The experimental apparatus and procedure have been described elsewhere (8–13). Consequently, only a brief outline is given here. The electrochemical cell consisted of two half cells, the reference electrode (RE) and a working electrode (WE), and an associated counter electrode (CE). The cell can be described schematically as

$$Na_{(RE)}//Na\text{–}\beta\text{-}Al_2O_3// \; Na\text{–}Bi_{(CE)}//Na\text{–}Bi\text{–}Pb_{(WE)}$$

The RE consisted of pure Na hermetically sealed in a Na–β-Al_2O_3 closed end tube. The WE consisted of an Na–Bi–Pb alloy sealed in a similar tube. A schematic diagram of a typical half-cell arrangement is given in Fig. 1. The composition of the WE was accurately varied by coulometric titration. Both half-cells were immersed to the same depth in a stirred Na–(95%)Bi alloy bath contained in a molybdenum crucible. Its function was to provide electrical contact, and to serve as a source and sink of alkali metal during coulometric titration.

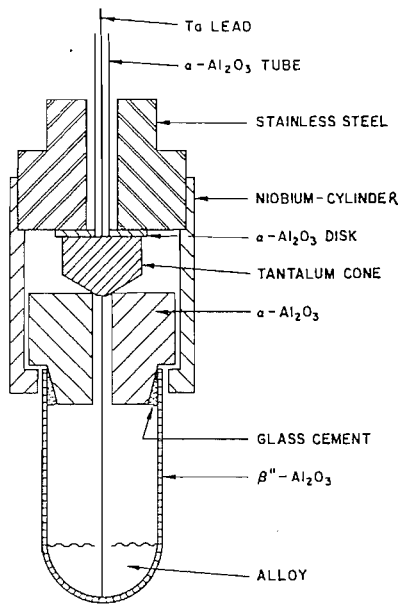

FIG 1. Typical half-cell arrangement.

Cells were loaded inside a high purity argon glove box. Accurately weighed amounts of high purity Bi and Pb were loaded into the cell in small pieces; the Na metal was generated by coulometric titration that involved the application of a potential across the electrolyte between the WE and the CE. At the temperatures of the experiments, there is negligible electronic transport through the solid electrolyte. Consequently, exactly one mole of the Na metal will be transported for each Faraday of charge. Compositional changes can be controlled down to the ppm range. Additionally, the introduction of oxides or impurity ions is avoided.

High purity Na (99.99%), Bi (99.999%), and Pb (99.999%) were used. The fabrication and the sealing procedures for the β-Al_2O_3 were described elsewhere (8–13). Temperatures were measured with a calibrated (Pt–Pt 10% Rh) thermocouple directly immersed in the CE.

Results and discussion

The cell reaction for the alkali metal concentration cell is

[1] $$Na_{(pure,\ liquid)} \Leftrightarrow Na_{(Na\text{–}Bi\text{–}Pb\ alloy,\ liquid)}$$

The cell voltage can be expressed with the corresponding Nernst equation in the form

[2] $$E = -\frac{R \times T}{F} \ln \gamma_{Na} - \frac{R \times T}{F} \ln X_{Na}$$

where F is the Faraday constant, R is the universal gas constant, T is the absolute temperature, and X_{Na} and γ_{Na} represent, respectively, the Na metal mole fraction and activity coefficient. The reference state corresponds to pure liquid Na metal at 723 K. Table 1 records the values of measured cell voltage at 723 K. The cell voltage data were collected for both directions of the current in the coulometric titration (i.e. $i > 0$ and $i < 0$). The cell voltages did not drift, and they were stable and reproducible for several days after each titration. This confirmed reversibility.

The Na activity coefficients were calculated with eq. [2]. Figure 2 is the compositional plot of the activity coefficients at 723 K for this study and for the previous work on the constituent binaries (1–2). It can be seen that Na activity coefficients are very small, and there is a marked deviation from ideality. The Na metal activity coefficients increase in the order (Na–Bi) → (Na–Bi–Pb) → (Na–Pb). The activity coefficients for all systems have been fitted to polynomial equations summarized in Table 2. Also included in Table 2 are the Henrian activity coefficients, γ^h_{Na}, and the partial excess free energy of mixing for Na at 723 K defined as

[3] $$\Delta\bar{G}^{xs}_{Na} = R \times T \ln \gamma^h_{Na}$$

The compositional dependence of the logarithm of the activity coefficients relates information on the solution correlation functions. Saboungi and Corbin (1), based on the work of Kirkwood-Buff (14), defined the limiting slope as

[4] $$\epsilon = \left(\frac{\partial \ln \gamma_{Na}}{\partial X_{Na}}\right)_{X_{Na} \to 0}$$

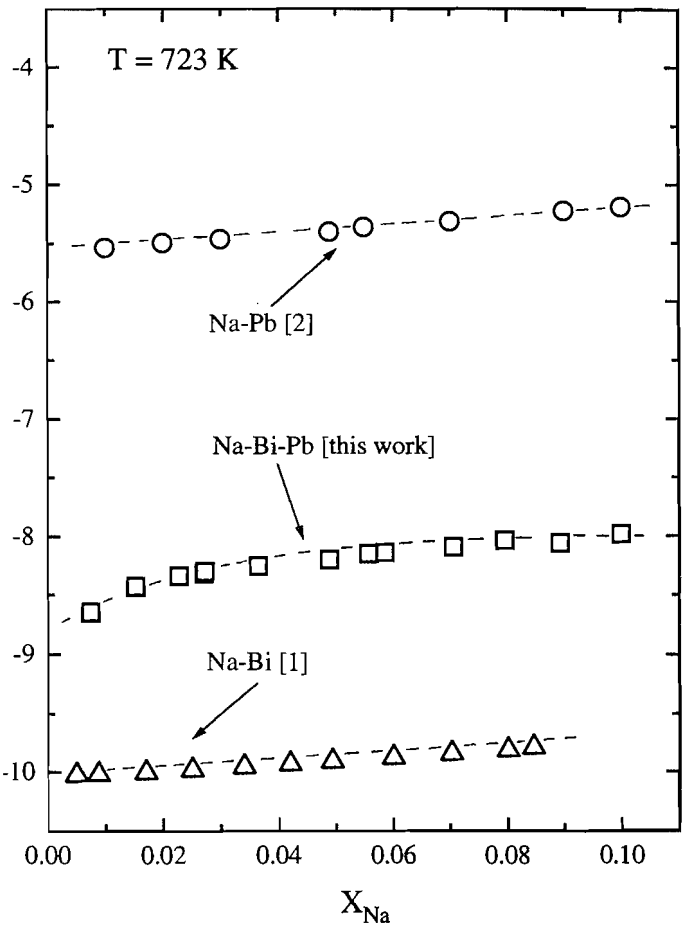

FIG. 2. Isothermal compositional variation of ln γ_{Na} for the Na–Bi–Pb system at 723 K.

This limiting slope is related to the solution correlation functions through

[5] $$\epsilon = -G^0_{22}/v_1$$

where G^0_{22} is the limit of the integral of the radial pair distribution function of the solute Na, and v_1 is the molar volume of the solvent at infinite dilution of the solute. The limiting slope is related to the kind and degree of ordering within solutions. A positive value for ϵ indicates attraction between the Na atoms and the solvent atoms (either Bi or Pb), and a high probability of preferred co-ordination (i.e. complex formation) in the liquid state. A zero value for ϵ means that there is a random distribution for the atoms. A negative value for ϵ represents the situation where there are attractive forces between like atoms and repulsive forces between unlike atoms. Such a situation may be represented by the formation of Na_2. However, the thermodynamic data must be supplemented by direct structural experiments like X-ray and neutron diffraction studies. The limiting slopes have been calculated and are tabulated in Table 2. The limiting slope for the Na–Bi–Pb alloy was calculated based on the linear portion of the curve as indicated in Fig. 2. It can be seen that the limiting slopes for all cases reported in Table 2 are positive, suggesting a repulsion between the Na atoms. There is probably some form of charge transfer and a local ordering. The theoretical limit of the magnitude of ϵ is the co-ordination number of an ideal ionic system (i.e., 4

→ 6). Since the value for ϵ in this study is slightly less than the lower theoretical limit, either long range electronic interactions or a screening effect which decreases the effective range of the coulombic repulsions between the charged Na atoms may be present. Values for ϵ increase in the solvent order (Bi) → (Bi–Pb) → (Pb) which is in consonance with the ionic radii and the activity coefficient data.

The role of catalyst activation in the enantioselective hydrogenation of methyl acetoacetate over silica-supported nickel catalysts

MARK A. KEANE[1]

Chemistry Department, University of Glasgow, Glasgow G12 8QQ, Scotland

Received August 18, 1993

MARK A. KEANE. Can. J. Chem. **72**, 372 (1994).

A range of Ni–SiO_2 catalysts have been prepared by homogeneous precipitation–deposition and impregnation techniques and modified with aqueous solutions of *R*-(+)-tartaric acid (TA) to induce enantioselectivity in the asymmetric hydrogenation of a prochiral β-ketoester (methyl acetoacetate) to a β-hydroxyester ((*R*)-(−)-methyl 3-hydroxybutyrate). The effects of catalyst precursor preparation, nickel loading, and precalcination on the reduction of the precursor were examined and the nature of the resultant nickel particle size distribution is described. The influence of metal–support interactions on the uptake of TA was investigated and data on the corrosive metal leaching and the consequent changes in metal dispersion are presented. Modification of the catalysts with TA not only induced enantioselectivity, but also increased the turnover frequency by up to 15 times that observed for the unmodified surface. The amount of TA adsorbed and the fractional surface coverage by TA is related to the degree of enantiodifferentiation. The effects of variations in supported nickel metal particle sizes (in the overall range of 1.4–13.6 nm) on the reaction rate and enantioselectivity were examined; while the selectivity was independent of metal particle size, the rate of hydrogenation was found to be structure sensitive and a correlation between reaction rate sensitivity and particle size is presented.

MARK A. KEANE. Can. J. Chem. **72**, 372 (1994).

On a préparé une série de catalyseurs Ni–SiO_2 par des techniques de précipitation–dépôt et d'imprégnation homogènes et on les a modifiés avec des solutions aqueuses d'acide *R*-(+)-tartrique (AT) dans le but d'induire de l'énantiosélectivité dans l'hydrogénation asymétrique d'un ester β-cétonique prochiral (acétoacétate de méthyle) en ester β-hydroxylé, (*R*)-(−)-3-hydroxybutyrate de méthyle. On a évalué les effets de la préparation des précurseurs des catalyseurs, de la quantité de nickel et de la précalcination sur la réduction du précurseur et on décrit la nature de la distribution des grosseurs des particules de nickel qui en résulte. On a étudié l'influence des interactions métal–support sur la quantité d'AT adsorbé et on présente des données concernant le lixiviation par des métaux corrosifs et sur les changements qui en résultent sur la dispersion du métal. La modification des catalyseurs par l'AT n'induit pas seulement de l'énantiosélectivité, le fréquence d'échange est 15 fois plus rapide que sur une surface non modifiée. La quantité d'AT adsorbée et la fraction de la surface qui est couverte sont reliées au degré d'énantiodifférentiation. On a examiné les effets des variations dans les grosseurs des particules du nickel supporté (grosseurs allant de 1,4 à 13,6 nm) sur la vitesse de réaction et sur l'énantiosélectivié; alors que l'on a trouvé que la sélectivité est indépendante de la grosseur des particules métalliques, la vitesse d'hydrogénation est sensible à la structure et on présente une corrélation entre la sensibilité de la vitesse réactionnelle et la grosseur des particules.

[Traduit par la rédaction]

Introduction

It is now well established (1 and 2, and references therein) that the heterogeneous hydrogenation of methyl acetoacetate (MAA) on nickel catalysts yields methyl 3-hydroxybutyrate (MHB) as the hydrogenated product. While the bare nickel metal generates a racemic product (3–5), modification of the nickel surface by treatment with an optically pure isomer of an amino or hydroxy acid results in the preferential formation of one of the possible enantiomeric forms of MHB (1–4, 6–38). Modification of the activated catalyst is generally achieved in an aqueous solution of the optically active modification reagent. The modified catalyst is then recovered, washed, and immersed in an organic liquid phase containing the reactant. The reaction has been carried out over a variety of supported (3, 4, 18–20, 28, 30, 31, 37, 38) and unsupported (1–3, 11, 28, 29, 32, 36) nickel systems, principally in the liquid phase (3, 4, 11, 19, 20, 27–32, 34, 35, 37, 38), but gas phase transformations have also been reported (23, 26, 30, 36). In attempting to define the nature of the surface sites that promote enantiodifferentiation, the effects of varying the modification conditions have been considered (1, 3, 4, 18, 24, 25, 27, 28, 32, 33) and the reaction variables have also been altered to optimize the enantioselectivity process (1, 4, 10, 12, 14, 17, 34). Regardless, there is still no consensus of opinion regarding the actual source of the enantiocontrol and, to date, the efforts made to relate optical yield to the coverage of the catalyst surface by the modifier have been largely unsuccessful (20, 27, 33, 35, 36). The system is further complicated by the corrosive nature of tartaric acid (TA) adsorption on the surface nickel metal, which can result in the dissolution of over half the initial metal content (3, 4, 25, 28). There is, however, general agreement (1, 3, 4, 20, 25, 31) that the overall values of enantiomeric excess reflect the relative contributions of the TA-modified selective and the bare nickel nonselective metal sites.

From the data presented previously (3, 4, 25), it has become apparent that to obtain maximum enhancement of enantioselectivity it is necessary to pay strict attention to the control of each of the steps involved in the genesis of the enantiodifferentiating sites. Although the modification and reaction steps have received considerable attention, the role of catalyst precursor preparation and activation has largely been ignored. The dependence (20, 21, 37, 38) or independence (30) of enantioselectivity on metal particle dimensions remains open to question. With regard to the published reports of MAA hydrogenation on nickel catalysts, reaction rates have either been omitted or included as addenda to the enantioselectivity data. It has, however, been concluded in a number of instances (7, 12, 17) that the adsorbed modifier lowers the hydrogenation rate by occlud-

ing part of the active metal surface. In addition, several workers have noted a difficulty in obtaining reproducible product compositions (10, 12, 18, 23, 24, 31). In this paper, accurate MAA hydrogenation rates and enantioselectivities are reported for a range of well characterized Ni–SiO_2 catalysts prepared by impregnation and homogeneous precipitation–deposition and modified with optically pure TA. The effect of systematically varying the metal crystallite size on the modification process and ultimately on the rate of MAA conversion and the degree of enantioselectivity is examined.

Experimental

Catalyst activation, modification, and characterization

A range of nickel-loaded (1.5–20.3% w/w Ni) catalysts were prepared by the homogeneous precipitation–deposition of nickel onto a nonporous microspheroidal Cab-O-Sil 5M silica as described in detail elsewhere (4). In addition, an 11.6% w/w Ni–Cab-O-Sil 5M silica catalyst was prepared by impregnation to incipient wetness (39). The water content of the precursors prepared by the deposition–precipitation technique was less than 5% w/w, while the impregnated precursor contained 8% w/w water. The hydrated supported precursors (sieved in the mesh range of 150–125 μm) were normally activated by heating in a 150 cm^3 min^{-1} stream of deoxygenated and predried hydrogen at a fixed rate of 5 K min^{-1} to a final temperature in the range of 673–1073 ± 3 K which was maintained for 18 h. For comparative purposes, certain samples were precalcined (at 5 K min^{-1}) at 723 ± 2 K for 16 h in a purified stream (150 cm^3 min^{-1}) of air, cooled to room temperature, and subjected to the hydrogen treatment described above. Temperature-programmed reduction experiments were performed separately; in each case, 200 mg of the hydrated precursor was heated (with or without in situ precalcination) at 5 K min^{-1} in a 150 cm^3 min^{-1} flow of 6% v/v H_2 in N_2 to temperatures in the range of 673–1073 ± 3 K and the hydrogen consumption was measured using a thermal conductivity cell. The reduction step was also monitored by thermogravimetry using a Pye Unicam thermobalance; both the weight loss (TG) and the rate of weight loss (DTG) were recorded.

The reduced catalysts were flushed in a purified stream (200 cm^3 min^{-1}) of nitrogen, cooled to room temperature, and contacted with 100 cm^3 of 0.01 mol dm^{-3} aqueous solutions of TA. The pH of the modifying solution was preadjusted to the isoelectric point (5.1) for TA using 1 and 0.01 mol dm^{-3} aqueous NaOH solutions for rough and fine adjustments, respectively. The modification was performed in air with constant agitation (600 rpm) for 2 h at 343 ± 2 K. TA was of AnalaR grade and the prepared solutions were found to be better than 99% pure by HPLC; the concentrations of the TA solutions used in the modifications were reproducible to within ±1%. After modification, the catalyst was decanted and washed with distilled water (1 × 25 cm^3), methanol (2 × 25 cm^3), and *n*-butanol (2 × 25 cm^3) before being stored in the latter prior to use. In accordance with the work of Smith and Musoiu (10), the total washing time was kept to within 40–50 min. All the solvents and modifying solutions used in this study were thoroughly degassed by purging with purified helium and heating under vacuum. The nickel content of the postmodifier solution, resulting from an acid leaching of the catalyst, was determined by AA spectrophotometry as described elsewhere (4). Nickel metal dispersions, before and after modification, were determined by carbon monoxide chemisorption (4). The supported metal phase was also characterized by transmission electron microscopy (JEOL JEM-1200EX); the samples were passivated in a 120 cm^3 min^{-1} flow of 1% v/v O_2 in N_2 at 298 ± 1 K for 1 h, before being dispersed on standard copper grids. Micrographs of the pure support were obtained for comparative purposes. The nickel metal particles were taken as being spherically shaped and the particle diameters were accordingly measured from the micrographs.

The amount of TA adsorbed on selected samples was determined by analyzing the pre- and postmodification solutions by HPLC (Spectra Physics). A Spherisorb 5μ C8 packed column (Alltech Association, 250 × 4.6 mm) was used with 0.2 mol dm^{-3} phosphoric acid (Aldrich, >99%) as the mobile phase and detection was by UV (λ = 187 nm). As nickel tartrate (NiTA) has been tentatively identified as the steroselective active site formed by the corrosive adsorption of TA on nickel (18, 30), a correction for the presence of NiTA in the postmodifier was made by preparing a range of aqueous TA–NiTA solutions (of varying NiTA concentration), which were then used to construct a 30-point calibration curve. To enhance sensitivity and accuracy (which was within ±3%), the signal from the integrator was digitized and stored on disc for subsequent analysis using a WINner LABNET routine. The amount of TA adsorbed was calculated as the difference between the values obtained for the solutions before and after modification. NiTA was prepared according to the method of Hoek and Sachtler (18).

Catalytic procedure

The liquid phase hydrogenation of MAA (10 cm^3), using *n*-butanol as a solvent (40 cm^3), was carried out at 343 ± 2 K in a 250-cm^3 glass vessel fitted with a condenser, hydrogen inlet, and thermocouple well. A 60 cm^3 min^{-1} stream of purified hydrogen was bubbled through the suspension that was kept under constant agitation at 600 rpm. Details of the catalytic apparatus are available elsewhere (4). The extent of hydrogenation was determined by HPLC using a Pirkle type 1A 5μ reversible column (250 × 4.6 mm) with a 10% isopropyl alcohol (IPA) – 90% hexane mixture as the mobile phase. The overall degree of hydrogenation was converted to mol% MHB using a 21-point calibration plot; a quadratic equation was used to fit these data to better than ±1%. Optical yields (O.Y.) were determined from measurements of optical rotation (AA-10 Automatic Digital Polarimeter) using the equation

$$\text{O.Y.} = \frac{[\alpha]_D^T}{[\alpha]_0^T} = \frac{100\,\alpha}{[\alpha]_0^T\, lc}$$

where $[\alpha]_D^T$ is the specific rotation of the product solution measured at the sodium D-line and temperature T (293 ± 3 K), $[\alpha]_0^T$ is the specific rotation of the pure enantiomer under the same conditions (−22.95° for *R*-(−)-MHB), α is the measured optical rotation, l is the path length (20 cm) of the cell, and c is the solute concentration. Optical rotation versus *R*-(−)-MHB concentration (in MAA–butanol) data were fitted to a quadratic equation to better than ±2%, which was then used to determine the optical yield of the product; optical yields were reproducible to ±4%. In this paper, optical selectivity is expressed in terms of enantiomeric excess (e.e.), which is defined as

$$\%\text{e.e.} = 100\,\frac{[R\text{-}(-)\text{MHB}] - [S\text{-}(+)\text{-MHB}]}{[R\text{-}(-)\text{MHB}] + [S\text{-}(+)\text{-MHB}]}$$

Results and discussion

Modification of the Ni–SiO_2, prepared by homogeneous precipitation–deposition (HPD) or impregnation (IMP), with *R*-(+)-TA yielded *R*-(−)-MHB as the preferred hydrogenation product. With regard to the published studies (20, 21, 37, 38) which have ascribed structure sensitivity to the asymmetric conversion of MAA, the quoted enantioselectivities were related, in each case, to the dimensions of the metal particles supported on the premodified catalyst. As shown in an earlier report (4), the composition of the modified catalyst differs considerably from the freshly reduced catalyst. To positively attribute a metal particle size effect to the reaction, it is imperative that the catalytic data are related to the conditions prevailing at the active surface during catalysis.

In this study the catalysts were activated, with or without a precalcination step, by temperature programmed reduction (TPR) where the ultimate metal dispersion was reproducible to within ±3%. Representative TPR profiles are presented in Fig. 1 and the pertinent reduction parameters are listed in Table 1.

The profiles generated during the direct reduction of the HPD catalysts (Fig. 1*a*) all exhibit the same basic shape, consisting of a major broad peak with a maximum intensity in the temperature range of 810–850 K and a minor peak that attains a maximum at ca. 580 K. These two distinct peaks suggest the presence of two nickel species that differ in the degree of interaction with the support and hence in the ease of reduction. The low temperature peak arises at a slightly higher temperature than that recorded for unsupported NiO (565 K) and can be attributed to the reduction of a precipitated hydroxide species, which interacts weakly with the support. The bulk of the hydrogen consumption occurs at much higher temperatures and can be interpreted as resulting from a reduction of nickel hydroxysilicate, which has been shown to form on catalysts prepared by precipitation–deposition (40, 41). It may be noted that the total hydrogen consumption exceeds, in most cases, the theoretical value for a complete reduction of the nickel content; the excess hydrogen may be due to a spillover from the nickel metal and is held on the support. From a consideration of peak areas, the higher loaded HPD catalysts exhibit a greater proportion of the readily reduced hydroxide species, i.e., 8% of the total nickel content in the case of Ni–SiO_2-20.3 compared with 2% in the case of Ni–SiO_2-1.5. In addition, the high temperature peak associated with the nickel-rich sample, while being broader, attains a maximum at a lower temperature than the nickel dilute samples (Table 1). It can, therefore, be inferred that nickel–support interactions are stronger at lower metal loadings with the result that a higher reduction temperature is required to attain a maximum in the reduction rate. The TPR profiles of the precalcined samples (representative profile shown in Fig. 1*b*) are characterized by a single broad peak that emerged over a higher temperature range (T_{max} = 850–875 K) than the main hydrogen consumption peak recorded for the uncalcined samples (Table 1). The calcination step, in effect, removed the low temperature peak and stabilized the unreduced surface nickel, possibly by eliminating some of the structural water of the hydrosilicate species and making it more difficult to reduce. In contrast to the HPD technique, catalyst preparation by impregnation has received considerable attention (41–44). The TPR profiles generated during the direct reduction and precalcination–reduction of the impregnated catalyst are shown in Fig. 1*c*. Four peaks were identified (Table 1) for the former case: a small ill-defined peak at T_{max} = 528 K, which has been ascribed (45) to an endothemic phase transition from rhombohedral to cubic NiO which occurs simultaneously with reduction; a minor (573 K) and a major (610 K) peak, which can be attributed to the process

$$H_2 + NiO \rightarrow H_2O + Ni$$

where the minor peak (with a T_{max} similar to that for bulk NiO) is associated with the reduction of very weakly interacting NiO and the higher temperature peak represents the reduction of NiO which interacts to a greater extent with the carrier; and a broad peak with T_{max} = 693 K, which may be due to the more difficult reduction of a surface nickel silicate species. The reduction of the precalcined sample generated a small peak at T_{max} = 503 K, which is thought to be due to the reduction of traces of Ni(III) oxide (43), and a broad peak at T_{max} = 658 K with a shoulder, which can be considered to represent the reduction of both surface NiO and nickel silicate. As with the HPD catalysts, the introduction of the calcination step shifted the T_{max} of the principal peak to a higher value. Taking an overview of the TPR data, it can be concluded that the activation of the HPD catalysts requires higher reduction temperatures owing to the stronger interaction of unreduced nickel with the support, and this interaction is further strengthened by the incorporation of a precalcination step.

The implications of different precursor–carrier interaction strengths due to the preparation and activation procedures on the dispersion of the surface active nickel metal phase are given in Tables 2 and 3. The nickel metal dispersion data were obtained from CO chemisorption and the metal dispersion is expressed as $(Ni_{surface}/Ni_{total}) \times 100\%$. The percentage of nickel dispersion was observed to decrease with increasing nickel loading and reduction temperature. However, under the same reduction conditions the metal phase generated from the HPD precursor was better dispersed than that supported on the activated IMP catalyst. The stronger interaction between nickel and the silica support must persist in the reduced state, with the result that the nickel metal particles are more strongly anchored to the HPD surface. In the case of the nickel-rich samples, there is an increased probability of metal atoms being in close proximity to facilitate agglomeration, a process that is further promoted at higher temperatures and results in a decrease in the exposed nickel area. In contrast to the impregnated samples, precalcination of the HPD catalysts had little effect on metallic dispersion (Table 3). As proposed elsewhere (41, 44), the precalcination of an impregnated precursor can result in the growth of the weakly interacting unreduced nickel species (presumably NiO), which in the reduced state generates a poorly dispersed supported metallic phase. The extent of the nickel–support interaction in the HPD precursors mitigates against such a sintering effect and, as shown in Fig. 1*b*, precalcination increased the stability of the catalyst precursor with an accompanying slight improvement in dispersion (Table 3). As with direct reduction, the percentage of nickel dispersion was lowered on raising the reduction temperature of the precalcined samples.

The supported nickel metal particle size was determined from the dispersion measurements according to the relationship (46) $d = 101/D$ where D is the dispersion or percentage of exposed metal atoms and d is the surface weighted average crystallite diameter, assuming (spherical) particles $\leq$1 nm to be 100% dispersed. In this study, reduction of the range of nickel-loaded HPD samples listed in Table 2 generated nickel particles with average diameters in the range of 1.4–3.7 and 1.7–5.9 nm for reduction temperatures of 723 and 1073 K, respectively. In contrast, the average diameter of nickel particles supported on the impregnated carrier was considerably greater (Table 3) as a direct consequence of the lower nickel–support interaction and higher mobility of the reduced metal leading to the formation of metal aggregates. The nature of the distribution of metal particle sizes, as determined by transmission electron microscopy, is illustrated in Fig. 2 for representative catalysts. Histograms were constructed based on counts of at least 500 particles and a smooth line was drawn through the midpoint of each bar maximum to facilitate the inclusion of a number of particle size distribution (PSD) plots in one figure. It can be seen that the range of sizes of the particles supported on the HPD catalyst is narrow (0.5–6 nm) and is broadened slightly (0.5–8 nm) upon elevating the reduction temperature. The impregnated sample, on the other hand, with a similar nickel content is characterized by a much broader PSD with supported particles of up to 20 nm detected. It should be noted that the average particle diameter computed from electron

microscopy data was up to 10% lower than that inferred from the CO chemisorption measurements.

It is now well established (3, 4, 25, 28) that the generation of the enantioselective site is a corrosive process and results in the extraction of nickel atoms from the metal lattice. There is strong spectroscopic evidence (1) to suggest that TA is adsorbed on the metal surface as a carboxylate. In accordance with the work of Sachtler and colleagues (18, 30), we can assume that TA interacts with the surface nickel to form a NiTA complex which can either remain on the silica carrier to form a supported selective site or diffuse into solution. As shown in Table 2, the concentration of nickel in the postmodifier increased with increasing nickel loading. Under identical modification conditions, a greater proportion of nickel was lost from the impregnated surface (Table 3). The stronger metal–support interactions observed for the HPD catalysts must enhance nickel stability and render the supported metal phase less susceptible to leaching during TA treatment. Precalcination, which has been shown to further enhance metal stability, was also observed to lower the concentration of leached nickel (Table 3). The effect of TA treatment on the particle size distribution is illustrated in Fig. 2. It is clearly evident that the TA treatment removes the smaller nickel particles and shifts the average crystallite diameter to a higher value (Table 3). The smaller nickel particles, which have a higher surface free energy (47), are therefore preferentially leached from the catalyst and nickel particles smaller than 2 nm are particularly susceptible to the corrosive effects of TA. It follows then that a high temperature sintering of the active metal inhibits nickel leaching, as shown in Table 3. The percentage of the initial nickel content leached as a function of reduction temperature is shown in Fig. 3*a* for three representative catalysts. The fraction of the initial nickel content remaining on the surface after modification was greater for the higher loaded samples and increased in each case as particle growth (via increased reduction temperature) was promoted. This effect is most pronounced for the nickel dilute sample where an elevation of the reduction temperature of Ni–SiO_2-1.5 from 673 to 1073 K resulted in over 1.5 times the concentration of nickel remaining on the support.

The number of TA molecules adsorbed was found to increase with increasing metal loading (Table 2). Under the stated modification conditions TA adsorption reached equilibrium after ca. 1 h. It has been demonstrated elsewhere (4) that the amount of TA adsorbed is both time and temperature dependent. On subjecting the calcined (unreduced) samples to the same TA treatment, the residual nickel in solution was less than 10 ppm, while the adsorbed TA phase was less than 6×10^{17} molecules per gram of catalyst. The site for TA adsorption is therefore the supported nickel metal, and TA interaction with the silica support and unreduced nickel is slight. At a particular nickel loading, decreased dispersion due to sintering lowered the concentration of adsorbed TA (Tables 2 and 3). The surface

coverage by TA (θ_{TA}) as a function of reduction temperature is shown in Fig. 3*b*. As TA is adsorbed from solution, there is an accompanying removal of nickel from the solid into the liquid phase, which in effect dilutes the concentration of surface adsorption sites. The fractional coverage by TA is governed by the interplay between the uptake of TA from solution, the number of available adsorption sites, and the extent to which the adsorption sites are removed in the corrosive adsorption step. In the case of the higher nickel-loaded samples, the values of θ_{TA} increased with increasing reduction temperature, although the concentration of surface TA was lower (Table 2) owing to the overwhelming effect of sintering which reduced the number of potential adsorption sites; i.e., the end result is a decrease in the number of adsorbed TA molecules (Table 2), but an increase in the fractional coverage of the more poorly dispersed adsorption sites. The nickel-dilute sample, on the other hand, exhibited a marked decrease in the degree of coverage by TA with an increase in the temperature of activation. In this case, while the elevation of reduction temperature was again accompanied by a decrease in the concentration of the adsorbed modifier, the enhanced stability of the surface nickel metal resulted in a greater number of adsorption sites surviving the corrosive TA treatment, all of which translates into a lower concentration of TA adsorbed on a surface bearing a greater number of adsorption sites.

The apparent reaction rate (expressed here as the number of moles of MAA reacted per hour) was obtained by treating the variation of hydrogenation activity with time (at $t > 1$ h, where

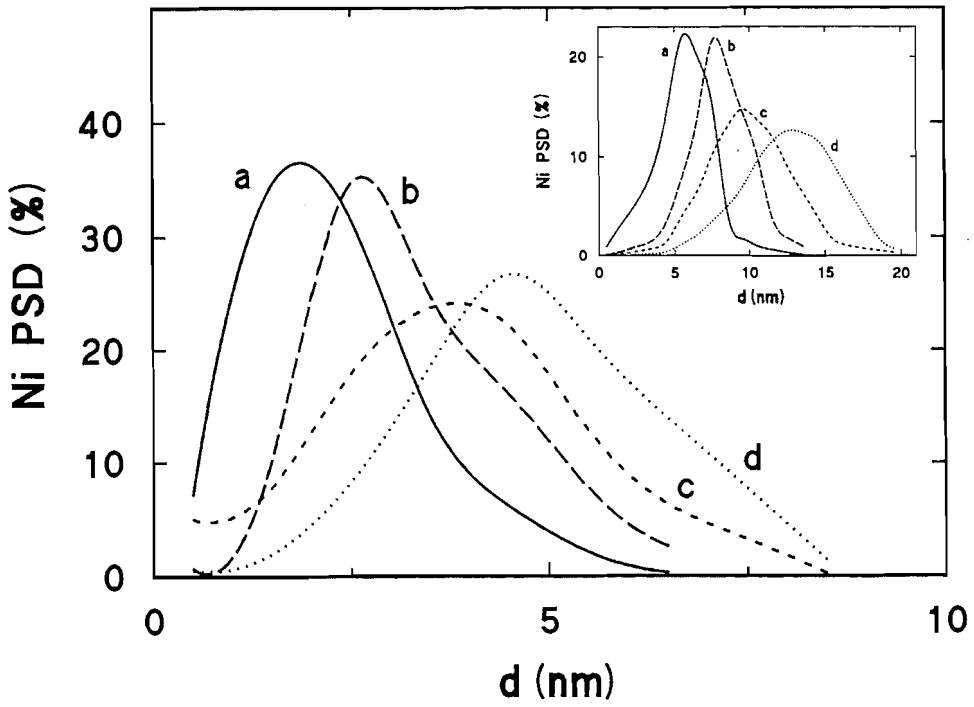

FIG. 2. Particle size distribution (PSD) of nickel supported on Ni–SiO_2-11.9 (HPD) reduced without precalcination at 723 K in the premodified (*a*) and postmodified (*b*) states and at 1073 K in the premodified (*c*) and postmodified (*d*) states. Inset: PSD of Ni–SiO_2-11.6 (IMP); *a–d*, as above.

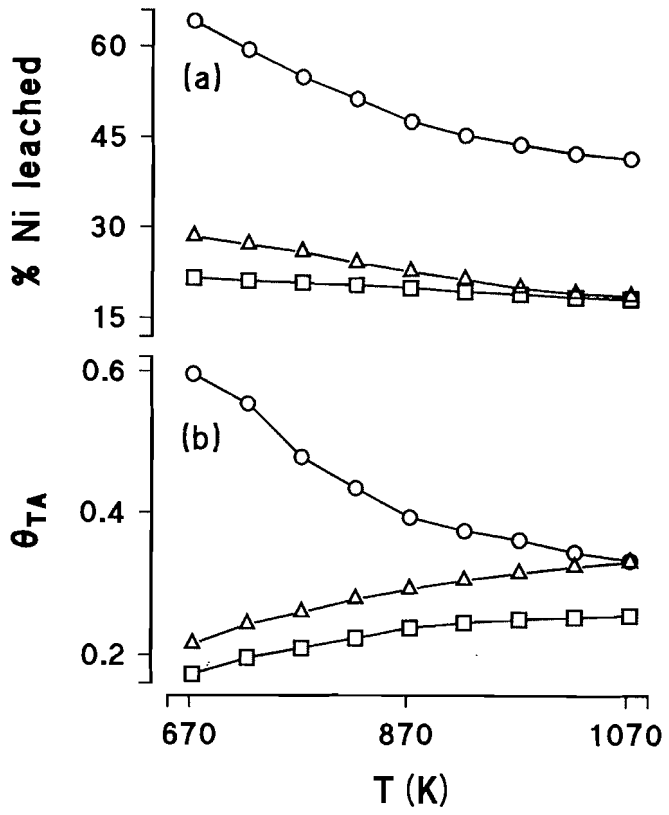

FIG. 3. The effect of reduction temperature (without precalcination) on (*a*) the percentage initial metal content leached and (*b*) the fractional surface coverage by TA. (○) Ni–SiO_2-1.5 (HPD); (△) Ni–SiO_2-11.9 (HPD); (□) Ni–SiO_2-20.3 (HPD).

the contribution of reactant diffusion and reactant–surface interactions is negligible (5)) as a linear relationship and determining the slope of the reaction profile. The effect of particle size (in the range of 1.3–6.9 nm) for the pre- and post-modified catalysts on the apparent rate is presented in Fig. 4, where the changes in particle diameter due to the TA treatment has been taken into account. The range of metal particle sizes were generated by variations in nickel loading and (or) reduction temperature. The graphical relationships presented in Fig. 4 show unambiguously that MAA hydrogenation to MHB is a structure-sensitive reaction and, over the range of particle sizes considered, activity decreased with increasing particle size. The variation in rate with the average nickel diameter for both the modified and unmodified systems has been fitted in Fig. 4 to an expression of the form $R/d = A\exp(-kd)$, to give

$$\text{Unmodified system: } R/d = 4.61(\pm 0.11)\exp[-0.454(\pm 0.012)d]$$

$$\text{Modified system: } R/d = 3.84(\pm 0.13)\exp[-0.249(\pm 0.009)d]$$

where A is a constant and k can be considered to reflect the dependency of the apparent rate on d. Deviations from the fit can be accounted for by a combination of experimental error and the assumptions used to estimate particle sizes. The apparent rates, over the range of particle sizes, were considerably higher for the modified samples. This observation is in direct conflict with earlier reports (7, 12, 17) where the adsorption of TA was observed to inhibit hydrogenation activity by blocking the active surface metal. However, Wells and co-workers (48) and Blaiser and co-workers (49) studying the enantioselective hydrogenation of α-ketoesters over platinum catalysts have also observed an increase in the hydrogenation rate due to the presence of the adsorbed cinchona alkaloid modifier. This

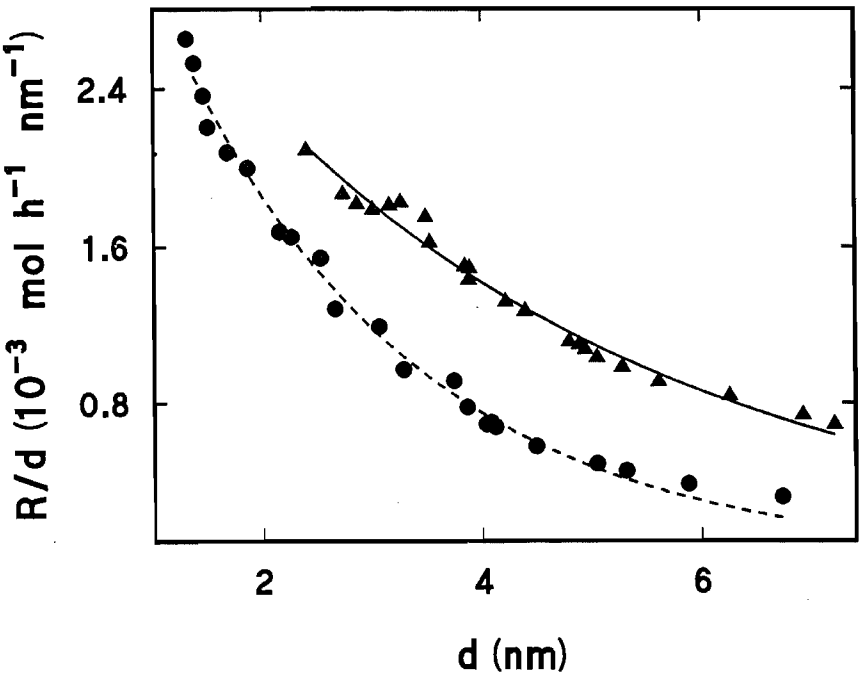

FIG. 4. The relationship between the reaction rate (expressed per nanometre of nickel metal) and the average diameter of the nickel crystallites (d) supported on a range of HPD catalysts reduced in the range of 673–1073 K in the premodified (●) and postmodified (■) states. The dashed line represents the relationship $R/d = 4.61(\pm0.11)\exp[-0.454(\pm0.012)d]$ and the solid line represents the relationship $R/d = 3.84(\pm0.13)\exp[-0.249(\pm0.009)d]$.

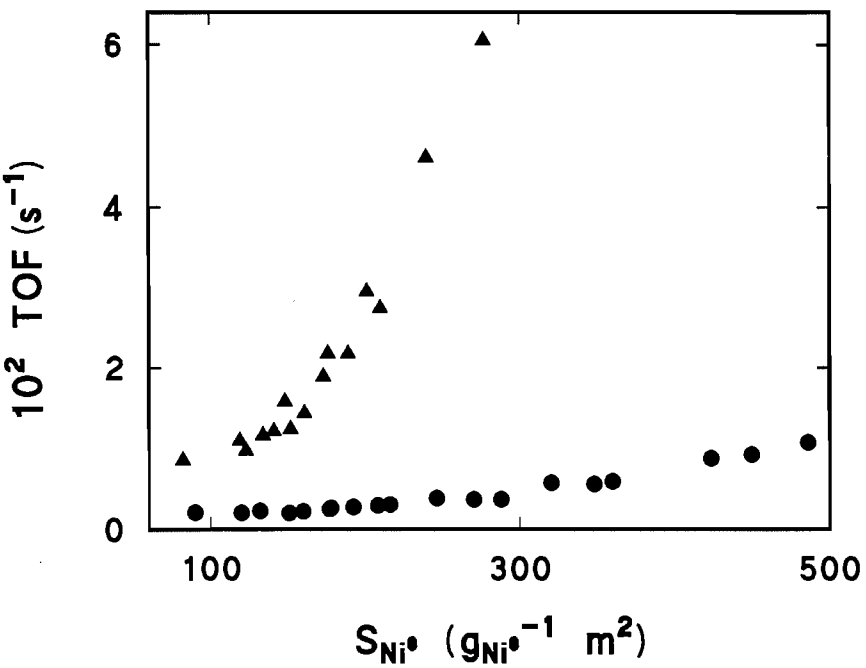

FIG. 5. The relationship between the turnover frequency (TOF) and the nickel metal surface area (per gram of supported nickel metal) for a range of premodified (●) and postmodified (▲) HPD catalysts.

enhancement of activity may be attributable to an increased concentration of surface-adsorbed hydrogen; while the adsorbed TA phase restricts the access of the MAA molecules to the surface metal atoms, the hydrogen can readily adsorb on these sites. Consequently, there is a greater reservoir of dissociated hydrogen on the modified surface, whereas the transport of hydrogen to the unmodified surface is achieved via multilayers of adsorbed MAA (5, 50). The contribution of the more active smaller (<2 nm) nickel metal particles to the overall rate is lower in the case of the modified samples because (*i*) these particles are preferentially leached from the surface into solution during modification and (*ii*) the increase in surface active hydrogen due to the presence of adsorbed TA may promote MAA hydrogenation to a greater extent than the combined action of the surviving small nickel particles. Consequently, the modified catalysts exhibit a lower dependency (lower k values)

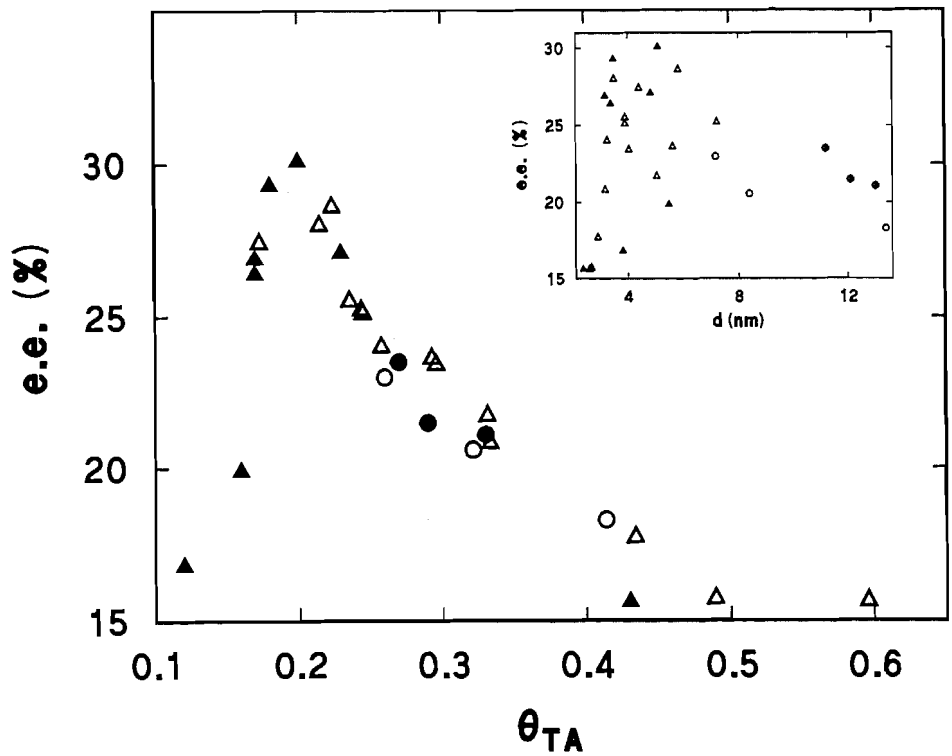

FIG. 6. The relationship between enantiomeric excess (e.e.) and surface coverage by TA (θ_{TA}) for a range of HPD catalysts reduced with (▲) or without (△) precalcination and the 11.6% w/w Ni-impregnated catalyst reduced with (●) or without (○) precalcination in the temperature range of 673–1073 K. Inset: relationship between enantiomeric excess and the average nickel crystallite diameter (d); symbols as above.

of apparent rate on crystallite size than is the case for the unmodified systems. The promoting effect of surface TA on the hydrogenation activity is better illustrated in Fig. 5 where the turnover frequency (TOF) or the number of MAA molecules converted per metal site per second is plotted against the surface metal area (expressed per gram of supported nickel metal), taking account of the changes in the nature of the surface metal as a result of modification. Both the modified and (to a lesser extent) the unmodified catalyst system exhibit an increase in turnover number with increasing metal area. Depending on the catalyst metal loading and pretreatment conditions, the TOF values were up to 15 times greater for the modified surface. Modification by TA, therefore, not only induces enantioselectivity, but also substantially promotes the rate of hydrogenation of MAA.

Nitta et al. (20, 21, 37, 38) have attributed observed differences in enantioselectivities to variations in the morphology of the supported nickel metal and to differences in the strength of nickel–support interactions. They concluded that optical yield was enhanced by surfaces where weak precursor–carrier interactions generated larger (more selective) nickel crystallites. In view of the high degree of structure sensitivity which they observed, Nitta et al. (37) have even suggested that the asymmetric hydrogenation of MAA may be used as a probe for the crystallite size distribution of nickel metal supported on a heterogeneous catalyst. However, as shown in the inset of Fig. 6, in the case of the HPD and IMP catalysts considered in this study there is no direct relationship between the average nickel particle diameter and the enantiomeric excess. Under the stated modification conditions, nickel particles of similar dimensions generated quite dissimilar e.e. values. The scatter of the selectivity data over the range of particle diameters is such that there is no discernible general trend in the e.e. versus d plot. Sachtler and colleagues (30) likewise observed no systematic change in enantioselectivity over the nickel particle size range of 4–11 nm. It must be stressed that the investigations carried out by Nitta et al. did not address the corrosive effects of TA adsorption and the optical yield in each instance was related to the nature of the metal phase in the premodified catalyst. The divergence in the data generated in this study with that reported by Nitta and co-workers (20, 21, 37, 38) highlights the difficulty in attempting to compare different enantioselective systems where the possible permutations of experimental variables involved in the catalyst preparation, activation, modification, and reaction steps mitigates against anything but a tentative qualitative comparison.

While there was no distinct relation between e.e. and d, enantioselectivity was observed to pass through a maximum at θ_{TA} = ca. 0.2 as illustrated in Fig. 6 where asymmetric data for 28 separate catalyst systems are related to surface coverage by modifier. The existence of a maximum in enantioselectivity at a low surface modifier coverage has been attributed to a sandwich effect (3, 4, 25) where both TA and MAA are coadsorbed on the catalyst surface. In the posited model, at θ_{TA} > ca. 0.2 there is a crowding effect, where the adsorbed MAA species is sandwiched between two TA molecules causing a destructive chemical interference, which results in the predominant formation of racemic MHB. Conversely, at θ_{TA} < ca. 0.2 only a fraction of the adsorbed MAA is sterically influenced, while the majority of MAA again undergoes racemic hydrogenation. Accordingly, the optimum TA treatment is one in which the distance between adsorbed TA molecules is large enough to ensure that an adsorbed MAA molecule interacts with only one modifier molecule, but small enough to minimize the number of racemic sites. The structural requirements of the nickel surface under the TA

overlayer are therefore facile in that there was no observable dependence of enantioselectivity on the regime of particle sizes which survive corrosion by TA. Rather, the fractional coverage of the surface by TA appears to be the critical factor in determining the ultimate enantiomeric excess. However, the modification step can perhaps be viewed as a structure-sensitive process in that the larger (>2 nm) supported nickel particles are more effective in anchoring the modifier to the support, whereas the smaller nickel particles are leached into solution.

Conclusions

1. Ni–SiO_2 precursors prepared by HPD exhibit stronger nickel–support interactions than do IMP precursors and consequently require higher temperatures (T_{max}) to attain maxima in hydrogen consumption during temperature-programmed reduction. The metallic phase supported on the HPD carrier is in the form of much smaller nickel crystallites, which are characterized by a narrow size distribution. Precalcination (in the case of the IMP precursor) and increased reduction temperatures (for both IMP and HPD precursors) generated larger metal particles.

2. Modification by TA is a corrosive process that preferentially leaches smaller nickel particles (<2 nm) from the surface, thereby shifting the average metal crystallite diameter to higher values. The metallic phase is more strongly held on the HPD surface and the percentage of the initial metal content leached from the surface decreases with increasing nickel loading. The fractional surface coverage by TA is governed by the extent of TA uptake from the liquid phase and the number of adsorption sites that survive the corrosive leaching by TA.

3. The dependency of the rate on the average crystallite diameter can be represented by (*i*) $R/d = 4.61(\pm 0.11)\exp[-0.454(\pm 0.012)d]$ for the unmodified catalyst system and (*ii*) $R/d = 3.84(\pm 0.13)\exp[-0.249(\pm 0.009)d]$ for the modified catalyst system. In both cases the apparent rate decreases with increasing metal particle size. The modified samples exhibit up to 15 times the turnover rate of the bare nickel metal owing to a higher surface coverage of active hydrogen on the modifier surface.

4. The ultimate degree of enantioselectivity is independent of the regime of particle sizes present after modification; i.e., enantioselectivity is a facile process, whereas the rate of hydrogenation is structure sensitive. Enantiomeric excess is, however, strongly influenced by modifier coverage and an optimum value of $\theta_{TA} = 0.2$ is identified as providing the surface conditions for optimum enantioselectivity, regardless of the average nickel particle diameter.

Received August 16, 1993

THERESA FAUCONNIER, COLIN J.L. LOCK, RUSSELL A. BELL, JAMES F. BRITTEN, and K.D. RAINSFORD. Can. J. Chem. **72,** 382 (1994).

The structure of azapropazone, 5-(dimethylamino)-9-methyl-2-propyl-1*H*-pyrazolo[1,2-*a*][1,2,4]benzotriazine-1,3(2*H*)-dione, was determined by single crystal X-ray diffraction. Crystals were orthorhombic ($P2_12_12_1$), with a = 5.570(1) Å, b = 14.593(3) Å, c = 19.270(4) Å, and Z = 4. Intensities were measured on a Rigaku AFC6-R diffractometer with Cu-Kα radiation and 2316 reflections were used to determine the structure. Contrary to previous postulates, the tricyclic portion of the molecule is not planar. Azapropazone is a zwitterion with the negative charge delocalized over the β-keto-enol system and with the proton on N(6) of the triazine ring. The nonplanarity of the molecule is caused by steric interaction of a methyl group on the exocyclic dimethylamino group with O(3) of the keto-enol system. Bond lengths and angles are normal. NMR studies showed that at room temperature rapid inversion occurs between the two enantiomers, but this inversion slows at low temperatures with $\Delta G^{\ddagger}$ = 44.9(2) kJ mol^{-1}. The product derived from opening of the pyrazolidine ring of azapropazone by formic acid is not as previously formulated. The compound is 3-dimethylamino-7-methyl-1-valeryl-1,4-dihydro-1,2,4-benzotriazine. Its structure was determined by single crystal X-ray diffraction. Crystals were monoclinic ($P2_1/n$), with a = 10.240(2) Å, b = 12.608(3) Å, c = 13.176(3) Å, β = 108.46(3)°, and Z = 4. Intensities were measured on a Rigaku AFC6-R diffractometer with Cu-Kα radiation and 2209 reflections were used to determine the structure. The conformation of the benzotriazine ring system was very similar to that observed in azapropazone and bond lengths and angles were normal.

THERESA FAUCONNIER, COLIN J.L. LOCK, RUSSELL A. BELL, JAMES F. BRITTEN et K.D. RAINSFORD. Can. J. Chem. **72,** 382 (1994).

On a déterminé la structure de l'azapropazone, la 5-(diméthylamino)-9-méthyl-2-propyl-1*H*-pyrazolo[1,2*a*]benzotriazine-1,3-(2*H*)-dione, par diffraction des rayons X. Les cristaux sont orthorhombiques ($P2_12_12_1$), avec a = 5,570(1) Å, b = 14,593(3) Å, c = 19,270(4) Å et Z = 4. On a mesuré les intensités à l'aide d'un diffractomètre Rigaku AFC6-R, avec le rayonnement Kα du Cu et on a utilisé 2316 réflexions pour déterminer la structure. Contrairement aux postulats antérieurs, la portion tricyclique de la molécule n'est pas plane. L'azapropazone est un zwitterion avec une charge négative délocalisée sur le système β-céto-énolique et avec le proton sur le N(6) du noyau triazine. Le caractère non-planaire de la molécule est provoqué par une interaction stérique du groupe méthyle porté par le groupe diméthylamino exocyclique avec le O(3) du système céto-énolique. Les longueurs des liaisons et les angles sont normaux. Les études de RMN ont montré que, à la température ambiante, il se produit une interconversion rapide entre les deux énantiomères, mais que l'inversion est ralentie à basse température avec un $\Delta G^{\ddagger}$ = 44,9(2) kJ mol^{-1}. Le produit obtenu par ouverture du noyau pyrazolidine de l'azapropazone par l'acide formique ne correspond pas à celui qui avait été formulé antérieurement. Le composé est le 3-diméthylamino-7-méthyl-1-valéryl-1,4-dihydro-1,2,4-benzotriazine. On a déterminé la structure par diffraction des rayons X par un cristal unique. Les cristaux sont monocliniques ($P2_1/n$), avec a = 10,240(2) Å, b = 12,608(3) Å, c = 13,176(3) Å, β = 108,46(3)° et Z = 4. On a mesuré les intensités à l'aide d'un diffractomètre Rigaku AFC6-R, avec le rayonnement Kα du Cu et on a utilisé 2209 réflexions pour déterminer la structure. La conformation du système du noyau benzotriazine est très semblable à celle observée dans l'azapropazone et les longueurs des liaisons et les angles sont normaux.

[Traduit par la rédaction]

Introduction

Nonsteroidal anti-inflammatory drugs (NSAIDs) are oral agents that inhibit prostanoid synthesis by blocking the production of cyclooxygenase (1). There are many useful NSAIDs, occurring in seven different chemical classes (2). Azapropazone was originally classified as a pyrazolone because of its structural similarities to another NSAID, phenylbutazone, but additional chemical studies suggest that it should be reclassified as a benzotriazine (3). The drug is used to treat various forms of arthritis and has found some success in European centres, although it is still not widely used in North America. The structure of azapropazone or 5-(dimethylamino)-9-methyl-2-propyl-1*H*-pyrazolo[1,2-*a*][1,2,4]benzotriazine-1,3(2*H*)-dione(**1**) as found in the Merck Index (4) is shown as **A**.

By use of NMR evidence, Fenner and Mixich determined that, in solution, there is no hydrogen atom at C(2) of the pyrazolone ring and suggested, therefore, that azapropazone is a zwitterion with the negative charge delocalized between the two ketone groups and with the proton on N(6) of the benzotriazine group, (shown as structure **B**) (5). Because the proton that is absent from the C(2) position cannot be located directly, since there is rapid exchange, there has been some debate in the literature as to its exact location. Despite references to the work by Fenner and Mixich, Dean interpreted the NMR results as giving evidence of a keto-enol structure with strong hydrogen bonding between the hydroxy proton and the exocyclic dimethylamino group, as seen in structure **C** (6). Such an interpretation seems most unlikely since, in our experience, exocyclic amine groups adjacent to ring double bonds tend to show considerable conjugation between the amine and the double bond, with consequent removal of the "lone pair" electron density and shortening of the

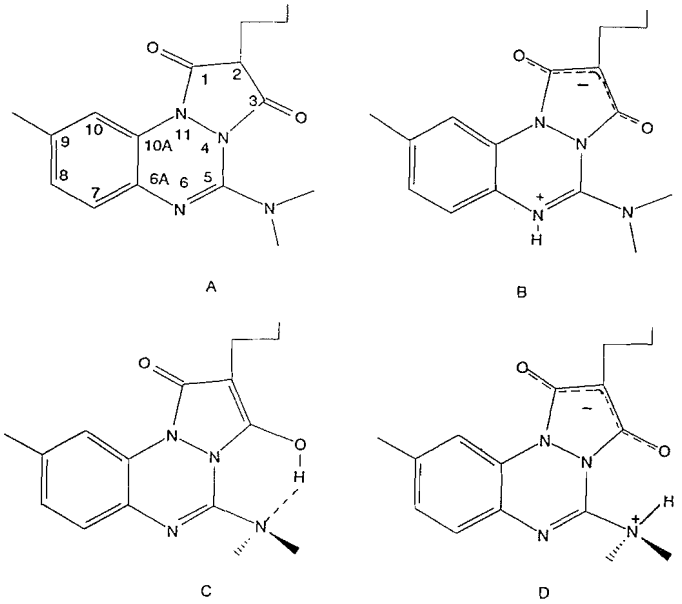
For personal use only.



C(ring)–N distance. In addition, the amine group is then usually nearly coplanar with the double bond system. Despite Dean's argument that there will be a repulsive steric interaction between the methyl group on the amine and the hydroxy group, we did not think this would be sufficient to completely overcome the conjugation and thus Dean's postulated structure seems doubtful. Another postulated structure is that shown as structure **D**, where the hydrogen atom is directly bonded to the nitrogen atom of the dimethylamino group (6). For reasons already given, this structure also seems unlikely. The NMR spectra show that the peak from the aromatic proton at C(10) is pushed downfield about 1 ppm from the other aromatic protons because of interaction of the proton with the deshielding cone of the carbonyl group at C(1). For this reason, and because of the delocalization in the molecule, Fenner and Mixich stated that the three rings of azapropazone form a "vollständig planaren trizyklischen System" (completely planar tricyclic system) (5). We were not convinced by this because, while there is considerable delocalization in the benzotriazine system and the pyrazolidine ring, it does not extend to the N–N region and thus there seems to be no absolute reason for the tricyclic system to be planar. Further, Walker assumed that, despite the solution results, the solid compound existed in the diketone form, although no rationale was given (7). Because of these conflicting views, we have determined the structure of azapropazone.

Experimental

The ^{1}H NMR spectra for azapropazone (**1**) and the product (**2**) derived from opening the pyrazolidine ring of **1** by formic acid were recorded with use of a Bruker AC-200 spectrometer operating at a frequency of 200.1300 MHz, equipped with a 4.70-T cryomagnet and an Aspect 3000 computer. The instrument zero was locked to deuterium of the solvent. The ^{1}H NMR spectra for both samples were obtained using CD_3OD solutions in 32 scans at a spectral width of 2.4 kHz (16K, 0.293 Hz/data point).

The low-temperature NMR data were obtained with use of a Bruker AC-300 spectrometer operating at a frequency of 300.1300 MHz, equipped with a 7.0463-T cryomagnet and an Aspect 3000 computer. The solvent was CD_3OD which provided the deuterium lock signal. Data were acquired in 8 scans at a spectral width of 2.994 kHz (16K, 0.3655 Hz/data point). The spectra were recorded every 5° from −85 to −65°C and −50 to −40°C and every 1° from −65 to −50°C (s, singlet; d, doublet; t, triplet; qt quartet of triplets; tt, triplet of triplets).

X-ray structure determination

Crystals were selected after examination for sharp extinctions with a polarizing microscope and mounted on glass fibres with epoxy glue. Unit cells were obtained by least-squares refinements of the angular coordinates of 24 reflections with θ from 25.0° to 37.4° for **1** and 21.2° to 39.7° for **2**. The details of data acquisition and treatment are given in Table 1. Hydrogen atoms adjacent to atoms in the tricylic ring system were found from the difference maps, but were not refined. Hydrogen atoms in the exocyclic alkyl groups were placed in calculated positions and rode on the atoms to which they were attached. Atomic coordinates and isotropic temperature factors are given in Tables 2 (**1**) and 3 (**2**). Both compounds presented difficulties in the refinement of atoms C(22) and C(23), which were clearly disordered. Many different refinements were tried, with partial occupancies of multiple sites or restraints on bond lengths, but none were satisfactory or better than the results presented here.[2]

Azapropazone, 1

Azapropazone was kindly provided by Siegfried Pahrma AG, Zotingen, Switzerland, as a yellow powder and recrystallized from methanol to give colourless needles, mp 244–247°C (lit. (4) mp 247–248°C). ^{1}H NMR (200 MHz in CD_3OD at 25°C) δ: 0.91 (3H, t, $J_{23,22}$ = 7.3 Hz, $-CH_2CH_2CH_3$), 1.49 (2H, qt, $J_{22,23}$ =7.3 Hz, $J_{22,21}$ = 7.4 Hz, $-CH_2CH_2CH_3$), 2.14 (2H, t, $J_{21,22}$ = 7.4 Hz, $-CH_2CH_2CH_3$), 2.29 (3H, s, CH_3 aromatic), 3.19 (6H, s, $-N(CH_3)_2$), 6.89 (1H, d, $J_{8,7}$ = 8.3 Hz, aromatic); 7.00 (1H, d, $J_{7,8}$ = 8.3 Hz, aromatic), 8.04 (1H, s, aromatic). ^{1}H NMR (300 MHz in CD_3OD) δ: at −40°C, 3.17 (6H, s, $-N(CH_3)$); at −85°C, 3.08 (3H, s, $N(CH_3)$), 3.21, (3H, s, $-N(CH_3)$).

3-Dimethylamino-7-methyl-1-valeryl-1,4-dihydro-1,2,4-benzotriazine, 2

Azapropazone (1 g) was refluxed with formic acid (10 mL) for 1 h. Volatile solvent was removed by rotoevaporation at 70°C under vacuum (1 Torr; 1 Torr = 133.3 Pa) to give a pale yellow oil. The oil was dissolved in 2-butanone and the solution was allowed to evaporate in air, whereupon pale orange crystals were separated. Yield, 0.544 g, 60%; mp 159–163°C (lit. (8) mp 161–162°C). ^{1}H NMR (200 MHz in CD_3OD at 25°C) δ: 0.95 (3H, t, $J_{23,22}$ = 7.2 Hz, $-COCH_2CH_2CH_2CH_3$), 1.41 (2H, qt, $J_{22,23}$ = 7.3 Hz, $J_{22,21}$ = 7.3 Hz, $COCH_2CH_2CH_2CH_3$), 1.63 (2H, tt, $J_{21,22}$ = 7.3 Hz, $J_{21,2}$ = 3.9 Hz, $-COCH_2CH_2CH_2CH_3$), 2.26 (2H, s, CH_3 aromatic), 2.69 (2H, t, $J_{2,21}$ = 3.9 Hz, $-COCH_2CH_2CH_2CH_3$), 2.95 (6H, s, $N(CH_3)_2$), 6.79 (1H, d, $J_{8,7}$ = 8.1 Hz, aromatic), 6.89 (1H, d, $J_{7,8}$ = 8.1 Hz, aromatic), 7.49 (1H, s, aromatic).

Results and discussion

The molecule of azapropazone is shown in Fig. 1 and bond lengths and angles are given in Table 4. The molecule is a zwitterion and, as postulated by Fenner and Mixich, the proton from C(2) appears at the N(6) position. As can be seen from Fig. 1B, the tricyclic part of the molecule is *not* planar. The nonplanarity of the tricyclic system is best exemplified by the dihedral angles between the best planes through each of the rings. These values are as follows: rings 1–2 (see below), 11.7(7)°; rings 2–3, 32.9(7)°; rings 1–3, 44.5(7)°. The nonplanarity at N(11) is

[2]Tables of anisotropic displacement coefficients, hydrogen atom coordinates, best planes, dihedral and torsional angles, and observed and calculated structure factors for **1** and **2** can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

Tables of hydrogen atom coordinates, best planes, and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[a]Diffractometer used, Rigaku AFC6-R; radiation, Cu-Kα (λ = 1.54178 Å); temperature, 298 K; monochromator, highly oriented graphite crystal; 2θ range, 5.0–120.0°; scan type, 2θ–θ; scan speed, variable; 2.00–29.30°/min in ω; scan range (ω), 2.00° plus Kα-separation; background measurement, stationary crystal and stationary counter at beginning and end of scan, each for 25.0% of total scan time; standard reflections, 3 measured every 100 reflections; absorption correction, DIFABS (14).

[b]System used, Siemens SHELXTL PLUS (PC version); solution, direct methods; refinement method, full-matrix least squares; quantity minimized, $\Sigma w(|F_o| - |F_c|)^2$; absolute structure, not determined; extinction correction, not applied; hydrogen atoms, riding model, fixed isotropic U; weighting scheme, $w^{-1} = \sigma^2(F)$.

almost certainly caused by the repulsive interaction of the methyl groups on the exocyclic amine with O(3). The effects of this repulsion, which is illustrated by the nonzero dihedral angle between the atoms of the amine group (C(51)N(5)C(52)) and N(4)C(5)N(6), 24.1(8)°), are transmitted through the rigid parts of the molecule where there is significant π bonding. Normally in systems such as this N(11) would be nearly coplanar with the three atoms attached to it, but N(11) is 0.395 Å out of the C(10A)C(1)N(4) plane. The nonplanarity is further reflected in two of the bond angles of 112.0(3)° for C(10A)N(11)N(4) and 104.8(3)° for C(1)N(11)N(4), which are substantially reduced from the normal 120°.

The benzene ring (ring 1) is nearly planar (maximum deviation, C(10), 0.014 Å), although there is some suggestion of a bend in the ring about the C(7)C(10) axis. The two halves are then planar (maximum deviation, C(8), C(9), 0.006 Å) and the dihedral angle between the two halves is 1.9(7)°. Bond lengths and angles within the ring are not significantly different and agree well with those recorded for other aromatic systems (9).

The triazine ring (ring 2) is nonplanar, adopting a skewed boat conformation. Thus N(11)C(10A)C(6A)N(6) is planar (maximum deviation, C(10A), C(6A), 0.006 Å) and at 1.3(7)° to C(7)C(6a)C(10A)C(10)), whereas C(5) is 0.433 Å and N(4) is 0.708 Å out of the former plane. Bond lengths within the ring show that N(11)—N(4) is a single bond and that there is relatively little conjugation in C(10A)—N(11) or C(6A)—N(6), where the lengths are close to single bond values (10). There is considerable conjugation in the N(6)C(5)N(4)N(5) system, although there is more conjugation of the N(6)—C(5) double bond (1.313(6) Å) with C(5)—N(5) than with C(5)—N(4) (1.313(7) versus 1.366(6) Å). This is also reflected in the size of the angles: 123.2(4) for N(6)C(5)N(5) >

120.6(4) for N(5)C(5)N(4) > 116.2(4)° for N(4)C(5)N(6). As expected, because of the steric interaction of the C(51) methyl group and O(3), the dimethylamino group is twisted from the plane of the triazine ring by an average 24.3. However, the torsional angles on either side of the dimethylamino group are unequal (N(4)C(5)N(5)C(51), 30.1(7)°; N(4)C(5)N(5)C(52), −160.9(5)°; N(6)C(5)N(5)C(51), −152.1(5)°; N(6)C(5)N(5)-C(52), 16.9(8)°). This suggests that the conjugation has been decreased and thus there is a small tendency to nonplanarity at the amino nitrogen atom (N(5)). N(5) is out of the plane of its surrounding carbon atoms by 0.076 Å, which is unusual in such a system.

The pyrazolidine ring (ring 3) is also roughly planar (maximum deviation, N(4), 0.038 Å), with O(1) and O(3) also close to this plane (0.009 and 0.097 Å). The planarity is caused by the delocalization of the negative charge around the diketone system, although this is not symmetric. Thus, C(1)—C(2) is longer than C(2)—C(3) (1.398(7) Å, 1.369(6) Å, 3.15σ, $\sigma = (\sigma_1^2 + \sigma_2^2)^{1/2}$) and C(1)—O(1) is longer than C(3)—O(3) (1.244(6) Å, 1.231(6) Å, 1.86σ), although this difference is hardly signif-

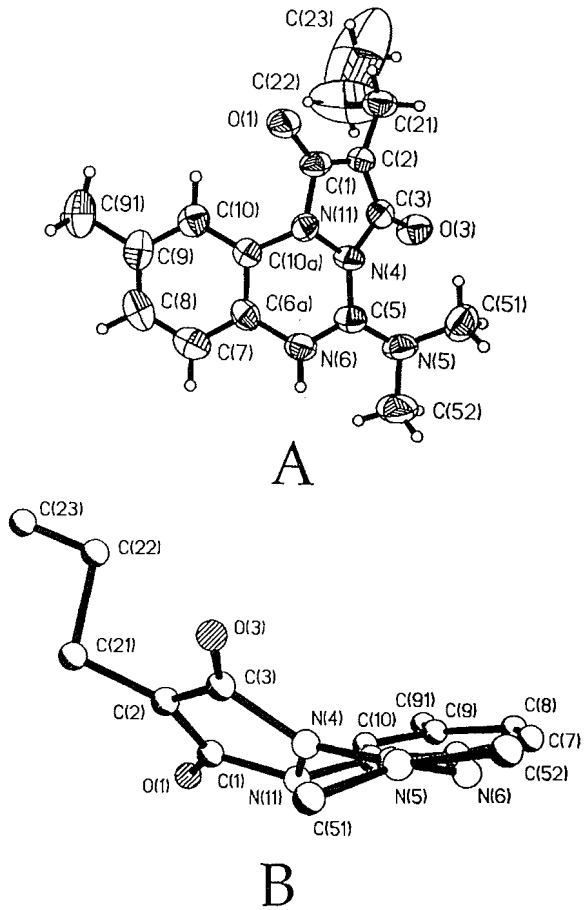

FIG. 1. (A) The molecule of azapropazone showing the atom numbering. (B) The nonhydrogen atoms in azapropazone viewed along N(5)C(5) and showing the nonplanarity of the tricyclic system.

icant. There is little conjugation of this system to N(11)—C(1) or C(3)—N(4) where the lengths are close to single bond values (10).

A legitimate question is whether the solid state structure is relevant to solution conditions, since the NMR spectra show that the methyl groups are equivalent, whereas the structure shows that this should not be so. In addition, one cannot locate the proton in solution because of exchange, so there may be some doubt as to whether it is still attached to N(6). The packing of the unit cell (Fig. 2) addresses the second question. The proton attached to N(6) (which was located from the difference map) forms a quite strong hydrogen bond to O(1) of an adjacent molecule (N(6)...O(1), 2.759(6) Å) (see Fig. 2). Thus, the proton could easily transfer to the oxygen atom if this was energetically preferable and the proton is not kept at N(6) because of steric hindrance. The crystal packing consists of spiral chains of molecules in the *b* direction, each molecule bound to the next by the N(6)—H(6)...O(1) hydrogen bond. In the *a* direction translationally equivalent molecules are adjacent and stacked so that there may be some weak π–π interactions,[3] but in the *c* direction the interactions are van der Waals.

[3]D.P. Santry has calculated (personal communication) that interactions between the π systems of aryl rings will be 6–9 kcal mol^{-1} if there is complete overlap of the rings and they are 3.4 Å apart. The variation in the values is caused by varying orientation of the rings. Such energies are reduced as the overlap is reduced.

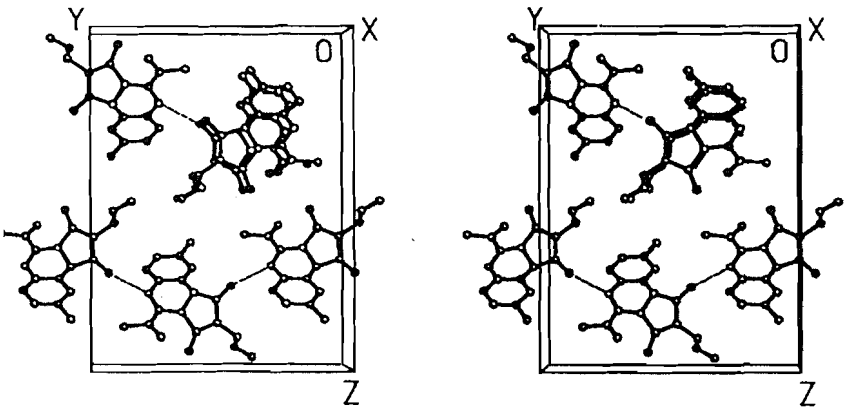

FIG. 2. The packing of azapropazone in the unit cell. Hydrogen bonds are given by broken lines.

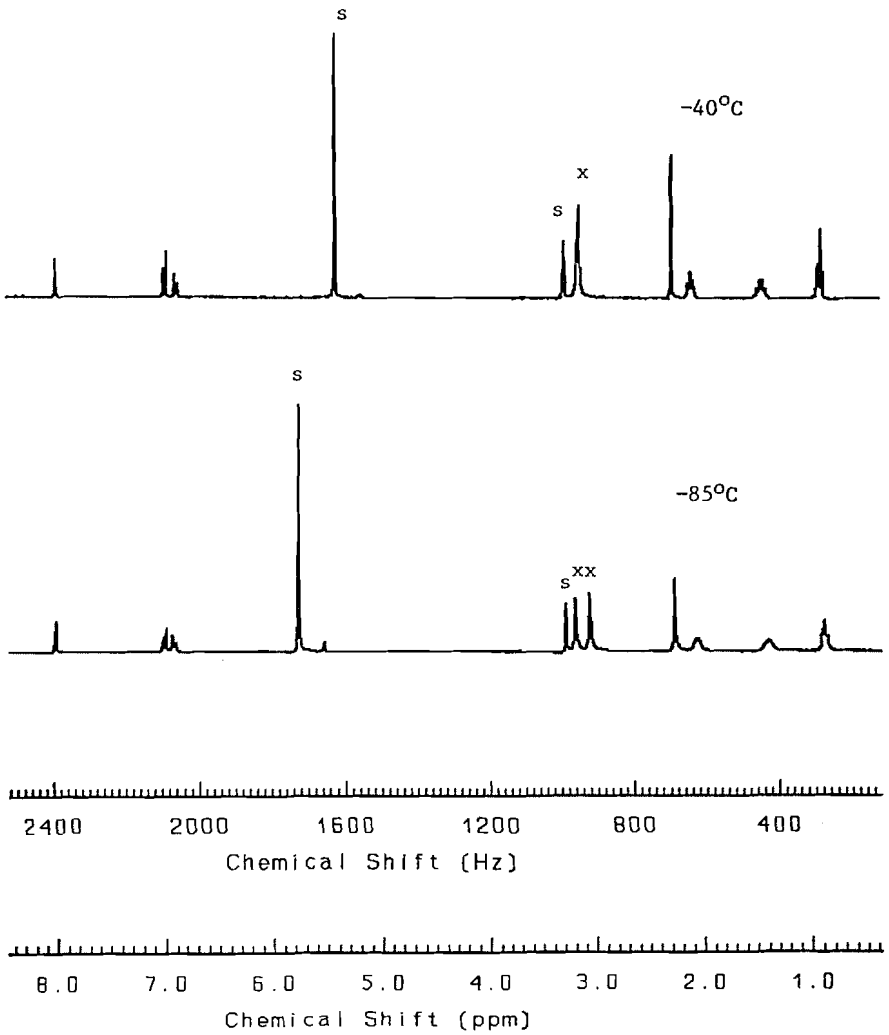

FIG. 3. The proton NMR spectra of azapropazone (**1**) at −40°C and −85°C, which show the resolution of the peak caused by the methyl groups on the exocyclic amine group (*x*) into two peaks at the lower temperature. The solvent peaks are indicated by *s*.

The equivalence of the methyl protons in the NMR spectrum could be because the ring system is rigidly planar with the dimethylamino group at right angles to this plane or the structure shown is the limiting structure in solution and the equivalence is caused by a rapid inversion of the molecule to the other enantiomer, with a consequent rotation of the dimethylamino group about C(5)N(5) by 310° when C(51) will be swapped with C(52).

We have tested this latter model by measuring the NMR spectra at various temperatures and found that it is correct. As can be seen in Fig. 3, the peak caused by the dimethylamino group is still a singlet at −40°C, but by −85°C it has been resolved into two peaks, corresponding to the two inequivalent methyl groups seen in the crystal structure. The variable temperature studies showed that the coalescence temperature for the two peaks was −54 ± 1°C and calculation showed that this

corresponded to $\Delta G^{\ddagger} = 44.9 \pm 0.2$ kJ mol^{-1} for the exchange of the dimethylamino methyl groups. The downfield shift of the aromatic proton at C(10) relative to the other aromatic protons, mentioned above, does not present a problem. The solid state structure shows that the proton is still close enough to the deshielding cone of the carbonyl group C(1)O(1) to allow for the downfield shift effect observed in the NMR spectra, and the relative positions of these two atoms do not shift significantly as inversion takes place.

As noted, the molecule found in the solid state is chiral and we have previously described problems that can be caused by the use of racemic mixtures of enantiomers in the treatment of patients (11–13). This is unlikely to be a problem with azapropazone because of the rapid inversion between the two enantiomers. Nevertheless, it is likely that one enantiomer of azapropazone is preferred for binding to the biological site of action.

To see whether the effects that we observed were peculiar to azapropazone itself, we decided to look at other derivatives. In particular, we tried to prepare the hydrochloride salt of azapropazone and one of the compounds where the pyrazolidine ring had been opened, 3-dimethylamino-7-methyl-2-valeryl-1,2-dihydro-1,2,4-benzotriazine, **2** (8). The former compound was of interest because it should have the distortions observed in azapropazone itself, and because Dean has argued that the protonation site will be N(6), whereas we know that this site is already protonated in the neutral compound. Unfortunately, we were unable to prepare crystals of the desired compound. Solutions of azapropazone acidified with hydrochloric acid decomposed very rapidly, becoming brown after 10 min, even when stored in the dark. The latter compound was of interest because with the opening of the pyrazolidine ring some of the strain caused by the interaction of the methyl group on the exocyclic amine with the ketone group will have been removed. The compound became of greater interest when examination of the proton NMR spectrum showed that the peak assigned to the hydrogen atom attached to C(10) showed a similar downfield shift to that observed in azapropazone.

The procedure used to make this molecule was that of Mixich, and involved refluxing azapropazone with formic acid for 1 h and then recrystallizing the product from 2-butanone (8). On the basis of NMR results Mixich suggested that the pyrazolidine opened at N(11). The NMR spectrum of the product seems to be consistent with the proposed structure but, as noted above, the aromatic proton at C(10) is downfield about 0.5 ppm from the other aromatic protons, which should not be the case if the carbonyl group is no longer proximate.

The determination of the crystal structure explained the NMR spectrum. The molecule (which is numbered incorrectly, but in the same way as azapropazone to facilitate comparisons) is shown in Fig. 4 and bond lengths and angles are given in Table 4. The structure shows that the pyrazolidine ring opened not at N(11) but at N(4). It is possible that the strain on the ring caused by the closeness of the methyl group of the dimethylamino group and O(3) in azapropazone caused the ring to open at N(4). As a result the carbonyl group is still close enough to the aromatic proton to cause a downfield shift. Based on the structure determined, **2** should be named 3-dimethylamino-7-methyl-1-valeryl-1,4-dihydro-1,2,4-benzotriazine.

Many of the structural features are similar to azapropazone, although there are significant differences.The benzene ring (ring 1) is nearly planar (maximum deviation, C(10A), 0.013

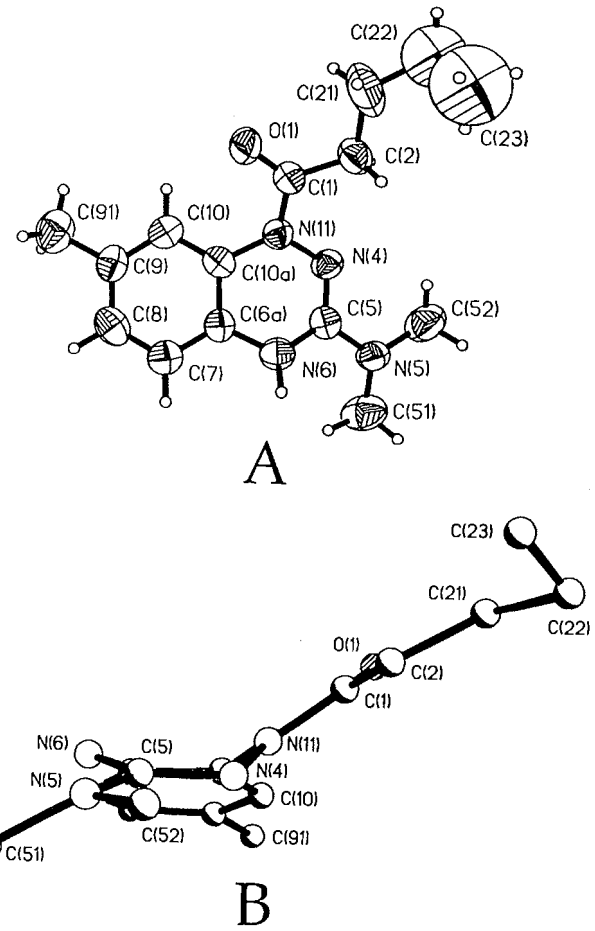

FIG. 4. (A) The molecule of **2** showing the atom numbering. (B) The nonhydrogen atoms in **2** viewed along C(5)...C(6A) and showing the nonplanarity of the tricyclic system.

Å), although again there is some evidence of a fold in the ring, but this time it is about C(8)C(10A) when the two halves are planar (maximum deviation C(7), C(6a), 0.006 Å) and the dihedral angle between the two planes is 4.5(9)°. Bond lengths and angles are normal (8).

The triazine ring (ring 2) shows some significant differences from ring 2 in **1**. The C=N double bond is now between N(4) and C(5), which leaves the protonated N(6) position uncharged. The ring adopts a boat conformation, but in this case it is much more symmetric (plane C(6A)N(6)C(10A)N(11), 4.7(8)° to the benzene ring; maximum deviation, C(6A), 0.028 Å; C(5), 0.629 Å; N(4), 0.754 Å out of plane). With the removal of the restrictions of the pyrazolidine ring N(11) is only 0.031 Å out of the plane C(10A)C(21)N(4). The delocalization around the dimethylamino portion of the ring is less than in **1**, as shown by the bond lengths (N(4)—C(5), 1.304(7) Å; N(6)—C(5), 1.368(6) Å; N(5)—C(5), 1.370(7) Å) and these changes are reflected in small changes in the other bond lengths in the ring. Again the dimethyl amino group is not coplanar with N(4)C(5)N(6) and in this case the average angle is 29.3°, but the differences in the torsional angles are greater (N(4)C(5)N(5)C(51), −146.1(5)°; N(4)C(5)N(5)C(52), 8.2(8)°; N(6)C(5)N(5)C(51), 33.6(7)°; N(6)C(5)N(5)C(52), −172.1(5)°). The smaller conjugation to the dimethylamino group leads to greater nonplanarity at N(5), which lies 0.183 Å out of the C(5)C(51)C(52) plane. The NMR spectrum (see Experimental) showed that the two methyl

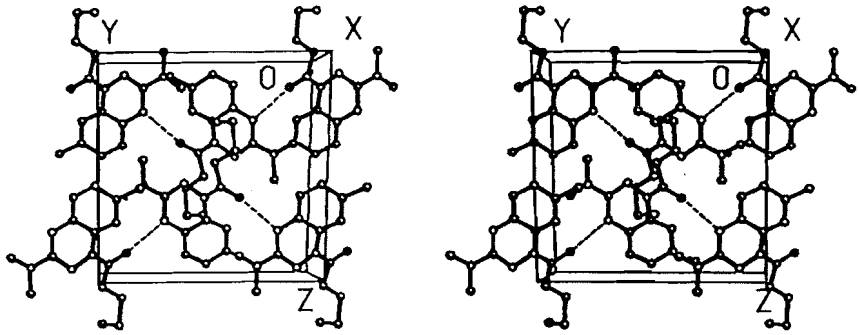

FIG. 5. The packing of **2** in the unit cell. Hydrogen bonds are given by broken lines.

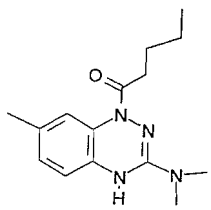

2

groups were equivalent, but this time they did not become inequivalent at low temperature (−85°C). This could be for two reasons. The separation of the individual methyl signals will be smaller and the barrier to rotation may be smaller because the conjugation of the dimethylamino group to the double bond in the ring is smaller, as noted above.

The crystal packing of **2** (Fig. 5) shows similarity to that of **1**. Spiral chains of molecules in the *b* direction are formed by each molecule forming an N(6)—H(6)...O(1) hydrogen bond to the next molecule (N(6)...O(1), 2.834(7) Å). However, the chains are related by a 2_1 axis, so that molecules do not lie adjacent to a translationally equivalent one, as in **1**; therefore interactions between chains in both the *a* and *c* directions are van der Waals.

In conclusion, we have shown by single crystal X-ray crystallography and NMR spectroscopy that the postulated structures for azapropazone and the open-ring derivative are wrong. These results suggest that the products of other reactions of azapropazone might bear reexamination.

TAKOUHI BOHOSSIAN, GENEVIÈVE DELMAS, and HENRI BENOÎT. Can. J. Chem. **72**, 390 (1994).

The characterization in butane of noncrystalline atactic polypropylene (ncPP) (**1**) with a narrow molecular weight distribution (MWD) is presented. It uses a new technique based on a thermogram, consisting of turbidity peaks developed in a solution at a Lower Critical Solution Temperature (LCST) during a step-by-step temperature increase. Several refinements concerning the analysis of data have been added to the expressions used in earlier work on polyethylene. The relation between the volume of the concentrated phase and the attenuation of light has been developed from an expression of the scattered light by a biphasic system. The thermograms gave a good agreement in M_w and M_w/M_n for four well-characterized ncPP samples. Wide MWD isotactic PP samples (**2**) were also analyzed in a mixture of butane and 2-methylbutane. Solution behavior at the LCST of **1** and **2** was compared.

TAKOUHI BOHOSSIAN, GENEVIÈVE DELMAS et HENRI BENOÎT. Can. J. Chem. **72**, 390 (1994).

Nous présentons la caractérisation dans le butane de polypropylene atactique ayant une distribution de poids moléculaire (DPM) étroite. Nous utilisons une nouvelle technique basée sur l'analyse d'un thermogramme. Celui-ci consiste de pics de turbidité développés dans une solution à une température critique de démixion inférieure lors d'une augmentation par palier de la température. L'analyse des données a été raffinée par rapport à un précédent travail sur le polyéthylène. À partir d'une expression de lumière diffusée par un système biphasique, nous avons developpé une relation entre le volume de la phase concentrée et l'atténuation de lumière. Les thermogrammes donnent un bon accord avec M_w et M_w/M_n pour quatre échantillons bien caractérisés de PP atactique. Des échantillons de PP isotactique ayant une large DPM sont aussi analysés dans un mélange de butane et 2-méthylbutane et leur comportement en solution comparé à celui du PP atactique.

Introduction

Before introduction of size exclusion chromatography (SEC), the molecular weight distribution (MWD) of polymers was determined through the preparation and analysis of fractions, the values of their different average molecular weights being obtained from light scattering (M_w) and osmotic pressure (M_n). The existence of a molecular weight dependent liquid–liquid phase separation, with an upper critical solution temperature (UCST) in appropriate solvents situated at low temperature for the amorphous polymers and usually at high temperature for crystalline samples, permits the separation of fractions of different average molecular weights (MW). At a lower critical solution temperature (LCST) situated usually above the solvent boiling point, fractionation can also be used for characterization purposes (1), with the fractions of lower and lower MW being prepared by a succession of temperature increases instead of temperature decreases (or addition of nonsolvent) used at a UCST. The method has not been widely applied because of the difficulties of separating phases under pressure. Modification of the LCST method to make it simpler would meet a need for an alternative to the SEC characterization, which is costly and whose operation is complex at high temperature.

The special feature of the present technique is avoiding the extraction of the concentrated phase, which is normally required for analysis of the amount of polymer and its MW. These two parameters are evaluated instead for each fraction from the attenuation of transmitted light and the temperature of phase separation.

The resolution of the technique is determined by the number of temperature increments that one chooses to make between T_1, the temperature of the onset of turbidity in the solution, and T_f, the temperature at which a temperature increment does not induce any further turbidity in the solution. Since the turbidity response to a phase separation is high, even for small values of the refractive index increment dn/dc, minute amounts of concentrated phase generated by small temperature increments above T_1 are measurable, which leads to a good resolution in the high MW tail of the distribution. The accuracy of the MWD will depend on many parameters, but in particular on the relations used to transform the temperature into average MW (eq. [4] below) and the attenuation of transmitted light into amount of polymer (eq. [5] below). Early work on turbidity at a UCST reported the possibility of quantitative analysis (2, 3) of MWD. In more recent investigations (4–8) on characterization of MWD at a LCST, two empirical equations have been shown to give satisfactory results for the characterization of polyethylene (PE) (4), linear low-density polyethylene (5), and polyisoprene (6). Analysis of polypropylene (PP) by the LCST technique met with difficulties since, in the solvent used for PE, the phase separation of PP occurs at high temperature (65 K higher than for PE) leading to poor resolution in MWD.

The aim of the present paper is to report results in volatile solvents that give good resolution in MWD. Well-characterized high M_w atactic PP (ncPP) samples with a narrow MWD are used to define the optimal forms for eqs. [1] and [2]. Analysis of wide MWD isotactic PP (iPP) samples in the same solvents is reported.

Experimental

Chemicals

Polymers

PP: The noncrystalline PP samples were given to us graciously by Dr. H.J. Barth (now at the Research Center of Du Pont in Wilm-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

ington). Their preparation and characterization have been reported recently (9, 10). Osmometry, light scattering, and intrinsic viscosity were measured to characterize the samples and establish a standard SEC curve for PP at different temperatures. They will be referred to in the following text as SEC-characterized samples. To make clear that these samples, which are hydrogenated poly(1,3-dimethyl-1-butenylene), are not the soluble PP produced commercially, the abbreviation ncPP will be used. The samples of iPP (B1, B2) were from Himont (Varennes, Que.). They were characterized by SEC, but the uncertainty in M_w and M_w/M_n was large.

PE: The narrow MWD samples (C1–C4), from the National Institute of Standards and Technology (NIST), have been analyzed previously (4).

Solvents

Pentane, 2-methylbutane, and 2,4-dimethylpentane were of the highest grade (>99%) from Aldrich and used without purification. Butane and the mixture of butane and 2-methylbutane (2:1 w/w) were from the Mathieson Company (Calgary). ncPP was analyzed in the volatile solvents and the mixture, iPP was analyzed in the mixture, and PE was analyzed in 2,4-dimethylpentane.

Antioxidant

Irganox B-215 is a Ciba-Geigy (1:2) mixture of Irganox 1010, a sterically hindered phenolic antioxidant, and of Irgafos 168, an organophosphite synergist. The antioxidant was used only for PP.

Method and apparatus

A step-by-step T increase in a solution at a LCST forms a succession of equilibria with concentrated phases richer and richer in lower molecular weights. Below T_1, the transmitted light is stable and is not changed by a temperature increment. At T_1 and above, a temperature increment produces a phase-separation induced turbidity. The apparatus consists of a small cylindrical oven that heats a sealed glass tube containing the solution to be analyzed. The oven is controlled by a temperature programmer (Eurotherm) that assures a temperature stability of the oven of 0.1 K. Absolute values of T are measured. A beam of coherent light (Reichert, Cambridge Instruments) passes radially through the glass tube and is received on a silicon photocell (Silonex NLS6161) situated at 15 cm from the oven.

I_0 and I are the intensities received on the sensitive surface s, from the clear and the turbid solutions, respectively. I decreases sharply after the temperature jump since the light goes across a two-phase medium, but increases again back to I_0 when the concentrated phase sediments. The only parameter used in the calculation is h_i, the maximum attenuation of light (i.e., $h_i = (I_0 - I)/I_0$), called later simply turbidity. With the turbidity peaks being numbered between 1 and f (the sum of the turbidity), the total thermogram is $\sum_{i=1}^{i=f} h_i$. This sum is used to obtain the fraction h_i^* of turbidity corresponding to each peak:

$$[1] \qquad \text{Sum of turbidity} = \sum_{i=1}^{i=f} h_i = S$$

$$[2] \qquad \text{Fraction of turbidity} = h_i^* = h_i S^{-1}$$

$$[3] \qquad \text{Cumulative turbidity} = \sum_{i=1}^{i} h_i^*$$

The cumulative turbidity, which varied between 0 and 1, was multiplied by 100 in Figs. 1 and 3. The value of I_0 does not come into the calculation, because if the relative maximum attenuation was calculated, I_0 would enter in the numerator and denominator of eq. [2].

The specific sum of turbidity (S/c) is needed for comparison of the thermograms made at different concentration c. The value of I_0 must be the same in each thermogram. The value of S/c, which does not depend on c in a small range of c, constitutes a good check of an adequate dissolution before the start of the thermogram.

$T_{1/2}$ is the temperature at which the cumulative turbidity is 0.5. To avoid interference with the kinetics of formation of the concentrated phase by lack of homogeneity in the solution (dust, bubbles), the first temperature increase leading to phase separation was initiated only after the solution had been left below T_1 for 2 h. For the same reason, the time interval between temperature increments was kept larger than the time necessary to recover I_0. The temperature increments, (ΔT_i) were chosen to obtain the best resolution in MWD, i.e., to have a large number of fractions particularly in the high MW range. For broad MWD samples, the first few fractions typically constitute a few percent of the total polymer, while for narrow MWD samples the first few T jumps separate a larger fraction (see Appendix). No fraction should be too large ($h_i < I_0/5$), because due to backscattering and other effects, eq. [2] would then be no longer valid. A temperature increment produces in the solution still another effect than the formation of the next fraction. It changes the temperature-dependent equilibrium between the phases that have already been separated; the concentrated phase loses some solvent since the equilibrium polymer volume fraction of the concentrated phase increased with T. Owing to the small temperature increments and the size of each fraction, this effect is small and was neglected.

Preparation of solution

For the homogeneous narrow MWD samples, T_1 was very consistent from one run to another. For wide MWD samples that were not received as fine powder but as pellets or films, the risk of scattered data due to sampling was not negligible. Since there was some difficulty in the preparation of a stock quantity of sample from solution (increased crystallinity, degradation), the present data came from "as received" samples on which several measurements were done. Samples with the same T_1 and somewhat different h_1 were used for computation. If T_1 was different, the measure was disregarded. The value of M_w was mainly sensitive to the magnitude of the turbidity peaks obtained at low T; i.e., h_1, h_2, and h_3 evolved usually at T_1, $T_1 + 1$, and $T_1 + 2$ K.

Choice of the solvent

The more volatile the solvent, the better, since it gave lower LCST and a better resolution, particularly in the high MW region as illustrated by the relation between T_i and M_i shown in Fig. 2. Curves *a*, *b*, and *c* correspond to the $T_i(M_i)$ relationship for butane, the mixture of butane and 2-methylbutane, and pentane, respectively. For crystalline and semicrystalline samples, it was necessary to compromise and use less volatile solvents to avoid the risk of stable crystalline aggregates.

Dissolution

Whatever the technique, the prerequisites for an adequate characterization in solution are to prepare a molecularly dissolved polymer and to avoid shear and thermal or oxidative degradation during the time of analysis. Polymer (2–8 mg), solvent, and antioxidant (2–8 mg) were introduced into a glass tube; N_2 was bubbled through the mixture, cooled by Dry Ice, for 2 h, after which the glass tube was sealed. Solutions whose final concentration c varied between 0.1 and 0.8% for PP and 0.6 and 2% for PE were obtained by rotating the tube gently. In the volatile solvents employed, dissolution was faster (3 h at 130°C) for iPP than in trichlorobenzene (12, 13) where a molecularly homogenous solution was obtained only after 30 h at 165°C. For ncPP, a residence time at 60°C of a few hours was sufficient to dissolve the aggregates. The addition of Irganox was not found necessary for the PE solutions.

Analysis of heterogeneity and conditions for homogenization

The quality of the dissolution was investigated by turbidity and calorimetry at the LCST itself as reported elsewhere (8). The value of T_1 and the shape of the turbidity peak gave an immediate assessment of the quality of the dissolution. A large first turbidity peak due to aggregates signalled incomplete homogenization. A finer quantitative measurement of homogenization was given by the cumulative turbidity which, in well-homogenized solutions, was found (4) to be constant when normalized by c. Homogenization was improved by dilution or, for crystalline samples, by slow crystallization in a temperature gradient and redissolution prior to the LCST analysis. As reported elsewhere (8), the migration of the concentrated phase towards the bottom of the tube could be followed in a sensitive C80 calorimeter programmed with a continuous temperature ramp. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

trace revealed the presence of aggregates and also the slow dissolution of microcrystals at high T. Conditions necessary for a homogeneous solution could be determined from the calorimetric trace at the LCST.

For each fraction, phase separation took place in a short time, i.e., during the beginning and the maximum of the turbidity peak (about 20 min). The fraction contained a distribution of molecular weights in equilibrium with the dilute solution from which it separated. The fact that the cumulative curves for well-dissolved solutions of different concentrations overlapped was an indication that the fraction that separated had the equilibrium distribution of molecular weights.

Prevention and analysis of degradation

Degradation in solution was limited owing to the absence of oxygen, the relatively low temperature, and the gentle stirring. These precautions were not sufficient for ncPP and iPP solutions that were protected by the addition of Irganox.

Degradation involving chain scission was detected by a decrease in the size of the first turbidity peak or (and) its shift to higher temperature. It was used to see the possible degradation occurring during the dissolution time or taking the thermogram itself. The fact that, in the actual conditions of the analysis, T_1 was unchanged and h_1 diminished by less than 10% after taking a complete thermogram attested to the reliability of the high temperature peaks of the first thermogram. The time for the total analysis (including dissolution), with temperature increments separated by 100 min, was between 15 and 28 h depending on the polydispersity. At the end of the first thermogram, the content of carbonyl groups measured by IR in the polymer was not higher than in the original sample.

Quantitative analysis of the data

Basic assumptions

A quantitative measurement of the MWD rests on the following assumptions (4).

1. A relationship between the temperature of phase separation (T_i) and the average MW (M_i) of the polymer phase separating at that temperature. The following equation is a reasonable relation verified in a similar form at the UCST.

$$[4] \qquad T_i = T_\infty + BM_i^{-1/2}$$

where T_∞ is the temperature of phase separation for an infinite MW and B is a constant that increases with solvent volatility.

2. A relationship between the turbidity (h_i) and weight fraction (m_i) of polymer phase separating. The attenuation of light is used as a balance for analyzing the fraction. The simple relation below is used, where k is a temperature-independent constant and n is a number to be determined in the following section. The value $n = 1$ has been used in previous work.

$$[5] \qquad m_i = kh_i^n$$

The differential and integral weight distributions and the average molecular weights M_w and M_n were only a function of the set of (h_i, T_i) and of T_∞ and B. With $n = 1$ in eq. [5] one obtains

$$[6] \qquad M_n = \frac{[\sum(h_i^*/M_i)]^{-1}}{M_w = \sum(h_i^* M_i)}$$

A distribution curve in semilogarithmic coordinates is obtained by differentiating the cumulative curve with respect to ln M.

Refinements in the analysis

Light attenuation and amount of the concentrated phase

Calculation of the amount of polymer undergoing a phase separation from turbidity data is difficult, since the size distribution of the droplets of the concentrated phase is unknown and changes with time. A justification of the empirical equation [5] (with an adequate value of n) would be desirable. An approximate expression is developed in the following paragraphs.

In the turbid systems analyzed at the LCST, the scattered light comes from the diphasic medium of different refractive index. The integral of Porod developed by Guinier (14) is a simple form for the scattered light. Since in nonpolar systems density and refractive index vary similarly, the scattered light is a function of ρ_1 and ρ_2, the density of the two phases:

$$[7] \qquad I(r)r^2\,dr = K(\rho_1 - \rho_2)^2\phi(1-\phi)$$

where I is the scattered light at the distance r from the axes of the beam, ϕ and $1-\phi$ are the volume fractions of the concentrated and dilute phases, and K is a constant. $I(r)$ becomes zero as soon as the solid angle of observation is larger than a few degrees. In the thermogram, the change of signal h_i on the photocell due to scattering of light can be written as

$$[8] \qquad \int I(r)2r\,dr \simeq \int I(r)r\,dr$$

To find a numerical relation between the integrals in eqs. [7] and [8], $I(r)$ is assumed to follow a Gaussian law:

$$I(r) = \bar{e}^{-(r^2/\alpha^2)}$$

where α is a constant. With $r/\alpha = u$, eq. [7] becomes

$$[9] \qquad \int I(r)r^2\,dr = \alpha^3 \int e^{-u^2}u^2\,du = \alpha^3 K'$$

with the same assumption, eq. [8] is written as

$$[10] \qquad \int I(r)r\,dr = \alpha^2 \int e^{-u^2}u\,du = \alpha^2 K''$$

with

$$K' = \int e^{-u^2}u^2\,du$$

and

$$K'' = \int e^{-u^2}u\,du$$

Numerical evaluation of eqs. [9] and [10] shows that for small values of u (or r) they are correlated with a good approximation by eq. [11] below.

$$[11] \qquad \left[\int I(r)r^2\,dr\right]^{1/3} = \left[\int I(r)r\,dr\right]^{1/2} \text{ or } \left[\int I(r)r^2\,dr\right] = \left[\int I(r)r\,dr\right]^{3/2}$$

The integral on the right is the quantity measured by the photocell $h_i^{3/2}$; the integral on the left is the quantity given by eq. [7].

After some rearrangement, the attenuation of light is found to be related to the volume fraction of the concentrated phase

formed at each T_i by the relation

[12] $h_i^{3/2} = \text{constant}(\rho_1 - \rho_2)^2\phi(1-\phi)$

which, in dilute solution, becomes

$$h_i^{3/2} = \text{constant}(\rho_1 - \rho_2)^2 m_i$$

Equation [5] will be then replaced by

[13] $m_i = kh_i^{3/2}$

The effect on M_w and M_n of using either eq. [13] or [5] will be given in Table 2.

Measurement of the incremental volume changes of the concentrated phase with the T steps was tried but did not lead to the establishment of a distribution curve, as explained in the Appendix.

Temperature of phase separation T_i *and the average molecular weight* M_i

The relationship between T_i and M_i in eq. [4] is a very convenient way to relate molecular size and phase-separation temperature. It has been justified by many experimental data on cloud-point curves (CPC) at the UCST and LCST. In the literature (15–17) the value of T^{-1} rather than T is related to $M^{-1/2}$. The present form reflects the increase of solubility of the low MW with T. If T^{-1} were used in the ordinate of Fig. 3, the slopes of the lines would change sign, but not magnitude. As indicated in the Appendix the interaction parameter χ increases with T at the LCST, while it decreases at a UCST. Since phase separation occurs over a large T interval (12–20 K for the narrow MWD standards), an average T_i, namely $T_{1/2}$, has to be used rather than T_i to obtain T_∞ and B from the thermograms of the standards. For a sample with a wide MWD, the interval of phase separation can vary between 20 and 90 K, the lower MW phase separating near the liquid–vapor critical temperature T_c of the solvent. Over this range of T, eq. [4] with a constant value of B is inadequate. Instead of making an empirical correction, an equation of state for the solvent is used that describes the variation of the volume V with temperature up to T_c. The relationship between the equation of state parameters and the LCST is given in the Appendix.

Free volume theory of polymer solutions

The free volume theories of polymer solutions (11, 15–17) predict the existence of LCSTs and their trend with MW. The relationship

[14] $T_i = f(M_i)$

can be calculated with different curvatures (such as the traces of Fig. 2) by changing the parameters related to the difference of free volume or chemical nature between polymer and solvent. For ncPP, the parameters are chosen to fit M_w and M_w/M_n but there is not a unique choice of parameters to attain this result. A linear relationship as in eq. [4] is quite satisfactory for the three samples with similar MW (A1–A3), but gives too high a M_w for sample A4. Details of the calculations are given in the Appendix.

Calculation of MW averages

The averages are calculated from smoothed cumulative curves with a small interval (0.10) of the abscissa, which is ln M. For samples whose MWD is not far from ln-normal, there are several advantages in using the ln-normal representation of Fig. 3. Smoothing is unambiguous over the main part of the cumulative curve, since the experimental points are on a straight line and also the departure from a ln-normal distribution at the high or low MW tails (of the distribution) is more apparent on a ln-normal scale than on a linear scale. The ln-normal distribution depends on two parameters, namely M_0, characterizing the molecular weight of the maximum of the distribution curve, and σ, characterizing its width (18). Due to the analytical expression of the distribution (see Appendix), M_0 and σ can be read directly from the cumulative curve and M_w and M_n can be calculated. If the experimental points do not all lead to a straight line but rather to a curve at the extremities, the averages must be calculated point by point as was done here.

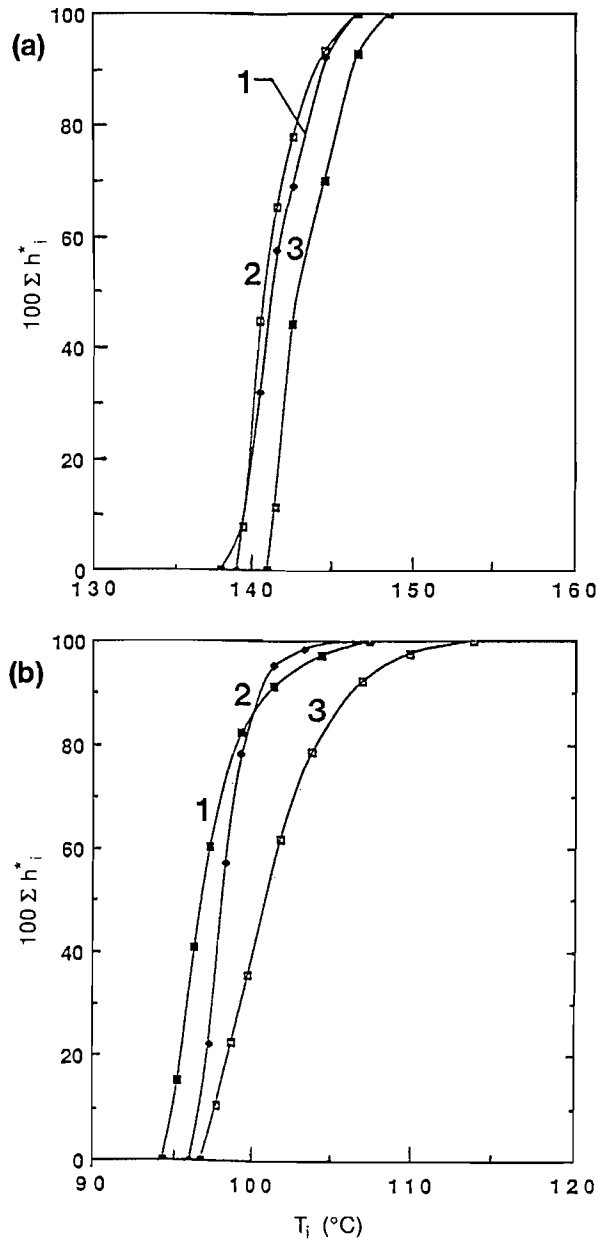

FIG. 1. Cumulative curves ($\sum h_i^*, T_i$) for three high MW and narrow MWD ncPP samples (A1–A3) in (*a*) 2-methylbutane and (*b*) butane. (1 = A1, 2 = A2, 3 = A3.) The curves $\sum h_i^{*3/2}$ not drawn here would be slightly steeper.

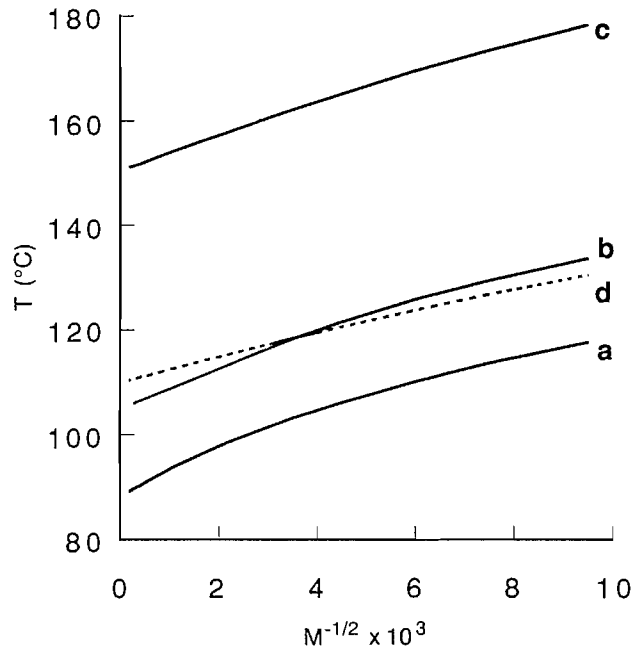

FIG. 2. Correlation between the temperature of phase separation T_i and the average MW in (*a*) butane, (*b*) the mixture of butane and 2-methylbutane, and (*c*) pentane. The equation of state parameters are fitted to the thermogram characteristics of the narrow MWD ncPP samples to obtain the SEC values of M_w and M_n. Dotted line, correlation used for wide MWD iPP.

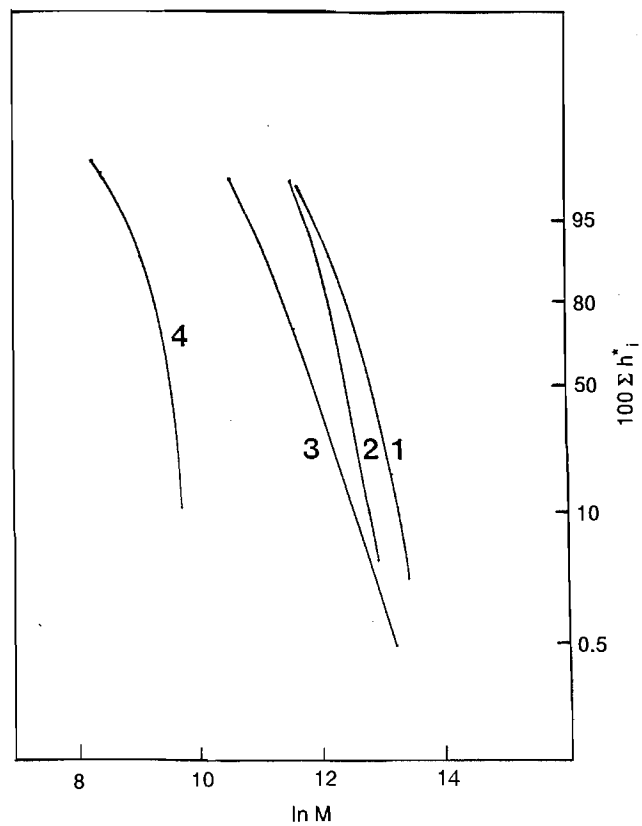

FIG. 3. The ln-normal cumulative curves for the four narrow MWD samples of ncPP in butane. The M_w and M_n are obtained by integrating the curves with $\Delta \ln M = 0.1$. The MW, M_0 of the maximum of the distribution curve M_0, corresponds to the abscissa with 0.5 as ordinate, on the cumulative curve. Curves 1–4 are for A1–A4.

Results and discussion

The MWD of the samples with not very different MWs were measured in four solvents (*n*-pentane, 2-methylbutane, butane, and the butane–2-methylbutane mixture) in order to determine the volatility needed for sufficient resolution. Figures 1*a* and 1*b* clearly give the answer: the resolution is satisfactory in butane (Fig. 1*b*), but just at the limit in 2-methylbutane (Fig. 1*a*). The spacing of the $T_{1/2}$ between the three samples whose M_w are 340 000, 268 000, and 202 000 is 6.5 K in butane and 2.5 K in 2-methylbutane.

The parameters of the equation of state have been calculated to fit the LCST results in these solvents. Numerical values for the relation $T_i = f(M_i)$ (eq. [14]) have been plotted in Fig. 2 for three solvent media: butane, the butane–methylbutane mixture, and *n*-pentane. The smaller slope of curve *c* for pentane, particularly in the high MW region, reflects the fact that this alkane (and obviously higher alkanes such as 2,4-dimethylbutane used for characterizing PE) cannot give a refined MWD for high MW samples.

The results for A1, A3, and A4 in the mixture of butane and 2-methylbutane are comparable to those in butane. The same constants except one (T^*) have been used for the butane and the mixture. T^* is higher in the mixture in order to raise the T_i by 16 K.

The cumulative curves with the ln-normal coordinates are given in Fig. 3 for A1–A4. One sees at a glance the lower polydispersity of A2 (curve 2) with a higher slope than curves 1, 3, and 4. The results are quite satisfactory, the M_w and polydispersity for the three samples being in the same order

[b]2,4-Dimethylpentane.

as those obtained by SEC. The reason for A3 having too low a MW in butane and in the mixture is not clear. Values of M_w and M_w/M_n nearer that obtained by SEC could be obtained by changing slightly curve a of Fig. 2.

Comparison of eqs. [5] and [13]

Changing n from 1 to 1.5 (eqs. [5] and [13]) corresponds to giving more weight to the large peaks, i.e., to reducing the polydispersity of the sample. Tables 1 and 2 give the results of M_w and M_w/M_n for the two equations. For the narrow MWD samples, ncPP (A1–A4) in butane or the mixture and PE (C1–C4) in 2,4-dimethyl pentane, the value $n = 1.5$ gives lower polydispersity by 0.1–0.2. In samples with a higher polydispersity (B1–B2), the effect is larger. Consequently, eq. [13] should be used for M_w and MWD calculations.

Since ultimately, the calibration developed for ncPP samples will be used to analyze isotactic industrial samples, the thermograms of two samples B1 and B2 of Table 2 have been analyzed in the mixture of solvents. B1 is more highly stereoregular than B2. It was found that to obtain the polydispersity value given by SEC, the calibration curve has to be changed as indicated by the dotted line in Fig. 2. Several explanations for this effect are presented. The LCSTs of ncPP and iPP have been found (19) to differ by about 1 K in solvents with a low volatility (LCST near 200°C): (*i*) the effect of tacticity. In systems like the present one with a low LCST, the effect will be probably larger: (*ii*) the effect of polydispersity on solubility. The T_i of narrow and broad MWD samples could be predicted to cross as is seen in Fig. 2 by a simple qualitative argument: (*iii*) the inherent difficulty of comparing techniques without a close control of conditions. Furthermore, using the SEC polydispersity values to test the LCST technique is not recommended, since many factors change the value of M_w/M_n. The value of M_w/M_n for wide MWD samples depends so much on the tails of the distribution that a more reliable way to compare different samples using the same SEC apparatus has been developed (13). It consists of the comparison of M_0 and of the distribution curve over a range of ln M on both sides of M_0. This test could be achieved easily using the SEC and LCST cumulative curves obtained on the same samples: (*iv*) the sensitivity of iPP to degradation in solution. The conditions used to dissolve and analyze iPP (high T residence, shear) are more severe for the SEC than for the LCST technique. The concentration of low M_w may have been increased by the SEC analysis itself, making comparison of the results inappropriate. Another unknown in the analysis of semicrystalline polymers is the concentration of aggregates. It has been shown by calorimetry (20) and intrinsic viscosity measurements (21) on PE and on iPP (unpublished) that the lifetime of strained crystals may be very long and is solvent dependent. Aggregates and small crystals are difficult to detect in solutions except by light scattering. However, since the light scattered by a solution at a LCST is about 10 000 times larger than that of the same solution far from a LCST, the method could be used to detect aggregates in complex polymer mixture. A definite analysis of the solution properties of narrow MWD samples and of wide MWD samples of ncPP and iPP should be made with as much control as possible of the effects mentioned above.

Conclusion

The method of characterizing the MWD by turbidity at a LCST has been reanalyzed in terms of the equations for the treatment of data. It is found that the relation $m = kh_i^n$ should be used with $n = 1.5$. The mixture of solvents (butane and 2-methylbutane) constitutes a suitable compromise to dissolve and characterize with good resolution highly stereoregular high MW PP samples. The small shift necessary to calibrate iPP from the calibration curve of ncPP may have several origins, such as different solubility (due to tacticity or polydispersity) or different state of the solutions in the SEC and LCST techniques.

Acknowledgements

The characterized ncPP fractions have made this work possible and we thank Dr. H.G. Barth for his gift of narrow MWD

Appendix

Justification of the hypothesis

The validity of the equations used in this paper is discussed in detail in ref. 4. We report here the three tests developed to ensure the suitability of eq. [5]. The first consists of analyzing the cumulative turbidities for 11 solutions of narrow MWD samples with ϕ_2 values such as $0.018 < \phi_2 < 0.04$. $\sum h_i$ is found to be a linear function of ϕ_2 that extrapolates to the origin. In the second test, a cumulative curve is made using solutions of different concentrations. When $(\sum h_i)/\phi_2$ is plotted against T_i, a single cumulative curve is obtained. The third test is a correlation of gravimetric and turbidimetric analysis. Several solutions at the same concentration are prepared and analyzed by their thermograms taken from T_1 to a temperature T_i which is different for each tube. The concentrated phase of each solution is characterized by $\sum_{i=1}^{i} h_i^*$, its cumulative turbidity between T_1 and T_i. After equilibrium at T_i the polymer concentrated phase is then separated and its weight w_i is determined gravimetrically for each solution. For seven solutions measured over the interval of phase separation, a good correlation is obtained between $\sum_{i=1}^{i} h_i^*$ or $\sum_{i=1}^{i} h_i^{*3/2}$ and w_i.

The ln-normal distribution

The ln(normal) distribution function is expressed (18) as

$$W(\ln M) = (\text{constant})(\sigma^{-1}) \times \exp[-(\ln M - \ln M_0)^2 0.5\sigma^{-2}]$$

[A1]
$$\sigma = (\sigma^+\sigma^-)^{1/2}$$
$$\sigma^+ = \ln M_A - \ln M_0$$
$$\sigma^- = \ln M_0 - \ln M_B$$

M_A and M_B are the abscissas of the points whose ordinates on the cumulative curve (Fig. 3) are 0.16 and 0.84, respectively, and

$$M_w = M_0 e^{0.5\sigma^2}$$
$$M_n = M_0 e^{-0.5\sigma^2}$$

Equation of state calculations

Parameters for the solvents and the polymer

The reduced volumes and temperatures can be calculated from the expansion coefficients α:

$$\tilde{v}^{1/3} = \frac{(4/3)\alpha T + 1}{\alpha T + 1}$$

and

$$\tilde{T} = \tilde{v}^{-1}(1 - \tilde{v}^{-1/3})$$
$$\tilde{T} = T/T^*$$

in the van der Waals model used by several authors (11, 15, 17, 19).

The T^*s are calculated to be equal to 3990 for butane, 4460 for 2,4-dimethylpentane, 6363 for PE, and 5962 for PP. c_1 $(= P^*V^*/T^*)$ is calculated equal to 1.1 for the solvents used. P^*, V^*, and T^* are the reducing parameters for P, V, and T. For instance, knowing $\tilde{v}$ from α and the above equation and $V/\tilde{v}$, the molar volume from the density $V^* = V/\tilde{v}$.

Parameters for the $T_i = f(M_i)$ *curve*

The critical χ parameter is equal to

$$\chi = c_1 v^2 f(\tilde{v}) + c_1 \tau^2 f'(\tilde{v})$$
$$= 0.5(1 + r^{-1/2})^2$$
$$\approx 0.5 + r^{-1/2}$$

with r being V (polymer)/V (solvent). The terms $c_1 v^2$ and $c_1 \tau^2$, the chemical and free volume differences between polymer and solvent, are independent of T.

The two functions $f(\tilde{v}) = (1 - v^{-1/3})^{-1}$, which diminishes when T increases, and $2f'(\tilde{v}) = [(4/3)\tilde{v}^{-1/3} - 1]^{-1}$, which increases with T, give an expression of the temperature variation of the two contributions to the χ parameter when the temperature increases. Approaching the LCST, the first term becomes negligible compared with the second one. Consequently, the reduced LCST (LCST/T_c) is, for several polymers in many solvents, almost exclusively a function of $c_1\tau^2$:

$$\tau^2 = [1 - (T^*_{\text{solvent}}/T^*_{\text{polymer}})]^2$$

with $c_1 v^2 = 0$. The calculated values of $c_1\tau^2$ are 0.115 for the system PE–2,4-DMC$_5$ and 0.095 for the PP–solvent mixture.

The values of T_1 are 155 and 130°C, respectively (instead of 130 and 110°C). Because of the inadequacy of the simple van der Waals model for the solvent near T_c, the range of the $T_i(M_i)$ curve is much lower than the experimental one.

The parameters have to be changed to fit the experimental temperatures. There is not a unique way to find the $T_i = f(M_i)$ curve that fits the experimental data. Parameters used are as follows: for ncPP in mixture, $T^* = 4400$, $c_1\tau^2 = 0.1083(1 + 1.1r^{-1/2})$, and $c_1\nu^2 = 0.023$; for ncPP in butane, same parameters except $T^* = 4235$; for iPP in mixture, $T^* = 4459$, $c_1\tau^2 = 0.159(1 + 0.3r^{-1/2})$, and $c_1\nu^2 = 0$.

No correction was made to the data to take into account the increase of pressure P between T_1 ($\approx$ 4 atm; 1 atm = 101.3 kPa) and T_f ($\approx P_c$).

Examples of thermograms

The peaks of the thermogram used to draw the cumulative curves are listed below for sample A1 ($c = 0.2\%$ in butane).

Temperature (°C)	$\frac{h_i}{\sum h_i}$	$\frac{h_i^{3/2}}{\sum h_i^{3/2}}$	$10^{-3}M_w$[a]
92.25	0.15	0.14	545
96.25	0.26	0.30	400
97.25	0.19	0.20	300
99.25	0.22	0.25	184
101.25	0.09	0.06	121
104.25	0.06	0.03	70
107.25	0.03	0.01	43.5

[a]From eq. [14].

In arbitrary units, $\sum h_i = 171$, $\sum h_i^{3/2} = 950$, and $J_0 = 230$.

Variation of the volume of the concentrated phase during the course of the thermogram

The concentrated phase accumulates at the bottom of the tube during the T steps. The increase of the volume of the concentrated phases, V(concentrated phase), or of the ratio V(concentrated phase)/V(dilute phase) versus T permits building a cumulative curve similar to that obtained by the turbidity measurements. However, it has been found that at higher T (i.e., above $T_{1/2}$) the ratio levels off and even diminishes. Several parameters (concentration, polydispersity, reequilibration of the phases at high T) influence the ratio of the two phases that has been calculated for an upper critical solution temperature in the case of monodiperse sample. At the LCST, besides the reequilibration of the phases at high T, another factor is important, namely the higher compressibility of the dilute phase than of the concentrated phase near T_c. Consequently, the measurements of volumes of phases cannot be used as a quantitative analysis of the MWD.

Thermograms obtained in a temperature ramp

When the turbidity of the solution is monitored in a temperature ramp (0.5 K/min for instance), it goes through a maximum and falls again to 0 due to sedimentation of the concentrated phases. The technique has been used for differentiating complex mixtures of homopolymers and copolymers whose LCST are situated at different temperatures (PE, PP, and EP copolymers) (7, 22). After the main peak, smaller turbidity peaks, similar to harmonics of the main peak, appear at high T over a period of 30–80 min at the end of the phase separation. They have been attributed to the displacement of the solvent towards the top of the tube during the reequilibration of the phases.

The oxidation of gluconic acid by chromium(VI) in perchloric acid has been found to follow the rate law: $-d[Cr^{VI}]/dt = (k'_1 + k'_2[GA])[H^+]^2[Cr^{VI}]$, where $k'_1 = (7.1 \pm 0.2) \times 10^{-4}$ M^{-2} s^{-1} and $k'_2 = (9.4 \pm 0.2) \times 10^{-2}$ M^{-3} s^{-1}. This rate law corresponds to the reaction leading to the formation of 2-ketogluconic acid by C—H cleavage when a 20-fold or higher excess of acid over chromium(VI) is employed. Buildup and decay of chromium(V) intermediates accompany the decay of chromium(VI). Chromium(V) rates of decay are similar or slower than those of chromium(VI), as observed by electron paramagnetic resonance (epr) and visible spectrophotometry.

SANDRA R. SIGNORELLA, MABEL I. SANTORO, MIRTA N. MULERO et LUIS F. SALA. Can. J. Chem. **72**, 398 (1994).

On a trouvé que l'oxydation de l'acide gluconique par le chrome(VI) dans l'acide perchlorique suit la loi de vitesse : $-d[Cr^{VI}]/dt = (k'_1 + k'_2[GA])[H^+]^2[Cr^{VI}]$ dans laquelle $k'_1 = (7{,}1 \pm 0{,}2) \times 10^{-4}$ M^{-2} s^{-1} et $k'_2 = (9{,}4 \pm 0{,}2) \times 10^{-2}$ M^{-3} s^{-1}. Cette loi de vitesse correspond à la réaction conduisant à la formation de l'acide 2-cétogluconique par le clivage de C—H lorsqu'on utilise une quantité d'acide qui est au moins 20 fois plus grande que celle du chrome(VI). Une accumulation et une décomposition des intermédiaires du chrome(V) accompagne la décomposition du chrome(VI). La résonance paramagnétique éléctronique (rpe) et la spectrophotométrie visible permettent d'observer que les vitesses de décomposition du chrome(V) sont semblables ou plus lentes que celles du chrome(VI).

[Traduit par la rédaction]

Introduction

It is well known that chromium(VI) compounds are carcinogenic (1) and mutagenic (2), and this deleterious behavior of chromium(VI) has been attributed to stable Cr(V) intermediates generated within the cells (3). Ligands that possess two oxygen atoms able to form five-membered rings about the metal atom, such as 1,2-diols and α-hydroxyacids, are reported to stabilize chromium(V) intermediates (4–6) after further interaction with biological reductants (7).

Chromic acid oxidation of α-hydroxyacids has been extensively studied (8–13). These oxidations may yield products coming from either C—C (8–13) or C—H cleavage (9, 10, 14), depending on the particular molecular characteristics, through mechanisms involving either two-electron or three-electron initial oxidation of substrate by chromium(VI). In any case, chromium(V) intermediates have been observed.

Since there are no general patterns for the oxidation of α-hydroxyacids by chromium(VI), we report here the first kinetic study on the chromic oxidation of a polyhydroxyacid (D-gluconic acid).

Experimental

Materials

D-Gluconic acid sodium salt (Sigma grade), potassium dichromate (Cecarelly c.a.), perchloric acid (G.R., E. Merck), acrylonitrile (Aldrich grade), and sodium perchlorate (Fluka grade) were used without further purifications.

Spectrophotometric measurements

Kinetics measurements were made at 350 nm by monitoring the absorbance changes on a Guilford Response II spectrophotometer with fully thermostated cell compartments. Rate constants deduced from multiple determinations were within ±5% of each other. In most experiments the concentration of chromium(VI) was kept constant at 7×10^{-4} M while the gluconic acid concentration was varied from 0.014 M to 0.091 M. In one set of experiments, [GA], $[H^+]$, and T were kept constant whereas $[Cr(VI)]_0$ was varied from 3×10^{-3} to 2×10^{-2} M. Mixtures of sodium perchlorate and perchloric acid were used to maintain a constant ionic strength of 1.50 M. Disappearance of Cr(VI) was followed until at least 80% conversion. Reactant solutions were previously thermostated, and were transferred into a cell of 1 cm path length immediately after mixing. Experiments were performed at 30°C, unless otherwise mentioned.

Cr(V) was monitored spectrophotometrically by following the absorbance growth and decay at 750 nm of mixtures of Cr(VI) (7×10^{-3} M) and gluconic acid (0.14–0.56 M) in 0.50 M $HClO_4$, $I = 1.50$ M, at 30°C, with a path length of 1 cm.

Electron paramagnetic resonance measurements

The epr spectra were recorded with a Bruker spectrometer model ER-200, and g values were measured by reference to diphenylpicrylhydracyl (DPPH, $g = 2.0036$). Spectra were acquired at a frequency of ca. 9.8 Hz with a centered field of 3557 G, a sweep width of 100 G, and a variable modulation amplitude. The sample tube and cavity were kept at 25°C.

Product analysis

Under conditions used in the kinetic measurements (ratios of gluconic acid (GA):Cr(VI) from 20 to 130), qualitative identification of 2-ketogluconic acid (KGA) as the reaction product was carried out by paper chromatography. KGA was identified against an authentic sample using *n*-butanol – acetic acid – water (4:1:5) as eluent. Paper chromatograms were visualized by two kinds of development reagents: a three-stage dip of silver nitrate, sodium hydroxide, and sodium thiosulfate (15) and *p*-anisidine reagent (16). Under these conditions, carbon dioxide was never detected.

To identify the Cr(III) complexes present in solution after reaction completion, uv–vis spectra of these solutions were registered and compared with spectra obtained from a Cr(III) solution and mixtures of gluconic acid or KGA and Cr(III) in 0.50 M $HClO_4$. Under these experimental conditions, KGA did not complex Cr(III), as revealed by a spectrum identical to that of the Cr(III) solution. On the other hand, GA–Cr(III) mixtures showed shifted Cr(III) bands with higher extinction coefficients, compared to those of the free ion, as previously reported for a similar system (17). Given the close agreement (vide infra) of both visible and uv spectral maxima and the intensities between the observed species in the reaction solution and that of the

TABLE 1. Concentration of gluconolactone and gluconic acid in the starting solutions[a]

$[HClO_4]$/M	C_T[b] 10^2/M	R[c]	[GL] 10^3/M	[GA] 10^2/M	$[G^-]$ 10^5/M
0.25	5.03	+0.133	1.23	4.91	3.54
0.75	5.28	+0.171	2.76	5.00	1.24
1.00	4.81	+0.192	4.21	4.39	8.47

[a]Values used in calculations: molar rotations: +23.5° (GL), +2.12° (GA), +5.25° (G^-); $K = [H^+][G^-]/[GL] + [GA] = 1.76 \times 10^{-4}$ (19).
[b]C_T = [GA] + [GL] + $[G^-]$, where GL and G^- refer to gluconolactone and gluconate, respectively.
[c]Optical rotation.

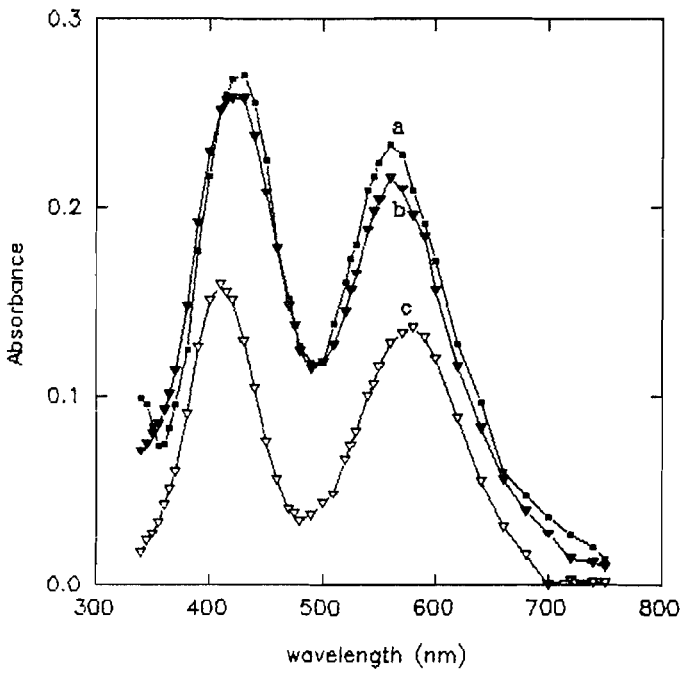

FIG. 1. Absorption spectra of (*a*) A reaction mixture after completion ($[Cr(VI)]_0 = 0.01$ M, [GA] = 0.50 M); (*b*) $[Cr(III)]_0 = 0.01$ M, [GA] = 0.50 M; (*c*) $[Cr(III)]_0 = 0.01$ M. In every case $[H^+] = 0.50$ M, $T = 30°C$, and $I = 1.50$ M.

GA–Cr(III) mixture prepared independently, the binary complex present in the solution may correspond to the complex GA–Cr(III) (428 nm, $\epsilon = 27\ M^{-1}\ cm^{-1}$; 560 nm, $\epsilon = 22\ M^{-1}\ cm^{-1}$) (Fig. 1).

Test for free radicals

A solution of $K_2Cr_2O_7$ (7×10^{-4} M, 2 mL) in 0.50 M $HClO_4$ was added to a mixture of 1.00 M (2 mL) gluconic acid in 0.50 M $HClO_4$ and 0.50 mL of 1.50 M acrylonitrile at 30°C. After 30 min a white precipitate of a polymer appeared slowly. Blank experiments in the absence of gluconic acid or $K_2Cr_2O_7$ did not show formation of any such precipitate.

Results and discussion

Gluconic acid lactonization is acid catalyzed and equilibrium mixtures are reached rapidly in highly acid solutions (18). The acid:lactone proportion in the starting solution may be calculated by optical rotation measurements at given hydrogen ion concentrations (19). Table 1 shows the composition of the substrate solution at three different perchloric acid concentrations. Given the high GA proportion in the starting solution, GA is considered the reactive species in the kinetic discussion below and [GA] is referred to as the total substrate concentration. Nevertheless a possible lactone cooxidation might not be disregarded.

Rate studies

We observed deviations from first-order decay of absorbance at 350 nm over short time periods. This behavior has frequently been attributed to strongly absorbing Cr(V) intermediates formed in the course of the reaction (20). Considering Cr(V) absorbance superimposition, absorbance data at 350 nm vs. time curves were fitted to eq. [1]:

$$[1]\quad Abs^{350} = Abs^{VI} + Abs^{V} = Abs_0 \exp(-2k_6t) + k_6[Cr(VI)]_0\epsilon^{V}(\exp(-k_5t) - \exp(-2k_6t))/(2k_6 - k_5)$$

where ϵ^V refers to the molar absorption due to Cr(V) at 350 nm and was assumed to be 1200 $M^{-1}\ cm^{-1}$ (21) and k_6 and k_5 refer to the rate of disappearance of Cr(VI) and Cr(V), respectively. In this equation, k_6 appears in the numerator of the preexponential term and $2k_6$ appears in the denominator and in the exponential terms because only half of the Cr(VI) reaches Cr(III) through a Cr(V) intermediate, according to the following reaction scheme:

$$[2]\quad Cr(VI) \xrightarrow[k_6]{GA} \text{+ KGA}$$

$$Cr(IV) \xrightarrow{GA} \underset{(fast)}{\xrightarrow{Cr(VI)}} Cr(V) + Cr(III) + KGA$$

$$Cr(V) \xrightarrow[k_5]{GA} Cr(III) + KGA$$

Figure 2 shows a typical curve for one run at 350 nm that fits experimental data well.

From eq. [1], values of k_{obs} ($2k_6$) and k_5 may be obtained and they are tabulated in Table 2. If Cr(V) decays faster than Cr(VI) oxidation, pseudo-first-order rate constants might be calculated from the linear part of ln Abs vs. time curves. However, values obtained from this approach differ from those calculated by eq. [1] at any hydrogen ion concentration. Observed rate constants were also calculated at various [Cr(VI)] ($(3–20) \times 10^{-3}$ M) but at constant T (30°C), [GA] (0.042 M), $[H^+]$ (0.5 M), and I = 1.5 M.

The rate constant was found to be constant with increasing amounts of Cr(VI), which affirms the assumption of a first-order dependence of the rate upon [Cr(VI)].

Values of k_5 and k_6 may be also calculated by eq. [3], which fits the experimentally observed Cr(V) intermediate growth and decay curve at 750 nm well (Fig. 2):

$$[3]\quad Abs^{750} = k_6[Cr(VI)]_0\epsilon^{V}(\exp(-k_5t) - \exp(-2k_6t))/(2k_6 - k_5)$$

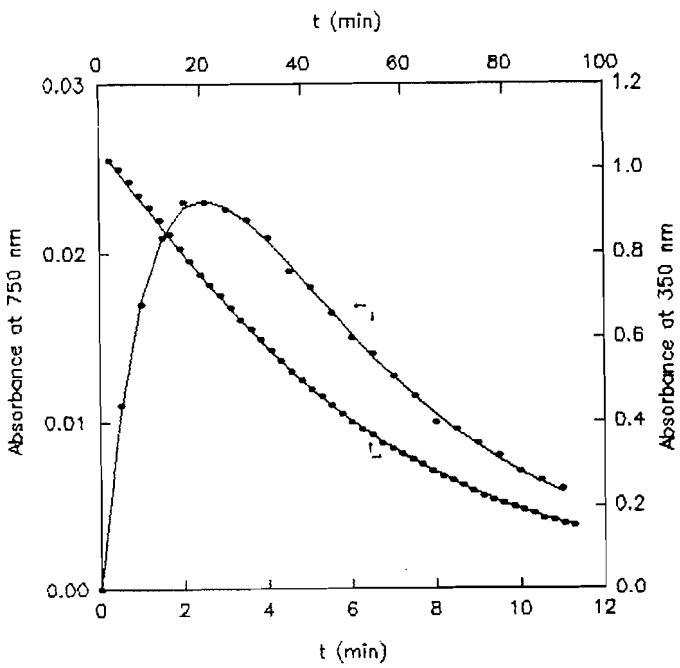

FIG. 2. Absorbance vs. time curves for Cr(VI) and chromium(V) oxidation of gluconic acid at 350 nm: $[Cr(VI)] = 7 \times 10^{-4}$ M, [GA] = 0.014 M, $[HClO_4] = 0.50$ M, $I = 1.50$ M, $T = 30°C$; and at 750 nm: $[Cr(VI)] = 7 \times 10^{-3}$ M, [GA] = 0.14 M, $[HClO_4] = 0.50$ M, $I = 1.50$ M, $T = 30°C$. $T_{max} = 2.5$ min.

where ϵ^V refers here to Cr(V) molar absorption at 750 nm. The best fit of data is obtained when $\epsilon^V = 38$ M^{-1} cm^{-1} (12). By using this ϵ^V, derived rate constants are coincident with those calculated by eq. [1]. Higher values of ϵ^V give rate constants increasingly different from those obtained by eq. [1] and simulated curves fit experimental data points more poorly. Since a 10-cm path length cell was not accessible when these studies were made, tenfold higher initial Cr(VI) and gluconic acid concentrations were necessary to follow absorbance changes at 750 nm. In this way, $k_5/10$ and $2k_6/10$ values calculated by eq. [3] were coincident with those obtained from eq. [1], when the same gluconic/Cr(VI) ratio and $[HClO_4]$ were employed.

The maximum Cr(V) concentration calculated at T_{max} represents up to 22% of the total chromium concentration. The growth and decay of Cr(V) were also followed by epr measurements. The epr spectrum is dominated by a sharp band at $g = 1.976$, with the four peaks ^{53}Cr (9.55% abundance, $I = 3/2$) and hyperfine bands at 18.1 spacing, typical of five-coordinate oxochromate(V) complexes (22). Figure 3 shows a typical curve for peak-to-peak heights of Cr(V) epr signals vs. t obtained on a reacting solution. T_{max} values observed by this technique are rather coincident with those expected by applying $(\ln(2k_6/k_5))/(2k_6 - k_5)$ derived from eq. [3]. T_{max} may be calculated by using k_5 or k_6 values obtained from either eq. [1] or eq. [3] (in the second case values of $k_5/10$ and $2k_6/10$ are used since tenfold higher initial reactant concentrations are needed to detect Cr(V) complexes at 750 nm). In this way, T_{max} observed by epr are within 5–10% of expected values; i.e., for conditions in Fig. 3, the expected T_{max} is 12.6 min ($2k_6 = 0.0498$ min^{-1} and $k_5 = 0.118$ min^{-1}) instead of the experimentally observed 13.5 min. This difference may be accounted for, in part, by the 5°C lower temperature for the epr measurements. Larger differences at higher chromium concentration are due to Cr(III) epr signal overlapping.

At six different acidities, plots of k_{obs} vs. GA concentration gave good straight lines with a positive intercept from which values of k_1 and k_2 were determined (Table 3). Plots of k_1 and k_2

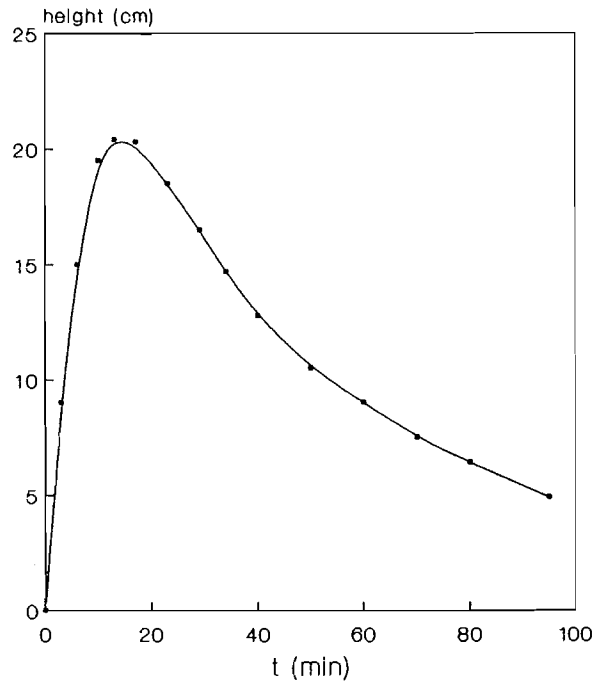

FIG. 3. Peak-to-peak heights of Cr(V) epr signals vs. time: [GA] = 0.035 M, $[Cr^{VI}]_0 = 7 \times 10^{-4}$ M, $[HClO_4] = 0.50$ M, $T = 25°C$. T_{max} = 13.5 min.

vs. $[H^+]^2$ gave straight lines, showing that the complete rate law is given by:

$$[4] \quad -d[Cr(VI)]/dt = k_{obs}[Cr^{VI}] = (k_1' + k_2'[GA])[H^+]^2[Cr^{VI}]_0$$

where $k_1' = (7.1 \pm 0.2) \times 10^{-4}$ M^{-2} s^{-1} and $k_2' = (9.4 \pm 0.2) \times 10^{-2}$ M^{-3} s^{-1}, and $[Cr^{VI}]_0$ represents the total Cr(VI) concentration.

Values of k_5 (Table 2) were not employed to determine the kinetic law for Cr(V) oxidation of GA because of the complex k_5 dependence on [GA] and $[H^+]$. Work is in progress to obtain more data points necessary for this study.

Mechanism

A mechanism consistent with experimental data, is given in the following scheme:

$$[5] \quad Cr(VI) + GA \underset{}{\overset{K_1}{\rightleftharpoons}} [Cr(VI) \cdot GA]^- \quad (A^-)$$

$$[6] \quad A^- + H^+ \overset{K_2}{\rightleftharpoons} AH$$

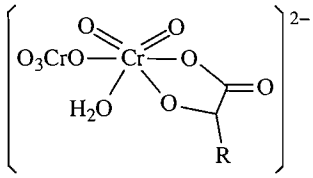
$$[7] \quad AH + H^+ \overset{K_3}{\rightleftharpoons} AH_2^+$$

$$[8] \quad AH_2^+ \xrightarrow{k_I} KGA + Cr(IV)$$

$$[9] \quad GA + AH_2^+ \xrightarrow{k_{II}} KGA + Cr(IV)$$

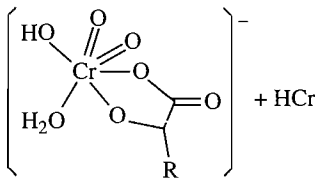
In the pH range studied here, Cr(VI) exists mainly as $Cr_2O_7^{2-}$ (23). Thus the first step of the proposed mechanism may be interpreted as the formation of a monochelate with GA acting as a bidentate ligand bound to Cr(VI) through the 2-hydroxylic and carboxylic groups, as shown in eqs. [10] or [11]:

[10] $Cr_2O_7^{2-} + GA \rightleftharpoons$



or

[11] $Cr_2O_7^{2-} + GA \rightleftharpoons$



$+ HCrO_4^-$

(A^-)

However, since the observed rate constants are independent of the initial concentration of Cr(VI), it is possible that the reactive species is the bis(chelate) and that all the Cr(VI) is converted to the monochelate in the first step:

$$[12] \quad [Cr_2O_7(GA)_2]^{2-} \rightleftharpoons 2A^-$$

In these equations a six-coordinate structure is proposed for A^-, even though a five-coordinate one might also be considered. This anionic intermediate may be doubly protonated (eqs. [6] and [7]) to form AH_2^+, which may decompose directly to Cr(IV) and KGA (eq. [8]) or in the presence of another GA molecule (eq. [9]) through two competitive two-electron pathways.

According to the proposed mechanism, the full rate law for the oxidation of GA by Cr(VI), under conditions studied in the kinetic measurements, can be written:

$$[13] \quad -d[Cr(VI)]/dt = (k_I + k_{II}[GA])K_1K_2K_3[GA][H^+]^2[Cr(VI)]_T$$

Since:

$$[14] \quad [Cr(VI)]_T = [Cr(VI)](1 + K_1[GA] + K_1K_2[GA][H^+] + K_1K_2K_3[GA][H^+]^2)$$

Replacing Cr(VI) in eq. [13]:

$$[15] \quad -d[Cr(VI)]/dt = \frac{(k_I + k_{II}[GA])K_1K_2K_3[GA][H^+]^2[Cr(VI)]_T}{1 + K_1[GA] + K_1K_2[GA][H^+] + K_1K_2K_3[GA][H+]^2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

Thus, if K_1[GA] is the largest term in the denominator, eq. [15] will be simplified to the experimentally observed form.

After the slow steps, reactions [16], [17], and [18] may take place:

$$[16]\quad GA + Cr(IV) \xrightarrow{\text{fast}} GA^{\bullet} + Cr(III)$$

$$[17]\quad GA^{\bullet} + Cr(VI) \xrightarrow{\text{fast}} KGA + Cr(V)$$

$$[18]\quad GA + Cr(V) \xrightarrow{k_{III}} KGA + Cr(III)$$

Cr(IV) formed in the slow steps yields the final Cr(III) and the GA· radical by a later fast step. GA· radical formation is supported by the observer polymerization after addition of acrylonitrile. These radicals may react with Cr(VI) to yield the oxidation product and Cr(V), which reacts with GA to produce KGA and Cr(III) in a two-electron step. The proposed mechanism is in agreement with the initial assumption that only half of Cr(VI) reaches Cr(III) through a Cr(V) intermediate.

Spectrophotometric analysis of the Cr(III) products showed that GA–Cr(III) is the binary complex present at the end of the reaction. Some authors (24) have concluded that initial one-electron reduction of the Cr(VI) leads to Cr(III) entrapment of oxidized substrate, whereas initial two-electron reduction leads to the Cr(III) entrapment of excess substrate. If this generalization were accepted, observation of the Cr(III)–GA complex as product implies an initial two-electron reduction of Cr(VI) by gluconic acid, such as proposed in the mechanism.

Conclusions

The above results show that reduction of Cr(V) occurs at a similar rate and concurrently with Cr(VI) and that the steady-state chromium(V) concentration may be up to 22% of the total chromium present in solution. Consequently, Cr(V) and Cr(VI) absorbances at 350 nm are always superimposed, and an equation taking this situation into account has to be employed. We have observed no effect of the substrate on the absorbance of Cr(VI) at 350 nm such as occurred in other systems in which Cr(VI) esters are observed (25). For example, cyclic aldohexoses, where hydroxyl groups seem to be better disposed to bind Cr(VI) or Cr(V) (6), yield detectable esters even in highly acid conditions. That KGA was the only detected reaction product clearly shows that C—H scission at the α-carbon is preferred to C—C scission for the oxidation of GA by Cr(VI). Oxidation of GA by Cr(VI) resembles that of lactic acid (10) more than that of sugars, though it plainly differs, either in mechanism or oxidation products, from other α-hydroxyacids studied (8).

The photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction. Part 5: methanol–monoterpenes (α- and β-pinene, tricyclene, and nopol), 1,4-dicyanobenzene[1]

DONALD R. ARNOLD[2] AND XINYAO DU
Department of Chemistry, Dalhousie University, Halifax, NS B3H 4J3, Canada

Received April 30, 1993

DONALD R. ARNOLD and XINYAO DU. Can. J. Chem. **72**, 403 (1994).

The reactivity of the radical cations of α- and β-pinene (**8** and **9**), tricyclene (**18**), and nopol (**23**) has been studied. The radical ions were generated, in acetonitrile–methanol (3:1), by single electron transfer (set) to the singlet excited state of 1,4-dicyanobenzene (**1**). Biphenyl (**3**) was used as a codonor. The cyclobutane rings of the initially formed radical cations of α- and β-pinene ($\mathbf{8}^{+\cdot}$ and $\mathbf{9}^{+\cdot}$) cleave to distonic radical cations that react as tertiary alkyl cations and allylic radicals. The results of *ab initio* molecular orbital calculations (STO-3G) are consistent with the observation that the positive charge is largely associated with the tertiary alkyl moiety while the spin density is largely distributed over the allylic radical. There was no evidence, experimental or theoretical, indicative of a bonding interaction between the cationic and allylic moieties of these distonic radical cations. The cyclobutane ring cleavage is irreversible. The radical cation of tricyclene (**18**) also gives 1:1:1 (nucleophile:cyclopropyl:aromatic) adducts. The regio- and stereochemistry of the adducts, and the nucleophile selectivity, are all indicative of nucleophile-assisted cleavage of the radical cation ($\mathbf{18}^{+\cdot}$). The radical cation of nopol ($\mathbf{23}^{+\cdot}$) also cleaves to the distonic radical cation. The cyclobutane ring cleavage must be rapid; intramolecular 1,5-*endo* cyclization of the hydroxyl group cannot compete.

DONALD R. ARNOLD et XINYAO DU. Can. J. Chem. **72**, 403 (1994).

On a étudié la réactivité des cations radicalaires des α- et β-pinènes (**8** et **9**), du tricyclène (**18**) et du nopol (**23**). On a générés les ions radicalaires dans un mélange acétonitrile–méthanol (3 : 1) par un transfert d'un seul électron (set) à l'état excité singulet du 1,4-dicyanobenzène (**1**). On a utilisé le biphényle (**3**) comme codonneur. Les noyaux cyclobutane des cations radicalaires qui se forment initialement à partir des α- et β-pinènes ($\mathbf{8}^{+\cdot}$ et $\mathbf{9}^{+\cdot}$) se clivent en cations radicalaires distoniques qui réagissent comme cations alkyles tertiaires et radicaux allyliques. Les résultats de calculs d'orbitales moléculaires *ab initio* (STO-3G) sont en accord avec l'observation que la charge positive est associée largement avec la portion alkyle tertiaire alors que la densité de spin est largement distribuée sur le radical allylique. Il n'y a pas d'indications, soit expérimentale ou théorique, pour suggérer l'existence d'une interaction de liaison entre les portions cationiques et allyliques de ces cations radicalaires distoniques. Le clivage du noyau cyclobutane est irréversible. Le cation radicalaire du tricyclène (**18**) donne aussi des adduits 1 : 1 : 1 (nucléophile : cyclopropyle : aromatique). La régio- et la stéréochimie des adduits et la sélectivité du nucléophile indiquent toutes que le clivage du cation radicalaire ($\mathbf{18}^{+\cdot}$) est assisté par le nucléophile. Le cation radicalaire du nopol ($\mathbf{23}^{+\cdot}$) se clive aussi en cation radicalaire distonique. Le clivage du noyau cyclobutane doit être rapide car la cyclisation intramoléculaire 1,5-*endo* du groupe hydroxyle ne peut lui faire compétition.

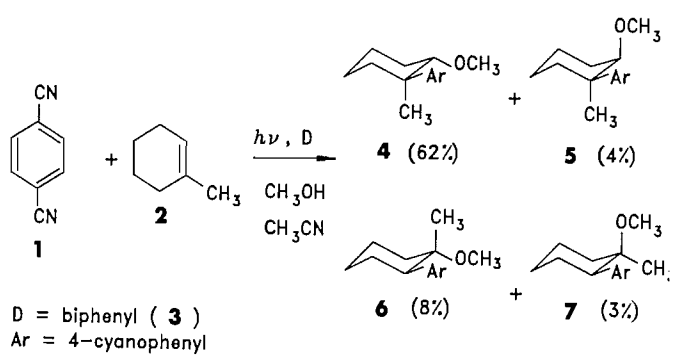
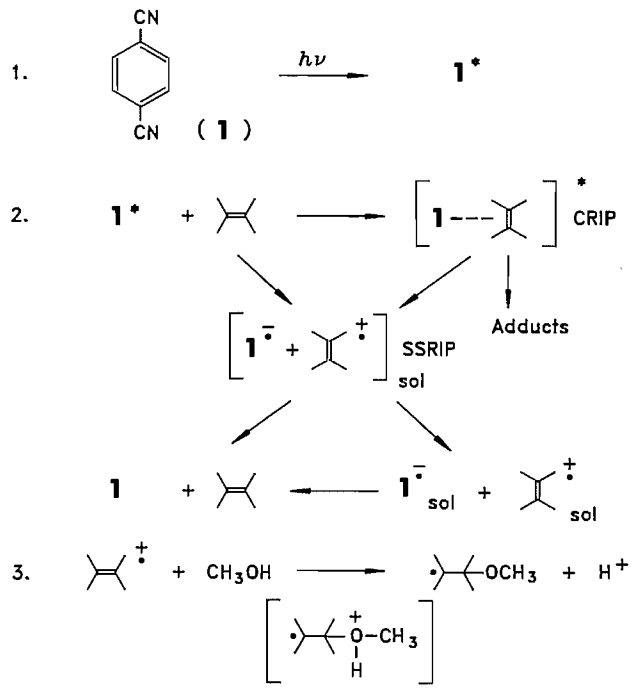
Introduction

In a typical photo-NOCAS reaction, irradiation of an acetonitrile–methanol (3:1) solution of 1-methylcyclohexene (**2**), 1,4-dicyanobenzene (**1**) and biphenyl (**3**) yields the photo-NOCAS adducts **4–7** (reaction [1]) (3). The *anti*-Markovnikov adducts **4** and **5** are the major products; minor products include the Markovnikov adducts **6** and **7**. Reaction occurs when the solution is irradiated in the absence of added biphenyl (**3**); however, the yield of products and the efficiency of the reaction are improved when this codonor is included in the irradiated solution. The proposed mechanism is summarized in Scheme 1 (4).

Reaction [1]





[1]This is also Part 31 of the series Radical Ions in Photochemistry; see refs. 1 and 2 for preceding parts of these series. A preliminary account of some of this work has been published (1*b*).

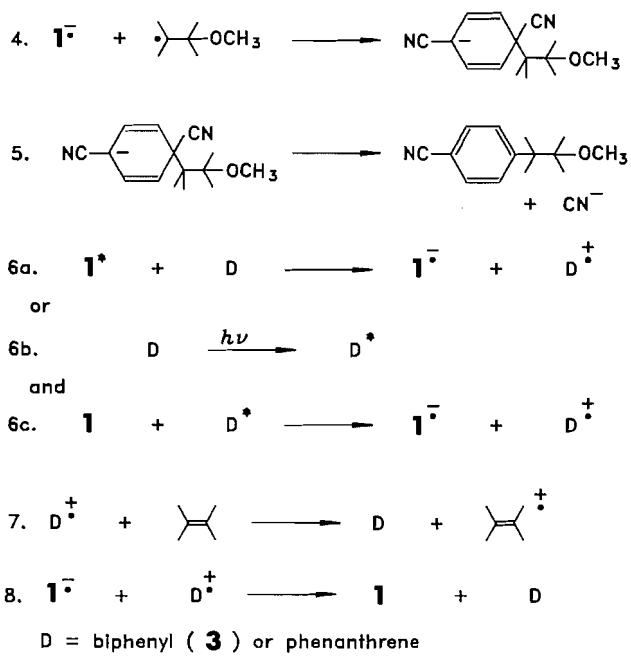
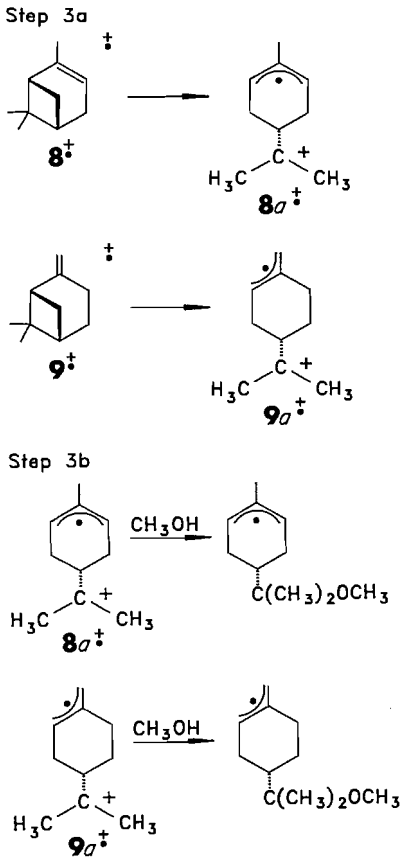




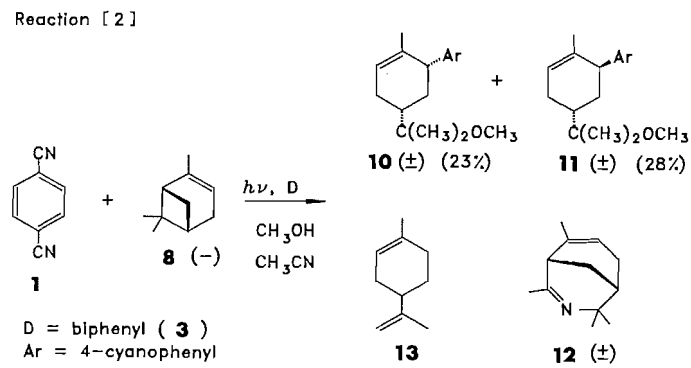
SCHEME 1

There were three initial objectives for this work: (*i*) to provide additional examples illustrating the scope and synthetic utility of the photo-NOCAS reaction; (*ii*) to add support for the proposed mechanism; and (*iii*) to learn more about the reactivity of the unusual intermediates involved.

This reaction is potentially useful for synthesis. A nucleophile, an olefin, and an aromatic compound are combined in one simple step. Two new bonds are made during the process. The products are often difficult to prepare by more traditional methods. Nevertheless, this procedure will not be considered generally in retrosynthetic analysis unless/until the scope and limitations of the reaction are well defined. Such an understanding is usually based upon knowledge of the reaction mechanism. In comparison to reactions involving the more common intermediates (carbocations, carbanions, and radicals), relatively little is known about the reactivity of radical ions. In the context of the present study, the reactivity of the intermediate carbocation and radical, formed as a result of electrophilic or radical addition to α- and β-pinene (**8** and **9**), has been determined (5, 6) and, in fact, could now be predicted. The cyclobutylcarbinyl cation and radical have been studied; both undergo rapid cyclobutane ring cleavage (7, 8). The reactivity of the radical cations of α- and β-pinene ($\mathbf{8}^{+\cdot}$ and $\mathbf{9}^{+\cdot}$) is less well understood (9). Will the cyclic-alkene radical cation remain intact or will the cyclobutane ring cleave? If the cyclobutane ring cleaves, what will be the charge and spin density distribution on the resulting distonic radical cation? If the cyclobutane ring cleaves, will cleavage be reversible, and will there be any bonding interaction between the radical and cationic centres of the distonic radical cation?

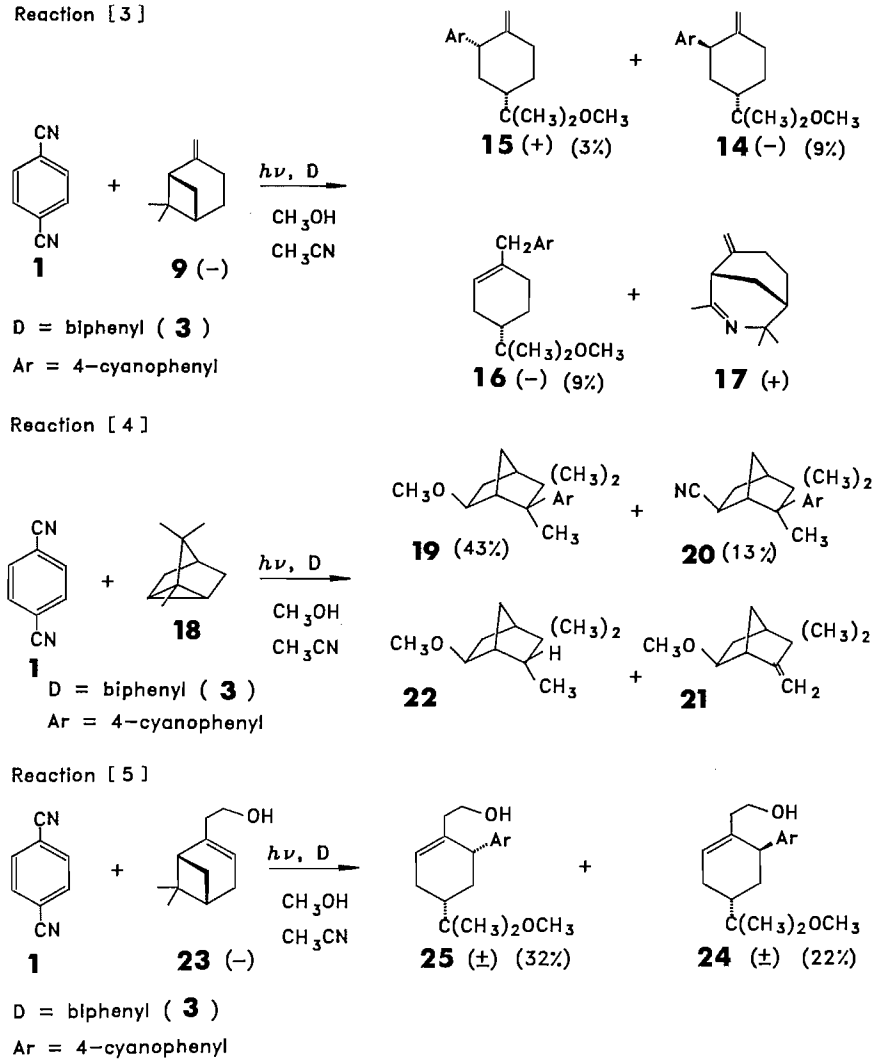
Results

Under the usual reaction conditions (1, 3), solutions of 1,4-dicyanobenzene (**1**) (0.05 M), biphenyl (**3**) (0.015 M), and α-pinene (**8**) or β-pinene (**9**) (0.1 M) in acetonitrile–methanol (3:1) were irradiated through a Pyrex filter with a medium-pressure mercury vapour lamp. Progress of the reaction was followed by capillary column gas chromatography using a mass selective detector (gc/ms). After more than 95% of **1** was consumed, the products were isolated by medium-pressure liquid chromatography on silica gel (mplc). The results are shown in reactions [2] and [3]. Yields are based upon 1,4-dicyanobenzene (**1**) as the limiting reagent.



The photo-NOCAS products obtained from α-pinene (**8**), **10** and **11**, indicate that the cyclobutane ring has cleaved before the addition of methanol (reaction [2]). An additional product, imine **12**, is also formed from a ring-cleaved intermediate. Solutions of **10**, **11**, and **12** are optically inactive; these products are formed as racemic mixtures. A sample of α-pinene (**8**), recovered from the photolysate, showed no decrease in optical activity. Limonene (**13**) was identified (gc/ms, retention time, and fragmentation pattern) but was not isolated from the chromatographic column (mplc).

Three photo-NOCAS adducts (**14–16**) and the cyclic imine (**17**) are formed from β-pinene (**9**) under these conditions (reaction [3]). All of these products are optically active; presumable, with retention of configuration at C-5, that is, *S* from the laevorotatory enantiomer of β-pinene (**9**) (10). A sample of β-



pinene (**9**) recovered from the crude photolysate had the same specific rotation as starting material.

Reactions [2] and [3] occur upon irradiation in the absence of added biphenyl (**3**); the ratio of the photo-NOCAS adducts and cyclic imine is unaffected. However, the yield of these products and the efficiency of reaction are increased upon the addition of this codonor. The polarity of the solvent also has an affect; the photo-NOCAS products were obtained, in the same ratio, from reaction [2] carried out in benzene–methanol (3:1), but the yield and efficiency were lower than when acetonitrile–methanol (3:1) was used as solvent.

Irradiation of a solution of 1,4-dicyanobenzene (**1**) (0.08 M), biphenyl (**3**) (0.08 M), and tricyclene (**18**) (0.1 M) in acetonitrile–methanol (3:1) gave two 1:1:1 adducts (**19** and **20**) as well as ethers (**21** and **22**) (reaction [4]). These products were not detected (gc/ms) in reaction [2]; nor were the photo-NOCAS adducts **14–16**, formed from α-pinene (**8**) in reaction [2], detected in this reaction. Little reaction occurred when a similar solution of **1** and **18**, without the codonor **3**, was irradiated.

When this irradiation was carried out under conditions identical to those described above (reaction [4]) except using acetonitrile–perdeuteriomethanol (3:1) as the solvent, the same four products were obtained; the mass spectra of **19**, **21**, and **22** reflect deuterium incorporation. For **19**, the base peak at 186 (*m/z*) due to $C_{12}H_{12}NO$ and the molecular ion peak at 269 due to $C_{18}H_{23}NO$ move to 189 and 272, consistent with the incorporation of three deuterium atoms on the methoxy methyl group. Also, for **21** the molecular ion ($C_{11}H_{18}O$) at 166 (*m/z*) is replaced by a peak at 169, indicative of three deuteria on the methoxy methyl group. In the mass spectrum of **22** the molecular ion ($C_{11}H_{20}O$) peak at 168 (*m/z*) and the second largest peak in the spectrum at 85 *m/z* (65%) due to C_5H_9O are replaced by peaks at 171 and 88, again indicative of incorporation of three (only) deuterium atoms. These observations provide evidence that the ethers **21** and **22** form by disproportionation of the intermediate radical; we will return to this point later. A solution of 1,4-dicyanobenzene (**1**) (0.06 M), biphenyl (**3**) (0.05 M), and (−) nopol (**23**) (0.1 M) in acetonitrile–methanol (3:1) was irradiated through a Pyrex filter with a medium pressure mercury vapour lamp (reaction [5]). The photo-NOCAS adducts **24** and **25** were isolated by dry-column flash chromatography (dcfc) on silica gel. Starting with laevorotatory nopol (**23**), neither **24** nor **25** showed any optical rotation; both are formed as the racemic mixture. There was no evidence for products resulting from intramolecular cyclization. Small amounts of an imine and of isomerization products, analogous to the imine **12** and limonene (**13**) formed in reaction [2], were detected (gc/ms) but were not isolated. When this irradiation was carried out in pure acetonitrile as solvent (no methanol), no volatile adducts (**1** + **23**) were detected (gc/ms).

Oxidation potentials, necessary for the discussion of the mechanism, were measured by cyclic voltammetry (Table 1).

TABLE 1. The oxidation potentials of some prospective donors and the calculated free energy change (ΔG) for the electron transfer process to the excited singlet excited state of 1,4-dicyanobenzene (**1**) as the acceptor

Donor	$E^{ox}_{1/2}$ (V)[a]	ΔG (kJ/mol)[b]
Biphenyl (**3**)	1.85	−75.1
α-Pinene (**8**)	1.75	−84.8
β-Pinene (**9**)	2.20	−41.4
Tricyclene (**18**)	2.31	−30.8
Nopol (**23**)	1.74	−85.8
Limonene (**13**)	2.15	—
1-Methylcyclohexene	1.93[c]	—
Methylenecyclohexane	>2.80	—

[a]Oxidation potentials, estimated as 0.028 V before the peak potential measured at a platinum electrode, relative to the saturated calomel electrode (sce) using tetraethylammonium perchlorate (0.1 M TEAP) as the electrolyte in acetonitrile (ref. 11).

[b]Based on the Weller equation (ref. 12); $E_{0,0}$ (**1**) = 408.4 kJ mol^{-1}, $E^{ox}_{1/2}$ (**1**) = −1.66 V. The Coulombic attraction term was taken to be 5.40 kJ mol^{-1} (ref. 4).

[c]Reference 3.

Structure determination

The mass spectra of the photo-NOCAS adducts (**10**, **11**, and **14–16**) from α-pinene (**8**) and β-pinene (**9**) (reactions [2] and [3]) all have base peaks at 73 *m/z* [-$C(CH_3)_2OCH_3$], evidence that the original four-membered ring has cleaved and the methoxy group is bonded to the isopropyl side chain, rather than to the ring. The ^{1}H and ^{13}C nmr spectra for the photo-NOCAS adducts **10** and **11** from α-pinene (**8**) have similar features. The stereochemical assignments were based on differences in the observed vicinal ^{1}H coupling constants. Adduct **10** was established as the *cis* isomer, having the benzylic hydrogen in the axial position, because of the large coupling constant observed (3.36 ppm, $J_{axial-axial}$ 9.3 Hz) compared to that of the *trans* isomer **11** in which the benzylic hydrogen shows up as a broad singlet (3.41 ppm).

The stereochemical assignments of **14** and **15** from β-pinene (**9**) were based on the same type of evidence. In the ^{1}H nmr spectrum of the product assigned as the *cis* isomer **15**, a large coupling constant (3.29 ppm, $J_{axial-axial}$ 11.3 Hz) was observed. In contrast, in the ^{1}H nmr spectrum of the *trans* isomer, a broad singlet was observed (3.77 ppm). In the ^{1}H nmr spectrum of **16**, a two-hydrogen singlet in the benzylic proton region (3.30 ppm) and evidence for only one vinyl hydrogen (5.49 ppm) are indicative of the assigned structure.

The structure assigned for the two 1:1:1 adducts, **19** and **20**, from reaction [4], were also based largely on an analysis of the ^{1}H nmr spectra. The bicyclo[2.2.1]heptane carbon skeleton was easily established. Stereochemical assignments were based largely upon observed nuclear Overhauser effects (nOe). For **19**, irradiation of the bridge hydrogens on C-7 (1.80 ppm) causes a significant increase in the intensity of the signal assigned to the *exo*-methyl group on C-5. The signal due to the methyl group on C-6 (1.24 ppm) was unaffected; therefore, this methyl group must be *endo*. Irradiation of the methyl group on C-6 causes an increase in the signal assigned to the hydrogen on C-2, which must therefore be *endo*, and in the aromatic region. Additional support for the C-2 hydrogen being in the *endo* position comes from the observed coupling pattern; the proton on C-2 (3.81 ppm) is not measurably coupled to the proton on C-1 and the small coupling constants (6.6, 2.0 Hz) observed between this proton and the protons on C-3 are typical of $J_{endo-endo}$ and $J_{endo-exo}$.

Similar reasoning was used for the stereochemical assignment of **20**. Irradiation of the methyl on C-6 (1.28 ppm) causes a definite nuclear Overhauser enhancement of the C-2 proton signal at 3.30 ppm: therefore, both the C-6 methyl and the C-2 proton must be *endo*. In support of this assignment, the signal due to the proton on C-2 is only weakly coupled (9.0, 4.2 Hz) to the vicinal protons on C-3.

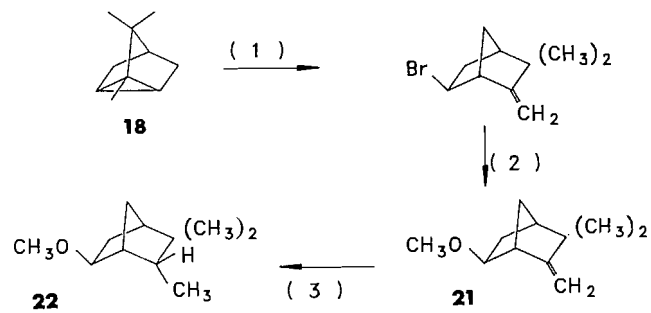
The structures assigned to the ethers **21** and **22** were confirmed by alternative synthesis (Scheme 2) and by comparison of spectra (^{1}H nmr, ir) with those reported for the analogous alcohol (13). A study of the effect, on the ^{1}H nmr spectrum, of adding the shift reagent Eu(fod)$_3$ was useful for assigning the stereochemistry of **22**. This reagent is known to complex with the oxygen of the methoxy group and to shift signals of nearby hydrogens downfield (14). The observed order of the magnitude of this downfield shift was *exo* H-3 > H-1 > H on the carbon of the methoxy group > H-2; the effect on the other signals was relatively small.

The ^{1}H nmr spectra of the photo-NOCAS adducts **24** and **25**, obtained from (−) nopol (**23**) (reaction [5]) were similar to those of **10** and **11** from α-pinene (**8**) (reaction [2]) described above. Solutions of **24** and **25** were optically inactive. Both **24** and **25** are oils; they were converted into crystalline 3,5-dinitrobenzoate derivatives, **26** (*trans*) and **27** (*cis*), by a standard procedure (15). The structural assignments of **26** and **27**, based initially upon ^{1}H nmr spectra, were firmly established by X-ray crystallography on single crystals.[3]

Computational details

Ab initio molecular orbital calculations were carried out with the GAUSSIAN 86 (16) or GAUSSIAN 90 (17) series of programmes. Open-shell species were treated in the unrestricted Hartree–Fock (UHF) formalism. The charge and spin distributions were calculated by Mulliken population analysis (18). The limitations of this method have been discussed (19). The calculated (STO-3G) total energies are summarized in Table 2.

The calculations on α-pinene (**8**) and on the radical cation of α-pinene (**8**$^{+\cdot}$) were carried out at the STO-3G level with full



SCHEME 2

Details of data collection, structural analysis and refinement, and tables of interatomic distances and bond angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

TABLE 2. The calculated (STO-3G) total energies (au) for α-pinene (**8**), tricyclene (**18**), and related radical cations

	Total energy (au)
α-Pinene (**8**)	−383.38502
α-Pinene radical cation ($\mathbf{8}^{+\bullet}$) (ring-closed)	−383.18284
α-Pinene radical cation ($\mathbf{8}a^{+\bullet}$) (distonic)	−383.16633
α-Pinene radical cation ($\mathbf{8}b^{+\bullet}$) (distonic)	−383.16531
Tricyclene (**18**)	−383.42385
Tricyclene ($\mathbf{18}^{+\bullet}$)	−383.20017

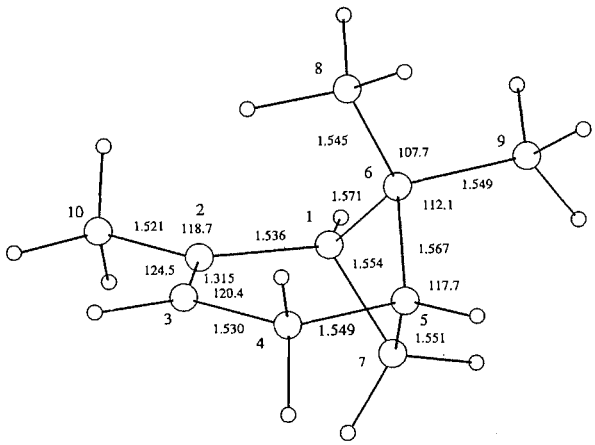

FIG. 1. The fully optimized (STO-3G) structure of α-pinene (**8**).

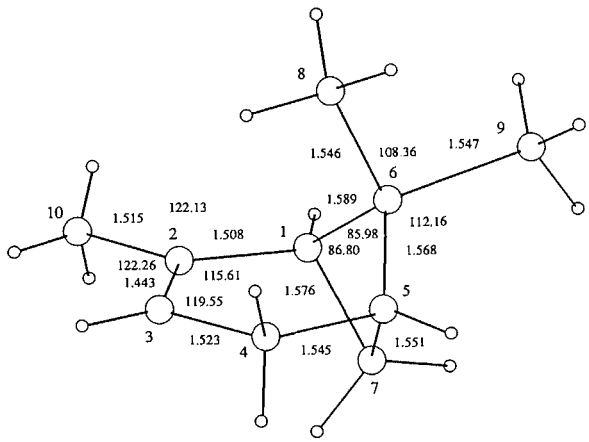

FIG. 2. The fully optimized (STO-3G) structure of the initial, ring-closed, radical cation of α-pinene ($\mathbf{8}^{+\cdot}$).

optimization of geometry. The optimized structures (Figs. 1 and 2) were confirmed to be minima by frequency calculation. The charge and spin distribution on $\mathbf{8}^{+\cdot}$ are listed in Table 3.

The ring-cleaved structure, the distonic radical cation of α-pinene ($\mathbf{8}^{+\cdot}$), could exist in at least three conformations: $\mathbf{8}a^{+\cdot}$, $\mathbf{8}b^{+\cdot}$, and $\mathbf{8}c^{+\cdot}$ (Fig. 3). Calculations on conformers $\mathbf{8}a^{+\cdot}$ and $\mathbf{8}b^{+\cdot}$ started with a C_s symmetry constraint; the alkyl moiety and the allylic moiety were perpendicular. A stationary point was identified which was then fully optimized. Figures 4 and 5 are of the fully optimized structures for conformers $\mathbf{8}a^{+\cdot}$ and $\mathbf{8}b^{+\cdot}$, and Tables 4 and 5 list the distribution of spin and charge. The fully optimized structure of conformer $\mathbf{8}a^{+\cdot}$ maintains C_s symmetry. In the optimized structure for conformer $\mathbf{8}b^{+\cdot}$, the plane of the alkyl moiety defined by C-8, C-9, and C-10 is not perpendicular to the plane of the allylic moiety C-1, C-2, and C3; the dihedral angle between C-5, C-7, C-8, and C-9 is ca. 30°.

TABLE 3. The charge and spin distribution calculated (STO-3G) for the radical cation of α-pinene ($\mathbf{8}^{+\bullet}$) (Fig. 2)

A convenient starting point for the calculation of conformer $\mathbf{8}c^{+\cdot}$ is the fully optimized structure for conformer $\mathbf{8}b^{+\cdot}$, revised by rotating the C-7, C-8 bond until the alkyl moiety and the allyl moiety were parallel. The fully optimized structure reverted to conformer $\mathbf{8}b^{+\cdot}$.

The *ab initio* calculations on tricyclene (**18**) and on the radical cation of tricyclene ($\mathbf{18}^{+\cdot}$) were also carried out with the STO-3G basis set; the open-shell, spin-unrestricted (UHF) pro-

cedure was used for $18^{+\cdot}$. The fully optimized structure for **18**, shown in Fig. 6, has C_s symmetry. For the radical cation $18^{+\cdot}$, the structure was first optimized with a C_s symmetry constraint. Further calculation found there was one imaginary frequency; therefore, this symmetric stationary point is a transition state, not an energy minimum. The total energy of this structure was

found to be −383.19049 (au) and the distances between C-2, C-6 and C-1, C-2 (or C-1, C-6) are 1.439 Å and 1.692 Å, respectively.

We were unable to find a minimum for a ring-cleaved structure for $18^{+\cdot}$. Beginning with an initial structure without a three-membered ring, one where the distance between C-1 and C-2 was 2.5 Å and that between C-2 (or C-1) and C-6 was 1.5 Å, the calculation converged to an optimized structure that does have a three-membered ring ($18^{+\cdot}$); however, the C-1, C-2 bond length is quite long (1.879 Å) (Fig. 7). Further calculation on this structure for $18^{+\cdot}$ showed that it is a minimum. The energy for this fully optimized structure is lower than that for the structure with a symmetry plane by 25.2 kJ mol^{-1}). As expected for $18^{+\cdot}$, the positive charge is delocalized over the whole radical cation, and the spin is mainly localized across the lengthened C-1, C-2 bond; the less heavily substituted carbon (C2) has the greater spin density (Table 6).

Discussion

Reactions of α- and β-pinene (8 and 9) (reactions [2] and [3])

The salient features of the proposed mechanism (Scheme 1) remain intact. Initial excitation (step 1) involves the ^1L_b transition of 1,4-dicyanobenzene (**1**). The prospective donors, **8** and **9**, are transparent in the ultraviolet at wavelengths transmitted through Pyrex; the ^1L_b absorption band of **1** extends out to ca. 290 nm.

Electron transfer from **8** and **9** to the singlet excited state of **1**

is spontaneous (step 2). When the ΔG for electron transfer, calculated by the Weller equation (equation [6]), is exergonic by –20 kJ mol^{-1} or more, quenching of the excited singlet state by the electron transfer process is diffusion controlled (12). In this polar solvent, acetonitrile–methanol (3:1), electron transfer leads directly to the solvent-separated radical ion pair (SSRIP). Further solvation/separation is competitive with back electron transfer.

[6] (ref. 12) $\Delta G_{et} = F[E^{ox}_{1/2}(D) - E^{red}_{1/2}(A) - e/\epsilon\alpha] - E_{0,0}(A)$

The efficiency of the reaction and the yield of products are increased upon addition of the codonor biphenyl (**3**). The radical cation of biphenyl ($\mathbf{3}^{+\cdot}$) can accept an electron from **8** or **9** (step 7). The overall increase in efficiency of the reaction is attributed to a slower rate of back electron transfer within the SSRIP ($\mathbf{1}^{-\cdot}$ and $\mathbf{3}^{+\cdot}$), the result of a smaller reorganizational energy, which leads to a greater proportion of freely solvated radical ions (1, 20).

The next step in the proposed mechanism, addition of the nucleophile (methanol) to the radical cation $\mathbf{8}^{+\cdot}$ or $\mathbf{9}^{+\cdot}$ (step 3), must be slower than cleavage of the cyclobutane ring. The rate constant for the addition of methanol to the radical cation of alkyl-substituted alkenes is not known; however, the addition of methanol to the radical cation of aryl-substituted alkenes has been measured (21). Methanol adds to the radical cation of 1,1diphenylethylene with a rate constant 1.6×10^9 M^{-1} s^{-1}; more stable or more sterically hindered radical cations react more slowly (21*a*). There was no evidence of products expected from addition of methanol to the original double bond of $\mathbf{8}^{+\cdot}$ or to the terminal methylene carbon of $\mathbf{9}^{+\cdot}$.

The observed cyclobutane ring cleavage of $\mathbf{8}^{+\cdot}$ and $\mathbf{9}^{+\cdot}$ (step 3a) raises the question — are these cyclic radical cations minima? The *ab initio* calculations carried out on $\mathbf{8}^{+\cdot}$ indicate the initially formed radical cation is indeed a minimum (Table 2); in fact, the initially formed cyclic radical cation $\mathbf{8}^{+\cdot}$ is 0.01651 au (43 kJ mol^{-1}) more stable than the ring-cleaved distonic radical cation $\mathbf{8}a^{+\cdot}$. This order of stability, pertinent to the gas phase, may be reversed in polar solvent. Solvation of the more localized cationic centre of the distonic radical cation will play a major role in stabilizing $\mathbf{8}a^{+\cdot}$ and $\mathbf{9}a^{+\cdot}$. While the initial radical cations $\mathbf{8}^{+\cdot}$ and $\mathbf{9}^{+\cdot}$ may be shallow minima, cyclobutane ring cleavage (step 3a) must be rapid.

The oxidation potentials of α- and β-pinene (**8** and **9**), listed in Table 1, are significantly lower that those of the model compounds 1-methylcyclohexene and methylenecyclohexane. These anodic processes are not reversible. The oxidation potentials listed have been estimated from the peak potentials observed on the cyclic voltammograms with a 100 or 200 mV s^{-1} sweep rate (11). Therefore, these values do not have thermodynamic significance; in fact, the peak potentials for **8** and **9** may be significantly shifted as a result of rapid/concerted cyclobutane ring cleavage during the anodic process. Further study is required.

Reactions [2] and [3] are regioselective; cleavage of the cyclobutane ring (step 3a) affords a distonic radical cation, which reacts as a radical at the allylic moiety and as a carbocation at the tertiary alkyl moiety (step 3b). These observations are consistent with the general rule: cleavage of radical cations occurs selectively to give the carbocation of that fragment with the lower radical oxidation potential (3, 22). The oxidation potentials of the relevant allylic radicals are not known; nevertheless, there is good reason to believe that the oxidation of the tertiary alkyl radical is the lower. The oxidation potential of the *tert*-butyl radical is 0.09 V (sce) and the oxidation potential of the benzylic radical is 0.73 V (23). Even the cumyl radical has an oxidation potential of 0.16 V, which is still greater than that of the *tert*-butyl radical (23). The observed regioselectivity is also in agreement with the calculations of spin and charge densities on the distonic radical cation $\mathbf{8}a^{+\cdot}$ (Fig. 4 and Table 4). The spin density is largely delocalized over the allylic moiety and the positive charge is largely on the tertiary alkyl moiety.

The specific rotation of α-pinene (**8**) recovered after 95% conversion of **1** (reaction [2]) is essentially the same as before irradiation. Under these reaction conditions, cleavage of the radical cation $\mathbf{8}^{+\cdot}$ to $\mathbf{8}b^{+\cdot}$ (step 3a) must be irreversible; reaction of the distonic radical cation with methanol must be rapid. Furthermore, there is no evidence for any bonding interaction between the radical and cation centres in the distonic radical cation $\mathbf{8}b^{+\cdot}$ that might maintain chirality; the photo-NOCAS adducts **10** and **11** are racemic. The *ab initio* calculations also show that there is no interaction between the allylic radical and cationic moieties. The distances between C-8 and C-1 (3.551 Å) and between C-8 and C-1 and C-3 (3.295 and 3.171 Å) are too great for appreciable interaction (Fig. 5). These observations contrast with the results obtained upon γ-radiation of α-pinene (**8**) where racemization was observed (9*e*).

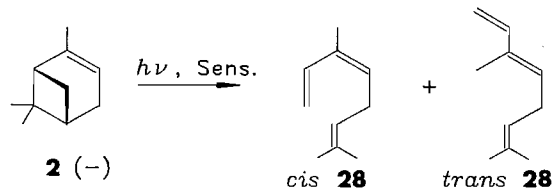
The reduction potentials of the intermediate allylic radicals must be more negative than that of **1** (-1.66 V); otherwise, electron transfer would occur and the allylic radical would thus be reduced to the allylic anion. The reduction potentials of these radicals are not known, but the results seem reasonable. The unsubstituted allyl radical is reduced at −1.63 V (sce) and alkyl substitution at the terminal position will make the reduction potential more negative by ca. 0.2 V (24).

Coupling of the allylic radicals with the radical anion of 1,4-dicyanobenzene ($\mathbf{1}^{-\cdot}$), at the *ipso* position, shows little stereo- or regioselectivity; **10** and **11** are formed in almost equal amounts and **14** and **16** are only slightly favoured over **15**. The preference for formation of the *trans* adducts **11** and **14** indicates that coupling from the *pseudo*-axial position is slightly favoured.

In addition to the photo-NOCAS adducts, two interesting products incorporating acetonitrile, imines **12** and **17**, are formed in reactions [2] and [3]. These products also derive from the distonic radical cations $\mathbf{8}a^{+\cdot}$ and $\mathbf{9}a^{+\cdot}$. The regiochemistry of **12** and **17** is consistent with initial attack of the cationic centres of the distonic radical cations on the nitrogen of the cyano group. These products have been observed upon electrochemical oxidation of the pinenes (**8** and **9**) (9*b*,*c*,*d*).

The mechanism for formation of the rearrangement product limonene (**13**) from α-pinene (**8**) in reaction [2] is also of interest. The triplet excited state of α-pinene (**8**), generated by triplet energy transfer using acetophenone as a photosensitizer (triplet energy transfer), gives *cis*- and *trans*-ocimene (**28**) as the major rearrangement products; limonene (**13**) was a minor product (reaction [7]) (25*a*). Limonene (**13**) is also a minor product

Reaction [7]



Sens. = acetophenone

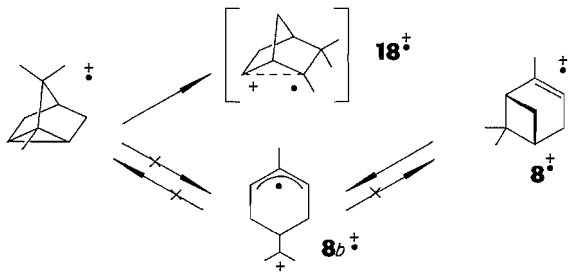


FIG. 8. The radical cations of α-pinene ($\mathbf{8}^{+\cdot}$) and tricyclene ($\mathbf{18}^{+\cdot}$) are related.

from the direct irradiation of α-pinene (**8**) (25*b*). We believe formation of **13** in reaction [2] also involves the radical cation $\mathbf{8}b^{+\cdot}$. A likely mechanism for formation of **13** entails a proton shift from one of the methyl groups of the tertiary cation to the allylic radical. The *ab initio* calculations indicate that one of the methyl hydrogens is close to the allylic radical; the C-3, H distance is only 2.5 Å in $\mathbf{8}^{+\cdot}$ and the C-2, H distance is only 2.7 Å in $\mathbf{8}b^{+\cdot}$ (Figs. 2 and 5).

Formation of this rearrangement product (**13**) in reaction [2] originally (before the structures of the adducts were firmly established) raised the possibility that the photo-NOCAS adducts **10** and **11** actually derive from secondary reaction of **13**. Irradiation of acetonitrile–methanol solutions of **1**, **3**, and **13** under these conditions does indeed lead to formation of photo-NOCAS adducts; however, these adducts are different from those obtained in reaction [2].[4]

Reaction of tricyclene (18) (reaction [4])

The radical cations of α-pinene ($\mathbf{8}^{+\cdot}$) and tricyclene ($\mathbf{18}^{+\cdot}$) are related (Fig. 8). A strong bonding interaction between the cation and the central carbon of the allylic radical in the distonic radical cation $\mathbf{8}b^{+\cdot}$ could lead to ring closure and formation of $\mathbf{18}^{+\cdot}$. Indeed, the calculations indicate that $\mathbf{18}^{+\cdot}$ is more stable (88.9 kJ mol^{-1}) than the distonic radical cation $\mathbf{8}b^{+\cdot}$, even more stable than $\mathbf{8}^{+\cdot}$ (45.5 kJ mol^{-1}) (Table 2). Nevertheless, the products from reaction [2] indicate that there is no interconversion of these radical cations.

The fact that only the *exo* isomers, **19–22**, are formed in reaction [4] suggests cyclopropyl ring opening is assisted by nucleophilic attack. The observed regiochemistry is also consistent with this mechanism; nucleophilic attack occurs at the less hindered centre (C-2, Fig. 7). Formation of the nitrile **20** as a major product, even though the only cyanide ion present is that generated during the rearomatization step (step 5), is also consistent with involvement of nucleophile during the cleavage step. Cyanide ion is significantly more nucleophilic than methanol; the rate of addition of methanol to $\mathbf{18}^{+\cdot}$ must be several orders of magnitude slower that addition of cyanide ion (21*b*, 26).

The calculations are in accord with these observations. The radical cation $\mathbf{18}^{+\cdot}$ has the three-membered ring still intact; the long C-1, C-2 bond (1.88 Å) bears a major portion of the spin and charge densities, with the positive charge largely on C-2 where nucleophilic attack occurs.

The ethers **21** and **22** result from disproportionation of the tertiary alkyl radical intermediate. An alternative mechanism for the formation of **22**, reduction of the intermediate tertiary radical by electron transfer from the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\cdot}$), followed by protonation of the resulting anion, is inconsistent with the incorporation of only three deuterium atoms upon irradiation in acetonitrile–perdeuteriomethanol (27). The reduction potential of the tertiary alkyl radical is more negative that the reduction potential of **1** (−1.66 V).

Reaction with (−) nopol (23) (reaction [5])

The radical cation of α-pinene ($\mathbf{8}^{+\cdot}$) apparently undergoes rapid cleavage of the cyclobutane ring giving the distonic radical cation $\mathbf{8}b^{+\cdot}$. Yet, the *ab initio* calculations show that the initial radical cation $\mathbf{8}^{+\cdot}$ is significantly (43.4 kJ mol^{-1}) more stable than the distonic radical cation $\mathbf{8}b^{+\cdot}$. This dichotomy has been explained on the basis of a solvent effect; the localized cationic centre of the distonic radical cation will be stabilized by solvent interaction. Nevertheless, a rapid reaction with nucleophile might trap the initially formed radical cation before the cyclobutane ring cleaves. It was with this possibility in mind that the reactivity of nopol (**23**) was investigated. Intramolecular 1,5-*endo* cyclization of the hydroxyl group with the radical cation $\mathbf{23}^{+\cdot}$ might be rapid enough to compete with ring cleavage.[5]

When the irradiation was carried out in the usual mixed solvent system, acetonitrile–methanol (3:1), the products **24** and **25** expected from the ring-cleaved distonic radical cation were obtained (reaction [5]). Both **24** and **25** are formed as the racemic mixtures; the distonic radical cation $\mathbf{23}^{+\cdot}$ is achiral. Irradiation in pure acetonitrile did not give cyclized products. Clearly, ring opening of the initially formed radical cation is more rapid that 1,5-*endo* cyclization.

Experimental

General methods

The ^{1}H and ^{13}C nmr spectra were recorded on either a Nicolet 360 NB (361.1 or 90.8 MHz) or a Bruker AC 250 (250.1 or 62.9 MHz) nmr spectrometer, and are reported in parts per million (ppm) to higher frequency from tetramethylsilane. Infrared spectra (ir) were recorded on either an air-purged Perkin–Elmer 180 or on a Nicolet 205 infrared spectrometer and are reported in wavenumbers (ν) relative to the 1602 cm^{-1} absorption of polystyrene film. Optical activity was determined with a Perkin–Elmer model 141 polarimeter using ca. 1% solutions in $CHCl_3$. Exact mass determinations were carried out using a ZAB-E spectrometer. Elemental analyses were performed by Canadian Microanalytical Services Inc., Delta, B.C., and agreed to within ±0.3 of the calculated values. Melting points were determined using a Cybron Corporation Thermolyne melting point apparatus linked to a digital thermocouple, and were corrected.

The photo-NOCAS products were isolated by medium-pressure liquid chromatography (mplc) using a 2.5 cm × 1 m column packed with thin-layer chromatography (tlc) grade silica gel (Merck) at 15 psi helium (1 psi = 6.9 kPa). The chromatograms were usually developed either with a hexane – methylene chloride or hexane – 50% diethyl ether in hexane linear solvent gradient. The eluent was monitored and collected by a uv spectrometer – fraction collector. Dry column flash chromatography (dcfc) was performed using tlc grade silica gel

[4]Limonene (**13**) can be viewed as a 1,5-diene; the radical cation of 2,5-dimethyl-1,5-hexadiene forms photo-NOCAS adducts indicative of 1,6-*endo*, *endo* cyclization. Limonene (**13**) forms photo-NOCAS adducts with methanol and 1,4-dicyanobenzene (**1**) analogous to those formed from 1-methylcyclohexene (**2**) (reaction [1]); we found no evidence for cyclization of the diene radical cation ($\mathbf{13}^{+\cdot}$) (D.R. Arnold and D. Connor, unpublished results).

[5]Cyclization, 1,5-*endo*, does compete favourably with intermolecular reaction with methanol with the radical cation of 2-(1-cyclohexen-1-yl)ethanol (X. Du and D.R. Arnold, unpublished results).

(Merck) (28). Preparative gas chromatography (prep-gc) was carried out on a Wilkens Aerograph A-700 instrument using a 3/8 in. × 10 ft aluminum column packed with 40% SE-30 on Chromosorb W 60/80 NAW.

Materials

(1*S*)-(−)-α-Pinene (**8**), $[\alpha]_D^{20°C}$ −50.7 (neat), (1*S*)-(−)-β-pinene (**9**), $[\alpha]_D^{20°C}$ −21 (neat), (*R*)-(+)-limonene (**13**), $[\alpha]_D^{20°C}$ + 123 (neat), tricyclene (**18**) (99%), and (1*R*)-(−)-nopol (**23**) (98%) were obtained from Aldrich. These compounds were used as received except samples used for the oxidation potential measurements were purified by prep-gc. The shift reagent, tris(6,6,7,7,8,8,8,)heptafluoro-2,2-dimethyl-3,5-octanedionato)europium ($Eu(fod)_3$), was obtained from Norell Chemical Co., Inc.

Cyclic voltammetric measurements

Oxidation potentials were measured by cyclic voltammetry using an apparatus similar to that previously described (29). Since the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (11).

Irradiations

Irradiations were generally carried out using a CGE 1-kW medium-pressure mercury vapour lamp contained in a water-cooled quartz immersion well. The temperature was maintained at 10°C. The solvent generally was acetonitrile–methanol (3:1 by volume) at a typical concentration of 1,4-dicyanobenzene (**1**) 0.05 M and olefin of 0.1 M. The concentration of biphenyl (**3**) varied over the range 0.02–0.1 M. Solutions were placed in 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, degassed by ebullition with dry nitrogen and sealed.

Formation of photo-NOCAS adducts from methanol, α-pinene (8), and 1,4-dicyanobenzene (1) (reaction [2])

A solution of α-pinene (**8**) 3.05 g (22.4 mmol), 1,4-dicyanobenzene (**1**) 1.44 g (11.2 mmol), and biphenyl (**3**) 0.52 g (3.4 mmol) in 160 mL acetonitrile–methanol (3:1) was degassed by nitrogen ebullition for 5 min and irradiated through Pyrex for 72 h. The volatile components of the photolysate, removed by distillation, included **8** and isomerization products (gc/ms). The major isomerization product has a retention time (gc/fid) and mass spectrum (gc/ms) identical with those of an authentic sample of limonene (**13**). The specific rotation of the starting material **8** was $[\alpha]_D^{20°C}$ −56.7 ($CHCl_3$); a sample of **8** isolated (prep-gc) from the reaction mixture, after 95% consumption of **1**, had $[\alpha]_D^{20°C}$ −54.4 ($CHCl_3$). The nonvolatile residue was separated by mplc using the hexanes – methylene chloride solvent gradient. The photo-NOCAS products were eluted, as oils, in the order **10**, then **11**. In addition to the photo-NOCAS products and limonene (**13**), another major product (**12**) was eluted from the column with ethyl acetate or with a methylene chloride – methanol solvent gradient. The crude yield of **12** ranges between 20 and 35% (based on the initial amount of **8**). A pure sample of **12** was obtained by prep-gc.

These spectra (ir, ^{1}H nmr, ^{13}C nmr) were identical to spectra provided by B. Delpech (9*b*,*c*). ms *m/z*: 177 (2), 136 (11), 121 (5), 94 (13), 93 (100), 92 (42), 91 (33), 80 (11), 79 (19), 77 (32), 65 (15).

Formation of photo-NOCAS adducts from methanol, β-pinene (9), and 1,4-dicyanobenzene (1) (reaction [3])

The procedure used was similar to that described above for the preparation of adducts from α-pinene (**8**). The specific rotation of the starting material **9** was $[\alpha]_D^{20°C}$ −15.5 ($CHCl_3$); a sample of **9** isolated (prep-gc) from the reaction mixture after ca. 90% of **1** was consumed had $[\alpha]_D^{20°C}$ −15.9 ($CHCl_3$). In this case, only traces of isomerization products of **9** were detected (gc/ms). The crude photolysate was partly separated by mplc eluting with the hexanes – dichloromethane solvent gradient. Fractions containing mixtures of photo-NOCAS products were combined and rechromatographed (mplc) with the hexane – 50% diethyl ether, hexane solvent gradient. Three photo-NOCAS adducts were eluted in the order **14**, **16**, and **15**, obtained as colourless oils. Further elution of the column with ethyl acetate gave imine **17** in 30% yield (based upon β-pinene (**9**)). The imine was further purified by prep-gc.

cis-2-(4-Cyanophenyl)-4-(1-methoxy-1-methylethyl)-1-methylenecyclohexane (**15**, 3%); $[\alpha]_D^{20°C}$ −51.9 ($CHCl_3$); ^{1}H nmr ($CDCl_3$, 360NB) δ: 7.60 (d, 8.2 Hz, 2H, arom), 7.23 (d, 8.2 Hz, 2H, arom), 4.72 (d, 1.5 Hz, 1H, vinyl proton), 3.88 (d, 1.5 Hz, 1H, vinyl proton), 3.29 (m, 1.7 Hz, 11.3 Hz, 1H, ArCH), 3.19 (s, 3H, OCH_3), 2.54 (m, 1H, 13.3 Hz), 2.20 (m, 1H), 2.03–1.92 (m, 2H), 1.86–1.78 (m, 1H), 1.50 (ddd, 1H, 12.3, 12.3, 12.2), 1.26 (dddd, 1H, 12.9, 12.9, 12.9, 4.0), 1.15 (s, 3H, CH_3), 1.12 (s, 3H, CH_3); ^{13}C nmr ($CDCl_3$, 360NB) δ: 151.50 (d, 4.0 Hz, arom), 148.99 (d, 6.9 Hz, =C), 131.97 (dd, 4.7 Hz, 159.4 Hz, arom), 129.52 (d, 160.4 Hz, arom), 119.06 (s, CN), 110.11 (d, 2.8 Hz, arom), 108.57 (t, 145.8 Hz, $=CH_2$), 76.37 (s, tertiary carbon),50.05 (q, 140.4 Hz, OCH_3), 48.79 (d, 125.1 Hz, ArCH), 46.31 (d, 127.2 Hz, CH), 36.21 (t, 126.7 Hz, CH_2), 34.59 (t, 131.1 Hz, CH_2), 28.21 (t, 125.3 Hz, CH_2), 22.43 (q, 125.5 Hz, CH_3), 21.95 (q, 124.6 Hz, CH_3). ms *m/z*: 237 (1.8), 194 (3.5), 140 (3.1) 127 (2.1) 116 (3.1), 74 (3.9), 73 (100). *Formation of 1:1:1 adducts and ethers from methanol, tricyclene (**18**), and 1,4-dicyanobenzene (**1**) (reaction [4])*

A solution of tricyclene (**18**) 445 mg (3.3 mmol), biphenyl (**3**) 450 mg (2.9 mmol), and 1,4-dicyanobenzene (**1**) 340 mg (2.7 mmol) in 35 mL acetonitrile–methanol (3:1) was degassed by nitrogen ebullition for 5 min and irradiated through Pyrex for 7 days. The volatile components of the photolysate, **18** and some of the ethers **21** and **22**, were removed by distillation. The nonvolatile residue was separated by repetitive dcfc; hexane–dichloromethane was used as eluent for the first column. Biphenyl (**3**) (98%) and unchanged **1** were partially recovered. The two 1:1:1 adducts (**19** and **20**) were partly separated. The ethers (**21** and **22**) were eluted as a mixture and were further separated by prep-gc (20% SE-30 150°C). Fractions containing **19** and **20** were rechromatographed (dcfc) using hexane – ethyl acetate as the solvent gradient. The methanol:**18**:**1** adduct (**19**) was isolated in 43% and the cyanide:**18**:**1** adduct (**20**) was obtained in 14% yield. Further purification of **19** and **20** was achieved by crystallization from methanol.

Preparation of exo-*6-methoxycamphene (**21**) and 5,5-dimethyl*-exo-*2-methoxy*-endo-*6-methyl-norbornane (**22**) (Scheme 2)*

A solution of tricyclene (**18**) (1.55 g) and *N*-bromosuccinimide (2.13 g) in $CHCl_3$ (15 mL) was refluxed for 2.5 h. The solvent was evaporated and a solution of Li_2CO_3 (1.0 g) in methanol–dioxane (1:1) (15 mL) was added; the resulting solution was refluxed for 15 h. The reaction mixture was filtered, the solution was concentrated on a rotary evaporator, and the resulting mixture was chromatographed (dcfc) using hexane–dichloromethane as eluent. A pure sample of **21** was obtained by prep-gc (40% SE-30). Catalytic hydrogenation of **21** (H_2, 1 atmosphere/Pd, 9 h) (1 atm = 101.3 kPa) gave **22**.

exo-*6-Methoxycamphene* (***21***): ^{1}H nmr ($CDCl_3$, 360NB) δ: 4.88 (dd, 1.5 Hz, 0.8 Hz, 1H), 4.66 (s, 1H), 3.31 (ddd, 6.9 Hz, 3.0 Hz, 3.0 Hz, 1H, H6), 3.30 (s, 3H, methoxy), 2.83 (br, s, 1H, H1), 2.12 (ddd, 13.5 Hz, 6.9 Hz, 2.8 Hz, 1H, *endo*-H5), 1.91 (ddd, 4.2 Hz, 1.3 Hz, 1.5 Hz, 1H, H4), 1.67 (dddd, 10.0 Hz, 3.0 Hz, 2.8 Hz, 1.5 Hz, 1H, H7s), 1.51 (ddd, 10.0 Hz, 1.3 Hz, 1.3 Hz, 1H, H7a), 1.23 (dddd, 13.5 Hz, 4.2 Hz, 3.0 Hz, 0.8 Hz, 1H, *exo*-H5), 1.05 (s, 3H, methyl), 0.99 (s, 3H, methyl); ^{13}C nmr ($CDCl_3$, AC250) δ: 161.45 (s), 102.90 (t), 83.13 (d), 56.33 (q), 51.30 (d), 47.25 (d), 41.40 (s), 34.11 (t), 33.75 (t), 29.28 (q), 25.45 (q). ms, *m/z*: 166 (0.9), 134 (52), 119 (100), 93 (47), 91 (43), 79 (20), 77 (22).

*The photosensitized (electron transfer) irradiation of tricyclene (**18**) in acetonitrile–perdeuteriomethanol (CD_3OD)*

When the irradiation of **18** was carried out as described above but in acetonitrile–methanol-d_4 (3:1) solution, the four products (**19–22**) were formed (gc/ms); however, the mass spectra indicate that incorporation of the deuterated methoxy group (CD_3) occurs in **19**, **21**, and **22**. The base peak and the molecular ion peak in the mass spectrum of **19**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

become 189 *m/z* ($C_{12}H_9D_3NO$) and 272, instead of 186 and 269. The only notable change in the mass spectrum of **21** is that the molecular ion peak becomes *m/z* 169. In the mass spectrum of **22** the molecular ion peak at 168 *m/z* and the peak at 85 are substituted by 171 and 88.

*Formation of photo-NOCAS adducts (**24** and **25**) from nopol (**23**) (reaction [5])*

A solution of (−)-nopol (**23**) 2.68 g (16.1 mmol), biphenyl (**3**) 1.14 g (7.4 mmol), and 1,4-dicyanobenzene (**1**) 1.33 g (10.4 mmol) in 160 mL acetonitrile–methanol (3:1) was degassed by nitrogen ebullition for 5 min and irradiated through Pyrex for 10 days. The volatile components of the photolysate were removed by distillation. The nonvolatile residue was chromatographed (dcfc) eluting with an ethyl acetate – hexane solvent gradient. The photo-NOCAS adducts (**24** and **25**) were partially separated; **24** was eluted before **25**. Fractions containing mixtures of the two were rechromatographed (dcfc). Optical rotation measurements show both **24** and **25** were optically inactive.

trans-*6-(4-Cyanophenyl)-1-(2-hydroxyethyl)-4-(1-methoxy-1-methylethyl)-1-cyclohexene (**24**)*: ir (liq. film, P.-E.) *ν*: 3410 (s), 3030 (w), 2970 (s), 2925 (s), 2227 (s), 1604 (s), 1500 (m), 1465 (m), 1380 (m), 1067 (s), 890 (s), 832 (s), 735 (s); ^{1}H nmr ($CDCl_3$, 360NB) δ: 7.59 (d, 2H, J = 8.1 Hz), 7.33 (d, 2H, J = 8.1 Hz), 5.88 (m, 1H, with small coupling constants), 3.61 (t, 2H, 6.54 Hz), 3.57 (s, br. 1H, $w_{1/2}$ = 14 Hz), 2.83 (s, 3H), 2.26–1.90 (5H), 1.80–1.57 (3H), 1.02 (s, 3H), 0.97 (s, 3H); ^{13}C nmr ($CDCl_3$, 360NB) δ: 150.11 (s), 133.15 (s), 131.80 (d), 129.18 (d), 127.11 (d), 118.83 (s), 109.62 (s), 75.84 (s), 60.41 (t), 48.13 (q), 43.73 (d), 38.50 (t), 34.34 (d), 31.92 (t), 26.84 (t), 21.97 (q), 21.87 (q); ms *m/z*: 267 (1.8), 206 (10), 116 (6), 91 (6), 77 (6), 73 (100), 55 (6).

cis-*6-(4-Cyanophenyl)-1-(2-hydroxyethyl)-4-(1-methoxy-1-methylethyl)-1-cyclohexene (**25**)*: ir (liq. film, P.-E.) *ν*: 3420 (s), 3035 (w), 2970 (s), 2925 (s), 2225 (s), 1604 (s), 1500 (m), 1465 (m), 1380 (m), 1067 (s), 890 (s), 830 (s), 730 (s); ^{1}H nmr ($CDCl_3$, 360NB) δ: 7.58 (d, 2H, J = 7.9 Hz), 7.28 (d, 2H, J = 7.9 Hz), 5.81 (m, 1H, J = 5.2 Hz), 3.46–3.55 (3H), 3.17 (s, 3H), 2.13–1.71 (7H), 1.26 (ddd, 1H, coupled to one of the protons at 3.46–3.55 ppm), 1.10 (s, 3H), 1.08 (s, 3H); ^{13}C nmr ($CDCl_3$, 360NB) δ: 151.17 (s), 134.36 (d), 132.14 (d), 128.76 (d), 126.97 (d), 118.75 (s) 109.70 (s), 75.96 (s), 60.24 (t), 48.64 (q), 46.88 (d), 42.11 (d), 37.77 (t), 35.32 (t), 27.00 (t), 21.99 (q), 21.30 (q); ms *m/z*: 267 (1.5), 206 (7), 116 (4), 91 (5), 77 (5), 73 (100), 55 (6).

Both photo-NOCAS adducts (**24** and **25**) were converted into 3,5-dinitrobenzoate esters by the standard procedure (15). In a typical preparation, 3,5-dinitrobenzoyl chloride 0.165 g (0.72 mmol) and **24**, 0.210 g (0.72 mmol) were dissolved in 1.5 mL pyridine. The solution was stirred at room temperature for 2 h. The derivative was isolated by dcfc using dichloromethane–hexane solvent gradient as eluent, followed by recrystallization using ethanol–acetone as solvent. Analytical samples were recrystallized from dichloromethane–hexane solution to give light yellow crystals.

Photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction. Part 6: methanol, nonconjugated dienes, and 1,4-dicyanobenzene[1]

DONALD R. ARNOLD,[2] KIMBERLY A. MCMANUS, AND XINYAO DU
Department of Chemistry, Dalhousie University, Halifax, NS B3H 4J3, Canada

Received March 1, 1993[3]

DONALD R. ARNOLD, KIMBERLY A. MCMANUS, and XINYAO DU. Can. J. Chem. **72**, 415 (1994).

Irradiation, through Pyrex, of an acetonitrile–methanol (3:1) solution of 1,4-dicyanobenzene (**1**) and 1,5-hexadiene (**9**) leads to formation of *ortho* and *meta* cyclic adducts (**13–16**) arising from the intermediate exciplex. There was no evidence for interaction between the two double bonds of this nonconjugated diene. The oxidation potential of **9** is high enough (>3 V vs. sce) to preclude single electron transfer (SET); no photo-NOCAS products are formed. Similar irradiation of acetonitrile–methanol solutions of **1** and 2-methyl-1,5-hexadiene (**10**) does yield a photo-NOCAS product (**17**); reaction occurs only on the more heavily substituted double bond. The additional substitution on the double bond lowers the oxidation potential (2.70 V vs. sce) of this diene to the point where SET from **10** to the excited singlet state of **1** can occur. In this case, no cycloaddition products are formed; the exciplex is quenched by electron transfer. There was no evidence for interaction between the two double bonds of the initially formed radical cation $\mathbf{10}^{+\cdot}$, or between the terminal double bond and the β-alkoxyalkyl radical of the intermediate leading to the photo-NOCAS product. The photo-NOCAS product (**19**) was also formed when 2,5-dimethyl-1,5-hexadiene (**11**) was subjected to these reaction conditions. In this case, when biphenyl (**4**) was added as a codonor, in addition to the photo-NOCAS product, products (**21** *cis* and *trans*) resulting from cyclization of the initially formed acyclic radical cation $\mathbf{11}^{+\cdot}$ to give the 1,4-dimethylcyclohexane-1,4-diyl radical cation were also observed. This 1,6-*endo*, *endo* cyclization of $\mathbf{11}^{+\cdot}$ must be rapid enough to compete with reaction with methanol. There was no evidence for cyclization (neither 1,4-*exo* nor 1,5-*endo*) of the intermediate β-alkoxyalkyl radical. When the radical cation of 2,5-dimethyl-1,4-hexadiene ($\mathbf{12}^{+\cdot}$) is generated under these reaction conditions, photo-NOCAS products **22** and **23** are formed at the more heavily substituted double bond, along with the conjugated tautomer 2,5-dimethyl-2,4-hexadiene (**24**). The mechanisms for these transformations are discussed.

DONALD R. ARNOLD, KIMBERLY A. MCMANUS et XINYAO DU. Can. J. Chem. **72**, 415 (1994).

L'irradiation, dans un tube de Pyrex, d'une solution acétonitrile–méthanol (3 : 1) de 1,4-dicyanobenzène (**1**) et de hexa-1,5-diène (**9**) conduit à la formation d'adduits cycliques *ortho* et *méta* (**13–16**) qui dérivent de l'exciplexe intermédiaire. On n'a aucune donnée suggérant l'existence d'une interaction entre les deux doubles liaisons de ce diène non conjugué. Le potentiel d'oxydation du composé **9** est suffisamment élevé (>3 V vs. sce) pour empêcher un transfert d'un seul électron (SET); il ne se forme aucun produit de photo-NOCAS. Une irradiation semblable de solutions acétonitrile–méthanol du composé **1** en présence de 2-méthylhexa-1,5-diène (**10**) conduit à la formation d'un produit photo-NOCAS, **17**; la réaction ne se produit que sur la portion la plus substituée de la double liaison. La substitution plus grande sur la double liaison abaisse le potentiel d'oxydation (2,70 V vs. sce) de ce diène au point où une réaction de transfert d'un seul électron du produit **10** vers l'état singulet excité du produit **1** peut se produire. Dans ce cas, il ne se forme pas de produits de photoaddition; l'exciplexe est désactivé par le transfert d'électron. Il n'y a pas de données suggérant la présence d'interactions entre les deux doubles liaisons du cation radicalaire $\mathbf{10}^{+\cdot}$ qui se forme initialement ou entre la double liaison terminale et le radical β-alcoxyalkyle de l'intermédiaire qui conduirait au produit photo-NOCAS. Le produit photo-NOCAS (**19**) se forme aussi lorsqu'on soumet le 2,5-diméthylhexa-1,5-diène à ces conditions réactionnelles. Dans ce cas, lorsqu'on ajoute du biphényle (**4**) comme codonneur, on observe, en plus du produit photo-NOCAS, la formation de produits (**21** *cis* et *trans*) qui résultent de la cyclisation du cation radicalaire acyclique $\mathbf{11}^{+\cdot}$ (qui se forme originalement) pour donner le cation radicalaire 1,4-diméthylcyclohexane-1,4-diyle. Cette cyclisation 1,6-*endo*, *endo* de $\mathbf{11}^{+\cdot}$ doit être assez rapide pour se faire de préférence à la réaction avec le méthanol. Il n'y a aucune donnée permettant de suggérer une cyclisation (soit 1,4-*exo* ou 1,5-*endo*) du radical intermédiaire β-alcoxyalkyle. Quand le cation radicalaire du 2,5-diméthylhexa-1,4-diène ($\mathbf{12}^{+\cdot}$) est généré dans ces conditions réactionnelles, les produits photo-NOCAS **22** et **23** se forment au niveau de la double liaison le plus substituée aux côtés du tautomère conjugué, 2,5-diméthylhexa-2,4-diène (**24**). On discute des mécanismes de ces transformations.

[Traduit par la rédaction]

Introduction

The photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction is a useful synthetic procedure. A nucleophile, an olefin, and an aromatic molecule can be combined to yield a more complex difunctional molecule in one simple step. Archetypical examples of this reaction are the combination of methanol and 2,3-dimethyl-2-butene (**2**), substituting on 1,4-dicyanobenzene (**1**) (reaction [1]); and the combination of methanol and 2-methylpropene (**6**), substituting on 1,4-dicyanobenzene (**1**) (reaction [2]) (3). The proposed mechanism is shown in Scheme 1 (3). This work is part of our continuing effort to define the scope and synthetic utility of the photo-NOCAS reaction. We have subjected 1,4- and 1,5-dienes to the photo-NOCAS reaction conditions, exploring the possibility that cyclized products might be obtained. A further objective of this project was to gain additional insight into the mechanism of the reaction and into the nature of the unusual intermediates involved.

Reaction occurs when acetonitrile–methanol (3:1) solutions of an olefin and an aromatic compound are irradiated through Pyrex (Scheme 1, steps 1–5). However, the efficiency of the reaction and the yield of photo-NOCAS products may be increased by the addition of a codonor, e.g., biphenyl (**4**) (steps 1, 6a, and 7), or by the addition of a photosensitizer (electron transfer), e.g., phenanthrene (**5**) (steps 6b, 6c, and 7). The actual

function of the codonor in increasing the efficiency of the reaction is not fully understood. The explanation we favour is that escape to fully solvated radical ions from the solvent-separated radical ion pair (SSRIP) formed between the aromatic electron acceptor and the codonor may be more efficient. The relative efficiency of formation of solvated radical ions is a function of differences in reorganization energy, influencing the rate of the competing back electron transfer process within the alternative SSRIPs (steps 2 and 8) (4). It has also been proposed that the codonor, or sensitizer, radical cation and the olefin may form a complex radical cation and that this may modify the reactivity of the alkene radical cation (*3b*, 5). The characterization of a benzene–ethylene radical cation complex adds credence to this suggestion (*5c*).

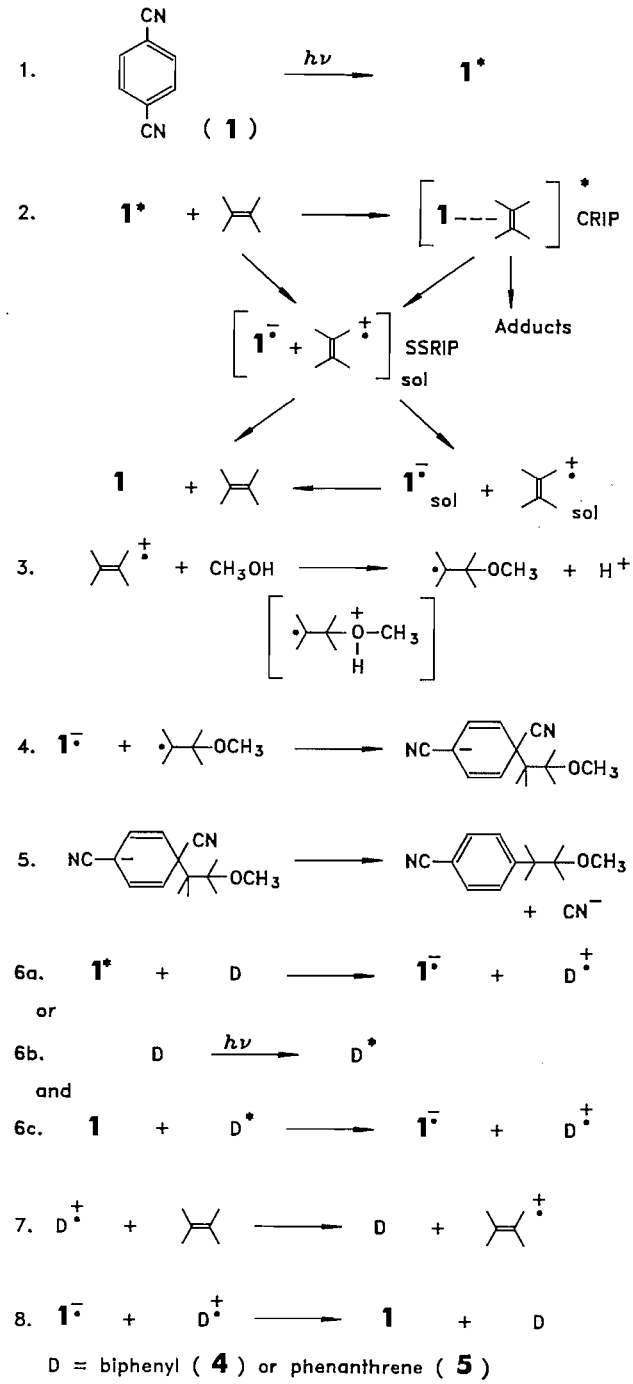
There are two steps in the proposed mechanism during which cyclization of an intermediate from a nonconjugated diene may occur: the radical cation of the diene may cyclize prior to reaction with nucleophile, that is, between steps 2 and 3 or between steps 7 and 3 (Scheme 1). For example, the initially formed radical cation of a 1,5-diene might cyclize 1,6-*endo*, *endo* to a cyclohexane-1,4-diyl radical cation in competition with reaction with methanol. Complex formation between the codonor or sensitizer radical cation and the diene (step 7) may influence the rates of these competing processes. Alternatively, the intermediate β-alkoxyalkyl radical may cyclize before substitution on the radical anion of the electron acceptor (between steps 3 and 4). These cyclization modes should be distinguishable based upon the structure of the product(s).

Rules for predicting rates and regiochemistry of cyclization of common intermediates, i.e., carbocations, carbanions, and radicals, have developed rapidly over the past few years, to the point where a cyclization step can be included in retrosynthetic analysis (6). Analogous rules for the cyclization of radical ions have not yet been defined.

Results

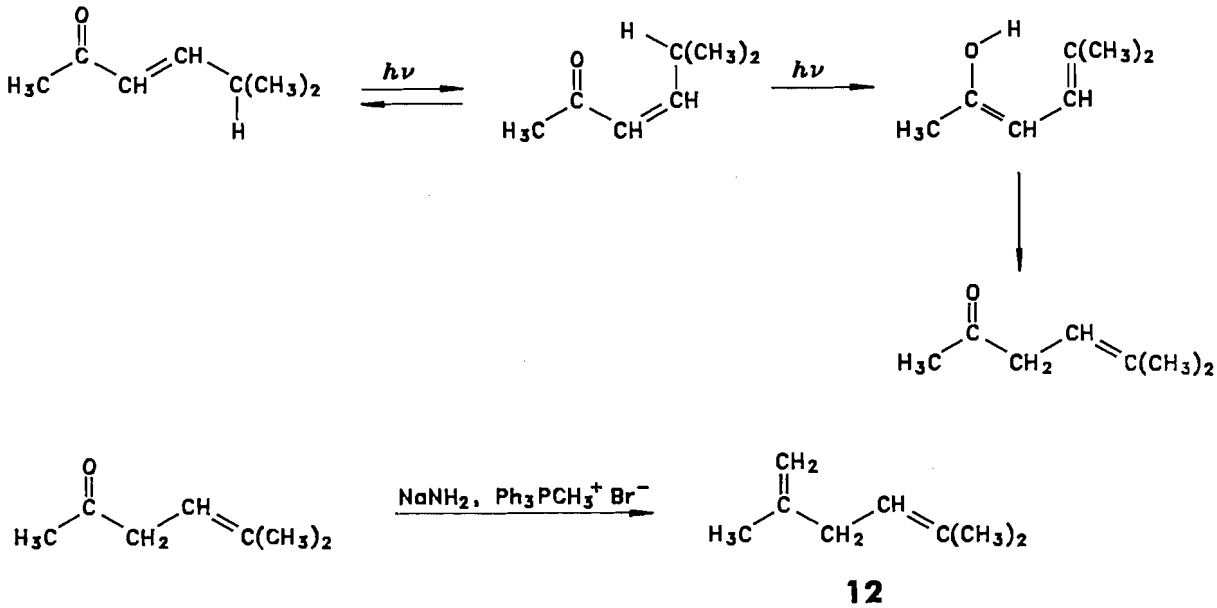
The nonconjugated dienes chosen for study were: 1,5-hexadiene (**9**), 2-methyl-1,5-hexadiene (**10**), 2,5-dimethyl-1,5-hexadiene (**11**), and 2,5-dimethyl-1,4-hexadiene (**12**); **9**, **10**, and **11** were available commercially. 2,5-Dimethyl-1,4- hexadiene (**12**) was prepared by a two-step procedure involving photochemically induced tautomerization of 5-methyl-3-hexen-2-one to the nonconjugated isomer 5-methyl-4-hexen-2-one followed by a Wittig reaction with triphenylphosphine methylene ylide (Scheme 2) (7).

The irradiations were generally carried out on acetonitrile–methanol (3:1) solutions of 1,4-dicyanobenzene (**1**) and the diene, with and without added biphenyl (**4**) or phenanthrene (**5**). Progress of the reaction was followed by capillary column gas



D = biphenyl (**4**) or phenanthrene (**5**)

SCHEME 1

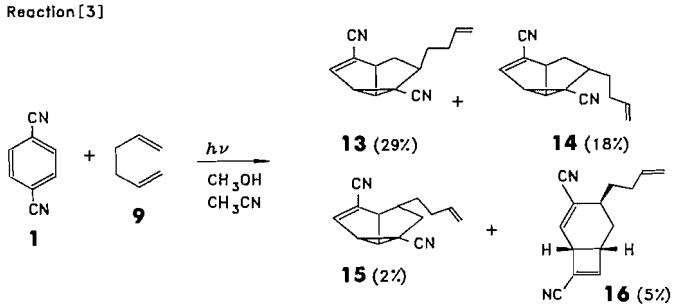


SCHEME 2 (ref. 7)

chromatography with a mass selective detector (gc/ms). Product ratios and yields were based upon isolated pure compounds, generally separated by medium-pressure liquid chromatography (mplc), or upon gas chromatography using a calibrated flame ionization detector (gc/fid). Yields were based upon the amount of 1,4-dicyanobenzene (**1**) consumed; the diene was generally present in excess.

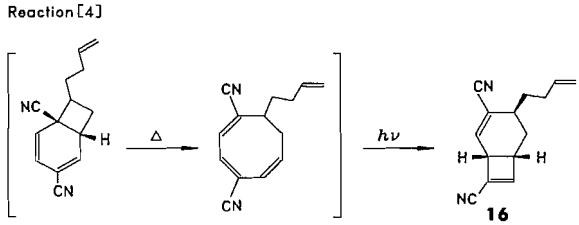
Irradiation of a solution of 1,4-dicyanobenzene (**1**) and 1,5-hexadiene (**9**) gave cycloaddition products **13–16** (combined yield 54%) (reaction [3]). The major products are *meta*

Reaction [3]



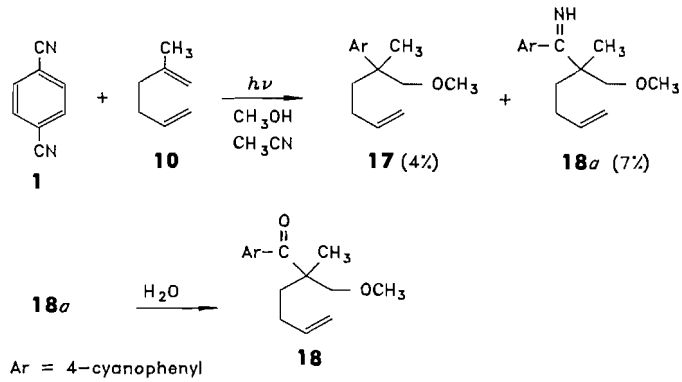
adducts **13**, **14**, and **15**. A minor product **16** is the result of *ortho*-cyclization followed by thermal or photochemical rearrangement (reaction [4]); there is precedence for this cyclization and rearrangement (8, 9). There was no evidence for any interaction between the two double bonds of the diene. No photo-NOCAS products were detected (gc/ms). The addition of biphenyl (**4**) to this reaction mixture caused a decrease in the efficiency of the reaction; still, no photo-NOCAS products were observed. The addition of phenanthrene (**5**) completely quenched the reaction.

Reaction [4]



Irradiation of an acetonitrile–methanol solution of 1,4- dicyanobenzene (**1**) and 2-methyl-1,5-hexadiene (**10**) gave the *anti*-Markovnikov photo-NOCAS adduct **17** in low yield (4%) (reaction [5]). Also isolated from this reaction was the

Reaction [5]



4-cyanophenyl ketone **18** (7%). This ketone was not present in the initial photolysate (gc/ms); imine **18***a* is the primary product. Hydrolysis of the imine to the ketone occurs during the isolation procedure.

The addition of the codonor, biphenyl (**4**), increased the efficiency and yield of formation of the photo-NOCAS product (**17**, 31%). There was no imine or ketone detected in this reaction. Phenanthrene (**5**) was less effective than biphenyl (**4**) in increasing the efficiency of this reaction.

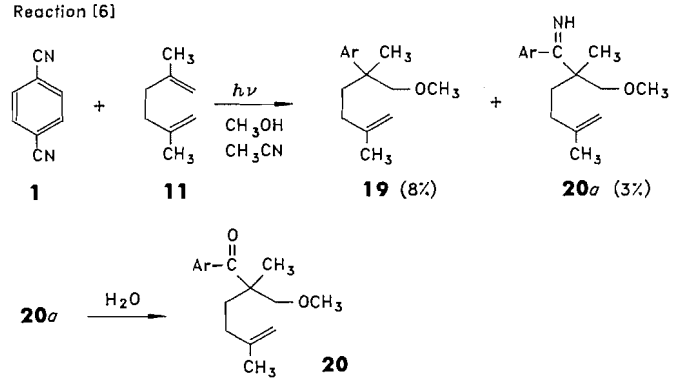
In these reactions of **10**, there was no evidence for formation of products resulting from cycloaddition to the aromatic ring, reaction occurs only at the more heavily substituted double bond, and there was no indication of interaction between the two double bonds.

Irradiation of an acetonitrile–methanol solution of 1,4-dicyanobenzene (**1**) and 2,5-dimethyl-1,5-hexadiene (**11**) also gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

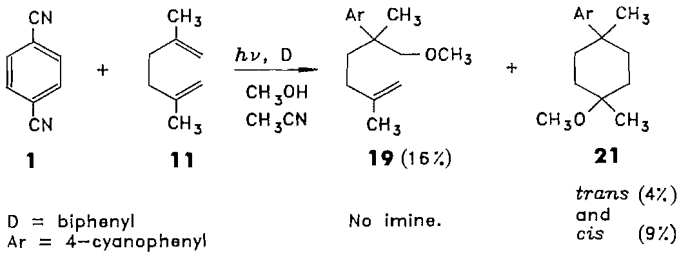
the photo-NOCAS adduct (**19**) in low yield (8%). Again, in this case, imine **20***a* was detected in the photolysate and ketone **20** (3%) was isolated following mplc (reaction [6]). **The addition**

Reaction [6]



of biphenyl (4) has a profound influence on this reaction. The yield of photo-NOCAS adduct **19** increases (to 16%); and, the *cis*- and *trans*-cyclized products (**21** *cis* and *trans*) are also formed (combined yield 13%). Imine **20***a* was not a product under these conditions (reaction [7]).

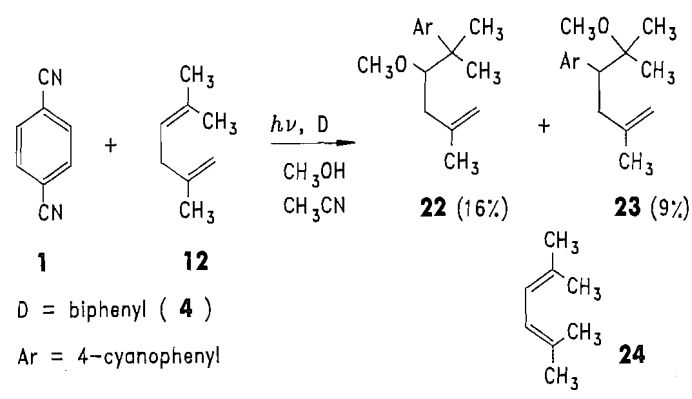
Reaction [7]



The ratio of cyclic to acyclic products (**21** *cis* and *trans*/**19**) depends upon the concentration of both biphenyl (**4**) and methanol. Increasing the concentration of biphenyl (**4**) increases the relative yield of cyclized products (Fig. 1). Increasing the concentration of methanol, between 0.2 and 2.0 M, leads to a decrease in the relative yield of cyclized products (Fig. 2). Further increase in methanol concentration has little effect (**21** *cis* and **21** *trans*/**19** = 0.35 at [CH_3OH] 7 M).

Irradiation of an acetonitrile–methanol solution of 1,4-dicyanobenzene (**1**), biphenyl (**4**), and 2,5-dimethyl-1,4-hexadiene (**12**) gave photo-NOCAS products (reaction [8]). Both the *anti*-Markovnikov (**22**, 16%) and Markovnikov (**23**, 9%)

Reaction [8]



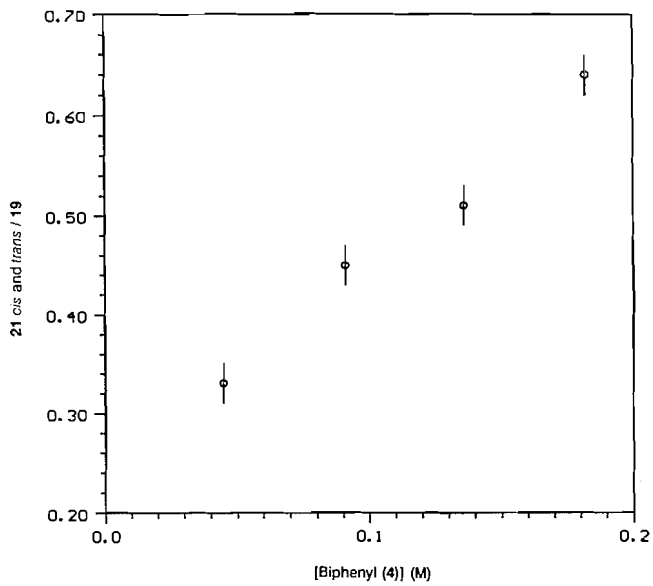


FIG. 1. In reaction [7], the ratio of cyclized products to acyclic product (**21** *cis* and *trans*/**19**) increases with increasing biphenyl (**4**) concentration.

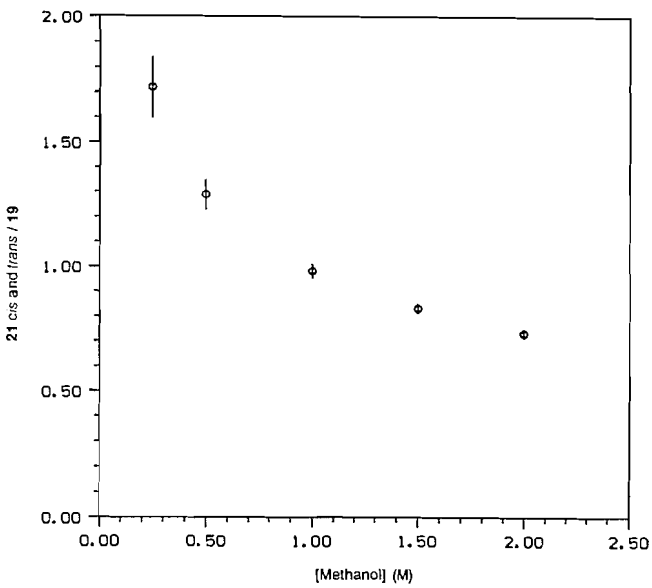

FIG. 2. In reaction [7], the ratio of cyclized products to acyclic product (**21** *cis* and *trans*/**19**) decreases with increasing methanol concentration.

adducts were obtained. Photo-NOCAS reaction occurs only at the more heavily substituted double bond. Another product of this reaction was the conjugated tautomer of **12**, 2,5-dimethyl-2,4-hexadiene (**24**).[4] There was no evidence for interaction between the two double bonds of **12**.

Generally, in those reactions carried out with added codonor (**4**) or photosensitizer (**5**), the codonor or photosensitizer was largely recovered. However, characterization of products formed in trace amounts found 2-cyanobiphenyl (**25**), 4-cyano-

[4]This conjugated diene (**24**) forms the photo-NOCAS adduct, *trans*-2-(4-cyanophenyl)-5-methoxy-2,5-dimethyl-3-hexene, in excellent yield (82%) under these conditions (K.A. McManus and D.R. Arnold, unpublished results).

TABLE 1. Oxidation potentials of the dienes and the calculated free energy change (ΔG_{et}) for the electron transfer process involving the singlet excited state of 1,4-dicyanobenzene (**1**) as the electron acceptor and the diene as electron donor

Diene	$E^{ox}_{1/2}$ (V)[a]	ΔG_{et} (kJ/mol)[b]
1,5-Hexadiene (**9**)	>3.00	>35.7
2-Methyl-1,5-hexadiene (**10**)	2.70	6.81
2,5-Dimethyl-1,5-hexadiene (**11**)	2.60	−2.84
2,5-Dimethyl-1,4-hexadiene (**12**)	2.28	−33.7

[a]Oxidation potentials were measured by cyclic voltammetry at a platinum electrode relative to the saturated calomel electrode (SCE) using tetraethylammonium perchlorate (0.1 M TEAP) as the electrolyte in acetonitrile. The anodic wave was irreversible, so the half-wave was estimated to be 0.028 V before the peak potential (10).

[b]Based upon the Weller equation (11): $E_{0,0}$ (**1**) 408.4 kJ/mol, $E^{red}_{1/2}$ (**1**) −1.66 V, the Coulombic attraction term was taken to be 5.4 kJ/mol (3*b*).

biphenyl (**26**), and 3,5-dimethoxy-4-phenylcyclohexanecarbonitrile (**27**) when **4** was used; and 9-methoxy-9,10-dihydrophenanthrene (**28**) and 9-cyano-9,10-dihydrophenanthrene (**29**) from irradiations containing **5**.

Oxidation potentials of the dienes (**9–12**), necessary for an understanding of the mechanism, were measured by cyclic voltammetry (Table 1).

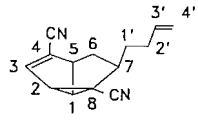
Structural assignments

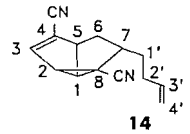
The structural assignments for new compounds were based primarily upon ^{1}H and ^{13}C nmr spectra. Mass spectra (including exact mass determination), infrared spectra, and elemental analyses were also helpful. In one case (**27**), the structure was determined by an X-ray analysis of a single crystal.

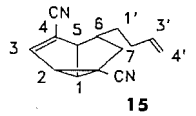
The cycloaddition products **13–16** obtained from 1,5-hexadiene (**9**) (reaction [3]) provided the greatest challenge. Assignments were based upon analysis of ^{1}H nmr spectra, aided by comparison with reported spectra for similar compounds (8, 9), by computer simulation, and by molecular mechanics calculations of the structure. Consider first the *meta* adducts **13–15**. Other possible structures, i.e., *ortho* or *para* cycloadducts or azetines, were easily ruled out; signals in the vinyl region of the ^{1}H nmr spectra of **13–15** are indicative of four olefinic protons. The 3-butenyl side chain was readily identified in all of these structures. There are 12 possible regio- and stereoisomers for the *meta* adducts.

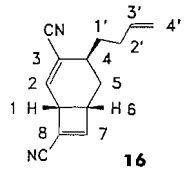
The ^{1}H nmr spectrum of the major product 7-*endo*-(3-butenyl)-4,8-dicyanotricyclo[3.3.0.0^{2,8}]oct-3-ene (**13**) shows a distinctive doublet of doublets, due to one proton, in the aliphatic region (1.80 ppm). This signal, assigned to the *endo* proton on C-6, is strongly coupled to the geminal *exo* proton (2.69 ppm, 13.2 Hz). Decoupling experiments show that this *exo* proton is also strongly coupled to the proton (3.5 ppm, 5.5 Hz) assigned to the methine group (C-5), and to the *exo* proton on C-7 (2.94 ppm, 11.4 Hz). The *endo* proton on C-6 is not significantly coupled to the proton on C-5 and is only weakly coupled to the *exo* proton on C-7 (0.9 Hz). The proton on C-5 is coupled (1.2 Hz) to the *exo* proton on C-7. This long-range W-coupling establishes the regiochemistry of the alkenyl side chain as *endo*. The proton on C-5 is also coupled to the vicinal proton on C-1 (3.45 ppm, 5.8 Hz). The proton on C-1 is coupled to another vicinal proton on C-2 (2.62 ppm, 6.6 Hz). And the proton on C-2 is coupled to the vinyl proton on C-3 (6.54 ppm, 2.5 Hz).

The other major *meta* adduct has been assigned structure 7-*exo*-(3-butenyl)-4,8-dicyanotricyclo[3.3.0.0^{2,8}]oct-3-ene (**14**). The spectrum of **14** is similar to that of **13**, the distinguishing features are in the coupling of the signals assigned to the protons on C-5, C-6, and C-7. The proton on C-5 is coupled (5.08 Hz) with the vicinal proton *exo* on C-6. This proton is strongly coupled (13.4 Hz) to a proton which must be geminal, *endo* on C-6, thus establishing the regiochemistry; the side chain must be attached at C-7. For **13**, long-range W-coupling between the proton on C-7 and the proton on C-5 is significant (1.2 Hz), indicative of an *exo* proton on C-7. For **14**, these protons are only weakly coupled (0.5 Hz), which is consistent with an *endo* proton on C-7; therefore, the alkenyl side chain is *exo*.









The minor *meta* cycloaddition product from reaction [3] has been assigned structure 6-*exo*-(3-butenyl)-4,8-dicyanotricyclo-[3.3.0.0^{2,8}]oct-3-ene (**15**). The absence of a distinctive doublet of doublets in the aliphatic region of the ^{1}H nmr spectrum of this isomer, characteristic of an *endo* proton on C-6, with strong geminal coupling to another proton on C-6, is an indication that this isomer has the alkenyl side chain in the *exo* position on C-6. The *endo* proton on C-6 shows up as a complex multiplet (2.20–2.30 ppm) coupled (6.8 Hz) to the nonequivalent protons on the adjacent methylene of the alkenyl side chain, and to the *endo* proton on C-7 (4.6 Hz). The protons on C-7 (1.92–2.02 ppm) show geminal coupling (5.7 Hz). The spectrum shows one proton (3.27 ppm) assigned to the proton at the bridgehead (C-5), coupled strongly to only one proton (3.29 ppm, 5.8 Hz) assigned to the proton at the apex of the three bridgeheads (C-1). The proton on C-5 shows no further coupling to adjacent proton(s); the four-carbon chain must be in the *exo* position on C-6. The proton on C-1 is coupled, not only to the proton on C-5, but also to the allylic proton on C-2 (2.74 ppm, 5.7 Hz). The proton at C-2 is also coupled to the vinyl proton on C-3, which shows up as a sharp doublet (6.46 ppm, 2.5 Hz).

The fourth compound from reaction [3] has been assigned structure *trans*-4-(3-butenyl)-*cis*-3,8-dicyanobicyclo[4.2.0]-octa-2,7-diene (**16**). Literature precedents for the complex thermal and photochemical rearrangements involved during reaction [4], and comparison of the ^{1}H nmr spectra of **16** with those reported for similar compounds were helpful in arriving at this conclusion (8, 9).

The protons associated with the four-carbon chain were readily identified by comparison with the spectra of **13–15**. One of the vinyl protons in the bicyclic system shows up as a doublet of doublets (C-2, 6.79 ppm), coupled to the allylic proton on C-4 (2.20 ppm, 2.5 Hz), and to the bridgehead proton on C-1 (3.74 ppm, 5.5 Hz). The other vinyl proton, on C-7, is a doublet (6.89 ppm, 1.2 Hz) coupled to the proton on the other bridgehead (C-6, 3.34 ppm). The proton on C-6 is a multiplet (couplings: 1.2, 3.3, 4.1, and 5.9 Hz). The proton on C-1 is a multiplet, coupled to the proton on C-5 (W-coupling, 1.5 Hz),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

to the proton on C-6 (4.1 Hz), and to the proton on C-2 (5.5 Hz). The proton on C-4 is a complex multiplet; the coupling constants for the protons on the adjacent methylene, C-5 (1.35 and 2.08 ppm), are 10.3 and 4.9 Hz, respectively. This large coupling is indicative of the four-carbon chain being *trans* to the cyclobutene ring. The remaining assignments are listed in the experimental section; they are all consistent with the structure, and are in good agreement with those reported for similar structures (8).

The photo-NOCAS product from reaction [5] was assigned the structure 5-(4-cyanophenyl)-6-methoxy-5-methyl-1-hexene (**17**). The aliphatic region of the ^{1}H nmr spectrum exhibits resonances corresponding to two adjacent methylene groups (C-3 and C-4) and a singlet corresponding to a methyl group bonded to a quaternary centre. A sharp singlet at 3.29 ppm represents a methoxy methyl group. A distinctive AB-type coupling pattern at 3.37 and 3.49 ppm supports a methoxy-substituted methylene group adjacent to a chiral centre; two sharp doublets are observed with a coupling constant of 9.1 Hz. There is evidence for three vinyl protons, indicative of the terminal alkene. The aromatic region of the ^{1}H nmr spectrum shows a distinctive AA′XX′ coupling pattern, which is consistent with the *para*-substituted ring.

The imine **18***a* was not isolated; hydrolysis of the imine to the ketone **18** occurs during the chromatographic separation of the crude photolysate. The gc/ms of the initial mixture indicates that the ketone is not present; however, there is a peak with a retention time similar to that of the ketone and with a similar ms fragmentation pattern that we attribute to the imine. The ^{1}H nmr spectrum of the ketone, 1-(4-cyanophenyl)-2-methoxymethyl-2-methyl-5-hexen-1-one (**18**), is similar to that of the photo-NOCAS product **17**. Proof for the aryl-conjugated carbonyl group was found in the infrared spectrum, a strong carbonyl stretch at 1687 cm^{-1}. The ^{13}C nmr spectrum also exhibits a singlet at 208.10 ppm, characteristic of a carbonyl carbon bonded to a tertiary centre.

The adducts formed from 2,5-dimethyl-1,5-hexadiene (reaction [6]) were assigned structures 5-(4-cyanophenyl)-6-methoxy-2,5-dimethyl-1-hexene (**19**) and 1-(4-cyanophenyl)-2-methoxymethyl-2,5-dimethyl-5-hexen-1-one (**20**). The ^{1}H nmr spectrum of **19** is similar to that of **17**; a sharp singlet at 3.29 ppm represents a methoxy methyl group and a distinctive AB-type coupling pattern at 3.38 and 3.49 ppm supports a methoxy-substituted methylene group adjacent to a chiral centre. Two sharp doublets with a coupling constant 9.1 Hz are observed. The ^{1}H nmr spectrum of **19** shows only two slightly broadened singlets in the vinyl-proton region, indicative of the terminal methylene group. The spectra from **20** were similar to those of **19**.

The gross structure of the cyclized photo-NOCAS adducts, *cis*- and *trans*-1-(4-cyanophenyl)-4-methoxy-1,4-dimethylcyclohexane (*cis* and *trans* **21**) from reaction [7] was easily established from the ABCD-type coupling pattern in the aliphatic region of the ^{1}H nmr spectra and two types of methylene groups in the ^{13}C nmr spectra. For *cis*-**21**, there are two singlets in the aliphatic region of the ^{1}H nmr spectrum, corresponding to the two methyl groups. A shift reagent (europium (III) tris-1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,5-octanedione) was used to determine which methyl group was attached to the quaternary carbon bearing the methoxy group. This shift reagent is known to complex with the oxygen of the methoxy group and, thus, selectively shift the geminal methyl group (12). The signal (1.00 ppm) due to the methyl group next to the methoxy group and the signal (1.14 ppm) due to the methyl group bound to the same carbon as the 4-cyanophenyl group were thus distinguished. The *cis* configuration of this compound was then established on the basis of a nuclear Overhauser experiment (NOE). When the high-frequency (1.14 ppm) signal due to the methyl group next to the 4-cyanophenyl group was irradiated, an increase in the signal due to the cyclohexane protons was observed. Therefore, this methyl group must be in the axial position, close to the axial protons on the cyclohexane ring. No change was observed when the low-frequency (1.00 ppm) methyl signal was similarly irradiated.

The ^{1}H nmr spectrum of the *trans* isomer was similar to that of the *cis* isomer just described. In this case, the signal due to the methyl group next to the methoxy group occurs at 1.18 ppm and that due to the methyl on the carbon bearing the 4-cyanophenyl group is at 1.24 ppm. Nuclear Overhauser enhancement experiments on this isomer show no enhancement of the signal due to the cyclohexane protons upon irradiation of either methyl group; thus, both methyl groups are in the equatorial position.

These configuration/conformation assignments are supported by molecular mechanics calculations.[5] Consider first the model systems: 1-methoxy-1-methylcyclohexane and 1-methyl-1-(4-cyanophenyl)cyclohexane. Molecular mechanics calculations indicate that both the methoxy and the 4-cyanophenyl groups prefer the axial position; the methyl group is equatorial in the global minimum for both compounds. For 1-methoxy-1-methylcyclohexane the difference in energy for the two conformations (methoxy equatorial − methoxy axial) is 5.4 kJ mol^{-1}, and for 1-methyl-1-(4-cyanophenyl)cyclohexane the 4-cyanophenyl axial conformer is 2.5 kJ mol^{-1} more stable than the conformer with the 4-cyanophenyl group equatorial. The evidence from the ^{1}H nmr study suggests that in the global minimum for *trans*-1-(4-cyanophenyl)-4-methoxy-1,4-dimethylcyclohexane (**21** *trans*), both of the methyl groups are in the equatorial position. This is consistent with the molecular mechanics calculations, which show this conformer to be 7.7 kJ mol^{-1} more stable than the conformer having both of the methyl groups in the axial position. For *cis*-1-(4-cyanophenyl)-4-methoxy-1,4-dimethylcyclohexane (**21** *cis*), the ^{1}H nmr evidence shows that the methyl group next to the 4-cyanophenyl group is in the axial position; the molecular mechanics calculations show that this conformer is 5.2 kJ mol^{-1} more stable than the conformer that places the methyl group next to the methoxy group in the axial position.

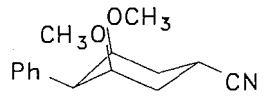
The ^{1}H nmr spectra of the photo-NOCAS products **22** and **23** (reaction [8]) both show four sharp singlets for the four methyl groups, two slightly broadened singlets in the vinyl-proton region, and a coupled pattern for the three protons associated with the methylene and methine groups. The distinction between the two isomers was made on the basis of chemical shift for the protons and carbon adjacent to the 4-cyanophenyl and methoxy groups. For **22**, the methylene and methine protons show up as an AA′X pattern. The proton on the carbon bearing the methoxy group shows up as an apparent triplet at relatively low field (3.32 ppm, 5.9 Hz) coupled to the adjacent

[5]The molecular mechanics programme used for these calculations was PCMODEL, a product of Serena Software, Bloomington, Ind. Similar results have been reported for 1-methyl-1-phenylcyclohexane and for 1-methoxy-1-methylcyclohexane (13).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

methylene hydrogens (1.91 ppm). This regiochemistry is supported by the ^{13}C nmr spectrum; the methine carbon bearing the methoxy group is a doublet at 87.98 ppm. A singlet at 43.74 ppm provides evidence that the aryl group is bonded to the quaternary carbon. For **23**, the methylene protons at 2.50 and 2.64 ppm and the methine proton at 2.95 ppm are coupled in a typical ABX pattern. The chemical shift of the methine proton is typical for a benzylic proton. The ^{13}C nmr spectrum of this isomer shows a singlet at low field (76.44 ppm), which is consistent with a methoxy-substituted quaternary carbon, and a doublet (53.38 ppm) for the carbon bearing the aryl group.

Generally the codonor and photosensitizer (electron transfer) were largely recovered; however, small amounts of 2-cyanobiphenyl (**25**), 4-cyanobiphenyl (**26**), and 3,5-dimethoxy-4-phenylcyclohexanecarbonitrile (**27**) were detected when biphenyl (**4**) was used as a codonor. Characterization of **25** and **26** was achieved by direct comparison (gc/ms, retention time, and fragmentation pattern) with authentic samples. The structure assigned to **27** rests firmly on an X-ray diffraction analysis of a single crystal, isolated from reaction [7] (see Appendix, Depository of Unpublished Data).[6] Molecular mechanics calculations on **27** are consistent; the conformer having the methoxy groups in the axial position is more stable than the alternative chair conformer by 7.2 kJ mol^{-1}. Minor products, 9-methoxy-9,10-dihydrophenanthrene (**28**) and 9-cyano-9,10-dihydrophenanthrene (**29**), obtained when phenanthrene (**5**) was used as a photosensitizer, were characterized by direct comparison (gc/ms, retention time and fragmentation pattern, ^1H nmr) with authentic samples.



27

Discussion

The proposed mechanism for the photo-NOCAS reaction, shown in Scheme 1, has been described in detail in previous publications in this series (1, 3); all of the results reported here are consistent with the general features of this mechanism. In the absence of added photosensitizer, the initial excitation involves absorption into the ^1L_b band of 1,4-dicyanobenzene (**1**) (step 1). These nonconjugated dienes, **9–12**, are transparent at wavelengths transmitted through Pyrex (>280 nm).

Step 2 in the proposed mechanism involves single electron transfer (SET) from the diene to the singlet excited state of 1,4-dicyanobenzene (**1**). The rate of this process can be predicted from the singlet energy and reduction potential of the electron acceptor (**1**), and the oxidation potential of the electron donor, i.e., the diene, on the basis of the Weller equation (eq. [9]) (11). These values are given in Table 1. Electron transfer occurs at the diffusion-controlled rate when the free energy for electron transfer (ΔG_{et}, eq. [9]) is exergonic by -20 kJ mol^{-1} or more (11). The free energy of electron transfer to the excited singlet state of **1** from 1,5-hexadiene (**9**) is highly endergonic (>35.7 kJ mol^{-1}). Electron transfer should not occur in this case and the observations (reaction [3]) are in accord with this prediction

$$[9] \quad \Delta G_{et} = F[E^{ox}_{1/2}\ (D) - E^{red}_{1/2}\ (A) - e/\epsilon\alpha] - E_{0,0}(A) \qquad \text{(ref. 11)}$$

The products obtained from reaction [3] are consistent with involvement of an intermediate polar exciplex (8, 9, 14). The mode of cycloaddition, *ortho* or *meta*, can be predicted on the basis of the polarity of the exciplex assessed by the ΔG_{et} for complete electron transfer. With benzonitrile, for example, *ortho* adducts form if ΔG_{et} is less than 164 kJ mol^{-1} while *meta* adducts result if ΔG_{et} is greater than 164 kJ mol^{-1} (14*b*). We have been unable to measure the oxidation potential of **9**; only a minimum value, >3 V (vs. sce), could be determined. This is consistent with literature values for other terminal alkenes, some of which have oxidation potentials greater than 3.5 V (vs. sce) (15). If the correlation observed with benzonitrile also pertains to **1**, the predominant formation of *meta* adducts from **1** and **9** requires the oxidation potential of **9** to be ca. 4 V. There is no evidence for interaction between the two double bonds of **9**, which would lower the oxidation potential below that expected for a normal terminal mono-alkene.

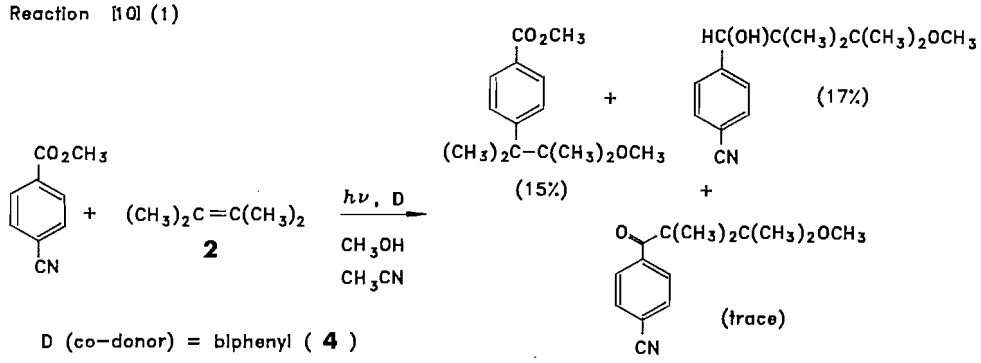
The major products from reaction [3], *meta* adducts **13**, **14**, and **15**, are the result of addition of **9** across the 1,3-position of the 1,4-dicyanobenzene ring. This regiochemistry is consistent with the detailed mechanism for *meta*-adduct formation, beginning with the initially formed polar exciplex (9*a*). Minor product **16** is the result of *ortho* addition of **9** across the 1,2-position of 1,4-dicyanobenzene. Subsequent thermal or photochemical ring opening followed by photochemical cyclization, illustrated in reaction [4], can account for formation of **16**. This sequence has adequate precedent (8).

The addition of the potential codonor, biphenyl (**4**), to the irradiation mixture quenches the formation of these cycloadducts. Biphenyl (**4**), of course, quenches the excited singlet state of 1,4-dicyanobenzene (**1**) by the electron transfer mechanism. This quenching leads to formation of the radical ions $\mathbf{4}^{+\cdot}$ and $\mathbf{1}^{-\cdot}$ (Scheme 1, step 6a). Still, no photo-NOCAS products are formed. Clearly, the oxidation potential of **9** is sufficiently greater than that of biphenyl (**4**) that the radical cation $\mathbf{4}^{+\cdot}$ cannot serve as a codonor with it; electron transfer from **9** to $\mathbf{4}^{+\cdot}$ (step 7) is endergonic by >115 kJ mol^{-1}. Phenanthrene (**5**)

[6]These data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Details of data collection, structural analysis and refinement, and tables of interatomic distances and bond angles have also been deposited with the Cambridge Crystallographic Data Centre and may be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Reaction [10] (1)



quenches the reaction simply by competitive light absorption. In this case also, radical ions $\mathbf{5}^{+\cdot}$ and $\mathbf{1}^{-\cdot}$ will form (steps 6b and c), but electron transfer from **9** to $\mathbf{5}^{+\cdot}$ is unfavourable. Back electron transfer (step 8) completes the quenching mechanism.

Electron transfer does occur from 2-methyl-1,5-hexadiene (**10**) to the excited singlet state of 1,4-dicyanobenzene (**1**) (step 2). Even though electron transfer is endergonic (6.8 kJ mol^{-1}), radical ions form and the photo-NOCAS product is obtained (reaction [5]). Radical ion formation involving electron transfer from 2-methylpropene (**6**) to the excited singlet state of **1**, in reaction [2], involves a similar endergonic process (3). As expected, the photo-NOCAS product **17** is the *anti*-Markovnikov adduct. The radical cation $\mathbf{10}^{+\cdot}$ reacts with methanol at the terminal carbon of the more heavily substituted double bond to give the β-alkoxy-*tert*-alkyl radical (step 3), this radical attacks the *ipso* position of the radical anion $\mathbf{1}^{-\cdot}$ (step 4), and the intermediate cyclohexadienyl anion rearomatizes, with loss of cyanide ion (step 5), to give the photo-NOCAS product. No products resulting from cycloaddition of diene **10** to the aromatic ring were detected (gc/ms) in this case; either the exciplex does not form or it is rapidly deactivated by electron transfer.

Another product of this reaction was imine **18***a*, isolated as ketone **18** following chromatography of the photolysate. One explanation for imine formation would involve radical – radical anion coupling at the carbon of the cyano group; however, the spin density (calculated, STO-3G) at the cyano carbon in the radical anion is relatively small, only ca. 0.1 that at the *ipso* position (1). An alternative explanation: the radical anion, $\mathbf{1}^{-\cdot}$, may reduce the β-alkoxyalkyl radical to the anion, then further reaction can be viewed as a nucleophilic attack of the anion on the cyano group of neutral 1,4-dicyanobenzene (**1**). The reduction potential of the tertiary radical may be less negative than the reduction potential of **1** (16). While reduction of the radical to the anion may be favourable, the rate of this electron transfer may be slow due to the large reorganization energy involved in this process (16, 17). We have never observed attack on the cyano group of 1,4-dicyanobenzene (**1**) before; however, we have used this mechanism to explain the analogous formation of products resulting from attack on the carboxyl carbonyl during the photo-NOCAS reaction of methyl *para*-cyanobenzoate (reaction [10]) (1).

The addition of biphenyl (**4**) increases the efficiency of formation and the yield of photo-NOCAS product **17**. No imine (or ketone) was formed under these conditions. Biphenyl (**4**) functions as a codonor (step 6a), followed by complex formation between $\mathbf{4}^{+\cdot}$ and **10**. Electron transfer from **10** to $\mathbf{4}^{+\cdot}$ (step 7) is endergonic (85 kJ mol^{-1}); reaction with methanol may involve the small equilibrium concentration of $\mathbf{10}^{+\cdot}$ or attack of methanol may occur on the complex. The increased efficiency of the reaction is thought to be due to slower back electron transfer between $\mathbf{1}^{-\cdot}$ and $\mathbf{4}^{+\cdot}$ within the SSRIP, the result of a smaller reorganization energy for $\mathbf{4}^{+\cdot}$ returning to **4**.

No cyclic products were observed from reaction [5]. The radical cation $\mathbf{10}^{+\cdot}$ apparently does not cyclize. Reaction occurs only at the more heavily substituted double bond. The rate of attack of methanol on the initially formed acyclic radical cation ($\mathbf{10}^{+\cdot}$) must be rapid enough to prevent cyclization. We will return to this point later.

The intermediate β-alkoxyalkyl radical also does not cyclize. A 1,4-*exo* radical cyclization is thermodynamically unfavourable and the alternative 1,5-*endo* radical cyclization is slow for steric reasons; as a result, reaction of the β-alkoxyalkyl radical with the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\cdot}$) is rapid enough to compete with cyclization (6*i*,*j*).

Results from the irradiation of an acetonitrile–methanol (3:1) solution of 1,4-dicyanobenzene (**1**) and 2,5-dimethyl-1,5-hexadiene (**11**) were similar to those observed with the monomethyl analog **10**. The oxidation potential of **11** is low enough that electron transfer to the excited singlet state of **1** is exergonic (−2.8 kJ mol^{-1}); both the photo-NOCAS adduct (**19**) and the imine (**20***a*) were obtained (reaction [6]). There was no evidence for cyclization of the initially formed radical cation $\mathbf{11}^{+\cdot}$ or of the intermediate β-alkoxyalkyl radical under these conditions.

However, cyclized products, *cis*- and *trans*-4-(4-cyanophenyl)-1-methoxy-1,4-dimethylcyclohexane (**21** *cis* and *trans*), were obtained when biphenyl (**4**) was added to the irradiation mixture (reaction [7]). The ratio of cyclic to acyclic products is a function of biphenyl (**4**) and methanol concentration (Figs. 1 and 2). The observation that the ratio of cyclic to acyclic product (**21** *cis* and *trans*/**19**) decreases with increasing methanol concentration, between 0.2 and 2.0 M, is good evidence that it is the acyclic radical cation ($\mathbf{11}^{+\cdot}$) that cyclizes — not the β-alkoxyalkyl radical. Furthermore, the regiochemistry of the cyclized products is inconsistent with prior formation of a β-alkoxyalkyl radical that involves preferential attack of methanol on the terminal carbon. The effect of biphenyl (**4**) can be explained if the reaction of the complex (**4** with **11**)$^{+\cdot}$ with methanol is slower than that of uncomplexed $\mathbf{11}^{+\cdot}$.

Scheme 1 must be modified to include a cyclization step between steps 7 and 3 to allow formation of the 1,4-dimethylcyclohexane-1,4-diyl radical cation (step 3a). Reaction of the cyclized radical cation with methanol leads to formation of the 4-methoxy-1,4-dimethylcyclohexyl radical (step 3b); addition of this radical to the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\cdot}$) continues the mechanistic sequence. On the reasonable assump-

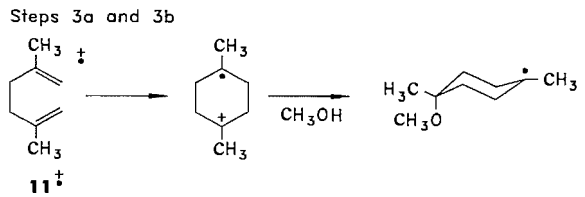
For personal use only.



tion that there is little interaction between the radical centre and the remote methoxy group, the preferred conformation of this cyclohexyl radical will be *pseudo*-chair with the methoxy group in the axial position. The dominant (70%) formation of the diastereomer bearing the methoxy and 4-cyanophenyl groups *cis* (**21** *cis*) is consistent with the favoured transition state for addition of this radical to the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\cdot}$) involving equatorial attack (18).

The observation that cyclic products are obtained from radical cation $\mathbf{11}^{+\cdot}$, while no cyclic products were observed from $\mathbf{10}^{+\cdot}$, is tentatively explained on thermodynamic grounds. The calculated (MINDO/3) activation energy for cyclization of the parent radical cation of 1,5-hexadiene (**9**) to the cyclohexane-1,4-diyl radical cation is <8 kJ mol^{-1} (19*a*). These calculations also indicate that the cyclohexane-1,4-diyl radical cation is 140 kJ mol^{-1} **more** stable than the acyclic diene radical cation $\mathbf{9}^{+\cdot}$. In marked contrast, recent thermochemical calculations suggest that the 1,4-dimethylcyclohexane-1,4-diyl radical cation is 10 kJ mol^{-1} **less** stable than the acyclic diene radical cation $\mathbf{11}^{+\cdot}$ (19*b*). Therefore, cyclization of the *syn, syn-gauche* conformation of $\mathbf{11}^{+\cdot}$ to 1,4-dimethylcyclohexane-1,4-diyl radical cation may be reversible. A rapid equilibration between the acyclic and cyclic radical cations may explain why the ratio of cyclic to acyclic products (**21** *cis* and *trans*/**19**) levels off at higher methanol concentration (>2 M).

It seems likely that 1-methylcyclohexane-1,4-diyl radical cation is even less stable relative to the acyclic radical cation $\mathbf{10}^{+\cdot}$. The lack of cyclic products from reaction [5] may be the result of an unfavourable equilibrium for the 1-methylcyclohexane-1,4-diyl radical cation.

Molecular mechanics calculations of **10** and **11** identify several low-lying conformations, differing little in energy; furthermore, the rotational barriers between conformers must be small, <15 kJ mol^{-1}.[7] Cyclization through a *pseudo*-chair transition state requires the *syn, syn-gauche* conformation of the diene (Figs. 3*b* and 4*b*). This reactive conformer of **11** has nine conformers of lower energy and is only 7.7 kJ mol^{-1} above the global minimum (Fig. 4*a*). In marked contrast, the reactive *syn, syn-gauche* conformer of **10** has 21 conformers of lower energy and is 9.5 kJ mol^{-1} above the global minimum (Fig. 3*a*). Clearly the conformation required for cyclization is statistically and energetically favoured in the case of **11** relative to **10**.

The rate constant for addition of methanol to aryl-substituted alkene radical cations is in the range 10^7–10^9 M^{-1} s^{-1} (20). The rate of reaction of alkyl-substituted alkene radical cations is not known but reaction is probably even more rapid. It therefore seems likely that the initial rate of 1,6-*endo*, *endo* cyclization is determined by the rate of conformational change to the *syn, syn-gauche* conformer. This can account for the dependence of the product ratio (**21** *cis* and *trans*/**19**) on methanol concentration.

[7]The molecular mechanics programme used for these calculations was MM3(92). Chiral conformers were counted as two individual conformers.

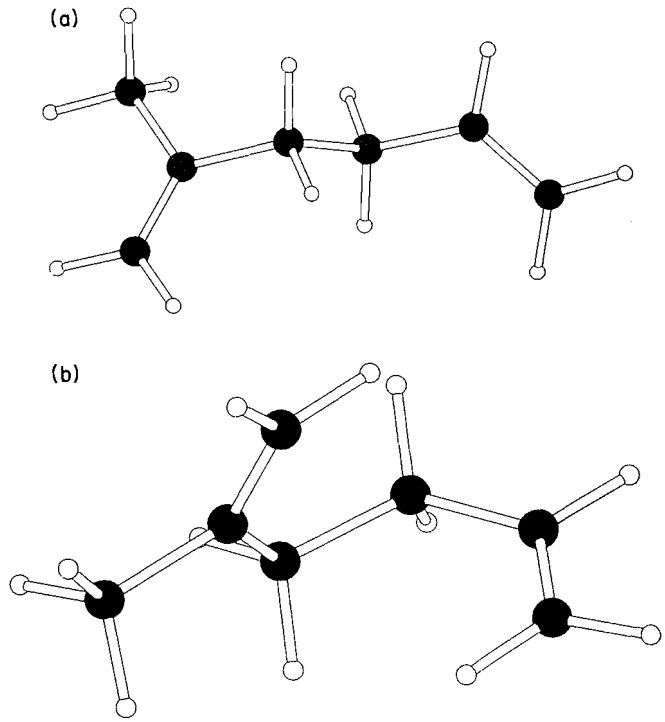


FIG. 3. (*a*) The global minimum (MM3) conformer of 2-methyl-1,5-hexadiene (**10**). (*b*) The *syn, syn-gauche* conformer of 2-methyl-1,5-hexadiene (**10**).

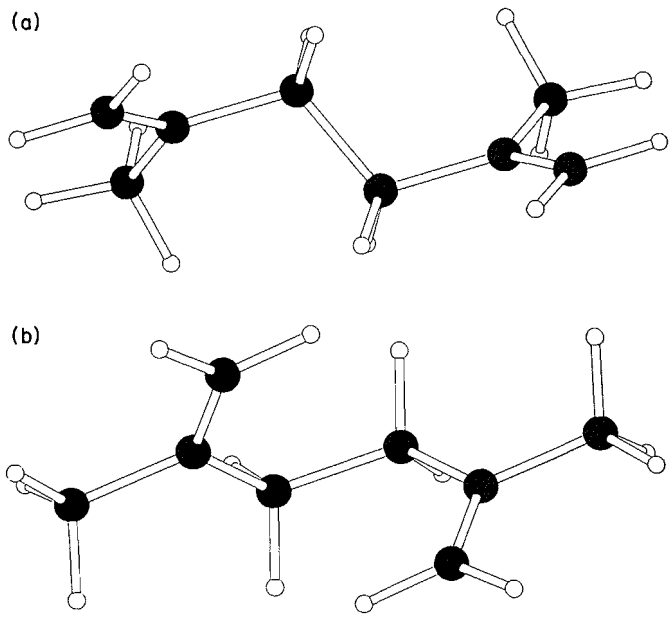

FIG. 4. (*a*) The global minimum (MM3) conformer of 2,5-dimethyl-1,5-hexadiene (**11**). (*b*) The *syn, syn-gauche* conformer of 2,5-dimethyl-1,5-hexadiene (**11**).

When a Freon (CF_3CCl_3) matrix of 1,5-hexadiene was subjected to radiolytic oxidation (irradiated with γ-rays) at 77 K, there was no evidence for the acyclic diene radical cation $\mathbf{9}^{+\cdot}$. The observed spectra were attributed to the cyclohexane-1,4-diyl radical cation (21). When the matrix was annealed or photobleached the signal from the cyclohexane-1,4-diyl radical cation decreased with a corresponding growth of the signal for the cyclohexene radical cation. When

2,5-dimethyl-1,5-hexadiene (**11**) was studied under somewhat different conditions, neither the acyclic radical cation $\mathbf{11}^{+\cdot}$ nor the 1,4-dimethylcyclohexane-1,4-diyl radical cation were detected; the observed spectrum was attributed to the *trans*-3,6-dimethylcyclohexene radical cation (22). Apparently, cyclization and rearrangement occurred rapidly under these conditions. In view of these reports of facile rearrangement of cyclohexane-1,4-diyl radical cations, it is significant that we found no evidence for the rearrangement of the 1,4-dimethylcyclohexane-1,4-diyl radical cation $\mathbf{11}^{+\cdot}$ during reaction [7].

Previous studies have shown that the cyclohexane-1,4-diyl radical cation is an intermediate in the SET-induced Cope rearrangement (19, 23). In the special case of 2,5-diphenyl-1,5-hexadiene, the radical cation produced by SET to the excited singlet state of 9,10-dicyanoanthracene cyclizes to the bis-benzylic, resonance-stabilized, 1,4-diphenylcyclohexane- 1,4-diyl radical cation, which could be trapped by oxygen to give the bicyclic peroxide (23*b*).

The products obtained from 2,5-dimethyl-1,4-hexadiene (reaction [8]) are consistent with the proposed mechanism (1, 3). The major photo-NOCAS product is the *anti*-Markovnikov adduct **22**. Formation of a small amount of Markovnikov adduct **23** is expected from this, a trisubstituted alkene (3). In this case also, reaction occurs only at the more heavily substituted double bond, i.e., the site of lower oxidation potential. Deprotonation of the radical cation $\mathbf{12}^{+\cdot}$, to give the allylic radical, reduction of this radical by $\mathbf{1}^{-\cdot}$, and reprotonation of the resulting ambident anion, gives the conjugated tautomer **24**. There was no evidence for cyclization of the acyclic radical cation or of the intermediate β-alkoxyalkyl radical.

The minor products, 2-cyanobiphenyl (**25**), 4-cyanobiphenyl (**26**), and 3,5-dimethoxy-4-phenylcyclohexanecarbonitrile (**27**), detected in reactions using biphenyl (**4**) as codonor, and isolated from reaction [7], are consistent with the involvement of $\mathbf{4}^{+\cdot}$. Similarly, 9-methoxy-9,10-dihydrophenanthrene (**28**) and 9-cyano-9,10-dihydrophenanthrene (**29**) are expected products following nucleophilic addition to the phenanthrene radical cation ($\mathbf{5}^{+\cdot}$), formed when phenanthrene is added as a photosensitizer. The mechanism for formation of **27** must involve several steps. Addition of cyanide ion, generated during the rearromatization step (step 5), to the *para* position of radical cation $\mathbf{4}^{+\cdot}$, followed by hydrogen abstraction by the resulting radical, will give a dihydro-4-cyanobiphenyl. Subsequent addition of two moles of methanol to the radical cation of the phenylcyclohexadiene and phenylcyclohexene can account for this product.

Experimental

General information

^{1}H and ^{13}C nmr spectra were obtained from a Bruker 300 MSL spectrometer or a Nicolet 360 NB spectrometer. Spectra are reported in parts per million (ppm) relative to tetramethylsilane. Infrared spectra (ir) were recorded on an air-purged Perkin–Elmer 180 grating spectrometer and are reported in wavenumbers (cm^{-1}) relative to the 1601.4 cm^{-1} absorption band of polystyrene film. Elemental analyses were performed by Canadian Microanalytical Service Ltd., B.C. Exact mass determinations were obtained on a ZAB-E mass spectrometer. Melting points were determined using a Cybron Corporation Thermolyne apparatus with a digital thermocouple and are corrected. Product yields were determined using a Hewlett–Packard (HP) 5890 gas chromatograph with a DB-1701 fused silica WCOT column (30 m × 0.25 mm, 0.25-μm film thickness) and a calibrated flame ionization detector (gc/fid) and are based upon 1,4-dicyanobenzene (**1**) as the limiting reagent. An HP 3392A integrator was interfaced with the gc/fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33-μm film thickness) interfaced with an HP 5970 mass selective detector (gc/ms) was also used for product analyses. Mass spectra are reported as *m/z* (relative intensity). Separation of product mixtures was generally carried out using preparative medium-pressure liquid chromatography (mplc) (3*b*). The mplc unit consists of a 2.5 cm × 1 m column packed with thin-layer chromatography (tlc) grade silica gel (without binder) (cat. no. 7747 Merck) at a pressure of 15 psi using helium (1 psi = 6.9 kPa). Connected to the mplc was a uv spectrophotometer – fraction collector that collects ca. 10-mL fractions. Another method used for product separation was flash chromatography (fc) on a 35 mm × 160 mm column (Column A) or a 30 mm × 180 mm column (Column B) (24*a*). The columns were packed with silica gel that was 230–400 mesh, 60 Å (Aldrich), under 3 psi of nitrogen. Dry column flash chromatography (dc/fc) was also used (24*b*). The column was packed with thin-layer chromatography grade silica gel (without binder) (cat. no. 7747 Merck). Fraction sizes were ca. 5 mL. Preparative-GC (prep/gc) was carried out using a Varian Aerograph A700 or 920, fitted with either 10% FFAP on Chromasorb W 60/80 or 40% SE-30 Chromasorb W 60/80 columns.

Materials

Acetonitrile (Fisher ACS grade) was distilled twice, first from sodium hydride and then from phosphorus pentoxide. It was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), fractionally distilled (under nitrogen), and stored over molecular sieves (3 Å) (25). Methanol was distilled and then stored over molecular sieves (4 Å). 1,4-Dicyanobenzene (**1**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized three times from water and then dried in a vacuum oven for 15 h, 70°C, 0.25 Torr (1 Torr = 133.3 Pa). 1,5-Hexadiene (**9**) 98%, 2-methyl-1,5-hexadiene (**10**) 99%, 2,5-dimethyl-1,5-hexadiene (**11**) 90% and 99%, and 5-methyl-3-hexen-2-one 80% were obtained from Aldrich Chemical Co.

Irradiations

Irradiations were generally carried out on solutions of acetonitrile–methanol (3:1) with 1,4-dicyanobenzene (**1**), the diene, and with or without a codonor/photosensitizer. Solutions were irradiated in either 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, which were degassed by nitrogen ebullition. These samples were irradiated at 10°C using a CGE 1-kW or an Hanovia 450-W medium-pressure mercury vapour lamp contained in a water-cooled quartz immersion well.

Cyclic voltammetric measurements

Cyclic voltammetry was used to obtain the oxidation potential of the dienes. The apparatus has been described (26). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (sce), which was connected to the solution (TEAP 0.1 M, acetonitrile) through a Luggin capillary. The dienes were purified by prep/gc using a 0.95 cm × 350 cm aluminum column packed with 40% SE-30 on Chromosorb W 60/80 NAW. The diene concentration was ca. 0.005 M. Since the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (10).

*Formation of 1,5-hexadiene (**9**) – 1,4-dicyanobenzene (**1**) cyclic adducts **13–16**: reaction [3]*

A solution of 1,5-hexadiene (**9**) (6.4 g, 0.078 mol) and 1,4-dicyanobenzene (**1**) (2.5 g, 0.020 mol) in acetonitrile–methanol (3:1, 270 mL) was degassed by nitrogen ebullition for 15 min and irradiated for 67 h. The solvent was removed by rotary evaporation to yield a dark brown photolysate (5.0 g). Methylene chloride was added to this mixture to precipitate unreacted **1**, which was then removed by suction filtration. Aliquots (0.3–0.5 g) of this mixture were chromatographed (mplc) using a linear solvent gradient (hexanes – 75% diethyl ether, 25% hexanes). The products eluted in the order **13**, **15**, **14**, and **16**.

The effect of added biphenyl on reaction [3]

A solution of 1,5-hexadiene (**9**) (0.4 g, 0.005 mol), 1,4-dicyanobenzene (**1**) (1.2 g, 0.010 mol), and biphenyl (**4**) (1.5 g, 0.0097 mol) in 160 mL of acetonitrile–methanol (3:1) was degassed by nitrogen ebullition for 15 min and irradiated for 123 h. The solvent was removed by rotary evaporation; 3.1 g (9% yield) of a mixture of **13–16** was obtained. Products were identified by comparison of retention times (gc/fid) with the products isolated from reaction [3]. No additional products were detected (gc/ms).

*Formation of the methanol, 2-methyl-1,5-hexadiene (**10**), 1,4-dicyanobenzene (**1**) photo-NOCAS adducts **17** and **18**: reaction [5]*

A solution of 2-methyl-1,5-hexadiene (**10**) (0.4 g, 0.004 mol) and 1,4-dicyanobenzene (**1**) (0.2 g, 0.001 mol) in acetonitrile–methanol (3:1, 40 ml) was degassed by nitrogen ebullition for 15 min and irradiated for 119 h. The solvent was removed by rotary evaporation to yield 0.4 g of a crude photolysate, which was separated by mplc using a linear solvent gradient (hexanes – 50% diethyl ether, 50% hexanes).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

Products were eluted in the order **17** (9 mg), then **18** (17 mg), followed by unreacted **1** (36 mg). Fractions rich in **18** were combined and rechromatographed (fc, column B) eluting with dichloromethane.

5-(4-Cyanophenyl)-6-methoxy-5-methyl-1-hexene (17)

The yield of **17** was 4%: the mass spectrum, fragmentation pattern, and retention time were identical to those for the compound obtained in greater yield when biphenyl (**4**) was present during the irradiation (see below).

1-(4-Cyanophenyl)-2-methoxymethyl-2-methyl-5-hexen-1-one (18)

The yield of **18** was 7%: infrared (PE-180) ν: 3084 (m), 2987 (s), 2932 (s), 2245 (s), 1687 (s), 1642 (m), 1606 (w), 1557 (w), 1477 (m), 1452 (m), 1417 (w), 1397 (m), 1386 (m), 1367 (w), 1277 (w), 1227 (m), 1202 (m), 1107 (w), 977 (m), 937 (m), 902 (m), 832 (m), 762 (w), 722 (w); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.29 (s, 3H, CH_3), 1.60 (m, 1H, H on methylene group), 1.95 (m, 3H, 3H of CH_2-CH_2), 3.29 (s, 3H, OCH_3), 3.37 (d, 1H, $^2J_{7a-7b}$ = 9.0 Hz, H on methoxy-substituted carbon (7a-H)), 3.55 (d, 1H, $^2J_{7a-7b}$ = 9.0 Hz, H on methoxy-substituted carbon (7b-H)), 4.96 (m, 1H, $^3J_{5-6cis}$ = 10.4 Hz, $^2J_{6cis-6trans}$ < 2.0 Hz, $^4J_{4-6cis}$ < 2.0 Hz, terminal vinyl H (6*cis*-H)), 5.00 (m, 1H, $^3J_{5-6trans}$ = 17.0 Hz, $^2J_{6cis-6trans}$ < 2.0 Hz, $^4J_{4-6trans}$ < 2.0 Hz, terminal vinyl H (6*trans*-H)), 5.73 (m, 1H, $^3J_{5-6trans}$ = 17.0 Hz, $^3J_{5-6cis}$ = 10.4 Hz, $^3J_{4-5}$ = 6.3 Hz, vinyl H (5-H)), 7.61 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to carbonyl-substituted aryl carbon (2′-H, 6′-H)), 7.69 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 20.19 (q, 128.0 Hz, CH_3), 28.43 (t, 124.1 Hz, CH_2 adjacent to allylic methylene), 35.00 (t, 126.0 Hz, allylic CH_2), 52.55 (s, quaternary carbon, methyl and aryl substituted), 59.14 (q, 141.2 Hz, OCH_3), 78.69 (t, 141.9 Hz, OCH_2), 113.79 (s, quaternary aryl carbon cyano substituted), 115.06 (t, 155.2 Hz, terminal vinyl CH_2), 118.15 (s, CN), 127.24 (dd, 166.4 Hz, 4.3 Hz, aromatic CH adjacent to carbonyl-substituted aryl carbon), 131.87 (d, 165.8 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 137.71 (d, 152.5 Hz, vinyl CH), 144.15 (s, quaternary aryl carbon carbonyl substituted), 208.10 (s, C=O); ms *m/z*: 55 (51), 67 (34), 68 (20), 81 (100), 85 (24), 95 (48), 102 (50), 130 (52), 171 (19), 203 (17), 229 (1) 257 (1). Formation of the methanol, 2,5-dimethyl-1,5-hexadiene (11): 1,4-dicyanobenzene (1) photo-NOCAS adducts 19 and 20, reaction [6]

A solution of 2,5-dimethyl-1,5-hexadiene (**11**) (0.8 g, 0.009 mol) and 1,4-dicyanobenzene (**1**) (0.5 g, 0.004 mol) in acetonitrile–methanol (3:1, 80 mL) was degassed by nitrogen ebullition for 15 min and irradiated for 115 h. The solvent was removed by rotary evaporation to yield 1.3 g of a photolysate that was separated by chromatography (mplc) using a linear solvent gradient (hexanes – 50% diethyl ether, 50% hexanes). Products were eluted in the order **19** and **20** followed by unreacted 1,4-dicyanobenzene (**1**).

5-(4-Cyanophenyl)-6-methoxy-2,5-dimethyl-1-hexane (19)

The yield of **19** was 8%: infrared (PE-180) ν: 3073 (w), 2973 (s), 2933 (s), 2883 (s), 2841 (m), 2241 (s), 1648 (m), 1608 (m), 1507 (m), 1451 (m), 1405 (w), 1386 (w), 1373 (m), 1305 (s), 1195 (m), 1173 (w), 1018 (w), 963 (w), 948 (w), 878 (m), 828 (m), 728 (w); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.37 (s, 3H, CH_3), 1.66 (s, 3H, CH_3), 1.62–1.89 (m, 4H, CH_2-CH_2), 3.29 (s, 3H, OCH_3), 3.38 (d, 1H, $^2J_{6a-6b}$ = 9.1 Hz, H on methoxy- substituted carbon (6a-H)), 3.49 (d, 1H, $^2J_{6a-6b}$ = 9.1 Hz, H on methoxy-substituted carbon (6b-H)), 4.60 (s, 1H, terminal vinyl H), 4.66 (s, 1H, terminal vinyl H), 7.44 (d, 2H, $^3J_{2'-3'}$ = 8.4 Hz, $^3J_{5'-6'}$ = 8.4 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.61 (d, 2H, $^3J_{2'-3'}$ = 8.4 Hz, $^3J_{5'-6'}$ = 8.4 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 22.49 (q, 126.2 Hz, CH_3), 22.60 (q, 126.2 Hz, CH_3), 31.97 (t, 123.3 Hz, CH_2), 37.14 (t, 127.1 Hz, CH_2), 42.76 (s, quaternary carbon, methyl and aryl substituted), 59.34 (q, 140.6 Hz, OCH_3), 81.23 (t, 141.2 Hz, OCH_2), 109.62 (t, 153.2 Hz, terminal vinyl CH_2), 109.72 (s, quaternary aryl carbon cyano substituted), 119.03 (s, CN), 127.37 (dd, 160.9 Hz, 5.4 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.89 (dd, 165.3 Hz, 5.4 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 145.70 (s, vinyl quaternary carbon), 151.67 (s, quaternary aryl carbon alkyl substituted); ms *m/z*: 55 (66), 69 (100), 102 (7), 116 (49), 129 (12), 130 (88), 142 (42), 143 (40), 174 (12), 175 (65), 188 (16), 198 (12), 243 (2). Anal. calcd. for $C_{16}H_{21}NO$: C 78.97, H 8.70, N 5.76; found: C 78.99, H 8.55, N 5.84.

1-(4-Cyanophenyl)-2-methoxymethyl-2,5-dimethyl-5-hexen-1-one (20)

The yield of **20** was 3%: infrared (PE-180) ν: 3075 (w), 2926 (s), 2235 (s), 1726 (m), 1688 (s), 1651 (m), 1606 (w), 1454 (m), 1398 (m), 1386 (m), 1376 (m), 1278 (m), 1236 (m), 1196 (m), 1176 (m), 1106 (s), 1018 (w), 976 (w), 941 (m), 876 (w), 836 (m), 761 (w); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.30 (s, 3H, CH_3), 1.68 (s, 3H, CH_3), 1.80–2.10 (m, 4H, CH_2-CH_2), 3.29 (s, 3H, OCH_3), 3.37 (d, 1H, $^2J_{7a-7b}$ = 9.0 Hz, H on methoxy-substituted carbon (7a-H)), 3.56 (d, 1H, $^2J_{7a-7b}$ = 9.0 Hz, H on methoxy-substituted carbon (7b-H)), 4.63 (s, 1H, terminal vinyl H), 4.70 (s, 1H, terminal vinyl H), 7.62 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to carbonyl-substituted aryl carbon (2′-H, 6′-H)), 7.69 (d, 2H, $^3J_{2'-3'}$ = 8.2 Hz, $^3J_{5'-6'}$ = 8.2 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 20.21 (q, 127.7 Hz, CH_3), 22.48 (q, 127.3 Hz, CH_3), 32.16 (t, 123.5 Hz, CH_2), 34.02 (t, 127.5 Hz, CH_2), 52.59 (s, quaternary carbon, methyl and aryl substituted), 59.15 (q, 141.2 Hz, OCH_3), 78.74 (t, 138.5 Hz, OCH_2), 110.28 (t, 152.7 Hz, terminal vinyl CH_2), 113.82 (s, quaternary aryl carbon cyano substituted), 118.16 (s, CN), 127.27 (dd, 165.6 Hz, 5.2 Hz, aromatic CH adjacent to carbonyl-substituted aryl carbon), 131.90 (dd, 166.4 Hz, 4.4 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 144.16 (s, quaternary carbon), 145.02 (s, quaternary carbon), 208.54 (s, C=O); ms *m/z*: 55 (93), 67 (84), 68

*The effect of added biphenyl (**4**) on reaction [7]*

A solution of 2,5-dimethyl-1,5-hexadiene (**11**) (1.8 g, 0.016 mol), 1,4-dicyanobenzene (**1**) (1.8 g, 0.014 mol), and biphenyl (**4**) (1.1 g, 0.0071 mol) in acetonitrile–methanol (3:1, 160 mL) was degassed by nitrogen ebullition for 15 min and irradiated for 88 h. The solvent was removed by rotary evaporation to yield 4.5 g of a photolysate that was separated by chromatography (mplc) using a linear solvent gradient (hexanes – 50% diethyl ether, 50% hexanes). Products were eluted in the order **26**, **25**, **19**, **21** *trans*, **21** *cis*, **27**, followed by unreacted **1**. Fractions rich in **21** *trans* were combined and rechromatographed (fc, column B) using dichloromethane as eluent. Fractions rich in **27** were combined and rechromatographed (fc, column A) using 40% diethyl ether – 60% hexanes as eluent.

*5-(4-Cyanophenyl)-6-methoxy-2,5-dimethyl-1-hexene (**19**)*

The yield of **19** was 13%: the mass spectrum and ^{1}H nmr spectrum were identical to the spectra of the compound described above (reaction [6]).

cis-*1-(4-Cyanophenyl)-4-methoxy-1,4-dimethylcyclohexane (**21** cis)*

The yield of **21** *cis* was 6%: ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.00 (s, 3H, equatorial CH_3 attached to a methoxy-substituted quaternary carbon), 1.14 (s, 3H, axial CH_3 attached to an aryl-substituted quaternary carbon), 1.70 (bd, 2H, $^2J_{3eq-3ax} = {}^2J_{5eq-5ax} = 13.7$ Hz, equatorial H's adjacent to CH_3, OCH_3-substituted carbon (3eq-H, 5eq-H)), 1.70–1.84 (m, 4H, axial H's adjacent to CH_3, OCH_3-substituted carbon and axial H's adjacent to CH_3, aryl-substituted carbon (2ax-H, 3ax-H, 5ax-H, 6ax-H)), 2.01 (bd, 2H, $^2J_{2eq-2ax} = {}^2J_{6eq-6ax} = 14.2$ Hz, equatorial H's adjacent to CH_3, aryl-substituted carbon (2eq-H, 6eq-H)), 3.20 (s, 3H, axial OCH_3 attached to methyl-substituted carbon), 7.48 (d, 2H, $^3J_{2'-3'} = 8.5$ Hz, $^3J_{5'-6'} = 8.5$ Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.62 (d, 2H, $^3J_{2'-3'} = 8.5$ Hz, $^3J_{5'-6'} = 8.5$ Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)).

*NOE experiment on **21** cis*

The high-frequency methyl signal (1.14 ppm) was irradiated and an increase in peak intensity of ca. 6% occurred in the cyclohexane hydrogen region, indicating an axial methyl group. The low-frequency methyl signal (1.00 ppm) was irradiated and no change was observed in the intensity of the peaks within the cyclohexane hydrogen region, indicating an equatorial methyl group.

*Shift reagent study used to assign chemical shifts to methyl groups of **21** cis*

Europium(III) tris-1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,5-octanedione ($Eu(fod)_3$) was used as the shift reagent. To 5 mg of *cis*-4-(4-cyanophenyl)-1-methoxy-1,4-dimethylcyclohexane (**21** *cis*) was added 4.5×10^{-6} mol of $Eu(fod)_3$ in five increments. With each addition a ^{1}H nmr spectrum was taken and the shift of each methyl group signal measured. A graph of the chemical shift of each methyl group as a function of $Eu(fod)_3$ concentration yielded slopes for the low (1.00 ppm) and high (1.14 ppm) frequency signals for the methyl groups in the ratio 1.6. The low-frequency signal was thus assigned to the methyl group attached to the methoxy-substituted carbon and the high-frequency signal to the methyl group on the aryl-substituted carbon.

Infrared (PE-180) ν: 3054 (w), 2939 (s), 2874 (m), 2826 (m), 2234 (s), 1604 (m), 1504 (m), 1462 (m), 1451 (m), 1394 (w), 1374 (m), 1304 (w), 1274 (m), 1197 (w), 1139 (m), 1114 (m), 1076 (s), 1039 (w), 1014 (w), 934 (m), 859 (m), 824 (m), 726 (w); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 24.05 (q, 125.6 Hz, CH_3), 24.05 (q, 125.6 Hz, CH_3), 32.24 (t, 125.8 Hz, two CH_2 groups), 32.32 (t, 125.8 Hz, two CH_2 groups), 38.60 (s, quaternary carbon, aryl methyl substituted), 48.54 (q, 141.3 Hz, OCH_3), 72.53 (s, methoxy, methyl-substituted quaternary carbon), 109.25 (s, quaternary carbon cyano substituted), 119.08 (s, CN), 127.00 (d, 165.0 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.20 (d, 171.0 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 153.54 (s, quaternary aryl carbon alkyl substituted); ms *m/z*: 55 (75), 72 (75), 77 (12), 85 (100), 86 (24), 115 (16), 116 (40), 128 (12), 130 (12), 142 (12), 143 (19), 196 (13), 212 (2), 228 (21), 243 (1). Anal. calcd. for $C_{16}H_{21}NO$: C 78.97, H 8.70, N 5.76; found: C 79.37, H 8.82, N 5.85.

trans-*1-(4-Cyanophenyl)-4-methoxy-1,4-dimethylcyclohexane (**21** trans)*

The yield of **21** *trans* was 3%: ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.18 (s, 3H, equatorial CH_3 attached to a methoxy-substituted quaternary carbon), 1.24 (s, 3H, equatorial CH_3 attached to an aryl-substituted quaternary carbon), 1.50–1.60 (m, 4H, axial and equatorial H's adjacent to CH_3, OCH_3-substituted carbon (3eq-H, 3ax-H, 5eq-H, 5ax-H)), 1.72 (bd, 2H, equatorial H's adjacent to CH_3, aryl-substituted carbon (2eq-H, 6eq-H)), 1.99 (m, 2H, axial H's adjacent to CH_3, aryl-substituted carbon (2ax-H, 6ax-H)), 3.15 (s, 3H, axial OCH_3 attached to methyl-substituted carbon), 7.49 (d, 2H, $^3J_{2'-3'} = 8.3$ Hz, $^3J_{5'-6'} = 8.3$ Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.60 (d, 2H, $^3J_{2'-3'} = 8.3$ Hz, $^3J_{5'-6'} = 8.3$ Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)).

*NOE experiments on **21** trans*

Both methyl group signals were individually irradiated and no increase of peak intensity was observed in the cyclohexane hydrogen region. This was taken as evidence that both methyl groups are equatorial.

Infrared (PE-180) ν: 2973 (s), 2943 (s), 2833 (m), 2241 (s), 1605 (m), 1504 (m), 1465 (m), 1433 (w), 1403 (w), 1373 (m), 1271 (m), 1218 (w), 1188 (w), 1128 (m), 1078 (s), 1013 (m), 953 (w), 843 (m), 828 (s); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 23.87 (q, 123.7 Hz, CH_3), 25.89 (q, 128.3 Hz, CH_3), 31.92 (t, 125.9 Hz, two CH_2 groups), 32.83 (t, 126.6 Hz, two CH_2 groups), 37.22 (s, quaternary carbon, aryl methyl substituted), 48.45 (q, 140.5 Hz, OCH_3), 72.41 (s, quaternary carbon, methoxy methyl substituted), 109.26 (s, quaternary carbon cyano substituted), 119.12 (s, CN), 126.30 (d, 159.6 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.99 (d, 159.5 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 156.62 (s, quaternary aryl carbon alkyl substituted); ms *m/z*: 55 (16), 72 (17), 77 (3), 85 (100), 86 (5), 115 (4), 116 (10), 128 (3), 130 (4), 142 (4), 143 (5), 196 (5), 212 (1), 228 (6), 243 (1). *3,5-Dimethoxy-4-phenylcyclohexanecarbonitrile (**27**)*

The melting point of **27** was 125.6–125.9°C: infrared (PE-180) ν: 2987 (m), 2957 (s), 2930 (s), 2884 (s), 2832 (m), 2242 (s), 1606 (w), 1497 (m), 1454 (m), 1442 (m), 1384 (w), 1372 (m), 1310 (w), 1192 (m), 1107 (s), 1077 (s), 1037 (m), 958 (w), 852 (w), 767 (m), 727 (w), 697 (s); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.75 (ddd, 2H, $^2J_{2ax-2eq} = 13.9$ Hz, $^3J_{1-2ax} = 12.7$ Hz, $^3J_{2ax-3} = 2.5$ Hz, axial H's on methylene groups (2ax-H)), 2.49 (ddd, 2H, $^2J_{2ax-2eq} = 13.9$ Hz, $^3J_{1-2eq} = 3.1$ Hz, $^3J_{2eq-3} = 2.0$ Hz, equatorial H's on methylene groups (2eq-H)), 2.68 (t, 1H, $^3J_{3-4} = 3.2$ Hz, benzyl H (4-H)), 3.25 (m, 1H, $^3J_{1-2ax} = 12.7$ Hz, $^3J_{1-2eq} = 3.1$ Hz, H on cyano-substituted methylene (1-H)), 3.26 (s, 6H, OCH_3), 3.67 (ddd, 2H, $^3J_{3-4} = 3.2$ Hz, $^3J_{2ax-3} = 2.5$ Hz, $^3J_{2eq-3} = 2.0$ Hz, H's on methoxy substituted methylene (3-H)), 7.23–7.51 (m, 5H, aryl H's); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 18.52 (d, 140.8 Hz, CH), 32.37 (t, 129.7 Hz, two CH_2 groups), 49.28 (d, 118.2 Hz, CH), 58.18 (q, 140.9 Hz, OCH_3), 77.99 (d, OCH), 122.96 (s, CN), 126.72 (d, 159.8 Hz, aryl CH), 128.03 (d, 159.7 Hz, aryl CH), 129.27 (d, 158.9 Hz, aryl CH), 140.42 (s, quaternary aryl carbon); ms *m/z*: 51 (3), 55 (3), 58 (6), 65 (5), 75 (3), 77 (4), 88 (3), 91 (19), 96 (21), 101 (3), 115 (22), 116 (3), 117 (21), 127 (3), 128 (5), 155 (100), 156 (11), 177 (7), 213 (7), 245 (3), 246 (1). X-Ray data: Appendix.[6]

*2,5-Dimethyl-1,4-hexadiene (**12**)*

5-Methyl-4-hexen-2-one was prepared by the photochemically

induced tautomerization of 5-methyl-3-hexen-2-one (*7a*). The Wittig reaction was carried out using the standard procedure (*7b*). Sodium (0.8 g, 0.04 mol) was placed in a three- necked round-bottom flask equipped with a Dry Ice condenser protected with a calcium chloride drying tube. A gas inlet tube was connected to an ammonia tank and ammonia was introduced, as a gas, until ca. 100 mL was condensed. A small portion of ferric nitrate was added. The mixture was stirred and after 15 min the colour turned from blue to dark gray. Methyltriphenylphosphonium bromide (10 g, 0.028 mol) was then added using a powder addition funnel and the reaction was stirred for 30 min. 5-Methyl-4-hexen-2-one (3.1 g, 0.028 mol) was added in decahydronaphthalene (100 mL, distilled under reduced pressure and stored over molecular sieves (4 Å)). The ammonia was allowed to evaporate and the Dry Ice condenser was replaced by a water-cooled condenser and a drying tube. The reaction mixture was allowed to stir overnight and was then washed with water until the aqueous layer was no longer basic. The organic layer was distilled under atmospheric pressure; fractions boiling between 142 and 189°C contained the desired diene. Pure 2,5-dimethyl-1,4-hexadiene was obtained by prep/gc (40% SE-30). The ^{1}H nmr spectrum was identical to that reported (*7c*). ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.62 (s, 3H, CH_3), 1.71 (s, 3H, CH_3), 1.73 (s, 3H, CH_3), 2.68 (d, 2H, $^3J_{3-4}$ = 7.6 Hz, CH_2 (3-H)), 4.68 (br s, 2H, $^2J_{1-1'}$ = 1.1 Hz, terminal vinyl methylene (1-H, 1′-H)), 5.18 (m, 1H, $^3J_{3-4}$ = 7.6 Hz, vinyl CH (4-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 17.62 (q, 133.9 Hz, CH_3), 22.55 (q, 125.0 Hz, CH_3), 25.77 (q, 126.2 Hz, CH_3), 36.53 (t, 126.8 Hz, CH_2), 109.62 (t, 154.8 Hz, terminal vinyl CH_2), 121.84 (d, 153.0 Hz, vinyl CH), 132.88 (s, quaternary carbon bearing two methyl groups), 145.44 (s, quaternary carbon monomethylated); ms *m/z*: 53 (24), 55 (43), 67 (92), 95 (100), 110 (30), 111 (3).

*Formation of the methanol, 2,5-dimethyl-1,4-hexadiene (**12**), 1,4-dicyanobenzene (**1**) photo-NOCAS adducts **22** and **23**: reaction [8]*

A solution of 2,5-dimethyl-1,4-hexadiene (**12**) (0.5 g, 0.004 mol), 1,4-dicyanobenzene (**1**) (0.6 g, 0.005 mol), and biphenyl (**4**) (1.5 g, 0.010 mol) in acetonitrile–methanol (3:1, 80 mL) was degassed by nitrogen ebullition for 15 min and irradiated for 26 h. The solvent was removed, on a rotary evaporator, and the crude photolysate was separated by chromatography (mplc) using a linear solvent gradient (hexanes – 50% diethyl ether, 50% hexanes). Products were eluted in the order **22**, then **23**, followed by unreacted **1**. Fractions rich in **23** were combined and rechromatographed (dc/fc) eluting with dichloromethane.

*5-(4-Cyanophenyl)-4-methoxy-2,5-dimethyl-1-hexene (**22**)*

The yield of **22** was 16%: the melting point was 42.1–42.8°C; infrared (PE-180) ν: 3072 (w), 2970 (s), 2930 (s), 2825 (m), 2128 (s), 1644 (w), 1602 (m), 1500 (m), 1440 (m), 1400 (m), 1380 (m), 1360 (m), 1171 (m), 1090 (s), 1050 (m), 1010 (m), 971 (m), 820 (m); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.34 (s, 3H, CH_3), 1.36 (s, 3H, CH_3), 1.71 (s, 3H, CH_3), 1.91 (d, 2H, $^3J_{3-4}$ = 5.9 Hz, CH_2 (3-H)), 3.27 (s, 3H, OCH_3), 3.32 (t, 1H, $^3J_{3-4}$ = 5.9 Hz, CH (4-H)), 4.71 (br s, 1H, terminal vinyl H), 4.74 (br s, 1H, terminal vinyl H), 7.52 (d, 2H, $^3J_{2'-3'}$ = 8.6 Hz, $^3J_{5'-6'}$ = 8.6 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.60 (d, 2H, $^3J_{2'-3'}$ = 8.6 Hz, $^3J_{5'-6'}$ = 8.6 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 22.67 (q, 122.1 Hz, CH_3), 23.89 (q, 120.0 Hz, CH_3), 25.16 (q, 122.3 Hz, CH_3), 40.11 (t, 125.7 Hz, CH_2), 43.74 (s, quaternary carbon aryl substituted), 61.14 (q, 141.1 Hz, OCH_3), 87.98 (d, 139.9 Hz, OCH), 109.60 (s, quaternary aryl carbon, cyano substituted), 112.78 (t, 154.1 Hz, terminal vinyl CH_2), 119.05 (s, CN), 127.47 (d, 160.2 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.66 (d, 165.3 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 143.19 (s, quaternary aryl carbon, alkyl substituted), 153.26 (s, vinyl quaternary carbon); ms *m/z*: 55 (6), 57 (4), 67 (25), 69 (16), 71 (6), 99 (100), 100 (6), 116 (16), 129 (8), 130 (7), 156 (13), 188 (24), 243 (1). Anal. calcd. for $C_{16}H_{21}NO$: C 78.97, H 8.70, N 5.76; found: C 78.90, H 8.84, N 5.72.

*4-(4-Cyanophenyl)-5-methoxy-2,5-dimethyl-1-hexene (**23**)*

The yield of **23** was 9%: the melting point was 62.9–63.9°C; infrared (PE-180) ν: 3181 (w), 3081 (m), 3036 (m), 2829 (m), 2229 (s), 1831 (w), 1801 (w), 1646 (m), 1606 (s), 1506 (s), 1461 (s), 1418 (s), 1382 (s), 1374 (s), 1365 (s), 1306 (w), 1276 (m), 1236 (s), 1181 (s), 1140 (s), 1066 (s), 1019 (m), 939 (w), 884 (s), 854 (s), 826 (s), 787 (m), 753 (m), 716 (w); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ_{TMS}: 1.05 (s, 3H, CH_3), 1.12 (s, 3H, CH_3), 1.56 (s, 3H, CH_3), 2.50 (dd, 1H, $^3J_{3a-3b}$ = 14.5 Hz, $^3J_{3a-4}$ = 12.0 Hz, H on methylene group (3a-H)), 2.64 (br d, 1H, $^3J_{3a-3b}$ = 14.5 Hz, $^3J_{3b-4}$ = 3.2 Hz, H on methylene group (3b-H)), 2.95 (dd, 1H, $^3J_{3a-4}$ = 12.0 Hz, $^3J_{3b-4}$ = 3.2 Hz, H on aryl-substituted carbon (4-H)), 3.22 (s, 3H, OCH_3), 4.44 (br s, 1H, terminal vinyl H), 4.55 (br s, 1H, terminal vinyl H), 7.33 (d, 2H, $^3J_{2'-3'}$ = 8.3 Hz, $^3J_{5'-6'}$ = 8.3 Hz, H's adjacent to alkyl substituted aryl carbon (2′-H, 6′-H)), 7.54, (d, 2H, $^3J_{2'-3'}$ = 8.3 Hz, $^3J_{5'-6'}$ = 8.3 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (90.80 MHz, $CDCl_3$) δ: 22.37 (q, 123.9 Hz, CH_3), 22.83 (q, 126.5 Hz, CH_3), 23.52 (q, 125.5 Hz, CH_3), 37.30 (t, 126.6 Hz, CH_2), 49.22 (q, 140.5 Hz, OCH_3), 53.38 (d, 125.5 Hz, CH, aryl substituted), 76.44 (s, quaternary carbon, methoxy substituted), 109.99 (s, quaternary aryl carbon, cyano substituted), 112.43 (t, 153.7 Hz, terminal vinyl CH_2), 119.13 (s, CN), 130.56 (d, 162.8 Hz, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.35 (d, 160.8 Hz, aromatic CH adjacent to cyano-substituted aryl carbon), 143.29 (s, quaternary aryl carbon, alkyl substituted), 147.51 (s, vinyl quaternary carbon); ^{13}C nmr (90.80 MHz, $(CD_3)_2CO$) δ: 22.24 (q), 22.94 (q), 23.51 (q), 37.75 (t), 49.11 (q, OCH_3), 53.65 (d), 76.96 (s, quaternary carbon, methoxy substituted), 110.58 (s, quaternary aryl carbon, cyano substituted), 112.47 (t, terminal vinyl CH_2), 119.50 (s, CN), 131.72 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.76 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 144.49 (s, quaternary aryl carbon, alkyl substituted), 148.74 (s, vinyl quaternary carbon); ms *m/z*: 53 (5), 55 (12), 73 (100), 74 (16), 89 (6), 103 (10), 115 (12), 116 (23), 127 (10), 128 (12), 129 (12), 130 (16), 140 (12), 154 (12), 156 (19), 196 (12), 211 (1), 243 (1). Chemistry of the shellfish toxin domoic acid: characterization of related compounds[1]

JOHN A. WALTER, MICHAEL FALK, AND JEFFREY L.C. WRIGHT[2]

Institute for Marine Biosciences, National Research Council of Canada, 1411 Oxford Street, Halifax, NS B3H 3Z1 Canada

Received September 28, 1993

JOHN A. WALTER, MICHAEL FALK, and JEFFREY L.C. WRIGHT. Can. J. Chem. **72**, 430 (1994).

Five new compounds related to the neurotoxin domoic acid have been characterized by spectroscopic methods. They include a diastereoisomer that occurs naturally with domoic acid in mussels and four hydrogenation products. The stereochemistry of the two epimeric tetrahydro derivatives could not be assigned on the basis of the NMR data alone because of high conformational flexibility. However, a clear-cut assignment was possible by molecular modelling in combination with the NMR data.

JOHN A. WALTER, MICHAEL FALK et JEFFREY L.C. WRIGHT. Can. J. Chem. **72**, 430 (1994).

Faisant appel à des méthodes spectroscopiques, on a caractérisé cinq nouveaux composés reliés à l'acide domoïque, une neurotoxine. Ils comprennent un diastéréoisomère que l'on retrouve naturellement avec l'acide domoïque présent dans les moules ainsi que quatre produits d'hydrogénation. À cause de la grande flexibilité conformationnelle, on n'a pas pu attribuer la stéréochimie des deux dérivés tétrahydrogénés épimères en faisant uniquement appel aux des données de la RMN. Toutefois, il a été possible de faire une attribution sans ambiguïté en faisant appel aux modèles moléculaires en combinaison avec les données de la RMN.

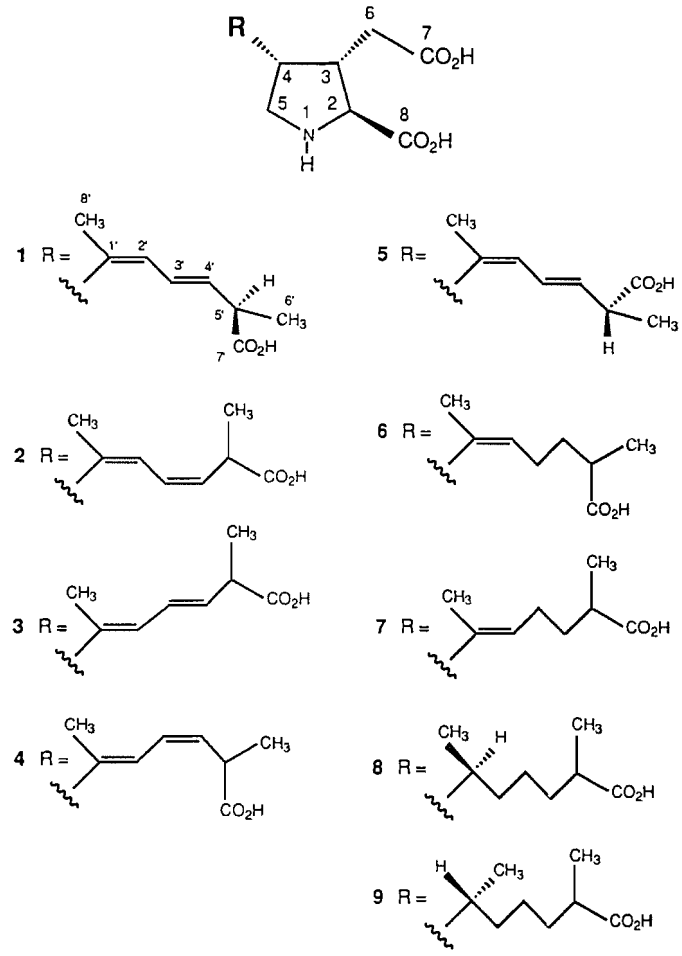
Introduction

The discovery of domoic acid **1** as a new shellfish toxin (1) has stimulated studies of its pharmacology and toxicology (2–9). It is the most potent member of a group of amino acid analogues called excitotoxins, which bind to specific membrane-bound kainate receptors and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors found in certain neuronal cells of the brain (8). Recently we reported a study of the binding of nine compounds (**1–9**) related to domoic acid, to kainate receptors, and to AMPA receptors in rat forebrain membranes (8). Four of these compounds, domoic acid **1** and its three geometrical isomers **2–4**, which were isolated from contaminated shellfish tissue and from the producing microalga *Nitzschia pungens* forma *multiseries*, have been characterized previously (1, 10). We now provide details of the preparation and characterization of the remaining five compounds used in the binding study, including a naturally occurring C5′ diastereoisomer **5** of domoic acid isolated from mussel tissue.

The assignment of the stereochemistry of the two tetrahydro derivatives **8** and **9** required molecular modelling. Modelling indicated that each epimer occurs in several stable conformations, which differ as to ring pucker and orientation of side chains. Nevertheless, a clear-cut distinction between the two epimers was possible upon comparing the conformationally averaged interproton distances, derived from molecular modelling, with the difference–NOE results. The distinction was further confirmed by a comparison of experimental and calculated interproton coupling constants. We report our modelling procedure in detail, because of its general applicability to conformationally flexible molecules.



Results and discussion

C5′ epimer of domoic acid

HPLC–DAD analysis of toxic mussel extracts containing domoic acid indicated the presence of other compounds having similar UV spectra. The most abundant of these were isolated and identified as the geometrical isomers **2–4**, which are more readily obtained by UV irradiation of domoic acid (10). Repeated HPLC yielded another related compound with a retention time very close to domoic acid (relative retention time (rrt) 1.07), identical UV and IR spectra, and virtually identical ^1H and ^{13}C spectra (Tables 1 and 2), but a different optical rotation ($[\alpha]_D^{25}$ −48.8). Our identification of this compound as the C5′ epimer **5** was aided by obtaining ^1H and ^{13}C spectra of a ca. 3:2 mixture (at pH 3.4) of **1** and **5**, respectively, which permitted

[a]Solvent, D_2O; reference TSP in concentric tube; temperature = 20°C; s, singlet; d, doublet; q, quartet; m, multiplet; b, broad. Data previously reported (1, 5) for domoic acid are included for comparison. Most spectra were obtained with a Bruker MSL-300 spectrometer at 300.13 MHz (^{1}H) and 75.5 MHz (^{13}C). HMQC and HMBC spectra used for assignment of ^{13}C spectra of **6–9** were recorded with a Bruker AMX-500 spectrometer at 500.13 MHz.

[b]Overlapping resonances, geminal coupling not measureable.

chemical shift differences between the two compounds to be measured with high precision. All ^{1}H chemical shifts and coupling constants of **5** and **1** agreed within error (ca. 0.3 Hz at 300 MHz), except for δ(H) of H4′ which in **5** was shifted to lower field by 0.017 ppm. Similarly, all ^{13}C chemical shifts were identical within <0.01 ppm except for very slight upfield shifts of the C2′ (0.02 ppm), C3′ (0.10 ppm), C4′ (0.08 ppm), C5′ (0.14 ppm), and C6′ (0.09 ppm) resonances of **5**. The ^{1}H NOEs (Table 3) of **5** were larger than those previously obtained for **1**, and some additional small NOEs were attributed to improvements in sample preparation and better elimination of paramagnetic impurities. The NOEs observed (Table 3) were all compatible with structures **1** and **5**, but would not have been consistent with changes in stereochemistry at any position other than C5′. The combined evidence, in particular the small chemical shift deviations that are greatest in the vicinity of the 5′ position, is only consistent with **5** being the 5′ epimer of **1**. This compound is present in trace amounts in mussel tissue, but was more conveniently obtained from domoic acid by epimerization following treatment with sodium methoxide. It is noteworthy that similar treatment of the geometrical isomer **4** yielded a compound presumed to be the corresponding C5′ diastereoisomer (HPLC resolved a component with very similar retention time to that of **4**).

Dihydro derivatives of domoic acid

Partial reduction of domoic acid with hydrogen in the presence of 10% Pd–charcoal yielded two major reduction products separable by reversed-phase chromatography. The FABMS data indicated that these compounds were both dihydro derivatives, and they were readily shown by ^{1}H NMR spectroscopy (Tables 1 and 2) to be the 1′,2′ *Z* (rrt 1.57) and 1′,2′ *E* (rrt 1.20) compounds **6** and **7**, respectively. Spin–spin coupling connectivity throughout each structure was analyzed from COSY spectra, leading to the ^{1}H assignments in Table 1. Coupling constants (Table 2) indicated negligible changes in average ring conformation. In each case, the position of the double bond in the major side chain was established by the observation of a small coupling between an olefinic methyl group and a single olefinic proton. The NOE results (Table 3) confirmed the double bond position and verified the double bond configuration in each derivative. In addition, the NOE data revealed the signifi-

[a]Error is ca. ±0.3 Hz unless stated. pH was as for ^{1}H data in Table 1. Coupling connectivity was confirmed by ^{1}H COSY spectra. Some couplings were determined by simulation using Bruker PANIC program. Geminal couplings were assumed negative; signs of other couplings were not determined and are given as magnitudes only.

[b]Overlapping resonances, geminal coupling not measureable.

cant effect of the geometry of the side-chain double bond on the preferred conformations of **6** and **7**. For example, the H_38' protons of the *Z* isomer **6** show NOE to H5α and H6b, suggesting a preferred orientation of the large side chain in which the H_38' methyl group tends to lie between these protons, with less tendency to rotate to the vicinity of H3, H4, or H5β. This observation is further supported by the occurrence of NOEs between H4 and H_23', and between H3 and H3′a. Interestingly, a similar pattern of NOEs involving H_38' is observed in **1** and **2** (10), which also possess a 1′,2′ *Z* configuration. By contrast, the corresponding pattern of NOEs to H_38' in the *E* isomer **7** to H2, H4, H6a, and H6b is indicative of a different preferred orientation in which the H_38' group tends to lie in the vicinity of H4, resembling **3** and **4** (10). The NOE between H2′ and H5α is also consistent with this orientation.

These results suggest that the preferred orientation of the larger side chain is strongly influenced by the configuration of the double bond. Furthermore, the orientation of the side chain also has a profound effect on the biological activity: the *Z* isomer **6**, in which the preferred conformers most strongly resemble those of the parent compound domoic acid **1**, has essentially equivalent potency compared with the natural toxin (8). In contrast, the binding efficiency of the *E* isomer **7** is diminished by three orders of magnitude (8).

Tetrahydro derivatives of domoic acid

Reduction of domoic acid with hydrogen in the presence of PtO_2 has been reported to yield a tetrahydro derivative (11), although details were incomplete and no reference was made to either of the possible C1′ diastereoisomers **8** and **9**. We were able to separate two products following PtO_2 reduction, the UV spectrum (end-absorbance only) and FAB mass spectrum (*m/z*: MH^+ 316), indicating complete reduction in each case. Later, both compounds were obtained also by Pd–charcoal reduction. Once again, confirmation of the structures **8** and **9** was based on NMR spectroscopy. The ^{1}H and ^{13}C NMR spectra (Tables 1 and 2) of these compounds were very similar and devoid of olefinic resonances. The differences in the spectral data for these compounds compared with **1** were readily accounted for by reduction only of the two side-chain double bonds without epimerization at the chiral centres in the ring. The difference in the J(2,3) coupling constant compared with **1** (Table 2) suggests a twisting of the ring so that the average H2C2C3H3 angle approaches 90°. NOE results (Table 3) indicated that the compounds differed in their C1′ stereochemistry; **8** showed NOEs between H5β and H_38' and between H4 and H_38', whereas **9** showed NOEs between H_38' and H3, H4, and H6a. Because of the high conformational flexibility of these molecules, the assignment of the C1′ stereochemistry was not possible on the basis of the NMR data alone. Molecular modelling using SYBYL and comparison with the NOE and spin–spin coupling results was necessary in order to assign **8** and **9**, respectively, to the 1′ *S* and 1′ *R* isomers of tetrahydrodomoic acid, as well as for the derivation of their preferred conformations, as follows.

Conformational search (see Experimental) yielded four conformers of **R** and five conformers of **S** with energies within 3 kcal/mol of that of the lowest-energy conformer. These low-energy conformers are listed in Table 4; the lowest energy conformers are shown in Fig. 1. In deriving the average distances and angles, we assumed that the fractional populations of conformers are determined by their Boltzmann factors, which neglects entropy differences.

The pyrrolidine ring in the low-energy conformers of **R** and **S** is in the 3-*exo* and 5-*exo* envelope forms (Table 4). (The number in the designation of these forms refers to the out-of-plane atom; *endo* and *exo* refer to that atom being on the same side as the C-2 carboxylate, or on the other side.) Our results indicate that about 90% of **R** and **S** molecules in solution has the 3-*exo* ring pucker. In this behaviour, **R** and **S** both differ from domoic acid, which according to our recent work appears to be largely in the 5-*exo* form. This explains the major differences in the measured values of the coupling constants for ring protons, notably J(2,3) and J(3,4) (Table 2).

The low-energy conformers of **R** and **S** include all three pos-

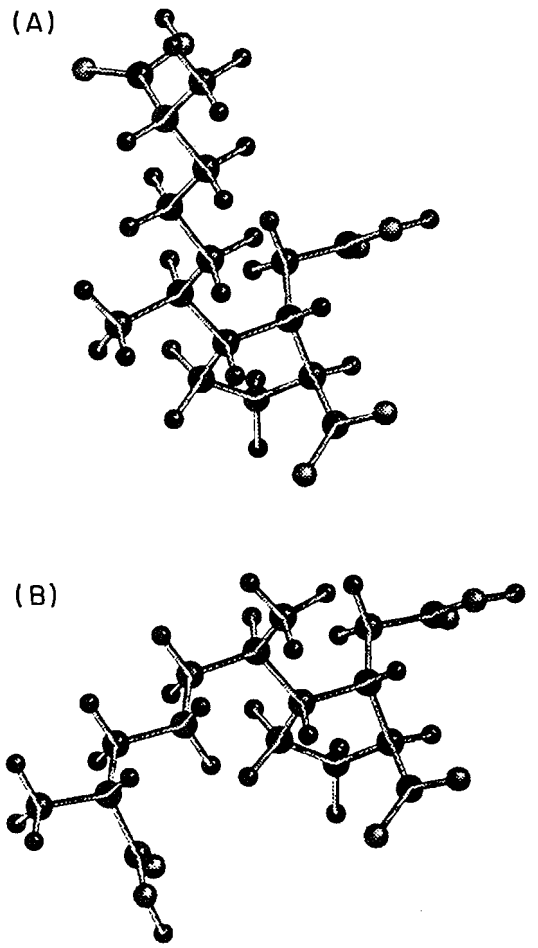

FIG. 1. The dominant conformers of tetrahydro domoic acid epimers **S** and **R** from SYBYL modelling. (A): **S** = **8**, conformer 1, energy = 12.8897 kcal/mol, population 63.23%. (B): **R** = **9**, conformer 1, energy = 13.5981 kcal/mol, population 60.15%.

ference in the conformational behaviour of these two epimers, permitting an unequivocal distinction on the basis of NMR spectral data.

Comparison of calculated H–H distances with NOE data

The interproton distances were determined for each conformer and the mean distance was obtained as a population-weighted average over all conformers, weighting the distances by inverse sixth power (12). The distances involving the three methyl hydrogens required further averaging in the same fashion. Table 5 compares the interproton distance obtained from modelling with NOE data adapted from Table 3. For each proton pair, the presence of an NOE in one epimer and not in the other was taken to indicate a shorter H–H distance. Under this condition, the comparison implies that **8** must be **S** and **9** must be **R**.

Comparison of experimental and calculated H,H couplings

Each HCCH dihedral angle, χ_i, involving vicinal ring protons was determined for every conformer i. From each of these dihedrals, the vicinal coupling constant J_i (Hz) was calculated by the Karplus-type equation $J_i = 8.5 \cos^2\chi_i + 1.4$ (for $0 \leq \chi_i \leq 90$) or $J_i = 10.5 \cos^2\chi_i + 1.4$ (for $90 \leq \chi_i \leq 180$), as recommended by Pogliani et al. (13). The mean coupling constant was obtained as the population-weighted average. The calculated coupling constants are compared with the experimental values in Table 6. The absolute values are not expected to fit well, considering the uncertainty of the numerical parameters in the Karplus equation. However, the relative values show clear trends consistent with the conclusions from NOEs. Any small modification of the constants in the Karplus equation would not affect these trends. Therefore, relative magnitudes of the experimental and calculated coupling constants confirm that **8** is **S** and **9** is **R**.

Conclusion

The potency of the few naturally occurring kainate (or domoate) neurotoxins has been investigated (14, 15). These neurotoxins are all characterized by a structural moiety that resembles glutamic acid and they can be considered as conformationally restricted forms of this amino acid. Furthermore, it has been shown that neurological activity in the kainoids requires that the stereochemistry of the C2 and C3 positions, bearing respectively carboxyl and carboxymethyl groups, be *S* (14, 15). Our binding studies (8) with the domoic acid derivatives discussed in this report have demonstrated the important influence of the major side chain, and specifically the essential requirement of a 1′,2′ double bond in the *Z* configuration, for strong binding to kainate and AMPA receptors.

The study of neurological processes using chemical probes

requires careful stereochemical and conformational definition of these probes. This study and our previous work (10) defines the stereochemical parameters for all the probes used in a recent study of binding efficacy to kainate and AMPA receptors present in certain neuronal cells. In addition, the modelling studies not only define the stereochemistry of the two C1′ epimers, but also reveal major differences in their solution conformation. These data will be valuable in future ligand–receptor binding studies with the purified receptor protein.

Experimental

All solvents were HPLC grade from Anachemia. Distilled water was further purified by passage through a Millipore water-purification system (Milli-QR) equipped with ion-exchange and carbon filters. Melting points are uncorrected and were observed with a Kofler-type hot-stage apparatus. Optical rotations and all IR, UV, NMR, and MS were, unless otherwise stated in the text or tables, recorded with instruments and conditions described previously (1). In HPLC experiments, the retention times of products were measured relative to domoic acid. NMR spectra were assigned and spin–spin coupling constants were measured with the aid of 2D COSY and $^{13}C,^{1}H$ heterocorrelation spectra and simulations using the Bruker PANIC program. ^{1}H and ^{13}C data for compounds **1** and **5–9** are reported in Table 1, with some previously reported data being included for convenience.

Isolation of domoic acid C5′ epimer

Large-scale purification of domoic acid from frozen, cooked mussel tissue (5 kg), following procedures already described (1, 5), yielded a fraction that, by HPLC–DAD analysis, contained mainly domoic acid **1** (>85%), three geometrical isomers **2–4**, and another compound **5** subsequently identified as the C5′ epimer of **1**. The latter had a fractionally longer retention time (rrt 1.07) than domoic acid. The epimer was collected from repeated small-scale semipreparative reversed-phase HPLC runs (Vydac 201 TP1010, 10 μm, isocratic elution 5% acetonitrile–water containing 0.1% TFA, flow rate 2.8 mL/min); $[\alpha]_D^{24}$ −48.8 (*c* 0.18, H_2O); $\lambda_{max}(H_2O)$: 242 nm.

Conversion of domoic acid to C5′ epimer

Domoic acid (31 mg) was dissolved in dry methanol (40 mL) containing sodium methoxide (0.77 g) and the mixture was warmed (68°C) under nitrogen for 75 h. The mixture was neutralized with HCl (1 N) and evaporated to dryness. Analysis of the mixture at this stage showed approximately equimolar amounts of domoic acid and **5**. The diastereoisomer was purified by gradient reversed-phase vacuum chromatography using acetonitrile–water with 0.1% acetic acid, followed by semipreparative HPLC (Vydac 201 TP1010, 5% acetonitrile – water with 0.05% TFA), and was identical (rrt, UV, IR, NMR, and MS) with the material isolated from toxic mussel tissue.

Preparation of Z- and E-dihydrodomoic acids

Domoic acid (50 mg) was dissolved in water–MeOH (1:1, 30 mL) containing 10% Pd–charcoal (20 mg, Matheson Coleman and Bell, Canada) and stirred (40–60 min) in an atmosphere of hydrogen. HPLC analysis (Vydac 201 TP1010) of the mixture revealed almost complete consumption of the starting material and the appearance of two new

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

major compounds shown later to be *Z*- and *E*-dihydrodomoic acids **6** and **7** (rrt 1.57 and 1.20, respectively). The catalyst was removed by filtration, the solvent was concentrated to dryness, and the products were isolated by semipreparative HPLC (conditions as above, 15% acetonitrile as eluant). Following many repeated HPLC runs, the faster-eluting product (12.7 mg) was obtained as a white powder and identified as **7**: $[\alpha]_D^{24}$ −19.8; FABMS *m/z*: MH^+ 314; IR (KBr): 2980 (br), 1713, 1676, 1200, 840, 800 cm^{-1}; ^1H and ^{13}C NMR, see Table 1. The slower-eluting product (4.16 mg) was obtained as a white solid and identified as **6**: $[\alpha]_D^{24}$ −71.6; FABMS *m/z*: MH^+ 314; IR (KBr): 2984 (br), 1712 (br), 1217, 825 (br) cm^{-1}; ^1H and ^{13}C NMR, see Table 1. Traces of the tetrahydro derivatives and some other minor products were observed, but no attempt was made to isolate them in this experiment.

Preparation of the C1′ diastereoisomers of tetrahydrodomoic acid

Domoic acid (30 mg) was dissolved in water (5 mL) containing PtO_2 (hydrate, 4.3 mg, Aldrich, U.S.A.) and stirred in an atmosphere of hydrogen. HPLC analysis of the reaction after 1 h indicated a less complex mixture than that obtained in the dihydro preparation, with complete reduction of domoic acid to compounds subsequently determined to be the tetrahydro C1′ diastereoisomers **8** and **9**. Removal of the catalyst and concentration to dryness gave a white solid from which the diastereomers were separated by semipreparative HPLC. The faster-eluting product (rrt 1.63, 9.6 mg) was obtained as a white solid and identified as **8**, the 1′ *S* tetrahydro derivative: FABMS *m/z*: MH^+ 316; IR (KBr): 2970 (br), 1708, 1414, 1224 cm^{-1}; ^1H and ^{13}C NMR, see Table 1. The slower-eluting product (rrt 2.35, 18.6 mg) was also obtained as a white solid and identified as **9**, the 1′ *R* tetrahydro derivative: FABMS *m/z*: MH^+ 316; IR (KBr): 2938 (br), 1718, 1415, 1224 cm^{-1}; ^1H and ^{13}C NMR, see Table 1.

Molecular modelling

Molecular modelling was carried out on a Personal Iris 4D/35 TurboGraphic workstation (Silicon Graphics, Inc., Mountain View, Calif.) using SYBYL molecular modelling software (Version 6.0, Tripos Associates, St. Louis, Mo.). SYBYL representations of the two tetrahydro isomers were derived from the crystallographic structure of domoic acid (16) by changing the two carbon–carbon double bonds to single bonds, adding four hydrogens, and minimization. The two isomeric structures thus generated, named **R** and **S** (corresponding to the chirality at C1′), were verified to have the following chirality:

	C2	C3	C4	C1′	C5′
R	*S*	*S*	*R*	*R*	*R*
S	*S*	*S*	*R*	*S*	*R*

It may be noted that the chirality at C4 is *S* for both domoic acid (16) and kainic acid (17), but it formally changes to *R* in the tetrahydrodomoic acids, because reduction of the C1′=C2′ bond switches the priorities of carbons C1′ and C3. The two structures were modelled as zwitterions, with a positively charged N atom, a negatively charged C8 carboxylate, and uncharged C7 and C7′ carboxyls. This state of zero net charge is appropriate to domoic acid and its analogues at pH ≈ 3, near their isoelectric point (18), at which the NMR data were collected. The minimizations and molecular dynamics simulations reported here were carried out with the TRIPOS force field (19), but analogous results were obtained under the MM2 force field (20). The electrostatic term was computed with atomic partial charges calculated according to the method of Gasteiger and Marsili (21, 22). The influence of aqueous environment was modelled by a dielectric continuum with the dielectric constant set at $\epsilon = 80$ (23).

Conformational search

Conformation space of **R** and **S** was searched by means of a molecular dynamics simulation with step size of 1 fs (23). Each epimer was subjected to a total sojourn of 50 000 fs at the effective temperature of 1500 K, this temperature–time combination having been found sufficient to ensure rapid and thorough exploration of the available conformation space. The instantaneous molecular geometry was recorded every 2000 fs until 250 geometries were collected. To save computer time, no annealing was attempted. The 250 molecular geometries were minimized and all distinct conformations with energies within 3 kcal/mol of the minimum were retained. The threshold of distinctness was 0.1 Å RMS deviation of nonhydrogen-atom distances, the lowest-energy representative of each conformation being retained.

ERWIN BUNCEL, ANURAG KUMAR, HAI-QI XIE, ROBERT Y. MOIR, and J. GARFIELD PURDON. Can. J. Chem. **72**, 437 (1994).

The reactions of β-phenylmercaptoethyl *p*-nitrophenolate (**1**) with three potassium oximates, viz. potassium 2,3-butanedione monoximate (BDOK), acetophenone oximate (APOK), and acetone oximate (AOK) have been investigated in two nonhydroxylic dipolar aprotic solvents, tetraglyme and dimethyl sulfoxide (DMSO). The reaction products, as determined by ^{1}H NMR spectroscopy, were *p*-nitrophenoxide ion and phenyl vinyl sulfide, in accord with an elimination process. A kinetic spectrophotometric study showed that in tetraglyme, the addition of oxime and water in small amounts drastically decreased the rate of reaction of **1** with APOK as a result of hydrogen-bonding interactions with the oximate anion. In tetraglyme as solvent the addition of 2.2.2 cryptand greatly enhanced the reactivity of the oximates but the macrocyclic crown ether DC-18-C6 had much smaller effect on rate. The results are consistent with formation of a crown ether-complexed potassium oximate ion pair, which is much less reactive than the free anion formed in the presence of 2.2.2 cryptand but more reactive than the potassium oximate ion pair. The kinetic data were analyzed to obtain specific rate coefficients for reaction of APOK as the dissociated anion, the ion-paired species, and as the crown ether-complexed oximate; equilibrium constants for potassium oximate ion pair formation and for the crown ether-complexed ion pair were obtained. In DMSO as solvent the rate of reaction remained unaffected on addition of the metal ion complexing agents, indicating that ion pairing is not important in this solvent. The reactivity of the free oximate anions in both solvents increased in the order BDOK < APOK < AOK, which parallels the pK_a's of the corresponding oximes in DMSO. The unusually high reactivity of oximates in the low polarity tetraglyme compared to polar DMSO could be explained on the basis of stabilization of the transition state in tetraglyme. Trends in k^{TG}/k^{DMSO} for the oximates follow reactivity–selectivity considerations.

ERWIN BUNCEL, ANURAG KUMAR, HAI-QI XIE, ROBERT Y. MOIR et J. GARFIELD PURDON. Can. J. Chem. **72**, 437 (1994).

On a étudié les réactions du *p*-nitrophénolate de β-phénylmercaptoéthyle (**1**) avec trois oximates de potassium, les sels de potassium du monooximate de la 2,3-butanedione (BDOK), de l'oximate de l'acétophénone (APOK) et de l'oximate de l'acétone (AOK), dans deux solvants dipolaires non hydroxyliques, le tétraglyme et le diméthylsulfoxyde (DMSO). Les produits réactionnels, tels que déterminés par la RMN du ^{1}H, sont l'ion *p*-nitrophénolate et le sulfure de phényle et de vinyle; ceci est en accord avec un processus d'élimination. Une étude cinétique réalisée par spectrophotométrie montre que, dans le diglyme, l'addition de l'oxime et de l'eau en faibles quantités réduit d'une façon drastique la vitesse de réaction du composé **1** avec l'APOK, à cause d'interactions par liaison hydrogène avec l'anion oximate. Dans le tétraglyme comme solvant, l'addition du cryptand 2.2.2 augmente d'une façon appréciable la réactivité des oximates, mais l'éther couronne macrocyclique, DC-18-C6, provoque un effet beaucoup plus faible sur la vitesse. Les résultats sont en accord avec la formation d'une paire d'ions oximate de potassium complexée par l'éther couronne qui est beaucoup moins réactive que l'anion libre qui se forme en présence du cryptand 2.2.2, mais plus réactive que la paire d'ions oximate de potassium. On a analysé les données cinétiques afin d'obtenir les coefficients de vitesse spécifique pour la réaction de l'APOK sous la forme d'anion dissocié, de paire d'ions et d'oximate complexé par l'éther couronne; on a obtenu les constantes d'équilibre pour la formation de la paire d'ions oximate de potassium et pour la paire d'ions complexée par l'éther couronne. Dans le DMSO comme solvant, la vitesse de la réaction n'est pas affectée par l'addition d'agents pouvant complexer les ions métalliques; ceci indique que la formation de paires d'ions n'est pas importante dans ce solvant. La réactivité des anions oximates libres dans les deux solvants augmente dans l'ordre BDOK < APOK < AOK; cet ordre est parallèle aux pK_a des oximes correspondantes dans le DMSO. On peut expliquer la réactivité inhabituellement élevée des oximates dans le tétraglyme de faible polarité par comparaison avec celle observée dans le DMSO par une stabilisation de l'état de transition dans le diglyme. Les tendances dans le rapport k^{TO}/k^{DMSO} des oximates suivent les considérations de réactivité–sélectivité.

[Traduit par la rédaction]

Introduction

Ever since mustard gas was used as a chemical warfare agent, its destruction has been a challenging problem to chemists. During the last several decades a number of reports have appeared in the literature on the nucleophilic reactions of 2-chloroethyl sulfide derivatives, as models of sulfur mustard, 2,2′-dichlorodiethyl sulfide (1–9).

The nature of the reaction medium plays an important role in determining the reaction pathways of ethyl sulfide derivatives. For reactions of 2-chloroethyl *p*-tolyl sulfide with ethoxide in ethanol, Oae and Yano (3) observed 47% elimination and 53% substitution, whereas in 80% aqueous ethanol (w/w) Bird and Stirling (5) found 100% substitution. The most widely accepted mechanism for substitution reactions of ethyl sulfide derivatives in hydroxylic solvents involves intramolecular displacement of chloride ion by sulfur yielding an episulfonium ion, followed by attack of nucleophile resulting in substitution,

an S_N intramolecular process (4–8). There appear to be only two reports of a direct S_N2 displacement, for the reactions of ethyl sulfide derivatives with thiophenolate ions in DMSO (10, 11).

To the best of our knowledge, no reports are available concerning nucleophilic reactions of ethyl sulfide derivatives under homogeneous conditions in nonhydroxylic solvents of low polarity where these compounds are expected to be fairly soluble in contrast to their low solubility in aqueous media. It was of interest, therefore, to examine how a change of reaction medium from hydroxylic to nonhydroxylic would affect the reactivity and reaction pathways of ethyl sulfide derivatives.

In this work, the nucleophilic reactions of β-phenylmercaptoethyl *p*-nitrophenolate (**1**) with three potassium oximates, namely, potassium 2,3-butanedione monoximate (BDOK), acetophenone oximate (APOK), and acetone oximate (AOK) were investigated. These so-called α-nucleophiles are known to be highly reactive due to the presence of an unshared electron pair on the atom adjacent to the reacting site (12–16). Two nonhydroxylic solvents of different polarity were examined, namely, tetraglyme and DMSO. Tetraglyme was chosen as the solvent of low polarity because of its potential advantages in nucleophilic displacement reactions (17). The effect of added metal ion complexing agents was examined in both solvents. The importance of hydrogen-bonding interactions on reactivity in tetraglyme was also examined.

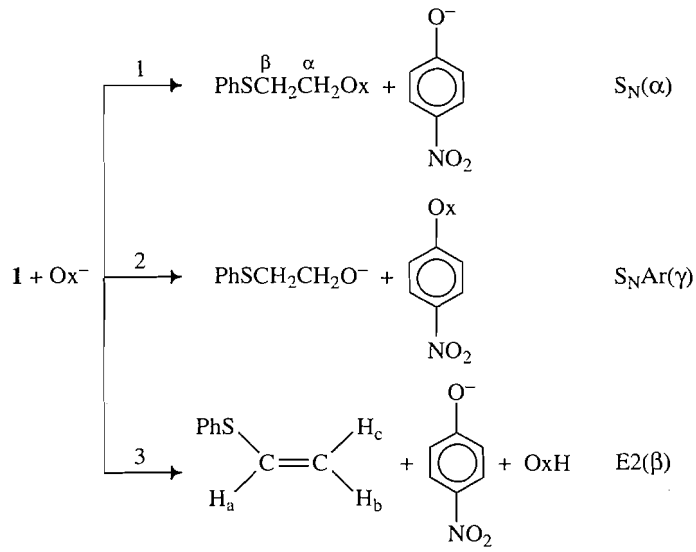
Results

Reaction product identification

There are four possible pathways for the reaction of **1** with an oximate anion (Ox^-): (1) nucleophilic substitution at the aliphatic carbon centre attached to the oxygen, yielding β-phenylmercaptoethyl oximate and *p*-nitrophenoxide ion; (2) nucleophilic substitution at the aromatic carbon centre attached to oxygen, yielding β-phenylmercaptoethoxide ion and *O*-(4-nitrophenyl)oxime; (3) elimination, yielding phenyl vinyl sulfide (PVS) and *p*-nitrophenoxide ion; and (4) nucleophilic substitution at the aliphatic carbon centre attached to the sulfur atom, yielding thiophenoxide ion and *p*-nitrophenylethyl oximate. Reactions (1)–(3) are shown in Scheme 1; reaction (4) is not shown since this is not expected to occur in the present case with *p*-nitrophenoxide as leaving group, though it remains a possibility with other phenolates.

Product analysis of the reactions of **1** with the oximates in tetraglyme and DMSO was carried out by ^{1}H NMR spectroscopy. The only process occurring in the reaction system examined in tetraglyme as well as DMSO was elimination. The formation of PVS was confirmed by the appearance of two doublets at δ 5.34 (H_c, J_{ac} = 16.6) and 5.43 (H_b, J_{ab} = 9.59), a double doublet at δ 6.72(H_a, J_{ac} = 16.6, J_{ab} = 9.59), and a multiplet at δ 7.33 for the PhS moiety. Two "doublets" at δ 5.90 (*ortho* 2H, J = 9.56) and 7.72 (*meta* 2H, J = 9.57) were assigned to *p*-nitrophenoxide ion, while a multiplet at δ 7.64 was due to the phenyl moiety of



SCHEME 1

acetophenone oximate anion/oxime. The ^{1}H NMR spectra of authentic samples of PVS and *p*-nitrophenoxide ion were used to confirm the formation of the elimination products.

Kinetic studies in tetraglyme

The kinetics of the reaction of **1** with oximates BDOK, APOK, and AOK in tetraglyme have been studied by standard or stopped-flow UV–VIS spectrophotometric methods in the absence and presence of metal ion complexing agents. The reactions were monitored under pseudo-first-order conditions with the oximate in large excess by following the changes in absorbance at λ_{max} of *p*-nitrophenoxide ion (424–435 nm). Pseudo-first-order rate constants (k_{obs}) were calculated from the linear plots of $\ln (A_\infty - A_t)$ versus time t by a least-squares linear regression method, Table 1.

The plot for the variation of k_{obs} with the oximate concentration in the reaction of **1** with APOK in the absence of metal ion complexing agents exhibits downwards curvature (Fig. 1). Addition of 2.2.2 ([2.2.2]/[APOK] = 1.23) to the reaction mixture drastically increased the rate of reaction and the plot of k_{obs} vs. [APOK] was linear (Fig. 1). The second-order rate constant for reactions of the free oximate anion, $k_2 = k_{Ox^-}$, calculated from the slope of the plot for the reaction containing 2.2.2 is 9.22 M^{-1} s^{-1} (Table 2). Addition of DC-18-C6, with [DC18-C6]/[APOK] = 14.9, was found to increase the rate to a much smaller extent and the plot of k_{obs} vs. [APOK] appears to be linear (Fig. 1).

The other two oximates, BDOK and AOK, were found to be insoluble in tetraglyme in the absence and presence of DC-18-C6, but both became soluble in the presence of 2.2.2. Rate data for the reaction of **1** with BDOK and AOK in the presence of 2.2.2 are given in Table 1. The plots of k_{obs} vs. [OxK] were linear (Fig. 2) and yield k_2 from the slope (Table 2).

The effect of varying the concentration of complexing agents at constant APOK is shown in Fig. 3 and results are given in Table 3. Increasing [2.2.2] at constant [APOK] led to a marked increase in rate until a maximum value (130-fold increase) was reached with [2.2.2]/[APOK] = 1.0, following which addition of more 2.2.2 had no effect on the rate. In contrast, added DC-18-C6 had a much smaller effect on the rate of reaction. A 3.5-fold increase in rate was observed with [DC18C6]/

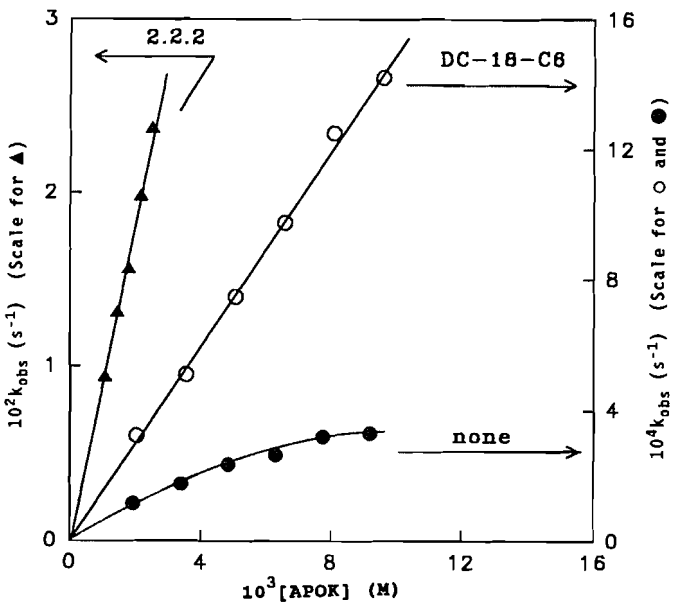

FIG. 1. Plots of k_{obs} vs. [APOK] for the reaction of **1** ((4.29–5.31) × 10^{-5} M) with APOK in tetraglyme in the absence (●) and presence (○, DC-18-C6 and ▲, 2.2.2) of metal ion complexing agents at 25°C.

[APOK] = 4.8, following which addition of more DC-18-C6 had almost no effect on the rate of reaction.

Our earlier investigations have shown the powerful role of hydrogen-bonding interactions in tetraglyme (17).[2] Therefore, it was thought worthwhile to examine the effect of added oxime and water on the rate of reaction of oximate with **1**. It was found that both acetophenone oxime (APOH) and water show a marked rate-retarding effect on the reaction of **1** with APOK in tetraglyme, see Figs. 4 and 5, and Tables 4 and 5.[3,4]

Kinetic studies in DMSO

Kinetic data for reaction of **1** with APOK and AOK were determined at 25°C (Table 6) but the reaction of **1** with BDOK in DMSO was found to be very slow at 25°C and rate constants were obtained at 60°C. The plots of log k_{obs} *vs* log[OxK] for the reactions of APOK and AOK are shown in Fig. 6. The effect of added DC-18-C6 and 2.2.2 cryptand was examined for the reac-

[2]E. Buncel, Ng. van Truong, and H.-Q. Xie, unpublished results.

[3]A referee has suggested that addition of H_2O to the oximate system could lead to generation of OH^-. This possibility cannot be rigorously excluded; pK_a values of oximes in tetraglyme containing H_2O are not known (in water, the pK_a of acetophenone oxime is 12.4).

[4]The possibility that addition of water could change the reaction pathway to some extent, from elimination to substitution, has also been suggested. For example, it has been observed by S.P. McManus and R.M. Karaman (unpublished work) that in the reaction system $PhSCH_2CH_2Cl$ + PhOK in *N*-methylpyrrolidone/water, substitution product can be observed in trace quantities by GC–MS with 12% water present. Since in the present study the percent water was ≤1%, the advent of substitution seems unlikely. We thank Prof. S.P. McManus for provision of these results prior to publication.

	2.87		4.68×10^{-2}

of **1** with oximates in tetraglyme and DMSO ruled out the possibility of nucleophilic substitution at any of the carbon centres. The only process observed was elimination, which could occur by an E1cb or E2 mechanism (18, 19). In another study from this laboratory (20), no H/D exchange was observed for reaction of **1** with EtOD–DMSO-d_6 containing EtO^-, excluding an E1cb mechanism. Since oximates are less basic than ethoxide, the concerted E2 mechanism is highly probable for the reaction of **1** in the present study. The competing pathways, substitution and elimination, for the present system are shown in Scheme 2.

It is noteworthy that, in the majority of the cases reported hitherto, nucleophilic reactions of 2-chloroethyl sulfide derivatives in hydroxylic solvents proceed largely by substitution at the carbon centre attached to chlorine (2, 5–7). However, in the present investigations of the reaction of **1** with oximates in non-hydroxylic solvents, base-promoted 1,2-elimination was found to be the only process occurring. It appears that the nature of the substituent on sulfur, the leaving group nucleofugality, base strength, and the reaction medium, all play important roles in determining the course of these reactions.

Oae and Yano (3) have reported the reaction of a number of 2-chloroethyl phenyl sulfide derivatives with EtONa in EtOH. They found that when *p*-methoxyphenyl on sulfur was replaced by the *p*-chlorophenyl moiety, the course of reaction changed from 50–50% elimination–substitution to 100% elimination. This suggests that an electron-withdrawing substituent on sulfur favours elimination, which is in accord with the present study, in that the electron-withdrawing phenyl group facilitates elimination over substitution.

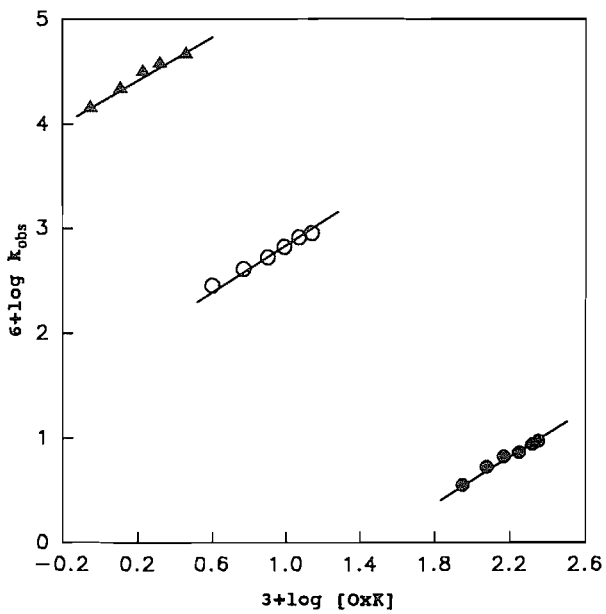

FIG. 6. Plots of log k_{obs} vs. log [OxK] for the reaction of **1** ((3.31–4.35) × 10^{-5} M) with BDOK (●) at 60°C, APOK (○), and AOK (▲) at 25°C, in DMSO.

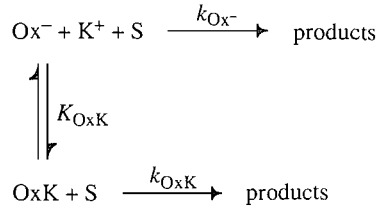
It is also apparent that unimolecular formation of the episulfonium ion intermediate, leading to substitution (path a in Scheme 2) would be favoured by a better leaving group, which would explain why substitution predominates with chlorine as leaving group and not with *p*-nitrophenoxy in the present study. However, the change in solvent from protic to aprotic would also favour elimination over substitution. Finally, the base-enhancing properties of DMSO towards nucleophiles is another factor which would tend to favour the elimination pathway b in Scheme 2, relative to the substitution pathway a.

Reactivity in tetraglyme

(a) Free oximate anions and ion pairs

As seen in Fig. 1 for the reaction of **1** with APOK in tetraglyme (data in Table 1), in the absence of metal ion complexing agents the plot of k_{obs} vs. [APOK] exhibits downward curvature. Addition of excess of DC-18-C6 ([DC18C6]/[APOK] = 14.9) increases the rate by a relatively small extent and in approximately linear manner. However, 2.2.2 cryptand ([2.2.2]/[APOK] = 1.23) greatly increases the rate of reaction and the plot of k_{obs} vs. [APOK] is linear (Fig. 1).

The downward curvature observed in the plot of k_{obs} vs. [APOK] in the absence of complexing agents (Fig. 1), as well as the very large increase in rate with added 2.2.2 (Figs. 1 and 3), are indicative of a mechanism in which the ion-paired nucleophile is much less reactive than the free ion. Considering that in the present system both free and ion-paired oximate could be reactive species, product formation will be according to Scheme 3 where S refers to the substrate.



SCHEME 3

The overall pseudo-first-order rate equation will be as in eq. [1]. The ion-paired and free anion species are interrelated by the equilibrium constant K_{OxK} (eq. [2]).

$$[1] \quad k_{obs} = k_{Ox^-}[Ox^-] + k_{OxK}[OxK]$$

$$[2] \quad K_{OxK} = \frac{[OxK]}{[Ox^-][K^+]}$$

TABLE 8. Comparison of observed and (DLS) calculated k_{obs} values for the reaction of **1** with APOK in tetraglyme and contribution of dissociated and ion-paired species at 25°C[a]

10^3 [APOK] (M)	10^4 k_{obs} ($^{-1}$)		% Contribution to rate	
	Obsd.	Calcd.	APO^-	APOK
1.93	1.16	1.25	78.4	21.6
3.39	1.75	1.78	73.3	26.7
4.84	2.34	2.24	69.6	30.4
6.29	2.64	2.66	66.8	33.2
7.74	3.20	3.06	64.4	35.6
9.19	3.30	3.44	62.5	37.5

[a] k_{Ox^-} = 9.22 M^{-1} s^{-1}, k_{OxK} = 0.0141 M^{-1} s^{-1}, K_{OxK} = 1.69 × 10^7 M^{-1}.

Scheme 3 contains two rate constants and one equilibrium constant: k_{Ox^-}, the rate constant for the reaction of free acetophenone oximate anion; k_{OxK}, the rate constant for the reaction of the acetophenone oximate ion pair; and K_{OxK}, the association constant of the acetophenone oximate ion pair. Since at equilibrium, $[K^+] = [Ox^-]$, then $[OxK] = K_{OxK}[Ox^-]^2$ and substitution for [OxK] in eq. [1] yields eq. [3].

$$[3] \quad k_{obs} = k_{Ox^-}[Ox^-] + k_{OxK}K_{OxK}[Ox^-]^2$$

The rate constant for the acetophenone oximate (Ox^-) free anion was obtained from the slope of the linear plot in Fig. 1 in the presence of 2.2.2 by linear regression analysis, as $k_{APO^-} = k_{Ox^-}$ = 9.22 M^{-1} s^{-1}. The nonlinear differential least-squares (DLS) curve fitting of the experimental data to eq. [3] yielded the values $k_{APOK} = k_{OxK}$ = 1.41 × 10^{-2} M^{-1} s^{-1} and K_{OxK} = 1.69 × 10^7 M^{-1}.

Thus dissection of k_{obs} into contributions by free and ion-paired acetophenone oximate by the DLS treatment yields $k_{APO^-}/k_{APOK} = k_{Ox^-}/k_{OxK}$ = 9.22/1.41 × 10^{-2} = 654, which is consistent with the qualitative observations in Fig. 1 that follow from free APO^- being much more reactive than ion-paired APOK.

Having obtained values for k_{Ox^-}, k_{OxK} (i.e., k_{APO^-} and k_{APOK}) and K_{OxK}, it is now possible to calculate the relative contribution of each species, i.e., free ions and ion pairs, to the overall rate (Table 8). It is seen from Table 8 that at the lowest concentration studied ([APOK] = 1.93 × 10^{-3} M) the contributions of APO^- and APOK to the overall rate are 78.4 and 21.6%, respectively, whereas at the highest concentration studied ([APOK] = 9.19 × 10^{-3} M) the contributions of APO^- and APOK change to 62.5 and 37.5%, respectively. This change, coupled with the fact that APOK is much less reactive than APO^-, leads to the downward curvature observed in Fig. 1 with increasing APOK concentration.

(b) Crown ether-complexed potassium oximate

It is interesting to contrast the kinetic behaviour in the reaction of **1** with APOK in tetraglyme in the presence of added 2.2.2 and DC-18-C6 (Figs. 1 and 3). It follows from Fig. 3 that addition of 1 equivalent of 2.2.2 leads to complete formation of cryptated K^+, i.e., $K^+ \subset$ 2.2.2, and the free anion. This results in the plateau in Fig. 3 corresponding to reaction of free APO^-, and the linear plot in Fig. 1 from which k_{APO^-} can be calculated. Qualitatively, the much smaller increase in rate and sensitivity to crown ether, which is apparent in Fig. 3 on increasing the ratio [DC18C6]/[APOK], would indicate that complexation by DC-18-C6 is much less effective and the linearity of the plot in Fig. 1 for data in the presence of DC-18-C6 would appear to be coincidental. This could be explained in light of the known complexing abilities towards K^+ of the solvent tetraglyme (21), which competes effectively with DC-18-C6 present in the system in relatively small concentrations.

Quantitatively, one can analyze the kinetic results for the reaction of **1** with APOK in tetraglyme in the presence of DC-18-C6 on the basis of formation of a crown ether-complexed potassium oximate ion pair, $APO^-K^+ \subset$ DC-18-C6. The expression for k_{obs} according to such a scenario would be as in eq. [4], where OxKCr refers to the crown ether-complexed ion pair for which the equilibrium constant of formation is given in eq. [5].

$$[4] \quad k_{obs} = k_{Ox^-}[Ox^-] + k_{OxK}[OxK] + k_{OxKCr}[OxKCr]$$

$$[5] \quad K_{OxKCr} = \frac{[OxKCr]}{[OxK][Cr]}$$

Equation [4] can be solved by DLS treatment assuming the k_{Ox^-}, k_{OxK}, and K_{OxK} values obtained previously from experiments in the presence and absence of 2.2.2 cryptand, respectively, apply equally to this situation.

Using the data in Table 1 at constant [Crown]/[OxK] ratio and varying [OxK], one obtains from DLS treatment the values k_{OxKCr} = 0.151 M^{-1} s^{-1} and K_{OxKCr} = 211 M^{-1} (Table 9). Data in Table 3 with a variable [Crown]/[OxK] ratio and constant [OxK] similarly yield k_{OxKCr} = 0.155 M^{-1} s^{-1} and K_{OxKCr} = 112. Using the combined set of "constant" and "variable" experimental data (Tables 1 and 3) in the DLS treatment yields k_{OxKCr} = 0.154 M^{-1} s^{-1} and K_{OxKCr} = 116 M^{-1}, however, with much better limits in the standard deviation and *p*-parameters (Table 9). Calculated k_{obs} values using these derived values of k_{OxKCr} and K_{OxKCr} agree very well with experimental values, no systematic deviations being apparent, which gives confidence to the validity of the DLS treatment and the model used.

The relative contributions of the different terms in the crown ether containing experiments can be calculated using the above values of k_{OxKCr} and K_{OxKCr} as well as the previously derived k_{Ox^-}, k_{OxK}, and K_{OxK} values. The results (Tables 10, 11) show that the crown ether-complexed ion pair is the predominant species present in concentration as well as the major contributor to the rate. The next major species is the ion pair but its contribution to the rate is less than that of the free anion even though the latter is the least abundant species present. There are also interesting trends in the relative abundance and the contributions of the various species as the overall oximate concentration is varied (Tables 10, 11).

Finally, one can comment on the relative magnitudes of the rate coefficients in these systems. That the free anion is by far the most reactive species (k_{Ox^-}/k_{OxK} = 654), is to be expected. It is interesting, however, that the crown-complexed potassium oximate ion pair is more reactive than the uncomplexed ion pair (k_{OxKCr}/k_{OxK} = 11). This order of reactivity is in agreement with a presumably looser binding of anion in the crown complex than in the ion pair itself. Alternatively, one can envisage a greater negative charge density on the oxygen centre of the oximate anion in the complexed species, and hence a greater reactivity.

TABLE 9. Determination of rate and equilibrium constants for crown-complexed potassium oximate (k_{OxKCr} and K_{OxKCr}) in the reaction of **1** with APOK in tetraglyme in the presence of DC-18-C6

[DC-18-C6]/[APOK]	k_{OxKCr} (M^{-1} s^{-1})	K_{OxKCr} (M^{-1})	S.D.	*p*-Parameter[e] (k_{OxKCr})	*p*-Parameter[e] (K_{OxKCr})
"Constant"[a,b]	0.151	211	0.0000263	198	1.15×10^7
"Variable"[c]	0.155	112	0.0000376	132	6.08×10^5
"Combined"[d]	0.154	116	0.0000285	78	5.50×10^5

[a]Constant ratio of [DC-18-C6]/[APOK] = 14.9, varying [APOK] (Table 1).
[b]A second solution in the DLS treatment for the constant [crown]/[OxK] data yielded $K_{OxKCr} = 8.0 \times 10^6$ but this high *p*-parameter (7.27×10^{13}) solution was discarded since it was not found for the solution of the "variable" or the "combined" data, as well as being chemically unreasonable because of competition between solvent tretraglyme and the crown for complexation of K^+ (see text).
[c]Variable ratio of [DC-18-C6]/[APOK], constant [APOK] = 7.4×10^{-3} M (Table 3).
[d]Combined "constant" and "variable" sets; the preferred set.
[e]The *p*-parameter offers a choice in the calculation of the standard deviations of the adjustable parameters. Commonly, the *p*-parameter is multiplied by the standard deviation from the calculated curve (e.g., 0.0000285), obtaining, e.g., standard deviations of 0.0022 (for k_{OxKCr}) and 15.7 (for K_{OxKCr}) in the last line of the table. However, for difficulties in this procedure, see for example ref. 30.

TABLE 10. Relative concentrations of contributing species (as percentage of total reagent concentration) for the reaction of **1** with APOK in tetraglyme in the presence of DC-18-C6 at 25°C[a]

[b]Data from Table 1.
[c]Data from Table 3.

(c) Relative reactivities of three oximates

The reactions of BDOK and AOK with **1** in tetraglyme could be studied in the presence of 2.2.2 only, because both oximates were found to be insoluble in tetraglyme in the absence and presence of DC-18-C6. It is interesting that when small quantities of the corresponding oximes are present, the oximate salts become soluble in tetraglyme in the presence of DC-18-C6, probably through hydrogen bonding. The inability of DC-18-C6 to solubilize BDOK and AOK in tetraglyme further demonstrates the relative ineffectiveness of DC-18-C6 to compete with tetraglyme solvent in complexation of K^+ and corroborates the above discussion on the relatively small effect of DC-18-C6 in enhancing the rate of the APOK reaction in tetraglyme.

The reaction of **1** with AOK in tetraglyme in the presence of 2.2.2 was found to be faster than with APOK and required study by stopped-flow spectrophotometry. The relative order of reactivity of oximates towards **1** in tetraglyme in the presence of 2.2.2 was BDOK < APOK < AOK, i.e., in order of their pK_a's (vide infra) with k_2 values of 0.00706, 9.22, and 182 M^{-1} s^{-1}, respectively, for the three oximates.

(d) Hydrogen-bonding effect on oximate reactivity

The effect of added acetophenone oxime (APOH) and water on the rate of reaction of **1** with 2.2.2-complexed APOK in tetraglyme was examined. Figures 4 and 5 show a marked rate-retarding effect of added APOH and water. The presence of only 0.04% H_2O causes a 5-fold decrease in the rate of reaction. It is apparent that hydrogen-bonding interactions with the acetophenone oximate anion (APO^-) result in decreased reactivity. Previously, for the reaction of *p*-nitrophenyl diphenylphosphinate with phenoxide ion in tetraglyme, added phenol was similarly found to greatly reduce reactivity (17).

3. Reactivity in DMSO

Whereas the reaction of **1** with APOK and AOK in DMSO could be studied conveniently at 25°C, BDOK was found to react very slowly and rate constants were obtained at 60°C. The plots of k_{obs} vs. [OxK] for the reaction of **1** with BDOK, APOK, and AOK in DMSO are linear with zero intercept, showing that reaction due to solvent alone is not significant. The relative order of reactivities of the oximates, shown in Fig. 6 as log–

9.57	14.9	3.73	0.57	95.70
Set 2[c]				
7.40	0.801	27.97	12.62	59.40
7.40	1.60	18.40	7.09	74.51
7.40	4.80	9.14	2.34	88.52
7.40	9.61	6.11	1.13	92.76
7.40	17.6	4.40	0.61	94.99

[a]k_{Ox^-} = 9.22 M^{-1} s^{-1}, k_{OxK} = 0.0141 M^{-1} s^{-1}, K_{OxK} = 1.69 × 10^7 M^{-1}, k_{OxKCr} = 0.154 M^{-1} s^{-1}, K_{OxKCr} = 116 M^{-1}.
[b]Data from Table 1.
[c]Data from Table 3.

log plots, parallel the pK_a's of the corresponding oximes in DMSO:

	AOK	APOK	BDOK
k_2, M^{-1} s^{-1}	17.6	6.82×10^{-2}	4.18×10^{-5}
Temperature (°C)	25	25	60
pK_a (DMSO) of oxime (22, 23)	26.0	21.5	16.9

For the reaction of **1** with APOK in DMSO the negligible effect of added DC-18-C6 and 2.2.2 on the rate (Table 7) suggests that ion-pairing phenomena are not important in DMSO, in contrast to the situation in tetraglyme. As a strongly ionizing solvent with a high dielectric constant (ϵ = 45), ion-pair phenomena are rarely observed in DMSO (24).

Solvent effects on reactivity: ground state versus transition state interactions

It is interesting that the overall reactivity in tetraglyme is greater than in DMSO. On the assumption that the potassium oximate + 2.2.2 system reflects the reactivity of free oximate anion in tetraglyme (TG) and that potassium oximate alone correspondingly represents free oximate anion reactivity in DMSO (since ion-pair phenomena are not important in DMSO), one obtains:

Oximate	BDOK	APOK	AOK
k^{TG}/k^{DMSO}	169	135	10

Medium effects on the rate of a chemical reaction are usually interpreted in terms of the relative stabilization/destabilization of the transition state compared to the ground state (reactants) (25). Thus, any factors stabilizing the transition state for elimination would accelerate reaction; conversely, stabilization of the ground state would lead to rate retardation, and combination of the two effects is also possible.We suggest that the higher reactivity in tetraglyme compared to DMSO in the present system may be explained on the basis of polarizability principles. The transition state involved in base promoted 1,2-elimination reactions (Scheme 2) has considerably delocalized charge density, and since the polarizability (α) of tetraglyme is higher than of DMSO ($\alpha_{TG} = 22.7 \times 10^{-24}$ cm^3 and $\alpha_{DMSO} = 7.98 \times 10^{-24}$ cm^3),[5] tetraglyme would tend to stabilize the transition state to a greater extent than DMSO. At the same time, one would expect that the reactants would have similar energy in DMSO and tetraglyme. We are considering here the cryptated potassium ion, $K^+ \subset 2.2.2$, the oximate anion, and **1**; these relatively large ionic species and the neutral substrate are not expected to be subject to large differential solvation in the two media. Thus, the overall effect is one of stabilization of the transition state in tetraglyme, which will tend to rate acceleration compared to DMSO as solvent.

Noteworthy above is that the ratio k^{TG}/k^{DMSO} decreases with increasing Ox^- reactivity, and parallels the increasing pK_a's of the oximates. This trend follows the reactivity–selectivity argument (27), i.e., the less reactive nucleophile is more selective. This behaviour may be explained by considering trends in the transition states involved in tetraglyme and DMSO. If the location of the transition states were the same in both solvents then a constant value for this ratio would be expected. The fact that k^{TG}/k^{DMSO} is greater in the direction of the weaker base is an indication that the transition state is earlier in tetraglyme than in DMSO, which is also in accord with Hammond's postulate (28).

Conclusions

The present study of the reaction of β-phenylmercaptoethyl *p*-nitrophenolate (**1**) with three potassium oximates, AOK, APOK, and BDOK, in DMSO and tetraglyme solvents has allowed us to draw a number of conclusions:

1. The reactions proceed via E2 elimination processes in these solvents.

[5]Polarizability (α) was calculated by using the equation (26): $\alpha = [(n^2 - 1)/(n^2 + 2)](M/d)(3/4\pi N)$.

2. In tetraglyme the small reactivity of oximates coupled with the large accelerating effect of 2.2.2 cryptand on rate points to formation of less reactive ion pairs in the absence of metal ion complexing agent. Added DC-18-C6 leads to a much smaller increase in rate since complexation of K^+ by the solvent tetraglyme competes with DC-18-C6. The kinetic data are analyzed in terms of parallel reactions of free oximate, ion-paired potassium oximate, and crown ether-complexed potassium oximate. Rate constants and equilibrium constants for these species are derived ($k_{Ox^-} \gg k_{OxKCr} > k_{OxK}$).

3. The relative order of reactivity of the three oximates in tetraglyme and DMSO, i.e., AOK > APOK > BDOK, was found to parallel the pK_a values of the corresponding oximes in DMSO.

4. The unusually high reactivity in tetraglyme compared to DMSO is explained on the basis of stabilization of the transition state in tetraglyme as a result of its higher polarizability.

5. Added oxime and water had a marked rate-retarding effect on rates in tetraglyme, indicating the powerful role of hydrogen-bonding interactions between oximate anion and oxime or water.

Experimental

Materials

β-Phenyl mercaptoethyl *p*-nitrophenolate (**1**) was synthesized by reaction of 2-chloroethyl phenyl sulfide with *p*-nitrophenol in aqueous ethanol (water:ethanol = 1:3 v/v) containing KOH and recrystallized from hexane, mp 79°C. (A representative procedure is given in the accompanying paper (20).) The resulting product was characterized by ^{1}H NMR, IR, and elemental analysis (Anal. calcd.: C 61.09, H 4.73, N 5.09; found: C 61.51, H 5.13, N 5.14). Phenyl vinyl sulfide (PVS) was prepared by a previously published procedure, bp 66°C/ 3 Torr (lit. (3) bp 83°C/14 Torr) (1 Torr = 133.3 Pa).

Dimethyl sulfoxide (DMSO) was refluxed over calcium hydride for 3 h, then fractionally distilled at low pressure, bp 35°C/2 Torr (20). Tetraglyme was refluxed over sodium metal for 3 h, then fractionally distilled (bp 110°C/2 Torr). Prior to use it was freshly redistilled from sodium (29). The purified solvents were stored under a nitrogen atmosphere and solvent was transferred by syringe while passing nitrogen. The 2.2.2-cryptand (Merck) and DC-18-C6 (Aldrich) were recrystallized from hexane and acetonitrile, respectively, and stored in a glove box.

The oximate samples, BDOK, APOK, and AOK, were procured from Raylo Chemicals and found to contain significant amounts of the corresponding oxime as impurity. The oximates were purified by two methods: (*i*) heating at 110°C under vacuum for 24 h; (*ii*) Soxhlet extraction with THF (for BDOK) and diethyl ether (for APOK and AOK). The purified oximates were stored under an argon atmosphere in a glove box. Their purity was examined spectrophotometrically by recording the spectra of the oximate solution, first in DMSO alone as reference, and then in the presence of EtOK/EtOH (for BDOK: [BDOK] = 2×10^{-2} M, [EtOK] = 1×10^{-2} M, 10-mm cell; for APOK: [APOK] = 6.58×10^{-2} M, [EtOK] = 8×10^{-3} M, 1-mm cell; final percentage of EtOH in DMSO was ca. 0.3% (v/v)). Any free oxime present is converted to oximate on addition of EtOK/EtOH, and the mol% of oxime could be estimated from the increase in absorbance in the spectra recorded in the absence and presence of EtOK. The samples of BDOK and APOK showed two absorption peaks in DMSO: BDOK (300 nm, $\epsilon = 22\,700$ M^{-1} cm^{-1} and 465 nm, $\epsilon = 67.5$ M^{-1} cm^{-1}); APOK (326 nm, $\epsilon = 14\,000$ M^{-1} cm^{-1} and 400 nm, $\epsilon = 133$ M^{-1} cm^{-1}). The analysis was carried out at the higher wavelength, less intense peak, which allowed analysis of higher oximate concentrations. The purified BDOK and APOK samples were found to be free of oxime. However, AOK could not be analyzed by this method as it does not show absorbance in the UV–visible region.

Kinetic procedures

Kinetics of the reaction of **1** with APOK and BDOK were studied spectrophotometrically under pseudo-first-order conditions by following the changes in absorbance at λ_{max} of *p*-nitrophenoxide ion (425–435 nm) on a Perkin Elmer Lambda-5 spectrophotometer equipped with thermostatted multiple cell transport system. Pseudo-first-order rate constants were calculated by a least-squares linear regression method using a Zenith computer. Experimental infinity absorbance values (closely similar to the theoretical values) were used in the linear plot of ln ($A_\infty - A_t$) vs. time, which gave k_{obs} from the slope. For the very slow reaction of **1** with BDOK in DMSO ($k_{obs} < 10^{-5}$ s^{-1}), theoretical infinity absorbance values were used to obtain pseudo-first-order rate constants. From replicate runs the error in any particular measured rate constant is estimated not greater than ca. ±3%.

The rate of the much faster reaction of **1** with AOK in tetraglyme in the presence of 2.2.2 was followed at λ_{max} of *p*-nitrophenoxide ion (432 nm) on a Hi-Tech stopped-flow spectrophotometer equipped with a thermostatable water bath coupled to a McPherson monochromator and Can-Tech transient recorder. The spectral traces were displayed on a B&K precision oscilloscope and the data were treated directly by a Zenith computer. The reproducibility of k_{obs} was found to be within ±1%.

Product analysis

The nature of the reaction products in tetraglyme and DMSO was determined by ^{1}H NMR spectroscopy using a Bruker 200 or 400 MHz instrument. In tetraglyme the reaction of **1** with the potassium oximates was carried out in the presence of 2.2.2 cryptand ([**1**] = 0.01 M, [OxK] = 0.02 M, and [2.2.2] = 0.03 M). The reaction mixtures were kept at room temperature for 12 h, after which ^{1}H NMR spectra were recorded. The spectra showed complete conversion into products as indicated by the absence of peaks due to **1**. The NMR data in tetraglyme were referenced with respect to CD_3SOCD_2H/CD_3SOCD_3 contained in a capillary tube inserted in the NMR tube, while for reactions in DMSO the solvent served as the reference.

Kinetic studies have been performed on the base-promoted 1,2-elimination reactions of a series of β-phenylmercaptoethyl phenolates with potassium ethoxide in EtOH–DMSO media, yielding phenyl vinyl sulfide. The E2 mechanism was indicated by the absence of H/D exchange in the substrate when the reaction in EtOD–DMSO-d_6 containing EtO^- was carried to partial completion. The Brønsted coefficient values (β_{LG}, effect of nucleofugality on reaction rate) of ca. 0.30 and ca. 0.98 were estimated for the reaction in pure DMSO and ethanol, respectively. Comparison of the results with reported reactions of substrates of similar structure revealed the important role of the phenyl group on sulfur, the leaving-group nucleofugality, and the medium basicity, in controlling the reaction pathways (elimination versus substitution).

HAI-QI XIE, NGUYEN TRUONG, ERWIN BUNCEL et J. GARFIELD PURDON. Can. J. Chem. **72**, 448 (1994).

On a réalisé des études cinétiques sur les réactions d'élimination-1,2 effectuées sur une série de phénolates de β-phénylmercaptoéthyle sous l'influence de bases comme l'éthylate de potassium dans un milieu EtOH–DMSO qui conduisent au sulfure de phényle et de vinyle. L'absence d'échange H/D dans le substrat lorsque la réaction, effectuée dans du EtOH–DMSO-d_6 contenant du EtO^-, n'est complétée que d'une façon partielle indique que le mécanisme est E2. Les valeurs du coefficient de Brønsted (β_{LG}, effet du caractère nucléofuge sur la vitesse de réaction) sont d'environ 0,30 et 0,98 et elles correspondent aux évaluations qui ont été faites pour les réactions dans le DMSO pur et dans l'éthanol pur respectivement. Une comparaison des résultats avec ceux rapportés pour les réactions de substrats de structure semblable révèlent le rôle important du groupe phényle sur le soufre, du caractère nucléofuge du groupe partant et de la basicité du milieu sur les voies réactionnelles (élimination vs. substitution).

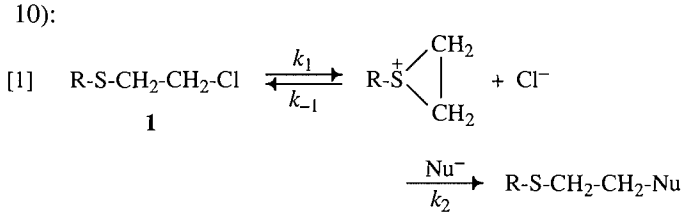
Introduction

Considerable information has accumulated in the past several decades on the reactions of β-chloroethyl sulfide derivatives, R-S-CH_2CH_2-Cl (**1**), with nucleophiles in various aqueous and nonaqueous media (1–9). However, there is controversy as to the mechanisms of these reactions as well as the prediction of reaction pathways, elimination versus substitution, under given conditions.

It is generally accepted that the mechanism of nucleophilic substitution of β-chloroethyl sulfide derivatives involves an anchimerically assisted intramolecular displacement of chloride ion by sulfur, which is accompanied by the formation of an episulfonium ion intermediate of some degree of stability (2–7, 10):



Stirling and co-workers (6) obtained strong evidence for rate-determining formation of the cyclic sulfonium ion intermediate in eq. [1] and reported the spectroscopic observation of cyclic sulfonium ions in several cases. However, Robertson and co-workers (8) questioned the existence of this species as a discrete intermediate since this should result in the formation of ethylene sulfide as well as the substitution product R-S-CH_2CH_2-Nu, whereas the latter is the only product detected.

In most investigations of the reactions of β-chloroethyl sulfide derivatives, nucleophilic substitution was the only reaction mode detected (1–8); only in one case were both base-promoted 1,2-elimination and nucleophilic substitution simultaneously observed (6*b*, 9). Thus it was reported in one study that β-chloroethyl *p*-tolyl sulfide undergoes 47% elimination – 53% substitution with EtONa in EtOH at 40–65°C (9), while in another study 100% substitution was observed in 80% aqueous EtOH (w/w) at 45°C for the same substrate (6*b*).

The present study is concerned with the title substrates **2**, in which substituted phenolates (X-PhO) are the leaving groups while the sulfur carries a phenyl group, and with the effect of varying the reaction medium on the rate. We report here the results of kinetic studies on the reactions of the family of β-phenylmercaptoethyl phenolates (**2**) with potassium ethoxide in ethanol – dimethyl sulfoxide (EtOH – DMSO) media.

Results

Product identification

There are several possible pathways for the reaction of **2** with potassium ethoxide in EtOH–DMSO mixtures (Scheme 1). Pathway (a) corresponds to nucleophilic substitution at C(α) with phenolate as the leaving group, while in path (b) substitution at C(β) would result in thiophenolate leaving. Path (c) corresponds to nucleophilic attack at aromatic carbon in an S_NAr process. Pathways (d) and (e) are elimination processes at C(α) and C(β), respectively, with thiophenolate and phenolate as leaving groups.

^1H NMR analysis of the reaction product for substrate **2***h*, a typical compound in this series, with EtOK in 20% EtOD – 80% DMSO-d_6 (v/v), showed that 1,2-elimination by pathway (e) was the only reaction occurring. The formation of PVS was

X = H (**2***a*); *p*-Me (**2***b*); *p*-Cl (**2***c*); *p*-CHO (**2***d*); *p*-$COCH_3$ (**2***e*); *p*-CN (**2***f*); *m*-NO_2 (**2***g*); *p*-NO_2 (**2***h*)

SCHEME 1

characterized by the appearance of multiplets at δ 7.1–7.4 for the PhS ring protons, a double doublet at δ 6.72 for H_a, and two doublets at δ 5.43 and 5.33 for H_b and H_c, respectively. The generation of potassium *p*-nitrophenoxide was shown by two doublets at δ 7.75 and 5.98, corresponding to the *meta* and *ortho* protons respectively. ^{1}H NMR spectra of the authentic compounds confirmed the formation of PVS and potassium *p*-nitrophenoxide in the reaction mixtures.

Hydrogen/deuterium exchange

Base-promoted 1,2-elimination may occur via an E1cb-reversible mechanism which would result in the observation of H/D exchange on C(β) of the substrate (11). To test whether such an exchange occurred, less than one equivalent of EtOK in EtOD was added to the solution of substrate **2***h* in DMSO-d_6 ([EtOK]/[**2***h*] = 1/2, 5% EtOD – 95% DMSO-d_6 v/v). The proton NMR spectrum of the solution was recorded after the reaction was allowed to take place overnight. By comparing the integrations of the signals corresponding to the ring protons and the β protons, it was found that no H/D exchange occurred on C(β) of the unreacted substrate, within experimental error of the measurement.

Kinetic studies with potassium ethoxide in EtOH–DMSO mixtures

Kinetic studies for the reactions of substrates **2** with EtOK were performed in various EtOH–DMSO mixtures. It was observed that at high ethoxide concentrations, the plots of k_{obs} vs. [EtOK] were curved upward. Figure 1 shows a typical curved plot of k_{obs} vs. [EtOK] for the reaction of **2***h* in 5% EtOH – 95% DMSO (v/v) at 25.0°C.

In most kinetic experiments, relatively low EtOK concentrations (≤0.1 M) were used and linear k_{obs} vs. [EtOK] plots were obtained. The second-order rate constants k_2 could therefore be calculated from the slopes of these plots. All the k_{obs} vs. [EtOK] plots showed negligible intercept at [EtOK] = 0, indicating the absence of significant contribution from solvent to the observed reaction rates.

A kinetic experiment was also performed on the reaction of **2***h* with ethoxide in the presence of the K^+-complexing agent, dicyclohexyl-18-crown-6-ether (DC18C6). The experiments conducted with **2***h* at [EtOK] = 0.02 M in 20% EtOH – 80% DMSO (v/v) at 25.0°C (Supplementary Table 1) showed that, within experimental error, added DC18C6 had no effect on the observed reaction rate (k_{obs} = 2.72 (±0.08) × 10^{-4} s^{-1}, [DC18C6]/[EtOK] = 0–4).

Two series of kinetic experiments were performed with potassium ethoxide as base in EtOH–DMSO mixtures. In the first set, the reaction of **2***h* with EtOK was studied at 25.0°C in EtOH–DMSO mixtures of DMSO content ranging from 50 to 95% DMSO (v/v) (45.6–94.1% DMSO (mol/mol)). The k_{obs} values are recorded in Supplementary Tables 2–9 while the k_2 values obtained are presented in Table 1. In the second set, kinetic experiments for the reactions of various substituted β-phenylmercaptoethyl phenolates, **2***a*–**2***h*, with EtOK were conducted at 45.0°C in three EtOH-DMSO mixtures, containing 65, 80, and 90% DMSO (v/v). The k_{obs} values are listed in Supplementary Tables 10–33 while k_2 values are listed in Table 2.[2]

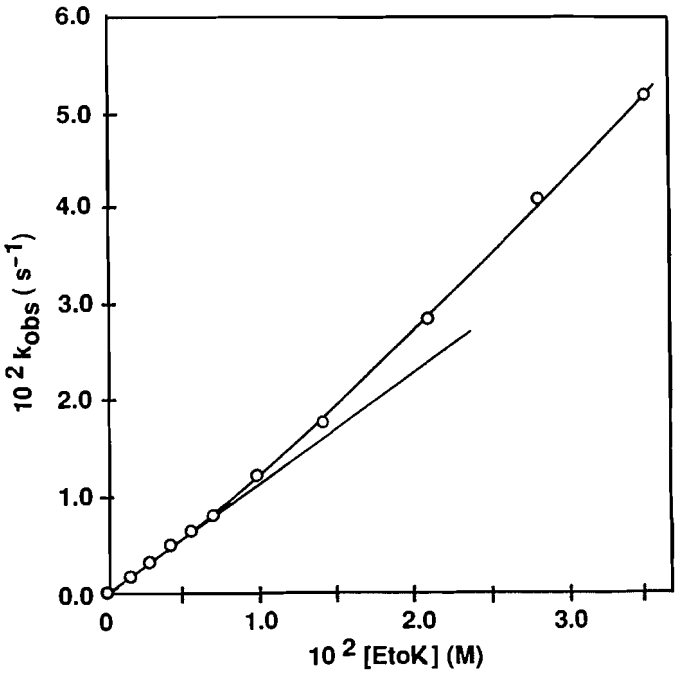

FIG. 1. Plot of k_{obs} vs. [EtOK] for reaction of **2***h* with EtOK in 5% EtOH – 95% DMSO (v/v) at 25.0°C.

Discussion

Reaction pathway

We have shown that the reaction of β-phenylmercaptoethyl

p-nitrophenolate **2*h*** with EtOK in EtOH–DMSO proceeds by 1,2-elimination to give phenyl vinyl sulfide and *p*-nitrophenoxide. The absence of hydrogen/deuterium exchange in the substrate when the reaction is carried out in EtOD–DMSO-d_6 to partial completion allows one to rule out the possibility of an $(E1cb)_r$ type-mechanism. The $(E1cb)_{ir}$ mechanism can also be ruled out by the observation of a significant leaving group effect (β_{LG}) and the requirement of σ^- values for the best fit in Hammett plots (vide infra). An E1 mechanism can readily be ruled out by the base concentration dependence of the rate. Hence an E2 mechanism for the reaction is established.

Reactivity of potassium ethoxide in EtOH–DMSO mixtures

The upward curvature that is apparent in the plots of k_{obs} vs. [EtOK] for **2*h*** in EtOH–DMSO mixtures at relatively high base concentrations, as illustrated in Fig. 1, could conceivably be the result of reactive ion-pair species (12, 13) such as $[(EtO)_2K]^-$, etc. and (or) excess basicity (14) of the media at high EtOK concentrations.

If ion pairing of EtOK in EtOH–DMSO mixtures in fact contributes to the upward curvature of the k_{obs} vs. [EtOK] plots, then addition of DC18C6 to the reaction mixtures should reduce the reaction rate compared to the rate at the same EtOK concentration but in the absence of complexing agent. The kinetic experiments conducted in the presence of DC18C6 unambiguously showed the absence of ion pairing of EtOK in the EtOH–DMSO mixtures, since the reaction rate was not affected by the addition of DC18C6. This conclusion is in accord with the commonly observed finding that DMSO, with a high dielectric constant ($\epsilon = 45$), is a strong ionizing solvent in which ion pairing is generally not significant. Although in ethanol ion pairing can often be important (12, 13), the solvent mixtures used in this study were in the region of high DMSO composition ((45.1–94.1% DMSO (mol/mol)), which would tend to diminish the ion pairing of EtOK.

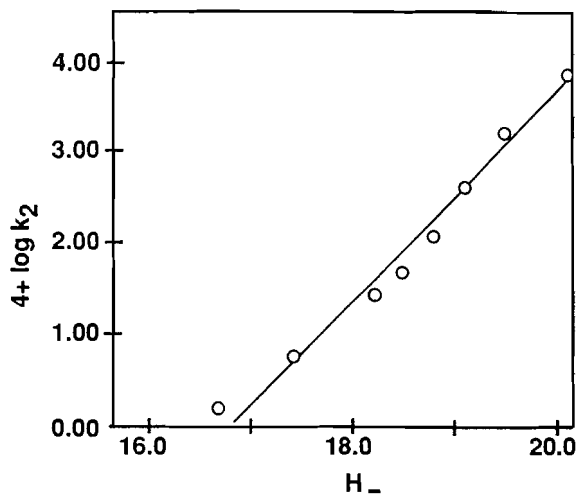

FIG. 2. Plot of log k_2 vs. H_- for reaction of **2*h*** with EtOK in various EtOH–DMSO mixtures at 25.0°C.

The upward curvature in the plot of k_{obs} vs. [EtOK] (Fig. 1) can hence be ascribed to excess basicity of EtOK in EtOH-DMSO mixtures (14). Base strength is known to be a major factor in determining reaction rates in elimination processes (15). At low base concentrations, both ion pairing and excess basicity are generally believed not to be significant and in the present study a linear dependence of k_{obs} upon [EtOK] was observed. Therefore, k_2 values were determined at low EtOK concentrations.

Table 1 shows that the second-order rate constants for reaction of **2*h*** with EtOK at low base concentrations are greatly enhanced on increasing the DMSO content, from 1.47×10^{-4} M^{-1} s^{-1} in 50% EtOH – 50% DMSO (v/v) to 1.13 M^{-1} s^{-1} in 5% EtOH – 95% DMSO (v/v). This observation is in complete accord with the well-known increased basicity of EtOK resulting on addition of DMSO to ethanol (14). Although H_- values for the EtOK–EtOH–DMSO system are not available, one can correlate the k_2 values with the H_- acidity function determined with Na^+ as the counterion at 20°C (14*a*). A plot of log k_2 versus H_- for EtONa–EtOH–DMSO is shown in Fig. 2. While the points may be represented by a linear graph as shown, with slope of 1.08 ± 0.06, they could also be joined in the form of a curved plot, which could be indicative of a mechanistic change.[3] It would be desirable to test other base-promoted elimination processes by changing the EtOH–DMSO composition, via the rate–H_- correlation, in order to obtain further insight into this mechanistic criterion.

Nucleofugality in reactions with potassium ethoxide

The kinetic data obtained on varying the substituent on the phenolate moiety (Table 2) show that the more electron withdrawing the substituent, the higher the reactivity of substrate **2** with potassium ethoxide in a given DMSO–EtOH medium. A

[3]We thank a referee for this suggestion.

TABLE 3. Hammett ρ and correlation coefficient values (R^2) for reactions of substituted β-phenylmercaptoethyl phenolates **2** with EtOK in EtOH–DMSO mixtures at 45.0°C as a function of mole fraction DMSO

	% DMSO (v/v)		
	65	80	90
f_{DMSO}	0.602	0.766	0.880
ρ (R^2)[a]	2.53 (0.93)	2.34 (0.94)	2.20 (0.95)
ρ^0 (R^2)[a]	2.57 (0.93)	2.38 (0.94)	2.24 (0.95)
ρ^- (R^2)[a]	1.74 (0.97)	1.58 (0.95)	1.49 (0.96)

[a]ρ, ρ^0, and ρ^- were obtained using the corresponding σ, σ^0, and σ^-, respectively (16).

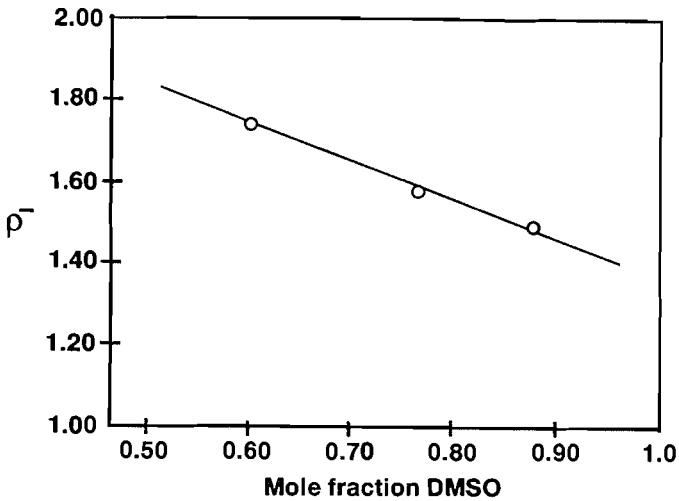

FIG. 3. Plot showing ρ^- as function of mole fraction DMSO for reactions of **2** with EtO^- in EtOH–DMSO media at 45.0°C.

Hammett-type treatment of the data in Table 2 showed that the fit of the various log k_2 – σ plots is dependent on the type of σ values chosen for the substituents (16). The results are summarized in Table 3 in the form of ρ values and correlation coefficients (R^2) resulting from use of different types of σ values in the log k_2 vs. σ plots. It is seen that use of σ^- leads to the best fit, indicating that substituents on the leaving aryloxy moiety interact with the oxygen center according to their resonance capability. This in turn is consistent with a substantial negative charge being developed on the aryloxy oxygen in the rate-determining transition state, i.e., a high degree of E2 character.

A plot of ρ^- values at the different DMSO–EtOH solvent compositions shows good linearity (Fig. 3) and can be extrapolated to 100% DMSO, yielding $\rho^- = 1.38$. The observed decreasing ρ^- values with increasing DMSO content, i.e., decreasing sensitivity of the reaction rate to substituents with increasing reactivity, are of interest since they apparently represent an example of adherence to the reactivity–selectivity principle (RSP) (17).

Poh has estimated the Hammett constant for the ionization of substituted phenols in pure DMSO, as $\rho^-(K_a) = 4.33$ (18). The ratio of $\rho^-(k_2)$ as estimated above to $\rho^-(K_a)$, i.e., β_{LG}, gives a measure of the effect of the leaving group on reactivity. This β_{LG} value is generally interpreted as being a measure of the extent of bond cleavage between the phenolate oxygen and the α-carbon in the transition state for elimination (19). Thus we obtain, for pure DMSO, $\beta_{LG} = \rho^-(k_2)/\rho^-(K_a) = 1.38/4.33 = 0.32$.

The high-quality linear regression in Fig. 3 (correlation constant = 0.9995) suggests that extrapolation to pure ethanol can be made, yielding $\rho^-(k_2) = 2.27$ in EtOH, although the extent of the required extrapolation brings some doubt to the procedure. Assuming that the resulting $\rho^-(k_2)$ value is valid, when combined with the ρ value (+2.23) for the ionization of phenol in EtOH (20*a*) this yields a β_{LG} value of 1.02. The greater value of β_{LG} in ethanol compared to that in DMSO is in accord with the Hammond postulate, noting that the reaction rate in ethanol is estimated to be ca. 10^8-fold slower than in DMSO, which will lead to a later transition state in ethanol medium.

Another approach was also used to estimate the β_{LG} values for reactions of **2** with potassium ethoxide in pure DMSO. First, plots of log k_2 vs. mole fraction of DMSO (f_{DMSO}) were constructed; these showed good linearity with correlation coefficients $R > 0.99$ for all substrates, **2***a*–**2***h*. The second-order rate constants k_2 for each substrate were then extrapolated to pure DMSO. Secondly, pK_a values of substituted phenols in pure DMSO were estimated graphically by interpolation on a plot of pK_a(DMSO) vs. $pK_a(H_2O)$. Then, a Brønsted plot of log k_2 versus pK_a in DMSO was constructed and yielded $\beta_{LG} = 0.28$ with a correlation coefficient of 0.96.

A similar procedure was applied for the estimation of β_{LG} in EtOH. The pK_a values in 95% EtOH – 5% H_2O were used as an approximation of pK_a values in pure EtOH. The plot of log k_2 vs. pK_a gave $\beta_{LG} = 0.94$ with a correlation coefficient $R = 0.98$. It is noteworthy that the β_{LG} values obtained with the second approach are identical, within experimental error, to those estimated by the method previously described. This encourages confidence in the validity of the estimated β_{LG} values.

It is interesting that the β_{LG} value determined in this study (ca. 0.98 EtOH) is higher than the values reported by Stirling and co-workers (20) in an investigation of the nucleofugality of the same leaving groups in E1cb processes induced by sulfone, sulfoxide, and cyano groups in ethanol medium (β_{LG} = 0.67, 0.54, and 0.79, respectively).

Elimination versus substitution

As stated in the Introduction, the majority of the investigations with substrates **1** have reported nucleophilic substitution (pathway a in Scheme 1) even in the absence of strong nucleophiles, e.g., hydrolysis in neutral aqueous solution (2, 8). However, in the present reaction systems no substitution products could be detected and the reactions are found to be completely 1,2-elimination processes.

The competition between elimination and substitution in the reaction of R-S-CH_2CH_2-L (**3**) with a base/nucleophile (B/Nu) can be analyzed by means of Scheme 2. Nucleophilic substitu-

tion in **3** can in principle occur either via the cyclic sulfonium intermediate mechanism or by a concerted direct S_N2 displacement process, but for simplicity we show only the episulfonium intermediate since omission of the S_N2 process will not affect the conclusions of our discussion.

Clearly, factors stabilizing **4** and the transition state leading up to it will promote substitution over elimination, while factors favoring **5** will increase alkene over substitution products. The most important factors controlling the reaction pathway are the nature of the substituent, R, the leaving group, L, the base/nucleophile, B/Nu, and the solvent. These will now be considered in turn.

Substituent R on sulfur

Oae and Yano (9) studied the reaction of a series of substituted β-chloroethyl aryl sulfides with EtONa in EtOH (eq. [2]) and obtained the following results on variation of X for the yield of alkene: CH_3O, 42.5%; CH_3, 47.9%; H, 76.0%; Cl, 100%; NO_2, 100%.

[2] $p\text{-X-C}_6\text{H}_4\text{-S-CH}_2\text{CH}_2\text{-Cl} +$

$$\text{EtONa} \xrightarrow[\text{EtOH}]{60^\circ} \begin{cases} \text{X-C}_6\text{H}_4\text{-S-CH=CH}_2 \\ \text{X-C}_6\text{H}_4\text{-S-CH}_2\text{-CH}_2\text{-OEt} \end{cases}$$

It is apparent that the stronger the electron-withdrawing nature of substituent X, the higher the olefin yield and vice versa. For example, replacement of the *p*-methoxyphenyl group on sulfur by *p*-chlorophenyl changes the reaction from ca. 58% substitution to 100% elimination. The unsubstituted phenyl residue favors elimination.

It is interesting that in a recent study Yang and co-workers (21) found that the series of substrates $\text{R-S-CH}_2\text{CH}_2\text{Cl}$ undergo hydrolysis concurrently with decomposition to dithioether when R = Me, Et, PhCH_2, ClCH_2CH_2, and HOCH_2CH_2, but when R = Ph no hydrolysis is observed. This suggests that the phenyl substituent on sulfur has an influence on susceptibility of the substrates to nucleophilic substitution.

The electron pair on sulfur can be delocalized on the phenyl ring, i.e.,

$$\underset{\mathbf{6}}{\text{Ar-S-CH}_2\text{-CH}_2\text{-OAr}} \longleftrightarrow \underset{\mathbf{6a}}{{}^-\text{Ar=S}^+\text{-CH}_2\text{-CH}_2\text{-OAr}}$$

Charge density on sulfur is reduced through structures such as **6***a* and the intramolecular substitution or anchimeric assistance pathway resulting in cyclic sulfonium **4** becomes inhibited. As well, the partial positive charge on sulfur enhances the acidity of the β-protons and stabilizes the elimination transition state **5**, with the result that elimination is favored.

Leaving group

A better leaving group should favor the formation of **4** relative to **5** and hence favor substitution. Since phenolates are poorer leaving groups than chloride, elimination in **2** and **6** will be favored relative to the β-chloroethyl sulfide derivatives **1**.

Base and solvent

It is well known that stronger bases favor elimination over substitution (15). DMSO is known to greatly increase the basicity of ethoxide compared to protic media by desolvating the ethoxide anion (22). However, a strongly solvating medium such as water would stabilize the charge-separated species **4** more effectively than **5** and hence favor substitution. A change of reaction medium from ethanolic to aqueous should hence lead to substitution rather than elimination. Accordingly, the reaction of β-chloroethyl *p*-tolyl sulfide with EtONa in EtOH at 60°C gives 47% elimination and 53% substitution (9). However, the same reaction conducted in 80% aqueous EtOH (w/w) at 40–65°C was reported to proceed entirely by substitution (8). Recent work by McManus and co-workers (23) on solvolysis of 2-chloroethyl methyl sulfide in methanol–water mixtures indicates that there is both transition state stabilization and ground state destabilization of alkyl β-chloroethyl sulfides by water molecules. Thus increased solvation promoting substitution over elimination is supported by the available evidence.

Conclusions

β-Phenylmercaptoethyl phenolates, **2**, react with potassium ethoxide in EtOH–DMSO mixtures exclusively by a base-promoted 1,2-elimination pathway. The reaction occurs by a concerted E2 mechanism in which negative charge is significantly delocalized onto the phenolate ring and partially stabilized by the β-phenyl sulfenyl group in the transition state. The preference for elimination rather than substitution in the present reaction system is believed to be due mainly to: (*a*) the electron-withdrawing phenyl group on sulfur; (*b*) relatively poor leaving-group ability of the phenolates; (*c*) enhanced basicity of potassium ethoxide in DMSO.

Experimental

Solvents and reagents

Ethanol and dimethyl sulfoxide (DMSO) were purified by standard literature methods (24). The mixed solvents were prepared by the following procedure. The desired volume of distilled EtOH was transferred to a septum-sealed 10-mL volumetric flask with a gas-tight syringe and DMSO was added up to the mark. The molar composition of the EtOH–DMSO mixtures was determined from the measured weights of ethanol and DMSO.

Potassium ethoxide solutions in EtOH or EtOD were prepared by allowing potassium metal (Aldrich Analytical Grade) cut under petroleum ether to react with freshly distilled ethanol under a nitrogen atmosphere. The EtOK solution was titrated against potassium hydrogen phthalate and stored in a freezer. Dicyclohexyl-18-crown-6-ether (DC-18-C-6, Aldrich) was recrystallized from acetonitrile and stored in a dry-box.

Synthesis of substrates 2

β-Phenylmercaptoethyl phenolates (**2**) were synthesized by the reaction of β-chloroethyl phenyl sulfide with a mixture of potassium hydroxide and the corresponding phenol in aqueous ethanol (water: ethanol = 1:2–1:3 v/v). A typical procedure is described below.

A mixture of potassium hydroxide (60.0 mmol) and the substituted phenol (79.5 mmol) in 100 mL aqueous ethanol (1:1 v/v) was added slowly with magnetic stirring to 60.9 mmol of β-chloroethyl phenyl sulfide in 100 mL ethanol contained in a 3-necked round-bottom flask. The resulting solution was refluxed overnight, then cooled to room temperature, and the precipitated product was filtered and washed with distilled water. The collected solid was recrystallized from hexane, petroleum ether – hexane, or acetone – hexane mixtures.

In the case of β-phenylmercaptoethyl *m*-nitrophenolate this procedure yielded an oily material that was separated from the ethanolic layer by means of a separatory funnel. Distillation yielded a pale yellow oil, bp 190–195°C/0.8–1 Torr(1 Torr = 133.3 Pa). This was dis-

solved in hot hexane and allowed to cool slowly, yielding the product as a crystalline material.

The purified products were characterized by NMR, IR, elementary analysis, and melting point. The physical constants as well as the NMR and IR parameters of compounds **2***a*–**2***h* are given in Supplementary Tables 34 and 35.[2]

Kinetic measurements

Reactions of potassium ethoxide with substrates **2** in EtOH–DMSO mixtures were studied spectrophotometrically by following the appearance of the absorption due to the generated aryloxide ions. The reactions were performed under pseudo-first-order conditions with base concentrations at least 50-fold in excess over the substrate. The observed rate constants (k_{obs}) were calculated from linear plots of $\ln(A_\infty - A_t)$ versus time. Generally, about four reaction half-lives were used in the calculation of k_{obs}. Kinetic studies were performed on a Perkin–Elmer Lambda 5 UV–visible spectrophotometer equipped with a temperature-controlled cell compartment (±0.1°C).

Hydrogen/deuterium exchange

A 25-μL aliquot of 1 M EtOK/EtOD was added to 0.5 mL CD_3SOCD_3 solution containing 14 mg **2***h* (0.051 mmol). The solution was allowed to stand overnight at room temperature, resulting in ca. 50% conversion to products, and the ^{1}H NMR spectrum of the reaction mixture was recorded.

NMR studies

NMR spectra were recorded on a Bruker 400 MHz NMR instrument with tetramethylsilane (TMS) or DMSO-d_6 as internal references.

JOSÉ PELETEIRO, CLARA A. TOVAR, ENRIQUE CARBALLO, JOSÉ L. LEGIDO, and LUIS ROMANÍ. Can. J. Chem. **72**, 454 (1994).

Excess molar volumes of mixtures of 2,5-dioxahexane + *c*-hexane, 2,5,8-trioxanonane + *c*-hexane, 2,5,8,11-tetraoxadodecane + *c*-hexane, and 2,5,8,11,14-pentaoxapentadecane + *c*-hexane were determined from density measurements at 283.15, 288.15, 298.15, and 308.15 K. These results allowed the following mixing quantities to be reported in the range of concentration: α, $(\delta V^E/\delta T)_P$, and $(\delta H^E/\delta P)_T$, at 298.15 K. The values obtained were then compared with the values calculated by using the Flory theory and the Nitta–Chao theory of liquid mixtures.

JOSÉ PELETEIRO, CLARA A. TOVAR, ENRIQUE CARBALLO, JOSÉ L. LEGIDO et LUIS ROMANÍ. Can. J. Chem. **72**, 454 (1994).

Utilisant des mesures de densités effectuées à 283,15, 288,15, 298,15 et 308,15 K, on a déterminé les volumes molaires en excès pour les mélanges de 2,5-dioxahexane + *c*-hexane, 2,5,8-trioxanonane + *c*-hexane, 2,5,8,11-tétraoxadodécane + *c*-hexane et 2,5,8,11,14-pentaoxapentadécane + *c*-hexane. Ces résultats ont permis de rapporter les quantités de mélange suivantes, pour les plages de concentration mentionnées: α, $(\delta V^E/\delta T)_P$ et $(\delta H^E/\delta P)_T$, á 298,15 K. On a alors comparé les valeurs obtenues avec les valeurs calculées en utilisant la théorie de Flory et la théorie de Nitta–Chao des mélanges liquides.
[Traduit par la rédaction]

Introduction

The behaviour of the polioxyethylenglycol dimethylethers, also called glymes and having the general formula (CH_3—O—(—CH_2—CH_2—O—)$_n$—CH_3), has been studied in different mixtures (1–3). The similarities of their chains with the *n*-alkane chains have been emphasized; nevertheless, there are significant structural differences with those. First of all, the glyme molecules are polar, with their dipolar momentum increasing as does the length of the chain (4, 5), whereas the *n*-alkanes are apolar. Secondly, glymes have less conformational flexibility than *n*-alkanes, due to the weak *anomeric effect* present in the groupings of atoms (—O—CH_2—CH_2—O—) (6). This effect is much more noticeable in acetals, which contain the group (—O—CH_2—O—).

Bhattacharyya and Patterson (7) have measured the densities and excess volume at several temperatures for cyclohexane + *n*-alkane mixtures. Starting from these, they have calculated the values of $(\delta V^E/\delta T)_P$ and $(\delta^2 V^E/\delta T^2)_P$ analyzing the results in terms of Flory theory.

The aim of present work is to study the differential behaviour of glyme + cyclohexane mixtures in relation to *n*-alkane + cyclohexane mixtures. As a first step, we have determined the densities of mixtures of *c*-hexane with monoglyme (2,5-dioxahexane, DOHX), diglyme (2,5,8-trioxanonane, TON), triglyme (2,5,8,11-tetraoxadodecane, TODD), and tetraglyme (2,5,8,11,14-pentaoxapentadecane, POPD) at different temperatures; starting from these experimental facts, the values of V^E, α, $(\delta V^E/\delta T)_P$ and $(\delta H^E/\delta P)_T$ have been calculated. By using the theories of Flory and Nitta–Chao, those same values are calculated and the capacity of both theories for the prediction of parameters of order in glyme–cyclohexane mixtures is then studied.

[1]To whom the correspondence should be addressed.

Experimental

Cyclohexane and monoglyme were obtained from Aldrich (HPLC grade, better than 99.9%); diglyme and triglyme were supplied from Fluka. Diglyme: puriss. p. a. >99.5%; triglyme: purum >98%), and tetraglyme from Merck (zur synthese, >98%). The chemicals were all partially degassed, dried over Fluka type 4Å molecular sieves, and otherwise used as supplied.

Densities of the pure liquids and mixtures were measured with a Kyoto Electronics densimeter. Using a Hetoterm PF-CBIIe thermostat, the vibrating-tube temperature was kept at better than ±0.005 K. The experimental technique has been previously described (8, 9). Through weighing, mole fractions were determined. The densities of the pure liquids agree closely with the literature values as shown in Table 1. The precision of the densities was ±0.00001 g cm^{-3} and mole fraction ±0.00005.

Experimental results

Experimental densities, ρ, of binary mixtures (Tables 2–5) were fitted as a function of the mole fraction and the temperature to a polynomial of the type:

$$[1] \qquad \rho/(\text{g cm}^{-3}) = \sum_{i=1}^{3}\sum_{j=1}^{3} A_{ij} x^{i-1}(T - T_0)^{j-1}$$

where x is the mole fraction of oxaalkane, T is the temperature, and T_0 is the temperature of 278.15 K.

The experimental excess molar volumes, V^E (also in Tables 2–5), were determined from the densities of the pure liquids and their mixtures. They were fitted as a function of the mole fraction and temperature, to a polynomial of the form:

$$[2] \qquad V^E/(\text{cm}^3\ \text{mol}^{-1}) = x(1-x)\sum_{i=1}^{3}\sum_{j=1}^{3} B_{ij}(2x-1)^{i-1}(T - T_0)^{j-1}$$

where x is the mole fraction of oxaalkane, T is the temperature, and T_0 is the temperature of 278.15 K.

The coefficients A_{ij} and B_{ij} and standard deviation given in Tables 6 and 7 were obtained by an optimization process which employed a Marquardt's algorithm (10). Figures 1–4 show the experimental excess molar volumes and the fitted curves $V^E(x,T)$.

Berti et al. (11) have measured the excess molar volumes of mixtures of monoglyme and diglyme with cyclohexane at 298.15 K. Their values, 1.27 $cm^3\ mol^{-1}$ at $x = 0.5$ for both mixtures, are similar to ours. The curve of mixtures cyclohexane + monoglyme is almost symmetrical whereas for the diglyme + cyclohexane is shifted towards greater concentration of cyclohexane. The excess molar volumes increase with temperature, the growth being more marked for the glymes of short chain.

The values of cubic expansion coefficient (α) for the liquids and their mixtures (Fig. 5) were computed by analytic derivation of eq. [1] for each mixture at 298.15 K.

We have obtained the following values of α for pure liquids: $\alpha_{DOHX} = 1.268 \times 10^{-3}\ K^{-1}$, $\alpha_{TON} = 1.060 \times 10^{-3}\ K^{-1}$, $\alpha_{TODD} = 0.965 \times 10^{-3}\ K^{-1}$, $\alpha_{POPD} = 0.921 \times 10^{-3}\ K^{-1}$, $\alpha_{c\text{-HEX}} = 1.212 \times 10^{-3}\ K^{-1}$. The bibliography values are $\alpha_{DOHX} = 1.274 \times 10^{-3}\ K^{-1}$ (12), $\alpha_{TON} = 1.0602 \times 10^{-3}\ K^{-1}$ (12), $\alpha_{TODD} = 0.9771 \times 10^{-3}\ K^{-1}$ (12) or $0.929 \times 10^{-3}\ K^{-1}$ (21), $\alpha_{c\text{-HEX}} = 1.215 \times 10^{-3}\ K^{-1}$ (13) or $1.217 \times 10^{-3}\ K^{-1}$ or $1.220 \times 10^{-3}\ K^{-1}$ (14). They agree closely.

$(\delta V^E/\delta T)_P$ and $(\delta H^E/\delta P)_T = V^E - (T)(\delta V^E/\delta T)_P$ values (Figs. 6 and 7) were computed by analytical derivation of eq. [2] at 298.15 K for each mixture.

Theoretical models

(a) Flory model

The Flory model (15, 16) permits a prediction of the molar volume of the mixture and the excess molar volume starting from the equation of the state as a function of the reduced variables:

$$[3] \qquad \tilde{p}\tilde{v}/\tilde{T} = [\tilde{v}^{1/3}/(\tilde{v}^{1/3} - 1)] - 1/(\tilde{v}\tilde{T})$$

where

$$[4] \qquad \tilde{v} = V/V^* = [(1 + (4/3)\alpha T)/(1 + \alpha T)]^3$$

$$[5] \qquad \tilde{p} = p/p^* = p/(\alpha T\tilde{v}^2/\kappa_T)$$

$$[6] \qquad \tilde{T} = T/T^* = (\tilde{v}^{1/3} - 1)/\tilde{v}^{4/3}$$

The excess molar volume can be determined from the expression:

$$[7] \qquad V^E = \left(\sum_{i=1}^{2} x_i V_i^*\right)\left(\tilde{v} - \sum_{i=1}^{2} \phi_i \tilde{v}_i\right)$$

where

$$\phi_i = x_i V_i^* / \sum_{j=1}^{2} x_j V_j^*$$

The parameter dV^E/dT (8) is calculated from the following expression:

[a] In K.
[b] In g cm^{-3}.

$$[8] \qquad dV^E/dT = \left[\left(\sum_{i=1}^{2} x_i V_i^*\right) \cdot (\tilde{T} \cdot (d\tilde{v}/d\tilde{T})) - \left(\sum_{i=1}^{2} x_i V_i^* \cdot (\tilde{T} \cdot (d\tilde{v}/d\tilde{T}))_i\right)\right] \cdot T^{-1}$$

where

$$[9] \qquad \tilde{T} = (\phi_1 p_1^* \tilde{T}_1 + \phi_2 p_2^* \tilde{T}_2)/[\phi_1 p_1^* + \phi_2 p_2^* - \phi_1\phi_2 X_{12}/(\phi_2 + (S_1/S_2)\phi_1)]$$

The parameter X_{12} was obtained by employing a Marquardt's algorithm (10) in an optimization process, using all experimental data at 298.15 K. The relationship of the molecular surface areas of contact was estimated from the characteristic volumes of the components, using the assumption that the molecules are approximately spherical (16).

Table 8 shows the data used in the application of the Flory model.

(b) Nitta–Chao model

The Nitta–Chao model (Nitta et al. (17)) is based on the cell theory, with the function of molecular cell partition being obtained by using the hard sphere state equation (Carnahan and Starling (18)). The equation of state expressed completely in reducing variables:

$$[10] \qquad \tilde{p}\tilde{v}/\tilde{T} = 1 + \tilde{v}(4\tilde{v} - 2)/(\tilde{v} - 1)^3 - (1 + \kappa\tilde{v})\exp(\kappa/\tilde{v})/(\tilde{v}\tilde{T})$$

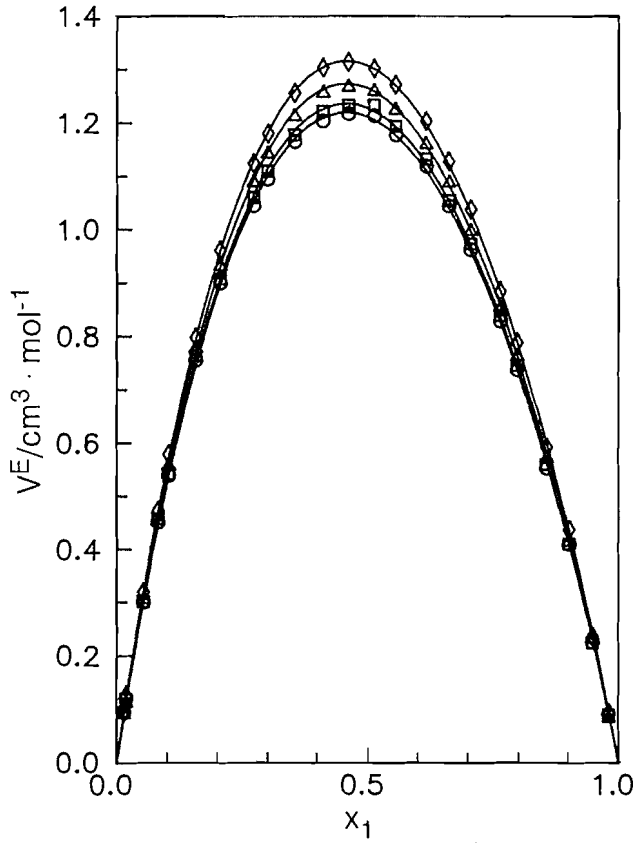

FIG. 1. Experimental excess molar volumes V^E, (x_1) monoglyme + ($1 - x_1$) c-hexane at (○), 283.15 K; (□), 288.15 K; (△), 298.15 K; (◇), 308.15 K.

where κ a constant whose value is 0.7, the reduced variables are defined by

$$[11] \qquad \tilde{p} = pV^*/cNkT^*$$

$$[12] \qquad \tilde{T} = 2ckT/n\tilde{Q}_e$$

where c is the number of external degrees and

$$[13] \qquad \tilde{Q}_e = \sum\sum N_{ij}E_{ij}$$

For N_{ij}, the number of contacts, the quasi-chemical approximation is used.

The energy of the interaction is expressed by

$$[14] \qquad E_{ij} = -(\epsilon_{ij}/\tilde{v}) \exp(\kappa/\tilde{v}) = \sigma_{ij}$$

where ϵ_{ij} is the dispersive interaction energy parameter.

The chemical association energy σ_{ij} is temperature dependent and is given by

$$[15] \qquad \frac{\sigma_{ij}}{T} = \frac{\sigma_{ij}^0}{T_0} + \sigma'_{ij}\left(\frac{1}{T} - \frac{1}{T_0}\right)$$

where σ_{ij}^0 and σ'_{ij} are characteristic parameters of this model.

The temperature dependence of the hard core volume of group i, V_i^*, is given by the empirical expression

$$[16] \qquad V_i^* = V_{i0}^* \exp\left[a_i\left(\frac{1}{T} - \frac{1}{T_0}\right)\right]$$

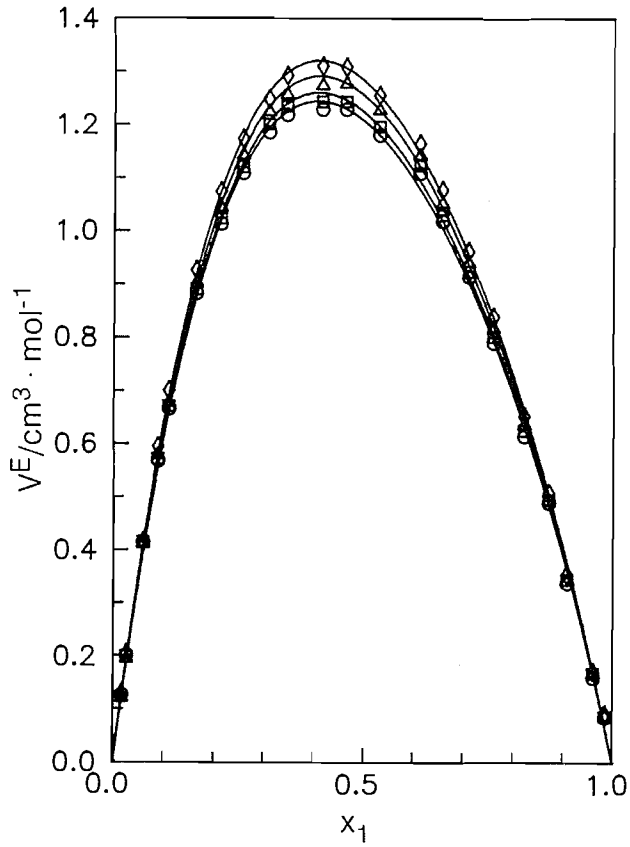

FIG. 2. Experimental excess molar volumes V^E, (x_1) diglyme + ($1-x_1$) *c*-hexane at (○), 283.15 K; (□), 288.15 K; (△), 298.15 K; (◇), 308.15 K.

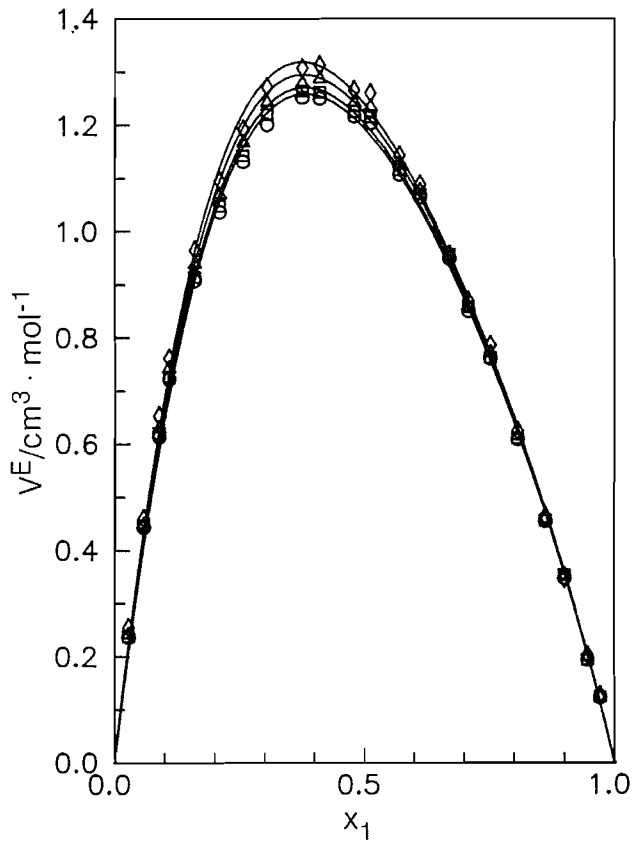

FIG. 3. Experimental excess molar volumes V^E, (x_1) triglyme + ($1-x_1$) *c*-hexane at (○), 283.15 K; (□), 288.15 K; (△), 298.15 K; (◇), 308.15 K.

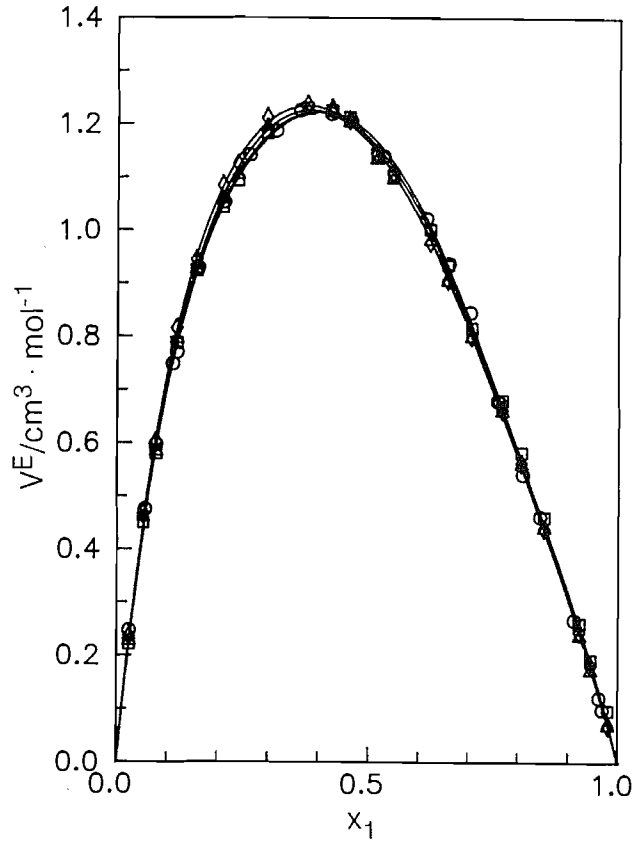

FIG. 4. Experimental excess molar volumes V^E, (x_1) tetraglyme + ($1-x_1$) *c*-hexane at (○), 283.15 K; (□), 288.15 K; (△), 298.15 K; (◇), 308.15 K.

where V^*_{i0} is the hard core volume at temperature T_0 (normally 298.15 K).

Both a_i and V^*_{i0} are characteristic parameters that are determined by fitting the theoretical equations to experimental data.

The configurational energy is given by

$$[17] \quad U_{conf}/NkT = -\sum\sum_{i\geq j} N_{ij}/NkT[(\epsilon_{ij}/\tilde{v}) + \exp(0.7/\tilde{v}) + \sigma'_{ij}] - (\delta \ln V^*/\delta \ln T)/(pV/NkT)$$

The molar heat of mixing for low pressure liquids is

$$[18] \quad H^E = U_{conf} - \sum x_A U_{A0,conf}$$

The expressions for the thermodynamic properties of both pure liquids and mixtures are derived by the standard methods of statistical thermodynamics.

Table 9 shows the characteristic parameters used.

Results and discussion

The V^E to mole fraction 0.5 as studied is represented in Fig. 8 as a function of the temperature, using eq. [2] and the coefficients B_{ij} in Table 7. An almost linear increase of the excess volume with the temperature can be observed. The lower the linear increase, the larger the glyme chain.

The calculated values for $(\delta V^E/\delta T)_P$, (shown in Fig. 6) are positive for the three systems, being negative for mixture with TODD at concentrations greater than 0.5. The values for $(\delta H^E/\delta P)_T$ (Fig. 7) are positive in the range of concentration

and inverted in relation to $(\delta V^E/\delta T)_P$ values increasing with the ether chains length.

Calculations from the Flory's theory showed that values for α, $(\delta V^E/\delta T)_P$, and $(\delta H^E/\delta P)_T$, are very different from the experimental ones. The theoretical values of $(\delta V^E/\delta T)_T$ parameter is three or five times bigger than the experimental value, although it reproduces both the decrease and the deviation of the maximum as a function of glyme chain. Theoretical values of $(\delta H^E/\delta P)_T$ are negative, while the experimental ones are positive. The V^E values at $x = 0.5$ (Fig. 8) are in the same order as the experimental ones except for DOHX + *c*-hexane. In view of this we conclude that the Flory's theory can not explain the behaviour of the glyme–cyclohexane mixture, just the opposite that of the alkane–cyclohexane mixture (7).

A possible explanation of this is to take into account the polarity of the glyme molecules, which produces dipole–dipole and dipole – induced dipole associations that are not considered in the Flory's model.

The Nitta–Chao theory was applied using the parameters for both alkane–alkane and alkane–ether interactions shown in Table 7. The latter have been calculated by Eckart et al. (19), beginning with experimental data on monoether-alkane

mixtures. The results obtained do not reproduce the experimental tendencies of V^E. For the parameters $(\delta V^E/\delta T)_P$ and $(\delta H^E/\delta P)_T$ the calculated values are closer to the experimental results than those of the Flory theory. These results suggest that the ether groups in glymes behave differently from the ether groups in monoethers. This is probably associated with the appearance of the anomeric effect in those molecules which have two atoms of oxygen separated by one or two methylene groups. This effect causes the glyme chains or acetal chains to have a more rigid structure than those of the monoethers or hydrocarbons of similar size.

Molecular recognition XIV.[1] Monte Carlo simulation of the hydration of the combining site of a Lectin[2]

H. BEIERBECK,[3] L.T.J. DELBAERE,[4] M. VANDONSELAAR,[4] AND R.U. LEMIEUX[5]

Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received February 3, 1993[6]

H. BEIERBECK, L.T.J. DELBAERE, M. VANDONSELAAR, and R.U. LEMIEUX. Can. J. Chem. **72**, 463 (1994).

Monte Carlo simulations of the hydration of the combining sites of the divalent lectin IV of *Griffonia simplicifolia* were carried out using the X-ray structure of the native lectin at 2.15 Å resolution. The regions of the combining sites are identical shallow polyamphiphilic cavities with a surface area of approximately 240 Å^2 and an average depth of only about 2.2 Å. To reduce the CPU time requirements for Monte Carlo simulations of the hydration of the combining site of the native lectin, a fragment of the protein structure was examined that contained only 62 of the 243 amino acid residues and was present in both of the two subunits of the protein. This portion of the lectin, which encompassed the combining site and its immediate surroundings, was examined, employing 250 water molecules to near symmetrically cover an area of about 370 Å^2 over and about the combining site with a density of 1 at 300 K. As was previously found in similar studies of the hydration of the Lewis b tetrasaccharide, the nonpolar regions are much less densely hydrated than the adjacent polar regions. This situation is considered to arise because of the hydrogen-bonding requirement for water molecules to bridge over nonpolar regions of varying dimensions. It is expected, therefore, that the association of complementary hydrophilic surfaces in aqueous solution must involve, in addition to the establishment of the usual intermolecular forces of attraction, a collapse of water structure over "flickering cavities" for return to bulk. This collapse can be expected to contribute to the driving force for association both through a decrease in enthalpy (higher density) and through an increase in entropy (greater disorder). This property of hydrated polyamphiphilic surfaces may contribute importantly to the driving force of all associations in aqueous solution since virtually all organic molecules are polyamphiphilic in character.

H. BEIERBECK, L.T.J. DELBAERE, M. VANDONSELAAR et R.U. LEMIEUX. Can. J. Chem. **72**, 463 (1994).

On a effectué des simulations de Monte Carlo sur l'hydratation de sites de combinaison de la lectine bivalente IV du *Griffonia simplicifolia* en utilisant la structure cristalline déterminée à une résolution de 2,15 Å par diffraction des rayons X de la lectine naturelle. Les régions des sites de combinaison sont des cavités polyamphiphiles identiques peu profondes d'une superficie d'environ 240 Å^2 et d'une profondeur moyenne d'environ 2,2 Å. Dans le but de réduire le temps d'ordinateur requis pour les simulations de Monte Carlo de l'hydratation du site de combinaison de la lectine naturelle, on a examiné un fragment de la structure de la protéine qui ne contenait que 62 des 243 résidus d'acides aminés mais qui est présent dans les deux sous-unités de la protéine. On a examiné cette portion de la lectine, qui comprend le site de combinaison et ses environs immédiats, en employant 250 molécules d'eau conduisant à une couverture pratiquement symétrique d'une surface d'environ 370 Å^2 au-dessus et autour du site de combinaison, avec une densité de 1 à 300 K. Comme on l'a observé dans des études similaires antérieures sur l'hydratation du tétrasaccharide b de Lewis, les régions non polaires sont moins hydratées que les régions polaires adjacentes. On considère que la situation découle des nécessités des liaisons hydrogènes des molécules d'eau qui doivent créer des ponts de dimensions diverses au-dessus des régions non polaires. On suppose donc que, dans une solution aqueuse, l'association de surfaces hydrophiles complémentaires doit impliquer, en plus de la création des forces intermoléculaires d'attraction, une désintégration de la structure de l'eau au-dessus « des cavités vacillantes P» et son retour vers l'ensemble de la solution. On peut s'attendre à ce que cette désintégration contribue à la force motrice aidant à l'association par le biais d'une diminution de l'enthalpie (plus grande densité) et d'une augmentation de l'entropie (plus grand désordre). Il est possible que cette propriété des surfaces polyamphiphiles hydratées contribue d'une façon importante à la force motrice de toutes les associations en solutions aqueuses puisque pratiquement toutes les molécules organiques possèdent un caractère polyamphiphile.

[Traduit par la rédaction]

Introduction

In the course of our studies of the recognition of oligosaccharides by antibodies and lectins (1), we became convinced that hydration effects should not be neglected in attempts to understand why molecular associations occur in aqueous media. Of course, the importance of changes in the interaction energies between water molecules in causing the association of nonpolar surfaces has long been appreciated. However, the classical hydrophobic effect (2) cannot be invoked to account for the noncovalent binding of highly hydrophilic surfaces in aqueous solution, as we have now established for the association of several oligosaccharides by proteins (3–6).

The polar interactions established between complementary, polyamphiphilic surfaces (4) provided by an oligosaccharide and the combining site of a protein are attractive and surely contribute importantly to the specificity of the recognition (1). However, these attractive polar forces are not necessarily of prime importance to the stability of the complex. This can arise should the difference between the energy of interaction of the two complementary surfaces with water (in large excess) prior to complexation be greater than the interaction between these surfaces once the complex has formed. To our knowledge, this possibility has not previously received quantitative analysis in the context of a model that represents a real situation. This is why we undertook computer simulations of hydration by Monte Carlo methods of a structually well-defined oligosaccharide, a lectin with a specific affinity for the oligosaccharide and the oligosaccharide–lectin complex that is formed.

The system used as a model is the association of the lectin, termed GS-IV, which is readily isolated (7) from the plant *Griffonia simplicifolia*, and a tetrasaccharide, termed Le^b-OMe, which corresponds in structure to the Lewis b human blood group determinant (8). The calculations reported in this communication were achieved using the X-ray structures for the native lectin at 2.15 Å resolution. Although the structures are now known at 2.0 Å resolution (9), the calculations were not repeated since the very small differences do not influence the conclusions reached in this initial study. A detailed description of Monte Carlo methods used to examine the hydration of Le^b-OMe has already been reported (10). As in the present study, the energies of interaction between the receptor and water and between water molecules were evaluated with Clementi's potentials (11–13).

The lectin GS-IV is a metalloglycoprotein that consists of two largely homologous subunits, each of which binds one molecule of Le^b-OMe in identical combining sites (14). A correspondence of the crystal structure of the complex with that in solution emerged from a comparison of the binding potencies of Le^b-OMe and selectively deoxygenated and *O*-methylated derivatives (15). Furthermore, the structure of Le^b-OMe in the crystalline complex (9, 15) is in close agreement with the solution conformational preference predicted by HSEA calculations and confirmed by ^1H nmr spectroscopy (16, 17). We were further encouraged to embark on the Monte Carlo simulations by the observation that the X-ray structures of the amino acid residues that form the combining site in the native GS-IV are virtually superimposable on their positions in the complex (see Fig. 2C) (9).

As mentioned above, we have reported the results of Monte Carlo simulations of the hydration of Le^b-OMe (10). There were significant differences in the interactions of the hydrophilic and hydrophobic surface areas with water. The hydrophilic groups were found to be tightly solvated and the water dipoles strongly aligned around polar substituents. In contrast, the hydrophobic surfaces were much more weakly solvated. The inner water shell was on average about 1 Å farther away from the ligand, and there was no correlation whatever between the orientation of the water dipoles and solute surface features. This picture supported earlier expectations (1) that the filling of voids present in a layer of perturbed water molecules at the surface of polyamphiphilic surfaces provides an important driving force for association.

That such changes in water structure can play an important role in the overall driving force for association is well demonstrated by the results we obtained on probing the combining site of Le^b-OMe with monodeoxy derivatives of the ligand (3, 15). The effect on binding could only be measured when, in the complex, the affected hydroxyl group was at or near the periphery of the combining site. In all cases the differential change in entropy was small because of enthalpy–entropy compensation. However, differential changes in enthalpy as high as 6 kcal/mol result from differences in the hydration shells over the small areas affected by the deoxygenation (3). In the case of an association involving the large surfaces from which water must be expelled to bulk, much larger changes involving water must occur that favor complex formation. The main purpose of this communication is to document in detail the molecular association that was chosen for study and to describe how the Monte Carlo method was used to simulate the hydration of the protein surface that provides the combining site. The preliminary results are seen to provide qualitative support for the expectation responsible for the project: namely, that the association of hydrophilic species is driven in part by a decrease in the exposure to water of polyamphiphilic surfaces.

Methods

The Monte Carlo method published by Metropolis et al. (18) was applied as previously reported for the hydration of Le^b-OMe (10). For the Monte Carlo simulation of GS-IV, the lectin was represented by a model comprised of 62 of the 243 amino acid residues of one subunit. These residues, listed in Table 1, were chosen on the basis of their distances from Le^b-OMe in the crystal structure of the complex and are not necessarily contiguous. This model for the protein is small enough to permit simulations at acceptable CPU times and large enough to accommodate at least three layers of water around the combining site, which is at the centre of the model and herein referred to as the receptor. N-terminal residues were converted to amines and C-terminal residues to amides, in order to minimize the structural changes resulting from cutting the peptide chain. All Asp, Glu, Lys, and Arg side chains were assumed to be electrically charged. The X-ray coordinates for the native GS-IV lectin (Fig. 2B) and its complex with Le^b-OMe (Fig. 2A) at 2.15 Å resolution were used throughout the calculations.

It was necessary to establish an enclosure for 250 water molecules on top and around the combining site with the dimensions along the x and y axes of sufficient length to provide at least three water molecules beyond the periphery of the site. The first step was to set the vector from the center of mass of the protein fragment in the complex to the center of mass of the ligand as the z-axis of a Cartesian coordinate system. The complex was then replaced by the native lectin by least-squares superposition (Fig. 2C). The water enclosure was then built on and above the orientation thus achieved for the combining site of the native lectin.

The cross section of the box on the lectin fragment is 21.0×17.6 Å. The final dimension of the box was established in two steps. The top of the box was first set arbitrarily and the volume of the box, so defined, determined. The surface of the protein inside the box was defined, following Connolly (19), by rolling a sphere of 1.5 Å radius over the lectin fragment so that distances from the top of the box could be determined. The top of the box was then divided into a grid of equal areas that were about 0.1×0.1 Å. The distances of the centers of these grid

Class designation	Substitution pattern
H01	Methyl group hydrogens
H12	α-Hydrogens
H13	Hydrogens on secondary and tertiary sp^3 carbons
H14	Hydrogens on sp^2 carbons
H18	Hydroxyl group hydrogens
H21	H_2-N hydrogens on N-terminal residues
H22	H_2N hydrogens of C-terminal residues and side chain amides
H23	H-N hydrogens of peptide bonds
H24	H-N(sp^2) hydrogens in *His, Trp*
H28[b]	H-N hydrogens of charged *Arg* and *Lys* side chains
C01	Methyl group carbons
C13	Secondary and tertiary sp^3 carbons
C14	NH_3^+-bearing carbon of *Lys*
C15	Alcoholic sp^2 and sp^3 carbons
C16	Carbon in C-terminal and side chain amides and C_ζ of *Arg*
C17	α-Carbons of peptide bonds
C18	Hydrogen-bearing sp^2 carbons
C19	C_γ, $C_{\delta 2}$, and $C_{\varepsilon 1}$ in *His*, C_γ and $C_{\delta 1}$ in *Trp*
C22	C_γ in *Phe* and *Tyr*, $C_{\delta 2}$ in *Trp*
C24	$C_{\varepsilon 2}$ in *Trp*
C28	Amide carbons in peptide bonds
C34[b]	Carboxylate carbons
N01	Nitrogen in C-terminal amides
N02	Nitrogen in N-terminal amino acids
N04	Nitrogen in peptide bonds
N05	$N_{\delta 1}$ in *His*
N06	$N_{\varepsilon 2}$ in *His*, $N_{\varepsilon 1}$ in *Trp*
N10[b]	*Arg* side chain nitrogen
N11[b]	*Lys* side chain nitrogen
O03	Oxygen in hydroxyl groups
O07	Oxygen in side chain amides
O08	Oxygen of peptide bonds and C-terminal amides
O17[b]	Carboxylate oxygen

[a]Class definitions and enery parameters taken from ref. 11, unless indicated otherwise (see footnote *b*).
[b]Class definitions and energy parameters taken from ref. 12.

squares from the surface of the protein were then summed up and multiplied by the area of the grid square to provide the volume of the box. The height of the box was then adjusted to provide the volume that would be occupied by 250 water molecules at a density of one.

Following the procedure developed by Metropolis et al. (18), in order to avoid the water interfacing with void, the box was surrounded in the *x*, *y* plane by eight boxes of identical dimensions and water contents. This 3×3 array was then topped by inverting the water coordinates in the bottom layer through the center of the top face of the original box. The internuclear distances used in the energy calculations were the distances from the water molecules in the original box to the receptor atoms in the same box and to the closest of the 18 images of each of the other water molecules in the original box.

The energies of interaction between the receptor and water and between water molecules were evaluated with Clementi's potentials (11–13), as previously described for the hydration of Le^b-OMe (10). The class assignments are shown in Table 2.

All simulations were carried out on a model consisting of one receptor and 250 water molecules at 300 K and unit water density. Each simulation consisted of 1000 equilibration and 5000 sampling cycles, starting from randomly positioned and oriented water molecules. In each cycle every water molecule was tentatively moved once, in a different random sequence and in random translational and rotational steps of maximally 0.1 Å and 0.1 radians along and around the three coordinate axes. The water coordinates after every tenth sampling cycle were stored in a file for later analysis. The convergence toward equilibrium of calculated energies of interaction is plotted in Fig. 3.

The energy and density plots of Figs. 4 and 5 were established by moving a 4 Å thick cross section of the water-accessible space above the combining site down through the box in 0.5 Å steps. The cuts through the hydration shell were either straight and parallel to the box top or followed the contours of the receptor surface, which was again defined by a probe sphere of 1.5 Å radius. The weight used in the density evaluations (Fig. 5) was the sum of the masses of all nuclei falling into any given volume slice.

The calculations were carried out on a Cray X-MP computer at the Ontario Center for Large Scale Computing and on Convex 210 and IBM RS/6000 model 560 computers at the University of Alberta.[7]

Discussion and results

Water is a unique liquid of crucial importance to life. Accordingly, hydration phenomena have received enormous attention. A series of comprehensive treatises of the more physical and chemical aspects of the subject, edited by Franks (20), review the developments up to 1981. These monumental efforts together with the publication (21) of the proceedings of a conference on the biophysics of water, held in 1981, remain highly pertinent. The subject is still under intensive investigation as evidenced by the search for a realistic view of the hydrophobic effect presented by Muller (22) in 1990 and the simple two-structure model for liquid water published by Benson and Siebert (23) in 1992. Nevertheless, the results of our investigations of the recognition of oligosaccharides by proteins are not well accommodated by prevailing notions on the subject, which largely focus on entropy barriers (24, 25) and the energies of interaction between groups at the complementary surfaces that interact to form the complex.

Franks (26) has suggested, "... if a sugar molecule is introduced into water, the ease of forming sugar–water hydrogen bonds will depend to a large extent on the spacings and orientations of the polar groups relative to the -OH geometry in water." Such considerations have led to an emphasis on how water may affect the molecular conformation of the presumed conformationally highly flexible reactants — either the protein (24) or the oligosaccharide (25). On the other hand, a great deal of evidence based on nuclear magnetic resonance has accumulated that the naturally abundant sugars and their glycosides show marked conformational preferences in aqueous solution. This characteristic is particularly evident for branched oligosaccharide structures (6, 27). Recently, Galema and Høiland (28) reported partial molar compressibilities for a variety of mono- and disaccharides. The results appear to indicate a dependence on how well the carbohydrate fits the presumed three-dimensional hydrogen-bonded structure of water. However, as recently reiterated by Benson and Siebert (23), water is a "structural" liquid because the molecules are held together by strong oriented polar forces, usually hydrogen bonds. Random network models are normally envisaged that lead, as suggested in 1957 by Frank and Wen (29), to highly transient well-defined clusters of water molecules of lower entropy than average for the system but with stronger than average hydrogen bonds. These structural fluctuations (flickering clusters) (29) do not allow water molecules to fill space well and voids are expected. For similar reasons, it was thought that water must have difficulty in filling the space over polyamphiphilic surfaces (3, 6) and this expectation found support in Monte Carlo simulations of the water structure at 300 K over the surface of the tetrasaccharide displayed in Fig. 1 (10). These calculations infer a random connectivity in that all the possible hydrogen bonds exist between structurally rigid molecules with some so stretched and bent as to be essentially broken. The potential functions used in the Monte Carlo calculations, to be discussed below, encompass all the forces often invoked in discussions of this type such as dispersion (van der Waals) forces, polar interactions, and hydrogen bonds. Thus, in view of the great complexity in a system employing 250 water molecules interacting over 62 amino acid residues, a number of simplifying assumptions had to be made. Nevertheless, the picture that evolved is expected to be of real significance to the appreciation of the role of water in biological associations and, thereby, of major heuristic value.

The X-ray crystal structure of a portion of the GS-IV (Le^b-OMe)$_2$ complex at 2.15 Å resolution involving 62 amino acid residues is displayed in Fig. 2A where the five hydroxyl groups that remain in contact with water are identified (see Fig. 1) (15). The corresponding 2.15 Å X-ray crystal structure of the native GS-IV is presented in Fig. 2B where five of the amino acid residues that form hydrogen bonds with Le^b-OMe (see Fig. 1) are identified. The region of the combining site is seen to be a shallow polyamphiphilic cavity with a surface area of approximately 240 Å^2 and average depth of about 2.2 Å. In Fig. 2C, the Le^b-OMe was removed from the complex (Fig. 2A) to leave the 62 amino acid residues in and about the combining site. Selected atoms at the periphery are displayed in yellow. These atoms are superimposed on top of the corresponding atoms of the native lectin (Fig. 2B), which are displayed in red. The purpose of this figure is to demonstrate that there occur only slight adjustments of the protein structure in the course of complex formation. Likely, little energy separates these two conformers and the range of fluctuation is small. Therefore, it is expected that the results obtained in the Monte Carlo simulation of the hydration of the native lectin will be well representative of the hydration clusters about all conformers at thermal equilibrium (300 K).

Figures 2D, 2E, and 2F display the water structure that was randomly built at 300 K over the receptor portion of the native lectin, which contains the combining site (Fig. 2B), and that

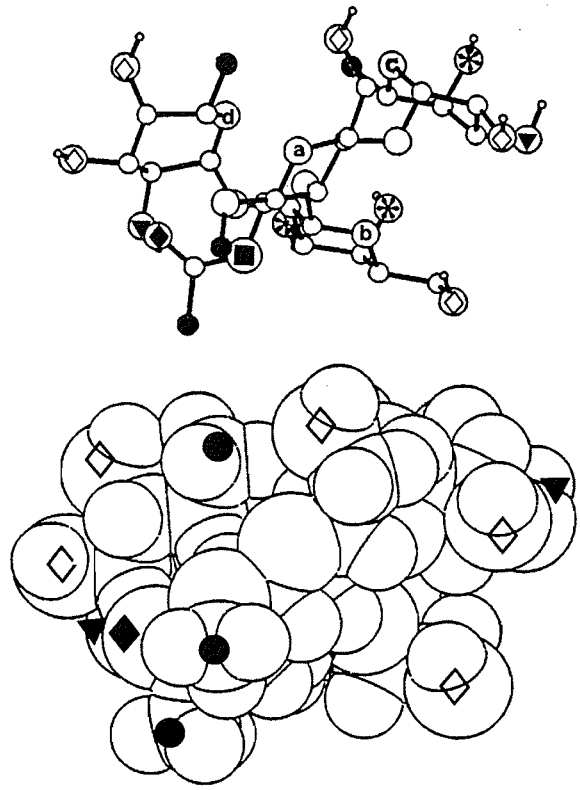

FIG. 1. Stick and CPK models of the Le^b-OMe tetrasaccharide, α-L-Fuc(1d → 2b)-β-D-Gal(1b → 3a)-[α-L-Fuc(1c → 4a)]-β-D-GlcNAc-OMe, as viewed in Fig. 2A in the complex with the lectin GS-IV. FIG. 2. CPK representations of the models used in the Monte Carlo simulations of the hydration of the combining site of the fourth lectin of *Griffonia simplicifolia* (GS-IV). A. X-ray structure at 2.15 Å resolution of the complex between GS-IV (dark colours) and Le^b-OMe (light colours). The five labelled hydroxyl groups of Le^b-OMe remain in contact with water. The combining site is represented in the simulations by 62 of the 243 residues of one of the two GS-IV subunits. B. X-ray structure at 2.15 Å of the same 62 residues in native GS-IV, shown in the same orientation as the complex in Fig. 2A. The labelled GS-IV residues are hydrogen bonded to hydroxyl groups 3b, 4b, and 4c of Le^b-OMe. All Monte Carlo simulations were carried out with this fragment. C. Structure of native GS-IV, as shown in Fig. 2B. Atoms that are hydrogen bonded to Le^b-OMe and atoms on the periphery of the combining site, i.e., in contact with both Le^b-OMe and water, are highlighted in red. The corresponding atoms in the GS-IV complex are superimposed in yellow. D. Side view of the 62 residues of GS-IV shown in Fig. 2B, covered by a block of 250 water molecules at the end of a typical Monte Carlo run at unit density and 300 K. The block of water in this figure and in Figs. 2E and 2F has a cross section of about 21.0 × 17.6 Å and an average height of 20.2 Å. E. The block of water shown in Fig. 2D, without the GS-IV residues. F. Top view of the hydration cluster shown in Fig. 2D. G. The GS-IV residues shown in Fig. 2B with the aromatic residues encircling the combining site highlighted. H. The GS-IV residues shown in Fig. 2B, with the seven oxygen atoms of water molecules (light blue) in the combining site found by X-ray crystallography. I. Native GS-IV with those seven water molecules (light blue) in the cluster in Figs. 2D–2F that most closely reproduce the X-ray water oxygen coordinates in Fig. 2H. The standard deviation between the water oxygen coordinates in Figs. 2H and 2I was about 1.2 Å.

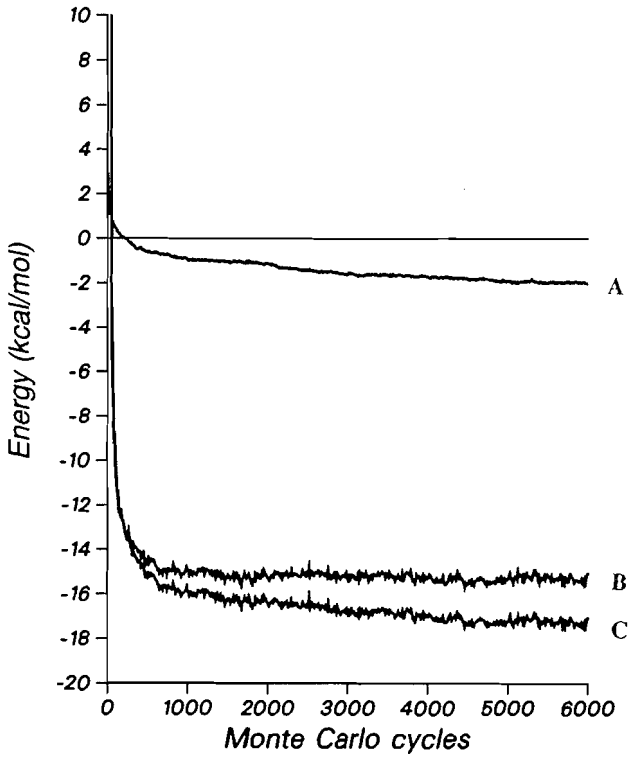

FIG. 3. The convergence toward equilibrium of calculated energies of interaction on extending the number of Monte Carlo cycles. A. was brought to simulated thermal equilibrium by 6000 Monte Carlo cycles. The course of this equilibrium study is presented in Fig. 3. Plot B of this figure indicates that the energy of interaction between water molecules reaches a steady state after 1000 cycles. This is not quite the case for the energy of interaction with the protein, as seen in Fig. 3A. Nevertheless, the foregoing discussions are based on samplings in the range of 1000–6000 Monte Carlo cycles since to do so was compatible with the available CPU times. In view of the necessarily overall semiquantitative nature of this study, the drift in energy of interaction of only about 1 kcal/mol over the 1000–6000 Monte Carlo cycles is considered insignificant especially since, as we shall see, this represents only a small fraction of the actual energies of interaction that come into play.

That the Monte Carlo calculations simulate well the hydration of the protein is supported by the following observations. First of all, the simulation of bulk water provided results that are acceptable in terms of certain known physical properties of water. Calculation of the hydrogen bond strength for the interaction of two water molecules for which the nuclei of the oxygen and a hydrogen of one are colinear with the nucleus of the other provides a bond strength of 5.8 kcal/mol (13), in good agreement with the about 5.7 kcal/mol value that is commonly accepted (23). The water–water interaction energies plotted in Fig. 4 are average energies of interaction between any one of the water molecules and all the others. The average calculated energy gained on condensation (or required for vaporization) is half the estimated value (−18 kcal/mol), since the sum of the average water–water interaction energies counts every pairwise interaction twice. This −9 kcal/mol value is in fair agreement with the experimental heat of vaporization, 10.5 kcal/mol (23). The calculations find further support in the close resemblance of Figs. 2H and 2I. A number of strongly held water molecules were located in the crystal structure of the native GS-IV (Fig. 2B). Those present in the cavity of the combining site are displayed in Fig. 2H. It is seen that a very similar array of seven water molecules was produced by the Monte Carlo simulation and, as seen from plot B of Fig. 4, must be strongly held in place near the surface of the receptor. We conclude, therefore, that the Monte Carlo simulations likely provide a realistic semiquantitative appraisal of the interaction energies between the molecules in the ensemble.

As seen in Fig. 3, the hydration of the protein fragment reached thermal equilibrium after 1000 Monte Carlo cycles. It is seen (plot B) that the equilibrium energy of interaction between the water molecules reached a steady state near −15 kcal/mol. The interactions of the water molecules with the protein fragments nearly reached equilibrium after 1000 cycles with an interaction energy of approximately −1.0 kcal/mol. However, in this case, the energy of interaction, as indicated above, changed slowly to about −2 kcal/mol after 6000 cycles. This small increase in the strength of the interaction with increasing Monte Carlo cycles likely resulted from water molecules slowly penetrating the protein structure. The occurrence of this phenomenon, however, has no bearing on the goal for the investigation, which was to demonstrate the presence of a strongly perturbed layer of water at the surface of the combining site. That this is in fact the case is readily appreciated from

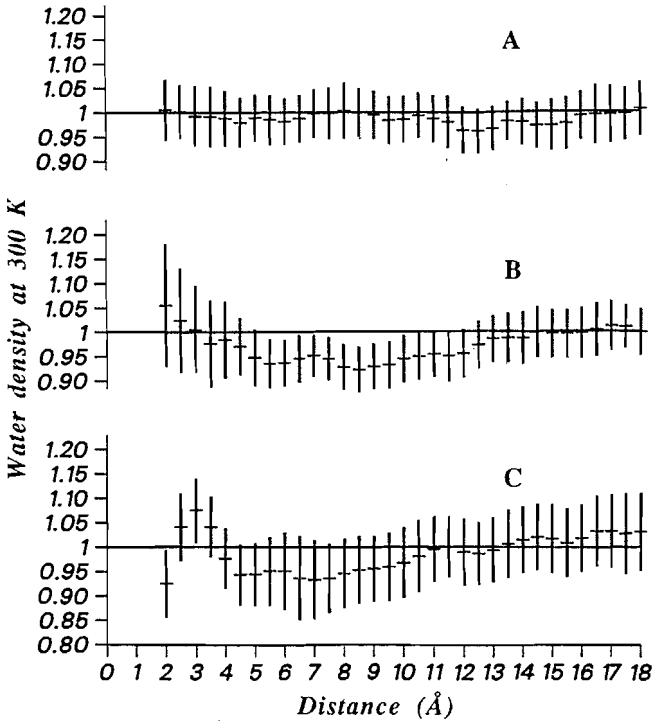

FIG. 5. Changes in density with distance for 4 Å cross sections of water structures averaged over 10 separate Monte Carlo runs taking samples every 50 cycles up to 5000 cycles in each run. A. Densities for a 21.0 × 17.6 × 20.2 Å rectangular block of 250 water molecules with initial density set at 1.0. B. Densities of the water structure displayed in Fig. 2D calculated in terms of straight cross sections. C. Same as in B except that the cross sections followed the contour of the combining site.

the slope of plot C in Fig. 4. It is seen that the energy of interaction between water molecules increases from about −10 kcal/mol to near −17 kcal/mol as the distance of the water molecules increases from 2 to 8 Å.

The plot in Fig. 4A indicates that our Monte Carlo simulation method assigns a value of close to −18 kcal/mol for the energy of interaction of water molecules in bulk. The averaging of the energies of interaction between water molecules near the protein surface with those approaching bulk conditions is responsible for the average interaction in Fig. 3B not reaching that for bulk water in the model used.

The structural changes revealed by the energy gradients (Fig. 4) are also reflected in density variations (Fig. 5). Near the receptor the density of the hydration shell is at a maximum. At intermediate distances the density goes through a minimum and at larger distances it approaches the density of bulk water. It is also noteworthy at this time that the strongly held water molecules of the first layer can be expected to be of lower entropy content than those in bulk water. Thus, their release on complex formation should counteract the increase in enthalpy required for dehydration of the receptor site. Furthermore, in a manner similar to the increases in entropy that arise from the release to bulk of the "flickering clusters" (29) of the hydrophobic effect, it can be expected that "flickering cavities" in the structure of water over polyamphiphilic surfaces also provide a favorable change in entropy. The next stage of this investigation will be Monte Carlo simulations of the actual association between Le^b-OMe and GS-IV.

We wish to emphasize that the interaction energies calculated are for only one energetically favorable conformer for each of the water, tetrasaccharide, and lectin molecules. The hydration of other conformers will surely not produce the same numerical values. However, we do not expect that our general conclusion will be radically changed. We consider, therefore, that the condensation of perturbed water molecules from polyamphiphilic surfaces will prove of broad involvement in the course of biological associations. This opinion appears supported by the thermodynamic data for polyphenol interactions with water recently reported by Dangles and Brouillard (30).

Gas and solution phase thermochemistry and transition energies of $NH_2^\bullet$ and $NH_3^{\bullet+}$, and their aquo complexes: an *ab initio* study

DAKE YU, ARVI RAUK,[1] AND DAVID A. ARMSTRONG[1]

Department of Chemistry, The University of Calgary, Calgary, AB T2N 1N4, Canada

Received May 5, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

DAKE YU, ARVI RAUK and DAVID A. ARMSTRONG. Can. J. Chem. **72**, 471 (1994).

Ab initio calculations were performed on several aquo complexes of $NH_2^\bullet$, and $NH_3^{\bullet+}$, and on monomeric parent species. The geometries were optimized at the HF/6-31+G* level and the vibrational frequencies were calculated. The total energies and the binding energies of complexes were evaluated at the MP2/6-31+G* + ZPE level of theory. Gas and aqueous solution phase thermodynamic properites of $NH_2^\bullet$ and $NH_3^{\bullet+}$ and several other species were calculated. The examination of solution phase properties of the radicals was facilitated by study of the structures and transition energies of aquo complexes. H-bonding interaction energies decreased in the order OH···N > OH···O > NH···O, but were generally stronger than σ–σ* interactions involving the unpaired electron. From calculations with the CIS method, the weak absorption observed at 520 nm for aqueous $NH_2^\bullet$ is confirmed as a $^2B_1 \rightarrow {}^2A_1$ transition, while the stronger $NH_2^\bullet$ absorption occurring below 250 nm and the absorption of $NH_3^{\bullet+}$, which rises monotonically below 370 nm, are attributed to solvent-to-solute charge transfer bands. The solution free energies and related E^0 values for $NH_2^\bullet$ and $NH_3^{\bullet+}$ are in agreement with those of Stanbury. The *ab initio* structure studies show that water protons are bound to N, and proton transfer from solvent in reaction [18], $NH_2^\bullet + e^- + H_2O \rightarrow NH_3 + OH^-$, is likely to be the dominant redox reaction of $NH_2^\bullet$ in alkaline solution. The free energy of solution of $NH_3^{\bullet+}$ is shown to be larger than that of NH_4^+.

DAKE YU, ARVI RAUK, et DAVID A. ARMSTRONG. Can. J. Chem. **72**, 471 (1994).

On a effectué des calculs *ab initio* sur plusieurs complexes aqueux du $NH_2^\bullet$ et $NH_3^{\bullet+}$ et sur les espèces monomères parentes. On a optimisé les géométries au niveau HF/6-31+G* et on a calculé les fréquences vibrationnelles. On a évalué les énergies totales et les énergies de liaison des complexes au niveau MP2/6-31+G*+ZPE de la théorie. On a calculé les propriétés thermodynamiques du $NH_2^\bullet$ et $NH_3^{\bullet+}$ et des plusieurs autres espèces en phase gazeuse et en solution. L'examen des propriétés des radicaux en solution a été rendu plus facile par l'étude des structures et des énergies de transition des complexes aqueux. Les énergies d'interaction des liaisons hydrogènes diminuent dans l'ordre OH···N > OH···O > NH···O; toutefois, elles sont généralement plus fortes que les interactions σ–σ* impliquant l'électron non apparié. Sur la base de calculs faisant appel à la méthode CIS, on peut confirmer que la faible absorption observée à 520 nm pour le $NH_2^\bullet$ aqueux est due à une transition $^2B_1 \rightarrow {}^2A_1$ alors que l'absorption plus forte du $NH_2^\bullet$ apparaissant en-dessous de 250 nm et celle du $NH_3^{\bullet+}$, qui augmente d'une façon monotone en-dessous de 370 nm, sont attribuées à des bandes de transfert de charge du soluté. Les énergies libres en solution et les valeurs de E^0 apparentées pour le $NH_2^\bullet$ et le $NH_3^{\bullet+}$ sont en accord avec celles de Stanbury. Les études de structures *ab initio* montrent que les protons de l'eau sont liés à l'azote et que le transfert de proton du solvant dans la réaction [18], $NH_2^\bullet + e^- + H_2O \rightarrow NH_3 + OH^-$, est probablement la réaction rédox la plus important du $NH_2^\bullet$ en solution alcaline. On montre que l'énergie libre de solution du $NH_3^{\bullet+}$ est plus importante que celle du NH_4^+.

[Traduit par la rédaction]

1. Introduction

The $NH_2^\bullet$ and $NH_3^{\bullet+}$ radicals, which can be formed by H atom or electron abstraction from ammonia, are of considerable importance in inorganic redox chemistry (1–3). They are also prototypes of the nitrogen-centered organic amino radicals that occur in numerous organic and biochemical systems (4, 5), and their reactions are of interest in corrosion chemistry (6). In aqueous solution, $NH_2^\bullet$ radicals can be made in reaction [1]

[1] $$Ti^{III} + NH_2OH \rightarrow Ti^{IV} + NH_2^\bullet + OH^-$$

or in pulse radiolysis by abstraction of H atoms from NH_3 with $OH^\bullet$ (7, 8)

[2] $$OH^\bullet + NH_3 \rightarrow H_2O + NH_2^\bullet$$

$NH_3^{\bullet+}$ cations can be made by photolysis of NH_3 complex ions (1, 9), e.g.,

[3] $$Co^{III}(NH_3)_6^{3+} + h\nu \rightarrow Co^{II}(NH_3)_5(NH_3^\bullet)^{3+}$$

I

[4] $$\mathbf{I} \rightarrow Co^{II}(NH_3)_5^{2+} + NH_3^{\bullet+}$$

[1]Authors to whom correspondence may be addressed.

Radicals produced by those methods have been examined by polarography (10, 11) and ESR (12, 13), and the kinetics of some of their reactions have been investigated by fast-reaction techniques (6–9, 13). Extensive gas phase investigations on the species have been conducted (14–16) and theoretical calculations on their energies and structures have been made at relatively high level (17).

Because of the very great interest in the reactions and properties of nitrogen-centered radicals in aqueous systems, we decided to examine the existing data on the gas phase structures and thermochemical properties of $NH^{\bullet-}$, $NH_2^\bullet$, and $NH_3^{\bullet+}$ and the related species shown in Scheme 1, in which the experimental and calculated (G2, in parentheses) values of enthalpy changes (14, 17) are given in kJ mol^{-1}.

We also used *ab initio* methods to investigate the aquo complexes of $NH_2^\bullet$ and $NH_3^{\bullet+}$. Here the objectives were to obtain an understanding of the interactions between the radicals and the H_2O solvent molecules, and to determine how the structures and energy levels of the nitrogen centers might be affected in these complexes. Three types of interaction have been considered: (a) H bonds of H_2O to the N lone pairs of the radicals, (b) H bonds of the $NH_x^\bullet$ radicals to lone pairs of H_2O, and (c) σ–σ* lone pair to unpaired electron interactions, as illustrated in Scheme 2.

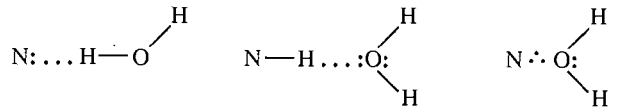

SCHEME 2

To the extent that it is important, the last type of interaction in particular would be expected to have a strong effect on the redox properties and absorption spectra of the radicals. Because of the possibility of radical–solute interactions in more concentrated ammonia solutions, we also examined the corresponding interactions between the radicals and NH_3 molecules.

The computational details are described in Sect. 2. The results of these computations are presented and discussed in Sect. 3. In Sect. 4, the results are used in a critical examination of the thermodynamic and redox properties, and the UV–visible absorption spectra of $NH_2^{\cdot}$ and $NH_3^{\cdot+}$ in aqueous solution. General conclusions are summarized in Sect. 5.

2. Computation details

Ab initio *calculations*

All *ab initio* calculations presented here were performed with the GAUSSIAN 90 molecular orbital packages (18). The geometries of the molecules were optimized at the HF level with the 6-31+G* basis set, which includes diffuse functions important for species with nonbonded electrons. Convergence of the geometry was to the limit imposed internally in GAUSSIAN 90. No symmetry was assumed at the beginning of each geometry optimization, but if the optimization ended with a nearly symmetric structure, the molecule's symmetry was verified. Vibrational frequencies were calculated to verify the character of all the structures as minima on the potential energy surfaces. The vibrational frequencies calculated at the HF/6-31+G* level were scaled by a factor of 0.89 (19) in considering the zero-point energy (ZPE) corrections and in the calculation of thermodynamic properties. Correlation corrections to the total energies were estimated by single-point calculations with the same basis set at the level of second-order Møller–Plesset perturbation theory (MP2). The energies and oscillator strengths of the lower electronically excited states were calculated using the all singles configuration interaction (CIS), as implemented in GAUSSIAN 90, with the same basis set. The CIS model is not expected to yield accurate excitation energies, but should correctly characterize the lower electronically excited states. For the complexes, the binding energies were defined as $E_b = E(\text{complex}) - \Sigma E(\text{fragment})$, where the E's are total electronic energies plus ZPE values of the species at the HF/6-31+G* optimized geometries. These binding energies were calculated using both the HF/6-31+G* and the MP2/6-31+G* energies. Overestimation of the binding energy because of basis set superposition effects is expected to be small (less than 3 kJ mol^{-1} on the basis of a previous study (20) on similar systems), and was not explicitly taken into account.

Thermodynamic properties

Ideal gas thermodynamic functions C_P^0, S^0, and $H^0 - H_0^0$ in the temperature range 0–298.15 K and at 1 bar (= 100 kPa) were calculated by standard statistical thermodynamic methods based on the rigid rotor – harmonic oscillator model. The lowest vibrational modes were treated as internal rotations. The barriers for the internal rotations around the hydrogen bonds are usually very low; therefore, the calculations were carried out using the free rotor model for such rotations. The values of S^0 and $H^0 - H_0^0$ for the reference elements are taken from ref. 21. The calculation of $\Delta_f H^0$ and $\Delta_f G^0$ values reliable to ±10 kJ mol^{-1} requires either the knowledge of $\Delta_f H_0^0$ from calculations at the G2 level (17) or an experimental value of $\Delta_f H^0$ of comparable or better reliability at at least one temperature. Values of $\Delta_f H^0$ were calculated for species where such results were available. The most reliable values of $\Delta_f H^0$ are used in conjunction with the entropy data to obtain $\Delta_f G^0$.

3. Computational results and discussion

The optimized geometries of the monomeric species and the complexes are plotted in Figs. 1 and 2, respectively. Ex-

cept for a few hydrogen atoms in $(H_2O)_2\cdots H_2N^\bullet\cdots HOH$ and $(H_2O)_3\cdots \boldsymbol{H}_3N^{\bullet +}$, the full geometries of the molecules can be determined from the listed characteristic parameters and the symmetry types. The formulae, total electronic energies, and ZPE values of the aquo complexes, which were found to be minima on the potential energy surfaces, and of the monomeric species are listed in Table 1, along with G2 energies for some of the species from other studies (17, 20). The vibrational frequencies are reported in Table 2. Gas phase thermodynamic data for the monomeric species and the complexes at 0–298.15 K have been given in Tables 3 and 4, according to whether the calculations of $\Delta_f H^0$ and $\Delta_f G^0$ were performed. The binding energies of the complexes are collected in Table 5.

Throughout the paper, three dots (···) have been used to separate complexed partners and proximity denotes the nature of the interaction. Thus $HOH\cdots NH_3$ denotes a complex between water and ammonia with an OH···N bond. The "isomeric" complex with an O···HN bond would be denoted as $H_2O\cdots HNH_2$. Where necessary for clarity, the hydrogen-bonded H atom is distinguished by bold italic font $\boldsymbol{H}$.

Monomeric species

The equilibrium structures of H_2O and NH_3 are well established and will not be discussed. However, it may be noted that the optimized geometries at the HF/6-31+G* level are reasonable compared with those of experiments (H_2O: expt. (21) HO = 0.9584 Å, < HOH = 104.45° and calcd. HO = 0.948 Å, < HOH = 106.5°; NH_3: expt. (21) HN = 1.0124 Å, < HNH = 106.67° and calcd. HN = 1.002 Å, < HNH = 108.1°).

The experimental geometries for NH_4^+ and $NH_2^\bullet$ are also available. For NH_4^+, calculated HN bond lengths are 0.01 Å shorter than the experimental value (expt. HN = 1.026 (22), 1.021±0.003 Å (23); calcd. 1.013 Å). For $NH_2^\bullet$ the calculated HN bonds are 0.01 Å shorter, while the HNH angle is larger by 2° than the experimental values (expt. (21) HN = 1.024 Å, < HNH = 103°, calcd. HN = 1.012 Å, < HNH = 105.2°). The optimized $NH_3^{\bullet +}$ has D_{3h} symmetry, with HN bond lengths identical to those in $NH_2^\bullet$.

The scaled (by a factor of 0.89) HF/6-31+G* vibrational frequencies obtained here for H_2O, 1599, 3623, and 3730 cm^{-1}, agree well with experimental values, 1595, 3657, and 3756 cm^{-1} (21). This was also true for NH_3 frequencies; calculated: 1039, 1644, 3292, and 3414 cm^{-1}; experimental (21): 950, 1627, 3336, and 3444 cm^{-1}, respectively. For NH_4^+, only the degenerate NH stretch frequencies have been measured (24), being 3343 cm^{-1} (calculated 3305 cm^{-1}). The calculated frequencies of $NH_2^\bullet$ (1502, 3220, and 3311 cm^{-1}) also show good agreement with the measured (21) ones (1499, 3173, and 3220 cm^{-1}).

The ideal gas thermodynamic properties at 298.15 K can be compared with the available experimental results, which are given in Table 3. For the values of C_p^0, S^0, and $H_0 - H_0^0$, which are used in the calculations of $\Delta_f H^0$ and $\Delta_f G^0$ at different temperatures in columns six, seven, and eight, the agreement is excellent. The agreement between the values of $\Delta_f H^0$ derived from G2 energies (column six) and the most reliable experimental values (column seven, bold font) is also good. Given that the values of NH_3 and $NH_2^\bullet$ are the best known (16), the experimental values of $\Delta_f H^0$ for the other species in column seven of Table 3 were checked from the enthalpy of reaction for the processes in Scheme 1. It may be noted that in most instances this confirmed the values reported in ref. 14 as being the most reliable.

Enthalpies of ionization and proton affinities at 298.15 K were calculated from the G2 energies of ref. 17, using the $H^0 - H_0^0$ data in Table 3. These are presented in Scheme 1, along with available experimental data, which were also corrected to 298.15 K where necessary. As previously observed

(25, 26), agreement is good to within a few kJ mol^{-1} in all cases where comparison is possible. For NH_2^- the experimental proton affinity leads to $\Delta_f H^0 = 114.6$ kJ mol^{-1} at 298 K, while the more recent and precise (±0.5 kJ mol^{-1} (15)) electron attachment enthalpy of $NH_2^\bullet$ yields 112.8 kJ mol^{-1}. The value adopted is 113.0 kJ mol^{-1}, the same as that previously listed in ref. 14. There is no experimental proton affinity for $NH_2^\bullet$. However, the G2 proton affinity of this species and the ionization enthalpy of NH_3 give $\Delta_f H^0$ of $NH_3^{\bullet +}$ 938 and 937 kJ mol^{-1}, respectively. Both are in acceptable agreement with 934 kJ mol^{-1} in Table 3, column seven, which can be calculated from the experimental IP of NH_3 as in ref. 14. The consistency of the data obtained by the two routes for both NH_2^- and $NH_3^{\bullet +}$ also confirms the reliability of $\Delta_f H^0_{298} = 189$ kJ mol^{-1} for $NH_2^\bullet$.

Scheme 1 gives only one route to each of the species NH_4^+ and $NH^{\bullet -}$. For the former the experimental and G2 proton affinities are effectively identical and the value of $\Delta_f H^0_{298}$ (630 kJ mol^{-1}) used here is the same as in ref. 14. For the latter, the G2 result in Table 3 is preferred, since it is more reliable than the current experimental result. The values of $\Delta_f G^0$ listed in the last column of Table 3 were calculated from the most reliable values of $\Delta_f H^0$ and the entropies in Table 3. They are used in Sect. 4 in the evaluation of solution properties.

Complexes

The structures of the complexes plotted in Fig. 2 are minima on the potential energy surfaces as verified by the fact that all their vibrational frequencies are real. However, in some cases, as indicated by the low vibrational frequencies in Table 2, the minima are so shallow that the relative orientations of the fragments can change substantially without significant change in energies. In other words, for some complexes more than one conformer with similar total energy might exist.

For binary complexes, there are six more vibrational modes than the sum in the fragments and the total ZPE correction is significant even for the weakly hydrogen-bonded complexes. With the frequencies of normal modes involving the hydrogen bond having fewer than a few hundred wave numbers, the ZPE corrections ranged from 6 to 9 kJ mol^{-1}. In the strongly bonded H_3N–$NH_3^{\bullet +}$ species, the six extra vibrational modes reduce the binding energy by 20 kJ mol^{-1} from the vibrationless binding energy. In $(H_2O)_2\cdots H_2N^\bullet\cdots HOH$, there are 4 hydrogen bonds and 18 extra vibrational modes. The ZPE correction is 24 kJ mol^{-1}. It is clear that ZPE corrections should be included in considering the binding energies in forming complexes.

As stated above, total energies of individual species at the G2 level are generally accurate to ±10 kJ mol^{-1}, and, because

of some cancellation of residual errors, the actual errors in the binding energies of complexes from calculations based on G2 energies should be similar. Another study (20) indicated that the magnitude of binding energies of hydrogen-bonded complexes evaluated from energies obtained at the HF/6-31+G* level were a few kJ mol^{-1} lower than those derived with G2 level energies, while MP2/6-31+G* level energies gave binding energies that were higher by a similar amount. The data for $H_2O\cdots HNH_2^{\bullet+}$ shown in Table 5 illustrate this point. The correct binding energies are therefore likely to lie somewhere between the HF/6-31+G* and MP2/6-31+G* values in Table 5. The relative magnitudes of either the HF or the MP2 values indicate clearly which types of interaction are significant and likely to affect the properties of the $NH_2^{\bullet}$ and $NH_3^{\bullet+}$ in an aqueous environment.

Complexes of $NH_2^{\bullet}$: implications for solution

The H-bond energies involving the neutral $NH_2^{\bullet}$ radical are similar to those for NH_3 (see Table 5). The higher basicity of the nitrogen lone pair and lower acidity of the NH bond are reflected in the fact that the binding energies of $HO\boldsymbol{H}\cdots NH_x$ species are larger than those of $H_2O\cdots HNH_x$. In fact $H_2O\cdots HNH_2$ did not converge to a stable geometry. With a C_s constraint, geometry optimization for $H_2O\cdots HNH_2$ results in a saddle point at an O$\cdots$H distance of 2.336 Å. The binding energies are then found to be 4.5 and 8.7 kJ mol^{-1} at the HF and MP2 levels, respectively. The higher amine lone pair basicity is also borne out from a comparison of the data for $HO\boldsymbol{H}\cdots NH_3$ in Table 5 (17.5 and 25.6 kJ mol^{-1} at the HF and MP levels, respectively) with results for $HO\boldsymbol{H}\cdots OH_2$, for which we found binding energies of 13.9 and 20.3 kJ mol^{-1} at the HF and MP2 levels, respectively. The water dimer has been studied at high levels of *ab initio* calculations by Frisch et al. (26). They found the binding energy of $HO\boldsymbol{H}\cdots OH_2$ to be 22.3 kJ mol^{-1} at the MP4/6-311++G(3df,3dp)//MP2/6-311++G(2d,2p) level before inclusion of ZPE. The ZPE-corrected binding energy (8.6 kJ mol^{-1} at the HF/6-31+G* level) is comparable to the present HF result.

In contrast to previous studies (27–29), we found that the H atoms from H_2O and NH_3 groups have an "eclipsed" arrangement in $HO\boldsymbol{H}\cdots NH_3$ as indicated in Fig. 2. The "staggered" conformer has similar electronic energy (differing by less than 1 kJ mol^{-1}), but has one imaginary frequency (34i cm^{-1}). This is also true for $H_3N\cdots \boldsymbol{H}NH^{\bullet}$ and $H_2N\boldsymbol{H}\cdots NH_3$. These results suggest that the bifurcated H–N to lone pair interactions are favored or the bifurcated H–H repulsions are disfavored.

Attempts were also made to study σ–σ^* (three electron – two orbital) interactions between H_2O and H_3N lone pair electrons and the unpaired electron of $NH_2^{\bullet}$. Although attractive, these did not converge to stable minima and showed no evidence for the formation of stable structures in the gas phase. In fact structures with such configurations reverted to the hydrogen-bonded conformations discussed above. However, to estimate the extent of σ–σ^* attraction that must be present in solution, we optimized the $O\cdots N$ distance by constraining the H_2O and H_2N planes parallel to each other and with the hydrogens having a staggered arrangement. This arrangement maximizes the HOMO–SOMO interaction. Without including the vibrational energy correction, the maximum binding energy was found to be 4.5 kJ mol^{-1} at the HF/6-31+G* level, at an $O\cdots N$ separation of 3.2 Å. Inclusion of the ZPE correction would make the binding energy negative. In similar calculations, the $H_2N^{\bullet}$ and NH_3 interaction was repulsive at all $N\cdots N$ distances, the repulsion increasing monotonically to 6 kJ mol^{-1} at the N–N van der Waals sparation of 3 Å. We conclude, therefore, that these σ–σ^* interactions are of minimal importance for the solvation of $NH_2^{\bullet}$.

From Table 5 it is evident that there are no cases where the binding of $NH_2^{\bullet}$ to NH_3 is significantly stronger than to H_2O.[2] Thus in aqueous systems with less than molar NH_3, $NH_2^{\bullet}$ will effectively be surrounded by H_2O molecules. In that regard the $(H_2O)_2\cdots \boldsymbol{H}_2N^{\bullet}\cdots \boldsymbol{H}OH$ complex (Fig. 2) is particularly interesting in that it reflects $H_2O\cdots H_2O$ bonding as well as $H_2O\cdots NH_2^{\bullet}$ bonding. It is therefore closer than the dimeric clusters to the type of structure likely to be encountered in aqueous solution. The four heavy atoms are coplanar. There are two $O\cdots \boldsymbol{H}N^{\bullet}$, one $O\boldsymbol{H}\cdots N^{\bullet}$, and one $O\boldsymbol{H}\cdots O$ bonds, with one of the $O\cdots \boldsymbol{H}N^{\bullet}$ bonds significantly nonlinear. The total binding energies at the HF and MP2 levels are 47 and 69 kJ mol^{-1}, respectively, in both cases just 5 kJ mol^{-1} higher than the sum of the energies of the individual hydrogen bonds as measured in appropriate binary complexes in Table 5.

The importance of bonds between the $(H_2O)_x\cdots \boldsymbol{H}_2N^{\bullet}$

[2]Note that ΔG^0 values for binding, which can be obtained from the thermodynamic data in Tables 3 and 4, and the binding energies in Table 5, lead to the same conclusions.

complexes and the H_2O network can be emphasized by comparing the relative stabilities of the above discussed $(H_2O)_2\cdots \boldsymbol{H}_2N^{\bullet}\cdots \boldsymbol{H}OH$ structure and that of the isomer $H_2O\cdots \boldsymbol{H}HN^{\bullet}\cdots \boldsymbol{H}O\boldsymbol{H}\cdots OH_2$, which can be formed by replacing an $O\cdots \boldsymbol{H}N^{\bullet}$ hydrogen bond with an $O\boldsymbol{H}\cdots O$ hydrogen bond. If the binding energy of $HO\boldsymbol{H}\cdots OH_2$ species is larger than that of $H_2O\cdots \boldsymbol{H}HN^{\bullet}$ as shown in Table 5 and above, $H_2O\cdots \boldsymbol{H}HN^{\bullet}\cdots \boldsymbol{H}O\boldsymbol{H}\cdots OH_2$ should be more stable than $(H_2O)_2\cdots \boldsymbol{H}_2N^{\bullet}\cdots \boldsymbol{H}OH$. Indeed, we found that the former is favored by 6.8 kJ mol^{-1} at the MP2/6-31+G* + ZPE level (5.2 kJ mol^{-1} at the HF/6-31+G* + ZPE level). Again, the binding energies of individual hydrogen bonds are fairly additive, with the total bonding energy only 3 kJ mol^{-1} higher than the sum of individual binding energies.

In $(H_2O)_2\cdots \boldsymbol{H}_2N^{\bullet}\cdots \boldsymbol{H}OH$ (Fig. 2), the HN$\boldsymbol{H}$ angle is increased from 105.2° in free $NH_2^{\bullet}$ to 107.1° to accommodate the cyclic $N\boldsymbol{H}\cdots O\boldsymbol{H}\cdots O\boldsymbol{H}\cdots N$ structure. However, the N$\boldsymbol{H}$ distances do not alter significantly, only one of them changing from 1.012 Å in free $NH_2^{\bullet}$ to 1.011 Å. The tendency for maintenance of the $NH_2^{\bullet}$ structure is also clear in $HO\boldsymbol{H}\cdots NH_2^{\bullet}$ and $H_2O\cdots \boldsymbol{H}NH^{\bullet}$, where the NH distances remain the same as in free $NH_2^{\bullet}$ and the HNH angles of both are 105.6°, only slightly altered from 105.2° in free $NH_2^{\bullet}$.

Complexes of $NH_3^{\bullet+}$

As indicated by the results in Table 5, the presence of the charge on the $NH_3^{\bullet+}$ cation radical causes the binding energies to increase by an order of magnitude, and the interactions become dipole oriented with linear H bonds. The structures of $H_2O\cdots \boldsymbol{H}NH_2^{\bullet+}$ and $(H_2O)_3\cdots \boldsymbol{H}_3N^{\bullet+}$ have been reported elsewhere (20) and we will only summarize their main features here. The optimized $H_2O\cdots \boldsymbol{H}NH_2^{\bullet+}$ structure has C_{2v} symmetry with the radical center $N^{\bullet+}$ being planar. The hydrogen atoms of the water molecule lie in a plane perpendicular to it, without significant change of structure from the isolated H_2O. In $(H_2O)_3\cdots \boldsymbol{H}_3N^{\bullet+}$, the planes defined by the water molecules form angles of 67.3° with the $NH_3^{\bullet+}$ plane and give this complex a D_3 structure. The hydrogen bonds in $(H_2O)_3\cdots \boldsymbol{H}_3N^{\bullet+}$ are 0.124 Å longer, and the average binding energy is 13 kJ mol^{-1} less than that of $H_2O\cdots \boldsymbol{H}NH_2^{\bullet+}$. For $H_2O\cdots \boldsymbol{H}NH_2^{\bullet+}$, the interaction energy, −91.2 kJ mol^{-1}, has been previously evaluated (20) at the G2 level, which is 3 kJ mol^{-1} more negative than the HF value and 6 kJ mol^{-1} less negative than the MP2 value. The $H_3N\cdots \boldsymbol{H}NH_2^{\bullet+}$ bond is about 30 kJ mol^{-1} stronger than the $H_2O\cdots \boldsymbol{H}NH_2^{\bullet+}$ bond. Thus if $NH_3^{\bullet+}$ were present in a solution where the NH_3 concentration was significant, there would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

be preferential complexation by this species. However, at pHs where $NH_3^{\cdot+}$ exists in water (see Sect. 4), NH_3 will be protonated and this interaction will not be significant. Since the isomeric interaction $H_3NH^+\cdots NH_2^{\cdot}$ is slightly weaker than that for $H_2O\cdots HNH_2^{\cdot+}$, it can also be neglected.

The optimized structures of $H_3N\cdots HNH_2^{\cdot+}$ and its "isomer" $H_3NH^+\cdots NH_2^{\cdot}$ are both dipole orientated ($< NHN \approx 180°$) with C_s symmetry. $H_3NH^+\cdots NH_2^{\cdot}$ is 34 kJ mol^{-1} more stable than $H_3N\cdots HNH_2^{\cdot+}$ at the MP2/6-31+G* + ZPE level. However, the binding energy is 39 kJ mol^{-1} less than that of $H_3N\cdots HNH_2^{\cdot+}$. In forming the hydrogen bond in $H_3N\cdots HNH_2^{\cdot+}$, the NH distance is lengthened by 0.08 Å and < HNH is narrowed by 4° from those of $H_3N^{\cdot+}$, while changes in NH_3 local structure are minor. The hydrogen bond length is 1.634 Å, shorter by 1.066 Å from the van der Waals separation.[3] In $H_3NH^+\cdots NH_2^{\cdot}$, the structures of the fragments are little altered.

The planar (D_3) structure of $(H_2O)_3\cdots H_3N^{\cdot+}$ means that in aqueous solution H_2O molecules will be free to approach the $N^{\cdot+}$ center from above and below the plane of the N—H bonds along the axis of symmetry. There will be a strong ion–dipole interaction, which will orient the dipole moment of the H_2O molecules toward the $N^{\cdot+}$ center. Calculations on $H_2O\cdot\cdot NH_3^+$ started with this orientation indicated that the binding energy was 34 kJ mol^{-1} (HF/6-31+G* + estimated ZPE). As well as the ion–dipole interaction, this includes a component due to σ–σ^* interaction, i.e., an interaction between the singly occupied MO (SOMO) and one of the lone pairs of H_2O. Attempts were made to establish whether the σ–σ^* part of the interaction is significant. However, as in the case of $NH_2^{\cdot}$, these structures did not correspond to stable minima in the gas phase. Calculations were performed for $H_2O\cdots NH_3^{\cdot+}$ constrained to adopt a geometry in which the ion–dipole interaction is minimized while maximizing the σ–σ^* interaction (SOMO–HOMO): with the O···N bond perpendicular to H_2O plane and with a staggered arrangement between the H atoms of the two fragments. The optimized (with the constraints) O···N distance is found to be 2.703 Å and the radical centre is within 1° of planarity. The binding energy at the HF/6-31+G* level is 25.6 kJ mol^{-1}. After correction by the estimated ZPE contribution (about 8 kJ mol^{-1}), the σ–σ^* attraction is about 18 kJ mol^{-1}. This represents a maximum value for the σ–σ^* interaction since it still includes a minor contribution from the ion–dipole interaction.

The optimized structure of $H_3N\cdots NH_3^{\cdot+}$ has staggered conformation with D_{3d} symmetry (Fig. 2). This structure was reported earlier by Gill and Radom (30), and our present results agree with theirs. As shown in Table 5, the σ–σ^* interaction for $H_3N\cdots NH_3^{\cdot+}$ does exhibit strong bonding. This difference from H_2O can be attributed to the match in the orbital energies when identical atoms are involved (31). Again, because free NH_3 is unimportant at pHs where $NH_3^{\cdot+}$ exists, the role of $H_3N\cdots NH_3^{\cdot+}$ should be minimal in aqueous systems. It could, however, be of importance in liquid ammonia. In the present study, H_3N–$NH_3^{\cdot+}$ is the only species in which the interactions between the fragments are dominated by the σ–σ^* interaction of heavy atoms.

[3]The van der Waals radii are 1.2, 1.4, and 1.5 Å for H, O, and N atoms, respectively, as given in the Handbook of Chemistry and Physics.

4. Solution properties

Absorption spectra

The results of the CIS/6-31+G* calculations of vertical excitation properties of $NH_2^{\cdot}$ and $NH_3^{\cdot+}$ are listed in Table 6.

$NH_2^{\cdot}$

For $NH_2^{\cdot}$ in the gas phase, only one transition is predicted to fall below 8 eV. The vertical transition from the $^2B_1$ ground state to the $^2A_1$ state is predicted to occur at 2.43 eV (511 nm), with oscillator strength $f = 0.0040$. The lowest excited $^2A_1$ state is linear and the transition in the gas phase displays pronounced nonvertical characteristics: a broad absorption band extending from 450 to 740 nm, with band maxima at 516, 571, and 630 nm (32). The computed vertical excitation wavelength agrees well with the first band maximum in the gas phase. The transition corresponds to the excitation of an electron from the doubly occupied nonbonding "*sp*^{n}" hybrid orbital ($3a_1$) to the higher singly occupied nonbonding orbital ($1b_1$), which is in essence the 2*p* orbital on nitrogen. In aqueous solution, as discussed above, the $NH_2^{\cdot}$ species experiences three types of interaction with the neighboring water molecules. The effects of these on the wavelength of the $^2B_1 \rightarrow {}^2A_1$ transition may be deduced from the data in Table 6. In complexes with water or ammonia of the type, X:···HNH$^{\cdot}$, this transition is largely unperturbed, being slightly red shifted. In complexes where the $3a_1$ orbital is involved in hydrogen bonding (of type, X–H···:$NH_2^{\cdot}$, the transition is blue shifted by an amount characteristic of the acidity of the X–H bond: X–H = H_2N–H, −15 nm; X–H = HO–H, −40 nm; X–H = H_3N–H^+, −110 nm. The blue shift is expected on the basis that the hydrogen-bonding interaction lowers the energy of the "*sp*^{n}" ($3a_1$) orbital relative to the 2*p* orbital (SOMO). It is also seen in $(H_2O)_2\cdots H_2N^{\cdot}\cdots HOH$ where both types of H bond are present. As mentioned above, no small complexes arising from "σ"-type interactions between the SOMO and nonbonded electrons of water or ammonia are stable. Nevertheless, such configurations must exist in solution. The three-electron two-orbital interactions effectively raise the energy of the singly occupied MO ($1b_1$) without affecting the energy of the $3a_1$ orbital, thereby causing a blue shift of the longest wavelength transition. We have assessed the effect of such a σ-type interaction on the wavelength (λ) and oscillator strength (f) of the $^2B_1 \rightarrow {}^2A_1$ transition by constraining the planes of a single $NH_2^{\cdot}$–H_2O pair to be parallel at several fixed separations, r: r = 2.5 Å, λ = 431 nm, f = 0.006; r = 3.0 Å, λ = 475 nm, f = 0.005; r = 3.5 Å, λ = 494 nm, f = 0.004. At the van der Waals distance (3Å), a modest blue shift is predicted with little gain in oscillator strength. In pulse-irradiated ammonia solutions at high pH, there is observed a broad (width ≈ 200 nm) but weak absorption band peaking near 520 nm, and this has been attributed to $NH_2^{\cdot}$ (7). Given the highly nonvertical nature of the transition, the theoretical data are satisfactorily compatible with the observed solution phase spectra. Also, as expected, the absorption intensity is very weak (ϵ = 80 M^{-1} cm^{-1} (7)).

The second absorption for gaseous $NH_2^{\cdot}$, $^2B_1 \rightarrow {}^2B_1$ ($3a_1 \rightarrow 4a_1$), is predicted by CIS/6-31+G* to occur at 145 nm with oscillator strength f = 0.0240. Inclusion of additional diffuse and polarization functions to the basis set (CIS/6-311++G**) alters the predicted properties of this absorption only slightly (154 nm, f = 0.0277), indicating that the lowest excited $^2B_1$ state is a valence state, as is the lowest $^2A_1$ state. In complexes

	2 ^2E_g	8.65	143	0.0	$1e_g \rightarrow 3a_{2u}(\sigma_{NN} \rightarrow \sigma^*_{NN})$

with one or three water molecules, however, the nature of the second lowest energy transition changes radically, to a charge transfer from water to $NH_2^{\bullet}$, near 165 nm, with $f = 0.0000$. The wavelength of the corresponding charge transfer band in solution will be poorly modelled by the data in Table 6, since the effect of a polarizable medium of high dielectric constant will be to stabilize the charge transfer state and lead to a substantial red shift of the absorption wavelength. According to the procedure of Treinin and Hayon (33), assuming a "radius" of 1.75 Å for $NH_2^{\bullet}$, one can predict the position of the charge transfer band to be near 200 nm. Experimentally, $NH_2^{\bullet}$ in liquid water has a second absorption beginning below 250 nm (7) that was attributed by Pagsberg to a charge transfer transition (7). The present analysis supports this assignment.

$NH_3^{\bullet+}$

The results of the CIS/6-31+G* calculations of the vertical excitation properties of $NH_3^{\bullet+}$ and several complexes with water and ammonia are listed in Table 6. In the gas phase, the lowest electronic absorption, $^2A_2'' \rightarrow {}^2E''$ ($1e' \rightarrow 1a_2''$) is predicted to occur at 155 nm with zero oscillator strength. In complexes with water, this transition is unperturbed, but a charge transfer transition is predicted to occur at longer wavelength, near 180 nm, also with almost zero oscillator strength. With the better donor, ammonia, the hydrogen-bonded complex, $H_3N\cdots HNH_2^{\bullet+}$, has a charge transfer transition at 250 nm. Ammonia also forms a three-electron σ-bonded complex with $NH_3^{\bullet+}$, H_3N–$NH_3^{\bullet+}$, symmetry D_{3h}, of stability comparable to the hydrogen-bonded complex. The lowest energy transition, $^2A_{2u} \rightarrow {}^2A_{1g}$ ($3a_{1g} \rightarrow 3a_{2u}$, $\sigma_{NN} \rightarrow \sigma_{NN}^*$), is predicted to occur at 282 nm and is strongly electric dipole allowed, $f = 0.3795$. As mentioned above, no water complexes with three-electron bonding comparable to H_3N–$NH_3^{\bullet+}$ are stable. As with $NH_2^{\bullet}$, however, such transient configurations must exist in solution and provide an opportunity for $\sigma_{ON} \rightarrow \sigma_{ON}^*$ transitions. Because of the polarization of the σ_{ON} and σ_{ON}^* orbitals, such transitions are, in fact, charge transfer transitions and may have appreciable oscillator strength. We have examined the qualitative functional dependence upon separation (r) of the absorption wavelength (λ) and oscillator strength (f) of charge transfer transitions by constraining the planes of water and $NH_3^{\bullet+}$ to be parallel at several fixed separations (r), the orientation of which maximizes the effects of σ–σ* interaction: $r = 2.5$ Å, $\lambda = 194$ nm, $f = 0.136$; $r = 3.0$ Å, $\lambda = 190$ nm, $f = 0.061$; $r = 3.5$ Å, $\lambda = 187$ nm, $f = 0.029$. Thus, at the van der Waals separation (3 Å), a transition near 190 nm with moderately strong oscillator strength is predicted in the gas phase. Experimentally, the UV spectrum of $NH_3^{\bullet+}$ exhibits a monotonic absorption beginning at 370 nm and increasing to the limit of measurement, 290 nm (9). Using an adaptation of the method of Treinin and Hayon (7), for the process

$$[5] \qquad h\nu + H_2O\cdots NH_3^{\bullet+} \rightarrow H_2O^{\bullet+}\cdots NH_3$$

one can predict that the charge transfer transition should occur near 250 nm.[4] The computations therefore support the charge transfer character of the transition observed in the low pH region of aqueous $NH_3^{\bullet+}$ (9).

[4]The transition energy is principally governed by the difference in the ionization potential of water, $I(H_2O)$, and the electron affinity of amminium, $E(NH_3^{\bullet+})$, modified by the solvation energy of $NH_3^{\bullet+}$ (Table 7), and the instantaneous solvent response to the development of charge on H_2O (32).

[h]Calculated as described in text.

Thermodynamic data

Solution thermodynamic data for NH_4^+, NH_2^-, and the radical species $NH_3^{\cdot+}$ and $NH_2^{\cdot}$ at 298.15 K are given in Table 7, along with the values of $\Delta_f G^0_{(g)}$ from Table 3. The values of $\Delta_f G^0_{(aq)}$ for NH_3 and NH_4, the pK_a of NH_4^+, and the free energy of solution of NH_3 have been taken from ref. 34. Other data have been derived as indicated in the footnotes and explained below. Here it is worth recalling that for negative B^- ions the free energy of formation in aqueous solution, $\Delta_f G^0_{(aq)}$ is given by the free energy change in reaction [6] (34),

$$[6] \qquad \text{ESSB} + \frac{1}{2} H_{2(g)} \rightarrow B^- + H^+$$

where ESSB means the stoichiometric quantities of Elements in their Standard States at one Bar needed to form B^-. For other species the subscript (g) indicates gas phase reactant, standard state 1 bar, while the absence of any notation indicates aqueous solution, standard state 1 molar. The free energy changes in reactions [7] and [8]

$$[7] \qquad \text{ESSB} + \frac{1}{2} H_{2(g)} \rightarrow BH_{(g)}$$

$$[8] \qquad BH_{(g)} \rightarrow B^-_{(g)} + H^+_{(g)}$$

respectively define $\Delta_f G^0_{(g)}$ of $BH_{(g)}$ and the gas phase acidity, $\Delta G^0_{(acid)}$ of $B^-_{(g)}$. The *conventional* free energy of solution of B^-, ΔG^0_s (con. of B^-), is equal to the sum of the absolute free energies of solution of B^- and H^+ ($\Delta G^0_s(B^-) + \Delta G^0_s(H^+)$), and is given by the free energy change of reaction [9] (34)

$$[9] \qquad B^-_{(g)} + H^+_{(g)} \rightarrow B^- + H^+$$

For present purposes it is equivalent to $\{\Delta_f G^0_{(aq)}(B^-) - \Delta_f G^0_{(g)}(BH) - \Delta G^0_{(acid)}(B^-_{(g)})\}$. These equations are needed for the calculation of the properties in Table 5. The analogous equations for positive ions are:

$$[10] \qquad \text{ESSB} + H^+ \rightarrow A^+ + \frac{1}{2} H_{2(g)}$$

$$[11] \qquad \text{ESSB} \rightarrow A^+_{(g)} + e^-$$

$$[12] \qquad e^- + H^+_{(g)} \rightarrow \frac{1}{2} H_{2(g)}$$

$$[13] \qquad H^+ + A^+_{(g)} \rightarrow H^+_{(g)} + A^+$$

and ΔG^0_s (con. of A^+), defined by the free energy change for reaction [13], is given by $\{\Delta_f G^0_{(aq)}(A^+) - \Delta_f G^0_{(g)}(A^+) + \Delta_f G^0_{(g)}(H^+)\}$. The gaseous free energy of formation of the proton, $\Delta_f G^0_{(g)}(H^+)$, calculated on the basis of the ion convention (14) used here, is 1517 kJ mol^{-1}.

For the $NH_2^{\cdot}$ radical, previous studies (3) have assumed that the energy of the σ–σ^* interaction between the N unpaired electron and the H_2O lone pairs would be too small to influence the solution free energy. The discussion in Sect. 3 confirms this. Also from Table 5 the strongest interaction with H_2O is the OH to N lone pair H bond, and this is slightly weaker for $NH_2^{\cdot}$ than for NH_3. That feature and the fact that there are only two H atoms for NH—O bonds in $NH_2^{\cdot}$, as opposed to three in NH_3, argues in favour of a slightly smaller magnitude of $-\Delta G^0_s$ for $NH_2^{\cdot}$ than for NH_3, for which $-\Delta G^0_s$ is 10 kJ mol^{-1}. The value of 8 kJ mol^{-1} used by Stanbury (3) on the basis of comparisons with model systems therefore seems entirely justified. $\Delta_f G^0_{(aq)}$ for $NH_2^{\cdot}$ in Table 5 was calculated from $\Delta_f G^0_{(g)}$ on the basis of this value. Errors in $\Delta G^0_{(s)}$ would not exceed 2 kJ mol^{-1} and, combined with the ±2 kJ mol^{-1} error uncertainty in $\Delta_f G^0_{(g)}$, lead to a ±4 kJ mol^{-1} error in $\Delta_f G^0_{(aq)}$ ($NH_2^{\cdot}$).

As in ref. 3, $\Delta_f G^0_{(aq)}$ for $NH_3^{\cdot+}$ was calculated from the free energy change in reaction [14]

$$[14] \qquad NH_3^{\cdot+} \rightarrow NH_2^{\cdot} + H^+$$

The pK_a of $NH_3^{\cdot+}$, pK_R, was first reported to be 3.65 (35) and then subsequently 6.7 (8). However, neither is valid because these studies did not recognize the correct mechanism of the reaction of protonated hydroxylamine with the solvated electron, which was later clarified in ref. 13. The only reliable value of pK_R, which is 2.3, is that of Hoffman and Olson (9), and gives $\Delta G^0_{[14]}$ = 13.1 kJ mol^{-1}. With this result and $\Delta_f G^0_{(aq)}$ for $NH_2^{\cdot}$ from Table 5, one finds $\Delta_f G^0_{(aq)}$ of $NH_3^{\cdot+}$ = 178 kJ mol^{-1}.

From that and $\Delta_f G^0_{(g)}$ of $NH_3^{\cdot+}$ (= 963 kJ mol^{-1}), ΔG^0_s (con.) for $NH_3^{\cdot+}$ is found to be 732 kJ mol^{-1}. Reference to Table 7 shows that this is 25 kJ mol^{-1} more negative than ΔG^0_s for NH_4^+. The difference is of the same magnitude as that found between ΔG^0_s for $(CH_3)_3N^{\cdot+}$ and $(CH_3)_3NH^+$ in our earlier publication (36). It therefore supports the conclusion that the planar amminium ions are more strongly solvated than the tetrahedral ammonium species. This conclusion was first arrived at by Pearson (37) for $NH_3^{\cdot+}$, but largely on the basis of the value pK_R = 6.7, now known to be incorrect. A value ΔG^0_s of $NH_3^{\cdot+}$, which is more negative than that of NH_4^+, is also strongly supported by the calculations of free energies of hydration of NH_4^+ and $NH_3^{\cdot+}$ in ref. 20.

The authors are unaware of any experimental data from which $\Delta_f G^0_{(aq)}$ or ΔG^0_s (con.) of $NH^{\cdot-}$ can be obtained. However, based on the Born model of ion solvation and a consideration of relative atomic dimensions, the magnitude of ΔG^0_s (con.) of $NH^{\cdot-}$ cannot be more than that of OH^-, which from current data in refs. 14 and 34 is −1535 kJ mol^{-1}. That value would yield $\Delta_f G^0_{(aq)}$ ($NH^{\cdot-}$) = 320 kJ mol^{-1} and a minimum pK_a of 22 for $NH_2^{\cdot}$ in reaction [15]:

$$[15] \qquad NH_2^{\cdot} \rightarrow NH^{\cdot-} + H^+$$

Thus ionization of $NH_2^{\cdot}$ would be unimportant in aqueous systems and $NH^{\cdot-}$ has not been considered further here.

The values of $\Delta_f G^0_{(aq)}$ and ΔG^0_s (con.) of NH_2^- in Table 7 are subject to a considerable uncertainty (±25 kJ mol^{-1}),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

because they were obtained from estimates of the pK_a of NH_3 and these involved extrapolations from nonaqueous systems (37). Based on the relative size of the ions one would expect ΔG^0_s (con.) of NH_2^- to lie in between those for OH^- and Cl^-, which from current data in refs. 14 and 34 are -1535 and -1408 kJ mol^{-1}, respectively. The value of -1463 kJ mol^{-1} in Table 7 is therefore in the expected range.

Redox chemistry

The standard reduction potential for the fundamental half-reaction [16], $E^0(NH_2^{\bullet}/NH_2^-)$,

[16] $\quad NH_2^{\bullet} + e^- \rightarrow NH_2^-$

is given by $-\{\Delta_f G^0_{(aq)}(NH_2^-) - \Delta_f G^0_{(aq)}(NH_2^{\bullet})\}/F$, where F is the Faraday constant. The values of $\Delta_f G^0_{(aq)}$ in Table 7 yield $E^0(NH_2^{\bullet}/NH_2^-) = 0.11 \pm 0.30$ V, and the large uncertainty makes meaningless any attempt to predict the redox properties of $NH_2^{\bullet}$ on the basis of reaction [16]. However, given the very high pK_a of NH_3, there is an enormous driving force for protonation. Thus reaction [17]

[17] $\quad NH_2^{\bullet} + e^- + H^+ \rightarrow NH_3$

is likely to be the more relevant half-reaction. In any case this is certainly the appropriate half-reaction when protonation equilibria are ensured and the pH is above 9.3 (i.e., both NH_4^+ and $NH_3^{\bullet+}$ deprotonated). From the structure of $(H_2O)_2 \cdots H_2N^{\bullet} \cdots HOH$ in Fig. 2, one can see that proton transfer from the solvent as represented in reaction [18]

[18] $\quad NH_2^{\bullet} + e^- + H_2O \rightarrow NH_3 + OH^-$

should be facile, and this path could be dominant at high pHs.[5]

Because of the relatively minor uncertainties in the $\Delta_f G^0_{(aq)}$ data for $NH_2^{\bullet}$ and NH_3 in Table 5, the standard reduction potential for half-reaction [17] ($E^0(NH_2^{\bullet}, H^+/NH_3) = 2.25 \pm 0.10$ V) can be obtained with much greater precision than $E^0(NH_2^{\bullet}/NH_2^-)$. More useful is an equation for the pH dependence of the redox potential of the radical/ammonia system with protonation equilibrium. Using the conventions in ref. 38, one can write:

$$[19] \quad E_{h(\text{radical/ammonia})} = E^0(NH_2^{\bullet}, H^+/NH_3) - \frac{RT}{F} \ln \frac{N_T}{N_R} - \frac{RT}{F} \ln \left(1 + \frac{a_{H^+}}{\gamma_{R^+} K_R}\right) \left[a_{H^+} \left(1 + \frac{a_{H^+}}{\gamma_{N^+} K_A}\right)\right]^{-1}$$

Here N_T and N_R are the total concentrations $\{[NH_3] + [NH_4^+]\}$ and $\{[NH_2^{\bullet}] + [NH_3^{\bullet+}]\}$, respectively, a_{H^+} is the hydrogen ion activity, γ_{N^+} and γ_{R^+} are the activity coefficients and K_A and K_R the ionization constants of NH_4^+ and $NH_3^{\bullet+}$, respectively. The activity coefficients of neutral species have been taken as unity. For $N_T = N_R$, $E_{h(\text{radical/ammonia})}$ is 1.48 V at pH 13 and it increases to 1.60 V at pH 11. Thus it is evident that $NH_2^{\bullet}$ is likely to be a much stronger oxidant in alkaline media than implied by even the highest estimate of $E^0(NH_2^{\bullet}/NH_2^-)$. Confirmation of that comes from the observation in ref. 13 of the oxidation of a series of substituted phenolate ions ($XC_6H_4O^-$) having $E^0(XC_6H_4O^{\bullet}/XC_6H_4O^-)$ values as high as 0.8 V. The fact that the rates tend to be slow ($\sim 10^7$ dm^3 mol^{-1} s^{-1}) is an indication of the substantial rearrangement needed for protonation to accompany electron transfer in reaction [18]. The situation may be similar to that reported for the tryptophan radical (39), and studies of the activation energy of these $NH_2^{\bullet}$ oxidations of phenolates would be well worthwhile.

Between pH 9.3 and 2.3 reaction [20]

[20] $\quad NH_2^{\bullet} + e^- + 2H^+ \rightarrow NH_4^+$

will replace [17] as the dominant equilibrium process, and $E_{h(\text{radical/ammonia})}$ reaches values of 1.85, 2.09, and 2.45 at pHs of 8, 6, and 3, respectively. From a kinetic point of view of course the acquisition of two protons is more difficult than one, and rates of oxidation by $NH_2^{\bullet}$ in this pH region will probably not reflect these large potentials. On the other hand the inherent stability of NH_4^+ toward oxidation can be appreciated. For example, taking $\Delta_f G^0_{(aq)}$ of $OH^{\bullet}$ equal to 26 kJ mol^{-1} (3) and using the data in Table 7, one finds values of 6 and -47 kJ mol^{-1}, respectively, for $\Delta G^0_{[21]}$ and $\Delta G^0_{[22]}$

[21] $\quad OH^{\bullet} + NH_4^+ \rightarrow H_2O + H^+ + NH_2^{\bullet}$

[22] $\quad OH^{\bullet} + NH_3 \rightarrow H_2O + NH_2^{\bullet}$

From the corresponding equilibrium constants, for reaction [21] with $[NH_4^+] = [H^+] \approx 10^{-2}$ M, the ratio of radicals, $[NH_2^{\bullet}]/[OH^{\bullet}]$, at equilibrium would be ≈ 0.1, while for reaction [22] above the pK_a of NH_4^+ the ratio would be $\approx 10^8 \times [NH_3]$. The well-recognized (7, 8, 13) difference in reactivity of NH_4^+ and NH_3 toward $OH^{\bullet}$ can therefore be understood.

Below pK_R the radicals are protonated and [23]

[23] $\quad NH_3^{\bullet+} + e^- + H^+ \rightarrow NH_4^+$

is the important equilibrium reaction. Here the H_2O molecules in the solvation shell of $NH_3^{\bullet+}$ have their protons directed away from the $N^{\bullet+}$ center, and proton transfer from solvent is not likely to be as facile as for $NH_2^{\bullet}$ in alkaline solution. From a kinetic point of view reaction [23] may therefore be a two-step process:

[24] $\quad NH_3^{\bullet+} + e^- \rightarrow NH_3$

[25] $\quad NH_3 + H^+ \rightarrow NH_4^+$

Based on the $\Delta_f G^0_{(aq)}$ data in Table 5, $E^0(NH_3^{\bullet+}/NH_3)$ is 2.12 V. This is in agreement with Stanbury's estimate (3), which was also based on $pK_r = 2.3$. Thus $NH_3^{\bullet+}$ is a very strong oxidant.

5. Summary and conclusions

The G2 results for isolated species have been shown to be in excellent agreement with available gas phase experimental data. This agreement and the consistency between different reaction paths has confirmed the reliability to ± 2 kJ mol^{-1} of the values of $\Delta_f H^0_{(g)}$ for $NH_2^{\bullet}$, NH_2^-, and $NH_3^{\bullet+}$. Gas phase thermodynamic functions, with $\Delta_f G^0_{(g)}$ based on the most reliable values of $\Delta_f H^0_{(g)}$, have been calculated for $NH_2^{\bullet}$, NH_2^-, $NH^{\bullet-}$, $NH_3^{\bullet+}$, and NH_4^+.

Ab initio calculations, which established the structures, binding energies, and transition energies of aquo complexes, have been used as an aid in evaluating the solution structure and free energies and interpreting the absorption spectra of $NH_2^{\bullet}$ and $NH_3^{\bullet+}$ in solution. The weak absorption observed experi-

[5] Note that $E_{[17]}$ and $E_{[18]}$ are identical at the same pH.

For personal use only.

mentally at 520 nm for the former is confirmed as a $^2B_1 \rightarrow {}^2A_1$ transition, probably slightly blue shifted due to interaction with H_2O. The stronger $NH_2^\bullet$ absorption occurring below 250 nm has been identified as a solvent-to-solute charge transfer band. The absorption of $NH_3^{\bullet+}$, which arises monotonically below 370 nm, is also attributed to a solvent-to-solute charge transfer band.

Based on the energetics of H-bonding interactions, Stanbury's value of $\Delta G^0_{(s)}$ of $NH_2^\bullet = -8.0$ kJ mol^{-1} is justified. The present study also confirms the reliability of his values of $E^0(NH_2^\bullet, H^+/NH_3)$, $E^0(NH_3^{\bullet+}/NH_3)$, and $\Delta_f G^0_{(aq)}$ for $NH_2^\bullet$ and $NH_3^{\bullet+}$. Also the free energy of solution of $NH_3^{\bullet+}$ is shown to be larger[6] than that of NH_4^+. Examination of the redox chemistry of $NH_2^\bullet$ in the light of the structures of the aquo complexes suggests that reaction [18],

$$[18] \qquad NH_2^\bullet + e^- + H_2O \rightarrow NH_3 + OH^-$$

which involves proton transfer from solvent, is likely to be the major half-reaction in alkaline solution. The present thermochemical data also explain the reason for the stability of NH_4^+ toward attack by $OH^\bullet$ radicals.

[6]Experimental results in 1991 (41) indicated that an increase of 14 kJ mol^{-1} in the proton affinity of NH_3 might be needed. Since the values of $\Delta_f H^0_{(298)}$ and $\Delta_f G^0_{(298)}$ for $NH_{4(g)}^+$ in Table 3 are calculated from this proton affinity, $\Delta G^0_{(s)}$ of NH_4^+ would be altered and the difference between $\Delta G^0_{(s)}$ of $NH_3^{\bullet+}$ and NH_4^+ would increase by 14 kJ mol^{-1}. The proton affinity of 854 kJ mol^{-1} used here is supported by more recent experimental results (42), which contradict the increase in proton affinity, and by higher level *ab initio* calculations reviewed in ref. 42. Thus the difference in $\Delta G^0_{(s)}$ of $NH_3^{\bullet+}$ and NH_4^+ remains near 25 kJ mol^{-1}.

Effect of multiple encounters on vibrational to translational energy transfer

Received June 4, 1993
This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

NEIL SNIDER. Can. J. Chem. **72**, 484 (1994).

Vibrational to translational energy transfer was studied computationally and analytically for collinear, impulsive collisions with square well oscillators, harmonic oscillators, and Morse oscillators. At a fixed temperature T the average number of encounters is between one and two if the vibrational energy E_v is large compared to kT and (or) if the relative mass of the collider is small. If these conditions are met, $\langle \Delta E \rangle$, the average energy transferred per collision, varies nearly linearly with E_v over a wide range. If the average number of encounters is greater than two, $\langle \Delta E \rangle$ as a function of E_v has a more complicated form. The average final energy, $\langle \Delta E \rangle + E_v$ is less than what is predicted by the single encounter impulsive collision (SEI) model. Other things being equal, the ratio of the actual average final energy to the SEI average final energy is roughly the same for all of the above mentioned oscillators.

NEIL SNIDER. Can. J. Chem. **72**, 484 (1994).

Faisant appel à des méthodes de calculs et analytiques, on a étudié le transfert d'énergie de vibration en énergie de translation de collisions colinéaires et impulsives avec des oscillateurs à puits carré, des oscillateurs harmoniques et des oscillateurs de Morse. À une température donnée, T, la moyenne des rencontres se situe entre un et deux si l'énergie de vibration, E_v, est importante par rapport à kT et (ou) si la masse relative de l'entité que entre en collision est faible. Lorsque ces conditions sont remplies, $\langle \Delta E \rangle$, l'énergie moyenne transférée par collision, varie d'une façon pratiquement linéaire avec E_v pour un grand ensemble de valeurs. Si le nombre moyen des rencontres est plus grand que deux, la variation de $\langle \Delta E \rangle$ en fonction de E_v prend une forme beaucoup plus compliquée. L'énergie finale moyenne, $\langle \Delta E \rangle + E_v$, est plus faible que la valeur prédite par le modèle de la collision impulsive à rencontre unique (SEI). Tous les autres facteurs étant égaux, le rapport de l'énergie finale moyenne réelle par rapport à celle calculée par le modèle de la collision impulsive à rencontre unique est approximativement la même pour tous les oscillateurs mentionnés plus haut.

Introduction

Vibrational excitation and deexcitation are known to be important in a number of chemical reactions. For example, in gas phase recombination of diatomic molecules the molecule is initially formed with a large amount of vibrational energy. The rate constant for such a reaction decreases with increasing temperature. Professor Polanyi (1) was one of the first to note that slow vibrational deactivation of the nascent diatomic is one factor that brings about this atypical temperature dependence of the rate constant. Also, in unimolecular reactions the importance of energy transfer is well known. Methods have been devised whereby one may decouple the energy transfer steps from the reaction steps and thereby extract energy transfer information from rate data for unimolecular reactions (2). More recently, experimental methods for obtaining energy transfer information by more direct means have been developed (3, 4). These developments have increased the interest in theoretical interpretation of vibrational energy transfer.

Given the power of present day computers, one may simulate by classical trajectories the energy transfer in systems with several degrees of freedom. These calculations have provided ample information concerning the factors that affect energy transfer. On the other hand, the amount of detail in a model with several degrees of freedom is so large as to limit one's understanding of the collision dynamics. Hence, there is a need to investigate simple models where the factors that influence energy transfer are in better focus. The simplest of such models even provide analytic formulas.

One factor that influences not only energy transfer but also energy disposal in chemical reactions is the occurrence of multiple encounters in the course of a collision. Professor Polanyi's group was the first to note the effect of multiple encounters on energy disposal in reactive collisions (5). Strictly speaking, multiple encounters only occur if the interaction potential is of the form of a hard wall. If the interaction potential is of finite range, then secondary, tertiary, etc. encounters are defined only in a rough sense. The earliest theoretical investigations (6–10) of the effects of multiple encounters on energy transfer were carried out on collinear, impulsive models of atom–diatom collisions,

$$AB(E_v) + C \longrightarrow AB(E_v') + C$$

where E_v and E_v' are the vibrational energies of AB before and after the collision. The present paper may be regarded as a sequel to these early works.

At its most detailed level, energy transfer is characterized by a probability distribution function $\rho(\Delta E)$ where ΔE is given by

$$\Delta E = E_v' - E_v$$

A more coarse-grained description of the energy transfer is obtained from the lower moments of ρ. Of these, the first moment $\langle \Delta E \rangle$ is the most easily accessible experimentally. If the A–B interaction is a square well, i.e., if AB is a "string oscillator" (6), then analytic formulas exist for $\rho(\Delta E)$ and for $\langle \Delta E \rangle$ (6, 9, 10). Thus it is of interest to establish the extent to which the string oscillator's $\rho(\Delta E)$ and $\langle \Delta E \rangle$ are good approximations to $\rho(\Delta E)$ and $\langle \Delta E \rangle$ for more realistic oscillators, i.e., the harmonic oscillator and the Morse oscillator.

The dependence of $\langle \Delta E \rangle$ on E_v is of some interest. In many studies, both experimental (11–14) and theoretical (15–17), $\langle \Delta E \rangle$ has been found to vary linearly with E_v in some intermediate range of E_v. At high E_v, $-\langle \Delta E \rangle$ has been found to level off or, at the least, to have a decreasing first derivative (11, 15). A classical trajectory study of AB + C with AB mod-

eled as a Morse oscillator showed that a leveling off and an eventual downturn of $-\langle\Delta E\rangle$ are consequences of increasing anharmonicity (18). At low E_v, $\langle\Delta E\rangle$ has been found to vary as E_v^p where p is around two or larger (14, 17). This behavior has been ascribed to a number of factors, one of which is multiple encounters (17). It is therefore of interest to investigate the form of $\langle\Delta E\rangle$ as a function of E_v for simple models wherein collisions consist of one or more impulsive encounters.

It has been argued that multiple encounters play an important role in collisions of a monatomic molecule with a large polyatomic molecule and that a simple model, namely the biased random walk model, makes accurate predictions for such collisions (19, 20). One of the notable predictions of the biased random walk model is that $\rho(\Delta E)$ is a Gaussian. It is therefore of interest to determine the form of $\rho(\Delta E)$ for collinear, impulsive models at mass ratios such that the average number of encounters per collision is large. The investigation here reported addresses this matter and those mentioned before it.

Equations of motion

The model here considered is one of a structureless particle of mass m_C colliding collinearly with a particle of mass m_B, which is bound to a third particle of mass m_A. The interaction potential between B and C is a hard wall. Thus a collision consists of N impulsive encounters. Three different potentials were assumed: the square well, the harmonic, and the Morse.

The equations of motion for such a model have been amply discussed in the literature (7–10). What follows is a summary of those basic relations which are necessary to indicate the way in which the results here reported were calculated.

If coordinates and time are suitably scaled, the B–C distance z may be expressed as

$$[1] \qquad z = \pm b_0 g_n^{1/2}\theta - \sigma(\theta)$$

where g_n is the ratio of the relative kinetic energy to the vibrational energy following the nth encounter, θ is a dimensionless variable proportional to time, and b_0 is related to the masses of A, B, and C,

$$[2] \qquad b_0 = \tan\psi = \left[\frac{m_B(m_A + m_B + m_C)}{m_A m_C}\right]^{1/2}$$

The angle ψ is the skew angle in the potential energy surface. The function $\sigma(\theta)$ depends on the nature of the A–B potential. For the string oscillator σ is given by

$$\sigma(\theta) = -\theta \qquad \text{for } \theta < \theta_n$$
$$= \theta - \theta_n \qquad \text{for } \theta > \theta_n$$

where θ_n is directly proportional to the time that the oscillator would have required to reach the point of the nth encounter if at time zero it had been at the origin of the oscillator coordinate. For the string oscillator the origin is here taken to be the inner turning point. For the harmonic oscillator with the origin at the outer turning point σ is given by

$$\sigma(\theta) = \cos(\theta + \theta_n) - \cos\theta_n$$

The Morse oscillator may be bound or unbound after the nth encounter, and the form of σ depends on this factor. In addition, σ depends not only on the parameter θ_n but also on a parameter α_n defined by

$$\alpha_n = \cos^{-1}\left[\left(\frac{E_{vn}}{d_e}\right)^{1/2}\right] \qquad \text{for } E_{vn} < d_e$$
$$= \cosh^{-1}\left[\left(\frac{E_{vn}}{d_e}\right)^{1/2}\right] \qquad \text{for } E_{vn} > d_e$$

where E_{vn} is the vibrational energy of the oscillator following the nth encounter and d_e is the dissociation energy. The Morse oscillator σ is given by

$$\sigma = \tan\alpha_n \ln\left[\frac{\cos\alpha_n\cos(\theta+\theta_n)+1}{\cos\alpha_n\cos\theta_n+1}\right] \text{ for } E_{vn} < d_e$$
$$= \tanh\alpha_n \ln\left[\frac{\cosh\alpha_n\cosh(\theta+\theta_n)-1}{\cosh\alpha_n\cosh\theta_n-1}\right]$$
$$\text{for } E_{vn} > d_e$$

One sees that the first of the above formulas for σ reduces to the harmonic oscillator formula in the limit of vanishingly small E_{vn}. For all three oscillators, the pertinent parameters have been absorbed into the dimensionless dynamical variables.

For θ positive but close to zero, z is positive. The necessary and sufficient condition for an $(n+1)$th encounter is that z go negative at some positive value of θ, call it θ'_{n+1}. For the string oscillator θ'_{n+1} may be found in closed form. For the other oscillators the appropriate zero of $z(\theta)$ must be determined numerically. Newton's method is a convenient computational method for this determination, but one must take care to choose the initial value of θ such that the iteration converges properly. In the investigation here reported the iteration was started at the first inflection point in $z(\theta)$. It should be noted that for the harmonic and the Morse oscillators θ_{n+1} generally differs from θ'_{n+1} because the location of the turning points depends on g_{n+1}. The relation between θ'_{n+1} and θ_{n+1} is established by the condition that the oscillator displacement relative to the potential minimum is unchanged in an impulsive encounter.

From θ'_{n+1} one may determine g_{n+1} from the law of conservation of energy and the fact that z-momentum only changes sign in an impulsive collision. One thereby obtains

$$[3] \qquad \pm g_{n+1}^{1/2} = (\pm g_n^{1/2}\cos 2\psi + u_n \sin 2\psi)$$
$$\times [1 + (g_n - u_n^2)\sin^2 2\psi \mp 2g_n^{1/2}u_n \sin 2\psi \cos 2\psi]^{-1/2}$$

where the upper sign refers to motion of C away from AB, ψ is given by eq. [2], and u_n is given by

$$u_n = \frac{d\sigma}{d\theta}\Big)_{\theta=\theta'_{n+1}}$$

If there is no subsequent encounter then, by conservation of energy, ΔE is given by

$$[4] \qquad \frac{\Delta E}{E_v} = (g - g_N)(1 + g_N)^{-1}$$

where N is defined above and g is the ratio of the initial relative kinetic energy E_r to the initial vibrational energy E_v.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

It is well known (7–10) that for the string oscillator and for the harmonic oscillator, g_N depends not on E_r and E_v separately but only on their ratio g. For the Morse oscillator, on the other hand, g_N does depend on E_r and E_v separately.

To obtain $\langle\Delta E\rangle$, one must average over an appropriate ensemble of θ_0's. For the string oscillator a uniform ensemble of θ_0's is the appropriate one. More generally, it is the ensemble derived from a uniform ensemble of z's. Thus the desired ensemble of θ_0's is obtained by solving eq. [1], taking for the left hand side values of z that are equally spaced. Such calculations are also done conveniently using Newton's method. Let the average of ΔE over this ensemble be denoted $\langle\Delta E\rangle_g$. The thermal average of $\langle\Delta E\rangle$ is found from $\langle\Delta E\rangle_g$ via Boltzmann averaging,

$$\frac{\langle\Delta E\rangle}{E_v} = \beta_v \int_0^\infty \frac{\langle\Delta E\rangle_g}{E_v} \exp(-\beta_v g)\, dg$$

with β_v equal to E_v/kT. In what follows the subscript g will be dropped if it is obvious that an average at fixed relative kinetic energy is being considered.

Results

Dependence of $\langle\Delta E\rangle$ *on initial vibrational energy*

Figure 1 shows plots of $-\langle\Delta E\rangle/kT$ vs. E_v/kT for the harmonic oscillator at b_0 values of 0.414, 1.000, and 2.414. These b_0 values represent ψ values of 22.5°, 45°, and 67.5°. The curve for $b_0 = 2.414$ is nearly a straight line, although careful inspection shows it to be slightly downward concave. The curve for $b_0 = 1.000$ has a minimum at E_v equal to a few tenths of kT. To a good approximation, both plots are straight lines over a considerable range of E_v. For E_v less than kT the curve for $b_0 = 0.414$ is rather similar to that for $b_0 = 1.000$. The most striking feature of the $b_0 = 0.414$ curve is the nearly level portion which extends from 5 kT to 10 kT. As will be shown below, this leveling of the curve is due to multiple encounters. Calculations at small g and $b_0 = 0.414$ indicate that $-\langle\Delta E\rangle$ increases linearly with E_v for this value of b_0 at E_v beyond the range covered by Fig. 1.

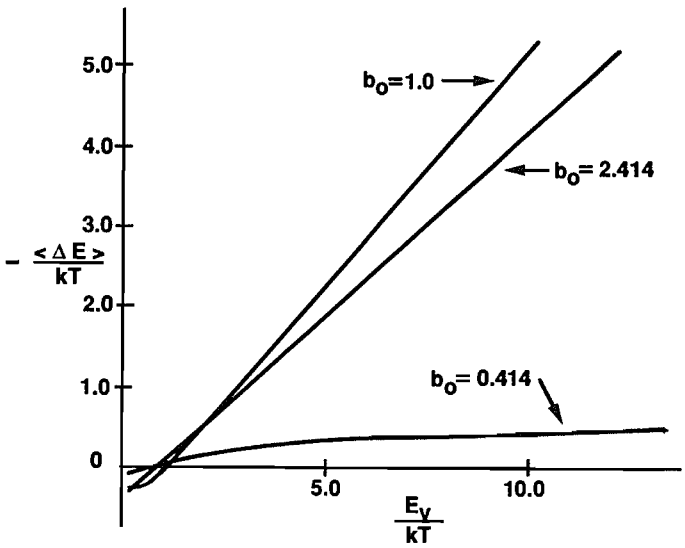

FIG. 1. Average energy transferred per collision as a function of initial vibrational energy for a harmonic oscillator in collinear, impulsive collisions at different mass ratios.

Energy transfer probability distributions

The function $\rho(\Delta E)$ for the string oscillator is obtainable in closed form. In general, the formula is quite complicated, but for small b_0 and moderate to large β_v it is not so complicated as to be uninstructive. In previous treatments of the string oscillator (6, 9) the distribution over final momenta was derived. Even though ΔE is related in a simple way to the squares of the initial and the final momenta, a derivation of $\rho(\Delta E)$ for the string oscillator seems appropriate here by way of reinforcing the connection between this work and what has gone before. This derivation is presented in Appendix A.

The final result is expressed more succinctly in terms of h, the ratio of the final vibrational energy to the initial,

$$h = 1 + \Delta E/E_v$$

For β_v sufficiently large that the condition

$$\exp(-\beta_v b_0^{-2}) \approx 0$$

is met one has for the string oscillator

$$[5]\quad \rho(h) \approx \beta_v \sum_{N>n_-(h)}^{\mathcal{N}-1} D_N^{-1}\{\cos[(N-1)\psi] - h^{-1/2}\cos[(N+1)\psi]\} \exp[-\beta_v \csc^2 2N\psi(h^{1/2} - \cos 2N\psi)^2] \quad \text{for } h < 1$$

$$\approx \beta_v \sum_{N>n_+(h)}^{\mathcal{N}-1} D_N^{-1}\{h^{-1/2}\cos[(N-1)\psi] - \cos[(N+1)\psi]\} \exp[-\beta_v \cos^2 2N\psi(h^{1/2} - \cos 2N\psi)^2] \quad \text{for } h > 1$$

where $\mathcal{N}$ is the largest integer such that $2\mathcal{N}\psi$ is less than π, $n_\pm(h)$ is given by

$$n_\pm(h) = \psi^{-1}\tan^{-1}\left(b_0 \frac{\pm h^{1/2} \mp 1}{h^{1/2}+1}\right)$$

and D_N is given by

$$D_N = (\cos 2N\psi + 1)\{\cos[(N-1)\psi] - \cos[(N+1)\psi]\}$$

The interested reader may consult Appendix A for the derivation of eq. [5]. Inspection of eq. [5] gives the impression that $\rho(h)$ is not far different from the exponential function

$$[6]\quad \rho(h) \sim \exp[\alpha(h-1)] \quad \text{for } h < 1$$

$$\sim \exp[\gamma(1-h)] \quad \text{for } h > 1$$

which has been used frequently to model the energy transfer distributions (2).

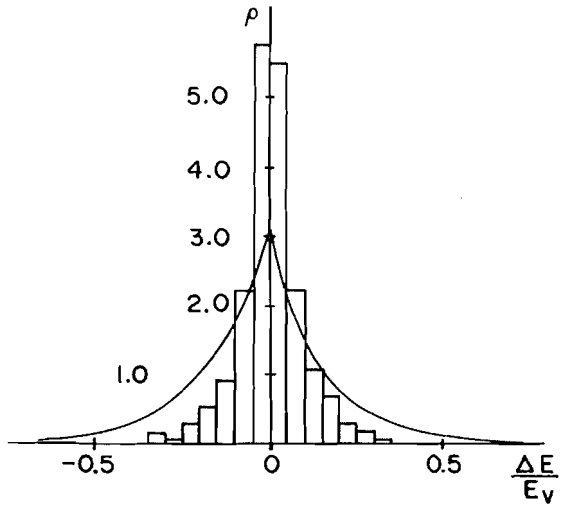

FIG. 2. Energy transfer probability distributions for collinear impulsive collisions at $kT = E_v$ and $b_0 = 0.132$. Histogram: harmonic oscillator. Solid line: string oscillator.

Figure 2 shows a plot of $\rho(\Delta E)$ derived from eq. [5] along with one computed for the harmonic oscillator, both for $b_0 = 0.132$ ($\psi = 7.5°$) and E_v equal to kT. The $\rho(\Delta E)$ for the harmonic oscillator is narrower, but both curves are closely approximated by eq. [6]. The average number of encounters for both of the ensembles to which these plots pertain is about six.

SEI model

In the SEI model the outcome of the collision is assumed to be that of the first encounter. The SEI model gives the following formula for $\langle \Delta E \rangle$ for all the oscillators considered when g is greater than b_0^2,

$$\langle \Delta E \rangle_{SEI}/E_v = [g - (2 - b_0^{-2})\langle E_k \rangle/E_v] \sin^2 2\psi$$

where $\langle E_k \rangle$ is the average kinetic energy of the oscillator. For the string oscillator $\langle \Delta E \rangle_{SEI}$ is also known analytically for g less than b_0^2,

$$\langle \Delta E \rangle_{SEI}/E_v = (g - 1) \sin^2 2\psi + g^{1/2} \sin 4\psi$$

These equations may be obtained easily from eqs. [3] and [4] by setting N equal to one and taking the lower sign on the right of eq. [3]. For the harmonic oscillator and the Morse oscillator one can show that for g approaching zero, $\langle \Delta E \rangle_{SEI}$ has the asymptotic form

$$[7] \qquad \langle \Delta E \rangle_{SEI}/E_v = -2\pi \tan\frac{\alpha}{2} \sin^2 2\psi b_0 g^{1/2}$$

where α is given by $\alpha = \cos^{-1}[(E_v/d_e)^{1/2}]$. The harmonic oscillator formula is obtained by setting α equal to $\pi/2$. A derivation of eq. [7] is provided in Appendix B.

For the string oscillator there are values of g for which the SEI model is exact, i.e., for which no multiple encounters occur. Figure 3 shows the regions of the ψ–χ_0 plane in which the SEI model is and is not exact for the string oscillator. The angle χ_0, which is defined by

$$[8] \qquad \chi_0 = \tan^{-1}(g^{-1/2})$$

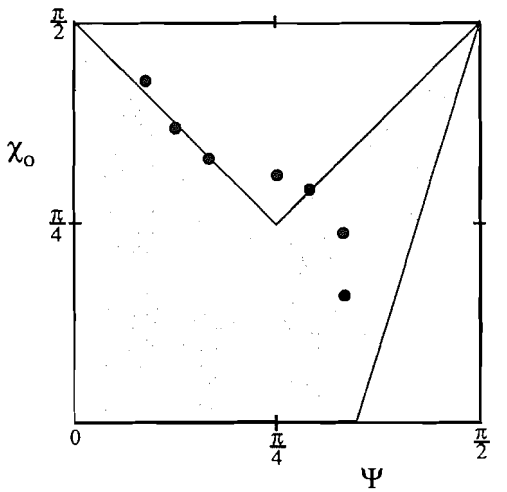

FIG. 3. Multiple encounter regions in the ψ–χ_0 plane for collinear impulsive collisions. Shaded region is the multiple encounter region for the string oscillator. Filled circles indicate the boundary of the region wherein the multiple encounters correction for the hamonic oscillator is less than 0.9.

is used in place of g in order to provide a neater representation. For all of the other oscillators the SEI model becomes exact asymptotically as g goes to zero, i.e., as χ_0 goes to $\pi/2$. Figure 3 also indicates the boundary of the region of the ψ–χ_0 plane wherein the average of h for the harmonic oscillator is less than 0.9 of the SEI average of h. Because it does yield simple formulas and because its underlying assumptions are correct in certain limits, the SEI model has merit as a standard of comparison.

It may be proven generally that $\langle \Delta E \rangle_{SEI}$ is greater than or equal to the actual $\langle \Delta E \rangle$ for the string oscillator at a given g.[1] The computations carried out in the course of this investigation suggest that this result is a general one for all oscillators. It implies that the ratio of the actual average final vibrational energy to the SEI final energy always lies between zero and one,

$$0 < \langle h \rangle/\langle h \rangle_{SEI} \leq 1$$

In Table 1 are shown values of $\langle h \rangle/\langle h \rangle_{SEI}$ for the different oscillators at the same values of b_0 and g. One sees that they are all less than one. What is also noteworthy is that they do not differ greatly for the different oscillators.

Discussion

It is apparent from the aforementioned results that multiple encounters have considerable effect on the energy transfer only if b_0 is less than one. For b_0 greater than one the average number of encounters is between one and two, and $\langle \Delta E \rangle$ differs appreciably, if at all, from $\langle \Delta E \rangle_{SEI}$ only in limited ranges of g. This point is illustrated in Fig. 3. It is to be noted in Fig. 3 that at sufficiently large ψ there is a lower boundary to the region in which multiple encounters take place. This boundary intersects the ψ axis at the minimum value of ψ for which multiple encounters do not take place in impulsive collisions for which the oscillator is initially moving outward. It has been known for some time that for the harmonic oscillator this value

of ψ is about 50° (8). It is equal to 60° for the string oscillator (9).

When multiple encounters do occur, they tend to lower the final vibrational energy, i.e., they enhance the deactivation of the oscillator. This effect may be roughly understood as follows: coming into the final encounter, the oscillator usually has a large amount of vibrational kinetic energy as a result of previous encounters. The oscillator is readily deactivated if its vibrational energy is in the form of kinetic energy rather than potential energy (18). Thus the final encounter results in considerable loss of vibrational energy from the oscillator. As seen from Tables 1 and 2, the final vibrational energy in a multiple encounter collision may be only a few tenths of what is predicted on the assumption of a single encounter.

As mentioned above, a linear dependence of $\langle\Delta E\rangle$ on E_v has been noted in several studies, both experimental and theoretical. Figure 1 shows that for the harmonic oscillator model considered here, $\langle\Delta E\rangle$ varies nearly linearly with E_v over a wide range of E_v. If b_0 is greater than or approximately equal to one, this range of linearity begins at E_v roughly equal to kT. Rather more complex behaviour of $\langle\Delta E\rangle$ as a function of E_v occurs at small values of b_0. This behaviour is analyzed in Table 2. It is shown there that the SEI final vibrational energy varies almost linearly with E_v when b_0 is equal to 2.414, and also when b_0 is equal to 0.414, provided that E_v is greater than 5 kT. For $b_0 = 2.414$ the multiple encounter correction factor is never less than 0.93. For $b_0 = 0.414$ this correction factor is considerably less than one at small E_v, and it approaches one as E_v increases. Since a more positive rate of change of the final energy results in a less positive rate of change of $-\langle\Delta E\rangle$, the increase of the multiple encounters correction factor arrests the increase of $-\langle\Delta E\rangle$. This effect is most pronounced for E_v between 5 kT and 10 kT where both the correction factor and its derivative are fairly large. At E_v above 10 kT the derivative of the multiple encounters correction factor is small enough that $-\langle\Delta E\rangle$ as a function of E_v is first concave upward and then linear.

For the Morse oscillator it has been known for some time that $-\langle\Delta E\rangle$ as a function of E_v goes through a maximum and eventually goes negative (18). It is well understood that this behaviour is due to anharmonicity. As seen from Table 1, the multiple encounter corrections for the Morse oscillator tend to be somewhat lower than those for the harmonic oscillator when g is small and somewhat higher when g is large. At low g, anharmonicity increases the likelihood of multiple encounters, both because the initial encounter may take place further from the outer turning point and because it is more probable that the first encounter will be with the oscillator when it is moving inward, a situation that may preclude reversal of the direction of motion of the collider. At high values of g these differences between the harmonic oscillator and the Morse oscillator are less important, and the deciding factor is the tendency for ΔE in a given encounter to be higher if the oscillator is anharmonic. In none of the cases here considered do the multiple encounters corrections differ greatly for the Morse oscillators as compared to the harmonic oscillator. This finding is not in agreement with results of a previous study of the effects of anharmonicity on energy transfer (21). This previous study was, however, limited to the case of zero initial vibrational energy and thus pertains to a different energy range.

As seen from Fig. 1, $\langle\Delta E\rangle$ for the harmonic oscillator varies linearly with E_v if E_v is somewhat larger than kT and if b_0 is greater than or about equal to one. For smaller b_0, linear behaviour also occurs but at higher values of E_v. At very large E_v, $\langle\Delta E\rangle$ varies as $E_v^{1/2}$, as is shown in Appendix B. The linear dependence may be explained as a consequence of there being more energy for the oscillator to transfer if E_v is large. For E_v sufficiently large this linear increase is offset by the restriction of collisions to single encounters with the oscillator near its outer turning point. When the oscillator is so positioned, most of its energy is in the form of potential energy, which is not transferable in an impulsive encounter. The computations here reported indicate that the resulting $E_v^{1/2}$ dependence of $\langle\Delta E\rangle$ does not set in until E_v is well above 10 kT.

In a qualitative sense the dependence of $\langle\Delta E\rangle$ on E_v found in the present study is similar to what has been found in other studies. The utility of collinear studies is limited, however, because quantitative comparisons are ambiguous: it is not clear what to take for E_v in the case of a molecule with many vibrational degrees of freedom. It has been proposed that one should take E_v to be the total vibrational energy divided by the total number of vibrational modes (20). A more reasonable course might be to divide the total vibrational energy by the number of active modes. How the active modes are to be determined is an open question.

It has been found that $\rho(\Delta E)$ may be a rather complicated function for collinear models (22). In particular, ρ often has secondary peaks, and these peaks may occur at large, negative, values of ΔE. Peaks at large, negative, ΔE are indicative of

so-called supercollisions, which have recently attracted some interest, both experimental (23) and theoretical (24). It is to be noted that such peaks are almost nonexistent in the $\rho(\Delta E)$'s calculated in this investigation, which focussed on cases in which the number of encounters is large. As seen from Fig. 2, $\rho(\Delta E)$ in such cases is very nearly exponential. The exponential behaviour arises because the range of possible ΔE's increases with the number of encounters. In turn, the number of encounters increases with increasing g. Thus, the exponential behavior is related to the Boltzmann factor $\exp(-\beta_v g)$, which weights the thermal average over g. In no case here considered was $\rho(\Delta E)$ well approximated by a Gaussian, as predicted by the biased random walk model. Apparently, the vibrational mode that interacts with the collider must interact with other modes as well if the biased random walk model is to be an appropriate model for the collision.

Conclusion

Early work on collinear models (6–10) provided a sketch of the role of multiple encounters in energy transfer. Multiple encounters have a major effect on energy transfer only for ψ less than 45°. Thus, impulsive collisions for which mass combinations are such that ψ is appreciably greater than 45° are, to a good approximation, single encounter events. It has been proposed here that the effect of multiple encounters be quantified in terms of a factor that corrects the final vibrational energy predicted by the SEI model. For ψ less than 45° this factor is small at low E_v, and it increases at a decreasing rate with increasing E_v. When combined with the more or less linearly varying SEI final energy, the result is a curve with a broad inflection. Other things being equal, and provided that E_r is not extremely large, this correction for multiple encounters is nearly the same for the string oscillator, the harmonic oscillator, and the Morse oscillator. This finding has an added appeal in that the correction factor can be expressed analytically in the case of the string oscillator.

The effect of multiple encounters on $\rho(\Delta E)$ is to make it more nearly like the ρ for the exponential model. This result suggests that the Gaussian form of $\rho(\Delta E)$ predicted by the biased random walk model requires not only multiple encounters between the collider and the vibrational modes of the molecule but also concurrent interactions among these modes. An investigation of this combination of interactions in a relatively simple model is presently under consideration.

Appendix A. Derivation of the energy transfer Probability distribution function for the string oscillator

Let h_N be the ratio of final vibrational energy to initial vibrational energy in an N-encounter collision. One sees from ref. 10 that for the string oscillator h_N is given by

$$[A1] \qquad h_N = \frac{\sin^2(\chi_0 + 2N\psi)}{\sin^2 \chi_0}$$

where χ_0 is given by eq. [8]. In terms of h, the final vibrational energy divided by the initial vibrational energy, the energy transfer distribution function is given by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

$$[A2] \qquad \rho(h) = \beta_v \int_0^\infty \sum_N f_N \delta(h - h_N) \exp(-\beta_v g)\, dg$$

$$= \beta_v \sum F_N(h) \exp[-\beta_v g_N(h)]$$

where β_v is E_v/kT, $f_N(g)$ is the probability of an N-encounter collision, and $F_N(h)$ is given by

$$[A3] \qquad F_N(h) = f_N \left(\frac{dg}{dh}\right)_{g=g_N(h)}$$

where $g_N(h)$ is the value of g for which an N-encounter collision results in a final to initial vibrational energy ratio equal to h. From eqs. [A1] and [8] one obtains

$$[A4] \qquad g_N(h) = \frac{h^{1/2} - \cos 2N\psi}{\sin 2N\psi}$$

The formula for f_N may be found in the literature (10). For χ_0 greater than ψ one has

$$f_N = -\frac{\sin N\psi \cos[\chi_0 + (N+1)\psi]}{\sin \psi} \qquad \text{for } \frac{\pi}{2} - (N+1)\psi < \chi_0 < \frac{\pi}{2} - N\psi$$

$$= 1 + \frac{\sin[(N-1)\psi] \cos[\chi_0 + N\psi]}{\sin \psi} \qquad \text{for } \frac{\pi}{2} - N\psi < \chi_0 < \frac{\pi}{2} - (N-1)\psi$$

Using eq. [8] to eliminate χ_0 in favor of g and then using eqs. [A3] and [A4], one obtains

$$[A5] \qquad F_N(h) = \{\cos[(N-1)\psi] - h^{-1/2} \cos[(N+1)\psi]\} D_N^{-1} \qquad \text{for } h < 1$$

$$= \{h^{-1/2} \cos[(N-1)\psi] - \cos[(N+1)\psi]\} D_N^{-1} \qquad \text{for } h > 1$$

where D_N is given by

$$D_N = \cos(2N\psi + 1)\{\cos[(N-1)\psi] - \cos[(N+1)\psi]\}$$

Thus for β_v sufficiently large that the condition

$$\exp(-\beta_v b_0^{-2}) \approx 0$$

is met, one has from eqs. [A2]–[A5]

$$[A6] \qquad \rho(h) \approx \beta_v \sum_{N > n_-(h)}^{\mathcal{N}-1} D_N^{-1} \{\cos[(N-1)\psi] - h^{-1/2} \cos[(N+1)\psi]\} \exp[-\beta_v \csc^2 2N\psi (h^{1/2} - \cos 2N\psi)^2]$$

for $h < 1$

$$\approx \beta_v \sum_{N > n_+(h)}^{\mathcal{N}-1} D_N^{-1} \{h^{-1/2} \cos[(N-1)\psi] - \cos[(N+1)\psi]\} \exp[-\beta_v \csc^2 2N\psi (h^{1/2} - \cos 2N\psi)^2]$$

for $h > 1$

where $\mathcal{N}$ is the largest integer such that $2\mathcal{N}\psi$ is less than π and the $n_\pm(h)$ are given by

$$n_\pm(h) = \psi^{-1} \tan^{-1}\left(b_0 \frac{\pm h^{1/2} \mp 1}{h^{1/2} + 1}\right)$$

Equation [A6] is the same as eq. [5] of the main text.

Appendix B. Derivation of large E_v asymptotic formula for $\langle \Delta E \rangle$ for collinear, impulsive collisions

If E_v is large compared to E_r, then encounters take place when the oscillator is near its outer turning point. If the force on the oscillator is continuous there, then eq. [1] may be approximated near the turning point by a quadratic equation,

[B1] $$z = -b_0 g^{1/2}\xi - 1/2C\xi^2 \text{ for } \xi < 0$$
$$= b_0 g^{1/2}(1-\xi) - 1/2C\xi^2 \text{ for } \xi > 0$$

where ξ is related to the θ of eq. [1] by a linear transformation and C is related to the restoring force on the oscillator at its outer turning point x_+ as in eq. [B2],

[B2] $$C = \frac{\tau}{(2\mu E_v)^{1/2}} \left(\frac{dV}{dx}\right)_{x=x_+}$$

The denominator $(2\mu E_v)^{1/2}$ in eq. [B2] is the maximum momentum of the oscillator. The other factor is the absolute value of the momentum that the oscillator would have if it were subjected for one period τ of its oscillation to a constant force equal to the force at the outer turning point. For the harmonic oscillator this ratio of momenta is equal to 2π. For anharmonic oscillators such as the Morse oscillator it is smaller than 2π, as will be discussed below.

To obtain $\langle \Delta E \rangle$, one averages over a uniform ensemble of z's. If g is small, ξ is limited to values from ξ_- to ξ_+ where ξ_- is the negative value of ξ at which the derivative of z changes sign. For ξ_+ one has

$$z(\xi_+) = z(\xi_-)$$

[B3] $$b_0 g^{1/2}(1-\xi_+) - 1/2C\xi_+^2 = \frac{b_0^2 g}{2C}$$

For small g one may solve for ξ_+, retaining only terms of order $g^{1/2}$. This gives

[B4] $$\xi_+ = \left(\frac{2b_0}{C}\right)^{1/2} g^{1/4}$$

The distribution function over ξ is proportional to minus the derivative of z,

[B5] $$\rho(\xi) \sim b_0 g^{1/2} + C\xi$$

The proportionality constant is of order $g^{-1/2}$ for small g. Since positive ξ may be of order $g^{1/4}$, one may neglect the first term in eq. [B5] for positive ξ and both terms for negative ξ,

[B6] $$\rho(\xi) \approx \frac{2\xi}{\xi_+^2} \qquad 0 \le \xi \le \xi_+$$

Equation [B6] is correct for sufficiently small g.

At small g, single encounters dominate. Thus the SEI formula is appropriate. This formula is found from eqs. [3] and [4] by setting N equal to one, taking the lower sign on the right of eq. [3], and setting u equal to $C\xi$. To lowest order in g, this gives

$$\frac{\Delta E}{E_v} = -C^2\xi^2 \sin^2 2\psi + O(g^{3/4})$$

Averaging over ξ using the distribution function of eq. [B6] and eliminating ξ_+ using eq. [B4] one obtains

[B7] $$\frac{\langle \Delta E \rangle}{E_v} = -Cb_0 g^{1/2} \sin^2 2\psi$$

For the Morse oscillator one may readily show that the force at the outer turning point and the period are given by

[B8] $$-F(x_+) = \left(\frac{dV}{dx}\right)_{x=x_+} = (2kE_v)^{1/2}(1-\cos\alpha)$$

$$\tau = 2\pi(\mu/k)^{1/2} \csc\alpha$$

where k is the harmonic force constant and α is defined in the main text following eq. [7]. Equations [B2], [B7], and [B8] give eq. [7] of the main text.

It is to be noted that for a Morse oscillator near its dissociation limit α goes to zero. Thus as this limit is approached, the period of the oscillator diverges as α^{-1}. This divergence is offset in eq. [B2] by the α^2 dependence of the force at the outer turning point, the result being that C approaches zero as α approaches zero.

Studies of femtosecond relaxation dynamics and fast ion–molecule reactions with low-energy electrons

L. SANCHE,[1] M. MICHAUD, AND L. PARENTEAU

Groupe du Conseil de recherches médicales du Canada, Faculté de médecine et Centre d'excellence en Dynamique moléculaire et interfaciale, Université de Sherbrooke, Sherbrooke, QC J1H 5N4, Canada

Received June 16, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

L. SANCHE, M. MICHAUD, and L. PARENTEAU. Can. J. Chem. **72**, 492 (1994).

Electron localization in solids and liquids is caused by time-dependent perturbations of the media surrounding the charge. The perturbations active on the femtosecond time scale include electronic polarization, as well as intra and intermolecular vibrational excitations, which contribute to the formation of a potential well around the charge. It is shown that information on these perturbations as well as on femtosecond reactions can be obtained by studying the formation of transient anions in dielectric solids and at their surfaces using high-resolution electron beam techniques at low energies (0–20 eV). The results obtained with Ar, N_2, O_2, and organic thin solid films condensed on a Pt substrate are described.

L. SANCHE, M. MICHAUD et L. PARENTEAU. Can. J. Chem. **72**, 492 (1994).

La localisation des électrons dans des solides et dans des liquides est provoquée par des perturbations du milieu entourant la charge qui sont dépendantes du temps. Les perturbations qui sont actives au niveau de la femtoseconde comprennent la polarisation électronique ainsi que les excitations vibrationnelles intra- et intermoléculaires qui contribuent à la formation d'un puits de potentiel autour de la charge. On démontre que l'on peut obtenir de l'information relative à ces perturbations ainsi qu'à celles des réactions d'une durée de l'ordre de la femtoseconde en étudiant la formation d'anions transitoires dans les diélectriques solides ainsi qu'à leurs surfaces en faisant appel à des techniques de faisceaux d'électrons à haute résolution à basses énergies (0–20 eV). On décrit les résultats obtenus avec les gaz Ar, N_2 et O_2 et des films organiques solides minces sur un substrat de Pt.

1. Introduction

The dynamics of solvation of charged species in liquids and solids as well as their effects on the mechanisms of fast reactions are topics of interest in many areas of chemistry and chemical physics (1). With the advent of femtosecond laser techniques, it is now possible to probe such dynamical processes at much shorter times and thus extend our comprehension of ultrafast reactions and of the mechanisms of solvation involved during the early stages of the charge localization (2). As the field is progressing, ultrafast reactions and charge-transfer dynamics are beginning to be probed at fluid interfaces (4, 5), but such measurements are technically extremely difficult mainly due to the small signal intensities and problems in delineating between interface and bulk signals. As a result, our present understanding of solvation dynamics at interfaces is limited to theoretical phenomenological models (6, 7) and simulations (8–10).

The purpose of the present article is to show that femtosecond studies are not necessarily limited to those performed with ultrashort laser pulses but that complementary information on processes occurring within the femtosecond time scale can be obtained from high-resolution low-energy electron beam experiments performed on molecular and dielectric thin films.[2] What appears as the most interesting aspect of the low-energy electron experiments is their ability to investigate ultrafast solvation processes and reactions at the surface and interfaces of solids as well as within very thin dielectric films, an experimental domain that is practically unexplored by present femtosecond pump-probe methods. Although many electron scattering and attachment experiments have been performed to date (3), the possibility of obtaining femtosecond information from some of them has, to our knowledge, never been explained and exploited. In this article we explain under what conditions such information can be obtained and for what sort of systems. We describe in the following sections three types of low-energy electron experiments and show the relationship between the results obtained from them and specific processes occurring on a femtosecond time scale. Depending on the experiment, different information can be obtained on ultrafast dynamical processes occurring in thin films and at the surfaces of dielectric solids. This is exemplified by the results obtained from the different types of experiments.

In Sect. 2, it is shown how high-resolution electron energy loss (HREEL) spectroscopy can provide information on the electronic polarization as well as intra- and intermolecular vibrational excitations that contribute to the solvation of an anion in a molecular solid at times of 1–100 fs. In Sect. 3, the electron-stimulated desorption (ESD) method for the detection of anions produced by slow electron impact is explained. It is shown that this method makes it possible to detect anion–molecule reactions occurring over a time scale of 10–100 fs. Finally, a technique capable of identifying ultrafast mechanisms, which eventually cause electron localization at the surface of a dielectric, is described in Sect. 4.

2. Femtosecond anion solvation dynamics

A. Principle of the method and experiment

The basic idea behind this experiment is to fabricate during a short time (1–100 fs) an anion within a molecular solid film or at its surface and study the effects of this transitory localization of an electron on a molecule. Such measurements can be performed with a high-resolution electron energy loss (HREEL) spectrometer of the type described (11) in Fig. 1. It consists essentially of two concentric hemispherical deflectors, a monochromator and an analyzer with appropriate electron optics and a closed-cycle refrigerated cryostat. Electrons leaving the monochromator are focused on a dielectric film that is condensed on a metal

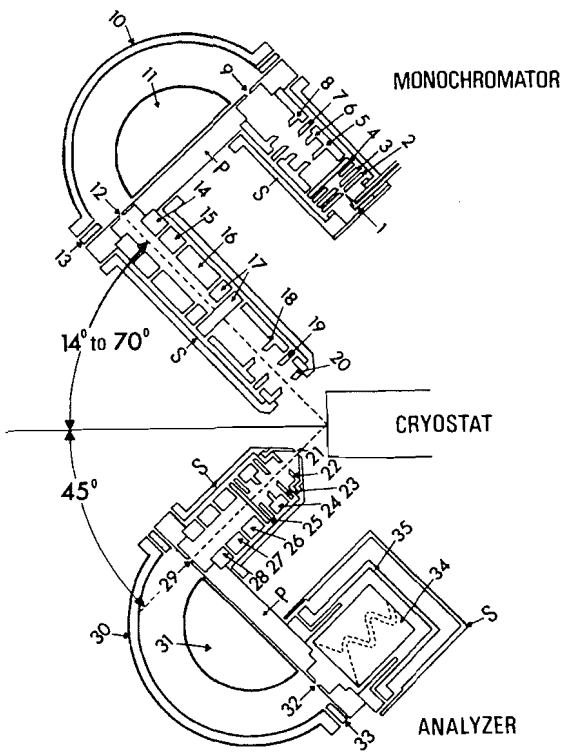

FIG. 1. Schematic diagram of hemispherical electron energy loss spectrometer. Electrons emitted from filament (1) are focused at the entrance (9) of the deflector region (10 and 11) by the zoom lens (6, 7, and 8). Energy dispersion is produced by applying a potential of about 1V between two concentric hemispheres (10, 11, 30, and 31). Imaging and energy control of the electron beam is achieved by means of electrostatic zoom lenses with cylindrical (14–16, 26–28) and aperture (6 to 8, 23 to 25) electrodes. Electrons are detected with a channeltron (34).

substrate. This latter is electrically isolated by a ceramic plate and secured by a press fit to the cold end of the cryostat. The angle of incidence θ_0 can be varied from 14° to 70° from the film's normal. Depending on the instrument, the target film can be rotated and may be cooled down to 15 K. Electrons reflected at $\theta_d = 45°$ from the film are measured by the analyzer. All components of the apparatus are housed in a UHV system reaching pressures below 10^{-10} Torr (1 Torr = 133.3 Pa). The current I_t (E) arriving at the metal substrate can be measured as a function of incident electron energy. In these experiments, I_t is in order of a nÅ and the absolute electron energy scale is calibrated within ±0.15 eV with respect to the vacuum level by measuring the onset of electron transmission through the films. The metal substrate consists of a polycrystalline metal sheet that can be cleaned by resistive heating. The condensed film is grown using a gas-volume expansion dosing procedure (12) and its thickness calibrated by monitoring the quantum size effect (QSE) features observed for ultrathin films (13). With this calibration, the film thicknesses (10–500 Å) can usually be estimated with an accuracy equal to or better than 30%, assuming a layer-by-layer growth.

Energy-loss spectra are recorded by fixing the energy of one deflector while sweeping the energy of the other one. The energy dependence of the magnitude of a given energy-loss event (i.e., the excitation function) is obtained by sweeping the energy of both deflectors with a potential difference between them corresponding to the probed energy loss. HREEL spectra are usually recorded with overall resolutions ranging from 8 to 20 meV FWHM.

As shown schematically in Fig. 2, electrons entering the dielectric film scatter elastically and inelastically with the atoms and (or) molecules forming the film. A large portion of those that exit the film have

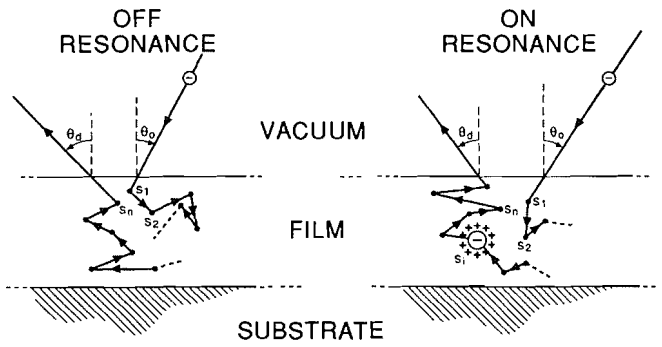

FIG. 2. Schematic diagram representing multiple scattering of an electron from sites s_1–s_n in a dielectric film. The incoming electron is incident at angle θ_0 and exists at angle θ_d with respect to the film normal. At site s_i on the right, the electron is temporarily captured by an atom or molecule of the film. This localization polarizes temporarily (1–100 fs) the lattice in the vicinity of site s_i.

lower energies because of energy losses after scattering on sites s_1–s_n. The exact relative amounts of energy imparted to the various inter- and intramolecular excitation modes in the solid can be known by measuring the energy distribution of these backscattered electrons (i.e., by recording HREEL spectra). Such HREEL spectra can be recorded at one particular emission angle θ_d, for different incident energies. At a specific well-defined incident electron energy, corresponding to that of an electron resonance at a site s_i (Fig. 2), the scattering electron can be trapped for a short time (10^{-15}–10^{-14} s) by an atom or a molecule of the solid and subsequently be released (3). Thus, at the resonance energy, the HREEL spectrum contains two types of information: that arising from multiple scattering plus that from the temporary formation of a negative ion at a molecular site s_i within the dielectric. The difference between the "on" and "off" resonance spectra provides information on energy transfer to inter- and intramolecular excitation modes of the solid during the lifetime of the transitory anion (on the solvation dynamics occurring at times of 1–100 fs). In other words, this technique measures the effect on the lattice of creating an anion for a short time, and the information obtained corresponds to changes initiated during its lifetime. The lifetime of condensed phase anions can be modified by changing their distance from a metal surface (14) or their environment (14, 15). The polarization energy of the anion in a given medium is another parameter that can be extracted from electron beam experiments (14). It simply arises from the energy difference between that of a given anion in vacuum and that recorded in a given material. If similar information is needed for an anion created at the surface of a dielectric, then a submonolayer consisting of molecules different from those of the multilayer dielectric film is deposited on it. Tuning the incident electron energy to that required to form a transient anion of the adsorbate molecule causes additional inter- and intramolecular vibrational excitation arising from the charge being temporarily trapped by the surface molecule. In this manner, the relaxation of the surface can be measured during the lifetime of the resonance.

B. Results and discussion

The early dynamics involved in the formation of an anion in a thin solid film can easily be demonstrated from electron-scattering experiments on rare gas solid (RGS) films. In RGS, an electron resonance occurs slightly below the energy threshold for creating the lowest bulk exciton (16). In solid Ar, for example, the lowest transient anion state of Ar^- occurs at 11.8 eV and has an estimated lifetime of 2.2×10^{-14} s (16). This Ar^- state is a core-excited resonance (i.e., a one-hole, two-electron state composed of a 4s electron bound to the electronic excited state formed from the atomic orbitals (...$3s^2$, $3p^5$, 4s)). It has the isolated (i.e., gas phase) configuration (...$3s^2$, $3p^5$, $4s^2$) $^2P_{3/2}$ $^2P_{1/2}$.

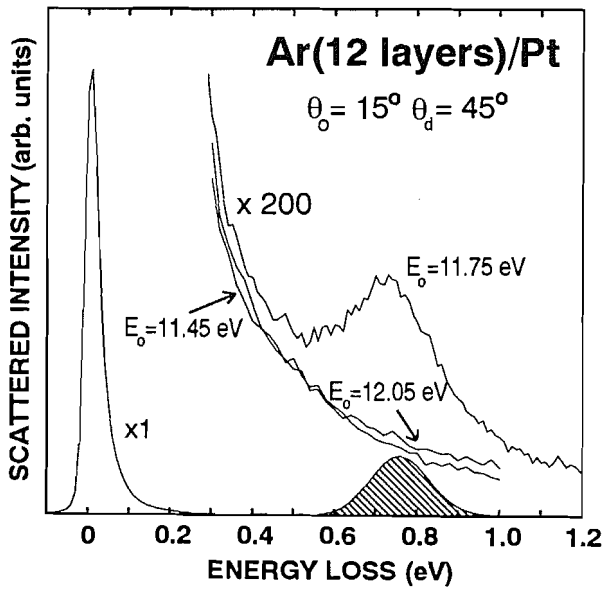

FIG. 3. Electron energy loss spectra of a 12-layer film of Ar recorded for three different incident energies E_0. The incident angle θ_0 is fixed at 15° and that of analysis θ_d at 45°. At incident energy E_0 = 11.75 eV an Ar^- state is formed in the solid causing the addition of a peak in the phonon energy loss tail recorded at E_0 = 11.45 and 12.05 eV. The hatched curve results from the calculation of the interaction between a time-dependent charge located on a lattice site and the acoustical phonons.

In the condensed phase, this resonance is 0.25 eV below the n = 1 bulk exciton; it is formed by the binding of an electron to the $n = 1,1'$ (the prime denoting the $j = \frac{1}{2}$ spin-orbit partner) excitons in the bulk. Since the anion state involves the coupling of an electron with an exciton, which occurs in condensed matter, it is more properly termed an *electron–exciton complex* (17).

Figure 3 shows HREEL spectra recorded with the spectrometer described in Fig. 1 (16). These spectra were obtained with a 12-layer film of Ar at θ_0 = 15° and θ_d = 45°, for incident energies slightly below the $n = 1,1'$ bulk-exciton energies, which are located at 12.06 and 12.24 eV, (18) respectively. The hatched curve results from the calculation of the energy-loss distribution, to be discussed later. The peak near 0 eV corresponds to electrons scattered quasielastically from the film whereas the tail arises from multiple energy losses to phonon modes of the crystal. At incident energies E_0 = 11.45 and 12.05 eV, the phonon tail is characteristic of "off-resonance" conditions and similar to other data recorded at energies where no resonances exist. However, "on resonance" (i.e., at E_0 = 11.75), the Ar^- state is formed and a phonon peak is superimposed on the phonon energy-loss tail attributed to multiple scattering within the solid. Subtracting the off-resonance data from the HREEL data recorded at E_0 = 11.75 eV provides the contribution to phonon excitation in the Ar lattice due to formation of an anion state during 2.2×10^{-14} s in solid Ar.

The effect of a transient anion state on the surrounding Ar matrix can be described by considering the interaction between a time-dependent charge located on a lattice site and the acoustical phonons treated by a quantum-mechanical description. Such a problem has been addressed in detail recently by Mills (19) in connection with the suppression of the resonant elastic peak (20) in electron scattering from a van der Waals solid. The results of the analysis leads, among other things, to an expression for the multiphonon loss feature whose intensity and mean energy loss depend mainly on the electron residence time τ_R and the polarizability of the surrounding atoms or molecules (i.e., dielectric constant ϵ of the medium). More specifically, it can be shown for a charge e, whose time dependency varies according to $e(t) = e \exp(-|t|/2\tau_R)$ on a lattice site, that the total probability to excite 1,2,..., m,... phonons with an energy loss between Ω and $(\Omega + d\Omega)$ is given by

$$[1a] \quad \frac{dP^{(tot)}}{d\Omega} = \sum_{m=1}^{\infty} \frac{\gamma^m \exp(-\gamma)}{m!} \frac{\exp\,[-(\Omega - m\bar{\omega})^2/2m(\Delta\omega)^2]}{(2\pi m)^{1/2}\,\Delta\omega}$$

In this expression $m\bar{\omega}$ and $m^{1/2}\Delta\omega$ correspond to the mean frequency and the frequency width of the m phonon-loss process, respectively (19). In the spirit of the Debye model for the longitudinal acoustic phonon at zero temperature, we have the prescription that $\bar{\omega} = 4\omega_D/5$ and $\Delta\omega = \omega_D\sqrt{2/75}$ with ω_D the Debye frequency (19). In eq. [1*a*], the term γ is referred to as a pseudo-Debye–Waller factor because it depends on the transient character of the scattering event, whereas the usual Debye–Waller factor involves only the overall momentum transfer (19). It is given explicitly by

$$[1b] \quad \gamma = \frac{2}{3} \frac{e^4(\epsilon - 1)^2\omega_D\tau_R}{\hbar M a_0^2 c_l^2[1 + (\omega_D\tau_R)^2]^2}$$

where M is the mass of the atom, a_0 the nearest-neighbor distance, c_l the longitudinal sound velocity, and ϵ the dielectric constant appropriate to the frequency range τ_R^{-1}.

Calculations were performed with eqs. [1] using only τ_R as an adjustable parameter and considering that solid Ar has a nearest-neighbor distance of 3.75 Å at 20 K, a dielectric constant of 1.66, a Debye energy of 8 meV, and a longitudinal velocity of sound of 1.64×10^{10} cm/s (18). The result of the calculation (16) with $\tau_R = 2.2 \times 10^{-14}$ s is displayed as the hatched curve in Fig. 3. It should be noted that the energy of the maximum was quite sensitive to τ_R; a variation of τ_R by 10% resulted in a 15% change for the energy of the maximum.

When similar short-lived anion states are formed in a molecular solid, they can also induce, besides phonon excitations, intramolecular vibrational excitation during their lifetime. When the scattering electron is temporarily captured at a molecular site ("on-resonance" condition, Fig. 2), the molecular orbitals at and near this site are strongly perturbed and the nuclei of the transient anion move to a new equilibrium position, thus initiating considerable nuclear motion (i.e., intramolecular vibrational excitation). This interaction is so effective in producing vibrationally excited molecules that it often dominates all other inelastic processes around the resonance energy. To illustrate this phenomena we have chosen the example of N_2^- formation in solid N_2. The energy-loss spectra for electrons of 2.9, 19.8, and 10.8 eV incident at θ_0 = 14° on a 25-layer solid film of N_2 are shown in Fig. 4 (21). The vertical gain for each curve or portion of a curve is referenced to the elastic peak of the top tracing. In the energy-loss range 0–2.5 eV, the top curve is composed of two overlapping series of vibrational levels (i.e, a weak and a strong progression). For low vibrational quantum numbers (v = 1–4) the two progressions cannot be separated, but at higher values (v = 5–8) sharp peaks belonging to the weak progression become visible on the low-energy side of much broader and more intense energy-loss

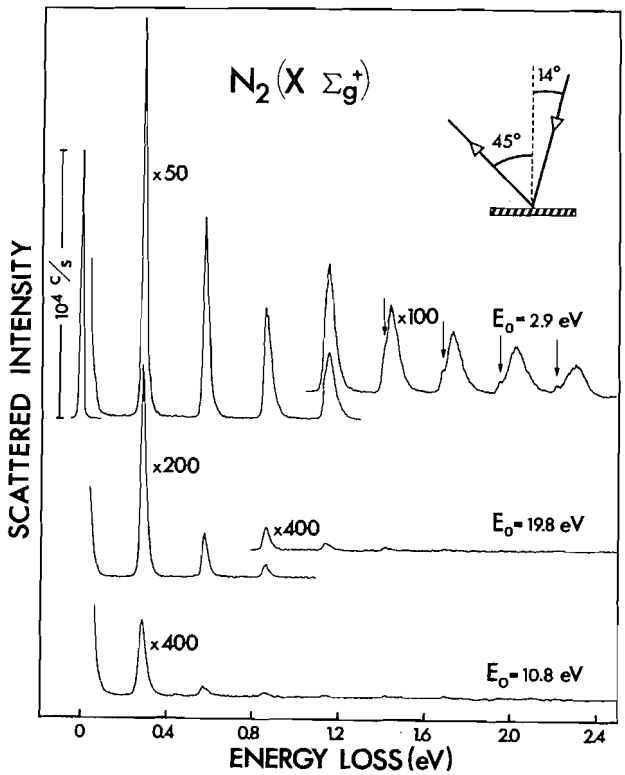

FIG. 4. Electron energy loss spectra of a multilayer disordered 25-layer film of N_2 recorded at primary energies of 2.9, 19.8, and 10.8 eV. The intensity of the elastic peak is indicated in counts/second (c/s). The enhancement in vibrational excitation of ground-state N_2 at 2.9 and 19.8 eV results from the formation of temporary negatively charged N_2^- states in the solid.

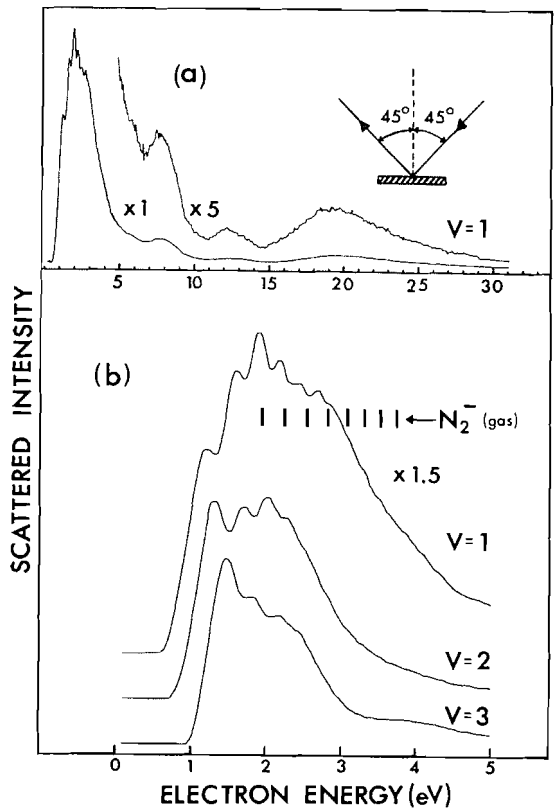

FIG. 5. (*a*) Energy dependence of the excitation of the first intramolecular vibrational level of a 12-layer film of N_2. The four maxima are interpreted as due to the formation of temporary N_2^- states. (*b*) Excitation functions from 0 to 5 eV for the first three intramolecular vibrational levels of a 12-layer film of N_2. The oscillatory structure is due to nuclear motion within the temporary N_2^- state.

peaks forming the strong progression. The latter exhibits a small anharmonicity (anharmonic constant = 0.22 ∓ 0.15 meV), whereas, for the former, the anharmonic constant is estimated to be 1.80 ∓ 0.15 meV from the last four vibrational levels. The anharmonicity of the weak progression is typical of vibrational excitation of ground-state molecular nitrogen (1.79 meV) in the gas phase (22). Both progressions result from vibrational excitation of ground-state $N_2(X^1\Sigma_g^+)$ in the solid; the weak series corresponds to single scattering events whereas the strong one results from multiple excitation of vibrational modes of N_2 convoluted with multiple intermolecular phonon modes (11). These multiple scatterings increase the energy and broaden the energy width of each peak. They indicate that *electrons scatter within the solid* since these effects are much weaker on single layer deposits and practically unobservable at submonolayer coverages.

The three energy-loss curves in Fig. 4 clearly indicate that the vibrational intensities are strongly dependent on the primary beam energy. The 10.8 eV spectrum correspond to a nonresonant condition whereas with incident electrons of 2.9 and 19.8 eV the $^2\Pi_g$ and $^2\Sigma_u$ states of the N_2^- state are formed, respectively. The lifetime of the $^2\Pi_g$ anion state has been estimated at a value of 3×10^{-15} s (23) and that of the $^2\Sigma_u$ state is of the order of 10^{-15} s. The effect of anion formation for such a short time is quite obvious from the results of Fig. 4. Compared to the values measured off resonance at an incident energy E_0 = 10.8 eV, the intensities of overtones of the fundamental frequency of N_2 are *enhanced by* approximately an order of magnitude at E_0 = 19.8 eV and by *two orders of magnitude* at E_0 = 2.9 eV. The increase in the magnitude of a given intramolecular vibrational mode at the resonance energies can be measured by monitoring the dependence on incident electron energy of the energy loss to that mode. Such an excitation function for the $v = 1$ vibrational level of ground state N_2 between 0 and 30 eV, recorded with a 12-layer film of N_2 film (23), is shown in Fig. 5(*a*). The four maxima can be ascribed to transient anion formation (24). The symmetries of the 2, 12, and 19 eV anions are $^2\Pi_g$, $^2\Delta_g$, and $^2\Sigma_g^+$, respectively, but the configuration of the 8 eV state is still undetermined in both the gas and solid phase. The lowest energy feature in Fig. 5(*a*) is displayed on an extended scale in the upper portion of Fig. 5(*b*) along with the excitation functions of the $v = 2$ and $v = 3$ vibrational levels. The oscillatory structure, which modulates the broad peak in each excitation function, results from vibrational motion of the $^2\Pi_g$ transient N_2^- state (23). The vertical bars in Fig. 5(*b*) represent the energies of the first eight "quasi-vibrational peaks" of that state as recorded in the $v = 1$ decay channel in gaseous N_2 (24). The average spacing for the first six peaks is 0.27 eV as compared to the corresponding value of 0.29 eV in the solid (23). From the shift of the first vibrational peak in the upper curve of Fig. 5(*b*) in going from 1.93 eV in the gas to 1.23 eV in the film, the value of 0.7 eV for the relaxation energy of N_2^- in N_2 is obtained. *This lowering of the energy of the $^2\Pi_g$ anion is due to electronic polarization of the surrounding N_2 molecules by the temporarily localized charge.*

3. Femtosecond ion–molecule surface reactions

A. Principle of the method and experiment

When molecular transient anion states are dissociative, they may produce fragments if the lifetime of the resonance is of the order of, or longer than, a vibrational period (3). Since at least one of the fragments usually has a positive electron affinity, dissociation of the anion state can produce a stable anion and a neutral molecule, atom, or radical (3). In the simplest case of a diatomic molecule AB, this process, named dissociative electron attachment (DEA), may be represented as $e + AB \rightarrow (AB^-)^* \rightarrow A + B^-$ or $A^* + B^-$. When this reaction occurs near the surface of a dielectric, the fragment anion B^- can escape into the vacuum only if it possesses sufficient kinetic energy to escape the polarization potential that it induces at the surface of the solid. For molecular solids, the kinetic energies required for the escape of the fragment anion in the direction normal to the surface are of the order of 0.5–1.0 eV. The steepness of the potential energy curve of the intermediate state AB^- is usually such that the B^- ion is propelled with sufficient energy to escape into the vacuum, if its velocity vector is properly oriented with respect to the surface. Of course, the B^- anion does not necessarily escape into the vacuum and may undergo reactive scattering with neighboring molecules. Assuming that the AB molecule is deposited at the surface of a molecular solid film composed of molecules CD, dissociative electron attachment to AB produces B^- ions that can react with electron volts of energies with CD. In this case, reactions of the type

$$[2] \quad B^- + CD \rightarrow BCD^- \rightarrow BC + D^-$$

are possible; i.e., there is the formation of a new intermediate anion BCD^- that can decay by dissociation into new products if, again, the lifetime of BCD^- is longer than, or of the order of, its vibrational period and one of the possible new fragments has a positive electron affinity. In the example of eq. [2], the D^- fragment must also have sufficient kinetic energy to be observed in vacuum. Thus, the observation of such D^- ions in vacuum necessarily implies that they were produced as the result of a dissociating state BCD^- (i.e., that both dissociation limits $B^- + CD$ and $BC + D^-$ lie below the BCD^- state) (25). Reactions of the type represented by eq. [1] therefore occur in times of the order of the vibrational periods of the intermediate anion BCD^- (i.e., 10^{-14}–10^{-13} s). Such ultrafast reactions can be detected by measuring the anion products (e.g., D^-) that escape to vacuum in electron-stimulated desorption (ESD) experiments. Anions desorbing from a multilayer film can be measured by replacing the analyzer shown in lower portion of Fig. 1 by a mass spectrometer. A portion of the negative ions, which are desorbed by electrons impinging on the film from the monochromator, is focused by the ion lenses at the entrance of the mass spectrometer. This latter measures, at a given mass, the yield of anions as a function of incident electron energy.

B. Results and discussion

Examples of anion production by DEA are illustrated by the two upper curves (*a*) and (*b*) in Fig. 6. The former represents the energy dependence of the O^- current produced by electron impact on a multilayer film of O_2 whereas the latter was recorded by discriminating anions having energies less than 1.8 eV with a retardation potential V_R. The broad peaks located around 8 and 13 eV in curves (*a*) and (*b*) have been ascribed to the dissociative attachment reaction (26).

$$[3] \quad e^- + O_2(^3\Sigma_g^-) \rightarrow O_2^-(^2\Pi_u, {}^2\Sigma_{g,u}^+) \rightarrow O^-(^2P) + O(^3P, {}^1D)$$

The 8 eV peak contains contributions from the decay of the $^2\Pi_u$ and $^2\Sigma_g^+$ transitory states of O_2^- whereas the 13 eV peak arises mainly from a higher- energy symmetry-forbidden $^2\Sigma_u^+$ O_2^- state. The O^- ions produced by the Σ states are, on the average, more energetic and therefore less affected by the retardation potential V_R. The remaining curves (i.e., (*c*)–(*g*) in Fig. 6) illustrate the energy dependence of the OH^- yields produced by electron impact on a 3-layer film of oxygen covered by a monolayer of C_nH_{2n+2} molecules (n = 1, 2, 4, 5, and 6). At submonolayer coverages, these OH^- yield functions exhibit the same characteristics but the signal is lower. In fact, in the submonolayer regime the magnitude of the OH^- signal is found to be directly proportional to the number of condensed hydrocarbon molecules. Since no compound at the film surface contains both hydrogen and oxygen. OH^- ions cannot be produced by direct electron impact. However, they can result from reactions between molecules (i.e., O_2 and C_nH_{2n+2}) in their ground states and anions produced directly by the electron beam (i.e., O^-, H^-, and CH_n^-, n = 1–3). A priori, OH^- can be formed via the reactions (25),

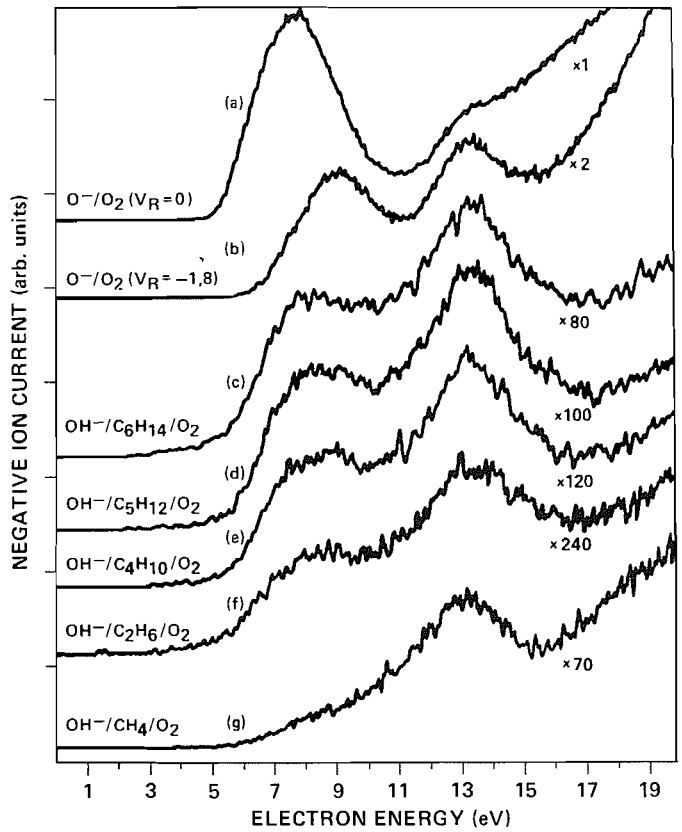

FIG. 6. Energy dependence of electron-stimulated desorption of negative ions in the range 1–20 eV. Curves (*a*) and (*b*), O^- desorption from a 3-layer O_2 film. V_R is a potential retarding the negative ions at the entrance of the mass spectrometer. Curves (*c*)–(*g*), OH^- desorption form a 3-layer O_2 film covered with a single layer of C_nH_{2n+2} (n = 1, 2, 4, 5, and 6) molecules. Curves (*c*)–(*g*) were recorded with V_R = 0.

$$[4] \quad O^- + C_nH_{2n+2} \rightarrow C_nH_{2n+2}O^- \rightarrow OH^- + C_nH_{2n+1}$$

or the reactions

$$[5a] \quad H^- + O_2 \rightarrow OH^- + O$$

and

$$[5b] \quad CH_n^- + O_2 \rightarrow OH^- + CH_{n-1}O$$

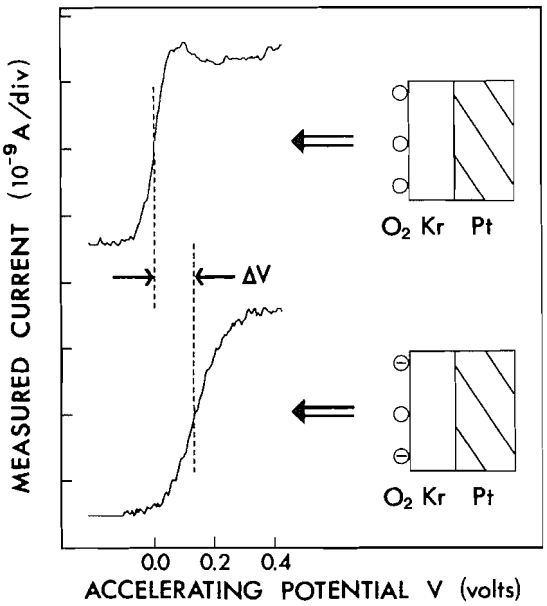

FIG. 7. Current transmitted through an uncharged (top) and a charged (bottom) 20-layer Kr film covered with 0.1 layer of O_2 as a function of the accelerating potential V of the incident electron beam.

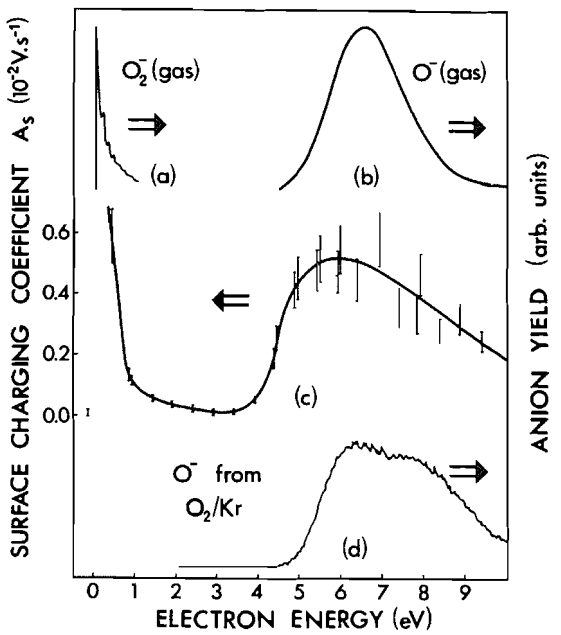

FIG. 8. Anion yields produced by 0–10 eV electron impact on (*a*) and (*b*) gaseous O_2 and on (*d*) a 0.1 layer of O_2 deposited on a 20-layer film of Kr. (*c*) Electron energy dependence of the surface-charging coefficient A_s for a 0.1 layer of O_2 deposited on a 20-layer film of Kr.

of the yield functions for H^- or CH_n^-. However, these are much different than that for O^- production (27) and the OH^- product can therefore only be ascribed to reaction [4] where the energetic O^- ions are generated by the DEA reaction described in eq. [3]. In other words, the features in the curves (*a*) and (*b*), which represent the electron energy dependence of the O^- yield, are reflected into the electron energy dependence of the OH^- yield and thus serve as a signature to detect and identify reaction [4]. As explained in the previous subsection, this reaction takes place during times of the order of the vibrational period of the C_nH_{2n+2}–O^- stretching bond.

4. Mechanism of electron trapping

A. Method and experiment

In this section it is shown that, from our knowledge of elementary excitations and transient anion formation in both gas and condensed phases, it is possible to identify the initial mechanism, *operative on a time scale of 10–1000 fs*, that is responsible for electron trapping near the surface of a dielectric. The initial mechanism can be inferred by measuring the incident electron energy dependence of the trapping cross section. This latter cross section is obtained from the measure of the charges that accumulate on a dielectric film after bombardment with a low-energy electron beam during a given time at a specific energy. The energy dependence of the electron-trapping cross section is obtained by repeating this measurement for different incident electron energies.

This new method of charge measurement (28) is derived from low-energy electron transmission (LEET) spectroscopy (12). In a LEET experiment, a monoenergetic electron beam impinges on a multilayer solid film grown on a metal substrate (12). Referring to the apparatus in Fig. 1, a LEET spectrum is recorded by measuring on the metal substrate the electron current, which traverses the film, as a function of a potential V applied between the substrate and the electron source (12). When electrons have just enough energy to enter into the film from vacuum, a sharp rise, termed the injection curve (IC), is seen in LEET spectra (28). The IC for an uncharged film is represented by the upper curve of Fig. 7. When the same film is charged at the surface by the electron beam, the IC is shifted by ΔV to a higher accelerating potential, as shown by the lower curve in Fig. 7, since the incoming electrons must possess additional kinetic energy to overcome the negative potential barrier. The IC is also broadened as a result of the spatial current-density distribution (28).

Treating the dielectric film as a charged capacitor, the potential barrier ΔV is related to the surface charge density $\sigma(t)$, which has accumulated after bombardment time t, by the relation (28)

$$[7] \quad \Delta V(t) = \sigma(t)h/\epsilon$$

where $\sigma(t) = \sigma_0(1 - e^{-\beta t})$ and $\beta = \mu J_0/e$; ϵ is the dielectric constant of the film, h is the film thickness, σ_0 is the initial ($t = 0$) trap density, μ is the trapping cross section, J_0 is the incident current density, and e is the unit charge. *In the limit* $t \rightarrow 0$ *we can define a charging coefficient* $A_s = d\Delta V/dt$ *that is directly proportional to the trapping cross section* (i.e., $d\Delta V/d|_{t=0} = (h\sigma_0 J_0/\epsilon e)\mu = A_s$). In the experiment, the IC of the uncharged film is first recorded before bombarding the film at a given energy. The IC is again rapidly recorded and the shift ΔV determined by comparison with the initial IC. Such a cycle can be repeated many times on the same film with the same potential V to obtain the time dependence of the process. Otherwise, to measure the thickness and the energy dependence, a new film has to be deposited for each data point. As an example, the shift ΔV= 130 meV in Fig. 7 was obtained after a bombardment at 7.3 eV of 20-layer film of Kr covered with 0.1 layer of O_2 (29). Here, the Kr solid does not charge significantly during the time of bombardment in the absence of the O_2 adsorbate, so that charging can be attributed to electron trapping near or at the position of O_2 molecules. By repeating such measurements for small bombardment times (i.e., in the limit $t \rightarrow 0$) at different energies, the incident electron energy dependence of the charging coefficient of trapping cross section can be obtained.

B. Results and discussion

The surface charging coefficient A_s for 0.1 layer of O_2 condensed onto a 20-layer film of Kr (29) is represented by the middle curve (*c*) in Fig. 8, as a function of the energy of the electron beam that causes charging. The result in Fig. 8 is comparable to the energy dependence of the anion yields derived from the gas-phase attachment rate coefficient for stable O_2^- production (30) (Fig. 8(*a*)) and the gas-phase DEA cross sec-

tion (31) (Fig. 5(*b*)). Curve (*d*) represents the ESD signal from a 20-layer film of Kr covered with 0.1 layer of O_2.

From the correspondence between the curves of Fig. 8, electron trapping at the surface of the Kr film above 4 eV can be ascribed to dissociation of the $^2\Pi_u$ state of O_2^- into the limit $O(^3P) + O^-(^2P)$. Although the desorbing $O^-(^2P)$ ions could also arise from the $^2\Sigma_g^+$ state of O_2^- as seen in Fig. 6, only a small fraction of the signal is thought to arise from that state since it must be formed near another O_2 molecule in order to violate the $\Sigma^- \leftrightarrow \Sigma^+$ selection rule (32). The maximum in the charging coefficient A_s is found about 0.6 eV below the maximum in the gas-phase O^- yield due to the lowering of the $^2\Pi_u$ resonance by the polarization potential of the Kr surface. Thus, the DEA maximum in the ESD yield arises from the same O_2^- surface state as that in the charging signal. However, the DEA maximum lies at a higher energy since, in order to overcome the polarization force of the Kr film, desorbing O^- ions must arise, on the average, from a higher energy portion in the Franck–Condon region of the O_2^- $^2\Pi_u$ potential energy curve.

In the 0–1.2 eV range, temporary electron attachment to gaseous O_2 leads to formation of the $^2\Pi_g$ resonance state of O_2^- that occurs in vibrational levels $v \geq 4$, since the $v < 4$ levels lie below the ground state of O_2 (30). However, if vibrational energy is transferred to another particle during the lifetime of the $^2\Pi_g$ anion, the $v < 4$ levels can be reached and the electron becomes permanently attached to the molecule. A similar stabilization process is responsible for surface charge accumulation in the range 0–2 eV. The electron can either lose energy to vibrationally excite O_2 via the $^2\Pi_g$ O_2^- state and afterwards stabilize at a trapping site, or the $^2\Pi_g$ state may itself stabilize by energy transfer to phonons. The estimated lifetime of the $^2\Pi_g$ O_2^- state within O_2 clusters is of the order of 10^{-12} s (33), which is comparable to the phonon vibrational period of the Kr lattice (5×10^{-13} s) (34). Hence, assuming a similar lifetime on Kr, the additional electron resides a sufficiently long time at an O_2 site to polarize the phonon modes of the Kr lattice. In conclusion, the initial mechanism of electron localization at the O_2 site in the 0–2 eV range is due to electron stabilization via the $^2\Pi_g$ resonance, whereas in the 4–10 eV region it is due to $O^-(^2P)$ formed by dissociation of the intermediate $^2\Pi_u$ state of O_2^-.

The vibrational dependence of the dipole moment of hydrogen fluoride

J.A. BARNES, T.E. GOUGH,[1] AND M. STOER
Department of Chemistry, University of Victoria, Victoria, BC V8W 3P6, Canada
Received June 24, 1993
This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

J.A. BARNES, T.E. GOUGH, and M. STOER. Can. J. Chem. **72**, 499 (1994).

Molecular beam laser Stark spectroscopy has been used to measure the $v = 3$ vibrational state dipole moment of hydrogen fluoride as 1.9614 ± 0.0021 debye. This measurement allows μ_v to be expressed as a power series expansion in $(v + \frac{1}{2})$ without the use of infrared intensity data. A detailed comparison is made with similar series based mainly on infrared intensity data and more recent *ab initio* calculations.

J.A. BARNES, T.E. GOUGH et M. STOER. Can. J. Chem. **72**, 499 (1994).

On a utilisé la spectroscopie au laser à faisceau moléculaire de Stark pour déterminer que le moment dipolaire de l'état vibrationnel $v = 3$ du fluorure d'hydrogène est égal à 1,9614 ± 0,0021 debye. Cette mesure permet d'exprimer μ_v comme une expansion d'une série de puissance en $(v + \frac{1}{2})$ sans être obligé d'utiliser des données d'intensité en infrarouge. On fait une comparaison détaillée de séries semblables obtenues principalement à l'aide d'intensités en infrarouge et avec des calculs *ab initio* plus récents.

1. Introduction

The dipole moment function of hydrogen fluoride continues to be a topic of interest, partly because the molecule is sufficiently small to be amenable to high-quality theoretical treatment and partly because of the availability of significant amounts of relevant experimental data. In addition, the central role of emission from vibrationally excited hydrogen fluoride in chemical lasers (1–3) and as a probe of reaction dynamics provides an incentive for as quantitative an understanding of the dipole moment of hydrogen fluoride as is possible.

The dipole moment function obtained by Werner and Rosmus using highly correlated Self-Consistent Electron Pairs/Coupled Electron Pair Approximation (SCEP/CEPA) wave functions long provided the best agreement between *ab initio* and experimental functions up to the $v = 9$ level (4). More recently, Zemke et al. have taken a potential energy function of hydrogen fluoride based on spectroscopic measurements (5) and imposed upon it the proper long-range behaviour by including both dispersion and exchange effects (6). This potential was then combined with a new *ab initio* dipole moment function, complete for all internuclear distances, to calculate line intensities and dipole moments (7). The results were in excellent agreement with experimental data, particularly that of Sileo and Cool (8). For high levels of vibrational excitation, the results of Zemke et al. represent a marked improvement over those of Werner and Rosmus. That this improvement is largely due to the more realistic potential energy function used can be inferred from the fact that the dissociation limit determined by this function ($D_e = 49362 \pm 5$ cm^{-1}) differs markedly from that obtained from the full CI, "benchmark" calculations of Bauschlicher et al. (48960 cm^{-1}) (9).

A calculation using density functional techniques (10), which are computationally more efficient, was found to improve upon the results obtained from self-consistent field methods that neglect electron correlation. However, the calculations were confined to the equilibrium geometry and seem less accurate than those performed using the SCEP/CEPA method.

Sileo and Cool performed an extensive series of measurements of overtone emission intensities for hydrogen fluoride (8) and these have been the main source of experimental data to which theoretical results have been compared. Many of the systematic errors inherent in measuring emission intensities are less important in Sileo and Cool's analysis, which only uses ratios of such intensities. However, one experimentally determined dipole moment is necessary to establish absolute values of dipole moments from Sileo and Cool's data (8). Measurements of the dipole moments of the $v = 0$ and $v = 1$ states of hydrogen fluoride provide a second source of experimental information that, although more limited, is both more precise and more accurate than that of emission intensities (11, 12). In addition, the intensity of the fundamental vibrational absorption of hydrogen fluoride has been carefully remeasured, once again providing precise but limited information (13). Comparison between experiment and theory is most conveniently done by converting the combined body of experimentally measured quantities, appropriately weighted, into an experimental dipole moment function. This is normally expressed as a power series in the internuclear distance, preferably augmented by some expression to enable extrapolation outside of the range of internuclear distances covered by the experiment. Ogilvie has published the coefficients of such a power series up to sixth order and also carefully analysed standard errors for these coefficients using a Monte Carlo method (14).

Zemke et al. (7) claim that their calculated dipole moments are numerically significant to 10^{-4} debye. This precision exceeds that of infrared intensity measurements, which are also subject to systematic errors on the order of a few percent. Therefore, it is of interest to measure the dipole moments of hydrogen fluoride in higher vibrational states than the $v = 0$ and $v = 1$ states so far reported. Below, the measurement of the dipole moment of hydrogen fluoride in $v = 3$ using Stark splitting of the 3←0 overtone is reported. Such measurements have a systematic error of 0.01% and a precision of 10^{-3} debye.

2. Experimental

The laser molecular beam spectrometer used in the present study is depicted in Fig. 1. The current apparatus is similar to that used previously (15); however, the laser system has been replaced by a Coherent 899 Ti–sapphire laser pumped by a Coherent Innova 200 Ar ion laser. The Ti–sapphire laser provides tunable near-infrared radiation (11 300–13 000 cm^{-1}), with a peak power of 2 W single frequency and a line width of ≈4 MHz. The line width was determined by mea-

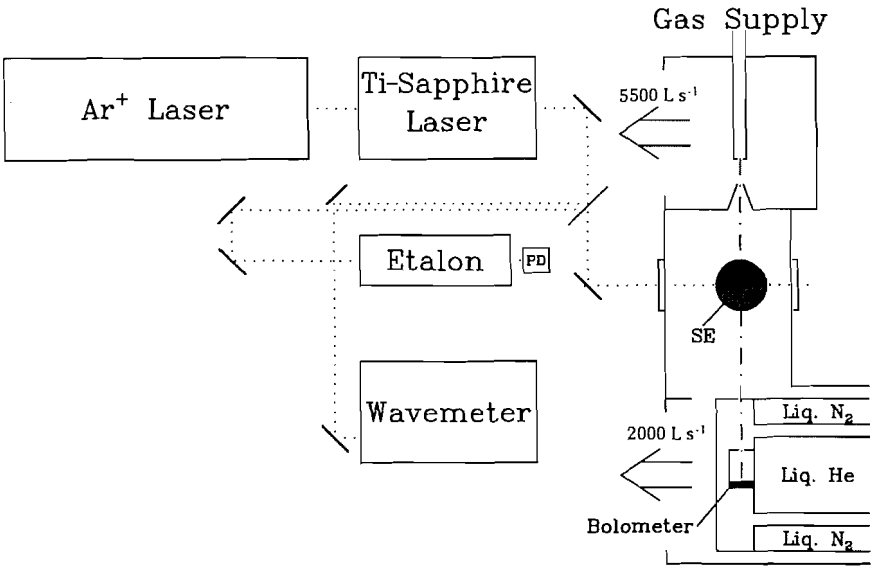

FIG. 1. Schematic of the apparatus used for the optothermal molecular beam Stark spectroscopy. SE, Stark electrodes; PD, photodiode; Liq., liquid.

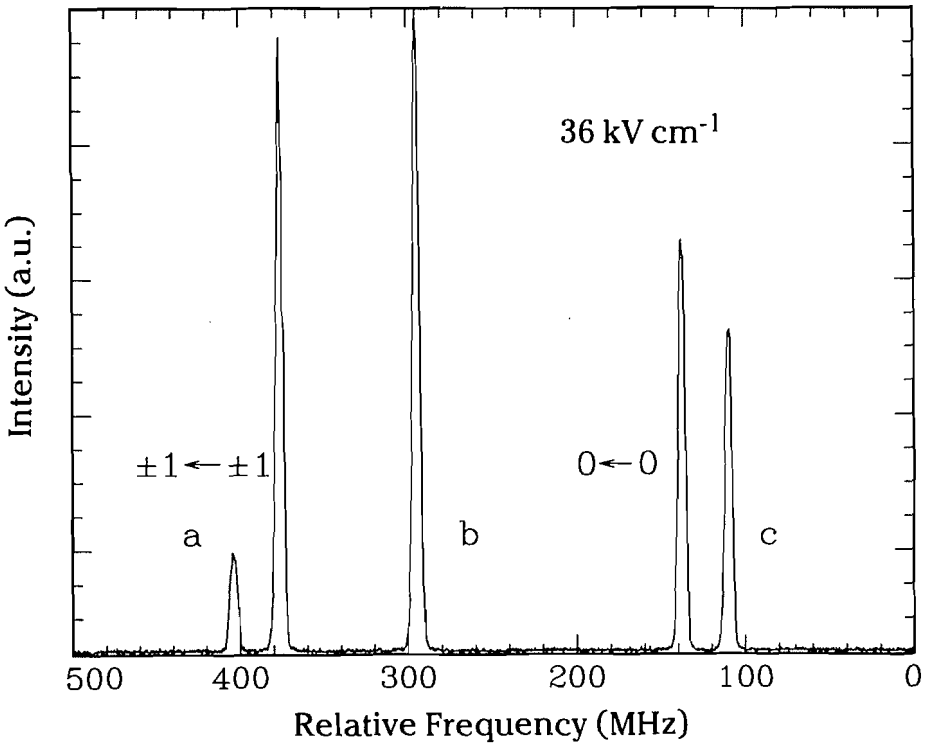

FIG. 2. Experimental Stark split spectrum of the $R(1)$ transition of the $v = 3 \leftarrow 0$ band of hydrogen fluoride, induced by an applied field of 36 kV cm^{-1}.

suring a rotational vibrational molecular beam transition. The output polarization of the laser was rotated 45° with respect to the Stark electric field, to allow observation of transitions obeying $\Delta M = 0, \pm 1$ selection rules. Although the Ti–sapphire laser is frequency stabilized, an etalon was used to verify the linearity of the laser scan. The free spectral range of the etalon was 300 MHz; however, it was slightly misaligned to provide stable transverse etalon modes with a frequency spacing of 100 MHz.

The 5% hydrogen fluoride in helium gas mixture was expanded through a 100-μm diameter nozzle, with a stagnation pressure optimized at 0.5 atm (1 atm = 101.3 kPa). A 500-μm skimmer was used to further collimate the molecular beam. Rather than using a gas cell, the HF rotational line positions for the $v = 3 \leftarrow 0$ vibrational transition were located using results from Fishburne and Rao (*16*) and a Burleigh wavemeter. The J=2←1 rotational transition at 11 441.41 cm^{-1} was split with Stark fields of ≈40 kV cm^{-1}. A typical spectrum is shown in Fig. 2 with the transitions labelled according to Fig. 3. Absolute frequencies were not needed and the Stark electrode spacing did not need to be known exactly because, as is shown later, only the ratio of the line splittings $(b - c)/(a - b)$ was of interest.

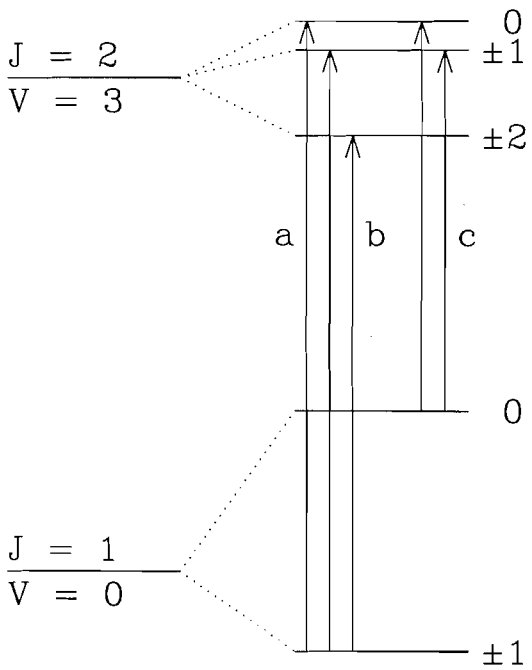

FIG. 3. Energy levels and transitions corresponding to the spectrum depicted in Fig. 2.

This ratio was found to be 1.679 ± 0.005 experimentally, gathered from the analysis of 40 separate scans. The principle source of error may be attributed to drifts in the frequency of the laser.

3. Analysis of data

For a diatomic molecule in an electric field, the electrical energies of the J and M levels will be given by

$$[1] \qquad \epsilon_{v,J,M} = \epsilon^{(2)}_{v,J,M} + \epsilon^{(P)}_{v,J,M} + \epsilon^{(4)}_{v,J,M}$$

where the dominant term is the second-order dipole – applied electric field interaction (17):

$$[2] \qquad \epsilon^{(2)}_{v,J,M} = \frac{\mu_v^2 E^2}{2hB_v} \frac{J(J+1) - 3M^2}{J(J+1)(2J-1)(2J+3)}$$

The dipole moment (μ_v) and the rotational constant (B_v) are for the specified vibrational state v, and the appropriate selection rules for the present experiment are given in Fig. 3. The effects due to the polarizability anisotropy ($\epsilon^{(P)}_{v,J,M}$) and the fourth-order dipole – applied electric field interaction $\epsilon^{(4)}_{v,J,M}$ are less than 0.5% for applied electric fields in the order of 40 kV cm^{-1}. It is therefore not necessary to know the exact electric field for the fourth-order correction. The electric field was estimated from the second-order term, after calculating the upper state dipole moment based on second-order perturbations alone.

The effects of the anisotropy of the polarizability are compensated for by applying the following correction (18):

$$[3] \qquad \epsilon^{(P)}_{J,M} = -\frac{(\alpha_\parallel - \alpha_\perp)E^2}{2} \frac{2J^2 + 2J - 1 - 2M^2}{(2J+3)(2J-1)}$$

where $(\alpha_\parallel - \alpha_\perp)$ or $\Delta\alpha$ is the anisotropy of the polarizability of the molecule. The vibrational dependence of $\Delta\alpha$ has been ignored, since $\epsilon^{(P)}_{J,M}$ is much less than $\epsilon^{(2)}_{v,J,M}$. Observing that both $\epsilon^{(2)}_{v,J,M}$ and $\epsilon^{(P)}_{J,M}$) are a function of E^2, one can express the excited state dipole moment in terms of the ratio $(b-c)/(a-b)$ for the $(v = 3, J = 2 \leftarrow v = 0, J = 1)$ transition, the ground state dipole moment, and the appropriate rotational constants:

$$[4] \qquad \mu_3^2 = \frac{B_3}{C_S}\left[\frac{63\mu_0^2}{20B_0} C_S + \Delta\alpha C_P \left(4\frac{(b-c)}{(a-b)} - \frac{42}{35}\right)\right] \times \left[\frac{(b-c)}{(a-b)} + \frac{3}{4}\right]^{-1}$$

where C_S and C_P are the second-order Stark and polarizability constants, respectively.

Once the second-order corrections had been evaluated, the electric field was estimated by comparison of the measured splitting $(a-c)$ with the splitting calculated from the second-order determination of the dipole. The fourth-order correction was then calculated using eq. [5] (18),

$$[5] \qquad \epsilon^{(4)}_{v,J,M} = \frac{\mu_v^4 E^4}{8h^3 B_v^3}\left\{\frac{[(J+1)^2 - M^2][(J+2)^2 - M^2]}{(2J+1)(2J+5)(J+1)^2(2J+1)^3} + \frac{[(J-1)^2 - M^2](J^2 - M^2)}{(2J-3)(2J+1)J^2(2J-1)^3} + \frac{(J^2 - M^2)[(J+1)^2 - M^2]}{(2J-1)(2J+3)(2J+1)^2J^2(J+1)^2} + \frac{[(J+1)^2 - M^2]^2}{(2J+3)^2(2J+1)^2(J+1)^3} - \frac{[J^2 - M^2]^2}{(2J+1)^2(2J-1)^2J^3}\right\}$$

Table 1 lists the required variables and the results of all of the calculations.

4. Discussion

Figure 4 provides a convenient format for assessing the information available concerning the dependence upon vibrational quantum number of the dipole moment of hydrogen fluoride. In this figure, the theoretical results of Zemke et al. (7) have been subtracted from the corresponding experimental values. The circles denote measurements made using Stark splitting of spectra using various molecular beam techniques and the diamonds are dipole moments as reported by Sileo and Cool. The discrepancy between the two sets of data arises because of the incorrect value of μ_e used in their analysis. It is perfectly valid to adjust the diamonds upwards a constant amount so that the two sets of data overlap at $v = -\frac{1}{2}$; it is essential to make such an adjustment before attempting comparisons with theoretical predictions of the quality claimed by Zemke et al. After the adjustment is made, the two sets of experimental data are in excellent agreement and it seems clear that the theory underestimates μ_e by 0.004 debye and overestimates the rate at which μ_v increases with v at least for $v < 4$. Nevertheless, the agreement over the full range of available data of better than ± 0.005 debye is most impressive.

The triangle in Fig. 4 represents the value for μ_2 calculated by Bass et al. (12) from an experimental dipole moment function based on molecular beam electric resonance measure-

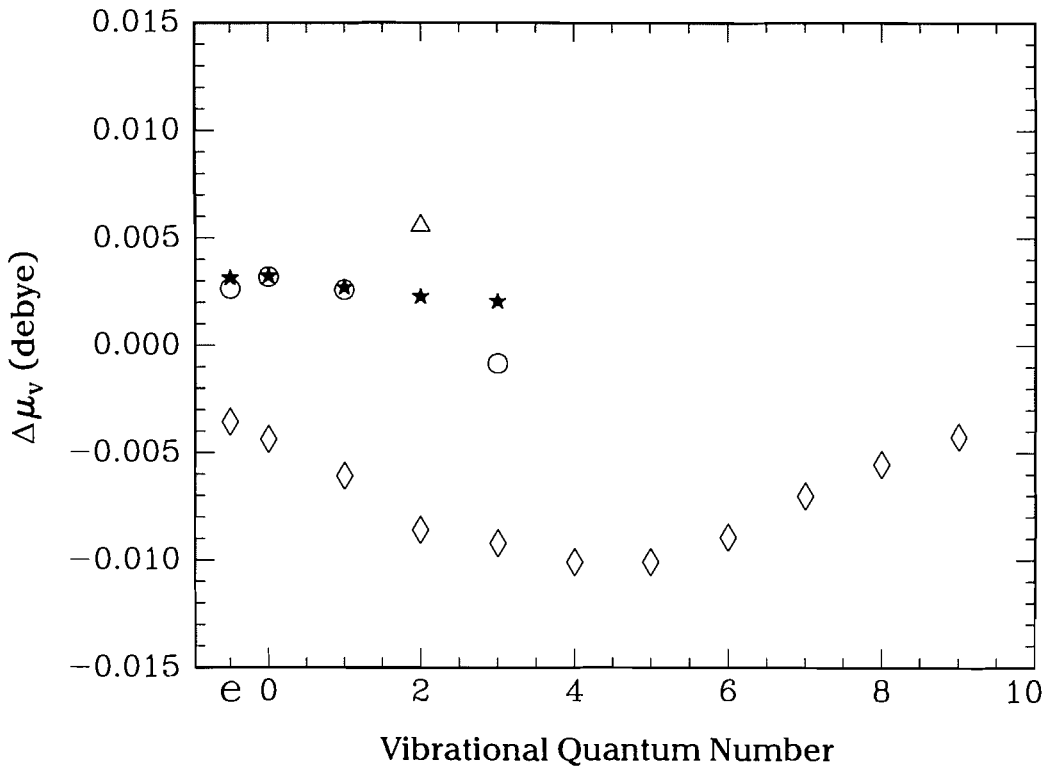

FIG. 4. Plot of the difference between the experimentally determined dipole moments and the *ab initio* dipole moment data taken from Zemke et al. (7) for hydrogen fluoride (see Table 2). ◇, data from Sileo and Cool (8); ○, data from Bass et al. (12) and the present work; △, calculated by Bass et al. (12) based on existing experimental data at the time; ★, calculated using the Herman and Short theory (19) together with values for the M_j and a_j taken from Ogilvie (14).

ments of μ_0 and μ_1 and the transition dipole moments $\langle 0|\mu|1\rangle$ and $\langle 0|\mu|3\rangle$. It seems clear that this value of 1.9232 debye for μ_2 is in error; in fact, the *ab initio* value of 1.9176 is five times closer to the interpolated value of 1.9185 debye established by the present measurement of μ_3. The problems encountered in establishing dipole moment functions have been discussed by Bass et al. (12). What follows examines the accuracy with which dipole moments may be extracted from these functions.

Experimental values for the dipole moment, observed for several vibrational states, are most conveniently expressed as a power series in $(v + \frac{1}{2})$ where v is the vibrational quantum number.

$$[6] \qquad \mu_v = \sum P_j \left(v + \frac{1}{2}\right)^j$$

The dipole moment function, on the other hand, is normally expressed as a Taylor series in the reduced internuclear displacement from equilibrium.

$$[7] \qquad M(x) = \sum M_j x^j; \qquad x = \frac{(R - R_e)}{R_e}$$

With this choice of dipole moment function, expressions for dipole moments and transition dipole moments can be written as a series of linear equations and thus experimental values of these quantities can be used to determine a set of values of M_j. The maximum value of j in either approach is determined by the quantity and quality of the available experimental data. Because the number of measurements of transition intensities greatly exceeds the number of measurements of vibrationally

state-specific dipole moments, the power series (eq. [7]) is the most commonly used. Indeed, for hydrogen fluoride the present measurement allows, for the first time, the determination of P_2 (Table 2), whereas values for M_j up to $j = 6$ are available in the literature. A third form of expansion, the wave function approximation, has been shown to be equivalent to the power series (eq. [7]) (14).

Interconversion between the coefficients of the two expansions is possible following the paper of Herman and Short (19) who showed that P_j may be expressed in terms M_j, B_e/w_e, and a_j, the potential energy coefficients in the Dunham function (20). Previous work seems to have overestimated the rate of convergence of this approach, partly perhaps in deference to the tedious algebra involved. Programs capable of implementing symbolic computation have removed this latter obstacle: accordingly, a Maple™ program was written to rederive the expressions given by Herman and Short, but including terms up to $(B_e/w_e)^4$ and Dunham potential energy coefficients up to a_6. These limits were established by the nonavailability of expressions for the Dunham coefficients higher than Y_{40}. Analytical expressions for P_j ($j = 0$ through 4) are given in the Appendix and Table 3 provides the numerical expressions for P_j as functions of M_j obtained by substituting the values of a_i given by Ogilvie (14) for hydrogen fluoride. As a test of these expressions, the dipole moment function of Zemke et al. (7) was fit to a power series and the resultant values of M_j were substituted into the expressions in Table 3 to obtain values of P_j. These were then used to calculate values of μ_v ($v = 0$ through 3), which agreed to within 10^{-3} debye of the corresponding values calculated by Zemke et al. (7), indicating that both the values of a_j and expressions for P_j are satisfactory for the present purpose. In Table 4 a comparison is made between the P_j values based on Ogilvie's M_j (14) and the expressions in Table 3, and the values obtained directly from eq. [6] and experimentally determined dipole moments.

TABLE 4. Comparison of the literature and present values for P_j

The values of M_j obtained by Ogilvie from a careful analysis of dipole moments and infrared intensities for hydrogen fluoride were then used, in a similar manner, to calculate values of μ_v for $v = -\frac{1}{2}$ and 0 through 3. These results have been inserted into Fig. 4 as solid stars. It can be seen that the M_j values suggested by Ogilvie provide better agreement with the trend established by the present measurement than that obtained by Muenter and co-workers (12). Even so, the agreement seems to be deteriorating with increasing v.

Experimental determination of the dipole moments of higher vibrational states seems advisable. The most obvious experiment is to use a dye laser working on R6G to interrogate $v = 4$. However, intracavity doubling of the Ti–sapphire laser will provide radiation of suitable energy to reach $v = 7$. With an efficient multipass system, the present apparatus should provide satisfactory signal to noise for the successful implementation of such an experiment.

The vibrational circular dichroism spectra of 2-methylaziridine: dominance of the asymmetric centre at nitrogen

ARVI RAUK,[1] THOMAS EGGIMANN, HELMUT WIESER, GENNADII V. SHUSTOV, AND DANYA YANG
Department of Chemistry, The University of Calgary, Calgary, AB, T2N 1N4, Canada
Received March 17, 1993
This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

ARVI RAUK, THOMAS EGGIMANN, HELMUT WIESER, GENNADII V. SHUSTOV, and DANYA YANG. Can. J. Chem. **72**, 506 (1994).

The experimental VCD spectrum of (2*R*)-2-methylaziridine has been measured in the region 800–1500 cm^{-1}. The *ab initio* implementation of the Vibronic Coupling Theory (VCT) of Nafie and Freedman, using the 6-31G$^{*(0.3)}$ basis set, in the common origin and distributed origin gauges and with uniformly and optimally scaled quantum mechanical force fields, is used to investigate the chiroptical properties. VCD spectra are computed for both *cis* and *trans* invertomers. The predicted VCD spectrum of 2-methylaziridine (the equilibrium mixture) is dominated by that of the *trans* diastereomer, not simply because of its greater abundance but because the rotatory strengths of many absorptions in the mid-IR are oppositely signed and of similar magnitude in the two invertomers which differ in absolute configuration at nitrogen. The VCD spectrum of 2-methylaziridine is compared in detail to that of 2-methyloxirane. In the region of the methyl group deformations and CH_2 scissor, the theoretical (*R*)-2-methyloxirane VCD spectrum displays a much closer similarity to the *cis*-(2*R*)-2-methylaziridine than to the *trans* diastereomer.

ARVI RAUK, THOMAS EGGIMANN, HELMUT WIESER, GENNADII V. SHUSTOV et DANYA YANG. Can. J. Chem. **72**, 506 (1994).

On a mesuré le spectre VCD expérimental de la (2*R*)-2-méthylaziridine dans la région de 800 à 1500 cm^{-1}. Pour l'étude des propriétés chiroptiques, on a fait appel à l'implantation *ab initio* de la théorie de couplage vibronique (TCV) de Nafie et Freedman, utilisant une base 6-31G$^{*(0.3)}$, dans des calibrations d'origines commune et dispersée avec des champs de force de mécanique quantique à graduations uniforme et optimale. On a calculé les spectres VCD pour les invertomères *cis* ainsi que *trans*. Le spectre VCD calculé pour la 2-méthylaziridine (mélange à l'équilibre) est dominé par celui du diastéréoisomère *trans*, non seulement á cause de sa plus grande abondance, mais parce que les forces rotatoires de plusieurs absorptions de l'IR moyen sont de signes opposés et d'amplitudes semblables dans les deux invertomères qui diffèrent par leur configuration au niveau de l'azote. On a effectué une comparaison détaillée du spectre VCD de la 2-méthylaziridine avec celui du 2-méthyloxirane. Dans la région des déformations du groupe méthyle et des vibrations de cisaillement du CH_2, le spectre VCD théorique du (*R*)-2-méthyloxirane présente une similarité beaucoup plus grande avec celle de la *cis*-(2*R*)-2-méthylaziridine qu'avec celle du diastéréoisomère *trans*.

[Traduit par la rédaction]

Introduction

The explicit connection between the infrared (IR) spectrum of a substance and its molecular structure has begun to be elucidated in the last decade with the increasing availability of reliable *ab initio* force fields and atomic polar tensors (APT) for intensity calculations. The coincident introduction of chiroptical techniques in the form of vibrational circular dichroism (VCD) spectroscopy and the Raman equivalent (ROA) has promised further insights. Extraction of the inherent information from the latter techniques (and to some extent the former) has been hampered by theoretical difficulties which have largely been overcome with the introduction of practical nonempirical formalisms by Nafie and Freedman (1), Stephens (2), and Buckingham, Fowler, and Galwas (3) and their computer implementations by Stephens and coworkers (4), Morokuma and Sugeta (5), and Dutler (6), Yang (7, 8), and Rauk (6–8). An *ab initio* approximate model, LMO-VCD (9), implemented by Polavarapu (10) has also proved to be effective. The structural rigidity and relatively small size of three-membered ring compounds makes them ideal platforms for assessment of both experimental and theoretical procedures. The parent achiral compounds can be rendered optically active by isotopic substitution. Investigations have been reported on 1,2-dideuterio- (4) and 1,2-dicyanocyclopropane (11), the deuterated oxiranes (6, 12, 13) and their (deuterated) methyl (7, 14, 15) and dimethyl (7, 16) derivatives, and on (deuterated) methyl- (17) and dimethylthiiranes (18). The analogous nitrogen heterocycle has escaped attention, perhaps since it lacks the conformational rigidity of the carbon, oxygen and sulfur analogues. 2-Methylaziridine exists as an equilibrium mixture of *trans* and *cis* diastereoisomeric forms whose composition has been determined by nmr (19) and IR (20) measurements. Following an earlier partial assignment on the basis of an empirical force field (21), a complete assignment of the IR spectrum has been carried out on the basis of scaled *ab initio* force fields (22).

The *ab initio* Vibronic Coupling Theory (VCT) formalism for IR and VCD intensities developed by Nafie and Freedman (1) has been used to investigate the complete IR and VCD spectra of (*S*,*S*)-2,3-dideuterooxirane and the other deuterated isotopomers (13), of ethanol and α-deuterioethanol (23), of a series of small model molecules, including isotopically chiral ammonia, hydrazine (24), hydrogen peroxide (24), oxaziridine (8), and of the methyl- (7) and dimethyl-oxiranes (7, 16) and thiiranes (18). Applications to substituted oxiranes (7, 13, 16) and thiiranes (18), where direct comparison with experimental VCD spectra was possible suggest that the basis set designated as 6-31G$^{*(0.3)}$ (obtained by reducing the exponent of 3*d* orbitals of C, N, and O from 0.8 to 0.3) provides reliable IR and VCD intensities.

We report herein an extension of the VCT/6-31G$^{*(0.3)}$ methodology to an investigation of the 2-methylaziridine system and compare the results with the investigation of 2-methyloxirane.

Theory

The vibronic coupling theory of Nafie and Freedman (1) as implemented at the *ab initio* level by Dutler, Yang, and Rauk (6–8) yields values for the dipole strength, D_j, and rotatory strength, R_j, of the jth normal mode:

$$[1] \qquad D_j = \mu^{VC}_{(00,01),j} \cdot \mu^{VC}_{(01,00),j}$$

$$[2] \qquad R_j = \mathrm{Im}\,(\mu^{VC}_{(00,01),j} \cdot m^{VC}_{(01,00),j})$$

where

$$[3.1] \qquad \mu^{VC}_{(00,01),j} = \left(\frac{\hbar}{2\omega_j}\right)^{1/2}\left[\sum_{n=1}^{n_{atoms}} \xi_n s_n^j - 2\sum_{n=1}^{n_{atoms}}\sum_{i=1}^{n_{electrons}}\sum_{e=1}^{n_{ex}} \langle\Psi_0^a|r_i|\Psi_e^a\rangle\langle\Psi_e^a\left|\frac{\partial}{\partial R_n}\right|\Psi_0^a\rangle s_n^j\right]$$

$$[3.2] \qquad = \left(\frac{\hbar}{2\omega_j}\right)^{1/2}\left[\sum_{n=1}^{n_{atoms}} \xi_n s_n^j - 2\sum_{n=1}^{n_{atoms}}\sum_{i=1}^{n_{electrons}} \langle\Psi_0^a\left|r_i\frac{\partial}{\partial R_n}\right|\Psi_0^a\rangle s_n^j\right]$$

and

$$[4] \qquad m^{VC}_{(00,01),j} = \frac{1}{2c}\left(\frac{\hbar\omega_j}{2}\right)^{1/2}\left[-i\sum_{n=1}^{n_{atoms}} \xi_n(R_n \times s_n^j) - \frac{2\hbar}{m_e}\sum_{n=1}^{n_{atoms}}\sum_{i=1}^{n_{electrons}}\sum_{e=1}^{n_{ex}} \langle\Psi_0^a|r_i \times p_i|\Psi_e^a\rangle\langle\Psi_e^a\left|\frac{\partial}{\partial R_n}\right|\Psi_0^a\rangle s_n^j \frac{1}{E_e^0 - E_0^0}\right]$$

The superscript VC denotes that these expressions describe a vibronic coupling mechanism for IR and VCD intensities. The subscript (00,01) (or (01,00)) signifies that the transition is between the $v = 0$ and $v = 1$ vibrational levels of the ground electronic state of the molecule. The reader is referred to references 6–8 for further explanation of the notation. Electric dipole strengths derived from eq. [3] are formally equivalent to the Atomic Polar Tensor (APT) theory. Stephens circumvents the summation over excited states in eq. [4] by invoking the magnetic field dependence of the wavefunction, a procedure which requires solution of the perturbed Hartree–Fock equations in the presence of a magnetic field (2). In VCT, the sum over excited states which appears in the second term of eq. [4] must be explicitly evaluated. In a normal implementation all transition moments are evaluated at a common origin, the molecular centre of mass (VCT-CO). The VCT has also been implemented in the distributed origin (with origins at nuclei) gauge of Stephens (25), VCT-DO (8).

Computational Details

The geometries of *trans*- and *cis*-2-methylaziridine, determined by complete optimization at the restricted Hartree–Fock level of theory using the 6-31G* and 6-31G*$^{(0.3)}$ basis sets, have been reported previously (22). Bond lengths are calculated to be a little longer by the 6-31G*$^{(0.3)}$ basis set than the usual 6-31G* basis set, an effect also observed with optimization at the MP2 level of theory. The computed energy separation of the two invertomers, 2.17 kJ mol^{-1}, assuming $\Delta S \approx 0$, implies a *trans/cis* mixture of 0.706:0.294 at 298 K. IR and VCD intensities were accomplished by the program system VCT90,[2] which implements the vibronic coupling theory (VCT) of Nafie and Freedman (1) at the *ab initio* level. Both uniformly scaled and optimally scaled force fields (22) were used, and the transition moments were evaluated with the 6-31G*$^{(0.3)}$ basis set in the common origin (molecular centre of mass — VCT-CO) and distributed origin (at nuclear centres — VCT-DO) gauges. Simulated IR and VCD spectra were obtained assuming a Lorentzian lineshape of width at half height of 10 cm^{-1}.

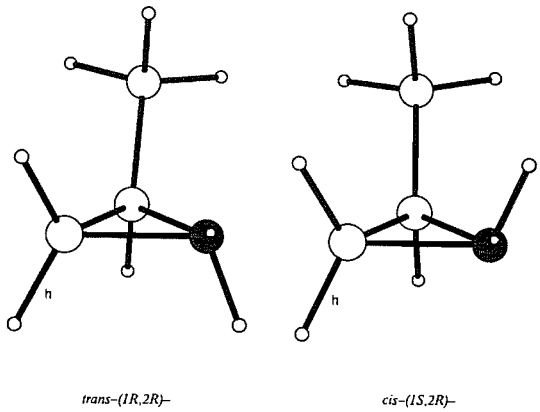

FIG. 1. The RHF//6-31G*$^{(0.3)}$ geometries of (1*R*,2*R*)-2-methylaziridine (*trans*) and (1*S*,2*R*)-2-methylaziridine (*cis*).

Experimental Details

(2*R*)-(+)-2-Methylaziridine, bp 65–66°, $[\alpha]_D^{20}$ +12.4° (c 1.7, 95% EtOH) (lit. 27, bp 66–67°, $[\alpha]_D^{25}$ + 12.4 (c 2.6, EtOH)) was prepared from (2*R*)-(−)-2-amino-1-propanol ($[\alpha]_D^{19}$ − 18° (neat), Aldrich) according to ref. 27 was purified additionally by distilling over Na (metal). An optical purity for the sample was not determined specifically. However, it is well established (28) that the conversion of 2-amino-1-propanol to aminopropyl hydrogen sulphate and further cyclization of the latter are carried out without affecting the chiral centre, and the optical purity of 2-methylaziridine will not be less than the optical purity of the starting material, i.e. 2-amino-1-propanol.

The absorption spectrum was measured with a Nicolet 8000 FT-IR spectrometer, and for VCD, a linear polarizer, a ZnSe photoelastic modulator (Hinds International), a *f*/1 ZnSe focusing lens, and the necessary electronic equipment were added to the instrument as described elsewhere (23). A narrow band MCT detector cooled with liquid nitrogen was used for all experiments. The interferometer was operated at an effective resolution of 4 cm^{-1}, coadding 50 scans and 20 000 scans for the absorption and VCD spectra, respectively.

Solutions of (2*R*)-2-methylaziridine in carbon tetrachloride were prepared to record absorption and VCD spectra. Neat CCl_4 was utilized to subtract the VCD background. In order to detect absorption dependent VCD artifacts as well as to positively identify genuine VCD bands, three spectra were recorded with solutions of different concentration in different cells. The bands reported in Tables 1 and 2 were reproduced in all experiments, except for the negative feature at 1265 cm^{-1}, which may be a spurious signal. The absorption and VCD spectra reported here (Figs 2 and 3) were measured with solutions of concentrations of 0.27 M (KBr cell, 0.5 mm) and 1.1 M (KBr cell, 0.1 mm), respectively. The poor signal-to-noise in the VCD spectrum is attributed firstly to the small signal size (caused by partial cancella-

[2]VCT90: based on FREQ85 (6) to which is added the VCT-DO implementations (8) and which has been modified to be compatible with GAUSSIAN 90 (26).

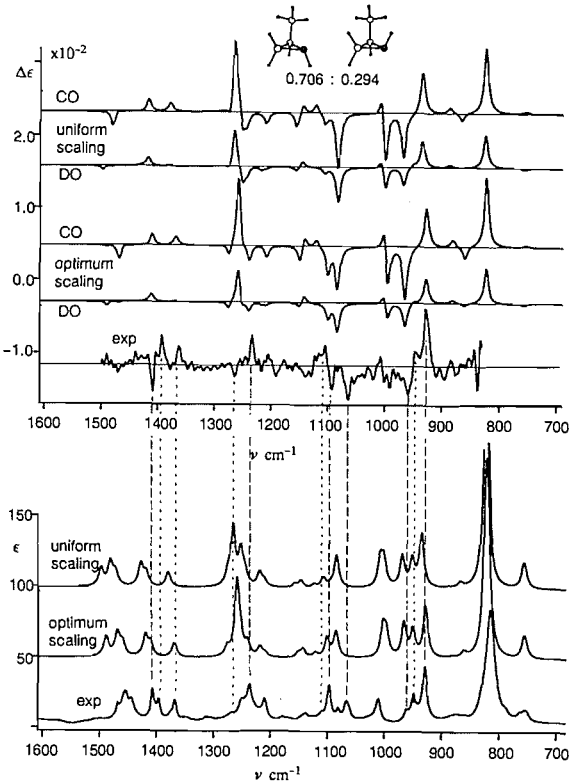

FIG. 2. Theoretically simulated (VCT/6-31G*(0.3); 0.706 *trans*: 0.294 *cis*) and experimental VCD and IR absorption spectra of (2*R*)-2-methylaziridine in the region 700–1600 cm^{-1}. Correlation of VCD and absorption features: *trans* – – – –; *cis* - - - - - -.

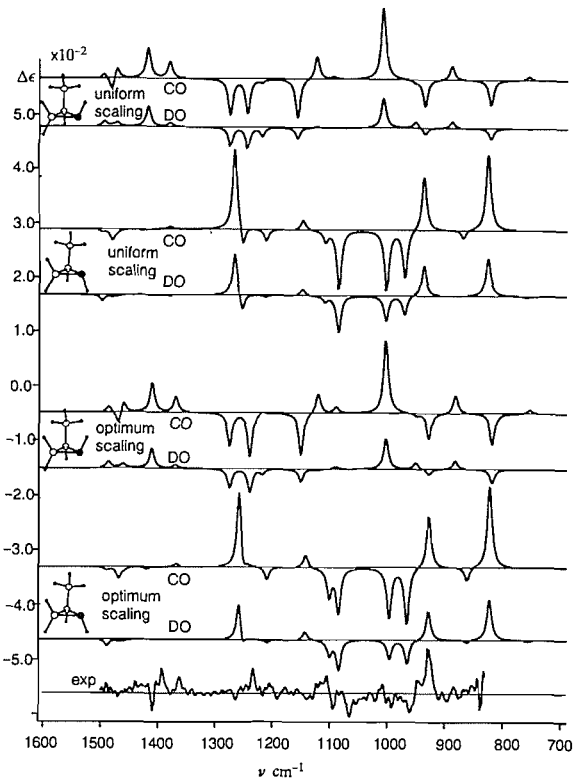

FIG. 3. Theoretically simulated (6-31G*(0.3) basis set) and experimental VCD spectra of *cis*- and *trans*-(2*R*)-2-methylaziridine in the region 700–1600 cm^{-1}.

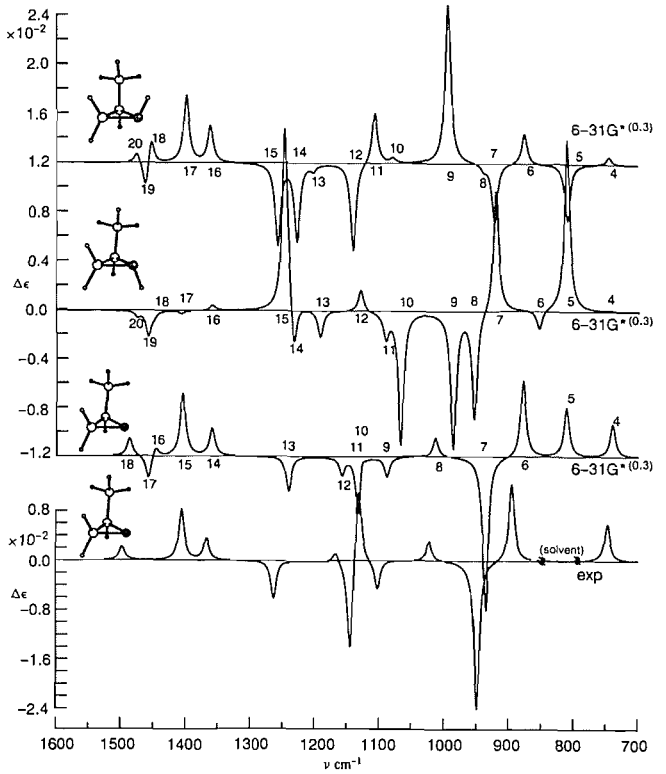

FIG. 4. Simulated VCD spectra VCT-CO/6-31G*(0.3) theory in the region 700–1600 cm^{-1} for the individual invertomers of (2*R*)-2-methylaziridine (top two spectra), and of the VCT-CO/6-31G*(0.3) (third spectrum) and experimental (bottom) VCD spectra of (2*R*)-2-methyloxirane. The experimental spectrum of the oxirane is simulated on the basis of published frequencies and intensities (ref. 15). The numbering refers to modes displayed in Figs 5 and 6, and (for the aziridine) listed in Tables 1 and 2.

tion of VCD bands of opposite sign arising from the two invertomers) and secondly to a deterioration of the interferometer optics.[3]

Results and discussion

The structures of *cis*- and *trans*-(2*R*)-2-methylaziridine are shown in Fig. 1. Geometric details, relative energies, and complete vibrational assignments of the two inversional diastereomers of 2-methylaziridine have been reported (22). Only details required for the discussion of the VCD spectra are repeated here (Tables 1 and 2). Some substantial differences are predicted in the frequencies of equivalent vibrational modes of the two isomers. Normal modes, ν_6 and ν_{11}, primarily rocking and wagging motions of the CH_2 group, occur 20 and 18 cm^{-1} to lower frequency in *trans*-2-methylaziridine (Table 1) than in the *cis* diastereomer (Table 2). On the other hand, ν_8, a mixed mode consisting of C—CH_3 stretch and ring distortion, is at higher frequency by 12 cm^{-1} for the *trans* isomer. Lesser perturbations to lower (ν_1, ν_9, ν_{10}, ν_{12}, ν_{13}, ν_{15}, and ν_{25}) and higher (ν_{14}, ν_{17}, ν_{23}, and ν_{27}) frequencies in the *trans* compared to the *cis* conformer are resolved in the experimental IR spectrum (22) and therefore may be significant for the in-

[3]Over the period of the last year, the alignment of the beamsplitter and mirrors of the Michaelson interferometer has been worsening, resulting in a loss of energy at the polarization optics. Furthermore, the optimal VCD signal is not located in the optical axis anymore, causing additional energy loss, and a deterioration of the appearance of the recorded VCD spectrum.

terpretation of the VCD spectrum of the equilibrium mixture discussed below. The nature of the vibrations are particularly complex in the range 800–1400 cm^{-1}. In the assignments listed in Tables 1 and 2, only the major group motions are identified, in decreasing order of their apparent involvement. The modes are discussed further in their connection to VCD spectra and in comparisons with 2-methyloxirane.

The VCD spectrum of (2R)-2-methylaziridine

VCT/6-31G*(0.3) optical rotatory strengths, *R*, calculated in the CO and DO gauges using uniformly and optimally scaled force fields, are listed in Tables 1 and 2. The close correspondence between optimum scaling and uniform scaling of 6-31G*(0.3) force fields has been noted (22), and is apparent in the similarities in the dipole and rotary strengths calculated from the two force fields (Tables 1 and 2). Previous experience with VCT/6-31G*(0.3) (7, 8, 16, 18) suggests that most calculated rotatory strengths in the mid-IR region will have the correct sign and will be within a factor of 2 in absolute magnitude of experiment and of the most accurate results achievable with the present level of theory. Comparison of the CO and DO columns of the two tables shows that the dominant effect of change of gauge is to reduce the intensities of the strongest transitions by approximately a factor of 2 in the mid-IR region. Several of the rotatory strengths of the weaker transitions change sign (Table 1, ν_{16}, ν_{17}, ν_{22}; Table 2, ν_4, ν_8, ν_{19}, ν_{23}) as a consequence of the change of gauge.

The experimental VCD spectrum of (2*R*)-2-methylaziridine is shown in Fig. 2 together with the observed IR spectrum. The VCD spectrum is very weak. Direct correlation (dashed lines, Fig. 2) of the VCD features with bands in the IR spectrum, as well as examination of the VCD spectra obtained at three different concentrations, assist to distinguish real features from the high background noise level. A quantitative analysis of the spectrum is not possible. However, the dominant feature, a positive Cotton Effect (CE) at 928 (929)[4] cm^{-1} (ν_7), as well as the negative CE at 960 (961) cm^{-1} (ν_8) coincide with the peak attributed to the *trans* isomer (Table 1), as do the two negative features at 1065 (1069) cm^{-1} (ν_{10}) and 1094 (1096) cm^{-1} (ν_{11}), the positive feature at 1235 (1243) cm^{-1} (ν_{14}) and the sharp negative feature at 1411 (1412) cm^{-1} (ν_{17}). Five features may be tentatively attributed to the *cis* isomer: 947 (949) cm^{-1} (ν_8), 1107 (1114) cm^{-1} (ν_{11}), 1265 (1268 cm^{-1}) (ν_{15}), 1364 (1373) cm^{-1} (ν_{16}), 1394 (1400) cm^{-1} (ν_{17}) (Table 2). Simulated VCD spectra of the equilibrium mixture at room

[4] In this section the number cited for wave length corresponds to that observed in CCl_4 solution. The value in parentheses is the corresponding position in the gas phase spectrum and coincides with the values listed in Tables 1 and 2.

temperature (298 K), in the range 700–1600 cm^{-1}, calculated in the CO and DO gauges and using uniformly and optimally scaled force fields, are also shown in Fig. 2. All spectra show the same gross characteristics. Nine of the eleven features identified in the experimental VCD spectrum and assigned to either the *trans* or *cis* aziridine, are reproduced in the simulated spectra. The dominant positive CE at 928 (929) cm^{-1} and the negative CE at 960 (961) cm^{-1} correspond closely to similar features in the simulated spectra and originate from the *trans* isomer. The predicted VCD spectrum of the *cis* isomer is completely different in this region (Fig. 3). The two negative features, 1065 (1069) cm^{-1} and 1094 (1096) cm^{-1}, also unambiguously assignable to the *trans* isomer, are more accurately reflected in the optimally scaled than the uniformly scaled spectra. However, the positive feature observed at 1235 (1243) cm^{-1} (ν_{14}, Table 1) must originate from the strong positive rotatory strength calculated for ν_{15} of the *trans* isomer, and may reflect a misassignment of this band. There is no calculated origin for the negative CE which coincides with the observed position of ν_{17} (1411 (1412) cm^{-1}) of the *trans* isomer. However, we believe this 'feature' to be real since it appears in VCD spectra measured at three different concentrations. The weak positive shoulder at 947 (949) cm^{-1}, attributed to ν_8 of the *cis* isomer, is reproduced correctly in the VCT-DO calculations but not by VCT-CO. On the other hand, the positive CE at 1107 (1114) cm^{-1}, assigned to ν_{11} of the *cis* isomer, is reproduced well by VCT-CO but all but vanishes with VCT-DO. All other features attributed to the *cis* isomer have plausible counterparts in the predicted spectra of the *cis* isomer, and are present in the simulated spectrum of the equilibrium mixture. Additional intriguing similarities between the observed and simulated spectra may be perceived upon examination of the spectra of Fig. 1, but only those experimental features which are also discernible in the VCD spectra of more dilute solutions than that shown herein have been discussed.

The equilibrium mixture consists of two species which have the same absolute configuration at C but opposite sterochemistry at N. The simulated VCD spectra of *trans*-(1*R*,2*R*)- and *cis*-(1*S*,2*R*)-2-methylaziridine are shown separately in Fig. 3. Examination of the VCD spectra of the individual diastereomers may be expected to reveal some features which are constant, reflecting the local configurational similarity at C, and some features which change sign in accordance with the different absolute configurations at N. A perusal of the data in Tables 1 and 2 reveals that of the 20 bands below 1500 cm^{-1}, 13 are predicted to be of opposite sign in the two diastereomers, suggesting a disproportionate influence of the absolute configuration at N. A number of the modes of the *cis* isomer have counterparts of oppositely signed Cotton effects at very nearly the same frequency in the more abundant *trans* iso-

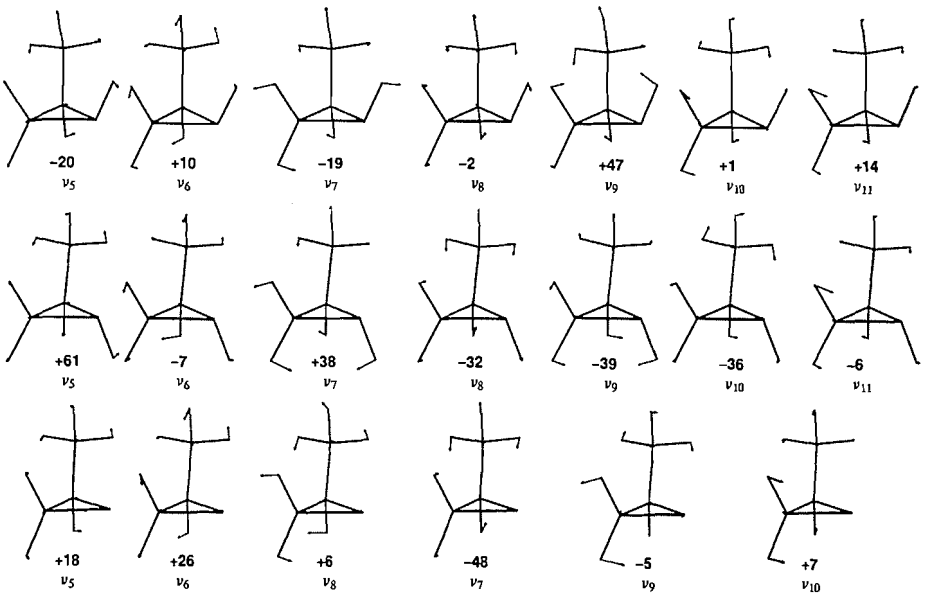

FIG. 5. Cartesian displacement vector representation of some of the normal modes between 800 and 1100 cm^{-1} of *cis*- and *trans*-(2*R*)-2-methylaziridine and (*R*)-2-methyloxirane (top, middle and bottom rows respectively). The bold-face numbers are the calculated rotational strengths in units of $esu^2\ cm^2$ ($\times 10^{44}$). The numbering is consistent with Fig. 4 and Tables 1 and 2.

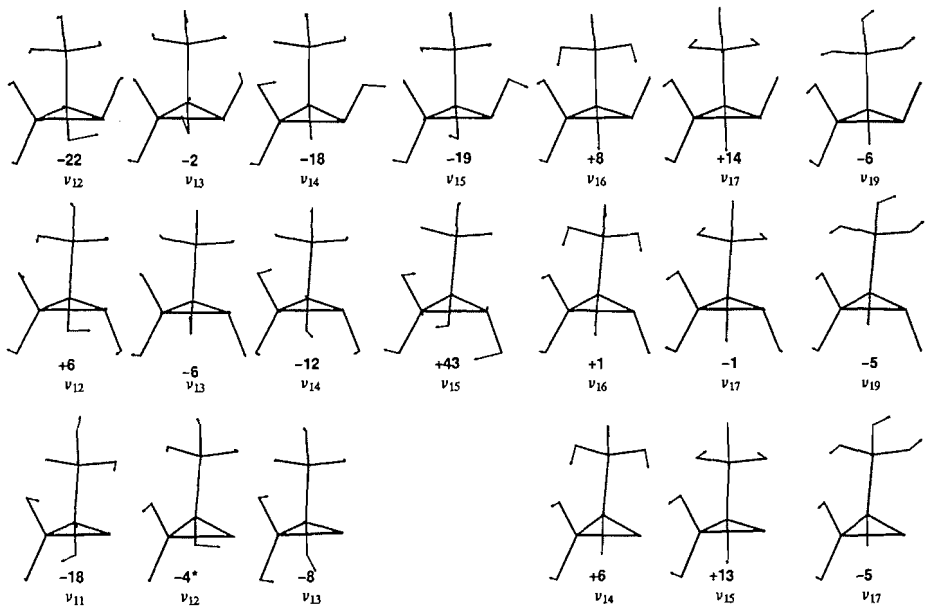

FIG. 6. Cartesian displacement vector representation of some of the normal modes between 1100 and 1500 cm^{-1} of *cis*- and *trans*-(2*R*)-2-methylaziridine and (*R*)-2-methyloxirane (top, middle and bottom rows, respectively). The bold-face numbers are the calculated rotational strengths in units of $esu^2\ cm^2$ ($\times 10^{44}$). The numbering is consistent with Fig. 4 and Tables 1 and 2.

mer and therefore do not show up in the VCD spectrum of the mixture. Thus complete occultation of the *cis* VCD spectrum occurs at ν_5, ν_7, and ν_9, and only a weak CD couplet survives at ν_{15}. Relatively strong CEs are predicted for these modes. Indeed, the only VCD signals which may be attributed to the *cis* conformer with some confidence, are five bands at 947 (949), 1107 (1114), 1265 (1268), 1364 (1373), and 1394 (1400) cm^{-1} ν_8, ν_{11}, ν_{15}, ν_{16}, and ν_{17}, respectively.

Although not observable with the present instrumentation, the data for the CH and NH stretching region are presented in Tables 1 and 2 for completeness. It is curious that all of the stretching vibrations, *including the NH stretch*, are calculated to have the same sign of CE in the two diastereomers.

Comparison with (R)*-2-methyloxirane*

The calculated VCD spectra (VCT-CO/6-31G$^{*(0.3)}$) of (1*S*,2*R*- and (1*R*,2*R*)-2-methylaziridine (*cis* and *trans*, respectively) are compared to the theoretical and experimental VCD spectrum of (*R*)-2-methyloxirane in Fig. 4. Most of the normal modes of all three species in the region 700–1600 cm^{-1} are displayed in displacement vector representation in Figs 5 and 6. In an earlier study of 2-methyl- and 2,3-dimethyloxirane (7),

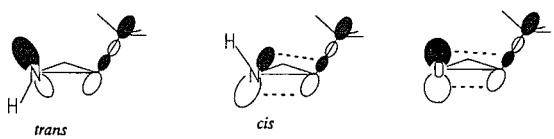
it was noted that most of the absorptions in the 800–1600 cm^{-1} range were characteristic of the absolute configuration in the two closely related compounds, i.e. might serve as configurational markers. As the structures of the two aziridines and the oxirane shown in Fig. 4 have the same absolute configuration at the asymmetric carbon atom, it is of interest to analyze those features of the VCD spectrum which remain constant and are consistent with the oxirane spectrum. A visual inspection of the structures of the three compounds reveals gross similarities between the skeletal distortions of the oxirane and the *trans* aziridine, but there is little similarity between the VCD spectra. Indeed, the VCD spectrum of 2-methyloxirane bears a stronger similarity to that of the *cis*-aziridine, particularly in the region above 1300 cm^{-1} which is dominated by the methyl umbrella motions and deformations and has a component of CH_2 scissoring motion. It has already been noted above that much of the VCD of the aziridines is dominated by the configuration at N. The normal modes above 1300 cm^{-1}, ν_{16}–ν_{20}, have little participation from the N—H group. Three of these are displayed in Fig. 6 together with the equivalent modes of 2-methyloxirane. One of the methyl umbrella–CH_2 scissor combinations ν_{16} (ν_{14} in the oxirane), has the same signed CE in all three species, as does one of the asymmetric methyl distortions, ν_{19} (ν_{17} in the oxirane). However, the second methyl umbrella – CH_2 scissor combination, ν_{17} (ν_{15} in the oxirane), while visually almost identical in the three compounds, has almost a zero CE in the *trans* aziridine and a moderately strong positive CE in the other two structures. Likewise, the second asymmetric methyl distortion ν_{18} ((ν_{16} in the oxirane), not shown in Fig. 6, is visually identical in all three substances but has the same signed CE in the oxirane and *cis*-aziridine (positive), but a weak negatively signed CE in the *trans* isomer. A significant difference between the *cis* and *trans* isomers is the orientation of the non-bonded electron pair of the nitrogen (n_N) relative to the C—CH_3 bond (σ_{CC}) (Scheme 1).[5] In the *cis* isomer, the alignment of the n_N and σ_{CC} orbitals favour maximum interaction between them whereas the overlap appears less favourable in the *trans* isomer. Interaction of the non-bonded electron pair of oxygen with the adjacent groups is always present. It is of interest to speculate that the similarity between the predicted *vibrational* CD spectra of (2*R*)-2-methyloxirane and *cis*-(2*R*)-2-methylaziridine in the region has an *electronic* origin.



SCHEME 1

In 2-methyloxirane, the in- and out-of-phase methyl rock – CH_2 rock combinations, ν_8 and ν_9, respectively (Fig. 5) have oppositely signed and almost equal CEs. The in-phase combination most closely resembles ν_7 in each aziridine, which additionally has a strong contribution from the perpendicular NH motion. The CE is determined by the NH motion, being strongly positive (as for ν_8 of the oxirane) in the *trans* isomer and moderately negative in the *cis*. There is no single mode in the aziridines which corresponds closely to the out-of-phase combination. Mode ν_9, which has a similar involvement of the NH bend has strong and oppositely signed CE in the two invertomers.

[5]Scheme 1 is intended only to demonstrate that the *cis* isomer bears an electronic similarity to 2-methyloxirane not shared by the *trans* invertomer. At present it cannot be determined whether the similarity in the predicted VCD spectra can be attributed to a n–σ^* interaction as shown, or to a n–σ interaction, or both.

Summary

The experimental VCD spectrum of (2*R*)-2-methylaziridine has been measured in the region, 800–1500 cm^{-1}. The *ab initio* implementation of the Vibronic Coupling Theory (VCT) of Nafie and Freedman, using the 6-31G$^{*(0.3)}$ basis set, in the CO and DO gauges, and with uniformly and optimally scaled *ab initio* force fields, is used to investigate the chiroptical properties. VCD spectra are computed for both *cis* and *trans* invertomers. The predicted VCD spectrum of 2-methylaziridine (the equilibrium mixture) is dominated by that of the *trans* diastereomer, due to its greater abundance and extensive cancellation of the rotatory strengths of many absorptions in the mid-IR which are oppositely signed and of similar magnitude in the two invertomers. Although weak, a number of the features of the experimental spectrum may be identified as originating from either the *trans* or the *cis* aziridine. The VCD spectrum of 2-methylaziridine is compared in detail to that of 2-methyloxirane. In the region of the methyl deformation and CH_2 scissor, the predicted VCD spectrum of (*R*)-2-methyloxirane displays a much closer similarity to the predicted VCD spectrum of *cis*-(2*R*)-2-methylaziridine than to that of the *trans* diastereomer, a phenomenon attributed to the possible interactions of the heteroatom lone pairs with the neighboring alkyl group.

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

BRIAN G. GOWENLOCK, MAILER CAMERON, ALAN S.F. BOYD, BAHEEJA M. AL-TAHOU, and PAUL MCKENNA. Can. J. Chem. **72**, 514 (1994).

The carbon-13 chemical shifts of several substituted nitrosobenzenes are reported. It is shown that the NO group can be orientated to lie in the plane of the ring when constrained either by a bulky *ortho* substituent or in the solid state. In the presence of 2,6-di-*tert*-butyl substituents the NO group is twisted into orthogonality with the ring. The changes in the ^{13}C chemical shifts are larger for the NO group than for other functional groups. It is suggested that these effects are a consequence of the electronic character of the NO group and that the nitrogen lone pair of electrons is of fundamental importance in producing these unique effects. The dimeric nitroso functional group does not display these properties.

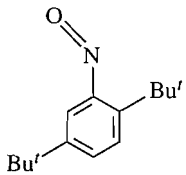
BRIAN G. GOWENLOCK, MAILER CAMERON, ALAN S.F. BOYD, BAHEEJA M. AL-TAHOU et PAUL MCKENNA. Can. J. Chem. **72**, 514 (1994).

On a mesuré les déplacements chimiques en RMN du ^{13}C de plusieurs nitrosobenzènes substitués. On montre que, sous l'influence d'un substituant *ortho* volumineux ou à l'état solide, le groupe NO peut être orienté de façon à se trouver dans le plan du noyau. En présence de substituants 2,6-di-*tert*-butyles, le groupe NO est déplacé et il est alors orthogonal au noyau. Les changements dans les déplacements chimiques du ^{13}C sont plus importants avec le groupe NO qu'avec d'autres groupes fonctionnels. On suggère que ces effets sont une conséquence du caractère électronique du groupe NO et que la paire libre d'électrons de l'azote est d'une importance fondamentale dans la production de ces effets uniques. Le groupe fonctionnel nitroso dimère ne présente pas ces propriétés.

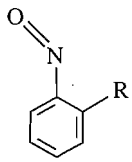
[Traduit par la rédaction]

Introduction

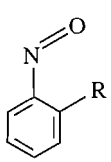
Over 20 years ago, Okazaki and Inamoto (1) studied the ^{1}H nmr spectra of *ortho*-substituted nitrosobenzenes. Their studies demonstrated that the chemical shifts of aromatic, methyl, methoxyl, and *tert*-butyl protons at the *ortho* positions are abnormal. They suggested that most of the unsymmetrically substituted nitrosobenzenes exist as a conformer where the oxygen atom of the nitroso group is on the opposite side (*anti*) to the substituent, and hence protons in the same side (*syn*) to the nitroso oxygen show unusually high chemical shifts and those *anti* to the nitroso oxygen exhibit unusually low chemical shifts. They showed that in 2,5-di-*tert*-butylnitrosobenzene the molecule existed almost entirely as conformer **1** whereas for other *ortho*-substituted nitrosobenzenes there was an equilibrium between the forms **2***a* and **2***b* (R = Me, MeO, Cl, Br) with the



1



2*a*



2*b*

form **2***a* predominating, particularly at low temperature. A similar conclusion had been reached by Sundberg (2) for R = Me, *n*Pr, *n*Bu. Okazaki and Inamoto extended their studies to the case of 2,4,6-tri-*tert*-butylnitrosobenzene (TBNB) where the chemical shifts of the *ortho tert*-butyl protons were interpreted in terms of the NO group being considered to be almost perpendicular to the plane of the benzene ring. This orthogonality of the NO group has also been invoked by Barclay in photochemical and other studies of TBNB (3, 4).

Because of our interest in the ^{13}C nmr spectra of substituted nitrosobenzenes (5), and the information available in the literature for the ^{13}C nmr effects of freezing out of the rotation of the NO group in nitrosobenzene (6) and of substituted *p*-nitrosoanilines (7, 8) at low temperatures, we embarked on the studies reported here. Subsequently we extended our studies to the coordination chemistry of C-nitrosoarenes (9, 10). A publication on the solid state ^{13}C CP/MAS nmr spectrum of *p*-nitrosodimethylaniline (11) has complemented our study.

In our earlier study (5) we noted the unique effect of the NO group in that its powerful π-electron-accepting property enabled it to dominate other electron-accepting groups in the *para* position of the ring and produce in them electron-donating properties. The monomeric nitroso group has long been realised (12) to be very different in character from the *cis* and *trans* dimeric $-N_2O_2$ functions. These differences are reflected in the very different substituent chemical shifts exhibited by nitrosobenzene and the two dimeric forms (13, 14).

Throughout this paper we shall refer to all aromatic nitroso compounds as derivatives of nitrosobenzene and hence adopt the numbering system based upon **3**. The steric effects of the

substituent groups arise therefore from substitution in the 2 and 6 positions.

Experimental

Nitroso compounds

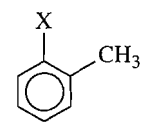
2,4,6-Tri-*tert*-butylnitrosobenzene and *trans*-dimeric 2-methyl nitrosobenzene were commercially available, *trans*-dimeric 2-iodo and 2-methoxynitroso benzene were donated by Professor W. Lüttke, having been prepared by the literature methods (15, 16). 2,5-Di-*tert*-butylnitrosobenzene (17) was prepared by mild oxidation of the corresponding aniline using *m*-chloroperbenzoic acid. 2-*tert*-Butylnitrosobenzene (18) was similarly prepared. 2,6-Di-*tert*-butylnitrosobenzene was prepared in a similar manner to the literature syntheses for other sterically hindered nitrosobenzenes (17). 2,6-Di-*tert*-butylaniline (0.5 g, 2.4 mmol) in dichloromethane (5 cm^3) was cooled in an ice–salt bath while perbenzoic acid (0.6 g, 4.8 mmol) in dichloromethane (5 cm^3) was added dropwise. The reaction mixture was kept overnight at −20°C and a brown colour developed. Column chromatography (silica, petroleum ether 40–60) gave 2,6-di-*tert*-butylnitrosobenzene (0.25 g, 45%) as a blue oil, λ_{max} ($CHCl_3$) 761 nm, ϵ 50.5 $dm^3\ mol^{-1}\ cm^{-1}$; δ_H (200 MHz, $CDCl_3$) 7.25 (3H, m, 3,4,5-H), 1.15 (18H, s, 2,6-di-*t*Bu); *m/z* 219 (M^+ 31%), 57 (*t*Bu, 100%). 2-Methyl-6-*tert*-butylnitrosobenzene was similarly prepared. 2-Methyl-6-*tert*-butyl aniline (1 g, 5.65 mmol) in dichloromethane (10 cm^3) was cooled in an ice–salt bath while perbenzoic acid (1.55 g, 11.0 mmol) in dichloromethane (10 cm^3) was added dropwise. The reaction mixture was kept overnight at −20°C, then neutralised with $NaHCO_3$ solution. Removal of the solvent using a rotary film evaporator at room temperature left a green oil that was purified by column chromatography as above, giving 2-methyl-6-*tert*-butylnitrosobenzene as a blue oil, λ_{max} ($CHCl_3$) 789 nm, ϵ 43 $dm^3\ mol^{-1}\ cm^{-1}$; δ_H (200 MHz, $CDCl_3$) 7.6 (1H, dd, 3-H), 7.35 (1H, t, 4H), 6.95 (1H, dq, 5-H), 1.85 (3H, s, CH_3), 1.65 (9H, s, *t*Bu). *trans*-Dimeric 2,6-dimethyl-, 2,6-diethyl-, and 2,6-diisopropylnitrosobenzene were prepared by controlled oxidation of the corresponding amines (18, 19). *p-N*-methylamino nitrosobenzene was donated by Professor F. Bell.

Instrumental

Natural abundance, broad band proton-decoupled ^{13}C nmr spectra were measured using a Bruker WP 200 spectrometer operating at 50.32 MHz, the solvent being either $CDCl_3$ or CD_2Cl_2. The ^{13}C nmr spectra of solid samples were measured by the SERC service at the Industrial Research Laboratories, University of Durham, at 75.431 MHz using cross polarization (CP) magic angle spinning (MAS) and high-power decoupling and also at the University of East Anglia at 50.3 MHz with CPMAS and high-power decoupling.

Results and discussion

The chemical shifts for the ring carbons of substituted monomeric nitrosobenzenes are listed in Table 1 and are considered under two major headings. The first group comprises those molecules with substituents in the 2 position and no substituent at C-6, together with the 2-methyl-6-*tert*-butyl substituents and solid 4-methylaminonitrosobenzene. The second group is restricted to the two examples where both the C2 and C6 positions carry *tert*-butyl groups. These two separate classes are expected to conform to those originally established by Okazaki and Inamoto (1). In the first group the NO is expected to lie in plane with the ring and displaced away from the 2-substituent (I, Me, MeO, *t*-Bu, 2,5-di-*t*-Bu), away from the larger substituent (2-Me-6-*t*-Bu), or in plane with the ring in a solid monomeric compound as noted by Penner and Wasylishen (11) and ourselves (10). The common feature of these spectra is that the C atom to which the NO group lies *syn* has a chemical shift much lower than would be predicted by use of substituent chemical shifts as given by Ewing (20) in combination with those for the NO group (5, 13, 14). This difference between calculated and observed shifts is 12–14 ppm and can best be appreciated by comparison with the calculated values for C-6 in 2-methyl-1-X-benzene, **4** (X = F, Cl, Br, I, NO_2, CHO, CN, OH, COOH, OMe, NH_2, NHEt, Me, Et, *cis*-N_2O_2, *trans*-N_2O_2)



4

where the difference varies between 4 ppm lower and 2 ppm higher. It is apparent that the effect of the NO group is unique, as suggested by Lunazzi et al. (6). A further example of the effect can be seen from comparison of the predicted and observed chemical shifts for the molecules **5** (21), **6** (22) and **7** (23). The observed C-6 chemical shifts are 110.5, 121.8, and 129.9 respectively.

Comparison of **5** with **6** implies that in the latter the steric restraints are such that the NO group can rotate freely at room temperature whereas in the former the NO group adopts the

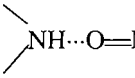
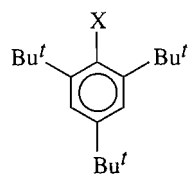
7

equilibrium position *anti* to the NHMe substituent. Comparison of **5** with **7** suggests that the absence of NO_2 *ortho* to the NHMe removes the steric constraints and allows the NO to rotate freely at room temperature. It should be noted that comparison with *o*-substituted benzaldehyde establishes that this effect on the ^{13}C nmr spectra is absent for the isoelectronic CHO group. A referee has suggested that hydrogen bond formation may take place between the NH and NO groups in compounds **5**, **6**, and **7** assisted by the "acidifying" of the NH by the presence of the nitro group at C5. Such a contribution would, however, orientate the NO group away from C6 and towards C2 because of the

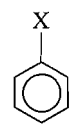


structural unit. We therefore prefer the explanation of a steric constraint that operates effectively for 5 but is absent for 6 and 7. It is necessary to have further study of related compounds to confirm our preference.

We now turn to the two examples where the bulky *tert*-butyl substituents are placed in both the 2 and 6 positions. The effect on the C-1 chemical shift is considerable and there is no difference between the C-2 and C-6 shifts. As free rotation is ruled out on steric grounds it therefore seems that the orthogonality of the NO group, as proposed originally by Okazaki and Inamoto, is the most probable cause of these effects. To substantiate such considerations it is necessary to compare the substituent chemical shifts for C-X in the molecules **8** and **9** to see whether the variation of X for a wide range of functional groups indicate any



8



9

features of note compared with X-NO. Such considerations were employed by Relles (24) for six different examples of X and in Table 2 we present a considerably expanded series of values.

Inspection of Table 2 shows that the effect on the substituent chemical shifts for X-NO is much greater (16.5 ppm) than for 17 other functional groups (average value 7.2 ppm). The isoelectronic groups CHO and $N{=}CH_2$ together with NNPh are different from NO in that the substituent chemical shift effect is much lower (9.4–6.6 ppm). The effect of 2,4,6-trisubstitution by the *tert*-butyl groups is expected to cause a pronounced twisting of many functional groups out of coplanarity with the ring (Br and CN are obvious exceptions). It should be noted that the inability of TBNB to self-dimerise is due to steric considerations. Cross dimerisation with other C-nitroso compounds has been established (4, 31) and therefore the electronic rearrangements necessary (12, 32) for formation of the $-N_2O_2-$ functions are unaffected by the presumed orthogonality of the NO group in TBNB. This may therefore imply that the unusual effect on the C-1 substituent chemical shift in TBNB arises from the changing interaction of the lone pair of electrons, located primarily on the N atoms, with the π-electrons of the ring.

We note therefore that ^{13}C nmr spectroscopy has revealed three features of unique interest for nitrosobenzene and derivatives thereof, namely, the *syn* effect of in-plane NO, and the orthogonal effect due to steric hindrance, in addition to the dominating effect of the π-electron-attracting NO over other π-electron-attracting groups in the *para* position (5). So far as the last of these effects is concerned, neither CNDO/2 nor STO-3G calculations have been successful in accounting for the difference between the NO group and all other functional groups (33). Theoretical studies for the *syn* effect are limited to the approximate magnetic anisotropy calculations for the nitroso group (1).

There is an STO-3G study of the conformation and charge distributions of a large number of monosubstituted benzenes (34) that is relevant to our study of the orthogonal NO group in TBNB. Hehre, Radom, and Pople point out that whereas the substituent withdraws π-electrons from the ring in planar nitrosobenzene there is π-charge donation from the nitrogen lone pair in the orthogonal form, and the charge alternation is reversed. The authors suggest that this may have interesting consequences in the properties of those nitrosobenzenes constrained to be orthogonal and note the absence of this effect in the orthogonal form of nitrobenzene. In addition to these theoretical calculations Batich and Donald (35) have demonstrated an unusual affect on the N(1*s*) peak in the XPS spectrum of TBNB and, in attempting to correlate this with the orthogonality of the NO group, have shown by CNDO/2 calculations that the charge on the N approximately doubles on going from an in-plane to an orthogonal conformation, while the charge on the O remains the same. These electronic effects may be mirrored by the distinctive difference for NO in the substituent chemical shifts summarised in Table 2.

It is also of interest to note that the orthogonal orientation of the NO group in TBNB implies that in the, yet to be synthesised, analogous molecule 1,3-di-nitroso-2,4,6-tri-*tert*-butylbenzene, atropisomeric forms will exist. These will be (*a*) the two nitroso groups having their O atoms on the same side of the ring and (*b*) the two nitroso groups having their O atoms above and below the plane of the ring.

In principle it would be appropriate to study the ^{13}C nmr spectra of the series of 2,4,6-trialkylnitrosobenzene monomers (alkyl = Me, Et, iPr, *t*Bu) to obtain information on the increasing steric constraints on the NO group. The triisopropylnitrosobenzene has yet to be synthesised and consequently we decided to limit our study to the series of 2,6-dialkylnitrosobenzenes. The first three members of the series form crystalline *trans* dimers and in solution at room temperature there is only a small amount of dissociation to the monomer for the 2,6-dimethyl compound. Heating the sample produces more monomer but decomposition reactions predominate for the ethyl (19) and isopropyl compounds. Consequently it is not possible to achieve the above objective. The ^{13}C nmr spectral data of the dimers are shown in Table 3. These are closely similar to the values predicted from substituent chemical shifts (14, 20).

In conclusion, it may be noted that the dimeric nitroso group does not possess a lone pair of electrons and that, as a consequence of the increase in both the CNO angle and the NO bond length as compared with the monomer, the distance between the O atom and the C-2 atom in the benzene ring will be slightly increased. These considerations encouraged us to study the CPMAS ^{13}C nmr spectrum of solid dimeric 4-bromonitrosobenzene in order to observe whether the splitting of the C-2 and C-6 chemical shifts, characteristic of the *syn* effect in monomeric nitrosobenzenes, would occur. As was to be expected, the compound displayed only four chemical shifts: 140.0 (C-1), 125.1 (C-2), 127.7 (C-3), and 126.4 (C-4) ppm. It is known that in the solid state the benzene rings are tilted only slightly from coplanarity with the $C_2N_2O_2$ central unit (36) and we therefore conclude that the *syn* effect is not a property of the dimeric nitroso functional group. Our studies point therefore to the importance of the nitrogen lone pair in producing the characteristic structural properties of the NO group. More advanced molecular orbital calculations than STO-3G would appear to be necessary to resolve this problem. The experimental techniques of ^{1}H and ^{13}C nmr spectroscopy produce complementary evidence for the *syn* and orthogonal effects of sterically constrained NO groups.

TABLE 3. ^{13}C Chemical shifts for dimeric 2,6-dialkylnitrosobenzenes in $CDCl_3$ solution at 19°C (values in ppm relative to Me_4Si)

Alkyl	C-1	C-2,6	C-3,5	C-4

A theoretical study on the interaction of dinitrogen with rhodium

T.H. FANG, M.L. MCKEE,[1] AND S. D. WORLEY[1]

Department of Chemistry, Auburn University, Auburn, AL 36849, U.S.A.

Received March 31, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

T.H. FANG, M.L. MCKEE, and S.D. WORLEY. Can. J. Chem. **72**, 519 (1994).

Ab initio theoretical computations have been performed for RhN_2, Rh^+N_2, $Rh(N_2)_2$, and $Rh^+(N_2)_2$ species. The computed vibrational frequencies and binding-energy trends are in qualitative accord with prior FTIR studies of N_2 interacting with supported Rh films. Computations of the type described herein should be useful in aiding the assignment of observed infrared bands to specific surface species in future work.

T.H. FANG, M.L. MCKEE et S.D. WORLEY. Can. J. Chem. **72**, 519 (1994).

On a effectué des calculs théoriques *ab initio* sur les espèces RhN_2, Rh^+N_2, $Rh(N_2)_2$ et $Rh^+(N_2)_2$. Les fréquences de vibrations calculées ainsi que les tendances observées dans les énergies de liaison sont en accord qualitatif avec des études de FTIR antérieures sur le N_2 en interaction avec des films supportés de Rh. Des calculs du type décrit dans ce travail devraient dans le future s'avérer utiles pour aider à attribuer des bandes, observées dans l'infrarouge, à des espèces de surface spécifiques.

[Traduit par la rédaction]

Introduction

Work has been progressing in these laboratories during the past decade pertaining to the study on the processes of interaction of small molecules with supported transition metals. The primary approach in these investigations has been to utilize Fourier transform infrared spectroscopy in identifying reactive surface species on supported catalyst films (see, for example, ref. 1). Recently, a novel high-pressure–infrared-cell reactor has been constructed for the purpose of identifying reactive surface species on supported transition-metal films upon exposure to gases at high pressures such as might be encountered in industrial chemical reactors. The first experiments employing the high-pressure-cell reactor involved the interaction of dinitrogen with supported rhodium at ambient temperature and pressures up to 8000 torr (2–4). Several interesting dinitrogen surface species were detected at ambient temperature using FTIR which had only previously been observed at low pressures (≤218 torr) and temperatures below 240 K (5). Employing the integrated areas of the N—N stretching mode band for $N_2/Rh/TiO_2$ as a measure of surface coverage, adsorption equilibrium constants as a function of temperature were obtained and used to predict the heat of adsorption for $N_2/Rh/TiO_2$ to be -10.2 kcal mol^{-1} extrapolated to zero coverage (4).

The purpose of the present study was to use *ab initio* theoretical computations to further our understanding of the interaction process for N_2/Rh. Of course, the computations necessarily refer to the gas-phase species, rather than to N_2 interacting with solid state supported Rh, and such calculations are difficult and tentative because of *d*-orbital participation, modeling the inner core, and the necessary use of unrestricted Hartree–Fock methods. Nevertheless, prior studies in these laboratories using similar computations have significantly aided our interpretation of the experimental observations for the interaction of CO (6) and H_2/CO (7) with supported Rh, so we feel justified in using the same theoretical approach for N_2/Rh.

There have been several elegant theoretical studies reported pertaining to the interaction of N_2 with Pd(8); Ti, Cr, Fe, Co, and Ni (9); Ni (10); and Cr^+ and Co^+ (11). However, in the case of Rh, as far as we are aware, only a semi empirical study of the electronic structure of RhN_2 (12) and an *ab initio* investigation of $RhCl(PH_3)_2N_2$ (13) have been reported, although several other interesting theoretical studies of rhodium carbonyl, oxide, and hydride species have recently appeared (14–16). There have been no reported computations of RhN_2 binding energies and vibrational frequencies; this work will address these important parameters.

Theoretical

For the *ab initio* computations in this study, the 36 core electrons of Rh were replaced by a relativistic effective core potential (RECP) as generated by Hay and Wadt (17). The outer valence orbitals (5*s*, 4*d*, and 5*p*) were represented by a (3*s*3*p*4*d*) primitive Gaussian basis contracted to (2*s*2*p*2*d*) to form a basis set denoted as BAS2 which has been employed earlier in these laboratories for Rh computations (6, 7). The valence double-ζ basis set of Dunning and Huzinaga (18) was used for nitrogen. Closed-shell systems were computed by using restricted Hartree–Fock formulism, while open-shell systems employed unrestricted Hartree–Fock formulism (19). All geometric variables were optimized (20) at the BAS2 level within an assumed symmetry point group. The most difficult aspect of this study was to ensure that the dominant configuration was correctly chosen. In order to ensure that the best choice was made, many optimizations were performed with alternate occupation of the starting molecular orbitals. The best choice for a particular electronic state was determined by the lowest PMP4/ECP D-ζ energy.

For the case of linear Rh^0N_2, symmetry breaking and spin contamination in the wave function required the use of the method described by the Herzberg (21) in computing the N—N vibrational stretching frequency.

Results and discussions

The various species for which computations were performed in this work are shown in Fig. 1. The optimized geometries for the various species are also indicated in Fig. 1. The computed absolute energies and $\langle S^2 \rangle$ values for the species are shown in Table 1. All levels of theory predicted that the ^4F state of Rh was lower in energy than the ^2D state. The computed excitation energy for the $Rh(^4F) \leftarrow Rh(^2D)$ was 0.0276 hartree units which was in reasonable accord with the experimental value (22) of 0.015 hartrees. The computed ionization energy for $Rh(^4F)$ was 0.247 hartrees, in good agreement with the experimental value (22) of 0.274 hartrees. The computed bond length

[c]No bonding interaction predicted.

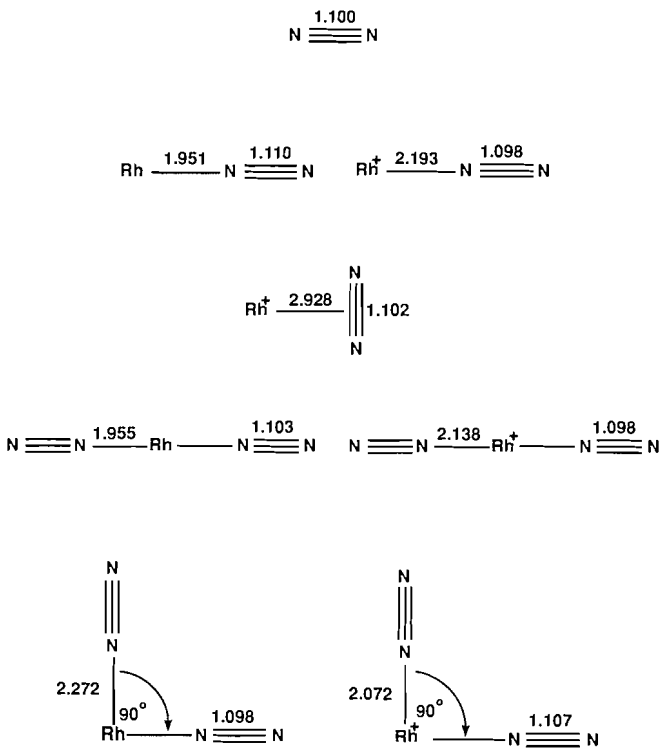

FIG. 1. Computed optimized geometries for the species considered in this work.

for dinitrogen (1.100 Å) was in excellent accord with experimental data (1.094 Å) (23), as was the computed vibrational stretching frequency (2331.5 cm^{-1} after correction by the standard factor of 0.9) as compared to 2331 cm^{-1} obtained from the Raman spectrum (5).

For the Rh^0N_2 species the *ab initio* computations predicted that N_2 should be bonded "end-on" to Rh. All attempts to compute a "side-on" Rh^0N_2 species were not successful, as the optimized geometry produced Rh and N_2 separated beyond reasonable bonding distance (>4 Å). On the other hand, for Rh^+N_2 both end-on and side-on species could be computed, but the calculations clearly predicted that end-on bonding represented the lower energy geometry by 0.034 hartrees (21.3 kcal mol^{-1}).

For the Rh^0 and Rh^+ gem dinitrogen species the computations in both cases predicted the optimum geometry to be linear for the gas-phase species. However, for supported Rh a linear geometry is rather unlikely for steric reasons. Hence calculations were carried out for the two species in which the NRhN bond angle was constrained to be 90°, the value reported for the Rh gem-dicarbonyl species for Rh/Al_2O_3 (24). These computations indicated that the energies of the bent gem dinitrogen Rh^0 and Rh^+ species lie above those of the corresponding linear species by 11.9 and 10.0 kcal mol^{-1}, respectively. Thus, the *ab initio* computations predict that the gas-phase gem-dinitrogen species should be linear, but a 10–12 kcal mol^{-1} decrease in energy for the bent species might clearly occur for a surface due to metal–support interactions and steric constraints.

The computations performed in this study which were most relevant to recent experimental work in these laboratories were the binding energies and N—N vibrational stretching frequencies for the various species given in Table 2. The end-on RhN_2 species at the PMP4 level of theory was predicted to have a binding energy of 33.1 kcal mol^{-1}, a value substantially greater than that measured from infrared data for $N_2/Rh/TiO_2$ (10.2 kcal mol^{-1}). The discrepancy can be attributed to the fact that supported Rh would be expected to bind N_2 to a different extent than gas-phase Rh because of the electronic and steric interaction of Rh with the support material. The *ab initio* computations reported here must be considered only as a qualitative aid in interpreting the experimental data. Nevertheless, the *ab initio* trends are informative. For example, the calculations predict that the end-on Rh^0N_2 species should be bound to a greater extent by 6.5 kcal mol^{-1} than is the Rh^+N_2 species and that the

[a]Calculated values have been corrected by the standard factor of 0.9.
[b]Symmetry breaking in the wave function; the 2239 cm^{-1} value was calculated by Herzberg's method (21).
[c]No bonding interaction predicted.
[d]Values of 21.5 and 5.7 kcal mol^{-1} were computed in ref. 13 for the complexes $RhCl(PH_3)_2$ (η^1–N_2) and $RhCl(PH_3)_2$ (η^2–N_2), respectively.
[e]Values are averages for the two N_2 moieties. In general the binding energy for the second N_2 moiety was slightly larger than for the first.

N—N stretching vibrational frequency should be lower for Rh^0N_2 (2239 cm^{-1}) than for Rh^+N_2 (2266 cm^{-1}). The experimental infrared spectrum for high-pressure N_2 interacting with Rh/Al_2O_3 contained bands at 2256, 2276, 2301 and 2330 cm^{-1} which were assigned tentatively to end-on Rh^0N_2, a $Rh^{\delta+}N_2$ species, a second $Rh^{\delta+}N_2$ species, and physisorbed N_2 on Al_2O_3 (2). Prior work performed at low temperatures and pressures had identified the same infrared bands and suggested similar band assignments (5). A matrix isolation study of RhN_2 species (25) exhibited an N—N stretching frequency of 2154 cm^{-1}, which was 100 cm^{-1} lower than the value for supported Rh; the calculated value falls between the two measured values. The 2256 cm^{-1} band was considerably more intense than the 2276 or 2301 cm^{-1} bands for a prereduced Rh/Al_2O_3 surface; whereas the converse was true for a preoxidized surface. Thus the computed frequencies and binding energies for Rh^0N_2 and Rh^+N_2 are qualitatively consistent with these observations. The computations suggest that the 2256 cm^{-1} band should indeed be assigned to an end-on Rh^0N_2 species (computed, 2239 cm^{-1}) while the 2276 cm^{-1} band could be assigned to an end-on Rh^+N_2 species (computed, 2266 cm^{-1}). The infrared band at 2301 cm^{-1} could then be assigned to a $Rh^+(N_2)_2$ species (computed, 2293/2298 cm^{-1}, linear; 2268.5/2268.8 cm^{-1}, 90° bent). Closely spaced bands corresponding to the gem disubstituted Rh^+ as predicted by the *ab initio* calculations would not have been resolved in the experiment, and the frequency might be expected to lie between the value for linear and 90° bent in that the NRhN bond angle would likely lie between the 90° and 180° extremes.

Thus, the experimental and theoretical data are consistent, at least in a qualitative sense. We believe that *ab initio* computations of the type used in this work, which employ relativistic core potentials for transition metals, can be useful in investigations of the structures and bonding of surface species. Upon refinement, these types of *ab initio* computations may become a primary means of assignment of infrared frequencies to specific surface species.

Transition state dynamics of F + Br_2 reactive scattering

ZHEN ZHENG ZHU, RICHARD W.P. WHITE, DAVID J. SMITH, AND ROGER GRICE
Chemistry Department, University of Manchester, Manchester, M13 9PL, England

Received January 15, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

ZHEN ZHENG ZHU, RICHARD W.P. WHITE, DAVID J. SMITH, and ROGER GRICE. Can. J. Chem. **72**, 523 (1994).

Reactive scattering of F atoms with Br_2 molecules has been studied at an initial translational energy $E \sim 16$ kJ mol^{-1} using a supersonic beam of F atoms seeded in Ne buffer gas. Laboratory angular and velocity distributions of BrF product have been measured. They show sharp peaking in the forward direction with almost isotropic wide angle scattering of relative intensity ~0.2. Approximately half the total available energy is disposed into product translation for scattering in the forward and backward directions with slightly lower translational energy for the sideways scattering. The combination of sharp forward scattering and high product translational energy is attributed to early migratory trajectories in large impact parameter collisions whereby the F atom reacts with the more distant Br atom of the Br_2 molecule lying in the forward hemisphere. The isotropic wide angle scattering arises from direct trajectories in which the F atom reacts with the nearer Br atom of the Br_2 molecule. Migratory dynamics are promoted by charge transfer interaction of the form $Br_2^+F^-$ which stabilises the potential energy surface in elongated isosceles triangular FBr_2 configurations as well as in slightly bent FBrBr configurations. Comparison is made with the dynamics of the F + Cl_2, I_2, and CCl_3Br reactions.

ZHEN ZHENG ZHU, RICHARD W.P. WHITE, DAVID J. SMITH et ROGER GRICE. Can. J. Chem. **72**, 523 (1994).

Utilisant un rayon supersonique d'atomes de fluor placés dans un gaz tampon de Ne et opérant à une énergie initiale de translation d'environ 16 kJ mol^{-1}, on a étudié la diffusion réactive des atomes de fluor par des molécules de brome. On a mesuré les distributions des vitesses et des angles du produit BrF; la vitesse présente un important maximum dans la direction avant avec un grand angle de dispersion pratiquement isotrope d'intensité relative d'environ 0,2. Environ la moitié de l'énergie totale disponible est utilisée pour provoquer une translation du produit dans les directions avant et arrière alors qu'une quantité légèrement inférieure d'énergie de translation est utilisée pour une diffusion latérale. On attibue la combinaison d'une diffusion importante vers l'avant et d'une énergie de translation élevée du produit à des trajectoires de migration précoces dans des collisions avec des paramètres d'impact importants alors que l'atome de fluor réagit avec l'atome de brome de la molécule de Br_2 se trouvant dans l'hémisphère avant. Le grand angle de dispersion isotrope découle de trajectoires directes dans lesquelles l'atome de fluor réagit avec l'atome de brome le plus près dans la molécule de Br_2. Les dynamiques migratoires sont amplifiées par l'interaction de transfert de charge de la forme $Br_2^+F^-$ qui stabilise la surface d'énergie potentielle dans les configurations élongées de forme triangle isocèle du FBr_2 ainsi que dans les configurations légèrement déformées du FBrBr. On a fait une comparaison des dynamiques des réactions des atomes de fluor avec respectivement le Cl_2, le I_2 et le CCl_3Br.

Stripping dynamics with the angular distribution of product scattering peaking sharply in the forward direction have been observed frequently in reactive scattering experiments since the earliest studies of the reactions of alkali atoms with halogen molecules (1). Classical trajectory studies (2) of these reactions which proceed via an electron jump mechanism (1) show sharply peaked scattering in the forward direction only when charge migration is allowed between the halogen atoms of the halogen anion formed by the electron jump with a consequent shift in the Coulomb attraction to the alkali cation. When charge migration is inhibited, then sharp scattering is observed only in the spectator stripping limit (1) when there is no repulsion between the halogen atoms of the halogen anion. Sharp forward peaking is also observed in the case of a short-lived collision complex (3) where the translational energy of the forward and the less intense backward scattering is determined by the centrifugal barrier (4) in the exit valley of the potential energy surface. The reaction of F atoms with ICl molecules (5, 6) shows short-lived collision complex behaviour while the reactive scattering of F atoms with I_2 molecules shows evidence (7–9) of migratory dynamics. The reaction of F atoms with Cl_2 molecules (10) was interpreted in terms of a very short-lived collision complex while the reaction of F atoms with Br_2 molecules (11) appears to follow a stripping mechanism with sharp forward peaking but also with disposal of almost half the total available energy into product translation. However, the F + Br_2 reaction has been studied only at an initial translational energy $E \sim 33$ kJ mol^{-1} which is more than half the reaction exoergicity. Consequently it is difficult to decide whether the high product translational energy arises primarily frpm the initial translational energy or from the repulsive energy released in the exit valley of the potential energy surface. The measurements reported here are carried out a lower initial translational energy of $E \sim 16$ kJ mol^{-1} to allow the role of repulsion between products in a stripping reaction to be examined in greater detail.

[1] $F + Br_2 \rightarrow BrF + Br$

This also provides a basis for comparison with recent scattering measurements on the F + Cl_2 reaction (12) at an initial translational energy of $E \sim 16$ kJ mol^{-1}.

Experimental

The apparatus was the same as that previously employed in the study of the F + ICl reaction (6) using a high pressure microwave discharge source (13) with an alumina discharge tube to produce a supersonic beam of F atoms seeded in Ne buffer gas. The velocity distribution of the F atoms peaked at $v_{pk} \sim 1310$ m s^{-1} with a full width at half maximum intensity of $v_{wd} \sim 485$ m s^{-1}, corresponding to a Mach number of $M \sim 4.5$. The Br_2 beam issued from a glass nozzle of diameter ~0.2 mm using a stagnation pressure ~ 30 Torr maintained by a reservoir at −12°C. The velocity distribution of the Br_2 beam measured by a rotatable mass spectrometer detector using a pseudo-random cross-correlation time-of-flight analysis (14), peaks at $v_{pk} \sim 445$ m s^{-1} with a full width at half maximum intensity of $v_{wd} \sim 147$ m s^{-1}, corresponding to a Mach number of M ~ 6.

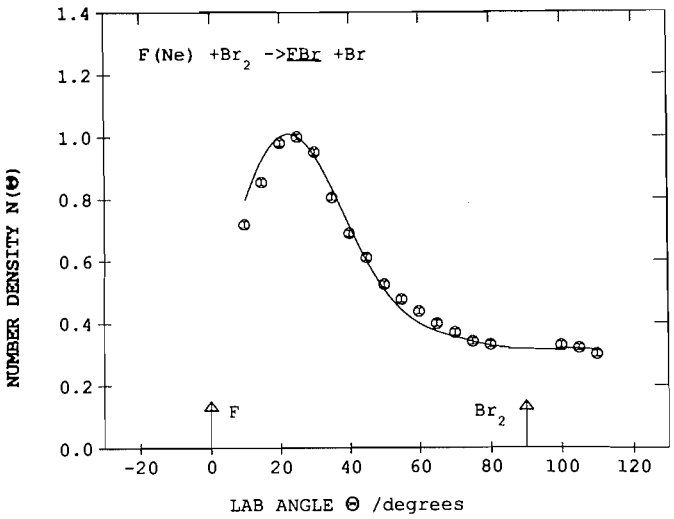

FIG. 1. Laboratory angular distribution (number density) for BrF reactive scattering from F + Br_2 at an initial translational energy of E = 16 kJ mol^{-1}. Solid line shows the fit of the Entemann kinematic analysis.

Results

Angular distribution measurements of BrF reactive scattering yield ~30 counts s^{-1} against a background of ~9 counts s^{-1}. The laboratory angular distribution of BrF number density shown in Fig. 1 peaks close to the F atom beam. The laboratory velocity distributions of BrF flux shown in Fig. 2 were measured using integration times of ~2500 *s* to gain signal-to-noise ratios of ~20 at the peaks of the distribution. Transformation of these laboratory data to centre-of-mass coordinates has been performed using the numerical inversion procedure of Siska (15) and yielded a contour map of the differential reaction cross section as showing in Fig. 3. Figure 3 shows a sharp peak in the forward direction at a centre-of-mass scattering angle of θ = 0° with a lower relative intensity ~0.20 at wider scattering angles. These features are very similar to those previously determined for F atoms seeded in He buffer gas (11).

For a more quantitative comparison, the kinematic analysis has also been carried out using the stochastic method of Entemann and Herschbach (16). Here the differential cross section is expressed as a product of an angular function $T(\theta)$ and a velocity distribution $U(u, \theta)$ which is parametrically dependent on scattering angle θ. The Halpern Strutinski formula (17) multiplied by an exponential decay (3) and with an additional constant term was employed for the angular function

$$[2]\quad T(\theta) = (1 - c)\exp(-\sin^2\theta/4\langle\cos^2\alpha'\rangle)I_0(\sin^2\theta/4\langle\cos^2\alpha'\rangle) \times \exp(-\theta/\theta^*) + c$$

where I_0 denotes the zeroth order modified Bessel function (18), α' the helicity angle between the initial orbital angular momentum **L** and the final relative velocity v' and θ^* the decay parameter. The velocity function was of the same form as that previously employed (11) at a higher initial translational energy. The resulting angular function with the parameters $\langle\cos^2\alpha'\rangle^{1/2} = 0.35$, $\theta^* = 70°$, and $c = 0.16$ and the product translational energy distributions shown in Fig. 4 confirm the results of the Siska transformation. The angular distribution is similar to that previously estimated at a higher initial translational energy (11) but with a somewhat broader forward peak of width ~30° at half maximum intensity compared with ~20° at higher initial translational energy. The product translational energy distributions, which are the same to within experimental uncertainty as those obtained at higher initial translational energy (11), show higher product translational energy for scattering in the forward and backward directions than for sideways scattering. The backfits of the Entemann transformation are shown as solid curves in Figs. 1 and 2. The peak E'_{pk} and average E'_{av} product translational energies are listed in Table 1, together with the initial translational energy E and reaction exoergicity ΔD_0 calculated from the BrF and Br_2 bond energies of Huber

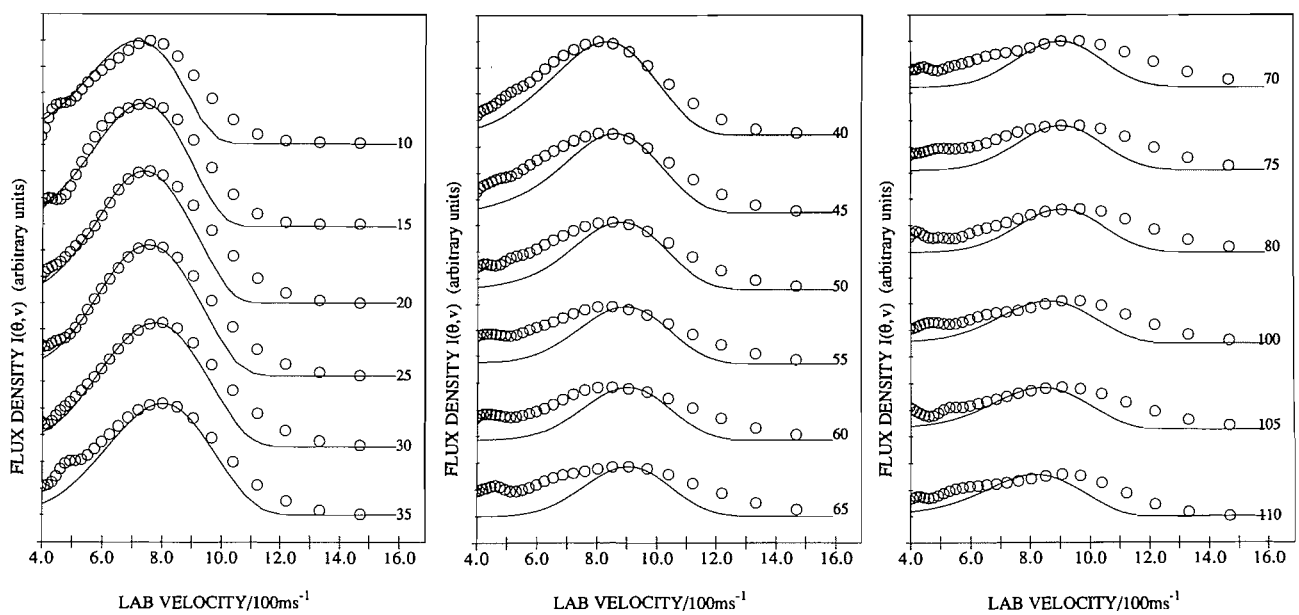

FIG. 2. Laboratory velocity distributions (flux density) of reactively scattered BrF from F + Br_2 at an initial translational energy of E = 16 kJ mol^{-1}. Solid lines show the fit of the Entemann kinematic analysis.

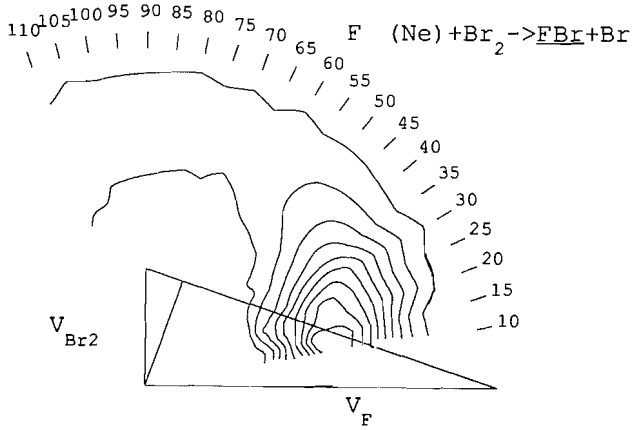

FIG. 3. Polar contour map of BrF flux from F + Br_2 as a function of centre-of-mass scattering angle θ and velocity u obtained by the Siska method. Incident F atom direction is denoted by θ = 0°, incident Br_2 direction θ = 180°.

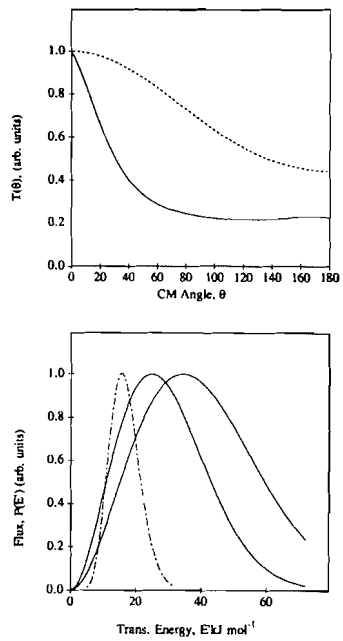

FIG. 4. Angular function $T(\theta)$ and translational energy distributions $P(E')$ for F + Br_2 at an initial translational energy E = 16 kJ mol^{-1}. Left-most product translational energy distribution corresponds to θ = 90°, right-most distribution to θ = 0°, 180°. Dashed curve shows the distribution of initial translational energy. Dotted curve shows the angular distribution predicted by the DIPR model with the parameters n = 0 and q = 4.0.

and Herzberg (19). Approximately half the total available energy $E + \Delta D_0$ is disposed into product translation for the forward and backward scattering $f_{pk}' \sim 0.49$ and $f_{av}' \sim 0.57$, while a significant though lower fraction $f_{pk}' \sim 0.35$ and $f_{av}' \sim 0.40$ is disposed into translation for the sideways scattering. These fractions are all slightly higher than those previously determined at a higher initial translational energy (11). The rate constant for the F + Br_2 reaction $k = 1.9 \times 10^{11}$ dm^3 mol^{-1} s^{-1}, determined at 298 K in a discharge flow experiment (20), corresponds to a total reaction cross section $Q_r \sim 60$ Å^2 at an initial translational energy $E \sim 2.5$ kJ mol^{-1}.

Discussion

The present results confirm the confluence of stripping dynamics with a relatively high product translational energy for the F + Br_2 reaction which was indicated by previous reactive scattering measurements (11) at a higher initial translational energy. The trajectory calculations by Kuntz, Mok, and Polanyi (2) suggest that this arises on a potential energy surface for an exoergic reaction with both attraction between the reactants and repulsion between the products, only when early migratory trajectories involve a transfer of the bonding of the reactant atom between the two atoms of the reactant diatomic molecule. Indeed more extensive migratory dynamics have been proposed (21) for the strongly exoergic F + I_2 reaction, yielding mainly vibrational and rotational excitation of the product IF molecules. In the case of a potential energy surface with a significant potential energy well, sharp forward peaking may also arise from shortlived collision complex dynamics (3) as is observed for the F + ICI reaction (5, 6). However, the peak product translational energy for scattering in the forward and backward directions is then governed by the maximum centrifugal barrier in the exit valley of the potential energy surface (4) where

$$[3] \quad B_m' \cong \mu E/\mu'$$

where μ, μ' denote the reactant and product reduced masses. Since eq. [3] predicts a value of only $B_m' \cong 6$ kJ mol^{-1} which lies far below the peak product translational energy $E_{pk}' = 35$ kJ mol^{-1} determined in these experiments, it may be concluded that the F +Br_2 reaction involves stripping dynamics over a surface with both attraction between the reactants and repulsion between the products rather than a short-lived collision complex on a surface with a deep potential energy well. The observed angular and product translational energy distributions are therefore determined by the reactant transition state located in the entrance valley of the potential energy surface.

As illustrated in Fig. 5 for reactant transition states lying in the plane of collision, the reactant F atom may interact initially either with the Br atom of the Br_2 molecule lying in the forward hemisphere (Fig. 5*a*) with respect to the initial relative velocity or with the Br atom lying in the backward hemisphere for collisions near the maximum impact parameter $b_m \sim 4.5$ Å. However, for collisions at smaller impact parameters $b < 3$ Å the F

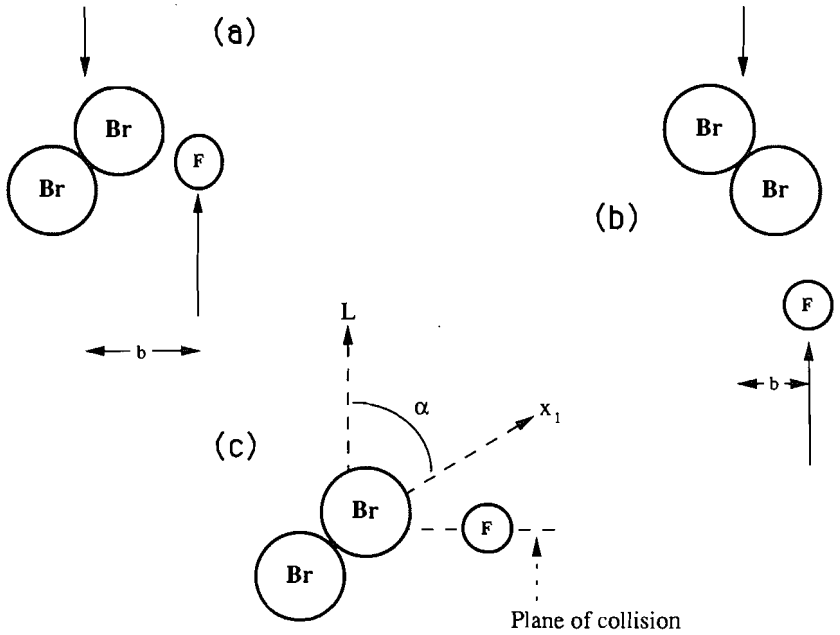

FIG. 5. Reactant transition state for the F + Br_2 reaction; *a*, *b* lying in the plane of collision, *c* lying out of the plane of collision. The principal axis of lowest moment of inertia is denoted by x_1. The initial orbital angular momentum $\boldsymbol{L}$ is perpendicular to the plane of collision.

atom can interact only with the Br atom of the Br_2 molecule lying in the backward hemisphere (Fig. 5*b*). For collisions with the Br atom located in the backward hemisphere, the initial momentum of the F atom will be directed toward the Br atom resulting in direct reaction dynamics. Since the F atom is lighter than the Br atoms by a factor 4, the bond direction of the Br_2 molecule is likely to be largely maintained as the transition state dissociates to reaction products. This is the basic assumption of the DIPR model (2, 22, 23), which predicts roughly isotropic wide angle scattering when the impulse imparted to the product Br atom is large compared with its initial momentum as a reactant. This momentum ratio may be estimated approximately (22) from the peak product translational energy for scattering in the sideways direction

$$[4] \quad q = [m_{FBr} m_{Br_2} E'_{pk}/(m_F m_{Br} E)]^{1/2}$$

which yields q ~ 4 using the values of E and E'_{pk} for the sideways scattering in Table 1. However, the experimental angular distribution is more sharply forward peaked than the DIPR angular distribution calculated from eq. [5] for an unbiased orientation dependence shown in Fig. 4.

$$[5] \quad I(\theta) = (2/q)\cos\theta + [(q + q^{-1}\cos 2\theta)/(q^2 - \sin^2\theta)^{1/2}]$$

For collisions with the Br atom located in the forward hemisphere, the contraction of the FBr bond is likely to be forestalled as the initial momentum of the F atom counteracts the attraction toward the Br atom. In these circumstances the precessional motion of the reactant transition state will become established before dissociation of the Br_2 bond occurs and the direction of product scattering then reflects both the initial orientation of the Br_2 molecule and the range of precessional motion of the transition state. Typical reactant transition states with the Br_2 bond length close to the equilibrium value ~2.3 Å, an extended BrF bond length ~3 Å, and an interbond angle ~135° provide an excellent approximation to a prolate symmetric top as shown by the moments of inertia listed in Table 2. Consequently, the Halpern Strutinski term in eq. [2] may be associated with the precession of such transition states while the isotropic term may be associated with more direct reaction dynamics. Figure 5*c* shows the reactant transition state with the axis of the Br_2 molecule inclined at a maximum angle to the plane of collision, such that the x_1 axis of the transition state lies at a helicity angle α to the initial orbital angular momentum $\boldsymbol{L}$ which is equal to the total angular momentum to a good approximation for large impact parameter collisions. Both the total angular momentum and its projection on the symmetry axis will be conserved as the prolate symmetric top transition state dissociates to products. Hence the value of $\langle\cos^2\alpha'\rangle^{1/2} = 0.35$ estimated for the Halpern Strutinski function of eq. [2] corresponds to reactant transition states with a helicity angle α ~ 70° and hence to Br_2 molecules initially inclined at an angle ~20° to the plane of collision. The decay parameter θ = 70° estimated from eq. [2] corresponds to the precession of reactant transition states persisting for ~$\frac{1}{5}$ of a rotational period in the plane of collision before dissociation in large impact parameter collisions. Integration of eq. [2] over the scattering angle θ

$$[6] \quad Q_r \propto \int_0^{\pi} T(\theta)\sin\theta d\theta$$

shows that the Halpern Strutinski function contributes some

44% to the total reaction cross section and the isotropic term 56%. If the Halpern Strutinski term were attributed entirely to collisions at large impact parameters, this would correspond to a range 3.5 Å $\leq b \leq$ 4.5 Å with the isotropic scattering being attributed to smaller impact parameters $b <$ 3.5 Å. The angular distribution measured previously for F + Br_2 (11) at a higher initial translational energy of $E \sim$ 33 kJ mol^{-1} shows similar behaviour though with a sharper forward peak corresponding to transition states precessing closer to the plane of collision and persisting for a smaller fraction of the rotational period.

The lifetime of the exponential decay in eq. [2] refers to the forward scattered peak at $\theta = 0°$ as the time origin, which in turn relates to the reaction of F atoms at large impact parameters in Fig. 5 with the Br_2 molecule axis lying almost parallel to the initial relative velocity vector. Forward scattering in this case requires migratory trajectories whereby the F atom interacts initially with the nearer Br atom, before passing through an elongated isosceles triangular FBr_2 configuration and finally interacting with the further Br atom as the Br_2 molecule dissociates to form BrF products scattering in the forward direction. Clearly, migratory trajectories of this kind require that the potential energy surface remain attractive in the elongated triangular FBr_2 configuration as well as in the slightly bent FBrBr configuration of the transition state shown in Fig. 5. Diatomics-in-molecules calculations on the F + F_2 (24) and Cl + Cl_2 (25) potential energy surfaces show that broadside approach is inhibited by conical intersections between $^2A_1$ and $^2B_2$ potential energy surfaces. However, the $^2B_2$ potential energy surface will be stabilised in the elongated isosceles triangular configuration by F^- + $Br_2^+(^2\Pi_g)$ ion pair states, arising from charge transfer interaction (26) in the F + Br_2 system. Indeed *ab-initio* calculations (27) show the strongly bent configuration of the FIH radical to be more stable than the slightly bent configuration. Hence early migratory trajectories are likely to be promoted by the charge distribution of the Br_2^+ cation which extends over both Br atoms in the F + Br_2 reaction.

The extent of charge transfer interaction in the reactions of F atoms with halogen and interhalogen molecules (26) depends upon the ionisation potential of the molecule. Nominal crossing radii (28) between the ionic F^+ + XY^- potential energy surface and the covalent F + XY surface may be calculated from the formula

$$[7] \quad r_c = e^2/4\pi\epsilon_0[I(XY) - A(F)]$$

where I(XY) denotes the ionisation potential of the halogen molecule (19, 29) and A(F) the electron affinity of the F atom (30). The values of the crossing radii listed in Table 3 only slightly exceed the equilibrium bond lengths of the halogen fluoride product molecules (19), which indicates that only partial charge transfer will occur in both the reaction intermediate and the halogen fluoride product molecule. This may be estimated crudely by taking the ratio of the dipole moment of the halogen fluoride molecule (31) to that of the corresponding alkali fluoride molecule (32) which yields fractional charge transfers of ~0.24 for IF, ~0.16 for BrF, and ~0.10 for ClF. The same trend of decreasing charge transfer is expected along the sequence of reactions F + I_2, Br_2, and Cl_2.

The most extensive charge transfer occurs in the F + I_2 reaction where trajectory calculations (21) suggest that the attractiveness of the potential energy surface gives rise to both early (2) and late (33–35) migratory dynamics. The diatomic halogen

TABLE 3. Nominal crossing radii r_c between ionic F^- + XY^+ and covalent F + XY potential energy surfaces compared with equilibrium bond lengths r_e of the product XF molecule

XY	r_c/Å	r_e/Å
Cl_2	1.8	1.63
Br_2	2.0	1.76
I_2	2.5	1.91

$BrCCl_3$	1.9	1.76
ICH_3	2.4	1.91

cations $XY^+(^2\Pi)$ are more strongly bound and have shorter bond lengths (19, 36) than the corresponding halogen molecules. Consequently, charge transfer interaction will reduce repulsion in the exit valley of the potential energy surface to a greater extent for F + I_2 than for F + Br_2, though the entrance valleys are attractive on both potential energy surfaces. In the F + Cl_2 reaction where there is more limited charge transfer interaction than for F + Br_2, the reactant transition state (12) is formed at the top of a low potential energy barrier in the entrance valley of the potential energy surface. As described previously (37), the dynamics of the F + CCl_3Br reaction show close agreement with the DIPR model and are consistent with the predominance of direct trajectories. This contrasts with the F + Br_2 reaction dynamics where migratory trajectories foster more sharply peaked forward scattering. The difference may be attributed to the more localised charge distribution of the CCl_3Br^+ cation which is located predominantly on the Br atom in the F + CCl_3Br reaction.

Dipole (e,e) spectroscopy has been used to measure the absolute photoabsorption oscillator strengths (cross sections) for the valence shells of CH_3NH_2, $(CH_3)_2NH$, and $(CH_3)_3N$ from the photoabsorption threshold to 250 eV at low resolution (~1 eV fwhm) and to 31 eV at high resolution (0.048 eV fwhm). The observed peaks in the photoabsorption spectra of the methylamines have been assigned to transitions to Rydberg orbital upper states. Our measured photoabsorption data, augmented by mixture rule estimates for high photon energies, have been used in conjunction with Thomas–Reiche–Kuhn sum rule and molar refractivity constraints, to construct constrained dipole oscillator strength distributions for each of the methylamines. From these constrained dipole oscillator strength distributions a wide range of related dipole properties have been calculated for each of the methylamines, and in most cases the results so obtained represent the first (reliable) determination of these properties.

GORDON R. BURTON, WING FAT CHAN, GLYN COOPER, C.E. BRION, ASHOK KUMAR et WILLIAM J. MEATH. Can. J. Chem. **72**, 529 (1994).

On fait appel à la spectroscopie dipolaire (e,e) pour mesurer la photoabsorption absolue, les intensités de l'oscillateur (section droite) des électrons de valence du CH_3NH_2, $(CH_3)_2NH$ et du $(CH_3)_3N$ à partir du seuil de photoabsorption de 250 eV à basse résolution (environ 1 eV fwhm) et à 31 eV à haute résolution (0,048 eV fwhm). On a attribué les pics observés dans les spectres de photoabsorption des méthylamines à des transitions de Rydberg des orbitales des états supérieurs. Nous avons utilisé nos données de photoabsorption mesurées et des évaluations par la règle de mélanges pour les photons de haute énergie, de concert avec la règle de la somme de Thomas-Reiche-Khulm et avec les contraintes de réfractivité molaire, pour construire la distribution des intensités de l'oscillateur du dipôle contraint de chaque méthylamine. A partir des distributions des intensités de l'oscillateur du dipôle contraint, on a calculé un très grand nombre de propriétés des dipôles apparentés pour chaque méthylamine et les résultats ainsi obtenus représentent dans la plupart des cas la première détermination (fiable) de ces propriétés.

1. Introduction

The absolute photoabsorption spectra of the methylamines are of interest and importance in many areas of science and technology. For example, monomethylamine has been observed in the interstellar medium (1), in the atmosphere of Halley's comet (2, 3), has been included in models of the atmospheres of Uranus and Saturn (4, 5), and is known from photochemistry to be a low-energy source of NH_2 and NH radicals (6). The use of trimethylamine as an additive ("seed" compound) to improve the performance of UV pre-ionized lasers has been explored (7). Therefore, absolute photoabsorption oscillator strength (cross section) data for the methylamines, and the associated dipole properties, are of importance in astrophysics, laser physics, photochemistry, or in any other application where the interaction of high-energy radiation or particles with these molecules is to be understood. Such measurements and properties should also provide a test-bed for *ab initio* calculations of absolute oscillator strengths and dipole properties. However, few such calculations have been reported for the methylamines. The study of photoabsorption oscillator strength data and dipole properties for series of related molecules also yields useful information about functional group additivity trends and their effects on the absorption of highly energetic electromagnetic radiation. A systematic study of such trends can be used to predict the oscillator strength distributions and dipole properties of larger, more complex molecules for which no data exist, or for which direct measurement may be difficult (8–11).

There is very little absolute photoabsorption oscillator strength data available in the literature for the methylamines which is in striking contrast to the wealth of quantitative information available for the parent member of this series, NH_3 (for a recent review see refs. 12, 13). Absolute photoabsorption spectra for the methylamines and ammonia have been reported by Tannenbaum et al. (14) in the limited energy region 4.8–7.8 eV. In other work, Bertrand et al. (15) have measured differential photoabsorption oscillator strengths for CH_3NH_2 and $(CH_3)_2NH$ at 10.03 eV, and Grosjean and Bletzinger (7) have measured the absolute photoabsorption spectrum of $(CH_3)_3N$ from 8.0–10.8 eV.

In our experimental study of the methylamines CH_3NH_2 (monomethylamine, methanamine), $(CH_3)_2NH$ (dimethyl-

amine, *N*-methylmethanamine), and $(CH_3)_3N$ (trimethylamine, *N*,*N*-dimethylmethanamine), detailed and wide-ranging absolute oscillator strength data are obtained for these molecules in the energy region from the first excitation threshold to 250 eV. In our associated theoretical work these measured oscillator strengths are used along with mixture rule data, and molar refractivity and Thomas–Reiche–Kuhn (TRK) sum rule constraints, to determine constrained dipole oscillator strength distributions (DOSDs) for these molecules. The DOSDs are, in turn, used to determine reliable values for many of the important dipole properties for the methylamines. Section 2 outlines the experimental techniques and methods used in the present work to determine the absolute high- and low-resolution oscillator strength data for the methylamines using dipole (e,e) spectroscopy. These data are presented in section 3 along with a detailed discussion of the measured spectra and the spectral assignments. The general method used for the construction of the DOSDs and for the evaluation of the dipole properties of the methylamines is outlined in section 4, and the results are given in section 5 along with an analysis of the uncertainty limits placed on the results for the dipole properties. Recently, these same procedures have been used to evaluate the DOSD and many of the dipole properties for NH_3 (12).

2. Experimental methods

The dipole (e,e) spectrometers and procedures used in the present work to determine the absolute low-resolution (~1 eV fwhm) (16–20) and high-resolution (0.048 eV fwhm) (21–23) oscillator strengths for the methylamines using dipole (e,e) spectroscopy have been described in detail previously. This technique involves high energy electron scattering at negligible momentum transfer and has been shown to provide data which are entirely equivalent to those obtained using conventional optical methods (24). In the dipole (e,e) method the continuously tuneable energy loss of the scattered electrons is entirely equivalent to a photon energy. Thus, it is possible to measure a photoabsorption spectrum from a few to a few hundred eV, spanning the UV, VUV, and soft X-ray regions of the electromagnetic spectrum, using a single apparatus. This type of measurement would not be possible with a single optical spectrometer since several monochromators would be necessary to span the same energy region.

The low-resolution (LR) measurements for the methylamines (~1 eV fwhm) were made using an incident electron beam of 8000 eV, and the scattered electrons were energy analyzed and detected at a mean scattering angle of zero degrees (acceptance angle of 1.4×10^{-4} sr) (16). The scattering conditions of high incident electron beam energy, small acceptance angles about a mean scattering angle of zero degrees, and small energy losses relative to the incident beam energy, ensure that the momentum transfer is small and that predominantly dipole-allowed transitions are excited. The absolute photoabsorption oscillator strengths were determined by Bethe–Born conversion and partial TRK sum-rule normalization of the measured background-subtracted electron energy-loss spectrum as follows. The relative oscillator strength spectra were measured for each of the methylamines from the electronic excitation threshold to an equivalent photon energy of 250 eV. These data were placed on an absolute scale by first fitting a curve of the form

$$[1] \qquad \frac{df}{dE} = AE^{-1.5} + BE^{-2.5} + CE^{-3.5}$$

to the high-energy portion of the valence-shell relative oscillator strength tail from 90 to 250 eV. In eq. [1], df/dE is the differential oscillator strength, E is the energy loss (or equivalent photon energy), and A, B, and C are best-fit parameters to the data. The values of the parameters were found to be 7.326 $eV^{0.5}$, 108.3 $eV^{1.5}$, and 4.980×10^4 $eV^{2.5}$, respectively, for monomethylamine, 9.932 $eV^{0.5}$, 151.6 $eV^{1.5}$, and 6.071×10^4 $eV^{2.5}$, for dimethylamine, and 14.53 $eV^{0.5}$, −200.6 $eV^{1.5}$, and 1.008×10^5 $eV^{2.5}$, for trimethylamine. In earlier work, curves having this empirical functional form have been found to provide much more satisfactory fits to the measured high-energy (typically 100–250 eV) of the valence-shell oscillator strength distributions of polyatomic molecules than the predicted Born dipole asymptotic $E^{-3.5}$ dependence which is only expected to be valid at extremely high photon energies (see section 4 below). For example, in the cases of C_2H_2 (25), C_2H_4 (26), and CH_3OH (27) these procedures have led to satisfactory absolute oscillator strength scales. This curve was then integrated from 250 eV to infinite energy for each spectrum in order to provide an estimate of the valence-shell oscillator strength contribution above the last measured differential oscillator strength data point at 250 eV. Using these procedures ~7% of the total valence-shell oscillator strength distribution is predicted to be above 250 eV for each of the three methylamines. The total area under the valence-shell spectrum (i.e., the contribution from the measured oscillator strengths plus that under the extrapolated curve) was normalized to 14.54 for monomethylamine, 20.75 for dimethylamine, and 26.96 for trimethylamine. These integrated values correspond to the total number of valence-shell electrons in these molecules plus a small contribution (~5%) to account for the Pauli-excluded transitions from the inner-shells (the nitrogen and carbon K shells) to the already-occupied valence-shell orbitals. The Pauli-excluded transition contribution was estimated for each molecule from sums of atomic corrections based on Hartree–Slater calculations (28, 29). The absolute oscillator strength data thus obtained are estimated to be accurate to ±5%. The small random errors associated with the photoabsorption measurements are indicated by the small scatter in the data points.

The high-resolution (HR) measurements (0.048 eV fwhm) of the methylamines were made using a 3000 eV monochromated incident electron beam (21). An empirical Bethe–Born conversion factor has recently been determined for this spectrometer (22) which permits the conversion of the measured background-subtracted energy-loss spectrum to a relative oscillator strength spectrum. The high-resolution relative oscillator strength spectrum thus obtained for each of the methylamines was placed on an absolute scale by single point normalization in the smooth continuum region to the corresponding low-resolution photoabsorption oscillator strength data obtained in the present work. The high accuracy of this method for determining high-resolution oscillator strengths has been verified by the excellent agreement (22, 30) between recently measured photoabsorption data for atomic helium, and molecular hydrogen, and high-level *ab initio* calculations.

The high-purity gas samples used in the present study, monomethylamine (98.0%), dimethylamine (99.0%), and trimethylamine (99.0%), were obtained from Matheson Gas Company lecture bottles and were used without further purification. No impurity peaks were detected in the high-resolution electron energy-loss spectra.

3. Results and discussion

3.1. Electronic structure of the methylamines

The symmetry groups of highest symmetry that CH_3NH_2, $(CH_3)_2NH$, $(CH_3)_3N$, belong to are C_s, C_s, and C_{3v}, respectively. The molecular orbital configurations of the ground states of these molecules in the independent particle model are as follows:

CH_3NH_2:

$$\underbrace{(1a')^2}_{N1s}\ \underbrace{(2a')^2}_{C1s}\ \underbrace{(3a')^2(4a')^2(1a'')^2(5a')^2(6a')^2(2a'')^2(7a')^2}_{\text{Valence shell}}$$

$(CH_3)_2NH$:

$$\underbrace{(1a')^2}_{N1s}\ \underbrace{(1a'')^2(2a')^2}_{C1s}\ \underbrace{(3a')^2(2a'')^2(4a')^2(5a')^2(6a')^2(3a'')^2(4a'')^2(5a'')^2(7a')^2(8a')^2}_{\text{Valence shell}}$$

The vertical ionization potentials (VIPs) of the valence-shell states of the methylamines have been determined using high-resolution HeI and HeII photoelectron spectroscopy (31–33), while the inner shell states have been measured using X-ray photoelectron spectroscopy (34–37). The electronic configurations and vertical ionization potentials for the methylamines are summarized in Table 1.

3.2. *Low resolution measurements for the methylamines*

The low-resolution (~1 eV fwhm) valence-shell absolute photoabsorption oscillator strengths for monomethylamine, dimethylamine, and trimethylamine measured in the present work from the first excitation threshold to 250 eV using dipole (e,e) spectroscopy are shown in Figs. 1, 2, and 3, and are given numerically in Tables 2, 3, and 4, respectively. Panel (*a*) of Figs. 1–3 shows the full measured spectra from the photoabsorption threshold to 250 eV, panel (*b*) shows the spectra from 30–100 eV, and panel (*c*) shows the 86–250 eV energy region. The absolute photoabsorption data below 30 eV are shown, and described, in greater detail in conjunction with the high-resolution results (see section 3.3 below). It is interesting to note from Figs. 1–3 that our measured low-resolution oscillator strength spectra each exhibit essentially the same trend with the sums of calculated (38) and experimental (39) atomic oscillator strengths for the constituent atoms. In particular, the summed atomic oscillator strength data agree quite well with the measured molecular photoabsorption oscillator strength data for the methylamines from 70 eV to the limit of the measured data at 250 eV. However, below 70 eV the summed atomic oscillator strength data (38, 39) are increasingly lower than the present data for all three molecules. Above 170 eV the atomic sums are slightly lower than the measured results.

It has often been assumed (see, for example, ref. 40), that the sums of atomic oscillator strengths are equal to molecular oscillator strengths sufficiently far (≥30 eV) above an atomic *inner-shell* ionization edge. At such photoelectron energies it is assumed that molecular effects, such as shape resonances, have died out and that the ejected electron "sees" mainly an atomic core as it is ionized. However, in the 70–250 eV energy region of the valence-shell photoabsorption spectra of the methylamines the electron is not ejected from an atomic-like (core) orbital, so it is interesting to note that there is generally quite good agreement between the sums of atomic data, and our reported molecular oscillator strengths in this energy region. The fact that the curves cross at ~170 eV, that is, that the atomic oscillator strength sums for each methylamine are higher than the corresponding measured oscillator strengths from 90 to 170 eV, but are slightly lower from 170 to 250 eV, is not surprising since both sets of data should be subject to the same *total* integrated oscillator strength over the entire energy range (from zero to infinity) according to the TRK sum rule. The small differences between the theoretical (38) and experimental (39) summed atomic oscillator strength data from 100 to 240 eV, as seen in panel *c* of Figs. 1–3, are due, at least in part, to errors involved in the digitization of the logarithmic plots reported for the theoretical data (38). The digitization error will compound as the number of carbon atoms increases.

3.3. *High resolution measurements for the methylamines*

The high-resolution (0.048 eV fwhm) absolute photoabsorption spectra of monomethylamine, dimethylamine, and trimethylamine from 4–31 eV are shown on Figs. 4, 5, and 6, respectively. Also shown on the figures are the low-resolution oscillator strength data obtained in the present work (see section 3.2 above). It can be seen that our high- and low-resolution oscillator strength data are in good agreement with each other

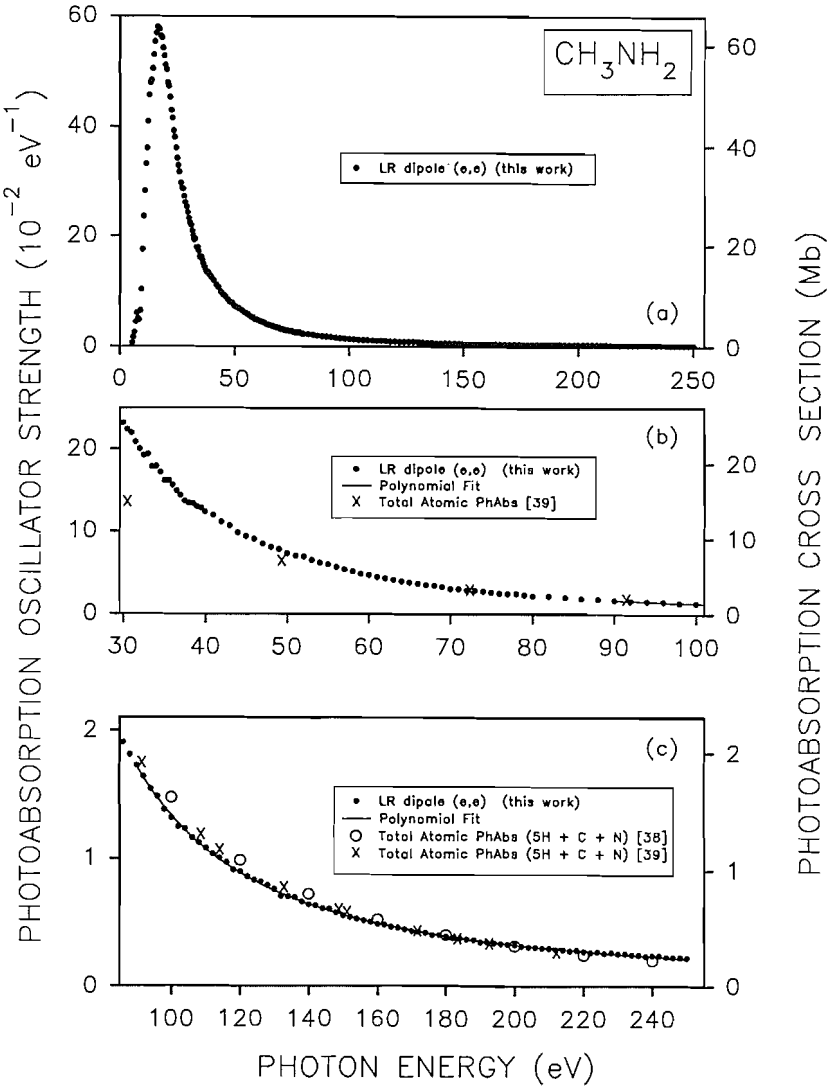

FIG. 1. Absolute oscillator strengths for the photoabsorption of CH_3NH_2 obtained at a resolution of ~1 eV fwhm: (*a*) the entire measured spectrum from 5.5–250 eV; (*b*) 30–100 eV; (*c*) the high-energy valence-shell tail from 86–250 eV. Also shown on (*b*) and (*c*) are the valence-shell polynomial fit (solid line), and the theoretical (38) and experimental (39) summed atomic oscillator strengths for the constituent atoms of CH_3NH_2 (open circles and crosses, respectively).

over the entire range of measurement (4–31 eV). This is an important consistency check on our measurements since the high- and low-resolution dipole (e,e) spectrometers have different Bethe–Born factors owing to their different scattering kinematics and geometries.

Since no *ab initio* calculations of transition energies and oscillator strengths have been reported for the methylamines, definite assignments of the spectra cannot be made. Therefore, in the present work, the transferability of Rydberg term values (41–43) has been used to make tentative assignments for the more prominent features observed in Figs. 4–6. It might be expected that the electronic spectra of the methylamines will be dominated by transitions to Rydberg orbitals from the occupied valence orbitals since this behaviour appears to be the situation for the related molecules CH_4 (44, 45) and NH_3 (44, 46). Transitions which have Rydberg upper states can be characterized by the fact that the observed term values, T, fit into a mathematical progression of the form:

$$[2] \qquad T = \mathrm{VIP} - E = \frac{R}{(n - \delta_l)^2}$$

where E is the measured absorption energy, VIP is the vertical ionization potential of the initial state, R is the Rydberg constant (13.606 eV), n is the principal quantum number, and δ_l is the quantum defect. Electron momentum spectroscopy has demonstrated that the highest occupied molecular orbitals (HOMOs) of the methylamines have a mixed s and p character with the s content increasing with successive methylation (47, 48). Therefore transitions are expected from the HOMO to s, p, and d Rydberg manifolds since atomic selection rule arguments have been found (41–43) to be a helpful guide for interpretation of molecular spectra. On this basis, we have assigned the lowest energy peaks in the spectra as transitions from the respective HOMO orbitals to the $3s$ and $3p$ Rydberg orbitals for each of the methylamines. From these HOMO assignments the energies of the corresponding $3s$ and $3p$ transitions from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12

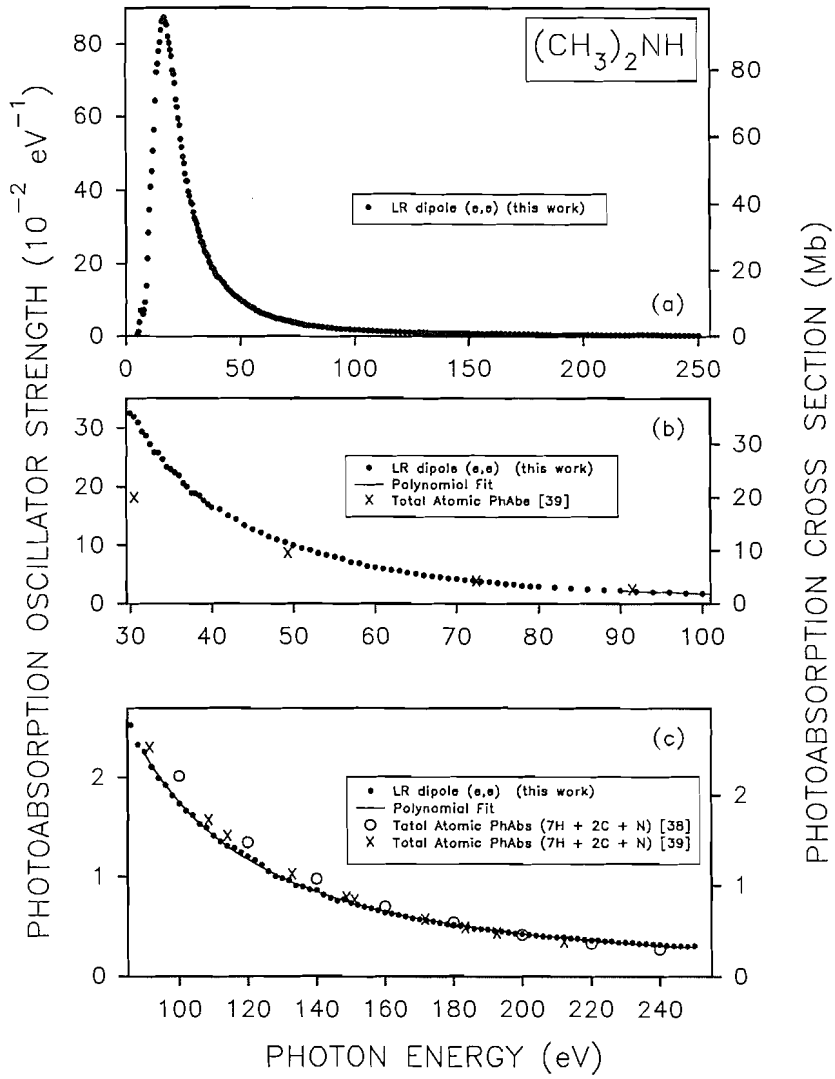

FIG. 2. Absolute oscillator strengths for the photoabsorption of $(CH_3)_2NH$ obtained at a resolution of ~1 eV fwhm: (*a*) the entire measured spectrum from 5.0–250 eV; (*b*) 30–100 eV; (*c*) the high-energy valence-shell tail from 86–250 eV. Also shown on (*b*) and (*c*) are the valence-shell polynomial fit (solid line), and the theoretical (38) and experimental (39) summed atomic oscillator strengths for the constituent atoms of $(CH_3)_2NH$ (open circles and crosses, respectively).

the other occupied molecular orbitals have been calculated assuming transferability of term values, and the resulting manifolds are shown in Figs. 4–6. The VIPs on the manifolds are from photoelectron spectroscopy measurements (31–33). The positions of the 3*d* and 4*s* Rydberg orbitals are degenerate and are each predicted from eq. [2] to have to term value of 1.51 eV, which assumes quantum defects of 1 and 0 for the *s* and *d* Rydberg orbitals, respectively (49). It can be seen from Figs. 4–6 that the excitation spectra of the methylamines correspond quite closely to a superposition of peaks due to the predicted transitions to Rydberg orbitals. The assignments suggested by the transferability of Rydberg term values, as shown in Figs. 4–6, are summarized in Tables 5, 6, and 7, for monomethylamine, dimethylamine, and trimethylamine, respectively. For each observed transition the term value (Tables 5–7) was calculated from the measured peak energy and the ionization potential of the initial state. Then, as a consistency check on each assignment, the denominator of the right-hand side of eq. [2] was evaluated for each term value and the predicted principal quantum number, and the predicted character of the final Rydberg state were considered to be confirmed if the quantum defect was in the range $0.8 \leq \delta_l \leq 1.3$ for *s* Rydberg orbitals, $0.4 \leq \delta_l \leq 0.8$ for *p* Rydberg orbitals, and $0.0 \leq \delta_l \leq 0.2$ for *d* Rydberg orbitals (49). As a result of this analysis and with the above assumptions, it is found that all of the major observed spectral features in the valence-shell photoabsorption spectra of the methylamines can be assigned using this Rydberg orbital scheme. The resulting Rydberg term values show good agreement with those for the corresponding transitions in the carbon and nitrogen K-shell inner-shell electron energy-loss (ISEELS) spectra of the methylamines reported earlier from this laboratory by Wight and Brion (44), and by Sodhi and Brion (46). Such transferability between inner shell and valence shell spectra is to be expected for Rydberg transitions (41–43).

The low energy portions of the valence-shell spectra of the

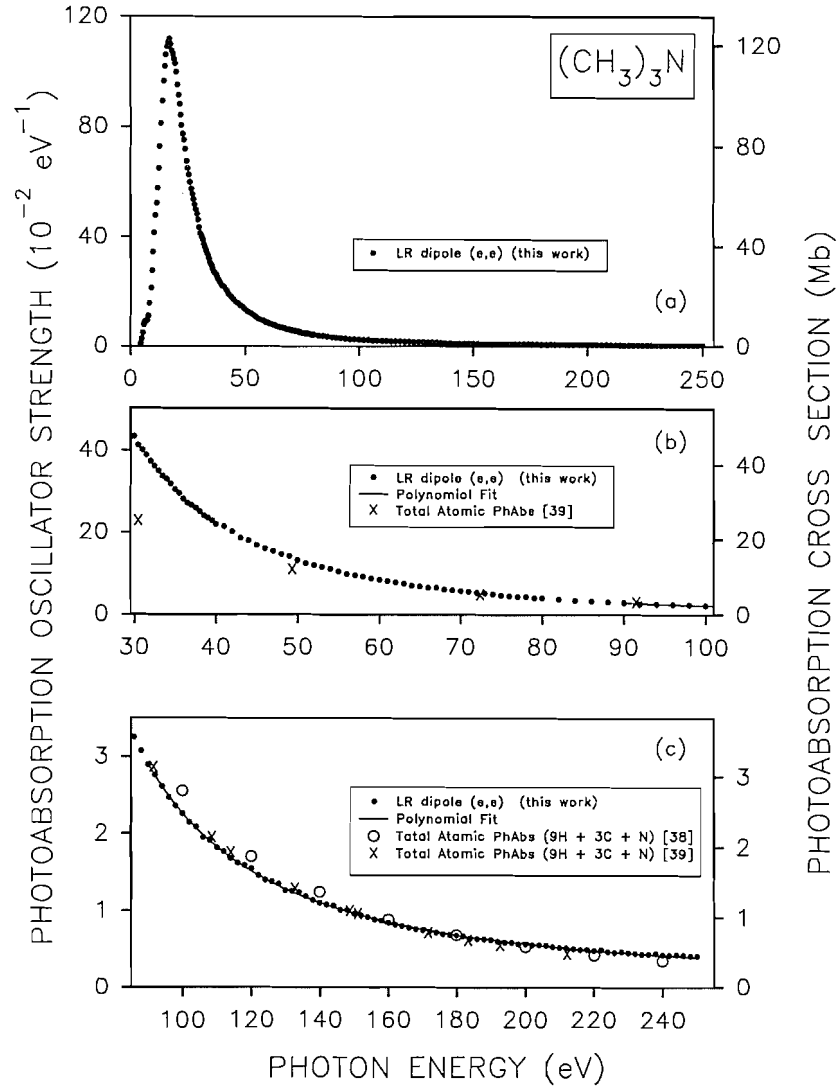

FIG. 3. Absolute oscillator strengths for the photoabsorption of $(CH_3)_3N$ obtained at a resolution of ~1 eV fwhm: (*a*) the entire measured spectrum from 4.5–250 eV; (*b*) 30–100 eV; (*c*) the high-energy valence-shell tail from 86–250 eV. Also shown on (*b*) and (*c*) are the valence-shell polynomial fit (solid line), and the theoretical (38) and experimental (39) summed atomic oscillator strengths for the constituent atoms of $(CH_3)_2N$ (open circles and crosses, respectively).

methylamines from 4–10 eV are shown in Fig. 7. In addition to the 3*s*, 3*p*, and the degenerate 3*d*, 4*s* assignments discussed above, the predicted positions of the 4*p* and 5*p* Rydberg orbitals are also shown. It can be seen that there is good correspondence between all the predicted Rydberg transition energies and the various structures in the oscillator strength data. Also shown are the previously reported and limited range photoabsorption data of Grosjean and Bletzinger (7), Tannenbaum et al. (14), and Bertrand et al. (15). It can be seen from the figure that the data reported by Tannenbaum et al. (14) are marginally higher, and have a slightly different shape than the present work for all three of the methylamines. The photoabsorption oscillator strength values reported by Bertrand et al. (15) at 123.6 nm (10.03 eV) are ~10% and ~20% higher than the present work for monomethylamine and dimethylamine, respectively. The data reported by Grosjean and Bletzinger (7) for trimethylamine agree well with the present results from 8.1–9.0 eV, but are lower above 9.0 eV to the limit of their data at 10.4 eV. In higher resolution optical work Tannenbaum et al. (14) observed vibrational progressions in the $3s \leftarrow 7a'$ and $3p \leftarrow 7a'$ transitions in monomethylamine, and in the $3p \leftarrow 8a'$ transition in dimethylamine. Evidence for these vibrational progressions in the $3p \leftarrow 7a'$ transition of monomethylamine and in the $3p \leftarrow 8a'$ transition of dimethylamine can be seen in the presently reported, somewhat lower resolution, spectra.

4. Computational methods for dipole oscillator strength distributions and related properties

The dipole oscillator strength distribution (DOSD) for a molecule is given by the molecular differential dipole oscillator strength, (df/dE), as a function of photon energy E, from the electronic photoabsorption threshold, E_0, to very high energy. Many important molecular dipole properties (50–52) can be evaluated if the DOSD for the given molecule is available. Those of particular interest for this paper include the dipole oscillator strength sums S_k, the analogous logarithmic dipole sums L_k, and the related mean excitation energies I_k, defined

[a] $\sigma(\text{Mb}) = 1.0975 \times 10^2\ df/dE\ (\text{eV}^{-1})$.

by

$$[3] \qquad S_k = \int_{E_0}^{\infty} \left(\frac{E}{E_H}\right)^k \left(\frac{df}{dE}\right) dE$$

$$[4] \qquad L_k = \int_{E_0}^{\infty} \left(\frac{E}{E_H}\right)^k \left(\frac{df}{dE}\right) \ln(E/E_H) dE$$

$$[5] \qquad I_k = E_H \exp[L_k/S_k]$$

where E_H is the Hartree unit of energy. The index k can take many different values (e.g. $k = 5/2, 2, 1, 0, -1/2, -1, -3/2, -2, -3, -4, \ldots$) and each choice corresponds to a different molecular property with respect to eqs. [3]–[5]. These properties are important in a variety of areas (9–11, 50–54). For example: the straggling (I_1, S_1), the stopping (I_0), and the total (I_{-1}, S_{-1}) inelastic scattering cross sections of fast charged particles in matter, charge densities at nuclei (S_2), Lamb shifts (I_2), moments of the DOSD ($S_{-2}, S_{-4}, S_{-6}, \ldots$) occur in the Cauchy expansion of the molar refractivity of molecules, $S_{-1}, S_{-3}, S_{-3/2}, S_{-2}$, and L_{-2} can be used to obtain estimates for the dipole–dipole dispersion energies between molecules, and accurate values for the dipole properties are of importance in testing *ab initio*, non-empirical, or other methods for evaluating the properties (53, 55–61). Another important property related to molecular DOSDs is the molar refractivity, R_λ, of a dilute molecular gas. R_λ is related to the refractive index, $n(\lambda)$, and the dynamic dipole polarizability, $\alpha(\lambda)$, of the gas at wavelength λ by

$$[6] \qquad R_\lambda = \frac{1}{\rho}\left[\frac{n^2(\lambda)-1}{n^2(\lambda)+2}\right] = \frac{4\pi}{3} N(E_H)^2 a_0^3 \int_{E_0}^{\infty} \frac{(df/dE)}{E^2 - (hc/\lambda)^2} dE = \frac{4\pi}{3} N\alpha(\lambda)$$

where a_0 is the Bohr radius, ρ is the molar density of the gas, h is Planck's constant, N is Avogadro's number, and c is

[a]$\sigma(\text{Mb}) = 1.0975 \times 10^2\ df/dE\ (\text{eV}^{-1})$.

the speed of light. The electronic static dipole polarizability is given by $\alpha_d = \alpha(\lambda = \infty) = a_0^3 S_{-2}$.

The constrained least-squares procedure employed to construct the DOSD for a given molecule, from a given initial data base of (df/dE) versus E values, has been discussed in some detail previously (50) and has been applied to a wide variety of atoms and molecules (62). In summary, the excitation energies for the molecule are divided into N_0 energy regions from threshold to very large values of E. The initial differential dipole oscillator strength data for the ith spectral region is modified according to

$$[7] \qquad (df/dE)^i_{\text{mod}} = (1 + a_i)(df/dE)^i_{\text{initial}},\ i = 1, 2, \ldots, N_0$$

such that the total modified DOSD satisfies constraints through the choice of the $\{a_i\}$. The constraints of choice are the molar refractivity, R_λ, for two well-spaced (63–65) λ values, and the TRK sum rule, $S_0 = N$, where N is the number of electrons in the molecule. A DOSD can be constructed for each initial data base for a given molecule. The amount of modification of the initial (df/dE) versus E data that is required to satisfy the constraints can be represented by the standard deviation (STD) defined by

$$[8] \qquad (\text{STD}) = \left[\sum_{i=1}^{N_0} (a_i - \bar{a})^2 / N_0\right]^{\frac{1}{2}}$$

where $\bar{a}$ is the mean of the a_i values.

Each adopted DOSD is represented by a set of data points, E_l and $(df/dE)_l$, for $l = 1, 2, \ldots, N_p \gg N_0$, and a set of interpolating functions to connect the points. For very high photon energies, i.e. $E \geq 10^9$ eV, the (df/dE) are represented by the Born dipole formula (66), $AE^{-3.5}$. The dipole properties represented in eqs. [3]–[6] are readily evaluated using this representation of the DOSDs (50).

5. Dipole oscillator strength distributions and properties for the methylamines

5.1. General considerations

The experimental dipole oscillator strengths used to construct the DOSDs for the methylamines are our low- and high-

resolution data reported in sections 3.2 and 3.3, respectively. Previous DOS data (see section 1), which are sparse as a function of E and limited to $E < 10.8$ eV, are not considered in the constrained DOSD analysis that follows. The input data are augmented, particularly for $E \geq 250$ eV, by the mixture rules

$$[9] \quad \frac{df}{dE}((CH_3)_nNH_{3-n} = \frac{df}{dE}(NH_3) + \frac{df}{dE}(C_{n+1}H_{2n+4}) - \frac{df}{dE}(CH_4),\ n = 1, 2, 3$$

$$[10] \quad \frac{df}{dE}((CH_3)_nNH_{3-n}) = \frac{df}{dE}(NH_3) + \frac{df}{dE}(CH_4) - \frac{df}{dE}(H_2),\ n = 1$$

$$= \frac{df}{dE}(CH_3NH_2) + (n-1)\left[\frac{df}{dE}(CH_4) - \frac{df}{dE}(H_2)\right],\ n = 2, 3$$

The input for these mixture rules are the recommended DOSD for NH_3 obtained from Burton et al. (12) and the recommended DOSDs for $C_{n+1}H_{2n+4}$, $n = 1, 2, 3$, CH_4, and H_2 developed by Jhanwar et al. (63), Thomas and Meath (67), and Zeiss et al. (50), respectively.

DOSDs for each methylamine have been constructed by considering the following combinations of DOS data:

DOSD1: E_0–E_f^{HR} (high-resolution data); E_f^{HR}–250.0 eV (low-resolution data); >250 eV (mixture rule [9]). The electronic absorption thresholds (E_0) and the upper energy limit of the high-resolution measurements (E_f^{HR}) are E_0 = 5.083, 4.962, and 4.711 eV and E_f^{HR} = 30.15, 31.26, and 30.96 eV for CH_3NH_2, $(CH_3)_2NH$, and $(CH_3)_3N$, respectively.
DOSD2: As in DOSD1 except the high-resolution data is replaced by the low-resolution data from $E_0 - E_f^{HR}$.
DOSD3: As in DOSD1 except mixture rule [9] is replaced by mixture rule [10].
DOSD4: As in DOSD2 except mixture rule [9] is replaced by mixture rule [10].

The photon energies in each case were divided into N_0 = 24

energy intervals as suggested by the structure in the input DOS data. The four initial DOSDs were each modified, for each molecule, using the constrained least squares approach outlined in section 4, to satisfy $S_0 = N$ and molar refractivity constraints which depend on the particular molecule considered (see what follows).

5.2. Monomethylamine

The molar refractivity constraints used are the values of R_λ for λ = 6440.24 Å and 4359.56 Å, obtained from the refractive index measurements of Ramaswamy (68). The STDs for the four resulting DOSD*i*s are 2.17, 2.59, 2.18, and 2.57 for $i = 1, 2, 3$, and 4, respectively. These results indicate that there is little to choose between the two mixture rules and that the high-resolution DOS data is more reliable for low E than the low-resolution data, as expected.

The integrated oscillator strengths for the constrained DOSD1, together with those corresponding to the initial DOS data for DOSD1, are given in Table 8. Generally the integrated oscillator strengths obtained from the initial high- and low-resolution measurements agree with each other, and with the constrained results, to within the estimated experimental errors of about ±5%. All exceptions are marginal except in the case of the low-resolution result for 10–11.8 eV which disagrees with the constrained integrated oscillator strength by ~12%. It should be pointed out that the integrated oscillator strengths obtained from the initial high- and low-resolution DOS data may be expected to differ in the discrete excitation

energy region since the fine structure in the DOSs is less well resolved in the low-resolution measurements (12).

The dipole properties evaluated using constrained DOSD*i*, $i = 1$–4, differ little from each other, particularly for DOSD1 and DOSD3. Nominally the results obtained from constrained DOSD1 are chosen as recommended values since they are derived using spectroscopically more reliable input data (DOSD1 also has, marginally with respect to DOSD3, the smallest STD of the four constrained DOSDs for monomethylamine). The recommended dipole properties S_k, L_k, and I_k for CH_3NH_2 are given in Table 9. Results for the molar refractivities of CH_3NH_2, evaluated using the constrained DOSD1, are listed in Table 10 which also contains the available experimental data for R_λ. The agreement with experiment is precise for the three values of R_λ not used as constraints; for most values of λ the results of Table 10 augment the (sparse) experimental data for R_λ as a function of λ.

It is interesting to note that our value of $S_{-2} = 26.50$ (Table 9) is ~0.15% higher than the value obtained by Ramaswamy (68) by fitting the relation $(n(\lambda) - 1) = A/(B - \lambda^{-2})$ to his refractive index data. The value of $(n(\lambda)-1)$ at $\lambda = 6440.24$ Å generated by this relation is ~0.1% lower than the measured value and therefore the extrapolated value for $\lambda = \infty$ (which yields S_{-2}) is also expected to be low in support of our recommended result for S_{-2}. The value of $S_{-2} = 26.75$ due to Wolf (69), obtained from dielectric constant measurements, is ~0.9% higher than our recommended value.

Table 9 also contains the values of the dipole properties S_k, L_k, and I_k obtained from the initial DOSD1 that lead to our constrained DOSD1 for methylamine. The results for the dipole and logarithmic dipole sums obtained from the initial DOSD are smaller in magnitude than the recommended values for all k (for example S_0 and S_{-2} are ~3% and ~4.5% lower). This is in agreement with the generally low, relative to the constrained integrated DOSs, initial DOS values used to construct the constrained DOSD.

There are apparently no *ab initio* calculations for the properties of CH_3NH_2. Metzger and Rhee (70), using a complete neglect of differential overlap/finite perturbation plus polarization approach, obtained $S_{-2} = 26.93$ which is ~1.6% higher than our recommended result. A value of $S_{-2} = 25.10$, about 5.6% lower than our value, has been calculated by Kaur et al.

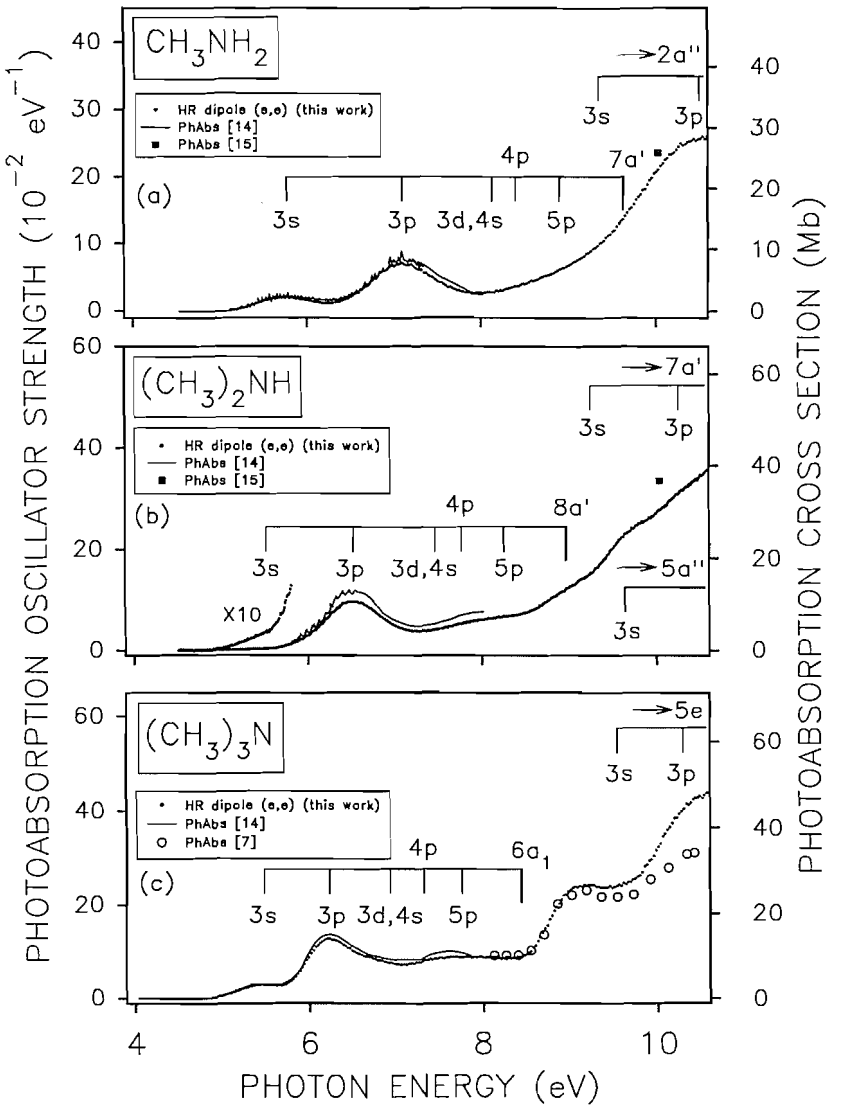

FIG. 7. High-resolution (0.048 eV fwhm) absolute oscillator strengths for photoabsorption of the methylamines in the low-energy valence-shell region from 4–10 eV: (*a*) monomethylamine; (*b*) dimethylamine; (*c*) trimethylamine. Also shown on the figures are previously reported absolute photoabsorption oscillator strength measurements (14, 15, 7). The Rydberg manifolds are as in Figs. 4–6 and Tables 5–7 with the addition of the predicted positions of the 4*p* and 5*p* Rydberg transitions (see text for details).

(71) using a double perturbation theory approach, developed by Amos and Yoffe (72), and a non-local pseudo-potential floating spherical gaussian model.

5.3. Dimethylamine and trimethylamine

There are no refractive index measurements for these molecules. Wolf (69) obtained a value of $S_{-2} = 39.06$ for $(CH_3)_2NH$ from dielectric constant measurements. For NH_3 and CH_3NH_2 his results for S_{-2} are ~1% higher than the recommended values evaluated from the constrained DOSDs for these molecules ((12) and section 5.2). Therefore, Wolf's S_{-2} value is not used as a constraint for constructing the DOSD for $(CH_3)_2NH$; there is no analogous result for $(CH_3)_3N$. For dimethylamine and trimethylamine the refractivity constraints are developed as outlined below.

The unmodified DOSD1 for CH_3NH_2 yields $R_{\lambda_1} = 9.6713$ and $R_{\lambda_2} = 9.9389$ cm^3 mol^{-1} for the values of λ, $\lambda_1 = 6440.24$ and $\lambda_2 = 4359.56$ Å, associated with the accurate values of R_λ, 10.1216 and 10.4032 cm^3 mol^{-1}, used as constraints in the construction of constrained DOSD1 for monomethylamine. These results yield ratios

$$[11] \quad \begin{cases} r_{\lambda_1} = R_{\lambda_1}(\text{accurate})/R_{\lambda_1}(\text{unmodified DOSD1}) \\ \qquad = 1.0466 \\ r_{\lambda_2} = R_{\lambda_2}(\text{accurate})/R_{\lambda_2}(\text{unmodified DOSD1}) \\ \qquad = 1.0467 \end{cases}$$

The experimental oscillator strengths for all three amines are measured using the same techniques and the refractivity constraints are completely dominated by the DOS data for $E \leq 150$ eV. Assuming that the experimental errors in the three sets of input data used to construct the DOSDs for the three molecules are essentially the same as a function of E, we assume that the ratios [11] apply to $(CH_3)_2NH$ and $(CH_3)_3N$ as well as CH_3NH_2. The molar refractivity constraints for dimethylamine and trimethylamine are therefore chosen to be the values evaluated using unmodified DOSD1 and λ_1 and λ_2 scaled by the ratios given by [11], namely $R_{\lambda_1} = 14.7845$ and

$R_{\lambda_2} = 15.1965$ cm^3 mol^{-1} for $(CH_3)_2NH$ and $R_{\lambda_1} = 19.0998$ and $R_{\lambda_2} = 19.6938$ cm^3 mol^{-1} for $(CH_3)_3N$. The value of $S_{-2} = 38.70$ obtained by using the refractivity constraints for $(CH_3)_2NH$ is ~0.9% lower than the result of Wolf (69) referred to earlier which is consistent with the analogous results for NH_3 and $(CH_3)_2NH$ also discussed previously (ref. 12, and section 5.2).

For dimethylamine and trimethylamine the STDs for the four constrained DOSDs, DOSDi with i = 1–4, are STD = 2.19, 3.96, 2.20, and 3.93, and STD = 2.42, 6.43, 2.39, and 6.42, respectively. The dipole properties for each molecule evaluated using constrained DOSDi, i = 1–4, are very similar, especially for DOSD1 and DOSD3 which are based on the most spectroscopically reliable DOS data. The results obtained from DOSD1 and DOSD3 are, nominally, recommended for $(CH_3)_2NH$ and $(CH_3)_3N$, respectively (they correspond, marginally, to the lowest STDs for the constrained DOSDs of the respective molecules).

The integrated oscillator strengths and the dipole properties S_k, L_k, and I_k corresponding to both the initial and constrained DOSD1 and DOSD3 for $(CH_3)_2NH$ and $(CH_3)_3N$, respectively, are given in Tables 11–14; the molar refractivi-

[a]This table contains the integrated oscillator strengths resulting from constrained DOSD1 and from the unmodified experimental or mixture rule data considered in this work.

ties evaluated from the constrained DOSDs are contained in Table 15 for 6709 Å $\geq \lambda \geq$ 2346 Å. For both molecules the integrated oscillator strengths obtained from the initial high- and low-resolution measurements, and from the constrained DOSDs, generally agree with each other to within the estimated experimental errors of $\sim \pm 5\%$. All the exceptions are marginal except for the low-resolution data for both molecules below $E \leq 9$ eV; as pointed out in section 5.2, see also ref. 12, the integrated oscillator strengths, in the discrete energy region, evaluated with low-resolution data need not be realistic.

A comparison of the dipole properties evaluated using the initial versus the constrained DOSD1 and DOSD3 for $(CH_3)_2NH$ and $(CH_3)_3N$, respectively, can be used to discuss the effects of the constrained DOSD method for these molecules. Analogous to monomethylamine, the values for the dipole and logarithmic dipole sums evaluated using the initial DOSDs for dimethylamine and trimethylamine are smaller in magnitude than the recommended values for all k. The effects are similar for all three molecules, particularly for the properties dominated by the photoabsorption spectra for $E \leq 250$ eV. For these properties, e.g., the S_k, $k \leq -1.5$, the effects of the constraint procedure are ~4–5% and are within the errors ($\pm 5\%$) associated with the high- and low-resolution experimental data used to construct the constrained DOSD for each molecule for $E \leq 250$ eV. A detailed discussion of the photon

S_{-10}	2.134(5)	2.251(5)	I_{-2} (eV)	1.575(1)	1.568(1)

energy dependence of the dipole properties can be found in the literature (8, 63–65, 73).

The recommended dipole properties for $(CH_3)_2NH$ and $(CH_3)_3N$, evaluated using the constrained DOSD1 and DOSD3, respectively, given in Tables 13 and 14 are apparently the only (reliable) values for these properties available in the literature to date.

5.4. The reliability of the calculated dipole properties

The uncertainties in our recommended values of the dipole properties of the methylamines can be estimated by comparing the recommended results with those derived from alternative constrained DOSDs satisfying the same constraints (12, 50, 62). The uncertainty estimates obtained in this way are less reliable for those properties that do not depend significantly on portions of the DOSD which dominate the constraints, for example properties corresponding to $k = 2$, to a lesser extent to $k = 1$, and for $k < -4$.

Using the results for the properties evaluated using various alternate constrained DOSDs for the methylamines, we estimate the uncertainties in the recommended results for the dipole properties of these molecules to be $\leq$2–3% for S_2, L_2,

4359.56	15.20	19.69			

I_2, S_1, L_1, $\leq 1\%$ for S_k, $-5 \leq k \leq 0$, R_λ for all λ, and for L_{-1}, L_{-2}, I_1, I_{-1}, I_{-2}, ≤ 2–3% for L_0 and I_0. For $k \leq -6$ the errors in the S_k are estimated to be ≤ 1–2% for S_{-6}, increasing to $\leq 8\%$ for S_{-12}. The estimation of the uncertainties in the recommended results for the dipole properties for the methylamines is based on the assumption that the molar refractivities used as constraints in the construction of the DOSDs have errors of the magnitude associated with accurate experimental measurements (a few tenths of a percent). While this is a valid assumption for monomethylamine, it becomes less probable for dimethylamine and trimethylamine due to the method, outlined in section 5.3, used to obtain the R_λ constraints for the two larger methylamines. The effects on the calculated properties S_k, L_k, and I_k of varying the R_λ constraints has been discussed previously and, as expected from the structure of integrals [3] and [4], it is largest for $k \leq -2$ and increases as k decreases from $k = -2$ (64, 74).

New dihydrogen complexes: the synthesis and spectroscopic properties of iron(II), ruthenium(II), and osmium(II) complexes containing the *meso*-tetraphos-1 ligand

MARIA TERESA BAUTISTA, KELLY ANNE EARL, PATRICIA ANNE MALTBY, ROBERT HAROLD MORRIS,[1] AND CAROLINE THERESIA SCHWEITZER

Department of Chemistry and the Scarborough Campus, University of Toronto, Toronto, ON M5S 1A1, Canada

Received July 19, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

MARIA TERESA BAUTISTA, KELLY ANNE EARL, PATRICIA ANNE MALTBY, ROBERT HAROLD MORRIS, and CAROLINE THERESIA SCHWEITZER. Can. J. Chem. **72**, 547 (1994).

The synthesis and properties of dihydrogen complexes *trans*-$[MH(H_2)L]^+$, M = Fe, Ru, Os, which contain the ligand *meso*-tetraphos-1, *S,R*-$Ph_2PCH_2CH_2P(Ph)CH_2CH_2P(Ph)CH_2CH_2PPh_2$ (L) are described. There are interesting possibilities of isomerism in such *trans* complexes because the axial binding sites at the metal are different, one being surrounded by four phenyl groups and the other by two phenyl groups. The osmium complex is prepared in an unusual reaction of *cis*-β-$Os(Cl)_2L$ with H_2 (1 atm) and $NaBPh_4$ (1 mol) in THF or by the reaction of *trans*-OsH(Cl)L with $NaBPh_4$ and H_2. The iron and ruthenium complexes were made by a reaction of HBF_4 with complexes *trans*-$M(H)_2L$ that have inequivalent *trans* hydrides. The ruthenium complex was also prepared starting from isomers of *trans*-RuH(Cl)L. The H—H distance in the rapidly spinning dihydrogen ligand has been calculated from T_1(min) data to be 0.88, 0.89, and 0.99 Å for the complexes of Fe, Ru, Os, respectively. The presence of the H—D bond in the isotopomers *trans*-$[MH(HD)L]^+$ and *trans*-$[MD(HD)L]^+$ is also confirmed by the observation of $^1J_{HD}$ coupling constants of 32, 33.5, and 26.4 Hz for Fe, Ru, and Os, respectively. There is no rapid intramolecular H atom exchange in these complexes in contrast to those with di-*tert*-phosphine ligands like $[MH(H_2)(dppe)_2]^+$ or to the trihydride $Re(H)_3L$. Described also are the properties of the precursor complexes including *cis*-β- and *trans*-$Ru(Cl)_2L$ and derivatives of the dihydrogen complexes *trans*-$[MH(L')L]^+$, L' = CH_3CN (on Ru and Os), PMe_2Ph (on Ru), and CO (on Os). Trends in the NMR properties of isostructural complexes are reported.

MARIA TERESA BAUTISTA, KELLY ANNE EARL, PATRICIA ANNE MALTBY, ROBERT HAROLD MORRIS et CAROLINE THERESIA SCHWEITZER. Can. J. Chem. **72**, 547 (1994).

On décrit la synthèse et les propriétés des complexes dihydrogénés *trans*-$[MH(H_2)L]^+$ (M = Fe, Ru et Os) qui contiennent le ligand *méso*-tétraphos-1, *S,R*-$Ph_2PCH_2CH_2P(Ph)CH_2CH_2P(Ph)CH_2CH_2PPh_2$ (L). Dans de tels composés, il existe des possibilités intéressantes d'isomérie parce que les sites de liaisons axiales sur le métal sont différents; en effet, l'un est entouré de quatre groupes phényles alors que l'autre est entouré par deux. On a préparé le complexe d'isomium par une réaction inhabituelle du *cis*-β-$Os(Cl_2)L$ avec du H_2 (1 atm) et du $NaBPh_4$ (1 mol) dans le THF ou par la réaction du *trans*-OsH(Cl)L avec du $NaBPh_4$ et du H_2. On a préparé les complexes du fer et du ruthénium par réaction du HBF_4 avec les complexes $M(H)_2L$ qui comportent deux hydrures inéquivalents. On a aussi préparé le complexe de ruthénium à partir des isomères du *trans*-RuH(Cl)L. En se basant sur des données de T_1(min), on a calculé que la distance H—H dans le ligand dihydrogéné avec un spin rapide sont respectivement 0,89, 0,89 et 0,99 Å pour les complexes du Fe, du Ru et du Os. On a aussi confirmé l'existence de la liaison H—D dans les isotopomères *trans*-$(MH(HD)L]^+$ et *trans*-$[MD(HD)L]^+$ par l'observation de constantes de couplages $^1J_{HD}$ de 32, 33,5 et 26,4 Hz respectivement pour les complexes du Fe, du Ru et du Os. Il n'existe pas d'échange rapide intramoléculaire d'atome de H dans ces complexes; ce comportement est en opposition avec ce qui a été observé avec les ligands di-*tert*-phosphines comme $[MH(H_2)(dppe)_2]^+$ ou le trihydrure $Re(H)_3L$. On décrit aussi les propriétés des complexes précurseurs, y compris celles des *cis*-β- et *trans*-$Ru(Cl)_2L$ et des dérivés des complexes dihydrogénés *trans*-$[MH(L')L]^+$ dans lesquels L' = CH_3CN (sur le Ru et le Os), PMe_2Ph (sur le Ru) et CO (sur le Os). On rapporte les tendances dans les propriétés RMN des complexes isostructuraux.
[Traduit par la rédaction]

Introduction

The reactions of complexes that contain an intact dihydrogen molecule (1) have represented a rapidly expanding field of study since the report of the first molecular hydrogen complex in 1984 (2). A common reaction of the complexes *trans*-$[M(H_2)(H)L_2]^+$, M = Fe, Ru, Os and L = $PEt_2CH_2CH_2PEt_2$ (depe) and $PPh_2CH_2CH_2PEPh_2$ (dppe), is the intramolecular exchange of H atoms between the hydride and H_2 sites (3–6). To better understand this intramolecular hydrogen atom exchange, we have prepared new dihydrogen complexes of the tetradentate phosphine $Ph_2PCH_2CH_2P(Ph)CH_2CH_2P(Ph)CH_2CH_2PPh_2$ (tet-1). This ligand exists as a mixture of two diastereomers, the *meso* (*S,R*) and *rac* (*S,S*; *R,R*) forms (7). The topologies that these diastereomers adopt when coordinated in an octahedral complex are denoted by the *cis*-α, *cis*-β, and *trans* nomenclature (8) (Fig. 1). All three configurations may be attained by *rac*-tet-1 (structure *cis*-α-III contains the *rac*-tet ligand), but the *cis*-α geometry is not physically possible for the *meso* ligand. Therefore octahedral *meso*-tet-1 complexes adopt either structure *trans*-I or *cis*-β-II.

This isomerism was not fully appreciated in early studies of its coordination chemistry (9–12) until the work of Brown and Canning (13). Taqui Khan and Mohiuddin partially characterized a complex [RuCl(tet-1)]Cl, which was a one to one electrolyte in nitromethane (9). This complex reacted with dihydrogen gas directly to give a partially characterized complex RuH(Cl)(tet-1). Unfortunately they did not determine if it was the *meso* or *rac* ligand that was involved and could not determine the stereochemistry of these complexes.

The preliminary report of our work (14) described how the complexes *trans*-$[M(H_2)(H)L]^+$, M = Fe, Os, L = *meso*-tet-1, held the H_2 and H ligands *trans* to each other so that no H-atom exchange occurred, while for the complex *cis*-α-$[OsH_3$(*rac*-tet-1)$]^+$ there was rapid exchange of the H atoms. The present work describes in full detail the properties of the Fe and Os

complexes as well as new Ru complexes containing the *meso*-tet-1 ligand (abbreviated below as L). A future paper will describe the *rac*-tet-1 chemistry (15).

An interesting feature of the *trans* structure I is that the axial sites are inequivalent due to the arrangement of the phenyl groups; site X is "surrounded" by four phenyl groups whereas site Y has only two phenyl groups near it. The crystal structures of *trans*-$[FeH(N_2)L]Br$ (11) and *trans*-$RuCl_2L$ (12) clearly demonstrate this feature. The dinitrogen ligand is located in the four-phenyl binding site in the former complex. Such complexes offer the interesting possibility of recognition of ligands on the basis of molecular size. The X-ray crystal structures of the square-planar complex $[PtL]BPh_4$ (16) and some dimolybdenum complexes Mo_2Br_4L (17) have also been reported.

Experimental

General

Oxygen and water were excluded at all times by the use of a glove box supplied with purified nitrogen or vacuum lines supplied with purified nitrogen or argon where necessary. Benzene, tetrahydrofuran (THF), diethyl ether, and hexanes were dried over and distilled from sodium-benzophenone ketyl. Methanol was dried over magnesium methoxide, and ethanol over magnesium ethoxide. Acetone was dried over potassium carbonate. Dichloromethane and 1,2-dichloroethane were distilled from calcium hydride. Deuterated solvents were dried over Linde type 4 Å molecular sieves and degassed prior to use. Reagents were obtained from commercial sources and used without further purification. The phosphine ligands were used as purchased from Strem Chemicals or Digital Specialty Chemicals Ltd. with the exception of tetraphos-1 which had to be separated into its *meso* and *racemic* forms (see below). Ruthenium(III) trichloride trihydrate, ammonium hexachloroosmate(IV), and sodium hexachloroosmate(IV) were received as a loan from Johnson-Matthey Co. Tri-μ-chloro-hexakis(ethyldiphenylphosphine)diosmium(II) chloride dihydrate, $[Os_2Cl_3(PEtPh_2)_6]Cl\cdot 2H_2O$, was prepared by the method described by Chatt and Hayter (18). The compounds *cis*-$RuCl_2(DMSO)_4$ (19–21) and $PPh_2CH_2CH_2Cl$ (22) were prepared by literature methods.

Infrared spectra were recorded on a Nicolet 5DX FTIR spectrometer as Nujol mulls. NMR spectra were recorded on Varian XL-400 (400 MHz for ^1H, 162 MHz for ^{31}P), Varian XL-200 (200 MHz for ^1H, 81 MHz for ^{31}P), Varian Gemini 200 (200 MHz for ^1H), or Varian Gemini 300 (300 MHz for ^1H, 120.5 MHz for ^{31}P) spectrometers. Attempted 2D NMR experiments and an NOEDIFF experiment were performed on a Bruker AM-500 (500 MHz for ^1H, 202.5 MHz for ^{31}P) at McMaster University by Dr. D. Hughes. VT T_1 measurements were obtained on the XL-400 spectrometer using the inversion–recovery method. ^{31}P chemical shifts were measured, either internally or externally, relative to 1% $P(OMe)_3$ in C_6D_6 sealed in coaxial capillaries, but are reported in parts per million (ppm) from 85% H_3PO_4 ($\delta P(OMe)_3 = 140.4$ ppm) (see Tables 1 and 2). ^1H chemical shifts were measured relative to partially deuterated solvent peaks, but are reported relative to tetramethylsilane (see Table 2 for the high-field data). First-order NMR spectra were simulated using the "First order NMR" program (23) and second-order spectra were simulated using the LAOCN 5 program (24). In the abbreviated NMR data listed below "p" refers to a pentet to distinguish it from "q", a quartet.

Microanalyses were performed on a sample handled under an inert atmosphere by Canadian Microanalytical Services, Delta, B.C. Several samples did not give acceptable analysis despite repeated attempts and despite the fact that they appeared pure by ^1H and ^{31}P NMR. Fast atom bombardment mass spectrometry (FAB MS) spectra were obtained with a VG 70-250S mass spectrometer using a 3-nitrobenzyl alcohol (NBA) or 2-nitrophenyloctylether (NPOE) matrix. A PAR model 273 potentiostat was used for cyclic voltammetry studies. The electrochemical cell contained a Pt working electrode, W secondary electrode, and Ag wire reference electrode in a Luggin capillary. The cyclic voltammograms were collected in THF containing 0.2 M n-Bu_4NPF_6 as the supporting electrolyte. Reported potentials are referenced to ferrocene, which was added to these solutions.

Synthesis of $Ph(Li)PCH_2CH_2P(Li)Ph\cdot 4THF$ (Lippe·4THF) (25)

Under 1 atm Ar (101.3 kPa), finely chopped lithium metal (2.3 g, 0.33 mol) was added to 60 mL THF. After cooling this mixture to 0°C, a solution of dppe (13.5 g, 0.0339 mol) in 80 mL THF was added dropwise, with stirring, over a period of 1 h during which time the mixture became orange-yellow. This mixture was then refluxed for 45 min resulting in a dark red solution. The warm solution was filtered through Celite to remove the excess lithium. The volume of the filtrate was reduced to 20 mL and cooled to −78°C. The yellow precipitate was then filtered and washed twice with 5 mL of cold diethyl ether. A bright yellow powder (12.6 g, 68%) was obtained. ^1H NMR (THF-d_8, 200 MHz) δ: 7.0–6.1 (m, PC_6H_5), 2.3 (m, PCH_2CH_2P), 3.6, 1.7 (m, THF). ^{31}P NMR (THF, 200 MHz) δ: 200.9 (s).

Synthesis of $Ph_2PCH_2CH_2P(Ph)CH_2CH_2P(Ph)CH_2CH_2PPh_2$ (tet-1) (7, 26)

Under 1 atm Ar, $Ph_2CH_2CH_2Cl$ (22) (8.0 g, 0.032 mol) in 100 mL THF was added dropwise over 1 h to an ice-cooled solution of Lippe·4THF (8.8 g, 0.016 mol) in 100 mL THF. During this time the solution discoloured from bright yellow to nearly colourless. This solution was refluxed for 0.75 h and then allowed to cool. 30 mL of saturated NH_4Cl (aq) solution was added with vigorous stirring. The THF layer was decanted and the aqueous layer was washed with 20 mL THF. The THF layers were combined and dried over $MgSO_4$. The $MgSO_4$ was then filtered from the THF and the volume was reduced to 30 mL. EtOH (90 mL) was added and the mixture was cooled overnight and filtered the next day. The white solid (8.2 g, 76%) obtained was a mixture of the *meso* and *racemic* isomers. The isomers were separated by adding 5 g of tet-1 to 100 mL of CH_2Cl_2 and 25 mL of EtOH. This suspension was heated for 1 h. Upon cooling, the insoluble portion was filtered off and washed with EtOH; the process of dissolving the insoluble portion and heating was repeated two more times, yielding 3.5 g of the *meso* isomer. All the filtrate portions were combined and the volume reduced to 25 mL. The *rac*-tet-1 isomer precipitated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

out and was filtered off. The yield of *rac*-tet-1 was 1.25 g. ^{1}H NMR (CD_2Cl_2, 200 MHz, both isomers) δ: 7.3 (m, PC_6H_5), 2.0–1.5 (at least 3 m, PCH_2CH_2P).

Properties of the *meso* isomer: mp 189°C, $^{31}P\{^1H\}$, δ (toluene, 81 MHz, 290 K): −13.2 ppm (P_A), −16.9 ppm (P_X, AA′XX′, $J_{AX} = J_{A'X'} = 27.4$ Hz, $J_{XX'} = 23.0$ Hz, $J_{AX'} = J_{A'X} = 0.3$ Hz, $J_{AA'} = 0$).

Properties of the *rac* isomer: mp 118°C, $^{31}P\{^1H\}$, δ (toluene, 81 MHz, 290 K): −13.2 ppm (P_A), −17.1 (P_X, AA′XX′, same couplings as the *meso* isomer).

Preparation of cis-α-*$OsCl_2$(rac-tet-1) and* cis-β-*$OsCl_2$L, L* = meso-*tet-1*

$[Os_2Cl_3(PEtPh_2)_6]Cl{\cdot}2H_2O$ (2.45 g, 1.33 mmol) and tet-1 (1.85 g, 2.76 mmol) were heated together with stirring. A brown liquid formed at 160°C and turned yellow at 185°C. The temperature was increased to 204°C and the viscous yellow solution allowed to cool. Free $PEtPh_2$ was washed from the lemon yellow mass with hexane (3 × 20 mL). The solid was stirred in THF (2 × 20 mL) and the *cis*-α-$OsCl_2$(*rac*-tet-1) isomer was filtered off, washed (3 × 5 mL THF), and dried in vacuo (0.8 g, 32%). The properties of the *rac*-tet-1 osmium complexes will be described elsewhere (15). *cis*-β-$OsCl_2$L was precipitated from the yellow filtrate, after volume reduction to 5 mL, by addition of hexane (15 mL). THF–hexane recrystallization yielded 1.63 g (66.5%) of the pale yellow solid. Anal. calcd. for $C_{42}H_{42}Cl_2OsP_4$:C 54.14, H 4.54; found: C 54.14, H 4.62. FAB MS calcd. for $C_{42}H_{42}{}^{35}Cl_2{}^{195}OsP_4$: 932.0; obsd.: 932 ($M^+$), 897 ($M^+ - Cl$).

Preparation of trans-*OsHClL*

Method A

A slurry of $LiAlH_4$ (0.036 g, 0.95 mmol) in THF (5 mL) was added to a stirred solution of *cis*-β-$OsCl_2$L (0.269 g, 0.289 mmol) in THF (10 mL). After refluxing for 10 min, and cooling, EtOH (5 mL) was added to the pale orange mixture. Solvent was removed under vacuum and the beige residue was treated with THF (15 mL) and filtered through Celite. The volume of the dirty yellow filtrate was reduced to dryness, NaCl (0.038 g, 0.65 mmol) and acetone (20 mL) were added, and the slurry refluxed for 2 h. After solvent removal and filtration of the THF soluble portion, the yellow filtrate was concentrated to 2 mL and the pale yellow product precipitated by addition of hexane (10 mL); 0.166 g (64%) was obtained. IR (Nujol): 1943 (w, br, Os-H cm^{-1}). FAB MS calcd.for $C_{42}H_{43}{}^{35}Cl{}^{192}OsP_4$: 898.1; obsd.: 898 ($M^+$), 861 ($M^+ - ClH_2$). $E_{1/2}(Os^{3+}/Os^{2+})$ is −0.31 V in THF, versus Fc^+/Fc; 0.2 M NBu_4BF_4. In some preparations a minor isomer is also obtained (see Table 2).

Method B

cis-β-$OsCl_2$L (0.085 mmol) and $NaBPh_4$ (0.096 mmol) were stirred for 20 min in 5 mL THF under 1 atm dihydrogen. Then NEt_3 (0.086 mmol) was added and the mixture was stirred for 15 min. The solvent was evaporated and the residue was dissolved in acetone-d_6. The only hydride resonances were due to major *trans*-OsH(Cl)L at −22.6 ppm (J_{PH} = 17.5 Hz) and an unknown compound in small amount at −10.6 ppm (br).

Synthesis of trans-*$RuCl_2$L (27)*

meso-tet-1 (1.00 g, 1.49 mmol) in 60 mL toluene was added dropwise to *cis*-$RuCl_2(DMSO)_4$ (0.722 g, 1.49 mmol) in 80 mL refluxing toluene. This yellow solution was refluxed for 1.5 h, after which time the solvent was removed under reduced pressure. The yellow residue was washed with hexanes (2 × 30 mL) affording 1.19 g (94%) of product.

Synthesis of trans-*RuHClL*

trans-$RuCl_2$L (4.50 g, 5.34 mmol) was dissolved in 80 mL THF and then, with stirring, $LiAlH_4$ (2.00 g, 52.7 mmol) was added. The mixture was refluxed for 24 h, cooled, and then 7 mL EtOH was added. After solvent evaporation, 100 mL of benzene was added to the residue and the mixture stirred overnight. The next day the lithium salts were removed by filtration through Celite. The filtrate was reduced to dryness and the tan residue was washed with hexanes and dried (2.00 g, 46%). IR (Nujol): 1989 (Ru-H) cm^{-1}. ^{1}H NMR (C_6D_6, 200 MHz) δ: 8.4–6.7 (m, PC_6H_5), 3.1–0.9 (at least 9 m, PCH_2CH_2P), −17.6 (p, Ru*H* of minor isomer, $^2J_{PH}$ = 17.6 Hz); −20.9 (p, Ru*H* of major isomer, $^2J_{PH}$ = 20.8 Hz). T_1 (measured at 400 MHz, THF-d_8) for hydride of minor isomer versus that of major isomer, respectively, at the indicated temperature: 819 vs. 717 ms at 294 K, 503 vs. 481 at 251 K, 422 vs. 417 ms at 230 K, 377 vs. 374 ms at 207 K, 298 vs. 287 ms at 187 K. Anal. calcd. for $C_{42}H_{43}ClP_4Ru{\cdot}C_6H_6$: C 65.0, H 5.6, Cl 4.0; found: C 65.3, H 6.2, Cl 3.9. FAB MS calcd. for $C_{42}H_{43}{}^{35}ClP_4{}^{102}Ru$: 808; obsd.: 771 ($M^+ - 2H - Cl$).

Observation of cis-β-*$Os(H)_2$L*

This was prepared from *cis*-β-$OsCl_2$L (0.059 g, 0.063 mmol), dihydrogen gas, $NaBPh_4$ (0.034 g, 0.093 mmol), NaO^{t}Bu (0.019 g, 0.20 mmol), and 10 mL of a THF–^{t}BuOH solvent mixture with 15 h of stirring. ^{31}P NMR indicated the presence of *cis*-β-OsH_2L. The mixture was allowed to stir for a further 19 h; the ^{31}P NMR spectrum did not change. A pale yellow residue, which proved difficult to crystallize, resulted from the benzene-soluble portion.

Synthesis of trans-*$Ru(H)_2$L*

Under 1 atm Ar, *trans*-RuHClL (0.090 g, 0.11 mmol) was dissolved in 4.5 mL THF and 1.5 mL EtOH. NaOEt (0.030 g, 0.44 mmol) was added and the solution was stirred overnight. The next morning, the pale yellow solution was evaporated to dryness and the residue was redissolved in benzene. The NaCl formed was filtered off through Celite and the volume of the filtrate was reduced to 1 mL. Addition of hexanes caused precipitation of a pale yellow solid (0.042 g, 49%). IR (Nujol): 1966 (w, Ru-H) cm^{-1}. ^{1}H NMR (C_6D_6, 200 MHz) δ: 8.6–6.7 (m, PC_6H_5), 2.7–0.9 (6 m, PCH_2CH_2P), −7.9 (m, Ru*H*, $^2J_{HP}$ = 15.0 Hz, 20.0 Hz, $^2J_{HH}$ = 14.0 Hz), −10.2 (dp, Ru*H*, $^2J_{HP}$ = 18.0 Hz, 19.0 Hz, $^2J_{HH}$ = 14.0 Hz). $E_{1/2}(Ru^{3+}/Ru^{2+})$ is –0.40 V in THF versus Fc^+/Fc. T_1 (measured at 400 MHz, THF-d_8) for hydride at −7.9 ppm versus that at −10.2 ppm, respectively, at the indicated temperature: 695 vs. 880 ms at 295 K, 463 vs. 580 at 249 K, 394 vs. 500 ms at 227 K, 315 vs. 415 ms at 207 K, 183 vs. 280 ms at 185 K. FAB MS calcd. for $C_{42}H_{44}{}^{102}RuP_4$: 774; obsd.: 773 ($M^+ - H$), 772 ($M^+ - 2H$), 771 ($M^+ - 3H$).

Synthesis of trans-*$Fe(H)_2$L*

$FeCl_2$ (0.10 g, 0.79 mmol) was added to the *meso*-tet-1 (0.54 g, 0.80 mmol) in 50 mL THF and stirred for 5 min to give a green solution. $NaBH_4$ (0.1 g, 2.64 mmol) in 5 mL ethanol was added and this mixture stirred for 6 h. After filtering off the borate salts, the volume of the yellow filtrate was reduced to 5 mL and the FeH_2L precipitated out by repeatedly adding 5 mL diethyl ether and reducing the volume to 5 mL until the precipitate formed. The bright yellow solid was filtered off and washed with diethyl ether (80% yield). IR (Nujol): 1724 (Fe-H) cm^{-1}; δ (^{1}H, C_6D_6, 400 MHz): −12.76 (dtt, 1H, J_{HP} = 41.1, 33.6, J_{HH} = 18.2 Hz, T_1 = 0.58 s), −14.68 (dp, 1H, J_{HP} = 38.2, J_{HH} = 18.2 Hz, T_1 = 0.63 s). FAB MS calcd. for $C_{42}H_{44}{}^{56}FeP_4$: 728.3; obsd.: 726 ($M^+ - 2H$).

Synthesis of trans-*$[OsH(H_2)L]BPh_4$*

Method A

cis-β-$OsCl_2$L (0.094 g, 0.10 mmol) and $NaBPh_4$ (0.038 g, 0.11 mmol) were placed under a H_2 atmosphere and 10 mL THF were added. The solid immediately reddened. The solution was degassed and the red-orange colour quickly faded to pale yellow with the production of a fine white precipitate (NaCl). The mixture was stirred under H_2 for 21 h, filtered through Celite under an argon atmosphere, and the solvent removed under vacuum to yield a a pale yellow mass. The solid proved unstable to recrystallization attempts and thus spectral solutions were prepared from the crude product under an argon atmosphere. Solutions exposed to air readily decompose to a green

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

solution. δ (^{1}H, CD_2Cl_2, 213 K, 400 MHz): −6.58 (s, 2H, T_1(min) = 31 ± 1 ms), −11.38 (p, 1H, J_{HP} = 18.9 Hz, T_1(min) = 143 ± 2 ms). FAB MS calcd. for $C_{42}H_{45}{}^{192}OsP_4$: 865.1; obsd.: 861 ($M^+$ − 4H).

Method B

This synthesis is analogous to that above with the exceptions that *trans*-OsHClL and not *cis*-β-$OsCl_2L$ is the precursor complex, and the only visual evidence of reaction is NaCl formation; shorter reaction times are generally employed.

Observation of Os(HD)H, Os(HD)D, and Os(D_2)H isotopomers of [OsH(H_2)L]BPh_4

Acetone-d_6 solutions of *trans*-[OsH(H_2)L]BPh_4 show changes in the high-field ^{1}H NMR spectrum (200 MHz) over time, owing to intermolecular H^+/D^+ exchange with acetone-d_6. Several ^{1}H NMR spectra of samples with varying degrees of deuterium incorporation were analyzed. Two 1:1:1 triplets grow in at −6.36 (J_{HD} = 26.4 Hz) and −6.28 ppm (J_{HD} = 26.4 Hz) due, respectively, to the Os(HD)H and Os(HD)D isotopomers. Concomitant change in the terminal hydride resonance is observed. Pentets (J_{PH} ~ 18.5 Hz) emanating from the Os(HD)H and Os(D_2)H isotopomers emerge at −11.29 and −11.37 ppm, respectively. The $[OsH(HD)L]^+$ isotopomer appears first.

J_{HD} values were confirmed at 400 MHz by using an inversion–recovery pulse sequence to null the H_2 signal (from Os(H_2)X, X = H, D, isotopomers) which has a shorter T_1 time than the HD signals.

Synthesis of trans-*[RuH(H_2)L]$^+X^-$, X^- = BPh_4^-, PF_6^-, BF_4^-*

Method A

trans-RuHClL (0.26 g, 0.32 mmol) was dissolved in 5 mL THF. Under 1 atm H_2, $NaBPh_4$ (0.165 g, 0.482 mmol) was added ($NaPF_6$ can be used in place of $NaBPh_4$) and the mixture was allowed to stir for 4.5 h. The yellow solution was then evaporated to dryness and the residue was redissolved in CH_2Cl_2. The mixture was then filtered through Celite and the volume of the filtrate reduced to 2 mL. Addition of MeOH caused precipitation of a tan solid (0.23 g, 66%). IR (Nujol): 1964 (Ru-H) cm^{-1}. ^{1}H NMR (CD_2Cl_2, 200 MHz) δ: 8.6–6.7 (m, PC_6H_5), 3.0–0.9 (6 m, PCH_2CH_2P), −5.1 (br s, Ru(H_2)), −12.7 (p, Ru*H*, $^2J_{HP}$ = 18.9 Hz). FAB MS calcd. for $C_{42}H_{45}P_4{}^{102}Ru$: 775; obsd.: 772 ($M^+$ − 3H).

Method B

trans-Ru(H_2)L (0.10 g, 0.12 mmol) was suspended in 3 mL diethyl ether. Under 1 atm H_2, 1 drop of $HBF_4{\cdot}Et_2O$ was added with stirring. A white solid immediately precipitated. This white solid was allowed to settle and the ether supernatant was syringed out. The solid (0.83 g) was then washed with diethyl ether (2 × 2 mL) to remove the excess acid.

Reaction of trans-*[RuH(H_2)L]BPh_4 with excess lithium chloride*

Under 1 atm Ar, *trans*-[RuH(H_2)L]BPh_4 (0.030 g, 0.027 mmol) was dissolved in 5 mL THF and LiCl (0.023 g, 0.54 mmol) was added. This mixture was stirred overnight, after which time the solvent was removed and the residue was redissolved in benzene. This was then filtered through Celite and the volume of the filtrate was reduced to 1 mL. Addition of hexanes produced a tan-yellow precipitate (0.015 g, 68%), which was identified as the major isomer of *trans*-RuH(Cl)L (see above).

Reaction of trans-*[RuH(H_2)L]BPh_4 with D_2*

trans-[RuH(H_2)L]BPh_4 (0.020 g, 0.18 mmol) was dissolved in 0.7 mL CD_2Cl_2 in a 5 mm NMR tube. Deuterium was gently bubbled through the solution for 1 min. A ^{1}H NMR spectrum (200 MHz) was collected immediately and again after 30 h, to observe any changes in the shape and (or) intensity of the hydride signal. Sets of 1:1:1 triplets were observed over time due to the Ru(HD)(H) and Ru(HD)(D) isotopomers (see below). The $^1J_{HD}$ values were confirmed by performing an inversion–recovery pulse sequence on the sample to null out the H_2 signal.

Synthesis of trans-*[FeH(H_2)L]BF_4*

Fe(H_2)L (0.5 g, mmol) was partially dissolved in 50 mL of diethyl ether to produce a yellow suspension. Under 1 atm of Ar or H_2, 0.5 mL of $HBF_4{\cdot}Et_2O$ (excess) was added dropwise over a period of 1 min with stirring. Immediately a yellow, powdery solid precipitated out, causing the solution to turn almost colourless. The solid was filtered off and washed several times with diethyl ether (80% yield). FAB MS calcd. for $C_{42}H_{45}{}^{56}FeP_4$: 729.3; obsd.: 729 (M^+).

Synthesis of [FeH(HD)L]BF_4

To prepare a solution of DBF_4, D_2O was added dropwise to 1 mL of $HBF_4{\cdot}Et_2O$ until the effervescence ceased. Addition of 0.1 mL of this mixture to a suspension of Fe(H_2)L (0.03 g, 0.041 mmol) in ether proceeded as described above. δ (^{1}H, CD_2Cl_2, 293 K): −9.80 (1:1:1 t, $^1J_{HD}$ = 32.3 Hz). δ (^{2}H{^{1}H}, CH_2Cl_2, 293 K): −9.81 (s).

Preparation of trans-*[OsH(CH_3CN)L]BPh_4*

trans-[OsH(H_2)L]BPh_4 (0.204 mmol) was prepared as a pale yellow residue as described previously. Under an Ar atmosphere, 2 mL THF and 2 mL CH_3CN were added to the pale yellow residue and the resulting solution refluxed for 2.5 h. After cooling, the solvent was removed and replaced with 2 mL acetone and 5 mL CH_2Cl_2. Addition of 5 mL MeOH followed by solvent reduction to ~6 mL and cooling yielded the cream-coloured product, which was washed with Et_2O and dried in vacuo (0.134 g, 52%). IR (Nujol): 2258 (w, C-N), 1952 (mw, Os-H) cm^{-1}. FAB MS calcd. for $C_{44}H_{46}N^{192}OsP_4$: 904.1; obsd.: 904 (M^+), 861 (M^+ − CH_3CN − H_2), and very weak peaks at 925 and 1077 due to Os species.

Preparation of trans-*[OsH(CO)L]BPh_4*

THF (10 mL) was added to a yellow residue of *trans*-[OsH(H_2)L]BPh_4 (0.10 mmol) and the pale yellow solution was refluxed under CO atmosphere for ~4 h. After cooling, the solution volume was reduced to ~0.5 mL and 1 mL acetone was added. Addition of 5 mL MeOH to the slurry followed by cooling yielded the cream-coloured product, which was washed with Et_2O and dried in vacuo (0.055 g, 45%). IR (Nujol): 1989 (m, C-O),1900 (w, Os-H) cm^{-1}. FAB MS calcd. for $C_{43}H_{43}O^{192}OsP_4$: 891.1; obsd.: 891 (M^+), 861 (M^+ − CO − H_2), and very weak peaks at 925 and 1077 due to Os species.

Synthesis of trans-*[RuH(PMe_2Ph)L]PF_6*

trans-RuHClL (0.10 g, 0.12 mmol) was dissolved in 5 mL THF. PMe_2Ph (0.017 g, 0.12 mmol) and $NaPF_6$ (0.021 g, 0.12 mmol) were added with stirring. This pale yellow mixture was stirred for 24 h, after which time the solvent was removed under reduced pressure. The residue was redissolved in CH_2Cl_2 and the solution was filtered through Celite. The volume of the filtrate was reduced to 2 mL and addition of diethyl ether afforded a pale yellow solid (0.073 g, 56%). ^{1}H NMR (THF-d_8, 200 MHz) δ: 8.3–6.5 (m, PC_6H_5), 2.8–1.0 (6 m, PCH_2-CH_2P), 0.8 (d, PCH_3), −13.7 (dp, RuH, *cis*-$^2J_{HP}$ = 20.6 Hz, *trans*-$^2J_{HP}$ = 59.3 Hz). FAB MS calcd. for $C_{50}H_{54}P_5{}^{102}Ru$: 912, obsd.: 912 ($M^+$), 772 ($M^+$ − H − PMe_2Ph).

Synthesis of trans-*[RuH(CH_3CN)L]PF_6*

trans-RuHClL (0.12 g, 0.15 mmol) was dissolved in 3 mL CH_3CN – 2 mL THF. $NaBF_4$ (0.024 g, 0.22 mmol) was added and the solution was stirred for 24 h. The solvent was then removed under reduced pressure and the pale yellow residue was redissolved in CH_2Cl_2. After filtering through Celite, the volume of the filtrate was reduced to 2 mL and addition of diethyl ether produced a pale yellow solid (0.072 g, 54%). IR (Nujol): 1991 (Ru-H) cm^{-1}. ^{1}H NMR (CD_2Cl_2, 200 MHz) δ: 8.0–6.8 (m, PC_6H_5), 2.8–1.0 (6 m, PCH_2CH_2P), 1.9 (s, CH_3CN), −18.3 (p, Ru*H*, $^2J_{HP}$ = 19.7 Hz). FAB MS calcd. for $C_{44}H_{46}NP_4{}^{102}Ru$: 814; obsd.: 771 ($M^+$ − 2H − CH_3CN).

Results and discussion

Synthesis of the tet-1 ligand

A new route was discovered for the preparation of tet-1 (eq.

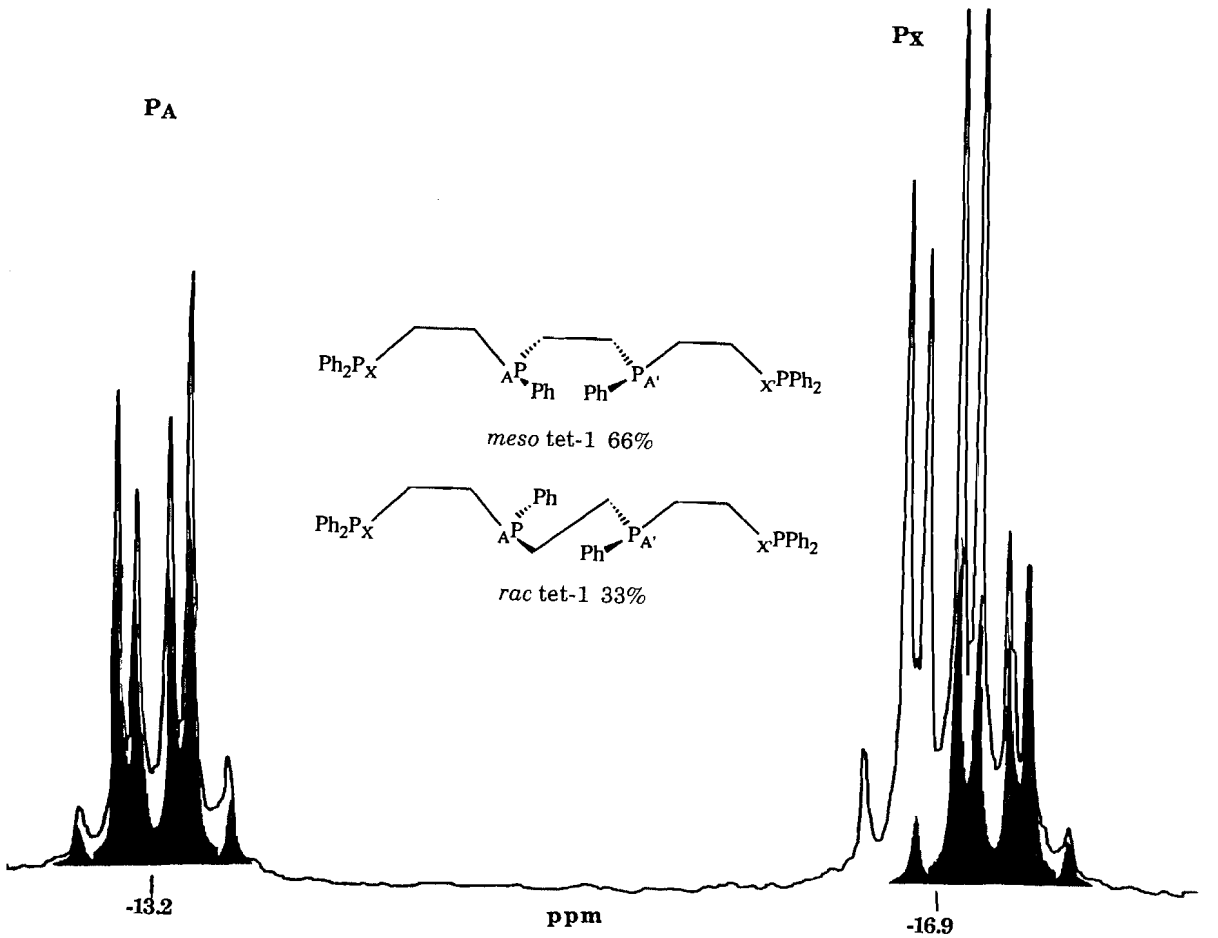

FIG. 2. $^{31}P\{^{1}H\}$ NMR spectrum of tet-1 in THF. Shaded resonances are due to the *rac* form of the ligand.

[1]) in higher yield than the published method (26). This involved the reaction of the dilithium diphosphide, Lippe·4THF, with 2 equiv. of $Ph_2CH_2CH_2Cl$ (eq. [1]) to give the tet-1 ligand as a ratio of about 70% *meso*/30% *rac* according to ^{31}P NMR.

[1] $Ph(Li)PCH_2CH_2P(Li)Ph \cdot 4THF + 2\ Ph_2CH_2CH_2Cl \rightarrow$

$Ph_2PCH_2CH_2P(Ph)CH_2CH_2P(Ph)CH_2CH_2PPh_2 + 2\ LiCl + 4\ THF$

The *rac* and *meso* forms are separated by fractional crystallization. The ^{31}P NMR spectrum of each isomer in THF is an AA'XX' pattern with the high-field XX' part displaying a slightly different chemical shift for each isomer (see Fig. 2). The X phosphorus nuclei are thought to be the terminal ^{31}P nuclei of the chain. As indicated in the introduction, this paper will describe the chemistry of the *meso*-tet-1 ligand, abbreviated L.

Synthesis of the precursor complexes

A mixture of the dichlorides *cis*-β-$OsCl_2L$ and *cis*-α-$OsCl_2$(*rac*-tet-1) (15) was prepared from $[Os_2Cl_3(PPh_2Et)_6]Cl \cdot 2H_2O$ and the commercially available *meso/rac* tet-1 mixture in the absence of solvent at 200°C (reaction [2]) by a method similar to that of Chatt and Hayter (18).

[2] $[Os_2Cl_3(PPh_2Et)_6]Cl + meso/rac\text{-tet-1} \rightarrow 1.4\ cis\text{-}\beta\text{-}OsCl_2L$

$+ 0.6\ cis\text{-}\alpha\text{-}OsCl_2(rac\text{-tet-1}) + 6\ PPh_2Et$

Under the reaction conditions employed, the phosphorus centres of the free ligand racemize to give the thermodynamic ratio of 66% *meso*, 33% *rac* (13) so that complexes containing both forms of the ligand are obtained. The osmium dichlorides are easily separated since the *rac*-tet-1 complex (33% of the mixture) is much less soluble in THF than *cis*-β-$OsCl_2L$. *cis*-β-$OsCl_2L$, as a light yellow powder, was characterized by elemental analysis, FAB MS, and ^{31}P NMR, for which the ANQY spin pattern is very distinctive (Table 1 and see below).

A mixture of isomers, *trans*-OsH(Cl)L, is produced in reaction [3], which is analogous to the one used to prepare *trans*-$OsHCl(depe)_2$ (28, 29).

[3] *cis*-β-$OsCl_2L + LiAlH_4$

$\xrightarrow[\text{2. EtOH}]{\text{1. reflux in THF}} \xrightarrow{\text{3. NaCl acetone}}$

major-*trans*-OsH(Cl)L + minor-*trans*-OsCl(H)L

The "major" isomer is the one produced in larger amount (≥70%) and sometimes exclusively. The light yellow mixture was characterized by FAB MS, IR, and ^{1}H and ^{31}P NMR (Table 2 and see below). Since the two axial sites of these *trans*-MXYL complexes are different, the two isomers differ in the placement of hydride and chloride ligands relative to the four-phenyl binding site. NMR methods establish that the com-

plexes are *trans* but do not allow the unambiguous assignment of the structure of the isomers. Crystals suitable for an X-ray study were not available. On the basis of steric repulsion arguments, it can be postulated that the major isomer has the smaller hydride ligand in the four-phenyl binding site.

We find that all three steps of reaction [3] are necessary. The reaction of lithium aluminum hydride with *cis*-dichlorobis(diphosphine)osmium(II) compounds is known to produce the corresponding dihydrido and *trans*-hydridochloro complexes (28, 30). However, addition of ethanol following the reaction often does not completely cleave aluminum species associated with the osmium centre. Treatment with sodium chloride in boiling acetone circumvents this problem (step 3 in reaction [3]) (29).

A alternative route to the major isomer of OsH(Cl)L is outlined in reaction [4].

[4] *cis*-β-$OsCl_2L$ + $NaBPh_4$ $\xrightarrow{\text{1. stir in THF, } H_2}$ $\xrightarrow{\text{2. } NEt_3}$ major-*trans*-OsH(Cl)L

In the first step, the complex $[OsH(H_2)L]BPh_4$ is generated along with HCl (see below). The second step produces $[NEt_3H]Cl$, which reacts with the dihydrogen complex to give the product, H_2, and $[NEt_3H]BPh_4$.

When *cis*-β-$OsCl_2L$ was reacted with $NaBPh_4$ and three equivalents of NaO^{t}Bu in THF under H_2, the complex *cis*-β-$Os(H)_2L$ was produced. This was characterized only by NMR (Table 1 and see below).

The starting material for the ruthenium chemistry, *trans*-$RuCl_2L$, is prepared in about 90% yield by the reaction of the pure *meso* isomer of L with the *cis*-$RuCl_2(DMSO)_4$ complex as in eq. [5].

[5] *cis*-$RuCl_2(DMSO)_4$ + L $\xrightarrow{\text{reflux in toluene}}$ *trans*-$RuCl_2L$ + *cis*-β-$RuCl_2L$

The yellow *trans* isomer has already been identified (27). A

small amount of the *cis*-β isomer is also identified in the reaction mixture by use of ^{31}P NMR (Table 1, see below).

Hydrido ruthenium complexes are prepared from the relatively inert complex *trans*-$RuCl_2L$ according to reaction [6].

[6] *trans*-$RuCl_2L$ + excess $LiAlH_4$ $\xrightarrow{\text{1. reflux in THF}}$ impure-*trans*-$Ru(H)_2L_2$ $\xrightarrow{\text{2. } Cl^-, EtOH}$ major-*trans*-RuH(Cl)L + minor-*trans*-RuCl(H)L

In the first step, the new complex *trans*-$Ru(H)_2L$ is produced along with aluminum salts that are difficult to remove; the dihydride is identified in the reaction mixture by ^{31}P NMR. An inseparable mixture of isomers of *trans*-RuH(Cl)L is produced in the second step. The minor isomer makes up about 15% of the mixture. The tan-coloured mixture was characterized by elemental analysis, FAB MS, and NMR as described below. The properties are analogous to those of the *trans*-OsH(Cl)L isomers. The mixture as a Nujol mull has a very weak hydride stretch at 1989 cm^{-1}. $^1H/^{31}P$ hetercorrelation and nOe difference NMR spectroscopy did not allow unambiguous assignment of the stereochemistry of these isomers (31). Two attempts were made at obtaining a crystal structure of needles of *trans*-RuHClL, both of which failed due to crystal degradation.

The second step of reaction [6] probably proceeds via protonation of RuH_2L by ethanol to give *trans*-$[RuH(H_2)L]^+$, which then reacts with chloride to give the RuH(Cl)L products. The reactions of alcohols with dihydrides to give dihydrogen complexes is well established (6, 32–34). The reaction of *trans*-$[RuH(H_2)L]^+$ with chloride to give *trans*-RuH(Cl)L is described below.

The pale-yellow dihydride *trans*-$Ru(H)_2L$ is prepared in 50% yield by reacting the mixture of RuH(Cl)L isomers with sodium ethoxide (eq. [7]).

[7] *trans*-RuH(Cl)L + NaOEt $\xrightarrow{\text{THF}}$ *trans*-$Ru(H)_2L$ + unidentified products

The FAB MS of the dihydride had peaks in the correct isotopic distribution for $[RuHL]^+$. The loss of dihydrogen from $[RuH(H_2)L]^+$ (see below), the product of the protonation of RuH_2L by the nitrobenzylalcohol matrix, would explain this observation. The ^1H and ^{31}P NMR spectra are fully consistent with the *trans*-dihydride formulation (Table 2 and see below). A weak absorption in the IR at 1966 cm^{-1} may be the Ru–H stretch. Attempts at making RuH_2L directly by reacting $RuCl_2L$ and NaOEt were only partially successful because some starting material remained after several days of reaction at reflux in THF.

trans-$Fe(H)_2L$ was prepared in 80% yield according to eq. [8] in a similar fashion to $FeH_2(dppe)_2$ (35).

[8] $FeCl_2$ + L + $NaBH_4$ $\xrightarrow{\text{THF/EtOH}}$ *trans*-$Fe(H)_2L$ + unidentified products

The bright yellow powder has a low-frequency H–Fe–H stretch at 1724 cm^{-1} characteristic of *trans* hydrides. The complex was also characterized by elemental analysis, FAB MS, and NMR (see Table 2). The major ion according to the mass spectrum was FeL^+; the loss of hydride ligands under these conditions is not uncommon (34).

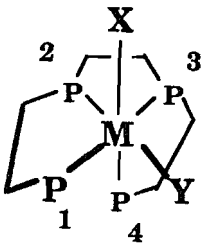

FIG. 3. Numbering scheme.

NMR spectra of the precursor complexes with a cis-β *geometry*

Table 1 lists the parameters that define the ANQY first-order spin systems of these complexes. The numbering of the nuclei are shown in Fig. 3 and follow the example of Brown and Canning (13).

The nuclei P_2 and P_3 are characterized in each case by the largest downfield shifts produced because they are part of two five-member rings (36). Nuclei P_1 and P_3 are uniquely defined by a large *trans*-$^2J_{13}$ coupling constant. This ranges from 253 Hz for *cis*-β-$Os(H)_2L$, to 327 Hz for *cis*-β-$OsCl_2L$, and to 416 Hz for the only complex of this type in the literature, *cis*-β-$[RhO_2L]^+$ (13). There is a marked similarity between the last complex and $Os(H)_2L$ in terms of chemical shifts and *cis* coupling constants. For all the complexes the following relation applies:

$$\delta P_2 > \delta P_3 > \delta P_4 > \delta P_1$$

By inspection of Fig. 3, one notes that the complex *cis*-β-$Os(H)_2L$ will have inequivalent hydrides. Indeed there are two resonances in the ^1H NMR spectrum, one at −7.7 ppm as a doublet of quartets of doublets (dqd) with coupling constants *trans*-$^2J_{PH}$ of 56, *cis*-$^2J_{PH}$ of 15, and *cis*-$^2J_{HH}$ of 4 Hz and the other at −10.21 ppm as a dqd pattern with *trans*-$^2J_{PH}$ of 64, *cis*-$^2J_{PH}$ of 15, and *cis*-$^2J_{HH}$ of 4 Hz.

NMR spectra of the precursor complexes trans-*MX(Y)L*

The $^{31}P\{^1H\}$ NMR spectra of the Ru and Os complexes are distinctive AA′QQ′ patterns with a large *trans*-$^2J_{AQ}$ coupling (Fig. 4). The *cis* couplings $^2J_{AA'}$, $^2J_{QQ'}$, and $^2J_{AQ'} = {}^2J_{A'Q}$ are not resolved at 81 MHz. The downfield resonance is always assigned to P_A, the central P atoms of the tet-1 chain, which are in two five-member rings. Table 2 lists the chemical shifts and *trans*-$^2J_{AQ}$ coupling constant. The Fe complexes have a smaller coupling *trans*-$^2J_{AQ}$, which is difficult to resolve (Fig. 5).

There is the usual trend (6) in chemical shifts for isostructural complexes MHClL, MH_2L, and $[MH(H_2)L]^+$ (see belowalso):

$$\delta(PFe) > \delta(PRu) > \delta(POs)$$

An additional trend is the downfield shift of $\delta(^{31}P)$ on substitution of chloride by hydride:

$$\delta(LRuH_2) > \delta(LRuHCl) > \delta(LRuCl_2)$$

There is a surprisingly large difference between the major and minor isomers of *trans*-MH(Cl)L, both for Ru and Os, in terms of the chemical shift of the P_A nuclei in the middle of the tet-1 chain. A simple interchange of *trans* H and Cl ligands

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

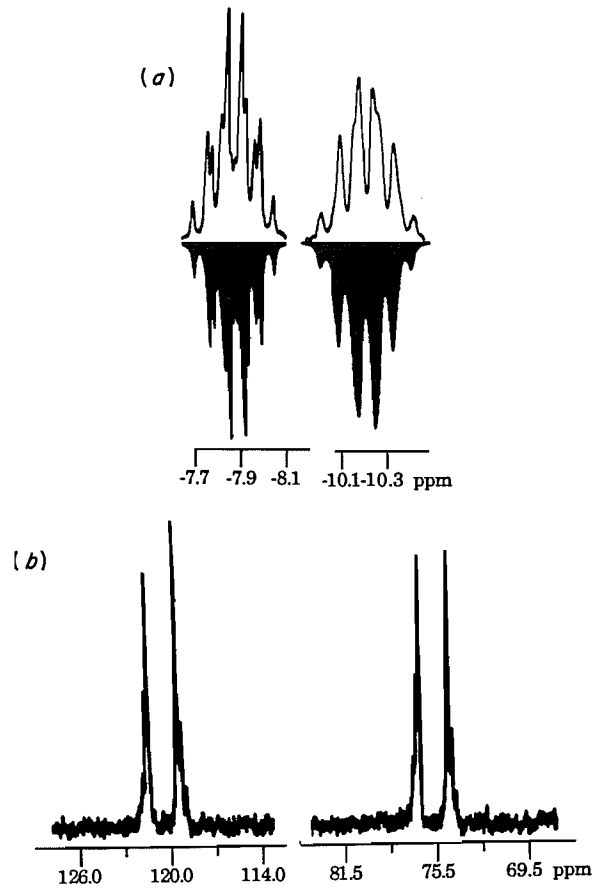

FIG. 4. (*a*) The observed ^1H NMR spectrum (200 MHz) and simulated (inverted spectrum) in the high-field region of *trans*-$Ru(H)_2L$ in C_6D_6. (*b*) The $^{31}P\{^1H\}$ NMR spectrum (120.5 MHz) of *trans*-$Ru(H)_2L$ in THF.

between the four-phenyl and two-phenyl binding sites greatly perturbs the chemical shift tensor of P_A.

In the high-field ^1H NMR spectra, resonances due to terminal hydrides in the *trans*-MH(X)L complexes should have different couplings *cis*-$^2J_{PH}$, between hydride and atoms P_A and P_Q. In most cases these constants are very similar and so pentets (or doublets of pentets for X = H) are observed.

The spectra of complexes *trans*-$M(H)_2L$ have distinct hydride resonances for the two inequivalent hydrides, one in the four-phenyl site and the other in the two-phenyl site. There is a rarely observed *trans*-$^2J_{HH}$ coupling because of this inequivalence. The magnitudes of these couplings for Ru and Fe are surprisingly small — 14 and 18 Hz, respectively — when compared to *trans*-$^2J_{PP}$ coupling constants (Table 2) and the *trans*-$^2J_{PH}$ coupling of 59.3 Hz for *trans*-$[RuH(PMe_2Ph)L]PF_6$ (see below). The other report of such a *trans*-$^2J_{HH}$ coupling is the 5.0 Hz coupling in *mer*-$IrH_3\{N(SiMe_2CH_2PPh_2)_2\}$ (37). We note that the following relationship might exist between *trans*-$^2J_{PH}$, *trans*-$^2J_{PP}$, and *trans*-$^2J_{HH}$ constants:

$$|trans\text{-}^2J_{PH}| \approx (trans\text{-}^2J_{PP})^{1/2}(trans\text{-}^2J_{HH})^{1/2}$$

For the Ru complexes of this work the absolute values are ≈60, ≈260, and 14, respectively. For Fe complexes the few values known are less than 20 Hz for each of these *trans* couplings (38–41).

If one assumes that the ring currents of the neighbouring phenyl groups diamagnetically shield the hydride, then one can assign the higher field resonance to the hydride in the four-phenyl site. On this basis the hydride with the resonance at −10.2 ppm for Ru and −14.7 for Fe is in the four-phenyl site in the complexes *trans*-$M(H)_2L$. One might also assume that the hydride in the four-phenyl site would have a shorter spin lattice relaxation time, T_1, because there are eight *ortho* protons on the phenyls near this site to relax the hydride nucleus while there are only four *ortho* protons potentially near to the other site. By this criterion the hydride with the other resonance (at −7.9 ppm for RuH_2L) is in the four-phenyl site because it has the shorter T_1, at all temperatures between 294 and 180 K, than the other hydride with δ −10.2 (see experimental section). Similarly, the downfield hydride resonance of FeH_2L also has a shorter T_1 at 293 K. Therefore these NMR arguments contradict each other and do not give an unambiguous assignment. The problem with these ideas is that the preferred orientation of the phenyl groups is not known.

These arguments do appear to be consistent when assigning the hydrides of the major and minor isomers of *trans*- RuH(Cl)L. The major isomer has the hydride with more negative chemical shift of −20.9 ppm versus −17.6 ppm for the minor isomer (Table 2). The T_1 values for the hydride of the major isomer are smaller at all temperatures between 294 and 180 K relative to those of the minor isomer (see experimental section). This assignment is also consistent with steric arguments where the major isomer will have the chloride at the two-phenyl site. Similarly, the major isomer of OsH(Cl)L has the higher field hydride resonance and probably also has the chloride at the two-phenyl site.

Preparation of the dihydrogen complexes $[MH(H_2)L]^+$

The white dihydrogen complexes *trans*-$[MH(H_2)L]^+$, M = Os, Ru, of which only one isomer is ever obtained, are made by the reaction of both isomers of *trans*-RuHClL or the pure major isomer of *trans*-OsHClL with a slight excess of $NaBPh_4$ under one atmosphere of hydrogen (eq. [9]).

[9] *trans*-MHClL + 1.5 $NaBPh_4$ + H_2 (g) → *trans*-$[MH(H_2)L]BPh_4$ + NaCl

It is therefore likely that rearrangement of the ligand framework occurs for one of the *trans*-RuHClL isomers prior to dihydrogen coordination to the vacant axial site. The complexes are unstable and difficult to precipitate. They have been characterized by ^1H and ^{31}P NMR (see below) and FAB MS. The Ru complex has a weak IR absorption at 1964 cm^{-1}, which might be assigned to the Ru—H stretch. There was no evidence for an absorption due to the H—H stretch. *trans*-$[RuH(H_2)L]BPh_4$ does not lose dihydrogen in solution or the solid state when under argon or vacuum as readily as does *trans*-$[RuH(H_2)(dppe)_2]BPh_4$ (6). A sample of *trans*-FeHClL failed to give the Fe dihydrogen complex under the conditions of reaction [9]. Similarly the five-coordinate complex [FeHL]Br (10) failed to react with 1 atm H_2 even though it reacted with N_2 to give $[FeH(N_2)L]Br$ (11).

trans-$[OsH(H_2)L]BPh_4$ is more readily prepared, in less than 24 h, directly from the dichloride precursor in THF at 293 K in the unusual reaction [10].

[10] *cis*-β-$OsCl_2L$ + $NaBPh_4$ + 2 H_2 → *trans*-$[OsH(H_2)L]BPh_4$ + NaCl + HCl

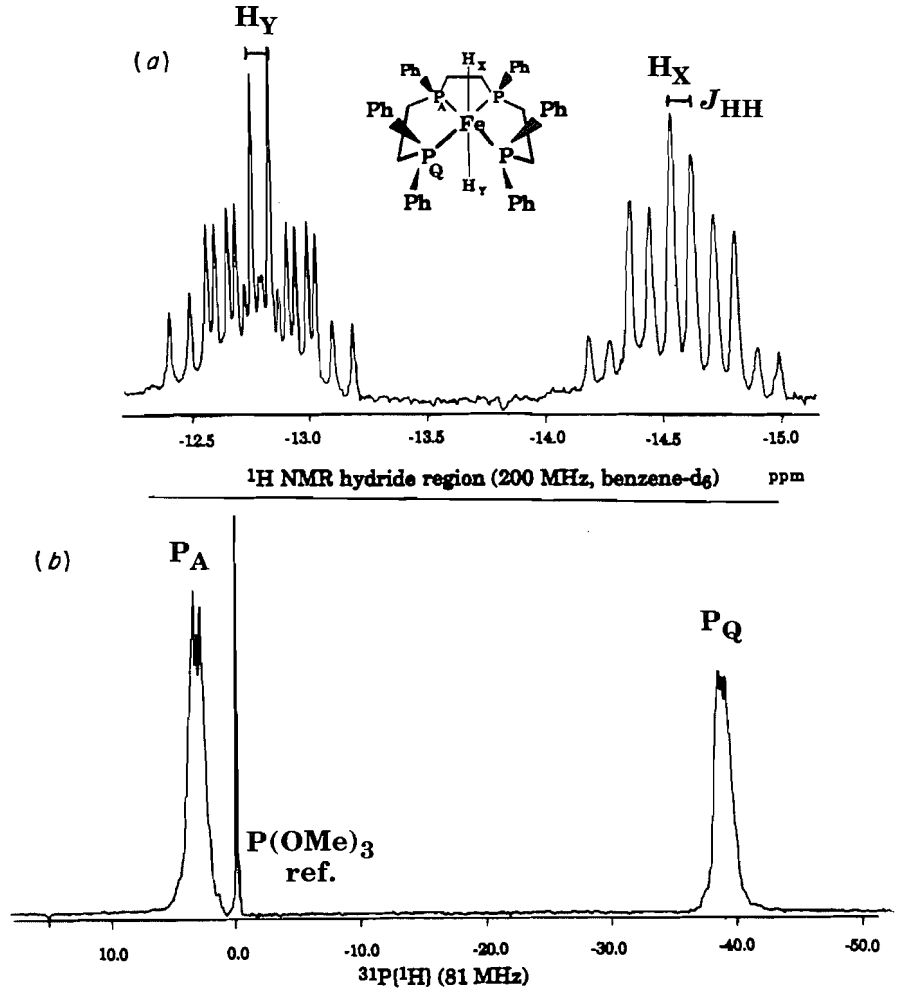

FIG. 5. The (*a*) ^{1}H NMR and (*b*) ^{31}P{^{1}H} NMR spectra of *trans*-Fe(H)$_2$L referenced to P(OMe)$_3$ (δ(P(OMe)$_3$) = 140.4 versus H_3PO_4).

The HCl was indirectly detected by ^{1}H NMR at the end of the reaction by adding NEt_3 and observing $HNEt_3^+$ and the OsH(Cl)L produced as in reaction [4]. The isomer of the dihydrogen complex is the same one as produced in reaction [9]. Reaction [10] probably proceeds via an, as yet undetected, intermediate complex $[OsCl(H_2)L]^+$, which readily loses HCl (42). The complexes *trans*$[MCl(H_2)(diphosphine)_2]^+$, M = Os, Ru, have been recently reported (31, 42, 43).[2]

Protonation of *trans*-M(H)$_2$L, M = Fe, Ru, in ether yielded H_2 complexes (reaction [11]).

[11] *trans*-M(H)$_2$L + HBF_4 → *trans*-[MH(H$_2$)L]BF_4

The Ru complex in solution produced by reaction [11] has identical properties to the one made via reaction [9]. The iron complex is an air-sensitive pale-yellow solid that was characterized by FAB MS and NMR (see below).

NMR properties of the dihydrogen complexes trans-*[MH(H$_2$)L]$^+$*

The ^{31}P NMR spectra (Table 2) of these complexes are AA′QQ′ patterns characteristic of the *trans* geometry of these complexes. The ^{1}H NMR spectra (Table 2) are all similar to that of the Fe complex shown in Fig. 6 (bottom). The dihydrogen peak is broad with a short T_1 value while the terminal hydride resonance is a sharp pentet with fortuitously equivalent *cis*-$^2J_{PH}$ coupling constants and with a long T_1 value (Table 3). The lack of a resolved *cis*-$^2J_{PH}$ coupling in the H_2 resonance is a common feature of dihydrogen complexes (6).

The sharp pentet resonance of the terminal hydride of the Fe and Os complexes contrasts with the broad resonances observed for the corresponding complexes $[MH(H_2)(dppe)_2]^+$ (see, for example, Fig. 6). The dppe complexes are fluxional because of H-atom exchange between the H and H_2 ligands and this causes line broadening at room temperature. This is clearly prevented in the tet-1 complexes because there is no line broadening or averaging of T_1 values of the H and H_2 ligands. The seven-coordinate trihydride complex $Re(H)_3L$ has rapid intramolecular H-atom exchange (44). Therefore the role of the tet-1 ligand in the cationic dihydrogen complexes is to favor six-coordination over seven-coordination.

Variable temperature measurements of the T_1 values of the hydrogen ligands (Table 3) were used to positively identify the presence of an H—H bond in these new dihydrogen complexes. Calculated curves were fitted to the observed T_1 values for the dihydrogen and hydride ligands to obtain an accurate minimum T_1 time, T_1(min), and a dihydrogen bond length, d_{HH}, with the assumption of rapid H_2 spinning as described previously (45). This assumption is valid because the deuterated isotopomers of these complexes have large J(H, D) couplings (see below). The

[a]See Table 4 for parameters used in calculating T_1 values.
[b]In CD_2Cl_2 at 400 MHz.

minimum T_1 and temperature data obtained are listed in Table 4. As anticipated, the observed T_1 values for hydrides are much higher than those for dihydrogen ligands. The T_1 value for the terminal hydride on osmium seems anomalously short; we have no explanation for this. Intramolecular exchange cannot explain this result because there is no temperature where the (H_2) and hydride T_1 values are completely averaged (fast exchange) or where they are near to those of the Fe and Ru complexes (the possible no exchange situation).

A correction of d_{HH} to account for relaxation of the H_2 nuclei by neighboring phenyl protons yields d_{HH}(corr.); this was done by subtracting the relaxation rate of the terminal hydride from the relaxation rate of the dihydrogen ligand by use of eq. [4] of ref. 6. The d_{HH}(corr.) distances are similar for the Fe and Ru complexes (0.88, 0.89 Å, respectively) while the Os complex has a somewhat elongated H—H bond (0.99 Å). These values are typical of dihydrogen complexes of the type *trans*-$[MH(H_2)(diphosphine)_2]^+$ (6, 34). For example, the corresponding distances for the series $[MH(H_2)(dppe)_2]^+$ are 0.87 for Fe, 0.90 for Ru, and 1.02 Å for Os.

$[OsD(HD)L]^+$	−6.28	26.4 ± 0.4	293	400

[a]*trans*-$^2J_{HH}$ of 4.5 Hz also resolved.

A number of NMR experiments were conducted to try to determine which axial site was occupied by the dihydrogen ligand of *trans*-$[RuH(H_2)L]^+$. An NOEDIFF experiment in which the terminal hydride was saturated resulted in an enhancement of a multiplet centred near 6.86 ppm corresponding probably to an *ortho* proton on a phenyl. Unfortunately a 2D ^{1}H–^{31}P COSY experiment and a selective phosphorus decoupling experiment failed to indicate to which phosphorus this phenyl group was attached.

NMR properties of isotopomers of the dihydrogen complexes $[MH(H_2)L]^+$

The osmium dihydrogen complex, when dissolved in acetone-d_6, slowly exchanges its hydrogen ligands for deuterium by an, as yet, unexplained mechanism. The reaction is observed by means of ^{1}H NMR where resonances ascribed to the following isotopomers grow and then diminish with the extent of reaction: $[OsH(HD)L]^+$ and $[OsD(H_2)L]^+$, then $[OsD(HD)L]^+$ and $[OsH(D_2)L]^+$. The complexes containing the HD ligand give spectra with 1:1:1 triplets with $^1J_{HD}$ coupling constants of 26.4 Hz, characteristic of an intact H—D bond (Table 5).

Isotopomers of the ruthenium complex were prepared by reaction of *trans*-$[RuH(H_2)L]^+$ with 1 atm D_2 in CD_2Cl_2. The $^1J_{HD}$ values were confirmed at 400 MHz by using an inversion–recovery pulse sequence (Fig. 7) to null the H_2 signals (from $Ru(H_2)X$, X = H, D) as they have a shorter T_1 time than the HD signals. Figure 7 shows three 1:1:1 triplets with $^1J_{HD}$ values of 33.5 ± 0.4 Hz. If only one isomer of *trans*-$[Ru(H_2)(H)L]^+$ exists, then one would expect two 1:1:1 triplets (due to the (HD)(H) and (HD)(D) isotopomers) and not three. The observed spectrum is explained as: the low-field 1:1:1 triplet (labelled as *) is due to the (HD)(D) isotopomer and the other two triplets (labelled as ◆ and ◇) are due to the (HD)(H) isotopomer, which has additional coupling between (*H*D)(*H*) ($^2J_{HH}$ = 4.5 Hz). The (HD)(H) isotopomer also has additional couplings in the HD resonance probably due to $^2J_{HP}$. The terminal hydride signal at −12.7 ppm appears as a broad pentet.

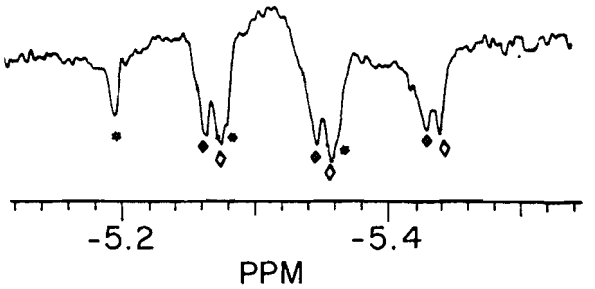

FIG. 7. ^{1}H NMR (400 MHz) of *trans*-$[Ru(H_2)(H)L]BPh_4$ isosopomers in CD_2Cl_2 at −5.3 ppm with H_2 signals nulled by the inversion–recovery method. The three 1:1:1 triplets are labelled as *, ◆, and ◇.

The complex $[FeH(HD)L]BF_4$ precipitated from ether when $Fe(H)_2L$ was reacted with an HBF_4–D_2O mixture. A ^{1}H NMR spectrum of this sample dissolved in CD_2Cl_2 has a 1:1:1 triplet with $^1J_{HD}$ = 32 Hz at −9.8 ppm corresponding to the HD ligand.

The formation of all possible isotopomers in the reactions of the Ru and Os dihydrogen complexes suggests that there may be very slow intramolecular exchange to equilibrate isotopomers $[MH(HD)L]^+$ with $[MD(H_2)L]^+$ and $[MD(HD)L]^+$ with $[MH(D_2)L]^+$. This equilibration might also proceed via intermolecular H^+/D^+ transfer reactions.

Comparison to the complexes $[MH(H_2)(dppe)_2]^+$

Table 6 summarizes some physical properties of the tetraphos complexes and related dppe complexes. The H—H bond lengths of the H_2 ligand determined from T_1(min) data decrease as Os > Ru ≈ Fe for both sets of complexes. The $^1J_{HD}$ couplings, however, suggest that the H—H bond order in the iron compounds is lower than in the ruthenium complexes. This contradiction has not yet been resolved. The possible reason for the elongation of the H—H bond in the osmium complexes has been discussed (5).

The slight H—H shortening of the tetraphos complexes relative to the dppe ones is probably because they are constrained to a less distorted octahedral geometry than the dppe complexes. In an extreme reversal of this effect, the large PPh_3 ligands in the trihydride complex $[Os(H)_3(PPh_3)_4]^+$ prevent the attainment of an octahedral geometry and therefore the formation of a dihydrogen ligand (46). The shortening cannot be attributed to a decrease in backbonding to the H_2 caused by lower energy *d* electrons in the tetraphos complexes because, in every case examined, the tetraphos complex is more reducing than the corresponding dppe complex (Table 6). The irreversible oxidation of *trans*-$[FeH(H_2)L]^+$ occurs at a more negative potential than that of the *trans*-$[FeH(H_2)(dppe)_2]^+$ complex. All of the

MH(Cl)L electrochemical potentials are more negative than corresponding dppe complexes. Even the ν(CO) of *trans*-$[OsH(CO)L]^+$ is lower than that of *trans*-$[OsH(CO)(dppe)_2]^+$.

Reactions that probe the stereochemistry of the complexes

When *trans*-$[RuH(H_2)L]BPh_4$ was reacted with an excess of LiCl, major-*trans*-RuHClL was exclusively formed, implying that the Cl^- ligand in this isomer occupies the same axial site as the H_2 ligand in *trans*-$[RuH(H_2)L]BPh_4$:

[12] *trans*-$[MH(H_2)L]^+ + Cl^- \rightarrow$ major-*trans*-MH(Cl)L

Similarly reaction [4] implies that the osmium dihydrogen complex also reacts stereoselectively with chloride to give the major isomer as indicated in reaction [12].

The coordinated dihydrogen in *trans*-$[OsH(H_2)L]^+$ when dissolved in THF is readily displaced by carbon monoxide or excess acetonitrile at reflux conditions or, allowing for longer reaction times, at room temperature.

[13] *trans*-$[OsH(H_2)L]BPh_4 + L' \rightarrow$ *trans*-$[OsH(L')L]BPh_4 + H_2$

(L′ = CO, $NCCH_3$)

Infrared (ν_{CO} = 1989; ν_{CN} = 2258 cm^{-1}), ^1H NMR (high-field pentet), and ^{31}P NMR (AA′QQ′, see Table 2) data advise an octahedral geometry for the products with L′ *trans* to the terminal hydride. For both products only one isomer is isolated, suggesting a stereoselective reaction where L′ assumes only one axial site, presumably that formerly occupied by the H_2 ligand.

The Cl^- ligand in *trans*-RuHClL is substituted for a CH_3CN or PMe_2Ph ligand in the presence of $NaBF_4$ or $NaPF_6$ in THF solvent (reaction [14]).

[14] *trans*-RuH(Cl)L + L′ + NaY → *trans*-[RuH(L′)L]Y + NaCl

(L′ = $NCCH_3$, PMe_2Ph, Y = BF_4 or PF_6)

The mixture of isomers of RuH(Cl)L produce the new pale-yellow complexes *trans*-[Ru(H)(L′)L]Y as only one isomer. As in the case of the preparation of *trans*-$[RuH(H_2)L]BPh_4$ (reaction [9]), this implies that some rearrangement of the ligand framework has occurred in one of the *trans*-RuHClL isomers prior to coordination of incoming ligand. It is very likely that the large PMe_2Ph ligand occupies the 2-phenyl binding site.

The high-field region of the ^1H NMR spectra of *trans*-$[Ru(H)(CH_3CN)L]^+$ consists of a pentet, again confirming the *trans* geometry. For *trans*-$[Ru(H)(PMe_2Ph)L]PF_6$, the hydride region in the ^1H NMR contains a doublet of pentets. The ^{31}P NMR resonances are also consistent with the *trans* geometry.

Conclusions

High-yielding routes to starting materials containing the ligand *meso*-tetraphos-1 have been developed. The topology of the ligand is either *cis*-β in the complexes $OsCl_2L$, $Os(H)_2L$, and $RuCl_2L$ or *trans* in the complexes $RuCl_2L$, MH(Cl)L, M = Os, Ru, and $M(H)_2L$, M = Ru, Fe. The *trans* complexes have axial binding sites with different steric requirements; the favored isomer is thought to be the one with the hydride in the four-phenyl binding site and the other larger ligand (e.g., Cl^-) in the two-phenyl site. The different sites make the *trans* hydrides in the complexes $M(H)_2L$ inequivalent and allow the observation of the coupling constant *trans*-$^2J_{HH}$ in the ^1H NMR spectrum.

Scheme 1 outlines the interconversions of the complexes and summarizes their relative stereochemistries with respect to the inequivalent axial sites. Until a single crystal X-ray diffraction study of one of the complexes in the chain is done, the assignments must be regarded as tentative. Scheme 1 starts with the dihydride complexes *trans*-$M(H)_2L$, which are prepared from the dichlorides $M(Cl)_2L$. The dihydrides *trans*-$M(H)_2L$ are isolated as pure solids or are observed as intermediates between the dichlorides and the hydridochloro complexes MH(Cl)L before treatment with EtOH in the presence of aluminum salts and then NaCl–acetone. The new dihydrogen complexes *trans*-$[MH(H_2)L]^+$ are prepared by one of two methods: (1) chloride abstraction from *cis*-β-MCl_2L or MH(Cl)L in the presence of hydrogen gas or (2) protonation of *trans*-$M(H)_2L$. Only one isomer of the dihydrogen complexes is obtained, probably the one with H_2 ligand in the two-phenyl site, and this is independent of the synthetic route. However, we speculate that if *trans*-$[FeH(H_2)L]Br$ could be prepared from [FeHL]Br in a similar fashion to *trans*-$[FeH(N_2)L]Br$ (11), which has the N_2 ligand in the four-phenyl site, then a different isomer should be produced than the one prepared by protonation of $Fe(H)_2L$. Only one isomer, major-*trans*-MH(Cl)L, is observed when the dihydrogen complexes are substituted with Cl^- (Scheme 1). Both isomers of *trans*-MHClL appear to be completely converted to the compounds *trans*-$[MH(L')L]^+$, L′ = H_2,

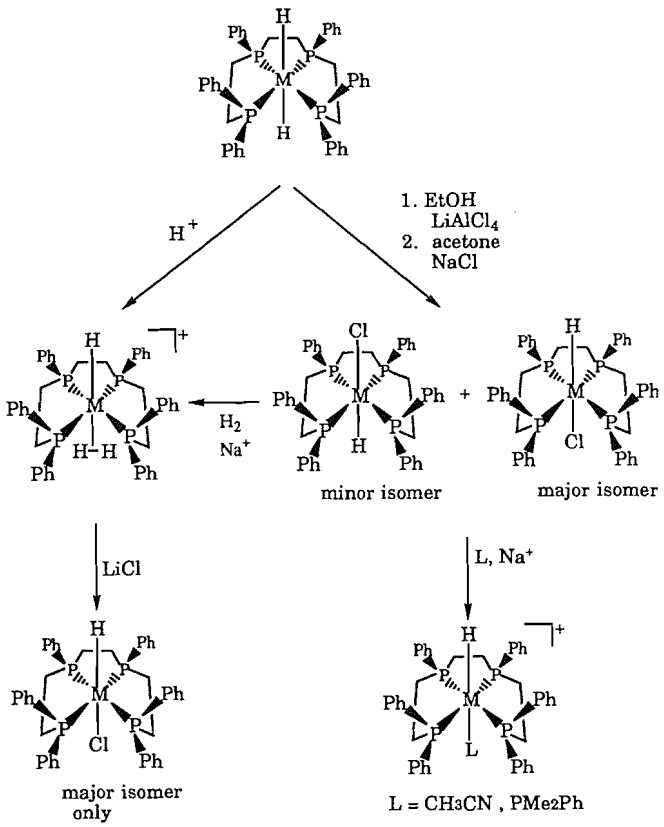
For personal use only.



SCHEME 1

CH_3CN, PMe_2Ph, of which only one isomer is obtained. The mechanism that allows the conversion of both isomers into one product is not yet known. For steric reasons, it is argued that the L′ ligand occupies the less sterically crowded two-phenyl site.

The dihydrogen ligand is thought to be rapidly spinning in the complexes *trans*-$[MH(H_2)L]^+$. The Fe and Ru complexes have similar bond lengths (0.88, 0.89 Å, respectively) while the Os complex has a somewhat elongated H—H bond of 0.99 Å. These dimensions are very similar to those of the complexes *trans*-$[MH(H_2)(dppe)_2]^+$. The complexes *trans*-$[MH(H_2)L]^+$ hold the dihydrogen and hydride ligands rigidly *trans* to each other. Unlike the complexes *trans*-$[MH(H_2)(dppe)_2]^+$ (M = Fe, Os) which exhibit rapid intramolecular exchange of H atoms between the hydride and H_2 sites at room temperature, the *meso*-tet-1 complexes do not. This tetraphos ligand is thought to disfavour the formation of the seven-coordinate trihydride $[M(H)_3L]^+$, which is responsible for the H-atom exchange. The seven-coordinate complex $Re(H)_3L$ does undergo rapid intramolecular H-atom exchange (44).

An *ab initio* study of the structures, barriers for internal rotation, vibrational frequencies, and thermodynamic functions of the hydrochlorofluorocarbon CH_3CF_2Cl and the corresponding radical CH_2CF_2Cl

S.J. Paddison, Yonghua Chen, and E. Tschuikow-Roux[1]

Department of Chemistry, University of Calgary, Calgary, AB T2N 1N4, Canada

Received June 24, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

S.J. Paddison, Yonghua Chen, and E. Tschuikow-Roux. Can. J. Chem. **72**, 561 (1994).

Ab initio molecular orbital calculations were performed using the GAUSSIAN 90 system of programs at the HF/6-31G* level of theory, on the hydrochlorofluorocarbon (HCFC) 1-chloro-1,1-difluoroethane and the 1-chloro-1,1-difluoroethyl radical. Equilibrium geometries, barriers for internal rotation, and harmonic vibrational frequencies were thus calculated. A single conformational minimum in the potential energy surface was located for both the radical and the parent molecule. The radical center in CH_2CF_2Cl was found to be nonplanar. Transition structures for internal rotation about the C—C bond were located for both the molecule and the radical using analytical methods. The rotation barriers, evaluated at the fourth-order Møller–Plesset perturbation theory ((U)MP4/6-311G**/6-31G*), were calculated after inclusion of zero-point vibrational energy differences to be 1.11 and 4.12 kcal/mol for the radical and the parent molecule, respectively. Computed thermodynamic properties including heat capacity, entropy, enthalpy, and free energy functions are reported as a function of temperature. Using an experimentally measured heat of formation of CH_3CF_2Cl at 298 K, the heat of formation of CH_2CF_2Cl was calculated to be -74.3 ± 1.7 kcal/mol. Tabulations of $\Delta H^0_{f,T}$, $\Delta G^0_{f,T}$, and $\log_{10} K_{f,T}$ over the temperature range of 0–1500 K are also reported for both species.

S.J. Paddison, Yonghua Chen et E. Tschuikow-Roux. Can. J. Chem. **72**, 561 (1994).

Utilisant des programmes du système GAUSSIAN 90 au niveau HF/6-31G* de la théorie, on a effectué des calculs *ab initio* d'orbitales moléculaires sur l'hydrocarbure fluoré et chloré (HCFC), 1-chloro-1,1-difluoroéthane, et sur le radical 1-chloro-1,1-difluoroéthyle. On a ainsi calculé les géométries à équilibre, les barrières à la rotation interne et les fréquences vibrationnelles harmoniques. Tant pour le radical que pour la structure fondamentale, on n'a localisé qu'une seule surface d'énergie potentielle. On a trouvé que, pour le CH_2CF_2Cl, le centre radicalaire n'est pas plan. Faisant appel à des méthodes analytiques, on a localisé les structures de transition pour la rotation interne autour de la liaison C—C tant de la molécule que du radical. On a évalué les barrières à la rotation par la théorie perturbationnelle de Møller–Plesset du quatrième ordre ((U)MP4/6-311G**/6-31G*) après inclusion des différences d'énergie vibrationnelle au point zéro et on a trouvé qu'elles sont respectivement de 1,11 et de 4,12 kcal/mol pour le radical et pour la structure fondamentale. On rapporte les propriétés thermodynamiques calculées, y compris la capacité calorifique, l'entropie, l'enthalpie et les fonctions d'énergie libre, en fonction de la température. Utilisant une valeur expérimentale pour la chaleur de formation du CH_3CF_2Cl, à 298 K, on a calculé que la chaleur de formation du CH_2CF_2Cl est égale à $-74,3 \pm 1,7$ kcal/mol. Pour chacune des deux espèces, on rapporte aussi des tableaux des valeurs des $\Delta H^0_{f,T}$, $\Delta G^0_{f,T}$ et du $\log_{10} K_{f,T}$ pour les températures allant de 0 à 1500 K.

[Traduit par la rédaction]

Introduction

Because of the influence of the fully halogenated chlorofluorocarbons (CFC's) on the equilibrium concentration of stratospheric ozone (1), and the fact that the presence of these CFC's in the stratosphere has largely been the result of their use as aerosol propellants and in the refrigeration and air conditioning industry, investigations continue to be made into determining environmentally acceptable substitutes. One such acceptable and promising refrigerant is the hydrochlorofluorocarbon, 1-chloro-1,1-difluoroethane (CH_3CF_2Cl) (2), commonly referred to in industry as HCFC-142b or simply R142b. Evaluation of the performance of a potential refrigerant requires knowledge and understanding of its thermophysical and thermodynamic properties. It has therefore been the purpose, in part, of this study to further the existing knowledge of the fundamental thermodynamic properties of CH_3CF_2Cl.

1-Chloro-1,1-difluoroethane is a promising alternate to the ozone-depleting CFC's because it offers the capability of hydrogen abstraction by tropospheric hydroxyl radicals, thus effectively limiting the amount of bound chlorine that reaches the stratosphere (3). This reaction is represented by the chemical equation:

$$CH_3CF_2Cl + OH \rightarrow CH_2CF_2Cl + H_2O$$

The resulting radical (CH_2CF_2Cl) is then converted into compounds that are less harmful with respect to atmospheric ozone depletion. Therefore, an understanding of this upper atmosphere chemistry requires knowledge of both kinetic and thermochemical data of the conjugate chloro-fluoro ethyl radical.

In this paper we report *ab initio* calculations on the CH_2CF_2Cl radical and the parent molecule, CH_3CF_2Cl. Equilibrium geometries and rotational transition structures were fully optimized at the Hartree–Fock level with the 6-31G* basis set. Fourth-order Møller–Plesset perturbation theory was then used to estimate electron correlation. These total energies were combined with the calculated harmonic vibrational frequencies and moments of inertia to facilitate a tabulation of standard thermodynamic functions: enthalpy, free energy, entropy, and heat capacity as a function of temperature for both the molecule and the radical. The calculated harmonic vibrational spectra and rotational barriers for CH_3CF_2Cl are compared with the corresponding experimentally determined data. Very recently, the vibrational frequencies for the equilibrium structure of CH_3CF_2Cl were calculated by *ab initio* methods: the GAUSSIAN 82 suite of programs being utilized with both the 3-21G** and 6-31G** basis sets (4). However, no *ab initio* calculations have been reported for the transition structure of the molecule.

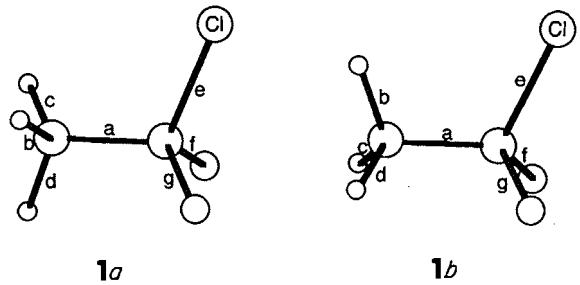

FIG. 1. Definition of the RHF/6-31G* optimized structural parameters for CH_3CF_2Cl (refer to Table 1): equilibrium geometry, **1***a*; transition structure, **1***b*.

From a homodesmic reaction involving the ethyl radical and a calorimetrically measured heat of formation of CH_3CF_2Cl (5), the heat of formation of the CH_2CF_2Cl radical has been evaluated. No experimental or theoretical studies have been reported in the literature for CH_2CF_2Cl and therefore this paper presents structural, spectroscopic, and thermodynamic information that has been heretofore unavailable.

Method

The GAUSSIAN 90 system of programs (6) was implemented for all calculations. The internal 6-31G* basis set (7) along with analytical gradients was used to completely optimize the geometry of the molecule CH_3CF_2Cl at the restricted Hartree–Fock (RHF) level of theory, and the geometry of the radical CH_2CF_2Cl at the unrestricted Hartree–Fock (UHF) level of theory. The minimum energy structures for both species were located using the Schlegel algorithm for gradient minimization (8). Minor spin contamination is suggested in the optimization of the geometry for the radical with the expectation value of $\hat{S}^2$ being approximately 0.76. Electron correlation changes on the relative energies of the stationary points were estimated by single-point calculations at the MP4/6-311G**//HF/6-31G* level (9, 10). Zero-point vibrational energy (ZPVE) corrections were obtained by way of a harmonic frequency analysis using analytical second derivatives at the HF/6-31G*//6-31G* level. The harmonic frequency analysis also provided the frequencies for the derivation of thermodynamic functions and, with calculated intensities, a prediction of the IR spectra. For each purpose, the harmonic frequencies were uniformly scaled by a factor of 0.9 to compensate for systematic overestimation of the values at the HF-SCF level (11). Rather than including the frequency of the "harmonic" torsional mode in ZPVE corrections to rotational barriers and thermodynamic calculations, the mode was treated as a hindered rotation (12).

Results and discussion

1. Geometries of equilibrium and transition structures

1-Chloro-1,1-difluoroethane, CH_3CF_2Cl (1)

Geometry optimization on the RHF/6-31G* potential energy surface for the CH_3CF_2Cl molecule confirms the expected single equilibrium conformation, **1***a*, and single transition structure, **1***b*, both of C_s symmetry. Figure 1 diagrams the two structures with definition of the parameters. The computed numerical values for these structural parameters and the total energies for the geometries are tabulated in Tables 1 and 2, respectively. Examination of the calculated bond distances and bond angles reveals an equilibrium structure that is intuitively expected and reasonable: the sp^3 hybridization of the methyl group is practically preserved and its position is staggered relative to the CF_2Cl group so as to minimize steric effects.

The calculated geometry for the equilibrium conformation is in quite good agreement with the microwave spectroscopic analysis of Graner and Thomas (13) (Table 1). The only significant difference is in the carbon–chlorine bond distance. Graner and Thomas assigned a value of 1.736 Å, based on a graphical correlation of C—C and C—F bond distances with C—Cl bond distances observed in chlorofluoromethanes, which is 0.039 Å shorter than the present value. It may be noted here that the structural parameters calculated at the higher MP2/6-31G* level of theory differ very little from the HF/6-31G* geometry as shown in an earlier study (14).

[d]Assumed.

The only *ab initio* MO calculation on CH_3CF_2Cl reported in the literature is the very recent work of Sakka et al. (4). Not surprisingly, their calculations using the 6-31G** basis set generated an equilibrium structure that is virtually identical to ours. They did not report any calculations for the transition structure.

The transition structure is also an anticipated structure with the two groups eclipsed relative to one another. Comparison with the equilibrium structure indicates that this higher energy structure is both elongated and flattened: the C—C, C—Cl, and C—F bond distances are all slightly longer and the carbon–carbon–chlorine bond angle is slightly larger (Table 1). This alteration in structure is obviously the result of steric repulsion between the halogen atoms and the hydrogen atoms.

Rotation about the C—C bond in the CH_3CF_2Cl molecule is hindered by the transition structure, **1***b* (Fig. 1). With the zero-point vibrational energy difference Δ(ZPVE) included, conformation **1***b* is higher in energy than **1***a* by 3.94 and 4.12 kcal/mol at the RHF/6-31G* and MP4/6-311G**//6-31G* levels, respectively. Comparison with the experimentally determined rota-

tional barriers of ethane (2.96 kcal/mol (15)), 1,1difluoroethane (3.215 kcal/mol (16)), and chloroethane (3.691 kcal/mol (17)) substantiates the observed increase in rotational barrier with halogen substitution. The experimentally determined values from far-infrared and microwave studies range from 3.7 (16) to 4.40 ± 0.10 (13) kcal/mol and thus the calculated values fall well within this range.

1-Chloro-1,1-difluoroethyl radical, CH_2CF_2Cl (2)

The CH_2CF_2Cl radical possesses C_s symmetry and exists as one equilibrium conformation, **2***a*, and one transition structure, **2***b*. Both structures are shown in Fig. 2. Structural parameters are listed in Table 3 and the total energies are given in Table 2. Conformation **2***a* has a nonplanar radical center, with an out-of-plane angle γ = 15.6° (γ is defined by the C—C axis and the plane formed by the radical site group). The pyramidalization of the radical center in CH_2CF_2Cl is very similar to that in CH_2CH_2Cl (γ = 15.0° (14)) and fairly similar to that in CH_2CF_2H (γ ≈ 12.8° (19)). The equilibrium conformations of CH_2CF_2Cl and CH_2CH_2Cl are nearly identical, with the pertinent feature being that the C—Cl bond is eclipsed with the singly occupied molecular orbital (SOMO) at the radical site. However, the CH_2CF_2H radical has two conformations, one in which the β hydrogen nearly eclipses with the SOMO and the other in which one of the fluorine atoms is in the plane of the SOMO. The strong geometrical preference observed in both the CH_2CF_2Cl and CH_2CH_2Cl radicals is a result of the strong two-center one-electron hyperconjugative interaction between

the SOMO and the σ^*_{CCl} antibonding orbital (20). Comparison of the equilibrium structures reveals that the C—Cl bond distance in the CH_2CF_2Cl radicals is 0.039 Å shorter than in the CH_2CH_2Cl radical, and that the C—F bond distance in CH_2CF_2Cl is approximately 0.02 Å shorter than in CH_2CF_2H. The shortening of these bonds is anticipated as a result of both electrostatic effects and negative hyperconjugation that accompanies halogen substitution at the β carbon atom (21).

The transition structure, **2***b*, hinders rotation about the C—C bond. Conformation **2***b* actually corresponds to both the rotation of the CF_2Cl group and the inversion of the CH_2 radical center, and thus may be referred to as a rotation/inversion transition structure. As recorded in Table 2, the transition structure

has a rotational barrier of 0.95 and 1.11 kcal/mol at the UHF/6-31G* and UMP4/6-311G** levels, respectively, which are approximately 0.4 kcal/mol lower than similarly calculated values for CH_2CH_2Cl (1.58 kcal/mol (14)) and approximately 1 kcal/mol higher than in CH_2CF_2H (0.02 kcal/mol (19)). In comparison with the CH_2CF_2H radical, the substantial increase in the rotational barrier of β-chlorine-substituted ethyl radicals (CH_2CH_2Cl, CH_2CF_2Cl) is mainly due to the fact that the transition structures of the chlorinated ethyl radicals are energetically not favored as a result of loss of strong negative hyperconjugation between the SOMO and the σ^*_{CCl} orbital, although there is a weak compensating hyperconjugation between π_{CH2} and σ^*_{CCl} (14). In CH_2CF_2H, the hyperconjugation between the SOMO and σ^*_{CF} orbital in the equilibrium geometry is relatively weak and comparable to the hyperconjugation between the π_{CH2} and σ^*_{CF} orbitals in the transition structure. The observation of a slightly lower rotational barrier in the CH_2CF_2Cl radical as compared to the CH_2CH_2Cl radical may be attributed to the slightly weak interaction between the SOMO and the σ^*_{CF} in the transition structure of CH_2CF_2Cl, which stabilizes the transition structure and thus reduces the rotational barrier of the CH_2CF_2Cl radical.

2. Vibrational frequencies, moments of inertia, and thermodynamic properties

The infrared (IR) and Raman spectra of 1-chloro-1,1-difluoroethane was first experimentally measured by Nielsen and co-workers (18). Far-infrared studies were later conducted by Sage (22) and Brown et al. (23). Durig et al. (24) measured the complete spectra of the molecule in both the solid and gas states and were able to complete and refine the normal mode assignments of earlier work. Their assignments are adopted for purposes of comparison and thermodynamic calculations, and are listed in Table 4. Sakka et al. (4) calculated the harmonic frequencies for the equilibrium conformation of CH_3CF_2Cl (**1***a* in our notation) at the 3-21G, 3-21G**, and 6-13G** levels of theory and then scaled the force field using a method originally developed by Shimanouchi (25) and later revised by Hirakawa and Hamada (26). Sakka et al. obtained good agreement with the experimentally measured frequencies. In the present paper we have carried out frequency calculations for both the equilibrium conformation (**1***a*) and the transition structure (**1***b*) at the UHF/6-31G*//6-31G* level of theory. The results, scaled by 0.9 (11), together with computed IR intensities for the equilibrium structure are listed in Table 4. Assignments based on inspection of animations of the normal modes of the equilibrium conformation are also provided. Comparison of our scaled frequencies with the experimentally measured spectra (24) is quite satisfactory. Also listed in Table 4 are the calculated moments of inertia, which are in good agreement with the microwave study of Graner and Thomas (13).

No experimental IR and Raman spectroscopic data for the 1-chloro-1,1-difluoroethyl radical are available in the literature. Table 5 lists the results of the frequency calculations for the

equilibrium and transition structures of the radical (**2***a* and **2***b*, respectively) performed at a similar level of theory as the parent molecule. However, unlike the parent molecule, the assignments of the normal modes of the radical were somewhat more difficult because many of the local modes are coupled. The most intense vibrational modes are seen in the C—C, C—F, and C—Cl bond stretches. These normal modes along with the CH_2 rock are the modes likely to be identified when the experimental IR spectra is measured.

The transition structures, **1***b* and **2***b*, each possess a single imaginary frequency (239i and 165i cm^{-1}, respectively) corresponding to the torsional mode.

Ideal gas thermodynamic functions C_p^0, S^0, $H^0 - H_0^0$, and $-(G^0 - H_0^0)/T$ in the temperature range 0–1500 K and 1 atm of pressure (101.3 kPa) were calculated by standard methods of statistical thermodynamics based on the rigid rotor — harmonic oscillator model. The results are listed in Tables 6 and 7. The reduced moments of inertia, I_r, for internal rotation of unsymmetrical groups were calculated on the basis of the formulation of Pitzer (27), using a Fortran computer program as employed by us previously (19, 28, 29).

With exception of the torsional modes, experimentally observed frequencies were used in the statistical thermodynamic calculations for CH_3CF_2Cl, and computed vibrational frequencies of the equilibrium conformation (scaled × 0.9 (11)) were used for CH_2CF_2Cl. To further assess the effect of residual frequency differences between observed and computed frequencies on thermodynamic properties of CH_3CF_2Cl, the heat capacity and entropy were also calculated based on computed (×0.9) frequencies for structure **1***a* (Table 6). The contributions of the torsional mode to the thermodynamic properties of both the parent molecule and the radical were calculated as a simple hindered rotation (12) based on (U)MP4/6-311G**//6-31G* evaluated barriers.

The calculation of the temperature dependence of $\Delta H^0_{f,T}$, $\Delta G^0_{f,T}$, and $K_{f,T}$ for either species requires knowledge of their enthalpy of formation at a reference temperature. Papina and Kolesov (5) determined the heat of formation of the parent molecule, CH_3CF_2Cl, to be -126.6 ± 1.2 kcal/mol at 298.15 K from a measurement of the enthalpy of combustion of gaseous CH_3CF_2Cl in a rotating bomb calorimeter. However, the literature does not contain any experimentally measured or theoretically estimated heat of formation of the radical CH_2CF_2Cl.

In previous publications (19, 28–30) we demonstrated the calculation and the reliability of "theoretical" radical heats of formation by coupling *ab initio* calculated energy changes for homodesmic reactions with the known heats of formation of other reaction components. For the purpose of determining the heat of formation of the CH_2CF_2Cl radical, the following homodesmic reaction was chosen:

$$CH_3CF_2Cl + CH_3CH_2 \rightarrow CH_2CF_2Cl + CH_3CH_3$$

The criteria for the choice of components in atom transfer reactions have been discussed previously (19, 29). It suffices to note here that the number of each type of bond must be conserved, and, furthermore, it is desirable to have maximum similarity in hybridization at the radical center (as measured by the out-of-plane angle, γ) between reactant and product radicals. This ensures that errors due to basis set and partial neglect of electron correlation will nearly cancel. We chose the CH_3CH_2 radical as the hydrogen-abstracting radical in the above homodesmic reaction because CH_3CH_2 has a similar nonplanarity (γ = 13.6° (28)) to that of the CH_2CF_2Cl radical (γ =

[b]Assigned, based on homodesmic reaction (see text).

15.6°). In addition, both the heat of formation of ethane ($\Delta H^0_{f,298} = -20.24 \pm 0.12$ (31)) and of the ethyl radical $\Delta H^0_{f,298} = 28.36 \pm 0.4$ (32)) are well established.

Table 2 lists the (U)MP4/6-311G**//6-31G* total energies and the calculated zero-point vibrational energies (ZPVE) for all relevant species in the above homodesmic reaction. The computed endothermicity after corrections for ZPVE and temperature is 3.69 kcal/mol, and the corresponding "theoretical" heat of formation of the radical is $\Delta H^0_{f,298}(CH_2CF_2Cl) = -74.3 \pm 1.7$ kcal/mol, where the error limit represents cumulative uncertainties in the ΔH^0_f values of the other compounds in the reaction.

The reactions of H atoms with CCl_3, CF_2Cl, and CH_2CH_2Cl radicals have been studied in a flow reactor at 300 and 475 K by observation of the infrared emission from the HCl and HF products. These reactions were observed as secondary reactions from the H + CCl_3Br, CF_2ClBr, and CH_2Cl–CH_2I chemical systems. The conditions in the flow reactor were controlled so that the nascent vibrational distributions of HCl and HF were recorded. The pattern of vibrational energy disposal to HCl was used to differentiate between Cl atom abstraction and recombination–elimination mechanisms. The H atom reactions with CCl_3 and CF_2Cl radicals occur only via a recombination–elimination mechanism and give HCl(v) or HF(v) in a unimolecular step. Thus, the Cl atom abstraction reactions must have $\geq$3.0 kcal mol^{-1} higher activation energy than the recombination reaction. From observation of the ratio of the HCl and HF products from CHF_2Cl*, the difference in threshold energies for HF and HCl elimination was determined to be ~13 kcal mol^{-1}. On the other hand, Cl atom abstraction does compete with recombination–elimination in the H + CH_2CH_2Cl reaction, the branching fraction is ~0.3 at 300 K and ~0.6 at 475 K.

E. ARUNAN, R. RENGARAJAN et D.W. SETSER. Can. J. Chem. **72**, 568 (1994).

Opérant dans un réacteur à écoulement, à 300 et 475 K, et faisant appel à l'observation de l'émission en infrarouge du HCl et du HF produits, on a étudié les réactions des atomes de H avec les radicaux CCl_3, CF_2Cl et CH_2CH_2Cl. On a observé ces réactions sous la forme de réactions secondaires des systèmes chimiques H + CCl_3Br, CF_2ClBr et CH_2Cl–CH_2I. Les conditions présentes dans le réacteur à écoulement sont contrôlées d'une façon telle que les distributions vibrationnelles naissantes du HCl et du HF puissent être enregistrées. On a utilisé les patrons de distribution de l'énergie vibrationnelle du HCl pour différencier entre les mécanismes d'enlèvement d'atome de Cl et d'élimination–recombinaison. Les réactions des atomes de H avec les radicaux CCl_3 et CF_2Cl ne se produisent que par un mécanisme d'élimination–recombinaison et elles conduisent à du HCl(v) et du HF(v) dans une étape unimoléculaire. Les réactions d'enlèvement d'atome de Cl doivent donc avoir une énergie d'activation qui est $\geq$3,0 kcal mol^{-1} plus élevée que celle de la réaction de recombinaison. En se basant sur le rapport de HCl et HF produits à partir du CHF_2Cl*, on a déterminé que la différence entre les énergies seuils pour l'élimination de HF et de HCl doit être −13 kcal mol^{-1}. Par ailleurs, l'enlèvement de l'atome de Cl est en compétition avec la réaction de recombinaison–élimination dans la réaction de H + CH_2CH_2Cl; la fraction de bifurcation est d'environ 0,3 à 300 K et d'environ 0,6 à 475 K.

[Traduit par la rédaction]

I. Introduction

The reactions of H atoms with CCl_3, CF_2Cl, and CH_2CH_2Cl radicals at 300 and 475 K have been studied by observation of the HCl and (or) HF product from the infrared chemiluminescence in a fast flow reactor (1–3). The objective was to employ the characteristic vibrational energy disposal patterns to differentiate between the unimolecular HCl or HF elimination reactions from fluorochloromethanes and ethanes (4–7) formed by H-atom recombination vs. the direct, bimolecular Cl-atom abstraction reactions by H atoms (3, 4, 8), even though the two pathways give the same chemical products. The pathway that we identify as Cl-atom abstraction frequently is called a disproportionation reaction in the free radical literature. The current experiments are a logical extension of our earlier report on the room temperature reactions of H with CF_3, CH_2CH_2F, CH_2CF_3, and other fluorine-containing organic radicals (5). These systems exclusively react by the H-atom recombination, HF-elimination pathway because abstraction of F atoms has a high activation energy, and these reactions can serve to define the typical energy disposal pattern for three- and four-centered HF-elimination reactions. Other studies in the literature (6), especially from multiphoton infrared excitation (9) and classical chemical activation (10), show that the dynamics for unimolecular HCl and HF elimination should be similar. The fundamental thesis of the present analysis is that direct abstraction can be identified by examination of the HCl(v) distributions, since the mean fraction of the vibrational energy released to HCl for direct Cl-atom abstraction will be 0.35–0.50 with an inverted distribution (3, 8), whereas the distribution for HCl elimination is expected to be non-inverted with $\langle f_V \rangle \sim 0.15$ (5–7).

The three reaction systems that were studied in the present work are summarized below with the ΔH_0^0 in kcal mol^{-1} given in parentheses. Reactions [1a], [2a], and [3a] represent the recombination plus unimolecular elimination mechanism. Reactions [1b], [2b], and [3b] represent direct abstraction on the singlet or triplet potentials.

$$[1a]\quad H + CCl_3 \rightarrow CHCl_3^* \rightarrow CCl_2(\tilde{X}^1A_1) + HCl \qquad (-41)$$

$$[1b]\quad \rightarrow CCl_2(\tilde{X}^1A_1 \text{ or } \tilde{a}^3B_1) + HCl \qquad (-41 \text{ or } -29)$$

$$[2a]\quad H + CF_2Cl \rightarrow CHF_2Cl^* \rightarrow CF_2(\tilde{X}^1A_1) + HCl \qquad (-54)$$

$$[2b]\quad \rightarrow CF_2(\tilde{X}^1A_1 \text{ or } \tilde{a}^3B_1) + HCl \qquad (-54 \text{ or } 4)$$

$$[2c]\quad \rightarrow CHF_2Cl^* \rightarrow CFCl(\tilde{X}^1A') + HF \qquad (-46)$$

$$[3a]\quad H + CH_2CH_2Cl \rightarrow CH_3CH_2Cl^* \rightarrow HCl + C_2H_4 \qquad (-84)$$

$$[3b]\quad \rightarrow HCl + C_2H_4 \qquad (-84)$$

TABLE 1. Thermochemistry[a] for the addition–elimination unimolecular reactions

Molecule	$\langle E\rangle^b$	ΔH_0^{0c}	$E_0^{\ddagger d}$	$\langle E\rangle - \Delta H_0^{0e}$	E_p^f	E_x^g
$CH_3CH_2Cl^*(-HCl)$	105.0 ± 2.0	17.0 ± 0.2	55.0 ± 2.0	88.0 ± 2.0	38.0 ± 2.0	50.0 ± 2.0
$CHF_2Cl^*(-HCl)$	102.0 ± 2.0	48.2 ± 2.0	57.0 ± 3.8	53.8 ± 2.0	8.8 ± 3.8	45.0 ± 3.8
$CHF_2Cl^*(-HF)$	102.0 ± 2.0	53.5 ± 4.0	70 ± 4	48.5 ± 4.0	16.5 ± 4.0	32.0 ± 4.0
$CHCl_3^*(-HCl)$	95.5 ± 2.0	55.0 ± 2.0	≈60[h]	40.5 ± 4.0	≈5.0	≈35.0

[a]All entries are in kcal mol^{-1} for reaction on the singlet potential surface.
[b]The total available energy released to the molecule from reactions [1*a*], [2*a*], and [3*a*] for 450 K experiments. The energy for CH_3CH_2Cl is reduced to 103.6 kcal mol^{-1} at 300 K.
[c]The enthalpy change for elimination of HCl (or HF) from the molecule.
[d]The threshold energy for HCl (or HF) elimination; see text for references. The $E_0^{\ddagger}$(HF) for CHF_2Cl was assigned in this work, see text.
[e]Total energy available to the products for the elimination pathway is $\langle E\rangle - \Delta H_0^0$; the available energy for abstraction could be slightly higher if there is an activation energy.
[f]Potential energy released during the reaction, $E_0^{\ddagger} - \Delta H_0^0$.
[g]Excess energy, $\langle E\rangle - E_0^{\ddagger}$, released during the reaction.
[h]The $E_0^{\ddagger}$ from ref. 12 is lower than the currently accepted ΔH_0^0. The reverse reaction is also likely to have a barrier, and $E_0^{\ddagger}$ was set at 60 kcal mol^{-1}.

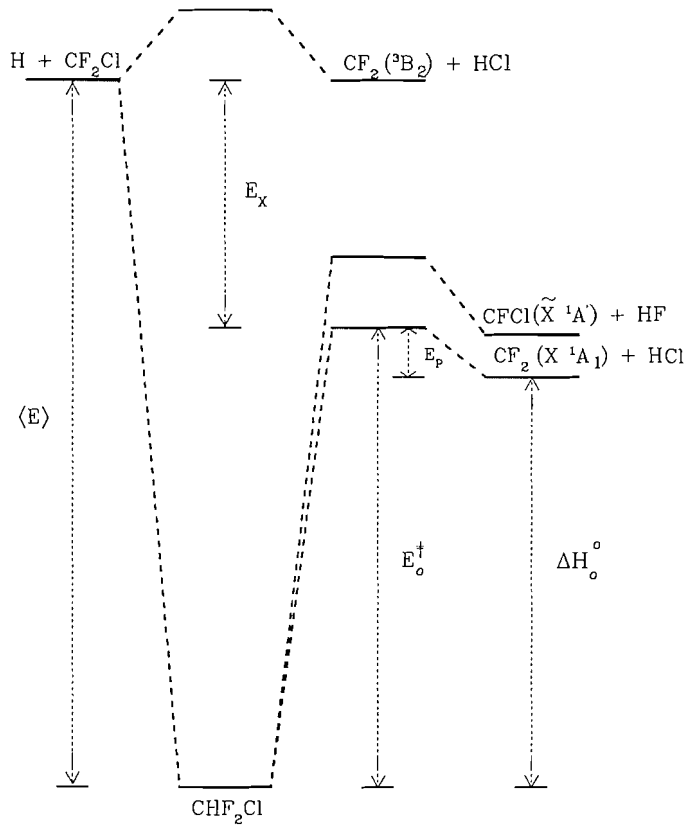

FIG. 1. Schematic representation of the reaction profile for the three-centered elimination reactions of H + CF_2Cl. The diagram is similar for four-centered elimination, but E_p is larger. The values for the energy quantities are given in Table 1.

Direct abstraction of F from CF_2Cl would have a larger activation energy than Cl abstraction, so that reaction is not listed for reaction [2]. The ground states of CCl_2, CF_2, and CFCl are the singlet states; thus, the potential surfaces that correlate to the triplet carbene states lie above the singlet potential surfaces. The recombination–elimination pathways are expected to involve only the singlet potentials. In principle, the Cl-atom abstraction reactions can proceed on either surface, but the singlet potentials probably have lower activation energy.

The HCl channel from CHF_2Cl^* previously was observed (5) using the F + CHFCl reaction to generate CHF_2Cl^*. The HF channel could not be observed in that work because of the strong HF emission from the primary reaction. The thermochemistry for the unimolecular reactions corresponding to [1*a*], [2*a*], and [3*a*] is summarized in Table 1 for 450 K and the symbols are defined in Fig. 1. The average energies of the molecules are given by $\langle E\rangle = D_0(\mathrm{H-R}) + E_a(\mathrm{H+R}) + nRT$ where E_a is the activation energy and nRT is the thermal energy of the H atom and radical reactants; the energies are $\gtrsim$100 kcal mol^{-1}. The activation energies were taken as zero. The C—H bond energies, D_0, for reactions [1]–[3] were obtained from ref. 11. The threshold energies, $E_0^{\ddagger}$, for HCl elimination from CH_3CH_2Cl (10*a*) and CHF_2Cl (12) were obtained from the literature. The E_a given in ref. 12 for the $CHCl_2$ reaction is smaller than the currently favored ΔH^0 for the reaction, which cannot be true. Also, the reverse reaction, CCl_2 + HCl, is likely to have a small barrier. Allowing for a 5 kcal mol^{-1} barrier for the reverse reaction, $E_0^{\ddagger}$ was set at 60 kcal mol^{-1} for reaction [1*a*]. The $E_0^{\ddagger}$ for HF elimination from CHF_2Cl was assigned from the ratio of rate constants for HF and HCl elimination and $E_0^{\ddagger}$(HCl) (12). The $\Delta H_{f0}^0(CF_2) = -42.6$ kcal mol^{-1} was taken from ref. 13*c* and $\Delta H_{f0}^0(CCl_2) = -52.1$ kcal mol^{-1} was taken from recent experimental work (13*a*, *b*). The thermochemistry for CFCl is not firmly established. We prefer the theoretical estimates of Francisco et al. (14*a*) ($\Delta H_{f0}^0 \approx 7$ kcal mol^{-1}) and Rodriquez and Hopkinson (14*b*) ($\Delta H_{f0}^0 = 3.3$ kcal mol^{-1}) over the experimental estimate of Lias et al. (15) ($\Delta H_{f0}^0 = -2 \pm 7$ kcal mol^{-1}), and we used 5 kcal mol^{-1}. The energy that would be available to the products from abstraction on the singlet surfaces would be larger than the value given in column 5 of Table 1 by the difference in E_a values for abstraction vs. recombination. The least certain values in Table 1 are the threshold energies for the three-centered elimination reactions. This affects the E_p values, which also are the threshold energies for addition of the carbenes to HCl or HF.

Reactions [1]–[3] were observed as secondary steps in a flow reactor containing excess H atoms with the precursor molecules CCl_3Br, CF_2ClBr, CH_2Cl-CH_2I (and also CH_2Cl-CH_2Br), respectively. Previously, we had used only iodine containing precursor molecules for generating the radicals (5). However, the primary reactions with some bromine-containing molecules are sufficiently fast, especially at 475 K, that they can augment the supply of useful precursor molecules for studies of H atom + radical reactions in our flow reactor. The HBr(v) chemilumines-

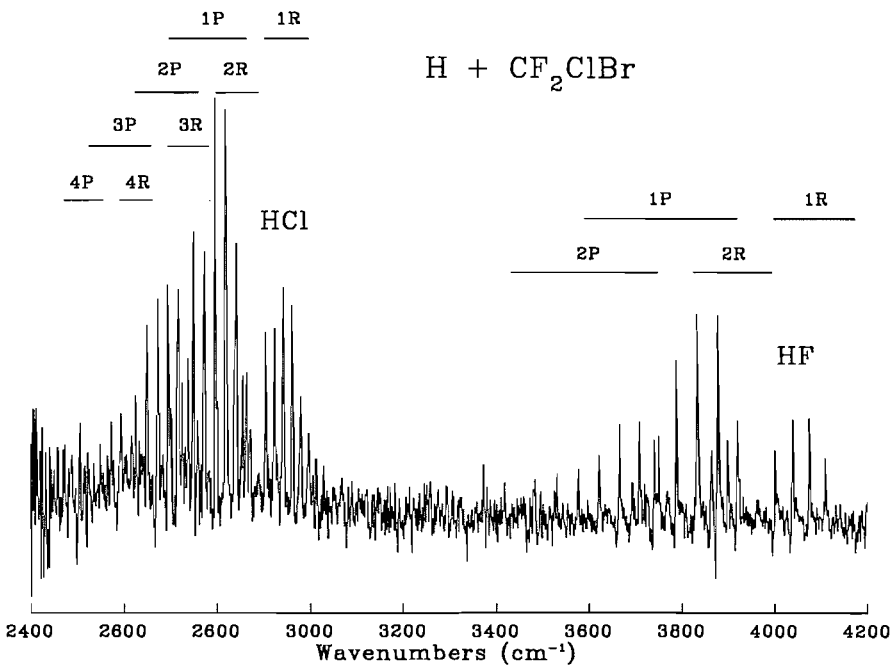

FIG. 2. Infrared emission spectrum from the H + CF_2ClBr system; the concentrations are 3.0×10^{13} and 2.0×10^{13} for [H] and [CF_2ClBr], respectively, and the reaction time is 0.5 ms.

cence from the primary steps could be observed, but the data are not very interesting because only HBr ($v = 0$ and 1) are generated. The H + CF_3 (generated from H + CF_3I) reaction also was studied at 475 K as a reference reaction, and the energy disposal pattern to HF was the same as in our previous room temperature study (5).

The vibrationally excited chloromethane and chloroethane molecules can be collisionally stabilized at high pressure (10), so the abstraction and addition–elimination mechanisms actually become identifiable in terms of the chemical products at high pressure. Dobis and Benson (16) recently emphasized that chlorination of hydrocarbons is an especially effective means to crack hydrocarbons because the recombination steps and direct abstraction (disproportionation) give olefins + HCl. The present work also has relevance to recent work for H + vinyl chloride kinetics (17). Typical values of disproportionation to recombination ratios of alkyl radicals range from 0.1 to 0.5 (18, 19). The question of direct abstraction vs. atom recombination at the radical site followed by unimolecular decomposition is of general importance for the interactions of open-shell atoms and polyatomic radicals. The infrared chemiluminescence technique may be one way to search for these abstraction reactions in atom plus radical encounters.

II. Experimental methods

The experimental method employed the reaction of excess H atoms with precursor molecules in a linear flow reactor. The H atoms were generated by a microwave discharge in H_2–Ar mixtures, and they were introduced at the front of the reactor. Additional Ar carrier gas was added separately at the entrance of the reactor to achieve a total pressure of 0.5–1.0 Torr (1 Torr = 133.3 Pa). The CF_3I, CCl_3Br, CF_2ClBr, and CH_2Cl–CH_2I (or CH_2Cl–CH_2Br) reagents were added via a ring injector 40 cm downstream from the H-atom inlet as a 5–10% mixture in Ar just before the observation window (a 4 cm diameter NaCl flat). Typical concentrations of H and the organic reagent were $(1–3) \times 10^{13}$ and $(0.5–5.0) \times 10^{13}$ molecules cm^{-3}, respectively. The H-atom concentration was assigned from measurement of 50% dissociation of the H_2. For some experiments the CH_2ClCH_2I (or CCl_3Br) was added by flowing Ar over the liquid sample at 300 K. Variable temperature experiments were done by heating the portion of the flow reactor extending from the H_2 and Ar inlets to the observation window (40 cm). The temperature of the reactor was regulated by the voltage supplied to the heating tapes. The temperature of the gas at the downstream edge of the NaCl window was measured with a thermocouple. This temperature was always the same as the temperature of the Boltzmann rotational distribution for HX(v) that was assigned from the emission spectra.

The highest possible flow velocity was ≈ 120 m s^{-1}, corresponding to a reaction time of ~0.2 ms for a reaction zone of 2.5 cm. The Ar pressure could be varied from 0.3 to 1.0 Torr without loss of pumping speed. The HF(v) and HCl(v) vibrational relaxation was fully arrested for these conditions and the rotational relaxation of HF was partly arrested (5, 20). Increasing the reaction time to ≈0.5 ms was required to observe some of the secondary reactions. For these conditions the vibrational distributions from the secondary reaction are hardly affected by relaxation, and the observed distributions are close to the nascent ones. Since HX emission could be observed from H + CF_3 and H + CH_2CH_2Cl (from CH_2ClCH_2I) for the fastest flow speed, we used these reactions for monitoring the degree of vibrational relaxation for other operating conditions.

The emission spectra were recorded at 1–2 cm^{-1} resolution with a Biorad (FTS-60) spectrometer; the individual rotational lines are easily observed, as shown in Fig. 2. A quartz filter with a cutoff at ≈ 2200 cm^{-1} was used to reduce the blackbody radiation for experiments at elevated temperature. The gain on the InSb detector also was reduced to avoid saturation. The rotational population in individual levels was obtained from the peak height of each vibrational–rotational line after division by the instrumental response function and the Einstein coefficient for the particular transition. Improved Einstein coefficients are available for HF and HCl, and their reliability should be better than 5% (21). The HBr coefficients (22) probably are less reliable, but only qualitative observations were made for HBr(v). The HCl and HBr rotational distributions were always Boltzmann at the temperature of the reactor. For some reactions, e.g., H + CF_3, the HF($v = 1$) distribution has a small component for $J \geq 8$ in addition to the Boltzmann component. But this was not the case for the H + CF_2Cl reaction.

Commercial tank grade Ar was purified by passage through molec-

[a]The P_0 values were assigned from linear vibrational surprisal plots. The vibrational distributions did not change significantly for experiments at 300 and 475 K.
[b]Example of a typical three-centered elimination distribution; the $\langle E \rangle - \Delta H_0^0$ is 52 kcal mol^{-1} and the data are from ref. 5.
[c]The number in parentheses is the mean fraction of vibrational energy for the prior distribution.
[d]Data from ref. 5 at 300 K from the F + CH_2FCl reaction system.

ular sieve traps cooled to liquid N_2 temperature. Tank grade H_2 was used without further purification. All reagents were purified by several freeze–pump–thaw cycles before loading. The CF_3I and CH_2ClCH_2I were purchased from PCR Inc. The CCl_3Br, CF_2ClBr, and CH_2Cl–CH_2Br were obtained from Columbia Organic Chemicals Co.

III. Results

A. *General observations*

The HBr emissions from the primary reaction with CCl_3Br, CF_2ClBr, and CH_2ClCH_2Br were not analyzed in detail, as our interest was in the atom + radical secondary reactions. The H + CH_2ClCH_2I reaction could be studied with maximum pumping speed (120 m s^{-1}) at 300 K and the observed HCl(v) distribution should be nascent, as judged from other extensive studies in this flow reactor. Even if the pumping speed was reduced by a factor of 2, the HCl(v) distribution was unchanged. If the pumping speed was reduced to ~70 m s^{-1}, HCl emission could be observed from the H + CCl_3Br and CF_2ClBr systems. By analogy to the H + CH_2ClCH_2I reaction, these HCl(v) (and HF(v)) distributions should be nascent. For all three systems the distributions were invariant to changes in [H] and [reagent] for the shortest times that could be used. The HF(v) and HCl(v) emission spectrum from H + CF_2ClBr is shown in Fig. 2. The CH_2ClCH_2Br reaction did not give emission at 300 K unless the pumping speed was greatly reduced. The activation energy for Br abstraction from CH_2ClCH_2Br is evidently higher than for CCl_3Br and CF_2ClBr, presumably because of a higher bond energy. With heating to 475 K, HCl emission could be observed from all four reactions. However, even at 475 K, the HCl emission from CH_2ClCH_2Br was observable only for relatively long reaction times, and the HCl(v) distribution was relaxed compared to the data from the CH_2ClCH_2I system. Table 2 gives a summary of the HX(v) distributions observed for the H + CCl_3Br and CF_2ClBr systems. Table 3 summarizes the experimental results from the H + CH_2ClCH_2I system.

The HCl emission arises only from secondary reaction, since Cl abstraction from the parent compounds has a large activation barrier compared to Br or I atom abstraction. As a test of this thesis, an experiment was done with the H + $CHCl_3$ reaction at 475 K, but no HCl emission was observed for our experimental conditions.

We made no effort to extract information from the temperature dependence of the total emission intensities. For the system with small E_a for the primary step, e.g., CF_3I and CH_2ClCH_2I, the HF and HCl emission intensities actually were slightly smaller at 475 K than at 300 K, because the concentrations and reaction time decrease with temperature, providing that the total pressure is constant and the gas flows delivered to the reactor are constant. The HBr emission intensity from CCl_3Br increased with temperature, but the HCl emission intensity was slightly reduced for the higher temperature. One difficulty with trying to interpret the dependence of the total emission intensity on temperature is that the [H] may not be constant because of the change in the rate of H atom recombination on the wall with temperature. Since the secondary reactions have a second-order dependence on [H], any loss of [H] severely affects the H + radical reaction rate. Direct measurement of the [H], at the observation window, is needed before the temperature dependence of the total emission intensities can be interpreted.

TABLE 3. Summary of HCl(v) distributions for H + CH_2ClCH_2I experiments[a]

No.	$[H_2]$[b]	T (K)	P_1	P_2	P_3	P_4	P_5[c]
1	4.1	300	16.7	27.6	30.3	16.2	9.2

8	24.0	475	15.5	22.7	26.0	22.5	13.2

[a]All experiments were carried out at 0.5 Torr Ar for a reaction time of 0.25 ms.
[b]$[H_2]$ in 10^{12} molecules cm^{-3}; the $[CH_2ClCH_2I]$ was fixed at 2.0×10^{13} molecule cm^{-3}.
[c]P_6 could be estimated as 1/2 P_5. For runs 6–8, trace amounts of $v = 7$ were also observed.

B. *H + CCl_3*

The HCl distribution from this reaction at 300 K was P_1–P_3 = 74:21:5; the distribution observed at 475 K, 72:23:5, was unchanged. These distributions were recorded for a reaction time of 0.4 ms and they were invariant to change in $[CCl_3Br]$ and $[H_2]$. Since the distribution does not change with temperature, HCl(v) seems to arise only from the recombination–elimination mechanism. The available energy is 40 kcal mol^{-1},

[a]The second line for the first three entries includes the P_0 obtained from the linear surprisal plot; the distribution is then renormalized.
[b]From ref. 26. The available energy is 64 kcal mol^{-1}.
[c]Pure elimination distribution calculated using $\lambda_V = -10.1$ and $\langle E \rangle - \Delta H_0^0 = 88$ kcal mol^{-1}. The elimination distribution is slightly different for the two temperatures due to the change in $\langle E \rangle$, but the difference is not significant. The $\langle f_V \rangle$ for the prior distribution is 0.04.
[d]Abstraction distribution obtained by deconvolution of the experimental distribution from the pure elimination distribution. The distribution from abstraction was forced to be the same for both temperatures.

which could give HCl(v = 5); however, the highest observed level was HCl(v = 3). The P_0 was estimated using a linear surprisal analysis, and the overall distribution after renormalizing is P_0–P_3 = 60:29:9:2. The full statistical model was used to calculate the vibrational prior. The λ_V for this reaction was −2.7 and the $\langle f_V \rangle$ was 0.11. To the best of our knowledge, there are no other theoretical or experimental HCl(v) distributions from the unimolecular decomposition of $CHCl_3$* available for comparison. This HCl(v) distribution is characteristic of three-centered elimination reactions with a small E_p (5, 6).

C. $H + CF_2Cl$

The HCl(v) distribution obtained from this reaction was P_1–P_4 = 57.8:27.4:9.4:5.4 at 300 K and 58.0:25.8:11.1:5.1 at 475 K. As demonstrated in Fig. 2, HF(v) emission also was observed. The HF(v) distribution was P_1–P_3 = 70.5:27.0:2.5 and 70.0:27.0:3.0 at 300 and 475 K, respectively. The HCl(v) and HF(v) distributions did not change with temperature and neither did the ratio of HF(v) to HCl(v). These distributions suggest that the HF and HCl are formed solely by unimolecular elimination from CHF_2Cl*. Linear surprisal plots were used to estimate the P_0 values, and the full distributions are given in Table 2. The HCl(v) distribution from CHF_2Cl* previously observed from the F + CHFCl reaction system is also given in Table 2 for comparison. The small difference in the two HCl distributions is a consequence of the larger $\langle E \rangle$ for F + CHFCl, and the $\langle f_V \rangle$ for the two reactions are almost the same: 0.13 and 0.12. The HF(v) distribution from CHF_2Cl is somewhat less extended than the HF(v) distribution from CHF_3 because the available energy is larger for the latter.

The HF and HCl intensities were corrected for the respective Einstein coefficients and instrumental response function to find the HF($v \geq 1$)/HCl($v \geq 1$) ratio, which was 0.17. Including the P_0 values from the surprisal calculations for HCl and HF distributions increases the ratio to 0.24. The CF_2 + HCl channel was observed to be the more important channel in the IRMPD studies of CHF_2Cl* (9*b*, 23). Martinez and Herron (23*a*) did observe CFCl, but they estimated that the CF_2 + HCl channel accounted for 99% of the reaction. The IRMPD experiments have a much lower $\langle E \rangle$ than the chemical activation experiments, and the HF/HCl ratio would be smaller. Our HF/HCl ratio suggests that the $E_0^{\ddagger}$ for the HF channel is ~13 kcal mol^{-1} higher than that of the HCl channel; this estimate was obtained by comparing the sums of states for the HF and HCl elimination transition states, vide infra.

D. $H + CH_2CH_2Cl$

A summary of the experimental results of various [H_2] and temperatures are given in Table 3. The HCl(v) emission intensity was strong and the results were always consistent. The emission was observed after a reaction time of 0.2 ms, and we believe that the HCl(v) distributions are the nascent vibrational distributions. A special search was necessary for HCl(v = 6) emission, since the HCl(6–5) band falls into the region where CO_2 background absorption occurs. Experiments with extensive flushing of the FTIR spectrometer and long time signal averaging gave a spectrum that could be analyzed and the P_5 to P_6 ratio was 2:1. Trace emission from v = 7 also could be seen. The average HCl(v) distribution observed from this reaction at 300 K was P_1–P_6 = 17:27:28:16:8:4. The available energy of 88 kcal mol^{-1} could give up to HCl(v = 11), and the highest observed HCl(v) level does not extend to the thermochemical limit. The HCl(v) distribution at 475 K was even more highly inverted: HCl(v) P_1–P_6 = 13:20:26:21:13:7. These HCl(v) distributions were highly reproducible at these two temperatures and they were invariant to changes of [H] and [CH_2ClCH_2I]. These slightly inverted distributions are very different from the HF(v) vibrational distributions observed from the HF elimination reactions of CH_3CH_2F and CH_3CF_3 (3).

Leone and co-workers (24) have studied the Cl + CH_3CH_2 reaction, which proceeds by the recombination–elimination mechanism to produce HCl(v). Their HCl(v) distribution, which is shown in Table 4, could be fitted with a linear surprisal plot, and the λ_V (−10.1) is very similar to the slope of the linear surprisal plot for HF elimination (5) from CH_3CH_2F and CH_3CF_3. Scaling a λ_V = −10.1 distribution to the energy for reaction [3] gives a "pure" HCl(v) elimination distribution suitable for comparison to our results. The comparison, see Table 4, clearly indicates that the HCl(v) from the H + CH_2CH_2Cl reaction must be the result of more than just the recombination–elimination reaction. We suggest that the observed HCl(v) distribution from H + CH_2CH_2Cl is the sum of recombination–elimination and abstraction components, with abstraction becoming more pronounced as the temperature is increased. Our

attempt to deconvolute the experimental distribution into the components representing the abstraction and elimination pathways is described in Sect. IV.3.

IV. Discussion

A. *Summary of energy disposal for addition–elimination vs. recombination reactions*

Although the chemical identity of the products is the same from recombination–elimination and from direct abstraction, the vibrational energy disposal patterns to the HCl (or HF) products from the two channels should be much different. The chemically activated halomethane and haloethane molecules with $\sim$100 kcal mol^{-1} of energy have unimolecular lifetimes (statistical limit) that range from picosecond (halomethanes) to nanosecond (haloethanes). The unimolecular elimination reactions yield HX(v) distributions that monotonically decline with increasing f_V and the $\langle f_V(HX)\rangle$ values are typically $\approx$0.15 with vibrational surprisal plots that are linear with slightly negative slopes (5–7). The transition state configurations and the dynamics of the HX elimination reactions are reasonably well understood (25–27). Since the excess energy for $CHCl_3$* and CHF_2Cl* is large, and since the formation steps are not state selective, the mode specific reaction pathways (27) found for photoexcited HFCO are not expected to be important. Stated another way, the relaxation of the energy released primarily in the H—C bond is expected to attain a microcanonical distribution before HX elimination occurs (28). In contrast, the characteristic HX(v) distributions from direct Cl or F abstraction by H atoms over repulsive potentials are sharply inverted and rather narrow with $\langle f_V(HX)\rangle = 0.4$; the vibrational surprisals are not linear and the distributions do not extend to the thermochemical limit (3, 4, 8). The rotational energy disposal from elimination and abstraction reactions are both rather modest (4–6), so the rotational energy disposal pattern is not very useful in distinguishing between the two reaction pathways. The energy disposal for Cl atom abstraction from polyatomic molecules by H atoms is representative of the class of reactions in which the dynamics are limited by kinematic constraints associated with the motion of the light H atom over a repulsive surface (3, 4, 8, 22). This pattern of energy disposal was characterized by Polanyi in a classic series of papers dealing with the reactions of H atoms with the diatomic halogen molecules (29).

Recombination reactions of methyl-type radicals with H atoms generally are considered to have nearly zero activation energies with rate constants of (1–2) $\times$ 10^{-10} cm^3 s^{-1} (30), whereas the abstraction pathways could have small positive activation energies. The halogen–carbon bond energies are large, D(Cl—CCl_2) = 62 kcal mol^{-1} and D(F—CF_2) = 87 kcal mol^{-1}, and Cl- or F-atom abstraction to give singlet carbenes is not expected to compete with recombination. Our method of observation would not be sensitive to direct abstraction on the triplet surface for H + CCl_3 and CF_2Cl giving triplet state carbenes because the available energy is rather low; see reactions [1b] and [2b]. The only case where H-atom abstraction might be expected at modest temperatures is H + CH_2CH_2Cl.

B. *HX elimination reactions from halomethanes*

The energy disposals to HX(v) from $CHCl_3$* and CHF_3*, respectively, are similar; but, the HF(v) distribution from CHF_3* does have a slightly larger negative λ_V and a larger $\langle f_V\rangle$. The HF(v) and HCl(v) distributions from CHF_2Cl* are more similar to the $CHCl_3$* reaction. The larger $\langle f_V(HF)\rangle$ from CHF_3* probably arises from the larger potential energy that is released in the exit channel. In our previous work (5), the energy released to the products from unimolecular processes with statistical lifetimes was treated as the sum of the statistical fraction of the excess energy (6), and the fraction of the potential released to HX, e.g., eq. [4].

$$[4]\quad \langle E_V(HX)\rangle = a\langle E_X\rangle + b\langle E_P\rangle$$

For the halomethanes the a value was $\approx$0.1 and the b value was $\approx$0.35. Using these a and b values with the thermochemistry in Table 1 gives good agreement with the experimental $\langle f_V\rangle$ values for $CHCl_3$* and CHF_2Cl*. For example, the $\langle f_V(HCl)\rangle$ for $CHCl_3$* and CHF_2Cl* are calculated to be 0.13 and 0.14 compared to the observed values of 0.11 and 0.13. The E_p is small for these reactions and the energy release is dominated by the excess energy, which is statistically distributed among the modes at the transition state geometry. As already noted, the mode-specific unimolecular rates (27) found for photoexcitation of HFCO at energies near $E_0^{\ddagger}$ are not expected for the highly energized $CHCl_3$* and CHF_2Cl* molecules.

The recombination rate constants (300 K) for H atoms with methyl-type radicals are large, near the orbiting limits (30), and little or no steric requirement exists. If we assume that a 5% contribution to HCl (high v) from abstraction could have been observed, then the activation energy for abstraction must be 3 kcal mol^{-1} (for similar pre-exponential factors for [1a] vs. [1b]). The H-atom reactions with NF_2 (31a), SF_5 (22), and CF_3O (31b) also proceed by addition–elimination mechanisms; however, these bimolecular rate constants are somewhat smaller than for H + methyl-type radicals. Comparison with the ClO (32a)[3] and NFCl (32b) reactions is worthwhile. The unpaired electron in these radicals is in a delocalized π orbital and the H atom seems to add to more than one site. For this reason and also because of the very short HOCl lifetime and a surface crossing in the exit channel, the energy disposal to HCl + O(^3P) differs from the normal HX elimination pattern.

The branching ratio for HF vs. HCl formation from CHF_2Cl* was 0.24 at $\langle E\rangle$ = 102 kcal mol^{-1}. This ratio is equal to the ratio of RRKM rate constants, which reduces to the ratio of sums of states of the two transition states. We assigned frequencies of 1275(1), 1050(2), 800(1), 670(2), 600(2) and 1160(1), 950(2), 780(3), 500(2) to obtain pre-exponential factors of $\sim 1.5 \times 10^{13}$ per reaction path for the thermal rate constants at 800 K for HCl and HF elimination, respectively. For these transition states a $\Delta E_0^{\ddagger}$ difference of 13 $\pm$ 1 kcal mol^{-1} was required to get a branching ratio of 0.12 for a reaction path degeneracy of 1 for each channel.

C. *H + CH_2CH_2Cl reaction*

The HCl(v) distribution and the $\langle f_V(HCl)\rangle$ from this reaction differ from the typical pattern found from the four-centered elimination reactions of CH_3CH_2Cl*, CH_3CH_2F*, and CH_3CF_3*. The recent work of Leone and co-workers (24) in which CH_3CH_2Cl* was formed by the Cl + CH_3CH_2 recombination reaction represents an important benchmark, because the HCl(v) distribution was as expected from a four-centered HX elimination process. Therefore, we infer that the Cl + CH_3CH_2 reaction proceeds entirely by atom–radical recombination fol-

[3]The broken line shown in Fig. 5 of ref. 32a should be ignored; the surprisal plot is not linear.

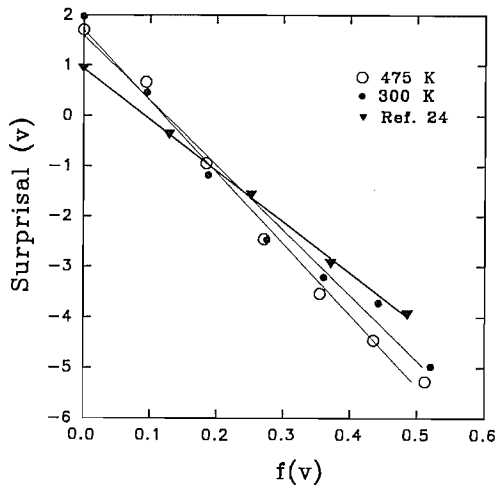

FIG. 3. Surprisal plots for the HCl(v) distributions from H + CH_2CH_2Cl at 300 K (filled circles) and 475 K (open circles) and the Cl + CH_3CH_2 reaction (filled triangles) from ref. 24. Note the smaller slope of the plot from the Cl + CH_3CH_2 reaction.

lowed by subsequent HCl elimination. Since the observed HCl(v) distribution from H + CH_2CH_2Cl differs from the distribution given by Cl + CH_3CH_2, we believe that the former is the sum of a direct abstraction pathway plus a recombination-elimination pathway. Our experiment cannot give the ground state vibrational population, P_0, but some estimate is needed before deconvolution of the experimental distribution can be made into abstraction and elimination components. Since the overall experimental distribution did fit (fortuitously) a linear surprisal plot, extrapolations were used to estimate the experimental P_0 values at both temperatures; see Table 4. The full statistical model for the HCl + CH_2CH_2 products was used to calculate the prior HCl(v) distribution. Figure 3 shows the surprisal plots for our data, and the corresponding plot from the HCl(v) distribution associated with the pure elimination reaction as provided by the Cl + CH_3CH_2 reaction. In some instances, surprisal analysis can distinguish two-component product distributions. However, direct abstraction pathways (by H atoms) do not give linear surprisals, and two linear portions of the surprisal plot for H + CH_2ClCH_2 would not be expected. It is fortuitous, but convenient, that the raw experimental distributions can be represented by a linear surprisal, but with a larger $-\lambda_V$ than for the "pure" elimination distribution.

The CH_3CH_2Cl* formation pathways of H(Cl) + CH_2CH_2-Cl(CH_3CH_2) seem unlikely to be sufficiently state selective to cause nonstatistical unimolecular lifetimes. The main difference in the formation process would be the considerably higher rotational energy carried into CH_3CH_2Cl* by the Cl + CH_3CH_2 recombination reaction. The vibrational energy disposal to HCl from unimolecular reaction of the chemically activated CH_3CH_2Cl* formed by the two recombination reactions should be similar. We used $\lambda_V = -10.1$ with $\langle E \rangle = 105$ kcal mol^{-1} to estimate the "pure" HCl(v) elimination distribution associated with our H + CH_2CH_2Cl reaction. The calculated "pure" HCl(v) distribution is presented in Table 4. There is a very definite difference between this "pure" HCl(v) elimination distribution and our experimental distributions.

Two assumptions are necessary in order to estimate a branching fraction and the HCl(v) distribution for the Cl atom abstraction reaction. We focused attention on the HCl($v = 0$) population

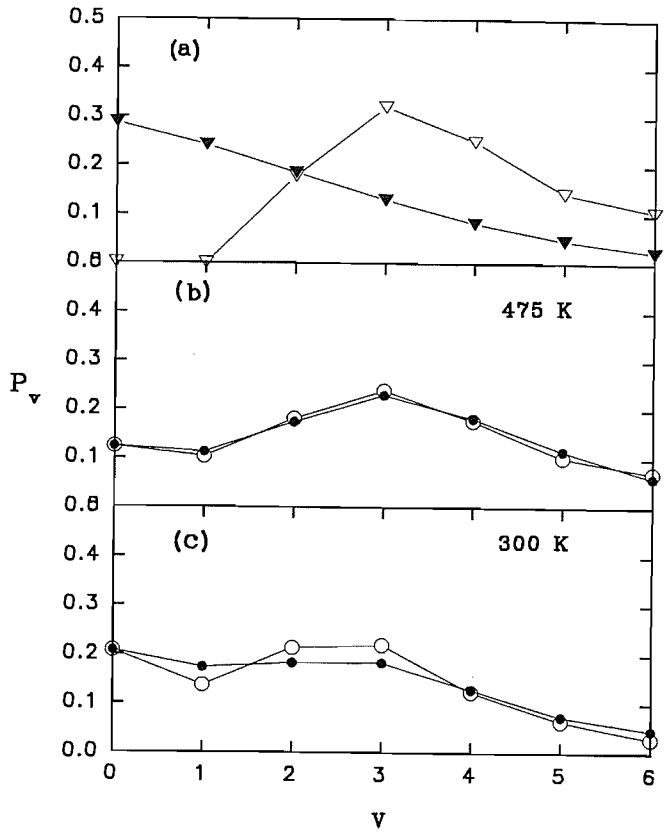

FIG. 4. (*a*) Comparison of the pure elimination (▼) and the abstraction (▽) HCl vibrational distributions from the H + CH_2CH_2Cl reaction. The abstraction distribution is the average distribution that best fits all the experimental distributions. (*b*) The 475 K experimentl distributions are compared to the sum of the two components with weights of 0.57 and 0.43 for abstraction and elimination, respectively. (●)-P_v observed and (○)-P_v calculated. (*c*) Same as Fig. 4*b* except at 300 K with weights of 0.28 and 0.72 for abstraction and elimination, respectively.

and assumed that HCl($v = 0$) arises only from the elimination reaction. This assumption together with using a linear surprisal distribution with $\lambda_V = -10.1$ for the elimination distribution directly leads to the fraction of the reaction going through the abstraction channel, f_a. Thus, f_a was determined to be 0.28 at 300 K and 0.57 at 475 K. To obtain an overall average distribution for abstraction, we assumed that the vibrational distribution from the abstraction channel does not change with temperature and adopted a single distribution for the abstraction process. The deconvolution method is not sufficiently sensitive to extract temperature-dependent distributions for the abstraction reaction. In any event, the change in thermal energy of CH_2ClCH_2 will not affect the HCl(v) distribution for abstraction, which depends on the release of repulsive energy by the potential. The best vibrational distribution for the abstraction channel was selected so that when combined with the "pure" elimination distribution, the experimental distributions were reproduced. Figure 4 shows the two separate components, and the synthetic overall distributions are compared with the experimental ones at 300 and 475 K. The agreement between the synthetic distribution and the experimental ones is satisfactory. The vibrational distribution that was assigned to the abstraction channel is given in the last line of Table 4. The $\langle f_V \rangle$ for this inverted distribution is 0.33, which is similar to the majority of other Cl-atom abstraction reactions from polyatomic inorganic

For personal use only.

molecules such as Cl_2O, NO_2Cl, and $NFCl_2$ (32*b*). The derived distribution for the abstraction reaction has a negligible P_1 value. Although the true value may not be zero, a small P_1 is consistent with direct abstraction.

The structure of the chloroethyl radical must closely resemble that for ethyl radical with sp^2 bonding at the localized radical center. The $D_0(Cl—CH_2CH_2)$ is only ~18.5 kcal mol^{-1}, which is lower than for the other Cl-containing polyatomic molecules, such as NO_2Cl, Cl_2O, and $NFCl_2$, that have been studied to obtain HCl(v) distribution. These inorganic molecules have rate constants (3, 31) in the 2×10^{-11} cm^3 molecule^{-1} s^{-1} range at 300 K. Assuming an enhancement in the abstraction rate constant with reduced bond energy, a competition between Cl-atom abstraction and recombination for CH_2CH_2Cl is reasonable. Based on the present knowledge, an abstraction channel from a radical may be expected for radicals with especially weak bond energies at a β-position to the radical center and for radicals with delocalized orbitals containing the unpaired electron (32). The question of abstraction vs. recombination for F + SiH_n (n = 1–3) reactions has been discussed (33). Abstraction seemed to be favored for SiH_2, but the singlet recombination pathways were favored over the triplet abstraction pathways for SiH_3 and SiH.

V. Conclusions

The H + CCl_3 and H + CF_2Cl reactions proceed by recombination, giving $CHCl_3$* and CHF_2Cl* molecules, which subsequently eliminate HCl (or HF) to give monotonically declining HCl(v) vibrational distributions with $\langle f_V \rangle$ equal to ~0.12. The H + CF_2Cl reaction also gives HF(v) + CFCl, and the HF/HCl ratio was assigned as 0.24. This ratio was combined with RRKM calculations and the experimental $E_0^{\ddagger}$(HCl) to estimate $E_0^{\ddagger}$(HF) as 70 kcal mol^{-1}. The small ratio of the HF to HCl strongly suggests that $\Delta H_f^0(HCl) + \Delta H_f^0(CF_2) < \Delta H_f^0(HF) + \Delta H_f^0(CFCl)$. Based upon comparison to the vibrational energy disposal to HCl from the Cl + CH_3CH_2 reaction, both direct Cl abstraction and recombination–elimination reaction pathways were assigned to the H + CH_2CH_2Cl reaction. Separating the two reaction pathways, based on an assumed "pure" HCl(v) elimination distribution, suggests that the branching fraction for abstraction is ~0.3 at 300 K. A weak temperature dependence enhances the abstraction pathway at higher temperature.

Acknowledgments

This work was supported by the National Science Foundation under grant CHE-9120489. We are extremely grateful for permission from Dr. Leone to use the data from ref. 24 prior to publication. We are pleased to contribute this paper in honor of the 65th birthday of Professor Polanyi. The development of the infrared chemiluminescence laboratory at Kansas State University was stimulated by the remarkably successful work of Professor Polanyi in this field.

Gas-phase association reactions of fullerene cations: modelling the influence of charge state and other molecular parameters on association efficiency

SIMON PETRIE AND DIETHARD K. BOHME[1]

Department of Chemistry and Centre for Research in Earth and Space Science, York University, North York, ON M3J 1P3, Canada

Received July 2, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

SIMON PETRIE and DIETHARD K. BOHME. Can. J. Chem. **72**, 577 (1994).

The efficiency of association reactions of fullerene cations observed in helium at pressures of 0.35–0.4 Torr sustained in a Selected-Ion Flow Tube (SIFT) at room temperature has been examined with a view to the influence of the charge state and the size of the fullerene ion and the size, structure, and degree of unsaturation of the neutral. The association efficiency is found to be strongly dependent on these molecular parameters. The calculated lifetime of the intermediate collision complex provides insight into the well depth associated with the formation of this complex and the effectiveness of vibrational and (or) rotational degrees of freedom of the reactants in the dispersal of the energy of complex formation. The results are considered in terms of single-well and double-well models for the potential energy surface leading to association and are best accommodated by the double-well model involving the formation of an initial electrostatic collision complex that must overcome a barrier to proceed to the formation of a chemically bonded adduct. The observed competition between association and charge transfer can also be accommodated with a double-well model, which provides a lower limit for the depth of the electrostatic well for those systems that exhibit such competition.

SIMON PETRIE et DIETHARD K. BOHME. Can. J. Chem. **72**, 577 (1994).

Dans le but de déterminer l'influence de l'état de la charge, de la grosseur de l'ion fullerène et la grosseur, la structure et le degré d'insaturation de l'espèce neutre, on a étudié l'efficacité des réactions d'association des cations de fullerène observées dans l'hélium, à des pressons de 0,35–0,4 Torr, et qui se produisent dans un tube à écoulement d'ion choisi (SIFT), à la température ambiante. On a trouvé que l'efficacité de l'association varie beaucoup avec ces paramètres moléculaires. Le temps de vie calculé du complexe de collision intermédiaire fournit des données sur la profondeur du puits associé à la formation de ce complexe et sur l'efficacité des degrés de liberté vibrationnels et (ou) rotationnels des réactifs dans la dispersion de l'énergie de formation du complexe. On considère les résultats en fonction des modèles à un et à deux puits pour la surface d'énergie potentielle conduisant à l'association et ils s'accommodent mieux avec le modèle à double puits impliquant la formation d'un complexe de collision électrostatique initial qui doit vaincre une barrière avant de procéder à la formation d'un adduit chimiquement lié. La compétition observée entre l'association et le transfert de charge peut aussi être accommodée avec un modèle à double puits qui fournit une limite inférieure pour la profondeur du puits électrostatique des systèmes qui présentent une telle compétition.

Introduction

The occurrence of bond formation is a central feature of chemistry. The process of association

[1] $$A + B \rightarrow AB$$

is the most direct means of chemical bond formation, and a study of the kinetics of association therefore offers insight into the factors affecting the efficiency of bond formation.

The laboratory study of the kinetics of association reactions in the gas phase has been dominated by the investigation of ion–molecule association processes

[2] $$A^+ + B \rightarrow AB^+$$

for two reasons. Firstly, ion–molecule reactions are easily studied by a variety of mass-spectrometric techniques (1). Secondly, owing to the attractive ion–dipole and ion – induced dipole interaction (2), ion–molecule reactions are generally of higher efficiency than neutral–neutral reactions (which are often inhibited by activation energy barriers).

Reactions of type [2] are also possible with multiply charged species A^{n+}, and indeed some examples of association reactions of simple (atomic and diatomic) gas-phase dications have been reported (3–5). However, ions bearing multiple charges are often prone to Coulomb explosion and, because of their relatively high appearance energies, their association with molecules must often compete with other processes: charge transfer or dissociative charge transfer in the case of multiply charged atomic and diatomic ions and proton transfer in the case of hydrogenated polyatomic ions. For these reasons, it has not been possible to examine the kinetics of association for multiply charged ions in any detail. Indeed, there appear to have been no previous measurements of reactions of type [2] involving trications A^{3+} or ions of higher charge state.

This situation has changed with the availability of Buckminsterfullerene, C_{60} (6). It is now relatively easy to produce the stable cations $C_{60}^{\cdot+}$, C_{60}^{2+}, $C_{60}^{\cdot 3+}$, C_{60}^{4+}, and $C_{60}^{\cdot 5+}$ in the laboratory for experimental study (7–9), so that a unique opportunity has arisen to explore the physicochemical aspects of association as a function of the reactant ion charge state. To this end, we previously reported the first quantitative measurements of the kinetics of association reactions involving the ions $C_{60}^{\cdot+}$, C_{60}^{2+}, and $C_{60}^{\cdot 3+}$ (10–18). For example, we characterized primary and higher order association leading to the formation of single-, double-, and triple-handled adducts as typified by structures **I** (10), **II** (13), and **III** (15).

Here we shall focus on selected-ion flow tube (SIFT) measurements on ion–molecule reactivity previously performed in our laboratory upon the fullerene ions $C_{60}^{\cdot+}$, C_{60}^{2+}, $C_{60}^{\cdot 3+}$, C_{56}^{n+}, C_{58}^{n+}, and C_{70}^{n+} ($n = 1, 2$) (10–18). We shall use the

results of these studies to investigate the dependence of association efficiency upon the physical parameters of the reactants (ion size and charge state; neutral size, structure, and degree of unsaturation), and hence to infer the nature of the potential energy surface leading to association. Furthermore, a number of systems are considered in which competing bimolecular channels have been observed. Our primary objective is to obtain an overall perspective for a range of novel association reactions involving fullerene ions and various neutral molecules.

Discussion

We previously reported a large number of reactions of the fullerene cations C_{60}^{n+} (n = 1, 2, 3) (10–18). Some of these results are presented in Tables 1–5. These tables are arranged to illuminate the general features of the efficiency of bond formation with fullerene ions: the influence of charge state, ion size, neutral size, degree of unsaturation of the neutral, and its structure. As is customary, we have defined the efficiency as the ratio of the measured effective bimolecular reaction rate coefficient to the calculated collision rate coefficient, $k(2)_{obs}/k_c$.

The pressure dependence of the efficiency of association has not been investigated systematically. However, results observed for the reaction of $C_{60}^{\cdot+}$ with ethylamine (10) and the reaction of C_{60}^{2+} with allene (11) have indicated that, for these systems, collisional stabilization, eq. [3]:

$$[3] \quad C_{60}^{n+} + X + M \rightarrow C_{60}.X^{n+} + M^*$$

dominates over radiative stabilization, eq. [4]:

$$[4] \quad C_{60}^{n+} + X \rightarrow C_{60} \cdot X^{n+} + h\nu$$

at the pressures of our SIFT experiments.

A few association reactions with multiply charged fullerene cations have been observed with other experimental techniques but these observations have been entirely qualitative. McElvany et al. (7, 21) used the FT–ICR technique to observe the occurrence of the association reactions

$$[5] \quad C_{56}^{\cdot 3+} + C_2H_2 \rightarrow C_{56} \cdot C_2H_2^{\cdot 3+}$$

$$[6] \quad C_{60}^{\cdot 3+} + C_2H_2 \rightarrow C_{60} \cdot C_2H_2^{\cdot 3+}$$

Garvey and co-workers (22) inferred the occurrence of the association reaction

$$[7] \quad C_{60}^{2+} + NH_3 \rightarrow C_{60} \cdot NH_3^{2+}$$

in a triple quadrupole MS/MS/MS apparatus, although the dicationic adduct $C_{60} \cdot NH_3^{2+}$ was not directly observable in their experiments. We have observed reaction [7] directly (9). Also, our observation of repeated association of 1,3-butadiene (16)

$$[8] \quad C_{60} \cdot (C_4H_6)_n^{2+} + C_4H_6 \rightarrow C_{60} \cdot (C_4H_6)_{n+1}^{2+}$$

for n = 0–5 was recently duplicated by Schwarz and coworkers[2] for n = 0–2 in an FT–ICR cell. The observation of the addition reactions [5], [6], and [8] under FT–ICR conditions ($P \sim 10^{-7}$–10^{-3} Torr; 1 Torr = 133.3 Pa) suggests that these reactions may be occurring in a bimolecular fashion by radiative association as in eq. [4].

A. Empirical correlations

Charge state of the fullerene ion

The efficiency of association increases dramatically with increasing charge, as shown in the values reported in Table 1. An increase in association efficiency of ~3 orders of magnitude operates for an increase in charge state from +1 to +2 for the reactions with NH_3 and n-C_3H_7CN, or from +2 to +3 for the reactions with HCN and C_2H_2. This enhancement in reaction efficiency with charge state is larger than (although within experimental uncertainty of) the factor of 100–500 found for the enhancement in association efficiency for reactions of M^{n+} (M = Mg, Ca, Ba; n = 1, 2) with H_2O, N_2, CO, CO_2, N_2O, and O_2 (3). For those reactions of C_{60}^{2+} that exhibit association with near unit efficiency, an enhancement in efficiency with increasing charge state from +2 to +3 is not observable. Similarly, an enhancement in efficiency is not experimentally observable when two successive charge states are both seen to be unreactive as is the case for the reactions of $C_{60}^{\cdot+}$ and C_{60}^{2+} with HCN and C_2H_2.

Size of the fullerene ion

The efficiency of association with various neutrals is noted in Table 2 for the species C_{56}^{n+}, C_{58}^{n+}, C_{60}^{n+}, and C_{70}^{n+}. Association is seen to be much more efficient for C_{56}^{n+} and C_{58}^{n+} than for the slightly larger ion C_{60}^{n+}, which in turn undergoes association with somewhat higher efficiency than C_{70}^{n+}.

Size of the neutral reactant

Association efficiency increases, sometimes dramatically, with increasing molecular size for molecules featuring the same functional groups, as shown in Table 3.

Degree of unsaturation of the neutral reactant

Two different trends are evident in the values reported in Table 4. For hydrocarbons, association efficiency is apparently highest when the hydrocarbon contains one C=C double bond; for functionalized organic molecules such as nitriles and ketones, however, efficiency is highest when the alkyl chain of the molecule is saturated.

Structure of the neutral reactant

Results reported in Table 5 indicate that the efficiency of association of C_{60}^{n+} with different isomers can differ by more than one order of magnitude.

B. Single-well model

We begin with a consideration of the simplest potential energy surface that may be used to describe the association of C_{60}^{n+} with a molecule X: the single-well model shown in Fig. 1. The kinetic and energetic parameters associated with such a model are straightforward and may be used to provide a first-order appreciation of the factors that affect association efficiency. At pressures at which the observed association reaction has not become saturated (i.e., above which collisional stabilization can still increase the efficiency of association), the association efficiency, $k(2)_{obs}/k_c$, is directly related to the lifetime of the collision complex, τ_d, since $k(2)_{obs} = k(3)_{obs}[He]$ and $k(3)_{obs} = k_c k_s \tau_d$. Here $k(3)_{obs}$ is the experimental termolecular rate coefficient for adduct formation, k_c is the theoretical rate coefficient for collision complex formation, and k_s is the theoretical rate coefficient for collisional stabilization.

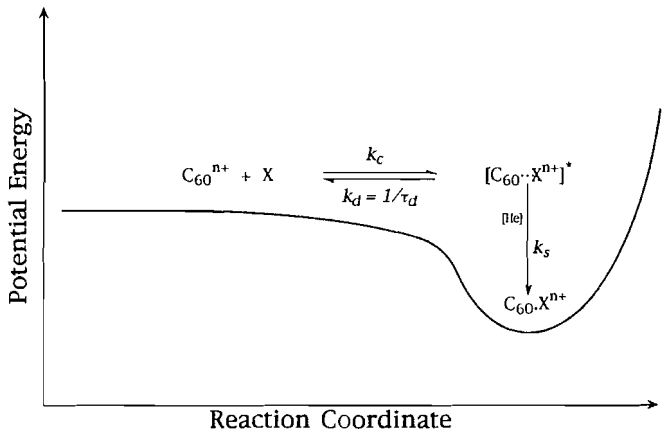

FIG. 1. Schematic diagram of the potential energy surface leading to association, for a single-well model. While such a model may not accurately represent the potential energy surface, consideration of the kinetic parameters involved is straightforward and provides an insight into the factors affecting association efficiency in the reactions of fullerene cations.

The mean lifetime, τ_d, of the collision complex can be determined with the expression

$$[9] \qquad \tau_d = k(3)_{obs}/k_c k_s$$

The usual value assumed for k_c is the ADO collision rate coefficient for this reaction, while k_s is assigned a value $k_s = \beta k_{s(c)}$ where β denotes the efficiency of the collisional stabilization process and $k_{s(c)}$ is the Langevin rate coefficient for collision with helium. In Tables 1–5, which list computed lifetimes, we have used values of $\beta = 0.03$ and 1.0 for the probability of stabilization per collision at 294 K, in the expectation that this range of values encompasses the true probability of collision complex stabilization. The upper limit of $\beta = 1$ is almost certainly unrealistic, since it is unlikely that every collision of a helium atom with the fullerene surface serves to stabilize the chemical bond between the adduct moiety X and one C atom of the fullerene lattice. Ion cyclotron resonance (ICR) studies on a number of association reactions (23, 24) have indicated values of $\beta \leq 0.3$ for helium buffer gas. In any event, we anticipate that β will remain essentially invariant for a series of reactions of fullerene ions C_{60}^{n+} with similar compounds X (for example, the series of nitriles $C_nH_{2n+1}CN$) and so any consistent trend in the calculated complex lifetimes in such a series is expected to be meaningful.

The collision complex lifetime τ_d is generally considered to depend strongly upon the number of degrees of freedom available for energy dispersal, and upon the depth of the potential well for collision complex formation. The expression (25):

$$[10] \qquad \tau_d = \tau_0 \left(\frac{D + 3RT}{3RT}\right)^{s-1}$$

indicates the nature of the expected dependence upon the well depth D and upon the number of degrees of freedom s. Although eq. [10] is overly simplistic in the light of current theoretical investigations of association reactions, we consider that this equation has sufficient qualitative validity to be useful in a consideration of collision complex lifetimes.

What do the computed lifetimes in Tables 1–5 tell us about the features of the single-well potential energy surfaces?

1. The very high apparent dependence of the collision complex lifetime upon charge state, showing a large increase in lifetime with increasing charge state in reactions featuring the same neutral and presumably possessing the same number of degrees of freedom, suggests that the depth of the potential well corresponding to collision complex formation increases substantially with increasing charge state.

2. The substantial enhancement in inferred collision-complex lifetimes for association reactions of C_{56}^{n+} and C_{58}^{n+} (over those apparent for C_{60}^{n+}) can be accounted for, as we have discussed previously (18), by a consideration of the degree of pyramidalization of the carbon atom sites upon the fullerene ion surface. Three types of carbon atom sites can be distinguished for fullerenes, on the basis of the geometry of the surrounding ring system. In Buckminsterfullerene, C_{60}, each C atom forms the apex of one pentagonal and two hexagonal faces (a [C_5, C_6, C_6] site). Other fullerenes also feature such sites, but small fullerenes (C_n, $n < 60$) also contain some

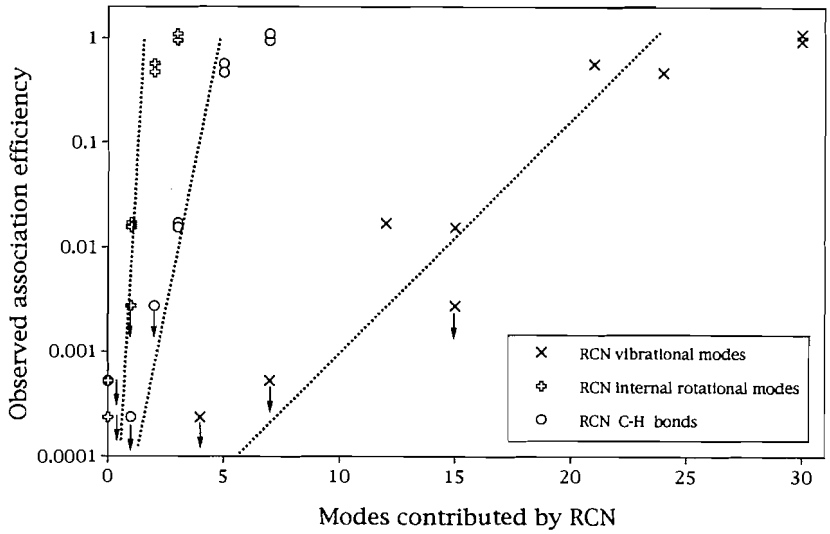

FIG. 2. Graph showing the observed efficiency of the association reaction C_{60}^{2+} + RCN for a variety of nitriles, plotted as a function of the total number of vibrational modes, the number of internal rotational modes, or the number of carbon–hydrogen bonds in the reactant nitrile RCN. Upper limits to the association reactions with HCN, with C_2N_2, and with $CH_2(CN)_2$ are denoted by downward-pointing arrows beside the appropriate symbol. Dotted lines are intended as an aid to visualizing the trends in the data rather than as a quantitative best-fit to the data. The general trend for association efficiency to increase with increasing reactant size is apparent. The kinetic data, which were presented previously in ref. 13, were obtained at 294 ± 2 K at a helium buffer gas pressure of 0.35 ± 0.01 Torr.

For personal use only.

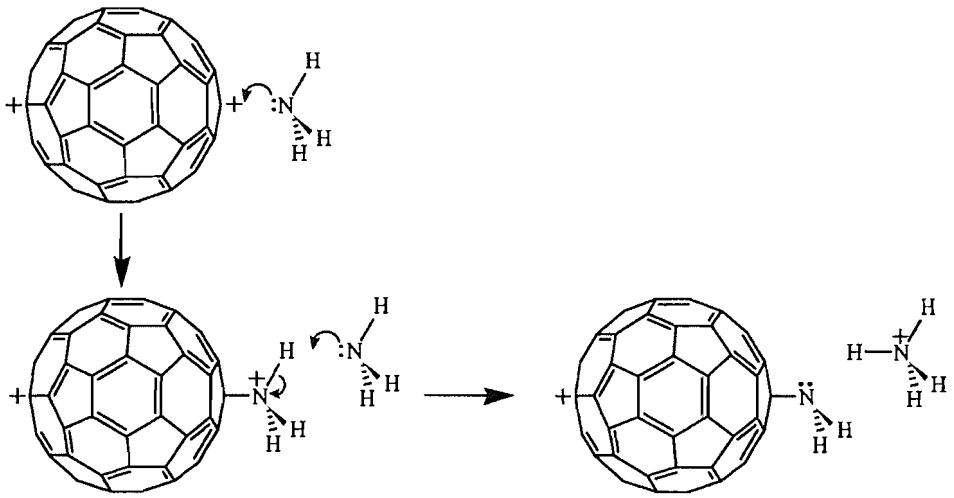
[C_5, C_5, C_6] sites, and larger fullerenes ($C_n, n > 60$) feature ($n - 60$) sites of type [C_6, C_6, C_6]. The degree of pyramidalization at the carbon atom in question increases with an increasing proportion of pentagonal C_5 rings. The experimental values reported in Table 2 suggest strongly that the more highly pyramidal [C_5, C_5, C_6] sites found in C_{56}^{n+} and C_{58}^{n+} are substantially more reactive than the [C_5, C_6, C_6] sites of C_{60}^{n+}; there is some indication, also, that the [C_6, C_6, C_6] sites (which have the lowest degree of pyramidalization) are the least reactive, since C_{70}^{n+} is seen to form adducts with a lower efficiency than is C_{60}^{n+}. The depth of the potential well involved in collision complex formation thus appears to be greatest for [C_5, C_5, C_6] sites and smallest for [C_6, C_6, C_6] sites, in keeping with expectations of the amount of distortion necessary at each site to attain tetrahedral coordination of the carbon atom concerned.

3. The trend evident in Table 2 also suggests that the fullerene ion contributes few degrees of freedom to the collison complex. C_{70}^{n+} has 105 C—C bonds whereas C_{60}^{n+} has 90 such bonds; C_{60}^{n+}, despite having fewer vibrational degrees of freedom than C_{70}^{n+}, is seen to associate more efficiently and therefore presumably has a longer-lived collision complex. This observation indicates that the increase in the number of degrees of freedom for C_{70}^{n+} over C_{60}^{n+} is not sufficient to overcome the effect of an apparently shallower potential well.

4. Table 3 indicates that the increasing alkyl substitution of the reactant noticeably increases the collision complex lifetime, presumably by increasing the number of degrees of freedom of the collision complex. Another effect of increasing alkyl substitution is perhaps that of charge stabilization by inductive donation of electrons to the charge site in question (that is, increasing the depth of the potential well). This inductive effect may play a role in the efficiencies seen for $C_{60}^{\cdot+}$ with the series of amines $(CH_3)_nNH_{3-n}$ (n = 0–3) and in the very large change in association efficiency of C_{60}^{2+} with ethylene and with propylene, but inductive charge stabilization cannot account for the trend seen in the nitriles (for example, an increase in the collision complex lifetime by a factor of at least 30 is apparent in the progression from CH_3CN to C_2H_5CN).

The data for the nitriles is also shown in Fig. 2, which plots the observed association efficiency against several molecular parameters for the reactions of C_{60}^{2+} with RCN given in Table 3, as well as for the reactions with the dinitriles C_2N_2 and $CH_2(CN)_2$ and with the unsaturated nitriles CH_2CHCN and CH_2CHCH_2CN. It is apparent from Fig. 2 that, although the general trend is for association efficiency to increase with the total number of substituent vibrational modes, the relation is not monotonic. A better fit is obtained in this instance for the dependence of association efficiency upon the number of C—H bonds within the nitrile, although too few of the reactants RCN exhibit association reactions within the range of efficiences $k(2)/k_c \sim 0.001$–0.3 (that is, above the limit for detection of a reaction by the SIFT technique, and below the expected onset of saturation of the association channel) for the fit to be compelling. These reactions, for which association is the sole observable product channel in all instances studied to date, should occur at lower efficiency at a substantially reduced buffer gas pressure. Therefore, the association reactions of C_{60}^{2+} with the larger nitriles (which occur with high efficiency under SIFT conditions) would seem to be a promising system for further study of association efficiency, using a lower pressure technique such as ICR, which has already been shown capable of detecting fullerene-ion addition products (7, 21, and footnote 2).

5. Association reactions do not occur with saturated hydrocarbons, but are observed with unsaturated hydrocarbons and with functionalized organic molecules (Table 4). This suggests that association involves bond formation without concomitant bond breaking, as we previously discussed elsewhere (11, 12). Also, where a functional group (C=C, or an atom such as O or N featuring a lone pair) is present within the molecule, further unsaturation serves to reduce the apparent collision complex



SCHEME 1

lifetime, most probably as a consequence of reduction in the number of available vibrational or internal rotational modes for excess energy dispersal.

6. Substantially different lifetimes are apparent for isomers of organic compounds (Table 5). A number of differing factors may affect the lifetime in such cases: inductive stabilization of charge by a differing number of alkyl groups, steric effects favouring bond formation with one isomer over another, and a difference in the number of effective degrees of freedom (for example, for rotation of alkyl groups in hindered and unhindered complexes). These effects may often occur in competition with each other and are, therefore, best considered on a case-by-case basis since they are not easily accommodated by a simple and general potential energy model for collision complex formation and stabilization.

C. Double-well model

The dependence of association efficiency upon ion charge state, evident in the data shown in Table 1, suggests that the electrostatic interaction between the reactant ion and the neutral is a major component of the collision complex potential well. However, the subsequent reactivity of fullerene adduct ions in several instances, often by proton transfer, (10, 13, 26):

[11] $C_{60} \cdot NH_3^{2+} + NH_3 \rightarrow C_{60} \cdot NH_2^{+} + NH_4^{+}$

[12] $C_{60} \cdot HCN^{\cdot 3+} + HCN \rightarrow C_{60} \cdot CN^{\cdot 2+} + HCNH^{+}$

but exhibiting also methyl cation transfer in some cases:

[13] $C_{60} \cdot HCOOCH_3^{\cdot 3+} + HCOOCH_3 \rightarrow C_{60} \cdot COOH^{\cdot 2+} + HC(OCH_3)_2^{+}$

is more consistent with the expected reactivity of chemically bonded adducts formed as shown in Scheme 1 than with the likely reactivity of electrostatically bound complexes. The greater facility for complex formation observed with the adjacent-pentagon fullerene ions C_{56}^{n+} and C_{58}^{n+} than with the isolated-pentagon ions C_{60}^{n+} and C_{70}^{n+} is suggestive of tetrahedral coordination at the site of addition and therefore also supports covalent bond formation. It thus appears likely that the potential energy surface may involve two minima rather than a single potential well. A double-well surface of this type is shown in Fig. 3. Nevertheless, we stress that the evidence favouring a double-well potential surface over a single-well model is rather circumstantial.

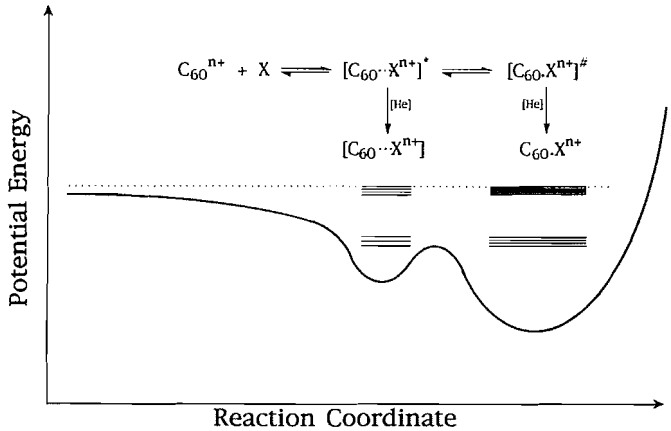


FIG. 3. Schematic diagram of the potential energy surface leading to association, for a double-well model. The barrier between the electrostatically bound complex, $[C_{60}\cdots X^{n+}]$, which is expected to correspond to the initial structure of the collision complex, and the covalently bonded adduct, $[C_{60}\cdot X^{n+}]$, is considered to arise from the energetic requirement to distort the fullerene surface in order to achieve sp^3 hybridization at the carbon atom involved in bond formation. The dotted line shows the total thermal and potential energy of reactants; also shown schematically are the relative densities of states for the electrostatically bound complex and the covalently bonded adduct at the total energy of reactants and at the height of the submerged barrier. The density of states ratio is expected to consistently favour covalent bond formation, since this potential well is expected to have greater depth.

A possible rationalization for the existence of a barrier between the electrostatically bound collision complex and the covalently bonded adduct is the necessity to distort the fullerene carbon framework at the site of the fullerene-substituent bond formation, so as to achieve sp^3 hybridization at this site on the fullerene surface. Such a barrier would presumably be more easily traversed for the adjacent-pentagon [C_5, C_5, C_6] charge sites in C_{56}^{n+} and C_{58}^{n+} (which, on geometric grounds, are expected to have a comparatively high degree of pyramidalization, and of sp^3 character, prior to interaction with the re-

For personal use only.

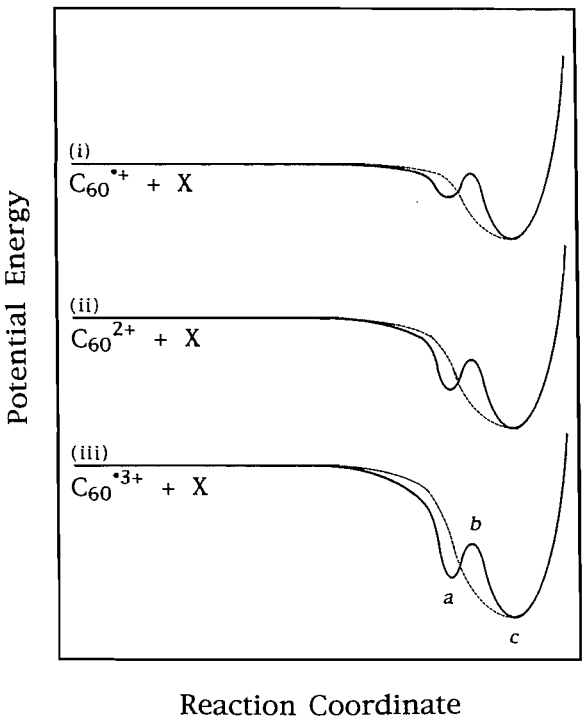

FIG. 4. Schematic diagram illustrating the increasing depth of the potential well(s) leading to adduct formation, and of the barrier to covalent bond formation in the double-well model, with increasing charge state.

actant neutral) than for the charge sites in C_{60}^{n+} and larger fullerenes: this can account for the observed trend (Table 2) for fullerene ion sizes. Traversal of the barrier should also be more facile for collision complexes having a higher charge state, since the barrier height (relative to the electrostatic well depth) should be essentially independent of charge state while the electrostatic well depth will increase with charge state. We have illustrated this point schematically in Fig. 4.

The double-well model provides for the collisional stabilization of the electrostatically bound collision complex as well as of the chemically bonded adduct, and thus two isomeric structures of the association product are possible. We have not yet observed any evidence (upon the basis of subsequent reactivity) that supports this possibility: however, if the well depth for chemical bond formation is substantially greater than the depth of the electrostatic well as we have suggested, then the density of states in the energy window above the barrier to interconversion is expected to consistently favour chemical bond formation and so the chemically bonded adduct should be the major product of the association reaction provided that the collision complex is sufficiently long-lived to allow an equilibrium to be attained between the two minima.

Several other examples can be found in the literature, of reaction processes in positive ion – molecule chemistry involving discrete potential wells for electrostatically and covalently bound complexes. The negative temperature dependence observed for the methyl cation transfer reaction

[14] $(CH_3)_2Cl^+ + C_6H_5CH_3 \rightarrow C_6H_5(CH_3)_2^+ + CH_3Cl$

suggests that this exothermic reaction occurs on a surface involving at least two minima (27), and studies of other alkyl cation transfer reactions of dialkylchloronium ions (28–31) also indicate that a barrier exists between electrostatic complex formation and the transition to a covalently bonded adduct.

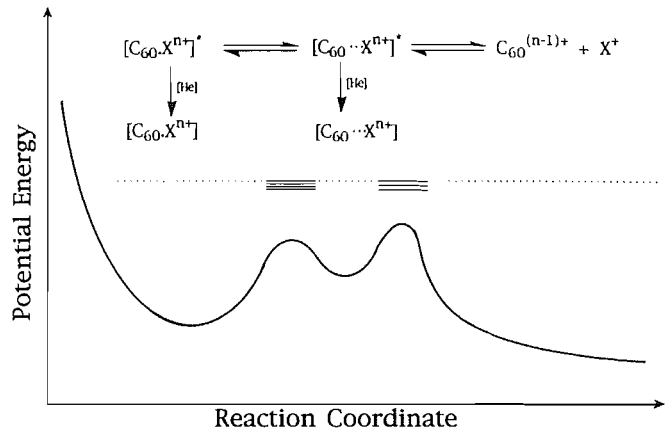

FIG. 5. Schematic diagram illustrating the potential energy surface involved in the competition between covalently bonded adduct formation and accessible charge transfer in the reaction of a polycation C_{60}^{n+} and a neutral X. For simplicity, the channel leading back from the (electrostatically bound) collision complex $[C_{60}\cdots X^{n+}]^*$ to reactants has not been included. Covalent bond formation can only compete effectively with charge transfer if the density of states above the (submerged) barrier to bond formation exceeds that above the (submerged) Coulombic barrier to charge transfer from a polycation: the occurrence of such competition in a reaction thus provides a lower limit to the depth of the potential well in the reaction concerned.

Similar potential energy surfaces have been proposed to explain the observed reactivity of gas-phase electrophilic aromatic substitution reactions (32, 33). The kinetics of ferrocene protonation (34):

[15] $BH^+ + Fe(C_5H_5)_2 \rightarrow Fe(C_5H_5)_2H^+ + B$

are similarly indicative of a barrier between electrostatically bound and covalently bonded adduct structures: this barrier is interpreted as arising from a change in geometry upon protonation. These examples demonstrate that the existence of barriers to bond formation in ion–molecule reactions may be rather common, especially when bond formation necessitates substantial distortion or deformation of the reactants.

D. Competition with charge transfer

The occurrence of association becomes a more complex issue in the presence of a competing exothermic bimolecular product channel such as charge transfer. This is especially true for reactions of the multiply charged ions C_{60}^{2+} and $C_{60}^{\bullet 3+}$, since charge separation reactions of such ions are inhibited by a substantial reverse activation energy barrier δ arising from the Coulombic repulsion between the product ions, which are initially formed in close mutual proximity (20, 35, 36). We have presented elsewhere a model for the potential energy surface involved in charge separation reactions of fullerene ions (37), which indicates a barrier height of $\delta = 1.80 \pm 0.16$ eV for reactions of the type

[16] $C_{60}^{2+} + X \rightarrow C_{60}^{\bullet +} + X^{\bullet +}$

and $\delta = 4.5 \pm 0.4$ eV for the reactions

[17] $C_{60}^{\bullet 3+} + X \rightarrow C_{60}^{2+} + X^{\bullet +}$

We have observed association reactions in competition with accessible charge transfer. Several reactions of this type are listed in Table 6. If our proposal of a double-well model is correct, then such reactions provide some indication of the relative barrier heights (in the forward direction) for chemical

bond formation and for charge transfer as we have illustrated in Fig. 5. The experimental results obtained to date show that association is able to compete to some extent with charge transfer reactions whose exothermicity exceeds the threshold value δ by up to ~0.6 eV for reactions of C_{60}^{2+}, and up to ~1.0 eV for $C_{60}^{\cdot 3+}$. At first glance there appears little evidence of a clear trend between exothermicity of charge transfer and the observed branching ratio for charge transfer, but this is understandable given the wide range in addition efficiencies that could be expected for these compounds in the absence of a competing charge transfer channel. For example, our studies of amine, nitrile, alcohol, and ketone addition reactions with C_{60}^{n+} indicate that nitrogen-containing nucleophiles (especially amines) are substantially more efficient at forming adducts than are the oxygen-containing nucleophiles (especially ethers). If these intrinsic differences in addition efficiency are taken into consideration, it is possible to discern a tendency (in any given class of compounds) for charge transfer to become dominant as it becomes sufficiently exothermic, as would be expected.

The results listed in Table 6 suggest that the barrier to bond formation for these reactions is submerged by at least 0.6 eV and 1.0 eV for doubly and triply charged ions, respectively. This places, also, a lower limit on the collision complex well depth in these examples (since this depth must exceed that of the submerged barrier to bond formation, if the double-well model is correct). If the collision complex well depth arises solely from the electrostatic and ion–dipole attractions between a (point-charge) fullerene ion and the neutral reactant in question, these lower limits indicate a separation of the reactants in the collision complex of no greater than 4.8 Å for C_{60}^{2+}+CH_3NH_2 and 4.5 Å for $C_{60}^{\cdot 3+}$ + NH_3. This distance restriction does not appear unreasonably restrictive — such a separation does not necessitate bond formation between the reactants. However, it is not clear how well the fullerene polycations conform to such a point-charge model: certainly the magnitude of the reverse activation energy barrier to charge transfer is better accommodated (in the case of charge transfer from C_{60}^{2+} and, we anticipate, from $C_{60}^{\cdot 3+}$) by assuming that the charges upon the fullerene polycation are initially as widely separated as is possible on the surface of a 7.0 Å spheroid. If the fullerene ion is not treated as a point charge, the required separation between the ion and the neutral (to produce an electrostatic well of greater depth than the submerged barrier to charge transfer) will be substantially less than the maximum separation permitted by a point-charge model.

Conclusions

The efficiency of association reactions of fullerene cations observed to occur in helium at the comparatively high pressures (0.35–0.4 Torr) sustained in a SIFT apparatus at room temperature has been scrutinized in terms of the influence of the charge state and the size of the fullerene ion and the size, structure, and degree of unsaturation of the neutral. The association efficiency is found to be strongly dependent on these molecular parameters. The magnitude of the efficiency, when translated into the lifetime of an intermediate collision complex, provides insight into the well depth associated with the formation of this complex and the effectiveness of vibrational and (or) rotational degrees of freedom in the fullerene cation

and the added neutral molecule in the dispersal of the excess energy of the complex.

The observed results are considered in the light of a single-well and a double-well model for the potential energy surface leading to association, but they are best accommodated by the double-well model involving the formation of an initial electrostatic collision complex, which must overcome a barrier (corresponding to the energetic requirement for localized surface deformation) to proceed to the formation of a chemically bonded adduct. The observation of competition of association with charge transfer can also be accommodated with a double-well model, which provides a lower limit for the depth of the electrostatic well for those systems that exhibit such competition. More insight into the nature of the potential energy surface would be provided by more detailed investigations of the pressure dependence (including the very low pressure regime) and of the influence of temperature upon association efficiency. Investigation of the chemistry of higher charge states such as C_{60}^{4+} and $C_{56}^{\cdot 5+}$ may also yield further information on the factors governing association reactions of fullerene ions.

The discussion of the models for the potential energy surfaces associated with fullerene-adduct formation is necessarily rather qualitative in nature. Several theoretical models do exist that treat, in a quantitative or semi-uantitative fashion, features of the potential energy surfaces for radiatively and collisionally stabilized association reactions (40). However, these models generally require a reasonably detailed knowledge of the exothermicity of adduct formation and the vibrational frequencies of the collision complex. In the present context, the thermochemistry of derivatized ionized fullerenes is as yet virtually unknown, and the ab initio calculation of vibrational spacings for a derivatized fullerene ion $C_{60}{\cdot}X^{n+}$ requires a major investment in computing time: at present, no such calculations have been reported. It is, therefore, not yet possible to model theoretically the efficiency of fullerene ion addition reactions, although such an aim is certainly desirable to augment or critically assess the models for the potential energy surface for association that we have presented here.

Experimental and theoretical study of monoligand complexes of nickel atoms with simple alkynes[1]

S.A. MITCHELL,[2] M.A. BLITZ, AND R. FOURNIER

Steacie Institute for Molecular Sciences, National Research Council of Canada, 100 Sussex Dr., Ottawa, ON K1A 0R6, Canada

Received July 20, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

S.A. MITCHELL, M.A. BLITZ, and R. FOURNIER. Can. J. Chem. **72**, 587 (1994).

Monoligand complexes of nickel atoms with simple alkynes have been investigated by kinetic studies of association reactions of nickel atoms with ethyne, propyne, and 2-butyne in the gas phase near room temperature, and by quantum chemical calculations on the Ni[C_2H_2] complex using a Linear Combination of Gaussian-Type Orbitals – Density Functional (LCGTO–DF) method. Experimental estimates of binding energies of the monoligand complexes have been made by using RRKM unimolecular reaction theory to model the pressure dependence of second-order rate coefficients for the association reactions: $\Delta E_0^0 = 46 \pm 6$, 37 ± 5, and 29 ± 5 kcal mol^{-1}, for Ni[C_2H_2], Ni[propyne], and Ni[2-butyne], respectively. The trend in binding energy with methyl substitution on ethyne is discussed and compared with similar data for monoligand complexes of alkynes with copper atoms. The harmonic vibrational frequencies and binding energy for the $^1A_1$ ground state of Ni[C_2H_2] have been calculated using the LCGTO–DF method, and the results are compared with experimental data on the infrared spectrum of matrix-isolated Ni[C_2H_2] and with the estimate of the binding energy of Ni[C_2H_2] from the present experimental study. There is excellent agreement between the experimental and theoretical results. The calculations indicate that at least one triplet state of Ni[C_2H_2] is bound relative to ground state Ni + C_2H_2 reactants. This is consistent with indications from the kinetic results that the association reaction occurs on more than one potential energy surface.

S.A. MITCHELL, M.A. BLITZ et R. FOURNIER. Can. J. Chem. **72**, 587 (1994).

On a étudié les complexes monocoordinés d'atomes de nickel avec des alcynes simples en réalisant des études cinétiques par réactions d'association d'atomes de nickel avec de l'éthyne, du propyne et du but-2-yne, en phase gazeuse, à la température ambiante et par des calculs chimiques quantiques sur le complexe Ni[C_2H_2] par une méthode de combinaison linénaire d'orbitales de type gaussien – densité fonctionnelle (LCGTO–DF). On a évalué les énergies de liaison expérimentales des complexes monocoordinés en utilisant la théorie de réaction unimoléculaire RRKM pour créer un modèle de la relation entre la pression et les coefficients de vitesse pour les réactions d'association du deuxième ordre : $\Delta E_0^0 = 46 \pm 6$, 37 ± 5 et 29 ± 5 kcal mol^{-1} respectivement pour Ni[C_2H_2], Ni[propyne] et Ni[but-2-yne]. On discute de l'évolution dans l'énergie de liaison avec des substitutions successives par des groupes méthyles et on la compare avec des données semblables obtenues avec des complexes monocoordinés de cuivre par des alcynes. Faisant appel à la méthode LCGTO–DF, on a calculé les fréquences vibrationnelles harmoniques et l'énergie de liaison de l'état fondamental $^1A_1$ du Ni[C_2H_2] et on a comparé les résultats avec les données expérimentales du spectre infrarouge du Ni[C_2H_2] isolé dans une matrice et avec les évaluations de l'énergie de liaison du Ni[C_2H_2] obtenus dans la présente étude expérimentale. Il existe un excellent accord entre les résultats expérimentaux et théoriques. Les calculs indiquent que, par rapport à l'état fondamental des réactifs Ni + [C_2H_2], au moins un état triplet du Ni[C_2H_2] est lié. Ceci est en accord avec les indications obtenues à partir des résultats cinétiques selon lesquels une réaction d'association se produit sur plus d'une surface d'énergie potentielle.

[Traduit par la rédaction]

1. Introduction

Interactions of unsaturated hydrocarbons with nickel atomic centres are important in several areas of chemistry including homogeneous and heterogeneous catalysis. This has led to extensive studies of the nature of bonding of alkenes and alkynes on single-crystal nickel surfaces and small nickel particles (1), and in nickel coordination complexes (2). Monoligand complexes of nickel atoms with ethene and ethyne are interesting model systems that may provide useful insights into the nature of bonding in more complex metal centres. Because of their relative simplicity, these model systems are well suited for detailed studies using quantum chemical theoretical methods. These methods, in turn, are important for interpreting experimental results. It is therefore of great interest to compare experimental and theoretical results for these 1:1 complexes. This paper describes such a comparison for monoligand complexes of nickel atoms with simple alkynes.

Infrared spectra have been reported for Ni[C_2H_2]$_n$ (n = 1 and 2) (3, 4) and Ni[C_2H_4]$_n$ (n = 1–3) (5, 6) complexes isolated in low-temperature inert gas matrices. An important step in the understanding of these systems was made with the ab initio calculations of Widmark et al. (7), which showed that the monoligand complexes Ni[C_2H_2] and Ni[C_2H_4] have ground states of singlet spin-multiplicity, similar to Ni[CO]. This is in contrast to the triplet ground state of atomic nickel. Recently, the complex Ni[C_2H_4] was investigated by gas phase kinetic studies of the association reaction of nickel atoms with ethene (8, 9), and by quantum chemical calculations using density functional methods (10). From the kinetic studies, the binding energy of Ni[C_2H_4] was estimated as 35.2 ± 4.2 kcal mol^{-1}. This estimate was made by modeling kinetic data using unimolecular reaction theory and by using in these model calculations the molecular structure and harmonic vibrational frequencies of the complex from density functional calculations (10). These calculated frequencies were in good agreement with experimental infrared spectra (6). Furthermore, the experimental estimate of the binding energy of the complex from the kinetic studies was in good agreement with the theoretical value from the density functional calculations. These studies show that Ni[C_2H_4] is a rather strongly bound π complex with a singlet ground state, and with at least one excited

state of triplet spin-multiplicity that is relatively weakly bound with respect to ground state nickel and ethene.

In the present study of complexes of nickel atoms with alkynes, a similar approach involving the combination of gas phase kinetic studies and density functional calculations has been used. Also similar to the study of $Ni[C_2H_4]$, the results of matrix-isolation infrared spectroscopic studies of $Ni[C_2H_2]$ (3, 4) proved very useful for comparison with predicted harmonic vibrational frequencies.

2. Experimental section

Details of the experimental method for kinetic studies of Ni atoms near room temperature have been described previously (8, 11). Nickel atoms were produced by pulsed laser photolysis of nickelocene vapour in a static pressure reaction cell, using an excimer laser pumped dye laser operating at 650 nm. Photolysis pulses were 0.75 mJ/pulse, and were focused using a 30 cm focal length lens. Detection of Ni atoms was by saturated resonance fluorescence excitation, using a second excimer laser pumped dye laser operating at 341.477 nm. Photolysis and probe laser beams were in a collinear and counterpropagating arrangement. Kinetic traces showing the time decay of the relative population of Ni atoms due to reaction with the precursor nickelocene or with added alkyne reactant were obtained by scanning the photolysis–probe interpulse delay in preset increments and averaging the fluorescence signal over 40–100 laser shots at each increment of delay. Kinetic traces typically consisted of 200 points, and were acquired over a period of several minutes using a laser repetition rate of 20 Hz. The traces were recorded by repetitively scanning the full range of interpulse delay, so that the stability of the signal could be monitored during the data acquisition period. Kinetic traces were fitted to single-exponential decays, allowing sufficient time at the beginning of the trace for complete relaxation of metastable states of Ni atoms (12). Exponential decays were fitted over at least three half-lives, and showed no systematic deviations from single-exponential decay behavior.

The Pyrex reaction cell was temperature stabilized by use of circulating ethylene glycol. Temperature measurement was by a Chromel–Alumel thermocouple probe that was situated near the reaction zone. Pressure measurement was by Baratron capacitance manometers. Ethyne was obtained from Matheson of Canada, propyne (96%) from Wiley Organics, and 2-butyne (99%) from Aldrich. All reactants were extensively degassed before use. The purity of the ethyne sample with respect to contamination by acetone was checked by FT-IR spectroscopy, and only a trace of acetone was observed.

3. Computational method

We performed all-electron Kohn–Sham calculations using the program deMon (13) in which the orbitals, charge density, and exchange-correlation potential are expanded in terms of Gaussian functions. A description of the Linear Combination of Gaussian-Type Orbitals – Density Functional (LCGTO–DF) formalism can be found in ref. 14. We did three sets of calculations: (1) with a local spin density (LSD) potential and energy functional (15); (2) with the LSD potential and adding gradient corrections of Becke (16) and Perdew (17) perturbatively to the exchange-correlation energy (BP/LSD); and (3) adding gradient corrections to the exchange-correlation potential and energy self-consistently (BP). In general, adding gradient corrections dramatically improves the binding energies; it often improves geometries but it usually does not give more accurate vibrational frequencies (18–20). Therefore the BP results should be regarded as more reliable and our discussion will be centred mainly around BP results.

The orbital basis sets we used have the contraction patterns (63321/5211/41) for the nickel atom, (6311/311/1) for carbon, and (311/1) for hydrogen. The auxiliary basis sets used for fitting the charge density and those for fitting the exchange-correlation potential had the same form. On nickel, the auxiliary bases had the form (10, 5, 5) (10 *s*, 5 *p*, and 5 *d* uncontracted functions), on carbon it had the form (8, 4, 4), and for hydrogen the bases were of the type (6, 2, 2). Further details are given in Appendix A. The basis set superposition error (BSSE) was estimated by the counterpoise method at the LSD level. It was found to be 4.6 kcal mol^{-1} at the equilibrium geometries of both the singlet and triplet states of the complex. This is somewhat larger than the counterpoise correction found in a similar study of the nickel–ethene complex, 3.6 kcal mol^{-1} (10). This is expected on account of the shorter nickel–carbon distances in $Ni[C_2H_2]$. Geometry optimization was carried out with a standard gradient method and harmonic vibrational analysis was performed through finite differences of analytical gradients. The $Ni[C_2H_2]$ binding energies that we report here were corrected for BSSE (−4.6 kcal mol^{-1} for both singlet and triplet) and include the change in zero-point energy (−1.0 kcal mol^{-1} for singlet, +0.1 kcal mol^{-1} for triplet).

The binding energies were calculated with respect to a nonspherical (integer occupation numbers) triplet $3d^9 4s^1$ nickel atom, which is the calculated ground state. In Kohn–Sham calculations, different occupations of the *d* orbitals for the same configuration give slightly different total energies (see, for instance, ref. 21). For both singlet and triplet $3d^9 4s^1$ configurations, the different *d* occupations gave energies that differed by at most 1.2 kcal mol^{-1}. For each of these configurations, we used the average of the largest and smallest calculated energies. When spherical symmetry is imposed, the energy of the triplet $3d^9 4s^1$ configuration is 9 kcal mol^{-1} larger than in the nonspherical treatment. The $3d^{n-1}4s^1$–$3d^{n-2}4s^2$ energy separation (*sd* splitting) is poorly described by most theoretical methods and, in particular, by DF calculations. When the ground state of a metal–ligand complex correlates to an excited $3d^{n-1}4s^1$ configuration of the atom in the dissociation limit, it is common to apply an empirical correction based on known atomic energy levels to the calculated dissociation energy (22, 23). For nickel, both the DF calculation and the multiplet-averaged experimental ground state configurations are triplet $3d^9 4s^1$ and no correction for the *sd* splitting is needed. The ground state $Ni[C_2H_2]$ complex dissociates to a ground state C_2H_2 molecule and a singlet $3d^9 4s^1$ nickel atom. Therefore, the $3d^9 4s^1$ singlet – triplet splitting of the nickel atom is relevant. The experimental value for this splitting is 7.7 kcal mol^{-1} (24) while the BP/LSD value for a nonspherical Ni atom is 9.6 kcal mol^{-1}. The agreement is good and we chose not to apply any correction for this atomic splitting. The calculated energy for the $3d^{10}$ configuration relative to the triplet ground state is 42.7 kcal mol^{-1}, which also compares well to experiment, 40.0 kcal mol^{-1}. Other configurations of the nickel atom are not expected to be important for a description of the complex: the $3d^8 4s^2$ configuration of nickel leads to a repulsive interaction with the ligand and the $3d^8 4s4p$ configuration has a very high energy and contributes very little to the bonding.

4. Results and discussion

4.A. Kinetic results

Kinetic traces were recorded for reactions of Ni atoms with ethyne, propyne, and 2-butyne in CO_2 buffer gas at 295 and 325 K. In the absence of added reactant, Ni was removed by reaction with the precursor nickelocene, which was present at a pressure of ≈3 mTorr (1 Torr = 133.3 Pa). A "background" removal rate was therefore present in all kinetic traces. This

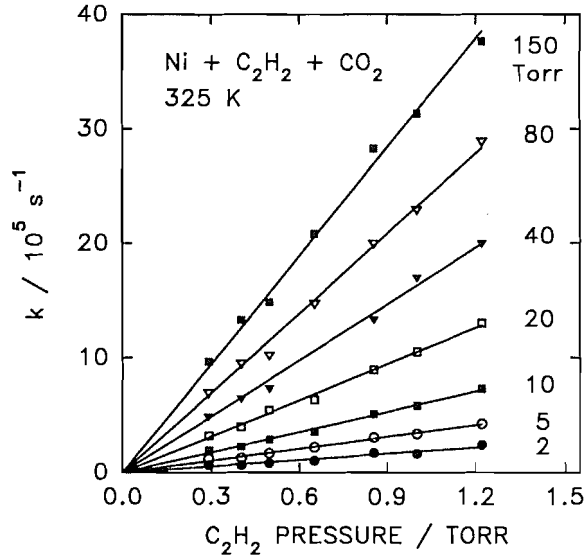

FIG. 1. Pseudo-first-order rate coefficients for reaction of nickel atoms with ethyne in carbon dioxide buffer gas at 325 K, versus ethyne pressure at various total pressures.

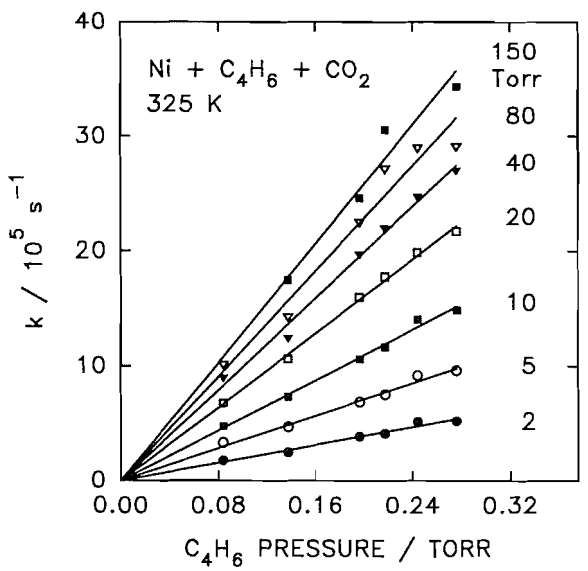

FIG. 2. Pseudo-first-order rate coefficients for reaction of nickel atoms with 2-butyne in carbon dioxide buffer gas at 325 K, versus 2-butyne pressure at various total pressures.

background rate was measured for each new nickelocene sample, before addition of reactant, and was subtracted from the rate measured with reactant present. The background rate was approximately 0.4×10^5 s^{-1}, and the corrected reaction rates were in the range $(0.8–38) \times 10^5$ s^{-1}. For each pressure of added reactant, the total pressure was made up to 2, 5, 10, 20, 40, 80, and 150 Torr, using CO_2 buffer gas. In Figs. 1 and 2 are shown pseudo-first-order removal rates of Ni atoms due to reaction with ethyne and 2-butyne, respectively, as a function of reactant pressure at the various total pressures at 325 K. These rates were corrected for the contribution due to reaction with precursor. The slopes of these plots constrained through the origin are second-order rate coefficients for the association reactions. All second-order rate coefficients are summarized in Tables 1 and 2, and are plotted against total pressure in Figs. 3, 4, and 5, for ethyne, propyne, and 2-butyne, respectively. The

uncertainties in Tables 1 and 2 are for 95% confidence limits and include only random errors. The lines drawn through the data points in Figs. 3–5 show fits to the data obtained by using RRKM calculations. From these calculations, the binding energies of the monoligand Ni–alkyne complexes were estimated. The method used to obtain these estimates is described in the following section.

4.B. Analysis of kinetic data

The rate coefficients in Tables 1 and 2 are for association reactions of the type shown in reaction [1]

[1] $$Ni + C_2H_2 + CO_2 \rightarrow Ni[C_2H_2] + CO_2$$

The bath gas, composed mainly of CO_2, serves to stabilize $Ni[C_2H_2]^*$ collision complexes, and this gives rise to a dependence of the second-order rate coefficient k_r on total pressure [M] that has the form shown in eq. [2].

[2] $$k_r = \frac{k_{r0}[M]}{1 + \frac{k_{r0}[M]}{k_{r\infty}}} \times F([M])$$

Here k_{r0} is the limiting low-pressure, third-order rate constant, $k_{r\infty}$ is the limiting high-pressure, second-order rate constant, and $F([M])$ is a function that approaches unity at both very low ($k_{r0}[M]/k_{r\infty} \ll 1$) and very high ($k_{r0}[M]/k_{r\infty} \gg 1$) pressure (25). There is thus a linear dependence of k_r on [M] at low pressure, with slope k_{r0}, and at high pressure k_r approaches a limiting value given by $k_{r\infty}$.

At very low pressure an equilibrium is established between Ni + C_2H_2 reactants and $Ni[C_2H_2]^*$ collision complexes. The low-pressure rate constant k_{r0} is proportional to the equilibrium constant for formation of $Ni[C_2H_2]^*$. Since this equilibrium constant is proportional to the volume of phase space associated with the collision complex, there is a correlation between

the magnitude of the low-pressure rate constant and the binding energy of the complex. This is the basis for the estimation of binding energies from kinetic data for association reactions (11). In practice, k_{r0} is calculated in terms of k_{u0}, the low pressure rate constant for the unimolecular dissociation reaction of the complex, i.e., the reverse of reaction [1]. k_{r0} and k_{u0} are related by the equilibrium constant K_{eq} for the association reaction, $k_{r0} = k_{u0}K_{eq}$. By using unimolecular reaction theory, k_{u0} may be calculated for an assumed threshold dissociation energy, if the structure and vibrational frequencies of the complex are known. If the molecular parameters of the dissociation products are also known, then this is sufficient to specify the equilibrium constant K_{eq}, and hence k_{r0}. This assumes that the threshold dissociation energy of the complex is equal to the thermochemical dissociation energy, i.e., there is no activation energy for the association reaction. In this case the vibrational frequencies and moments of inertia of the Ni + alkyne fragments and the Ni[alkyne] complex are sufficient to calculate k_{r0} for an assumed binding energy. The binding energy may therefore be estimated by systematically varying this parameter until agreement is found between calculated and observed low-pressure association rate constants. In practice there are additional details of the reaction that need to be specified, but these are of secondary importance. These details are given for the Ni + alkyne reactions in Sect. 4.C below.

The kinetic data for Ni + alkyne association reactions shown in Figs. 3–5 are in the falloff region of eq. [2], between limiting high- and low-pressure behavior. It is the low-pressure rate constant that is important for estimating the binding energy of the complex, but the falloff region is strongly influenced by the low-pressure rate constant, and therefore carries information on the binding energy. To model the falloff behavior it is necessary to explicitly consider the limiting high-pressure rate constant $k_{r\infty}$. RRKM theory provides a means of modeling the pressure dependence of the unimolecular dissociation rate constant k_u, and, by use of the equilibrium constant, that of the association (or recombination) rate constant k_r (26). In previous work on association reactions of Ni atoms with ethene and propene, we estimated binding energies of the monoligand complexes by modeling kinetic data in the falloff region, using RRKM calculations (8, 9).

An important feature of the Ni + alkene association reactions is that reaction occurs on more than one potential energy surface, and this is the case for the Ni+alkyne reactions as well. This is shown by the observation of rate coefficients near the high-pressure limit that are too large to be consistent with reaction only on the ground state surface of singlet

spin-multiplicity. As described in Sect. 4.E, the ground state of the Ni[C_2H_2] complex is a singlet, and there is at least one triplet state that is bound relative to ground state Ni(^3F) + C_2H_2. There is a restriction on the maximum value of the high-pressure rate constant for reaction on a singlet potential surface, due to the low value of the ratio of electronic partition functions of the product and the reactants in this case. The maximum value is given by a rate constant for capture, determined by the long-range part of the atom–molecule interaction potential, multiplied by the ratio of electronic partition functions $Q_{el}(\text{Ni}[C_2H_2])/Q_{el}(\text{Ni}) = 1/11.66$ (at 295 K) (9). Estimates of rate constants for capture for Ni + alkynes, described in Sect. 4.C, are near 7×10^{-10} cm^3 s^{-1}, so the maximum value of $k_{r\infty}$ for reaction on the ground state potential surface is near 6×10^{-11} cm^3 s^{-1} in all cases. As shown in Figs. 3–5, the observed rate coefficients extend to significantly higher values than this maximum. This can be explained by considering that reaction may occur on excited state potential surfaces as well as on the ground state surface. As noted above, the theoretical results in Sect. 4.E indicate that one or more triplet states of Ni[C_2H_2] are bound relative to Ni + C_2H_2 reactants. These states are in all likelihood responsible for the large apparent values of $k_{r\infty}$.

A simple rate equations model for recombination on two potential energy surfaces has been described (9). In this model collision complexes are formed in, and may be collisionally stabilized in, both electronic states, and transitions may occur between the electronic states in the isolated collision complex. It was shown that, if the excited electronic state is significantly less strongly bound than the ground state, then for moderate total pressure the form of the pressure dependence of the association rate coefficient is the same as that shown in eq. [2], i.e., the same as that for reaction on one potential energy surface. In this case the occurrence of reaction in the excited electronic state is reflected in the apparent value of the limiting high-pressure rate constant. This apparent value is larger than the maximum value consistent with reaction only in the ground electronic state, to an extent governed by the relative rates of dissociation and electronic relaxation of the collision complex in the excited electronic state (9). The data for Ni + alkyne reactions can be understood in these terms. It is important to note that in the limiting case considered, the low-pressure association rate constant is not significantly affected by the excited state reaction, even though the high-pressure rate constant may be strongly affected. This has implications for the use of unimolecular reaction theory for the estimation of binding energies from kinetic data. In particular, it is justifiable to model kinetic data in the falloff region, and to obtain an estimate of the binding energy of the complex, by proceeding in the same manner as for the case where reaction occurs only in the ground electronic state. The only difference is that in this case it is necessary to treat the limiting high-pressure rate constant as an apparent value, with magnitude between k_∞ and $k_\infty + k'_\infty$, where k_∞ is the (hypothetical) high-pressure rate constant for reaction only in the ground state, and k'_∞ is that for reaction only in the excited state (9). In the RRKM calculations, discussed in the following section, this is described by considering that reaction occurs only in the ground electronic state, but allowing the electronic degeneracy of the transition state (denoted $g^{\ddagger}$) to be effectively greater than that of the ground electronic state (9).

In a previous study of Ni + alkene reactions (9), k_∞ and k'_∞ were estimated by assuming that the transition states for the association reactions were loose transition states, in the phase space limit of RRKM theory (26). In this limit the high-pressure rate constants are at their maximum values, given by the rate constant for capture multiplied by the ratio of electronic partition functions, as noted above. The same approach was used in the present study of Ni + alkyne reactions. Details of the estimation of capture rates are given in the following section.

The model for the association reaction thus involves recombination on both the ground state, singlet potential surface of the complex and on one or more excited state, triplet potential surfaces. Collision complexes in the relatively weakly bound excited electronic states undergo electronic relaxation to the ground state in competition with collisional relaxation and dissociation on the excited state potential surfaces. The occurrence of reaction on singlet and triplet potential surfaces implies that the triplet surfaces that correlate with ground state Ni(^3F) + alkyne reactants are crossed by a singlet surface, and spin changing transitions occur readily in the crossing region due to spin-orbit coupling. On the basis of comparisons with potential curves for the complex Ni[CO] (11), and considering a simple model for the magnitude of the spin-orbit coupling interaction in the complex, it has been argued that this is a plausible model for Ni + alkene reactions (9). The same arguments can be used for Ni + alkyne reactions. The important singlet surface correlates the ($^1A_1$) ground state of Ni[C_2H_2] with Ni(d^9s^1 ^1D) + C_2H_2 reactants, for which the excitation energy is ≈ 8 kcal mol^{-1} relative to ground state reactants.

4.C. RRKM calculations

RRKM calculations were performed using the UNIMOL suite of FORTRAN programs (26). The general approach was to select a model for the Ni–alkyne complex, including vibrational frequencies and moments of inertia, and then fit calculated to observed Ni + alkyne recombination rate coefficients by varying two parameters in the calculations: the binding energy of the complex (dissociation energy at 0 K), ΔE_0^0; and the electronic degeneracy of the transition state, $g^{\ddagger}$. Examples of fitted

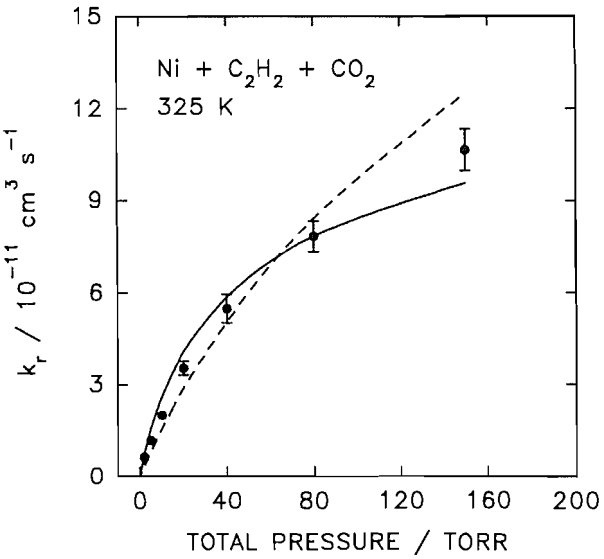

FIG. 6. Second-order rate coefficients for reaction of nickel atoms with ethyne in carbon dioxide buffer gas at 325 K, versus total pressure. Solid and broken lines show fitted rate coefficients from RRKM calculations, obtained by varying the parameter $g^{\ddagger}$ with the binding energy constrained as 49 and 43 kcal mol^{-1}, respectively.

rate coefficients at 295 and 325 K are shown in Figs. 3–5. The parameter ΔE_0^0 controls the slope of the pressure dependence at low pressure (rate constant k_{r0}), and $g^{\ddagger}$ controls the asymptotic limit of the rate coefficient at high pressure (rate constant $k_{r\infty}$). Note that since $g^{\ddagger}$ describes the extent of the participation of excited electronic states of the complex in the association reaction, it has a minimum value of 1.0, corresponding to reaction only in the ground state of singlet spin-multiplicity (electronic degeneracy = 1.0), and a maximum value given by the magnitude of the electronic partition function of atomic Ni (11.7 at 295 K and 11.9 at 325 K). This maximum value corresponds with the case where every collision of Ni with alkyne leads to motion on the ground state potential surface of the complex. In this case the apparent high-pressure rate constant is given by the rate constant for capture (see below).

In the fits to the data the parameters $g^{\ddagger}$ and ΔE_0^0 are to some extent correlated, but the effect of the correlation on the parameter ΔE_0^0 is rather small. This is because the dependence of k_{r0} on ΔE_0^0 is very strong, increasing with the complexity of the ligand molecule. Thus, the exponent n in the relationship $k_{r0} \sim (\Delta E_0^0)^n$ was found to be n = 7.1, 11, and 13, for the complex with ethyne, propyne, and 2-butyne, respectively. The correlation between the parameters ΔE_0^0 and $g^{\ddagger}$ for the C_2H_2 reaction at 325 K is illustrated by the fits shown in Fig. 6. The solid and dashed lines show fitted rate coefficients obtained by optimizing $g^{\ddagger}$ with ΔE_0^0 constrained to be 3 kcal mol^{-1} greater and smaller, respectively, than the value obtained when both parameters were optimized, 46 kcal mol^{-1}. The corresponding values of $g^{\ddagger}$ are 2.5, 7.7, and 3.5, for the solid and broken lines in Fig. 6 and for the case where both parameters were optimized, respectively. This shows that the binding energy is much better determined by these data than is $g^{\ddagger}$. The values of ΔE_0^0 and $g^{\ddagger}$ obtained by optimizing both parameters for each alkyne, using the same parameters to describe the 295 and 325 K data, are summarized in Table 3. Also given in Table 3 are the fitted values of k_{r0} and $k_{r\infty}$. The fits to the data are shown in Figs. 3–5.

In the calculations for the Ni + C_2H_2 reaction, the vibrational frequencies and structural parameters for Ni[C_2H_2] were taken from the results of density functional calculations described in Sect. 4.E. The vibrational frequencies and moment of inertia of C_2H_2, needed for the calculation of the equilibrium constant, were taken from the JANAF thermochemical tables (27). A different approach was required for the reactions involving propyne and 2-butyne, because explicit calculations of vibrational frequencies and equilibrium structures are not available for these Ni–alkyne complexes. In these cases two models were considered for each complex, models I and II. These were chosen to represent opposite extremes in their effects on the parameter ΔE_0^0, and descriptively represent relatively loose (model I) and tight (model II) vibrational frequencies for the complex. For simplicity, in both models the vibrational frequencies of the free ligand molecules (28) were assumed to be unperturbed in the complex, and the vibrations of the nickel atom relative to the ligand were described by a single, doubly degenerate frequency, designated $\bar{\omega}$. In both Ni[propyne] and Ni[2-butyne] the number of methyl torsional modes exceeds by one the number present in the respective free ligand molecule (0 in propyne and 1 in 2-butyne). Models I and II differed in the treatment of these torsional modes and in the assumed value of the frequency $\bar{\omega}$. In model I the torsions were treated as free rotors and $\bar{\omega}$ was assigned the relatively low value 300 cm^{-1}, and in model II the torsions were treated as vibrations, with frequency corresponding to 300 cm^{-1}, and $\bar{\omega}$ was assigned the relatively high value 500 cm^{-1}. In all cases

the geometry of the complex was chosen to resemble as closely as possible the calculated equilibrium geometry of Ni[C_2H_2] (Sect. 4.E). The vibrational frequencies and moments of inertia used in the RRKM calculations are given in Appendix B. In Table 3, the parameters $g^{\ddagger}$ and ΔE_0^0 are given for calculations using models I and II for the propyne and 2-butyne reactions. The fits to the data shown in Figs. 4 and 5 were obtained using model II in both cases.

The relationship between the parameter $g^{\ddagger}$ and the apparent value of the high-pressure rate constant, $k_{r\infty}$ in Table 3, is as follows: $k_{r\infty} = g^{\ddagger} \times k_{\infty}$, where k_{∞} is the high-pressure rate constant for reaction only on the ground state potential surface. As noted in the previous section, k_{∞} was calculated assuming a loose transition state, and is therefore given approximately by a capture rate multiplied by the ratio of electronic partition functions of the complex and separated reactants. The capture rate may be estimated in a straightforward manner form the polarizabilities of Ni and the alkyne reactant (9). In the RRKM calculations, this capture rate was approximately reproduced as the variationally minimized rate constant (26) for the specified long-range potential. Details are given in Appendix B.

4.D. Binding energies

There are several sources of uncertainty in the binding energies of the Ni[alkyne] complexes obtained by modeling the kinetic data using RRKM calculations. In the first place there are uncertainties in the details of the molecular models, including particularly the vibrational frequencies. This is illustrated by the differing binding energies obtained by using models I and II for the propyne and 2-butyne reactions, as shown in Table 3. The model I and model II results are seen to differ by $\approx$6 kcal mol^{-1} in both cases. From these results it is estimated that there is an error of at least $\pm$3 kcal mol^{-1} in the binding energies of these complexes due to uncertainty in the molecular models. The situation is different for the Ni[C_2H_2] complex, because in this case there are available theoretical predictions of vibrational frequencies, and, as discussed in Sect. 4.E, the predicted frequencies are in excellent agreement with experimental data from matrix-isolation studies. An estimate of the associated uncertainty in the binding energy may nevertheless be made by allowing for a systematic error of $\pm$5% in all calculated frequencies. This would lead to an error of $\pm$2 kcal mol^{-1} in the binding energy for Ni[C_2H_2].

Even in the case where structural parameters and vibrational frequencies of the Ni[alkyne] complexes are accurately known, the RRKM calculations may lead to incorrect binding energies because of insufficient knowledge or limitations of the method of calculation of other factors, including particularly collisional energy transfer parameters. We assume that the fundamental assumptions of RRKM theory are valid for the reactions considered. Evidence in support of this assumption for the case of the Ni + C_2H_4 association reaction has been described elsewhere (9). The most significant limitation of the method of calculation is thought to be associated with the collision efficiency factor β_c. This is because the low-pressure rate constant k_{r0} is directly proportional to β_c, and there are no well-established methods for the calculation of this quantity (26). It may be noted, however, that the calculated collision efficiency factors for CO_2 buffer gas, $\beta_c \approx 0.4$ (see Appendix B), appear reasonable in comparison with many studies of unimolecular reactions (26). For the purpose of error estimation, we have assumed that the methods used are capable of calculating k_{r0} to within a factor of 2 (26). This corresponds to contributions to the uncertainties in the estimated binding energies of approximately $\pm$5, $\pm$3, and $\pm$2 kcal mol^{-1}, for the complexes with ethyne, propyne, and 2-butyne, respectively.

As noted in the previous section, the parameters ΔE_0^0 and $g^{\ddagger}$ obtained from the fits to the data are to some extent correlated. In addition, there are uncertainties and scatter in the data, and both of these effects contribute to the uncertainty in the binding energies. By performing fits to the data of the type illustrated in Fig. 6, these contributions have been estimated as $\pm$1, $\pm$3, and $\pm$3 kcal mol^{-1}, for the complexes with ethyne, propyne, and 2-butyne, respectively. An additional source of uncertainty is due to the involvement of excited electronic states of the complexes in the association reactions, and their possible contributions to the low-pressure rate constants. It was noted in Sect. 4.B that, if the excited states are much less strongly bound than the ground state, then these contributions are expected to be negligible, even though the effect on the *high*-pressure rate constant may be large. The theoretical results in Sect. 4.E indicate that the assumption of relatively weakly bound excited states is justified. RRKM calculations were performed using simple models for the triplet states of the complexes, based on the theoretical results in Sect. 4.E. For triplet state binding energies as high as 16 kcal mol^{-1}, the contributions to the observed low-pressure rate constants were found to be negligible. It therefore appears reasonable to disregard this source of uncertainty in the binding energies. If this were not justified, then the estimated binding energies would tend to be too high. By propagating the above-mentioned estimates of relative uncertainties, and considering the results in Table 3, the following estimates of binding energies were obtained: $\Delta E_0^0 = 46 \pm 6$, 37 ± 5, and 29 ± 5 kcal mol^{-1}, for Ni[C_2H_2], Ni[propyne], and Ni[2-butyne], respectively.

Our results therefore show a distinct trend to lower binding energy of the Ni[alkyne] complex with methyl substitution on ethyne. This trend can be understood in terms of the inductive effect of the methyl group in the free ligand molecule. In propyne and 2-butyne the methyl groups are electropositive (29), and cause a buildup of electronic charge on the unsaturated carbon atoms, relative to the charges for ethyne. This results in a destabilization of the highest occupied (π-bonding) molecular orbital and a pronounced drop in the ionization potential (eV) (30): ethyne (11.41), propyne (10.36), and 2-butyne (9.56). A similar destabilization is thought to occur for the π^*-antibonding molecular orbitals, and accounts for the near constancy of the experimentally observed $\pi \rightarrow \pi^*$ valence state transition energies among the simple alkynes (31). According to the description of the bonding mechanism of Ni[C_2H_2] discussed in the following section, an important component of the bond arises from a transfer of charge from a *d*-orbital on nickel to the π^*-orbital of ethyne. Such a transfer of charge should be relatively disfavored for propyne, and more so for 2-butyne, because of the polarization of electronic charge in the alkyne due to the inductive effect of the methyl group.

It is interesting to note that the trend in the binding energies of the Ni–alkyne complexes is opposite to the trend found for the corresponding Cu–alkyne complexes (32). Thus, the binding energies of the copper complexes increase with methyl substitution on ethyne. Note, however, that the copper complexes are much less strongly bound ($\approx$8 kcal mol^{-1}) (32). The weaker binding correlates with a reduced importance

[a]The experimental bond distances are R(CC) = 1.203 Å and R(CH) = 1.060 Å, see ref. 36.
[b]The calculated energies for the nickel atom in its triplet $3d^9 4s$ ground state are −1505.35327 (LSD) and −1508.25429 (BP).

of metal→ligand backdonation of electronic charge compared to the nickel complexes. This is shown by the trend in binding energies with methyl substitution, and also by the shifts of the CC stretching frequencies (cm^{-1}) in the infrared spectra of matrix-isolated Ni[C_2H_2] ($\Delta\omega \approx -330$) and Cu[$C_2H_2$] ($\Delta\omega \approx -100$) complexes (4), relative to the frequency for the free ethyne ligand.

4.E. Calculated properties of Ni[C_2H_2]

The ground state of Ni[C_2H_2] is a singlet ($^1A_1$) with C_{2v} geometry. The calculated binding energies for this singlet are 71 kcal mol^{-1} (LSD), 46 kcal mol^{-1} (BP/LSD), and 46 kcal mol^{-1} (BP). It is not easy to make an empirical estimate of the true binding energy on the basis of BP/LSD calculations. The BP/LSD scheme overestimates the true binding energies of Cr[CO], Ni[CO], and Cu[CO] by about 12 kcal mol^{-1}. On the other hand, BP/LSD bond energies for Cu_2 (33), $(CO)_5Cr$–CO and $(CO)_3Ni$–CO (19), and for many organic molecules (34) are within 4 kcal mol^{-1} of the experimental values. We think that comparisons of BP/LSD calculations with experiments for metal–ligand complexes are too few to establish a clear trend in the accuracy of BP/LSD bond energies for these systems. Empirical evidence from previous BP/LSD calculations only suggests that BP/LSD dissociation energies of metal–ligand complexes can either overestimate the true value (by up to 15 kcal mol^{-1}) or be very close to it, but that it probably does not underestimate it.

TABLE 5. Harmonic frequencies for five isotopomers of C_2H_2 obtained from density functional (BP) calculations and from analysis of experimental data. The numbers in parentheses are the calculated infrared intensities (km/mol)

[a]See ref. 35.
[b]The harmonic frequencies calculated by the LSD method for HCCH are 561, 718, 2032, 3337, and 3438 cm^{-1}.

The geometry of the ethyne ligand relaxes upon bonding to nickel (see Table 4). As expected, the CC bond length increases (by 0.08 Å), the CH bond length remains almost unchanged, and the CH bonds move out of the CC axis and away from the nickel atom (by 29°). A LCGTO–DF–(BP/LSD) calculation shows that this distortion on the isolated ethyne molecule increases its energy by 16 kcal mol^{-1}.

The lowest triplet state ($^3A''$) is bound but is much less stable, the binding energies being 33 kcal mol^{-1} (LSD), 14 kcal mol^{-1} (BP/LSD), and 14 kcal mol^{-1} (BP). The equilibrium geometry of this triplet is planar but only has C_s symmetry, one of the nickel–carbon interatomic distances being about 0.15 Å larger than the other.[3] The Kohn–Sham orbital energies suggest that there may be two other triplet states stable relative to

[3]In their study of triplet nickel–ethene, Pápai et al. (ref. 10) found that the equilibrium geometry is sensitive to the accuracy of the integration grid. Our present optimized geometry for the triplet state of nickel–ethyne may not be very precise, but there is little doubt that it has C_s symmetry.

TABLE 6. Harmonic frequencies (cm^{-1}) and infrared intensities (km/mol, in parentheses) calculated with gradient corrections (BP) for five isotopomers of NiC_2H_2 in the singlet ground state; assigned observed fundamentals are shown in brackets below the corresponding calculated values

[a]Abbreviations used: asy = asymmetric, sym = symmetric, s = stretch, b = bend, ip = in-plane, op = out-of-plane. The description of the modes refers to NiC_2H_2 but also applies fairly well to the other four isotopomers. When a mode has important contributions from two internal coordinates, the most important contributor is given first.

[b]For NiC_2DH the description of some normal modes differs from that in the four other cases. The descriptions are as follows:

479 cm^{-1}: NiC_D stretch, where C_D is the carbon atom bonded to deuterium.
496 cm^{-1}: NiC asymmetric stretch with some CD out-of-plane bend.
575 cm^{-1}: NiC_H stretch, where C_H is the carbon atom bonded to hydrogen.
618 cm^{-1}: CH out-of-plane bend.
687 cm^{-1}: CD in-plane bend.
816 cm^{-1}: CH in-plane bend.
1592, 2396, 3197: similar to the other isotopomers with H changed to D where appropriate.

[c]Experimental frequencies are taken from ref. 4.

[d]In agreement with Kline et al., we think that this band and the one at 1590.7 cm^{-1} arise from the combination of the fundamental of the CC stretch and first overtone of the CH asymmetric in-plane bend.

dissociation and having approximate BP binding energies of 11 and 2 kcal mol^{-1}.

Since vibrational frequencies are key quantities in the RRKM modeling, it is important to assess the reliability of the frequencies we calculated. A detailed comparison of frequencies calculated by the LCGTO–DF method with experiment has been done for the nickel–ethene complex (10). It showed that the LCGTO–DF frequencies of $Ni[C_2H_4]$ are within a few percent of experimental values and that IR intensities, while in error by typically 40%, are accurate enough to help assign IR spectra.

In Table 5 we show our calculated harmonic frequencies for five isotopomers of ethyne and a set of harmonic frequencies deduced from experimental data (35). The calculated frequencies and intensities for HCCH are qualitatively correct. The average percent error on the calculated frequencies is only 3.8% and most of this error comes from the lowest CCH bending mode. The isotopic shifts are also qualitatively correct but the error for the two lowest frequency modes of HCCD is about 25%. The CC stretch frequency and all its isotopic shifts are remarkably well reproduced by the calculations. The CH stretches and isotopic shifts are very good. Not unexpectedly, the largest errors occur for the two relatively low-frequency bending modes. If we compare our calculated frequencies with the experimental fundamentals (36) instead, the overall agreement for HCCH is just as good while the agreement for the isotopic shifts deteriorates slightly.

Now we compare our calculated frequencies for the nickel–ethyne complex to the infrared bands observed by Kline et al. in a matrix isolation study (4). Note that Kline et al. observed groups of closely spaced lines instead of sharp lines, possibly due to interaction with the matrix. In our table we show only the average value of the close-lying lines seen in the experiment. In Table 6 we list the calculated harmonic frequencies and IR intensities (in parentheses); the positions of the bands observed by Kline et al. are shown in square brackets underneath the calculated ones. There are two differences between our assignment and the one given in ref. 4. First, we assign the 657 cm^{-1} band in $Ni[C_2H_2]$ (and related bands in the other isotopomers) to a CH symmetric out-of-plane bend, not to a CH in-plane bend. Second, we do not find a mode in $Ni[C_2H_2]$ with wavenumber near 730 cm^{-1} and appreciable intensity (the CH symmetric in-plane bend has near-zero intensity) and therefore we tentatively assign this band (and the related ones in other isotopomers) to the intense CH bend of unreacted ethyne. With the exception of the calculated 618 cm^{-1} band of NiC_2HD, we find observed bands corresponding to each of the modes with calculated frequency larger than 500 cm^{-1} and intensity larger than 10 km mol^{-1}. Conversely, we can relate almost every group of observed bands to calculated fre-

quencies with appreciable intensity. Overall, the agreement between calculated and observed wavenumbers is excellent, but one should bear in mind that the harmonic approximation may partly cancel other sources of error. The important point, however, is that calculated frequencies are qualitatively correct and within a few percent of the observed values. Moreover, if the assignments are correct, the frequency shifts with isotopic substitutions are typically within 10 or 20% of those observed.

In Table 7 we list the set of frequencies and infrared intensities for the singlet and triplet states calculated with the LSD and BP methods. Similar to what was found for nickel–ethene (10), the bands are generally more intense in the triplet state than in the singlet ground state. Adding gradient corrections to the exchange-correlation has a modest effect on the harmonic frequencies although the lower frequencies usually decrease by a few percent. If we ignore the low-intensity modes, for which the calculated values are not very reliable, the effect of gradient corrections on intensities in the singlet state is small. In the triplet state, the effect of gradient corrections on the intensity of the two nickel–carbon stretches is large. Although the LSD and BP equilibrium geometries differ significantly, the BP/LSD and BP binding energies are within 1 kcal mol^{-1} of each other.

The bonding in singlet $Ni[C_2H_2]$ is mostly due to a donation–backdonation mechanism involving the bonding and antibonding π orbitals of ethyne in the plane of the complex and a nickel d orbital. The number of electrons donated to the metal (n_D) and backdonated to the ligand (n_B) are essentially identical to those found for the nickel–ethene complex: $n_D \approx 0.28$ and $n_B \approx 0.56$. The orbital energy differences between the predominantly CC π bonding orbital with nickel d admixture and the predominantly nickel d orbital with CC π^*-antibonding admixture are also very similar: 1.69 eV for the nickel–ethyne complex and 1.78 eV for nickel–ethene. It is not easy to rationalize the somewhat larger binding energy of nickel–ethyne compared to nickel–ethene (the calculated values are 46 and 40 kcal mol^{-1}, respectively, see ref. 10) on the basis of the calculations. The bonding mechanism and extent of donation and backdonation are similar in the two complexes. One factor does clearly favor a sightly larger binding energy in nickel–ethyne: the mixing of the nickel $4p_y$ orbital into the out-of-plane ethyne π bonding orbital. The Mulliken population of the nickel $4p_y$ orbital is 0.08 in $Ni[C_2H_2]$ whereas it is zero in $Ni[C_2H_4]$ since it cannot mix effectively with any orbital of ethene.

The bond order for each of the nickel–carbon bonds is 0.90 while the CC bond order is decreased from its value of 2.96 in ethyne to 1.76. The decrease in CC bond strength is mostly due to π backdonation from the d_{xz} orbital of nickel into the in-plane $C(2p_z)$—$C(2p_z)$ π^*-antibonding orbital of ethyne.

The three lowest energy valence orbitals of the complex are essentially unperturbed orbitals of ethyne, the CC $2s$ σ-bonding orbital and two CH bond orbitals. The next two lowest are the bonding π orbitals of ethyne with roughly 15% admixtures of nickel s and d_{zz} orbitals (for the in-plane, orbital energy $\epsilon = -8.3$ eV) and nickel d_{yz} and $4p_y$ (for the out-of-plane, $\epsilon = -7.8$ eV). These two orbitals are less CC bonding than in ethyne and are bonding between the nickel and carbon atoms. The next orbital ($\epsilon = -6.6$ eV) has 70% nickel d_{xz} character and 25% CC in-plane antibonding π character. It contributes to the nickel–carbon bond and weakens the carbon–carbon bond. The next three orbitals, with energies −5.0, −4.7, and −4.4 eV, are essentially nonbonding nickel d orbitals with some nickel $4s$ character. The next orbital, which is the HOMO, has energy −4.2 eV and is roughly 80% nickel d_{yz} with a 20% contribution from the ethyne out-of-plane π-bonding orbital: it is antibonding between nickel and carbon. The LUMO has an energy of −2.7 eV and is an *spd* hybrid centered almost entirely on the nickel atom.

[a]See footnote to Table 6 for the meaning of the abbreviations.

[b]C_2 is the carbon atom furthest from the nickel atom, C_1 is the nearest.

The bonding in the triplet state differs from the above description. Although the triplet is much less stable than the singlet, the sum of the two nickel–carbon bond orders is 1.89, compared to 1.80 for the singlet state. The nickel $4p$ population is 0.27 (it is 0.11 in the singlet) most of which is in the majority spin HOMO orbital, an *spd* hybrid on nickel with some ethyne π^* character. This hybrid orbital is centred mostly on nickel and points away from the carbon atom furthest from it. This polarization of the nickel atom offsets the partial atomic charges and, as a result, the dipole moment in the triplet has its positive end pointing toward the carbon atom furthest from nickel. This is contrary to the singlet state in which the dipole moment is "normal" (the positive end is on the nickel atom). These characteristics show that the smaller binding energy of the triplet can be attributed to a larger repulsion of the nickel $4s$ orbital with the in-plane π orbital of ethyne. In the singlet state, hybridization of the nickel s and d orbitals reduces this repulsive interaction. This mechanism is not possible in the triplet state and, instead, the $4s$ orbital of nickel is hybridized with the $4p$ orbital. This is reminiscent of the situation in NiCO (37) and, more generally, in high-spin transition metal

monocarbonyls (22). The C_{2v} to C_s distortion in going from the singlet to the triplet state of nickel–ethyne can also be put in parallel with the linear and bent geometries of low-spin and high-spin transition metal monocarbonyls (22). It is tempting to invoke the same explanation, namely, the decrease in σ repulsion upon "bending". Finally, the energy differences between the singlet and triplet states of nickel–ethyne and nickel–carbonyl complexes are also similar: 32 and 36 kcal mol^{-1}, respectively.

5. Conclusion

Nickel atoms form strongly bound π complexes with simple alkynes. Kinetic studies show that there is no activation energy for bond formation, and indicate that both the ground state and one or more excited electronic states of the complex take part in the association reaction. The binding energies of Ni[C_2H_2], Ni[propyne], and Ni[2-butyne] have been estimated by using unimolecular reaction theory to model kinetic data for the association reactions. There is a distinct trend to lower binding energy with methyl substitution on ethyne. This trend is opposite to the one found in previous work on copper–alkyne complexes, and has been explained by considering the influence of the inductive effect of the methyl group on the extent of metal→ligand backdonation in the complex. Quantum chemical calculations using a LCGTO–DF method indicate that the electronic structure of Ni[C_2H_2] is very similar to that of Ni[CO] and Ni[C_2H_4]. This is consistent with experimental results that show these complexes have similar binding energies. Harmonic vibrational frequencies calculated using the LCGTO–DF method for the $^1A_1$ ground state of Ni[C_2H_2] in several isotopic variants are in good agreement with fundamental frequencies observed in the infrared spectra of matrix-isolated Ni[C_2H_2]. When the calculated equilibrium structure and vibrational frequencies of Ni[C_2H_2] are used in the unimolecular reaction theory calculations to estimate the binding energy of Ni[C_2H_2] from kinetic data, there is excellent agreement between the experimental estimate and the theoretically predicted binding energy.

Appendix A: Basis sets

The orbital basis set used for nickel was devised by Godbout et al. (42) and those for carbon and hydrogen are essentially those given in ref. 43. The exponents and coefficients for orbital basis sets are given below in the format: ("exponent 1 of function 1": "coefficient 1 of function 1"; "exponent 2 of function 1"...), ("exponent 1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12

Appendix B: Details of RRKM calculations

Program and options

All calculations were performed using the UNIMOL suite of FORTRAN programs (26). The calculations included angular momentum conservation in the falloff region. The intermolecular potential for the buffer gas CO_2 and Ni[alkyne] complex was specified by Lennard–Jones parameters σ and ϵ. These were estimated by using the methods described by Gilbert and Smith (26), taking 16.3 Å^3 as the additive volume increment associated with Ni, and taking the ϵ associated with Ni[alkyne] to be the same as the value estimated for the alkyne by using the boiling point of the alkyne. This led to σ/Å = 4.50, 4.75, and 4.97, and ϵ/K = 177, 213, and 233, for the reactions with C_2H_2, propyne, and 2-butyne, respectively. Weak collision effects were included by running the MASTER segment of the program, using the exponential-down form of the energy transfer distribution function, and taking 500 cm^{-1} as the average downward energy transfer. This led to calculated values of the collision efficiency $\beta_c \cong 0.49$, 0.40, and 0.37, for the reactions with C_2H_2, propyne, and 2-butyne, respectively.

Vibrational frequencies (cm^{-1}) and moments of inertia (amu Å^2)

High-pressure rate constants

The transition states for the association reactions were taken to be in the phase space limit, with unperturbed ligand molecules undergoing free rotation at a distance of ≈6 Å from the nickel atom. The parameter used to describe the Morse potential for the metal–ligand interaction was adjusted in such a way that the variationally minimized high-pressure rate constant for the association reaction (not including electronic degeneracy factors) was in approximate agreement with a capture rate estimated from the C_6 parameter for the Ni–alkyne interaction. C_6 parameters were estimated (39) from the polarizabilities (Å^3) of Ni (7.9) (40), C_2H_2 (3.4) (39), propyne (5.6) (39), and 2-butyne (7.4) (41). These values led to capture rate constants of $\approx 7 \times 10^{-10}$ cm^3 s^{-1} for all reactions.

Electron spin resonance study of the reaction of hydrogen atoms with methane

PAUL-MARIE MARQUAIRE,[1] ASHOK GHOSE DASTIDAR, KIM C. MANTHORNE, AND PHILIP D. PACEY[2]

Department of Chemistry, Dalhousie University, Halifax, NS B3H 4J3, Canada

Received July 12, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

PAUL-MARIE MARQUAIRE, ASHOK GHOSE DASTIDAR, KIM C. MANTHORNE, and PHILIP D. PACEY. Can. J. Chem. **72**, 600 (1994).

The reaction: $H + CH_4 \rightarrow CH_3 + H_2$ has been investigated in a flow system between 348 and 421 K. Hydrogen atoms were generated in a microwave discharge, introduced to the reactor through a movable injector, and monitored by electron spin resonance. After an initial decay attributed to reaction with impurity, the hydrogen atom concentration decayed in a pseudo-first-order manner. Ethane was detected by gas chromatography, consistent with its formation by the following reaction: $2CH_3 \rightarrow C_2H_6$. The amount of ethane formed at 421 K was only 0.015 times the amount of hydrogen atoms reacting. Most methyl radicals were assumed to have been removed by the process: $H + CH_3 + M \rightarrow CH_4 + M$. Because of this process, two hydrogen atoms were removed each time the title reaction occurred. Applying this stoichiometric factor, the rate constant for the elementary reaction was calculated to be 2.5×10^3 L mol^{-1} s^{-1} at 348 K, increasing to 2.0×10^4 L mol^{-1} s^{-1} at 421 K. Most of the previous discrepancy between kinetics and thermochemistry has been eliminated; the exothermicity at 0 K was reduced to 0.8 ± 0.4 kJ mol^{-1}, which corresponds to a standard heat of formation of the methyl radical of 145 kJ mol^{-1}. Properties of the activation barrier have been inferred from the experimental data with the aid of transition state theory. The fitted barrier height was 63 ± 1 kJ mol^{-1}, the average of five low-frequency vibrational term values was 640 ± 30 cm^{-1}, and the characteristic tunnelling temperature was 500 ± 30 K.

PAUL-MARIE MARQUAIRE, ASHOK GHOSE DASTIDAR, KIM C. MANTHORNE et PHILIP D. PACEY. Can. J. Chem. **72**, 600 (1994).

Opérant dans un système à écoulement, à des températures allant de 348 à 421 K, on a étudié la réaction : $H + CH_4 \rightarrow CH_3 + H_2$. On a généré les atomes d'hydrogène par une décharge microonde, introduite dans le réacteur par une injecteur mobile et on les a suivis par résonance paramagnétique électronique. Après une décroissance initiale attribuée à une réaction avec une impureté, la concentration des atomes d'hydrogène diminue en suivant un pseudo-ordre un. La chromatographie gazeuse nous a permis de détecter la présence d'éthane qui se formerait par la réaction : $2CH_3 \rightarrow C_2H_6$. La quantité d'éthane qui se forme à 421 K ne correspond qu'à 0,015 fois la quantité d'atomes d'hydrogène qui réagit. On fait l'hypothèse que la plupart des radicaux méthyles sont éliminés par le processus : $H + CH_3 + M \rightarrow CH_4 + M$. Par ce processus, deux atomes d'hydrogène sont enlevés chaque fois que la première réaction se produit. En appliquant ce facteur stoechiométrique, on a pu calculer que la constante de vitesse pour la réaction élémentaire est égale à $2,5 \times 10^3$ L mol^{-1} s^{-1}, à 348 K, et qu'elle augmente jusqu'à $2,0 \times 10^4$ L mol^{-1} s^{-1}, à 421 K. On a ainsi éliminé les anciennes divergences entre la cinétique et la thermochimie; l'exothermicité à 0 K est réduite à $0,8 \pm 0,4$ kJ mol^{-1}, ce qui correspond à une chaleur de formation standard du radical méthyle de 145 kJ mol^{-1}. On a déduit les propriétés de la barrière d'activation à partir des données expérimentales et en faisant appel à la théorie de l'état de transition. La hauteur ajustée de la barrière est de 63 ± 1 kJ mol^{-1}, la moyenne de cinq valeurs pour des termes vibrationnels de basse fréquénce est de 640 ± 30 cm^{-1} et la température caractéristique de l'effet tunnel est de 500 ± 30 K.

[Traduit par la rédaction]

Introduction

The reaction

$$[1, -1] \quad H + CH_4 \rightleftarrows H_2 + CH_3$$

is important in combustion and is reasonably simple to treat theoretically. However, the reaction is controversial because the ratio of forward and reverse rate constants disagrees with the equilibrium constant calculated from accepted thermodynamic parameters (1–6). The discrepancy is a factor of six in the rate constant ratio at 372 K, or 5 kJ mol^{-1} in the enthalpy of reaction. Both the forward and reverse reactions have been studied repeatedly with no resolution to this problem. Most studies of the forward reaction at low temperature, where the disagreement with thermochemistry is clearest, have employed the flow discharge technique (7–12). Some results are presented in Table 1. However, there has been disagreement regarding the stoichiometry of the system. Some authors (8–10) assumed that hydrogen atoms were removed only by reaction [1]. Others (7) assumed reaction [1] was always followed by reaction [2]:

TABLE 1. Rate constants from the literature in the present experimental temperature range

Kurylo and Timmons (9)	426	4–8

$$[2] \quad H + CH_3 + M \rightarrow CH_4 + M$$

In this article we report results of a new flow discharge study in which we attempt to address the issues above. To study the stoichiometry, we have determined absolute hydrogen atom concentrations by electron spin resonance spectrometry (ESR) and have measured the rate of ethane formation by gas chromatography. We have simulated the system by computer using recent values (13–15) of the rate constant for reaction [2] and for other secondary reactions.

Experimental

The apparatus and experimental procedure were similar to those used for an earlier study of the reaction of H with D_2(16). Methane (Linde,

[a]The first entry in this column was obtained by the method of ref. 18; the second by a fit to eq. [5].

UHP, 99.9%, or Matheson Research, 99.99%), helium (Atlantic Oxygen Ltd., 99.996%), and hydrogen (Atlantic Oxygen Ltd., 99.99%) flowed through traps packed with molecular sieve (5 Å, 80–100 mesh) to ballast bulbs of known volumes and then to needle valves or MKS 1159B mass flow controllers. The flow rates could be determined by cutting off the flow to a bulb and observing the rate of pressure decrease with a Bell and Howell (model CEC1000) pressure transducer. The helium and hydrogen then passed through the cavity of a microwave generator (Microtron 200, Electro-Medical Supplies) and along a 7 mm o.d., cylindrical quartz injector into the reactor. The interiors of the injector and the reactor had been coated with Teflon liquid (Dupont 856-200). Above 390 K the surface rate constant on Teflon was found to increase and phosphoric acid was used in the hot part of the reactor and Teflon in the ESR cavity. The injector could be moved along the axis of the 22-mm i.d., cylindrical Pyrex reactor by passing through an o-ring seal. A 70 cm length of the reactor was surrounded by an insulated jacket connected to an external thermostatted circulating bath (Lauda, RCS-6). Two Cu–constantan thermocouples were located in wells in the jacket for temperature measurements. For experiments at 421 K the insulated jacket was replaced by an 80 cm long, 3 cm o.d. copper pipe, wrapped with mullite paper and with nichrome heating ribbon. Methane or the blank gas, He, was introduced at the upstream end of the reactor. At the downstream end was an E-235 large-access, cylindrical cavity, part of a Varian E-1096, X-band spectrometer, followed by a connection for withdrawing samples for gas chromatographic analysis, an MKS (Baratron 122AA) pressure transducer, and an MKS (model 248A) exhaust control valve, controlled by an Omega (CN-2000) pressure controller.

The experimental procedure involved setting the CH_4 and blank gas flow rates to equal values and setting the pressure controller to the desired reactor pressure. The H atom peak at 2921 G was traced with the injector at the upstream end of the jacket, first with the blank gas flowing and then with CH_4 flowing. The injector was moved successively along the reactor and sets of peaks were recorded.

The ESR spectrometer and cavity were calibrated by tracing the F and G peaks in the spectrum of O_2 with instrument settings like those in a kinetic experiment but with a measured pressure of air in the cavity. Provided the air pressure was below 3 Torr (1 Torr = 133.3 Pa), the O_2 peaks were well resolved and gave consistent calibrations. The procedure of Westenberg (17) was then used to translate measured first moments of hydrogen atom peaks to absolute concentrations of hydrogen atoms. Both O_2 and H peaks were traced at a number of instrument settings to check that the response was linear. Hydrogen atom peak widths were independent of concentration, enabling peak heights to be used for routine kinetic analysis.

Gas chromatographic analysis was performed using a 1.7 m silica gel column at 25°C with flame ionization detection.

Results

Experimental conditions are listed in Table 2. The upper limit on the pressure was set by the need to maintain low pressures and fast flow in the discharge to provide measurable hydrogen atom concentrations. The lower limit was set by the need to keep the gas phase reaction substantially greater than the wall reaction. In all cases the wall rate constant, k_3, was found from a plot of $\ln[H]_0$ against time (18). Calculation of k_1 will be described in the Discussion.

$$[3] \quad H \rightarrow \tfrac{1}{2}H_2$$

Figure 1 shows the results of two experiments at 421 K. Plotted horizontally are the residence times of the atoms in contact with methane in the hot zone of the reactor, calculated as the distance from the tip of the injector to the downstream end of the jacket or furnace, divided by the flow velocity, v. Plotted vertically is the natural logarithm of the hydrogen atom concentration observed in the ESR cavity. The points on the left-hand axis (at $t = 0$) correspond to replacement of the reactant, methane, by helium. It can be seen that at times less than about 0.2 s, the hydrogen atom concentration dropped sharply with increasing time. After about 0.2 s, the peaks fell more gradually with increasing residence time. The slopes depended on the concentration of methane in the system. At lower temperatures, there

0.37	42	5.7	0.015
0.49	32	5.9	0.015
0	685	0	
0.59	13	8.4	0.013

was again a sharp drop between the point on the left-hand axis in plots like Fig. 1 and subsequent points, but there was usually no detectable curvature among the latter points.

Table 3 gives a comparison of the decline in hydrogen atom concentration with the increase in ethane concentration as the residence time increased in two experiments at 421 K. The initial hydrogen atom concentration, $[H]_0$, was about 60% greater in the second experiment. The ethane yields were much smaller than the decreases in hydrogen atom concentrations. The average ratio was 0.015. At lower temperatures the amounts of ethane produced were so small they could not be detected.

The ESR spectrum (17) of the oxygen atom was detected at 4262 G when no methane was flowing in the system. The peak corresponded to a concentration of oxygen atoms one-tenth the concentration of hydrogen atoms.

Discussion

There are two experimental observations that require explanations before we may interpret the results.

Stoichiometry

The first observation is the measurement of ethane yields only 0.015 times as great as the loss of hydrogen atoms. Each ethane molecule formed resulted from the removal of two radicals:

[4] $2CH_3 \rightarrow C_2H_6$

Thus, from the experimental data in Table 3 it may be concluded that reaction [4] removed methyl radicals 0.03 times as often as hydrogen atoms were removed by all processes. In three earlier studies (8–10) it was assumed that methyl radicals formed in reaction [1] would always recombine by reaction [4]. If this were true, ethane yields would be half the loss of hydrogen atoms, 30 times greater than we observed. Except for possible surface reactions, these studies equated the rate of removal of H with the rate of reaction [1]. In other words, the stoichiometric factor was assumed to be unity. In ref. 7, on the other hand, it was assumed that ethane formation by reaction [4] did not occur and that reaction [1] was always followed by reaction [2]. In this case the rate of removal of H would be twice the rate of reaction [1] and the stoichiometric coefficient would be two. At temperatures below 400 K we were unable to detect ethane peaks, in agreement with this assumption. From our experiments at 421 K in Table 3, with an ethane yield 0.03 times as great as expected under the first assumption, the stoichiometric coefficient is calculated to be 1.97. Sepehrad et al. (11) found final ethane yields at 640–818 K that were between 0.003 and 0.32 times their decreases in hydrogen atom concentrations.

Initial decay

The second observation requiring explanation is the curvature of plots, like those in Fig. 1, of logarithm of concentration vs. time. The experiments were designed to have three orders of magnitude more CH_4 than H, so that [H] was expected to decline in a pseudo-first-order fashion, giving a linear plot of ln[H] versus time.

A possible explanation would be parallel removal of hydrogen atoms by two different reactants, one of which was depleted before the other. One such reactant would be methane, and another could be an impurity in the methane. The olefins are the only group of known impurities that could react rapidly enough to affect the kinetics (19). However, the stated impurity content of the research grade methane was less than 1 ppm of C_2H_4 and less than 2 ppm of C_3H_6; these amounts would be insufficient to account for the observed initial decrease in H atom concentration. We have confirmed by gas chromatographic analysis that these impurities were undetectable at the 1 ppm level in both grades of methane used. However, Kurylo et al. (9, 10) used only 99.5% pure methane (20), so olefin impurities may have affected their results.

Another possible source of impurity is the gases flowing in the injector tube. The oxygen atoms observed may have resulted from oxygen or water in the helium. These atoms react with methane an order of magnitude faster than hydrogen atoms (4, 21), by the mechanism in Table 4. The methyl and formyl radicals and formaldehyde formed by attack of O atoms and OH radicals would act as apparent impurities in the methane, removing hydrogen atoms by several rapid reactions. The mechanism in Table 4 was simulated on a VAX 8800 computer by numerical integration of the differential equations for the rates of formation and removal of all the species listed. Results of integrations by the Euler, Runge–Kutta, and Gear methods (22) agreed with each other within 1%, provided suitable convergence limits were used. Rate constants were taken from recent compilations (4, 21) or from a fit to experimental data (14). For reaction [2], CH_4 was assumed to be an equally effective third body as C_2H_6. The limiting high-pressure rate con-

stant was used for reaction [4] because compilations indicate there is little pressure dependence in the present conditions (6). The concentrations and temperature employed in the calculations for Table 4 corresponded to the second and fourth lines of Table 3 and to the second and eighth points in the upper curve in Fig. 1. The initial oxygen atom concentration was adjusted to roughly fit the figure. The O atom concentration was predicted to fall by three orders of magnitude between the first and second points on the curve and continue to decline in a first-order manner. In addition to reactions [1] and [2], hydrogen atoms were calculated to be removed significantly by four reactions with CH_2O, CHO, and CH_3O. The reaction of H with C_2H_6 was not included because its rate was only about 1% of the rate of reaction [4]. At the shorter residence time, the stoichiometric coefficient, $(-d[H]/dt)/R_1$, was 4.06, explaining the steep slope observed at this point in Fig. 1. By 0.49 s the stoichiometric factor was calculated to be only 2.26, close to the value of 1.97 estimated from ethane yields in the first part of the Discussion. The quotient, $[C_2H_6]/([H]_0 - [H])$ was estimated to have values of 0.007 and 0.011, somewhat less than the experimental values of 0.016 and 0.015. This is reasonable agreement, considering that k_2 is uncertain by a factor of two and that other rate constants have similar uncertainties.

There is a possibility that radical–radical reactions could occur in the cool zone between the end of the heated reactor and the ESR cavity or sample bulb. Based on the simulation described above, we estimate that such reactions should only affect measured concentrations by about 1%.

We have employed two methods to extract the rate constant for reaction [1] from data like those in Fig. 1.

The simplest method involved dropping the point on the vertical axis, obtained from experiments with blank gas flowing, as well as the next point, if this point were clearly above the line formed by the remaining points. The slope of this line was then taken, k_3 was subtracted, and the resulting apparent first-order rate constant was divided by $[CH_4]$ and by the stoichiometric coefficient of two. This method was based on that recommended by Westenberg and de Haas (18) and involves the assumption that k_3 is not affected when He is replaced by CH_4/He mixtures. The results are the first entries in the final column of Table 2.

We have also fitted a biexponential decay equation to the experimental data by nonlinear least squares (23).

$$[5] \quad [H] = A \exp(-at) + B \exp(-bt)$$

The slower decay constant, a, was reduced by k_3, and was then divided by two and by $[CH_4]$ and equated to the rate constant, k_1. The results are the second entries in the final column of Table 2. The faster decay constant, b, corresponded to the rapid initial drop in [H]. The sum, $A + B$, was equated to the initial concentration, $[H]_0$, but the ratio, B/A, was treated as a third variable parameter. Two results of these fits are shown as the smooth curves in Fig. 1.

In most cases values obtained by the two techniques in Table 2 were in good agreement. The cases where the first value exceeded the second involved the two curved plots in Fig. 1. The values obtained at identical temperatures but otherwise differing conditions also agreed well, as seen in Table 2. The biexponential decay expression was considered to allow for the initial decay in a more consistent and objective manner, so values obtained in this way were used to obtain the averages quoted.

The present results at 421 K are a factor of eight slower than

the results reported in ref. 10 at 424 K. The difference is due partly to the stoichiometric factor of two. There was also a clear trend in the results in ref. 10 toward lower rate constants at longer residence times, similar to the trend noted in Fig. 1. In two experiments at slow flows Kurylo et al. (9) obtained a rate constant of 4×10^4 L mol^{-1} s^{-1}, which, when divided by the stoichiometric coefficient, would agree with the present result.

Thermochemical and kinetic parameters

The present, slower rate constants can be expected to agree better with the accepted thermochemistry and the rate constant of the reverse reaction. To test this we have fitted a transition-state theory model by nonlinear least squares to the data of the present work and literature data for the reverse reaction. The model was described in detail in ref. 5. One change was made by including an extra $\frac{1}{3}$ in the classical partition function (24) for rotation of H_2 in the reverse reaction:

$$[6] \quad Q_r = \frac{8\pi^2 I k_B T}{\sigma h^2} + \frac{1}{3}$$

The extra term adjusted the partition function for quantum effects. Moments of inertia and vibrational frequencies of the reactants were taken from the JANAF Thermochemical Tables (25). The products of moments of inertia of the transition state were taken from a bond energy, bond order calculation (26). This is the most uncertain part of the input, but we have shown elsewhere that it does not significantly affect the output (5). The latter consists of the effective barrier height in the forward direction, E_f; the characteristic tunnelling temperature, T^*; the geometric mean of five low-frequency, transition-state bending term values, ω_B; and the difference between forward and reverse barrier heights, $E_f - E_r$.

The results of these fits are shown in Table 5. In the second column are listed values of $E_f - E_r$, which is equal to ΔH_0^0, the enthalpy of reaction at 0 K. Zero point vibrational energies are included in the barrier heights. In the first line are our results from three years ago (5), incorporating data available until that time. The reaction was found to be 5.5 kJ mol^{-1} exothermic, in contrast to the 0.1 kJ mol^{-1} exothermicity from the JANAF tables (25) in the third line. In the second line are the results obtained by discarding the old data for the forward reaction and including only the results of the present work and the recently published shock tube study by Rabinowitz et al. (27). The exothermicity is now found to be 1.0 ± 0.4 kJ mol^{-1}. The quoted uncertainty is one standard deviation. Considering the possibility of systematic errors in either the forward or reverse kinetic studies, we feel these results are essentially in agreement with the JANAF value. If the shock tube data were not included, the exothermicity would be 0.8 ± 0.4 kJ mol^{-1}. Alternatively, equilibrium constants can be calculated from the present results at 373–421 K and individual rate constants for the reverse reaction from the literature (28–31). With the partition functions calculated as above, but without the use of transition state theory, the exothermicity was calculated to be 0.9 ± 0.7 kJ mol^{-1}. In the fourth line of the table is given the result of an ab initio calculation (32), which predicts the reaction to be endothermic.

One can turn the present result around and use it to find the heat of formation of the methyl radical. Using JANAF results (25) for the other species and the value of $E_f - E_r$ from the new experiments, one finds $\Delta_f H^0 298(CH_3) = 34.6$ kcal mol^{-1} or 145 kJ mol^{-1}. This may be compared to 34.8 kcal mol^{-1} from JANAF (25) and 35.1 kcal mol^{-1} from forward and reverse kinetics on the Cl atom analogue (33) of reaction [1]. There is room for further refinement, but clearly the thermochemistry of reaction [1] has now rejoined the mainstream.

The remaining three columns in Table 5 give the fitted properties of the transition state. First is E_f, the height of the activation barrier including zero point energy. This is 7 kJ mol^{-1} higher with the new experimental data than it had appeared to be with the old. It is now in better agreement with the ab initio results (32) in the table and with a new ab initio value of 60 kJ mol^{-1}.[3] Comparisons with other surfaces are available in ref. 5. The mean of the transitional bending frequencies has moved lower, away from the ab initio result. It has been pointed out elsewhere (34) that these frequencies change quickly near the barrier top and the reaction bottleneck does not coincide with the top of the potential energy barrier. The characteristic tunnelling temperature is a measure of the curvature across the top of the barrier and of the importance of quantum mechanical tunnelling through the barrier. This parameter is unchanged within experimental uncertainty with the new experimental results. Tunnelling dominates this reaction even at a temperature of 500 K. The value of T^* from the ab initio calculations is not directly comparable, as it refers to curvature of the potential energy barrier without vibrational zero point energy.

It is interesting to note that Polanyi (35) calculated a classical barrier height of 56 kJ mol^{-1} many years ago.

The experimental data and the fitted curves are illustrated in Fig. 2. The curves were obtained using the transition-state theory model of ref. 5, adjusted by the inclusion of eq. [6], with the parameters in the second line of Table 5. The two fitted curves are closely parallel, indicating that the equilibrium constant is almost independent of temperature. The experiments at low temperatures on the reverse reaction, all obtained by static photolysis (28–31), are consistent with each other. For the forward reaction we have not shown the earlier flow discharge results (7–11), as they may have been affected by impurities or effects of reaction [2].We have also omitted some combustion studies (1, 3, 4, 6), where the temperature often changed rapidly during the reaction. To prevent crowding, we have only been able to show a quarter of the plentiful points of Rabinowitz et al. (27).

We have recently learned of new shock tube experiments on reaction [1] and its reverse. Wintergerst and Frank (WF)(40) obtained rates for reaction [1] about twice as fast as those of Rabinowitz et al. (27). For the reverse reaction they found rate constants twice as fast as unpublished results of Klemm.[4] Clearly, more work is needed at high temperatures. However, WF said their forward and reverse rate constants, on their own, agree with the established thermochemistry, and that the

Brookhaven results of Rabinowitz et al. and Klemm, on their own, are also consistent with the established thermochemistry.

The central conclusions of this work are that in measurements of the rate constant for reaction [1] careful attention must be paid to stoichiometric factors and impurity effects, that the rate constants for reaction [1] at 348–421 K are much slower than previously thought, and that the thermochemistry for reaction [1] from kinetic studies is now in reasonable agreement with results of other techniques. More generally, "direct" studies, like most studies (7, 9, 10) of reaction [1], are not necessarily more reliable than indirect studies involving a composite mechanism, like the photochemical studies (28–31) of reaction [−1]. We can now see that some studies of the forward reaction involved an unsuspected composite mechanism. The accuracy of the indirect photochemical studies is confirmed by the present work.

Infrared–ultraviolet double resonance measurements on the temperature dependence of rotational and vibrational self-relaxation of NO($X^2\Pi$, $v = 2, j$)

MICHAEL J. FROST,[1] MEEZANUL ISLAM, AND IAN W.M. SMITH[2]

School of Chemistry, The University of Birmingham, Edgbaston, Birmingham B15 2TT, U.K.

Received August 5, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

MICHAEL J. FROST, MEEZANUL ISLAM, and IAN W.M. SMITH. Can. J. Chem. **72**, 606 (1994).

Infrared–ultraviolet double resonance experiments have been performed to measure the rates of rotational and vibrational self-relaxation in NO at three temperatures: 295 K, 200 K, and 77 K. Pulses of tunable infrared radiation from an optical parameteric oscillator have been used to excite molecules into selected rotational levels (j = 0.5, 6.5, or 15.5) in the $|v = 2; \Omega = 1/2\rangle$ vibronic component of the $X^2\Pi$ electronic ground state of NO. Loss of population from the initially excited level was observed by making time-resolved laser-induced fluorescence measurements on appropriate lines in the $A^2\Sigma^+ - X^2\Pi(2,2)$ band. The rate constants for removal of population from specific rovibronic levels are essentially independent of j and at 295 K agree well with previous direct measurements on a range of v, j levels. The rotationally thermalized population in $v = 2$ relaxes by vibration–vibration (V–V) energy exchange, NO($v = 2$) + NO($v = 0$) → 2 NO($v = 1$), at a rate which is almost independent of temperature and which seems to be uninfluenced by the presence of spin-orbit degeneracy in, and attractive forces between, the NO collision partners.

MICHAEL J. FROST, MEEZANUL ISLAM et IAN W.M. SMITH. Can. J. Chem. **72**, 606 (1994).

Dans le but de mesurer les vitesses d'autorelaxation rotationnelle et vibrationnelle du NO, on a réalisé des expériences de double résonance infrarouge–ultraviolet à trois températures, 295 K, 200 K et 77 K. On a utilisé des pulsations d'une radiation infrarouge ajustable, obtenues à l'aide d'un oscillateur optique paramétrique, pour exciter les molécules vers des niveaux rotationnels choisis (j = 0,5, 6,5 ou 15,5) du $|v = 2; \Omega = 1/2\rangle$ composante vibronique de l'état électronique fondamental $X^2\Pi$ du NO. On a observé la perte de population de l'état excité initial en effectuant, sur les raies appropriées de la bande $A^2\Sigma^+ - X^2\Pi(2,2)$, des mesures de fluorescence induites au laser et résolues dans le temps. Les constantes de vitesse pour les pertes de population à partir de niveaux rovibroniques donnés sont essentiellement indépendantes de j et, à 295 K, elles sont en bon accord avec les mesures directes effectuées antérieurement sur un ensemble de niveaux v, j. La relaxation de la population thermalisée par rotation dans $v = 2$ se fait par un échange d'énergie vibration–vibration (V–V), NO($v = 2$) + NO($v = 0$) →2NO($v = 1$), à une vitesse qui est pratiquement indépendante de la température et qui ne semble pas être influencé par la présence d'une dégénérescence spin-orbite dans ou par les forces d'attraction entre les partenaires de collision du NO.

[Traduit par la rédaction]

1. Introduction

The capacity of double resonance techniques to reveal the state-resolved details of energy transfer processes has been appreciated for some time. In experiments of this kind, the Boltzmann distribution of molecules over rovibronic levels is perturbed by pumping a particular spectroscopic transition using a powerful monochromatic source, usually a laser, and then the rates and pathways of the relaxation processes which reestablish equilibrium are examined using spectroscopic techniques. When the pump and probe sources are both pulsed tunable lasers, two types of measurement can be performed. In the first, the frequency of the probe laser is fixed to correspond to the frequency of a discrete transition in the molecule under investigation, and the time delay between excitation and probe lasers is scanned to yield kinetic information about how the population in the selected level evolves in time. Alternatively, the time delay between the two laser pulses is fixed and the frequency of the probe laser is scanned. The spectrum that is obtained contains information about the relative populations in different molecular states at the instant the second laser is fired. If the chosen delay is much shorter than the average time between collisions in the gas sample, then the populations in levels other than that directly accessed in the pump process directly reflect the state-to-state rate coefficients for transfer from the initially populated level into neighbouring levels.

Experiments in which laser-induced fluorescence is used to probe the kinetic behaviour of populations in excited rovibrational levels of electronic ground states have been pioneered by Orr and co-workers, in a series of elegant experiments, initially on D_2CO and HDCO (1) and more recently on C_2H_2 and C_2D_2 (2). In addition, Crim and co-workers (3), Zacharias and co-workers (4), and Frost and Smith (5) have all performed recent double resonance experiments on different states of C_2H_2. Earlier in our laboratory, Smith and Warr (6) had performed preliminary measurements on the vibrational relaxation pathways in HCN using the double resonance technique. In the present work, as in the experiments of Frost and Smith (5) and Smith and Warr (6), a $LiNbO_3$ based optical parametric oscillator (OPO) is used as the "pump" source to prepare an initial population in a selected rovibronic level of the molecule under investigation.

The present paper reports infrared–ultraviolet double resonance measurements on the temperature dependence of collisional energy transfer processes in NO. Radiation from the OPO has been used to prepare molecules in either the j = 0.5, 6.5, or 15.5 rotational level in the $\Omega = 1/2$ lower spin-orbit component of the $X^2\Pi$, $v = 2$ vibronic level. In this paper, we report rate coefficients for *total* removal of population (i.e.,to all final states) with NO itself as the collision partner for several initial rotational states, as well as rate coefficients for vibrational self-relaxation from $v = 2$. The temperature dependences of these processes have been investigated by carrying out experiments at 295 K, 200 K, and 77 K.

The rates of collisional rotational and vibrational energy

transfer provide a probe of the intermolecular potential acting between the collision partners. In this respect, double resonance experiments on NO are especially interesting, as well as being relatively easy to perform, because the electronic ground state of NO is $^2\Pi$. NO is known to form a dimer with a dissociation energy (D_0) equivalent to ca. 800 cm^{-1} (7) and to undergo unusually rapid vibrational–translational (V–T) relaxation (8), probably as a result of an electronically non-adiabatic mechanism (9). In this context, it is particularly interesting to examine relaxation processes at low temperature, where the dissociation energy of $(NO)_2$ becomes appreciably greater than kT.

Our experiments and the results that we have obtained on rotational energy transfer are closely related to those of Sudbo and Loy (10), reported in 1982. They excited specific (j,Ω) levels in NO($v = 2$) using the output from a pulsed F-centre laser pumped by a Nd:YAG laser. Populations in specific ($v = 2$, j, Ω) levels were then detected using a tunable ultraviolet laser to ionize molecules via levels in the $A^2\Sigma^+(v = 2)$ vibronic level in a (1 + 1) resonance-enhanced multiphoton ionization process. As well as obtaining total relaxation rates out of particular (j,Ω) levels, they obtained state-to-state rate coefficients by fixing the frequency of the probe laser and scanning that of the excitation laser with the delay between the two laser pulses set at a fraction of the average time between NO–NO collisions. However, their measurements were all performed at room temperature and they could only derive an upper limit to the rate constant for vibrational relaxation of NO($v = 2$).

More recently, Wodtke and co-workers obtained rotational (11, 12) and vibrational (11, 13) relaxation rates within and for high vibrational levels of NO ($8 \leq v \leq 24$). Theirs might be described as a *triple* resonance method. Levels in the $X^2\Pi$ ground state are populated by stimulated emission pumping (SEP), two tunable dye lasers being deployed to "*pump-and-dump*" molecules into selected rovibronic levels with high v. A third tunable laser is then used to observe how the excited population that has been created evolves as collisions cause relaxation.

2. Experimental

The apparatus and experimental procedures used in the present work were very similar to those described previously by Frost and Smith (5), so only essential details of the experiments, and ways in which they differ from the earlier ones, are described here. A schematic diagram of the experimental arrangement is given as Fig. 1 in the paper by Frost (5*b*).

In the present experiments, NO was excited to single selected rovibronic levels using pulses of tunable radiation at ca. 2.7 μm from a $LiNbO_3$ OPO that was pumped by the fundamental output from a Nd:YAG laser. The pulse energy in the idler beam of the OPO at the required wavelength was in the range 0.1–1.0 mJ, its fluence at the observation region was 0.5–5.0 mJ cm^{-2}, and its bandwidth was ca. 0.3 cm^{-1}. This output was tuned into resonance with lines in the P-branch of the ($v = 2 \leftarrow 0$; $\Omega = 1/2 \leftarrow 1/2$) sub-band using a monochromator and a spectrophone containing 20 Torr of NO and 20 Torr of argon (1 Torr = 133.3 Pa).

The probe radiation was provided by a dye laser (Lambda Physik, FL2000) pumped by an excimer laser (Lumonics, series 400) operating on XeCl. The fundamental output from the dye laser was frequency-doubled in a BBO crystal to provide radiation at 222 nm, in order to excite NO in the (2,2) band of the $A^2\Sigma^+$–$X^2\Pi$ band system. The probe radiation contained <10 μJ per pulse, had a bandwidth of ca. 0.2 cm^{-1}, and irradiated a region ca. 2 mm in diameter in the centre of the cylindrical volume illuminated by the output from the OPO. To discriminate against scattered radiation from the probe laser, the fluorescence was observed, using a photomultiplier tube (EMI, model 9781B), through a UG11 broad-band filter, which effectively cuts out radiation below ca. 250 nm. In some experiments (see below), NO in $v = 1$ was observed. In these the probe radiation was tuned to lines in the (1,1) band; the arrangements for observing fluorescence remained the same.

The cell used for the present experiments was different from that employed by Frost and Smith (5). However, it was very similar to that used recently (14) in experiments to determine the rate constants for reactions of OH radicals at low temperatures. It is constructed from three concentric Pyrex tubes, so that the inner tube, in which the gas sample of pure NO or NO diluted in argon is placed, is surrounded by a double jacket. The outer jacket is permanently evacuated and refrigerant is placed in, or circulated through, the inner jacket, which is 30 cm long. To achieve low temperatures in the present experiments, either liquid N_2 was placed in the inner jacket or methanol that had been cooled in Dry Ice was flowed slowly through it. The vapour pressure of NO at 77 K is only 81 mTorr (= 1.02×10^{16} molecule cm^{-3}), but this was quite adequate for all the experiments that were carried out in the present series. Statistical mechanical calculations based on the spectroscopic properties of the $(NO)_2$ dimer (7, 15) show that the mole fraction of $(NO)_2$ under these conditions is less than 10^{-4}. We assume here that the static gas in the observation region is at the temperature of the walls. This is consistent with spectroscopic observations made on NO that had rotationally been completely relaxed. We also note that the rates of the processes under investigation in the present work show very little dependence on temperature.

CaF_2 windows were mounted at each end of the central tube in which NO was placed. The two laser beams counterpropagated along the central axis of this cell. To view the LIF from electronically excited NO, the cell had to be fitted with quartz windows. One window is attached to a short sidearm, which is joined to the central tube at its midpoint and passes through the inner jacket. The second window is mounted on the outer wall of the evacuated jacket. The photomultiplier tube, the filter, and a collecting lens are mounted in a housing that is clamped to the jacketed cell so that fluorescence, which passes through the quartz windows, is collected and directed onto the photomultiplier tube. Pressures in the cell are measured directly, using a 0–10 Torr capacitance manometer (MKS Baratron, model 222BA).

The equipment for controlling the firing of the two lasers and for recording, accumulating, and analysing the LIF signals has been described by Frost and Smith (5) and the description is not repeated here.

NO (Electrochem Ltd., 99.99%) was admitted to the vacuum line via a liquid N_2 trap and was purified by trap-to-trap distillations until it condensed in liquid N_2 as a pure white solid. Ar (BOC, zero grade, 99.998%) was used without further purification.

3. Results and discussion

In the present experiments the fraction of NO excited by the OPO laser pulse in the region probed by the ultraviolet laser was estimated. This was done by using the intensities of lines in the (1,1) band of the $A^2\Sigma^+$–$X^2\Pi$ system excited in a room temperature sample for calibration. The intensities of these lines could then be compared either with those excited in the (2,2) band, making due allowance for differences in Franck–Condon factors and dye laser intensities, or by comparing the (1,1) spectrum from a thermal sample with that recorded following the excitation of NO to $v = 2$, with a delay time chosen to be sufficiently long to allow complete rotational relaxation and for the vibration-to-vibration (V–V) energy exchange process:

$$[1] \quad NO(v = 2) + NO(v = 0) = 2\,NO(v = 1); \quad \Delta E/hc = 28\ cm^{-1}$$

to have gone to completion, but short enough for insignificant V–T relaxation to have occurred. These comparisons indicated that, for excitation to $v = 2$, $j = 6.5$ at room temperature, the concentration of NO excited by the pulse from the OPO was ca. 10^{-3} times the *total* concentration of NO present.

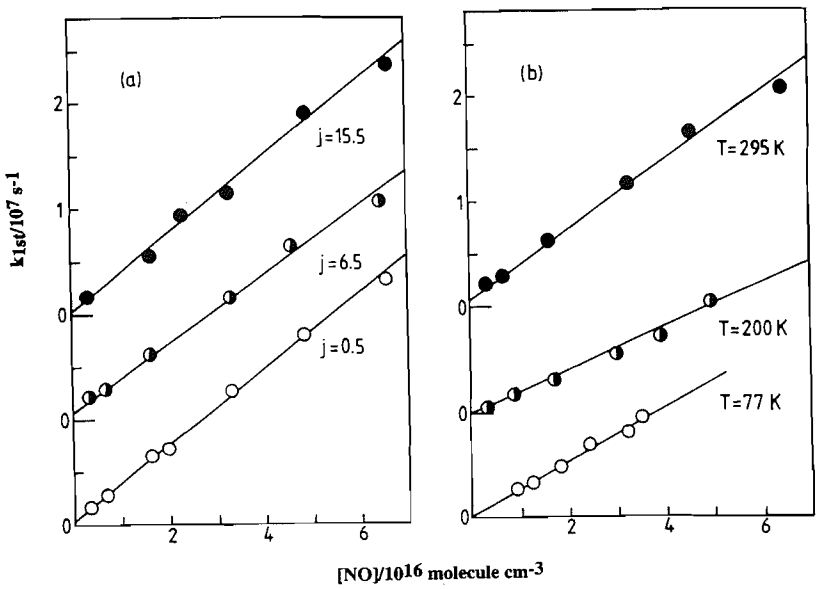

FIG. 1. First-order rate constants for the decay of LIF signals from initially populated rovibronic state $|v = 2, j, \Omega = 1/2\rangle$ plotted against concentration of NO: (*a*) for $j = 0.5$ (○), 6.5 (◑), and 15.5 (●) at 295 K: (*b*) for $j = 6.5$ at 295 K (●), 200 K (◑), and 77 K (○). The values of k_{1st} and [NO] for the data at 77 K are both one third for the values indicated on the axes, and the plots are displaced vertically for clarity.

(a) Rotational self-relaxation of NO (v = 2; j = 0.5, 6.5, 15.5; Ω = 1/2)

Experiments on rotational self-relaxation were carried out on samples of undiluted NO. Measurements were performed using NO concentrations in the range $(0.3 - 6.0) \times 10^{16}$ molecule cm^{-3}. The intensities of the LIF signals, which were recorded at different delay times, always accurately fitted a single exponential decay yielding a first-order rate constant (k_{1st}) for relaxation of population in the initially excited level for the chosen temperature and concentration of NO. For the range of NO concentrations used, mean relaxation lifetimes varied between ca. 1 μs and 50 ns.

The values of k_{1st} determined in a given series of experiments and at a particular temperature were then plotted against the corresponding concentrations, [NO], yielding a second-order rate constant for self-relaxation of the initially excited $|v, j, \Omega\rangle$ state in NO–NO collisions at that particular temperature. This rate constant corresponds to that for overall relaxation from the initial rovibronic level. It may contain contributions from transfers to j levels in both Ω components. Several plots of k_{1st} versus [NO] are showing in Fig. 1. Panel (*a*) compares data for relaxation from different rotational levels at room temperature, 295 K. Panel (*b*) shows results for relaxation from the state, $|v = 2, j = 6.5, \Omega = 1/2\rangle$, at the three temperatures of our experiments: 295 K, 200 K, and 77 K. The second-order rate constants for rotational self-relaxation resulting from all our experiments are summarized in Table 1. Each value quoted is the average of at least two series of experiments on a particular rovibronic level and at a given temperature. It can be seen that, at room temperature, the overall rotational relaxation rates are independent of j, in the range of j, Ω covered in our experiments.

The rate constants derived in the way just described are clearly not obtained under single collision conditions, and they characterize the rate at which the initial population ($N_{i,0}$) in the selected state i relaxes to the population ($N_{i,e}$) in the same state once complete rotational (and spin-orbit) relaxation has occurred. The equation describing the rate of change of population $N_{i,t}$ is

TABLE 1. Rate constants ($k/10^{-10}$ cm^3 molecule^{-1} s^{-1}) for relaxation and for total transfer from specific rovibronic levels, $|v = 2, j, \Omega = 1/2\rangle$, together with collisional probabilities for total transfer, in collisions with NO at different temperatures

[a]Obtained by dividing the observed rate constant by Z^0_{LJ}, the second-order rate constant for all collisions assuming a Lennard–Jones potential between the NO collision partners.

$$dN_{i,t}/dt = -\Sigma k_{i\to j}[NO]N_{i,t} + \Sigma k_{i\leftarrow j}[NO]N_{j,t}$$

where $k_{i\to j}$ and $k_{i\leftarrow j}$ are state-to-state rate constants for transfer from and to the observed state, $N_{j,t}$ are populations in all other rotational and spin-orbit states in $v = 2$ at time t, and both summations are over j. The first term on the right-hand side of this rate equation can clearly be written as $-k_{i\to}[NO]\ N_t^*$, where $k_{i\to} = \Sigma k_{i\to j}$ is the rate constant for *total* removal of population from the prepared state i.

To estimate values of $k_{i\to}$, we assume that the second term on the right-hand side of the rate equation can be written as $k_{i\leftarrow}[NO]\Sigma N_{j,t}$. Within this approximation, the observed relaxation rate constant is equal to $(k_{i\to} + k_{i\leftarrow})$ and, since at long times $dNi/d_t = 0$, the ratio of the rate constants is given by $k_{i\leftarrow}/k_{i\to} = N_{j,t=\infty}/\Sigma N_{j,t=\infty}$ and can be calculated using statistical mechanics. The rate coefficients $k_{i\to}$ for *total* removal of population from specific rovibronic levels are listed as the second entry in each element of Table 1. The values decrease slightly as

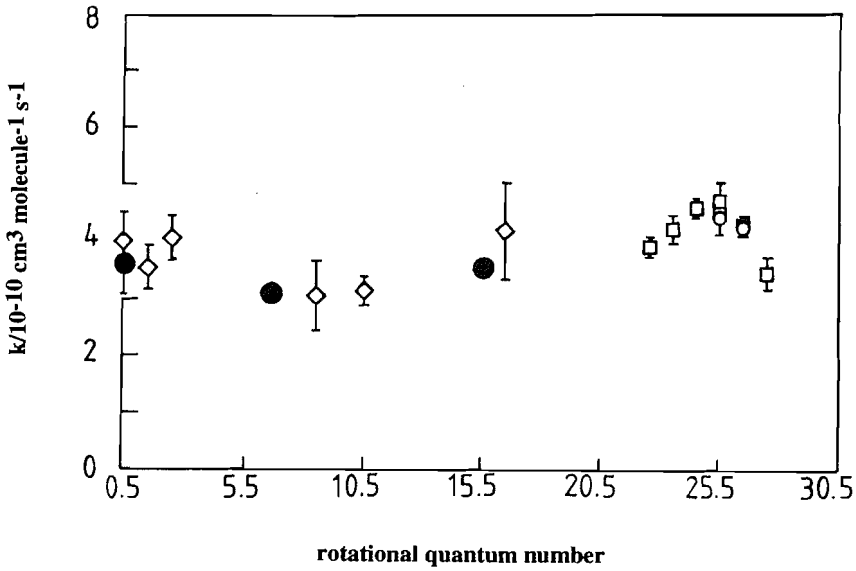

FIG. 2. Second-order rate constants for removal from specific rotational levels $j = 0.5$, 6.5, and 15.5 in $|v = 2, \Omega = 1/2\rangle$ (●) compared with similar data for levels in $v = 2$ (◇) (10) and in $v = 8$ (○) and 19 (□) (13).

the temperature is lowered and this effect appears to be greatest for the lowest rotational state investigated.

Table 1 also lists the collisional probabilities for removal from specific levels. These numbers are derived by dividing the observed second-order rate constants for *total* removal by the rate constants calculated for all collisions assuming that a Lennard–Jones potential acts between two NO molecules. The collisional probabilities are all within a factor of two of unity, confirming again the efficiency of rotational energy transfer. The reduced collision rate goes some way to explaining the reduction in relaxation rate coefficients that is observed below room temperature, but the probabilities do seem somewhat reduced at lower temperatures. This could reflect a reduction in the endothermic state-to-state rate coefficients (e.g., those for transfer to levels in the higher Ω component) as the temperature is lowered.

Our results at room temperature can be compared most directly with those of Sudbo and Loy (10) and of Yang and Wodtke (12). To facilitate these comparisons, Fig. 2 displays the rate constant for total decay from selected rovibronic levels obtained for different v, j levels in these three sets of measurements. It can be seen that the rate coefficients are essentially independent of both rotational and vibrational level over quite wide ranges of v and j, within the accuracy of the experimental results. A similar conclusion has been reached for rotational energy transfer in C_2H_2, as a result of a number of recent measurements (2–5).

Rate constants for total removal of population from a given rovibronic level can also be compared with line-broadening data for spectroscopic transitions terminating on the same state. For states in the electronic ground states of N_2 (16) and C_2H_2 (5*a*), for example, it appears that rate constants derived from the two kinds of measurements correlate well, indicating that energy transfer, rather than elastic m_j-changing collisions, are predominantly responsible for collision broadening in rovibrational transitions in these $^1\Sigma_g^+$ molecules. A large number of studies have been carried out on the pressure broadening of infrared transitions of NO. One of the most recent and thorough is that carried out by Pine et al. (17) on lines in the (2,0) first overtone band. The collision-broadening coefficients, which they determined at room temperature, are slightly higher for lines between $^2\Pi_{3/2}$ components than for lines in the $^2\Pi_{1/2} - {}^2\Pi_{1/2}$ sub-band. The self-broadening coefficients for the R(0.5), R(6.5), and R(15.5) lines in the latter sub-band translate into rate coefficients varying from 5.5×10^{-10} to 4.8×10^{-10} to 4.5×10^{-10} cm^3 molecule^{-1} s^{-1}, there being a slight decrease in the broadening coefficients as the rotational energy levels involved in the transition increase. These rate coefficients are about 50% higher than those observed in the direct studies of population transfer made by Sudbo and Loy (10), Yang and Wodtke (12), and ourselves.

The reason for this difference is not obvious. Sudbo and Loy's analysis indicates that, in the case of self-relaxation, the transfer of molecules between Ω components makes a significant contribution to population transfer, as well as j-changing transitions within the same Ω component, but that this is not true when the collision partner is other than NO. In any case, there seems to be no reason why this effect should destroy the correlation between rate coefficients derived from collision-broadening data and those determined directly in relaxation experiments. However, calculations by Orlikowski and Alexander (18) suggest that NO–NO collisions may be unusual in another respect: namely, in that the usual propensity for m_j-preserving collisions is relaxed in this case due to the $^2\Pi$ electronic nature of both collision partners. It therefore seems possible that m_j-changing collisions make some contribution to pressure broadening in pure NO. It will be interesting to check whether the difference between rotational energy transfer rates for NO measured directly and inferred from line-broadening measurements extends to collision partners other than NO itself.

(b) Vibrational self-relaxation of NO (v = 2)

Experiments on vibrational self-relaxation of NO($v = 2$) were carried out on samples of NO diluted to 10 Torr in argon. The argon diluent helps to cause rapid equilibration of the excited population over rotational levels, and decreases the rate at which the excited state population diffuses out of the region

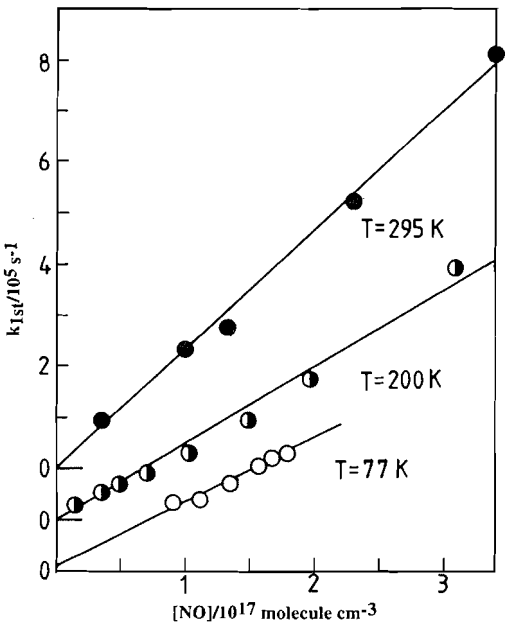

FIG. 3. First-order rate constants for the decay of LIF signals from NO(v = 2), in which the rotational and spin-orbit populations have become thermalised, plotted against concentration of NO. The values of k_{1st} and [NO] for the data at 77 K are one fifth and one tenth respectively, of the values indicated on the axes, and the plots are displaced vertically for clarity.

illuminated by the probe laser. Its effect on the rate of vibrational relaxation was negligible (8). Vibrational relaxation of NO(v = 2) is approximately two orders of magnitude slower than rotational relaxation. Therefore, in these measurements, the concentrations of NO used were in the range $(3 - 30) \times 10^{16}$ molecule cm^{-3}. As before the LIF signals always accurately fitted single exponential decays yielding first-order rate constants for transfer of population from $|v = 2\rangle$ with a thermal distribution of molecules over the rotational levels of both spin-orbit components.

Examples of the plots of k_{1st} against [NO] are shown in Fig. 3. The gradients of the lines yield the second-order constants ($k_{e'}$) for vibrational relaxation from NO(v = 2), which undoubtedly occurs by the slightly endothermic V–V exchange process represented by eq. [1]. These rate constants, those (k_e) for the reverse exothermic process calculated by applying the principle of detailed balance, and collisional probabilities for both processes are listed in Table 2.

The rate constants and probabilities for V–V energy transfer obtained in the present experiments at 295 K are compared with previous values for the same process determined at room temperature. Neither the measurements of Macdonald and Sopchyshyn (19) nor those of Horiguchi and Tsuchiya (20) can be described as direct, since in neither case was the mode of vibrational excitation state-specific. Stephenson's measurements (8) were made by exciting NO(v = 1) with a frequency-doubled CO_2 laser and observing the time-dependent behaviour of the (2,1) band emission as the vibrational level populations came into equilibrium, using a cold gas filter to discriminate against (1,0) emission. Our result at 295 K is in reasonable agreement with that of Stephenson (8).

Yang, Kim, and Wodtke (13) measured room temperature rate constants for the deactivation of NO($v \geq 8$) by NO. Their conclusion is that up to ca v = 8 the removal of NO molecules

from excited vibrational levels in collisions with unexcited NO is dominated by V–V energy exchange. At higher levels of excitation, other mechanisms involving chemical forces appear to come into play. Using their data, one can compare the value of k_e/v for NO(v − 1) + NO(v = 1) → NO(v) + NO (v = 0) and v = 8, with our value of the same quantity for v = 2. The resultant "reduced rate constants" are 2.25×10^{-13} and 1.3×10^{-12} cm^3 molecule^{-1} s^{-1}, respectively. The decrease in the reduced rate constant that is observed with the increase in energy discrepancy from $\Delta E/hc$ = 28 cm^{-1} to 223.5 cm^{-1} is in sensible agreement with both theoretical expectation (13, 21, 22) and from extensive work on vibrational relaxation in CO (23).

We are unaware of any measurements of V–V energy exchange in NO–NO collisions at temperatures below room temperature. However, Stephenson and Mosburg (24) studied this process in CO at temperatures between 100 K and 300 K. Values of k_e for 2 CO(v = 1) → CO(v = 2) + CO(v = 0) are given for comparison in Table 2. A comparison of both the absolute values of the rate constants for V–V exchange and their variation with temperature suggests that the $^2\Pi$ electronic character of the ground state of NO exerts no significant influence on the rate of V–V energy exchange in contrast to its role in facilitating V–T energy transfer (8, 9). The similarity of the rate constants for V–V energy exchange in NO–NO and CO–CO collisions and their insensitivity to temperature suggest that, in both cases, energy transfer occurs under the influence of long-range attractive forces, arising from the electrostatic charge distributions in the molecules and their modulation by the molecular vibrations, in accord with the long-established theory of Sharma and Brau (25).

4. Summary and conclusions

A double resonance method, using tunable laser sources of infrared and ultraviolet radiation, has been employed to determine rate constants for rotational energy transfer in collisions between NO(v = 2, j, Ω = 1/2) and other NO molecules, for three different j levels and at three different temperatures. The rate constants are insensitive to the initial rotational level but decrease slightly as the temperature is lowered. The reasons for this change will be explored in future measurements of state-to-state rate coefficients and their dependence on temper-

ature, and the generality of this finding will be examined by investigating the effect of collision partners other than NO.

By performing similar experiments on NO samples diluted in argon and over longer pulse–probe time-scales, rate constants have also been measured for the self-relaxation of NO($v = 2$) by V–V energy transfer. The rate constants and their relative insensitivity to temperature indicate that in NO, at least for low vibrational levels, as for CO, V–V energy exchange occurs under the influence of long-range, attractive forces and the existence of spin-orbit degeneracy in NO is unimportant.

Dynamics of the reaction of nascent ethynyl with hydrogen

SHINTARO TASAKI, SUNITA SATYAPAL, AND RICHARD BERSOHN
Department of Chemistry, Columbia University, New York, NY 10027, U.S.A.

Received May 6, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

SHINTARO TASAKI, SUNITA SATYAPAL, and RICHARD BERSOHN. Can. J. Chem. **72**, 612 (1994).

At room temperature ethynyl radicals, C_2H, react only slowly with hydrogen molecules in spite of the fact that the reaction $C_2H + H_2 \rightarrow C_2H_2 + H$ is exothermic by 26 kcal/mol. Nascent C_2H (C_2D) radicals produced by photodissociation of C_2H_2 (C_2D_2) at 193 nm are shown to be as reactive with D_2 (H_2) as fluorine atoms with rate constants of $(2.3 \pm 0.4) \times 10^{-11}$ and $(3.2 \pm 0.5) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} respectively. The H and D atoms have average kinetic energies of 7.6 ± 0.7 and 7.8 ± 1.0 kcal/mol, respectively. About 70% of the available energy is therefore released as internal energy. The enhanced reactivity of the nascent ethynyl is ascribed to partial mixing of the vibrationally excited *X* state with the *A* state. This reactivity is rapidly lost in collisions with N_2. Overall the reaction of excited C_2H with H_2 is shown to be remarkably similar to the reaction of F atoms with H_2.

SHINTARO TASAKI, SUNITA SATYAPAL et RICHARD BERSOHN. Can. J. Chem. **72**, 612 (1994).

Même si la réaction $C_2H + H_2 \rightarrow C_2H_2 + H$ est exothermique (26 kcal/mol), les radicaux éthynyles, C_2H, ne réagissent que lentement avec l'hydrogène moléculaire à la température ambiante. On a montré que, vis-à-vis du D_2 (H_2), les radicaux C_2H (C_2D) naissants, obtenus par photodissociation du C_2H_2 (C_2D_2) à 193 nm, sont aussi réactifs les atomes de fluor; les constantes de vitesse sont respectivement de $2,3 \pm 0,4 \times 10^{-11}$ et $3,2 \pm 0,5 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}. Les énergies cinétiques des atomes de H et de D sont respectivement de 7,6 ± 0,7 et 7,8 ± 1,0 kcal/mol. Environ 70% de l'énergie disponible est donc émise sous forme d'énergie interne. On attribue la plus grande réactivité des radicaux éthynyles naissants à un mélange partiel de l'état *X* vibrationnellement excité avec l'état *A*. Cette réactivité est rapidement perdue lors de collisions avec N_2. On démontre que, dans l'ensemble, la réaction du C_2H excité avec le H_2 est très semblable à la réaction des atomes de F avec le H_2.
[Traduit par la rédaction]

One of the most extensively studied reactions in chemical dynamics is $F + H_2$. Its attractiveness stems from the facts that (*a*) H_2 has only two electrons and therefore *ab initio* calculations of the potential surface are conceivable and (*b*) H_2 and the HF product have a sparse set of widely spaced internal states. There is a set of three closely related reactions which have the essential similarity that they are highly exothermic reactions with H_2. These are

[1] $F + H_2 \rightarrow HF + H$ $\quad \Delta H = -35$ kcal/mol

[2] $CN + H_2 \rightarrow HCN + H$ $\quad \Delta H = -16$ kcal/mol

[3] $C_2H + H_2 \rightarrow HCCH + H$ $\quad \Delta H = -27$ kcal/mol

There are chemical connections. CN, being a pseudohalogen, has some chemical properties similar to those of a fluorine atom. C_2H is isoelectronic with CN and therefore might be expected to react similarly. All three reactants, F, CN, and C_2H have high electron affinities, 3.62, 3.82 (ref. 1), and 2.94 (ref. 2) eV, respectively. The extreme exoergicity of the $F + H_2$ reaction results in an early barrier which in turn leads to strong vibrational excitation of the HF product. The activation energy in each case is relatively small, being 1.0 ± 0.5, 5.6 ± 0.6, and 2.9 kcal/mol for reactions [1], [2], and [3], respectively (3). The barrier for the $F + H_2$ reaction is known to be least in the collinear geometry and at low energies the reaction is an abstraction with the HF recoiling backward in the center-of-mass system. Here we report a study of the dynamics of the reaction of C_2H with H_2 to see how similar it is to the reaction of F with H_2.

The rate constant for reaction [3] has been studied by a number of groups with generally concordant results (3–5). Table 1 lists the rate constants at room temperature measured in different ways. In the earliest measurement C_2H was generated by a discharge in a mixture of C_2HBr and excess H_2 (2). C_2H concentrations were measured as a function of time and H_2 pressure by mass spectroscopy (4). In other experiments C_2H was generated by a shock wave in a mixture of C_2H_2 and H_2 and the concentration of C_4H_2 was measured as a function of time and H_2 pressure (4). A competition was set up between the reaction of C_2H with C_2H_2 and with H_2 allowing both rate constants to be measured. In still another experiment a C_2H_2 and H_2 mixture in an excess of He was photolyzed and C_4H_2 was measured as a function of time and H_2 pressure (5).

There was excellent agreement between the results of six different groups (4–8) that the rate constant for reaction [3] at room temperature is in the range 1.5 to 7×10^{-13} cm^3 molecule^{-1} s^{-1}. Shock wave experiments showed that the rate constant increases by a factor of 50 between 300 and 2800 K from which an activation energy of 2.9 kcal/mol can be inferred.

Renlund et al. generated C_2H by 193 nm dissociation of C_2H_2, C_2HBr, and HC_2CHO (9). They monitored the CH(*A*–*X*) emission resulting from the reaction:

[4] $C_2H(X^2\Sigma) + O_2(^3\Sigma_g) \rightarrow CH(A^2\Delta) + CO_2(^1\Sigma)$

as a function of time and H_2 pressure. From these data they found a value for the rate constant of reaction [3] at room temperature of $(1.2 \pm 0.3) \times 10^{-11}$. Later this same group found a value of 2.7×10^{-11} by monitoring the decay of the C_2H $A \rightarrow X$ emission (10). Total pressures in their experiments never exceeded 0.8 Torr and were carried out at observation times of 2–10 μs. In contrast, Laufer and Bass (5) used pressures of 20–700 Torr of He at observation times of 5–20 μs without seeing any pressure effect. Lange and Wagner (4) used 4.2 Torr in a 300–900 μs observation time. Typical pressures and times in the shock wave experiments were 5 Torr and 100 μs.

The results of Wittig's group (9, 10) differ from those of all other workers. Our explanation is that they were generating

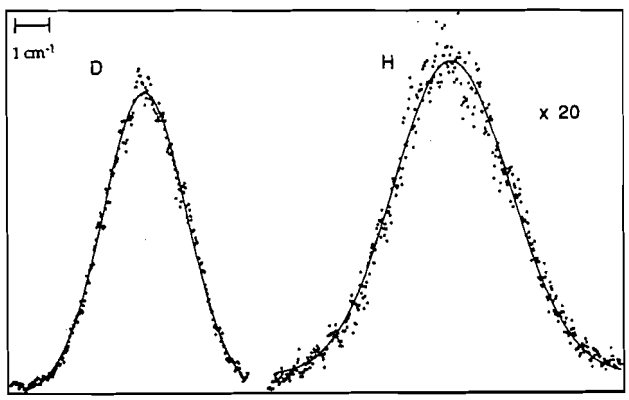

FIG. 1. Fluorescence excitation curves for reactant D atoms generated by photodissociation of C_2D_2 mixed with H_2 at 193.3 nm and product H atoms.

C_2H species with excess internal energy from all the molecules which they photodissociated whereas the other workers' measurements were made with thermalized C_2H radicals. A rough measure of the degree of relaxation of the C_2H radicals is furnished by the product in Torr–μs of the total pressure and the time over which the reaction is observed. For the Wittig experiments this product was 1.6 but it was 100 in the work of Laufer and Bass and 1260 in the experiments of Lange and Wagner. The experiments to be described here were carried out at pressures ≤ 0.1 Torr and times of 200 ns yielding a product of 0.02 Torr–μs.

Experimental

The techniques of hydrogen atom detection have been described previously (11). Briefly, a 193.3 nm ArF laser is used to dissociate C_2H_2 and at a later time, typically 200 ns later a probe laser at 121.6 nm is used to excite H atoms or D atoms in the system (Fig. 1). No H atom signal was seen in the absence of 193.3 nm light. To minimize two photon effects which would dissociate the C_2H ArF laser fluences were kept below 25 mJ/cm^2 (12, 13). Typical pressures were 20 millitorr of acetylene and 50 millitorr of hydrogen. The gases were premixed with different ratios with no change in the measured rate constants. H/D ratios were measured at various time delays and gave consistent rate constants. The vuv light was generated by two photon resonant frequency difference mixing in Kr and by frequency tripling in Kr with the same results in each case. Errors in the rate constants and average kinetic energies are the standard deviations of 5–6 runs. The kinetic energies are subject to an additional error due to difficulty in establishing the baseline.

Results

Because it was necessary to distinguish between hydrogen atoms formed by photodissociation of acetylene and those formed by reaction of ethynyl with hydrogen molecules, reaction [3] could not be directly studied. Instead two isotopic versions were used.

TABLE 2. Rate coefficients and energy disposal

Reaction	k (cm^3 $molecule^{-1}$ s^{-1})	$\langle E_T \rangle$ (kcal/mol)	$\langle b_T \rangle$
$HCC + D_2$	$(2.3 \pm 0.4) \times 10^{-11}$	7.8 ± 1.0	0.29
$DCC + H_2$	$(3.2 \pm 0.5) \times 10^{-11}$	7.6 ± 0.7	0.28
$F + H_2$	2.6×10^{-11}[a]	12.9 ± 1.9[b]	0.37

[5] $C_2D + H_2 \rightarrow C_2DH + H$

[6] $C_2H + D_2 \rightarrow C_2HD + D$

The ethynyl radicals were generated by dissociating acetylene or deuteroacetylene. The great advantage in this choice is that for every $C_2H(D)$ generated by photodissociation an H(D) is simultaneously formed. Therefore the ethynyl radical in all its complex distribution over internal states does not have to be detected; only the two isotopic hydrogen atoms need be detected. The product H(D) can then be measured simultaneously with the reactant $C_2H(C_2D)$. The simple kinetic equation for the H atom concentration:

[7] $d(H)/dt = k(C_2D)(H_2)$

can be solved at short times, t for the rate coefficient k with the result that

[8] $1/k = (C_2D)/(H)(H_2)t = (D)/(H)(H_2)t$

The ratio of the atomic concentrations is given simply by the ratio of the areas under the fluorescence excitation curves. The results for the rate coefficients k, the average translational energy of the products and the fraction of the available energy released as translational energy $\langle f_T \rangle$ are given in Table 2. The ratio of the rate coefficient for the reaction of H_2 to that of the reaction with D_2 is roughly the square root of two, the ratio of the relative reactant velocities of the two reactions. Also the rate coefficient for this almost totally unrelaxed or nascent ethynyl radical is within experimental error the same as the result of Wittig (6) which was also obtained using unrelaxed ethynyl radicals. The agreement between these rate coefficients obtained by rather different experiments is satisfying.

One should distinguish between rate constants and rate coefficients. Rate constants can be defined as the constants extracted from kinetic equations describing the reactions of

reactants at thermal equilibrium. Rate coefficients have the same dimensions as rate constants but apply to reactants which are not in thermal equilibrium.

Discussion

In the foregoing it has been tacitly assumed that when acetylene is photodissociated at 193.3 nm three energetic species are formed directly: ethynyl radicals, hydrogen atoms, and triplet vinylidene. In principle, any of them could react with hydrogen molecules to form hydrogen atoms. Reactive collisions between D(H) and $H_2(D_2)$ can be ruled out by the following arguments. The hydrogen atoms produced by the photodissociation of acetylene have an average kinetic energy of 8.0 ± 1.4 (D) and 9.5 ± 1.5 (H) kcal/mol in the lab frame. However, in the center of mass frame, the average relative kinetic energy is only about 4 kcal/mol for the D + H_2 pair and about 5 kcal/mol for the H + D_2 pair. Because the barrier for the H + H_2 reaction is 8 kcal/mol most of the hydrogen atoms do not have enough kinetic energy to react. Moreover, the reaction cross section just above the threshold is very small (11, 14). Finally, addition of 2 torr of He to the reaction mixture of C_2D_2 and H_2 substantially slows down the hydrogen atoms (15) but had no effect on the product yield.

The other possible reactant with hydrogen is the still mysterious triplet vinylidene which is the principal product of absorption of a 193 nm photon by acetylene. Fahr and Laufer (16) found that when C_2D_3Cl is dissociated at wavelengths >155 nm that the resulting D_2CC ($^3B_2$) was quenched by H_2 without any reaction. In other words, during the collision the molecule passed from the triplet surface to a singlet surface on which it rapidly isomerized to DCCD. The rate constant for quenching was $(3.38 \pm 0.61) \times 10^{-14}$ cm^3 molecule^{-1} s^{-1}, three to four orders of magnitude smaller than a gas kinetic rate constant. This rate, characteristic of a forbidden process, is much slower than any of the rates of reaction listed in Table 1. Indeed the quenching rate constant for N_2 molecules is $(8.5 \pm 0.2) \times 10^{-15}$ cm^{3}molecule^{-1} s^{-1}. On the other hand, the rate coefficient for quenching by N_2 of the reaction of C_2D with H_2 inferred from a 50% quenching by 200 mtorrr is 1.5×10^{-12} in the same units. The easy quenching of the reaction by N_2 implies an easy V–V energy transfer in which the N_2 molecule can accept about 2300 cm^{-1} from the nascent C_2D.

Thus by a process of elimination we conclude that the reactant with the hydrogen molecules is ethynyl. The rate coefficient which we obtain is very close to that obtained by Wittig (9, 10) which in turn was much larger than the thermal rate constant measured by others. However, this difference is presumed to be the result of a great difference in reactivity between unrelaxed nascent ethynyl (this work and Wittig (10)) and thermally equilibrated ethynyl.

The origin of the enhanced reactivity of the nascent ethynyl is not immediately obvious. The average internal energy of ethynyls generated by 193.3 nm photodissociation of room temperature acetylene is 8–9 kcal/mol or 2800–3150 cm^{-1}. Thus the average ethynyl can have at most one or two quanta in the vibrational modes which stretch bonds which will not be broken during the reaction. It is also not clear how excitation of the HCC bend would affect a reaction barrier. However, the $A^2\pi$ state lies only 3600 cm^{-1} above the $X^2\Sigma$ ground state. Consequently there will be extensive mixing of the vibrationally excited ground state with the electronically excited state. A rough description of the *A* state is that an electron in a π bonding state has been promoted to a Σ state (17). The potential surface *vis-a-vis* an incoming H_2 molecule should be quite different from that of the ground state and the small barrier to reaction may be removed. Table 2 shows that the only isotope effect on the ethynyl–hydrogen reaction is that the H_2 molecules have an average speed $(2)^{1/2}$ times that of the D_2 molecule. This is again consistent with a negligible barrier to reaction for these excited ethynyl radicals.

In conclusion we have demonstrated that nascent ethynyls generated by photodissociation of acetylene are far more reactive with H_2 than room temperature ethynyls. In this reaction about 70% of the available energy is released as internal energy, presumably mainly as vibration. This reaction of nascent C_2H has much in common with the paradigm F + H_2 reaction in exothermicity, rate constant and high vibrational energy release. In fact Harding et al. did an *ab initio* calculation of the potential surface for ground state C_2H and H_2 (18). They found that the saddle point was collinear and located in the reagent region of configuration space with the H_2 bond distance elongated by only 6% and the bond distances in C_2H unchanged. The theoretical prediction is that the reaction $C_2H + H_2$ like the reaction F + H_2 is a collinear abstraction with an early barrier (19).

We have studied the reaction of translationally excited hydroxyl radicals with molecular hydrogen at different center-of-mass energies. H/D atoms produced in the reaction have been detected under single collision conditions by means of vacuum ultraviolet laser-induced fluorescence at the Lyman-α transition. By calibrating the H/D signals from the reaction against H atom signals from the H_2S and HCl photolysis, respectively, the following absolute reactive cross sections were determined: $OH + H_2 \rightarrow H + H_2O$: $\sigma_R(0.17\ eV) = (0.08 \pm 0.03)$ Å^2, $\sigma_R(0.22\ eV) = (0.60 \pm 0.30)$ Å^2; $OH + D_2 \rightarrow D + HOD$: $\sigma_R(0.28\ eV) = (0.22 \pm 0.05)$ Å^2, $\sigma_R(0.37\ eV) = (0.43 \pm 0.09)$ Å^2. With translationally excited H atoms, we have also studied the reverse reaction system, $H + D_2O$. In this case the OD product radicals were detected under single collision conditions with quantum state resolution by means of laser-induced fluorescence. By calibrating the OD signals from the reaction against OH signals from the H_2O_2 photolysis, absolute reaction cross sections were measured for $H + D_2O \rightarrow OD + HD$: $\sigma_R(1.5\ eV) = (0.07 \pm 0.04)$ Å^2, $\sigma_R(1.8\ eV) = (0.10 \pm 0.03)$ Å^2, and $\sigma_R(2.2\ eV) = (0.11 \pm 0.03)$ Å^2. At different center-of-mass collision energies nascent population distributions of the OD product fine-structure components were determined. It has been found that at all collision energies OD radicals are produced exclusively in their vibrational ground state, with only a small amount of the total available energy appearing in the rotational degree of freedom. A comparison of the dependence of the reaction cross section on the translational energy shows that relative reagent translation is more effective to promote reactivity in the reaction $OH + H_2$ and $OH + D_2$ than in the reaction $H + D_2O$. This, together with a preferential population of the symmetric $^2\Pi(A')$ Λ-doublet state (with the unpaired π orbital lying in the plane of rotation) at high OD rotational quantum numbers, suggests that the reaction $H + D_2O \rightarrow OD + HD$ proceeds through a planar transition state via a direct mechanism, where the OD moiety acts as a spectator, and where the reaction barrier is located at a "later" position of the reaction coordinate.

STEFAN KOPPE, THOMAS LAURENT, PRAKASH D. NAIK, HANS-ROBERT VOLPP et JÜRGEN WOLFRUM. Can. J. Chem. **72**, 615 (1994).

On a étudié la réaction de radicaux hydroxyles excités d'un point de vue translationnel avec de l'hydrogène moléculaire, à diverses énergies du centre de masse. On a détecté les atomes H/D produits dans la réaction dans des conditions de collision unique, en faisant appel à la fluorescence induite par un laser dans l'ultraviolet lointain au niveau de la transition Lyman-α. En calibrant les signaux de H/D de la réaction à l'aide des signaux d'atomes H provenant de la photolyse du H_2S et du HCl respectivement, on a déterminé les sections droites réactives absolues suivantes : $OH + H_2 \rightarrow H + H_2O$: $\sigma_R(0,17\ eV) = (0,08 \pm 0,03)$ Å^2, $\sigma_R(0,22\ eV) = (0,60 \pm 0,30)$ Å^2; $OH + D_2 \rightarrow D + DOH$: $\sigma_R(0,28\ eV) = (0,22 \pm 0,05)$ Å^2, $\sigma_R(0,37\ eV) = (0,43 \pm 0,09)$ Å^2. Utilisant des atomes d'H excités d'une façon translationnelle, on a aussi étudié le système réactionnel inverse, $H + D_2O$. Dans ce cas, pour détecter les radicaux OD produits dans des conditions de collision unique, avec une résolution de l'état quantique, on a fait appel à la fluorescence induite au laser. En calibrant les signaux OD de la réaction à l'aide de signaux OH obtenus par photolyse de H_2O_2, on a mesuré les sections droites absolues de la réaction $H + D_2O \rightarrow OD + HD$: $\sigma_R(1,5\ eV) = (0,07 \pm 0,04)$ Å^2, $\sigma_R(1,8\ eV) = (0,10 \pm 0,03)$ Å^2 et $\sigma_R(2,2\ eV) = (0,11 \pm 0,03)$ Å^2. On a déterminé, à diverses énergies de collision du centre de masse, les distributions de population naissante de composantes de la structure fine du produit OD. On a trouvé que, pour toutes les énergies de collision, les radicaux OD ne sont produits que dans leur état vibrationnel fondamental; seule une faible partie de l'énergie totale disponible apparaît dans le degré de liberté rotationnel. Une comparaison de la dépendance de la section droite de la réaction sur l'énergie de translation montre que la translation relative du réactif est plus efficace pour promouvoir la réactivité dans les réactions $OH + H_2$ et $OH + D_2$ que dans la réaction $H + D_2O$. Ce résultat, pris avec le fait que la population de l'état doublet symétrique-Λ, $^2\Pi(A')$ (comportant une orbitale π non appariée se trouvant dans le plan de rotation), est préférée pour les nombres quantiques élevés de OD, suggère que la réaction $H + D_2O \rightarrow OH + HD$ se produit par un mécanisme direct impliquant un état de transition plan alors que la portion OD agit comme spectateur et que la barrière à la réaction se trouve dans la « dernière » partie des coordonnées de la réaction.

[Traduit par la rédaction]

1. Introduction

Since the first pioneering infrared chemiluminescence studies of Cashion and Polanyi (1), observation and interpretation of vibrational product state distributions as well as the investigation of the influence of selective reagent vibrational (2, 3) and (or) translational excitations on the rate of reaction have remained central in the field of bimolecular reaction dynamics (4–6). A reaction that has been the subject for a large number of dynamical, both experimental and theoretical, studies, is the reaction $F + H_2 \rightarrow HF + H$ (which is isoelectronic to the four-atom $OH + H_2$ reactive system, investigated in this paper) and its deuterated counterparts. This reaction, as one of the simplest examples of an exothermic chemical reaction, has become a benchmark system (besides the thermoneutral hydrogen exchange reaction $H + H_2 \rightarrow H_2 + H$ (7)) for comparison between experimental and theoretical studies of atom + diatomic molecule systems. For this reaction detailed information about the product energy distribution has been determined

by infrared chemiluminescence experiments (8), chemical laser experiments (9), and from crossed molecular beam experiments (10). Thermal rate constants have also been measured over a wide temperature range (11, 12). Extensive theoretical studies of this reaction system have been carried out by Muckerman (13) and Polanyi and Schreiber (14) using the quasi-classical trajectory (QCT) method, developed in the 1960s by Bunker, Karplus, Polanyi, and their co-workers. Especially in Polanyi's studies, emphasis was given to studying the fundamental relationships between features of the underlying PES (potential energy surface) and the related dynamical aspects of the reactive collision of A + BC → AB + C systems. Based on the results of a series of extensive QCT studies (15) on different model semi-empirical, LEPS (London–Eyring–Polanyi–Sato) (16), and BEBO (bond-energy bond-order) (17) potential energy surfaces it was possible to derive several general principles (18). Although it emerged mainly from investigations of atom–diatom systems, as we will see later in this article, Polanyi's general description still holds in a variety of reactions, even those involving polyatomic reagents. In trajectory calculations of A + BCD → AB + CD systems Raff (19) and Smith (20) found that, compared to the newly formed bond AB, the "old" CD bond is only moderately excited. The influence of special mass combinations (e.g., where A is light compared to BCD) and geometries (bent transition states) on the efficiency of channelling energy into vibration of the "old" CD bond has been discussed in ref. 21.

Among bimolecular four-atom systems, the reaction

[1] $H + H_2O \rightarrow OH + H_2 \qquad \Delta H_0^0 = 62$ kJ/mol

and its reverse reaction

[2] $OH + H_2 \rightarrow H + H_2O$

have become prototypes for comparison between quantum state resolved experiments and bimolecular collision theory of reactions involving four atoms. LEPS and BEBO potential energy surfaces were constructed by Zellner and Smith in 1973 (22). The fact that three of the atoms involved in the reaction are hydrogen atoms furthermore favoured the development of a global *ab initio* potential energy surface. Already in the year 1980 an *ab initio* PES of the HHOH(A') gound state, the so called WD/SE (Walch–Dunning/Schatz–Elgersma) potential energy surface (23, 24), was constructed. The H-H-O-H transition state of reaction [1] was found to be bent and planar, with the H—O—H angle being very close to that in the free H_2O molecule, and with an O—H—H angle of 15° (25). The WD/SE-PES has a classical barrier of 0.923 eV for reaction [1], which is very close to the vibrationally adiabatic barrier of 0.94 eV, reported in ref. 26, and has an overall endoergicity of 0.659 eV. New *ab initio* surfaces were derived only recently by Isaacson (27) and Dunning et al. (28).

The first pioneering QCT studies of reaction [1] were carried out by Schatz et al. (29). They examined the influence of reagent translational excitation as well as normal-mode and local-mode excitation on the reactivity and the product state energy partitioning in reaction [1]. Additional quasi-classical (30–32) and quantum-classical (33) studies were carried out for reactions [1] and [2]. Quantum scattering studies on the dynamics of reaction [1] carried out by Clary in 1991 (34) represent the first quantum mechanical calculations for a four-atom reaction with realistic nonlinear geometry. Further quantum calculations of mode specificity in reaction [1] were reported also by Bowman and Wang (35), and by Clary (36). Most recently, quantum mechanical calculations on the dynamics of reaction [1], applying negative imaginary potentials (37), have been reported by Baer and co-workers (38).

The first experiments on the influence of translational excitation and isotopic substitution on the dynamics and on the absolute reaction cross section of reaction [2] were carried out by Wolfrum and co-workers (39, 40). Dynamics studies of reaction [2] have also been carried out by Kessler and Kleinermanns (41) and Honda et al. (42). Different experiments on the influence of selective vibrational excitation of H_2O on the reaction dynamics of reaction [1] and its isotopically substituted counterparts have been carried out. The first example of mode-selective chemistry of highly vibrationally excited H_2O with room temperature H atoms was reported by Crim and coworkers (43). The first experiments on the reaction of translationally excited H atoms with HOD/D_2O molecules, which are prepared only with low levels of vibrational excitation, were reported by Zare and co-workers (44). Measurements in which the HD product molecules from the reaction H + D_2O were detected with quantum state resolution were also reported recently from Zare's laboratory (45). Also recently, in Leone's group (46), the first measurements were carried out in which the rotational and vibrational excitation of water molecules by translationally excited H atoms has been investigated.

Due to the great importance of reaction [2] in combustion and atmospheric chemistry, the thermal rate constant was measured over an extended temperature range (47, 48). Additionally, in several experiments on the state specific kinetics of reaction [2], it was found that H_2 vibrational excitation promotes reactivity more than does vibrational excitation of OH (49). Only recently experimental results of a reaction dynamics study of the reaction OH + D_2 were reported in a communication by Casavecchia and co-workers (50), who measured the HOD product angular distribution using a crossed molecular beams setup.

In this article we report the first results of reaction dynamics studies of reaction [2] with translationally excited reactants. To study the influence of isotopic substitution on the dynamics we also investigated the reaction of OH with molecular deuterium, for which the two following reaction pathways

[3*a*] $OH + D_2 \rightarrow HOD + D$

[3*b*] $OH + D_2 \rightarrow D_2O + H$

are possible. In addition we studied the influence of reagent translation on the dynamics and the absolute reactive cross sections of reaction [1] by investigating the reaction H + D_2O.

[4*a*] $H + D_2O \rightarrow OD + HD$

$\rightarrow OH + D_2$

For all reactions [2], [3], and [4] we measured absolute reactive cross sections and branching ratios at different collision energies.

2. Experimental

The experiments we report here were performed using two separate experimental setups, which are depicted schematically in Figs. 1 and 2. In all experiments we used the laser photolysis/laser-induced fluorescence (LP/LIF) "pump–probe" technique. It is essentially the same

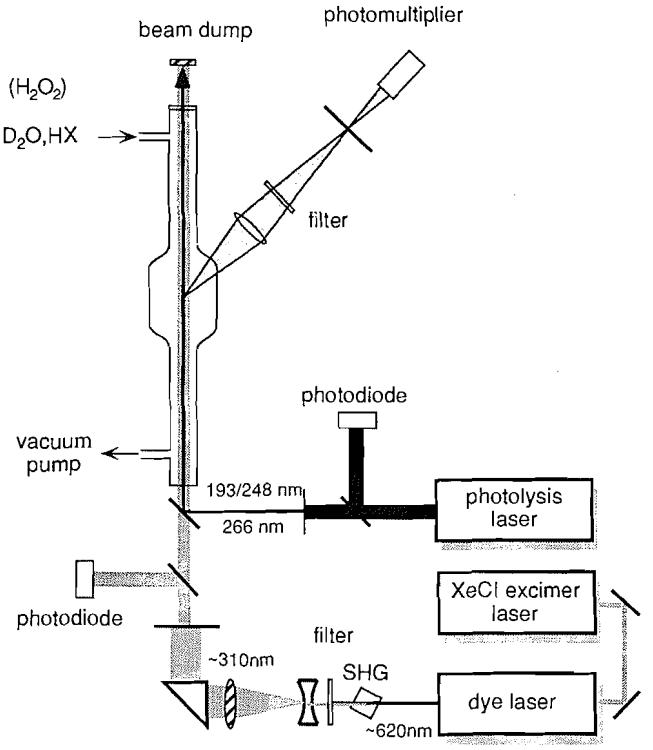

FIG. 1. Schematic diagram of the experimental setup that was used to study the reaction H + D_2O.

method already used to measure reaction cross sections and OH quantum state distributions for the reactions H + NO (51*a*), H + O_2 (51*b*), and H + CO_2 (51*c*).

Reaction [4] was studied in a Teflon-coated quartz reactor (depicted in Fig. 1) equipped with long sidearms acting as a baffle system to keep scattered light out of the fluorescence-collecting optics. The experiments were carried out in flowing mixtures of HX (with HX being either H_2S UCAR, electronic grade, or HI UCAR, 98%) and room temperature D_2O (Merck 99.8%) with a ratio of 1:10 at a total pressure of typically 50–70 mTorr (measured by a MKS Baratron) (1 Torr = 133.3 Pa). H_2S was used without further purification; HI was pumped through a cooling trap to remove I_2 impurities before entering the reaction cell. Translationally excited H atoms were generated by photodissociation of the HX precursor using an excimer laser (Lambda LPX 205) with unstable resonator optics. The laser was operated at 20 Hz with an ArF mixture (emission wavelength 193 nm) to photodissociate H_2S and with a KrF mixture (emission wavelength 248 nm) to photodissociate H_2S and HI. A circular diaphragm with an aperture of 3 mm was used to skim off a homogeneous irradiated part of the unfocused rectangular excimer profile to provide the photolysis beam. In addition we used the fourth harmonic of a Nd:YAG laser (Spectra Physics GCR 11, operated at 10 Hz) to photodissociate HI at 266 nm. Energies of 5 mJ/pulse at 193 nm (at this pulse energy no OD background from the direct D_2O photolysis was detectable), 10 mJ/pulse at 248 nm, and 5 mJ/pulse at 266 nm (measured with an energy detector Gentec ED 200) were used in the experiment. With these pulse energies both the OD signals from the reaction as well as the OH signals from the H_2O_2 photodissociation showed a linear dependence on the photolysis laser intensity. We therefore conclude that with the above-mentioned pulse energies no nonlinear effects in either the HX or the H_2O_2 photodissociation were present. For the calibration measurements H_2O_2 was pumped through the cell at a total pressure of typically 10 mTorr. Prior to use, the H_2O_2 (85% PEROXID Chemie) was pumped through the cell for at least 3 days until it reached a final concentration >99.8% (determined by titration).

Typically, 60–150 ns after the photolysis laser pulse, the nascent OD/OH product radicals were probed by a second copropagating laser beam via laser-induced fluorescence of the $A^2\Sigma^+ \leftarrow X^2\Pi$ system. The UV probe beam (bandwidth 0.2 cm^{-1}) in the wavelength region of 305–320 nm was provided by a frequency-doubled dye laser (Lambda FL 2002 EC) working with Rhodamine B, pumped by a XeCl excimer laser (Lambda EMG 201 MSC). To ensure a linear dependence of the OH/OD fluorescence on the probe laser intensity the probe beam was attenuated and expanded with a telescope to a diameter of 12 mm and aligned to overlap the 3 mm diameter photolysis beam in the focus of observation. The emitted OH fluorescence was collected by a lens ($f = D = 50$ mm) and projected through a 1 × 5 mm slit aperture and a UV filter (Schott UG 11, 1 mm) upon the cathode of a photomultiplier (EMI 9781 B, voltage 620 V). The OH/OD LIF signal as well as the photolysis and probe intensities (both measured with photodiodes) were recorded with a 3-channel boxcar system (SRS 250) and transferred to a microcomputer (HP series 9000, model 320) via an analog-to-digital converter (SRS 235). The OH/OD fluorescence signals were normalized to both photolysis and probe laser intensity. OH/OD LIF spectra were recorded between 306.5 and 324 nm, where most of the OH/OD($A^2\Sigma^+$, $v' = 0, 1 \leftarrow X^2\Pi$, $v'' = 0, 1$) transitions are located. Line positions of the OH/OD(A–X) transitions were taken from refs. 52 and 53.

The experiments in which H/D atoms from reactions [2] and [3] were detected were carried out in a flow reactor with a slightly modified design. Due to the need to directly connect the VUV generation cell to the reactor, we had to switch to a crossed laser beam setup, schematically shown in Fig. 2. These experiments were carried out in a flowing mixture of H_2O_2 and room temperature H_2 (>99.999%) or D_2 (>99.7%) with a ratio of 1:10 at a total pressure of 60–120 mTorr, using the 248 nm (193 nm) laser photolysis of H_2O_2 to produce translationally excited OH radicals. For the calibration measurements H_2S (UCAR electronic grade), HCl (>99.999%) was pumped through the cell at a total pressure of 5 mTorr. The H,D product atoms were probed by a VUV laser beam, via laser-induced fluorescence at the corresponding Lyman-α transition, 80–150 ns after the photolysis laser pulse. The VUV probe laser beam was carefully aligned to overlap the photolysis beam at right angles in the viewing region of the detector. The LIF signal was measured by a solar blind photomultiplier (Hamamatsu model R1259, denoted as PM 1 in Fig. 2) at right angles to both the pump and probe laser beam, through a band pass filter (ARC, model 122-VN-ID, $\lambda_c = 122$ nm, FWHM = 20 nm). The VUV probe beam intensity was monitored before and after passing through the reaction cell with two additional solar blind photomultipliers (denoted PM 2 and PM 3 in Fig. 2).

The VUV probe laser light (bandwidth 0.4 cm^{-1}) for H (121.567 nm) and D (121.534 nm) atom detection was generated by resonant third-order sum-difference frequency conversion ($\omega_{VUV} = 2\omega_R - \omega_T$) in a phase-matched Kr–Ar mixture (54). The frequency ω_R ($\lambda_R = 212.55$ nm) is in resonance with the 4*p*-5*p* (1/2, 0) two-photon transition in Kr and ω_T is the tuning frequency ($\lambda_T = 844$–848 nm). The fundamental laser radiation was obtained from two tunable dye lasers (Lamda FL 2002 EC), simultaneously pumped by a XeCl excimer laser (Lambda 201 MSC), one of which (ω_R) was frequency doubled with a BBO II crystal. The generated Lyman-α light was separated from the fundamental lasers by a monochromator lens (denoted as ML in Fig. 2). The Lyman-α probe beam via photolysis of the precursor molecule H_2O_2 produces a significant amount of additional H atoms. To distinguish these H atoms from the H atoms produced in the reaction, a shutter was inserted in the photolysis beam path. At each step of the scan, the signal was first averaged with the shutter opened and again averaged with the shutter closed. A point-by-point subtraction procedure was adopted, to obtain a signal free from the background H atoms described above. All photomultiplier signals (from PM 1, PM 2, PM 3), as well as the photolysis and probe laser intensity signals were recorded with a 4-channel boxcar system (SRS 250) and transferred to the laboratory computer, via an analog-to-digital converter (SRS 235), where the H/D atom LIF signal was normalized to both photolysis and probe laser intensities. To obtain a satisfactory S/N ratio each point in the recorded spectra was averaged over at least 30 laser shots. In all the experiments we carefully checked

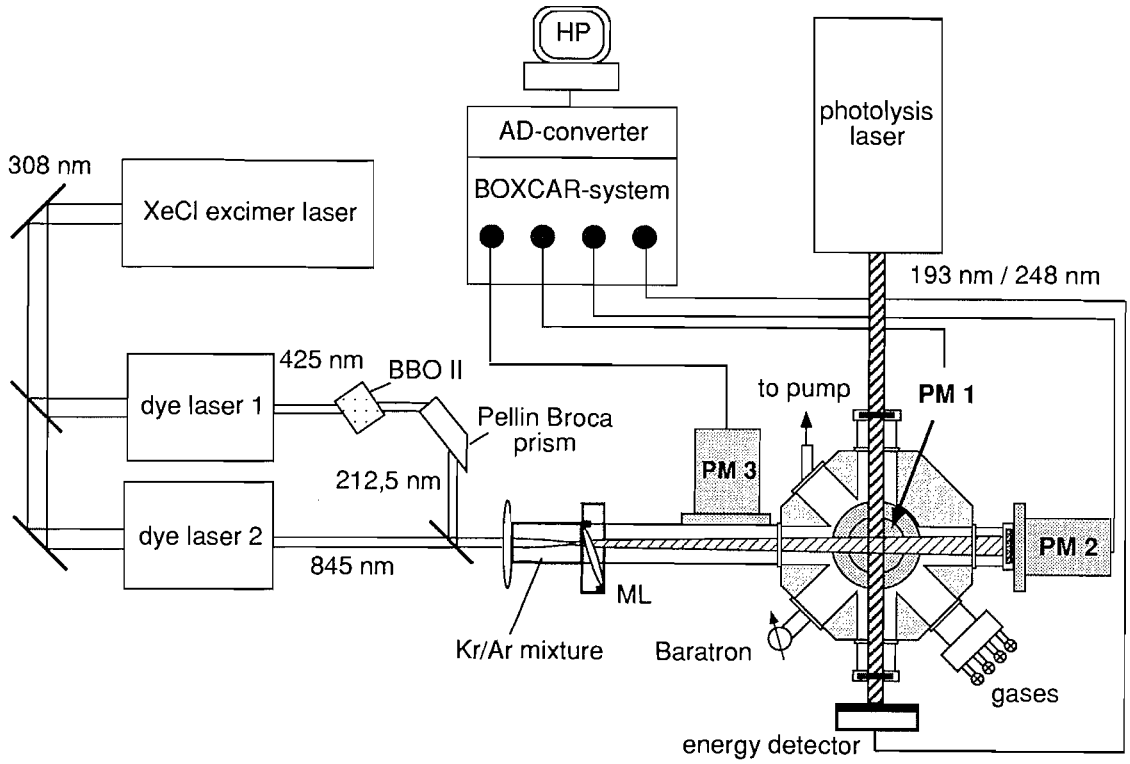

FIG. 2. Schematic diagram of the experimental setup that was used to study the reactions OH + H_2/D_2 (ML = monochromator lens; PM = photomultiplier).

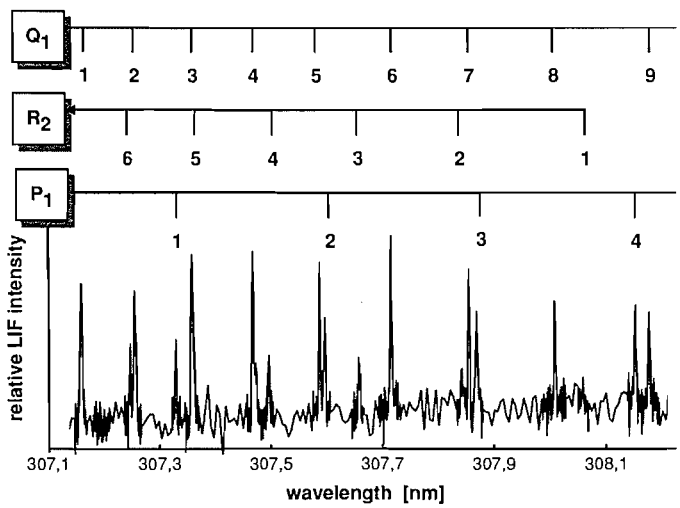

FIG. 3. Part of the OD($A^2\Sigma^+$, $v' = 0 \leftarrow X^2\Pi$, $v'' = 0$) LIF spectrum from the reaction H + D_2O at $E_{c.m.}$ = 2.2 eV

that the flow rate in the reaction cell was high enough to ensure total gas renewal in the volume sampled between two successive laser shots.

3. Experimental results

In Fig. 3 a typical LIF spectrum of OD radicals produced in reaction [4*a*] is shown, where the "hot" H atoms with an average center-of-mass energy of $E_{c.m.}$ = 2.2 eV were generated by 193 nm photolysis of H_2S. Each point in the recorded spectrum was averaged over 40 laser shots. To determine the relative number densities n_i of OD and OH radicals in the absorbing rotational level i we used the following linear relationship

$$[5] \quad I_{meas,ik} = Cn_iB_{ik}\nu_{ik}I_{probe}I_{photo}$$

where B_{ik} is the Einstein coefficient of absorption (taken from (refs. 55 and 56) and ν_{ik} is the wavenumber for the transition $i \rightarrow k$. I_{probe} is the probe laser intensity and I_{photo} the intensity of the photodissociation laser. C is a factor that describes the effects of the detector system such as quantum efficiency, geometrical collection efficiency, etc. on the measured LIF intensity. $I_{meas,ik}$ is determined by numerical integration of the corresponding spectral line profile $i \rightarrow k$ in the digitized LIF spectrum. Overlapping lines were deconvoluted by fitting separate Gaussian functions to the digitized LIF spectrum using a numerical least-squares fitting procedure. For overlapping satellite and main lines the sum was determined and separated into components by the known ratio of their Einstein coefficients.

Typical Lyman-α H atom and D atom spectral lines are shown in Fig. 4. The H atoms were generated from the 248-nm photodissociation of H_2S. The D atoms were produced in the reaction OH + D_2. From the spectral line, relative H and D atom number densities were determined by numerical integration of the corresponding spectral line profiles using a linear relationship similar to eq. [5].

3.A. $H + D_2O$

The electronic ground state of the OH/OD radical is a $^2\Pi$ state. Therefore there is an unpaired π orbital lying perpendicular to the internuclear axis. Due to the interaction between the spin of the electron and the electronic angular momentum, every rotational state is split into two spin-orbit states, $\Pi_{1/2}$ and $\Pi_{3/2}$. In the rotating molecule the interaction between the electronic angular momentum and the rotational angular momentum splits every spin-orbit state into two Λ components (57), denoted as $\Pi(A')$ and $\Pi(A'')$ according to ref. 58. In the high J limit, where Hund's case (*b*) description is appropriate, the electronic wave function in both spin-orbit states has a definite

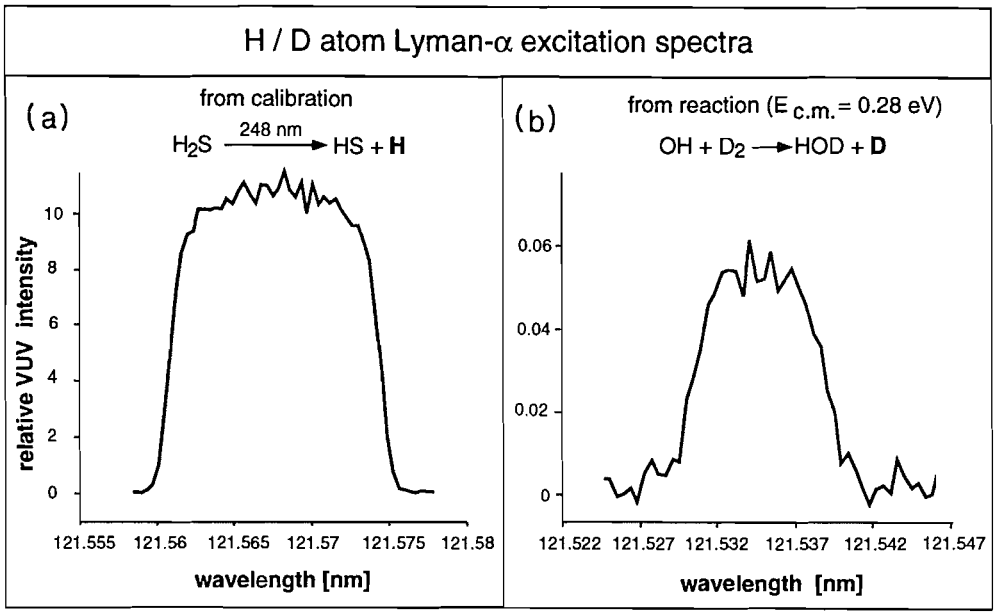

FIG. 4. H/D atom spectral lines. (*a*) H atoms from the 248 nm photolysis of H_2S. (*b*) D atoms from the reaction OH + D_2 → HOD + D at $E_{c.m.}$ = 0.28 eV.

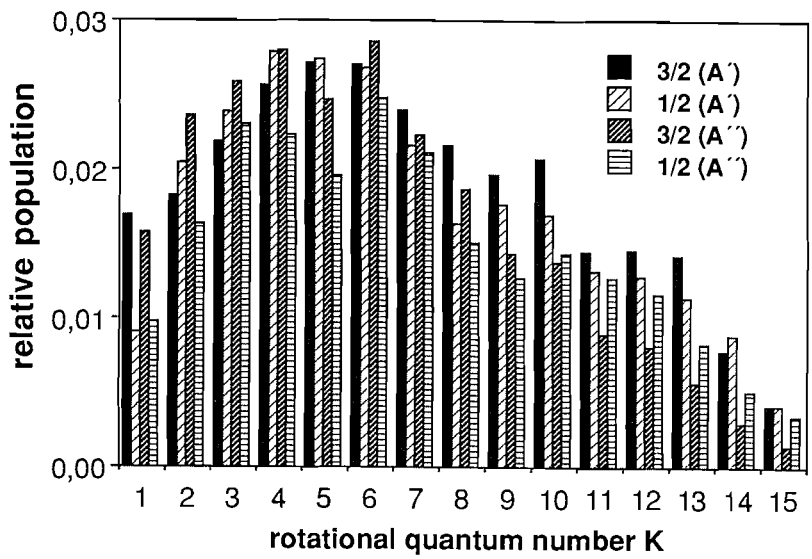

FIG. 5. Population distribution of the rotational fine structure states of the OD($v = 0$) products from reaction [4*a*] at $E_{c.m.}$ = 2.2 eV. The distribution has been normalized to have a total population of unity.

reflection symmetry with respect to the plane of rotation. In this case the $\Pi(A')$ Λ-doublet states can be characterized by the π molecular orbital lobes being located in the plane of rotation, while in case of the $\Pi(A'')$ Λ-doublet states the π molecular orbital lobes are oriented perpendicular to the plane of rotation.

In Fig. 5 the OD($v = 0$) product rotational fine-structure distribution from reaction [4*a*] at $E_{c.m.}$ = 2.2 eV is shown. From the relative population of the fine-structure energy levels we calculate the average OD rotational energy to be $\langle E_{Rot} \rangle$ = 0.06 eV. This means that only about 4% of the excess energy in the reaction appears in the rotational degree of freedom of the OD radicals. At the other collision energies we found a similar behaviour. At 1.5 eV, 7%, and at 1.8 eV, 5% of the total available energy appears as rotational energy of the OD products. At none of the collision energies used in our investigation could any OD($v = 1$) products be observed. From our S/N ratio we determined the upper limit for the OD $v = 1/v = 0$ ratio to be 0.05 ± 0.01.

From the fine-structure distribution we determined the population ratio of the two spin-orbit components. The $\Pi_{3/2}/\Pi_{1/2}$ ratio (weighted by $K/(K + 1)$ to account for the different degeneracy of the two spin-orbit states) is almost unity for all rotational quantum numbers K. On the other hand a markedly preferential population for the $\Pi(A')$ states at high rotational quantum numbers was found, when we calculated the Λ-doublet ratio $\Pi(A')/\Pi(A'')$, shown in Fig. 6.

Absolute reactive cross sections were measured applying the method introduced by Kleinermanns and Wolfrum (59). Using pulsed laser systems (typical pulse duration 8–10 ns), this method allows measurements of absolute product radical num-

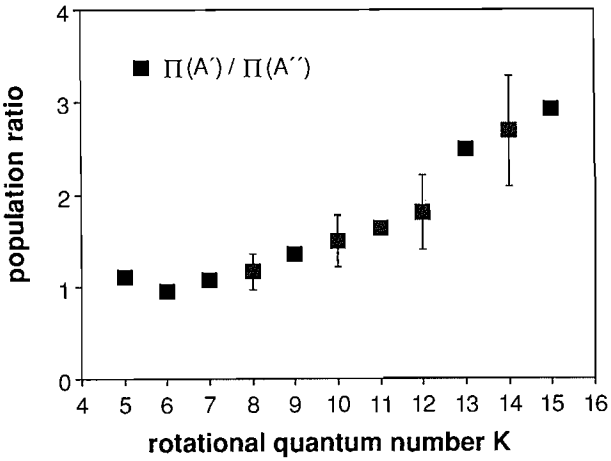

FIG. 6. Population ratio $\Pi(A')/\Pi(A'')$ of the OD(v = 0) Λ-components at high rotational numbers.

ber densities with a time resolution high enough to determine absolute reaction cross sections under single collision conditions. This method utilizes a well-defined radical source to calibrate the LIF signal from unknown number densities obtained in the reaction. In this work we used the well-characterized photodissociation of H_2O_2 (60) to generate well-defined OH number densities. The final equation [6], to calculate the absolute reaction cross section given in ref. 40, consists of several directly measurable parameters.

$$[6]\quad \sigma = (n_{R,i} f_{C,n} \phi^{OH} \sigma^{H_2O_2}[H_2O_2])/(n_{C,i} f_{R,n} \sigma^{HX}[HX][D_2O] t v_{rel})$$

Here [A] denote the concentrations of species involved (usually given in cm^{-3}), which are calculated directly from the corresponding partial pressures. Values for the H_2O_2 absorption cross sections $\sigma^{H_2O_2}$ and the corresponding quantum yields ϕ^{OH} were taken from ref. 61. σ^{HX} denotes the absorption cross section of the H atom precursor molecule HX. Absorption cross sections for HI at 248 and 266 nm were taken from ref. 62. In the case where the 248 and 266 nm HI photolysis was used to generate H atoms, the absorption cross sections given in ref. 62 were multiplied with the $I(^2P_{3/2})/I(^2P_{1/2})$ branching ratios given in ref. 62. This was necessary to account for the fact that at both photodissociation wavelengths only the "fast" H atoms from the $H + I(^2P_{3/2})$ dissociation channel have enough energy to overcome the reaction barrier. v_{rel} is the relative velocity of the reactants, calculated from energy and momentum conservation of the HX photodissociation at the given photolysis wavelength of the experiment using the formulas given in ref. 63. In the case of the 193-nm H_2S photodissociation (where X = HS) the average relative velocity was determined by weighted averaging over the measured H atom distribution reported in ref. 64. $n_{R,i}$ denotes the relative number density (calculated using eq. [3]) of OD radicals from the reaction in the fine-structure state i, $n_{C,i}$ is the relative number density of OH radicals in the same fine-structure state i from the H_2O_2 photolysis. $f_{R,i}$ and $f_{C,i}$ refer to the corresponding relative population of the fine-structure state i. The delay time t was determined directly by measuring the time difference between the pump and probe stray light pulses on a fast oscilloscope (Tektronik model 485, 350 MHz).

As one can see from eq. [6], prior to the measurement of the absolute reaction cross section, the complete OD/OH vibrational and rotational distribution for the reaction and the H_2O_2 photolysis had to be determined. After this, a single spectral OD line starting from one fine-structure level i was recorded in the reaction. After flushing the cell with N_2 (for at least 30 min), H_2O_2 was flowed through the reactor (again for at least 20 min, to ensure complete wall passivation of the reaction cell) and the corresponding OH spectral line was recorded in the H_2O_2 photodissociation. With this procedure, which was repeated several times for different nonoverlapping Q and P branch spectral lines, we determined the following absolute reactive cross sections for reaction [4a]:

$$\sigma_R(1.5\text{ eV}) = (0.07 \pm 0.04)\ \text{Å}^2$$

$$\sigma_R(1.8\text{ eV}) = (0.10 \pm 0.03)\ \text{Å}^2$$

$$\sigma_R(2.2\text{ eV}) = (0.11 \pm 0.03)\ \text{Å}^2$$

Each of the following values represents the mean value calculated from at least eight independent calibration measurements using the method described above. The experimental error was calculated from the errors of the entries of eq. [6] on the basis of simple error propagation. Errors of the absorption cross sections and quantum yields were taken from the corresponding references. The absolute error in the measurement of the delay time t between photolysis and probe laser pulse (which is due to the intrinsic time jitter of both lasers) was estimated to be ±5 ns.

In several of the OD spectra we recorded, we found weak but clearly detectable OH(v = 0, K = 1–8) signals. In contrast to this, within our detection limit, no OH(v = 1) were found. Several test runs at a photolysis wavelength of 193 nm were carried out, where only D_2O was pumped through the cell. In this case no OH signals were detectable. So we conclude that the OH signals are not due to the direct photolysis of H_2O/HOD impurities of our D_2O sample. In all the measurements we found that OH signals were only present when HX/D_2O mixtures were pumped through the reactor. Even though the HX and D_2O were mixed just before entering the reaction cell we cannot rule out the possibility of fast heterogenous isotope exchange reactions in the short part of the line where both compounds are present. This could lead to H_2O/HOD and later in the reactor, via H + H_2O/HOD, to OH formation. Therefore we suggest that our values R^* represent upper limits for the ratio $R = \sigma[4b]/\sigma[4a]$ of the reaction cross sections. By comparing the relative number densities of the observed OH rotational levels (which have been corrected to account for the OH contribution arising from the reaction of H atoms with the small amount of H_2O/HOD impurities (0.2%) specified by the D_2O manufacturer, using the cross sections reported in refs. 39a and 44b) with those of the corresponding OD rotational levels, we determined the following values:

$$R^*(1.5\text{ eV}) = (4.1 \pm 0.5) \times 10^{-3}$$

$$R^*(1.8\text{ eV}) = (4.2 \pm 0.5) \times 10^{-3}$$

$$R^*(2.2\text{ eV}) = (4.9 \pm 0.4) \times 10^{-3}$$

These values are consistent with the qualitative observation made in ref. 42 and the ratio of the thermal rate constants $k[4b]/k[4a]$ reported in ref. 65.

3.B. OH + H_2/D_2

The method used to determine absolute reaction cross sections for these reactions is in principle the same as already described above. The differences are that here H_2O_2 was used as a precursor for translationally excited OH radicals and that H/D atoms were detected on the product side. The H/D atom signals from the reaction of OH with molecular hydrogen and deuterium were calibrated against H atom signals from the HX (X = Cl, HS) photolysis.

As already discussed in ref. 60, H_2O_2 photodissociation at 248 and 193 nm is a convenient source of translationally almost monoenergetic OH($v = 0$) radicals. At 193 nm only 2% OH($v = 1$) frequents have been detected, and at 248 nm the OH radicals are produced exclusively in the vibrational ground state. At both wavelengths the population of the OH rotational states can be described by a sharply peaked Gaussian-like distribution. At 193 nm the maximum of the rotational state distribution is located at $K = 12$, with a FWHM of $\Delta K \approx 3$, and at 248 nm the maximum of the distribution is located at $K = 6$, with a FWHM of $\Delta K \approx 4$.

To calculate the absolute reaction cross sections we used an equation similar to eq. [6]. The absolute reaction cross section for reaction [3*a*], for example, was determined using the following expression:

$$[7] \quad \sigma = (n_R \sigma^{HX}[HX])/(n_C \phi^{OH} \sigma^{H_2O_2}[H_2O_2][D_2] t v_{rel})$$

In this case n_R denotes the relative number density of the D atoms produced in the reaction and n_C is the relative number density of H atoms produced in the HX photolysis. The mean relative velocity v_{rel} in the center-of-mass frame was calculated from the average laboratory velocities (4.0 km/s at 248 nm and 4.6 km/s at 193 nm) given in refs. 66 and 51*c*, using the formulas from ref. 63. In the special case of reactions [2] and [3*b*], the direct photolysis of H_2O_2 at 193 nm already generates an H-atom background signal. So, n_R in eq. [7] has to be taken as the difference between the relative number densities of H atoms produced in the reaction and the H atom background generated by direct 193 nm photolysis of H_2O_2. In the case of H_2O_2 photolysis at 248 nm, no H atoms were observed from the direct photolysis, within our detection limit. So in this case it was not necessary to apply the above-mentioned subtraction method.

Repeating the calibration procedure several times at different reactant pressures and delay times, the following absolute reactive cross sections for the reactions [2] and [3*a*] were determined:

$$\sigma_{R,[2]}(0.17 \text{ eV}) = (0.08 \pm 0.03) \text{ Å}^2$$

$$\sigma_{R,[2]}(0.22 \text{ eV}) = (0.60 \pm 0.30) \text{ Å}^2$$

$$\sigma_{R,[3a]}(0.28 \text{ eV}) = 0.22 \pm 0.05) \text{ Å}^2$$

$$\sigma_{R,[3a]}(0.37 \text{ eV}) = 0.43 \pm 0.09) \text{ Å}^2$$

The subtraction procedure to eliminate the H atom background originating from the 193 nm photolysis of H_2O_2 magnifies significantly the experimental error involved in the cross section measurement. As a consequence, for reactions [2] and [3*b*] it was not possible to measure reaction cross sections with an accuracy better than 0.1 Å^2 in the case of photolysis at 193 nm. Nevertheless, we could not detect any H atom signals that could clearly be assigned to reaction [3*b*]. Therefore, we determined an upper limit of the reaction cross section to be 0.1 Å^2 for $E_{c.m.} = 0.37$ eV (photolysis wavelength 193 nm) taking into account the above-mentioned errors, and 0.001 Å^2 for $E_{c.m.} = 0.28$ eV (photolysis wavelength 248 nm). Thus we report the following K^* values, being upper limits for the ratio $K = \sigma[3b]/\sigma[3a]$ of the reaction cross sections.

$$K^*(0.28 \text{ eV}) = 4.5 \times 10^{-3}$$

$$K^*(0.37 \text{ eV}) = 2.3 \times 10^{-1}$$

It should be noted that, due to the special mass combination of the reactants, the width (FWHM) in the collision energy distribution arising from the thermal motion of the reactants is substantially large (0.095 and 0.11 eV at $E_{c.m.} = 0.17$ eV and $E_{c.m.} = 0.22$ eV, for reaction [2]; 0.12 and 0.15 eV at $E_{c.m.} = 0.28$ eV and $E_{c.m.} = 0.37$ eV, for reaction [3]). This large inherent spread in $E_{c.m.}$ limits the resolution for closer investigation of the variation of the cross section with energy, so that additional measurements of cross sections near threshold with this method will hardly provide more detailed information regarding the excitation function.

4. Discussion

The rather small branching ratios R^* and K^* that we determined in our study clearly indicate that reactions [1] and [2] proceed almost exclusively with a direct mechanism rather than with an indirect mechanism via an H_3O intermediate.

The low rotational excitation and the absence of vibrational excitation of the OD product radicals from reaction [4*a*] (identical results were found in previous studies of reaction [1]) furthermore support the conclusion that the reaction proceeds by a direct abstraction mechanism without forming a long-lived complex (which would lead to a statistical distribution of the available energy over the product degrees of freedom). As already discussed in refs 44 and 42, the low degree of vibrational excitation of the OD products can be attributed to special features of the transition-state geometry (24). A comparison of the OD bond length of the nonreacting OD bond at the transition state with the equilibrium values in the D_2O and OD molecules shows that the OD bond length is almost unchanged in going from reagents through the transition state to the products. This condemns the OD moiety to play the role of a spectator during the reactive collision.

Different explanations have been given to account for the generally low rotational excitation of OH radicals produced via reaction [1]. In ref. 39*a* an impulsive model was presented, in which OH rotation is excited by impulsive forces between the O atom and the departing H_2 molecule. In this model the degree of OH rotational excitation is limited by the small mass of the H_2 fragment and the small "lever arm" (which is defined as the distance between the center of mass of the OH molecule and the O atom) on which the impulsive force can exert torque during the breakup of the transition state. Owing to the fact that in the case of OD the lever arm is about twice as long as it is in OH, one would expect in general a higher degree of rotational excitation for OD products from reaction [4*a*] than for the OH products from reaction [1].

In refs. 29 and 40 a simple stripping model was discussed. In this picture the OH rotational excitation is produced by simply mapping reagent (H_2O) bend excitation onto the OH rotation.

The final average rotational energy of the OH/OD products from reaction [1]/[4*a*] should therefore be proportional to the energy in the H_2O/D_2O zero-point bending motion, which becomes a free OH/OD rotational motion after the reaction. Thus the average rotational energy of OH products from reaction [1] should always be about 1.4 times the average rotational energy of OD products from reaction [4*a*].

The results of several experimental and theoretical studies have shown that it is not possible to explain all the experimental results within the framework of simply one of the above-mentioned models (43, 44). At $E_{c.m.}$ = 1.5, 1.8, and 2.2 eV we and other workers (44*c*) found more rotational excitation in OD from reaction [4*a*] than in OH from reaction [1], while at a higher energy of 2.5 eV (39*b*, 40) the opposite behaviour was found. This led us to conclude that the mechanism responsible for the hydroxyl product rotational excitation changes from an impulsive mechanism at lower collision energies to a stripping mechanism at higher energies. In QCT studies of reaction [4*a*] it was found that, in qualitative agreement with our experimental results, the OD product rotational excitation indeed decreases with increasing collision energy (32*c*).

In Fig. 6 the population ratio $\prod(A')/\prod(A'')$ of the OD Λ-doublet components is plotted against the rotational quantum number K. At $E_{c.m.}$ = 2.2 eV we found that the $\prod(A')/\prod(A'')$ ratio of the OD radicals from reaction [4*a*] increases monotonically with increasing rotational quantum number, reaching a value of about 3 at the highest K probed. The same behaviour was found at $E_{c.m.}$ = 1.5 eV (44) and 1.8 eV. Preferential population of the symmetric OH $\prod(A')$ Λ-doublet component has also been reported for the OH fine-structure distributions from reaction [1] (39, 42, 44*b*, 44*c*). Integration of the observed $\prod(A')/\prod(A'')$ ratio over the rotational quantum states populated in the reaction furthermore shows that the total cross section for producing OD in the $\prod(A')$ state in reaction [4*a*] is significantly larger than the total cross section for producing OD in the $\prod(A'')$ state. This may be understood on the basis of a simple classical model: An analysis of the normal mode eigenvector of the imaginary frequency in the transition state of reaction [1] shows that this mode is mainly an OH stretch (35*c*). So, the preferential population observed for the OD A' states in reaction [4*a*] simply reflects that a perpendicular collision of H with D_2O (which would lead to OD in the A'' state) has less chance to couple with the O—D stretching in the transition state, which would move the system along the reaction coordinate. On the other hand, a planar approach has more chance to couple with the O—D stretching, leading to the higher cross section for OD formation with the unpaired π orbital lobes left in the plane of reagent approach.

In Fig. 7 we have compared our experimental absolute reactive cross sections of reaction [4*a*] with the results of recent QCT calculations (32*c*). For comparison, QCT results for reaction [1] are also included, together with experimental values reported in refs. 39*a*, 40, and 41. As one can see, the reaction cross sections are generally small, showing a pronounced isotope effect, which is very well reproduced by the QCT calculation. For reaction [4*a*] the reaction cross section increases only about 30% when the collision energy is increased from 1.5 to 2.5 eV. This has to be compared to the increase of reactivity when energy is added as D_2O reagent vibration. In ref. 44*c* it was demonstrated that an increase of 0.35 eV in the asymmetric stretch vibration (0, 0, 1) of D_2O increases the cross section by at least 400%. Similar enhancement in the reactivity has been

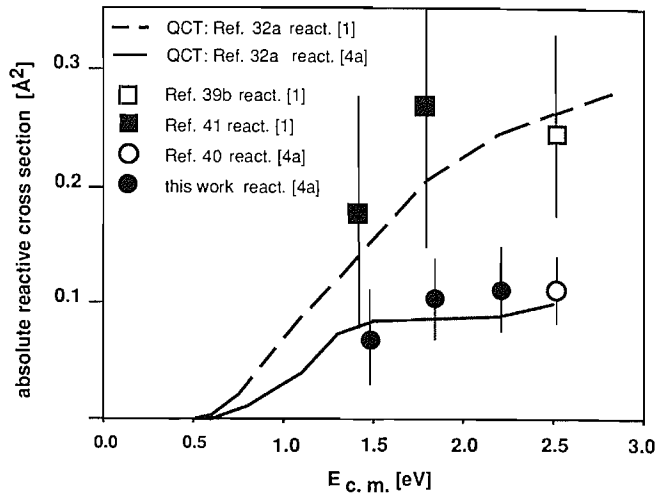

FIG. 7. Absolute reactive cross section for $H + D_2O \rightarrow OD + HD$ (reaction [4*a*]). For comparison, both experimental and theoretical results obtained for $H + H_2O \rightarrow OH + H_2$ (reaction [1]) have also been included.

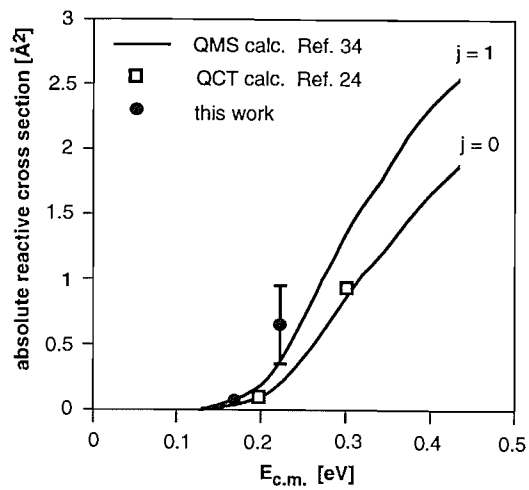

FIG. 8. Absolute reactive cross section of the reaction $OH + H_2 \rightarrow H_2O + H$.

observed in the studies of Crim and co-workers (43), where the influence of H_2O vibrational overtone excitation on the reactivity of reaction [1] was investigated. This behaviour is consistent with the general principle for the effects of translational versus vibrational energy on the reaction cross section of endothermic reactions with a "late" barrier (15*b*). In several *ab initio* studies it has been found that the reactions [1] and [4*a*] have a "late" barrier (23) and thus the behaviour described above is as expected.

In Fig. 8 we have compared our experimental absolute reaction cross sections of reaction [2] with results from recent QMS (quantum mechanical scattering) calculations (34) and previous QCT studies (24) of reaction [2]. In the case of reaction [2] we found that translational excitation is more efficient in promoting reactivity than it is for the reverse reaction [1]. This is in good agreement with the above-mentioned principle, because the reaction barrier is now located at an "early" stage of the reaction coordinate.

At this point it should be mentioned that the experimental conditions are somewhat different from the assumptions made

in the dynamical calculations. In the experiments the OH radicals are highly rotationally excited, while, for example, the QCT cross sections (depicted in Fig. 8) were calculated for nonrotating OH (24). The influence of OH rotation on the reactivity was investigated in a separate study on the original WD/SE PES (which has some well-known nonphysical features in the OH + H_2 channel) by the same workers (29*d*), where they found that the cross section decreases with increasing rotational number. The QMS cross sections (depicted in Fig. 8) were calculated for nonrotating OH and for OH with one quantum of rotation using a slightly modified version of the WD/SE potential (in which a damping function was added to remove the above-mentioned defects of the original PES).

Harrison and Mayne (31) carried out a detailed QCT study on the influence of reagent rotation on the reactivity of reaction [2], using the original WD/SE PES and the RB (Rashed–Brown) modification (30*b*) of the WD/SE PES. They found that the way OH rotation influences the reactivity is very sensitive to details (and therefore also to the defects) of the potential. Their results suggest that most of the previous results (29*d*, 30*b*) were affected by the presence of artificial wells (hills, in case of the RB modification) in the OH + H_2 entrance channel.

For comparison with our experimental results, additional studies (both quantum mechanical and quasi-classical) of the influence of OH rotation (up to at least 20 quanta) and isotopic substitution on the reactive cross section of [2] on new PES are clearly needed. This would allow us to average the theoretical OH rotational state specific cross sections over the OH reagent rotational state distributions and the collision energy distribution used in the experiments, a procedure that is clearly necessary for a detailed comparison.

Rate constants for charge transfer and vibrational deactivation in the $N_2^+(X^2\Sigma_g^+, v = 0, 1, 2)$ + Ar and O_2 reactions are directly measured by a state-resolved optical detection method. The novel, selected-ion flow tube, laser-induced fluorescence (SIFT–LIF) technique is used to study the vibrationally specific reactions at near-thermal collision energy. The total rate constant for $N_2^+(v = 1, 2)$ + Ar increases by more than a factor of 40 relative to $N_2^+(v = 0)$. This enhancement is due exclusively to an increase in the charge transfer channel. The charge transfer rate constants for the $N_2^+(v)$ + Ar reaction are found to be almost identical for $v = 1$ and $v = 2$; this differs slightly from previous results at higher collision energies. The vibrational deactivation rate constant for the $N_2^+(v = 1)$ + Ar reaction is measured for the first time; the upper limit for the branching fraction is ≈3%, confirming that this reaction is a useful monitor for $N_2^+(v > 0)$. The total rate constant for $N_2^+(v = 1, 2) + O_2$ increases by factors of 2.6 and 3.3, respectively, relative to $N_2^+(v = 0)$. In contrast to the N_2^+ + Ar reaction, this enhancement is largely due to the occurrence of vibrational deactivation, which is found to be slightly faster for $v = 2$ than for $v = 1$. For $N_2^+(v = 2) + O_2$, the $v = 2 \rightarrow 1$ and $v = 2 \rightarrow 0$ vibrational deactivation channels are found to occur with comparable rates. The lack of substantial enhancement in the charge transfer channel in the $N_2^+(v) + O_2$ reaction by vibrational excitation (up to $v = 2$) is in contrast to the observed translational enhancement, which opens a higher lying, endothermic $O_2^+(a^4\Pi_u)$ product channel. These results are consistent with a short-range, curve-crossing mechanism that efficiently channels energy into the $O_2^+(a^4\Pi_u)$ state.

Faisant appel à une méthode de détection optique résolue par état, on a mesuré directement les constantes de vitesse du transfert de charge et de la désactivation vibrationnelle dans les réactions $N_2^+(X^2\Sigma_g^+, v = 0, 1$ et $2)$ + Ar et O_2. On utilise la nouvelle technique de fluorescence induite au laser avec tube à écoulement pour ion choisi (SIFT–LIF) pour étudier les réactions vibrationnellement spécifiques à une énergie de collision pratiquement thermale. La constante de vitesse totale pour la réaction $N_2^+(v = 1$ et $2)$ + Ar augmente 40 fois plus rapidement que celle pour $N_2^+(v = 0)$. Cette différence est presqu'exclusivement due à une augmentation dans le canal du transfert de charge. On a trouvé que les constantes de vitesse de transfert de charge pour la réaction $N_2^+(v)$ + Ar sont pratiquement identiques pour $v = 1$ et $v = 2$; ces observations diffèrent légèrement des résultats antérieurs obtenus à des énergies de collision plus élevées. On a mesuré pour la première fois la constante de vitesse de la désactivation vibrationnelle de la réaction $N_2^+(v = 1)$ + Ar; la limite supérieure pour la fraction de bifurcation est d'environ 3%, confirmant que cette réaction est une façon utile de suivre le $N_2^+(v > 0)$. La constante de vitesse globale pour la réaction $N_2^+(v = 1$ et $2) + O_2$ augmentent respectivement par des facteur de 2,6 et 3,3 par rapport à la réaction de $N_2^+(v = 0)$. Par opposition à ce qui est observé pour la réaction N_2^+ + Ar, cette augmentation est principalement due à l'existence d'une désactivation vibrationnelle qui est légèrement plus rapide pour $v = 2$ que pour $v = 1$. Pour la réaction $N_2^+(v = 2) + O_2$, on a trouvé que les vitesses des canaux de désactivation vibrationnelle $v = 2 \rightarrow 1$ et $v = 2 \rightarrow 0$ sont comparables. Le manque d'augmentation substantielle dans le canal de transfert de charge de la réaction de $N_2^+(v) + O_2$ par l'excitation vibrationnelle (jusqu'à $v = 2$) est en opposition avec l'augmentation translationnelle observée pour cette réaction qui ouvre une voie vers un produit endothermique $O_2^+(a^4\Pi_u)$, de niveau plus élevé. Ces résultats sont en accord avec un mécanisme à courte distance, avec croisement de courbe, qui oriente efficacement l'énergie dans l'état $O_2^+(a^4\Pi_u)$.

[Traduit par la rédaction]

Introduction

The effect of vibrational excitation on ion–molecule reactions is one of the most fundamental issues of interest in state-selective and state-to-state chemistry (1–3), as well as in the chemistry of the upper atmosphere (see, for example, ref. 4). We recently developed a selected-ion flow tube, laser-induced fluorescence (SIFT–LIF) instrument to study vibrationally state-specific, thermal energy ion–molecule reactions (5). Here, N_2^+ ions in a mixture of vibrational states are mass selected and injected into a relatively high-pressure He buffer gas. The translational and rotational temperatures of the N_2^+ ions are rapidly thermalized by collisions with He, while the vibrational temperature can be high (5). The vibrational states of the reactant and product ions are monitored with sensitive LIF detection using a high repetition rate dye laser. Under low-energy conditions where translation-to-vibration (T–V) energy transfer is negligible, we recently demonstrated an efficient vibration-to-vibration (V–V) energy transfer during the resonant charge exchange between $^{15}N_2^+(v = 2)$ and $^{14}N_2$ (6).

Direct optical detection of ion vibrational states with the SIFT–LIF instrument allows us to explore new aspects of ion–molecule reactions, e.g., vibrational specificity for charge transfer (CT) versus deactivation (q) at thermal energies,

$$[1] \qquad N_2^+(v) + M \xrightarrow{k_{CT}} N_2 + M^+$$

$$[2] \qquad \xrightarrow{k_q} N_2^+(v' < v) + M$$

which occur with rate constants k_{CT} and k_q, respectively. Although there have been a number of SIFT measurements of k_{CT} and k_q using monitor reactions that are specific to the ion vibrational states (7), this approach is limited by the availability of appropriate monitor reactions. Photoelectron–photoion coincidence (PEPICO) techniques can examine the reactions of vibrationally selected reactants, but are blind to the change in the vibrational states of the ions (1, 2). Measuring both k_{CT} and k_q by direct state selection in a flow tube will give detailed insight into the dynamics of ion–molecule reactions under low-energy conditions where there have been relatively few studies. In the present paper, we study the vibrational specificity for the reactions $N_2^+(v = 0, 1, 2)$ with Ar and O_2.

For the $N_2^+(v)$ + Ar reaction, we investigate the charge transfer rate constants at lower collision energies than in previous studies. The N_2^+ + Ar reaction is nearly thermoneutral and has been extensively studied both experimentally and theoretically (1*a*, 2, 8). Detailed information on the potential energy surfaces for the reverse process, $Ar^+ + N_2$, has also been obtained. Recently, Ng and co-workers (9) studied the charge transfer cross sections for $N_2^+(v = 0, 1, 2)$ with Ar in the range of center-of-mass collision energies (E_{cm}) from ≈1 eV to 320 eV. The classical path theory of Parlant and Gislason (10) reproduced these results quite well. What is most striking in the experimental and theoretical results is that the Franck–Condon mechanism, which has usually been considered valid for a wide range of E_{cm}, is applicable only above ≈200 eV for this reaction. In the lower E_{cm} region, energy resonance becomes more important. Between 1 and 10 eV, a mechanism involving curve crossing on adiabatic vibronic potential energy surfaces reproduces the experimental results well (10). However, the charge transfer reaction at collision energies below 1 eV is less well explored both experimentally and theoretically. In this region, curve crossing might be inefficient due to the reduced collision energy, and alternatively an intermediate complex might play a significant role. In the SIFT–LIF instrument, k_{CT} can be studied as a function of the vibrational excitation in N_2^+ at these lower values of E_{cm}.

The vibrational deactivation of $N_2^+(v)$ by Ar can also be investigated. This process cannot be studied with a conventional monitor reaction, because Ar is the only monitor species available to distinguish between $N_2^+(v = 0)$ and $N_2^+(v > 0)$. It has long been assumed that collisional deactivation by Ar is negligible, and this is a prerequisite for using Ar as a monitor of $N_2^+(v)$ (7). However, this assumption has never been tested. The N_2^+ + Ar reaction also has practical importance, because it is an excellent reference reaction for other studies with the SIFT–LIF instrument; direct measurement of absolute rate constants is difficult with this technique because of the complicated flow characteristics, and hence a reference reaction is required (5).

In contrast to the $N_2^+(v)$ + Ar reaction, the $N_2^+(v) + O_2$ charge transfer reaction is highly exothermic (3.509 eV for $N_2^+(v = 0)$) and electronically excited product states are energetically accessible. Koyano et al. used the PEPICO technique to study this reaction at relatively high E_{cm} and concluded that *vibrational* excitation of N_2^+ did not result in the formation of electronically excited O_2^+ products (11). On the other hand, Schultz and Armentrout recently reported experimental evidence that reactant *translational* energy can couple to an electronically excited product state (12). Using the SIFT–LIF technique, we investigate the vibrational enhancement of the charge transfer channel at thermal energies, where translational enhancement is negligible.

The reaction of $N_2^+(v) + O_2$ is also an ideal system for studying level-specific vibrational deactivation, since for this reaction the relatively efficient vibrational deactivation can compete with the charge transfer channel, which occurs with a moderate rate. Vibrational deactivation in ion–molecule collisions is known to be much more efficient than that in neutral–neutral collisions (7). This efficient deactivation has been explained by the formation of an intermediate complex due to the charge-induced dipole interaction. However, little is known about the level-specific vibrational deactivation in ion–molecule systems, in contrast to neutral–neutral systems where direct V–T, V–V, and vibrational predissociation mechanisms are known to play a major role. Finally, the reaction of $N_2^+(v) + O_2$ is important in the chemistry of the E and F regions of the earth's atmosphere (13).

Experimental

The SIFT–LIF instrument is described in ref. 5. The apparatus (Fig. 1) consists of an electron-impact ion source, a SIFT mass filter to select ions, an ion injector, and a reaction flow tube. The flow tube section is equipped with neutral reactant inlets, an LIF detection port with a photomultiplier assembly, and a downstream mass filter for final product analysis. An excimer laser-pumped dye laser is used for the LIF probing of ion internal states using time-gated photon-counting detection.

Ion production, injection, and reaction

Vibrationally excited N_2^+ ions are generated in an electron-impact ion source. The source unit has a rhenium filament, a grid, and an electron repeller. The grid potential is set at 47 V relative to experiment ground, and the bias between the grid and the filament is fixed at −80 V in order to produce 80 V electron impact on ≈2.7 Pa (20 mTorr) N_2 in the ion source. The N_2^+ ions are quickly extracted from the ion source region into the SIFT chamber, before vibrational deactivation or reaction occurs by collisions with N_2 precursors. The SIFT chamber (3×10^{-3} Pa under operation) contains a differentially pumped quadrupole mass filter (1×10^{-3} Pa under operation). After passing through a series of focusing elements (ring electrodes and an Einzel lens), the ions enter the mass filter, which selects only N_2^+ ions from other undesired ions produced in the ion source, such as N^+. The selected N_2^+ ions pass through another Einzel lens, and are focused onto the ion injection orifice (2 mm in diameter) at the exit of the SIFT chamber. The ions are efficiently injected into a stream of He buffer gas, which is at a pressure of 80 Pa (0.6 Torr), with the aid of a venturi inlet that minimizes the backstreaming of He into the SIFT chamber (5). The injection orifice is set at a potential of 0 V, and the potential difference between the grid and the injection orifice determines the nominal injection potential of the ions (47 eV for singly charged ions). The flow tube section downstream of the SIFT injector is at a common potential of 0 V, so that there is no potential gradient in the region where the ion–molecule reactions take place. A radial reactant inlet, located 4.4 cm downstream of the injection orifice, introduces the reactant gases (argon (99.996% pure) and oxygen (99.997% pure)). The inlet has 18 pinholes (0.37 mm in diameter) equally spaced around the perimeter to provide rapid and uniform mixing of the reactant gas and the N_2^+ ions that are entrained in the He buffer gas.

LIF detection

The LIF detection of N_2^+ is performed 11 cm downstream of the injection orifice with an excimer laser-pumped dye laser operating at typically 100 Hz. The $B^2\Sigma_u^+ \leftarrow X^2\Sigma_g^+$ electronic transition is used to monitor the rotational and vibrational states of N_2^+ ions. In all cases the pump transition is saturated. The (1,0) band at 358 nm is used for excitation followed by (1,2) emission at 424 nm for the LIF detection of $N_2^+(v = 0)$; excitation of (0,1) at 428 nm and (0,2) at 471 nm, both followed by (0,0) emission at 391 nm, is used for detection of $N_2^+(v = 1)$ and $N_2^+(v = 2)$, respectively. The intense (0,0) fluorescence, due to a favorable Franck–Condon factor, facilitates good LIF

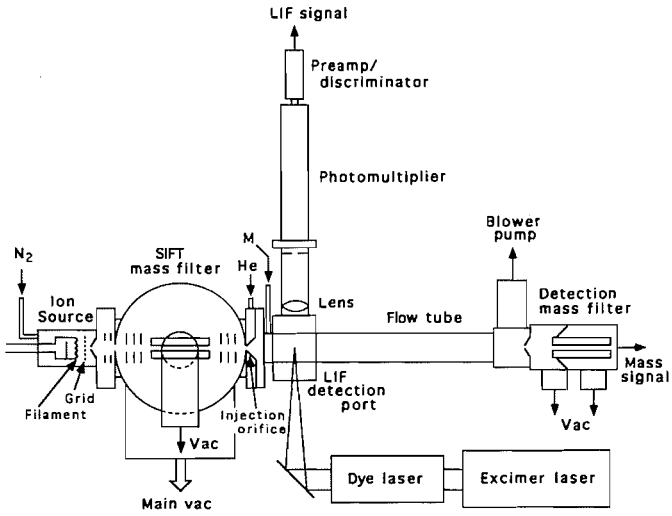

FIG. 1. SIFT–LIF instrument.

detection of the $v = 1$ and $v = 2$ states even with relatively small populations compared to $v = 0$. For a measurement of the vibrational population ratio between $v = 1$ and $v = 2$ using a single laser scan, excitation of (1,2) at 424 nm followed by emission of (1,1) at 388 nm is used for $v = 2$ detection, and this is combined with the above measurement for $v = 1$. The output signal is acquired with gated photon-counting detection after a short delay (≈10 ns) following the laser pulse and a sufficiently long collection time (≥200 ns). The gating time is at least three times the radiative lifetime of N_2^+ (B) (≈60 ns), and the fraction of molecules that radiate during the gating time is greater than 95%. The total $N_2^+(v)$ ion density at the LIF detection region is estimated to be $\approx 1 \times 10^5$ cm^{-3} (5). Signals are collected for a given flow rate of a neutral reactant, and then more than 10 data points are taken to construct a full kinetic plot in one run. Usually at least two complete runs are carried out to check the experimental reproducibility and construct a final kinetic plot.

Analytical procedures

Figure 2 summarizes the kinetic scheme for the reaction of $N_2^+(v = 0, 1, 2)$ with Ar and O_2. The fraction of $N_2^+(v = 3)$ was previously shown to be negligible (6). The $N_2^+(v > 0)$ states decay via charge transfer (eq. [1]) and vibrational deactivation (eq. [2]) with rate constants, $k_{CT,v}$ and $k_{q,vv'}$, respectively ($v > v'$). The loss of N_2^+ vibrationally excited states by collision with He buffer or by radiative decay is completely negligible during the short reaction time (5). Charge transfer is the only channel for $N_2^+(v = 0)$ decay. The sum of $k_{CT,v}$ and $k_{q,vv'}$ gives the total rate of removal ($k_{total,v}$) for each vibrational level, v. The population of each vibrational state is described by

$$[3]\quad d[N_2^+(v=2)]/dt = -(k_{CT,2} + k_{q,21} + k_{q,20})[N_2^+(v=2)][M]$$

$$[4]\quad d[N_2^+(v=1)]/dt = k_{q,21}[N_2^+(v=2)][M] - (k_{CT,1} + k_{q,10})[N_2^+(v=1)][M]$$

$$[5]\quad d[N_2^+(v=0)]/dt = k_{q,10}[N_2^+(v=1)][M] + k_{q,20}[N_2^+(v=2)][M] - k_{CT,0}[N_2^+(v=0)][M]$$

where M represents the neutral reactant (M = Ar or O_2). We transform the variables in eqs. [3]–[5] as:

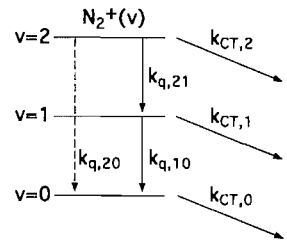

FIG. 2. Kinetics scheme for the $N_2^+(v = 0, 1, 2)$ + M reaction. The $k_{CT,v}$ and $k_{q,vv'}$ ($v > v'$) are the rate constants for charge transfer and vibrational deactivation, respectively, of $N_2^+(v)$ with M (=Ar, O_2).

$$[6]\quad [M]dt = d([M]t) \equiv dX$$

$$[7]\quad Y_i \equiv [N_2^+(v=i)]/[N_2^+(v=i)]_0 \qquad (i = 0, 1, 2)$$

where Y_i is the population for $N_2^+(v = i)$ at a certain [M], normalized to that at [M] = 0. The solutions to eqs. [3]–[5] are

$$[8]\quad Y_2 = \exp(-A_1X)$$

$$[9]\quad Y_1 = \exp(-A_3X) + \frac{A_2}{A_1 - A_3} \times (\exp(-A_3X) - \exp(-A_1X))$$

$$[10]\quad Y_0 = \exp(-A_5X) + \frac{A_4}{A_3 - A_5}(\exp(-A_5X) - \exp(-A_3X)) + \frac{A_6}{A_1 - A_5}(\exp(-A_5X) - \exp(-A_1X)) + \frac{A_2A_4}{(A_1 - A_3)(A_3 - A_5)(A_5 - A_1)}\{(A_3 - A_1) \times \exp(-A_5X) + (A_1 - A_5)\exp(-A_3X) + (A_5 - A_3)\exp(-A_1X)\}$$

where

$$[11]\quad A_1 \equiv k_{CT,2} + k_{q,21} + k_{q,20}$$

$$[12]\quad A_2 \equiv k_{q,21}R_{21}$$

$$[13]\quad A_3 \equiv k_{CT,1} + k_{q,10}$$

$$[14]\quad A_4 \equiv k_{q,10}R_{10}$$

$$[15]\quad A_5 \equiv k_{CT,0}$$

$$[16]\quad A_6 \equiv k_{q,20}R_{20}$$

and

$$[17]\quad R_{ij} \equiv [N_2^+(v=i)]_0/[N_2^+(v=j)]_0$$

The second term in Y_1 and the second and third terms in Y_0 (the double exponentials) correspond to the rise and decay due to relaxation from their upper levels, $v = 2 \rightarrow 1$, $v = 1 \rightarrow 0$, and $v = 2 \rightarrow 0$, respectively. The last triple-exponential component in Y_0 corresponds to the stepwise relaxation from

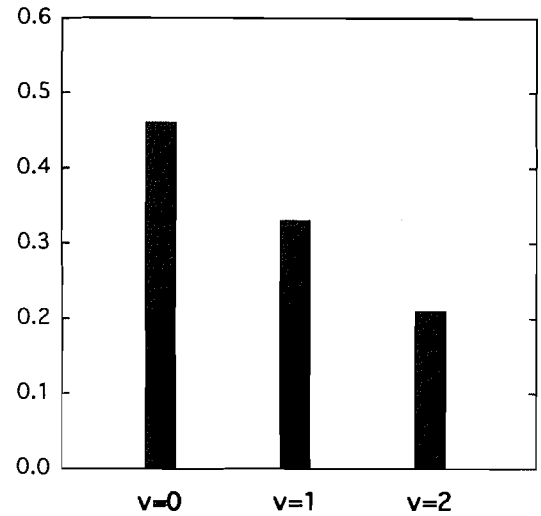

FIG. 3. Vibrational population distribution of N_2^+ observed at an injection potential of 47 eV.

$v = 2$ to $v = 1$ to $v = 0$. The equation for Y_2 is fit to a $v = 2$ kinetic plot to determine A_1. Using this value of A_1, Y_1 is fit to a $v = 1$ plot for A_2 and A_3. In a similar manner, Y_0 can be fit to the $v = 0$ data for A_4, A_5, and A_6. However, the simultaneous three-parameter best fit to Y_0 is not always unique. Thus, in the $N_2^+ + O_2$ reaction, we conducted an additional experiment using the downstream mass filter to reduce the number of parameters to be fit, as will be discussed later.

Results

Vibrational distribution of N_2^+

The rotational structure in an observed LIF spectrum confirms that the rotational temperature (T_{rot}) of N_2^+ at the LIF detection point is thermalized to ≈300 K (5), because of fast rotational equilibration of the $N_2^+(v)$ entrained in the relatively high buffer gas pressure (80 Pa). It is reasonable that the translational temperature (T_{trans}) of $N_2^+(v)$ is also ≈300 K at the point of LIF detection, since relaxation of translational energy should be even faster. Because of the high stagnation pressure behind the venturi inlet, the He flow just downstream of the inlet is an intense hypersonic flow where T_{rot} and T_{trans} must be extremely low. However, shock wave recovery across the Mach disk immediately results in the recovery of T_{rot} and T_{trans} to ≈300 K even before the neutral reactant addition (5). Therefore the He flow provides a bath for ion–molecule reactions at $T_{trans} \approx T_{rot} \approx 300$ K, although the laboratory-frame kinetic energy of N_2^+ (E_{lab}) can be high because of the initial velocity of the He flow after recovering from the Mach disk.

We previously showed (5) that the vibrational population of N_2^+ is dependent on the injection potential. The population ratio between $v = 2$ and $v = 1$ is measured directly by integrating specific rotational lines in the LIF spectrum, as discussed in ref. 5. This population ratio is combined with the fraction of $v = 0$, which is measured using the Ar-monitor reaction or the $N_2^+ + N_2$ resonant charge transfer reaction (5). The vibrational population distribution is determined to be (46 ± 1%) for $v = 0$, (33 ± 1%) for $v = 1$, and (21 ± 1%) for $v = 2$ at an injection potential of 47 eV (Fig. 3). Since vibrational levels up to $v = 2$ are appreciably populated, the effective vibrational temperature (T_{vib}) is estimated from the observed distribution as ≈8000 K. The population of $v = 3$, however, seems to deviate from a prediction (≈10%) based on the effective T_{vib}, and is rather small. Because of the relatively large populations of the higher vibrational levels ($v = 1$ and $v = 2$), the deactivation of a specific vibrational level can appear as an obvious rise in the kinetic plot for the corresponding lower level. This initial population distribution will be used in eqs. [12], [14], and [16] to determine $k_{q,21}$, $k_{q,10}$, and $k_{q,20}$.

$N_2^+(v) + Ar$ reaction

Kinetic plots for the $N_2^+(v) + Ar$ reactions are shown in Fig. 4(*a*)–(*c*). The reactions of $N_2^+(v = 2)$ and $N_2^+(v = 1)$ are almost equal in their decay rates, and are as fast as the $N_2^+(v = 2 \text{ and } 1) + N_2$ resonant charge transfer reactions (5). The $v = 2$ reactions should obey a single exponential decay since the population of the upper level ($v = 3$) is negligible, and indeed an exponential decay curve provides a good fit to the data shown in Fig. 4(*a*). The $v = 1$ reaction can be fit with a single exponential decay curve (Fig. 4(*b*)), or with the exact expression in eq. [9]. This indicates that the branching fraction for the $v = 2$ vibrational deactivation is extremely small compared to that for the $v = 2$ charge transfer; thus the minor contribution of the $v = 2$ to $v = 1$ deactivation cannot be detected as a superposition on the $v = 1$ kinetic plot, which decays very rapidly.

The situation is different for the $N_2^+(v = 0) + Ar$ reaction (Fig. 4(*c*)). The charge transfer reaction of $N_2^+(v = 0)$ with Ar is slightly endothermic, and is known to be very slow ($k_{CT,0} = 2 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}) at 300 K (14). Furthermore, the time constant for the appearance of a $v = 1 \rightarrow 0$ deactivation component is very short due to the large total rate of removal of $v = 1$ ($k_{total,1}$). Thus the extent of vibrational deactivation from $v = 1 \rightarrow 0$ can in principle be observed in the kinetic plot for $v = 0$. Each data point in Fig. 4(*c*) contains 5–10 measurements and the error bars represent one standard deviation of the mean. In the analysis here, the last term in eq. [10] for stepwise $v = 2 \rightarrow 1 \rightarrow 0$ relaxation is negligible compared to the second, double exponential term for $v = 1 \rightarrow 0$ relaxation, since the amount of $N_2^+(v = 1)$ arising from $v = 2$ is appreciably smaller than that originally in $v = 1$. The $v = 0$ plot is represented slightly better by the exact analytical formula (solid curve) than by a single exponential decay curve (long-dashed line) for which no vibrational deactivation is assumed (the ratio of the chi squared values, χ^2 (exact formula)/χ^2 (single exponential) = 0.83). The short-dashed line in Fig. 4(*c*) represents only the first term in eq. [10], giving $k_{CT,0}$, and the rise of the solid line above the short-dashed line corresponds to the best fit for vibrational deactivation from $v = 1 \rightarrow 0$ (≈3% of the total rate of removal of $N_2^+(v = 1)$).

$N_2^+(v) + O_2$ reaction

The kinetic plot for $N_2^+(v = 2) + O_2$ (Fig. 5(*a*)) shows that the total removal rate is smaller than that for $N_2^+(v = 2) + Ar$. The reaction obeys a simple exponential decay, which again is consistent with a negligible amount of $N_2^+(v = 3)$. The kinetic plot of $N_2^+(v = 1)$ (open circles in Fig. 5(*b*)) reveals a definite deviation from a single exponential decay, and fitting by the exact formula (eq. [9]) is shown by the solid curve. The single exponential component in eq. [9] is subtracted from the total kinetic plot, and the residual component, which corresponds to the vibrational deactivation from $v = 2$ to $v = 1$, is shown by the open triangles and the associated solid curve.

The kinetic plot for $N_2^+(v = 0) + O_2$ (Fig. 5(*c*)) more clearly reveals the vibrational deactivation from upper levels, with

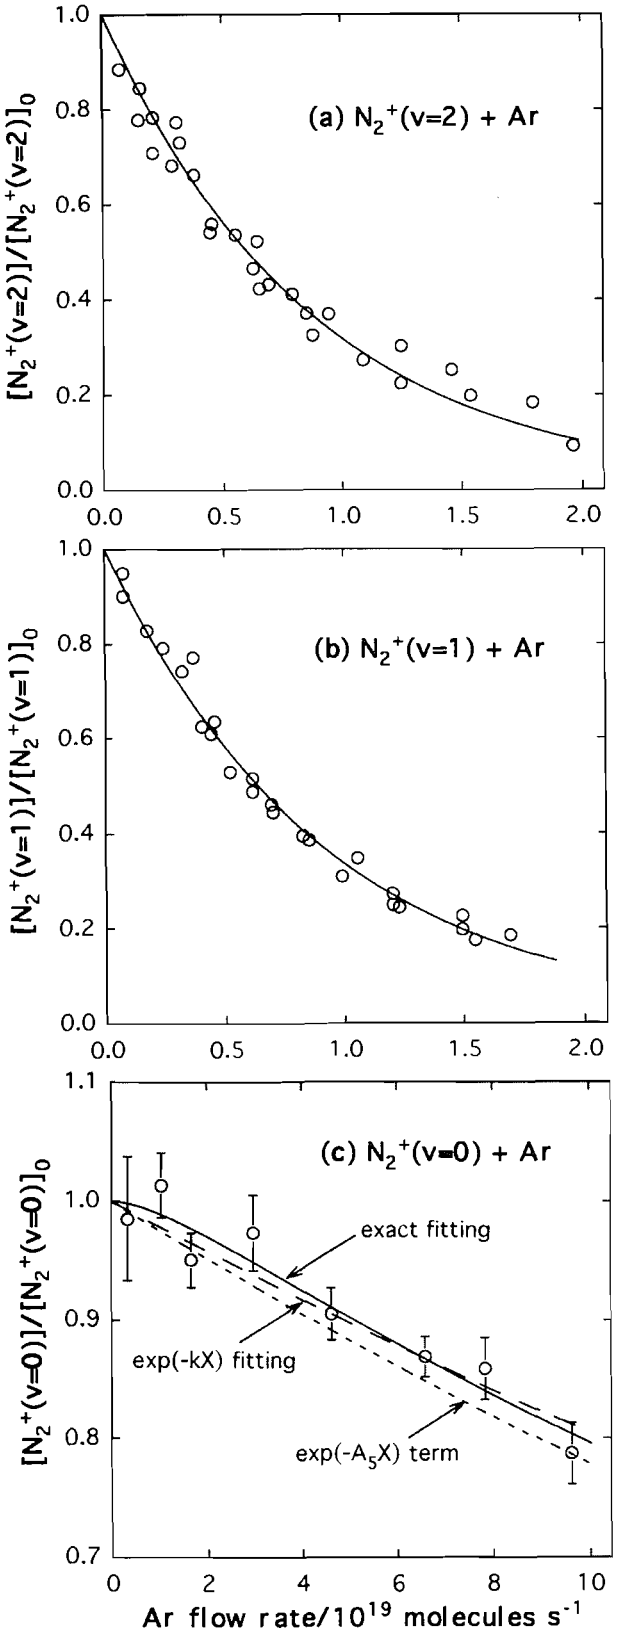

FIG. 4. Kinetic plots of (*a*) $N_2^+(v = 2)$ + Ar, (*b*) $N_2^+(v = 1)$ + Ar, and (*c*) $N_2^+(v = 0)$ + Ar reactions. In (*c*), the solid line represents the fitting with the exact analytical formula (eq. [10]), and the long-dashed line (– –) the fitting with a single exponential (e^{-kX}) for which no vibrational deactivation is assumed. The ratio of the chi squared values, χ^2 (exact formula)/χ^2 (single exponential) = 0.83. The short-dashed line (- - -) in (*c*) represents only the first term in eq. [10]. The rise of the solid line above the short-dashed line corresponds to the $v = 1 \rightarrow 0$ vibrational deactivation.

an obvious initial rise peaked at O_2 flow rates of (1–2) × 10^{19} molecules s^{-1} (open circles). Although it should be possible to separate the $v = 1 \rightarrow 0$ and $v = 2 \rightarrow 0$ processes by an analysis of the $N_2^+(v = 0) + O_2$ kinetic plots, it is difficult in practice, since the total rates of loss for $N_2^+(v = 2)$ and $N_2^+(v = 1)$ are unfortunately very close in magnitude. The $v = 2 \rightarrow 0$ component, if any, should thus appear in the $N_2^+(v = 0) + O_2$ kinetic plot with almost the same rise and decay time constants as those of the $v = 1 \rightarrow 0$ component and cannot be separated. Thus, in a separate experiment with the downstream mass filter, the N_2^+ ion counts are measured as a function of O_2 flow rate (Fig. 6). Although there is slight nonlinearity in Fig. 6, within experimental error, the N_2^+ counts are found to decrease exponentially. The absence of a significant faster decaying component superimposed on the single exponential decay indicates that the rate constants for charge transfer ($k_{CT,2}$, $k_{CT,1}$, and $k_{CT,0}$) have similar values. Thus the fitting parameters in eq. [10], A_4, A_5, and A_6, can be reduced to a single value ($k_{CT,0} \equiv A_5$). When Y_0 is fit to the $v = 0$ plot and the single exponential component in eq. [10] is subtracted from the total kinetic plot, the open triangles and the associated solid curve show the residual component due to the vibrational deactivation of higher levels. The residual is automatically fractioned into three components for vibrational relaxation, $v = 1 \rightarrow 0$ and $v = 2 \rightarrow 0$, which produce a faster decay, and $v = 2 \rightarrow 1 \rightarrow 0$, which produces a more gradual decay (dashed curves). We note that if the slight deviation from a single exponential decay in Fig. 6 is fit exactly, the best fit is obtained when $N_2^+(v = 2)$ (≈21% of the total $N_2^+(v)$ population) is assumed to transfer charge ≈50% faster than $N_2^+(v = 1)$ or $N_2^+(v = 0)$. Thus the present experimental data do not allow us to exclude a slight vibrational enhancement of the $N_2^+(v = 2)$ charge transfer channel. However, a dramatic effect, as observed in the translational enhancement of the $N_2^+ + O_2$ reactivity, is clearly ruled out.

Rate constants

Because of the close proximity of the neutral reactant inlet and the LIF detection port to the ion injector, the He flow in this region is not well developed and laminar. The flow characteristics near the SIFT injector were discussed in detail previously (5); this discussion included experimental observations of the $N_2^+(v)$ rotational temperature, effects of He flow rate on kinetic plots, dependence of the product yield in the Ar-monitor reaction on the reactant inlet position, and theoretical considerations of shock wave recovery. These considerations suggest that there is fast, turbulent flow in the reaction volume just downstream of the SIFT injector, consistent with previous studies (15, 16). Therefore absolute rate constants cannot be determined directly.

However, the $N_2^+(v = 2) + O_2$ and $N_2^+(v = 1$ or 2) + Ar plots demonstrate that the reactions exhibit first-order kinetics with respect to the amount of added reactant, when relaxation from upper levels is negligible. Therefore the mixing efficiency of the reactant and the He buffer gas is independent of the amount of the reactant added, even under the nonideal flow conditions near the SIFT injector. Thus a reference reaction can be used to infer relative rate constants, and kinetic plots can be analyzed using the expressions in eqs. [8]–[10]. We use the $N_2^+(v = 1) + Ar$ reaction as a reference because (*i*) it is a simple system where vibrational relaxation from upper levels is negligible, (*ii*) the reaction is relatively fast and hence is less affected by possible impurities, (*iii*) the rate constant

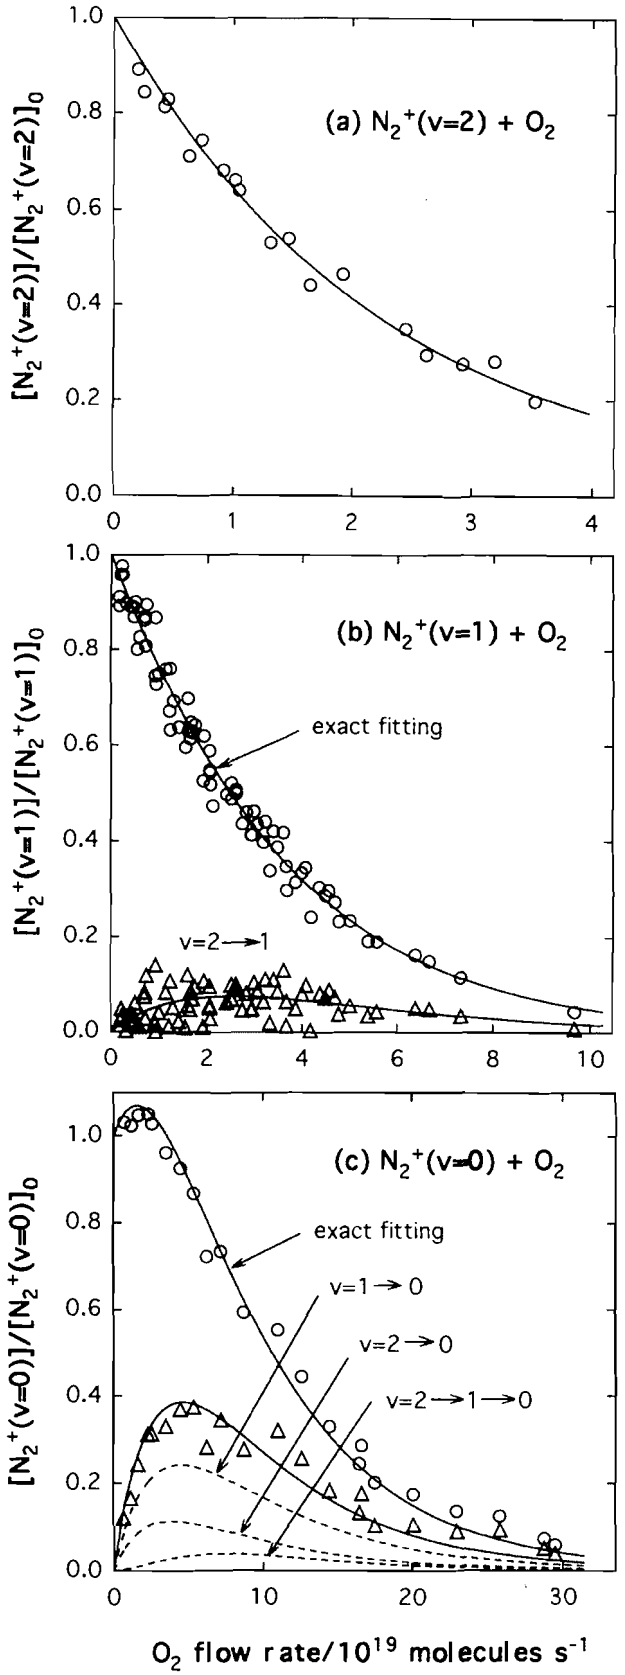

FIG. 5. Kinetic plots of (*a*) $N_2^+(v = 2) + O_2$, (*b*) $N_2^+(v = 1) + O_2$, and (*c*) $N_2^+(v = 0) + O_2$ reactions. In (*b*), the total kinetic plot (open circles) is fitted with the exact formula (eq. [9]). The single exponential component in eq. [9] is subtracted from the total plot, and the residual component for the $v = 2 \rightarrow 1$ deactivation is shown by the open triangles and the associated solid curve. In (*c*), the total kinetic plot (open circles) is fitted with the exact formula (eq. [10]). The single exponential component in eq. [10] is subtracted from the total plot, and the residual component for the vibrational deactivation of higher levels is shown by the open triangles and the associated solid curve. The residual is separated into three components for $v = 1 \rightarrow 0$, $v = 2 \rightarrow 0$, and $v = 2 \rightarrow 1 \rightarrow 0$ vibrational deactivation, as shown by the dashed curves.

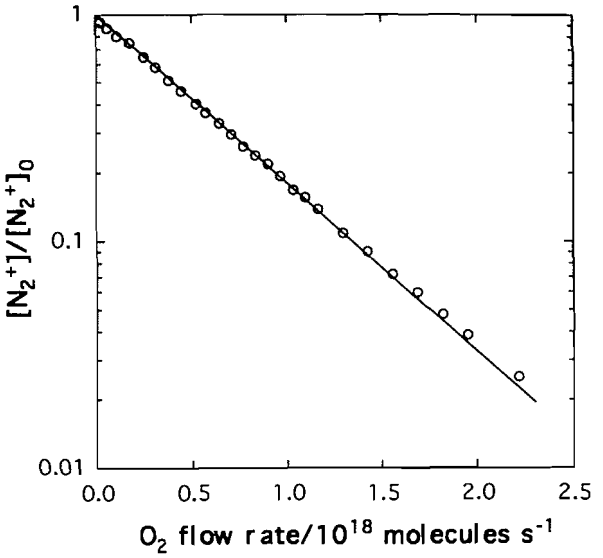

FIG. 6. The N_2^+ ion counts (open circles) detected with the downstream mass filter as a function of O_2 flow rate. The N_2^+ counts are normalized to that at zero O_2 flow ($\equiv [N_2^+]_0$). The solid line represents the single exponential decay.

for a mixture of vibrationally excited states ($v > 0$, i.e., a mixture of $v = 1$ and $v = 2$) has been reported (4×10^{-10} cm^3 molecule^{-1} s^{-1} (14)) and the vibrational energy dependence is very small as is evident from Fig. 4(*a*) and (*b*), and (*iv*) the kinetic energy dependence for $N_2^+(v > 0)$ + Ar is also known to be very minor (17).

Table 1 summarizes the rate constants for $N_2^+(v)$ + Ar and O_2, which are obtained by using the $N_2^+(v = 1)$ + Ar reaction as a reference. The errors should accumulate toward lower vibrational levels because of the sequential fitting procedure; however, only relative errors are included in Table 1 (1σ of the mean) in order to emphasize the reactivity difference between two adjacent vibrational levels. The results show there is a negligible difference between the reactivities of $N_2^+(v = 1)$ and $N_2^+(v = 2)$ with Ar. The extent of vibrational deactivation for $N_2^+(v = 1)$ is estimated to be $\approx$3% ($k_{q,10} = 1.2 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}). However, this value may be an upper limit, since the quality of the fit by the exact analytical formula in eq. [10] is only slightly better than that from a single exponential. Accordingly, the value of $k_{CT,1}$ (3.88×10^{-10} cm^3 molecule^{-1} s^{-1}) can be regarded as a lower limit. Note that the $N_2^+(v = 0)$ + Ar reaction is $\approx$45 times slower than $N_2^+(v > 0)$ + Ar, but at the same time this value is $\approx$45 times faster than the reported rate constant at 300 K (14). This enhanced reactivity of $N_2^+(v = 0)$ has been discussed in detail (5) and is attributed to a higher collision energy of $N_2^+(v = 0)$ in the vicinity of the SIFT injector, as will be discussed in the next section. For the $N_2^+(v = 2)$ + O_2 reaction, $k_{q,21}$ and $k_{q,20}$ each constitute about half of the overall quenching rate constant, $k_{q,2}$. Thus the $v = 2 \rightarrow 1$ and $v = 2 \rightarrow 0$ channels are comparable in the vibrational deactivation of $N_2^+(v = 2)$.

TABLE 1. Reaction rate constants for $N_2^+(v)$ + M reactions

M	k^a	$v = 0$	$v = 1$	$v = 2$
Ar	k_{total}	0.092 ± 0.013^b	4.00 ± 0.08^c	4.21 ± 0.14
	k_{CT}	0.092 ± 0.013^b	$\geq 3.88 \pm 0.09$	—[d]
	k_q	—	$\leq 0.12 \pm 0.04$	—[d]
O_2	k_{total}	0.49 ± 0.02	1.27 ± 0.10	1.62 ± 0.05
	k_{CT}	0.49 ± 0.02	0.49 ± 0.02	0.49 ± 0.02^e
	k_q	—	0.78 ± 0.08	1.13 ± 0.05^e

[a] k_{CT}, k_q, and k_{total} (= k_{CT} + k_q) are the rate constants for charge transfer, vibrational relaxation, and total decay, respectively, in units of 10^{-10} cm^3 molecule^{-1} s^{-1}. The errors respresent 1σ of the mean.

[b] Larger than 300 K values due to the higher collision energy (<0.23 eV).

[c] Reference reaction. The error in the rate constant of the reference reaction is not shown, and the error bar for k_{total} (±0.08) simply reflects the fitting error.

[d] Not measured.

[e] These values and their error bars result if the data in Fig. 6 are treated as a single exponential decay. If the slight curvature is fit exactly, k_{CT} increases by ≈50% and k_q decreases accordingly. Thus a slight vibrational enhancement of the $N_2^+(v = 2) + O_2$ charge transfer channel cannot be ruled out by the current experimental data.

TABLE 2. Rate constants for the $N_2^+(v) + O_2$ reaction at 300 K[a]

[c] Refer to footnote *e* in Table 1.

Table 2 compiles previous results for the $N_2^+(v) + O_2$ reaction (12, 13, 18–26). With $N_2^+(v = 1)$ + Ar as a reference reaction, our value of $k_{CT,0}$ for the $N_2^+(v = 0) + O_2$ reaction (Table 1) agrees well with these previous values. Also for the $N_2^+(v) + N_2$ reaction (27), k_{total} agrees with previous values by using $N_2^+(v = 1)$ + Ar as a reference reaction. Since the collision energy in the vicinity of the SIFT injector may be higher than thermal, however, the possible dependence of the rate constant on kinetic energy could be important for other systems. The rate constants for $N_2^+(v = 1)$ and $N_2^+(v = 2)$ with O_2, on average, agree with previous overall values for $N_2^+(v > 0)$ at 300 K.

Discussion

Charge transfer between N_2^+(v = 0) and Ar

The charge transfer reaction of $N_2^+(v = 0)$ with Ar (eq. [18]) is slightly endothermic (0.178 eV) and extremely slow at 300 K (2×10^{-13} cm^3 molecule^{-1} s^{-1}), while the charge transfer of $N_2^+(v = 1)$ (eq. [19]) is nearly resonant and very fast (4×10^{-10} cm^3 molecule^{-1} s^{-1}) (14).

[18] $N_2^+(v = 0) + Ar \rightarrow N_2(v = 0) + Ar^+(^2P_{3/2}) - 0.178$ eV

[19] $N_2^+(v = 1) + Ar \rightarrow N_2(v = 0) + Ar^+(^2P_{3/2}) + 0.092$ eV

Since the average collision energy at 300 K (0.039 eV) is smaller than the enthalpy required for the endothermic reaction [18], only those $N_2^+(v = 0)$ ions in the Boltzmann distribution with high translational (and possibly rotational) energies can participate in the charge transfer. Indeed, the charge transfer of $N_2^+(v = 0)$ is suppressed to an immeasurable level at 80 K (14). We also confirmed the 300 K rate constant for reaction [18] by measuring both the N_2^+ and Ar^+ ion counts using the downstream mass filter in the traditional way.

In contrast, the $N_2^+(v = 0)$ + Ar reaction near the LIF region proceeds at a much faster rate (Table 1), although it is still a very slow reaction. The enhanced reactivity is due to greater collision energies of $N_2^+(v = 0)$ immediately downstream of the ion injector, and the origin of the enhancement is discussed in this section. There has been some controversy concerning the kinetic energy dependence of the $N_2^+(v = 0)$ + Ar reaction (9, 17, 28–31): Lindinger et al. (17) first observed a strong kinetic energy dependence of reaction [18], while beam experiments reported only a moderate dependence (9, 28, 29). Later, Lindinger and co-workers (30) studied the vibrational

excitation of $N_2^+(v = 0)$ in collisions with He buffer gas using a drift tube at E_{cm} above 0.2 eV, and they observed that vibrational excitation was significant at higher collision energies. In ref. 30, they interpreted their previous results for the enhanced reactivity of the $N_2^+(v = 0)$ + Ar reaction (17) in terms of contributions from vibrationally excited N_2^+. Recently, Schultz and Armentrout conducted an important experiment (31) in which they measured the kinetic energy dependence of reaction [18] under single collision conditions at energies down to $E_{cm} \approx 0.1$ eV. Their study clearly revealed a pure kinetic energy dependence, which was as steep as the apparent E_{cm} dependence previously observed using a drift tube (17). Therefore, at kinetic energies where the E_{cm} does not significantly exceed the vibrational spacing of the N_2^+ ions (0.27 eV) and only $N_2^+(v = 0)$ ions are present, the $N_2^+(v = 0)$ + Ar reaction is enhanced by kinetic energy.

The approximate collision energy in the SIFT–LIF instrument can be inferred from previous observations. Unfortunately, there have been no drift tube data specifically for the $N_2^+(v = 0)$ + Ar reaction at kinetic energies appreciably below 1 eV. However, if the drift tube data by Lindinger et al. (17) are extrapolated to lower E_{cm}, our rate constant of 9.2×10^{-12} cm^3 molecule^{-1} s^{-1} (Table 1) would correspond to a collision energy of $\approx$0.3 eV. Other results suggest an upper limit for the collision energy in the SIFT–LIF experiment. Recently, Schultz and Armentrout (12) observed the onset of N_2O^+ formation from $N_2^+(v = 0)$ + O_2 at $E_{cm} < 1$ eV, which corresponds to the thermochemical threshold of 0.74 eV. We observe no N_2O^+ product from the $N_2^+(v)$ + O_2 reaction for $v \leq 2$. This energy would correspond to an E_{cm} of 0.23 eV in our experiment for N_2^+ + Ar. In summary, we believe that the average kinetic energy in collisions of N_2^+ with Ar in the SIFT–LIF instrument is significantly greater than thermal, but probably below 0.23 eV; this is also supported by a flow analysis of the He buffer gas (5). This slightly enhanced kinetic energy increases the rate coefficient of the $N_2^+(v = 0)$ + Ar reaction above that of its thermal energy value, in keeping with the results of Schultz and Armentrout.

Vibrational deactivation of N_2^+(v = 1) by Ar

The vibrational deactivation of $N_2^+(v = 1)$ in collisions with Ar is found to be very slow ($k_{q,10} \leq 1.2 \times 10^{-11}$ cm^3 molecules^{-1} s^{-1}), in keeping with previous SIFT results at 300 K for other rare gas atoms: 4.5×10^{-15} cm^3 molecule^{-1} s^{-1} for He (30*b*), 4.5×10^{-12} for Ne (23), and 5×10^{-12} for Kr (32). Kemper and Bowers measured the vibrational deactivation of $N_2^+(v > 0)$ with He, Ne, Kr, and Xe (25) using an ICR. They interpolated their results and estimated the Ar deactivation rate as $\approx 9 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} at collision energies of $\approx$0.3 eV. Our measured value for Ar is in good agreement with these expectations; Ar is not a special quencher for $N_2^+(v)$ compared to other rare gas atoms in spite of its rapid charge transfer probability. The inefficient vibrational deactivation ensures that Ar is a good monitor for detecting $N_2^+(v > 0)$ with negligible perturbation of the vibrational states.

The potential well depth for $N_2^+(v = 0)$ + Ar has been experimentally estimated as 0.91 eV (Teng and Conway (33) and Linn et al. (34)), in good agreement with a recent theoretical value (0.785 eV (35)); the electron exchange interaction between the reagents contributes to this well depth (36). The potential well for this system is also highly anisotropic (35). Although a deep well with large anisotropy usually results in high efficiencies for vibrational deactivation (7), this is not the case for $N_2^+(v = 1)$ + Ar where rapid charge transfer occurs. The diabatic potential energy surface for $N_2^+(v = 1)$ + Ar is pushed upward because of the avoided crossing with the charge transfer state $Ar^+(^2P_{3/2})$ + $N_2(v = 0)$, resulting in a rather shallow well (35). The potential energy surface is similar for $N_2^+(v = 2)$ + Ar (35), and the vibrational deactivation of $N_2^+(v = 2)$ with Ar, although not measured, is also expected to be very inefficient.

Charge transfer between N_2^+(v = 1 and 2) and Ar

There are two energetically accessible channels for the charge transfer between $N_2^+(v = 2)$ and Ar:

$$[20] \quad N_2^+(v = 2) + Ar \rightarrow N_2(v = 1) + Ar^+(^2P_{3/2}) + 0.069 \text{ eV}$$

$$[21] \quad N_2^+(v = 2) + Ar \rightarrow N_2(v = 0) + Ar^+(^2P_{1/2}) + 0.180 \text{ eV}$$

The first of these has an even smaller energy defect than does $N_2^+(v = 1)$ + Ar, eq. [19]. The charge transfer of $N_2^+(v = 1$ and 2) + Ar can be discussed in terms of total rates of removal (k_{total}) since vibrational deactivation is extremely inefficient. The total removal rate of $v = 2$ is slightly greater than that of $v = 1$, although the difference of 5% lies within experimental error. This result differs from those at higher E_{cm} where the cross section for $v = 2$ is significantly greater than that for $v = 1$ (Kato et al., $E_{cm} \geq 0.3$ eV (28), Govers et al., ≥ 8 eV (29), Ng and co-workers, ≥ 5.8 eV (9)). At the lowest energy of 1.2 eV, Ng and co-workers (9) observed a slight preference for the $N_2^+(v = 1)$ charge transfer over $N_2^+(v = 2)$, although the error bars are relatively large (9*b*); the most advanced theory of Parlant and Gislason (10*b*,*c*) agrees with the results of Ng and co-workers, including the reversal of the reactivities between $v = 2$ and $v = 1$ at 1.2 eV. At an estimated collision energy of 0.3–0.5 eV, Mahan et al. (37) detected no measurable vibrational dependence of the charge transfer for $N_2^+(v = 1)$ and $N_2^+(v = 2)$ with their rf quadrupole ion trap. Unfortunately, systematic data (experimental and theoretical) are lacking in this energy region. Nevertheless our observation that $k_{CT,1} \approx k_{CT,2}$ is in general agreement with other low-energy data and suggests that a different mechanism e.g., formation of an intermediate complex, may be operative, compared to that at high collision energies.

Charge transfer between N_2^+(v) and O_2

Figure 7 summarizes the results of k_{total}, $k_{CT,}$, and k_q for the $N_2^+(v)$ + O_2 reaction. The values of $k_{CT,}$ for $v = 0$, $v = 1$, and $v = 2$ are similar; we conclude that k_{CT} is insensitive to vibrational excitation of N_2^+. In addition, the total rates of removal of $N_2^+(v = 1)$ and $N_2^+(v = 2)$ are substantially larger than that of $N_2^+(v = 0)$, indicating that vibrational deactivation is efficient. However, we do not believe that charge transfer is suppressed by competition with vibrational deactivation since the total rate is still only about 20% of the collision rate.

At thermal energies, there have been several measurements of the $N_2^+(v > 0)$ + O_2 charge transfer rate constant (Table 2) using flow tube techniques coupled to mass spectrometry (22–24, 26). These measurements used the Ar-monitor reaction to probe $N_2^+(v > 0)$, and hence no distinction could be made between $v = 1$ and $v = 2$, although Ferguson et al. (26) suggested that the vibrational excitation of N_2^+ was predominantly $v = 1$. In their kinetic plots of N_2^+ (consisting of a mixture of $v = 0, 1, \ldots$) + O_2, they detected only a single decay component, which had the same slope as that of

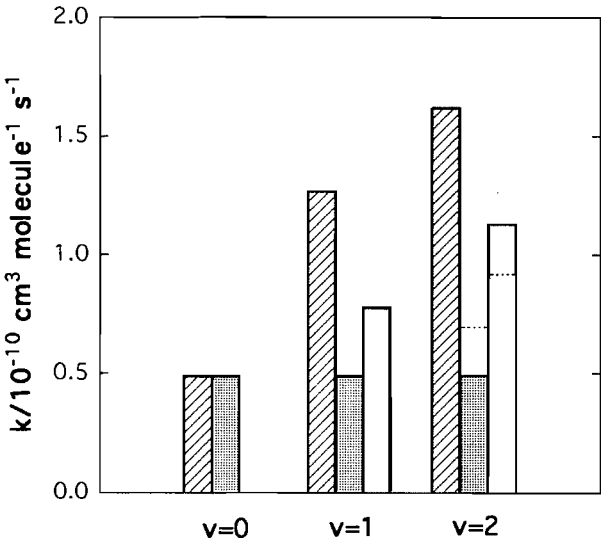

FIG. 7. Rate constants, k_{total} (striped bar), k_{CT} (shaded bar), and k_q (white bar), for $N_2^+(v) + O_2$ reaction (data from Table 1), assuming a single exponential decay in Fig. 6. For $N_2^+(v = 2)$, the dotted bars indicate the values of k_{CT} and k_q determined by fitting the slight curvature in Fig. 6 exactly. Refer to footnote *e* in Table 1.

the $N_2^+(v = 0) + O_2$ decay, and concluded that the charge transfer for $N_2^+(v > 0) + O_2$ has the same rate constant as $N_2^+(v = 0) + O_2$. Our results are consistent with these previous data, and demonstrate that the $N_2^+ + O_2$ charge transfer is not substantially enhanced by N_2^+ vibrational excitation up to $v = 2$.

Koyano et al. (11) were the first to study the $N_2^+(v) + O_2$ charge transfer reaction with selected vibrational states, although at a relatively high E_{cm}. Using the PEPICO technique, they reacted $N_2^+(X^2\Sigma_g^+, v = 0\text{–}3)$ and $N_2^+(A^2\Pi_u, v = 0\text{–}3)$ with O_2 at $E_{cm} = 2.1$ eV. They detected no change in the charge transfer cross sections for $N_2^+(X, v)$ as a function of vibrational quantum number up to $v = 3$, while the charge transfer was dramatically enhanced for $N_2^+(A)$. Figure 8 shows the energy level diagram for the set of state-to-state reactions,

$$[22] \quad N_2^+(X^2\Sigma_g^+, A^2\Pi_u; v) + O_2 \rightarrow N_2(X^1\Sigma_g^+, v') + O_2^+(X^2\Pi_g, a^4\Pi_u; v'').$$

The most recent compilation by Laher and Gilmore (38) is used to calculate the energy levels. The potential well depth of the $(N_2 \cdots O_2^+)$ complex with respect to the $N_2 + O_2^+(X)$ product state is experimentally estimated to be ≈0.23 eV (39–41). Based on the lack of vibrational enhancement of the $N_2^+(X, v) + O_2$ charge transfer reaction for higher v levels that are resonant with the $O_2^+(a, v'' = 0)$ product state (0.523 eV), Koyano et al. concluded that the products are $O_2^+(X)$, not $O_2^+(a)$. However, this seems to disagree with the high probability for the reverse reaction $O_2^+(a) + N_2 \rightarrow O_2 + N_2^+$ (42).

Schultz and Armentrout (12) recently reported a guided-ion beam mass spectrometry study of the $N_2^+(v = 0) + O_2$ reaction at E_{cm} from thermal (0.04 eV) to 20 eV. The charge transfer cross section monotonically decreases with E_{cm} up to ≈1 eV (more rapidly than the energy-dependent Langevin cross section decreases), and then suddenly increases above ≈1 eV. For the higher E_{cm} regime where a long-range direct mechanism might dominate the charge transfer process, their results and interpretation may be understood. According to the

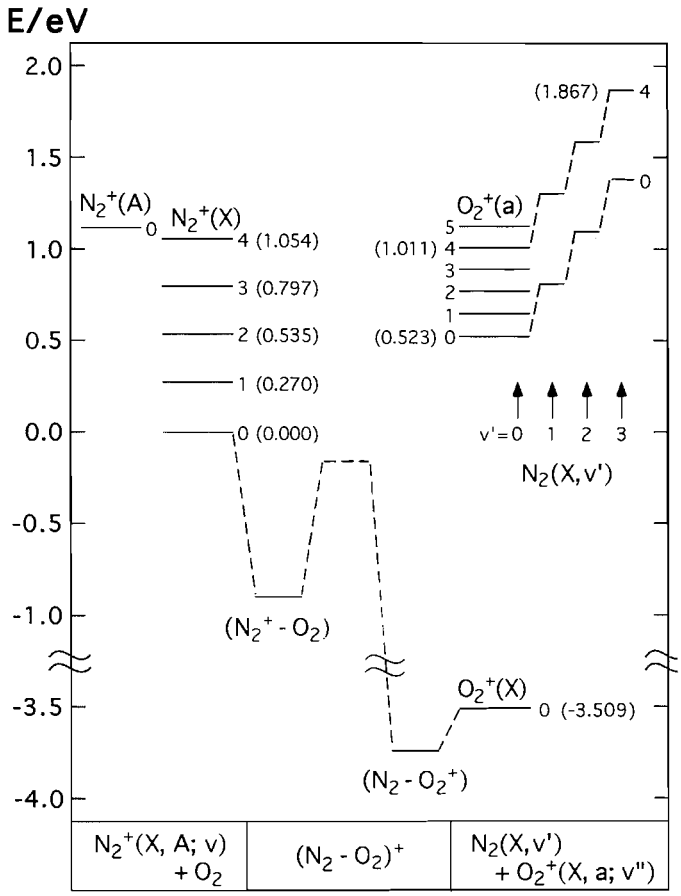

FIG. 8. Energy level diagram for the state-to-state reaction, $N_2^+(X^2\Sigma_g^+, A^2\Pi_u; v) + O_2 \rightarrow N_2(X^1\Sigma_g^+, v') + O_2^+(X^2\Pi_g, a^4\Pi_u; v'')$. The vibrational quantum number is designated by the arabic number attached to each level. Energy values relevant to the discussion are shown in parentheses (in eV).

Franck–Condon criteria for a long-range vertical transition, the product state is *not* $O_2^+(a, v'' = 0)$, which corresponds to the adiabatic ionization potential (I.P.) of O_2, but $O_2^+(a, v'' \approx 4)$ (43), where the vertical ionization is peaked at 1.011 eV (Fig. 8). The product state of $N_2(v')$ is most likely $v' = 0$, since the $N_2^+(X) \rightarrow N_2(X)$ transition is almost vertical and $v' \approx v$ will hold. Thus the charge transfer cross section for $N_2^+ + O_2$ increases above $E_{cm} \approx 1$ eV by opening of the $O_2^+(a)$ channel.

Therefore, it is not surprising that Koyano et al. did not observe a vibrational enhancement in the $N_2^+(v) + O_2$ charge transfer. At their E_{cm} of 2.1 eV, the charge transfer might be dominated by the long-range direct process. Two cases may be distinguished. If the translational energy is not effectively channelled into the $O_2^+(a)$ product state, then vibrational excitation of $N_2^+(v)$ even up to $v = 3$ (0.797 eV) is not sufficient to access $N_2(v' = 0) + O_2^+(a, v'' = 4)$ at 1.011 eV. Furthermore, Franck–Condon arguments would favor formation of $N_2(v' = 3) + O_2^+(a, v'' = 4)$ products from the $N_2^+(v = 3) + O_2$ reaction (Fig. 8), which lie at even higher energy. Alternatively, as Schultz and Armentrout pointed out (12), the $N_2^+(v = 0)$ state might already be coupled with the $O_2^+(a)$ product state if the 2.1 eV translational energy is effectively channelled into the reaction coordinate. Then, further vibrational excitation of the N_2^+ reactant is not as effective in enhancing the charge transfer. In their interpretation, however, it seems difficult to explain the significantly enhanced reactivity of $N_2^+(A)$ observed by Koyano et al. (11).

For personal use only.

It is important to explore the effects of vibration on the $N_2^+ + O_2$ charge transfer reaction at low E_{cm}. Under our experimental conditions, collision energies are so low that a short-range charge transfer mechanism will be operative, as suggested for the $^{15}N_2^+(v = 2) + {}^{14}N_2$ reaction (6). The Franck–Condon mechanism will not apply and adiabatic ionization to $O_2^+(a, v'' = 0)$ becomes feasible via an ion–molecule intermediate complex. The $N_2^+(v = 2)$ state (0.535 eV) is almost exactly resonant with the final product state ($O_2^+(a, v'' = 0) = 0.523$ eV) (Fig. 8). The observed $k_{CT,2}$, however, does not show a noticeable increase relative to $k_{CT,0}$ or $k_{CT,1}$. This implies that the vibrational energy is isolated and cannot be effectively channeled into the reaction coordinate or necessary surface crossings to access the $O_2^+(a)$ state. Once coupled with the $O_2^+(X)$ product state, the reaction is very exothermic (3.509 eV for $N_2^+(v = 0)$) and additional vibrational excitation of the $N_2^+(v)$ reactant is not effective in promoting the reaction.

For the $Ar^+ + O_2$ reaction, which has nearly the same energetics as $N_2^+ + O_2$, channeling of translational energy into the $O_2^+(a)$ product state has recently been demonstrated by Scherbarth and Gerlich (44). They used laser-induced photofragmentation detection of $O_2^+(a)$ and directly observed its formation at collision energies above the thermochemical threshold (0.345 eV). It would not be surprising if this type of energy coupling also occurs for the $N_2^+ + O_2$ reaction, since there is a drastic change in the charge transfer cross section with E_{cm} (12). However, the long-range, Franck–Condon mechanism is probably not responsible for the energy coupling; this coupling requires that the translational energy be converted to compensate for the reaction endothermicity, whereas the direct Franck–Condon mechanism produces little momentum transfer.

Another mechanism that might be operative in the $N_2^+ + O_2$ charge transfer is a short-range interaction, i.e., curve crossing to the $O_2^+(a)$ product state at a repulsive part of the potential energy surface. This mechanism can account for the different effects of translational and vibrational energy in the $N_2^+ + O_2$ reaction. An alternative short-range mechanism is curve crossing to the $O_2^+(a)$ state at an attractive part of the potential (Landau–Zener or Demkov type), which is promoted only by the translational energy. With these mechanisms, the different reactivity of the $N_2^+(A)$ reactant (11) may be discussed in terms of a curve crossing on a different potential energy surface.

It is difficult, however, to consider further details because of the lack of information on the structure of the $(N_2^+ \cdots O_2)$ complex and its relevant potential energy surface: Molecular orbital considerations suggest that the equilibrium structure of the $(N_2^+ \cdots O_2)$ complex is either rectangular or T-shaped (with O_2 forming the top of the T) (26). On the other hand, based on a dissociation product distribution at higher collision energies ($E_{cm} \geq 1$ eV), Schultz and Armentrout recently suggested a linear or bent $(N–N \cdots O–O)^+$ structure for the intermediate complex leading to charge transfer or dissociation (12).

Vibrational deactivation of $N_2^+(v)$ by O_2

There have been several previous measurements of the $N_2^+(v) + O_2$ deactivation rate constants. Dobler et al. (23, 24) and Ferguson et al. (26) measured k_q at thermal energies using flow tube techniques, while Kemper and Bowers (25) used an ICR instrument at $E_{cm} \approx 0.3$ eV (Table 2). All previous studies employed the Ar-monitor reaction and hence did not resolve the N_2^+ vibrationally excited states. In contrast, our experiment measures k_q for individual vibrational levels of N_2^+. Apart from our recent work with $N_2^+(v)$, there have been only a few other studies of ion deactivation with vibrational state discrimination (3*a*, 45). The deactivation rate constant of $O_2^+(v = 2)$ has been found to be approximately twice that of $O_2^+(v = 1)$ for several collision partners, which was explained in terms of predissociation of van der Waals clusters (45). Level-specific vibrational deactivation of $NO^+(v)$ was studied for some alkyl halide collision partners (3*a*). No systematic trend was observed for the $NO^+(v)$ deactivation; however, in this system deactivation competes with charge transfer, i.e., the sum of k_{CT} and k_q equals the collision rate constant (3*a*).

For $N_2^+(v)$ deactivation with O_2, only a weak dependence upon vibrational level is found (Fig. 7). On average, the values $k_{q,2}$ and $k_{q,1}$ agree with the values of the overall $k_q(v > 0)$ of 1×10^{-10} cm^3 molecule^{-1} s^{-1} reported at thermal energies. The smaller $k_q(v > 0)$ obtained with the ICR technique (Table 2) might be due to a kinetic energy effect; Dobler et al. observed a slight decrease (≈25%) of $k_q(v > 0)$ at $E_{cm} \approx 0.5$ eV (24).

We believe that the vibrational deactivation of $N_2^+(v)$ with O_2 occurs via a short-range mechanism at the low E_{cm} of our study. Neither N_2^+ nor O_2 has a permanent dipole moment that would facilitate long-range V–V transfer, although ion-induced dipole forces can be large. Further, the energy defect between the vibrational levels of N_2^+ and O_2 is rather large (≈620 cm^{-1} exothermic). This large gap would also hamper direct V–V energy transfer from $N_2^+(v)$ to O_2 upon collision. Since the rate constant for the vibrational deactivation of $N_2^+(v)$ with O_2 has a negative kinetic energy dependence in the relatively low E_{cm} region (24), a direct V–T (Landau–Teller) mechanism for the vibrational energy transfer is unlikely at the E_{cm} of our study. Therefore, nibrational relaxation most likely occurs in the $(N_2^+ \cdots O_2)$ intermediate complex (Fig. 8). Since vibrational deactivation is even more efficient than charge transfer, the charge transfer leading to $O_2^+(X)$ most likely takes place in the short-range intermediate complex as well. If formation of $O_2^+(X)$ occurred at long distances, the resulting $(N_2 \cdots O_2^+(X))$ complex would immediately dissociate to $N_2 + O_2^+(X)$ products due to the large exothermicity (3.509 eV), and no vibrational deactivation of $N_2^+(v)$ could occur.

Apart from symmetric charge transfer systems such as $N_2^+ + N_2$ and $O_2^+ + O_2$, the $N_2^+(v) + O_2$ reaction exhibits anomalously efficient vibrational deactivation compared to other ion–molecule systems (26). Ferguson et al. interpreted this in terms of a short-range, electron exchange interaction between N_2^+ and O_2 that effectively deepens the attractive well of the $(N_2^+ \cdots O_2)$ intermediate complex and increases the complex lifetime (26), e.g.,

$$[23] \qquad N_2^+ + O_2 \rightarrow N_2 + O_2^+(a^4\Pi_u) - 0.523 \text{ eV}$$

Separation of the complex to the $O_2^+(a)$ product is endothermic and does not occur (36). Assuming a moderate exchange integral of 0.8 eV for the electronic coupling between the N_2^+–O_2 and N_2–$O_2^+(a)$ states, we estimate interaction energies of 0.6, 0.7, and 0.8 eV for the $N_2^+(v = 0)$, $N_2^+(v = 1)$, and $N_2^+(v = 2)$ reactants, respectively. These interaction energies are added to the electrostatic interaction energy between N_2^+ and O_2 (≈0.2 eV) to give the effective well depths. The value of $k_{q,2}$, which is slightly greater than $k_{q,1}$, can be accounted for by this short-range mechanism.

The idea of vibrational deactivation via an intermediate complex is consistent with the kinetic energy dependence of k_q. Dobler et al. (24) observed a gradual decrease of k_q with E_{cm} in the $N_2^+(v)$ + O_2 system for the E_{cm} region below 0.5 eV; an increased E_{cm} shortens the lifetime of the complex, resulting in a smaller k_q. Above 0.5 eV, on the other hand, they observed a gradual increase in k_q. This implies that a short-range, impulsive interaction becomes important in the higher E_{cm} region. This kinetic energy effect complies with the proposed mechanism for the channeling of translational energy into the $O_2^+(a)$ product state, i.e., a short-range interaction is operating above ≈1 eV. We also believe that the steeper decrease in the charge transfer cross section with E_{cm} in the region below ≈1 eV (12) can be explained by this intermediate complex mechanism, rather than by the long- range, Franck–Condon arguments of Schultz and Armentrout (12). The overlap between the lowest unoccupied molecular orbital of N_2^+ and the highest occupied molecular orbital of $O_2(\Pi_g^* 2p)$, which leads to the $O_2^+(X)$ product state, is poor (26). Thus charge transfer to the $O_2^+(X)$ state can be inefficient and depends critically on the lifetime of the complex.

Finally, it is noted that both $\Delta v = -1$ and $\Delta v = -2$ processes occur in the deactivation of $N_2^+(v = 2)$. The $\Delta v = -1$ loss mechanism is most likely for direct V–T and V–V processes, but $\Delta v = -2$ loss may be important for low-energy collisions involving an ion–molecule intermediate complex. Indeed, an efficient V–V transfer ($\Delta v = -2$) was recently observed in the $^{15}N_2^+(v = 2)$ + $^{14}N_2$ resonant charge transfer reaction (6). It is likely that vibrational deactivation during an ion–molecule interaction depends on multiple factors, e.g., collisional energy and trajectory, structure, vibrational frequency, and lifetime of the ion–molecule pair. More studies are needed to establish a comprehensive understanding of vibrational phenomena in ion–molecule collisions.

Conclusions

Vibrational specificity for charge transfer versus deactivation in the $N_2^+(X, v = 0, 1, 2)$ + Ar and O_2 reactions was studied at near-thermal collision energy with the SIFT–LIF technique. The $N_2^+(v = 1)$ + Ar reaction proves to be an excellent reference reaction for obtaining absolute rate constants for other ion–molecule reactions.

Some enhancement is observed for the reactivity of $N_2^+(v = 0)$ with Ar in the LIF region compared to that at 300 K, most likely because of a slightly higher collision energy (<0.23 eV). The charge transfer rate constants for $v = 1$ and $v = 2$ with Ar are nearly the same, contrary to the behavior observed previously at higher collision energies. The vibrational deactivation of $N_2^+(v = 1)$ with Ar is very inefficient (≤3% of the total reaction), similar to the $N_2^+(v)$ deactivation with other rare gas quenchers. This is rationalized by a rather shallow potential well for the $N_2^+(v = 1)\cdots$Ar system due to an avoided crossing of the potential energy curves.

The vibrational dependence of the $N_2^+(v)$ + O_2 charge transfer reaction was studied at near-thermal energy where the effect of translational energy is negligible; reaction enhancement by an energy coupling to the endothermic $O_2^+(a^4\Pi_u)$ product state was not observed for $N_2^+(v)$ + O_2 following vibrational excitation of up to $v = 2$, while translational energy has been reported to couple efficiently into the $O_2^+(a^4\Pi_u)$ product state. Since it is unlikely that a long-range, direct Franck–Condon mechanism with little momentum transfer is effective in converting relative translational energy into product internal excitation, the energy coupling to the $O_2^+(a^4\Pi_u)$ state must take place via another mechanism, i.e., crossing of potential energy curves at shorter distances. Highly efficient, slightly level-dependent vibrational deactivation of $N_2^+(v = 1, 2)$ with O_2 is explained by a deep potential well due to an electron exchange interaction within a short-range ion–molecule intermediate complex. The observed vibrational energy dependence of the $N_2^+(v)$ + O_2 rate constants (charge transfer and deactivation), along with a variety of previous results, is consistent with a mechanism involving short-range interactions.

$O(^3P_j)$ atom formation from photodissociation of ozone in the visible and ultraviolet region

SAYED MOHAMMED SHAMSUDDIN, YOUSUKE INAGAKI, YUTAKA MATSUMI, AND MASAHIRO KAWASAKI[1]

Institute for Electronic Science and Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060, Japan

Received May 10, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

SAYED MOHAMMED SHAMSUDDIN, YOUSUKE INAGAKI, YUTAKA MATSUMI, and MASAHIRO KAWASAKI. Can. J. Chem. **72**, 637 (1994).

The photodissociation of ozone at 266, 308, and 532 nm has been studied for $O_3 \rightarrow O_2(X^3\Sigma_g^-) + O(2p^3P_j)$, probing $O(^3P_j)$ atomic photofragments by a vacuum ultraviolet laser-induced fluorescence method. Angular distributions and average kinetic energies are determined by measuring Doppler profiles of the $O(^3P_j)$ photofragments. Anisotropy parameters β for the angular distributions are 0.81 ± 0.10 at 266 nm, 0.60 ± 0.10 at 308 nm, and −0.68 ± 0.09 at 532 nm. These values are consistent with the assignment of the photoexcited states, that is, $^1B_2$ in the ultraviolet and $^1B_1$ in the visible region. Average center-of-mass translational energies are 44, 38, and 21 kcal/mol for photodissociation at 266, 308, and 532 nm, respectively. The j-branching ratios of $O(^3P_j)$ produced from the photodissociation at 266 nm are $(j = 2)/(j = 1)/(j = 0) = (0.55 \pm 0.03)/(0.32 \pm 0.03)/(0.12 \pm 0.03)$, which are close to the state degeneracy $(2j + 1)$ ratios. At 308 and 532 nm the branching ratios are $(j = 2)/(j = 1)/(j = 0) = (0.66 \pm 0.03)/(0.27 \pm 0.03)/(0.09 \pm 0.01)$ and $(0.74 \pm 0.03)/(0.20 \pm 0.02)/(0.05 \pm 0.01)$, respectively. Population of the $j = 2$ level increases with decreasing photon energies. The ratios obtained are discussed in terms of the adiabaticity of the potential surfaces during bond breakup as a function of the relative speed of separation.

SAYED MOHAMMED SHAMSUDDIN, YOUSUKE INAGAKI, YUTAKA MATSUMI et MASAHIRO KAWASAKI. Can. J. Chem. **72**, 637 (1994).

Faisant appel à une méthode de fluorescence induite au laser dans l'ultraviolet lointain pour déterminer les photofragments atomiques $O(^3P_j)$, on a étudié la photodissociation de l'ozone à 266, à 308 et à 532 nm selon la réaction $O_3 \rightarrow O_2(X^3\Sigma_g^-) + O(2p^3P_j)$. On a déterminé les distributions angulaires et les énergies cinétiques moyennes en mesurant les profils de Doppler des photofragments $O(^3P_j)$. Les paramètres d'anisotropie β des distributions angulaires sont respectivement 0,81 ± 0,10 à 266 nm, 0,60 ± 0,10 à 308 nm et −0,68 ± 0,09 à 532 nm. Ces valeurs sont en accord avec l'attribution des états photoexcités qui sont respectivement $^1B_2$ dans l'ultraviolet et $^1B_1$ dans la région du visible. Les énergies de translation moyennes du centre de masse sont 44, 38 et 21 kcal/mol respectivement pour les dissociations à 266, 308 et 532 nm. Les rapports de bifurcations du $O(^3P_j)$ produit par dissociation à 266 nm sont $(j = 2)/(j = 1)/(j = 0) = (0{,}55 \pm 0{,}03)/(0{,}32 \pm 0{,}03)/(0{,}12 \pm 0{,}03)$; ces résultats sont très proches des rapports pour l'état dégénéré $(2j + 1)$. À 308 et à 532 nm, les rapports de bifurcations sont respectivement $(j = 2)/(j = 1)/(j = 0) = (0{,}66 \pm 0{,}03)/(0{,}27 \pm 0{,}03)/(0{,}09 \pm 0{,}01)$ et $(0{,}74 \pm 0{,}03)/(0{,}20 \pm 0.02)/(0{,}05 \pm 0.01)$. La population du niveau $j = 2$ augmente avec une diminution des énergies du photon. On discute des résultats obtenus en termes de l'adiabaticité des surfaces de potentiel durant le bris de la liaison en fonction de la vitesse relative de séparation.

[Traduit par la rédaction]

Introduction

The visible and ultraviolet absorption spectrum of ozone consists of three diffuse bands, known as the Hartley band $^1B_2 \leftarrow \tilde{X}^1A_1$, 200–300 nm, f = 2.3×10^{-1}; the Huggins band $^1B_2 \leftarrow \tilde{X}^1A_1$, 300–360 nm; and the Chappuis band $^1B_1 \leftarrow \tilde{X}^1A_1$, 450–850 nm (1–3). The Hartley band, which is essentially diffuse because of its dissociative nature, is the most intense of these bands. The Hartley band corresponds to transitions into the saddle-geometry region of the $^1B_2$ excited state surface corresponding to ground state equilibrium configurations with strong Franck–Condon overlap as shown in Fig. 1. To the red end of the Hartley band there is a much weaker bank system called the Huggins band. The Huggins system corresponds to transitions into the bound portions of the $^1B_2$ surface with weak Franck–Condon factors (1). The $2^1A_1 \leftarrow \tilde{X}^1A_1$ transition was calculated by Hay and Dunning (2) to appear at ~270 nm with $f = 2.0 \times 10^{-6}$. Hence this band is too weak to be observed in a one-photon excitation due to the overlap of the intense Hartley band.

There are two significant photodissociation paths for O_3 in the Hartley band:

[1] $O_3 \rightarrow O(^1D) + O_2(a^1\Delta_g)$, $\Delta H = 92$ kcal/mol

[2] $O_3 \rightarrow O(^3P) + O_2(X^3\Sigma_g^-)$, $\Delta H = 24$ kcal/mol

The following path is spin-forbidden from the photoprepared $^1B_2$ state and is expected to play a lesser role in the photochemistry:

[3] $O_3 \rightarrow O(^3P) + O_2(a^1\Delta_g)$, $\Delta H = 47$ kcal/mol

The dissociation channel [1], which has a quantum yield of 0.85–0.9 (4, 5), is referred to as a singlet channel and the quantum yield of the triplet channel [2] is 0.1–0.15 (4) in the Hartley band. Fairchild et al. (6) and Sparks et al. (7) reported the formation of both $O(^3P) + O_2(X^3\Sigma_g^-)$ and $O(^1D) + O_2(a^1\Delta_g)$. Kinugawa et al. (8) studied the photodissociation of O_3 by probing $O(^3P_j)$ atomic fragments with a resonance-enhanced multiphoton ionization method. They reported the angular and kinetic energy distributions determined by measuring time-of-flight spectra. Daniels and Wiesenfeld (9) probed the vibrationally excited $O_2(X^3\Sigma_g^-, v'' = 9, 12, \text{and } 15)$ produced from the 248-nm photodissociation of O_3. They estimated that the rovibrational energy is one half of the available energy (E_{avl}).

For the Chappuis band photodissociation of O_3, Valentini and co-workers (10, 11) reported the nascent vibrational and rotational distribution of O_2. They found that the O_2 photofragments are always formed in the ground O_2 $(X^3\Sigma_g^-)$ state, and there was no evidence for production of the excited $O_2(^1\Delta_g)$

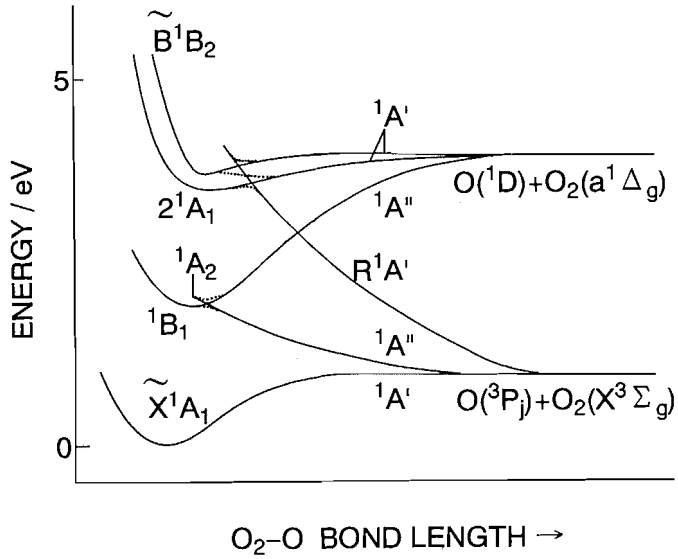

FIG. 1. Schematic section through the approximate low-lying singlet potential energy surfaces of O_3 along a dissociation coordinate $R(O_2—O)$ taken from Hay et al. (3), Daniels and Wiesenfeld (9), and Banichevich and Peyerimhoff (26). Broken lines represent avoided crossing. Symmetry representations are shown in C_{2v} near the equilibrium positions and in C_s at the asymptotic region. The curves for $^1B_1$ and $^1A_2$, which were estimated from the results calculated by Hay and Dunning (2), are added to the original figure of Hay et al. (3).

state, although both channels [2] and [3] are thermochemically allowed after Chappuis band excitation at $\lambda < 611$ nm.

To understand photodissociation dynamics, which involves the generation of atoms that possess nonvanishing electronic angular momentum, it is important to obtain branching ratios among fine-structure states of photofragment atoms. The $O(^3P_j)$ electronic states are split in energy due to spin-orbit interactions. The energy separations are $\Delta E(^3P_1–^3P_2) = 0.45$ kcal/mol and $\Delta E(^3P_0–^3P_1) = 0.19$ kcal/mol. These energy separations are very small compared with the available energy E_{avl} in the photodissociation of O_3 at 532 nm ($E_{avl} = 30$ kcal/mol), 308 nm (69 kcal/mol), and 266 nm (83 kcal/mol). The j-branching ratios of $O(^3P_j)$ atoms generated from the photodissociation of oxygen molecules have been reported at several wavelengths (12–14). Resulting j-branching ratios were interpreted by the nonadiabatic couplings of potential energy surfaces during bond breakup.

In this paper, we report the laser-induced fluorescence (LIF) detection of $O(^3P_j)$ from the photodissociation of O_3. We present the angular distributions, average kinetic energies, and j-branching ratios of $O(^3P_j)$ in the photodissociation of O_3 molecules to $O(^3P_j)$ + $O_2(^3\Sigma_g^-)$ fragments at the Hartley band (266 nm), the Huggins band (308 nm), and the Chappuis band (532 nm).

Experimental

Oxygen atoms were detected by a vacuum ultraviolet (VUV) laser-induced fluorescence method for $O(3s^3S^0 \leftarrow 2p^3P_j)$ at 130.22 nm for $j = 2$, 130.48 nm for $j = 1$, and 130.60 nm for $j = 0$. The VUV laser was generated by four-wave difference mixing ($2\omega_1–\omega_2$) with Kr gas (15), using two dye lasers (Lambda Physik FL 3002E) pumped by a XeCl excimer laser (Questek 2520vβ). The wavelength of ω_1 was 212.56 nm, which was two-photon resonant with Kr $5p[1/2]_0$, and the wavelength of ω_2 was around 578.1, 572.8, and 570.6 nm for $j = 2$, 1, and 0, respectively. The laser power was about 0.3 and 2 mJ/pulse for ω_1 and ω_2, respectively, at a pulse duration of 15 ns. The ω_1 and ω_2 light beams were focused into a Kr (25 Torr; 1 Torr = 133.3 Pa) cell with a lens ($f = 200$ mm). The generated VUV laser light was introduced into a photodissociation chamber through a LiF window. The VUV laser light reflected by a surface of a LiF window held in the chamber was led into a cell filled with nitric oxide gas (3.5 Torr). Thus, intensity of the VUV light was monitored by the photoionization current of the NO gas. At ~130 nm, near the ionization threshold of the NO molecules, the ionization efficiency varies as a function of the VUV laser wavelength. We calibrated this efficiency by observing relative populations of thermalized $O(^3P_j)$ atoms at 300 K. The laser line width of the probe VUV laser light was obtained experimentally by measurement of the line width for thermalized $O(^3P_2)$ atoms. The laser line width was 0.3 cm^{-1} as a full width at half maximum (FWHM). Under the conditions of O_3 (5 mTorr) + N_2 (1 Torr) and 10–20 μs delay between photolysis (266 nm) and probe laser pulses, Doppler widths and relative j-level intensities of $O(^3P_j)$ atoms did not change as a function of delay (10–20 μs) because the $O(^3P_j)$ atoms were translationally thermalized with the Boltzmann population among the j-levels at 300 K. We thus calibrated the j-branching ratios with the thermalized j-level intensities at 20 μs delay.

The resonant LIF signal of $O(^3P_j)$ from the photodissociation of O_3 (5–20 mTorr) was detected by a solar blind photomultiplier (Hamamatsu, R1259), a narrow band interference filter at 130 nm (Acton Research, 130-N-1D), and a gated integrator (Stanford Research Systems, SR250). The harmonics of a YAG laser system (Quanta-Ray, DCR-11) were used for 266 and 532 nm photodissociation, the polarization degree of which was more than 99%. An excimer laser (Lambda Physik, EMG 101 MSC) was also used as a dissociation light source, which was operated in the XeCl mode. A polarizer comprising 10 quartz plates was used to linearly polarize the 308-nm light. The degree of polarization of the output was 0.94. The dissociation laser light was focused with a cylindrical lens ($f = 500$ mm), which was introduced into the chamber through light baffles with a quartz window at right angles to the VUV laser and the fluorescence monitor direction. The intensity of the dissociation light was 1, 5, and 20 mJ/pulse at 266, 308, and 532 nm, respectively. The delay between the photolysis and probe laser pulses was 80 ns.

Ozone, freshly prepared from dry oxygen by using a commercial ozonizer, was trapped on silica gel at liquid N_2 temperature prior to storage at room temperature in a glass bulb at a pressure of 100 Torr. Ozone gas was introduced into the vacuum chamber through tubing and a needle valve which were made of poly(tetrafluoroethylene). LIF signals of oxygen atoms were detected without the dissociation laser light when the ω_1 probe laser intensity was high. Since this signal was due to photodissociation of ozone at 212.56 nm of the ω_1 laser light, we reduced this ω_1 intensity as much as possible for the photolysis experiment.

Results

A. Fine-structure branching ratios

Ozone molecules were photodissociated by linearly polarized laser light at 266, 308, and 532 nm. Figure 2 shows VUV LIF excitation spectra of the $O(^3P_j, j = 2, 1, 0)$ around 130 nm resulting from the photodissociation of O_3 at 532 nm. These atomic lines are broadened due to the Doppler effects. Figure 3 shows the linear dependence of the LIF signal of $O(^3P_2)$ on the vacuum ultraviolet probe laser intensity in the photodissociation at 266 nm. The LIF signal of $O(^3P_1)$ also had a linear dependence on the probe laser intensity. The j-branching ratios of $O(^3P_j)$ for O_3 photodissociation at 266, 308, and 532 nm were obtained from the excitation spectra and are listed in Table 1. To check the saturation effect we measured the j-branching ratios at two different dissociation laser intensities, namely, 0.3 and 1.0 mJ/pulse at 266 nm. Both results gave the same j-branching ratios. The j-branching ratios reach the state degeneration ratios (2j + 1) in the photodissociation at 266 nm while

the population of the $j = 2$ level increases with decreasing photon energy at 308 and 532 nm.

B. Doppler profiles of the oxygen atom photofragments and kinetic energy release

Figure 4 shows the Doppler profiles for $O(^3P_2)$ from photodissociation of O_3 at 266, 308, and 532 nm by the VUV LIF technique. By scanning the laser wavelength around the resonance frequency of the oxygen atom at ~130 nm, the shapes of the fluorescence excitation curve were measured. Two Doppler profiles are shown for each excitation wavelength; these were taken under the $\Theta = 0°$ and 90° configurations. Θ is the angle between the electric vectors of the linearly polarized dissociation laser ($\boldsymbol{E}_d$) and the propagation direction of the probe laser ($\boldsymbol{k}_p$).

The following eq. [4] gives an average translational energy of

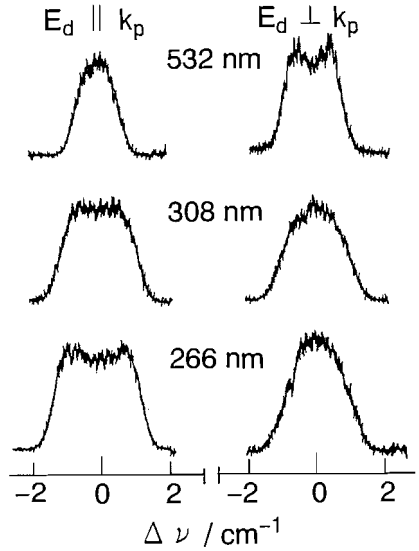

FIG. 4. Doppler profiles of $O(^3P_2)$, from photodissociation of ozone (5–20 mTorr) at 266, 308, and 532 nm, by vacuum ultraviolet laser-induced fluorescence at 130.22 nm. $\boldsymbol{E}_d//\boldsymbol{k}_p$ and $\boldsymbol{E}_d \perp \boldsymbol{k}_p$ imply that the directions of the electric vector of linearly polarized dissociation laser light are parallel with and perpendicular to the propagation directions of the probe laser beam, respectively.

oxygen atom fragments in the laboratory frame, $\langle E_t^{lab}(O)\rangle$, for photodissociation with linearly polarized light,

$$[4] \quad \langle E_t^{lab}(O)\rangle = (1/2)m(O)\{\langle v_\parallel{}^2\rangle + 2\langle v_\perp{}^2\rangle\}$$

where $m(O)$ is the molecular weight of an O atom and $\langle v_\parallel{}^2\rangle$ and $\langle v_\perp{}^2\rangle$ are the averages of the squared velocity projection parallel and perpendicular to the polarization vector of the photolysis laser, respectively (17). The values of $\langle v_\parallel{}^2\rangle$ and $\langle v_\perp{}^2\rangle$ can be derived from the second moments of the Doppler profiles. The kinetic energy release in the center-of-mass frame, $\langle E_t\rangle$, is calculated by

$$[5] \quad \langle E_t\rangle = [m(O_3)/m(O_2)][\langle E_t^{lab}(O)\rangle - (3/2)kTm(O)/m(O_3)]$$

where the $(3/2)kTm(O)/m(O_3)$ term in the right-hand side of eq. [5] is attributable to the thermal motion of O_3 parent molecules at 300 K and is negligibly small (~0.3 kcal/mol).

The Doppler widths of the $O(^3P_j)$ atom from the O_3 photodissociation at 266 and 308 nm are about six times larger than

[b]$\beta = \beta_{eff}/f$ where f is the correction factor for molecular rotation in eq. [10] and β_{eff} is a weighted average value for $j = 2$, 1, and 0. β at 308 nm is corrected for imperfect polarization of the dissociation laser light.

the probe laser line width (FWHM = 0.3 cm^{-1}), and hence the contributions of this laser line width to the calculated values of the second moments are negligibly small (<3%). However, at 532 nm this line-width effect is not negligible. We simulated the Doppler profiles with the convolution of the laser line width and estimated the correction factors for the average kinetic energies due to the laser line width. Our simulation indicated the overestimation due to the line width is 13 and 9% at a kinetic energy of 20 and 24 kcal/mol, respectively. The values obtained for the average kinetic energy release in the center-of-mass frame, $\langle E_t \rangle$, at 266 and 308 nm, and the corrected values at 532 nm are listed in Table 2 for each j-level of the $O(^3P_j)$ atoms.

C. Angular distribution of the oxygen atom fragments

The general velocity distribution of atoms from the photodissociation of molecules with linearly polarized light is given by

$$[6] \quad f(v) \propto 1 + \beta P_2 (\varepsilon \cdot v)$$

where β is the anisotropy parameter, $P_2(x)$ is the second Legendre polynomial, and ε is the electric vector of incident photons. This leads to a spectral profile of photofragment atoms with a speed of $v = (2E_t^{lab}(O)/m(O))^{1/2}$ (16),

$$[7] \quad g(v) \propto \left[1 + b\beta P_2\left(\frac{v_z}{v}\right)\right]\Theta(v - |v_z|)$$

where v_z is $(v - v_0)c/v_0$, c the speed of light, and $\Theta(x)$ is the step function: $\Theta(x) = 1$ for $x \geqq 0$ and $\Theta(x) = 0$ for $x < 0$. The value of b is 1 for E_d perpendicular to k_p and $-1/2$ for E_d parallel to k_p.

The effective anisotropy parameter β_{eff} for the angular distributions of the photofragments is calculated (17) by

$$[8] \quad \beta_{eff} = 5\{\langle v_\parallel^2 \rangle - \langle v_\perp^2 \rangle\}/\{\langle v_\parallel^2 \rangle - \langle v_\perp^2 \rangle\}$$

The effective anisotropy parameters thus calculated are listed in Table 3 for 266, 308 and 532 nm. The β_{eff} values averaged for the j-populations are positive at 266 and 308 nm while that at 532 nm is negative.

When the dissociation lifetime of the photoexcited state is shorter than the rotational period of the parent molecule, the value of the anisotropy parameter β is given by

$$[9] \quad \beta = 3\cos^2\chi - 1$$

where χ is the angle between the directions of the electronic transition moment and the dissociation bond (18). However, parent molecular rotation reduces anisotropy by a factor f, which can be approximated for a small deflection of the original velocity vector (18):

$$[10] \quad f = 1 - 3RT/[(2)^{1/2}E_t]$$

Since E_t is 21 kcal/mol at 532 nm, f is ~0.94 and a small amount of distortion is produced in the value of β_{eff}. The corrected value for the anisotropy parameter is −0.68 ± 0.09, which is given by $\beta = \beta_{eff}/f$. A similar correction was made for the photodissociation at 266 and 308 nm. At 308 nm, our β value should be corrected due to the incomplete polarization of the excimer laser light according to Dzvonik et al. (19). The corrected values, β, are listed in Table 3. Fairchild et al. (6) presented a β value of −0.73 for the photodissociation at 600 nm to the $O(^3P_j)$ + $O_2(^3\Sigma_g^-)$ channel, which is in good agreement with our value of −0.68 ± 0.09 at 532 nm. For the $O(^3P_j)$ + O_2 $(^3\Sigma_g^-)$ channel, they also reported values of 0.52, 0.77, and 1.20 at 274, 277, and 281 nm, respectively. Kinugawa et al. (8)

reported $\beta = 0.7 \pm 0.1$ at 226 nm. Our value of 0.81 ± 0.10 at 266 nm agrees with their values.

Discussion

A. *Photoexcitation and dissociation processes*

A one-dimensional sketch of the diabatic potential curves along a dissociation coordinate, $R(O_2—O)$, is presented in Fig. 1. The ground state $O_3(\tilde{X}^1A_1)$ has a C_{2v} equilibrium geometry ($R = 1.2717$ Å, $\theta = 116.78°$) and correlates asymptotically with $O_2(^3\Sigma_g^-) + O(^3P_j)$. The $^1B_2$ state of O_3 has a C_{2v} saddle point at $R = 1.405$ Å and $\theta = 108.4°$ (2). An avoided crossing takes place between the $^1B_2$ and repulsive R^1A' states due to the same representation $^1A'$ in the C_s symmetry of the dissociation path. This repulsive R^1A' potential surface correlates to $O(^3P_j) + O_2(^3\Sigma_g^-)$. Another avoided crossing may occur between the R^1A' and 2^1A_1 states, since the symmetry of the 2^1A_1 states becomes $^1A'$ at the C_s symmetry. Consequently, the adiabatic dissociation path of O_3 molecules excited to the $^1B_2$ surface leads to $O(^1D) + O(^1\Delta_g)$ fragments (3). Upon UV band excitation, ozone molecules are excited to the $^1B_2(^1A')$ state and then predominantly dissociate to $O(^1D) + O_2(a^1\Delta_g)$ along the adiabatic surface. However, about 10% of the excited ozone molecules dissociate to $O(^3P_j) + O_2(^3\Sigma_g^-)$ along the R^1A' state due to non-adiabatic transitions (4).

The visible band (400–700 nm) is assigned to the $^1B_1$–$\tilde{X}^1A_1$ transition (2). The $^1B_1$ state has $R = 1.370$ Å and $\theta = 117.7°$, which becomes the $^1A''$ state in the C_s symmetry and correlates to $O(^1D) + O_2(^1\Delta_g)$ (2). The $^1A_2$ state that locates near the $^1B_1$ state at their equilibrium geometries is correlated with $O(^3P_j) + O_2(^3\Sigma_g^-)$. The avoided crossing takes place between these $^1B_1$ and $^1A_2$ states, since the symmetries of these two states become $^1A''$ at the asymptotic C_s region. At 532 nm, ozone molecules are excited to the $^1B_1(^1A'')$ state and then dissociate to $O(^3P_j) + O_2(^3\Sigma_g^-)$ through this repulsive $^1A_2(^1A'')$ state.

B. *Dissociation anisotropy*

Fairchild et al. (6) calculated an anisotropic parameter of the photofragment angular distribution of the $O(^1D) + O_2(^1\Delta_g)$ channel for the UV transition of $O_3(\tilde{B}^1B_2 \leftarrow \tilde{X}^1A_1)$. They obtained $\beta = 1.17$, assuming that (a) the transition moment lies perpendicular to the C_{2v} axis, (b) the dissociation lifetime τ is zero, and (c) the bond angle θ is the same as that of the ground state (116.7°). Their experimental results for the $O(^1D) + O_2(^1\Delta_g)$ channel indicate that the angular distribution is independent of photodissociation wavelengths over the range 274–300 nm and their β values (1.2 ± 0.2) are close to the calculated value of $\beta = 1.17$. For the predissociative formation of $O(^3P)$, our β value is 0.81 ± 0.10 at 266 nm. Since a β value is a function of both a lifetime τ and an angle χ of the dissociating state, the difference in the β values between the $O(^1D)$ and $O(^3P)$ channels would be due to different lifetimes and (or) structures of the dissociating O_3 parent molecules for the singlet and triplet channels. However, the lifetime of the photoprepared $^1B_2$ state must be the same for both the singlet and triplet channels. Since the β value for $O(^1D)$ is close to the calculated value, the lifetime should be very short. The difference in the β values between the singlet and triplet channels may be due to a structural change in the triplet channel. Daniels and Wiesenfeld (9) reported sharply peaked rotational distributions of $O_2(X^3\Sigma_g^-, v'' = 9, 12, 15)$ in the photodissociation of O_3 at 248 nm. They proposed an impulsive approximation, which reproduces their experimental peak positions and approximate widths of the distributions. If this impulsive model is an accurate depiction of the dissociation, the lifetime should be very short. The only way to obtain agreement between the peaks of their rotational and our angular distributions within the context of the impulsive model is to assume that the lifetime is very short and the bond angle $\theta = 102 \pm 4°$, which leads to $\beta = 0.81 \pm 0.10$. This bond angle θ is a little smaller than those of the equilibrium position between the ground $^1A_1$ and the excited $^1B_2$ states. That geometry might approximate a configuration for which coupling is strong between the photoprepared $O_3(^1B_2)$ and the interacting R^1A' states.

At 308 nm, the Huggins band is assigned to transition into $O_3(\tilde{B}^1B_2)$ with weak Franck–Condon factors (1). The quantum yield of $O(^1D)$ formation is ca. 0.9 at 266 nm, ca. 0.5 at 300 nm, and less at 308 nm (4, 20). In addition, the observed anisotropy parameter at 308 nm is 0.60 ± 0.10, which is smaller than 0.81 ± 0.10 at 266 nm. Because the formation of $O(^3P)$ atoms from $O_3(^1B_2)$ is predissociative, the dissociation dynamics would be sensitive to the available energy in the dissociation process as well as to the internuclear distance to which the O_3 molecule is excited. Hence, the photodissociation dynamics of O_3 at 308 nm would not be the same as that at 266 nm.

The first diffuse absorption band at 450–850 nm is assigned to a transition from the ground $\tilde{X}^1A_1$ state into the repulsive $^1B_1$ state. Since the transition moment for the $^1B_1$–$\tilde{X}^1A_1$ absorption lies perpendicular to the molecular plane of ozone, this transition corresponds to $\beta = -1$, based on eq. [9], if the dissociation lifetime is very short. The obtained value of -0.68 ± 0.09 is a little smaller than -1, which may be explained by the geometrical change after the photoexcitation or by the lifetime longer than the rotational period during curve crossing of this $^1B_1$ state to the repulsive $^1A''$ state.

C. *Kinetic energy release in the photodissociation*

A fraction of the available energy released into the translational energy, $\langle f_t \rangle = \langle E_t \rangle / E_{avl}$, is shown in Table 2. Since our Doppler measurement is not very sensitive to a translational energy distribution, only the average translational energy is obtained from eq. [4]. About one half of the available energy goes into the translational freedom in the photodissociation at the UV band, while 70% of the available energy is released into the translational freedom at the visible band. The results obtained are in good agreement with the values estimated from the vibronic distribution of the O_2 fragment for both the visible and ultraviolet bands (9, 10).

D. *The* j*-branching ratios in the* $O(^3P_j)$ *levels*

The j-branching ratios of $O(^3P_j)$ and $Cl(^2P_j)$ that are produced from the photodissociation of O_2 (12–14), HCl (21), Cl_2 (22), and chlorinated methanes (23) have been studied. The j-branching ratios in photodissociation processes should be determined by two factors: one is the adiabatic correlation between the dissociating molecular states and the atomic states. The other is non-adiabatic coupling during bond breakup. Two extreme cases can be considered, that is, adiabatic and diabatic or recoil limits (24). When the fragment separation is sufficiently fast, the electronic and spin angular vectors do not recouple according to the adiabatic state correlation, since there is not enough time for electrons to adjust themselves during bond breakup. In this diabatic or recoil limit, only the density of the product states is considered and hence the population of the specific j-level of $O(^3P_j)$ is proportional to the degeneracy $(2j + 1)$, that is, $(j = 2)/(j = 1)/(j = 0) = 0.56/0.33/0.11$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

On the other hand, when the fragments separate more slowly, the dissociation is expected to proceed according to the adiabatic state correlation between the molecular states and the separated fragments. For the photodissociation of diatomic molecules, the correlation diagram is constructed so that the projection (Ω value) of the total angular momentum along the nuclear axis is conserved between molecular states and atomic states. In the case of the O_3 photodissociation process, the molecule keeps C_s symmetry during bond breakup. The combination of the $O_2(^3\Sigma_g^-)$ + $O(^3P_j)$ product states generates, in total, 27 electronic levels of the O_3 molecular electronic states, which are two $^1A'$, two $^3A'$, two $^5A'$, one $^1A''$, one $^3A''$, and one $^5A''$. The adiabatic correlation diagram connects the lowest 15 molecular electronic levels of the 27 molecular levels with the $O(^3P_j, j = 2)$ + $O_2(^3\Sigma_g^-)$ product state, the next nine electronic states with $j = 1$, and the next three with $j = 0$. The R^1A' and $^1A''(^1A_2)$ surfaces, which are responsible for the dissociation of O_3 after the photoexcitation at ultraviolet and visible wavelengths, respectively, should be adiabatically correlated with the $O_2(^3\Sigma_g^-)$ + $O(^3P_j, j = 2)$ product states, taking into account the ab initio electronic states (2). If the dissociation takes place adiabatically on the R^1A' or $^1A_2(^1A'')$ surfaces, the formation of $O(^3P_2)$ is expected according to this adiabatic state correlation. The expectation values for the j-branching ratios in the adiabatic limit are $(j = 2)/(j = 1)/(j = 0) = 1/0/0$.

Our experimental results on the branching ratios at 266 nm are $(j = 2)/(j = 1)/(j = 0) = 0.55/0.32/0.12$, which are quite close to the diabatic limit values. Those at 308 and 532 nm are between the diabatic and adiabatic limit values as shown in Table 1. Non-adiabatic couplings during bond breakup with other electronic surfaces of the same symmetry are responsible for the formation of $j = 1$ and $j = 0$ levels of $O(^3P_j)$ due to the fast nuclear kinetic motion. Those non-adiabatic couplings may take place in the O_2—O long-distance region, since the potential surfaces become asymptotically degenerate in that region due to the small energy separations among the j-levels. The degree of adiabaticity is expressed by the following relation:

$$[8] \quad \xi = (R/v)/(\hbar/\Delta E)$$

where R is the length of the interaction region and v is the relative speed of the separating atoms (25). When the separation speed between the fragments is slow in the asymptotic interaction region, the adiabaticity parameter ξ is large. ΔE is the energy separation of the interacting states. The value of ξ is large for a large value of ΔE. The spin-orbit energy separations ΔE_{so} of each j state of the fragment atoms can be used for the value of ΔE in the long nuclear distance region, and hence, $\hbar/\Delta E$ or $\hbar/\Delta E_{so}$ is considered as a time for relevant electrons to precess during the breakup. When the dissociation wavelength is longer, that is, the speed is slower in the long nuclear distance region, the j-branching ratios become closer to the adiabatic limit. Thus, the dissociation wavelength dependence of the j-branching ratios listed in Table 1 is explained by the adiabaticity of the relevant potential curves.

Conclusion

We have measured the average kinetic energies, the anisotropy angular parameters, and the j-branching ratios of the $O(^3P_j)$ photofragments from photodissociation of O_3 in the Hartley (266 nm), the Huggins (308 nm), and the Chappuis (532 nm) bands. The obtained values of the anisotropic angular parameters are consistent with assignment of the optical transitions, $^1B_2$–$\tilde{X}^1A_1$ for the Hartley and the Huggins bands and $^1B_1$–$\tilde{X}^1A_1$ for the Chappuis band. The j-branching ratios of the $O(^3P_j)$ products depend solely on the separation speed of the photofragments.

The dry etching reaction of solid copper surfaces with fluorine atoms or molecules has been studied with laser-induced fluorescence spectroscopy. The reaction product, copper monofluoride, CuF, is produced in the $X^1\Sigma^+$ electronic ground state and desorbs into the gas phase at surface temperatures above approximately 750 K. Rotationally resolved LIF excitation spectra of the $C^1\Pi \leftarrow X^1\Sigma^+$ band system of CuF molecules desorbing from an isotopically purified ^{63}Cu polycrystalline sample are obtained under conditions of coherent saturation. From the product state analysis it is deduced that the rovibrational product populations are in thermal equilibrium with the surface. The same holds for the translational velocity distribution obtained by Doppler-shift measurements. A pronounced polarization effect, particularly strong for Q branch transitions, can be traced back to photoselection of single-parity levels in the Λ doublets of the $C^1\Pi$ state. A theoretical analysis for the distribution of J vectors, based on the formalism of Greene and Zare, shows that the measured degree of polarization is quantitatively in agreement with an isotropic distribution of rotational angular momentum vectors. The vibrational and translational product equilibration is not affected by changing the reactants from F_2 molecules to F atoms, which increases the exoergicity of the overall reaction. The results are interpreted in terms of the absence of a barrier for desorption and a long residence time of the chemisorbed CuF molecules at the copper surface. The lack of any translational and rotational cooling is discussed within the framework of a model.

Faisant appel à la spectroscopie de fluorescence induite au laser, on a étudié la réaction de gravure à sec de surface solides de cuivre par des atomes ou des molécules de fluor. Le monofluorure de cuivre, CuF, produit par la réaction se forme dans l'état électronique fondamental $X^1\Sigma^+$ et il se désorbe vers la phase gazeuse à des températures de surface supérieures à environ 750 K. Les spectres d'excitation LIF, résolus en fonction de la rotation, du système de bandes $C^1\Pi \leftarrow X^1\Sigma^+$ des molécules de CuF qui se désorbent d'un échantillon polycristallin de ^{63}Cu isotopiquement purifié, ont été obtenus dans des conditions de saturation cohérente. En se basant sur une analyse de l'état du produit, on en déduit que les populations de produit rovibrationnel sont en équilibre thermique avec la surface. Il en est de même pour la distribution de la vitesse de translation obtenue par des mesures de déplacement Doppler. On peut attribuer un effet important de polarisation, particulièrement fort pour les transitions des branches Q, à une photosélection des niveaux de parité unique dans les doublets Λ de l'état $C^1\Pi$. Une analyse théorique de la distribution des niveaux J, basée sur le formalisme de Greene et Zare, montre que le degré de polarisation mesuré est en bon accord quantitatif avec une distribution isotrope des vecteurs des moments de rotation angulaire. L'équilibre vibrationnel et translationnel du produit n'est pas affecté par un changement de réactifs de molécules F_2 à atomes F qui augmente l'exoergicité de la réaction globale. On interprète les résultats en fonction de l'absence d'une barrière à la désorption et à un temps de résidence élevé des molécules de CuF chemisorbées à la surface du cuivre. On discute du manque de refroidissement translationnel et rotationnel à l'aide d'un modèle.

[Traduit par la rédaction]

1. Introduction

As in the field of gas-phase reaction dynamics, measurements of product state distributions by laser spectroscopy have proven essential in understanding the dynamics of reactive desorption (1, 2). Primarily, these measurements address the question of exoergicity sharing between the solid and the various degrees of freedom of the gaseous products. Contrary to a common assumption, both systems are not necessarily at equilibrium. This can be true for both direct and indirect gas–surface reactions. For a direct surface reaction, the product state distribution reflects the dynamics of the entire process from gaseous reactants to products. An example of this is the relatively rare Eley–Rideal mechanism for an exoergic reaction in which a gaseous atom reacts with an adsorbate. This mechanism has recently been invoked to explain the results of three independent studies of the recombination of H atoms at metal surfaces (3–5). The high vibrational product excitation has been modelled with quantum mechanical calculations by Kratzer and Brenig (6). The potential energy surface results in dynamics that in many respects resemble that seen for direct gas phase reactions (see, for example, the work of John C. Polanyi (7)). Most cases, however, involve an indirect mechanism, where the initial reactants are dissociatively adsorbed and then associatively desorbed (Langmuir–Hinshelwood mechanism). Even though the adsorbed reactants are fully equilibrated with the surface, a pronounced disequilibrium in the various degrees of freedom of the desorbing products may occur. The following nonequilibrium features have been observed in the desorption step of indirect surface reactions.

The most typical example for nonequilibrium in the vibrational degree of freedom is the recombinative desorption of hydrogen from Cu surfaces as shown first by Kubiak et al. (8). The experimental observation of "vibrational heating" has been interpreted by Brenig et al. in terms of an early barrier

for desorption (9) in analogy with the Polanyi rules for gas phase reactions (7). Consequently for this system a significant "translational heating" was reported by Comsa and David (10). The barrier to adsorption was then probed by Rendulic et al. in experiments of vibrationally assisted sticking (11).

In studies of associative or recombinative desorption by the groups of Lin, Somorjai, Zacharias, and co-workers (OH(OD)/Pt(111) (12), NO/Pt(111) (13, 14), and H_2 (D_2)/Pd(100) (15)), rotational product analysis showed a "rotational cooling" effect, in which the desorbing diatomics take up on average less rotational energy per molecule than accommodation to the surface temperature would allow. This effect was small for OH and OD desorbing from Pt (12) but quite large for NO/Pt (13, 14) and H_2/Pd (15). Microscopic reversibility arguments by Brenig et al. (16) and Muhlhausen et al. (17) provide a plausible explanation of this effect: strongly rotating molecules have a lower sticking coefficient, which implies a lower desorption yield at high J.

In a detailed theoretical treatment of associative desorption, Yang and Rahman (18) predicted that rotational cooling should be associated with an alignment effect, where the rotational angular momentum is preferentially aligned parallel to the surface normal. From a mechanistic point of view their model assumes a strong coupling between rotational and translational degrees of freedom of the desorbing molecules. The same holds for calculations done by Muhlhausen et al. (17). Experimentally, no alignment effect was observed for the associative desorption of OH and OD from Pt(111) (12). However, in the trapping–desorption channel of NO scattered from a Pt(111) surface, the helicopter type of rotation was preferred while direct inelastic scattering was dominated by the cartwheel motion (19).

In this work we report a detailed product state analysis of copper monofluoride, which is the dominant product in the heterogeneous reaction of gaseous fluorine with solid copper at temperatures of about 900 K as applied in this experiment.[6] We report results on rotational, vibrational, and translational energy distributions of associatively desorbing CuF molecules as well as on their angular momentum distribution. To our knowledge this is the first complete state-specific investigation of an etching reaction. Rotationally resolved excitation spectra were obtained by applying laser-induced fluorescence (LIF) to the CuF $C^1\Pi$–$X^1\Sigma^+$ band system. This transition has the highest transition probability of a series of electronically excited states of CuF that are accessible to a LIF experiment in the visible spectral range. Besides the P and R branches, a Q branch can also be used for the rovibrational analysis.

In an earlier article reporting a preliminary vibrational product state analysis based on rotationally unresolved excitation spectra (20), we found that the distribution of the gaseous products seems to be largely determined by the surface temperature. This observation was independent of the copper crystal face. Also, the vibrational distributions were not affected when the fluorine reactant beam energy was increased, or when fluorine molecules were replaced by atoms, both of which increase the exoergicity in the entrance channel of the CuF formation reaction. We thus noted that a product state analysis only gives insight into the final step of the surface reaction, namely, the desorption of the products (20). This observation is in contrast to molecular beam scattering of molecules from surfaces for which the initial state of the reactants does influence the product state (21); the associative desorption process in our case may therefore be characterized as a half collision. In this paper we address the question of whether or not thermal equilibrium is maintained throughout the overall reaction, i.e., whether nonthermal effects influence the internal energy distribution of the desorbing CuF product.

This paper is organized as follows: After the experimental description in Sect. 2, we present in Sect. 3A the laser excitation spectra. In Sects. 3B and 3C the rotational and vibrational analyses are presented. In Sect. 3D we derive the translational product distribution from a Doppler-shift technique and in 3E we determine the distribution of J vectors from polarization measurements. In Sect. 4 we discuss our results within the framework of the present theoretical understanding of the dynamics of molecules desorbing from surfaces. The conclusions are summarized in Sect. 5.

2. Experiment

Figure 1 shows a diagram of the experimental setup. A molecular beam of fluorine impinges on a copper surface, which can be heated up to 1100 K. The cryobaffled vacuum chamber is pumped to a base pressure of 3×10^{-8} mbar (1 bar = 100 kPa), caused mostly by N_2 and O_2. The high sample temperature during the experiments (750–1100 K) and the fluorine exposure, however, effectively prevent accumulation of residual gas particles on the surface, as verified by Auger spectroscopy.[7] No time dependence of the measured fluorescence intensities is found after starting the experiment and we thus conclude that artifacts due to minor surface contaminants are below our detection limit. In initial experiments, polished Cu(111) and Cu(110) single crystals of 99.999% purity were used. Since the outcome of the reaction was found to be independent of the copper crystal face, a polycrystalline sample of purified ^{63}Cu (99.6% purity) was prepared to simplify the data analysis. A blind with a 1×5 mm slit above the copper sample was used to minimize thermal background radiation in the photomultiplier and to reduce the spot size of desorbing CuF.

The fluorine molecular beam (99.999% purity) expanded at a typical flow of 0.5 standard cubic centimeters/min (sccm) from a sapphire nozzle with an i.d. of 0.2 mm, which was mounted in a differentially pumped chamber. The fluorine beam entered the main chamber through a skimmer, and led to a pressure increase to the 10^{-7} mbar range. For some experiments referred to in the discussion, fluorine molecules were exchanged with F atoms as reactants. In this case the dissociation of F_2 was achieved by a microwave discharge, also indicated in Fig. 1.

Rotationally resolved excitation spectra of the $C^1\Pi \leftarrow X^1\Sigma^+$ band system of the desorbing CuF molecules were recorded with an actively stabilized ring dye laser with coumarin 102 dye pumped by a Kr^+ laser. In single-mode operation at several megahertz bandwidth, the tunable laser yielded a typical output power of 60 mW. The laser wavelength was measured by a homebuilt wavemeter of the Hall and Lee type with an accuracy of ± 0.02 cm^{-1} (22, 23). The laser beam was directed parallel to the copper surface at a distance of 13 mm. CaF_2 windows with an antireflection coating were mounted at the chamber ports perpendicular to the laser beam. Stray laser light is suppressed by a set of light baffles shown in Fig. 1. The detection system consisted of an imaging system, a cutoff filter to reduce background radiation from the surface for $\lambda \geq 550$ nm, a photomultiplier tube, and a photon counting system. The linewidth of the individual rotational transitions under these conditions is essentially determined by Doppler broadening. For additional experiments with increased spectral resolution, a slit of 1.0 mm width shown in Fig. 1 was placed in front of the detection system. For the determination of

[6]Besides CuF there are also higher polymers desorbing into the gas phase. These are the subject of another publication: K. Sugawara, Th. Wach, and J. Wanner, to be published.

[7]P. Jakob, Th. Wach, and J. Wanner, unpublished results.

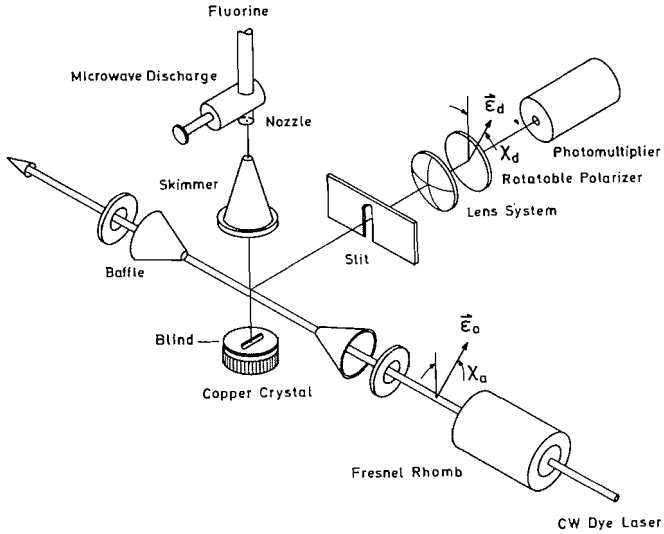

FIG. 1. Experimental arrangement for investigating the reaction of fluorine with solid copper.

translational velocities of the desorbing products, the blind with one slit was replaced by a double slit arrangement (see Sect. 3D).

A Fresnel rhomb was inserted in the laser beam to rotate the polarization plane. Care was taken that no other polarizing optical elements were in the beam path. For the rotational population measurements the plane of polarization was parallel to the copper surface. For the alignment measurements, a mutually orthogonal geometry was established between the laser beam and the axis of the detection system and the surface normal. For these experiments a rotatable polarization filter was placed in front of the photomultiplier tube.

3. Results

A. *Excitation spectrum of the* $C^1\Pi \leftarrow X^1\Sigma^+$ *transition*

Because of their low vibrational frequency (24) and the high temperature of the copper surface (in the range of 750–1100 K), the desorbing CuF molecules are observed in vibrational product levels $v'' = 0$ to $v'' = 4$ of the $X^1\Sigma^+$ ground state. In principle, a rotational analysis is possible in each of these levels. The spectroscopic constants of the various branches and vibrational levels have been published by Ahmed et al. from absorption measurements (25). With our experimental setup, considerably more accurate values of the rotational constants can be obtained (26). Rotational levels up to $J = 78$ have been studied, corresponding to a spectral range between 20 246 and 20 313 cm^{-1}.

Figure 2 shows a typical ring laser scan (approximately 35 GHz width) of the Q branch band head of the ($v' = 0, v'' = 0$) transition. Except for low J lines, the rotational structure is fully resolved. Figure 3 shows the Q band heads of the (0,0), (1,1), and (2,2) transitions with increased resolution using the setup of slits depicted in Fig. 1. As becomes evident, the rotational lines are subject to a hyperfine splitting due to the $I_{Cu} = 3/2$ and $I_F = 1/2$ nuclear spin of ^{63}Cu and ^{19}F, respectively. A comprehensive illustration and analysis of the hyperfine effects will be given elsewhere (27).

B. *Rotational population analysis*

Before describing our results we need to consider another topic of relevance to this particular system. In narrow-band fluorescence excitation spectra, saturation occurs readily, even at modest laser power. In a rotational product state analysis of the IF molecule (also using a ring dye laser), Billy et al.

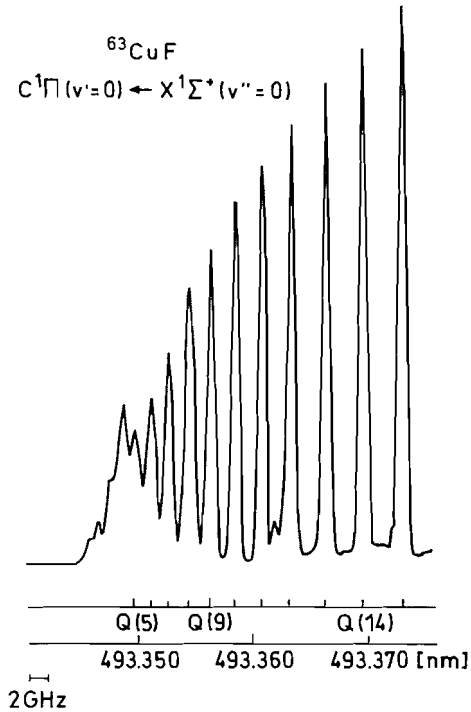

FIG. 2. Typical laser excitation spectrum of the Q branch head of the $C^1\Pi \leftarrow X^1\Sigma^+$ ($v' = 0, v'' = 0$) band of associatively desorbing CuF molecules. Due to the use of an isotopically pure polycrystalline copper sample, the rotational structure is well resolved.

observed, in agreement with coherent saturation theory, a linear dependence of single-line fluorescence intensity with the transition dipole moment and the laser field strength (28). The same result was found for the $C \leftarrow X$ transition of CuF (23, 29). This is depicted in Fig. 4 by plotting the intensity of an arbitrary rotational line vs. the laser intensity in a double logarithmic scale. The slope of the curve is 0.5 in the range of 0.5–20 mW typically used in the experiments. Earlier data in the range of 1–100 mW confirm this behavior (23). Below 0.5 mW, the saturation effect gradually diminishes and the slope of the curve becomes steeper. For our experiments this implies that the population of the individual rotational levels within one band can be derived from the measured integrated intensities by normalization using [laserpower × Hönl–London factors × Franck–Condon factors/$(2J'' + 1)$]$^{1/2}$. The complete formula for deriving rotational population number densities $N(v'', J'')$ in different vibrational levels used in this work is given by:

$$N(v'', J'') \propto \frac{I_{\text{fluores.}}\sqrt{(2J'' + 1)}}{v\sqrt{I_{\text{Laser}} q_{v'v''} S_{J'J''}}}$$

where v denotes the frequency of the transition and I_{Laser} the laser intensity. Franck–Condon factors $q_{v'v''}$ were taken from ref. 30. Hönl–London factors $S_{J'J''}$ for the C–X transition of CuF were adapted from Herzberg (31). In the data evaluation, fluorescence line intensities $I_{\text{fluores.}}$ are determined by integration of the individual peak areas. This procedure accounts for resolved or unresolved splitting due to hyperfine effects occurring for Q lines at low J and for P and R lines at low as well as high J. For unsplit lines, the fluorescence intensity can be approximated by the product of peak height and linewidth. With this type of analysis, as expected, a single distribution

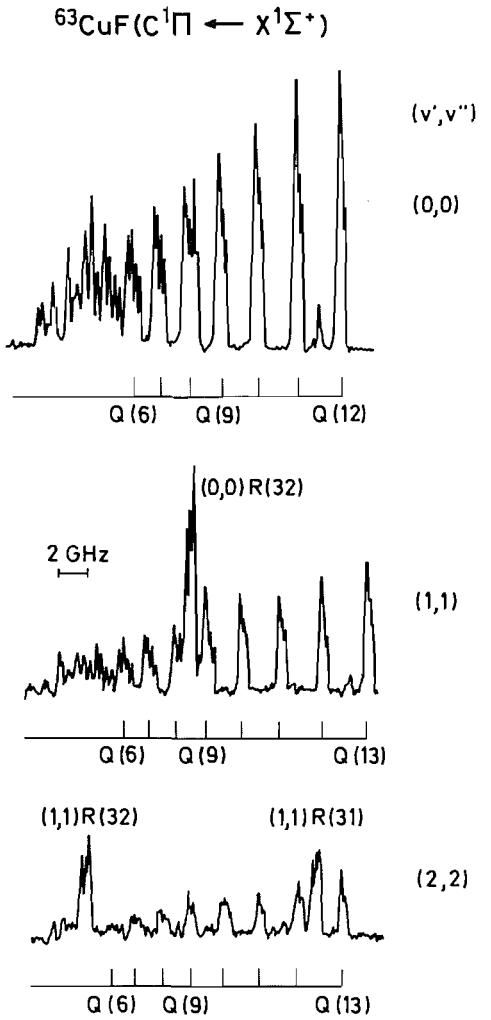

FIG. 3. Q branch heads of the (0,0), (1,1), and (2,2) bands. These spectra show that a rotational population analysis is possible in different vibrational levels. The resolution is improved by observing the fluorescence with a slit placed in front of the detection system as depicted in Fig. 1. Under these conditions of reduced Doppler width, the hyperfine splitting becomes apparent, particularly for low J levels.

measured in the P branch is identical with the Q branch distribution measured at the same surface temperature (not shown). Since the translational velocities belonging to individual v, J levels are found to be identical (see below), no flux–density correction needs to be considered, i.e., measured relative number densities and product flux are identical.

The experimentally determined populations of rotational levels J and vibrational manifolds v, in the following referred to as $N'(v,J)$, are displayed in Fig. 5 in a Boltzmann logarithmic plot for surface temperatures T_s = 890 K (*a*) and 935 K (*b*). This format is generally chosen since thermal equilibrium distributions will produce straight lines with the slope indicating the corresponding temperature. The rotational temperatures agree well with the surface temperatures and there is only a slight dependence on the vibrational level. The higher v manifolds seem to give somewhat lower values of the rotational temperature, which, however, still fall within the error limits. To test whether the measured distributions are affected by secondary collisions in the gas phase, additional argon was passed through the nozzle, which was kept at room temperature. The distributions did not change to any measurable extent. In our

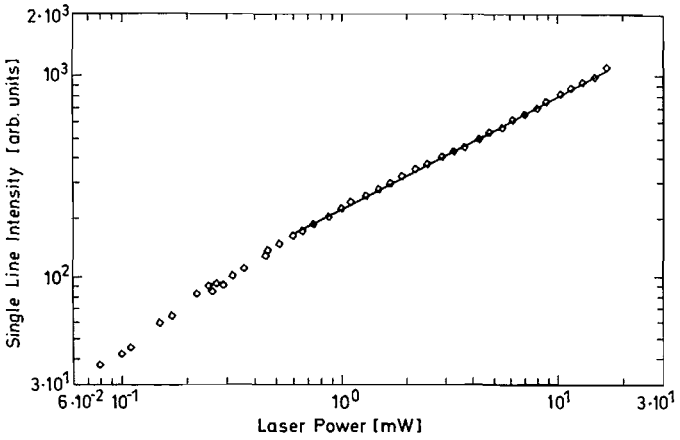

FIG. 4. Dependence of the fluorescence intensity of the Q(29) line on laser power, plotted on a double logarithmic scale. The straight line with a slope of 0.5 denotes the region where the fluorescence intensity is proportional to the square root of the laser power. According to coherent saturation theory, this implies a linear dependence of the laser power on the transition dipole moment.

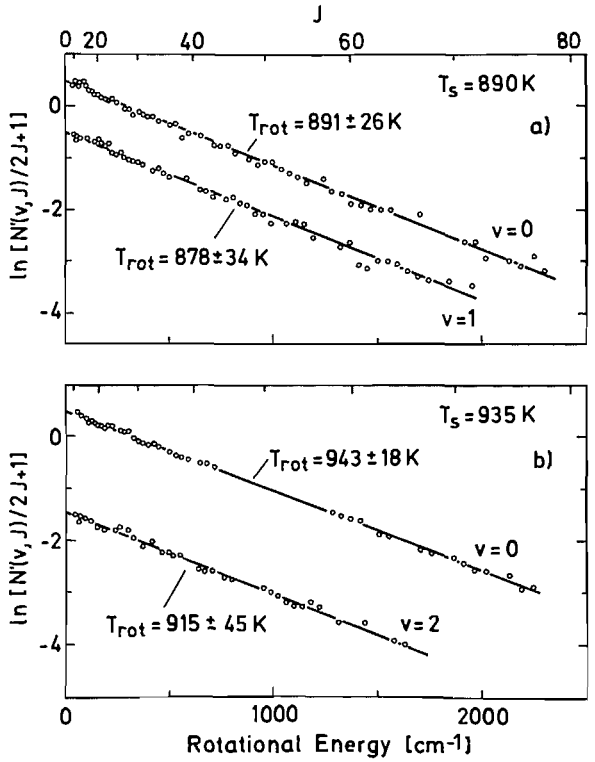

FIG. 5. Boltzmann plots of the rotational populations for different vibrational levels v = 0, 1, 2 and surface temperatures (a) 890 K; (b) 935 K. The slopes yield rotational temperatures that are equivalent to the surface temperatures, indicating complete rotational accommodation of the desorbing CuF molecules with the copper surface.

preliminary paper on the rotational analysis of v = 1, an incomplete treatment of saturation theory was used that resulted in a slight upward bending of the Boltzmann plot at low J values, leading to a lower rotational temperature for these levels (29). Hence at this stage it is important to note that the CuF molecules do not show any rotational cooling effect.

C. Vibrational population analysis

Generally, the vibrational population analysis is done by summing up the rotational populations in each vibrational

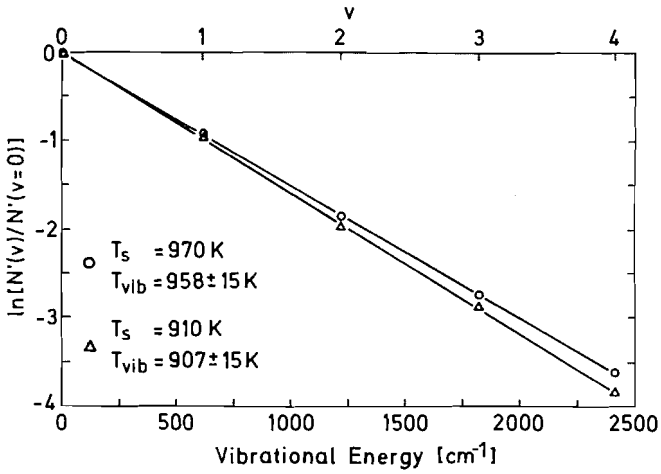

FIG. 6. Vibrational Boltzmann plots for product levels $v = 0$–4 and two surface temperatures. The open circles refer to $T_s = 970$ K; the triangles to $T_s = 910$ K. Both lines are normalized to N' ($v = 0$). The slopes indicate full equilibrium with the surface temperature.

level. In our case the analysis is simplified by the fact that the rotational distributions are of the Boltzmann type and that the rotational temperature is independent of the vibrational level. Hence it is possible to derive the vibrational population distribution from intensity measurements of one particular rotational line occurring in all vibrational bands under consideration. One such line, Q(29) occurs in the (0,0)–(4,4) bands without overlapping with other transitions. A correction for the rotational anharmonicity, i.e., the decrease of the rotational constant with the vibrational quantum level, was applied, leading to a small change only. For details of this type of analysis see ref. 32. The analysis was eased by the fact that the linewidth of this particular Q branch transition is essentially given by its Doppler width, which, as will be shown below, is independent of the vibrational level. Finally it was verified that the result of this analysis is independent of the rotational level J.

The result of the vibrational population analysis is displayed in a logarithmic Boltzmann plot in Fig. 6 for two different surface temperatures $T_s = 910$ K and 970 K. Again, in each case we obtain a straight line with the slope identical to the surface temperature within the error bars. If we compare this observation with earlier results deduced from rotationally unresolved excitation spectra, the Boltzmann behavior and the dependence of the vibrational population distribution on the surface temperature is confirmed. The previously noted slight vibrational heating (20), however, has vanished. This may be mainly due to overlapping bands in the analysis of rotationally unresolved excitation spectra.

D. Product translational analysis

To measure translational energies of the desorbing CuF molecules, we use the fact that the linewidth of the laser is considerably narrower than individual Doppler-broadened CuF rotational lines. Shifting the laser frequency by $\Delta\nu$ from the nominal resonance frequency ν of the CuF transition then selects a particular velocity component $v_\parallel$ of the molecules parallel to the laser beam according to:

$$\Delta\nu = \nu \frac{v_\parallel}{c}$$

For a well-defined source spot, $v_\parallel$ is related to the velocity v

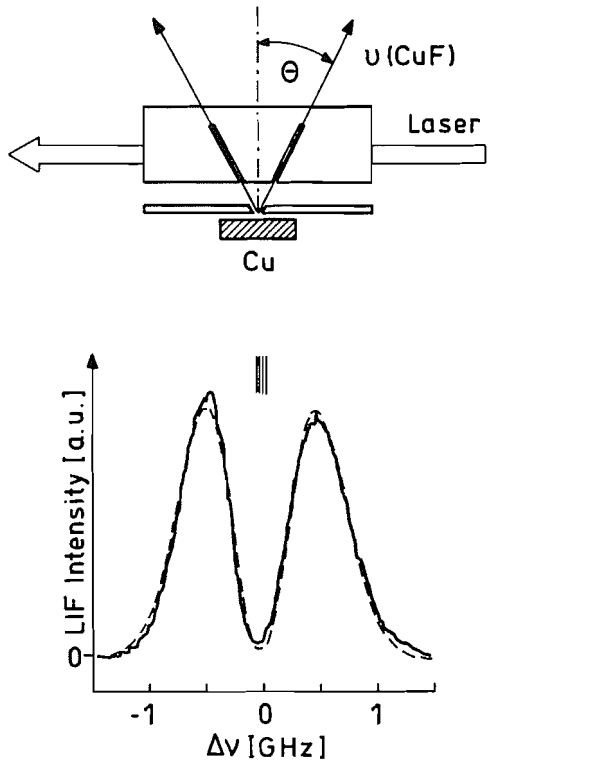

FIG. 7. The upper part of the figure shows an arrangement of slits placed in front of the detection system to measure the translational velocity. According to the position of the slits, the originally Doppler broadened line ($v' = 0, v'' = 0$) P(17) splits into two components shown in the lower part of this figure. The solid line refers to the experiment. Vertical bars denote the hyperfine splitting pattern of the P(17) line. The broken line represents a fit to the data (see text for the parameters of the velocity distribution).

of the CuF molecule via $v_\parallel = v \sin\theta$, with θ being the angle of desorption with respect to the surface normal. We therefore attached a blind with two slits at angles $\pm\theta$, as depicted in Fig. 7; the velocity distribution then is directly obtained via

$$v = c \frac{\Delta\nu}{\nu \sin\theta}$$

To correlate values of the velocity v obtained by this method to a particular product translational distribution at a temperature T_t, we need to understand our mode of detection in more detail. In the simplest case, for a cw laser in the limit of weak excitation and for short lifetimes of the excited states, number densities with a $v^2 f(v) = v^2 \exp(-mv^2/2kT_t)$ distribution are measured. However, variations from these conditions change this to $v^{2+\delta} f(v)$, with $-1 < \delta < 1$. An excellent description of this issue is given by Hefter and Bergmann (33). For a measured distribution $v^{2+\delta} f(v)$, the most likely velocity $\bar{v}$ is given by

$$\bar{v} = \left[(2+\delta)\frac{kT_t}{m}\right]^{1/2}$$

and the corresponding temperature of the distribution, T_t, can be calculated according to

$$T_t = \frac{m\bar{v}^2}{(2+\delta)k}$$

The lower part of Fig. 7 shows a typical spectrum of the (0–0) P(17) line obtained at T_s = 1025 K and θ = 31°. The four vertical bars indicate the hyperfine splitting of this line. To estimate δ and T_t, we fit this spectrum to a distribution $v^{2+\delta}f(v)$ for each hyperfine component by using a least-squares method. The dotted line in the figure shows the best fit. The fitted values of δ and T_t were 0.03 ± 0.09 and 1036 ± 41 K, respectively, indicating that in the present case we measure the density distribution and that the translational energy of CuF is at thermal equilibrium with the surface temperature.

Independent of the absolute value of $\bar{v}$, however, we can draw important conclusions just by comparing the measured splittings of lines belonging to various J and v levels. In our case we find that the splitting, and thus the corresponding velocity, is independent of the rotational and vibrational level. This indicates that the rovibrational and the translational degrees of freedom are decoupled.

E. Polarization measurements

LIF experiments offer the possibility of relatively uncomplicated determination of molecular alignment by varying the polarization direction of the laser. In the simplest case the spectrally unresolved fluorescence is detected without any polarizing elements, thus representing the sum over all polarizations. From such measurements, it is possible to determine the dominant parameter of the distribution function, i.e., the polarization anisotropy. This method is particularly straightforward if the molecular transition used for the investigation is a Q branch of a $\Sigma \rightarrow \Pi$ transition for which the electronic transition dipole moment is parallel to the J axis in the high-J limit (34). The treatment, however, is based on the assumption that the unresolved fluorescence represents an unweighted sum over P, Q, and R branches, which means it is isotropic (21, 35).

We used the Q branch of the $C^1\Pi$–$X^1\Sigma^+$ band of CuF for analysis. The result of such a polarization measurement (according to Fig. 1, with the polarizer in front of the detection system being removed) is shown in Fig. 8. Here the LIF intensity of the (0,0) Q (29) line is plotted as a function of the angle χ_a between the linear polarization vector of the laser and the surface normal. Clearly a polarization effect can be seen. Under the assumption of isotropic fluorescence this result would imply that on average a greater fraction of the desorbing molecules have their J axis aligned parallel to the surface normal, thereby representing a preference for helicopter motion (29).

However, the assumption of isotropic fluorescence due to superposition of P, Q, and R branches is not valid for the C–X transition of CuF: the $C^1\Pi$ state shows a strong Λ-doubling effect. The sublevels e and f of each rotational quantum state J have opposite parity. In the $X^1\Sigma^+$ state, on the other hand, there is no doubling, and the rotational quantum states have alternate parity with succeeding values of J. As transitions between two states must satisfy the selection rule $\pm \leftrightarrow \mp$ (31), there is a direct correlation: Q transitions $\leftrightarrow f$ levels and P/R transitions $\leftrightarrow e$ levels. Therefore excitation and fluorescence transitions are restricted to Q↑Q↓ and PR↑PR↓, respectively. Hence, the Q excitation leads by photoselection to an anisotropic distribution of J vectors that may be fully responsible for the measured polarization effect.

To distinguish between this photoselection effect and a possible dynamical effect, we carried out a test for the presence of

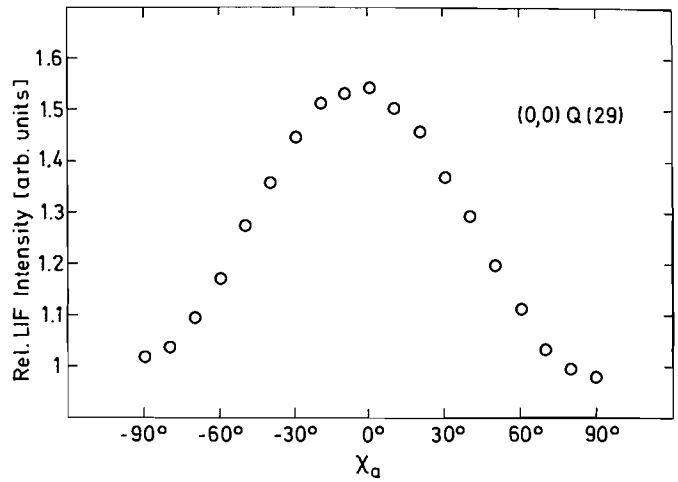

FIG. 8. Polarization effect of the LIF signal of desorbing CuF as a function of the angle χ_a between the laser electric field vector and the surface normal. The data for this figure are based on a measurement using the Q(29) line at a laser power of 1 mW. The fluorescence light is spectrally unresolved and recorded without a polarizer in front of the detection system.

alignment as described by Greene and Zare (36). This requires an experimental configuration with the excitation direction, detection direction, and the axis of cylindrical symmetry (i.e., the surface normal) being mutually orthogonal, and a polarization-sensitive detection of the fluorescence intensity (Fig. 1). The LIF intensity is now measured as a function of the settings of the polarization analyzer, χ_d, and the Fresnel rhomb, χ_a. Setting χ_d = 90° in our system, the LIF intensity of any rotational line of CuF turned out to be independent of χ_a. This finding, according to Greene and Zare (36), clearly indicates an isotropic distribution of the CuF molecules, i.e., no alignment of the desorbing molecules occurs.

To explain the observed polarization effect (Fig. 8) quantitatively, we adapted the expression for the LIF intensity in the high-J limit $I(\chi_a, \chi_d)$ given by Greene and Zare (eq. 21 of ref. 36) to a Q↑Q↓ transition:

$$I(0°, 0°) = \frac{9}{5} + \frac{18}{7}A_0^{(2)} + \frac{72}{35}A_0^{(4)}$$

$$I(90°, 0°) = \frac{3}{5} + \frac{3}{14}A_0^{(2)} - \frac{36}{35}A_0^{(4)}$$

$$I(0°, 90°) = \frac{3}{5} + \frac{3}{14}A_0^{(2)} - \frac{36}{35}A_0^{(4)}$$

$$I(90°, 90°) = \frac{3}{5} - \frac{3}{7}A_0^{(2)} + \frac{9}{35}A_0^{(4)}$$

For unpolarized detection one has to sum over the intensities for $\chi_d = 0°$ and $\chi_d = 90°$:

$$I(0°) = \frac{12}{5} + \frac{39}{14}A_0^{(2)} + \frac{36}{35}A_0^{(4)}$$

$$I(90°) = \frac{6}{5} - \frac{3}{14}A_0^{(2)} - \frac{27}{35}A_0^{(4)}$$

In our case of an isotropic distribution of product species, the molecular alignment parameters $A^{(k)}$ with $k > 0$ are identically zero. Then we obtain for the degree of polarization:

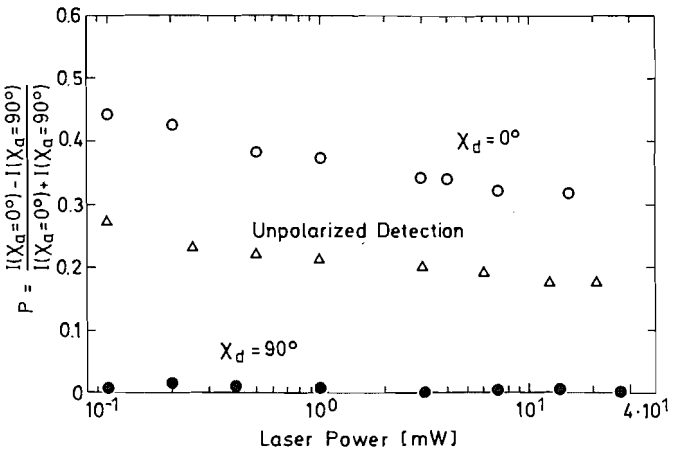

FIG. 9. Dependence of the polarization effect for the line Q(29) on the power of the exciting laser. The open circles denote the data points obtained using a polarizer in the detection system with $\chi_d = 0°$ (see Fig. 1). The full circles refer to $\chi_d = 90°$. For comparison with Fig. 8, the corresponding data with no polarizer in the detection system are marked by triangles.

$$P = \frac{I(\chi_a = 0°) - I(\chi_a = 90°)}{I(\chi_a = 0°) + I(\chi_a = 90°)}$$

$$P = \begin{cases} \frac{1}{2} & \text{for } \chi_d = 0° \\ 0 & \text{for } \chi_d = 90° \\ \frac{1}{3} & \text{without polarization analyzer} \end{cases}$$

The results of the measurements of P are depicted in Fig. 9. As the formalism of Greene and Zare does not take into account saturation effects, our measurements were extended to the lowest possible laser power. The theoretical values represented above for P in the limit of no saturation are in good agreement with the data. Also, the observed decrease of polarization with increasing laser power (Fig. 9) agrees qualitatively with the theoretical treatment of saturation effects on alignment measurements by Janssen et al. (37).

The polarization effect of P and R lines can be treated in the same manner: In the case of a PR↑PR↓ transition, an isotropic distribution of desorbing molecules and unpolarized detection, one obtains the value $P = 1/13$, in good agreement with our results for the (0,0) P(29) line of the C–X, as well as for the (0,0) P(30) line of the B–X, system of CuF (32).

4. Discussion

We include in the discussion two additional experimental observations not described in the main body of this paper. First, the validity of the CuF product state analysis under conditions of coherent saturation described in the present paper was confirmed in the following calibration experiment: An effusive CuF beam was produced by thermal dissociation of CuF_2 (38). This was done by heating a mixture of CuF_2 and copper powder in a copper oven with a 0.5 mm orifice. Temperatures between 850 and 1100 K were used. We assume that the CuF molecules are formed by the reaction $CuF_2 + Cu \rightarrow 2$ CuF and effuse at complete equilibrium with the oven temperature. Applying the analysis outlined above, this assumption was indeed confirmed for the vibrational, rotational, and translational degrees of freedom of the beam molecules. Also, an analogous polarization effect was found as reported in Sect. 3E.

In a second series of experiments, F_2 was replaced by F atoms as reactants in the etching of the copper surface. In this way the exoergicity of the system was significantly increased from about $\Delta H = -8$ kJ/mol to $\Delta H = -87$ kJ/mol, as can be calculated using values for bond dissociation energies given in ref. 24. No change was noticed regarding the internal product state distributions and the alignment measurements of the CuF molecules.

The invariance of product state distributions as the reactants are changed from F_2 molecules to F atoms provides clear evidence that the exoergicity of any intermediate step in the CuF formation reaction has no effect on the product state distribution of the desorbed molecules. In other words, CuF molecules have lost any memory of the initial formation reaction and the observations of this study refer to the last step in the sequence of elementary processes: adsorption, diffusion, reaction, and desorption. Further, the exoergicity of the reaction is dissipated to the surface until thermal equilibrium is reached. Hence the residence time of CuF at the surface must be significantly longer than the time needed for equilibration with the heat bath of the sample, which should be on the order of a few picoseconds. This estimate assumes that CuF is chemisorbed at the Cu surface before it thermally desorbs.

As mentioned in the introduction, even for thermally desorbing molecules, deviations of product state distributions from thermal equilibrium with the surface temperature T_s may occur. We therefore discuss why thermal equilibrium distributions were in fact observed in this system.

First, nonequilibrium product distributions may result from vibrational and translational heating. These are dynamic effects observed, for example, for the hydrogen/Cu system (8–11, 39). They are most likely to occur if the desorption process is correlated with a change in the bond length of the desorbing molecule and if there is a barrier in the reaction path for desorption. Our result of surface-equilibrated translational and vibrational product state distributions therefore implies the absence of a barrier in the desorption channel of CuF molecules leaving the Cu surface. This interpretation is in agreement with our experimental observation that the translational and vibrational degrees of freedom are decoupled to a high degree and that higher than thermal velocities have not been observed.

A second possibility for the occurrence of nonequilibrium effects has been termed "cooling," for example, of translational and rotational energies of thermally desorbing molecules. This effect has been attributed to the relative inefficiency of energy transfer between the surface and the molecule as it escapes. There is a consensus that the molecules gradually acquire the energy necessary for desorption while they vibrate in the binding well (hindered translation in z-direction) (40). In a model for translational cooling introduced by Tully (41) it is assumed that there is a limited amount of energy E_{ex} that can, on average, be exchanged per vibrational period between the substrate and the molecule. If $E_{ex} < kT_s$, the molecules that finally pass the binding well will, on average, have less excess energy than kT_s, which is seen as cooling. This relation may be conveniently deduced by applying microscopic reversibility arguments to the reverse process. For adsorption of molecules with a gas temperature T_g equal to T_s, sticking would be inhibited if the average energy E_{ex} transferred to the substrate per vibrational period is less than kT_g. In this case the sticking

coefficient would decrease with increasing normal component of the translational energy of the incoming molecules. In contrast, increasing E_{ex} would result in an increasing sticking coefficient, which finally approaches the value of 1 for $E_{ex} \gg kT_s$ (for simplicity any orientational effects are omitted in this discussion). On the basis of detailed balance this implies that the cooling effect vanishes completely for $E_{ex} \gg kT_s$.

Internal degrees of freedom, mainly rotation, that are correlated with the desorption process may be subject to a cooling effect as well. In the case of $E_{ex} \gg kT_s$ there is no rotational cooling effect expected, since the trans–rot coupling in general has a small influence on the sticking coefficient, which is dominated by E_{ex}. For $E_{ex} < kT_s$, the extent of cooling then varies according to the coupling strength of a particular molecular motion to the adsorbate liberation mode. In general the rotational cooling is accompanied by a small alignment effect, since the cartwheel mode is depleted (18, 19). This effect is expected to disappear for a high sticking coefficient.

In summary, the model of Tully rationalizes in a descriptive way that the translational and rotational energy distributions will be thermalized when $E_{ex} \gg kT_s$ or cooled for $E_{ex} < kT_s$. In the case of CuF, E_{ex} seems to be much higher than kT_s ($T_s = 1100$ K), since we found no deviations from equilibration with the surface temperature for any of our experimental conditions. This implies a large energy transfer rate between CuF and the copper surface. The experimental observations are quite different for the NO/Pt(111) system, where significant rotational cooling was found in trapping desorption molecular beam scattering (42, 43) as well as in associative desorption (13, 14) and TPD experiments (44) at values for $T_s > 350$ K.

5. Conclusions

We have shown that the CuF/Cu system is one of the few examples of a gas–surface reaction for which a complete product characterization can be obtained in a single experiment by means of laser spectroscopy. The main result of our investigation of the dynamics of associatively desorbing CuF molecules is that all internal degrees of freedom and the translational energies are fully equilibrated with the surface temperature. Also, the distribution of J vectors is isotropic and no alignment is found. The results of the product state analysis are interpreted in terms of the absence of a barrier for desorption and a long residence time of the chemisorbed CuF molecules at the copper surface after the formation reaction of Cu with adsorbed fluorine atoms. Applying microscopic reversibility arguments, our result of complete thermal equilibration of desorbing CuF molecules indicates a high sticking coefficient for CuF on copper surfaces that is largely independent of E_{kin} and the internal energy distributions of CuF.

The role of molecular flexibility in accelerating intramolecular vibrational relaxation

G.A. BETHARDY, XIAOLIANG WANG, AND DAVID S. PERRY[1]

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

G.A. BETHARDY, XIAOLIANG WANG, and DAVID S. PERRY. Can. J. Chem. **72**, 652 (1994).

Evidence is presented to show that intramolecular vibrational relaxation (IVR) is faster in flexible molecules when the initially prepared vibration is close to the bond about which the large-amplitude motion occurs. In each of 1-pentyne, ethanol, and propargyl alcohol, IVR lifetimes are known for two different hydride stretches and in each molecule internal rotation connects *gauche* and *trans* conformers. In each case the vibration that is closer to the center of flexibility shows faster relaxation. This trend is supported by the available IVR lifetimes for other flexible molecules (hydrogen peroxide, 1-butene, *n*-butane, methyl formate, and propargyl amine) and for some "rigid" molecules (1-butyne, isobutane, propyne, *trans*-2-butene, and *tert*-butylacetylene). The lifetimes for the halogenated molecules, 2-fluoroethanol, 1,2-difluoroethane, *trans*-1-chloro-2-fluoroethane, and trifluoropropyne are all in the range expected for rigid molecules. An algorithm is presented for the consistent calculation of IVR lifetimes from discrete frequency-resolved spectra, which range from the sparse through intermediate coupling cases. Wherever possible, the reported lifetimes have been calculated (or recalculated) from the original line positions and intensities. The lifetimes may be compared directly to those deduced from homogeneously broadened spectral features with a Lorentzian contour.

G.A. BETHARDY, XIAOLIANG WANG et DAVID S. PERRY. Can. J. Chem. **72**, 652 (1994).

On présente des données pour démontrer que la relaxation vibrationnelle intramoléculaire (RVI) est plus rapide dans les molécules flexibles lorsque la vibration préparée initialement est proche de la liaison autour de laquelle le mouvement de grande amplitude se produit. Dans le pent-1-yne, l'éthanol et l'alcool propargylique, les temps de vie des RVI des deux modes différents d'élongation de l'hydrure sont connus et, pour chaque molécule, la rotation interne permet de joindre les conformères *gauche* et *trans*. Dans chaque cas, la vibration la plus proche du centre de flexibilité présente la relaxation la plus rapide. Cette tendance est supportée par les temps de vie RVI disponibles pour d'autres molécules flexibles (peroxyde d'hydrogène, but-1-ène, *n*-butane, formate de méthyle et amine propargylique) et pour quelques molécules « rigides » (but-1-yne, isobutane, propyne, *trans*-but-2-ène et *tert*-butylacétylène). Les temps de vies des molécules halogénées, 2-fluoroéthanol, 1,2-difluoroéthane, *trans*-1-chloro-2-fluoroéthane et trifluoropropyne sont tous de l'ordre de grandeur attendu pour des molécules rigides. On présente un algorithme qui permet de calculer d'une façon cohérente les temps de vie RVI à partir de spectres discrets résolus en fréquence qui couvrent les cas des couplages faibles à intermédiaires. Dans tous les cas possibles, les temps de vie rapportés ont été calculés (ou recalculés) à partir des positions et des intensités originales des bandes. On peut comparer les temps de vie directement à ceux déduits à partir de caractéristiques spectrales élargies d'une façon homogène avec un contour lorentzien.

[Traduit par la rédaction]

Introduction

McIlroy (1) found that the presence of a low-energy skeletal isomerization accelerated the intramolecular vibrational relaxation (IVR) of aliphatic C—H stretches in the series of small hydrocarbons that he studied. For example, 1-butyne, propane, isobutane, and *trans*-2-butene cannot isomerize easily and exhibited IVR lifetimes in the range from 130 ps up to several hundred ps. On the other hand, *n*-butane, 1-butene, and 1-pentyne can isomerize and appear to have IVR lifetimes for the aliphatic C—H fundamentals in the vicinity of 30 ps. The pertinent isomerization pathways involve conformational change of the carbon skeleton as the result of internal rotation about a carbon–carbon bond. Since all of the molecules with longer lifetimes contain aliphatic methyl groups, McIlroy did not conclude that IVR was accelerated by the internal rotation of a methyl group.

Chemical timing experiments (2) have shown that relaxation of the ring vibrations, 3^1 and 3^15^1, in the S_1 electronic state of *p*-fluorotoluene and d_3-*p*-fluorotoluene is much faster (τ = 1–15 ps) than for the corresponding vibrations in *p*-difluorobenzene ($\tau \geq 150$ ps). The acceleration of IVR in the former compounds was attributed to the methyl rotor, which increases the density of vibrations interacting with the prepared ring vibrations.

The loss of rotational structure in the C=O fundamental and overtone bands of a series of carbonyl compounds has been correlated with the number and proximity of the methyl rotors (3). The decrease in the rotational band structure in the series, methyl formate, acetaldehyde, methyl acetate, and acetone, was attributed to vibrational mode mixing but the authors did not attempt to deduce IVR lifetimes from the unresolved spectra.

In this paper, additional IVR lifetimes will be derived for molecules capable of large-amplitude motion. Facile internal rotation about certain chemical bonds gives rise to both flexibility and conformational change. We will refer to such bonds as *centers of flexibility*. It will be shown that the acceleration of IVR is correlated with the *proximity* of the prepared vibration to a center of flexibility. McIlroy's shorter lifetimes were obtained from estimates of the homogeneous widths in partially resolved spectra. Where possible, we will use discretely resolved and rotationally assigned spectra for the calculation of lifetimes. This approach ensures that the results are free of interferences from inhomogeneous structure.

Other factors that have been correlated with fast IVR are a high density of low-order resonances in the energy region of

the excited chromophore (4, 5) and excitation of extreme motion states, which concentrate the vibrational amplitude into a single internal coordinate (6). Extremely fast IVR can result from a strong low-order resonance. In the C—H overtones of benzene (7) and of some hydrocarbons with a single C—H bond (8), the 1:2 C—H stretch–bend resonance gives rise to interaction widths of about 100 cm^{-1} ($\tau \approx 50$ fs). To investigate the role of molecular flexibility, we concentrate on systems where such strong low-order resonances are not involved and where the other factors mentioned in this paragraph are thought to be approximately constant. IVR lifetimes for vibrations that are in the same molecule but at different distances from a center of flexibility will be compared.

Experimental lifetimes

The largest body of systematic data on IVR lifetimes comes from frequency-resolved infrared spectra. At low resolution, IVR results in broadened infrared spectral features. When the features are Lorentzian in shape and arguably free of interfering inhomogeneous structure, the IVR lifetime is given by

$$[1] \qquad \tau = \frac{1}{2\pi\Delta\nu}$$

where $\Delta\nu$ is the full-width-at-half-maximum (FWHM) of the broadened lineshape. Equation [1] assumes that only the upper state of the infrared transition relaxes. In the time domain, a Lorentzian lineshape corresponds to an exponential decay

$$[2] \qquad |\langle\Psi(t=0)|\Psi(t)\rangle|^2 = \exp\left(-\frac{t}{\tau}\right)$$

At high resolution for bound systems, each broadened lineshape is revealed as a clump of discrete transitions from the vibrational ground state to a set of molecular eigenstates. Excitation of a single eigenstate does not result in any time-dependent relaxation; it is simply the direct preparation of a mixed state. Each eigenstate is a mixture of the bright state, that is, the vibrational mode responsible for the infrared oscillator strength, and a number of dark states. However, a hypothetical coherent excitation of an entire clump of eigenstates by a very short pulse of light would result in the preparation at $t = 0$ of the zero-order bright state. This coherent superposition would then decay in time, resulting in the transfer of vibrational amplitude from the bright state to other vibrational degrees of freedom. The survival probability of the bright state is given by (9, 10)

$$[3] \qquad |\langle\Psi(t=0)|\Psi(t)\rangle|^2 = \frac{\sum_i \sum_j I_i I_j \cos\left[\frac{(E_i - E_j)t}{\hbar}\right]}{\left(\sum_j I_j\right)^2}$$

where the I_i are the intensities of the eigenstates in the clump and the E_i are their energies. Each summation in eq. [3] extends over all of the pure sequence lines in a clump of molecular eigenstates. Radiative decay, which would give a homogenous width to each eigenstate, has been neglected.

Both eqs. [2] and [3] dictate an initial decay of the bright state, but there are two important differences. First, eq. [2] decays to zero at long times but eq. [3] decays to the dilution factor, which is given by

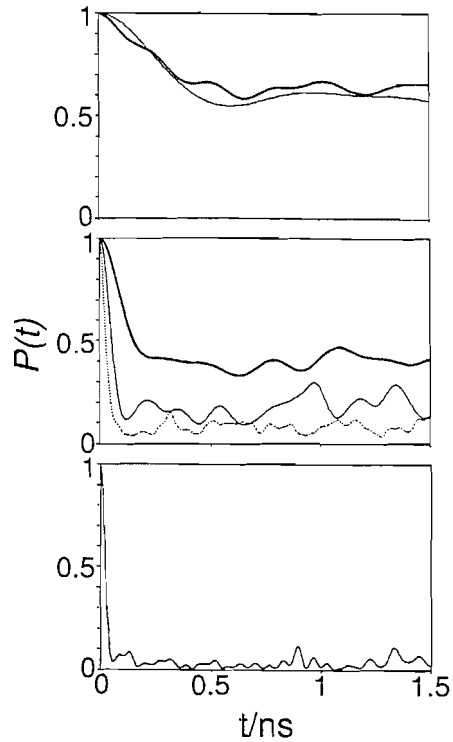

FIG. 1. Averaged decay curves for hydride stretches prepared with one quantum of excitation as calculated from discrete frequency-resolved spectra. Upper: 1-Butyne ν_{16} methyl C—H (thick line) and ν_1 acetylenic C—H (thin). Middle: Ethanol ν_{14} methyl C—H for $K_a = 0$ (thick), 1 (thin), and 2 (dotted). Lower: Ethanol ν_1 O—H.

$$[4] \qquad \phi_d = \frac{\sum_i I_i^2}{\left(\sum_i I_i\right)^2}$$

When there are only a few intense lines in a clump, the long time limit may be much greater than zero as shown in the top panel of Fig. 1. Second, the form of eq. [3] dictates that quantum beats, which are seen as oscillations around the long time limit, will follow the initial decay. Equation [3] approaches the form of eq. [2] in the statistical limit where there are a great many lines in the clump.

We wish to derive IVR lifetimes from decays of the type given by eq. [3] that may be compared directly with those obtained from eq. [1]. For this purpose, quantum beats are not relevant, therefore we average the decay curves for all of the available bright states within a certain group. The averaged survival probability is given by

$$[5] \qquad P(t) = \frac{1}{n}\sum_{k=1}^{n} |\langle\Psi_k(t=0)|\Psi_k(t)\rangle|^2$$

where k labels each of the n combinations of rotational and nuclear spin quantum numbers that contribute to the average. Figure 1 shows $P(t)$ for hydride stretches in 1-butyne and ethanol. The effect of averaging is to reduce the apparent amplitude of the quantum beats. Other types of averaging,

TABLE 1. Experimental IVR lifetimes

Molecule	Band	Reference	Frequency (cm^{-1})	K_a'	τ (eqs. [3]–[6]) (ps)	$\tau = 1/2\pi\langle\Delta\nu\rangle$ (ps)

alcohol	≡C-H	14	3331		500[e]	

[a]Recalculated by us from the original line positions and intensities.

[b]Lifetimes are given for the asymmetric methyl C—H stretch, ν_{16}. The lifetime for the symmetric C—H stretch, ν_3, is given on p. 253 of ref. 1 as 664 ps but line positions and frequencies were not published. If eqs. [3]–[6] were applied to the original data for ν_3, a somewhat shorter lifetime would be expected.

[c]This value reduces to 25 ps when an approximate correction for water absorption is applied.

[d]Conflicting values of the ≡C-H lifetimes are given by these authors; the lifetimes listed here are from p. 253 of ref. 1 and are consistent with Fig. 11 of ref. 9.

[e]Could not be recalculated using eqs. [3]–[6] because the detailed line positions and intensities are not yet published.

e.g., with Boltzmann weights, could be implemented where the data are sufficient in order to simulate specific kinds of time-domain experiments.

To account for the long time limit, $P(t) \rightarrow \phi_d$, $P(t)$ will be compared to the form

$$[6] \qquad P(t) = \phi_d + (1 - \phi_d) \exp\left(-\frac{t}{\tau}\right)$$

The relaxation time τ can then be estimated as the time required for $P(t)$ to decay to $\phi_d + (1/e)(1 - \phi_d)$. Use of $1/e$ as a reference point for the definition of τ when $\phi_d > 1/e$ is clearly inappropriate, and even when $\phi_d < 1/e$, it would give systematically longer lifetimes. For the purpose of calculating τ, ϕ_d is conveniently estimated as the time average of $P(t)$ for a period of several nanoseconds beginning after the initial decay.

The suitability of eq. [6] for defining τ is demonstrated by the agreement (Table 1) with eq. [1] where Δν is now the FWHM of the clump. The algorithm for evaluating Δν for clumps of eigenstates has been shown to be consistent with the Bixon–Jortner formula right down into the sparse limit (11).

The application of eq. [3] requires pure sequence spectra, that is, spectra that represent only a single set of good quantum numbers. In some cases, such as 1-butyne and ethanol, the vibrational ground state is actually a closely spaced doublet that results from tunnelling between equivalent positions of the methyl group. The eigenstate-resolved spectra of these molecules are the superposition of two pure sequences, which must be at least approximately separated for the purpose of determining lifetimes (1, 9, 10, 12). The effect of such approximate separations on the accuracy of the derived IVR lifetimes is discussed in the appendix.

Figure 1 shows decay curves for 1-butyne (1, 9, 10) and ethanol (12, 13). The IVR lifetimes taken from these curves and those for 1-pentyne (1, 9) and propargyl alcohol (14) are listed in Table 1. These four are the only molecules for which we have IVR lifetimes data for two different hydride stretch fundamentals.

Proximity to a center of flexibility

The IVR lifetimes of the methyl and acetylenic C—H stretching vibrations in 1-butyne are nearly identical at about 270 ps (10). Evidently, for the consideration of IVR, there is no intrinsic difference between these aliphatic and acetylenic C—H stretches. However, in 1-pentyne (1) the methyl C—H ($\tau \leq 40$ ps) relaxation rate is much faster than that of the acetylenic C—H ($\tau = 241$, 442 ps). 1-Pentyne contains the accelerating influence of a skeletal isomerization. Internal rotation about the C3—C4 bond gives rise to *gauche* and *trans* forms of pentyne. The faster relaxation rate of the methyl hydrogen (C5) could be because it is *closer* to the center of flexibility (the C3—C4 bond) than the acetylenic hydrogen (C1).

In ethanol, both the methyl C—H (12) and the O—H (13) relax rapidly, indicating that the internal rotation about the C—O bond may be accelerating the IVR. As in pentyne this internal rotation give rise to *gauche* and *trans* forms of the molecule. Accordingly, in ethanol the C—O bond is identified as the center of flexibility. The O—H chromophore, which is adjacent to the C—O bond, relaxes more rapidly than the methyl C—H, which is two bonds away. Note that internal rotation about the C—O bond only involves the movement of the hydroxyl proton and therefore cannot be called a skeletal isomerization. We attribute the acceleration of IVR in ethanol primarily to the internal rotation of the hydroxyl group because internal rotation of an aliphatic methyl group *by itself* has not been associated with greatly accelerated IVR. As noted in the introduction, the methyl C—H vibrations in 1-butyne, propane, isobutane, and *trans*-2-butene all have longer relaxation times than in the systems where *gauche–trans* isomerization is possible.

These trends are supported by recent data (14) on propargyl alcohol ($H\text{-}C{\equiv}C\text{-}CH_2OH$). As in ethanol, internal rotation about the C—O bond connects the *gauche* and *trans* geometries. Once again, the O—H, which is adjacent to the center of flexibility, relaxes much more rapidly than the acetylenic C—H, which is three bonds away.

The data are summarized in Fig. 2 where the lifetimes are

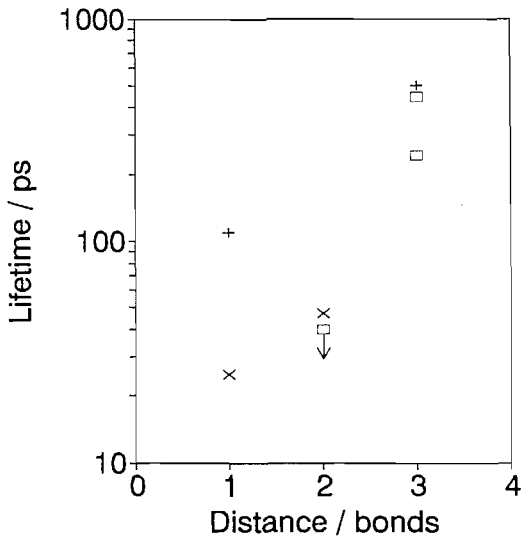

FIG. 2. IVR lifetimes are plotted against the distance of the chromophore from the isomerizing bond. For ethanol (×), there is the O—H stretch (n = 1) and the methyl C—H (n = 2). For pentyne (η), there is the methyl C—H (n = 2) and the *gauche* and *trans* forms for the acetylenic C—H (n = 3). For propargyl alcohol (+), there is the O—H (n = 1) and the acetylenic C—H (n = 3). The downward pointing arrow indicates that the plotted point is an upper bound.

plotted against the distance of the chromophore from the center of flexibility. We use the integer n to denote the distance in bonds between the chromophore and the center of flexibility. To address the role of molecular flexibility in enhancing IVR, we propose a model defined by the following points:

1. All hydride stretches are equivalent. Differences between relaxation rates will be attributed to the local environment of the hydride bond and not specifically to its chemical identity.

2. Proximity to a center of flexibility tends to accelerate the rate of IVR. Clearly, other systematic effects such as those mentioned in the introduction must be taken into account where they are relevant, and extremely strong low-order resonances will dominate the rate when they are present.

Discussion

Alternative point of view

An alternative point of view would be to focus on the chemical identity of the chromophore. For example, in Fig. 2, all of the points for which the chromophore is three bonds removed from the center of flexibility are acetylenic C—H stretches and they are all long lifetimes. All of the O—H stretches relax quickly. Then, only for the methyl C—H's would it be necessary to consider the role of molecular flexibility.

Although the alternative point of view may also be consistent with the data, the model proposed above offers the following advantages:

1. It offers a very general way of thinking about IVR. There are many molecules that have one or more internal rotations that allow conformational change. The concept of proximity to a center of flexibility provides for the scaling of IVR rates for very large molecules and for molecules embedded in a condensed phase. For subject molecules larger than a certain size, addition of more substituents remote from the chromophore should have a negligible effect on the IVR rate. From the available data, the typical length scale appears to be two or three chemical bonds. The proximity requirement is also apparent from condensed phase hydroxyl relaxation times (15, 16), which are found to depend strongly on the local environment of three or four atoms, but which vary only over a small range for a wide variety of condensed phase environments. These studies included surface-bound O—H, the solid state, and liquid solution. Indeed, the O—H lifetime for ethanol is only a little different in the isolated molecule (25 ps (13)) from that in CCl_4 solution (70 ps (16)).

2. The model makes a wide range of predictions based on points 1 and 2 above. Experiments can be designed that would test the equivalence of chemically distinct chromophores or that would test the prediction of accelerated IVR.

3. The model raises questions that point to further experiments. What kinds of molecular flexibility accelerate IVR? Which is most important, the barrier height or the symmetry of the potential? What role is played by ring puckering or other types of fluxional behavior? The lifetimes presented above are for the relaxation of hydride stretches. What is the role of molecular flexibility in the relaxation of other types of vibrations?

What kind of flexibility?

The existing data already give some indication about the types of large amplitude motion that accelerate IVR. The low-barrier cases for which we have data all exhibit fast IVR. These include ethanol (374 cm^{-1} for *trans*→*gauche*[2] (17)) and propargyl alcohol (68 cm^{-1} for *gauche*→*gauche* (18)). The low-barrier (30 cm^{-1}) 6-fold symmetric methyl internal rotation of S_1 *p*-fluorotoluene is associated with fast relaxation of the Franck–Condon active modes (2).

We have seen that methyl internal rotation is not very effective in enhancing the rate of IVR for cases (e.g., 1-butyne) where the barrier is high (≈1100 cm^{-1}) and 3-fold symmetric. On the other hand, the high barrier in 1-pentyne (1088 cm^{-1} for *gauche*→*gauche* (19)) is associated with fast relaxation of the methyl C—H. The relaxation in 1-pentyne might be faster because the three minima in the isomerization coordinate are inequivalent or because isomerization causes a significant reorientation of the rotational axes (20).

In Fig. 2, the O—H lifetime (n = 1) for propargyl alcohol is seen to be longer than for ethanol and even is longer than the methyl C—H lifetime (n = 2) of ethanol and 1-pentyne. The latter two molecules have a high-barrier methyl internal rotation in addition to the *gauche–trans* isomerization coordinate whereas propargyl alcohol does not. This comparison provides a hint that aliphatic methyl internal rotation, in combination with another large-amplitude coordinate, might play a role in enhancing IVR even if, by itself, it is generally less effective than some other types of molecular flexibility.

Comparison to other molecules

There are several other flexible molecules for which IVR lifetimes are known for a single chromophore (Table 2). For hydrogen peroxide (21–23) there are data for three bands but each of these represents predominantly O—H excitation. The trend of the data for these flexible molecules supports the proposed model. The longest lifetime in this group is for the

[2]The Fourier components of the potential, V_1 = 57, V_2 = −0.8, and V_3 = 360.7 cm^{-1}, were adjusted from those given in ref. 17 (57, +0.8, and 395 cm^{-1}, respectively) in order to obtain agreement with the observed torsional energy differences (listed in Table VIII of ref. 17) of O-H and O-D ethanol.

[b]Source of the spectroscopic data.

[c]Number of bonds between the chromophore and the center of flexibility.

[d]The available data for rotational levels $K = 0$–2 and $J \leq 16$ were used in each case. Where discrete line positions and frequencies are available, τ was calculated by us using eqs. [3]–[6].

[e]Calculated from estimated homogenous widths as in the last column of Table 1.

[f]Could not be recalculated using eqs. [3]–[6] because the line positions and intensities have not yet been published.

[g]There are at most two observed features in each pure sequence clump. Even the averaged decays, $P(t)$, show very prominent quantum beats.

[h]The observed clumps are the superposition of A' and A'' (in C_s) pure sequence clumps. Reasonable but approximate separations into A' and A'' clumps were accomplished by the method described in ref. 10.

acetylenic C—H in propargyl amine (24), which is distant from the center of flexibility. In 1-butene (1), *n*-butane (1), and methyl formate (25), where the chromophores are closer to the center of flexibility, the lifetimes are shorter. The shortest lifetimes are for hydrogen peroxide where the excitation is adjacent to the O—O bond about which internal rotation can occur. The *trans* barrier is 386 cm^{-1} (26), which places it in the low-barrier group mentioned above. Note that hydrogen peroxide is above the dissociation limit in these bands but that the width of the wider features is dominated by IVR.

Molecules that do not have flexibility of the type that enhances IVR may be called "rigid" molecules. According to our model, rigid molecules ought to relax as slowly as in cases for which the chromophore is distant from a center of flexibility. Indeed, we find that the IVR lifetimes for all of the rigid molecules listed in Table 2 are greater than 100 ps.

Note that the acetylenic C—H fundamentals in $(CD_3)_3C$-C≡C-H and $(CF_3)_3C$-C≡C-H both relax faster (40 ps and 60 ps, respectively) than is the case for $(CH_3)_3C$-C≡C-H (200 ps) (4). In the d_9 compound, the enhanced relaxation rate is understood in terms of an increase in the number of low-order resonances (4, 5). Similarly, a decrease in the number of low-order resonances accounts for the exceptionally long lifetime (2 ns (27)) found for in $(CH_3)_3Si$-C≡C-H. The reasons for the fast relaxation in the f_9 compound are not known.

The role of extreme motion states in accelerating IVR (6) can also be seen in Table 2. Because of the nature of the dipole selection rules, infrared spectroscopy tends to prepare hydride stretches that are localized and therefore qualify as extreme motion states. With the advent of double resonance excitation schemes it has become possible to deliberately prepare initial states in which the energy is divided between widely separated hydrogens. Such delocalized combination vibrations should, by implication, relax more slowly than extreme motion states. In propyne, the acetylenic C—H plus methyl C—H combination band (28) does relax more slowly than either of the localized overtones of the acetylenic C—H.[3,4] For hydrogen peroxide, the relaxation times increase in the order: 6 O—H < 5 O—H + O—O < 4 O—H + O—H′, which is also consistent with an enhancement of the relaxation rate by extreme motion states.

It is evident from this discussion that these other systematic effects must be taken into account in addition to the distance of the chromophore from a center of flexibility.

The data in Table 2 provide further insight into the possible role of aliphatic methyl internal rotors. Among the flexible

For personal use only.

molecules in Table 2, only *n*-butane has two methyl internal rotors in addition to the *gauche–trans* isomerization coordinate and it has the shortest lifetime of those listed for $n = 2$. Among the rigid molecules, those with two or more methyl rotors (isobutane, *trans*-2-butene, and *tert*-butylacetylene) have shorter lifetimes than does propyne or 1-butyne. The shortest lifetimes in this group are for isobutane and *trans*-2-butene where the methyl C—H's are excited. However, in 1-butyne the single methyl rotor does not cause the methyl C—H to relax more quickly than the acetylenic C—H. The effects mentioned in this paragraph are rather small in comparison with the possible range of variation of IVR lifetimes, so that confident conclusions are not possible at this time. Let us only say that the data are consistent with a modest enhancement of IVR by aliphatic methyl rotors, particularly when there are two or more interacting internal rotors within the molecule.

The lifetimes for the halogenated molecules listed in Table 2 are all very long. 2-Fluoroethanol (29) has two internal rotors, which connect five distinct conformations, yet the lifetime of the methyl C—H is in the range of hundreds of picoseconds as would be expected for a rigid molecule. The most stable geometry is the *Gg'* conformer in which there are intramolecular interactions between the fluorine and the hydroxyl hydrogen. Conversion to the next most stable conformer (*Tt*) has a barrier of more than 1500 cm^{-1} and involves motion along both internal rotation coordinates. It seems that 2-fluoroethanol behaves as a more rigid molecule than ethanol. It is also possible that halogenation produces a decrease in the number of low-order resonances. In 1,2-difluoroethane (30) and 1-chloro-2-fluoroethane (31), the mass of the halogen atoms brings the density of states into the range (five and nine symmetry-allowed states per cm^{-1}, respectively (31)) where IVR is expected (32, 33) but the intramolecular interactions remain slight. The lifetimes for the four halogenated molecules, including trifluoropropyne (34), all fall in the range expected for rigid molecules even though three of them may undergo conformational change by movement of a halogen (X) atom. It appears that internal rotation of a CH_2X group does not provide molecular flexibility of the type that accelerates IVR.

Why does molecular flexibility accelerate IVR?

While the experimental results provide empirical evidence that molecular flexibility plays an important role in accelerating IVR, we would also like to know why this is so. A definitive answer to this question can only come from careful dynamical calculations on realistic potentials for a number of molecules. However, some insight can be obtained from an examination of the potential for the large-amplitude degrees of freedom.

Consider the torsional potential about the C—O bond of ethanol[2] as an example. In Fig. 3, this potential is compared to a harmonic potential with the same curvature at the minimum. Even at energies as low as the hydride fundamentals, it can be seen that these potentials are very different and that the energy level structures bear little resemblance. In general, we expect that the large-amplitude coordinates that are responsible for molecular flexibility will be the most anharmonic degrees of freedom in the molecule.

Of more relevance than the form of the potential for any single coordinate is the nature of the coupling between coordinates. For example, the barrier to methyl internal rotation of ethanol increases from 1158 cm^{-1} to 1331 cm^{-1} on conversion from the *trans* to the *gauche* form. This change of barrier height can be modelled by allowing the V_3 term of

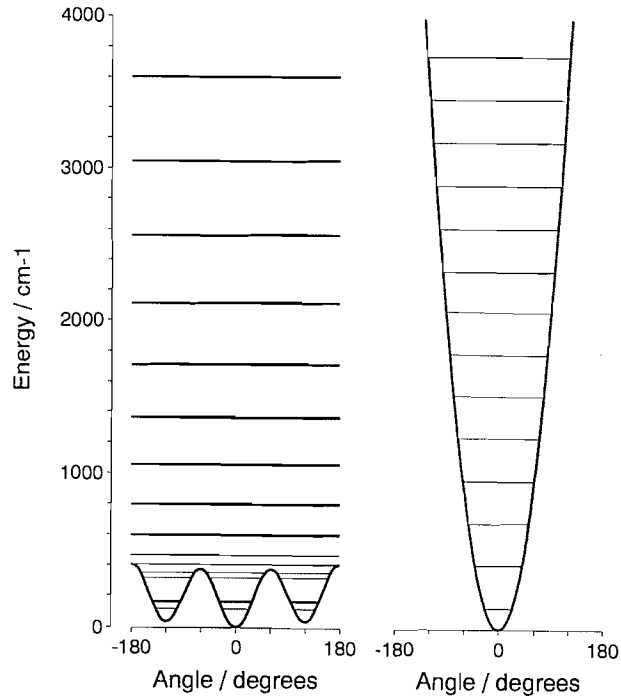

FIG. 3. Potential energy curves (see footnote 2) and energy levels for the C—O torsion of ethanol (left) and for a harmonic oscillator with the same curvature at the minimum (right). The *trans* minimum is at 0° and the *gauche* minima are at ±120°. The energy levels result from a diagonalization of the one-dimensional torsional problem using the kinetic energy coefficients given in ref. 17. Nondegenerate levels are shown as a thin line. Levels that are doubly degenerate within the resolution of the figure are represented with a thick line. The highest energy levels displayed are comparable to one quantum of the O—H stretch.

the methyl internal rotation potential to depend on the C—O torsion angle, α:

$$[7] \qquad V_3 \approx (1273 - 115\cos\alpha)\,cm^{-1}$$

If we use a product-free rotor basis

$$[8] \qquad \psi_m(\alpha)\psi_n(\beta) = \frac{1}{2\pi}\exp(im\alpha)\exp(in\beta) \quad \text{with } m,\ n = 0, \pm1, \pm2, \ldots$$

then the potential matrix elements coupling the two internal rotors are

$$[9] \qquad \langle\psi_{m'}\psi_{n'}|\frac{115}{2}\cos\alpha\cos3\beta|\psi_m\psi_n\rangle = \frac{115}{8}\delta_{m',m\pm1}\delta_{n',n\pm3}\,cm^{-1}$$

The angle β is the coordinate of the methyl internal rotation. Coupling matrix elements also arise from the kinetic energy operator (35). At first glance eq. [9] appears to be a coupling of relatively low order; however, this apparent simplicity exists only in the free rotor basis. The one-dimensional eigenfunctions, $\phi(\alpha)$ and $\phi(\beta)$, bear little resemblance to free rotor wavefunctions. To illustrate this point, the ground state eigenfunctions, $\phi_0(\alpha)$ and $\phi_0(\beta)$, are given in Table 3 in the free rotor basis.

Therefore matrix elements of eq. [9], when expressed in the product basis, $\phi(\alpha)\phi(\beta)$, will yield both low- and high-order couplings between the two internal rotors. Although we do not

TABLE 3. Ground state torsional eigenfunctions for ethanol in the free rotor basis

m or n	C—O Torsion[a]	C—C Torsion[b]
0	0.57	0.63
±1	0.44	0.00
±2	0.30	0.00
±3	0.20	0.49
±4	0.10	0.00
±5	0.04	0.00
±6	0.02	0.24
±7	0.01	0.00
±9	0.00	0.08
±12	0.00	0.02

[a]For the C—O torsion, the one-dimensional eigenfunctions are given as the coefficients of the expansion $\phi_0(\alpha) = \Sigma c_m \exp(im\alpha)$ and were obtained by diagonalization of the torsional Hamiltonian (see footnote 2).

[b]For the C—C torsion, the expansion is $\phi_0(\beta) = \Sigma c_n \exp(in\beta)$. The potential coefficient, $V_3 = 1158\ cm^{-1}$; and the kinetic coefficient, $\mu^{(0)} = 6.445\ cm^{-1}$ are from ref. 17.

have convenient analytical expressions for the matrix elements, we should not be surprised to find other instances of relatively strong high-order coupling between an internal rotor and vibrations having significant amplitude in its vicinity. One such example is the coupling of the methyl rotor to ring modes in *p*-fluorotoluene (36). Therefore, relatively strong couplings of both low and high order can result from the extreme anharmonicity of large-amplitude coordinates and may contribute to the importance of molecular flexibility in accelerating IVR.

Conclusion

Empirical evidence has been presented to show that the proximity of a prepared vibration to a center of flexibility is associated with accelerated IVR. It has been pointed out that molecular flexibility can give rise to substantial low- and high-order couplings that may enhance the rate of intramolecular relaxation.

It must be emphasized that the role of molecular flexibility is only a part of the story about IVR. Other systematic effects such as the density of low-order resonances and the properties of extreme motion states must also be taken into account. Specific strong low-order resonances can dominate the relaxation in the cases where they are active. The unique properties of individual molecules generate scatter in the measured lifetimes and some exceptions to generally valid trends should be expected.

Appendix: Errors from the approximate separation of tunnelling states

The procedure for approximately separating the two pure sequences that are related by a tunnelling motion has been described previously (10). The separation relies on the fact that the tunnelling splitting of the zero-order bright state is negligible compared to the spectral resolution. Therefore, one has the requirement that the two pure sequence clumps share a common center of gravity. This, together with the known nuclear spin weights, allows an approximate separation of the observed spectra that should, in principle, yield reliable average IVR lifetimes.

However, in real spectra, some of the weaker lines will be missed. In this case, the centers of gravity of the pure sequence clumps may no longer coincide, giving systematic errors in the way the observed lines are separated into tunnelling species. Relative to a correct separation of the observed lines, the estimated homogeneous clump widths would be too large and therefore the estimated IVR lifetimes would be too short. On the other hand, most of the missed lines will be in the wings of the clump, which will tend to give an estimated width that is too low and a lifetime that is too long.

Some insight into the net result of these two opposing effects can be found in our existing random matrix calculations (11). These calculations simulate the experimental spectra as the superposition of two pure sequences under a range of signal-to-noise conditions. The average calculated clump widths for the 1-butyne ν_{16} band are found to be about 10% less at the signal-to-noise of the experiment than at infinite signal-to-noise. By implication, the estimated lifetimes would be about 10% too long. We conclude that, when the assumptions of the random matrix calculation are valid, the loss of weak lines in the wings of the clumps is a more important source of error than the misalignment of the centers of gravity of the pure sequence clumps. The crucial assumption that the dark states are strongly coupled to each other is thought to be at least approximately valid for 1-butyne (11) and ethanol (12).

However, when this assumption does not hold, the error in the lifetimes may be larger and in the opposite direction. For example, the bright state could couple with a large matrix element to a particular zero-order dark state that has a large tunnelling splitting. If the dark state is off resonance and borrows insufficient intensity to be detected in the spectrum, the pure sequence clumps would be shifted by different amounts or even in different directions. This may be the case for propargyl amine. Rigorous assignment of the tunnelling species by a double resonance technique showed that the misalignment between the pure sequence clumps was about one quarter of the clump width (24).

The title reaction has been studied in a crossed molecular beam apparatus. Both the product state distributions and the translational energy dependence of the reaction cross sections were measured under single collision conditions. Excellent agreement was found over a wide temperature range (26–3800 K) between rate constants deduced from the translational excitation function and recent thermal kinetic data. The rotational state distribution was found to be very cold compared to the reaction exothermicity, and could be described by a Boltzmann temperature of 110 K for all *K*-doublet levels. The vibronic state distribution was also found to be cold, with 70% of the products formed in the vibrational ground state. By comparing the molecular beam results for vibronic state distributions with those obtained from recent bulb experiments, it was conjectured that there appears to be a strong correlation between rotation in the reactants and bending excitation in the products.

R. GLEN MACDONALD, KOPIN LIU, DAVID M. SONNENFROH et DI-JIA LIU. Can. J. Chem. **72**, 660 (1994).

On a étudié la réaction mentionnée dans le titre à l'aide d'un appareil à faisceau moléculaire croisé. Utilisant des conditions de collision unique, on a étudié les distributions des états des produits ainsi que la relation entre l'énergie de translation et les sections droites de la réaction. Sur une large plage de températures (26–3800 K), on a observé un excellent accord entre les constantes de vitesse obtenues à partir de la fonction d'excitation translationnelle et des données récentes de cinétique thermique. On a trouvé que la distribution de l'état rotationnel est très froide si on la compare avec l'exothermicité de la réaction et qu'on peut la décrire par une température de Boltzmann de 110 K pour tous les niveaux *K*-doublets. On a aussi trouvé que la distribution de l'état vibronique est froide; en effet, 70% des produits se forment dans l'état vibrationnel fondamental. En comparant les résultats des faisceaux moléculaires pour les distributions de l'état vibronique avec ceux obtenus lors d'expériences récentes avec des bulbes, on peut imaginer qu'il existe une forte corrélation entre la rotation des réactifs et l'excitation de déformation des produits.

1. Introduction

The reaction of the cyano radical (CN) with O_2 is an important step in NO_x formation and destruction in fuel-rich flames, and in other combustion processes such as the burning of coal. It is perhaps also becoming one of the most thoroughly studied radical–radical and four-atom reaction systems. The reaction has three exothermic product channels:

[1]	$CN + O_2 \rightarrow NCO + O$	$\Delta H_0 = -13.7$ kcal mol^{-1}
[2]	$\rightarrow CO + NO$	$\Delta H_0 = -110$ kcal mol^{-1}
[3]	$\rightarrow N + CO_2$	$\Delta H_0 = -93$ kcal mol^{-1}

A new, precise determination of the heat of formation of NCO by Cyr et al. (1) was used in calculating the exothermicity of reaction [1]. There are many indications that the reaction of $CN + O_2$ is dominated by channel [1], whereas channel [3] is generally believed to be unlikely. Schmatjko and Wolfrum (2) monitored CO formed in channel [2] and estimated it to account for 6% of the total $CN + O_2$ reaction rate at room temperature. However, more recently Cooper et al. (3) measured the temperature dependence of the yield of channel [2] and found it to be 23% at 300 K, decreasing to a few percent at 600 K. Such a high yield at low temperature and a negative temperature dependence are quite surprising in that the formation of CO + NO is expected to proceed through a four-center transition state, generally involving a sizable barrier to reaction. Consequently, a small yield at low temperatures increasing with temperature would seem more reasonable.

In terms of overall reaction rate, only quite recently has the kinetic behavior of this reaction been accurately determined over a wide temperature range, from 26 K to 4000 K (4–7). It was found that the thermal rate constant was relatively large and exhibited a pronounced negative temperature dependence, i.e., the rate constant decreased with increasing temperature. The exact origin of this negative temperature dependence is subject to some controversy. The large rate constant and negative temperature dependence suggest that the reaction proceeds through an intermediate complex on an attractive potential energy surface with no significant barrier to complex formation. On the other hand, a recently developed rotationally adiabatic capture theory (8) predicts that even a direct abstraction reaction, as opposed to a complex formation reaction, could also exhibit a negative temperature dependence. According to this approach, the reaction cross section decreases as internal rotation, j, of the reactants increases at a given temperature. As a result, the negative temperature dependence arises from the Boltzmann averaging over the initial rotational state distribution, which shifts the population towards the higher rotationally excited (less

reactive) states, with increasing temperature. Thus, the observed negative temperature dependence of the thermal rate constants can be rationalized equally well by two opposite reaction mechanisms.

The theoretical characterization of the reaction between CN + O_2 is complicated by the very nature of radical–radical processes. Considering the most important channel [1], in planar geometry, there are two NCOO potential energy surfaces of $^2A''$ and $^4A''$ symmetries that correlate with both CN ($X^2\Sigma^+$) + O_2 ($^3\Sigma^-$) and NCO ($X^2\Pi$) + O (^3P). The doublet surface will have lower energy because of its lower spin multiplicity, and is believed to be the reactive one. As just alluded to in the previous paragraph, one of the outstanding questions concerning reaction [1] is whether or not the reaction involves a transient, bound NCOO complex. The $^2A''$ state arises from the bonding interactions between the unpaired electron on CN and one of the unpaired electrons on O_2. From a comparison of the known bond strengths in related compounds, such as X—NO (X:F, Cl), CN—NO, and X—O_2, it has been estimated (9) that the bond energy for a NC—OO complex would be about 15 kcal mol^{-1}. This estimate is very close to the new value of 13.7 kcal mol^{-1} for the exothermicity of reaction [1]. Based on these considerations, it is likely that there is at most a very shallow well on the NCOO surface, and reaction [1] would occur essentially via a direct O-atom abstraction path. On the other hand, a recent *ab initio* calculation (10) yielded a bond energy of about 45 kcal mol^{-1}, which is closer to Benson's estimate (10) of 35 kcal mol^{-1}. These values will lead to a considerably deeper well on the NCOO potential energy surface, ca. 20–30 kcal mol^{-1} more stable than the NCO + O products. A transient, bound NCOO intermediate would then be expected, which could play a significant role in the kinetics/dynamics of this reaction. Clearly, a more precise determination of the bond energy of the NC – OO intermediate is needed. Despite the current uncertainties in this quantity, it is likely that no substantial potential well (>20 kcal mol^{-1}) is involved. However, the observed pressure independence of thermal rate constants over a limited range does not necessarily rule out a complex formation reaction mechanism.

Reported here is a crossed-beam investigation of reaction [1]. A nearly complete characterization of the NCO ($\tilde{X}^2\Pi$) product state distributions under single collision conditions was attempted. This vast amount of information was then used to shed light on some of the controversies and unresolved issues posed above. During the course of this study, we became aware of two independent investigations, in Dagdigian's (11) and Smith's (9) groups, on the vibronic state distribution of the NCO product from reaction [1]. A comparison of the results from all three studies leads to an intriguing correlation between the bending excitation of NCO product and the rotational motion of the "spectator" CN reagent. Implications of this correlation for future study of polyatomic reaction dynamics are also outlined.

2. Experimental

The experiments were carried out in a crossed-beam machine described previously (12), so that only a brief description of the apparatus will be given here. It consists of two collimated, pulsed supersonic beam sources that are differentially pumped and independently rotatable through 2π radians. The CN ($X^2\Sigma^+$) radical was produced almost exclusively in $N = 0$ by photolyzing C_2N_2 directly in front of a pulsed molecular beam valve at 193 nm using an ArF laser. The C_2N_2 was diluted (~4%) in N_2 or mixtures of N_2 and H_2. The CN state distribution in the primary beam was monitored by laser-induced fluorescence (LIF) using the CN $B^2\Sigma^+ \leftrightarrow X^2\Sigma^+$ transition (13) and is shown in Fig. 1 for the case with N_2 as carrier gas. As is evident from the figure, the CN radical is rotationally relaxed because of the strong supersonic expansion (backing pressures of ~15 atm (1 atm = 101.3 kPa) and a nozzle diameter of 0.5 mm). Photolysis of C_2N_2 at 193 nm produces vibrationally excited CN (14), and about 6% of the CN radicals remained vibrationally excited even after this strong supersonic expansion. Various relaxation partners (CF_4, NO, and Xe) were added to the gas mixture to vibrationally relax CN radicals; however, only a modest reduction in the vibrational population of CN ($X^2\Sigma^+$) was found over that with N_2 as carrier gas. A similar CN ($X^2\Sigma^+$) internal state distribution to that shown in Fig. 1 was found when using a mixture of N_2 and H_2 as carrier gas.

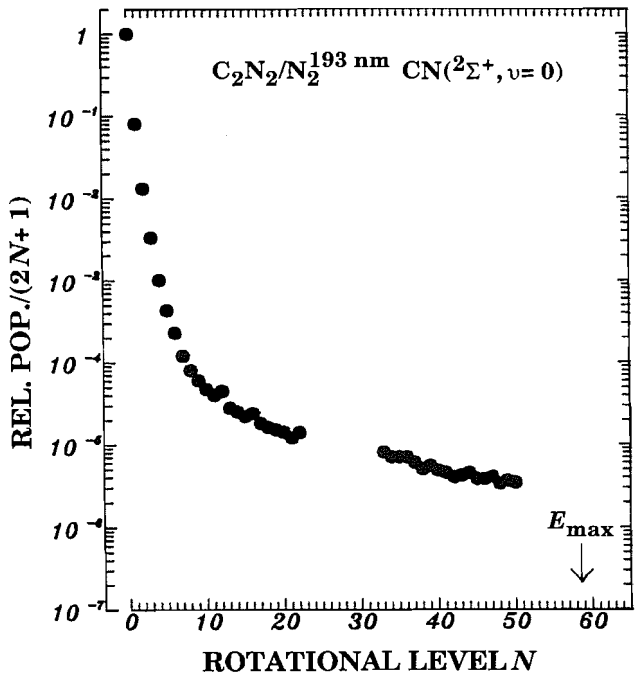

FIG. 1. Relative population of CN ($X^2\Sigma^+$) produced in 193 nm photolysis of C_2N_2 (~4%) dilute in N_2 carrier gas. The initial few rotational states are described by a Boltzmann rotational temperature of ~2 K while the tail is described by 70 K. The gap between $N = 22$ and 32 is due to bandhead formation.

A unique feature of this apparatus is the ability to select the initial translational energy by merely changing the intersection angle between the two beam sources without varying any other beam parameter. In this mode of operation it is possible to measure the excitation function for a selected product state by setting the dye laser at a wavelength that probes a selected product state and then varying the angle between the two beam sources. The product state distribution may also be determined for a fixed initial translational energy of the reactants by fixing the intersection angle of the beams and then scanning the dye laser to obtain a LIF excitation spectrum.

To facilitate data analysis and to improve spectral resolution by reducing power-broadening effects, the LIF spectra were taken in the linear power dependence regime, typically 2–4 μJ/pulse with a laser beam diameter of 5–6 mm, for the complete determination of the product rotational and fine-structure state distributions of the NCO vibrational ground state. A gated photon counting technique, using a Stanford Research model SR-400, was employed to enhance the S/N ratio. No other NCO $\tilde{X}^2\Pi$ vibrational level was sufficiently populated from reaction [1] to allow such detailed measurements. Instead, near-saturated LIF (~200 μJ/pulse, and boxcar averaging) scans around the bandheads were used to obtain the vibronic state distributions. Near-saturated LIF also reduces most of the Franck–Condon factor dependence of the observed signals.

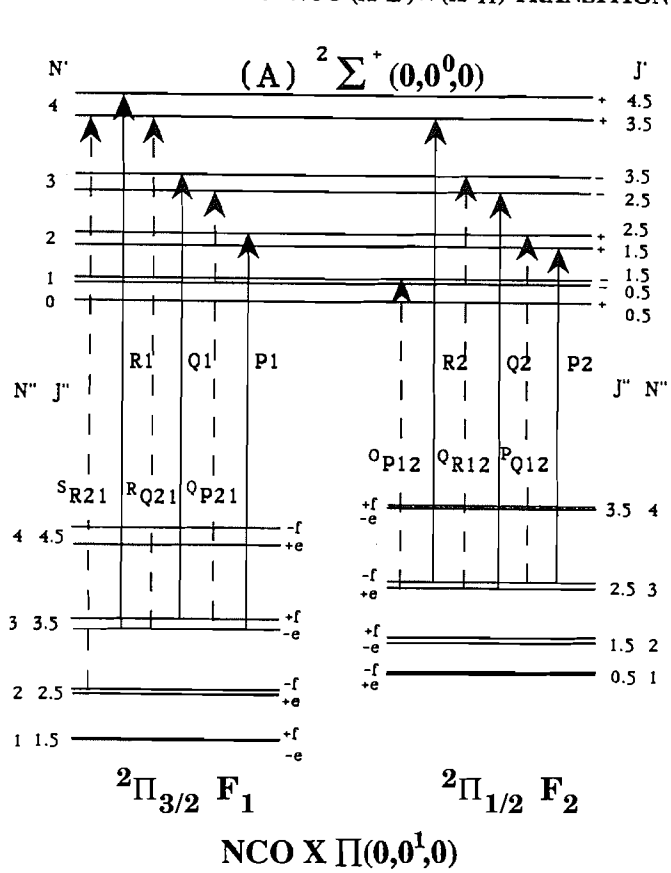

FIG. 2. A schematic representation of the NCO $\tilde{A}^2\Sigma^+(000) \leftrightarrow \tilde{X}^2\Pi(00^10)$ transition. The solid lines represent main branch transitions while the dotted lines represent satellite branches. The closely spaced levels labeled by alternating parity and *e/f* are the *K* doublets. Like OH, *A* is negative for NCO and the lower energetic spin-orbit state is $^2\Pi_{3/2}$.

The spectroscopy of the NCO $\tilde{A}^2\Sigma \leftrightarrow \tilde{X}^2\Pi$ transition has been well documented (15). For clarity, a schematic of the energy levels involved in probing the rotational states of the two spin-orbit manifolds of the ground vibrational level are shown in Fig. 2. Because of the large spin-orbit constant, *A*, and smallrotational constant, *B*, the NCO $\tilde{X}^2\Pi$ (00^10) state is a prototypical Hund's case (a) radical ($Y = A/B = -245$), and the spectroscopic labeling is similar to that for the analogous transition in the more familiar OH radical. The dye laser resolution (0.08 cm^{-1}) is not sufficient to separate some of the main branch transitions from their associated satellite branches (see Fig. 2) in either spin-orbit manifold. Thus, the nascent *K*-doublet population (the closely spaced *e/f* labeled states for a given rotational quantum number *J*, analogous to the λ-doublet of a diatomic radical) was determined by comparing the intensity of satellite transitions such as the $^sR_{21}$ branch probing 1*f* levels in the $^2\Pi_{3/2}$ manifold to the sum of the intensities of the main branch R_1 and associated satellite branch $^rQ_{21}$, probing 1*e* levels, of the same *J*. Similarly, in the $^2\Pi_{1/2}$ spin-orbit manifold the intensity of the main branch R_2 was used for probing 2*f*-labeled states, and the sum of the main branch Q_2 and its associated satellite branch $^qR_{12}$ probed 2*e*-labeled states. The branches, P_1 and $^OP_{12}$, also probing *e*-labeled levels, were used as a check on the populations obtained from the other branch probing the same *K*-doublet levels. The necessary rotational line strengths of the transitions were calculated according to the intermediate case formulae given in ref. 16. The unique levels of a Renner–Teller manifold, those designated by $K = |l + \Lambda|$, are characterized by bandhead formation in the $Q_1 + {}^qP_{21}$ branch in the lower spin-orbit component and the P_2 branch transitions in the upper spin-orbit component (15). These features were used to determine the vibronic state distribution as well as the excitation functions.

Generally, the LIF technique acts as a number density detector; however, in a scattering experiment the desired quantity is the cross section, which is proportional to particle flux. A number density-to-flux transformation is necessary to extract the cross-section information from measured LIF populations. A simple method has been developed in this laboratory to correct for this transformation without a prior knowledge of the product angular distribution (17). Briefly, this method relies on the fact that different kinematics should lead to the same cross section for production of the same product state at the same initial translational energy. With the present apparatus it is possible to vary the radical beam velocity by changing the effective mass of the carrier gas (mixtures of C_2N_2 and N_2 versus C_2N_2, N_2, and H_2) without changing any other characteristic of the molecular beams. The same cross-section measurement can therefore be made with very different kinematic arrangements. Indeed, it has been shown (17) that by applying this method to the present reaction even a qualitative picture of the product angular distribution can be inferred in a favorable kinematic situation.

3. Results

A. *Rotational state and K-doublet distribution*

A survey LIF excitation spectrum of the NCO $\tilde{X}\,^2\Pi_{3/2}$ (00^10) product from reaction [1] is shown in Fig. 3 for an initial translational energy of 0.7 kcal mol^{-1}. This spectrum was taken under partially saturated LIF (~100 μJ) conditions, and illustrates two important observations. An inspection of the $Q_1 + {}^qP_{21}$ bandhead, which occurs at $J \sim 13.5$, clearly reveals that the nascent NCO is formed with little rotational excitation. A cold rotational distribution is also evident from the appearance of the other branches shown in the figure. This is remarkable considering that the energy available to the reaction products is 14.4 kcal mol^{-1}, and rotational levels up to $J \sim 110$ in the vibrational ground state could be populated on energetic grounds alone. Also note that there appears to be an underlying unresolved feature on the blue side of the $Q_1 + {}^qP_{21}$ bandhead. From this scan alone, it is not clear whether this is due to overlapping of adjacent lines because of power broadening or to the presence of some other unresolved transition. Nevertheless, it is apparent that spectral congestion is a severe problem if the nascent population in *K*-doublet states is to be determined.

In Fig. 4 is shown a scan over the $R_1 + {}^rQ_{21}$ and $^sR_{21}$ branch region for a similar initial translational energy as that of Fig. 3, but under much reduced laser power (~3 μJ). It is obvious from Fig. 4 that many of the previously overlapped lines are now resolved, and a clearer picture of the final product state distribution of NCO emerges. Note that the peaks of low *J* for the $R_1 + {}^rQ_{21}$ branch still do not reach the baseline and that the unresolved feature, evident in Fig. 3, still persists though much less pronounced. In a preliminary account (18) of this study little work had been done on any state other than NCO $\tilde{X}^2\Pi_{3/2}$ (00^10), and spectra similar to that shown in Fig. 4 were analyzed under the assumption that the unresolved feature was due to spectral congestion. This analysis led to the conclusion that there was an unusual preference for production of *K*-doublet levels of *f*-type symmetry at *low J* quantum numbers. Since then a large amount of information has accumulated about the vibronic state distribution of NCO from reaction [1] and also about the spectroscopy of higher vibronic states. The exact frequency of the transitions involving low *J* quantum states for the NCO $\tilde{A}^2\Sigma$ $(010) \leftrightarrow \tilde{X}\kappa\Sigma^-(01^10)$ transition are still not known; however, they can be calculated to be in the low *J* region of the $R_1 + {}^rQ_{21}$ and $^sR_{21}$ branches. More convincingly, other work (19) on the inelastic scattering of NCO $\tilde{X}^2\Pi_{3/2}$ (00^10) by He carried out in this laboratory does not show the same behaviour as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

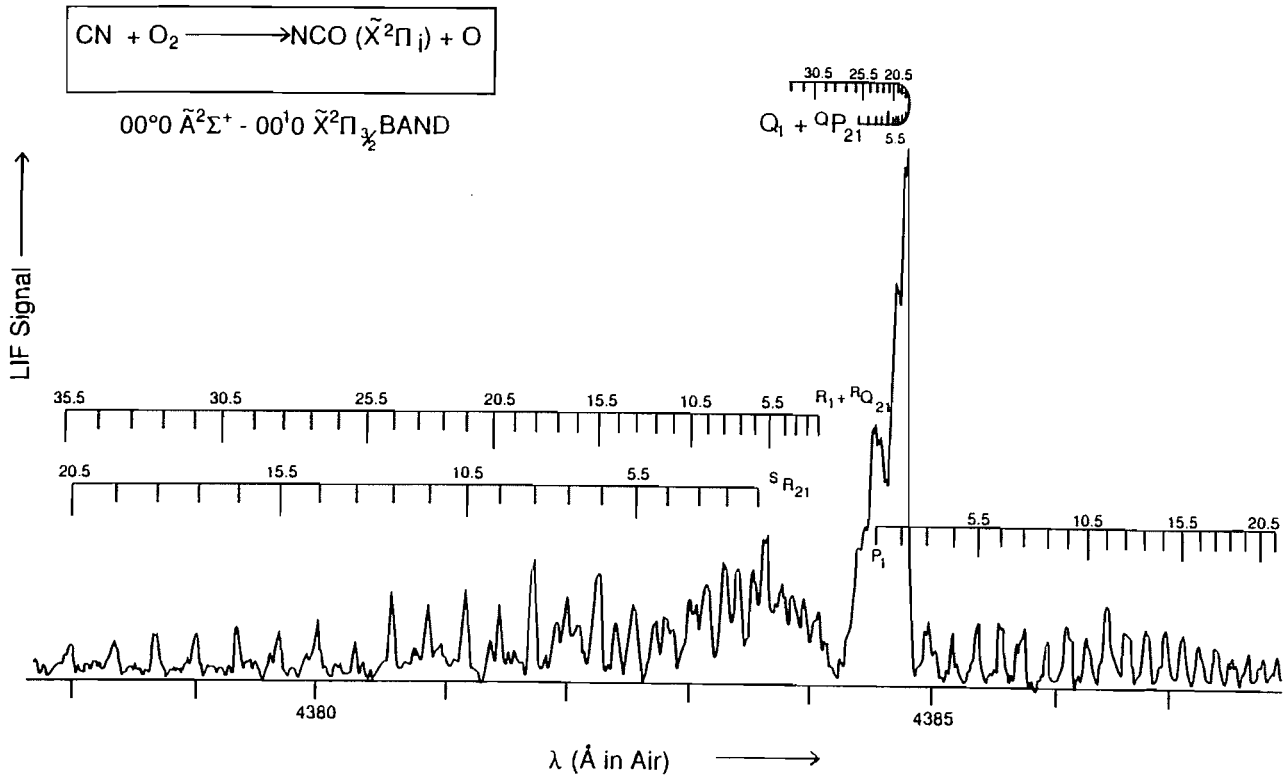

FIG. 3. A rapid survey scan over the $Q_1 + {}^qP_{21}$ bandhead region of NCO $\tilde{A}^2\Sigma^+ \leftrightarrow \tilde{X}^2\Pi$ indicating that the nascent rotational product state distribution from reaction [1] is cold. This LIF spectrum was obtained under partially saturated conditions and should be compared to the spectrum in Fig. 4. The collision energy was 0.7 kcal mol^{-1}.

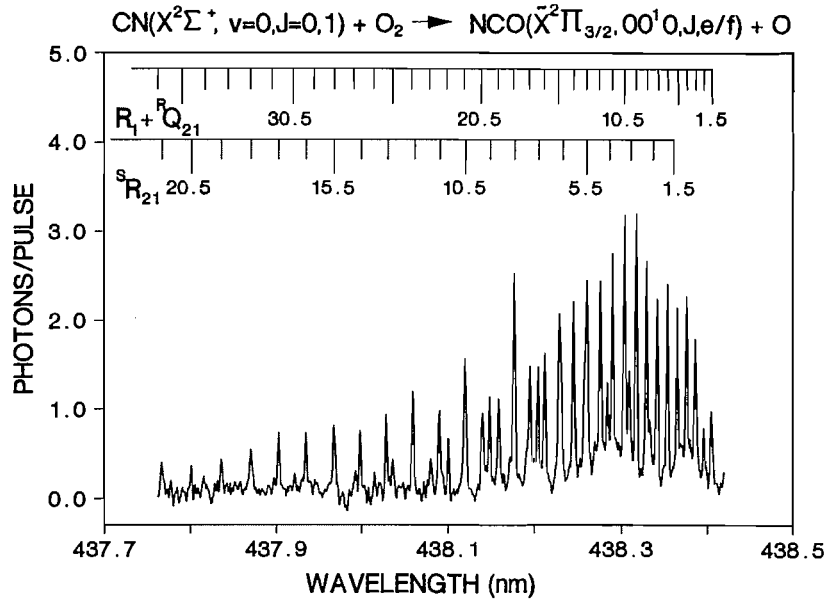

FIG. 4. An unsaturated LIF spectrum of the ${}^sR_{21}$ and $R_1 + {}^rQ_{21}$ branches of the NCO $\tilde{A}^2\Sigma^+(000) \leftrightarrow \tilde{X}^2\Pi_{3/2}(00^10)$ band recorded using single photon counting. Note that lines of low J do not terminate on the baseline (see text). This spectrum was recorded at an E_0 of 0.8 kcal mol^{-1}.

seen in Figs. 3 and 4. The peaks arising from the low J states of the $R_1 + {}^rQ_{21}$ and ${}^sR_{21}$ branches do indeed terminate on the baseline, even at higher laser power. It thus appears that the underlying feature in Figs. 3 and 4 is more likely due to transitions arising from the vibrationally excited $\tilde{X}\kappa\Sigma^-(01^00)$ state. A re-analysis of the low J data for the $R_1+{}^rQ_{21}$ and ${}^sR_{21}$ branches, assuming that the $\tilde{X}\kappa\Sigma^-(01^00)$ vibronic level contributed to the observed unresolved background, was carried out. The results of this new analysis are presented in Fig. 5. The uncongested $P_1(e)$ branch was also used to measure cross sections for the production of 1e-labeled K doublets. Generally, the agreement in cross sections for the different branches was better than $\pm 10\%$. The error bars in Fig. 5 reflect ± 2 standard deviations from the average of at least 5 spectra and the average of the branches for production of 1$e$labeled K doublets. The ratio of the populations in the two K doublets for different J states is

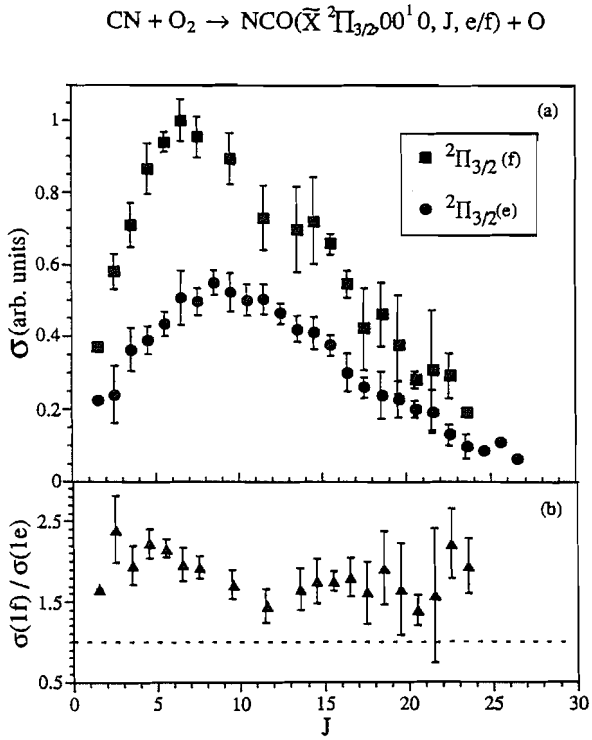

FIG. 5. (*a*) The nascent rotational and *K*-doublet population of NCO $\tilde{X}^2\Pi_{3/2}(00^10)$ from reaction [1] for an initial E_0 of 0.8 kcal mol^{-1}. NCO is formed with little rotational excitation. The error bars indicate the scatter in at least five independent measurements. Missing rotational states, especially in the *f*-labeled *K*-doublet manifold, are due to severely overlapped lines in the spectrum. Panel (*b*) is the ratio of *f*/*e*-labeled *K*-doubletstates vs. rotational quantum number showing a propensity of ~2 favoring *f* levels independent of *J*. A statistical distribution would give 1.

shown in panel (*b*) of Fig. 5. A comparison of this panel to the earlier work reveals that the propensity for production of 1*f*-labeled *K* doublet is approximately constant for all the observed *J* states, and the unusual increase in this propensity for low *J* states reported previously is *not* present. It should be noted that the peak in the rotational level distribution is indeed very low, peaking at $J \sim 6.5$ for 1*f* levels and at 8.5 for 1*e* levels.

Figure 6 is a typical LIF spectrum for the NCO $\tilde{A}^2\Sigma(000) \leftrightarrow \tilde{X}^2\Pi_{1/2}(00^10)$ band showing the $Q_2 + {}^qR_{12}$ (probing 2*e* levels) and R_2 (probing 2*f* levels) branches for the excited spin-orbit state of NCO produced in reaction [1]. The ${}^oP_{12}$ (*f*) branch was used as a check for cross sections derived from the R_2 branch. Again, the cross section appears to peak at low *J* values, just as for the lower spin-orbit state, NCO $^2\Pi_{3/2}$, shown in Fig 4. The gaps in the spectrum indicate that only the peak was scanned and the baseline in this region was not scanned. Shown in Fig. 7 are the *K*-doublet cross sections deduced from spectra such as shown in Fig. 6. Similar to the lower NCO $(00^10)^2\Pi_{3/2}$ spin-orbit component, the rotational state population appears to peak near $J \sim 9.5$ for both *K*-doublet components. In the lower panel of Fig. 7 the propensity for favoring the 2*f K* doublet is shown. As shown in Figs. 5 and 7, the *K*-doublet preference for the *f*-level is approximately independent of *J* by a factor of about 1.7 in both spin-orbit manifolds.

A closer inspection of Figs. 5 and 7 suggests a Boltzmann like behavior for the rotational level distributions. This is borne out in Fig. 8 where the complete rotational level distributions for the vibronic ground state manifold are plotted in a Boltzmann manner. In each *K*-doublet manifold, except for the lowest few *J* states, which appear to have a slight excess population over a Boltzmann prediction, the distributions are well characterized by a straight line with slope corresponding to a rotational temperature of 110 K. When summed over all *K*-doublet populations within each spin-orbit manifold, a propensity of $^2\Pi_{3/2}/^2\Pi_{1/2} \sim 2.3$ is found. This, in conjunction with the *K*-doublet preference of $1f/1e \sim 2f/2e \sim 1.7$, yields an approximate fine-structure propensity of $1f > 1e > 2f > 2e$ for all *J* at a translational energy, E_0, of 0.8 kcal mol^{-1}.

B. Vibronic state distribution

As already noted, the signal-to-noise ratio was not sufficient to obtain resolved single rotational state spectra for any vibronically excited state. However, it was possible to extract the total population in a given vibronic state by integrating over the bandhead regions under saturated LIF conditions. Typical spectra at $E_0 = 0.8$ kcal mol^{-1} are shown in Fig. 9 for the unique levels of the Renner–Teller vibronic manifold. In Fig. 9 the panels on the left probed the $Q_1 + {}^qP_{21}$(e) bandhead for the energetically lower spin-orbit component, while those on the right probed the P_2 (f) bandhead of the more energetic spin-orbit component. It is clear from Fig. 9 that the reaction does not populate excited vibronic states of NCO to any significant extent under crossed-beam conditions. This is in dramatic contrast to the vibronic state distribution obtained in other work under bulb conditions (9, 11). It should be pointed out that with high laser power the bandheads in the difference spectra are actually superimposed over a broad featureless background. The exact nature of this collision-induced background is not yet clear, and it was subtracted out in the data analysis.

A summary of the vibronic state distribution, as measured in this work, is shown in Fig. 10. The contribution from all the rotational states of a vibronic component were estimated by integrating over the bandhead region, and using the *J*-averaged rotational line strengths for saturated LIF detection (20). For the unique levels, only one *K*-doublet component of a spin-orbit pair forms a bandhead; thus, to account for the population in the other *K*-doublet component the population ratio measured for the two spin-orbit components of the $^2\Pi(00^10)$ manifold, Fig. 5 and Fig. 7, was used. The underlying unresolved feature near the blue side of the Q_1 bandhead, similar to that shown in Fig. 3, was tentatively assigned to the $\kappa\Sigma^-(01^00)$ state as discussed in the previous section. The exact locations of the bandheads of most of the excited vibronic states of NCO were previously measured by Dagdigian and co-workers (21), and by Sears and co-workers (22). Information about most of the Franck–Condon factors involved is also available from the dispersed fluorescence experiment (22).[3] Based on the relative magnitudes of the Franck–Condon factors, the dependence of observed signals on them is likely to be largely eliminated using the near-saturated LIF detection scheme. Many regions where vibronic transitions have previously been observed were scanned in the present experiments; however, only a few, as exemplified in Fig. 9, were detected with sufficient signal-to-noise to be analyzed. Populations in the other vibronic states are presumably so small that they are below our detection sensitivity. A complete summary of the vibronic levels and the

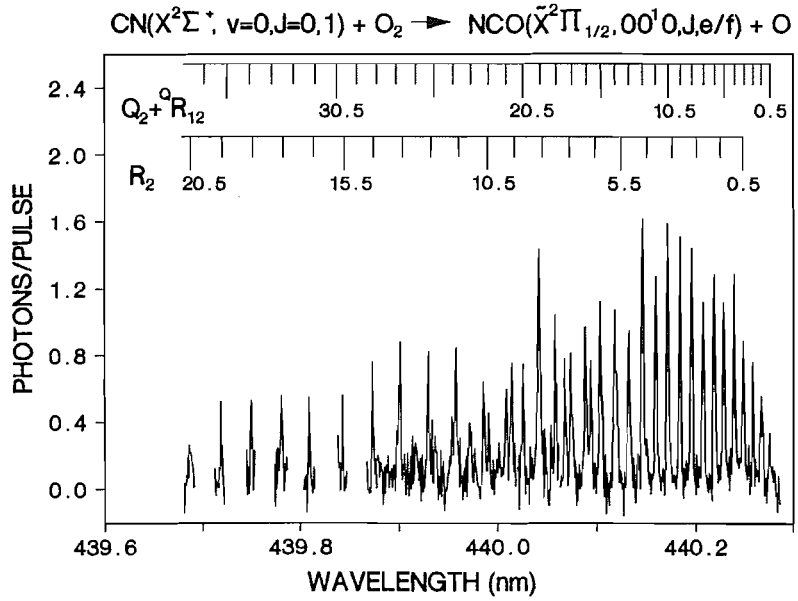

FIG. 6. An unsaturated LIF spectrum of the R_2 and $Q_2 + {}^qR_{12}$ branches of the NCO $\tilde{A}^2\Sigma^+(000) \leftrightarrow \tilde{X}^2\Pi_{1/2}(00^10)$ band recorded using single photon counting. This spectrum was recorded at an E_0 of 0.8 kcal mol^{-1}.

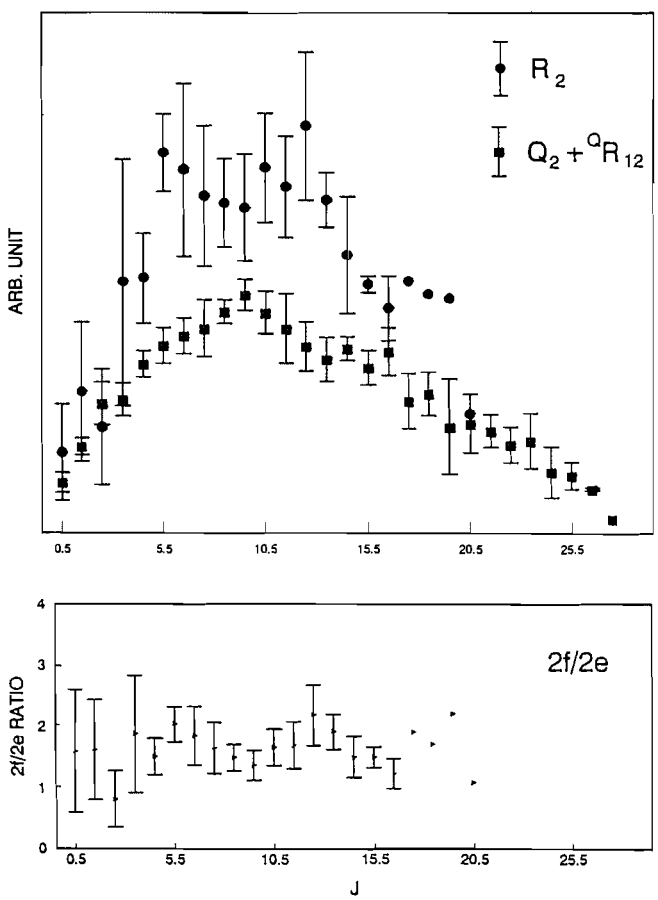

FIG. 7. (*a*) The nascent *K*-doublet level population of NCO $\tilde{X}^2\Pi_{1/2}(00^10)$ from reaction [1] for an E_0 of 0.8 kcal mol^{-1}. The error bars are $\pm 2\sigma$ in the data. Clearly the nascent NCO population peaks at low rotational excitation. The bottom panel is the ratio of $2f/2e$ as a function of rotational state showing $2f$ is favored by ~ 1.8 independent of J. A statistical distribution would give 1.

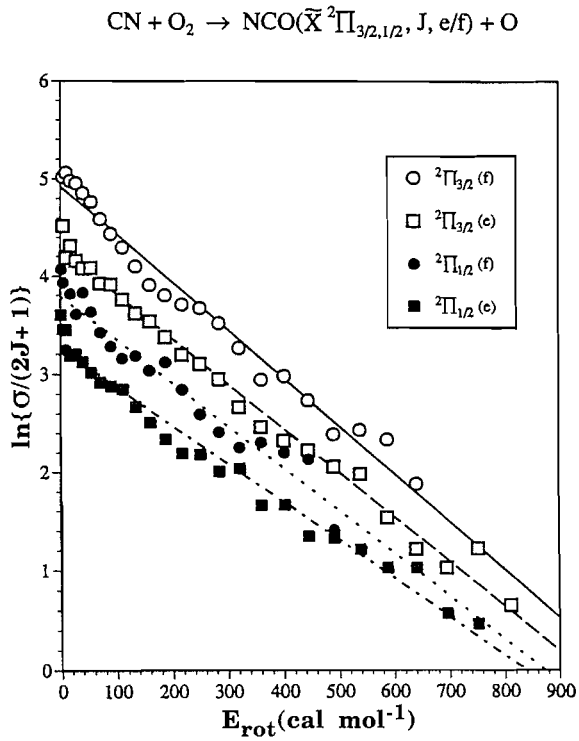

FIG. 8. A Boltzmann rotational temperature plot of the complete *K*-doublet level distribution of the vibronic ground state for NCO from reaction [1] at an E_0 of 0.8 kcal mol^{-1}. The distribution for each *K*-doublet manifold is well described by a rotational temperature of 110 K.

spectroscopic transitions scanned in this work is given in Table 1.

There are several notable features about this vibronic state distribution. First, the overall distribution is quite cold with almost half of the nascent NCO product formed in the lowest vibronic state, $^2\Pi_{3/2}(00^10)$. Second, a clear mode selectivity is

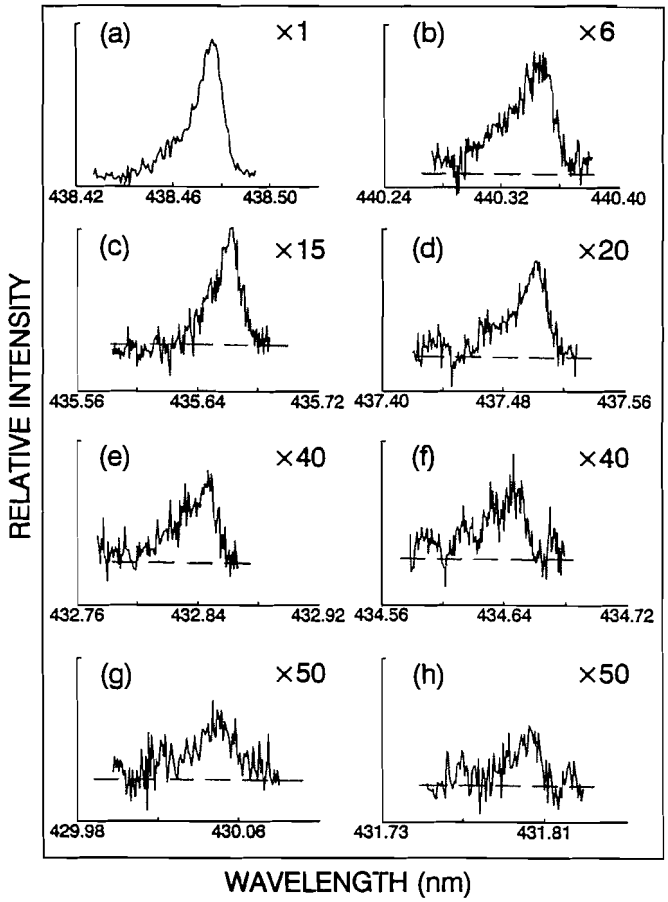

FIG. 9. Selected unique level vibronic bandhead spectra for the NCO product from reaction [1] for an E_0 of 0.8 kcal mol^{-1}. The left-hand panels ((*a*), (*c*), (*e*), and (*g*)) monitor the $Q_1 + {}^qP_{21}$ bandhead of the lower energy spin-orbit component while the right-hand panels ((*b*), (*d*), (*f*), and (*h*)) monitor the $P_2 + {}^pQ_{12}$ bandhead of the more energetic spin-orbit component. Note that the area of the bandhead region was used as a measure of the total population with the zero signal level indicated by the dashed line, *not* the *x*-axis. There is a broad collision-induced signal, which becomes more obvious for the more sensitive scales. Panels (*a*) and (*b*) probe $^2\Pi(00^10)$, (*c*) and (*d*) $^2\Delta(01^20)$, (*e*) and (*f*) $^2\Phi(02^30)$, and (*g*) and (*h*) $^2\Gamma(03^40)$.

revealed, with the order of selectivity: bend > anti-symmetric stretch > symmetric stretch. Third, the population in bending states decreases quite dramatically with increasing excitation. Fourth, within each bending excitation there is a strong propensity for the formation of the unique levels, and the only non-unique Renner–Teller components that have significant population to be detected are those with Σ vibronic symmetry.

In Fig. 11 is plotted the observed spin-orbit propensity for the unique levels. There is a clear preference for the lower spin-orbit component with this preference decreasing slightly as the internal vibronic energy increases. The energy difference between spin-orbit components is much smaller than the available reaction exothermicity, and if they were populated statistically in reaction [1], the ratio would be one. Note that the ratio of 2.45 for the $^2\Pi(00^10)$ ground vibronic state is in excellent agreement with that obtained from the rotational state distribution measurement. For the non-unique levels (i.e., Σ vibronic states), however, the more energetic spin-orbit component is favored by approximately a factor of two, as can be seen in Fig. 11.

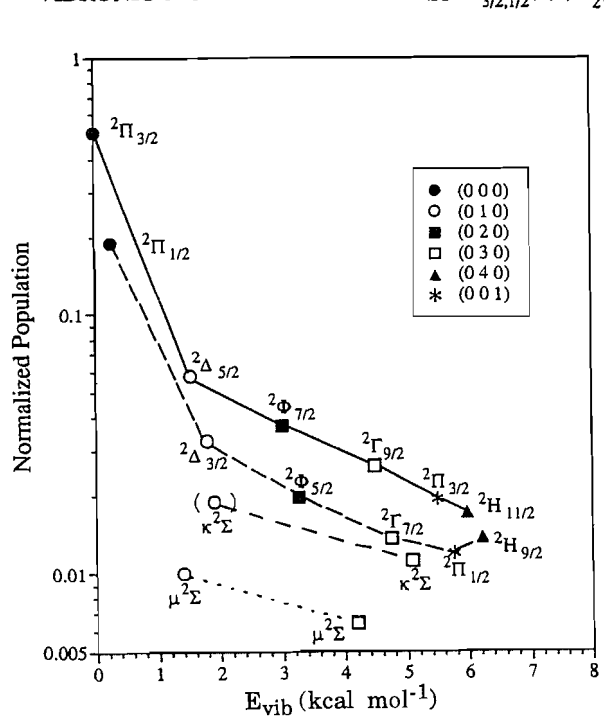

FIG. 10. The complete vibronic state distribution of those manifolds that were detected in this work measured at an E_0 of 0.8 kcal mol^{-1}. The parentheses indicate only a tentative estimate for $\kappa^2\Sigma$ population, see text. Note that the ground vibronic state accounts for 70% of the NCO reaction product from reaction [1].

C. *Excitation function*

In a previous publication (17) the excitation function for the ground vibronic state, $^2\Pi_{3/2}(00^10)$, was reported. That measurement was carried out by fixing the probe laser wavelength at the bandhead peak while the translational energy was varied. The monitored product states, thus, have *J* values ranging from approximately 10.5 to 16.5. Alternatively, one can do a short wavelength scan over the bandhead region at each energy to cover the complete *J* populations and to eliminate the possible change in bandhead shape as the energy changes. The results of these measurements are shown in Fig. 12(*a*) for both $^2\Pi_{3/2}(00^10)$ and $^2\Pi_{1/2}(00^10)$ states. The excitation function for the $^2\Pi_{3/2}(00^10)$ state is in good agreement with the previous peak-height determination, indicating no dramatic change in *J* distributions with an increase in translational energy. In the bottom panel of Fig. 12 is shown the translational energy dependence of the ratio of the cross sections of the spin-orbit states, $^2\Pi_{3/2}$ to $^2\Pi_{1/2}$. A nearly constant propensity was observed over the energy range from 0.7 to 7 kcal mol^{-1}. The average value of 2.4 is again consistent with the other two independent determinations, as alluded to earlier.

A similar determination could be made for the unique levels of the first excited bending manifold, $^2\Delta_{5/2,3/2}(01^20)$. To improve the statistical uncertainties this measurement was done using the peak-height approach, and the result is shown in Fig. 13(*a*). As can be seen, the cross section for producing $^2\Delta_{5/2,3/2}(01^20)$ has almost the identical translational dependence as that for the ground vibronic manifold. Shown in Fig. 13(*b*) is the translational energy dependence of the ratio of the cross sections $^2\Delta_{5/2}$ to $^2\Delta_{3/2}$. Similar to the ground vibronic level, Fig. 12(*b*), this ratio is nearly constant over this energy

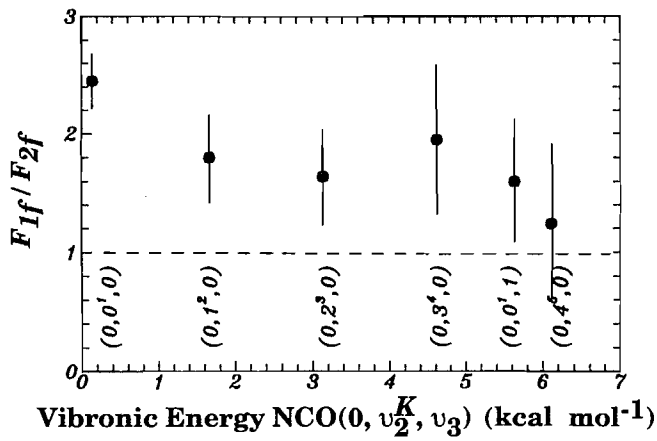

FIG. 11. Final product state distribution for spin-orbits states of NCO for an E_0 of 0.8 kcal mol^{-1} vs. internal energy. The vertical lines are the uncertainty in the data of $\pm 2\sigma$. Only the branches observed are plotted with the levels denoted by F_{1f} (the lower energetic state) and F_{2f} (the upper state), see Fig. 2. Note the apparent decrease in the preference for the lower energetic spin-orbit state as the product vibronic energy increases.

range, but the lower spin-orbit component is favored by a factor of 1.9, slightly smaller than that for the ground vibronic manifold. Again, this ratio is in good agreement with the independent measurement reported in Fig. 10.

4. Discussion

A. *Comparison with kinetic rate constants*

As mentioned in the Introduction, it has only been over the past few years that the thermal rate constants for reaction [1] have been measured reliably over a wide temperature range by several groups (4–7). The reported negative temperature dependence (though in a non-Arrhenius form) of the thermal rate constants was conjectured to be typical of radical–radical reactions possessing little or no barrier to reaction. Stoecklin et al. (23) recently applied a rotationally adiabatic capture theory, combined with various sudden approximations, to calculate rate constants and their temperature dependence for reaction [1]. In their approach, the reaction rate is determined by "capture" arising from the long-range interaction between the dipole moment of CN and the quadrupole moment of O_2. The calculated rotationally selected rate constants, $k_j(T)$, were found to increase with increasing temperature but decrease significantly with increasing j at a given temperature, T. As a result of this very strong sensitivity of $k_j(T)$ to j, the overall thermal rate constant exhibits a negative temperature dependence. When compared with the experimental results, however, the calculated values display a more gradual temperature dependence. For example, the calculated value at 26 K of $\sim 0.9 \times 10^{-10}$ cm^3 molec^{-1} s^{-1} is in excellent agreement with the experimental value of 1.08×10^{-10} cm^3 molec^{-1} s^{-1}. However, at room temperature the theoretical value is ~ 5 times greater than the experimental one. Stoecklin et al. (23) suggested that this discrepancy is likely due to the short-range chemical interactions or nonadiabatic electronic transitions involved in this reaction. Indeed, this suggestion has received considerable support from a more recent calculation (10) based on a "realistic" *ab initio* potential that fully incorporates the short-range interactions. By using a version of variational RRKM theory on this potential, Klippenstein and Kim (10) were able to decrease the discrepancy by a factor of approximately two. Although two different theories were employed to calculate the rate constant for reaction [1], both calculations dealt with only the rate of association between CN and O_2 so that they are only sensitive to the features of the potential energy surface in the entrance channel.

The observed negative temperature dependence of the ther-

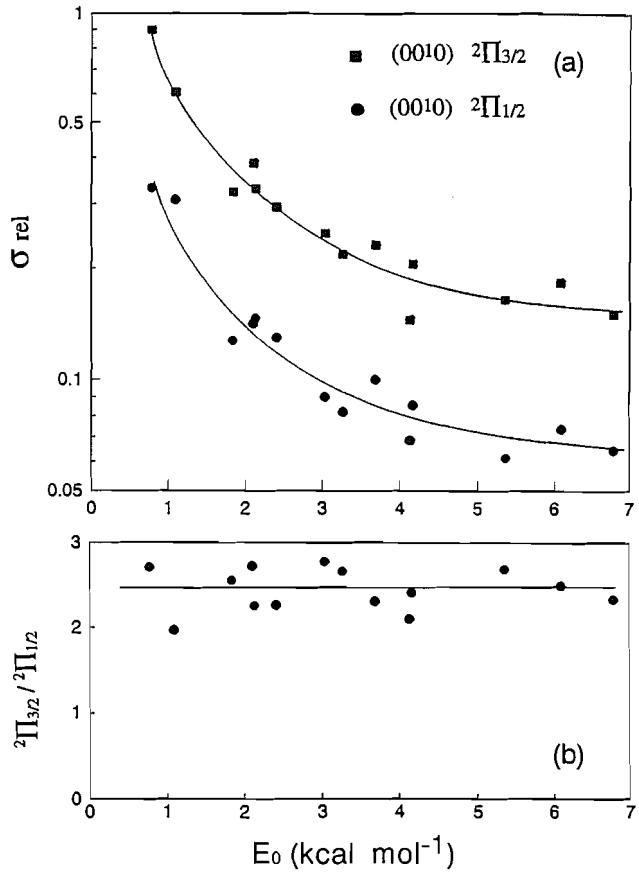

FIG. 12. (*a*) Excitation function for $^2\Pi_{3/2}(00^10)$, ■, and $^2\Pi_{1/2}(00^10)$, ●, manifold NCO produced in reaction [1]. Panel (*b*), ratio of the cross sections for the production of $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$ of the ground vibronic state vs. E_0. The preference for the lower energetic spin-orbits state is independent of initial energy.

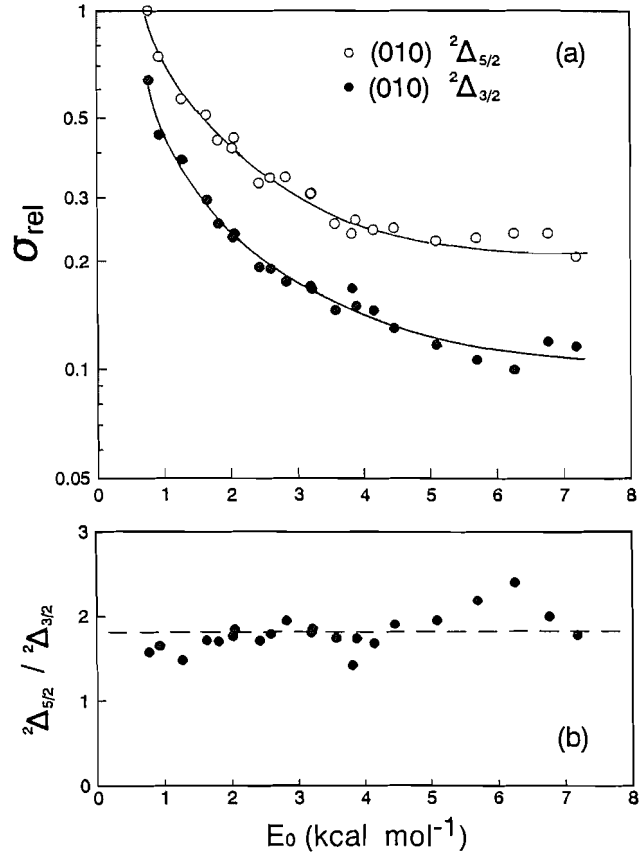

FIG. 13. (*a*) Excitation function for the unique Renner–Teller components, (○) $^2\Delta_{5/2}(01^20)$, and (●) $^2\Delta_{3/2}(01^20)$ for NCO produced in reaction [1]. Panel (*b*), same as Fig. 12, except ratio $^2\Delta_{5/2}$ and $^2\Delta_{3/2}$ of (01^20) is plotted. Note that the preference for the lower energetic spin-orbit manifold is slightly smaller upon bending excitation.

mal rate constant is in qualitative accord with the rapidly decreasing excitation functions found in this work, Figs. 12 and 13. More quantitative comparison can be made by noticing that the general shape of the excitation function shows no sign of a reaction barrier even at E_0 as low as 0.7 kcal mol^{-1}. Moreover, the vibronic-resolved cross sections shown in Figs. 12 and 13 exhibit the same dependence on translational energy, and these four states account for nearly 80% of the final NCO product state distribution. The cross sections, σ, shown in Figs. 12 and 13 have a functional dependence of E_0 of $\sigma \propto E_0^{-1}\exp(0.0323E_0)$, and it is anticipated that the total reaction cross section to produce all product states will behave in a similar fashion. Using this analytic expression and averaging it over a Boltzmann translational energy distribution, the temperature dependence of a molecular beam derived thermal rate constant was determined. These results and the available thermal rate constant data are summarized in Fig. 14. The molecular beam derived rate constant was arbitrarily normalized to the 298 K data of Durant and Tully (4). Considering that this comparison is made over such a wide range of the temperature, from 26 K to 3800 K, the overall agreement between the molecular beam data and the thermal rate constant data is quite gratifying and remarkable. Even at the low- and high-temperature ends, the deviations are no more than 50%. At the low-temperature end, the deviation could easily arise from an imprecise extrapolation of $\sigma(E_0)$ from the beam results. At the high-temperature end, the small difference may reflect an increasingly important role of channel [2] because the overall reaction rate constant for removal of reactants is measured in thermal experiments, whereas only the NCO + O product channel was monitored in the beam experiments.

The near-perfect agreement between thermal rate constant measurements and the beam-derived rate constant, shown in Fig. 14, provides compelling evidence not only that channel [1] dominates the overall reaction rate constant, but also that the negative temperature dependence for this reaction is entirely determined by the translational energy dependence of the reaction cross section for the lowest few reactant rotational states. It is instructive to examine this comparison more closely. Under molecular beam conditions the initial rotational state distribution of CN ($^2\Sigma^+$) was measured to have 90% of the CN radicals in the lowest two rotational states, Fig. 1. Similarly, the O_2 molecule is expected to be rotationally cold, although the rotational state distribution was not measured. This should be contrasted with the thermal situation where many rotational states of the reactants are populated and the distribution shifts dramatically towards higher values j with increasing temperature. Without losing generality let us consider the state-specific rate constant for a single rotor. The thermal rate constant, $k(T)$, can be expressed as a sum over the rotational state-specific rate constant, $k_j(T)$, weighted by the corresponding population factor, $P_j(T)$, i.e.,

$$[4] \quad k(T) = \sum_j P_j(T)k_j(T)$$

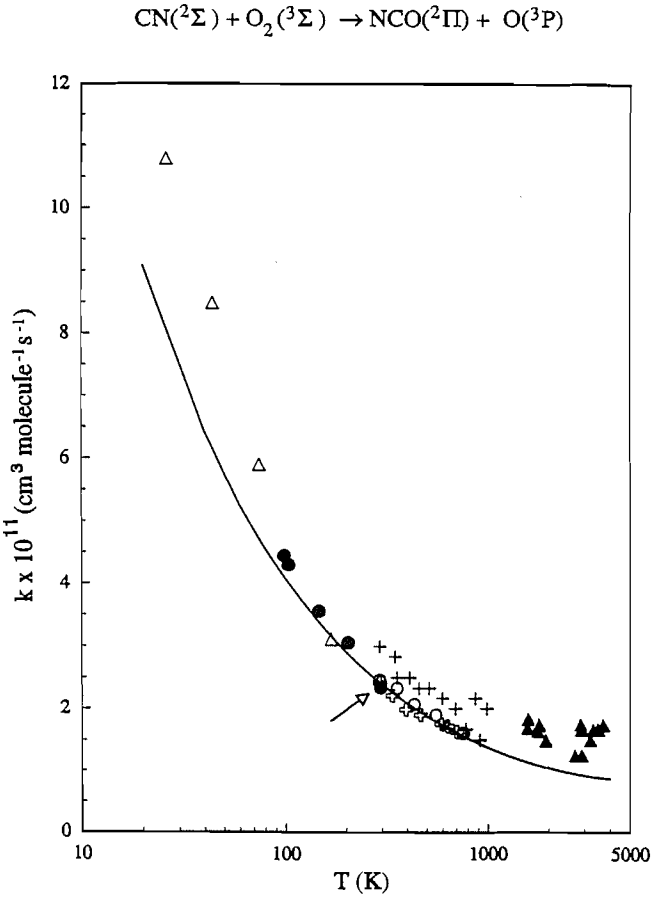

FIG. 14. A comparison of a Boltzmann averaged excitation function, Figs. 12(*a*) and 13(*a*), for essentially CN ($J = 0$) and O_2 ($J = 1$) reactants with available thermal rate constant data: (Δ) Sims et al. 5 (*c*); (●) Sims and Smith, 5(*b*); (⌖) Sims and Smith, 5(*a*); (○) Durant and Tully (4); (+) Atakan et al. (6); and (▲ Davidson et al. (7). Solid line thermal rate constant derived from fit to excitation function, this work (see text). The arrow indicates where the molecular beam derived rate constant was normalized to the kinetic data.

This may be rearranged to factor out the Boltzmann-averaged molecular beam derived rate constant, $k_{j=0}(T)$, as

$$[5] \quad k(T) = k_{j=0}(T) \sum_j P_j(T)(k_j(T)/k_{j=0}(T))$$

The excellent agreement in the temperature dependencies between $k(T)$ and $k_{j=0}(T)$, as shown in Fig. 14, implies that

$$[6] \quad \sum_j P_j(T)(k_j(T)/k_{j=0}(T)) \sim \text{constant}$$

Because $P_j(T)$ is simply the normalized Boltzmann factor for the rotational state j of the reactant, i.e., $\Sigma_j P_j(T) = 1$, it is very likely that $k_j(T)/k_{j=0}(T) \sim$ constant, or a near j-independence of rotational state-selected rate constant, $k_j(T)$, is implied. These implications are in sharp contrast to the above-mentioned predictions of the rotationally adiabatic capture theory. As will be argued later, the assumption of rotational adiabaticity may still be valid for this reaction. Hence, entirely consistent with previous theoretical suggestions (23), the failure of the adiabatic capture theory is likely caused by the dominance of short-range chemical interactions rather than long-range electrostatic forces in defining the transition-state region for this reaction.

B. Energy disposal and vibronic state distribution

A nearly complete characterization of the product state distributions was carried out in this study. Cold distributions were found for all internal degrees of freedom of the NCO product. Assuming a similar rotational state distribution for all vibronic states, as suggested by the LIF bandhead shape, the energy disposal into the NCO product is summarized as follows: $\langle f \rangle_{\text{elect.}} \sim 0.6\%$, $\langle f \rangle_{\text{rot.}} \sim 1.7\%$, $\langle f \rangle_{\text{bend}} \sim 5.5\%$, and $\langle f \rangle_{\text{asym.stretch}} \sim 1.3\%$. The remaining~91% of the available energy must then be channelled into O-atom internal states and (or) translational motion of the products. Energetically, only the ground electronic state, ^3P, of the O-atom is allowed. Even if all O-atoms from the reaction are produced in the highest spin-orbit state, $^3P_0$, there still remains ~85% of the available energy for the product translational degree of freedom. Such high specificity in energy disposal is very difficult to reconcile if the NCOO intermediate has a deep potential well with a small exit channel barrier. Under such circumstances, some degree of energy randomization would be expected.

In terms of vibronic state distribution, Fig. 10 reveals (as guided by the connecting lines) that, except for ground vibronic states, the population for a given spin-orbit or Renner–Teller component exhibits a near-exponential decline with the vibrational energy content of the NCO product. Furthermore, within a factor of two, the slopes of these exponential declines are roughly the same regardless of the nature of the final state components. The vibronic distribution for this reaction was also determined by two other groups using a pump-and-probe technique under bulb conditions. Sauder et al. (11) photolyzed C_2N_2 at 193 nm and probed the NCO product vibronic state distribution by LIF. Phillips et al. (9) used a very similar procedure, except that NCNO was photolyzed at 532 nm to generate the +CN radical. The latter technique prepares CN radicals with little internal excitation energy, while photolysis of C_2N_2 produces a rotationally and translationally hot CN reagent. In spite of the different methods of generating the CN radical, relaxation of rotational and translational degrees of freedom is assumed to occur more rapidly than CN reaction. The initial translational energy in the molecular beam experiments, $E_0 = 0.8$ kcal mol^{-1}, is very close to the mean kinetic energy available to 300 K reactants, so that all three studies, Sauder et al. (11) Phillips et al. (9), and this work should be comparable, at least as far as initial translational energy is concerned.

The results for the nascent unique level vibronic state distributions of the bending manifold are shown in Fig. 15 for all three studies. There is clearly a striking difference between the measurements from the beam and the bulb experiments. Substantially more excitation in the bending motion of NCO was found in the bulb experiments, even though there is only a qualitative agreement between their distributions. In the beam experiments it was found that bending excitation was the preferred mode and that the unique levels were always more populated. On the other hand, under bulb conditions, substantially more population was found in the non-unique levels of the bending excitations as well in the stretching modes. Thus, if the total vibronic state distribution (i.e., including all contributions for a given $(v_1 v^K 2 v_3)$ vibronic manifold) is examined, the difference between the beam and bulb results becomes even more dramatic. For example, nearly 70% of the NCO was found to be formed in the two spin-orbit states of the ground vibronic level in this work, while only ~3% was estimated under bulb conditions!

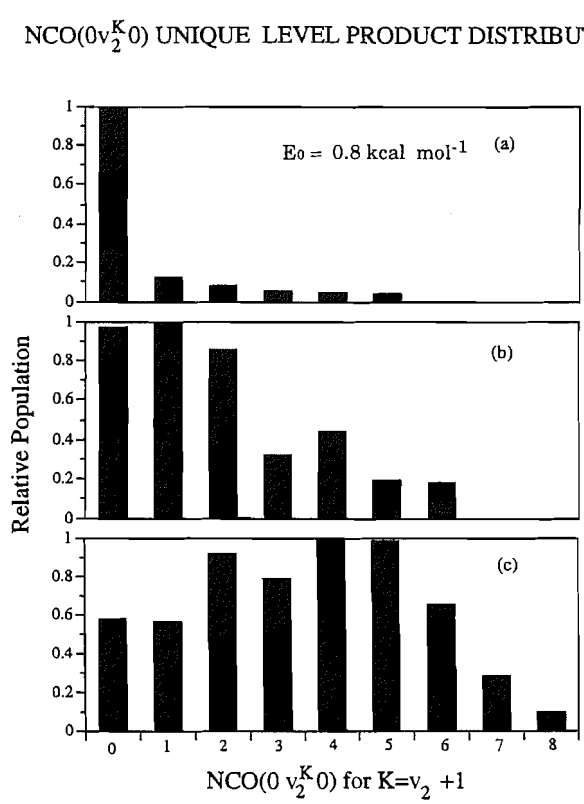

FIG. 15. A comparison of initial NCO unique level vibronic state distributions determined for reaction [1]. Top panel, this work; middle, Sauder et al. (11); and bottom, Phillips et al. (9). Note the dramatic difference in the molecular beam derived distribution for rotationally unexcited reactants and the bulbderived distribution for a "thermalized" rotational state distribution of both reactants.

Some of these discrepancies could arise from the different ways of extracting the population information from LIF spectra. Based on available spectroscopic data, Sauder et al. (11) calculated NCO $A \leftrightarrow X$ vibronic band strengths and used these results to deduce population distributions. On the other hand Phillips et al. (9) assumed that the bandhead intensities of the unique levels could be used to directly determine their populations. A similar assumption was made in this work; however, here the LIF spectra were taken under near-saturated conditions to ensure their validity. Judging from the reported vibronic band strength values and the data from dispersed fluorescence measurements,[3] only a minor deviation is anticipated between the two population-extraction approaches. This anticipation is also consistent with the appearance of the reported LIF spectra, Fig. 9 of this work, Fig. 3 of ref. 9, and Fig. 7 of ref. 11. A second problem concerns the extent of relaxation in the bulb experiments. Two kinds of vibronic relaxation can take place. First, there are collision-induced intermixing processes among the spin-orbit and Renner–Teller components in a given bending vibronic manifold. A recent study (24) of the inelastic scattering of NCO + He in this laboratory clearly demonstrated that these intermixing processes are highly selective and can be as efficient as rotational relaxation. Thus, these rapid processes could distort the vibronic component populations within a given vibrational manifold under bulb conditions. Second, there are collisional relaxation processes that change vibrational quantum numbers, i.e., the typical V–V and V–(R,T) processes similar to those for closed-shell molecules. These processes were examined in the bulb experiments by monitoring the temporal profiles of the LIF signals as a function of the time delay between the pump and probe lasers. The estimated relaxation rate constants, on the order of 10^{-13} cm^3 molec^{-1} s^{-1}, are consistent with those obtained for NCO + noble gases from an independent study (25). Thus, it appears that although the relative populations among the spin-orbit and Renner–Teller components could be partially equilibrated in the bulb experiments, the overall vibronic distribution should still largely reflect the nascent one. Yet, as shown in Fig. 15, the bulb experiments yielded much hotter distributions than the beam results.

The origin of these differences is quite intriguing. It can be reconciled if there is a strong dependence of the NCO vibrational distribution on the initial CN and (or) O_2 rotational states, as has been discussed in previous work (9, 11). Briefly, this strong dependence on reactant rotational states could arise from an adiabatic correlation between the bending excitation in the NCO product and the rotations of the reagents. Adiabaticity implies a retention of quantum state throughout a reactive collision. A low (high)-j reagent will then transform into a low (high) excitation in the bending motion of the product. A similar concept was also introduced in a recent theoretical calculation by Clary (26) on a diatom + diatom reaction system, H_2 + OH $\rightarrow$ H_2O + H. In these quantum scattering calculations it was found that there was a strong correlation between the spectator rotor, OH(j) in this case, and H_2O bending excitation. This observation was rationalized by a Franck–Condon projection of the bending motion of H_2O onto the rotational quantum states of the spectator diatom, OH. Clary noted that this correlation could be a unique feature, and quite general for many other diatom + diatom systems. It appears that the comparison of NCO vibronic distributions from the beam and the bulb studies provides an excellent experimental example of this prediction. From this view, the difference in vibronic bending excitation reported in the two bulb experiments may well arise from slight differences in the initial rotational state distribution of CN, the spectator rotor. Again, if the NCOO intermediate involves a long-lived complex, such strong adiabaticity would be lost due to strong couplings of the internal motions in the complex.

The above-mentioned adiabatic correlation is intimately related to the more familiar concept of vibrational adiabaticity often encountered in reaction dynamics (27). In the case of a simple A + BC system, there is the notion of a vibrationally adiabatic barrier to the reaction in interpreting the effect of reagent vibrational excitation on the reaction dynamics, as well as the use of vibrationally adiabatic transition-state theory analysis for rate constant calculations (28). In the case of AB + CD (or A + BCD) vibrational adiabaticity has also been invoked for describing the spectator bond (or mode specificity in the triatom). In these cases adiabaticity involves the "conserved" vibrational motion, which is only weakly coupled to the reaction coordinate and consequently exhibits little change in character, e.g., bond length and frequency, throughout the reaction process, or at least during the motion up to the transition state. One intriguing aspect of the present reagent-rotation to product-bend correlation is the large disparity in their energy content as rotational quantum states evolve through bending motions in the transition state and then finally transform into product-bending states. This situation bears some resemblance to the well-known correlation found in direct photofragment processes (29), in which the rotational distribution of the diatom fragment is often found to be strongly correlated with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by EESC ESCOLA DE ENGENHARIA on 09/08/12
For personal use only.

bending motion of the parent molecule. However, this half-collision correlation arises from the sudden nature of the Franck–Condon projection of the optical transition and the limit of negligible exit channel effects. In this spirit, one would perhaps expect that for a chemical reaction such adiabaticity between reagent rotation and product bend may not be strong enough to survive at all due to the forces involved in the chemical transformation and the smallness of rotational energy spacings. Evidence gathered thus far, however, points to the opposite finding, at least, for the spectator rotor. Clearly, weak anisotropies of the interaction potential with small barriers in both the entrance and exit channels will be the prerequisites for the existence of such a correlation. More importantly, this interpretation, if correct, will have significant implications for future studies of polyatomic reaction dynamics. It should at least send a cautious warning when one tries to infer the transition state geometry and (or) potential energy surface from product rovibrational state distributions for a polyatomic reaction system, a usual practice in the study of a typical A + BC reaction.

C. Spin-orbit and Renner–Teller propensities

Under beam conditions, within a given bending excitation the unique levels are always preferentially populated, as is evident from Fig. 10. The unique levels are so called because the electronic orbital angular momentum is largely unquenched (30) and still strongly coupled to the, now nonlinear, internuclear axis, even though the bending vibration is excited. As a consequence, electron spin can readily couple to Λ, the projection of electronic orbital angular momentum on the internuclear axis, and the spin-orbit interaction is retained. For all other Renner–Teller components Λ is no longer a good quantum number and the spin-orbit interaction is quenched. In other words, Renner–Teller and spin-orbit interactions are two competing forces. It is speculated that the observed propensity for unique levels may be the imprint of a linear geometry for the NC··O backbone in the transition state, because it is in this region that the electronic configuration for the NCO product is established. It is gratifying to note that this speculation is in accord with a recent *ab initio* calculation (10), as well as with a simple molecular orbital picture outlined in ref. 11. Due to the competing nature of spin-orbit and Renner–Teller interactions, at higher bending excitations the Renner–Teller interaction will prevail and the strength of the spin-orbit interaction will weaken. Thus, the spin-orbit propensity is anticipated to diminish with increasing bending excitation. This expectation is nicely borne out in Fig. 11, in which a statistical spin-orbit ratio is approached at higher bending excitations. The *ab initio* results (10) also predicted a C—O—O angle to be ~115°; however, a bent NCO··O structure is not inconsistent with the cold rotational and bending distributions observed in this study. The *ab initio* calculations (10) revealed that as the reaction proceeds the CO bond formation is accompanied by a gradual dissolution of the O_2 bond. As a result, only a small torque is expected to be exerted on the NCO product by a nonimpulsive departure of the O atom.

5. Conclusion

The reaction of $CN + O_2 \rightarrow NCO + O$ has been studied under crossed-beam conditions. A nearly complete characterization of energy disposal and excitation functions has been reported. Through extensive comparisons with previous kinetic and dynamic studies a clearer picture of this reaction has emerged. It is a barrierless radical–radical reaction. The attractive nature of the potential in the entrance channel results in a rapid decrease in reaction cross sections with increasing translational energy. This in turn leads to a negative temperature dependence of the thermal rate constant. The near j-independence of state-specific rate constants implies a weak anisotropy in the entrance channel. The association of CN and O_2 forms, at most, a weakly bound collision intermediate, which has little influence on the reaction dynamics. As a result, the reaction behaves more like a direct O-atom abstraction process. This is in sharp contrast to a typical radical–radical reaction, in which a deep potential well is usually involved, resulting in complex formation with the reaction proceeding via successive bond-forming, bond-breaking processes. A strong correlation between CN rotation ("spectator" rotor) and NCO bending excitation was conjectured. Weak anisotropies of the interaction potential with small or no barriers in both the entrance and exit channels are the necessary conditions for such an adiabatic correlation. This finding is believed to be generic and should have significant implications in our further understanding of polyatomic reaction dynamics in general. For example, will the concept of a rotationally adiabatic transition state be essential in our theoretical description of reaction kinetics/dynamics? Many of the fine-structure propensities observed in this work are not yet fully understood, e.g., the K-doublet propensity, the preferences for spin-orbit components and non-unique levels (i.e., $\Sigma >$ the others)? Further theoretical developments in this area will be needed.

Molecules in strong laser fields: vibrational inversion and harmonic generation

ERIC E. AUBANEL AND ANDRÉ D. BANDRAUK[1]

Laboratoire de chimie théorique, Faculté des sciences, Université de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada

Received July 2, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

ERIC E. AUBANEL and ANDRÉ D. BANDRAUK. Can. J. Chem. **72**, 673 (1994).

We examine two consequences of the unique behaviour of molecules in strong fields. First, by time gating of laser-induced avoided crossings with femtosecond laser pulses, one can obtain efficient vibrational inversion into a narrow distribution of vibrational levels of a molecular ion. We demonstrate this by numerical solution of the time-dependent Schrödinger equation for H_2^+. Second, we show results of numerical calculation with vibrationally excited H_2^+ of harmonic generation up to the 11th order of an intense 1064-nm laser. We predict that competition of photodissociation can be minimized by trapping the molecule in high-field-induced potential wells, thus enhancing the high-order harmonic generation process. Furthermore, the harmonic spectrum can serve as a measure of the structure of these laser-induced potentials.

ERIC E. AUBANEL et ANDRÉ D. BANDRAUK. Can. J. Chem. **72**, 673 (1994).

On examine deux conséquences du comportement particulier des molécules dans un champ fort. En premier lieu, la provocation, à l'aide de pulsations laser de femtoseconde, d'un déclenchement intermittent des croisements évités par une induction au laser permet d'obtenir une inversion vibrationnelle efficace dans une distribution étroite des niveaux vibrationnels d'un ion moléculaire. On démontre cette affirmation par une solution numérique de l'équation de Schrödinger en fonction du temps pour le H_2^+. En deuxième lieu, on présente les résultats de calculs numériques avec du H_2^+ vibrationnellement excité d'une génération harmonique jusqu'au 11^e ordre d'un laser intense à 1064 nm. On fait la prédiction qu'il est possible de minimiser la compétition de la dissociation en piégeant la molécule dans des puits de potentiel de champ élevé et que l'on peut ainsi améliorer le processus de génération harmonique d'ordre élevé. De plus, le spectre harmonique peut servir à la mesure de la structure de ces potentiels induits au laser.

[Traduit par la rédaction]

1. Introduction

The study of molecules in strong fields is establishing itself as an important part of chemical physics, particularly because of its role in the control of photodissociation dynamics (see, e.g., ref. 1). Strong laser fields induce high-order multiphoton absorption and emission that can lead to the creation of field induced potentials (2). In this paper we will show how one can exploit field-induced potentials to obtain efficient vibrational inversion, and multiphoton absorptions to generate high-order harmonics of a 1-μm laser.

High vibrational excitation in a molecule is desirable either as a means to achieve selective dissociation of chemical bonds or to prepare selectively excited reactants. Over 30 years ago, J.C. Polanyi proposed an infrared laser based on vibrational excitation achieved by chemical reaction in the gas phase (3). Other ways to achieve high vibrational excitation include the climbing of the vibrational ladder using a frequency-chirped infrared laser pulse (4) and excitation via an electronically excited state with visible–ultraviolet lasers (stimulated emission pumping, SEP) (5). In the case of infrared-inactive molecules, the SEP method is required. This method is complicated, however, if the lifetime of the excited state is shorter than the interaction time with the laser needed to achieve complete inversion. If the electronically excited state is bound, one can use the STIRAP (stimulated Raman adiabatic passage) or counterintuitive method (6), where the order of the pump and Stokes lasers is reversed from the usual intuitive order. If the excited electronic state is repulsive, a special high-field method is necessary, as was recently examined in detail by us (7), so that stimulated emission becomes more rapid than dissociation.

In this paper we will summarize our method, which we call vibrational inversion via time gating of laser-induced avoided crossings, and present new results of high harmonic generation from vibrationally excited H_2^+. The latter will show interesting features of vibrational trapping via the laser-induced avoided-crossing mechanism.

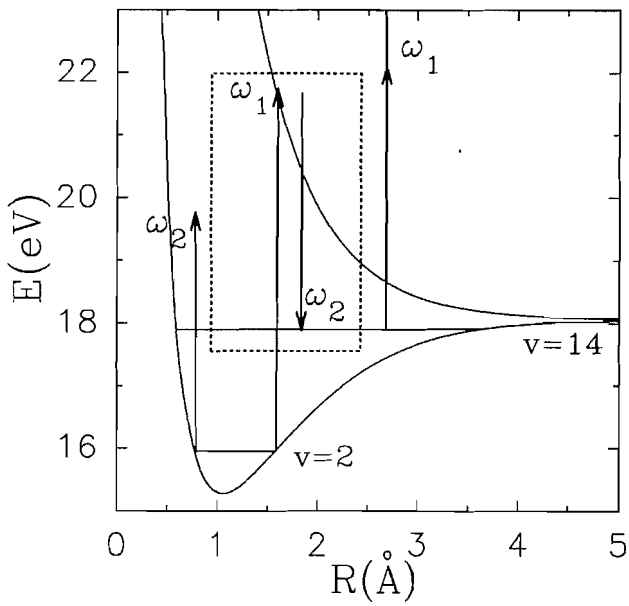

FIG. 1. Inversion scheme (inside dotted box) for H_2^+, starting from $v = 2$ and ending at $v = 14$, using two lasers of wavelengths $\lambda_1 = 213$ nm and $\lambda_2 = 320$ nm. Also shown are two one-photon nonresonant processes that can compete.

2. Vibrational inversion

Consider the problem of inverting the vibrational population of H_2^+ in its bound $^2\Sigma_g^+$ state. One must do so via the excited $^2\Sigma_u^+$ state. Figure 1 (inside dotted lines) illustrates the case for inver-

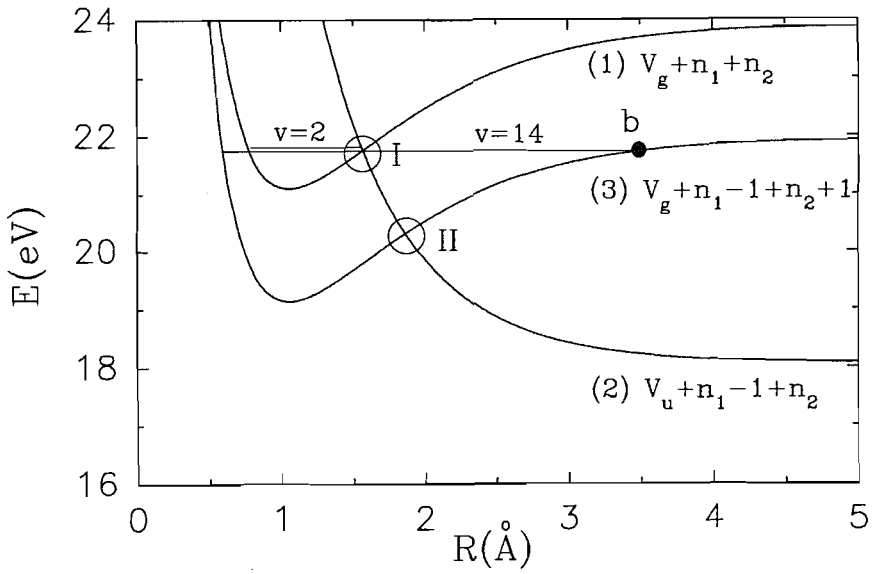

FIG. 2. Three-dressed-state representation of the excitation scheme of Fig. 1, showing crossing I due to laser 1 and crossing II due to laser 2.

sion from vibrational level $v = 2$ to $v = 14$ using lasers of frequencies $\lambda_1 = 213$ nm and $\lambda_2 = 320$ nm. If one simply applies laser 1 followed by laser 2, most of the excitation is lost as photodissociation. The same thing happens if one applies the lasers in the reverse order, unlike the situation in Na_2 (6) where the excited electronic state is bound, unless the laser intensities are high enough. The reason for this is evident when one considers the dressed states of the molecule–field system (Fig. 2) (1): (*i*) $V_g + n_1\hbar\omega_1 + n_2\hbar\omega_2$, where population initially resides; (*ii*) $V_u + (n_1 - 1)\hbar\omega_1 + n_2\hbar\omega_2$; and (*iii*) $V_g + (n_1 - 1)\hbar\omega_1 + (n_2 + 1)\hbar\omega_2$. The second state corresponds to absorption of one photon ω_1 and the third state to subsequent emission of one photon ω_2. Curve crossings I and II due to lasers 1 and 2, respectively, become avoided crossings as each laser is turned on, through the field–molecule coupling:

$$[1] \quad \hbar\Omega_i(\text{eV}) = 1.45 \times 10^{-7} \sqrt{I_i\,(\text{W/cm}^2)}\ \mu\ (\text{a.u.})$$

where Ω_i is the Rabi frequency of laser i ($i = 1, 2$), I is the laser intensity, and $\mu = eR/2$ is the electronic transition moment (8). Note that we do not take into account rotational excitation, so we place the molecule parallel to the laser polarization.

One can see from Fig. 2 how the counterintuitive method might work: first turn on laser 2 so that crossing II is adiabatic (1) (i.e., the crossing probability between the two field–molecule states is high), then turn on laser 1 to release the initial vibrational wave function through crossing I, and finally turn off both lasers before the wave packet returns to the initial state after hitting turning point *b*. This leaves H_2^+ in the ground state at $v = 14$. For crossing II to be adiabatic, laser 2 must be very intense ($>10^{13}$ W/cm^2). Laser 1 must be intense as well, to dissociate all of the initial wave function in a time shorter than the return time from turning point *b*.

The discussion in the previous paragraph has only taken into account resonant transitions (inside the dotted line, Fig. 1). At the high intensity required to make crossing II adiabatic, the initial $v = 2$ state can be nonresonantly photodissociated with laser 2. The solution that we propose to avoid this problem is to apply two simultaneous pulses. Competition with other multiphoton nonresonant processes leads to possible dissociative loss into two channels: a nonresonant low kinetic energy channel corresponding to net absorption of one photon of frequency ω_2 from $v = 2$, which dominates at high intensity, and a resonant high kinetic energy channel corresponding to net absorption of one photon of frequency ω_1 from $v = 2$, which dominates at low intensity. An optimum intensity can be found that minimizes dissociative loss in both channels (7). Figure 3 shows the final bound state population after application of two simultaneous pulses of wavelengths $\lambda_1 = 213$ nm and $\lambda_2 = 320$ nm, having a 10-fs rise to a 13-fs plateau at 2×10^{13} W/cm^2 followed by a 10-fs fall, to H_2^+ in $v = 2$, from numerical solution of the time-dependent Schrödinger equation assuming the molecule to be aligned with the field polarization and neglecting rotational excitation (7). Less than 20% dissociation and almost complete

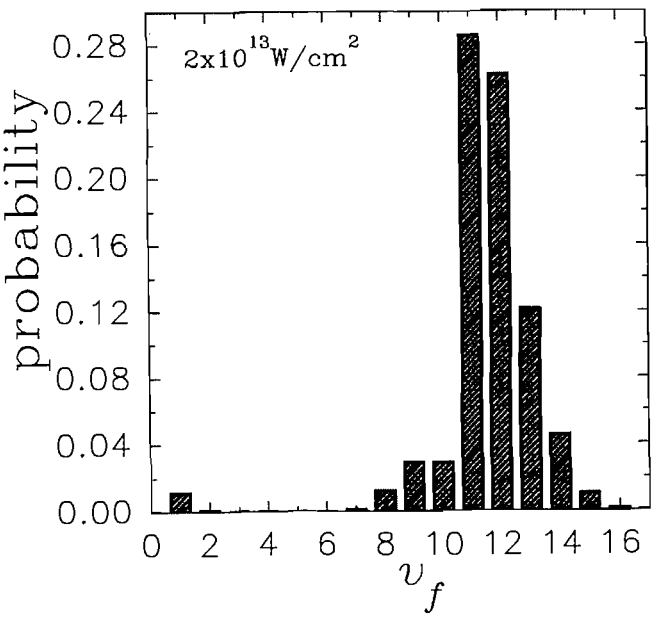

FIG. 3. Final vibrational populations of $^2\Sigma_g^+$ state from exact calculations of rotationless H_2^+ initially in $v = 2$, for two simultaneous pulses of wavelengths $\lambda_1 = 213$ nm and $\lambda_2 = 320$ nm, having a 10-fs rise to a 13-fs plateau at 2×10^{13} W/cm^2 followed by a 10-fs fall. The total final ground state population is 0.81.

inversion of the remaining bound population occurred into a distribution centered around $v = 11$. Inversion into $v = 14$ alone did not occur, owing to the large dynamic Stark shifts resulting from the high intensities used. We have also shown in ref. 7 that rotational excitation increases slightly the dissociative loss and broadens the distribution of excited vibrational levels.

Thus we have exploited the concept of laser-induced avoided crossings (Fig. 2), necessary to interpret high-field effects, to control population inversion. We expect that heavier diatomic molecular ions, with less steep repulsive potentials and slower nuclei, would allow even better control. The increased electronic complexity of heavier molecules would not pose a problem if resonant transitions were used, and if the two desired electronic potentials were linked by a particularly large transition moment, as is the case for charge-transfer transitions (9, 10).

3. Harmonic generation

One of the features of strong laser fields is their ability to induce a nonlinear response in atoms and molecules:

$$[2] \quad \mu^{ind}(t) = \alpha\, E(t) + \beta\, E(t)^2 + \gamma\, E(t)^3 + \ldots$$

where μ^{ind} is the induced dipole, $E(t)$ is the applied field, and α, β, and γ are the first-, second-, and third-order polarizabilities of the atom or molecule. For centrosymmetric systems such as H_2^+, one expects only odd-order polarizabilities ($\alpha,\gamma,\ldots$) to contribute. Even-order polarizabilities ($\beta,\ldots$) can only occur in symmetry broken systems (11). At laser intensities of the order 10^{13} W/cm^2 and higher, the response of the system becomes highly nonlinear, i.e., many terms in eq. [2] become large. For sinusoidal time-dependent fields, one can see that the second term in eq. [2] will produce oscillations of μ^{ind} at twice the laser frequency (second harmonic), the third term will produce oscillations at three times the laser frequency (third harmonic), and so on (11). The study of harmonic generation in atoms in intense fields has been actively studied in recent years (see, e.g., ref. 12), and now attention is being focused on molecules. Molecular ions in particular have been the focus of attention (9, 10) because of their charge resonance states, which couple very strongly to electromagnetic fields (transition moments proportional to $R/2$ (8); see eq. [1]).

The induced dipole in H_2^+ can be evaluated from a time series of the nuclear wave functions χ_g and χ_u obtained from numerical solution of the time-dependent Schrödinger equation. The induced dipole is obtained by evaluating the expectation value of the electronic coordinate along the laser polarization (z); here we use a double electronic state ($^2\Sigma_g^+$ and $^2\Sigma_u^+$) representation of H_2^+ and ignore rotation:

$$\begin{aligned}[3] \quad \mu_{H_2^+}^{ind}(t) &= \langle \chi_g(R,t)\, \phi_g(r,R) + \chi_u(R,t)\, \phi_u(r,R)\, |z|\, \phi_g(r,R) \\ &\quad \times \chi_g(R,t) + \phi_u(r,R)\, \chi_u(R,t) \rangle \\ &= 2\mathrm{Re}\langle \chi_g(R,t)\, \phi_g(r,R)\, |z|\, \phi_u(r,R)\, \chi_u(R,t) \rangle \\ &= \mathrm{Re}\langle \chi_g(R,t)\, |R|\, \chi_u(R,t) \rangle \end{aligned}$$

where r and R are the electronic and internuclear coordinates, respectively.

Before we proceed we should address three possible processes that could compete with harmonic generation in molecules: photoionization, photodissociation, and rotational excitation. The first is partly circumvented by the choice of molecular ions, which have higher ionization potentials than their parent neutral molecules. Calculations show that the ionization rate for H_2^+ exceeds 10^{13} s^{-1} for intensities greater than 10^{14} W/cm^2 (13). The competition between ionization, photodissociation, and harmonic generation is the subject of ongoing study by our group. We will address here only the competition of photodissociation with harmonic generation. The effect of rotation will be the subject of an upcoming publication (14).

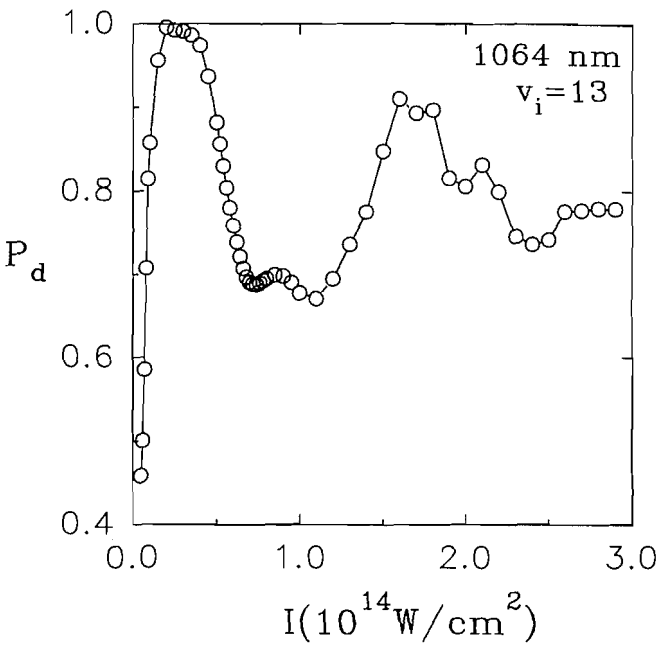

FIG. 4. Photodissociation probability from initial level $v = 13$, $\lambda = 1064$ nm, and 30-cycle pulse with 5-cycle linear ramp.

Numerical calculations have shown that molecular photodissociation can be stabilized in the presence of strong laser fields, owing to trapping in laser-induced bound states (1, 2, 15–18). An example of this is shown in Fig. 4, where the photodissociation probability P_d for H_2^+ starting in $v = 13$ and a laser wavelength of 1064 nm is shown as a function of peak intensity. The pulses used consisted of a 5-cycle linear ramp to a 25-cycle plateau (total time 106 fs). For details of the calculation, which employed a split-operator algorithm, refer to refs. 14–16. After a rise to complete dissociation, P_d goes through a series of minima, which can be attributed to trapping in laser-induced potential wells (14–16).

For our harmonic generation spectra we use a longer pulse of 200 cycles with the same 5-cycle linear ramp. The power spectra are calculated by Fourier transforming the dipole moment:

$$[4] \quad P(\omega_0 \nu) = \int_0^\infty \mu_{H_2^+}^{ind}(t)\, e^{i\omega_0 \nu t}\, \chi(t)\, dt$$

where ν is the harmonic order and ω_0 is the laser frequency; the function $\chi(t)$ is equal to one between 6 and 200 cycles, and zero otherwise; this reduces the noise in the spectra due to the turn-one of the pulse (10, 19). In Figs. 5 and 6 we show harmonic generation spectra at intensities of 7.4×10^{13} and 1.6×10^{14} W/cm^2, corresponding to a minimum and maximum in P_d (Fig. 4), respectively. In Fig. 5 one can see that split peaks at even and odd harmonics are produced up to 11th order. The even harmonics can be interpreted as odd harmonics that are split (Rabi splitting) by the strong laser field (9, 10). Alterna-

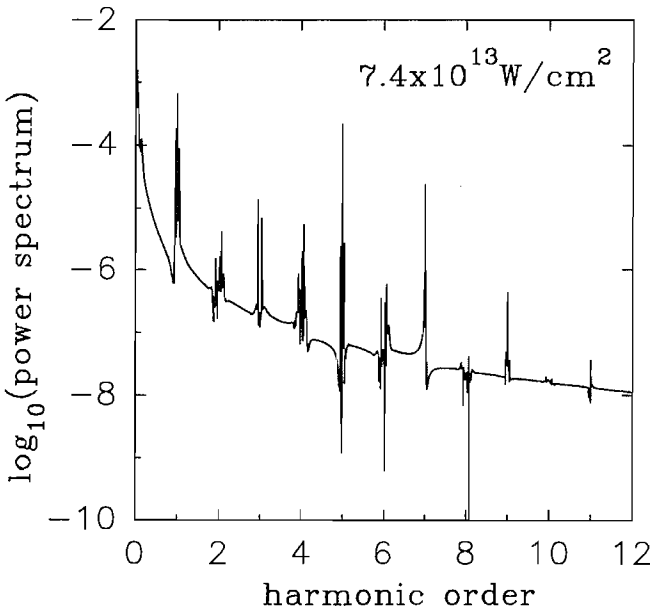

FIG. 5. Harmonic generation spectrum at 7.4×10^{13} W/cm^2, $v = 13$, and $\lambda = 1064$, and with 200-cycle pulse with a 5-cycle linear ramp, obtained from induced dipole moment (eq. [4]) from 6 cycles to end of pulse.

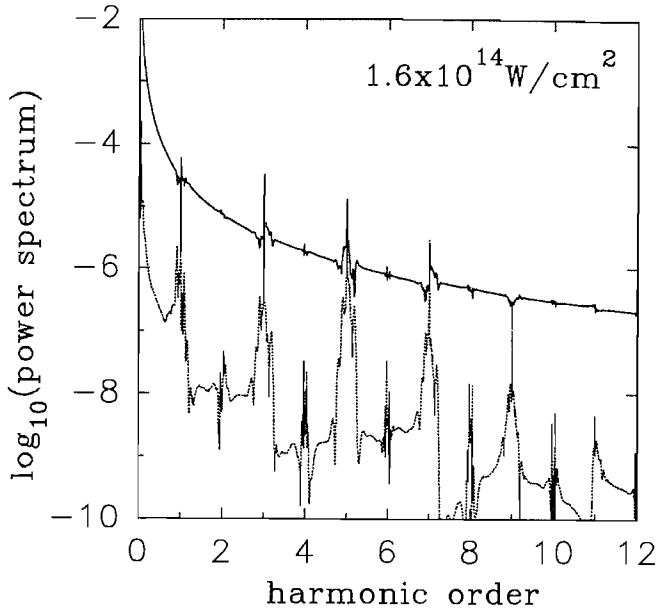

FIG. 6. Same as Fig. 5, except at 1.6×10^{14} W/cm^2 (solid line). Also shown is the result of subtracting the linear trend in the dipole moment before Fourier transforming to obtain the spectrum (dotted line).

tively, one can think of the field creating a symmetry-broken electronic state, $1\sigma_g + 1\sigma_u \propto 1s_{a(b)}$; i.e., the electron becomes localized on one atom on a femtosecond time scale; this will result in generation of even harmonics. This spectrum correlates very well with a simple two-level calculation with the internuclear distance fixed at 6 a.u. (the right turning point of $v = 13$) (10, 14); i.e., the relative efficiencies of the harmonics are well reproduced. Additional structure results from the nuclear motion that allows harmonic generation into several adiabatic vibrational levels, i.e., levels of the field- induced potential well (10, 14). From exact calculations (i.e., electronic motion treated exactly) on H_2^+ fixed at $R = 6$ au., it is observed that the molecular contribution, reproduced by the two-level model and the two-electronic state results shown here (minus structure due to vibrational motion), is separate from the atomic contribution that occurs at higher harmonic order (10).

The harmonic generation spectrum at 1.6×10^{14} W/cm^2 (Fig. 6, solid line) is nearly obscured by the background. The peaks that do appear are all less intense than those in Fig. 5. This contrasts with calculations based on H_2^+ with fixed nuclei, and with the two-level model, where higher order harmonic generation is obtained at higher intensity (10). The explanation lies in the competition between harmonic generation and photodissociation. We found that harmonic generation occurs only at short ($R < 5$ Å) internuclear distances, where the electronic states are nondegenerate. This is not surprising, since both from the point of view of perturbation theory, and from the high-field analytic solution of the two-level model, no harmonic generation can occur in a system of degenerate states (10). With this in mind, one can make the link between photodissociation and harmonic generation, namely, that more of the former means less of the latter. All that the photodissociating fragments contribute is a linear trend in $\mu_{H_2^+}^{ind}(t)$ that gives rise to the large background in the solid line in Fig. 6. The dotted line in the same figure shows the result of subtraction of this linear trend from the dipole moment before Fourier transforming to obtain the spectrum; the background is greatly reduced and a similar structure as in Fig. 5 is revealed, i.e., split peaks around even and odd harmonics, but much weaker in intensity. The interplay between photodissociation and harmonic generation should now be evident. At intensities where photodissociation is minimized, owing to trapping in laser-induced potentials, harmonic generation will be maximized and vice versa.

4. Conclusions

In this note we have shown that laser-induced avoided crossings, necessary to explain laser–molecule interactions in strong laser fields, can be exploited to achieve vibrational inversion into a narrow distribution of vibrational levels in diatomic molecules via a dissociative excited state. We then showed that vibrationally excited H_2^+ can generate harmonics up to 11th order of an intense, but less than 10^{14} W/cm^2, 1064-nm laser. Of course, harmonic generation could be produced from vibrationally relaxed H_2^+, but less efficiently, owing to a smaller transition moment ($\propto R/2$) and a larger number of photons needed to make the transition from the ground to the excited state. Harmonic generation from vibrationally relaxed H_2^+ with a higher frequency laser would be less efficient as well, since the intensity of a given harmonic depends inversely on the laser frequency (10), and competition from ionization would be more important. Finally, for harmonic generation to compete with photodissociation, laser-induced avoided crossings must be exploited to achieve stabilization of photodissociation. One sees that high-order (nonperturbative) harmonic generation can serve as an excellent diagnostic tool to probe intense field–molecule interactions and dynamics.

Matthews (1992) has proposed that HCN "polymer" is ubiquitous in the solar system. We apply vacuum deposition and spectroscopic techniques previously used on synthetic organic heteropolymers (tholins), kerogens, and meteoritic organic residues to the measurement of the optical constants of poly-HCN in the wavelength range 0.05–40 μm. These measurements allow quantitative comparison with spectrophotometry of organic-rich bodies in the outer solar system. In a specific test of Matthews' hypothesis, poly-HCN fails to match the optical constants of the haze of the Saturnian moon, Titan, in the visible and near-infrared, derived from astronomical observations and standard models of the Titan atmosphere. In contrast, a tholin produced from a simulated Titan atmosphere matches within the probable errors. Poly-HCN is much more N-rich than Titan tholin.

BISHUN N. KHARE, CARL SAGAN, W. REID THOMPSON, EDWARD T. ARAKAWA, CAROLINE MEISSE et PAGE S. TUMINELLO. Can. J. Chem. **72**, 678 (1994).

Matthews (1992) a suggéré que le HCN à l'état de polymère est omniprésent dans le système solaire. Dans ce travail, on applique des techniques de déposition sous vide et spectroscopiques utilisées antérieurement sur des hétéropolymères organiques de synthèse (« tholines »), des kérogènes et des résidus organiques météoritiques pour mesurer les constantes optiques du poly-HCN aux longueurs d'onde allant de 0,05 à 40 μm. Ces mesures permettent d'établir une comparaison quantitative avec la spectrophotométrie de corps riches en produits organiques dans le système solaire externe. Dans le cas spécifique de la vérification de l'hypothèse de Matthews, le poly-HCN ne concorde pas avec les constantes optiques de la brume de la lune de Saturne, Titan, dans le visible et le proche infrarouge qui ont été obtenues à partir d'observations astronomiques et de modèles standard de l'atmosphère de Titan. Par ailleurs, une tholine produite dans un atmosphère de Titan simulé concorde aux erreurs probables. Le poly-HCN est beaucoup plus riche en N que la tholine de Titan.
[Traduit par la rédaction]

1. Introduction

In a long series of papers, Clifford Matthews has argued that "polymeric" HCN may be readily formed in the solar system and may account for the dark surface coatings seen on many objects in the outer solar system. Specifically, claims are made for the dark involatile surface of the nucleus of Comet Halley, D-class asteriods, the rings of Uranus, the dark hemisphere of Iapetus, the orange-brown clouds of Jupiter and Saturn, and the haze of Titan (1–3).

Laboratory experiments have demonstrated that complex organic solids are readily formed by the action of UV light and (or) charged particles on atmospheres and icy surfaces containing simple carbon-bearing molecules. These heteropolymers are often generated by the participation of many chemical species, and mechanisms by which gas-phase species participate in forming the chemical structure of the solid have been proposed. Under more limited conditions, polymers may form from nearly pure starting materials — for example, UV light catalyzes the formation of "polyacetylenes" (polyethyne) in planetary atmospheres (4), and UV acting on solid ethyne in outer planet condensation hazes also produces polymeric residues.

Another widely discussed candidate for polymerization is HCN. While HCN is more often just one of many participating species in polymer formation (e.g., in the radiation chemistry of N_2–CH_4 atmospheres), "pure" HCN polymers are possible in principle. Whatever its chemical origin, the -C≡N (nitrile) group is important in organic residues in several types of solar system bodies: the 2.2 μm C≡N overtone band has been tentatively identified in the dust of "new" comets, on D-type asteroids, in the Uranian rings, and on the dark side of Iapetus (5). Matthews (6) claims that the polymerization of hydrogen cyanide is a universal process; CH_4 and NH_3 are simple cosmically abundant molecules that easily produce (7) HCN on irradiation with charged particles or UV photons; also, HCN is known to polymerize (8) in the condensed state or when irradiated as a gas, to "poly-HCN". The argument for "poly-HCN" rests on its alleged ease of formation and its dark color. No measurements of its optical constants have been made heretofore; no detailed comparison of laboratory and astronomical spectra has shown a best fit for "poly-HCN"; and no radiative transfer models have been used to compare laboratory optical constants of "poly-HCN" with the spectra of solar system bodies.

Generally, organic heteropolymers produced in astronomical environments where N atoms are available contain some nitrile component. Khare and Sagan (9) produced a brown organic solid by long-wavelength ultraviolet irradiation of abundant gases in reducing planetary atmospheres; the solid exhibits a 4.5 μm C≡N nitrile or isocyanide fundamental band. We proposed (9) that a heteropolymer containing nitriles and polynitriles may be a common constituent of aerosols in the outer solar system, and later coined the name tholin (10) for such complex materials. The 4.5 μm band was also found in tholin

made from equimolar amounts of CH_4 and NH_3 with 2.5% water vapor (11), and in Titan tholin (12) made from 90% N_2 and 10% CH_4.

In the identification, by Cruikshank et al., (5) of the 2.2 μm first overtone band of the C≡N fundamental in reflection spectra of several bodies throughout the outer solar system, the fit to tholins was at least as good as the fit to "poly-HCN". The two are far from being the same materials. At the very least, we can say that the 2.2 μm feature is not diagnostic of "poly-HCN". However, while we believe the C≡N bond in these materials usually arises from heteropolymers in whose formation HCN played at most only a part, pure "poly-HCN" provides an interesting end member of this class of organic solids.

Poly-HCN (henceforth, we drop the quotation marks) can be categorized (13) into three major forms: (*a*) true polymeric $(HCN)_n$, the repetition of the same monomeric unit *n* times; (*b*) HCN heteropolymer or oligomer (not polymer), which has the same rough abundance of organic functional groups producing roughly the same IR spectrum, but is not repetitive, especially in its hydrocarbon and other side chains; and (*c*) HCN aqueous solution polymer or oligomer, which contains oxygenated side chains and other components. These three different forms of poly-HCN need not have the same IR spectrum; e.g., form *c* does not exhibit the 4.5 μm C≡N absorption, or its corresponding 2.2 μm overtone. While HCN is an important minor species in some astronomical environments, it is hard to imagine atmospheres or ices in the solar system or beyond made of pure HCN, free of other components, and producing pure poly-HCN.

Laboratory experiments, done at Cornell University (14–16) and elsewhere, show that the gas- and solid-phase product molecules are diverse even in simulation experiments starting with only a few major precursor gases. We have found that tholin synthesized from a crude simulation of Jupiter is not pure poly-HCN but is a heteropolymer with a variety of moieties (13). The same conclusion is also drawn from the pyrolytic GC–MS results on this tholin as well as on Titan tholin (14, 15, 17); hundreds of pyrolytic products were detected in both tholins. But a diagnostic test is the comparison of laboratory optical constants of poly-HCN with optical constants derived from astronomical and spacecraft observations.

We previously (18, 19) applied the technique of thermal evaporation and successfully determined the optical constants of kerogen, the organic residue obtained from the Murchison carbonaceous chondrite, and ice tholin (made from charged particle irradiation of $C_2H_6/H_2O \sim 1{:}6$ at 77 K). Here we present results of measurements of the optical constants of poly-HCN in the form of thermally evaporated thin films.

Lunin et al. (20) have studied the properties of thin films of polyparacyanogen that, like poly-HCN, contains C≡N in its structure. They prepared a thin film by electron-beam evaporation in vacuum, a technique sometimes substituted for thermal evaporation in vacuum. They found that the preparation of thin films is very dependent on the structure of the original polymer. On the basis of the preservation of elemental (C, H, N) ratios and agreement of IR spectra of the original polymers and films, they conclude that electron-beam spray coating in vacuum leads to splitting of the macromolecules into low-molecular-weight fragments that completely preserve the chemical structure of the original polymer. These fragments, on deposition on the substrate, recombine to form macromolecules. Our experience with the vacuum evaporation technique applied to other organic residues indicates a similar preservation of the chemical character of the original material (18, 19).

2. Production of poly-HCN

2.1. Synthesis of HCN and poly-HCN

Hydrogen cyanide is readily produced by the action of electric discharges, high temperatures, or ionizing radiation upon a variety of reducing or nonoxidizing atmospheres. The yields are particularly high if electric discharges are applied. The type of atmosphere used for the source of H, C, and N atoms to produce HCN seems relatively unimportant until higher oxidation states are reached. Miller (21) produced HCN along with CO, CO_2, and N_2 from a mixture of CH_4, NH_3, H_2O, and H_2 after coronal discharge. Sagan and Miller (22), in an experiment crudely simulating the deep atmosphere of Jupiter, found HCN, CH_3CN, C_2H_2, C_2H_4, and C_2H_6 in a coronal discharge through a gas mixture containing H_2, CH_4, and NH_3, with H_2 in excess. Many subsequent experiments in neutral to reducing C- and N-containing gas mixtures also found HCN to be a major product. Cyanogen is routinely found in sunspots and in the photospheres of cool stars.

One of the common methods for preparing anhydrous hydrogen cyanide in the laboratory is by the action of sulfuric acid on sodium cyanide, potassium cyanide, or potassium ferrocyanide (23); for example,

$$[1] \qquad NaCN + H_2SO_4 \rightarrow HCN + NaHSO_4$$

In the Andrussow process, the major commerical method (24) for producing HCN gas, the reaction takes place between NH_3, CH_4, and air over a platinum catalyst at 1100°C:

$$[2] \qquad CH_4 + NH_3 + 1.5O_2 \rightarrow HCN + 3H_2O$$

Poly-HCN employed in our study was obtained from E.I. du Pont de Nemours & Co., Inc. Its infrared spectrum indicates that it is probably composed of a mixture of all three types of poly-HCN (13). Its IR spectrum is nearly identical to that of poly-HCN prepared by Matthews (see ref. 5).

Poly-HCN formation normally occurs in aqueous solution. It can also occur in anhydrous solvents, but requires a compound capable of creating CN^- ions in the solvent. Polymerization occurs readily when both CN^- and HCN are major components in solution, specifically, when $4.0 < pH < 10.5$. The rate of polymerization and the form of the final polymer will depend on the interactions with other species in solution. HCN does not polymerize in the vapor phase.

We obtained poly-HCN samples from two places in the du Pont manufacturing system. One sample came from piping immediately after the HCN production reactors. The products in reaction [2] are cooled to very near the dew point to remove water produced in the reaction. There are places in the piping where the gases are cooled locally to below the dew point and these aqueous droplets absorb some HCN and unreacted NH_3, which brings the pH into the polymerization range.

Another sample came from the purification train. Here HCN polymerizes from HCN in water with no additional solutes. The solutions are normally stabilized to pH <2 with an acid, but if HCN condenses in a spot where there is no acid, it will begin to polymerize and seed further polymerization. We used this poly-HCN sample collected from the walls of the purification line for optical constants measurements.

Völker (25, 26) proposes that poly-HCN is formed via imi-

noacetonitrile, which is a dimer of hydrogen cyanide and is considered to be formed by reaction between HCN and CNH according to a scheme known for the addition of isonitriles to nitriles:

[3] $HCN + CNH \rightarrow H-C(=N-H)-C\equiv N$

A recent study of HCN dimers was made by Evans et al. (27, 28). Some controversy over the structure of dimeric HCN is summarized by Ferris and Hagan (29). A detailed study of the mechanism of HCN polymerization has been given by Sanchez et al. (30), Ferris et al. (31), Ferris and Edelson (32), and Ferris (33).

2.2. *Properties of HCN and poly-HCN*

While HCN is a colorless, poisonous, low-viscosity liquid said to have an odor characteristic of bitter almonds, poly-HCN is a brown-black solid having hardly any odor, although a freshly prepared poly-HCN has a slight odor of the monomer and, occasionally, of ammonia (26). Poly-HCN is not known to have any toxic effects. Details on the synthesis and structure of poly-HCN were given recently by Matthews and Ludicky (34) and earlier by Völker (26).

HCN has a melting point of −13.24°C, a boiling point of 25.70°C, and a density 0.7150 g cm^{-3} at 0°C. It can polymerize violently in the presence of heat, alkaline materials, or moisture. Once initiated, polymerization becomes uncontrollable since the reaction is autocatalytic, producing heat and alkalinity (NH_3). Confined polymerization can cause a violent explosion.[3] This is part of the appeal of the proposal that cometary outbursts are due to HCN polymerization (35).

The density of poly-HCN was measured by determining the weight and volume of a 13 mm pellet of poly-HCN prepared by compressing du Pont poly-HCN powder at 1700 atmospheres. A density of 1.49 g cm^{-3} was obtained; this is a lower limit due to residual void space inside the pellet. The density of our evaporated films, prepared subsequently, was measured using the float and sink method (employing a series of varying density solutions made from CCl_4 and CH_3OH). This method yielded a value of 1.54 ± 0.005 g cm^{-3}. The density of unpressed fluffy du Pont poly-HCN powder, determined by helium pycnometry, gave a value of 1.620 ± 0.004 g cm^{-3}. This technique avoids error caused by void volume and should be taken as the best value for the density of du Pont poly-HCN.

The average value of the atomic composition of du Pont poly-HCN determined by Schwarzkopf Microanalytical Laboratory and Galbraith Laboratories, Inc. (after correcting for oxygen and hydrogen due to exposure of poly-HCN to 0.034% SO_2 and 0.026% H_2SO_4 used as a stabilizer for HCN gas in the du Pont manufacturing plant) is given in Table 1. The balance of the remaining large amount of oxygen in this kind of sample probably occurs from the interaction of the poly-HCN with H_2O during formation from the product stream. No correction for oxygen or hydrogen due to exposure of poly-HCN to water (or subsequent exposure to air) is made.

The sulfur, oxygen, and incremental hydrogen impurities are due to exposure of poly-HCN to sulfur compounds and water in the plant and, perhaps, to the air during storage of the poly-HCN. These impurities do not affect the measurement of the optical constants, since infrared spectra of the evaporated and redeposited film of poly-HCN at 800 K agree with those of the anhydrous poly-HCN of Völker (26) and Cruikshank et al. (5).[4] Table 1 also includes; for comparison, the average elemental composition of Titan tholins determined by Schwarzkopf and Galbraith. It clearly shows that poly-HCN and Titan tholin have very different elemental compositions, as is also reflected in their optical constants (see below).

2.3. *Comparison of the infrared spectra of poly-HCN from several sources*

Völker (26) has shown that poly-HCN synthesized in water has elemental composition 41.4% C, 4.0% H, and 43.2% N. The remaining ~11% he attributes to O atoms without indicating any specific position for the oxygen atoms in the proposed structure of the poly-HCN (Fig. 1(*a*)). No IR band corresponding to the C≡N stretching vibration at 4.5 μm is found in the transmission spectrum. Anhydrous poly-HCN (Fig. 1(*b*)) made in organic solvents such as chloroform has elemental composition 45% C, 4.0% H, and 51.3% N and exhibits a strong C≡N band at 4.5 μm. The presence and absence of this feature results from different structures of the monomer units as shown in Figs. 1(*a*) and (*b*). Völker (26) finds that the oxygen does not react with the polymer, but the presence of water vapor in moist air causes oxygen to be incorporated into the polymer. Cruikshank et al. (5) report that anhydrous poly-HCN (Fig. 1(*b*)) shows a diminution of the 4.5 μm feature with time, on treating with water at room temperature until its complete disappearance after 6 months.

Figure 2 shows the transmission and reflectance spectra of poly-HCN from du Pont Co. thermally evaporated and redeposited in our laboratory, compared with poly-HCN from several sources. "Electropolymeric" HCN (36) prepared by

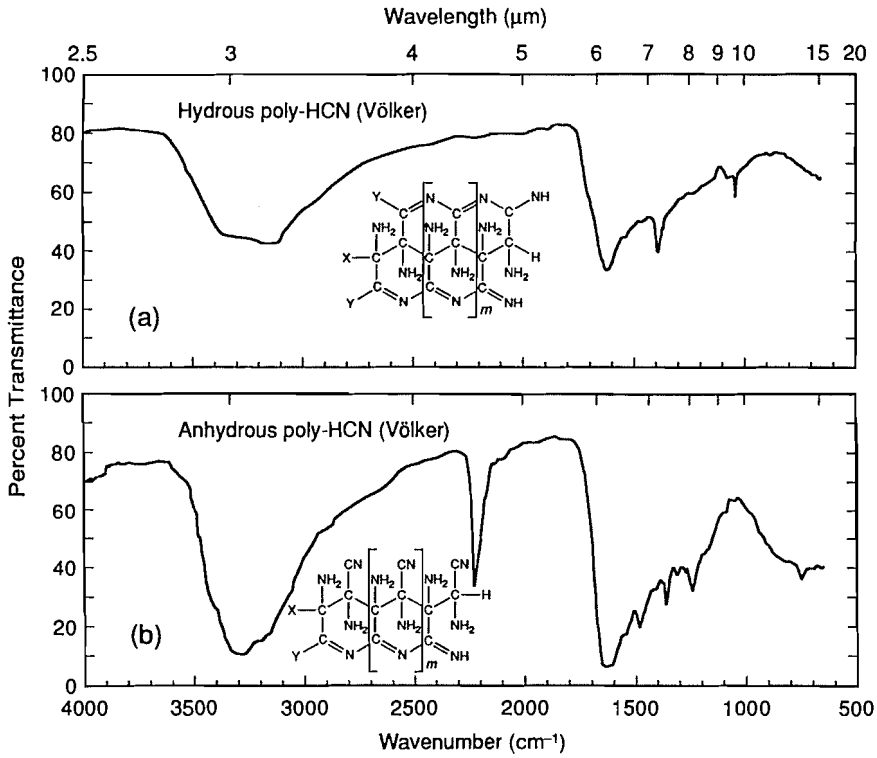

FIG. 1. Infrared spectra of poly-HCN (*a*) synthesized in water and (*b*) synthesized in organic solvents such as chloroform. Both spectra are taken from Völker (26). Note the similarity of (*b*) with Fig. 2(*b*) below, allowing for the lower resolution here.

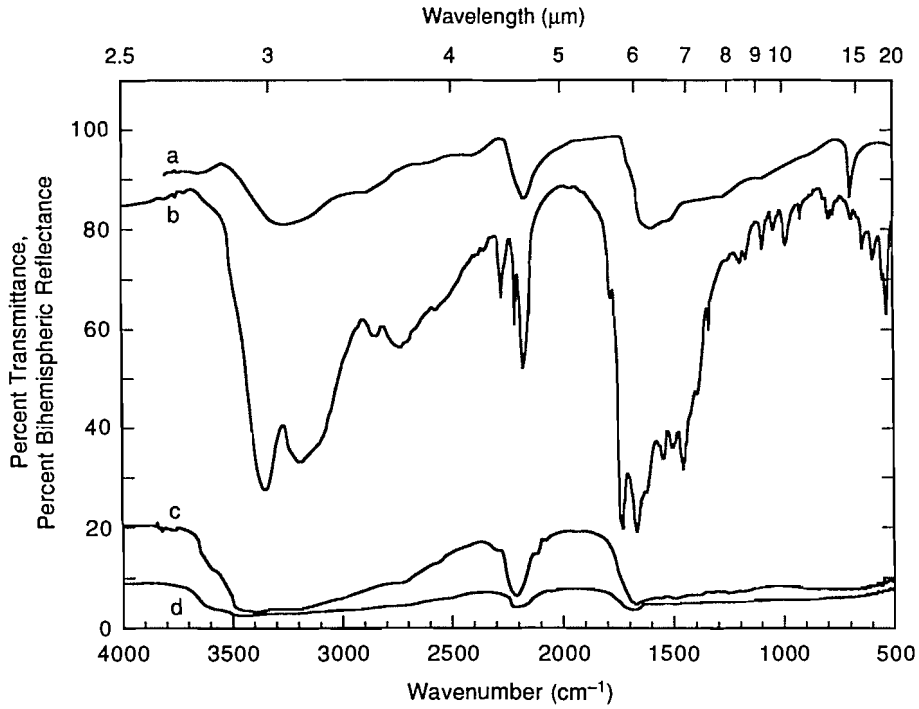

FIG. 2. Comparison of the infrared transmission spectra of (*a*) electropolymeric-HCN (arbitrary units) (36) with (*b*) thermally evaporated and redeposited poly-HCN from du Pont de Nemours under high vacuum in the present work, (*c*) bihemispheric reflectance spectrum of anhydrous poly-HCN (5, footnote 4), and (*d*) bihemispheric reflectance spectrum of hydrous poly-HCN (5, footnote 4).

0.5 mA arc discharge through HCN shows weak IR absorptions. The reflection spectrum of anhydrous poly-HCN is from a sample prepared by Matthews and Ludicky in which liquid HCN with a catalytic trace of triethylamine was allowed to stand at room temperature for 30 days. Ammonia can also be used in place of triethylamine as a catalyst (7, 8). The initially colorless liquid becomes a yellow-orange-brown sludge, ending as a dark brown, almost black, powder (5). The hydrated poly-HCN is obtained by stirring this powder in cold water for 3 days and drying to yield a black solid material. The

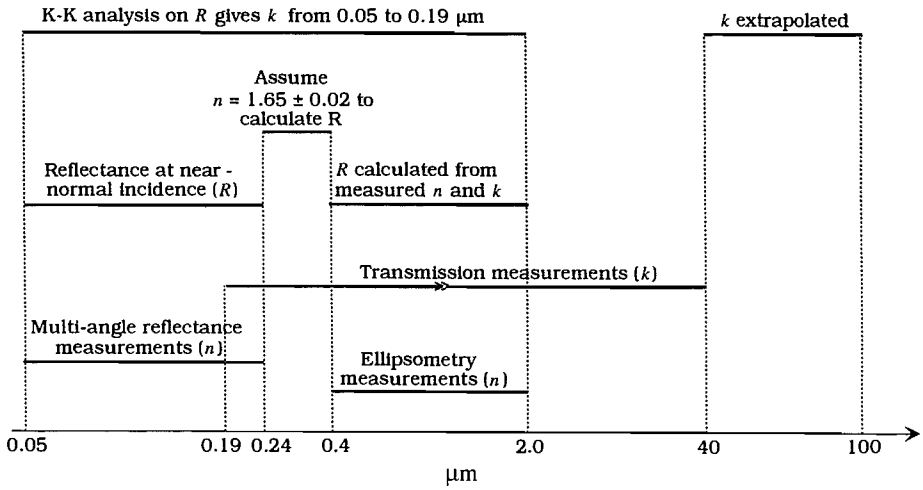

FIG. 3. Techniques employed in the measurement of the optical constants of a film prepared by thermal evaporation of poly-HCN and redeposition under high vacuum. The assumed value of n derives from ellipsometry.

reflection spectra of both anhydrous and hydrous poly-HCN obtained by Cruikshank et al.[4] are also reproduced here (Fig. 2). The comparison is only qualitative. Our vacuum-evaporated film exhibits all the major bands corresponding to functional groups present in the unheated poly-HCN from other sources, but the relative strength of the bands varies considerably. It is not expected that poly-HCN prepared under different conditions will produce identical infrared spectra (13).

3. Experimental

As discussed earlier (18, 19) in our continuing studies of the optical properties of organic residues, it is difficult to measure the imaginary part, k, of the complex refractive index by transmission measurements of solid materials that are in powdery form, since pulverized samples cause severe multiple scattering of the incident light. It is necessary instead to prepare optical quality films, particularly for the transmission measurements in the UV and visible where scattering is the greatest.

3.1. Thin film preparation

We prepared optical quality thin films of poly-HCN by thermal evaporation under high vacuum as described elsewhere (19). It was not possible to make suitable films thicker than $t = 1.5$ μm since thick films contained foggy areas. We therefore produced films of various thicknesses ranging from 0.05 to 1.5 μm. The exact thickness of the films is checked only after the spectral measurements are completed. A Sloan Angstrometer (model M-100) was used to measure the thickness of the thinner films. For $t \simeq 0.75$ μm, we measured the thickness from the interference pattern produced by light reflected from the front and back surfaces of the film in the wavelength range 0.4–2.5 μm, assuming an index of refraction $n = 1.65 \pm 0.02$ for this region. This value of n was determined previously by an independent ellipsometric measurement on a pressed pellet of poly-HCN.

Evaporation took place at a temperature of 800 ± 100 K at 10^{-5}–10^{-6} Torr (1 Torr = 133.3 Pa). The color of the molybdenum crucible at which the poly-HCN began to evaporate was used to determine the temperature. Evaporated poly-HCN was condensed onto optical quality CsI and CaF_2 substrates transparent from 0.3 to 50 μm and from 0.13 to 9 μm, respectively, and kept at room temperature. The thin films were colorless initially, turning yellowish with increasing thickness. By weighing the molybdenum crucible before and after evaporation, we determined that ~80% of the poly-HCN was evaporated.

3.2. Spectroscopic measurements

The infrared spectrum from 2.5 to 40 μm of unheated poly-HCN was obtained by measuring the transmission through a compressed pellet in a CsI matrix using a Mattson Galaxy 6020 FTIR spectrometer at 1 cm^{-1} resolution. The transmission spectrum from 2.5 to 40 μm of vacuum-evaporated films of poly-HCN on CsI substrates was obtained using a Perkin–Elmer model 983 spectrometer, also at 1 cm^{-1} resolution. Shimadzu UV250 and Cary 14 spectrophotometers were used in the ranges 0.19–0.9 μm and 0.4–2.5 μm, respectively. A Seya–Namioka monochromator was used from 0.13 to 0.4 μm for transmission measurements and from 0.13 to 0.24 μm for reflectance measurements. A McPherson model 247 grazing incidence monochromator enabled us to extend the reflectance measurements down to 0.05 μm.

Figure 3 summarizes the techniques used in the determination of the optical constants n and k, as discussed in detail elsewhere (12, 18, 19). Figure 4(*a*) shows the spectrum of unheated poly-HCN in a CsI matrix using a technique described by Khare and Sagan (37), and Fig. 4(*b*) shows the spectrum of a vacuum-evaporated and redeposited film of poly-HCN. We find that the du Pont poly-HCN (Fig. 4(*a*)) is not as hydrous as the hydrous poly-HCN of Völker (26) (Fig. 4(*d*)). The features in unheated du Pont poly-HCN better resemble those of the anhydrous poly-HCN (Fig. 4(*c*)) of Völker (26). This is reasonable since the du Pont poly-HCN is a mixture of both hydrous and anhydrous polymers. The infrared spectrum of our thermally evaporated film (Fig. 4(*b*)) is close to that of anhydrous poly-HCN (Figs. 1(*b*), 4(*c*)). The thermal evaporation technique has the advantage of removing adsorbed water and producing films exhibiting the strong band at 4.5 μm (2222 cm^{-1}) characteristic of C≡N as seen in the spectrum of anhydrous poly-HCN.

Films prepared by thermal evaporation under high vacuum (Fig. 4(*b*)) were used in the present investigation for the determination of the optical constants. These films are suspected to be more anhydrous than the anhydrous poly-HCN of Völker (26) as seen in the increase in the strength and multiplicity of the C≡N band at 4.5 μm if the decrease in the strength and multiplicity of the C≡N band is directly related to the degree of hydrolysis of poly-HCN. Table 2 lists all the bands found in our thermally evaporated films of poly-HCN. The infrared spectrum of a complex organic solid such as poly-HCN shows absorption bands that are due to well-known chemical functional groups. Possible assignments of some of the bands based on Bellamy (38), Szymanski (39), Pasto and Johnson (40), and Colthup (41) are presented in Table 2. These assignments are tentative and could change when the structure of this poly-HCN is better determined. The appearance of the C≡N spectral feature, as well as its strength and position, is known to vary from sample to sample. Our evaporated poly-HCN, being a mixture of all three types of poly-HCN and free from water, produces four distinct peaks, varying in intensity and wavelength, near 4.5 μm.

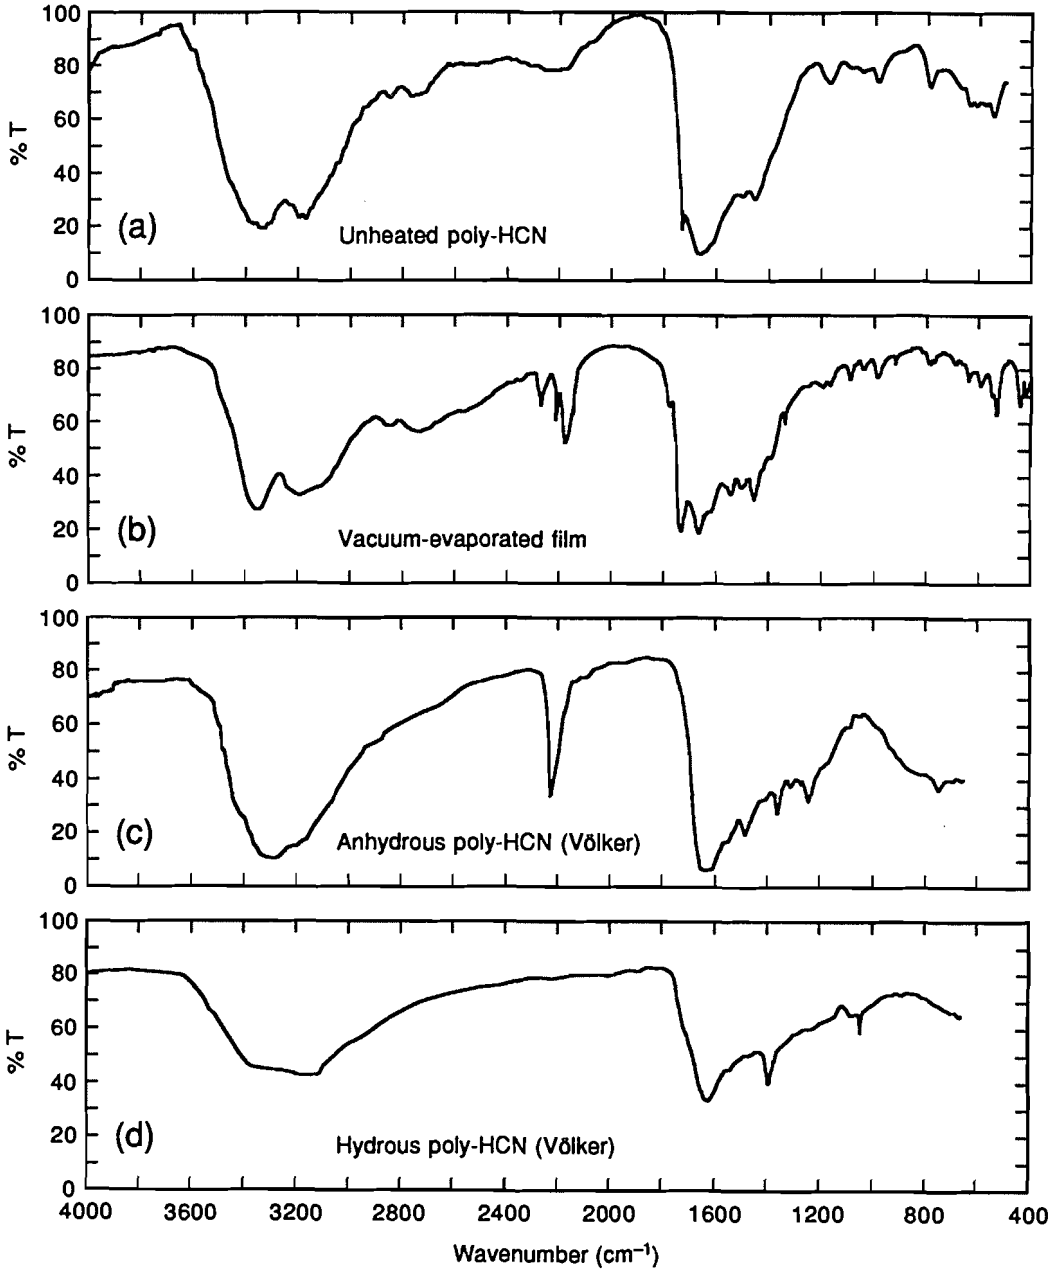

FIG. 4. Infrared spectra of poly-HCN (*a*) unheated in CsI matrix, (*b*) vacuum evaporated and redeposited at 800 ± 100 K on a CsI substrate, compared with (*c*) anhydrous poly-HCN made in organic solvents such as chloroform (26), and (*d*) hydrous poly-HCN made in water (26).

4. Optical constants

4.1. Direct measurements of the real part of the refractive index n

We measure n directly on films of evaporated poly-HCN using ellipsometry from 0.4 to 2 μm and multi-angle reflectance from 0.05 to 0.24 μm, as previously described (12). We also carried out ellipsometric measurements on solid pressed pellets made from unheated poly-HCN.

4.2. Direct measurement of the imaginary part of the refractive index k

The transmittance T of a thin film with thickness t on a thick substrate is given by Khare et al. (12) as

$$[4] \qquad T = T_s \frac{(1-R)}{(1-R_0)^2} \exp(-4\pi kt/\lambda)$$

where T_s = transmission of the bare substrate, R = normal-incidence reflectance of the film–substrate system, $R_0 = [(n_s - 1)/(n_s + 1)]^2$ is the normal-incidence reflectance at the substrate–air interface, and n_s is the real part of the refractive index of the substrate.

By considering R as independent of t, we determined k from the slope of the straight line drawn by plotting $\ln(T_s/T)$ against t. The advantage of this method is that we did not need to know n for either the substrate or the film. k was determined in this way from 0.19 to 40 μm.

4.3. Kramers–Krönig (K–K) analysis of k

For the wavelength range 0.05–0.19 μm, where it was not possible to measure k directly due to low film transmission and lack of suitable substrates, we determined k from reflectance measurements using the Kramers–Krönig relation given by dis-

persion relation analysis. This relationship is given by

$$[5] \qquad k(\omega) = \frac{-2\sqrt{R_N(\omega)}\sin\phi(\omega)}{1 + R_N(\omega) - 2\sqrt{R_N(\omega)}\cos\phi(\omega)}$$

where $R_N(\omega)$ is the normal-incidence reflectance at energy $\hbar\omega$ and $\phi(\omega)$, the phase change upon reflection at photon energy $\hbar\omega$, is given by

$$[6] \qquad \phi(\omega) = \frac{\omega}{\pi} P \int_0^\infty \frac{\ln R_N(\omega')}{(\omega')^2 - \omega^2}\, d\omega'$$

where P stands for the Cauchy principle value (42).

Normal-incidence reflectance values from 0.05 to 0.24 μm, where the reflectance was too low to measure directly, were extrapolated from the reflectance measured at non-normal angles of incidence. R_N was calculated in the 0.4–2.0 μm region using Fresnel's equation

$$[7] \qquad R_N = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2}$$

with the n and k values determined from ellipsometric and transmission measurements, respectively. For the 0.24–0.4 μm region, we calculated R_N by assuming that the real part of the index of refraction n equals 1.65 ± 0.02 for the entire region. The k values were determined from transmission measurements. For $\lambda > 0.4$ μm, we assumed a constant reflectance equal to the value at 0.4 μm since the reflectance in this low-energy region will not influence the values of k calculated in the K–K analysis in the 0.05–0.24 μm region. For the high-energy extrapolation ($\lambda < 0.05$ μm), we used the exponential form $R(E) = a \exp(-b)$ where the constants a and b were determined by requiring that the k values obtained in the K–K analysis agree with those determined earlier from transmission measurements in the region 0.19–0.24 μm.

The values of k obtained from this analysis are plotted in Fig. 5 and tabulated in Table 3. The k values are estimated to be accurate to ±20%. A detailed plot of k that clearly shows the 2.2 μm overtone band is shown for the wavelength range 1.5–5 μm (Fig. 6).

4.4. *Kramers–Krönig analysis of* n

A program based on the Kramers–Krönig relation between n

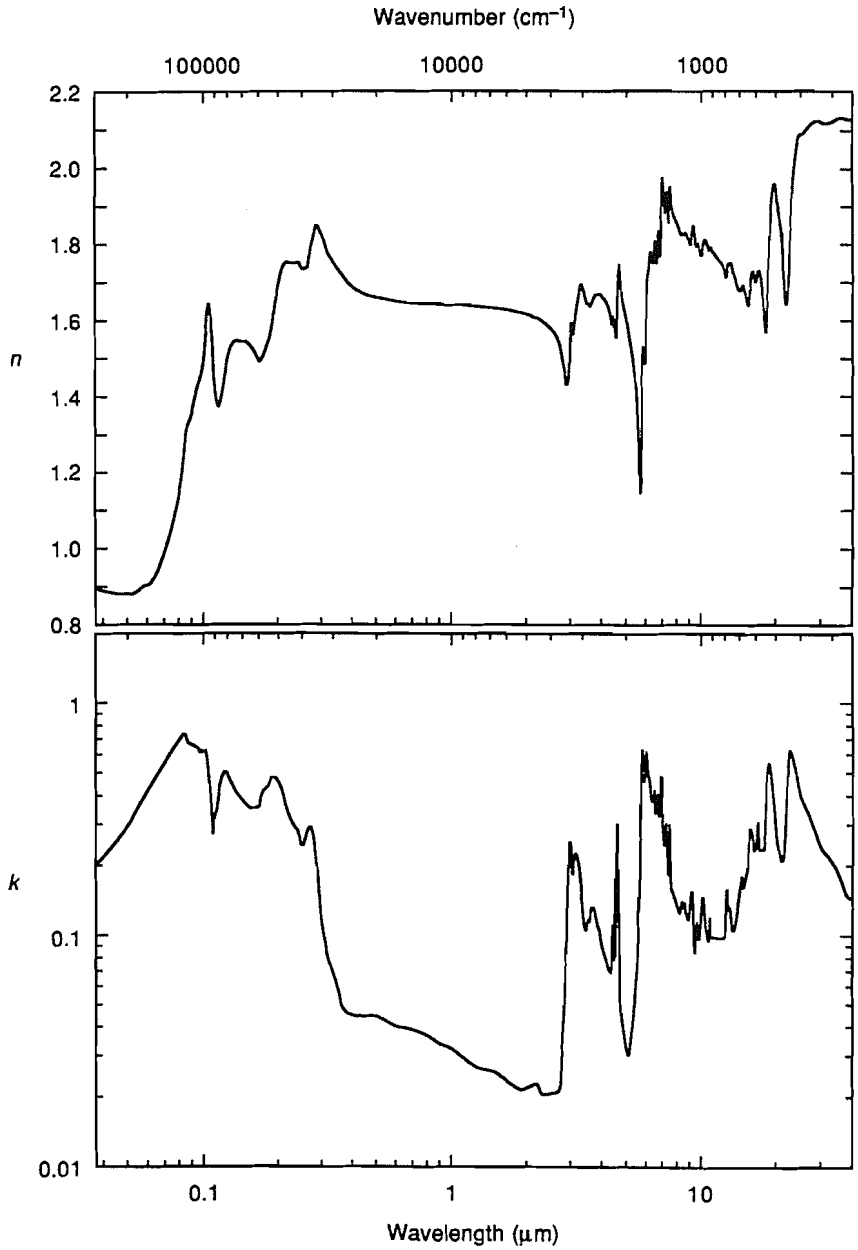

FIG. 5. Real (n) and imaginary (k) values of the complex refractive index as a function of wavelength of films prepared by thermal evaporation and redeposition under high vacuum of poly-HCN from du Pont Co.

and k (43) gave us n over the entire range of the measurements from the k values obtained above between 0.05 and 40 μm. The values of n were obtained from the following integral over the photon energy E

$$[8] \qquad n(E) - 1 = \frac{2}{\pi} P \int_0^\infty \frac{E'k(E')}{(E')^2 - E^2} \, dE'$$

The low-energy integration in eq. [8] was truncated at 100 μm, since the contribution to the integral from above 100 μm has no significant effect on the n values in the region of interest. A linear interpolation was chosen between $k = 0.144$ at $\lambda = 40$ μm and $k = 0.001$ at 100 μm. For the high-energy integration, the k values were extrapolated for $\lambda < 0.05$ μm using a power law $k = k(E_u)E^{-2}$, where $k(E_u)$ was the measured value of the imaginary part of the refractive index at 0.05 μm (24.8 eV), and E is in electron volts. The exponent −2 comes for the theoretical behavior of the imaginary part of the refractive index at high energies (42, 44). The high-energy cutoff for the integration was chosen to make the calculated values of n agree with the measured values in the 0.4–2.0 μm region. The values of n obtained from the Abeles (45) method from 0.4 to 0.625 μm agreed well with the values of n obtained using ellipsometry. The Abeles method is a variation of the Brewster angle method in which n is determined from scans of angular reflectance of thin films on thick substrates. The values of n from the K–K analysis agreed well with the values of n in the region from 0.05 to 0.24 μm determined by multi-angle reflectance measurements. The complete n spectrum from 0.05 to 40 μm is shown in Fig. 5. The n values

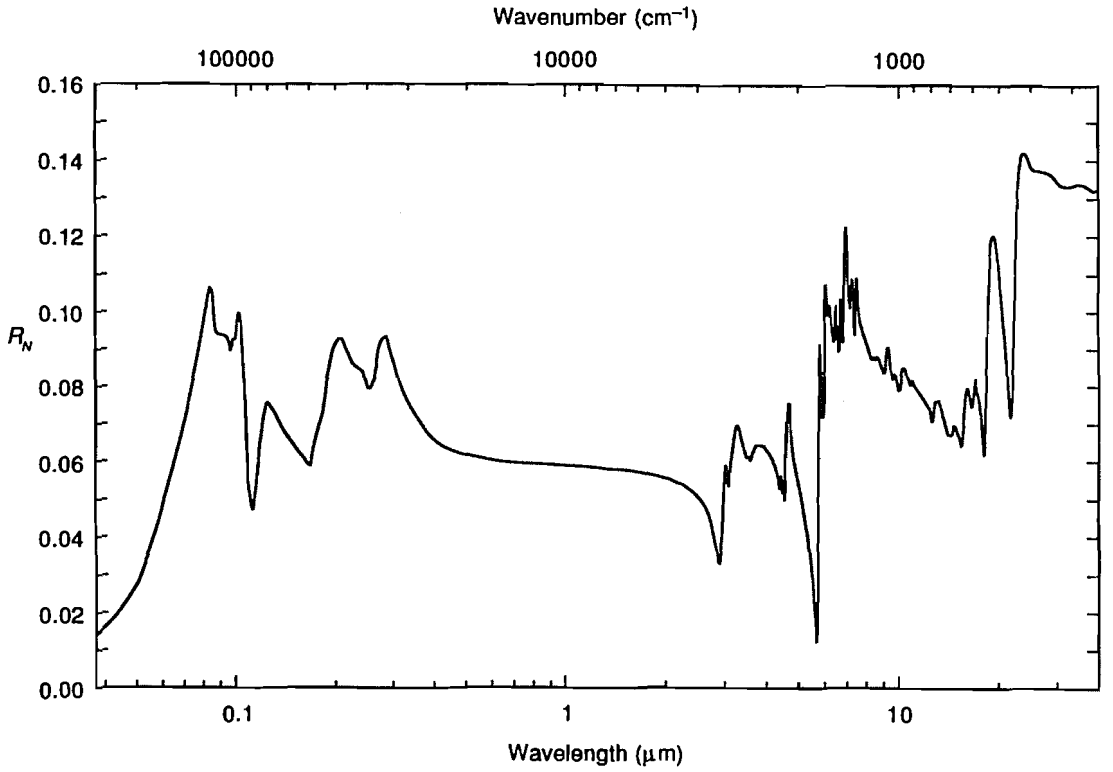

FIG. 8. Normal-incidence reflectance versus wavelength of evaporated and redeposited poly-HCN films.

are tabulated in Table 3 and are accurate to ±0.01 in absolute value and to ±0.002 on a relative scale.

4.5. Absorption coefficient, normal-incidence reflectance, dielectric function, and optical energy-loss function $Im(-1/\epsilon)$

The absorption coefficient α as a function of wavelength is shown in Figure 7. The normal-incidence reflectance R_N calculated from eq. [7] for a specular surface of poly-HCN is shown in Fig. 8. Dielectric constants $\epsilon_1 = n^2 - k^2$ and $\epsilon_2 = 2nk$ and the optical energy-loss function $\text{Im}(-1/\epsilon) = \epsilon_2/(\epsilon_1^2 + \epsilon_2^2)$ as a function of incident photon energy are shown in Fig. 9.

5. Comparison with the polymers of Bar-Nun et al. and Podolak et al.

Figure 10 shows the comparison of the imaginary part of the refractive index (k) of the evaporated and redeposited poly-HCN films determined in our investigation with the values calculated from the absorption coefficient ($-\log I/I_0$ per μm film thickness) of "poly-HCN" produced by Bar-Nun et al. (46) and Podolak et al. (47) from the photolysis of 5% HCN in CH_4 or argon. These authors identify their film as poly-HCN. Bar-Nun et al. (46) compare the absorption coefficients of their photochemically produced "poly-HCN" film with their photochemically produced polymers of C_2H_2 and C_2H_4, after correcting for the loss of light due to scattering. We assume that this correction also includes the loss of light due to reflection from the substrate and film. Thus, k is calculated for their photo-produced polymer (46) by substituting $-\log I/I_0$ values in the equation, $k = -0.183\lambda \log I/I_0\ \mu m^{-1}$, where λ is the wavelength in μm. We find poor agreement between our data and those of Bar-Nun et al. (46) and Podolak et al. (47), especially in the ultraviolet. For example, our k value at 0.21 μm is 3.96×10^{-1}, which is about an order of magnitude higher than the Bar-Nun et al. and Podolak et al. value of 2.5×10^{-2}. These authors have not displayed the infrared spectra of their putative poly-HCN so we cannot compare with the infrared spectra of other investigators.

Direct photolysis of HCN in the gas phase at 1850 Å yields $(CN)_2$, H_2, CH_4, NH_3, N_2H_4, C_2H_6, and CH_3NH_2 along with some undefined polymeric material (48). Becker and Hong (49) find similar products in their photolysis of HCN gas at 1850 Å except for H_2 and C_2H_6. They believe that H_2 is present but are unable to confirm this because of instrumental limitations. No "poly-HCN" is indicated by Mizutani et al. (48) or Becker and Hong (49) in their photolytic products. Mizutani et al. (48), in their study of the photochemical reaction of HCN and its polymeric products, refer to such polymers as "HCN polymers" only for convenience, since neither the composition nor the structures of the components of these materials are determined. Mizutani et al. caution that the degree of polymerization for some of the compounds may be sufficiently small that it may not be proper to call them polymers in the strict sense. Mizutani et al. (50) exhibit the infrared spectra of the brown polymer produced by the photochemical reaction of hydrogen cyanide in gas phase at 1849 Å; this may be what Bar-Nun et al. (46) would have obtained for their polymer. On comparing this spectrum with our unheated poly-HCN and vacuum-evaporated film of poly-HCN (Fig. 11), we find, as expected, spectral differences, although they are perhaps no more than the spectral differences among the several varieties of poly-HCN (Figs. 1, 2, 4). $(CN)_2$ is a major photolytic product of HCN and readily produces $(CN)_2$ ethanedinitrile homopolymers $(CN)_n$, also known as paracyanogen,

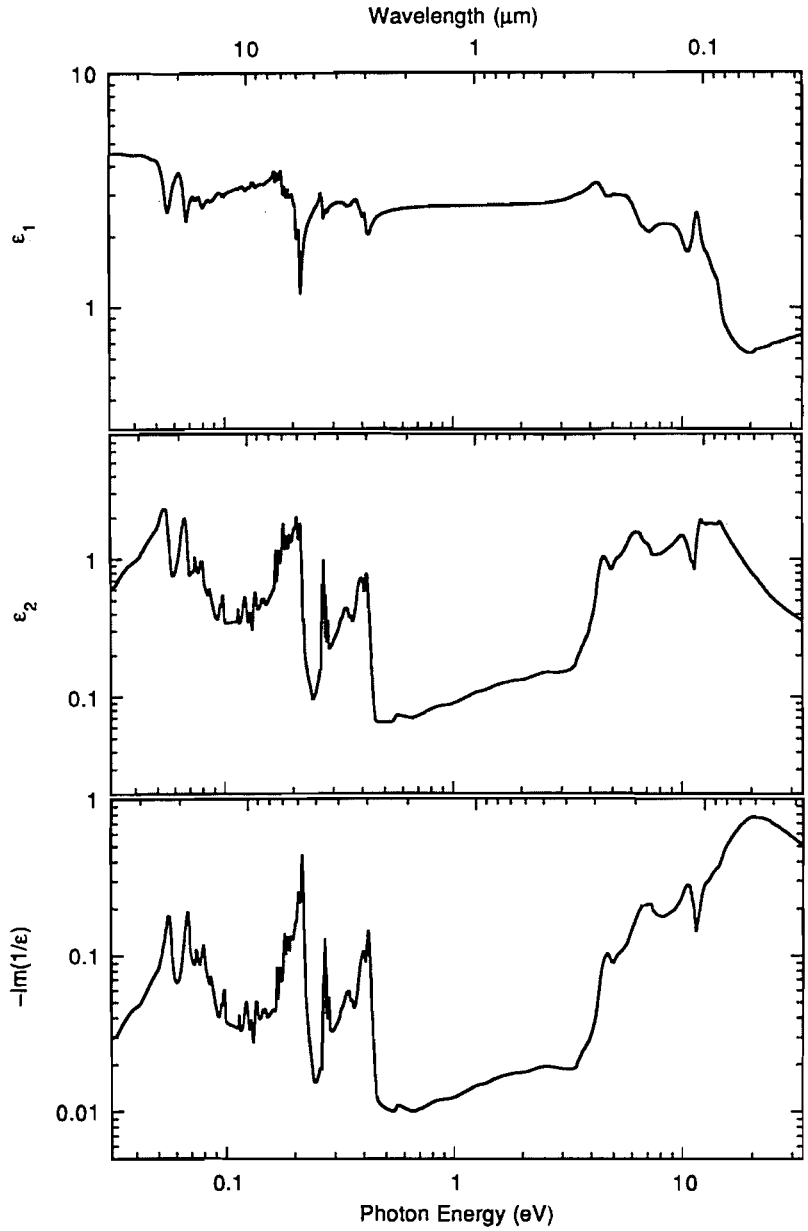

FIG. 9. Dielectric constants, ϵ_1 and ϵ_2, and energy loss function, $\mathrm{Im}(-1/\epsilon)$, of evaporated and redeposited poly-HCN as a function of photon energy.

on heating to above 400°C. It may be that Bar-Nun et al. and Podolak et al. have produced $(CN)_n$ polymer, possibly along with a Titan tholin-like material. This is further substantiated by the results of Hogness and Ts'ai (51) who found that C_2N_2 gas upon ultraviolet absorption between 2145 and 2240 Å dissociates either into two normal CN radicals or one normal and one excited CN radical, which combine with C_2N_2 producing $(CN)_3$. Thus the quantum efficiency for the photochemical reaction $(CN)_2 \rightarrow$ paracyanogen $[(CN)_n]$ is 3 moles per einstein.

Photons at 1847 Å employed by Bar-Nun et al. (46) and Podolak et al. (47) from a Hg-lamp photolysis of 5% HCN in CH_4 or argon have an energy of 6.7 eV. The approximate dissociation energy of the H—CN bond is 5.64 eV (52). Even if all the remaining 1.07 eV is partitioned to the H atom as kinetic energy, it is still insufficient to dissociate CH_4 (the bond dissociation energy for H—CH_3 is 4.42 eV.) However, it may be possible that the CN radical could attack CH_4, triggering reactions leading to Titan tholin-like material. A comparison with the imaginary part of the refractive index (k) of Titan tholin (12) is also shown in Fig. 10. The data of Bar-Nun et al. and Podolak et al., as expected, do not fit the optical constants data for Titan tholin either. Bar-Nun et al. and Podolak et al. also state that their $-\log I/I_0$ values are essentially the same whether the polymer is produced by photolyzing 5% HCN in CH_4 or Ar. This clearly indicates that CH_4 does not participate in the production of their polymer, eliminating the possibility of a Titan tholin-like material being produced.

Bar-Nun et al. and Podolak et al. did not measure the density of their polymer, but instead assumed a value of 1.18 g cm^{-3}, that of polyacrylonitrile (53). We measured the density of the du Pont poly-HCN employed in our measurement of the opti-

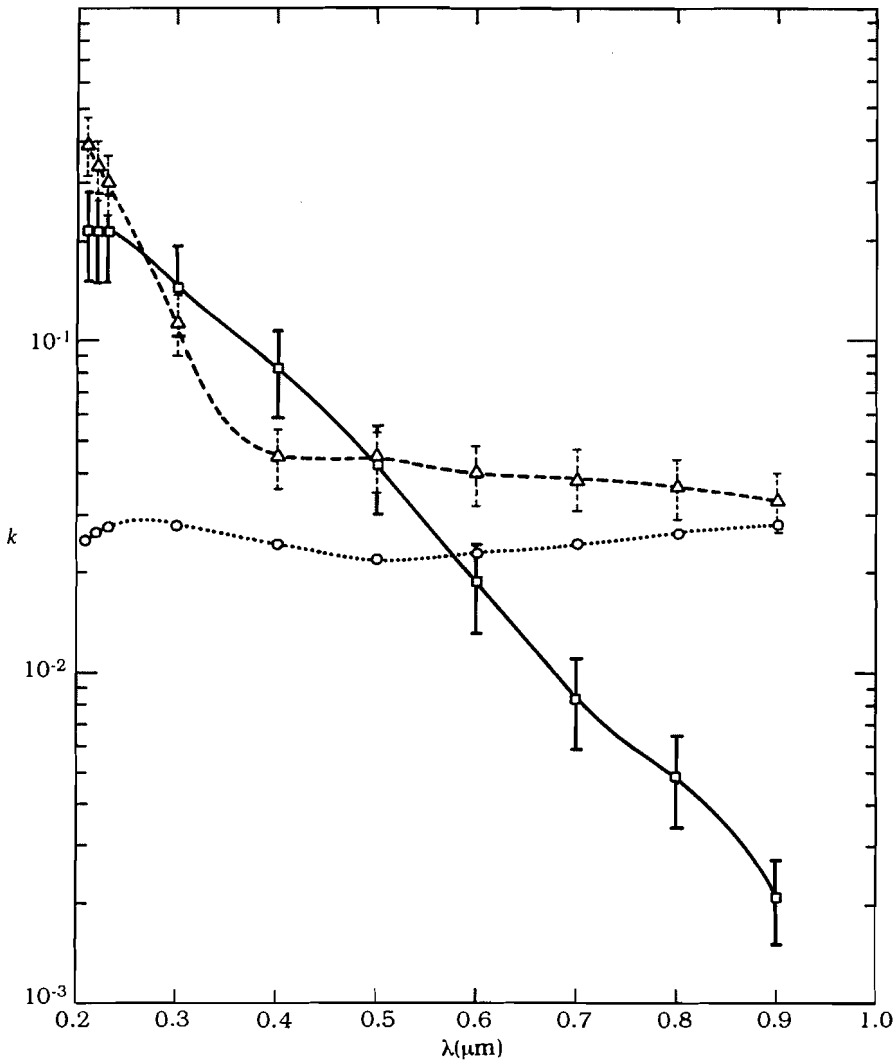

FIG. 10. Comparison of the imaginary part of the refractive index (k) of poly-HCN determined in this investigation (△) with the values calculated from the $-\log I/I_0$ per μm thick film of poly-HCN produced from the photolysis of 5% HCN in CH_4 or argon by Bar-Nun et al. (46); Podolak et al. (47) (○). Imaginary part of the refractive index (k) of Titan tholin (12) is also shown (□).

cal constants by helium pycnometry and found a value of 1.620 ± 0.004 g cm^{-3} for the du Pont poly-HCN. With this higher density, a thinner film thickness, which produces higher k values, is obtained. However, these new k values still do not help produce a match with the k values reported here. We conclude that the polymer produced by Bar-Nun et al. and Podolak et al. is not poly-HCN. It could be mainly paracyanogen with a Titan tholin-like material and a minor component of poly-HCN.

6. Comparison with other bodies in the solar system

The specular reflectance of smooth surfaces of poly-HCN in the visible part of the spectrum (Fig. 8) is about 6%. This is in the range of estimates for cometary nuclei and other dark surfaces in the outer solar system. But many other plausible organic materials have similar reflectances, for example, organic residues produced by irradiation of mixtures of hydrocarbon and water ices (19).

As an example of the application of these optical constant results to claims of abundant poly-HCN in the outer solar system, consider the haze of Saturn's large satellite Titan. Matthews (1, 54) proposes that this is due to poly-HCN and generated from HCN in the Titanian atmosphere. In Fig. 12, we plot in crosshatching the values of k from 0.3 to 0.9 μm for the Titan haze (55) deduced from groundbased data of the geometric albedo (56–58) and from 16.67 to 40 μm from Voyager spacecraft observations (59). The deduced values for $k(\lambda)$ are derived from standard models of atmospheric structure and aerosol distribution. The reduced data apply from the near ultraviolet to the middle infrared, with, unfortunately, no observations available between about 1.5 and about 10 μm, where possibly diagnostic chemical functional groups lie. If spectral features were detectable in the near- to middle-infrared, other diagnostic distinctions might be made (for example, note the difference in ratios of the 3 μm C—H absorption features and the 4.5 μm C≡N features in poly-HCN compared with Titan tholin.) Plotted in the same figure are the results of the present paper for poly-HCN and the optical constants obtained in the laboratory for Titan tholin, the organic solid produced by irradiating simulated Titanian atmospheres (12, 60). Estimated uncertainties in the model-dependent values of k for the Titan haze are about ±40% (61), while those for the laboratory observations are estimated to be about ±20% for poly-HCN and ±30% for Titan tholin. Titan tholin fits the Titan observations

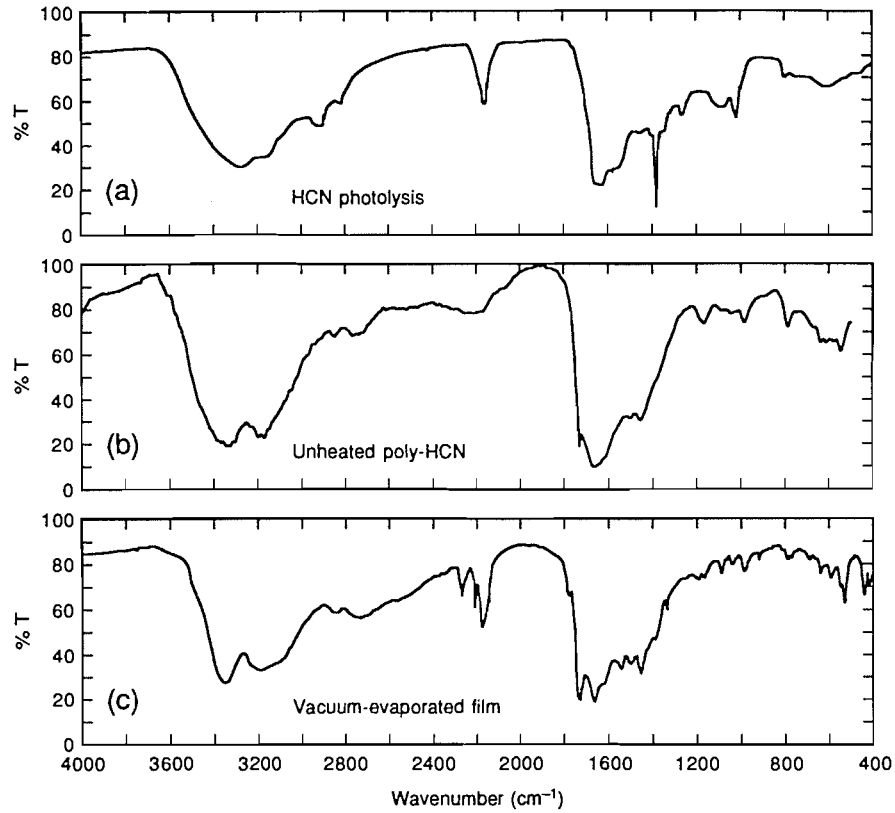

FIG. 11. The infrared spectra of (*a*) brown polymer produced by the photochemical reaction of hydrogen cyanide in gas phase at 1849 Å (50) is compared with (*b*) unheated poly-HCN and (*c*) vacuum evaporated film of poly-HCN.

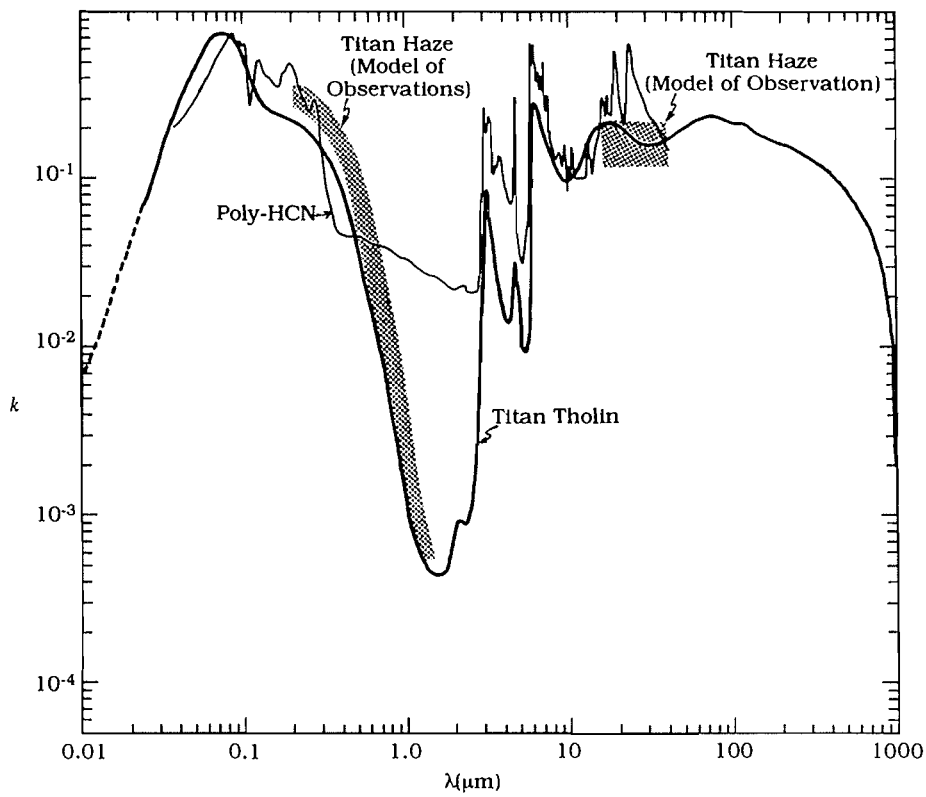

FIG. 12. Comparison of the imaginary part, *k*, of the complex refractive index from 0.3 to 0.9 μm of the organic haze of Titan (55), derived from groundbased data of the geometric albedo (56–58) and from 16.67 to 40 μm (59) after normalizing *k* at 40 μm, with *k* for poly-HCN (this paper), and for the organic residue (Titan tholin) obtained from plasma discharge through a 9:1 N_2/CH_4 mixture (60, 12). Probable errors of the groundbased data are shown by the stippling from 0.2 to 1.0 μm, *k* from 16.67 to 40 μm is normalized to Titan tholin at 40 μm. Probable errors for the laboratory measurements are about ±20% for poly-HCN and ±30% for Titan tholin.

within the probable errors (60), and no other proposed material does. It is apparent that, in the visible and near-infrared, the fit is far better for Titan tholin than for poly-HCN. Titan tholin is much redder in the visible than poly-HCN, and poly-HCN displays a sharp discontinuity (absorption edge) at about 0.35 μm, which neither the Titan haze nor Titan tholin display. In the long visible and near-infrared, poly-HCN exhibits one to two orders of magnitude larger values of k than does Titan or Titan tholin. Poly-HCN can therefore be at best a minor constituent of the Titan haze.

The volatile component of Titan tholin, when examined by sequential and nonsequential pyrolytic GC–MS, reveals over 100 products, including aliphatic hydrocarbons, nitriles, polycyclic aromatic hydrocarbons, amines, pyroles, pyrazines, pyridines, pyrimidines, and, perhaps, the purine adenine (15, 17). Independent evidence for the presence of PAHs has now been found (62). A number of these compounds are not present in poly-HCN and would not be expected to be released on volatilization of poly-HCN. In addition, of course, it makes intuitive sense that the organic solid generated by irradiation of simulated Titanian atmospheres, experiments that successfully and quantitatively reproduce the gas-phase organics in Titan's atmosphere (63), should be the best candidate for the organic haze of Titan (60).

Pesce-Rodriguez et al. (64) suggest that the similarity between "HCN polymers" and the Murchison meteorite is "striking", at least in the middle infrared. However, a comparison of the optical constants of poly-HCN, reported here, and those of an organic residue from the Murchison carbonaceous chondrite (18) reveals major discrepancies. Meteoritic organics are not poly-HCN.

As model optical constants of other hazes and surfaces in the outer solar system become available, they also can be compared with laboratory optical constants of poly-HCN, tholins, and other materials, as done here for Titan, and the claims for poly-HCN assessed on a case-by-case basis. Much simpler comparisons of laboratory with planetary spectra may also be useful, but may not be nearly as definitive. The exclusion of poly-HCN as the principal constituent of the Titan haze does not exclude its presence elsewhere. It might, for example, be that poly-HCN is too neutrally colored in the visible to explain reddish clouds and surfaces, but might be a useful model for much blacker surfaces. However, other, perhaps more likely, materials — such as some PAHs or elemental carbon (or tholins produced from CH_4) — may prove more successful. Because of its low albedo and explosive polymerization, poly-HCN is a reasonable candidate for the dark lag deposit of cometary nuclei. Our measured values of the optical constants may find use in modelling of the cometary dust.

We have recently used Hapke scattering theory and a linear superposition of the optical constants of a number of materials in an attempt to explain the observed spectrum of 5145 Pholus, a very red asteroid or comet on an eccentric orbit with aphelion beyond Uranus (65). All good fits seem to require ~10% poly-HCN, or some other material with similar strong absorption in the near-infrared.

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

MAGGIE A. AUSTEN, LEIF A. ERIKSSON, and RUSSELL J. BOYD. Can. J. Chem. **72**, 695 (1994).

The linear combination of Gaussian-type orbitals – density functional theory (LCGTO–DFT) approach is used to study geometries and hyperfine structures of a set of neutral radicals. Each of the title molecules is investigated by means of local density approximation calculations, and using the Becke–Perdew and Perdew–Wang–Perdew corrections to the exchange and correlation functionals. The effects of local vs. non-local potentials and of various basis sets are investigated. Total densities and unpaired spin densities are compared. The isotropic couplings are found to be very dependent on the type of exchange functional used, whereas the anisotropic couplings are relatively insensitive to the choice of basis set and functional. In most cases, the Perdew–Wang exchange corrections provide isotropic couplings in satisfactory agreement with experiment.

MAGGIE A. AUSTEN, LEIF A. ERIKSSON et RUSSELL J. BOYD. Can. J. Chem. **72**, 695 (1994).

On a utilisé la combinaison linéaire d'orbitales de type gaussien avec la théorie de densité fonctionnelle (LCGTO-DFT) pour étudier les géométries et les structures hyperfines d'un ensemble de radicaux neutres. On a étudié chacune des molécules mentionnées dans le titre à l'aide de calculs d'approximation de la densité locale et en utilisant les corrections de Becke–Perdew et Perdew–Wang–Perdew pour les fonctions d'échange et de corrélation. On a examiné les effets des potentiels locaux et non locaux ainsi que de divers ensembles de base. On a comparé les densités totales et les densités de spin non pairés. On a trouvé que les couplages isotropes sont très dépendants sur le type de fonction d'échange utilisé alors que les couplages anisotropes sont relativement insensibles au choix de l'ensemble de base et de la fonction. Dans la plupart des cas, les corrections d'échange de Perdew–Wang fournissent des couplages isotropes qui sont en accord satisfaisant avec les données expérimentales.

1. Introduction

The six molecules investigated — NH_2, NF_2, NCl_2, PH_2, PF_2, and PCl_2 — have previously been subject to detailed theoretical and experimental studies. Most theoretical work has, quite naturally, been devoted to the structure and properties of the smallest of the compounds, NH_2. In particular, the detailed work by Grein and co-workers (1, 2), using multireference configuration interaction theory (MRCI) and extended basis sets, has yielded geometries and hyperfine (hf) structures of very high accuracy. The coupled cluster (CC) calculations by Sekino and Bartlett (3) and the coupled electron pair approximation (CEPA) studies by Pöhlchen et al. (4) have also yielded very accurate determinations of the properties of NH_2.

The hyperfine structures of NH_2 and NF_2 have recently been investigated by means of CI including all single and double excitations from a single reference determinant (CISD) (5). In this study, the fairly small but highly successful basis sets by Chipman (6) were employed. Chipman previously pointed out the importance of very high exponents of the *s*-functions in the bases (6), and uses, as opposed to many other scientists in the field, only a very moderate expansion in terms of higher orbital quantum numbers.

In an *ab initio* study of the geometry of difluoroamidogen (NF_2), Cai et al. (7) have shown that both correlation effects and a basis set that includes polarization functions are important for an appropriate description of the ground state geometry. For NF_2 (8), and for PH_2 (9), multiconfiguration SCF (MCSCF) studies have yielded geometries and ground state properties in very good agreement with experiment.

On the other hand, UHF calculations by Hinchliffe and Bounds (10), on the entire series presently investigated, also yielded geometries in good agreement with experiment. The computed hyperfine (hf) coupling constants also reported in that study are, after annihilation of the spin contamination, in reasonable agreement with experiment in most cases.

The aim of the present study is to investigate how well density functional theory (DFT) can perform on this group of compounds, in terms of equilibrium geometries as well as their hyperfine structures. We have previously shown that DFT can yield highly accurate equilibrium geometries and isotropic hf couplings for hydrocarbon radical cations (11, 12) even at the local density level, whereas for heteroatoms a non-local description of the exchange and correlation functional is often required in order to reproduce experimental data (13).

The paper is organized as follows. We first outline the theoretical model used, although we refer to previous work (12, 13) for more detailed descriptions of the hf calculations. For two excellent reviews, see also ref. 14. In Sect. 3, the optimized geometries, isotropic and anisotropic hf structures, and the total and unpaired spin densities are presented. We conclude in Sect. 4 with a summary of the results.

2. Method

In this study, we use the linear combination of Gaussian-type orbitals – density functional theory (LCGTO–DFT) program deMon (15) for all geometry optimizations. The particular version employed was slightly modified (16) to allow for partial inclusion of symmetry in the calculations. The hyperfine calculation routine is by Malkin and co-workers (12, 13). The isotropic hf coupling on centre N is obtained from the equation

$$[1] \quad a^{(N)}_{\text{isotropic}} = \frac{8\pi}{3} g\beta g_N \beta_N \sum_{\mu,\nu} P^{\alpha-\beta}_{\mu,\nu} \langle \phi_\mu(0) | \phi_\nu(0) \rangle$$

and is a direct measure of the spin density at the corresponding nucleus. The elements of the anisotropic hf tensor are obtained as

$$[2] \quad T_{i,j} = g\beta g_N \beta_N \sum_{\mu,\nu} P^{\alpha-\beta}_{\mu,\nu} \langle \phi_\mu | r^{-5}(r^2\delta_{i,j} - 3r_i r_j) | \phi_\nu \rangle$$

and are indirectly related to the spatial distribution of the density. This arises as a result of interactions between the magnetic moments of the electron and the nuclei, and is also referred to as the dipolar hf coupling due to the integral expression. The local density approximation (LDA) of Vosko, Wilk, and Nusair (17) is used. In addition, a non-local correction to the correlation functional, by Perdew (18), is used in conjunction with two different non-local corrections to the exchange functional, one by Becke (19), and one by Perdew and Wang (20). These combinations of corrections to the exchange and correlation functionals will be referred to as BP and PWP, respectively. In all calculations, the auxiliary basis sets used are (5,1;5,1) for H, (5,2;5,2) for N and F, and (5,4;5,4) for P and Cl (21). The orbital basis sets used are all based on Huzinaga's $9s5p$ or $11s7p$ series ($5s$ or $6s$ for the hydrogens) (22), to which we add a set of one or two polarization functions. These are loosely contracted to form the (51111/2111/1) and (5111111/211111/11) bases, respectively (23). These basis sets have been employed with great success in *ab initio* and DFT calculations of nuclear magnetic resonance (NMR) parameters (23, 24), as well as in previous DFT studies of hyperfine structures (12, 13). The contracted basis sets will be referred to as IGLO-II and IGLO-III, respectively, from their original individual gauge of localized orbitals (IGLO) – NMR applications (23). The IGLO-III bases are also used in uncontracted form, and then are labelled IIIu-d_2 and IIIu-d_4 in the present study. In IIIu-d_2, the two d-type polarization functions are added to the $11s7p$ bases, whereas in IIIu-d_4, four polarization functions are added. IGLO-III is used for all atoms, IGLO-II is used for P and Cl, IIIu-d_2 and IIIu-d_4 are used for N, H, and F.

2.1 Geometry optimization and hyperfine structure calculations

In all calculations, the hf structures were computed at the same level of theory as in the corresponding geometry optimizations. For some of the systems, the hf calculations were also performed on the experimental geometries.

NH_2: The orbital basis sets are varied such that the same set is used for both atomic types in all calculations. Thus the molecule is studied using nine different theoretical models: LDA/IGLO-III, LDA/IIIu-d_2, LDA/IIIu-d_4, BP/IGLO-III, BP/IIIu-d_2, BP/IIIu-d_4, PWP/IGLO-III, PWP/IIIu-d_2, and PWP/IIIu-d_4.

NF_2: The same combinations of basis sets and potentials are used as in NH_2.

NCl_2: The IGLO-III basis set is used for N in all calculations. The IGLO-III and IGLO-II basis sets are used for Cl, giving a total of six theoretical models. No experimental geometries have been reported for this molecule.

PH_2: Only the IGLO-III orbital basis set is used for P together with the IGLO-III, IIIu-d_2, and IIIu-d_4 basis sets for H, giving nine sets of data.

PF_2: The same models are used as in the PH_2 study. No experimental geometries are found in the literature.

PCl_2: The orbital basis sets IGLO-II and IGLO-III are used. This gives six data sets. For this molecule also, there are no experimental geometries available for comparison.

Finally, the hyperfine structures are calculated for NH_2, NF_2, and PH_2, using the experimental geometries. Only the IGLO-III basis set is employed, but the effect of non-local corrections is examined. All anisotropic hf parameters are in the principal magnetic coordinate system.

2.2 Density study

The total and unpaired spin densities (ρ^{tot} and ρ^u, respectively), and the Laplacian of ρ^{tot} ($\nabla^2\rho^{tot}$) are plotted for NH_2, NF_2, and PH_2, at the experimental geometries. The calculations required for this study were done using the PROAIM package by Bader and co-workers (25). Only the IGLO-III basis set was used, and the Laplacians were analysed using the LDA only. For the densities, however, all three potential forms were used in each case, giving three plots per density analysed. For the final analysis, density differences between the three functionals were plotted. All plots are done in the molecular (yz) plane, the z axis being the C_2 axis of the system, with an increment in density of 0.100 au between each contour in the plots.

3. Results

3.1 Geometries

Optimized and experimental geometries are presented in Tables 1*a* and 1*b*, along with previous theoretical data. The DFT-optimized geometries show very little dependence on basis set, but are affected by the choice of functional form.

In amidogen (NH_2), all the optimized bond lengths are very similar, and all are somewhat overestimated. Bond angles are well reproduced, but slightly too small. The LDA gives the longest bond lengths and the largest angles.

In NF_2, the bond lengths are again somewhat too long. In this case, the LDA gives the shortest bond lengths, which are in excellent agreement with experiment. The bond angles are also very well reproduced, and all potentials give very similar results. The uncontracted IIIu-d_2 basis set, however, gives noticeably smaller angles than the other two.

In NCl_2, the LDA gives the smallest angles and, as in NF_2, the shortest bonds. Relative to previous UHF results (10), R_{NCl} is shorter and $\angle$ClNCl is larger at all DFT levels presently used. An examination of the nitrogen series shows that non-local corrections do affect the optimized geometries slightly, but that the potentials have different effects on different molecules.

In PH_2, the bond lengths are consistently too long relative to experiment, and the angles are underestimated by 0.9°–1.7°. In this case, the LDA gives the worst agreement with experiment, with some of the longest bonds and the smallest angles.

In the rest of the phosphorus series, the LDA gives the shortest bonds and the smallest angles.

Looking at both the phosphorus and the nitrogen compounds it can be seen that in the halide-containing molecules, the non-local corrections tend to lengthen the bonds, and open the angles, whereas in the hydrogen-containing molecules, the corrections tend to shorten the bond. All potentials overestimate the bond lengths and underestimate the bond angles in NH_2, NF_2, and PH_2, relative to experiment.

The success of the LDA to produce accurate ground state geometries is well known (11, 26, 27), and it has also been found, in the case of hydrogen-containing compounds, that non-local effects generally lead to shorter X—H bonds. Bonds between heteroatoms, on the other hand, generally become enlongated at the BP and PWP levels, relative to the LDA results (13, 28). The present results are in good agreement with the previous findings.

Comparing the changes in geometry down the nitrogen series with those down the phosphorus series, some interesting differ-

	IIIu-d_4	1.035	103.0	1.395	103.5

ences are found. The experimental angles in NH_2 and NF_2 are identical, and the optimized values differ by only 0.5°. The angle in NCl_2 is calculated to be 8° larger. On the other hand, between PH_2 and PF_2, the calculated angles widen by 8°. Between PF_2 and PCl_2 the angle increases by just over 4°.

The smaller changes in angle are accompanied by larger changes in bond length, to compensate for the increased steric repulsion. The bond length increases by 30% (+0.35 Å) between NH_2 and NF_2, and by 20% (+0.35 Å) between NF_2 and NCl_2. Going down the phosphorus series, from PH_2 to PF_2 to PCl_2, the bond lengthens by 10% (+0.2 Å) and then by 30% (+0.5 Å).

As a whole, the geometries obtained in the present study agree well with experiment, where available, and are in qualitative agreement with previous theoretical data (cf. Table 1*a*). Interesting to note is that the non-local DFT calculations consistently predict more elongated bonds for the phosphorus compounds than does UHF, although the bond angles generally differ very little between various levels of theory.

3.2 Hyperfine structures

3.2.1 Isotropic couplings

Most hyperfine calculations are done directly following the corresponding LCGTO–DFT geometry optimization, using the same theoretical model (basis set and potential). Previous work has shown that isotropic coupling constants are highly geometry dependent (13, 29). However, by comparing the results computed at the experimental and DFT–optimized geometries, it can be seen that the geometry changes involved in this study are too small to make a significant difference. Furthermore, the changes are much larger when introducing non-local corrections than when the geometry and (or) basis sets are varied.

An examination of the isotropic coupling constants for ^{14}N in NH_2 (Table 2*a*) shows that the geometry is a much less significant factor than the basis set. Looking at the BP results we see that the optimized geometries from the three basis sets (cf. Table 1*b*) are virtually identical, although not in perfect agreement with the experimental geometry (cf. Table 1*a*). Nevertheless, the Fermi contact term calculated with the IGLO-III basis set at the experimental geometry is very similar to that obtained at the IGLO-III optimized geometry, but quite different from the IIIu-d_2 and IIIu-d_4 values. This trend continues through the rest of the molecules.

From these considerations it can be concluded that in this study geometry effects are of minor importance, particularly for the three smallest systems. The choice of basis set, however, does have a small effect on the isotropic coupling constant. Tables 2*a* and 2*b* also show that the largest factor affecting the Fermi contact term is the non-local correction used. Changing the potential can cause a doubling or tripling of the a_{iso} value. This was also observed in a detailed study of the hf structure of ^{17}O in the water cation (13), and is related to the corrections in the core and valence tails of the density, brought about by the non-local gradient corrections (cf. ref. 31). Consequently, the LDA and the BP corrections generally give numerically too small values.

The PWP level of theory gives excellent results for N in NH_2

and H in PH_2, and very good results for P in PF_2. BP gives the best agreement with experiment for H in NH_2. The Cl results are difficult to evaluate, as the coupling constants are very small. The absolute value of the calculated Fermi contact term is never greater than 6 MHz. Both in NCl_2 and PCl_2, the LDA and BP give negative results, and PW gives positive results. The experimental values are (−)9.7 and (+)15.4 MHz, respectively.

Experimentally, only absolute numbers can be obtained, and the assignment of signs is often based on discussions of direct vs. induced spin densities or with the aid of theoretical predictions. For NCl_2 the interpretation of ESR spectra has led to some disagreement regarding the size of $a_{iso}(^{14}N)$, and the signs of the $a_{iso}(^{35}Cl)$, $A_x(^{14}N)$, and $A_y(^{14}N)$ values (30, 32) ($A_q = T_q + a_{iso}$). The anisotropic $A(^{14}N)$ couplings have been reported as ±14, ±14, and 112 MHz for A_x, A_y, and A_z, respectively. Choosing the convention +14 MHz for A_x and A_y leads to an $a_{iso}(^{14}N)$ value of 47 MHz and the anisotropic T_x, T_y, T_z values −33, −33, +65 MHz, respectively. However, letting the experimentally observed A_x and A_y couplings assume the values $2 \times (-14)$ MHz, we instead obtain 28, −42, −42, and 84 MHz for a_{iso}, T_x, T_y, and T_z. These agree better with the calculated hf couplings.

Regarding the sign on the $a_{iso}(^{35}Cl)$ coupling in NCl_2, both the present PWP and previous UHF calculations (10) yield a positive number. We are therefore inclined to believe that an error has also occurred in the assignment of the experimental chlorine coupling.

As a whole, the isotropic hf couplings are in satisfactory agreement with experiment, when computed at the PWP level. The agreement is, however, not perfect for all cases studied; in particular the phosphorus and difluoroamidogen couplings deviate a fair amount. An explanation for this could be either that the basis sets employed are not sufficiently large for describing the atomic orbital integrals at the various nuclei, or that we lack diffuse functions in the bases, whereby we do not fully take into account the very diffuse electron clouds in the P atom and the halides. It should be noted that the basis sets employed, although being of "TZP" quality, have not been optimized with respect to producing highly accurate hf structures.

The differences in isotropic couplings in the nitrogen and phosphorus series show very clearly the influence of the 3*s* shell on the P atoms. The differences in spin angular momenta ($I(^{14}N) = 1$; $I(^{31}P) = 1/2$) and magnetic dipole moments (ratio $^{14}N/^{31}P \approx 0.36$), cf. eq. [1], only partially account for the difference of a factor of 5–10 in a_{iso} values of the two nuclei (cf. Tables 2*a* and 2*b*). The larger spin density at the P nuclei also affects the isotropic couplings of the substituents, where those bonded to phosphorus have numerically smaller couplings than those bonded to nitrogen.

3.2.2 Anisotropic results

Anisotropic hf couplings computed at the DFT level are generally highly insensitive to basis set and functional form (13).

TABLE 3. Theoretical and experimental[a] hyperfine structures. All couplings are in MHz. All calculations from the present study employ the IGLO-III basis set, and optimized geometries. The isotopes investigated are ^{1}H, ^{14}N, ^{19}P, and ^{35}Cl

This is also observed in the present study. Most of the results are in very good agreement for N and P (especially using the LDA), and in fair agreement for F and Cl. The experimental values found for the anisotropic coupling constants of H in PH_2 are quite uncertain and are not well reproduced by the theory. All other calculated couplings have the correct sign and approximate magnitude. Most of the calculated coupling constants for N, F, and Cl (in PCl_2) are larger than the experimental absolute values, whereas the anisotropic ^{31}P and ^{35}Cl (in NCl_2) couplings generally are underestimated (cf. Tables 2*a* and 2*b*, and Table 3).

The anisotropic results vary much less than the isotropic ones. The non-local corrections still affect the results, but to a much smaller degree. BP and PWP generate very similar results. Geometry and basis set effects are about the same as for the isotropic couplings. PWP calculations done on PH_2 using the IGLO-II basis set for P, and the three different bases for H, show that the geometries and isotropic and anisotropic hf couplings were no more affected by changing the basis set for P than they were when only varying that of H.

The anisotropic ^{14}N couplings and ^{31}P couplings are quite similar in each series of compounds, irrespective of substituent. The substituents, on the other hand, show large variations in anisotropic values, depending on the central atom. The N-containing compounds always yield numerically much larger anisotropic couplings on the H, F, and Cl atoms. This is partially a reflection of the smaller angles observed in the P compounds, leading to larger modifications in the $T_{x,y,z}$ values. The lower substituent isotropic couplings in the P series, on the other hand, can be partially related to the longer bond distances observed in these systems, through the resulting decrease in overlap integrals.

3.3 Total and unpaired spin densities

We now turn to the analysis of the total and unpaired spin densities in an attempt to explain the observed differences in hf structures for the various compounds investigated. Analysis of

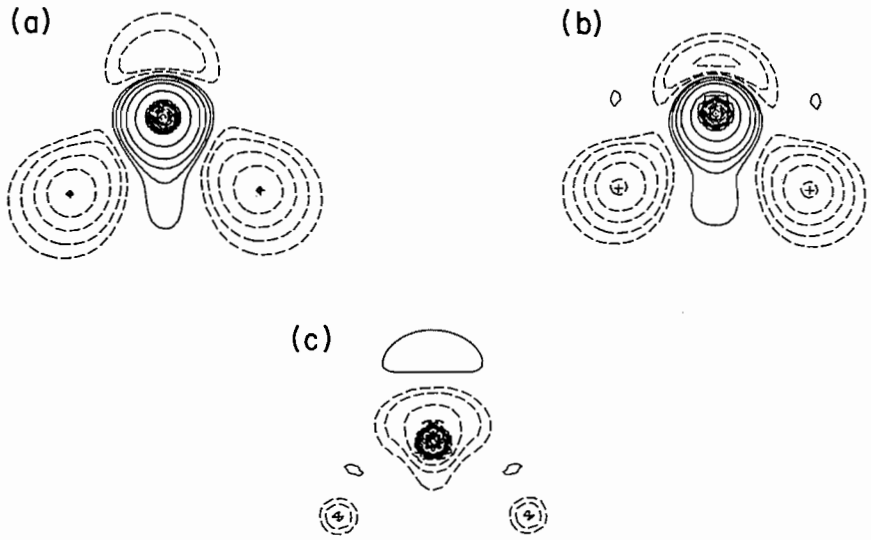

FIG. 2. Difference in ρ^{tot} of NH_2 between the (*a*) LDA/IGLO-III and BP/IGLO-III, (*b*) LDA/IGLO-III and PWP/IGLO-III, and (*c*) BP/IGLO-III and PWP/IGLO-III levels.

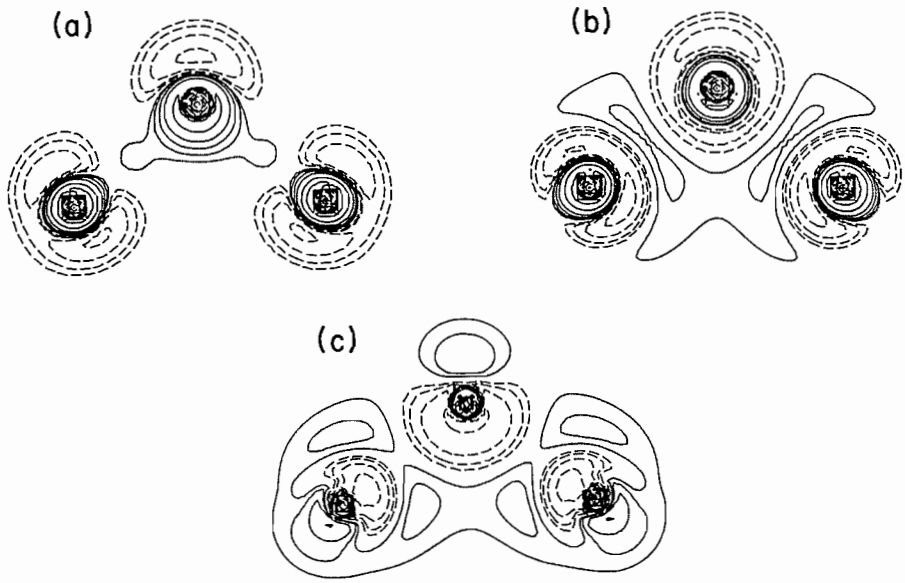

FIG. 3. Difference in ρ^{tot} of NF_2 between the (*a*) LDA/IGLO-III and BP/IGLO-III, (*b*) LDA/IGLO-III and PWP/IGLO-III, and (*c*) BP/IGLO-III and PWP/IGLO-III levels.

the differences in the spin densities obtained from the various DFT calculations, or from the LDA and different *ab initio* methods, has proven to be a very successful tool for understanding the fundamentally different results observed in the molecular calculations (13, 33). In the present study we will concentrate on the three systems NH_2, NF_2, and PH_2.

In Fig. 1, we show the total charge densities and their Laplacians, for the three systems as obtained from the LDA/IGLO-III calculations at the experimental geometries. The Laplacians of the LDA densities clearly indicate the shell structures of the N, F, and P atoms, as well as the buildup of electron density along the bonds. The latter effect is a reflection of the covalent character of the bonds. $\nabla^2\rho^{tot}$ (NF_2) differs markedly from the other two in that there is a very strong polarization of the valence shells, although there is also a region of electron depletion between the atoms. In Figs. 2–4 the corresponding differences in ρ^{tot} are displayed (*a* = LDA − BP; *b* = LDA − PWP; *c* = BP − PWP). When considering the differences in total densities, we note that plots *a* and *b* of each molecule have very similar features. For all three molecules, the LDA seems to favour the inner-valence shells of the heavy atoms (solid lines), whereas the BP and PWP non-local corrections lead to a larger density in the core and outer-valence regions of the molecules (broken lines). These methods also generate a much higher amount of total density at the hydrogen atoms. The differences in ρ^{tot} between the two non-local correction schemes (Figs. 2–4*c*) show that the BP method (solid lines) enhances these effects to a greater extent than does PWP at the heavy atoms, whereas the reverse is true at the hydrogens.

The LDA unpaired spin densities and the LDA – BP, LDA –

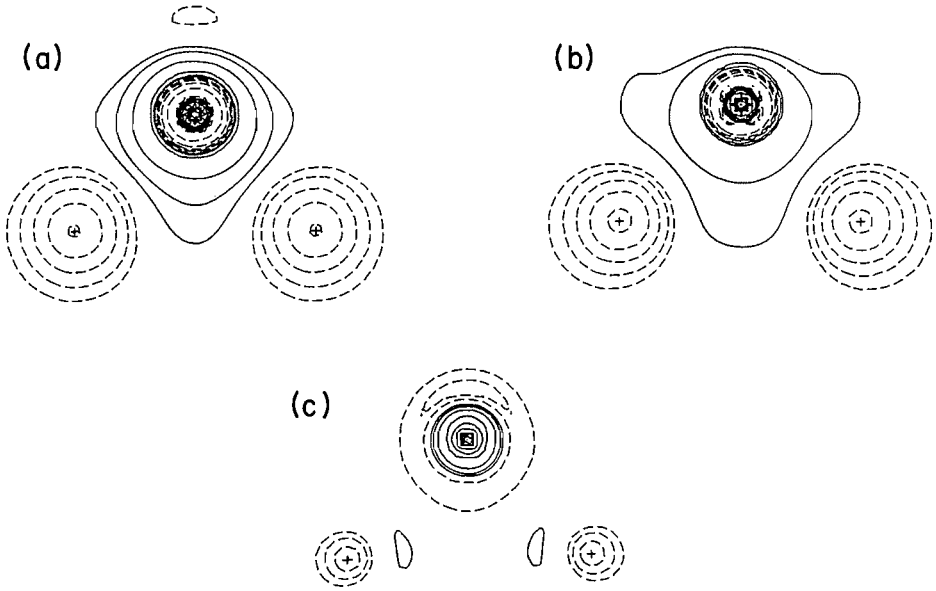

FIG. 4. Difference in ρ^{tot} of PH_2 between the (*a*) LDA/IGLO-III and BP/IGLO-III, (*b*) LDA/IGLO-III and PWP/IGLO-III, and (*c*) BP/IGLO-III and PWP/IGLO-III levels.

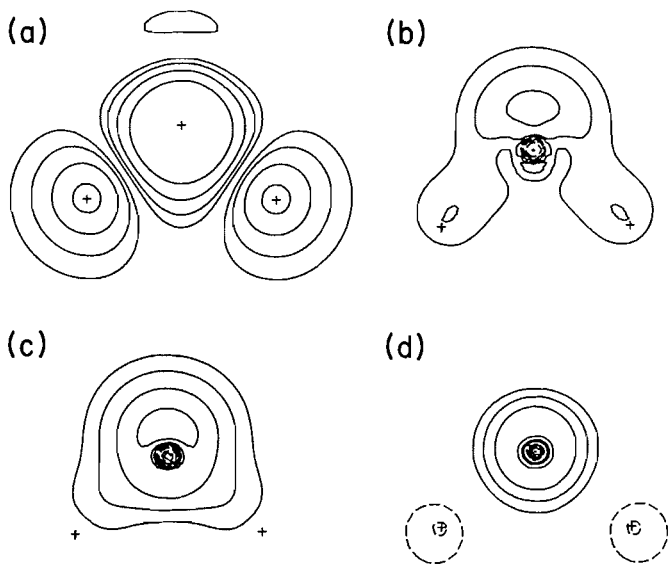

FIG. 5. (*a*) Unpaired spin density of NH_2. Differences in ρ^u of NH_2 between the (*b*) LDA/IGLO-III and BP/IGLO-III, (*c*) LDA/IGLO-III and PWP/IGLO-III, and (*d*) BP/IGLO-III and PWP/IGLO-III levels.

PWP, and BP – PWP differences in ρ^u are depicted in Figs. 5–7. The ^{14}N unpaired spin densities (Figs. 5*a* and 6*a*) are very similar, whereas for the phosphorus atom (Fig. 7*a*) ρ^u is more contracted to the core region. The fluorine densities differ considerably from the other ones, and clearly indicate the presence of the 2*p* shell. For the ρ^u difference plots of NH_2 and PH_2 (Figs. 5 and 7) the same observation is made as for $\Delta\rho^{tot}$, that electron density is transferred by the non-local corrections towards the core regions of the heavy atoms. The non-local corrections thus localize quite strongly the unpaired electron density at the nuclei of the central atoms. The differences between the BP and PWP methods are, as opposed to the observations made for $\Delta\rho^{tot}$, that PWP enhances the effect to a greater extent than does BP. This can be directly related to the magnitudes of the isotropic hf couplings, which increase significantly along the series LDA–BP–PWP.

Similar arguments also hold for the substituents. In the case of the fluorine atoms, Fig. 6 indicates a significant buildup in spin density along the same series, which is very nicely reflected in the $a_{iso}(^{19}F)$ couplings (Table 3). For hydrogen, on the other hand, there is little difference in spin density between the three potentials, and correspondingly little difference in the a_{iso} values.

4. Summary

The six neutral radicals NH_2, NF_2, NCl_2, PH_2, PF_2, and PCl_2 have been studied at the LCGTO–DFT level of theory. The ground state geometries were optimized at the local and non-local levels, and were found to agree well with experimental and previous theoretical results (Tables 1*a* and 1*b*). In particular, the bond angles are remarkably stable, whereas the non-local corrections lead to an elongation of the bonds between heteroatoms. The effects of contracting the basis set, as well as the number of polarization functions added, are negligible in terms of equilibrium geometries.

The isotropic hyperfine parameters, also computed in the present study, are far more sensitive to basis set contraction and, even more so, to functional form used. Overall, the PWP non-local correction gives the most satisfactory agreement with previous ESR and laser magnetic resonance (LMR) measurements. As has previously been observed (13), the fluorine atoms seem particularly difficult in this respect. The anisotropic hf couplings, on the other hand, are reproduced very well at all levels of theory, and for all systems, except the hydrogens in PH_2. A reinterpretation is suggested for the previously reported hf parameters of NCl_2, lowering the value of $a_{iso}(^{14}N)$ by 19 MHz. The remaining differences in hf structures can be explained in terms of insufficient basis sets or, to some extent, matrix effects in the ESR measurements that may cause changes in geometry and (or) electron distribution in the molecules. In particular, the spin densities for NF_2, PF_2, and PCl_2 have been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12

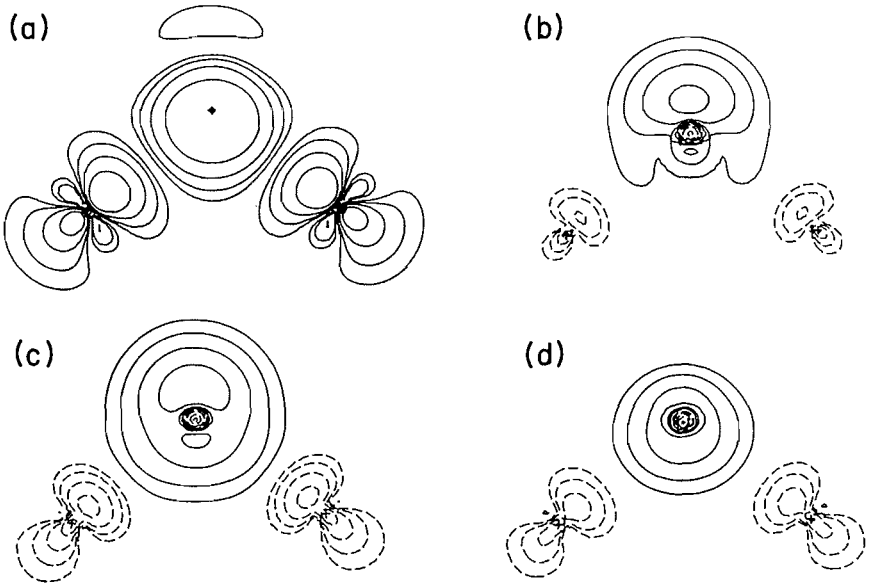

FIG. 6. (*a*) Unpaired spin density of NF_2. Differences in ρ^u of NF_2 between the (*b*) LDA/IGLO-III and BP/IGLO-III, (*c*) LDA/IGLO-III and PWP/IGLO-III, and (*d*) BP/IGLO-III and PWP/IGLO-III levels.

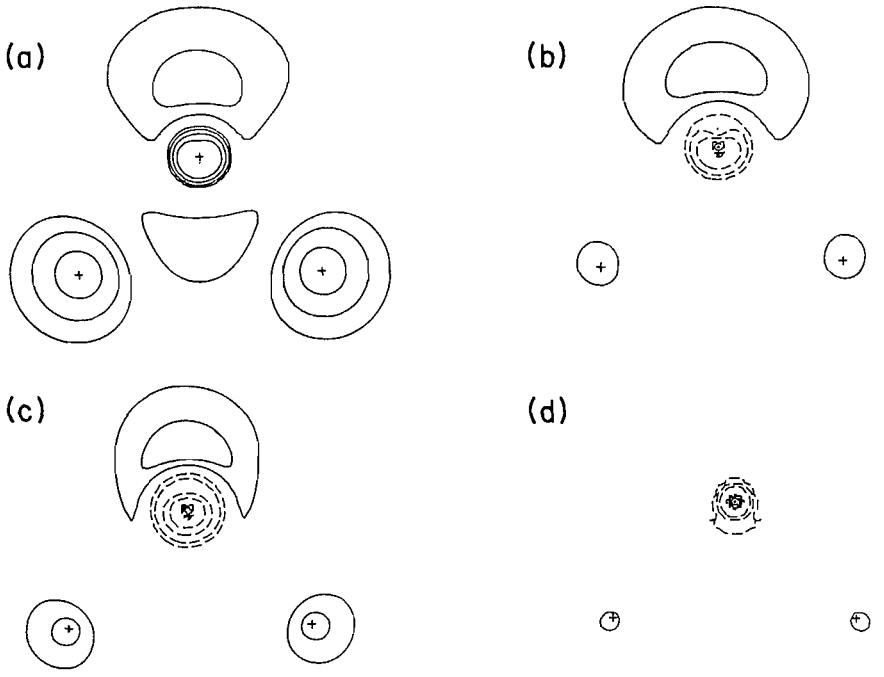

FIG. 7. (*a*) Unpaired spin density of PH_2. Differences in ρ^u of PH_2 between the (*b*) LDA/IGLO-III and BP/IGLO-III, (*c*) LDA/IGLO-III and PWP/IGLO-III, and (*d*) BP/IGLO-III and PWP/IGLO-III levels.

shown to be relatively uncertain (34) due to molecular motion in the matrices, even at temperatures as low as 4 K. In PCl_2, observed in a PCl_3 matrix at 25 and 77 K, raising the temperature was furthermore found to shift both the isotropic and anisotropic hf parameters towards the chlorine atoms.

The differences in isotropic hf couplings in NH_2, NF_2, and PH_2 are explained by analyzing the differences in unpaired spin densities, as obtained at the LDA, BP, and PWP levels of theory. Both the non-local corrections to the exchange and correlation functionals transfer unpaired spin from the inner-valence to the core and the outer-valence regions of the heavy atoms. The effect is stronger at the PWP level, and the differences in unpaired spin densities directly reflect the differences in a_{iso} values obtained with the different methods. The differences in densities between the BP and PWP methods show the effects of the functionals used for describing the electron exchange (19, 20), since both methods employ the same corrections to the correlation functionals (18).

The lowest energy excited states of the binuclear silver(I) halide complexes, $Ag_2(dmb)_2X_2$. Metal-centered or charge transfer states?

DANIEL PICHÉ[1] AND PIERRE D. HARVEY[2]

Département de chimie, Université de Sherbrooke, Sherbrooke, PQ J1K 2R1, Canada

Received May 21, 1993

This paper is dedicated to Professor John A. Polanyi on the occasion of his 65th birthday

DANIEL PICHÉ and PIERRE D. HARVEY. Can. J. Chem. **72**, 705 (1994).

The nature of the lowest energy excited states of the $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br, I; dmb = 1,8-diisocyano-p-menthane) have been addressed both experimentally and theoretically. It is shown that the lowest energy excited states of the complexes are charge transfer states from the silver-halide frame to the isocyanide ligands (M/XLCT) based upon UV–visible spectra and emission polarization ratio measurements, and extended Hückel molecular orbital calculations (EHMO). The metal-centered $d\sigma^* \rightarrow p\sigma$ bands have been observed in the higher energy region of the spectra (232–242 nm). The complexes are luminescent ($440 \leq \lambda_e \leq 480$ nm) both in a glass and in the solid state at 77 K where the emission lifetimes, τ_e, range from 20 to 90 μs, which depend upon the nature of the halide (for the solid state data) and the media. No emission is observed at room temperature.

DANIEL PICHÉ et PIERRE D. HARVEY. Can. J. Chem. **72**, 705 (1994).

La nature des états excités de plus basse énergie des complexes $Ag_2(dmb)_2X_2$ (X = Cl, Br, I; dmb = 1,8-diisocyano-p-menthane) a été étudiée expérimentallement et théoriquement. Il est montré que ces états sont des états de transfert de charge des centres argent-halogènes aux ligands isocyanures (M/XLCT) tels que montrés par les spectres UVvisible et les mesures des rapports de polarisation, et des calculs d'orbitales moléculaires Hückle étendue (EHMO). Les bandes métal-centrée du type $d\sigma^* \rightarrow p\sigma$ ont été observées dans les régions de haute énergie des spectres (232–242 nm). Les complexes sont luminescents ($440 \leq \lambda_e \leq 480$ nm) pour l'état solide et les solutions rigides à 77 K, où les durées de vie d'émission, τ_e, se situent entre 20 et 90 μs, lesquels dépendent de la nature de l'halogène (pour les mesures de l'état solide) et le milieu. Aucune émission n'a été observée à la température ambiante.

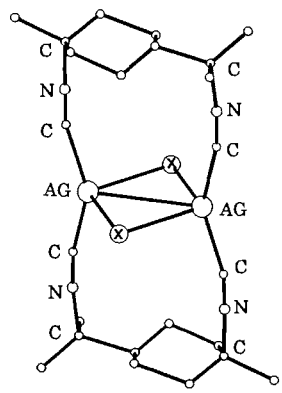
Introduction

The investigation of the luminescence properties of the mono-, bi- and polynuclear d^{10} species (M = Ni^0, Pd^0, Pt^0 and Cu^+, Ag^+, Au^+) has become a subject of increasing interest (1–5). For the bi- and polynuclear complexes, the role of (ground and excited states) metal–metal interactions of these and related d^{10} species have attracted substantial attention among experimentalists (6, 7), have been the topic of research from a theoretical point of view (4*c*, 8), and have also been the subject of occasional reviews (4*d*, 7*f*, 9). There has been some discussion concerning the assignment of the lowest energy emission of tetranuclear cuprous halide clusters, $Cu_4X_4L_4$ (where X = Cl, Br, or I, and L = a nitrogen or phosphine organic base), where both halide-to-ligand charge transfer (XLCT) and ligand-to-copper charge transfer (XMCT) assignments have been proposed along with a metal-centered (MC) assignment (4*b–g*). In some occasions double emissions have been reported where both MC and XLCT states are found to be luminescent (4*g*). Such properties lead to the obvious difficulty in making the appropriate assignment. We have recently synthesized and characterized by X-ray diffraction, a series of new silver polynuclear complexes of the type $Ag_2(dmb)_2X_2$ (see Scheme I) and $Ag_n(dmb)_2I_n$ (where X = Cl, Br, I and n = 2–4) (6*a*, *b*). In particular, the binuclear series is of particular interest since it is a prototype example for weak metal–metal interactions. In comparison with the tetranuclear species, $Cu_4X_4L_4$, cited above where multiple Cu···Cu (and X···X) interactions occur within the cubane-like structure of the clusters, the d^{10}–d^{10} dimeric species $Ag_2(dmb)_2X_2$ (X = Cl, Br, I) represent ideal systems to study the true nature of the lowest energy excited state, and the effect of the halide atoms on these states.



SCHEME I. Structure of the $Ag_2(dmb)_2X_2$ complexes.

Indeed, the $Ag_2(dmb)_2X_2$ (X = Cl, Br, I) complexes exhibit Ag···Ag separations ($r(Ag_2)$) ranging from 3.347 to 3.452 Å where the silver–silver stretching frequencies ($\nu(Ag_2)$) are found between 33 and 42 cm^{-1} (6*a*). We now wish to report our recent spectroscopic, photophysical, and Extended Hückel Molecular Orbital (EHMO) results on the binuclear silver-halide complexes. The lowest energy excited states are found to be silver-halide-to-isocyanide charge transfer excited states (M/XLCT), they exhibit luminescence properties at 77 K.

Experimental section

Materials

$Ag_2(dmb)_2X_2$ (X = Cl, Br, I) (6*a*), $[Ag_2(dmpm)_2)_2](PF_6)_2$ (10), and $Ag_2(dmpm)_2Br_2$ complexes (6*c*) were prepared according to literature procedures. Ethanol (Fisher), acetonitrile (Fisher), and butyronitrile (Aldrich Chemical Company) were purified according to standard pro-

cedures (11). All spectroscopic measurements were performed immediately after Ar(g) bubbling degassing of the solutions, unless stated otherwise.

Apparatus

The absorption spectra were acquired on a Hewlett Packard 8452 A diode array spectrophotometer. The emission and excitation spectra were obtained using either a Spex Fluorolog II spectrometer or a PTI LS100 spectrometer. Part of the emission lifetime measurements were also performed on the PTI LS100 instrument. The second part of the measurements was made using the Spex Fluorolog II spectrometer equipped with the Spex 1934 D phosphorimeter set-up (for lifetimes > 20 ps).

Experimental procedures

The Φ_E values were measured using 9,10-diphenylantracene as the standard according to published procedures (12). The polarization ratios (N) were measured according to literature procedures (see, for examples, ref. 13).

The polarization ratio, N, is given by $(I_V/I_H)_V(I_H/I_V)_H$ where $(I_V/I_H)_V$ is the ratio of the intensities of vertically to horizontally polarized emissions when excited with vertically polarized light $(I_H/I_V)_H$ is the ratio of the intensities of horizontal and vertical emissions with horizontally polarized excitation. N is then related to the relative orientation of transition moments in absorption and emission.

Computational details

All MO calculations were of the extended Hückel type (EHMO) using a modified version of the Wolfsberg–Helmholz formula (14). The atomic parameters used for C and H are taken from ref. 15. The atomic parameters used for Ag (16*a*), Cl (16*b*), Br (16*c*), and I (16*d*) were also from literature. The Ag—C, C≡N, Ag—X (X = Cl, Br, I), and C—H bond lengths used for the computations are 2.14, 1.13, 2.70 (X = Cl), 2.80 (X = Br), 2.92 (X = I), and 1.05 Å as found crystallographically (6*a*). All angles were also taken from our previous X-ray studies. Because of limitations in the size of the molecules handled by the program, dmb was replaced by two methylisocyanide ligands. Pictorial representation of the orbitals was obtained using CACAO graphics package included in the software (17).

Results and discussion

Ultraviolet–visible spectra

The MO scheme for two linear L—M—L moieties interacting in a D_{2h} configuration has already been reported by Zietlow-Heinrich (18). For d^{10} species, the lowest energy electronic transition arises from a "d-to-p" type transition (3*a*). In our recent investigations on d^9–d^9 Pd_2 species (19), HOMO and LUMO are found to be $d\sigma$ and $d\sigma^*$ orbitals where both orbitals were composed of a combination of $d_{x^2y^2}$ and d_{z^2} metal atomic orbitals as major components, and some p_z, s, and ligand orbitals as minor components. The assignment of the $d\sigma \rightarrow d\sigma^*$ electronic transitions is based on the intensities of the electronic bands, the temperature dependence of the band-shapes (and of the absorption wavelength maxima). Typically an electronic band associated with a $d\sigma \rightarrow d\sigma^*$ transition undergoes a blue-shift along with an increase in intensity upon cooling of the sample (20). The behavior reflects the disappearance of "hot bands" for vibrationally-active Franck–Condon modes which are thermally populated. In the case of $d\sigma \rightarrow d\sigma^*$ transitions, the Franck–Condon active vibrational mode is $\nu(M_2)$ (100–180 cm^{-1}) (19, 20*a*). For systems related to this work, the d^{10} species $(L—M—L)_2$ will give rise to $d\sigma^* \rightarrow p\sigma$ electronic transitions (2). The electronic bands associated with the latter transitions also exhibit sensitive spectroscopic changes with temperature, notably for the band width. The d^{10}–d^{10}

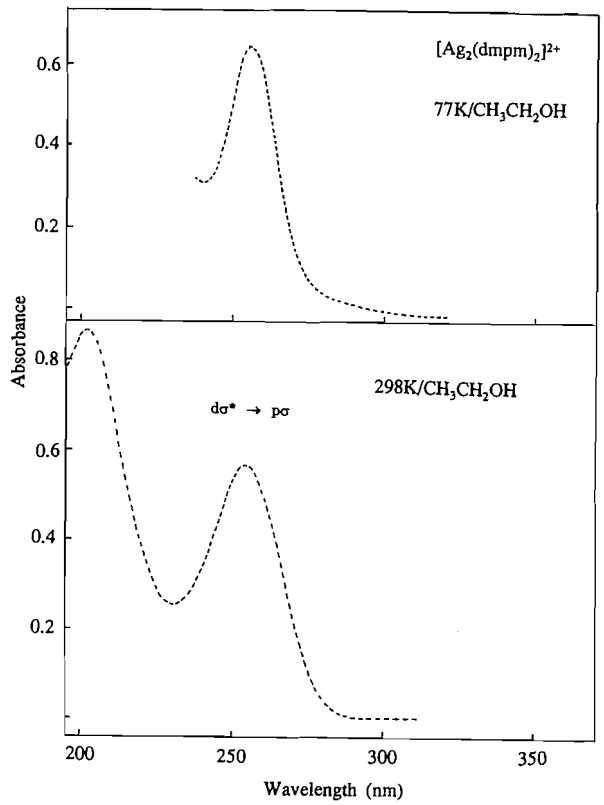

FIG. 1. Ultraviolet–visible spectra of $Ag_2(dmpm)_2^{2+}$ in ethanol at 77 and 298 K. The spectra were recorded using two different solution concentrations and cell set-ups.

$Ag_2(dmpm)_2^{2+}$ compound (dmpm = $((CH_3)_2P)_2CH_2$) was used as a reference point for the assignments. All attempts to make $Ag_2(dmb)_2^{2+}$ dimers failed. Using counter anions PF_6^-, BF_4^-, and NO_3^-, the only isolated and well-characterized products are found to be the relatively insoluble polymeric $\{[Ag(dmb)_2](Y)\}_n$ compounds (Y = PF_6^-, BF_4^-, NO_3^-) (1*a*). This $Ag_2(dmpm)_2^{2+}$ binuclear compound has been crystallographically characterized by others (as PF_6^- salt) (21); where a D_{2h} local symmetry is observed with $r(Ag_2)$ = 3.041 Å. The PF_6^- anion is not known to be a ligand capable of strong interactions with an unsaturated metal, and it is reasonably therefore assumed that no $Ag^+\cdots PF_6^-$ interaction occurs in solution. The spectrum for $Ag_2(dmpm)_2^{2+}$ is characteristic of a binuclear compound without other types of interaction (except for $Ag^+\cdots$solvent interaction). The uv-spectra for $Ag_2(dmpm)_2^{2+}$ in ethanol at 298 and 77 K (Fig. 1) exhibit the typical spectroscopic behavior of a $d\sigma^* \rightarrow p\sigma$ transition similar to those previously encountered for other related d^{10}–d^{10} complexes ($M_2(dppm)_3$: M = Pd, Pt; dppm = $((C_6H_5)_2P)_2CH_2$, $r(M_2)$ ~3 Å) (2*b*); and $Au_2(dppm)_2^{2+}$ (22)). The absorptivity of this band is typical, 18 200 ± 200 M^{-1} cm^{-1} (λ_{max} = 254 nm; ethanol at 298 K), and confirm the assignment. The small red shift (from 254 (298 K) to 258 nm (77 K)) is indicative of the expected increase in force constant of the Franck–Condon active mode (in this case a metal–metal force constant) (23). For d^{10}–d^{10} $M_2(dppm)_3$ complexes (M = Pd, Pt), time-resolved resonance Raman spectroscopy (TRS) confirmed that the $\nu(M_2)$ values increased from the ground to the lowest energy triplet excited state (120 to 152 cm^{-1} for Pd, 102.5 to 120 cm^{-1} for Pt) (24).

To obtain information on the effect of halides on the absorption spectra of Ag_2 systems, the $Ag_2(dmpm)_2Br_2$ spectrum,

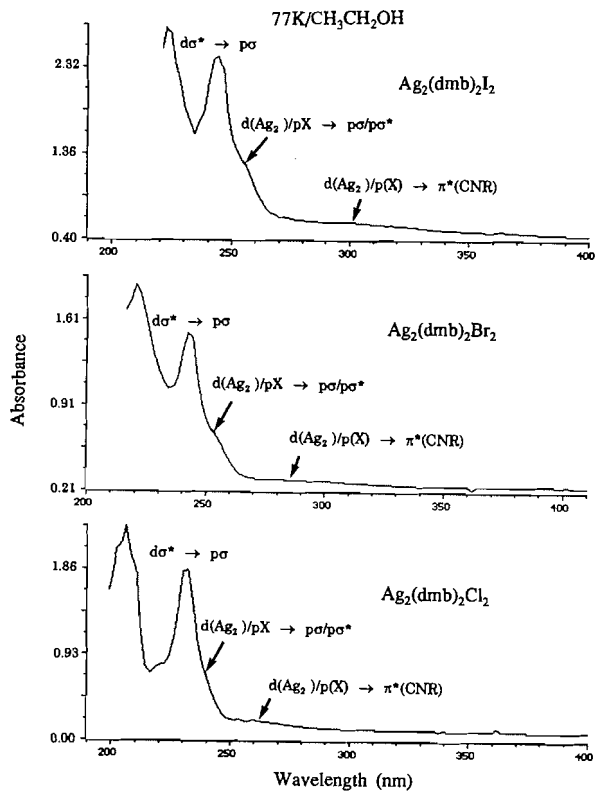

FIG. 3. Ultraviolet–visible spectra of the $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br, I) in ethanol at 77 K.

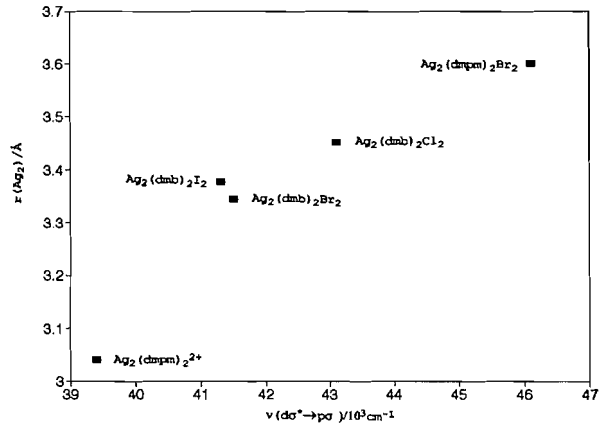

FIG. 4. Graph of $r(Ag_2)$ vs. λ ($d\sigma^*$–$p\sigma$).

recently characterized crystallographically by our group (6*c*), has been measured. The $r(Ag_2)$ value is 3.601 Å in this case, which should place the $d\sigma^* \rightarrow p\sigma$ transition well below 258 nm (λ_{max} found for $Ag_2(dmpm)_2^{2+}$). Indeed, a strong absorption is found at 217 nm for $Ag_2(dmpm)_2Br_2$ ($\epsilon \sim 19\,400 \pm 200$ M^{-1} cm^{-1}, ethanol, 298 K) associated with the $d\sigma^* \rightarrow p\sigma$ transition (Fig. 2). Moreover, a weaker broad band is observed at ~244 nm ($\epsilon = 4200$ M^{-1} cm^{-1}) with a long tail spreading to 300 nm. These features are undoubtedly due to the presence of the Br ion. This behavior is also systematically observed for $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br, I) as shown in Fig. 3 (at 77 K). The $d\sigma^* \rightarrow p\sigma$ bands are well-resolved and are found at 232 (Cl), 241 (Br), and 242 nm (I). The absorptivity values ($d\sigma^* \rightarrow p\sigma$; in ethanol at 298 K) are as follows: 19 600 (Cl), 18 300 (Br), and 20 400 M^{-1} cm^{-1} (I) (experimental uncertainty is 10%). As expected, the $\lambda(d\sigma^* \rightarrow p\sigma)$ values correlate with $r(Ag_2)$ (Fig. 4) and further support the assignment. Similar to the $Ag_2(dmpm)_2Br_2$ spectra, weaker intensity features ($\epsilon \sim$ 5000–8000 M^{-1} cm^{-1}) appear as a shoulder in the $Ag_2(dmb)_2X_2$ spectra (X = Cl, Br, I) ~ 10–15 nm on the low energy side of the $d\sigma^* \rightarrow p\sigma$ band. Finally, weak and broad features ($\epsilon \sim$ 800–1500 M^{-1} cm^{-1}) are observed in the 250–350 nm range. It is possible that unresolved singlet-triplet absorptions also occur in this same region contributing to the broadening of the bands. The spectroscopic data for these five compounds are compared in Table 1. These results are now interpreted from a theoretical point of view.

Molecular orbital calculations

In this work, the Extended Hückel Molecular Orbital calculation methods (EHMO) were used for assignment purposes. They are known to be qualitative (25) but are also found to give the correct relative energy MO levels in most cases. Recently our research group (26) used EHMO to compute MO levels for polynuclear $M_3(dppm)_3CO^{2+}$ complexes (M = Pd, Pt), which

[b]The assignments are based upon the comparison of the ν_{max} and ε values, and the EHMO findings (see text).

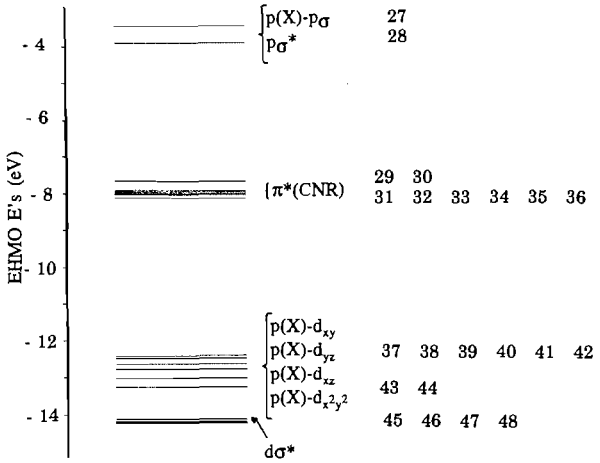

FIG. 5. General MO energy diagram for the model compounds $Ag_2(CNCH_3)_4X_2$ (X = Cl, Br, I). The numbers on the right are the numbers used in the text.

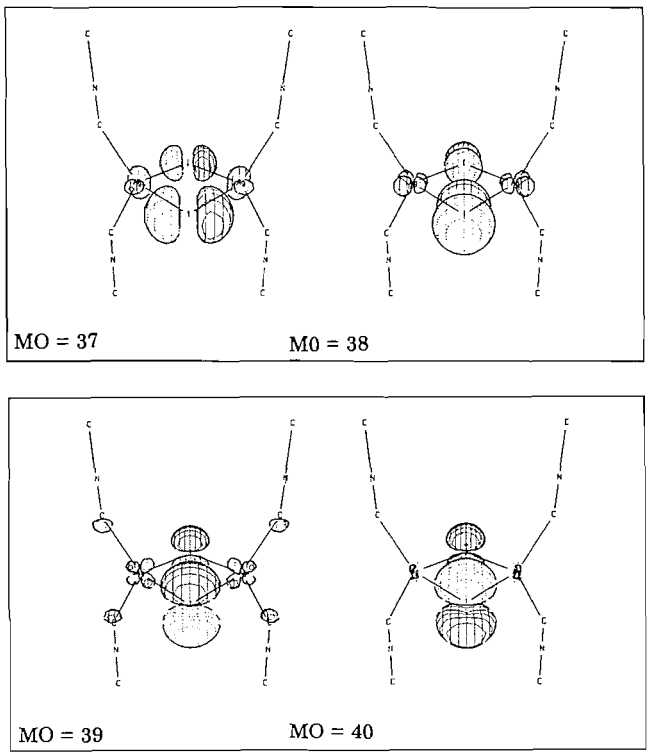

FIG. 6. Picture of the HOMO and HOMO-*n* (MO #37 to 40).

were eventually compared to the ones obtained by the more "accurate" approximate density function theoretical computations (27). The MO levels did not change in relative order between the two types of calculations (except for one level above LUMO). This comparison implies some degree of reliability for EHMO calculation in this case, despite the fact that there is almost a two-fold difference in transition energies between EHMO computations and experimental results. This phenomenom is not unusual with EHMO. The energy separation between the nd^{10} and $nd^9(n+1)s^1$ configurations of Ag^+ is ~39 000 cm^{-1} (4.83) eV (28).

The key features of the present calculations are (*1*) LUMO is a MO of the CNR π* system, (*2*) HOMO is very difficult to establish because of the proximity of many other MO levels, (*3*) HOMO is mixed in character where both silver and halide atomic orbitals are involved, and (*4*) above the set of eight MO π* (CNR) levels lie more MO levels associated with some interactions between metal and halide atomic orbitals. The latter MO's are also close to one another. A general MO scheme is presented in Fig. 5.

The computed EHMO HOMO–LUMO energy gap varies a little with the halide (~5.0, 4.7, and 4.5 eV for X = Cl, Br, I, respectively) and would correspond to an electronic transition taking place in the 250–275 nm range. We find that the nearly degenerate LUMO and LUMO + *n* (*n* = 1–7), orbitals #29 to #36, and the HOMO and HOMO-*n* (*N* = 1–5), orbitals #37 to #42, are essentially orthogonal (Figs. 6 and 7 show the MO picture for MO #37 to #42). An electronic transition between these LUMO (and LUMO + *n*), and the HOMO (and HOMO − *n*) would lead to uv–visible with very weak intensities. The broad bands located in the 250–350 nm range are in reasonable agreement with this description. It is not surprising that the set of π*(CNR) MO systems is found to be LUMO, since recently Ziegler *et al.* have shown that the LUMO in $Pt(CN)_4^{2-}$ was indeed one of the ligand π*(CN^-) orbitals using approximate density function theoretical calculations (29), which was eventually confirmed by Patterson *et al.* using relativistically modi-

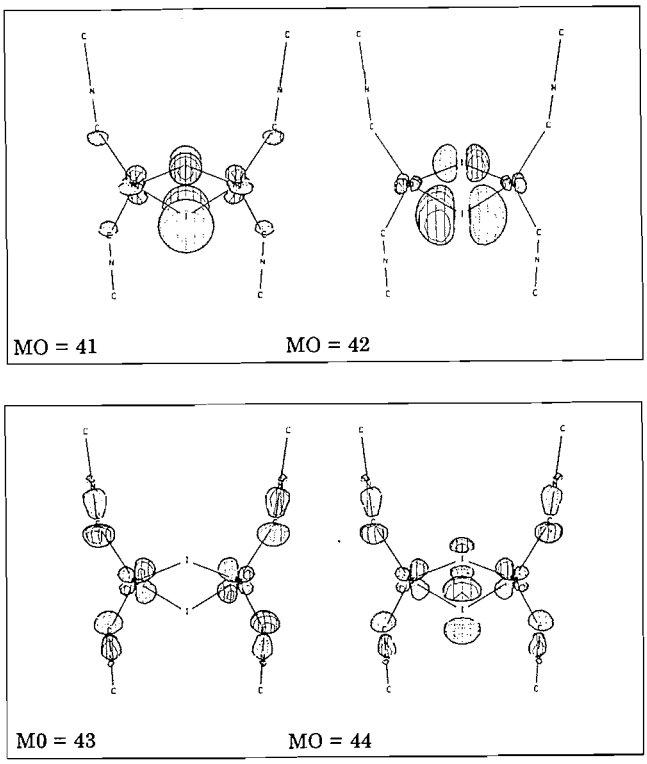

FIG. 7. Picture of MO's #41 to #44.

fied EHMO computations (7*b*). No other MO is found within ~4 eV of the LUMO. The nature of the LUMO appears to be well addressed. For the purpose of this work, it does not appear possible or relevant to identify which of the MO (#29 to #36) is the actual true LUMO. These MO's are practically identical in nature and are nearly degenerate.

The nature of the HOMO is more difficult to address since in all three cases (X = Cl, Br, I), the MO #37 to #42 are located within 1 eV, and the relative MO ordering for each individual MO differs slightly from one another. Many MO's between #37 and #44 arise essentially from interactions between the Ag_2 $d\pi$, $d\pi^*$, $d\delta$, and $d\delta^*$ MO's, and the halide p_x, p_y, and p_z orbitals. Due to the complexity of the MO's, it appears more reasonable to treat them as a whole. They will be referred to as $d(Ag_2)/p(X)$. A detailed list of the atomic orbital contributions to each individual MO's has been deposited.[3] The lowest energy electronic transition will also be referred to as $d(Ag_2)/p(X) \rightarrow \pi^*(CNR)$.

The presence of the shoulders located at ~240, 253, and 257 nm for X = Cl, Br, and I, respectively (Fig. 3) is now considered. The absorptivities of these features (6 000 – 8 000 M^{-1} cm^{-1}) appear to be too great to arise from an electronic transition between two orthogonally oriented orbitals ($d(Ag_2)/p(X)$ and $\pi((CNR))$. The upper MO's (#27 and #28) must be considered. These are $p\sigma$ and $p\sigma^*$ orbitals, and are mainly composed of $p_z(Ag)$ orbitals with some contribution of the *s* orbitals. The mixture of silver p_z and *s* orbitals is consistent with the previous theoretical calculations (SFC-Xα) reported by Cotton et al. (8*e*) on the $Ag_2(RN_3R)_2$ complex (R = C_6H_5). MO's #27 ($p\sigma$) and #28 ($p\sigma^*$) are shown in Fig. 8. Intuitively, one would have placed $p\sigma^*$ above $p\sigma$, but EHMO suggested otherwise. The reason is that $p\sigma^*$ (Ag_2) interacts very weakly with halide *p* orbitals (4–6%), while $p\sigma$ interacts more strongly with MO composed of 10%, 14%, and 18% of halide *p* orbitals for X = Cl, Br, and I, respectively. The latter interactions are found to be anti-bonding in nature, explaining why the $p\sigma$ orbital is unusually more destabilized. The energy gap between $p\sigma$ and $p\sigma^*$ is small, which is consistent with the long Ag···Ag separations (3.35 to 3.45 Å) and the low-frequency $\nu(Ag_2)$ (33 to 42 cm^{-1}) (6*a*). The shoulders (~240 nm, Cl; 253 nm, Br; 257 nm, I) are assigned to one (or more) $d(Ag_2)/p(X) \rightarrow p\sigma/p\sigma^*$ electronic transition(s).

For the $d\sigma^* \rightarrow p\sigma$ transition discussed in the previous section, both $d\sigma$ and $d\sigma^*$ MO's are found among MO #45 and #46 (depending on the halide), which lie about 1 to 1.8 eV below the $d(Ag_2)/p(X)$ orbitals. The $d\sigma^*$ orbital is also composed of some $\pi^*(CNR)$ orbitals, which is consistent with previous findings for d^7–d^7 system (see, for instance, $(M_2(CO)_{10}$, M = Mn, Re (30)), but does not include any halide component. Consequently, $d\sigma^* \rightarrow p\sigma$ electronic transition carries only some weak charge transfer character (as the $p\sigma$ is found to possess from 4 to 6% *p*(X) component).

Contrary to d^{10}–d^{10} $M_2(dppm)_3$ complexes (M = Pd, Pt), $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br, I) do not exhibit $^{1,3}(d\sigma^*p\sigma)^*$ states as lowest energy excited states. This fact is due not only to the presence of halides, but also to the presence of isocyanide ligands. The complexes are found to be luminescent, and their emissive spectroscopic properties are as follows.

The observed absorptivities ($5000 < \epsilon < 8000$ M^{-1} cm^{-1}; Table 1) are in the appropriate range for transitions of the type $d\pi(M_2) \rightarrow d\sigma^*$ (20, 30). Typically, the latter ranges from 2 200 to 5 300 M^{-1} cm^{-1} for d^7–d^7 Mn_2 and Co_2 $d\pi(M_2) \rightarrow d\sigma^*$ bands (20, 30). The difference here is the contribution of the halide orbitals to the HOMO, and the possibility of more than one electronic transition occurring at nearly the same energy, which explains the slightly higher intensity in the Ag_2 complexes.

Emission spectra and lifetimes

Luminescence of $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br, I) is readily observed at 77 K as shown in Figs. 9–11. The emission wavelength maxima (λ_{max}) appear at 440, 458, and 443 nm for X = Cl, Br, and I, respectively. The energy gap between the emission and the intense $d\sigma^* \rightarrow p\sigma$ bands are 20 400 cm^{-1}, 19 700 cm^{-1}, and 18 700 cm^{-1}, for X = Cl, Br, and I, respectively. Interestingly, the λ_{max} values in the solid state do not follow perfectly the halide trend ($\lambda_{max}(Cl) < \lambda_{max}(Br) < \lambda_{max}(I)$), but rather follow *r*(Ag···Ag): $\lambda_{max}(Cl) < \lambda_{max}(I) < \lambda_{max}(Br)$ (for *r*(Ag···Ag) = 3.451, 3.378, 3.345 Å, respectively). For comparative purposes the emission spectrum of $Ag_2(dmpm)_2^{2+}$ in ethanol at 77 K is obtained and exhibits a structureless band at λ_{max} = 371 nm (27 000 cm^{-1}), which is only 11 800 cm^{-1} away from the $d\sigma^* \rightarrow p\sigma$ absorption band in this case. This comparison confirms that the metal-centered $^{1,3}(d\sigma^*p\sigma)^*$ cannot be the lowest energy excited state in the $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br, I).

Emission lifetimes range from 20 to 90 μs for samples in solid state and in glasses at 77 K (see Table 2 for details). By taking the λ_{max} values for the lowest energy absorption bands ($d(Ag_2)/p(X) \rightarrow \pi^*(CNR)$), the energy gap between the

[3]Tables of atomic orbital contributions of the MO's #27–#46 for the $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br, I; 18 pages) have been deposited. [a]In NaCl matrix.

absorption and emission bands (Δ) is ~4000 cm^{-1}. This value compares favorably with those reported for related d^{10}–d^{10} $M_2(dba)_3$ complexes (M = Pd, Pt; $\Delta \sim 5000\ cm^{-1}$) for which MLCT excited states are found as the lowest excited states (*2b*). Hence, the long emission lifetimes and this separation between absorption and emission peaks indicate that the luminescence is phosphorescence.

The polarization ratio, N, as a function of emission wavelength has also been measured. Theoretically N varies from 0.5 to 3. A value of $N = 3$ indicates that the emission is polarized parallel to the dipole moment change involved in the absorption process, while when $N = 0.5$, the luminescence is polarized perpendicular to the absorption. Figures 9 and 10 show the N graph vs. λ (insets) at 77 K (ethanol glasses) for the emission spectra of the $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br). The iodo compound was not investigated. The N values for both Cl and Br derivatives range between 0.75 and 0.80 across the spectrum, demonstrating clearly that the emission does rise from an absorbing state with a transition moment perpendicularly polarized to the emission. Two comments must be made. First, the fact that N does not reach the theoretical value of 0.5 could be due to depolarization induced by glass imperfection and solvent-induced depolarization. Second, N values higher than 0.5 could be due to the possibility that the excitation may be taking place into two differently polarized and undeconvoluted

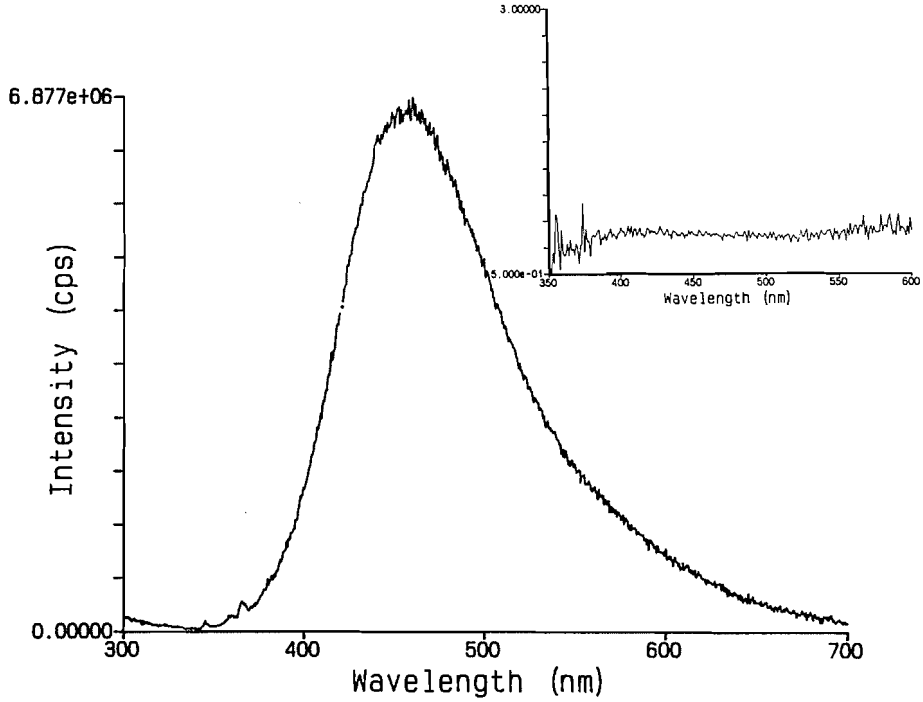

FIG. 10. Emission spectrum of $Ag_2(dmb)_2Br_2$ in ethanol at 77 K (λ_{ex} = 240 nm). Inset: Polarization ratio N vs. λ_{em} (λ_{ex} = 240 nm).

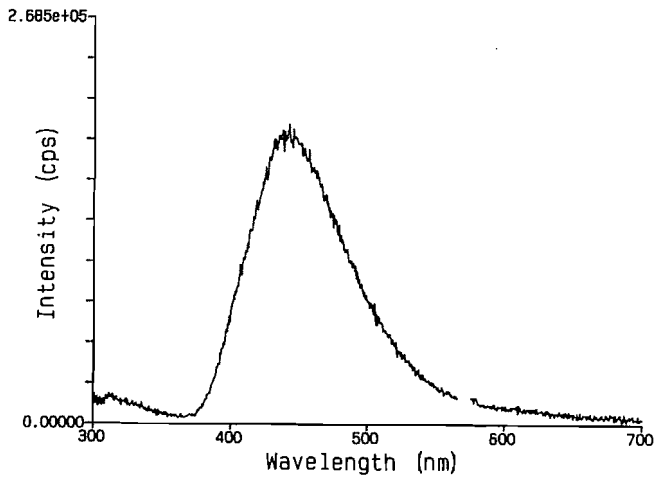

FIG. 11. Emission spectrum of $Ag_2(dmb)_2I_2$ in ethanol at 77 K (λ_{ex} = 270 nm). The weak feature located at 310 nm is due to a residual impurity.

bands. The $d\sigma^*p\sigma$ band where the excitation takes place is z-polarized. The emission (phosphorescence) of the $^3(d\sigma^*p\sigma)^*$ states is known to be z-polarized (31). The experimental results indicate that the emission must be either x- or y-polarized. This result shows that the $^3(d\sigma^*p\sigma)^*$ state is not the lowest. Unfortunately, this result does not *prove* that the emission arises from a charge transfer state as discussed in the previous section, but it is consistent with the assignment.

We have compared the emission lifetimes (τ_e) of the complexes in the solid state and in solution at 77 K (Table 1). In the solid state (all in NaCl pellets), the τ_e values behave in a typical fashion expected for internal heavy atom effect for X = Cl → X = I where τ_e decreases from 88, to 54, to 33 μs (X = Cl, Br, I, respectively). In solution τ_e decreases significantly (for Cl and Br) and appears to be only slightly dependent upon the nature of the solvent (ethanol vs. butyronitrile), and the nature of the halide (some halide-dependence of λ_{max} is also observed). For comparative purposes, τ_e for $Ag_2(dmpm)_2^{2+}$ (PF_6^- salt) in ethanol at 77 K has been measured; τ_e = 49.3 ± 0.9 μs in this case. This value appears in the appropriate range (of the investigated complexes) but is significantly larger under the same experimental conditions. If we consider that the dmb and dmpm ligands are similar in terms of excited state deactivation via the bridging ligands, then the overall lifetime results can be tentatively explained by the presence of some small degree of photo-induced lability of the halides (also involving the solvent molecules to keep the metal centers saturated). A careful study of both emission spectra and lifetimes vs. temperature is needed to address this behavior. This was not the purpose of this work. All emission decays were monoexponential and time-resolved emission spectra did not reveal the presence of a second emission, ruling out the possibility of an upper emissive state. No emission was observed at room temperature. Except for $Ag_2(dmpm)_2^{2+}$ (this work) and solid $[AgP(OCH_3)_3Cl]_4$ (32), a literature search confirms that the absence of luminescence at room temperature for d^{10} species is general, and could be due, in part, to the photochemical sensitivity of the Ag^+ compounds.

Concluding remarks

Lai and Zink (4*h*) used Franck–Condon analysis to assign the emission band of a titrameric Cu(I) complexes ($Cu_4X_4(dmpp)_4$; X = Cl, Br, I; dmpp = 1-phenyl-3,4-dimethylphosphole). The emission spectrum was assigned to a one-electron transition terminating on the phosphole ligand on the basis of the vibronic analysis. The MLCT (Cu → phosphole ligand) assignment was preferred over a halide ligand-to-ligand phosphate charge transfer (XLCT) because there was no significant shift in the energies of the emission bands of the complexes for X = Cl, Br, and I (4*h*). On the other hand, Ford *et al.* (4*g*) compared the spectro-

scopic properties of $Cu_4X_4L_4$ complexes (X = Cl, Br, I; L = pyridine (py) and 2-(diphenylmethyl) pyridine(dpmp)) and were able to demonstrate evidence for multiple emission arising from XMCT and MC triplet excited states, strongly arguing on the dependencies of the emission band energies with X and r(Cu···Cu) (4*g*). In this work there is a sensitive halide dependence on λ_{max} and τ_e, and some trend associated with r(Ag···Ag) for the solid state emission data (λ_{max}). This dual dependency strongly supports this assignment for the lowest energy transition ($d(Ag_2)/p(X) \rightarrow \pi^*(CNR)$. Overall, these experimental and theoretical investigations have allowed us to understand how the nature of the lowest energy excited states in the d^{10}–d^{10} species may vary with the nature of the ligands. Clearly, the presence of unsaturated ligands (such as isocyanide) place the π^*(CNR) MO's right at the LUMO position automatically inducing a CT state in the d^{10}–$d^{10}Ag_2$ MO frame. There should not be any surprise to induce charge transfer state in the d^{10} species (Cu^I, Ag^I, and Au^I) with unsaturated ligand (with relatively low π^* MO's) since the unoccupied silver/halide orbitals are relatively highly destabilized. It appears that if the synthesis of such complexes is possible, the nature of the LUMO can be changed (i.e. for instance via pyridine-like ligands (33)), where depending upon the substitution, the HOMO–LUMO gap and the excited state redox properties can be altered in a predictable way. We have also shown how the $d\sigma^* \rightarrow p\sigma$ transition energy varies with $r(Ag_2)$. For these complexes, the $r(Ag_2)$ values appear to be set by the presence of bridging halides rather than the bridging dmb ligands. It does not seem to be trivial to change $r(Ag_2)$ as a means of lowering the $^{1,3}(d\sigma^*p\sigma)$ state to the lowest energy excited state. Hence, the photochemical behavior of the $Ag_2(dmpm)_2^{2+}$ and $Ag_2(dmb)_2X_2$ complexes (X = Cl, Br, I) are strongly suspected to be different.

Non-equilibrium kinetics of bimolecular reactions. Part 6. Transient rate coefficients

CHRIS CARRUTHERS AND HESHEL TEITELBAUM[1]
Department of Chemistry, University of Ottawa, Ottawa, ON K1N 6N5, Canada
Received June 30, 1993
This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

CHRIS CARRUTHERS and HESHEL TEITELBAUM. Can. J. Chem. **72**, 714 (1994).

The master equation is solved numerically for the time dependence of the vibrational level populations of HCl (treated as a simple harmonic oscillator) during the bimolecular exchange reaction, Br + HCl → HBr + Cl, taking into account the competition between reaction and vibrational equilibration subject to Landau–Teller T–V excitation. Strong deviations from Boltzmann distributions are found. A wide range of reactant concentrations, diluent concentrations and temperatures were explored. It was found that no significant reaction occurs before the establishment of a steady vibrational population distribution, confirming that the rate coefficient for non-equilibrium bimolecular exchange reactions can be determined from a simple analytical steady state treatment (J. Chem. Soc. Faraday Trans. **87**, 229 (1991)). The rate of an isolated elementary bimolecular reaction, A + BC → AB + C, under non-equilibrium conditions can deviate seriously from the standard expression, k_{eq}[A][BC], and is better given by the law

$$d[BC]/dt = -k_{eq}[A]\,[BC]/\{1 + 1/(a + g[R]/[A])\}$$

where [R] is the concentration of the collisional equilibrator, R, and a and g are constants depending only on temperature. This generalized rate law describes not only the initial rate but also the rate all the way up to completion, in the absence of the reverse reaction.

CHRIS CARRUTHERS et HESHEL TEITELBAUM. Can. J. Chem. **72**, 714 (1994).

On a résolu l'équation maîtresse d'une façon numérique pour la corrélation avec le temps des populations des niveaux vibrationnels du HCl (traité comme un oscillateur harmonique simple) au cours de la réaction d'échange bimoléculaire, Br + HCl → HBr + Cl, en tenant compte de la compétition entre la réaction et l'équilibre vibrationnel sujet à l'excitation Landau–Teller T–V. On a trouvé d'importantes déviations par rapport aux distributions de Boltzmann. On a examiné une grande variété de concentrations de substances réactives, de concentrations des diluants et de températures. On a trouvé qu'il ne se produit aucune réaction significative avant qu'une distribution stationnaire de la population vibrationnelle ne s'établisse; ceci confirme que le coefficient de vitesse des réactions d'échange bimoléculaire non équilibrées peut être déterminé par un traitement analytique simple de l'état stationnaire (J. Chem. Soc. Faraday Trans. **87**, 229 (1991)). Il est possible que la vitesse d'une réaction bimoléculaire élémentaire isolée, A + BC → AB + C, soumise à des conditions non équilibrées puisse dévier d'une façon importante par rapport à l'expression standard, k_{eq}[A][BC], et elle est mieux exprimée par la loi

$$d[BC]/dt = -k_{eq}[A][BC]/\{1 + 1/(a + g[R]/[A])\}$$

dans laquelle [R] est la concentration de l'équilibreur collisionnel, R, et a et g sont des constantes qui ne dépendent que de la température. Cette loi de vitesse ne décrit pas seulement la vitesse initiale et, en l'absence de réaction inverse, elle décrit aussi la vitesse jusqu'à la fin de la réaction.

[Traduit par la rédaction]

Introduction

In chemical kinetics the rate of low pressure diatomic or polyatomic dissociation of the molecule AB in collision with itself or with an inert species, M,

[1] $$AB + M \rightarrow A + B + M$$

is given by the simple expression

[2] $$d[AB]/dt = -k_d[AB]\{[AB] + [M]\}$$

where k_d is termed the rate coefficient. It has been shown that k_d depends in a complicated way on the concentrations of AB and M, leading to the non-linear mixture rule (1, 2), but that k_d is otherwise constant, except through the implicit dependence of [AB] on time. This result is valid on condition that the molecular dissociation occurs isothermally and that a steady-state vibrational level population is established quickly. Before the steady state is established, i.e. during this "incubation period", reaction occurs with negligible rate. The properties of the incubation time have been discussed in the case of diatomic dissociation (3, 4), and in the case of polyatomic dissociation (5) from a theoretical point of view. The phenomenon is manifested as a delay in the onset of chemical reaction, and it has been observed at high temperatures for the thermal dissociation of diatomic molecules (6–9) and of polyatomic molecules (10). However, the phenomenon has never been evaluated in detail for bimolecular reactions, even though exactly the same principles are involved. The incubation time, the depressed value of the rate coefficient and activation energy, as well as the non-linear mixture rule are all caused by depleted vibrational (and rotational) energy level populations which are directly involved with the reaction in question. The competition between reaction and energy transfer processes establishes the degree of severity of the effect, and this competition is also present in the bimolecular reaction

[3] $$A + BC \rightarrow AB + C$$

In the past few years we have embarked on a series of studies (11–15) designed to investigate the non-equilibrium kinetics of reaction [3]. One of the most interesting results was the discovery that, even though there are a large number of components to [3], one for each vibrational state of BC, and a correspondingly large number of energy transfer processes, it was still possible to express the rate of reaction simply and to still account for the non-equilibrium vibrational level populations. Thus, instead of the usual "equilibrium" rate for the forward reaction being given by

$$[4] \qquad \mathrm{d[A]/d}t = -k_{eq}[\mathrm{A}][\mathrm{BC}]$$

we have the improved version

$$[5] \qquad \mathrm{d[A]/d}t = -k_{eq}[\mathrm{A}][\mathrm{BC}]/\{1 + f(T)[\mathrm{A}]/[\mathrm{R}]\} = \mathrm{d[BC]/d}t$$

where $f(T)$ is a temperature-dependent constant involving the reactive rate constants and the energy transfer rate constants, while [R] is the concentration of the molecules, R, responsible for (de-)exciting BC (11).

If one writes the more exact rate expression, eq. [5], in the usual phenomenological form, eq. [4] (with k_{eq} replaced by k), one can see that the phenomenological rate coefficient, k, is related to k_{eq} by

$$k/k_{eq} = \{1 + f(T)[\mathrm{A}]/[\mathrm{R}]\}^{-1}$$

Equation [5] was derived by solving the master equation, which describes the rate of change with time of [BC(v)], the concentration of BC in the specific vibrational level, v. In order to obtain a closed form expression like [5] it was assumed that (*a*) the rotational distribution is equilibrated and therefore plays no special role; (*b*) reaction occurs for the most part from a single most important vibrational level; (*c*) BC is a truncated harmonic oscillator; (*d*) only a single species, R, is responsible for vibrationally relaxing BC; (*e*) only single-quantum T–V relaxation processes are significant; (*f*) a steady state vibrational distribution is established before the reagents react to a significant extent; or (*g*) before the reverse reaction begins to interfere. The philosophy of our approach is to examine each assumption separately. In this process we have found that use of eq. [5] is indeed not as restricted as implied by the above list. For example, even if reaction occurs from all possible levels, and even if all species, A, BC, and R participate in the vibrational relaxation of BC, eq. [5] is still valid (12). A more general version of [5] is nevertheless available (13). We also found that when anharmonicity, and multiple quantum-jumps, and non-Landau–Teller vibrational transitions are accounted for, the deviation from eq. [5] is of the order of 1% (14). Some aspects of the reverse reaction have been examined as well (15). As the deviations from eq. [4] predicted by eq. [5] can be very large (11) under some conditions, it is worthwhile examining all factors affecting the general usefulness of eq. [5]. Therefore in this study we examine one of the remaining assumptions: How good is the steady-state assumption?

The most sensitive test of eq. [5] can be carried out when its predictions are dramatic. Therefore we have chosen the test case

$$[6] \qquad \mathrm{Br} + \mathrm{HCl} \rightarrow \mathrm{HBr} + \mathrm{Cl}$$

for which k/k_{eq} can be as small as 0.03 (12). We present the results as predicted by the steady-state calculation whose method is described in ref. 12 and compare them with the results of a full solution of the master equation, including transient effects.

Procedure

Reaction [6] can be decomposed into the following elementary processes:

$$[7] \qquad \mathrm{Br} + \mathrm{HCl}(v) \rightarrow \mathrm{HBr} + \mathrm{Cl}$$

$$[8] \qquad \mathrm{R} + \mathrm{HCl}(v) \rightarrow \mathrm{R} + \mathrm{HCl}(v')$$

where R represents all relaxer species present (here Br, HCl, and an inert diluent, M = Ar or He). We have shown (14) that the single-quantum jump harmonic oscillator approximation is a very good one for the purposes of generalizing the reaction rate expression [5]. Therefore, we set $v' = v + 1$ or $v' = v - 1$, and use the Landau–Teller scaling relations

$$[9] \qquad k_{v,v-1} = vk_{1,0}$$

$$[10] \qquad k_{v,v+1} = (v+1)k_{0,1}$$

to relate transitions between higher vibrational levels and those between $v = 0$ and $v = 1$. If k_v and $k_{v,v'}$ are the rate constants for reactions [7] and [8], respectively, then the differential equation describing the rate of change of the population, N_v, of HCl in level v is given by

$$[11] \qquad -\mathrm{d}N_v/\mathrm{d}t = k_{v,v-1}N_vN_\mathrm{R} + k_{v,v+1}N_vN_\mathrm{R} - k_{v-1,v}N_{v-1}N_\mathrm{R} - k_{v+1,v}N_{v+1}N_\mathrm{R} + k_vN_\mathrm{Br}N_v$$

In eq. [11] each term containing N_R is actually a sum of terms

$$[12] \qquad k_{i,j}N_\mathrm{R} = k_{i,j}{}^{\mathrm{Br}}N_\mathrm{Br} + k_{i,j}{}^{\mathrm{HCl}}N_\mathrm{HCl} + k_{i,j}{}^{\mathrm{M}}N_\mathrm{M}$$

where terms of the form N_X represent the concentration of species X. In its present form eq. [11] ignores the reverse reaction which is exothermic and very fast. The implication is that the reverse reaction does not interfere with the establishment of a steady forward process. In other words, we are concentrating only on that early part of reaction [6] before products begin to form significantly. We have already shown that this is legitimate (11) when we are interested in merely determining the contribution of reaction [6] to the total rate.

Equation [11] can be solved analytically in the steady-state limit, by setting $\mathrm{d}(N_v/N_\mathrm{HCl})/\mathrm{d}t = 0$. The result is eq. [5]. We use that result in order to establish a baseline for comparison with the more complex case, where the steady-state assumption is not made. In both cases we use the same set of microscopic rate constants.

We integrated the set of stiff differential equations [11] using an implementation of the algorithm of Byrne and Hindmarsh (16) which is based on the work of Gear (17, 18). Both the initial integration step-size and the tolerance parameter space was explored to find sufficiently stringent values such that the end result for the phenomenological rate coefficient, k, was invariant to better than one part in 10^6. Additionally, we checked for chemical accuracy by comparing the results of $\sum_v N_v$ with the integral of $\mathrm{d}N_\mathrm{Br}/\mathrm{d}t = \sum_v k_vN_\mathrm{Br}N_v$. The two results were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

identical within one part in 10^{10} by the end of the integration, indicating that round-off errors did not accumulate to serious levels. Two other checks were performed. First, the absolute values of the concentrations of the reagents were changed by 12 orders of magnitude (keeping the relative concentrations the same). The expectation (12) that there would be no change in the value obtained for k was indeed borne out. Second, the value of $k_{1,0}$ was artificially increased by orders of magnitude. As the relaxation rate gets larger and larger, there is less and less depletion of the vibrational levels caused by reaction from those levels, and therefore the value of k should approach k_{eq} at all times. This was indeed observed.

As initial conditions we chose five temperatures in the range 300–3000 K, and three mole fractions (i.e. [Br]/[M] = 0.01 to 1.0). The analytical solution (11, 12) assumed that either He or HCl was the collider but not both. In the case of the numerical solution, a finite amount of HCl must be present even if R = He, but the amount of HCl present must be such that it does not contribute significantly to relaxation in order that the present study be validly compared to the analytical study. Therefore, whatever value is chosen for [HCl], the ratio of [HCl]/[He] must be sufficiently small — at least as small as $k_{1,0}^{He}/k_{1,0}^{HCl}$ or 2.8×10^{-3}. We found that [HCl]/[He] = 10^{-6} represented the situation M = He accurately.

The values of the microscopic reactive and non-reactive rate constants used as input to the calculation are given in ref. 11. The output of the calculation is the set of N_v i.e. [HCl(v)] as a function of time. From this we could calculate the fractional level population, $y_v = N_v/\sum_v N_v$. The phenomenological rate coefficient is defined in exactly the same way that is done in an experiment, namely

$$[13] \qquad k = -\mathrm{d[HCl]}/\mathrm{d}t/([\mathrm{Br}][\mathrm{HCl}])$$

This can be rewritten in a more convenient form (12) as

$$[14] \qquad k = \sum_v y_v k_v$$

from which we can see how each level contributes to the observed rate coefficient. Depending on the choice of the initial population distribution, y_v and hence k vary with time. We started the integration with the population distribution equal to the Boltzmann population distribution at the temperature, T, in question. For comparison purposes we also evaluated the equilibrium value of k, i.e. k_{eq}, according to

$$[15] \qquad k_{eq} = \sum_v y_v^{eq} k_v$$

which is equivalent to the k_{eq} defined in eq. [4]. Here y_v^{eq} is the Boltzmann fractional level population at the temperature T. Having started out at $t = 0$ with the Boltzmann distribution, the value of k at $t = 0$, i.e. $k_{t=0}$, is the same as k_{eq}. Hence $k/k_{t=0}$ is simply k/k_{eq}.

Results

Figures 1 and 2 are plots of k normalized by its initial value, $k_{t=0}$, for the six sets of initial conditions at $T = 300$ K. Note that the abcissa is log ξ where ξ is the extent of reaction. Extent of reaction is here defined as $\xi = ([\mathrm{Br}]_0 - [\mathrm{Br}])/[\mathrm{Br}]_0$ if Br is the limiting reagent, or $\xi = ([\mathrm{HCl}]_0 - [\mathrm{HCl}])/[\mathrm{HCl}]_0$ if HCl is the limiting reagent, with $[\mathrm{Br}]_0$ and $[\mathrm{HCl}]_0$ being the

initial reagent concentrations. This choice of variables allows for the significant events over the whole course of the reaction to be displayed on a single graph and facilitates comparison of different sets of initial conditions. As can be seen in Figs. 1 and 2, $k/k_{t=0}$ starts out at unity and decreases monotonically to a smaller constant value; at later times, depending on the initial concentrations, $k/k_{t=0}$ either remains at that constant value (Fig. 1) or rises to its equilibrium value, $k_{eq}/k_{t=0} = k_{eq}/k_{eq} = 1$ (Fig. 2). The latter case prevails when Br, as the minor or limiting reagent, begins to disappear. Then the reaction perturbs the population distribution less and less until the y_v return to their original values, y_v^{eq}. The plateau which appears at log $\xi = -10$ to -8 will be discussed below. It is the intermediate values, during which the reagent concentrations are changing (log $\xi = -3$ to -1), which are most interesting. With some expected exceptions, the phenomenological rate coefficient is constant in this time regime and, it turns out, is equal in all cases to the value predicted by the analytical steady-state procedure of ref. 12 (see below).

Figures 3 to 6 are plots of the normalized rate coefficient at the other temperatures for R = HCl. The same general forms are evident as in Figs. 1 and 2, but with increasing temperature (and presumably increasing disturbance to the vibrational population distribution) the time regime where k is constant becomes shorter and shorter, until at 3000 K there are no vestiges of this constant regime, except when [Br]/[HCl] = 1. (That special case will be discussed below.) This could mean, in principle, that under some conditions, the reaction is so fast that a steady distribution is never established in time, i.e. the reaction proceeds during the transient phase. Note, however, that the distortion from constancy begins around log ξ

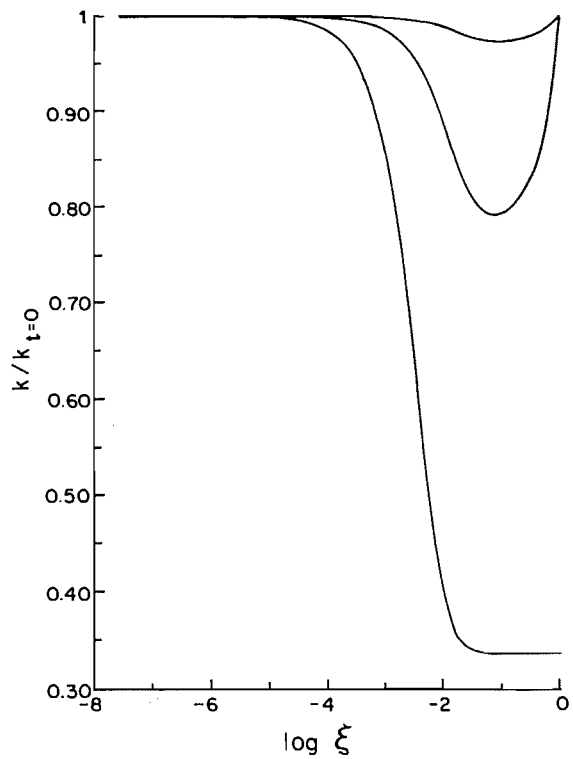

FIG. 5. The normalized phenomenological rate coefficient as a function of the reaction progress variable for R = HCl, T = 2000 K. From top to bottom, [Br]/[R] = 0.01, 0.1, and 1, respectively.

$= -1$, i.e. when approximately 10% of the reagents have already disappeared. When reagent disappearance is taken into account, as we shall see below, the distortion nevertheless fits exactly into the pattern predicted by eq. [5] because, as is well known, a steady state condition does not necessarily imply constant reagent concentrations or constant fractional level populations.

The dependence of $k/k_{t=0}$ on R was as expected (11), with the most dramatic effects for R = He, the least efficient relaxer. The temperature dependence also turned out as expected (12). It is around 500 K that the disparity between k and k_{eq} is the largest.

Discussion

Table 1 shows a comparison between the results of the minimum value of the exact numerical integration (the fourth column) and the prediction of the steady state analysis (the last column) for k/k_{eq}. The latter results are taken from ref. 12, where they obey a variant of eq. [5]. Using eqs. [5] and [13], we see that the steady state results can essentially be considered as equal to $\{1 + f(T)[A]/[R]\}^{-1}$. For the exact results we chose the constant plateau value or the minimum value for $k/k_{t=0}$. Note the excellent agreement between the analytical and the exact results. The cases where agreement was not better than 1 part in 10^5 were those where $k/k_{t=0}$ reached a minimum and immediately increased, i.e. where significant reagent loss was occurring. However, even under these extreme conditions agreement was still around 1 part in 100, indicating that significant reaction occurred only after a steady vibrational population distribution was established.

Equation [5] can be tested, as suggested in ref. 12, by plotting a graph of $k/(k_{eq}-k)$ vs. $k_{1,0}[R]/[Br]$. Such a graph should be linear. In this study $k_{1,0}[R]$ is $(k_{1,0}^{He}[He] + k_{1,0}^{HCl}[HCl])$. Figure 7*a* shows such a plot to be linear over 4 orders of magnitude of the abcissa at 500 K, whether M = He or M = HCl. We chose 500 K because it is at that temperature where k deviates most from k_{eq}. However, it is more instructive to examine the case of 3000 K, where deviations are relatively small, because the smaller the deviations the more stringent the test, and because it affords an opportunity to test eq. [5] not only when k/k_{eq} is constant but also when it is changing due to the disappearance of reagents. Again here the test plot (see Fig. 7*b*) is linear for the regime where k is constant. Therefore Fig. 7 shows that

$$[16] \qquad d[Br]/dt = \frac{-k_{eq}[Br][HCl]}{1 + \dfrac{1}{a + bk_{10}[R]/[Br]}}$$

where a and b are constants (slope and intercept in Fig. 7). Under conditions of extreme reactivity, eq. [16] is essentially the same as eq. [5].

The regime where k reapproaches k_{eq} coincides exactly with $\log \xi = -1.5$ or greater, i.e. where reagents begin to disappear significantly. Consequently, for this regime we must first evaluate [Br] as a function of time before determining the abcissa values. This can be done by integrating eq. [11] numerically, as in this study, or eq. [16] analytically. Before doing so, how-

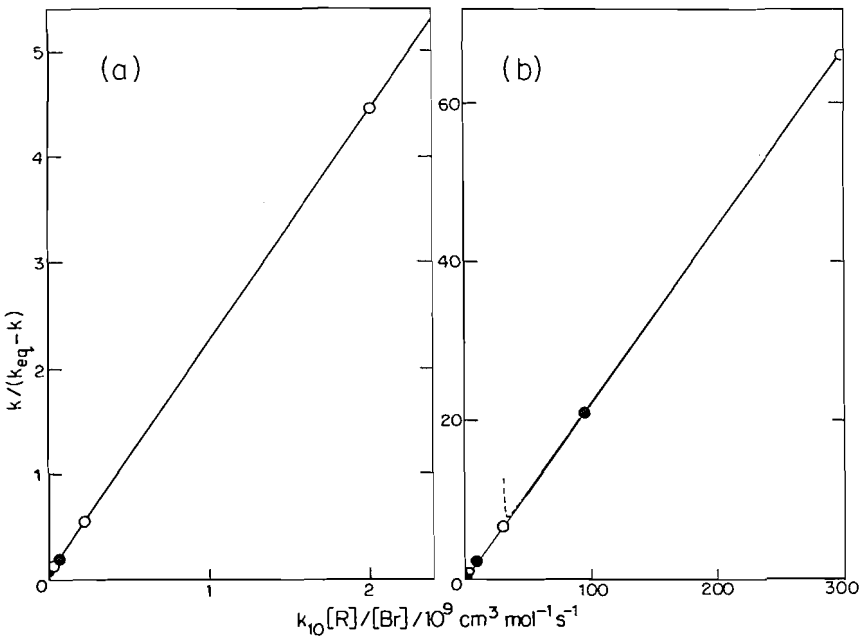

FIG. 7. Dependence of the relative depression of the nonequilibrium rate coefficient on the relative relaxability and reactivity of the bimolecular reagent. ○ R = HCl; ● R = He. (*a*) T = 500 K; abcissae of the points cover the range 5.3 × 10^5 to 2.0 × 10^9 cm^3 mol^{-1} s^{-1}; (*b*) T = 3000 K. The straight lines correspond to the steady state conditions. Superimposed on (*b*) is a dashed line corresponding to the transient regime, and a heavy line corresponding to conditions prevalent during the disappearance of the reagents.

ever, we note the special case of R = He. In this case, there is so little HCl that HCl is the limiting reagent. Hence [Br] is a quasi-constant, and the denominator in eq. [16] is time-invariant. Therefore it is not surprising to see in Fig. 1 that once the steady state regime commences, k remains constant. In the case of R = HCl, k returns to its equilibrium value except for the special case [Br]/[HCl] = 1. Because of the stoichiometry, if this ratio is initially unity, it will be unity at all times. Hence the denominator in eq. [16] is a pure constant again, and Figs. 2–6 can be understood. In all other cases, as the reaction proceeds and [Br] → 0, the denominator in eq. [16] approaches unity.

The abcissa for the test plot (when R = HCl and $[HCl]_0 \neq [Br]_0$) is simply $k_{1,0}^{HCl}[HCl]/[Br]$. Its evaluation, even when [HCl] and [Br] vary strongly with time, is facilitated by using ξ directly. Thus, using mass balance and the definition of ξ here, i.e. $\xi = ([Br]_0 - [Br])/[Br]_0$, we see that

$$[17] \quad k_{1,0}[R]/[Br] = k_{1,0}^{HCl}\{[HCl]_0 + [Br] - [Br]_0\}/[Br]$$
$$= k_{1,0}^{HCl}\{[HCl]_0/[Br]_0 - \xi\}/\{1 - \xi\}$$

It is now easy to analyze the regime, log ξ = −1.5 to 0, and add the continuous set of points to Fig. 7*b*. We chose the case $[Br]_0/[HCl]_0$ = 0.1 at 3000 K, corresponding to the middle curve in Fig. 6. The results fall on the same straight line as the steady-state results, confirming the validity of eq. [16] (and its high reactivity version, eq. [5]) over several orders of magnitude in $[Br]_0/[R]_0$ and over the portion of the reaction where reagents are changing dramatically. Also shown in Fig. 7*b* as a dashed line, for comparison, is the portion of the reaction occurring in the transient zone. Although, for this extreme case, 10% of the reagent Br has disappeared before a steady vibrational distribution is established, once the steady distribution is formed, eq. [16] is mathematically valid at all times thereafter. (Of course, once we account for the reverse

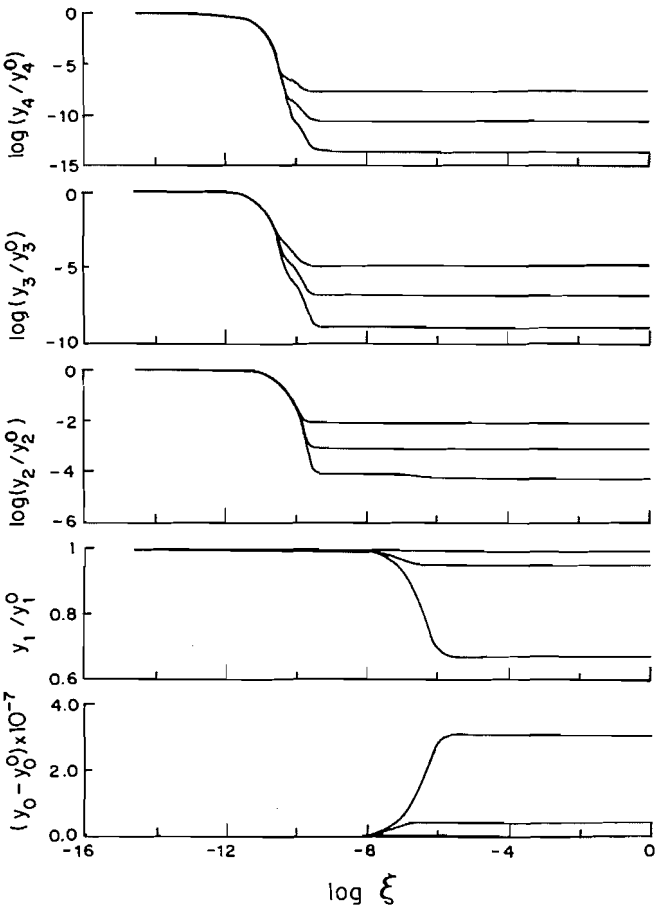

FIG. 8. Changes in the relative fractional level population as a function of the reaction progress variable for v = 0–4, R = He, T = 300 K, and various values of [Br]/[R] as in Fig. 1. From top to bottom in each plot [Br]/[R] = 0.01, 0.1, and 1, respectively. Superscripts refer to initial values of y_v.

For personal use only.

process, the application of eq. [16] is limited in practice to those times before significant amounts of products are formed.)

Some of the transient behaviour visible in Figs. 1 and 2 is also of interest. Figure 1 shows a sudden drop in k at log $\xi = -11$ and another drop at log $\xi = -7$ when R = He at 300 K. The first feature is seen from Fig. 8 to be the effect of the depletion of y_2, the fractional level population of $v = 2$. Closer examination of the curves for y_2, y_3, and y_4 in Fig. 8 reveals that these levels are seriously depleted (by as much as a factor of 10^{15} in the case of y_4), and so all of these variables decrease at log $\xi = -11$ to the point where none of them makes any contribution to the phenomenological rate coefficient, k. k then remains constant until log $\xi = -7$, at which point y_1 becomes depleted, resulting in the second feature. Similar behaviour occurs in Fig. 2 for R = HCl at 300 K. A shoulder is visible at log $\xi = -9$, but is less pronounced than in Fig. 1 because of the higher reactivity of the lower vibrational levels and the consequently smaller spread in the magnitudes of the microscopic rate constants and their associated time scales. At higher temperatures all levels are depleted on the same time scale, and no plateaux are observed.

Conclusion

Except for very high temperatures no significant amount of reaction occurs before the establishment of a steady state vibrational level population distribution of the bimolecular reagent for the reaction Br + HCl $\longrightarrow$ HBr + Cl. Under all conditions the numerically exact phenomenological rate coefficient obeys the analytical rate law, eq. [16], from the end of the transient zone right up to the end of the reaction, $\xi = 1$ (in the absence of the reverse reaction).

Fluorimetric measurement of the activity of surface-immobilized monolayers of enzyme using a dual emission probe

JOHN D. BRENNAN,[1] VANJA KUKAVICA, KRISHNA M.R. KALLURY, AND ULRICH J. KRULL[2]

Chemical Sensors Group, Department of Chemistry, Erindale Campus, University of Toronto, 3359 Mississauga Road North, Mississauga, ON L5L 1C6, Canada

Received June 25, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

JOHN D. BRENNAN, VANJA KUKAVICA, KRISHNA M.R. KALLURY, and ULRICH J. KRULL. Can. J. Chem. **72**, 721 (1994).

A sensitive assay for measurement of the activity of hydrolase enzymes that are immobilized onto quartz and silicon dioxide surfaces was developed. Measurements are based on the changes of the fluorescence properties of the probe carboxy-seminaptharhodafluor-X that are caused by pH variations associated with the reaction of urea with urease. The results indicated a loss of activity in 8 days, and a half-life of 3 days, when urease was immobilized onto quartz surfaces that were first derivatized with a 16-carbon spacer chain.

JOHN D. BRENNAN, VANJA KURKAVICA, KRISHNA M.R. KALLURY et ULRICH J. KRULL. Can. J. Chem. **72**, 721 (1994).

On a développé une méthode sensible pour mesurer l'activité des enzymes hydrolases immobilisées sur des surfaces de quartz ou de dioxyde de silicium. Les mesures sont basées sur les changements dans les propriétés de fluorescence de la sonde carboxy-seminaphtarhodafluor-X qui sont causées par des variations de pH associées à la réaction de l'urée avec l'uréase. Les résultats indiquent que, lorsque l'uréase est immobilisée sur des surfaces de quartz qui ont été antérieurement soumises à une dérivatisation à l'aide d'une chaîne d'espacement contenant 16 carbones, il y a perte d'activité en 8 jours et que la demi-vie est de 3 jours.

[Traduit par la rédaction]

Introduction

One of the major steps in the preparation of biosensors involves the immobilization of a selective biorecognition element onto the surface of a transducer (1). Selectivity is normally achieved through the use of antibodies or enzymes (2), and these proteins are generally immobilized (3–5) onto substrates such as metals (electrochemical sensors) or quartz (piezoelectric or optical sensors). The goal of the immobilization technique is to place the protein onto the surface at a high density and with a high biochemical activity. It is also desirable to maintain the activity of the protein over a long period of time to permit repetitive and continuous use of the sensor. To investigate the effects of the immobilization technique on the stability of the protein, an assay of the activity of the immobilized protein is required. Ultimately, knowledge of the initial activity and rate of denaturation of immobilized proteins may enable the determination of the optimum parameters for operation of the sensor in terms of its sensitivity and long-term stability.

Several techniques for measuring the activity of immobilized antibodies have been reported (6–8), but there has been much less progress in the measurement of the activity of immobilized enzymes. The general approach for determining the activity of immobilized enzymes is to use silica gel or control pore glass to maximize the surface area and thus the amount of enzyme that is immobilized (4). This allows a standard colourimetric assay to be done. The development of more sensitive methods designed to determine the activity of enzymes that are immobilized onto the surface of a small optically transparent device such as an optical fiber is only now being addressed, and requires new technology since the very small amount of enzyme present (typically on the order of 1–2 μg, of which only a portion is active) precludes the generation of a measurable signal over short time periods when using standard methods such as UV–visible absorption measurements (9). The sensitivity of fluorescence methods may permit an activity assay to be done for such small amounts of active enzyme in a volume on the order of microlitres.

A particularly useful pH-sensitive fluorophore is carboxy-seminaphtharhodafluor-X (SNARF-X), which has a single excitation wavelength that is insensitive to changes of pH, and two emission maxima that change in relative intensity as a function of pH (10). The ratio of the intensities at the two emission maxima can be used to remove instrumental drift and photobleaching problems. Since the amount of product formed in the enzyme–substrate reaction is small, only a small change in pH and fluorescence intensity will be observed. This would lead to limitations of signal-to-noise if detection was done at only a single wavelength. The ability to compute a ratio of two peaks within a single spectrum can reduce such difficulties since the absolute intensity of fluorescence becomes unimportant, and the ratio method avoids interference associated with long-term drift of the instrument and the concentration of the probe.

An enzyme that has been used extensively in the development of biosensors is urease (11), mainly owing to the chemical significance of urea, and the high turnover number and inherent stability of the protein (12). Urease catalyzes the hydrolysis of urea to produce ammonium and carbonate ions, and yields products that render a solution more basic as the reaction proceeds. This paper describes the use of SNARF-X as an indicator in the activity assay of urease that is immobilized onto quartz wafers. The results indicate that the new assay technique is capable of measuring activities as low as 1000 units g^{-1} from less than 2 μg of enzyme in a period of less than 1 h. Studies of the practical application of chemically modified surfaces have shown that the rate of denaturation of urease is reduced when the enzyme is immobilized on a quartz surface via a 16-carbon spacer chain.

Experimental

Chemicals

Urease (EC 3.5.1.5) type 1V from jack bean, urea, and phenol red were purchased from Sigma Chemical Company (St. Louis, Mo.), and used without further purification. Two different lots of urease were used, one with an activity of 105 000 units g^{-1}, the other with an activity of 30 000 units g^{-1}, where 1 unit is equivalent to the hydrolysis of 1 μmol of urea per minute at pH 8.0. 16-Hydroxy hexadecanoic acid, dimethyldichlorosilane, and chloroplatinic acid were purchased from Aldrich Chemical Company (Milwaukee, Wis.), and were used as received.

The fluorescent probe carboxy-seminaphtharhodafluor-X (SNARF-X) was purchased from Molecular Probes (Eugene, Oreg.). All water was obtained from a Milli-Q 5-stage cartridge purification system (Millipore Corp., Mississauga, Ont., Canada) and had a specific resistance not less than 18 MΩ cm. All other chemicals were of reagent grade. The quartz wafers and silicon wafers (p-doped, naturally oxidized) were purchased from Heraeus-Amersil Inc. (Sayerville, N.J.) and International Wafer Service (Portola Valley, Calif.), respectively.

Equipment

For the development of the fluorescence assay, excitation and emission spectra were collected using an SLM 4800 spectrofluorimeter (SLM Instruments, Inc., Champaign, Ill.). The spectrofluorimeter used concave holographic monochromators of 2 nm mm^{-1} dispersion and spectra were collected digitally using an 8 nm bandwidth for both the excitation and emission monochromators. The output of the quartz halogen lamp was corrected for intensity drift by using the ratio of the emission for the sample and the emission of a reference cell containing a Rhodamine B quantum counter at a concentration of 3 g L^{-1} in ethanol (13). For the bulk assay, all samples were placed in a 1 cm^2 quartz cuvette and fluorescence was collected at an angle of 90° with respect to the excitation beam. For the assay of urease immobilized on a surface, the quartz or silicon wafer was placed in a 1 cm^2 cuvette with an internal volume of 500 μL. A model 9817A "Red Sensitive" PMT (Hamamatsu, Bridgewater, N.J.) was used for this work.

X-ray photoelectron spectroscopy (XPS) of covalently stabilized monolayers was done using a Leybold MAX-200 spectrometer (Leybold-Heraeus, Cologne, Germany) with excitation by unmonochromatized Mg K_α radiation and a spot size of 2×4 mm^2. An excitation voltage of 1253.6 eV, a detection voltage of 2.65 eV, and an emission current of 20 μA were utilized. Pass energies of 192 and 48 eV were used for broad and narrow region scans, respectively. A take-off angle of 90° was used for both broad region and narrow region scans. The reported intensities were corrected for Scofield factors and instrument transmission factors using software routines provided by Leybold. The shapes of the peaks indicated that no compensation for differential surface charging was necessary. Satellite peaks that resulted from the unmonochromatic Mg K_α radiation were subtracted from all spectra. The binding energy scale of the spectrometer was calibrated to the Ag($3d_{5/2}$) and Cu($2p_{3/2}$) peaks at 368.3 and 932.7 eV, respectively, and the binding energy scale was shifted to place the C(1*s*) peak at 285.0 eV.

Ellipsometry of silicon wafers that were coated with immobilized enzymes was done with a Rudolph Research AutoEL-II null reflection ellipsometer (Rudolph Research Corp., Flanders, N.J.) utilizing a wavelength of 632.8 nm and an incident angle of 70°. Measured values of Δ and Ψ were converted to thickness and refractive index information using software originally developed by McCracken (14).

Absorption spectra were recorded with a Hewlett Packard 8452A diode array spectrometer using a total integration time of 1 second per spectrum.

Procedures

Colourimetric assay of enzyme activity in bulk solution

The colourimetric measurement of the activity of urease in solution was based on the procedure of Stefanac et al. (9). A stock solution of phenol red was prepared by adding 2 g of phenol red to 28.4 mL of 0.1 M NaOH and diluting with water to 1 L. A standard solution of phenol red was prepared by diluting 10 mL of the stock phenol red solution to 1 L with 0.066 M phosphate buffer solution. A standard urea solution was prepared by dissolving 12 g of urea in 1 L of 0.066 M phosphate buffer to give a final concentration of 0.2 M urea. Standard solutions of urease in water were prepared with concentrations ranging from 0 to 1.0 mg mL^{-1}.

For measurement of urease activity, a volume of 0.1 mL of urease solution was added to a volume of 2.4 mL of the standard urea solution, and 2.5 mL of the standard phenol red solution was immediately added. The solution was mixed and 3 mL of the solution was added to a cuvette. Absorbance was measured from each solution at a wavelength of 560 nm. The activity was calculated by using a standard calibration curve, which was constructed by measuring the absorbance of ammonium carbonate solutions in 0.066 M phosphate buffer.

Fluorimetric assay of enzyme activity in bulk solution

A stock solution of 10^{-6} M SNARF-X was prepared in 0.066 M phosphate buffer at a pH of 7.4 immediately before use. Fresh solutions of 0.2 M urea were prepared in 0.066 M phosphate buffer at pH 7.4 immediately before use. Solutions of urease were prepared immediately before use at concentrations ranging from 0 to 1.0 mg mL^{-1} in distilled water. Volumes of 2.5 mL of the SNARF-X solution, 2.4 mL of the urea solution, and 0.1 mL of the urease solution were added to a solution vessel, mixed, and 3 mL of the solution was immediately transferred to a 1 cm^2 cuvette for fluorescence measurements. Fluorescence spectra were measured at 21°C at 10 min intervals over a period of 60 min. Excitation was at 337 or 488 nm, and emission was collected between 550 and 750 nm. A 340-nm long-pass filter was used in cases where the excitation was at 337 nm to remove the second harmonic radiation at 674 nm that was reflected from the sample. The activity was calculated by using a standard calibration curve, which was constructed by measuring the fluorescence from ammonium carbonate solutions (0–50 μM) in 0.066 M phosphate buffer that contained 1×10^{-6} M SNARF-X.

Analysis of emission spectra involved the smoothing of the spectra, determination of the position of the two peak maxima, integration of each peak over a 30 nm window that was centered on the peak maximum, and ratioing of the intensity of the two fluorescence peaks, which were centered at approximately 595 and 650 nm. The emission ratio stated in the results is 650 nm/595 nm for the pH titration curve of SNARF-X and urease assay results.

Preparation of immobilized enzymes

Quartz and silicon wafers were cleaned as described elsewhere (15). Adsorption of urease onto silicon wafers was done by incubating the wafers in a solution consisting of 1 mg mL^{-1} of urease in phosphate buffer (pH 7.4) for a period of 12 h. The extent of coverage was determined by ellipsometry assuming a refractive index of 1.50 for the coating (16). A minimum of five spots were measured to provide an average thickness value for each sample.

Covalent immobilization of urease onto C-16 spacer chains began with the preparation of covalently immobilized membranes with acyl chains consisting of 16 carbons and containing carboxylic acid headgroups. The multistep synthesis is described below and shown in Fig. 1.

16-Hydroxy hexadecanoic acid (1 mmol) was refluxed in a solution of 10 mL of methanol and 0.5 mL of concentrated hydrochloric acid for 5 h under anhydrous conditions. The reaction mixture was then poured into a 100 mL solution of 2% sodium bicarbonate at pH 8. An extraction with ether was carried out and the ether layer was washed thoroughly with water, dried over anhydrous magnesium sulfate, and concentrated in a rotary evaporator. The resulting methyl ester of 16-OH hexadecanoic acid was obtained in almost 100% yield. The purity of the methyl ester was checked using FTIR and ^1H NMR.

The methyl ester (1 mmol) was dissolved in 25 mL of a mixture of dry toluene containing 1.1 mmol of dimethyldichlorosilane and 10 mg of chloroplatinic acid catalyst. This mixture was refluxed for 16 h. The

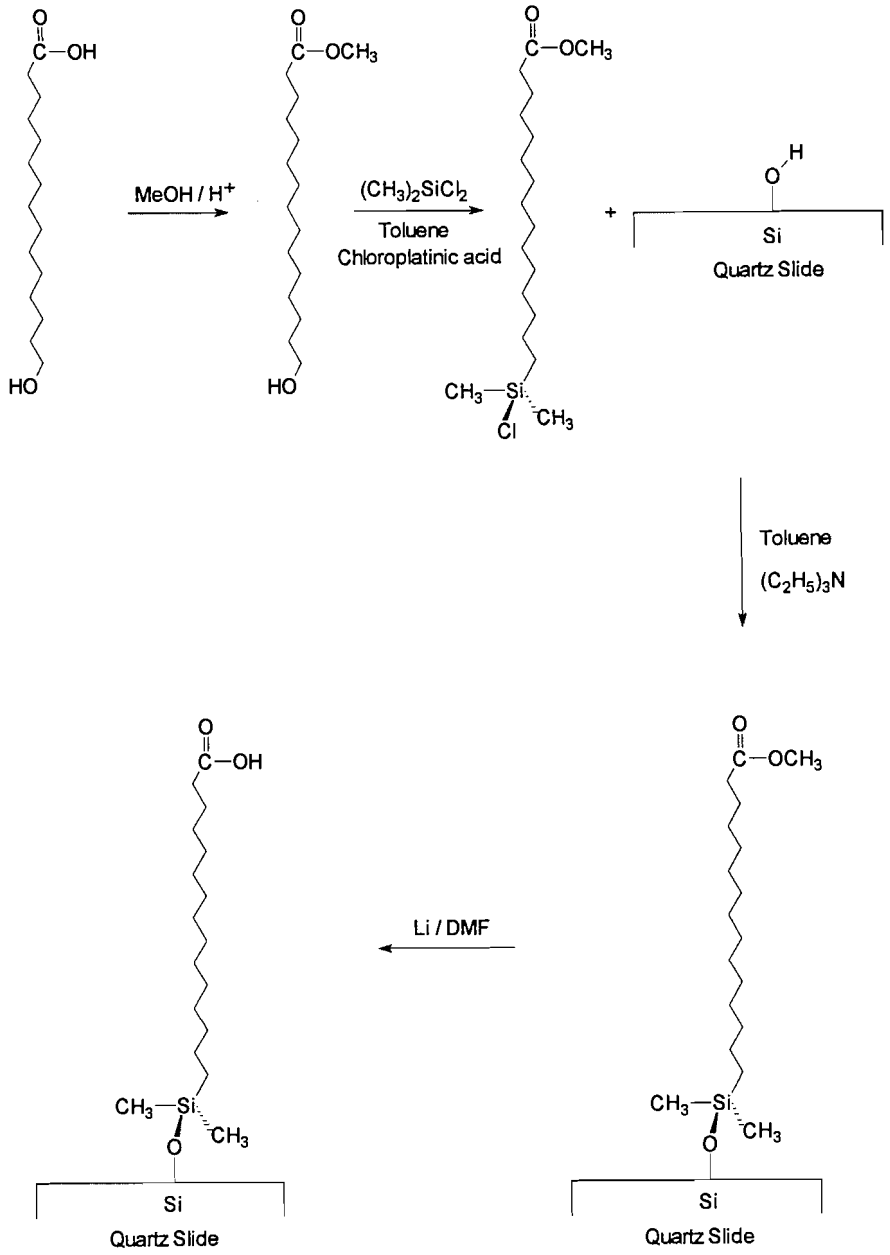

FIG. 1. An outline of the synthetic procedure used to covalently immobilize fatty acid membranes onto quartz wafers starting from 16-OH hexadecanoic acid.

solvent and unreacted silane were removed under vacuum. The mixture was then distilled under vacuum and the fraction boiling at 140–145°C at a pressure of 1 Torr (= 133.3 Pa.) was collected.

Quartz wafers were washed in hot detergent for 30 min, and were then sonicated for 30 min. The wafers were washed in distilled water, soaked in chromic acid for 10–15 min, and rinsed thoroughly with distilled water. The wafers were then dried, for at least 30 min, in an oven at 110°C. The clean wafers were suspended in 10 mL of a 1% solution of 16-(dimethylchlorosilyloxy) hexadecanoic acid methyl ester in toluene. A few drops of triethylamine catalyst was added and the mixture was allowed to stand under nitrogen at room temperature overnight. The wafers were removed, washed thoroughly with dichloromethane, and dried in a vacuum desiccator.

The quartz wafers were suspended in 10 mL of dimethyl formamide and 500 mg of lithium iodide was added. This mixture was refluxed under nitrogen for 16 h after which the wafers were washed with water, methanol, chloroform, and then acetone. The wafers were then dried in a vacuum desiccator.

Urease was immobilized onto the carboxylic acid membranes by activating the membrane with carbonyl diimidazole (CDI) prior to immobilization of urease. This reaction scheme is shown in Fig. 2. The substrate was suspended in THF (5 mL) and 20 mg of CDI was added. The substrate was allowed to stand at room temperature for 2 h and was then washed with THF. The substrate was suspended in water (1 mL) and urease (1 mg) was added. The mixture was allowed to stand for 12 h at 5°C. The substrate was washed with water and stored at −20°C until used.

Fluorimetric assay of activity of immobilized enzymes

The assay of immobilized urease was first done using enzyme that was adsorbed on silicon wafers. The enzyme-coated wafers (dimensions of 1.8 cm × 0.6 cm) were placed in a 500 μL cuvette containing 0.2 M urea and 10^{-6} M SNARF-X. A blank sample, consisting of a clean silicon wafer, was also prepared. Fluorescence spectra of both the enzyme-coated wafer and a blank wafer were collected every 10 min for a period of 1 h, and were compared to calibration curves to

determine the activity of the immobilized enzyme. Following each assay the silicon wafers were again characterized by ellipsometry to determine the extent of desorption of the protein during the assay.

Results and discussion

Assay of activity of urease in bulk solution

The new fluorimetric assay of enzyme activity was based on changes in the emission spectrum of the fluorescent probe SNARF-X that occurred as a result of changes in the pH of solution as the catalytic reaction proceeded. The structure of the probe in the protonated and deprotonated forms is shown in Fig. 3. SNARF-X was chosen over other dual emission probes such as SNARF-1, because the pK_a of SNARF-X ($pK_a = 7.8$) (10) is closest to the pH range of interest in this work. The pK_a values of the other dual emission probes were in the region of 6.5–6.9 (10). SNARF-X was also chosen because it is possible to excite the probe over a broad range of wavelengths. In the work reported here, the probe was excited using radiation at a wavelength of either 337 or 488 nm, which correspond to the output of a nitrogen laser and an argon ion laser, respectively. The ability to excite fluorescence using a wide range of sources is a major advantage of this probe. Finally, the SNARF-X probe was chosen because the ability to monitor the ratio of two emission peaks eliminates problems that may arise from instrumental drift. This is especially important in cases where small amounts of fluorophore are present, such as assays of surface-immobilized enzymes, since the instrument is usually operating at the limits of performance.

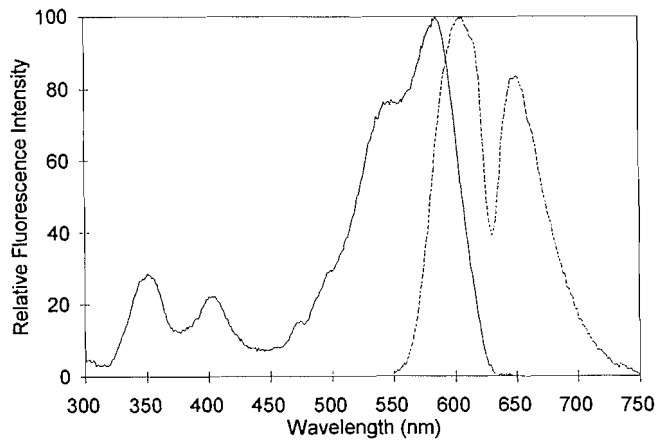

FIG. 4. Excitation and emission spectra of SNARF-X at pH 7.4. (—) Excitation spectrum, (---) emission spectrum.

The presence of two emission peaks in SNARF-X arises from the fact that the energy associated with the singlet state is different when the dye is in the protonated and deprotonated forms. SNARF-X has emission wavelengths of about 595 and 650 nm, which correspond to the protonated and deprotonated form of the probe, respectively. The presence of negative charges on the ring structure for the deprotonated form of the probe will result in a redistribution of electron density throughout the ring system. The new electronic structure will cause the energy of the excited state to decrease, and the energy of the ground state to increase slightly, owing to an increase in solvent dipolar reorientation around the probe (i.e., the charged probe has a larger dipole moment and thus the solvent red shift will occur to a larger extent) (17). The excitation and emission spectra for SNARF-X at pH 7.4 are shown in Fig. 4.

To determine the sensitivity of SNARF-X to changes in pH, solutions of the probe (concentrations of 10^{-6} M) were tested at pH values between 6.5 and 9.2. Figure 5*a* shows spectra of SNARF-X at various pH values. As the pH increases, the intensity of the peak that is centered at 650 nm increases accordingly.

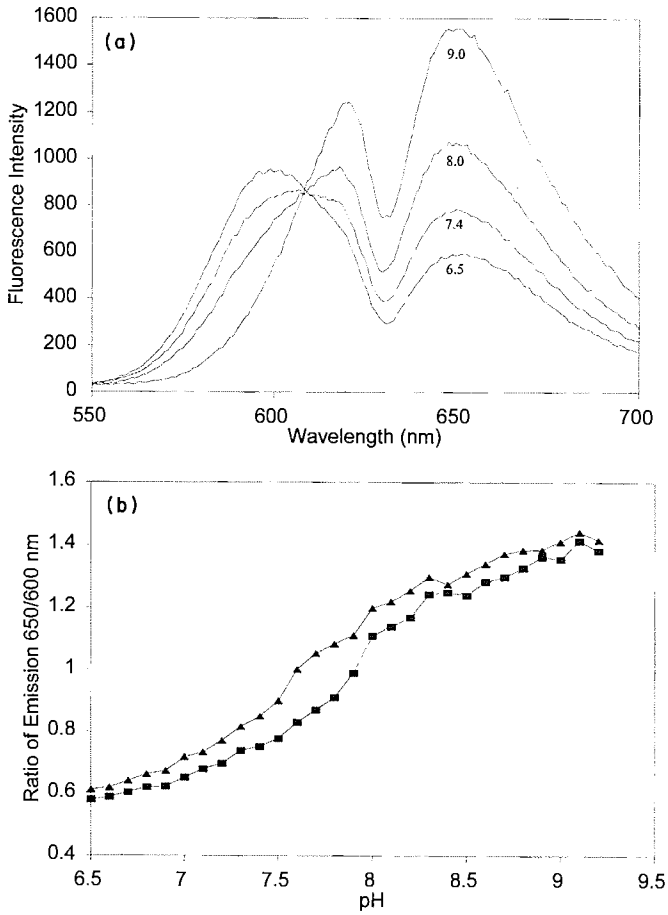

FIG. 5. Sensitivity of SNARF-X emission to pH. (A) Spectra of 10^{-6} M SNARF-X in 66 mM phosphate buffer at various values of pH; (B) Ratio of emission of SNARF-X (650 nm/595 nm) at various values of pH. (▲) Excitation at 337 nm, (■) Excitation at 488 nm.

At low values of pH, the protonated form of the probe has an emission peak centered at 595 nm. However, as the pH increases, this peak not only decreases in intensity but shifts to a maximum of 620 nm. It seems likely that the peak that is originally at a wavelength of 595 nm is due to the protonated form of the probe, and that the peaks at 620 and 650 nm are both due to the deprotonated form of the probe. The peaks at 620 and 650 nm correspond to the real emission peak and a Woods Anomaly peak, respectively (for the deprotonated form). The Woods Anomaly peak is used in this work to provide the largest signal-to-noise ratio, and to avoid spectral overlap with the peak at 595 nm. It is evident that even at pH 6.5 the peak at 595 nm has a shoulder at 620 nm, indicating that emission from the deprotonated form is still occurring.

The analysis of the SNARF-X emission was based on calculating the ratio of the two emission peaks. A variety of different methods could have been utilized to calculate the ratio. For example, it was possible to simply measure the intensity at wavelength values of 595 and 650 nm and compute the ratio of the values (18). However, this method is highly susceptible to problems with noise in the spectrum, since only two data points are being used to calculate the ratio. An alternative would be to calculate the average intensity within two different regions of the spectrum, which would reduce many of the problems associated with noise in the spectrum, and would provide more precise data. In this work, the averaging was done over the regions centered at 595 and 650 nm, and the ratio of the two intensity values was calculated (see Fig. 5*b*). Using this method, changes in the emission ratio of SNARF-X could be used to detect changes of pH as small as 0.02 units in the region between pH values of 7.0 and 8.5 with a precision of ±0.01 pH unit.

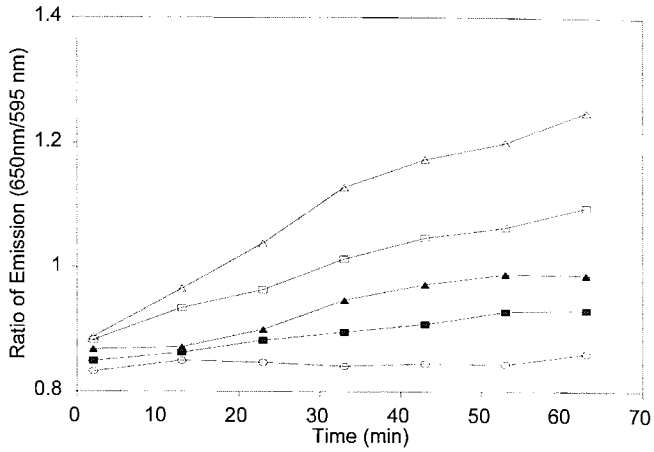

FIG. 6. Fluorimetric assay of the activity of urease in bulk solution. (○) 0 μg mL^{-1} urease, (■) 5 μg mL^{-1} urease, (▲) 10 μg mL^{-1} urease, (□) 15 μg mL^{-1} urease, (△) 20 μg mL^{-1} urease.

The activity of an enzyme depends on the kinetics associated with the enzyme–substrate reaction. The turnover number for urease in solution is 1.0×10^{-4} s^{-1} (12), and the Michaelis constant is 2.5×10^{-2} M (12). These constants may change when urease is immobilized on a surface because of limitations in mass transport of the urea to the surface. The assay of urease activity in solution and on surfaces utilized conditions in which the substrate (urea) was in large excess of the Michaelis constant for the enzyme (ca. 8 K_M), so that the rate of reaction was limited mainly by the rate of turnover of the urea to ammonium and carbonate ions, and was not dramatically affected by mass transport limitations for surface-based assays. All urease assays were done at an initial pH value of 7.4. The assay was done in a 66 mM phosphate buffer to eliminate problems with pH shifts that resulted from autohydrolysis of urea and absorption of CO_2 gas into solution. The presence of the buffer also allowed the sensitivity of the assay to be adjusted so that different concentrations of enzyme could be analyzed in a reasonable time without the pH rapidly shifting outside the useful range of the fluorescent probe.

Final enzyme concentrations between 0 and 20 μg mL^{-1} were used for all assays since higher concentrations of enzyme caused the pH to shift outside the useful range of the SNARF-X probe (i.e., above pH 9.2) in periods of minutes, making it difficult to determine the initial slope of the response curve. Assays were generally done over a period of 60 min. However, activities were calculated using the initial slope of the response curve since some of the curves showed asymptotic behaviour at longer times owing to the insensitivity of SNARF-X to changes of pH at values above 9.2.

Figure 6 shows a typical response curve for an assay of urease in bulk solution at concentrations of 0, 5, 10, 15, and 20 μg mL^{-1}. The activity of this lot was determined to be 32.0 ± 3.0 units mg^{-1}, which was in good agreement with the activity stated by the supplier (30 units mg^{-1}). There was some variation in the initial ratio of the two peaks for the various enzyme concentrations studied, which suggested that the initial pH val-

ues of the individual solutions were slightly different. Since it is the initial slopes that are of concern in this work, the initial pH is not very important provided that it is close to pH 7.4. Figure 6 indicates that significant autohydrolysis does not occur during the course of the assay. Nonetheless, the slope calculated for the blank was subtracted from the slopes obtained in the presence of urease to remove any contribution that could be attributed to autohydrolysis. The values of the specific activity as calculated by either the SNARF-X or phenol red assay for two different lots of urease are given in Table 1.

Assay of activity from immobilized enzymes

An oxidized silicon wafer was suspended into a solution containing 1 mg mL^{-1} of urease (activity of 105 units mg^{-1}) in 10 mM phosphate buffer, and was stirred over a period of 12 h at 4°C. The low temperature was employed to minimize denaturation of the enzyme. Ellipsometric measurements were used for determination of the amount of protein adsorbed onto the silicon dioxide layer at the surface of the wafer. The thickness of the urease layer that was immobilized onto the wafer was found to be 12.3 ± 1.6 nm. Thickness values (averaged over three samples) for all samples studied as measured by ellipsometry and XPS are given in Table 2. All thickness values obtained by ellipsometry assumed an organic film refractive index of 1.50 (16). The dimensions of urease are about 10.0 nm × 10.0 nm × 11.0 nm (19). The results of Table 2 show that the thickness values that were calculated by XPS or ellipsometry were accurate to within about 25% of the expected thickness value of 10.3 nm, and to within 15% of the thickness values calculated by ellipsometry. The excellent agreement between the thickness values obtained by either XPS, which requires that the sample be in ultra-high vacuum, or ellipsometry, which requires that the sample be in air, and the expected thickness values for a monolayer of urease suggests that dehydration of the protein was not a serious problem.

If a monolayer is assumed to have an average thickness of 10.3 nm, then there are approximately 1.19 ± 0.15 monolayers of urease adsorbed onto the surface (using the thickness values obtained by ellipsometry). The silicon wafer had dimensions of 1.8 cm × 0.6 cm, resulting in a surface area of 1.08 cm^2 per side. If the area per urease molecule is taken to be ca. 100 nm^2, then there will be $(1.08 \pm 0.14) \times 10^{12}$ molecules or $(1.79 \pm 0.23) \times 10^{-12}$ moles of urease per monolayer on the surface, or a total of $(2.13 \pm 0.28) \times 10^{-12}$ moles of urease. The molecular weight of urease is 478000 g mol^{-1}, which corresponds to a mass of 1.02 ± 0.13 μg of urease on the surface of the silicon wafer. Since both sides are coated, there is a total of 2.04 ± 0.18 μg of urease.

The coated silicon wafer was placed in a 1 cm^2 cuvette with an internal volume of 500 μL. The reduced volume was used so that the products of urea hydrolysis would be more concentrated than would be possible in a standard cuvette with an internal volume of 3 mL. The cuvette also contained 0.2 M urea and 10^{-6} M SNARF-X. Spectra were collected over a period of 1 h for the coated wafer and showed a gradual increase in the emission ratio of SNARF-X over time. An assay was also done with a blank consisting of bare silicon suspended in a solution of 0.2 M urea and 10^{-6} M SNARF-X in 66 mM phosophate buffer at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

pH 7.4. No change was observed in the emission ratio of SNARF-X for the blank sample, which suggested that the change in the emission ratio in the urease–silicon sample was due to the reaction of urea with urease. The results clearly showed that there was a large signal present for the silicon wafer that was coated with urease. The bulk assay used concentrations of 5–20 μg mL^{-1} of urease in a volume of 3 mL, giving a total mass of 15–60 μg of urease. Thus the amount of urease studied in the surface-based assays was roughly 7-fold less than the amount used for the bulk assays. Nonetheless, the activity of the enzyme could easily be measured.

The specific activity of urease calculated for the adsorbed enzyme was 85.6 ± 7.5 units mg^{-1}. This value is slightly lower than the specific activity measured in solution (101.6 units mg^{-1} as in Table 1) or that stated by the supplier (105 units mg^{-1}), which indicates that some of the urease may have been denatured in the process of immobilization, or may have adsorbed with the catalytic site not exposed to solution. Another possibility is that the diffusion rate of urea to the adsorbed urease may have decreased since the urease was no longer distributed randomly in solution, thereby decreasing the apparent activity of the protein. It is not possible to determine which of the above factors is most directly responsible for the observed decrease in activity upon immobilization of urease. The decrease in the activity of immobilized urea indicates that the activity values measured from the surface are not necessarily absolute; however, comparison of relative activity values from different surfaces or from a single surface as a function of time is still possible, and can give information on parameters such as rates of denaturation, which are of greatest importance in the work described herein.

To confirm that the measured activity was not from protein present in bulk solution due to desorption from the surface, a silicon wafer that was coated with ca. 2 μg of urease was placed in a solution of 10^{-6} M SNARF-X in 66 mM phosphate buffer, left for 1 h, and then removed from the solution. The substrate was then added to the solution and the assay was run for 1 h. The results showed that there was no change in the emission ratio of SNARF-X, indicating that no significant desorption had occurred during the time period used for the assay. The thickness of the adsorbed urease layer was measured by ellipsometry both before and after the assay, showing thickness values of 12.3 ± 1.4 and 12.1 ± 0.9 nm, respectively. This measurement confirmed that the urease had not desorbed during the assay.

To confirm that the pH changes were indeed the result of an enzyme–substrate reaction, the urease was denatured prior to adsorption onto silicon. The denaturation process involved heating the enzyme for 1.5 h at a temperature range of 70–80°C. The thickness of an adsorbed coating of denatured urease was determined to be 8.2 ± 0.9 nm, corresponding to a mass of 1.4 ± 0.2 μg. The assay of the denatured urease was compared to a blank, and showed that no change in the ratio of emission of SNARF-X occurred over time. This result confirmed that the urease–urea reaction was responsible for the observed changes of pH.

Assay of urease covalently immobilized onto CIMs

The SNARF-X assay was sensitive enough to measure the activity of small amounts of an enzyme located on a surface, and was therefore used to measure the activity of a sample composed of urease that was linked onto a C-16 carboxylic acid membrane with the CDI activating agent. The membranes, both with and without immobilized urease, were characterized by ellipsometry and XPS. The results are given in Table 2. Two sets of samples were tested, one that had been examined by XPS before the assay, and the second, which had XPS measurements done only after the SNARF-X assays were complete. In the first case, angularly resolved measurements were done on the sample, and suggested that there was about 6.7 nm of urease on the surface, or about 60% coverage (see Table 2). The second set of samples was tested by XPS (at a single angle) only after the assays were done. The XPS studies again indicated a thickness of 6.7 nm of urease for each sample, while ellipsometry suggested a thickness of 5.7 nm for each sample.

Table 2 indicates that the thickness of the covalently immobilized membranes as measured by either ellipsometry or XPS differed by almost a factor of 2. The large discrepancies between the thickness values obtained for the membranes by ellipsometry and XPS are the result of the different assumptions of each technique when used for measurement of organic layers on inorganic substrates. The assumptions of the Drude equations, which are used to convert the ellipsometric Δ and Ψ to thickness values, are: (1) the samples are homogeneous, isotropic, non-absorbing and non-amplifying, (2) the films have uniform thickness and refractive index, (3) the sample and substrate are smooth, (4) the area of the film is many times its thickness, and (5) the boundaries between sample, substrate, and ambient are discrete and plane-parallel (20). Under optimum conditions in which all assumptions are valid, changes in thickness on the order of 0.1 nm can be detected while changes in refractive index on the order of 0.002 can be measured. In this work, the films that are measured do not strictly adhere to the assumptions of the Drude equations in that they are not isotropic, and thus the thickness values are accurate only to within 25% of the "true" value.

The thickness values measured by XPS used the ratio of the C(1*s*) peak of the protein and the Si(2*p*) peak of the substrate. The use of the C(1*s*) peak will introduce some inaccuracy into the thickness value owing to the presence of organic contamination. Airborne organic matter is known to adsorb to both hydrophilic and hydrophobic surfaces. In fact, it has been shown that an ultraclean surface prepared in ultrahigh vacuum will become coated with organic contaminants in a matter of seconds upon exposure to air, and that such contaminants are not removed when the sample is returned to an ultrahigh vacuum environment (21). Additional errors are introduced if the value used for the escape depth is not accurately known. The difficulty in establishing accurate escape depths and the problems with organic contamination result in the thickness values calculated by XPS being semi-quantitative at best. The thickness values obtained by XPS are therefore likely to be less accurate than those obtained by ellipsometry.

Fluorimetric assays were done over a period of 7 days on two covalently immobilized urease samples that were tested by XPS at a single angle only after the assays were done. Between assays, the samples were stored in phosphate buffer at 4°C. The activity values are given in Table 3. The SNARF-X assay was also done every 12 h over a period of 2 days for samples that were composed of urease adsorbed onto silicon. Ellipsometry measurements showed an initial thickness of 11.9 nm and a final thickness of 12.0 nm for the adsorbed protein layer, suggesting that the urease had not desorbed from the silicon, and leaving denaturation as the likely cause of the loss of activity.

The retention of activity of urease that was immobilized onto

a C-16 carboxylic acid membrane, as compared to urease that was present on oxidized silicon with no spacer group, suggested that the presence of the C-16 acyl chains helped to decrease the rate of denaturation, but was unable to prevent significant denaturation over a period of a week. The results obtained from samples stored in solution are significant when compared to the results of Kallury et al. (4), which indicated that urease linked to carboxylic acid membranes with C-10 or C-23 acyl chains remained active for a period of about 7 days when stored dry. The similar rate of denaturation of samples that were hydrated and stored in dry conditions was not expected. These results suggest that linkage of urease to membranes composed of ionizable phospholipids should be attempted, since these have been shown to stabilize the activity of urease to the point where 95% activity remains after a period of 7 days when stored dry, with the half-life of the activity being on the order of months (4).

Conclusions

A fluorescence-based assay of enzyme activity was developed that was based on the emission of the probe seminaphtharhodafluor-X. This probe has two emission maxima, which shift in intensity relative to one another with changes of pH. The fluorescence-based assay was able to determine the activity of urease in bulk solution with an accuracy comparable to standard colourimetric assays. Urease was adsorbed onto silicon wafers or covalently linked onto the surface of a covalently immobilized carboxylic acid membrane with retention of some activity, thereby providing a completely stabilized monolayer–protein system. The SNARF-X assay used for samples of immobilized monolayers of enzyme (typically containing about 1 $\mu g\ cm^{-2}$ of protein) provided activity values accurate to within 10%. The fluorimetric assay suggested that the urease that was placed onto a C-16 carboxylic acid membrane had a high activity directly after covalent immobilization, but that the activity decreased substantially over a period of 7 days. The rate of denaturation of urease significantly limits the potential for development of biosensors based on this covalently immobilized enzyme.

Trajectory study of the effect of energy barrier location on the energy disposal for the reaction $O(^3P) + Cl_2 \rightarrow OCl + Cl$

AGNIE M. KOSMAS
Department of Chemistry, University of Ioannina, GR 451 10 Ioannina, Greece

Received June 24, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

AGNIE M. KOSMAS. Can. J. Chem. **72**, 729 (1994).

The mode of partitioning of total energy available in the reaction $O(^3P) + Cl_2 \rightarrow OCl + Cl$ is investigated as a function of the initial collision energy, in correlation with Polanyi's adiabaticity rules, using a series of related LEPS-type potential energy functions. All surfaces possess a classical energy barrier of similar height located in the entrance valley of the reaction, but present a small, gradual displacement of the top of the barrier to later positions along the approach coordinate. Quasiclassical trajectory calculations on these surfaces indicate marked differences in the disposal of total energy and the dynamical behaviour of the reaction. Also the effect of excess reagent vibration is investigated.

AGNIE M. KOSMAS. Can. J. Chem. **72**, 729 (1994).

Utilisant une série apparentée de fonctions d'énergie potentielle de type LEPS, on a étudié le mode de partition de l'énergie totale disponible dans la réaction $O(^3P) + Cl_2 \rightarrow OCl + Cl$ en fonction de l'énergie de collision initiale, en corrélation avec les règles d'adiabaticité de Polanyi. Toutes les surfaces possèdent un barrière d'énergie classique de hauteur semblable, située à l'entrée de la vallée réactionnelle; toutefois, elles présentent un léger déplacement graduel du sommet de la barrière vers des positions ultérieures le long de la coordonnée d'approche. Des calculs de trajectoires quasiclassiques sur ces surfaces indiquent qu'il existe des différences importantes dans la façon de disposer de l'énergie totale et dans le comportement dynamique de la réaction. On a aussi étudié l'effet de la vibration du réactif en excès.

1. Introduction

In a series of pioneering papers Polanyi and co-workers investigated in great detail the sensitive role of the location and the height of the energy barrier in the dynamics of elementary gas-phase chemical processes (1–4). Among the significant outcomes the effect of energy barrier location was proven very important in determining the mode of disposal of total energy available in the reaction products.

The reaction $O(^3P) + Cl_2 \rightarrow OCl + Cl$ has been studied extensively in discharge-flow systems (5–8) and in molecular beam experiments (9–11) and consequently represents a system suitable for theoretical investigation. No ab initio or any other information exists about the potential energy surface. It is a moderately exothermic reaction with a reaction exothermicity of 26.5 kJ/mol and an activation energy of 13.5 kJ/mol (12). In a previous classical trajectory study theoretical calculations of the total reaction cross section and the thermal reaction coefficient were carried out with good success. Also the simulation of the dynamical pattern of the reaction was examined using potential energy functions with quite different dynamical features with respect to the location of the classical energy barrier and the geometry of the minimum energy path configuration (13). Very good reproduction of the experimental differential cross sections $I(\theta, w)$, θ being the c.m. scattering angle and w the product relative velocity, and in particular of the interesting feature of forward scattered molecules having three times more kinetic energy than the wide angle scattering was accomplished when the reaction was assumed to take place on a PES with a collinear minimum energy path configuration and an energy barrier located in the entrance valley of the reaction. When the barrier was displaced towards the exit valley of the PES the dynamical pattern obtained was completely altered. On the other hand a bent transition state configuration did not advance the understanding of the dynamics over the collinear minimum energy configuration, a fact also observed in the trajectory study of the reaction $F + I_2 \rightarrow FI + I$ where a bent configuration did not improve the description of the cross section over the collinear geometry (14, 15).

The molecular beam experiments indicate that the reaction proceeds through a stripping mechanism for both low and high collision energies with a low fraction of total available energy deposited into product recoil energy, increasing as the collision energy rises. In the present work we employ the quasiclassical trajectory method to investigate the sensitive role of the location of the energy barrier in the mode of partitioning of the total energy available in the $O(^3P) + Cl_2 \rightarrow OCl + Cl$ reaction as a function of the collision energy, in correlation with Polanyi's adiabaticity rules (16–18). The calculations are carried out using a family of related LEPS-type PES, which all possess similar energetics in a collinear minimum energy path configuration and an energy barrier located in the entrance valley of the reaction but which present a gradual displacement of the saddle point location along the reaction coordinate. Average product translational distributions are calculated and compared with molecular beam results. Also the variation in average c.m. scattering angle and product vibrational energy distribution with increasing collision energy is studied and the influence of barrier position in the total reaction cross section is examined for a series of values of the initial kinetic energy. Finally, the effect of reagent vibrational energy in the disposal of total energy and the magnitude of the cross section is investigated.

2. PES and trajectory calculations

As already mentioned, no ab initio or any other information exists about the PES of the reaction $O(^3P) + Cl_2 \rightarrow OCl + Cl$. Only the ground-state surface has been reported to be reactive at the range of energies considered, so it is assumed that the reaction proceeds via a single adiabatic surface (10, 11, 13). A series of four PES, denoted A–D, were constructed using the generalized LEPS potential energy function, with a classical energy barrier of the same height, ~13.5 kJ/mol, located in the entrance valley of the reaction. By systematic variation of the

Sato parameters, S_{OCl} in the range −0.100–0.100 and S_{ClCl} in the range 0.000–0.300, the displacement of the saddle point along the reaction coordinate $r_1 = r$(O—Cl) was investigated and a contradictory correlation was found. Lowering the values of S(Cl–Cl) and raising the values of S(O–Cl) moves the barrier to later positions along the entrance valley. After several preliminary calculations the four surfaces were chosen so as to present a progressive shifting of the top of the barrier by 0.57 Å, 0.53 Å, 0.49 Å, and 0.45 Å with respect to the OCl equilibrium distance $r_{1e} = 1.57$ Å from surfaces A to D, respectively, while at the same $r_2 = r$(Br–Br) distance, equal to 2.02 Å in all cases. Surfaces A and D are depicted in Fig. 1 and the values of Sato parameters along with the saddle point dimensions are given in Table 1. In Fig. 2 the energy profiles of the reaction are given for all surfaces.

Trajectory calculations were performed for eight values of the initial collision energy E_T, using standard computational techniques (19). The diatomic was chosen initially as being in the zero vibrational level and the rotational level $J = 1$. For the lowest collision energy, $E_T = 13.5$ kJ/mol, 30 000 trajectories were computed for each of the four surfaces while for the higher values of the collision energy 20 000 trajectories for each surface were sufficient to obtain satisfactory statistics. Close to threshold enery and for surfaces A and D a second series of calculations were performed, assuming the diatomic as being in the $v = 1$ and $v = 2$ vibrational levels, 30 000 trajectories in each case, in order to examine the effect of excess reagent vibrational energy on the reaction cross section and the mode of disposal of the available energy. The maximum value of impact parameter was found the same in all cases in the study of the collisional energy effect, depending only on the value of E_T. The variation in b_{max} with increasing E_T is given in Fig. 3. Also displayed are

the b_{max} values found appropriate in the study of the effect of excess reagent vibration.

The total energy, E_{tot}, available in an $O(^3P) + Cl_2$ collision, results from three contributions: the difference in binding energies, ΔD_0, the collision kinetic energy, E_T, and the internal energy of the diatomic molecule. It is assumed to be disposed exclusively into product recoil and internal energy.

$$[1] \quad E_{tot} = \Delta D_0 + E_T + E_{int} + E'_T = E'_{int}$$

where the prime quantities refer to products. Indeed, in all experimental studies only $^2P_{3/2}$ Cl atoms were ever detected. Also the contribution of $O(^3P)$ fine structure is assumed to be negligible in the study of energy disposal although this factor must be taken into account in the calculation of thermal reaction rate coefficient, as has been shown for the analogous reaction $O(^3P) + I_2 \rightarrow OI + I$ (20).

3. Results

In Fig. 4*a* the mean product recoil energy, $\langle E'_T \rangle$, and the average fraction of total energy deposited into product translational energy, $\langle f'_T \rangle$, are depicted vs. the initial kinetic energy of the reaction. Serious differences appear in the prediction of the amount of energy entering translation on each of the four PES. A set of parallel curves are obtained with a roughly linear dependence of product kinetic energy on rising collision energy and an approximate slope of 0.5. They predict, however, quite a different amount of energy disposed into translation close to threshold. Surface A directs a low amount of total energy into product translation in contrast to surface D, where enhanced product translation results, presumably from reaction through more compressed configurations. Also surfaces A, B, and C predict an increase in $\langle f'_T \rangle$, in accordance with the experimental results, while surface D approaches a reverse dependence. Indeed, it shows rather a slight decline in $\langle f'_T \rangle$ as E_T rises, indicating a total disagreement with the dynamical behaviour of the system in molecular beam experiments. From the other three surfaces, B shows better agreement at low E_T and A at high E_T although the experimental results are too limited to permit drawing definite conclusions.

A rising dependence of product translational excitation is assumed in several direct models for energy disposal (21–24) but they predict a faster rising fraction of total energy channeled

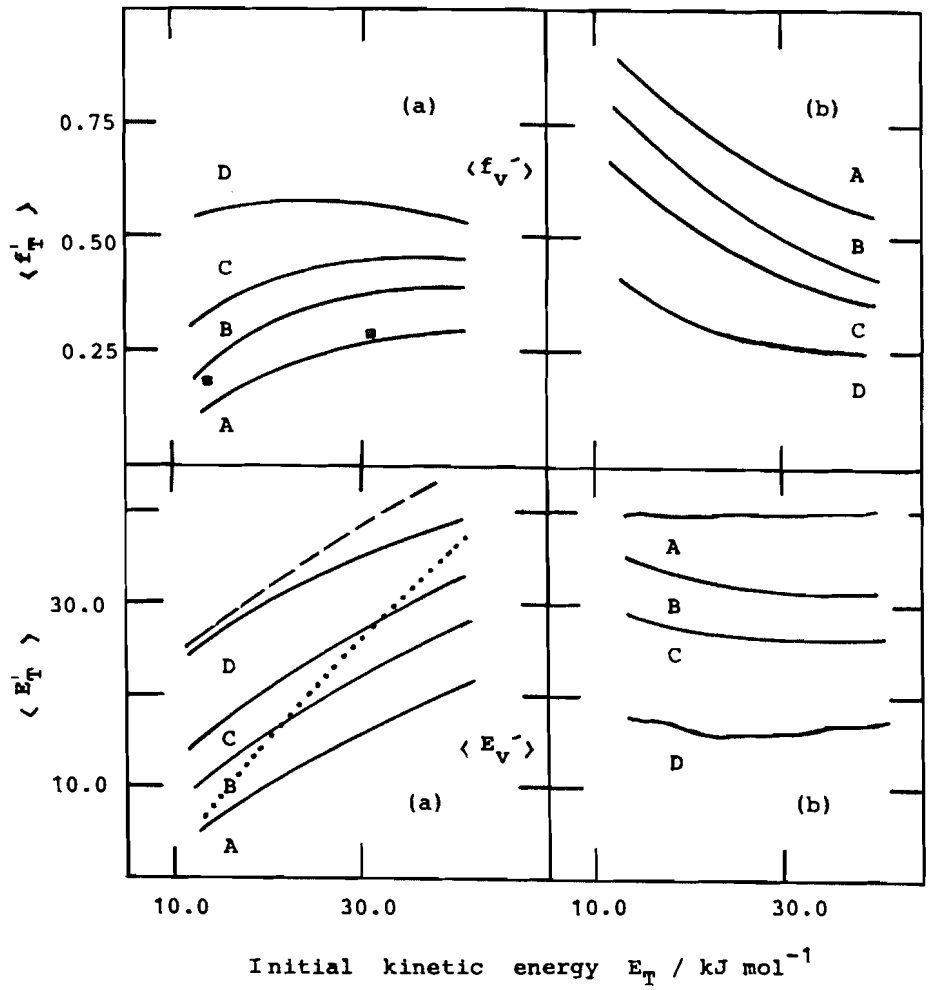

FIG. 4. (*a*) Mean product translational energy and average fraction of total energy transferred into product translation vs. initial collision energy. The marks indicate experimental points. Broken line represents the modified hard sphere model and dotted line the direct model with repulsive energy release. (*b*) Mean product vibrational energy and average fraction of total energy transferred into product vibration vs. initial collision energy.

into translation. For example, the modified hard sphere model with inclusion of conservation of angular momentum (25, 26) and the extension to the direct model with repulsive energy release (27, 28) are also displayed for comparison in Fig. 4*a*. In the first model the mean product translational energy is given by

$$[2]\quad \langle E'_T\rangle = \frac{(E_T + Q_{max})^2 - y^2 E_T{}^2}{36(E_T + Q_{max}) - 3yE_T}, \qquad E_T < Q_{max}/(y-1)$$

$$[3]\quad = (2/3)(E_T + Q_{max}), \qquad E_T > Q_{max}/(y-1)$$

where Q_{max} is the reaction exoergicity and $y = \mu/\mu'$ is the ratio of reduced masses of reactants and products. Good agreement is obtained with the results of surface D but the model assumes a faster rising amount of energy disposed into product translation. In the direct model with repulsive energy release the mean product kinetic energy is given by

$$[4]\quad \langle E'_T\rangle = [(\mu'/\mu)^{1/2} E_T{}^{1/2} + \sin\beta\, R^{1/2}]^2$$

where R is the repulsive energy release and $\cos^2\beta$ is the mass factor (29). Equation [4] reproduces the result of surface A at low E_T with $R = 4.8$ kJ/mol but again the model assumes a much faster rising amount of energy disposed into product translation with increasing E_T.

Figure 4*b* shows the mean product vibrational excitation and the average fraction of total energy, $\langle f'_v\rangle$, channeled into product vibration. In direct correlation with the translation excitation results, quite different amounts of energy are predicted to be transferred into product vibration for each surface, in the order A to D. On surface A most of the available energy around threshold is directed into product vibrational excitation while on D a low amount of energy enters product vibration. Concerning the dependence on E_T, all surfaces show analogous behaviour, i.e., the amount of total energy entering vibration changes very little or is similar to that transferred to vibration at the threshold region and independent of the collision energy. This behaviour is well demonstrated in Fig. 5 where product vibrational distributions are displayed for E_T equal to 13.5, 20.0, and 31.0 kJ/mol. In all cases the peak of the distribution moves to lower vibrational levels but becomes much broader since the mean product vibrational energy remains about constant for each surface, independent of E_T.

From the point of view of Polanyi's adiabaticity rules, surface A and, to a smaller extent, surfaces B and C seem to comply with the type of surface I (attractive surface) representing an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

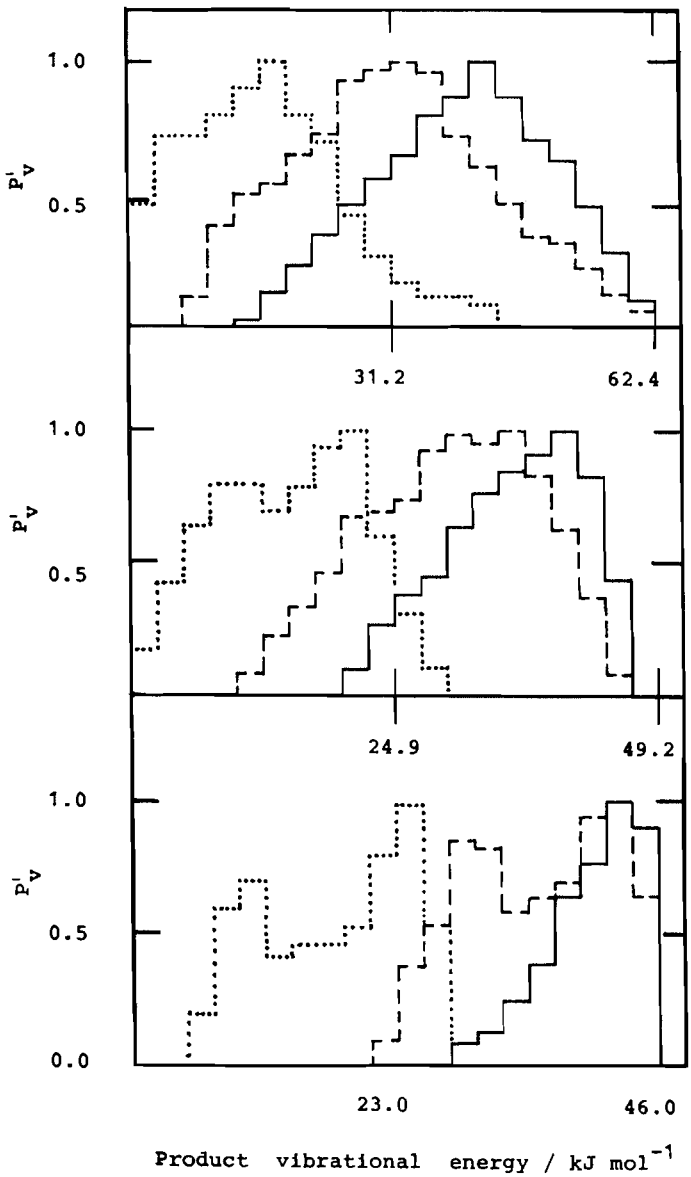

FIG. 5. Product vibrational distributions, arbitrarily normalized, for E_T = 13.5 kJ/mol (lower panel), 20.0 kJ/mol (middle panel), and 31.0 kJ/mol (upper panel) for surfaces A (—), B (– – – –), and D(·····).

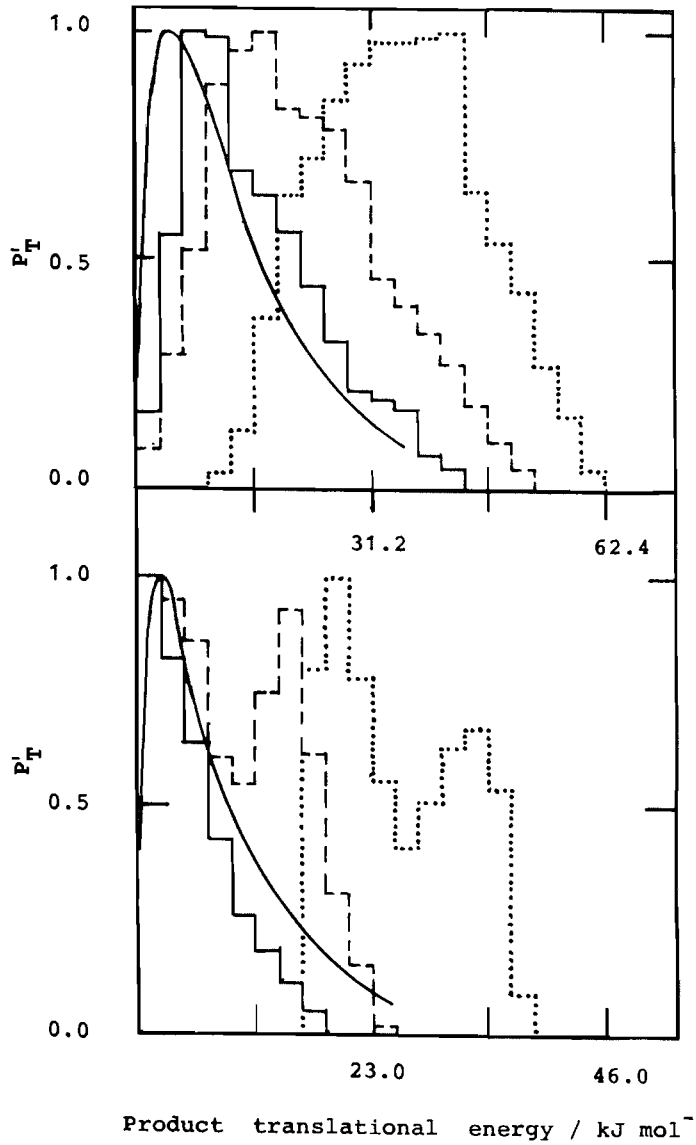

FIG. 6. Product translational distributions, arbitrarily normalized, for E_T = 13.5 kJ/mol (lower panel) and 31.0 kJ/mol (upper panel) for surfaces A (—), B (– – – –), and D(·····). Solid curves represent experimental data taken from refs. 10 and 11.

early barrier location (1, 2). Thus, on surface A for reagent kinetic energy near the threshold, reaction transposition appears to occur, i.e., the main fraction of total available energy is channeled into product vibration, $E_{tot} \rightarrow \Delta E'_v$. As the initial kinetic energy rises, the amount of energy deposited into vibration remains practically invariant while the excess collision energy ΔE_T leads to extra translational and rotational energy in the products:

$$[5] \quad \Delta E_T \sim \Delta E'_T + \Delta E'_{rot}$$

On the other hand, surface D approaches the behaviour of surface type II (repulsive surface) representing a late barrier although still along the approach coordinate at $r_1 = 2.02$ Å, i.e., displaced by 0.45 Å with respect to O–Cl equilibrium. Consequently, it predicts an unreasonably high fraction of total energy deposited into product recoil energy with low product vibrational excitation. Surfaces B and C seem to behave somewhere between surfaces A and D, predicting an equipartition between translation and vibration at high collision energies. Analogously, $\langle f'_v \rangle$ drops as the collision energy rises at a rate decreasing from A to D. Qualitatively this behaviour may be attributed to the stripping mechanism by which the reaction takes place while the old bond has not yet broken. The r_2 coordinate of the saddle point equals 2.02 Å, i.e., still very close to the Cl—Cl bond equilibrium distance r_{2e}. Apparently, the more extended the distance as the new bond is formed, the more vibrationally excited the products will be.

In Fig. 6 the product translational distributions from surfaces A, B, and D are compared to experimental average translational distributions observed at 13.5 and 31.0 kJ/mol in the molecular beam experiments of Grice and co-workers (10, 11). Good agreement is obtained for the results of surface A, which show that surface provides a satisfactory description of the translational energy profile of the reaction products.

For personal use only.

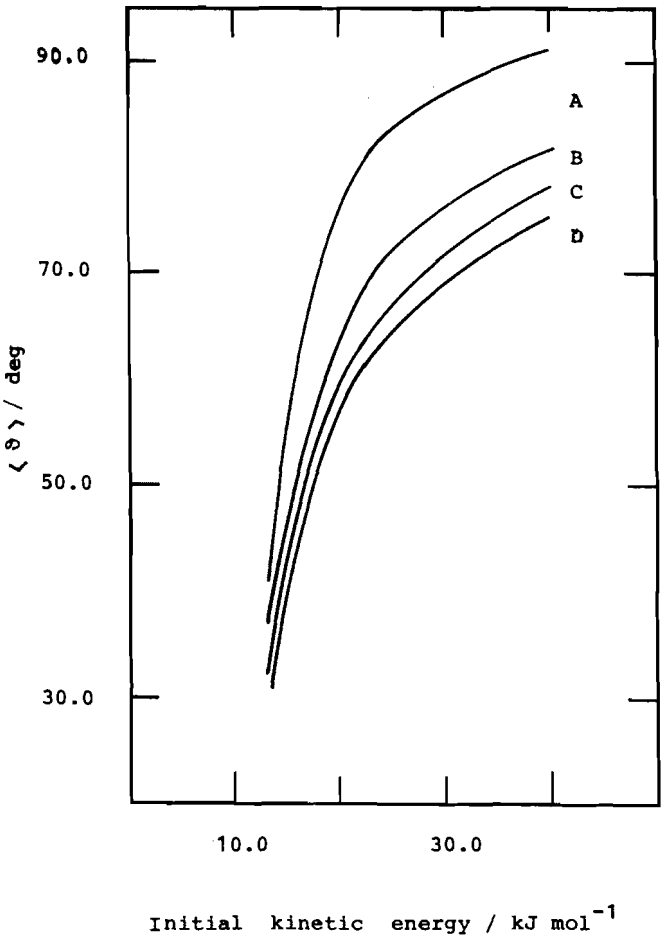

FIG. 7. Average c.m. scattering angle vs. initial kinetic energy.

The variation in average c.m. scattering angle, $\langle\theta\rangle$, vs. the initial kinetic energy of the reaction is shown in Fig. 7. All surfaces present the same pattern, i.e., mainly forward scattering at low collision energy with increasing tendency for sideways scattering as E_T rises, with surface A being the most demonstrative of this pattern. This general behaviour and, in particular, that of surface A is in good agreement with the considerable increase in wide angle scattering observed experimentally. The same effect is also clearly shown in Fig. 8 where detailed angular distributions are depicted for surfaces A, B, and D at E_T = 13.5 and 31.0 kJ/mol. The narrow distributions are typical of direct reactions and exclude the possibility of a shallow well in the potential energy function later along the reaction coordinate.

4. Effect of reagent vibrational excitation and cross sections calculations

In the second series of calculations the effect of reagent vibrational energy is investigated. In Table 2 the average amount of energy transferred into product translation and vibration is presented for surfaces A and D, assuming the diatomic to be in the v = 1 and v = 2 vibrational levels at a low collision energy E_T = 13.5 kJ/mol. These results are compared to the corresponding values in the v = 0 case where similar sums of kinetic and vibrational energies are provided initially. For surface A the reagent vibrational excitation seems to have a low effect on the mode of disposal of available energy, increasing slightly the mean energy transferred into product vibration. In contrast, due to the later barrier position on surface D, additional reagent vibrational excitation tends to remain as product vibration following the $\Delta V - \Delta V'$ adiabaticity rule. Thus, surface D changes markedly the mode of partitioning exhibited so far, showing the same tendency towards the behaviour of surface type II where excess reagent vibrational energy is channeled into product vibration once the late barrier is overcome.

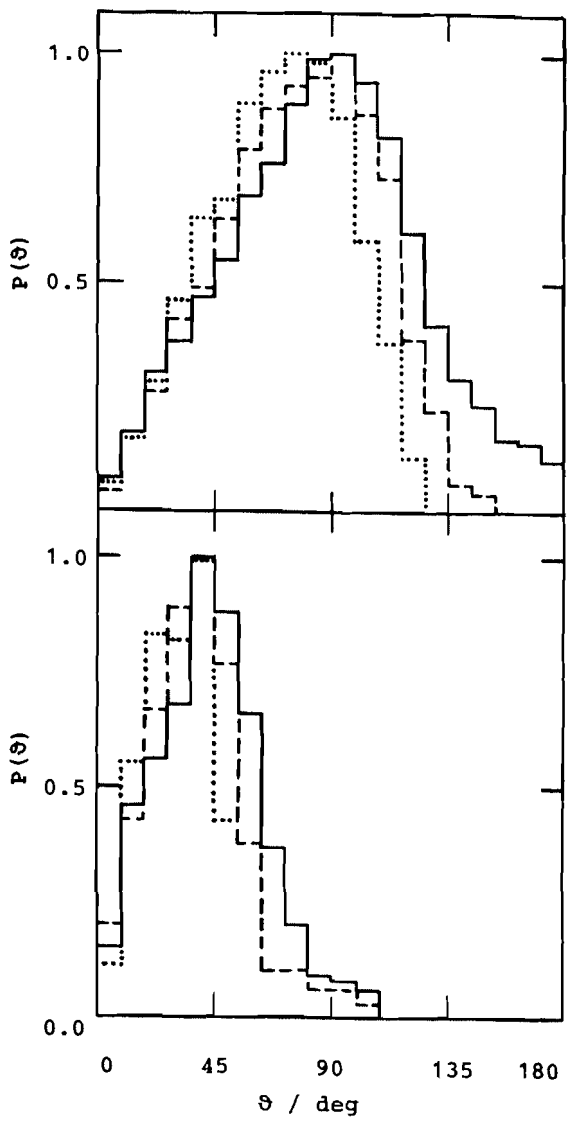

FIG. 8. Arbitrarily normalized angular distributions vs. cm scattering angle. Notation the same as in Fig. 6.

Table 3 shows the calculated cross sections for all surfaces and also for the cases v = 1 and v = 2. With the specified initial conditions employed here, the total reactive cross section at each particular collision energy depends only on E_T and was calculated as

$$[6] \quad \sigma_r = \pi b^2_{max} N_r(E_T)/N_{tot}(E_T)$$

where $N_r(E_T)$, $N_{tot}(E_T)$ are the number of reactive encounters and the total number of collisions at each E_T, respectively. The computed values are, on average, in good agreement with the experimental findings as deduced from thermal rate constant measurements. The thermal rate coefficient was found to follow the temperature dependence relation (6, 7)

13.5	0.51			0.93 ± 0.02

[a]The error limits on the reaction cross sections are given by the statistical error $\sigma_r[(N_{tot} - N_r)/N_{tot}N_r]^{1/2}$ (33).

[7] $\log k_1 = (9.76 \pm 0.18) - (13000 \pm 500)/(2.303RT)$

which corresponds to $\sigma_r = 0.25$ Å^2 for thermal conditions at $E_T = 13.5$ kJ/mol.

The main result that may be quoted at first sight from Table 3 is the significant increase in the magnitude of the cross section as the collision energy rises, following the general pattern of an exothermic reaction that proceeds on a surface with an energy barrier located in the entry valley. In addition, the cross section increases with E_T at a rate decreasing from surfaces B to D, in close correlation with the general trends observed in the mode of energy disposal, reconfirming the decreasing cabability of E_T to promote reaction as the barrier moves to later positions. However, a decline in σ_r is also observed when the barrier moves to earlier positions. Thus, closer inspection shows evidence of a maximum in the variation of the cross section with the displacement of the barrier position, the maximum value resulting from surface B. Indeed, preliminary trials with earlier and later barrier positions confirm this tendency. The maximum in σ_r variation should be expected since its location must reflect the barrier position in the true PES. The other interesting point is the insignificant increase in the cross section with reagent vibration, which complies with the typical behaviour of exothermic reactions. Finally, here again we must notice that surface D produces a larger increase in the cross section, with increasing reagent vibration, than does surface A, in agreement with the behaviour of repulsive-type surfaces where initial vibration is more effective in promoting reaction than translation.

5. Conclusion

The total energy disposal of the reaction $O(^3P) + Cl_2 \rightarrow OCl + Cl$ is examined with respect to energy barrier location in a series of quasiclassical trajectory calculations, using a family of related LEPS-type PES. The calculations have been performed for a series of values of the initial collision energy and the reagent vibration and show a radical change in the mode of energy disposal. Moving the barrier from $r_1 = 2.14$ Å to $r_1 = 2.02$ Å directs ~80% of total energy from product vibration to product translation. Thus, the results demonstrate the extreme sensitivity of the dynamical behaviour of the title reaction to the exact position of the energy barrier and the finest details of the PES that reflect the long-range repulsive forces that dominate the reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

The results produce good evidence that the true PES possesses a minimum energy barrier in a collinear transition state configuration located early along the approach coordinate. The dynamical behaviour seems to fluctuate between surfaces A and B. In view of these findings and in agreement with the experimental data, the simplest conclusion would be that the reaction takes place through interaction of the O atom unpaired p electron with the π electrons of the Cl_2 molecule in a stripping mechanism, in which no stable O—Cl—Cl intermediate is formed because of the strong orbital repulsion in the collinear configuration. The saddle point dimensions of surfaces A and B, 2.14 and 2.10 Å, respectively, are considerably larger than the equilibrium distance 1.57 Å of the OCl bond in OCl species or in dichlorine monoxide Cl_2O for which matrix isolation studies (30) produced a bond angle of 120° and a ClO bond distance of 1.587 Å. Therefore no PES involving intermediate formation of such species would be appropriate for the description of the reaction.

We conclude that the dynamics of the title reaction are adequately described by a surface intermediate between surfaces A and B where the early barrier position appears to account to a large extent for the long-range repulsive forces that govern the mechanism of the process. The dynamics suggested are consistent with collinear or near-collinear transition-state geometries, in accordance with the electronegativity ordering rule proposed by Herschbach and co-workers (31), which anticipates very low stability for a O—Cl—Cl intermediate where all atoms have similar, very high electronegativities.

Photolysis of ClNO adsorbed on MgO(100)

L. Hodgson,[1] G. Ziegler,[2] H. Ferkel, H. Reisler, and C. Wittig

Department of Chemistry, University of Southern California, Los Angeles, CA 90089-0482

Received June 28, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

L. Hodgson, G. Ziegler, H. Ferkel, H. Reisler, and C. Wittig. Can. J. Chem. **72**, 737 (1994).

The 365 nm pulsed laser photolysis of nitrosyl chloride adsorbed on a rough MgO(100) surface at 90 K has been studied. Mass spectrometric detection was used to record time-of-flight (TOF) spectra by monitoring Cl^+ and NO^+. These ions can derive from parent ClNO, which fragments completely in the mass spectrometer, as well as from Cl and NO photofragments. The TOF distributions are considerably slower than for the corresponding gas phase photodissociation process. NO was also detected state selectively by using resonance enhanced multiphoton ionization (REMPI), and a channel corresponding to direct adsorbate photolysis was identified. The state selective detection of NO molecules that emerge from the surface following photolysis shows unambiguously that their rotational degrees of freedom reflect the surface temperature (T_{rot} = 100–140 K), even at low coverages. At similar photolysis wavelengths, gas phase ClNO photodissociation is known to produce highly rotationally excited NO with a distinctive non-statistical distribution peaked at $J'' = 46.5$. Our studies suggest that, contrary to the gas-phase photolysis results, Cl and NO are not ejected rapidly following photolysis of surface-bound species on a repulsive potential energy surface. We postulate that ClNO grows in islands, with MgO defect sites serving as nucleation centers. Photofragment rotational and translational excitations are quenched efficiently due to strong attractive interactions that equilibrate NO to the surface temperature. Desorption of intact ClNO may also take place, but following (i.e., not during) the photolysis pulse. Such desorbed species can contribute to the TOF spectra, but not the REMPI spectra.

L. Hodgson, G. Ziegler, H. Ferkel, H. Reisler et C. Wittig. Can. J. Chem. **72**, 737 (1994).

Opérant à 90 K, on a étudié la photolyse à 365 nm, par laser pulsé, du chlorure de nitrosyle adsorbé sur du MgO(100) rugueux. On a utilisé la détection par spectrométrie de masse en temps de vol (TOF) pour détecter le Cl^+ et le NO^+. Ces ions peuvent provenir du ClNO parent qui se fragmente complètement dans le spectre de masse ainsi que des photofragments Cl et NO. Les distributions dans les spectres en TOF sont beaucoup plus lentes que dans le cas du processus correspondant de photodissociation en phase gazeuse. On a aussi détecté sélectivement divers états du NO en faisant appel à la résonance par ionisation multiphotonique améliorée (REMPI) et on a identifié un canal correspondant à une photolyse directe de la substance adsorbée. La détection sélective d'états des molécules de NO qui émergent de la surface à la suite de la photolyse démontre sans ambiguïté que leurs degrés de liberté de rotation sont des reflets de la température à la surface (T_{rot} = 100–140 K), même à de faibles taux de couverture. À des longueurs d'onde de photolyse semblables, il est connu que la photodissociation en phase gazeuse de ClNO conduit à du NO dont l'excitation rotationnelle est élevée et qui présente une distribution non-statistique distinctive avec un sommet à $J'' = 46{,}5$. Nos études suggèrent que, contrairement aux résultats en photolyse en phase gazeuse, le Cl et le NO, sur une surface d'énergie potentielle répulsive, ne sont pas éjectés rapidement après la photolyse d'espèces liées à la surface. On fait le postulat que le ClNO croît sous forme d'îles sur les défauts des sites du MgO qui servent de centres de nucléation. Les excitations de rotation et de translation du photofragment sont désactivés efficacement à cause des fortes interactions qui permettent au NO de s'équilibrer avec la température de la surface. Il est possible que la désorption de ClNO intact puisse aussi se produire après (et non pas durant) la pulsation photolytique. De telles espèces peuvent contribuer au spectre de TOF, mais pas auz spectres REMPI.

[Traduit par la rédaction]

I. Introduction

The use of ultraviolet lasers to initiate photochemical transformations at gas–surface interfaces is an area of both technological importance and scientific interest. Potential applications involve areas of long-standing investment such as catalysis (1) and the photochemical deposition and etching processes that are used widely in the microelectronics industry (2). Topics of scientific interest include understanding the myriad photoinduced processes that occur on surfaces and the influence of the surface on the photodissociationdynamics of the adsorbate.

The photochemistry of adsorbates on metal surfaces is often quite complicated (3, 4). Direct adsorbate photodissociation has been seen on a few metal substrates (3), but this is frequently not the case. The substrate can quench photoexcited adsorbates, thereby minimizing direct adsorbate photolysis. Additionally, the substrate competes for absorption of the ultraviolet light needed for adsorbate photolysis. Substrate absorption can lead to many different processes driven by photoemitted electrons, subvacuum level excitation, plasmon excitation, phonon excitation, etc. Reference 3 is an extensive review of the field of the photochemistry of adsorbates on metal surfaces.

Insulator surfaces typically transmit ultraviolet and visible light, making substrate-mediated processes less probable than on metal surfaces. This makes them better candidates for studying processes driven by adsorbate excitation. The direct photolysis of adsorbates on insulator surfaces has been seen in the following systems: CH_3Br (5–8), H_2S (6, 9), HBr (10, 11), HCl (11), OCS (12), C_2H_3Cl (13*a*), and NO_2 (13*b*) on LiF(001), CH_2I_2 on Al_2O_3 (14), $Fe(CO)_5$ on Al_2O_3 (15), thick polycrystalline layers of CH_3I on LiF(100) (16), C_6H_5I on LiF (17), CH_3I and CD_3I on MgO(100) (18) and NO_2 on Al_2O_3(1120) (19). In addition, the photodissociation of HBr (20) and CH_3Br (21) on LiF(001), IBr (22) and ICI (23) on MgO(001), and CH_3I on MgO(100) (18*c*) have been examined theoretically.

The detection of products in most of these systems has been achieved by using time-of-flight (TOF) mass spectroscopy, and information has been obtained regarding the different types of photochemical processes taking place and the geometries of the

molecules on the surface. Several groups have used resonance enhanced multiphoton ionization (REMPI) to detect reaction products (16–19). This has enabled photodissociation products to be detected unambiguously and state-selectively and, in certain cases, has enabled comparisons to be made with vibrational state distributions obtained from the photolysis of gas phase molecules (16, 18).

An important characteristic of most of the insulator systems studied previously has been the presence of two channels observed in TOF mass spectroscopy: a slow one corresponding to desorption of the parent molecule and a fast one corresponding to direct photolysis of the adsorbate. Different mechanisms for parent desorption were proposed: excitation of color centers leading to shock waves which cause desorption (5, 6, 8, 9, 12, 13), thermal heating (7), substrate quenching of excited adsorbates followed by desorption (17), explosive desorption (14, 16), and laser annealing where molecules in unstable sites desorb (15).

Another important issue is the pattern of adsorbate growth on the insulator surface. In metals, the adsorbate often wets the surface, since the surface–adsorbate bonds are much stronger than the adsorbate–adsorbate bonds (24). This is not always the case with inert insulators. For example, based on their temperature programmed desorption (TPD) data, Tabares et al. concluded that CH_3Br forms 3-dimensional islands on their 30 K LiF(001) surface (7). Harrison, et al. found that CH_3Br wets LiF(001), but at temperatures ~117 K (8), i.e., just below the desorption temperature. Polanyi and co-workers reported island formation for OCS (12*c*) and HBr (10, 11, 25) adsorbed at 85 K on LiF(001) and CH_3I on TiO_2 (26). In addition, they observed photoejection of HBr clusters (27) and photoreactions of HBr dimers (11).

ClNO was chosen for several reasons. Its gas phase photochemistry has been studied in great detail and exhibits several distinctive features (23–31). Dissociation takes place on a steep repulsive surface (28), and thus might occur before energy can be transferred to the surface. The NO product can be detected sensitively with REMPI, thereby providing unambiguous identification of NO photoproducts. In addition, rotational and vibrational state distributions can provide valuable dynamical information that is lacking in TOF studies. ClNO has a low bond dissociation energy (13 000 cm^{-1}) (29) and absorbs light throughout the visible and ultraviolet — spectral regions that are easily accessed with tunable dye lasers. The 300 K absorption spectrum consists of several broad absorption bands (32), which have recently been assigned (30). Its NO product state distributions, photofragment yield spectra, recoil anisotropy, rotational alignment, NO Λ-doublet populations and the nature of the orbitals involved in electronic transitions have been determined both experimentally and theoretically (28–31).

At 355 nm, gas phase ClNO is excited via a parallel transition, $S_3(2^1A') \leftarrow S_0(1^1A')$, yielding rotationally hot NO, i.e., $J''_{peak} = 46.5$ (29, 30). Almost all of the NO is in $v'' = 0$. Both NO spin–orbit states are nearly equally populated and there is a large propensity to form the Λ-doublet component that has its Π orbital perpendicular to the plane of NO rotation (29, 30). These signatures facilitate the determination of how the MgO crystal affects the photodissociation dynamics of adsorbed ClNO.

In the present study, ClNO adsorbed at 90 K on a *rough* MgO(100) surface was photolyzed at 365 nm. Species emanating from the surface were detected using a quadrupole mass spectrometer (QMS), and state distributions of NO fragments were determined by using two-photon, two-frequency laser ionization (REMPI). Single crystal MgO(100) is transparent to the 365 nm photolysis radiation, therefore substrate absorption and electron-induced processes seen on metal surfaces should be minimized. ClNO is weakly bound to the inert insulator surface, thus perturbation of its ground electronic potential energy surface should be slight. Due to this weak bond to the surface, island formation is likely. On the other hand, the nature of the electronically excited states of surface-bound ClNO is presently unknown. Specifically, these may interact more strongly with the substrate than does ground state ClNO. Therefore, we leave open the possibility that excited state dynamics of surface bound species differ qualitatively from those of their gas phase counterparts.

Following irradiation, TOF distributions are obtained by monitoring Cl^+ and NO^+. Since parent ClNO fragments completely in the mass spectrometer, yielding Cl^+ and NO^+, the TOF spectra contain contributions from ClNO molecules that desorb intact following irradiation, as well as from Cl and NO emerging from the surface. The TOF distributions are considerably slower than for the corresponding gas phase photodissociation process (28). This indicates a qualitative difference in the behavior of ClNO following photoexcitation. Specifically, there is no evidence for rapid ejection of products from the surface. The NO rotational distributions obtained by using REMPI are cold and can be fit with T_{rot} = 100–140 K, which differs greatly from the highly non-statistical gas phase distributions. These results, together with temperature programmed desorption (TPD) data, suggest that ClNO photolysis is dominated by strong attractive interactions with its surroundings and that ClNO aggregates as islands on the surface, nucleating around defect sites.

The main focus of the present paper is twofold: (*i*) demonstrating unambiguously the remarkable difference between the photophysics and photochemistry of adsorbed versus gas phase ClNO; and (*ii*) examining the possibility that nucleation and growth that takes place around defect sites are responsible for the observed differences.

II. Experimental

The experimental arrangement was described in detail elsewhere (33). Therefore only a brief description will be given, emphasizing modifications introduced for the photodissociation experiments. The vacuum system consisted of three chambers: a source chamber containing the molecular beam, a buffer chamber, and an ultrahigh vacuum (UHV) chamber. Figure 1 shows the UHV chamber, the major components being a rotatable sample manipulator equipped with liquid nitrogen cooling, two quadrupole mass spectrometers (UTI 100C), an Auger electron spectrometer (PHI 3017 with a 0.6% resolution CMA), a fast argon gun (Ion Tech), a channeltron electron multiplier (Galileo) for ion detection, a photolysis laser and a probe laser. The fast argon gun is not shown. The probe laser enters the chamber from below and ionizes NO 2–3 cm from the surface.

ClNO (Matheson, 99.2%) was purified in several freeze–pump–thaw cycles with a pentane slush (−131°C). The sample was stored at liquid nitrogen temperature and used in a darkened glass bulb. The crystal was dosed with ClNO using a pulsed molecular beam (Physik Instrumente). All experiments were performed at a backing pressure of 40–60 Torr neat ClNO. This low backing pressure was necessary to attain low coverages of the crystal, and to avoid clustering of ClNO in the molecular beam, which may become a problem with the greater cooling obtained at higher backing pressures. The coverage on the surface was varied by either changing the opening of the nozzle by controlling the voltage on the piezoelectric crystal, or by varying the dosing time, Δt. The product of Δt and the pressure increase in the

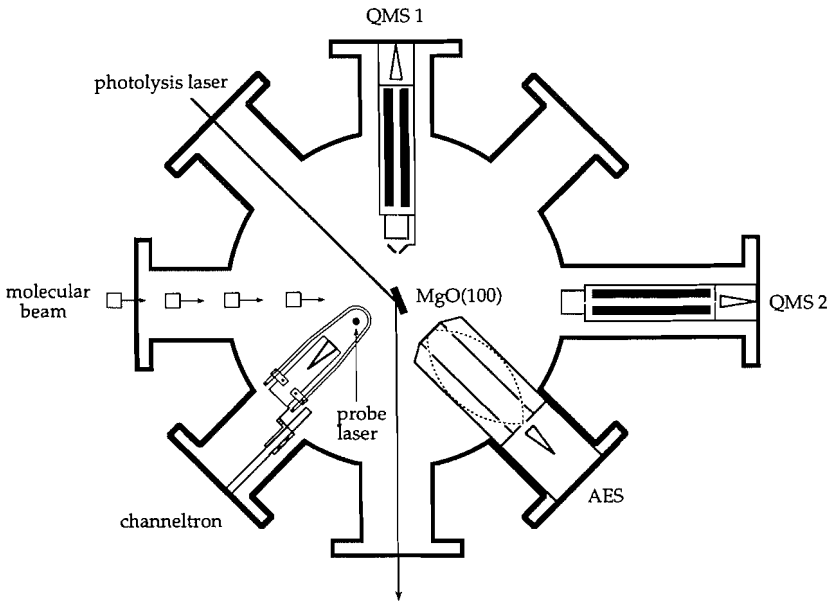

FIG. 1. Schematic of the UHV chamber for the adsorbate photolysis experiments. The photolysis radiation is incident on the MgO(100) crystal. The probe beam enters from below and ionizes NO 2–3 cm from the surface.

source chamber upon switching on the molecular beam, Δp, was proportional to coverage.

The MgO(100) crystal (Atomergic, $10 \times 10 \times 1$ mm^3) was cleaved and polished by the manufacturer. It was mounted on a molybdenum block which could be resistively heated to 800 K. Ideally, temperatures of ~1100 K would be needed for complete annealing. In our case, the surface can be characterized as clean but rough, exhibiting many steps, kinks, and vacancies. The surface temperature was measured using a chromel–alumel thermocouple attached to the molybdenum clamp of the sample holder. A temperature controller interfaced to a computer controlled the heating rate for the TPD experiments. The surface temperature was normally ramped at a rate of 0.5 K/s.

The surface was cooled with an open loop liquid nitrogen flow system. Liquid nitrogen flowed from a dewar outside the apparatus through an insulated feedthrough into the UHV chamber. Inside, flexible stainless steel bellows (connected to a small liquid nitrogen reservoir) and a sapphire plate joined the molybdenum surface holder to the reservoir. The sapphire acted as a thermal switch permitting cooling down to 90 K as well as high temperature annealing. Auger electron spectra (AES) of the MgO crystal could be taken at room temperature with a primary energy of 3 kV, but not always at liquid nitrogen temperature due to charging of the crystal. By reducing the primary energy to 800 eV, as suggested by Wei (34), reliable AES spectra could be obtained. Carbon was the main contaminant of the MgO crystal, as seen by the Auger spectrometer. This contamination was removed by fast argon atom bombardment (3 min, ~0.01 mA emission) followed by annealing (800 K, ~1 h). Auger spectroscopy is not very useful for quantitatively determining coverage if the molecules are weakly physisorbed, since the high energy electrons may cause desorption as well as dissociation.

A quadrupole mass spectrometer oriented in line with the ClNO molecular beam (QMS 2 in Fig. 1), was used to determine the composition of the direct molecular beam. The ion signals from the direct beam consisted of Cl^+ and NO^+ in a ratio of 1:5. Parent ClNO completely fragmented in the ionizer. Another mass spectrometer, QMS 1, collimated with ~5.5° angular resolution, was used to detect products in the TPD and TOF experiments. The surface to ionizer distance was 8.4 cm.

The photolysis laser was a XeCl excimer (Questek 2200) pumped dye laser system (Lambda Physik, FL 2002) operating at 365 nm. In order to obtain a uniform beam profile, the beam was expanded using a telescope and only the center portion was used. The laser beam diameter could be varied from 1 to 5 mm. For TOF measurements the laser beam diameter was 4–5 mm with energies of ~250 μJ. The photolysis laser entered and exited the UHV chamber through quartz windows.

The rotational state distribution of NO molecules leaving the surface after photolysis was measured by REMPI. The probe laser was a Nd:YAG pumped tunable dye laser system (Quanta-Ray DCR2/PDL1) that was frequency doubled and Raman shifted. The 226 nm photons (~4 μJ) excite the NO γ(0–0) transition and the 280 nm photons (~1 mJ) ionize the NO. The detection laser system was described in detail previously (33). The NO^+ ions were extracted from the ionization region and detected with a high sensitivity channeltron.

The determination of surface coverage on insulator surfaces by TPD is difficult. The difference in bond energies, i.e., between substrate–adsorbate and adsorbate–adsorbate is too small to produce a distinguishable break in the TPD spectra indicating the onset of multilayer coverage. The possibility of island growth further complicates the issue. In order to quantitatively determine the ClNO dosage in this experiment, a method commonly used for ionization gauge calibration was used. It makes use of the fact that the flux of molecules from a pressure stabilized reservoir through a known conductance into an evacuated chamber is fully computable (35). This flux calibration is reliable for molecules such as N_2 for which ionization gauge calibration factors are available. For a molecule such as ClNO, the flux must be calibrated through comparison with N_2.

The determination of the sticking probability was achieved by dosing the surface with a ClNO molecular beam, and comparing the background pressure in the UHV chamber when the surface was maintained alternately well below and well above the ClNO desorption temperature. The sticking probability is close to zero for temperatures higher than the desorption temperature. The pressure component due to the molecular beam decreased when the temperature of the surface was lowered beneath the desorption temperature, indicating that ClNO sticks to MgO. If all molecules that hit the surface are adsorbed, the molecular beam component would be zero. A reduction of the molecular beam contribution of 50% was obtained, indicating a sticking probability of ~50% at a surface temperature of 90 K. There were no indications that heating the surface affected the pumping speed due to the change in cold areas cryopumping the chamber. This is a reasonable assumption due to the small area of the surface.

III. Experimental results

A. *Temperature Programmed Desorption (TPD)*

TPD was used to help determine the nature of ClNO adsorption. In Fig. 2, the Cl^+ and NO^+ mass spectrometer signals ver-

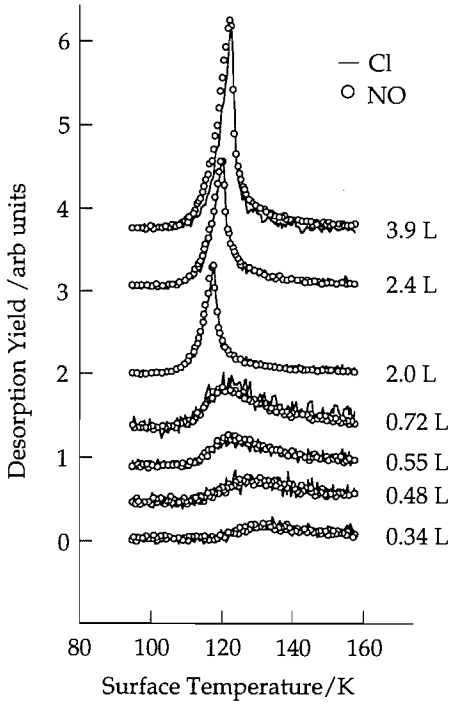

FIG. 2. TPD spectra of Cl^+ (lines) and NO^+ (circles) at different coverages with a heating rate of 0.5 K/s.

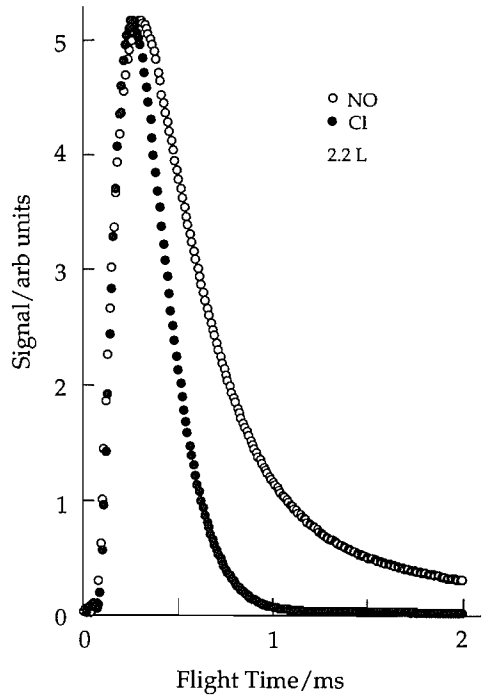

FIG. 3. Cl^+ (●) and NO^+(○) TOF signals after 365 nm photolysis of 2.2 L of ClNO adsorbed on MgO(100). Velocity dependent ionization efficiencies and ion flight times in the QMS have been taken into account. The signals were normalized to the same peak intensity.

sus temperature, obtained at a heating rate of 0.5 K/s, are shown for different coverages. In each case, the Cl^+ and NO^+ signals were normalized to the same height, and the curves are offset for clarity. As mentioned previously, parent ClNO cannot be seen due to complete fragmentation in the QMS. However, ClNO most likely adsorbs molecularly on MgO(100) since the desorption peaks for Cl^+ and NO^+ both occur at the same temperature. No other peaks were present in the TPD spectra, indicating that ClNO does not dissociate or react to form other molecules on the surface. It also does not thermally decompose during TPD and the sample is not contaminated, though NO cannot be completely eliminated because of an equilibrium between ClNO, NO, and Cl_2 (29). The main desorption peak for NO on MgO(100) was below the lowest temperatures attainable (~90 K), so its presence is restricted to defect sites.

B. TOF following laser irradiation

Samples with ClNO adsorbed on MgO(100) were irradiated at 365 nm and species that subsequently leave the surface were detected with the QMS. Cl^+ and NO^+ were the only ions seen in the mass spectrometer and no positive ions were seen with the ionizer off. TOF data were typically taken with the photolysis laser wavevector at 45° to the surface normal. Products were detected with the surface facing QMS 1. Signals from the first 3–4 laser shots were discarded.

The data presented in Fig. 3 show TOF distributions for a coverage of 2.2 L. Signals were corrected for the velocity dependent QMS detection efficiency and the ion flight times in the QMS. The Cl^+ and NO^+ signals are normalized to the same height and their risetimes are almost identical. The NO^+ signal exhibits a tail due to background NO; when this is subtracted the signal is essentially the same as that of Cl^+. Such data alone do not enable us to distinguish between ClNO molecules that reach the mass spectrometer intact, as opposed to Cl and NO fragments that travel from the surface to the mass spectrometer. Thus, we conclude that the TOF signals may include contributions from both desorbed parent ClNO and Cl and NO fragments generated in the photolysis of surface-bound ClNO. Details will be given in a future publication.

C. Photodissociation cross section of adsorbed ClNO

An upper limit to the ClNO photodissociation cross section can be obtained from the variation of the NO^+ signal versus the number of laser pulses, for specific initial coverages. Time integrated NO^+ signals were obtained with the surface normal pointing towards QMS 1. Signals decrease with the number of pulses directed at the same spot on the surface due to adsorbate depletion. This variation depends on initial coverage, as shown in Fig. 4*a*. The laser intensity was kept constant throughout these measurements.

Several conclusions can be drawn from the plots presented in Fig. 4. NO^+ signals only decrease exponentially at low coverages and for a modest number of laser firings. At higher coverages, they are almost constant. This suggests that species from the topmost layers are being released into the gas phase upon irradiation. If the total photoexcitation cross section, σ, is independent of coverage, the signal at low coverages is given by (3)

$$[1] \quad S = S_0 \exp(-n\sigma\Phi)$$

where S is assumed to be proportional to the surface coverage; S_0 is the corresponding signal for the first laser shot; Φ is the number of photons per unit area; and n is the number of laser pulses. Because of the likelihood that some parent molecules are desorbed intact from the surface, the parameter σ should be interpreted as an upper limit to the photodissociation cross section. From the slope of the low coverage curve shown in Fig. 4*b*,

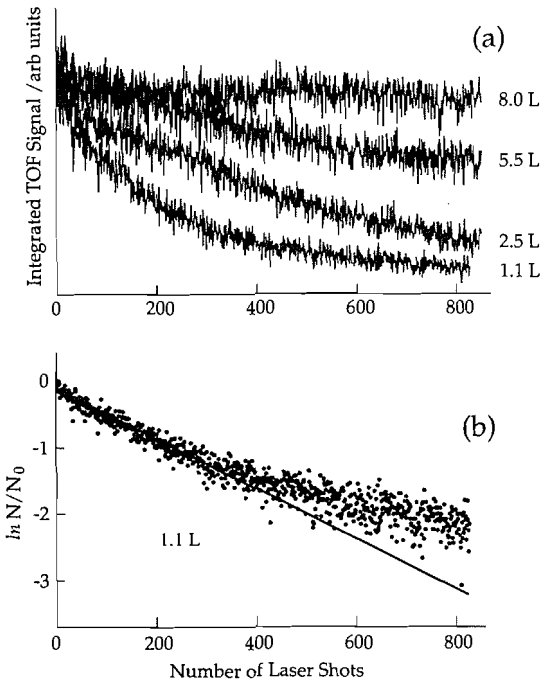

FIG. 4. Panel (*a*) shows the decrease in the time-integrated NO^+ TOF signal when ClNO is photolyzed at 365 nm at various coverages. Panel (*b*) is a semilogarithmic plot of the signal versus photon fluence at low coverages, from which an upper bound to the photodissociation cross section is obtained.

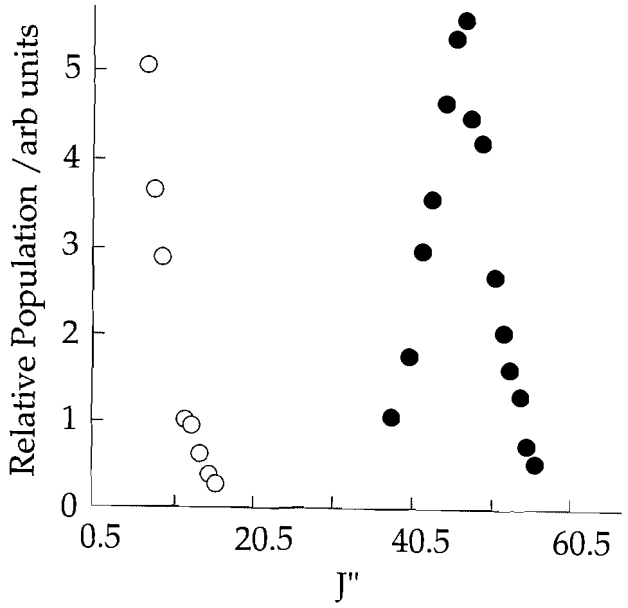

FIG. 5. Open circles: NO($v'' = 0$) rotational distribution from the 365 nm photolysis of ClNO adsorbed on MgO(100). Data are for the $R_{11} + Q_{21}$ branch of the lower energy $^2\Pi_{1/2}$ spin-orbit state; they can be fit with $T_{rot} \sim 140$ K. Filled circles: NO($v'' = 0$) rotational distribution from 355 nm photolysis of gas phase ClNO. Data are for the $Q_{11} + P_{21}$ branch of $^2\Pi_{1/2}$.

σ can be determined. This curve is not purely exponential, as can be seen from the deviation from a straight line after ~400 laser shots. Such deviation at longer times was also seen with $Fe(CO)_5$ adsorbed on Al_2O_3 (15). This probably arises because the laser beam is not spatially homogeneous: if the beam is more intense at the center, the signal will be dominated by this region initially, but as molecules at the center are depleted, contributions from the lower intensity wings will begin to dominate. From the initial slope we derive $\sigma \sim 4 \times 10^{-19}$ cm^2. As stated above, this is an upper limit to the ClNO absorption cross section, since parent molecules that desorb following irradiation contribute to the observed signal decrease just as if they had been dissociated. This upper bound can be compared to the known gas phase absorption cross section of approximately 0.8×10^{-19} cm^2 (32). Additionally, interference between the incident, transmitted, and reflected radiation was not taken into account (12). No pronounced surface-enhanced photodissociation was seen, as has been reported for rough metal surfaces (36, 37) and for OCS on unannealed LiF(001) (12*a*,*b*). We also note that the QMS samples a small solid angle (~5.5°), while for accurate cross section measurements all particles must be detected, i.e., angular distributions may vary with coverage, as noted by Polanyi and co-workers (9).

D. State-specific NO detection by REMPI

NO($v'' = 0$) rotational distributions were determined by using REMPI. A scan over transitions in the region 225.7–227.0 nm required about 800 points, averaging 10 shots per point. Thus, stability of the experimental conditions over 8000 shots of the photolysis laser was necessary. At low coverages, when the signal drops exponentially with each laser pulse, this requirement could not be fulfilled without replenishing the surface. For example, an initial coverage of about 1 L would be removed with 3000 laser shots.

By using the pulsed molecular beam as a doser, the crystal could be dosed between photolysis laser pulses, thereby maintaining a steady state of molecules on the surface during the measurement (5–13, 16, 38). The molecular beam and photolysis laser both operated at 10 Hz. Typical steady state surface coverages were 0.2–0.8 L. The stable signals obtained by using this alternating dose-and-desorb condition have proven to be invaluable for measurements of NO rotational distributions. With the surface positioned as shown in Fig. 1, rotationally resolved spectra were obtained under steady state conditions. Results are summarized as the open circles in Fig. 5 for a coverage of ~0.5 L. The time delay between the photolysis and probe laser was optimal at 150 μs. The data shown are for the $R_{11} + Q_{21}$ branch in the lower energy $^2\Pi_{1/2}$ spin orbit state. The NO rotational distributions corresponded to $T_{rot} = 100$–140 K — remarkably different from the hot NO rotational distributions seen in gas phase photolysis (29, 30) and reproduced in Fig. 5 (filled circles). No NO($v'' = 1$) was detected, paralleling the gas phase photolysis results, in which very little NO($v'' = 1$) is produced.

IV. Discussion

A. Evidence for adsorbate photodissociation

The results presented above indicate that the TOF and REMPI signals are a consequence of irradiating samples in which ClNO is adsorbed molecularly on MgO(100). We checked for contributions from gas phase ClNO photodissociation by the 365 nm photolysis laser, since the background pressure in the UHV chamber increased slightly when the molecular beam was on. With the molecular beam on and the crystal at 300 K (i.e., too high a temperature for ClNO to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.246.54.202 on 09/08/12
For personal use only.

adsorb), no signal was seen with the QMS, confirming that the observed signals are associated with molecules that are adsorbed on the crystal. The most convincing evidence against gas phase photodissociation, however, comes from the NO rotational distributions, which differed remarkably from those obtained in the gas phase photolysis of ClNO at any wavelength.

All signals depend linearly on 365 nm fluence over a large range of coverages, and therefore are not due to photodesorption of ClNO followed by its photolysis. Note that this rules out photodissociation of gaseous ClNO that is desorbed *within* the laser pulse, but leaves open the issue of ClNO that desorbs *following* the photoexcitation pulse. Signals were also checked for photodissociation of ClNO by the probe laser, since the absorption cross section of ClNO at 226 nm is a factor of 10^2 higher than at 365 nm (32). The laser signal depended on one photon each of the 226 and 280 nm radiations, confirming that absorption of the probe laser light by background ClNO is insignificant. This is also expected on the basis of the 226 nm photon fluence and the ClNO absorption cross section: only $\sim 10^{-4}$ of the ClNO will be photodissociated. The most conclusive evidence for direct photodissociation of adsorbed ClNO comes from the observation of NO by REMPI under conditions where photodissociation of desorbed ClNO is insignificant.

Preliminary experiments at other photolysis wavelengths are consistent with the suggestion that adsorbate photodissociation is taking place. Though fragments were detected following 475 nm photolysis (which coincides with the ClNO $S_1 \leftarrow S_0$ system), almost no signal was seen following irradiation in the weak $T_1 \leftarrow S_0$ system near 600 nm. At 600 nm, the cross section for gas phase ClNO photodissociation is small compared to 475 and 365 nm (32). It is also possible that surface and bulk defects, as well as photoproducts that remain bound to the surface (e.g., at defects), have absorptions that vary throughout these wavelength ranges.

B. Island formation

MgO(100) has many surface defects (predominantly oxygen vacancies) (39). Electrons can be trapped at these sites, creating states within the 7.8 eV band gap (40). States located 2.3 and 6 eV below the vacuum level have been seen by Henrich et al. using electron energy loss spectroscopy and were discussed in terms of oxygen vacancies and intrinsic surface effects (39). One indication of the existence of such defect states on the rough MgO(100) crystal used in the present experiments is the observation of a blue fluorescence upon electron bombardment. This fluorescence could be seen readily by the eye and was strongest for a clean MgO surface. After exposure to ClNO and desorption of ClNO by heating the surface ~150 K, the fluorescence disappeared and a small amount of chlorine could be seen on the surface with AES. This suggests that some ClNO dissociatively adsorbs on the surface with the chlorine occupying defect sites in the MgO crystal, most likely oxygen vacancies. These Cl atoms are strongly bound. They cannot be removed at temperatures as high as 800 K, but they can be removed with fast argon bombardment. Thus, it is possible that the nucleation center is a Cl atom attached to a defect.

The temperature at which exposures were carried out prior to TPD is only ~30 K lower than the main desorption peak at ~120 K. We assume that, following ClNO adsorption at 90 K, molecules are able to diffuse across the surface and may either find an unoccupied defect site, or may collide with other

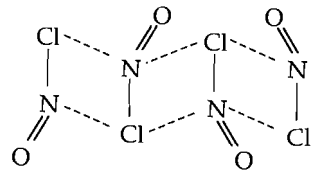

FIG. 6. Molecular solid of ONCl-II as proposed by Jones and Swanson (44).

so-called "walkers" (41), as well as with islands already formed. At higher exposures, defect-free areas become covered, presumably beginning with sites adjacent to the decorated defects. In this picture, adlayer growth over defect-free areas is in the form of two-dimensional islands and is nucleated by decorated defects. It should be mentioned that an island randomly formed on a defect-free area is not necessarily stable and can decay before exceeding the critical size to become stable (42). Therefore, the density on the surface during dosing can influence the ultimate size distribution of islands, at least at low coverage. Dosing the surface with a pulsed molecular source may cover the surface somewhat differently than a doser that maintains a constant density on the crystal after initiating the dosing procedure.

Desorption between 120 and 140 K is attributed to molecules evaporating from defect-free areas, perhaps at the edge of islands or dendrites. The desorption peak is seen to shift to lower temperatures with increasing coverage (Fig. 3). In general, such behavior of a TPD peak can be indicative of a variety of phenomena, including recombinative desorption (following dissociative adsorption), collision mediated desorption, and repulsive lateral interaction. Simulations of the TPD results indicate that the magnitude of the observed shift is consistent with each of these. At higher coverages, zeroth order desorption (typical of multilayers, clusters and chains of molecules) is seen.

Some information regarding ClNO aggregates can be obtained from spectroscopic studies of ClNO ices and thin films. Killough et al. (43) showed that in the range 85–190 K, ClNO ice exists as covalent dimers (ONCl-II), while in the range 74–85 K, an ionic phase exists (ONCl-I). Later, Jones and Swanson used infrared spectroscopy to study ClNO in matrices and thin films deposited on a cold CsI window (44). They suggested that ONCl-II consists of long chains with strong intermolecular covalent bonds, as shown in Fig. 6. This geometry agrees with *ab initio* calculations which show that nitrogen has a partial positive charge while chlorine and oxygen have partial negative charges (30). Formation of these chains leads to weakening of the Cl—NO bonds. The surface temperature of ~90 K used in our study is near the ONCl-I/ONCl-II phase transition. Dimer or chain formation is consistent with our observation of islands. However, if ClNO is ionic when adsorbed on the ionic MgO crystal, comparison to the gas phase photochemistry may be unjustified. A direct determination of the geometry and structure of ClNO on MgO(100) is clearly needed.

C. Rotational and translational energy distributions

As stated earlier, NO rotational distributions were very cold (100–140 K), i.e, close to the surface temperature. This differs markedly from the rotationally hot distributions seen in gas phase photodissociation.

As stated above, the TOF distributions observed mass spec-

trometrically may originate both from desorbed ClNO and photodissociation fragments. However, the observed distributions all correspond to species that are traveling much more slowly than in the case of gas phase photodissociation and there is no indication of a fast, instantaneous component. We note that the desorbates have average kinetic energies of ~10 meV, while in the gas phase photodissociation of ClNO, the Cl and NO fragments have 580 and 670 meV of translational energy, respectively, in the center-of-mass system. These values were obtained by assuming that 70% of the available energy goes into translation, as reported for the gas phase photolysis of ClNO at 347 nm by Busch and Wilson (28).

The observed cold translational and NO rotational energy distributions at nominal submonolayer coverages are consistent with island formation, where photofragments can experience strong, attractive interactions with other molecules in the island and the surface before escaping. Thus, their translational and rotational energies are quenched and are quite different from the products of gas phase photolysis. Similar TOF spectra were also seen with CH_3I on LiF (16) and HBr islands on LiF(001) (11) and interpreted in terms of products formed in lower layers which undergo many collisions before escaping. In the case of HBr, the H-atom TOF low energy tail increased with surface coverage.

It is surprising that other products (e.g., Cl_2) were not detected. In many systems, species other than the parent and photolysis products have been seen, indicating photoinitiated reaction (PRXN) on the surface (6, 9–11, 12*c*, 13, 17, 18). In these cases, surface-bound molecules are aligned due to interactions with the surface as well as each other and photolysis initiates reaction with an adjacent molecule. Attack angles and impact parameters are restricted, leading to a surface aligned PRXN.

It is known that the gas phase reaction $Cl + ClNO \rightarrow Cl_2 + NO$ has a large rate constant (45), and produces vibrationally excited NO (46). Thus, Cl_2 is potentially a PRXN product. However, no signal was observed at $m/e \cong 71$, indicating that the Cl^+ signals do not derive from Cl_2. Moreover, Cl_2 does not stay on the surface, since TPD spectra (to 200°C) taken after as many as 100 laser shots were identical to those taken with the photolysis laser off. The binding energy of Cl_2 to MgO has recently been calculated to be 4.1 kcal/mol (47). Thus, the photolysis laser does not initiate the formation of other products on the surface. The absence of a PRXN may result from the restricted geometries of surface-bound molecules. More work is needed to clarify this point.

Although the exact geometry of ClNO on the surface is unknown, it is reasonable that it lies flat on the surface, in analogy with the suggested geometry of its thin films on CsI surfaces (Fig. 6) (44). Consequently, photoproducts may be ejected preferentially in the plane of the surface. Since TOF products were typically detected along the surface normal, our observations may be biased toward molecules that undergo collisions. To examine this, TOF distributions were obtained with the detector at the surface normal and at 45° to the normal. Both measurements gave identical results. Though this is consistent with there being no surface order, it is also consistent with the surface being too rough for its plane to be well defined.

The TOF distributions obtained by Polanyi and co-workers for CH_3Br adsorbed on rough LiF also indicated slow products relative to smooth surfaces or gas phase photodissociation (6, 8). They attributed this to strong adsorption at different defect sites. The reduced translational energy was attributed to increased internal energy of the fragments and/or energy transfer to the surface, since bonding to the defect is strong. In our case, NO has *less* internal energy than in the corresponding case of gas phase photodissociation. After photodissociation the fragments may stick to the surface before desorbing. For example, Watson, NoorBatcha, and Lucchese (21), in trajectory simulations of the 222 and 193 nm photodissociation of CH_3Br on LiF(001), see a significant amount of sticking, especially on a rough surface. With our time resolution, it is not possible to determine if molecules stick briefly before desorbing.

Obviously the situation is complex and without knowing the geometry and nature of the surface-bound molecules it is imprudent to propose a complete model. It is unknown whether ClNO on the surface adsorbs in planar or non-planar geometries, and whether its structure is covalent, ionic, a molecular chain, or a 2- or 3-dimensional island. Presently experiments are being conducted to determine the nature of the bonding and the geometry of the molecules on the surface. In addition, experiments on smooth MgO crystals aimed at further establishing the role of defect sites are in progress in our laboratory (48). Preliminary results from these latter experiments confirm the interpretation suggested in this paper.

V. Conclusions

This study establishes that ClNO adsorbs molecularly on rough MgO(100) surfaces at 90 K. Following 365 nm laser irradiation, products due to ClNO photolysis are unambiguously identified by REMPI. TOF distributions indicate that only very slow species emanate from the surface. The NO^+ and Cl^+ mass spectrometer signals are probably due to both photodissociation and cracking of desorbed parent ClNO. The slow TOF distributions are remarkably different than gas phase photolysis, which yields high translational energies of products. NO rotational distributions reflect the surface temperature (T_{rot} = 100–140 K) and, again, are much colder than the corresponding gas phase distributions which peak at $J'' = 46.5$, suggesting that strong attractive interactions with the surface take place prior to desorption. Evidence points to ClNO island formation, with nucleation occurring around defect sites, but the nature and geometry of ClNO on the surface are presently unknown. One possibility is the chain-like structure observed by Killough et al. on cold CsI. Work is currently in progress to determine the geometry of ClNO on MgO(100), and the role of defects on the dissociation.

Received August 31, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

BENOIT SIMARD, VALERIE J. MACKENZIE, PETER A. HACKETT, and RONALD P. STEER. Can. J. Chem. **72**, 745 (1994).

The $\tilde{a}(^3A_2)$ and $\tilde{B}(^1A_1)$ states of jet-cooled thiophosgene (Cl_2CS) have been studied by optical–optical double resonance (OODR) spectroscopy. Two OODR schemes have been used to probe the $\tilde{B}(^1A_1)$ state. One scheme uses selected vibronic levels of the $\tilde{A}(^1A_2)$ state as the intermediate state, while the other uses the vibrationless and $2_1 3_1$ levels of the $\tilde{a}(^3A_2)$ state. All of the vibronic levels in the 33 980 – 35 600 cm^{-1} region can be rationalized with the following origin band and fundamentals: 0^0 = 34 277 cm^{-1}, ν_1 = 505 cm^{-1}, ν_2 = 470 cm^{-1}, ν_3 = 213 cm^{-1}, ν_6 = 249 cm^{-1}, 4^2 = 341 cm^{-1}, 4^4 = 627 cm^{-1}. The discrepancies among the various studies of the $\tilde{B}(^1A_1)$ state will be discussed and reconciled. It is conjectured that the $\tilde{B}(^1A_1)$ state potential along the C—S coordinate exhibits an asymmetric double-minimum potential resulting from the interaction of the $^1A_1$ states arising from the $(\pi^1_{CS}\ n^2_S\ \pi^{*1}_{CS})$ and $(\pi^2_{CS}\ n^0_S\ \pi^{*2}_{CS})$ configurations. The minimum corresponding to the $(\pi^1_{CS}\ n^2_S\ \pi^{*1}_{CS})$ configuration lies higher in energy and the principal decay mechanism for molecules pumped to its first few vibronic levels is fluorescence. On the other hand, molecules pumped to the minimum corresponding to the nominal $(\pi^2_{CS}\ n^0_S\ \pi^{*2}_{CS})$ configuration decay nonradiatively. The barrier height to inversion and the out-of-plane bending angle along the out-of-plane bending coordinate, ν_4, have been determined to be 945 cm^{-1} and 25°, respectively, by fitting quartic-quadratic and quadratic-Gaussian double-minimum potentials to the observed energy levels. The $\tilde{a}(^3A_2)$ state has been studied by a novel OODR scheme which uses the fluorescent vibrationless level of the $\tilde{B}(^1A_1)$ state to monitor $\tilde{a}(^3A_2)$–$\tilde{X}(^1A_1)$ transitions. A vibronic analysis has been carried out and the following origin band and fundamentals derived for the $\tilde{a}(^3A_2)$ state: 0^0 = 17 499 cm^{-1}, ν_1 = 923 cm^{-1}, ν_2 = 474 cm^{-1}, ν_3 = 247 cm^{-1}, 4^2 = 297 cm^{-1}, 4^4 = 560 cm^{-1}, 4^6 = 741 cm^{-1}. With the exception of a few corrections and additions, the results confirm the findings of previous studies, notably regarding the bent geometry and barrier height to inversion. An overall comparison of the data suggests that the wavenumber of ν_6 in the $\tilde{A}(^1A_2)$ state is 279 cm^{-1} instead of 189 cm^{-1}.

BENOIT SIMARD, VALERIE J. MACKENZIE, PETER A. HACKETT et RONALD P. STEER. Can. J. Chem. **72**, 745 (1994).

Faisant appel à la spectroscopie de double résonance optique – optique (DROO), on a étudié les états $\tilde{a}(^3A_2)$ et $\tilde{B}(^1A_1)$ du thiophosgène (Cl_2CS) refroidi par un jet. On a utilisé deux schémas de DROO pour examiner l'état $\tilde{B}(^1A_1)$. Un schéma utilise des niveaux vibroniques choisis de l'état $\tilde{A}(^1A_2)$ comme état intermédiaire, alors que l'autre fait appel aux niveaux sans vibration et $2_1 3_1$ de l'état $\tilde{a}(^3A_2)$. On peut rationaliser tous les états vibroniques de la région 33 980 à 35 600 cm^{-1} en utilisant la bande d'origine et les fondamentales suivantes: 0^0 = 34 277 cm^{-1}, ν_1 = 505 cm^{-1}, ν_2 = 470 cm^{-1}, ν_3 = 213 cm^{-1}, ν_6 = 249 cm^{-1}, 4^2 = 341 cm^{-1}, 4^4 = 627 cm^{-1}. On discute et on réconcilie les différences observées entre les divers études de l'état $\tilde{B}(^1A_1)$. On fait l'hypothèse que le potentiel de l'état $\tilde{B}(^1A_1)$ le long de la coordonnée C—S présente un potentiel à double minimum asymétrique résultant de l'interaction des états $^1A_1$ découlant des configurations $(\pi^1_{CS}\ n^2_S\ \pi^{*1}_{CS})$ et $(\pi^2_{CS}\ n^0_S\ \pi^{*2}_{CS})$. Le minimum correspondant à la configuration $(\pi^1_{CS}\ n^2_S\ \pi^{*1}_{CS})$ se trouve à une énergie plus élevée et le principal mécanisme de relaxation pour les molécules portées à leurs premiers niveaux vibroniques est la fluorescence. Par ailleurs, pour les molécules portées au minimum correspondant à la configuration nominale $(\pi^2_{CS}\ n^0_S\ \pi^{*2}_{CS})$, la relaxation ne se produit que d'une façon non radiative. En ajustant les potentiels de double minimum quartique/quadratique et quadratique/gaussien avec les niveaux d'énergie observés, on a déterminé que la hauteur de la barrière à l'inversion et l'angle de la déformation hors plan le long de la coordonnée ν_4 sont respectivement de 945 cm^{-1} et 25°. On a étudié l'état $\tilde{a}(^3A_2)$ par un nouveau schéma DROO qui fait appel au niveau fluorescent sans vibrations de l'état $\tilde{B}(^1A_1)$ pour déterminer les transitions $\tilde{a}(^3A_2)$–$\tilde{X}(^1A_1)$. On a effectué une analyse vibronique et on en a tiré la bande à l'origine et les fondamentales suivantes pour l'état $\tilde{a}(^3A_2)$: 0^0 = 17 499 cm^{-1}, ν_1 = 923 cm^{-1}, ν_2 = 474 cm^{-1}, ν_3 = 247 cm^{-1}, 4^2 = 297 cm^{-1}, 4^4 = 560 cm^{-1} et 4^6 = 741 cm^{-1}. À l'exception de quelques corrections et additions, les résultats confirment les résultats obtenus antérieurement, principalement en ce qui a trait à la géométrie inversée et à la hauteur de la barrière d'inversion. Une comparaison globale des données suggère que le nombre d'onde pour ν_6 de l'état $\tilde{A}(^1A_2)$ est 279 cm^{-1} au lieu de 189 cm^{-1}.

[Traduit par la rédaction]

I. Introduction

Thiophosgene (Cl_2CS) has been the subject of extensive spectroscopic and photophysical studies in both the gaseous and condensed phases (1–3). This molecule has also been the subject of a number of *ab initio* investigations (4–8). This remarkable interest arises from the facts that (*1*) unlike its carbonyl counterpart, Cl_2CS exhibits beautiful discrete electronic spectra, and (*2*) it fluoresces from both the first and second excited singlet states, in violation of Kasha's rule (9). This "anomalous" photophysical behavior, combined with its good thermodynamic stability (Cl_2CS is the only small thiocarbonyl that is commercially available) has made thiophosgene a prototypical species for both spectroscopic and dynamics studies. Despite this, there are still fundamental points about Cl_2CS that remain unclear. This paper addresses one unresolved ques-

tion, namely, the energy level structure in the $\tilde{B}(^1A_1)$ state, a point that has been the subject of exciting debate for about 20 years. This paper will also present a reinvestigation of the $\tilde{a}(^3A_2)$ state by a scan up – scan down optical–optical double resonance technique (OODR), a simple variation of the usual OODR technique which has applications for any molecules requiring searches for new states or linkages between states.

II. Background

Thiophosgene belongs to the C_{2v} point group. The ground state structure has been accurately determined by microwave spectroscopy, which has revealed that the C═S and C—Cl bond lengths are 1.600 and 1.727 Å, respectively, and the S═C—Cl angle is 124.4° (10). The electron configuration giving rise to the ground state has been determined by photoelectron spectroscopy to be [core] $(11a_1)^2(7b_2)^2(3b_1)^2(12a_1)^2(2a_1)^2(8b_2)^2(13a_1)^2(4b_1)^2(9b_2)^2$, where the $11a_1$, $7b_2$, and $12a_1$ molecular orbitals (MO) contain the σ bonding electrons, the $3b_1$, $2a_2$, $8b_2$, and $13b_1$ MOs contain the chlorine lone pairs electrons, the $4b_1$ MO contains the π bonding electrons, and the $9b_2$ MO contains the sulfur lone pair electrons (11). The ground state is therefore of $^1A_1$ symmetry.

In all three excited states discussed below, the molecule is non-planar and non-rigid. Consequently it belongs to the non-rigid point group G_4 which is isomorphous with the C_{2v} representation. Thus, the symmetry arguments that should apply when discussing vibronic transitions are those of the C_{2v} point group.

The first excited singlet and triplet states arise from the promotion of a $9b_2$ electron to the $5b_1$ MO, and hence are of $^{1,3}A_2$ symmetries. Since the $5b_1$ MO is largely π* in character, this corresponds to a $\pi^* \leftarrow n$ electron promotion. The $\tilde{a}(^3A_2)$–$\tilde{X}(^1A_1)$ transition is spin-forbidden but gains appreciable intensity ($f \sim 10^{-6}$) owing to the $\tilde{a}(^3A_2)$–$\tilde{B}(^1A_1)$ interaction contained in the spin-orbit operator. Due to rapid nonradiative decay to the ground state, the $\tilde{a}(^3A_1)$ state does not exhibit measurable phosphorescence in the gas phase. For this reason this state has thus far been studied only by absorption spectroscopy. Our current understanding of its spectroscopy is mainly due to the room temperature work of Moule and Subramanian (12, 13), and Clouthier and Moule (14). Both studies are consistent with each other: the origin is placed at 17 491.9 cm^{-1}, the C—S bond length elongates from its ground state value by about 0.1 Å, the equilibrium out-of-plane bending angle is 32° and the inversion barrier height is 726 cm^{-1}. Only the antisymmetric Cl—C—Cl stretching mode (ν_5) was found to be inactive in the $\tilde{a}(^3A_2)$–$\tilde{X}(^1A_1)$ spectrum. The present work offers two advantages over the previous ones. First, due to supersonic cooling, all hot bands are eliminated so that assignment ambiguity is minimized. Second, the experimental scheme used here is much more sensitive and selective than prior ones so that vibronic features not observed before can be detected, thus providing greater insight into the $\tilde{a}(^3A_1)$ state.

The $\tilde{A}(^1A_2)$–$\tilde{X}(^1A_1)$ system is electronically forbidden but gains intensity through either magnetic dipole-induced interactions or vibronic mixings. The $\tilde{A}(^1A_2)$ state is very well-characterized spectroscopically (14, 15). Since this state is used only as an intermediate in the present study a detailed review of our current understanding of it will be omitted. The reader can refer to recent reviews. It suffices to know here that the extensive vibronic analyses of Brand *et al.* (15) together with the few minor reassignments of Clouthier and Moule (14) have been used to select the energies and symmetries of the intermediate levels in our OODR scheme. We consider the latter two works to be essentially accurate.

The second excited singlet state is of A_1 symmetry, and arises from the promotion of a $4b_1$ electron to the $5b_1$ MO. The $\tilde{B}(^1A_1) \leftarrow \tilde{X}(^1A_1)$ transition is therefore $\pi^* \leftarrow \pi$ in character, and results in lowering the C—S bond order from 2 to 1 and lengthening the equilibrium C—S bond length by about 0.5 Å. As a result, the $\tilde{B}$—$\tilde{X}$ band system is broad and the 0_0^0 band very weak with an estimated Franck–Condon factor of the order of 10^{-5}–10^{-6}. To compound the problem, the minimum in the $\tilde{B}(^1A_1)$ state potential is very shallow so that progressions can only be followed up to a few quanta.

Several attempts have been made to elucidate the electronic structure of the $\tilde{B}(^1A_1)$ state. The first vibronic analyses were reported by Duchesne (16) and Burnelle (17) in the late fifties. They assigned the absorption bands as being due to two distinct $\sigma^* \leftarrow n$ transitions; one located in the C—S group, the other in the C—Cl_2 group. The origin of the first system was located at 33 380 ± 468 cm^{-1} while the second was located at 36 045 cm^{-1}. Some 15 years later, Farnworth and King (18), on the basis of a medium resolution absorption spectrum showed that this interpretation was erroneous and correctly reinterpreted the spectrum in term of a $\pi^* \leftarrow \pi$, $^1A_1 \leftarrow \tilde{X}(^1A_1)$ transition. Their analysis indicated that the molecule is non-planar in the upper state with an out-of-plane angle of 20° and an inversion barrier of 126 cm^{-1}. The origin band was located at 36 007 cm^{-1}. Four years later, Oka et al. (19) from fluorescence quantum yield measurements and quenching effects showed that the origin band must lie to the red of 36 007 cm^{-1} and proposed the band at 35 112 cm^{-1} as the origin of the $\tilde{B}$–$\tilde{X}$ system. The self-quenching cross section, σ^2, for the vibronic levels lying near 35 000 cm^{-1} was determined to be of the order of 95 $Å^2$. In 1980, Judge and Moule (20) photographed the $\tilde{B}$–$\tilde{X}$ system at high enough resolution to resolve the splittings between the chlorine (35,35) and (35,37) isotopes of Cl_2CS. From these splittings, progressions in ν_1' (C—S stretch) and ν_4' and ν_4'' (out-of-plane bend) were assigned and the origin was moved again further to the red at 34 277 cm^{-1}. Their analysis was shown to be consistent with double minimum potentials along both the C—S stretching and out-of-plane bending coordinates. The inversion barrier heights along ν_1 and ν_4 were estimated to be 4855 and 729 cm^{-1}, respectively. Unfortunately, their analysis proved difficult as only 30% of the observed bands were assigned. More recently, Dixon and Western (21) attempted to locate the $\tilde{B}$–$\tilde{X}$ origin band unequivocally by using $\tilde{A}(^1A_2)$ as an intermediate state in an optical–optical double resonance scheme. A point that will be of great importance later is that their experiment was performed using a static cell filled with 0.5 Torr of Cl_2CS. By carefully selecting the vibronic levels of the $\tilde{A}(^1A_2)$ state the symmetries of the $\tilde{B}$ state levels were unequivocally determined. The lowest energy band of a_1 symmetry was observed at 33 991 cm^{-1} and this was proposed by Dixon and Western as the (new) origin band for the $\tilde{B}$–$\tilde{X}$ system. Progressions in ν_1, ν_2, ν_3, and ν_6 could be built on that origin but none of the derived vibrational frequencies were found to be in agreement with those proposed by Judge and Moule. A point that is particularly troubling is that Dixon and Western proposed that the out-of-plane bending mode is inactive in the OODR spectrum while Judge and Moule argued the contrary from the $\tilde{B}$–$\tilde{X}$ absorption spectrum. The disagreement is severe and has been causing great confusion among spectroscopists. This prompted Ludwiczak et al.

(22) to investigate the $\tilde{B}$–$\tilde{X}$ band system using a jet-cooled expansion so that the problem of hot bands could be eliminated, or, at least reduced to a minimum. Similar to Judge and Moule, they used the isotope effect as an aid to assign the spectrum. Their work showed unequivocally that the lowest energy cold band lies at 34 277 cm^{-1}, and since the isotope splitting within this band is small and negative, and that progressions could be built on it, they assigned the band as the origin band of the $\tilde{B}$–$\tilde{X}$ system in agreement with Judge and Moule. Ludwiczak et al. assign most of the observed bands in term of ν_1, ν_2, and ν_4, either alone or in combination. Several of the assignments are the same as those reported by Judge and Moule. The onset of predissociation was placed at 35 277 ± 50 cm^{-1} i.e. 1450 ± 50 cm^{-1} above the presumed zero point level in the $\tilde{B}$ state. Thus, the work of Ludwiczak et al. confirms that a major disagreement between the one-photon and sequential two-photon studies remains. In order to reconcile these studies Ludwiczak et al. suggested that the OODR study of Dixon and Western may have accessed an excited state other than $\tilde{B}(^1A_1)$. On the basis of the recent large scale MCD-CI calculations of Hachey et al. (8) on H_2CS, they further suggested that the $^1A_1$ state arising from the $\ldots\pi^2n^0\pi^{*2}$ configuration could be a potential candidate. This state is expected to have a long radiative lifetime, and under the experimental conditions used by Dixon and Western any molecules promoted to it may be collisionally transferred to the luminescent $\tilde{B}(^1A_1)$ state. This is a very interesting suggestion which warrants further investigation. The present OODR study has been carried out in a molecular beam under collision-free conditions so that both collision-induced phenomena and problem due to hot band absorption are eliminated.

III. Experimental procedure

The apparatus for producing a jet-cooled molecular beam is of standard design. A schematic diagram is shown in Fig. 1. The expansion chamber was a stainless steel high vacuum cube type cell mounted on an Edwards, model 250/2000, diffusion stack backed with a Varian, model SD 700, mechanical pump. The static pressure in the chamber was of the order of 1–2 × 10^{-7} Torr. A piezoelectric pulsed molecular beam valve constructed from the design of Proch and Trickl (23), was used to expand helium doped with about 6% thiophosgene (Aldrich, 97%). The sample was prepared as follows: the thiophosgene (10 mL) was placed in a 150 m stainless steel reservoir fitted with a dip-stick inlet and an outlet port located at the top of the reservoir, helium made to flow through the reservoir from the dip-stick inlet to the outlet in the direction of the valve, thus ensuring that the helium flow entrains a constant amount of thiophosgene to the nozzle. The backing pressure was 1 atm, and the nozzle orifice was 0.5 mm in diameter which, as shown in Fig. 2, was sufficient to eliminate most of the hot bands in the $\tilde{A}(^1A_2)$–$\tilde{X}(^1A_1)$ spectrum. The very few hot bands which remain are very weak. No band was detected to the red of the 4_0^1 band. This great cooling at rather mild expansion conditions is attributed to the high pulse intensity of the piezoelectric valve.

The pump laser was a Lumonics YM 1000 YAG operated at 10 Hz and tuned to its third harmonic (355 nm). The 350 mJ output was split into two equiergic beams in order to pump two dye lasers; a Lumonics HD 500, and a Lumonics HD 300. The former was used to pump thiophosgene from the ground state to either the $\tilde{A}(^1A_2)$ or the $\tilde{a}(^3A_2)$ state using either C 540 A or R 590 dye. The HD 300 dye laser was used to pump excited

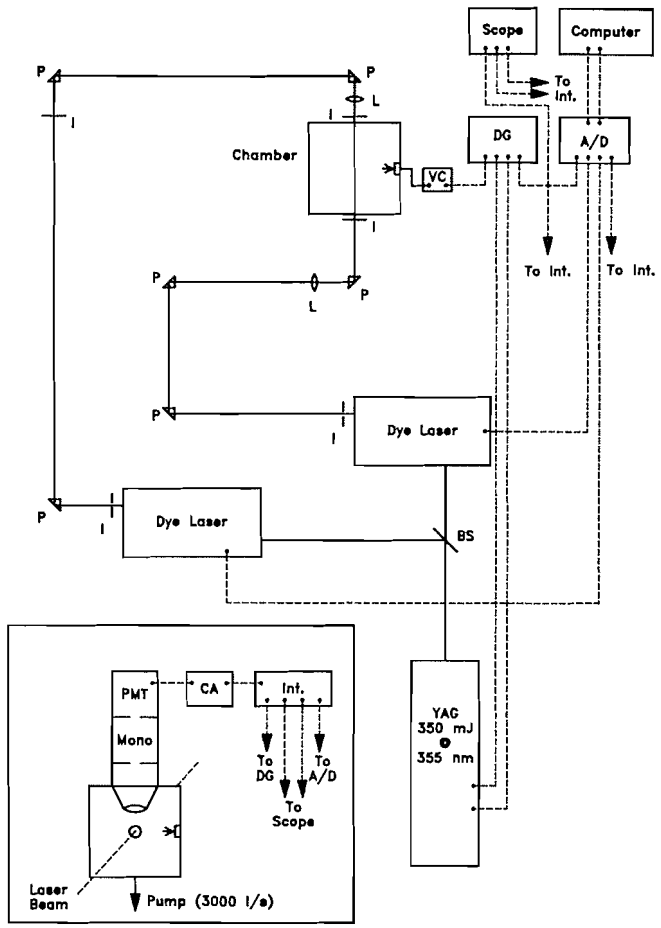

FIG. 1. Schematic diagram of the experimental arrangement. P, prism; I, iris; L, lens; BS, beam splitter; VC, valve controller; DG, delay generator; CA, current amplifier; Int, integrator.

thiophosgene from either $\tilde{A}(^1A_2)$ or $\tilde{a}(^3A_2)$ to the $\tilde{B}(^1A_1)$ state by using the R590, KR620, and DCM dyes. The two laser beams were made to counter-propagate, and overlap spatially and temporally in the center of the chamber. The pump and probe laser beams were focused in the chamber using a 25 cm and a 50 cm focal length lenses, respectively. The various delays were synchronized using a Stanford Research System, model DG 535 digital delay/pulse generator.

Fluorescence from thiophosgene was collected at right angles from the expansion and excitation axes by a biconvex, f/0.5, 5 cm focal length lens, was imaged at the slits of a 20 cm, Bausch and Lomb monochromator equipped with a 1200 lines/mm grating, and was viewed by a red sensitive RCA C31034 photomultiplier. The signal was sent to a Keithley, model 427 current amplifier, then to a home-built sample and hold integrator, and finally to the computer which also drives the dye lasers.

Laser wavelength calibration was effected using a Candela LS-1 laser spectrometer whose accuracy is specified to be 0.01 nm (approximatively 0.5 cm^{-1} at 500 nm). The calibration was often double-checked using neon atomic lines.

IV. Results and analysis

(A) Study of the $\tilde{B}(^1A_1)$ *state*

Two double resonance schemes have been used to probe the $\tilde{B}(^1A_1)$ state and these are shown in Fig. 3 as Schemes 1 and

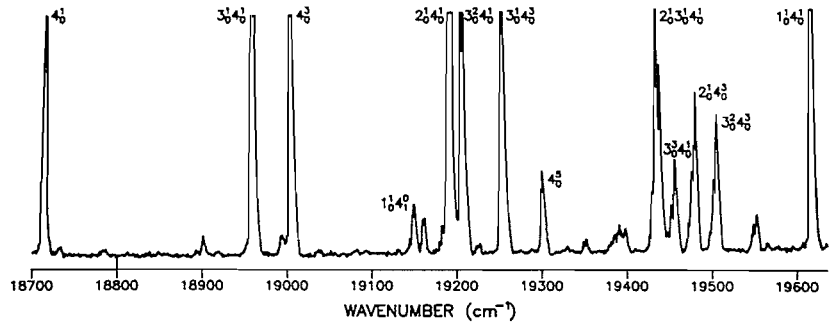

FIG. 2. Jet-cooled fluorescence excitation spectrum of the $\tilde{A}(^1A_2)$–$\tilde{X}(^1A_1)$ system of thiophosgene. The vertical axis is the intensity in arbitrary units.

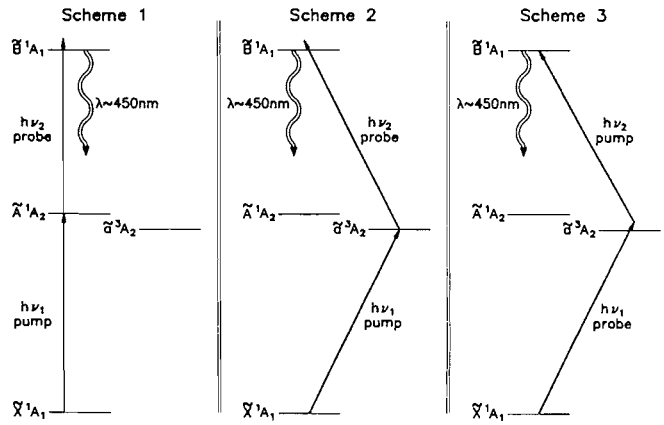

FIG. 3. Energy level diagrams showing the optical–optical double resonance schemes used in this work.

2. In Scheme 1, the molecules are PUMPed from the ground state to a specific vibronic level of the $\tilde{A}(^1A_2)$ state, and the PROBE laser is scanned so as to excite fluorescence from the $\tilde{B}(^1A_1)$ state. The vibronic levels of the $\tilde{A}(^1A_2)$ state that have been used are 4^1, 4^3, 4^5, 1^14^1, 3^14^1, 1^1, and 3^2. The first five of these are of $A_2 \otimes b_1 = b_2$ total vibronic symmetry while the last two are of $A_2 \otimes a_1 = a_2$ total symmetry. In Scheme 2, the molecules are PUMPed from the ground state to either the vibrationless or the 2^13^1 level of the $\tilde{a}(^3A_2)$ state, and the PROBE laser is scanned so as to excite fluorescence from the $\tilde{B}(^1A_1)$ state. In both schemes, the fluorescence is viewed at 450 nm which corresponds to the approximate maximum of the $\tilde{B} \rightarrow \tilde{X}$ emission.

Figures 4*a* and 4*b* show composite OODR spectra obtained by joining 100 cm^{-1} segments and using the 2^13^1 (Fig. 4*a*) and the vibrationless (Fig. 4*b*) levels of $\tilde{a}(^3A_2)$ as intermediate states. Figures 5, 6*a*, and 6*b* show composite OODR spectra obtained using the 1^1, and the 4^1 (Fig. 6*a*) and 1^14^1 (Fig. 6*b*) levels of the $\tilde{A}(^1A_2)$ state as intermediate states, respectively. In addition to the region covered by the latter spectra (Figs. 6*a* and *b*), the 33 580 – 33 945 cm^{-1} region was also investigated but no band was observed even when using the highest sensitivity available. It is clear from these spectra that the first vibronic band occurs at 34 277 cm^{-1} (Figs. 4 and 6). This band must therefore be connected to the vibrationless level of the $\tilde{B}$ state. Thus, we assign the vibronic level at 34 277 cm^{-1} as the vibrationless level of the $\tilde{B}$ state, in agreement with Judge and Moule, and Ludwiczak et al.

The band next highest in energy lies +213 cm^{-1} (34 490 cm^{-1}) from the origin. It is observed from the 4^1 and 1^1 levels of the $\tilde{A}$ state but is not observed from the vibrationless or the 2^13^1 level of the $\tilde{a}$ state. This wavenumber must be a fundamental and we assign it here as the wavenumber of the Cl—C—Cl bending mode (ν_3). In the ground state, $\nu_3 = 289$ cm^{-1} so that the $\tilde{B}/\tilde{X}$ ratio is 0.737 for this mode. In F_2CS (24) and ClFCS (25), the $\tilde{B}/\tilde{X}$ ratios are 0.760 and 0.728, respectively. The close correspondence makes the present assignment unequivocal. This band was also observed by Dixon and Western who assigned the upper state level as 2^13^1. Although this assignment is erroneous because of their mislocation of the origin, they correctly determined ν_3 to be 213 cm^{-1}.

Within the constraint of the C_{2v} point group, the 3^1 level of the $\tilde{B}$ state cannot be reached from the 1^1 level of the $\tilde{A}$ state but can from the 4^1 level. However, there is one means by which the band at 34 492 cm^{-1} can be observed from the 1^1 level of the $\tilde{A}$ state. If the separation between the $v = 0$ and $v = 1$ level of the out-of-plane bending mode (ν_4) in the $\tilde{B}$ state is very small (<0.5 cm^{-1}), then the separation between the 3^1 and 3^14^1 levels would be smaller than the experimental resolution. Thus, the level at 34 492 can also be assigned as 3^14^1. This assignment would be in agreement with the work of Judge and Moule, and Ludwiczak et al. who report a 0–1 separation of 0.11 cm^{-1} in mode 4 of the $\tilde{B}$ state.

The next highest wavenumber band lies at 34 525 cm^{-1}, +248 cm^{-1} from the origin. It is observed from the 4^1 and 1^1 levels of the $\tilde{A}$ state, and also from the 2^13^1 level of the $\tilde{a}$ state. Again, this separation must be a fundamental. We assign it here as the wavenumber of the Cl—C—Cl rocking mode, ν_6. In the ground state, $\nu_6 = 305$ cm^{-1}, so that the $\tilde{B}/\tilde{X}$ ratio is 0.813. This mode has not been reported to be active in F_2CS (24) and ClFCS (25), and comparisons with Cl_2CS are therefore not possible. A progression of up to 3 quanta can be found in the $\tilde{B}$–$\tilde{A}(4^1$ or $1^14^1)$–$\tilde{X}$ spectrum. Combination bands involving ν_3 and ν_6 can readily be found in the $\tilde{B}$–$\tilde{a}$–$\tilde{X}$ and $\tilde{B}$–$\tilde{A}(4^1$ or $1^14^1)$–$\tilde{X}$ spectra. The 34 525 cm^{-1} band was also observed by Dixon and Western who assigned the upper state level as 2^16^1. Again, this assignment is erroneous, and the 248 cm^{-1} interval in their spectrum has been incorrectly associated with ν_2.

The next band in the spectrum lies +341 cm^{-1} from the origin at 34 615 cm^{-1}. It is observed via the vibrationless or the 2^13^1 level of the $\tilde{a}$ state and also from the 4^1 (or 1^14^1) level of the $\tilde{A}$ state. This band was also observed by Ludwiczak et al. who assigned it as 4_0^2. This band was not observed directly by Judge and Moule but they did deduce a 341 cm^{-1} interval from combination differences which they associated with $2\nu_4$.

We agree with this assignment. This band was also observed by Dixon and Western who erroneously assigned the upper state level as $1^1 6^1$. The 341 cm^{-1} interval was established but was incorrectly associated with ν_1, the C—S stretching mode. Combination bands involving either ν_3 and ν_6 or both are readily found in the spectra.

The band at 34 747 cm^{-1} lies +470 cm^{-1} from the origin. It is observed only from the 1^1 level of the $\tilde{A}$ state. This band acts as a sub-origin for *all* the bands lying to the blue of it. We associate the 470 cm^{-1} interval with ν_2, the symmetric Cl—C—Cl stretching mode. In the ground state, its wavenumber is 505 cm^{-1}, so that the $\tilde{B}/\tilde{X}$ ratio is 0.930. This ratio compares very well with the corresponding ratios in F_2CS ($\tilde{B}/\tilde{X}$ = 0.926) (23) and ClFCS ($\tilde{B}/\tilde{X}$ = 0.964) (25). The band was not reported in the one-photon $\tilde{B}$–$\tilde{X}$ studies but was observed in the previous OODR study. However, Dixon and Western incorrectly assigned this $\tilde{B}$ state level as $2^1 3^1 6^1$ and they did not associate the 470 cm^{-1} interval with a fundamental.

At this point 70% of the observed bands have been assigned. The next lowest lying wavenumber band that has not yet been assigned lies +505 cm^{-1} (34 782 cm^{-1}) from the origin. It is observed only from the 4^1 level of the $\tilde{A}$ state. The band was observed by Judge and Moule, and Ludwiczak et al. in their one-photon $\tilde{B}$–$\tilde{X}$ studies and was assigned as 1^1_0. We agree with this assignment. Mode 1 is the C—S stretch. Its wavenumber in the $\tilde{X}$ state is 1139 cm^{-1}, so that the $\tilde{B}/\tilde{X}$ ratio is 0.443. This ratio compares very well with the corresponding one in ClFCS ($\tilde{B}/\tilde{X}$ = 0.450). Such a dramatic drop in the C—S wavenumber is expected because the bond order, which is nominally 2 in the ground state drops to 1 in the $\tilde{B}$ state. In the $\tilde{A}$ state, the bond order is nominally 1.5 and the C—S wavenumber 907 cm^{-1}. This band was also observed in the OODR study of Dixon and Western. However, they incorrectly assigned the $\tilde{B}$ state level as $3^1 6^2$ or $1^1 2^1 3^1$, and did not associate the 505 cm^{-1} interval with a fundamental.

Combination bands involving 1^1 with ν_2, ν_3, 4_2 and ν_6 are readily found in the spectra. At this point, only two bands remain to be assigned, and these lie +627 (34 904 cm^{-1}) and +828 cm^{-1} (35 103 cm^{-1}) from the origin. Both of them are observed from the 4^1 or $1^1 4^1$ level of the $\tilde{A}$ state. The former is also observed via the $2^1 3^1$ level of the $\tilde{a}$ state. The only plausible assignments for these intervals are 4^4 and 4^6. One may argue that the 627 cm^{-1} interval could be 5^1 but these would leave the 828 cm^{-1} band unassigned. Mode 5 is the antisymmetric Cl—C—Cl stretch. Its wavenumber in the ground state is 818 cm^{-1}. Assuming that the $\tilde{B}/\tilde{X}$ ratio is the same as for ν_6, then the wavenumber for ν_5 in the B state should be around 665 cm^{-1}.

All of the observed bands are now assigned. The assignments are given in Tables 1, 2, and 3. Table 4 summarizes the wavenumbers of the fundamentals and compares them with the corresponding ones in the $\tilde{X}$ and $\tilde{A}$ states.

(B) Study of the $\tilde{a}(^3A_2)$ *state*

The double resonance scheme that has been used to probe the $\tilde{a}(^3A_2)$ state is shown as Scheme 3 in Fig. 3. In this scheme the $\tilde{a}$–$\tilde{X}$ system is probed, and when absorption occurs the molecules are pumped to the vibrationless level of the $\tilde{B}(^1A_1)$ state. The absorption is detected by the occurrence of a fluorescence signal from the $\tilde{B}(^1A_1)$ $v = 0$ level. This requires that the total energy ($h\nu_{probe} + h\nu_{pump}$) be kept constant which is possible by scanning synchronously the probe laser up in energy and the pump laser down in energy. Since a signal is detected only when absorption from $\tilde{X}$ to $\tilde{a}$ occurs and since the $\tilde{B}$ state has the same symmetry as the $\tilde{X}$ state, the resulting fluorescence spectrum mimics the $\tilde{a}$–$\tilde{X}$ spectrum and would be similar to a phosphorescence excitation spectrum if the $\tilde{a}$ state were phosphorescent. The only difference would be in the relative intensity of individual vibronic bands because in the OODR experiment the $\tilde{B} \rightarrow \tilde{X}$ signal intensity is dictated by the product of the Franck–Condon factors $\tilde{a} \leftarrow \tilde{X}$ and $\tilde{B} \leftarrow \tilde{a}$, while in the one-photon $\tilde{a} \leftarrow \tilde{X}$ spectrum the intensity depends only on the $\tilde{a} \leftarrow \tilde{X}$ Franck–Condon overlap.

A portion of the spectrum is shown in Fig. 7. The wavenumber scale has a calibration error of +6 − 7 cm^{-1} compared with the work of Clouthier and Moule (14), and Moule and Subramaniam (12, 13). This spectrum is clear of hot bands from both the $\tilde{A}(^1A_2)$–$\tilde{X}(^1A_1)$ and $\tilde{a}(^3A_2)$–$\tilde{X}(^1A_1)$ systems. Rotating the laser field polarization by 90° produced no intensity change in the spectrum. The same wavenumber region has been re-

peated three times with no significant change in the relative intensities. Most bands clearly show resolved splittings due to the three chlorine isotopomers of thiophosgene. These splittings have been a useful aid in assigning the spectrum.

The $\tilde{a}(^3A_2)$–$\tilde{X}(^1A_1)$ system gains its intensity by intensity borrowing from the strong $\tilde{B}$–$\tilde{X}$ system. This borrowing arises because the $\tilde{a}(^3A_2)$ state mixes with the $\tilde{B}(^1A_1)$ state through the spin-orbit operator. The selection rules should therefore resemble those for the $\tilde{B}(^1A_1)$–$\tilde{X}(^1A_1)$ system, namely that the C_{2v} point group applies and that the transition moment is z-polarized. For transitions originating from the vibrationless level of the ground state the vibrational symmetry of the $\tilde{a}(^3A_2)$ state must be a_1.

The five lowest wavenumber bands of the spectrum were also observed by Moule and Subramaniam, and Clouthier and Moule who assigned them as the 0_0^0, 3_0^1, 4_0^2, 2_0^1, 3_0^2 bands, respectively. We agree with these assignments.

The next two bands lie 534 cm^{-1} (18 033 cm^{-1}) and 560 cm^{-1} (18 059 cm^{-1}) from the origin, and have similar isotope splittings (see Table 5). The former was assigned as 4_0^4 while the latter was not observed in the previous two studies. The reason why this band was not observed before is not clear but it may be due to the fact that the 4_2^3 band (18 066 cm^{-1}) of the $\tilde{A}$–$\tilde{X}$ system overlaps this region. This hot band should be prominent under the experimental conditions used in the previous studies. Here, the substantial vibrational cooling provided by supersonic expansion makes the population of the 4_2 level too small to produce a measurable signal from the 4_2^3 transition. Furthermore, the isotope splittings clearly indicate that this is not the band observed here. There is only one plausible set of assignments for these bands; 4_0^4, and 6_0^2. Specific individual assignments are more difficult to make but on the basis on Franck–Condon envelope, we assign the band at 18 033 cm^{-1} as the 6_0^2 band, and the band at 18 059 cm^{-1} as the 4_0^4 band. This makes $\nu_6 = 267$ cm^{-1}, in reasonable agreement with expectation based upon the value of ν_6' for the $\tilde{B}(^1A_1)$ state (see Table 4).

The next band to be assigned lies 704 cm^{-1} (18 203 cm^{-1}) from the origin. It is the strongest band of the entire spectrum. It was assigned as the 4_0^6 band in the previous two studies but judged from its intensity, this assignment is difficult to sustain. The relative intensities of the 4_0^0, 4_0^2, and 4_0^4 bands are approximately 1, 2, 1, respectively. On that basis, the relative intensity of the 4_0^6 band should be <1. The relative intensity of the 18 203 cm^{-1} band is approximately 2.5. We prefer to assign this band as $2_0^13_0^1$ (although the isotope splitting appears slightly too small) and to leave the 4_0^6 assignment to the band at 18 240 cm^{-1}. The latter shows the expected intensity and isotope splitting. However, it partly overlaps with the 3_0^3 band and this may be the reason why it could not be extracted in the previous studies.

Based upon the Franck–Condon envelope of the 4_0^{2n} ($n = 0$, 1, 2, 3) progression, the 4_0^8 band should be observable. We thus tentatively assign the weak feature at 18 430 cm^{-1} as the 4_0^8 band.

Moule and Subramaniam assigned a feature lying at 18 749 cm^{-1} as the 1_0^1 band. Subsequently, Clouthier and Moule, using the powerful technique of magnetic rotation spectroscopy, showed that this assignment was in error, and that the 18 749 cm^{-1} band probably does not belong to the $\tilde{a}(^3A_2)$–$\tilde{X}(^1A_1)$ system. Indeed, in our study there is no band at this wavenumber (it should have appeared at 18 756 cm^{-1}). Clouthier and Moule observed no band that could be due to the activity of mode 1 alone but found an interval of ca. 923 cm^{-1} from combination bands that they associated with ν_1'. In our spectrum, there is a band of reasonable intensity that lies 918 cm^{-1} from the origin that has a small (perhaps negative) isotope shift and that has not otherwise been assigned. This band is therefore assigned as the 1_0^1 band.

The remaining bands can readily be assigned as combination bands. All the assignments are given in Table 5 along with the assignments from the previous two studies. The isotope shifts are accurate to about ± 0.5 cm^{-1}.

V. Discussion

There have been three recent attempts to rationalize the electronic structure of the $\tilde{B}(^1A_1)$ state. These are the 1980 $\tilde{B}$–$\tilde{X}$ absorption study of Judge and Moule, the 1986 OODR study of Dixon and Western, and the 1991 $\tilde{B}$–$\tilde{X}$ laser-induced fluorescence study of Ludwiczak et al. In each case the results were interpreted differently. The present work adds another in-

terpretation. It is clear that all these works must be reconciled if one wishes to consider the analysis satisfactory.

Comparison and reconciliation with the work of Dixon and Western (21) — Speculations about the $\tilde{B}(^1A_1)$ state potential

A comparison of our results with those of Dixon and Western shows that only 11 of the 23 bands observed by them are observed in the present study. These bands lie at 33 991, 34 203, 34 240, 34 331, 34 414, 34 452, 34 542, 34 577, 34 618, 34 663, 35 038, 35 122 cm^{-1}. It is clear that if we could find an explanation for these 12 "extra" bands, then the two studies would be reconciled. As mentioned before, the only conceptual difference between the two studies is that one has been performed in a cell at static pressure of 500 mTorr (Dixon and Western's) while the other (the present study) has been performed in a free-jet molecular beam apparatus at pressure below 5×10^{-5} Torr, i.e. in a collision-free environment. We therefore hypothesized that these 12 "extra" bands might be associated with transitions which (*1*) originated from excited vibrational levels of the ground state, or (*2*) resulted in some way from a "collision-assisted" process.

We have verified experimentally these hypotheses by using the molecular beam chamber as a static cell (simply by closing the gate valve to the diffusion pump) and by recording OODR spectra at various pressures in the regions of interest. Figure 8 shows a typical result for the 34 184 – 34 255 cm^{-1} region. It is clear that the bands near 34 200 and 34 230 cm^{-1} rapidly grow with increasing pressure. This is also the case for the band at 33 991 cm^{-1}. We have not performed the experiment for the other "extra" bands but it seems plausible that they also arise from (*1*) vibrationally excited molecules, or (*2*) molecules which have undergone collisions. Thus, excluding these transitions the work of Dixon and Western is entirely consistent with the present study. The origin is now unequivocally and firmly located at 34 277 cm^{-1} in agreement with the other work of both Judge and Moule, and Ludwiczak et al. We shall now examine these two explanations separately.

The first is the "hot band hypothesis". If a hot band underlies the cold band which is nominally being pumped, a second level lying higher in energy will be populated in addition to the preselected intermediate level, and this will produce an OODR signal at an apparent wavenumber below the true origin. In the present case, all of the 12 extra bands lie 286–289 cm^{-1} lower in energy than OODR bands observed under collision-free conditions. This interval corresponds approximately to the Cl—C—Cl bending wavenumber (ν_3) in the ground state. It is very tempting at this point to conclude that these 12 extra bands are the result of hot band overlap, but this would require that all seven of the $\tilde{A}(^1A_2)$–$\tilde{X}(^1A_1)$ vibronic bands selected by Dixon and Western are overlapped by hot bands involving ν_3''. Such coincidences are unlikely although near-coincidences exist for several of these bands. The closest agreements are between the 4_0^1 (18 716 cm^{-1}) and the $3_1^0 4_0^3$ (18 719 cm^{-1}) bands which lie 3 cm^{-1} apart, and the $4_0^1 6_1^1$ band (18 602 cm^{-1}) of the $\tilde{A}$–$\tilde{X}$ system and the $1_0^1 2_0^1 3_1^0$ band (18 600.5 cm^{-1}) of the $\tilde{a}$–$\tilde{X}$ system which lie only 1.5 cm^{-1} apart (using Clouthier and Moule's assignments (14)). The problem here is that it is not clear how much of the rotational structure of the underlying hot bands overlaps with the "targeted" bands considering that the laser linewidth in Dixon and Western's experiment was about 0.3 cm^{-1}. However, it seems clear that in these two cases

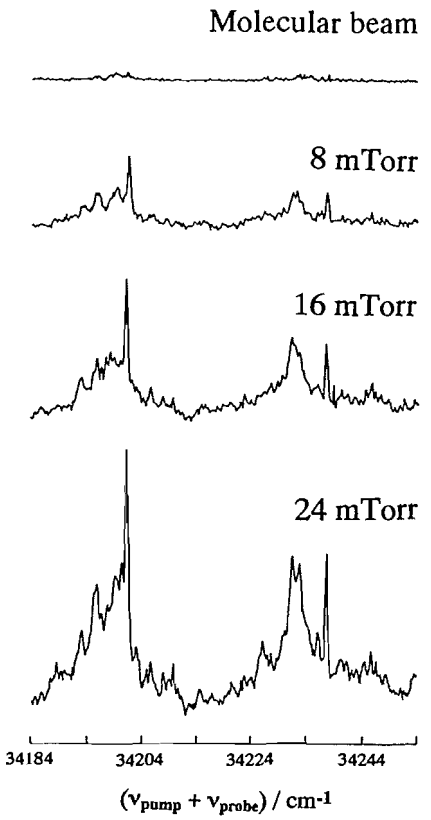

FIG. 8. Effect of pressure on the $\tilde{B}(^1A_1,v')$–$\tilde{A}(^1A_2,4^1)$ –$\tilde{X}(^1A_1,0_0)$ optical–optical double resonance spectrum of thiophosgene in the 34 184 – 34 254 cm^{-1} region. The vertical axis is the intensity in arbitrary units.

overlapping might be possible. The situation is less clear for the other 5 bands used by Dixon and Western. These bands are the $3_0^1 4_1^2$, and presumably the 4_1^0, 6_0^1, $3_0^1 4_1^0$, and $3_0^1 4_0^1$ bands (using Clouthier and Moule's assignments). Here potential hot bands should lie no closer than ±5–6 cm^{-1}. The problem here is that none of these bands have ever been observed in previous studies. For instance, the $2_0^1 3_1^0 4_0^1$ band should lie at +5 cm^{-1} from the 6_0^1 band but no such band has ever been reported despite the fact that the room temperature absorption spectrum is sparse in this region. In summary, some but not all of the extra bands might result from hot bands involving ν_3''.

The second explanation is the "dark state hypothesis" and the arguments run as follows. The experimental conditions and simple considerations clearly indicate that collision-assisted transitions occur once the molecules are excited in the final state i.e. after the absorption of the second photon. Collisional interactions in the intermediate state do not play an important role because the two laser pulses overlap both spatially and temporally. Furthermore, it was noticed by Dixon and Western that identical spectra were obtained when the probe laser was temporally overlapped with the pump beam and when it was delayed by 24 ns.

For collisions to occur, the excited molecules must be in real (as opposed to virtual) vibrational levels (prior to collisions). Regardless of whether the collisional interactions lead to vibrational activation, vibrational relaxation, direct passage through a barrier, or modification of the barrier, the laser wavenumbers at which the "collision-assisted" transitions are observed indicate the presence of real vibronic levels. Thus, there are non-fluorescent vibronic levels lying below the vibrationless

For personal use only.

level of the fluorescent $\tilde{B}(^1A_1)$ state that can be easily populated from the $\tilde{A}(^1A_2)$ state. The presence of a "dark" state (DS) in the 295 nm region has already been established recently by Maciejewski et al. (26) from absorption measurements on Cl_2CS in perfluoroalkane solution at room temperature. The DS–$\tilde{X}$ oscillator strength has been estimated to be about 5×10^{-5} and the quantum yield of emission, $\phi_e \leq 10^{-8}$ under these conditions.

If the "dark" state seen by Maciejewski et al. is the one seen in the OODR studies then this state can be populated from both the $\tilde{X}(^1A_1)$ and $\tilde{A}(^1A_2)$ states, although our observations suggest that the DS—$\tilde{A}(^1A_2)$ oscillator strength is much larger than DS—$\tilde{X}$. This new piece of evidence supports the suggestion put forward by Maciejewski et al. that the identity of this "dark" state is of $^1A_1$ symmetry and is described in large measure by the $(\pi^2_{CS}\ n^0_S\ \pi^{*2}_{CS})$ configuration. If this suggestion is true, there should be two diabatic potential wells of $^1A_1$ symmetry along the C—S coordinate; one associated with the $(\pi^1_{CS}\ n^2_S\ \pi^{*1}_{CS})$ configuration whose minimum is at about 2.1 Å, and the other associated with the $(\pi^2_{CS}\ n^0_S\ \pi^{*2}_{CS})$ configuration whose minimum lies at somewhat larger internuclear distance. We now suggest that due to an avoided crossing, the resulting adiabatic potential of lower energy is described by an asymmetric double-minimum whose lower minimum corresponds to the minimum of the diabatic dark state, and whose higher minimum corresponds to the minimum of the diabatic fluorescent $\tilde{B}(^1A_1)$ state.

The existence of such an asymmetric double-minimum potential along the C—S coordinate would yield results consistent with the combined spectroscopic observations if the barrier separating the fluorescent from the dark minimum is of the appropriate height. Particularly, it would provide an explanation for the collision-assisted fluorescence. Consider a molecule pumped in a vibronic level lying in the "dark" minimum. If this level lies somewhat below the barrier but above the vibrationless level of the fluorescent minimum (here the $\tilde{B}(^1A_1)$ state) then collisions can transfer molecules to the fluorescent levels and consequently can make their detection possible by laser induced fluorescence. Obviously, in the absence of collision no transfer occurs and no fluorescence is detected as rapid non-radiative decay through other channels takes place.

We suggest that such a double-minimum potential along the C—S coordinate would explain the photophysical behavior of thiocarbonyls pumped to the $\tilde{B}(^1A_1)$ state. This is because the photophysical behavior of the $\tilde{B}(^1A_1)$ state now depends on the barrier height separating the fluorescent from the "dark" minimum. For instance, if the barrier height is very low then pumping the molecule to the $\tilde{B}(^1A_1)$ state minimum will not lead to fluorescence because the molecule will rapidly "flow" to the "dark" minimum which lies lower in energy. This is probably the situation which prevails in F_2CS which does not fluoresce from the $\tilde{B}(^1A_1)$ state but which nevertheless exhibits a discrete $\tilde{B}$–$\tilde{X}$ absorption spectrum.

The idea of a double-minimum potential along the C—S coordinate is not new. Indeed, Judge and Moule in their analysis of the $\tilde{B}$–$\tilde{X}$ absorption spectrum observed the doubling of some bands which they associated with the activity of mode 1, the C—S stretching mode, in a double-minimum potential. They fitted the energy levels to a symmetric double-minimum function represented by a Gaussian-type barrier function superimposed on a quadratic potential function, and obtained a barrier height of 4855 cm^{-1}. Unfortunately, the finding of Judge and Moule could not be corroborated by Ludwiczak et al. as they could not observe the inversion doublings seen by Judge and Moule presumably on account of poorer resolution. However, the data of Judge and Moule appears unquestionable.

TABLE 6. Comparisons between assignments of the vibronic levels of the $\tilde{B}(^1A_1)$ state of thiophosgene

Wavenumber (cm^{-1})	Assignment		Isotope shift[a] [ν(35,35)–ν(35,37)]
	Ref. 22	This work	
34 275	0^0	0^0	−0.4
34 616	4^2	4^2	2.6
34 771	2^1	6^2	2.0
34 781	1^1	1^1	1.4
34 960	4^4	2^13^1	5.5
35 105	2^14^2	4^6	5.0
35 111	1^14^2	4^26^2	4.2
35 258	2^2	1^12^1	4.1
35 268	1^2	N.O.[b]	3.4
35 278	4^6	1^16^2	—
35 430	2^14^4	2^23^1	—
35 444	1^14^4	$2^13^16^2$	7.2
35 579	2^24^2	$2^14^26^2$	6.5

[a]The isotope shifts are those of Ludwiczak et al. (22).
[b]N.O. = not observed.

Such a high barrier to inversion appears to be at odds with the evidence presented herein, although the idea of a double-minimum along the C—S coordinate is now firmly established. This discrepancy may be due to two effects. Firstly, it is possible that the model used by Judge and Moule overestimates the barrier height by several thousands wavenumbers. This is because their model assumes a symmetric double-minimum potential while the true potential is an asymmetric one. Their model also assumes that the diabatic potentials are well approximated by quartic functions which is certainly not the case here both because the fluorescent minimum is known to be very shallow and also because the two states in question are likely to be perturbed by nearby states. It is clear that the whole problem of fitting the double-minimum potential must be reviewed but this is beyond the scope of this paper. Secondly, it is also possible that the barrier height be modified upon collisions since intermolecular interaction is known in general to affect the shapes of potential wells. In the present case the two diabatic potentials arise from different electron configurations and hence will be affected differently by the collisional interaction. It is not difficult to imagine how such a process would yield a smaller barrier.

Since the 12 "extra" bands seen by Dixon and Western correspond to transitions terminating in the "dark" potential, it is therefore possible to use them to determine the wavenumbers of some fundamentals. Using the band at 33 991 cm^{-1} as a sub-origin, the following intervals are found; 212, 249, 340 and 627 cm^{-1}. These are sufficient to reproduce all twelve of these "extra" bands. Identical intervals were found in our OODR spectra and were ascribed to the activities of mode, 3, 4 (4^2 = 340 cm^{-1} and 4^4 = 627 cm^{-1}), and 6. Thus, the wavenumbers of these modes are the same in the fluorescent $^1A_1(\pi^1_{CS}\ n^2_S\ \pi^{*1}_{CS})$ and the "dark" $^1A_1(\pi^2_{CS}\ n^0_S\ \pi^{*2}_{CS})$ states. This is consistent with the fact that the transition is localized on the C—S moiety and the fact that the C—S bond order is nominally the same in both states. It would be interesting to verify this theoretically through *ab initio* calculations.

TABLE 7. Observed and calculated energy levels of thiophosgene excited in the out-of-plane bending potential of the $\tilde{B}(^1A_1)$ state

Comparison with the work of Judge and Moule (20), and Ludwiczak et al. (22)

Having reconciled the two OODR studies, we now compare them with the one-photon $\tilde{B}$–$\tilde{X}$ studies of Judge and Moule, and Ludwiczak et al. It is clear that due to different selection rules, the number of features observed in the OODR studies is different from the number observed in the one-photon studies. However, with the exception of two which appear at 35 268 and 35 585 cm^{-1}, all cold bands that have been observed by Judge and Moule and Ludwiczak et al. in the 33 580 – 35 261 cm^{-1} region have also been observed in the present OODR study. The two features that have not been observed by OODR spectroscopy appear as the most intense features in the fluorescence excitation spectrum of Ludwiczak et al. These bands have been assigned by both groups as 1_0^2 (35 268 cm^{-1}) and $1_0^2 4_0^2$ (35 585 cm^{-1}) and we believe that these assignments are correct. Since the 1^1 and 4^2 levels are accessed in the OODR study, the only plausible reason for not accessing the 1^2 and $1^2 4^2$ levels is the poor Franck–Condon overlap with the 4^1 and $1^1 4^1$ levels of the $\tilde{A}(^1A_2)$ state. In the $\tilde{B}$–X system the Franck–Condon factors for the 1_0^2 and $1_0^2 4_0^2$ transitions are substantially larger because of the larger difference in the internuclear distances between the two states.

Among the 15 cold bands observed by Ludwiczak et al. in the 33 580 – 35 261 cm^{-1} region, only 5 (including the two bands not observed in the OODR experiment) share the same assignments as the corresponding bands in the OODR study. However, as shown in Table 6, most of the discrepancies are settled once the values of 470, 213, and 240 cm^{-1} for ν_2, ν_3, and ν_6, respectively, are introduced. The new assignments are entirely consistent with the selection rules for $\tilde{B}(^1A_1) \leftarrow \tilde{X}(^1A_1)$ transitions and are supported by the isotope splittings measured by Ludwiczak et al., with the exception of the band at 35 105 cm^{-1} which has an isotope splitting too small to support the 4^6 assignment proposed here. However, we maintain this assignment until the isotope splitting is corroborated by a new measurement.

Judge and Moule reported five cold bands in the wavenumber region covered by the present work. We agree with four of their assignments. Once the value of 248 cm^{-1} for ν_6 is introduced, complete agreement is obtained.

The double-minimum potential along the out-of-plane bending coordinate (ν_4) in the $\tilde{B}(^1A_1)$ state

It has been known for some time that upon occupation of the π^* orbital the molecule becomes bent. This behavior can be rationalized satisfactorily on the basis of Walsh's postulates, although vibronic couplings have been shown to play an important role. The out-of-plane angle and the barrier height to inversion can be derived by fitting a double-minimum function to the observed the energy levels. The present study places the 4^2, 4^4, and 4^6 levels at 341, 628, and 828 cm^{-1}, respectively. The energies of the 4^1, 4^3, and 4^5 levels could not be determined although it clearly appears that the 0–1 and 2–3 separations are very small; smaller than the experimental accuracy. However, the energies of the 4^1 and 4^3 levels can be determined from the data of Judge and Moule, and Ludwiczak et al. because they unambiguously determined the positions of the 4_1^1 and the 4_1^3 hot bands in their $\tilde{B}(^1A_1) \leftarrow \tilde{X}(^1A_1)$ spectra. Due to experimental inaccuracies, the energies of the 4^1 level is still not particularly well determined although it is clear from the work of Judge and Moule that it should be ≤ 0.15 cm^{-1}. The position of the 4^3 level is exclusively due to Ludwiczak et al. Two types of double-minimum functions have been fitted to these five energy levels and the results of the fits are presented in Table 7. One of these models is due to Laane (27) and consists of a quartic potential perturbed by a quadratic function while the other is due to Coon et al. (28) and consists of a quadratic potential superimposed by a Gaussian function. The details of these models can be found in the seminal papers of Laane (27), and Coon et al. (28).

The quadratic-Gaussian model appears to fit better than the quartic-quadratic one at $v \leq 3$ but the converse is observed for $v > 3$. In general both model give satisfactory agreement with experiment. The barrier height to inversion can be set at 845 ± 20 cm^{-1} while the out-of-plane angle is estimated to

about 25°. It is difficult to establish the accuracy of the latter because the necessary structural parameters of the $\tilde{B}(^1A_1)$ state are not known. In the present case, the C—Cl bond length and the S—C—Cl bond angle were assumed to be the same as the ground state values while the C—S bond length was set 0.5 Å longer than the ground state value. Should better structural parameters become available a new out-of-plane angle can be computed from the relation

$$\theta_{\text{out-of-plane}} = \frac{Q_{\text{minimum}}}{\mu^{1/2} r_{\text{C—S}}}$$

where $Q_{\text{minimum}} = 1.40 \times 10^{-20}$ g$^{1/2}$ cm, $r_{\text{C—S}}$ is the C—S bond length, and μ is the reduced mass; the latter being estimated from the following relation used by Coon et al. for H_2CO

$$\frac{1}{\mu} = \left(\frac{1}{M_S} + \frac{1}{M_C}\right) + \frac{2r_{\text{C—S}}}{M_C Z} + \left(\frac{1}{M_C} + \frac{1}{2M_{Cl}}\right)\frac{r_{\text{C—S}}^2}{Z^2}$$

where Z is the distance from the carbon atom to the line joining the two chlorine atoms.

The derived barrier height and out-of-plane angle may be compared to the $\tilde{a}(^3A_2)$ and $\tilde{A}(^1A_2)$ state values which are 726 cm^{-1} and 32°, and 620 cm^{-1} and 32°, respectively. The out-of-plane angle is therefore smaller in the $\tilde{B}(^1A_1)$ state than in the $\tilde{a}(^3A_2)$ and $\tilde{A}(^1A_2)$ states but the barrier to inversion is at least 220 cm^{-1} higher in the $\tilde{B}(^1A_1)$ state. This is not surprising since vibronic couplings are certainly more important in the $\tilde{B}(^1A_1)$ state than in the $\tilde{a}(^3A_2)$ and $\tilde{A}(^1A_2)$ states on account of the larger density of states in the neighborhood of the $\tilde{B}(^1A_1)$ state. This conclusion is borne out by the two-state calculations of Innes on H_2CO which show that the non-planarity is in large part attributable to vibronic couplings rather than solely to electronic effects (29).

The double-minimum potential along the out-of-plane bending coordinate (ν_4) in the $\tilde{a}(^3A_2)$ state

The barrier height to inversion and the out-of-plane angle in the $\tilde{a}(^3A_2)$ state were determined by Moule and Subramaniam by fitting a quadratic-Lorentzian potential to the ν_4' energy level structure established from their vibronic analysis of the $\tilde{a}(^3A_2) \leftarrow \tilde{X}(^1A_1)$ absorption spectrum. The present study performed with a novel OODR scheme challenges some of their assignments. In particular, the 4^4 and 4^6 levels have been placed at 560 and 741 cm^{-1} rather than 534 and 704 cm^{-1}, respectively. However, these changes have little effects on the barrier height and out-of-plane angle. In fact, it turns out that the new value for 4^6 enhances the quality of the fit done by Moule and Subramaniam, and consequently reaffirms the currently accepted structural parameters. However, the proposed new value for 4^4 diverges from the calculated by about 30 cm^{-1} while the divergence was only 5 cm^{-1} in the previous study. Nevertheless, we maintain our assignment because of the relative intensity of the 4_0^{2n} progression (*vide supra*).

Concerning the (ν_6) fundamental in the $\tilde{A}(^1A_2)$ state

An examination of Table 4 indicates that the vibrational frequencies of ν_1, ν_2, ν_3, and ν_4 in the $\tilde{a}(^3A_2)$ and $\tilde{A}(^1A_2)$ states are the same within 20 cm^{-1} but that the vibrational frequency of ν_6 differs by about 80 cm^{-1}. Furthermore, it is seen that $\nu_6(\tilde{a}(^3A_2))$ and $\nu_6(\tilde{B}(^1A_1))$ differ by only 18 cm^{-1}. This unexpected result makes the value of $\nu_6(\tilde{A}(^1A_2))$ dubious. It is clear from Table 4 that it should be of the order of 270 cm^{-1}. A careful examination of the jet-cooled $\tilde{A}(^1A_2) \leftarrow \tilde{X}(^1A_1)$ fluorescence excitation spectrum shown in Fig. 2 reveals the presence of a weak cold band near 18 995 cm^{-1}, just barely resolved from the strong 4_0^3 band which lies immediately to the blue. As this band is located close to the expected region we assign it as the 6_0^1 band and this makes $\nu_6 = 279$ cm^{-1}, in good agreement with expectation. It is unlikely that this band would have been observed in the previous studies because it nearly overlaps the 4_0^3 band.

VI. Conclusion

The $\tilde{B}(^1A_1)$ state of jet-cooled thiophosgene has been studied by optical–optical double resonance spectroscopy and all of the observed vibronic bands have been rationalized in terms of the activities of ν_1, ν_2, ν_3, ν_4, and ν_6. The discrepancies among the previous studies have been entirely reconciled. The $\tilde{B}(^1A_1)$ state is characterized by two double-minimum potentials; one along the C—S stretching coordinate and the other along the out-of-plane bending coordinate. The barrier to inversion along ν_4 and the out-of-plane angle have been determined to be 945 cm^{-1} and 25°, respectively. The double-minimum along ν_1 is particularly intriguing as one minimum leads to radiative decay while the other leads to rapid non-radiative decay. It is hoped that this study has opened the way to a greater understanding of the photophysics and photochemistry of thiophosgene and small thiocarbonyls in general. In particular, it would be rewarding to pursue this study by examining the details of the photophysics of thiophosgene excited in various part of the double-minimum surface along ν_1. Detailed photodissociation studies will also be very rewarding and are underway in our laboratory.

The $\tilde{a}(^3A_2)$ state has been probed by a novel and powerful optical–optical double resonance scheme which uses the fluorescent vibrationless level of the $\tilde{B}(^1A_1)$ state to monitor $\tilde{a}(^3A_2) \leftarrow \tilde{X}(^1A_1)$ absorption. A vibrational analysis has been performed and several reassignments have been proposed. These reassignments had little effect on the shape of the double-minimum potential along ν_4. The vibrational frequency of $\nu_6(\tilde{a}(^3A_2))$ has been determined for the first time. It is hoped that this novel OODR scheme will be used to probe non-fluorescent states by laser induced fluorescence or to determine the linkage between or parentage of states by using fluorescence or ionization techniques as means of detection.

Non-adiabatic photodissociation dynamics of BrCl

JIANYING CAO, HANS-PETER LOOCK, AND CHARLES X.W. QIAN[1]

Department of Chemistry, University of Victoria, P.O. Box 3055, Victoria, BC V8W 3P6, Canada

Received July 7, 1993

This paper is dedicated to Professor John C. Polanyi on the occasion of his 65th birthday

JIANYING CAO, HANS-PETER LOOCK, and CHARLES X.W. QIAN. Can. J. Chem. **72**, 758 (1994).

Nozzle-cooled BrCl was excited with tunable laser radiation at selected wavelengths between 389 and 500 nm. The chlorine atomic fragments in their $Cl^*(^2P_{1/2})$ and $Cl(^2P_{3/2})$ state were stated-selectively probed by resonance-enhanced multiphoton ionization. The branching ratio $(Cl^*/(Cl + Cl^*))$ was measured as a function of the excitation wavelength. The relative Cl^* yield reaches a maximum at around $\lambda_{phot} = 460$ nm. Decomposition of these branching ratios into Cl and Cl^* photofragment yield spectra provides insight into the BrCl *B*-state $^3\Pi(0^+)$ non-adiabatic dissociation dynamics. Our results suggest that the dissociation mechanism involves non-adiabatic transitions among 0^+ potential energy curves.

JIANYING CAO, HANS-PETER LOOCK et CHARLES X.W. QIAN. Can. J. Chem. **72**, 758 (1994).

On a excité du BrCl refroidi à l'aide d'un rayonnement laser adjustable à diverses longueurs d'onde allant de 389 à 500 nm. Faisant appel à une ionisation multiphotonique rehaussée par résonance, on a examiné sélectivement les divers états des fragments atomiques du chlore dans leurs états $Cl^*(^2P_{1/2})$ et $Cl(^2P_{3/2})$. On a mesuré le rapport de branchement $(Cl^*/(Cl + Cl^*))$ en fonction de la longueur d'onde de l'excitation. Le rendement relatif de Cl^* atteint un maximum à environ $\lambda_{phot} = 460$ nm. La décomposition de ces rapports de branchement en spectres de rendement des photofragments Cl et Cl^* fournit des données sur la dynamique de la dissociation non-adiabatique de l'état *B*, $^3\Pi(0^+)$, du BrCl. Nos résultats suggèrent que le mécanisme de dissociation implique des transitions non-adiabatiques parmi les courbes d'énergie potentielle 0^+.

[Traduit par la rédaction]

Introduction

When two or more potential energy surfaces (PES) are involved in photodissociation processes, non-adiabatic interactions among these surfaces can influence the dynamics significantly. In particular, if at least one of the photofragments has a non-vanishing angular momentum, non-adiabatic transitions are most likely to be observed. In this situation, more than one exit channel is readily accessible so that, even if the dissociation was initiated on a single PES, the non-adiabatic interactions are unavoidable during the fragmentation process (1).

A simple example of non-adiabatic transitions is given when only two potential energy curves with an avoided crossing are involved (see, for example, ref. 2). If the kinetic energy near the interaction region is small, the dissociation will proceed adiabatically, i.e., the molecule stays on the initially prepared adiabatic curve throughout the dissociation. For significantly higher kinetic energy, the dissociation can proceed diabatically and the molecule jumps to the other potential energy curve.

In a realistic molecular system, however, several potential curves are normally involved. It is important to study the non-adiabatic transitions among these curves to understand the underlying fragmentation dynamics. With adequate kinetic energy, several exit channels can participate in the dissociation process. Such a problem presents a challenge to both the experimentalist and the theoretician.

BrCl photodissociation provides a unique opportunity to study the non-adiabatic interactions. Since both the chlorine and the bromine fragments have two spin-orbit states, there are four possible exit channels near the dissociation limit. From the UV and near-UV absorption spectrum (3) it was concluded that at least two excited states are involved. It is believed that the $^1\Pi(1)$ and the $^3\Pi(0^+)$ curves are responsible for the absorption in this region. Spectroscopy studies from several groups (4–6) have established the bound part of the $^3\Pi(0^+)$ curve. However, the repulsive part of both potential curves and the consequent dissociation dynamics remain to be investigated in detail.

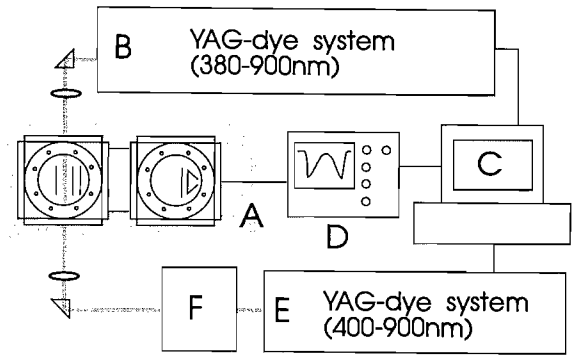

FIG. 1. Block diagram of the experimental setup: (A) the high-vacuum chambers house the TOF-MS grids and the molecular beam valve (not displayed); (B) photolysis laser; (C) computer and timing control; (D) digital oscilloscope; (E) probe laser system; (F) frequency doubler.

In this communication, we present our preliminary study of the BrCl UV and near-UV photodissociation dynamics. In particular, we report the chlorine spin-orbit state branching ratio $(Cl^*/(Cl+Cl^*))$ measured at different photolysis wavelengths. The implications of these measurements on the photodissociation dynamics and the non-adiabatic transitions among several exit channels are discussed.

Experimental

As shown schematically in Fig. 1, the experimental setup consists of two frequency tunable laser systems, a molecular beam source, and a time-of-flight mass spectrometer (TOF-MS). The molecular beam source and TOF-MS were mounted in a high-vacuum system with two differentially pumped chambers.
