**13**) of the cuprate reaction of **12** offered a tactical variation for the synthetic plan, the possibility of carrying out the C-formylation step after both side chains had been introduced. Treatment of enone **12** with the cuprate derived from two equivalents of vinylmagnesium bromide and one equivalent of cuprous iodide, and then trapping the enolate with trimethylsilyl chloride in the presence of HMPA (15) provided **13** (R = SiMe$_3$) in 55% yield. It has recently become apparent that having the silylating agent present during the reaction with the cuprate can lead to enhanced

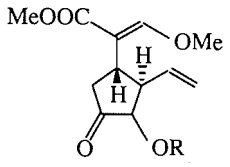
12 13

reaction rates, yields, and selectivity (16–19). When the enone **12** and an excess of trimethylsilyl chloride in tetrahydrofuran (THF) were added slowly to a solution of vinylmagnesium bromide and a catalytic amount of cuprous iodide in THF at −78°C, and 4-(dimethylamino)pyridine (DMAP) and triethylamine were then added sequentially, the yield of **13** was raised to 70% and no trace of a second stereoisomer could be detected by ^1H and ^{13}C nmr spectroscopy in **13** (R = $SiMe_3$) or in the ketone obtained by desilylation of **13**, and the ketone was homogeneous on gas chromatography. Much less satisfactory results were obtained if DMAP was not added.

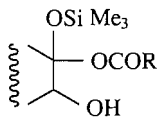
Attempts to prepare the analog **13** (R = $SiMe_2t$-Bu) by these methods with a more robust protecting group failed. We turned, therefore, to the use of cuprates derived from vinyllithium and, after a considerable amount of experimentation, found conditions suitable for the purpose. First, it was necessary to use very pure vinyllithium prepared from tetravinyltin (20). Of the various cuprous salts that have recently been recommended for preparing organocuprates, we found the cyanide (21) to be clearly the best for the present purpose. The "higher order" cuprate (21) prepared from two equivalents of vinyllithium and one equivalent of cuprous cyanide reacted readily at −78°C with enone **12** (the vinylated cyclopentanone could be isolated in 85% yield), but the enolate could not be trapped with *tert*-butyldimethylsilyl chloride unless DMAP was present along with HMPA and triethylamine; under the latter conditions, the product isolated in 75% yield was a 5:1 mixture of **13** (R = $SiMe_2t$-Bu) and its *cis* isomer. The ratio, determined by ^1H nmr spectroscopy, showed that the stereoselectivity had been relatively poor.

Neither **13** (R = $SiMe_3$) nor **13** (R = $SiMe_2t$-Bu) was successfully C-formylated, but the conditions developed for preparing **13** (R = $SiMe_3$), viz., the use of vinylmagnesium bromide, a catalytic amount of cuprous iodide (the preferred salt in this case), trimethylsilyl chloride, HMPA, and DMAP, successfully converted enone **5** to the trimethylsilyl enol ether **4**; yields varied from 75% to 100% and the stereoselectivity was practically complete since no trace of an isomer could be detected spectroscopically in the product or the ketone obtained on desilylation, and gas chromatography showed that the ketone was homogeneous.



Selective oxidative cleavage of 4

The final major operation of the synthesis required the selective oxidative cleavage of **4** to give **3**. In our original plan this oxidation was to be carried out stepwise by the use of a peracid to oxidize **4** to the hydroxy ketone **14** and then periodate to cleave **14**. To prepare for this operation, we explored oxidations of the model compounds of formula **13** and of silyl enol ethers of cyclopentanone itself, and problems soon became apparent. Peracids such as *m*-chloroperbenzoic acid (mCPBA) oxidize trimethylsilyl enol ethers derived from cyclohexanones (and other unstrained ketones) to the siloxy epoxides (22), which generally rearrange immediately to the α-siloxy ketones (23). However, when we treated trimethylsilyl enol ethers derived from cyclopentanones with mCPBA a mixture was obtained in which the *m*-chlorobenzoate ester of the α-hydroxycyclopentanone was the major component. Rubottom, Boeckman, and co-workers (24) have demonstrated that, under certain conditions, the reaction of the trimethylsilyl enol ether of cyclohexanone with mCPBA can be caused to give the *m*-chlorobenzoate of α-hydroxycyclohexanone. Their mechanistic rationale was that the peracid reacted with the enol ether to give the siloxy epoxide and *m*-chlorobenzoic acid, and the carboxylic acid then opened the epoxide to form an intermediate of type **15**; in the next step the silyl group normally migrates to the hydroxyl site and the carboxylic acid is eliminated, leading to the formation of the α-siloxy ketone. However, the alternative process, migration of the ester and elimination of the silanol, can become competitive under some conditions. Our results indicate that the second process, leading to an acyloxy ketone, is dominant even under standard reaction conditions when the substrates are cyclopentanone derivatives. It seems probable that the difference in the behavior of cyclohexanone and cyclopentanone derivatives has a steric explanation; if the acyloxy and hydroxy substituents in **15** are *cis* to each other on a five-membered ring, the acyl group can migrate much more easily than the silyl group. If the siloxy epoxide is, indeed, an obligatory intermediate, the formation of **15** with the acyloxy and hydroxy substituents *cis* to each other implies that the carboxylic acid has opened the epoxide by a synchronous process in which the oxygen is protonated and the incipient siloxycarbonium ion is carboxylated. Whatever the mechanism may be, our results showed that our proposed route to an α-hydroxycyclopentanone through the siloxy ketone was not available. Jones and Denmark (15) have noted briefly that peracid oxidations are not applicable to silyl enol ethers of cyclopentanones.



The careful oxidation of the trimethylsilyl enol ether of cyclopentanone with one equivalent of *tert*-butyl hydroperoxide in the presence of $MoO_2(acac)_2$ in benzene (26) provided α-(trimethylsiloxy)cyclopentanone in 55% yield, but this oxidizing system did not give satisfactory results with *tert*-butyldimethylsilyl enol ethers or, more importantly, with our key intermediate **4**.

In the light of our results with model systems, we undertook to oxidize the trimethylsilyl enol ether **4** with mCPBA and then seek conditions that would selectively hydrolyze the expected *m*-chlorobenzoate **16** to the hydroxy ketone **14**. However, mCPBA reacted extremely sluggishly with **4** under standard conditions, and very little of the expected product was obtained; hydrolysis of the silyl enol ether to the parent ketone appeared to be the main reaction. Increasing the relative amount of mCPBA in the reaction did not improve the yield of **16**, but a new product was isolated in 13% yield. This compound proved to be **17**, the Baeyer–Villiger oxidation product of **16**, and was extremely important for several reasons. First, the oxidative cleavage of **4** had been accomplished, and **17** was a protected form of the target compound **3**. Secondly, we could, for the first time, use ^1H nmr spectroscopy with confidence to confirm the stereochemistry assigned to intermediates on the reasonable expectation that the cuprate reaction of cyclopentenones such as **5** would lead stereoselectively to *trans* products such as **4**. The key vicinal coupling constants in the spectrum of **17** are $J_{a,b}$ = 11.5 Hz, showing that the side chains are *trans*-diequatorial, and $J_{b,c}$ = 2.7 Hz; since H_b is axial, the latter value must be an axial–equatorial coupling, and the ester substituent must,

14 R = H
16 R = *m*-ClC_6H_4CO
18 R = CH_3CO

15

5 **4**
17 R = *m*-ClC_6H_4
19 R = CH_3

consequently, be axial and *cis* to the vinyl group. The further coupling, J = 10.9 Hz, exhibited by H_b was shown to be with H_d in the vinyl side chain.

Because it seemed possible that the *m*-chlorobenzoic acid produced in the reaction was responsible for the poor yields obtained in the oxidation of **4** with mCPBA, we sought a peracid that would produce a weaker carboxylic acid. Peracetic acid is usually a less convenient oxidizing agent than mCPBA, but for the present purpose it proved to be clearly superior. Commercial 32% peracetic acid was first treated with sodium carbonate and sodium acetate to remove traces of mineral acid, and then it was used to oxidize the trimethylsilyl enol ether **4**. When one equivalent of peracetic acid was used, a single product, the α-acetoxy ketone **18**, was isolated in 63% yield. When the amount of peracetic acid was increased, two equivalents were consumed and the Baeyer–Villiger product **19** was obtained in 71% yield as the only isolable product. All of the spectroscopic properties of **19** are in accord with the assigned structure, and the ^1H and ^{13}C nmr spectra show that it is a single isomer. As was the case with **17**, its stereochemistry is confirmed by its ^1H nmr spectrum; the critical coupling constants for **19** are $J_{a,b}$ = 11.4 Hz (axial–axial) and $J_{b,c}$ = 2.9 Hz (axial–equatorial); $J_{b,d}$ = 8.7 Hz.[2] It may be noted that if the conversion of **18** to **19** is, indeed, a Baeyer–Villiger oxidation that proceeds with the normal retention of configuration, the complete stereochemistry of **18** is also defined. The spectroscopic properties of **18** were in accord with its being a single isomer. The same observations were made with the mCPBA oxidation products **16** and **17**, but the much inferior yields in that series made the corresponding conclusions less secure.

Products **17** and **19** are protected forms of the target aglucone **3**, incorporating the proper 10-carbon framework, differentially protected functional groups, and stereochemistry. The yield for the conversion of **5** to **19** was 55–60% (about 7.5% from the norbornenone precursor) and diastereoselectivity was extremely high. The material in hand is racemic, but the route is now available to synthesize both enantiomers starting from the corresponding enantiomer of the norbornenone **9** (12). A route leading towards natural or unnatural enantiomers of secoiridoids and alkaloids is, consequently, opened.

[2]Since **17** and **19** are lactones, they clearly cannot adopt a simple chair conformation. A consequence of the flattening of the molecule by the carbonyl group can be seen in the coupling constants of H_a with the two protons in the adjacent methylene group. These do not have the usual axial–axial and axial–equatorial values; e.g., in **19** their values are 7.8 and 8.9 Hz. Nevertheless, the $J_{a,b}$ and $J_{b,c}$ values clearly define the stereochemical relationship of the substituents.

Experimental

Infrared spectra were obtained on a Nicolet 5DX FT spectrometer with samples as liquid films; selected absorptions are reported in wavenumber units (cm^{-1}). The spectra were obtained with samples dissolved in $CDCl_3$; Varian T-60, XL-200, and XL-400 spectrometers were used for ^1H spectra, and chemical shifts (for 60-MHz spectra unless otherwise indicated) are reported on the δ_H scale, followed in parentheses with an abbreviation showing the multiplicity of the signal, J values in Hz units, and the number of protons assigned to the signal; Varian XL-200 and XL-400 spectrometers were used for ^{13}C spectra, and chemical shifts are reported on the δ_C scale, followed by (e) to show 0 or 2 attached protons or (o) to show 1 or 3 attached protons as determined by the Attached Proton Test (APT) (27). A VG 70-250S mass spectrometer was used to obtain mass spectra and exact mass measurements. Analytical gas–liquid chromatography was carried out on a Varian 3400 chromatograph with fused silica capillary columns coated with DBWax or OV101 and hydrogen as the carrier gas. Merck 40–60 μm (grade 60) silica gel was used for flash chromatography (28).

Pd-catalyzed reactions of cyclopentadiene monoepoxide (ref. 8)

Diester 6

A solution of dimethyl malonate (5.00 g; 37.8 mmol) in 20 mL of dry THF was deoxygenated with Ar and added to $Pd(PPh_3)_4$ (1.00 g; 0.87 mmol) contained under Ar in a thoroughly dried 50-mL 2-necked flash equipped with a rubber septum and an Ar inlet, and the mixture was cooled to −2°C. A solution of cyclopentadiene monoepoxide (7.50 g; 91.3 mmol) in 5 mL of dry THF was deoxygenated by four freeze–pump–thaw cycles, and then added dropwise over 25 min by syringe to the stirred reaction mixture. The flask was protected from light by Al foil, and after 20 min the solution was allowed to warm to room temperature. After it had been stirred for 12 h, the solution was poured into 50 mL of saturated brine, and the mixture was thoroughly extracted with ether. The extract was worked up to provide a residue, which was dissolved in ether and passed through a Florisil plug; flash chromatography (1:1 hexane – ethyl acetate) gave the hydroxy diester **6** (8) as an oil (7.33 g; 34.3 mmol); ir: 3420 (br), 1740; ^1H nmr: 1.28–3.44 (complex, 5H), 3.76 (s, 6H), 4.75 (m, 1H), 5.88 (s, 2H); ^{13}C nmr: 169.2 (e), 168.9 (e), 135.8 (o), 134.1 (o), 76.5 (o), 55.9 (o), 52.5 (o), 52.5 (o), 43.8 (o), 37.2 (e).

Dimethylhydrazone 7

The dimethylhydrazone of methyl formylacetate was prepared by

treating the dimethylhydrazone of acetaldehyde with LDA and then dimethyl carbonate. The product was a yellowish oil. This material (0.50 g; 3.47 mmol) in 2 mL of THF was treated with $Pd(PPh_3)_4$ (0.15 g; 0.13 mmol) and cyclopentadiene monoepoxide (1.50 g; 18.3 mmol) by the same procedure as above except that the reaction mixture was heated to reflux for 13 h. The product **7** (0.37 g; 1.64 mmol) was isolated as an unstable yellow oil; ir: 3410 (br), 1732; ^{1}H nmr: 1.27–3.33 (complex, 5H), 2.81 (s, 6H), 3.73 (s, 3H), 4.77 (m, 1H), 5.85 (m, 2H), 6.52 (m, 1H). *Exact Mass* calcd. for $C_{11}H_{18}O_3N_2$: 226.1317; found: 226.1314.

Methyl cis*-(4-hydroxy-2-cyclopenten-1-yl)acetate 8*

A solution of sodium hydroxide (5.68 g; 140 mmol) in 50 mL of water at 0°C was added to a cooled (0°C) solution of 5-norbornen-2-one (12.80 g; 119 mmol) in 50 mL of ether. Hydrogen peroxide (30% aqueous; 29 mL; 260 mmol) was added dropwise over 45 min to the vigorously stirred reaction mixture, which was maintained at 10–25°C. The mixture was stirred for a further 15 min, and then allowed to warm to room temperature. The aqueous layer was extracted with ether (3 × 25 mL), cooled to 0°C, and brought to pH 5 (pH paper) by dropwise addition of concentrated hydrochloric acid. Saturated aqueous sodium sulfite was cautiously added to the cooled solution to destroy excess peroxide. Ethyl acetate (50 mL) was added and the cooled (0°C) aqueous solution was brought to pH 3 by the addition of concentrated hydrochloric acid. The organic layer was separated, the aqueous layer was extracted with ethyl acetate (5 × 100 mL), and the combined organic layers were dried (Na_2SO_4) and concentrated at room temperature on a rotary evaporator to a viscous oil. The oil was dissolved in ether (100 mL), cooled to 0°C, and a cold ethereal solution of diazomethane was slowly added until a slight yellowish color persisted. Excess diazomethane was destroyed with acetic acid, the solution was washed with saturated $NaHCO_3$ (2 × 50 mL), dried (Na_2SO_4), and worked up. The product was flash chromatographed (2:1 hexane – ethyl acetate) and **8** (7.76 g; 54 mmol) was isolated as a clear mobile oil (11); ir: 3400 (br), 1734; ^{1}H nmr: 1.3–3.2 (complex, 6H), 3.65 (s, 3H), 4.77 (m, 1H), 5.80 (s, 2H).

The monosubstituted cyclopentenone 5

Pyridinium *p*-toluenesulfonate (2 g; 8 mmol) was added to a solution of the hydroxy ester **8** (7.76 g; 54 mmol) and ethyl vinyl ether (10.5 mL; 110 mmol) in dry dichloromethane at 0°C. The stirred reaction mixture was allowed to warm to room temperature and stirring was continued a further 4 h. The solution was diluted with 250 mL of ether, washed with 10% aqueous $NaHCO_3$ (3 × 50 mL), dried ($MgSO_4$), and evaporated to provide the EE derivative of **8** as an oil (9.83 g; 43 mmol). This material was used in the next step; in one run a sample was flash chromatographed (5:1 hexane – ethyl acetate) and a colorless liquid was obtained; ir: 1739; ^{1}H and ^{13}C nmr showed that the sample was a 1:1 mixture of diastereoisomers (epimeric in EE group).

The EE derivative (9.83 g; 43 mmol) in 20 mL of dry THF was added dropwise over 1 h to a stirred solution of LDA (prepared from *n*-butyllithium (116 mmol) and diisopropylamine (139 mmol)) in 120 mL of THF at −78°C under Ar. The solution was allowed to warm slowly (75 min) to −2°C, stirring was continued for 30 min more, and the solution was then recooled to −78°C. Methyl formate (13.0 mL; 210 mmol) in 10 mL of THF was added dropwise over 15 min, and the mixture was stirred at −78°C for 15 min, allowed to warm to −45°C over 15 min, stirred for a further 30 min, and then poured into 100 mL of ice-cold water. The aqueous phase was separated, extracted with ether (2 × 100 mL), acidified with concentrated hydrochloric acid, and reextracted with dichloromethane (4 × 50 mL). The combined organic extracts were dried (Na_2SO_4) and evaporated to afford the C-formyl derivative as a dark oil (19.5 g). The oil was dissolved in 150 mL of acetone, K_2CO_3 (20 g) and dimethyl sulfate (5.0 mL; 53 mmol) were added, and the suspension was stirred vigorously under Ar for 23 h. After filtration, the solution was concentrated on a rotary evaporator without heating, and the residue was partitioned between 200 mL of ether and 50 mL of water. The organic phase was washed with water (4 × 40 mL), dried ($MgSO_4$), and evaporated to a dark oil. Flash chromatography (3:1 hexane – ethyl acetate) of the oil provided two products: **11** (8.52 g; 31.6 mmol) was obtained as a yellowish oil (a mixture of EE epimers); ir: 1706, 1639; ^{1}H nmr (400 MHz): 1.17 (t, *J*, 7.1; 3H), 1.30 (d, *J*, 5.4; 3H), 1.74 (m, 1H), 2.50 (m, 1H), 3.46 (m, 1H), 3.6–3.7 (complex, 2H), 3.65 (s, 3H), 3.75 (s, 3H), 4.77 (m, 2H), 5.72 (m, 1H), 5.79 (m, 1H), 7.28 (s, 1H), ^{13}C nmr: 168.2 (e), 159.5 (o), 136.4 and 136.3 (o), 130.7 and 130.2 (o), 111.3 (e), 98.7 and 98.5 (o), 79.9 and 79.7 (o), 61.4 (o), 60.3 and 60.0 (e), 50.8 (o), 39.3 and 39.2 (o), 38.5 and 37.8 (e), 20.5 (o), 15.1 (o). The second product was the *Z* isomer of **11** (0.84 g; 3.1 mmol); ir: 1720, 1690, 1642; ^{1}H nmr: 1.21 (t, *J*, 6; 3H), 1.31 (d, *J*, 5.5; 3H), 1.57 (m, 1H), 2.71 (m, 1H), 3.2–3.9 (complex, 3H), 3.71 (s, 3H), 3.76 (s, 3H), 4.77 (m, 2H), 5.76 (complex, 2H), 6.35 (s, 1H).

The EE protecting group was removed by stirring a solution of **11** (8.52 g; 31.6 mmol) in 270 mL of acetone with pyridinium *p*-toluenesulfonate (7.92 g; 31.6 mmol) under Ar at room temperature for 7 h. The suspension was filtered, the filtrate was evaporated under reduced pressure (it was necessary to avoid heating the material), and the residue was partitioned between 100 mL of water and 100 mL of ethyl acetate. The aqueous phase was further extracted with ethyl acetate (3 × 50 mL), the organic phases were combined, washed with saturated aqueous $NaHCO_3$ (2 × 50 mL) and dried (Na_2SO_4), and the solvent was removed under reduced pressure. The cyclopentenol was isolated as an orange oil (5.66 g; ca. 28 mmol), which was used in the next step. In one run a sample was flash chromatographed (2:1 hexane – ethyl acetate) to give an oil; ir: 3471 (br), 1697, 1635; ^{1}H nmr (400 MHz): 1.64 (m, 1H), 2.55 (m, 1H), 3.63 (s, 3H), 3.79 (br, 1H), 3.82 (s, 3H), 3.84 (m, 1H), 4.67 (m, 1H), 5.62 (m, 1H), 5.89 (m, 1H), 7.16 (s, 1H), ^{13}C nmr: 167.7 (e), 159.0 (e), 134.8 (o), 133.4 (o), 111.4 (e), 77.0 (o), 61.3 (o), 50.8 (o), 38.4 (o), 28.1 (e). *Exact Mass* calcd. for $C_{10}H_{14}O_4$: 198.0892; found: 198.0882.

The cyclopentenol (5.66 g) was dissolved in 20 mL of ethyl acetate and added to a suspension of pyridinium dichromate (16.1 g; 43 mmol) and activated 4-A molecular sieves in 300 mL of ethyl acetate, and the mixture was stirred under Ar for 22 h. Solids were removed by filtration and washed well with ethyl acetate. The combined organic solutions afforded a dark oil, which was flash chromatographed (3:1 hexane – ethyl acetate) to provide the cyclopentenone **5** (3.70 g; 19 mmol) as a yellowish oil; ir: 1710, 1640; ^{1}H nmr (400 MHz): 2.37 (ddd, *J*, 1, 3, 18.5; 1H), 2.58 (ddd, *J*, 1, 7, 18.5; 1H), 3.66 (s, 3H), 3.80 (s, 3H), 4.15 (m, 1H), 6.15 (dd, *J*, 2.5, 5.5; 1H), 7.36 (s, 1H), 7.45 (dd, *J*, 2.5, 5.5; 1H); ^{13}C nmr: 209.8 (e), 167.3 (3), 166.0 (o), 160.4 (o), 132.8 (o), 108.6 (e), 61.8 (o), 51.3 (o), 40.4 (e), 37.1 (o). *Exact Mass* calcd. for $C_{10}H_{12}O_4$: 196.0736; found: 196.0724.

Reactions with vinyl cuprates

Synthesis of ***13*** *(R = $SiMe_3$)*

The cyclopentenol **8** was oxidized to the cyclopentenone **12** in the manner just described. Recrystallized (29) CuI (0.25 g; 1.2 mmol) was added under Ar to a cold (−3°C) solution of vinylmagnesium bromide prepared from Mg turnings (0.39 g; 16 mmol) and vinyl bromide in 30 mL of THF under Ar. After 3 min, hexamethylphosphoramide (HMPA) (3.0 mL; 27 mmol) was added, the solution was stirred for another 3 min, and then cooled to −78°C. A solution of **12** (0.50 g; 3.2 mmol) and chlorotrimethylsilane (3.0 mL; 24 mmol) in 10 mL of THF was added dropwise over 50 min to the stirred reaction mixture. Stirring at −78°C was continued for a further 3 h, and 4-(dimethylamino)pyridine (DMAP) (0.46 g; 3.9 mmol) in 5 mL of THF was then added. After this mixture had been stirred at −78°C for 10 h, triethylamine (4.0 mL) was added dropwise and stirring was continued for 3 h longer. The reaction mixture was poured into 100 mL of ice-cold saturated aqueous $NaHCO_3$, 100 mL of water and 10 mL of hexane were added, and the mixture was then shaken and filtered through Celite. The filter cake was washed well with hexane, the aqueous layer was separated and extracted with hexane (3 × 25 mL), and the combined organic solutions were washed with saturated aqueous $NaHCO_3$ (2 × 25 mL), dried ($MgSO_4$), and evaporated to a yellow oil. The oil was partitioned between 50 mL of hexane and 25 mL of dimethyl sulfoxide, the dimethyl sulfoxide layer was extracted with hexane (5 × 20 mL), and the combined hexane extracts were washed

with water (2 × 25 mL) and saturated aqueous $NaHCO_3$ (2 × 25 mL), dried ($MgSO_4$), and worked up. The trimethylsilyl enol ether **13** (R = $SiMe_3$) was obtained as an oil (494 mg; 1.94 mmol); ir: 1739, 1644; ^1H nmr: 0.22 (s, 9H), 1.8–3.0 (complex, 6H), 3.63 (s, 3H), 4.47 (br, 1H), 4.8–5.1 (complex, 2H), 5.73 (m, 1H); ^{13}C nmr: 172.7 (e), 154.0 (e), 141.8 (o), 113.1 (e), 103.6 (o), 51.8 (o), 50.7 (o), 38.9 (e), 38.6 (o), 38.4 (e), −0.7 (o). *Exact Mass* calcd. for $C_{13}H_{22}O_3Si$: 254.1338; found: 254.1340. A sample of **13** was desilylated in a mixture of saturated aqueous NH_4Cl and dichloromethane, and the ketone was obtained as an oil, which analytical glc showed to be homogeneous and contain <2% of impurities. Material purified by flash chromatography (4:1 hexane – ethyl acetate) showed ir:1747, 1733, 1645; ^1H nmr: 1.7–2.9 (complex, 8H), 3.62 (s, 3H), 4.9–5.2 (complex, 2H), 5.68 (m, 1H); ^{13}C nmr: 215.7 (e), 172.4 (e), 138.4 (o), 116.8 (e), 51.5 (o), 46.9 (o), 44.9 (e), 44.3 (e), 38.5 (o), 37.2 (e). *Exact Mass* calcd. for $C_{10}H_{14}O_3$: 182.0943; found: 182.0927.

*Synthesis of **13** (R = $SiMe_2$-Bu)*

Cuprous cyanide (460 mg; 5.1 mmol) and 5 mL of dry toluene were placed in a thoroughly dried 100-mL 3-necked flask equipped with a gas inlet, pressure-equalizing addition funnel, rubber septum, and stirring bar (assembled under Ar). The toluene was removed by vacuum distillation at room temperature to dry the CuCN. Ether (5 mL) was added and the slurry was cooled to −78°C. A 0.78 M ethereal solution of vinyllithium (13.0 mL; 10.1 mmol) prepared from tetravinyltin (20) was added dropwise over 20 min. The suspension was allowed to warm to −40°C over 25 min, and then to −23°C over 10 min. The clear solution so formed was stirred and cooled to −78°C. A solution of the cyclopentenone **12** (605 mg; 3.9 mmol) in 5 mL of ether was added dropwise over 13 min, and stirring was continued at −78°C for 1 h. A solution of *tert*-butyldimethylsilyl chloride (1.45 g; 9.6 mmol), DMAP (0.1 g; 0.8 mmol), HMPA (2.0 mL), and triethylamine (2.0 mL) in 25 mL of dry THF was added dropwise over 10 min. The mixture was stirred at −78°C for 1 h, allowed to warm to room temperature, stirred for 16 h, and then cooled to 0°C. Water (100 mL) was added dropwise over 15 min, stirring was continued for 30 min, and 100 mL of ether was then added. The resulting emulsion was filtered through Celite, and the filter cake was washed with water (2 × 50 mL) and with ether (2 × 50 mL). The aqueous layer was separated and washed with ether (4 × 100 mL), and the ether solutions were combined, washed with water (4 × 50 mL), dried (Na_2SO_4), and worked up to provide a yellow oil. The ^1H nmr spectrum of this material showed it to be a 5:1 mixture of isomers. Flash chromatography (30:1 hexane – ethyl acetate) provided silyl enol ether **13** (R = $SiMe_2t$-Bu) (837 mg; 2.8 mmol); ir: 1742, 1645; ^1H nmr (400 MHz):0.12 (s, 3H), 0.13 (s, 3H), 0.88 (s, 9H), 2.0–2.9 (complex, 6H), 3.62 (s, 3H), 4.46 (m, 1H), 4.93–4.97 (complex, 2H), 5.77 (m, 1H); ^{13}C nmr: 173.3 (e), 154.5 (e), 142.1 (o), 113.5 (e), 104.5 (o), 52.4 (o), 51.4 (o), 39.5 (e), 39.2 (o), 39.0 (e), 25.6 (o), 18.1 (e), −4.7 (2 signals; o).

*Synthesis of **4***

The procedure used for the synthesis of **13** (R = $SiMe_3$) was applied to the cyclopentenone **5** (0.55 g; 2.8 mmol); vinylmagnesium bromide (16 mmol), CuI (0.15 g; 0.8 mmol), HMPA (5 mL), chlorotrimethylsilane (6.0 mL; 47 mmol), and DMAP (0.31 g; 2.6 mmol) were used. The trimethylsilyl enol ether **4** (0.62 g; 2.1 mmol) was obtainable as a mobile liquid; ir: 1708, 1643; ^1H nmr: 0.23 (s, 9H), 2.1–3.6 (complex, 4H), 3.70 (s, 3H), 3.80 (s, 3H), 4.60 (br, 1H), 4.7–5.0 (complex, 2H), 5.73 (m, 1H), 7.29 (s, 1H); ^{13}C nmr: 168.4 (e), 159.7 (o), 154.0 (e), 143.0 (o), 112.6 (e), 111.5 (e), 105.2 (o), 61.4 (o), 51.3 (o), 51.0 (o), 38.4 (o), 38.2 (e), 0.00 (o). *Exact Mass* calcd. for $C_{15}H_{24}O_4Si$: 296.1444; found: 296.1447. A sample of **4** was desilylated by the procedure used for **13** (R = $SiMe_3$), and analytical glc showed that the ketone obtained was homogeneous. Flash chromatography (4:1 hexane – ethyl acetate) provided material that showed ir: 1747, 1702, 1637; ^1H nmr (200 MHz): 2.06 (m, 1H), 2.30 (m, 1H), 2.48 (m, 1H), 2.71 (m, 1H), 3.1–3.2 (complex, 2H), 3.66 (s, 3H), 3.80 (s, 3H), 4.96 (m, 1H), 4.97 (m, 1H), 5.69 (m, 1H), 7.38 (s, 1H); ^{13}C nmr: 216.7 (e), 167.4 (e), 160.4 (o), 139.0 (o), 114.8 (e), 108.1 (e), 61.4 (o), 50.8 (o), 44.6 (e), 43.8 (o), 41.9 (e), 38.2 (o). *Exact Mass* calcd. for $C_{12}H_{16}O_4$: 224.1049; found: 224.1054.

*Peracid oxidations of silyl enol ether **4***

m-*Chloroperbenzoic acid*

A solution of **4** (700 mg; 2.36 mmol) in 25 mL of hexane was added dropwise over 1 h to a stirred suspension of commercial 85% *m*-chloroperbenzoic acid (530 mg; 2.6 mmol) in 25 mL of hexane at −23°C under Ar. The mixture was allowed to warm to room temperature and was stirred for 36 h. The suspension was filtered, and the filtrate was diluted with 50 mL of ether and washed with aqueous $NaHCO_3$ (3 × 25 mL). The organic solution afforded an oil, which was flash chromatographed (2:1 hexane – ethyl acetate) to afford the pentanolide derivative **17** (118 mg; 0.3 mmol) as a gum; ir: 1756, 1736; ^1H nmr (200 MHz):2.85 (dd, *J*, 7.4, 17.8; 1H), 2.92 (dd, *J*, 9.3, 17.8; 1H), 3.25 (ddd, *J*, 2.7, 10.9, 11.5; 1H), 3.76 (m, 1H), 3.70 (s, 3H), 3.86 (s, 3H), 5.1–5.2 (complex, 2H), 5.48 (m, 1H), 6.63 (d, *J*, 2.7; 1H), 7.39 (s, 1H), 7.4–7.6 (complex, 2H), 7.9–8.0 (complex, 2H); ^{13}C nmr: 168.9 (e), 167.3 (e), 163.0 (e), 160.9 (o), 134.7 (e), 133.8 (o), 133.1 (o), 130.6 (e), 130.0 (o), 129.9 (o), 128.1 (o), 120.4 (e), 109.2 (e), 94.6 (o), 62.0 (o), 51.4 (o), 44.2 (o), 33.8 (e), 28.1 (o). *Exact Mass* calcd. for $C_{19}H_{19}O_7Cl$: 394.0819; found: 394.0778.

Peracetic acid (1 equiv.)

Commercial 32% peracetic acid (1.0 mL; 4.75 mmol), anhydrous Na_2CO_3 (2.0 g; 19 mmol), and anhydrous sodium acetate (0.5 g; 6 mmol) were stirred in 40 mL of dichloromethane under Ar for 1 h, and the mixture was then cooled in an ice – water bath. A solution of **4** (1.29 g; 4.35 mmol) in 20 mL of dichloromethane was added dropwise over 1 h to the stirred reaction mixture, which was then allowed to warm to room temperature. Further pretreated peracetic acid (1.9 mmol) was added dropwise while the progress of the reaction was followed by tlc, and after 1 h no **4** remained. The mixture was filtered through Celite, and the filter cake was washed with dichloromethane. The combined filtrate was worked up to provide the α-acetoxy ketone **18** as a yellow oil (680 mg; 2.4 mmol). Flash chromatography (2:1 hexane – ethyl acetate) gave material that showed ir: 1758, 1748, 1703, 1640; ^1H nmr (400 MHz):2.06 (s, 3H), 2.46 (dd, *J*, 9.0, 18.7; 1H), 2.72 (dd, *J*, 8.5, 18.7; 1H), 3.25 (m, 1H), 3.48 (m, 1H), 3.67 (s, 3H), 3.81 (s, 3H), 5.06 (d, *J*, 9.9; 1H), 5.07 (d, *J*, 18.1; 1H), 5.28 (d, *J*, 7.8; 1H), 5.61 (m, 1H), 7.36 (s, 1H); ^{13}C nmr: 211.5 (e), 169.4 (e), 167.3 (e), 160.3 (o), 133.5 (o), 117.5 (e), 109.2 (e), 74.9 (o), 61.5 (o), 50.9 (o), 48.0 (o), 39.2 (e), 34.3 (o), 20.3 (o). *Exact Mass* cald. for $C_{14}H_{18}O_6$: 282.1103; found: 282.1101.

Peracetic acid (excess)

An ice-cold mixture of peracetic acid (1.2 mmol), Na_2CO_3 (0.4 g), and sodium acetate (0.1 g) in 5 mL of dichloromethane was prepared as described above. A solution of **4** (107 mg; 0.36 mmol) in 5 mL of dichloromethane was added dropwise over 15 min to the stirred mixture, and stirring was continued for 1 h further. The stirred mixture was allowed to warm to room temperature, and the progress of the reaction was followed by tlc. After 4 h the mixture was worked up as described above, and the product **19** (77 mg; 0.26 mmol) was obtained as a glass that, on recrystallization from ether, afforded white crystals, mp 99–101°C; ir: 1749, 1692; 1639; ^1H nmr (400 MHz): 2.15 (s, 3H), 2.88 (dd, *J*, 7.8, 17.8; 1H), 2.93 (dd, *J*, 8.9, 17.8; 1H), 3.27 (ddd, *J*, 2.9, 8.7, 11.4; 1H), 3.65 (ddd, *J*, 7.8, 8.9, 11.4; 1H), 3.79 (s, 3H), 3.96 (s, 3H), 5.15 (d, *J*, 10.3; 1H), 5.16 (d, *J*, 17.5; 1H), 5.25 (ddd, *J*, 8.7, 10.3, 17.5; 1H), 6.52 (d, *J*, 2.9; 1H), 7.48 (s; 1H); ^{13}C nmr: 169.0 (e), 168.5 (e), 167.2 (e), 160.7 (o), 133.2 (o), 119.8 (e), 109.0 (e), 93.6 (o), 61.7 (o), 51.1 (o), 43.4 (o), 33.5 (e), 27.8 (o), 20.6 (o). *Exact Mass* calcd. for $C_{14}H_{18}O_7$: 298.1052; found: 298.1025.

HERBERT L. HOLLAND, FRANCES M. BROWN, P. CHINNA CHENCHAIAH, MICHAEL J. CHERNISHENKO, SHAHEER H. KHAN, and J. APPA RAO. Can. J. Chem. **67**, 268 (1989).

The fungus *Gnomonia fructicola* ATCC 11430 hydroxylates testosterone at C-2β in 40–60% yield. The enzyme involved has been shown to be an inducible CO sensitive, cyanide insensitive oxygenase, with a requirement for the Δ^4-3-ketosteroid substrate functionality. The use of 2α- and 2β-deuterium labelled substrates has shown that hydrogen loss from C-2 during 2β hydroxylation is isotope dependent and non-stereospecific. This is interpreted in terms of a $\Delta^{2,4}$-dienolic enzyme-bound intermediate form of the substrate.

Key words: *Gnomonia fructicola*, hydroxylation, steroids, testosterone.

HERBERT L. HOLLAND, FRANCES M. BROWN, P. CHINNA CHENCHAIAH, MICHAEL J. CHERNISHENKO, SHAHEER H. KHAN et J. APPA RAO. Can. J. Chem. **67**, 268 (1989).

Le champignon *Gnomonia fructicola* ATCC 11430 provoque une hydroxylation en position C-2β de la testostérone, avec un rendement de 40–60%. On a démontré que l'enzyme implique une oxygénase qui peut être induite, qui est sensible au CO et insensible au cyanure et dont le substrat doit contenir une fonctionnalité Δ^4-céto-3 stéroïde. Utilisant des substrats marqués au deutérium dans les positions 2α et 2β, on a pu démontrer que l'hydroxylation dépend de l'isotope et qu'elle n'est pas spécifique. On peut interpréter ce résultat, en suggèrant que le substrat est lié à l'enzyme par le biais d'une forme intermédiaire $\Delta^{2,4}$-diénolique.

Mots clés : *Gnomonia fructicola*, hydroxylation, stéroïdes, testostérone.

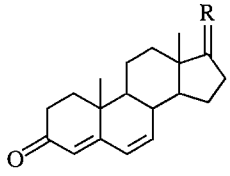
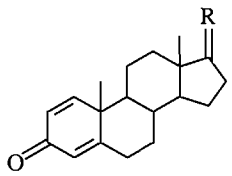
The introduction of a hydroxyl functionality into a steroid molecule by fungal biotransformation, first discovered over 40 years ago (1), is still the most efficient route for the preparation of many hydroxysteroids, particularly in the corticosteroid family.



The enzymes responsible for this reaction were slow to yield their secrets, but their essential nature is now understood (2). Their characterization as cytochrome P-450 dependent monooxygenases preceded investigation of enzyme–substrate interactions: the latter have centred on the nature of enzyme–substrate binding through existing electronegative substituents such as substrate carbonyl or hydroxyl groups (2), and on the activation of ketosteroids towards electrophilic hydroxylation at positions adjacent or vinylogous to carbonyl by substrate enolization (3).

A report of the hydroxylation of testosterone (**1**) at C-2β by *Gnomonia fructicola* ATCC 11430 in unspecified yield (4), and the continued question of the intermediacy of a 2β-hydroxylation step in the conversion of testosterone to estradiol by the human aromatase enzyme (5, 6), suggesting a possible role for enzymic 2β hydroxylation of steroids in the control of human breast tumour cell proliferation (7, 8), prompted us to examine both mechanistic and synthetic parameters of the fungal hydroxylation of testosterone at C-2β by *G. fructicola*. In addition, hydroxylation of testosterone at C-2β by mammalian liver enzymes represents one of the major routes of testosterone metabolism in the liver (9, 10), suggesting a further role for the fungal biotransformation as a possible model for mammalian metabolism.



The original report of the steroidal 2β hydroxylating capacibility of *G. fructicola* was concerned largely with the use of Δ^4-3-ketopregnane substrates, reporting 2β hydroxylation of cortexone in 40% isolated yield (4, 11), with a more complex pattern of metabolism for progesterone, including hydroxylation at the C-2β, -6β, -14α, and -16β positions (11). To establish the best substrate for mechanistic purposes, we first investigated the fungal metabolism of the simple Δ^4-3-keto-steroids **1**–**4**, using a simplified procedure for biotransformation that replaced the original conditions (incubation in a complex growth medium (11)) with growth in a simpler medium followed by replacement culture incubation with resting cells in distilled water (for details, see experimental section). Under our conditions, testosterone was routinely converted to the 2β-hydroxy derivative **23** in isolated yields of 40–60%, accompanied by a trace of oxidation at C-17 to give the dione **4**. The results of this and other incubations are summarized in Table 1. Testosterone

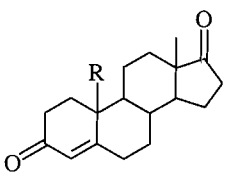
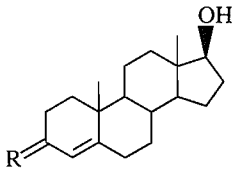
*Following enzyme induction by testosterone.



acetate is similarly transformed but in lower yield, presumably following enzymic hydrolysis of the ester function at C-17, but androst-4-ene-3,17-dione (**3**) underwent oxidation predominantly in the D-ring, yielding the 17β-hydroxy-16-ketone **30**. This compound may be formed by the rearrangement of an intermediate but not isolated 16-hydroxy-17-ketosteroid, a common phenomenon during fungal biotransformation (12). The biotransformation of progesterone gave, as originally reported (11), a mixture of products, from which the 2β and 14α alcohols and 2β,6β and 6β,14α diols were identified.

In view of the experiments outlined above, further work concentrated on steroids of the androstane skeleton, which carried the 17β-alcohol functionality. Substrate specificity was investigaed by using a series of substrates (**5**, **7**, **9**, and **11**–**17**); in only one instance (**11**) was 2β hydroxylation observed, and then in minor amount together with other reactions. Alternative modes of biotransformation that were noted included alcohol oxidation (for **5**, **7**, **12**, and **17**), carbonyl reduction (for **11**, **12**, and **14**), 16α hydroxylation (for **9** and **11**), and 5β hydroxylation of **12**.



Product structure determination relied heavily on the interpretation of ^{13}C nmr data (see Experimental), the following shifts being particularly characteristic: for 16α hydroxylation (products **10**, **37**, and **38**) the regiochemistry of hydroxylation is given by downfield shifts of signals assigned to C-17 and C-15 compared with their position in the corresponding 16-unsubstituted steroids (13), and stereochemistry is confirmed by a γ upfield shift at C-14 of 2.8–3.3 ppm; for 5β hydroxylation (products **40** and **41**), regiochemistry is reflected in downfield shifts at C-4 and C-6, together with a γ upfield shift at C-1, and stereochemistry by the latter and by the characteristic C-9 signal of 5β steroids (13); for 2β hydroxylation (products **23**, **28**, **34**, and **38**), regiochemistry is given by upfield shifts at C-1, and characteristic shifts at C-4, -5, -9, and -10, and stereochemistry by a downfield shift of the C-19 signal by 3–5 ppm (13).

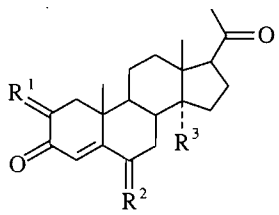
30

The α stereochemistry of reduction of the C-3 carbonyl group in 5α steroids (product **38**) is reflected in γ upfield shifts for C-1 and C-5, while the β stereochemistry of reduction (products **36** and **37**) is apparent from direct comparison with literature values reported for C-1–C-5, C-10, and C-19 for 3β-hydroxy-5α-androstanes (13). The stereochemistry of reduction at C-3 in the 5β-androstane series, giving the 3α-hydroxy product **41**, is confirmed by the absence of a γ-*gauche* upfield shift on the C-1 resonance in the spectrum of **41** compared with that of **40**.



It is apparent from the above that the 2β-hydroxylase enzyme requires a Δ^4-3-keto steroid substrate with a C-19 methyl group for normal activity. It is noteworthy that neither 19-nortestosterone (**9**) nor the 19-functionalized steroids **13** and **14** are substrates for this enzyme. Complete removal of the C-3 oxygen function (compounds **15** and **16**) produces steroids that are not hydroxylated, while reduction at C-3 (compound **17**) is reversed by fungal oxidoreductases prior to hydroxylation (see Table 1).

The occurrence of 16α hydroxylation (substrates **9**, **11**, and possibly **3**) may involve the 2β-hydroxylase enzyme binding the substrate in an inverted manner, a common phenomenon for fungal steroid hydroxylases (2), and other steroid metabolizing enzymes (14) as suggested in Fig. 1, but in the absence of

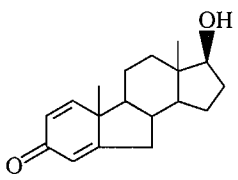
FIG. 1. Possible method for 16α hydroxylation by a 2β-hydroxylase.



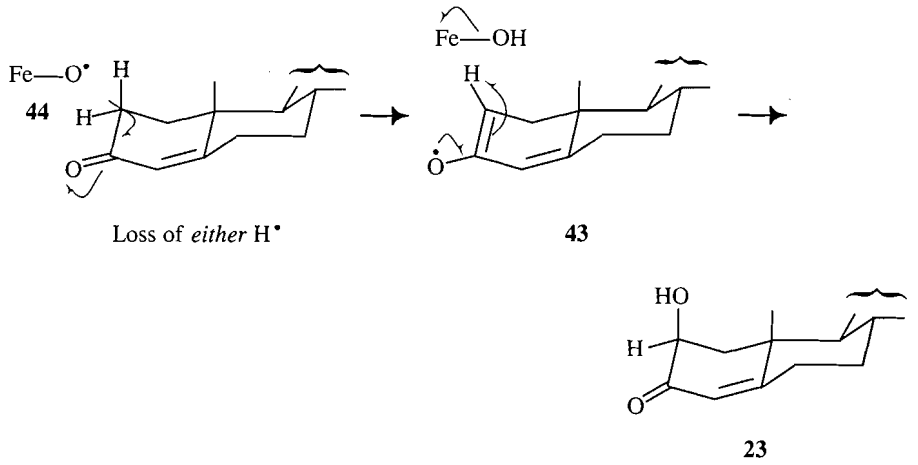
isolated enzymes this proposal must remain speculative. As previously noted (4), the 2β hydroxylase is able to tolerate an *A*-nor-$\Delta^{3(5)}$-2-one skeleton such as that of *A*-nortestosterone (**20**), giving a low yield of hydroxylation product **22**, analogous in structure to that observed for the normal Δ^4-3-keto skeleton. The *B*-norsteroid **18** was not hydroxylated under normal incubation conditions, the only biotransformation product (**19**) being the result of oxidation at C-17, but when testosterone was used as an enzyme inducer during the fungal growth period, as described in the experimental section, and **18** subsequently used as substrate, a low yield of the *B*-nor-$\Delta^{1,4}$-diene **42** was

39

40 R = O
41 R = αH, βOH

42

obtained. This may have arisen by acid-catalysed dehydration of a 2β-hydroxy intermediate in the growth medium (pH 4.6 at the end of the incubation), but in the absence of an isolated intermediate this proposal is speculative. The use of testosterone as an enzyme inducer was also investigated for incubations with substrates **7**, **9**, **11**, and **20**, but in each case the products were the same as those obtained from non-induced fungus.



We have addressed the question of enzymic activation of the substrate towards electrophilic oxidation via formation of the $\Delta^{2,4}$-dienol **43** (Scheme 1) by the use of testosterone substrates labelled with deuterium at C-2β and C-2α (**24** and **25**, respectively), and the results of these experiments are summarized in Table 2. A meaningful interpretation depends upon a fuller knowledge of the nature of the 2β-hydroxylase enzyme, and to this end the experiments summarized in Table 3 were performed.

The enzyme uses molecular oxygen as the source of hydroxyl, giving 2β-hydroxytestosterone-2-^{18}O (**27**, ^{18}O content 50%) when the reaction was performed under an $^{18}O_2$ enriched atmosphere (^{18}O content 62%); it is insensitive to the presence of cyanide but is inhibited by carbon monoxide at saturation concentration in water, and is substrate inducible, the reaction being completely suppressed by the presence of the protein synthesis inhibitor, cycloheximide, unless preinduction with testosterone was carried out. All of these properties are consistent with the 2β-hydroxylase enzyme being a cytochrome P-450 dependent mono-oxygenase (15*a*), although in the absence of an isolated, purified enzyme this cannot be definitively proven.

The active site species of cytochrome P-450 dependent mono-oxygenases has been formulated as the ironoxy radical complex **44** of Schemes 1 and 2, and the current consensus of opinion favours the radical abstraction/recombination mechanism for hydroxylation outlined in Scheme 2 (15*b*). The data presented in Table 2 can now be interpreted on the basis of this mechanistic outline.

The substrates whose hydroxylation is summarized in Table 2 were prepared as described elsewhere (16). The β-labelled isomer (62% d_1, 85% of label in the β position (16)) was hydroxylated to give a product that contained 39% d_1 species, the location of label at C-2α being apparent from ^{1}H nmr integration, and from ^{2}H nmr and ^{13}C nmr data. The α-labelled isomer (80% d_1, 87% of label in the α position (16)) was hydroxylated to give 2β-hydroxytestosterone with 75% d_1 in the 2α position. It is therefore apparent that, within error, label originally present at C-2α is maintained during the hydroxyla-

TABLE 3. Transformations of testosterone by *G. fructicola*

Conditions of incubation	Product (%)
Normal	**23** (40–60)
Under $^{18}O_2$ atmosphere	**27** (58)
In 5 × 10^{-4} M KCN	**23** (50)
Under 15% CO atmosphere	0
In 3 × 10^{-4} M cycloheximide	0
In 3 × 10^{-4} M cycloheximide, cells preinduced with testosterone	**23** (10)

tion (94% retention). While this result alone would indicate hydroxylation with retention of configuration (the mode of cytochrome P-450 dependent hydroxylation most commonly observed (15*b*)), the data obtained from the β-labelled substrate, which retains 63% of the original label, show that this cannot be the case.

The analysis of the data of Table 2 depends on the relationship between stereoelectronic effects (SEE) (favouring axial (β) loss or addition of groups from C-2 (17)), and the intramolecular kinetic isotope effect (KIE) favouring loss of H over D, by a factor that may be as large as 11 in cytochrome P-450 hydroxylations (18). As outlined in Scheme 1, the loss of H from C-2 to the enzyme would be exclusively from the β face if the KIE and SEE are cooperative (for 2α-deuterium labelled substrate, **25**). However, these effects become counteractive for the C-2β labelled substrate, **24**, in which case the ratio of loss from the α and β sides is the result of an SEE/KIE competition. In both the cases reported in Table 2, recovered substrate shows no loss or epimerization of label, confirming that the phenomena reported are indeed a consequence of the hydroxylation process. The final stereochemistry of hydroxylation (conversion

SCHEME 2. Mechanism of C hydroxylation by cytochrome P-450 dependent mono-oxygenase enzymes.

of **43** to **23**) would be expected, proceeding under SEE control, to produce exclusive β product (17).

The magnitude of the SEE for hydrogen loss from C-2 during enolization of Δ^4-3-ketosteroids has been estimated at 4:1 (β:α) (17). The data of Table 2 suggest that, of the 39% d_1 species obtained from the β-labelled isomer, 30% was formed by epimerization of label from the β to the α position during the reaction (the remaining 9% being obtained from the 9% of **25** originally present). In this event, the ratio of β:α loss from C-2 of **24** can be estimated as (53–30):30 or 1:1.3, requiring an intramolecular KIE of ca. 1.3 × 4 or 5.2, well within the observed range of such effects (18, 19). The above analysis is approximate, ignoring as it does the role of intermolecular KIE's, but as these are usually close to unity in cytochrome P-450 dependent hydroxylation (19, 20), their contribution is generally small.

The phenomenon of non-stereospecific hydrogen loss followed by stereospecific hydroxylation is one that we have previously reported for enzymic hydroxylation (19, 20), and the present analysis is analogous to that given by us for the steroid 6β-hydroxylase enzyme of *Rhizopus arrhizus* (3, 12), where the stereochemistry of hydrogen loss is also isotope-dependent. This phenomenon may be a general one for hydroxylations at sites subject to stereoelectronic effects due to their proximity to carbonyl groups or other centres of π-electron density.

The data reported herein for the 2β-hydroxylase enzyme of *G. fructicola* therefore suggest that this enzyme is a cytochrome P-450 dependent mono-oxygenase, operating via a stepwise oxidation mechanism, the stereochemical details of which are subject to substrate stereoelectronic and kinetic isotope effects.

Experimental

Apparatus, material, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with an Analect 6260FX spectrometer. Proton nmr spectra were recorded at 80 MHz with a Bruker WP80CW or at 200 MHz with an AC200 spectrometer, using CDCl, as solvent (except where stated) and TMS as internal standard. Carbon spectra were recorded at 50.3 MHz (JMOD mode) using the latter instrument with chloroform as solvent and internal standard. Deuterium spectra were recorded at 30.72 MHz (AC200) or at 76.8 MHz (Bruker AM500, McMaster University), using chloroform as solvent and natural abundance $CDCl_3$ as internal standard. Mass spectra were obtained with an AEI MS30/Kratos DS55 system. Isotopic abundances were determined from the molecular ion or M − H_2O spectral regions following standard correction procedures for natural ^{13}C abundances, and are accurate to ±2.5%. Thin-layer chromatography was performed on Merck silica gel 60F-254, and flash column chromatography on silica gel (230–400 mesh, Merck 9385).

Maintenance of microorganisms

Gnomonia fructicola ATCC 11430 was grown at 24–26°C on slopes of potato dextrose agar containing 0.5% strawberry petiole extract (21), then stored at 4°C and transferred at intervals not exceeding 8 weeks.

Preparation of substrates

With the exception of those listed below, the substrates used were commercial samples. Hitherto unreported spectral data are tabulated below for substrates not commercially available. 3-Deoxytestosterone (**15**): preparation, ref. 22; ^{13}C nmr, δ: 11.0 (C-18), 19.3 (C-2), 19.5 (C-19), 21.0 (C-11), 23.4 (C-15), 25.8 (C-6), 30.5 (C-16), 32.0, 32.5 (C-3, C-7) 36.0 (C-8), 36.8 (C-12), 37.1 (C-10), 37.9 (C-1), 42.7 (C-13), 50.9 (C-14), 54.6 (C-9), 81.7 (C-17), 117.2 (C-4), and 144.0 (C-5) ppm. 3-Methyleneandrost-4-en-17β-ol (**16**): preparation, ref. 23; ^{13}C nmr, δ: 11.1 (C-18), 18.6 (C-19), 21.1 (C-11), 23.5 (C-15), 27.3 (C-2), 30.6 (C-16), 32.4 (2C, C-6, C-7), 36.1 (C-8), 36.8 (C-12), 37.4 (C-1), 37.7 (C-10), 43.0 (C-13), 50.9 (C-14), 54.4 (C-9), 82.0 (C-17), 108.0 (=CH_2), 122.8 (C-4), 144.0 (C-3), and 149.0 (C-5) ppm. Androst-4-ene-3β,17β-diol (**17**): preparation, ref. 24; ^{13}C nmr, δ: 11.0 (C-18), 19.0 (C-19), 20.6 (C-11), 23.4 (C-15), 29.5 (C-2), 30.5 (C-16), 32.1, 32.6 (C-6, C-7), 35.4 (C-1), 36.0 (C-8), 36.6 (C-12), 37.4 (C-10), 42.9 (C-13), 50.8 (C-14), 54.6 (C-9), 67.9 (C-3), 81.8 (C-17), 123.5 (C-4), and 147.4 (C-5) ppm. *B*-Norandrost-4-en-17β-ol-3-one (**18**): preparation, ref. 25. *A*-Norandrost-4-en-17β-ol-3-one (**20**): preparation, ref. 26. Androst-4-en-17β-ol-3-one-2β-d_1 (**24**): preparation, ref. 16. Androst-4-en-17β-ol-3-one-2α-d_1 (**25**): preparation, ref. 16.

Fungal biotransformations

General procedure

G. fructicola was grown in a medium of potato dextrose broth (200 mL) in a 1-L Erlenmeyer flask, maintained on a rotary shaker (180 rpm) at 24–26°C. After a growth period of 5 days, the fungus was collected by centrifugation and resuspended in distilled water (200 mL) in a 1-L Erlenmeyer flask. In a typical procedure, 15 such flasks were used to transform 1 g of substrate, added at the rate of 70 mg in 2 mL 95% ethanol per flask. Incubations with substrate were then performed under conditions identical with those described above (24–26°C, 180 rpm), for a 5-day period, following which the fungus was removed by filtration and products isolated by continuous extraction of the aqueous medium (methylene chloride), and purified by column chromatography. Extraction of the fungal biomass led to the recovery of starting material in most cases. This latter process was not routinely performed and was not quantified.

Controlled atmosphere and inhibitor experiments

The experiments summarized in Table 3 were performed in closed 1-L vessels ($^{18}O_2$ and 15% CO atmospheres), or by replacement of distilled water in the above procedure by the appropriate inhibitor solution. Preinduction of enzymes by testosterone was carried out by the addition of testosterone (4 mg in 1 mL 95% ethanol per flask) to the growing fungus 4 days after inoculation, followed by a further 24-h growth period. Subsequent procedures were carried out as described above. In all cases, yields reported in Table 3 refer to isolated, purified products.

Substrates

Isolated yields of products are listed in Tables 1 and 2. The following paragraphs contain (in order) substrate; recovered substrate from aqueous medium (%); products (%), in order of elution from column chromatography, together with hitherto unpublished spectral and (or) analytical data.

Androst-4-en-17β-ol-3-one (testosterone, **1**), 17; androst-4-ene-3,17-dione (**3**), 1, identified by comparison with authentic material; androst-4-ene-2β,17β-diol-3-one (**23**), 40–60; ^{13}C nmr, δ: 11.3 (C-18), 22.5 (C-11), 22.8 (C-19), 23.3 (C-15), 30.4 (C-16), 33.0 (C-7), 34.5 (C-6), 35.8 (C-8), 36.5 (C-12), 39.5 (C-1), 41.4 (C-10), 43.4 (C-13), 50.3, 50.5 (C-9, C-14), 68.6 (C-2), 81.4 (C-17), 118.8 (C-4), 175.2 (C-5), 199.9 (C-3) ppm, identified by comparison with authentic material (27).

Androst-4-en-17β-ol-3-one, 2β-d_1 (**24**), 9; ^2H nmr, δ: 2.40 (C-2β^2H) ppm; androst-4-ene-2β,17β-diol-3-one, 2α-d_1 (**23** + **26**), total 25, ^1H nmr included signals at δ: 3.63 (1H, t, C-17αH), 4.15 (0.61 H, dd, C-2αH), and 5.78 (1H, s, C-4H) ppm; ^2H nmr δ: 4.16 (C-2α^2H) ppm.

Androst-4-en-17β-ol-3-one, 2α-d_1 (**25**), 9; ^2H nmr, δ: 2.32 (C-2α^2H) ppm; androst-4-ene-2β,17β-diol-3-one, 2α-d_1, (**23** + **26**), total 20; ^1H nmr included signals at δ: 3.63 (1H, t, C-17αH), 4.15 (0.25 H, dd, C-2αH), and 5.79 (1H, s, C-4H) ppm; ^2H nmr δ: 4.16 (C-2α^2H) ppm.

Androst-4-en-17β-ol-3-one, 17 acetate (testosterone acetate, **2**), 0; androst-4-ene-3,17-dione, 1; androst-4-ene-2β,17β-diol-3-one (**23**), 30; androst-4-en-6β-ol-3,17-dione (**31**), 2, identified by comparison with authentic material (20).

Androst-4-ene-3,17-dione (**3**), 5; androst-4-en-2β-ol-3,17-dione (**28**), 4, identified by comparison with an authentic sample (27); androst-4-ene-17β-ol-3,16-dione (**30**), 5; ^1H nmr included signals at δ: 0.78 (3H, s, C-18H), 1.2 (3H, s, C-19H), 3.75 (1H, s, C-17αH) and 5.7 (1H, s, C-4H) ppm, identified by spectral, tlc, and mp comparisons with data from authentic material (28).

Pregn-4-ene-3,20-dione (progesterone, **4**), 10; pregn-4-en-2β-ol-3,20-dione (**32**), 5, identified by comparison of spectral and physical data with those reported (11); pregn-4-en-14α-ol-3,20-dione (**33**), 8, identified by comparison with reported spectral data (29, 30); pregn-4-ene-2β,6β-diol-3,20-dione (**34**), 12; ^1H nmr including δ: 0.68 (3H, s, C-18H), 1.48 (3H, s, C-19H), 2.1 (3H, s, C-21H), 4.2–4.4 (2H, m, C-2 and -6 H's), and 5.82 ppm, obtained in admixture with pregn-4-ene-6β,14α-diol-2,20-dione (**35**), 21. The latter compound was purified by repeated chromatography and had physical and spectral data identical with those reported (29, 30).

Androsta-4,6-dien-17β-ol-3-one (**5**), 25; androsta-4,6-diene-3,17-dione (**6**), 16, identical with an authentic commercial sample.

Androsta-1,4-dien-17β-ol-3-one (**7**), 15; androsta-1,4-diene-3,17-dione (**8**), 7, identical with an authentic samples prepared by Jones' oxidation of **7**.

19-Norandrost-4-en-17β-ol-3-one (19-nortestosterone, **9**), 12; 19-norandrost-4-ene-16α,17β-diol-3-one (**10**), 6, mp 172–174°C (lit. (31) mp 185–186°C); ^1H nmr included peaks at δ: 0.78 (3H, s, C-18H), 3.49 (1H, t, C-16βH), 4.10 (1H, br s, C-17αH), and 5.81 (1H, s, C-4H) ppm; ^{13}C nmr δ: 12.2 (C-18), 25.7 (C-11), 26.5 (C-1), 30.6 (C-7), 33.7 (C-15), 35.4 (C-6), 36.4 (2C, C-2 and C-12), 40.0 (C-8), 42.6 (C-10), 43.6 (C-13), 47.6 (C-14), 49.5 (C-9), 78.4 (C-16), 89.7 (C-17), 124.7 (C-4), 166.5 (C-5), and 200.0 (C-3) ppm; ms *m/z* (%): 290 ($M^{+\cdot}$, 90), 272 (100), 257 (25), 254 (35).

5α-Androstan-17β-ol-3-one (**11**), 12; 5α-androstane-3β,17β-diol (**36**), 3, analytical and spectral data identical with those reported (13); 5α-androstane-3β,17β,16α-triol (**37**), 20, mp 238–240°C (lit. (32) mp 256–260°C corr.); ^1H nmr included signals at δ: 0.66 (3H, s, C-18H), 0.73 (3H, s, C-19H), 3.26 (d, J = 5.6 Hz, C-17αH), 3.30–3.45 (1H,

Reçu le 14 juillet 1988

JAIRO SAEZ, ESTELLA FERNANDEZ, AKINO JOSSANG, ANDRÉ CAVÉ et ADRIEN CAVÉ. Can. J. Chem. **66**, 275 (1988).

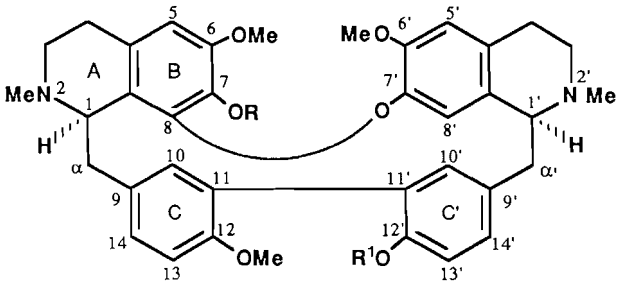
Quatre nouveaux alcaloïdes : la (−)-cordobine **1**, la (−)-montérine **2**, la (−)-granjine **3** et la (−)-cordobimine **4** ont été isolés d'une Annonacée de Colombie, *Crematosperma* sp. Leurs structures ont été élucidées par analyse des données spectrales et par réactions chimiques. Ils constituent les premiers alcaloïdes possédant la configuration absolue 1*R*, 1′*S* dans les groupe des bisbenzyltétrahydroisoquinoléines liées par un pont diaryléther 8,7′ et par un pont biphénylique 11,11′.

Mots clés : Annonaceae, *Crematosperma*, alcaloïdes, biphénylbisbenzylisoquinoléines.

JAIRO SAEZ, ESTELLA FERNANDEZ, AKINO JOSSANG, ANDRÉ CAVÉ, and ADRIEN CAVÉ. Can. J. Chem. **66**, 275 (1988).

Four new alkaloids, (−)-cordobine **1**, (−)-monterine **2**, (−)-granjine **3**, and (−)-cordobimine **4** have been isolated from a Colombian Annonaceous plant, *Crematosperma* sp. Structures were elucidated from spectral data and chemical reactions. These alkaloids are the first 1*R*, 1′*S* bisbenzyltetrahydroisoquinolines including 8,7′ ether and 11,11′ biphenyl linkages.

Key words: Annonaceae, *Crematosperma*, alkaloids, biphenylbisbenzylisoquinolines.



Le genre *Crematosperma*, Annonacées, est représenté, selon Fries, par 17 espèces sud-américaines (1). Jusqu'ici une seule d'entre elles, *C. polyphlebum*, a été étudiée; un alcaloïde bisbenzylisoquinoléique biphénylique, la phlebicine, en a été isolé (2). L'espèce étudiée ici, *Crematosperma* sp., est originaire de Colombie et a été récoltée à Urrao.

Des écorces de ce *Crematosperma*, quatre alcaloïdes nouveaux ont été isolés, la (−)-cordobine **1**, la (−)-montérine **2**, la (−)-granjine **3** et la (−)-cordobimine **4**. Les spectres uv de ces alcaloïdes sont caractéristiques des benzyltétrahydroisoquinoléines, et leurs spectres de masse, avec le pic moléculaire entre *m/z* 592 et 636, indiquent une structure de dimère (3, 4).

La (−)-cordobine **1**, obtenue amorphe, $[\alpha]_D^{20}$ −140($CHCl_3$), répond à la formule brute $C_{37}H_{40}N_2O_6$ ($M^{+\cdot}$ 608) déduite de son spectre de masse. Un léger effet bathochrome en milieu alcalin sur le spectre uv indique la présence d'une fonction phénolique. Le spectre de rmn ^1H (360 MHz) (Tableau 1) indique la présence de deux groupements N-méthyle à 2,42 et 2,64 ppm, trois groupes méthoxyle et neuf protons aromatiques. Les fragmentations du spectre de masse résultant d'une coupure 1-α et 1′-α′, pics à *m/z* 382, 381 et 191, correspondent aux ions monochargés et doublement chargés d'une *N,N′*-diméthylbistétrahydroisoquinoléine diméthoxylée et hydroxylée comportant un pont éther-oxyde (5). Le troisième méthoxyle est donc porté par la partie benzylique.

Les six protons aromatiques résonnant en deux systèmes ABX, 3H en 13, 14, 10 et 3H en 13′, 14′, 10′, révèlent surtout la présence d'une liaison biphénylique C-11, C-11′ entre les cycles C et C′ et les substitutions en C-12 et C-12′. Les positions des trois méthoxyles en 6, 6′ et 12 et des deux fonctions phénol en 7 et 12′ ont été établies grâce à des mesures de nOe. La structure plane de la (−)-cordobine **1** est ainsi établie et se révèle identique à celle de la (+)-antioquine (6).

La valeur du pouvoir rotatoire de la (−)-cordobine **1** ($[\alpha]_D^{20}$ −140) est de valeur comparable à celle de l'antioquine mais de signe opposé ($[\alpha]_D$ +214). De plus la courbe de dichroïsme circulaire de la (−)-cordobine **1** est l'inverse de celle de la (+)-antioquine. La configuration absolue de la (−)-cordobine **1** est donc 1*R*,1′*S*, énantiomère de la (+)-antioquine dont la stéréochimie a été établie comme étant 1*S*,1′*R* par une étude de diffraction de rayons X (6). Le spectre de rmn ^1H de la (−)-cordobine **1** est en accord avec cette conclusion. On observe en effet que l'ensemble des protons aromatiques résonnent entre 6,36 et 7,44 ppm, ce qui est caractéristique des bisbenzyltétrahydroisoquinoléines possédant ce type de liaison (pont éther-oxyde 8,7′, pont biphényle 11,11′) et ayant la configuration «*syn*» (8). La position du signal correspondant au proton en 10 à 7,17 ppm corrobore également cette configuration, le proton en 10 des produits de configuration «*anti*» résonnant à des champs nettement plus faibles, vers 7,55 ppm (8).

(-)-Cordobine **1** : R = R¹ = H
(-)-Montérine **2** : R = H, R¹ = Me
(-)-Granjine **3** : R = R¹ = Me

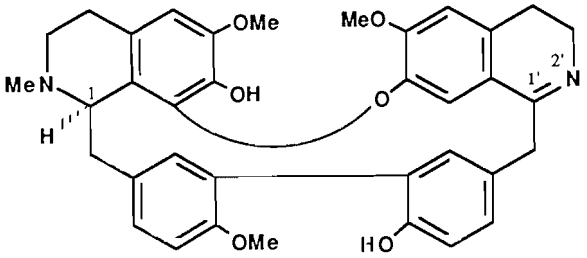
CH_3O-7	—	—	3,32 et 3,43	3,44
CH_3O-12	3,55	3,56	3,57	3,66
CH_3O-12′	3,72	3,78	3,74	3,78
9 H ar.	6,33–7,70	6,30–7,60	6,35–7,67	6,30–7,45

La (−)-montérine **2**, obtenue amorphe, $[\alpha]_D^{20}$ −135, a une structure apparentée à celle de la (−)-cordobine **1**. Son spectre de masse montre un pic moleculaire à m/z 622 ($C_{38}H_{42}N_2O_6$) indiquant 14 uma supplémentaires et des fragments à m/z 382, 381 et 191, correspondant à la partie bisisoquinoléique, identiques à ceux observés sur le spectre de la (−)-cordobine **1**. Donc, le méthoxyle supplémentaire doit se trouver en position 12′. La parenté avec la (−)-cordobine ainsi que la position du méthoxyle supplémentaire en 12′ sont confirmées par l'examen du spectre de rmn ^1H. Celui-ci présente des signaux dédoublés à température ambiante dus à l'existence de conformères stables *a* et *b* dans une proportion égale. Ceci est confirmé par la simplification du spectre enregistré à 90°C dans la pyridine-d_5 (Tableau 2). Une attribution complète des signaux des protons a été effectuée par une étude des découplages sélectifs et des nOe. La configuration 1*R*, 1′*S* de la (−)-montérine **2** est déduite de sa courbe de dc superposable à celle de la (−)-cordobine **1**.

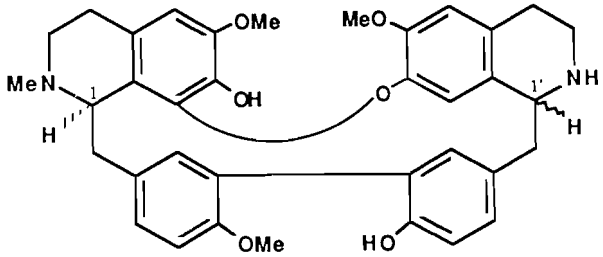
La (−)-granjine **3**, également obtenue amorphe, $[\alpha]_D^{20}$ −63, possède une masse moléculaire $M^{+\bullet}$ à m/z 636 compatible avec la formule brute $C_{39}H_{44}N_2O_6$. Les fragments à m/z 396, 395 et 198 montrent que la (−)-granjine **3** comporte 14 uma de plus que la (−)-montérine **2**. Son spectre de rmn ^1H est très voisin de celui de la (−)-montérine **2** et également dédoublé en raison de la présence de conformères *a* et *b* dans une proportion 2 : 1. Il comporte un signal dédoublé à 3,27 et 3,42 ppm correspondant au méthoxyle en 7, en plus de ceux figurant sur le spectre de la (−)-montérine **2**. Les signaux correspondant aux protons de la (−)-granjine **3** ont été attribués par une étude de découplage sélectif et par comparaison aux valeurs déterminées pour la (−)-montérine **2**. Le spectre de dc, identique à celui de la (−)-cordobine **1**, indique la même configuration 1*R*, 1′*S* pour la (−)-granjine.

Il est à noter que les alcaloïdes biphényliques, lorsque la position 7 ou les deux positions 12 et 12′ sont substituées par un méthoxyle, donnent lieu à l'existence de conformères stables, ceci étant lié à l'encombrement stérique de la molécule. Les règles établies pour fixer les configurations en 1 et 1′ (8) présentent alors des exceptions pour l'un des deux conformères (6).



La corrélation entre ces trois alcaloïdes a été effectuée par O-méthylation de la (−)-cordobine **1** et de la (−)-montérine **2**, qui a fourni la *O*,*O*-diméthylcordobine et la *O*-méthylmontérine en tous points identiques à la (−)-granjine **3**.

La (−)-cordobimine **4**, amorphe, $[\alpha]_D^{20}$ −185, est un alcaloïde nouveau, de formule brute $C_{36}H_{36}N_2O_6$ déduite de son



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

spectre de masse ($M^{+\bullet}$ 592). Le spectre uv, caractéristique de celui des benzylisoquinoléines, montre un épaulement supplémentaire à 308 nm et présente un important effet bathochrome en milieu acide à 346 nm caractéristique d'une dihydro-3,4 isoquinoléine, indiquant ainsi la présence d'une fonction imine. Le spectre ir confirme la présence d'une fonction imine conjuguée (bande à 1620 cm^{-1}).

Le spectre de rmn ^1H montre la présence de trois groupes méthoxyle et présente un seul signal de N-méthyle à 2,28 ppm, donc en 2, indiquant que la fonction imine se trouve sur la partie droite de la molécule, en 1′,2′. Par conséquent le singulet déblindé à 7,77 ppm est attribué au proton en 8′. La présence de deux autres singulets à 6,37 et 6,43 ppm et de deux systèmes ABX de six protons appartenant aux cycles C et C′, indique que la (−)-cordobimine **4** possède également une structure de bisbenzyltétrahydroisoquinoléine, comportant un pont éther-oxyde 8,7′ et un pont biphénylique 11,11′. Un découplage sélectif et une étude des nOe a permis de placer les trois groupes méthoxyle dans les positions 6, 6′ et 12 et par suite les deux hydroxyles en 7 et 12′.

(-)-Cordobimine **4**

(-)-Dihydrocordobimine **5** : 1′S

(-)-Dihydrocordobimine **6** : 1′R

Le signe négatif du pouvoir rotatoire indique que la (−)-cordobimine possède la configuration 1*R*, ce que confirme la courbe de dichroïsme circulaire. La réduction de la (−)-cordobimine **4** par $NaBH_4$ donne naissance à deux amines secondaires nouvelles, la dihydrocordobimine 1′*S* **5** et la dihydrocordobimine 1′*R* **6**, en proportion 1 : 2. Le composé **5**, *F* 205–209°C (MeOH), $[\alpha]_D^{20}$ −215, présente une courbe de dichroïsme circulaire superposable à celle de la (−)-cordobine **1**. Le dérivé N′-méthylé de **5** s'est révélé identique à la (−)-cordobine **1**, 1*R*, 1′*S*. La configuration 1*R* de la (−)-cordobimine est ainsi doublement confirmée. Le composé **6**, *F* 185–190°C (MeOH), $[\alpha]_D^{20}$ −9, doit donc avoir la configuration absolue 1*R*, 1′*R*, ce que montre la courbe de dc bien différente de celles de la (−)-cordobine **1**, de la (+)-antioquine et inverse de celle de la (+)-guattaguianine 1*S*, 1′*S* (8).

Trois autres Annonacées sud-américaines, *Crematosperma polyphlebum* (2), *Pseudoxandra sclerocarpa* (7) et *Guatteria guianensis* (8) contiennent le même type de bisbenzylisoquinoléines biphényliques, mais avec la configuration 1*S*, 1′*R* ou 1*S*, 1′*S*. *Crematosperma* sp. RC 3110 se caractérise par la configuration 1*R* de ses alcaloïdes, la (−)-cordobine **1**, la (−)-montérine **2** et la (−)-granjine **3**, qui constituent ainsi les premiers alcaloïdes possédant la configuration absolue 1*R*, 1′*S* dans le groupe des bisbenzyltétrahydroisoquinoléines liées par un pont diaryléther 8,7′ et un pont biphénylique 11,11′. Par contre, cette configuration a été trouvée dans le cas de bisbenzyltétrahydroisoquinoléines biphényliques comportant deux ponts diaryléther telles la tiliacorine (9) et la dinklacorine (10) isolées d'une Ménispermacée. La (−)-cordobimine **4** est également le premier alcaloïde présentant une configuration 1*R* du groupe des imino-bisbenzylisoquinoléines biphényliques.

Partie expérimentale

Points de fusion déterminés sur microscope Reichert. Pouvoirs rotatoires mesurés sur polarimètre Schmidt–Haensch, type Polartronic 1. Spectres enregistrés sur les appareils suivants : uv, Unicam SP 1800; ir, Perkin–Elmer 257; rmn ^1H, Cameca (250 MHz) et Bruker (360 MHz); sm, VG Micromass 70; dc, Auto-Dichrograph Mark V. Chromatographies sur colonne réalisées sur Kieselgel 60 (Merck 7734) ou 60H (Merck 7736); ccm analytiques sur DC Alufolien Kieselgel 60 F 254 (Merck 554); ccm préparatives sur Kieselgel 60 GF 254 (Merck 7730).

Matériel végétal

Les écorces de tiges de *Crematosperma* sp. ont été récoltées à Urrao (Antioquia), Colombie, en décembre 1986. Un échantillon d'herbier est déposé sous le numéro RC 3110 à l'Université d'Antioquia à Medellin et à Rijks Universiteit à Utrecht (en cours d'identification par le Pr. P. J. M. Maas; espèce nouvelle?).

Extraction et isolement des alcaloïdes

La poudre sèche des écorces de *Crematosperma* (1,07 kg) a été dégraissée par l'éther de pétrole. Le marc a été extrait au MeOH contenant 3% d'acide citrique par percolation jusqu'à réaction de Mayer négative. Après l'évaporation du MeOH, l'extrait alcaloïdique a été extrait par HCl à 2%. Les phases aqueuses ont été alcalinisées par l'ammoniaque et extraites au CH_2Cl_2. Après évaporation du solvant, on obtient les alcaloïdes totaux non quaternaires (21,4 g; 2%).

Les alcaloïdes totaux ont été chromatographiés sur colonne de silice. L'élution par le mélange hexane–CH_2Cl_2–diéthylamine (6 : 3 : 1) a fourni 2,00 g de (−)-granjine **3**, 5,35 g de (−)-montérine **2**, 3,20 g de (−)-cordobine **1** et, à la fin, 6,40 g de (−)-cordobimine **4**.

(−)-Cordobine 1

$C_{37}H_{40}N_2O_6$, amorphe; $[\alpha]_D^{20}$ −140 (*c* 0,7, $CHCl_3$); uv, λ_{max} (MeOH) : 213 (log ε 4,60), 238 (log ε 4,32) (épaule), 285 (log ε 3,99); dc (MeOH) : $\Delta\varepsilon_{218}$ +31,6, $\Delta\varepsilon_{231}$ 0, $\Delta\varepsilon_{246}$ −12,8, $\Delta\varepsilon_{260}$ 0, $\Delta\varepsilon_{285}$ −4,9 $\Delta\varepsilon_{305}$ 0, $\Delta\varepsilon_{320}$ +0,9, $\Delta\varepsilon_{335}$ 0; rmn ^1H, $CDCl_3$, nOeds (la solution a été dégazée sous pression réduite à la température de l'azote liquide, puis saturée par de l'argon) : NMe-2 → H-1 (10%), H-1 → NMe-2 (2), H-1 → H-10 (5), H-5 → OMe-6 (5), OMe-6 → H-5 (14), H-5′ → OMe-6′ (5), OMe-6′ → H-5′ (9), NMe-2′ → H-1′ (6), OMe-12 → H-13 (7), H-13 → OMe-12 (3); sm (ie), *m/z* (%) : 608 ($M^{+\bullet}$, 21), 607 (21), 593 (3), 577 (2), 382 (30), 381 (70), 367 (21), 353 (13), 192 (47), 191 (100), 174 (26).

O,O-*Diméthylcordobine*

Composé **1** (10 mg) dans 3 mL MeOH a été traité par 5 mL de CH_2N_2–Et_2O pendant 24 h. Après évaporation de l'éther, le résidu a été purifié sur ccm préparative (éluant : CH_2Cl_2–MeOH–ammoniaque (95 : 5 : 0,1)) et on a obtenu 9 mg d'un produit identique à la (−)-granjine **3** (ccm, sm, rmn ^1H, $[\alpha]_D$, dc).

(−)-Montérine 2

$C_{38}H_{42}N_2O_6$, amorphe; $[\alpha]_D^{20}$ −135 (*c* 0,4, $CHCl_3$); uv, λ_{max} (MeOH) : 213 (log ε 4,53), 238 (log ε 4,16) (épaule), 285 (log ε 3,75); dc (MeOH) : $\Delta\varepsilon_{225}$ +37,1, $\Delta\varepsilon_{233}$ 0, $\Delta\varepsilon_{246}$ −44,2, $\Delta\varepsilon_{264}$ 0, $\Delta\varepsilon_{283}$ −14,5, $\Delta\varepsilon_{305}$ 0; rmn ^1H, $CDCl_3$, 0°C, nOeds (% du conformère *a* est

souligné) : NMe-2 → H-1 (8%, 13%), NMe-2′ → H-1′ (6), H-1 → H-10 (6), H-10 → H-1 (6), H-10 → H-10′ (5), H-10 → H-8′ (4), H-10′ → H-10 (3, 7), H-10′ → H-8′ (4), H-1′ → H-8′ (4), CH_3O-12 → H-13 (12, 12), CH_3O-12′ → H-13′ (16), NMe-2 → H-14 (4), H-14 → H-13 (6), NMe-2′ → H-14′ (5), H-14′ → H-13′ (7), CH_3O-6 → H-5 (6), CH_3O-6′ → H-5′ (9, 6); sm (ie), m/z : 622 ($M^{+\bullet}$, 47), 621 (34), 607 (7), 591 (4), 382 (37), 381 (100), 367 (30), 192 (14), 191 (53), 175 (5), 174 (10).

O-*Méthylmontérine*

Composé **2** (10 mg) dans 3 mL de MeOH a été traité par 5 mL de CH_2N_2–Et_2O pendant 48 h. Après purification du résidu comme indiqué ci-dessus, on a obtenu 8 mg d'une substance identique à la (−)-granjine **3** (ccm, sm, rmn ^1H, $[\alpha]_D$, dc).

(−)-Granjine 3

$C_{39}H_{44}N_2O_6$, amorphe; $[\alpha]_D^{20}$ −63 (*c* 0,6, $CHCl_3$); uv, λ_{max} (MeOH) : 211 (log ε 4,61), 238 (log ε 4,28) (épaule), 284 (log ε 3,92); dc (MeOH) : $\Delta\varepsilon_{227}$ +22, $\Delta\varepsilon_{235}$ 0, $\Delta\varepsilon_{246}$ −30,0, $\Delta\varepsilon_{282}$ −10,4, $\Delta\varepsilon_{310}$ 0; sm, ie, m/z: 636 ($M^{+\bullet}$, 27), 635 (16), 621 (3), 396 (21), 395 (54), 381 (17), 199 (30), 198 (100), 175 (34), 174 (30).

(−)-Cordobimine 4

$C_{36}H_{36}N_2O_6$; amorphe; $[\alpha]_D^{20}$ −185 (*c* 0,5, $CHCl_3$); uv, λ_{max} (MeOH) : 218 (log ε 4,64), 284 (log ε 4,07), 308 (log ε 3,85) (épaule); MeOH–NaOH : 230, 302; MeOH–HCl : 218, 245 ép., 288, 346; dc (MeOH) : $\Delta\varepsilon_{215}$ +20,0, $\Delta\varepsilon_{226}$ −35,5, $\Delta\varepsilon_{250}$ −35,2, $\Delta\varepsilon_{260}$ 0, $\Delta\varepsilon_{269}$ +10,4 $\Delta\varepsilon_{279}$ 0, $\Delta\varepsilon_{301}$ −36,0, $\Delta\varepsilon_{337}$ 0; ir, ν (KBr): 1620 cm^{-1}; rmn ^1H, $CDCl_3$, nOeds : H-10 → H-1 (2%), H-1 → NMe-2 (3), H-5 → OMe-6 (4), OMe-6 → H-5 (15), OMe-12 → H-13 (14), H-10 → H-10′ (7), OMe-6′ → H-5′ (13), H-5′ → OMe-6′ (5), H-8′ → H-10′ (12), H-10′ → H-8′ (12); sm, ie, m/z : 592 ($M^{+\bullet}$, 100), 591 (89), 577 (18), 561 (22), 367 (2), 296 (15), 192 (7), 191 (12), 190 (13).

Reduction de la (−)-cordobimine 4

Composé **4** (130 mg) dans du MeOH a été réduit par 80 mg de $NaBH_4$. Après évaporation du solvant, le résidu a été acidifié par HCl, alcalinisé par de l'ammoniaque et extrait au CH_2Cl_2. Le résidu soumis à une ccm préparative sur silice (éluant : CH_2Cl_2–MeOH–ammoniaque (90 : 10 : 0,5)) a fourni 25 mg de dihydrocordobimine 1′*S* **5** et 54 mg de dihydrocordobimine 1′*R* **6**.

Dihydrocordobimine 1′S 5

$C_{36}H_{38}N_2O_6$, *F* 205–209°C (MeOH); $[\alpha]_D^{20}$ −215 (*c* 1, $CHCl_3$); uv, λ_{max} (MeOH) : 215 (log ε 4,44), 238 (log ε 4,16) (épaule), 286 (log ε 3,83); dc (MeOH) : $\Delta\varepsilon_{217}$ +18,4, $\Delta\varepsilon_{225}$ 0, $\Delta\varepsilon_{244}$ −26,3, $\Delta\varepsilon_{284}$ −8,9, $\Delta\varepsilon_{315}$ 0; rmn ^1H, $CDCl_3$, nOeds : H-1 → NMe-2 (1%), OMe-6 → H-5 (6), OMe-6′ → H-5′ (5), OMe-12 → H-13 (7); sm, ie, m/z : 594 ($M^{+\bullet}$, 40), 593 (42), 580 (4), 579 (9), 559 (7), 368 (36), 367 (68), 353 (43), 208 (16), 192 (62), 191 (36), 190 (25), 184 (100).

N-*Méthyldihydrocordobimine 1′S = (−)-cordobine 1*

Composé **5** (15 mg) dans 1 mL de MeOH a été traité par 0,1 mL de HCHO à 30% à 20°C, 30 min, puis réduit par $NaBH_4$. Après extraction, on a obtenu 13 mg d'alcaloïde identique à la (−)-cordobine **1** (sm, rmn ^1H, ccm, $[\alpha]_D$, dc).

Dihydrocordobimine 1′R 6

$C_{36}H_{38}N_2O_6$, *F* 185–190°C (MeOH): $[\alpha]_D^{20}$ −9 (*c* 1, $CHCl_3$); uv, λ_{max} (MeOH) : 220 (log ε 4,60), 238 (log ε 4,40) (épaule), 286 (log ε 4,05); dc (MeOH) : $\Delta\varepsilon_{226}$ −38,0, $\Delta\varepsilon_{238}$ 0, $\Delta\varepsilon_{243}$ +3,5, $\Delta\varepsilon_{246}$ 0, $\Delta\varepsilon_{254}$ −13,3, $\Delta\varepsilon_{273}$ 0, $\Delta\varepsilon_{296}$ −5,1, $\Delta\varepsilon_{320}$ 0; rmn ^1H, $CDCl_3$, nOeds : H-1 → NMe-2 (2%), NMe-2 → H-1 (9), H-1 → H-10 (6), H-10 → H-1 (7), H-5 → OMe-6 (4), OMe-6 → H-5 (14), H-10 → H-10′ (9), H-10′ → H-10 (9), OMe-12 → H-13 (13), H-1′ → H-8′ (2), H-5′ → OMe-6′ (4), OMe-6′ → H-5′ (12); sm, ie, m/z : 594 ($M^{+\bullet}$, 42), 593 (44), 580 (5), 579 (9), 563 (3), 368 (36), 367 (64), 353 (40), 208 (13), 192 (43), 191 (22), 190 (15), 184 (100).

Remerciements

Les auteurs expriment leur vive gratitude à M. R. Callejas (Université d'Antioquia, Colombie) pour la récolte du matériel végétal et à M. C. Mérienne (Faculté des Sciences d'Orsay, France) pour l'enregistrement des spectres de rmn du proton à 250 MHz.

Formation of hexacyanomanganate(II) in cyanide medium and kinetics and mechanism of its oxidation by chromate

GUILLERMO LÓPEZ-CUETO[1] AND MIGUEL DUARTE
Analytical Chemistry Division, University of Alicante, Apdo. 99, 03080 Alicante, Spain

Received April 30, 1987[2]

GUILLERMO LÓPEZ-CUETO and MIGUEL DUARTE. Can. J. Chem. **67**, 279 (1989).

The rate of formation of hexacyanomanganate(II) is first-order in Mn(II) and depends on both the cyanide and hydroxide concentrations. The experimental results agree with a reaction mechanism which involves manganese(II) cyano- and hydroxo-complexes. Chromate slowly oxidizes hexacyanomanganate(II). The kinetics of this reaction is first-order on hexacyanomanganate(II), and the experimental rate constant depends on the chromate concentration according to the equation $k_{exp} = 3kK[Cr(VI)]/(1 + K[Cr(VI)])$. The effect of both the CN^- and the OH^- ions is slighter. A tentative mechanism is proposed which involves a pre-equilibrium with the formation of a hexacyanomanganate(II)–chromate complex, followed by a monomolecular decomposition. By comparing this reaction mechanism with that of other one-electron chromate reductions, it appears that hexacyanomanganate(II) behaves like octacyanomolybdate(IV) rather than like hexacyanoferrate(II) and other substitution-inert reductants. Both the equilibrium constants for the complex formation and the rate constant for its decomposition are evaluated, and voltammetric evidence of the formation of hexacyanomanganate(III)–chromate complexes is also presented.

Key words: hexacyanomanganate(II), formation rate, oxidation with chromate, kinetics, mechanism.

GUILLERMO LÓPEZ-CUETO et MIGUEL DUARTE. Can. J. Chem. **67**, 279 (1989).

La vitesse de formation de l'hexacyanomanganate(II) est du premier ordre en Mn(II) et dépend à la fois de la concentration en cyanure et en hydroxyde. Les résultats expérimentaux sont en accord avec un mécanisme réactionnel impliquant des complexes cyano- et hydroxy- manganèse(II). Le chromate oxyde lentement l'hexacyanomanganate(II). La cinétique de la réaction est du premier ordre en hexacyanomanganate(II) et la constante expérimentale de vitesse est reliée à la concentration en chromate par l'équation suivante : $k_{exp} = 3kK[Cr(VI)]/(1 + K[Cr(VI)])$. Les effets des ions CN^- et OH^- sont plus faibles. On propose un mécanisme impliquant un pré-équilibre, avec la formation d'un complexe hexacyanomanganate(II)–chromate, qui est suivi par une décomposition monomoléculaire. En comparant ce mécanisme réactionnel avec celui d'autres réductions effectuées par le chromate et impliquant un électron, il semble que l'hexacyanomanganate(II) se comporte plutôt comme l'octacyanomolybdate(IV) que comme l'hexacyanoferrate(II) et d'autres réducteurs qui sont inertes par rapport à la substitution. On a évalué la constante d'équilibre pour la formation du complexe ainsi que la constante de vitesse de sa décomposition; de plus, on présente des données voltamétriques concernant la formation de complexes hexacyanomanganate(III)–chromate.

Mots clés : hexacyanomanganate(II), vitesse de formation, oxydation par le chromate, cinétique, mécanisme.

[Traduit par la revue]

Introduction

Manganese(II) in cyanide solution forms a reducing complex. The standard potential of the $Mn(CN)_6^{3-}/Mn(CN)_6^{4-}$ couple is about −0.24 V (1), but not much is known about its reactions. In the presence of cyanide, manganese(II) readily reacts with several oxidizing substances, such as atmospheric oxygen, hydrogen peroxide, peroxydisulfate, vanadate, and hexacyanoferrate(III). The reaction with $Fe(CN)_6^{3-}$, which is very fast, has been studied for analytical purposes, and has been applied to both the coulometric titration of hexacyanoferrate(III) (2) and the volumetric and coulometric titration of manganese(II) (3). Chromate also oxidizes manganese(II) in cyanide medium but this reaction is slow. This paper is concerned primarily with the kinetics and mechanism of this reaction, in order to contribute to the knowledge of the redox behavior of manganese(II) in cyanide medium. This is the first kinetic study that has been reported about a redox reaction of manganese(II) in this complexing medium. Moreover, some aspects of the kinetics of formation of the hexacyanomanganate(II) ion are studied. In this medium manganese(II) is easily oxidized if oxygen is present; therefore, the monitoring technique must necessarily let us operate properly in an inert atmosphere. Amperometry with a rotating disc platinum electrode was used for the kinetic measurements.

Experimental

Reagents

Manganese(II) solutions were prepared with $MnSO_4.H_2O$ and were standardized with $K_3Fe(CN)_6$ standard solution to a potentiometric end point (3). Chromate solutions were prepared with K_2CrO_4 and were standardized by back titration with standard Fe(II) and $K_2Cr_2O_7$ solutions. NaCN, NaCl, and NaOH were also used in the preparation of the solutions. All of the chemicals used were of reagent grade.

Apparatus

A 506 E Metrohm polarograph provided with a three-electrode circuit has been used to obtain both the current–voltage and the current–time curves. The indicator electrode was a 628-10 Metrohm rotating disc platinum electrode, the reference electrode was a home-made saturated calomel electrode and the auxiliary electrode was a platinum wire.

A 50 mL EA 880 Metrohm vessel was used as the reaction cell. The temperature was kept constant within ±0.1°C by means of a Haake K circulation bath. Nitrogen was used to remove previously the dissolved oxygen.

Procedure

The required amounts of solid NaCN and NaCl were dissolved in the adequate volume of NaOH solution. After dilution to 50 mL, a gentle nitrogen stream was bubbled through the solution for 15–20 min. Then, 1 mL of the Mn(II) solution was added, and the anodic limiting current was measured at 0 V on the recorder chart. The appearance of a cathodic component in the current–voltage curves revealed that a certain amount of manganese(II) was oxidized by the dissolved oxygen introduced with the Mn(II) solution. However, no effect was observed

from the Mn(III) on the kinetics, and therefore it was not necessary to carry out a more rigorous deaeration. Once the current has been stabilised, 1 mL of the CrO_4^{2-} solution was added and the current was continuously recorded against time.

The rate of formation of the $Mn(CN)_6^{4-}$ complex was monitored by recording the anodic limiting current measured at -0.3 V from the addition of manganese(II) to the cyanide solution.

Kinetic experiments were made at 25°C and at 1.0 *M* ionic strength excepting when the effects of these variables were studied.

Results and discussion

The formation of $Mn(CN)_6^{4-}$

Formation of the $Mn(CN)_6^{4-}$ complex is not an instantaneous reaction. Current–voltage curves of fresh cyanide solutions of manganese(II) at different times are shown in Fig. 1. The early voltammograms consist of several anodic waves. The first one, with a halfwave potential of about -0.5 V, is well defined and increases with time, while the other poorly defined waves decrease. When the equilibrium has been reached, only the first wave remains. This wave is probably due to the anodic oxidation of the $Mn(CN)_6^{4-}$ to $Mn(CN)_6^{3-}$, while the other waves would probably be due to the anodic oxidation of some transient Mn(II) cyanide complexes with a lower cyanide content. This behavior agrees with that observed by Kemula *et al.* (4) in the polarographic reduction of Mn(II) in cyanide medium. These authors reported two cathodic waves with half-wave potentials of -1.33 and -1.61 V, attributed to the reduction of $Mn(CN)_6^{4-}$ and of other complexes of smaller coordination number, respectively.

When the limiting current measured at -0.3 V is recorded against time after the reaction has been started by the manganese(II) addition, formation curves as that of the Fig. 2 are obtained. The experimental curves are fairly fitted to the equation

$$[1] \quad \ln \frac{i_\infty - i}{i_\infty} = -kt$$

which reveals a pseudo-first-order dependence, in accordance with the results of Kemula *et al.* (4). The pseudo-first-order rate constant reported by Kemula *et al.* in a 1.0 *M* KCN solution at 20°C was $3 \times 10^{-2}\ s^{-1}$. We found a value of $8.4 \times 10^{-3}\ s^{-1}$ in a 1.0 *M* NaCN and 0.01 *M* NaOH solution at 25°C. We believe that the difference can be attributed chiefly to the higher alkalinity of our solution. Indeed, the pseudo-first-order rate constant is influenced by both the cyanide and the hydroxide concentrations (Table 1). A rapid rise in the value of the rate constant is produced when the sodium cyanide concentration increases between 0.3 and 1.0 *M*, while an increase of the sodium hydroxide concentration from 0.01 to 0.09 *M* causes a decrease in the rate constant. The dependence of the rate constant on both the CN^- and the OH^- concentrations seems to reflect that some equilibria between manganese(II) cyano- and hydroxocomplexes are involved in the formation of hexacyanomanganate(II). The expected reaction scheme would have the following general form[3]

$$[2] \quad Mn^{2+} + pCN^- \xrightarrow{\text{fast}} Mn(CN)_p$$

$$[3] \quad Mn(CN)_p + (n-1)CN^- \overset{K_a}{\rightleftharpoons} Mn(CN)_{p+n-1}$$

[3]The authors are grateful to a reviewer for his valuable suggestions on the reaction scheme.

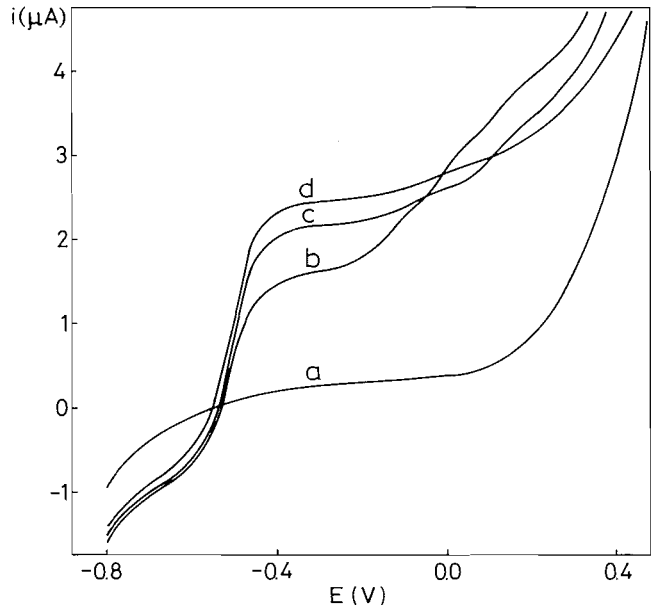

FIG. 1. Evolution of the current–voltage curves of a fresh solution of manganese(II) in the presence of cyanide: NaCN, 1.0 *M*; NaOH, 0.01 *M*; *T*, 25°C. [c] Cr(III), 10^{-3} *M*.

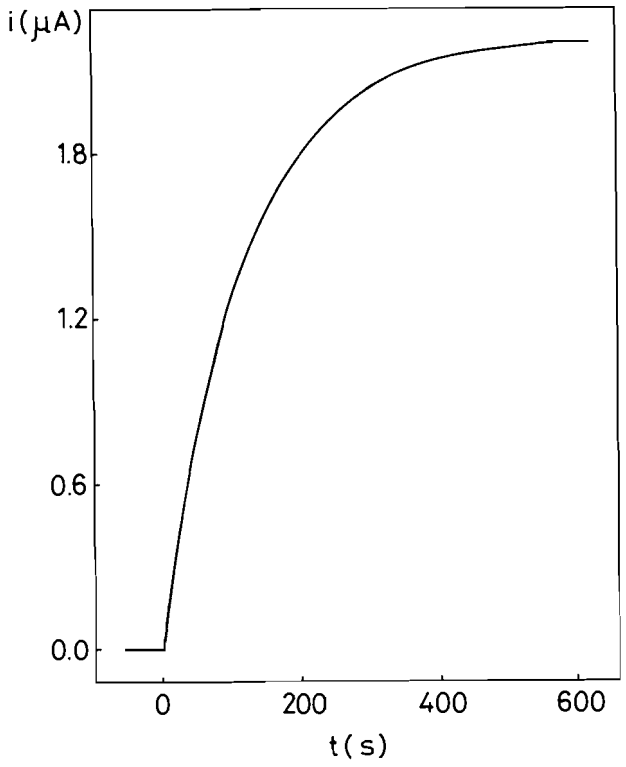

FIG. 2. Formation of $Mn(CN)_6^{4-}$. Variation of the anodic current measured at −0.3 V during the reaction: Mn(II), 10^{-4} *M*; NaCN, 1.0 *M*; NaOH, 0.01 *M*; *T*, 25°C.

$$[6] \quad k = \frac{k_1 K_a [CN^-]^n}{1 + K_a [CN^-]^{n-1}(1 + K_b [OH^-])} + k_{-1}$$

The experimental results can be fitted to this equation for $n = 3$, and the following values can be calculated

$$k_1 K_a = (1.00 \pm 0.02) \times 10^{-2}\ L^3\ mol^{-3}\ s^{-1}$$

$$K_a K_b = 45.5 \pm 1.8\ L^3\ mol^{-3}$$

$$\frac{1 + K_a}{k_1 K_a} = 101 \pm 8\ s$$

$$k_{-1} = (9.3 \pm 0.1) \times 10^{-4}\ s^{-1}$$

The individual values for the constants k_1, K_a, and K_b cannot be determined from the disposable data, because $K_a \ll 1$. The calculated values of the pseudo-first-order constant agree with the experimental ones (Table 1).

The $Mn(CN)_6^{4-}$–CrO_4^{2-} reaction

Kinetics of reaction

It has been found that the kinetics of the $Mn(CN)_6^{4-}$–CrO_4^{2-} reaction is first-order on the hexacyanomanganate(II) ion at least for the 95% of reaction. The pseudo-first-order constant over a range of initial Mn(II) concentrations from 0.1 to 3.0×10^{-4} *M* was $(1.48 \pm 0.05) \times 10^{-3}\ s^{-1}$ for 2×10^{-3} *M* CrO_4^{2-}, 1.0 *M* CN^-, 0.01 *M* OH^- and 25°C (Table 2). At low chromate concentrations the experimental rate constant increases almost linearly with the chromate concentrations (Table 2); however, the slope of the k_{exp} vs. $[CrO_4^{2-}]$ plot decreases as the $[CrO_4^{2-}]$ increases. Experimental values can be correlated quite well to

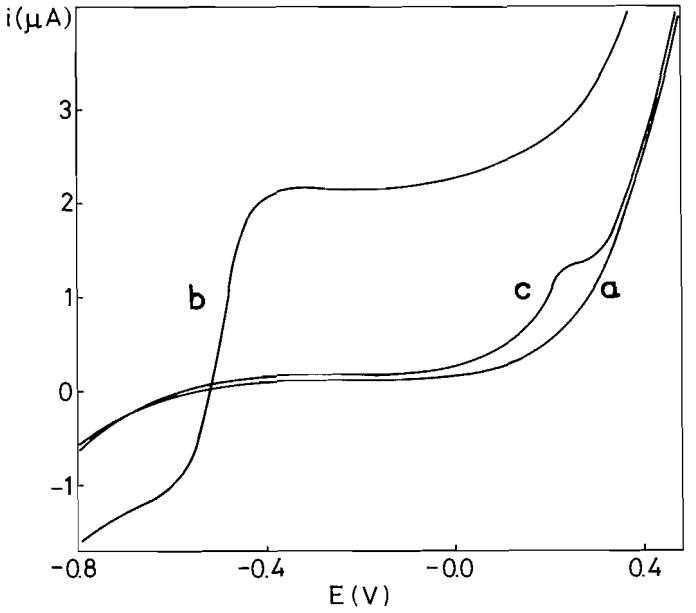

FIG. 3. Oxidation of $Mn(CN)_6^{4-}$ by CrO_4^{2-}. Current–voltage curves: NaCN, 1.0 *M*; NaOH, 0.01 *M*; *T*, 25°C. (*a*), supporting electrolyte alone; (*b*), $Mn(CN)_6^{4-}$, 10^{-4} *M* ($Mn(CN)_6^{4-}$ has been partially oxidized by dissolved oxygen); (*c*), after addition of 2×10^{-3} *M* CrO_4^{2-}, once the redox equilibrium has been reached.

the equation

$$[7] \quad -\frac{d[Mn(CN)_6^{4-}]}{dt} = \frac{[CrO_4^{2-}]}{A + B[CrO_4^{2-}]}[Mn(CN)_6^{4-}] = k_{exp}[Mn(CN)_6^{4-}]$$

where $A = 1.18 \pm 0.01$ L^{-1} mol s and $B = 93 \pm 11$ s in 1.0 *M* NaCN, 0.01 *M* NaOH and at 25°C. Observed and calculated values of the rate constant are given in Table 2.

It appears that the Mn(III) and the Cr(III) produced do not affect to the reaction kinetics and, on the other hand, only a slight effect has been observed from both the CN^- and the OH^- concentrations (Table 2). When the cyanide concentration is lower than 0.6 *M*, a small decrease on the experimental rate constant is produced, while the constant slightly decreases as the hydroxide ion concentration increases. The effect of the CN^- and the OH^- concentrations may be interpreted in terms of solution equilibria involving both aquo- and hydroxo-complexes, besides the hexacyanomanganate(II).

Stoichiometry of reaction

The stoichiometry of the reaction was determined by measuring amperometrically the decrease of the anodic wave of $Mn(CN)_6^{4-}$ after addition of measured chromate amounts to an excess of manganese(II) in sodium cyanide solution. Chromate and manganese(II) reacted by a ratio close to 1:3. The nature of the reaction products has not been well established. The oxidation product of Mn(II) seems not to be the $Mn(CN)_6^{3-}$ ion, as happens when the $Mn(CN)_6^{4-}$ is oxidized by other oxidizing substances, such as oxygen or hexacyanoferrate(III). Indeed, a composite reversible wave, with a half-wave potential of about −0.5 V, is usually obtained at a platinum electrode when both the $Mn(CN)_6^{3-}$ and the $Mn(CN)_6^{4-}$ ions are present in a cyanide solution. However, the products of the $Mn(CN)_6^{4-}$–CrO_4^{2-} reaction do not give any cathodic wave, but a poorly-defined anodic peak at about 0.2 V (Fig. 3). From this, it is apparent that the $Mn(CN)_6^{3-}$ ion has been masked by some species present in the solution. Masking of the products of chromate oxidations of $Fe(CN)_6^{4-}$, $Fe(bip)(CN)_4^{2-}$, and $Fe(bip)_2(CN)_2$ (bip = 2,2′-bipyridine) has been reported to occur, and this has been attributed to the formation of binuclear complexes with Cr(III) (5). Nevertheless, according to the reaction stoichiometry only one third of the Fe(III) is masked by Cr(III). In our case, the $Mn(CN)_6^{3-}$ cathodic wave did not appear at all, which indicates that the $Mn(CN)_6^{3-}$ ion was completely masked. A voltammogram similar to curve (*c*) in Fig. 3 was obtained when an excess of CrO_4^{2-} was added to a $Mn(CN)_6^{3-}$ solution. However, if a $Mn(CN)_6^{4-}$ solution is oxidized by an air stream in the presence of Cr(III), no interaction is observed to be produced between Mn(III) and Cr(III). Undoubtedly, the substitution-inert Cr(III) cannot share in such a reaction. These facts seem to reflect that the interaction takes place between the hexacyanomanganate(III) and the chromate ions. A similar interaction has been reported between Fe(III) and Cr(VI), which form a cationic complex of formula $FeCrO_4^+$ (6). Of course, the conditions in which these two reactions take place are quite different, and the product of the $Mn(CN)_6^{3-}$–CrO_4^{2-} interaction will surely have a different structure from that of the $FeCrO_4^+$ ion, probably a CN^-–bridged Mn—Cr binuclear compound. No attempt has been made to elucidate the nature of the electrode reaction responsible for the anodic peak appeared at about 0.2 V.

Mechanism of reaction

Oxidations of one-electron reductants by chromate proceed generally by three consecutive one-electron steps (5, 7, 8). The kinetics of these reactions are either first or second-order on the reductant, depending on whether the determining step is the reduction of Cr(VI) to Cr(V) (without change in the coordination number) or the reduction of Cr(V) to Cr(IV) (accompanied by a change in the coordination number from 4 to 6) (5, 6). The first type of behavior is followed by substitution-inert reductants, such as $Fe(phen)_3^{2+}$ (phen = 1,10-phenanthroline) (6), $Fe(CN)_6^{4-}$, $Fe(bip)(CN)_4^{2-}$, $Fe(bip)_2(CN)_2$, and $Fe(bip)_3^{2+}$ (5), and the reduction of Cr(VI) proceeds by an outer-sphere mechanism. On the other hand, substitution-labile reductants, such as $Fe(H_2O)_6^{2+}$ (6), show a behavior of the second type, and an inner-sphere mechanism involving an oxygen-bridged transition state takes place in the reaction with Cr(VI). Although these correlations between rate equation, lability or inertness of the reductant and mechanism has been proved to be significant for a series of one-equivalent chromium(VI) reductions, it appears that they can be not generalized. Octacyanomolybdate(IV) is a substitution-inert complex, its reaction with chromium(VI) shows a pseudo-first-order kinetics, and there is evidence that it proceeds via the formation of a CN^--bridged $Mo(CN)_8^{4-}$–CrO_4^{2-} binuclear complex in an inner-sphere mechanism (9). On the basis of these results, McKnight and Haight considered that the cyanocomplexes which coordinate directly to Cr(VI) through CN^- bridges form a third type of one-electron reductants against chromium(VI) (9).

The rate equation [7] for the $Mn(CN)_6^{4-}$–CrO_4^{2-} reaction is first-order on the reductant. Hexacyanomanganate(II) is more labile than both the isoelectronic hexacyanoferrate(III) and hexacyanoferrate(II), but it can be considered a rather inert complex (10). From this viewpoint, it can be expected that the $Mn(CN)_6^{4-}$–Cr(VI) reaction proceed via an outer-sphere mechanism, as does the $Fe(CN)_6^{4-}$–Cr(VI) reaction (5). On the other hand, the possibility of formation of a binuclear Mn(II)—Cr(VI) complex with a CN^- bridge allows for an inner-sphere mechanism like that observed in the $Mo(CN)_8^{4-}$–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

Cr(VI) reaction (9). The generalized rate expression for the one-electron reduction of chromium(VI) is obtained by assuming that Cr(V) reaches a steady-state concentration (5, 8), and a first-order dependence on the reductant is obtained when the rate-determining step is the Cr(VI) to Cr(V) reduction. The kinetics of the $Mn(CN)_6^{4-}$–CrO_4^{2-} reaction cannot completely be explained by such a mechanism. The rate law given by eq. [7], in which a slight inhibiting effect from the CrO_4^{2-} is observed, suggests a preequilibrium in which a complex is formed between the reactants, followed by an inner-sphere electron transfer as the rate-determining step:

$$[8] \quad Mn(II) + Cr(VI) \overset{K}{\rightleftharpoons} [Mn(II).Cr(VI)]$$

$$[9] \quad [Mn(II).Cr(VI)] \overset{k}{\longrightarrow} [Mn(III).Cr(V)]$$

$$[10] \quad [Mn(III).Cr(V)] + Mn(II) \overset{fast}{\longrightarrow} [Mn(III).Cr(IV)] + Mn(III)$$

$$[11] \quad [Mn(III).Cr(IV)] + Mn(II) \overset{fast}{\longrightarrow} [Mn(III).Cr(III)] + Mn(III)$$

$$[12] \quad 2Mn(III) + 2Cr(VI) \overset{fast}{\longrightarrow} 2[Mn(III).Cr(VI)]$$

The successive Mn—Cr compounds are probably binuclear CN^--bridged complexes, including the [Mn(III).Cr(VI)] compound introduced in the last step to explain the masking that involves the $Mn(CN)_6^{3-}$ ion. Although only binuclear complexes have been considered in the mechanism, one cannot discount the possible formation of polycoordinated Mn(III)–Cr(III) compounds as those obtained as a product of the $Mo(CN)_8^{4-}$–CrO_4^{2-} reaction (9). From the proposed scheme the following rate equation may be derived

$$[13] \quad -\frac{d[Mn(II)]}{dt} = \frac{3kK[Cr(VI)]}{1 + K[Cr(VI)]}[Mn(II)]$$

which is in good agreement with the experimental results represented by equation [7]. The suggested mechanism approaches to that proposed for the $Mo(CN)_8^{4-}$–CrO_4^{2-} reaction, and the rate equation [13] takes a simplified second-order form for low CrO_4^{2-} concentration

$$[14] \quad -\frac{d[Mn(II)]}{dt} = 3kK[Cr(VI)][Mn(II)]$$

which is equivalent to the rate equation reported for the $Mo(CN)_8^{4-}$–CrO_4^{2-} reaction at a constant pH value (9). By comparison of eqs. [7] and [13] the values for both the equilibrium and the rate constants are calculated: $K = 79 \pm 9\,L\,mol^{-1}$ and $k = (3.6 \pm 0.4) \times 10^{-3}\,s^{-1}$.

Effects of ionic strength and temperature

When the ionic strength is increased from 1.0 to 5.0 *M* by addition of sodium chloride, a slight increase is produced in the pseudo-first-order constant. From the dependence of the experimental rate constant on the temperature, a value of $56.8 \pm 1.4\ kJ\ mol^{-1}\ K^{-1}$ has been obtained for the apparent energy of activation.

Dielectric polarization and molecular interaction. Part II. Acetylacetone, benzoylacetone, and dibenzoylmethane – triethyl amine – cyclohexane systems

GAMAL R. SAAD, MAGDI M. NAOUM, AND HANNA A. RIZK[1]
Department of Chemistry, Faculty of Science, University of Cairo, Cairo, Egypt

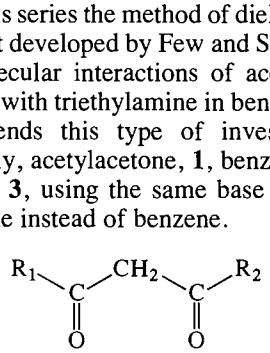
Received July 6, 1988

GAMAL R. SAAD, MAGDI M. NAOUM, and HANNA A. RIZK. Can. J. Chem. **67**, 284 (1989).

A modified form of Few and Smith equation applicable to dilute solutions of acetylacetone, benzoylacetone, and dibenzoylmethane in constant-ratio mixtures of triethylamine in cyclohexane is confirmed. The changes in dielectric polarization of diketones with amine concentration in the mixed solvents are used to deduce the equilibrium constants of the association process, and the dipole moments of the complexes formed. Further, an inference is made of the relative polarities of the keto and enol tautomers of these diketones, and of the ketoanilides previously investigated (1).

Key words: dielectric polarization, molecular interaction, β-diketones, triethylamine.

GAMAL R. SAAD, MAGDI M. NAOUM et HANNA A. RIZK. Can. J. Chem. **67**, 284 (1989).



On a confirmé l'utilité d'une forme modifiée de l'équation de Few et Smith pour étudier des solutions diluées d'acétylacétone, de benzoylacétone et de dibenzoylméthane dans des mélanges à rapport constant de triéthylamine dans le cyclohexane. On utilise les changements de polarisation diélectrique des dicétones en fonction de la concentration d'amine dans les solvants mixtes pour déduire les constantes d'équilibre du processus d'association ainsi que les moments dipôlaires des complexes formés. De plus, on peut déduire les polarités relatives des tautomères cétoniques ou énoliques de ces dicétones ainsi que des cétoanilides étudiés antérieurement (1).

Mots clés : polarisation diélectrique, interaction moléculaire, β dicétones, triéthylamine.

For personal use only.

In part I (1) of this series the method of dielectric polarization measurements, first developed by Few and Smith (2), was used to investigate molecular interactions of acetoacetanilide and benzoylacetanilide with triethylamine in benzene solution. The present work extends this type of investigation to three β-diketones, namely, acetylacetone, **1**, benzoylacetone, **2**, and dibenzoylmethane, **3**, using the same base and the non-polar solvent cyclohexane instead of benzene.

1, $R_1 = R_2 = CH_3$; **2**, $R_1 = CH_3$, $R_2 = C_6H_5$; **3**, $R_1 = R_2 = C_6H_5$

However, since in an inert solvent, S, the acid, A, whether it is a β-diketones as in the present investigation, or β-ketoanilide as in the previous (1) one, exists in solution as an equilibrium mixture of the keto and enol tautomers, the presence of an interacting base, B, such as triethylamine will not only cause complexation through hydrogen bonding between the enolic OH group and the amine nitrogen, but also a shift in the position of equilibrium towards enol formation (3) as a consequence. This, in turn, might lead one to suggest that the standard value of polarization of the solute, which does not involve short-range interactions leading to complex formation (2, 4, 5), would be better taken as the extrapolated value of the polarization, P^*_A, in the solvent mixture, BS, in the limit when the concentration of the interacting base, B, approaches zero, rather than the polarization, P_A, in the non-polar solvent, S, as previously suggested (1, 2). Thus denoting $(P^*_A)_{w_B=0}$ as P'_A, where w_B is the weight fraction of the base in the constant-ratio solvent mixture, the equation of Few and Smith (2) can easily modified into

$$[1] \quad \frac{\Delta P}{P^*_A - P'_A} = 1 + \frac{M_B}{K w_B d}$$

where $\Delta P = P_{AB} - P'_A - P_B$, the other terms having their usual significance (1).

This equation has, therefore, been preferentially used in the present work for the calculation of both the equilibrium constants, K's of the association process between the β-diketone (**1**–**3**) and triethylamine in cyclohexane, and the dipole moments μ_{AB}'s, of the complexes formed. Recalculation of these two parameters has also been made for acetoacetanilide, **4**, and benzoylacetanilide, **5**, which were previously investigated (1).

Experimental and results

Acetylacetone (PROLABO, France) was purified by repeated distillation, benzoylacetone and dibenzoylmethane (HOPKINS & WILLIAMS, England) by two-fold crystallization from ethanol, and cyclohexane and triethylamine according to recommended procedures (6). The purity of compounds was checked by comparing their physical constants with those cited in literature (6).

Preparation of solutions and measurements of dielectric constant, ϵ, density, d, and refractive index for the sodium-D line, n_D, were carried out as described before (1, 7).

For the calculation of the equilibrium constant, K, of the association process and the dipole moment, μ_{AB}, of the complex, eq. [1] was used, the value of P'_A being first obtained by graphical extrapolation of P^*_A at $w_B = 0$.

The results obtained are summarized in Tables 1–3 for acetylacetone-, benzoylacetone-, and dibenzoylmethane–triethylamine–cyclohexane systems, respectively.[2]

Furthermore, since triethylamine has an appreciable dipole moment in cyclohexane, which is 0.83 D as determined in the present work, use was made of the modified Onsager equation (8, 9) for the determination of the apparent solution moment,

μ_2, of the β-diketone in the constant-ratio solvent mixtures of the amines and cyclohexane. The results obtained are summarized in Tables 14–16.

Discussion

First, since the equilibrium position between the keto and enol tautomers of the acid A (whether a diketone in cyclohexane or ketoanilide in benzene) is shifted in favour of the enol form in the presence of triethylamine, owing to the hydrogen bonding between the enolic OH group and the nitrogen lone pair of electrons, we would expect that its polarization, P_A, at infinite dilution in the non-polar solvent, S, should be either higher or lower than its polarization, P'_A, at infinite dilution in the solvent mixture, BS, in the limit when the concentration of the base approaches zero, depending upon the relative polarities of the two tautomers. That is, if the keto form of the acid is of more polarity than the enol form, P_A will be greater than P'_A and vice versa. Based on this, an inspection of the results obtained as

shown in Table 17 would lead to the inference that whilst the keto tautomer is more polar than the enol in the case of β-diketones, the opposite takes place in the case of β-ketoanilides, which is consistent with previous findings (10). Subsequently, use can be made of the value P'_A to calculate by the refractivity method, the corresponding molecular dipole moment, μ'_A. Thus the results obtained are also listed in Table 17, together with the dipole moments, μ_{enol} and μ_{keto}, which were previously (10) deduced from other lines of evidence.

It will be evident from this table that in the case of diketones there is a fair agreement between the values of μ'_A and μ_{enol}, and that in the case of ketoanilides there is a marked difference between these values, namely, μ'_A are appreciably lower than μ_{enol}. This in turn might suggest that in extreme dilute solutions of the acid A, the effect of the base B through the hydrogen bonding action is either to cause practically complete conversion of this acid into its enol form if it is a diketone in cyclohexane solution, or to shift largely the position of equilibrium in favour of the enol form (but not to completion) if it is a ketoanilide in benzene solution.

This conclusion might be accepted in view of the experimental facts (10, 11) that in the case of β-diketones the amount of enol present at infinite dilution in cyclohexane (as well as in carbon tetrachloride) is of the order of 98–100 mol%, whereas in the case of β-ketoanilides at infinite dilution in the less inert solvent benzene, in which preferential solvation of the keto tautomer takes place, it is less than 40 mol%.

Consequently, in the case of diketones a rough estimate has been made of the dipole moment, δm, of the intramolecular hydrogen bond of the enol tautomer by applying the method of bond moments (11) and making use of the value μ'_A which was taken as equal to μ_{enol}. The results obtained are again listed in Table 17. It will be evident from this table that δm increases in the order

[2] **1 < 2 < 3**

signifying that the acidity of the diketones decreases in the opposite order; that is,

[3] **1 > 2 > 3**

This is consistent with the observations that the values (12) of pK_a increase in the order given by eq. [2], whereas those of the equilibrium constant, K, as determined in the present work, decreases in the sequence given by eq. [3] (again see Table 17).

It may be pointed out here that in the case of ketoanilides an estimate of the dipole moment of the intramolecular hydrogen bond of the enol form could not be made as in the case of diketones, since μ'_A cannot be equated to μ_{enol}, as noted above. Also that the values of the equilibrium constant, K, of the association process in benzene solution, as obtained by applying eq. [1], which is a modified form of Few and Smith (2) original equation, are 364 and 720 cm^3/mol for acetoacetanilide and benzoylacetanilide, respectively. These values might be regarded as more correct than those previously (1) obtained. On the other hand, the fact that they are still much lower than those of the association process of the diketones with the same amine in cyclohexane solution (see Table 17) although the ketoanilides are of higher acidity, as can be evidenced from the pK_a values, can be accounted for on the basis that since benzene is more active than cyclohexane the formation of hydrogen bonded complexes in the former solvent necessitates the breaking of the bonds which the ketoanilides (and probably the base triethylamine) form with it.

It might be added here that although the apparent solution moments, μ_2's, of the diketones in the various constant-ratio mixtures obtained by either the usual Debye equation, or the modified Onsager (8, 9) equation could be regarded "incorrect", owing to the fact that no account is taken in any of these equations of the short-range forces that lead to complex formation, their apparent increase with increasing concentration of the amine (see Tables 1–3, and 14–16) suggests an increase in complex formation. An estimate of this increase can, in turn, be made by the calculation of the fraction, $\Delta w_A/w_A$, of the diketone introduced in the constant-ratio mixture of triethylamine and cyclohexane, which is complexed with the amine at infinite dilution. For this purpose, the following equation also suggested by Few and Smith (2) except that P'_A is substituted for P_A, as pointed out above, has been used.

[4] $$P^*_A - P'_A = \Delta P(\Delta w_A/w_A)$$

The results obtained are shown in Table 18. It is obvious from this table that an increase in the proportion of triethylamine in the solvent mixture favours complex formation; as is to be expected. Moreover, for a given solvent mixture, the tendency toward complex formation with the amine is highest for acetylacetone, **1**, and least with dibenzoylmethane, **3**. This agrees with the above conclusion drawn from the values of the dipole moment, δm, of the intramolecular hydrogen bond, as well as from those of the equilibrium constant, K, of complexation, and of the acidity, pK_a, of the diketones.

Owing to the limited number of investigated compounds in the present work, it is difficult to investigate the effect of change in acidity of these compounds in a given solvent upon the equilibrium constant of the association process. For the same reason, it is also difficult to check whether there is a correlation between the magnitude, $\Delta\mu$, of the dipole moment change associated with the formation of the intermolecular hydrogen bond, N---H—O, and the equilibrium constant expressed in terms of the free energy change, ΔG^0, of formation of the complex.

If, however, in a preliminary investigation one confines oneself just to the three diketones investigated here, it can be easily seen from Table 17 that there is a correlation between ΔG^0, and the acidity, pK_a, the trend being given by the relation

[5] $$\Delta G^0 = -15.6 + 1.07pK_a$$

and that there is no correlation between $\Delta\mu$, which was roughly calculated by the vector summation method of bond moments (11, 13–15), and ΔG^0. This is to be expected on the basis that a breaking of the intramolecular hydrogen bond in the enol tautomer of the acid should precede the formation of the intermolecular hydrogen bond.

Obviously, a clear justification of these inferences could only be obtained by extending measurements on a larger number of compounds.

This study is to compare the adsorption of phenanthrene — a polynuclear aromatic hydrocarbon — (apolar molecule) and water (polar molecule) on chrysotile, a mainly ionic solid and on one silica (Aerosil), a covalent solid. The adsorption of water shows that the adsorption capacity and the interaction energies are much higher for chrysotile than for silica. With phenanthrene, the adsorption mechanism on these two materials is very different: on chrysotile — a solid with a surface having a basic character — there is a multilayer adsorption, with lateral interactions between PAH molecules vertically oriented with regard to solid surface, whereas on silica (acidic solid), the PAH molecules are adsorbed flat and form only one layer. Chrysotile turns out to be a much more powerful adsorbent than silica towards both polar molecules and apolar molecules. The calorimetric data concerning the adsorption of phenanthrene on chrysotile in xylene reveal three thermal stages, showing the influence of preadsorbed water and solvent and permit to propose a model of adsorption mechanism. The formation of multilayers of phenanthrene on chrysotile converts its marked hydrophilic surface into a hydrophobic one which may act as a carrier of organic molecules and slowly release them into the biological medium. These phenomena may provide a possible interpretation for some synergistic effects concerning lung cancers observed after asbestos and cigarette-smoke exposure.

Key words: adsorption, phenanthrene, chrysotile, silica, water.

JEANINE FOURNIER, BICE FUBINI, VERA BOLIS et HENRI PEZERAT. Can. J. Chem. **67**, 289 (1989).

La comparaison des propriétés d'adsorption d'un solide ionique, le chrysotile avec celles d'un solide covalent, une silice (Aérosil), est fondée sur l'étude de l'adsorption d'un hydrocarbure polycyclique aromatique, le phénanthrène (molécule apolaire) dans le xylène et d'une molécule polaire à l'état gazeux, l'eau. L'adsorption de l'eau montre que la capacité d'adsorption et l'énergie d'interaction (solide-H_2O) sont beaucoup plus importantes dans le cas du chrysotile que dans le cas de la silice. L'adsorption du phénanthrène diffère selon le matériau étudié. En effet, pour le chrysotile dont la surface présente un caractère basique, les isothermes révèlent une adsorption en multicouches avec la présence d'interactions latérales entre les molécules adsorbées, ces molécules étant orientées verticalement par rapport à la surface. Par contre, pour la silice, seule une monocouche est formée avec des molécules adsorbées à plat. Tous ces résultats font apparaître que le chrysotile a une capacité d'adsorption pour le phénanthrène et pour l'eau très supérieure à celle de la silice. La présence de trois étapes thermiques lors de l'adsorption du phénanthrène sur le chrysotile révèle l'influence du solvant et de l'eau préadsorbée. Ces données calorimétriques permettant de proposer un modèle de mécanisme d'adsorption. La surface du chrysotile, initialement hydrophile devient hydrophobe du fait de la présence de multicouches de phénanthrène. Le chrysotile peut être considéré comme un collecteur et un transporteur de molécules organiques qui sont ainsi introduites dans le milieu biologique. Cette étude peut contribuer à expliquer, du moins en partie, les effets de synergie observées entre amiante et fumée de cigarette dans l'initiation de cancer du poumon.

Mots clés : adsorption, phénanthrène, chrysotile, silice, l'eau.

Introduction

It is well known that the risk of bronchopulmonary cancers upon exposure to asbestos is much greater in people with smoking habits. Several epidemiological studies have in fact shown an effect of synergy between asbestos and cigarette smoke (1, 2). Among the carcinogenic organic compounds present in cigarette smoke, an important role is generally attributed to some polynuclear aromatic hydrocarbons (PAH).

The synergistic effect between PAH (e.g. benzo(*a*)pyrene or dimethyl-7,12-benzanthracene) and different varieties of asbestos has been confirmed by animal experimentations when the PAH preadsorbed on asbestos was introduced by intratracheal injection (3, 4). These studies have shown a great rate of bronchopulmonary cancers for preadsorbed PAH by comparison with solid PAH introduced alone.

Furthermore, several works *in vitro* (5, 6) confirm the results of epidemiology and of experimentations *in vivo*. The *in vitro* results have in fact revealed that the kinetics of PAH uptake in the hydrophobic zone of cells vary depending on whether PAH is previously adsorbed on asbestos.

The mechanisms of this synergy have not yet been clarified. We can suppose that the synergy involves either some complex interplay between the two pathological processes initiated by the two toxic agents as in the model proposed by Cohen (7) or some interaction between the inorganic solid and the PAH which could increase the intrinsic carcinogenic activity of one or both compounds. In the latter hypothesis, a detailed surface study on the adsorption properties of the solid is required. Both mechanisms, however, can act together.

In parallel with what happens in liquid–liquid interactions, it

is generally accepted that polar molecules will be preferentially adsorbed on ionic solids whereas apolar molecules will be preferentially adsorbed on covalent ones. In this respect, several studies (8–10) have shown that long-chain *n*-alkanes in apolar solvents are strongly preferentially adsorbed onto graphitised carbon black and also that the adsorption of acids or alcohols from aqueous solutions on a type of carbon (Spheron) increased with chain length of the solute.

In previous studies by some of us (11, 12), we have revealed that several inorganic solids such as asbestos are very good adsorbents for polynuclear aromatic hydrocarbons (PAH) like phenanthrene and dimethylbenzanthracene in organic solvent, phenomena in agreement with the study of Gerde and Scholander (13), and in spite of that their surface has to be considered mainly ionic. With these materials, we have obtained adsorption isotherms with multisteps which indicated the formation of bidimensional condensed layers (2D) at the surface of substrates.

If we take the example of chrysotile, an asbestos variety, the studies of Bonneau *et al.* (14, 15) have shown the presence of electron donor surface sites. Chrysotile, a magnesium silicate, presents an external surface (brucitic sheet) having hydroxyl ions in low coordination, at least at the exposed surface.

The present work compares the adsorptive properties of chrysotile with ones that are found for an amorphous silica of relatively low surface area, considered mainly as a covalent solid. Silicas have surface properties which strongly depend upon thermal pretreatments, crystallinity, and particle size (16, 17). Their capacity for adsorbing polar molecules is rather poor and decreases when siloxane (Si—O—Si) bridges present at the surface replace silanol couples[1] (18).

Two different kinds of molecules have been used as adsorptive surface probe: phenanthrene, as a typical apolar polynuclear aromatic hydrocarbon and water, as a typical polar molecule.

In order to assess both adsorptive capacity and interaction energy, calorimetric measures were carried out in parallel with traditional evaluation of adsorption isotherms.

In the case of water the two measurements were realized simultaneously, by dosing small amounts of water vapour onto the solid placed into the calorimetric vessel. This technique has already been used for the evaluation of hydrophilicity and hydrophobicity of a material[1] (19).

The adsorption isotherms of phenanthrene, already reported for chrysotile (12), were obtained using xylene solutions of phenanthrene in a wide range of concentrations. The corresponding heat of interaction in equilibrium conditions could not be obtained because of kinetic reasons. Thermokinetic data, obtained upon contact between the solid and the solutions, will be reported and will allow a useful insight into the thermodynamics of the early stages of adsorption and on the role of surface impurities on the adsorption mechanisms.

A model will be proposed which accounts for the role of solvent and surface preadsorbed species on the adsorption mechanism. This model presents evidence that chrysotile, a very powerful adsorbent for PAH, in spite of its ionic character, can act as a possible collector and carrier of PAH into the lungs.

Experimental

Materials

Two inorganic solids were used: (*i*) Rhodesian chrysotile, consisting of asbestos fibres, provided by UICC (International Union Against Cancer) with BET specific surface area (nitrogen) of 24 $m^2 g^{-1}$ for batch 1 and of 18 $m^2 g^{-1}$ for batch 2. (*ii*) Amorphous silica, Aerosil OX 50 (Degussa) obtained by pyrolisis of $SiCl_4$, with BET specific surface area (nitrogen) of 50 $m^2 g^{-1}$.

The solvents, xylene and *n*-hexane (Merck) and the solute, phenanthrene (Aldrich) are products of high purity.

The water used for vapour adsorption was gas-free, having been distilled several times *in vacuo*.

Methods

(i) Adsorption isotherms of phenanthrene in xylene medium

At room temperature, the adsorption of phenanthrene has been performed by contacting chrysotile (250 mg, batch 1) with solutions (50 mL) of different concentrations of PAH according to a process previously described (11).

The scale of concentrations in xylene used varies from 1×10^{-3} to 1 mol L^{-1}. This highest concentration value is very close to the one at saturation (C_S = 1.17 mol L^{-1}).

The analysis of the residual concentration of PAH after adsorption was performed by means of UV spectrofluorometry (Perkin Elmer, Hitachi MPF 3). This enables a plot of PAH adsorbed quantities (n_a in 10^{-6} mol m^{-2}) as a function of equilibrium concentrations (C_{eq} in 10^{-3} mol L^{-1}).

Standard conditions mean that the solvent and the solid have not been dried or degassed. For the study in dried and degassed medium, both substrate and solvent, which has been previously dried over potassium carbonate, were degassed under a nitrogen stream. During adsorption, the solid suspension was kept under nitrogen.

Desorption has been carried out by adding pure xylene to a suspension after the PAH adsorption stage. After every addition, the equilibrium concentration was measured.

(ii) Heat of interaction of phenanthrene with chrysotile

The adsorption of phenanthrene in liquid medium has been realized at fixed temperature (306 K) by adding the solution of PAH (2 mL) to chrysotile, batch 2 (100 mg). The initial concentration of PAH was 0.5 mol L^{-1} in xylene and 0.25 mol L^{-1} in *n*-hexane. The concentration in *n*-hexane is lower than in xylene because the 0.5 mol L^{-1} value corresponds to the saturated concentration in this solvent.

A microcalorimeter Calvet type (C-80 Setaram) was used: it is a turn flow calorimeter which in the present case was operated at 306 K. The calorimetric cells employed mainly consist of two concentric vessels which can be filled separately with two reactants. In the "measure" cell the solid was placed in the central vessel and the solution in the external vessel. The two compartments were separated, but in equilibrium with the same gas phase. The "reference" cell was filled only with the solid. Both cells were placed into the calorimeter and when the equilibrium was attained, an automatic mechanism for continuous alternative reversing of the calorimeter allowed the mixing of the reactants initially separated. A calorimetric signal was then recorded.

Calorimetric measurements were also performed in dried and degassed conditions, similar to the above-mentioned ones: both substrate and solvent previously dried on dehydrated zeolites were degassed under an argon stream.

(iii) Heat of adsorption of water vapour and related isotherms

For adsorption of water vapour, chrysotile (batch 2) and Aerosil have been outgassed in vacuum into a Tian Calvet microcalorimeter at the temperature of adsorption (303 K) until no endothermic deviation from the baseline was detectable, i.e., no more preadsorbed gases from the atmosphere could be desorbed.

Stepwise adsorption of water was performed following a technique previously described (20), by admitting successive small doses of H_2O vapour onto the sample up to an equilibrium pressure of ~10 Torr. For each dose the adsorbed amount and released heat were evaluated. The sample was then evacuated and a second adsorption run was performed in order to evaluate, by comparing the first and the second adsorption, if any H_2O was irreversibly held at the surface.

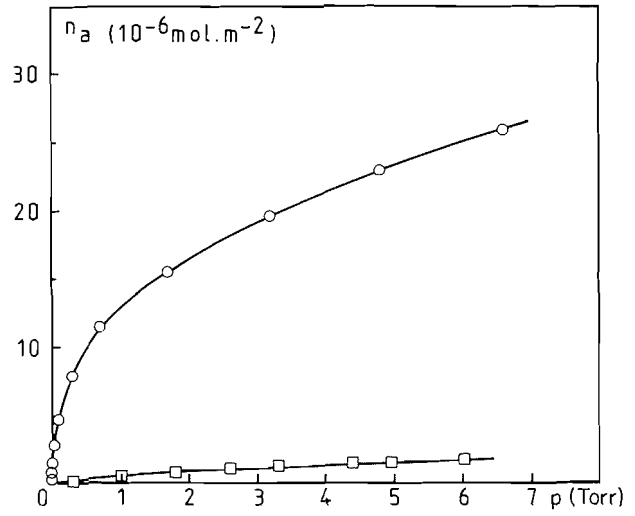

FIG. 1. Adsorption isotherm of water vapour on chrysotile (○) and amorphous silica (□) at 303 K.

Results

(a) Adsorption of water

Figure 1 reports the adsorption isotherms of water on chrysotile (batch 2) and amorphous silica (Aerosil 50) as adsorbed molecules, as a function of the equilibrium pressure of water.

Both isotherms exhibit the typical trend for adsorption of water on hydrophilic heterogeneous surfaces where adsorption in multilayers takes place. The isotherm shows a continuous increase with pressure and no plateau is detectable.

A marked difference in the adsorptive capacity of the two solids appears when we compare the adsorbed amounts per unit surface at the same pressure. At the equilibrium pressure of 5 Torr the uptake on silica is 1.5×10^{-6} mol m^{-2} whereas on chrysotile it is 23×10^{-6} mol m^{-2}. On chrysotile, densely packed layers of H_2O molecules are fixed on the brucitic hydroxyl exposed on the surface. On the pyrogenic amorphous silica, where only isolated patches of silanols are present,[1] much less water molecules per unit surface area are fixed, on top of silanols.

The molar enthalpy measured upon adsorption of each subsequent H_2O vapour dose is reported in Fig. 2 as a function of adsorbed amounts.

Chrysotile exhibits a small fraction of very strong sites (0.5×10^{-6} mol m^{-2}) which likely dissociates H_2O at the beginning of the experiment. From that point on, a regular trend (normal for an heterogeneous hydrophilic surface) is found, the $-\Delta H_{ads}$ value decreasing regularly from ~100 kJ mol^{-1} down to ~60 kJ mol^{-1}. Water is adsorbed via two H-bonds onto surface hydroxyls. The monolayer coverage is attained (with the hypothesis of one water molecule per two adjacent OH and 1.2×10^{19} (OH) groups per m^2 (15)), for an adsorption of 15×10^{-6} mol m^{-2}. Then the adsorption involves multilayers of H_2O molecules with a heat of ~60 kJ mol^{-1}, approximately constant with coverage.

A similar trend is found on silica with the following exceptions: (*i*) a much lower coverage interval of heterogeneity is detected (0.05×10^{-6} mol m^{-2}); (*ii*) the plateau value, corresponding to multilayer adsorption is much lower than on chrysotile, being near 44 kJ mol^{-1}, i.e. the latent heat of liquefaction of water.

This indicates that a strong surface field is present on chrysotile, so that even in multilayer adsorption, the energy of the process is much higher than the heat of liquefaction, whereas on silica, once the monolayer on hydroxylated patches is attained, multilayer condensation mainly occurs as in water liquefaction.

(b) Adsorption isotherms of phenanthrene

Figure 3 reports the adsorption isotherms of phenanthrene on chrysotile (*a*) and Aerosil (*b*) in xylene medium (standard conditions).

The two curves have a different shape and the isotherm (*b*) is situated in the scale of high concentrations by comparison with the isotherm (*a*).

The shape (S type) for chrysotile reveals the presence of lateral interactions between adsorbed molecules (21). This curve shows successive plateaus corresponding to a defined degree of coverage (θ).

By reference to Giles and McKay (22) on the adsorption studies of several PAH in liquid medium, the presence of lateral interactions between adsorbed molecules involves an orientation end-on of the PAH molecule onto the solid surface. Taking into account the basic character of this mineral surface (15), we had proposed this type of orientation with the most electrophilic C—C bond parallel to the solid surface (11). This orientation, very close to one encountered in the molecular structure of solid phenanthrene (23), involves an area of overlap of 33 Å^2.

With this value and the BET area, the two plateaus corresponded to the successive formation of a monolayer ($\theta = 1$) and then a bilayer ($\theta = 2$). We have obtained a multilayer curve with the formation of bidimensional condensed layers (2D), this phenomenon continuing after the second plateau (12).

Unlike chrysotile, silica exhibits an isotherm of Langmuir type. In this case, the molecule of phenanthrene is adsorbed flat onto surface, without lateral interactions between adsorbed molecules (24). In this position, the PAH molecule with its π electrons delocalized plays a nucleophilic role on the acidic surface of silica. With this orientation, the area of overlap is 92 Å^2. The plateau of the curve (*b*) corresponds to the formation of a monolayer ($\theta = 1$), in a field of concentrations very close to the saturated concentration C_s ($\ln C_{eq}/C_s \rightarrow 0$).

By comparison with chrysotile, the adsorption capacity is lower for silica, and very high concentrations of PAH are needed in order to initiate the adsorption process (Fig. 3).

Figure 4 compares the adsorption isotherms of phenanthrene on chrysotile in xylene under standard conditions of Fig. 1 (curve *a*) with the one obtained under dried and degassed conditions (curve *b*). Isotherm (*b*) shows an increase of the adsorbed quantity for a fixed concentration at equilibrium and the presence of only one short plateau. According to the criteria previously established, this plateau corresponds to the direct formation of a bilayer ($\theta = 2$). These phenomena are due to the partial elimination of preadsorbed molecules such as H_2O, O_2, CO_2 originated by contact of the solid with the atmosphere.

(c) Adsorption–desorption hysteresis

An hysteresis is found when adsorption of a first monolayer phenanthrene in standard conditions is followed by desorption (Fig. 5). In the whole concentration range covered, the desorption curve lies above the adsorption one. This fact which is reminiscent of phenomena related to capillary condensation is rather unusual, the hysteresis involving the monolayer range and not the multilayer one as in capillary condensation.

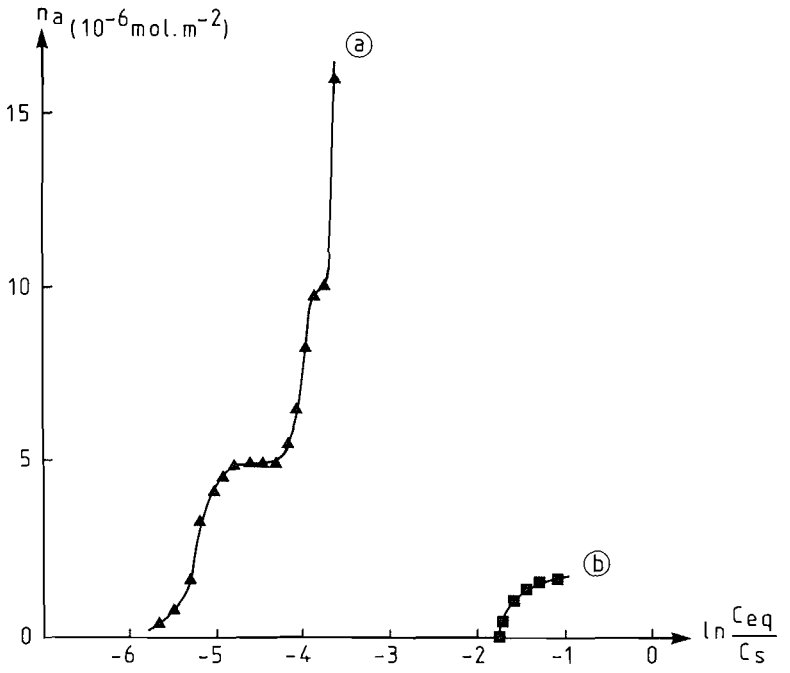

FIG. 3. Adsorption isotherms of phenanthrene in xylene (standard conditions): (*a*) chrysotile (batch 1); (*b*) Aerosil.

(d) Calorimetric data for phenanthrene adsorption on chrysotile

The calorimetric data concern, in this case, only the first stages of the adsorption phenomena and not the formation of multilayers of PAH on chrysotile.

Figure 6 presents thermokinetic curves obtained upon contact of phenanthrene solutions, with chrysotile (batch 2) in the calorimeter. The three curves refer to three different experiments. (*a*): Chrysotile, solution of phenanthrene in xylene (0.5 mol L^{-1}) under standard conditions; (*b*): chrysotile treated under argon, solution of phenanthrene in dried xylene (0.5 mol L^{-1}); (*c*): chrysotile, solution of phenanthrene in *n*-hexane (0.25 mol L^{-2}) under standard conditions.

These experiments were conducted under conditions clearly different from that used for the adsorption isotherms, because the vessel volume in calorimetry was small (2 mL), the thermic phenomenon was at the limit of sensitivity, and therefore we have increased the ratio: mass of solid/volume of solution (ratio m/v) which is raised from 5 (adsorption isotherms) to 25, and we have chosen a high value for the phenanthrene concentration in xylene (0.5 mol L^{-1}).

Under these experimental conditions we are not capable of reaching the equilibrium during the calorimetric experiment time. Indeed, the increase of the m/v ratio allows an increase of the water quantity in the medium and a slackening of the adsorption kinetics as illustrated by the data of Table 1 and Fig. 7. In Table 1 the adsorbed quantities of PAH (n_a) are measured for two values of m/v (5 and 25) after 1 h of contact of a PAH solution (8×10^{-3} mol L^{-1}) with chrysotile (batch 1). In

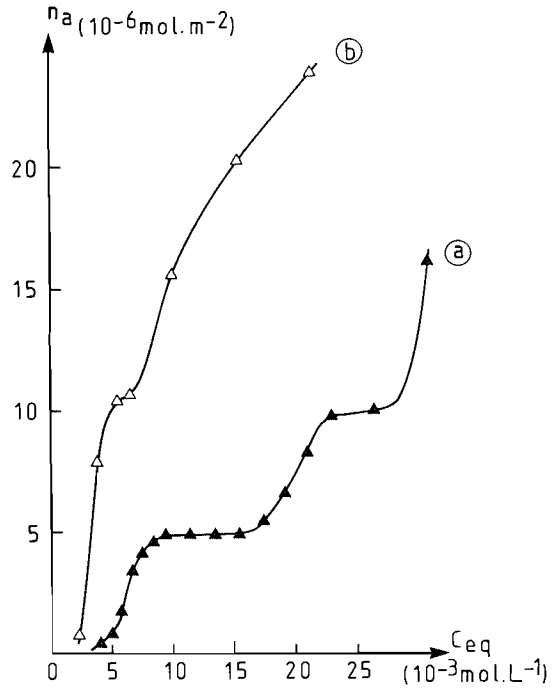

FIG. 4. Adsorption isotherms of phenanthrene in xylene on chrysotile (batch 1): (*a*) standard conditions; (*b*) substrate dried under nitrogen; solvent dried and degassed.

standard conditions, we observe that for the larger m/v (m/v = 25), we obtain the smaller value of n_a, whereas after a previous treatment of drying, the difference between the degrees of coverage (θ) for the two ratios is reduced and becomes insignificant when the dried system is degassed. In Fig. 7, with the same conditions as for the calorimetric experiment represented in Fig. 6(*a*), we observe that the equilibrium is reached only after a time of about 150 h, as against less than 1 h with a m/v ratio of 5 (adsorption isotherms). In dry medium (Fig. 6(*b*)), it is also very probable that we are far from the equilibrium conditions.

A third factor unfavorable for these calorimetric experiments is the use of chrysotile of batch 2, because of the exhausting batch 1 stock. Batch 2 has a weaker density of basic sites and a higher water content of hydration than batch 1 (H. Suquet, to be published). This involves for batch 2 a very weak adsorptive capacity towards PAH, but the adsorption mechanism is similar to the one observed with batch 1 (24).

Consequently the calorimetric results of Fig. 6 do not allow us to evaluate the heats of adsorption but only the three initial successive stages (exothermic, endothermic, exothermic) of the adsorption phenomena. The first step appears when the solution is brought into contact with the solid. The exothermic peak is more or less large according to the experimental conditions. This is due to the presence of endothermic phenomenon following the exothermic peak. By comparison with standard conditions (*a*) in xylene, the endothermic step and also the following exothermic phenomena are much less marked in dried medium (*b*). The drying of system reveals an influence of preadsorbed water on the endothermic phenomenon and on the following exothermic part.

Under standard conditions, the endothermic effect is also much strongly marked for xylene solution (*a*) than for *n*-hexane solution (*c*). This reveals the influence of solvent on the phenomenon of adsorption of PAH on chrysotile.

Discussion

All the results obtained from adsorption of both water and phenanthrene indicate a remarkable difference in surface properties between silica and chrysotile. Chrysotile appears as being a much more powerful adsorbent than silica towards both the molecules chosen (water and phenanthrene).

(1) Adsorption of water

As expected from the more ionic character of the chrysotile surface by comparison with silica, adsorptive capacity and interaction energy are higher on chrysotile than on silica. At the same equilibrium pressure the adsorption value is ~20 times larger on chrysotile than on Aerosil (Fig. 1). The interaction energy is much larger on chrysotile than on silica, both in the heterogeneous first part of the differential heat curve (Fig. 2) and at the plateau value which is ~60 kJ mol^{-1} on chrysotile and

close to the latent heat of liquefaction of water (44 kJ mol^{-1}) on Aerosil 50. This latter finding is in agreement with that reported by Zettlemoyer *et al.* (25) for the overall heat of adsorption of water on chrysotile (67 kJ mol^{-1}).

However, it has to be pointed out that the affinity of Aerosil 50 for water is very poor even when compared with results on other silicas.[1]

(2) Adsorption of phenanthrene

Phenanthrene being an apolar aromatic hydrocarbon, one would expect that upon adsorption, this molecule would behave

in the opposite way of water, i.e. be preferentially adsorbed on the less ionic solid, namely silica. This is not the case, as clearly shown by data in Fig. 3, because of the large polarisability of the molecule itself and of the basic character of the chrysotile surface which determine the mode of adsorption. As a consequence multilayers are only formed on chrysotile whereas on silica where the Langmuir model is followed, only a single layer of adsorption is possible.

Chrysotile, having electron donor sites on the surface (15) vertically adsorbs phenanthrene at the C_2–C_3, the most electrophilic bond (11). As a consequence, the molecule is polarized, lateral interactions between adsorbed molecules take place, and the strong surface field allows multilayer formation. The multistep isotherm of Fig. 3 is typical for this model of adsorption. Silica is an acidic covalent solid which implies molecule adsorption on flat. In this case, there are no lateral interactions and thus only one monolayer is formed. This orientation has been reported for the adsorption of aromatic compounds on graphon (26, 27).

The adsorption of phenanthrene on chrysotile however is not such a simple phenomenon as indicated by three main experimental facts whose interpretation is not straightforward: (*i*) the presence of an endothermic step upon adsorption whose

For personal use only.

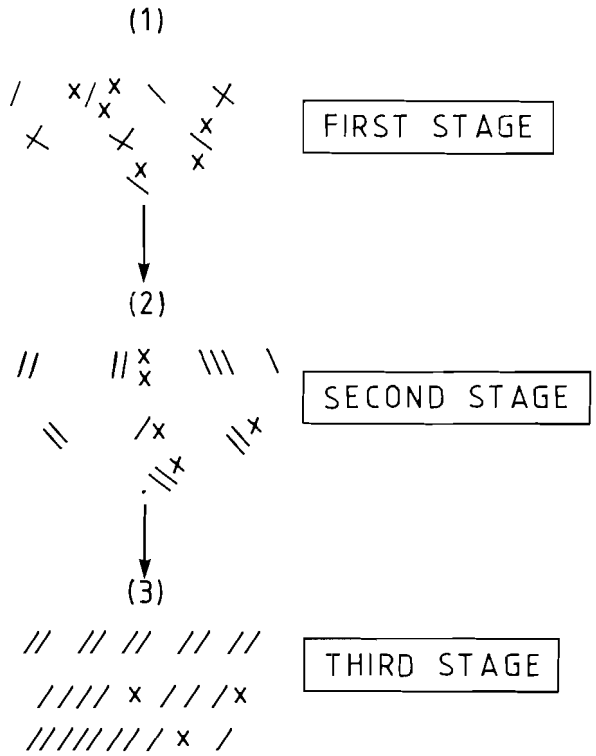

FIG. 8. Model of adsorption mechanism on chrysotile in standard conditions: / molecule of PAH; × preadsorbed molecule.

magnitude is related both to preadsorbed molecules (likely water) and to the solvent employed; (*ii*) the presence of an hysteresis in adsorption–desorption in the monolayer region; (*iii*) an enhancement of adsorption when a low mass of solid/volume of solution ratio is used which appears to be related to the presence of preadsorbed molecules on the solid surface (Table 1).

The endothermic step can be explained as follows: after the first contact between solid and solution which is always exothermic (phenomenon of wetting), phenanthrene displaces from the surface both the solvent molecules just adsorbed, and the pollutant molecules preadsorbed, mainly water. At this stage this process is endothermic, the energy of adsorption of water being likely higher than the one of phenanthrene because of strong hydrogen bonding. Adsorption of phenanthrene at this stage occurs for entropic reasons, taking into account that the number of phenanthrene molecules in the system largely exceeds the one of water molecules and that the molecular size of PAH being larger than H_2O, xylene and *n*-hexane, several molecules of H_2O or solvent will be displaced by one single PAH molecule. When the PAH concentration on the surface increases, lateral interactions take place and the adsorption becomes exothermic. This latter process continues for very long periods in the experimental conditions adopted (Fig. 6) and is not accomplished in the calorimetric experiment. Thus, unfortunately, the overall heat of adsorption in equilibrium conditions could not be measured. The endothermic step is very small if the experiment is carried out in dry conditions (Fig. 7(*b*)) because much less water will be fixed on the surface. If the experiment is carried out from *n*-hexane solution, *n*-hexane being an apolar molecule will be much less competitive for surface sites than xylene (24). In this case, therefore, the lower endothermicity recorded with respect to xylene solutions will be due to a lesser displacement of solvent because of its poor affinity for the surface.

In standard conditions, not all preadsorbed water molecules are displaced by phenanthrene. In fact, the difference between isotherms of Fig. 4 indicates that the presence of preadsorbed molecules in equilibrium conditions involves the edification of one monolayer followed by the second one whereas in dried conditions, the second layer is probably built up before the end of the first layer formation and for lower values of C_{eq} than those in standard conditions. Moreover, the quantity of pollutant molecules in the medium is more or less important according to the m/v ratio. For a high value of m/v, adsorption of PAH occurs only on isolated sites at a low extent. This situation is less favourable to adsorption. By either decreasing the m/v ratio or eliminating preadsorbed molecules, lateral interactions can take place, thus adsorption occurs at a much larger extent (Table 1).

Taking into account all the above data, we propose the following model (schematized in Fig. 8) for the adsorption features of phenanthrene onto chrysotile in standard conditions: (*1*) Isolated adsorption: in spite of the initial ionic character of chrysotile, there is the intervention of two parallel phenomena: (*i*) direct adsorption of PAH molecule on an electron donor site which is not poisoned by water or other pollutants; (*ii*) displacement of preadsorbed molecules by a PAH molecule which in turn is adsorbed onto an active site. In the two cases, the PAH molecules are fixed individually, i.e. one molecule for one active site, and these molecules are strongly polarized by the solid surface. (*2*) Cooperative phenomenon: lateral interactions between adsorbed PAH molecules are established and the formation of little "blocks" of PAH molecules appears. These "blocks" could grow either by the inclusion of new adsorbed molecules or by the displacement of the surrounding preadsorbed molecules. (*3*) The last step corresponds to the end of the monolayer. After the elimination of a great part of preadsorbed molecules, the "blocks" merge together, the driving force being the presence of lateral interactions. This stage involves the formation of a condensed layer (2D).

During stages *2* and *3*, the union of the PAH "blocks" implies that the global energetic term of lateral interactions increases.

Desorption will follow a different path from adsorption. In fact, at the same coverage, the presence of preadsorbed molecules during adsorption is a limiting factor for lateral interactions whereas upon desorption, when most preadsorbed molecules will be eliminated, more lateral interactions will be operating. As a consequence at any coverage below monolayer $C_{eq_{des}} < C_{eq_{ads}}$.

The thermodynamic descripiton of the process will be $\Delta G_{ads} < 0$, because in all cases adsorption occurs. At low coverage, phenanthrene will displace solvent and preadsorbed molecules. $\Delta H_{disp} > 0$, $T\Delta S_{disp} > 0$, displacement occurs for entropic reasons only.

At high coverage, strong lateral interactions will be established between adsorbed molecules of PAH:

$$\Delta H_{ads} < 0, \qquad T\Delta S_{ads} < 0$$

As a consequence, chrysotile will be covered by several layers, as in bulk phenanthrene, but probably with a high degree of disorder.

Conclusions

In spite of the ionic character of its external surface (brucitic sheet) chrysotile acts as a very powerful adsorbent for PAH, being able to adsorb at its surface several layers (2D) of apolar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

molecules. Inversely, with the covalent character of its surface, Aerosil is only able to adsorb one layer of PAH molecules. Multilayer adsorption of PAH converts the marked hydrophilic surface of chrysotile into a hydrophobic one, which can facilitate the interaction of the asbestos particles with the external membrane of the cells (28).

The multilayer adsorption of PAH on asbestos can explain the observations of Chang *et al.* (5) and Eastman *et al.* (6) who have shown that the uptake kinetics of PAH (e.g. benzo(*a*)pyrene preadsorbed on asbestos) toward the hydrophobic zone of cells is different from that which occurs when the PAH is introduced into the cell culture as a solid phase or in solution in a solvent medium.

Eastman *et al.* observed a longer uptake time and a more marked DNA alkylation, with B(*a*)P adsorbed on chrysotile.

Our results suggest that in the first period of contact with cells, the high surface of the adsorbed PAH can allow a rapid uptake, but that the more strongly adsorbed molecules of the monolayer will be solubilized in the hydrophobic zone of the cells with difficulty and more slowly, from which the metabolisation of these latter molecules can appear delayed in time.

Therefore, the preadsorption of PAH on inorganic solids plays a role in the distribution and the availability of these PAH in biological medium, which also explains the results of the animal experiments (3, 4) where a great percentage of broncho-pulmonary cancers is observed when the PAH is introduced as preadsorbed on a basic, inorganic solid by intratracheal injection.

For asbestos, we must add a role of collector of air pollution and thus a role of carrier of these organic pollutants toward the pulmonary medium. These two roles depend directly on the adsorption properties of the inorganic solids.

This fact may provide a possible interpretation for some synergistic effects observed, for example between asbestos and cigarette-smoke exposure.

The ion-pair mechanism and bimolecular displacement at saturated carbon. VII. Racemization of substituted 1-phenylbromoethanes; ionic strength effects

ALLAN R. STEIN

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received May 8, 1988

ALLAN R. STEIN. Can. J. Chem. **67**, 297 (1989).

No, or at most very small, salt effects have been detected for second-order racemizations of various 1-phenylbromoethanes, confirming that the "mixed kinetics", previously reported for 4-methyl- and 3,4-dimethylphenylbromoethanes with tetrabutylammonium bromide in acetonitrile and nitromethane, did not reflect a salt effect on a unimolecular reaction. Thus the uni- and bimolecular rate components can be evaluated using the equation:

$$\text{observed rate} = k_1 + k_2'[Bu_4NBr]$$

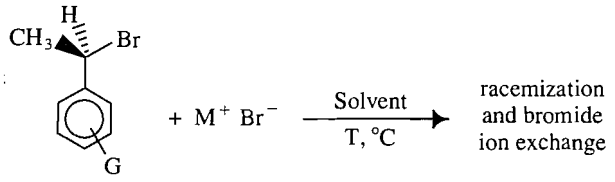
where k_1 = first-order or unimolecular rate constant, the intercept, and $k_2' = 2k_2$, the latter being the rate constant for the bimolecular substitution. A "special salt effect" was found for the unimolecular component; it was especially pronounced for 3,4-dimethyl substrate in acetonitrile with Bu_4NClO_4 as the electrolyte. In acetone, where no unimolecular reaction component was detected even with those substrates giving the most stable carbocations, the only salt effect was a common ion, Bu_4N^+, effect on the incomplete dissociation of Bu_4NBr. From an iterative best fit for plots of observed rate versus calculated bromide ion activity for unsubstituted, 4-methyl, and 3,4-dimethyl substrates, $K_{assoc} \sim 15 \pm 1$ at 40°C. The results are interpreted as additional support for a progression of mechanism with nucleophilic attack possible at any stage of the series of equilibria: substrate $\rightleftharpoons$ contact ion pair $\rightleftharpoons$ various solvated ion pairs $\rightleftharpoons$ dissociated ions.

Key words: special salt effects, ionic strength effects, racemization of 1-phenylbromoethanes, mechanism of nucleophilic substitution, ion pair mechanism.

ALLAN R. STEIN. Can. J. Chem. **67**, 297 (1989).

Pour les racémisations du deuxième ordre de divers phényl-1 bromoéthanes, on n'a détecté aucun, ou tout au plus de très faibles, effet de sels; ces résultats confirment que les « cinétiques mixtes » qui ont été observées antérieurement lors des réactions des méthyl-4 et diméthyl-3,4 phénylbromoéthanes avec le bromure de tétrabutylammonium dans l'acétonitrile et le nitrométhane, ne sont pas le reflet d'un effet de sel sur une réaction unimoléculaire. On peut donc évaluer les composantes uni- et bi-moléculaires de la vitesse en utilisant l'équation

$$\text{vitesse observée} = k_1 + k_2'[Bu_4NBr]$$



dans laquelle k_1 = constante de vitesse du premier ordre ou unimoléculaire, l'ordonnée à l'origine, et $k_2' = 2k_2$ où k_2 est la constante de vitesse de la substitution bimoléculaire. On a observé un « effet de sel spécial » sur la composante unimoléculaire; cet effet était particulièrement prononcé pour le substrat diméthyle-3,4, dans l'acétonitrile, avec le Bu_2NClO_4 comme électrolyte. Dans l'acétone, on n'a détecté aucune composante reliée à une réaction unimoléculaire (même pas avec les substrats qui donnent les carbocations les plus stables) et le seul effet de sel qui a pu être observé est celui d'un ion commun, Bu_4N^+, dû à une dissociation incomplète du Bu_4NBr. En se basant sur des itérations des courbes des vitesses observées versus l'activité calculée de l'ion bromure pour les réactions des substrats méthyle-4, diméthyl-3,4 ou non-substitués, on a évalué que $K_{assoc} \sim 15 \pm 1$, à 40°C. On interprète les résultats en fonction d'un support additionnel pour une progression du mécanisme avec l'attaque nucléophile qui est possible à tous les stages des séries d'équilibre: substrat $\rightleftharpoons$ paire d'ion de contact $\rightleftharpoons$ diverses paires d'ions solvatés $\rightleftharpoons$ ions dissociés.

Mots clés : effets de sel spécials, effets de force ionique, racémisation de phényl-1 bromoéthane, mécanisme de substitution nucléophile, mécanisme de paires d'ions.

[Traduit par la revue]

Chemists have long been aware that an important factor in medium effects is ionic strength, which, among other things, changes the dielectric constant and increases ionizing power (1). For reactions in which the ionic strength is changing during the reaction, that is for ion creating (for example, solvolysis of alkyl halides or esters) or ion destroying reactions (for example, ion combination reactions and some additions), ionic strength and hence the medium changes throughout the reaction. To facilitate mechanistic interpretation, it is the usual practice to use high concentrations of inert electrolyte to overwhelm the reaction's contribution to ionic strength.

For reactions such as the Finkelstein Reaction, especially an "identity process" such as $Br^- + RBr^* \rightarrow BrR + Br^{*-}$ as is the case for the studies in the current series of publications, as outlined in Scheme 1, there is no change in ionic strength nor, indeed, in the concentration of any species during the reaction. The addition of inert electrolyte is less critical. Still, even for these reactions, there is a change in charge or charge density in going from reactants to transition state whether the reaction follows the S_N2, S_N1, or an ion-pair mechanism. Consequently, the ability of the medium to support ionic charges, its ionizing power, and hence its ionic strength, can be important. Obviously, varying the concentration of the bromide ion, that is of M^+Br^-, to establish reaction order (2) and to permit separation of uni- and bimolecular components (2, 3), changes the ionic strength, and hence ionizing power, unless inert electrolyte is used to maintain constant ionic strength. Of course, if comparisons of,

G = H, 4-(CH_3, Br, or NO_2), 3-CH_3, 3,4-$(CH_3)_2$

say racemization and bromide–*radio*-bromide exchange rates, or of one substrate with another, are made at the same M^+Br^- concentrations and temperatures, fixed ionic strengths may not be required. Still, ideally, even for identity processes such as ours, working at constant ionic strength is desirable.

For our initial study of the racemization of chiral 1-phenylbromoethane in acetone with added LiBr, we used $LiNO_3$ to maintain constant lithium ion concentration and, hence, ionic strength (4). The apparent rate constant decreases with increasing LiBr concentration in the absence of added electrolyte but is constant at fixed ionic strength, that is, with constant lithium ion concentration. The falloff in the apparent rate constant with LiBr concentration was assigned to incomplete dissociation; the activity coefficient of Br^- decreases with increasing LiBr concentration. This was later confirmed by using data of Beronius *et al.* (5) for the association of LiBr in acetone to correct for bromide ion activity (2). Beronius and Gupta have reported similar behavior for methyl iodide and Et_4NBr (6).

To follow the bromide–*radio*-bromide exchange kinetics, the silver electrodeposition method of Beronius has been employed (7). Unfortunately, the various lithium salts tested (chlorate, perchlorate, nitrate, picrate...) either interfered with the silver bromide electrodeposition, were themselves incompletely dissociated, or both (4), so that attempts to work at constant ionic strength were abandoned; all subsequent kinetics were done at the same fixed concentrations ranging from 5.00 to 100.00×10^{-4} M in bromide ion. With the extension of the study to the more polar solvents acetonitrile and nitromethane, we found that tetrabutylammonium bromide, Bu_4NBr, was apparently completely dissociated over the concentration range used: plots of observed racemization rate versus Bu_4NBr concentration were linear (3). (In acetone, Bu_4NBr is partially associated, as is LiBr in the two more polar solvents.)

In acetonitrile and nitromethane, those substrates that are able to form more stable carbocations, the 3,4-dimethyl- and the 4-methylphenylbromoethane, racemize at a rate that increases linearly with Bu_4NBr concentration but with a large positive intercept (3). Equation [1] thus applies; k_1 is the intercept that is the first-order or unimolecular rate constant while k_2' is the slope or second-order rate constant for racemization. Since the rate of racemization is twice the inversion rate, $k_2' = 2k_2$ where k_2 is the rate constant for the bimolecular substitution.

$$[1] \quad \text{Observed rate} = k_1 + k_2'[Bu_4NBr]$$

There are, however, problems in apportioning the observed rate in this fashion. Ionization processes are prone to ionic strength effects, normally increasing with ionic strength, an effect that can be quite large in nonpolar solvents but would most likely be only moderate here (*1a*, *1f*). Thus questions remain to be answered. What is the ionic strength effect on the unimolecular process? How significant a contribution does that make to the apparent bimolecular rate? (In the extreme case, all of the apparent bimolecular component could be an ionic strength effect on a unimolecular, carbocation process.) Finally, what is the ionic strength effect on the bimolecular process? (It would be expected to be relatively small and probably negative.)

Unlike the silver bromide electrodeposition used to follow exchange kinetics, racemization studies can readily be done with added electrolyte. Thus the racemizations of the substrates that showed mixed kinetics and several that showed only bimolecular kinetics (3) were reexamined in acetonitrile and in nitromethane at constant and at varying ionic strengths using several electrolytes. In acetone, all substrates racemize with bimolecular kinetics with, at most, a very small unimolecular component (2). The 4-methyl substrate shows considerable internal return with racemization, presumably from a solvated ion pair, while the 3,4-dimethyl substrate shows stereochemical behavior halfway between that expected for an S_N1 and an S_N2 substitution.[1] The ionic strength effect study was extended to acetone solution since, for example, "special salt effects" are possible for those substrates (*1c*, 8, 9).

Finally, while ionic strength or salt effect studies are numerous, especially for solvolyses (1), there are almost none for identity processes such as ours (4, 6). Obviously, studying such effects for strictly bimolecular processes presents problems since very low ionic strengths cannot be used. Without added nucleophile (salt) there can be no substitution. Unimolecular processes or the unimolecular portion of reactions showing mixed kinetics should be more amenable to scrutiny and might show special salt effects (1, 8, 9).

Results

In Tables 1–3 and Figs. 1 and 2 the racemization rate behavior of various substrates, as a function of tetrabutylammonium bromide concentration in acetone, acetonitrile, and nitromethane, are presented. The data is for 40.00 ± 0.05 or 30.00 ± 0.05°C as indicated. With each substrate in each solvent, Bu_4NBr concentrations of 0.0000, 2.500, 5.000, 10.00, 15.00, 20.00, and 25.00×10^{-3} M were used, both without added electrolyte, and at constant ionic strength, i.e., Bu_4N^+ concentration of 25.00×10^{-3} M using ClO_4^- and BF_4^- counterions. In a number of cases, lower concentrations of Bu_4NBr, 0.500, 1.000, 1.500, 2.000, 2.500, 3.000, 3.500, 4.000, and 4.500×10^{-3} molar were also used. When no systematic deviations from linearity for a plot of observed racemization rate versus Bu_4NBr concentration were found, linear regression analysis was applied to the data to extract the second-order or bimolecular substitution rate constant, k_2 (k_2 = slope/2) and the first-order or unimolecular racemization rate constant, k_1 (intercept). These are reported, with the standard deviations, in Table 1. Correla-

[1] A referee has pointed out that the origin of the low $k_{rac}:k_{exch}$ value of 1.52 for 1-(3′,4′-dimethylphenyl)bromoethane in acetone could be quite different from that suggested in ref. 2. The low optical activity, and hence high substrate concentrations, required for the racemizations, together with a little pre-reaction elimination (with concomitant HBr formation), could result in a significant reduction in bromide ion activity through the equilibrium $HBr + Br^- \rightleftharpoons HBr_2^-$ (see, for example, ref. 13). Comparison of the racemization and bromide exchange rates at the same concentrations of LiBr could give the low rate ratio reported. Similar but lesser factors would apply to the *p*-methyl substrates; the actual ratio could be higher than the reported value of 2.36.

Using nmr, F. Y. Fujiwara and J. S. Martin (14) estimated the equilibrium constant for the above equilibrium as $K \approx 200$ in symmetrical tetrachloroethane. They were unable to obtain a value in acetonitrile because of solvent protonation, that is HBr dissociation (see also ref. 15). Like acetonitrile, acetone and nitromethane are "bases" so at least partial dissociation would be expected. Additionally, HCl has been shown to catalyze racemization and chloride exchange with 1-phenylchloroethane in nitromethane according to the equation, rate = $k_1[RCl] + k_2[RCl][HCl]$ (16). It should be noted that if the HBr formed reduces the bromide ion activity, the reaction rate should decrease, not increase, with time as the parallel elimination reaction proceeds. Finally, for the acetone results, LiBr was used; it is incompletely dissociated in that solvent. Bromide ion would be, in effect, "buffered" by the equilibrium $LiBr \rightleftharpoons Li^+ + Br^-$.

Obviously the effect of elimination on the $k_{rac}:k_{exch}$ rate ratio is not simple nor is it easily predicted. Additional work is planned in this area.

tion coefficients ranged from excellent for 4-nitrophenylbromoethane (R = 0.9998–0.99998) and phenylbromoethane (R = 0.9996–0.9999) to fair for 3,4-dimethylphenylbromoethane (R = 0.997–0.9995). In obtaining the initial rate data, that is, the individual observed rates for the lowest bromide ion concentrations with the methyl- and dimethyl-substituted substrates, initial slopes were used. Sometimes as little as one sixth of a half-life was used because elimination, a competing reaction, results in increasing bromide ion concentration and, hence, an increase of racemization rate with time (refs. 2, 3. See also footnote 1). Even with the above substrates at higher bromide ion concentrations, generally two to three half-lives were used and, with the nitro- and unsubstituted substrates, three to five.

Results for several systems that did not show good linear observed rate of racemization versus Bu_4NBr concentration behavior are presented in Figs. 1–4. Figure 1 shows the rate behaviour of 1-(3′,4′-dimethylphenyl)bromoethane in nitromethane (set of curves with the higher intercepts) and in acetonitrile (set of curves with the lower intercepts) with curves labelled A through E for Bu_4NBr alone (A), for Bu_4NBr at constant ionic strength with Bu_4NClO_4 (B), for Bu_4NBr with Bu_4NBF_4 (C), for Bu_4NClO_4 alone (D), and finally for Bu_4NBF_4 alone (E). The greatest deviations were found for the same substrate in acetonitrile with Bu_4NClO_4 as electrolyte, so these results are shown separately in Fig. 2. Curves labelled A, B, and D are analogous to those in the previous figure, curve E is the racemization rate versus $[Bu_4NClO_4]$ at $[Bu_4NBr]$ = 0.00100 M. Results for various substrates in acetone are presented in Figs. 3 and 4. Rate data for specific concentrations

of Bu_4NBr and of electrolyte in acetone are presented in Tables 2 and 3.

Discussion

Incomplete dissociation

In acetonitrile and nitromethane, even at the highest concentration used, 0.025 M, the Bu_4NBr is apparently completely dissociated. With the 4-nitro substrate, excellent linearity is obtained in the plot of observed rate vs. [Bu_4NBr] and the plots for constant and variable ionic strength are coincident as can be seen from the data presented in Table 1 (Sets 1, 2, 3, and 10, 11, 12). The intercept in all cases is, essentially, zero; there is at most a negligible unimolecular component.

In acetone the Bu_4NBr is not completely dissociated. Figures 3 and 4, curves A, show that in the absence of added electrolyte the rate falls off with increasing Bu_4NBr concentration due to partial association of the salt, probably simply as ion pairs (1*a*). Use of an iterative method for best fit with the data for each of the three substrates allows estimation of $K_{assoc} = 15 \pm 1$ for Bu_4NBr in acetone at 40°C. Table 3 contains the actual rate constants, the calculated activity for the bromide ion, and the resultant slopes and intercepts and correlation coefficients for unsubstituted, 4-methyl-, and 3,4-dimethyl-phenylbromoethanes.

As Figures 3 and 4 also show, the effect of working at constant ionic strength in acetone is also different from that for the 4-nitro substrate in acetonitrile or nitromethane. In acetone, good linearity of rate vs. [Bu_4NBr] is obtained if Bu_4NBF_4 is used as the electrolyte to maintain constant ionic strength (Figs. 3 and 4, curves B; Table 1, sets 19, 20, 21). With Bu_4NClO_4, the rate profile is concave (Figs. 3 and 4, curves C). These results suggest that the association constant for Bu_4NBF_4 is about equal to that of Bu_4NBr. Constant ionic strength would then maintain constant Bu_4N^+ activity and hence Br^- activity would vary linearly with Bu_4NBr concentration, resulting in the observed rate behavior. By contrast, the association constant for the perchlorate salt is less than that for Bu_4NBr. Consequently, the higher activity of Bu_4N^+ leads to association of more of the bromide, reduced Br^- activity, and a dip in the rate profile.

Ionic strength effects

For all data sets in acetone, whether the rate ratio of racemization to bromide–*radio*-bromide exchange is 2.0 as for unsubstituted, 2.4 as for 4-methyl, or 1.5 as for 3,4-dimethyl substrate (2, 3), there is no or very little apparent ionic strength effect other than that due to incomplete dissociation of the nucleophile (see above). As Figs. 3 and 4 show, all substrates give essentially a zero intercept both with and without added electrolyte. Also, the lower line of Fig. 4, curve D, illustrates the typical behavior of racemization rate with added electrolyte. For the 4-methyl substrate at [Bu_4NBr] = 5.00×10^{-4} M, the observed rate constant changes from 5.38 ± 0.04 through 5.19 ± 0.01 to 4.34 ± 0.03 for ionic strengths of 0.500, 2.500, and 25.00 $\times 10^{-3}$ M (with BF_4^- counterion).[2] This very small

[2]Linear regression for the observed rate constant vs. ionic strength gives an intercept (k_{obs}) of $(5.33 \pm 0.04) \times 10^{-5}$ s^{-1} and a slope of $(-4.31 \pm 0.39) \times 10^{-4}$ L mol^{-1} s^{-1} for Winstein's *b*-value (ref. 1*c*).

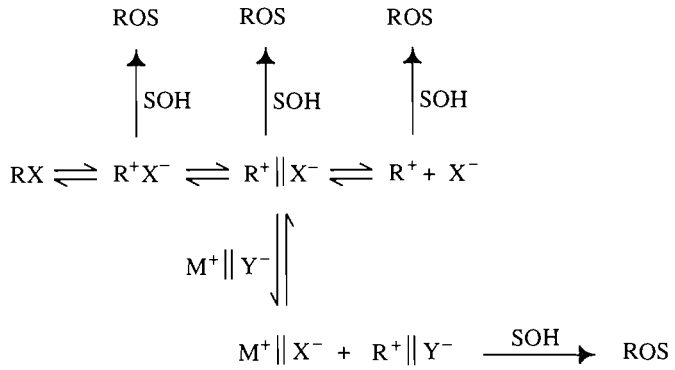
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

decrease in observed rate upon going from a Br^- to BF_4^- ratio of infinity to very low (2×10^{-2}) and an ionic strength increase of 50-fold, could arise from a very small negative salt effect or, perhaps equally likely, from a small change in bromide ion activity as the Bu_4N^+ concentration was changed, also 50-fold.

Similarly, for the 4-nitro substrate in acetonitrile and in nitromethane (Table 1, sets 1, 2, 3, and 10, 11, 12 respectively), there is no evidence of a significant ionic strength effect. With no bromide salt added, there is no change in optical rotation for hours whether the solution is 0.00 or 25.00×10^{-3} M in electrolyte, and the constant and varying ionic strength plots of observed rate versus [Bu_4NBr] are coincident throughout. Clearly the observed rate constants are unaffected by added electrolyte.

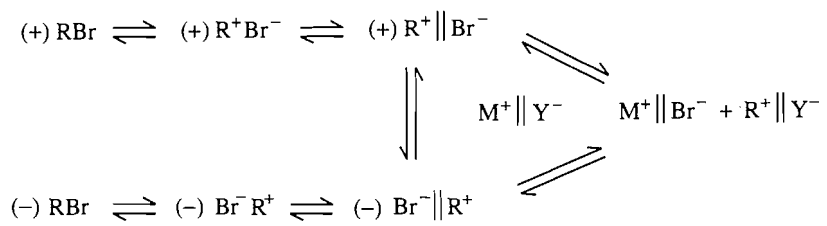
For those substrates showing mixed kinetics in acetonitrile and nitromethane, a different picture emerges. For 3,4-dimethyl substrate for example, as shown in Fig. 1, good colinearity for the observed rate of racemization at fixed and with varying ionic strength still applies at all but the lowest Bu_4NBr concentrations in nitromethane with Bu_4NBF_4 and Bu_4NClO_4 and in acetonitrile with Bu_4NBF_4. The data points that deviate significantly upwards from the line at low Bu_4NBr concentration were omitted in calculating the first- and second-order rate constants reported in Table 1 (sets 4–9, 13–18). Deviations are most pronounced for 3,4-dimethylphenylbromoethane in acetonitrile with Bu_4NClO_4, so the results illustrated in Fig. 2 will be considered first.

Curve A of Fig. 2, despite some scatter at low concentrations of Bu_4NBr, shows that the reaction rate increases linearly with nucleophile concentration. When Bu_4NClO_4 is used to maintain fixed ionic strength (curve B), the rate deviates markedly upward for low Br^-, high ClO_4^- concentrations. Since perchlorate ion is unlikely to serve as a nucleophile—ClO_4^- is recognized as an extremely poor nucleophile and alkyl perchlorates are very reactive (1, 10)—the deviation represents a salt effect. At higher bromide ion concentrations, the curves for fixed ionic strength and for no added electrolyte converge. Thus using the three highest Bu_4NBr concentration points for the constant ionic strength data set and all data points for the set with no added electrolyte gives slopes differing by only about six percent (Table 1, sets 17, 18). This establishes that the salt effect is principally in the unimolecular component of the reaction.



Special salt effects

There is apparently a special salt effect (1*c*) operating. Curve D of Fig. 2 shows the rate profile without any Bu_4NBr added as a function of ionic strength, i.e., concentration of Bu_4NClO_4 in acetonitrile. Initial rates of racemization were used because the liberated bromide ion from elimination serves as a nucleophile in racemization and the rate accelerates with time (ref. 2, see also footnote 1). For the data of curve D, generally only one fifth to one tenth of a half-life was used. Similarly, for the data of curve F and the lower bromide ion concentrations of curves A and B initial slopes were used but generally from larger fractions of a half-life. The short runs and the accelerating rates account for the scatter and poorer reproducibility. Still, the concentration – rate profiles of curves B and D clearly show a special salt effect.



Special salt effects have been observed regularly since Winstein *et al.* first reported them about 35 years ago (1*c*). They are most commonly reported for solvolysis reactions with substrate giving quite stable carbocations, such as benzhydryl (8*f*) and 4-methyl or methoxybenzyl carbocations (1*c*), and carbocations that are sterically hindered to back-side nucleophilic attack, such as cholesteryl (1*a*), norbornyl (1*c*), and β-phenylethyl systems that react, at least in part, with assistance by the phenyl group (1*c*, 8*b*,*d*). Special salt effects have been reported for the addition of aryl sulfenyl chlorides, ArSCl, to rigid alkenes (8*e*) where the resultant ion pair must solvate so the chloride ion can migrate to the carbocation centre and, also, for other ArSCl reactions (8*g*). In all of these cases, the special salt effect is manifest kinetically as a marked rate acceleration at low ionic strengths. Recently special salt effects that manifest themselves as a marked rate deceleration have been reported for photolysis or pulsed radiolysis generated ion pairs (9). Thus time-resolved or picosecond spectroscopy of photogenerated charge-transfer ion pairs, from aromatic hydrocarbons and tetranitromethane (9*a*), and from benzophenones and dialkylanilines (9*b*), show special salt effects that markedly extend the lifetime of the ion pairs. Here, as for the solvolysis studies, special salt effects manifest themselves when ion pair exchange gives a new ion pair for which collapse is undesirable. Ion lifetimes are increased and, sometimes, other reaction pathways can compete with initial ion-pair collapse. For the solvolysis studies, the effects were noted in moderately ionizing but weakly nucleophilic solvents, especially in acetic acid. For the other studies, solvents were generally aprotic, ranging in polarity from ethers and dimethoxyethane through dichloromethane to acetonitrile and nitromethane.

Winstein's explanation of the special salt effect has stood the test of time (1*c*). Briefly, in a solvolysis situation, such effects reflect interception of an ion pair, formed reversibly from the substrate, by ion-pair exchange with a non-nucleophilic salt, typically $LiClO_4$. The carbocation–perchlorate ion pair then proceeds to give solvolysis products as illustrated in Scheme 2.

A similar mechanism is, no doubt, operating in our case. The ion pair formed from the 3,4-dimethylphenylbromoethane exists as various solvated ion pairs in equilibrium with the substrate. In the absence of any nucleophile, racemization requires a moderate degree of ion-pair separation and solvation to facilitate bromide ion migration or carbocation rotation and hence collapse of the ion pair with racemization. Added non-nucleophilic salt such as Bu_4NClO_4 facilitates such ion-pair separation and bromide ion migration by "ion-pair exchange," resulting in a marked increase in the observed rate of racemization. This mechanism is confirmed by the "competition" between added nucleophile, Bu_4NBr, and inert electrolyte, Bu_4NClO_4, as shown in Fig. 2, Curve F. Even at very low concentrations, the bromide ion competes very effectively with the perchlorate special salt effect: the rate is independent of

SCHEME 2. Special salt effects in solvolysis.

SCHEME 3. Special salt effects on internal return with racemization.

perchlorate concentration until it is more than five times that of the bromide ion.

Simon and Peters (9*b*) have presented evidence that the species most efficient at undergoing ion-pair exchanges are ones with similar degrees of separation; contact ion pairs exchange best with contact ion pairs, solvent separated ion pairs with solvent separated ones. Other results are also best interpreted in this fashion (8*f*, 9*c*). Thus a possible explanation of the special salt effect in our racemization studies is presented in Scheme 3. For simplicity, only two types of ion pairs, contact (R^+Br^-) and solvent separated ($R^+||Br^-$), are included even though dissociation of contact ion pairs must be progressive or stepwise with one, two, three ... "layers" of solvent separating the ions.

With Scheme 3 as a model, the solvent separated ion pairs must return to substrate faster than they undergo inversion and, hence, return with racemization, possibly because quite-well-separated ions are required for the carbocation inversion (or bromide ion migration). The presence of an "inert" ion pair, $Bu_4N^+||ClO_4$, introduces a new, faster-pathway, ion-pair exchange–reexchange to facilitate the racemization. With added bromide ion, an additional pathway for racemization/inversion, a nucleophile assisted one, is introduced. This latter pathway, which is not included in Scheme 3, competes very successfully with the special salt effect as shown by curve F of Fig. 2.

The special salt effects with Bu_4NBF_4 are much less pronounced in acetonitrile and in nitromethane. In the latter solvent, as can be seen in Fig. 1, deviations from linearity, from the line with no added electrolyte (curve A), are much smaller with either Bu_4NClO_4 (curve B) or Bu_4NBF_4 (curve C). As in acetonitrile, in nitromethane Bu_4NClO_4 shows the greater, if reduced, special salt effect (curve D vs. curve E). If Simon and Peters (9*b*) are correct, less of the Bu_4NBF_4 than of the Bu_4NClO_4 is in the appropriately solvated ion pair in both acetonitrile and nitromethane, but both salts have less of that ion pair in the latter solvent. The special salt effect pathway of Scheme 2 is thus less competitive with the "unassisted" pathway.

The salt effects and special salt effects for 4-methylphenylbromoethane with Bu_4NClO_4 in acetonitrile and nitromethane are analogous but considerably less marked. For the other substrates and for all substrates in acetone, no salt effect other than those attributable to incomplete dissociation of Bu_4NBr is found. This is presumably because the separation of contact ion pairs to solvated ones is too limited. Racemization requires nucleophile involvement of ionic bromide.

Conclusions

Special salt effects have traditionally been observed for solvolysis reactions that are forced to go via a unimolecular mechanism, *exo*-norbornyl toluenesulfonate for example (1*c*), or for which a carbocation is especially stable, 2-(4-methoxyphenyl)ethyl toluenesulfonate for example (8*d*). Thus it is not surprising that special salt effects appear only in the racemization of 3,4-dimethyl- and 4-methylphenylbromoethanes in the moderately ionizing solvents, acetonitrile and nitromethane, and then only in the absence of appreciable concentrations of bromide ion nucleophile, that is, for the unimolecular racemization. No other salt effect was detected in these more polar solvents. In acetone, a common ion effect by Bu_4N^+ on the dissociation of Bu_4NBr leads to a rate depression at high electrolyte concentrations, but no other salt effect was noted.

These results establish the validity of the separation of uni- and bimolecular components using eq. [1] (3). They also lend further support for racemization via internal return from solvated ion pairs. Additionally, the very successful competition of bromide ion with Bu_4NClO_4 or Bu_4NBF_4 for the substrate ion pair from 3,4-dimethyl- and 4-methylphenylbromoethane in acetonitrile and in nitromethane suggests there is an ion-pair process involved in the bimolecular racemization as well.

Together with our previously published results, these studies support a mechanistic progression for nucleophilic substitution at saturated carbon. Using bromide ion as the nucleophile with arylbromoethanes, we find systems showing cleanly bimolecular kinetics where there is a one-to-one correlation of bromide substitution and inversion of stereochemistry (e.g., phenylbromoethane in acetone (2, 4) or other solvents (3)), where there is an excess of inversion (i.e., internal return with racemization also occurs, e.g., 4-methylphenylbromoethane in acetone (2)), and where there is "mixed stereochemistry" (i.e., exchange with racemization accompanies exchange with inversion, e.g., 3,4-dimethylphenylbromoethane in acetone (2)). Other reactions show mixed unimolecular and bimolecular kinetics, ranging from almost exclusively bimolecular (e.g., 3-methylphenylbromoethane in acetonitrile (3)) to those having a major unimolecular component (e.g., 3,4-dimethylphenylbromoethane in nitromethane (3)), and now we have shown that the unimolecular reaction can be markedly accelerated by the addition of inert electrolyte. Thus, depending upon substrate, nucleophile, leaving group, medium, and other factors, nucleophilic substitution can, and presumably does, occur at any stage of the ionization/dissociation process, substrate $\rightleftharpoons$ intimate ion pair $\rightleftharpoons$ variously solvated ion pairs $\rightleftharpoons$ dissociated or free ions. Kinetics and stereochemistry run the gamut from those expected for the classical S_N2 to the classical S_N1 mechanisms with, apparently, no clear demarcations between them. Such conclusions are in broad agreement with those of others (12).

Experimental

Reagent, Analar, or HPLC grade solvents were stored over and freshly distilled, with moderate reflux ratio, from calcium hydride under tank dry nitrogen, which was further dried by bubbling through concentrated sulfuric acid followed by a column of type 3A molecular sieves. Analytical or reagent grade tetrabutylammonium bromide (Eastman), perchlorate (Baker), and fluoroborate (Aldrich) were dried

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

by pumping overnight at <0.1 Torr (1 Torr = 133.3 Pa) at 50–60°C. The salts were stored under vacuum or, for relatively short periods, tightly stoppered in the dry nitrogen filled glove box. After distillation and (or) drying, all weighings, transfers, and dilutions were done in the glove box using oven-dried glassware throughout. Stock solutions, $(2.500 \pm 0.005) \times 10^{-2}$ M, of the various salts were prepared and stored for up to several weeks in hypo-vials with Teflon coated septa. The chiral arylbromoethanes were prepared as previously described (11).

Racemization kinetics were followed using a Perkin–Elmer model 141MC polarimeter equipped with a potentiometric recorder. Solutions were prepared by directly pipetting a total of 5 mL of the appropriate stock or diluted stock solution(s) and (or) solvent into the 10-cm jacketted quartz cell. A known mass of substrate, 20–100 mg depending on the optical activity as previously described (2), was then added by syringe. The Teflon stoppers were inserted, the cell was removed from the glove box and connected to the circulatory constant-temperature bath operating at 30.00 or 40.00 ± 0.05°C. While the cell was equilibrating, the contents were thoroughly mixed by tilting and shaking the cell for several minutes. The cell was inserted into the polarimeter and the rotation change followed for usually 4–5 half-lives at 365 nm or, with nitromethane solutions or 4-nitrophenylbromoethane, at 434 nm. Infinity values differed very little from the no-cell zero value, so the latter was used in determining k_{obs}, i.e., the slope from the standard linear regression treatment of rotation vs. time data (as read from the recorder chart output) for the pseudo-first-order reactions.

Counterion micellar effects upon the reaction of low-spin diimine iron(II) complexes

FRANCISCO ORTEGA AND ELVIRA RODENAS[1]

Departamento de Química Física, Universidad de Alcalá de Henares, Alcalá de Henares, Madrid, Spain

Received August 25, 1987[2]

FRANCISCO ORTEGA and ELVIRA RODENAS. Can. J. Chem. **67**, 305 (1989).

The rate of reaction of tris(1,10-phenanthroline)iron(II) ion (**1***a*), tris(3,4,7,8-tetramethyl-1,10-phenanthroline)iron(II) ion (**1***b*), and tris(4,7-diphenyl-1,10-phenanthroline)iron(II) ion (**1***c*) with hydroxide ion, in cationic micelles, is strongly affected by the concentration of micellar counterion in solution. The reaction of **1***a* in CTACl is modestly speeded up by the addition of added KCl, while the reactions of **1***b* and **1***c* are strongly inhibited by the addition of large amounts of KCl and KBr to micellar solutions of CTACl and CTABr, respectively. These rate effects fit the pseudophase-ion exchange model, assuming the binding of the substrates to the micelles depends upon the counterion concentration.

Key words: counterion micellar effects, low-spin diimine iron(II) complexes.

FRANCISCO ORTEGA et ELVIRA RODENAS. Can. J. Chem. **67**, 305 (1989).

La vitesse de réaction de l'ion hydroxyde avec les ions tris(phénanthroline-1,10)fer(II) (**1***a*), tris(tétraméthyl-3,4,7,8 phénanthroline-1,10)fer(II) (**1***b*) et tris(diphényl-4,7 phénanthroline-1,10)fer(II) (**1***c*), dans des micelles cationiques, est fortement influencée par la concentration des contre-ions dans la solution micellaire. La vitesse de la réaction du composé **1***a*, dans le CTACl, est légèrement plus rapide lorsqu'on ajoute du KCl; par ailleurs, les vitesses de réaction des composés **1***b* et **1***c* sont fortement inhibées par l'addition de grandes quantités de KCl et de KBr à des solutions respectivement de CTACl et de CTABr. Si l'on fait l'hypothèse que la liaison des substrats aux micelles dépend de la concentration du contre-ion, ces effets sur les vitesses des réactions sont en accord avec le modèle d'échange ionique pseudophase.

Mots clés : effets des contre-ions dans des micelles, complexes de diimine fer(II) « low-spin ».

[Traduit par la revue]

Introduction

The rates of many bimolecular reactions are known to be affected by micellized aqueous surfactant. It is now generally accepted that this effect arises primarily from the concentration of both reactants in the small volume of the Stern-layer of micelles (1–6).

For a large number of bimolecular reactions, micellar effects have been interpreted using the pseudophase-ion exchange model (2, 5), assuming that the fraction β of micellar bound counterions is constant and independent of counterion and surfactant concentration. However, several different physical measurements suggest that β increases on addition of counterions (7, 8), and a variety of kinetic results in the literature either at high counterion concentration (9–11) or with hydrophilic reactive counterions (12–14) cannot be explained by this model.

In earlier papers (15, 16) we published results on the reaction of some diimine iron(II) complexes with hydroxide and cyanide ions in cationic micelles (CTABr, CTACl, CTAOH, and CTACN, where CTA is cetyltrimethylammonium). The results were interpreted using the pseudophase-ion exchange and mass-action models, taking into account the very important "salting-out" of the substrates into the micelles. In view of these results, we studied the effect of added counterions, Br^- and Cl^-, on the reaction of tris(1,10-phenanthroline)iron(II) ion (**1***a*), tris(3,4,7,8-tetramethyl-1,10-phenanthroline)iron(II) ion (**1***b*) and tris(4,7-diphenyl-1,10-phenanthroline)iron(II) ion (**1***c*) with hydroxide ion in presence of CTAB and CTACl micelles. Our aim was to test the pseudophase-ion exchange model at high counterion concentration and if possible to correlate added counterion effects with the interaction between cationic micelles and cationic substrates of different hydrophobicities.

[2]Revision received October 11, 1988.

Experimental

Materials

Solutions of **1***a* and **1***c* were prepared "in situ", by mixing stoichiometric amounts of iron(II) sulphate (Merck) and ligand (Calo Erba). Substrate **1***b* (G. Frederick Smith Chemical Co.) was dissolved in water.

CTABr (Merck) was recrystallized from $MeOH/Et_2O$ mixture (17). CTACl was prepared by ion-exchange from CTABr using Amberlite 21K anionic resin (15), and MeOH as solvent. The absence of Br^- was tested with fluorescein. CTACl was recrystallized from $MeOH/Et_2O$ mixture. Here the cmc (critical micelle concentration) are as follows: cmc(CTAB) = 9×10^{-4} *M*, cmc(CTACl) = 1.2×10^{-4} *M*.

Kinetics

All reactions were run at 25 ± 0.1°C in a thermostated Spectronic 2000 Bausch and Lomb spectrophotometer. The reactions were followed at 513, 479, and 353 nm for substrates **1***a*, **1***b*, and **1***c*, respectively. Substrate stock solution, 0.1 *M*, was added to mixtures of CTAB (CTACl), NaOH and KBr (KCl) at given concentrations in the thermostated cuvettes of the spectrophotometer. The final complex concentration was 5×10^{-5} *M*.

The hydroxide ion was always in large excess over substrate and pseudo-first order rate constants were obtained by least-squares fits with correlation coefficients greater than 0.999.

Results and discussion

Second-order rate constants for reaction of both substrates **1***a* and **1***b*, in absence of surfactant, were obtained directly from the kinetic data in aqueous solution with values 1.06×10^{-2} and 6.05×10^{-4} M^{-1} s^{-1}, respectively. Substrate **1***c* is not soluble in pure water and the second order rate constant in water was obtained from rate constants in $MeOH/H_2O$ mixtures by extrapolation to zero concentration of methanol. The value obtained was 2.09×10^{-3} M^{-1} s^{-1}.

Rate constant – surfactant concentration profiles for the reaction of substrates **1***a* nd **1***b* with OH^- in CTACl and CTABr are shown in Figs. 1 and 2 at 0.1 *M* added KBr and no added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

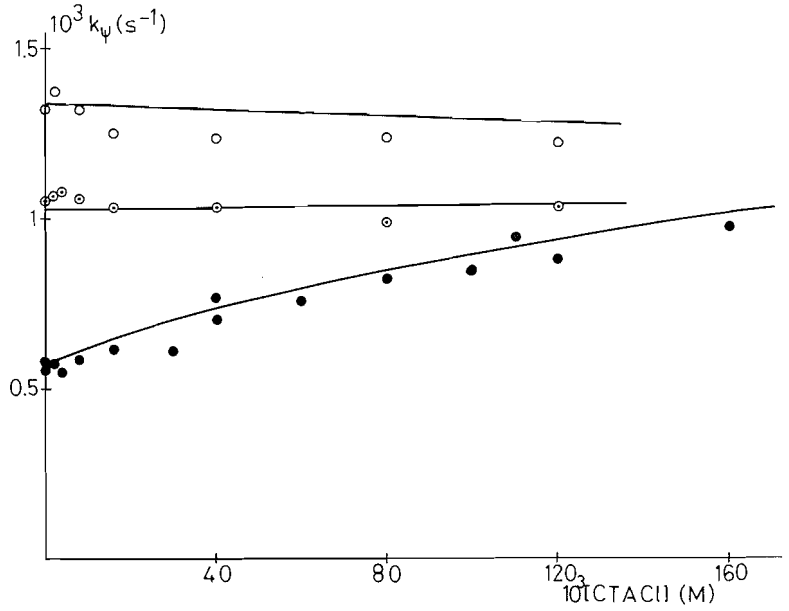

FIG. 1. Variation of the pseudo-first order rate constant, k_ψ, with CTACl concentration for reaction of **1***a* with OH^- (0.08 *M*): ○ in absence of added KCl; ⊙ [KCl] = 0.1 *M*; ● [KCl] = 0.4 *M*. Lines are predicted values from eqs. [1], [2], and [3] and parameters in Table 1.

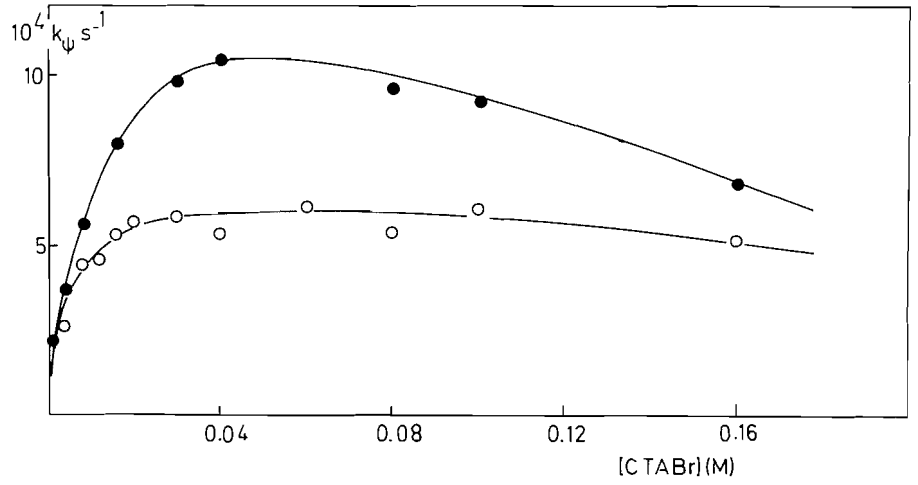

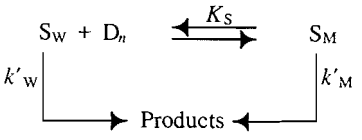

FIG. 2. Variation of the pseudo-first order rate constant, k_ψ, with CTABr concentration for substrate **1***b* with OH^- (0.04 *M*): ● in absence of added KBr; ○ [KBr] = 0.1 *M*. Lines are predicted values from eqs. [1] and [2] and parameters in Table 2.

counterion. Figures 3 and 4 show the rate constant – counterion concentration profiles for reaction of substrates **1***b* and **1***c* at a fixed surfactant concentration.

In the absence of added counterion the reaction rate for substrate **1***a* (Fig. 1) is not appreciably affected by micelles of CTACl. But in 0.4 *M* of KCl, added CTACl produces a small catalytic effect. In the case of substrates **1***b* and **1***c*, different counterion effects are observed. Both reactions are inhibited by added KBr while the reaction rate of **1***b* in CTACl is enhanced by 0.1 *M* KCl (Fig. 3).

We attempted to simulate all of these results using the pseudophase ion-exchange model developed by Bunton (4) and Romsted (2, 18).

The total volume of micelles is treated as a separate phase, uniformly distributed in the aqueous phase, with the reaction occurring in both phases according to Scheme 1.

SCHEME 1

D_n is the concentration of micellized surfactant equal to the stoichiometric surfactant concentration minus the cmc, K_S is the binding constant of substrate to the micelle, and k'_W and k'_M are pseudo-first order rate constants for the reaction in aqueous and micellar phases, given by $k'_W = k_W[OH^-_W]$ and $k'_M = k_M[OH^-_M]/[D_n]$.

Romsted (2, 18) proposed that when two ions compete for the micellar surface the distribution of counterions between the

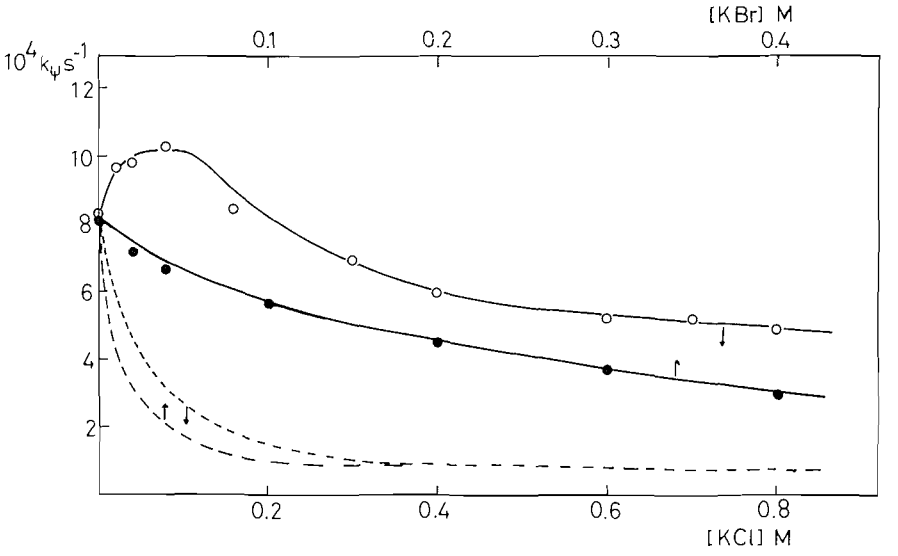

FIG. 3. Variation of the pseudo-first order rate constant, k_ψ, with micellar counterion concentration for the reaction of substrate **1***b*: ○ [NaOH] = 0.04 *M*, [CTACl] = 0.02 *M*; ● [NaOH] = 0.04 *M*, [CTABr] = 0.02 *M*. Dashed lines are predicted by eqs. [1] and [2] and continuous lines by eqs. [1], [2], [4], [5], and [6] with parameters given in Table 2 and [KBr + CTABr]: $A = 3500\ M^{-2}$, $p = 3$, $K_S^0 = 7.1\ M^{-1}$, and $\beta_0 = 0.8$; [KCl + CTACl]: $A = 200\ M^{-1}$; $p = 1$; $K_S^0 = 3.2\ M^{-1}$, and $\beta_0 = 0.71$.

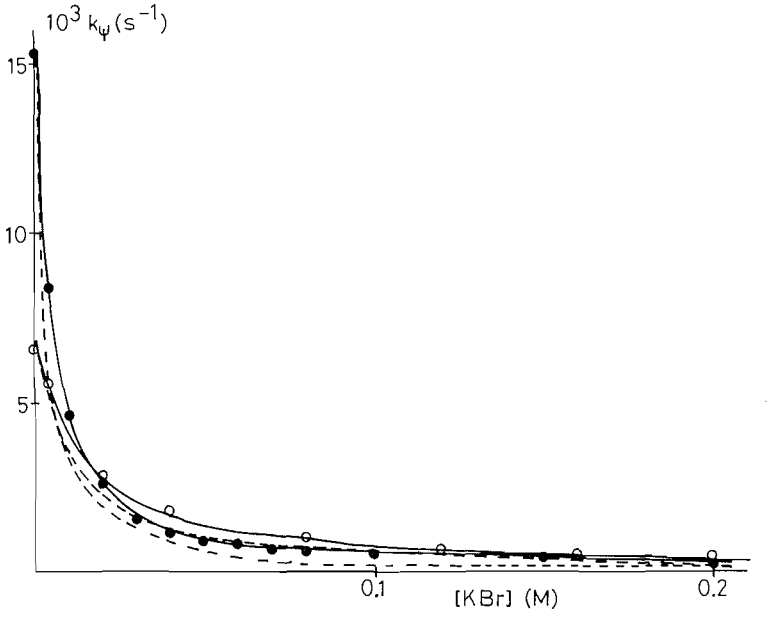

FIG. 4. Variation of the pseudo-first order rate constant, k_ψ, with micellar counterion concentration for the reaction of substrate lc: ○ [NaOH] = 0.04 *M*, [CTABr] = 0.020 *M*; ● [NaOH] = 0.04 *M*, [CTABr] = 0.002 *M*. Dashed lines are predicted from eqs. [1] and [2] and continuous lines by eqs. [1], [2], [5], and [6] with parameters given in Table 2 and $A = 1.5 \times 10^5\ M^{-1}$, $K_S^0 = 800\ M^{-1}$, $p = 0$, and $\beta_0 = 0.8$.

micelle surface and the aqueous phase is governed by an ion-exchange equilibrium as:

$$OH_M^- + Br_W^- \overset{K_{Br}^{OH}}{\rightleftharpoons} OH_W^- + Br_M^-$$

with the fraction of micellar head groups neutralized, β, constant.

According to this model the pseudo-first order rate constant is given by:

$$[1] \quad k_\psi = \frac{k_W[OH^-]_T + (k_M K_S - k_W) m_{OH}[D_n]}{1 + K_S[D_n]}$$

where m_{OH} can be obtained by:

$$[2] \quad m_{OH}^2 + m_{OH}\left[\frac{[OH^-]_T + K_{Br}^{OH}[Br^-]_T}{(K_{Br}^{OH} - 1)[D_n]} - \beta\right] - \frac{\beta[OH^-]_T}{(K_{Br}^{OH} - 1)[D_n]} = 0$$

This model predicts that the addition of counterion to micellar solutions should decrease the pseudo-first order rate constant by displacement of the reactive ion from the micellar to the aqueous phase. Thus, assuming K_S is constant, this treatment cannot account for the increase in k_ψ with added counterion for substrates **1***a* and **1***b* (Figs. 1 and 3).

[a]Data in absence of added KX, taken from ref 15.

These results can be explained by considering counterion effects upon both the substrate binding to micelles and the fraction of neutralized micellar head groups (9, 11, 16, 19). The values of parameters that best fit the experimental results for substrate **1***a* in CTACl micelles are in Table 1; the solid lines in Fig. 1 represent the values of k_ψ calculated from eqs. [1] and [2]. In the calculation, the salt effect on the reaction in water is accounted for by the empirical equation:

$$[3] \quad k_W = 10^{(-\log k_W^0 - 0.92[KCl]^{0.5})}$$

where k_W^0 is the second order rate constant at ionic strength 0.2 *M*, obtained using 0.08 *M* hydroxide ion concentration and the appropriate amount of KCl to yield 0.2 *M*.

The reaction of substrate **1***a* in the absence of KCl or at 0.1 *M* occurs almost completely in the water phase as can be seen in Fig. 1. This indicates the absence of significant substrate binding to CTACl micelles. All the results can be explained by assuming a large variation in K_S and in the fraction of micellar head groups neutrallized, β, as can be seen from the parameters in Table 1. Solid lines in Fig. 1 correspond to calculated values with eqs. [1] and [2] and the given values of parameters.

The values of K_S and β must be adjusted to fit the results for substrates **1***b* and **1***c*. In Figs. 3 and 4, dashed lines correspond to k_ψ values calculated with parameters obtained for reactions carried out in absence of added counterion (Table 2). To fit the results in the presence of added 0.1 *M* KBr, larger values of K_S and β are needed (Table 2 and Fig. 2). The solid lines in Figs. 3 and 4 correspond to calculated values using the following empirical variations in K_S and β:

$$[4] \quad K_S = K_S^0(1 + a[Br^-]^2)$$

or

$$[5] \quad K_S = K_S^0(1 + A[Cl^-])$$

and

$$[6] \quad \beta = \beta_0(1 + p[X^-])$$

where K_S^0 and β_0 correspond to the values of K_S and β found in absence of added electrolyte, and the parameter, *a*, *A*, and *p* are given in the captions of Figs. 2 and 3. β_0 is 0.71 for CTACl and 0.8 for CTAB.

From these results we conclude that the binding of these like-charged substrates to micelles increases with added salt and from the variation obtained with substrate **1***b* it can be deduced that Br^-, a more hydrophobic ion, promotes the binding of these cationic substrates better than a hydrophilic ion such as Cl^-. As discussed previously (15) two opposing forces contribute to the binding of these substrates to micelles, hydrophobic attraction, and coulombic repulsion. At high salt concentration the coulombic repulsion is screened and the hydrophobic effect becomes more important. This is consistent with results in the literature (20) for other substrates, for which an increase in K_S was also found using fluorescence quenching measurements. The results can be explained by a decrease in the net micellar surface potential with increasing salt concentration.

This salt effect is less important for substrate **1***c*, for which hydrophobic forces are more important than electrostatic ones in the binding to cationic micelles. For this substrate any kind of variation of K_S with salt concentration, linear or quadratic, could fit the experimental results.

A similar variation in K_S with ions was observed for non-charged substrates and rationalized as a salting-out effect (21). Different effects have been found for substrates of opposite charge to the surfactant, for which kinetic results at high counterion concentration have been explained by a displacement of substrates from the micellar to the aqueous phase, resulting in a decrease in the K_S value (22).

A simple variation in K_S is not enough to explain all the kinetic data; an increase in the fraction of micellar bound counterions with salt concentration is necessary to obtain results that agree with a variety of different physical measurements (7, 8, 23–25). The influence of micellar counterions on these reactions is due to competition between three different effects: displacement of the substrate from the aqueous to the micellar phase, displacement of reactive ions by counterions from the micellar phase and an increase in the fraction of micellar group neutralized.

We recognize that some other kind of empirical variation could also explain the experimental data, but our approach agrees with other results in literature and makes it possible to see how much the results depart from the model.

At high salt concentrations the value of β does not have any physical sense that can be related to changes in micellar structure because added salt induces micelle growth from spherical to ellipsoidal (23–25). Even so the variation in K_S and in β necessary to fit the results cannot be accommodated by perturbations in the model. We must recognize that the pseudophase ion-exchange model fails to explain results at high salt concentrations, and other theoretical treatments to account for these effects need to be developed.

Analysis of wood vacuum pyrolysis solid residues by diffuse reflectance infrared Fourier transform spectrometry

H. PAKDEL, J. L. GRANDMAISON, AND C. ROY

Chemical Engineering Department, Université Laval, Pavillon Adrien-Pouliot, Ste-Foy, P.Q., Canada G1K 7P4

Received June 27, 1988

H. PAKDEL, J. L. GRANDMAISON, and C. ROY. Can. J. Chem. **67**, 310 (1989).

Vacuum pyrolysis of wood furnishes high yields of oils which are a source of liquid fuels and chemicals. Wood charcoal is a solid residual by-product. Solid residues produced at 200, 263, 327, 363, 401, and 448°C in a Process Development Unit were analyzed using wet chemical methods and chromatography and infrared spectrometry.

A Diffuse Reflectance Infrared Fourier Transform (DRIFT) study of the solid residues which contained various proportions of organic polymeric constituents consisting of unconverted lignin, polysaccharides, and recondensed materials was performed. Polysaccharide contents were determined by hydrolysis in trifluoroacetic acid followed by derivatization and gas-chromatographic analysis. The DRIFT study showed that the solid residue retained its wood nature below 263°C. Significant degradation, decomposition, and recondensation reactions occurred with increasing temperature and coal-like nature prevailed above 327°C. Occurrence of a new band at 1700 cm^{-1} in samples produced at 363°C and above was found to be indicative of a new carbonyl group, presumably in recondensed material.

A series of equations were also developed to predict semiquantitatively Klason residue, glucose and xylose content of the solid residues. The usefulness of each equation is discussed in the article.

Key words: wood, vacuum pyrolysis, solid residue, DRIFT, spectrometry.

H. PAKDEL, J. L. GRANDMAISON et C. ROY. Can. J. Chem. **67**, 310 (1989).

Lorsqu'on pyrolyse du bois sous vide, on obtient des rendements élevés d'huiles qui sont une source de combustibles et de produits chimiques. On obtient aussi du charbon de bois comme sous-produit résiduel solide. Faisant appel à des méthodes chimiques humides ainsi qu'à la chromatographie et à la spectrométrie infrarouge, on a analysé les résidus solides obtenus par traitement à 200, 263, 327, 363, 401 et 448°C, dans une unité de développement de procédé.

On a réalisé une étude de réflexion diffuse par infrarouge transform de Fourier (DRIFT) des résidus solides qui contenaient diverses proportions de constituants organiques polymériques formées de lignine non-transformée, de polysaccharides et de matériaux recondensés. On a déterminé la teneur en polysaccharides en procédant à une hydrolyse dans de l'acide trifluoroacétique, puis à la formation de dérivés et finalement à une analyse par chromatographie en phase gazeuse. L'étude par la méthode DRIFT a permis de démontrer que, à des températures inférieures à 263°C, le résidu solide garde sa nature ressemblant à celle du bois. Avec une augmentation de la température, on observe de plus en plus de réactions de dégradation, de décomposition et de recondensation et, au-dessus de 327°C, le résidu obtenu est principalement d'une nature ressemblant à celle du charbon. Dans les échantillons de résidus obtenus à des températures supérieures à 363°C, on observe une nouvelle bande à 1700 cm^{-1}; celle-ci suggère la présence d'un nouveau groupement carbonyl qui provient probablement d'un produit de recondensation.

On a aussi développé une série d'équations qui permettent de prédire d'une façon semi-quantitative les teneurs en résidu de Klason, en glucose et en xylose des résidus solides. On discute de l'utilité de chacune de ces équations.

Mots clés : bois, pyrolyse sur vide, résidu solide, DRIFT, spectrométrie.

[Traduit par la revue]

Introduction

Vacuum pyrolysis of wood enables the production of high yields of oils which are a source of liquid fuels and chemicals (1, 2). Wood charcoal is a by-product of the vacuum pyrolysis reactions. This solid residue has been found to be rather reactive (3). Two recent studies of wood charcoal have used ESCA (4) and fluorescence and reflectance (5) measurements to investigate the mechanism of wood pyrolysis. This article presents new data obtained using the DRIFT technique. The specific advantages of DRIFT are discussed in this article.

The composition of solid residues from pyrolysis reactions of wood has been investigated by several researchers. Authors reported wet chemistry methods for the determination of moisture, insoluble and soluble lignins and carbohydrates (6–8). Schulz *et al.* (9) used the FTIR method with diffuse reflectance cell to determine the three major components of pretreated lignocellulosic materials at temperatures ranging from 140 to 280°C. Recently, this approach has been extended for qualitative and semiquantitative studies of thermally modified lignocellulosic constituents of *Populus tremuloïdes* produced by supercritical extraction (SCE) at 350°C under various pressures and flow rates (10). An ESCA study was also performed on the same SCE samples (11).

Until recently, infrared spectrometric measurements of carbonaceous materials have used the KBr pellet technique in transmission mode (12). The KBr technique has some drawbacks including a high scattering background and the possibility of strong Christiansen effects which are associated with preparation of the pellets (13). The DRIFT technique can alleviate these problems and provides more spectral information. In addition, it can be used to perform *in situ* studies (e.g. oxidation) using an appropriate chamber. Useful spectra may be obtained using neat samples (undiluted) (10, 14) but the best spectra are usually obtained in a non-absorbing matrix like KCl (15). Nevertheless, there are various problems associated with qualitative and quantitative DRIFT analysis in particular. Due to the assumptions made, Kubelka-Munk equation for diffuse reflectance measurements has been reported to be valid for dilute dispersion of an analyte in non-absorbing matrices (16, 17). Its linearity could be further improved by improving sample preparation technique (18, 19) and optical geometry of the system (20).

This work contributes to the knowledge of thermal conversion solid residue characteristics and extends the previously reported semiquantitative infrared approach to wood charcoals produced under vacuum pyrolysis (VP) conditions within a higher range of temperatures. Emphasis has been made on usefulness of DRIFT technique in fast determination of constituents of many lignocellulosic solid residues obtained by various liquefaction techniques.

Experimental

Debarked *Populus deltoïds* (Forintek clone D-38) wood chips sieved to 1/4″ to 1/2″ Tyler mesh sizes were pyrolysed in a Process Development Unit vacuum pyrolysis multiple hearth furnace. The mass flowrate through the six hearth reactor was 3.5 kg h^{-1}. In this process, the organic vapor and gas products are removed from the reactor chamber by a mechanical vacuum pump and are subsequently condensed in a series of receivers. Charcoal is collected at the bottom of the reactor. The reactor hearth temperatures were stabilized at 200, 263, 327, 363, 401, and 448°C from top to bottom of the reactor respectively (hearths H-I to H-VI). The radial temperature gradient for any heating plate was lower than 5° during a run. At the end of the run, a few particles of wood charcoal were left behind on top of each heating plate. Such solid residues along with the raw wood sample were analyzed as described below, using wet chemistry as well as chromatographic and IR spectroscopic methods. Operation of the Process Development Unit has been described elsewhere (21).

Hydrolyses of the residual polysaccharides were performed in trifluoroacetic acid (TFA) following the Fengel and Wegener procedure (22). About 100 mg of the charcoal sample was soaked in 10 g TFA overnight at room temperature. The mixture was then heated in an oil bath under reflux for 1 h, diluted to 80% (w/w) TFA in water and refluxed for 15 min. The mixture was further diluted to 30% (w/w) TFA, refluxed for 2 h, and filtered. The residue was washed with 100 mL of water and the filtrate was mixed with the mother liquors and evaporated in a rotary vacuum evaporator at 50°C to dryness to yield hydrolyzate. Approximately 30 mL of water was added to the hydrolyzate which was subsequently evaporated to dryness in order to completely eliminate any TFA traces. The hydrolyzate was finally derivatized using trimethylsilylimidazole (TMSI) in pyridine.

Gas-chromatographic analyses of the derivatized samples are presented in Table 1. Analyses were performed using a Varian 6000 chromatograph with 30 m × 0.25 mm i.d. DB-5 capillary column and split/splitless injector with 1:100 split ratio. He and N_2 were used as carrier and make-up gas, respectively. The FID and injector temperatures were set at 290 and 300°C, respectively. The column temperature was maintained at 150°C for 2 min then programmed to 190°C at 20°C min^{-1} and then to 290°C at 30°C min^{-1}.

Samples were dried for spectrometric analysis at 105°C for 12 h and ground in a SPEX stainless steel mill in air (30 min for wood and samples 1 and 2, and 10 min for samples 3 to 6). The samples were then further ground for an additional minute with dry KCl (Anachemia) in 1:100 ratio and analyzed immediately. FTIR spectra were obtained with a Digilab FTS-60 spectrometer equipped with a DTGS detector. A Harrick-2CE diffuse reflectance cell was used with coadding of 250 scans at 4000–700 cm^{-1} frequency range, 2 cm^{-1} resolution and triangular apodization.

Results and discussion

Table 1 presents wet chemistry (Klason residue and TFA soluble) and GC (total sugars) analytical results obtained for the raw material and the six solid pyrolysis residues. TFA treatment of the solid residues partially hydrolyzed the carbohydrates into monosaccharides. The remaining carbohydrates were degraded into water soluble non-carbohydrates e.g. furanic-type compounds. Despite a comparable Klason residue content of the solid residues determined by both sulfuric and TFA methods (8), the TFA method was preferred due to the ease of complete TFA removal by evaporation after hydrolysis. Since the solid residues obtained by relatively severe thermochemical conversion process are composed of unconverted and structurally modified lignin, therefore the term "Klason residue" is used instead of "Klason lignin" (8). The solid residue left on H-IV (Table 1) contained a high percentage of Klason residue (TFA insoluble) and a low content of TFA soluble monosaccharides produced by both pyrolysis and hydrolysis. Earlier, Wayman and Chua (23) suggested that carbohydrates and lignin as well as furfural type compounds participate in recondensation reactions.

DRIFT spectra of the original wood and of the solid residues from hearth H-I to H-VI are shown in Fig. 1 (designated as H-I to H-VI, respectively). Comparison of IR spectra of wood feedstock with H-I (200°C) and H-II (263°C) charcoals shows the wood-like nature of the solid residues with characteristic vibrational bands at 895 cm^{-1} (β-pyranose ring in cellulose, (24)); 1740 cm^{-1} (uronic acid and acetyl group in hemicellulose, (24)); 1235 to 1605 cm^{-1}, and 1505 cm^{-1} in particular (typical of lignin aromatic ring vibration, (25)) and 950 to 1100 cm^{-1} (mainly carbohydrate C—O vibrations, (24)). As the temperature increases from 263°C (H-II) to 327°C (H-III), significant differences appear in the IR spectra of H-II and H-III, associated with severe degradation, decomposition and recondensation reactions. Evolution of a coal-like pattern could be observed by disappearance of lignin (1235 to 1605 and 1505 cm^{-1}) and carbohydrate (e.g. 1740 and 895 cm^{-1}) bands as the reactor bed temperature was further increased from 327°C (H-III) to 448°C (H-VI). Interestingly, the moderate intensity band at about 1740 cm^{-1} in the raw material and H-I (200°C) and H-II (263°C) spectra disappeared which is probably due to

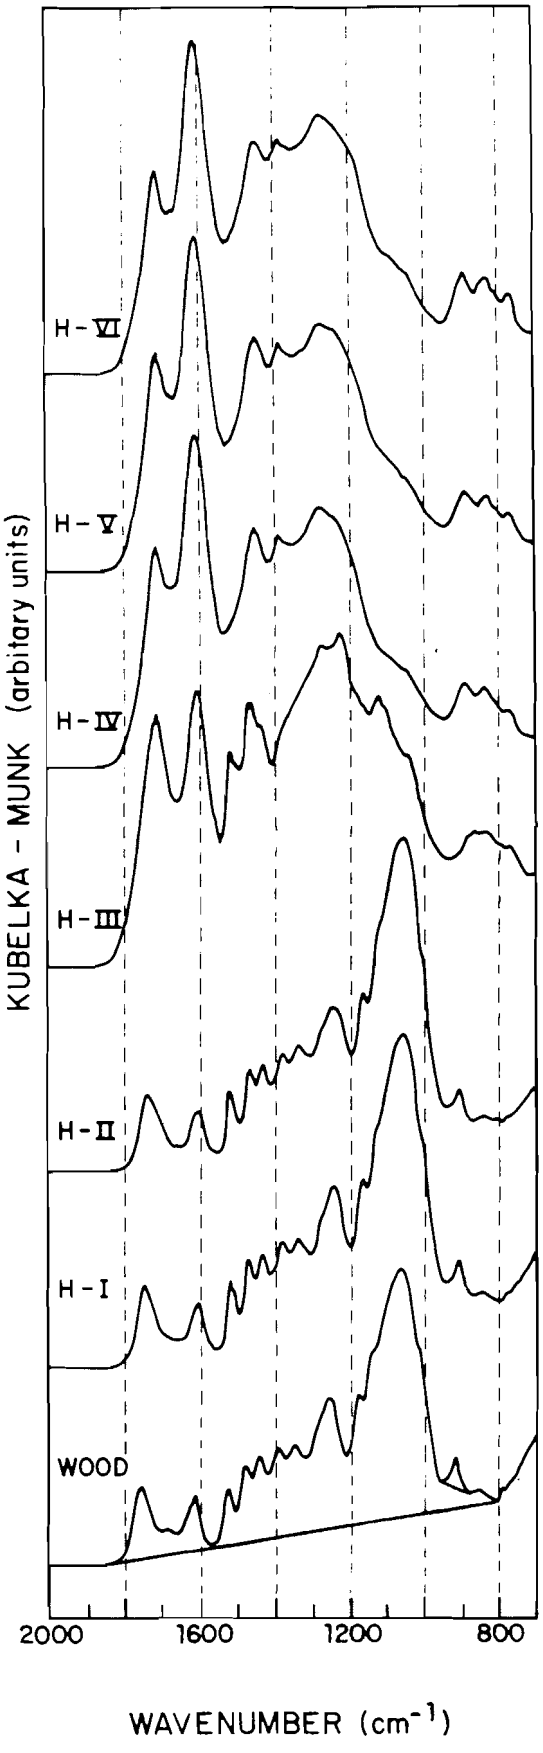

FIG. 1. DRIFT spectra of *Populus deltoïdes* and solid residues from six reactor hearths produced at different temperatures.

decarboxylation and a new band appeared instead near 1700 cm^{-1} in H-III (327°C) to H-VI (448°C) which is attributed to a new carbonyl group (Fig. 1). Occurrence of a band near 1700 cm^{-1} in Klason extracts of wood SCE residues was attributed to the conjugated carbonyl structure (8). Occurrence of the band at 1700 cm^{-1} in H-III to H-VI with a similar intensity on the other hand seemed to be more specifically indicative of various recondensation reactions during pyrolysis reactions or rearrangement of wood carbonyl or carboxyl group between 263°C and 327°C. Earlier we performed KBr pellet IR analysis of the same solid samples without milling and prior drying (26). A similar band at 1700 cm^{-1} was observed for H-III to H-VI samples instead of 1740 cm^{-1} in H-I and H-II. Although this may not completely rule out any possible post-pyrolysis oxidation of the solid samples, but indicates the absence of any significant effect due to drying and milling processes on 1700 cm^{-1} band. Further works are under investigation to characterize the nature of the 1700 cm^{-1} band in our laboratory. Increased intensity of band near 1700 cm^{-1} has been found also in early stages of aerial oxidation of Wyodak coal (12).

Recently ESCA analysis showed that recondensed materials are the main constituents of vacuum pyrolysis of *Populus deltoïdes* chars produced at 315°C (4). Change in the nature of IR spectra was also observed previously in SCE solid residues which have some IR spectral pattern similarities to VP solid residues (10). The SCE residues were prepared at 250, 300, and 350°C and various flow rates and pressures of the supercritical solvent. The SCE residue which was obained at 250°C showed a wood-like infrared pattern and its Klason residue content (measured by thioglycolic acid) was representative of the unconverted lignin. In contrast, samples obtained at 300 and 350°C showed coal-like IR patterns and their Klason residues were recondensed materials with possible polycyclic aromatic nature. Their aromaticity increased with the increase of the extraction temperature and pressure which was demonstrated by IR and ESCA analyses (27). Unlike the SCE samples, the VP solid residues obtained at 327°C and above gave rise to an enhanced band at about 1595–1600 cm^{-1}. This band is attributed to the aromatic vibrational band with methylene, ether, and carbonyl linkage (27).

The change in infrared spectra of wood-like and coal-like VP solid residues was found to be in good agreement with the results obtained previously using optical measurements of wood charcoals derived from *Populus tremuloïdes*. The VP solid residues were prepared in a bench scale batch reactor at temperatures ranging from 207 to 534°C, with about 40°C intervals (5). Raw wood and residual materials obtained below 287°C were characterized by their fluorescence properties. Those obtained above 287°C were characterized by their reflectance. It was concluded that an increase in reflectance from 0.13 to 2.19% is associated with aromatization of the molecular structure. In vacuum pyrolysis process, the woody material was transformed into a vitrinite-like substance which resembled the cell tissues encountered in peats and low rank coals.

Recently a series of equations were published to calculate Klason residue, unconverted lignin, recondensed material as well as glucose and xylose contents of SCE residues using a nonlinear least-squares regression analysis (10). Such correlation is further extended in this paper to VP solid residues for the calculation of Klason residue and glucose and xylose contents. Intensity of twelve bands between 1595 and 895 cm^{-1} were

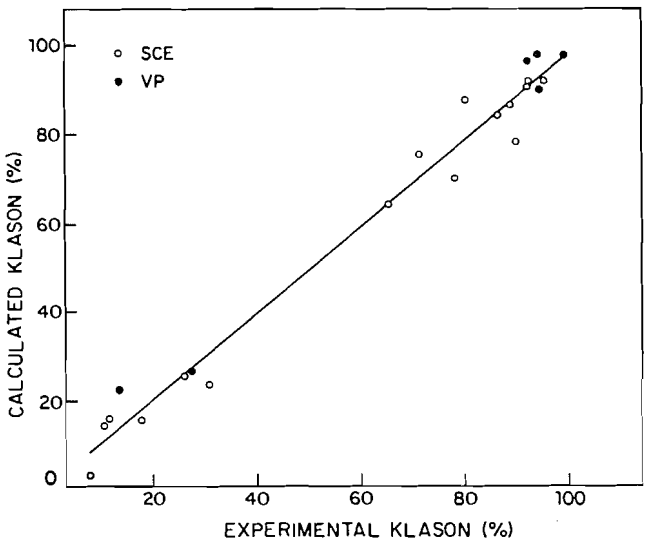

FIG. 2. Klason residue content, measured by standard procedure, vs. Klason residue content calculated by DRIFT spectrometry.

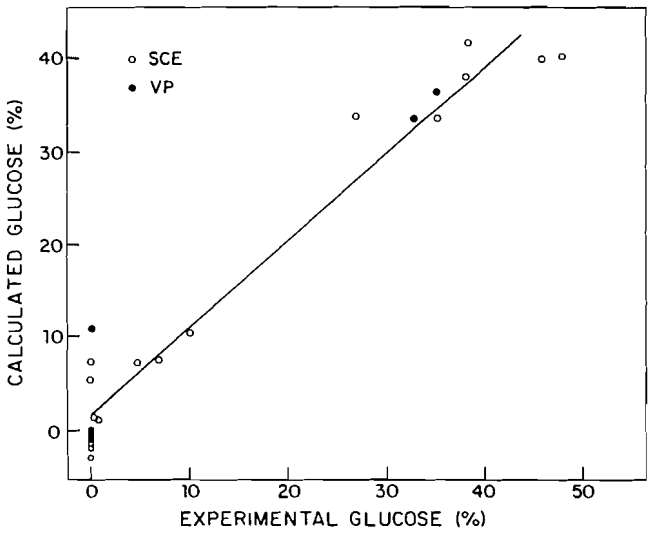

FIG. 3. Glucose content, measured by standard procedure, vs. glucose content calculated by DRIFT spectrometry.

measured by defining the IR base line as shown in Fig. 1. The regression equations as function of possible combinations of intensity ratios of twelve bands against Klason residue, glucose and xylose values (Table 1) as well as the previously published data of SCE residues (27) are as following:

$$[1]\quad \%\text{Klason residue} = 106.3 + \left(13.0 \times \frac{I_{1220}}{I_{1100}}\right) - \left(50.95 \times \frac{I_{1035}}{I_{1100}}\right) - \left(164.3 \times \frac{I_{895}}{I_{1100}}\right)$$

$$[2]\quad \%\text{glucose} = 1.43 + \left(27.77 \times \frac{I_{1505}}{I_{1210}}\right) - \left(23.1 \times \frac{I_{1370}}{I_{1210}}\right) + \left(15.6 \times \frac{I_{1035}}{I_{1210}}\right)$$

$$[3]\quad \%\text{xylose} = -11.66 + \left(29.65 \times \frac{I_{1260}}{I_{1595}}\right) - \left(24.10 \times \frac{I_{1210}}{I_{1595}}\right) + \left(9.33 \times \frac{I_{1160}}{I_{1595}}\right) - \left(33.79 \times \frac{I_{895}}{I_{1595}}\right)$$

The correlation between Klason content as calculated by eq. [1] and the conventional analysis on both VP and SCE solid residues is shown in Fig. 2. A good correlation coefficient with a value of 0.981 and a standard error of 7.6% was obtained. Klason content can be used to estimate the lignin content (unconverted lignin) of wood-like samples (treated at lower temperatures). Klason residue of the samples produced above 327°C represent the sum of unconverted lignin and recondensed material. Figure 3 shows the plot of glucose content measured by chromatographic procedure against the value as predicted by DRIFT (eq. [2]). A correlation factor of 0.976 with a high standard error of 27.9% was found for Fig. 3. Coal-like samples with less than 10% glucose content exhibit a non-linear correlation (low value) with high standard error. We concluded that DRIFT technique will be less accurate to predict glucose content of coal-like residues. Similarly, Fig. 4 shows the plot of xylose content against the value predicted by DRIFT (eq. [3]).

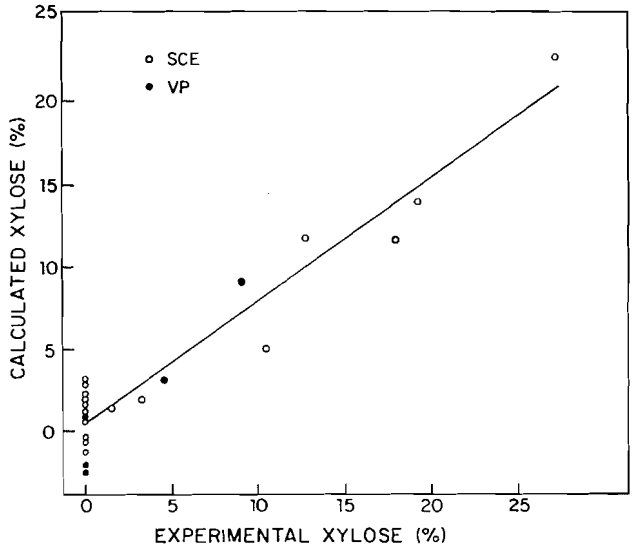

FIG. 4. Xylose content, measured by standard procedure, vs. xylose content calculated by DRIFT spectrometry.

A correlation factor of 0.957 and a standard error of 38.0% was obtained in this case. It is concluded that the xylose content also shows significant divergence from the straight line for coal-like samples containing 3% or less xylose. Glucose and xylose contents of wood-like samples on the other hand, show a good correlation and could be predicted by eq. [2] and eq. [3], respectively.

Conclusion

Solid residues were produced by vacuum pyrolysis of wood at different temperatures. Their composition was studied by wet chemistry and DRIFT techniques. Klason residue of the charcoals obtained by vacuum pyrolysis and SCE techniques was positively predicted by a regression equation derived from IR information. The usefulness of the two other equations has also been shown for the prediction of glucose and xylose content of low-temperature charcoals. The DRIFT study showed that the solid residues containing more than 10% glucose and 3%

For personal use only.

xylose retain their wood-like nature below 263°C. Degradation, decomposition, and recondensation reactions proceed as the reactor hearth temperature increases. Ultimately, coal-like nature prevails above 327°C. Occurrence of a new IR band at 1700 cm^{-1} in samples produced at 363°C and above was found to be rather characteristic of vacuum pyrolysis solid residues and was attributed to a new carbonyl group formed by recondensation reactions.

Depending on the liquefaction process, wood experiences extensive degradation and modification. Thus, the DRIFT technique with its fast analysis capability could be further modified to study solid residues obtained by various liquefaction techniques.

Deprotonation and transfer energetics of glycine in aqueous mixtures of urea and glycerol from emf measurements at different temperatures

HIMANSU TALUKDAR, SIBAPRASAD RUDRA, AND KIRON K. KUNDU[1]
Physical Chemistry Laboratories, Jadavpur University, Calcutta 700 032, India
Received July 15, 1988

HIMANSU TALUKDAR, SIBAPRASAD RUDRA, and KIRON K. KUNDU. Can. J. Chem. **67**, 315 (1989).

Deprotonation constants, $K_a(RH_2^+)$ and $K_a(RH^\pm)$, of glycine ($RH^\pm$) have been determined at five equidistant temperatures ranging from 15 to 35°C by measuring the emf of galvanic cells comprising Pt/H_2 and Ag–AgCl electrodes in aqueous mixtures of protophilic protic urea (UH) and protophobic protic glycerol (GL). Medium effects on deprotonation of the acid: $\delta(\Delta X^0_{diss}{}^N) = {}_s\Delta X^0 - {}_w\Delta X^0$ ($X = G$ or S) have been dissected into transfer free energies ($\Delta G^0_t(i)$) and entropies ($\Delta S^0_t(i)$) of the species involved as obtained by measuring the transfer energetics ΔX^0_t of $RH^\pm$ from solubility measurements at different temperatures and of H^+ based on tetraphenylarsonium tetraphenylborate (TATB) reference electrolyte assumption determined earlier. The $\Delta G^0_{t,ch}(i)$ values obtained after due correction from the cavity effect based on scaled particle theory (SPT) and electrostatic effects including Born and ion–dipole effects for the charged species involved in the two deprotonation equilibria enable better understanding of the solvent effect on the deprotonation constants. Moreover, the $T\Delta S^0_{t,ch}(i)$–composition profiles are found to exhibit similar characteristic maxima and minima as for simple cations and anions in these solvent systems, thus providing useful information on the structural characteristic of these cosolvents.

Key words: deprotonation energetics, glycine, aqueous urea, aqueous glycerol, EMF measurements.

HIMANSU TALUKDAR, SIBAPRASAD RUDRA et KIRON K. KUNDU. Can. J. Chem. **67**, 315 (1989).

Faisant appel à des mesures de fem des cellules galvaniques formées par des électrodes de Pt/H_2 et de Ag–AgCl et opérant dans des mélanges aqueux d'urée protique protophile (UH) et de glycérol protique protophobe, on a déterminé les constantes de déprotonation, $K_a(RH_2^+)$ et $K_a(RH^\pm)$, de la glycine à cinq températures équidistantes entre 15 et 35°C. On a divisé les effets du milieu sur la déprotonation de l'acide, $\delta(\Delta X^0_{diss}{}^N) = {}_s\Delta X^0 - {}_w\Delta X^0$ ($X = G$ ou S), en énergies ($\Delta G^0_t(i)$) et en entropies ($\Delta S^0_t(i)$) libres de transfert des espèces impliquées; pour ce faire, on a déterminé les énergies de transfert ΔX^0_t du $RH^\pm$ à partir de mesures de solubilité à diverses températures ainsi que celles du H^+ en se basant sur l'hypothèse de l'électrolyte de référence tétraphénylborate tétraphénylarsonium (TBTA) qui a été proposée antérieurement. Les valeurs de $\Delta G^0_{t,ch}(i)$ qui sont obtenues après avoir effectué une correction pour l'effet de cavité, qui est évaluée à l'aide de la théorie de la particule scalaire (TPS), et pour les effets électrostatiques, y compris les effets de Born et d'ion–dipôle des espèces chargées impliquées dans les deux équilibres de déprotonation, fournissent une meilleure compréhension de l'effet de solvant sur les constantes de déprotonation. De plus, on a trouvé que les profils des $T\Delta S^0_{t,ch}(i)$ vs la composition présentent des maxima et des minima caractéristiques semblables à ceux observés avec des cations et des anions simples dans ces solvants; on peut en tirer des réflexions utiles sur la caractéristique structurale de ces cosolvants.

Mots clés : énergies de déprotonation, glycine, urée aqueuse, glycérol aqueux, mesures de FEM.

Introduction

Deprotonation constants and the associated energetics of amino acids and peptides in water and aqueous mixtures of ionic and non-ionic cosolvents form vital thermochemical quantities that will help understand the role of these key biochemicals in biological systems. Unfortunately, despite unusual interests the knowledge of deprotonation energetics of amino acids and peptides is quite limited in aqueous mixtures of ionic and non-ionic cosolvents except for some studies by Roy *et al.* (1) and others (2, 3). It is well known that glycine exists in aqueous solution predominantly in the zwitterionic form, $H_3N^+—CH_2—COO^-$ (symbolised as $RH^\pm$). In acidic solution, it is present as $H_3N^+—CH_2—COOH$ (symbolised as RH_2^+), whereas in alkaline solution it is present as $H_2N—CH_2—COO^-$ (symbolised as R^-). The contributions of these species at different pH in aquo-organic and biological systems are still an involved problem as the knowledge of the protolytic dissociations of these species in different solvents is yet fairly limited. The change in pK_a as a function of the properties of solvent is likely to provide useful information not only in the identification of the nature of the solute–solvent interaction patterns (in binary solvent systems) but also in the interaction of the carboxylate site ($NH_2.CH_2.COO^-$) and the nitrogen site ($\overset{+}{N}H_3.CH_2.COOH$) of glycine with water and with the components of binary solvent systems.

With this in mind, we report here the first and second deprotonation constants, ($K_a(RH_2^+)$ and $K_a(RH^\pm)$, of glycine as represented by [1] and [2]

$$[1] \quad RH_2^+ \underset{}{\overset{K_a(RH_2^+)}{\rightleftharpoons}} H^+ + RH^\pm$$

$$[2] \quad RH^\pm \underset{}{\overset{K_a(RH^\pm)}{\rightleftharpoons}} H^+ + R^-$$

in the aqueous mixtures of 10, 30, and 50 wt.% glycerol (GL) and 11.52, 20.31, and 29.64 wt.% urea (UH) and the related thermodynamic quantities. These have been determined using the Harned–Ehler type cells (4) [P] and [Q], respectively

[P] Pt; H_2(g, 1 atm)/$RH_2^+Cl^-(m_1)$, $RH^\pm(m_2)$, solvent/AgCl(S)–Ag

[Q] Pt; H_2(g, 1 atm)/$RH^\pm(m_1)$, $Na^+R^-(m_2)$, NaCl(m_3), solvent/AgCl(S)–Ag

at five equidistant temperatures ranging from 15 to 35°C. To evaluate the thermodynamic parameters of the species involved in processes [1] and [2], the free energies of transfer (ΔG^0_t) and entropies of transfer (ΔS^0_t) values of $RH^\pm$ and H^+ in these solvents were taken from our previous papers (5). We chose

these solvent systems because urea is a well known denaturant of proteins (6) while glycerol stabilizes them (7). It is hoped that knowing the thermodynamic behaviour of the species might be useful in finding out the behaviour of the cosolvents urea and glycerol.

Experimental

Purification of glycine (E Merck, GR grade) and the solvents has been described (5). For the first dissociation process, a stock solution of glycine was prepared by dissolving weighed amounts of glycine in known amounts of the solvent for a particular composition. Stock HCl (GR) solutions were prepared separately and their molalities were obtained by alkali–metric titration using phenolphthalein as indicator. The stock cell solutions were prepared by mixing appropriate weighed amounts of each of the two solutions and those of different ionic strengths (μ) by mass dilution with the solvents, which varied from 0.01 to 0.10 unit. For the second dissociation process, stock solutions of both glycine and NaCl (GR, E Merck) were similarly prepared, stock NaOH (E Merck, GR) solutions were also prepared separately, the molalities of which were determined titrimetrically with phenolphthalein as indicator. The stock cell solutions were then prepared by mixing appropriate weighed amounts of these three solutions and also those of different ionic strengths by mass dilution.

General experimental procedures including the preparation of the Ag–AgCl and H_2(Pt) electrodes, and the measurements of emf were similar to those described earlier (8). The equilibrium was attained in about 2–3 h. We assume equilibrium when the emf readings was constant to about ±0.1 mV per h. The pK_a data of glycine in water were taken from previous experiments (9) since the results obtained at 25°C by the above method (see Table 1) were found in good agreement with King's data (9).

Results

The measured emf of cells [P] and [Q] corrected to $P_{H_2} = 1$ atm gave the values of E. $pK_a(RH_2^+)$ values of the acid salt in those mixtures were then obtained at different molalities (m) using the following relation

$$[3] \quad \frac{E - E^0}{k} + \log \frac{m_{RH_2^+} . m_{Cl^-}}{m_{RH^\pm}} - 2A\sqrt{\mu} = pK_a(RH_2^+) + f(\mu)$$

where $k = 2.303RT/F$, $A = 1.824 \times 10^6 (\epsilon_s T)^{-3/2} d_s^{1/2}$ and μ = ionic strength = $\frac{1}{2}(m_{RH_2^+} + m_{Cl^-}) = m_1$. The required E^0 values, dielectric constants (ϵ_s), and densities (d_s) at different temperatures in GL + H_2O (10–12) and UH + H_2O (13) are taken from previous studies.

The plot of the left-hand side of eq. [3] against μ in each solvent mixture are found to be straight lines, which on extrapolation to $\mu = 0$, yield the values of $pK_a(RH_2^+)$. Notably, as the acid RH_2^+ is partially dissociated into H^+ and $RH^\pm$, $m_{RH^\pm} = m_2 + m_{H^+}$ and $m_{RH_2^+} = m_1 - m_{H^+}$. The values of m_{H^+} i.e., the H^+ ion concentrations, have been obtained from eq. [4].

$$[4] \quad -\frac{RT}{F} \ln m_{H^+} = E - E^0 + \frac{RT}{F} \ln m_{Cl^-} - 2kA\sqrt{\mu}$$

Similarly, for the second dissociation constants for cell [Q], the left-hand side of eq. [5] i.e.,

$$[5] \quad \frac{E - E^0}{k} + \log \frac{m_{RH^\pm} . m_{Cl^-}}{m_{R^-}} = pK_a(RH^\pm) + f(\mu)$$

was plotted against μ and the intercept for $\mu = 0$ gives $pK_a(RH^\pm)$. The emf data (E) of cells [P] and [Q] at different temperatures and the corresponding molalities of Cl^-, RH_2^+, $RH^\pm$ for cell [P] and those of NaCl, $RH^\pm$, and R^- for cell [Q] for the different solvent mixtures are deposited with the Depository of Unpublished Data.[2] The observed deprotonation constants of the acids (on molal scale) correct to ±0.01 unit are listed in Table 1.

These pK_a values in each of the solvents were then fitted into Harned–Robinson (14) type expression [6], although there is no complete agreement as to its correct form (15).

$$[6] \quad pK_a = AT^{-1} + B + CT$$

The maximum deviation of the pK_a values was found to be ±0.01. The thermodynamic parameters, namely standard Gibbs free energy (ΔG^0_{diss}) and entropy (ΔS^0_{diss}) accompanying deprotonation of the acids were then evaluated on the molal scale (m) by using the standard relations [7], [8]

[2]A complete set of the data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a](1) and (2) refer to same as indicated in Table 1. The estimated uncertainties in the values of ΔG^0 and $T\Delta S^0$ are of the order: ±0.06 kJ mol^{-1} and ±0.60 kJ mol^{-1}, respectively.

[7] $$\Delta G^{0,m}_{diss} = 2.303R[A + BT + CT^2]$$

[8] $$\Delta S^{0,m}_{diss} = -2.303R[B + 2CT]$$

These values were then obtained on the mole fraction scale (N) by eq. [9] viz.,

[9a] $$\Delta G^{0,N}_{diss} = \Delta G^{0,m}_{diss} + RT \ln \frac{1000}{M_s}$$

and

[9b] $$\Delta S^{0,N}_{diss} = \Delta S^{0,m}_{diss} - R \ln \frac{1000}{M_s}$$

where M_s = mean molar mass of the solvent mixtures. The values of $\Delta X^{0,N}_{diss}$ ($X = G, S$), A, B, and C for both the dissociations are listed in Table 2. The solvent effects on deprotonation constants of the acids RH_2^+ and $RH^\pm$ relative to that in water, $\delta(\Delta X^{0,N}_{diss})$ were computed on mole fraction scale using relations [10] and [11] (see Table 2).

[10] $$\delta\Delta X^{0,N}_{diss}(RH_2^+) = {}_s\Delta X^{0,N}_{diss}(RH_2^+) - {}_w\Delta X^{0,N}_{diss}(RH_2^+)$$
$$= \Delta X^0_t(H^+) + \Delta X^0_t(RH^\pm) - \Delta X^0_t(RH_2^+)$$

[11] $$\delta\Delta X^{0,N}_{diss}(RH^\pm) = {}_s\Delta X^{0,N}_{diss}(RH^\pm) - {}_w\Delta X^{0,N}_{diss}(RH^\pm)$$
$$= \Delta X^0_t(H^+) + \Delta X^0_t(R^-) - \Delta X^0_t(RH^\pm)$$

where the subscripts w and s denote water and aqueous cosolvent and $\Delta X^0_t(i)$ represents the transfer parameter of any species (i) from the standard state in the reference solvent water (w) to the standard state of any of the compositions of the aqueous solvent(s). Since $\Delta X^0_t(H^+)$ values have been recently evaluated (5*b*) by a reasonable extrathermodynamic assumption such as the widely used tetraphenylarsonium tetraphenylborate (Ph_4AsBPh_4 = TATB) reference electrolyte (RE) assumption (16): $\Delta X^0_t(Ph_4As^+) = \Delta X^0_t(Ph_4B^-) = \frac{1}{2}\Delta X^0_t(TATB)$ and $\Delta X^0_t(RH^\pm)$ values are already known (5*a*), $\Delta X^0_t(RH_2^+)$ and $\Delta X^0_t(R^-)$ values were easily evaluated by eqs. [10] and [11], and were shown in Table 3.

Discussion

Table 1 shows that pK_a values of glycine increase with increasing GL concentration in the mixtures, pK_a values in UH + H_2O mixtures decrease with increasing UH concentration, while the dielectric constant of the cosolvent decreases and increases, respectively. Moreover, although the magnitude of this variation is much smaller than those of the corresponding carboxylic acids, the temperature coefficients of the pK_a values are practically negligible, particularly in the case of $pK_a(RH_2^+)$. Thus, as in HA-type acids (17), the variation of $pK_a(RH^\pm)$ with temperature is not significant, the small variation of $pK_a(RH_2^+)$ with temperature unlike BH^+-type acids (17) (for which the deprotonation is an isoelectric one) is an involved one in both the cosolvent systems. Evidently, the relative solvation of each species in the deprotonation equilibria and their induced structural changes factors to be considered.

Free energies of transfer

Figure 1 ilustrates the $\delta(\Delta G^{0,N}_{diss})$–composition profiles of both RH_2^+ and $RH^\pm$ in different solvent systems at 25°C. Notably $\delta(\Delta G^{0,N}_{diss})$ values for both acids are increasingly negative in UH + H_2O mixtures as expected from the increased basicity (13) and/or the dielectric constant of the solvents (13). However, in GL + H_2O mixtures, $\delta(\Delta G^{0,N}_{diss})$ values remain more or less invariant with cosolvent composition in spite of the decreased basicity (18) and dielectric constant of the medium (12). To understand the overall dissociation behaviour of these acids, analysis of the behaviour of the individual species is in order.

Moreover, as discussed in our previous papers (5, 8, 19), transfer energetics ΔX^0_t may be factorized into cavity forming effect $\Delta X^0_{t,cav}$ (especially for large-sized molecular species), Born-type electrostatic effect $\Delta X^0_{t,Born}$, and the chemical interaction effect $\Delta X^0_{t,ch}$, i.e.,

[12] $$\Delta X^0_t(i) = \Delta X^0_{t,cav}(i) + \Delta X^0_{t,Born}(i) + \Delta X^0_{t,ch}(i)$$

Thus the discussion of chemical transfer free energies of the

[a]These values are taken to be same with that of $RH^{\pm}$ from ref. 5*a*, since the required diameter in the cavity calculation for RH_2^+, R^-, and $RH^{\pm}$ for glycine may be assumed to be equal.

[b]Since the charges are localised at one end, radius used for computing Born effect for $RH_2^+ \equiv 0.148$ nm which is being equal to N—H bond distance of NH_4^+ (28) and for R^- taken to be equal to 0.126 nm (as C—O bond distance in COO^- of the zwitterion) (29).

[c]The required diameters of the species are obtained from the corresponding radii of the species as indicated in *b*. Instead of using tetra-coordination round the ions as assumed by Kim *et al.* (22) for Ph_4B^-, tri-coordination has been assumed in these cases.

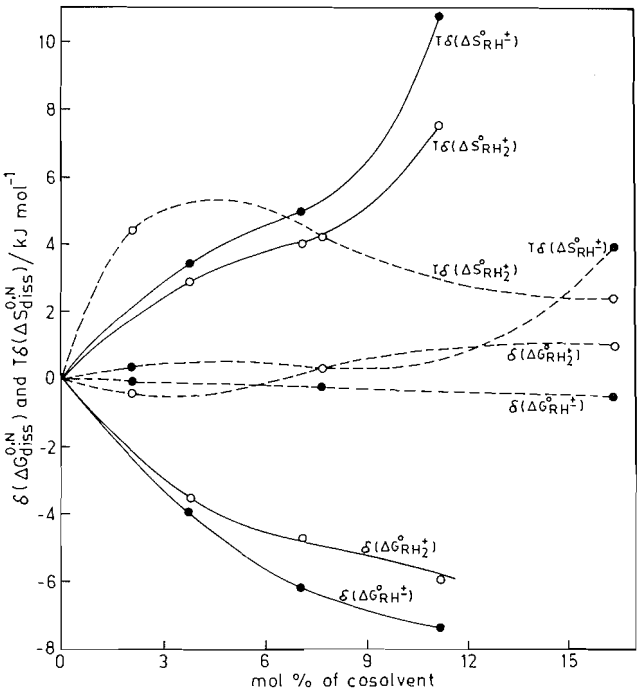

FIG 1. Variation of $\delta(\Delta G_{diss}^{0,N})$ and $T\delta(\Delta S_{diss}^{0,N})$ of glycine ($RH^{\pm}$) for the dissociation of RH_2^+(○) and $RH^{\pm}$(●) with cosolvent composition in the aqueous mixtures of urea (—) and glycerol (---) at 25°C.

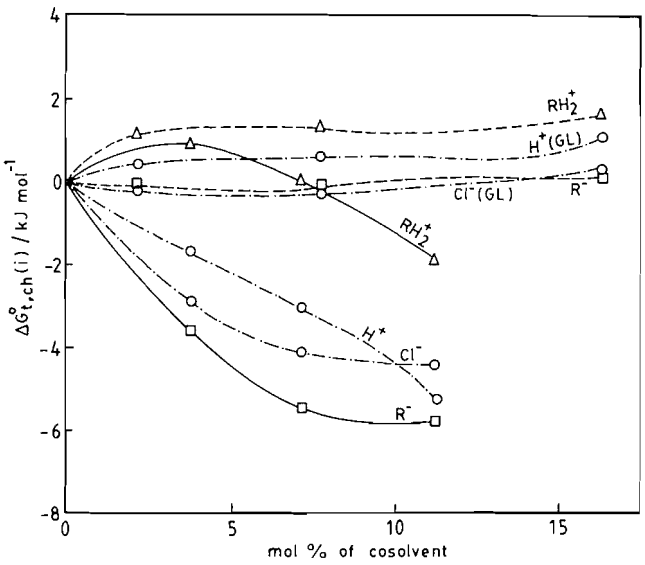

FIG 2. Variation of $\Delta G_{t,ch}^0(i)$ of RH_2^+(△) and R^-(□) of glycine and of H^+, Cl^- (·····) with cosolvent composition in the aqueous mixtures of UH (—) and GL (----) at 25°C.

species RH_2^+, R^-, and $RH^{\pm}$ i.e., $\Delta G_{t,ch}^0(i)$ rather than $\Delta G_t^0(i)$ should be more informative. Consequently, we have tentatively computed $\Delta G_{t,Born}^0$ of RH_2^+ and R^- by using simple Born equation (20) and also $\Delta G_{t,cav}^0(i)$ of RH_2^+ and R^- by scaled particle theory (SPT) (21) as formulated in the previous papers (5, 8, 19). The required solvent parameters are obtained from ref. 5*a*. The values of $\Delta G_{t,Born}^0(i)$, $\Delta G_{t,cav}^0(i)$, and $\Delta G_{t,ch}^0(i)$ so obtained are given in Table 3.

Figure 2 illustrates the $\Delta G_{t,ch}^0(i)$–composition profiles of the said species including H^+ and Cl^- ions (for comparison) (5*b*) in

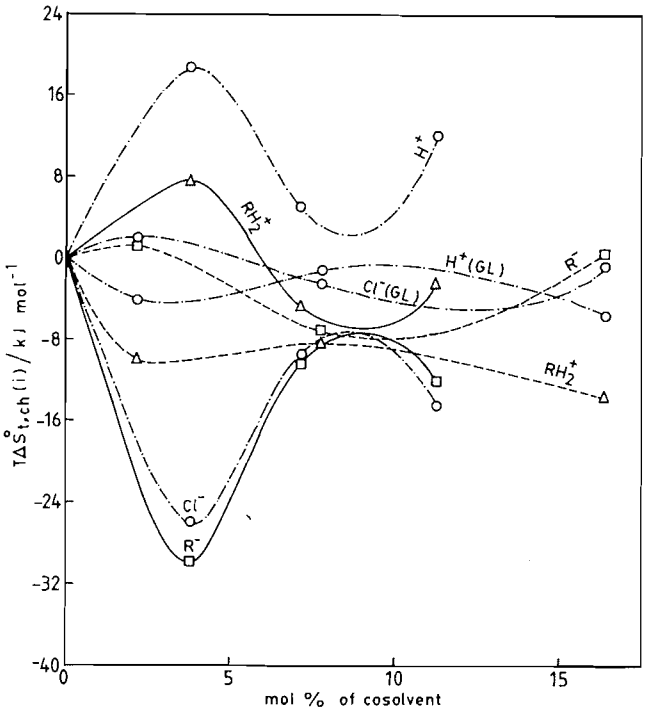

FIG 3. Variation of $T\Delta S^0_{t,ch}(i)$ of RH_2^+(△) and R^-(⊡) of glycine and of H^+, Cl^- (·····) with cosolvent composition in the aqueous mixtures of UH (—) and GL (----) at 25°C.

the aqueous mixtures of glycerol and urea, which will be largely guided by the cosolvent's acid–base properties, ion–dipole and dispersion interactions. The nature of $\Delta G^0_{t,ch}(RH^{\pm})$–composition profiles in both systems has already been described (5*a*).

Table 3 shows that in the GL + H_2O solvent system, whilst $\Delta G^0_{t,cav}$ values for RH_2^+ and R^- are increasingly negative with cosolvent composition, the reverse is true for Born effects for RH_2^+ and R^-. Consequently the $\Delta G^0_{t,ch}$–composition profiles (dotted lines) in Fig. 2 of RH_2^+ become increasingly positive, and slightly negative or invariant for R^-. Hence, while the RH_2^+ profile resembles that of H^+ (5*b*) the observed slight stabilisation of R^-, like Cl^- (5*b*), evidently results partly from the effect of increased ion–dipole or ion – induced dipole effect as indicated earlier in the case of Ph_4B^- (19). Since the contribution of ion – induced dipole interaction is negligibly small, we have tentatively computed only the ion–dipole (id) effect i.e. $\Delta G^0_{t,id}$ for RH_2^+ and R^- in each of the cosolvents of glycerol and urea according to the formulations adopted by Kim *et al.* (22). These values are given in Table 3. Thus the values of $\Delta G^0_{t,id}$ in GL + H_2O system indicate that the ion–dipole effect contributes positively, and opposes the combined effect of increased acidity (18) and dispersion interaction thus explaining the slightly negative profile or invariant nature of R^- in Fig. 2. Again, the $\Delta G^0_{t,ch}(RH_2^+)$–composition profile suggests that solvation of RH_2^+ is chiefly guided by increased dispersion interactions but opposed by the effect of decreased basicity as indicated by the upward trend of $\Delta G^0_{t,ch}(H^+)$–composition profile (5*b*, 18), thus resulting in the observed near invariance of relative solvation of RH_2^+ at those compositions. Moreover, it can also be observed that the combined effect of Born and ion–dipole interactions of RH_2^+ opposes the cavity effect (see Table 3) which indicates that the $\Delta G^0_{t,ch}(RH_2^+)$ values are invariant as a result of opposing effects of increased dispersion interaction and decreased basicity of GL + H_2O mixtures.

Similarly, in the case of UH + H_2O mixtures apart from the differences in magnitudes, the general features of $\Delta G^0_{t,ch}(i)$ of simple cation like H^+ (5*b*) and anion like Cl^- (5*b*) in this solvent system are retained in both the cationic RH_2^+ and the anionic R^- respectively, as shown in Fig. 2 (solid lines). Thus, $\Delta G^0_{t,ch}(i)$–composition profile of R^-, like Cl^-, becomes increasingly negative and then tends to become nearly invariant after ~7 mol% urea, that for RH_2^+ becomes increasingly more negative after an upward trend at initial composition like that of K^+ (5*b*). This implies that like Cl^-, R^- is seemingly stabilised by increased ion–dipole (see Table 3) and acid–base type interactions (5*b*, 23) of the negative charge centre of R^- with the zwitterionic form $NH_2{=}C(NH_2)O^-$, the predominant contributor to the resonating structure of urea (24). Similarly, the behaviour of RH_2^+ is seemingly guided by the increased basicity, ion–dipole (see Table 3) and dispersion effects at higher compositions of urea. The observed initial positive trends for $\Delta G^0_{t,ch}(RH_2^+)$ like that of K^+ (5*b*) is possibly indicative of the effect of possible steric hindrance of hydrogen-bonded UH + H_2O complexes (25, 26) which perhaps reduce the actual number of these interacting solvent complexes compared to that in pure water (5*b*, 23).

Thus, following the relative magnitudes of $\Delta G^0_{t,ch}(i)$ values of RH_2^+ and R^- of glycine, it can be inferred that while in GL + H_2O system the probable peptide–water interaction is appreciable, in UH + H_2O system the UH–peptide interaction is predominant, particularly at high UH content.

Entropies of transfer

The $T\delta(\Delta S^{0,N}_{diss})$–composition profiles for GL + H_2O and UH + H_2O mixtures are shown in Fig. 1. It can be noted that while the total entropy changes in both the deprotonation processes are similar in UH + H_2O system (solid lines), they differ appreciably in GL + H_2O system (dotted lines). As in the cases of free energies of deprotonation, to understand the overall behaviour of $T\delta(\Delta S^{0,N}_{diss})$, the entropic contributions of RH_2^+, R^-, and $RH^{\pm}$ are required. Moreover, for a better understanding of the entropic effects, tentative estimates of both the cavity and Born-type electrostatic effects towards the total $T\Delta S^0_t(i)$ of RH_2^+, R^-, and $RH^{\pm}$ have been made as in earlier papers (5, 8, 27). These values, along with $T\Delta S^0_{t,ch}(i)$ values, are listed in Table 3. Since the radius of glycine hardly differ within this small range of temperature, the ion–dipole effect towards $T\Delta S^0_{t,ch}(i)$ was considered negligible.

Figure 3 illustrates the $T\Delta S^0_{t,ch}(i)$–composition profiles of RH_2^+ and R^- and those of H^+ and Cl^- (for comparison) (5*b*) in GL + H_2O and UH + H_2O mixtures. The profiles for $RH^{\pm}$ of glycine has already been discussed in a previous paper (5*a*). Incidentally, while the profiles for RH_2^+ resemble the profiles of simple cations like H^+, the profiles for R^- resemble those of simple anions like Cl^- in each of the solvent systems. Thus, while the $T\Delta S^0_{t,ch}(i)$–composition profiles of RH_2^+, like H^+ or K^+ (5*b*), exhibit the "characteristic maxima" and that of R^-, like Cl^- (5*b*), exhibit the "characteristic minima" in UH + H_2O system as well as in other aquo-organic (5*b*, 27) and aquo-ionic systems (27), the reverse is true in the GL + H_2O system as well as in aqueous methanol system (5*b*). Evidently, fluctuations of these profiles are expected because of the structural variations in the solvent mixtures. Thus, the structural changes induced by the charged species in these cosolvents are similar to the changes induced by simple cations and anions. An opposite behaviour has been discussed earlier not only in these systems

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

(5*b*) but also in an aquo-ionic system (27). The observations substantiated the earlier contention that urea acts as a three-dimensional (3D) water structure breaker right from the initial composition but induces some structural order due to the possible formation of UH + H_2O and biurate complexes (25, 26) around 4–10 mol% UH, while small amounts of glycerol slightly promote the 3D water structure initially and large amounts break up the same afterwards. Moreover, the transfer process of all the species of glycine appeared to be non-spontaneous because of a large decrease in the entropy term in these systems as expected.

Single-ion transfer energetics of some ions using tetraphenylarsonium tetraphenylborate reference electrolyte assumption in aqueous mixtures of urea and glycerol

HIMANSU TALUKDAR, SIBAPRASAD RUDRA, AND KIRON K. KUNDU[1]
Physical Chemistry Laboratories, Jadavpur University, Calcutta 700 032, India

Received July 20, 1988

HIMANSU TALUKDAR, SIBAPRASAD RUDRA, and KIRON K. KUNDU. Can. J. Chem. **67**, 321 (1989).

Single-ion transfer free energies [$\Delta G_t^0(i)$] and entropies [$\Delta S_t^0(i)$] of some ions from water to aqueous mixtures of urea and glycerol have been determined using the widely used tetraphenylarsonium tetraphenylborate reference electrolyte assumption from solubility and emf measurements of some appropriate electrolytes at five different temperatures (15 to 35°C). Analysis of $\Delta G_t^0(i)$ and $T\Delta S_t^0(i)$ values of the ions as well as their respective "chemical" effect, $\Delta G_{t,ch}^0(i)$ and $T\Delta S_{t,ch}^0(i)$, as obtained after correcting for their cavity and Born-type electrostatic effects, estimated by the scaled particle theory (SPT) and simple Born equation, respectively, show a complex dependence upon solvent composition. Attempts have been made to explain the observed mirror-image entropic behaviour of simple cations and anions in the light of Kundu *et al.*'s four-step transfer process and to compare the results with those obtained in other aquo-ionic and nonionic systems.

Key words: single ion, transfer energetics, TATB assumption, aqueous glycerol, aqueous urea.

HIMANSU TALUKDAR, SIBAPRASAD RUDRA et KIRON K. KUNDU. Can. J. Chem. **67**, 321 (1989).

Opérant à cinq températures différentes (de 15 à 35°C), en se basant sur des mesures des solubilités et des fem de quelques électrolytes appropriés et utilisant le tétraphénylborate de tétraphénylarsonium comme électrolyte de référence, on a déterminé les énergies libres [$\Delta G_t^0(i)$] ainsi que les entropies [$\Delta S_t^0(i)$] de transfert de quelques ions de l'eau à des mélanges aqueux d'urée et de glycérol. En se basant sur une analyse des valeurs de [$\Delta G_t^0(i)$] et de [$\Delta S_t^0(i)$] des ions ainsi que de leurs effets «chimiques» respectifs, [$\Delta G_{t,ch}^0(i)$] et de [$\Delta S_{t,ch}^0(i)$], qui ont été obtenus après avoir apporté des corrections pour leur cavité et pour les effets électrostatiques du type de Born qui ont été évaluées respectivement par la théorie de la particule réduite (SPT) et par une équation simple de Born, on a pu déduire qu'elles présentent une relation complexe avec la composition du solvant. On a tenté d'utiliser le processus de transfert en quatre étapes proposé par Kundu pour expliquer le comportement entropique en image dans un miroir qui a été observé avec quelques cations et anions simples; on a aussi tenté de comparer ces résultats avec ceux obtenus dans d'autres systèmes aquo-ioniques ainsi que non-ioniques.

Mots clés : seul ion, énergétique de transfert, hypothèse TATB, glycérol aqueux, urée aqueuse.

Introduction

It is now well recognised that transfer enthalpies (ΔH_t^0) and entropies (ΔS_t^0) of electrolytes and non-electrolytes often provide useful information regarding the relative structuredness of solvents. However, the interpretation of the experimental results on ΔS_t^0 lately proved somewhat difficult and conflicting with the general recognition that the entropic behaviour of the oppositely charged species like H^+ and X^- (X = Cl, Br, or I) as based on the widely used tetraphenylarsonium tetraphenylborate (TATB) reference electrolyte (RE) assumption (1) show nearly mirror-image behaviour in some aquo-organic (2–6) and aquo-ionic (7) systems imparting more refined information on the solvent structural features.

Evidently, it should be of particular interest to extend this type of study to some other aquo-organic solvents and especially urea (UH) + H_2O and glycerol (GL) + H_2O systems, since it is well known that these two co-solvents exhibit opposite behaviour towards the conformational stability of proteins and enzymes. Moreover, while urea acts more like a statistical structure breaker in water (8), glycerol lies on the border line of the structure-making mono-ols and structure-breaking poly-ols (9).

Hence, with a view to have detailed reflection on the structuredness of these two cosolvents, the $\Delta P_t^0(i)$ (P = G, S, or H) of some cations like Ph_4As^+ (Ph = phenyl), K^+, H^+, and some anions like Pi^- (Pi = picrate), Ph_4B^-, and Cl^- from water to the aqueous mixtures of 11.52, 20.31, 29.64 wt% UH and 10, 30, and 50 wt% GL have been determined by the RE assumption. The required solubility data of $KBPh_4$, KPi, and Ph_4AsPi at different temperatures and also of ΔP_t^0 values of KCl computed from the standard emf's (ΔE^0) of the double cell (A)

[A] Ag–AgCl/KCl(m), solvent/K(Hg)/KCl(m), water/AgCl–Ag

were obtained at different temperatures ranging from 15 to 35°C since the corresponding data for HCl are already known in the literature (10, 11). The usual formulations regarding the RE assumption has been described earlier (1).

Experimental

The quality and method of purifications of the solvents and solutes have already been described (10–12). The general experimental procedure for measuring the emf's of the cell (A) were also exactly similar to those of our previous measurements (12).

Preparation of the salts $KBPh_4$, Ph_4AsPi, and KPi and measurements of their saturated solubilities at different temperatues by spectrophotometric method were essentially similar to those described earlier (12). Constancy of the absorbance to within 1% was taken as the criterion of the attainment of the saturated solubility of the salts. At least two sets of measurements were made for all the solutes and the results were found to agree to within 1%. The molar extinction coefficient (ϵ) values of the salts in the media and the wavelengths of light used are given elsewhere (12*a*, 13). Notably, in the case of GL + H_2O systems, all solubility measurements were made at five different temperatures ranging from 15 to 35°C while that for UH + H_2O mixtures were done in the temperature range 10 to 30°C (except for $KBPh_4$, which was done in the range of 5 to 25°C) to avoid the possible effect of irreversible change undergone by UH + H_2O mixtures above 30°C (14).

Results

The observed emf (ΔE) values of cell (A) at different molalities, m (mol kg^{-1}) of KCl for the different solvent mixtures at different temperatures are given elsewhere.[2] The standard ΔE^0 values (Table 1) were obtained by extrapolating the function $\Delta E^{0\prime}$ defined by eq. [1] against m to $m = 0$

$$[1] \quad \Delta E^{0\prime} = \Delta E - 2k[f_s(m) - f_w(m)] = \Delta E^0 - 2k\Delta bm$$

where $f(m) = -A_0B_0m^{1/2}(1 + a_0B_0m^{1/2})^{-1} + \ln(1 + 0.002Mm)$ and the symbols have their usual significance (12). The required densities and dielectric constants at different temperatures were taken from the literature (10, 15). The estimated standard deviations in ΔE^0 values for all the cases lie within ±0.5 mV.

Standard free energies of transfer, ΔG_t^0, of KCl from water to the mixed solvents on mole fraction scale (N) were derived at each temperature from eq. [2]

$$[2] \quad \Delta G_t^0 = F\Delta E^0 - 2RT \ln (M_s/M_w)$$

where M_w and M_s are the molar and mean molar masses of pure water and the solvent mixtures, respectively. The ΔG_t^0(KCl) values at different temperatures were then fitted to eq. [3]

$$[3] \quad \Delta G_t^0 = A + BT + CT \ln T$$

where A, B, and C are constants and thus the ΔS_t^0 values on the mole fraction scale were obtained by eq. [4]

$$[4] \quad \Delta S_t^0 = -[B + C(1 + \ln T)]$$

These values along with the constants A, B, and C were listed in Table 1.

For salts $KBPh_4$, Ph_4AsPi, and KPi, the observed saturated solubilities (S) in mol dm^{-3} in both UH + H_2O and GL + H_2O systems are given elsewhere.[2] The ΔG_s^0 values at different temperatures were calculated on the molar scale using

$$[5] \quad \Delta G^0 = -2RT \ln S \qquad \gamma_\pm = 2.303RT\, pK_{sp}$$

where $\gamma_\pm$ is the mean molar activity coefficient of the electrolyte which was computed using the extended Debye–Hückel equation as before (12). pK_{sp}^c values thus obtained on molar scale (c) at different temperatures were listed in Table 2. The same in water has been obtained from our previous experiments (7*b*). The ΔG_s^0 values were then fitted to the temperature equation

[a]Data for UH + H_2O, ref. 10; for GL + H_2O, ref. 11. Maximum uncertainties in ΔG_t^0 and $T\Delta S_t^0$ values are within ±0.05 and ±0.6 kJ mol^{-1}, respectively.

on the mole fraction scale using

$$[7]\quad \Delta G_t^0 = {}_s\Delta G_s^0 - {}_w\Delta G_s^0 = 2.303RT[p_sK_{sp} - p_wK_{sp}] - 2RT \ln (M_s d_w/M_w d_s) = (a_s - s_w) + (b_s - b_w)T + (c_s - c_w)T \ln T - 2RT \ln (M_s d_w/M_w d_s)$$

and

$$[8]\quad \Delta S_t^0 = (b_w - b_s) + (c_w - c_s) + (c_w - c_s) \ln T + 2R \ln (M_s d_w/M_w d_s) + 2RT(\mathrm{d} \ln d_w/\mathrm{d}T - \mathrm{d} \ln d_s/\mathrm{d}T)$$

where T = 298.15 K and subscripts s and w refer to co-solvent and water, respectively. The values were tabulated in Table 3. These were then utilised to compute ΔP_t^0 of the RE with the help of eq. [9].

$$[9]\quad \Delta P_t^0(Ph_4AsBPh_4) = \Delta P_t^0(Ph_4AsPi) + \Delta P_t^0(KBPh_4) - \Delta P_t^0(KPi)$$

These were then apportioned into individual ionic contributions by TATB assumption (1). $\Delta P_t^0(i)$ values of other ions were then estimated by the additivity rule from the ΔP_t^0 values of the appropriate electrolytes which were listed in Table 4.[2] $\Delta P_t^0(HX)$ values were taken from previous papers (10, 11).

Discussion

Free energies of transfer

Figures 1 and 2 illustrate the variation of the $\Delta G_t^0(i)$–composition profiles (solid lines) of the individual ions with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

co-solvent composition in UH + H_2O and GL + H_2O mixtures, respectively. Evidently, the profiles vary to a very little extent with that of previous experiments (12*a*, 13) which indicate the consistency of the experimental results in both the cases.

However, the discrepancies between the $\Delta G_t^0(H^+)$ values (so also for the other ions) obtained by Wells' method (16) and the present TATB method in these co-solvent systems have already been discussed earlier (12*a*). It was concluded that Wells equated $\Delta G_t^0(H^+)$ with the Born-type electrostatic contribution only, neglecting the chemical or basicity effects, thereby accounting in part for the disagreement between the transfer parameters. Not only that, recently both Blandamer (17) and Marcus (18) have pointed out some important shortcomings of the Wells' method and preferred the TATB assumption among the various existing extrathermodynamic assumptions for the estimation of single ion transfer properties not only at 25°C but also at other temperatures too.

As per discussions in our previous papers (7, 19), transfer energetics ΔP_t^0 can be taken to comprise cavity forming effect $\Delta P_{t,cav}^0$, long-range Born-type electrostatic effect, $\Delta P_{t,Born}^0$, and the chemical effect $\Delta P_{t,ch}^0$ i.e.

$$[10] \quad \Delta P_t^0(i) = \Delta P_{t,cav}^0(i) + \Delta P_{t,Born}^0(i) + \Delta P_{t,ch}^0(i)$$

Thus, the discussions of chemical transfer free energies of ions (which result from short-range interactions like ion–dipole, ion–quadrupole, dispersion, acid–base, H-bonding, specific, if any) i.e. $\Delta G_{t,ch}^0(i)$ should be more informative. Consequently, we have tentatively computed $\Delta G_{t,Born}^0(i)$ and $\Delta G_{t,cav}^0(i)$ terms for the different ions as per formulations described and referred to in the previous papers (7, 19). The values so obtained are given in Table 4 and depicted by dotted lines in Figs. 1 and 2.

Significantly enough, in the case of small-sized ions, the cavity effect is less and in fact gets nullified to a larger extent by the opposing Born effect, resulting in similar profiles for $\Delta G_t^0(i)$ and $\Delta G_{t,ch}^0(i)$. In the case of big ions, the cavity interaction term plays an important role as expected in both co-solvents as also observed in the case of $NaNO_3$ solutions (7).

Thus, in the UH + H_2O system, the $\Delta G_{t,ch}^0$–composition profile of H^+ indicates increased basicity and that of Cl^- indicates increased acidity of the co-solvent as before (13). Although there are several reasons for the nature of the observed $\Delta G_{t,ch}^0(H^+)$–composition profile as evidenced from various experiments (20, 21), the same reasoning for Cl^- might seem confusing. However, this may be possible in the sense that though UH molecules bring in "statistical structure breaking" (8) of water releasing free more monomeric water molecules, those water molecules are engaged in the formation of H-bonded urea–water clusters (10, 22), thus depleting the number of free water molecules. But then again it is difficult to understand why the alkali metal cation like K^+ should be hydrated more in pure water as reflected in Fig. 1. On the other hand, if one assumes, which is not quite unlikely either, that due to possible steric hindrance, the number of H-bonded UH + H_2O complexes interacting with these small sized K^+ ion is much less than that in pure water, and hence the resulting $\Delta G_{t,ch}^0(i)$ values of K^+ ion would be increasingly positive. The fact that $\Delta G_t^0(K^+)$ values obtained by the RE method are also increasingly positive in aqueous mixture of methanol (23), ethanol (24), and ethylene glycol (25) seemingly indicate such possibility.

Besides, since the dipole moment (μ) of urea is greater than that of water (μ_{UH} = 4.56 D; μ_{H_2O} = 1.87 D) (26), the other electrostatic effects like ion–dipole, ion – induced dipole etc. might also affect the solvation of these ions. Hence, in order

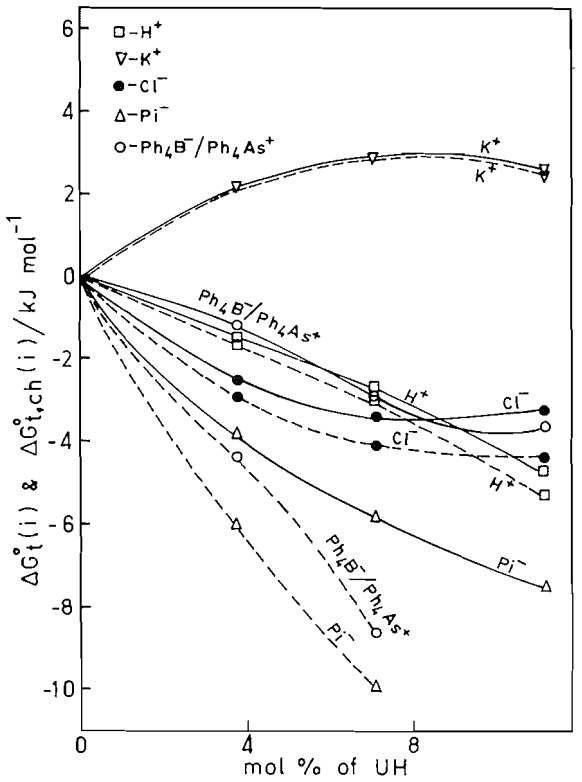

FIG. 1. Variation of $\Delta G_t^0(i)$ (solid lines) and $\Delta G_{t,ch}^0(i)$ (dotted lines) of different ions with mol% of urea (UH) at 25°C.

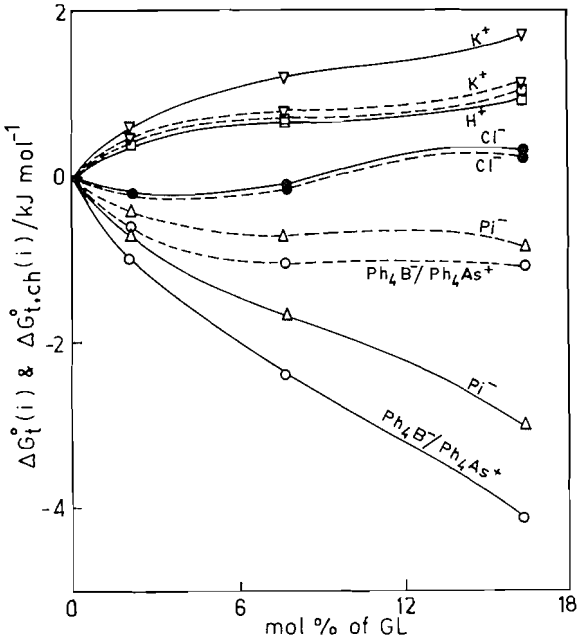

FIG. 2. Variation of $\Delta G_t^0(i)$ (solid lines) and $\Delta G_{t,ch}^0(i)$ (dotted lines) of different ions with mol% of glycerol (GL) at 25°C.

to have a picture about these interactions, the ion–dipole (id) effects have only been computed by the formulations of Kim (27) as has been done in a recent paper (19). The estimated $\Delta G_{t,id}^0(i)$ values were shown in Table 4. It is evident from this table that all ions, particularly small ions, are stabilised appreciably due to the id effect in the UH + H_2O system and this effect increases as the UH content in water increases. As a result, one can easily measure the chemical effect arising from

acid–base and other properties of this co-solvent which guide the behaviour of these small ions.

Unlike in UH + H_2O, in the case of GL + H_2O system, all the $\Delta G^0_{t,ch}(i)$–composition profiles for small ions are shifted towards the zero axis, indicating that the effect of chemical interactions of ions in the solvent mixtures are more or less the same as that in water. Moreover, the observed behaviour of these profiles is seemingly due partly to the decreased basicity and increased acidity of the solvent molecule glycerol compared to the water molecule, and partly to the id effect as evidenced from Table 4. For this reason, the decreased stabilization of Cl^- at high concentration of glycerol is mainly due to the positive contribution of $\Delta G^0_{t,id}(Cl^-)$ (see Table 4) as expected. Thus the observed increasing destabilization on cations like H^+ and K^+ and comparatively less stabilization of anion like Cl^- also conform to what is expected from the acid–base type interactions in this co-solvent as has already been described (12*a*). Moreover, if $\Delta G^0_{t,id}(i)$ values are subtracted from the corresponding $\Delta G^0_{t,ch}(i)$ values, it will be seen that all profiles are shifted nearer to zero axis (except for big ions) which indicate that glycerol though initially appears to be acidic, actually behaves more like an inert solvent (or slightly acidic) when various interactions are considered, as is done in the present case.

On the other hand, the increasing negative magnitudes of $\Delta G^0_{t,ch}(i)$ for Ph_4B^-/Ph_4As^+ in both these co-solvent mixtures can be attributed, as in other co-solvent systems (23–25), to the dispersion interaction of four phenyl groups with the co-solvent molecules. Moreover, the relative positions of $\Delta G^0_{t,ch}(i)$–composition profiles of Ph_4B^-/Ph_4As^+ and Pi^- in both UH + H_2O and GL + H_2O systems appear to suggest that like other aquo-organic solvents, UH + H_2O mixtures show more dispersion interactions with hydrocarbon moieties of Ph_4B^-/Ph_4As^+ or Pi^- compared to GL + H_2O mixtures. This appears to suggest that in GL + H_2O system hydrophobic solutes are likely to be relatively less solvated and hence more prone to undergo hydrophobic interactions among themselves than in the UH + H_2O system. Besides, the observed tentatively increased stabilization of Pi^- compared to Ph_4B^-/Ph_4As^+ in UH + H_2O mixtures is probably the result of pronounced H-bonding stabilization of Pi^- through three NO_2-groups with the zwitterionic form of UH molecule. On the other hand, the reverse relative behaviour of these ions in GL + H_2O mixtures is indicative of the larger hydrophobic interaction of Ph_4B^-/Ph_4As^+ than the acidity effect on Pi^-.

Entropies of transfer

Figures 3 and 4 (solid lines) illustrate the $T\Delta S^0_t(i)$–composition profiles of the single ions in UH + H_2O and GL + H_2O mixtures, respectively. Notably, while the profiles for cations (H^+, K^+) for aqueous urea system like other aquo-organic (2–6) and aquo-ionic (7) systems exhibit roller-coaster type behaviour with a maximum around 5 mol% urea followed by a minimum around 8–9 mol% urea, that for anions (Cl^-, Pi^-) exhibit exact mirror-image projection. But that for Ph_4B^-, however, exhibits an increasing positive trend up to 5 mol% UH beyond which it takes a downward trend.

In the case of GL + H_2O system, unlike the UH + H_2O system but as in the MeOH + H_2O system (a comparison of $T\Delta S^0_t(i)$–composition profiles in some aquo-organic systems (2, 3, 6) have been shown in Fig. 5) while the profiles for H^+ and Cl^- show reverse mirror-image behaviour as that observed in UH + H_2O mixtures, that for K^+ shows an increasingly negative trend and those for both Pi^- and Ph_4B^- show an increasingly upward trend.

Before we analyse the implications of the observed behaviours, let us make, at least a tentative estimate of $\Delta S^0_{t,ch}(i)$ which has been obtained after subtracting $\Delta S^0_{t,cav}(i)$ and $\Delta S^0_{t,Born}(i)$ from the total $\Delta S^0_t(i)$, exactly similar to what has been done in the case of $NaNO_3$ solution (7). The calculated values have been shown in Table 4 and illustrated by dotted lines in Figs. 3 and 4. Evidently, there are little differences between $T\Delta S^0_t(i)$– and $T\Delta S^0_{t,ch}(i)$–composition profiles for most of the ions save Pi^- and Ph_4B^-/Ph_4As^+ which become more negative, particularly in the GL + H_2O system (Fig. 4).

Now, as before (7), by following Kundu *et al.*'s four-step transfer process, $\Delta S^0_{t,ch}(i)$ may be formulated as

$$[11]\quad \Delta S^0_{t,ch}(i) = \Delta S^0_1 - \Delta S^0_2 + \Delta S^0_3 - \Delta S^0_4$$

It was also indicated (7) that for small cations like H^+, K^+ etc., $(\Delta S^0_1 - \Delta S^0_2)$ may be considered to be a constant positive quantity and the same will be a constant negative quantity for anions like Cl^-, Br^- etc., since ΔS^0_1 and ΔS^0_2 are both referred to water only (7); the implications for ΔS^0_3 and ΔS^0_4 referred to the solvents, however, would be as follows.

In the case of the UH + H_2O system, which may be assumed to comprise three distinct regions (Fig. 3), the $\Delta S^0_3 = 0$ for cations in the initial water-rich region since, addition of small amount of urea causes the breakdown of water structure (10, 22) leaving free monomeric H_2O and UH molecules to solvate the incoming cations. Also, since the translational degrees of freedom of both H^+ and K^+ are arrested in step 4 of the process, $-\Delta S^0_4$ would be increasingly negative. Consequently, the increasingly negative $(\Delta S^0_3 - \Delta S^0_4)$ would nullify the positive $(\Delta S^0_1 - \Delta S^0_2)$, thus resulting in a maximum in the profiles for cations (7), as observed. Beyond the intermediate region, the possible formation of UH + H_2O clusters and particularly the biurate complexes (22) contribute positively to ΔS^0_3, resulting in a positive trend of the said profiles for cations at higher compositions of urea.

Similarly, for anions, since $\Delta S^0_3 = 0$, $T\Delta S^0_{t,ch}(i)$ will be increasingly negative, from the initial composition (7). However, after about 5 mol% UH, ΔS^0_3 would be an increasingly positive quantity as the free species are now replaced by UH + H_2O clusters. Evidently, after the intermediate region $(\Delta S^0_3 - \Delta S^0_4)$ would become increasingly positive, and consequently, the opposing effects of $(\Delta S^0_1 - \Delta S^0_2)$ and $(\Delta S^0_3 - \Delta S^0_4)$ will result in a minimum in $T\Delta S^0_{t,ch}(i)$–composition profiles for the anions. At still higher compositions, the downward trend of the profiles of Cl^- indicate that Cl^- is probably unable to break the proposed UH—UH aggregates (22), so that $\Delta S^0_3 = 0$ as is evident from the invariant nature of $\Delta G^0_{t,ch}(Cl^-)$–composition profiles after 7 mol% UH (Fig. 1) which indicate that Cl^- prefers the more water-like environment in this region.

In the case of large ions, Pi^- shows predominating effect of anionic character (Fig. 3), while for more larger Ph_4B^-, transfer to the mixed solvents leads to considerable increase in $T\Delta S^0_{t,ch}(i)$ values similar to that observed in other co-solvents like ACN (4), DMF (5), and MeOH (6). The ions are presumably preferentially solvated by urea as indicated by large $-\Delta G^0_{t,ch}(i)$ values, dismantling the possible clusters, resulting in positive entropy changes in the transfer process.

As indicated earlier, the same observations in the present GL + H_2O system are somewhat unusual as they are also found in the MeOH + H_2O system (Fig. 5), some considerations about the solvent structure may be taken up for the sake of simplicity

[a]The required diameters of H_2O, UH, and GL molecules are 0.276 nm (7), 0.441 nm (32), and 0.498 (32), respectively. The values for the scale effect i.e. $RT \ln V_w/V_s$ are obtained from density (d_s) and M_s data of the solvents (10, 11). α (= $-$d ln d_s/dT) values for water and for the solvent mixtures are taken from ref. 33. The required diameters of the solute species are $b_{Ph_4B^-}$ = 0.84 nm (7), b_{Pi^-} = 0.72 nm as tentatively taken to be equal to that of *p*-nitroaniline (pNA) given in ref. 7, b_{Cl^-} = 0.362 nm (7), b_{K^+} = 0.270 (7), $b_{H_3O^+}$ = 0.276 nm (7). The required dipole moments (μ) in computing $\Delta G_{t,id}^0(i)$ are μ_{H_2O} = 1.87 D (26), μ_{UH} = 4.56 D (26), and μ_{GL} = 2.68 D (19).

[b]The required radii of the ionic species are obtained from the corresponding diameters of the species as indicated in *a* and that of H^+ as equal to 0.276 nm (7).

[c]The estimated uncertainties in $\Delta G_t^0(i)$ and $T\Delta S_t^0(i)$ values are within ±0.05 and ±0.6 kJ mol^{-1}, respectively.

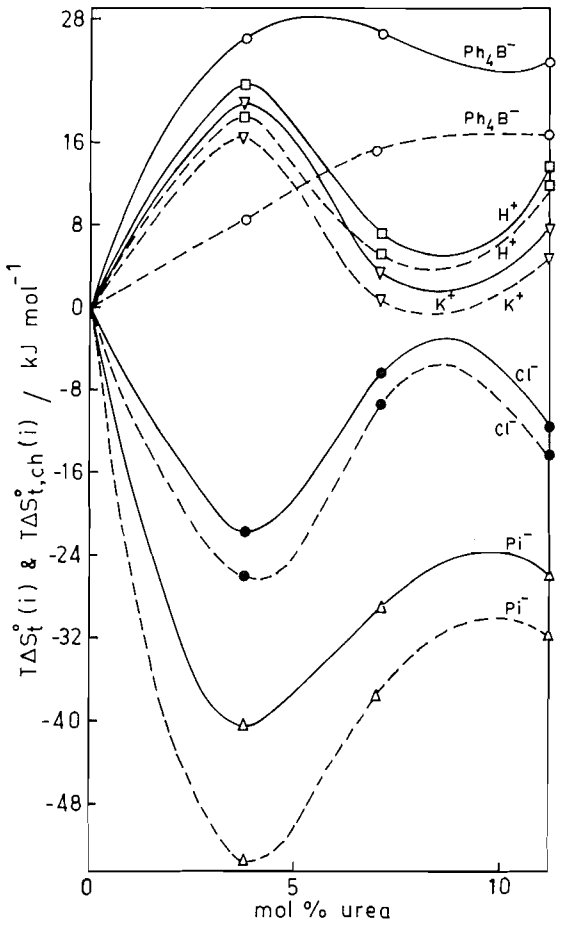

FIG. 3. Variation of $T\Delta S_t^0(i)$ (solid lines) and $T\Delta S_{t,ch}^0(i)$ (dotted lines) of different ions in the aqueous mixtures of urea at 25°C.

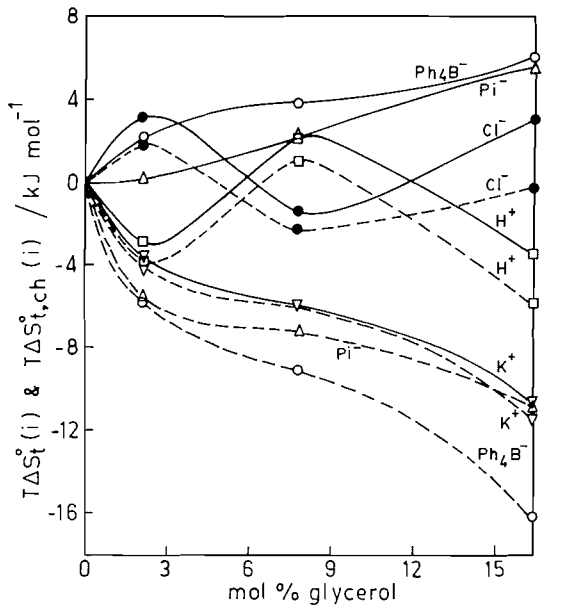

FIG. 4. Variation of $T\Delta S_t^0(i)$ (solid lines) and $T\Delta S_{t,ch}^0(i)$ (dotted lines) of different ions in the aqueous mixtures of glycerol at 25°C.

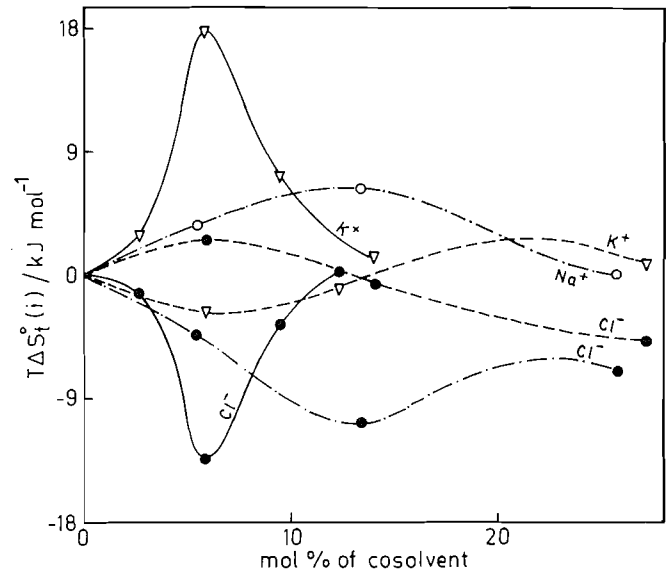

FIG. 5. Variation of $T\Delta S_t^0(i)$ of K^+ (▽), Na^+ (○), and Cl^- (●) with cosolvent composition in aqueous mixtures of *t*-BuOH (—), MeOH (----), and DMSO (·-·-·-·) at 25°C.

of the explanation, although both the co-solvents hardly affect the structure of water (9, 28). Hence, just as in ACN + H_2O (4*a*), in the water-rich region of GL, the voids inside the aqueous framework of the water lattice may be assumed to be progressively filled with GL molecules, since the "O—O" distance in GL molecule (4.75 Å) (29) is comparable with zero-spacing in water, resulting no significant enhancement of 3D water lattice. This region may, therefore, be stated as "essentially aqueous". In the intermediate region, on the other hand, the large aggregates formed in the former region are considered to be progressively broken down into smaller ones after filling up the voids. Thus, the mixed solvent can be regarded as slightly "structure maker" of the water lattice initially and a "structure breaker" in the intermediate region as observed previously (11).

Now, recalling Kundu *et al.*'s four-step transfer process, since cations (such as H^+, K^+) are expected to be solvated mainly by water as reflected in the $\Delta G_{t,ch}^0(i)$ values, the observed decrease in $T\Delta S_{t,ch}^0(H^+, K^+)$ values from the initial position, though somewhat abnormal, could be ascribed to some "preferential" solvation by monomeric water dipoles, this results in negative $(\Delta S_3^0 - \Delta S_4^0)$ values which probably exceed the positive magnitudes of $(\Delta S_1^0 - \Delta S_2^0)$, giving rise to negative $T\Delta S_{t,ch}^0$–composition profiles from initial composition. However, the observed positive hump for H^+ or H_3O^+ at the intermediate region is not surprising as either this small H^+ or H_3O^+ ion can occupy an interstitial location in the structure, resulting in $(\Delta S_3^0 - \Delta S_4^0) \sim 0$.

For the anions, since these are expected to be more solvated in the GL + H_2O system than in water by breaking down the possible water-lattice in the water-rich region, the contribution of ΔS_3^0 will be large and hence $(\Delta S_3^0 - \Delta S_4^0)$ would be increasingly positive quantity. This $(\Delta S_3^0 - \Delta S_4^0)$, however, is not expected to exceed the constant negative magnitude of $(\Delta S_1^0 - \Delta S_2^0)$ for the anions. But this has happened in this case for Cl^- as is observed by the low positive magnitude of $T\Delta S_{t,ch}^0(i)$ values (compared to that in UH + H_2O system) in this region (maximum nearly ~2 kJ). But near the intermediate

region ΔS_3^0 would be zero since the clusters have already been broken down. Evidently, the combined effect $(\Delta S_1^0 - \Delta S_2^0) + (\Delta S_3^0 - \Delta S_4^0)$, i.e., $T\Delta S_{t,ch}^0(i)$–composition profile will be increasingly negative.

In the solvent-rich region, $T\Delta S_{t,ch}^0(i)$ values do not rise sharply. This region may be interpreted as one in which GL molecules begin to penetrate the inner hydration structure of the ions, with preferential solvation becoming important above the observed minimum. Although Cl^- is relatively small, the orienting electrostatic effects of high fields may be much more important than the structural effects arising from changing the H-bond network in aqueous glycerol, relative to pure water (30).

Regarding the behaviour of Ph_4B^-/Ph_4As^+ and Pi^-, as found by Abraham *et al.* for transfer to MeOH + H_2O system (6), values of $T\Delta S_t^0(i)$ for these hydrophobic ions in GL + H_2O are all the more positive than for the small ions. The relative positions of the composition profiles of $T\Delta S_t^0(i)$ and $T\Delta S_{t,ch}^0(i)$ in this system for Ph_4B^-/Ph_4As^+ and Pi^- suggest that the cavity effect plays an important role (see Table 4). Moreover, the nature of the latter profiles, in contrast to the profiles of Cl^-, is indicative that entropic contribution of the characteristic features of the hydrophilic anions as discussed above, are largely subdued by the opposing hydrophobic/solvophilic effects of the aromatic rings of Pi^- and Ph_4B^-.

Therefore, similar to the observation by Dollet *et al.* (31) in aqueous *t*-butanol and also by others in some other aquo-organic solvents (2–6), it must be true that anions and cations are not accommodated in the same way in both UH + H_2O and GL + H_2O systems, as in other aquo-organic systems.

Vinylogous nucleophilic catalysis. The tertiary amine promoted reaction of ethenesulfonyl chloride with alcohols[1]

JAMES FREDERICK KING,[2] SHEENA MAY LOOSMORE, JOHN HENRY HILLHOUSE, AND KISHAN CHAND KHEMANI
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received August 15, 1988

JAMES FREDERICK KING, SHEENA MAY LOOSMORE, JOHN HENRY HILLHOUSE, and KISHAN CHAND KHEMANI. Can. J. Chem. **67**, 330 (1989).

Ethenesulfonyl chloride (**1**) reacts with alcohols in the presence of tertiary amines to give a mixture of the alkyl ethenesulfonate (**5**) and the alkyl betylate ($R_3'N^+CH_2CH_2SO_2OR\ Cl^-$). With pyridine and neopentyl alcohol the product composition from the reaction of **1** is identical to that from the pyridinio-sulfonyl chloride (**9**). These results, when taken with experiments with deuterium labelled reagents, lead to the conclusion that the major (~80%) reaction pathway involves conversion of **1** or **9** to the sulfene **8**, which reacts with the alcohol to form **5** or the betylate, and hence vinylogous nucleophilic catalysis is the major process leading to **5**. The labelling experiments disclosed a minor pathway, evidently involving interconversion of **1** and **9**. Examination of possible mechanisms leads to the suggestion that the sulfene is formed from **1** or **9** by way of the carbanion (**14**), i.e., that **9** reacts by an E1cB process, and that the minor pathway is simply the result of side reactions of the carbanion (**14**).

Key words: sulfenes, sulfonyl transfer mechanisms, vinylogous nucleophilic catalysis.

JAMES FREDERICK KING, SHEENA MAY LOOSMORE, JOHN HENRY HILLHOUSE et KISHAN CHAND KHEMANI. Can. J. Chem. **67**, 330 (1989).

Le chlorure d'éthènesulfonyle (**1**) réagit avec les alcools, en présence d'amines tertiaires, pour conduire à un mélange d'éthènesulfonate d'alkyle (**5**) et de bétylate d'alkyle ($R_3'N^+CH_2CH_2SO_2OR\ Cl^-$). La réaction du composé **1** avec l'alcool néopentylique en présence de pyridine conduit à un mélange dont la composition est identique à celle obtenue à partir du chlorure de pyridinio-sulfonyle (**9**). Lorsqu'on considère ces résultats de concert avec les expériences effectuées à l'aide de réactifs marqués au deutérium, on arrive à la conclusion que la principale voie réactionnelle (~80%) implique la transformation des composés **1** ou **9** en sulfène **8** qui réagit avec l'alcool pour former le composé **5** ou le bétylate; on en déduit que la catalyse nucléophile vinylogue est le processus principal conduisant au produit **5**. Les expériences de marquage ont mis en évidence l'existence d'une voie secondaire impliquant évidemment une interconversion des composés **1** et **9**. Un examen des divers mécanismes possibles conduit à suggérer que le sulfène se forme à partir des composés **1** ou **9** par le biais du carbanion **14**, c'est-à-dire que le composé **9** réagit par un processus E1cB et que le produit mineur n'est que le résultat de réactions secondaires du carbanion **14**.

Mots clés : sulfènes, mécanismes de transfert sulfonyle, catalyse nucléophile vinylogue.

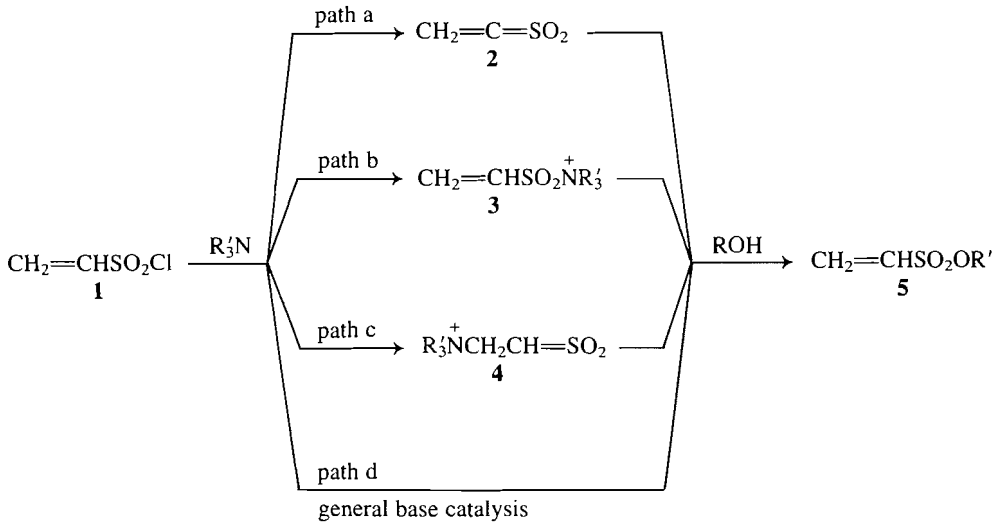
Introduction

In the context of a continuing study of the mechanisms of the reactions of sulfonyl chlorides and related species (5, 6), it became evident some years ago that current knowledge of the mechanisms of reactions of alkanesulfonyl and arenesulfonyl chlorides did not predict the mode of reaction of 1-alkenesulfonyl chlorides. As may be seen in Scheme 1, the reaction of ethenesulfonyl chloride (**1**) with an alcohol and a tertiary amine might well be imagined to proceed by way of any of three different intermediates (**2**, **3**, and **4**), or even by a fourth process involving a one-step, general base-assisted direct displacement. The first two pathways correspond to the usual reactions of the alkane- and arenesulfonyl chlorides (6–10), while the third is a variation on nucleophilic catalysis, labelled "vinylogous nucleophilic catalysis" (11, 12). This last process was unknown at the time, but we have subsequently shown that this can be the chief route of the tertiary amine promoted hydrolysis of 1-alkenesulfonyl chlorides (11, 12). The present paper describes extension of this work to the reaction of alcohols with tertiary amines and 1-alkenesulfonyl chlorides; a preliminary report of the earliest stages has appeared (13).

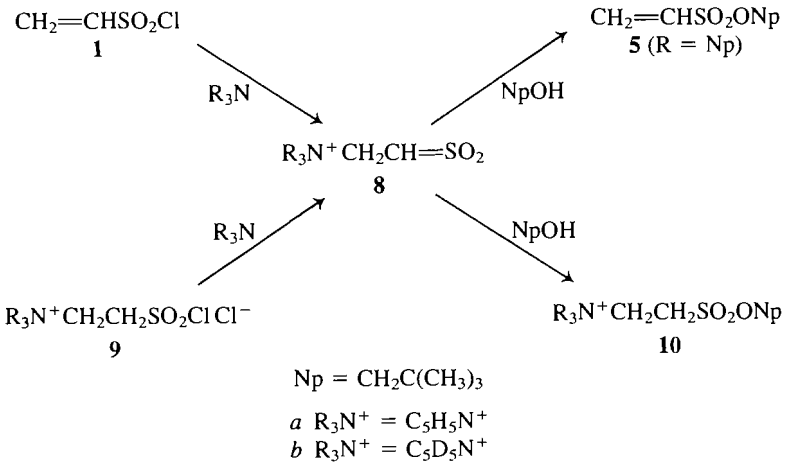
Results and discussion

Initial experiments and related work



We were unable to find any reports of the preparation of ethenesulfonate esters by the direct base-promoted reaction of **1** with alcohols. These esters had been prepared, however, under similar conditions from 2-chloroethanesulfonyl chloride (14, 15), which is known to yield **1** on treatment with 2,6-lutidine (16). In addition, Truce and Campbell (8) had looked at the action of triethylamine and alcohols on 1-propene-1-sulfonyl chloride and had noted the formation of both the 1-propene- and 2-propenesulfonate esters, $CH_3CH{=}CHSO_2OR$ and $CH_2{=}CHCH_2SO_2OR$.

In our first experiments (13), simple mixing of **1** with 2-propanol in the presence of pyridine or trimethylamine followed by conventional work-up gave the ethenesulfonate ester (**5**, R = Pr^i) in mediocre (40–50%) yield. To find out what had happened to the rest of the material, we examined the product directly by ^{1}Hmr, which showed the presence of about 60% of the ester (**5**, R = Pr^i) along with another product (~40%), which appeared to be $Me_3N^+CH_2CH_2SO_2OPr^i\ Cl^-$ (**6**), i.e. what we subsequently called the [2]betylate ester (17); this was verified by synthesis of **6**. Since the betylate **6** was found to be converted to **5** with aqueous sodium carbonate, the conversion of **1** into **5** was then readily carried out in good yield (≥90%) by incorporating a sodium carbonate wash in the work-up (17). When the reaction of **1** with 2-propanol was carried out with pyridine, we saw a second set of peaks also ascribable to the corresponding betylate, $C_5H_5N^+CH_2CH_2SO_2OPr^i\ Cl^-$ (**7**). Synthesis of **7** by a route analogous to that of **6** was not feasible and the assignment at this point was based on the ^{1}Hmr spectrum.



Rough estimates of rates by titration or by working up reaction products at different times and temperatures showed

[1]Part 30 in the series Organic Sulfur Mechanisms; for part 29 see ref. 1. Owing to delays in the preparation of the manuscript this paper appears after parts 31, 32, and 33, respectively, refs. 2, 3, and 4.

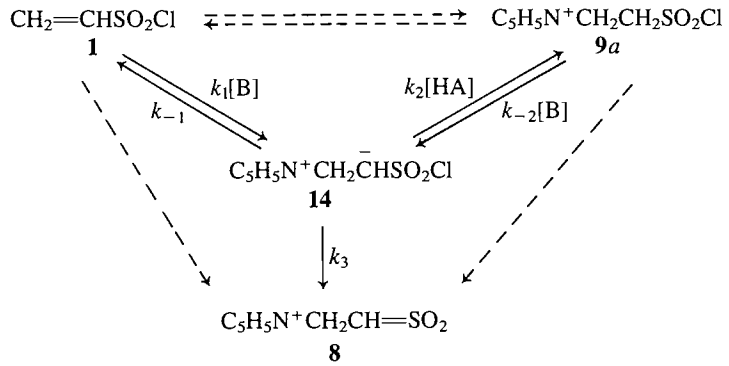
SCHEME 2

the patterns expected of nucleophilic attack of the amine at C–2 of the sulfonyl chloride, specifically, a roughly 10^4-fold greater rate for pyridine vs. 2,6-lutidine in reaction with **1** (to give a mixture of **5** and the presumed betylate), and an approximately 500-fold slower reaction of 1-propene-1-sulfonyl chloride ($CH_3CH{=}CHSO_2Cl$) than **1** with pyridine (at −70°C).



At this stage work on this project was channeled into two other directions, first to examine the usefulness of betylates as alkylating agents (17), and second to study the reaction of **1** with tertiary amines in an aqueous medium (11, 12). We then returned to the topic of the present paper, namely, the reaction of alcohols in an organic medium, a process of significance from the point of view of synthetic use. The key question was, does the reaction with alcohols in an organic medium proceed by a pathway exactly analogous to that of the aqueous system, i.e., as in Scheme 2, or does it differ? The short answer is that the hydrolysis and esterification reactions evidently have much the same overall mechanism but there are differences in detail.

Evidence for the principal pathway

For reasons detailed elsewhere (2), the more recent experiments were carried out with neopentyl alcohol in CD_3NO_2. Reaction of **1** with pyridine-d_5 and the alcohol for 1 min at 37°C gave a mixture of **5** (R = Np) and the betylate (**10***b*), in the ratio 67:33. The product ratio was not visibly altered on standing for 0.5 h, but on longer standing the ethenesulfonate ester (**5**, R = Np) was gradually converted to the betylate (**10***b*), and after 45 h the betylate made up 88% of the reaction mixture. This latter reaction, which is presumably a simple Michael addition to the electrophilic double bond of **5** (R = Np), made it possible to obtain a pure crystalline sample of the betylate (**10***a*), which was characterized by spectra and elemental analyses. The ^{1}Hmr spectrum of **10***a* was similar to that provisionally ascribed above to the corresponding isopropyl betylate (**7**) and served to confirm the earlier assignment.

Similar reaction of the pyridinio-sulfonyl chloride (**9***a*) gave exactly the same proportion of the ethenesulfonate and betylate esters, 67% of **5** (R = Np) and 33% of **10***b*; this on long standing also changed to the 12:88 ester mixture. As in the case of the corresponding reaction in water (12), this observation points strongly to a common pathway for the two reactions. For the aqueous system mentioned earlier it was possible to show, from appropriate labelling experiments, that essentially all of the products were formed via the sulfene (**8**) with no detectable interconversion between **1** and **9***a*. We accordingly carried out the analogous labelling test with the present esterification reaction. With the pyridinio-d_5-sulfonyl chloride (**9***b*) and ordinary (protiated) pyridine (in 6-fold excess) the betylate produced was largely (~80%) the deuterated product (**10***b*) with about 20% of the undeuterated betylate (**10***a*). We conclude that

SCHEME 3

about 20% of the starting material (**9***b*) undergoes elimination to ethenesulfonyl chloride (**1**), which subsequently reacts with ordinary pyridine to form the undeuterated ester (**10***a*).

To obtain further information about the mechanism, ethenesulfonyl chloride (**1**) was treated with pyridine-d_5 and neopentyl alcohol-*d* (93% D). The product consisted of a mixture of (*i*) neopentyl ethenesulfonate (total 67%) of which 80% was the undeuterated ester (**5**, R = Np) and 20% the monodeuterated ester, $CH_2{=}CDSO_2ONp$ (**11**), and (*ii*) the betylate (total 33%) consisting (as judged by its ^{1}Hmr spectrum) of about 80% $C_5D_5N^+CH_2CHDSO_2ONp$ (**12**) and 20% of the α-dideuterated ester $C_5D_5N^+CH_2CD_2SO_2ONp$ (**13**). Again, most of the reaction proceeds by direct formation of the sulfene (**8**), which is immediately trapped by NpOD to give the undeuterated ethenesulfonate (**5**, R = Np) and the α-monodeuterated betylate (**12**). The extra deuterium in **11** and **13** may be presumed to have arisen from the α-monodeuterated pyridinio-sulfonyl chloride, $C_5D_5N^+CH_2CHDSO_2Cl\ Cl^-$. We reiterate that the reaction in water gave neither $CH_2{=}CDSO_3^-$ nor $C_5D_5N^+CH_2CD_2SO_3^-$, and a simple formation of **8** from either **1** or **9** (without any conversion of **1** to **9** or **9** to **1**) accounted for all of the products. With the esterifications, however, it is evident that although the principal reaction mode corresponds to that in water, some interconversion of **1** and **9** may occur. Consideration of how this latter reaction might take place leads to a circumstantial case for the detailed mechanism of the formation of the sulfene (**8**) in this system, as described in the next section.

The detailed mechanisms

It should be recalled that the pyridinio-sulfonyl chloride (**9**) is prepared simply by mixing ethenesulfonyl chloride and pyridinium chloride in dichloromethane solution and collecting the crystals of **9** (12). The reaction is very facile and neither the formation of **9** nor its reversal to **1** and $C_5H_5NH^+$ under the conditions of the present study should occasion surprise.

In this context we suggest the sequence shown by the solid arrows in Scheme 3, where B and HA are the base (e.g., pyridine) and proton source, e.g., NpOH and (or) $C_5H_5N^+H$. From the deuteration experiments we may obtain[3] values of $k_3/k_{-1} = 4$ and $k_3/k_2[HA] \approx 3 \pm 1$; such low rate ratios are in accord with what one would expect with a very short-lived intermediate such as **14**. Previous work with alkanesulfonyl chlorides has concluded that these substrates probably react by way of an E1cB-like E2 mechanism (5), though the closely related $(E1cB)_I$ process has been demonstrated or implicated in reactions with other leaving groups (18–20). With such a strongly nucleofugal leaving group as chloride we would expect the E1cB process to become favoured only with particular stabilization of the α-sulfonyl carbanion. Thomas and Stirling (21), however, have shown that the ease of formation of such carbanions is remarkably facilitated by electron-withdrawing β-substituents,[4] and hence **14** is as likely as most α-chlorosulfonyl carbanions to be sufficiently long-lived to be an actual intermediate in the formation of a sulfene.

Other possible pathways, however, could conceivably account for the observed products. The broken arrows in Scheme 3 show another way of getting to the same compounds, but on closer examination it is difficult to devise a likely route for the reaction **1** → **9***a* that does not involve **14** as intermediate. Once **14** is accepted as a component of the reaction mixture there then seems to be no rational basis for excluding formation of **8** from **14** while at the same time permitting the direct (concerted) processes **1** → **8** and **9***a* → **8**. This situation is simply another example of the general question of the coexistence of concerted and stepwise carbanion eliminations, a point that seems to have first been brought to notice by a comment by Breslow (22), and which has been the subject of a very recent paper by Fishbein and Jencks (23). These authors concluded after detailed analysis that their results (at least in the case of the reactions of β-cyanothioethers) provided evidence against the coexistence of stepwise and concerted mechanisms, and in the face of this we favour the relatively simple process involving only the solid arrows in Scheme 3.

Another possibility is that the dideuterated product **13** arises by trapping of the sulfene (**8***b*) with pyridine-d_5 to form $C_5D_5\overset{+}{N}CH_2\overset{-}{C}HSO_2\overset{+}{N}C_5D_5$ (**15**), which in turn can exchange the α-hydrogen for deuterium in a manner analogous to that proposed for the hydrogen multiexchange reaction found with methanesulfonyl chloride and small tertiary amines (6). This reaction would explain the formation of **11** and **13** but would not, in itself, account for the formation of **10***a* from **9***b*. The latter reaction would require either (*a*) that the scheme be

[3]In the experiment starting with **9***b* and ordinary pyridine k_3/k_{-1} is equal to the product ratio [**10***b*]/[**10***a*], which was found to be 4. Defining the product ratio r = [**5**, R = Np]/[**11**] = [**12**]/[**13**] for the experiment with **1** and NpOD, we find that

$$r = (1 + k_{2D}/k_{2H})k_3/k_2$$

From the observation that $r = 4$ and the restriction of k_{2H}/k_{2D} to values ≥ 1, $k_3/k_2[HA]$ is limited to the range 2–4, i.e., 3 ± 1. (Since [HA] may change during the reaction, this represents an average value for the whole reaction.)

[4]Correlation with σ* of the rate of detritiation of $PhSO_2CHTCH_2Z$ with ethoxide in ethanol gave $\rho^* = 4.89$ (21). A very similar strong dependence of the rate of the reaction $XCH_2CH_2SO_2Cl + Et_3N \rightarrow XCH_2CH{=}SO_2$ on X has been observed in these laboratories (J. F. King and L. Lyubechansky, unpublished work).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

supplemented with the concurrent conversion of **9***b* to **1**, and would therefore also suffer from the difficulties associated with the coexistence of the concerted and stepwise processes, or (*b*) that **15** be able to exchange the pyridine attached to C-2 via $CH_2{=}CHSO_2N^+C_5D_5$. The latter possibility, though appearing to be rather complex, does not seem to be excluded by our present results.

We may conclude by noting that the mechanism shown by the solid arrows in Scheme 3 accounts very simply for the products and is fully consistent with earlier work. It cannot be regarded at this stage as proved, however, and a definitive description of mechanism must await further study.

As a final comment we note that although the formation of a minor amount of the monodeuterated ethenesulfonate ester (**11**) could be taken as evidence for formation of some of the cumulated sulfene (**2**), we exclude this for two reasons. First, such a mechanism leaves unexplained the formation of the dideuterated betylate (**13**) in the same reaction. Second, and more seriously, this constitutes another route from **1** to **5** that is unavailable to the pyridiniosulfonyl chloride (**9**); such a circumstance would not give the identical products that have been consistently observed starting from either **1** or **9**.

Experimental

Instrumentation, methods, and provenance of most of the starting materials and comparison compounds have been previously described (2, 12, 17).

Reaction of ethenesulfonyl chloride (1) with 2-propanol and tertiary amines

A series of small-scale experiments was carried out in which **1** (50–100 mg) and 2-propanol (10–20 equiv.) in CH_2Cl_2 (1–10 mL) were mixed with pyridine (~5 equiv.) at temperatures varying from 0°C to room temperature and allowed to stand for times varying from 0.5 to 4 h. Work-up by washing with dilute HCl, drying over Na_2SO_4, and evaporation of the solvent gave consistently 40–50% yields of isopropyl ethenesulfonate (**5**, R = Pr^i), identified by the ^{1}Hmr signals ($CDCl_3$) at δ 1.4 (d, 6H), 4.8 (septet. 1H), and a characteristic ABC multiplet in the range 5.9–6.7 (3H) (cf. ref. 17). The same product and yield were obtained similarly from 2-chloroethanesulfonyl chloride (15), and from **1** with Me_3N, Et_3N, diisopropylethylamine, 2,6-lutidine, 2-picoline, and 1,4-diazabicyclooctane. 2-Propanol-*d* instead of the ordinary alcohol also gave a product with the ^{1}Hmr spectrum (T-60) exactly as above with all amines tested (Me_3N, Et_3N, pyridine, and 2,6-lutidine).

When the reaction of **1** (31 mg) with 2-propanol (21 μL) and pyridine (20 μL) in $CDCl_3$ (~0.5 mL) at 0°C was observed by ^{1}Hmr, after about 15 min the signals due to **5** (R = Pr^i) at δ 1.4, 4.8, and 6.0–6.8 were accompanied by peaks at δ 1.2 and 4.0 due to unreacted 2-propanol and, in addition, by new peaks at δ 1.3 (d), 5.0 (partly obscured septet), 4.3 and 5.6 (apparent triplets), and pyridinio signals from 7.5 to 9.5 ppm, assigned to the pyridiniobetylate (**7**); ratio **5**:**7**, about 60:40. Addition of D_2O removed the signals assigned to **7** (and the pyridinium ion) leaving those of **5** (R = Pr^i) and 2-propanol.

Reaction of **1** in $CDCl_3$ in an nmr tube as above except that Me_3N replaced the pyridine gave a spectrum showing **5** (R = Pr^i), unreacted 2-propanol, Me_3NH^+ (δ 3.0, d), and signals at δ 1.5 (d), 3.5 (br s), 4.1 (br s), and 5.1 (apparent septet) assignable to the [2]betylate (**6**). An authentic sample of isopropyl [2]betylate fluorosulfate was prepared as follows (cf. ref. 17). Isopropyl ethenesulfonate (**5**, R = Pr^i) (155 mg) in CH_2Cl_2 was treated with excess Me_2NH for 10 min and the solvent and unreacted amine evaporated. Addition of methyl fluorosulfate (115 mg) and CH_2Cl_2, and, after 20 min, evaporation of the CH_2Cl_2, gave the [2]betylate ester; ^{1}Hmr (CD_3CN) δ: 1.4 (d, 6H), 3.2 (br s, 9H), 3.7 (br s, 4H), 5.0 (septet, 1H); with the addition of ~2 equiv. of Et_4N^+ Cl^- the two singlets are shifted downfield to δ 3.4 and 4.0, respectively (the other two signals also move downfield by about 0.05 ppm).

The reaction of **1** (50 mg) and 2-propanol (0.5 mL) with pyridine (0.15 mL) in CH_2Cl_2 (50 mL) was allowed to proceed for 36 s at −70°C and then quickly quenched by addition of excess HCl in CH_2Cl_2 (at −70°C). The ^{1}Hmr spectrum (T-60) showed the presence of **5** (R = Pr^i) and unreacted **1** in the ratio 67:33 by comparison of the integral of the complex signal from 5.8 to 7.3 (due to **1** plus **5**) with that of the methyl doublet (δ 1.4) due to **5** (R = Pr^i) alone. Similar reaction for 18 s gave a 52:48 mixture of **5** (R = Pr^i) and **1**; estimated $k_{obs} \approx 3.5 \times 10^{-2}$ s^{-1} (at −70°C). With 2,6-lutidine instead of pyridine as above, ratios of 25:75 after 10 min at −20°C and 50:50 after 5 min at 0°C, were found; estimated $k_{obs} \approx 3 \times 10^{-6}$ s^{-1} (at −70°C).

Reaction of trans*-1-propene-1-sulfonyl chloride with 2-propanol and pyridine*

Pyridine (0.14 mL) in CH_2Cl_2 (1 mL) was added to a solution of the sulfonyl chloride (50 mg, 0.36 mmol) and 2-propanol (0.43 mL) in CH_2Cl_2 (4 mL) at 0°C and the mixture stirred for 5 min. Work-up as above gave a product clearly identifiable as isopropyl *trans*-1-propene-1-sulfonate by ^{1}Hmr signals at δ 1.4, (6H, d, J = 6 Hz), 2.0 (3H, d of d, J = 7 and 2 Hz), 4.8 (1H, septet, J = 6 Hz), plus an AB quartet of 1:3:3:1 quartets (total 2H) δ 7.2 (J_{AB} = 15 Hz, J_{Me} = 2 Hz), and 5.9 (J_{Me} = 7 Hz). The above reaction after 60 s at −20°C showed an ester to unreacted chloride ratio of 23:77, and after 4.75 h at −70°C a ratio of 57:43 (corresponding to $k_{obs} \approx 5 \times 10^{-5}$ s^{-1} at −70°C). 2-Propanol-*d* instead of ordinary 2-propanol gave no detectable change in the ^{1}Hmr spectrum (T-60) of the product.

N-*[2-(2′,2′-Dimethylpropoxysulfonyl)ethyl]pyridinium chloride (10*a*)*

Ethenesulfonyl chloride (**1**) (880 mg, 7.0 mmol) was combined with neopentyl alcohol (650 mg, 7.4 mmol) in methylene chloride (30 mL) at room temperature. Pyridine (2.5 mL, 31 mmol) was injected and the solution allowed to stand for 8 days; the reaction mixture turned orange and deposited colorless needles during this time. The precipitate of **10***a* was filtered and recrystallized from dry acetonitrile (1.3 g, 65%), mp 154–155°C; ir (Nujol): 3130 (w), 3075 (m), 1635 (m), 1335 (s), 1268 (s), 1200 (vs), 1135 (s), 1050 (s), 950 (s) cm^{-1}; ^{1}Hmr (CD_3CN) δ: 0.93 (s, 9H), 4.01 (s, 2H), 4.21 (t, 2H), 5.18 (t, 2H), 8.11 (t, 2H), 8.60 (t, 1H), 9.28 (d, 2H); ^{1}Hmr (CD_3NO_2) δ: 0.92 (s, 9H), 4.02 (s, 2H), 4.26 (t, 2H), 5.36 (t, 2H), 8.22 (t, 2H), 8.62 (m, 1H), 9.36 (d, 2H). *Anal.* calcd. for $C_{12}H_{20}ClNO_3S$: C 49.06, H 6.86, N 4.77, S 10.91, Cl 12.07; found: C 49.25, H 6.82, N 4.83, S 10.99, Cl 12.01.

Reaction of ethenesulfonyl chloride (1) with pyridine-d_5 *and neopentyl alcohol*

Ethenesulfonyl chloride (**1**) (17 mg, 0.13 mmol) was dissolved in nitromethane-d_3 (0.25 mL) containing neopentyl alcohol (20 mg, 0.23 mmol) and placed in an nmr tube. To this solution (at 37°C, probe temperature) pyridine-d_5 (60 μL, 0.7 mmol) was injected and the solution thoroughly mixed. The ^{1}Hmr spectrum was obtained immediately (≈1 min after mixing), and showed absorptions at δ 3.8 and 4.0 (singlets), a triplet at 5.3, and a multiplet of the characteristic pattern observed with **5** (R = Np) from 6.0 to 7.0 ppm. The peaks were identified as characteristic of neopentyl ethenesulfonate (**5**, R = Np) and the neopentyl betylate chloride (**10***b*), by comparison with ^{1}Hmr spectra of authentic specimens. The ratio of **5** (R = Np) to **10***b* was found, by integration of the singlets at 3.8 and 4.0 ppm, to be 33:67. After 6 days at 37°C the relative proportion of the betylate ester was found to be 88%, with the signal at 5.3 appearing as a superposition of a doublet on the original triplet, pointing to the presence of **12** ($C_5D_5N^+CH_2CHDSO_2ONp$ Cl^-) as well as **10***b*.

Reaction of N*-[2-chlorosulfonylethyl]pyridinium chloride (9) with neopentyl alcohol and pyridine-*d_5

The sulfonyl chloride (**9***a*) (25 mg, 0.1 mmol) was mixed with neopentyl alcohol (14 mg, 0.16 mmol) and nitromethane-d_3 (250 μL) in an nmr tube at 37°C. To this mixture pyridine-d_5 (45 μL), 0.53 mmol) was injected. After thorough mixing, the ^{1}Hmr spectrum was obtained (~1 min after injection of pyridine). The spectrum showed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

absorptions identical to those described above, indicating the presence of neopentyl ethenesulfonate (**5**, R = Np) and the neopentyl betylate chloride (**10***a*) in relative proportions 67 and 33%, respectively. After 45 h at 37°C the ^{1}Hmr spectrum of the solution showed a relative proportion of **10** of 88%, with partial deuteration as before, and no other products.

Reaction of N-*[2-chlorosulfonylethyl]pyridinium*-d_5 *chloride (9b) with pyridine*

Freshly prepared pyridinio-d_5-sulfonyl chloride (**9***b*) (27 mg, 0.11 mmol) was mixed with neopentyl alcohol (17 mg, 0.19 mmol) and nitromethane-d_3 (400 μL) at 37°C in an nmr tube. Pyridine (50 μL, 0.62 mmol) was injected and the mixture thoroughly shaken, and the ^{1}Hmr spectrum of the resulting solution obtained immediately. The absorptions in the spectrum indicated the presence of neopentyl ethenesulfonate (**5**, R = Np) and the pyridine-d_5 betylate (**10***b*), along with the absorption around 9.4 ppm that was ascribed to the completely protiated betylate (**10***a*). Comparison of the multiplet at δ 9.4 with the singlet at 4.0 (for **10***a* and **10***b*) gave the proportion of **10***a* as 20% of the total amount of **10** formed in the reaction.

Neopentyl ethenesulfonate (5, R = Np) with pyridine-d_5 *and neopentyl alcohol*

Neopentyl ethenesulfonate (**5**, R = Np) (30 mg, 0.17 mmol) was dissolved in nitromethane-d_3 (0.40 mL) containing neopentyl alcohol (60 mg, 0.68 mmol) at room temperature. Pyridine-d_5 (0.075 mL, 0.90 mmol) was added, and the solution monitored by ^{1}Hmr spectroscopy for 24 h, after which period no reaction was observed. To this solution pyridinium-d_5 chloride (40 mg, 0.33 mmol) was added, and the solution monitored for a further 22 h. The presence of the neopentyl betylate chloride (**10***b*) was initially observed in the ^{1} Hmr spectrum after 2 h, eventually making up ~85% of the mixture of **5** (R = Np) and **10** after 22 h at room temperature (signals due to both **10***b* and **12** were observed).

Reaction of ethenesulfonyl chloride (1) with pyridine-d_5 *and neopentyl alcohol*-d

When the reaction of **1** (63 mg, 0.50 mmol) and pyridine-d_5 (215 μL, 2.5 mmol) in CD_3NO_2 was carried out as above with neopentyl alcohol-*d* (93% D, 223 mg, 2.5 mmol), the singlets in the ^{1}Hmr spectrum (XL-200) at δ 3.8 and 4.0 gave the ratio of total neopentyl ethenesulfonate (**5**, R = Np, plus **11**) to the betylate total (**12** plus **13**) as 67:33. The 6–7 ppm region showed 1:1:1 triplets at 6.13 and 6.19 ppm ascribable to about 20 ± 5% of **11** in the total neopentyl ethenesulfonate. Examination of the $-N^+CH_2$ signal (around 5.4 ppm) of the betylate showed a (broadened) doublet at δ 5.45 due to **12**, and a small singlet about 1 Hz upfield from the doublet and consistent with the presence of roughly 20 ± 10% of **13**; there was no sign of any triplet appropriate to **10***b*. The poorly resolved apparent triplet of 1:1:1 triplets at δ 4.35 due to $CHDSO_2$ was consistent with this assignment though the signal could not be integrated accurately because it was partly obscured by the solvent (CD_2HNO_2) signal. In another experiment using a 1:1 mixture of NpOH and NpOD the superimposed peaks at 5.4–5.5 ppm due to **10***b* and **12** were clearly seen, with the triplet for **10***b* about 1 Hz downfield from the doublet for **12**.

E. KIEHLMANN and R. W. LAUENER. Can. J. Chem. **67**, 335 (1989).

All 16 bromination products of phloroglucinol and its methyl ethers, as well as five bromoresorcinols and three of their dimethyl ethers, were synthesized and analyzed by nuclear magnetic resonance spectroscopy. Two or three equivalents of bromine convert phloroglucinol to di- and tribromophloroglucinol, 5-methoxyresorcinol to the tri- and 2,4-dibromo, 3,5-dimethoxyphenol to the tri- and 2,6-dibromo, and 1,3,5-trimethoxybenzene to the dibromo compound. With one equivalent of bromine, 3,5-dimethoxyphenol reacts preferentially at C-2 while 5-methoxyresorcinol gives both monobromo isomers. Partial debromination with sodium sulfite yields successively 2,4-dibromo- and 2-bromo-5-methoxyresorcinol from the tribromo compound but fails with brominated 3,5-dimethoxyphenol. In the resorcinol series, C-2 is invariably the least reactive position. 4,6-Dibromo-5-methoxyresorcinol and 2,4-dibromo-3,5-dimethoxyphenol are accessible by methylation of dibromophloroglucinol, obtained from 3,5-dibromo-2,4,6-trihydroxybenzoic acid by decarboxylation. In contrast to resorcinol and tribromoresorcinol, the partial bromination of phloroglucinol and debromination of tribromophloroglucinol are not selective. The ^{13}Cmr spectra of bromophloroglucinol methyl ethers show characteristic downfield shifts for methoxy groups orthogonal to the aromatic ring plane.

Key words: bromophloroglucinols, synthesis, nmr, and debromination; bromo-5-methoxyresorcinols, synthesis, nmr, and debromination; bromo-3,5-dimethoxyphenols, synthesis and nmr.

E. KIEHLMANN et R. W. LAUENER. Can. J. Chem. **67**, 335 (1989).

On a effectué la synthèse des 16 produits de bromination du phloroglucinol et de ses éthers méthyliques ainsi que de cinq bromorésorcinols et de trois de leurs éthers diméthyliques et on a pu effectuer une analyse de tous ces dérivés par spectroscopie en résonance magnétique nucléaire. Deux ou trois équivalents de brome transforment le phloroglucinol en di- et en tri-bromophloroglucinols, le méthoxy-5 résorcinol en dérivés tribromo et dibromo-2,4, le diméthoxy-3,5 phénol en dérivés tribromo et dibromo-2,6 et le triméthoxy-1,3,5 benzène en composé dibromé. Avec un équivalent de brome, le diméthoxy-3,5 phénol réagit préférentiellement en C-2 alors que le méthoxy-5 résorcinol fournit les deux isomères monobromés. Si on soumet le dérivé tribromé à une débromation partielle à l'aide de sulfite de sodium, on obtient successivement le dibromo-2,4 et le bromo-2 méthoxy-5 résorcinol; toutefois, on ne peut effectuer de débromation partielle sur le diméthoxy-3,5 phénol bromé. Dans la série du résorcinol, la position C-2 est toujours la moins réactive. Les dibromo-4,6 méthoxy-5 résorcinol et dibromo-2,4 diméthoxy-3,5 phénol sont accessibles par méthylation du dibromophloroglucinol qui est obtenu par décarboxylation de l'acide dibromo-3,5 trihydroxy-2,4,6 benzoïque. Par opposition avec ce qui est observé avec le résorcinol et le tribromorésorcinol, la bromation partielle du phloroglucinol et la débromation du tribromophloroglucinol ne sont pas sélectives. Dans les spectres rmn du ^{13}C des éthers méthyliques des bromophloroglucinols, les groupements méthoxyles orthogonaux par rapport au plan du cycle aromatique présentent des déplacements caractéristiques vers les bas champs.

Mots clés : bromophloroglucinols, synthèse, rmn et débromation; bromo méthoxy-5 résorcinol, synthèse, rmn et débromation; bromo diméthoxy-3,5 phénol, synthèse et rmn.

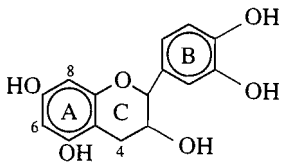
Introduction

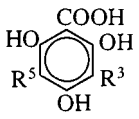
Catechin or epicatechin (**1**) is the terminal unit of most condensed tannins found in various plant tissues. It contains a phloroglucinol-type A-ring with two centers of high nucleophilicity (C-6 and C-8) that, on reaction at the electrophilic C-4 carbon of the heterocyclic ring of flavan-3,4-diols, yield oligomeric polyhydroxy flavanoids. The regiospecific synthesis of a diflavanoid tannin precursor requires temporary blockage of C-6 (or C-8) of catechin with an easily removable protecting group such as bromine. This objective has been partially met by the synthesis of 6-bromocatechin via dibromination of catechin followed by regioselective bromine removal from C-8 with sodium sulfite (1).

To gain a better understanding of the factors determining the regiochemistry of bromination and debromination, with the goal of developing an efficient procedure for the synthesis of 8-bromocatechin, and to assist in the structure elucidation of halogenated flavanoids (2, 3), we prepared and studied the nmr spectra of mono-, di-, and tribromophloroglucinol and their 13 methyl ethers as well as a series of brominated resorcinol derivatives.



Results and discussion

The three phloroglucinol methyl ethers used as starting materials are readily accessible by methylation of phloroglucinol (**2***a*). With methanol and dry HCl, only 5-methoxyresorcinol (**3***a*) and 3,5-dimethoxyphenol (**4***a*) are formed (4), probably via a hemiketal intermediate (5). They have also been obtained by methylation and decarboxylation of phloroglucylic acid (**6***a*) (6) and by partial demethylation of 1,3,5-trimethoxybenzene (**5***a*) with boron trichloride (7). With excess dimethyl sulfate or methyl iodide in alkaline medium, phloroglucinol is converted to **5***a* (4*a*, 8).



Considering the strong activating effect of three *meta*-oriented hydroxy and (or) methoxy groups toward electrophilic aromatic substitution at their respective *ortho* and *para* positions, it is not surprising that tribromination occurs rapidly, and that most of the mono- and dibromo compounds have not been described in the literature. Thus, tribromophloroglucinol (**2***d*) (9), frequently accompanied by penta- and hexabromo-1,3,5-cyclohexatrione (10), results from the reaction of phloroglu-

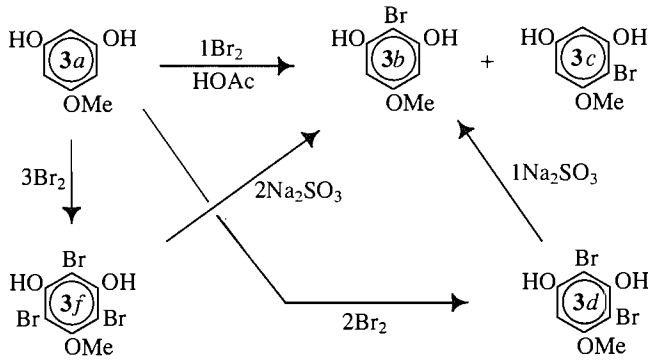
cinol (**2***a*) with excess bromine in glacial acetic acid or in aqueous solution. It is also the major product when only two equivalents of bromine are added to an ice-cooled suspension of **2***a* in carbon disulfide, i.e., under conditions that permit the partial bromination of resorcinol (11). Small samples of the minor components monobromophloroglucinol (**2***b*) and dibromophloroglucinol (**2***c*) can be isolated from the crude product mixture by fractional crystallization (from benzene) and chromatography. However, the partial debromination of **2***d* with one molar equivalent of sodium sulfite in the presence of sodium bicarbonate is a more satisfactory procedure, yielding mainly **2***b* (32%) and **2***c* (42%). The best route to **2***c* (eq. [1]) involves bromination of 2,4,6-trihydroxybenzoic acid (phloroglucylic acid) followed by decarboxylation (12). This reaction sequence is also applicable to the preparation of **2***b* although the lack of selectivity in the initial bromination step leads to a mixture of mono- and dibromophloroglucylic acid (**2***b* and **2***c*), which cannot be separated without concomitant loss of carbon dioxide. The acetylation of **2***b* gives 1,3,5-triacetoxy-2-bromobenzene with spectral properties identical to those reported by Glombitza and Gerstberger (13) for a component of an acetylated extract from brown algae, thereby verifying their structure assignment. Dibromophloroglucinol (**2***c*) has also been found in marine organisms (14) but neither **2***b* nor **2***c* has been previously synthesized and spectroscopically characterized.



Only one of the five possible bromination products of the slightly less reactive 5-methoxyresorcinol, namely tribromo-5-methoxyresorcinol (**3***f*), has been reported in the literature (15). Monobromination is not regiospecific (eq. [2]) and gives mainly the two monobromo compounds (**3***b* and **3***c*) as well as smaller amounts of 2,4-dibromo-5-methoxyresorcinol (**3***d*) and **3***f* but none of the 4,6-dibromo isomer (**3***e*) of **3***d*. With two equivalents of bromine in acetic acid, **3***d* (accompanied by some **3***f*) is obtained in 90% yield. The absence of **3***e* shows that C-6 of 4-bromo-5-methoxyresorcinol is considerably less nucleophilic than C-2, which emphasizes the importance of coplanarity of the methoxy group with the aromatic ring for effective charge delocalization (*ortho*/*para* activation). The same reason appears to be responsible for the preferred removal of bromine from C-4 and C-6 to provide predominantly 2-bromo-5-methoxyresorcinol (**3***b*) when **3***f* or **3***d* is treated with sodium sulfite (eq. [2]). The latter reaction parallels the regioselective debromination of 6,8-dibromocatechin at C-8 under comparable conditions (1) and suggests that stabilization of the proposed α-hydroxysulfonate intermediate (16, 17) or the final product by OH....Br hydrogen bonding (18) is also a contributing factor.

To gain further insight into its mechanism and to optimize the reaction conditions, we reexamined the debromination of 2,4,6-tribromoresorcinol (**7***f*) (9*c*, 10*b*, 19) with sodium sulfite (eq. [3]), studied originally by Davis and Harrington (20), and confirmed the formation of 2-bromoresorcinol (**7***b*) (12*b*, 21) and 2,4-dibromoresorcinol (**7***d*) (12*b*, 22). The application of this method to 4,6-dibromoresorcinol (**7***e*) (11, 23) constitutes a good alternative synthesis for 4-bromoresorcinol (**7***c*) (16), which can also be prepared by decarboxylation of 5-bromo-2,4-dihydroxybenzoic acid (11, 12*b*, 24), or by bromination of resorcinol with *N*-bromosuccinimide in dimethylformamide (25) or with dioxane dibromide in ether (23*a*). Using two moles of sodium sulfite per mole of tribromoresorcinol (**7***f*), or a mixture of one mole of sodium sulfite and one mole of sodium hydroxide, we obtained **7***d* in high yield while only **7***b* was formed with the reagents Na_2SO_3/NaOH/**7***f* in the molar ratio 2:2:1. When sodium sulfite is replaced by sodium thiosulfate, no reaction takes place; the addition of base leads to the slow formation of **7***d* and partial decomposition. With sodium hydroxide alone, both tribromophloroglucinol and tribromo-

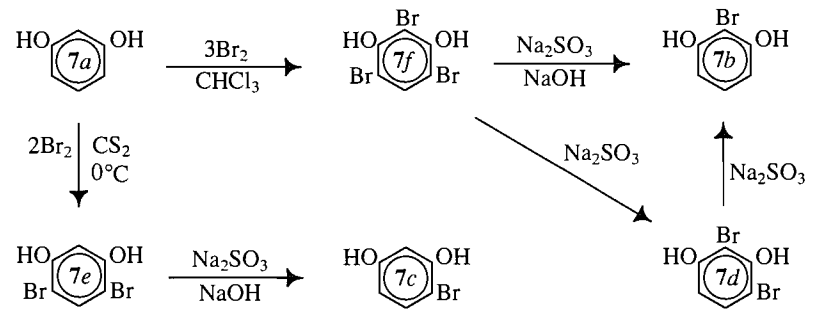
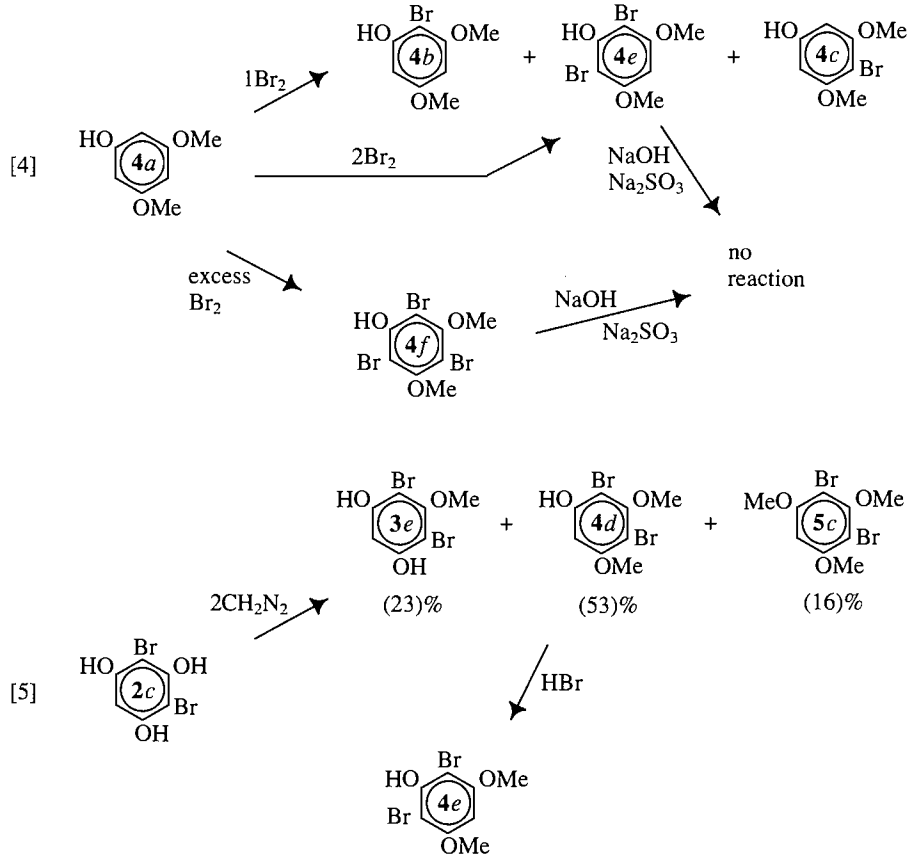
[2] 



resorcinol undergo rapid decomposition (9*a*). As observed for tribromo-5-methoxyresorcinol (**3***f*), the bromine atom *ortho* to both hydroxy groups is removed less easily than Br-4 and Br-6; i.e., the reaction is regiospecific, proceeds in a stepwise fashion, and yields resorcinol with excess sulfite and base. 4,6-Dibromo-3-methoxyphenol (16), 4,6-dibromo-1,3-dimethoxybenzene (**8***b*), 2,4-dibromo-1,3,5-trimethoxybenzene (**5***c*), 2,6-dibromo-3,5-dimethoxyphenol (**4***e*), 2,4,6-tribromo-3,5-dimethoxyphenol (**4***f*), and 6,8-dibromocatechin tetramethyl ether were found to resist debromination under these conditions, even when refluxed for several hours in aqueous methanol.

These experimental results suggest a mechanism similar to that proposed for the dehalogenation of bromouracil (26) and of 4-bromo-3-arylsydnones (27). Either sulfite adds at the carbonyl carbon of an initially formed "ketobromide" tautomer of the starting material to give an α-hydroxysulfonate intermediate, which undergoes oxidation at sulfur and halide elimination at the α-carbon (16), or it attacks the bromine atom of the α-haloketone directly. In view of recent spectroscopic evidence for a phloroglucinol/sulfite adduct (17), we favor the former route. According to this scheme, sulfite serves as base to catalyze enol/keto equilibration (28), as nucleophile to protect the intermediate α-bromoketone by complexation, as reducing agent to abstract the halogen, and again as base to neutralize the bisulfate formed in the reduction step. The latter function explains why, in the absence of sodium hydroxide, two moles of sulfite are required for the removal of one halogen, i.e., the reaction succeeds only in alkaline medium. Neutral aqueous thiosulfate fails to react but is slowly converted to sulfite in the presence of base. We attribute the failure of monohydric bromophenols to react by this mechanism to their lower acidity, which renders the concentration of their keto tautomers negligibly small at a given pH.



The bromination of 3,5-dimethoxyphenol (**4***a*) (eq. [4]) with two or three equivalents of elemental bromine in chloroform or methylene chloride gives 2,6-dibromo-3,5-dimethoxyphenol (**4***e*) (29) and tribromo-3,5-dimethoxyphenol (**4***f*), respectively, in high yields. The latter can be readily separated from the former on account of its higher solubility in benzene and aqueous bicarbonate solution. With one equivalent of bromine, 2-bromo-3,5-dimethoxyphenol (**4***b*) (29) is formed as the main product (44% yield) together with lesser amounts of **4***e* (8%) and the 4-bromo isomer (**4***c*, 5%). As expected, electrophilic substitution occurs preferentially at the sterically more accessible C-2 and C-6 positions. No 2,4-dibromo-3,5-dimethoxyphenol (**4***d*) was detected, since the elimination of a proton from the cation formed by electrophilic attack of bromine at C-4 of **4***b* would force the 3-methoxy carbon to rotate out of the aromatic ring plane. To synthesize this elusive compound, we treated dibromophloroglucinol (**2***c*) with a limited quantity of diazomethane and obtained a product mixture that, much to our surprise, contained **4***d* as major and 4,6-dibromo-5-methoxyresorcinol (**3***e*) and 2,4-dibromo-1,3,5-trimethoxybenzene (**5***c*) as minor components (eq. [5]). Clearly the hydroxy group flanked by two *ortho*-bromo substituents exhibits enhanced nucleophilicity toward the methylating agent. This result is analogous to the formation of 3-methoxy-2,4-dibromophenol from 2,4-dibromoresorcinol and dimethyl sulfate, as reported by Rice (12*b*), and parallels the enhanced reactivity of *ortho*-disubstituted anisoles toward dealkylating agents (7, 30). In the presence of hydrogen bromide, **4***d* rearranges to the more stable 2,6-dibromo isomer (**4***e*), and both compounds were found to undergo slow debromination as well as H/D exchange at the unsubstituted ring carbon after several days of exposure to hydrochloric acid in acetone-d_6 solution (monitored by nmr).

The results of the bromination of 1,3,5-trimethoxybenzene (**5***a*) are primarily a function of bromine quantity, reaction time, and temperature (31), yielding mainly 2-bromo-1,3,5-trimethoxybenzene (**5***b*) (32) with one equivalent (2 h at 25°C), 2,4-dibromo-1,3,5-trimethoxybenzene (**5***c*) (33) with three equivalents (1 h at 25°C), and 2,4,6-tribromo-1,3,5-trimethoxybenzene (**5***d*) (**4***a*, 34) with excess neat bromine.

Systematic analysis of the nmr data summarized in Tables 1 and 2 (^{1}Hmr and ^{13}Cmr of 32 compounds in acetone-d_6) and in Table 3 (^{1}Hmr of 19 methyl ethers in chloroform-*d*) reveals interesting trends, which parallel similar observations for

flavans with phloroglucinol-type A-rings (2, 3, 35) and are potentially useful for the structure elucidation of naturally occurring polyphenols. Ten of the 18 brominated phloroglucinol derivatives are new compounds and, to the best of our knowledge, ^{1}Hmr parameters have been previously reported only for 2,6-dibromo-3,5-dimethoxyphenol (**4***e*) (36), monobromo- (**5***b*) (37), dibromo- (**5***c*) (31, 33*d*, 38), and tribromo-1,3,5-trimethoxybenzene (**5***d*) (31, 34), and ^{13}Cmr data only for **5***b* (37). Although the following discussion focuses mainly on the 16 bromophloroglucinols and their methyl ethers, dissolved in acetone-d_6, similar conclusions may be drawn for the corresponding resorcinol (**7** and **8**) and phloroglucylic acid (**6**) derivatives.

The proton assignments for 2-bromo-3,5-dimethoxyphenol (**4***b*) and 4-bromo-5-methoxyresorcinol (**3***c*) are based on nuclear Overhauser effect (nOe) studies (2). In the former compound, saturation at the MeO-3, OH, and MeO-5 frequencies increases the peak intensities of H-4, H-6, and both H-4 and H-6, respectively. In the latter compound, only H-6 is enhanced when the methoxy protons are irradiated. In the presence of cadmium nitrate (2, 39), the two hydroxy peaks of 2,4-dibromo-5-methoxyresorcinol (**3***d*) are well separated, and saturation at 9.03 ppm leads to more efficient H-6 relaxation than saturation at 8.25 ppm. Thus double irradiation for the short duration of 1 s minimizes saturation transfer between the two hydroxy groups, yet produces a sufficiently strong nOe to permit assignment of the downfield signal to OH-1. In the 1,3-dimethoxy-4,6-dibromo compounds **4***e*, **5***c*, and **8***b* the methoxy protons resonate at relatively high frequencies (3.91–3.93 ppm) and H-2 experiences a large upfield shift (by 0.35 ± 0.02 ppm) when the solvent is changed from acetone to chloroform, indicating strong nonbonding interactions in the favored planar "crab" (or *cis*) conformation, which places four of the six methyl protons into the immediate vicinity of the aryl hydrogen. In general, the ^{1}Hmr spectra of the title compounds show the expected downfield shifts for *meta* protons on bromination (by about 0.2 ppm) and for *para* protons on O-methylation (by 0.06–0.12 ppm). The latter effect is particularly strong (0.21–0.22 ppm) when the hydroxy group is located between two *ortho*-bromo substituents that force the methoxy carbon into a position orthogonal to the aromatic ring plane. This rotation interferes with effective resonance delocalization of an oxygen lone pair and thereby reduces the electron density at the *para* hydrogen, as observed for **3***d* → **4***d*, **2***c* → **3***e*, and **4***e* → **5***c*.

The ^{13}Cmr spectra show even stronger evidence for such stereoelectronic substituent effects (3). To arrive at reliable peak assignments as an essential prerequisite for subsequent correlations, we first recorded the spectra of the bromine-free parent compounds and found good agreement with published literature values for phloroglucinol (17, 28, 40) and its three methyl ethers (**3***a*, **4***a*, **5***a*) (37, 41). High molecular symmetry and the large chemical shift differences between oxygenated, brominated, and unsubstituted ring carbons lead to facile identification of the peaks for tribromophloroglucinol (**2***d*), its trimethyl ether (**5***d*), and tribromoresorcinol (**7***f*) as well as for 4,6-dibromoresorcinol (**7***e*) and its dimethyl ether (**8***b*). The distinction between the oxygenated ring carbons of phloroglucylic acid (**6***a*), dibromophloroglucylic acid (**6***c*), mono- and dibromophloroglucinol (**2***b* and **2***c*), 4,6-dibromo- and tribromo-5-methoxyresorcinol (**3***e* and **3***f*), 2,6-dibromo- and tribromo-3,5-dimethoxyphenol (**4***e* and **4***f*), and dibromo-1,3,5-trimethoxybenzene (**5***c*) is based on the different intensities of their resonance signals in inverse-gated proton-decoupled spectra as well as on the larger magnitude of bromination shift increments for *ortho* (upfield by 3.3–5.5 ppm) than for *para* carbons (upfield by 0.5–1.7 ppm), as previously reported (3) for

bromocatechin derivatives. Using monobromophloroglucinol (**2***b*) as reference compound and the general rule (41*b*) that in the absence of steric hindrance O-methylation has a negligible effect on the chemical shift of the *meta* carbon, the absorption peaks of the monobromophloroglucinol methyl ethers at 156 ppm must be assigned to C-1 (**3***b* and **4***b*) and C-3 (**3***c*), those at 159.0 and 159.5 ppm, respectively, to C-1 (**3***c* and **4***c*), the signals at 161–162 ppm to C-5 (**3***b*, **4***b*, and **5***b*), and, consequently, those near 158.5 ppm to the methoxy-substituted carbons *ortho* to bromine (**3***c*, **4***b*, **4***c*, and **5***b*). Similarly, **3***d*, **3***e*, and **4***d* can be considered as O-methylation products of dibromophloroglucinol (**2***c*), i.e., the resonance lines near 152.8 and 155.5 ppm are due to C-3 (**3***d*) and C-1, respectively. Brominated carbons are characterized by very weak absorptions, on account of their long spin-lattice relaxation times (42), and unsubstituted ring carbons by their doublets in proton-coupled spectra. Since three-bond coupling to the methoxy and two-bond coupling to the *ortho* proton are of approximately equal magnitude (4 Hz), the broad quintet patterns centered near 157.5 ppm established the resonance frequencies for C-5 of **3***d* and **4***d*, C-3 of **4***e*, and C-1 of **5***c*. This analysis leaves only the assignments for C-2 and C-4 of 2,4-dibromo-5-methoxyresorcinol (90.5 vs. 91.2 ppm) uncertain and suggests a reversal of the C-1 (157.4 ppm in $CDCl_3$) and C-5 (160.5 ppm) assignments for **5***b* published by Fischer and Henderson (37).

In their recent paper (43) on the non-additivity of ^{13}Cmr substituent chemical shifts (SCS) for 1,3-disubstituted benzenes Bromilow *et al.* noted the large deviations from additivity observed for molecules with conformationally flexible substituents such as methoxy. They excluded bromine from their considerations because of its anisotropic contributions to paramagnetic screening, and pointed out that *meta* SCS values are always small because of the absence of direct mesomeric interactions between the substituents. In *meta*- and *para*-substituted phenols and phenoxides, ipso effects are largely governed by substituent electronegativities, and the superposition of electronic and steric effects makes SCS calculations for *ortho*-disubstituted benzenes particularly difficult (44). While we agree with these observations, our results indicate that limited chemical shift predictions are possible for polysubstituted aromatic compounds as long as structural variations are kept to a minimum (45).

The operation of steric effects is clearly evident from the chemical shift difference of 1.7 ppm for C-6 of 2- and 4-bromo-5-methoxyresorcinol (**3***b* and **3***c*) and of 5.6 ppm for C-2 of the two isomeric dibromo-3,5-dimethoxyphenols (**4***d* and **4***e*). The extra shielding observed for **3***c* is common for anisoles and has been attributed to steric enhancement of resonance by the methoxy group (46), which tries to achieve coplanarity with the benzene ring. In the case of **4***d*, the two large bromine atoms force the methoxy carbon at C-3 into a perpendicular orientation relative to the ring plane, which interferes with effective delocalization of an oxygen electron pair. Therefore, the electron density at the *ortho* and *para* carbons is reduced. The calculation of bromination shift increments leads to the same conclusion: Bromine introduced at C-6 of 2-bromo-3,5-dimethoxyphenol (**4***b*) has a net shielding effect on the ring carbons that is felt most strongly at the ipso and *ortho* positions (−3.1, −3.6, and −3.8 ppm). Bromination at C-4, on the other hand, deshields C-2 (+6.4 ppm), C-4 (+5.5 ppm), and C-6 (+2.4 ppm) since these three carbons are *ortho* and *para* to the MeO-3 group, which rotates out of the ring plane and thereby loses its electron-releasing effect. In general, this

2,4,6-Tribromo-	**8***c*	7.73	3.90

[a]In ppm downfield from TMS ($CHCl_3$ at 7.26 ppm).
[b]Phenolic OH: δ 5.0–6.1 ppm.
[c]Listed in order of decreasing nomenclature priority.
[d]Assignments may be interchanged.

conformational change is associated with a downfield shift of 5.5–7.3 ppm for each CBr carbon (0.7–1.5 ppm when coplanarity can be maintained). The most dramatic illustration of *ortho/para* deshielding by steric inhibition of resonance is seen in the high δ value of 110.7 ppm for the three brominated carbons of tribromo-1,3,5-trimethoxybenzene (**5***d*). Comparison of the chemical shift sums for the six ring carbons shows that O-methylation of phloroglucinol changes the electron density very little (765.8 → 768.5 ppm), and that tribromination leads to shielding (765.8 → 728.8). However, the loss of mesomeric interaction with three oxygen atoms that accompanies the trimethylation of tribromophloroglucinol (**2***d*) results in deshielding by more than 70 ppm (728.8 → 800.6 ppm). The low reactivity of dibromo-1,3,5-trimethoxybenzene (**5***c*) toward excess bromine is, of course, but another manifestation of the reduced *ortho/para* activating effect of orthogonal methoxy groups (31). The primary deuterium isotope effect found (31) for the bromination of mono- and dibromo-1,3,5-trimethoxybenzene (but not for the monobromination of 1,3,5-trimethoxybenzene) shows that in these cases proton loss from the initially formed carbocation intermediate becomes the rate-determining step. Contrary to expectation, the methoxy peaks also shift downfield (by 4–5 ppm) when two bulky *ortho* substituents prevent free rotation (47), so that their chemical shifts may serve as sensitive probes to distinguish between crowded and uncrowded polysubstituted aromatic rings. Examining the oxygenated ring carbons, we found that their chemical shifts fall into narrow, non-overlapping regions that depend on the number of *ortho*-bromo substituents: each bromine atom shields the adjacent carbon by 1.5–4.5 ppm. The internal consistency of the observed SCS values lends further support to the initial peak assignments.

Finally, the one-bond coupling constants increase gradually with increasing bromine substitution: from 143.7 to 146.2 Hz for the methoxy and from 158.8 to 162.6 Hz for the aromatic protons in the phloroglucinol series (157.3–173.8 Hz for C-5 of resorcinol derivatives). Since bromine consistently affects *ortho*-methoxy coupling more strongly (by 0.6–1.3 Hz) than *para* (0.3–0.7 Hz), this trend may be used as an alternative to selective heteronuclear decoupling to distinguish MeO-3 (56.4 ppm, *J* 144.9 Hz) from MeO-5 (55.6 ppm, *J* 144.2 Hz) in 2-bromo-3,5-dimethoxyphenol (**4***b*). Long-range carbon/hydrogen coupling constants range from 3.1–4.3 Hz for RO—*C*—C—H and *C*—O—CH_3 to 4.2–5.1 Hz for *C*—C—C—H and 7.5–9.0 Hz for Br—*C*—C—C—H, in agreement with literature values (42).

In summary, all 16 bromophloroglucinols and their methyl ethers are readily accessible by simple bromination, debromination, and methylation reactions. Their spectral properties are similar to those reported for bromocatechins (2, 3), featuring substantial deshielding for aromatic protons, and for methoxy carbon and ring carbon atoms *ortho* and *para* to methoxy groups that have been forced out of the ring plane by two adjacent bromine atoms. Successive bromination shifts oxygenated sp^2 carbon-13 signals gradually upfield; the magnitude of SCS values is not only a function of electronic substituent effects but varies also with conformational changes induced by the new bromine substituent.

Experimental

Commercial phloroglucinol dihydrate was dried *in vacuo* over P_2O_5 (110°C/12 h); 2,4,6-trihydroxybenzoic acid monohydrate (phloroglucylic acid), 1,3-dimethoxybenzene, 1,3,5-trimethoxybenzene, and resorcinol were used as commercially supplied (Aldrich). Melting points (uncorrected) were recorded on a Fisher–Johns melting point apparatus, mass spectra (70 eV) on an HP-5985 quadrupole instrument, and nmr spectra on a Bruker spectrometer (400 MHz). Gas chromatographic analyses were carried out on a Hewlett–Packard instrument (model HP-5890A) with integrator (model HP-3392A) and 15-m DB-1 capillary column (temperature programmed to increase between specified values at 20°/min; carrier gas, helium). For other chromatographic separations we used the following systems: (a) analytical tlc in $CHCl_3$/MeOH/HOAc/H_2O (85:15:10:3 v/v, solvent A, or 90:5:3:2, solvent B), petroleum ether (30–60°C)/EtOAc (1:1, solvent C), and $CHCl_3$/MeOH/HOAc (90:6:4, solvent D) on Merck Kieselgel 60F-254 (0.2 mm) DC-Plastikfolien; (b) preparative tlc on Merck Silica Gel 60HF254/366, and (c) flash chromatography on Kieselgel 60 (230–400 mesh) with the same solvents. Elemental analyses were performed on a Carlo Erba Elemental Analyzer model 1106. A 3:1 (v/v) mixture of petroleum ether (65–110°C) and chloroform (solvent E) was used for several recrystallizations.

Methylation of phloroglucinol (2a)

5-Methoxyresorcinol (**3***a*) and 3,5-dimethoxyphenol (**4***a*) were obtained in 41 and 10% yield, respectively, by methylation of anhydrous phloroglucinol in methanol saturated with hydrogen chloride, as described in the literature (4*b*), and purified by distillation and recrystallization from benzene (**3***a*: bp 160°C/0.3 Torr (1 Torr = 133.3 Pa); mp 74–76°C (lit. (4*b*) mp 75–78°C); **4***a*: bp 130–140°C/0.3 Torr; mp 37–39°C (lit. (4*b*) mp 36–38°C).

Bromination of phloroglucinol (2a)

(a) Tribromophloroglucinol (2d)

To a stirred suspension of 5.21 g (41.3 mmol) anhydrous phloroglucinol in 130 mL dichloromethane was added dropwise (1 h/25°C) a solution of 19.8 g (124 mmol) bromine in 20 mL dichloromethane. Solvent evaporation from the clear yellow solution and recrystallization of the beige residue (14.55 g, 97%) from 100 mL benzene gave 8.95 g (60%) pure **2***d*, long colorless needles, mp 151–152°C (lit. (9*b*) mp 148–149°C).

(b) Partial bromination

The dropwise addition (4.5 h) of a solution of 13.5 g bromine (84.4 mmol) in 20 mL carbon disulfide to a stirred, ice-cooled suspension of 5.32 g (42.2 mmol) anhydrous phloroglucinol in 300 mL carbon disulfide led to instant decolorization and precipitation of a fluffy white solid. Solvent evaporation left a solid residue (11.64 g) containing **2***d* and dibromophloroglucinol (**2***c*) as major and monobromophloroglucinol (**2***b*) and unreacted phloroglucinol as minor components (by ^{1}Hmr, tlc, and glc at 160–240°C). Trituration with hot benzene (3 × 150 mL) and cooling gave three crops of crystals containing mainly **2***d* and **2***c* (3.81 g, first fraction), **2***c* and **2***b* (1.70 g, second fraction), **2***b* and **2***a* (0.53 g, third fraction), and an insoluble residue (mainly **2***a*). A small sample of pure **2***b* (R_f 0.44) was obtained from the third fraction (**2***b*/**2***a* molar ratio 6:1, with traces of **2***c* (R_f 0.75)) by preparative tlc (solvent A); mp 162.5–163.5°C; *m/z*: 206 (100), 204 (91), 188 (4.7), 186 (5.3), 177 (4.2), 175 (4.0), 97 (19), 85 (11), 79 (11), 78 (14), and 69 (88). *Anal.* calcd. for $C_6H_5BrO_3$: C 35.12, H 2.44%; found: C 35.25, H 2.38%.

*Partial debromination of tribromophloroglucinol (2*d*)*

A solution of 1.0 mmol Na_2SO_3 and 2.0 mmol $NaHCO_3$ in 3 mL water was added to a suspension of 1.0 mmol **2***d* in 3 mL aqueous methanol (2:1 v/v) and magnetically stirred for 15 min at 25°C. After acidification with 10% HCl, evaporation of the methanol *in vacuo* (50°C/15 min), extraction with ether (6 × 4 mL), drying ($MgSO_4$), and ether evaporation, the solid residue (210 mg) was dried *in vacuo* over P_2O_5 (1 h/25°C) and found by ^{1}Hmr and glc (160–240°C) analysis to contain 32% **2***b*, 42% **2***c*, and 6% **2***a* as well as some unreacted starting material and unidentified decomposition products. With different ratios of reducing agent and base, we obtained the following results (sulfite/base ⇢ yields): 1.0 mmol Na_2SO_3/1.0 mmol NaOH → 20% **2***b*/30% **2***c*/35% **2***a*; 1.0 mmol Na_2SO_3/1.0 mmol $NaHCO_3$ → 10% **2***b*/40% **2***c*/4% **2***a*. With Na_2SO_3 alone, only **2***a* and **2***d* were detected, and the ^{1}Hmr spectrum of the brown, tarry product formed with NaOH alone (no Na_2SO_3) showed no identifiable peaks. Because of slow H/D exchange with the nmr solvent (acetone-d_6), the yields reported above are only approximate.

*Dibromophloroglucylic acid (6*c*) and dibromophloroglucinol (2*c*)*

A solution of 3.26 g (20.4 mmol) bromine in 50 mL carbon disulfide was dropped into a stirred suspension of 1.88 g (10.0 mmol) phloroglucylic acid monohydrate (**6***a*) in 100 mL carbon disulfide at 5°C. After stirring for 1 h at 25°C, the white solid was filtered off, washed with ice-cold water (3 × 20 mL), ground in a mortar, and dried *in vacuo* over KOH (8 h/56°C) to give 2.39 g (73%) **6***c*, mp 199–200°C (dec.). *Anal.* calcd. for $C_7H_4Br_2O_5$: C 25.64, H 1.23%: found: C 25.55, H 1.21%. Heating a solution (orange) of 2.10 g **6***c* in 150 mL water at 75°C for 2 h (until acidity drops from pH 2 to pH 6), refrigeration (12 h/4°C), filtration, and drying *in vacuo* over P_2O_5 (48 h/25°C) yielded long beige needles (1.74 g, 83%) of **2***c*, mp 170–172°C (recrystallized from water) (lit. (12*a*) mp 171–172°C; *m/z*: 286 (50), 284 (100), 282 (54), 268 (5.4), 266 (11.6), 264 (5.8), 206 (5.5), 204 (5.9), 177 (4.0), 175 (5.3), 159 (5.3), and 157 (5.7). *Anal.* calcd. for $C_6H_4Br_2O_3$: C 25.38, H 1.42%; found: C 25.34, H 1.57%.

*Partial bromination of phloroglucylic acid (6*a*)*

A solution of 1.60 g (10.0 mmol) bromine in 50 mL carbon disulfide was dropped slowly (2.5 h) into a stirred, ice-cooled suspension of 1.98 g (10.0 mmol) phloroglucylic acid monohydrate in 100 mL carbon disulfide. After another 80 min of stirring at 25°C, the colorless reaction mixture was filtered through a sintered glass funnel, and the precipitate washed with water (2 × 20 mL, removal of **6***c*, loss of some **6***b*) and dried in air on clay (12 h) to give 0.83 g of a mixture of bromophloroglucylic acid (**6***b*) and unreacted starting material (molar ratio 11:5). Purification of **6***b* by tlc failed because of slow decarboxylation on silica. However, evaporation to dryness (at 70°C) of an aqueous solution of the crude product yielded a mixture of monobromophloroglucinol (**2***b*) and phloroglucinol, which could be readily separated by preparative tlc (solvent A) and purified (**2***b*) by recrystallization from benzene.

1,3,5-Triacetoxy-2-bromobenzene

Acetylation of monobromophloroglucinol (**2***b*) with acetic anhydride and pyridine (16) gave the triacetate in 72% yield (recrystallized from ethanol), mp 107–108°C; ^{1}Hmr (ppm, acetone-d_6): 7.06 (2H, ArH), 2.32 (6H, AcO-1,3), and 2.26 (3H, AcO-5); ^{13}Cmr (ppm, acetone-d_6): 169.0 (AcO-5), 168.4 (AcO-1,3, ^2J = 7.2 Hz), 151.4 (C-5), 150.6 (C-1,3), 116.3 (C-4,6, ^1J = 169.4 Hz, ^3J = 5.0 Hz), 108.7 (C-2), 20.8 (AcO-5, ^1J = 130.5 Hz), and 20.6 (AcO-1,3, ^1J = 130.5 Hz). The ^{1}Hmr chemical shifts in $CDCl_3$ and the mass spectrum are identical to those reported in the literature (13). *Anal.* calcd. for $C_{12}H_{11}BrO_6$: C 43.53, H 3.35%; found: C 43.76, H 3.37%.

*Bromination of 5-methoxyresorcinol (3*a*)*

A solution of 1.17 g (7.31 mmol) bromine in 5 mL glacial acetic acid was added dropwise to a stirred, cooled solution of 1.00 g (7.14 mmol) **3***a* in 10 mL acetic acid. Evaporation of the solvent and vacuum drying gave 1.83 g of a brown oil that was found to contain 2-bromo- (**3***b*), 4-bromo- (**3***c*), 2,4-dibromo- (**3***d*), tribromo-5-methoxyresorcinol (**3***f*), and unreacted starting material in the approximate molar ratio 6:5:4:1:4 (analysis by glc at 120–200°C and by ^{1}Hmr). With 2.33 g (14.6 mmol) bromine and 1.02 g (7.3 mmol) **3***a*, the same procedure gave 2.46 g of a light brown solid containing **3***d* and **3***f* (ratio 9:1) from which pure **3***d* was obtained by recrystallization from petroleum ether (65–110°C)/$CHCl_3$ (1:1 v/v) and hexane. For **3***d*, mp 109–111°C; *m/z*: 300/298/296 (base peak, molecular ion), dibromo fragments at 285/283/281, 271/269/267, 270/268/266, and 257/255/253, and monobromo fragments at 219/217, 204/202, 203/201, 191/189, 190/ 188, 189/187, 176/174, and 175/173. *Anal.* calcd. for $C_7H_6Br_2O_3$: C 28.22, H 2.03%; found: C 28.44, H 1.98%. With excess bromine, **3***f* was isolated in 69% yield after two recrystallizations from benzene and petroleum ether/$CHCl_3$ (3:1), mp 122–123°C (lit. (15) mp 123°C).

*Partial debromination of 2,4-dibromo-5-methoxyresorcinol (3*d*) and tribromo-5-methoxyresorcinol (3f)*

A solution of 252 mg (2.00 mmol) Na_2SO_3 in 3 mL water was added dropwise to a stirred solution of 300 mg (1.01 mmol) **3***d* in 10 mL aqueous methanol (1:1 v/v). After acidification with 10% HCl and flash evaporation of the methanol (5 min/50°C), the residual yellow aqueous solution was extracted with ether (4 × 10 mL). Drying ($MgSO_4$) and solvent evaporation gave 140 mg of crude product containing 2-bromo-5-methoxyresorcinol (**3***b*) and **3***a* (molar ratio 5:2) and a trace of the 4-bromo isomer (**3***c*) from which **3***b* was isolated by flash chromatography (solvent C). For **3***b*, mp 73–75°C; *m/z*: 220/218 (base peak, molecular ion), 191/189, 190/188, 177/175, 172/170, 140, 111, 110, 95, and 69. *Anal.* calcd. for $C_7H_7BrO_3$: C 38.38, H 3.22%; found: C 38.50, H 3.02%.

With 2.68 g (21.2 mmol) Na_2SO_3 in 25 mL water and 2.00 g (5.31 mmol) **3***f* in 50 mL aqueous methanol, the same procedure gave 1.10 g of a light brown oil containing **3***a*, **3***b*, and **3***c* in the approximate molar ratio 5:3:2 (also traces of **3***d*) from which a small sample of pure 4-bromo-5-methoxyresorcinol was obtained by flash chromatography (solvent B) and recrystallization from hexane. For **3***c*, mp 117–118°C; mass spectrum nearly identical to that of **3***b* (172/170 fragment absent). *Anal.* found: C 38.66, H 3.10% (for calcd. values, see **3***b* above). The two isomeric monobromo-5-methoxyresorcinols **3***b* and **3***c* were clearly distinguished by their different melting points, nmr spectra (Tables 2 and 3), and glc retention times (2.98 and 3.82 min at 160–240°C). When only 2 mmol Na_2SO_3 (with or without additional NaOH) was used per mmol **3***f*, the reaction remained incomplete, **3***b* was formed as major product (together with **3***d*), and no **3***c* was detected in the product mixture.

*Partial debromination of 2,4,6-tribromoresorcinol (7*f*)*

To synthesize the known (18–25) bromoresorcinols and record their nmr spectra, we reinvestigated and optimized the reaction conditions reported by Davis and Harrington (20) for the debromination of tribromoresorcinol (**7***f*). Starting from 1.00 mmol **7***f* (19*b*) in 3 mL aqueous methanol (2:1 v/v) and 2.00 mmol Na_2SO_3 in 3 mL water, and following the standard procedure described for the partial debromination of tribromophloroglucinol (see above), 2,4-dibromoresorcinol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

(**7***d*) was obtained in 94% yield. Both **7***d* (56%) and 2-bromoresorcinol (**7***b*, 31%) were formed when the methanol/water ratio was increased from 1:5 to 1:1 (v/v) and the reaction mixture stirred for 18 h, while the use of 2 mmol Na_2SO_3 and 2 mmol NaOH under standard conditions (15 min reaction time, solvent composition $MeOH/H_2O$ = 1:5) led to the exclusive formation of **7***b* (98%). Other reagent combinations (per mmol **7***f*) resulted in the following product yields: 4 mmol $Na_2SO_3 \rightarrow$ 31% **7***b* and 37% **7***d*; 1 mmol Na_2SO_3/1 mmol NaOH → 80% **7***d*; 1 mmol Na_2SO_3/2 mmol $NaHCO_3 \rightarrow$ 67% **7***d*; 2 mmol $Na_2S_2O_3 \rightarrow$ 67% **7***d*; 2 mmol $Na_2S_2O_3$/2 mmol NaOH → 50% **7***d*.

*Bromination of 3,5-dimethoxyphenol (***4***a)*

A solution of 5.84 g (36.6 mmol) bromine in 20 mL dichloromethane was added dropwise (65 min) to a stirred solution of 2.00 g (13.3 mmol) **4***a* in 40 mL dichloromethane. Solvent evaporation after an additional 15 min of stirring, and vacuum drying of the residue gave 4.99 g of a crude pink product, which was found (by ^{1}Hmr) to contain 65% tribromo- (**4***f*) and 35% 2,6-dibromo-3,5-dimethoxyphenol (**4***e*). Recrystallization from benzene (15 mL) yielded 1.00 g **4***e*, which was further purified by sublimation and recrystallization from solvent E, mp 164–165°C (lit. (29) mp 165–167°C). The filtrate of the first recrystallization (from C_6H_6) was evaporated to dryness, the residue dissolved in 5% aqueous $NaHCO_3$ and washed with ether. Acidification of the aqueous layer, extraction with ether, solvent evaporation, and recrystallization (solvent E) gave 1.53 g **4***f*, white crystals, mp 73–75°C; *m/z*: 394/392/390/388 (base peak, molecular ion), tribromo fragments at 379/377/375/373, 351/349/347/345, and 336/334/332/330, dibromo fragments at 298/296/294, 297/295/293, 283/281/279, 269/267/265, and 255/253/251, and 232/230 (M − 2Br). *Anal.* calcd. for $C_8H_7Br_3O_3$: C 24.58, H 1.81%; found: C 24.58, H 1.80%. The bromination of 1.00 g (6.49 mmol) **4***a* with 2.07 g (12.94 mmol) bromine in dichloromethane gave 1.39 g (69%) pure **4***e* after recrystallization of the crude product (1.91 g, 93%) from solvent E. With equimolar amounts of **4***a* and bromine (6.5 mmol) a dark red solid was obtained, which on treatment with charcoal in boiling benzene, cooling, and filtration gave 1.10 g (75%) of crude product (red) consisting of 19% **4***a*, 44% 2-bromo- (**4***b*), 5% 4-bromo-3,5-dimethoxyphenol (**4***c*), and 8% **4***e*. A mixture (1:1) of **4***a* and **4***c* and a sample of pure **4***b*, mp 79–81°C (from hexane (lit. (29) mp 79–81°C) were isolated by preparative tlc (solvent B). The two isomeric monobromo-3,5-dimethoxyphenols (**4***b* and **4***c*) had nearly identical mass spectra (gc–ms, 120–240°C) but were clearly distinguished by their different glc retention times (5.50 and 7.65 min, respectively) and nmr spectra (Tables 2 and 3). For **4***c*, *m/z*: 234/232 (base peak, molecular ion), 191/189, 176/174, 138, 125, 124, 123, 108, 95, 93, and 69.

*Methylation of dibromophloroglucinol (***2***c)*

A solution of 852 mg (3.00 mmol) **2***c* in10 mL ether was methylated by slow addition of an ethereal solution (10 mL) of diazomethane prepared from 927 mg (9.00 mmol) *N*-nitroso-*N*-methylurea and 3 mL 40% KOH at 5°C. The residue left after solvent evaporation was taken up in 20 mL 0.3 N KOH and extracted with ether (3 × 25 mL), the organic layers were dried ($MgSO_4$), and the solvent evaporated to give 162 mg (0.50 mmol) dibromo-1,3,5-trimethoxybenzene (**5***c*). Acidification of the green aqueous layer, ether extraction (4 × 40 mL), washing with 0.4 M aqueous $NaHSO_3$ (10 mL) to pH 4, drying ($MgSO_4$), and solvent evaporation gave a mixture (740 mg) containing 2,4-dibromo-3,5-dimethoxyphenol (**4***d*) and 4,6-dibromo-5-methoxyresorcinol (**3***e*) in the approximate molar ratio 7:3 (by glc at 120–200°C and ^{1}Hmr) together with traces (<3%) of **3***d*, **4***e*, and **2***c*. The two major products were separated by preparative tlc (solvent D). For **3***e* (R_f 0.45), mp 103–106°C; gc–ms (retention time 4.18 min) *m/z*: 300/298/296 (base peak, molecular ion), 257/255/253, 219/217, 204/202, 203/201, 175/173, 138, 131, 110, and 69. *Anal.* calcd. for $C_7H_6Br_2O_3$: C 28.22, H 2.03%; found: C 27.70, H 2.25%; for **4***d* (R_f 0.74), gc–ms (retention time 4.90 min) *m/z*: 314/312/310 (base peak molecular ion), 271/269/267, 218/216, 217/215, 203/201, 175/173, 152, 131, 124, and 69. *Anal.* calcd. for $C_8H_8Br_2O_3$: C 30.80, H 2.58%; found: C 31.71, H 2.70%. 2,4-Dibromo-3,5-dimethoxyphenol (**4***d*) was not obtained in crystalline form. Storage in a vial (8 months) led to partial, exposure to HBr (48 h, desiccator) to complete, rearrangement to 2,6-dibromo-3,5-dimethoxyphenol (**4***e*), as shown by nmr spectroscopy. The addition of 4 μL concentrated HCl to a solution of the partially rearranged sample in acetone-d_6 resulted in slow debromination (monitored by ^{1}Hmr over a period of 4 days) of both compounds to 3,5-dimethoxyphenol (δ(OMe) 3.69 ppm), presumably by bromine transfer to the solvent.

*Bromination of 1,3,5-trimethoxybenzene (***5***a)*

A solution of 502 mg (3.14 mmol) bromine in 10 mL dichloromethane was added dropwise (2 h) to a stirred solution of 556 mg (3.31 mmol) **5***a* in 10 mL dichloromethane. Washing with 5% aqueous Na_2SO_3 and water, drying ($MgSO_4$), and solvent evaporation gave 820 mg of a white solid containing 2-bromo-1,3,5-trimethoxybenzene (**5***b*) and **5***a* in the approximate molar ratio 7:2 (by glc at 160°C and ^{1}Hmr). Recrystallization from heptane yielded 475 mg (58%) **5***b*, which was purified by a second recrystallization (from 50% aqueous EtOH), mp 95–97°C (lit. (32*a*) mp 97–99°C). With 3 mmol bromine per mmol **5***a*, 2,4-dibromo-1,3,5-trimethoxybenzene (**5***c*), mp 129–130°C (from solvent E) (lit. (33*c*) mp 129–130°C), was obtained in quantitative yield by the same procedure. In refluxing chloroform, a 1:1 mixture of **5***c* and tribromo-1,2,4-trimethoxybenzene (**5***d*) was formed in 84% yield from 1 mmol **5***a* and 5 mmol bromine. Since the preparative separation of these two compounds proved difficult, we prepared **5***d* by adapting Will's method (4*a*): Excess neat bromine (13.4 mmol) is added in two portions to **5***a* (2.0 mmol), the bromine excess is allowed to evaporate, and the crude product is dissolved in ether and washed with 5% aqueous Na_2SO_3 and water. Drying ($MgSO_4$) and solvent evaporation gives 645 mg **5***d* (80%), mp 142–143°C (from 95% EtOH) (lit. (4*a*) mp 145°C).

*Bromination of 1,3-dimethoxybenzene (***8***a)*

A solution of 3.20 g (20.0 mmol) bromine in 30 mL dichloromethane was added dropwise (1 h) to a stirred solution of 1.38 g (10.0 mmol) **8***a* in 30 mL dichloromethane. Evaporation of the solvent gave 2.94 g (99%) 4,6-dibromo-1,3-dimethoxybenzene (**8***b*), mp 139–141°C (from $MeOH/C_6H_6$ 4:1) (lit. (12*b*) mp 141°C). 2,4,6-Tribromo-1,3-dimethoxybenzene (**8***c*) was obtained from **8***a* and excess neat bromine by Will's method (ref. 4*a*, see above) in 86% yield, white needles, mp 69–70° (from 95% EtOH) (lit. (48) mp 68–69°C).

Solvent effects on S_N2 transition state structure. II: The effect of ion pairing on the solvent effect on transition state structure

KENNETH CHARLES WESTAWAY[1] AND ZHU-GEN LAI
Chemistry Department, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received October 6, 1987[2]

KENNETH CHARLES WESTAWAY and ZHU-GEN LAI. Can. J. Chem. **67**, 345 (1989).

Identical secondary α-deuterium kinetic isotope effects (transition state structures) in the S_N2 reaction between *n*-butyl chloride and a free thiophenoxide ion in aprotic and protic solvents confirm the validity of the Solvation Rule for S_N2 Reactions. These isotope effects also suggest that hydrogen bonding from the solvent to the developing chloride ion in the S_N2 transition state does not have a marked effect on the magnitude of the chlorine (leaving group) kinetic isotope effects. Unlike the free ion reactions, the secondary α-deuterium kinetic isotope effect (transition state structure) for the S_N2 reaction between *n*-butyl chloride and the solvent-separated sodium thiophenoxide ion pair complex is strongly solvent dependent. These completely different responses to a change in solvent are rationalized by an extension to the Solvation Rule for S_N2 Reactions. Finally, the loosest transition state in the reactions with the solvent-separated ion pair complex is found in the solvent with the smallest dielectric constant.

Key words: ion pairs, transition state, solvent effects, nucleophilic substitution, isotope effects.

KENNETH CHARLES WESTAWAY et ZHU-GEN LAI. Can. J. Chem. **67**, 345 (1989).

Les effets isotopiques cinétiques secondaires des deutérium en α (états de transition ressemblant aux structures) qui sont observés au cours de la réaction S_N2 du chlorure de *n*-butyle avec l'ion thiophénolate libre sont identiques que les solvants soient aprotique ou protique; ces résultats confirment la validité de la règle de solvatation pour les réactions S_N2. Ces effets isotopiques suggèrent aussi que la liaison hydrogène qui se développe, dans l'état de transition S_N2, entre le solvant et l'ion chlorure qui se forme n'a pas d'influence marquée sur l'amplitude des effets isotopiques cinétiques du chlore (groupement nucléofuge). Par opposition avec ce qui est observé lors des réactions des ions libres, l'effet isotopique cinétique secondaire des deutérium en α (structure ressemblant à l'état de transition) qui caractérise la réaction S_N2 entre le chlorure de *n*-butyle et la paire d'ions complexe de l'ion thiophénolate de sodium séparé par le solvant dépend fortement sur le solvant. Pour rationaliser ces réponses complètement différentes à un changement de solvant, on fait appel à une extension de la règle de solvatation pour les réactions S_N2. Enfin, dans les réactions comportant une paire d'ions complexe séparée par le solvant, c'est avec le solvant possédant la plus faible constante diélectrique qu'on observe l'état de transition le plus lâche.

Mots clés : paires d'ions, état de transition, effets du solvant, substitution nucléophile, effets isotopiques.

Introduction

In an earlier paper (1), a "Solvation Rule for S_N2 Reactions" was proposed. This rule states that "a change in solvent will not lead to a change in the structure of an S_N2 transition state if the charges on the two nucleophiles in the transition state are the same (a Type I reaction) but will lead to a change in structure of the transition state when a negatively charged nucleophile and a neutral nucleophile (a Type II reaction) are present in the transition state." Although this theory was based on many experimental results, one of the strongest pieces of supporting evidence was the constant chlorine (leaving group) kinetic isotope effects, Table 1, found for the S_N2 reaction between *n*-butyl chloride and sodium thiophenoxide, eq. [1], in a wide

[1] $CH_3CH_2CH_2CL_2—Cl + C_6H_5S^- Na^+ \rightarrow CH_3CH_2CH_2CL_2—SC_6H_5 + Na^+ Cl^-$ L = H, D

range of aprotic and protic solvents (2). The constant chlorine kinetic isotope effects were taken as evidence that the length of the α-carbon–chlorine transition state bond and the transition state did not change when the solvent was altered. However, theoretical calculations by Sims and co-workers (3, 4) suggest that hydrogen bonding to the developing chloride ion by solvent in the transition state can reduce significantly, or even level, the chlorine kinetic isotope effect and mask changes that occur in the length of the α-carbon–chlorine transition state bond. If this is the case, the constant chlorine kinetic isotope effects do not mean that the transition state remains constant when the solvent is altered in the *n*-butyl chloride – sodium thiophenoxide reaction, and the Solvation Rule for S_N2 Reactions might not be valid.

If the Solvation Rule holds for the S_N2 reaction between *n*-butyl chloride and thiophenoxide ion (a Type I reaction with a negatively charged nucleophile and leaving group), the secondary α-deuterium kinetic isotope effect (transition state structure) will not be altered when the solvent is changed. If, on the other hand, the transition state shifts with a change in solvent, the secondary α-deuterium kinetic isotope effects will be different in each solvent. The secondary α-deuterium kinetic

isotope effects for the *n*-butyl chloride – sodium thiophenoxide reaction have been measured in three different solvents, DMSO, DMF, and methanol, to determine whether the transition state of this S_N2 reaction changes when the solvent is altered. The results will establish or refute the validity of the Solvation Rule.

Finally, the secondary α-deuterium kinetic isotope effects have also been determined for the S_N2 reaction between *n*-butyl chloride and the solvent-separated sodium thiophenoxide ion pair complex (5) to learn how the form of the reacting nucleophile affects the solvent effects on transition state structure for an S_N2 reaction.

Results and discussion

Graczyk *et al.* reported that the S_N2 reaction between *n*-butyl chloride and sodium thiophenoxide gave only the substitution products *n*-butyl phenyl sulfide and chloride ion, and was not complicated by a competing elimination reaction (2). This was confirmed when HPLC analyses of reaction mixtures for the substitution product, *n*-butyl phenyl sulfide, showed that substitution accounted for 100 ± 1% of the product in each solvent. Conductivity studies and uv spectroscopic studies of alkali metal thiophenoxide solutions, as well as secondary α-deuterium kinetic isotope effect measurements in the presence and absence of 15-crown-5 ether, have shown that *n*-butyl chloride reacts with a free thiophenoxide ion at some sodium thiophenoxide concentrations and with a solvent-separated sodium thiophenoxide ion pair complex at other concentrations in DMSO, DMF, and methanol (5).

The presence of the solvent-separated ion pair complex at high sodium thiophenoxide concentrations in DMSO, DMF, and methanol (5) was indicated by (*i*) the decrease in the slope of the conductance versus concentration plot at a particular sodium thiophenoxide concentration, (*ii*) the rapid change in the uv spectrum with concentration at this same concentration, and (*iii*) because 15-crown-5 ether caused the same changes as dilution in the uv spectrum of sodium thiophenoxide solutions. The cation independent λ_{max} of the uv spectra of lithium, sodium, and cesium thiophenoxide solutions at concentrations where the salts were known to exist as the ion pair complex in DMSO, DMF, and methanol demonstrated that the nucleophilic reactant in these three solvents is a solvent-separated ion pair (6). Finally, the extremely sharp change in the uv spectrum, and in the secondary α-deuterium kinetic isotope effects, with concentration indicates that the solvent-separated ion pair must exist as a complex consisting of several solvent-separated sodium thiophenoxide ion pairs, eq. [2].

$$[2] \quad m\mathrm{Na}^+ + m\mathrm{SC_6H_5}^- \rightleftarrows (\mathrm{Na}^+(\mathrm{solvent})_n(\mathrm{SC_6H_5}^-))_m$$

All of the experimental findings are consistent with such an equilibrium. First, the form of the reacting anion would change rapidly with concentration if this equilibrium existed. Also, the rapid change in the uv spectra and in the secondary α-deuterium kinetic isotope effects with concentration are expected. The conductivity data are also consistent with the formation of the ion pair complex because the conductance of the ion pair complex is lower than that of the free ions (7). Finally, the secondary α-deuterium kinetic isotope effects found at high sodium thiophenoxide concentrations in the 15-crown-5 ether reactions are identical to those found in the free ion reactions because the 15-crown-5 ether complexes the sodium ions (8) and the ion pair complex cannot form.

Testing the Solvation Rule for S_N2 reactions

The secondary α-deuterium kinetic isotope effects found for the S_N2 reaction between *n*-butyl chloride and the free thiophenoxide ion in three different solvents, Table 2, are the same within experimental error. These identical kinetic isotope effects are impressive because the rate constant changes by 1400 times when the solvent is changed from DMF to methanol. A change in the length of either the nucleophile–α-carbon and (or) α-carbon – leaving group bonds in the S_N2 transition state would change the steric crowding around the α carbon and alter the frequencies of the C_α–H(D) out-of-plane bending vibrations, which primarily determine the magnitude of the secondary α-deuterium kinetic isotope effect (9, 10). Thus, the simplest explanation is that the transition states do not change when the solvent is altered in the free ion S_N2 reaction, i.e., the identical isotope effects indicate that the transition states are identical in all three solvents.

Although other factors such as a change in the amount of conjugation to the phenyl ring on the α carbon (3, 12), changes in the reaction coordinate motion (13, 14), tunnelling (13, 14), and changes in product composition (15) can affect the magnitude of secondary α-deuterium kinetic isotope effects, the simplest explanation for the identical isotope effects in the free ion reaction is preferred because (*i*) the substrate is saturated,

[a]Each isotope effect was determined with a different batch of solvent and by a different worker except for the isotope effects in methanol.

[b]Standard deviation from at least three kinetic runs.

[c]The error is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively (5).

[d]Standard deviation on the average isotope effect.

[e]The different rate constants were found at different times and at different sodium thiophenoxide concentrations. The variation in the rate constants is probably due to a small salt effect.

(*ii*) quantitative yields of the S_N2 product are found in these reactions (2, *vide supra*), and (*iii*) the secondary α-deuterium kinetic isotope effects for the free ion reactions ($k_H/k_D = 1.06$/α-D) are well within the range expected for an S_N2 reaction of an alkyl chloride (16, 17). Since large secondary α-deuterium kinetic isotope effects, significantly greater than the equilibrium isotope effect, are found when changes in the reaction coordinate motion and (or) tunnelling affect the magnitude of the isotope effect (13, 14), it seems unlikely that these factors affect the magnitude of these secondary α-deuterium kinetic isotope effects significantly. As a result, the most likely explanation is the simple one, i.e., that the magnitude of the isotope effects is related to the structure of the transition state and that the identical isotope effects indicate that the S_N2 transition states do not change with solvent when the reacting nucleophile is a free ion.

The failure to detect a change in the secondary α-deuterium kinetic isotope effect (structure of the S_N2 transition state), even though the change in solvent markedly changes the rate constant for the reaction, is, in fact, predicted by the Solvation Rule for S_N2 Reactions because both the thiophenoxide ion and the developing chloride ion are negatively charged in the transition state. Thus, one is forced to conclude that the Solvation Rule for S_N2 Reactions is valid.

The effect of solvation on chlorine kinetic isotope effects

The secondary α-deuterium kinetic isotope effects found in this study are also useful because they support the contention (2) that chlorine (leaving group) kinetic isotope effects can be used for determining the relative length of the C_α—Cl transition state bonds in S_N2 reactions. The identical secondary α-deuterium kinetic isotope effects indicate that the transition state for the S_N2 reaction between *n*-butyl chloride and sodium thiophenoxide does not change when the solvent is changed from the dipolar aprotic solvents, DMF or DMSO, to a protic solvent, methanol. This observation is important because it confirms that the length of the α-carbon–chlorine bond does not change appreciably in these transition states when the solvent is altered. Thus, the virtually identical chlorine isotope effects found by Graczyk *et al.* for this S_N2 reaction (2) do reflect accurately the length of the α-carbon–chlorine transition state bond and the magnitude of the chlorine kinetic isotope effects for S_N2 reactions are not lowered as much by hydrogen bonding with the solvent as the theoretical calculations suggest (3, 4). In fact, a close examination of the chlorine kinetic isotope effects in Table 1 suggests that hydrogen bonding of the developing chloride ion has only a very small (within experimental error) effect on the magnitude of the chlorine kinetic isotope effect. The chlorine isotope effects for the reactions in dipolar aprotic and aprotic solvents, where the developing chloride ion is only weakly solvated (relative to its solvation energy in protic solvents) (1, 18), are only slightly larger (1.00952 ± 0.00009) than those found in the protic solvents (1.00934 ± 0.00007) where hydrogen bonding to the developing chloride ion could lower the magnitude of the chlorine isotope effect. In fact, the difference of 0.00018 between the average kinetic isotope effects in the aprotic and protic solvents is barely outside the error of 0.00015 reported for the individual isotope effects (2) and one is forced to conclude that hydrogen bonding to the developing chloride ion has only a very small effect on the chlorine kinetic isotope effect for S_N2 reactions. This conclusion is particularly important because the chlorine kinetic isotope effects for this reaction are near the maximum found for S_N2 reactions. Thus, the amount of C_α—Cl bond rupture in the transition state and the effect of hydrogen bonding by solvent must be at or near the maximum for S_N2 reactions. This suggests that chlorine (leaving group) isotope effects can be used as a probe of transition state structure for S_N2 reactions. It is important to note, however, that hydrogen bonding to the developing chloride ion by solvent in the transition state should cause a greater reduction in, and may

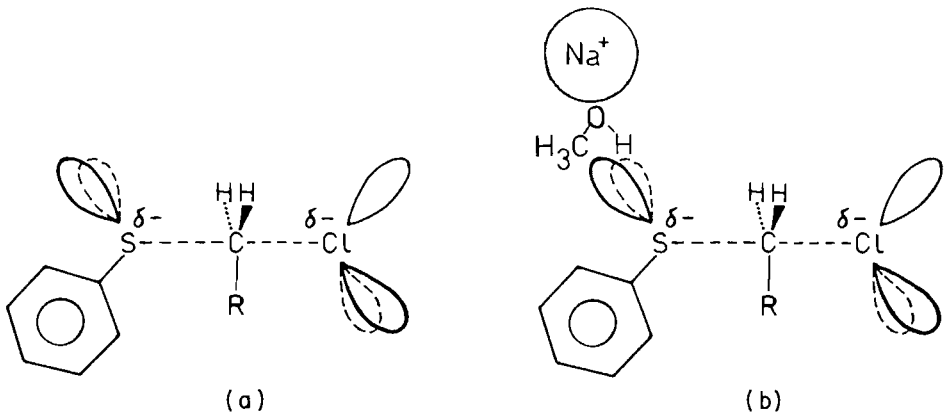

FIG. 1. The S_N2 transition states for the reaction between *n*-butyl chloride and (a) the free thiophenoxide ion; (b) the solvent-separated sodium thiophenoxide ion pair complex.

even level, the chlorine isotope effects of carbocation S_N reactions that have looser transition states with more α-carbon–chlorine bond rupture (19–22).

The effect of ion pairing on the solvent effects on transition state structure

The results in Tables 2 and 3 indicate that the secondary α-deuterium kinetic isotope effect and transition state structure for the S_N2 reaction between *n*-butyl chloride and sodium thiophenoxide are affected very differently by a change in solvent when the sodium thiophenoxide reacts as a solvent-separated ion pair complex (ref. 5, *vide supra*) and as a free ion. While the secondary α-deuterium kinetic isotope effects in the free ion reactions are identical in both aprotic and protic solvents, the α-deuterium kinetic isotope effects in the reactions where the reacting nucleophile is the solvent-separated ion pair complex are different in each solvent. In fact, these kinetic isotope effects cover the range from much smaller ($(k_H/k_D)_\alpha$ = 1.034) to slightly larger ($(k_H/k_D)_\alpha$ = 1.141) than the average secondary α-deuterium kinetic isotope effect of 1.125 ± 0.008 found in the free ion reactions. Moreover, the average kinetic isotope effects for the reactions with the solvent-separated ion pair complex, Table 3, are significantly different in each solvent. Thus, one must conclude that the transition state structure (the secondary α-deuterium kinetic isotope effect) changes significantly when the solvent is changed in the S_N2 reaction between *n*-butyl chloride and the solvent-separated sodium thiophenoxide ion pair complex.

The very different solvent effects on the secondary α-deuterium kinetic isotope effects and transition state structures for the free ion and ion pair reactions can be rationalized with the Solvation Rule for S_N2 Reactions. The S_N2 transition states for the free ion and ion pair complex reactions, Fig. 1, are very different from the point of view of solvation. The S_N2 transition state for the free ion reaction will be mainly, if not exclusively, solvated at the two negatively charged nucleophiles, the sulfur of the thiophenoxide ion and the developing chloride ion. Since the charges, and perhaps the charge density, on these two nucleophiles are the same in the S_N2 transition state, a change in solvent will cause the same changes in solvation at the two nucleophiles. For example, if the solvent is changed from methanol to DMSO, the solvation at both nucleophiles changes in the same way, i.e., from hydrogen bonding in methanol to an ion–dipole interaction in DMSO. As a result, the relative nucleophilicity of the two nucleophiles will not be changed by a change in solvent, and the transition state will not be altered (1).

The variable secondary α-deuterium kinetic isotope effects in the solvent-separated ion pair complex reactions are consistent with a tight solvent-separated ion pair. In a tight S_N2 ion pair transition state (an approximation of the transition state is shown in Fig. 1(b)) the solvation will be mainly at the sodium ion, which has a full positive charge, and the developing chloride ion, which has a partial negative charge. More important, however, the sodium ion blocks the normal solvation of the partially charged sulfur anion. As a result, changing from the protic solvent, methanol, to the dipolar aprotic solvent, DMSO, will have very different effects on the solvation and nucleophilicity at the sulfur and chloride ions in the ion pair S_N2 transition state.

The solvent change from methanol to DMSO changes the solvation from hydrogen bonding to an ion–dipole interaction at the negatively charged chloride ion. Since hydrogen bonding lowers the electron density of an anion, the loss of hydrogen bonding to the developing chloride ion will increase the electron density (the nucleophilicity) of the chloride ion.

The methanol molecule(s) in a tight solvent-separated ion pair complex could not hydrogen bond to the sulfur anion in the tight ion pair S_N2 transition state because the distance between the sodium and sulfur ions would be too small to form linear hydrogen bonds to methanol. Thus, no hydrogen bonding is lost when the solvent changes, i.e., the change in solvent from methanol to DMSO only changes one dipole–ion interaction for another at the sulfur ion. As a result, the electron density on the sulfur anion is not markedly affected by the change in solvent.

Since the solvent change alters the charge density on the chloride anion much more than that on the sulfur ion, the relative nucleophilicity of the chloride and sulfur anions is altered significantly by a change in solvent. As a result, the ion pair S_N2 transition state behaves like a Type II system (1) and the transition state structure (the secondary α-deuterium kinetic isotope effect) is altered by a change in solvent. An extension of the Solvation Rule for S_N2 Reactions states that the structure of the transition state containing a tight, solvent-separated ion pair nucleophile and a negatively charged leaving group will be altered by a change in solvent (behave like a Type II transition state) because the cation in the tight ion pair alters the solvation of the nucleophile.

Finally, the smallest secondary α-deuterium kinetic isotope effect and tightest transition state in the ion pair complex reactions are found in the most polar solvent, DMSO, and the largest isotope effect and loosest transition state are found in the least polar solvent, diglyme, Table 4. In fact, the correlation

TABLE 4. The dielectric constant of the solvent and the secondary α-deuterium kinetic isotope effects for the S_N2 reaction between *n*-butyl chloride and the solvent-separated sodium thiophenoxide ion pair complex in DMSO, DMF, methanol, and diglyme at 20°C

Solvent	Dielectric constant[c]	$(k_H/k_D)_\alpha$
DMSO	46.6	1.034±0.002[a]
DMF	36.7	1.084±0.001[b]
Methanol	32.6	1.100±0.000[b]
Diglyme	7.3	1.141±0.003[b]

[a]The error is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively (5).
[b]Standard deviation for the average isotope effect, see Table 3.
[c]Taken from ref. 24.

coefficient for the plot of the secondary α-deuterium kinetic isotope effect versus the dielectric constant of the solvent is 0.95. This crude relationship is presumably found because the influence of the negatively charged sulfur of the thiophenoxide ion pair complex is transmitted for greater distances through the less polar solvent, i.e., the charge on the sulfur atom is felt by the α carbon at larger distances when the dielectric constant (polarity) of the solvent is lower (11). In the more polar solvents, the sulfur anion has to come closer to the α carbon before it distorts the α-carbon–chlorine bond and causes reaction.

Conclusion

The identical secondary α-deuterium kinetic isotope effects found in aprotic and protic solvents for the S_N2 reaction between *n*-butyl chloride and the free thiophenoxide ion demonstrate that the Solvation Rule for S_N2 Reactions (1) is valid. The identical isotope effects (transition states) in the different solvents also support the contention by Graczyk *et al.* (2) that hydrogen bonding to the developing chloride ion by solvent in an S_N2 transition state does not have a significant effect on the magnitude of chlorine leaving group kinetic isotope effects, as theoretical calculations suggest (3, 4). In fact, the changes in the chlorine isotope effect for this reasonably loose S_N2 transition state are almost within the experimental error when the solvent is changed from a poorly solvating aprotic solvent to a strongly solvating hydrogen-bonding solvent.

The large solvent effect on the secondary α-deuterium kinetic isotope effects (transition state structure) for the S_N2 reaction between *n*-butyl chloride and the solvent-separated sodium thiophenoxide ion pair complex is completely different from the effect on the corresponding free ion reaction. These differences are consistent with the Solvation Rule for S_N2 Reactions if one considers that the metal cation changes the normal solvation of the ion pair nucleophile in the transition state. Finally, the loosest transition state in the reactions with the ion pair complex is found in the solvent with the smallest dielectric constant. This presumably occurs because the charge on the nucleophilic sulfur atom distorts the electron density in the α-carbon–chlorine bond and causes reaction at a greater distance in the less polar solvent.

Experimental

Preparation of reagents

The purification of the solvents and the preparation of the sodium thiophenoxide and the deuterated and undeuterated substrates are described elsewhere (5).

Kinetic method

The kinetic methods in the various solvents are described in ref. 5.

HPLC analysis

The percent yield of *n*-butyl phenyl sulfide was determined by using diphenyl ether as the internal standard (23). The separation was done isocratically with 67% methanol – 33% water on a Waters 5PAH 10 Radial Pak column at a flow rate of 2 mL/min. A Waters model 600 and a Waters 490 uv detector set at 275 nm were used for the analysis.

P. F. VIDAL, J. BOUCHARD, E. CHORNET, R. P. OVEREND, H. GIROUX, and F. LAMY. Can. J. Chem. **67**, 350 (1989).

Two strains of *Streptomyces*, *S. badius* and *S. virdosporus*, when incubated with kraft lignin (Indulin ATR) produce water soluble acid precipitable compounds. We show by a combination of elemental analysis, amino acid analysis, and FTIR that these are complexes of lignin fragments strongly associated with proteins. The latter, which can be separated by solvent extraction, are added by the microorganisms themselves. The lignin fraction, which represents approximately 60% of the complex weight, consists of lower molecular weight, lower methoxyl content Indulin fragments.

Key Words: lignin, Indulin, lignin–protein complexes, Fourier transform infrared spectrophotometry, high performance size exclusion chromatography, *Streptomyces*.

Lorsque incubées avec une lignine kraft (Indulin ATR), deux souches de *Streptomyces : S. badius* et *S. viridosporus* produisent des composés solubles dans l'eau qui précipitent en milieu acide. Ceux-ci sont des complexes formés de lignine fortement associée à des protéines qui peuvent être dissociés par solubilisation séquentielle. La fraction ligneuse qui représente environ 60% de la masse du complexe est constituée de fragments d'Indulin ATR de plus faibles poids moléculaires et teneur en méthoxyles.

Mots clés: lignine, Indulin, complexes lignine–protéine, spectrophotométrie infra-rouge à transformé de Fourier, chromatographie d'exclusion stérique haute performance, *Streptomyces*.

Introduction

The biodegradation of lignin, the second most abundant biopolymer found in vascular plants, has been studied for many years in the laboratories of Nord (1), Eriksson (2), and Kirk (3). These studies were mainly concerned with the degradation of lignocellulose under the influence of white-rot fungi, leading to the isolation, from *Phanerochaete chysosporium*, of an enzyme able to cleave the C_α—C_β bond in lignin model compounds (4). Later, it was shown that this enzyme was a peroxidase, catalysing electron transfer processes (5, 6). The mechanism of lignocellulose degradation by bacteria, especially by actinomycetes, is as yet not understood. It has been shown by Broda and co-workers (7, 8) and by Crawford and co-workers (9–12) that several species of actinomycetes could solubilize the insoluble substrate, but so far no bacterial ligninolytic enzyme has been found.

We have shown recently that *Streptomyces viridosporus* and *Streptomyces badius*, the two species extensively used in Crawford's laboratory, could solubilize a commercial kraft lignin, Indulin (13). The amounts of Indulin solubilized (7%), recovered as a water soluble, Acid Precipitable Polymeric Lignin (APPL), were comparable to the amounts reported by Crawford with a lignocellulosic substrate; 3.7% for spruce, 8.6% for maple, and 13.4% for corn stover (12). When the extra- and intra-cellular bacterial proteins were incubated with Indulin, a solubilization of the substrate was observed that, in the case of *S. badius*, was enhanced by H_2O_2. Some of the results collected do not support the enzyme hypothesis and, therefore, in this paper a second, new hypothesis will be proposed and discussed.

Material and methods

Lignin preparation

Indulin AT lignin was obtained from Westvaco chemical division, Charleston, SC, USA, and before use it was treated according to the manufacturer's specifications—essentially an acid washing overnight—to produce Indulin ATR.

Bacterial growth and APPL recovery

The cultures of *S. badius* 252 (ATCC39115) and *S. viridosporus* T7A (ATCC 39117) were carried out with agitation, at pH 7.5 and 37°C, in salt media containing Indulin at a concentration of 0.5% (w/vol), glucose (0.2%), and yeast extract (0.6%) (13, 17). The APPL samples used in our characterization studies were recovered after 35 days incubation as described in ref. 7. In some experiments the yeast extract was replaced with NH_4Cl (0.02%) (see results and discussion).

Elemental analyses

The percentages of carbon, hydrogen, and nitrogen present in the APPLs were determined with a Perkin–Elmer 240C elemental analyzer. The oxygen content was calculated by difference.

Carbohydrate analyses

We used a milder version of the standard method for wood hydrolysis (14). Fifty milligrams of APPL was suspended in 1 mL of 24.0 N H_2SO_4 for 1 h at 30°C. This solution was diluted with distilled water to an acid concentration of 0.8 N and autoclaved for 1 h at 120°C. Neutralization was carried out with a saturated solution of $Ba(OH)_2$ and the $BaSO_4$ precipitate removed by centrifugation. After the supernatant was evaporated until completely dry, the monosaccharides were converted into their trimethylsilyl ether derivatives using trimethylsilyl imidazole (Sigma Chem. Co.) (15), and were subjected to quantitative gas–liquid chromatography using the sorbitol derivative as the internal standard. The glc analyses were performed using a Hewlett–Packard HP-5880 A instrument equipped with a flame ionization detector (FID). The column (530 μm × 10 m) was coated with methyl silicone gum and temperature programmed at 3°C/min from 100°C to 250°C.

Methoxyl group quantification

The methoxyl content of the different samples was determined using a modified Zeisel procedure (16). The alkyl iodides formed were measured by glc using a methyl silicone phase (SP-2100 10% on Supelcoport, Supelco) on a 4 mm × 2 m column. The chromatograph (HP-5706A) was programmed for an isotherm of 4 min at 30°C and heated to 100°C at 32°C/min. Detection was made by FID. The calibration was done using vanillic acid, and decane as used was the internal standard.

Amino acids analyses

These analyses were carried out as described in Giroux *et al.* (13) with a pre-column derivatization of the protein hydrolysates to form PTC (phenylthiocarbamide) amino acid derivatives and a subsequent separation of these on C-18 μ-Bondapak column.

Sequential solubilization by tetrahydrofuran (THF) and dimethylformamide (DMF)

About 100 mg of APPLs was suspended in 20 mL of THF (Anachemica Co.) for 5 h. After centrifugation, the filtrate was evaporated to dryness and weighed. The residue was then resuspended in the same volume of the subsequent solvent mixture for 5 h and this procedure was repeated to the obtention of the final residue. The solvent sequence was the following: THF, THF:DMF (85:15), THF:DMF (50:50), and DMF (Aldrich Co.).

Fourier transform infrared analysis

A 5-DXB Nicolet system with a TGDS detector was used at a resolution of 4 cm^{-1}. The samples were mixed with pure KBr (Aldrich) at a concentration of 1–2% (w/w), milled in a steel ball mill for 40 s, and pressed in pellets with a vacuum dye. Sixty-four scans were collected and pure KBr was used as a background spectrum.

High performance size exclusion chromatography (HPSEC)

A Varian model 5000 liquid chromatograph equipped with a variable wavelength UV-100 detector was used. Two columns in series were used (PLgel 300 × 7.5 mm, particle size 5 μm, Polymer Laboratories), the first having a porosity of 50 Å and the second of 500 Å. The linearity of the calibration curve for this system is effective from a peak average molecular weight (M_p) of 100 to a M_p of 20 000 as evaluated with low dispersity polystyrene standards ($M_w/M_n < 1.10$). Filtered and degassed THF was eluted at room temperature and at a flow rate of 1.0 mL/min. Ten-microlitre samples (0.1% in THF) were injected and detection was made at 280 nm. Preparative APPL fractionation for further FTIR characterization was performed in the same apparatus using a 200-μL loop, a sample concentration of 1%, and a Gilson fraction collector.

Results

Part I: Crude APPL analysis

The elemental composition and methoxyl content of Indulin ATR and of the APPLs are presented in Table 1. The APPLs have a substantial amount of nitrogen compared to the very low value initially present in Indulin ATR. To determine where this nitrogen fraction originates, we carried out amino acid analyses, which are summarized in Table 2. They show clearly that proteins are indeed found associated with APPL collected from cultures of either *S. badius* or *S. viridosporus*. The main point to note is that the amino acid compositions are similar for the two APPLs and that they are not influenced by the presence or absence of yeast extract in the culture media. Some differences can be found in yeast extract and the APPL. For example, the ratio Polar amino acid/Aliphatic amino acid (A.A.) is equal to 0.9 in the extract while it is 0.6 ± 0.1 for the APPL (all values pooled). On the other hand, the values for the ratios Aliphatic A.A./Hydroxylated A.A. are very similar: 3.14 for yeast extract and 3.5 ± 0.3 for the APPL. The difference found in the overall recovery of amino acids in the analyses (11 ± 1 pmol L^{-1} in the APPL and 19 pmol L^{-1} in the yeast extract) is due to the fact that identical sample weights (10 mg) were initially hydrolyzed in 6 N HCl. The true weights of the APPL protein fractions were of course lower due to the presence of the lignin fragments.

TABLE 1. Elemental analyses and methoxyl group quantification of Indulin ATR and of the APPLs

Sample	%N	%C	%H	%O*	$\%OCH_3$
Indulin ATR	0.2	66.1	5.9	27.8	13.7
APPL *S.bad*	6.1	51.6	5.6	36.7	6.8
APPL *S.vir*	6.0	54.2	5.8	34.1	6.5

*Percentage of oxygen is calculated by difference.

TABLE 2. Amino acid composition of the yeast extract and of the APPL associated proteins

	Amino acid concentrations (pmol L^{-1})				
		APPL (+) yeast extract		APPL (−) yeast extract	
Amino acid categories	Yeast extract	S.bad	S.vir	S.bad	S.vir
Polar	7.23	3.16	4.27	3.85	2.81
Aliphatic	8.31	5.36	5.31	6.30	5.30
Aromatic	0.95	0.68	0.64	0.73	0.62
Hydroxylated	2.65	1.71	1.59	1.61	1.52
Total	19.14	10.91	11.81	12.49	10.25

*Initial freeze-dried samples, hydrolyzed in 6.0 N HCl, had identical weights (10 mg).

Since the protein fractions are methoxyl-free, it appears that the APPL fractions have a lesser methoxyl content when compared to the starting material, the decrease being 14% for *S. badius* and 19% for *S. viridosporus*.

The percentage of carbohydrates in Indulin ATR and in the APPLs is given in Table 3. Despite the variations among the five analyzed sugars, the summative percentages of carbohydrates remain constant, with carbohydrates being less than 1% on a weight basis.

The Fourier transform infrared spectra of the APPLs, depicted in Fig. 1, show similar patterns for the APPLs produced by *S. viridosporus* and *S. badius* but are quite different from the spectrum of Indulin ATR in the 1800–800 cm^{-1} area. Figure 2 is an expansion of this area for Indulin ATR and the APPLs produced by *S. badius* in culture media containing yeast extract or NH_4Cl as nitrogen source. The same patterns (not shown) were obtained from the APPLs derived from *S. viridosporus*.

All of the Indulin ATR infrared bands (we used the empirical assignment of lignin ir bands proposed by Hergert (18)) may be identified in the APPL spectra but variations in relative intensity and displacement of frequencies of the bands are noticeable. In the 3600–2500 cm^{-1} area, the difference between APPLs and lignin may be summarized as firstly, the existence of shoulders around 3290 and 3080 cm^{-1} in APPLs, representing peptidic bonds, and secondly, the variation in the relative intensity of bands related to alkyl groups, especially at 2965 and 2845 cm^{-1}.

From Fig. 2, the important increase of the 1700 and 1660 cm^{-1} bands, related respectively to unconjugated and conju-

gated carbonyl in lignin, can be seen. Consequently, the lignin aromatic ring band at 1595 cm^{-1} is overlapped. The appearance of the 1540 cm^{-1} band, related to amide groups, does not affect the aromatic ring band at 1515 cm^{-1}.

The following four bands: 1460, 1427, 1370, and 1270 cm^{-1}, respectively assigned to alkyl, aromatic ring, alkyl and (or) hydroxyl, and finally aryl C—O of aryl–alkyl ethers in lignin, are only distorted in the APPLs spectra. The intensities of the five subsequent bands: 1220, 1150, 1130, 1080, and 1030 cm^{-1}, are strongly modified. These bands, related to C—H and C—O vibrations of syringyl and guaiacyl units, are overlapped with similar vibrations of different intensities from protein. Finally, new bands appear at 887 and 783 cm^{-1} in the APPLs spectra due to aromatic ring and amine group absorptions of some of the amino acids that compose the protein fraction.

Part II: Dissociation of the protein–polyphenolic complex and characterization of the polyphenolic fraction

The main objective of the dissociation of the protein–polyphenolic complex is to obtain the polyphenolic fraction as pure as possible for characterization purposes and to determine the extent of depolymerization. On the assumption that the complex is not strongly bound, we tried to dissociate by preferential solubilization.

Indulin ATR is almost totally soluble in THF (about 95%) and is routinely analysed by size exclusion chromatography using THF as eluent. The solubility of APPL in THF is quite low: 8.0% and 2.3% for the APPL produced by *S. badius* and *S. viridosporus* respectively, by comparison with that in DMF: 95%. These results indicate that a combination of these solvents may be able to dissociate the complex.

As shown in Table 4, we solubilized the APPLs sequentially with different ratios of THF:DMF. The quantification of each fraction as percentage of the starting material shows that the solubility distribution is different for each APPL.

In both cases, an important residue is obtained, indicating that the association of the fractions solubilized by the THF-rich solvents is required for complete solubilization of APPL in DMF.

The nitrogen quantification by elemental analysis of each fraction indicates an increase in nitrogen content as the sequential solubilization proceeds, with a maximum between

*Percentage of oxygen is calculated by difference.

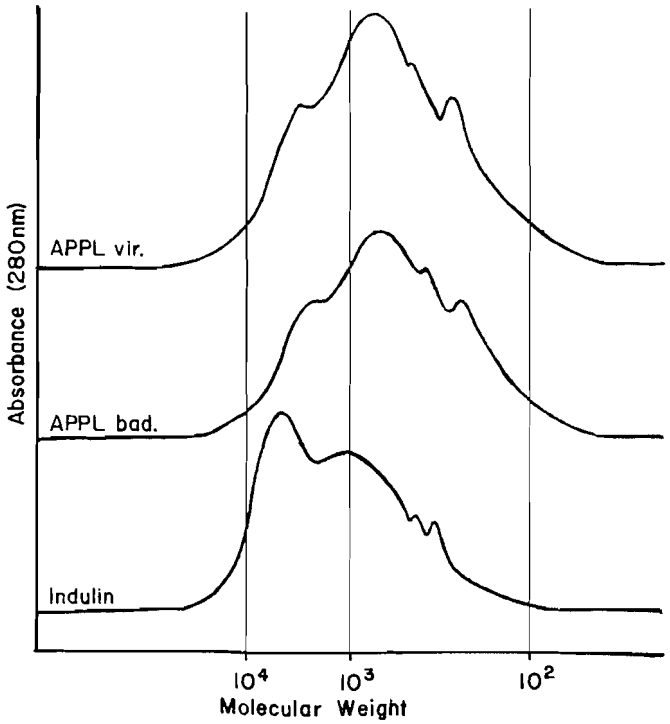

FIG. 4. High performance size exclusion chromatography of Indulin ATR and of the THF soluble fraction of each APPL.

8.7% and 9.9% for the insoluble residues. It thus appears that the THF fraction is the more polyphenolic, with only 1% nitrogen, and the residue is more protein-like, with about 9% nitrogen. These features become more obvious from the FTIR spectra for each fraction of *S. badius* APPL (Fig. 3). As the fractionation proceeds with increasing solvent polarity, the characteristic lignin bands: 1515, 1460, 1265, 1095, 1035, and 810 cm^{-1}, disappear and the characteristic amide bands at 3290 and 3080 cm^{-1} appear.

The THF-soluble fractions of each APPL and Indulin ATR were subjected to high performance size exclusion chromatography using THF as eluent. The data are reported in Fig. 4. THF-soluble fractions of the APPLs derived from *S. viridosporus* and *S. badius* consisted of a broad range of molecular weights, the distribution being similar to that of Indulin ATR, with the difference that the proportion of high MW was lower in the APPL fractions. For both there was a significant increase in the amount of the middle MW range (MW 1000) accompanied by a decrease in the amount of high molecular weight material (MW > 2500).

Moreover, all the fractions obtained after HPSEC fractionation and analyzed by FTIR are chemically equivalent and are similar to the parent Indulin ATR (data not shown).

Discussion

This paper deals with the chemical characterization of acid precipitable intermediates found in the cultures of *S. badius* and *viridosporus* grown with Indulin ATR lignin as a carbon source. We have shown in a previous paper (13) that about 7% of the initial Indulin ATR could be recovered as water soluble acid precipitable intermediates in the medium of 35-day bacterial cultures of these *Streptomyces*. Furthermore, bacterial intra- and extra-cellular proteins incubated with Indulin ATR also brought about a partial solubilization of the substrate. Given the fact that an increase of the bacterial biomass was observed during the incubation of Indulin ATR for both *Streptomyces*, we can conclude that a kraft lignin can be degraded by such species, as has been shown by Crawford *et al.* with lignocellulosics, their work being quoted and accepted as evidence. The most widely accepted hypothesis is one that states that the degradation is due to enzymatic attack. Despite their extensive studies, Crawford *et al.* have not reported the isolation of ligninolytic enzymes.

The most important result presented in this paper, which will lead us to a second, new hypothesis, is that the APPL intermediates are in fact associative complexes of lignin and protein. The first indication that led to such a conclusion is the high percentage of nitrogen detected by elemental analysis in the crude APPLs, the possibility of an association being confirmed first by an amino acid analysis, then by FTIR and sequential solubilization. The presence of characteristic lignin bands in the APPLs infrared spectra indicates that, indeed, the intermediates contain Indulin ATR fragments, while other bands characteristic of amino acids confirm the presence of a protein fraction associated with the lignin part. The fact that yeast extract is not a source of contamination is supported both by the amino acid and the FTIR analyses of the APPLs obtained from a medium with or without extract.

Both the yields and the distribution of the amino acids recovered in the analyses are similar (Table 2). Furthermore, a significant difference is found in the ratio polar/aliphatic A.A. determined for the yeast extract as compared to the same ratio in the case of proteins associated with the soluble intermediates.

The FTIR spectra in each case, with and without, are identical. This indicates that the protein fraction is indeed added by the microorganisms themselves and is not taken from the incubation medium.

The protein-free fraction represents approximately 60% of the APPL weight. Thus, the corrected yield of APPL production after a 35-day incubation is about 3.5–4% and is very close to that obtained when *S. viridosporus* was grown on spruce lignocellulose (9).

Despite the variations among the five analyzed sugars, the summative percentage of carbohydrates remains constant with carbohydrates being less than 1% of the mass. This result shows that APPLs are not significantly complexed with polysaccharides, in agreement with Crawford (11), who found that neither *S. viridosporus* nor *S. badius* cells produce substantial amounts of extracellular polysaccharides.

The fact that proteins are detected in the intermediates suggests that they may be responsible for a detergent-like action. This new hypothesis states that these proteins associate themselves with smaller, pre-existing lignin fragments found in Indulin ATR (19) in much the same way that detergent surrounds oil. This action causes the lignin fragments to go into solution in the form of a complex.

Observations such as differences in the HPSEC chromatograms and methoxyl content between the starting material and the lignin part of the intermediates can be explained by the hypothesis of detergent-like action as well as by that of enzymatic attack.

The enzymatic degradation of Indulin should *a priori* cause a shift in the molecular weight distribution of the lignin derivatives towards smaller values. To obtain this distribution it is necessary to initially dissociate the soluble complexes so as to obtain as pure a polyphenolic fraction as possible. Table 4 shows that pure THF solubilizes a small amount of material with a low percentage of nitrogen. A series of subsequent extractions using mixtures of THF:DMF that grow progressively richer in DMF leads to fractions with a higher nitrogen content. Finally in 100% DMF the insoluble residue contains 9–10% nitrogen. Thus, in this system, the Indulin fragments are progressively washed out. This is confirmed by the infrared analyses (Fig. 4) in which we see the progressive disappearance of the characteristic lignin bands and the appearance of the amide bands as the polarity of the solvent increases. Although it is clear that proteins and Indulin fragments are not covalently bound, the separation of the two constituents of the complex is difficult and only the fraction soluble in pure THF contains reasonably pure lignin. Size exclusion chromatography of these fractions derived from APPL produced in cultures of *S. badius* and *S. viridosporus* (Fig. 4) reveals polydisperse distributions, the largest difference between these data and Indulin ATR being that the predominant high molecular weight lignol detected in the APPL is DP 16 while in Indulin ATR it is DP 32. This does not necessarily indicate that the APPL lignin fragments are depolymerized Indulin ATR resulting from a specific enzymatic attack since they only represent a fraction of the APPL, which is also a fraction of the starting material. These lower molecular weight fragments could also result from a preferential Indulin solubilization.

The decrease in the methoxyl content could be explained as well by the existence of demethoxylating enzymes or by preferential solubilization of low methoxyl content fragments via a detergent-like mechanism.

Since we cannot prove conclusively which is the correct hypothesis to explain the APPL formation, further experiments must be planned to determine if one or the other hypothesis, or a combination of both, could explain the phenomenon. Meanwhile, we believe that these two theories are not contradictory. Moreover, the fact that the bacterial biomass increases cannot be a result of anything other than the use of Indulin ATR as a carbon source, this certainly due to an enzymatic attack. The production of APPL in itself being a side effect is probably due to surfactant-like reaction, as the presence of proteins would seem to indicate.

S. P. MOULIK and SYAMASRI GUPTA. Can. J. Chem. **67**, 356 (1989).

The hydration numbers of some polyhydroxy non-electrolytes and polyoxyethylenated non-ionic surfactants have been determined and found to depend considerably on the method used, the general order being conductometry < ultrasonic interferometry < ir, spectrophotometry. PEG and Tx-100 are exceptions to this trend. The results from ultrasonic interferometry study strongly depend on the data treatment. The maximum hydration obtained using the ir method shows fair agreement with recent nmr and low angle light scattering results on similar compounds. The results indicate the existence of both strongly and loosely bound water molecules with the micelles as well as the penetration of water in the non-polar micellar region.

Key words: hydration, non-electrolytes, non-ionic surfactants, conductometry, ultrasonic, near infrared.

S. P. MOULIK et SYAMASRI GUPTA. Can. J. Chem. **67**, 356 (1989).

On a déterminé les nombres d'hydratation de quelques composés non-électrolytes polyhydroxylés et de quelques agents de surface non-ioniques polyoxyéthylénés et on a trouvé que ces valeurs dépendent grandement de la méthode utilisée pour les déterminer et que l'ordre général est le suivant : conductimétrie < interférométrie ultrasonique < spectrophotométrie ir. Le PEG et le Tx-100 sont des exceptions à cette tendance. Les résultats obtenus à l'aide de l'interférométrie ultrasonique dépendent beaucoup de la façon dont les données sont traitées. L'hydratation maximale qui est réalisée par la méthode ir présente une bonne corrélation avec celle obtenue récemment par rmn et par diffusion de la lumière sur des composés semblables. Les résultats suggèrent l'existence de molécules d'eau tant fortement que faiblement liées aux micelles ainsi que la pénétration de l'eau dans la région non-polaire de la micelle.

Mots clés : hydratation, non-électrolytes, agents de surface non-ioniques, conductimétrie, ultrasonique, infrarouge proche.

[Traduit par la revue]

Ions and non-polar molecules interact with water so that the molecules of the latter get attached to the former, lose their identity from the bulk water and ultimately yield separate kinetic entities. Polyhydroxy compounds readily hydrate and non-ionic surfactants with polyhydroxy groups are solubilised in water through hydration at their available hydroxy centres. The outer mantle of the micelle is protected through hydration, their microscopic properties such as catalysis, local viscosity, solubilisation etc. are functions of hydration and the vicinal water structure. In our effort to characterise micelles and polyhydroxy compounds in aqueous medium we have been interested in their hydration behaviour (1, 2). Informations on small hydroxy non-electrolytes are available but those on relatively large molecules are rather meager. Different methods (3–6) such as viscosity, diffusion, light scattering, etc. have been mostly used for this purpose. Nuclear magnetic resonance studies (7, 8) have also been found suitable. We have used conductometry, ultrasonic interferometry, and near-ir spectrophotometry as experimental approaches. In some recent and earlier studies (9–15) similar methods have been used. The results of investigations are likely to depend on the methodology (7), particularly so if different methods are based on equilibrium or non-equilibrium principles. If the hydrated entities are under constant shearing stress (as in viscosity) or are under constant influence of compression and rarefaction (as in ultrasound) the method would essentially monitor the strongly attached water molecules. On the other hand an unperturbed equilibrium method (as ir spectrophotometry) should yield the total hydration, which includes both strongly and weakly bound water molecules. A comprehensive single study employing equilibrium as well as non-equilibrium methods is therefore warranted. The present article is an attempt to achieve this.

The polyhydroxy compounds studied include D-fructose, D-glucose, sucrose, two polyethylene glycols, and five non-ionic surfactants containing polyoxyethylene residues. Such surfactants find extensive applications in biomedical, pharmaceutical, and industrial fields.

Experimental

Materials

D-Fructose, D-glucose, sucrose, the two polyethylene glycols of average molecular weights 400 and 600, respectively, and *p-tert*-octyl phenoxy polyoxyethylene ether (Triton-100) were of BDH pure grade and used without further purification. Polyoxyethylene sorbitan monolaurate (PSML), polyoxyethylene sorbitan monopalmilate (PSMP), polyoxyethylene sorbitan menostearate (PSMS), and polyoxyethylene sorbitan mono oleate (PSMO) were products of Sigma Chemical Company, USA. All the compounds contained 20 oxyethylene units and 27 oxygen centres. They were purified by partitioning between water and chloroform. Thin layer chromatography (6, 16) of the purified samples and Tx-100 with water-saturated butanol as the mobile phase indicated the absence of free polyethylene glycols. Microanalysis of the elements carbon, hydrogen, and oxygen agreed on the average to within 1% of the calculated values.

The critical micelle concentrations of the surfactants were measured by surface tension method and compared with the literature values (17, 18) (PSML, 0.05 m*M*, lit. 0.05 m*M*; PSMP 0.02 m*M*, lit. 0.023 m*M*; PSMP 0.019 m*M*, lit. 0.021 m*M*; PSMO 0.012 m*M*, lit. 0.01 m*M*; Tx-100, 0.22 m*M*, lit. 0.20 m*M*).

Techniques

All the solutions were made with double distilled conductivity water

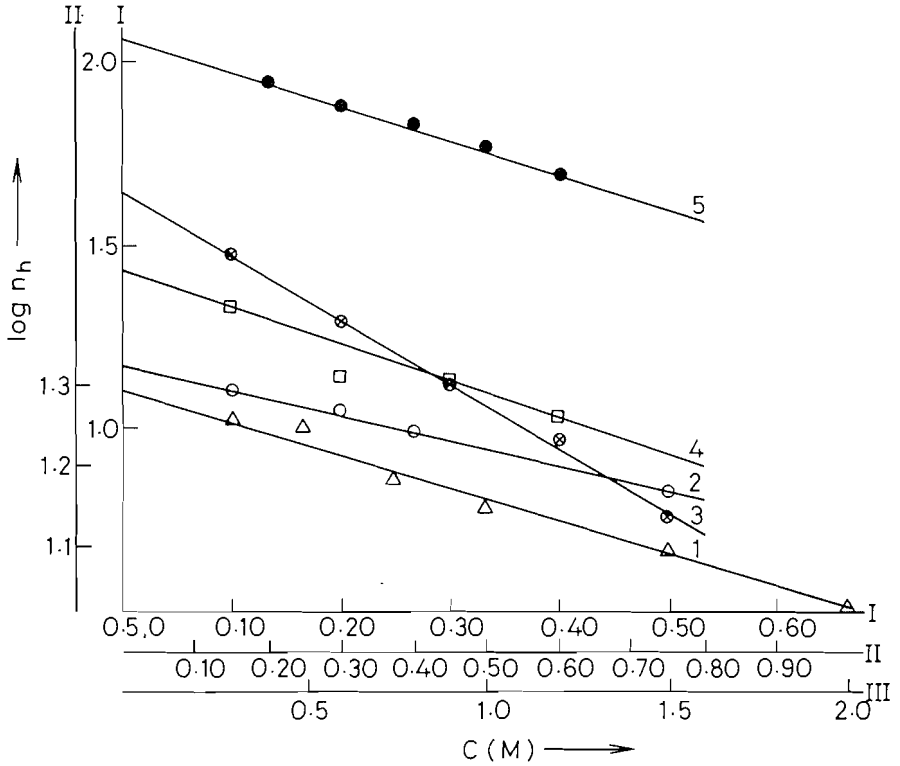

FIG. 1. Concentration-dependent hydration obtained by the near ir method. Lines 1–5 represent Sucrose (II–III), PEG 400 (I–I), Tx-100 (I–I), PEG 600 (I–I), PSML (I–II).

of specific conductance 1.0–2.0 μmho cm^{-1} at 303 K. The experimental temperature was maintained at 303 ± 0.10 K. The near-ir spectrophotometric measurements were recorded at 958 nm in a Carey 17 D apparatus using a 5 mL stoppered quartz cell. The absorbances of pure water and solution were measured against air in a set. Each set was duplicated and the mean absorbance used in the calculation.

The ultrasonic velocities were measured at a frequency of 1 MHz in an ultrasonic interferometer of Mittal Enterprises, New Delhi, India. The instrument generated ultrasound waves by a pulsating quartz crystal. The average of at least 20 readings was considered for each concentration in a set. The sets were duplicated to minimise experimental errors.

The conductance measurements were taken with a PR 9500 Philips India conductivity bridge using a cell of cell constant 1.0 cm^{-1}. The calibration of the bridge was checked against a standard resistance. At least duplicate measurements were made and the average value used in the calculation. For the procedural details please see our earlier publications (1, 9, 10). The densities of the solutions were measured in a calibrated pycnometer (1) of long uniform neck with close graduations.

The standard deviations of absorbance, sound velocity, specific conductance, and density were ±0.5%, ±0.36%, ±1%, and ±0.006%, respectively.

Treatment of data

Infrared spectrophotometry

The spectrophotometric data were processed following the procedure of Bonner and Woolsey (14) and Hollenberg and Ifft (15). The relevant equation is given by

$$[1] \quad A_d = A_r - A_s = k_1\{[H_2O]_r - [H_2O]_s\} + k_2(1-f)[X]_r$$

where A_r and A_s refer to the absorbances of the reference (pure water) and the solution, respectively. $[H_2O]_r$, $[H_2O]_s$, and $[X]_r$ are the concentrations of water monomers in reference medium, water monomers in the solution and the hydrogen bonded or polarized water in reference medium respectively, k_1 and k_2 are the respective molar absorptivities multiplied by path length ($k = \epsilon L$) of water monomer and hydrogen-bonded water, and f is the volume fraction of water in the solution. Bonner and Woolsey (14) have shown how $k_1[H_2O]_r$ and $k_2[X]_r$ can be evaluated from the absorbance of pure water and that of a saturated solution of a non-absorbing solute. Such values when used in eq. [1] can yield the value of $k_1[H_2O]_s$.

The hydration number is envisaged as the fraction of monomeric water molecules removed by a mole of solute in 1000 g solvent. If Y is the fraction of monomeric water removed due to hydration of the solute, then

$$[2] \quad Y = \frac{k_1[H_2O]_r - k_1[H_2O]_s}{k_1[H_2O]_r}$$

and the hydration number

$$[3] \quad n_h = \frac{Y(55.5)}{m} = \frac{55.5}{m}\left(\frac{k_1[H_2O]_r - k_1[H_2O]_s}{k_1[H_2O]_r}\right)$$

where m is the molal concentration of the solute. The reported n_h values are obtained by plotting log n_h vs. m, extrapolated to zero concentration (Fig. 1).

Ultrasonic interferometry

The velocity of sound wave u was determined (19) from the relation

$$[4] \quad u = \lambda F$$

where F is the frequency and λ is the wavelength.

The adiabatic compressibilities of the solvent water and the solution were determined from the relationship,

$$[5] \quad \text{Compressibility} = -\left(\frac{\partial v}{\partial P}\right)_T \frac{1}{V} = \frac{1}{\rho u^2}$$

where V, P, ρ, and u stand for the volume, pressure, density, and sound velocity, respectively. The hydration numbers were computed from the following relation (20)

$$[6] \quad n_h = \frac{n_w}{n_s}\left(1 - \frac{\beta}{\beta_0}\right)$$

where n_w and n_s are the number of moles of water and solute, respectively, present in solution; β and β_0 represent the compressibilities of solution and water, respectively. The n_h values were calculated for different concentrations using eq. [6]. The values reported in Table 1 are the extrapolated values of n_h vs. c plots shown in Fig. 4 (unprimed numbers). Equation [6] is applicable to only small molecules and ions assuming them to be incompressible. Except for the carbohydrates, most of the solutes used in our study were compressible. Thus a more judicious choice would be the equation of Shiio (11) valid for both compressible and non-compressible solutes.

$$[7] \quad (\beta/\beta_0 - V_0)/C = (\beta_1/\beta_0)\frac{1}{\rho_1} - \left(v_0 - \frac{v_2\beta_2}{\beta_0}\right)\Big/ C$$

where β, β_0, β_1, and β_2 represent adiabatic compressibilities of the solution, solvent, solute, and bound water respectively, v_0, v_2 and V_0 are the apparent specific volume fraction of bound water, specific volume fraction of bound water and apparent specific volume fraction of the total solvent, respectively. ρ_1 is the density of the solute and C is the concentration of the solute in g/mL of solution. Gekko and Noguchi (21) have recently used this equation for polymeric carbohydrates. For a non-compressible solute $\beta_1 = 0$, hence eq. [7] becomes

$$[8] \quad (\beta/\beta_0 - V_0)/C = -(v_0 - v_2\beta_2/\beta_0)/C$$

Equation [7] can be rearranged as

$$[9] \quad (\beta/\beta_0 - V_0)/C - \left(\frac{\beta_1}{\beta_0}\right)\frac{1}{\rho_1} = -(v_0 - v_2\beta_2/\beta_0)/C$$

and used for compressible solutes. The left hand side of eqs. [7] and [8] has been plotted against concentration for compressible and non-compressible solutes, respectively, and the extrapolated values used to calculate hydration. A representative presentation on the basis of eq. [8] is shown in Fig. 2. In the

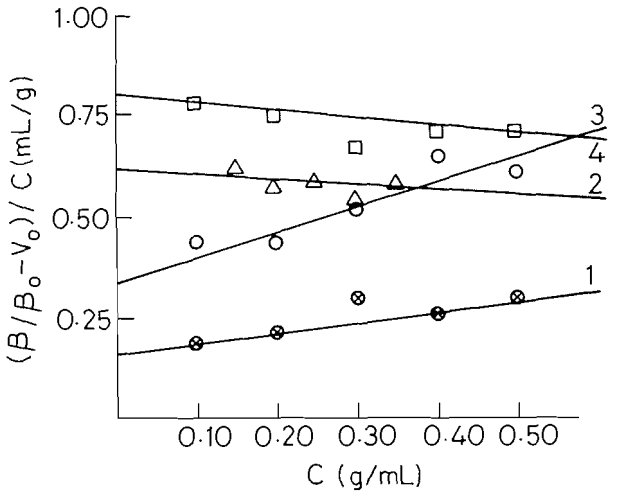

FIG. 2. $(\beta/\beta_0 - V_0)/C$ versus C plots from ultrasonic measurements; lines 1–4 represent PEG (600), PSMS, PSMP, Tx-100.

calculation v_2 has been assumed identical with the compressibility of ice (12, 21) i.e. 18×10^{-12} cm^2/dyn. β used in eq. [6] can be corrected for the solute compressibility by an alternative treatment of the ultrasonic data. The term β of eq. [6] must include the compressibility of the hydrated solute over and above that of free water. The ratio β/β_0 is therefore greater than that obtained and derived hydration is thus lower than the actual value.

The observed compressibility β may be written as

$$[10] \quad \beta = \beta_0 v_0^f + \beta_1 v_1^f$$

where β_0 and β_1 are the compressibilities of pure water and solute respectively; v_0^f and v_1^f are their respective volume fractions. The required quantity for the calculation of hydration using eq. [6] is the compressibility of the unbound water, $\beta_0 v_0^f = (\beta - \beta_1 v_1^f)$ and not β. By eqs. [6] and [10] we have

$$[11] \quad n_h = \frac{n_w}{n_s}\{1 - (\beta - \beta_1 v_1^f)/\beta_0\}$$

The hydration numbers calculated by eq. [11] have been plotted against concentration (primed numbered lines of Fig. 4) and the extrapolated values are presented in column 7 of Table 1.

Conductometry

The hydration values were obtained using the equation

$$[12] \quad K'/K = 1 - 1.98\, v_h(K'C/K)$$

where K' and K are the specific conductances of a non-interacting strong electrolyte in the presence and absence of a solute having hydrated specific volume, v_h, respectively: C is the concentration in g/mL. The v_h values have been obtained from the slopes of the linear plot of K'/K against $K'C/K$ (Fig. 3). Subtraction of the anhydrous specific volume from v_h has yielded the hydration values presented in Table 1. Equation [12] is valid in low concentration range (9), therefore the reported hydration is considered independent of concentration.

Partial molal quantities

The apparent molal volume $\bar{V}_1$ of the solute has been calculated from the following relation

$$[13] \quad \bar{V}_1 = \frac{M}{d} + \left(\frac{d_0 - d}{Mdd_0}\right) \times 10^3$$

where d_0 is the density of water, d is that of the solution, and M is the molecular weight of the solute. The partial molal volume of the solute $\bar{V}_1^0$ has been obtained from the extrapolated value of the linear plot of $\bar{V}_1$ vs. m.

The partial specific compressibility of the solute $\bar{\beta}_1^0$ has been calculated from the relation

$$[14] \quad \bar{\beta}_1^0 = (\beta_0/\bar{v}_1^0) \lim_{C \to 0} \left(\frac{\beta}{\beta_0} - V_0\right)\Big/ C$$

where the new term $\bar{v}_1^0$ is the partial specific volume of the solute, given by the relation

$$[15] \quad \bar{v}_1^0 = \lim_{C \to 0} (1 - V_0)/C$$

The partial molal compressibility $\bar{V}_1^0\bar{\beta}_1^0$ has been then calcu-

lated. It signifies the pressure-dependent differential coefficient of the partial molal volume.

Results and discussion

Comparison of the methods

This work is a comprehensive approach of determining hydration using equilibrium as well as non-equilibrium methods. Representative graphs for the three methods are presented in Figs. 1, 3, and 4 which signify that individual methods are applicable to the solid compounds D-fructose, D-glucose, and sucrose as well as to the liquid compounds, the polyethylene glycols, Tx-100, and the polyoxyethylene sorbitan class (the tweens). Columns 2–4 of Table 1 show that except for the polyethylene glycols, the infrared spectrophotometry has given

significantly higher hydration numbers than either conductometry or ultrasonic interferometry. There is no general agreement between the last two methods, particularly for compressible solutes. The degree of disagreement depends on the ways of accounting for the compressibility of the solutes. The hydration numbers are found to depend on the methodology.

The analysis of the results obtained by the non-equilibrium method of conductometry is based on the concept of obstruction (22–24) to the ionic transport offered by the hydrated solutes or surfactant micelles. When obstructed, the ions take a detour, resulting in an increase in the overall resistance of the solution. They may, however, penetrate (22) the loosely solvated portion of the solute. This may lead to lower hydration that corresponds to the primary hydration envisaged by Frank and Evans (25). In the equilibrium ultrasonic method, the solvent molecules in the bulk as well as in the loosely attached portion of the hydration envelope undergo repeated compression and rarefaction, the strongly held portion being least affected. This method would thus monitor only a part of the total hydration. On the other hand, the near-ir equilibrium spectrophotometric method remains unperturbed by any of the above effects, and should thus monitor both the rigidly and loosely held water molecules by the solute. The results obtained support this view.

There is an apparent agreement between the conductance and ultrasonic results of hydration when eq. [6] is used. Except for the carbohydrates, all the other compounds studied are large and compressible. Shiio's equation [9] is applicable to these. The hydration derived from eq. [9] is greater than that from eq. [6].

The hydration numbers calculated by eq. [11] (column 7 of Table 1) show improvement over the values obtained by using eq. [6] as well as eq. [9] (cf. Fig. 4). They are considered reasonable but do not satisfactorily agree with the results from the ir method. It is to be noted that the hydration results evaluated by the ultrasonic interferometry strongly depend on the data treatment. We may mention here that the simple proportional contributions of the solvent and the solute to the overall compressibility, considered in eq. [11] is a limitation of the approach. The assumption of comparable compressibilities of ice and hydrated water in the calculation (12, 21) is also not above criticism. In principle the compressibility of water bound to a solute is expected to be different from the compressibility of water in ice (18×10^{-12} cm^2/dyn). For lack of such data the overall compressibility of ice has been used in the calculation.

The hydration numbers of the solutes have been found to significantly depend on the method, the general order being conductometry < ultrasonic interferometry < ir spectrophotometry. Tx-100 and PEG are exceptions; they do not fit into this trend. We are unable to explain this discrepancy.

Solute-dependent hydration

The hydration behaviours of carbohydrates studied by different methods show rather wide variations. Ultrasonic results by Shiio *et al.* (12) resemble the conductance results. The hydration values of D-glucose and sucrose estimated by conductometry are comparable to those reported using the non-equilibrium viscosity method (3). From thermodynamic considerations, Stokes and Robinson (26) have shown the hydration of sucrose to be 11, and other carbohydrates are expected to bind water molecules equivalent to the number of oxygen atoms present in the molecule. The hydration results of sucrose and glucose from the ultrasonic method (eq. [6]) lend support to this view. However, these values are higher than those reported by Shiio *et al.* (11,12) (column 5, Table 1). The spectrophotometric results on sucrose, nevertheless, show fair agreement with that reported by Bonner and Woolsey (14). The subsequent discussion on surfactants is based on the results by ir spectrophotometry. It will be seen that these are consistent with the recent light scattering and nmr results on similar compounds.

In recent years, there has been much controversy over micellar hydration, particularly in the matter of water penetration into the micelles. Hartley's original model (27) of a water-free "oil droplet surrounded by an ionic coat" has been seriously questioned. Menger (28) has proposed the porous cluster model which portrays the micelle as a loose cluster of surfactant molecules with water-filled cavities. A few experimental evidence supports water penetration (29–33). Cabane (34) has presented a critical study of different micellar models. In this context reliable hydration studies are considered primary prerequisites. The present investigation is an attempt in this direction.

The experimental concentration of the surfactants studied are well above their cmc's and the hydration behaviour, therefore, ought to be considered as the weighted contributions of the monomers and the micelles. If phase separation model of the micelles is considered, the monomer concentration may be taken as constant at all concentrations above the cmc. Well above cmc, the monomer concentration is not only constant but also much smaller than the concentration of the surfactants in the micellar state. To minimize the effect of intermicellar interaction on hydration, graphical extrapolation up to cmc is required. Since measurements were taken at concentrations fairly much higher than cmc, the extrapolated to zero concentration hydration values essentially correspond to the hydration of the surfactants in their micellar state.

Nilsson and Lindman (7) have studied self-diffusion coefficient of D_2O in penta- and octaoxyethylene dodecyl ether solutions by nmr and have obtained 4.0 to 6.0 water molecules bound per oxygen of the surfactant molecules. Similar value per oxygen for a polyethylene glycol of molecular weight 20 000 has been also obtained. The increased hydration over and above the two water molecules per oxygen atom has been attributed to the ordering of water molecules around the polyoxyethylene chain. Minor temperature dependence of hydration has been observed. Saito and Sato (6) have reported light scattering studies on the water binding capacities per gram of several non-ionic surfactants such as polyoxyethylene monostearates and also polyoxyethylene octylether having 20, 30, 40 units of ethylene oxide residues, respectively (Table 2). The present hydration values from the ir method for polyoxyethylene containing surfactants (Table 2) are in reasonable agreement with the above mentioned nmr and light scattering results (6, 7). The moles of water bound per mole of oxygen are 4.0 for Tx-100, 4.42 for PSML, 5.30 for PSMP, 6.07 for PSMS, 8.84 for PSMO, 1.53 for PEG 400, and 1.93 for PEG (600). Polyoxyethylene residues present in the surfactant micelles bind more water than when they are free. The last four surfactants (Table 2) have identical hydrophilic head groups but differ in their non-polar tails. With increasing molecular length the micellar aggregation number decreases and the overall micellar size increases (6, 35–38). Large micelles trap more water. PSMS and PSMO have the same number of carbon and oxygen atoms but the latter contains unsaturation in the hydrocarbon chain. But the increased hydration of PSMO compared to PSMS is difficult to rationalize. The conductance results claim about 15% of the (maximum) hydration obtained from the ir method. This may be the strongly attached fraction of the total hydration. About 50% reduced hydration obtained by the ultrasonic method (eq. [11]) suggests that nearly one half of the total

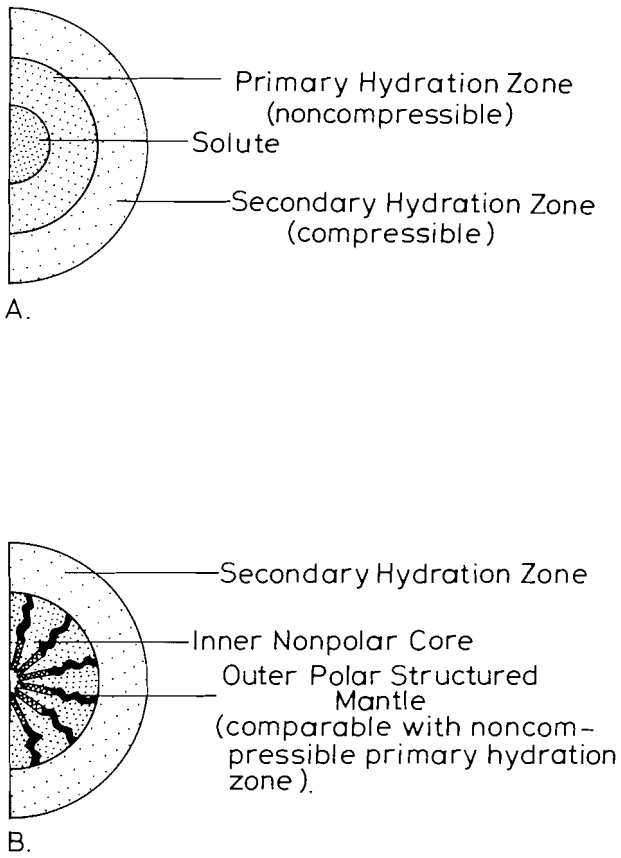

FIG. 5. Model two dimensional half profile representations of hydrated solute and micelle. *A*: a hydrated non-micelle forming solute molecule; *B*: a hydrated nonionic micelle.

hydration is softly bound, which can be melted by applying pressure. According to the recent statistical theory of Flory and Dill (39), based on lattice model, "Spectroscopic methods measure the proximity of the probe to water, interfacial and internal; whereas measurement of thermodynamic and transport properties measure only the amount of water bound internally in the core" of the micelles. In the ir method the absorbance of the water monomer in the solutions are monitored and we believe that the hydration results manifest the total water, penetration, interfacial, and internal in the micelles. The hydration values by the ir method are thus higher than those by other methods. Probable models of hydrated solutes and micelles are presented in Fig. 5. A general correlation of hydration with the total number of carbons is depicted in Fig. 6. Similar correlation with the number of oxygen atoms embracing all the solutes has not been observed. The contribution of the overall length of the molecule towards hydration is anticipated. The enthalpies of hydration of Tx-100, PSML, and PSMS have been evaluated conductometrically and found to be in the range of 20–28 kJ mol^{-1}. Shiio (11) has reported values of nearly 50 kJ mol^{-1} for carbohydrates. This appreciable enthalpy of hydration is in contrast to the results of Nilsson (7) and Lindman (6) who have observed a minor temperature dependence of hydration.

Molal and partial molal quantities

The molal volumes, partial molal volumes, excess volumes, and the partial specific and partial molal compressibilities of the solutes are presented in Table 3. The partial molal volumes are all less than molal volumes, thus the excess volumes are all negative. PSML, PSMP, PSMS, and PSMO have shown large change in volume, the last member being odd in the series. It has also shown irregularities in hydration (Table 1). We have found partial molal compressibilities of glucose and fructose to be negative, an observation similar to that of Milero *et al.* (40) who have attributed the negative compressibility for the large extent of hydration of the molecules. Their results are shown in Table 3 for comparison. The partial molal compressibilities of the other compounds are positive. The trend in the excess volume gives the order of interaction with water. The compounds of the carbohydrate family have shown negative partial molal compressibilities in good solvents (11, 18) while other polymeric compounds have shown positive partial molal compressibilities (21, 41, 42). The positive values originate from the deorganisation and the release of loosely bound water molecules from the hydrated micelles by the application of pressure. The configurational changes of the polymeric compounds may also add to this effect.

Isotherme d'adsorption du phénanthrène et de ses dérivés hydrogénés sur du nickel de Raney

FRANÇOIS BOSSÁNYI, CHAKIB AMEZIANE HASSANI, HUGUES MÉNARD[1] ET JEAN LESSARD
Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Reçu le 19 avril 1988

FRANÇOIS BOSSÁNYI, CHAKIB AMEZIANE HASSANI, HUGUES MÉNARD et JEAN LESSARD. Can. J. Chem. **67**, 365 (1989).

Des études chromatographiques ont permis de déterminer les isothermes d'adsorption du phénanthrène et de ses dérivés hydrogénés, du naphtalène et de la tétraline sur le nickel de Raney. L'adsorption de ces molécules sur le nickel de Raney dépend du nombre d'électrons π, de la position et de l'orientation des hydrogènes pouvant empêcher ou diminuer l'interaction des électrons π avec le catalyseur.

Mots clés : adsorption, phénanthrène, études chromatographiques.

FRANÇOIS BOSSÁNYI, CHAKIB AMEZIANE HASSANI, HUGUES MÉNARD, and JEAN LESSARD. Can. J. Chem. **67**, 365 (1989).

The adsorption isotherms of phenanthrene and its hydrogenated derivatives, of naphthalene, and of tetralin on Raney nickel have been determined by chromatographic studies. The adsorption of these molecules on Raney nickel depends on the number of π electrons and on the position and orientation of hydrogen atoms that can interfere with the interaction of the π electrons with the catalyst.

Key words: adsorption, phenanthrene, chromatographic studies.

Introduction

Lors de l'hydrogénation ou de l'électrohydrogénation catalytique d'un composé organique insaturé sur un catalyseur, Horiuti et Polanyi (1) et Lessard et ses collaborateurs (2, 3) décrivent les mécanismes de réaction à la surface comme suit :

[1] $2H_2O + M + 2e \rightleftarrows 2M \ldots H + 2OH^-$

[2] $M + H_2 \rightleftarrows 2M \ldots H$

[3] $M + Y = Z \rightleftarrows M \ldots (Y = Z)$

[4] $2M \ldots H + M \ldots (Y = Z) \rightleftarrows M \ldots (YH - ZH)$

[5] $M \ldots (YH - ZH) \rightleftarrows YH - ZH + M$

Dans un premier temps, il y a formation d'hydrogène adsorbé à la surface du catalyseur obtenu par réduction de l'eau (éq. [1]) dans le cas d'une électrohydrogénation, ou par adsorption dissociative de l'hydrogène moléculaire, souvent sous pression (éq. [2]), dans le cas d'une hydrogénation catalytique. Par la suite, on a adsorption du substrat sur le catalyseur (éq. [3]) et réaction de ce dernier avec l'hydrogène adsorbé (éq. [4]). Finalement, il y a désorption du substrat (éq. [5]). Mitsui *et al.* (4–6) ont suggéré que l'étape déterminante d'une hydrogénation sur le nickel de Raney est l'adsorption du substrat sur le catalyseur.

Dans la présente étude, nous allons tracer les isothermes d'adsorption du phénanthrène et de ses dérivés hydrogénés, du naphtalène et de la tétraline sur le nickel de Raney dans le but d'identifier les facteurs qui influencent l'adsorption de ces composés. Les isothermes ont été obtenus par chromatographie en phase liquide et l'approche mathématique, pour le calcul de ces isothermes, était la même que celle utilisée par Ménard *et al.* (7) à partir de la méthode de Chuduk *et al.* (8).

Section expérimentale

Appareillage

L'équipement utilisé pour cette étude consiste en une pompe HPLC Beckman modèle 100-A, couplé avec un détecteur UV Altex Hitachi, modèle 100-40, muni d'une cellule de détection de 20 µL, relié à un enregistreur (Varian modèle FE-2). L'acquisition et le traitement des données ont été faits à l'aide d'un micro-ordinateur de type RX-8800, tel qu'utilisé par Noël (9).

Le remplissage des colonnes a été effectué avec une pompe Haskel. Les colonnes ont une longueur de 3,5 cm avec un diamètre interne de 4,6 mm.

Réactifs

Le naphthalène purifié a été obtenu de la compagnie Fisher Scientifique, le phénanthrène (≥95%) de la compagnie BDH, et le dihydrophénanthrène (≥97%) de la compagnie (Aldrich Chemical. L'octahydrophénanthrène symétrique (≥95,4%) et asymétrique (≥97,5%) ont été obtenus à partir de l'électrohydrogénation catalytique du phénanthrène sur le nickel de Raney et séparés sur colonne chromatographique. Le tétrahydrophénanthrène (≥99%) a été obtenu à partir du naphtalène selon la synthèse décrite par Haworth (10). Le nickel de Raney a été obtenu de la compagnie Aldrich Chemical.

Le dichlorométhane et l'hexane de qualité Accusolve ont été obtenus de la compagnie Anachemia. Les solvants ont été séchés sur tamis moléculaire (Type 3 Å, Grade 564) de la compagnie Fisher Scientifique.

Procédure

Tous les solvants utilisés pour le HPLC ont été désoxygénés sous vide pendant une période de 15 min et une légère surpression d'azote sec circulait au-dessus du solvant pendant la durée de l'expérience.

Le nickel de Raney, de granulométrie 53–105 µm (−140 à +270 mesh), a été lixivié par une solution de NaOH 30% pendant 7 h à 70°C. Le nickel de Raney d'activité W_4 (11) résultant a été lavé à l'eau jusqu'à la neutralité, puis 2 fois au méthanol. Finalement, on a séché sous vide pour éliminer l'hydrogène présent sur le catalyseur.

La colonne et la buse ont été remplies et compactées à sec avec le nickel de Raney W_4 et par la suite, du propanol a été pompé sous pression (31 MPa) à travers la colonne et la buse par une pompe Haskel. La colonne a été placée dans un cyclindre thermostaté à 25°C ± 0,1°C et reliée au HPLC. Le débit de l'éluant était de 0,2 mL/min.

Le HPLC a été utilisé avec une boucle d'échantillonnage de 50 µL, et les concentrations injectées étaient comprises entre 100 et 500 nmol pour tous les solutés dilués dans le toluène et entre 20 et 100 nmol pour les solutés dilués dans le dichlorométhane.

Résultats et discussion

La figure 1 représente les isothermes obtenus pour le phénanthrène, le dihydrophénanthrène, le naphtalène et la tétraline sur un catalyseur de type nickel de Raney ayant une

1. Auteur à qui adresser toute correspondance.

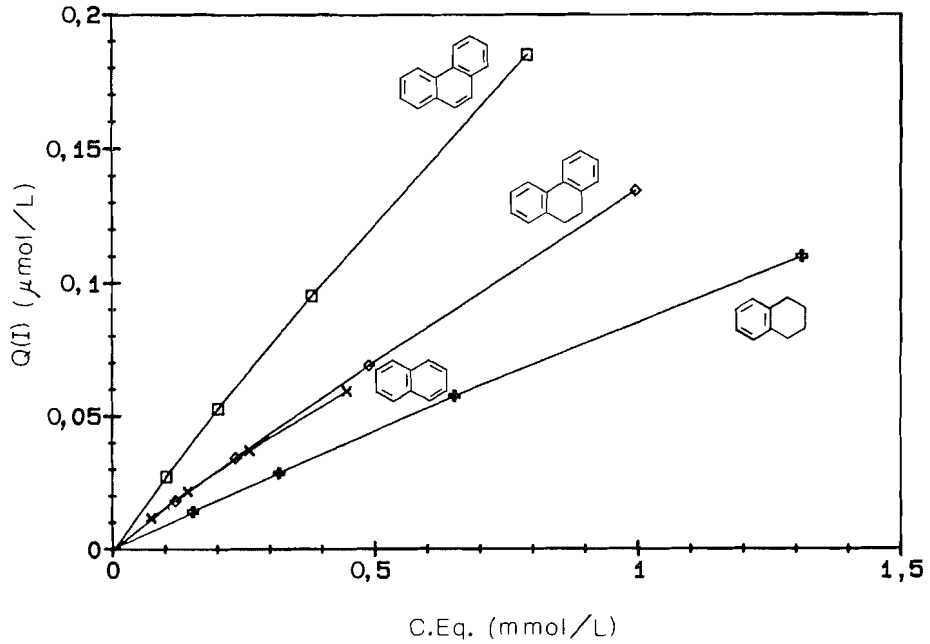

FIG. 1. Isotherme d'adsorption du phénanthrène, du dihydrophénanthrène, du naphtalène et de la tétraline sur du nickel de Raney (activé) à 25°C dans l'hexane comme solvant.

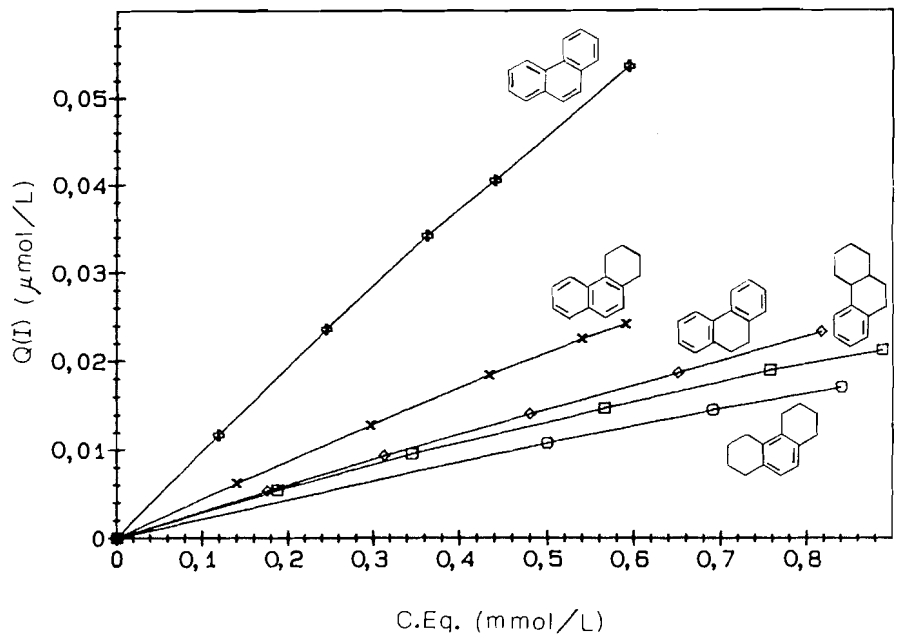

FIG. 2. Isotherme d'adsorption du phénanthrène, du tétrahydrophénanthrène, du dihydrophénanthrène et des octahydrophénanthrènes (asymétrique et symétrique) sur nickel de Raney (désactivé) à 25°C dans le dichlorométhane comme solvant.

granulométrie inférieure à 105 μm. Le solvant utilisé est l'hexane. Nous remarquons que le phénanthrène est très fortement adsorbé par rapport au naphtalène. Le dihydrophénanthrène présente une adsorption comparable à celle du naphtalène tandis que la tétraline est le composé le moins fortement adsorbé. La force d'adsorption de ces molécules dépend donc du nombre d'électrons π (14 pour le phénanthrène, 10 pour le naphtalène et six pour la tétraline).

Dans la figure 2, nous avons le tracé des isothermes d'adsorption du phénanthrène et de ses dérivés hydrogénés sur un catalyseur de type nickel de Raney ayant une granulométrie de 53–105 μm. Dans le tableau 1 sont indiquées les valeurs de la constante de Henry. Le dichlorométhane a été utilisé comme solvant. Les résultats montrent que l'adsorption dépend là encore du nombre d'électrons π. En effet les octahydrophénanthrènes avec six électrons π sont moins fortement adsorbés que le tétrahydrophénanthrène qui en compte 10. Cependant, le nombre d'électrons π n'est pas le seul facteur influençant l'adsorption puisque le dihydrophénanthrène qui comporte 12 électrons π est moins fortement adsorbé que le tétrahydrophénanthrène qui en compte 10.

L'adsorption de ces molécules fait donc intervenir une interaction entre les électrons π et le métal. Plus il y a d'électrons π en contact avec le métal, plus l'adsorption devait être forte. Il

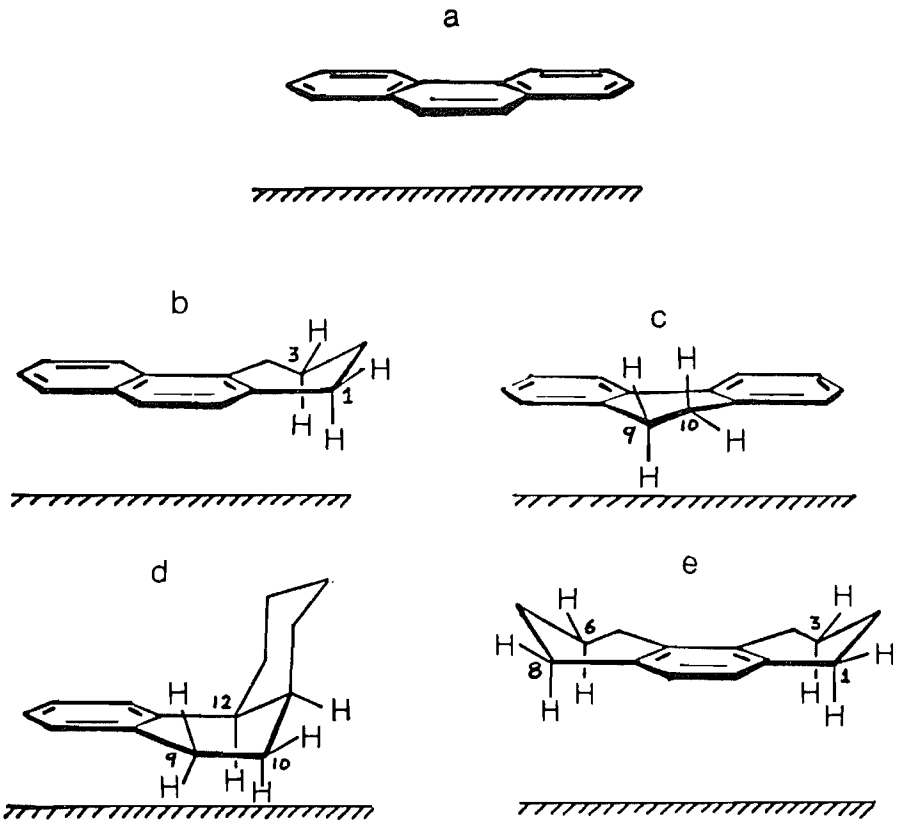

FIG. 3. Modèle moléculaire d'adsorption sur catalyseur de nickel de Raney : (a) phénanthrène; (b) tétrahydrophénanthrène; (c) dihydrophénanthrène; (d) octahydrophénanthrène asymétrique; (e) octahydrophénanthrène symétrique.

TABLEAU 1. Valeur de la constante de Henry (K_H) pour l'adsorption du phénanthrène et de ses dérivés hydrogénés sur du nickel de Raney dans le chlorure méthylène à 25°C

Substrat	K_H (cm^3/m^2)
Phénanthrène	0,0058
Dihydro-9,10 phénanthrène	0,0018
Tetrahydrophénanthrène	0,0026
Octahydrophénanthrène asymétrique	0,0016
Octahydrophénanthrène symétrique	0,0011

n'y a rien qui empêche des molécules planaires comme le phénanthrène et le naphtalène de se coucher sur la surface du catalyseur de façon à ce que tous les électrons π interviennent dans l'adsorption tel qu'illustré à la figure 3(a) dans le cas du phénanthrène[2]; ce dernier, avec ses 14 électrons π, est alors beaucoup plus fortement adsorbé que le naphtalène qui n'en compte que 10.

Eltekov et Khopina (12) ont montré par HPLC que l'adsorption des composés aromatiques sur le gel de silice dépend du nombre d'électrons π et de la longueur de la molécule selon la relation linéaire [6] :

[6] $\log K = A + B(n_\pi + n_\pi/1)$

où $K = Q(I)/C_{éq}$ *où* $Q(I)$ est la quantité adsorbée par unité de surface et $C_{éq}$ la concentration à l'équilibre, A et B sont des constantes, n_π le nombre d'électrons π, et l la longueur de la molécule selon l'axe le plus long. Cette relation, strictement parlant, devrait plutôt avoir la forme [7] :

[7] $\log K = A + Bn_\pi + Cn_\pi/1$

où C est une constante. Les auteurs ont supposé, de façon arbitraire, que les constantes B et C avaient la même valeur.

L'adsorption du dihydrophénanthrène, du tétrahydrophénanthrène et des octahydrophénanthrènes ne peut dépendre uniquement du nombre d'électrons π et de la longueur de la molécule mais doit être influencée également par la gêne stérique causée par les hydrogènes des sites saturés (voir figure 3)[2]. En effet, la molécule de dihydrophénanthrène et celle du tétrahydrophénanthrène ont sensiblement la même longueur et même si le dihydrophénanthrène a plus d'électrons π que le dérivé tétrahydro, il est moins fortement adsorbé que ce dernier. La gêne stérique causée par les hydrogènes aux positions 9 et 10 du dihydrophénanthrène doit être plus grande que celle causée par les hydrogènes aux positions 1 et 3 du dérivé tétrahydro (voir figure 3 (b et c)). Les effets stériques doivent être aussi responsables du fait que l'octahydrophénanthrène symétrique est moins fortement adsorbé que son isomère asymétrique. En étant au centre de la molécule, le noyau aromatique du dérivé symétrique ne peut pas s'approcher aussi facilement de la surface du catalyseur (interférence des hydrogènes aux positions 1, 3, 6 et 8) que le noyau aromatique situé à l'extrémité de la molécule du dérivé asymétrique (voir figure 3 (e et d)), car une légère inclinaison de la molécule de l'octahydrophénanthrène asymétrique devrait permettre de minimiser l'interférence des hydrogènes aux positions 9, 10 et 12.

2. La figure 3 est basée sur l'étude des modèles moléculaires de type Dreiding et nous n'avons pas mesuré expérimentalement l'orientation des molécules adsorbées à la surface du catalyseur.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

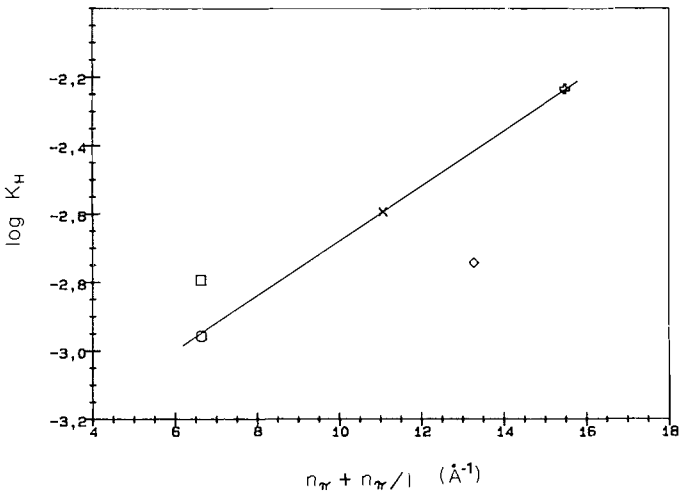

FIG. 4. Rapport de log K sur $n_\pi + n_\pi/l$ pour le phénanthrène (+), le tétrahydrophénanthrène (X), le dihydrophénanthrène (◇), l'octahydrophénanthrène asymétrique (□) et l'octahydrophénanthrène symétrique (○).

Lorsque l'on porte en graphique la quantité de molécules adsorbées en fonction du nombre d'électrons π et de la longueur de la molécule selon l'équation [6] pour l'adsorption du phénanthrène et de ses dérivés hydrogénés sur le nickel de Raney, on obtient le graphique de la figure 4. Dans la série phénanthrène, tétrahydrophénanthrène et octahydrophénanthrène symétrique, la variation des effets stériques est telle que la relation est tout-à-fait linéaire. Il s'agit évidemment d'une coïncidence. La figure illustre bien que les effets stériques sont plus importants dans le cas du dihydrophénanthrène et moins importants dans le cas de l'octahydrophénanthrène asymétrique.

Conclusion

L'obtention des isothermes d'adsorption du naphtalène, de la tétraline, du phénanthrène et de ses dérivés hydrogénés sur le nickel de Raney, montrent que l'adsorption des molécules dépend du nombre d'électrons π mais aussi de la disposition de ses électrons π dans la molécule lorsque des hydrogènes peuvent créer des interférences stériques entre la molécule et le catalyseur.

Remerciements

Les auteurs remercient le Fonds pour la formation de chercheurs et l'aide à la recherche du Québec pour le financement du projet et Monsieur Yvon Couture pour la synthèse du tétrahydrophénanthrène.

The synthesis and reactivity of α-oxosulfines[1]

IAN W. J. STILL,[2] DONALD V. FRAZER, DONNA K. T. HUTCHINSON, AND JEFFERY F. SAWYER
Department of Chemistry, University of Toronto, 80 St. George Street, Toronto, Ont., Canada M5S 1A1

Received June 9, 1988

IAN W. J. STILL, DONALD V. FRAZER, DONNA K. T. HUTCHINSON, and JEFFERY F. SAWYER. Can. J. Chem. **67**, 369 (1989).

Thiochroman-4-one and cyclohexanone have been converted into the corresponding α-oxosulfines and the behaviour of these reactive intermediates with a range of alkenes and alkynes has been examined. In contrast to some earlier work, the major reaction pathway does not involve formation of the initially expected Diels–Alder adducts but instead a series of adducts involving electrophilic addition to the alkene or alkyne, with concomitant deoxygenation and incorporation of chlorine. The structures of these adducts have been determined by the usual spectroscopic means and, in two representative cases, by X-ray crystallographic analysis. The crystal structures, which include unusual features such as relatively short S...O nonbonding contacts, are discussed in detail.

Key words: (α-oxo)sulfines, sulfenic acids, X-ray analysis, electrophilic addition.

IAN W. J. STILL, DONALD V. FRAZER, DONNA K. T. HUTCHINSON et JEFFERY F. SAWYER. Can. J. Chem. **67**, 369 (1989).

On a transformé la thiochromanone-4 ainsi que la cyclohexanone en α-oxosulfines correspondantes et on a étudié le comportement de ces intermédiaires réactifs avec un certain nombre d'alcènes et d'alcynes. La réaction principale diffère de celles qui ont été observées aux cours de travaux antérieurs; elle n'implique pas la formation initiale des adduits de Diels–Alder attendus, mais plutôt une série de produits impliquant une addition électrophile sur l'alcène ou sur l'alcyne accompagnée d'une déoxygénation concomitante et de l'incorporation du chlore. On a déterminé la structure de ces adduits en faisant appel aux méthodes spectroscopiques habituelles et, dans deux cas représentatifs, à la diffraction des rayons-X. On présente une discussion détaillée des structures qui comportent des caractéristiques inhabituelles comme des contacts non-liants S...O qui sont très courts.

Mots clés : (α-oxo)sulfines, acides sulfeniques, diffraction des rayons-X, addition électrophile.

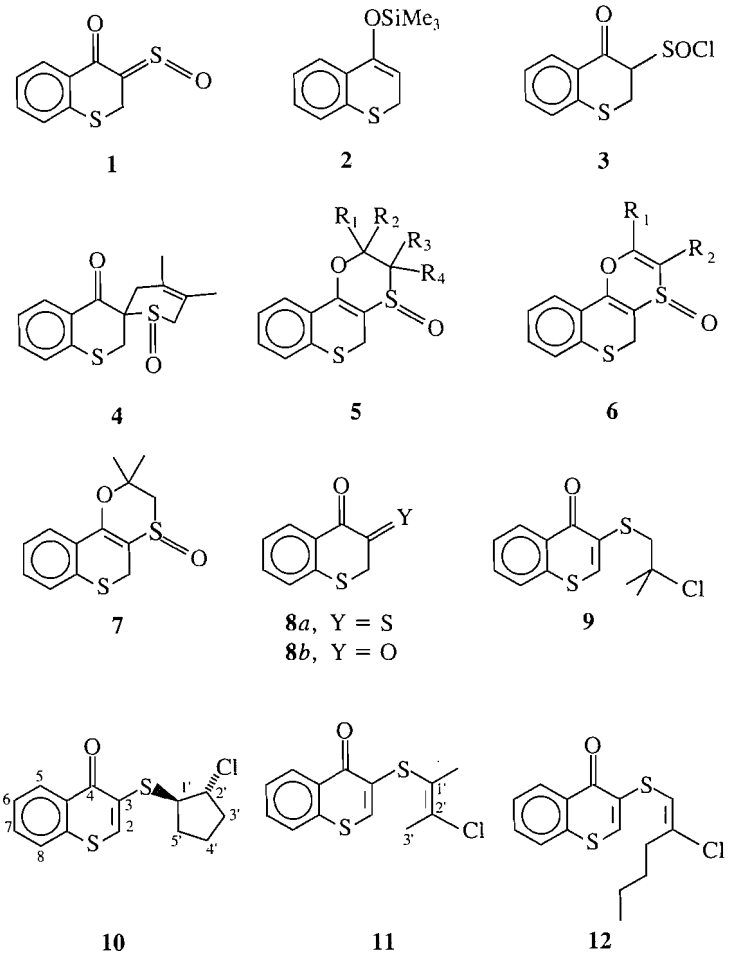
Introduction

While the chemistry of the class of organosulfur compounds known as sulfines has been thoroughly investigated in the last 25 years since their first unambiguous characterization (1) and has been reviewed recently by Zwanenburg (2), the availability of an interesting sub-class of sulfine, the α-oxosulfines, $R^1C(=O)C(=SO)R^2$ was only recently reported, independently, by the research groups of Still and Ablenas (3) and Zwanenburg and co-workers (4). Matturo and Reynolds (5) have very recently generated a vinylogous oxosulfine by the thermal decomposition of a thioozonide, the endoperoxide from 2,5-dimethylthiophene (6).

Interest in the ability of various thione and sulfine units to function as components of cycloaddition reactions, leading to a variety of heterocyclic ring systems, has recently been intense. Huisgen and Rapp (7), for example, have reported the successful addition of thiobenzophenone *S*-sulfide (a thiosulfine) with various dipolarophiles. Steliou *et al.* (8) have examined the generation and Diels–Alder dienophile reactivity of disulfur (S_2). Ando and co-workers (9) have successfully trapped 1,2-dithiones with suitable olefins although, interestingly, a 1,2-dithione prepared by Cava and Atwood (10) was unreactive towards both electron-rich and electron-poor dienophiles. In another interesting contrast, Huisgen and Peng (11) showed that thionitroso *S*-sulfides (thiosulfinylamines) react as 1,3-dipoles with suitable alkenes to give 1,2,3-dithiazolidines, whereas Zoller and Rona (12) have found that *N*-sulfinylanilines react as *dienes* in Diels–Alder reactions with benzalanilines to give six-membered thiadiazine derivatives.



While C=S units in both simple sulfines (2, 13) and α-oxosulfines (3, 4, 14) have been observed to function as *dienophiles* in the Diels–Alder reaction with conjugated dienes such as 2,3-dimethyl-1,3-butadiene, we were interested in examining the potential use of α-oxosulfines as *dienes* in this type of reaction (14). Since we expected α-oxosulfines to be basically electron-poor, we have examined the use of various electron-rich alkenes and alkynes for this purpose. The "inverse-demand" Diels–Alder reactions which might be expected to result would lead to 5,6-dihydro-1,4-oxathiins or 1,4-oxathiins, respectively, — compounds of considerable potential interest for their fungicidal activity (15, 16). We now present our findings involving two separate series of α-oxosulfines and their behaviour towards various alkenes and alkynes. Surprisingly, and in sharp contrast to earlier results (3, 14), the products observed do not result from the Diels–Alder reaction.

Results and discussion

We decided to first prepare 3-sulfinylthiochroman-4-one **1** by modifying our successful approach to the synthesis of the 3-alkylidene analogues (17), using the trimethylsilyl enol ether **2** as the starting point. It is well known that activated methylene compounds react directly with thionyl chloride in many cases (18, 19) and this subject has been comprehensively reviewed by Oka (20), but mixtures of products are frequently formed and the reactions are notoriously sensitive to the reaction conditions employed. The initially expected α-sulfinyl chloride **3**, arising from C-sulfinylation of **2**, would be expected to rapidly lose HCl (20) to form the α-oxosulfine **1**. This elimination was found to proceed even in the absence of base, but best results were achieved using 2,2,6,6-tetramethylpiperidine (1 equiv.) at low temperatures. Since the α-oxosulfine did not precipitate from the reaction mixture, and hence was expected to be unstable (14), its presence was first confirmed by trapping with 2,3-dimethyl-1,3-butadiene to form the expected Diels–Alder adduct **4**. Compound **4** showed the expected C=O and S=O

bands in the ir spectrum at 1670 and 1052 cm^{-1}, respectively. Its ^1H nmr spectrum (see Experimental) was also in accord with expectation and the molecular formula ($C_{15}H_{16}O_2S_2$) was confirmed by high-resolution mass spectral analysis. (The intermediate sulfine **1** is assumed to possess the *Z*-configuration shown, since the corresponding *E*-isomer would exhibit a very unfavourable dipole–dipole repulsion.) Some of the ketone corresponding to the enol ether **2** was also isolated in the above reaction, due either to hydrolysis and desulfonylation (21) of unreacted α-oxosulfine during work-up or to hydrolysis of unreacted silyl enol ether.

Having demonstrated the effectiveness of this approach to the generation of the α-oxosulfine we then proceeded to examine the behavior of **1**, a potential electron-deficient *diene* component, in the Diels–Alder reaction with a number of relatively electron-rich alkene and alkyne dienophiles (3, 4). Added interest derived from the fact that success in this endeavour might produce novel 1,4-oxathiins such as **5** and **6**. This type of ring system was virtually unknown until our earlier work with the thiochroman-4-one 1,1-dioxide analogs (3).

Our first attempt at this type of trapping of **1** employed an excess of 2-methylpropene at −78°C under similar conditions to those used to prepare **4**. On the basis of the charge densities in both the diene and the dienophile, it was predicted that the regiochemistry of the Diels–Alder reaction of **1** and 2-methylpropene would lead to **7**. After extensive purification by crystallization, two products — a yellow solid *A*, mp 87–88°C (19%), and tan needles *B*, mp 156–157°C, were isolated. Five aromatic protons and two singlets corresponding to six and two protons, respectively, were observed in the ^1H nmr spectrum of *A*. This did not correlate with the spectrum expected for **7**. The mass spectrum of *A* showed two peaks corresponding to mass units 284 and 249, with relative intensities of 5 and 41% respectively. Compound **7** ($C_{13}H_{14}O_2S_2$) would have an expected molecular ion peak at m/z = 266. The observed ion at m/z 284, however, indicates a product of formula $C_{13}H_{13}ClOS_2$ (^{35}Cl isotope). The peak at m/z 249 could then be attributed to loss of chlorine. Sodium fusion and Beilstein tests independently confirmed the presence of chlorine in *A*. In the infrared spectrum of *A*, there was, in addition, no peak indicating the presence of a sulfoxide group. Confirmation of the molecular formula of *A* as $C_{13}H_{13}ClOS_2$ was also obtained from the elemental analysis.

Compound *B*, the other product isolated from the reaction mixture above, remains unidentified. However, evidence from the ^1H nmr, ir, and mass spectra and elemental analysis indicates that *B* is probably a low molecular weight polymer of 3-thioxothiochroman-4-one, **8***a*. Loss of oxygen from the *S*-oxide probably occurs in the α-oxosulfine **1** itself, or possibly after polymerization.

An analogous trapping reaction of the α-oxosulfine **1** with cyclopentene was also carried out. The spectral evidence (^1H nmr, ir, mass spectrum) and elemental analysis once again indicated that the product (41%) was *not* a Diels–Alder adduct of type 5 — but a compound with the composition $C_{14}H_{13}ClOS_2$. The ^1H nmr spectrum showed a multiplet at δ 2.1 corresponding to the six methylene protons of a 1,2-disubstituted cyclopentane and two multiplets at δ 3.7 and 4.2. Three aromatic protons

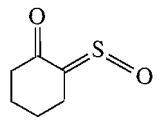
8.5	129.07	C-5

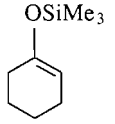
[a]The 2D nmr spectra were recorded on a different spectrometer from the original ^1H and ^{13}C nmr spectra, accounting for the slight differences in chemical shift observed.

appeared as a multiplet at δ 7.4 and additional signals were observed in this region as a singlet at δ 7.7 and a multiplet at 8.5. At this stage a single-crystal X-ray analysis was carried out (*vide infra*) which confirmed that the product was the 3-substituted thiochromone **10**. Independent proof of structure was obtained from a 2D nmr (HETCOR) analysis (22) of **10**, to correlate the protons with the carbons to which they are attached (see Table 1).



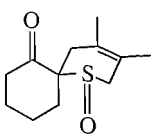
Some of the parent ketone corresponding to **2**, thiochroman-4-one, was recovered from the reaction mixture during chromatography of the crude product and indeed from all the reactions in this series. Under aqueous conditions, α-oxosulfines are known to be hydrolysed to the parent ketone, or to the corresponding α-diketone (21). In our case, it is probable that hydrolysis to thiochroman-4-one occurred on silica gel during chromatography. The alternative product of acid-catalyzed hydrolysis, the α-diketone **8***b*, was not detected in the reaction mixture.

Re-examination of the spectral data for the adduct from the previous reaction of **1** with 2-methylpropene, in the light of the very detailed structural examination of **10**, leads us to identify the analogous structure **9** as the correct one for this adduct.



With the successful formation of the cyclopentene adduct **10**, analogous preparations of the corresponding cyclohexene and cyclooctene adducts were attempted. The presence of adducts analogous to **10** could be detected in the respective reaction mixtures by ^1H nmr, but these products proved incapable of isolation in a pure state. They appear to decompose during chromatography on either silica gel or alumina. The reasons for the apparent instability of these cycloadducts are not at all clear but may be due in part to the larger, more conformationally mobile, alicyclic rings present.

Trapping of the α-oxosulfine **1** was also attempted with various alkynes to verify the generality of the above reactions. When **1** was reacted with 2-butyne at −78°C, the now expected *E*-3-(2′-chloro-1′-methyl-1′-propenylthio)thiochromone[3] **11** was isolated in 26% yield. Interestingly, this reaction was unsuccessful when attempted at −23°C. The only product isolated at the higher temperature was a tan solid which had similar physical and spectroscopic properties to those of solid *B* in the 2-methylpropene trapping experiment (*vide supra*). The ^1H nmr spectrum of **11** shows two peaks at δ 2.5 and 2.1, corresponding to the two methyl groups. A singlet for the C-2 proton appears at δ 7.3. Three aromatic protons appear as a multiplet at δ 7.5 and a further multiplet at 8.5 is assigned



[3]The *E*-geometry of **11** is assigned by analogy with the structure of the 2-butyne adduct in the 2-sulfinylcyclohexanone series (*vide infra*).

to the C-5 proton. The ^{13}C nmr spectrum (see Experimental) confirmed the presence of two methyl groups, five sp^2 *CH* carbons and six sp^2 quaternary carbons, in agreement with the assigned structure.

The trapping of **1** was also attempted using an unsymmetrically substituted alkyne, 1-hexyne. A mixture of regioisomers was isolated as a red oil, in 20% yield, in a ratio of 4:1. Only the major regioisomer **12** could be isolated in crystalline form. The ^1H nmr spectrum of **12** shows a multiplet for four aromatic protons at δ 7.5 and a peak corresponding to one proton at 8.5. The side-chain vinylic proton appears as a sharp singlet at δ 6.5. The signal for the methyl group appears as a triplet at δ 0.95 and the six methylene protons are observed as two distinct signals, a triplet (2H) at 2.5 and a multiplet (4H) at 1.5. The assignment of the structure of **12** is based on analogy with the adduct **9** from 2-methylpropene. We will return to this point later in the discussion of a probable mechanism for formation of these adducts.

We have also examined the behaviour of a much simpler α-oxosulfine **13**, derived from cyclohexanone via the usual trimethylsilyl enol ether precursor **14**, followed by reaction with thionyl chloride in the presence of 2,6-dimethylpyridine (2,6-lutidine). The expected formation of the α-oxosulfine **13** was confirmed as in the series above by a simple trapping experiment with 2,3-dimethyl-1,3-butadiene. A product ($C_{12}H_{18}O_2S$), which showed the expected bands in the ir spectrum at 1707 (C=O) and 1050 (S=O) cm^{-1}, was formed in 46% yield. In the ^1H nmr spectrum, the most downfield signal observed was at δ 3.30, in sharp contrast to the ^1H nmr spectra of the adducts formed from simple alkenes and alkynes (*vide infra*). These data strongly indicate the expected spiro-ketone **15** as the structure of this adduct and hence **13** as the structure of the intermediate α-oxosulfine.

Trapping reactions were first carried out on **13** with a series of simple alkenes — 2-methylpropene, cyclopentene, cyclo-

^{1}H nmr (δ)	^{13}C nmr (δ)	Position
1.96	21.26	CH_3(C-1′)
1.95	22.47	C-5
2.25	24.04	CH_3(C-2′)
2.38	26.82	C-4
2.45	38.22	C-6
6.47	143.03	C-3

[a]The 2D nmr spectra were recorded on a different spectrometer from the original ^{1}H and ^{13}C nmr spectra, accounting for the slight differences in chemical shift observed.

hexene, and cylcooctene. Adducts which were liquids at 25°C were obtained in all cases. All four products displayed a very strong ir band in the range 1682–1688 cm^{-1}, indicative of an unsaturated carbonyl group, and a triplet signal far downfield in the ^{1}H nmr spectrum, in the range δ 6.90–7.05, indicative of a vinylic proton. As in the thiochromanone series above, these data clearly did not accord with expectation for a Diels–Alder adduct. Since the four adducts so obtained were liquids, however, we decided to examine the analogous reactions of **13** with simple alkynes in the hope that the more rigid structures so obtained would be more likely to provide us with a crystalline product for X-ray analysis.

When the α-oxosulfine **13**, generated in the same manner as for the above cycloadditions, was allowed to react with a two-fold excess of 2-butyne between −78° and 25°C, a pale yellow crystalline solid, mp 42–44°C, was obtained in 35% yield, after initial purification by flash chromatography. This product possessed an ir band at 1689 cm^{-1}, similar to that in the alkene adducts above, and also showed the distinctive downfield triplet (J = 4 Hz) in the ^{1}H nmr spectrum, albeit slightly further upfield at δ 6.60. The formula $C_{10}H_{13}ClOS$ for this adduct was confirmed by elemental analysis. ^{13}C nmr analysis with APT-editing indicated the presence of two CH_3 groups (at δ 21.6 and 24.4), three CH_2 groups (at δ 22.8, 27.1, and 38.5), one sp^2-CH (at δ 143.0), and four other quaternary sp^2 carbons (three in the range δ 122.0–134.4 and what appeared to be a carbonyl carbon at δ 195.7). A two-dimensional, ^{1}H–^{13}C shift-correlated nmr (HETCOR) analysis (22) confirmed the respective assignments (see Table 2) and in particular the matching of the proton signal at δ 6.60 with the sp^2 carbon at δ 143.0.

A very similar result was obtained when diphenylacetylene was used as the trapping species, although the adduct in this case was a colourless, viscous oil and the yield of purified adduct was very low. Preliminary examination of the trapping reaction with 1-hexyne and with acetylene itself also yielded crude products which showed the now characteristic ir band at 1682 cm^{-1} and a downfield triplet in the ^{1}H nmr spectra at δ 6.70 and 6.90, respectively. Extensive purification was not carried out on these adducts, however, since we were by now convinced that these products were fully analogous to the above adduct from 2-butyne.

Since we had obtained a crystalline sample of the 2-butyne adduct of **13** and since more than one structure was potentially consonant with the spectral data presented above, we subjected the 2-butyne adduct to single crystal X-ray analysis (*vide infra*). As a result, this adduct has now been unambiguously identified as *E*-2-(2′-chloro-1′-methyl-1′-propenylthio)-2-cyclohexenone **16***a* (see Fig. 1). By analogy, the diphenylacetylene adduct above is assigned structure **16***b* and, more tentatively, we can assign the impure adducts from 1-hexyne and acetylene to the same structural class. Because of the close correspondence of the ir and ^{1}H nmr data in these cases, it also seems reasonable to assign structures **17** and **18***a–c*, respectively, to the (liquid) 2-methylpropene and cycloalkene adducts described above. Structure **18***a* was also confirmed by nmr (HETCOR) analysis similar to those described earlier for **10** and **16***a* (see Table 3).

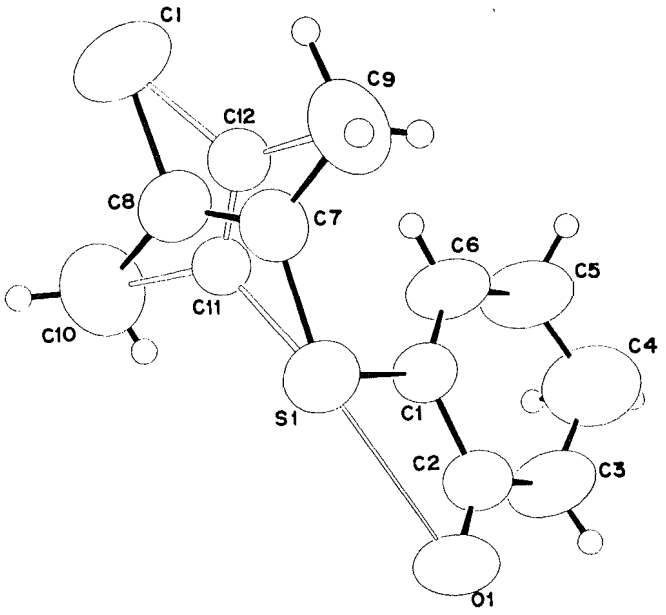

FIG. 1. ORTEP view of compound **16***a* showing the crystallographic numbering scheme. Thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms with uniform isotropic temperature factors. Both arrangements of the disordered chloro-methylpropenyl moiety are indicated. The close S...O contact referred to in the discussion is indicated by the thinner unfilled bond.

Discussion of crystal structures

X-ray analyses have indicated that compound **16***a* and both independent molecules in the asymmetric unit of compound **10** do not contain conjugated ring systems but instead consist of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12

For personal use only.

thioether linked molecules. In **16***a* the sulfur atom bridges between cyclohexenone and chloro-methylpropenyl moieties, while in **10** 2-chlorocyclopentane and thiochromone moieties are bridged. In **16***a*, the cyclohexenone ring exists in a flattened envelope conformation with C(4) and C(5) −0.440(10) and −0.089(8) Å respectively above the planar C(1)—C(2)—C(3)—C(6) section of the ring.[4,5] Similarly, S(1) and O(1) are 0.087(1) and 0.021(4) Å, respectively, out of this plane. The chloro-methylpropenyl moiety in this molecule is slightly disordered, with the double bond in ca. 15% of molecules in the unit cell rotated by 90° with respect to the major orientation, while preserving the positions of the peripheral S, Cl, and Me atoms (Fig. 1). A least-squares mean plane through these peripheral atoms and both orientations of the double bond indicate that these atoms remain planar to ±0.059(26) Å. A similar disordered arrangement has been observed for dimethylstilbene (23) and has been suggested for *trans*-stilbene (with ca. 20% probability of disorder (calculated) at room temperature) (24). The observed C(7)=C(8) double bond and C(8)—Cl distances for the major orientation (1.299(10) and 1.759(5) Å (Table 4)) are generally comparable with values observed for *E*-1-chloro-2-methoxy-1,2-diphenylethene (1.336(4) and 1.737(3) Å) (25) and 2,2′-(2,2-dichlorovinylidene)bis(4-chloro-6-nitrophenol) (1.330(12) and 1.719(5) Å) (26), while the carbon–chlorine distances in the two molecules of compound **10** are 1.798(16) and 1.777(23) Å (major component).

The two S—C(sp^2) distances (1.771(3) and 1.797(6) Å (major orientation)) are somewhat longer and the C(7)—S(1)—C(1) angle somewhat smaller (101.5(2)°) than distances and angles in compounds such as bis(3-phenyl-1,4-benzodioxin-2-yl) sulfide (1.749(2) Å, 103.2(2)°) (27) and bis(3-hydroxy-2-oxo-cyclohepta-3,5,7-trienyl) sulfide **21** (C—S = 1.75, 1.76, 1.78 and 1.83(1) Å and CSC = 103.5° and 102.1(5)° (two independent molecules)) (28). In **10** the S—C(sp^2) and S—C(sp^3) distances and the C(n3)—S(n2)—C(n9) angles at the bridging atom are 1.754(16) Å (1.729(17) Å) and 1.810(17) Å (1.791(21) Å) and 103.8(8)° (103.4(9)°) in the two independent molecules (Table 4).

A notable feature of the structure of **16***a* is the close intramolecular S...O contact distance of 2.829(3) Å. This distance is significantly shorter than the van der Waals distance (3.25 Å) and ca. 0.13 Å shorter than a distance calculated with "normal" (120°) SCC and CCO angles. The 14° difference in the S(1)—C(1)—C(2) and S(1)—C(1)—C(6) bond angles is in the direction of pushing S towards O, although contacts involving H(61) and atoms in the chloropropenyl group are as short as 2.550 Å (C(7)...H(61)).[6] Both of the angles C(7)—S(1)...O(1) and C(11)—S(1)...O(1) are somewhat distorted from 180° (156.7(1) and 148.0(8)°). Similarly, the O(1)—C(2) bond length (1.215(4) Å) is slightly longer than that observed in 2,6-dimethyl-4*H*-1-thiopyran-4-one (1.189(4) Å) (29) but comparable to that observed in 2-(1,3-dithiol-2-ylidene)cyclopent-4-ene-1,3-dione (1.213(3) Å), a molecule with a close S...O contact of length 2.944(3) Å (30). In the sulfide **21** above, the shortest intramolecular S...O contacts have been calculated as 2.731 and 2.664 Å and the two carbonyl bonds involved have lengths of 1.22 and 1.24(1) Å (27).

The crystal packing of **16***a* consists of layers of molecules in the (10$\bar{1}$) plane (Fig. 2). The shortest intermolecular contacts are S(1)...H(42) $(-\frac{1}{2} + x, \frac{1}{2} - y, -\frac{1}{2} + z) = 3.02$ Å, Cl...H(52) $(-\frac{1}{2} + x, \frac{3}{2} - y, -\frac{1}{2} + z) = 3.19$ Å and O(1)...H(31) $(1 - x, -y, 1 - z) = 2.88$ Å.

In **10** the quality of the crystals has limited the precision of the geometrical parameters of both molecules. However, both molecules contain sulfur-linked 2-chlorocyclopentane and thiochromone ring systems. Both thiochromone rings are essentially planar, although the maximum deviation of atom C(113) (0.134(17) Å) and the deviation of S(12) (0.250(5) Å) from the least-squares mean plane are significantly larger than those values obtained for the second molecule, which is planar, to 0.056(13) Å and S(22) is 0.106(6) Å out of plane. Where the two molecules differ most is in the orientation of the cyclopentane rings with respect to the thiochromone moieties, the change in configuration at the chloro-substituted atom C(n13) and the presence of a small amount (ca. 15%) of disorder of the Cl atom in molecule **2**. Thus, in molecule **1**, the Cl is pseudoaxial and *anti* to the S(12)—C(19) bond (τ (S(12)—C(19)—C(113)—Cl) = −164(1)°), whereas in molecule **2** the Cl is on the opposite side of the cyclopentane ring in a pseudoequatorial configuration, with τ (S(22)—C(29)—C(213)—Cl) = 82(2)°. The disorder in molecule **2** places the alternative Cl position (ca. 15%) on C(29). Similarly, the difference in the torsion angles τ (S(12)—C(19)—C(110)—C(111)) = −93(2)° and τ (S(22)—C(29)—C(213)—C(212)) = −159(2)° would indicate that the cyclopentane ring in molecule **2** is rotated by ca. 66° towards a more "perpendicular" arrangement with respect to the thiochromone plane (Fig. 3). Internal torsion angles (Table 5), however, indicate that both pentane rings have the same conformation within the measured standard deviations.

As with compound **16***a*, both molecules contain S(n2)...O(n1) intramolecular contacts (2.778 and 2.775(13) Å) slightly shorter in length than the S...O distance in **16***a* above. Although the errors are quite large, it does appear that the C(n4a)—C(n4)—O(n1) angles (122.7(16) and 123.5(16)°) are slightly larger than the C(n3)—C(n4)—O(n1) angles (117.5(16) and 115.1(16)°). In the thiochromone rings the bond lengths and bond angles for the thiopyranone moiety are substantially different from those observed in 2,6-dimethyl-[4*H*]-1-thiopyran-4-one (29), in which a localised valence bond structure predominates, but are more consistent with the dimensions of the thiopyranone ring in 3-[2(*Z*)-(benzylthio)-2-phenylethenyl]-2,6-diphenyl-[4*H*]-thiopyran-4-one (31) (Fig. 4). The authors concluded that bond lengths in the latter structure were consonant with contributions in a 2:1 ratio of localised and delocalised valence bond structures (31). The presence of the negative charge on O in the delocalised structure presumably favours the S...O contacts.

Apart from the S...O contacts mentioned above, similar contacts have been noted in a variety of compounds over a spectrum of S...O distances, especially when the contact results in a 5-membered ring system (32), and have been the subject of theoretical calculations (33). Notably, there are several structures, including **21** above, in which the significance of similar contacts has been overlooked.

[4]The crystallographic numbering schemes used to identify atoms as indicated in Figs. 1 and 3 are used throughout the following discussions of the structures of **10** and **16***a*. In **10** the first digit in any atom number refers to molecule **1** or molecule **2**.

[5]A complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[6]Cf. H(61) contacts with S(1), C(9), C(11), and C(12) of lengths 2.881, 2.947, 2.732, and 2.861 Å, respectively.

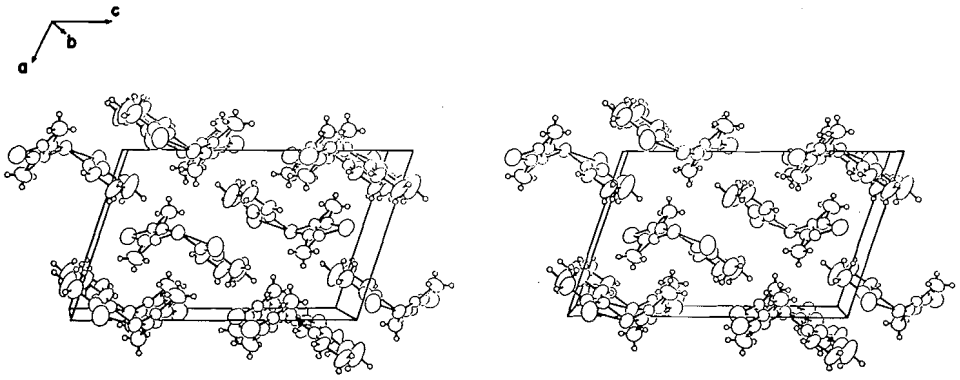

FIG. 2. The crystal packing in compound **16***a* as viewed down ***b***.

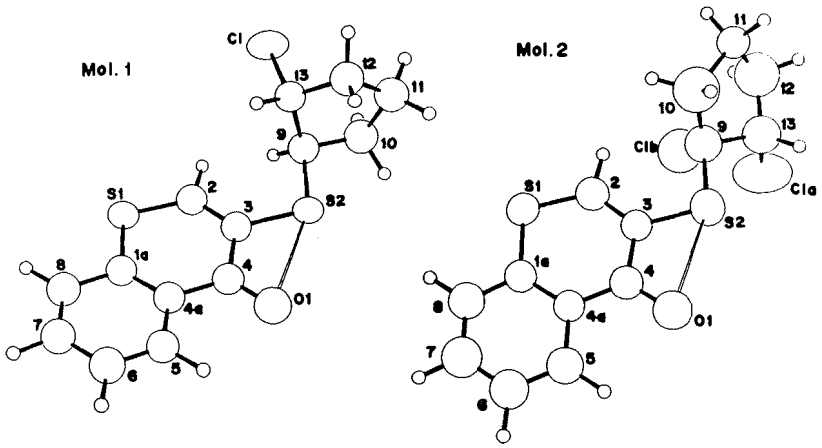

FIG. 3. ORTEP view of the two molecules of compound **10**. The close S...O contacts are indicated by the thinner unfilled bonds.

A view of the crystal packing is given in Fig. 5. The shortest intermolecular contacts of note are the S(11)...S(12)′ and S(22)...S(22)″ contacts of lengths 3.92 and 4.13 Å, S(11)...Cl(11)‴ = 3.46 Å, Cl(11)...H(11) = 3.00, Cl(21)...H(15) = 2.92, Cl(21)...H(19) = 3.02, S(21)...H(12) = 2.81, S(22)...H(213) = 3.02 and O(11)...H(21) = 2.31 Å.

Conclusions

Mechanistically, the formation of adducts such as **16**, **17**, and **18** from **13** can be rationalized in a number of ways. We think it quite plausible, however, that both the α-oxosulfines studied, **1** and **13**, may initially tautomerize to the unsaturated sulfenic acid species **19***a* or **20***a*, respectively. Formation of the corresponding mixed anhydride derivatives may occur with the excess $SOCl_2$ present, to form **19***b* or **20***b* respectively. Well precedented, stereospecific electrophilic addition of such reactive species (34) to the respective alkyne or alkene would then be expected to occur, possibly by way of an intermediate thiirenium or thiiranium ion (35) (see Scheme 1). While the α-oxosulfine **1** appears to undergo similar tautomerization, and hence reacts via the non-Diels–Alder pathway, it should be noted that **13** is, to our knowledge, the first example of a purely aliphatic α-oxosulfine to be studied. Whatever the reason, the α-oxosulfine systems of **1** and **13** are simply too short-lived or, possibly, too conformationally mobile, to follow the Diels–Alder reaction pathway, at least with those dienophiles reported here.

Further studies to delineate the scope of the Diels–Alder reaction of α-oxosulfines, and to explore further the chemistry and novel structural features of the adducts reported in the present work, are presently under way.

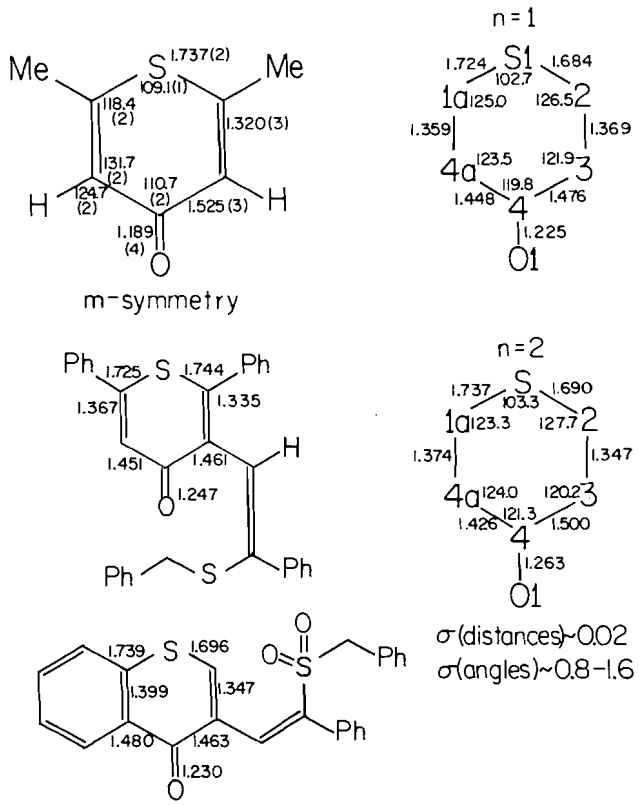

FIG. 4. Principal bond lengths and some bond angles in the thiochromone rings of compound **10** and some related molecules (see text for appropriate references).

Experimental

Infrared spectra were recorded as KBr discs (solids) or as neat films (liquids), using a Nicolet 5DXB FT-IR spectrometer. The ^{1}H nmr spectra were obtained on a Varian EM-360L spectrometer in $CDCl_3$ solution, unless otherwise indicated. High field ^{1}H nmr and ^{13}C nmr spectra were obtained on Varian XL-400 or XL-200 spectrometers. High- and low-resolution mass spectra were recorded on a VG-70-250S mass spectrometer. Column chromatography was carried out on grade 60, 60 Å silica gel supplied by E. Merck (Darmstadt). Elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25, 2730 Herlev, Denmark.

Dichloromethane and chloroform were dried by distillation over phosphorus pentoxide and stored over 4 Å molecular sieves. Diethyl ether was dried by distillation from sodium benzophenone ketyl. Triethylamine was dried by distillation over calcium hydride and thionyl chloride was purified by distillation over triphenyl phosphite. Potassium iodide was dried at ~140°C for 3 h.

4-Trimethylsilyloxythiochrom-3-ene **2** *(17)*

Dry chloroform (60 mL) was added to potassium iodide (65.70 g, 0.40 mol) with stirring under nitrogen. The mixture was cooled to 0°C and chlorotrimethylsilane (18.0 mL, 0.14 mol) was added. A solution of thiochroman-4-one (9.64 g, 0.059 mol) and triethylamine (33.1 mL, 0.24 mol) in dry chloroform (50 mL) was then added dropwise. The mixture was allowed to warm to room temperature, then the flask was covered with foil paper and refluxed in the dark for 16 h. The reaction mixture was diluted with diethyl ether. The precipitated solid was removed by vacuum filtration and the filtrate was dried ($MgSO_4$). Removal of the solvents on the rotary evaporator yielded **2** as a brown oil (13.5 g, 97%) (36). This was distilled (Kugelrohr) at 180–190°C/0.5 mbar, or used without further purification; ir: ν 1638 (C=C), 1255 (C—O) cm^{-1}: ^{1}H nmr: δ0.2 (s, 9H), 3.4 (d, J = 5 Hz, 2H), 5.2 (t, J = 5 Hz, 1H), 7.1 (m, 3H), 7.5 (m, 1H). (For literature values, see ref. 36.)

2-Benzo-9,10-dimethyl-4,7-dithiaspiro[5.5]undec-9-en-1-one 7-oxide, **4**

A solution of **2** (1.50 g, 6.35 mmol) in dry diethyl ether (5 mL) was cooled to −23°C with stirring under nitrogen. 2,2,6,6-Tetramethylpiperidine (0.90 g, 6.35 mmol) and 2,3-dimethyl-1,3-butadiene (3 mL, 26.5 mmol) were added to the solution. Thionyl chloride (0.76 g, 6.35 mmol) in diethyl ether (3 mL) was then added dropwise. After stirring at −23°C for 6 h, the mixture was allowed to warm to 25°C and stirred for an additional 16 h. The yellow reaction mixture was diluted with diethyl ether. The hydrochloride salt of the base was then removed by vacuum filtration and the filtrate was dried ($MgSO_4$). Removal of the solvent yielded an impure yellow solid (1.42 g). The solid was washed with cold carbon tetrachloride and thiochroman-4-one was recovered from the filtrate. Recrystallization of the remaining solid from CH_2Cl_2/pentane gave tan crystals (0.27 g, 15%) mp 125–126°C; ir: ν 1670 (C=O), 1052 (S=O) cm^{-1}; ^{1}H nmr: δ1.7 (s, 6H), 2.6 (d, J = 4 Hz, 2H), 3.2 (m, 3H), 3.8 (d, J = 14 Hz, 1H), 7.3 (m, 3H), 8.0 (d, J = 6 Hz, 1H); ms m/z (% rel. int.): 274 (33), 273 (42), 272 (100), 257 (28), 255 (38), 243 (89), 229 (19), 227 (29), 201 (32), 147 (18), 136 (31), 121 (15), 100 (27), 91 (16). High-resolution ms: exact mass calcd. for $C_{15}H_{16}O_2S_2$: 292.0592; found: 292.0584.

3-(2'-Chloro-2'-methylpropylthio)thiochromone, **9**

Thionyl chloride (0.62 mL, 8.46 mmol) and 2,6-lutidine (1.0 mL, 8.46 mmol) in dry dichloromethane (4 mL) were cooled to −78°C with stirring under nitrogen. A solution of **2** (2.0 g, 8.46 mmol) in dichloromethane (8 mL) was added dropwise. After 45 min isobutylene was bubbled into the mixture for 5 min and the mixture allowed to warm to 25°C. After 30 h, the mixture was washed with dilute hydrochloric acid, followed by saturated sodium bicarbonate, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 41.223.56.140 on 09/07/12
For personal use only.

dried ($MgSO_4$). Filtration and removal of the solvent gave a yellow–brown solid (1.74 g). The nmr spectrum of the crude product indicated the presence of some of the ketone corresponding to **2**. Purification by recrystallization from CH_2Cl_2/pentane yielded tan needles of *B* (see Results and discussion). Further cooling of the filtrate yielded yellow crystals of **9**(*A*), mp 87–88°C (0.45 g, 19%); ir: ν 1596(m), 1582(s) cm^{-1}; ^1H nmr: δ1.7 (s, 6H), 3.4 (s, 2H), 7.6 (m, 3H), 7.9 (s, 1H), 8.6 (m, 1H); ^{13}C nmr ($CDCl_3$): δ31.84q (CH_3's)), 47.32t (SCH_2), 69.46s (CCl), 126.27d, 127.81d, 129.01d, 130.40s, 131.24d, 131.92s, 133.85d, 136.60s, 174.0s (C=O): ms *m/z* (% rel. int.): 286 (2), 284 (5), 249 (41), 248 (38), 215 (31), 194 (100), 162 (21), 149 (33), 136 (24), 121 (17), 112 (32), 108 (16). *Anal.* calcd. for $C_{13}H_{13}ClOS_2$: C 54.82, H 4.60, Cl 12.45, S 22.51; found: C 54.94, H 4.61, Cl 12.00, S 22.02.

trans-*3-(2'-Chlorocyclopentylthio)thiochromone,* ***10***

A solution of **2** (1.50 g, 6.35 mmol) in dry dichloromethane (5 mL) was stirred at −23°C under nitrogen. 2,2,6,6-Tetramethylpiperidine (0.90 g, 6.35 mmol) and cyclopentene (2.0 mL, 22.7 mmol) were added. Thionyl chloride (0.76 g, 6.35 mol) in dichloromethane (3 mL) was added dropwise to the reaction mixture. The hydrochloride salt of the base was removed by vacuum filtration, the filtrate dried ($MgSO_4$), and the solvent removed. The resultant brick-red mixture was stirred at −23°C for 6 h then allowed to warm to 25°C. After 14 h, the mixture was diluted with diethyl ether and the resultant solid (1.98 g) flash chromatographed on silica gel. Dichloromethane eluted a brown oil (1.58 g). Crystallization from CH_2Cl_2/pentane gave yellow needles of **10**, mp 79.5–80.5°C (0.77 g, 41%). (The ^1H nmr spectrum showed that thiochroman-4-one was also recovered by chromatography.) Infrared: ν 1603(s), 1586(s) cm^{-1}; ^1H nmr: δ2.1 (m, 6H), 3.7 (m, 1H), 4.2 (m, 1H), 7.4 (m, 3H), 7.7 (s, 1H), 8.5 (m, 1H); ^{13}C nmr ($CDCl_3$): δ22.58t (C-4'), 30.05t (C-5'), 35.05t (C-3'), 52.05d (C-1'), 65.73d (C-2'), 126.33d, 127.87d, 129.13d, 131.29d, 131.71d, 132.52s, 136.20s, 136.87s, 176.98s (C=O); ms *m/z* (% rel. int.): 299 (27), 297 (65), 262 (13), 261 (35), 260 (100), 227 (19), 194 (62), 149 (14), 136 (12), 121 (19), 108 (11), 89 (9). *Anal.* calcd. for $C_{14}H_{13}ClOS_2$: C 56.65, H 4.41, Cl 11.94, S 21.60; found: C 56.91, H 4.53, Cl 12.16, S 21.42.

E-*3-(2'-Chloro-1'-methyl-1'-propenylthio)thiochromone,* ***11***

A solution of **2** (1.50 g, 6.35 mmol) in dry dichloromethane (5 mL) was stirred at −78°C under nitrogen. 2,2,6,6-Tetramethylpiperidine (0.90 g, 6.35 mmol) and 2-butyne (2.0 mL, 25.6 mmol) were added. Thionyl chloride (0.76 g, 6.35 mmol) in dichloromethane (4 mL) was added dropwise. After stirring at −78°C for 6 h, the reaction mixture was allowed to warm to 25°C and stirred for an additional 14 h before diluting with diethyl ether. The hydrochloride salt of the base was then removed by vacuum filtration, the filtrate was dried ($MgSO_4$) and the solvent removed, resulting in a brown liquid (1.84 g). Flash chromatography on silica gel afforded **11** (0.46 g, 26%). (The ^1H nmr spectrum showed that thiochroman-4-one was also recovered by chromatography.) Dichloromethane/hexane (53:47) eluted a product, recrystallized from CH_2Cl_2/pentane, as off-white crystals of **11**, mp 131–132°C; ir: ν 1615 (s) 1585 (s) cm^{-1}; ^1H nmr: δ2.1 (d, J = 1 Hz, 3H), 2.5 (d, J = 1 Hz, 3H), 7.3 (s, 1H), 7.5 (m, 3H), 8.5 (m, 1H); ^{13}C nmr ($CDCl_3$): δ21.85q, 24.58q, 121.98s, 126.34d, 127.78d, 127.93d, 128.91d, 130.08s, 131.32d, 131.73s, 137.13s, 138.47s, 176.78s; ms *m/z* (% rel. int.): 284 (1), 282 (2), 257 (5), 247 (8), 196 (7), 195 (17), 194 (69), 193 (100), 162 (73), 149 (48), 136 (47), 121 (20), 108 (32), 89 (47). *Anal.* calcd. for $C_{13}H_{11}ClOS_2$: C 55.21, H 3.92, Cl 12.54, S 22.68; found: C 55.48, H 4.19, Cl 12.61, S 22.55.

E-*3-(2'-Chloro-1'-hexenylthio)thiochromone,* ***12***

A solution of **2** (1.50 g, 6.35 mmol) in dry dichloromethane (5 mL) was stirred at −78°C under nitrogen. 2,2,6,6-Tetramethylpiperidine (0.90 g, 6.35 mmol) and 1-hexyne (2.0 mL, 17.4 mmol) were added. Thionyl chloride (0.76 g, 6.35 mmol) in dichloromethane (3 mL) was added dropwise. After stirring at −78°C for 6 h, the reaction mixture was allowed to warm to 25°C and stirred a further 14 h. The mixture was diluted with diethyl ether and the hydrochloride salt of the base removed by vacuum filtration. The filtrate was dried ($MgSO_4$) and the solvent removed, giving a brown oil (1.63 g). Flash chromatography on silica gel (CH_2Cl_2) yielded a dark red oil (0.39 g, 20%). The nmr spectrum showed this to be a mixture (4:1) of the two possible regioisomers. (Thiochroman-4-one was also recovered after chromatography.) Recrystallization from dichloromethane/pentane gave **12**, mp 64–65°C; ir: ν 1600 (m) 1584 (s) cm^{-1}; ^1H nmr: δ0.95 (t, J = 6 Hz, 3H), 1.5 (m, 4H), 2.5 (t, J = 7 Hz, 2H), 6.5 (s, 1H), 7.5 (m, 4H), 8.5 (m, 1H); ms *m/z* (% rel. int.): 312 (9), 310 (19), 277 (12), 276 (20), 275 (100), 247 (9), 196 (10), 195 (16), 194 (96), 149 (28), 136 (36), 121 (32), 108 (35), 89 (56). *Anal.* calcd. for $C_{15}H_{15}ClOS_2$: C 57.96, H 4.86, Cl 11.40, S 20.63; found: C 57.99, H 5.04, Cl 11.71, S 20.33.

9,10-Dimethyl-7-thia-spiro[5.5]undec-9-en-1-one 7-oxide, ***15***

To a solution of 1-trimethylsilyloxycyclohexene **14** (1.00 g, 5.88 mmol) 2,6-lutidine (0.629 g, 0.68 mL, 5.88 mmol) and excess 2,3-dimethyl-1,3-butadiene (2.9 g, 35.4 mmol) in dry CH_2Cl_2 (25 mL) at room temperature, was added thionyl chloride (0.7 g, 5.88 mmol) in dry CH_2Cl_2 (5 mL), dropwise over 10 min with vigorous stirring. The reaction mixture was then stirred at 25°C for 24 h before being washed with water twice. The aqueous layers were combined and re-extracted with CH_2Cl_2. All the CH_2Cl_2 phases were then combined, washed (20 mL 5% $NaHCO_3$), dried ($MgSO_4$), filtered, and concentrated to yield a brown oil (1.0 g) which, upon flash chromatography (EtOAc), yielded the product **15** as a slightly brown oil (0.61 g, 46%); ir: ν 1707 (C=O), 1050 (S=O) cm^{-1}; ^1H nmr: δ1.77 (s, 6H, CH_3), 1.85–2.30 (m, 6H), 2.43 (s, 4H), 3.30 (s, 2H).

E-*2-(2'-Chloro-1'-methyl-1'-propenylthio)-2-cyclohexenone,* ***16***a

A 100 mL flask containing **14** (1.5 g, 8.82 mmol), dissolved in dry CH_2Cl_2 (30 mL) was cooled to −78°C, whereupon 2,6-lutidine (1.1 g, 10.3 mmol) was added in one portion, followed by thionyl chloride (1.63 g, 13.7 mmol) in one portion after 10 min. The solution was then stirred for 30–40 min (during which time it became yellow), before a solution of 2-butyne (1.04 g, 19.2 mmol) in dry CH_2Cl_2 (10 mL) was added dropwise over 10–15 min. After maintaining the reaction temperature at −78°C for 4–5 h the reaction mixture was allowed to warm to room temperature and stirred for a further 16 h. The organic phase was then successively washed with 1 *M* HCl (3 times), saturated $NaHCO_3$ (3 times) and saturated NaCl, before being dried (Na_2SO_4), filtered, and concentrated to yield the crude product as a light brown oil (1.54 g). Purification by flash chromatography (hexane:CH_2Cl_2 = 4:6) yielded a yellow oil (1.0 g) which subsequently crystallized. Recrystallization from pentane yielded pale yellow crystals (0.67 g, 35%) of ***16a***, mp 42–44°C; ir (CCl_4): ν 1689 (C=O), 1596 cm^{-1}; ^1H nmr: δ1.93 (m, 5H), 2.30 (m, 7H), 6.53 (t, J = 4 Hz, 1H); ^{13}C nmr ($CDCl_3$): δ21.59q, 22.78 (C-5), 24.39q, 27.07 (C-4), 38.50t (C-6), 122.03s (C-1'), 134.36s (C-2'), 136.41s (C-2), 143.03d (C-3), 195.75s (C-1). *Anal.* calcd. for $C_{10}H_{13}ClOS$: C 55.42, H 6.00, Cl 16.39, S 14.78; found: C 55.42, H 6.11, Cl 16.30, S 14.76.

Test for ionic Cl

The adduct was dissolved in ethanol and treated with a 3% solution of $AgNO_3$ in ethanol (10–15 drops). After 15 min at 25°C a bulky white precipitate had formed.

E-*2-(2'-Chloro-1',2'-diphenylethenylthio)-2-cyclohexenone,* ***16***b

1-Trimethylsilyloxycyclohexene **14** (1.0 g, 5.87 mmol), 2,6-lutidine (0.70 g, 6.54 mmol) and diphenylacetylene (3.14 g, 17.6 mmol) were dissolved in dry CH_2Cl_2 (30 mL). Thionyl chloride (0.17 g, 5.96 mmol) in dry CH_2Cl_2 (5 mL) was added dropwise over 10 min. The solution immediately turned yellow and was stirred at room temperature for 24 h. After washing the reaction mixture twice with water, the aqueous layers were combined and re-extracted with CH_2Cl_2. The CH_2Cl_2 phases were then combined and washed with 5% $NaHCO_3$ (3 × 20 mL), dried ($MgSO_4$), filtered, and concentrated to yield a yellow solid. Purification by flash chromatography (CH_2Cl_2) yielded the crude product as a brown oil (0.75 g). Further purification by flash chromatography (CH_2Cl_2: hexane = 3:1) yielded a viscous brown oil (0.23 g). A third and final purification by flash chromatography

[a]Enraf-Nonius CAD4 diffractometer: MoKα radiation (graphite monochromator), λ = 0.71069 Å; T = 298 K.

[b]The $P2_1/c$ and $P2_1/n$ cells have very similar dimensions so that the transformation (100/102/0–10) defines a paraorthorhombic C centred cell of dimensions 10.620 × 31.943 × 6.571 with γ = 90.12°, but without the required higher Laue symmetry.

[c]Prescan at 10 deg min^{-1}, other scan speeds chosen to give $I/\sigma(I) \geq 25$ within maximum scan time specified. Backgrounds were obtained by extending scan by 25% on either side of peak and were measured for half the time taken to collect peak.

[d]Declines of 23% and 8.5% in the measured intensities of the standard reflections of **16***a* and **10**, respectively, were corrected for after data reductions (maximum rescale factor on F = 1.441 (1.179) for **16***a*, **10**, respectively).

[e]Rejection of 168 standards and 549 systematically absent or zero F_{obs} data and averaging 220 symmetry equivalent data ($R_{merge}(F)$ = 0.031) gave the indicated number of non-zero data.

[f]Rejection of 78 standards and 721 reflections with F_{obs} = 0.0 gave the indicated number of non-zero data.

[g]Sum of population parameters of disordered double bond atoms constrained to equal 1.0; all non-hydrogen atoms except C(10) and C(11) anisotropic; H-atom parameters allowed to refine (179 variables).

[h]One peak close to atom C(29) and the significantly higher temperature factor for the Cl atom in the second molecule suggested the possibility of some disorder. These two positions were therefore allowed to refine such that the sum of their population parameters was 1.0. Refinement of the second peak position with isotropic thermal motion indicated that it represented ca. 16(2)% of an alternative chlorine position.

trans-*2-(2′-Chlorocyclohexylthio)-2-cyclohexenone*, ***18***b

A solution of dry CH_2Cl_2 (35 mL) containing **14** (1.5 g, 8.82 mmol) was cooled to −78°C before 2,6-lutidine (1.1 g, 10.3 mmol) was added in one portion. After 20 min thionyl chloride (1.63 g, 13.7 mmol) was added in one portion and the mixture stirred for 1 h (became yellow), whereupon cyclohexene (1.57 g, 19.2 mmol) in dry CH_2Cl_2 (10 mL) was added dropwise over 20–30 min. The reaction mixture was then stirred at −78°C for 4–5 h, followed by 18 h at 25°C. The CH_2Cl_2 phase was successively washed with 1 *M* HCl (3 times), saturated $NaHCO_3$ (3 times) and saturated NaCl (3 times), dried (Na_2SO_4), filtered, and concentrated. This yielded a brown oil containing the desired product (1.7 g). Purification by flash chromatography (CH_2Cl_2) yielded a yellow oil (0.55 g, 26%); ir: ν 1682 (C=O), 1589 cm^{-1}; ^{1}H nmr: δ1.2–2.8 (br m, 14H), 3.35 (br q, 1H, *SCH*), 4.20 (m, 1H, Cl*CH*), 7.07 (t, J = 4 Hz, 1H, =CH).

trans-*2-(2′-Chlorocyclooctylthio)-2-cyclohexenone*, ***18***c

A solution of **14** (1.5 g, 8.82 mmol) in dry CH_2Cl_2 (30 mL) was cooled to −78°C. 2,6-Lutidine (1.1 g, 10.3 mmol) was added in one portion, followed 20 min later by thionyl chloride (1.63 g, 13.7 mmol), also added in one portion. After stirring for 1 h, cyclooctene (2.1 g, 19.2 mmol) in dry CH_2Cl_2 (10 mL) was added dropwise over 10–15 min to the now yellow reaction mixture. After 4–5 h at −78°C the reaction mixture was allowed to warm to room temperature and stirred for a further 22 h. The reaction mixture was successively washed with 1 *M* HCl (3 × 30 mL), saturated $NaHCO_3$ (3 × 30 mL) and saturated NaCl (3 × 30 mL), before being dried (Na_2SO_4), filtered, and concentrated to yield the crude product as a brown oil (2.20 g). Purification by flash chromatography (hexane:CH_2Cl_2 = 4:6) yielded the desired product as a yellow oil (1.3 g, 54%); ir: ν 1682 (C=O), 1589 cm^{-1}; ^{1}H nmr: δ1.2–2.4 (br m, 14H), 2.5 (br q, 4H), 3.5 (br m, 1H, S*CH*), 4.2 (br m, 1H, Cl*CH*), 7.00 (t, J = 4 Hz, 1H, =*CH*).

X-ray crystallography

Crystals of **16***a* suitable for X-ray work were obtained from pentane as low mp colourless or slightly yellow plates or flakes with a waxy appearance and somewhat rounded edges. A crystal of maximum dimensions 0.30 × 0.42 × 0.12 mm in the ***a***, ***b***, ***c*** directions was used throughout. Crystals of **10** were cloudy white rhombs. Despite the crystal used being of more than sufficient size (0.113 × 0.16 × 0.275 mm), diffraction intensities from this crystal were weak and very broad. Consequently it was difficult to centre even the low angle reflections of sufficient intensity. This has resulted in a somewhat inaccurate cell and led to the decision not to extend the data collection beyond $2\theta_{max}$ of 42°. Further work on the diffractometer gave the crystal data for both compounds summarized in Table 6, which also contains a summary of the intensity measurements and structure refinements undertaken. A slow steady decline in the intensities of the standard reflections for both crystals was observed during the data collections and at the end the crystal of **16***a* had turned slightly cloudy. Lorentz, polarization, and corrections for crystal decay were applied to all data collected. The structures were solved by the use of direct methods. Towards the end of the refinement of **16***a* two residual peaks clearly indicated that there was some disorder in the arrangement of the double bond with respect to S, Cl, and the two methyl groups. Similar disordered arrangements of stilbene and related molecules have been observed. For compound **10** the small number of observed data (even with the criterion $I \geq 2.5\sigma(I)$) has limited the refinement of anisotropic thermal parameters to only the S and Cl atoms.

For personal use only.

A significant difference in the thermal parameters for the Cl atoms and the observation of a significant peak near C(29) in the second molecule has been refined as a 85:15 disordered arrangement of the Cl(2) atom. Hydrogen atoms have been placed in calculated positions. Least-squares refinements minimizing $\Sigma w \Delta F^2$ with the conditions specified have converged to the indicated residuals (Table 6). The final atomic positional and equivalent isotropic thermal parameters are given in Table 7. Tables of anisotropic thermal parameters, calculated hydrogen atom positions, least-squares mean planes, and final structure factor amplitudes for the observed reflections for both compounds have been deposited.[5]

Fermi level pinning or semiconductor electrodes in aqueous and non aqueous electrolytes: influence of the modification of the electrode surface

O. SAVADOGO

Département de Génie Métallurgique, École Polytechnique de Montréal, C.P. 6079, succ. "A", Montréal (Qué.), Canada H3C 3A7

Received May 25, 1988

O. SAVADOGO. Can. J. Chem. **67**, 382 (1989).

Modification of several semiconductors material surfaces with $H_4SiW_{12}O_{40}.nH_2O$ have been carried out to produce an increase in the open circuit photopotential at the semiconductor/electrolyte interface (V_{oc}) without changing the flat-band potential. The augmentation of V_{oc} is shown to be attributed to a decrease of the minority carriers recombination at the semiconductor/electrolyte interface along with the suppression of Fermi level pinning. The enhancement of V_{oc} and the electrocatalytic activity of the hydrogen evolution reaction in acidic medium of the derivatized electrodes is attributed to the Fermi level unpinning.

Key words: photoelectrodes, photoelectrocatalysis, pinning, modification improvement.

O. SAVADOGO. Can. J. Chem. **67**, 382 (1989).

La modification des surfaces de matériaux semiconducteurs avec $H_4SiW_{12}O_{40}.nH_2O$ conduit à une augmentation de la tension en circuit ouvert des cellules photoélectrochimiques (V_{oc}) et à une diminution de la surtension des cellules photoélectrocatalytiques pour la réaction de dégagement d'hydrogène en milieu acide. Les potentiels de bandes plates des matériaux ne sont pas influencés par cette modification. Ces résultats sont attribués à une diminution du taux de recombinaison des porteurs minoritaires due à la suppression de l'ancrage du niveau de Fermi des matériaux.

Mots clés : photoélectrodes, photoélectrocatalysis, accrochage, modification amelioration.

Introduction

Because of their acidic and redox properties, the heteropoly compounds (HPCs) have been recognized and used as heterogeneous catalysts (1–6). The homogeneous catalytic properties of HPCs have also been investigated and related to their redox properties (7–12). Further, other electrochemical studies have shown that formation of various HPC complexes (13, 14) was possible by changing the pH, and their analytical properties have been considered (15–18). In view of these interesting properties they appeared to be valuable candidates for conversion and for storing high energy (19–22).

The activation of electrodes surfaces by HPCs has been established and the electrocatalysis of the hydrogen evolution reaction at modified electrodes by heteropolyanions have been studied (23). Hence, the exchange current densities for the hydrogen reaction on various electrode materials improved after derivatization of the electrodes with heteropolyanions (23–26); the potential also improved. In general, it has been found that heteropolyanions (HPA), isopolyanions (IPA), and monotungstate (MW) electrolytes can modify metal or semiconductor electrode surfaces (26). In particular, the reduction of oxygen on HPA modified glassy carbon electrode has been investigated with improvements in exchange current density and decrease in overpotential of the oxygen reduction reaction (27).

The effect of acidity on the behaviour of cyclic voltammetric curves of phosphotungstic and silicotungstic heteropolyanions in water and *N*-dimethylformamide which are in contact with a glassy carbon electrode has been determined by Keita and Nadjo (28). They showed that the evolution of the voltammetric pattern for several heteropolycompounds appeared to be largely dominated by acido-basic properties. Further, their study of the reduction process of silicotungstic species by cyclic voltammetry in strongly acidic aqueous solutions and in dimethylformamide with stepwise increase of perchloric acid shows important morphological changes in the waves. These observations were explained on the basis of solvent effects. Hence, solvation and ion pairing of silicotungstic and phosphotungstic species in acidic concentrated aqueous solutions of alkali-metal salts have shown that $SiW_{12}O_{40}^{4-}$ and $PW_{12}O_{40}^{3-}$ were suitable reference redox systems in acidic aqueous solutions (29). This study of the reduction currents of heteropolyanions shows that $SiW_{12}O_{40}^{4-}$ appears to be a good discriminating probe for the structure of electrolytes in aqueous solutions (30).

The purpose of this paper is to present the results of a study on the behaviour of the flat band potentials of several semiconductors derivatized by silicotungstic acid in aqueous solution. For comparison, the flat band potentials of modified electrodes have been measured in 1,2-dichloroethane with tetra-*n*-butylammonium perchlorate as supporting electrolyte.

Experimental

Electrodes

The reference electrode was a saturated calomel electrode (SCE). The counter electrode was a platinum gauze of large surface area, and the working electrode, monocrystalline semiconductors. These semiconductor crystals employed were n- and p-GaAs, n- and p-InP, n-GaP, and n- and p-Si. The sources of the single crystals, their doping density, and the etching procedures are given in Table 1.

Each experiment to determine current–potential and capacitance–potential characteristics were carried out at least three times to insure reproducibility of the data.

Electrochemical equipment and apparatus

The capacitance of the electrode/electrolyte interface at various electrode potentials was measured with a PARC frequency response analyzer (Model 378) and a PARC electrochemical interface (Model 276).

Chemicals

All chemicals were reagent grade quality, $H_4SiW_{12}O_{40}.nH_2O$ (Fisher Scientific) and H_2SO_4 (BDH) were used. Pure water was obtained by bidistillation. 1,2-Dichloroethane with tetra-*n*-butyl ammonium perchlorate (TBAP) (Fisher Scientific) was used for non-aqueous medium and was not purified before use.

pH variation

The variation of the pH in the 1,2-dichloroethane electrolyte was obtained by a method described elsewhere (31). Briefly, changes of the

TABLE 1. Electrodes and etching processes

Semiconductor	Density (n or p) (in cm^{-3})	Origin	Etching

TABLE 2. Derivatization potentials and times of the different electrodes in 1 M H_2SO_4 with 5×10^{-4} M $H_4SiW_{12}O_{40}.nH_2O$

Semiconductor	Potential (in V/SCE)	Time (in min)
p-Si	−1.0	~30
n-Si	−1.2	~30
p-GaAs	−1.1	~45
n-GaAs	−1.3	~45
p-InP	−1.1	~45
n-InP	−1.0	~45
n-GaP	−2.0	~25

pH toward more acidic values were obtained by saturating the electrolyte with gaseous HCl. The HCl solubility was determined by measuring the pH of a known volume of pure water equilibrated with a saturated HCl solution in 1,2-dichlorethane. At room temperature HCl is soluble up to 5×10^{-2} M. Measurements were carried out after stirring the two phases and waiting for their separation.

Results and discussion

Electrodes derivatization and electrocatalysis

The modification of the material surfaces was performed under potentiostatic conditions during illumination of the surface for p-type materials and under darkness for n-type materials. The supporting electrolyte for derivatization was 1 M H_2SO_4 which contains 5×10^{-4} M $H_4SiW_{12}O_{40}.nH_2O$ in a nitrogen atmosphere. The modifications were achieved with very negative potentials to the cathodic–anodic transition potential. The derivatization procedure of Keita and Nadjo (23) was employed.

During the derivatization process the observed current gradually increased with gas evolution. The time derivatization was determined after stabilisation of the current. For p-type electrodes, power input of 50 mW cm^{-2} with a He–Ne laser was used to achieve the modifications. The derivatization times and potentials of the different electrodes are collected in Table 2. Typical examples of cyclic voltammetry patterns obtained during the surface modification of p-type GaAs and p-type InP

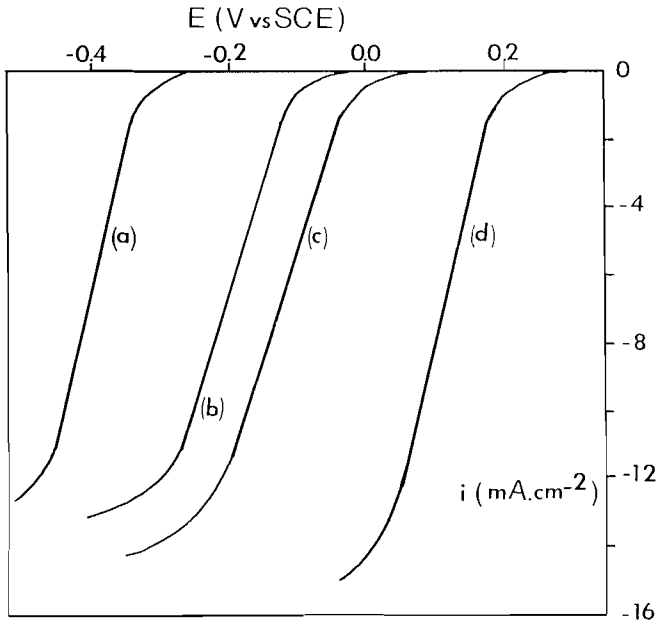

FIG. 1. Current–potential curves obtained in stirred solutions at a potential sweep of 100 mV/s. (*a*) and (*c*) cathodic: current–potential (I–V) curve for p-type GaAs and p-type InP electrodes in 1 M HCl alone; (*b*) and (*d*): cathodic I–V curve for p-type GaAs and p-type InP electrodes in 1 M HCl, following derivatization with 5×10^{-4} M $SiW_{12}O_{40}^{4-}$ in a supporting electrolyte of 1 M H_2SO_4.

are shown in Fig. 1. As indicated the successive cycles obtained after derivatization showed longer increases in cathodic current than those measured before derivatization. The cathodic electrocatalysis were even maintained after transferring the electrode to a supporting electrolyte without $H_4SiW_{12}O_{40}.nH_2O$. As for other published data (23, 24), stability of the derivatization is observed.

The improvement in overpotential for hydrogen evolution on p-type materials has been determined by measuring the potential shift between modified photocathodes and base photocathodes (ΔV) at a light power input of 50 mW cm^{-2} and a current density

of 5 mA cm^{-2} (see Table 3). The stability of the improvement in potential for hydrogen evolution reaction (h.e.r.) has been checked by comparing the measurements done at one month interval. Experiments over longer periods of time would be necessary to further support their stability. This variation in overpotential is not atributed to certain thermodynamics consideration but to certain kinetics phenomena. In particular, a decrease of the available minority carrier recombination at the semiconductor/electrolyte interface can account for the results. This is favored by electrode surface modifications. Analogous results have been obtained on p-type GaAs modified with cobalt (32). Thus, a systematic comparison of other photoelectrocatalytic and electrocatalytic properties of the modified p-type GaAs and p-type InP to efficient hydrogen cathodes or photocatocathodes is planned.

TABLE 5. Open circuit photopotentials V_{oc} (V/SCE) in 0.1 *M* HCl of some semiconductors after modification by $H_4SiW_{12}O_{40}.nH_2O$

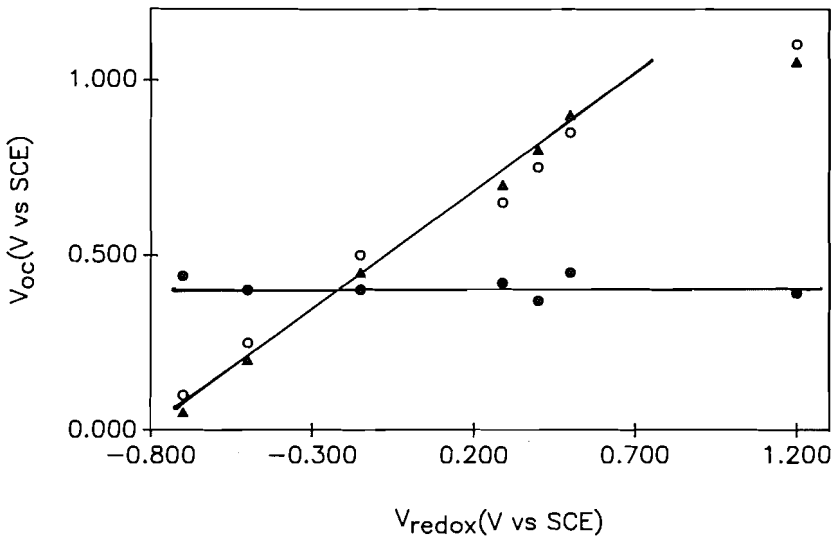

FIG. 3. Variation of V_{oc} with V_{redox} using data of Tables 5 and 7, ○, n-GaAs; ▲, n-InP after derivatization with $H_4SiW_{12}O_{40}.nH_2O$; ●, n-GaAs before derivatization with $H_4SiW_{12}O_{40}.nH_2O$.

Effect of the derivatization on the flat band potential and the open circuit photopotential of the photoelectrodes

The energy levels of the materials were determined from the knowledge of the flat band potential (V_{fb}). The V_{fb} was deduced from impedance measurements. Plots of C^{-2} vs. V are straight lines in a large potential interval (see Fig. 2). Thus the Schottky–Mott (S–M) model is verified for these interfaces, i.e. the following equation applies:

$$[1] \quad \frac{1}{C^2} = \frac{2}{e \in \epsilon_0 N}\left(V - V_{fb} - \frac{kT}{e}\right)$$

Here C is the interface capacitance per unit area, e the electron charge (1.6×10^{-19} C), $\in$ the semiconductor dielectric constant, ϵ_0 the vacuum permittivity (8.85×10^{-14} F/cm), and N, the donor (n-type) or acceptor (p-type) density. From the measurement, V_{fb} was determined with an accuracy of ±0.100 V.

(1) Studies in aqueous acidic medium

The flat band potential values in darkness are collected in Table 4. For the p-type silicon, capacitance–voltage measurements were done after stabilization of the p-Si/electrolyte interface by cycling the electrode between −0.5 V and −1.5 V vs. SCE until no further change in current potential curve was observed. Here, no significant difference exists in the reproducibility of the capacitance–voltage curves measured with and without $[Fe(CN)_6]^{3-}$. The measurements were carried out in the electrolyte with and without $[Fe(CN)_6]^{3-}$. $[Fe(CN)_6]^{3-}$ was added because it has been shown that this species produces reproducibility (33). Hence, under our experimental conditions, cycling of the interface is an efficient means of obtaining reproducible capacitance–voltage curves. Since illumination has no influence on V_{fb} the data obtained under illumination are not shown. As can be seen in Table 4 there is a remarkable variation of V_{fb} with the (H_3O^+) species before modification of the electrode surface. This variation of V_{fb} with (H_3O^+) is generally attributed to the adsorption of H_3O^+ or OH^- ions on the electrode surface (34, 35) depending on the acid–base character of the surface. On the other hand, modification of the surface with $H_4SiW_{12}O_{40}.nH_2O$ (with an acidic character (7–12)) did not result in variation of V_{fb} with (H_3O^+). From these data it can be concluded that modification of the electrodes results in the adsorption of species at the surface, thus preventing the adsorption of (H_3O^+). Further they confirm that the acid–base of $H_4SiW_{12}O_{40}.nH_2O$ determine the behaviour of the interface. A systematic study using electrochemical techniques and Scanning Auger Microscopy is planned to monitor the chemical nature of the electrode surfaces before and after derivatization.

The presence of either $Eu^{2+/3+}$, $V^{2+/3+}$, $[Fe(CN)_6]^{4-/3-}$, $Fe^{2+/3+}$, or $Ce^{3+/4+}$ as redox couple in the electrolyte was shown to have no effect on V_{fb} after electrode derivatization, and thus the data obtained with redox couples are not shown. This can be attributed to Fermi level unpinning (36, 37). Further support to this conclusion can be found through measuring the open circuit photopotentials V_{oc} of the modified photoelectrodes. V_{oc} is the barrier height of semiconductor/liquid junction. It varies with the electrochemical potential of the redox couple, V_{redox}, according to eq. [2]. The V_{oc} values were determined with an accuracy of ±0.100 V under an illumination of 50 mW cm^{-2}. As can be seen in Table 5, V_{oc} is clearly

dependant on V_{redox}. Thus, if Fermi level unpinning is to be occurred, V_{fb} will not (and does not) change with V_{redox}. Because V_{oc} varies as $(V_{fb} - V_{redox})$ (36, 38, 39), it will also vary with V_{redox} as shown by the results.

[2] $V_{oc} = |V_{fb} - V_{redox}|$

As can be seen in Fig. 3, a slope of unity is obtained with n-GaAs and n-InP. According to eq. [2], this implies an important suppression of the Fermi level pinning.

It should be pointed out that the measurements of V_{fb} and V_{oc} obtained with the same electrodes in acidic medium, but without modification of the surface, show that V_{fb} varies with the redox couples (see Table 6) whereas V_{oc} is independent over a large range of V_{redox} (see Table 7). It should be pointed out that constant V_{oc} values are found for n-GaAs (E_g = 1.43 eV), and n-InP (E_g = 1.27 eV) cells for a large number of redox (see Fig. 3 for n-GaAs) systems whose V_{redox} span a range of 2.1 V. Moreover, the potential range over which V_{oc} is independant of V_{redox} is considerably wider than the band gap energy values. This implies Fermi level pinning which is believed to be due to the presence of a high density of interface or surface states (36, 38, 40, 41) or carrier injection due to a sufficient band bending to change the relative carrier density (42–44). Analogous to other published data obtained in non-aqueous (36, 38, 41, 44) and aqueous (35, 40, 45–47) solvents, it could be concluded that a "surface-controlled model" appears to be appropriate to explain these experimental results. We are in the process of determining the effect of material surface chemistry on Fermi level energy. The unpinning of the Fermi level, which occurred after the derivatization, suggests that the effects of the high density of the interface states are suppressed. Thus Fermi level behaviour is governed by material surface chemistry.

Analogous to other published data (31), it is interesting to note that the flat band potential values after modification of n-type ($V_{fb}^{(n)}$) and p-type ($V_{fb}^{(p)}$) Si, with doping density of $\sim 10^{15}$ cm^{-3} and 5×10^{14} cm^{-3}, are +0.05 and −0.60 V/SCE. Thus the difference between these two potentials, i.e. $|eV_{fb}^{(p)} - eV_{fb}^{(n)}|$ equals 0.65 eV. This value compares well with the theoretical value of

[3] $E_g - (\mu_1 + \mu_2) = 0.60$ eV

Here E_g is the energy of the material bang gap, μ_1 is the energy difference between the top of the valence band (E_{Vb}) and the Fermi level (E_F) for the p-type material, and μ_2 the difference of energy between the top of the conduction band (E_{cb}) and E_F. μ_1 and μ_2 can be calculated if the effective state density in the conduction band (N_c) and that in the valence band (N_v) are known (34, 35). For silicon, the values of N_c and N_v are 2.8×10^{19} cm^{-3} and 1.04×10^{19} cm^{-3}, respectively (48). Further, from the n and p values given in Table 1, μ_1 and μ_2 equal 0.25 eV. For n-type and p-type silicons with doping density of 10^{18} cm^{-3} the experimental values of the flat band potential are −0.40 V/SCE $V_{fb}^{(n)}$ and +0.80 V/SCE $V_{fb}^{(p)}$. The difference between these two potentials is 1.20 eV, which is close to the

TABLE 10. Open-circuit photopotentials V_{oc} (V/SCE) of modified semiconductors by $H_4SiW_{12}O_{40}.nH_2O$ in "neutral" 1,2-dichloroethane containing different redox couples

	V_{oc}			
Material	I^-/I_2	$Fe(Cp)^{0/+}$	$Perylene^{0/+}$	(Pn^0/Pn^+)
n-GaAs	0.65	0.85	1.10	Pn^+ is quasi
p-GaAs	0.45	0.65	0.90	insoluble in 1,2-
n-InP	0.30	0.55	0.80	dichloroethane

theoretical value of E_g (i.e. 1.12 eV). For InP it is also found that the experimental value agrees with the theoretical value (1.20 eV vs. 1.27 eV). All these findings are similar to those obtained without electrodes modifications in 1,2-dichloroethane media (31), aqueous media (49, 50) or ammonia media (51). Thus, they confirm that the observed variation of the flat band potentials is independent of the conductivity type of the material. In other words, the modification of the electrodes does not change the type of conductivity. Furthermore, the experimental results show that also V_{fb} for modified electrodes does not vary with redox species in the electrolyte.

(2) Studies in 1,2-dichloroethane

The flat band potentials of several materials in 1,2-dichloroethane and acidic pH are given in Table 8. The variations of V_{fb} with different redox species in the electrolyte are presented in Table 9 for modified electrodes.

As can be seen in Table 8 the flat band potential does not change with the presence of (H_3O^+) in the electrolyte after modification of the electrode. Table 9 shows that the band edges at the semiconductor/electrolyte interfaces remain fixed in the presence of different redox couples as in aqueous acidic medium. Again, this can be attributed to Fermi level unpinning (39). A support to this conclusion can also be found through the measurements of the open-circuit photopotentials V_{oc} which are shown in Table 10. In view of the above results, the same conclusions other than those obtained with the study in the aqueous medium, apply.[1]

Conclusion

Based on the results reported here, it can be concluded that the modification of semiconductor materials with $H_4SiW_{12}O_{40}.nH_2O$ decreases the overpotential of hydrogen evolution at the photocathodes along with improvement of the open circuit photopotentials of the photoelectrochemical cells. It was also shown that suppression of Fermi level pinning is possible. This suppression is accomplished by surface electrode modifications. It is therefore necessary to understand the origin of Fermi level pinning at semiconductor/electrolyte interfaces. A systematic work in this area is planned.

[1]It should be pointed out that previous experiments (31) carried out with similar electrodes in 1,2-dichloroethane, but without modification of the surface, has shown Fermi level pinning due to the presence of a high density of surface states. Accordingly, the band edges at the semiconductor/electrolyte interface varied as a function of different redox couples, whereas V_{oc} was relatively independent of V_{redox} (52).

Protected porous polymers

CAI-YING WU[1] AND WALTER A. AUE[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 7, 1988

CAI-YING WU and WALTER A. AUE. Protected porous polymers. Can. J. Chem. **67**, 389 (1989).

This study was designed to answer the question whether the chromatographic performance of porous polymers — serving here as a model system for pressure-sensitive separation media of relatively large mass transfer resistance — could be improved (*a*) by imposing on them a chromatographically favorable, extrinsic macrostructure and (*b*) by protecting that macrostructure against physical deformation. Packed-column gas chromatography was used as the test system.

Protected porous polymers (PPP's) were synthesized from pure divinylbenzene (DVB) inside conventional diatomaceous supports, using various amounts and types of porogens. The non-extractable polymer loads ranged from 10 to 40% and conformed to (i.e. formed layers on) the diatomaceous macrostructures. The best plate numbers were in excess of 4000/m on a 100/120 mesh Chromosorb W base. The mass transfer resistance of these materials was very low and permitted high flow rates. The PPP's could be used up to 280°C and did not appear to suffer deformation; in fact, the polymer appeared to shield the diatom supports from abrasion. The data indicate that the porous polymer deposits had relatively high specific surface areas, and produced a relatively large value for the free energy of sorption per methylene group, as compared with conventional porous polymer beads. Otherwise, protected and unprotected types of porous polymers had similar chromatographic characteristics.

Key words: porous polymer, poly(divinylbenzene), gas chromatography, protected polymer, diatoms.

CAI-YING WU et WALTER A. AUE. Protected porous polymers. Can. J. Chem. **67**, 389 (1989).

On a réalisé cette étude dans le but de déterminer s'il est possible d'améliorer la performance chromatographique de polymères poreux — servant ici de système modèle pour un milieu de séparation sensible à la pression et possédant une résistance au transfert de masse qui est relativement importante — (*a*) en leur imposant une macrostructure extrinsèque qui est favorable d'un point de vue chromatographique et (*b*) en protégeant cette macrostructure contre les déformations physiques. Comme système de vérification, on a utilisé la chromatographie gazeuse à l'aide de colonnes remplies.

On a synthétisé les polymères poreux protégés (PPP) à l'intérieur de supports diatomées conventionnels, à partir du divinylbenzène (DVB) et utilisant diverses quantités et divers types de porogènes. Les quantités ajoutées de polymère qui ne peuvent être extraits varient de 10 à 40% et elles se conforment (c'est-à-dire qu'elles forment des couches sur) aux macrostructures de diatomées. Sur une base de Chromosorb W, 100/120 mesh, les meilleurs nombres de plateaux dépassaient 4000/m. La résistance au transfert de masse de ces matériaux est très faible et ils permettent des vitesses d'écoulement élevées. On peut utiliser les PPP jusqu'à 280°C et ils ne donnent pas de signes de déformation; en fait, il semble que le polymère protège le support diatomée contre l'abrasion. Les données indiquent que les dépots de polymère poreux possèdent des surfaces spécifiques relativement élevées et que, comparées aux valeurs correspondantes pour des billes conventionnelles de polymère poreux, leur énergie libre de sorption par groupement méthylène est relativement élevée. Autrement, les polymères poreux protégés et non-protégés possèdent des caractéristiques chromatographiques semblables.

Mots clés : polymères poreux, polydivinylbenzène, chromatographie gazeuse, polymères protégés, diatomées.

[Traduit par la revue]

Introduction

As both scientific literature and scientific supply catalogues will readily demonstrate, the so-called "porous polymers" occupy a steady if somewhat specialized niche in the chromatographer's arsenal. These separation media usually come in the form of porous beads that are made by polymerizing in emulsion, together with a porogen (diluent), a variety of olefinic materials, e.g. styrene/divinylbenzene. Porous polymers can also be produced in bulk and ground, or be coated or synthesized inside chromatographic supports or capillaries. Reference 1 presents an overview of the area, refs. 2 to 4 deal with synthesis and chromatographic behavior, ref. 5 investigates the basic polymer chemistry, and refs. 6 to 8 discuss aspects of porous polymers that are of particular relevance to this study. There are, of course, many more references — indeed far too many to cite.

The main advantage of porous polymers in gas chromatography is their strong retention of various gases and non-protic organics, coupled with a relatively short retention of, and good chemical resistance to, water. The main disadvantage — in the conventional bead form — is their generally poor chromatographic efficiency (plate number), coupled with a relatively low dimensional stability.

Although this is not commonly done, we were interested in producing some porous polymers by and for ourselves. However, we wanted to obtain high efficiency phases that would not shrink inside the gas chromatographic column. More importantly, we wanted to find out whether the comparatively low plate numbers of porous polymers were intrinsic and therefore inevitable (e.g. originating from the slow diffusion of solute into the cross-linked polymer) — or whether they were accidental and therefore remediable (e.g. by preserving the dominant retention while reducing the dominant dispersion process).

The point has been made that the plate numbers of porous polymer beads are comparatively low — that is, low *in comparison to* typical gas–liquid chromatography involving thin layers of liquid phases on low-surface area supports. Now, the pores of the former are much smaller than the open internal spaces of the latter. Resistance to mass transfer in the mobile phase is therefore the most likely major contributor to the poor efficiency of porous polymers. The second contributor may be

physical deformation. High pressure, or even relatively low pressure at high temperature, can deform soft beads and hence their pores.

One of the most obvious ways of improving mass transfer in the mobile phase is to use porous polymers in a geometry patterned after that of the traditional stationary phase in gas–liquid chromatography. That is, one would want the narrow-pore polymer to form thin layers inside a wide-pore support structure; thus effectively uncoupling the retention effect of large surface areas and narrow pores from the mass transfer resistance effect of very long, tortuous and constricted passages.

Inside a wide-pore silicic structure of suitable physical strength, the porous polymers would also be protected from the detrimental effect of pressure. Note that this detrimental effect is due to the differential, not the absolute, pressure on a particular particle. Thus, a soft gel bed (as, for instance, in Sephadex chromatography) may be compressed longitudinally by a relatively low flow/pressure regime. Yet, beads of such a gel, when simply suspended in water and not pressed against each other, would be stable at any pressure — much as jellyfish retain their shape at various ocean depths. The question of what types of chromatographic beds are stable against pressure is therefore the question of what material provides the counter-force to the force of the moving mobile phase — not what material produces the chromatographic separation. This seems obvious for conventional gas–*liquid* chromatography — and it should also be correct for a soft porous polymer nestled inside a hard inorganic framework.

It would stand to reason that the most important consequences of a (successful) attempt to protect soft separation media in this manner should occur in chromatographic techniques characterized by high pressure and/or the need to use very soft phases. However, for a demonstration of principle it seemed advisable to choose the easiest handled system: In our case, that was packed-column gas chromatography on porous polymers. For a first try, styrene–divinylbenzene on Chromosorb W appeared to be the obvious choice. As had been the case on several occasions earlier on, a methodology successfully developed on packed columns would likely find itself transferred without too much delay to other chromatographic modes of higher power and price.

To recapitulate, the incorporation of a porous polymer into a Chromosorb particle should be helpful in two ways: not only should the diatomaceous structure of the host provide a template for the physical shape of the polymer and allow easy access to its innermost deposits, but it should also protect it from the deleterious effects of deformation by the longitudinal column pressure gradient. Even if the polymer layer were to shrink, the column bed would still stay intact (as long as the carrier particles did not abruptly deform, i.e. break). Following this line of thought, one might want to refer to such materials as "protected porous polymers" (PPP's).

Incorporating or suspending an active medium on the high-surface area structure of a support is an approach found in several areas of chemistry, e.g. in the synthesis of supported catalysts. In the chromatographic realm — where supports and polymers play crucial roles — the work closest to our interests is that of Fuller (7). He focussed primarily on polymer characterization and described the physical bonding to Chromosorb of porous copolymers from mixtures of divinylbenzene, ethylvinylbenzene, and styrene. Straight-chain alkanes gave particular high efficiencies (a H_{min} of ca. 0.48 mm for pentane, i.e. close to 2100 plates/m) — although branched hydrocarbons did not do as well, and polar solutes tailed.
